[c,d,e]Values for piglets fed formula without a common superscript are significantly different, $P < 0.008$.

usual and specific positioning of 16:0 at the triacylglycerol 2-position is also a characteristic feature of human, pig, and several other mammalian milks (10,11,17). Again, the explanation for this is not clear.

The portal-venous transport of 8:0, 10:0, and 12:0, followed by rapid carnitine-independent oxidation in liver, and the low activity of acyltransferases with medium-chain fatty acids (24,25,30,31) are well known. Previous studies have suggested that preferential oxidation of 8:0–12:0 in animals fed diets with 8:0–12:0 rather than 16:0 as the source of saturated fat may result in higher availability of dietary 18:1 and 18:2n-6 for storage in growing tissue lipids (32). The results of this report, which show higher 18:1, and to a smaller extent higher 18:2n-6, in liver triglycerides of piglets fed the formula with MCT rather than oils with 16:0 as the source of saturated fat, are consistent with this.

The higher levels of 16:0 in the plasma and liver triacylglycerol 2-position fatty acids of piglets fed the formula with synthesized triacylglycerols than in piglets fed sow milk could be due to the higher percentage of 16:0 in the 2-position of the dietary synthesized triacylglycerols (69.9% 16:0) than in the sow milk (55.3% 16:0). However, the results of these studies also show significant amounts of 16:0 esterified at the 2-position of fasting plasma and liver triacylglycerols of piglets fed the formula with palm oil (mean ± SE percentage of 16:0, 16.4 ± 1.1 and 15.1 ± 0.8, for plasma and liver, respectively). Whether the high 16:0 in the 2-position of plasma triacylglycerols in piglets fed the palm-olein formula could have originated from monoacylglycerols with 16:0 released from adipose tissue is not known. Release of adipose tissue fatty acids involves hormone-sensitive lipase (EC 3.1.1.3) which hydrolyzes first one, then a second fatty acid from the triacylglycerol to form monoacylglycerol. Complete hydrolysis to glycerol and unesterified fatty acid is then catalyzed by monoacylglycerol lipase (EC 3.1.1.23) (33). Uptake and re-esterification of monoacylglycerols from adipose tissue and subsequent release in very low density lipoprotein triglycerides could explain the close relationship between the distribution of fatty acids in the piglet liver and plasma triacylglycerols found in this study. However, there seems to be no experimental evidence that monoacylglycerols are released by adipose tissues. However, consistent with the results of the study reported here, work by Christie and Moore (13) over 20 years ago noted about 36% 16:0 in the *sn*-2 position fatty acids of plasma triacylglycerols from domestic pigs, a substantially higher value than in the liver triacylglycerols.

The similar proportion of 16:0 in the 2-position of adipose tissue triacylglycerols in piglets fed sow milk and piglets fed the formula with palm oil or synthesized triacylglycerols, despite the large differences in the positional distribution of 16:0 in the diets, indicates that the α-glycerophosphate pathway probably predominates in adipose tissue triacylglycerol synthesis, at least in piglets. The much lower 16:0 in adipose tissue of piglets fed the formula with MCT or coconut oil, providing 8:0–12:0 rather than 16:0 as the major dietary saturated fatty acids suggests that exogenous fatty acids, rather than fatty acids synthesized *de novo*, are predominately used for the adipose tissue growth of young piglets. Similarly, others have shown that diets with safflower, sunflower, or canola oil, all of which are low in 16:0, decrease pig adipose tissue 16:0 when compared with a diet with animal fat (34). In the latter study, although the adipose tissue percentage of 16:0 was reduced by the vegetable oil diets, the proportion of total 16:0 in the 2-position was increased to 92%. Similarly, in the studies here, about 96% of the 16:0 in the adipose tissue triacylglycerols of piglets fed the formula with MCT or coconut oil was in the 2-position. Studies with rat adipose tissue have also suggested that, whereas the supply of exogenous fatty acids determines the relative proportions of fatty acids entering the triacylglycerols, the distribution of 16:0 and 18:1 to the 2-position is controlled entirely by the transacylases of the glycerol-3-phosphate pathway (14). Leray *et al.* (35), however, recently reported that the positional distribution of fatty acids in the white adipose tissue of rats fed fish oil was similar to that in the fish oil which was fed. Because the distribution of fatty acids in the 2-position of circulating triacylglycerols resembles that in the dietary fat (16,17,36,37), it is possible that 2-monoacylglycerols formed by LPL could be taken up and re-esterified *via* the monoacylglycerol pathway (9). Alternatively, esterification and remodeling reactions in fish and rats could be similar.

Several studies have suggested that the composition of lung phospholipid fatty acids, particularly 20:4n-6, is important to various lung functions (38–42). Studies on the effect of dietary fat on the lung have recently shown that the ability of lung to synthesize 20:4n-6-derived eicosanoids, which have many important roles in normal lung function, is reduced by dietary treatments which lower lung 20:4n-6 (40,41). The studies described here show that feeding formula, particularly formula low in 16:0, results in reduced lung 20:4n-6, when compared with milk feeding in piglets. Whether this has physiological significance, or if similar changes occur in infants fed formula, is not known. The results of these studies have also shown that the composition and distribution of saturated fatty acids in the dietary triacylglycerols influence the composition of fatty acids in the plasma, liver, and adipose tissue triacylglycerols of growing piglets. Whether or not the differences in liver fatty acid composition which result from feeding formula differing in saturated fatty acids, or which result from feeding formula rather than milk, are associated with any functional differences in this organ is not yet known. However, caution is warranted before extrapolating the results of these studies, particularly for adipose tissue, to the human infant fed formula because of the species differences in adipose tissue fatty acid distribution.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of Janette D. King and Laurie Nicol with the piglet feeding. Funding for these studies was in the form of grants from Loders Croklaan, The Netherlands and Mead Johnson Nutritional Group, Evansville, IN. SMI is a Career Investigator of the B.C.'s Children's Hospital Foundation.

Rat Gastric Hydrophobic Barrier: Modulation of Phosphatidylcholine Molecular Species by Dietary Lipids

W. Bernhard[a,*], A.D. Postle[b], M. Linck[a], and K.-Fr. Sewing[a]

[a]Department of General Pharmacology, Hannover Medical School, D-30625 Hannover, Germany and [b]Child Health, Faculty of Medicine, Southampton General Hospital, University of Southampton, Southampton SO16 6YD, United Kingdom

ABSTRACT: Phospholipids protect the gastric mucosa by forming a proton-repellent hydrophobic layer on its luminal surface. We have recently shown that two molecular species of phosphatidylcholine (PC), PC16:0/18:1, and PC16:0/18:2, but not PC16:0/16:0, are predominantly released into gastric mucus. We investigated whether these molecular species in mucus are modified by dietary fat. Rats were fed (for three weeks) a diet supplemented with either 10% cod liver, palm, or sunflower oil, or 10% corn starch as a control. In tissue, cod liver oil decreased PC16:0/20:4 and PC18:0/20:4. Cod liver oil and palm oil increased PC16:0/18:1, whereas sunflower oil decreased PC16:0/18:1. Palm oil additionally decreased PC16:0/18:2, whereas the other diets had no effect on PC16:0/18:2. In mucus, however, PC16:0/18:1 and PC16:0/18:2 were not significantly altered by any diet. They were increased over tissue values and comprised 37.6 ± 3.3 and 33.1 ± 1.4 mol% in controls. PC16:0/16:0 was lower in mucus than in mucosa and even decreased by cod liver oil (1.2 ± 0.2 vs. 2.7 ± 0.3 mol%; $P < 0.01$). We conclude that PC16:0/18:1 and PC16:0/18:2 are modified by dietary fat in tissue. In gastric secretions, however, PC16:0/18:1 and PC16:0/18:2 are kept constant and together comprise 70 mol% of the released PC species, whereas PC16:0/16:0 does not play a role for the gastric hydrophobic barrier under any dietary treatment. Additionally, cod liver oil decreases the content of PC16:0/20:4 and PC18:0/20:4 in gastric mucosa, thereby possibly decreasing the formation of eicosanoids.

Lipids 31, 507–511 (1996).

The gastric mucosa is normally able to resist the acidic environment of the stomach luminal contents, but a defective mucosal barrier against diffusion may result in the development of ulceral lesions (1–3). There is considerable evidence that the hydrophobic nature of gastric mucus is an essential factor in the protection of the gastric mucosal surface against the damaging effects of acid. Release of phosphatidylcholine (PC) by porcine gastric mucous cells is stimulated by prostaglandin E_2 (4), and the phospholipid content of gastric mucus is, in turn, thought to be a major determinant of its hydrophobicity (5,6). Consequently, by analogy with pulmonary surfactant, the term "gastric surfactant" has been used to describe gastric mucus phospholipids (7,8). However, any relationship between pulmonary surfactant and a putative gastric surfactant can only be superficial. We have recently demonstrated unambiguously that gastric mucus from both pig and rat contains only negligible amounts of PC16:0/16:0, the major surface tension-lowering component of lung surfactant. Instead, gastric mucus PC was enriched in the two unsaturated molecular species PC16:0/18:1 and PC16:0/18:2, suggesting a specific functional role for these two PC molecular species (9). One consequence of this suggestion could be that mechanisms exist to maintain a constant composition of gastric mucus PC that is substantially independent of dietary lipid intake. If so, then protective effects of dietary fats against mucosal damage, for instance that of n-3 fatty acids against ethanol-induced damage (10), cannot be mediated by changes of gastric mucus composition. In this study we have tested the hypothesis that composition of rat gastric mucus is not altered significantly by feeding diets based on palm oil, sunflower oil, or cod liver oil.

MATERIALS AND METHODS

Materials. Male rats (Wistar strain, 140–150 g body weight) were from the Zentralinstitut für Versuchstiere (Hannover, Germany). Disposable Varian 100 mg Bondelut^R NH_2-propyl columns were from Jones Chromatography (Hengoed, Mid Glamorgan, United Kingdom). Solvents for high-performance liquid chromatography (HPLC) were of HPLC grade from Baker (Deventer, The Netherlands). All other chemicals were of analytical grade and from various commercial sources.

Feeding experiments. Animals were given regular rodent chow for three days until start of the experiment. Afterwards, animals were fed for three weeks on a regular rodent chow supplemented with either 10% corn starch (controls), cod liver oil, palm oil, or sunflower oil (Ssniff Spezialdiäten GmbH, Soest, Germany). Fatty acid concentrations of the different diets are shown in Table 1. Food was withdrawn from the animals 20 h before sacrifice. The rats had free access to water at all times. Their body weights were 250–270 g after dietary treatment and did not differ between the experimental groups.

[a]Diets were extracted with chloroform/methanol, the extracts transmethylated with acid methanol and fatty acid composition determined by gas chromatography. Fatty acid content was calculated from the content in total fat in the diet, i.e., 3% (w/w) in control diet and 13% (w/w) in the other diets.
[b]Not detected.

Analysis of fatty acids. Fatty acids of dietary fat were methylated/transmethylated according to Stoffel *et al.* (11). Methyl esters of fatty acids were separated on a fused silica CW20M-DF-0.25 column (17 m; Machery & Nagel, Düren, Germany) using a Varian (Palo Alto, CA) model 3400 gas chromatograph equipped with a flame-ionization detector. Peak area integration was performed by means of a Varian 4290 integrator.

Harvesting of gastric tissue and mucus. Gastric tissue and mucus fractions were harvested as previously described (9). Briefly, rats were injected intraperitoneally with 60 mg/kg body weight pentobarbital sodium (Nembutal®; Sanofi-Ceva, Luibourné, France) and 1500 I.U. heparin sodium (Liquemin®; Hoechst, Frankfurt/Main, Germany). After completion of anesthesia, the abdomen was opened and the stomachs were freed of blood by vascular perfusion with 150 mmol/L saline. The stomachs were excised and the lumen gently rinsed with 20 mL 150 mmol/L saline to remove any remaining food. The stomachs were then filled with 500 mmol/L saline at capacity and kept at 4°C for 20 min to harvest gastric secretions (8). Thereafter, the lumen of the stomach was vigorously lavaged with the 500 mmol/L saline three times (total volume 20 mL). The lavage fluid and post-lavage stomach tissue were stored at −20°C under nitrogen until use for lipid analysis.

Determination of PC molecular species. Phospholipids were extracted from gastric tissue according to the method of Folch *et al.* (12) and from gastric lavage fluid according to Bligh and Dyer (13). Phospholipids were quantitated according to Bartlett (14) and PC was prepared from lipid extracts by the following method, as described previously (9). In brief, 1 mg phospholipid was dissolved in 1 mL chloroform and placed on a 100-mg disposable NH_2-propyl Bondelut^R cartridge. After adsorption for five minutes the cartridge was washed twice with absolute chloroform to remove neutral lipids. No phospholipid was lost during this procedure. PC was eluted with 1 mL chloroform/methanol (70:30, vol/vol). Molecular species of PC were then separated according to Postle (15) by reverse-phase HPLC using methanol/water (925:75, vol/vol) supplemented with 40 mmol/L choline chloride as the mobile phase. Quantitation was achieved by fluorescence detection (excitation: 340 nm; emission: 460 nm) after post-column formation of mixed micelles with 1,6-diphenyl-1,3,5-hexatriene.

Statistics. One-way analysis of variance was calculated using GraphPad Instat Version 1.11a (GraphPad Software, San Diego, CA). Significance levels were corrected by means of the Bonferoni method for multiple group comparisons.

RESULTS

In gastric tissue PC16:0/18:1 and PC16:0/18:2 were the major PC molecular species comprising 15.5 ± 0.3 and 26.7 ± 0.7 mol%, respectively, in controls (Table 2). All dietary fats influenced the concentration of PC16:0/18:1. Cod liver oil and

[a]Gastric tissue was extracted with chloroform/methanol, PC prepared from the extracts and PC species were separated by high-performance liquid chromatography as indicated in the Materials and Methods section.
[b]$P < 0.001$ vs. control.
[c]$P < 0.01$ vs. control.
[d]$P < 0.05$ vs. control.

palm oil increased PC16:0/18:1, but sunflower oil decreased PC16:0/18:1. PC16:0/18:2 was only decreased by palm oil. The ratio between PC16:0/18:1 and PC16:0/18:2 was increased by cod liver oil and palm oil for 31 ± 5 and 40 ± 5%, respectively ($P < 0.05$). Tissue PC16:0/16:0, however, was 7.0 ± 0.3 mol% in controls and remained unaffected by any diet. Highly unsaturated PC species, PC16:0/20:4 and PC18:0/20:4, were decreased by 41 ± 2 and 35 ± 3%, respectively ($P < 0.001$ each), by cod liver oil, whereas the other diets had no major effect. PC species containing 20:5n-3 were not detected in measurable amounts in gastric tissue.

Molecular species composition of mucus PC is shown in Table 3. Concentration of PC16:0/18:1 and PC16:0/18:2 was higher in mucus than in gastric tissue and comprised 37.6 ± 3.3 and 33.1 ± 1.4 mol% of total PC, respectively. In contrast to mucosal PC, no diet caused any significant change to these major components of mucus PC. There was only a tendency for the sunflower oil diet to increase mucus PC16:0/18:2 content at the expense of that of PC16:0/18:1; the ratio of PC16:0/18:1 to PC16:0/18:2 decreased from 1.15 ± 0.12 for animals on the control diet to 0.87 ± 0.04 for those on the sunflower oil diet (Table 3). Nevertheless, the PC16:0/18:1 to PC16:0/18:2 ratio was still higher in mucus than in gastric tissue of sunflower oil-fed rats. Concentration of the highly unsaturated PC species, PC16:0/20:4 and PC18:0/20:4, was less in mucus than in mucosa (Tables 2 and 3) ($P < 0.01$).

There were a number of changes in some of the minor components of mucus PC for animals fed experimental diets. Intriguingly, different effects were found depending on the nature of the fatty acid esterified at the *sn*-1 position, which would not have been apparent from simple fatty acid rather than molecular species analysis of PC. For instance, cod liver oil diet decreased mucus PC16:0/20:4 from 3.9 ± 0.5 to 1.9 ± 0.1 mol%, but had no effect on the content of PC18:0/20:4. And although concentrations of both 20:4n-6–containing PC species in mucus were increased by feeding rats the palm oil diet, this increase was considerably greater for PC18:0/20:4 (115%) than for PC16:0/20:4 (41%). The contents of neither PC16:0/20:4 nor PC18:0/20:4 were increased in gastric mucus in rats fed the sunflower oil diet, for which the only significant change was a selective increase in PC18:0/18:2 content from 8.0 ± 0.7 to 12.9 ± 1.5 mol%. The concentration of PC16:0/16:0, which comprised 2.7 ± 0.3 mol% of total mucus PC in rats fed the control diet, was not increased by any of the experimental diets. Instead, its content was decreased even further to 1.2 ± 0.2 mol% in rats fed the cod liver oil diet.

DISCUSSION

Although mucus phospholipids are thought to be an essential component for the hydrophobic protection of the gastric mucosa against acid (5–7), the molecular basis for this action remains unclear. It has been proposed that secreted gastric mucus PC represents a gastric surfactant analogous to the pulmonary surfactant layer lining the lung alveolus (7,16). Our previous findings demonstrated clearly, however, that this so-called gastric surfactant had a very different composition from pulmonary surfactant (9). PC16:0/16:0, the major lipid component of pulmonary surfactant, was present in only negligible concentration in gastric mucus. By contrast, PC16:0/18:1 and PC16:0/18:2 were the major PC molecular species released into gastric mucus; moreover, these two species were significantly enriched in gastric mucus compared with mucosal PC.

The present study provides confirmatory evidence for our hypothesis that this composition of mucus PC secretion from the gastric mucosa is tightly regulated. Modification of the composition of dietary fat produced relatively substantial changes in mucosal PC composition, but exerted a much less significant effect on the PC composition of the mucus fraction. For all three experimental diets, irrespective of changes to gastric tissue PC, the sum of PC16:0/18:1 and PC16:0/18:2 as the major PC species was consistently higher in mucus

than in mucosa. This difference was probably an underestimate, as the mucosal fraction will have contained a potentially substantial, but not readily quantifiable, contribution from nascent mucus PC. While cod liver oil and palm oil diet significantly increased the ratios of PC16:0/18:1 to PC16:0/18:2 in gastric tissue (Table 2), they exerted a much lower effect on mucus PC (Table 3). Importantly, none of the experimental diets increased the low content of PC16:0/16:0 previously reported in both gastric mucosa and mucus of rats fed standard control diet (9). This result confirmed that modification of PC16:0/16:0 secretion into gastric mucus PC does not contribute significantly to any hydrophobic protection of the gastric mucosa.

Identification of the effective absense of PC16:0/16:0 in gastric mucus PC has far reaching consequences for our understanding of the mechanism underlying the protection of the gastric mucosal surface by hydrophobic components, in many respects simplifying the concepts involved. PC16:0/16:0 is essential in pulmonary surfactant to oppose surface tension forces at the air–liquid interface in the lungs (17). This function is dependent on the high gel to sol phase transition temperature (41°C) of PC16:0/16:0 which, consequently, is an inert solid material at body temperature (18). Pulmonary surfactant contains specialized unsaturated phosphatidylglycerol and specific apoprotein components designed to facilitate adsorption of this solid PC16:0/16:0 to the air–liquid interface (17,18). These constraints imposed on pulmonary surfactant by the saturated nature of PC16:0/16:0 will not apply to gastric surfactant, as this is composed principally of the more fluid molecules PC16:0/18:1 and PC16:0/18:2. This conjecture is in agreement with our previous findings that negligible PG was present in gastric secretions of either pig or rat (9). One protein characteristic of lung surfactant, surfactant protein D, is expressed by gastric mucosal cells (19), but this protein is not thought to contribute directly to the surface activity. Rather, it is a component of the innate defense system and probably contributes in both tissues to host defense rather than to surfactant function (17,19).

The lack of effect of cod liver oil diet on the PC molecular species composition of gastric mucus demonstrated clearly that its protective action against ethanol-induced tissue damage (20) was not due to modification of any hydrophobic protective mechanism. Instead, feeding cod liver oil dramatically decreased concentrations of arachidonoyl-containing species PC16:0/20:4 and PC18:0/20:4 in gastric mucosa, resulting in a decrease of potential substrate for generation of noxious leukotrienes C_4 and D_4 (10,20) and leaving unaffected or even improving the vascular perfusion of gastric mucosa (21,22). Consequently, any protective effect of n-3 fatty acids on the gastric mucosa may be due to modulation of release of such arachidonic acid-derived eicosanoid mediators.

Although in gastric mucus PC comprises 60 mol% of total phospholipids, the concentration of phosphatidylethanolamine (PE) is only 20 and 30 mol% in the rat and in the pig, respectively (9). Although *de novo* synthesis rates of PC and PE are similar in isolated porcine gastric mucous cells, palmitic acid incorporation into PE is only 15–20% the value of PC (23). These findings show that palmitoylated PE species do not play a major role in gastric secretions. However, a contribution of PE to the hydrophobic barrier of the stomach cannot be discounted. So far, no data exist for the gastric hydrophobic barrier in humans, particularly not in terms of individual molecular species of phospholipids. Therefore, further studies will be necessary to investigate the phospholipid concentration and composition as well as the regulation of phospholipid synthesis and secretion in the stomach in humans. This is particularly important as impaired hydrophobicity facilitates the development of gastric lesions in humans (5,24–26).

We conclude that PC16:0/18:1 and PC16:0/18:2, but not PC16:0/16:0, are the major PC species being released from the mucosa into gastric mucus. The concentration of these PC molecular species is kept relatively constant in mucus. Therefore, the molecular basis of the hydrophobic barrier of the stomach is different from that of the pulmonary surfactant. We further conclude that protection of the stomach by dietary n-3 fatty acids may be mediated by decreasing arachidonic acid, thereby leading to less formation of noxious leukotrienes, rather than by influencing the molecular composition of the gastric hydrophobic barrier.

Changes in Lipid Composition During Metamorphosis of Bonefish (*Albula* sp.) Leptocephali

David Padrón[a,1], Virginia A. Lindley[b,2], and Edward Pfeiler[a,c,*]

[a]Departamento de Ciencias Marinas, Instituto Tecnológico y de Estudios Superiores de Monterrey (ITESM), Guaymas, Sonora 85400, Mexico, [b]Electron Microscopy Consultants, Tucson, Arizona 85719, and [c]Department of Zoology, Arizona State University, Tempe, Arizona 85287

ABSTRACT: During metamorphosis of bonefish (*Albula* sp.) larvae (leptocephali) all energy requirements are provided by breakdown of endogenous compounds, with lipid catabolism accounting for about 80% of total energy production. The principal objective of the present study was to characterize the lipid classes and fatty acids utilized. Analysis of whole-body lipid content indicated that larvae lost about half (3.6 mg) of their total lipid during the 10-d period. Percentages of neutral and polar lipid in early metamorphosing larvae were 64.2 and 35.8%, respectively; these values showed little change during metamorphosis, indicating that both lipid classes were catabolized. Triacylglycerols, the principal neutral lipid of all metamorphic stages, decreased by 1.8 mg, accounting for half of the decrease in total lipid. Levels of phosphatidylethanolamine, the principal polar lipid in early larvae, decreased by more than 50% during metamorphosis; levels of phosphatidylcholine, which was not detected in early larvae, increased. Fatty acids showing the largest net decreases, presumedly used as energy sources, were 16:0 (30.4%), 14:0 (13.8%), 16:1n-7 (12.2%), 20:5n-3 (7.7%), 18:1n-9 (7.4%), and 18:4n-3 (6.9%). Most of 22:6n-3, the second most abundant fatty acid of early larvae, was conserved.

Lipids 31, 513–519 (1996).

Metamorphosis of leptocephalous larvae of the bonefish from the Gulf of California (Albuliformes: Albulidae: *Albula* sp.) is characterized by rapid and dramatic changes in morphology and chemical composition (1,2). During a period of approximately 10 d, metamorphosing leptocephali lose about 80% of their wet mass and about 60% of their length as they transform into juvenile fish (3). Nutrient requirements are provided by catabolism of endogenous reserves formed during the premetamorphic growth interval and are stored mainly in the transparent, extracellular gelatinous matrix that forms the bulk of the body mass (4); feeding does not resume until near the end of metamorphosis (5; Pfeiler, E., unpublished data).

Previous studies on changes in biochemical composition indicated that endogenous substances used as energy sources are lipid and carbohydrate (keratan sulfate glycosaminoglycan) (2). Metamorphosing larvae show about a 50% net loss of total lipid and about an 80% loss in keratan sulfate. Lipid breakdown accounts for about 80% of the total energy requirements during metamorphosis (Pfeiler, E., unpublished data).

Given the importance of lipid as a nutrient source during this period of rapid and extensive remodeling of larval tissues, we addressed the following questions: (i) What is the lipid class and fatty acid composition of bonefish leptocephali at the beginning of metamorphosis? (ii) What changes in content and composition occur during metamorphosis? and (iii) What lipid classes and fatty acids provide the main metabolic energy sources during metamorphosis?

MATERIALS AND METHODS

Animals. Metamorphosing bonefish larvae were collected with a beach seine in coastal lagoons of the Gulf of California, near Guaymas, Sonora, Mexico (3), during January and February 1994. Larvae were transported live to the laboratory in Guaymas and were either placed in plastic bags and frozen (−18°C) or placed in a 60-L aquarium with running, aerated seawater at ambient temperature (18°C) and allowed to continue the metamorphosis until a desired stage was reached. Before analysis, larvae were separated into three groups based on size: early [>55 mm standard length (SL) measured from tip of snout to base of caudal fin], intermediate (35–45 mm SL), and advanced (<30 mm SL). Maximum size of early larvae is about 70 mm SL (6), and metamorphosis is complete at about 25 mm SL (3). Individual wet weight is about 0.5 g in early larvae and decreases to about 0.1 g in advanced larvae (3).

Lipid extraction. Larvae from each group were pooled to give the desired total wet mass (usually between 1–14 g), and total lipid was extracted using the method of Folch *et al.* (7). Yields were determined gravimetrically after evaporating

samples at 50°C under a stream of nitrogen and cooling to room temperature in a desiccator flushed with nitrogen. Samples were dissolved in chloroform and either used immediately or stored at −18°C under nitrogen.

Lipids were separated into neutral and polar fractions on a 21 × 3 cm column of Silica Gel 60 (70–230 mesh; Merck, Darmstadt, Germany). Samples (0.1–0.2 g) were dissolved in 2 mL chloroform and applied to the column. Neutral lipids were eluted with 150 mL chloroform. The column was then washed with 100 mL chloroform/methanol (49:1, vol/vol). After monitoring the composition of the wash by thin-layer chromatography (TLC), it was combined with the neutral fraction. Finally, polar lipids were eluted with 150 mL methanol. Yields of each fraction were determined gravimetrically after evaporating the solvent under a stream of nitrogen. Samples were dissolved in chloroform (neutral fraction) or chloroform/methanol (2:1, vol/vol) (polar fraction) at a concentration of about 30 mg × mL^{-1} and stored under nitrogen at −18°C.

Lipid analysis. One-dimensional TLC was used for preliminary qualitative analysis of the lipid class composition of total lipid extracts and to monitor column separations of neutral and polar fractions. Twenty × 20 cm plates of Silica Gel 60 G, with a thickness of about 0.25 mm, were prepared. Approximately 400 μg of sample, in a volume of 10–20 μL, was applied to plates which were developed with hexane/ethyl ether/acetic acid (90:10:1, by vol) for neutral fractions and chloroform/methanol/water (65:35:4, by vol) for polar fractions. Spots were visualized by charring after spraying with an aqueous solution of 50% sulfuric acid.

High-performance TLC (HPTLC), followed by scanning densitometry of individual spots, was used for quantification of the lipid class composition of neutral and polar fractions. A known quantity of lipid, ranging from 0.1–0.3 mg, was applied to 10 × 10 cm HPTLC plates (precoated Silica Gel 60). Neutral lipids were separated in one dimension as described previously for qualitative separations. Polar lipids were separated by two-dimensional HPTLC. The solvent for the first dimension was chloroform/methanol/28% aqueous ammonia (65:35:5, by vol); chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1, by vol) was used for the second dimension. Spots were visualized by charring after spraying with an aqueous solution of 55% sulfuric acid/0.6% sodium dichromate. Spots were identified by running known standards. Lipid classes were quantitated by scanning densitometry using VISAGE Electrophoresis Gel Analysis System software (Millipore Corp., Milford, MA) on a Sun Microsystems (Mountain View, CA) Computer linked to an Aristo Image Acquisition Console.

Phospholipids also were identified in separate, two-dimensional HPTLC runs by spraying with the phosphate group stain of Dittmer and Lester (8) as modified by Vaskovsky and Kostetsky (9); ethanolamine glycerophospholipids were visualized by spraying separate plates with 0.2% (wt/vol) ninhydrin in *tert*-butyl alcohol/water (4:1, vol/vol) (10).

Fatty acid methyl esters (FAME) were prepared from both neutral and polar fractions by acid-catalyzed transmethylation using 3 N methanolic HCl (10). Prior to the procedure, 0.22 mg of internal standard (17:0) was added to samples containing 1.5–3.0 mg total lipid in order to quantitate individual fatty acids. FAME, dissolved and stored in hexane, were separated and analyzed on a Hewlett-Packard (Avondale, PA) gas chromatograph (Model 5840 A) using an Omegawax 320 capillary column (length, 30 m; i.d., 0.32 mm; Supelco, Inc. Bellefonte, PA) of fused silica (film thickness: 0.25 μm). Nitrogen was used as the carrier gas under isothermal (190°C) conditions. Fatty acids were identified by comparison of column retention times with known standards. Peak quantification was performed with a Hewlett-Packard GC Terminal recorder and peak integrator.

Electron microscopy. Metamorphosing larvae were fixed whole by immersion in filtered seawater containing 4% paraformaldehyde and 1% glutaraldehyde (11). Fixed larvae were measured, rinsed with distilled water, and transversely sectioned with a razor blade at mid-body. Sections approximately of 2-mm thickness were rinsed with distilled water, postfixed in 1% osmium tetroxide/0.15% ruthenium red (aqueous solution), and prepared for transmission electron microscopy (TEM) as described previously (11). Thin sections (90–150 nm) were viewed and photographed on either an H-500 Hitachi (Tokyo, Japan) or a JEOL (Tokyo, Japan) 100CX transmission electron microscope.

Chemicals. Reagents used for lipid extraction and analysis were analytical grade (J.T. Baker, Phillipsburg, PA) and were purified by redistillation (12) when required. Standards used for HPTLC were from Sigma Chemical Co. (St. Louis, MO). Fatty acid standards used for gas chromatography were from Supelco, Inc. (Bellefonte, PA) and from Sigma; methanolic HCl was from Supelco.

RESULTS

Lipid extractions were performed on eight separate groups of metamorphosing bonefish leptocephali—three each on early and advanced larvae, and two on intermediate larvae. Mean total lipid content per larva (individual values in parentheses) was 7.8 (6.5, 8.3, 8.5), 5.6 (5.2, 6.1), and 4.2 (3.7, 3.8, 5.1) mg for early, intermediate, and advanced larvae, respectively, representing a net loss of about 3.6 mg, or 46%, of total lipid during metamorphosis. Mean individual wet weights for the three groups were 0.50, 0.33, and 0.20 g, respectively. Single-factor analysis of variance showed that mean values for lipid content in early and advanced larvae were significantly different at the 5% level.

In order to estimate total lipid levels as percent larval dry weight, wet weight in grams (x) of metamorphosing larvae was converted to dry weight in milligrams (y) using the regression equation: $y = 18.445 + 59.610x$; $r^2 = 0.76$; $n = 40$ (2). The resulting lipid levels were 16.2, 14.7, and 13.8% dry weight for early, intermediate, and advanced larvae, respectively.

Preliminary one-dimensional TLC analysis (not shown) of total lipid extracts of metamorphosing larvae showed the presence of triacylglycerols (TAG), cholesterol, cholesteryl esters, and phospholipids.

Neutral lipids predominated at all metamorphic stages, comprising approximately two-thirds of the total in each group (Table 1). TAG were the principal neutral lipid component in each group, but absolute amounts of TAG decreased by about 1.8 mg per larva, or about 50%, during metamorphosis, a percentage decrease similar to that seen in total lipid. Cholesterol showed little change during metamorphosis, but levels of cholesteryl esters tended to decrease slightly. Free fatty acids were not seen in the neutral fraction from any of the metamorphic stages.

Lipid class analyses of polar fractions indicated that phosphatidylethanolamine (PE) accounted for more than 50% of the total in early metamorphosing larvae, but that about 65%, or 1.0 mg, of PE was lost during metamorphosis (Table 1). Especially interesting was the apparent absence of phosphatidylcholine (PC) in early larvae. However, PC content showed a progressive increase during metamorphosis (Table 1), and in advanced larvae it accounted for about 9% of total polar lipids, although PE still predominated (35% of total). Table 1 shows also that free fatty acids were found in the polar fraction and that their content increased threefold during metamorphosis, accounting for 35% of the total in advanced larvae. Free fatty acids in the polar fraction most likely did not arise from breakdown of phospholipids on storage. Both neutral and polar fractions were stored under identical conditions before analysis, and no free fatty acids were evident in the neutral fraction. Sphingomyelin and cardiolipin were minor components and showed no apparent changes in content during metamorphosis.

Neutral lipids of early metamorphosing larvae were composed principally of polyunsaturated fatty acids (PUFA) (46.7%), followed by saturated (33.6%) and monounsaturated (18.9%) fatty acids (Table 2). These proportions showed little change during metamorphosis, although total fatty acid content decreased by 1.11 mg, or about 38%. Principal fatty acids in the neutral fraction of early-metamorphosing larvae were 16:0 (22.3%), 22:6n-3 (17.4%), 20:5n-3 (10.0%), 16:1n-7 (8.2%), and 18:1n-9 (6.4%); these percentages also showed little change during metamorphosis, although individual amounts decreased, together accounting for a loss of 752 μg, or about 68% of the loss. The fatty acid showing the largest change was 16:0, which decreased by 307 μg, or almost half, accounting for 28% of the loss. Next in importance was 22:6n-3, which decreased by 194 μg, accounting for 17% of the loss.

Polar lipids of early-metamorphosing larvae were composed principally of saturated fatty acids (50.0%), followed by PUFA (40.1%) and monounsaturated fatty acids (9.9%) (Table 3). In advanced larvae, saturated fatty acid content decreased to 40.1% and PUFA increased to 49.6%; monounsaturated fatty acids showed little change. The saturated fatty acid, 16:0, predominated in the polar fraction of early-metamorphosing larvae, accounting for 38.0% of the total, followed by 22:6n-3 (24.7%) and 18:0 (9.7%). Total fatty acid content of the polar fraction showed a 519 μg (2.6×) increase during metamorphosis, with most (33.7%) of the increase due to 22:6n-3 and 16:0 (23.5%). A significant fraction (300 μg) of the increase can be attributed to free fatty acids (Table 1).

In order to assess overall fatty acid metabolism during metamorphosis, net change for each fatty acid was calculated by subtracting its content in advanced larvae from the content in early larvae, for both neutral (Table 2) and polar (Table 3) fractions, and then summing the differences. Except for negligible increases in 18:0, 20:3n-6, and unidentified compounds (3–5 μg per larva for each), all fatty acids showed net decreases. Total loss (ignoring the aforementioned increases) was 608 μg per larva. Percentage losses for saturated, PUFA, and monounsaturated fatty acids were 44.2, 32.4, and 23.4%, respectively. The greatest loss (30.4% of the total) was seen in 16:0, followed by 14:0 (13.8%), 16:1n-7 (12.2%), 20:5n-3 (7.7%), and 18:1n-9 (7.4%). In addition to 20:5n-3, most of the net loss in PUFA was seen in 18:4n-3 (6.9%), 18:3n-3 (4.3%), and 20:3n-3

[a]Values for individual fatty acids are means ± SE of three determinations, except for the three fatty acids of the C_{22} series, where values are means and ranges of two determinations. Mean values for individual fatty acids of early and advanced larvae, with the exception of those from the C_{22} series, were analyzed by single-factor analysis of variance; all values, except those for 14:1, 18:4n-3, and 20:3n-3, were significantly different at the 5% level. Abbreviations as in Tables 1 and 2.

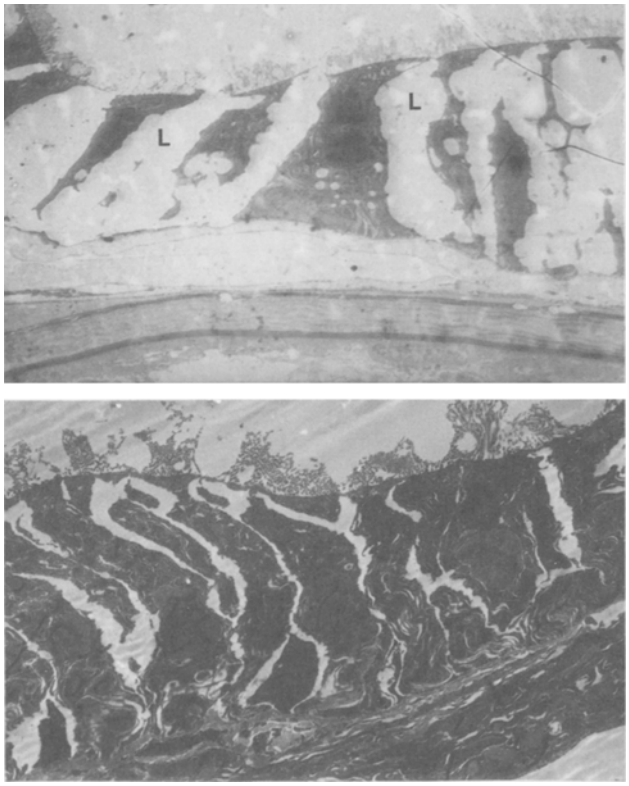

FIG. 1. Transmission electron micrograph of midgut epithelium of early [61 mm standard length (SL); upper] and advanced (26 mm SL; lower) metamorphosing leptocephali of the bonefish *Albula* sp. Note the abundance of intercellular lipid deposits (L) in early larvae and the decrease in these deposits in advanced larvae. Midgut lumen is at the top of each figure. Magnification: × 1,504 (upper); × 6,284 (lower).

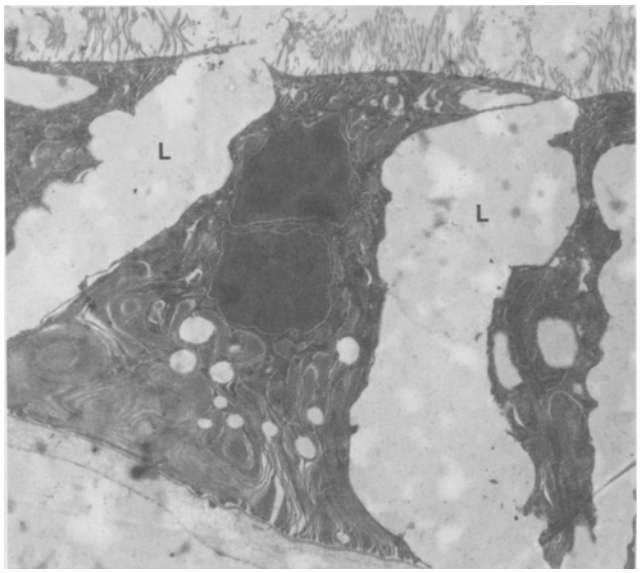

FIG. 2. Higher-power transmission electron micrograph of an early (61 mm SL) metamorphosing leptocephalus of the bonefish *Albula* sp. showing details of the ultrastructure of the midgut epithelial cell seen in the center of Figure 1 (upper). Note the extensive system of invaginations of the basal membrane which contains lipid droplets, the numerous mitochondria closely associated with these droplets, intercellular lipid deposits (L), and well-developed microvilli of the apical membrane. Magnification: × 3,995.

(3.6%). The principal PUFA, 22:6n-3, in both neutral and polar fractions of early-metamorphosing larvae (Tables 2 and 3), showed a net loss of only 19 μg per larva (3.1%).

TEM (Figs. 1 and 2) revealed that part of the lipid catabolized during metamorphosis arose from deposits located in midgut epithelium. Early-metamorphosing larvae (Fig. 1, upper) showed abundant osmiophobic areas among the epithelial cells, typical of lipid with high saturated fatty acid content. Relative amounts of lipid showed a progressive decrease in intermediate (not shown) and advanced (Fig. 1, lower) metamorphosing larvae. Higher magnification of a midgut epithelial cell of early metamorphosing larvae (Fig. 2) also showed the presence of apparent lipid droplets in channels formed by extensive infoldings of the basal membrane. These droplets, not found in all cells, were localized predominantly in the basal area and were closely associated with abundant mitochondria, some of which were very large, slender, and curved. The abundance of mitochondria suggests that these cells are very active metabolically.

DISCUSSION

The present study has provided a clearer picture of lipid metabolism in metamorphosing leptocephali of the bonefish. The total amount of lipid catabolized per larva agrees well with results from an earlier study (2). Although neutral lipid is deposited in the extracellular gelatinous body matrix during early (premetamorphic) larval development (5), and is the most likely source of the majority of lipid mobilized during metamorphosis, we have shown that highly-saturated lipid deposits in the midgut region also are utilized.

Ultrastructure of midgut epithelial cells of early-metamorphosing bonefish leptocephali was similar to that described for premetamorphic eel (*Conger myriaster*) leptocephali (13). However, no evidence was seen for either lipid droplets within basal infoldings or for intercellular lipid deposits in *C. myriaster*, suggesting that in bonefish these may be deposited just prior to metamorphosis. This possibility is supported by results on the eel *Ariosoma balearicum*, where it was found that most of the whole-body lipid is deposited during the latter part of the premetamorphic interval (14). In addition, the level of total lipid (4.0 mg × larva^{-1}) in a single extract from relatively advanced premetamorphic bonefish leptocephali was about half that seen in early-metamorphosing larvae (Padrón, D., and Pfeiler, E., unpublished data), again suggesting that a significant fraction of lipid deposition occurs relatively late in the premetamorphic interval.

Whole-body lipid content in early-metamorphosing bonefish larvae, approximately 16% of total dry weight (2; this study), is similar to that of tarpon (*Megalops atlanticus*) and ladyfish (*Elops saurus*) leptocephali (Donnelly, J., Torres, J.J., and Crabtree, R.E., unpublished data), as well as to that of yolk-sac larvae of other teleost fishes (15–17). In addition to

providing the principal source of energy during bonefish metamorphosis, lipid also probably functions as a hydrostatic agent as premetamorphic and early metamorphic larvae lack a functional swimbladder (4). However, lipid content alone is insufficient to achieve neutral buoyancy because leptocephali sink when swimming movements cease (4). The swimbladder does not become functional until metamorphosis, and lipid breakdown, is already underway (4). Although about 50% of total lipid content is lost during metamorphosis, lipid levels expressed as percentage dry weight show little change (2; this study) because about 50% of total larval dry weight also is lost (3).

The principal lipid class broken down during metamorphosis was TAG. All classes of fatty acids (saturated, monounsaturated, and PUFA) were utilized and probably contributed to energy production. Although major decreases in PUFA occurred during metamorphosis, and relatively large amounts of 22:6n-3 were lost from the neutral fraction as TAG were degraded, most (90%) of this fatty acid was conserved.

In both neutral and polar fractions, n-3/n-6 ratios were high (8.1–8.9) and relatively constant during metamorphosis. High n-3/n-6 ratios (>8.0) are typical of neutral and polar lipids of eggs and larvae of marine fishes (18–20).

Although PC was not evident in early-metamorphosing larvae, it could have been present at levels below our detection limits. Another possibility is that PC was present, but lost during column separations; the observation that PC was present in intermediate and advanced larvae, showing a progressive increase in level during metamorphosis (Table 1), argues against this interpretation.

The source of PE that was catabolized during metamorphosis is unknown, but histochemical tests indicate that phospholipids are absent from the gelatinous matrix (5). Some PE may be released from membranes of degraded skin epithelial cells. Skin surface area decreases by approximately 75% during metamorphosis (see Fig. 1 in Ref. 2), and scanning electron microscopy and TEM of skin of metamorphosing larvae have demonstrated the presence of degenerating cells (11), reminiscent of cells undergoing "programmed cell death" or apoptosis (21).

Although many studies have dealt with changes in lipid class and fatty acid composition during embryonic and larval development in teleost fishes (e.g., Refs. 15–17,22), no previous data are available for developing leptocephali, a unique life history stage found only in fishes of the subdivision Elopomorpha, which includes bonefishes, tarpon, and true eels (4). However, lipid class and fatty acid composition of postmetamorphic "glass eels" of the American eel (*Anguilla rostrata*) are similar to those of advanced metamorphic bonefish larvae (23). This suggests that patterns of lipid class and fatty acid metabolism during metamorphosis of eels also may be similar, although this remains to be shown.

ACKNOWLEDGMENTS

We thank Raúl Molina and the Centro Regional de Investigación Pesquera, Guaymas, Sonora, Mexico, for obtaining premetamorphic bonefish leptocephali, and Susan McKinley and David Bently for technical assistance. We also acknowledge Joseph Donnelly, Jose J. Torres, and Roy E. Crabtree for generously providing results of unpublished work. We are especially grateful to Jeffrey Hazel for his advice, for providing laboratory facilities, and for kindly reviewing the manuscript. This work was supported in part by NSF grant IBN-9205234 to Dr. Hazel, and by CONACYT (Consejo Nacional de Ciencia y Tecnología, Mexico).

Purification and Characterization of Deep Sea Shark *Centrophorus squamosus* Liver Oil 1-*O*-Alkylglycerol Ether Lipids

Catherine G. Bordier[a,*], Nicole Sellier[b], Alain P. Foucault[a], and François Le Goffic[a]

[a]Laboratoire de Bioorganique et Biotechnologies, and [b]Laboratoire de Spectrométrie de Masse, ENSCP-CNRS, 75231 Paris Cedex 05, France

ABSTRACT: The 1-*O*-alkylglycerol composition of the liver oil of the deep sea shark *Centrophorus squamosus*, a species which provides edible flesh, has been determined. After various fractionations of the oil, the unsaponifiable fraction was characterized by means of gas chromatography/mass spectrometry, electron impact, and positive-ion chemical ionization. The oil is composed of 60% unsaponifiable matter, containing 45% squalene, 4.5% cholesterol, and 10% of linear saturated and monounsaturated glycerol ethers with 14–18 carbon atoms. After a first separation by chromatography on silicic acid, monounsaturated glycerol ethers have been separated from the saturated homologues, in particular from 1-*O*-octadecylglycerol (batyl alcohol) and 1-*O*-hexadecylglycerol (chimyl alcohol), *via* urea complexation. This newer application of the urea method, already used in the past to extract saturated from polyunsaturated fatty acids, allowed the purification of the main components of the complex unsaturated glycerol ether fraction, namely, 1-*O*-octadecen-9'ylglycerol (selachyl alcohol) and 1-*O*-hexadecen-9'ylglycerol.
Lipids 31, 521–528 (1996).

The deep sea shark *Centrophorus squamosus* (1) lives at depths below 1000 m; it can provide large quantities of squalene-rich liver oil, because this fish, which can reach 1 m in length, has a liver comprising 50% of body weight (2). We recently reported (3) the characterization of fatty acid methyl esters from this liver oil by gas chromatography/mass spectrometry (GC/MS), and the purification of two esters each of docosahexaenoic acid (DHA or 22:6) and of docosamonoenoic acid (DMA or 22:1), by countercurrent chromatography. We then directed our investigations to the complementary unsaponifiable fraction, more particularly to the 1-*O*-alkylglycerol fraction, because of its potential applications in industry.

Abbreviations: APRL, antihypertensive polar renomedullary lipid; DHA, docosahexaenoic acid; DMA, docosamonoenoic acid; EI, electron impact; EPA, eicosapentaenoic acid; FID, flame-ionization detector; GC/MS, gas chromatography/mass spectrometry; GE, glycerol ethers; PAF, platelet-activating factor; PCI, positive-ion chemical ionization; TLC, thin-layer chromatography; TMS, trimethylsilyl radical. The abbreviation "en-n'yl" for 1-*O*-alkylglycerols indicate a normal *cis* ethylenic bond on the *nth* carbon from the ether oxygen.

The unsaponifiable matter of this liver oil contains squalene and glycerol ethers. Squalene is used as a food additive and as a precursor of squalane; the latter compound is utilized largely as an excipient in cosmetics and pharmaceuticals (4). Glycerol ethers, including those of chimyl or batyl alcohol (or their monounsaturated derivatives), have enormous economic potential because they exhibit bacteriostatic and fungistatic properties (5,6), anti-inflammatory activities (7), and hemopoietic effects (8,9). They are also believed to protect against radiation damage and to possess antitumor properties (10). With the recent interest in platelet-activating factor (PAF) (11,12), and the antihypertensive polar renomedullary lipid (APRL) (13), both of which contain a glycerol ether in their structure, ether lipids can also be considered as biochemical mediators (14,15).

MATERIALS AND METHODS

Shark oil. Centrophorus squamosus liver oil was obtained from the IS-FRANCE Company (Lorient, France).

Standards. Racemic batyl alcohol came from Fluka (Buchs, Switzerland) and (+) batyl alcohol from Extrasynthese (Genay, France). Squalene originated from Robeco Chemicals, Inc. (New York, NY) and cholesterol from Janssen Chimica (Geel, Belgium).

Chemicals. AR Normapur solvents and salts used came from Prolabo (Paris, France). The BF_3 was purchased from Fluka, chlorotrimethylsilane from Janssen Chimica, and *N,O*-Bis(trimethylsilyl)acetamide from Aldrich Chemie (Steinheim, Germany).

Shark liver oil fractionation. The saponification was performed according to the procedure recommended by the *Pharmacopée Française* (16). Crude oil (20 g) was diluted with 20 mL of heptane and 40 mL of methanol with 4.5 g of KOH (dissolved with heating); the reaction was carried out under magnetic stirring at 70°C for 30 min.

The potassium salts of fatty acids produced after the saponification were converted into the corresponding methyl esters by adding 150 mL of BF_3 in methanol (10%, by wt) (17); the reaction was achieved with magnetic stirring at 70°C for 15 min. After addition of 170 mL of heptane, the solution was washed with an equal volume of water saturated with

NaCl and dried over Na_2SO_4. An oily mixture (20 g), of a pale yellow color, including both neutral and polar nonfatty acid materials, was obtained after evaporation of the solvent.

Separation of the neutral and polar materials. Esters and other materials (10 g) were submitted to chromatography on a 30 cm × 3 cm column filled with 100 g of silicic acid (ASTM, 230–400 mesh; Merck, Darmstadt, Germany). The eluent was a mixture of heptane and diethyl ether of increasing polarity (18). Five fractions (F1, F2, F3, F4, and F5) were obtained; the final fraction (F5), corresponding to very polar compound(s), was eluted with methanol; the methanol of the last fraction was evaporated and diethyl ether added to the residue, the solution was then filtered on a Büchner funnel to eliminate silica residues.

Collected fractions were analyzed by thin-layer chromatography (TLC) on silica gel 60 F_{254} Special from Riedel-de-Haën (Seelze, Germany), with two different eluents. The less polar fractions were eluted with a mixture of heptane/diethyl ether/formic acid (1:0.25:0.025, by vol), the more polar with the same mixture in the proportions (0.25:1:0.025, by vol) (19). Compounds were visualized by spraying with H_2SO_4 and heating; results are shown in Tables 1 and 2.

Silylation of glycerol ether and cholesterol fractions. Nonvolatile compounds such as 1-*O*-alkylglycerols (F4) and cholesterol (F3) had to be converted into more volatile silyl ethers prior to GC, which is a technique well suited for the analysis of molecules of this kind (20). Silylation was performed by adding 200 µL of *N,O*-Bis(trimethylsilyl)acetamide and 100 µL of chlorotrimethylsilane to 10 mg of such compound(s); the reaction was carried out at 70°C for 20 min with magnetic stirring. After addition of 200 µL of diethyl ether 1 µL of each silylated fraction was injected into the GC.

Analysis of F1, F3, and F4 by GC. Unsaponifiable fractions were first examined by GC to optimize the conditions for further analysis by GC/MS. The analytical system was a Shimadzu Model GC-14A, connected to a flame-ionization detector (FID), controlled with a chromatopac C-R5A integrator (Shimadzu Corporation, Kyoto, Japan), and equipped with a nonpolar dimethylpolysiloxane CP-Sil 5 CB (Chrompack, Delft, The Netherlands) fused-silica capillary column (25 m × 0.25 mm × 0.12 µm). The final optimized analytical conditions were: T_{inj} and T_{det} 285°C, T_{col} isothermal at 190°C for 5 min followed by a programmed temperature gradient from 190 to 285°C at 10°C/min^{-1}, P_{He} 10^5 Pa, split of 80 mL/min, injected quantity 1 µL of silylated compound(s) dissolved in diethyl ether or (20 g/L) for the fraction(s) which were not silylated. See Figure 1 for the results for F4.

Analysis of F1, F3, and F4 by GC/MS. The structures of compounds were characterized by GC/MS experiments with a combination of a chromatograph gas Varian Model 3000 (Sunnyvale, CA), using the same column and conditions as previously described, and a Nermag R10-10C mass spectrometer controlled by a Digital PDP11-23 Plus System (Delsi-Nermag, Argenteuil, France). Electron impact (EI) spectra were recorded at 70 eV, and positive-ion chemical ionization (PCI) studies were performed with NH_3 (Air Liquide, Le Plessis-Robinson, France) as reagent gas at a pressure of 0.1 Torr (1 Torr = 133.3 Pa) in the ion source.

Purification of monounsaturated glycerol ethers (GE) of F4 by urea complexation of saturated GE. Five grams of GE fraction (F4) was dissolved at 70°C in 50 mL of ethanol and 10 mL of methanol, with 5, 15, or 30 g of urea, corresponding, respectively, to the weight ratios $R = 1$, $R = 3$, and $R = 6$ (with R = U/F4, by wt). Urea and urea complexes were allowed to crystallize overnight at 4°C. The crystallized material was separated by filtration on a Büchner funnel.

To recover the noncomplexing materials held in solution, 60 mL of water was added to each filtrate. Then, 6 N HCl was added, with magnetic stirring, until the mixture reached a pH of 4–5. Each solution was then extracted with 2 × 100 mL of diethyl ether. The extracts were separately dried over Na_2SO_4 and filtered. After evaporation of the solvent, a white wax was obtained for each extract of the three filtrates.

Each urea complex precipitate was also dissolved in 150 mL of water and neutralized by 6 N HCl to pH 4–5. Solutions were individually extracted with 2 × 100 mL of diethyl ether and dried over Na_2SO_4. After filtration and solvent evapora-

tion, pale yellow waxes were obtained. All diethyl ether extracts were silylated prior to GC, following the experimental procedure previously described.

RESULTS

Chromatography of C. squamosus *liver oil products on silica gel.* The original crude, deep sea shark liver oil, the saponified oil, and the esterified materials were first analyzed by TLC. Spots were compared with standards and with TLC profiles of other oils found in the literature (21). Table 1 shows that crude oil is composed of three kinds of molecules, i.e., squalene, free cholesterol, and fatty acids as various esters of glycerol or 1-*O*-alkylglycerols. Saponification, followed by esterification, leads to a mixture of squalene, fatty acid methyl esters, cholesterol, and the monoalkylglycerols. The monoalkylglycerols were easily recovered by column chromatography, as shown in Table 2. It appears that this species of deep sea shark has a liver oil which contains an important amount of unsaponifiable matter (60%), of which a very large proportion is squalene (see Table 2). This marine oil also contains significant amounts of ether lipids (10%) and a small quantity of cholesterol (4.5%).

F1, F3, and F4 GC/MS analysis. To confirm the composition of the unsaponifiable matter of the deep sea shark liver oil, fractions F1, F3, and F4 (as defined in Table 2), were first analyzed by GC, then by GC/MS experiments. GC analysis of fraction F1 showed only one chromatographic peak with a retention time of 17.69 min identical with the retention time of a squalene standard. This was confirmed by comparing the EI spectrum of F1 with that of squalene, given by the library (22). Both spectra showed the following characteristic fragments: $[M]^{+\bullet}$ of *m/z* 410, $[M - CH_3]^+$ of *m/z* 395, $[M - C_3H_7]^+$ of *m/z* 367 and $[M - C_5H_9]^+$ of *m/z* 341. The molecular ion and isoprenic fragments of the spectrum were clear enough to identify the compound from F1 as squalene.

In GC experiments, silylated fraction F3 appeared as a pure compound with a single chromatographic peak with a retention time of 20.88 min, coinciding with that of the silylated cholesterol standard. The EI-spectrum of F3 was also comparable to that of silylated cholesterol given by the literature (23), confirming the previous data: *m/z* 458 represents the molecular ion of silylated cholesterol, whereas the following fragments, $[M - CH_3]^+$ of *m/z* 443, $[M - TMSOH]^{+\bullet}$ of *m/z* 368, $[M - (CH_3 + TMSOH)]^+$ of *m/z* 353, $[M - (C_3H_4 + TMSO)]^+$ of *m/z* 329, and $[M - (TMSOH + C_9H_{13})]^+$ of *m/z* 247, (TMS for trimethylsilyl radical) were also present.

GC/MS analysis of silylated fraction F4 demonstrated that it contained several silylated glycerol ethers. Comparison with silylated batyl alcohol standard, and with results found in the literature for 2-*O*-alkyl-1,3-di-*O*-TMS-glycerols, and di- and tri-*O*-alkyl-TMS-glycerols (24), proved that the silylated fraction F4 was mainly a mixture of GE in the 1-*O*-alkyl-2,3-di-*O*-TMS-glycerol form. The gas chromatogram and GE composition of the silylated fraction F4 are shown in Figure 1 and Table 3, respectively. The EI-spectrum of silylated batyl alcohol (Fig. 2) and those of peaks numbers 1–7 of the silylated fraction F4 gas chromatogram present the following similarities: a base peak of *m/z* 205; peak relative to the TMS radical appears in all cases; ions derived from the glycerol-2,3-di-*O*-TMS moiety, namely, *m/z* 147, 133, 130, 117, and 103 are present with 5–25% relative intensity; (M –

15)$^+$ is always present with 5–10% relative abundance, as well as (M – 90)$^{+\bullet}$, (M – 104)$^{+\bullet}$, (M – 147)$^+$, and (M – 180)$^{+\bullet}$ with lower relative intensities; in the lower mass range, the alkyl ions with *m/z* 43, 57, 71, 85, etc., for the saturated compounds and *m/z* 41, 55, 69, 83, etc., for the unsaturated ones, are of significant intensity; the molecular ion with low relative abundance could be observed only in unsaturated GE; the molecular weight of saturated GE was verified by PCI experiments. Assigments of fragment ions are indicated in Figure 3. Examples of EI and PCI-spectra of 1-*O*-hexadecyl-,2,3-di-*O*-TMS-glycerol and EI-spectrum of 1-*O*-hexadecenyl-,2,3-di-*O*-TMS-glycerol (Fig. 4) found in the silylated fraction F4 show the characteristic fragmentations of 1-*O*-alkyl-2,3-di-*O*-TMS-glycerols. Our GC/MS experiments demonstrate that the ether lipids of the esterified deep sea shark liver oil are a mixture of saturated and monounsaturated 1-*O*-alkylglycerols with linear alkyl chains composed of 14–18 carbon atoms, the major compound of which is 1-*O*-octadecenylglycerol. Although substituted GE, namely, 1-*O*-(2-methoxyalkyl) and 1-*O*-(2-hydroxyalkyl) (27) glycerols, were previously isolated by Hallgren *et al.* (25–27) from Greenland shark and other marine animals, we have not detected these compounds in *C. squamosus* liver oil.

*Purification of 1-*O*-octadecen-9′yl and 1-*O*-hexadecen-9′ylglycerol mixture* via *urea complexation.* Urea complexation of saturated fatty acids has been widely used for their removal from a mixture containing polyunsaturated fatty acids such as eicosapentaenoic acid (EPA or 20:5n-3) and DHA or 22:6n-3 (28,29). Due to their flexible chain, saturated molecules form urea complexes (host-guest molecules) more easily than their unsaturated homologues which have *cis* double bonds and are therefore partly rigid (30). We successfully applied this procedure to the purification of unsaturated glycerol ethers by selectively removing their saturated congeners with urea from fraction F4.

The composition of the filtrate, determined by GC, and the yield in monounsaturated GE, are shown in Figure 5 for three different ratios of urea to that of fraction F4, R = U/F4 (by wt). For each ratio R, the presence of saturated GE and other impurities in the filtrate is negligible compared with that of monounsaturated GE. Increasing the amount of urea results in a decrease in both yield and purity of the monounsaturated GE, and as a consequence does not favor their purification. This is, of course, a very important parameter in large-scale preparation, because it minimizes the amount of urea to be used. The proportion of the two main compounds found in the filtrate, namely 1-*O*-octadecen-9′yl and 1-*O*-hexadecen-9′yl-glycerol, varies with the ratio R = U/F4 as well, as shown in Figure 6. These results prove that the ratio R also has an effect on the efficiency of the purification procedure because monounsaturated GE do not have identical behaviors toward urea complexation. Behavior seems to depend upon the carbon chain length of the monounsaturated GE; a higher R does not result in discrimination based on the carbon chain length, whereas a lower R allows purification of longer monounsaturated GE from shorter ones.

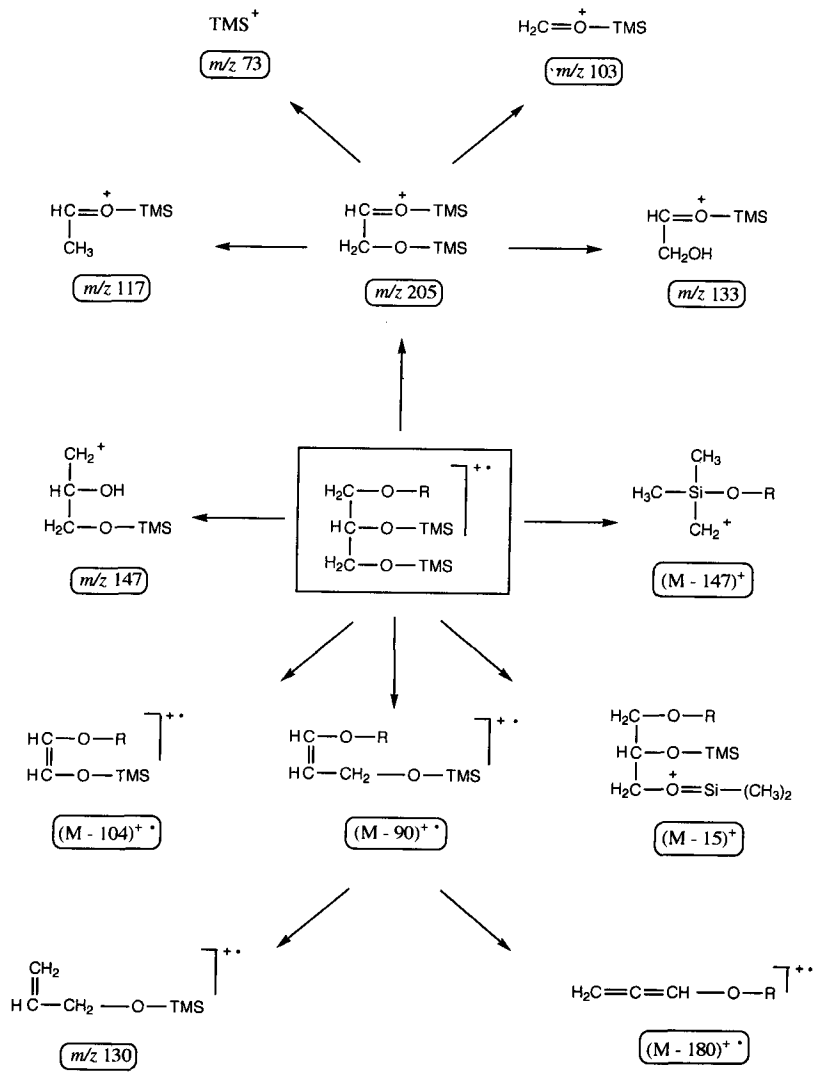

FIG. 3. Scheme of specific fragmentations of 1-*O*-alkyl-2,3-di-*O*-TMS-glycerols (TMS-trimethylsilyl radical).

DISCUSSION

Significance of the notable ether lipid and squalene contents of the liver oil of C. squamosus. Elasmobranch fish (sharks, skates and rays) usually have large livers, containing important quantities of low-density oil, presumably to serve as a substitute for the commonly found gas-filled swim bladder of teleost species (31). The liver oil of *C. squamosus* differs from that at pelagic or sedentary deep sea sharks and contains a larger proportion of low-density lipids (squalene and ether lipids) (32), probably because it is a fast-swimming deep sea shark species (33). Various hypotheses have been put forward to explain the high percentages of these compounds in the hepatic oil of this kind of fish (34). One is the possibility that the fast-moving deep sea sharks use these molecules, and particularly squalene (35), or diacyl- and monoalkylglycerols (36), to maintain an appropriate buoyancy during vertical migrations. Another explanation must be sought for the high percentage of squalene, a molecule that is highly susceptible to oxidation (37).

The use of silylated glycerol ethers to resolve the structures of these compounds of natural complex oils by GC/MS. While the potential of GC/MS for the identification of ether lipids in natural samples is enormous, there have been few reports of the use of silylated glycerol ether derivatives, although they were described by Myher *et al.* (38). Isopropylidene derivatives are usually preferred to identify 1-O-monoalkylglycerols (39). Silylated ether lipids are generally examined by capillary GC on polar liquid phases. This work demonstrates that capillary GC on a nonpolar liquid phase, coupled with MS detection of silylated ether lipids, is also an effective method which can be used to sucessfully separate and determine ether lipid compositions from complex mixtures such as natural extracts of marine origin. For many natural samples, the retention times relative to authentic standards should serve as identification guides. However, this procedure is not suitable to identify the double bond positions of such compounds, even through further use of isopropylidene derivatives on nonpolar GC phases. The unsaturation posi-

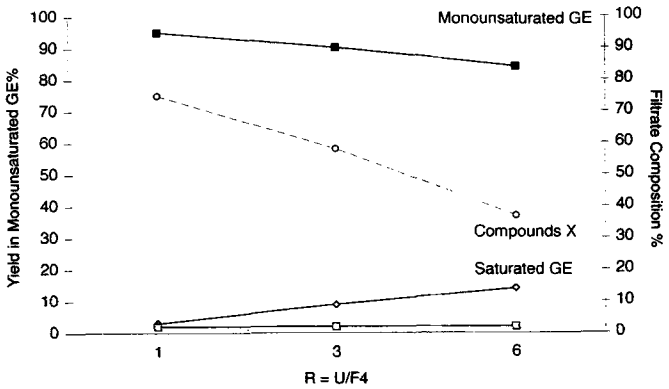

FIG. 5. Yield of monounsaturated glycerol ethers (GE) and composition of monounsaturated, saturated GE, and undetermined compounds X, obtained in the filtrate from the GE fraction F4 after overnight urea complexation at 4°C, with various amounts of urea (U), given by the ratio *R* = U/F4 (by wt); percentages acquired by gas chromatography.

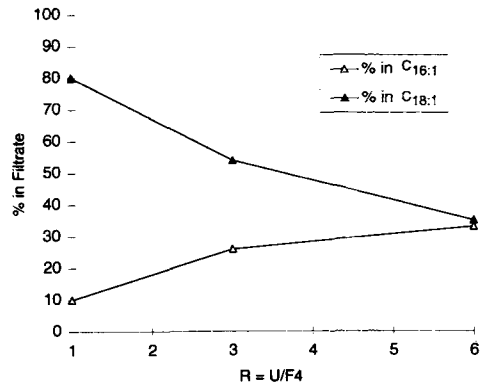

FIG. 6. Influence of the quantity of urea (U) given by the ratio *R* = U/F4 (by wt), used for the urea complexation overnight at 4°C, on the proportion of 1-*O*-hexadecenylglycerol ($C_{16:1}$) and 1-*O*-octadecenylglycerol ($C_{18:1}$), the main constituents of the glycerol ether fraction F4; percentages given by gas chromatography.

tions in the alkyl chains of the shark liver oil ether lipids have been determined recently in our laboratory by GC/MS, using and comparing two different approaches to fix the position of the ethylenic bond. First, a classical procedure was used, namely, the preparation of methoxy ether derivatives at the ethylenic have position of the alkylchain (40); second, an original technique, the use of soft chemical ionization with nitric oxide as reagent gas, developed by Malosse and Einhorn (41) for straight long-chain unsaturated olefins, alcohols, acetates, and aldehydes, was also performed satisfactorily on monounsaturated 1-*O*-alkylglycerols. These results will be published elsewhere.

*The use of urea complexation to produce substantial amounts of pure 1-*O*-monoalkyl and monoalkenylglycerols.* From the data of our urea complexation experiments, it is possible to imagine an efficient purification procedure as follows. Step 1: urea complexation of the initial fraction containing both saturated and monounsaturated GE with a high ratio of urea to GE (*R*), which will lead to the recovery of a pool of pure monounsaturated GE in the filtrate, but with a poor yield (40%); the yield can of course be improved by reprocessing the precipitate. Step 2: urea complexation of the monounsaturated GE fraction with a low *R*, to separate the GE as a function of the carbon chain length.

This procedure will be reduced to step 2 if only long-chain monounsaturated GE are of interest, and this makes urea complexation a powerful means for removal of the longer-chain monounsaturated ethers from a mixture of saturated and monounsaturated glycerol ethers. This novel use of the urea complexation method can provide useful amounts of pure 1-*O*-monoalkylglycerols. These compounds could be utilized as precursors in the large-scale synthesis of a series of molecules with important potential uses in cosmetic as well as pharmaceutical areas.

Microscale Preparation of Natural and Labeled Oxysterols

Louis H. Krut*, Gustav Schonfeld, and Richard E. Ostlund, Jr.

Metabolism Division and Division of Atherosclerosis, Nutrition, and Lipid Research, Washington University School of Medicine, St. Louis, Missouri 63110

ABSTRACT: The preparation of cholesterol and radiocholesterol oxidation products on a microscale is difficult. Cholesterol generally resists oxidation unless it is well dispersed under controlled conditions. A method was developed to reliably produce 7α- and 7β-hydroxycholesterol and 7-ketocholesterol. Small changes in pH, metal ions present, or in the colloidal dispersion, resulted in production of completely different oxysterols. Attempts to oxidize aged radiocholesterol were not successful even after purification by several thin-layer chromatographic steps, and this appeared to be due to a time-related change in the radioactive material. Fresh radiocholesterol oxidized readily.

Lipids 31, 529–534 (1996).

Recent intense interest in cholesterol and lipoprotein oxidation products prompted us to prepare oxysterols from cholesterol tracers labeled with carbon-14, carbon-13, and deuterium. The oxidation of cholesterol has been extensively studied and comprehensively documented (1). Our aim was to oxidize cholesterol in a way such as to yield a limited number of major products by a method that would give reasonable reproducibility. The method was based on that described by Bergstrom and Wintersteiner (2), in which air is bubbled through a heated colloidal dispersion of cholesterol. We chose this method because it yields the oxysterols 7α- and 7β-hydroxycholesterol and 7-ketocholesterol as its major products, leaving some unaltered cholesterol, which suited our purpose. Furthermore, the additional oxygen functions are introduced at the C-7 position where they would not interfere with the isotopic substitutions we intended to use. The method as originally described was for oxidizing 5.0 g cholesterol and it can be scaled up easily to process several times that quantity (3,4). However, it was not possible simply to scale down the method to oxidize milligram to microgram amounts of cholesterol because the reaction was not reproducible with respect to the yield of oxysterols. Furthermore, it was open to the atmosphere and soap bubbles tended to escape from the top of the reaction vessel during bubbling of oxygen, which was clearly unsuitable for oxidizing radioisotopes. To overcome these difficulties we devised a closed system in which cholesterol was uniformly distributed and oxygen bubbling was unnecessary. In this system yields of oxysterols were highly reproducible.

MATERIALS AND METHODS

Materials. Cholesterol (Sigma grade), sodium stearate, and methoxyamine hydrochloride were purchased from Sigma (St. Louis, MO). 4-^{14}C-Cholesterol was purchased from Amersham (CFA.128, 55 mCi/mMol; Arlington Heights, IL) and from Dupont New England Nuclear (NEC-018, 51 mCi/mMol; Boston, MA). Aged lots were purchased 5–6 yr before use and kept at −15°C in their original containers in toluene. Fresh 4-^{14}C-cholesterol was used within three weeks of synthesis and was supplied in ethanol solution and stored at −15°C. Stable isotopic cholesterols—[26,26,26,27,27,27-^{2}H]cholesterol and [23,24,25,26,27-^{13}C]cholesterol—have been characterized previously (5). The ^{13}C-cholesterol tracer also contained 26% [23,24,25-^{13}C]-[26,27]*bis*-norcholesterol. Authentic oxysterols were purchased from Steraloids (Wilton, NH) and Sigma. Regisil RC-3 [*bis*(trimethylsilyl) trifluoroacetamide + 10% trimethylchlorosilane] was purchased from Regis (Morton Grove, IL). Thinlayer chromatography (TLC) microplates, 2.5 × 7.5 cm, coated with silica gel 60, were purchased from Alltech (Deerfield, IL).

Milligram scale. The following procedure is used to oxidize 40 mg of cholesterol: 8.0 mg of sodium stearate is introduced into a test tube and to this is added 8.0 mL water with pH adjusted to 8.5–9.5 by adding a few μL of 10% aqueous KOH, heated to 85°C and vortexed to bring the stearate into solution. This solution is not stable and is best if freshly prepared and kept at 85°C until used. The cholesterol is dissolved in 2.0 mL ethanol at 60–65°C and is added slowly in a fine stream to the stearate solution through a Pasteur pipette with a finely drawn-out tip while the solution is being vortexed. The colloidal preparation is brought to 85°C and transferred to a preheated 50-mL conical flask with a long neck stabilized on a heater with magnetic stirrer. It is necessary for the contents to be well stirred throughout and for the temperature to be maintained at 83–85°C. Oxygen is bubbled gently through the solution for six hours *via* a pipette with a fine tip.

Copyright © 1996 by AOCS Press

The soap bubbles and vapors rising in the flask are condensed on strips of aluminum foil hanging into the opening of the flask. The contents are allowed to cool, aliquots transferred to test tubes, and extracted three times with two volumes of ethyl ether. The ether is evaporated with heat in a stream of nitrogen. The products in ethanol are monitored by TLC on microplates eluted with ethyl acetate/heptane (3:1 or 3:2,vol/vol).

The constituents are visualized (6) by briefly dipping the plate, freed of solvent, in a solution of 10% $CuSO_4$ in 8.5% H_3PO_4 and heating it on a Pyrex dish on a hot plate. On heating, cholesterol appears as a magenta color, the 7-OH compounds (and others) are Prussian blue, and the 7-ketocholesterol becomes yellow/ocher after a delay. Charring depends on time and temperature. The compounds are identified by running suitable reference compounds in the same way and are verified by gas chromatography/mass spectrometry (GC/MS). The proportion of cholesterol oxidized in this system varied substantially and oxidation sometimes failed. This seems to be due to early destabilization of the sol recognized by the deposition of solids on the side of the flask.

Microgram scale. Because this system is not desirable for oxidizing 4-^{14}C-cholesterol due to the danger of spillage with bubbling oxygen and lack of reproducible yield, a new closed system was developed. Some of the variations tried in this system are described in detail to highlight points of interest.

System A. System A consists of 200 µg cholesterol plus 10 µL ethanol plus 40 µL of sodium stearate preparation (8.0 mg in 8.0 mL water at pH 8.5–9.5). This is simply a scaled-down reaction according to Bergstrom and Wintersteiner (2), except that no oxygen was bubbled through the reactants.

System B. System B is 200 µg cholesterol plus 100 µL ethanol plus 40 µL of sodium stearate preparation plus 360 µL of water at pH 8.5–9.5. (This is the method of choice for preparing the desired oxysterols.) In this system the concentration of cholesterol is reduced to 0.4 mg/mL from 4 mg/mL by the method of Bergstrom and Wintersteiner (2), but the ratios of cholesterol/stearate and ethanol/water are unchanged.

System C. System C contains 200 µg cholesterol plus 100 µL ethanol plus 40 µL of sodium stearate preparation. The ratio of ethanol/water is increased 3.6-fold over System B. This was done to examine whether the ratio of ethanol/water was critical to yield the desired products.

System D. This system has 200 µg cholesterol plus 100 µL ethanol plus 50 µL of 30 µM $CuCl_2$ in water to give a final concentration of 10 µM. Here copper is added as an oxidant to determine whether it would increase the yield of the desired oxysterols.

Oxidation is carried out in 2-mL thick-walled glass v-vials with Teflon-lined screw caps. The cholesterol is added to the vial from a stock solution in ethanol and the solvent evaporated with heat under a stream of nitrogen. The volumes of ethanol given previously are added, the vial capped, and it is vital to ensure that all the cholesterol is brought into solution using heat. The vial is brought to ambient temperature and centrifuged to bring down droplets. The heated aqueous material is then added, the vial immediately capped, vortexed, and heated at 93–95°C for the next 18–20 h. An hour after heating has commenced the vials are cooled, centrifuged, the air displaced with oxygen and returned to the heating block. This is done three times in the first 8–12 h and the vials are vortexed every few hours over the full period. The preparation is then dried by lyophilization in a Speed-Vac (Savant Instruments, Farmingdale, NY) and taken up in ethanol. Stearic acid can be removed by TLC, applying the sample to a microplate in which the bottom 16 mm has been briefly dipped in a solution of 10% aqueous KOH/ethanol (1:9, vol/vol) and the plate well dried prior to chromatography. If the plate is not treated with KOH/ethanol, stearic acid migrates as a distinct band near natural cholesterol and separates well from oxysterols.

GC/MS. For derivatization of samples for GC/MS, a few µg of the dry sample is heated in Teflon-lined screw-capped glass vials for 2 h at 80°C in 0.5 mL dry pyridine with methoxyamine hydrochloride (20 mg/mL), and then at 65°C for 30 min after adding 1.0 mL of 1/1 Regisil RC-3 in dry pyridine. Sterols are chromatographed on a 15 m × 0.25 mm DB-210 capillary column (J&W Scientific Folsom, CA) at 255°C and analyzed with a Hewlett-Packard (Wilmington, DE) 5970 electron impact ionization mass spectrometer (Fig. 1). Cholesterol, 7α- and 7β-hydroxycholesterol, and 7-ketocholesterol had principal ions of *m/z* 368, 456, 456, and 470, respectively. The 7-OH compounds have the same masses, but are widely separated on GC and easily distinguished. The appropriate reference compounds gave the same findings. Three small peaks appearing between 4.5 and 4.9 min on the total ionization current tracing (TIC) (Fig. 1, top line) each accounted for less than 1% of the TIC area. Oxidized hexadeuterated cholesterol was separated on a 2 mm × 137 cm column packed with 3% OV-17 on gaschrom Q (Applied Science Laboratories Inc., State College, PA) at 250°C with a 30 mL/min helium flow rate and admitted to a Finnigan (Sunnyvale, CA) 3300 mass spectrometer. The deuterated and ^{13}C-enriched sterols had principal ions higher by 6 and 5 mass units, respectively, with the same retention times as the natural compounds.

The yield and reproducibility of System B was assessed by oxidizing 200 µg quantities of natural cholesterol. This was dried and taken up in ethanol, a 50 µg aliquot was taken, and 10 µg 5α-cholestane (Sigma) in toluene was added as an internal standard. The mixture was derivatized as described previously, and analyzed in duplicate by GC with a flame-ionization detector using a 60 m × 0.75 mm glass capillary coated with 1µ SPB-1 at 310°C (Supelco Inc., Bellefonte, PA). The areas of the oxysterols, cholesterol, and 5α-cholestane were proportional to the mass present.

RESULTS

The development of a closed oxidation system for microgram quantities was undertaken for use with radioactive cholesterol. Unlike the open milligram-scale system, the closed microgram-scale system consistently gave the desired products using either natural cholesterol, deuterated cholesterol, ^{13}C-cholesterol, or fresh 4-^{14}C-cholesterol. An additional advan-

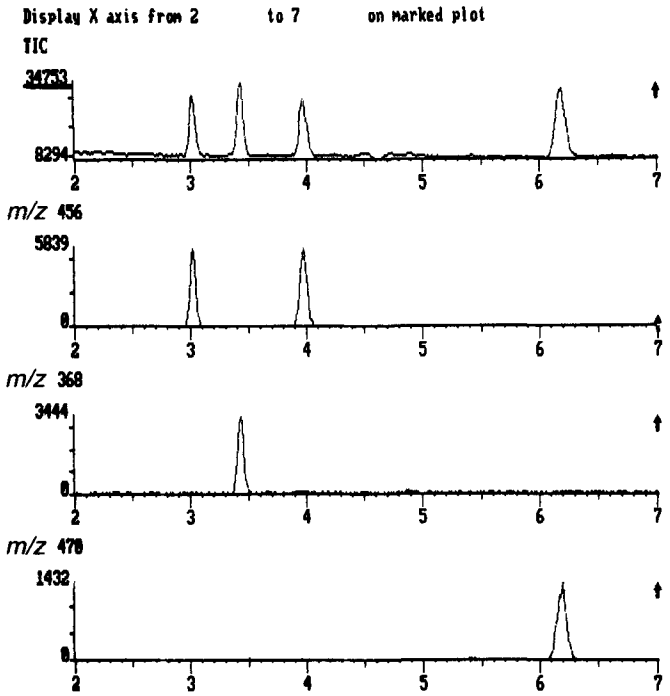

FIG. 1. Gas chromatography/mass spectrometry (GC/MS) of oxidized cholesterol. Natural cholesterol oxidized by System B was analyzed by capillary column GC/MS as described in the Materials and Methods section with monitoring of ions between *m/z* 250–600. The total ionization current (TIC) (top line), *m/z* 456 (second line, 7α- followed by 7β-hydroxycholesterol), *m/z* 368 (third line, cholesterol), and *m/z* 470 (bottom line, 7-ketocholesterol) are shown.

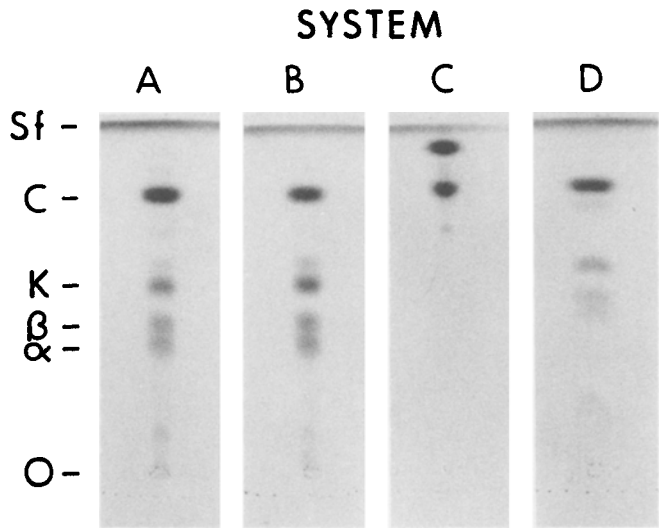

FIG. 2. Thin-layer chromatography of cholesterol and its products after oxidation in Systems A–D (see text for details). O is origin, α is 7α-hydroxycholesterol, β is 7β-hydroxycholesterol, K is 7-ketocholesterol, C is cholesterol, and Sf is solvent front.

tage is that it need not be closely monitored. Figure 2 shows charred TLC plates of cholesterol oxidized in Systems A–D. Systems A and B give much the same results with principal products of 7α- and 7β-hydroxycholesterol and 7-ketocholesterol. System C, which differs from A and B in having a higher proportion of ethanol to water, yielded a large amount of a compound less polar than cholesterol. System D, which included copper as an oxidant, produced little 7α- or 7β-hydroxycholesterol, but did produce 7-ketocholesterol identified by GC/MS. The differences between Systems A and B compared with Systems C and D (Fig. 2) might depend on the colloidal dispersion achieved. Preparations A and B were different in that A was densely opalescent and B very faintly so, although both remained homogeneous. We found System B most suitable for our purposes. The o.d. of System B at 600 nm standardized against water was 0.062, and was 0.056 to 0.058 at the end of treatment. This system can be adjusted to treat more or less starting material and one can easily cope with a considerable number of vials at the same time. In Systems C and D there is a precipitate. These preparations become homogeneous on heating, but the precipitates reform on cooling after oxidation and there is a separation into two phases. The physical dispersion of cholesterol thus differs considerably in these systems.

The method of extracting the sterols unexpectedly proved to be critical. For example, if 200 μg of cholesterol is oxidized by System B and, instead of drying, chloroform and ethanol are added in proportions to give a Folch-type of phase split (7), and a few μL of 2N HCl is added to this to promote phase separation, the phases separate readily with the aqueous phase at pH 2.0. However, the oxysterols recovered in the chloroform phase are substantially altered qualitatively (Fig. 3). Numerous new compounds are generated while others dis-

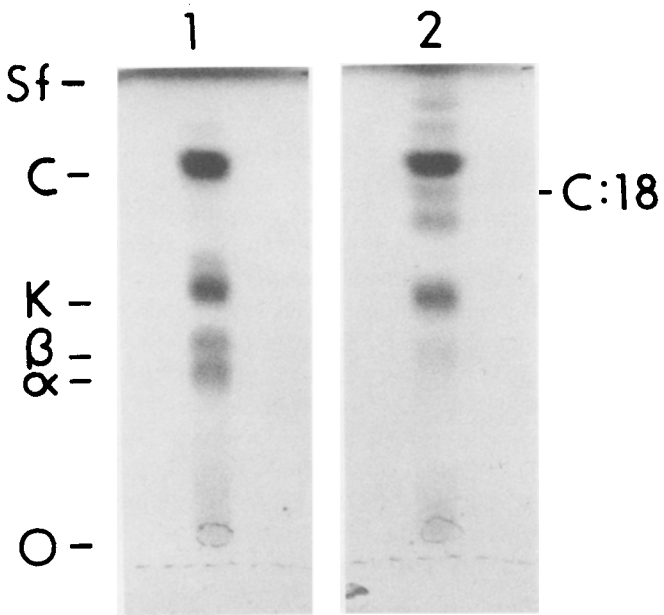

FIG. 3. Effect of acidification of solvent extract. Compounds are as named in Figure 2 and C:18 is stearic acid. Plate 1 is standard extraction procedure and plate 2 is an aliquot of the same preparation in which the solvent was acidified to promote a phase split (see text for details).

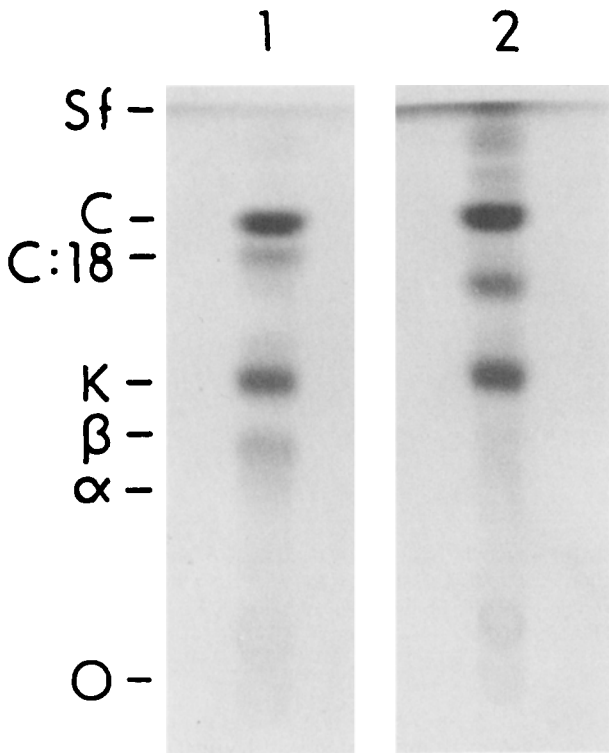

FIG. 4. Effect of alkali wash of solvent extract. Plate 1 is standard extraction procedure and plate 2 is after an aliquot was washed with potassium hydroxide as described in the text. Compounds identified as in Figures 2 and 3.

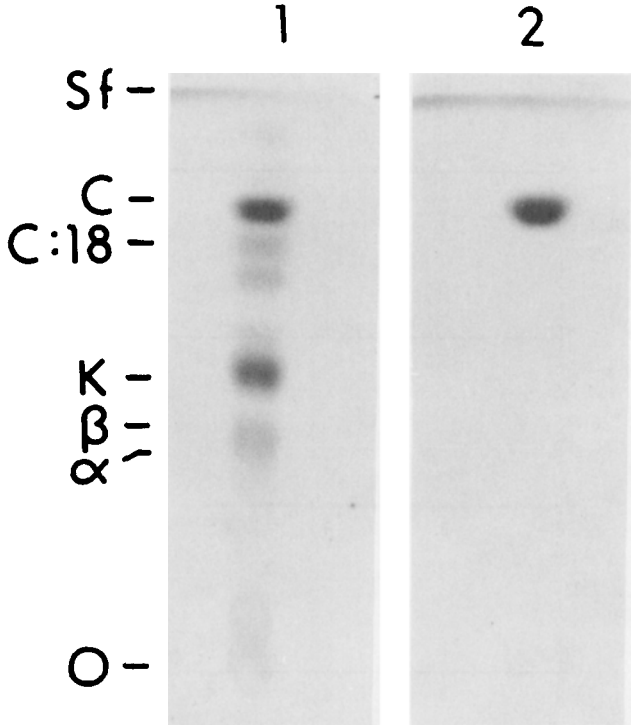

FIG. 5. Effect of bubbling oxygen through a colloidal dispersion of cholesterol. Plate 1 is standard microgram-scale oxidation method, whereas plate 2 shows recovery of unaltered cholesterol after bubbling of oxygen for 6 h at 85°C. Compounds identified as in Figure 2.

appear. If a similar experiment is done except that no acid is added and an alkaline wash of the organic phase is done to remove the stearate (2), then the nature of the oxidation products is also altered (Fig. 4). Bascoul *et al.* (8) appear to have made a similar observation with alkali, but they gave no details.

The effect of mild acid used to promote a phase split in the extraction of the oxysterols generated in System B was studied in more detail by GC/MS using a capillary column. The use of mild acid at pH 2.0 resulted in further oxidation of the oxysterols. It was found that 7α-hydroxycholesterol had disappeared, 7β-hydroxycholesterol was greatly reduced, and 7-ketocholesterol remained relatively abundant. Two principal new peaks appeared. One was identified as cholesta-3,5-diene-7-one by its retention time and a molecular ion of *m/z* 411 (methoxyamine derivative) and a major fragment at *m/z* 380 (411-OCH_3), identical to an authentic standard. The other new compound was derived from 7α-hydroxycholesterol, as demonstrated from reference material. It had prominent ions at *m/z* 412 and 456. The latter is the major fragment ion of the 7-hydroxycholesterols, suggesting that the new compound is a further oxidation product of those oxysterols.

The need for appropriate conditions in order to oxidize cholesterol is illustrated by the following experiment in which the cholesterol dispersion was destabilized by vigorously bubbling oxygen. Forty μL of sodium stearate preparation was added to 200 μg of cholesterol in 2.0 mL ethanol, and to this mixture 8.0 mL water at pH 8.5–9.5 was added. The material was then heated to 85°C for 6 h as oxygen was bubbled vigorously through a fine capillary. The recovered material (Fig. 5) was completely unchanged. The reason for resistance to oxidation is presumably destabilization of the solution as small particles appeared to precipitate from what had been a homogeneous solution and the o.d. of this dilute dispersion declined from 0.011 to 0.002.

Attempts to oxidize aged ^{14}C-cholesterol by the microscale method, with the mass of material calculated from the specific activity, failed repeatedly. The radiocholesterol was purified on silicic acid-coated plates in petroleum ether/ethyl ether/acetic acid (90:10:1, by vol) and also in antioxidant-free ethyl acetate/heptane (3:1 and 3:2, vol/vol) with over 87% of the radioactivity recovered in the position of cholesterol. An autoradiograph of the ^{14}C-cholesterol after purification is shown in Figure 6. The adjacent figure is an autoradiograph of the same material after attempted oxidation in System B. The yield of new compounds was barely detectable in numerous attempts at oxidation.

Figure 7 shows an autoradiograph of a preparation of fresh 4-^{14}C-cholesterol oxidized in System B, which has yielded the desired products in about the same proportions as found in simultaneously oxidized natural cholesterol. The distribution of radioactivity, obtained from scrapings taken from the TLC plate, was cholesterol, 45%; 7-ketocholesterol, 33.1%;

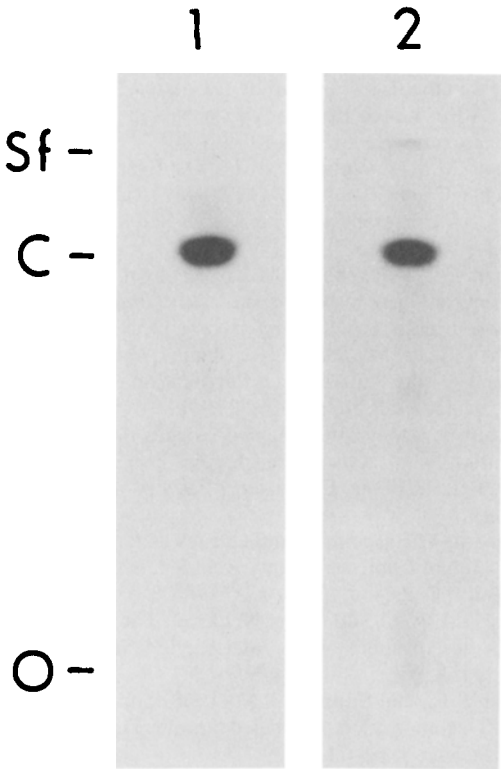

FIG. 6. Failure to oxidize purified aged ^{14}C-cholesterol. Autoradiographs of thin-layer chromatographic separations of purified "old" 4-^{14}C-cholesterol (plate 1) and of the same material after oxidation (plate 2), the latter showing the generation of negligible amounts of a number of new compounds. Compounds identified as in Figures 2 and 3.

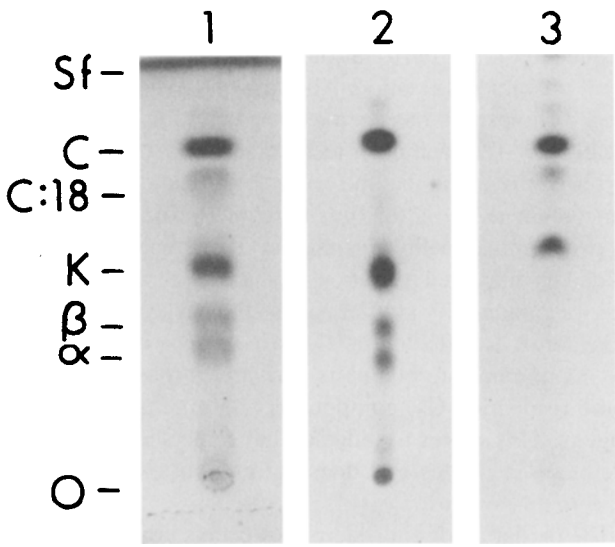

FIG. 7. Oxidation of fresh ^{14}C-cholesterol. From left to right: (1) thin-layer chromatographic (TLC) separation of natural cholesterol and its oxysterols treated by the microgram-scale method, (2) autoradiograph of a TLC separation of fresh 4-^{14}C-cholesterol treated by the microgram-scale method and extracted as recommended, and (3) autoradiograph of a TLC separation of material in 2 in which the sterols had been extracted with solvents that had been acidified (see text for details). Compounds identified as in Figures 2 and 3.

7β-hydroxycholesterol, 9.4%; and 7α-hydroxycholesterol, 12.5%. The effect of acidification of the solvent extract prior to recovery of the radioactive material is shown in the adjacent autoradiograph, again demonstrating changes similar to those found with natural cholesterol (see Fig. 3). It should be noted that the fresh 4-^{14}C-cholesterol had not been run on TLC prior to its oxidation.

The yield of oxysterols using the closed System B was quantitated by GC using a flame-ionization detector. In three experiments analyzed in duplicate the reaction products were cholesterol, 45.3 ± 1.8% (SE); 7α-hydroxycholesterol, 11.6 ± 0.5%; 7β-hydroxycholesterol, 13.6 ± 0.6%; and 7-ketocholesterol, 29.8 ± 0.8%.

DISCUSSION

The oxidation of free cholesterol is recognized to present problems in its execution (8,9). However, the method of Bergstrom and Wintersteiner (2), described decades ago, is highly effective and adaptable, once one recognizes those aspects that are vital for its success. With this method the creation of a colloidal dispersion of cholesterol and its maintenance are crucial for oxidation. Oxidation was prevented when the dispersion was disrupted by vigorously bubbling oxygen through the reaction mixture (Fig. 5). The conditions under which cholesterol is dispersed clearly affects the nature of the oxidation products (Fig. 2), as does altering the pH of the oxidized preparation during lipid extraction (Figs. 3, 4, and 7). There is obviously the potential for producing a wide range of compounds, probably many more than is shown here, both by modifying the nature of the colloidal dispersion, as well as by altering the pH of the final extract.

In contrast to the difficulty and variability of achieving controlled cholesterol oxidation for small samples by existing techniques, our preferred microscale method (System B), which is closed to the atmosphere, is highly consistent, both with respect to the products formed (Fig. 1) and their amounts (coefficient of variation 3.5–5.8% for percentage of each compound). To achieve this reproducibility, however, one must note the caveats given in the Methods and Materials section.

The most intriguing and taxing aspect of the work was the failure to oxidize aged ^{14}C- cholesterol, despite repeated purifications, whereas fresh material oxidized readily. The reason for that failure is by no means clear. It has been demonstrated that stored, labeled steroids are far from stable and some factors influencing stability have been identified (10,11). Purification of stored material at fairly frequent intervals seems to be obligatory for preventing breakdown and the presence of certain tars in the solvent are also deleterious.

TLC is commonly used to ensure purity and chemical

identity of labeled compounds. The failure to oxidize cholesterol that had been stored for some years under the conditions in general use leaves one uncertain about both points. Conceivably this was because the material was no longer cholesterol or that there persisted impurities, or that impurities were introduced during purification and/or recovery procedures, which prevented oxidation. Aberrant physiological behavior of aged cholesterol has been reported previously despite purification by TLC and other techniques (12).

It is worth noting that the original ^{13}C-cholesterol preparation contained 26% [26,27]*bis*-norcholesterol, which is missing two terminal methylene groups. Oxidation of this mixture yielded the expected oxidation products of cholesterol and, in addition, apparently similar oxidized derivatives of *bis*-norcholesterol, as reflected in TLC separations of the mixture. The *bis*-norcholesterol and its derivatives run slightly ahead of the respective C_{27} compounds and give the same chromogens. This serves to indicate that some shortening of the side chain of cholesterol does not prevent oxidation of the sterol in this system.

The oxidation of cholesterol has been studied extensively in a variety of systems (1). These include prolonged exposure of free cholesterol in the dry state at high temperature (9,13), the use of esters (8,9), and the dispersion of cholesterol in aqueous medium (9,14–16) the latter dating from the work of Bergstrom and Wintersteiner (2). More than 50 oxidation products have been identified (1,17). The purpose of this communication is to describe a micromethod for the oxidation of cholesterol, as well as of radioactive cholesterol, which is both simple and highly reproducible with limited oxidation products. By controlling the dispersion of cholesterol in sodium stearate, the pH, and the method of extracting the product, it is possible to produce selected cholesterol autoxidation products useful in biological studies. This will allow physiological studies of tracer oxysterols in intact animals and cell culture models.

An Improved Method for Rapid Analysis of the Fatty Acids of Glycerolipids

Ken'ichi Ichihara[a,*], Akira Shibahara[b], Kohei Yamamoto[c], and Takao Nakayama[c]

[a]Department of Agricultural Chemistry, Kyoto Prefectural University, Kyoto 606, [b]Department of Clinical Nutrition, Osaka Prefectural College of Health Sciences, Habikino 583, and [c]General Testing Research Institute of Japan Oil Stuff Inspectors' Corporation, Kobe 658, Japan

ABSTRACT: An improved rapid procedure to determine the fatty acid composition of glycerolipids is described. The procedure includes KOH-catalyzed transesterification and high-speed gas chromatography. Glycerolipids (20–40 mg) were mixed with 2 mL of hexane and 0.2 mL of 2 M methanolic KOH at room temperature for 1–2 min. The fatty acid methyl esters in the hexane layer were analyzed by gas chromatography on 10% SP-2340 at 240°C. Methyl linolenate and docosahexaenoate eluted within 2 and 5 min, respectively. Analysis was thus completed within 5 min for common vegetable oils and 8 min for fish oils.

Lipids 31, 535–539 (1996).

The fatty acid (FA) composition of fats and oils is determined by gas chromatography (GC) as fatty acid methyl esters (FAME). FAME are usually prepared by (i) saponification of glycerolipids followed by methylation, (ii) acid-catalyzed methanolysis, or (iii) alkali-catalyzed methanolysis. Of the many procedures that have been proposed and used for FAME preparation (1–5), the KOH-catalyzed methanolysis (transesterification) has the great advantage of rapid and simple preparation (6–11). Nevertheless, this preparative method is not popular, probably due to researchers' apprehensions that glycerolipids may be saponified with KOH even in methanol to form free FA. In the most conventional methods of alkali- and acid-catalyzed methanolysis (1–5), lipid samples are refluxed with CH_3ONa in methanol and with anhydrous HCl in methanol, respectively, which are time-consuming procedures.

In 1969, Christopherson and Glass (12) reported an alkali-catalyzed methanolysis method and subsequent GC analysis for milk fat. In the present study, we thoroughly verified that the KOH-catalyzed methanolysis does not produce appreciable amounts of free FA and is superior to other methods in terms of rapidity, safety, and cost. We suggest the use of this convenient methanolysis as a superior method for preparation of FAME from glycerolipids. The combination of this method and high-speed GC has enabled the rapid analysis of FA compositions of various fats and oils.

Abbreviations: DEGS, diethylene glycol succinate polyester; DGDG, digalactosyldiacylglycerol; FA, fatty acid; FAME, fatty acid methyl ester; GC, gas chromatography; PC, phosphatidylcholine; TG, triacylglycerol; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Reagents. Triacylglycerol (TG) and oleyl oleate were purchased from Nu-Chek-Prep (Elysian, MN). FA, cholesteryl oleate, and digalactosyldiacylglycerol (DGDG) were from Serdary Research Laboratories (London, Canada). SP-2340 is the product of Supelco (Bellefonte, PA). Methanol, hexane, and KOH were of reagent grade and were used without further purification.

Preparation of FAME from glycerolipids. In a small glass tube were placed 20–40 mg of TG, 2 mL of hexane, and 0.2 mL of 2 M methanolic KOH. Plastic microcentrifuge tubes (1.5 mL) were also used in a scale of operation 20-fold smaller. In a typical reaction, the tube was vortexed at room temperature for 2 min or at 30–37°C for 1 min. An aliquot of the upper hexane layer was directly injected in to GC (Hitachi 263-70, a 2-m glass column packed with 10% SP-2340 on 100–120 mesh Chromosorb WAW). The column temperature was 240°C for high-speed GC.

The total FA composition of a lipid mixture was determined by a conventional saponification/methylation procedure. The lipid mixture (20–60 mg), contained in a screw-capped glass tube, was hydrolyzed with 2 mL of 0.5 M KOH in 70% methanol at 70°C for 1 h. After acidification with 0.6 mL of 2 M HCl, the FA released were extracted with hexane. The hexane solution was washed with water and then evaporated *in vacuo*. The free FA obtained were methylated with 15% methanolic BF_3 for 20 min at room temperature.

The reaction products were analyzed by thin-layer chromatography (TLC) on silica gel (No. 5721; E. Merck, Darmstadt, Germany). The solvent system used for methanolysis products of TG was hexane/acetone/acetic acid (95:5:0.5, by vol). The products of polar lipids were analyzed by double development; the first solvent was chloroform/methanol/water/acetic acid (55:45:7:0.5, by vol), and the second was hexane/acetone/acetic acid (95:5:0.5, by vol). Lipids separated were visualized by spraying 50% (w/w) sulfuric acid and then heating at 135°C.

RESULTS AND DISCUSSION

Effects of the KOH concentration and the reaction time on FAME formation. The maximum conversion of TG into FAME was obtained at 2 M KOH (Fig. 1A), when the reaction mixture was vortexed at room temperature for 2 min (Fig. 1B). A trace amount of TG remained unchanged at room temperature at 1 M KOH, while no TG remained at 30–37°C (data not shown). The FA compositions obtained from these complete and incomplete methanolysis procedures were almost the same. Although vortexing for 2 min at room temperature or for 1 min at 30–37°C is recommended, vortexing for 1 min at room temperature or for 0.5 min at 30–37°C can also be used for more rapid analysis. It has been reported that mixing for 2 min is enough for methanolysis (12).

When TG in hexane was allowed to stand overnight with methanolic KOH at room temperature, using diluted methanolic KOH solutions (0.1–0.2 M) gave better results than using more concentrated solutions (0.5–2 M) (Fig. 1C). Appreciable amounts of free FA were detected at concentrations higher than 0.5 M, although no TG was found in the range of the concentrations tested. Another practical procedure that can be used in FAME preparation is to allow TG to stand for 2 h with 0.2 M KOH. It should be noted, especially for autosampler users, that the methanolysis of soybean oil with 2 M KOH for 24 h decreased the linoleic acid (18:2) and linolenic acid (18:3) methyl ester contents from 53.7 to 52.5% and from 7.9 to 7.3%, respectively, compared with the contents obtained by the 2-min reaction. NaOH can be replaced with KOH, but the former is less soluble in methanol than the latter. The methanolic KOH solutions can be stored in tightly capped plastic bottles at room temperature for at least two months, without any decrease in reactivity.

Effects of the water content of methanol on FAME formation. The water content of methanol at 2% or less did not affect FAME formation (Fig. 1D), and hence commercial methanol of reagent grade can be used without drying. When TG in hexane was allowed to stand overnight with 0.2 M methanolic KOH, even 10% water in methanol did not affect the methanolysis (data not shown). The reaction proceeded in the presence of silica gel and small amounts of water, and hence glycerolipids that were separated by TLC could be treated without extraction with solvents.

Effects of the amounts of methanolic KOH and TG on FAME formation. An amount of methanolic 2 M KOH solution in the range of 0.1–0.8 mL did not affect the reaction (Fig. 2A). In this reaction system, 200 mg of TG was completely converted into FAME (Fig. 2B). Thus, the amounts of both methanolic KOH and TG do not affect the reaction efficiency.

Specificity for ester linkage. DGDG and PC were also transesterified with methanolic KOH (Fig. 3A). Most of the PC molecules were converted into FAME within 5 s; after

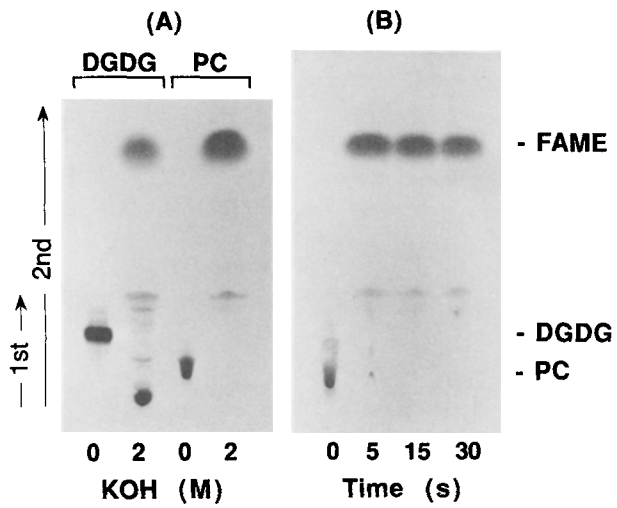

FIG. 3. (A) Methanolysis of digalactosyldiacylglycerol (DGDG) and phosphatidylcholine (PC). (B) Time course of the methanolysis of PC. After the termination of reaction by acidification with acetic acid, the solvents in the reaction mixture were evaporated *in vacuo*. The total residue was dissolved in chloroform/methanol (1:1, vol/vol) and double-developed on silica gel with two different solvent systems (see the Materials and Methods section). Other abbreviation as in Figure 1.

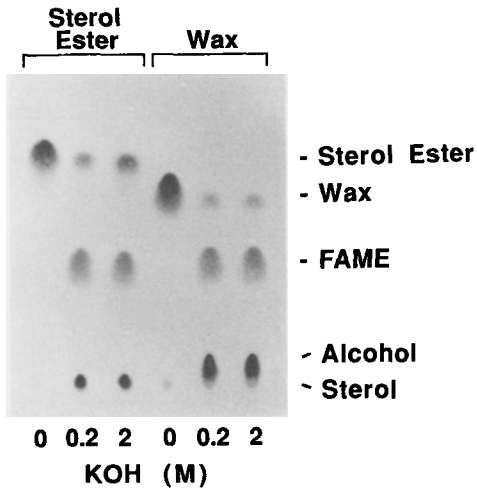

FIG. 4. Methanolysis of sterol ester (cholesteryl oleate) and wax (oleyl oleate). The reaction time was 15 h. The solvent system was hexane/benzene/acetic acid (50:50:0.5, by vol). Abbreviation as in Figure 1.

treatment for 15 s, no PC remained (Fig. 3B). The high reaction-rate for PC is probably due to its high solubility to methanol. In contrast to these glycerol esters, sterol ester and higher-alcohol ester (wax) did not react with methanolic KOH under the conditions described in the Materials and Methods section. Even when the hexane solutions of these inert esters were allowed to stand overnight with 0.2 or 2 M methanolic KOH, small amounts of the original esters remained unchanged (Fig. 4). Methanolysis of sterol esters requires the addition of benzene (40%) and a prolonged reaction time (2 h) (13).

Determination of the FA composition of glycerolipids. The present method was compared with two conventional methods, saponification/methylation and CH_3ONa-methanolysis with reflux, as to the FAME products (Table 1). The lipid sample was a mixture of TG (oleic acid, 18:1), PC (erucic acid, 22:1), and free FA (18:2). In spite of the presence of large amounts (37–60%) of free FA (18:2), only trace amounts of 18:2 were detected in FAME prepared by the KOH-catalyzed methanolysis. The mechanism by which the methyl linoleate was formed is not known. No appreciable difference was found between the present method and CH_3ONa-catalyzed methanolysis with reflux. Because free FA in fats and oils are not converted into methyl esters by alkali-catalyzed methanolysis, the FA composition obtained by the present method does not precisely reflect the total FA composition. However, free FA are a minor component of natural fats and oils (usually less than a few percent of TG), and the FA composition of free FA is similar to that of TG. The FA compositions determined for natural fats and oils by the present method are therefore expected to be almost the same as the total FA compositions. The FA composition of soybean oil was determined by the above three methods. The results were almost identical (Table 2). These data clearly

show that the FA compositions of glycerolipids can be determined accurately by KOH-catalyzed methanolysis.

GC. The polyester liquid phase, diethylene glycol succinate polyester (DEGS), is one of the most widely used column-packings for FAME analysis. If DEGS is used to replace SP-2340 (used in this study), the KOH-catalyzed methanolysis should be terminated by adding 3 mL of 0.15 M acetic acid before GC analysis. If this is not done, DEGS will quickly deteriorate. DEGS is not suitable for high-speed GC because its maximum temperature of operation is 210°C.

SP-2340 is a more polar liquid phase than DEGS, and it is also more thermostable (up to 260°C) than DEGS. All of the common C_{18} saturated and unsaturated FAME were well separated from each other within 2 min at 240°C on 10% SP-2340 (Fig. 5A). Under the same conditions, the retention times of eicosapentaenoic acid (20:5) and docosahexaenoic acid (22:6) methyl ester prepared from a 22:6-enriched fish oil were 2.8 and 4.2 min, respectively (Fig. 5B). GC was also successfully carried out at 225°C with 5% SP-2340 on 80–100 mesh Chromosorb WAW. Retention times were shorter under the latter conditions than under the former ones, whereas separation was better under the former conditions than under the latter ones. The analytical values obtained under these two different conditions were almost the same (data not shown). The major disadvantage of SP-2340 is that hydroxy FAME, such as methyl ricinoleate, are eluted very slowly. The amounts of glycerolipids could also be determined using an internal standard.

Concluding remarks. Methanolysis that is conventionally carried out with reflux can be replaced by the KOH-catalyzed methanolysis without reflux. If free FA are not a major component of a lipid sample, HCl-catalyzed methanolysis, which converts both glycerolipids and free FA into FAME but requires heating for 1–2 h in sealed tubes, can also be replaced by this method. The only reagents used for the present procedure are KOH, hexane, and methanol. Harmful solvents such as benzene or chloroform are not used, and neither heating nor reflux is required. Only glass or plastic tubes are required, with no need for elaborate apparatus such as reflux condensers. Many lipid samples can be treated without difficulty. The data obtained are identical to those determined by other time-consuming methods. Thus, the FA composition of a lipid sample can be determined easily in a short time, e.g., 4–5 min for common vegetable oils and 7–8 min for fish oils, by the combination of KOH-catalyzed methanolysis and high-speed GC with SP-2340.

Synthesis of 1,2-Diacyl-*sn*-Glycerophosphatidylserine from Egg Phosphatidylcholine by Phosphoramidite Methodology

Margarita Morillo[a], M. Luisa Sagristá[a,*], M. Africa de Madariaga[a], and Ramón Eritja[b]

[a]Department of Biochemistry and Physiology, Faculty of Chemistry, University of Barcelona, 08028 Barcelona, Spain, and [b]Department of Molecular Genetics CID-CSIC, 08034 Barcelona, Spain

ABSTRACT: A simple chemical method for the synthesis of 1,2-diacyl-*sn*-glycerophosphatidylserine (PS), with the same fatty acid composition in the *sn*-1 and *sn*-2 glycerol positions as egg phosphatidylcholine (PC), is described. PS synthesis was carried out by a phosphite–triester approach, using 2-cyanoethyl-*N,N,N',N'*-tetraisopropylphosphorodiamidite (phosphoramiditate) as the phosphorylating agent, for the formation of phosphate linkage between serine and diacylglycerol. 1,2-Diacylglycerol, obtained from PC hydrolysis by phospholipase C, was coupled with *N-t*-BOC-L-serinebenzhydryl ester phosphoramidite with tetrazole as catalyst. Phosphite–triester was oxidized to the corresponding phosphate–triester with 30% H_2O_2 in CH_2Cl_2. The cyanoethyl group was removed by addition of an Et_3N/CH_3CN/pyridine mixture, and trifluoroacetic acid was used to eliminate the protecting groups of *O*-(1,2-diacylglycero-3-phospho)-*N-t*-BOC-serinebenzhydril ester. Purified PS was identified by thin-layer chromatography, infrared, and ^1H nuclear magnetic resonance.

Lipids 31, 541–546 (1996).

Phospholipids are major components of cell membranes, have many functions in living organisms, and are involved in a myriad of industrial processes (1). Phospholipids, particularly phosphatidylcholine (PC) and phosphatidylserine (PS), are used extensively in the formation of liposomes that have an enormous potential as drug delivery systems (2,3). Liposomes have also been used as model membrane systems to study cell–cell or liposome–cell interactions, as well as the molecular mechanisms of biological membrane fusion (4).

The isolation of phospholipids in pure and homogeneous form from natural sources or phospholipids mixtures, as well as the total synthesis of phospholipids by chemical reactions, is a complicated, expensive, and time-consuming task (5). Preparation of pure phospholipids, including PS, have been an area of interest because of their use in biochemical and membrane research. The conversion of phospholipids using synthetic methodology can be achieved both chemically and enzymatically. The economic efficiency of the chemical or biochemical process depends mainly upon high rates of production of desired products and minimizing the formation of undesirable by-products (6).

Although PS formation by enzymatic methods, using cabbage phospholipase D, has been reported by many scientists (7–9), the yields obtained were low and formation of the by-product phosphatidic acid was very high. Nevertheless, conversion of PC to PS by streptomyces phospholipase D was achieved in high yield (10).

PS with saturated or unsaturated acyl moieties also have been synthesized by a variety of chemical methods, most of which involve condensation of phosphatidic acid with serine protected at the amino and carboxyl functions or the coupling of diacylglyceroliodohydrines with suitable protected *O*-phosphoserines (5,11–14). In some cases, the amino and carboxyl protecting groups have been removed by two successive reactions leading to lower yield of the end product (12). Hermetter *et al.* (13) used the *N-tert*-butoxycarbonyl (*t*-BOC) residue and the benzhydryl group to protect serine at the amino and carboxyl groups, respectively. These two protective groups can easily be coupled to serine and removed in a single step under mild conditions, but the condensation yield of *N-t*-BOC-serine benzhydryl ester with defined molecular species of phosphatidic acids depends on the acyl chain lengths and their unsaturation degree (13).

We have studied the synthesis of PS starting from PC, the main constituent of natural phospholipids, using the phosphite–triester approach for the formation of a phosphate linkage between the serine and the diacylglycerol (DAG). Although phosphite coupling reactions have been well established and applied for oligonucleotides synthesis (15–19), the utilization of these tactics for the construction of phospholipids and their derivatives has received limited attention (20–25). Traditional phosphate coupling procedures and modifications thereof have generally provided a suitable mean for the preparation of phosphatidylethanolamine, PC, and deriva-

tives bearing different fatty acid side chains and/or polar head groups, in general, with good to excellent yields. However, the application of these standard techniques to achieve an efficient synthesis of PS may be problematic; in fact, only single molecular species of PS have been synthesized by this technology.

The aim of this work was the synthesis of a PS with the same fatty acid composition in the *sn*-1 and *sn*-2 glycerol positions as egg PC used as the starting material. This will enable us to prepare liposomes with different PC/PS ratios but identical fatty acyl composition of each component, thus allowing us to correlate the changes in behavior of these model systems with the head polar group modification.

MATERIALS AND METHODS

Egg lecithin (65%) for synthesis was purchased from Merck A.G. (Darmstadt, Germany) and purified by column and thin-layer chromatography (TLC) before use. CH_3CN [Solvants Documentation Syntheses (SDS), Peypin, France; water content <50 ppm] was stored over CaH_2 (Merck A.G.). All other reagents were of analytical grade. Water was twice-distilled (Millipore Systems, Molsheim, France), and all organic solvents were redistilled before use.

DAG was obtained by PC hydrolysis with phospholipase C (26) (Lecithinase C; E.C. 3.1.4.3.) Type I of *Clostridium perfringens* (*C. welchii*, 10–20 units per mg protein; Sigma Chemical Co., St. Louis, MO). Phospholipase C (33 mg) dissolved in 60 mL of 0.1 M Tris-HCl buffer (pH 7.2) and 75 mL of a 5 mM $CaCl_2$ solution were added to a solution of PC (300 mg, 0.4 mmol) in peroxide free diethyl ether (75 mL). The mixture was stirred under N_2 at room temperature for 2 h and 45 min. 1,2-DAG_s were then extracted with diethyl ether (4 × 75 mL). The combined organic extracts were evaporated under reduced pressure, without heating, to reduce the initial volume four times. The resulting suspension was dried over anhydrous Na_2SO_4, the solvent was evaporated under reduced pressure to give a crude product, which was dissolved in dry CH_2Cl_2, and the drying and evaporation processes were repeated. This compound was used without further purification in the next step. The extent of the phosphocholine group elimination was checked by TLC, ^1H nuclear magnetic resonance (NMR), and infrared. DAG was used immediately in order to prevent isomerization from 1,2-DAG to 1,3-DAG .

Diazodiphenylmethane (DDM), often used as a carboxyl protecting group, was prepared from benzophenone hydrazone (>98%; Merck) by oxidation with metachloroperbenzoic acid (55%; Merck) in the presence of iodine as catalyst and *N,N,N′,N′*-tetramethylguanidine as base (Merck A.G.) (27). *N,N,N′,N′*-tetramethylguanidine (1.6 mL) and a solution of I_2 (1%, p/v) in 0.32 mL of distilled $CHCl_3$ were added to a solution of benzophenone hydrazone (1638.1 mg, 8.36 mmol) in 8 mL of distilled $CHCl_3$. After stirring for 5 min at 0°C, solid 55% metachloroperbenzoic acid (3409.8 mg, 10.87 mmol) was added slowly over 1 h at 0°C. The mixture was stirred for an additional 15 min, then washed with water until the washings were at pH 6. The resulting suspension was dried over anhydrous Na_2SO_4, the solvent was evaporated under reduced pressure and the residue suspended in MeOH. An assay at 526 nm (ε^{526}_{DDM} (MeOH) = 100 M^{-1} cm^{-1}) of a suitable diluted sample corresponded to a 90% yield of DDM.

Tetrazole (99%) and 2-cyanoethyl *N,N,N′,N′*-tetraisopropylphosphorodiamidite (phosphoramiditate) were from Aldrich Chemical Co. Ltd. (Milwaukee, WI). The phosphoramiditate was checked by ^{31}P NMR (δ_P 123.5) and TLC (Table 1) before use. Impurities observed were 5.1% $(^iPr)_2NP(OCH_2CH_2CN)_2$ (δ_P 149.06), 1% $((^iPr)_2N)_2PO(CH_2CH_2CN)$ (δ_P 31.4), and phosphoramiditate hydrolysis products with low δ_P values.

N-t-BOC-L-serine benzhydril ester phosphoramidite (BEP) was obtained from *N-t*-BOC-L-serine benzhydril ester (BE). First, BE was prepared from *N-t*-BOC-L-serine (Sigma Chemical Co.) and an excess of DDM (13). DDM (938 mg, 4.83 mmol) was added to a solution of *N-t*-BOC-L-serine (717.7 mg, 3.5 mmol) in dry diethyl ether (20 mL), and additional diethyl ether was added to give a total volume of 30 mL. The reaction mixture was stirred overnight at room temperature. The excess of DDM was destroyed by the addition of glacial acetic acid and followed by the color change from red to yellow. The solvent was removed by evaporation under reduced pressure. The crude product was dissolved in $CHCl_3$ containing 1% per volume of aqueous NH_3 and purified afterwards by column chromatography on silica gel (27 g, 0.063–0.1 mm; Macherey Nagel, Düren, Germany). Elution was performed with chloroform containing 0.5% NH_3 to prevent decomposition of the product. Then 10-mL fractions were collected at a flow rate of 0.8–1.1 mL/mim. BE was contained in fractions 8–24. The combined fractions were filtered, dried, and evaporated under reduced pressure. BE (149 mg, 0.401 mmol) was dried by its dissolution in dry CH_3CN, and the solvent was evaporated under reduced pressure. Dry BE was redissolved under N_2 in dry CH_3CN (1.46 mL) by continuous stirring. Tetrazole

[b]Solvent systems: (1) $CHCl_3$/MeOH/NH_3 (28%) (65:35:5, by vol); (2) hexane/diethyl ether/Et_3N (30:60:1, by vol); (3) hexane/diethyl ether (30:70, vol/vol). Adsorbent: Silica Gel G (Merck, Darmstadt, Germany). Data represent the mean ± SD of at least five determinations.

(26 mg, 0.37 mmol) was added with stirring at room temperature, followed by phosphoramiditate (120.4 mg, 0.4 mmol). The molar ratio of reagents was BE/phosphine/tetrazole (1:0.99:0.93). After stirring for 40 min, the reaction was stopped by the addition of 5% Et_3N in CH_2Cl_2. The diisopropylammonium tetrazolide formed was removed by washings with saturated aqueous NaCl and filtration. The solution was evaporated to dryness, and the residue was redissolved in CH_2Cl_2 and dried again with Na_2SO_4. The product, BEP, was identified by ^{31}P NMR and TLC on silica gel.

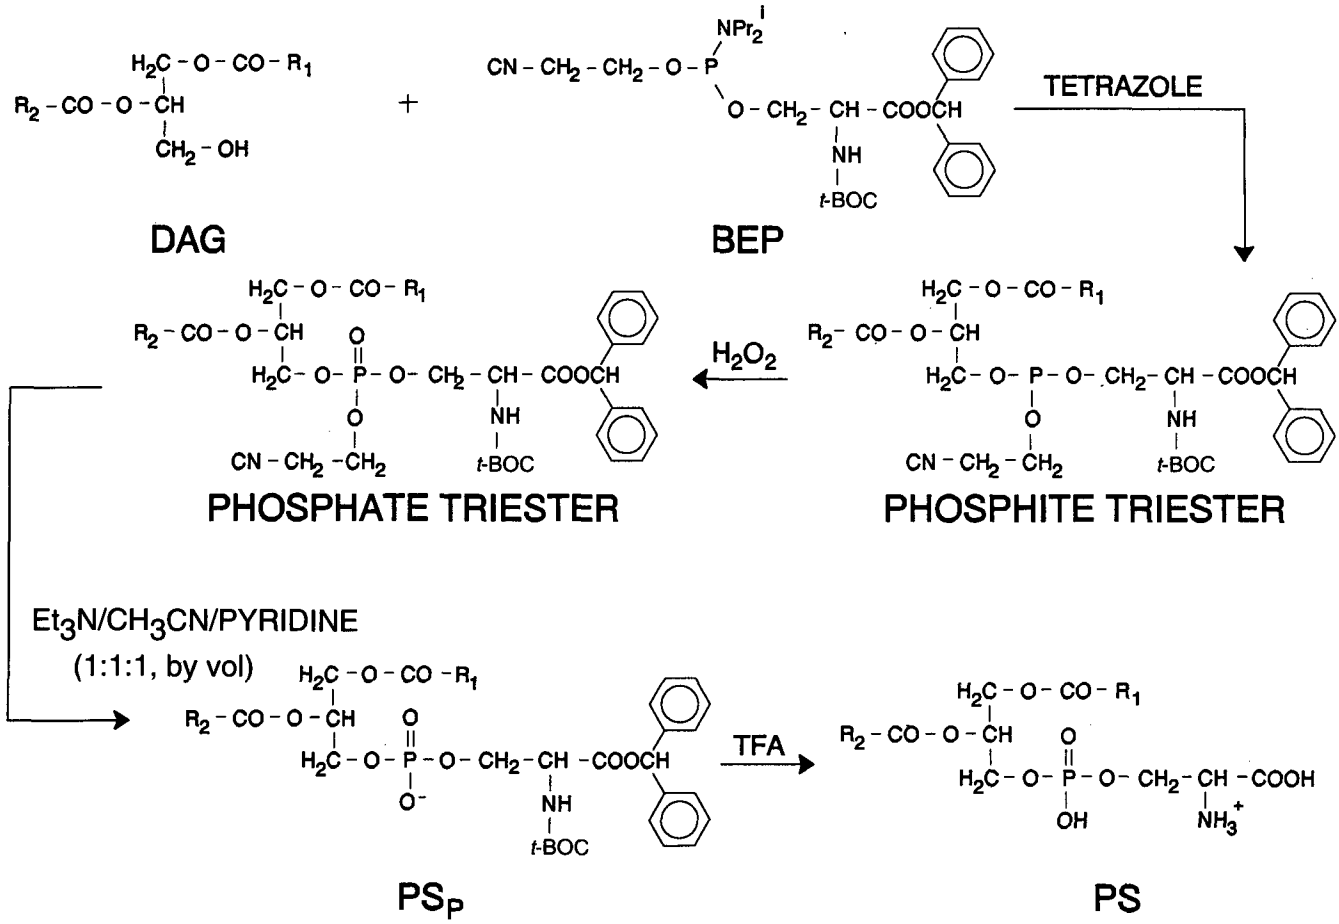
DAG (156.58 mg, 0.26 mmol) and BEP (265.9 mg crude BEP, 0.34 mmol pure BEP) were coevaporated in dry CH_3CN. The residue was dissolved in 1.65 mL of CH_3CN, and tetrazole (90.92 mg, 1.3 mmol) was then added. The reaction vessel was deaerated with N_2, and the mixture was stirred for 15 min (reagents molar ratio was DAG/BEP/tetrazole, 1:1.3:5). The reaction was stopped by the addition of 1.6 mL of 5% Et_3N in CH_2Cl_2, and the solution was washed in the same way as indicated for BEP. The amount of tetrazole necessary to activate the phosphoramidite was higher than that required to activate the phosphorodiamidite.

Subsequent oxidation of the intermediate phosphite delivered the corresponding phosphate–triester. The oxidation was carried out by the addition of 1.2–1.5 equivalent of an aqueous solution of H_2O_2 (30%) to the residue containing the phosphite–triester dissolved in 1.6 mL of CH_2Cl_2. The mixture was stirred vigorously at room temperature for two hours. The reaction mixture was washed with a saturated aqueous NaCl solution (2 × 1.6 mL), the layers were separated, and the combined organic phases were dried with anhydrous Na_2SO_4 and evaporated under reduced pressure. The phosphate–triester was deprotected without further purification.

Egg PC, and most of the naturally-occurring and biologically-active phospholipids, contain unsaturated *sn*-2-acyl chains possessing from one to four double bonds which can easily undergo oxidation. Thus, before the development of the synthetic method presented in this paper, we tested the H_2O_2 effect on fatty acid double bonds. We prepared an incubate containing a mixture of unsaturated fatty acids in CH_2Cl_2 and twice the theoretical amount of H_2O_2 necessary for the oxidation of the phosphite to the phosphate–triester. The mixture was stirred vigorously for two hours at room temperature and, after standard work up, fatty acids analysis by gas–liquid chromatography showed the same composition as the starting mixture (results not shown). Thus, no evidence of oxidation of fatty acyl double bonds in the presence of hydrogen peroxide used for phosphite oxidation was detected.

The cyanoethyl group was removed by addition of 1 mL of an Et_3N/CH_3CN/pyridine (1:1:1, by vol) mixture to the dry residue. After 90 min, the solvent mixture was eliminated by vacuum. The *O*-(1,2-diacylglycero-3-phospho)-*N*-*t*-BOC-serine benzhydril ester (PS_p) obtained was purified by column chromatography on silica gel (27 g, 0.1–0.2 mm; Macherey Nagel) saturated with $CHCl_3$ containing 0.5% NH_3 and eluting with $CHCl_3$ and $CHCl_3$/MeOH mixtures containing 0.1% NH_3. Then 5-mL fractions were collected at a flow rate of 0.7–1.0 mL/min. Pure PS_p was eluted when the $CHCl_3$/MeOH ratio was 90:10 (vol/vol). The combined fractions were filtered, dried, and evaporated under reduced pressure. trifluoroacetic acid (TFA) (1 mL) was added to the product dissolved in 1 mL of $CHCl_3$ to eliminate protecting groups of PS_p and was then removed by vacuum. Et_3N (0.4 mL), dissolved in $CHCl_3$, was added to the residue to neutralize any remaining TFA. The organic layer was washed with the following cold mixtures—MeOH/H_2O/$NaHCO_3$sat (2:1:1), MeOH/100 mM NaHCOO pH 3.0 (4:5), and MeOH/100 mM *N*-tris(hydroxymethyl)methyl-2-aminoethane-sulfonic acid pH 7.4—to eliminate remaining Et_3N. The solvent was evaporated under reduced pressure and the product was dried over P_2O_5. The crude PS was purified by CM-Cellulose (CM52; Whatman, Kent, England) column chromatography using $CHCl_3$/MeOH mixtures as eluent, at a flow rate of 0.48 mL/min. Pure PS was eluted with $CHCl_3$/MeOH, 65:35 (vol/vol). The combined fractions were filtered, dried, and evaporated under reduced pressure.

Infrared spectra were obtained from a film of lipid solutions in chloroform (approximately 5 mg/mL) on a KCl pellet, using a Perkin-Elmer 687 infrared spectrophotometer (Norwalk, CT). All spectra were recorded at room temperature against a reference KCl pellet.



^1H NMR (200 MHz) and ^{31}P NMR (81 MHz) spectra were obtained, in $CDCl_3$ (15–25 mg lipid/mL), on Geminis-200 (Palo Alto, CA) and Varian XL-200 (Palo Alto, CA) spectrometers, respectively, operating in the Fourier transform mode, at room temperature. Typically 200–300 scans were averaged. Chemical shifts values are expressed in units of δ relative to tetramethylsilane set at 0 ppm or trimethyl phosphite set at 140–141 ppm, respectively, for ^1H and ^{31}P NMR spectra.

Methyl esters of the fatty acids were analyzed by gas–liquid chromatography on a Perkin-Elmer 990 gas chromatograph equipped with flame-ionization detector. Data were obtained with a 2 m × 2 mm i.d. column packed with 15% polymeric ethyleneglycol succinate as stationary phase on Chromosorb W (100–120 mesh; Johns-Manville, Denver, CO). Helium at 30 mL/min was used as carrier gas. Injector, column, and detector temperatures were 230, 188, and 250°C, respectively. Samples were applied as hexane solutions.

RESULTS AND DISCUSSION

Scheme 1 shows the scheme used for PS synthesis *via* phosphite coupling. ^{31}P NMR was used to check the reaction course.

DAG (98%) obtained by PC hydrolysis gave single spots on silica gel G plates using different solvent systems (Table 1), showing that the isomerization of 1,2 diglyceride to 1,3 diglyceride (side product) was not done during the reaction time course. Moreover, the extent of acyl migration was low (<4%) during the condensation step between DAG and BEP. The signal at δ_H 3.35 corresponding to $(CH_3)_3N^+$- from PC disappears for DAG, and the signals at δ_H 3.8–4.6

SCHEME 1

due to $-(CH_2O)_2P(O)O^-$ are not shown in DAG spectrum. On the other hand, the absorption bands at 970, 1090, and 1240 cm^{-1} related with the phosphate group are missing in DAG infrared spectrum.

BE was identified by TLC (Table 1), ultraviolet-spectrum ($CHCl_3$) (λ_{max}= 258 nm, ε = 450 $M^{-1}cm^{-1}$) and ^1H NMR (signals at δ_H 1.44 and δ_H 7.32–7.34 ppm corresponding to $-C(CH_3)_3$ and $-C_6H_5$ groups, respectively) (13).

The homogeneity of BEP, obtained from *N-t*-BOC-L-serine, was checked by TLC (Table 1). BEP ^{31}P NMR spectrum showed two main signals at δ_P 148.1 and 147.4 ppm. The two signals at similar δ_P obtained for BEP with different values showed the stereoselectivity of the reaction. The only impurities observed were little amounts of dimers (δ_P 137.8 ppm) and hydrolysis products (δ_P 2.1–18.5 ppm). The process was carried out with an excellent yield (95.5%), and BEP purity was *ca.* 71.7%.

The appearance in the ^{31}P NMR spectra of two new signals, after DAG and BEP condensation, at δ_P 136.37 and 135.85 ppm and the disappearance of the characteristic peaks of BEP isomers showed the formation of the desired phosphite–triester (93%). The oxidation of the phosphite to phosphate–triester was performed using a two-phase system with aqueous H_2O_2 and dichloromethane (21). This milder treatment was preferred over iodine oxidation (16) to avoid possible addition of iodine to fatty acid double bonds and because the oxidation solution is easy to remove from the phospholipid solution. The oxidation reaction was completed after two hours (94%) as confirmed by the substitution of phosphite–triester signals by two signals at δ_P –4.54 and –4.93 ppm in the ^{31}P NMR spectra.

The elimination of the cyanoethyl group and the purification of the obtained PS_P by column chromatography on silica gel was achieved by a 50% yield. BEP, phosphite–triester, and phosphate–triester were not extensively purified since the side products, largely consisting of hydrolysis products, did not interfere with the coupling, oxidation, and cyanoethyl group elimination processes.

PS obtained after deprotection with TFA was purified by CM-Cellulose (51%) column chromatography because the utilization of silica gel always gave impure PS. CM-Cellulose was used in older literature to separate PS and phosphatidic acid (8), although the basis for lipid separation on CM-Cellulose is not completely understood. It seems likely that in chloroform, which has a low dielectric constant, phospholipids are bound to CM-Cellulose by nonspecific adsorp-

TABLE 2
Fatty Acids Molar Content (%) Determined by Gas Chromatography[a]

Lipid species	Total fatty acids[b] (mol%)						
	16:0	16:1	18:0	18:1	18:2	20:4	22:6
PC	35.3 ± 0.7	1.1 ± 0.1	11.3 ± 0.8	30.0 ± 0.3	18.4 ± 1.0	3.3 ± 0.1	0.5 ± 0.1
DAG	36.1 ± 1.4	0.9 ± 0.1	12.1 ± 0.7	29.7 ± 1.2	17.5 ± 1.3	3.2 ± 0.1	0.5 ± 0.1
PS_p	35.6 ± 0.6	1.1 ± 0.1	11.4 ± 0.7	29.8 ± 0.5	18.2 ± 0.8	3.4 ± 0.1	0.6 ± 0.1
PS	35.7 ± 2.0	1.1 ± 0.1	11.9 ± 0.8	30.1 ± 1.0	17.6 ± 1.4	3.2 ± 0.1	0.5 ± 0.1

[a]PC, Phosphatidylcholine; other abbreviations as in Table 1.
[b]Data represent the mean ± SD of at least three determinations.

tion and possibly by hydrogen bonding. The addition of methanol will increase the dielectric constant and the repulsion of gradually dissociating negative charges, resulting in elution of lipids.

The analysis by gas–liquid chromatography of PS, obtained after the elimination of all protecting groups and purified by CM-Cellulose column chromatography, showed that PS and PC fatty acids compositions were the same (Table 2). This result seems to indicate that the coupling of particular molecular species is not preferred and that the double bonds were not affected under the mild oxidation conditions used.

PS was identified by infrared and ^1H NMR (Fig. 1), being the obtained spectra identical to those reported in the bibliography (13,28). PC and PS ^{31}P NMR spectra showed a sole signal at δ_P −1.244 and −0.265 ppm, respectively. The relative upfield shift of phosphate group of PC vs. PS can be correlated with the quaternary nitrogen of choline (29).

The methods previously described for obtaining PS by the phosphoramidite approach (20–23,25) have been applied to molecular species with the same fatty acid composition at the *sn*-1 and *sn*-2 positions of glycerol. This paper describes a new method, and with excellent yield, for the synthesis of PS with the same fatty acid composition at the *sn*-1 and *sn*-2 positions of glycerol as egg PC, using a phosphite–triester approach.

Phosphodiester (14) and phosphate–triester (14) methods have been described for the preparation of PS. Low yields, formation of undesirable products, and long reaction times have been some of the problems associated with these methodologies. The methods described here are faster, simpler, and more selective. It is based on the phosphite–triester method that has been proven to be more efficient in solid phase oligonucleotide synthesis (16,19). The separation of the unreacted materials also is easier due to the large differences on their polarity, and it could be performed using materials readily available. Moreover, phosphorothioate and other phosphate derivatives of PS can be prepared from the intermediate phosphite–triester.

On the other hand, PS also could be prepared in higher yields by the transphosphatidylation method using streptomyces phospholipase D (10). Nevertheless, the differences in

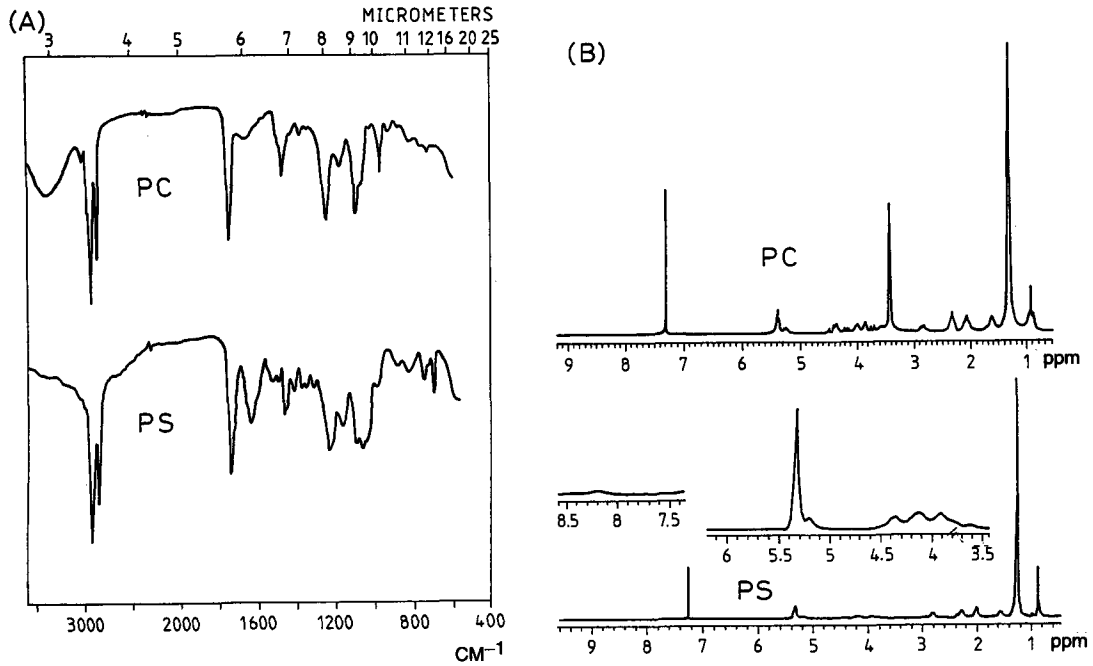


FIG. 1. (A) Infrared and (B) ^1H nuclear magnetic resonance spectra of phosphatidylcholine (PC) and phosphatidylserine (PS).

yields obtained with the method we propose and the transphosphatidylation viewed in the context of the costs of reagents indicate that the synthetic method described in this paper may be less expensive, depending upon the relative costs of phospholipase D from streptomyces species and additional labor needed for our method.

The protective groups would be easily cleaved in two steps. The cyanoethyl group was eliminated by addition of Et_3N/CH_3CN/pyridine mixture, and TFA was used to simultaneously eliminate the protecting groups of PS_p. It was not possible to use other functional protective groups which could be uniformly removed since phosphorous protecting groups cleavable in acid media are not available. A β-elimination mechanism for cyanoethyl group removal could yield phosphatidic acid as a by-product, but that secondary reaction did not take place since phosphatidic acid was not detected by TLC analysis.

Effect of Medium-Chain Triglycerides on Calbindin-D9k Expression in the Intestine

Angela Devlin, Sheila M. Innis*, Katharine Wall, and John Krisinger[1]

Department of Paediatrics, University of British Columbia, Vancouver, British Columbia V5Z 4H4, Canada

ABSTRACT: These studies determined the effect of the saturated fat source in infant formula on the expression of calbindin-D9k (CaBP-9k). Piglets were fed from birth to 8 d with milk or formula containing saturated fatty acids as medium-chain triglycerides (MCT), coconut oil, palm oil (Palm 1), or synthesized triglycerides with 16:0 directed to the *sn*-2 position (Palm 2). Levels of intestinal CaBP-9k mRNA were significantly ($P < 0.01$) higher in piglets fed formula with MCT than in piglets fed the other formula or milk; and higher in piglets fed the Palm-1 than in piglets fed Palm-2 formula. This is the first evidence that MCT alter piglet intestinal CaBP-9k mRNA.

Lipids 31, 547–549 (1996).

The effect of dietary fatty acids on small intestinal gene expression has received little attention. Enterocytes are the absorptive cells of the small intestine and are responsible for production of proteins involved in transepithelial transport and metabolism of nutrients (1). The enterocytes originate in the proliferative, crypt region of the villus, differentiate as they migrate toward the villus tip, and are then extruded into the gut lumen. Intestinal gene expression is known to follow a horizontal gradient of expression along the proximal to distal axis and variable expression along the crypt to villus axis (2,3).

Medium-chain triglycerides (MCT), containing 8:0 plus 10:0, are used as the source of saturated fatty acids in formula for preterm infants and other infants with reduced ability for fat absorption. Palmitic acid (16:0) is the major saturated fatty acid in human milk and is predominantly esterified at the center (*sn-2*) position of the milk triglycerides. Formula for term infants usually contains 12:0 plus 14:0 from coconut oils, or palm or other oils with 16:0 mainly esterified at the *sn*-1,3 positions of the triglycerides (4–6). The effect of MCT on the absorption of other nutrients is not known; however, previous studies have reported higher serum calcium concentrations in piglets fed formula with MCT than in piglets fed sow milk (7).

Abbreviations: CaBP-9k, calbindin-D9k; MCT, medium-chain triglycerides; Palm-1 and Palm-2, 16:0 esterified predominantly to the triglyceride at *sn*-1,3 and *sn*-2, respectively.

Although little is known about the potential effects of dietary MCT on enterocyte metabolism, increased jejunal villus height and increased cell proliferation in the proximal small intestine (8,9), and higher alkaline phosphatase and lower sucrase-isomaltase activities (10,11) have been found in rats fed MCT than in rats fed long-chain triglycerides. MCT may influence nutrient absorption *via* nonspecific changes in intestinal morphology which encompasses alterations in enterocyte metabolism.

Calcium absorption is dependent on vitamin D and requires calbindin-D9k (CaBP-9k), a cytosolic calcium binding protein. CaBP-9k is involved in the intracellular movement of calcium (12,13). In response to low blood calcium, increased parathyroid hormone stimulates renal 1,25-dihydroxycholecalciferol production, resulting in increased intestinal CaBP-9k production and, consequently, increased intestinal calcium absorption (14). This report describes the results of studies determining if formula-feeding or the saturated fatty acid composition of formula, when compared to milk, influences piglet intestinal CaBP-9k expression.

METHODS

Animals and diets. Male Yorkshire piglets were randomly assigned to milk- or formula-feeding at birth ($n = 8$/group), and fed from birth to 8 d of age (15). The formula contained saturated fatty acids as 8:0 plus 10:0 (MCT), 12:0 plus 14:0 (coconut oil), or 16:0 esterified predominately to the triglyceride *sn*-1,3 (Palm-1) or *sn*-2 (Palm-2) position (Table 1) (7).

Tissue collection. The piglets were sacrificed after 8 d of feeding (7). The entire small intestine was dissected, measured, and divided into three equal segments. The upper third was flushed with ice-cold phosphate buffered saline (50 mmol/L phosphate, 100 mmol/L NaCl, pH 7.4) and immediately frozen in liquid nitrogen.

Extraction of RNA and Northern blot analysis. Total RNA was isolated from the upper third of the small intestine using guanidine thiocyanate followed by cesium chloride density gradient centrifugation (16). Total RNA (5 μg) was separated on 1% agarose denaturing gels containing 2.2 M formaldehyde and transferred to nylon membranes (Hybond-N; Amersham, Oakville, Ontario, Canada). The membranes were hybridized overnight in buffer containing 50% formamide, 5 ×

18:1n-9	37.5	40.3	39.0	41.0	40.6
18:2n-6	11.1	16.0	15.6	16.4	16.4
18:3n-3	1.1	3.6	3.2	3.2	3.2
CaBP-9k[b] (Bq)	11.4 ± 5	19.7 ± 9.9[c]	10.3 ± 4.8	14.0 ± 7.7	5.2 ± 2.9[d]

[a]The formula had <0.13 mmol, and the sow milk had 0.5–1.0 mmol cholesterol/L. The sow milk, 16:0 predominantly esterified to the triglyceride *sn*-1,3 (Palm-1) or *sn*-2 (Palm-2) formula had 55, 4, and 70% 16:0 at the *sn*-2 position, respectively; MCT, medium-chain triglycerides.
[b]The relative abundance of calbindin-D9k (CaBP-9k) mRNA as determined by Northern blot hybridization. Values are in Bq, means ± SD, $n = 8$ per group.
[c]Significantly different from the sow milk, coconut oil, and Palm-2 groups ($P < 0.01$).
[d]Significantly different from the Palm-1 group ($P < 0.01$).

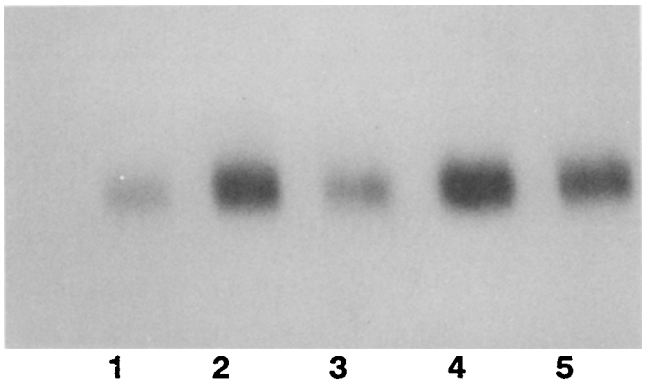

FIG. 1. Representative Northern blot of intestinal total RNA (5 μg) from 8-day-old piglets fed: Lane 1, 16:0 esterified predominantly to the triglyceride *sn*-2 formula; Lane 2, medium-chain triglyceride formula; Lane 3, coconut oil formula; Lane 4,16:0 esterified predominantly to the triglyceride *sn*-1,3 formula; and Lane 5, sow milk.

Denhardt's solution, 5 × sodium chloride, sodium phosphate, EDTA, 0.1% SDS, and 0.1 μg/L denatured salmon sperm DNA with a rat CaBP-9k cDNA (17) probe radiolabelled with [∝–^{32}P]dCTP (Amersham) by random priming (Lifetechnologies, Inc., Burlington, Ontario, Canada). The filters were washed, 42°C for 30 min in 1 × sodium chloride, sodium citrate and 0.1% SDS, then at 55°C for 30 min in 0.1 × sodium chloride, sodium citrate and 0.1% SDS, and then exposed to Kodak (Rochester, NY) XOMAT-AR film using an intensifying screen. The bands were assayed for radioactivity by Cerenkow counting. The levels of β-actin mRNA per μg RNA did not vary among the groups (data not included).

Statistical analysis. Results were compared among the groups of formula-fed piglets and between the formula-fed and sow-fed piglets using analysis of variance with tests of significant differences made using Number Cruncher Statistical System, version 5.01 (Number Cruncher, Kaysville, UT).

RESULTS

The relative intensities of the bands corresponding to the CaBP-9k mRNA abundance in piglets fed milk or formula are listed in Table 1. A representative Northern blot analysis from each diet group can be seen in Figure 1. Piglets fed the MCT formula had significantly ($P < 0.01$) higher CaBP-9k mRNA relative abundance than piglets fed sow milk, or those fed the coconut oil or Palm-2 formula. Piglets fed the Palm-2 formula had significantly lower CaBP-9k mRNA than piglets fed the Palm-1.

DISCUSSION

These studies are the first demonstration that dietary MCT have a significant effect on CaBP-9k mRNA abundance in developing intestine. It should be noted that these are preliminary studies and did not include measures of calcium absorption or changes in intestinal absorption. Although CaBP-9k may be regulated at transcriptional and post-transcriptional levels, mRNA abundance appears to correlate well with the amount of CaBP-9k protein produced (18). It is not known if the changes in CaBP-9k mRNA abundance among piglets fed the different diets were accompanied by changes in intestinal cell calcium translocation. The effect of dietary calcium on CaBP-9k expression is indirect, suggesting that differences in intraluminal calcium availability are unlikely to explain the difference in CaBP-9k mRNA. The changes in CaBP-9k mRNA, however, are consistent with the changes in serum calcium found in previous studies with these diets (7).

Dietary MCT are known to induce changes in intestinal morphology by increasing the rate of epithelial cell renewal, villus length, and crypt depth (8). Changes in intestinal enzyme activity induced by feeding MCT may also be a result of diet-induced changes in intestinal morphology (3,10). Diet-induced differences in epithelial cell turnover could be important if CaBP-9k mRNA abundance differs along the intestinal crypt to villus axis. In this regard, the expression of avian CaBP-28k in crypt compared to villus cells does vary with enterocyte differentiation and developmental stage (19). Whether the effects of dietary MCT on the piglet intestinal CaBP-9k mRNA abundance are specific for this gene or secondary to changes in intestinal morphology remains to be determined.

ANNOUNCEMENTS

SPECIAL *LIPIDS* SUPPLEMENT—PROCEEDINGS OF THE ISSFAL 2ND INTERNATIONAL CONGRESS

Extra copies of the March *Lipids* Supplement—"Fatty Acids and Lipids from Cell Biology to Human Disease," the Proceedings of the 2nd International Congress of the ISSFAL (International Society for the Study of Fatty Acids and Lipids)—which includes 57 full manuscripts from participants in oral presentations at the Congress (332 total pages), are available for individual purchase at $60 each. Information: AOCS Press, P.O. Box 3489, Champaign, IL 61826-3489 (Phone: 1-217-359-2344, extension 128; Fax: 1-217-351-8091).

CALENDAR

June 1996

Symposium on Diet, Nutrition and Health: An Update, University of Western Ontario from June 16–19, 1996, sponsored by the Royal Society of Canada. Sessions on Diet and Cardiovascular Disease, Diet and Cancer, Diet and Selected Health Problems, Including Hypertension, Diabetes, Obesity, Kidney Disease, Osteoporosis and Alcohol Abuse, as well as Diet and Health Maintenance in People at Various Stages of Life, Including the Elderly. Information: The Centre for Human Nutrition, The University of Western Ontario, London, ON N6A 5C1, Canada (Phone: 519-661-3096; Fax: 519-661-4006).

July 1996

European Thrombosis Research Organisation and the International Society for the Study of Fatty Acids and Lipids in cooperation with Summer University of Maastricht, July 10–12, 1996, University of Maastricht, The Netherlands, presents "Lipids, Membranes and Thrombosis (fundamental basis of cardiovascular disease and its prevention)." Information: Gerard Hornstra, Department of Human Biology, P.O. Box 616, 6200MD Maastricht, The Netherlands (Phone: +31-43-88 16 25; Fax: +31-43-67 09 76; E-mail: G. Hornstra @ HB.RuLimburg.NL).

September 1996

37th International Conference on the Biochemistry of Lipids, Antwerp, Belgium, Sept. 4–7, 1996. Themes: enzymes and transfer proteins related to lipoprotein metabolism, aspects of protein lipidation, and peroxisomal lipid metabolism. Poster communications may relate to the three conference themes or any other area of lipid metabolism. Information: Dr. P. van Dyck, Secretariat 37th ICBL, Department of Biochemistry, Physiology and Genetics, Division of Human Biochemistry, State University Centre Antwerp, Groenenborgerlaan 171, B2020 Antwerp, Belgium (Phone: 32 3 218 0329; Fax: 32 3 218 0326).

7th International Congress on Phospholipids, Sept. 9–11, 1996, Brussels, Belgium. Program topic areas include Growth, Death and Cancer; Choline, Choline Phospholipids and the Brain; Importance of Phospholipids in Health and Disease. Information: AOCS Meetings Department, P.O. Box 3489, Champaign, IL 61826-3489 USA (Fax: 1-217-351-8091).

IV. International Dermatology Symposion Berlin, Sebaceous Gland and Its Disorders, Basic and Clinical Research, Clinical Entities and Treatment, Sept. 13–15, 1996, University Medical Center Benjamin Franklin. Information: Docent Dr. Ch. C. Zouboulis, Department of Dermatology, University Medical Center Benjamin Franklin, The Free University of Berlin, Hindenburgdamm 20, D-12200 Berlin, Germany (Phone: 49-30-8445-2808; Fax: 49-30-8445-4262).

Training in Free Radical Methodologies, Sept. 23–27, 1996, CERLIB, University of Grenoble, Grenoble, France. Production, damages, repair: ESR, nitric oxide, DNA oxidation, DNA repair, apoptosis, chemical-trapping, lipoprotein oxidation, protein oxidation, cellular production and toxicity. Information: Arlette Alcaraz, Laboratoire de Biochimie C, CHU Grenoble BP 217, 38043 Grenoble Cédex 9, France (Phone: 33 76 76 57 54; Fax: 33 76 76 56 64; E-mail: CERLIB@ujf-grenoble.fr).

October 1996

Frontiers in Lipid and Lipoprotein Research: Basic Science, Analytical, Clinical, and Public Health Applications, Oct. 4–6, 1996, Stouffer Renaissance Hotel, Dallas, Texas. Sponsored by the Lipids and Lipoproteins Division of the

American Association for Clinical Chemistry, the Centers for Disease Control and Prevention, and the American Heart Association. An integrated review of relevant recent advances in basic science, measurement technology, epidemiological and clinical research, and public health issues will be presented. This review will help define state-of-the-art techniques for understanding and preventing morbidity and mortality due to heart disease. Information: Paula M. Steiner, Medical Research Laboratories, 2 Tesseneer Dr., Highland Heights, KY 41076 (Phone: 606-781-8877, Extension 252; Fax: 606-781-9310; E-mail: lipf@cehehll.em.cdc.gov).

American College of Nutrition, 37th Annual Meeting, Oct. 11–13, 1996, San Francisco, California (Phone: 212-777-1037; Fax: 212-777-1103).

Certification Board for Nutrition Specialists, Oct. 11, 1996, San Francisco, California. Certifying examination for nutritionists and dieticians with advanced degrees. Information: CBNS, 1562 First Avenue, Box #258, New York, NY 10028 (Phone: 212-332-0774 (leave message); Fax: 212-777-1103).

Seminar: Interconversion of Polyunsaturated Fatty Acids, and Their Functions in Membranes, Oslo, Norway, Oct. 11–12, 1996. Information: Georg Lambertsen, Secretary, Lipidforum, Breistølen 1, N-5035, Bergen, Norway (Phone: 4755 + 32 89 56; Fax: 47 55 + 32 57 24).

November 1996

AOCS Conference on PUFA in Infant Nutrition: Consensus and Controversies, Nov. 7–9, 1996, Barcelona, Spain. Information: Susan E. Carlson (E-mail: scarlson@utmem1.utmem.edu); Robert A. Gibson (E-mail: rgibson@paed_nnu.fmc.flinders.edu.au); Berthold Koletzko (Fax: 49-89-5160-4733); or AOCS Meetings Department, P.O. Box 3489, Champaign, IL 61826-3489 USA (Fax: 1-217-351-8091).

March 1997

CERLIB 3rd Winter Research Conferences, Les Arcs 1800, France, March 9–14, 1997. Proteins and Free Radicals, from Radical Enzymes to Damages; Oxidative Effects of Radiations on Biomolecules and Cells; Oxidative Stress and Apoptosis. July–August 1997

Fourth International Congress on Essential Fatty Acids and Eicosanoids, July 27–August 1, 1997, Edinburgh, Scotland. Information: Secretariat, c/o Meeting Makers, 50 George St., Glasgow G1 1QE, Scotland, United Kingdom.

REVIEW

Uses of Biotechnology in Modifying Plant Lipids

Greg J. Budziszewski, Kevan P.C. Croft, and David F. Hildebrand*

Department of Agronomy, University of Kentucky, Lexington, Kentucky 40546

ABSTRACT: This review discusses fatty acid modification of oilseeds with additional emphasis on production of oxygenated derivatives. In a relatively short period, less than a decade, our understanding of the enzymes involved in plant fatty acid synthesis has increased to the point where we understand how they might be used in oilseed modification. Further, through modern molecular biological techniques, the actual genes for many of these important enzymes have been cloned. Use of genetic transformation systems has allowed us to fundamentally alter the normal biosynthetic pathways in highly specific ways, in manners that would be either difficult or impossible using traditional breeding techniques. Alteration of plant lipid biosynthesis is not restricted to using genes from the plants themselves, but interspecies transfer is possible, either from completely unrelated plant species (often of no commercial value but possessing unusual biochemical properties) or from animals, fungi, and prokaryotic organisms. In this way "designer" plants possessing altered metabolism, tailored to the interests or needs of certain industries, nutritionists, and the consumer can be created.
Lipids 31, 557–569 (1996).

In recent years, the field of plant molecular biology has advanced rapidly, moving from an area of academic research to applied use in agro-industries. Exciting new prospects in agricultural production are being developed through the use of plant metabolic engineering. The myriad of plant secondary metabolites and primary metabolites, estimated to number in excess of 20,000 unique chemical structures (1), potentially could be cultivated and harvested in commercial crop species through the transfer of critical genes within a metabolic path. Presently developed crops, maximized for agronomic productivity, could be turned into chemical factories *via* a redirection of metabolic flow, utilizing the sun's radiant energy toward the production of desired high-value metabolites. Recent success in the engineering of select oilseed crops for an increase in the production of desired fatty acids (FA) provides evidence of the commercial potential to be exploited through the metabolic engineering of plants.

The cloning of plant and animal genes and the sequencing of their DNA have now become commonplace, and the list of cloned and identified genes has grown impressively and continues to do so (see Table 1 for a list of genes encoding plant lipid biosynthetic genes now cloned). In addition to the genes listed in Table 1, there is a whole array of other genes now known from animals, fungi, and prokaryotes which for reasons of brevity are not listed here. Large databases of known DNA sequences exist and are available for use by research scientists, i.e., through the NCBI GenBank in the United States, the DNA Data Bank of Japan (DDBJ), and the European Molecular Biology Laboratory (EMBL) database. The increase in information deposited in the databases is quite dramatic. For example, in the months between June and October 1995, the number of bases deposited in Genbank increased by 21% to 3.85×10^8 bases total and the total number of individual sequences by 31% to 556,000 clones. As little as five years ago, none of the FA biosynthetic enzymes had been fully characterized and none of the genes had been cloned. Table 1 shows the current standing in cloned and fully characterized plant FA biosynthesis genes and, as can be seen, many of the genes necessary for altering lipid biosynthesis are now available.

The high level of interest in the area of biotechnological alteration of plant lipids for science and industry has become apparent from the publication of several excellent reviews (1–6). Several approaches are presently being pursued both by industry and academia to alter lipid metabolism in transgenic plants. Changing the FA composition of seed storage, triacylglycerols (TAG) can increase the economic value of the plant-derived oil. The value of oil crops may be enhanced simply by removal of undesirable characteristics from the oil, an example being the reduction of high levels of saturated FA in food oils. Alternatively, the plant oil also may be modified for the accumulation of novel and unique high value substances for use in the pharmaceutical, chemical, or other industries.

The predominant FA contained in the TAG of most oilseed crops are palmitic (16:0), oleic (18:1), linoleic (18:2), and linolenic (18:3) FA. A small percentage of stearate (18:0) is also present (7). As exemplified through the work of Knutzon and colleagues (8), FA metabolic modification can be accomplished by altering the levels of proteins expressed by na-

	Cucumis sativus	1
	G. max	15
	H. vulgare	3
	Lens culinaris	1
	Lycopersicon esculentum	2
	Phaseolus vulgaris	2
	Pisum sativum	6
	Solanum tuberosum	1
	Z. mays	2
P450 Hydroxylase	*Z. mays*	2
Hydroxylase	*R. communis*	1
Allene oxide synthase	*L. usitatissimum*	1

[a]The number of gene clones for some of these enzymes might be somewhat inflated in some cases due to different labs cloning and sequencing essentially the same cDNA or genomic DNA clones from different libraries, different plant genotypes, etc. Detailed information on all of these and for other lipid biosynthesis enzymes from animals, fungi, and prokaryotes is available from any of the Internet WWW (worldwide web) databases mentioned in the introduction. Information on NCBI GenBank is available on the WWW (at http://www.ncbi.nlm.nih.gov/). ACP, acyl carrier protein.

tive genes within a particular plant species. Alternatively, as exemplified by a rapeseed cultivar engineered for high lauric acid accumulation (9,10), new and valuable FA metabolites, normally not produced by a particular commercial oilseed crop, can be produced by the transfer of genes from one species to another. The genes used to metabolically engineer oilseed crops need not be limited to the plant kingdom, for there are examples of plants engineered for altered FA metabolism *via* the introduction of animal and yeast genes (11,12). In addition, Δ6, Δ9, and Δ12 desaturases have been cloned from the cyanobacterium *Synechocystis* (13,14), which may prove useful in the genetic engineering of oilseeds for altered FA composition.

With many genes involved in plant lipid biosynthesis isolated and characterized, there is, within the next five years, likely to be a dramatic increase in the number of engineered oilseed crops in commercial production. In this review we will focus on the alteration of plant lipids through the use of biotechnological techniques, discussing the current status and future prospects for this field of applied technology.

PLANT FA METABOLISM

Figures 1 and 2 provide a summary of the current understanding in plant FA and TAG biosynthesis, showing the major biochemical steps and compartmentalization of the process.

First steps in de novo *FA synthesis.* Most *de novo* plant FA synthesis occurs in the plastids and begins with the first committed step, a reaction between acetyl-CoA and a bicarbonate ion. The reaction, catalyzed by acetyl-CoA carboxylase (ACCase, E.C. 6.4.1.2,), results in the formation of malonyl-CoA and is believed to be rate-limiting for the production of FA (15). Table 1 shows that several ACCase genes have been cloned from several plant species. The genes should aid the elucidation of ACCase's regulatory role in plant FA metabolism.

The next stage of FA synthesis, the initiation of an FA carbon chain, is catalyzed by 3-ketoacyl-ACP (ACP = acyl carrier protein) synthase (β-ketoacyl synthase) (KAS) III associated within a Type II dissociable FA synthase (FAS) II complex (16). In this reaction, malonyl-ACP condenses with an acetyl-CoA molecule. The initial product of the condensation, a β-ketoacyl-ACP molecule, is converted to butyryl-ACP (butyric acid esterified to ACP) *via* a reduction, dehydration, and second reduction of the β-ketoacyl derivative. The reactions following the condensation are catalyzed by the enzymes associated in the FAS II complex. Table 1 shows that KAS genes and ACP have been isolated from several plant species.

FA chain elongation. Elongation of the FA chain, from 4-C butyryl-ACP to 16-C palmitoyl-ACP, proceeds *via* two carbon additions with malonyl-CoA supplying the carbons. Each malonyl-ACP (malonyl-CoA is transferred to an ACP molecule prior to condensation) condensation with the growing fatty acyl-ACP, up to 16-C palmitoyl-ACP, is catalyzed by KAS I, associated within the FAS II complex (17). The conversion of the 16 carbon FA thioester, palmitoyl-ACP, to the 18 carbon FA thioester, stearoyl-ACP, is catalyzed by KAS II associated in the FAS II complex (18). Stearoyl-ACP is largely converted to the monounsaturated FA thioester oleoyl-ACP by the activity of stearoyl-ACP desaturase (E.C. 3.1.2.14) (19), a soluble enzyme located in the chloroplast stroma which introduces a double bond between the ninth and tenth carbons of the FA chain.

The mechanism by which plants control the FA chain length involves a complex kinetic interplay between enzymes competing for FA substrates. As an FA chain is being built

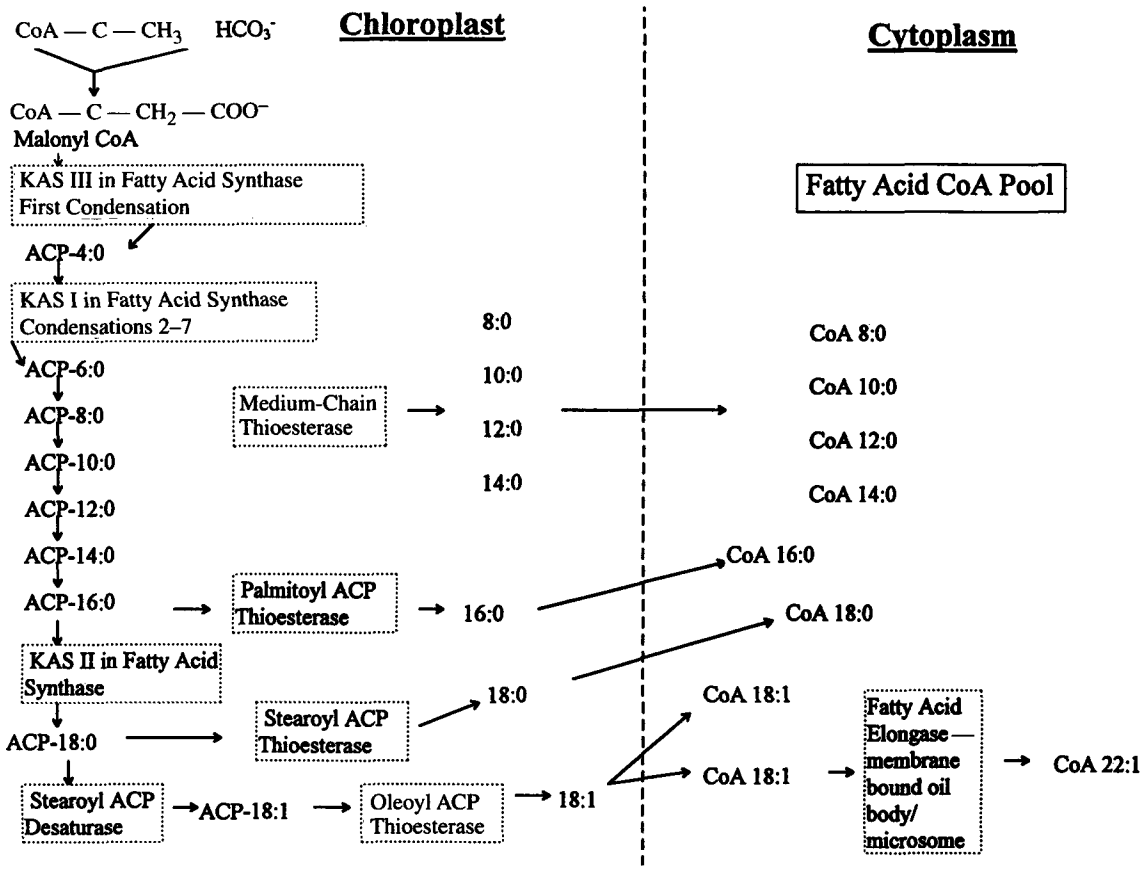

FIG. 1. Schematic overview of fatty acid synthesis in plant tissues. See text for detailed description. KAS, β-ketoacyl synthase; ACP, acyl carrier protein.

(C_4 to C_{18}), it is attached to an ACP *via* a thioester linkage. Severing of the thioester linkage can be brought about at specific substrate chain lengths by the activity of either an acyl-ACP hydrolase (thioesterase) or an acyltransferase. The result of either enzymatic activity is the termination of FA chain length extension. The "competition" for substrate is thus a competition between the termination of synthesis, a function of thioesterase and transferase activity, and extension, a function of the KAS I and II isoforms. An example of the complex kinetic interplay related to the FA chain length can be viewed with the California bay *(Umbellularia californica)*. California bay's TAG profile in seeds may consist of up to 70% lauric acid (12:0). These short-chain FA are produced by a thioesterase which shows maximal hydrolytic activity on 12C-ACP thioesters (9,20). The medium-chain thioesterase thus diverts a portion of FA from the elongation pathway and forms lauric acid.

FA of 18 and 16 carbons in length tend to predominate in the tissues of most commercially grown plant species. C_{18} FA generally range from 60 to 95% and C_{16} FA range from 5 to 45% of total FA of such tissues (21), depending on plant species. However, unique FA of unusual chain length (i.e., $< C_{16}$ or $>$ than C_{18}) or with atypical side groups (hydroxyl, epoxide, keto, etc.) can often be found in noncommercial members of the plant kingdom, although usually these lipids are maintained in the storage TAG (22).

Extra-plastidial metabolism of FA. FA molecules, formed in the chloroplast stroma, are released and cross the membrane by an unknown mechanism. As the FA cross the membrane, they are converted to fatty acyl-CoA esters through the activity of an acyl-CoA synthetase, located on the outer chloroplastic membrane (3). In the cytoplasm, the fatty acyl-CoA form a pool from which they have several possible fates.

In some cruciferous oilseed crops, 18:1-CoA from the acyl-CoA pool may be elongated to eicosenoyl-CoA (20:1-CoA) or erucoyl-CoA (22:1-CoA), known as very long chain FA (VLCFA). The reactions are thought to be catalyzed by a multiprotein, microsomal, membrane-bound complex (23). Recently the cDNA sequence of a constituent FA elongase (FAE) I of the multiprotein elongation complex has been isolated from *Arabidopsis* (24). The protein sequence deduced from the cDNA shows sequence homology with chalcone synthase, stillbene synthase, KAS III from *Escherichia coli*, and KAS III from spinach.

The mechanism of VLCFA synthesis involves the condensation of 18:1-CoA with malonyl-ACP, forming the β-ketoacyl derivative. As previously described, the steps following the initial condensation involve the reduction and dehydration of the β-ketoacyl molecule, followed by a second reduction. The resulting 20:1 fatty acyl-CoA molecule then may be acted upon *via* the same mechanism of the elongation complex producing 22:1-CoA. The mechanism of the FAE I con-

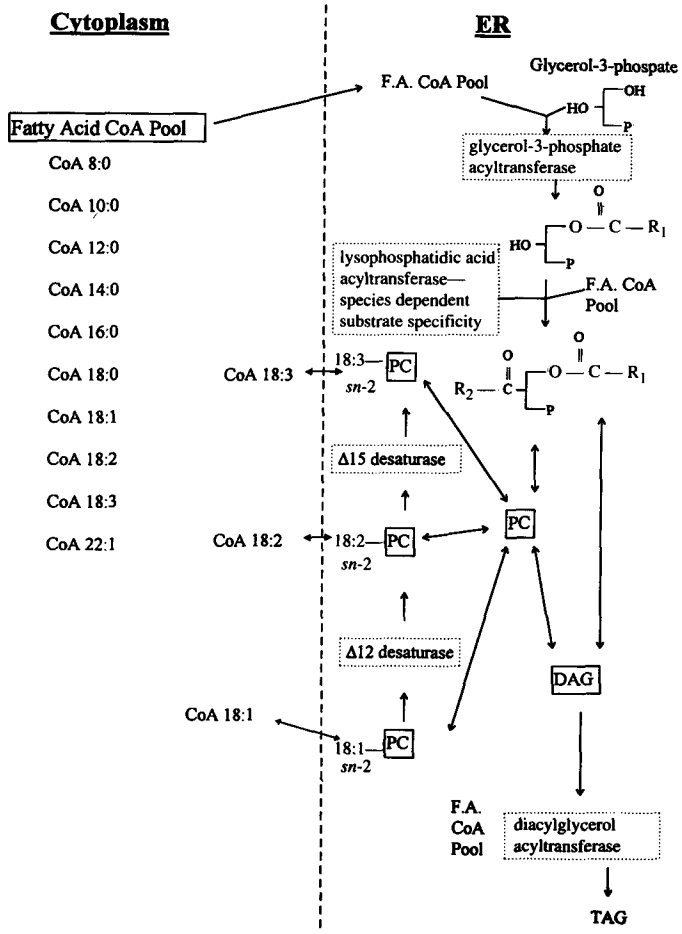

FIG. 2. Schematic overview of phospholipid and triacylglycerol (TAG) synthesis in plants. See text for detailed description. F.A., fatty acid; PC, phosphatidylcholine; DAG, diacylglycerol.

densation resembles the reaction catalyzed by KAS III, where malonyl-ACP condenses with an acyl-CoA (acetyl-CoA). The reaction differs from the 4-carbon to 18-carbon elongation where the malonyl-ACP is condensing with fatty acyl-ACP molecules (24). In select cruciferous oilseed crops, VLCFA are present in the fatty acyl-CoA pool.

Phospholipid and triglyceride synthesis. The fatty acyl pool serves as a source of FA used in the production of phospholipids and TAG. The phospholipids, phosphatidic acid (PA) and phosphatidylcholine (PC), are precursors to diacylglycerol (DAG) which, in turn, is the immediate precursor of TAG. PC, the major substrate of the oleoyl desaturase and the linoleoyl desaturase, is also a source of polyunsaturated FA for the fatty acyl-CoA pool. Formation of TAG begins with the acylation of glycerol-3-phosphate at the *sn*-1 position. The enzyme catalyzing the reaction, glycerol-3-phosphate acyltransferase (G3PAT; E.C. 2.3.1.15), is located in the microsomes and is most active in acylating saturated FA (25). The resulting molecule, lysophosphatidic acid, is then acted upon by a second microsomal enzyme, the lysophosphatidic acid acyltransferase (LPAAT; E.C. 2.3.1.51). The reaction forms PA through the transfer of a fatty acyl group to the *sn*-2 position. LPAAT is usually highly selective, showing highest enzymatic activity for the acylation of unsaturated FA (26–28). PA may be converted to PC by the addition of a choline headgroup or it may be dephosphorylated, forming DAG, by the activity of PA phosphatase (E.C. 3.1.3.4). DAG acyltransferase (DAGAT; E.C. 2.3.1.20), located in the microsomal membranes, converts DAG to TAG by acylating the *sn*-3 position with an acyl-CoA substrate from the fatty acyl-CoA pool.

FA desaturation. PC molecules are acted upon in the microsomes by the membrane-bound desaturases, oleoyl desaturase and linoleoyl desaturase. These desaturases convert the fatty acyl group at the *sn*-2 position from oleic to linoleic acid and from linoleic to linolenic acid, respectively. A reversible acyl exchange reaction, involving the acyl-CoA dependent fatty acylation of lysophosphatidylcholine (LPC) at the *sn*-2 position or, conversely, the transfer of an acyl group from the *sn*-2 position of PC to CoA, is catalyzed by acyl-CoA-LPC acyltransferase (LPCAT). The polyunsaturated thioesters (18:2 and 18:3), produced at the *sn*-2 position, are thus made available to the fatty acyl-CoA pool *via* the activity of the LPCAT (29–32). PC also may be converted to DAG, and subsequently to TAG, in a reversible reaction, through the activity of choline phosphotransferase (33,34).

PLANT GENETIC ENGINEERING

Altering a plant's biochemistry by genetic engineering requires that genes of interest be delivered into plant cells, stably integrated into the genome, and readily expressed by the cell. Transformed plant cells must then be converted to healthy, fertile adult plants. A variety of methods have been developed to accomplish the task of plant genetic engineering. Two of the most developed and successful methods involve the use of *Agrobacterium* (35) and particle bombardment (gene gun) (36).

A gene construct, prepared for introduction into a plant's genome, is equipped with a promoter region and a poly-A addition site. This enables the gene to be transcribed and translated normally in the cell. Use of tissue-specific gene promoters can allow for the expression of genes in desired tissues or at specific developmental stages. The capability for targeted gene expression is of immense importance, particularly with regard to altering FA metabolism, as the introduction of a gene can radically alter a plant's normal biochemistry. For commercial use of genetic engineering in common crop plants, it is desirable to target the alteration of lipid metabolism only to the seed, so as not to effect desirable agronomic qualities of the rest of the plant. The use of seed-specific promoters in gene constructs (37), introduced into plant cells for the purpose of altering the FA profile of seed TAG, ensures that the spatial expression of the gene occurs only in seeds. In addition, the seed-specific promoters allow for the temporal expression of the gene to coincide with the time at which the seed's metabolism is highly active in TAG production.

The orientation of a gene, with respect to the promoter, may be varied when inserted into the plant genome. A gene

oriented with the N-terminal translating region immediately succeeding the promoter is said to be of the "sense orientation" while the reverse orientation, with the C-terminal translating region immediately succeeding the promoter, is called "anti-sense." The "sense orientation" corresponds to the native orientation of a gene, and the "anti-sense orientation" corresponds to the reversal of a gene's native orientation.

When inserted into a plant genome, the sense gene construct normally produces the enzymatic activity encoded by the gene. The biochemical activity can be new to the plant, if the gene is not native or, alternatively, if the gene is native to the plant, the introduction of additional gene copies may raise the level of the native enzyme beyond standard levels. This has the potential of increasing substrate to product conversion at a particular biochemical step (sense upregulation). If a gene is inserted into the genome in the "anti-sense orientation," the effect may be to reduce the levels of enzymes that are highly homologous to the introduced gene within (38,39). A reduction in enzyme levels may cause a reduction of substrate flow through the biochemical step catalyzed by the affected enzyme (anti-sense downregulation). At times the use of the "sense orientation" has had the unexpected effect of decreasing the level of homologous enzymes. This phenomenon is termed "co-suppression" or "trans-switching" (40). Though the mechanism of co-suppression is not understood, it has become another method used in downregulation of specific genes. Any of the genetic engineering phenomena just mentioned (anti-sense downregulation, co-supression, or sense upregulation) may serve as a tool for affecting the accumulation of desired FA.

ALTERATION OF SATURATED/UNSATURATED FA LEVELS

A variety of molecular strategies may be employed to alter the saturated and unsaturated FA levels in oilseed crops. One strategy for increasing stearic acid levels in oilseed crops could employ the use of anti-sense supression or co-supression to reduce or knock out the activity of stearoyl-ACP desaturase (see Table 1 for cloned ACP). Stearoyl-ACP desaturase is the enzyme responsible for converting stearoyl-ACP (saturated FA) to oleoyl-ACP (unsaturated FA). Another possible metabolic target with the potential for increasing stearic acid accumulation is the stearoyl-ACP thioesterase (see Table 1). The enzyme's substrate to product conversion (converting stearoyl-ACP to free stearate) could be increased (upregulated) by sense-orientated reintroduction of the stearoyl-ACP thioesterase. An increase in stearate release from the ACP before stearoyl-ACP desaturase can act, effectively bypasses the conversion of saturated to unsaturated FA. A combination of the two strategies would likely lead to an even greater accumulation of stearic acid.

The first successful genetically engineered alteration of FA metabolism involved the modification of saturated/unsaturated FA levels in rapeseed. The levels of a saturated FA, stearic acid, was increased at the expense of a monounsaturated FA, oleic acid (8). Knutzon and co-workers (8) used the "anti-sense" supression strategy to reduce levels of the stearoyl-ACP desaturase in rape. The decrease in stearoyl-ACP desaturase levels resulted in a decrease in the conversion of stearoyl-ACP to oleoyl-ACP. This created a metabolic "traffic jam" at the biochemical step where saturated FA is converted to unsaturated FA and, in turn, allowed more stearate to be released from the ACP *via* the activity of stearoyl-ACP thioesterase. The anti-sense supression strategy ultimately resulted in an engineered rapeseed line that accumulated up to 40% stearic acid (normally not an abundant constituent of rapeseed oil) in its seed TAG. Stearic acid has the potential to be used in confectionary foods (as a cocoa butter substitute) and in the pharmaceutical and cosmetic industries (3). Though rapeseed has proven to be the easiest oilseed crop to genetically alter and regenerate, there is the potential for replicating the mentioned metabolic engineering strategies in other oilseeds (soybean, sunflower, peanut), especially as a wide range of these genes now have been cloned. Table 2 shows some of the currently modified oilseed crops.

Plant FA metabolism also may be engineered to alter the levels of unsaturated FA. The target enzymes for this goal include the stearoyl-ACP desaturase, oleoyl desaturase, and linoleoyl desaturase. Increasing the oleic acid content of seed oil at the expense of linoleic and linolenic acids has been set as a major goal of many researchers. A reduction in the levels

TABLE 2
A Brief List of Some of the Agronomically Important Oilseed Crops That Have Been Genetically Modified and Their Lipid Biosynthesis Pathways Altered

Crop species	Introduced gene	Genetic alteration	Reference
Brassica napus	Stearoyl ACP[a] desaturase in anti-sense orientation	Stearic acid accumulation	7
	C_{12} Acyl-[ACP] thioesterase	Lauric acid accumulation	4, 8

[a]ACP, acyl carrier protein.

of the di- and trienoic polyunsaturates would increase the oxidative stability of an oil along with reducing processing (hydrogenation) costs (41). In the past few years, both the microsomal and plastidial forms of a variety of desaturases have been cloned from a range of plants (Table 1). The increase in oleic acid content could be accomplished *via* the reduction of the oleate desaturase (FAD2) levels using anti-sense supression or co-supression. Researchers at DuPont have demonstrated the validity of this strategy in both rapeseed and soybean (41). In rapeseed lines engineered with anti-sense cDNA of the oleate desaturase, levels of seed oil oleate were reported to be 83% (compared with 63% in control). The engineered rapeseed was crossed with a mutant line containing 77.8% oleate in seed oil, and the resultant cross had an oleate seed oil content of 88%. In soybean, anti-sense engineering produced a line of soybean with 78.9% oleate in seed oil (compared with 22% in control) (1).

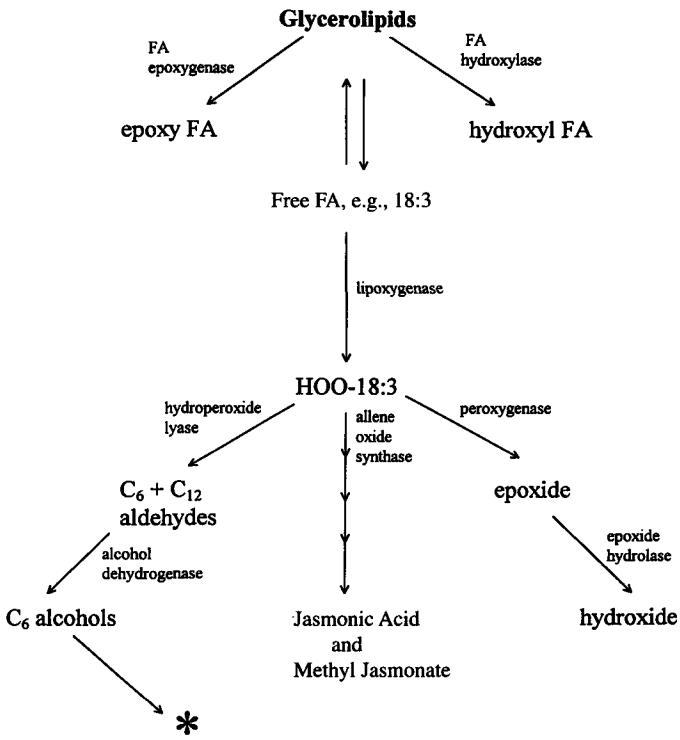
Raising the levels of linolenic acid in seed oil serves as another potential goal. If produced in economic quantities, linolenic acid could compete with petrochemicals for use in paints, varnishes, coatings, and drying oils (1). In soybean seed oil, 18:3 and 18:2 levels usually run around 10 and 60%, respectively. A strategy for increasing linolenic acid in TAG employs increasing the level of linoleoyl desaturase (FAD3). Sense-oriented reintroduction of extra copies of the linoleoyl desaturase gene should increase enzyme levels and increase the conversion of 18:2 to 18:3. The increase in linolenic acid levels in the fatty acyl pool should, in turn, increase the percentage of linolenic acid in TAG.

Possible strategies for maximizing the linolenic acid levels involve a combined strategy of up- and downregulation of critical genes. This would involve multiple gene insertions. Reducing levels of the two thioesterases involved in freeing saturated FA (palmitoyl-ACP thioesterase and stearoyl-ACP thioesterase) should provide FA, normally destined to be incorporated into TAG as saturated FA, to be available for unsaturation. Anti-sense supression or co-supression of each gene should accomplish the goal. The reduction of the thioesterase levels combined with an increase in levels of the three enzymes involved in desaturation (stearoyl-ACP desaturase, oleolate desaturase, and linoleate desaturase) could maximize linolenic acid levels.

UNUSUAL FA PRODUCTION

There are a number of unusual FA that accumulate in the seed oil of various plants which might be useful if the genes encoding the key biosynthetic enzymes were transferred into oilseeds. We will cite one example here and focus particularly on oxygenated FA and derivative synthesis later in the review. One unusual FA, petroselinic acid (*cis*-6-octadecenoic acid), an isomer of oleic acid, has its double bond between the sixth and seventh carbon. The difference in double-bond positioning on the carbon chain alters the melting point, which is 33°C for petroselinic as opposed to 12°C for oleic acid. The higher melting point means that petroselinic acid is solid at room temperature and makes it potentially useful as a component of margarines and shortenings. The industrial potential of petroselinic acid as a chemical feedstock exists with the products produced by its ozone-catalyzed oxidation and scission products—lauric acid (dodecanoic acid, 12:0) and adipic acid (hexanedioic acid, 6:0). Lauric acid is used in detergents, and adipic acid is used in the production of nylon 6,6 (1,3).

Petroselinic acid, not produced in any commercial oilseed crop, may make up as much as 85% of the total FA in the Umbelliferae, Araliaceae, and Garryaceae plant families. Thus, knowledge of the biochemical steps involved in petroselinic acid production and isolation of the genes responsible for those steps are precursors to engineering oilseed crops for its production. Information gleaned regarding petroselinic acid production indicates that three genes may be involved (42). A palmitoyl-ACP desaturase, which has been cloned (43), introduces the double bond between the fourth and fifth carbons of palmitic acid. This is followed by activity of a postulated condensing enzyme, specific for the $cis^4$16:1 molecule, that elongates the substrate to $cis^6$18:1 petroselinic acid. Finally, release of the petroselinic acid molecule from the ACP molecule may necessitate a unique thioesterase. Thus, engineering of an oilseed crop for significant petroselinic acid accumulation would apparently require the introduction of at least three genes, not all of which have yet been cloned.



ALTERATION OF FA CHAIN LENGTH

Another thrust in the engineering of oilseed metabolism involves altering the chain lengths of FA that normally accumulate in seed oil. As stated previously, researchers at Calgene have successfully engineered oilseed rape to produce up to 40% lauric acid with no apparent effect on agronomic qualities (9). Production of medium-chain FA was brought about with the introduction of a medium-chain thioesterase (sense-orientation) under control of a seed-specific promoter, introducing the new enzymatic activity into rapeseed. The thioesterase, which shows maximal activity on 12:0-ACP, hydrolyzes the thioester linkage connecting the 12 carbon FA and ACP. The FA, once separated from the ACP, is no longer a substrate for elongation. It joins the fatty acyl-CoA pool in the cytoplasm and is eventually incorporated into TAG (9,20). Due to the absence of any activity of a native rapeseed LPAAT for lauric acid introduction at the *sn*-2 position of glycerol, the maximal lauric acid production was limited. In order to boost the production of lauric acid in rapeseed, it was hypothesized that an LPAAT (specific for medium-chain, saturated FA) if introduced into oilseed rape, would boost the accumulation of lauric acid in TAG. Researchers at Calgene have recently purified the LPAAT protein from immature coconut endosperm (44,45), which subsequently led to the cloning of the corresponding gene. Engineering of the lauric acid-producing rapeseed lines with the LPAAT gene has significantly increased the incorporation of lauric acid at the *sn*-2 position of TAG (H.M. Davies, personal communication).

A similar strategy will likely be necessary for the production of rapeseed with greater erucic acid levels in seed oil. If accumulated at greater than 90% of the seed oil content, erucic acid would compete more favorably with petrochemicals used in the production of nylon 13,13. Erucic acid also serves as a slip agent in plastic film production (1). Due to the specificity of the native LPAAT in rapeseed, erucic acid is excluded from the *sn*-2 position of TAG. This limits the maximum erucic acid content to around 60% in high erucic acid rapeseed (HEAR) lines (46). Recently, cDNA clones encoding erucoyl CoA-specific LPAAT from *Limnanthes douglasii* were isolated (47). Introduction of this gene into HEAR varieties should increase the erucic acid levels in TAG. Further metabolic modification might be necessary to maximize erucic acid production. The reduction of native LPAAT enzyme levels through anti-sense engineering combined with the increase of the FAE levels through sense reintroduction, along with the introduction of the erucoyl-specific LPAAT into HEAR varieties, would likely maximize erucic acid production.

PRODUCTION OF OXYGENATED FA

As described previously, most of the FA found in plant tissues are comprised of five major types, the saturated 16-carbon and 18-carbon FA and the mono-, di-, and triunsaturated 18-carbon FA. Also, as mentioned earlier in this review, altered thioesterase or elongase activities can result in accumulation of FA of different chain lengths. In addition to the control of differing degrees of FA unsaturation and chain lengths, plants have the capacity to produce a wide variety of FA derivatives. The plant kingdom has been found to contain more than 200 different FA (48), and this list is likely to grow as additional plant species are examined. Most of these "unusual" FA only accumulate in the triglycerides of seed oils. The biological roles of most of these "unusual" FA are not known, but it is thought that many or most of them may have a role in defense against pests, as do many secondary products in plants. Here we will focus only on some of the oxygenated FA derivatives. The formation of these oxygenated FA derivatives in plant tissues is outlined in Scheme 1 (FA esterified to phospholipids, especially PC, can be converted by epoxygenase or hydroxylase into epoxy or hydroxy derivatives. FA also can be converted by lipoxygenase into hydroperoxy derivatives. Most lipoxygenases are thought to act on FA which are first "released" by phospholipase or lipolytic acyl hydrolase before peroxidation. Lipoxygenase can peroxidize linoleic or linolenic acids forming hydroperoxy linoleic or linolenic acids. The primary products of lipoxygenase, the FA hydroperoxides usually do not accumulate in plant tissues and can be rapidly converted into additional products by one of three known pathways. Most plant tissues appear to have the hydroperoxide lyase and allene oxide synthase branches of the lipoxygenase pathway. To date, peroxygenases have only been demonstrated in seedlings of some plants. Hydroperoxide lyase can cleave FA hydroperoxides forming 6- and 12-carbon aldehydes. Many plants have the

SCHEME 1

capacity to convert the 6-carbon aldehydes into alcohols. Allene oxide synthase converts the FA hydroperoxides into an unstable epoxy intermediate, which can be converted into a cyclic ketone by a cyclase. A series of subsequent reactions can result in formation of jasmonic acid, which can be converted into methyl jasmonate. Peroxygenases convert fatty acid hydroperoxides into epoxides which can be converted to hydroxides by hydroxylases.)

Hydroxylases and epoxygenases. Transformation of plants with heterologous genes from other organisms may be a way to produce entirely new novel compounds previously not seen in those plants. Often these genes come from noncrop plants or from plants that are not suitable for particular agricultural regions. By putting these genes into agriculturally valuable crops to modify lipid synthesis, we can essentially create new forms of currently high yielding plants. This will allow us to use the plants as chemical factories, accumulating potentially valuable compounds. Epoxy and hydroxy FA are instances of high-value FA derivatives.

An example of a hydroxy FA which can accumulate in the storage oil of higher plant seeds is 12*R*-hydroxyoctadec-*cis*-9-enoic acid (ricinoleic acid). This FA has been found in at least a dozen genera of ten different higher plant families (48). One species which accumulates ricinoleic acid in the seed oil is the castor oil plant (*Ricinus communis* L.). The castor oil plant does not have agronomic characteristics such that it can be grown commercially on a large scale. Thus there has been interest in cloning the hydroxylase gene responsible for hydroxy FA synthesis in order to genetically engineer more productive oilseeds for hydroxy FA accumulation. There has been little

biochemical information characterizing the enzymes that are involved in hydroxy FA synthesis. This is apparently due to the fact that hydroxylase, such as that in developing castor endosperm, is labile and associated with the endoplasmic reticulum (49,50). Early *in vivo* labelling experiments indicated that the ricinoleic acid of maturing castor endosperm is synthesized *via* direct hydroxylation of an oleic acid precursor (51). This microsomal hydroxylase apparently requires oleoylphosphatidylcholine, O_2, and NADH. Also, iron appears to be involved in the catalysis of this enzyme, but this enzyme is not a cytochrome P-450 protein (49,50). These characteristics of the castor hydroxlyase indicated a superficial resemblance to ω6 FA desaturases (52,53) and led to the development of a successful strategy for cloning of the oleate 12-hydroxylase from developing castor oil endosperm. Expression of a full-length putative hydroxylase cDNA clone in transgenic tobacco caused the accumulation of low levels of ricinoleic acid in the seed, indicating that they had indeed cloned an oleate 12-hydroxylase. The poor accumulation of ricinoleic acid in the transgenic tobacco seed indicated to van de Loo *et al.* (52) that other enzymes, such as acyltransferases with specificity for transfer of hydroxy FA into TAG, are needed.

Epoxides are valuable for the production of several industrial products and are currently chemically synthesized at some expense. Engineering productive oilseeds with enzymes responsible for epoxide synthesis could potentially allow us to have an abundant renewable source of these valuable chemicals. Genetic engineering of oilseeds for epoxy FA accumulation would increase the value of the oil of such modified seeds for industrial uses. A considerable market currently exists for epoxy FA, particularly for epoxy coatings and plasticizers. The current United States plasticizer market is about two billion pounds per year (54). Presently most of this is derived from petroleum. In addition, there is industrial interest in the use of epoxy FA in oil-based paints, lubricants, and lubricant additives, adhesives, insecticides and insect repellants, crop oil concentrates, and the formulation of carriers for slow-release pesticides and herbicides (55,56). Also, epoxy FA can readily and economically be converted to hydroxy FA and their derivatives, which are useful starting materials for the production of plastics, as well as for detergents and lubricants. Examples of plastics which can be produced from hydroxy FA are polyurethanes and polyesters (57). If a soybean and/or other major oilseed were developed which accumulated epoxy FA, it is likely that other valuable products would be developed using this as an industrial chemical feedstock in the future.

Epoxidized oil would likely be more economical if the biosynthetic reactions in oilseed crops, such as soybean, were altered such that the seeds themselves converted the polyunsaturated FA into epoxy FA. There is no known way to produce a soybean which accumulates epoxy FA by conventional breeding and genetics. However, certain genotypes of several plant species accumulate high levels of epoxy FA in the seed oil. Epoxy FA, like vernolic (*cis*-12,13-epoxyoctadeca-*cis*-9-enoic) and coronaric (*cis*-9,10-epoxyoctadeca-*cis*-12-enoic) acids, have been found as a component of the seed oil of species represented by a number of plant families, such as Compositae, Euphorbiacea, Onagraceae, Dipsacaceae, and Valerianacea (58). Plant epoxygenases are known which transform unsaturated FA into epoxy FA (59,60). The best examples of epoxy FA accumulating plants are *Vernonia galamensis* and *Euphorbia lagascae,* both of which accumulate vernolic acid (55,61,62). Some accessions of *V. galamensis* have as much as 40% oil, which is comprised of 80% vernolic acid (63). Although soybeans do not accumulate large quantities of epoxy FA in their oil, they are known to contain the requisite enzymes for producing epoxy FA from unsaturated FA. Soybean seedlings have been shown to contain an enzyme known as peroxygenase that was shown to epoxidize either oleic or linoleic acid using a hydroperoxy oxygen of hydroperoxylinoleic acid (64). A similar enzyme has been found in broad bean (65). In addition to utilizing hydroperoxylinoleic acid as a source of oxidation potential, the broad bean enzyme was shown to be capable of utilizing H_2O_2 (66) and cumene hydroperoxide in the epoxidation process (65). Peroxygenase and related reactions will be discussed further in the following section.

Although major oilseeds such as soybeans clearly have the enzymes, such as lipoxygenase and peroxygenase required to produce epoxy FA, the process by which the seeds of certain species of *Vernonia* and *Euphorbia* accumulate epoxytriglycerides appears to be due to an enzyme not present in major commercial oilseeds such as soybeans. The production of epoxy FA and derivatives in defense responses appears to be widespread in plants (see below), but the accumulation in storage oil of certain seeds such as *Vernonia* and *Euphorbia* appears to be due to a different, much less common mechanism (67). Biochemical studies by Bafor *et al.* (62) indicate that developing seeds of these plants contain an enzyme known as an epoxygenase which converts linoleic acid into vernolic acid in a one-step reaction. Most epoxygenation reactions in biological systems appear to be catalyzed by cytochrome P-450 monooxygenase enzymes. This epoxygenase also appears to be a cytochrome P-450 monooxygenase (62).

Epoxy and hydroxy FA are apparently formed in plant defense reactions (68) but *via* a different mechanism than the accumulation in the oilseeds mentioned previously. These compounds can have antimicrobial properties and also can provide monomers for cutin synthesis. Cutin is the insoluble polymeric structural component of the cuticle of all aerial parts of plants except periderms (69,70). Cutin monomers include epoxy, monohydroxy, epoxy-hydroxy, and dihydroxy 16- and 18-carbon FA. Blée and Schuber (71) provided good evidence that the formation of these cutin monomers, at least in wound-induced cutin formation, involves epoxidation of oleic acid by peroxygenase using lipoxygenase-derived hydroperoxides. The epoxide is hydrolyzed to the corresponding diol by hydrolase and the ω-hydroxylation most probably is catalyzed by a cytochrome P450. The ω-hydroxy 16- and 18-carbon FA, which are the major aliphatic monomer components of suberin, might be formed

via the same mechanism as the ω-hydroxy FA involved in cutin formation. Cutin and suberin formation can be formed in plant pest defense reactions as a physical barrier to invading organisms (68,72).

Lipoxygenase (LOX) and related enzymes. LOX are ubiquitous plant enzymes that catalyze the peroxidation of *cis,cis*-1,4-pentadiene moieties of FA such as 18:2 and 18:3. LOX can affect the quality of vegetable oils by initiating FA peroxidation prior to oil extraction. Many plants have been shown to contain multiple LOX isozymes encoded by different genes. Table 1 shows the wide range of cloned LOX from 11 different plants. It is estimated that there are up to 12 different LOX genes expressed at different times in the lifecycle of the soybean (73–76). LOX 1–3 are the major isozymes expressed in cotyledons and embryonic axes seen from the maturation phase of seed development until maturity, but they are not expressed in seedcoats (75). Preliminary evidence indicates that a minor isozyme, different from LOX 1–3, is constitutively expressed in most or all tissues. The complete coding regions of all three soybean embryo LOX cDNAs have been sequenced (77–80), and LOX from a variety of other plants also have been sequenced in recent years (Table 1). All three soybean seed LOX show a high degree of homology, at least 70% at the amino acid sequence level (78), with LOX 1 and 2 being particularly homologous [81% at the amino acid sequence level (Refs. 78,81)]. Plant LOX have been divided into two major groups, LOX1 and 2, based on general homologies (82). Most plant LOX are of the LOX1 class, an example of which is soybean LOX1. There are two representatives known for the LOX2 class, both of which have putative plastid transit sequences, one from rice and one from *Arabidopsis* (83,84). Interestingly, the other known *Arabidopsis* LOX is a LOX1 type (82,85). Recently, Bell *et al.* (86) provided good evidence that the type 2 LOX of *Arabidopsis* is chloroplast localized.

The FA hydroperoxides resulting from LOX action in higher plants, including soybeans are metabolized by one of several major pathways operative in plant tissues (Scheme 1; Refs. 64,68,76,87–90). In one pathway, hydroperoxide lyase catalyzes the cleavage of 13-hydroperoxylinoleic or linolenic acid into the 12-carbon compound, 12-oxo-*cis*-9-dodecenoic acid, and the 6-carbon aldehydes, hexanal or *cis*-3-hexenal. The C_6 aldehydes have distinct odors or aromas. Hexanal is undesirable in most food applications, but *cis*-3-hexenal and *trans*-2-hexenal are often desirable. Hexanal and hexenals are frequently converted to their corresponding alcohols by alcohol dehydrogenase, and the alcohols can be converted into esters. Many of these alcohols and esters are also quite aromatic and important in the flavor of many fruits and vegetables including in the so-called "fresh notes."

Soybean seeds have high 6-carbon aldehyde production capacity, but this often appears to be limited by free FA availability (91,92) and is dependent on formation of 13-hydroperoxy products by LOX and/or the selectivity of hydroperoxide lyases. Some LOX form 9-hydroperoxy derivatives in plants, which can be converted into 9-carbon aldehydes in some plant tissues such as cucumber, melons, and some other fruit (93–96).

The predominant FA in soybean seeds is linoleic acid. Hence the main LOX/hydroperoxide lyase product in soybean seeds is the saturated aldehyde, hexanal. Hexanal is undesirable in most food applications using soybean seed, contributing a rancid odor (97). Also, as mentioned previously, LOX may reduce vegetable oil stability. Soybean seeds are especially rich in LOX, and breeders have long been interested in the genetic reduction of LOX activity of soybean seed. LOX null mutants lacking LOX1–3 have been produced by traditional plant breeding methods (98,99), but so far no transgenic plants have been produced with LOX anti-sense insertions. The hydroperoxide lyase protein has been previously purified from green tea (*Thea sinensis)* (100) and recently characterized (101), but the gene has not yet been isolated. Bell pepper hydroperoxide lyase is a 55 kD heme protein resembling the cytochrome P450 (102), allene oxide synthase, from flaxseed (Refs. 103,104; see Table 1 and following text). The hydroperoxide lyase does not show a spectral change upon carbon monoxide treatment characteristic of cytochrome P450, but it may still be an unusual type of cytochrome P450. Due to their wide distribution among plant species and tissues and role in volatile, odiferous compound generation, LOX/hydroperoxide lyase can significantly impact quality of many foods based on or containing plant products.

A second pathway for metabolism of hydroperoxy FA (at least for linolenic acid) in plants is the conversion to an allene oxide by allene oxide synthase (also known as hydroperoxide dehydratase) (103–105). The allene oxide can undergo hydrolysis resulting in the formation of ketols. Alternatively, the allene oxide can undergo rearrangement and cyclization resulting in the formation of 12-oxo-phytodienoic acid (103). The 12-oxo-phytodienoic acid can be converted by a series of reactions involving a reductase and β-oxidations into jasmonic acid (88). There has been considerable interest in the physiological role of jasmonates. Jasmonic acid and related metabolites appear to be important signal molecules in plant storage product accumulation and response to stress, such as a water deficit or pest attack. Hamberg and Gardner (89), Sembdner and Parthier (106), Parthier (107), and Reinbothe *et al.* (108) recently reviewed this subject. Jasmonic acid has been shown to occur in many plant tissues including soybeans, especially in immature pericarp (109). Simpson and Gardner (105) examined the activity of the first two enzymes of the jasmonic pathway in soybean tissues. The highest activity was found in seedcoats followed by pericarp of immature fruit. This is consistent with studies on levels of jasmonic acid in soybean tissues (109). A cDNA encoding the allene oxide synthase from flaxseed has been cloned (104). Transgenic potato plants have been produced using this flax allene oxide synthase cDNA, which have 6- to 12-fold higher levels of jasmonic acid than nontransformed control plants (110).

The subcellular location of oxylipin pathway enzymes has not been clearly elucidated. It has been postulated that putative phospholipases thought to be involved in oxylipin for-

mation might be plasma membrane-located (111), but some studies indicate that this is not always the case (112). Most LOX isozymes in plant tissues appear to be cytoplasmically located but, as mentioned before, LOX of the 2 class appear to be located in plastids (84,86). Hydroperoxide lyase and allene oxide synthase also appear to be plastid located (59,110,113,114).

Peroxygenase is a unique membrane-associated oxygenase, occurring in soybean seedlings and other higher plant tissues, which catalyzes the hydroperoxide-dependent epoxidation of mono- and polyunsaturated FA (115,116). In developing seeds of *E. lagascae,* both peroxygenase and a cytochrome P-450 epoxygenase activity can be found, but in germinating seedlings only peroxygenase activity is detectable (67). Unlike the cytochrome P450 epoxygenase from *E. lagascae*, the peroxygenase is not a P450 oxygenase. In the peroxygenase reaction, the hydroperoxide is converted into hydroxy and hydroxy–epoxy FA (67,90). Soybean seedlings contain an enzyme, epoxide hydrolase, capable of hydrating the epoxide products of peroxygenase into their corresponding diols (117–119). The soybean FA epoxide hydrolase protein has been purified (117), and this will allow the isolation of the DNA clone with future work. Epoxy FA derivatives have been shown to induce resistance to pathogens in rice (120). The involvement of LOX/peroxygenase/epoxide hydrolase in a cascade is thought to be a defense reaction in plants in response to pathogen infection (115).

WRRC, ARS, USDA, Albany, California 94710

ABSTRACT: We have characterized the oleoyl-12-hydroxylase in the microsomal fraction of immature castor bean using the putative substrate, 1-acyl-2-oleoyl-*sn*-glycero-3-phosphocholine (2-oleoyl-PC). Previous characterizations of this enzyme used oleoyl-CoA as substrate and relied on the enzyme transferring oleate from oleoyl-CoA to lysophosphatidylcholine to form 2-oleoyl-PC (acyl-CoA:lysophosphatidylcholine acyltransferase) in addition to oleoyl-12-hydroxylase. The present assay system and characterization use 2-oleoyl-PC as substrate (oleoyl-12-hydroxylase alone). Use of the actual substrate for assay purposes is important for the eventual purification of the oleoyl-12-hydroxylase. Ricinoleate (product of oleoyl-12-hydroxylase) and linoleate (product of oleoyl-12-desaturase) were identified as metabolites of oleate of 2-oleoyl-PC by high-performance liquid chromatography and gas chromatography/mass spectrometry. The activity of oleoyl-12-hydroxylase in the microsomal fraction reached a peak about 44 d after anthesis of castor, while the activity of oleoyl-12-desaturase reached a peak about 23 d after anthesis. The optimal temperature for the oleoyl-12-hydroxylase was about 22.5°C, and the optimal pH was 6.3. Catalase stimulated oleoyl-12-hydroxylase while bovine serum albumin and CoA did not activate oleoyl-12-hydroxylase. The phosphatidylcholine analogue, oleoyloxyethyl phosphocholine, inhibited the activity of oleoyl-12-hydroxylase. These results further support the hypothesis that the actual subtrate of oleoyl-12-hydroxylase is 2-oleoyl-PC.

Lipids 31, 571–577 (1996).

Castor plants (*Ricinus communis* L.) have long been cultivated and harvested for production of oil. Castor oil obtained from the seeds is unique in that ricinoleic acid [D(+)-12-hydroxy-*cis*-9-octadecenoic acid] comprises roughly 90% of its fatty acids, and triricinolein makes up 70% of its triglycerides (1). Ricinoleic acid has many industrial uses, including the manufacture of lubricating oils, paints, coatings, cosmetics, thermopolymers, and other plastics. However, castor bean contains a toxic albumin, ricin, and protein polysaccharides that are potent allergens (2). Because of the potential danger of these components in harvest and processing, it is desirable to produce ricinoleic acid in an oilseed lacking these components.

Research on the enzymology of oleoyl-12-hydroxylase began nearly 30 years ago. The studies showed that the enzyme catalyzes the hydroxylation of oleoyl-CoA to ricinoleic acid in a reaction requiring oxygen and NADH, and has the properties of a microsomal mixed function oxidase (3). Ricinoleic acid is synthesized by direct hydroxy substitution at the 12-position of oleic acid with retention of configuration at the 12-position, and the hydrogen lost is of the D-configuration (4). The enzyme, which has not been purified yet, is located in the endoplasmic reticulum (microsomal) fraction (5). The hydroxylation requires reduced cytochrome b_5. Cytochrome P-450 is not involved (6), although many hydroxylation reactions in living systems involve cytochrome P-450. The immediate substrate for the oleoyl-12-hydroxylase has been suggested to be 1-acyl-2-oleoyl-*sn*-glycero-3-phosphocholine (2-oleoyl-PC) based on rapid incorporation of [^{14}C]oleate from oleoyl-CoA into phosphatidylcholine (PC) (7,8). We report here the characterization of oleoyl-12-hydroxylase using 2-oleoyl-PC as substrate. Recently, the castor oleoyl-12-hydroxylase was cloned; however, expression in the seed of transgenic tobacco was very low (9). Our ultimate goal is to develop a transgenic plant, producing ricinoleate in large quantity. For this purpose, the biosynthetic pathway of ricinoleate and triricinolein, and the enzymes involved, must be better understood to maximize the expression. Since oleoyl-12-hydroxylase gene has been cloned, we should try to understand the regulation of the enzyme, oleoyl-12-hydroxylase.

EXPERIMENTAL PROCEDURES

Plant material and chemical. Castor plants (*R. communis* L., United States Department of Agriculture accession 215679) were grown in a greenhouse. Harvested immature fruits were cut in half, and the endosperm was excised and used for the preparation of microsomes. Removed endosperm was immediately frozen in liquid nitrogen and stored in a freezer at –80°C until used for microsomal preparation. The microsomal

fractions used to measure enzyme activity and protein concentration vs. maturity of the bean were prepared from whole beans except the shells. Oleoyloxyethyl phosphocholine (OEPC) was purchased from Calbiochem (La Jolla, CA).

Microsomal preparation. Microsomes were prepared in a cold room (4°C) using a procedure similar to that of Bafor *et al.* (7). The endosperms (about 8 g) were ground in a mortar with 5 parts (vol/wt) of extraction buffer, 0.1 M sodium phosphate pH 6.3, containing 0.1% bovine serum albumin (BSA), 0.33 M sucrose, and 1000 units of catalase/mL. The homogenate was filtered through two layers of Miracloth and a layer of cheesecloth. The residue was ground again with extraction buffer and filtered. The total volume of extraction buffer used was 80 mL. The combined filtrates were centrifuged at 10,000 × *g* for 20 min using four tubes. The resulting supernatant was filtered through Miracloth and centrifuged at 105,000 × *g* for 90 min in eight 10-mL tubes. The fat pads and supernatants were removed and the pellets were suspended in the buffer, 0.1 M sodium phosphate pH 6.3, containing 0.1% BSA, and 1000 units of catalase/mL by repeated pipetting into a disposable plastic pipette with a very small opening (about 0.75 mm) on the tip. The volume of the buffer used was 1 mL/g of starting material. After the pellet was uniformly suspended, it was aliquoted and frozen in liquid nitrogen and then stored at −80°C. Protein concentration was determined by the bicinchoninic acid method (10).

Microsomal incubation. The microsomal incubation mixture included, in general, in a total volume of 1 mL, sodium phosphate (0.1 M, pH 6.3), NADH (0.5 μmol), ATP (0.5 μmol), $MgCl_2$ (0.5 μmol), catalase (1000 units), the microsomal fraction from castor bean (10 μL, about 92 μg of protein), and 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-phosphocholine (0.125 μCi, 2.16 nmol, 58.0 mCi/mmol; Amersham, Arlington, IL) in 20 μL of ethanol. The radioactive subtrate in 20 μL of ethanol was added last into a screw-capped tube followed by immediate mixing. The incubation mixture in the tube was then incubated in a shaking water bath (Dubnoff metabolic shaking incubator; Precision Scientific, Chicago, IL) for 30 min at 22.5°C. The incubation was stopped by addition of 3.75 mL of chloroform/methanol (1:2, vol/vol). Duplicate incubations were done under each incubation condition with variations shown in Figures 2, 4–10.

Extraction and hydrolysis of lipids. After the incubation was stopped, the mixture was again mixed with 0.63 mL of chloroform and 0.63 mL of water. The upper layer was removed by a Pasteur pipette. The lower lipid phase was dried by evaporator under a stream of nitrogen and then hydrolyzed and methylated in 5% HCl/methanol (1 mL) at 80°C for one hour. The fatty acid methyl esters formed were extracted with 2 × 1 mL of hexane.

High-performance liquid chromatography (HPLC) on short column. HPLC of the methyl esters was carried out on a liquid chromatograph (Waters Associates, Milford, MA) consisting of two pumps (M510), a multiwavelength detector (M490), and a chromatography manager (Millenium 2010). For the purpose of quantifying the radioactivities of the methyl esters of ricinoleate, linoleate, and oleate, a short reversed-phase C_{18} column (5 cm × 0.46 cm, 3 μm, Microsorb-MV; Rainin, Woburn, MA) was used to save time. The eluent was delivered at a linear gradient ranging from 90 to 100% methanol in 15 min at a flow rate of 1 mL/min for 10 min. The methyl esters of ricinoleate (1.5 min), linoleate (4.8 min), and oleate (6.7 min) were detected at 205 nm and were well separated (Fig. 1). The radioactivities of these methyl esters were quantified by a radioactivity flow detector (Flow-one, Model CR; Packard, Downers Grove, IL). The radioactivity flow detector included a flow cell of 0.5 mL, with delay time of 30 s comparing with the multiwavelength detector. The flow rate of liquid scintillation fluid (Ready Safe; Beckman Instruments Inc., Fullerton, CA) used by the radioactivity flow detector was 3.0 mL/min. The enzyme activities were calculated from the radioactivity percentage conversion of ricinoleate and linoleate.

HPLC on long column. The metabolites, radiolabelled ricinoleate and linoleate, were identified by the HPLC of the fatty acid methyl esters using a long reversed-phase C_{18} col-

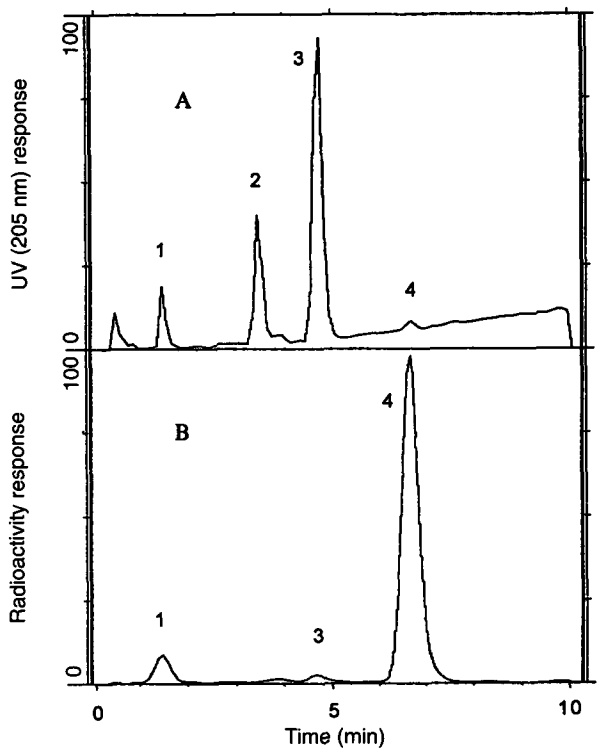

FIG. 1. Typical high-performance liquid chromatography (HPLC) radiochromatogram of the incubation products after methanolysis (produced methyl esters of fatty acids). For HPLC conditions, see HPLC on short column in the Experimental Procedures section. A: chromatogram detected by ultraviolet (UV) at 205 nm; B: chromatogram detected by radioactivity flow detector; 1: methyl ester of ricinoleic acid (1.5 min), 2: methyl ester of linolenic acid (3.5 min), 3: methyl ester of linoleic acid (4.8 min), 4: methyl ester of oleic acid (6.7 min). Minor radioactive peak (chromatogram B) at retention time 3.9 min was unknown and was also shown in the incubation without microsomal fraction. The fatty acids shown in chromatogram A were endogenous in the microsomal fraction.

umn (25 cm × 0.46 cm, 5 μm, Ultrasphere ODS; Beckman Instruments Inc.) (11). The eluent used was delivered at a linear gradient ranging from 90 to 100% methanol in 40 min at a flow rate of 1 mL/min. The retention times for the methyl esters were 7.87 min for ricinoleic acid, 21.52 min for linoleic acid, and 27.02 min for oleic acid. Samples were identified by cochromatography with standards and by matching the retention times of the standards from the ultraviolet detector and the radioactivity flow detector. The radiolabelled methyl esters of ricinoleate and linoleate were also identified by gas chromatography/mass spectrometry (12) of the HPLC fraction of the radioactive peaks.

Analysis of intact lipids. The lipid extracts from the microsomal incubations were dissolved in 2 mL chloroform/acetic acid (100:1, vol/vol) and fractionated on Sep-Pak silica columns (Waters Associates) into neutral lipid, glycolipid, and phospholipid fractions by the method of Lynch and Steponkus (13). Phospholipid and neutral lipid separations by thin-layer chromatography (TLC) have been described (14). Phospholipids were separated by TLC on silica gel plates (EM Separations Technology, Gibbstown, NJ) which were first immersed in 100 mM ammonium sulfate and dried for 1.5 h at 120°C. Phospholipids were applied to the plates in a spotting chamber. Separation was in the solvent system 1-propanol/chloroform/propanoic acid/0.1% (wt/vol) KCl, (3:2:2:1, by vol). Bands containing lipids to be analyzed were routinely localized by iodine staining. Lipids were identified by comigration with standards, and for phospholipids, by staining with molybdenum blue reagent (Sigma, St. Louis, MO). Lipid bands were removed from the plates by scraping, and counts in lipid bands were determined by liquid scintillation counter.

RESULTS AND DISCUSSION

In this report, we present the first characterization of oleoyl-12-hydroxylase in the microsomal fraction of immature castor bean using the putative substrate, 2-oleoyl-PC. Previous characterizations of this enzyme (3,7,8) used oleoyl-CoA as substrate and relied on the prior enzyme transferring oleate from oleoyl-CoA to lysoPC to form 2-oleoyl-PC (acyl-CoA:lysoPC acyltransferase) in addition to oleoyl-12-hydroxylase. The present assay system and characterization use oleoyl-PC as substrate (oleoyl-12-hydroxylase alone). Use of the actual substrate for assay purposes is important for the eventual purification of the oleoyl-12-hydroxylase, when it is separated from the acyl-CoA:lysoPC acyltransferase.

HPLC with ultraviolet detector and radioactive flow detector is an effective method to identify and quantify radioactive oleate, ricinoleate, and linoleate. A typical radiochromatogram is shown as Figure 1. The incubation of the microsomal fraction from castor bean with 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-PC followed by the methanolysis of incubation products (produced methyl esters of fatty acids) showed the presence of radiolabelled ricinoleate (due to oleoyl-12-hydroxylase) and linoleate (due to oleoyl-12-desaturase) by HPLC. Radiolabelled linolenate (due to the further desaturation of linoleate) was not detected (Fig. 1). We believe that the enzyme is active on *sn*-2 position, but we cannot rule out the possibility that [1-^{14}C]oleate at the *sn*-2 position of PC is incorporated into ricinoleate and linoleate after reacylation. The reacylation problem may be avoided by using the ether analog as substrate (15). The enzymes in the microsomal fraction remained active at −80°C for at least eight months. Radiolabelled oleoyl-CoA has previously been used as substrate in most studies of oleoyl-12-hydroxylase (3,7,8). Also, microsomal membranes labelled *in situ* with 1-acyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-PC were used recently (6). The latter was made by the incubation of microsomes with [^{14}C]oleoyl-CoA, and only 71% of [^{14}C]oleate was in position 2 of PC, which was the presumed substrate of oleoyl-12-hydroxylase. The characterization of oleoyl-12-hydroxylase using this microsomal substrate has not been reported (6). In the present study, we used commercially available 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-PC, and the activity was more than twice that using microsomal membranes labelled *in situ* with 1-acyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-PC. The radioactive substrate, 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-PC, dissolved in 20 μL of ethanol, was added to the other incubation components, followed immediately by mixing the incubation mixture before the incubation. The addition of the substrate dissolved in ethanol was the most effective way to suspend the substrate based on availability for the enzymic reaction. Diethyleneglycol monoethyl ether and detergent (TX-114) as substitutes for ethanol to suspend the substrate gave inferior results, as activity was much lower. It seems that ethanol can deliver the substrate more effectively to the active site of the oleoyl-12-hydroxylase, with minimal inactivation at this final ethanol concentration (2%). We previously have used ethanol instead of commonly used detergents to deliver lipid substrate to the enzyme (16). The amount of ethanol used should be minimal to minimize the inactivation and large enough to deliver lipid substrate quantitatively and accurately. We chose to use 20 μL of ethanol. Other alcohols were not tried since ethanol was effective.

The activities of oleoyl-12-hydroxylase and oleoyl-12-desaturase in developing castor bean are dependent on the maturity of the bean as shown in Figure 2. At about 16 d after anthesis, no oleoyl-12-hydroxylase or oleoyl-12-desaturase activity was detected. At this developmental stage, the seed coat (shell) was soft and white or very light green. The endosperm occupied only about 5% of the seed volume. The highest activity of oleoyl-12-desaturase was seen at about 23 d after anthesis. At this developmental stage, endosperm filled only about 15% of the shell. The shell was soft and light green or white, and less than10% of the seedcoat area was violet. As the bean developed, the violet spot enlarged, darkened, and hardened to eventually cover the whole shell. The highest activity of oleoyl-12-hydroxylase was seen at about 44 d after anthesis. At this developmental stage, endosperm almost filled the shell (95%), and the shell just turned dark brown and hard without any area of soft and light color remaining. The enzyme activities decreased but remained measurable

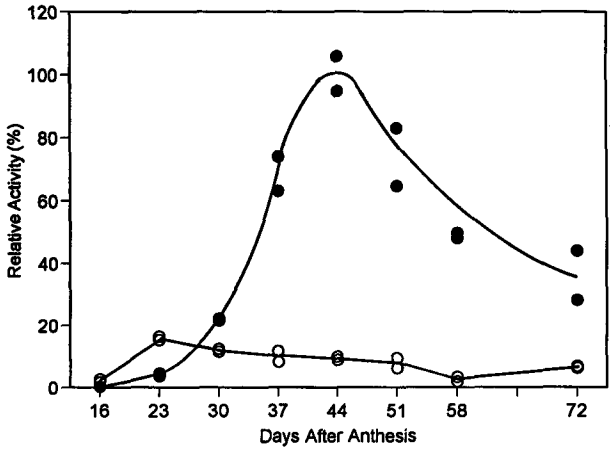

FIG. 2. Relative activities of oleoyl-12-hydroxylase (●) and oleoyl-12-desaturase (○) in the castor microsomal fractions at various times after anthesis. Circles represent individual determinations.

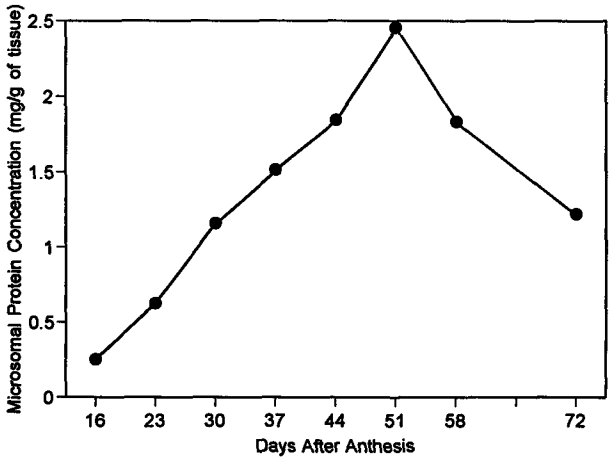

FIG. 3. Protein concentrations in the castor microsomal fraction vs. time after anthesis. Circles represent individual determinations.

until the capsule became dry and brown. The peak of activity of oleoyl-12-desaturase in castor bean development was thus much earlier than that of oleoyl-12-hydroxylase. The activity of oleoyl-12-hydroxylase at the later developmental stages was much higher than that of oleoyl-12-desaturase (Fig. 2). Since the substrates of both enzymes are the same, the activity difference of these two enzymes in the later developmental stage is obviously one of the reasons castor oil is composed of 85–90% ricinoleate. This is the first study that has simultaneously monitored and compared the activities of the oleoyl-12-hydroxylase and oleoyl-12-desaturase (two enzymes that share a common substrate and have other properties in common) in developing castor bean. Oleoyl-12-hydroxylase has not been purified yet, but it has been shown to be a member of the membrane-bound desaturase family based on DNA sequence (9); however the oleoyl-12-desaturase in spinach chloroplast has been purified and the gene cloned (17). Microsomal oleoyl-12-desaturase reported here desaturates PC, and the electron donor has been identified as reduced cytochrome b_5 (6) while chloroplast oleoyl-12-desaturase desaturates a variety of substrates including free oleic acid, free erucic acid, 1-oleoyl-*sn*-glycerol 3-phosphate, and galactolipids; the electron donor has been identified as reduced ferredoxin (18). Protein concentration in the microsomal fraction was highest at about 51 d after anthesis as is shown in Figure 3. At this developmental stage, the endosperm just filled the seed inside the shell completely.

The amount of the microsomal fraction affects the activity of oleoyl-12-hydroxylase as is shown in Figure 4. We chose 10 µL of microsomal fraction (equivalent to 92 µg of microsomal protein) for our routine incubations, and the activity was about half of the maximum activity shown in Figure 4. The higher specific activity at the lower microsome concentration (shown in Fig. 4) might be due to the fact that the concentration of the unlabelled endogenous substrate in the microsomal fraction was also reduced. The radioactive substrate thus had less competition probably from the endogenous substrate in the incubation. The amounts of the microsomal fraction used were much lower than used in previous studies (300 µg–1 mg) (3,6,7) in which radioactive oleoyl-CoA was used as substrate. Interestingly, the conversion of oleoyl-CoA into ricinoleate (McKeon, T.A., Lin, J.T., and Stafford, A.E., unpublished data) in the microsomal fraction was about eight times that of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-PC. It seems that oleoyl-CoA gets incorporated into the PC pool more readily than exogenous PC.

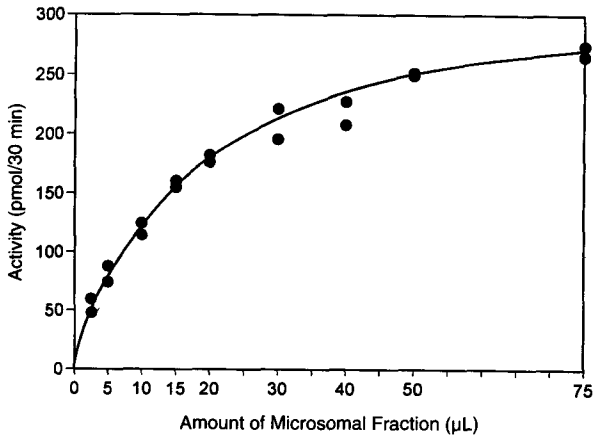

FIG. 4. Effect of various amounts of microsomal fraction on the activity of oleoyl-12-hydroxylase. Protein concentration of microsomal fraction was 9.2 µg/µL.

The rationale for using 2-oleoyl-PC as the substrate is twofold: to use the actual substrate in incubations and to eliminate the need for extraneous enzymes such as the acyl-CoA:lysoPC acyltransferase in the incubations. It was important, then, to optimize incubation conditions using 2-oleoyl-PC as the substrate. We therefore examined oleoyl-12-hy-

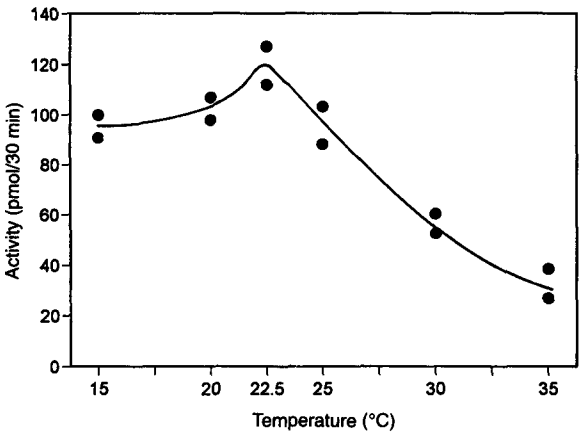

FIG. 5. Effect of temperature on the activity of oleoyl-12-hydroxylase in the microsomal fraction of castor bean.

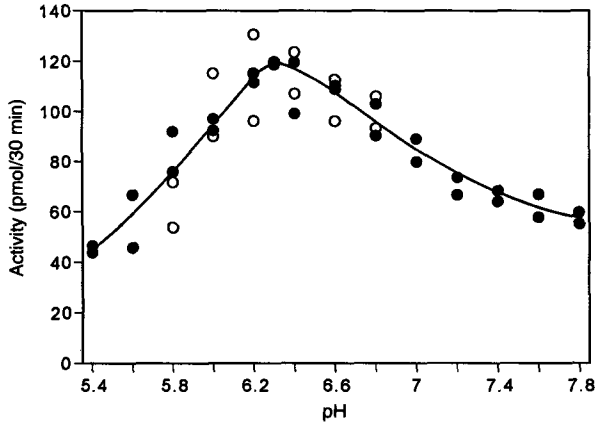

FIG. 7. Effect of pH on the activity of oleoyl-12-hydroxylase in the microsomal fraction of castor bean. The activities using phosphate buffer (0.1M) are represented by ● (with best-fit curve), while the activities using 2[*N*-morpholino]ethanesulfonic acid buffer (0.1M) are represented by ○.

droxylase activity as a function of temperature, incubation time, and pH, and we examined the effect of various additions routinely (3,7,8) added to hydroxylase incubations. Figure 5 shows the activities of oleoyl-12-hydroxylase at various temperatures. The maximum activity was observed at 22.5°C and was therefore used in our routine incubations. A temperature optimum has not been reported for the oleoyl-12-hydroxylase when oleoyl-CoA was used as substrate. Figure 6 shows the efficiency of conversion of oleate to ricinoleate for various incubation times. To obtain sufficent radioactive ricinoleate for analyses, 30-min incubations were used. The activity of oleoyl-12-hydroxylase was also dependent on pH, as is shown in Figure 7. The optimal activity was at pH 6.3 when sodium phosphate buffer, 0.1 M, was used. The same pH optimum for activity and the same maximal activity were seen using 2-[*N*-morpholino]ethanesulfonic acid buffer. The enzymic reaction was not buffer ion-dependent. The optimal pH of oleoyl-12-hydroxylase has not been reported previously although pHs of 7.0 (5,8), 7.1 (3), and 7.2 (7) were used in the incubations with oleoyl-CoA as substrate. Figure 8 shows that inclusion of BSA (1 mg) and CoA (0.5 μmol) does not affect oleoyl-12-hydroxylase while catalase (1000 units) enhances the activity. Although the microsomal fraction used in the incubations was suspended in buffer containing catalase, further addition of catalase to the incubation increased activity by about 10%. ATP (0.5 μmol) and $MgCl_2$ (0.5 μmol) enhance the activity slightly, and the effects may be due to some secondary effect. The cofactor, NADH, could be substituted with NADPH but led to less activity than NADH (Fig. 8), as previously reported (3).

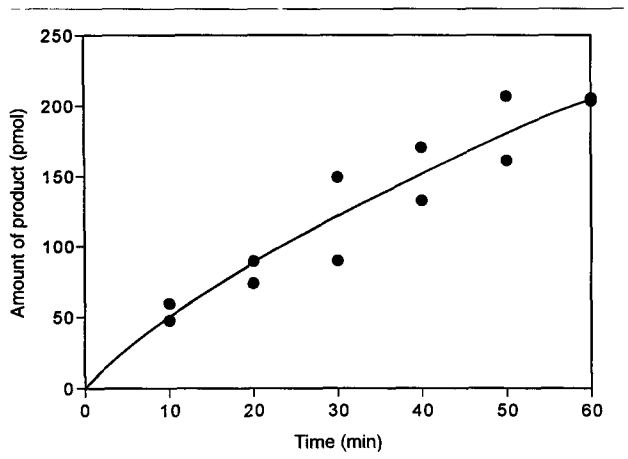

FIG. 6. Ricinoleate produced at various incubation times using microsomal fraction from castor bean.

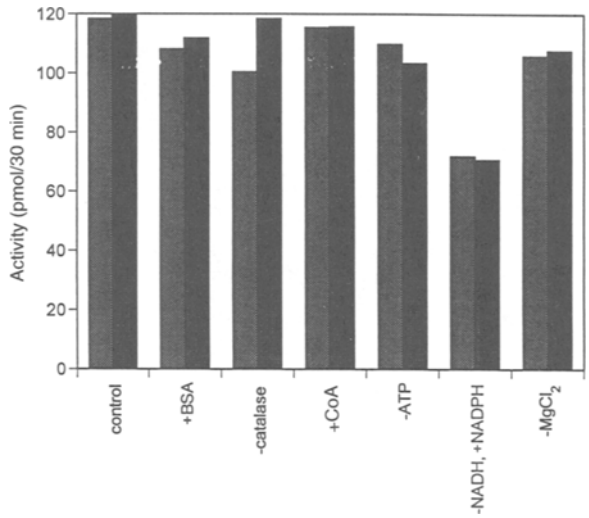

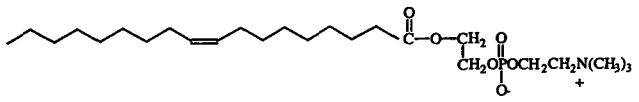

FIG. 8. Effect of some incubation components on the activity of oleoyl-12-hydroxylase in the microsomal fraction from castor bean. For control incubation, see microsomal incubation of the Experimental Procedures section. Two bars represent two determinations; BSA, bovine serum albumin.

SCHEME 1

The PC analogue, OEPC (Scheme 1), strongly inhibits the activity of oleoyl-12-hydroxylase as is shown in Figure 9. An incubation mixture containing 200 μM OEPC produced virtually no ricinoleate, with half inhibition at 40 μM. We do not know the precise mechanism of inhibition. Possible mechanisms are the passive binding to the active site blocking the hydroxylation, hydroxylation of the oleate of OEPC itself, or a detergent effect. To rule out the detergent effect, the inhibition by 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine, an ether lipid structurally similar to OEPC, was studied and the results are shown in Figure 10. Hexadecyl-lysoPC also showed a strong inhibition on oleoyl-12-hydroxylase. We have not yet ruled out any of the proposed mechanisms for OEPC inhibition of the hydroxylase.

Under optimal incubation conditions, 90% of the radioactivity at the end of incubation was associated with PC when the intact lipids were analyzed by TLC. Based on fatty acid methyl ester analysis, this PC fraction included the radioactive substrate and the putative product of oleoyl-12-hydroxylase, 1-acyl-2-ricinoleoyl-*sn*-glycero-3-PC, and a relatively small amount of the likely product of oleoyl-12-desaturase, 1-acyl-2-linoleoyl-*sn*-glycero-3-PC. These three PCs were not separated, and the positional analysis was not done. About 5.5% of the radioactive oleate was converted to ricinoleate. Thus, about 85–90% of the radioactive substrate, 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-PC, still remained at the end of the incubation period. The other radioactive intact lipids shown on TLC plates corresponded to phosphatidic acid, neutral lipids, lysophosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol in the order of decreasing radioactivity.

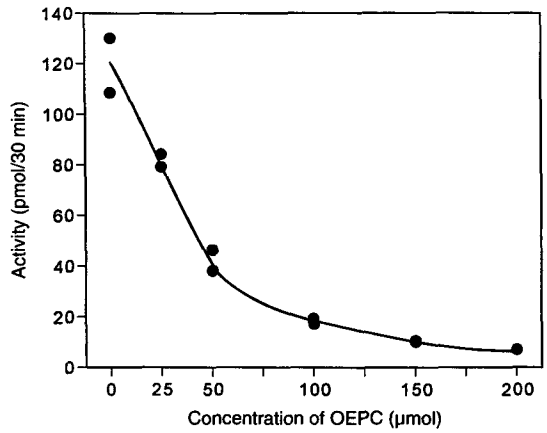

FIG. 9. Effect of oleoyloxyethyl phosphocholine (OEPC) on the activity of oleoyl-12-hydroxylase. Two determinations at each concentration.

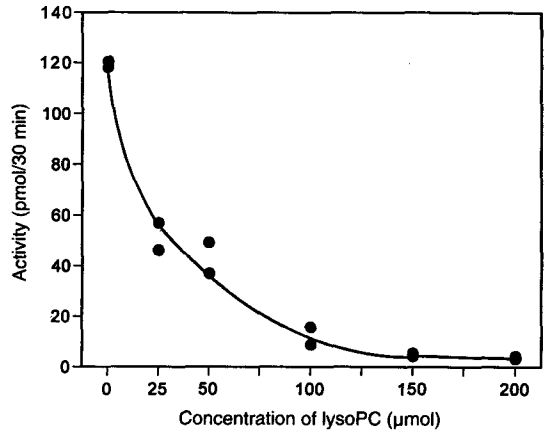

FIG. 10. Effect of 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine on the activity of oleoyl-12-hydroxylase.

The ability to use 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycero-3-PC to assay provides us with a means to assay the oleoyl-12-hydroxylase in isolation from endogenous microsomal enzymes required for incorporation of [^{14}C]oleate from oleoyl-CoA into PC. This report represents the first characterization of oleoyl-12-hydroxylase using the endogenous substrate directly.

ABSTRACT: The aim of the present study was to investigate whether eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) was responsible for the triglyceride-lowering effect of fish oil. In rats fed a single dose of EPA as ethyl ester (EPA-EE), the plasma concentration of triglycerides was decreased at 8 h after acute administration. This was accompanied by an increased hepatic fatty acid oxidation and mitochondrial 2,4-dienoyl-CoA reductase activity. The steady-state level of 2,4-dienoyl-CoA reductase mRNA increased in parallel with the enzyme activity. An increased hepatic long-chain acyl-CoA content, but a reduced amount of hepatic malonyl-CoA, was obtained at 8 h after acute EPA-EE treatment. On EPA-EE supplementation, both EPA (20:5n-3) and docosapentaenoic acid (DPA, 22:5n-3) increased in the liver, whereas the hepatic DHA (22:6n-3) concentration was unchanged. On DHA-EE supplementation retroconversion to EPA occurred. No statistically significant differences were found, however, for mitochondrial enzyme activities, malonyl-CoA, long-chain acyl-CoA, plasma lipid levels, and the amount of cellular fatty acids between DHA-EE treated rats and their controls at any time point studied. In cultured rat hepatocytes, the oxidation of [1-^{14}C]palmitic acid was reduced by DHA, whereas it was stimulated by EPA. In the *in vivo* studies, the activities of phosphatidate phosphohydrolase and acetyl-CoA carboxylase were unaffected after acute EPA-EE and DHA-EE administration, but the fatty acyl-CoA oxidase, the rate-limiting enzyme in peroxisomal fatty acid oxidation, was increased after feeding these n-3 fatty acids. The hypocholesterolemic properties of EPA-EE may be due to decreased 3-hydroxy-3-methylglutaryl–CoA reductase activity. Furthermore, replacement of the ordinary fatty acids, i.e., the monoenes (16:1n-7, 18:1n-7, and 18:1n-9) with EPA and some conversion to DPA concomitant with increased fatty acid oxidation is probably the mechanism leading to changed fatty acid composition. In contrast, DHA does not stimulate fatty acid oxidation and, consequently, no such displacement mechanism operates. In conclusion, we have obtained evidence that EPA, and not DHA, is the fatty acid primarily responsible for the triglyceride-lowering effect of fish oil in rats.
Lipids 31, 579–592 (1996).

Administration of marine fish oil rich in n-3 polyunsaturated fatty acids, especially eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), decreased plasma triglycerides by 25–35% in normolipidemic subjects (1,2) and in rats (3,4). Their greatest effect on plasma triglycerides is under conditions of overproduction when lipogenesis is increased (5,6). There is considerable evidence that increased dietary intakes of n-3 fatty acids reduce hepatic synthesis of very low density lipoproteins (VLDL) triglycerides in humans (5,7,8), as well as in various animal species and in HepG2 cells (9–11). In cultured rat hepatocytes, n-3 fatty acids also have been reported to impair assembly and/or secretion of VLDL (12,13). Moreover, it has been reported that changes in *de novo* fatty acid synthesis is integral to the adaptation to n-3 fatty acids. Short-term experiments with hepatocyte suspensions and primary cultures (14–16) indicate that EPA and DHA are either poor substrates for triglyceride synthesis or that these fatty acids acutely affect the triglyceride synthetic pathway. Inhibition of hepatic VLDL secretion appeared to be secondary to the effects on triglyceride synthesis in those studies. Furthermore, Otto *et al.* (13) reported a positive relationship between fasting plasma insulin and plasma triglycerides and suggested that insulin contributes to the regulation of plasma triglycerides by fish oil.

In addition to the effect on VLDL, many other pathways of hepatic fatty acid metabolism may be affected by fish oil and contribute to the triglyceride-lowering effect. Such mech-

anisms include suppression of phosphatidate phosphohydrolase (PAP) (17), the enzyme catalyzing the esterification of phosphatidic acid to diglycerides, and acyl-CoA:1.2-diacylglycerolacyltransferase (ADGAT) (14), which mediates the next step. In animals fed high fish oil diets, lowered circulating triglycerides have been associated with increased peroxisomal β-oxidation (3,18) and ketone body formation (19), indicating that increased peroxisomal fatty acid oxidation may be responsible for the hypotriglyceridemic effect. Moreover, Surette *et al.* (20) have shown an association between circulating triglyceride levels and mitochondrial fatty acid oxidation after n-3 polyunsaturated fatty acid feeding. However, it is not known whether these changes in liver enzyme activities and fatty acid oxidation are related to the effect of EPA or DHA or both.

Nearly all studies that have been conducted have used a mixture of the two components of fish oil attracting the most attention, namely EPA and DHA. In our previous reports from feeding experiments in rats administered highly purified EPA and DHA as ethyl esters (EPA-EE and DHA-EE, respectively) for 10–15 d (21,22), EPA, and not DHA, appeared to be responsible for the triglyceride-lowering effect observed. Feeding rats highly purified EPA ethyl ester lowered plasma triglycerides within 1–2 d of treatment, and stimulation of mitochondrial β-oxidation was observed as a primary event (21). We also showed that mitochondrial β-oxidation was stimulated in cultured hepatocytes in the presence of EPA (21). In contrast, administration of highly purified DHA ethyl ester in three animal models produced neither hypotriglyceridemic nor hypocholesterolemic effects, and no effect on mitochondrial β-oxidation was observed, whereas peroxisomal β-oxidation was stimulated after both EPA and DHA feeding (21,22). These results confirm and extend previous findings in normo- and hypertriglyceridemic rats (23,24), perfused rat livers (25), and humans (26), but are in contrast to other reports (27,28).

It is well documented that fish oil feeding decreases plasma cholesterol in rats (29,30), whereas in human studies there is no consistent cholesterol-lowering effect after fish oil feeding (31). The mechanism behind the hypocholesterolemic effect of n-3 fatty acids in rats is not known in detail, but it has been reported that the cholesterol-lowering effect is accompanied by a reduction of the 3-hydroxy-3-methylglutaryl (HMG)–CoA reductase activity (29).

A controversy exists concerning the efficacy of highly concentrated n-3 fatty acids in the form of alkyl esters compared to less concentrated natural triglycerides (32–34). During prolonged feeding, ethyl esters of n-3 fatty acids are highly bioavailable (35,36), whereas the markedly slower hydrolyzation by pancreatic lipase theoretically could influence the absorption of EPA-EE and DHA-EE in short-term studies. In this study we had the opportunity to address the question of whether EPA or DHA as ethyl esters executes the biological effects independent of differences in the absorption.

To precisely determine the biological role of fish oil constituents (n-3 fatty acids), it is imperative that experiments with highly purified n-3 polyunsaturated fatty acids are executed. We agree with Ikeda *et al.* (23) that determining the effects of dietary EPA and DHA on hepatic fatty acid and triglyceride synthesis and β-oxidation seems to be important to clarifying the precise mechanism(s). Therefore we studied the acute effects of a single dose of highly purified EPA-EE and DHA-EE on plasma lipids and on key enzymes in lipid metabolism, focusing on mitochondrial and peroxisomal β-oxidation, to contribute to the understanding of the triglyceride-lowering mechanism of EPA and/or DHA.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Palmitic acid (56 mCi/mmol), L-[U-^{14}C]-glycerol-3-phosphate (171 mCi/mmol), [^{14}C]acetyl-CoA (60 mCi/mmol), and $NaH^{14}CO_3$ (0.1 mCi/mmol) were purchased from the Radiochemical Center (Amersham, England). EPA-EE (purity 95%) and DHA-EE (purity 93%) were obtained from Norsk Hydro AS, Research Center (Porsgrunn, Norway). Palmitic acid (Palm) was from Sigma Chemical Co., (St. Louis, MO). All other chemicals were obtained from common commercial sources and were of reagent grade.

Care of animals. One hundred fifty male Mol:WIST rats from Möllegaard Breeding Laboratory (Ejby, Denmark), weighing approximately 170 g, were housed in pairs in bottom-grid metal wire cages in a room with a controlled temperature (20 ± 3°C), humidity and air changes, and with a 12-h light/dark cycle (light 0700–1900 h). The animals were acclimatized for one week under these conditions before the start of the experiment. All animals had free access to water and food. The rats were fed a conventional pelleted chow diet, RM1 expanded diet (Special Diet Services, Whitam, United Kingdom).

EPA-EE, DHA-EE, and Palm were suspended in 0.5% sodium carboxymethylcellulose (CMC) and 0.5% α-tocopherol. A single dose of 2000 mg/kg body weight was administered by gavage in volumes of 0.8–1.0 mL. In order to provide an equal amount of energy, the control animals received Palm. There were no significant differences in food consumption or weight gain between the experimental groups.

At the time of sacrifice (2, 4, 8, 12, and 24 h after administration), rats were anesthetized with 0.6 mL Hypnorm Dormicum (fluanisone-fentanyl-midazolam) injected subcutaneously in the neck. Anesthesia depth was evaluated by means of the interdigital and palpebral reflexes. The anesthesia was sufficiently deep when there was no response to either of the reflexes (usually within 2–3 min). None of the animals responded to initial abdominal opening. Cardiac puncture was performed, blood was collected into a syringe containing 0.25 mL of 0.2 M EDTA (pH 7.4), and plasma was collected by centrifugation at 1000 × *g* for 10 min at 4°C. The animal experiments were approved by the Norwegian State Board of Biological Experiments with Living Animals.

Preparation of subcellular fractions. The livers were removed, weighed, and parts were immediately chilled on ice and the other parts freeze-clamped in liquid N_2 and stored at

–80°C. Portions of the livers from individual rats were homogenized in ice-cold sucrose-medium (0.25 M sucrose in 10 mM HEPES buffer, pH 7.4, and 1 mM EDTA). Mitochondrial, peroxisomal, microsomal, and cytoplasmic fractions were prepared as described earlier (37). The fractions were stored at –80°C.

Enzyme assays. PAP was determined by measuring the release of free phosphate in the presence of 5 mM $MgCl_2$ (38). Glycerol-3-phosphate acyltransferase (GPAT) was assayed for 3 min at 30°C, as essentially described earlier (39). The reaction was started by the addition of mitochondria or microsomes (200 μg protein), and terminated by the addition of 2.0 mL of 1-*n*-butanol. The incorporation of ^{14}C into butanol-soluble products was determined as described (39,40). ADGAT was assayed for 5 min at 37°C. The reaction was initiated by the addition of microsomes (30–40 μg protein), and terminated by the addition of 7.5 mL of 2-propanol/hexane/water (89:20:16). The extraction of triglycerides into hexane was performed as previously described (41). HMG–CoA reductase activity was measured in the isolated microsomal fraction essentially as previously described (42).

Fatty acyl-CoA oxidase activity (43) and mitochondrial β-oxidation, using radiolabeled palmitoyl-L-carnitine and L-carnitine in the presence of palmitoyl-CoA (43), were determined as described earlier. Acetyl-CoA carboxylase activity was measured in the cytosolic fraction as fixation of $^{14}CO_2$ from $NaH^{14}CO_3$ into malonyl-CoA essentially as described earlier (44). 2,4-Dienoyl-CoA reductase activity was measured in the mitochondrial fraction, and the incubation contained 50 mM KH_2PO_4/K_2HPO_4 pH 7.4, 0.01% (vol/vol) Triton X-100 (Sigma Chemical Co.), 100 μM NADPH, and 100 μg protein. The assay was started by the addition of 100 μM 2-*trans*, 4-*cis*-decadienoyl-CoA and run for 10 min at 30°C at 340 nm (45).

Determination of malonyl-CoA and long-chain acyl-CoA. Malonyl-CoA and free CoASH levels were quantitated by a modification of the high-performance liquid chromatography method originally described by Corkey *et al.* and Demoz *et al.* (46,47). Briefly, 0.1 g liver was homogenized in 1 mL 5% sulfosalicylic acid containing 50 mM dithioerythritiol. The sample was centrifuged at 600 × *g* for 10 min at 0°C. Twenty μL of the acid-soluble extracts were injected into a Spectra Physics (San Jose, CA) SP 8800 HPLC system. Absorbance measurements were made at 254 nm using a 3 mm Hypersil C18 reverse-phase column (HiChrom Ltd., Reading, Berkshire, England). The mobile phase was 0.1 M NaH_2PO_4, pH 4.9 (buffer A) and buffer B (a mixture of buffer A and methanol in a ratio of 7:3), pH 4.9. The flow rate was 2.0 mL/min. The profile of the elution was as follows: 0–10 min: 10–40% B; 10.1–17.6 min: 40–90% B. The retention times were 9.3 and 13.7 for free CoA and malonyl-CoA, respectively. Total hepatic long-chain acyl-CoA was estimated by incubating liver tissue precipitates with 1.5 M KOH at 55°C for 1 h. The liberated free CoASH found in the supernatant was determined as described previously. Individual working standards were prepared by dissolving malonyl-CoA or free CoASH, for determination of malonyl-CoA or long-chain acyl-CoA, respectively, in 5% sulfosalicylic acid containing 50 μM of dithioerythritol. They were then mixed to give a final concentration of 100 μM. Standard curves of the different CoA-esters were obtained at 25, 50, 100, and 200 mM concentrations and showed linear conditions ($r^2 > 0.999$; Ref. 47). The recovery obtained by the method was approximately 90%.

Lipid analysis. Protein was assayed by a Bio-Rad protein assay kit (Bio-Rad, Richmond, CA). Lipid analyses were carried out by the Monotest cholesterol enzymatic kit (Boehringer, Mannheim, Germany), the Monotest phospholipid enzymatic kit (Boehringer), and the Biopak Triglyceride enzymatic kit (Biotrol, Paris, France). Hepatic lipids were quantified after extraction from total liver homogenates (48). Plasma free fatty acids were determined by an enzymatic colorimetric method (WACO NefaC; Waco Chemicals, Neuss, Germany) (49,50).

Total fatty acid determination. Total lipids were extracted from liver as described by Lie *et al.* (51). The lipid fractions were evaporated, saponified, 19:0 was added as internal standard, and the fatty acids esterified in 12% BF_3 in methanol. The methyl esters were separated using a Carlo Erba (Milan, Italy) 2900 gas-chromatograph ("cold on column" injection, starting at 60 and increasing at 49°C/min to 160, increasing at 1°C/min to 190, increasing at 4°C/min to 220°C), equipped with a 50 m CP-Sil 88 (Chrompack) fused silica capillary column (0.32-mm i.d.). The fatty acid composition was calculated using a Maxima 820 Chromatography Workstation software, installed in an IBM-AT, connected to the gas–liquid chromatograph and identification ascertained by standard mixtures of methyl esters (Nu-Chek-Prep, Elysian, MN). Certified reference material (CRM 162, CRM 163) from Community Bureau of Reference (BCR, Brussels, Belgium) was used.

Preparation of cultured hepatocytes. Hepatocytes were prepared as described earlier (52). In short, the rats were anesthetized as described here, and hepatocytes were isolated by collagenase perfusion, washed and plated in Dulbecco's modified Eagle's medium containing HEPES (20 mM), Ultroser G (2%), and gentamicin (50 mL) at a density of 3×10^6 cells/dish or culture flask (1×10^6 cells/mL). The culture medium was replaced after 6–7 h (2 mL/dish, medium as before). The cells were incubated at 37°C in an atmosphere of air containing 5% CO_2.

Fatty acid oxidation. Fatty acid oxidation to acid-soluble products and CO_2 (to determine the rate of β-oxidation) was measured as described earlier (53). Two mL Dulbecco's modified Eagle's medium containing HEPES (20 mM), gentamicin [1-^{14}C] Palm (0.5 μCi/mL, 200 μM), and 500 μM L-carnitine hydrochloride was added to the cultured hepatocytes, and the hepatocytes were incubated for 4 and 9 h in the presence of increasing concentrations of EPA and DHA (see Fig. 1).

The culture flasks contained a center well (Kontes, Vineland, NJ) and a folded filter paper and were closed with stopper tops (Kontes). After incubation, 300 μL of phenylethylamine/methanol (1:1, vol/vol) was added to the center

well and 300 mL of $HClO_4$ (1 M) to the cell through the stopper top by means of a syringe, and the flasks were further incubated for 1 h at room temperature to trap all $^{14}CO_2$. After incubation, the well was cut off, and radioactivity was measured by liquid scintillation counting.

Preparation of hybridization probes. DNA fragments were labelled by random priming using the oligolabelling technique of Feinberg and Vogelstein (54), resulting in specific activities ranging from 0.8 to 5 × 10^9 cpm/mg DNA. The DNA probes were purified fragments of cloned rat genes: (i) 2,4-dienoyl-CoA reductase: 632 bp Pst I/Eco RI insert in pGem-4Z and (ii) 28 S rRNA: 1.4 kb Bam HI fragment of pA (Dr. I.L. Gonzales, personal communication).

RNA purification and analysis. Total cellular RNA was isolated by the guanidinium-thiocyanate method described by Chomczynski and Sacchi (55). The RNA concentrations were determined spectrophotometrically. Slot blotting of RNA onto nylon was carried out as described by Aasland *et al.* (56). Hybridization to immobilized RNA was performed as described by Sambrook *et al.* (57), in the presence of 50% formamide, 5 × saline–sodium–citrate, 200 μg/mL heat denatured herring-sperm DNA, 0.1% SDS, 25 mM sodium phosphate pH 6.5, 8.25% dextran sulfate at 42°C for 24 to 48 h. Filters were washed to high stringency (0.2 × saline–sodium–citrate, 0.1% NaPPi, 0.1% SDS at 65°C) and exposed on Kodak XAR-5 X-ray films in the presence of intensifying screens at −80°C. Densitometric scanning of autoradiograms was performed using the LKB Ultrogel laser-densitometer (Bromma, Sweden), or the hybridized membranes were analyzed by Instant Imager, Electronic Audioradiography (Packard, Downer's Grove, IL). When the filters were to be rehybridized, the bound probe was first stripped off in 0.1% SDS at 90–100°C for 7 min. The hybridization results were normalized to the signal of 28 S rRNA hybridization in the individual samples. Relative mRNA induction of the different genes was then calculated.

Statistical analysis. The *in vivo* results are means ± SD of duplicate or triplicate measurements on six animals of each experimental group. Results from cultured rat hepatocytes are presented as means ± SD of at least three culture dishes/flasks of hepatocytes from two or more animals.

The effects of EPA and DHA treatment compared to controls were tested by a one-way analysis of variance. Fisher's Least Square Difference was used to determine the significance of difference between the mean at 95% confidence interval using a statistical software StatView SE + Graphics on an Apple Macintosh. $P < 0.05$ was taken to be statistically significant.

RESULTS

Effect of n-3 fatty acids on oxidation of [1-^{14}C]Palm in cultured rat hepatocytes. In agreement with earlier findings (21), oxidation of [1-^{14}C]Palm was significantly higher in cells grown with L-carnitine than in cells grown without L-carnitine (data not shown). Oxidation of Palm to carbon dioxide and acid-soluble products was significantly stimulated in cultured hepatocytes in the presence of EPA, whereas it was significantly reduced in the presence of DHA (Fig. 1A). Oleic acid had no effect on Palm oxidation (data not shown). A significant difference in Palm oxidation by EPA and DHA was already observed after 4 h of incubation (Fig. 1B).

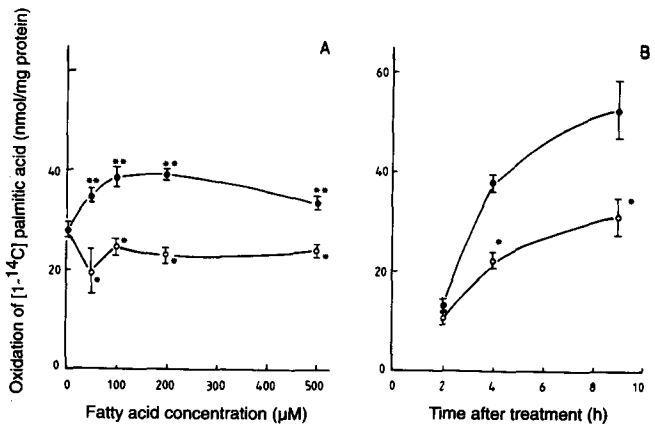

FIG. 1. Effect of eicosapentaenoic acid (EPA) (●) and docosahexaenoic acid (DHA) (○) on oxidation of [1-^{14}C]palmitic acid (0.2 mM) in cells plated and incubated with increasing concentrations (A) and for different times (B). A, cultured hepatocytes were incubated for 4 h; B, 200 μM EPA and DHA was used. In all experiments the fatty acid/bovine serum albumin ratio was 2.5:1, and 0.5 mM L-carnitine was added to the medium. Acid-soluble radioactivity was determined as described in the Materials and Methods section. Results are given as means ± SD for values obtained from three independent experiments. Asterisks correspond to the statistical comparison between values from EPA and DHA and values from DHA and controls (*) and values from EPA and controls (**).

Acute treatment. As shown in Table 1 plasma triglycerides, cholesterol and phospholipids were not changed at any of the time points studied in the different control groups. As shown in Figure 2, plasma triglycerides and cholesterol were reduced 8 h after the acute treatment with EPA-EE as compared to controls. Restoration to control levels occurred at 12 and 24 h. Plasma triglycerides and cholesterol were unaffected by DHA-EE treatment (Fig. 2). Figure 3A shows that plasma phospholipids were reduced 8 h after acute treatment with EPA-EE as compared to controls and DHA-EE administration. The plasma free fatty acid (FFA) concentration in the control and DHA-EE treated rats was significantly reduced at 4 h compared to 2 h, and this reduced level was maintained up to 12 h after feeding. The FFA concentration in the EPA-EE treated rats maintained high until 8 h time point, when it was reduced to the same level as the other two groups (Fig. 3B). No statistically significant difference was found either for hepatic triglycerides, cholesterol, phospholipids (Table 2), or for activities of PAP, acetyl-CoA carboxylase (Table 2), and GPAT (data not shown) between EPA-EE and DHA-EE treated rats and their controls at any time of the time points studied, except that PAP was reduced 8 and 12 h after acute treatment with DHA-EE as compared to controls. However, EPA-EE and DHA-EE feeding caused increased fatty acyl-CoA oxidase activity at 12 h compared to controls (Table 3).

[a]TG, triglycerides; CHOL, cholesterol; PL, phospholipids. Plasma concentrations of lipids are given in nmol/L and were analyzed as described in the Materials and Methods section. The values are expressed as means ± SD. There were no statistical differences between the groups evaluated by one-way analysis of variance and Fisher's Protected Least Square Differences used to determine differences between means at 95% confidence interval.

As shown in Table 3, the 2,4-dienoyl-CoA reductase activity was not changed at any of the time points studied in the control group, and no statistically significant difference was found for the activity between DHA-EE treated rats and their controls. As also shown in Table 3, the reductase activity was increased 4 and 12 h after acute treatment with EPA-EE as compared to controls and DHA-EE administration.

Figure 4A summarizes the activities of fatty acid oxidation in mitochondrial fraction in treated rats and controls at different times after acute treatment. Oxidation of fatty acids in the mitochondrial fraction, using palmitoyl-L-carnitine as substrate, was significantly increased 8 h after acute treatment with EPA-EE as compared to controls, and this difference disappeared at 12 and 24 h (Fig. 4A). The oxidation of fatty acids in mitochondrial fraction was decreased 12 and 24 h after acute treatment with DHA-EE as compared to controls

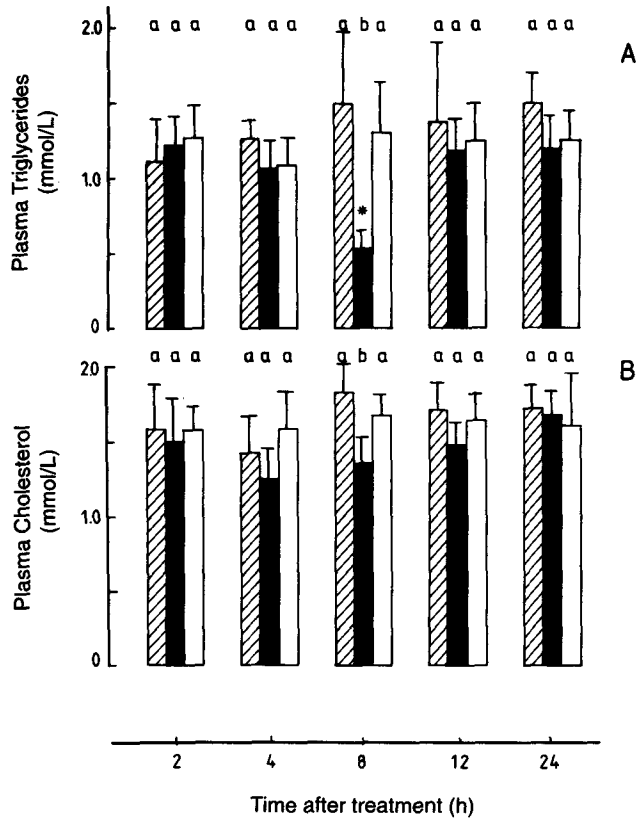

FIG. 2. Concentrations of plasma triglycerides (A) and cholesterol (B) at different times after a single oral administration of EPA as ethyl esters (EPA-EE) (black columns) and DHA as ethyl esters (DHA-EE) (open columns) in the rat and of controls (hatched columns). The results are presented as means ± SD of six rats per group. *Significantly different from each of the time points studied ($P < 0.05$). Means in a column with different superscripts are significantly different ($P < 0.05$) determined by one-way analysis of variance, Fisher's test. Abbreviations as in Figure 1.

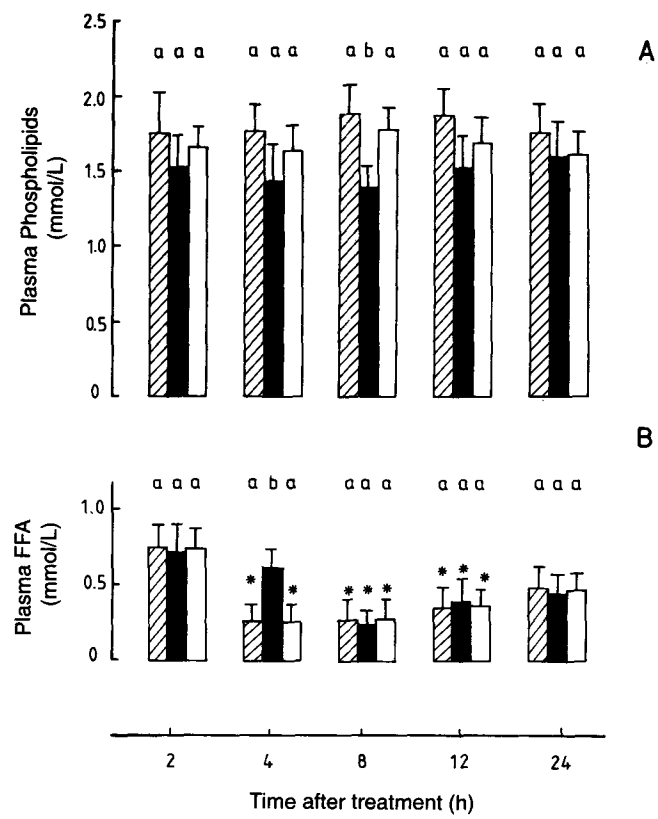

FIG. 3. Concentrations of plasma phospholipids (A) and free fatty acids (FFA) (B) at different times after a single oral administration of EPA-EE (black columns) and DHA-EE (open columns) in the rat and of controls (hatched columns). The results are presented as means ± SD of six rats per group. *Significantly different from values at two hours of individual treatment ($P < 0.05$). Means in a column with different superscripts are significantly different ($P < 0.05$) determined by one-way analysis of variance, Fisher's test. Abbreviations as in Figure 2.

[a]The acyl-CoA oxidase activity was determined in the isolated peroxisome-enriched fraction, whereas the 2.4-dienoyl-CoA reductase activity was measured in the isolated mitochondrial fraction. The values are expressed as means ± SD of six rats per group. Statistical comparison between EPA-EE, DHA-EE, and controls are shown by the *P* values. [a,b]Correspond to the statistical comparison between the groups at each of the time points studied (hours), where the same letter within one enzyme activity means that there is no statistical differences between the corresponding groups ($P < 0.05$). Abbreviations as in Table 2.

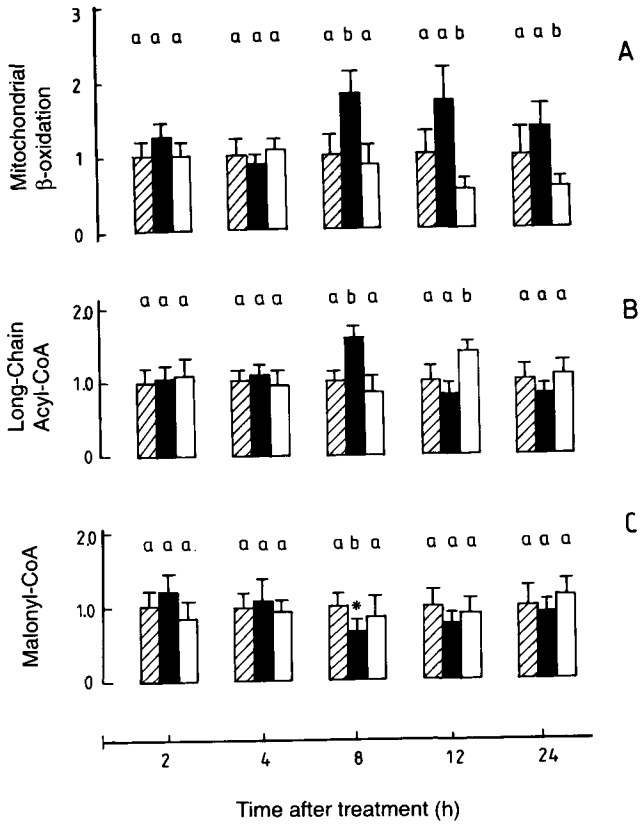

FIG. 4. Relative specific activities of mitochondrial β-oxidation, with palmitoyl-L-carnitine as substrate (A), relative concentration of hepatic long-chain acyl-CoA (B), and relative concentration of liver malonyl-CoA (C) at different times after a single oral administration of EPA-EE (black columns) and DHA-EE (open columns) in the rat. The relative values are calculated to those of palmitic acid-fed controls (hatched columns) = 1.0 at each of the time points studied. The results are presented as means of six rats per group. Means in the column with different superscripts are significantly different ($P < 0.05$) determined by one-way analysis of variance, Fisher's test. *Significantly different from values at two hours of individual treatment ($P < 0.05$). Abbreviations as in Figure 2.

creased significantly 4 h after treatment (Fig. 5), and continued to rise more than 1.5-fold above control values at 12 h after exposure. No evidence was found for induction of 2,4-dienoyl-CoA reductase after acute administration of DHA-EE during this experiment compared to the 28 S rRNA (Fig. 5).

As shown in Figure 4B, hepatic long-chain acyl-CoA content was increased 8 h after acute treatment with EPA-EE as compared to controls and DHA-EE treated rats. At 12 h the long-chain acyl-CoA level in EPA-EE treated rats was normalized. In contrast to the changes of long-chain acyl-CoA level observed after EPA-EE feeding, the malonyl-CoA level was reduced from the second to the eighth hour (Fig. 4C), where the mitochondrial β-oxidation was increased (Fig. 4A), and at 8 h the malonyl-CoA values became significantly lower in EPA-EE treated rats than in controls (Fig. 4C).

As shown in Table 4, the total amount of the different fatty acids in the liver was not changed at any of the time points studied in the Palm treated group (controls). Treating the rats with Palm did not change the fatty acid composition, including the amount of Palm (16:0) compared to rats only treated with CMC (data not shown). The total amounts of monoenes and polyenes were decreased and increased, respectively, 4 h after acute treatment with EPA-EE as compared to Palm (controls) and DHA-EE administration (Table 4). Palmitoleic acid (16:1n-7) and vaccenic acid (18:1n-7) were significantly reduced after EPA-EE treatment compared to DHA-EE feeding, whereas the amount of oleic acid (18:1n-9) was reduced compared to controls. No statistically significant difference was found for either stearic acid (18:0), linoleic acid (18:2n-6), α-linolenic acid (18:3n-3), and arachidonic acid (20:4n-6) between EPA-EE, DHA-EE, and Palm treated rats at any of the time points studied. The total amount of cellular EPA (20:5n-3) and docosapentaenoic acid (DPA) (22:6n-3) increased from the second to the fourth hour after EPA-EE administration, and these fatty acids were increased at all time points studied with EPA-EE compared to controls and DHA-EE feeding. Table 4 further shows that the amount of cellular DHA (22:6n-3) increased at all time points studied in DHA-EE treated rats compared to controls except at 8 h, but 22:6n-3 did not reach a peak at 4 h as 20:5n-3 after EPA-EE administration. Moreover, at all time points studied, the fold increase of 22:6n-3 after DHA-EE treatment was much lower than the increase of 20:5n-3 after EPA-EE feeding. No statistically significant difference was found for 22:5n-3 between controls and DHA-EE administration at any of the time points studied (Table 4). Noteworthy, however, was the fact that DHA-EE supplementation elevated the amount of 20:5n-3 the first 8 h after administration.

As shown in Table 5, the HMG–CoA reductase activity in the control group was increased at 8 h and this increase was maintained to 12 h after feeding. As also shown in Table 5, the HMG–CoA reductase activity was reduced 8 h after acute treatment with EPA-EE as compared to controls and DHA-EE administration.

DISCUSSION

It has been assumed that EPA or DHA, the major polyunsaturated fatty acids of fish oil, or both are responsible for the triglyceride-lowering effect. Most studies have used fish oil with various contents of EPA and DHA, and only a few studies have examined the effect of EPA and DHA separately to determine the effects of each fatty acid. The present study reports that EPA, and not DHA, is the fatty acid primarily responsible for the triglyceride-lowering effect of fish oil in rats. These acute effects are consistent with observations in normolipidemic and hyperlipidemic rats (21–24). Studies in perfused livers and cultured cells have shown that EPA reduces triglyceride synthesis/secretion in perfused rat liver (19,58), in rat (12,59), rabbit hepatocytes (12,59,60), and in HepG2 cells (9,61). Furthermore, Zhang *et al.* (58) observed in a liver perfusion study that only EPA, and not DHA, decreased triglyceride synthesis and VLDL secretion. In contrast, Williams *et al.* (62) observed that feeding pure DHA re-

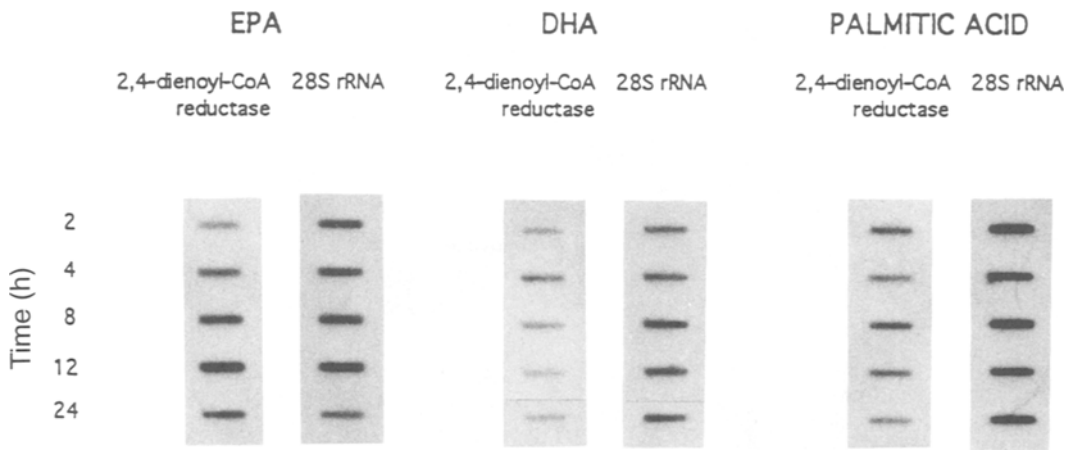

FIG. 5. Kinetics of 2,4-dienoyl-CoA reductase and 28S rRNA after acute treatment with DHA-EE and palmitic acid. One representative slot blot of a total of three from six rats in each group is shown. Mouse 28S rRNA was used as a probe to evaluate the amount of RNA applied on the filter, which was 5, 2, and 1 μg. Abbreviations as in Figure 1.

duced hepatic triglyceride secretion *in vivo*. Similarly, Martin *et al.* (63) reported a reduction of triglyceride secretion in rat hepatocytes following incubation with DHA, but concluded that inhibition of hepatocyte triglyceride synthesis is not obligatory for the 22:6, n-3-induced diminution of triglyceride secretion.

In humans, supplementation with purified EPA has lowered triglycerides in plasma (64–67), whereas the few studies reported on purified DHA on human serum lipoprotein levels are conflicting (26–28,68). Worne and Smith (68) reported a marked reduction in total serum lipids by EPA, by DHA, and by arachidonic acid administration (triglyceride levels were not measured), and Hirai *et al.* (27) showed a significant reduction of serum triglycerides and cholesterol in hypertriglyceridemic patients of Type IIa and Type IIb hyperlipidemia following both highly purified EPA and DHA ingestion. In contrast, a report by Harris (26) at the recent ISSFAL meeting found that EPA, but not DHA, appeared to be responsible for the triglyceride-lowering effect of fish oil in humans. This is in contrast to the Tromsø study, reported at the same meeting, where it was concluded that DHA was more efficient than EPA in decreasing plasma triglyceride concentrations (28). The cause of the differences between the results in the human studies is not clear, but one explanation might be that the Japanese and Norwegian people consume more fish and thereby have higher basal values of EPA and DHA compared to the healthy subjects in Kansas City, Missouri, where fish consumption is lower.

A large number of reports have been published demonstrating that ethyl esters of n-3 fatty acids execute the same biological effects as other chemical forms of these fatty acids (67,69). However, it is clear that the *in vitro* hydrolysis of ethyl esters of very long-chain n-3 fatty acids is markedly reduced as compared to the free forms and triglycerides of these fatty acids (34,70). During prolonged feeding, ethyl esters of n-3 fatty acids are highly bioavailable, whereas the markedly slower hydrolyzation by pancreatic lipase theoretically could influence the absorption of n-3 fatty acids in short-term studies. Our results from fatty acid composition in liver of rats treated with a single dose of EPA-EE and DHA-EE show that EPA-EE feeding increases (20:5n-3) after two hours and that feeding EPA-EE also increases DPA (22:5n-3), whereas DHA (22:6n-3) remains unchanged (Table 4). Furthermore, we observed triglyceride-lowering effect by EPA-EE after eight hours (Fig. 2). Concerning DHA-EE feeding, an increase in fatty acid composition in liver was observed after two hours. Our results show that EPA-EE and DHA-EE are rapidly absorbed and exert their effects on plasma lipids and key enzyme activities of lipid metabolism within hours. Thus, the discrepancy regarding the separate effects of EPA and DHA is not due to the bioavailability of ethyl esters of n-3 fatty acids compared to n-3 fatty acids esterified to triacylglycerol or phosphoacylglycerol.

We had the opportunity in this study to address the question of the mechanism behind this lipid-lowering effect. EPA-EE treatment for either hours (Figs. 2 and 3) or given over a 15-d period (21) to normolipidemic rats decreased plasma triglycerides, cholesterol, and phospholipids. Prolonged treatment with EPA-EE is reported to increase the activity of acyl-CoA:diacylglycerol acyltransferase and to decrease the acetyl-CoA carboxylase activity (21). No change of the last enzyme activity was observed after acute treatment (Table 2). EPA-EE increased mitochondrial fatty acid oxidation (Fig. 4A) and, most plausible, also peroxisomal β-oxidation, as the fatty acyl-CoA oxidase activity was increased (Table 3). EPA-EE treatment either for prolonged feeding (21) or given acutely to rats had no effect on the PAP activity (Table 2). It is conceivable that, whereas the hypolipidemic effect of EPA-EE after prolonged treatment (18,21) may be influenced by alterations of the triglyceride biosynthesis and lipogenesis, its effect after acute treatment appears to be independent of changes of these pathways. The triglyceride-lowering effect after acute EPA-EE treatment may be a consequence of its effect on hepatic fatty acid oxidation.

TABLE 4
Changes in Fatty Acid Composition in Liver of Rats Treated with EPA-EE, DHA-EE, and Palmitic Acid (Palm) (controls)

Fatty acid	Treatment/hours	Fatty acid composition (mol%) 2	4	8	24

[a,b]Values in a row with different superscripts are significantly different ($P < 0.05$). Abbreviations as in Table 2.
[c]$P < 0.05$ for difference between EPA-EE and DHA-EE treated rats.
[d]$P < 0.05$ for difference between EPA-EE and controls.
[e]$P < 0.05$ for difference between DHA-EE and controls.

The results from this study demonstrated that both EPA-EE and DHA-EE administration resulted in the induction of fatty acyl-CoA oxidase activity (Table 2). As the fatty acyl-CoA oxidase mRNA levels were increased (Vaagenes, H., Asiedu, D., Demoz, A., and Berge, R.K., unpublished results), the induction of fatty acyl-CoA oxidase by these peroxisome proliferators is partly, if not entirely, due to an increase in the transcription rate of the gene. EPA-EE lowered plasma triglycerides, but DHA-EE supplementation had no hypotriglyceridemic effect. Thus, increased triglyceride clearance by fish oil is not due to enhanced activity of peroxisomal β-oxidation, which confirms and extends previous reports by hypolipidemic peroxisome proliferating fatty acid analogues (71).

To our knowledge, the results from this study demonstrate for the first time that EPA-EE (but not DHA-EE) treatment results in the induction of rat liver 2,4-dienoyl-CoA reductase gene expression, an enzyme which is necessary for oxidation

TABLE 5
HMG–CoA Reductase Activity at Different Times After Acute EPA-EE and DHA-EE Administration in the Rat[a]

[a]The 3-hydroxy-3-methylglutaryl (HMG)–CoA reductase activity was measured in the isolated microsomal fraction. Statistical comparison between EPA-EE, DHA-EE, and controls is shown by the *P* values.
[a,b]Correspond to the statistical comparison between the groups at each of the time points studied (hours), where the same letter within one column means that there is no statistical differences between the corresponding groups. Abbreviations as in Table 2.

of unsaturated fatty acids. Furthermore, the induced activity of 2,4-dienoyl-CoA reductase on the transcriptional induction of the enzyme gene expression by EPA-EE supports previous reports that modification of the mitochondrial fatty acid oxidation system is related to the mitochondrial induction produced by non-β-oxidizable fatty acid analogues, i.e., 3-thia fatty acids (71) and by fish oil (72). Increased fatty acid oxidation of EPA, but not DHA (free forms of the n-3 fatty acids), seen in cultured rat hepatocytes (Fig. 1) is in keeping with the animal data. Thus, the triglyceride-lowering effect of EPA may be due to the increased mitochondrial fatty acid oxidation.

McGarry and Foster (73) have shown that fatty acid oxidation is inhibited by malonyl-CoA, *via* inhibition of carnitine palmitoyltransferase I. Depression of the hepatic malonyl-CoA content (Fig. 4C) therefore appears to be the mechanism by which EPA stimulates mitochondrial fatty acid oxidation. It is tempting to suggest that EPA, by decreasing malonyl-CoA, may promote acyl carnitine formation and, consequently, acylcarnitine transport across the inner mitochondrial membrane followed by β-oxidation of long-chain acyl-groups to acetyl-CoA.

A number of animal studies have demonstrated increased hepatic β-oxidation capacity and ketone body production after fish oil feeding (17,19,25,74,75). Surette *et al.* (20) observed an increased activity of hepatic carnitine palmitoyl transferase I in fish oil-fed Syrian hamsters, which was highly correlated with the diet-induced change in serum triacylglycerol concentrations. These findings are in agreement with the results in this study and previous findings (21,22), and one reason for the different results with EPA and DHA might be that the bioavailability of EPA and DHA for the mitochondrial and peroxisomal β-oxidation is different. Very long chain fatty acids (VLCFA) (>C_{20}) are oxidized predominantly, if not exclusively, by peroxisomes (76,77) and very long chain fatty acyl-CoA synthetase (necessary for the activation of the fatty acids to their CoA derivatives, a prerequisite for β-oxidation and esterification) is present in endoplasmic reticulum and peroxisomes, but not in mitochondria (77,78). Apparently, the site of activation determines the subsequent fate of VLCFA. VLCFA are not oxidized by isolated mitochondria, indicating that the absence of very long chain acyl-CoA synthetase from mitochondria is the reason why these organelles do not oxidize VLCFA (79). Because DHA is a good substrate for peroxisomes and increases peroxisomal β-oxidation, but not the mitochondrial β-oxidation (Table 3 and Fig. 4), we suggest that DHA is mainly metabolized (chain-shortened/retroconverted) by peroxisomes. This is in agreement with studies in isolated liver cells (80). In contrast, EPA and other long-chain fatty acids (LCFA; C_{16}–C_{20}) are mainly directed to mitochondrial β-oxidation, as long-chain acyl-CoA synthetase (C_{16}–C_{20}) is located in mitochondria and they have a lower apparent K_m for LCFA (81,82). The different results of EPA and DHA on triglyceride-lowering effect and hepatic fatty acid oxidation may partly reflect the diversion of EPA (as a LCFA) to mitochondrial β-oxidation and ketogenesis, whereas DHA is diverted to the peroxisomes for further metabolism.

Circulating FFA and glycerol are mainly taken up by the liver where they are partially converted into triglycerides for later export to the circulation in the form of VLDL-triglycerides. Several studies have reported a marked reduction in FFA concentration after fish oil supplementation, indicating that decreased lipolysis from adipose tissue could be the reason for decreased VLDL synthesis and/or secretion (13,75, 83). However, the activities of lipoprotein lipase and hepatic lipase have uniformly shown no change after fish oil feeding both in humans (84,85) and in animals (86,87). Otto *et al.* (88) observed a dose-dependent reduction in plasma FFA by n-3 fatty acids in rats fed *ad libitum*, but not in rats fasted overnight (88). In the present study, administration of EPA-EE reduced the plasma FFA at eight hours, whereas plasma FFA in DHA-EE treated animals showed a marked decrease in plasma FFA after only two hours. At that time the plasma FFA in EPA-EE treated rats were significantly higher than in DHA-EE treated rats and controls (Fig. 3B). A possible explanation for this might be the recently published observations by Raclot and Groscolas (89) that individual fish oil n-3 polyunsaturated fatty acids are selectively mobilized from and stored in adipose tissue. The preferential mobilization of EPA could contribute to its maintenance in the circulation at four hours compared to DHA, and that this effect was overcome at later time points.

In general, hepatic fatty acid oxidation is proportional to plasma FFA concentration (90) but, at equal FFA concentrations, perfused livers from fish oil-adapted rats have shown

significantly higher rates of ketogenesis than livers from animals fed chow or safflower oil (19). This is in agreement with our results where all three fatty acid supplements resulted in decreased concentrations of plasma FFA at eight hours, but at the same time point mitochondrial β-oxidation was significantly increased in the EPA-EE treated rats (Fig. 4). This supports our data that decreased plasma triglycerides following EPA-EE supplementation is due to increased mitochondrial β-oxidation, resulting in decreased amount of substrate for triglyceride synthesis, and is not due to increased lipolytic activity.

There is no consistent change in plasma cholesterol after fish oil feeding in humans, whereas the cholesterol-lowering effect of fish oil in rats is well documented (29,31). One explanation might be that rats are deficient in lipid transfer protein (91) and in this species fish oils lower plasma cholesterol concentrations, probably as a consequence of this lack. In humans and marmosets who have lipid transfer protein, there may be even a small increase in plasma cholesterol after ingestion of fish oil and EPA (as ethyl ester), respectively (92,93). Human studies also have demonstrated that fish oil reduces the expected increase in plasma cholesterol levels with an atherogenic diet (94). As with the hypotriglyceridemic effect, it remains unknown whether EPA or DHA or both are responsible for the cholesterol-lowering effect in rats. In this and a previous study, we have observed a hypocholesterolemic effect of EPA-EE, and not DHA-EE, associated with a significant inhibition of HMG–CoA reductase activity (Table 5) (22). This suggests that EPA-EE, in contrast to DHA-EE treatment, might decrease cholesterol biosynthesis, thereby contributing to the decrease in VLDL secretion.

Another important observation made in this study was that EPA-EE, but not DHA-EE, given acutely affected the cellular fatty acid composition by decreasing the amounts of monoenes (16:1n-7, 18:1n-7, and 18:1n-9) and increasing the amount of polyenes (20:5n-3 and 22:6n-3). Replacement of the ordinary fatty acids, i.e., the monoenes with EPA and some conversion to DPA concomitant with increased fatty acid oxidation, is probably the mechanism leading to changed fatty acid composition. The paradox that administration of pure EPA-EE did not increase DHA concentration in liver (Table 4) may be explained by reduced Δ^6 desaturase activity as 22:5n-3 is metabolized to 22:6n-3 through three steps: namely elongation to 24:5n-3, Δ^6-desaturation to 24:6n-3, and finally β-oxidation to DHA (95). Indeed, dietary supplementation with n-3 fatty acids depresses rat liver Δ^6-desaturase activity (96), which is necessary for the second step of the conversion of 22:5n-3 to 22:6n-3.

The results from this study argue against a direct conversion of EPA to DHA, but rather in favor of retroconversion of EPA to DHA (Table 4). Retroconversion of DHA to EPA also has been reported by others (23,27). This implies that it will be difficult to study the unique effects of DHA as some of it will always be converted to EPA. Whether the effects observed in the DHA-EE treated group were due to the EPA generated from DHA, and not from DHA itself, must then be considered.

In conclusion, we have shown that EPA is the hypotriglyceridemic fatty acid in fish oils, and increased mitochondrial fatty acid oxidation may be responsible. DHA has little impact on serum lipid levels, but can be retroconverted to EPA. In summary, the present observations provide evidence for the following events in the liver following exposure to EPA: (i) inhibition of malonyl-CoA formation possibly due to increased long-chain acyl-CoA levels (Fig. 4) (most plausible attributed to EPA-CoA); (ii) increased mitochondrial fatty acid oxidation; (iii) incorporation into triglycerides and phospholipids and displacement of easily oxidizable fatty acids into β-oxidation in mitochondria; and (iv) decreased production of VLDL-triglycerides.

ACKNOWLEDGMENTS

This work was supported by grants from The Norwegian Cancer Society, Pronova AS, and by means and grants from The Norwegian Council on Cardiovascular Disease, The Heart Foundation, University of Bergen, Nansen Foundation, and Fam. Blix Foundation. We thank professor H. Osmundsen, University of Oslo, and professor J.K. Hiltunen, University of Oulu, for kindly providing us with 2,4-dienoyl-CoA and cDNA probe of 2,4-dienoyl-CoA reductase, respectively. We thank S. Krüger and R. Sandvik for their skillful technical assistance.

Δ8 Desaturation *in vivo* of Deuterated Eicosatrienoic Acid by Mouse Liver

Patricia A. Schenck, Henry Rakoff, and Edward A. Emken*

NCAUR, ARS, USDA, Peoria, Illinois 61604

ABSTRACT: *In vitro* evidence has been reported for an alternate pathway that involves Δ8 desaturation of n-6 and n-3 polyunsaturated fatty acids (PUFA). The present study was designed to allow detection of Δ8 desaturation *in vivo* and to provide an estimation of the relative contribution of Δ8 desaturation to the *in vivo* synthesis of n-3 fatty acids. Male adult ICR mice were fed a semisynthetic fat-free diet for eight days, and then the diets were supplemented for three days with deuterated 11,14,17-eicosatrienoic acid (20:3-d_8) labeled at the 3,3,4,4,8,8,9,9 carbon positions. Analysis of liver total lipid by gas chromatography/mass spectroscopy indicates that the total deuterated fatty acids contained 22.3% 20:3n-3-d_8 and 28.9% of metabolites formed by elongation and Δ5 desaturation of 20:3n-3-d_8. Deuterated metabolites resulting from retroconversion to 18:3-d_6 and subsequent metabolism by classical pathways represented 35.3% of the total deuterated fatty acids. The retroconversion product (18:4n-3-d6) of 20:4n-3-d_6 and/or -d_8 was 9.0% of the total. A minor percentage (4.4%) of the products identified (20:4n-3-d_6, 20:5n-3-d_6, 22:5n-3-d_6, 22:6n-3-d_5 and 24:6n-3-d_5) were formed by Δ8 desaturation. This study provides the first clear evidence of Δ8 desaturation *in vivo* in the mouse liver. Whether Δ8 desaturation would have a greater importance *in vivo* when the Δ6 desaturase pathway is disrupted remains to be determined.

Lipids 31, 593–600 (1996).

All mammals require the presence of both n-6 and n-3 polyunsaturated fatty acids (PUFA) in the diet. The essential fatty acids, linoleic (18:2n-6) and linolenic (18:3n-3), are desaturated and elongated by a series of reactions, forming longer chain PUFA (1). The major end-products of linoleic acid metabolism are primarily arachidonic acid (20:4n-6) and docosapentaenoic acid (22:5n-6), and the major metabolites derived from linolenic acid are eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3).

The classical pathway of PUFA formation from linolenic acid involves a series of desaturation and 2-carbon chain elongation steps. Starting with a Δ6 desaturation, the first product is 18:4n-3. A chain elongation then occurs producing 20:4n-3, followed by a Δ5 desaturation producing 20:5n-3. Another chain elongation takes place to form 22:5n-3 and is followed by a Δ4 desaturation step to produce 22:6n-3. This same series of reactions is responsible for the formation of 22:5n-6 from linoleic acid (2,3). An alternate pathway for the formation of 22:6n-3 and 22:5n-6 has been described (4). In this pathway, 22:5n-3 or 22:4n-6 is elongated to 24:5n-3 or 24:4n-6, and then Δ6 desaturated to produce 24:6n-3 or 24:5n-6, respectively. A 2-carbon chain shortening then occurs, forming 22:6n-3 or 22:5n-6.

Although both enzymatic studies and results from rats fed and injected with carbon-14 labeled n-6 and n-3 PUFA have led to the conclusion that 8-desaturation does not occur in rat liver (5,6), a number of other studies have reported both direct and indirect evidence that 8-desaturation is an alternate pathway for formation of n-6 and n-3 PUFA from linolenic and linoleic acid. Rat testes injected with [1-^{14}C]eicosa-11,14-dienoic acid resulted in the appearance of radiolabeled eicosa-8-11-14-trienoic acid, providing initial evidence for the existence of Δ8 desaturation (7). This study was later substantiated by a similar study with human testicular tissue (8). Cultured rat C_6 glioma cells have been shown to produce eicosapentaenoic acid (20:5n-3) when 11,14,17-20:3-8,8,9,9-d_4 was added to the medium (9), and rat C_6 glioma, mouse neuroblastoma (N1E-115), human neuroblastoma (HTB-10, HTB-11), and human infant male foreskin fibroblast (F8) cells have shown Δ8 desaturase activity *in vitro* when 11,14,17-20:3-3,3,4,4,8,8,9,9-d_8 was added to media (10). Studies with human cancer and noncancerous cells indicated that substantial conversion of 11,14-20:2 to 20:4n-6 occurred *in vitro* (11). The fatty acid composition of liver lipids from rats fed 5,11,14,17-20:3 (12) and of human leukemia cells that lack Δ6 desaturase were also consistent with the possibility of Δ8 desaturation (13).

The present study was designed to investigate whether Δ8 desaturation of n-3 fatty acids occurs *in vivo* and to determine if Δ8 desaturation contributes to the *in vivo* synthesis of n-3 fatty acids. The specific labeling pattern for the 20:3n-3-d_8 substrate used was selected to allow differentiation between the deuterated n-3 fatty acids formed by retroconversion of 20:3n-3-d_8 and subsequent conversion to n-3 fatty acids by the classical pathway and deuterated n-3 fatty acids formed by an 8-desaturation pathway. The presence of any d_6 n-3 fatty acid products would be evidence of 8-desaturation since 4 or 6 deuterium labels would be lost by any other pathways.

MATERIALS AND METHODS

Animals and diets. Male adult (approximately 7 mon old) ICR mice (Sprague-Dawley, Indianapolis, IN) of similar body weight (approximately 45 g) were used in this study. Mice were housed individually, with a 12 h light/12 h dark cycle, an ambient temperature of 22°C, and controlled humidity. Purina Laboratory Rodent Chow 5001 (Purina Mills, Richmond, IN) and water was available *ad libitum* prior to the feeding of the experimental diet. Food consumption was monitored, and body weight recorded weekly.

For the experiment, seven mice were fed a semi-synthetic fat-free (FF) diet (7 g/d) containing 65% sucrose, 20% vitamin-free casein, 3.5% salt mixture (AIN Mineral Mixture 76), 2.2% vitamin mixture, 0.3% methionine, and 9.0% cellulose for 8 d. Dietary ingredients were purchased from Sigma Chemical Co. (St. Louis, MO) and ICN Nutritional Biochemicals (Cleveland, OH). Three mice were maintained on this FF diet for an additional three days as a control group—FF and the diets of four mice were supplemented with 30 mg/d deuterated 11,14,17-eicosatrienoic acid (20:3n-3-d_8) labeled at the 3,3,4,4,8,8,9,9 carbon positions [fat-free supplemented (FFS)], for three days. Methyl esters of 11,14,17-20:3-d_8 were prepared by previously described synthetic methods (14). Chemical purity was 99.8%, and isotopic purity was 7.9 deuterium atoms per molecule (4.0% d_7, 93.5% d_8, 2.4% d_9). Analysis of samples extracted from unused test diet two hours after exposure to air at room temperature indicated that oxidation was not a problem and that the saponification and esterification reactions did not cause loss or scatter of deuterium or the formation of fatty acid isomers. The free fatty acid of 11,14,17-20:3-d_8 was prepared for feeding by saponification (15), and stored at −20°C under nitrogen until feeding; 30 mg of 11,14,17-20:3-d_8 free fatty acid were diluted with 1 mL of anhydrous ether (J.T. Baker Inc., Phillipsburg, NJ), and added to the individually weighed portion of diet daily. The ether was removed by evaporation, and the diet immediately fed. Mice were fed late in the afternoon shortly before the start of the dark cycle. All diet was normally consumed within two hours of feeding.

Sample collection. At the end of the feeding period, mice were euthanized by halothane (Halocarbon Laboratories, Inc., North Augusta, SC) overdose, and livers were excised, rinsed with cold 0.9% saline, blotted dry, placed in tared vials, and weighed. Livers were stored in chloroform/methanol (2:1, vol/vol) under nitrogen at −20°C until extracted and processed for fatty acid analysis.

Extraction. Liver samples (approximately one gram) were homogenized in 40 mL chloroform/methanol (2:1, vol/vol) for approximately 30 s (Tissumizer, Model #SDT1810; Telmar, Cincinnati, OH) and filtered. Liver lipids were extracted according to previously described procedures (16). Heptadecanoic acid (17:0; Nu-Chek-Prep, Elysian, MN) was added to lipid extracts as an internal standard. Lipid extracts were esterified with 4% H_2SO_4/methanol according to standard procedures (15).

Analysis of fatty acids. The fatty acid composition of liver tissue was determined using a Hewlett-Packard 5890 Series II GC (Hewlett-Packard, Avondale, PA) equipped with a flame-ionization detector and a 0.25 mm × 30 m fused silica SP2330 capillary column (0.2 μm film thickness; Supelco, Inc., Bellefonte, PA). The initial temperature of the column was 165°C for an initial time of 19 min; the temperature was then increased to 210°C at the rate of 1°C/min. Helium was used as the carrier gas (linear flow rate = 19.2 cm/s), and the injector and detector temperatures were 245 and 250°C, respectively. Fatty acids were identified by comparison of retention times to those of authentic standards (Nu-Chek 68A Standard to which known weights of 17:0, 20:3n-9, 20:5n-3, 22:3n-6, 22:4n-6, and 22:5n-6 had been added; Nu-Chek-Prep). Peak areas were measured using an HP 3396A Integrator (Hewlett-Packard), and compared to the internal 17:0 standard peak area.

Liver methyl esters were also analyzed by gas chromatography/mass spectrometry (GC/MS) using a modification of a previously published method (17). The GC/MS system used was a Hewlett-Packard 5980 Series II GC/5988A Research Grade MS/Pascal 59970C Chem Station with a Supelcowax-10 (30 m × 0.25 mm, 0.25 μm film thickness) column (Supelco, Inc.). The GC conditions were: initial column temper ature 70°C; initial hold 1 min; program rate 1, 30°C/min to 190°C; program rate 2, 4°C/min to 232°C; program rate 3, 3.5/min to a final temperature of 260°C; injection temperature 265°C. The flow rate of the helium carrier gas was 0.91 mL/min. Splitless injection was used. The mass spectrometer conditions were: filament voltage 70 ev; filament emission current 230 ma; multiplier setting 1800 to 2400 volts; source temperature 200°C; isobutane pressure 1.0 torr. Selected-ion monitoring of ions with even masses was used for quantitative analysis except when qualitative analysis had identified the presence of fatty esters with an odd-number of deuterium labels.

The Nu-Chek 68A standard mixture containing added fatty esters (described earlier) was used to calculate GC/MS response factors. The response factors were updated before and after the analysis of each series of four samples. Methyl esters from *Ephedra campylopoda* seed oil were used to determine retention times and response factors for 5*c*,11*c*,14*c*-20:3 and 5*c*,11*c*,14*c*,17*c*-20:4 (5*c*20:4n-3) (18). The response factor for 4,7,10,13,16,19-22:6 was used as the response factor for 9,12,15,18,21-24:5 and 6,9,12,15,18,21-24:6.

Statistical analysis of data. The Student's *t*-test was used to determine significant differences in body weight, tissue weight, and liver fatty acid content. Statistical procedures were performed using NWA Statpak, version 4.1 (Northwest Analytical, Inc., Portland, OR) on an IBM compatible computer.

RESULTS

Animal data. There was no significant difference in the amount of diet consumed between the FF diet-fed mice and

the 20:3n-3-d_8 FFS mice. Also, there were no significant differences in body weights (45.7 ± 3.6 g) or total liver weights (2.5 ± 0.56 g) at the end of the feeding period between the mice fed 20:3n-3-d_8. Weights for the total liver lipid extracts (29.5 ± 3.55 mg/g) were also similar for both groups of mice. Percentages of liver lipids in FF mice were in agreement with previously published values (19).

Liver fatty acid profile. The fatty acid profile of liver lipids for both FF mice and FFS mice is shown in Table 1. In both FF and FFS mice, saturated and monoenoic fatty acids accounted for greater than 80% of the total liver fatty acids (81 and 83%, respectively). Liver lipids from FFS mice contained 4.4 and 4.9% 18:2n-6, respectively. Predominant PUFA present in both FF and FFS mouse livers were 20:4n-6 (4.5 and 5.7%, respectively) and 22:6n-3 (5.0 and 5.1%, respectively). The 1.1 to 1.2% of 20:3n-9 in the livers from both groups of mice indicate that the short-term lack of dietary essential fatty acids (EFA) had not caused a large increase in this marker for EFA deficiency. There was no significant difference in the presence of any of the n-6 series of PUFA in FF or FFS mouse livers. However, 20:3n-3-d_8 supplementation resulted in significantly higher concentrations of 18:4n-3, 20:3n-3, 5*c*20:4n-3, and 7*c*,13*c*,16*c*,19*c*-22:4n-3 (7*c*22:4n-3) in liver, primarily due to the presence of deuterated forms of these fatty acids.

Metabolism of deuterated 20:3n-3-d_8. Supplementation of an FF diet with 11,14,17-20:3-d_8 for three days resulted in the incorporation into mouse liver of a number of metabolites formed from 20:3n-3-d_8. Portions of some of the selected ion tracings obtained by GC/MS are shown in Figures 1 and 2 in order to qualitatively illustrate the separations and the signal-to-noise ratios. The combination of both GC retention times and molecular ion data greatly reduces the possibility of misidentification of the d_2, d_4, d_5, d_6, and d_8 products from 20:3n-3-d_8. For example, 5*c*20:4n-3-d_6 with a mass of 325 was easily distinguished from 5*c*20:4n-3-d_8 with a mass of 327, and the small amount of 20:4n-3-d_4 present with a mass of 323 could be detected separately from 20:4n-3 with a mass of 319 (Fig. 1A). Using this method, 22:6n-3-d_5 with a mass of 348 could be identified separately from 22:6n-3-d_4 with a mass of 347 (Fig. 1B). In Figure 2, the *m/z* 325 and *m/z* 323 ion scans have been expanded to show GC/MS data for the small amounts of 20:4n-3-d_6 and 20:5n-3-d_6 product obtained by Δ8 desaturation. The slightly earlier elution of the deuterated fatty acids relative to the undeuterated fatty acids was also used to confirm identifications. No peaks were found in samples of liver fatty methyl esters from the mice fed the nonsupplemented FF control diet that would coelute with any of the identified d_4, d_5, d_6, and d_8 PUFA peaks.

Supplementation of an FF diet with 20:3n-3-d_8 resulted in the production of a number of deuterated PUFA. The quantitative data for the 20:3n-3-d_8 substrate that was fed and the deuterated products identified in the liver lipids are listed in Table 2. Deuterated fatty acids accounted for 0.6% of the total liver fatty acids. The fatty acid fed, 20:3n-3-d_8, was present in the highest quantity in the liver (22.3% of total deuterated fatty acids). Major deuterated metabolites of 20:3n-3-d_8 were 5*c*20:4n-3-d_8 (20.6% of total deuterated fatty acids), 18:4n-3-d_6 (9.0%), 18:4n-3-d_4 (8.6%), 7*c*22:4n-3-d_8 (7.6%), and 18:3n-3-d_6 (5.4%). The deuterated metabolites formed from Δ8 desaturation of 20:3n-3-d_8 were 20:5n-3-d_6, 22:5n-3-d_6, 22:6n-3-d_5, and 24:6n-3-d_5. The sum for these deuterated fatty acids was 4.4% of the total deuterated fatty acids.

DISCUSSION

The present evaluation of the metabolism of 20:3n-3 has been facilitated by the availability of this fatty acid labeled with deuterium atoms at specific locations in the fatty acyl chain. Selective mass detection allowed a variety of metabolites derived from 20:3n-3-d_8 to be identified and quantified (17).

The classical pathway for synthesis of 20-carbon PUFA from 18:2n-6 and 18:3n-3 occurs by an alternating sequence of desaturation and elongation reactions has long been established (5,20). The feeding of 20:3n-3-d_8 resulted in the incorporation of 23.6 μg/g of 20:3n-3-d_8 per gram of liver, repre-

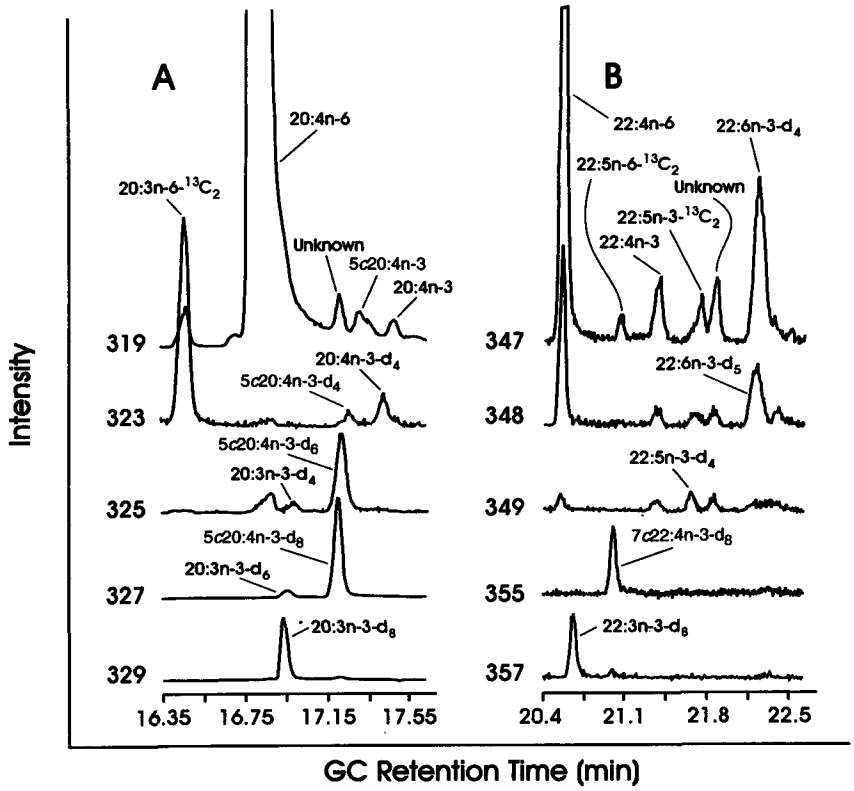

FIG. 1. Selected gas chromatography (GC)/mass spectrometry ion scans for methyl esters of liver total lipids from mouse fed 20:3n-3-d_8: A: 20-carbon fatty esters, B: 22-carbon fatty esters. The selected ion scans have been manually scaled to minimize overlap between tracings and should be used only for qualitative purposes.

senting 22.3% of total deuterated fatty acids. Classical metabolites of 20:3n-3-d_8 were present, and accounted for 28.9% of the total deuterated fatty acids detected (Scheme 1). These metabolites included 22:3n-3-d_8, 5*c*20:4n-3-d_8, and 7*c*22:4n-3-d_8. The metabolite 22:3n-3-d_8 is formed *via* an initial 2-carbon chain elongation of 20:3n-3-d_8. The metabolite 5*c*20:4n-3-d_8 is formed after a Δ5 desaturation of 20:3n-3-d_8, resulting in no loss of deuterium atoms; 7*c*22:4n-3-d_8 is produced after the 2-carbon chain elongation of 5*c*20:4n-3-d_8.

A number of deuterated metabolites also resulted from apparent retroconversion and subsequent classical pathway metabolism of 20:3n-3-d_8 (Scheme 2). These metabolites accounted for 35.3% of the total deuterated fatty acids observed. *Via* retroconversion, 18:3n-3-d_6 is produced by the loss of 2-carbons and the 2 deuterium atoms at the 3 position. Once 18:3n-3-d_6 is formed, either a 2-carbon chain elongation can occur producing 20:3n-3-d_6, or Δ6 desaturation can result in the formation of 18:4n-3-d_4 since two deuterium atoms are lost in this desaturation. The 20:3n-3-d_6 can undergo the classical Δ5 desaturation, producing 5*c*20:4n-3-d_6, and then a subsequent 2-carbon chain elongation, forming 7*c*22:4n-3-d_6. The 18:4n-3-d_4 produced *via* Δ6 desaturation can undergo a sequence of 2-carbon chain elongations and desaturations (Δ5, Δ4) producing 20:4n-3-d_4, 20:5n-3-d_4, 22:5n-3-d_4, 22:6n-3-d_4, and 24:6n-3-d_4. Alternately, 22:5n-3-d_4 may be elongated to 24:5n-3-d_4 and then undergo Δ6 desaturation and retroconversion to produce 22:6n-3-d_4. No deuterium atoms are lost in this sequence of elongations and desaturations.

Retroconversion of 11,14,17-20:3-3,3,4,4,8,8,9,9-d_8 also resulted in a small quantity of 18:3n-3-6,6,7,7-d_4 formation *via* the loss of four deuterium atoms (Scheme 3). One possible reason for why some deuterium-label at the C4 position is lost is because the intermediate formed during β-oxidation has an enol structure that allows hydrogen–deuterium exchange to occur at the 4 position. Another possibility is that a second β-oxidation cycle produced 7,10,13,16-16:3n-3-d_4 which was then reelongated to 18:3n-3-d_4. This second explanation is consistent with the deuterium distribution pattern for 18:3n-3. Mostly d_4 and d_6 18:3n-3 were found, and there was very little of the 18:3n-3-d_5 product that would be formed by an exchange mechanism. The 16:3n-3-d_4 was detected which would be consistent with the second possibility. The 18:4n-3-d_2, 20:3n-3-d_4, and 20:4n-3-d_4 products can be formed from 18:3n-3-d_4 by the previously described pathways.

Several deuterated metabolites were identified which could not be synthesized by the classical fatty acid metabolism or retroconversion pathways. A possible explanation for the presence of these metabolites involves a Δ8 desaturation in the metabolic pathway of 20:3n-3-d_8 (Scheme 4). The feed-

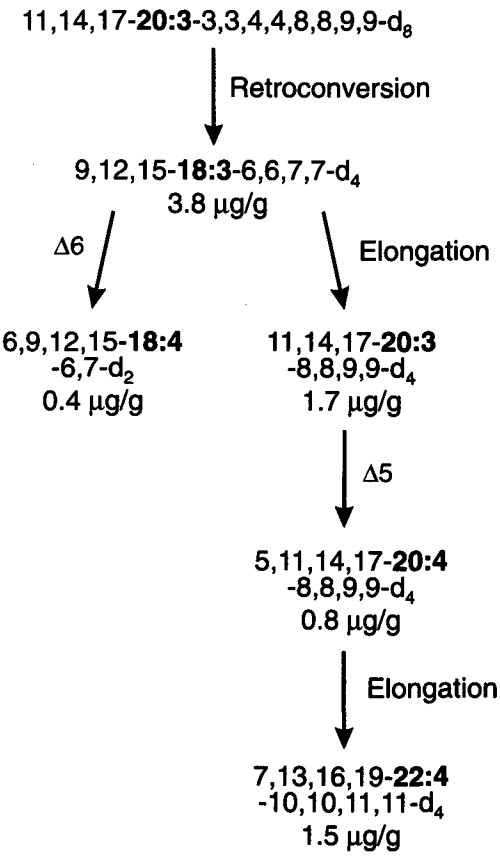
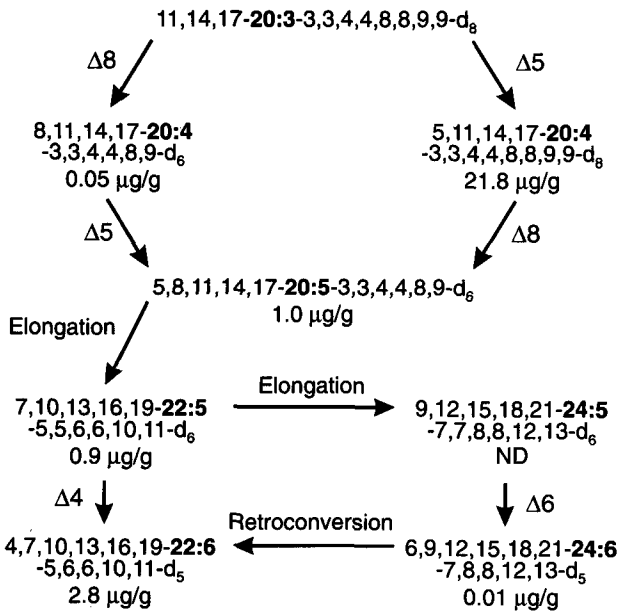
ing of 20:3n-3-d_8 resulted in the formation of 20:4n-3-d_6, which can only arise *via* a Δ8 desaturation, with the loss of two deuterium atoms. This metabolite can then undergo Δ5 desaturation, producing 20:5n-3-d_6. The 20:5n-3-d_6 metabolite also can be produced *via* the Δ5 desaturation of 20:3n-3-d_8 forming 5*c*20:4n-3-d_8, which can undergo a Δ8 desaturation, resulting in the loss of two deuterium atoms. A 2-carbon chain elongation, Δ4 desaturation, and another 2-carbon chain elongation would result in the production of 22:5n-3-d_6, 22:6n-3-d_5, and 24:6n-3-d_5, respectively. Alternately, 22:5n-3-d_6 may undergo a 2-carbon elongation, forming 24:5n-3-d_6, and then this product may undergo Δ6 desaturation and retroconversion producing 22:6n-3-d_5. Those products that could only be formed as a result of a Δ8 desaturation include 20:4n-3-d_6, 20:5n-3-d_6, 22:5n-3-d_6, 22:6n-3-d_5, and 24:6n-3-d_5, and accounted for 4.4% of the total deuterated products.



A summary of the deuterated metabolites of 20:3n-3-d_8 is presented in Table 3. Deuterated fatty acids resulting from Δ8 desaturation, retroconversion, and classical pathway accounted for 4.4, 35.3, and 28.9 of the total deuterated fatty acids, respectively. The sum of these products accounts for 68.6% of total deuterated fatty acids isolated. The fed fatty acid 20:3n-3-d_8 comprised 22.3% of the total deuterated fatty acids, and 18:4n-3-d_6, the retroconversion product of 20:4n-3-d_6 and/or -d_8, were responsible for the remaining 9.0% of the total deuterated fatty acids. By comparing the percentage of products resulting from each pathway to the total percentage

SCHEME 1



SCHEME 2

SCHEME 3

of products from all three pathways, an approximation of the contribution of each metabolic pathway can be made. Using this approach, 42.1% of metabolites resulted from the classical pathway, 51.5% arose from metabolites involving initial retroconversion, and 6.4% of deuterated metabolites arose only from Δ8 desaturation. However, the percentage contribution of Δ8 desaturation is underestimated in this manner because some of the 5*c*20:4n-3-d_8 formed in the classical pathway also may have been converted to 20:5n-3-d_6 *via* Δ8 desaturation. The reaction sequence of 20:3n-3-d_8 → 18:3n-3-d_6 → 20:3n-3-d_6 would yield 20:4n-3-d_4 *via* Δ8 desaturation of 20:3n-3-d_6. By a similar sequence, 20:5n-3-d_4 could be formed from 5*c*20:4n-3-d_6 (Scheme 2, dashed lines). By feeding 11,14,17-20:3-3,3,4,4,8,8,9,9-d_8, the percentages of 20:4n-3-d_4 and 20:5n-3-d_4 that were formed by Δ8 desaturation cannot be determined.

The presence of Δ8 desaturation activity has been shown in cultured rat glioma cells (9,10), rat testes (7), mouse and human neuroblastoma cells (10), human fibroblast cells (10), human testes (8), and normal and cancerous ovarian, colonic, and urinary bladder tissues (11). However, *in vivo* studies have denied the possibility that Δ8 desaturation occurs in the rat liver (5,6) or in the brain (21,22) which is inconsistent with the presence of small amounts of deuterium labeled Δ8 desaturation products in mouse liver lipids (Table 2). An explanation for the difference between these results is that larger amounts of the deuterium labeled substrate were fed for a much longer time in this study compared to previous studies (3 d vs. 6–8 h). This difference in experimental design could have resulted in the accumulation of detectable amounts of deuterium labeled Δ8 desaturation products whereas the levels of radioactive Δ8 desaturation metabolites

formed in previous *in vivo* studies were below detection limits.

The present study provides the first clear evidence for Δ8 desaturation *in vivo* in the mouse liver. The overall contribution of Δ8 desaturation to metabolism of fatty acids in the normal mouse remains unclear. In this study, mice were marginally EFA-deficient as evidenced by an accumulation of 1.1% 20:3n-9 in the liver lipids (23). This EFA deficiency can enhance desaturase activities (19), but it is unknown how each specific desaturase is affected. It is possible that Δ8 desaturation is depressed in healthy animals, and only becomes active when the primary Δ6 desaturase pathway is disrupted or inhibited. An inhibition of Δ6 desaturase activity may allow alternative reactions to be enhanced. K562 human leukemia cells, which lack Δ6 desaturase activity, were still able to produce 22:5n-3 and 22:6n-3 from linolenic acid (13). These results are consistent with the suggestion of a Δ8 desaturase as an alternative pathway.

The placement of the deuterium label at the 8,8,9,9 positions in the fed 20:3n-3-d_8 may have played a role in the detection of Δ8 desaturation in this *in vivo* study. The feeding of 11,14,17-20:3-3,3,4,4,8,8,9,9-d_8 resulted in the production of 9,12,15-18:3-2,2,6,6,7,7-d_6 (5.4% of total deuterated fatty acids). This fatty acid would undergo Δ6 desaturation, but the presence of deuterium at the 6 and 7 carbon positions may have reduced the rate of Δ6 desaturation due to a deuterium isotope effect, such as observed for Δ9 desaturation (24). If Δ6 desaturation was reduced, Δ8 desaturation, elongation, and chain-shortening pathways that would not experience a deuterium isotope effect may have been favored. The determination of the magnitude of the deuterium isotope effect on Δ6 desaturase activity is currently under investigation.

ABSTRACT: Wistar male rats were treated for six days with broad spectrum β-lactam antibiotics, latamoxef, and cefotaxime. On the seventh day, the number of fecal anaerobic microbes decreased, total fecal bile acids decreased, and bile acid pools increased. Secondary bile acids such as β-hyocholic, hyodeoxycholic, lithocholic, and deoxycholic acids decreased in the feces while the primary bile acids, cholic, β-muricholic, and chenodeoxycholic acids, became predominant. Coprostanol, a microbial metabolite of cholesterol, also disappeared from the feces during the treatment. The cecum enlarged to almost twice the size of that in control rats, whereas the liver weight was not significantly changed. After treatment was stopped, the number of fecal microbes returned to the initial counts within a week, but restoration of bile acid and cholesterol metabolism required at least three weeks.

Lipids 31, 601–609 (1996).

Intestinal bacteria can transform bile acids and sterols (1–3). Typical reactions are deconjugation, dehydroxylation, oxidation–reduction, and epimerization of bile acids, and also the reduction of cholesterol to coprostanol. Therefore, changes in the intestinal microflora can affect the metabolism of bile acids and sterols. When the numbers of intestinal bacteria were decreased by antibiotics, the fecal bile acid and sterol profiles resembled those under germ-free conditions (4–6). Lindstedt and Norman (4) have reported that treating rats with phthalylsulfatiazole and terramycin affected intestinal microflora and prolonged the elimination rate of cholic acid. Gustafsson *et al.* (5) have examined the effects of neomycin, kanamycin, benzylpenicillin, erythromycin, and bacitracin and showed that the germ-free profile of bile acids lasted for a long time after treatment was stopped. Furthermore, Madsen *et al.* (6) have studied the influence of aureomycin on bile acid metabolism and reported that the hyodeoxycholic acid/β-hyocholic acid (previously named ω-muricholic acid) ratio decreased significantly. These studies showed that antibiotics affected bile acid metabolism, but the relationships among the changes in intestinal microflora and bile acids with cholesterol metabolism remained unknown. Latamoxef (LMOX) and cefotaxime (CFTX) have been recognized to be effective antibiotics and have been widely used for some years (7). The antibacterial spectra of these injectable antibiotics were broader than those of oral cefem antibiotics. After injection of these broad spectrum cefem antibiotics, a part of them was excreted into bile (8–10), and therefore affected the intestinal flora (11). The changes in the flora were expected to affect bile acid metabolism, causing diarrhea or changes in lipid metabolism. In this study, we investigated the changes in bile acid and cholesterol metabolism after treatment with LMOX and CFTX in relation to changes in intestinal microflora in rats.

MATERIALS AND METHODS

Animals. Seven-week-old male Wistar rats were obtained from Aburahi Laboratories, Shionogi (Shiga, Japan) and maintained in an air-conditioned room (25 ± 1°C, 50–60% humidity) under a 12-h photoperiod (8:00–20:00). The rats were caged individually and given a commercially available diet (CA-1, Japan CLEA, Tokyo, Japan) and tap-water *ad libitum.* At the start of the study, the eight-week-old rats were divided into three groups of eight, that were administered saline, LMOX, and CFTX.

Reagents. LMOX was obtained from Shionogi & Co., Ltd. (Osaka, Japan), and CFTX was purchased from Hoechst Japan (Kobe, Japan). Piperidinohydroxypropyl Sephadex LH-20 (PHP LH-20) was obtained from Shimadzu Co., Ltd. (Kyoto, Japan). Other reagents were of analytical grade.

Antibiotic administration and sample collection. LMOX and CFTX were dissolved in sterilized water to make a 25% solution. At 9:00–10:00 a.m., the antibiotics were injected into the rats *via* the tail vein, at a dose of 300 mg/kg/d, once a day for six days. The control rats were given saline *via* the tail vein (1.2 mL/kg/d). At 24 h after the final administration, the bile duct was cannulated with polyethylene PE10 tubing (Clay Adams, Parsippany, NJ), and bile was collected from three rats of each group for 30 min under sodium pentobarbital (65 mg/kg, i.p.) anesthesia. The liver was then removed from each rat, blotted on paper, and weighed. The small and large intestines were removed with their contents. Similarly, at the end of the study (on day 49), bile was collected, and the liver and intestines were removed from five rats in each

group. Feces were collected for two days, dried by lyophilization and powdered in a coffee mill as described previously (12).

Fecal sterol and bile acid determination. Bile acids and sterols were extracted from the powdered feces and determined by gas–liquid chromatography essentially according to Uchida *et al.* (12,13) and Chikai *et al.* (14). The alcoholic extracts of bile acids from the feces on day 7 were separated into conjugated and unconjugated bile acids using a PHP LH-20 column (200 mg per extract from 1 g of dried feces powder) according to Goto *et al.* (15) before alkaline hydrolysis.

Biliary lipid determination. Biliary cholesterol, phospholipids, and bile acids were determined using 0.5 mL of bile by the methods described by Uchida *et al.* (12,13) and Chikai *et al.* (14).

Determination of intestinal bile acids. The small and large intestines with their contents were homogenized and lyophilized. The bile acids were extracted and determined as reported (13).

Determination of intestinal microflora. The fecal contents in the rectum were collected from the anus of three rats in each group, placed in reduced transportation medium (16), and kept at 4°C for 15 h until processed. The method used for analyzing the fecal microflora (17) was essentially the same as described by Mitsuoka *et al.* (18). Briefly, feces was suspended in an anaerobic diluent (19) and serial 10-fold dilutions from 10^{-1} to 10^{-8} were prepared. These dilutions were cultured in 0.05 mL vol onto the surfaces of four nonselective media and 11 selective media (20–22). The dilutions were also heated at 80°C water bath for 10 min to detect clostridial spores. The heated dilutions were cultured on the surfaces of Eggerth-Gagnon (22), glucose blood liver (22), and 5% horse blood Trypticase Soy blood (BBL Microbiology Systems, Cockeysville, MD) agar plates and neomycin-Nagler (22) agar. For the bacterial groups identified, the bacterial count per one g wet feces was calculated and converted into a logarithmic equivalent. The total viable count was calculated from the sum of the counts of each bacterial species. The minimum number detected was 10^2/g wet feces.

RESULTS

Diet intake, body weight gain, and feces dry weight. The diet intake decreased during treatment with the antibiotics, but it was restored to the control level after cessation of the treatment (Fig. 1A). The body weights of the rats given LMOX or CFTX decreased, but then increased after the treatment was stopped (Fig. 1B), in parallel to that in the control rats, but did not exceed the latter throughout the experimental period. The feces dry weight decreased on day 2 but remained almost constant thereafter (Fig. 1C). The rats treated with antibiotics excreted diarrhetic, or soft and wet feces until day 14. The feces were round and larger than those of the control rats. However, the feces excreted on and after day 21 were as hard, dry, and small as those of the control rats.

Weight of the liver and large intestine. The data are shown in Table 1. The liver weight decreased in the rats treated with

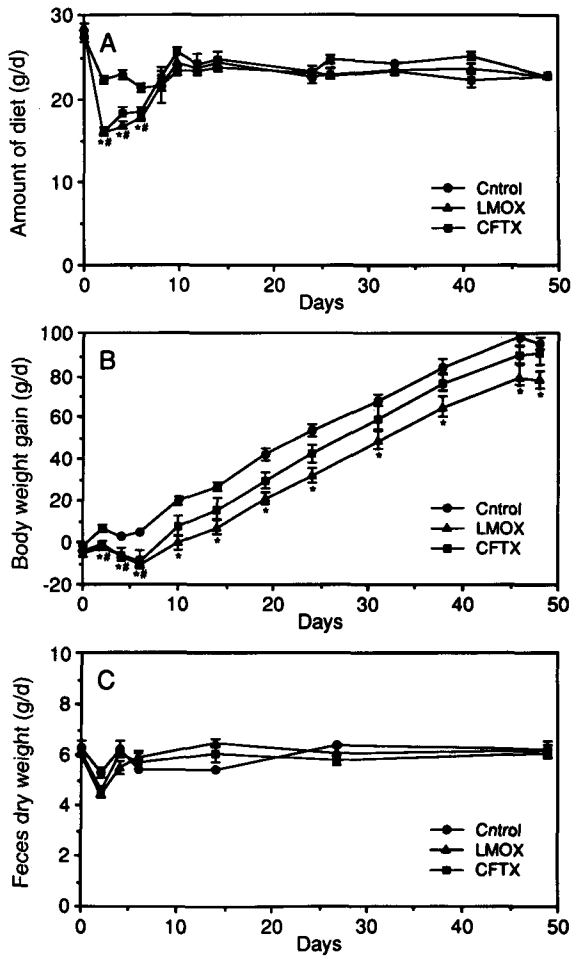

FIG. 1. Changes in diet intake, body weight gain, and feces dry weight in control and antibiotic-treated rats. Both antibiotics, latamoxef (LMOX) and cefotaxime (CFTX), were given intravenously (i.v.) once a day for six days (day 1 through day 6).

LMOX on day 7, but no difference was found on day 49. CFTX tended to reduce the liver weight on day 7, but the change was statistically insignificant. The cecum was markedly dilated by the antibiotics. Therefore, the large intestine weights markedly increased on day 7, but were restored to the control value on day 49.

Intestinal microflora. The intestinal microflora consisted mainly of eight bacterial groups before the course of antibiotics (Table 2). LMOX caused most of them to disappear, thus decreasing the total count, but the levels of *Streptococci* remained unchanged and a few *Lactobacilli* were found in one rat. However, these bacteria recovered to the original counts one week after cessation of the treatment (on day 14) and remained unchanged thereafter. In the CFTX-treated rats, *Enterobacteriaceae* were abolished, and the levels of *Bacteroidaceae* and *Micrococci* were partially decreased, but all reappeared after treatment was stopped.

Fecal bile acids and sterols. The fecal excretion of bile acids and sterols in the control and the antibiotic treated rats

[a]Antibiotics (300 mg/d/rat) were injected intravenously for six days (day 1 through day 6). See Table 1 for abbreviations.
[b]Values are Log number of bacteria per gram wet weight of feces. Numbers of rats are three and values in parentheses indicate number of rats which had a single type of bacterium.

on day 7 and day 49 is shown in Table 3. The total fecal bile acids in the LMOX- or CFTX-treated rats markedly decreased, to less than 30% of the controls, but were restored to the control level on day 49. The levels of the secondary bile acids, such as deoxycholic, lithocholic, β-hyocholic, and hyodeoxycholic acids, decreased and the percentages of the primary bile acids, such as cholic, chenodeoxycholic, and β-muricholic acids, increased on day 7. Similarly, the total fecal sterols in the treated rats decreased on day 7 but were restored on day 49. The cholesterol levels in the treated rats on day 7 were comparable with that in the controls, but coprostanol was almost completely diminished in the treated rats.

The bile acid levels periodically examined in the feces are shown in Figure 2. The control levels, though they fluctuated somewhat, were almost constant throughout the experimental period, with values of 7–8 mg/d/rat. The levels in the treated rats decreased after one week but were similar to those in the controls in the other determination days. The primary bile acids which comprised cholic, chenodeoxycholic, α-muricholic, and β-muricholic acids increased after one and two weeks, while the secondary bile acids decreased on day 7 but were almost completely restored to the control levels after four weeks or later.

Changes in the individual fecal bile acids are shown in Figure 3 in three groups, since cholic acid is considered to be converted by the intestinal bacteria to 7-oxo-deoxycholic and 7β-cholic acids, β-muricholic acid to β-hyocholic acid then to hyodeoxycholic acid, and chenodeoxycholic acid to lithocholic acid. The percentages of the individual bile acids were quite constant in the control rats, but deoxycholic acid decreased with a concomitant increase in cholic acid after one week, β-hyocholic acid plus hyodeoxycholic acid decreased with an increase in β-muricholic acid after one and two weeks, and lithocholic acid decreased with an increase in chenodeoxycholic acid after one week in both LMOX- and CFTX-treated rats.

The changes in the fecal sterols are shown in Figure 4. Coprostanol almost completely disappeared after one week but reappeared after two weeks or later. The fecal excretion of cholesterol after two weeks in the treated rats was significantly higher than that in the controls.

Most of the fecal bile acids in control rats were deconjugated, but they were excreted into feces as conjugates after treatment with the antibiotics. As shown in Table 4, about 94% of the fecal bile acids in the LMOX-treated rats were conjugated with taurine. This value was lower (70%) in the CFTX-treated rats. However, β-muricholic acid was 100%

conjugated with taurine in both groups. Cholic acid was 93 and 53% conjugated in the LMOX- and CFTX-treated rats, respectively. Neither glycine conjugates nor sulfates were detected.

Bile flow and biliary lipid concentrations. The bile flow and biliary lipid concentrations are given in Table 5. The bile flow of the treated rats was lower than that of the control rats, but this difference was statistically insignificant. The biliary cholesterol and phospholipid concentrations were not changed, but the bile acid concentration increased in the treated rats, and the increases were sustained until day 49.

Biliary bile acid composition. The changes in the biliary bile acid composition are given in Table 6. Rat biliary bile acids consisted of two major primary bile acids, cholic and β-muricholic acids, as well as minor primary and secondary bile acids. The percentages of cholic acid were similar in all the groups, while those of β-muricholic acid were increased by the antibiotics (day 7) but rather decreased after treatment was stopped (day 49).

Pool size of bile acids. The pool size of bile acids was calculated by totaling the amounts in the bile (collected for 30 min) and the small and large intestines (Table 7). The pool size was increased by the antibiotics (day 7), but returned to the control level after treatment was stopped (day 49). The percentages of cholic acid were similar in all the groups, but those of β-muricholic acid increased on day 7 in the antibiotic-treated groups. The percentages of the secondary bile acids, though they were minor, decreased on day 7 but returned to the control values on day 49.

The small intestine contained most of bile acids in the pool, amounting to around 80%. The percentages in the large intestine on day 7 were lower in the treated rats than in the controls, though the weight of the large intestine increased by almost twice in the treated rats (Table 1).

DISCUSSION

The antibiotics, LMOX and CFTX, decreased intestinal bacteria, increased the cecal weight, and caused changes in bile acid and cholesterol metabolism in conventional male rats. In the LMOX-treated rats, most of the intestinal bacteria disap-

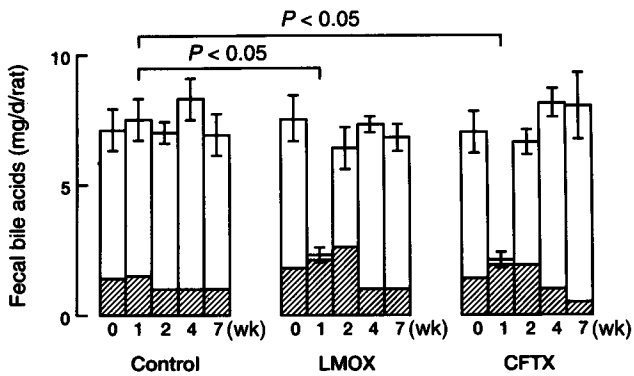

FIG. 2. Changes in fecal bile acids in control and antibiotic-treated rats. The columns and bars show the mean values and standard errors. Shaded columns correspond to the mean value of the primary bile acids. Both antibiotics, LMOX and CFTX, were given intravenously once a day for six days (day 1 through day 6). See Figure 1 for abbreviations.

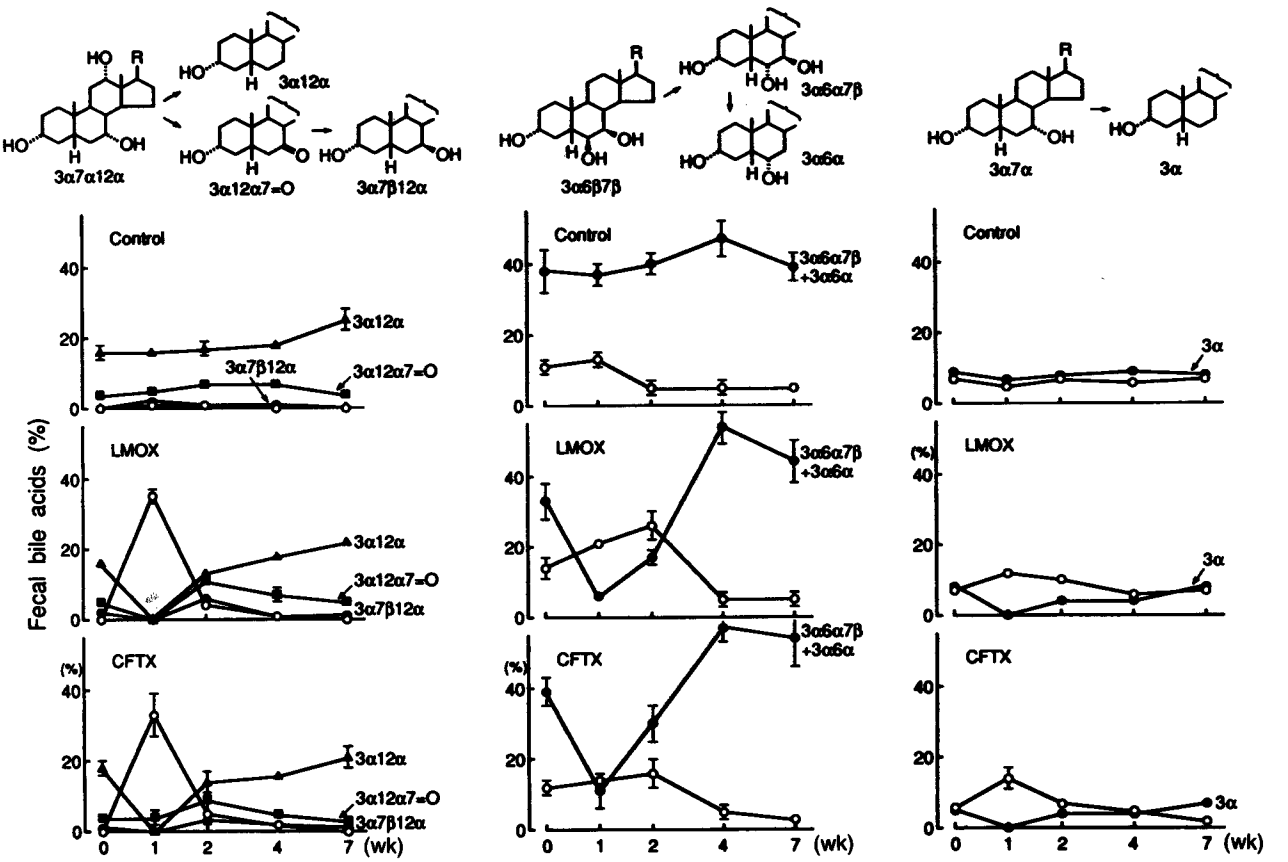

FIG. 3. Changes in fecal bile acid composition in control and antibiotic-treated rats. Both antibiotics, LMOX and CFTX, were given intravenously once a day for six days (day 1 through day 6). The left part shows the changes in cholic acid, the middle in β-muricholic acid, and the right in chenodeoxycholic acid. These primary bile acids are shown as open circles. See Figure 1 for abbreviations.

peared, but *Streptococci* survived in all of them and a few *Lactobacilli* remained in one out of three.

These data were similar to the findings of Benno *et al.* (11), who examined the effect of LMOX on fecal bacteria in humans and reported a significant decrease in most of the anaerobes, but one species of *Clostridium* (*C. innocum*), as well as *Lactobacillus*, *Streptococcus*, and *Candida* survived. In the CFTX-treated rats, *Enterobacteriacea* disappeared but *Clostridium*-others (*Clostridium* species other than *C. difficile*), *Lactobacillus*, and *Streptococcaceae* remained. The difference in surviving microflora between LMOX and CFTX was partially due to the biliary excretion of the antibiotics. The biliary excretion of LMOX is about 20% after intravenous injection (8), but that of CFTX is maximally 8% in rats (9,10). The fecal microflora, however, returned to the initial counts one week after cessation of the treatment in both groups.

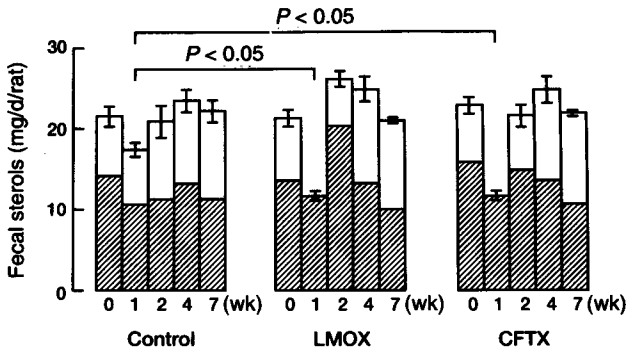

FIG. 4. Changes in fecal sterols in control and antibiotic-treated rats. The columns and bars show the mean values and standard errors. Shaded columns correspond to the mean values of cholesterol. Both antibiotics, LMOX and CFTX, were given intravenously once a day for six days (day 1 through day 6). See Figure 1 for abbreviations.

A pronounced enlargement of the cecum is a general feature in germ-free rodents (23–25). Wostmann *et al.* (25) have suggested that this is due to lack of an enzyme(s) of microbial origin that inhibits the accumulation of high molecular weight and negatively charged mucopolysaccharide(s) in the cecum. In this study, LMOX caused a larger decrease in the fecal bacterial counts and a larger increase in the cecum weight when compared with CFTX.

The diet-intake and body weight gain decreased during the treatment, though the maximal "no effect" dose of LMOX was reported to be 1260 mg/kg/d (i.v.) from a subacute toxicity study in rats (26). Handling of rats sometimes caused decreases in food-intake and body weight gain, but the larger decreases in the antibiotic-treated rats were statistically significant.

During the treatment with the antibiotics, the level of secondary bile acids decreased with a concomitant increase in that of primary bile acids in the feces. Furthermore, most of the primary bile acids in the feces were conjugated with taurine. Glycine-conjugated bile acids, as well as those conjugated with taurine and their sulfates, are found in various animal species, but glycine–conjugates and sulfates are found at low levels in rats (27). Neither glycine–conjugates nor sulfates were detectable in this study. The percentages of taurine–conjugates differed according to individual bile acids and antibiotics, the highest level being with β-muricholic acid and the lowest with chenodeoxycholic and cholic acids in the LMOX- and CFTX-treated rats, respectively. We demonstrated that *Bacteroides vulgatus* preferentially deconjugated tauro-β-muricholic acid and *Bifidobacterium longum* taurocholic acid (14). *Clostridium ramosum* deconjugated both bile acids, but *Escherichia coli* deconjugated neither. Furthermore, we found that *Peptostreptococcus products* and *Lactobacillus gasseri* deconjugated both bile acids in rats, though to a lesser extent than that of *C. ramosum* (28). In this study, the bacteria remaining after the antibiotic administration exerted deconjugation activities to some extents, especially in the presence of CFTX. Cholylglycine hydrolase isolated from *C. perfringence* (29,30) and *B. fragilis* (31) can hydrolyze both taurocholic acid and taurochenodeoxycholic acid, but a hydrolase isolated from *B. vulgatus* (32) preferentially hydrolyzes taurochenodeoxycholic and tauro-β-muricholic acids with far less activity to taurocholic acid. The low percentages of taurochenodeoxycholic acid in the CFTX-treated rats can be explained by the high counts of *Clostridium*-others in this group. On the other hand, *B. vulgatus* possesses high hydrolase activity for tauro-β-muricholic acid (32), but this genus (*Bacteroides*) is sensitive to LMOX and CFTX (Table 2) (11). This would explain the high percentages of tauro-β-muricholic acid in the feces.

A major secondary bile acid from cholic acid is deoxycholic acid, but a small amount of 7β-cholic acid is also formed probably *via* 7-oxo-deoxycholic acid. The latter is also converted to deoxycholic acid *in vivo* (33). LMOX and CFTX decreased these secondary bile acids, while the primary cholic acid concomitantly increased. These changes returned to the initial state three weeks after the treatment was stopped. Chenodeoxycholic acid is a minor primary bile acid in the rat, and its secondary bile acid is lithocholic acid. LMOX and CFTX decreased lithocholic acid and increased chenodeoxycholic acid levels, but they returned to the initial state three weeks after cessation of the treatment. Another major primary bile acid in rats is β-muricholic acid which is formed from chenodeoxycholic acid in the liver (34). Intestinal bacteria convert β-muricholic acid to β-hyocholic acid; Robben *et al.* (35) have proposed that *Clostridium* sp. is responsible not only for this conversion, but also for the further conversion to hyodeoxycholic acid by bacterial 7β-dehydroxylation. Ohta *et al.* (36) have postulated that hyodeoxycholic acid is formed directly from β-muricholic acid by 7β-dehydroxylation *via* 3α,7β-dihydroxychol-6-enoic acid. When hyodeoxycholic acid was given to rats, no significant increase in β-hyocholic acid was found in the feces, but when ursodeoxycholic acid was given, β-hyocholic acid, hyodeoxycholic acid, and also β-muricholic acid levels increased in the feces (37). It is presumed, therefore, that ursodeoxycholic acid is converted to β-muricholic acid in the liver, then to β-hyocholic acid and to hyodeoxycholic acid by intestinal bacteria in the rat. The amounts of β-hyocholic acid plus hyodeoxycholic acid in the feces were quite constant, though they varied individually in inverse proportion (38,39). The sum of β-hyocholic acid and hyodeoxycholic acid was almost constant during the period of experiment in the control rats, but were decreased by LMOX and CFTX, then restored the initial values about three weeks after stop of the treatment.

As long as hepatic and intestinal function are unaltered, the amounts of bile acids excreted into feces are considered to correspond to the amounts of bile acids synthesized in the liver. The fecal excretion of bile acids markedly decreased during the antibiotic treatment and returned to the control level after stopping the treatment. However, since the bile acid pools in the treated rats increased during the period, some of the bile acids, which normally would have been excreted into feces, were stored in the pool. However, the decrease in the fecal bile acids was far larger than the increase in the pool. Therefore, it seems likely that bile acid synthesis was decreased by the antibiotics. In addition, it is possible that antibiotic-induced changes in intestinal function could have resulted in increased resorption of bile acids. Both cholic and chenodeoxycholic acid groups decreased during the treatment, but the decrease in the latter was larger than that in the former. In other words, the synthesis of β-muricholic acid may have decreased more than that of cholic acid, and this could explain why β-muricholic acid in the feces did not increase as much as cholic acid during the antibiotic administration (Fig. 3).

It also was presumed that the decrease in deconjugation and transformation of the primary bile acids increased the reabsorption of bile acids in the intestine, resulting in an increase in the bile acid pool. In other words, the secondary bile acids were less absorbable than the conjugated primary bile acids in the ileum.

Cholesterol is also transformed by intestinal bacteria mainly to coprostanol (3), involving cholest-4-en-3-one and coprostanone (2). Coprostanol comprised about 40% of the total sterols in feces before LMOX and CFTX were administered, but disappeared during the treatment and appeared again thereafter. The percentages of coprostanol in the treated rats were lower than those in the control rats one week after the treatment stopped, but returned to the control level three weeks later. In addition, the amounts of the total sterols in feces were lower during antibiotic administration, probably due to a decrease in the food intake during this period, since the diet contained 0.05–0.1% of cholesterol.

Bile acid metabolism in germ-free rats differs from that in conventional rats (40). Taurine conjugated primary bile acids are detected in germ-free rats, but various bile acids, including the secondary bile acids, are found in conventional rats. The pool size of bile acids is remarkably expanded, the biliary bile acid secretion slightly increased, and the apparent bile acid synthesis based upon reduced fecal bile acid excretion, decreased when compared with the age-matched conventional rats. The relative synthesis of cholic acid is decreased compared to chenodeoxycholic acid (actually β-muricholic acid in the rat), resulting in a decrease in the cholic acid group/chenodeoxycholic acid group ratio in germ-free rats. These changes in germ-free rats seem to resemble those in the present antibiotic-treated rats, except for a remarkable increase in the biliary bile acid secretion in the antibiotic-treated rats.

The evidence described above suggested that treating conventional rats with broad spectrum β-lactam antibiotics brought their bile acid and cholesterol metabolism to the levels of those in a germ-free state. The recovery of fecal microflora population occurred one week after cessation of the treatment, but that of bile acid and cholesterol metabolism required at least three weeks.

ACKNOWLEDGMENTS

We thank Haruto Takase and Yasuharu Nomura of the Research & Development Division of Diagnostics for their help and valuable discussions. We also thank Michiko Katayama and Keiko Suzumura for help in preparing the manuscript.

Dietary Fatty Acid Composition Induces Comparable Changes in Cardiolipin Fatty Acid Profile of Heart and Brain Mitochondria

ABSTRACT: The fatty acid profile of cardiolipin (CL) from brain and cardiac mitochondria was measured to determine whether CL isolated from these two tissue sources responded similarly to alterations in dietary fat composition. Male Wistar rats were fed 20% (w/w) diets containing 2 to 12% (w/w) 18:2n-6 for four weeks. Despite higher baseline levels of CL 18:2n-6 in cardiac (54 ± 1% of total fatty acids) compared to brain (13 ± 1%) mitochondria, CL 18:2n-6 levels increased in proportion to dietary 18:2 levels. The degree of change in 18:2n-6 was comparable with both tissues showing an approximate 1.5- to 2-fold increase. The time course of changes in CL fatty acid profile was examined in a subsequent experiment in which animals were fed 20% (w/w) fat diets containing either 3 or 15% α-linoleate. Changes in cardiac CL 18:1, 18:2n-6, and 22:6n-3 levels were observed within one week of feeding. While statistically significant differences were not observed in brain CL until the second week of feeding, the time course did not differ substantively from that observed in heart. The results from this study suggest that while baseline fatty acid profile of cardiac and neural CL differ, mitochondria from both tissues show comparable sensitivity to changes in dietary fat composition. Furthermore, it would appear that the turnover rate of fatty acids in CL is similar in both tissues.
Lipids 31, 611–616 (1996).

Qualitative differences in dietary fat affect the fatty acid composition of most, if not all, membranes in mammalian species. These effects are more evident with essential fatty acid (EFA) deficiency, or during periods of rapid tissue, and hence biomembrane, accretion that characterize fetal and neonatal growth. The degree of sensitivity of membranes appears to differ, with it generally being considered that brain is less susceptible to dietary-induced changes in comparison to peripheral tissues (see for example Refs. 1–4), based originally on the assumption that the blood-brain barrier restricts the passage of fatty acids to brain (5). Nevertheless, dietary fat-induced alterations in brain phospholipid fatty acid profile are observed even in the absence of EFA deficiency when dietary treatment is commenced in post-weanling rats (6–8) and can be accompanied by changes in membrane-bound enzyme activity (9,10). The physiologic relevance of these diet-induced alterations can be attested to by the fact that behavioral changes, including pain sensitivity (11), feeding behavior (6,9), and cognition (12–15), occur in tandem with the biochemical alterations.

Most studies examining the effect of dietary fat on neural membrane fatty acid composition have focused upon differences in the long-chain polyenoic metabolites of linolenate (18:3n-3), namely eicosapentanoate (22:5n-3) and docosahexanoate (22:6n-3) (8,16–18). Recently we (19) described differences in neural α-linoleate (18:2n-6) in response to variable amounts of dietary EFA. The effect was most evident in mitochondrial cardiolipin (CL), and could be observed within one week of feeding the experimental diets. Maximal differences occurred after three weeks of dietary treatment.

Other reports have described the effect of dietary fat on mitochondrial fatty acid composition in peripheral tissues (20–27). However, specific comparisons between brain and peripheral tissues with respect to mitochondrial CL sensitivity to alterations in EFA have not been made. The objective of this study was to compare the effect of dietary 18:2n-6 on mitochondrial CL fatty acid composition in neural and cardiac tissues. We chose to compare the effect of dietary fat on the fatty acid composition of CL because mitochondria from these two tissues differ both from a biochemical and histologic perspective. That is, in comparison to brain mitochondria, mitochondria isolated from heart are more numerous (greater number of mitochondria/cell), have a larger inner membrane leaflet resulting in greater folding of the inner membrane, have higher amounts of CL in the inner leaflet, and have higher concentrations of 18:2n-6 within the CL. These differences in the mitochondria may result in different sensitivities to dietary-induced modification.

EXPERIMENTAL PROCEDURES

Animals and diets. Male Wistar rats (Charles River, St. Constant, Quebec, Canada) were housed individually in galva-

nized wire-mesh cages in a temperature-controlled environment (24 ± 1°C) with a 12-h light/dark cycle. Initial body weights were 60–90 g. Animals were weighed at the beginning and the end of the experimental period.

Diets were nutritionally adequate, purified granular mixtures containing 20% fat, 40% carbohydrate, 24% protein, 5% nonnutritive fiber, 2.5% vitamin mix, 5.1% mineral mix, and 0.25% L-methionine. A detailed description of diet ingredients has been published (6). Protein content was verified with the microkjeldahl technique (28). Diets contained vitamin E as an antioxidant (4400 I.U. α-tocopheryl acetate/kg diet). In similar diets, levels of thiobarbituric acid reactive substances ranged from 1.96 to 5.02 μmol/kg diet after 48 h at room temperature (29).

Experiment 1. Rats (n = 10–11/treatment) were randomly assigned to 20% (w/w) fat diets with polyunsaturated fatty acid (PUFA) content ranging from 2–12% (w/w) of total fat. Dietary fat profiles were obtained by blending oils as previously described (30), and fatty acid composition of mixed diets was determined by gas chromatography (Table 1). After rats consumed diets for 4 wk, they were decapitated, and hearts and brains were removed.

Experiment 2. Rats (n = 6 treatment) were randomly assigned to 20% (w/w) fat diets with either 3 or 15% (w/w) of total diet as 18:2n-6. The fatty acid profiles were designed to produce similar n-6/n-3 ratios (Table 2). Following 0, 1, 2, 4, or 6 wk, rats were decapitated and hearts and brains removed.

Isolation of mitochondria. Brain mitochondria were isolated according to the method of Whittaker and Barker (31). Freshly isolated brains were homogenized in 0.32 M sucrose and centrifuged at 3,000 × g at 1°C for 15 min. The supernatant was decanted and recentrifuged to obtain the P2 pellet containing mitochondria, synaptosomes, and myelin. This pellet was applied to a discontinuous sucrose gradient and centrifuged at 100,000 × g for 60 min at 1°C. The mitochondrial pellet was resuspended in 1 mL isolation medium containing 0.21 M mannitol, 0.07 M sucrose, 0.1 M EDTA, 0.01 M Epps, pH 7.4, and heparin (330 U/mL solution).

TABLE 1
Fatty Acid Composition of Experiment 1 Diets[a]

Fatty acid	Diets					
	1	2	3	4	5	6
	(% of total diet)					
16:0	5.72	3.14	4.78	3.74	4.28	2.30
16:1	0.62	0.28	0.46	0.28	0.40	ND[b]
18:0	4.10	0.10	2.52	2.30	2.48	1.62
18:1	7.36	13.90	7.58	7.04	6.18	2.90

TABLE 2
Fatty Acid Composition of Experiment 2 Diets[a]

Fatty acid	3% 18:2n-6	15% 18:2n-6
	(% of total diet)	
16:0	5.15	1.42
16:1	0.40	ND[b]
18:0	3.22	0.50
18:1	8.34	2.57
18:2n-6	2.82	15.04
18:3n-3	0.07	0.47
SFA	8.37	1.92
MUFA	8.74	2.57
PUFA	2.89	15.51
n-6/n-3	41.40	32.00

[a]Fat was extracted from premixed diets, and fatty acid profiles were determined by gas chromatography. Abbreviations as in Table 1.
[b]ND = Not detected.

Heart mitochondria were isolated by the method of Schnaitman and Greenwalt (32). Freshly removed hearts were washed to remove excess blood and were then individually homogenized in 10 vol of cold isolation medium (as above). The homogenate was centrifuged at 500 × g at 1°C, filtered to remove suspended lipid droplets, then recentrifuged at 12,000 × g at 1°C. The mitochondrial pellet was washed with 10 mL of isolation medium containing 0.5% (wt/vol) heparin, recentrifuged, and suspended in 1 mL of isolation medium.

Fatty acid analysis. Lipids were extracted from membrane preparations by a modification of the method of Folch *et al.* (33). The CL fraction was separated by thin-layer chromatography (34), and fatty acid methyl esters were prepared by methylation with boron trifluoride (35). CL fatty acid methyl esters were analyzed by gas–liquid chromatography using flame-ionization detection (Vista 402; Varian, Palo Alto, CA). Fatty acids were identified by comparing their retention times with those of authentic standards (Nu-Chek-Prep, Elysian, MN). Results are expressed as percentage of total fatty acids.

Statistical analyses. The sample size was selected to give power = 0.8. Data were analyzed using SAS 6.03 (SAS Institute, Inc., Cary, NC). For all analyses, the acceptable level of significance was 0.5%. Experiment 1 data were analyzed by two-way analysis of variance (ANOVA) to examine the main effects of diet, organ, and their interaction. Within organ comparisons of fatty acid, data were analyzed by one-way ANOVA followed by Student-Newman-Keul's test for multiple comparisons (36).

Data for experiment 2 were first analyzed by a three-factor ANOVA with diet, organ, and time as main effects. Because of many significant three-factor interactions, two-way ANOVA was used to test for the following interactions: diet by organ, diet by time, and organ by time. One-way ANOVA followed by Student-Newman-Keul's test for multiple comparisons was performed on data from each organ at each time period to examine the effect of diet on cardiac and neural membrane CL fatty acid composition.

RESULTS

Experiment 1. Both diet and organ had significant main effects on CL fatty acid profiles (Table 3). In addition, there were diet by organ interactions for 20:4n-6 and other less metabolically important fatty acids, 20:2n-6 and 20:3n-6. Heart CL had greater levels of 18:2n-6 and PUFA, and lower levels of 18:1, 20:4n-6, 22:6n-3, saturated (SFA) and monounsaturated (MUFA) fatty acids in comparison to neural mitochondria (Fig. 1).

To more closely examine the effect of dietary fat on CL fatty acid profile, data for each organ were subjected to an analysis of the simple effects of diet (37). In brain, diets with greater amounts of 18:2n-6 resulted in a higher percentage of CL 18:2n-6 and PUFA, and a lower percentage of 18:1, 22:6n-3, and MUFA than diets with lesser amounts of dietary 18:2n-6 (Fig. 2). Percentages of neural CL 18:0, 20:4n-6, and SFA were not affected by dietary fat.

Dietary fat had a similar effect on heart CL fatty acid composition. Rats that consumed diets with a greater amounts of 18:2n-6 tended to have a higher percentage of CL 18:2n-6 and a lower percentage of 18:1, 20:4n-6, 22:6n-3, and MUFA compared to rats that consumed diets with lesser amounts of 18:2n-6 (Fig. 2). Dietary fat did not affect heart CL fatty acid profiles of 18:0, SFA, or PUFA.

It is important to note that the lack of significant organ by diet interaction for 18:2n-6 suggests that the proportional changes (i.e., slopes of the response) were similar for both tissues despite the absolute differences in CL 18:2n-6. That is, CL 18:2n-6 increased by 1.5- to 2-fold in each tissue when comparing diets with the highest and lowest PUFA content, suggesting that the tissues responded similarly to the dietary manipulation. Nevertheless, since baseline levels of CL 18:2n-6 differ substantially (see Fig. 3), the absolute increase in CL 18:2n-6 in heart was 17% compared to an 8% increase in brain.

Experiment 2. When the effects of diet, time, and organ were examined using three-way ANOVA, third-order interactions for membrane CL 18:0, 18:2n-6, 20:4n-6, 22:4n-6, 22:6n-3, SFA, and PUFA were observed (data not shown). This indicates that the effect of diet on CL fatty acid composition is dependent upon the organ, i.e., heart or brain, and duration of treatment, i.e., 0 to 6 wk. Analysis of the data also revealed several two-way interactions (data not shown). There was a significant diet by time interaction in heart CL 20:4n-6 and a significant organ by time interaction for 18:2n-6 and 20:4n-6 in rats fed the high 18:2n-6 diet, and for 20:4n-6 in rats fed the low 18:2n-6 diet.

TABLE 3
Main Effects of Diet, Organ, and Their Interaction on Mitochondrial Membrane Cardiolipin Fatty Acid Composition

Fatty acid	Diet	Organ	Diet by organ
		P-value	
18:0	N.S.[a]	N.S.	N.S
18:1	0.0001	0.0001	N.S.
18:2n-6	0.0001	0.0001	N.S.
20:4n-6	0.001	0.0001	0.002
22:4n-6	0.0004	0.0001	N.S.
22:6n-3	0.0001	0.0001	N.S.
SFA	N.S.	0.03	N.S.
U.I.[b]	N.S.	0.0001	N.S.

[a]N.S. = Not significant. [b]U.I. = Unsaturation index. Other abbreviation as in Table 1.

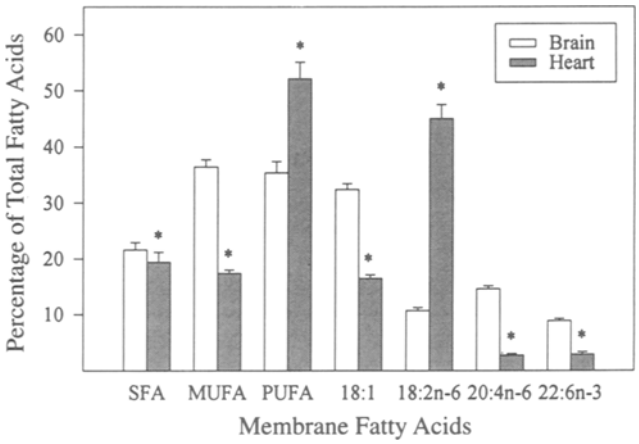

FIG. 1. Effect of organ on fatty acid composition of mitochondrial cardiolipin. Weanling rats were randomly assigned to 20% (w/w) fat diets with polyunsaturated fatty acid content ranging from 3 to 13% (w/w) of total diet. Diets were consumed for four weeks. Values are mean ± SEM; n = 10–11/treatment. An asterisk indicates a significant difference between organs ($P < 0.05$); SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

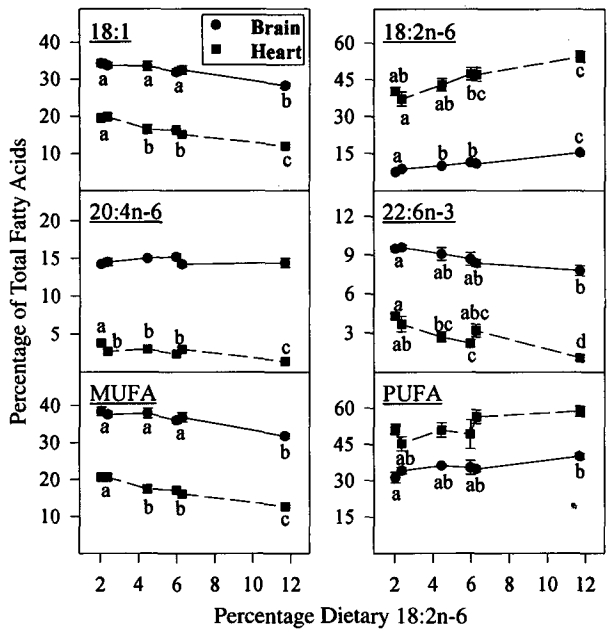

FIG. 2. Fatty acid composition of mitochondrial cardiolipin by organ and diet. Weanling rats consumed 20% (w/w) fat diets with 3 to 13% (w/w) polyunsaturated fatty acid content for four weeks. Values are mean ± SEM; n = 10–11/treatment. Values within the same organ and not sharing a common superscripted letter are significantly different ($P < 0.05$). Abbreviations as in Figure 1.

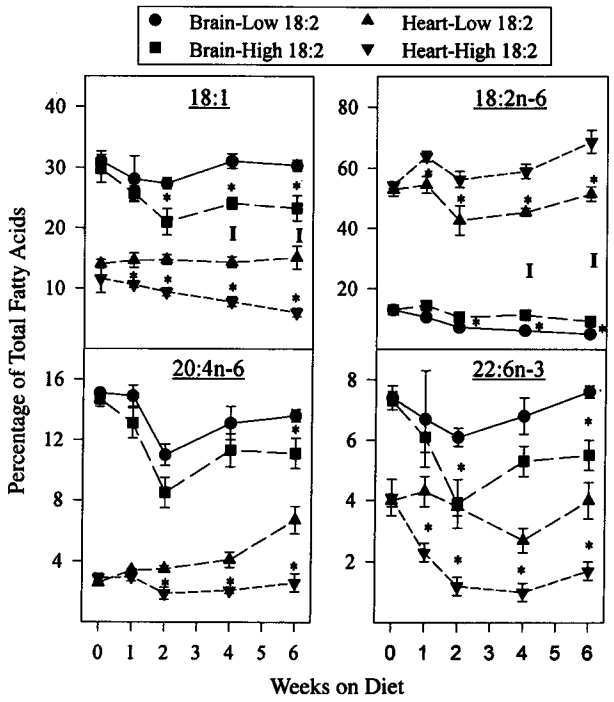

FIG. 3. Fatty acid composition of mitochondrial cardiolipin by organ and diet. Weanling rats consumed 20% (w/w) fat diets with either 3 or 15% of total diet as 18:2n-6 for one, two, four, or six weeks. Values are mean ± SEM; n = 6/treatment. An asterisk indicates a significant difference between diets within each organ and "I" indicates a significant diet by organ interaction ($P < 0.05$).

Examination of diet and organ effects within each time period revealed a significant interaction for CL 18:1 and 18:2n-6 after 4 and 6 wk of feeding the experimental diets (Fig. 3). In addition, there was a significant interaction term for PUFA at 6 wk (data not shown). An analysis of the simple effects of diet within each organ within each time revealed a significant diet effect (Fig. 3). Rats that consumed the high 18:2n-6 diet had greater levels of neural mitochondrial CL 18:2n-6 after 2, 4, or 6 wk than rats fed the low 18:2n-6 diet. In contrast, neural mitochondrial CL 18:1 was lower after 2, 4, or 6 wk in rats fed the high 18:2n-6 diet compared to rats fed the low 18:2n-6 diet. CL 22:6n-3 was lower in rats fed the high 18:2n-6 diets after 2 and 6 wk, whereas CL 20:4n-6 was lower in rats fed the high 18:2n-6 only after 6 wk.

Heart CL fatty acids showed a similar pattern of changes. Consistent with findings in experiment 1, the absolute differences between dietary treatments tended to be greater in heart mitochondrial CL fatty acids than in brain. CL 18:2n-6 was greater in hearts of rats fed the high 18:2n-6 diet for only 1 wk. This difference was evident at each subsequent time point. In contrast, heart mitochondrial CL 18:1 and 22:6n-3 were significantly lower in rats fed the high 18:2n-6 diet compared to those fed the low 18:2n-6 diet at each time point. In addition, CL 20:4n-6 was lower in rats fed the high 18:2n-6 diet at 2, 4, and 6 wk.

DISCUSSION

The results of this study demonstrated that both heart and brain mitochondrial membrane CL fatty acids are affected by dietary fat despite large biochemical and histologic differences in mitochondria from these two tissues. Importantly, the results suggest that mitochondria isolated from both tissues show similar sensitivity to dietary-fat induced alterations in CL fatty acid profile. That is, membrane CL levels of 18:2n-6 and PUFA increased, whereas the levels of 18:1, 22:6n-3, and MUFA decreased with increasing 18:2n-6 content (Fig. 2), and the magnitude (slope) of the response was similar in both tissues. When changes in CL fatty acid composition were examined periodically during a 6-wk interval, the response to dietary fat treatment tended to follow a similar pattern in both organs. Nevertheless, a significant effect of diet was noted somewhat earlier in cardiac tissue compared to neural tissue for 18:1, 18:2n-6, 20:4n-6, and 22:6n-3 (Fig. 3). These results suggest that changes in heart mitochondria display a faster time course in comparison to brain; however, brain mitochondrial CL fatty acid changes only lagged behind by 1 wk.

One objective of this study was to determine whether central and peripheral tissues would respond in a similar direction and similar degree to manipulations in dietary fatty acid composition. Previous work has demonstrated that mitochondria from a variety of peripheral tissues (liver, heart, kidney, and testes) responded differently to increasing dietary levels of 18:2n-6 (23). In general, CL 18:2n-6 levels increased in proportion to the dietary content of α-linoleate with CL from testes being notably resistant to the dietary manipulation. Our present data continue to show that brain mitochondrial CL is responsive to dietary α-linoleate content (19) and now suggest that the sensitivity of brain CL to dietary α-linoleate levels is comparable to that observed in CL isolated from cardiac mitochondria. That is, the proportional difference in CL 18:2n-6 between the diets with lowest and highest α-linoleate content was similar; nevertheless, the absolute difference in CL 18:2n-6 levels was greater in heart in comparison to brain.

There is a clear preference in heart mitochondria for the incorporation of 18:2n-6 into CL. α-Linoleate represents between 40 and 90% of total CL fatty acids depending upon the diet fed and is preferentially located in the 1(1″)- rather than the 2(2″)-position (23,25). In contrast, brain mitochondria has high levels of both 18:1 as well as the elongated EFA metabolites, namely 20:4n-6 and 22:6n-3. This overall profile of fatty acids in brain CL differs from that reported in testes (23) which also has low levels of 18:2n-6, but substitutes predominantly 16:0 rather than 18:1 in its place.

The degree to which this difference in fatty acid profile of CL from these various tissues represents differences in directed enzymatic incorporation of fatty acids or simply alterations in fatty acid supply to the mitochondria is uncertain. Like most other phospholipids, reacylation to obtain desirable fatty acid profiles is felt to occur post synthesis (38). However, unlike other phospholipids, synthesis of CL is be-

lieved to occur on the inner side of the mitochondria (39). Thus, fatty acid availability for reacylation will be governed by inner mitochondrial rather than cytosolic levels of fatty acids. Clearly the higher baseline levels of linoleate in mitochondria from most tissues is suggestive of greater preference for its incorporation into CL. Furthermore, studies demonstrating a preferential incorporation of *cis*-9,*cis*-12,*trans*-15 18:3 into CL in the absence of α-linoleic acid (26) also point to enzymatic specificity for 18:2n-6. The results of this study demonstrate that as dietary intake of α-linoleate increases parallel increases in α-linoleate incorporation into CL in brain occurs. This could suggest that brain mitochondria also has a preference for 18:2n-6, but that local supply is limiting its incorporation. This conclusion is supported by the fact that brain CL substitutes 18:2n-6 with 18:1n-9, 20:4n-6, and 22:6n-3 rather than 16:0 (as in testes) in an attempt to maintain overall chain length and unsaturation. Thus, it would appear that factors governing overall supply of fatty acids to neural tissues, and specifically to mitochondria within neural tissues, will have a specific effect on the fatty acid profile of brain CL.

Unlike many peripheral tissues, fatty acids that are components of phospholipids and triacylglycerides are not readily available to brain since they are not readily transported through the cerebral capillaries which form the anatomical basis of the blood brain barrier (40). Rather, plasma free fatty acids probably provide an important source of fatty acids to brain. Since free fatty acids are bound by high affinity sites on circulating albumin (40–42), only approximately 5% of plasma free fatty acids are unidirectionally taken up by the brain on a single pass through the cerebral microcirculation (41). Although recent studies have established that transport of SFA into the brain is protein-mediated (40,42), 18:2n-6 may cross the blood brain barrier by simple diffusion (40,42). Alternatively, 18:2n-6 may be taken up by target tissues *via* a receptor-mediated endocytosis. Such a mechanism has been suggested for retinal transport of 22:6n-3 (17). Although the precise mechanism for transport of EFA into brain is ill-defined at this time, these data collectively suggest that factors governing the plasma profile of free fatty acids, rather than those contained within lipoproteins, will have the greatest impact on brain fatty acid availability and, hence, mitochondrial CL fatty acid profile.

The time course of mitochondrial membrane changes observed in this study is consistent with our knowledge of its rate of turnover. The half-life of fatty acyl components has been reported to be about 3 d for fatty acids in CL obtained from peripheral tissues. Using this estimate, about 12 d of diet treatment would be required for greater than 90% turnover of phospholipid fatty acyl chains (21). Thus our data from cardiac CL is readily explained on the basis of this estimate. Nevertheless, it has generally been believed that the fatty acid turnover rate of brain membrane phospholipids is slower than that of peripheral tissues. This assumption has been based upon observations such as a lower rate of activity for CoA ligase, a microsomal enzyme that catalyzes the initial step for acylation of fatty acids. Additionally, experiments using an EFA deficiency model indicate that brain shows a slower rate of depletion of the EFA in comparison to peripheral tissues (1). Paradoxically, normal neural fatty acid profiles occur rapidly when EFA are restored to the diets of deficient rats. These observations could be consistent with a higher percentage of reutilization of fatty acids for reacylation reactions in brain in comparison to peripheral tissues rather than a decreased rate of phospholipid turnover. Such an argument would then be consistent with our present data suggesting, at least for CL, that the turnover rate of this phospholipid in brain and cardiac tissues does not differ substantively.

The degree to which these alterations in CL fatty acid profile are of physiologic relevance to the animal is ill-defined. However, CL is believed to be an integral part of some protein complexes where it may influence their conformation and hence activity (39). For example, cytochrome C oxidase, F_1-F_0-ATPase and the ADP/ATP carrier appear to be associated with CL (23,27). Changes in the affinity of CL to enzymes occur with changes in the unsaturation of the CL fatty acids. Furthermore, diets rich in sardine oil altered the fatty acid profile of cardiac CL and decreased the activity of cytochrome c oxidase and increased the activity of F_1-F_0-ATPase (27). These dietary effects on enzyme function may occur as a consequence of a perturbed fluid environment that affects protein aggregation, or due to changes in boundary lipids surrounding the membrane protein that affects conformation (2). Nevertheless, results from these studies suggest that the diet-induced alterations in CL profile may influence mitochondrial function, particularly as it relates to electron transport.

In summary, results from this study continue to demonstrate that brain CL fatty acid profile is sensitive to dietary fat consumption with notable changes in α-linoleate levels occurring. Despite large differences in baseline 18:2n-6 levels in neural and cardiac CL, the degree of sensitivity to dietary fat composition is comparable in terms of both the time course and degree of change observed. These results suggest that brain membranes continue to show sensitivity to dietary fat consumption even beyond periods of rapid brain growth and development.

ABSTRACT: The effect of fish oil high in docosahexaenoic acid (22:6n-3) and low in eicosapentaenoic acid (20:5n-3) in formula on blood lipids and growth of full-term infants was studied. Infants were fed formula with about 15% oleic acid (18:1), 32% linoleic acid (18:2n-6), 4.9% linolenic acid (18:3n-3) and 0, 0.10, or 0.22% 22:6n-3, or 35% 18:1, 20% 18:2n-6, 2.1% 18:3n-3 and 0, 0.11, or 0.24% 22:6n-3 from 3 d to 16 wk of age (n = 16,18,17,21,17,16, respectively). The formulae had <0.1% 20:5n-3 and no arachidonic acid (20:4n-6). Breast-fed infants (n = 26) were also studied. Plasma phospholipid and red blood cell (RBC) phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fatty acids were determined at 3 d and 4, 8, and 16 wk of age. These longitudinal analyses showed differences in blood lipid 22:6n-3 between breast-fed and formula-fed infants depending on the feeding duration. At 16 wk, infants fed formula with 0.10, 0.11% 22:6n-3, or 0.22% 22:6n-3 had similar 22:6n-3 levels in the plasma phospholipid and RBC PC and PE compared with breast-fed infants, and higher 22:6n-3 than infants fed formula without 22:6n-3. Formula with 0.24% 22:6n-3, however, resulted in higher plasma phospholipid 22:6n-3 than in breast-fed infants at 16, but not 4 or 8 wk of age. Plasma and RBC phospholipid 20:4n-6 was lower in formula-fed than breast-fed infants, but no differences in growth were found. Higher blood lipid C_{20} and C_{22} n-6 and n-3 fatty acids in infants fed formula with 20% 18:2n-6 and 2.4% 18:3n-3 compared with 32% 18:2n-6 and 4.9% 18:3n-3 show the increase in blood lipid 22:6n-3 in response to dietary 22:6n-3 depending on other fatty acids in the formula.
Lipids 31, 617–625 (1996).

Docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (20:4n-6) are long-chain polyunsaturated fatty acids which are present in cell membrane phospholipids and are important to many biochemical and physiological functions (1). Synthesis of 22:6n-3 and 20:4n-6 occurs *in vivo* by desaturation and elongation of the dietary essential fatty acids, linolenic acid (18:3n-3), and linoleic acid (18:2n-6), respectively (1–3). Human milk fatty acids usually contain 0.1 to 0.4% 22:6n-3, about 0.5% 20:4n-6 and variable amounts of 18:2n-6 and 18:3n-3 (4). Plasma and red blood cell (RBC) phospholipid levels of 22:6n-3 are lower in infants fed formula containing 18:3n-3 (but lacking 22:6n-3) than in most breast-fed infants (1,5–8). This has led to suggestions that 22:6n-3 should be added to formula, and results of several studies with term and preterm infants fed formula containing 22:6n-3 (9–15) have been published. In nonhuman primates and rodents, diets very low in 18:3n-3 (<0.1% energy) result in decreased brain and retina levels of 22:6n-3, altered learning abilities, and reduced visual function (1,16–18). In these species, a dietary source of 22:6n-3 does not seem to be necessary to achieve high brain and retina 22:6n-3 as long as the diet provides sufficient 18:3n-3. The importance of a dietary source of 22:6n-3 in healthy term infants fed with adequate amounts of 18:3n-3 is controversial (5,8,9,14,15,19,20). Despite this, it is reasonable to try to modify infant formulae to achieve blood lipid levels of 22:6n-3 in formula-fed infants which are similar to those of breast-fed infants.

Several studies have shown that plasma and RBC levels of 22:6n-3 in young infants can be increased by providing a dietary source of 22:6n-3 (10,11,15). In one study with premature infants, formula with 0.2% 22:6n-3 and 0.3% eicosapentaenoic acid (20:5n-3) from fish oil resulted in higher visual acuity scores at two and four months post-term, reduced blood lipid 20:4n-6, and lower growth and lower novelty preference scores and Bayley psychomotor, but not mental, developmental index scores than in premature infants fed formula without fish oil (11–13). It is not clear if these problems were due to the dietary 20:5n-3, or the relatively high total amount of n-3 fatty acids in the formula. Studies with piglets, however, have shown the amounts of 18:2n-6 and 18:3n-3 (and 18:1) in formula also influence blood and tissue levels of C_{20} and C_{22} n-6 and n-3 fatty acids (21). The present study, therefore, was undertaken to determine: (i) the amount of an oil high in 22:6n-3 and low in 20:5n-3 needed in formula to achieve a similar blood lipid 22:6n-3 to that of breast-fed infants, and (ii) if the amounts of 18:2n-6 and 18:3n-3 (and

18:1) in formula alter the infant's blood lipid C_{20} and C_{22} n-6 and n-3 fatty acids. This was accomplished by comparison of the plasma and RBC phospholipid fatty acids and growth of term infants fed formula differing in 18:1, 18:2n-6, and 18:3n-3 and containing different amounts of a fish oil high in 22:6n-3 and low in 20:5n-3.

MATERIALS AND METHODS

Study design and subjects. This was a longitudinal study with term gestation infants fed one of six formulae using a 2 × 3 design, or breast-fed to 16 wk of age. Eligible infants were full-term (37–42 wk gestation), appropriate weight for gestational age, with 1 min Apgar scores greater than 7, and no known physical or metabolic disease, no history of intravenous lipid infusion or blood transfusion. Infants born to mothers with a history of diabetes, tuberculosis, or infection with known adverse effects on the fetus were excluded. Eligible infants were enrolled, monitored, and blood samples were obtained by the Philadelphia Association of Clinical Trials (PACT), Clinical Studies Inc., (Canton, OH), the Clinical Research Institute, (San Diego, CA), and the Children's Hospital of Philadelphia (Philadelphia, PA). Ethical approval for these studies was obtained from PACT Human Research Review Board, the Great Lakes Institutional Review Board, and Mercy Hospital and Medical Centre Institutional Review Committee, respectively. Written, informed consent was obtained from a parent for each infant prior to enrollment.

Infants who were not breast-fed were randomly assigned to one of the six formula groups within 3 d of birth using a randomization schedule developed centrally, which controlled for gender across the groups. Mothers were requested not to provide supplemental nutrients or foods, other than fluoride and water, to their infants during the study. Body weight, crown-heel length, and head circumference were measured at 3 d, and 4, 8, and 16 wk of age (5,6). Formula intake was obtained by parental recording for the 3 d immediately preceding each infant visit.

Formulas. The composition of the formulae was based on Similac® with Iron (Ross Products Division, Abbott Laboratories, Columbus, OH) with differences only in the fat blends (Table 1). Three formulae contained soy and coconut oil and were relatively low in 18:1, but high in 18:2n-6 and 18:3n-3 (high 18:2n-6 formulae). The other three formulae contained high-oleic safflower, soy and coconut oil, and were high in 18:1 but lower in 18:2n-6 and 18:3n-3 (low 18:2n-6 formulae). The formulae contained three different levels of a high 22:6n-3–low 20:5n-3 fish oil to provide 0.0, 0.10–0.11 and 0.22–0.24% 22:6n-3 in each of the fat blends. The formulae are abbreviated to indicate the fat blend and amount of 22:6n-3 as: high 18:2n-6—0.0%, 0.10 or 0.22% 22:6n-3, and low 18:2n-6—0.0%, 0.11 or 0.24% 22:6n-3. The ratio of 22:6n-3 to 20:5n-3 in the fish oil was approximately 4:1, resulting in less than 0.1% 20:5n-3 in all the formulas. Samples of breast milk were not obtained, but extensive analyses are available for North American women (4).

Blood sampling and analysis. Blood samples were collected by venipuncture from each infant at 3 d, and at 4, 8, and 16 wk of age. The plasma and RBC were separated by centrifugation, the RBC pellet washed, the samples coded, then immediately frozen and shipped on dry ice to Vancouver (6). Preliminary experiments were done to ensure that the methods of shipping resulted in delivery of frozen samples, and that there was no change in fatty acid composition of the samples during shipping or handling. Plasma and RBC lipids were extracted, and the plasma phospholipids and RBC phos-

[a]Values are percentage total oil blend and percentage total fatty acids by weight. The following are not shown but represent 0.1 to 4% total fatty acids: 6:0, 8:0, 10:0, 16:1n-7, 20:0, 20:1, 22:0, and 24:0. The formulae had no 20 or 22 carbon chain n-6 fatty acids; n.d. indicates not detected, <0.1 indicates 0.0 to 0.05%.

[b]Docosahexaenoic acid (DHA) reflects percentage of 22:6n-3 in the formula.

[c]From 5, values are ranges for mature human milk, 20:4n-6 0.3–0.8%.

[d]HO Saffl, high oleic safflower oil.

phatidylcholine (PC) and phosphatidylethanolamine (PE) were separated by thin-layer chromatography and recovered (5,6). The fatty acids were converted to their respective methyl esters, separated and quantified using capillary column gas–liquid chromatography (22).

Statistical analysis. Continuous variables were analyzed using analysis of variance (ANOVA) to determine the effects of the diets on the plasma and RBC fatty acids. When significant differences were found, Tukey's multiple comparison procedure was used to determine which pairwise comparisons were statistically significant. Contrasts within the ANOVA were used to make comparisons for specific formula fat combinations: low 18:2n-6 compared with high 18:2n-6, irrespective of 22:6n-3, comparison of the formulae with 22:6n-3 compared with and without 22:6n-3, and of formulae with 0.10–0.11% compared with 0.22–0.24% 22:6n-3. Categorical (frequency) variables for formula tolerance, such as predominant stool color and predominant stool consistency, were analyzed by Chi-Square, and were repeated after sorting the data to correspond with the contrasts in the ANOVA procedures. The level of statistical significance was set at 5% for all analyses.

RESULTS

Of 206 infants enrolled, 131 successfully completed the study with 26, 16, 18, 17, 21, 17, and 16 infants in the breast-fed, high 18:2n-6 formula with 0.0, 0.10, or 0.22% 22:6n-3, and low 18:2n-6 formula with 0.0, 0.11, and 0.24% 22:6n-3 groups, respectively. There were no statistically significant differences in weight at birth or gender among the groups (Table 2). Fifty-six infants were withdrawn because of failure to complete the protocol (stopped breast feeding, $n = 12$; failure to attend an appointment for blood collection, $n = 29$; feeding >10% energy/d with formula for breast-fed babies or formula other than the study formula for formula-fed infants $n = 7$; illness and voluntary withdrawal, $n = 8$) and 19 infants were withdrawn by the infant's physician because of loose stools, diarrhea, rash, spitting-up, vomiting, crying, fussiness, gassiness, or other problems. There were no statistically significant differences in the incidence of the latter problems among the groups; 9 infants were fed formula with no 22:6n-3 and 10 were fed formula with 22:6n-3; 8 were fed a low 18:2n-6, and 11 were fed a high 18:2n-6 formula.

(i) Growth. There were no significant differences in weight, length, weight-to-length ratios, or head circumference, or standardized Z-scores for weight, length, or head circumference among the groups (Table 2) or in energy intake among the formula-fed groups (data not shown). However, it should be noted that in order to detect a difference of one standard deviation in the measures of growth with 80% power, this study would have required 30 infants per group.

(ii) Plasma and RBC phospholipid fatty acids. The fatty acid composition of the infants' plasma phospholipid, RBC PC, and RBC PE at 16 wk of age is shown in Tables 3–5, respectively. The changes in the blood lipid 22:6n-3 from 3 d to 16 wk of age are illustrated in Figures 1–3.

n-3 Fatty acids. At 16 wk of age, the infants fed formula had a significantly higher plasma phospholipid percentage 18:3n-3 and lower 22:5n-3 than infants fed human milk (Table 3). The RBC PC and PE percentage 18:3n-3 was also significantly higher in infants fed the high 18:2n-6 formulae than in the breast-fed infants (Tables 4 and 5). The RBC PE and PC percentage 18:3n-3 of infants fed the low 18:2n-6 formulae, on the other hand, was not different from that of infants fed human milk, except for a significantly higher percentage 18:3n-3 in the RBC PE of infants fed the formula with 0.0% 22:6n-3 (Table 4). Infants fed the formulae with no 22:6n-3 had significantly lower levels of 22:6n-3 in plasma phospholipids (Table 3) and RBC PE (Table 4) and PC (Table

[a]Values given are means ± SE, 0.0 indicates value of <0.05 and >0.01. Values for 12:0, 14:0, 20:0, 22:0, 24:0, 14:1, 16:1, 22:1, 24:1, and 18:3n-6 are not shown. See Table 1 for abbreviation.
[b]Amount of DHA (% total fatty acids) in formula.
[c]Values for infants fed low 18:2n-6 formulae significantly different from values for infants fed high 18:2n-6 formulae, $P < 0.05$.
[d]Values for infants fed formulae with DHA different from infants fed same formulae without DHA, $P < 0.05$.
[e]Values for infants fed formula with 0.22 or 0.24% DHA different from values for infants fed the same formula with 0.10 or 0.11% DHA, $P < 0.05$.
[f]Values for group of infants fed formula significantly different from values for infants fed human milk, $P < 0.05$.

5) than the breast-fed infants. In contrast, infants fed the formula with 0.1 or 0.11% 22:6n-3, or the high 18:2n-6 formula with 0.22% 22:6n-3 had plasma phospholipid, and RBC PC and RBC PE levels of 22:6n-3 which were not different from the breast-fed infants. Infants fed the formula with low 18:2n-6 and 0.24% 22:6n-3, however, had a significantly higher percentage of 22:6n-3 in plasma phospholipids than the breast-fed infants. The levels of 22:6n-3 in RBC PC and PE were also higher in infants fed the low 18:2n-6 formula with 0.24% 22:6n-3 than in the breast-fed infants, but the differences were not of statistical significance.

Infants fed the formulae with high 18:2n-6 had consistently higher levels of 18:3n-3 and 22:5n-3, and lower 22:6n-3 levels in plasma phospholipid, RBC PE, and RBC PC than infants fed the formulae with low 18:2n-6. Increasing the amount of 22:6n-3 in the formulae resulted in progressively higher 22:6n-3 levels in the plasma and RBC phospholipids (Tables 3–5, Figs. 1–3). Thus, levels of 22:6n-3 were significantly higher in infants fed formula with rather than without 22:6n-3, and higher in infants fed formula with 0.22 or 0.24% 22:6n-3 rather than 0.10 or 0.11% 22:6n-3. Levels of 20:5n-3, although significantly higher in the plasma phospholipid and RBC PE of infants fed the formulae with rather than without fish oil, were not significantly higher than in the breast-fed infants.

The difference in percentage 22:6n-3 in plasma phospholipid, RBC PE, and RBC PC between the breast-fed infants and infants fed formula with 22:6n-3 differed with the duration of feeding (Figs. 1–3). At 4 and 8 wk of age, infants fed the formula with 0.22 or 0.24% 22:6n-3 had plasma phospholipid and RBC PE and PC 22:6n-3 levels which were not different from that of the breast-fed infants. At 16 wk of age, however, the plasma phospholipid percentage 22:6n-3 was significantly higher in infants fed the formula with 0.24% 22:6n-3, but not different between infants fed the formula with 0.22, 0.11, and 0.10% 22:6n-3 and the breast-fed infants. Of importance, these longitudinal analyses show that the percentage 22:6n-3 in plasma and RBC phospholipid continues to change from 4 to 16 wk of age. The differences in blood lipid 22:6n-3 between breast-fed and formula-fed infants thus depend on the duration of feeding. These analyses also show that formula with about 20% 18:2n-6 and 2.1% 18:3n-3 results in consistently higher blood lipid levels of 22:6n-3 than formula with about 32% 18:2n-6 and 4.9% 18:3n-3.

n-6 Fatty acids. The levels of 18:2n-6 and 20:2n-6 in the plasma phospholipid, RBC PC, and RBC PE were significantly higher in infants fed formula with high (32%) 18:2n-6 than in infants fed human milk, or formula with low (20%) 18:2n-6. Infants fed the low 18:2n-6 formulae also had significantly higher plasma phospholipid and RBC PE 18:2n-6, and higher RBC PE and PC 20:2n-6 than infants fed human milk. In contrast to 18:2n-6 and 20:2n-6, the plasma phospholipid percentage 20:3n-6 was significantly lower in infants fed formula with high 18:2n-6 than in breast-fed infants, or in infants fed formula with low 18:2n-6.

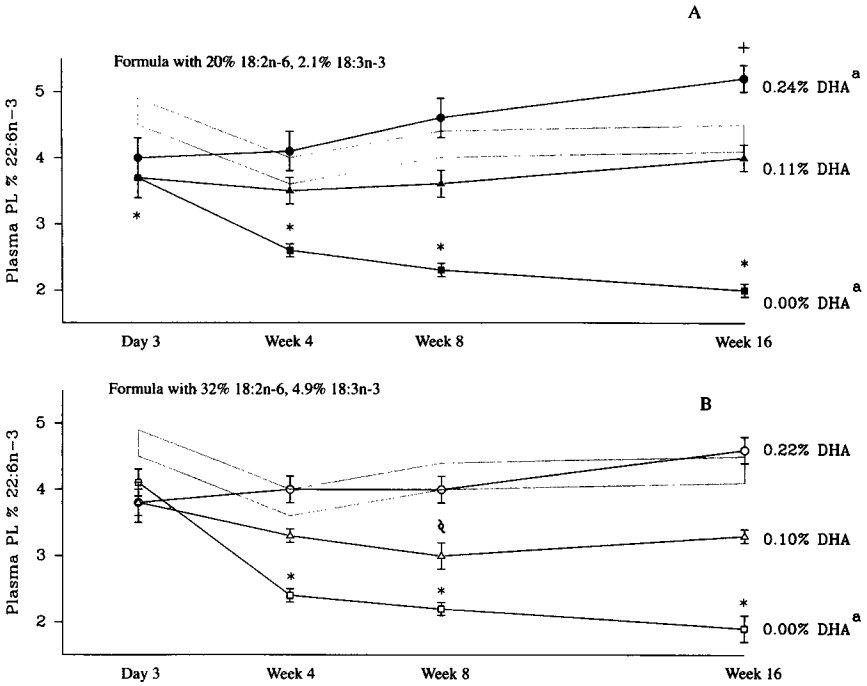

FIG. 1. Plasma phospholipid (PL) 22:6n-3 (% total fatty acids) of infants fed a formula with about (A) 20% 18:2n-6, 2.1% 18:3 or (B) 32% 18:2n-6, 4.9% 18:3n-3 and differing amounts of docosahexaenoic acid (DHA). Values given represent means ± SEM for each formula group. The mean ± SEM range for the group of breast-fed infants is indicated by the open box. The number of samples (infants) for the breast-fed infants and infants fed the 20% 18:2n-6 formula with 0.0, 0.11, or 0.24% DHA or 32% 18:2n-6 formula with 0.0, 0.10, or 0.22% DHA were: day 3, 16, 19, 15, 12, 11, 14, 15; wk 4, 21, 18, 11, 9, 12, 14, 12; wk 8, 21, 17, 11, 8, 11, 13, 12; wk 16, 20, 13, 10, 11, 12, 17, 11, respectively. The symbols *, §, and + indicate the value for infants fed 0.0%, or 0.10 or 0.11, or 0.22 or 0.24% DHA, respectively, is significantly different from the value for breast-fed infants, $P < 0.05$. The superscript a indicates value at 16 wk significantly different from value for the same infants at 4 wk, $P < 0.05$.

The infants fed formula had consistently lower levels of 20:4n-6 in plasma phospholipids (Table 3) and RBC PC (Table 5) than the breast-fed infants. The percentage 22:5n-6 was also significantly lower in the plasma phospholipids, RBC PE, and RBC PC of infants fed the formula with high 18:2n-6 than in the breast-fed infants, with the exception of the RBC PC in infants fed the high 18:2n-6 formula with 0.0% 22:6n-3. The percentage 20:4n-6 in the plasma phospholipid, but not RBC PE or PC, was significantly lower in infants fed formula with high rather than low 18:2n-6. Levels of 22:4n-6 and 22:5n-6, on the other hand, were significantly lower in the RBC PE of infants fed formula with high 18:2n-6 rather than low 18:2n-6 (Table 4).

The amount of 22:6n-3 in the formula had no statistically significant effect on the n-6 fatty acid composition of the infants' plasma phospholipids, RBC PC, or RBC PE, except for a significantly lower RBC PE percentage 22:4n-6 and 22:5n-6 in infants fed the formula with rather than without 22:6n-3 (Table 5).

Saturated fatty acids. Despite the lower 16:0 in the formulae than in human milk (Table 1), the percentage 16:0 and 18:0 in plasma phospholipids and RBC PC and PE were not significantly different between the breast-fed and formula-fed infants, except for a significantly higher percentage 18:0 in the plasma phospholipids of infants fed the high 18:2n-6 formula with 0.0 or 0.10% 22:6n-3, and in RBC PC of infants fed the high 18:2n-6 formula with 0.1% 22:6n-3 than in infants fed human milk (Tables 3–5). The percentage 18:0 in the plasma phospholipid, RBC PC, and RBC PE was significantly lower in infants fed the formulae with low 18:2n-6 than in infants fed the formulae with high 18:2n-6. This occurred despite similar amounts of 18:0 (3.9–4.5% fatty acids) in the formula (Table 1). The percentage 16:0 in the RBC PE, but not PC or plasma phospholipids, was also consistently lower in infants fed the formula low in 18:2n-6 than in infants fed the formula high in 18:2n-6. Part of this difference may be due to the difference in 16:0 in the formulae (about 8.3% compared with 10% 16:0 in the low and high 18:2n-6 formulae, respectively). The 22:6n-3 content of the formula had no significant effect on the saturated fatty acid composition of the infant's plasma phospholipids, RBC PC, or RBC PE.

Monounsaturated fatty acids. Human milk usually has about 36–45% 18:1, similar to that in the low 18:2n-6 formulae (about 36% 18:1) and about 2-fold higher than in the high

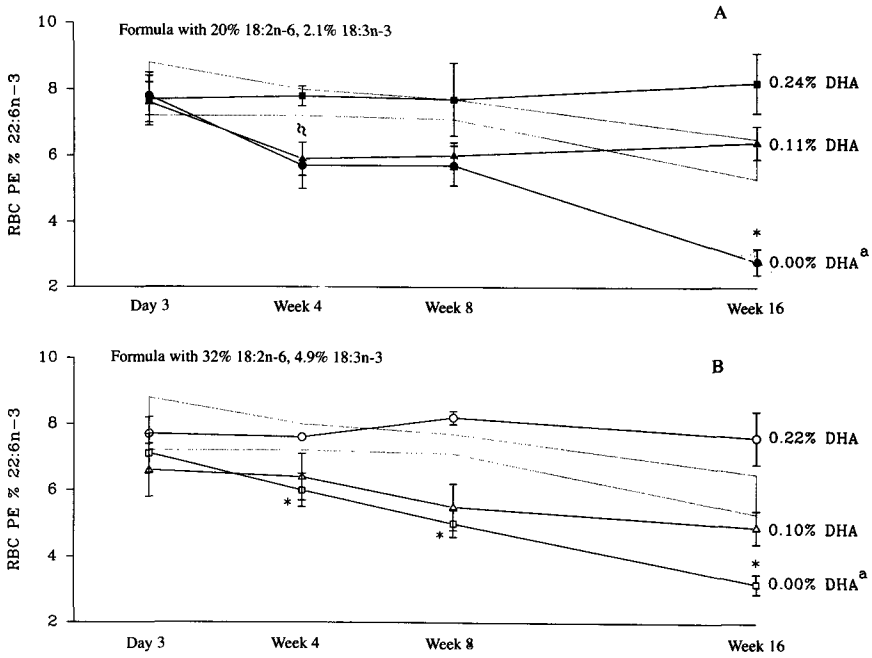

FIG. 2. Red blood cell phosphatidylethanolamine (RBC PE) 22:6n-3 (% total fatty acids) of infants fed a formula with about (A) 20% 18:2n-6, 2.1% 18:3 or (B) 32% 18:2n-6, 4.9% 18:3n-3 and differing amounts of DHA. Values given represent means ± SEM for each formula group where the SEM does not show the range is smaller than the symbol. The mean ± SEM range for the group of breast-fed infants is indicated by the open box. The number of samples (infants) for the breast-fed infants and infants fed the 20% 18:2n-6 formula with 0.0, 0.11, or 0.24% DHA or 32% 18:2n-6 formula with 0.0, 0.10, or 0.22% DHA were: day 3, 11, 9, 9, 8, 8, 10, 10; wk 4, 15, 8, 8, 6, 12, 10, 8; wk 8, 16, 9, 11, 6, 8, 10, 9; wk 16, 19, 14, 7, 9, 9, 13, 9, respectively. The symbols * and § indicate the value for infants fed 0.0 or 0.10% DHA, respectively, is significantly different from the value for breast-fed infants, $P < 0.05$. The superscript a indicates value at 16 wk significantly different from the value for the same infants at 4 wk, $P < 0.05$. See Figure 1 for other abbreviation.

18:2n-6 formulae (14.5–16.1% 18:1, Table 1). The plasma phospholipid and RBC PC of the infants fed formula with high 18:2n-6, and the RBC PE of infants fed the high 18:2n-6 formula with 0.0% 22:6n-3 had a significantly lower percentage 18:1 than in the breast-fed infants (Tables 3–5). The plasma phospholipids and RBC PE, but not RBC PC, of infants fed the formula with low 18:2n-6 with 0.0 or 0.11% 22:6n-3, however, had significantly higher levels of 18:1 than the breast-fed infants. The percentage 20:1 in the plasma phospholipids and RBC PC and PE was significantly higher in infants fed the formulae with low 18:2n-6 than in infants fed the formulae high in 18:2n-6. The 22:6n-3 content of the formula had no significant effect on the monounsaturated fatty acid composition of the infants' plasma or RBC phospholipids.

DISCUSSION

In the studies reported here, formula containing fish oil to provide similar amounts of 22:6n-3 and 20:5n-3 to that in mature human milk in North America (0.1–0.24% 22:6n-3, 22:6n3/20:5n-3 ratio of 4:1) resulted in higher blood lipid levels of 22:6n-3 than in infants fed formula without 22:6n-3. The plasma and RBC phospholipid percentage 20:4n-6 was lower in infants fed formula than in breast-fed infants, but was not further reduced by inclusion of 22:6n-3 in the formula. In contrast, studies with very premature infants have found lower levels of 20:4n-6 in plasma and RBC phospholipids of infants fed a formula with 0.2% 22:6n-3 and 0.3% 20:5n-3 than in infants fed formula with no 22:6n-3 and 20:5n-3 (11). Possibly, the absence of significant amounts of 20:5n-3, or the lower total amount of C_{20} and C_{22} n-3 fatty acids in the formulae explains the difference between the studies.

Evidence for retroconversion of 22:6n-3 to 20:5n-3 has been published (23). No consistent evidence was found in this study to suggest that increasing 22:6n-3 to up to 0.24% of formula fatty acids will increase the blood lipid 20:5n-3 or 22:5n-3 in healthy term gestation infants. Infants fed the formulae with 0.22 or 0.24% 22:6n-3 did not have higher plasma or RBC levels of 20:5n-3 or 22:5n-3 than infants who were breast-fed. This could be explained by the relatively low amount of 22:6n-3 in the formula (≤0.3% fatty acids), leading to incorporation of the dietary 22:6n-3 into tissue phospholipids rather than chain shortening.

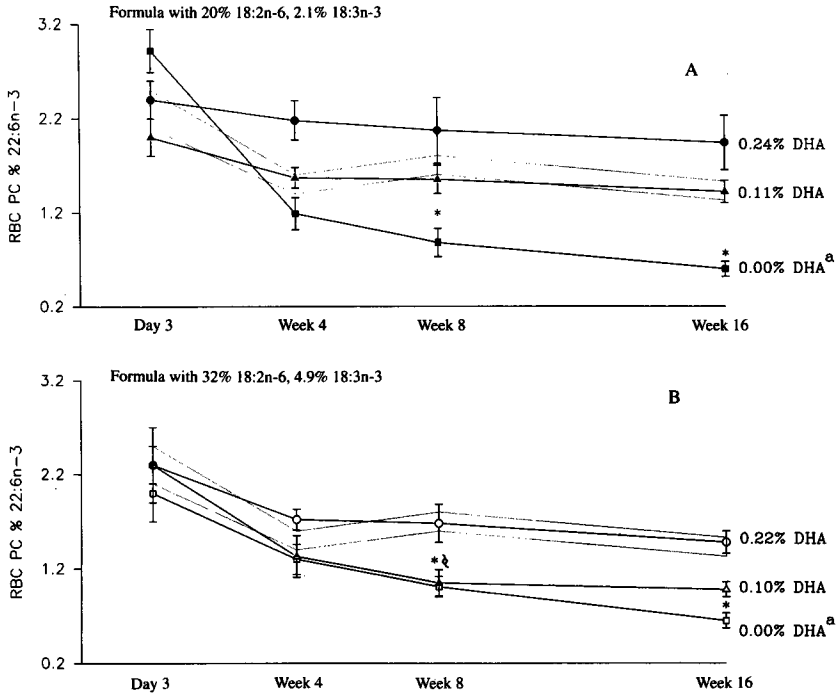

FIG. 3. Red blood cell phosphatidylcholine (RBC PC) 22:6n-3 (% total fatty acids) of infants fed a formula with about (A) 20% 18:2n-6, 2.1% 18:3 or (B) 32% 18:2n-6, 4.9% 18:3n-3 and differing amounts of DHA. Values given represent means ± SEM for each formula group. The mean ± SEM range for the group of breast-fed infants is indicated by the open box. The number of samples (infants) for the breast-fed infants and infants fed the 20% 18:2n-6 formula with 0.0, 0.11, or 0.24% DHA or 32% 18:2n-6 formula with 0.0, 0.10, or 0.22% DHA were: day 3, 11, 9, 8, 8, 9, 8, 10, wk 4, 17, 10, 7, 7, 11, 12, 8; wk 8, 17, 11, 9, 6, 8, 14, 10; wk 16, 19 14, 7, 8, 8, 12, 10. The symbol * or § indicates the value for infants fed 0.0% DHA or 0.11% DHA, respectively, is significantly different from the value for breast-fed infants, $P < 0.05$. The superscript a indicates value at 16 wk significantly different from value for the same infants at 4 wk, $P < 0.05$. See Figure 1 for other abbreviation.

Although no biochemical explanation is available, results of long-term studies with premature infants fed formula have suggested a relationship between blood lipid 20:4n-6 and growth (24). Despite differences in blood lipid 20:4n-6, no evidence of slower growth was found between the breast-fed and formula-fed term infants in the study reported here. Conclusions regarding growth, however, should not be drawn from this study because of the relatively small numbers of infants in each group. Other studies involving large numbers of infants, however, have found that formula-fed term infants grow at least as well as breast-fed infants (25). Whether the difference in blood lipid 20:4n-6 between term gestation breast-fed and formula-fed infants has any physiological significance is thus unknown.

In the studies reported here, infants fed the formula with about 32% 18:2n-6 and 4.9% 18:3n-3 had lower levels of plasma phospholipid 22:6n-3, 20:4n-6, and 20:3n-6 and higher 20:2n-6, than infants fed formula with about 20% 18:2n-6 and 2.1% 18:3n-3. These differences suggest that dietary intakes of 18:2n-6 and/or 18:3n-3 may reduce desaturation of 18:2n-6 to 20:3n-6 and 20:4n-6, with concomitant increased elongation of 18:2n-6 to 20:2n-6. Consistent with this, piglets fed formula high in 18:2n-6 had lower plasma, liver, and kidney, but not brain, phospholipid levels of 20:4n-6 and 22:6n-3 than piglets fed formula with lower 18:2n-6 (26). Evidence of reduced tissue 20:4n-6 and 22:6n-3 with increasing dietary 18:2n-6 also has been found in rodents (27). Other possible explanations include competition of 18:2n-6 with 20:4n-6 and 22:6n-3 for acylation to the 2-position of phospholipids. Although the explanation is uncertain, the findings suggest that the amount of 18:2n-6 and 18:3n-3 (or 18:1) in infant formula can determine in part the amount of 22:6n-3, and possibly 20:4n-6, needed to achieve blood lipid n-6 and n-3 fatty acid levels comparable to those in infants fed human milk. The longtitudinal analyses in this study also show that the age of the infant and/or the duration of feeding is important in determining differences in blood lipid n-6 and n-3 fatty acids between breast-fed and formula-fed infants.

In summary, this study has shown that the inclusion of fish oil to provide 0.10 to 0.22% 22:6n-3, with <0.1% 20:5n-3, in formula results in plasma and RBC phospholipid levels of 22:6n-3 in healthy term infants similar to those in infants fed human milk. The fish oil, which had a 22:6n-3 to 20:5n-3 ratio of about 4:1, had no significant adverse effects on

growth during the first four months after birth when added to give up to 0.24% 22:6n-3 in the formula fatty acids. The blood lipid 22:6n-3 response to dietary 22:6n-3 was consistently higher in infants fed formula with about 20% 18:2n-6 and 2.4% 18:3n-3 rather than 32% 18:2n-6 and 4.9% 18:3n-3. This suggests that the amount of 22:6n-3 required in formula to match the blood lipid levels of 22:6n-3 found in breast-fed infants will depend in part on the levels of other fatty acids in the formula.

ABSTRACT: The electric organ membrane has been the subject of many studies, due principally to its rich content of nicotinic acetylcholine receptor (AChR). Knowing its lipid composition is clearly important. Although its major membrane lipids have been characterized, its ganglioside composition has not been as well-described. In this study, gangliosides were characterized in membranes prepared from two species of electric organ, *Torpedo californica* and *T. nobiliana*. The ganglioside content of total electric organ membranes and AChR-enriched membranes was similar in both species, accounting for from 0.9 to 1.5% of membrane lipid by weight. However, the AChR-enriched membranes contained significantly less ganglioside relative to AChR than did the total membrane preparations. Five major gangliosides were purified from *T. californica* and identified as II^3NeuNAc-$GgOse_3$ (GM2); $II^3(NeuNAc)_2$-$GgOse_3$ (GD2), IV^3NeuNAc, II^3NeuNAc-$GgOse_4$ (GD1a), IV^3NeuNAc, $II^3(NeuNAc)_2$-$GgOse_4$ (GT1b), and IV^3-$(NeuNAc)_2$,$II^3(NeuNAc)_2$-$GgOse_4$ (GQ1b). Together these five gangliosides accounted for over 90% of the total ganglioside present in the two membrane preparations from both species. The most abundant ganglioside by far was GM2, which accounted for about one-half of the ganglioside content, followed by GD2. Determination of the N-fatty acid composition was performed on gangliosides purified from *T. nobiliana*. The lower-order gangliosides, GM2, GD2, and GD1a, contained substantial amounts of very long chain fatty acids (>20 carbons), including α-hydroxynervonic acid (15–21% of total). In contrast, unsubstituted, 14–18 carbon chains accounted for about 90% of the fatty acids on the two higher-order gangliosides, GT1b and GQ1b.

Lipids 31, 627–633 (1996).

Electric organ-derived membranes from various species of fish have been the subject of many studies on the nicotinic aceytylcholine receptor (AChR). Knowing their lipid composition is of major importance to understanding the structure and function of this protein *in situ*. For example, specific membrane lipids were found to be necessary in order to reconstitute full activity of the AChR in artificial membranes (1,2). Although the membrane content of phosphoglycerides and sphingolipids has been well-documented (for review see Ref. 3), the content of minor lipids, such as gangliosides, has not been as thoroughly investigated.

Some previous studies have described the ganglioside composition of electric organs and have revealed clear species differences. The electric organ from the bony fish, *Electrophorus electricus*, contained $II^3(NeuNAc)_2$-LC (GM3) as the only monosialoganglioside, as well as a substantial amount of Gal(β1-3)GalNAc(β1-4)Gal(β1-4)Glc-(β1-1′)ceramide (GgOse4)-based higher-order (three or more sialic acid residues) gangliosides (4). In contrast, electric organ gangliosides from the bony fish *Gnathonemus petersi* did not contain significant amounts of monosialogangliosides, only higher-order gangliosides (5). The cartilaginous fish, *Torpedo marmorata*, appeared, on thin-layer chromatography (TLC), to contain the monosialogangliosides II^3NeuNAc,-II^3NeuNAc-$GgOse_4$ (GM1) and II^3NeuNAc-$GgOse_3$ (GM2) as major components with relatively smaller amounts of higher-order gangliosides (6–9). The ray, *Discopyge tschudii*, contained GM2 as the major ganglioside (55% of total), with lesser amounts of GM1 (7%), $II^3(NeuNAc)_2$-LC) (GD3) (10%), a ganglioside "running just below IV_3NeuNAc,-II^3NeuNAc-$GgOse_4$ (GD1a)" (12%), and higher-order gangliosides (13%) (5). A *T. californica* "membrane fraction" displayed a prominent band migrating "close to GM2" and a second major component with mobility between GD1a and $II^3(NeuNAc)_2$-$GgOse_4$ (GD1b) (10). Cholera toxin B binding after neuraminidase treatment showed that the majority of *T. californica* (10), *T. marmorata* (11), and *D. tschudii* (5) gangliosides did not contain the $GgOse_4$ oligosaccharide.

AChR-enriched, postsynaptic membranes isolated from *T. marmorata* contained GM1 as the major ganglioside (38% of total), with lesser amounts of GM2 (7%), GD3 (15%), a component running just below GD1a (20%), and higher-order gangliosides (less than 15%) (5). A separate study on *T. marmorata* AChR-enriched membranes also found that GM1 and GM2 predominated over higher-order gangliosides (11). *Discopyge tschudii* AChR-enriched membranes resembled those of *T. marmorata* except that GM2 was the major ganglioside (30%) in that species instead of GM1 (23%) (5). The ganglioside patterns of AChR-enriched membranes from both of

these species resembled those from the whole organ, except that enrichment of GM1 at the expense of GM2 was seen (5). The ganglioside content and composition of *T. marmorata* AChR-enriched membranes were very different from that of presynaptic membranes (11). Presynaptic membranes contained about fifteen times more lipid-bound sialic acid relative to protein than AChR-enriched membranes and were almost free of monosialogangliosides, but were enriched in higher-order gangliosides.

It should be noted that these previous studies have identified electric organ gangliosides based exclusively on the TLC mobility of native or neuraminidase-treated, cholera toxin B-labelled gangliosides. The only exception to this was the cholinergic-specific antigen, Chol-1β, which was purified from *T. marmorata* and found to be a novel trisialoganglioside that accounted for less than 0.1% of the total (9). This paper is the first structural analysis on purified major electric organ gangliosides and was undertaken to identify and quantify the major gangliosides in membrane preparations from the electric organs of the Pacific ray, *T. californica*, possibly the most frequently-used source of AChR-enriched membranes, and the Atlantic ray, *T. nobiliana*.

Furthermore, nothing is known about the fatty acid composition of electric organ gangliosides. The N-fatty acid composition of the major gangliosides purified from *T. nobiliana* electric organ is reported here for the first time.

MATERIALS AND METHODS

Preparation and characterization of membranes. Total and AChR-enriched membranes were prepared from frozen *T. californica* (Pacific Biomarine, Venice, CA) and *T. nobiliana* (Biofish Associates, Boston, MA) electric organ as previously described (12). Membrane preparations were assayed for protein content (13) and for [^{125}I]-α-bungarotoxin binding sites (DuPont-New England Nuclear, Boston, MA) (12). On average, the total and AChR-enriched membranes contained 0.4 and 0.9 nmoles of α-bungarotoxin binding sites per mg of membrane protein, respectively.

Ganglioside isolation and purification. Gangliosides were extracted from membrane preparations and partitioned into the aqueous phase following a previously described method (14). A sample of the total lipid extract was taken prior to partitioning for gravimetric determination of total lipids. The concentrated aqueous phase was applied to C_{18} reverse-phase cartridges (Millipore, Milford, MA) and washed with several volumes of distilled water followed by elution with methanol (15). The dried residue was solubilized in chloroform/methanol/water (60:30:4.5, by vol), filtered, and then applied to a DEAE-Sephadex A-25 ion exchange column (Pharmacia, Uppsala, Sweden) (16). The column was washed with methanol and then eluted with 0.5 M ammonium acetate in methanol. This sample was desalted on C_{18} cartridges, made 0.1 M in NaOH, heated at 45°C for 4 h to hydrolyze contaminating acidic phosphoglycerides (17), and then desalted again on C_{18} cartridges. TLC analysis showed that this sample contained no detectable free fatty acids or other contaminating lipids. Ganglioside recovery was not quantified in these studies but has been shown to be over 90% using this method (14). Individual gangliosides were purified on 500 μm silica gel TLC plates developed with chloroform/methanol/water (50:45:1, by vol) and eluted with chloroform/methanol/water (5:5:1, by vol), followed by washing on C_{18} cartridges.

Ganglioside characterization. Lipid-bound sialic acid was determined by the method of Svennerholm (18) and sphingosine by the method of Lauter and Trams (19). Analytical TLC was performed on 150 μm silica gel high-performance TLC plates (Alltech, Deerfield, IL) and developed with chloroform/methanol/aqueous 0.2% $CaCl_2$ at different volume ratios (see figure legends). Densitometric scanning at 580 nm of TLC plates stained for sialic acid was performed on a Beckman (Fullerton, CA) DU7 spectrophotometer.

For mild acid desialidation of gangliosides, a dried sample containing approximately 200 μg sialic acid was heated in 500 μL of 1 M formic acid in a stoppered Teflon-lined vial at 90°C for 1.5 h (20). The sample was dried under N_2, resuspended in upper phase, and washed on a C_{18} cartridge. Lipids were eluted with methanol and characterized by TLC.

For enzymatic desialidation, a dried ganglioside sample containing approximately 200 μg sialic acid was incubated at 38°C in 450 μL of 0.05 M sodium acetate at pH 5.0 containing 0.01 M $CaCl_2$ and 50 mU of *Clostridium perfringens* Type X neuraminidase (Sigma, St. Louis, MO) (21) either for 2 h (partial enzyme treatment) or for 18 h with an additional 50 mU of enzyme added at 12 h (complete enzyme treatment). Samples were handled as for mild acid desialidation. Parallel blanks containing enzyme, but no added ganglioside, were run to assure the enzyme preparations did not contain glycolipid contaminants.

Fatty acid and sugar composition were analyzed by gas chromatography/mass spectrometry (GC/MS) of their trimethylsilyl (TMS)–methyl esters and TMS–methylglycosides, respectively. The purified ganglioside was subjected to methanolysis in 0.1 mL of 0.9 M anhydrous methanolic HCl at 90°C for 16 h in a 1-mL sealed vial. After cooling, 300 μL of hexane was added and mixed well for 1 min. The hexane phase containing the fatty acid methyl ester (FAME) was removed to a clean 1-mL vial, and both phases were evaporated under N_2 in a 40°C water bath. The sugar methylglycosides sample was then dissolved in 100 μL of methanol to which 2 μL of pyridine and 10 μL of acetic anhydride had been added. This was allowed to stand at room temperature for 15 min to re-N-acetylate amino sugars and then dried under N_2. Both the FAME and sugar methylglycoside samples were then dissolved in 50 μL of pyridine/hexamethyldisilane-trimethylchlorosilane/bistrimethylsilyltrifluoroacetamide (2:1:1:2, by vol) and heated at 60°C for 30 min to form TMS–ethers of hydroxy–FAME and sugar methylglycosides. GC/MS was performed with a Finnigan 4500 MS system (Finnigan-MAT, San Jose, CA) equipped with a Hewlett-Packard (Avondale, PA) 5890 GC. From 1 to 3 μL of the TMS methylglycoside sam-

ples were injected *via* a dropping needle injector (Chrompac Inc., Raitan, NJ) maintained at 270°C. GC was on a 30 m by 0.25 mm i.d. DB-1 fused silica capillary column (J&W Scientific, Folsom, CA) with helium as the carrier gas. The column temperature was programmed from 190 to 250°C at 3°C/min and then to 270°C at 70°C/min, where it was held for 4 min. Hexoses eluted during the first ramp and sialic acids during the final hold. Ammonia chemical ionization was used with selected ion monitoring of the $[M + NH_4]^+$ ion from the neutral hexoses and the $[M + H]^+$ ions for N-acetylaminohexoses and sialic acids. FAME and TMS–hydroxyFAME were separated on a Hewlett-Packard 5890 gas chromatograph in the on-column injection mode with a flame-ionization detector on a 30 m by 0.25 mm i.d. DB-1701 column with 0.25 µm phase thickness. Helium was the carrier gas at 15 psi. Initial column temperature was held at 50°C and then programmed first to 200°C at 16°C/min and finally to 300°C at 4°C/min. All the FAME eluted during the final ramp. FAME from each ganglioside also were run on GC/MS and analyzed in the ammonia chemical ionization mode to confirm peaks seen on GC.

RESULTS

The lipid-bound sialic acid and ganglioside content of total and AChR-enriched membranes from both species studied are summarized in Table 1. The sialic acid content of total and AChR-enriched membrane preparations was about the same, although *T. californica* AChR-enriched membranes may contain slightly less lipid-bound sialic acid than total membranes relative to protein ($P < 0.1$). Because the AChR-enriched membranes contained over twice as much AChR, the amount of ganglioside relative to AChR in these membranes is lower than in the total membrane preparations.

TLC resolved the AChR-enriched membrane ganglioside fraction from *T. californica* into five major components (Fig. 1: A, C, D, E, and F). The same pattern was observed with AChR-enriched membranes from *T. nobiliana* and with total membranes from both species (not shown). Gangliosides purified from *T. californica* were used for structure determinations. The fastest ganglioside (A) moved just ahead of bovine brain II^3NeuNAc-$GgOse_3$ (GM2) on TLC, running as a wide band which often resolved into a doublet (Fig. 2). Sugar analysis revealed glucose, galactose, N-acetylgalactosamine, and N-acetylneuraminic acid at molar ratios of 1.0:0.8:0.8:0.9; N-acetylneuraminic acid was the only form of sialic acid detected. Mild acid hydrolysis generated one major product which displayed TLC mobility and staining behavior similar to bovine brain asialo-GM2 and, like the parent compound, often resolved into a doublet (Fig. 2); small amounts of lactocerebroside and glucocerebroside were also

TABLE 1
Ganglioside Content and Composition of Electric Organ Membrane Preparations

	Torpedo californica membranes		*T. nobiliana* membranes	
	Total	AChR-enriched	Total	AChR-enriched

[a]*Torpedo californica* values are expressed as the mean ± 1 SD from four samples (total membranes) or six samples [nicotinic acetylcholine receptor (AChR)-enriched membranes]. *Torpedo nobiliana* values are expressed as the average of two samples (total membranes) or that from a single sample (AChR-enriched membranes).

[b]Molar values were calculated from lipid-bound sialic acid values after estimation of the average sialic acid stoichiometries, which were derived from the quantification and structural determination of the major individual gangliosides. Ganglioside as percentage of lipid by weight was calculated after determining the average ganglioside molecular weights for each preparation.

[c]Gangliosides were identified as described in the text and then quantified by densitometric scanning at 580 nm of thin-layer chromatography plates stained for sialic acid followed by correction for sialic acid stoichiometry. *Torpedo californica* values are expressed as the mean ± 1 SD from four samples (total membranes) or three samples (AChR-enriched membranes). *Torpedo nobiliana* values are from single samples. GM2, II^3NeuNAc-$GgOse_3$; GD1a, IV^3NeuNAc, II^3NeuNAc-$GgOse_4$; GD2, $II^3(NeuNAc)_2$-$GgOse_3$; GT1b, IV^3NeuNAc, $II^3(NeuNAc)_2$-$GgOse_4$; GQ1b, $IV^3(NeuNAc)_2$-$II_3(NeuNAc)_2$-$GgOse_4$.

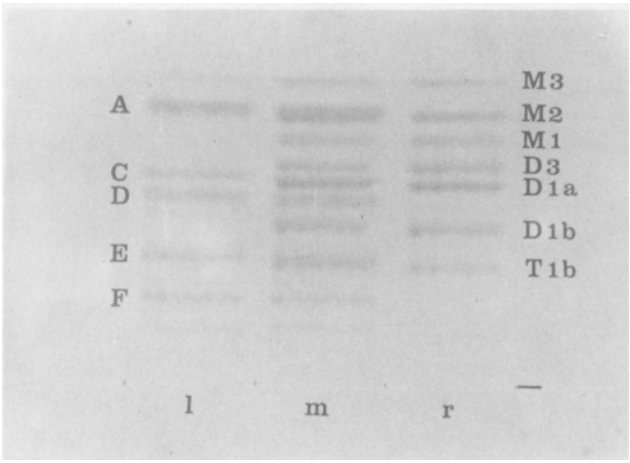

FIG. 1. Thin-layer chromatography of the total ganglioside fraction purified from *Torpedo californica* nicotinic acetycholine receptor-rich membranes (lane l). Lane r: bovine brain gangliosides; lane m: contents of lane l and lane r combined. Plate was developed with chloroform/methanol/aqueous 0.2% $CaCl_2$ (56:40:9, by vol) and visualized by spraying with 18 mM resorcinol and 0.25 mM $CuSO_4$ in concentrated HCl, followed by heating at 90°C for 15 min. All bands appeared violet.

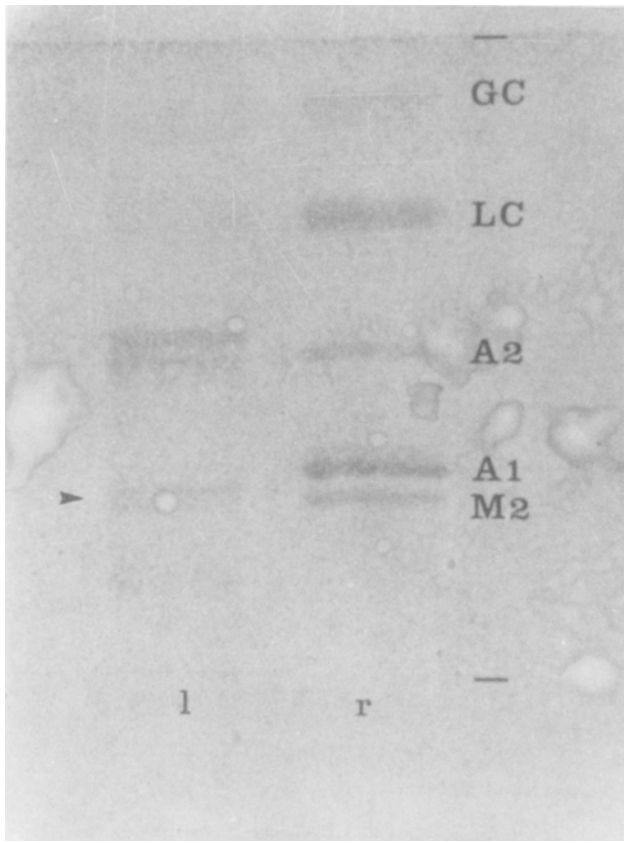

FIG. 2. Thin-layer chromatography of purified *Torpedo californica* ganglioside A following treatment with 1 M formic acid for 1.5 h at 90°C (lane l). Some unhydrolyzed A can still be seen (arrow). Lane r: untreated bovine brain lipids (A1: asialoGM1; A2: asialoGM2; LC: lactocerebroside; GC: glucocerebroside). Plate was developed with chloroform/methanol/aqueous 0.2% $CaCl_2$ (65:35:8, by vol) and visualized as described in Figure 1. Bands labelled with arrow and M2 appeared violet; all other bands appeared yellow or brown.

seen. Mild acid hydrolysis of bovine brain GM2 gave essentially the same results. These findings confirm that *Torpedo* ganglioside A is GM2.

Ganglioside C displayed TLC mobility just slightly faster than bovine brain $IV^3NeuNAc,II^3NeuNAc\text{-}GgOse_4$ (GD1a). The purified ganglioside had a sialic acid/sphingosine ratio of 2.17 and was degraded by neuraminidase to one major product, which comigrated with bovine brain GM1 (Fig. 3). These findings are consistent with ganglioside C being GD1a.

Ganglioside D always localized between bovine brain GD1a and GD1b on TLC. Like ganglioside A, it ran as a relatively wide band which often resolved into a doublet (Fig. 4). Purified ganglioside D had a sialic acid/sphingosine ratio of 2.06. It was degraded by neuraminidase to one major product which, like *Torpedo* GM2, migrated just ahead of bovine brain GM2 and also resolved into a doublet (Fig. 4). These findings indicate that ganglioside D is $II^3(NeuNAc)_2\text{-}GgOse_3$ (GD2).

Ganglioside E displayed TLC mobility similar to bovine brain $IV^3NeuNAc,II^3(NeuNAc)_2\text{-}GgOse_4$ (GT1b). Its sialic acid/sphingosine ratio was 3.10. Partial desialidation of E with neuraminidase generated a ganglioside comigrating with bovine brain GM1 as the major degradation product (Fig. 5); gangliosides comigrating with GD1b and GD1a were minor products. This same degradation pattern was seen with bovine brain GT1b. These findings indicate that ganglioside E is GT1b.

Ganglioside F consistently migrated just behind GT1b on TLC (Fig. 1) and corresponded closely with bovine brain $IV^3(NeuNAc)_2$, $II^3(NeuNAc)_2\text{-}GgOse_4$ (GQ1b) in mobility when run against total bovine brain gangliosides (not shown). Purified ganglioside F had a sialic acid/sphingosine ratio of 3.83, indicating that it is a tetrasialoganglioside. Formic acid treatment completely desialidated ganglioside F and gave two major products comigrating with asialoGM1 and lactocerebroside on TLC (not shown). These findings indicate that ganglioside F is most likely GQ1b.

Using these structural assignments, the relative molar amounts of the five major gangliosides were calculated from densitometry data (Table 1). On a molar basis, the most abundant ganglioside found in electric organ membranes from both species was GM2, accounting for roughly one-half of the ganglioside present. In fact, GM2 was the only monosialoganglioside found in substantial amounts. GD2 was the second most abundant ganglioside, so that $GgOse_3$-containing molecules made up about two-thirds of the ganglioside present. Together, the five major gangliosides accounted for more than 90% of the total ganglioside present in all membranes studied. The remaining sialic acid was distributed among several minor components, identified by TLC mobility as GM3, GM1, GD3, and an unidentified polysialoganglioside slower than GQ1b.

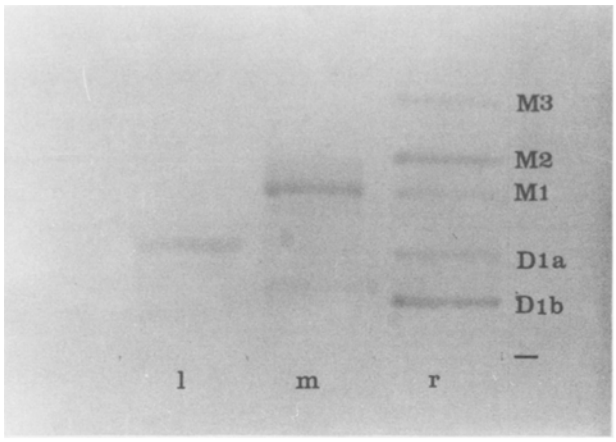

FIG. 3. Thin-layer chromatography of purified *Torpedo californica* ganglioside C following treatment with neuraminidase for 18 h at 38°C (lane m). Lane l: untreated ganglioside C; lane r: untreated bovine brain gangliosides. Plate was developed and visualized as described in Figure 1. All bands appeared violet.

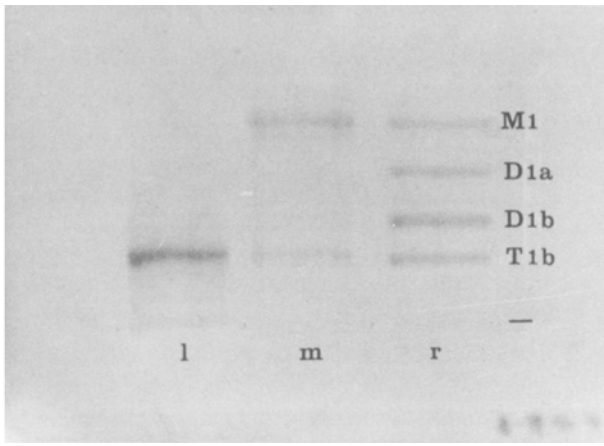

FIG. 5. Thin-layer chromatography of *Torpedo californica* ganglioside E following treatment with neuraminidase for 2 h at 38°C (lane m). Lane l: untreated ganglioside E; lane r: untreated bovine brain gangliosides. Plate was developed and visualized as described in Figure 4. All bands appeared violet.

Gangliosides purified from *T. nobiliana* electric organ were used to determine N-fatty acid content, which is summarized in Table 2. The majority of the fatty acids on all five major gangliosides were unsubstituted; however, α-hydroxynervonic acid [24:1(α-OH)], the only substituted fatty acid present in detectable amounts, accounted for 15–21% of the fatty acids on GM2, GD2, and GD1a. In contrast, the two higher-order gangliosides, GT1b and GQ1b, contained only 3% 24:1(α-OH). Unsubstituted fatty acids with chain lengths from 14 to 18 carbons predominated over those with 20 to 24 carbons in all five gangliosides; however, this was particularly evident among the higher-order gangliosides where 14 to 18 carbon fatty acids accounted for about 90% of their total fatty acid content. Saturated unsubstituted fatty acids predominated over monounsaturated chains on all five gangliosides; however, the unsubstituted fatty acids of GM2 and, to a lesser extent, GD2 and GD1a, did contain substantial amounts of monounsaturated chains with 22 or 24 carbons.

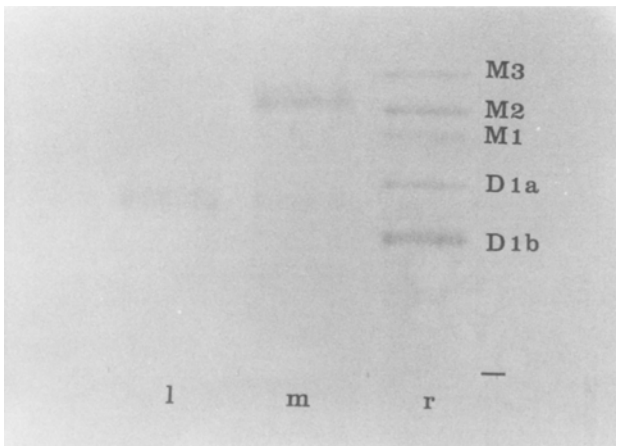

FIG. 4. Thin-layer chromatography of *Torpedo californica* ganglioside D following treatment with neuraminidase for 18 h at 38°C (lane m). Lane l: untreated ganglioside D; lane r: untreated bovine brain gangliosides. Plate was developed with chloroform/methanol/aqueous 0.2% $CaCl_2$ (50:45:10, by vol) and visualized as described in Figure 1. All bands appeared violet.

[a]Fatty acids were determined by gas chromatography as described in the Materials and Methods section. Only fatty acids that accounted for 1% or more of the total are shown. Column totals may not equal 100% due to rounding; ND, not detected; other abbreviations as in Table 1.
[b]Values include unsubstituted fatty acids only; SFA/MFA, saturated/monounsaturated fatty acids.

DISCUSSION

The ganglioside content of the *T. californica* and *T. nobiliana* electric organs (0.9–1.5% of membrane lipid by weight) is similar to that reported for other extraneural tissues, for example, cardiac muscle (0.3–0.9%; Ref. 22) and liver (1.1–1.2%; Refs. 17,23). It is also similar to that estimated for *E. electricus* electric organ (0.7%; Ref. 4). The lipid-bound sialic acid content of the AChR-enriched membranes from *T. californica* (1.9 ± 0.5 μg/mg protein) and *T. nobiliana* (2.1 μg/mg protein) is similar to that reported for *T. marmorata* membranes (3.2 ± 0.2 μg/mg protein) (10). By comparison, these values are much lower than those of presynaptic electric organ membranes (10) and other nerve-derived tissue from this genus (6).

An important finding is the predominance of GM2 in *T. californica* and *T. nobiliana* electric organ membranes. A major band running "close to GM2" had also been noted in a *T. californica* membrane fraction (11). The predominance of GM2 is unusual, but not unprecedented, in an extraneural tissue. GM2 accounted for 55% of the gangliosides in the *D. tschudii* electric organ (5) and for 72% of the ganglioside present in eggs from the bony fish, *Mugil cephalus* (24). Interestingly, *T. marmorata* electric organ also contains GM2, but in relatively lower amounts (5,10).

This paper is the first to report finding substantial amounts (11–14%) of GD2 in the electric organ, although a prominent band between GD1a and GD1b can be seen in a membrane fraction from *T. californica* (11). It is quite possible that the major band from *D. tschudii*, which ran "just below GD1a," accounted for about 12% of the total and did not produce GM1 by neuraminidase treatment, may actually have been GD2 (5). Similarly, a prominent band between GD1a and GD1b in the gangliosides from *T. marmorata* did not appear to label with cholera toxin B following neuraminidase treatment and may also have been GD2 (10). The finding that the majority of *T. californica* (10), *T. marmorata* (11), and *D. tschudii* (5) electric organ gangliosides did not contain the $GgOse_4$ oligosaccharide supports these possibilities and suggests that an abundance of $GgOse_3$-based gangliosides may be a general feature of postsynaptic membranes from the electric organs of cartilaginous fish.

One of the most striking findings on AChR-enriched membranes from *T. californica* and *T. nobiliana* was the near absence of GM1. This contrasts with similar membranes from *D. tschudii* (5) and *T. marmorata* (5,10), where GM1 is a major component. Because *T. marmorata* presynaptic and synaptic vesicle membranes were found to be devoid of monosialogangliosides, it was even suggested that GM1 might be used to estimate postsynaptic contamination of presynaptic membrane preparations (10). Clearly, this criterion could not be used for *T. californica* or *T. nobiliana*, whose postsynaptic membranes are devoid of GM1. *Torpedo californica* and *T. nobiliana* also differed from *D. tschudii* and *T. marmorata* in their lack of GD3 (5). The present study reconfirms that there are important species differences in the ganglioside compositions of electric organ membrane preparations. These differences are not due to different methodological approaches, as the techniques used for preparing electric organ membranes and isolating the ganglioside fraction in these labs were very similar to the ones described in the present report (5,11).

The ganglioside patterns of *T. californica* and *T. nobiliana* indicate that both the "a" and "b" biosynthetic pathways are active in the electrocyte. The finding that the fatty acid patterns of the two higher-order gangliosides, GT1b and GQ1b, differed markedly from that of their putative precursor, GD2, suggests that extensive fatty acid remodeling may occur following their synthesis. Although no "c" pathway gangliosides were detected, they could still be present in minor amounts, as was seen with *D. tschudii* using monoclonal-antibody labelling (10).

The closely-spaced doublets seen on the chromatograms of GM2 and GD2 (e.g., see Figs. 2 and 4) may be due to their enrichment with 24:1(α-OH). Similar doublets seen on chromatograms of human liver GM3 were attributed to its α-hydroxyfatty acid content (25). The GM2 doublet cannot be due to different forms of sialic acid, as its desialidated derivative also resolved into a doublet (Fig. 2). The fatty acid compositions may also explain why *Torpedo* GM2 and GD1a appeared to move slightly faster than their bovine brain counterparts on TLC, and the higher-order gangliosides did not (see Fig. 1). The greater amounts of very long chain fatty acids on the lower-order gangliosides would tend to increase their mobility on TLC relative to the bovine standards, where 18 carbon fatty acids predominate. Relatively faster mobility was also observed with *T. marmorata* GM2 and GM1 (6,10), suggesting that the monosialogangliosides from that species may have a similar fatty acid pattern.

This study was not designed to determine if gangliosides interact with the AChR, but the results do allow for some speculation. The lower ratio of total ganglioside to AChR seen in the AChR-enriched membranes does not rule out a specific ganglioside-AChR interaction. However, if there were a strong interaction between a particular ganglioside and the AChR, one would expect membrane fragments enriched with AChR also to display enrichment with the ganglioside. This was not observed among the major gangliosides in *T. californica* and, although there is a suggestion of GM2 enrichment in *T. nobiliana*, the data is insufficient to draw this conclusion. This contrasts with *T. marmorata* and *D. tschudii*, whose AChR-enriched membranes were enriched with GM1 at the expense of GM2 (5). The present studies show that GM1 enrichment is not a general property of AChR-enriched membranes. This study's main contribution in this area is the definitive identification of candidate gangliosides on which to base future studies aimed at addressing the question of specific ganglioside–AChR interactions in the postsynaptic membrane.

ABSTRACT: *Listeria monocytogenes* is a Gram-positive bacterium that can adapt to high salinity and cold. Because the membrane lipids may play a role in its survival and adaptation, we have examined the polar lipids of *L. monocytogenes*. Extraction of total lipids from *L. monocytogenes* yielded 7 ± 1 mg/mL wet cells. Polar lipids represented 64% of total lipids and contained 9% lipid–phosphorus. Polar lipids were separated into 14 components by two-dimensional thin-layer chromatography. Eight components (88% of polar lipids) contained lipid–phosphorus; among these was one major component (34% of polar lipids). Two other phospholipids were ninhydrin-positive components and accounted for 15% of the polar lipids. Orcinol staining revealed two glyco- or sulfo-lipids accounting for 9% of polar lipids. Five components (4% of polar lipids) were amino components free of phosphorus. The major component contained 46% of its fatty acids as 15:0 *anteiso*, 24% as 17: 0 *anteiso*, and 11% as 15:0 *iso*. The fatty acid profile of the remaining polar lipids was variable, consisting primarily of 16:0, 18:0, 15:0 *anteiso*, and 17:0 *anteiso*. Their unsaturation level was ≤20%; however, the major phosphoaminolipid component was 46% unsaturated. The ratios of 15:0 *anteiso*/17:0 *anteiso* and 15:0 *anteiso*/15:0 *iso* were similar in all classes, averaging 1.5 and 4.5, respectively. Since the adaptation process to stressful environments involves activation of a membrane transport system for the protectant glycine betaine, the membrane lipids may play a role in enabling transport.
Lipids 31, 635–640 (1996).

Since the mid 1980s, *Listeria monocytogenes* has become recognized as a major cause of food-borne illness (1). This Gram-positive organism can cause septicemia, meningitis, and encephalitis, with a 20–40% mortality rate (2,3), in susceptible individuals such as pregnant women, the very old or very young, those with AIDS, those with neoplastic disease or renal collagen disease, and those undergoing immunosuppressant therapy. *Listeria monocytogenes* is found in low-acid cheeses, ice cream, milk, vegetables, raw and ready-to-eat meat, poultry (including eggs), and seafood (4). The organism is notably resistant to osmotic stress, and grows relatively well at temperatures as low as 1°C (e.g., 5). Therefore, food handling and storage practices, such as refrigeration, that suppress competitors can promote its growth.

The role of the membrane of *L. monocytogenes* in osmotic and chill adaptation is twofold. An immediate response to salt or chill stress by *L. monocytogenes* is the activation of a transport system for the protectant glycine betaine (2) from the medium. This response is particularly significant in the response to chill stress because low temperature is expected to lead to a phase transition of the lipids from liquid crystal to gel (lipid phase transition), which would not support normal membrane functions such as active transport. It appears that the presence of high levels of glycine betaine in the cytoplasm enables long-term adaptation processes to occur more readily. Chief among these adaptation processes is likely the restructuring of the membrane (e.g., 6–9). Thus the composition of the membrane of cells grown at mesophilic temperatures, which supports active transport when shifted to low temperature, is of paramount importance to the survival of the organism.

Previous studies by Von Graevenitz *et al.* (10) and Püttmann *et al.* (11) have been conducted on total fatty acid patterns for taxonomic classification of bacterial strains. These investigators reported changes in total fatty acids in response to growth at low temperature. In addition, Hether *et al.* (12) studied the immunological properties of cell wall preparations from a virulent strain of *L. monocytogenes*.

In 1971, Kosaric and Carroll (13) isolated the phospholipids of *L. monocytogenes* and obtained structural data with the aim of isolating and identifying the active substance that produced a "monocytosis" in rabbits similar to that seen in other animals infected with the bacterium (14,15). They reported that three of the major components are phosphatidylglycerol, diphosphatidylglycerol, and bisphosphatidylglycerolphosphate. Detailed analysis of the structure of these bacterial lipids has not been reported. This investigation was designed to analyze in detail the lipid classes, with the aim of targeting the interpretation of the distinct behavior of *L. monocytogenes*.

Our first step in understanding the dual role of the membrane in adaptation is to define in detail the composition of the membrane at mesophilic temperature. This paper reports the fractionation and separation of major polar lipid compo-

nents, the fatty acid composition of the separated components, and suggestions for their structures.

MATERIALS AND METHODS

Culture of organism. Listeria monocytogenes strain DP-L1044 (D. Portnoy, University of Pennsylvania), a strain rendered avirulent by insertion of a transposon (16), in the gene encoding a virulence factor of the parent strain (Lm10403S), was grown in brain heart infusion (Difco Laboratories, Detroit, MI) broth at 30°C (*ca.* 24 h). Ten mL of this culture were used to inoculate one liter of brain heart infusion broth, which was then incubated at 30°C until late log phase. Cell density was determined by turbidity with a Klett-Summerson colorimeter with a green (No. 54) filter (209–212 Klett units). Cells were harvested by centrifugation at 5800 × *g* for 10 min and washed in 100 mM phosphate buffer, pH 7.0. Cells were washed again with the same buffer and harvested by centrifugation at 5,000 × *g* for one hour.

Extraction and isolation of polar from neutral lipids. Extraction of lipids was performed essentially according to the method of Folch *et al.* (17). After phase equilibration, the lower chloroform layer (total lipids) was evaporated to dryness, redissolved in chloroform/methanol (2:1, vol/vol), and stored at 0°C

Total lipids were fractionated by solid-phase extraction, using the method of Berger *et al.* (18) modified as follows. A lipid extract (~7 mg) was dissolved in 0.5 mL chloroform/hexane, 1:1, and applied to a pre-washed 100-mg silica column equipped with a stainless-steel frit and a 10-mL reservoir (Bond Elut; Varian Sample Preparation Products, Harbor City, CA). The columns were mounted on a Visiprep™ solid-phase extraction vacuum manifold (Supelco Inc., Bellefonte, PA). Neutral lipids were eluted three times with 6-mL aliquots of chloroform, and polar lipids were eluted with 7 mL methanol.

Chromatography of polar lipids. High-performance thin-layer chromatography (HPTLC) was carried out on precoated silica gel 60 plates (E. Merck, Darmstadt, Germany). For separation and detection of bacterial polar lipids, two-dimensional development (2D-HPTLC) was used with two solvent systems. System A consisted of the following: dimension 1, chloroform/methanol/acetic acid/water (50:25:6:2, by vol); dimension 2, chloroform/methanol/water (65:20:3, by vol). System B consisted of the following: dimension 1, chloroform/methanol/acetic acid/water (50:25:6:2, by vol); dimension 2, chloroform/methanol/28% ammonium hydroxide (65:35:5, by vol). Visualization of spots was effected by exposure to iodine vapor, followed by spraying with ninhydrin reagent and/or a phosphomolybdenum blue reagent (19). Lipid bands also were visualized using cupric sulfate spray and heating at 100°C for 2–5 min. The cupric sulfate reagent was 10% (wt/vol) cupric sulfate in 8% (by vol) phosphoric acid (20,21). An orcinol ferric chloride spray was used for detection of glyco- or sulfo-lipids (Sigma Chemical Co., St. Louis, MO). Tentative identification of the components was based on HPTLC mobilities relative to standards.

Lipid standards. The reference lipid standards bovine heart cardiolipin (sodium salt), L-α-phosphatidyl-DL-glycerol from egg yolk lecithin (sodium salt), L-α-phosphatidylcholine, β-arachidonyl-γ-stearoyl, L-α-phosphatidyl-L-serine from bovine brain, and dioleoyl L-α-phosphatidylethanolamine were purchased from Sigma Chemical Co.

Isolation and purification of individual polar lipids. Individual polar lipid components were isolated after separation by HPTLC with the two-dimensional solvent system (see A above). Spots were visualized by exposure to iodine vapors, and the individual spots were scraped and eluted from silica gel with 1 mL chloroform/methanol/water (1:2:0.8, by vol) three times. Two mL chloroform/water (1:1, vol/vol) were added to the solution, and after mixing, the chloroform extracts were evaporated and the residual lipids were used for further chromatographic analysis as well as for infrared (IR) and ^1H nuclear magnetic resonance spectroscopy. Individual spots were rechromatographed on one-dimensional (1D)- or 2D-HPTLC for confirmation of purity.

Analytical methods and quantitation of lipid components. Total phosphorus in the total combined lipids was determined by the method of Long and Staples (22). The polar lipids in bulk were quantitated by weight after elution from solid-phase extraction columns as described above. Individual polar lipid components were quantitated after development on 2D-HPTLC plates and staining with cupric sulfate by estimation of the spot intensities using a Bio Image Whole Band Analyzer (Millipore Corporation, Ann Arbor, MI).

Methanolysis of lipids' gas chromatography and gas chromatography/mass spectrometry analysis. Fatty acid methyl esters of individual polar lipid classes were prepared by scraping 2D-HPTLC spots directly into digestion tubes and converting the fatty acids to methyl esters with dry acid methanolysis using the method of Vance and Sweely (23) with the following modification: 400 µL of 3 M methanolic–HCl (10%, wt/vol; Supelco Inc.) reagent were added to each lipid sample, and methylation was allowed to proceed at 100°C for 5–6 h. Fatty acid methyl esters were extracted four times with 0.8 mL aliquots of petroleum ether. The samples were then dried and redissolved in hexane for gas chromatographic analysis. Fatty acid methyl esters were separated using a Varian 3400 gas chromatograph (Varian, Sunnyvale, CA) equipped with a septum-programmable injector, an on-column injector, and a flame-ionization detector. Methyl esters were separated on a DB™-23 30 m × 0.25 µm capillary column (J&W Scientific, Folsom, CA) with 50% cyanopropylphase, 0.25 µm film thickness. The carrier gas was He (head pressure 10 psi), and the make-up gas was N_2. The oven temperature was programmed from 90 to 130°C at the rate of 50°C/min and 130 to 210°C at 3°C/min. The injector temperature was programmed from 90 to 250°C at 70°C/min.

A standard mixture of bacterial fatty acid methyl esters (CP™ Mix catalog No.1114; Matreya, Inc., Pleasant Gap, PA) was chromatographed on two different capillary columns, a

DB™-23 (described above) and a DB™-5 20 m × 0.25 μm capillary (J&W Scientific) 5% phenyl column. Each peak of standard mixture was identified by mass spectrometry according to the method of Berger *et al.* (18). The fatty acid methyl esters of every unknown sample were chromatographed on the DB™-23 column and identified by comparison with the standard mixture. A confirmatory identification was performed by gas chromatography/mass spectrometry on the same column. Each peak with a retention time different from that of the standard was examined separately by gas chromatography/mass spectrometry on both the DB™-23 and DB™-5 columns, as was the standard.

Physical measurements. The isolated individual polar lipid components were further subjected to IR analysis. IR spectra were measured on thin liquid films between NaCl plates with a Perkin-Elmer (Norwalk, CT) 16PC FT-IR spectrometer.

RESULTS AND DISCUSSION

General observations. The total lipids of harvested *L. monocytogenes* cells extracted according to the procedure of Folch *et al.* (17), from four different cultures, amounted to 7 ± 1 mg/mL wet harvested cells, corresponding to approximately 7 ± 1 mg/100 mg dry cells. The lipid phosphorus content of the total lipids was approximately 5–6%. The polar lipids after separation from neutral lipids by solid-phase extraction amounted to 64% of total lipids, and the lipid–phosphorus content of the total polar lipids was approximately 9%.

By 2D-HPTLC separation in both solvent systems A and B, the most effective solvent was system A (dimension 1: acidic; dimension 2: neutral) (Fig. 1). In system B (dimension 1: acidic; dimension 2: alkaline), the components in the second dimension were concentrated for the most part near the solvent front.

The mobilities of the components of the total polar lipids were compared with those of cardiolipin, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylcholine, and phosphatidylserine standards in a single HPTLC separation using chloroform/methanol/acetic acid/water (50:25:6:2, by vol) as the solvent system. The results indicated a component that co-chromatographed with phosphatidylglycerol and another that had an R_f lower than that of cardiolipin.

As determined by 2D-HPTLC ($n = 5$), the polar lipid fraction contained 14 components, which were designated as g_1, g_2, f_1, f_2, f_3, e_1, e_2, e_3, d, c_2, c_1, b, a, and those at the Origin (Fig. 1). The quantitative composition of this fraction is shown in Table 1. The major portion of the polar lipid components, components g_1, g_2, f_2, f_3, e_2, e_3, d, and b, accounted for 88% of the total and were phosphorus-positive. Of the phospholipids, components $g_1 + g_2$ were 55% of the total; $f_2 + f_3$, 15%; $e_2 + e_3$, 17%; and d and b, 5 and 6%, respectively. Among the phosphorus-positive components, components e_2 and e_3 were intensively ninhydrin-positive; thus phosphoaminolipids were 15% of the total. A small portion of the polar lipids of *L. monocytogenes* was aminolipid free of phosphorus (components e_1, c_2, c_1, a, and the Origin, which accounted for 3.7% of the total). Orcinol staining revealed two glyco/sulfo-lipids, components f_1 and a, which accounted for 8.7% of the total polar lipids.

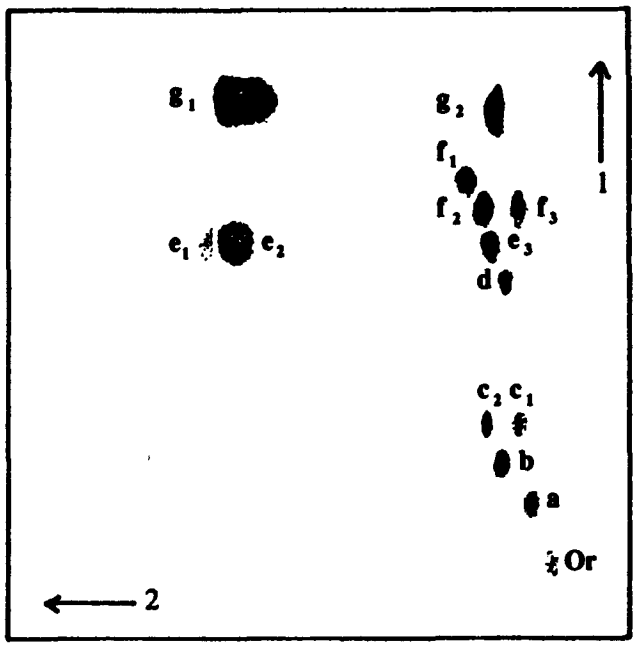

FIG. 1. Two-dimensional thin-layer chromatographic separation of polar lipids of *Listeria monocytogenes* on high-performance thin-layer chromatography silica gel 60. Plates were developed in direction 1 with chloroform/methanol/acetic acid/water (50:25:6:2, by vol) and in direction 2 with chloroform/methanol/water (65:20:3, by vol). The plate was stained by cupric sulfate/H_3PO_4 and charring. The letters a, b, c_1, c_2, d, e_1, e_2, e_3, f_1, f_2, f_3, g_1, g_2, and Origin (Or) denote the polar lipid components as described in the text.

The isolation and purification of each component was performed by separation of total polar lipids on a 2D-HPTLC with solvent system A, and after visualization by iodine vapor, the individual spots were scraped and eluted from silica gel as described above.

Fatty acid methyl esters identified after methanolysis are listed in Table 2. Generally, the fatty acids of the different polar lipid fractions exhibited notable differences in their relative complexities. Only component e_2 (11% of the total), which was an aminophospholipid, was characterized by high percentages of unsaturated fatty acids (47%), which was largely the 18:1n-9 *cis* species. In contrast, the major phospholipid component g_1 (34% of the total) had a negligible amount of unsaturated fatty acids. The remaining components, mainly the 18:1n-9 *cis* species, never exceeded 20% unsaturated fatty acids.

It is noteworthy that despite the differences in the relative complexity of the fatty acids of each component, the ratios of 15:0 *anteiso*/17:0 *anteiso* and 15:0 *anteiso*/15:0 *iso* were similar in all classes, averaging 1.5 and 4.5 , respectively. Nevertheless, the ratios of 17:0 *anteiso*/17:0 *iso* revealed a significant difference in their relative complexity. Also of interest is that the fatty acid profiles of the polar lipid components, with the exception of major phospholipid g_1, were characterized

[a]Abbreviations are: C, chloroform; M, methanol; AA, acetic acid; W, water; CL, cardiolipin; PG, phosphatidylglycerol; Molyb., molybdenum; i, indistinguishable; nd, not detected; trace (<0.4%).
[b]The polar lipids after separation by two-dimensional high-performance thin-layer chromatography (2D-HPTLC) on silica gel 60 plates were scraped and eluted as described in the Materials and Methods section. The letters denote each polar lipid component of *L. monocytogenes*.
[c]Components were quantitated as described in the Materials and Methods section.

primarily by the presence of four major saturated fatty acids, 16:0, 18:0, 15:0 *anteiso*, and 17:0 *anteiso*. The phospholipid component g_1 had a preponderance of the 15:0 *anteiso* species (see *The group of major phosphocomponents g_1 and g_2* section below).

Structural studies of the major polar lipids of L. monocytogenes. IR data showed a strong absorption band at 1730 cm^{-1}, indicating the presence of carboxylic esters in all major spots. Signficant information was obtained about each spot from chromatographic behavior.

The group of major phosphocomponents g_1 and g_2. Both components had the same (and the highest) R_f value on 1D-HPTLC in a chloroform/methanol/acetic acid/water (50:25:6:2, by vol) system but could be resolved by 2D-HPTLC into two phosphorus-positive spots, g_1 (higher R_f) and g_2 (lower R_f), in a chloroform/methanol/water system (65:20:3, by vol) (Fig. 1). This was considered to be due to differences in the nature of their constituent fatty acids, with the basic structure the same as that of beef heart cardiolipin as previously reported by Kosaric and Carroll (13). They indicated that 15:0 *br* (branched) plus 17:0 *br* species represent 78–100% of the fatty acids of polar lipids. Our results (Table 2) indicate that *L. monocytogenes* contains four major fatty acids (15:0 *anteiso* 49%, 17:0 *anteiso* 26%, 15:0 *iso* 10%, and 16:0 6%), which represent the 85% of fatty acid composition of polar lipids. It is in agreement with these results that species g_2 had HPTLC mobilities more similar to those of standard cardiolipin in the acidic, neutral, and alkaline solvent systems. Comparing these data with those of Kosaric and Carroll (13), it seems that g_1 plus g_2 might have overlapped when chromatographed in chloroform/methanol/water (65:25:4, by vol) and could have been identified as cardiolipin. Quantitatively the amount of components $g_1 + g_2$ is 55%, and the corresponding value of cardiolipin from Kosaric and Carroll (13) is 45%. Also, g_2 had 15.6% unsaturated fatty acids in contrast to species g_1, which contained a small amount of unsaturated fatty acids (see Table 2).

The g_1 species (the major polar lipid component, 34 .4%) contained 45.9% of its fatty acids as 15:0 *anteiso*, 23.7% as 17:0 *anteiso*, and 10.9% as 15:0 *iso*. The fatty acid composition of g_1 species was similar to that of component e_3 (see *The component group e_1, e_2, and e_3* section). The fatty acid profile of the g_2 species was appreciably different from that of the rest of the components, containing a variety of fatty acids but none in preponderance. Also, its unsaturated fatty acids included 5.6% 18:1n-9 *trans* fatty acid.

The component group f_1, f_2, and f_3. All of these components had the same R_f value on 1D-HPTLC in a chloro-

[a]The letters a, b, c_1, c_2, e_1, e_2, e_3, f_1, f_2, f_3, g_1, and g_2 denote the polar lipid components of *L. monocytogenes* as described in the text.
[b]*i*: *iso*, *a*: *anteiso*, *iso* and *anteiso* isomers of branched-saturated fatty acids.

form/methanol/acetic acid/water (50:25:6:2, by vol) system and could be resolved by 2D-HPTLC into three spots in a chloroform/methanol/water (65:20:3, by vol) system. One species, f_1, was free of phosphorus and was an orcinol-positive component (see below for *the components f_1 and a*). The other two components were phosphorus-positive molecular species, f_2 (higher R_f) and f_3 (lower R_f) in a neutral system (see Fig. 1). This separation in the second dimension was possibly due to differences in the nature of their constituent fatty acids. The components f_2 and f_3 were therefore tentatively identified as phosphatidylglycerols. This supposition was in agreement with the HPTLC mobilities of standard phosphatidylglycerol in the neutral, acidic, and alkaline solvent systems (Table 1). Phosphatidylglycerol is reported to be among the lipids of *L. monocytogenes* (13). In the present separation, we have used the solvent system chloroform/methanol/water (65:20:3, by vol) in the second dimension, which is of slightly different composition than that used by Kosaric and Carroll (13), chloroform/methanol/water (65:25:4, by vol). Components f_2 and f_3 are not well resolved when chromatographed in chloroform/methanol/water (65:25:4, by vol) may have been identified by Kosaric and Carroll (11) as phosphatidylglycerol.

The f_2 component contained palmitic acid (16:0) and stearic acid (18:0) as the predominant fatty acids, at 31.8 and 19.5%, respectively. This species had a higher proportion of unsaturated fatty acids (21.6%), which included 14.3% of 18:1n-9 *trans* fatty acids and a high percentage (10%) of the 14:0 species (Table 2).

The component group e_1, e_2, and e_3. The compounds e_2 and e_3 had the same R_f value on HPTLC in a chloroform/methanol/acetic acid/water (50:25:6:2, by vol) system but could be resolved by 2D-HPTLC into its three components. Species e_2 and e_3 were intensely phosphorus and amine-positive and were considered to be two molecular species differing only in the nature of their constituent fatty acids. Their HPTLC mobilities in the alkaline system were similar (see Table 1). Species e_2 was a major component of the total polar lipids (11%) and its predominant fatty acid moiety was 18:1n-9 *cis* (46.4%).

In the alkaline system, e_2 and e_3 had the same HPTLC mobility as the component g_2. Component e_1 was in trace quantity and only slightly separated from e_2; it was not possible to distinguish whether it was phosphorus-positive, but it was a ninhydrin-positive component. Of note, e_2 and e_3 were the only amino phospholipids of *L. monocytogenes* polar lipids, and they amounted to 15% of the total. The fatty acid composition of e_3 was indistinguishable from that of g_1 (see *The group of phosphocomponents g_1 and g_2*).

The components f_1 and a. These components are suspected

to be glyco- or sulfo-compounds because they were the only components that stained with orcinol reagent. Of note, component a was also an aminolipid (see also *The component group f_1, f_2, and f_3*).

Component f_1 had a preponderance of 17:0 *anteiso* and 15:0 *anteiso* fatty acid species (32.5 and 29.8%, respectively) and was characterized by a very low content of unsaturated fatty acids (2.8%). In contrast, the fatty acid profile of component a contained a variety of fatty acids. The following were the major species: 16:0, 18:0, 15:0 *anteiso*, 17:0 *anteiso*, 18:1n-9 *cis*, accounting for 22.3, 13.3, 13, 9.8, and 9.7%, respectively. Component a also contained substantial percentage (15%) of unsaturated fatty acids (Table 2).

The analysis of *L. monocytogenes* lipids revealed a complex lipid pattern; further studies are necessary to identify each component. Furthermore, the variation in several TLC R_f values depends on structural differences and the extent of ionization of the molecular constituents and, to a significant extent, the presence of intramolecular hydrogen bonding (24–26). Due to clear differences in R_f values and staining, the lipid spots were described separately. Finally, there is the possibility that *L. monocytogenes* contains polar hopanoid lipids (a class of pentacyclic triterpene lipids) as Moreau *et al.* (27) reported for several species of bacteria.

[a]Tohoku National Fisheries Research Institute, Shinhama, Shiogama, Miyagi 985, Japan and [b]Niigata Prefectural Fisheries Experimental Station, Igarashi San-nomachi, Niigata, Niigata 950-21, Japan

ABSTRACT: Determination of free fatty acids (FFA) in hepatopancreas of mussel, *Mytilus coruscus,* contaminated by diarrhetic shellfish poisoning (DSP) toxins, was carried out by high-performance liquid chromatography–fluorometry as their 9-anthryldiazomethane derivatives. The FFA in the hepatopancreas of mussels during May 30–June 14 were 443–666 μg/g. A marked increase in FFA content was observed on June 20 (2197 μg/g hepatopancreas) and June 27 (6322 μg/g hepatopancreas). The proportion of polyunsaturated fatty acids (PUFA), including 20:4n-6, 20:5n-3, and 22:6n-3, in mussel FFA increased during the experimental period. Diatoms almost completely dominated the phytoplankton community at the experimental site, suggesting that diatoms were the origin of the PUFA accumulated in mussels. The toxicity of FFA in mussel hepatopancreas on June 27 was sufficiently high as to interfere with the mouse bioassay by injection of an extract of shellfish, the official method for DSP toxin analysis.

Lipids 31, 641–645 (1996).

Diarrhetic shellfish poisoning (DSP) has become a well-known and worldwide problem since it was first reported by Yasumoto *et al.* (1,2). The monitoring of DSP toxin contents in shellfish is officially carried out by the mouse bioassay. Many commercially important shellfish are banned from harvesting during the toxicity period, causing serious economic damage to the shellfish industry. The accumulation of DSP toxins in shellfish is presumed to result from their ingestion of phytoplankton producing DSP toxins (3). However, the mouse bioassay for shellfish collected at a monitoring site at which DSP toxin-producing phytoplankton have not been observed occasionally shows positive results. The reason for this is partly because of the false positive results caused by free fatty acids (FFA) contained in shellfish; FFA show toxicity in the mouse bioassay (4–7).

In 1994, an incident of DSP occurred on the Niigata coast, Japan. Shellfish harvesting was prohibited from May 16 to August 2 (8). We determined the DSP toxins in mussels collected on the Niigata coast during the toxicity period by the mouse bioassay and by an instrumental method (5), and clarified that the contents of principal DSP toxins, okadaic acid (OA) and dinophysistoxin-1 (5), were too low to account for the mouse lethality of mussel extracts (8).

The present paper applies determination of FFA by high-performance liquid chromatography (HPLC)–fluorometry to elucidate the short-term changes in content and proportion of FFA in toxic mussel hepatopancreas collected on the Niigata coast during the DSP outbreak. The mouse lethality of FFA was also examined.

EXPERIMENTAL PROCEDURES

Sample material. Toxic mussels, *Mytilus coruscus,* were collected at a depth of 8 m at a monitoring station in the Niigata coastal area, Japan, from May 30 to June 27, 1994. Dates of the collection are shown in Table 1. The specimens selected were within a size range of 100–115 mm in shell length. The toxic hepatopancreas from five individual mussels were combined and used for each analysis.

One-liter sea-water samples for phytoplankton analyses also were collected at a depth of 8 m at the monitoring site with a Van Dorn sampler and fixed with formalin (5%). The counting and identification of phytoplankton was performed with a light microscope.

Extraction of FFA and derivatization. Extraction of FFA from mussel hepatopancreas was carried out immediately after sampling to avoid the production of FFA by exposing lipid to lipolytic enzymes during the storage of mussels. FFA in hepatopancreas of mussels were extracted with acetone by the procedures of the official mouse bioassay applied for DSP toxin analysis (9). About 10 g of the sample (combining the hepatopancreas of five individual mussels) was extracted in a homogenizer with 30 mL of acetone for two minutes at room temperature. After filtration, the residue was extracted two times with two 20-mL portions of acetone in a similar way. The combined acetone extract was made up to 100 mL by acetone. An aliquot (about 5 mL) of acetone extract corresponding to 0.5 g of hepatopancreas was evaporated to dryness under reduced pressure and dissolved in 2.5 mL of 80% methanol. FFA were extracted three times with 2.5 mL of *n*-hexane. The combined *n*-hexane extract was made up to 10

mL by *n*-hexane. An aliquot (25–250 μL) of the *n*-hexane extract was put in a colored vial and dried under nitrogen. The residue was esterified in 100 μL of 0.1% 9-anthryldiazomethane (ADAM) methanol solution for one hour in the dark at ambient temperature, and 10 μL of the solution was directly analyzed by HPLC (10).

HPLC. HPLC separation was carried out with a Hitachi (Tokyo, Japan) L-6200/L6000 gradient system equipped with a Develosil ODS-5 column containing octadecyl phase bonded to 5 μm silica gel particles (250 mm × 4.6 mm i.d.; Nomura Chemical, Seto, Japan) with a gradient of solvent A (acetonitrile/methanol/water, 8:1:1, by vol) and solvent B (methanol) at 20°C and a flowrate of 1.1 mL/min (10). The following linear gradient was used: segment 1, 100% A for 20 min; segment 2, initial conditions changed to 100% B over 30 min; segment 3, 100% B for 50 min. The peaks of fluorescent derivatives were monitored with a Hitachi F-1050 spectrofluorometer. The excitation and emission wavelengths were set at 365 and 412 nm, respectively. Eluate containing 14:0 and 16:1n-7 was collected from the outlet of the fluoromonitor and rechromatographed on a Capcell Pak CN SG120 column containing cyanopropyl phase bonded to 5 μm silica gel particles (250 × 4.6 mm i.d.; Shiseido, Tokyo, Japan) with acetonitrile/water (7:3, vol/vol) as the mobile phase at ambient temperature (11). The flowrate was kept at 1.1 mL/min. Excitation and emission wavelengths of the fluoromonitor were 365 and 412 nm, respectively.

Identification and quantification of the FFA peaks were carried out by comparing relative retention times (as listed in Table 1) and peak area, respectively, with those of known ADAM derivatives of FFA standards (10).

RESULTS AND DISCUSSION

HPLC separation. Figure 1 shows a representative chromatogram of ADAM derivatives of FFA extracted from hepatopancreas of mussels separated on the Develosil ODS-5 column. A good separation of the principal FFA, except for 14:0 and 16:1n-7 having the same relative retention time (0.73) (Table 1), was obtained. Linearity of the total content of FFA in the extract with increasing amount of extract reacted with ADAM was confirmed (Fig. 2). This indicates that the reaction of ADAM with FFA is quantitative and reproducible. Up to *ca.* 30 μg of FFA was quantitatively reacted with ADAM in 100 μL of 0.1% ADAM methanol solution. Resolution of 14:0 and 16:1n-7 acids collected from HPLC on the Develosil ODS-5 column was carried out by second HPLC run on the Capcell Pak CN SG120 column to calculate the proportion of these two FFA (11).

Short-term changes in proportion and content of FFA. Table 1 shows the proportion and content of FFA in hepatopancreas of mussels determined by HPLC–fluorometry. The major FFA were 16:0, 16:1n-7, 20:5n-3, and 22:6n-3. This is consistent with earlier observations on mussel lipids

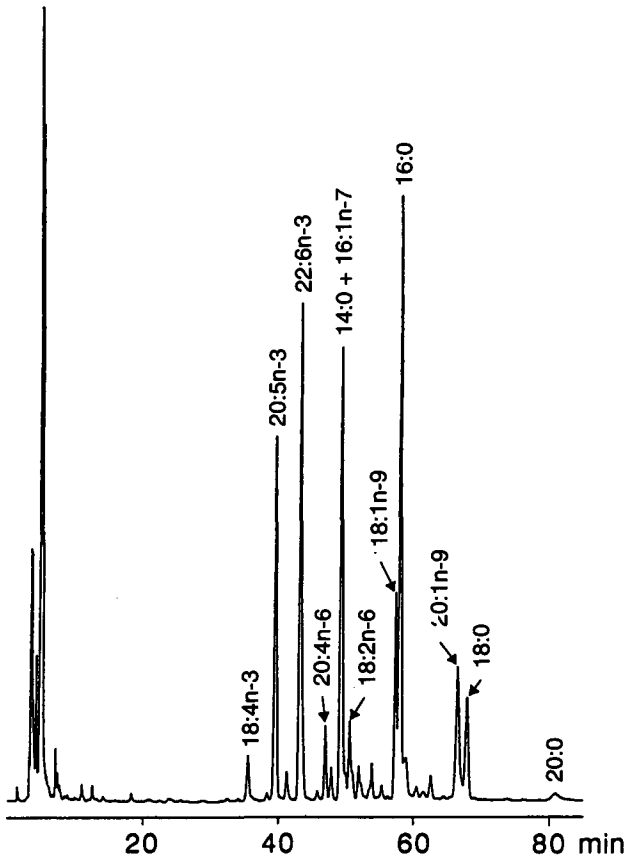

FIG. 1. High-performance liquid chromatography separation of 9-anthryldiazomethane derivatives of free fatty acids from the hepatopancreas of mussels collected at the Niigata coast (June 20) on the Develosil ODS-5 column (Nomura Chemical, Seto, Japan). An aliquot of the extract (1/800 of 1 g hepatopancreas of mussels) was injected. For derivatization procedure and chromatographic conditions, see text.

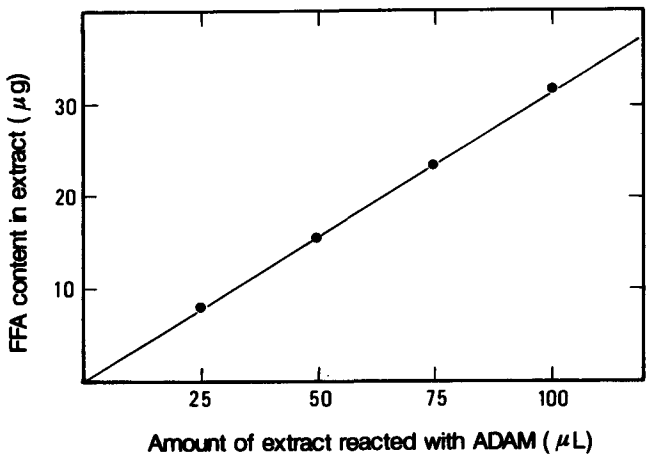

FIG. 2. Linearity of total content of free fatty acids (FFA) in extract (mussels, June 27) with increasing amount of extract reacted with 9-anthryldiazomethane (ADAM). An aliquot of the *n*-hexane extract was reacted with ADAM in 100 μL of 0.1% ADAM methanol solution. Extracts from hepatopancreas of mussels collected on June 27 were used.

(12–15). The total contents of FFA observed in hepatopancreas for the period from May 30 to June 14 were 443–666 μg/g. The values were higher than those in mussels collected in the Gulf of Trieste (136–360 μg/g) (16) and in scallops from Mutsu Bay (270 μg/g) (10). A marked increase in FFA contents in hepatopancreas of mussels was observed on June 20 and 27. The proportion of polyunsaturated fatty acids (PUFA), especially 20:4n-6, 20:5n-3, and 22:6n-3, increased together with the decrease in 14:0, 16:0, 18:0, and 20:0 acid percentages. Although the proportion of FFA does not directly reflect that of total lipids, an increase in the PUFA percentages in the FFA compositions indicates accumulation of these fatty acids in total lipids of mussels. Generally, the fatty acid composition of marine invertebrates is influenced by a host of environmental factors. The most important contributing factors to any variation in fatty acid composition are temperature and food availability (12,13,15). Since the water temperature where the mussels were cultured (8 m depth) did not change significantly (Table 1), an effect of temperature on the FFA composition in mussels was not considered. Because mussels are incapable of synthesizing n-3 and n-6 series PUFA (12), an increase of PUFA is likely to be a consequence of food abundance or changes in the intensity of feeding activity.

Table 2 shows the compositions and cell densities (cells/L) of phytoplankton present where the mussels were cultured. The most abundant plankton species were diatoms, *Leptocylindrus danicus* (May 30 and June 6), and *Chaetoceros* spp. (June 14 and 27). The total cell densities of phytoplankton did not change significantly (Table 2). Although the qualitative compositions of phytoplankton species observed at this site changed markedly, diatoms almost completely dominated the phytoplankton community. While there was 12.5% of dinoflagellates in the total phytoplankton population of June 27, a peak corresponding to 18:5n-3 which has been proposed as a biological marker for dinoflagellates in marine food-chain study (17) was not detected from mussel hepatopancreas collected on June 27. This suggests that the increases of both FFA contents and proportion of PUFA in mussels on June 27 are not related to dinoflagellates. These results suggest that PUFA accumulated in mussels are derived from diatoms because diatoms produce such PUFA (11,18–21). The FFA accumulated in hepatopancreas of mussels on June 20 and 27 may be intact or semi-intact algal cells because molluscs feed partly by phagocytosis.

Mouse lethality induced by FFA. The calculated toxicity of hepatopancreas of mussels assigned to FFA during the experimental period was on May 30 (0.02 MU/g), June 6 (0.02 MU/g), June 14 (0.02 MU/g), June 20 (0.11 MU/g), June 27 (0.37 MU/g). The mouse lethality for FFA was calculated from the respective FFA contents (Table 1) and the toxicity of standard FFA data reported previously (4). Generally, the mouse bioassay for DSP toxin analysis expresses toxicity by a mouse unit (MU), which is defined as the amount of a toxin, or toxins, to kill a male mouse of ddY strain of 20 g body weight in 24 h. Hepatopancreas having mouse lethalities

[a]Total diatom percentages.

above 0.5 MU/g are regarded as toxic and unsatisfactory for food use (9). The toxicities of hepatopancreas used in the present study as determined by the mouse bioassay and by HPLC were 0.5–1.0 and 0.02–0.13 MU/g, respectively (8). The calculated toxicity from May 30 to June 14 was 0.02 MU/g. This value was far below that required for a quarantine level (0.5 MU/g) in shellfish hepatopancreas. A marked increase in the calculated toxicity was obtained on June 20 and 27. The calculated toxicity of FFA on June 27 was of a high enough value to conceivably give rise to a false-positive result in the official mouse bioassay for DSP toxins. Although the FFA content in the hepatopancreas of mussels on June 27 was 9.5 times higher than that on May 30 (Table 1), the calculated toxicity from FFA on June 27 was 18.5 times that on May 30. This discrepancy arises from the difference in toxicity of respective FFA; long-chain PUFA, especially 20:4n-6 and 20:5n-3, are agents active as mouse lethal material (4).

In the official mouse bioassay for DSP toxins, material extracted from shellfish is injected i.p. into mice. Generally, material injected i.p. is absorbed into the lymph system, and this drains into the circulating blood *via* two channels, the thoracic duct and the right lymphatic duct, respectively. The thoracic duct receives all materials from the abdomen. It is known that direct injection of 20:4n-6 acid into the blood vessels of animals is almost immediately lethal (22). Mouse lethality induced by i.p. injection of FFA suggests that the mice may have died as a result of sufficient FFA being rapidly passed into the circulating blood. FFA are formed in foods by lingual and gastric lipases, and the previous experiments in animals and humans fed PUFA as FFA does not refer to any toxicity assignable to these FFA (23–25). On the other hand, DSP toxin, such as OA, is a very potent inhibitor of protein phosphatase 1 and protein phosphatase 2A (26). It is suggested that OA causes diarrhea by stimulating the phosphorylation of the protein(s) that control sodium secretion by intestinal cells (26). Therefore, it is very important to recognize that FFA are not implicated directly in any way in the human exhibiting symptoms of DSP.

In conclusion, results of the present study demonstrate that the proportion and content of FFA in mussel hepatopancreas show considerable short-term changes. It is suggested that PUFA accumulated in mussels were derived from diatoms. The calculated toxicity of FFA in mussel hepatopancreas on June 27 demonstrates that there was a value sufficiently high to interfere with the mouse bioassay. The result suggests that the determination of FFA in mussels coupled with the official mouse bioassay for DSP toxin analysis is necessary for a more accurate interpretation of DSP toxicity.

Unusually High Levels of Eicosatetraenoic, Eicosapentaenoic, and Docosahexaenoic Fatty Acids in Palestinian Freshwater Sponges

Valery M. Dembitsky[a,*] and Tomas Rezanka[b]

[a]Natural Products Laboratory, Department of Organic Chemistry, The Hebrew University of Jerusalem, Jerusalem 91904, Israel and [b]Institute of Microbiology, Videnska 1083, Prague 142 20, Czech Republic

ABSTRACT: The fatty acid composition of three freshwater sponges—*Ephydatia syriaca, Nudospongilla* sp., and *Cortispongilla barroisi*—were studied. Twenty principal fatty acids, and unusually high levels of eicosatetraenoic (5,8,11,14-20:4 up to 10.1% of the total acid mixture), eicosapentaenoic (5,8,11,14,17-20:5 up to 11.6%), and docosahexaenoic acids (4,7,10,13,16,19-22:6 up to 11.8%) were detected. The only demospongic acid found was 5,9,17-hexacosatrienoic acid (1.8–3.7%).

Lipids 31, 647–650 (1996).

At the present time, a definite opinion has been formed concerning the unique nature of sponge biomembranes (1). Sponges can be regarded as live fossils of the contemporary animal world due to the fact that they have undergone practically no evolutionary development, i.e., their present representatives probably remain at the evolutionary level of their remote precursors (2). Sponge lipids differ markedly in their chemical and biochemical properties from lipids obtained from other living organisms (1). Rare lipids, including fatty acids, have been identified in marine sponges, mostly long-chain fatty acids (C_{24}–C_{36}) of straight, branched, and brominated structure (3). Because these acids were isolated for the first time from marine sponges, they are often called "demospongic acids" (1). The total content of demospongic acids can reach up to 80% in some marine sponge species (3,4), and a major part of them is found in individual phospholipid classes (1,3). There is limited information on whether freshwater sponges contain demospongic acids (5–12).

In this work we report a study of the fatty acid composition of three freshwater sponges, which were collected in an expedition to the Jordan river, Lake Hula, and the Sea of Galilee, Palestine.

MATERIALS AND METHODS

Sampling and lipid analyses. The freshwater sponge *Ephydatia syriaca* was collected in August 1993, in the spring of the Jordan river (Banias, near Mountain Hermon); the freshwater sponge *Nudospongilla* sp. was collected in May 1994, in Lake Hula; and the freshwater sponge *Cortispongilla barroisi* was collected in July 1994, in the Sea of Galilee (Lake Tiberias, Lake Kinneret, Palestine). All sponges were washed in water, carefully cleaned of all debris, and cut into small pieces. Immediate lipid extraction after collection was done as described elsewhere (9).

Gas chromatographic/mass spectrometric analyses of fatty acid methyl esters. High-resolution mass spectrometry was done using a MAT 90 magnetic sector mass spectrometer (Finnigan, San Jose, CA) in the electron ionization mode. Gas chromatography/mass spectrometry of fatty acid mixture was done using a Finnegan 1020 B single-state quadrupole gas chromatography/mass spectrometry instrument in the electron ionization mode. Injection temperature (splitless injection) was 100°C, and a fused-silica capillary column (Supelcowax 10; 60 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco, Bellefonte, PA) was used. The temperature program was as follows: 100°C for 1 min, than increased at 20°C/min to 180°C and at 2°C/min to 280°C, which was maintained for 1 min. The carrier gas was helium at a linear velocity of 60 cm s^{-1}. All spectra were scanned within the range *m/z* 70–450.

RESULTS AND DISCUSSION

The fatty acid compositions of three sponge species are presented in Table 1. Twenty principal fatty acids were detected in the sponge total lipids. All the principal fatty acids identified are "classical" acids which are found in invertebrates (13). Only one demospongic acid, namely 5,9,17-26:3 (from 1.8 to 3.7%) was found in all sponge species. Over the last two decades it has been established that the majority of marine sponges contain trace amounts of both 20:4/20:5 and/or 22:6 fatty acids (3,14–30). Both isomers of eicosatetraenoic acid were found in some freshwater sponges ranging in amount from 1.4 to 11.8% (5–7,10–12) and in marine sponges ranging from 0.2 to 18.3% (16,31–49) (see Table 2). Higher

5,9,17-26:3	3.6	3.7	1.8
Trienoic	16.3	16.9	16.2
6,9,12,15-18:4	1.7	0.7	0.6
5,8,11,14-20:4	10.1	9.5	9.5
5,8,11,14,17-20:5	9.7	9.5	11.6
4,7,10,13,16,19-22:6	11.8	8.0	6.3
Sum	33.3	27.0	27.4

amounts were found in *Phakellia aruensis*, 12.5% (40); *Ectyoplasia ferox*, 14.1% (35); and in *Spheciospongi confoederata*, 18.3% (47).

Eicosapentaenoic acid was found in some marine sponges (see Table 2) and larger amounts were detected in freshwater sponges (up to 17.2% (10). Docosahexaenoic acid was the major lipid component in the marine sponge *Microciona prolifera*, varying from 15.4 to 25.4% of total lipids (43,45–47). Freshwater sponges usually contained this acid in amounts which ranged from 0.8 to 4.1% (Table 2). In the present study, unusually high levels of eicosatetraenoic, eicosapentaenoic, and docosahexaenoic acids were found in all freshwater sponges (Table 1). The percentage of total lipids formed by these three fatty acids as detected in *E. syriaca* was 31.5%; in *Nudospongilla* sp., 26.3%; and in *C. barroisi*, 26.8%. Weissmann *et al.* (43) reported that a high level of 22:6 fatty acid was found in two phospholipids of the marine sponge *M. prolifera*, namely in phosphatidylcholine (52%) and in phosphatidylinositol (29%). The authors indicated that the high level of 22:6 acid could be the result of differences in the local environment of the samples collected, and appeared to be related to a role for this fatty acid in stimulus–response coupling in these cells.

More interesting data could be associated with 5,9,17-26:3 fatty acid, which was found to be the major demospongic fatty acid in some Palestinian freshwater sponges. According to Hahn *et al.* (7) and Dembitsky *et al.* (9), who studied the fatty acid total content of the freshwater sponges *E. fluviatilis* and *Euspongilla lacustris*, only 5,9,19-26:3 acid was 14.9%

[a]Two isomers, namely 5,8,11,14-20:4 and 6,9,12,15-20:4. [b]20:5 = 5,8,11,14,17-20:5. [c]22:6 = 4,7,10,13,16,19-22:6. [d]Total phospholipids. [e]Collected in July. [f]Collected in December. [g]Without cyanobacteria.

of the total fatty acid methyl esters (phosphatidylethanolamine, 19.8%; and phosphatidylserine, 14.8%) and 10.3% (phospholipid fraction, 20.9%), respectively, in these two species.

Previous gas chromatography/mass spectrometry analyses of the fatty acid levels in three freshwater sponges from Lake Baikal (11,12) indicated that 5,9,17-26:3 acid is the major demospongic fatty acid. Prior and current data show the principal biosynthetic sequence that seems to be operative in the freshwater sponge species. The biosynthetic pathway of the 5,9,17-26:3 acid is predominant.

The results presented in this work are of interest because they clearly demonstrate that three polyunsaturated fatty acids—eicosatetraenoic, eicosapentaenoic and docosahexaenoic—and the demospongic acid 5,9,17-26:3 are the principal fatty acids in freshwater sponges. Further work is in progress toward elucidating the structure of some unusual minor fatty acids.

Lipidic Characterization of Full-Grown Amphibian Oocytes and Their Plasma Membrane-Enriched Fractions

Hugo A. Caldironi[a,b] and Telma S. Alonso[a,*]

[a]Instituto de Investigaciones Bioquímicas de Bahía Blanca (UNS-CONICET), 8000 Bahía Blanca, Argentina and [b]Cátedra de Química Biológica, Facultad de Agronomía, UNCPBA, 7300 Azul, Argentina

ABSTRACT: The content and composition of neutral lipids and phosphoglycerides from full-grown prophase-arrested *Bufo arenarum* Hensel oocytes and from their ghost preparations were studied. The ghosts obtained are highly enriched in plasma membrane as suggested by the activity of 5'-nucleotidase, a marker enzyme, and the level of typical membrane components such as sphingomyelin, phosphatidylserine (PS), phosphatidylinositol (PI), and phosphatidic acid. In whole oocytes, triacylglyceride (TAG) comprises about 60% of the total lipids followed by phosphatidylcholine (PC), cholesterol, and phosphatidylethanolamine (PE). TAG and diacylglycerides have a similar unsaturation index. PC and PE account for about 80% of the phosphoglycerides in the whole oocyte and in their plasma membrane-enriched fractions. Arachidonic acid (20:4n-6), 18:0, and 16:0 make up about 80 mol% of the total fatty acids in PI in whole oocytes and ghost fractions. The unsaturation index in PS is higher in intact oocytes than in ghost preparations, probably owing to the significant amount of 20:4n-6 which comprises 23 mol% of the total fatty acids in whole oocytes. The fatty acid profile in phosphatidic acid from whole oocytes is rather different from that in ghosts. Sphingomyelin contains mainly saturated and monounsaturated fatty acids, 24:1 being the principal very long chain unsaturated fatty acid in both oocytes and ghosts.
Lipids 31, 651–656 (1996).

Amphibian oocytes are larger and simpler than most mammalian cell types, a phenomenon which facilitates their use for electrophysiological and biochemical measurements. The full-grown amphibian oocyte system offers several advantages for investigating the responses of both endogenous receptors (1) and exogenous receptors which have been translated, processed, and rendered active from injected mammalian mRNA (2). The ability of agonist-receptor complexes to bind to effector molecules may be modulated by the head group and fatty acid composition of membrane lipids (3). Some phosphoglycerides and fatty acids are crucial for the activity of certain enzymes such as protein kinase C, adenylate cyclase, and guanylate cyclase (4–6). In addition, long-chain fatty acids applied to the cytoplasmic membrane surface of intact BC_3H-1 muscle cells triggered drastic changes in acetylcholine receptor gating properties (7). It is clear that lipid composition is involved in the modulation of nicotinic acetylcholine receptor function (8). There is growing evidence that physiological response to progesterone, the hormone that acts at the full-grown amphibian oocyte plasma membrane receptor to induce meiotic division, may be modulated by changes in the phosphoglyceride microenvironments within the plasma membrane (9).

A detailed knowledge of the native hydrophobic environment is required for the exploration of those specific features of lipids associated with the presence of oocyte receptors. An understanding of the membrane's composition is also a prerequisite to metabolic studies focused on the understanding of the possible involvement of lipids in the receptor functions. This paper is concerned with the content and fatty acid profile of neutral lipids and phosphoglycerides in whole *Bufo arenarum* Hensel oocytes arrested in the prophase of the first meiotic division. In addition, highly enriched plasma membrane fractions (ghosts) were obtained, and a characterization of their lipids was performed.

MATERIALS AND METHODS

Experimental system. Mature females of the toad *B. arenarum* Hensel were obtained commercially and maintained under laboratory conditions. The ovarian tissue was surgically removed and transferred to ND 96 solution (96 mM NaCl, 1 mM Mg Cl_2, 2 mM KCl, 5 mM HEPES, pH 7.4; Sigma, St. Louis, MO). After rinsing, it was cut into small pieces, and full-grown prophase-arrested oocytes, stage V according to Valdéz Toledo and Pisanó (10), were isolated under a stereotaxic microscope. Only those ovaries containing a large population of full-grown oocytes were used. Oocytes were treated with 0.25% (wt/vol) collagenase (Sigma Type I) in ND 96 solution with agitation for one hour at room temperature. After collagenase treatment, oocytes free from follicular cells were rinsed several times with ND 96 solution.

Ghost preparations. The methodology originally developed for obtaining ghosts (enriched-plasma membrane preparations) from sea urchin oocytes (11) was adapted. Oocytes were transferred to 10 vol of a solution containing 0.1 M $MgCl_2$, 0.01 M TRIS (Sigma), pH 7.5, and kept there for at least 30 min in order to stabilize the oocyte membrane and to wash the surface. The oocytes were sedimented at 3,000 rpm for 5 min and the supernatant discarded. Oocytes were osmotically lysed by resuspension in 0.01 M $MgCl_2$, 0.01 M TRIS, pH 8.0 for 30 min. Lysis was augmented by gently homogenizing with a Teflon pestle. Lysed cells were sedimented, and the resulting pellet was resuspended in the diluted $MgCl_2$ and then sedimented again. The pellet contained oocyte ghosts was applied on 40% sucrose solution and centrifuged at 3,000 rpm for 5 min. The purified ghosts were recovered from the interphase and washed with diluted $MgCl_2$ to eliminate sucrose.

Lipid analysis. Lipid extraction from whole oocytes and ghost preparations was performed following Folch *et al.* (12). Phosphoglycerides were separated by two-dimensional thin-layer chromatography (TLC) on silica gel H according to Rouser *et al.* (13). Neutral lipids were separated by monodimensional TLC on silica gel G using hexane/diethyl ether/acetic acid (40:60:1, by vol). Phosphoglycerides were located after exposure of the plates to I_2 vapors and quantitated by phosphorus analysis (13) after digestion with perchloric acid.

For determination of fatty acid composition, the lipids were separated by TLC as described above, and spots were visualized under ultraviolet light after spraying the plates with 2′-7′-dichlorofluorescein in methanol. Fatty acid methyl esters were prepared according to the method of Morrison and Smith (14) using boron trifluoride (14% in methanol; Sigma). Fatty acid analysis was performed by temperature-programmed gas–liquid chromatography using 21:0 methyl ester as internal standard. Two glass columns (2 m × 0.2 cm i.d.) packed with 15% OV-275 on 80-120 Chromosorb WAW (Supelco, Bellefonte, PA) were connected to two flame-ionization detectors operated in the dual-differential mode. The initial and final oven temperatures were 160 and 220°C, respectively, and the rate of increase was 5°C/min. Injector and detector temperatures were 220 and 230°C, respectively. The carrier gas was N_2 (30 mL/min). Chromatograms were quantitated with a CDS-111 Varian integrator (Palo Alto, CA). Peaks were identified by comparison of retention times with those of standards. Unsaturation index was determined as the sum of percentage of individual unsaturated fatty acids times number of double bonds.

During all the procedures (lipid extraction, solvent evaporation, TLC spotting, drying and spraying of TLC plates, and the described derivatization), the lipids were kept in an N_2 atmosphere. All organic solvents were of analytical grade. Cholesterol spots were scraped from TLC plates, eluted with chloroform, and quantitated using a commercially available nonenzymatic assay (Wiener Laboratories, Rosario, Argentina). In this procedure, cholesterol was subjected to oxidation with ferric ions in sulfuric medium. The absorbance of the formed red chromogen was measured spectrophotometrically at 560 nm.

Other analytical methods. Proteins were determined by Lowry *et al.* (15) after extraction with 1 N NaOH using crystalline bovine serum albumin as standard. The activity of 5′ nucleotidase as an enzyme marker of plasma membrane was measured according to Michell and Hawthorne (16). Statistical analysis was performed using Student's *t*-test with the values representing the mean standard deviation of the total number of samples indicated in each legend.

RESULTS AND DISCUSSION

The results of this study provide the first detailed lipid analysis of full-grown prophase-arrested amphibian oocytes. The content and composition of neutral and polar lipids of *B. arenarum* full-grown oocytes and their plasma membrane-enriched fractions (ghosts) were analyzed.

Although there is evidence to suggest that physiological responses to agonists may involve changes in the lipid microenvironment within the plasma membrane, to date there are no biochemical analyses of the lipid composition of amphibian oocyte plasma membrane. In order to analyze lipid composition, a procedure to obtain ghosts (Fig. 1) was adapted to permit the preparation of milligram quantities of plasma membrane. Typically, 15 mg of plasma membrane protein was obtained from 300–400 mg protein of oocytes. The activity of 5′-nucleotidase, a plasma membrane marker enzyme, was about 17-fold higher in ghosts than in oocyte homogenates, suggesting a significant enrichment in plasma membrane in these preparations (data not shown). This finding is consistent with the net increases in the amount of typical plasma membrane phosphoglycerides such as phosphatidic acid, phosphatidylserine (PS), phosphatidylinositol (PI), and sphingomyelin (SM) (Table 1). The percentage of phosphatidic acid in whole oocytes was 0.1, whereas in ghost preparations it was 1.3. The respective values for PS and PI ranged between 1.0 and 2.9 and 3.4 to 5.4, respectively, when whole oocytes and ghost preparations were compared with-

TABLE 1
***Lipid Composition of Whole Full-Grown Prophase-Arrested Ooctyes and of Their Plasma Membrane-Enriched Fractions*[a]**

	Whole oocytes	Ghosts
Triacylglycerides	144.17 ± 0.19	—
Diacylglycerides	1.87 ± 0.17	1.77 ± 0.49
Free fatty acids	0.83 ± 0.19	9.24 ± 0.84
Cholesterol	20.12 ± 2.20	9.90 ± 0.25
Phosphatidic acid	0.09 ± 0.01	1.69 ± 0.31
Phosphatidylserine	0.93 ± 0.08	3.80 ± 0.15
Phosphatidylinositol	3.19 ± 0.22	7.03 ± 0.75
Sphingomyelin	7.93 ± 0.23	9.82 ± 0.58
Phosphatidylcholine	41.33 ± 6.02	63.74 ± 5.11
Phosphatidylethanolamine	18.78 ± 2.06	23.23 ± 1.82

[a]Lipids were isolated and quantitated as described in the Materials and Methods section. Results are presented as nmol of lipids per mg protein and are mean values ± SD from five independent samples.

FIG. 1. Ghosts of *Bufo arenarum* oocytes in stage V of oogenesis according to Valdéz Toledo and Pisanó (Ref. 10). Ghosts were obtained as described in the Materials and Methods section (20×).

out considering triacylglyceride (TAG) amounts which was not present in ghost preparations. SM content in ghost fractions was 1.2-fold higher than in whole oocytes.

In whole oocytes, TAG represented 60% of the total lipid amount followed by phosphatidylcholine (PC) (17%), cholesterol (8.5%), and phosphatidylethanolamine (PE) (7.9%). Neutral lipid content in whole oocytes was 2.3-fold higher than that of phosphoglycerides. In ghost preparations, PC comprised 49% of the total lipid content followed by PE (18%) and cholesterol (7.6%) (Table 1). In contrast to the case of whole oocytes, total phosphoglyceride content in ghosts was 5-fold higher than the level of neutral lipids. Identical results were obtained when phosphoglycerides were measured by phospholipidic phosphorus determination (data not shown) or by gas–liquid chromatography.

With regard to neutral lipid content in whole full-grown oocytes, TAG made up 86% of the total amount followed by cholesterol (12%), diacylglycerides (DAG) (1.1%), and free fatty acids (FFA) (0.5%). The high content of TAG is consistent with the putative employment of these neutral lipids in supplying the energy required after fertilization since there was a net fall in their content at this time. Fatty acids originating in TAG were rapidly utilized in other metabolic reactions (17,18). In coincidence, neutral lipids comprised most of the label when *B. arenarum* and *Xenopus laevis* full-grown oocytes were incubated with (^{3}H)-glycerol evidencing capacity to biosynthesize their own lipids (19).

When phosphoglyceride content was analyzed, it was found that in whole oocytes and ghost preparations the major constituents were PC and PE, followed by SM and PI (Table 1). In full-grown oocytes, SM and PC comprised 67% of the total content. In many systems, the sum of the two choline lipids constituted about half of the total phosphoglycerides, although the ratio of the amounts of these two components varied greatly (20). In *X. laevis* full-grown prophase-arrested oocytes, PC and PE comprised about 89% of the total phosphoglyceride amount. *Bufo arenarum* oocytes showed a lower amount of PE and a higher PC level than those of *X. laevis*. Other phosphoglycerides such as phosphatidic acid, PI, and SM were present in similar amounts in the two amphibian species (19). The fatty acid composition of neutral lipids in whole full-grown oocytes and ghosts is depicted in Table 2. Oleic (18:1), 16:0, 18:2n-6, and 16:1 were the principal fatty acids in TAG (about 89 mol% of the total fatty acid content) in whole oocytes. The 20:4n-6 was the major long-chain (C_{20}–C_{22}) polyenoic fatty acid. In DAG, 18:1, 16:0, and 18:0 amounted to 66 mol% of the total fatty acids. TAG and DAG showed a similar unsaturation index (UI) (about 113). The 18:1 was the principal FFA followed by 16:0, 18:2n-6, and 16:1. The 18:1 comprised about 30 mol% of the total fatty acids in all the neutral lipid classes analyzed. The high levels of 16:0, 18:1, and 18:2n-6 found in oocyte neutral lipids might serve as a storage pool for metabolic precursors, since these fatty acids are required as substrates for fatty acid elongation and desaturation or they may be important as a form of fuel, *via* β-oxidation.

In ghosts (Table 2), the major fatty acid in DAG was 16:0. Other quantitatively important fatty acids were 18:1 and 18:0. The 16:0, 18:1, and 18:0 comprised about 74 mol% of the total FFA. The FFA UI (70) was higher than that of DAG (49). Polyunsaturated fatty acids showed low values (about 10 mol%) in both lipid classes.

The acyl group distribution of PC, PE, and PI in full-grown oocytes and ghosts is shown in Table 3. The 16:0, 18:1, 18:2n-6, and 16:1 comprised 86 mol% of the total fatty acids of PC in whole oocytes. Fatty acids with carbon chain lengths between 20 and 22 represented 6 mol% in the total acyl group distribution, 20:4n-6 being the principal one. The acyl group distribution in PC was similar in full-grown *B. arenarum* and *X. laevis* oocytes (19). In PE, 18:1, 18:0, and 16:0 were the major fatty acids. There was a significant amount of 20:4n-6 in this phosphoglyceride. PE with 20:4n-6 at the 2-position was most abundant among the molecular species in the unfertilized *Rana nigromaculata* eggs (21). In full-grown *X. laevis* oocytes, the UI of PE was higher than in *B. arenarum,* owing to the contribution of 20:4n-6 and 22:6n-3 (19). The compositional analysis of PI in whole full-grown *B. arenarum*

[a]Results are presented as mean values ± SD (mol%) from five independent samples; SFA: saturated fatty acids; MUFA: monounsaturated fatty acids; PUFA: polyunsaturated fatty acids; UI: unsaturation index; TAG: triacylglycerides; DAG: diacylglycerides; FFA: free fatty acids.

oocytes indicates that 20:4n-6 constituted the major fatty acid representing 40 mol% of the total acyl groups (Table 3). Unfertilized eggs from *R. nigromaculata* and *B. arenarum* also were found to contain a large percentage of 20:4n-6 (22,23). Other important fatty acids in PI from full-grown *B. arenarum* oocytes were 18:0 and 16:0.

In ghosts, 16:0 and 18:1 were the principal fatty acids in PC followed by 18:2n-6 and 16:1, comprising altogether about 88 mol% of the total fatty acid amount. The 18:1, 16:0, and 18:0 were the principal acyl groups in PE. The UI was higher in PE than in PC. The 18:0 was the principal component in PI followed by 20:4n-6 and 16:0. The UI of PI was higher than that of PE and PC. PI from whole oocytes was more unsaturated than PI from ghost preparations.

The composition of PS, phosphatidic acid, and SM in whole oocytes and in ghost preparations is shown in Table 4. The UI in PS was higher in whole oocytes than in ghost preparations, owing probably to the marked content of 20:4n-6 and 22:6n-3. According to reports on other tissues, PS in whole oocytes denoted the highest UI among all lipids analyzed. The

[a]Results are presented as mean values ± SD (mol%) from five independent samples. Abbreviations as in Table 2.

fatty acid distribution in phosphatidic acid from whole oocytes was rather different from that in ghost preparations. The presence of 22:4n-6 in whole oocytes is of interest since this fatty acid is not widely prevalent in other cells.

SM contained mainly saturated and monounsaturated fatty acids. The 16:0 was the major saturated fatty acid in both whole oocytes and ghosts. Other quantitatively important saturated fatty acids were 22:0 and 24:0. The major very long chain unsaturated fatty acid was 24:1 which occurred in similar proportions in the two cases analyzed. SM showed the highest saturated fatty acid content (about 80 mol%) among all lipids analyzed.

Many vital cell functions are intimately dependent on the type and extent of polyunsaturation present in the membrane (24). The high unsaturation degrees of the whole oocyte PI and PS suggest that the new membranes to be formed after fertilization may require a degree of unsaturation higher than that required by the oocyte cell membrane itself. During *B. arenarum* early embryonic development, there is an active phosphoglyceride synthesis (18), but probably it is not enough to support the period of cell division. Amphibian eggs may be not only supplied with TAG reserves but also with phosphoglyceride reserves.

An Improved Ultracentrifugation Method for the Separation of Cholesterol Carriers in Bile

Nariman Ayyad, Bertram I. Cohen*, Akira Ohshima[1], and Erwin H. Mosbach

Departments of Surgery, Beth Israel Medical Center, New York, and Albert Einstein College of Medicine, Bronx, New York

ABSTRACT: Vesicles and micelles, the major carriers of cholesterol in bile, play a role in the formation of cholesterol gallstones. A simple and rapid ultracentrifugation method was developed to isolate these biliary cholesterol carriers when only microliter amounts of bile were available. The proposed method employs a 46 to 0% sucrose density gradient, a NVT90 near-vertical rotor, and a centrifugation time of one hour. As little as 25 μL of bile can be used with no disruption of the carriers. The method was validated by comparison with gel filtration column chromatography using 6 mM taurocholate in the elution buffer. The sucrose linear density gradient ultracentrifugation procedure described here is simple, fast, and compares favorably with the gel filtration chromatography method for the separation of cholesterol carriers from bile.

Lipids 31, 657–660 (1996).

Cholesterol is solubilized in bile in unilamellar and multilamellar vesicles, as well as in simple and mixed micelles (1,2). It has been shown that patients with gallstones usually have a higher proportion of vesicles in their bile compared to control subjects without gallstones (3,4). It is believed that cholesterol crystals nucleate from cholesterol-rich multilamellar vesicles (5–8). Two analytical methods have been used to quantitate these cholesterol carriers in bile—gel filtration column chromatography (9–11) and density gradient ultracentrifugation (4,12–15). The amount of cholesterol in each carrier is difficult to determine as each of these methods has inherent analytical limitations. Gel filtration requires 100–200 μL of bile, exogenous bile salts in the elution buffer to maintain the integrity of the micelles, and a fractionation time of approximately 3 h (7,11,16–19). The ultracentrifugation method does not require added bile salts; however, artifacts may develop due to the effects of centrifugal force on the cholesterol carriers in the tube, the high hydrostatic pressure within the medium, and dilution during long run times (12,20). Run times as long as 18 h, required when using the swinging bucket rotor, may lead to the conversion of a proportion of the micelles to vesicles (15). Gradient formation using metrizamide, which was dissolved directly into bile, has been used to reduce the dilution factor (12,13). However, this method requires relatively large quantities of bile (about 5 mL).

Our laboratory has used a hamster model to study cholesterol gallstone disease in relationship to the distribution of the cholesterol carriers in bile (9,21). The hamster has, on average, 50 μL of bile in the gallbladder; no good estimate for the percentage distribution of vesicular cholesterol in bile is available when only microliter amounts of bile are present. Sömjen *et al.* (14; G. Sömjen, personal communication) used sucrose density gradient ultracentrifugation to separate the carriers in as little as 200 μL of bile. This method used a swinging bucket rotor and a centrifugation time of 18 h; this time period tended to alter the distribution of the cholesterol among its carriers. Vertical and near-vertical rotors can be used to obtain separations similar to those of the traditional swinging bucket rotor but with significantly reduced run times (usually 1–2 h). Vertical rotors have a shorter pathlength, resulting in greater efficiency and faster separations; therefore, there is a reduction in the centrifugal forces and the hydrostatic pressure on the medium that may result in artifacts (20,22).

The purpose of this study was to develop a rapid microanalytical ultracentrifugation method to separate the vesicles and micelles from hamster and model biles. We separated the cholesterol carriers in as little as 25 μL of bile using a sucrose density gradient in a near-vertical rotor with a run time of only 1 h. This new ultracentrifugation method gave similar results to gel filtration column chromatography (9).

MATERIALS AND METHODS

Bile samples. Fresh gallbladder bile was obtained from hamsters fed either a lithogenic or chow diet (23,24). Model bile (53.9% sodium taurocholate, 24.7% egg yolk lecithin, and 21.4% cholesterol, 3.7 g/dL total lipids; Sigma, St. Louis, MO) was made according to previously published methods (11). Bile was centrifuged at 5,000 rpm for 30 min. The supernatant was used immediately for separating the cholesterol carriers by either gel filtration chromatography or sucrose density gradient ultracentrifugation. A toluene solution of 0.12 μCi

[1α,2α(n)-^{3}H]cholesterol and a chloroform/methanol (1:1) solution of 0.075 μCi 1-palmitoyl-2-[1-^{14}C]oleoyl phosphatidylcholine (Amersham Life Science, Arlington Heights, IL) were mixed and evaporated under N_2. Bile was added to the radioactive compounds and incubated for 1 h at 37°C with shaking to label the biliary cholesterol carriers.

Gel filtration column chromatography. The cholesterol carriers in labelled bile were separated on Sepharose CL-4B-200 with 6 mM taurocholate in the elution buffer using a modified procedure of Pattinson *et al.* (9,21,25,26).

Sucrose gradient ultracentrifugation: formation of sucrose gradient (Sömjen, G., personal communication). Sucrose was dissolved in 25–50 μL of bile (772 mg/mL bile) and placed at the bottom of a 5 mL centrifuge tube. A 46 to 0% (wt/vol) sucrose gradient containing 50 mM Trizma Hydrochloride (pH 8.0) and 1.5 mM EDTA (Sigma Chemical Co.) was carefully layered on top of the bile sample using a Jule J5 Gradient Former (Jule Inc., Biotechnology Division, New Haven, CT).

Rotors. OptiSeal polyallomer centrifuge tubes (#362185, 1/2 × 2 in., 4.9 mL; Beckman Instruments, Palo Alto, CA) containing the samples were spun at 50,000 rpm for either 1/2, 1, or 2 h in a titanium NVT90 near-vertical rotor (Beckman Instruments).

For comparison, some samples were placed in polyallomer centrifuge tubes (#326819, 1/2 × 2 in.; Beckman) and spun in an AH-650 swinging bucket rotor (DuPont Instruments/Sorvall, Wilmington, DE) at 40,000 rpm for 18 h at room temperature (Sömjen, G., personal communication). A Beckman Optima L-60 ultracentrifuge was used with both rotors.

Collection of fractions. Fractions were collected using a Beckman Fraction Recovery System. Recovery was made from the bottom of the puncturable polyallomer tubes with either needle puncture from the bottom of the tube or by putting a thin tube from the top to the bottom. The gradient was dispensed by an infusion pump equipped with an air-filled 25 mL disposable syringe. Twenty-five to 30 fractions were collected using a Pharmacia LKB FRAC-100 fraction collector (Pharmacia LKB Biotechnology AB, Uppsala, Sweden) equipped with a drop counter (10 drops/fraction, 150–200 μL). An aliquot (20 μL) of each fraction was counted in a Beckman LS 3801 liquid scintillation system with automatic quench correction, using Aquasol-2 (NEN Products, Boston, MA) as the scintillation fluid.

Calculations and statistics. The percentage cholesterol in vesicles was determined using PeakFit v3.0, a nonlinear curve-fitting software from Jandel Scientific (San Rafael, CA). Data are reported as mean ± SD.

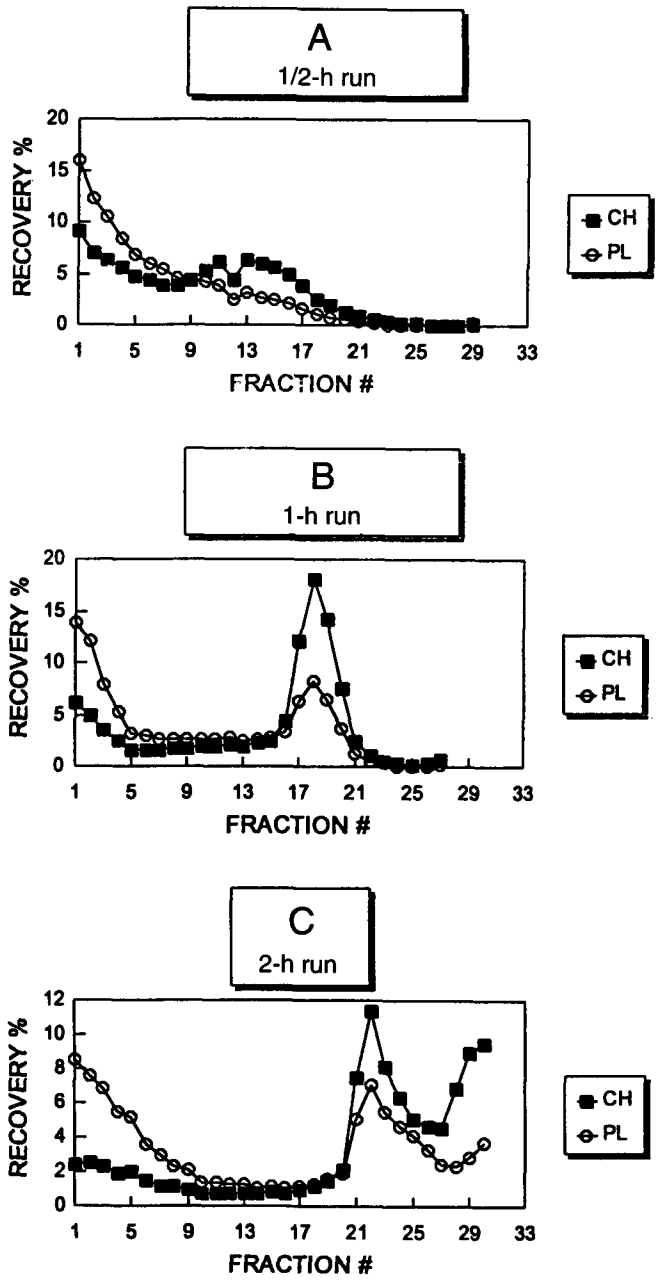

FIG. 1. Sucrose gradient ultracentrifugation (46 to 0%) of saturated model bile (cholesterol saturation index 309%) in an NVT90 near-vertical rotor (Beckman Instruments, Palo Alto, CA) spinning at 50,000 rpm for (A) 1/2 h, (B) 1 h, and (C) 2 h. Fractions were collected from the bottom of the tubes (fraction 1). See the Materials and Methods section for details of the ultracentrifugation procedure; CH, cholesterol; PL, phospholipid.

RESULTS AND DISCUSSION

The cholesterol carriers were separated from saturated and unsaturated model and hamster biles. Figure 1 compares run times for the sucrose gradient ultracentrifugation method in a near-vertical rotor using supersaturated model bile [cholesterol saturation index (CSI) 309%]. Two distinct peaks (micelles, fractions 1–6; vesicles, fractions 15–22) were detected using a run time of 1 h (Fig. 1B). A 1/2-h run was insufficient to separate the micelles from the vesicles (Fig. 1A); there was considerable overlap of the carriers as the vesicles did not fully migrate to the top of the tube. A 2-h run resulted in a micelle peak which was broad and tailed into the vesicle region (Fig. 1C). In addition, the vesicle region was now separated into two distinct peaks. The amount of cholesterol in the vesi-

[a]Sucrose gradient ultracentrifugation (46 to 0%) at 50,000 rpm in a near-vertical rotor for 1 h and gel filtration column chromatography with 6 mM taurocholate (TCA) in the elution buffer. See the Materials and Methods section for details of the two analytical methods. Values are mean ± SD; BA, bile acid; PL, phospholipids; CH, cholesterol; CSI, cholesterol saturation index.

cle region was 65% after 1/2 h, 78% after 1 h, and 80% after 2 h (Fig. 1). Thus, spinning the bile sample for either 1 or 2 h gave the same percentage cholesterol in vesicles. Nonlithogenic bile (CSI 55%) was separated into its carriers in the same manner. As expected, only one peak (fractions 1–7) was present after both 1 and 2 h, with some broadening after 2 h. Therefore, the micelle integrity was preserved under the ultracentrifugation conditions employed. Clearly, dilution was not a factor as cholesterol carriers were not detected in the vesicle region (figure not shown).

For comparison, we analyzed the cholesterol carriers in nonlithogenic bile (CSI 55%) using a swinging bucket rotor for 18 h. The micellar integrity was not preserved, about 40–50% of the cholesterol–phospholipid components were detected in the vesicular region. This artifact could have resulted from a longer run time for the tubes in a swinging bucket rotor as opposed to the near-vertical rotor (22). The carriers in the gradient were subjected to prolonged forces and high hydrostatic pressures, and their integrity was not maintained (20,22). Such artifacts do not seem to be a factor in the sucrose gradient ultracentrifugation method when runtimes are short (1–2 h).

The micelle and vesicle fractions isolated by ultracentrifugation were subsequently chromatographed by gel filtration using 6 mM taurocholate in the elution buffer. Vesicles and micelles were eluted from the column as expected, with no interconversion of one carrier to another. This result showed that (i) the ultracentrifugation method adequately separated the carriers and (ii) the integrity of the carriers was maintained on the gel filtration column using the 6 mM taurocholate elution buffer. If the bile salt concentration used in the elution buffer for gel filtration column was too low, micelles would be converted to vesicles; if the concentration was too high, the vesicles would be transformed to bile salt-rich micelles (16,17). The 6 mM taurocholate in our elution buffer maintained the integrity of each cholesterol carrier under these gel filtration conditions.

Table 1 compares the separation of vesicles and micelles from three different hamster biles using sucrose density gradient ultracentrifugation and gel filtration column chromatography. We were limited to one gel filtration column as only 50–75 μL of bile was obtained from each hamster. We have previously reported that the percentage cholesterol in vesicles from triplicate separations using gel filtration chromatography were similar [34 ± 4%, mean ± SD] (9). Sample a (Table 1) was not lithogenic (CSI 57%); gel filtration column chromatograph revealed no cholesterol in vesicles while ultracentrifugation showed 8% cholesterol in the vesicular region. Samples b and c (Table 1) were lithogenic (CSI 104 and 114, respectively). Gel filtration and ultracentrifugation showed 42 vs. 44% vesicles for sample b and 50 vs. 46% vesicles for sample c. These results indicate close agreement (better than 90%) between two independent analytical procedures.

In conclusion, we have developed a reliable, reproducible, and rapid ultracentrifugation method for the separation and quantitation of vesicles and micelles in microliter amounts of bile.

ABSTRACT: Cells from rats fed with a tripalmitin diet showed a depletion of phospholipid arachidonate and n-3 fatty acids such as eicosapentaenoic and docosahexaenoic acids (EPA and DHA). In rats fed fish oil diet, a significant reduction in arachidonic acid (AA) content was observed whereas EPA and DHA were incorporated into membranes lipids. These changes in lipid composition of membranes did not affect cellular adherence, phagocytic capability, or [^{3}H]AA incorporation. However, both tripalmitin and fish oil diets induced a decrease in [^{3}H]AA mobilization stimulated by 4β-phorbol-12-myristate 13-acetate, A23187, or opsonized-zymosan in rat peritoneal macrophages. These results demonstrate that the antiinflammatory effects of essential fatty acids deficiency or n-3 enrichment diets may be associated with a decreased AA mobilization in resident rat peritoneal macrophages treated with proinflammatory agents.

Lipids 31, 661–666 (1996).

Linoleic acid and α-linolenic acid are considered to be essential fatty acids (EFA) for growth and development in humans and animals (1–3). One of the main biochemical functions of the EFA is participated in the control of membrane-associated phenomena such as transport, enzyme activities, and receptor function (4–6). In addition, EFA can affect the production of eicosanoids, which are known to influence cell function. Following dietary deprivation of these fatty acids, a state of EFA deficiency is induced, which is characterized by depressed inflammatory response (7,8).

On the other hand, dietary supplementation with polyunsaturated fatty acids (PUFA) prominent in marine fish oils, which are rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), may participate in many enzymatic steps, thought at one time to be selective for arachidonic acid (AA) (9,10). These fatty acids have been reported to attenuate some of the physiopathological effects of arachidonate metabolites in certain diseases by competing with AA for the enzymes involved in eicosanoid formation. Based on these results, several authors have proposed that dietary fish oil supplementation has potential antiinflammatory effects (11,12). Furthermore, epidemiological studies have demonstrated a lower incidence of psoriasis in Greenland Eskimos than in European controls (13); this has been attributed to the Eskimo's fish diet, which is high in n-3 fatty acids (14). EPA has been demonstrated to be metabolized by both the cyclooxygenase and lipoxygenase pathways by mononuclear cells, producing functionally attenuated analogs of the AA metabolites such as thromboxane A_3 or leukotrienes of the 5 series (15). The biosynthesis of AA metabolites and presumably EPA and DHA metabolites were thought to be initiated in the mononuclear cells by the activation of phospholipase A_2 (PLA_2, E.C. 3.1.1.4.) during cell stimulation (16,17). Thus, PLA_2 is the main rate-limiting enzyme responsible for the mobilization of AA. However, we have to consider that sequential action of a phospholipase C and diacylglycerol lipase (18) or phospholipase D, phosphatidic acid phosphatase, and a diacylglycerol lipase (19) could also induce AA release.

Our purpose was to determine the extent of AA mobilization in resident peritoneal macrophages from rats fed with diets that differed in fatty acid composition.

MATERIALS AND METHODS

Materials. [^{3}H]AA (180–240 Ci/mmol) was obtained from DuPont-NEN (Boston, MA). 4β-Phorbol-12-myristate 13-acetate (PMA), calcium ionophore A23187, and zymosan A were purchased from Sigma Chemical Co. (St. Louis, MO). Opsonized-zymosan was prepared according to Bonney *et al.* (20). All other reagents were of analytical grade.

Animals and diets. Twelve male weanling Sprague-Dawley rats were divided into three homogeneous groups after weaning. Food and tap water were provided *ad libitum*, and the rats were weighed weekly. For 16 wk they were fed isoenergetic semisynthetic diets (INRA, Jouy-en-Josas, France). The nutrient composition of diets was casein (22%), DL-methionine (0.1%), mineral mix (4.5%), vitamin mix (1%), cellulose 2%, corn starch 43.6%, sucrose 21.8%, and 5% of

Abbreviations: AA, arachidonic acid (20:4n-6); DHA, docosahexaenoic acid (22:6n-3); EFA, essential fatty acids; EPA, eicosapentaenoic acid (20:5n-3); PLA_2, phospholipase A_2; PMA, 4β-phorbol-12-myristate 13-acetate; PUFA, polyunsaturated fatty acid.

Copyright © 1996 by AOCS Press

lipids of either standard (2.5% rapeseed oil and 2.5% peanut oil), tripalmitin or fish oil (sardine oil; Afampes 160 from Afamsa, Vigo, Spain). Thus, the three diets differed in their fatty acid composition (Table 1). All diets contained 100 IU/kg of vitamin E, 50 IU/kg were carried-over from oils in order to avoid the PUFA peroxidation, and 50 IU/kg were conventionally added. Diets were stored under vacuum, wrapped in opaque polyethylene foil, stored at 4°C, and were given to the animals daily. Uneaten food remains were removed from the cage each day. Animal care standards and experimental protocols were in accordance with the E.C. guidelines.

Macrophages. Resident peritoneal macrophages were collected from rats killed by carbon dioxide asphyxiation, and the peritoneal cavity was lavaged as described previously (21). Differential cell counts of macrophages were performed microscopically using May Grünwald-Giemsa solution, and $20 \pm 2 \times 10^6$ resident peritoneal macrophages were recovered per rat. Cell viability was measured by the Trypan blue exclusion test. Macrophages were further purified by adherence to plastic tissue culture plates (21). Previous experiments demonstrated that [^{3}H]AA mobilization was triggered simply by contact between cell and plastic substrate (22). Besides, cell activation triggered by cellular adherence disappeared within 16–20 h. In consideration of these results, functional and biochemical assays with [^{3}H]AA labelled macrophages were performed 24 h after cells were purified by adherence to plastic surface.

Peritoneal macrophages adherence. To determine the cellular adherence, macrophages from peritoneal cavity lavaged were counted microscopically. Then, macrophages (10^6 cells/well) were allowed to adhere for a 1-h period in plastic 12-well cluster dishes (Costar, Cambridge, MA), after which the supernatant was removed and nonadhered mononuclear cells were determined using May Grünwald's solution. Cellular adherence was expressed as the percentage of macrophages adhered to plastic.

Phagocytic index. Phagocytic indices were determined by phase contrast microscopy of cells fixed in 2.5% (wt/vol) glutaraldehyde after the ingestion of zymosan (23). Phagosome–lysosome fusion was evaluated by fluorescence microscopy using acridine orange by the method of Hart and Young (24). Then 10^6 macrophages per well were cultured for 24 h in 12-well cluster dishes in RPMI 1640 containing 10% fetal calf serum and antibiotics. Then, cells were pulsed for 20 min with acridine orange, which is concentrated in lysosomes, causing them to appear orange by fluorescence. After zymosan ingestion, zymosan particles are first seen as green inclusions within the cell. Upon fusion of the phagosome with lysosomes, the zymosan becomes stained with acridine orange, resulting in its changing to an orange fluorescence. The phagocytic index was the ratio of orange fluorescing vs. nonfluorescing cells.

Fatty acid analysis. Cells from peritoneal lavage were adhered to cluster wells (5×10^6 cells/well) for 1 h, in RPMI 1640 (Gibco, Grand Island, NY). Macrophages were removed by treatment with trypsin/EDTA, and lipids were extracted sequentially (25) with chloroform/methanol (1:2, vol/vol), chloroform/saline (1:1, vol/vol), and one part chloroform (2 ×) (25). Total phospholipids were separated by thin-layer chromatography silica gel plates DC-Alufolien (Merck, Darmstadt, Germany) using the solvent system dietyl ether/acetone (90:30, vol/vol). The fatty acid composition of total phospholipids was transmethylated (26) and was determined by gas chromatography following the procedure described by García *et al.* (27). Briefly, fatty acid methyl esters dissolved in hexane were analyzed using a Packard Model 427 gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame-ionization detector and a CP WAX 52 CB bonded fused silica capillary column (Chromopack, Les Ulis, France) (50 m × 0.2 mm internal diameter). Hydrogen was the carrier gas, with a flow rate of 1–2 mL/min. The detector and the injector were, respectively, set at 300 and 260°C, and the oven temperature was programmed from 140–225°C at a heating rate of 6°C/min. Peaks were identified by comparison of retention times obtained from equivalent methylated standard mixture injections (Sigma Chemical Co.), and concentrations were calculated from the peak areas obtained by a Delsi (ENICA 10) integrator (Delasi Instruments, Suresnes, France). Results are expressed as percentages of the total fatty acid content.

Incorporation and release of AA. After a 20-h incubation of macrophages (10^6 cells/well) in RPMI 1640 supplemented with 10% heat-inactivated fetal calf serum (Gibco) and antibiotics (100 units of penicillin/mL and 100 μg/mL of streptomycin), the medium was removed and replaced with 0.5 mL of RPMI 1640 containing 0.1 μCi of [^{3}H]AA. Samples were incubated for another 6 h at 37°C. Cells were then washed three times in medium containing 0.5% bovine serum albumin to remove unincorporated [^{3}H]AA. To determine the [^{3}H]AA incorporated into the lipid fraction, cellular lipids were extracted by the method of Bligh and Dyer (28), and radioactivity was measured. The labelled cells were incubated with stimulating agents for 2 h. Then, the medium was removed for analysis of radioactivity released. At the end of

each experiment, the cell monolayer was overlaid with 0.1% Triton-X100, and the cells were scraped off the dishes. Finally, radioactivity present in medium and cell fraction was measured by scintillation counting, using a Packard Tri-Carb 1500 counter.

Statistical analysis. All experimental determinations were performed at least three times to ensure consistency of the observations. Results were expressed as mean ± SEM. Significance of differences between data points and control was determined using the (two-tailed) Student's *t*-test with $P < 0.05$ confidence limits.

RESULTS

We did not observe significant differences in food consumption or growth rates due to diet in any of the three groups of rats. Thus, the total food consumption during the 16-wk period, expressed as kg diet/rat, were 2.6 ± 0.1 for the standard diet group, 3.0 ± 0.2 for the tripalmitin diet group, and 2.5 ± 0.1 for the fish oil diet group. The final body weights were 620 ± 32 g for standard diet animals, 585 ± 34 g for rats fed the tripalmitin diet, and 612 ± 14 g in the fish oil group.

The cells from rats deprived of dietary PUFA by an exclusive tripalmitin diet exhibited a depletion of phospholipid arachidonate (20:4n-6, 50%), EPA (20:5n-3, 36%), and DHA (22:6n-3, 50%), although the AA/EPA ratio was approximately the same (Table 2). Furthermore, an accumulation of monounsaturated fatty acid was also observed (Table 2), in agreement with the results described by Lefkowith *et al.* (29).

In fish oil-fed rats, EPA and DHA were incorporated into membrane lipids and their fatty acid composition revealed several significant changes (Table 2). Thus, the fish oil diet induced a significant reduction in AA content (57%) and concomitant 34- and 1.7-fold rises in EPA and DHA content vs. rats fed with standard diet. Moreover, the AA/EPA ratio was clearly reduced in fish oil-fed rats.

Cell viability was greater than 90% in the three experimental groups and was not modified by dietary manipulation. The percentage of macrophage adherence on plastic culture dishes was similar in the three diet groups (Fig. 1). Similarly, there were no significant differences in a [^{3}H]AA incorporation into lipids of macrophages between diet groups (Fig. 1). Thus, the macrophages incorporated approximately 38% of the [^{3}H]AA under our experimental conditions. Similarly, the changes in lipid composition of membranes by diet did not modify phagocytic capability of the cells (Fig. 1).

The release of [^{3}H]AA from cellular phospholipids after macrophage activation was an early, essential response to stimuli. Thus, PMA (10 μM), ionophore A23187 (1 μM), and opsonized-zymosan (150 μg/mL) were able to induce a significant [^{3}H]AA mobilization (32.5 ± 0.7%, 29.2 ± 2.2%, and 22.3 ± 1.8%, respectively) in prelabelled macrophages obtained from rats fed with standard diet. Similarly, under these same activation conditions, when we used macrophages obtained from rats fed with tripalmitin diet or fish oil diet, the levels of released [^{3}H]AA were inhibited, as compared with cells from rats fed standard diet. This effect was significant when cells were stimulated with PMA or ionophore A23187 in the tripalmitin group and when macrophages were activated with PMA, calcium ionophore A23187, or opsonized-zymosan in the fish oil group (Fig. 2).

DISCUSSION

The phospholipids of macrophages are highly enriched in AA, and under *in vitro* conditions these cells can release AA resulting in extracellular concentrations of AA metabolites (30). The release and metabolism of AA from cellular phospholipids after cell activation are early, essential responses to initiate the inflammatory processes. Since the macrophage is one of the main cellular constituents of the inflammatory lesion, the effect of a PUFA-deprived diet and a fish oil supplementation diet on AA mobilization was examined in resident rat peritoneal macrophages.

[a]Cell lipids were extracted as described in the Materials and Methods section by the Folch method. The fatty acid composition of phospholipids was analyzed as fatty acid methyl esters by gas chromatography. Each value, expressed as percentage with respect to total fatty acid of total phospholipids, is the mean ± SEM of duplicate determinations from four rats; SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.
[b]Significant difference from the standard diet group ($P < 0.05$).

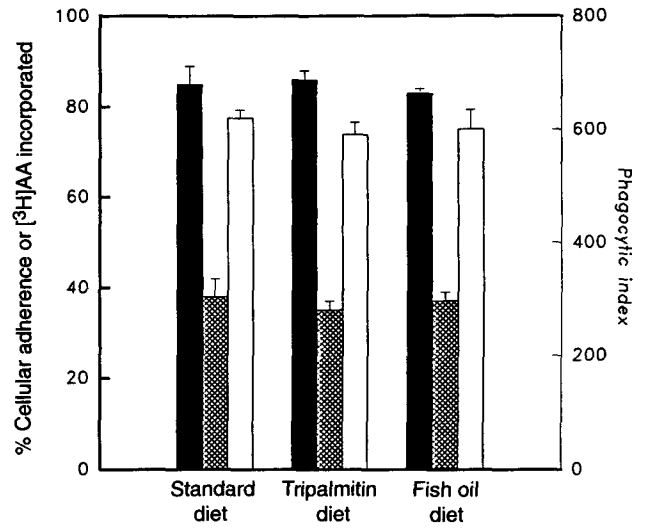

FIG. 1. Effect of tripalmitin or fish oil diets on cellular adherence (closed box), [^{3}H] arachidonic acid (AA) incorporation (cross-hatched box), and phagocytic capability (open box) in rat resident peritoneal macrophages. The data are the means ± SEM of four animals.

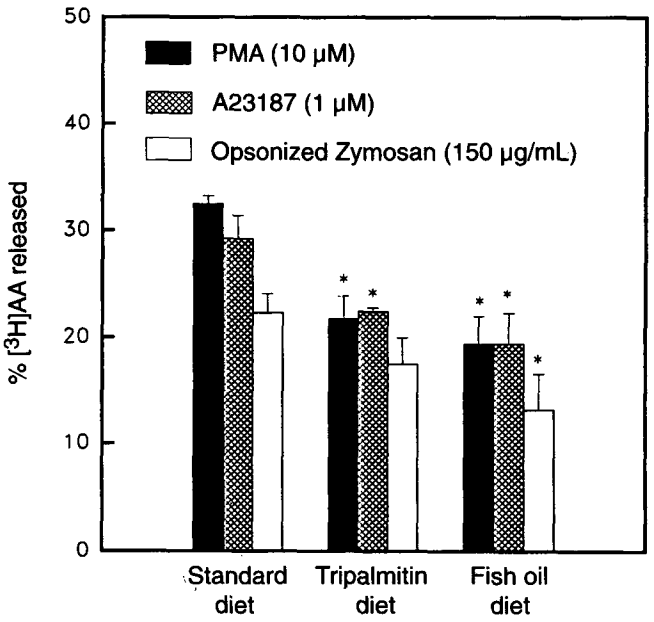

FIG. 2. Effect of tripalmitin or fish oil diet on [^{3}H] arachidonic acid (AA) mobilization induced by 4β-phorbol-12-myristate 13-acetate (PMA) (10 μM), A23187 (1 μM) or opsonized-zymosan (150 μg/mL). Cells labelled with [^{3}H]AA were incubated with agonist for 2 h. The spontaneous [^{3}H]AA released by nonstimulated cells was 5.6 ± 1.2%. The data are the means ± SEM of four animals. *$P < 0.05$, vs. standard diet group.

The fatty acid composition of cell membranes is determined by the fatty acid content of the diet (31). Because synthesis of certain inflammatory mediators may be reduced when membrane fatty acid content is altered, numerous studies have been performed to identify the effects of specific dietary manipulations. Exclusive provision of tripalmitin in the diet induces a deficiency in EFA as indicated by the triene/tetraene index (32). In EFA deficiency diet group, the levels of α-linolenic and linoleic acids are reduced to a point that 18:1 competes for Δ6 desaturase resulting in generation of 20:3n-9 that replaces longer chain n-3 and n-6 fatty acid derivatives. In contrast to EFA deficiency, provision of a fish oil diet induced significant changes in fatty acid composition of membrane phospholipids under our experimental conditions. These changes followed the same trends demonstrated in other phagocytic cells such as neutrophils (33,34).

Furthermore, we found that both tripalmitin and fish oil diets induced a decrease in [^{3}H]AA mobilization stimulated by soluble agents (PMA, A23187) or by a phagocytic stimulus such as zymosan. However, the changes induced by diets in lipid composition of membranes did not disturb other cell functions such as adherence or phagocytic capability.

The inability to alter membrane fluidity in response to changes in membrane fatty acid composition in neutrophils and monocytes (33) could indicate that the modulation of AA release by dietary modifications may be attributable to factors other than alteration of the physical properties of cell membranes.

It is important to note that tripalmitin and fish oil diets induced a significant decrease in cell membrane AA, although the cells of these animals incorporated [^{3}H]AA to the same extent as cells of standard diet-fed animals. However, macrophages isolated from rats fed fish oil suffered a more significant reduction of their capacity to release [^{3}H]AA. These results could indicate that AA mobilization is, at least in part, regulated by the fatty acid composition of the phospholipid bilayer, but perhaps not by substrate availability. Thus, Ballou and Cheung (35) have demonstrated *in vitro* that micromolar concentrations of some PUFA such as DHA can inhibit the activity of semipurified PLA_2. Additionally, increase in the content of some PUFA in microsomal membrane preparations of white blood cell (36) and liver (37) decreased PLA_2 activity. This action was also suggested in a study of the generation of platelet-activating factor by monocytes from volunteers who were fed a fish oil supplement (33).

The efficacy of the dietary manipulations on inflammation (11,12,38,39) is compatible with the view that diet supplemented with EPA- and DHA-enriched oils can exert profound effects on lipid fatty acid compositions, as well as on the endogenous release of AA and biosynthesis of the pro-inflammatory eicosanoids. Synthesis of pro-inflammatory arachidonate metabolites can be affected not only by EPA or DHA competition for the cyclooxygenase and lipoxygenase pathways, but also by the availability of substrate, AA. We hypothesize that the observed anti-inflammatory effect of specific fatty acid manipulations may be associated with a decreased AA mobilization as a consequence of impairment of PLA_2 activity induced by the changes in fatty acid composition of cell membranes.

ANNOUNCEMENTS

SPECIAL *LIPIDS* SUPPLEMENT—PROCEEDINGS OF THE ISSFAL 2ND INTERNATIONAL CONGRESS

Extra copies of the March *Lipids* Supplement—"Fatty Acids and Lipids from Cell Biology to Human Disease," the Proceedings of the 2nd International Congress of the ISSFAL (International Society for the Study of Fatty Acids and Lipids)—which includes 57 full manuscripts from participants in oral presentations at the Congress (332 total pages), are available for individual purchase at $60 each. Information: AOCS Press, P.O. Box 3489, Champaign, IL 61826-3489 (Phone: 1-217-359-2344, extension 128; Fax: 1-217-351-8091).

CALENDAR

July 1996

European Thrombosis Research Organisation and the International Society for the Study of Fatty Acids and Lipids in cooperation with Summer University of Maastricht, July 10–12, 1996, University of Maastricht, The Netherlands, presents "Lipids, Membranes and Thrombosis (fundamental basis of cardiovascular disease and its prevention)." Information: Gerard Hornstra, Department of Human Biology, P.O. Box 616, 6200MD Maastricht, The Netherlands (Phone: +31-43-88 16 25; Fax: +31-43-67 09 76; E-mail: G. Hornstra @ HB.RuLimburg.NL).

September 1996

37th International Conference on the Biochemistry of Lipids, Antwerp, Belgium, Sept. 4–7, 1996. Themes: enzymes and transfer proteins related to lipoprotein metabolism, aspects of protein lipidation, and peroxisomal lipid metabolism. Poster communications may relate to the three conference themes or any other area of lipid metabolism. Information: Dr. P. van Dyck, Secretariat 37th ICBL, Department of Biochemistry, Physiology and Genetics, Division of Human Biochemistry, State University Centre Antwerp, Groenenborgerlaan 171, B2020 Antwerp, Belgium (Phone: 32 3 218 0329; Fax: 32 3 218 0326).

7th International Congress on Phospholipids, Sept. 9–11, 1996, Brussels, Belgium. Program topic areas include Growth, Death and Cancer; Choline, Choline Phospholipids and the Brain; Importance of Phospholipids in Health and Disease. Information: AOCS Meetings Department, P.O. Box 3489, Champaign, IL 61826-3489 USA (Fax: 1-217-351-8091).

IV. International Dermatology Symposion Berlin, Sebaceous Gland and Its Disorders, Basic and Clinical Research, Clinical Entities and Treatment, Sept. 13–15, 1996, University Medical Center Benjamin Franklin. Information: Docent Dr. Ch. C. Zouboulis, Department of Dermatology, University Medical Center Benjamin Franklin, The Free University of Berlin, Hindenburgdamm 20, D-12200 Berlin, Germany (Phone: 49-30-8445-2808; Fax: 49-30-8445-4262).

Training in Free Radical Methodologies, Sept. 23–27, 1996, CERLIB, University of Grenoble, Grenoble, France. Production, damages, repair: ESR, nitric oxide, DNA oxidation, DNA repair, apoptosis, chemical-trapping, lipoprotein oxidation, protein oxidation, cellular production and toxicity. Information: Arlette Alcaraz, Laboratoire de Biochimie C, CHU Grenoble BP 217, 38043 Grenoble Cédex 9, France (Phone: 33 76 76 57 54; Fax: 33 76 76 56 64; E-mail: CERLIB@ujf-grenoble.fr).

October 1996

Frontiers in Lipid and Lipoprotein Research: Basic Science, Analytical, Clinical, and Public Health Applications, Oct. 4–6, 1996, Stouffer Renaissance Hotel, Dallas, Texas. Sponsored by the Lipids and Lipoproteins Division of the American Association for Clinical Chemistry, the Centers for Disease Control and Prevention, and the American Heart Association. An integrated review of relevant recent advances in basic science, measurement technology, epidemiological and clinical research, and public health issues will be presented. This review will help define state-of-the-art techniques for understanding and preventing morbidity and mortality due to heart disease. Information: Paula M. Steiner, Medical Research Laboratories, 2 Tesseneer Dr., Highland Heights, KY 41076 (Phone: 606-781-8877, Extension 252; Fax: 606-781-9310; E-mail: lipf@cehehll.em.cdc.gov).

Hydroperoxides of Erythrocyte Phospholipid Molecular Species Formed by Lipoxygenase Correlate with α-Tocopherol Levels

Patrice Therond[a], Martine Couturier[a], Jean François Demelier[b], and Frédérique Lemonnier[a,*]

[a]INSERM U347, Hôpital de Bicêtre, 94276 Le Kremlin Bicêtre and [b]Laboratoire de Biochimie, Hôpital R. Debré, 75019 Paris, France

ABSTRACT: The hydroperoxides corresponding to the main molecular species of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were determined after lipoxygenase treatment of erythrocyte membranes from healthy children. This work was a preliminary study prior to applying this analytical procedure to erythrocyte membranes from children with diseases associated with vitamin E deficiency. The total molecular species corresponding to 20:4 and 22:6 associated with 16:0 and 18:0 were significantly higher in PE (26.94 ± 4.70 nmol/mg protein) than in PC (20.14 ± 6.70 nmol/mg protein); these concentrations represented 63% of the total molecular species in PE and 22% in PC. However, the concentrations of hydroperoxides produced from these polyunsaturated fatty acid molecular species were in the same order of magnitude in PC (3.98 ± 1.56 nmol/mg protein) and in PE (3.61 ± 1.63 nmol/mg protein). In contrast, the molecular species concentrations containing two double bonds, such as 16:0/18:2 and 18:0/18:2 and their corresponding hydroperoxides, were clearly more elevated in PC than in PE. There was a positive relationship between the concentrations of α-tocopherol and each hydroperoxide of PC and PE, and this association was particularly strong in PE ($P \leq 0.0001$). These results suggest that α-tocopherol exerts a stabilizing effect toward hydroperoxides, limiting their further degradation into peroxyl radicals. The protective effect of α-tocopherol could be more effective in PE because more polyunsaturated fatty acids were present.

Lipids 31, 703–708 (1996).

Many procedures have been described to test the susceptibility of polyunsaturated fatty acids (PUFA) in biomembranes to oxidation. It has been shown that the lipid peroxidation process is affected by the concentration and the degree of unsaturation of fatty acids in the cell membrane (1). Among the free-radical inducers, soybean lipoxygenase (E.C. 1.13.11.12), which catalyzes the oxidation of unsaturated fatty acids (containing a 1,4-*cis,cis* pentadiene system) to hydroperoxides, is the most efficient physiological inducer. Furthermore, esterified fatty acids in phospholipids are acceptable substrates for soybean lipoxygenase (2).

The aim of this work was to study the main molecular species of human erythrocyte membrane phospholipids and their corresponding hydroperoxides after lipoxygenase induction. We attempted to determine if the hydroperoxides produced varied in relation to saturated or unsaturated fatty acids from the *sn*-1 or *sn*-2 position of phosphatidylethanolamine (PE) and phosphatidylcholine (PC). We also attempted to identify relationships between hydroperoxide concentrations and the levels of two main active antioxidant systems, α-tocopherol and glutathione peroxidase (GPx). To obtain a better and more specific marker of lipid peroxidation than malondialdehyde (3,4), we applied to erythrocyte membranes an original technique previously described in soybean phospholipids (5). This simultaneously determines the main molecular species from PE and PC and their corresponding hydroperoxides. We chose the erythrocyte membrane because it is considered a good model for peroxidation processes containing high concentrations of PUFA and has a very effective antioxidant system (1). This work, carried out in erythrocyte from healthy children, represents a preliminary study prior to investigating erythrocyte membranes from children with diseases associated with vitamin E deficiency in an attempt to determine whether such vitamin E deficiency will induce changes in the production of phospholipid hydroperoxides.

ment equipped with a 25 m × 0.32 mm, 0.25 μm film thickness glass capillary column containing PEG-20 M (Supelco, Bellefonte, PA) and connected to a Delsi-Nermag (Argenteuil, France) integrator. The temperature was programmed from 155 to 250°C (2°C per min). The high-performance liquid chromatography (HPLC) equipment (Thermo Separation Products, Les Ulis, France) included an automatic injector with a 200 μL sample loop, a 250 × 4.6 mm C18 and a 150 × 4.6 mm C8 Kromasil 5 μm (Touzart et Matignon, Les Ulis, France) analytical columns and an ultraviolet (UV)-visible light detector (Thermo Separation Products). The fluorometer (Spectroflow 980 fluorescence detector; Applied Biosystems, Ramsey, NJ) was equipped with a 5 μL flow cell.

Reagents and chemicals. HPLC-grade solvents and analytical-grade chemicals were from Carlo Erba (Milano, Italy) or from Merck (Darmstadt, Germany). Microperoxidase (MP11), isoluminol (6-amino-2,3-dihydro-1,4-phthalazinedione), soybean lipoxygenase (type IB, E.C. 1.13.11.12), and 15-hydroperoxyeicosatetraenoic acid (15-HPETE) were from Sigma (St. Louis, MO).

Ghost preparation. Blood was drawn into heparinized Vacutainer tubes from 12 healthy children (mean age 7 yr, range 1–15 yr) who had fasted overnight. The present study was approved by the local Ethics Committee. Blood was centrifuged for 10 min at 1,000 × *g*, and the cell pellet was washed three times with isotonic buffer. Erythrocyte ghosts were prepared by lysing packed cells in a sevenfold volume of hypotonic phosphate buffer (5 mM, pH 7) with EDTA (1 mM) according to the method of Burton *et al.* (6). The washing procedure was repeated as many times as necessary to obtain white membranes. Ghosts were stored at −70°C until use.

Peroxidation of erythrocyte membranes. All incubations were performed at a membrane protein concentration of 500 μg/mL. The total reaction volume of the membrane pellets was brought up to 1 mL by the addition of 0.1 M borate buffer pH 9.2 containing 10 mM deoxycholic acid. The presence of deoxycholate and also pH 9.2 were necessary for the optimal activity of the enzyme (2). The reaction was started by addition of lipoxygenase at a final concentration of 50 μg/mL. The mixture was incubated with gentle shaking at 30°C for 45 min. The reaction was stopped by addition of molar citric acid to obtain a final pH of 3.5, and the samples were placed on ice for 5 min. A sample was incubated in the same conditions but without lipoxygenase to determine the molecular species of phospholipids before peroxidation.

Lipid extraction and phospholipid separation. Lipids were extracted with chloroform/methanol (2:1, vol/vol). The mixture was partitioned between the chloroform layer (lower organic phase) and the methanol/water layer (upper phase) by centrifugation at 1,500 × *g* for 5 min. After two extractions, the lower chloroform layers were collected, evaporated under a stream of nitrogen, and then dissolved in methanol. Silica-SepPak columns were used to separate phospholipids into PC and PE, using the extraction technique described by Hamilton and Comai (7). The two fractions corresponding to PC and PE were evaporated to dryness, then dissolved in methanol, and injected into the HPLC system. We have previously shown in soybean phospholipids (5) that there was a strong relationship between the concentration of transformed molecular species after peroxidation and the concentration of the corresponding hydroperoxides. Consequently, the chloroform/methanol extraction is suitable for quantitative determination of phospholipid molecular species and hydroperoxides.

Molecular species detection of PC and PE and their corresponding hydroperoxides. The procedure described in detail elsewhere with soybean PC and PE (5) was applied with slight modifications. Separation was done on the liquid chromatograph using two serial analytical columns: a C8 (150 × 4.6 mm) and a C18 (250 × 4.6 mm) Kromasil 5 μm, maintained at 40°C. The mobile phase was 6% 10 mM ammonium acetate, pH 5, and 94% methanol (flow rate 1.5 mL/min). The molecular species of PC and PE were detected at 205 nm before and after 45 min of peroxidation. The eluate was then mixed at a flow rate of 1.5 mL/min with the chemiluminescent reagent, prepared as described by Yamamoto *et al.* (8), with slight modifications. Isoluminol (55 mg) was dissolved in a mixture of methanol/0.1 M borate buffer, pH 9.2 (3:7, vol/vol), and 10 mg/L of microperoxidase was added to the mixture. The solution was passed through a fluorometer used as a photon detector with the excitation source turned off.

Molecular species and hydroperoxide identification—expression of the results. Fatty acid molecular species were identified by GLC with comparison to a commercial standard mixture as follows: 16:0/18:2, 16:0/20:4, 16:0/22:6, 18:0/18:2, 18:0/20:4, and 18:0/22:6 in PC and PE. The corresponding hydroperoxides were identified by peroxidation of the standard molecular species (5). In our conditions of chromatography, both hydroperoxides (16:0/20:4 and 16:0/22:6 or 18:0/20:4 and 18:0/22:6) had the same retention time. It was not possible to separate them even if the experimental conditions were changed including the column, mobile phase, and temperature. Each hydroperoxide was quantified on the basis of the relative sensitivity of the chemiluminescence assay for 15-HPETE, using a coefficient which included the detection limit for the various hydroperoxides relative to 15-HPETE. Under these conditions the correction coefficient was 0.8 for 16:0/20:4 including 16:0/22:6, 0.8 for 18:0/20:4 including 18:0/22:6, and 3.5 for 16:0/18:2 or 18:0/18:2. In erythrocyte membranes, the limit of detection for hydroperoxides containing 16:0/18:2 was 1 nmol/mg protein, and the limit for hydroperoxides containing 16:0/20:4 plus 16:0/22:6 was 0.25 nmol/mg protein. The reproducibility of the hydroperoxide species was 82% ± 8 for PE and 85% ± 7 for PC. Using single molecular species, we verified that the steps of extraction and SepPak separation did not modify the percentage of hydroperoxide recovery (5).

α-Tocopherol and glutathione peroxidase. α-Tocopherol was determined by using an HPLC technique derived from that of Zaspel and Csallany (9). GPx activity was determined according to Paglia and Valentine (10), using Triton X100 to dissolve the membranes. One unit of GPx was defined as 1 μM of substrate converted in 1 min. Malondialdehyde con-

tent was expressed as thiobarbituric acid-reactive substances (TBARS) and was measured by HPLC with fluorescence detection (11).

Statistical analysis. Data were expressed as mean ± SD. The statistical significance of differences was determined by the Mann-Whitney test. Correlation analysis was performed by means of the linear correlation coefficient.

RESULTS

α-Tocopherol, TBARS, and GPx. Before peroxidation the mean concentration (±SD) of α-tocopherol was 483 ± 187 ng/mg protein and showed a large range of values, from 268 to 878 ng/mg protein, which was not related to the children's age. TBARS concentration was 282 ± 52 pmol/mg protein, and that of GPx activity was 35.9 ± 11.6 mU/mg protein. After peroxidation, only TBARS were evaluated, and the mean concentration found was 1680 ± 350 pmol/mg protein. We observed that no α-tocopherol remained after lipoxygenase treatment. There was no relationship between α-tocopherol concentration and either TBARS or GPx activity.

Molecular species. Six main molecular species were separated from PC (Fig. 1A) and PE, and the concentrations of these different molecular species in PE and PC were determined (Table 1). The main molecular species in PC were 16:0/18:2 and 18:0/18:2 which represented 55 and 22%, respectively, of the total molecular species. In PE, 16:0/18:2 corresponded to 29% of the total molecular species and 18:0/18:2 only to 8%. In contrast, the total PUFA 20:4 and 22:6 associated with 16:0 or 18:0 represented 63% of total molecular species in PE and 22% in PC. The concentrations

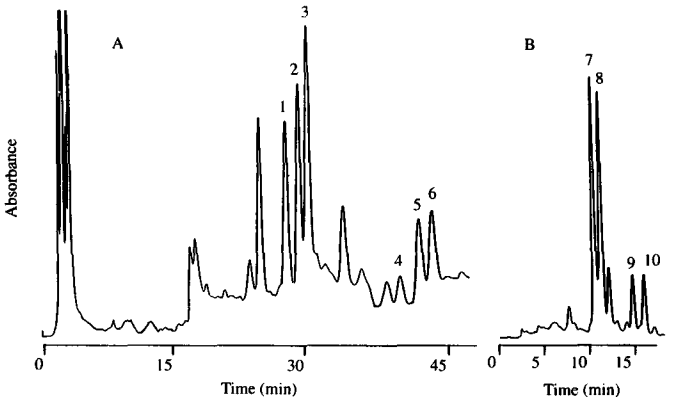

FIG. 1. Separation of phosphatidylcholine (PC) molecular species in human erythrocyte membrane before lipoxygenase treatment (A) and separation of the corresponding hydroperoxides after lipoxygenase treatment (B) using two serial Kromasil C8 and C18 analytical columns (Touzart et Matignon, Les Ulis, France) at 40°C. The mobile phase was methanol/10 mM ammonium acetate (94:6, vol/vol; pH 5.0) delivered isocratically at 1.5 mL/min. Fatty acid molecular species were detected at 205 nm, and hydroperoxides were detected with the chemiluminescence reagent at a flow rate 1.5 mL/min. A, 1 = PC 16:0/22:6, 2 = PC 16:0/20:4, 3 = PC 16:0/18:2, 4 = PC 18:0/22:6, 5 = PC 18:0/20:4, 6 = PC 18:0/18:2. B, 7 = phosphatidylcholine hydroperoxides (PCOOH) 16:0/18:2, 8 = PCOOH 16:0/20:4 + 16:0/22:6, 9 = PCOOH 18:0/18:2, 10 = PCOOH 18:0/20:4 + 18:0/22:6.

of PUFA (20:4 and 22:6) associated with 16:0 were in the same order of magnitude in PC as in PE, but the same PUFA associated with 18:0 was significantly higher in PE than in PC ($P \leq 0.001$). Thus, the total PUFA concentration in PE (26.94 ± 4.70 nmol/mg protein) was significantly higher ($P \leq 0.01$) than in PC (20.14 ± 6.70 nmol/mg protein). After per-

18:0/18:2	3.36 ± 1.25	31	Not detected	—
Sum PE	39.30 ± 7.70	67	6.67 ± 2.71	25

[a]Values are mean ± SD from twelve erythrocyte membranes. [b]Percentage of phospholipid hydroperoxides produced was calculated from the concentrations of molecular species transformed after lipoxygenase treatment. [c]Sum of 16:0/22:6 and 16:0/20:4 hydroperoxides. [d]Sum of 18:0/22:6 and 18:0/20:4 hydroperoxides.

oxidation, the amounts of molecular species consumed from PC or PE were in the same order of magnitude for the fatty acid containing more than two double bonds. The biggest difference concerned the 16:0/18:2, which was more transformed in PE (56%) than in PC (40%). However, it is difficult to conclude that PE was more reactive than PC on the basis of this single difference. Therefore, it appears that lipoxygenase is rather nonspecific to molecular species. In the presence of lipoxygenase, the amounts of molecular species transformed increased with the number of double bonds in both PC and PE. For example, in PC, 78% was transformed for 16:0/22:6, 67% for 16:0/20:4, and 40% for 16:0/18:2.

Hydroperoxides. The hydroperoxides corresponding to the main molecular species were detected after lipoxygenase treatment (Fig. 1B), and their concentrations were determined (Table 1). No hydroperoxides were detectable before peroxidation. We have not detected hydroperoxide from the 18:0/18:2 molecular species in PE due to the low concentration of the corresponding molecular species and the low percentage of molecular species transformed.

The amount of hydroperoxides after lipoxygenase induction varied from 0.31 nmol/mg protein to 16 nmol/mg protein according to the molecular species. Also, hydroperoxide concentration showed a wide range of values owing to differences between the different membrane preparations. The total hydroperoxide concentration from PUFA containing more than two double bonds was not significantly different between PC and PE (4.81 ± 1.97 nmol/mg protein and 5.33 ± 2.00 nmol/mg protein, respectively). For the sum of 16:0/20:4 and 16:0/22:6 in PC and in PE, the same molecular species concentration produced in average approximately the same concentrations of hydroperoxides, 3.98 ± 1.56 and 3.61 ± 1.63 nmol/mg protein, respectively. For 18:0/20:4, the hydroperoxide concentration was two times greater in PE than in PC and corresponded to a twofold larger molecular species concentration before peroxidation. In PC, the largest mean hydroperoxide concentration was obtained from 16:0/18:2 (9.78 ± 4.13 nmol/mg protein), and this concentration represented about half of the molecular species transformed. Comparing this last result with that obtained for 18:0/18:2, hydroperoxide concentrations were lower, exhibiting only 30% of the amount of the molecular species transformed. In PE, the mean hydroperoxide concentration produced from 16:0/18:2 was low, 1.35 ± 0.64 nmol/mg protein compared to PC and this concentration represented 26% of the amount of molecular species transformed.

Relationships between antioxidants and hydroperoxides. There was a positive relationship between α-tocopherol before lipoxygenase treatment and each hydroperoxide concentration for PC and PE (Table 2) after lipoxygenase treatment. This relationship is specially marked for the hydroperoxides produced from 16:0/20:4 + 16:0/22:6 molecular species in PE (Fig. 2). In contrast, there was no relationship between the amount of molecular species transformed and α-tocopherol concentrations. Furthermore, there was no link between hydroperoxide concentration and GPx activity in either PC or PE.

DISCUSSION

We studied the main molecular species of human erythrocyte membrane phospholipids and their corresponding hydroperoxides after lipoxygenase treatment. Only total evaluation of hydroperoxides from PC and PE was reported in the literature with different methods of detection (8,12,13). The method described in the present work represents a significant improvement over the usual TBARS determination, which only accounts for a small percentage of fatty acids consumed compared to the amount of hydroperoxides recovered (14). The experimental model used in this work, phospholipid–bile salt micelles, does not directly reflect the event in biological membranes, but the antioxidant effect of α-tocopherol was

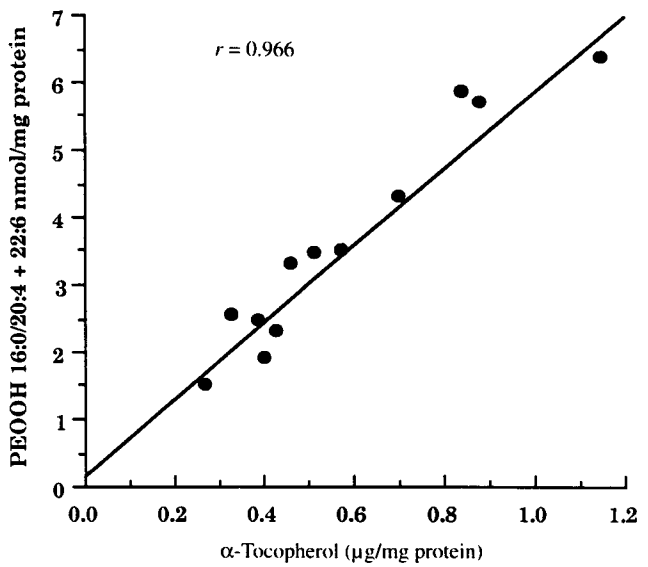

FIG. 2. Relationship between the concentration of α-tocopherol before lipoxygenase treatment and the concentration of phosphatidylethanolamine (PE) 16:0/20:4 + 16:0/22:6 hydroperoxides (PEOOH) after lipoxygenase treatment in human erythrocyte membrane.

observed either in micelles or in biological membrane (15). Therefore, determination of hydroperoxide molecular species from the main classes of phospholipids should improve our knowledge of the peroxidation process in membrane.

As seen in Table 1, the main differences observed between PC and PE concerned the peroxidation of 16:0/18:2. The amount of this molecular species transformed by lipoxygenase was higher in PE (56%) than in PC (40%). However, only 26% was recovered as hydroperoxides in PE compared to 48% in PC. This result is consistent with the recent study of Guo *et al.* (16) using 2,2′-azo*bis*(2-amidinopropane) dihydrochloride as the initiator of the peroxidation process in erythocyte membranes. According to this author, the high susceptibility of 16:0/18:2 to peroxidation in PE might be due to an attack on another part of the phospholipid including oxidation of primary amino groups. These last oxidation products, which represent about 50% of the molecular species transformed (16), are not recovered as hydroperoxides and could not be detected in our experimental conditions.

The amount of molecular species transformed from PC and PE was not related to the concentrations of the molecular species prior to the peroxidation but to the number of double bonds. These results confirm the greatest susceptibility of PUFA to the peroxidation process as a function of fatty acid unsaturation (1). The percentages of the molecular species transformed containing fatty acids with more than two double bonds, and hydroperoxides produced were in the same order of magnitude in PC as in PE. Despite a significantly higher concentration of these PUFA in PE, we observe about the same concentration of hydroperoxides produced. As PUFA are a good target for free radicals, the corresponding hydroperoxides would be expected to be more abundant in PE than PC. The link between unsaturation of fatty acids in membane phospholipids and hydroperoxide production is unclear (17,18). Other factors probably influence the degree of peroxidation, such as the different antioxidant systems located in the membrane, especially α-tocopherol.

The fundamental role of α-tocopherol in the membrane was evident when we considered the relationships between the concentrations of α-tocopherol and hydroperoxides: the higher the concentration of α-tocopherol, the higher the concentration of hydroperoxides. This is surprising given the antioxidant role of this vitamin. However, the role of α-tocopherol in the different steps of lipid peroxidation process could partly explain this strong relationship. Because α-tocopherol acts as a hydrogen donator, it scavenges chain-propagating radicals, suppresses peroxyl radicals, and thus contributes to stabilizing the hydroperoxides produced. In the absence of effective hydrogen donators, such as vitamin E, peroxyl radicals increase and their transformation into hydroperoxides is reduced. Peroxyl radicals from fatty acids with more than two double bonds undergo intramolecular cyclization (19). In the case of peroxyl radicals from linoleic acid whereby intramolecular cyclization is impossible, other reactions occur such as peroxide-linked dimers with hydroperoxides (20) concurring to minimize hydroperoxide production.

Different arguments strengthen the specific effect of α-tocopherol toward hydroperoxides formation. First, GPx activity in the presence of deoxycholate was inhibited during the lipoxygenase treatment (21). Second, the extent of peroxidation corresponding to the amounts of molecular species transformed did not vary with α-tocopherol content.

The inhibitory effect of α-tocopherol toward 15-lipoxygenase *via* a noncompetitive interaction with the enzyme protein (22,23) could also be advanced. Thus, the protective effect of α-tocopherol can occur through the formation of an inactive complex with lipoxygenase, besides the trapping of peroxyl radicals. However, the inhibitory effect was unlikely because our experimental conditions were not suitable (alkaline pH) and the concentration of α-tocopherol found in erythrocyte membranes was not in the inhibitory range (24).

In conclusion, we suggest that α-tocopherol may, *in vivo*, first interact with the lipoxygenase and secondly may stabilize the hydroperoxides, reducing their further decomposition into secondary products in relation with the concentration of α-tocopherol. This protective effect of α-tocopherol should be more efficient in PE where more PUFA were present, as previously suggested (25) for the inner layers of liver mitochondrial membranes. A similar experiment will be carried out using erythrocyte membranes from children with diseases associated with vitamin E deficiency, such as cystic fibrosis and chronic cholestasis. We previously observed vitamin E deficiency in erythrocyte membranes from children with cystic fibrosis who do not have plasma vitamin E deficiency despite vitamin E treatment (Thérond, P., Couturier, M., Lemonnier, F., Demelier, J.F., and Navarro, J., unpublished data). Consequently, it will be interesting to determine whether this vitamin E deficiency induces modification of the peroxidation process involving the main phospholipid classes and molecular species in each. The present method will be used to monitor the effect of vitamin E and fatty acids supplementation on the composition of the membrane phospholipids and to determine what species of hydroperoxides are produced at various vitamin E levels.

Plasma Concentrations of Dihydro-Vitamin K_1 Following Dietary Intake of a Hydrogenated Vitamin K_1-Rich Vegetable Oil

Sarah L. Booth, Kenneth W. Davidson, Alice H. Lichtenstein, and James A. Sadowski*

Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University, Boston, Massachusetts 02111

ABSTRACT: Dihydro-vitamin K_1 is a dietary form of vitamin K_1 (phylloquinone) produced during the hydrogenation of vegetable oils. To determine if dihydro-vitamin K_1 is present in plasma following dietary intake of a hydrogenated fat, eight healthy adults consumed each of two diets containing 30% of calories from fat, of which 20% was either soybean oil or a partially hydrogenated soybean oil-based stick margarine. Of the fats and oils analyzed, dihydro-vitamin K_1 was only found in the hydrogenated products. The soybean oil diet contained 180 ± 12 μg (mean ± SD) of vitamin K_1/day and nondetectable levels of dihydro-vitamin K_1, whereas the stick margarine diet contained 199 ± 7 μg of vitamin K_1/day and 23 ± 2 μg of dihydro-vitamin K_1/day. After consuming each diet for five weeks, plasma dihydro-vitamin K_1 concentrations were higher ($P = 0.002$) in all eight subjects when consuming the stick margarine diet (0.56 ± 0.33 nmol/L) compared to the soybean oil diet (0.12 ± 0.11 nmol/L). There was no significant change in plasma vitamin K_1 concentrations when the two diets were compared. In conclusion, dihydro-vitamin K_1 is detectable in plasma following dietary intake of a hydrogenated vitamin K_1-rich vegetable oil. *Lipids 31*, 709–713 (1996).

Certain vegetable oils are important dietary sources of vitamin K_1 (phylloquinone), which is the predominant form of vitamin K found in the diet (1,2). Of these vegetable oils, the highest concentrations of vitamin K_1 are measured in soybean, canola, and olive (3). Food consumption data for this century show a general shift from animal to vegetable sources of dietary fat, attributed to health concerns associated with the intake of saturated fats and cholesterol (4). Soybean oil is the most commonly consumed vegetable oil in the American diet, often in a hydrogenated form (5).

We recently described high-performance liquid chromatography (HPLC) methodology for the determination of vitamin K_1 in various food matrices (6). In our analysis of bread, we observed a peak that corresponded to the retention time of 2′,3′-dihydro-vitamin K_1. The identity of dihydro-vitamin K_1 has since been confirmed by gas chromatography/mass spectrometry, along with its conversion from vitamin K_1 during the hydrogenation process (7).

The physiological importance of this observation is dependent on the biological activity of the hydrogenated form of vitamin K. Vitamin K-dependent reactions are related to both the length and the isomeric configuration of the side chain (8). The effect of saturation of the 2′,3′ double bond on the biological activity of vitamin K was examined using the chick bioassay, as reviewed in 1941 by Fieser *et al.* (9). There was an overall loss in potency of the vitamin when saturated, although the data on the magnitude of the reduction in biological activity were inconsistent when compared to the parent compound, vitamin K_1. As this hydrogenated form of vitamin K is abundant in the food supply (10), the biological activity of dihydro-vitamin K_1 in humans needs to be determined. In this paper, we report plasma concentrations of vitamin K_1 and dihydro-vitamin K_1 following dietary intake of known amounts of a hydrogenated and nonhydrogenated vegetable oil.

EXPERIMENTAL PROCEDURES

Study design. This study was a subset of a larger human metabolic study examining the effects of hydrogenated fat intake on lipid profiles. Eight moderately hypercholesteremic, but otherwise healthy participants (three men, five women), were selected for this study. They ranged in ages from 58 to 72 yr (mean = 64 yr). All participants were in good health as determined by a physical examination and screening laboratory results. Exclusion criteria were as follows: (i) use of medications known to affect lipid metabolism or clotting function; (ii) history of renal, hepatic, endocrine, or gastrointestinal disease; and (iii) women currently on postmenopausal estrogen replacement therapy.

All participants consumed each of the two test diets according to a randomized study design. Each diet phase had a duration of five weeks, with a minimum two-week washout period between phases. The diet phases consisted of a mixed diet containing only naturally occurring foods, and were composed of 15% protein, 55% carbohydrate, and 30% of kcals from fat. A rotating three-day menu was used throughout the study. Of the calories derived from fat, 20% was provided by either soybean oil or a commercial soybean oil-based stick

margarine. The diet was designed to provide nutrient adequacy by meeting the recommended dietary allowance (RDA) for energy, protein, minerals, and vitamins (11). Replicates of each meal (based on a 2,000 kcal intake) were prepared as for consumption, and the entire contents of each single day menu were homogenized in a stainless-steel blender (Waring Products Division, New Hartford, CT). Aliquots were then frozen at −20°C and protected from light until the time of vitamin K_1, dihydro-vitamin K_1, and total fatty acid analyses.

Although study participants were free-living, they were only allowed to eat and drink foods and beverages provided to them by the Metabolic Research Unit at the Jean Mayer USDA Human Nutrition Research Center on Aging (Boston, MA) where all meals were prepared under the supervision of a dietitian. The caloric content of the diet was adjusted to maintain body weight within 1.5 kg throughout the study. Each participant was weighed three times per week. In the fifth week of each diet phase, a single fasting blood sample was drawn, aliquoted, and stored at −70°C until analyses.

The study protocol was approved by the Human Investigation Review Committee of Tufts University, and a written consent form was obtained from each study participant.

Analytical procedures. The solvents used in sample extraction and chromatography were HPLC grade (Fisher Scientific Inc., Springfield, NJ). Vitamin K_1 was purchased from Sigma Chemical Co. (St. Louis, MO). 2′,3′-Dihydro-vitamin K_1 was synthesized by hydrogenation of vitamin K_1 using a modification of the procedure reported by Langenberg and Tjaden (12). The internal standard $K_{1(25)}$ [2-methyl-3-(3,7,11,15,19-pentamethyl-2-eicosenyl)-1,4-napthalenedione] was a gift from Hoffman-La Roche & Co. (Basel, Switzerland). Standard solutions were diluted to known concentrations in 100% methanol and characterized spectrophotometrically and chromatographically. Working solutions were stored at 4°C and protected from light. All procedures involving sample processing and preparation were performed under yellow lighting since vitamin K compounds are sensitive to photodegradation.

Vitamin K_1 and dihydro-vitamin K_1 concentrations in plasma were determined by reverse-phase HPLC using post-column reduction and fluorometric detection as described in detail elsewhere (6,13).

Sample extracts were prepared for injection on the HPLC as follows: 2 mL of plasma were transferred to a disposable borosilicate screw-cap culture tube (16 × 100 mm) to which 4.0 ng (0.02 mL) of the internal standard $K_{1(25)}$ was directly added. Plasma proteins were denatured by adding 4 mL of ethanol and vortexing for 10 s, followed by the addition of 1 mL of H_2O and 12 mL of hexane. Following mixing for 1 min and centrifugation at 1,000 × *g* for 5 min, the upper (hexane) layer was transferred to a disposable borosilicate culture tube (16 × 100 mm) and evaporated to dryness in a centrifugal evaporator (Savant Instruments Inc., Farmingdale, NY). The residue was redissolved in 1 mL of hexane and further processed by two-stage solid-phase extraction (SPE). SPE silica gel columns (3 mL) (J.T. Baker Inc., Phillipsburg, NJ) were preconditioned by a wash of 8 mL of hexane/diethyl ether (93:3, vol/vol), followed by 8 mL of 100% hexane. The 1 mL extract was applied directly onto the preconditioned column packing, followed by a wash with 8 mL of 100% hexane. The phylloquinone-containing fraction was eluted from the SPE columns with 8 mL hexane/diethyl ether (93:3, vol/vol). The eluants were collected into clean 16 × 100 culture tubes and evaporated to dryness. To further purify the lipid extract for injection on the HPLC, a reverse-phase C18 SPE extraction was used. After evaporation, the residue from the eluate of the silica gel SPE columns was dissolved in 200 µL of isopropanol with heat (45°C) for 10 min. The reverse-phase C18 columns (3 mL) (J.T. Baker Inc.) were preconditioned by successive washes with 3 mL of methanol/methylene chloride (80:20, vol/vol), followed by 3 mL of 100% methanol and 3 mL of 100% H_2O. The reconstituted extracts were applied directly to the preconditioned packing. The column was washed with 3 mL of methanol/H_2O (95:5, vol/vol) followed by 3 mL of 100% acetonitrile, and the vitamin K-containing fraction was eluted from the column with 6 mL of methanol/methylene chloride (80:20, vol/vol). The eluant was evaporated to dryness and reconstituted in 25 µL of 100% methylene chloride with swirling to completely dissolve the residue. Immediately after dissolving, 100 µL of methanol (containing 10 mM $ZnCl_2$, 5 mM acetic acid, and 5 mM sodium acetate) was added. A volume of 100 µL was injected for analysis by HPLC.

Every fourth injection was of a calibration standard containing vitamin K_1, dihydro-vitamin K_1, and the internal standard, vitamin $K_{1(25)}$. In addition, a plasma control was analyzed with every sample batch. The coefficients of variation for ten replicates of the control plasma analyzed on the same day were 5.3 and 7.1% for vitamin K_1 and dihydro-vitamin K_1, respectively.

Analytical procedures used for the analyses of metabolic diets, and the individual fats and oils incorporated into diets, have been described elsewhere (6,7). Different hydrogenated fat sources were analyzed for their vitamin K_1 and dihydro-vitamin K_1 concentrations as part of the protocol for the larger human metabolic study. The soybean oil and margarines used in the diets were obtained from a local commercial vendor, with each sample representing a single lot. The *trans* fatty acid content of the diets were analyzed by Best Foods Research and Engineering Center (Union, NJ) (14).

Statistical analysis. A paired samples *t*-test was used to compare differences between the two test diets for both plasma vitamin K_1 and dihydro-vitamin K_1 concentrations. A *P*-value <0.05 was defined as statistically different.

RESULTS

The vitamin K_1 and dihydro-vitamin K_1 concentrations of soybean oil, a variety of hydrogenated fats, and butter are presented in Table 1. Dihydro-vitamin K_1 was only present at detectable levels in the three hydrogenated products, which was supported by corresponding increases in the percentage of total *trans* fatty acid content.

TABLE 1
Vitamin K_1 and Dihydro-Vitamin K_1 Concentrations of Different Oils and Hydrogenated Fats, with Corresponding Total *Trans* Fatty Acid Composition

Description	Vitamin K_1 (μg/100 g ± SD)	Dihydro-vitamin K_1 (μg/100 g ± SD)	Total *trans* fatty acid (%)
Butter	5.4 ± 1.3	nd[a]	2.6
Soybean oil	238 ± 17	nd	0.3
Liquid (soybean-based) margarine	25 ± 1.3	nd	0.6
Tub (soybean-based) margarine	64 ± 0.7	34 ± 1.1	9.4
Commercial partially-hydrogenated cooking fat	212 ± 5.9	96 ± 2.8	13.6
Stick (soybean-based) margarine	50 ± 1.9	132 ± 4.9	26.1

[a]nd = Below the lower limit of detection of 0.01 μg of dihydro-vitamin K_1/100 g.

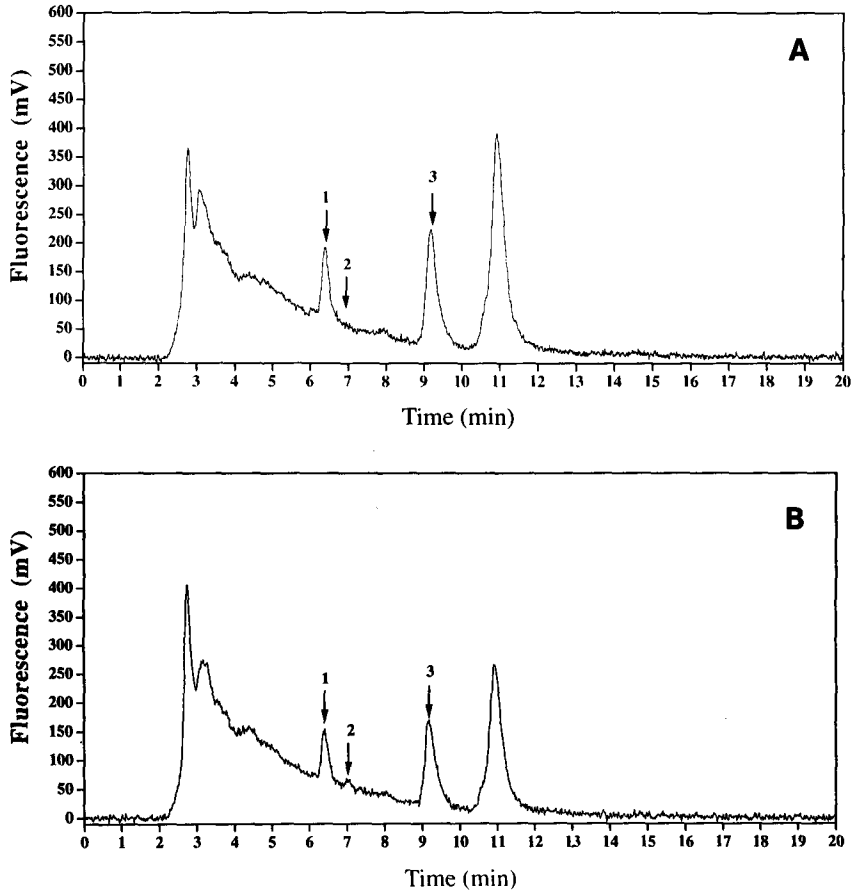

FIG. 1. Representative high-performance liquid chromatography chromatograms of vitamin K_1 and dihydro-vitamin K_1 in human plasma following consumption of (A) soybean oil diet, and (B) stick margarine diet. Peaks correspond to (1) vitamin K_1, (2) dihydro-vitamin K_1, and (3) the internal standard, $K_{1(25)}$.

The mean ± SD daily intake of vitamin K_1 during the soybean oil phase was 180 ± 12 μg, compared to a mean ± SD daily intake of vitamin K_1 during the stick margarine phase of 199 ± 7 μg ($P = 0.08$). In adults, the current daily RDA for vitamin K is 65–80 μg of phylloquinone (11). The stick margarine diet contained a mean ± SD dihydro-vitamin K_1 concentration of 23 ± 2 μg/day, whereas dihydro-vitamin K_1 was not detected in the soybean oil diet. The lower limit of detection was 0.01 μg of dihydro-vitamin K_1/100 g of food. Vegetables, such as lettuce, broccoli, and peas, were the primary dietary sources of vitamin K_1 in the two diets.

Representative chromatograms of plasma vitamin K_1 and dihydro-vitamin K_1 following five weeks of consumption of the soybean oil diet (A) and the stick margarine diet (B) are presented in Figure 1. The dihydro-vitamin K_1 concentrations were significantly higher in all eight study participants in the stick margarine phase than the soybean oil phase ($P = 0.002$) (Fig. 2A). There was no significant difference in plasma vita-

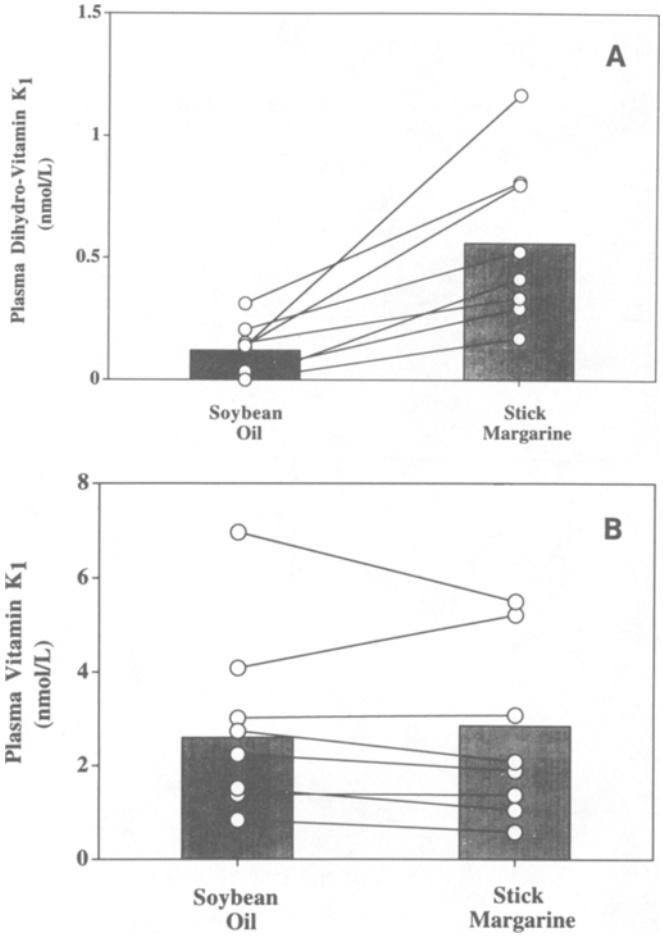

FIG. 2. Comparisons of (A) plasma dihydro-vitamin K_1 concentrations and (B) plasma vitamin K_1 concentrations in each individual in response to a five-week soybean oil diet and a five-week stick margarine diet. The lines connect the paired values for each individual. The bars represent the group mean for each diet: (A) the mean ± SD dihydro-vitamin K_1 concentrations were 0.12 ± 0.11 and 0.56 ± 0.33 nmol/L for the soybean oil and stick margarine diets, respectively ($P = 0.002$), and (B) the mean ± SD vitamin K_1 concentrations were 2.85 ± 1.95 and 2.60 ± 1.86 nmol/L for the soybean oil and stick margarine diets, respectively ($P = 0.41$).

min K_1 concentrations when the two-diet phases were compared ($P = 0.408$) (Fig. 2B).

DISCUSSION

The results of this study show that 2′,3′-dihydro-vitamin K_1 does appear in plasma following the dietary intake of a hydrogenated vitamin K_1-rich vegetable oil. There is an abundance of this hydrogenated form of vitamin K_1 in the American diet, accounting for up to 30% of the total dietary vitamin K_1 consumed (10). Therefore, it is important to determine if dihydro-vitamin K_1 can act as a cofactor for vitamin K-dependent γ-glutamyl carboxylase required for the synthesis of vitamin K-dependent proteins. In 1941, Fieser *et al.* (9) used the chick bioassay to compare the biological activity of dihydro-vitamin K_1, among other naphthoquinone-related compounds, with the parent compound, vitamin K_1. Whereas these authors reported an 8-fold reduction in biological activity associated with the saturation of the 2′,3′ double bond of the side chain, other authors reported greater losses in biological activity (15). If dihydro-vitamin K_1 is biologically active in humans, this hydrogenated form of vitamin K_1 may have an important contribution to vitamin K nutrition and would need to be considered in studies that investigate the role of dietary vitamin K intake on human health.

In this study, the dihydro-vitamin K_1 to vitamin K_1 plasma ratio during the stick margarine phase was 1:5, which was greater than the 1:9 ratio in the diet. In an analysis of the Food and Drug Administration's Total Diet Study (FDA TDS), the estimated vitamin K_1 and dihydro-vitamin K_1 daily intakes for a comparable age and gender group were 79 and 19 μg, respectively (10). Therefore, the intake of dihydro-vitamin K_1 in the stick margarine phase of this study is similar to the amount of dihydro-vitamin K_1 normally consumed in the American diet as estimated by the FDA TDS. However, the dietary intakes of vitamin K_1 were ~2.5 times greater than both the current RDA for vitamin K (11) and the estimated intakes from the FDA TDS. Therefore, the higher ratio of dihydro-vitamin K_1 to vitamin K_1 in the plasma as compared to the ratio in the diet may be indicative of either greater absorption or slower clearance of dihydro-vitamin K_1 than vitamin K_1.

In an earlier study that established the normal range for plasma vitamin K_1 (16), dihydro-vitamin K_1 was used as an internal standard so it was not possible to determine the plasma concentrations of endogenous dihydro-vitamin K_1 in these free-living individuals. It is also not known the extent to which earlier studies underestimated circulating vitamin K_1 concentrations, which were based on the direct comparison of peak area ratios of the plasma samples to authentic standards of vitamin K_1 and the corresponding internal standard, dihydro-vitamin K_1. However, continuous modifications to the original assay developed in our laboratory (13) have increased the sensitivity of detection by 3–4-fold. It was only with this enhanced detection that we were able to measure dihydro-vitamin K_1 in plasma of individuals consuming diets that contained vitamin K_1-rich hydrogenated oils. Intake data from the FDA TDS suggest that dihydro-vitamin K_1 is abundant in the American diet, and since it is now known that this compound is absorbed from the diet, the internal standard $K_{1(25)}$ is now used for vitamin K_1, dihydro-vitamin K_1, and vitamin K_1–epoxide assays in our laboratory.

In summary, 2′,3′-dihydro-vitamin K_1 has recently been identified as a dietary form of vitamin K produced during the hydrogenation of vitamin K_1-rich vegetable oils (7). In this study, dihydro-vitamin K_1 was measured in plasma following ingestion of known amounts of a hydrogenated vegetable oil. Dietary intake data from national food consumption surveys indicate that this hydrogenated form of vitamin K_1 is abundant in the American diet (10). Therefore, it is now important to determine the biological activity of dihydro-vitamin K_1 in humans relative to its parent compound, vitamin K_1.

ACKNOWLEDGMENTS

Dihydro-Vitamin K_1: Primary Food Sources and Estimated Dietary Intakes in the American Diet

Sarah L. Booth[a], Jean A.T. Pennington[b], and James A. Sadowski[a,*]

[a]Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University, Boston, Massachusetts 02111 and [b]Division of Nutrition Research Coordination, National Institute of Health, Bethesda, Maryland 20892

ABSTRACT: Dihydro-vitamin K_1 was recently identified as a dietary form of vitamin K produced during the hydrogenation of vitamin K_1-rich vegetable oils. Dihydro-vitamin K_1 is absorbed, with measurable levels in human plasma following dietary intake. To determine the primary food sources of dihydro-vitamin K_1 in the American diet, 261 foods from the U.S. Food and Drug Administration's (FDA) Total Diet Study (TDS) were analyzed by high-performance liquid chromatography. Of these foods, 36 contained dihydro-vitamin K_1. Fast-food items that were otherwise poor sources of vitamin K_1, such as french fries and fried chicken, contained appreciable amounts of dihydro-vitamin K_1 (36 and 18 μg/100 g, respectively). These nutrient values were then applied to the FDA TDS consumption model to determine average dietary intake of dihydro-vitamin K_1 in 14 age–gender groups. With the exception of infants, all age–gender groups had estimated mean daily dihydro-vitamin K_1 intakes of 12–24 μg, compared to mean daily vitamin K_1 intakes of 24–86 μg. The vitamin K_1 and dihydro-vitamin K_1 intakes were summed, and the dietary contribution of dihydro-vitamin K_1 was expressed as a percentage of total vitamin K intake. Children reported the highest intakes of dihydro-vitamin K_1 (30% of total vitamin K intake), followed by a progressive decrease in percentage contribution with age. There are currently no data on the relative bioavailability of dihydro-vitamin K_1 but, given its abundance in the American diet, this hydrogenated form of vitamin K warrants further investigation.
Lipids 31, 715–720 (1996).

The relationship between the dietary intake of vitamin K_1 and vitamin K status has been inadequately studied because of the limited amount of food composition data available (1). It also has been assumed that a healthy population is not at risk of dietary vitamin K deficiency (2). The current Recommended Dietary Allowance (RDA) for vitamin K is currently set at 80 and 65 μg for adult men and women, respectively (3). This dietary recommendation was established on the assumption that optimal vitamin K nutriture could be determined by the amount of vitamin K required to maintain blood clotting times (4). However, with the understanding that the function of vitamin K is not limited to its role in hemostasis, more sensitive methods for assessing vitamin K nutritional status have been developed by using direct measurements of vitamin K and vitamin K-dependent proteins in blood. Recent studies indicate that the current RDA does not fully support the carboxylation of γ-carboxyglutamic acid residues in extra-hepatic vitamin K-dependent proteins, such as osteocalcin (5,6).

The use of high-performance liquid chromatography (HPLC) has facilitated the routine determination of vitamin K_1 concentrations in common foods and, in the most recent provisional table for vitamin K_1, only food composition data derived exclusively from HPLC analyses were used (7). Vitamin K_1 (phylloquinone) is considered the predominant form of vitamin K found in the diet (8). One of the outstanding characteristics of the provisional table was the overall absence of data on processed foods and mixed dishes.

We recently described HPLC preparation procedures for the determination of vitamin K_1 in various food matrices that were selected to represent foods commonly consumed in the United States (9). In the analysis of foods containing hydrogenated oils, we detected a peak that corresponded to 2′,3′-dihydro-vitamin K_1, a hydrogenated form of vitamin K. We have since confirmed the identity of dihydro-vitamin K_1 using gas chromatography/mass spectrophotometry, and its derivation from vitamin K_1 during the process of hydrogenation (10). Furthermore, we have measured dihydro-vitamin K_1 in human plasma following dietary intake of this compound in the form of margarine (11).

In this article, we present data on the dihydro-vitamin K_1 content in foods obtained from the U.S. Food and Drug Administration's (FDA) Total Diet Study (TDS). In the FDA TDS, more than 250 core foods in the American food supply, representing foods consumed in the United States, were purchased from retail markets four times per year from different geographic regions (12). These food values were then applied to the FDA TDS consumption model for 14 age–gender groups, which was based on data from the United States Department of Agriculture's (USDA) 1987/1988 Nationwide Food Consumption Survey (NFCS) (13). Analysis of these

foods have identified food classes that are potential contributors to dihydro-vitamin K_1 intake in the United States, and provide dietary intake estimates of this hydrogenated form of vitamin K_1 by 14 age–gender groups.

EXPERIMENTAL PROCEDURES

Collection and preparation of foods. The 1990 FDA TDS food list identified core foods in the American diet on the basis of data from the USDA 1987/1988 NFCS (12). Individual foods and ingredients are collected from four sites per year in the United States and sent to the FDA Field Office Laboratory (Kansas City, MO) for preparation and processing according to instructions described in detail by Pennington (14). For this study, 261 foods were selected from the August 1993 TDS collection for vitamin K_1 and dihydro-vitamin K_1 determination. Each food was homogenized and a 10-g portion was packed in domestic quality ziplock-type plastic bags. The 10-g portions were frozen, packed with frozen ice packs, and shipped by air to the Vitamin K Laboratory at the Jean Mayer USDA Human Nutrition Center at Tufts University, where they were stored, protected from light, at –20°C until analysis.

Vitamin K_1 and dihydro-vitamin K_1 determination in foods. Each homogenate was analyzed in triplicate for vitamin K_1 and dihydro-vitamin K_1 by an HPLC method as described elsewhere (9). Briefly, 0.25–0.50 g aliquots of each homogenate were weighed directly into 50-mL polypropylene centrifuge tubes (Corning Co., Corning, NY). An appropriate amount of the internal standard, vitamin 2-methyl-3-(3,7,11,15,19-pentamethyl-2-eicosenyl)-1,4-napthalenedione [$K_{(1,25)}$], was added directly to the test portions. Fifteen milliliters of 2-propanol/hexane (3:2, vol/vol) and 4 mL of H_2O were added, followed by sonification using a Branson Model 350 sonifer-cell disrupter (Branson Ultrasonics Corp., Danbury, CT). The mixtures were then vortexed (10 min), and centrifuged at 1000 × *g* (10 min). After phase separation, the upper hexane layer was aspirated into a 16 × 100 culture tube, evaporated to dryness under reduced pressure in a centrifugal evaporator (Savant Instrument Inc, Farmingdale, NY), and the residue was redissolved in 4 mL of hexane. An aliquot of the reconstituted lipid extract was applied to a 6-mL solid-phase extraction (SPE) silica column (J.T. Baker Inc., Chicago, IL) which had been preconditioned by successive washes of 8 mL of hexane/diethyl ether (93:3, vol/vol), followed by 8 mL of hexane. The SPE silica column was then washed with an additional 8 mL of hexane to remove the hydrocarbons. The fraction containing vitamin K_1 was eluted with 8 mL of hexane/diethyl ether (97:3, vol/vol), collected, and evaporated to dryness.

To further purify foods with a high lipid content, such as meat, butter, and margarine, a reversed-phase C_{18} SPE extraction was used. After evaporation, the residue from the hexane–ether eluate was dissolved in 200 µL of 2-propanol by heating (45°C) for 10 min. The reversed-phase C_{18} columns (6 mL; J.T. Baker) were preconditioned by successive washes with 6 mL of methanol/methylene chloride (80:20, vol/vol), followed by 6 mL of 100% methanol and 6 mL of 100% H_2O. The dissolved residue was applied directly to the preconditioned packing. The column was washed with 6 mL of methanol/H_2O (95:5, vol/vol), followed by 6 mL of 100% acetonitrile, and the analyte was eluted from the column with 10 mL of methanol/methylene chloride (80:20, vol/vol), collected, and evaporated to dryness. The final residue was reconstituted initially in 30 µL of 100% methylene chloride, followed by 270 µL of methanol containing 10 mM zinc chloride, 5 mM acetic acid, and 5 mM sodium acetate. A 150-µL aliquot was injected into the HPLC.

Quantitation of vitamin K_1 and dihydro-vitamin K_1 in the homogenates was performed by direct comparison of peak area ratios of the foods to authentic standards of vitamin K_1, dihydro-vitamin K_1, and vitamin $K_{1(25)}$, using a Waters 860 chromatography data system (Waters Chromatography, Milford, MA). The lower limit of detection was set at 0.01 µg of vitamin K_1 and/or dihydro-vitamin K_1/100 g of food. Vitamin $K_{1(25)}$, the internal standard that was used for all the FDA TDS analyses, was a gift from Hoffman-La Roche and Co. (Basel, Switzerland). All foods were analyzed within seven months of collection and preparation. The vitamin K_1 concentrations of the 261 homogenates have been reported elsewhere (15).

Survey design. The 1990 revision of the FDA TDS was based on data from the 1987–1988 NFCS, which was a nationwide area probability sample of the population in 48 coterminous states (12). Food intake data were collected over four seasons, with a different sample of participants in each season (16). Individual dietary data consisted of a single 24-h recall and a 2-d food record collected on consecutive days.

Fourteen age–gender groups were selected for the 1990 revision of the TDS, as described in detail by Pennington (13). Of the NFCS participants who were within the selected 14 age–gender groups (total 7,891), the TDS only included those participants from whom three days of dietary data were available (total 3,634). Although this exclusion of participants may have created an additional response bias, it is assumed that an increase in the days of dietary recording by each participant will reduce the impact of intraindividual random variation in dietary intake (17).

Estimation of vitamin K_1 and dihydro-vitamin K_1 intakes. As described in detail elsewhere, 6,148 food codes, food names, and food descriptions used in the 1987–1988 NFCS were divided among 14 major categories (13). These foods were then manually aggregated into groups (total 261) within these 14 categories on the basis of similarity of food type, use in the diet, preparation methods, and composition.

The vitamin K_1 and dihydro-vitamin K_1 values were matched with corresponding food items in the TDS, and the daily intakes of each food were calculated for each of the 14 age–gender categories as described by Pennington (13). The daily intakes of vitamin K_1 and dihydro-vitamin K_1 were specified in µg/d and as a percentage of total daily µg intake. The results of the analyses of phylloquinone in the TDS have been reported elsewhere (18).

RESULTS

Food composition. Of the 261 foods analyzed in the FDA TDS August 1993 collection for vitamin K, 36 foods contained dihydro-vitamin K_1 in concentrations greater than 1.0 μg/100 g of food (Table 1). All 36 foods contained hydrogenated fats or oils, with the highest concentrations of dihydro-vitamin K_1 measured in assorted cookies and stick margarine. However, when expressed in μg per average serving size, the richest sources of dihydro-vitamin K_1 were commercial apple pie (27 μg), followed by fast-food french fries (25 μg), and baked biscuits from refrigerated dough (21 μg).

Foods that are otherwise poor dietary sources of vitamin K_1, such as root vegetables and animal products (7,15), can contribute to overall vitamin K nutriture when processed with vitamin K_1-rich vegetable oils, as demonstrated for potatoes and chicken (Figs. 1 and 2). The vitamin K_1 concentrations of roasted chicken and homemade fried chicken measured in the August 1993 FDA TDS collection were <0.001 and 3.8 μg/100 g of chicken, respectively (15). Fast-food items, such as french fries and chicken nuggets, had large concentrations of dihydro-vitamin K_1 relative to their vitamin K_1 contents (Table 1).

Dietary intake. The total mean dihydro-vitamin K_1 intake reported for the infants was 1 μg/d, which accounted for ~1% of the total vitamin K intake (Table 2). This was an expected

TABLE 1
Primary Food Sources of Dihydro-Vitamin K_1 in the American Diet: Data from the August 1993 Collection of the FDA TDS[a]

Food description	Average serving (g)	Vitamin K_1		Dihydro-vitamin K_1	
		μg/100 g of food	μg/serving	μg/100 g of food	μg/serving

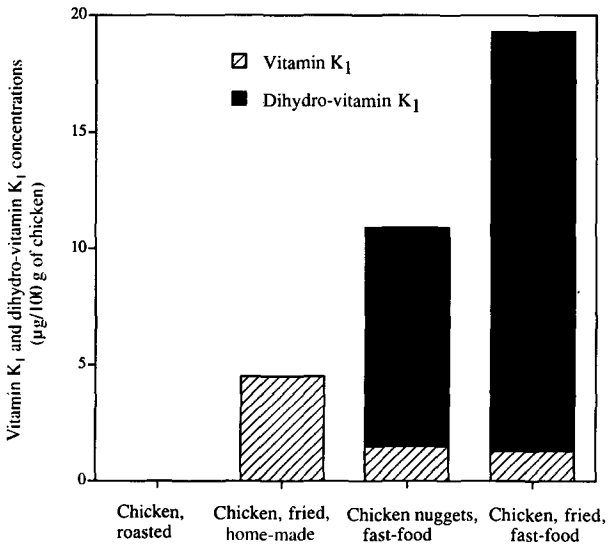

FIG. 1. The effects of processing on the vitamin K_1 and dihydro-vitamin K_1 concentrations of chicken. Vitamin K_1 data for roasted, homemade, and fried chicken were obtained from Booth *et al.* (Ref. 15). Homemade chicken was fried in a vegetable oil blend.

result because 87% of total dietary vitamin K_1 intake for this age group is attributed to infant formula (18), which contains no dihydro-vitamin K_1. In contrast, the estimated mean dihydro-vitamin K_1 intake for the two-year-old group was 12 μg/d, which accounted for 33% of the total vitamin K intake, assuming equivalent bioavailability of dihydro-vitamin K_1 compared to vitamin K_1. The five primary dietary sources of dihydro-vitamin K_1 for this age group were fast-food french fries, sugar cookies, instant mashed potatoes, margarine, and chocolate chip cookies (19, 9, 7, 7, and 6% of total dihydro-vitamin K_1 intake, respectively). The percentage contribution of dihydro-vitamin K_1 to total vitamin K intake was greatest among the two-year-old children, with a progressive decrease in percentage contribution with age. There was a higher percentage contribution of dihydro-vitamin K_1 to total dietary vitamin K intake among men when compared to the women. Among the adults, the five primary food sources of dihydro-vitamin K_1 were fast-food french fries, margarine, mayonnaise, heated french fries, and macaroni and cheese prepared from a package, each of which contributed 5% or less of the total vitamin K intake.

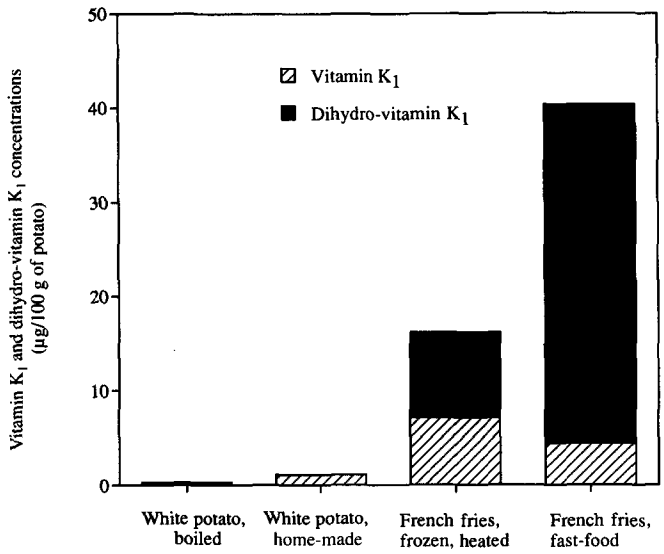

FIG. 2. The effects of processing on the vitamin K_1 and dihydro-vitamin K_1 concentrations of potatoes. Vitamin K_1 data for boiled and baked potatoes were obtained from Booth *et al.* (Ref. 15).

DISCUSSION

We have recently demonstrated that the hydrogenation of vitamin K_1-rich vegetable oils converts vitamin K_1 to dihydro-vitamin K_1, with an overall loss of the vitamin that is proportional to the degree of hydrogenation (10). The data presented in this study identify those food classes that are most affected by the impact of hydrogenation on the vitamin K_1 content of the diet. Foods that are otherwise poor sources of vitamin K_1, such as the root vegetables and animal meats, have a significant dihydro-vitamin K_1 content when they are processed using partially hydrogenated vitamin K_1-rich vegetable oils, such as soybean, canola, and cottonseed. There is also a small increase in the vitamin K_1 content of these processed foods because partial hydrogenation of vitamin K_1-rich oils does not completely convert all the vitamin K_1 to dihydro-vitamin K_1.

These are the first available dihydro-vitamin K_1 food composition data for commonly-consumed foods in the American diet. Given that the dihydro-vitamin K_1 and vitamin K_1 values presented in this study were derived from a single TDS collection, the FDA TDS foods do not reflect the regional and seasonal differences in the phylloquinone content of plant oils (19,20), nor do they reflect the variation in dihydro-vitamin K_1 content associated with conditions of hydrogenation (10). Therefore, the dihydro-vitamin K_1 values associated with the FDA TDS lack the sensitivity to reflect the range of individual intakes. Despite the limitations of the FDA TDS model, this study does indicate that dihydro-vitamin K_1 is abundant in the average American diet.

Dihydro-vitamin K_1 is absorbed from a dietary source, such as margarine, as indicated by corresponding peaks measured in human plasma by HPLC following consumption of known amounts of dihydro-vitamin K_1 (11). If there is an equivalent bioavailability of dihydro-vitamin K_1 compared with vitamin K_1, the intake data presented in this study would have important implications for several population groups. Although in the FDA TDS model, children had estimated mean vitamin K_1 intakes equivalent or above the current RDA for their respective age groups (18), the amount of dihydro-vitamin K_1 in the diet would increase the absolute intake of vitamin K by 30% if this hydrogenated form of vitamin K is indeed bioavailable. In the FDA TDS model, the 25–30-year-old adults had estimated mean dietary vitamin K_1 intakes lower than the current RDA of 65–80 μg of vitamin K_1 (3). The addition of dihydro-vitamin K_1 to the total dietary intake of vitamin K shifted intakes above the current RDA, assuming equivalent bioavailability. This is particularly critical because recent studies among young and older adults indicate that the current RDA for vitamin K does not sufficiently support full carboxylation of the γ-carboxyglutamic acid in extra-hepatic vitamin K-dependent proteins, such as osteocalcin (5,6).

Of concern is the high-fat content of those foods that are rich sources of dihydro-vitamin K_1, such as margarine, high-fat desserts, high-fat potatoes, and high-fat grain based dishes. Other foods, such as leafy vegetables, are excellent dietary sources of vitamin K_1 and should be promoted if the goal is to increase dietary intake of vitamin K_1. However, this study has demonstrated that this hydrogenated form of vitamin K is present in 36 of the 261 most commonly-consumed foods in the American diet, and the estimated dietary intakes could account for as much as 30% of the total vitamin K intake in certain age groups. A comparison of dietary practices among older Americans indicated that there have been only minor changes in fat consumption from foods such as high-fat desserts, between 1977–1978 and 1987–1988 (16). Furthermore, younger women have been identified as the age group among women that are consuming more meals away from home, with higher intakes of total and saturated fat associated with fast-food consumption (21). Therefore, the abundance of 2′,3′-dihydro-vitamin K_1 in the American diet warrants further investigation into its biological activity as consumption could increase otherwise low current vitamin K intake estimates if this hydrogenated form has equivalent biological activity to the parent compound, vitamin K_1. Conversely, if 2′,3′-dihydro-vitamin K_1 does not contribute to vitamin K nutriture, commercial hydrogenation of vitamin K_1-rich vegetable oils may be reducing the already low vitamin K_1 intakes reported in the FDA TDS.

ACKNOWLEDGMENTS

We gratefully acknowledge the laboratory director, chemists, and technicians at the FDA Kansas City District Office in Lenexa, Kansas, for providing prepared food samples. This project has been funded by the USDA Human Nutrition Research Center on Aging at Tufts University (Contract No. 53-1950-5-003).

Prevention of Cholesterol Cholelithiasis by Dietary Unsaturated Fats in Hormone-Treated Female Hamsters

Nariman Ayyad, Bertram I. Cohen*, Akira Ohshima[1], and Erwin H. Mosbach

Departments of Surgery, Beth Israel Medical Center, New York, New York and Albert Einstein College of Medicine, Bronx, New York

ABSTRACT: We examined the effect of diet on gallstone incidence and the composition of biliary phosphatidylcholines in methyltestosterone-treated female hamsters. These hamsters were fed a nutritionally adequate purified lithogenic diet containing 2% corn oil, 4% butterfat, 0.3% cholesterol, and 0.05% methyltestosterone, resulting in a cholesterol gallstone incidence of 86%. This incidence was lowered when mono- and polyunsaturated fats or fatty acids were added to the diet: 2.5% oleic acid resulted in total prevention of cholesterol cholelithiasis, 2.5% linoleic acid, and 4% safflower oil (78% linoleic acid content) reduced gallstone incidence to 26 and 8%, respectively. An additional 4% butterfat (29% oleic acid content) produced gallstones in 50% of the animals. At the end of the 6-wk feeding period, the bile of all hamsters was supersaturated with cholesterol. The major biliary phosphatidylcholine species in all groups were (*sn*-1–*sn*-2): 16:0-18:2, 16:0-18:1, 18:0-18:2, 16:0-20:4, and 18:2-18:2. The safflower oil- and linoleic acid-fed hamsters exhibited an enrichment of 16:0-18:2 (16–18%); added butterfat or oleic acid increased the proportion of 16:0-18:1 (9 and 25%, respectively). We conclude that the phosphatidylcholine molecular species in female hamster bile can be altered by dietary fats/fatty acids and that mono- and polyunsaturated fatty acids play a role in suppressing the induced cholelithiasis.

Lipids 31, 721–727 (1996).

We previously employed male Sasco hamsters as a model of cholesterol cholelithiasis (1). In this model, gallstone induction was accomplished with a nutritionally adequate purified diet which contained 4% butterfat and 0.3% cholesterol. Female hamsters from the same source did not develop supersaturated bile or gallstones when fed the standard lithogenic diet (LD) (2). However, when the synthetic androgen, methyltestosterone (MeT), was added to the LD, female hamsters developed cholesterol gallstones at the same rate as the males (3). We previously showed that stone incidence in the male hamster was modulated by the specific fats or fatty acids in the experimental diet: saturated fats and fatty acids (palmitic acid) enhanced gallstone formation while unsaturated fats (safflower oil, corn oil, olive oil) had the opposite effect (4–9). It was not known whether stone incidence in hormone-treated female hamsters was affected by the type of dietary fat in a similar manner.

Biliary components are believed to effect cholelithiasis. Attempts to correlate cholesterol gallstone formation in humans and experimental animals with modifications of the molecular species of biliary phosphatidylcholines (PC) have yielded conflicting data and interpretations (10–21). A number of investigators have reported the total biliary fatty acid composition of hamsters fed different diets ranging from Dam's essential fatty acid-deficient diet to nutritionally adequate diets with defined fatty acid composition (13,22–24). In none of these studies was it attempted, however, to analyze individual PC species. We previously found that in male hamsters, dietary fat affected the distribution of biliary cholesterol between vesicles and micelles (9). We now report experiments in hormone-treated female hamsters describing the correlation between dietary fatty acid composition, gallstone incidence, and biliary PC species.

MATERIALS AND METHODS

Animals and diet. Four-week-old (50–60 g) female golden Syrian hamsters (*Mesocricetus auratus*) were obtained from Sasco Inc. (Omaha, NE). The hamsters were fed a pelleted nutritionally adequate purified LD (Dyets, Inc., Bethlehem, PA) containing 0.3% cholesterol and 0.05% MeT with supplementation of specific unsaturated fats or fatty acids for 6 wk. The composition of the LD was as follows: 43.4% cornstarch, 20.0% casein, 14.6% dyetrose (soluble starch), 10.0% fiber (cellulose), 5.0% salt mix (modified U.S.P. XIV salt mix no. 200951), 4.0% butterfat, 2.0% corn oil, 0.5% vitamin mix (no. 300000), 0.3% cholesterol, 0.2% choline chloride, and 0.05% Met. The hamsters were placed into one of five groups: group 1 [22 hamsters], LD; group 2 [23 hamsters], LD + 2.5% linoleic acid (18:2); group 3 [24 hamsters], LD + 2.5% oleic acid (18:1); group 4 [26 hamsters], LD + 4.0% butterfat;

group 5 [24 hamsters], LD + 4.0% safflower oil. At the end of the feeding period, the gallbladders were examined for gallstones and cholesterol crystals. Cholesterol gallstones could be seen through the gallbladder wall and were between 1–5 mm in diameter. The bile (30–50 μL per hamster) was removed for determination of the biliary lipid composition and the major PC molecular species. The gallstones as well as an aliquot of bile was examined under polarized light microscopy using an Olympus MCHAP light microscope as described earlier (4,6) (Olympus Corp., Lake Success, NY).

Analytical procedures. Liver and plasma cholesterol levels were determined as described earlier (25). Biliary bile acids were determined as the methyl ester acetates by gas–liquid chromatography (GLC) (26). Total biliary phospholipids were measured using the Wako phospholipid B kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan). Cholesterol concentrations in bile were determined by GLC as previously described (26). Gallstones were analyzed by diffuse reflectance Fourier transform infrared spectroscopy (27).

The molecular species of PC in bile were determined as the benzoyl diacylglycerol derivatives by reverse-phase high-performance liquid chromatography (HPLC). The PC was isolated by HPLC from pooled hamster bile (50 μL) using a LiChrospher Si-100 column (25 cm × 4.0 mm, 5 μ particle size; E. Merck, Darmstadt, Germany) according to the method of Patton *et al.* (28). The PC fraction was hydrolyzed to diglycerides with phospholipase C Type IV from *Bacillus cereus* (Sigma Chemical Co., St. Louis, MO) and then derivatized using benzoyl chloride as described by Patton *et al.* (29) and Ullman and McCluer (30). Analysis of individual PC was carried out by HPLC on a 5 μ Ultrasphere C-18 column (250 mm × 4.6 mm; Beckman Instruments, Fullerton, CA). The fatty acids of the individual PC were then isolated and identified after formation of the methyl esters (Meth Prep II; Alltech Associates Inc., Deerfield, IL) by capillary gas chromatography on a Supelcowax fused silica capillary column (30 m, 0.32 mm i.d., 0.25 μm film thickness; Supelco, Bellefonte, PA). The amount of cholesterol present in biliary cholesterol–phospholipid vesicles and micelles was carried out as previously described (5).

Reference compounds. PC used as standards were purchased from Avanti Polar-Lipids, Inc. (Alabaster, AL). 1,2-Dipalmitoleoyl-*sn*-glycero-3-phosphocholine [PC(16:1-16:1)] was used as an internal standard. 1-Palmitoyl-2-arachidonoyl [PC(16:0-20:4)], 1-palmitoyl-2-linoleoyl [PC(16:0-18:2)], 1-stearoyl-2-linoleoyl [PC(18:0-18:2)], and 1-palmitoyl-2-oleoyl [PC(16:0-18:1)] were also purchased from Avanti for use as standards. Individual fatty acid methyl ester standards were purchased from Alltech.

Calculations and statistics. The cholesterol saturation indices (CSI) were determined using previously published methods (31,32). The total bile acid and PC molecular species hydrophobicity indices (HI) were determined using the relative retention times obtained by GLC and HPLC, respectively, as described earlier (33,34). All data were reported as mean ± SD. Differences between groups were calculated using analysis of variance to determine the F statistic. Student's *t*-test was then used for values for which the F statistic was significant ($P < 0.05$) (35).

RESULTS

As depicted in Table 1, butterfat, the major fat in the standard LD, contains mostly palmitic (16:0, 27%) and oleic (18:1, 29%) acids. Safflower oil contains mostly linoleic acid (18:2, 78%).

Liver and plasma cholesterol levels are summarized in Table 2. Liver cholesterol in the LD diet + 4% butterfat group 4 (77 mg/g) was significantly lower than the other experimental animals (range, 77–109 mg/g); in contrast, plasma cholesterol levels (406 mg/dL) in this group were significantly higher compared to the other experimental groups (range, 318–406 mg/dL).

Table 3 summarizes the incidence of gallstones as a function of different fats/fatty acids in the diet. The control LD (group 1) had a gallstone incidence of 86% which was significantly reduced by the fatty acids, 18:2 (26%, group 2) and 18:1 (0%, group 3). Gallstone incidence was also reduced by added fats, 4% butterfat (50%, group 4) and 4% safflower oil (8%, group 5). Table 3 also shows the biliary lipid composition. Total lipids were similar, ranging from 9.32 to 11.32 g/dL. The CSI was lowest in the 18:2- and safflower oil-fed groups (96% for both groups 2 and 5). All other hamsters had a CSI greater than unity. The mole % phospholipids ranged from 16.10 to 18.38%; the mole % cholesterol in the 18:2- and safflower oil-fed hamsters was lower than in the controls (5.77 and 5.75%, groups 2 and 5, respectively vs. 7.04%, group 1). The amount of cholesterol present in biliary cholesterol–phospholipid vesicles ranged from 58% (group 4) to 70% (group 2).

Table 4 summarizes the bile acid composition of hamster gallbladder bile. Cholic acid was lowered by 18:2 (37.84%,

group 2), 18:1 (36.13%, group 3), and butterfat (37.72%, group 4) as compared to the control diet (41.79%, group 1). The 18:1-fed hamsters had less hyodeoxycholic acid (7.84%, group 3) as compared to the 18:2 (10.23%, group 2), butterfat (9.97%, group 4), and safflower oil (9.48%, group 5). The HI were similar in all groups.

Table 5 summarizes the major PC molecular species in hamster bile. The major species present were (*sn*-1–*sn*-2): 16:0-18:2, 16:0-18:1, 18:0-18:2, 16:0-20:4, and 18:2-18:2, The four minor species: 16:1-18:2, 18:1-18:2, 18:0-20:4, and 18:1-18:1 comprised less than 10% of PC. Feeding 18:2 and safflower oil increased 16:0-18:2 (54.39%, group 2 and 53.54%, group 5 vs. 46.21%, group 1) and 18:0-18:2 (9.54%, group 2 and 10.27%, group 5 vs. 7.80%, group 1). Feeding 18:1 and butterfat elevated 16:0-18:1 (30.26%, group 3 and 26.47%, group 4 vs. 24.21%, group 1). The HI was lowered by 18:2 and safflower oil (0.19, groups 2 and 5), raised by 18:1 (0.27, group 3), and unaffected by butterfat (0.23, group 4) as compared to the controls (0.23, group 1).

DISCUSSION

We have developed a hamster model of cholesterol cholelithiasis that is responsive to specific fats and/or fatty acids in the diet. Unlike the males, female hamsters form cholesterol gallstones only when the synthetic androgen, MeT is added to the standard LD (2,3). Our LD which contained 4% butterfat and 0.3% cholesterol produced cholesterol gallstones in male

[a]Numbers are mean ± SD; see the Materials and Methods section for composition of the LD (lithogenic diet). Phosphatidylcholine (PC) molecular species were determined as benzoyl derivatives by high-performance liquid chromatography. 1-Acyl-2-acyl-*sn*-glycerol-3-phosphocholines: 18:2-18:2, 1-linoleoyl-2-linoleoyl; 16:0-20:4, 1-palmitoyl-2-arachidonoyl; 16:0-18:2, 1-palmitoyl-2-linoleoyl; 16:0-18:1, 1-palmitoyl-2-oleoyl; 18:0-18:2, 1-stearoyl-2-linoleoyl. 16:1-18:2, 18:1-18:2, 18:1-18:1, and 18:0-20:4. The minor species 16:1-18:2, 18:1-18:2, 18:1-18:1, and 18:0-20:4 totalled 7–9% of PC. a, Differs from group 3, $P < 0.05$; b, differs from groups 2, 3, and 5, $P < 0.01$; c, differs from groups 2, 3, and 5, $P < 0.01$; group 4, $P < 0.03$; d, differs from groups 2, 4, and 5, $P < 0.01$; e, differs from groups 2, 3, and 5, $P < 0.02$; f, differs from groups 3 and 4, $P < 0.01$; g, differs from groups 4 and 5, $P < 0.01$; h, differs from groups 4 and 5, $P < 0.02$; i, differs from group 4, $P < 0.02$; group 5, $P < 0.01$; j, differs from group 5, $P < 0.01$.

hamsters that was enhanced by the saturated fatty acid, palmitic acid, and suppressed by unsaturated fats such as safflower, olive, and corn oils (4–9). The mechanism(s) for the effects of different fats is not known but was ascribed to changes in the vesicular/micellar distribution of biliary cholesterol or the molecular species of biliary PC.

It has been previously reported that dietary modifications affect the fatty acid composition of biliary PC (23,24,36–41). In several studies, attempts were made to find a correlation between changes in biliary PC molecular species and cholelithogenesis, but no clear cause-and-effect relationship has emerged (11–14,18,19,22,37). We used our hamster model to examine systematically how changes in dietary fatty acid composition affect the biliary PC species and whether such changes are correlated with gallstone formation. To our knowledge, this is the first study of biliary PC composition in the hamster.

In the present study, female hamsters were fed an LD supplemented with either butterfat, safflower oil, or an unsaturated fatty acid (linoleic acid, 18:2 or oleic acid, 18:1). Safflower oil and 18:2 reduced the gallstone incidence; 18:1 totally inhibited it during the 6-wk feeding period. We previously showed that dietary olive oil (71% 18:1 content) effectively lowered the induced cholelithiasis (6,7). Under the conditions employed, it does not seem to matter whether the unsaturated fatty acids are supplied in the free form or as triacylglycerols. Interestingly, additional butterfat reduced stone incidence in this model. This finding may be ascribed to the fact that butterfat contains both saturated (66%) and unsaturated (34%) fatty acids. Oleic acid (18:1) accounts for 29% of the total fatty acids in butterfat. Thus the relative proportions of the many different fatty acids in butterfat (Table 1) may play a role in gallstone development. Perhaps, some critical threshold amount of one of the unsaturated acids is important, but additional studies are needed to verify this point. It was also shown in a different hamster model that saturated fatty acids enhanced while unsaturated (18:1) reduced cholelithogenesis (42). In the present investigation, the cholesterol saturation of bile was high in all five groups studied, but was just below unity in the groups receiving safflower oil or linoleic acid. The molar cholesterol content of the biles does not provide an adequate explanation for our findings.

PC comprise more than 90% of biliary phospholipids (43,44). The four major PC species (85–88%) in hamster bile were 16:0-18:2, 16:0-18:1, 18:0-18:2, and 16:0-20:4. These PC are identical to those found in human bile (17). The predominant PC species in most mammalian biles are 16:0-18:2 and 16:0-18:1 (18,44–46). The PC transfer protein is highly specific for these two PC species (47). The addition of unsaturated fatty acids to the standard hamster diet altered the relative proportion of the biliary PC species. With added 18:2 or safflower oil, the proportion of 16:0-18:2 in PC increased by 16–18% in comparison with the control LD. When the diet was enriched with 18:1, the 16:0-18:1 species increased by 25%; when additional butterfat was added, this increase amounted to 9%. Berr *et al.* (24) fed diets rich in safflower oil, coconut oil, or fish oil to hamsters and found that the total fatty acid pattern of the bile was modified as a function of the major dietary fatty acids; however, they did not analyze the individual PC species. Kajiyama *et al.* (22) fed Dam-type diets to female hamsters to induce cholelithiasis. In their model, total biliary 18:2 decreased and 18:1 increased as stone incidence increased. However, the experimental diet was deficient in the essential fatty acid (18:2), in contrast to our diet, which contains 2% corn oil to prevent essential fatty acid deficiency.

Increased polyunsaturated fatty acid intakes reduce the conversion of linoleic acid to arachidonic acid (20:4) by limiting Δ6-desaturase activity (48). This may be the case in the present experiment, since feeding 18:2 in the form of safflower oil or as the free acid resulted in the accumulation of 18:2 in biliary PC while 20:4 remained relatively constant (Table 5). Glenn *et al.* (23) fed hamsters either a butterfat diet or a diet containing a margarine high in 18:2 and found that the proportion of 18:2 in biliary phospholipids increased in the margarine group; 20:4 also remained constant. This suggested that dietary 18:2 was not converted to 20:4 but was incorporated directly into PC.

Data on the role of specific PC species in gallstone formation have led to conflicting conclusions. For example, LaMorte *et al.* (40) reported that in prairie dogs, diets rich in linoleic acid accelerated cholesterol gallstone formation by stimulating the secretion of biliary cholesterol. In contrast to our hamster model, diets rich in linoleic acid inhibited cholesterol gallstone formation. Nevertheless, there is some evidence that the solubilization of cholesterol in bile is influenced by the nature of the fatty acids and the headgroups of the biliary phospholipids (49). It seems likely that cholesterol nucleation occurs from vesicles with a high cholesterol-to-phospholipid ratio (50–53). Nucleation time studies with model biles suggest that the cholesterol-holding capacity of vesicles depends on the hydrophobicity of the vesicular lecithin. Vesicles containing lecithins with unsaturated fatty acyl chains tend to release cholesterol more rapidly than those containing more saturated lecithins which bind cholesterol more firmly (54). The degree of acyl chain unsaturation of PC affects the molecular packing of cholesterol–lecithin monolayers (55). We have found that vesicles were present in all groups (1 to 5); conceivably the 16:0-18:1 and 16:0-18:2 lecithin species stabilize these vesicles. In model and human biles, the more saturated PC species such as 16:0-18:1 are preferentially associated with vesicles (56,57). Further studies are needed to determine whether the 16:0-18:2 and 16:0-18:1 species (which are diet-dependent in our model) favor either micelles or vesicles. Another study with model bile suggested that the more saturated lecithins decrease the initial rate of crystallization of cholesterol, possibly due to high affinity binding of such lecithins to cholesterol crystals and to each other (58). This binding could interfere with crystal nucleation since cholesterol crystallizes as filamentous crystals that are covered with a surface layer of lecithin molecules (58). An increase in either 16:0-18:1 or 16:0-18:2 could have this effect.

In conclusion, in the hormone-treated female hamster model of cholesterol cholelithiasis, supplementation of the diet with oleic or linoleic acid resulted in the incorporation of these fatty acids into biliary PC. This was associated with a decrease in the incidence of cholesterol gallstones. Diet-induced changes in biliary lecithin species may play a role in stabilizing cholesterol–phospholipid vesicles and preventing cholelithiasis.

Platelet and Aorta Arachidonic and Eicosapentaenoic Acid Levels and *in vitro* Eicosanoid Production in Rats Fed High-Fat Diets

Andrew J. Sanigorski[a], Andrew J. Sinclair[b,*], and Tomohito Hamazaki[c]

ABSTRACT: There is a significant interest in the interrelationship between long-chain n-3 and n-6 fatty acids due to their ability to modulate eicosanoid production. In general, the intake of arachidonic acid (AA) results in enhanced eicosanoid production, whereas n-3 polyunsaturated fatty acids (PUFA) decrease the production of eicosanoids from AA. The purpose of this study was to investigate whether the effects of dietary AA on eicosanoid production in the rat were correlated with the AA and EPA levels in platelets and aorta (eicosanoid-producing tissues). Four groups of male Sprague-Dawley rats were fed a high-fat diet enriched with eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (approximately 100 mg/day of EPA + DHA) for 24 d. During the last 10 d, the four groups were orally supplemented with 0, 30, 60, and 90 mg/day of ethyl arachidonate. A further group of rats was fed a control diet (without long-chain n-3 PUFA) for 24 d. *In vitro* aorta prostacyclin (PGI_2) production, serum thromboxane A_2 (TxA_2) production and plasma, and platelet and aorta phospholipid (PL) fatty acids were measured. Enriching the diet with n-3 PUFA resulted in significant reductions in tissue AA levels and an increase in the n-3 PUFA, particularly EPA. On this diet, the AA to EPA ratio was 1:1 in platelet PL, and it was 2:1 in the aorta PL. There were significant decreases in the *in vitro* PGI_2 and TxA_2 production compared with the control animals. The inclusion of AA in the diet resulted in marked increases in AA levels in the platelet and aorta PL with corresponding decreases in EPA. The lowest dose of AA (30 mg/rat) reversed the effects of 100 mg/day of n-3 PUFA on AA levels in platelet and aortic PL and on *in vitro* aorta PGI_2 and serum TxA_2 production. The dietary AA caused a differential (twofold) increase in TxA_2 relative to PGI_2 for all three levels of AA supplementation. There were greater changes in the levels of AA and/or EPA in platelet PL compared with the aorta PL, which might have accounted for the differential effects of these PUFA on thromboxane production compared with PGI_2 production in this study.

Lipids 31, 729–735 (1996).

It is now well established that n-3 polyunsaturated fatty acids (PUFA) can modulate the production of eicosanoids from arachidonic acid (AA). Some studies in humans have reported that these PUFA selectively decrease thromboxane (TxA_2) production while exerting only a modest suppressive effect on prostacyclin (PGI_2) synthesis (1,2). In other studies in rats and mice, the production of both of these eicosanoids was decreased by n-3 PUFA (3–6).

Although most tissue AA is derived from linoleic acid, there is interest in the consequences of the ingestion of AA as it has been argued that this could lead to an overproduction of eicosanoids, particularly TXA_2 and, therefore, an increase in thrombosis (7). Several animal studies have shown that dietary AA increases the production of eicosanoids (TxA_2 and PGI_2) and leukotrienes (8–10).

Dietary AA is found in foods of animal origin and is usually present together with long-chain n-3 PUFA (11,12). We have proposed that the n-3 PUFA present in diets containing animal products would differentially decrease TxA_2 production compared with PGI_2 production (11). However, Li *et al.* (10) have reported that dietary AA, when present at the same level in the diet as the EPA, abolishes the depressive effect of dietary eicosapentaenoic acid (EPA) on *in vitro* eicosanoid production in mice. These authors showed that when AA and EPA were present in the diet in equal quantities, there was very little EPA incorporated into the liver phospholipids (PL).

The purpose of this study was to investigate whether the effects of dietary AA on eicosanoid production in the rat were correlated with the AA and EPA levels in platelets and aorta (eicosanoid-producing tissues). The dietary protocol used was one which we have shown is capable of responding to dietary AA by increases in eicosanoid production (9). In this model, rats are fed a high saturated fat diet for about two weeks, which reduces the tissue AA and eicosanoid levels (13). Addition of AA to this dietary regime results in significant rises in tissue AA and eicosanoid levels (9). Using this scheme, we proposed to add 100 mg/day of long-chain n-3 PUFA to the saturated fat diet to further depress eicosanoid synthesis and to test the effect of the addition of 30, 60, or 90 mg of AA on platelet and aorta fatty acid levels and eicosanoid production.

MATERIALS AND METHODS

Materials. Ethyl arachidonate (>99% pure) was purchased from Nu-Chek-Prep (Elysian, MN). Ethyl arachidonate (91% AA, 9% γ-linolenic acid) was a generous gift from Suntory Ltd., Institute for Biomedical Research (Osaka, Japan). Sodium pentothal was purchased from Abbott Australasia (Sydney, Australia). Scintillation proximity assay radioimmunoassay (RIA) kits for 6-keto-$PGF_{1\alpha}$ and thromboxane B_2 (TxB_2) were purchased from Amersham Australia Pty. Ltd. (Sydney, Australia). All solvents used in lipid extractions were of nanograde standard supplied by Mallinckrodt Australia Pty. Ltd. (Melbourne, Australia). The dry n-3 encapsulated fish oil powder was a generous gift from Danochemo A/S, Malmparken (Ballerup, Denmark). Sodium metrizoate was purchased from Nycomed (Oslo, Norway). The capillary column was supplied by Restek Corporation (Chromalytic Technology Pty. Ltd., Melbourne, Australia).

Animals. Forty male Sprague-Dawley rats weighing between 80–130 g were housed in a temperature controlled (22 ± 1°C) room with a 12-h light–dark cycle. The animals were randomly assigned to five dietary groups of eight animals each; one group was fed the control diet for 24 d while the other four groups were fed the control diet plus n-3 PUFA for the 24 d, with variable amounts of AA being provided for the final 10 d. Food and water were provided *ad libitum,* and body weights and food intakes were recorded every day. The animals were not fasted overnight prior to sacrifice.

Diets. The nutrient composition of the experimental diets is shown in Table 1, and the fatty acid compositions of the semisynthetic diets are given in Table 2. Two diets were prepared, a control diet and another diet enriched with n-3 fatty acids, providing a combined total of 100 mg of EPA and docosahexaenoic acid (DHA) per 15 g of food. The diets were designed to provide 50% of the energy as fat, 30% as carbohydrate and 20% as protein, and were based on those used in our previous studies (9,13–15). Vitamins and minerals were added to the diets in accordance with the recommendations by the American Institute of Nutrition (16). The n-3 PUFA were incorporated into the diet as a dry n-3 powder which consists of fish oil encapsulated in a gelatine coating. In this form, oxidation of the fish oils is likely to be minimal. The main fatty acids of the encapsulated fish oil were 14:0 (7.3%), 16:0 (14.9%), 16:1 (8.7%), 20:5n-3 (17.1%), 22:5n-3 (2.3%), and 22:6n-3 (11.2%). Gelatine was added to the control diet to balance that present in the dry n-3 powder. During the last 10 d of the study, four groups of animals receiving the n-3 enriched diet were orally supplemented with 30, 60, and 90 mg/day of ethyl arachidonate. The ethyl arachidonate was given orally to minimize oxidation. Four animals in each of the AA-supplemented group received ethyl AA from Nu-Chek-Prep and the other four received the Suntory ethyl AA.

. In vitro *PGI_2 production.* At the conclusion of the 24-d feeding period, the animals were anesthetized intraperitoneally with sodium pentothal (100 mg/kg body weight). Blood was taken by cardiac puncture for TxB_2 production and plasma fatty acid analysis. Immediately after blood collec-

[a]The n-3 polyunsaturated fatty acid (PUFA)-enriched diet refers to a diet containing butter which was enriched with eicosapentaenoic acid and docosahexaenoic acid.
[b]These values vary between diets because they are calculated as a percentage of energy density to give a constant amount per gram of dry weight of diet (that is, butter contains 20% water and in the latter diet there is a lower percentage of butter).

[a]The n-3 PUFA-enriched diet refers to a butter diet which was enriched with eicosapentaenoic acid and docosahexaenoic acid. See Table 1 for abbreviation.
[b]Fatty acids identified by retention time in excess of 0.1% reported.

tion, the animals were perfused with Krebs Ringer Bicarbonate buffer at pH 7.4 administered *via* the left ventricle to flush the remaining blood from the animal, leaving the artery preparation free of adhering blood thrombi. The abdominal aorta was dissected, split longitudinally, stabilized in Krebs Ringer Bicarbonate buffer at 37°C for 15 min in a water bath, and incubated for a further 15 min as described in detail previously (17). Aliquots were taken from the incubation medium and stored at –20°C for RIA determination of 6-keto $PGF_{1\alpha}$ (stable metabolite of PGI_2). It is highly unlikely that the antibody used in this RIA technique differentiates between the dienoic and trienoic metabolites (6-keto $PGF_{1\alpha}$ and Δ^{17}-6-keto $PGF_{1\alpha}$). At the end of the incubation, aorta segments were removed, blotted on filter paper, and then frozen in liquid nitrogen and weighed. The connective tissue was cleared from the aorta by cutting the top of the aorta arch. The remaining aorta was stored in Krebs Ringer Bicarbonate buffer at –20°C for later determination of the fatty acid composition.

In vitro *thromboxane production.* Blood taken by cardiac puncture was incubated for 1 h at 37°C and centrifuged for 2 min in a Beckman (Beckman Instruments, Melbourne, Australia) benchtop microfuge. The serum was removed and stored at –20°C for the RIA measurement of serum TxB_2 production (stable metabolite of TxA_2), using the method described previously by Block *et al.* (18). It is highly unlikely that the antibody used in this RIA technique differentiates between the dienoic and trienoic TxA metabolites.

Isolation of platelets. Blood taken by cardiac puncture was immediately placed into two 5-mL tubes containing 0.105 M sodium citrate. These tubes were kept between 30 and 35°C until the analyses could be completed. Platelet-rich plasma was prepared by spinning the citrate tubes at 200 × *g* for 10 min. Using a plastic pipette, the platelet-rich plasma was gently transferred into a plain 10-mL tube, then 2 mL of 13.7% sodium metrizoate (diluted from 32.8% using sodium/glucose buffer) was gently added to the bottom of the plain tube (that is, under the platelet-rich plasma layer) using a silanized glass pipette. A further 2-mL of 32.8% sodium metrizoate was gently added below the 13.7% sodium metrizoate layer using a silanized glass pipette to provide a density gradient for the collection of platelets. After centifugation (10 min) at 3000 × *g* at room temperature, the separated platelets (which were concentrated between the density gradient created by the two metrizoate layers) were transferred into a silanized glass tube containing 10 mL of tris saline buffer (0.05 M, pH 7.2). The tube was inverted several times and placed in a centrifuge set at 2000 × *g*, for 10 min. The buffer was discarded and the platelet pellet suspended in 10 mL of chloroform/methanol (1:1). The tube was vortexed and left in a freezer (–20°C) until the analysis of the fatty acids.

Fatty acid composition of plasma, aorta, and platelet PL. The lipids were extracted from plasma, thoracic aorta, and platelets by chloroform/methanol (1:1) lipid extraction, followed by thin-layer chromatography separation of the fatty acid classes to obtain the PL fraction as described previously (14). The PL were subjected to saponification and methylation (14), and the resultant fatty acid methyl esters were separated by capillary gas–liquid chromatography on a 60 m × 0.32 mm i.d. Rtx-2330 crossbonded column (phase thickness 0.25 μm). Helium was used as the carrier gas with a flow rate of 43 cm/s. Cold on-column injection was used, and the flame-ionization detector temperature was 280°C. Individual fatty acid methyl esters were identified by comparing their retention time with those of a standard fatty acid methyl ester mixture and by the inclusion of an internal standard of diheptadecanoyl phosphatidylcholine in the aliquots prior to methyl ester formation. The results were corrected by the use of response factors which were calculated using standard fatty acid methyl esters.

Statistical analysis. Differences between groups were established using analysis of variance with the aid of a multiple comparison test (Tukey-HSD) to establish where the differences between groups occurred. The *in vitro* eicosanoid data was not consistent with the hypothesis of normality. Therefore, differences between groups were tested by the Kruskal-Wallis nonparametric analysis of variance and Dunn's multiple comparison test. Statistical analyses were performed on Minitab Version 8 (Minitab Inc., State Collage, PA). All results are expressed as mean ± SEM, $P < 0.05$ for all significant changes.

RESULTS

The main source of fat in both diets was butter, and this was evident from the diet fatty acid composition (Table 2) which had a high proportion of saturated fatty acids, monounsaturated fatty acids, and low levels of linoleic acid and α-linolenic acid. The control diet enriched with n-3 PUFA was designed so that animals consuming 15 g/day of food would ingest 100 mg/day of EPA and DHA. In this diet, the fish oil provided EPA and DHA at 1.7 and 1.1% of the total dietary fatty acids, respectively, and the total n-3 fatty acid level was 4.5% compared with the control diet, which contained 2.0% n-3 PUFA.

There were no significant differences in the average weight gain or food intake between groups. The average initial weight for animals per group was 102 g, and the average final weight was between 281–304 g. The average weight gain between groups varied from 7.5 to 8.2 g/day/rat. Food intake for the animals fed the control diet and that enriched with n-3 PUFA was 15.5 g/day/rat.

Enriching the control diet with n-3 PUFA led to substantial increases in EPA and 22:5n-3, but not in DHA (except for the aortic PL) in comparison with the control rats (Tables 3, 4, and 5). The increases in the n-3 PUFA were generally at the expense of 18:1n-9, 20:3n-9, 18:2n-6, and 20:3n-6. There was a fivefold decrease in the AA to EPA ratio in the plasma, aorta, and platelets of the animals fed the n-3 PUFA-enriched diet in comparison with the control rats. In the plasma and the platelets of the animals fed the n-3 enriched PUFA diet, the AA to EPA ratio was about 1:1, although it was 2:1 in the

[a]Rats were fed the n-3 PUFA-enriched diet which contained 60 mg eicosapentaenoic acid (EPA)/day and 40 mg docosahexaenoic acid/day. These animals were supplemented with ethyl arachidonate (0, 30, 60, or 90 mg per day) during the last ten days of the study. AA, arachidonic acid; see Tables 1 and 3 for abbreviations. Results are shown as mean ± SEM. Fatty acids identified by retention time in excess of 0.1% reported. The values in the same column with different lettered superscripts (a, b, c, d) differ significantly (analysis of variance, $P < 0.05$). Rows of data with no following letters indicate no significant differences.

aorta. There were substantial reductions in the *in vitro* production of immunoreactive PGI_2 (24% reduction) and TxA_2 (54% reduction) in the rats fed the n-3 PUFA-enriched diet compared with the control animals (Figs. 1 and 2, respectively). While the ratio of TxA to PGI declined by almost 60%, this was not significant (Fig. 3).

The inclusion of AA to the diet of rats fed the n-3 PUFA diet resulted in dose-dependent increases in AA levels in plasma, aorta, and platelet PL. Two different ethyl arachidonate preparations were used for this study. One was supplied by Nu-Chek-Prep, and the other was from Suntory Ltd. For each group of animals supplemented with AA, four of the eight animals received one preparation and the remaining four animals the other. Unpaired Student's *t*-tests (results not supplied) showed that there were no significant differences in the AA levels of the plasma, platelet, aorta PL, or *in vitro* PGI_2 and TxA_2 production within dietary groups regardless of which type of AA was administered. Therefore, the results of the two groups of four animals were combined and discussed as one group consisting of eight animals.

There was a greater increase (more than a doubling) of AA levels for plasma and platelet PL compared with the aortic PL in the rats supplemented with 90 mg/day, while the EPA levels in all tissues fell to about half the level of the 0 mg/day AA group (fed the n-3 PUFA-enriched diet). The 30 mg/day dose of AA resulted in significant increases (more than a doubling) in the AA to EPA ratio all three tissues. AA supplementation resulted in significant reductions in EPA, 22:5n-3, and DHA in all three tissues.

The inclusion of AA in the diet of rats receiving the n-3 PUFA-enriched diet resulted in significant increases for both vascular PGI_2 and serum TxA. The TxA and PGI production in the rats supplemented with 30 mg of AA/day was signifi-

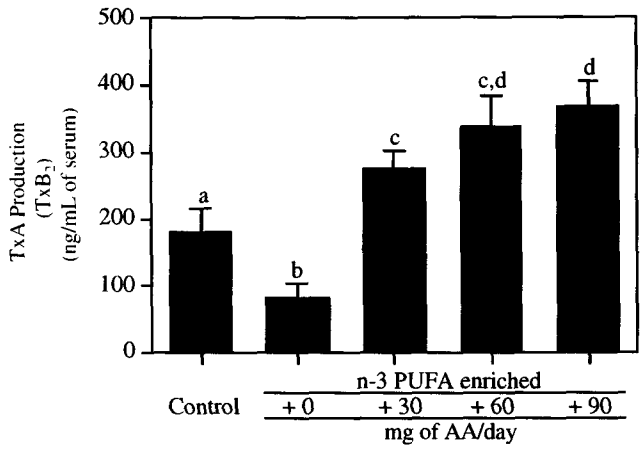

FIG. 1. *In vitro* serum thromboxane A_2 (TxA_2) production measured as TXB_2 (ng/mL serum); mean ± SEM. The rats fed the n-3 polyunsaturated fatty acid (PUFA) enriched diet were orally supplemented with ethyl arachidonate (0, 30, 60, and 90 mg per day) during the last ten days of the study. The columns with different lettered superscripts (a, b, c, d) differ significantly (analysis of variance, $P < 0.05$). AA, arachidonic acid.

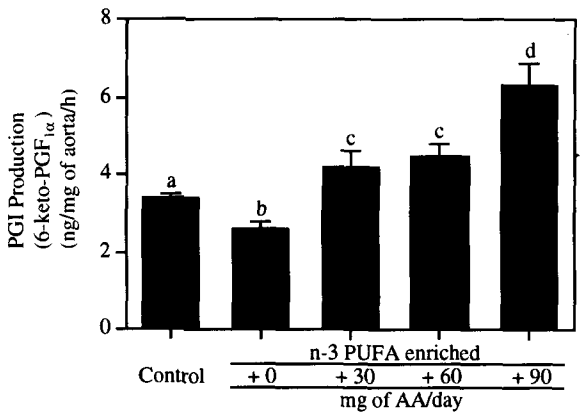

FIG. 2. *In vitro* aorta prostacyclin (PGI_2) production measured as 6-keto-$PGF_{1\alpha}$ (ng/mg aorta/h) mean ± SEM. The rats fed the n-3 PUFA-enriched diet were orally supplemented with ethyl arachidonate (0, 30, 60, and 90 mg per day) during the last ten days of the study. The columns with different lettered superscripts (a, b, c, d) differ significantly (analysis of variance, $P < 0.05$). See Figure 1 for abbreviations.

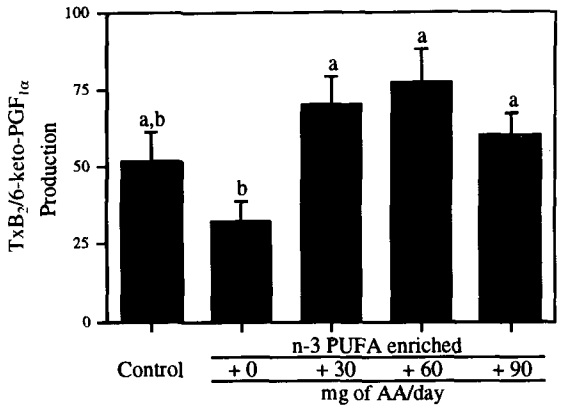

FIG. 3. Ratio of *in vitro* serum thromboxane (TXA_2) production measured as TXB_2 (ng/mL serum) relative to *in vitro* aorta prostacyclin (PGI_2) production measured as 6-keto-$PGF_{1\alpha}$ (ng/mg aorta/hour); mean ± SEM. The rats fed the n-3 PUFA-enriched diet were orally supplemented with ethyl arachidonate (0, 30, 60, and 90 mg per day) during the last ten days of the study. The columns with different lettered superscripts (a, b, c, d) differ significantly (analysis of variance, $P < 0.05$). See Figure 1 for abbreviations.

cantly greater than the 0 mg/day AA group (who were fed 100 mg/day of long-chain n-3 PUFA). The ratio of TxA to PGI was more than doubled by the inclusion of AA in the diet (Fig. 3).

DISCUSSION

The purpose of this study was to investigate whether the effects of dietary AA on eicosanoid production in the rat were correlated with the AA and EPA levels in platelets and aorta (eicosanoid-producing tissues). In order to do this, we studied the consequences of combined dietary intakes of AA and long-chain n-3 PUFA on platelet and aorta fatty acids and eicosanoid production in the rat.

When the rats were fed the diet containing 100 mg/day of EPA plus DHA for 24 d, there were differential effects on the AA to EPA ratios in platelets and aorta PL. The AA/EPA ratio was 1:1 in the platelet PL after the n-3 PUFA period, compared with 2:1 in the aorta PL. The n-3 PUFA-enriched diet was associated with significant reductions in the *in vitro* production of immunoreactive TxA_2 (54%) and PGI_2 (24%) in the group fed the n-3 PUFA, as compared with the control animals. A possible explanation for the greater reduction in TxA_2 production might relate to the lower AA/EPA ratio in the platelets.

The second finding of these experiments was that increasing the level of AA supplementation in rats fed the diet enriched with n-3 PUFA led to significant increases in AA levels in the plasma, platelets, and aorta PL at the expense of the n-3 PUFA, particularly EPA (Tables 3, 4, and 5). The lowest dose of AA (30 mg/rat) reversed the effects of 100 mg/rat of EPA plus DHA on both platelet and aorta PL, by restoring the AA levels to that equal to the control rats. These fatty acid changes were associated with significant increases for both *in vitro* aorta PGI_2 and serum TxA_2 production. This extends the observations reported by Li *et al.* (10) in mice who showed that equal amounts of AA and EPA overcame the inhibitory effects of EPA on *in vitro* eicosanoid production. In our experiment, only 30 mg AA/day was required to prevent the inhibitory effect of 100 mg/day of n-3 PUFA.

The third finding of this study was that, in the rats fed both AA and n-3 PUFA for ten days, there was a differential (twofold) increase in TxA production relative to PGI production for all three levels of AA supplementation (Fig. 3). A possible explanation could be attributed to the substantially increased availability of AA in platelets compared with aorta, following AA supplementation (the proportion of AA in the platelet PL increased from 12.1 to 26.7% compared with the aorta PL, where the AA level increased from 13.3 to 20.9%). In these studies, we are aware that the RIA procedures used are unlikely to distinguish between the diene and triene forms of the Tx and PGI; however, we do not believe this would substantially alter the conclusions drawn in the AA supplementation period of the study.

We have noted previously (17) that *in vitro* PGI_2 production is dependent on the level of AA in the aorta PL, and *in vitro* TxA_2 production is related to the level of AA in the platelet PL. The results of the present study support these observations, with the platelet AA levels being significantly correlated with *in vitro* TxA_2 production irrespective of the dietary regimen ($r = +0.713$, $P < 0.05$). Likewise, aortic AA levels and PGI_2 were also similarly correlated ($r = +0.559$, $P < 0.05$). Based on these *in vitro* data, this study highlights the importance of AA levels in eicosanoid-producing tissues compared with that of the n-3 PUFA.

In conclusion, these results show that 30 mg/day of dietary AA abolishes the depression of Tx and PGI production by 100 mg/day of n-3 PUFA. The probable explanation for these results was that the 30 mg/day of dietary AA restored the AA levels in platelet and aortic PL to a level equal or greater than

that of the control animals. These data imply that AA has a greater affinity for esterification into platelet and aorta PL than the long-chain n-3 PUFA. The greater magnitude of the changes in the levels of AA and/or EPA in platelet PL compared with the aorta PL might have accounted for the differential effects of these PUFA on Tx production compared with PGI production in this study.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Neil Mann and Glenda Warrick for their skilled technical assistance, advice, and support throughout the study. Suntory Ltd., Japan are thanked for their generous gift of ethyl arachidonate. This work was partly supported by a grant from the Meat Research Corporation of Australia, and the Department of Nutrition and Public Health, Deakin University, Geelong.

The Ratio of n-6 to n-3 Polyunsaturated Fatty Acids in the Rat Diet Alters Serum Lipid Levels and Lymphocyte Functions

N.M. Jeffery, P. Sanderson, E.J. Sherrington, E.A. Newsholme, and P.C. Calder*

Department of Biochemistry, University of Oxford, Oxford OX1 3QU, United Kingdom

ABSTRACT: Previous studies have reported that feeding rats diets rich in fish oils, which contain high proportions of the n-3 polyunsaturated fatty acids (PUFA) eicosapentaenoic and docosahexaenoic acids, results in lowering of blood lipid levels and suppression of lymphocyte functions tested *ex vivo* and *in vivo*. The effects of other n-3 PUFA, such as α-linolenic acid, which is found in high proportions in linseed oil, are not as well documented. Therefore, in the present study, weanling male rats were fed for six weeks on one of five high-fat (20% by weight) diets made by mixing together sunflower and linseed oils; the resulting blends had n-6/n-3 PUFA ratios of 112.5:1 (pure sunflower oil), 14.8:1, 6.5:1, 0.8:1, and 0.33:1 (pure linseed oil); the levels of all other components in the diet were identical. The final body weight and total dissectable fat were lowest in rats fed the pure linseed oil diet. Serum cholesterol, triacylglycerol and nonesterified fatty acid concentrations decreased as the n-6/n-3 PUFA ratio of the diet decreased. The fatty acid composition of the serum and of spleen lymphocytes was influenced by the diet fed—there was a progressive decrease in the proportions of linoleic and arachidonic acids and a progressive increase in the proportion of α-linolenic acid as the n-6/n-3 PUFA ratio of the diet decreased. Eicosapentaenoic and docosahexaenoic acids were detected in the serum but not in spleen lymphocytes. Inclusion of α-linolenic acid in the diet resulted in significant suppression of spleen lymphocyte proliferation in response to the T-cell mitogen concanavalin A and in spleen lymphocyte natural killer cell activity, both measured *ex vivo*. The localized graft vs. host response, a measure of cell-mediated immunity *in vivo*, progressively decreased as the n-6/n-3 PUFA ratio of the diet decreased. Thus, this study shows that dietary α-linolenic acid results in lowered blood lipid levels and suppressed lymphocyte functions *ex vivo* and *in vivo*. With respect to these effects, α-linolenic acid is as potent as dietary fish oil.

Lipids 31, 737–745 (1996).

Fat constitutes a large proportion of the Western diet, accounting for approximately 35 to 40% of energy intake. For some time there has been evidence that both the amount and type of dietary fat play a role in the health of the individual. For example, the consumption of lipids which contain a high proportion of saturated fatty acids has been linked with an increased risk of developing coronary heart disease (CHD), and this may be caused partly by the elevated blood cholesterol and triacylglycerol (TAG) concentrations which result from the consumption of such diets (1). Hence, there has been much interest in the use of diets containing unsaturated, rather than saturated, fatty acids to prevent the development of CHD. Consumption of fish oils, which are rich in the n-3 polyunsaturated fatty acids (PUFA) eicosapentaenoic and docosahexaenoic (20:5n-3 and 22:6n-3, respectively), has been reported to result in significant lowering of blood lipid levels in both humans (see Ref. 2 for a review) and in rats (3–8). Therefore, as might be expected from the link between elevated blood lipid concentrations and development of CHD, fish oil consumption is associated with lowered mortality from CHD (9–12).

In addition to a potential effect upon blood lipid levels and CHD, dietary lipids may have immunomodulatory effects. An immunosuppressive effect of dietary fish oils is suggested by epidemiological studies which show that populations such as Greenland Eskimos, who consume large quantities of fish oils, have a very low incidence of inflammatory and autoimmune disorders (12), and by clinical studies which show that fish oil supplementation has some beneficial effects in rheumatoid arthritis, multiple sclerosis, and psoriasis, and also prolongs the survival of grafts (see Ref. 13 references therein). The potential clinical use of fish oils has given rise to a number of studies investigating the effects of fatty acids and dietary oils upon immune cell functions. *In vitro* studies have shown that n-3 PUFA, or TAG containing n-3 PUFA, inhibit a number of lymphocyte functions, including proliferation (14–21), interleukin-2 production (17,18,20), activation marker expression (17), natural killer (NK) cell activity (22), and antigen presentation (23). These studies indicate that consumption of n-3 PUFA in the diet might suppress lymphocyte functions and, thus, the immune response.

Studies of the effects of dietary lipids upon lymphocyte functions have been largely restricted to investigating lymphocyte proliferation in response to various stimuli. A num-

ber of studies have shown that feeding laboratory animals (rats, mice, rabbits, chickens) diets rich in n-3 PUFA [canola, linseed, fish oils; the former two oils contain α-linolenic acid (18:3n-3)] results in suppressed lymphocyte proliferation *ex vivo* (13,24–30); investigations which have directly compared the effects of these oils indicate that fish oil is more suppressive than linseed oil which is, in turn, more suppressive than canola oil (see Refs. 31, 32 and references therein). Diets rich in n-6 PUFA appear to be less suppressive than those containing n-3 PUFA or even to be without effect (see Refs. 13,31,32 and references therein). *Ex vivo* cytotoxic T lymphocyte activity is also suppressed by feeding laboratory animals fish, linseed, and n-6 PUFA-containing oils (33–37); again, fish oil is more suppressive than linseed oil, which is more suppressive than n-6 PUFA-containing oils. Recent studies have reported that feeding rats or mice fish oil results in suppressed NK cell activity compared with feeding linseed or n-6 PUFA-containing oils (29,36,38–40). Taken together, these *ex vivo* observations indicate that consumption of diets containing n-3 PUFA, particularly diets rich in fish oil, may result in immunosuppression *in vivo*. Indeed, three studies have reported that feeding laboratory rodents fish oil results in diminished *in vivo* graft vs. host and/or host vs. graft responses (41–43); feeding diets rich in n-6 PUFA did not suppress these responses (43).

Thus, it is now quite clear that consumption of diets rich in n-3 PUFA causes marked immunosuppression, whereas those rich in n-6 PUFA are less suppressive. However, there is little information about how much n-3 PUFA, particularly in relation to n-6 PUFA, needs to be present to bring about these effects. Therefore, in this study we used mixtures of sunflower and linseed oils to create a series of diets with differing ratios of n-6 to n-3 PUFA. We have investigated the effect of feeding these diets to rats upon serum lipid levels and fatty acid composition, upon spleen lymphocyte fatty acid composition and functions, and upon the graft vs. host response.

MATERIALS AND METHODS

Animals and diets. Weanling male Lewis rats (aged three weeks, weighing between 65 and 85 g) were obtained from Harlan-Olac (Bicester, Oxfordshire, England). The animals were housed in the Department of Biochemistry at the University of Oxford (Oxford, United Kingdom) for a period of six weeks prior to sacrifice, during which time they were allowed access, *ad libitum*, to water and to one of five experimental diets. The diets contained 20% by weight of sunflower oil or linseed oil or mixtures of the two designed to yield different ratios of n-6 to n-3 PUFA; the levels of other components of the diets were identical. It is important, to note that the proportions of fatty acids other than linoleic and α-linolenic were not different among the different diets. The ratios of n-6 to n-3 PUFA used in this study were 112.5:1 (all sunflower oil), 14.8:1 (93% sunflower oil), 6.5:1 (85% sunflower oil), 0.8:1 (30% sunflower oil), and 0.33:1 (all linseed oil). The ratio of 6.5:1 was chosen to approximate the n-6 to n-3 PUFA ratio of the average United Kingdom diet, which is 6.9:1 (44). The ratio of 14.8:1 was chosen as it approximates the upper extreme of the n-6 to n-3 PUFA ratio found in Western societies. For example, the average n-6 to n-3 PUFA ratio of human breast milk in the United Kingdom is 11:1, and some infant formula have ratios as high as 15:1 (44). The ratio of 0.8:1 was chosen so a diet with approximately equal proportions of n-6 and n-3 PUFA could be investigated. The diets used in this study contain at least ten times more fatty acid double bonds per g than standard laboratory chow, and it was considered important to include a significantly higher level of vitamin E than would normally be present in order to prevent fatty acid oxidation. Therefore, these diets were supplemented with 300 IU of vitamin E per kg, ten times the recommended level. The composition of the diets is shown in Table 1 and the fatty acid composition is shown in Table 2. Diets were stored at 4°C and were provided fresh to the animals every two days. Rats were killed in the fed state by an overdose of CO_2.

Chemicals. Chemicals and cell culture medium and supplements were obtained from the sources described elsewhere (8,13,40,43,45).

Cholesterol, TAG, and nonesterified fatty acid (NEFA) measurements. Cholesterol and TAG concentrations were determined enzymatically (46,47). NEFA concentrations were measured using a commercially available enzymatic assay kit (Boehringer, Mannheim, Germany).

Lipid extraction and fatty acid composition analysis. Lipid was extracted from serum or from lymphocytes with chloroform/methanol (2:1, vol/vol). Fatty acids were prepared by overnight saponification at 70°C in methanolic 0.5 M KOH.

TABLE 1
Composition of the Diets Used

Component (g/kg)	Diet A	B	C	D	E
High nitrogen casein	200	200	200	200	200

E	0.1	7.6	0.5	4.6	22.0	16.3	48.8	0.33

Samples were neutralized using concentrated sulfuric acid, and fatty acids were extracted into ethyl acetate. After evaporation to dryness, fatty acids were prepared by reaction with an excess of diazomethane in ether (48). Fatty acid methyl esters (dissolved in methyl acetate) were separated by gas chromatography in a Hewlett-Packard (Avondale, PA) 6890 gas chromatograph fitted with a 30 m × 0.32 mm DB23 capillary column (J&W Scientific, Folsom, CA), film thickness 0.25 mm. Nitrogen at 2.0 mL/min was used as the carrier gas and the split/splitless injector was used with a split/splitless ratio of 10:1. Injector and detector temperatures were 170 and 250°C, respectively. The column oven temperature was maintained at 170°C for 12 min after sample injection, and was programmed to then increase from 170 to 200°C at 5°C/min before being maintained at 200°C for 15 min. The separation was recorded with HP GC Chem Station software (Hewlett-Packard). Fatty acid methyl esters were identified by comparison with previously run standards.

Lymphocyte proliferation. Spleen lymphocytes were prepared as described elsewhere (13). They were cultured at 37°C in an air/CO_2 (19:1) atmosphere in 96-well micro-titer-culture plates at a density of 5×10^5 cells/well and a total culture volume of 200 µL in HEPES-buffered (RPMI) supplemented with 2 mM glutamine, 2.5% (vol/vol) autologous serum, antibiotics (streptomycin and penicillin) and, for stimulated lymphocytes, 5 µg/mL concanavalin A (Con A). After 48 h of culture, [6-^{3}H]thymidine was added to each well (0.2 µCi/well), and the cells were incubated for a further 18 h. The cells were then harvested onto glass fiber filters and washed and dried using a Skatron Cell Harvester (Skatron Instruments, Lier, Norway). Radioactive thymidine incorporation was determined by liquid scintillation counting. The results are expressed as a stimulation index:

$$\text{stimulation index} = \frac{\text{incorporation of [}^3\text{H]thymidine in the presence of Con A}}{\text{incorporation of [}^3\text{H]thymidine in the absence of Con A}} \quad [1]$$

Spleen lymphocyte NK cell activity. Spleen lymphocytes (100 µL) suspended in RPMI supplemented with 2 mM glutamine and YAC-1 cells (2×10^4 cells/100 µL) suspended in RPMI supplemented with 2 mM glutamine and 1% (wt/vol) bovine serum albumin were added, in triplicate, to each well of a 96-well, flat-bottomed micro-titer plate to yield lymphocyte/target cell ratios of 100:1, 50:1, and 25:1. Plates were centrifuged at 300 rpm for 3 min to bring lymphocytes and target cells into contact, and were then incubated at 37°C in an air/CO_2 (19:1) atmosphere for four hours. The plates were centrifuged at 500 rpm for 5 min after the incubation. Target cell killing was determined by release of lactate dehydrogenase (LDH) into the medium, as measured by a "cytotoxicity assay kit" purchased from Proteins International Inc. (Rochester Hills, MI). Maximal LDH release was determined by incubating YAC-1 cells with 2.5% (vol/vol) Triton X-100 in RPMI, instead of the lymphocytes. Spontaneous LDH release from YAC-1 cells was determined by incubating them with glutamine- and antibiotic-supplemented RPMI in place of the lymphocytes. Spontaneous LDH release from lymphocytes was determined by incubating them at the appropriate cell number with glutamine-, albumin; and antibiotic-supplemented RPMI in place of the YAC-1 cells. Percentage cytolysis was calculated as:

$$\% \text{ cytolysis} = \frac{\text{LDH release - lymphocyte spontaneous LDH release - YAC-1 spontaneous LDH release}}{\text{maximum LDH release - YAC-1 spontaneous LDH release}} \times 100 \quad [2]$$

Analysis of lymphocyte subpopulations. Flow cytometry was used to measure the presence of various markers on the surface of freshly-prepared spleen lymphocytes. Approximately 10^6 cells [resuspended in phosphate-buffered saline (PBS) supplemented with 0.1% (wt/vol) bovine serum albumin and 10 mM sodium azide (modified PBS)] were incubated for 20 min at 4°C with monoclonal antibodies to CD4 (W3/25), CD8 (MRC OX-8), κ-light chain of immunoglobulins (MRC OX12; a B-cell marker), CD11b/c (MRC OX42; a macrophage marker), or CD16 (3.2.3; an NK cell marker). Incubation with a monoclonal antibody to the human C3b inactivator protein (MRC OX-21) was used as a negative control. Following staining with monoclonal antibodies, the cells were washed twice with modified PBS and incubated with fluorescein isothiocyanate-labelled rabbit anti-mouse IgG for 20 min at 4°C. They were washed twice with modified PBS and then suspended in 2% (vol/vol) formaldehyde in PBS and examined for fluorescence using a Becton Dickinson FACScan fluorescence-activated cell sorter (Becton Dickinson, Lincoln Park, NJ). Fluorescence data were collected on 10^4 viable cells.

Popliteal lymph node (PLN) assay. To elicit the graft vs. host response, 6×10^6 lymph node lymphocytes prepared from adult male Lewis rats (maintained on standard laboratory chow) were injected subcutaneously into the footpad of one leg of weanling male DA/Lewis rats which had been fed the diets previously described, for four weeks. The total in-

jection volume was 0.1 mL, and the cells were resuspended in PBS; the footpad of the control leg was injected with 0.1 mL PBS. The animals were sacrificed seven days after injection; during this time they were fed the same diet that they had been previously fed. The PLN were dissected out and weighed. Preliminary experiments indicated that injection of 6×10^6 cells and sacrifice 7 d post-injection resulted in maximal PLN size (43). Injection of PBS or of 6×10^6 DA/Lewis lymph node lymphocytes did not cause any increase in PLN weight (43).

Data presentation. Data are mean ± SEM of separate observations made on the indicated number of animals fed each diet. Statistical significance was determined using one-way analysis of variance followed by Student's *t*-test; a value for *P* of less than 0.05 was taken to indicate a statistically significant difference.

RESULTS

Animal growth. The diets used in this study were isocaloric, and there was no difference in food intake between animals fed the different diets (data not shown). Despite this, the final body weights, and therefore the total growth, of rats fed diet E were less than those of rats fed diets B and C (Table 3). Seven distinct adipose tissue depots were dissected out and weighed; the sum of these weights was termed the total dissectable fat. Total dissectable fat was less in animals fed diet E than in those fed diets A, B, or C (Table 3). Total dissectable fat accounted for a smaller percentage of body weight in the animals fed diet E than those fed diets A or B (Table 3). Thus, feeding the 20% linseed oil diet reduced adipose deposition compared with a diet containing 20% sunflower oil or diets containing more linoleic acid than α-linolenic acid. There was little difference in liver weight between animals fed the different diets (Table 3).

Serum cholesterol, TAG, and NEFA concentrations. The concentrations of TAG, cholesterol, and NEFA all progressively decreased as the n-6/n-3 ratio of the diet decreased (Table 4). The TAG concentration in the serum of animals fed the diet with the lowest n-6/n-3 ratio (diet E) was 40% of that of animals fed the diet with the highest ratio (diet A). The cholesterol concentration in the serum of rats fed the diet with the lowest n-6/n-3 ratio was significantly less than that in the serum of animals fed the diets with the three highest ratios (Table 4). The NEFA concentration in the serum of rats fed diets C, D, or E was significantly lower than that in the serum of animals fed diet A (Table 4).

Serum and spleen lymphocyte fatty acid composition. The fatty acid composition of the serum was influenced by that of the diet (Table 5). As the n-6/n-3 PUFA ratio of the diet decreased, the proportion of n-6 PUFA (linoleic, arachidonic) in serum lipids progressively decreased. This was parallelled by a progressive increase in the proportion of α-linolenic acid (Table 5). Eicosapentaenoic acid was found in the serum of animals fed the diets which were richest in n-3 PUFA (diets D and E), and docosahexaenoic acid was present in the serum of all animals fed n-3 PUFA-containing diets (Table 5). The proportions of the other principal serum fatty acids (palmitic, stearic, oleic) were largely unaffected by the diet fed (Table 5).

The fatty acid composition of the lipids of spleen lymphocytes was also affected by that of the diets fed (Table 5). As the n-6/n-3 PUFA ratio of the diet decreased, the proportion of n-6 PUFA (linoleic, arachidonic) in lymphocyte lipids progressively decreased. This was parallelled by a progressive increase in the proportion of α-linolenic acid (Table 5). Despite the incorporation of significant levels of α-linolenic acid, neither eicosapentaenoic nor docosahexaenoic acid was detected in spleen lymphocyte lipids (Table 5).

Proliferation of spleen lymphocytes. Feeding each of the diets containing linseed oil (i.e., diets B, C, D, or E) significantly decreased Con A-stimulated proliferation of spleen lymphocytes compared with feeding diet A (Fig. 1). There was no difference in the proliferation of spleen lymphocytes from rats fed the diets containing linseed oil (Fig. 1).

Spleen NK cell activity. Feeding each of the diets containing linseed oil (i.e., diets B, C, D, or E) decreased spleen lymphocyte NK activity compared with feeding diet A (Table 6).

TABLE 3
Effect of Feeding Diets of Different Fatty Acid Compositions upon Animal and Liver Weights[a]

Diet	Initial body weight (g)	Final body weight (g)	Total dissectable fat (g)	Liver weight (g)
A	45.0 ± 2.4	296.0 ± 10.7	24.9 ± 2.0[e]	12.7 ± 0.3[b]
			(8.4 ± 0.5[e])	(4.3 ± 0.1)
B	44.2 ± 2.2	317.0 ± 8.4[e]	27.1 ± 1.7[e]	13.9 ± 0.2[a]
			(8.3 ± 0.4[e])	(4.4 ± 0.1)

			(8.4 ± 0.7)	(4.4 ± 0.2)
D	50.0 ± 4.3	306.0 ± 6.9	22.2 ± 1.3	13.8 ± 0.6
			(7.2 ± 0.3)	(4.5 ± 0.1)
E	42.5 ± 1.6	281.0 ± 7.1[b,c]	18.9 ± 0.8[a,b,c]	13.2 ± 0.6
			(6.9 ± 0.2[a,b])	(4.7 ± 0.1)

[a]Data are mean ± SEM of separate observations made on six animals fed each diet. Numbers in parentheses are total dissectable fat or liver weight as a percentage of final body weight. [a]vs. Diet A; [b]vs. diet B; [c]vs. diet C; [d]vs. diet D, and [e]vs. diet E.

TABLE 4
Effect of Feeding Diets of Different Fatty Acid Compositions Upon Serum Lipid Levels[a]

Diet	Cholesterol (mg/mL)	TAG (mg/mL)	NEFA (mM)
A	1.20 ± 0.06[e]	0.88 ± 0.12[e]	0.67 ± 0.02[c,d,e]
B	1.21 ± 0.05[e]	0.62 ± 0.08[e]	0.56 ± 0.04
C	1.14 ± 0.04[e]	0.73 ± 0.12[e]	0.51 ± 0.03[a]
D	1.08 ± 0.04	0.50 ± 0.10	0.54 ± 0.04[a]
E	0.93 ± 0.04[a,b,c]	0.36 ± 0.05[a,b,c]	0.50 ± 0.03[a]

[a]Data are mean ± SEM of separate observations made on six animals fed each diet. Superscript letters a, b, c, d, e are explained in Table 3. TAG, triacylglycerol; NEFA, nonesterified fatty acid.

There was no difference in the NK cell activity of spleen lymphocytes from rats fed the diets containing linseed oil, except at a lymphocyte/target cell ratio of 25:1 (Table 6).

Spleen lymphocyte subsets. There was no effect of diet upon the proportions of cells staining positive for CD4, CD8, κ-light chain, or CD11b/c (Table 7). Thus, changing the n-6/n-3 ratio of the diet does not differentially affect the proportions of $CD4^+$, $CD8^+$, or B-cells or macrophages in the spleen. However the proportion of $CD16^+$ cells (i.e., NK cells) was affected by diet; the proportion of these cells was higher in the spleens of animals fed diets D and E than in those of animals fed some of the other diets (Table 7).

PLN weights. The weight of the PLN following the graft vs. host response progressively decreased as the n-6/n-3 ratio of the diet decreased (Fig. 2). Weights of PLN from animals fed diet E were 35% lower than those from animals fed diet A. Weights of PLN from rats fed diets D and E were significantly lower than those from animals fed diet A. In addition, PLN weights from animals fed diet E were lower than those from the diet B-fed animals (Fig. 2).

DISCUSSION

Compared with feeding rats diets rich in n-6 PUFA, diets rich in fish oil result in lower serum cholesterol (4,8) and TAG (7) concentrations. Linseed oil also has been reported to result in a lower serum cholesterol concentration when fed to rats (49). In accordance with these observations, we found that feeding rats diets containing linseed oil resulted in lower serum cholesterol and TAG concentrations than observed after feeding a sunflower oil-rich diet (Table 4). The serum cholesterol concentration of rats fed 20% linseed oil (i.e., diet E) was higher than that which we had previously found following 20% fish oil feeding (0.71 mg/mL; Ref. 8), whereas the serum TAG concentration was lower (0.77 mg/mL; Ref. 8). Thus, in rats, linseed oil may be more effective than fish oil at lowering TAG concentrations, but less effective at lowering cholesterol concentrations. Despite these differences, it is clear that n-3 PUFA have a blood lipid-lowering effect in rats whether they are derived from fish or linseed oils. This effect of n-3 PUFA may be due to suppressed lipoprotein synthesis and/or secretion or to enhanced clearance of circulating lipoproteins or both. In agreement with the observations of Rustan *et al.* (50), the linseed oil-containing diets also resulted in lowered serum

TABLE 5
Effect of Feeding Diets with Different n-6/n-3 Fatty Acid Ratios upon Serum and Spleen Lymphocyte Fatty Acid Composition[a]

[a]Data are mean ± SEM for separate observations made on at least six animals fed each diet; n.d. indicates that a fatty acid was not detected; a, b, c, d, e, are explained in Table 3.

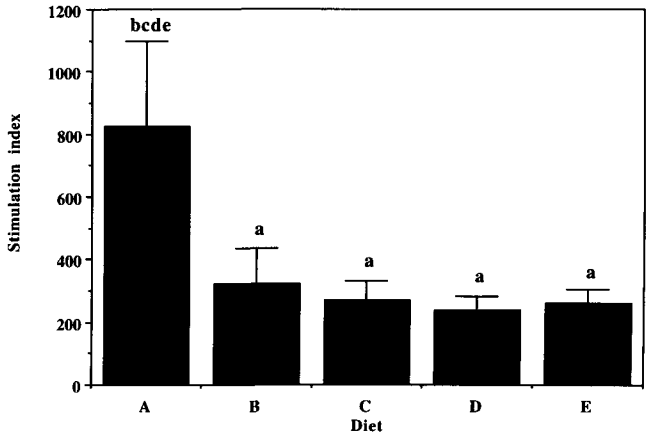

FIG. 1. Effect of feeding diets of different fatty acid compositions upon the proliferation of spleen lymphocytes. Lymphocytes were cultured in autologous serum in the absence or presence of concanavalin A; lymphocyte proliferation is expressed as stimulation index (see the Materials and Methods section). Data are mean ± SEM of separate observations made on three to five animals fed each diet. a vs. Diet A, b vs. diet B, c vs. diet C, d vs. diet D, and e vs. diet E.

NEFA concentrations (Table 4). This may indicate that oxidation of fatty acids is enhanced in these animals. α-Linolenic acid is a better substrate for β-oxidation than linoleic acid (51), and so its inclusion in the diet at the expense of linoleic acid may promote fatty acid oxidation. Furthermore, like the n-3 PUFA found in fish oil (50,52), dietary α-linolenic acid promotes hepatic peroxisomal proliferation (50) and this, in turn, will lead to enhanced oxidation of fatty acids. As a result of the enhanced fatty acid oxidation, less fatty acid will be available for hepatic TAG synthesis, and so circulating lipid levels will be reduced. The lowered circulating TAG level means that less TAG is available for deposition in adipose tissue. Indeed, the total dissectable fat was significantly reduced in animals fed diet E (Table 3). This decrease in adipose deposition, which we have reported previously for animals fed fish oil (53), partially accounts for the lower weight of animals fed diet E.

It has previously been shown that feeding rats a diet containing 20% fish oil results in suppressed *ex vivo* lymphocyte proliferation (13,29,30) and NK cell activity (29,40) and diminishes the graft vs. host response *in vivo* (43). Similar effects of fish oil feeding have been reported in other species, including mice (28,36,38,39,42), rabbits (25), chickens (26), and humans (54–56). Feeding linseed oil to laboratory animals also has been reported to suppress lymphocyte proliferation *ex vivo* (24–26); this effect was confirmed in the current study (Diet E of Fig. 1). This suppressive effect is consistent with the potent inhibitory effects of α-linolenic acid and of TAG rich in α-linolenic acid upon lymphocyte proliferation *in vitro* (14-21). An effect of dietary linseed oil upon NK cell activity, as observed in the current study (Table 6), has not been previously reported. Furthermore, it was found that a 20% linseed oil diet diminished the graft vs. host response (Diet E of Fig. 2), an *in vivo* measurement of cell-mediated immunity. We now report, also for the first time, that the inclusion of a small amount of linseed oil in a diet rich in n-6 PUFA is sufficient to bring about these suppressive effects.

The maximal effect of dietary α-linolenic acid upon *ex vivo* proliferation of spleen lymphocytes (a reduction by 65%) was observed with diet B; increasing the amount of α-

TABLE 6
Effect of Feeding Diets of Different Fatty Acid Compositions upon Spleen Lymphocyte NK Cell Activity[a]

Diet	% Cytolysis (L/T)		
	100:1	50:1	25:1
A	28.2 ± 1.8^{b,d,e}	19.9 ± 2.1^{d,e}	10.7 ± 1.6^{d,e}
B	22.0 ± 1.8^{a}	13.6 ± 2.0	11.1 ± 1.6^{d,e}
C	22.7 ± 1.8	15.4 ± 0.8	9.7 ± 0.5^{d,e}
D	18.6 ± 0.6^{a}	12.9 ± 1.1^{a}	6.8 ± 0.7^{a,b,c}
D	19.7 ± 1.7^{a}	13.1 ± 1.6^{a}	6.5 ± 0.9^{a,b,c}

[a]Natural killer (NK) cell activity was determined at different lymphocyte to target cell ratios (L/T) as described in the Materials and Methods section. Data are mean ± SEM of separate observations made on five animals fed each diet. Superscript letters a, b, c, d, e are explained in Table 3.

TABLE 7
Effect of Feeding Diets of Different Fatty Acid Compositions upon Spleen Lymphocyte Subpopulations[a]

Diet	Percentage of positive cells				
	CD4	CD8	κ-Light chain	CD11b/c	CD16
A	53.9 ± 2.0	34.9 ± 1.4	37.1 ± 1.6	22.0 ± 0.9	6.7 ± 0.6^{d}
B	52.2 ± 2.5	35.0 ± 3.8	39.2 ± 2.0	28.2 ± 4.4	6.1 ± 0.7^{d}
C	53.4 ± 1.9	33.3 ± 0.6	40.9 ± 1.3	23.0 ± 3.4	5.8 ± 0.4^{d,e}
D	53.0 ± 1.5	36.5 ± 1.7	41.5 ± 2.9	26.2 ± 3.5	9.3 ± 0.9^{a,b,c}
E	51.3 ± 2.4	33.5 ± 1.3	42.1 ± 1.7	23.9 ± 3.8	8.0 ± 0.9^{c}

[a]The proportion of cells expressing each marker was determined as described in the Materials and Methods section. Data are mean ± SEM of separate observations made on five animals fed each diet. Superscript letters a, b, c, d, e, are explained in Table 3.

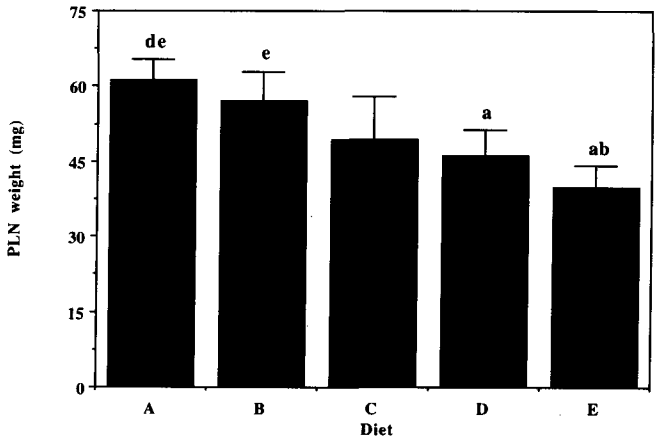

FIG. 2. Effect of feeding diets of different fatty acid compositions upon the graft vs. host response. Lymphocytes from Lewis rats were injected into the footpad of DA/Lewis rats (see the Materials and Methods section). Seven days later the popliteal lymph nodes (PLN) were dissected out and weighed. Data are mean ± SEM of separate observations made on 10 to 12 animals fed each diet; a, b, d, e, are explained in Figure 1.

linolenic acid had no further effect (Fig. 1). It is likely that a progressive effect of dietary α-linolenic acid upon lymphocyte proliferation would have been observed had a diet with an n-6 to n-3 PUFA ratio between those of diets A and B been used. The n-6 to n-3 PUFA ratio of such a diet would have been greater than 15 and would have been much higher than that consumed in the human diet.

The n-3 PUFA-induced inhibition of lymphocyte function did not involve a change in the proportions of $CD4^+$ cells, $CD8^+$ cells, B-cells, or macrophages in the spleens of these animals (Table 7). However, linseed oil feeding did increase the proportion of $CD16^+$ cells (i.e., NK cells) in the spleen (Table 7). Therefore, the diminished NK cell activity of spleen lymphocytes was not due to there being less NK cells present. Indeed, as there were more NK cells present, but lower overall NK cell activity, activity per NK cell must have been significantly decreased in rats fed diets D and E. This effect may be explained by the lowered arachidonic acid content of lymphocytes from animals fed diets C, D, and E. The arachidonic acid-derived eicosanoid leukotriene (LT) B_4 is a potent activator of NK cell activity (57), and it is known that feeding linseed oil diminishes the production of 4-series LT (58). Thus, diminished production of LTB_4 in cultures of lymphocytes isolated from animals fed diets C, D, and E may account for the decreased NK cell activity observed (Table 6).

The n-6/n-3 ratio of the 20% fish oil diet used in our previous experiments (8,13,28–30,40,43,45,52,53) was 0.3:1, very similar to the ratio of the 20% linseed oil diet used in the present study (diet E). The effects observed after feeding these two diets are very similar. As indicated previously, both diets result in significant lowering of blood lipid levels. Furthermore, both diets result in significant suppression of *ex vivo* spleen lymphocyte proliferation and NK cell activity and of the graft vs. host response, an *in vivo* measure of cell-mediated immunity; the effects of the linseed oil diet (Figs. 1 and 2, Table 6) are as strong as those of the fish oil diet (13,40,43). However, in contrast to fish oil feeding (45), the linseed oil diet did not result in significant incorporation of eicosapentaenoic and docosahexaenoic acids into spleen lipids (Table 5). This was despite the appearance of these long-chain n-3 PUFA in the serum of linseed oil-fed animals. These observations indicate that the immunomodulatory actions of n-3 PUFA are not restricted to those present in high proportions in fish oil (i.e., eicosapentaenoic and docosahexaenoic acids), but that plant oils rich in n-3 PUFA (e.g., linseed oil) also exert potent effects. These effects were elicited when only relatively small amounts of linseed oil were added to sunflower oil. For example, the inhibition of *ex vivo* spleen lymphocyte proliferation (Fig. 1) and NK cell activity (Table 6) were observed following the feeding of diet B; this inhibition did not increase as the n-3 PUFA content of the diet increased. The effect upon cell-mediated immunity *in vivo* (i.e., the graft vs. host response) did increase as the α-linolenic acid content of the diet increased (Fig. 2).

In conclusion, this study indicates that dietary n-3 PUFA other than those found in fish oils elicit potent effects upon blood lipid levels and immune cell function in the rat, and that only a relatively small amount of such fatty acids need to be added to the diet to bring about these effects. It will be important to find out whether similar linseed oil-induced immunoregulatory effects occur in humans. Fish oil consumption has been suggested as a means for lowering blood lipid levels in man and to offer protection against the development of CHD and inflammatory disorders. Because α-linolenic acid is available from plant sources and as it is less susceptible to oxidative damage than the longer chain n-3 PUFA, it may be a useful alternative to fish oil.

Dalhousie University, Halifax, Nova Scotia B3H 4H7, Canada

ABSTRACT: Peroxisomal proliferators and retinoids have been reported to interact to regulate lipid metabolism, particularly β-oxidation of fatty acids. Based on postulated interactions of these agents at the levels of receptors and response elements, we examined whether interactions exist between the peroxisomal proliferator, clofibrate (CLF), and retinoic acid (RA) in modulation of phospholipid turnover in cultured human skin fibroblasts. Treatment of cultured cells with either 25 μM CLF or 1 μM RA alone decreased [^{14}C]ethanolamine incorporation into ethanolamine phosphoglycerides (EPG) by 20–30%, and simultaneous exposure to both agents resulted in additive inhibition. By contrast, [^{3}H]choline incorporation into phospholipid was stimulated 5–30% by incubation with either agent; when CLF and RA were administered together, the stimulatory effects were additive. Different types of pulse–chase studies examining effects on uptake, biosynthesis, and degradation of labelled phospholipids indicated stimulation of EPG degradation and inhibition of phosphatidylcholine degradation by CLF; no effect on catabolism of either phospholipid was observed with RA. Combinations of modifiers of protein kinase activity [4β-12-*O*-tetradecanoylphorbol-13-acetate (β-TPA), 1-(5-isoquinolinesulfonyl)-2-methylpiperazine dihydrochloride, *N*-(2′-guanidinoethyl)-5-isoquinolinesulfonamide hydrochloride, *bis*-indolylmaleimide, staurosporine] indicated that β-TPA-responsive protein kinases were not involved. Accordingly, CLF and RA regulate biosynthesis and degradation of ethanolamine and choline phosphoglycerides in cultured skin fibroblasts by different mechanisms that do not involve classical protein kinase C (PKC) isoforms, even though turnover of phospholipids generating lipid activators of PKC occurs.
Lipids 31, 747–755 (1996).

Clofibrate (CLF) is a hypolipidemic drug commonly used in the treatment of patients with hypertriglyceridemia (1). This agent also is known for its properties as a peroxisomal proliferator in rodent species, where dietary intake for several weeks causes marked increases in peroxisomal size, number, and concomitant induction of peroxisome-associated enzymes, particularly catalase and those catalyzing β-oxidation of fatty acids (2,3). Other effects on lipid metabolism not specifically involving peroxisomes include alterations of mitochondrial enzyme activities and intracellular transport by fatty acid binding proteins (4,5). Some of the diverse effects of CLF appear to be mediated by peroxisomal proliferator-activated receptors (PPAR). These members of the steroid/thyroid hormone superfamily of ligand-activated transcription factors recently have been cloned and characterized (6,7).

Retinoic acid (RA), a naturally-occurring metabolite of vitamin A (retinol), is an important regulator of cellular proliferation, differentiation, and metabolism with a wide range of effects in many cells and tissues (8,9). Most, if not all, biological actions of RA are thought to be mediated by receptors (e.g., RAR and RXR) which, like the PPAR, have been shown to belong to the steroid hormone receptor superfamily (10–12). Retinoids can interact with peroxisomal proliferators, presumably *via* their receptors, to modulate lipid metabolism, specifically, β-oxidation of fatty acids (13–15).

Previous studies from our laboratory showed that CLF inhibits turnover of ethanolamine phosphoglycerides (EPG) in cultured human skin fibroblasts with selectivity relative to its effects on metabolism of choline phosphoglycerides (16). As recent reports have described interactions between peroxisomal proliferators and retinoids in the regulation of lipid metabolism and receptors for these two agents interact in the regulation of gene expression (13–15), the present study was initiated to determine whether clofibrate and retinoic acid might interact to coordinately or synergistically alter phosphoglyceride turnover in cultured human skin fibroblasts. We provide evidence supporting differential regulation of EPG and choline phosphoglyceride synthesis and catabolism by CLF and RA. As stimulators of protein kinase C (PKC) also alter phospholipid turnover (17–19) and PKC may be involved in

some actions of CLF and RA (20–22), we investigated whether PKC might participate in the actions of these agents. Our results suggest that phorbol ester-sensitive isoforms of PKC do not initiate or mediate the differential effects of CLF and RA on phospholipid metabolism, even though turnover of these classes of phospholipid can potentially supply lipid activators of PKC, particularly diacylglycerol species for sustained activation (23).

MATERIALS AND METHODS

Materials. [methyl-^{3}H]Choline (86.6 Ci/mmol) and [γ-^{32}P]ATP were purchased from DuPont Canada, Inc. (NEN Research Products, Montreal, Quebec, Canada). [1,2-^{14}C]Ethanolamine hydrochloride (11.7 mCi/mmol), unlabelled choline, RA, 2-(*p*-chlorophenoxy)-2-methyl-propionic acid ethyl ester (CLF), dimethylsulfoxide (DMSO), phenylmethylsulfonylfluoride (PMSF), leupeptin, digitonin, forskolin, dideoxyforskolin, and bovine serum albumin were from Sigma Chemical Co. (St. Louis, MO). *Bis*-indolylmaleimide hydrochloride was purchased from Calbiochem-Novabiochem Corporation (LaJolla, CA), 1-(5-isoquinolinsulfonyl)-2-methylpiperazine dihydrochloride (H-7), *N*-(2′-guanidinoethyl)-5-isoquinolinesulfonamide hydrochloride (HA-1004), staurosporine, and 4β-12-*O*-tetradecanoylphorbol-13-acetate (β-TPA) were from LC Laboratories (Woburn, MA). Phosphatidylserine was from Serdary Research Laboratories Inc. (London, Ontario, Canada). All other chemicals and reagents were of high quality and obtained from commercial sources. PKC assay kits were from Amersham Canada Ltd. (Oakville, Ontario, Canada).

Cell culture. Human skin fibroblasts (F8) were subcultured, as described previously (16,24), in 60-mm plastic dishes in 5 mL Eagle's minimal essential medium (MEM) containing 10% fetal bovine serum. Cultures were maintained at 37°C, under 95% air/5% CO_2, for 7 to 8 d. Protein content ranged from 0.4–0.6 mg per dish at initiation of experiments.

Cell incubation. All incubations were carried out at 37°C. For pulse experiments, confluent cultures were placed in 2 mL fresh MEM without fetal bovine serum and incubated for 24 h. Appropriate reagents and labelled substrate [either [^{14}C]ethanolamine (65 μM; 1.5 μCi) or [^{3}H]choline (7 μM; 3 μCi)] were added to each dish and incubated for the indicated times. All reagents were dissolved in DMSO (final concentration not exceeding 1%), except for H-7 and HA-1004, which were dissolved in water. Cells were rinsed twice with 2 mL phosphate-buffered saline at pH 7.4, harvested by scraping in methanol/water (5:4, vol/vol), and disrupted by sonication (2 × 10 s bursts). Aliquots were taken for protein determination (25) using bovine serum albumin as standard. Lipids were extracted from cell lysates using a modified Folch procedure (26). Radioactivity in aliquots of cell aqueous phase, lipid phase, and medium was quantitated by liquid scintillation counting. Calculation of substrate incorporation was based on the specific activity of labelled precursor added to the medium. Recovery of label typically was 90 ± 5%. Analysis of labelled lipids by thin-layer chromatography on Silica Gel G (Fisher Scientific, Ottawa, Canada) in chloroform/methanol/acetic acid/water (85:15:10:3.5) revealed that virtually all label from [^{14}C]ethanolamine was present as [^{14}C]phosphatidylethanolamine ([^{14}C]PtdEtn) and all [^{3}H]choline label as [^{3}H]phosphatidylcholine ([^{3}H]PtdCho) with or without agents present.

Pulse–chase experiments. In one type of pulse–chase experiment, preincubation conditions were identical to those described for pulse studies, except that either [^{14}C]ethanolamine (65 μM; 1.5 μCi) or [^{3}H]choline (7 μM; 3 μCi) was present in the culture medium. After 24 h, medium was removed and cells were washed twice with 2 mL MEM. Fresh chase medium (2 mL MEM) containing appropriate reagents and either 100 μM ethanolamine or 1 mM unlabelled choline was added. After 2 h incubation, chase medium was collected, and cells were harvested and processed as described previously for pulse studies. Similar experimental conditions have been used previously to evaluate catabolism of prelabelled phospholipids by measuring release of labelled head group to the culture medium (17,27–29). In other experiments to examine potential differences in cellular uptake of labeled precursors, cultures were pulsed with radiolabel for 1 h and chased for 30 min in the presence or absence of test agents.

PKC assay. Enzyme activity was measured in cytosolic and particulate cell fractions using a commercially available assay kit. Cultures were washed twice with 1 mL ice-cold phosphate buffered saline (pH 7.4) and incubated on ice for 5 min in 1 mL solubilization buffer (50 mM Tris-HCl, 0.5 mg digitonin/mL, 5 mM EGTA, 2 mM EDTA, 0.2 mM PMSF, 1 mM leupeptin, pH 7.5) to yield the cytosolic fraction (30). The particulate fraction was suspended in 1 mM lysis buffer (50 mM Tris-HCl, 250 mM sucrose, 5 mM EGTA, 2 mM EDTA, 0.2 mM PMSF, pH 7.5) and disrupted by sonication. Cell fractions were kept on ice and enzyme activity determined immediately, using a modified mixed micelle assay (31) following activation with β-TPA. PKC activity was measured as Ca^{2+}- and PtdSer-dependent incorporation of ^{32}P from [γ-^{32}P]ATP into substrate peptide (supplied in assay kit). Protein content ranged from 4–8 μg in a 75-μL incubation. Reaction was initiated with addition of [γ-^{32}P]ATP and, after 15 min incubation at 25°C in assay buffer (50 mM Tris-HCl, 1 mM calcium acetate, 8 mole% phosphatidylserine, 13 μM β-TPA, 75 μM substrate peptide, 2.5 μM DTT, 50 μM ATP, and 3.75 mM magnesium acetate, pH 7.5), was terminated with 100 μL of dilute acid (provided in assay kit). After mixing, 125 μL aliquots of reaction mixture were spotted on 6.25 cm^2 binding papers. Squares were washed twice for 10 min in 500 mL 5% acetic acid, transferred to scintillation vials, and counted. All values were corrected for background radioactivity (determined from reaction mixtures containing buffer instead of enzyme).

Statistical analysis. Results represent mean ± SEM. Statistical significance was determined by Student's *t*-test.

RESULTS

Effects of CLF and RA on EPG and choline phosphoglyceride synthesis and turnover. The effects of CLF and RA on

[^{14}C]ethanolamine incorporation into EPG by cultured human skin fibroblasts were examined during 15 min and 2 h incubations. Agent concentrations were based on preliminary dose–response experiments and previous investigations (16) such that possible synergism between the two agents could be assessed; accordingly, conditions were established to give relatively low levels of inhibition or activation (10–20%) by the agents alone, so that greater than additive effects potentially could be demonstrated. Figure 1A shows that CLF inhibited [^{14}C]ethanolamine incorporation into EPG during both 15-min and 2-h incubations, confirming earlier observations with other precursors of EPG (16). Inhibition was more pronounced during the 15-min incubation. RA also inhibited [^{14}C]ethanolamine incorporation into EPG, but the level of inhibition was similar at both times. Simultaneous addition of CLF and RA resulted in a level of inhibition at 15 min similar to that obtained with CLF alone. By contrast, the inhibition resulting from simultaneous exposure to both agents for 2 h was equivalent to the sum of the effects of each agent alone. Total cell-associated radioactivity was not altered by these agents, either alone or in combination, indicating that uptake of labelled ethanolamine was not a limiting factor.

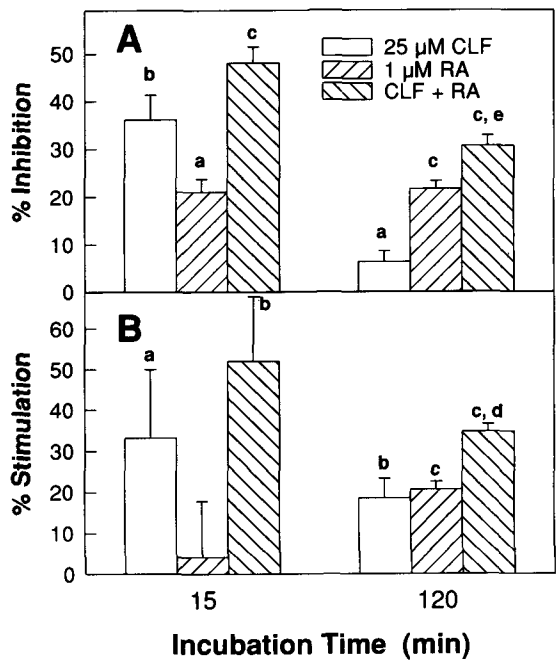

FIG. 1. Effects of clofibrate (CLF) and retinoic acid (RA) on [^{14}C]ethanolamine and [^{3}H]choline incorporation into phospholipids by cultured human skin fibroblasts. Cells were incubated for 15 or 120 min with either [1,2-^{14}C]ethanolamine (1.5 μCi, 67 μM; panel A) or ([methyl-^{3}H]choline, 3 μCi, 7 μM; panel B) and either 25 μM CLF, 1 μM RA, or both agents simultaneously. Control cells were incubated with equivalent volume of dimethylsulfoxide (DMSO) vehicle. Cells were harvested, lipids extracted, and radioactivity determined, as indicated in the Materials and Methods section. In panel A, data are expressed as percentage inhibition, where 0% inhibition (incorporation under control conditions) equals 48 ± 5 and 755 ± 55 pmol/mg protein for 15- and 120-min incubations, respectively. In panel B, results are shown as percentage stimulation, where 0% stimulation (control incorporation) equals 3.6 ± 0.3 and 152 ± 8 pmol/mg protein for 15- and 120-min incubations, respectively. Each value represents the mean ± SEM of $n = 4$–12. a, $P < 0.05$; b, $P < 0.005$, c, $P < 0.0005$, agent(s) vs. DMSO control; d, $P < 0.05$; e, $P < 0.005$, both agents together vs. each agent alone.

In distinct contrast, CLF stimulated [^{3}H]choline incorporation into PtdCho during both 15-min and 2-h incubations (Fig. 1B). Although RA was without effect during the shorter incubation time, it was significantly stimulatory at 2 h. When CLF and RA were added simultaneously, the stimulatory effect at 15 min was not different from that achieved with CLF alone. By contrast, simultaneous exposure to both agents for 2 h resulted in an additive stimulation of [^{3}H]choline incorporation into PtdCho. These agents, alone or in combination, did not alter total cell-associated radioactivity, again indicating that uptake of labelled choline was not a limiting factor.

To further confirm this latter point, effects of CLF and RA on incorporation of [^{3}H]choline from the cellular aqueous fraction into lipid-soluble components, independent of choline uptake or transport across the plasma membrane, were determined in 1-h pulse–30-min chase studies. Similar to the observations with the pulse experiments, CLF (25 μM) stimulated [^{3}H]choline incorporation into phospholipid (174 ± 12% of control, $n = 6$, $P < 0.005$). One μM RA was without effect (95 ± 17%, $n = 5$); however, 10 μM RA stimulated the incorporation of [^{3}H]choline into lipid-soluble components (212 ± 37%, $n = 6$, $P < 0.01$). Simultaneous exposure to both agents (25 μM CLF and 1 μM RA) resulted in a greater-than-additive stimulation of [^{3}H]choline incorporation into phospholipid.

The effects of CLF and RA on catabolism of EPG and choline phosphoglycerides and release of metabolites to the culture medium following long-term prelabelling were examined in 24-h pulse–2-h chase experiments. CLF stimulated release of [^{14}C]metabolites to the medium from [^{14}C]ethanolamine-labelled EPG. RA was without effect (Fig. 2). The effect of the two agents added simultaneously was not significantly different from that observed with CLF alone. Results were similar in experiments with 1 μM unlabelled choline instead of 100 μM ethanolamine in the chase medium (data not shown), suggesting that preferential uptake or recycling of ethanolamine and choline metabolites was not appreciable.

By contrast, CLF slightly inhibited the release of radioactive metabolites to the culture medium from [^{3}H]choline-labelled cells (Fig. 2). RA, at 1 μM, either alone or in combination with 25 μM clofibrate, did not significantly affect the release of label to the medium. However, inhibition of label release was evident with 10 μM RA [34.8 ± 2.5% inhibition, ($n = 6$), $P < 0.0005$].

Evaluation of protein kinase involvement in CLF- and RA-induced alterations in ethanolamine and choline phosphoglyceride metabolism. RA or CLF at concentrations and in combinations used to alter phospholipid synthesis and turnover had no appreciable effect on cellular PKC activities in either cytosolic or particulate fractions (Fig. 3). In contrast, 100 nM β-TPA caused translocation of PKC activity from the cytosolic to the particulate fraction and 2 μM β-TPA treat-

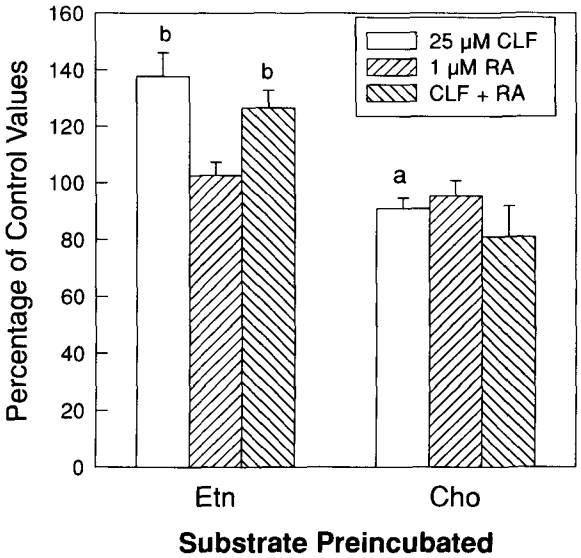

FIG. 2. Effects of CLF and RA on release of label from [^{14}C]ethanolamine (Etn) and [^{3}H]choline (Cho) to medium of cultured human skin fibroblasts. Cells were pulse-labelled for 24 h with either [1,2-^{14}C]ethanolamine (1.5 μCi, 67 μM) or [methyl ^{3}H]choline (3 μCi, 7 μM). Pulse medium was then removed and cells washed with fresh medium. Chase medium containing either 25 μM CLF, 1 μM RA, or both agents simultaneously, as well as 100 μM unlabelled ethanolamine or 1 mM choline, to dilute and trap released radioactive metabolites, was added and cells were incubated for 2 h. Cells were harvested, lipids were extracted, and radioactivity in the medium was determined as described in the Materials and Methods section. Data are expressed as percentage stimulation, where 0% stimulation (release from control cells incubated with DMSO vehicle) equals 4849 ± 312 pmol/mg protein for ethanolamine and 475 ± 76 for choline. Each value represents the mean ± SEM of $n = 6$. a, $P < 0.05$, b, $P < 0.005$ agent(s) vs. DMSO control. See Figure 1 for other abbreviations.

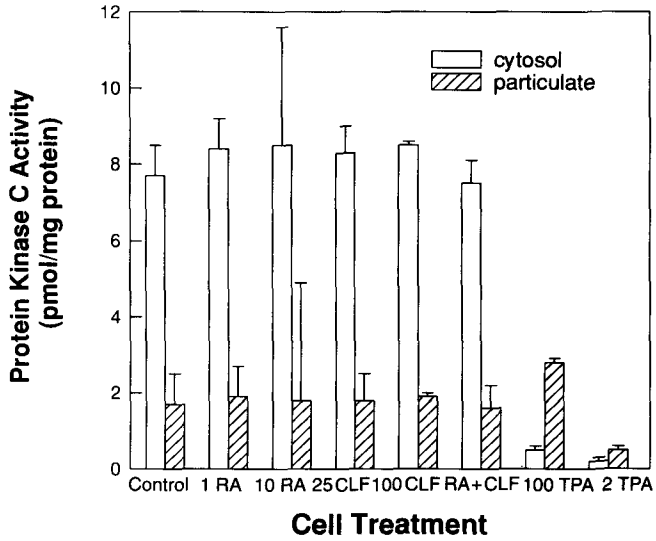

FIG. 3. Effects of CLF and RA on protein kinase C (PKC) activity in cultured human skin fibroblasts. Cells were incubated for 15 min with either RA (1 or 10 μM), CLF (25 or 100 μM), or both agents simultaneously (25 μM CLF and 1 μM RA). Control cells were incubated with an equivalent volume of DMSO. Cells also were treated with 100 nM β-TPA (β-12-*O*-tetradecanoylphorbol-13-acetate) for 15 min (100 TPA) or 2 μM β-TPA for 24 h (2 TPA). Cytosolic and particulate fractions were prepared and PKC activity determined, as described in the Materials and Methods section. Each value represents the mean ± SEM of $n = 2$–6 See Figure 1 for other abbreviations.

ment for 24 h gave appreciable downregulation of PKC activity in both fractions. Activation of PKC by exposure to 100 nM β-TPA for 15 min was without significant effect (8.1 ± 7.3% inhibition, $n = 8$) on [^{14}C]ethanolamine incorporation into EPG, whereas [^{3}H]choline incorporation into phospholipid was stimulated >3-fold, as shown for other cultured cells (17,32). The effects of two protein kinase inhibitors, H-7 and HA-1004 (33,34), on [^{14}C]ethanolamine and [^{3}H]choline incorporation into phospholipid, were compared in the absence and presence of CLF and RA (Fig. 4). Neither H-7 nor HA-1004 had any effect on basal [^{14}C]ethanolamine incorporation into EPG by control cultures, i.e., treated with DMSO vehicle during a 2-h incubation (Fig. 4A). CLF-induced inhibition of label incorporation was completely reversed by co-incubation with 100 μM H-7. By contrast, 100 μM HA-1004 was without effect. RA-treated cells also showed reduced [^{14}C]ethanolamine incorporation into phosphoglyceride relative to vehicle-treated controls. Co-incubation with either 100 μM H-7 or HA-1004 only partially countered the retinoid-induced inhibitory effect.

Incorporation of [^{3}H]choline into PtdCho by control cultures was unaffected by 100 μM HA-1004, but it was slightly increased ($P < 0.05$) by 100 μM H-7 (Fig. 4B). Co-incubation with 100 μM HA-1004 almost completely reversed the CLF-induced stimulation, whereas 100 μM H-7 had no effect. Neither H-7 nor HA-1004 significantly altered the stimulatory effect of RA. Although 100 μM H-7 was effective in inhibiting PKC *in vitro* (Fig. 5A, D), it had little effect on cellular PKC activity and subcellular distribution when incubated with intact cells (Fig. 5B, D). Similarly, treatment of intact cells with 100 μM HA-1004 did not alter PKC activity or distribution (Fig. 5B, E).

The effects of another protein kinase inhibitor, staurosporine, known to inhibit PKC and other kinases (35), were investigated. Staurosporine (5 μM) completely inhibited PKC activity *in vitro* (Fig. 5A, F) and was almost equally effective with intact cells (Fig. 5B, F). Effects of staurosporine on [^{14}C]ethanolamine incorporation into EPG were investigated in cultures treated with either vehicle, CLF or RA. Staurosporine (5 μM) inhibited [^{14}C]ethanolamine incorporation by control cultures treated with DMSO by 20.1 ± 1.3% ($n = 4$, $P < 0.0005$) during a 2-h incubation. Cells treated with 100 μM CLF showed a 27.5 ± 2.2% ($n = 9$) reduction in [^{14}C]ethanolamine incorporation into phospholipid relative to control. Co-incubation with staurosporine resulted in a level of inhibition (28.6 ± 7.3%, $n = 10$) similar to that observed with either compound alone. Cultures treated with 2 μM RA also exhibited decreased [^{14}C]ethanolamine incorporation (33.1 ± 1.7%, $n = 6$). Simultaneous exposure to the retinoid and staurosporine resulted in additive inhibition of [^{14}C]ethanolamine incorporation (47.2 ± 2.4%, $n = 6$). Another agent, *bis*-indolylmaleimide, has been reported to have

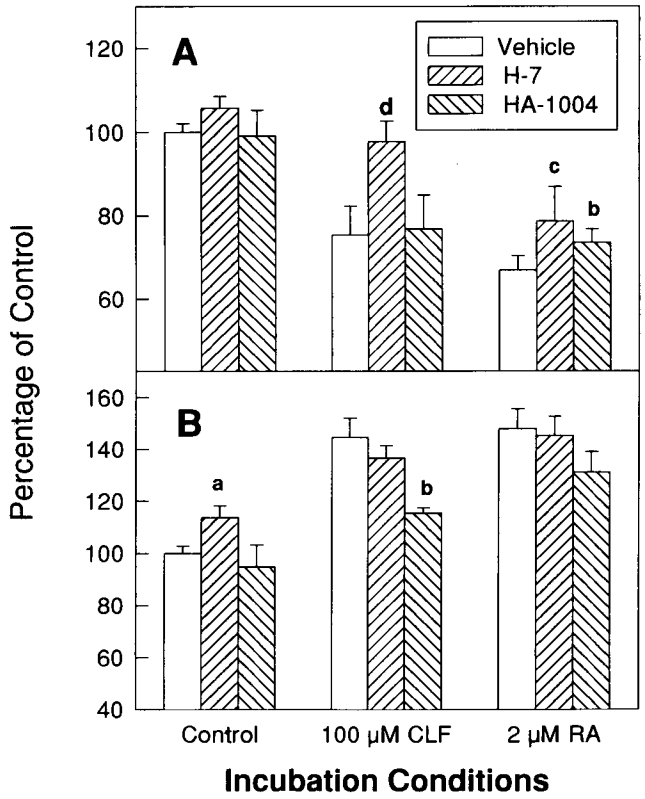

FIG. 4. Effects of protein kinase inhibitors on [^{14}C]ethanolamine and [^{3}H]choline incorporation into phospholipids by cultured human skin fibroblasts. Cells were incubated for 2 h with either [1,2-^{14}C]ethanolamine (1.5 μC, 67 μM; panel A) or [methyl-^{3}H]choline (3 μCi, 7 μM; panel B), and either 100 μM CLF, 2 μM RA, or an equivalent volume of DMSO (control) as indicated. Incubations also contained either 100 μM 1-(5-isoquinolinesulfonyl-2-methylpiperazine dihydrochloride H-7 (LC Laboratories, Woburn, MA), 100 μM *N*-(2′-guanidinoethyl)-5-isoquinolinesulfonamide (HA-1004; LC Laboratories), or an equivalent volume of water. Cells were harvested, lipids extracted, and radioactivity determined. Data are expressed as percentage of control (measured in presence of DMSO and water only), where control incorporation equals 327 ± 25 and 152 ± 8 pmol/mg protein in panels A and B, respectively. Each value represents the mean ± SEM of n = 4–12 for panel A and n = 4–6 for panel B. a, $P <$ 0.05 protein kinase inhibitor vs. DMSO control; b, $P < 0.05$; c, $P < 0.005$; d, $P < 0.0005$ protein kinase inhibitor and agent vs. agent alone. See Figure 1 for abbreviations.

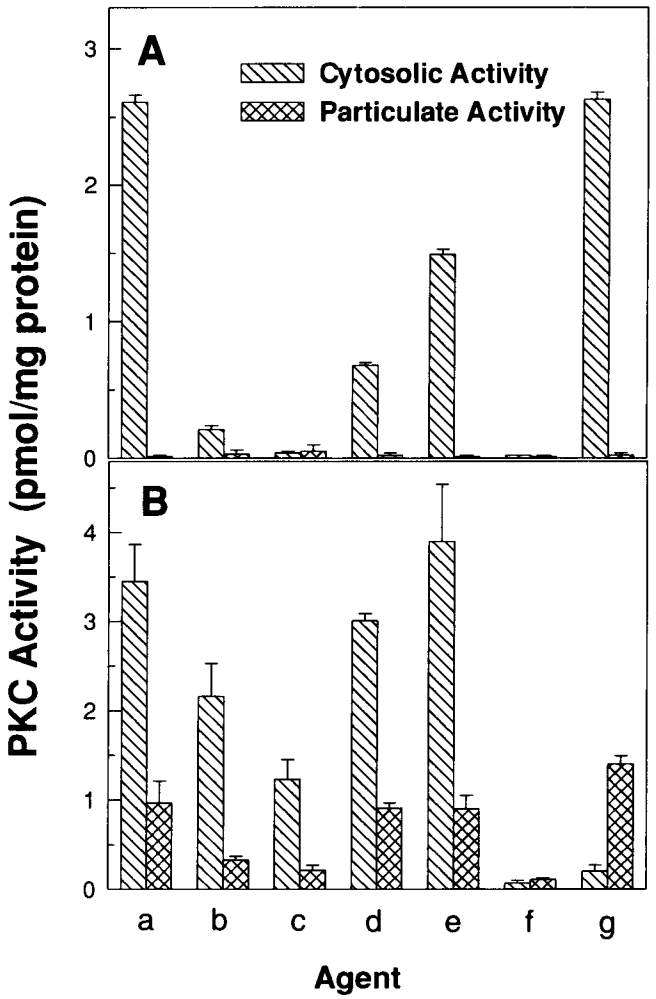

FIG. 5. Effects of various agents on activity of PKC in cytosolic and particulate fractions of fibroblast cells. In panel A, cytosolic and particulate fractions were isolated from fibroblasts as described in the Materials and Methods section and were incubated for 15 min with each agent added to the *in vitro* assay. In panel B, fibroblasts were incubated for 2 h with each agent before isolation of cytosolic and particulate fractions, and then PKC activity was assayed *in vitro* with optimal assay parameters. Conditions tested were: a, control with addition of the solvent carrier of agents to the cells or *in vitro* assay; b, 0.1 μM *bis*-indolylmaleimide; c, 1 μM *bis*-indolylmaleimide; d, 100 μM H-7; e, 100 μM HA-1004; f, 5 μM staurosporine; g, 0.1 μM β-TPA. Values are means ± SEM for n = 4. See Figure 3 for abbreviations and Figure 4 for company source.

high selectivity and potency for inhibition of PKC (36). One μM *bis*-indolylmaleimide effectively inhibited PKC *in vitro* (Fig. 5A, B, C) and reduced total cellular PKC in both cytosolic and particulate fractions of pretreated cells by at least 70% (Fig. 5B, C). In addition, 100 μM *bis*-indolylmaleimide completely inhibited phorbol ester-stimulated (β-TPA; Fig. 6B) incorporation of choline into phospholipid. Despite these effects, *bis*-indolylmaleimide had no effect on control, or CLF- and RA-altered, levels of ethanolamine (Fig. 6A) incorporation into phospholipids.

The inhibitory effect of CLF on [^{14}C]ethanolamine incorporation into EPG was examined following downregulation of PKC by β-TPA. Cultures treated with 2 μM β-TPA for 24 h showed higher [^{14}C]ethanolamine incorporation into phospholipid relative to vehicle-treated control cells (778 ± 29 vs. 568 ± 16 pmol/mg protein, respectively). Thus, phorbol ester- and vehicle-treated groups were compared after normalization to their respective controls. CLF (100 μM) inhibited [^{14}C]ethanolamine incorporation into EPG comparably in β-TPA- or vehicle-treated cells (39 ± 3% inhibition vs. 33 ± 3%, n = 6, respectively). At a lower concentration (25 μM) of the peroxisomal proliferator, a similar lack of a β-TPA effect on inhibition also was observed. Further, β-TPA-induced PKC downregulation did not alter RA-induced inhibition of [^{14}C]ethanolamine incorporation either at 1 μM (8.6 ± 3.9% vs. 11.9 ± 1.9%, n = 6 for β-TPA- and vehicle-treated cells, respectively) or 10 μM RA (72.6 ± 1.7% vs. 68.2 ± 1.6%, n = 6).

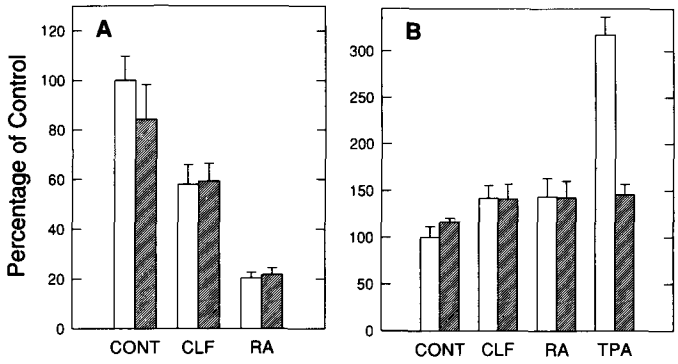

FIG. 6. Effects of *bis*-indolylmaleimide on CLF-, RA-, and phorbol ester induced alterations of choline and ethanolamine incorporation into lipids of fibroblast cells. In panel A, cells were incubated for 2 h with [1,2-^{14}C]ethanolamine (1.5 μCi, 67 μM) and in panel B [methyl-^{3}H]choline (3 μCi, 7 μM). Incubations also included 100 μM CLF, 2 μM RA, or 100 nM β-TPA, without (white bar) or with (striped bar) 1 μM *bis*-indolylmaleimide present. Control cells were incubated with equivalent volume of vehicle. Values are means ± SEM for n = 4–8. CONT is control. See Figures 1 and 3 for other abbreviations.

Incorporation of [^{14}C]ethanolamine was inhibited by forskolin (16.1% at 0.1 μM and 33.0% at 1 μM forskolin), whereas dideoxyforskolin (0.01–10 μM) had no effect. In combination with CLF or RA, forskolin did not alter the effects of either agent. Effects of forskolin alone on [^{3}H]choline incorporation were indistinguishable from those of dideoxyforskolin, and in combination with the other agents, forskolin did not alter effects of either CLF or RA.

DISCUSSION

Influences of peroxisomal proliferators, such as CLF, and of retinoids, such as RA, on cellular metabolism and physiology are numerous and varied (9,37–39). Some studies indicate similarities between these classes of agents and the potential for interaction at the level of common or shared receptor and response elements (13–15). Based on earlier observations that CLF somewhat specifically alters EPG metabolism in cultured fibroblasts (16), we have investigated relationships between CLF and RA in modifying membrane lipid turnover. As both similarities and differences in the effects acid of the two agents on synthesis and catabolism of ethanolamine and choline phosphoglycerides were observed, we explored potential points of metabolic regulation of these effects.

From these studies, it is apparent that ethanolamine and choline phosphoglyceride metabolism in cultured skin fibroblast cells involves different levels of regulation by CLF and RA. Although the effect of CLF on both phospholipid classes is rapid, occurring within 15 min, inhibition of ethanolamine incorporation into EPG by CLF diminishes with time; in contrast, stimulation of choline incorporation by this agent remains elevated after two hours of incubation. This observation is consistent with earlier findings (16) that ethanolamine phospholipid synthesis in skin fibroblasts undergoes a time-dependent release from CLF-induced inhibition. The longer (18–24 h) recovery period in that earlier study probably relates to the higher concentration (100 μM) of CLF and use of a different precursor to monitor phospholipid turnover. Metabolic inactivation of CLF is unlikely to account for reversal of inhibition of ethanolamine incorporation, as it is not observed in experiments with choline. Rather, our findings suggest differences in the mode of action of CLF with regard to the two phospholipid classes. A similar differential effect was observed with RA. The inhibitory effect of the retinoid on ethanolamine incorporation into EPG is rapid and sustained, but RA-induced stimulation of choline incorporation is slower.

Previous studies describing effects of peroxisomal proliferators and retinoids on lipid metabolism have focused on β-oxidation of fatty acids (40–42) and other aspects of lipid metabolism (37,38,43–45). Although each agent independently activates genes involved in fatty acid β-oxidation, simultaneous exposure to both activators results in synergistic induction of gene expression (14). Our findings indicate that the effects of CLF and RA on ethanolamine and choline incorporation into phosphoglycerides generally are additive rather than synergistic, supporting distinct, noninteracting modes of action for each agent rather than a convergence of regulatory pathways through retinoid receptors or PPAR.

CLF- and RA-induced alterations in the incorporation of ethanolamine and choline into phospholipid potentially could reflect effects of these agents on one or more metabolic processes, including uptake/transport of the exogenous precursor, biosynthesis involving several enzymes and alternative pathways (19,44) or degradation by lipases, including phospholipases C (PLC) and D (PLD). Uptake and transport of ethanolamine and choline seem unlikely targets for regulation in the present study, as neither CLF nor RA had any effect on total cell-associated radioactivity. Further, similar effects of these agents were observed when cells were prelabeled with base precursors in short-term pulse–chase experiments (to eliminate potential effects on uptake and transport). On the other hand, phosphoglyceride degradation appears to be involved as a potential regulatory target at least in the case of CLF. Long-term pulse–chase experiments with ethanolamine (to label the EPG pool, followed by chase in the presence of CLF to determine effects on degradation of phospholipid) show CLF increases label release to the culture medium, indicating stimulation of EPG degradation. In contrast, degradation of prelabeled PtdCho is inhibited by this agent, in agreement with *in vivo* observations in rodents (44). Several agonists have been shown to influence degradation of PtdCho through their action on PLC or PLD (46–48). No effects on degradation of either phospholipid were observed with RA.

Based on previous reports of interactions between PKC activity and CLF and retinoids (20–22), we examined the possibility that PKC might be mediating some or all of the effects of these agents on differential turnover of PtdCho and PtdEtn. H-7 is widely used as an inhibitor of protein kinases (33,34); although potent, it is relatively nonspecific, with similar IC_{50} values for PKC, PKA, and PKG (protein kinases A and G)

(3–6 μM). HA-1004, although a good inhibitor of PKA and PKG, is tenfold less effective as an inhibitor of PKC. By comparing relative abilities of these protein kinase inhibitors to prevent CLF- or RA-induced alterations in ethanolamine or choline phospholipid turnover, we anticipated evidence for which of these protein kinases, if any, are likely mediators of the observed responses. CLF-induced inhibition of ethanolamine incorporation into EPG was prevented completely upon incubation with H-7, but not HA-1004, suggesting PKC involvement in this process. By contrast, both H-7 and HA-1004 partially countered the inhibitory effect of RA on ethanolamine incorporation, suggesting that at least part of this retinoid effect may be mediated by kinases. The stimulatory effect of CLF on choline incorporation into PtdCho was partially reversed by HA-1004, consistent with at least part of the drug's action being mediated by other kinases. Neither protein kinase inhibitor prevented the RA-induced stimulation of choline incorporation, suggesting that kinases were not involved in this process. Lack of effect of RA on choline incorporation at 15 min further supported involvement of a protein kinase-independent mechanism. Thus, our observations implicated kinase-mediated signal transduction pathways in the regulation of some, but not all, aspects of ethanolamine and choline phospholipid turnover initiated by CLF and RA.

Potential involvement of PKC in CLF-induced inhibition of EPG turnover was more extensively examined. Several approaches were taken, as none of the commonly used methods to assess PKC involvement is without limitations. Additional evidence argues against a role for classical PKC isoforms: (i) *bis*-indolylmaleimide, a highly selective PKC inhibitor (36), did not reverse the inhibitory effect of clofibrate on ethanolamine incorporation into EPG; this agent effectively inhibited fibroblast PKC activity *in vitro,* although even at the highest (1 μM) concentration tested with intact cells, as much as 30% of PKC activity remained; (ii) TPA-induced downregulation of PKC, under conditions that eliminated >90% of cytosolic PKC activity, did not prevent CLF-induced inhibition of ethanolamine incorporation; however, substantial membrane activity remained; (iii) TPA-induced activation of PKC did not mimic the inhibitory effects of clofibrate; and (iv) CLF did not activate PKC in either cytosolic or particulate cellular fractions. Accordingly, our data indicate that classical, TPA-sensitive isoforms of PKC do not mediate the effects of CLF and RA on phospholipid turnover. However, given the residual PKC activity that remains following TPA-induced downregulation or *bis*-indolylmaleimide treatment, we cannot exclude the possibility that isoforms in the atypical class of PKC (23,49), some of which are found in fibroblast and other skin cells (50,51), may be involved.

Results with the nonspecific kinase inhibitor, staurosporine, differed from those obtained with H-7 and *bis*-indolylmaleimide. Although basal ethanolamine incorporation decreased in response to staurosporine treatment, this inhibition could involve more than inhibition of PKC. Micromolar concentrations of staurosporine have been shown to elicit effects, such as direct activation of PLD, independent of PKC inhibition (52). Activation of phospholipases, possibly PLD, may be one means whereby CLF alters ethanolamine incorporation into phospholipid, but direct evidence remains to be determined. Studies with forskolin suggest that activation of PKA may inhibit EPG synthesis but, in combination with CLF and RA, do not support involvement of PKA as an explanation for the action of these two agents.

In summary, our study supports differential regulation of ethanolamine and choline phosphoglyceride turnover by clofibrate and retinoic acid. Ethanolamine incorporation into phospholipid is inhibited, whereas PtdCho turnover is stimulated by these agents. Alterations in both biosynthesis and degradation are involved. Mechanisms underlying CLF- and RA-induced alterations in ethanolamine and choline phospholipid turnover differ and appear not to involve TPA-sensitive PKC isoforms.

ACKNOWLEDGMENTS

This study was supported by a Program Grant (PG-1 1476) from the Medical Research Council of Canada. The skilled technical assistance of Susan Powell, Robert Zwicker, and Gladys Keddy are gratefully acknowledged.

[Received May 30, 1995, and in final revised form February 28, 1996; Revision accepted March 12, 1996]

The High Content of Monoene Fatty Acids in the Lipids of Some Midwater Fishes: Family Myctophidae

Hiroaki Saito* and Masakazu Murata
Laboratory of Lipid Chemistry, National Research Institute of Fisheries Science, Ministry of Agriculture, Forestry and Fisheries, Yokohama-shi 236, Japan

The total lipids of eleven species of Myctophids caught at depths between 20 and 700 m in the northern Pacific Ocean were analyzed using silicic acid column chromatography (lipid classes) and capillary gas chromatography (fatty acid and fatty alcohol composition). The major components in the lipid classes were triacylglycerols or wax esters; triacylglycerols were the dominant acyl neutral lipids (68.1–96.1%) in eight species, and wax esters were found as the dominant lipid (85.5–87.9%) in three species. The major fatty acids and alcohols contained in the wax esters of the three fishes were 18:1n-9, 20:1n-9, 20:1n-11, and 22:1n-11 for fatty acids, and 16:0, 18:1, 20:1, and 22:1 for fatty alcohols. Fatty acids in the triacylglycerols ranging from C_{14} to C_{22} were predominantly of even chain length. The major components were 16:0, 16:1n-7, 18:1n-9, 20:1n-11, 22:1n-11, 20:5n-3 (icosapentaenoic acid), and 22:6n-3 (docosahexaenoic acid). In both the triacylglycerols and the wax esters, the major fatty components were monoenoic acids and alcohols. It is suggested from the lipid chemistry of the Myctophids that they may prey on the same organisms as the certain pelagic fishes such as saury and herring, because the large quantities of monoenoic fatty acids are similar to those of saury, herring, and sprats whose lipids originate from their prey organisms such as zooplanktons which are rich in monoenoic wax esters.
Lipids 31, 757–763 (1996).

It has been reported that triacylglycerols are usually contained in the lipids of pelagic surface fishes as deposit lipids; however, deep-sea teleost fishes often have considerable amounts of wax esters as a substitute for glycerides (1–3). Fatty acids and other lipid components of deep-sea fish have been examined by Nevenzel and Menon (4) and Nevenzel (5), Buisson *et al.* (6), Takagi *et al.* (7), and Bakes *et al.* (8).

The deep-sea fish, family Myctophidae, is the most widespread family of the mesopelagic deep-sea fishes in the world's oceans. Myctophids are known to be important prey items of various marine animals, and the lipid of the Myctophids is an important energy source for higher predatory fishes (9). For example, Nevenzel *et al.* (10) reported the fatty acid and alcohol compositions of wax esters from the lipids of some Myctophid species, and Kayama and Ikeda (11) reported the wax esters in some deep-sea fishes Myctophidae.

The present paper deals with the analyses of lipids of eleven species of Myctophids caught at different depths, which are common and numerous species in the transition zone between the Oyashio (the cold current off the eastern Japanese coast) and the Kuroshio (the warm current running along the southern coast of Japan) in the northern Pacific Ocean. In addition, the lipid classes and the fatty acid and alcohol compositions of the individual lipid classes are compared with those of other marine pelagic fish species already reported to discuss the relationship between the lipids of Myctophids and their feeding habits.

MATERIALS AND METHODS

Materials. All specimens of Myctophids were caught by trawlers belonging to the Japan Marine Fishery Resource Research Center between latitudes 39 to 42°N and longitudes 143 to 150°E in the northern Pacific Ocean in August 1994. The seawater temperatures were between about 4°C (at depths 350–700 m) and 20°C (at depth 20–50 m).

All samples were frozen immediately, and kept frozen at –40°C for three weeks until extracted. Identifications generally were made by qualified experts, as acknowledged later.

Lipid extraction and the analysis of lipid classes. The total lipids from all specimens of Myctophids were obtained by extraction into chloroform/methanol (2:1, vol/vol) according to the Folch procedure (12). The crude total lipids were separated into classes on silicic acid columns, and the quantitative analysis of the constituents of the lipids was carried out by gravimetric analysis of column chromatography. The glass columns (ϕ 30 mm × 400 mm) were prepared with 50 g of silicic acid (Kieselgel 60, 70–230 mesh; Merck & Co. Ltd., Darmstadt, Germany) suspended in dichloromethane/*n*-hexane (2:3, vol/vol). The sample (300 mg) of total lipids in 3 mL of the same solvent was placed on top of the packing just as it was draining dry. The sample was followed with a few small portions (3–5 mL) of the same solvent and then additional solvent in a total amount of 300 mL. The eluate was collected as the wax ester fraction.

Dichloromethane (300 mL) was then passed through the column, and the triacylglycerol fraction was collected. This was followed with dichloro-methane/ether (35:1, vol/vol) eluting the diglycerides, dichloromethane/ether (9:1, vol/vol) eluting the sterols, dichloromethane/methanol (10:1, vol/vol) eluting the free fatty acids, and dichloromethane/methanol (1:5, vol/vol) and dichloromethane/methanol (1:20,vol/vol) eluting the phospholipids.

Individual lipids separated from each lipid class were identified with authentic samples by thin-layer chromatography (Kieselgel 60, thickness of 0.25 mm for analysis; Merck & Co. Ltd.), nuclear magnetic resonance (NMR), and mass spectrometry. All sample lipids were dried under argon at room temperature and stored at –40°C.

The preparation of methyl esters and gas–liquid chromatography (GLC). The individual components of triacylglycerols were converted to fatty acid methyl esters (FAME) by direct transesterification with boiling methanol containing 1% of concentrated hydrochloric acid under reflux for 1.5 h under argon atmosphere. The methyl esters thus obtained were purified by column chromatography with silica gel by elution with a mixture of dichloromethane and ether (10:1, vol/vol).

The wax esters fractionated also were converted to FAME and fatty alcohols by the same procedure, and the reaction mixture of the wax esters was separated by silicic column chromatography with a elution of the mixture of dichloromethane and ether (35:1, vol/vol), and then the FAME were purified, and the residual wax alcohols were purified with the elution by the similar solvents (dichloro-methane/ether, 9:1, vol/vol).

Analysis of FAME and fatty alcohols contained in the wax esters were performed on an HP 5890 series II gas chromatograph (Hewlett-Packard Co., Yokogawa Electric Corporation, Tokyo, Japan) equipped with an omegawax-320 fused silica capillary column (30 m × 0.32 mm i. d., 0.25 μm film; Supelco Japan Co. Ltd., Tokyo, Japan). The temperatures of the injector and the column were held at 250 and 190°C, respectively, and the split ratio was 1:100. Helium was used as the carrier gas at a constant inlet rate of 40 mL/min.

Quantitative analyses were performed on the capillary columns by means of a Shimadzu Model C-R5A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) electronic integrator.

Peak identification. FAME and wax alcohols were identified using: (i) marine lipid methyl esters as standards (omegawax test mixture No. 4-8476; Supelco Japan Ltd.), (ii) semilogarithmic plot of relative retention time (RRT) against carbon chain lengths of the fatty acids of fish oil and fitting the logarithm of RRT of the fatty acids into these plots, comparison of the equivalent chain length values according to the method of Ackman (13), and (iii) comparison of the determination of the data by gas chromatograph mass spectroscopy (JMS-DX303; JEOL Co. Ltd., Tokyo, Japan) attached to the capillary column. The injector and separation temperature were 250 and 190°C, and the ionization voltage was 70 eV, respectively.

NMR spectrometry. Spectra were recorded on a GSX-270 NMR spectrometer (JEOL Co. Ltd.) in the pulsed Fourier transform mode at 270 MHz in deuterochloroform solution using tetramethylsilane as an internal standard.

Statistical analyses. More than three replications were made of the samples for all treatments. The significant differences of means for the data were inspected by Student's *t*-test at the level of $P < 0.05$.

RESULTS AND DISCUSSION

All specimens were caught at depths between 20 and 700 m in the northern Pacific Ocean between latitudes 39 to 42°N and longitudes 143 to 150°E in August 1994. The majority of these species show diel vertical migration because peak catch of samples occurred in the near-surface waters (20–200 m) at night and in the mesopelagic zone (400–700 m) during the daytime, with the exception of the three stationary species (*Lampanyctus jordani, L. regalis*, and *Stenobrachius nannochir*) (Table 1).

TABLE 1
The Average Lipid Content of the Fishes in Mycotophidae with Relevant Data[a]

Name	Catching depth (m)		Length (cm)	Weight (g)	Lipids (%)[b]
	Day	Night			
First group					
Notoscopelus japonicus	300–500	50–200	13.9 ± 0.6	36.3 ± 5.1	26.0 ± 3.8
Symbolophorus californiensis	400–500	20–100	10.7 ± 0.4	17.5 ± 3.3	25.4 ± 4.1

[a]Results are expressed as mean ± SD for five samples.
[b]Results of lipid contents are expressed as weight percentage of wet tissues.

Lipid contents in the respective species. The lipid content of the whole bodies of the sampled Myctophids with their weights and standard lengths are shown in Table 1, and the total lipid content based on the fresh tissue varied between species and ranged between 3.5 to 26.0%. The examined Myctophids were divided into three types according to the lipid contents ($P < 0.05$); the first group of high lipid content (20.0–26.0%, *Notoscopelus japonicus*, *Symbolophorus californiensis*, and *Lampadena luminosa*); the second group of medium lipid content (12.0–18.6%, *Protomyctophum thompsoni*, *S. leucopsarus*, *Ceratoscopelus warmingi*, *S. nannochir*, and *L. regalis*); the third group of the low lipid content (3.5–6.8%, *Diaphus theta*, *D. gigus*, and *L. jordani*).

Lipid classes (analysis of lipid composition of total lipids). The total lipids were fractionated into various classes as neutral lipids (wax esters, triacylglycerols, and sterols) and polar lipids (phospholipids) by silicic column chromatography, and the lipid compositions are given in Table 2. The lipids of all species examined generally contained a large amount of neutral lipids (85.3–98.6%) with only small quantities of polar lipids (1.4–13.2%).

All of the three fatty fish species belonging to the first group have significantly high ratios of triacylglycerols (93.7–96.1%) in total lipids, and the three lean species of the third group have high ratios of phospholipids (7.3–13.2%) ($P < 0.05$). The total lipid of eight species of Myctophids were mainly comprised of glyceride derivatives such as triacylglycerols (the eight species in the first, second, and third groups) and phospholipids (the three species in the third group). Triacylglycerols (85.7 ± 9.3%) were the major component among their lipid classes; sterols and phospholipids were found as minor components, and wax esters were only slightly detected (0.4–2.0%).

The three species (*S. leucopsarus*, *S. nannochir*, and *L. regalis*) belonging to the second group have wax ester as the major component with a small amount of glycerides derivatives and sterols being found (10). Low levels of sterols (5.4 ± 5.1%) in the free and combined state were encountered in all samples, and they were mostly nonesterified. The sterol distributions were very simple, with only cholesterol accounting for >99% of the total sterols identified with the authentic cholesterol by the measurement of NMR and GLC equipped with a fused silica capillary column (HP-5, 30 m × 0.32 mm i.d.; 0.25 μm film, Hewlett-Packard Co., Yokogawa Electric Corporation). Hydrocarbons were hardly detected in any specimen examined.

In the three Myctophid species, which had similar lipid compositions containing *ca.* 90% (85.5–87.9%) wax esters, *S. nannochir* and *L. regalis* showed no diel vertical migration patterns being caught day and night between 400 and 700 m, while *S. leucopsarus* was caught at two different depths by day (400–500 m) and by night (20–100 m). The seven Myctophid species, which had high triacylglycerol contents, showed clear vertical migrations being caught at different depths by day and by night with the exception of *L. jordani* (Tables 1 and 2). Therefore, there may be some relationship between the Myctophids containing the triacylglycerols as the dominant lipid and the behavior of diel vertical migration.

Fatty acid and fatty alcohol compositions of wax esters, major components for three species of the Myctophids. Fatty acids and alcohols of the wax esters in the three Myctophid species, *S. leucopsarus*, *S. nannochir*, and *L. regalis*, are shown in Table 3. The major components in the wax esters in all species were 16:1 (2.5–10.0%), 18:1 (31.0–37.5%), 20:1 (14.1–34.6%), and 22:1 (11.5–16.2%) for fatty acids, and 16:0 (4.3–35.7%), 18:1 (4.5–8.4%), 20:1 (9.8–22.7%), 22:1 (24.2–52.0%), and 24:1 (3.2–6.1%) for fatty alcohols. The total amounts of these major components reached 65.4–87.7 and 48.3–87.9% of the total fats for the acids and alcohols, respectively. Various kinds of fatty acids were found because more than 25 peaks were detected at a level of 0.3% or more of the total fatty acids; however, in the case of the alcohols, only ten kinds of the fatty alcohols were simply detected at the same level of the total fatty alcohols (Table 3). The alcohols were characterized by a predominance of 16:0, 18:1, 20:1, and 22:1, and the respective amounts of the other fatty

[a]Results are expressed as weight percentage of total fatty acids. Data are mean ± SD for three samples, "trace" denotes <0.3%. [b]Mixture of 20:1n-9 and 20:1n-11. [c]Mixture of 22:1n-9 and 22:1n-11. [d]Mixture of 24:1n-9 and 24:1n-11.

alcohols were less than 0.1% or not detected (Table 3). The ratios of the total monoenoic fatty alcohols (48.3–87.9%) in the wax alcohols of the three species were very high and similar to those of other deep-sea fish species containing wax esters as a major component, and the same trend has been noted in the reports about the lipids of some other deep-sea fishes (14–17).

Although various kinds of fatty acids were observed in the wax esters of the Myctophids examined and were similar to those in general of other marine fish species, the markedly high levels of total monoenoic acids being found (65.4–87.7%) differ from other general marine fish species. In particular, the monoene fatty acids, 18:1 to 24:1 inclusive, made up 62.9–82.1% of the total acids similar to the case of the monoene alcohols (18:1, 20:1, 22:1, and 24:1) in their wax esters, because the total ratios of the alcohols were 45.1–85.9% of the total fatty alcohols. Sargent *et al.* (18) reported that the relatively large amount of monoenes in some midwater fishes and crustaceans was caused by high levels of wax esters. In accordance with Sargent *et al.* (18), our results suggest that Myctophids rich in wax esters have high proportions of monoenes in both the acid and the alcohol portion of the wax esters.

Fatty acid composition of triacylglycerols, major components for eight species of the Myctophids which vertically migrate except L. jordani. The mean fatty acid composition of the triacylglycerols as the major component in the lipids of eight species of Myctophids detected by GLC are compared in Table 4. Various kinds of fatty acids in the triacylglycerols of the eight species were detected (at least 25 peaks, Table 4) similar to the case of wax esters of the three species (Table 3). Even numbers of carbon atoms, ranging from C_{14} to C_{22}, were abundant as compared with odd numbers, 15:0 and 17:0, whose amounts were only in small quantities (<1%). The major saturated fatty acids of all species were 16:0 (10.3–23.0%) and 18:0 (2.0–7.5%). The major monounsaturated fatty acids were 16:1n-7 (3.3–7.3%), 18:1 (18.2–35.3%), 20:1 (3.3–13.3%), and 22:1 (1.5–16.4%), with 20:5n-3 (icosapentaenoic acid, EPA) (2.2-8.2%) and 22:6n-3 (docosahexaenoic acid, DHA) (3.3–8.6%) being the major

constituents among polyenoic fatty acids. All these major components were detected at a level of 3% or more of the total fatty acids in one or both samples, and the total amount of these major components was higher than 85% in each sample. Appreciable amounts of 14:0 (1.5–4.8%), 18:0 (2.0–7.5%), and 24:1 (0.3–2.3%) were also present. Interestingly, monoenoic acids such as 18:1 and 22:1 were also the major components in the total fatty acids of the Myctophids containing triacylglycerols as the major constituent similar to those in wax esters. The ratio of total monoene fatty acids reached to 42.1–66.5% of the total fatty acids (Table 4), and the major fatty acids of triacylglycerols in eight species contained considerable amounts of monoenes. Both the wax esters and the triacylglycerols in the Myctophid species contained only several percentage or less of each polyunsaturated fatty acids (PUFA) such as EPA and DHA, as shown in Tables 3 and 4, compared to the fatty acid compositions of other marine fish species, which are generally rich in PUFA (18). Therefore, there is little difference in the tendency of low total PUFA contents between the wax esters (three species) and the triacylglycerols (eight species). It is suggested that Myctophids that contain not only wax esters but also triacylglycerols as major component may have high proportions of monoenes in their lipids differing from other marine fish species.

High content of monoenes in lipids of Myctophids. It is concluded that the lipids in Myctophids caught in the oceanic front (mean seawater temperature 20°C) of the cold current of the Oyashio in northern Pacific Ocean contained high amounts of monoenes. Especially, 18:1, 20:1, and 22:1 were the dominant fats both for triacylglycerols and wax esters in the lipids of all samples, and polyunsaturated fats were found only in small amounts.

Similarity of the lipids between Myctophids and some surface pelagic fish species, and the effect of feeding habits on the high content of monoenes in the lipid of Myctophids. In general, fish lipids contain various amounts of many kinds of fatty acids (19); however, consistently high amounts of monoenoic fats are found in the lipids of some pelagic surface fish species such as saury (20), capelin (21,22), sprats (23), and herring (24, 25), whose lipids originate from their prey organisms such as zooplanktons (26–30). Ratnayake and Ackman (24,25) reported that these fishes actively prey on zooplankton, and pointed out that the planktonic fatty alco-

hols are assimilated efficiently and are converted directly to the fatty acids of the above pelagic fish species. Copepods and euphausiids are the most important prey on the basis of biomass, and some copepod species often contain large amounts of wax esters as energy reserves instead of triacylglycerols, and the monoene alcohols are generally the major constituents in the esters (26–30).

On the other hand, it is known that common Myctophids feed primarily on the zooplankton such as euphausiids and copepods, and these diets are diverse and overlap broadly. For example, Tyler and Pearcy (9) reported that the myctophids, such as genus *Diaphus* and *Stenobrachius,* mainly feed on copepod of the genus *Calanus* and euphausiid of the genus *Euphausia.*

In the present paper, the Myctophid species contained triacylglycerols and wax esters, and the fatty acid and alcohol compositions of these lipids were mainly composed of monoenes similar to those of the surface pelagic fish species. It is estimated that these deep-sea fishes accumulate in entirety the wax esters from their prey organisms, or transform the wax esters to the triacylglycerols without synthetic modification such as carbon chain elongation and desaturation of fats. The Myctophid species may prey on similar planktons as the pelagic fishes do because the fats of all the Myctophids examined consisted of 18:1, 20:1, and 22:1, being extremely similar to those of these pelagic fish species. It is suggested that the feeding habits of these eleven species of Myctophids caught in the transition zone between the Oyashio and the Kuroshio may be similar to those of the pelagic fish species such as saury caught in the same sea area, and it is assumed that the monoene fats in the wax esters of copepods, which may have a wide vertical distribution, are the precursors of the monoene fats of the Myctophids.

ACKNOWLEDGMENTS

We thank Yuko Uesugi for her valuable technical assistance. We thank the Marino-Forum 21 and Japan Marine Fishery Resource Research Center for donating all the specimens which made this work possible, and we also thank Prof. Hiroshi Kawaguchi, Ocean Research Institute, Tokyo University, for identification of the deep-sea fishes used.

ABSTRACT: ^{31}P Nuclear magnetic resonance (NMR) spectra of human erythrocyte lysates dissolved in sodium cholate were acquired. The narrow resonances of phospholipids were mostly well resolved, allowing identification and accurate quantitative analysis of phospholipid classes of the erythrocyte membranes. The ether-linked phosphatidylethanolamine components of the erythrocyte membranes were identified, based on the removal of plasmalogens by acidolysis and of diacyl phospholipid species by degradation using phospholipase A_1. It was also shown that the introduction of double bonds on the acyl chains of phosphatidylcholine shifted the ^{31}P NMR resonances to lower frequencies. Quantitative analyses of phospholipids from the spectra were based on their apparent molar concentrations. The recoveries of phospholipids from erythrocytes were significantly higher than those using conventional extraction procedures.

Lipids 31, 765–770 (1996).

The importance of phospholipids in membrane structure and their significant role in many physiological processes are well known (1,2). Quantitative analysis of the phospholipid composition of human erythrocyte membranes is of particular interest in clinical investigations. It has been reported that in hyperlipidemic patients, the ethanolamine plasmalogen content of erythrocyte membranes is significantly decreased and the concentration of sphingomyelin (SPH) increased (3,4). Plasma high density lipoprotein levels in these patients are positively correlated with the content of ethanolamine plasmalogen in the erythrocyte membranes (3). A variation in outer-to-inner lamellar phospholipids of erythrocyte membranes in various clinical disorders, including coronary heart disease, also has been reported (5). These examples indicate why an accurate quantitative determination of individual phospholipid classes in erythrocyte membranes is important.

Abbreviations: Lyso-PC, lysophosphatidylcholine; lyso-PE, lysophosphatidylethanolamine; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; $PC_{s,m}$, saturated and monounsaturated-diacyl phosphatidylcholine; PCp, polyunsaturated-diacyl phosphatidylcholine; PE, phosphatidylethanolamine; PLA_1, phospholipase A_1; PL, phospholipid; PS, phosphatidylserine; SPH, sphingomyelin.

A variety of methods have been employed for the quantitative analysis of phospholipids in erythrocyte membranes including thin-layer chromatography and high-performance liquid chromatography (6–10). These methods are usually multistep and require phospholipid extraction using organic solvent mixtures. ^{31}P and ^{1}H nuclear magnetic resonance (NMR) techniques also have been used for quantitative determination of erythrocyte phospholipids (11,12), but these methods have also involved sample extraction. Extraction of various phospholipids from erythrocyte membranes is time-consuming, and the recovery is usually influenced by the conditions of extraction. It has been shown that widely used solvents do not completely extract all phospholipid classes from erythrocyte membranes and the particular solvents must be selected to optimize the extent of extraction according to the phospholipid classes that are being analyzed (13).

In this study, we have quantified for the first time the concentrations of phospholipid classes in human erythrocyte membranes by using ^{31}P NMR and detergent. The values obtained were compared with those determined by techniques which involve lipid extraction. We have shown that the recoveries of phospholipid classes from erythrocytes were significantly higher by using detergent addition to erythrocytes than by using extraction methods. This novel method is a rapid, simple, one-step procedure, and is significantly more accurate than conventional analyses of erythrocyte phospholipids, which require complicated and time-consuming extractions.

In addition to this novel method of phospholipid quantification of erythrocyte membranes, we have further identified and determined the ether-linked phosphatidylethanolamine (PE) components of erythrocyte membranes based on the removal of plasmalogens by acidolysis and of diacyl phospholipid species by phospholipase A_1 (PLA_1) degradation. The values of PE components of erythrocytes obtained by using hydrolysis were also compared with those obtained by detergent addition to erythrocytes.

MATERIALS AND METHODS

Materials. Cholic acid (sodium salt), phosphatidylcholine (PC), PE, PE with 60% alkenylacyl PE (plasmalogen),

lysophosphatidylcholine (lyso-PC), and phosphatidylserine (PS) were obtained from Sigma Chemical Co. (St. Louis, MO). D_2O (99.75%) was from the Australian Institute of Nuclear Science and Engineering (Lucas Heights, NSW, Australia). Deuterated methanol and chloroform were from Merck (Montreal, Canada). All other reagents were A.R. grade.

Sample preparation. Human erythrocytes were prepared from freshly drawn venous blood from a healthy donor and anticoagulated with heparin [~15 IU (mL whole blood)$^{-1}$]. Erythrocytes were then washed three times in isotonic saline (154 mM NaCl; 277 K, 5 vol). Cell suspensions were adjusted to hematocrits between 0.50 to 0.55 and were then subjected to tip sonication (Model B-12 Sonifier; Branson Sonic Power Co., Danbury, CT) for 10 s. For sodium cholate experiments, 2.5 mL of sonicated erythrocytes were transferred to 10-mm NMR tubes, and 0.5 mL Na cholate (with 5 mM EDTA) in D_2O was added with a final Na cholate concentration of 200 mM. The samples were bath sonicated for 2–5 min prior to NMR measurements. For lipid extractions, 0.5 mL of distilled water was added to 2.5 mL of sonicated erythrocyte sample, and the phospholipids were then extracted using chloroform/isopropanol and chloroform/methanol according to the methods of Rose and Oklander (14) and Bligh and Dyer (15), respectively, and dried under a stream of nitrogen. Dried lipids were dissolved in 3 mL of $CDCl_3/CD_3OD$ (2:1, vol/vol) for NMR measurements.

Hydrolysis of phospholipids. The methods of hydrolysis of plasmalogens and diacyl phospholipids by HCl and PLA_1, respectively, in human erythrocytes were based on those described by Diagne *et al.* (16). Fresh erythrocytes were washed in isotonic saline as described previously, and the lipids were extracted by the method of Rose and Oklander (14). Nonlipid contaminants were removed by partition against water (17), and the total lipid content was weighed. The samples were then divided into four parts and evaporated to dryness under vacuum in round-bottom flasks. One sample (control) was treated with Na cholate as described previously and was transferred to a 10-mm NMR tube. A second sample was inverted over a beaker of concentrated HCl for 10 min, flushed with nitrogen, and placed under vacuum for a further 10 min (HCl hydrolysis). The sample was treated with Na cholate before being transferred to an NMR tube. This procedure degrades the plasmalogen-containing phospholipids. Two other samples were sonicated in 0.2 M Tris-HCl buffer, pH 8.0, containing 2.4 mM sodium deoxycholate (approximately 400 nmol phospholipid per mL) for 30 s. The samples were then incubated for 3 h with a crude preparation of guinea pig pancreatic PLA_1 at 37°C in a shaking water bath. This treatment degrades the diacyl phospholipids, producing 2-acyl-lysophospholipids. The lipase was prepared according to the method of El Tamer *et al.* (18) and passed through a Sephadex G25 column (Pharmacia, Uppsala, Sweden). Sufficient PLA_1 enzyme activity was used in the incubation to completely hydrolyze an amount, similar to that in the extracts, of pure diacyl-PC standard to lyso-PC. After phospholipase treatment, the samples were either freeze-dried overnight or "Folch-washed" (17) and then dried under vacuum. One sample was then subjected to a further hydrolysis by exposure to HCl fumes, leaving only those phospholipids corresponding to the 1-alkyl-2-acyl species. Both samples were then supplemented with sodium cholate and were transferred to NMR tubes.

NMR spectroscopy. ^{31}P NMR spectra were recorded on a Bruker AMX-400 wide-bore spectrometer (Karlsruhe, Germany), operating at 161.98 MHz in the Fourier transform mode, with the probe temperature controlled to 25 ± 1°C. Broad-band proton irradiation was applied to eliminate ^1H–^{31}P NMR coupling. All measurements were done on 3-mL samples in 10-mm NMR tubes with D_2O ($CDCl_3$ in the case of extracts) as the internal field/frequency lock. Samples were spun at 10 Hz. Rapid pulsing using the method of Homer and Roberts (19) was used to acquire the spectra. Each spectrum was derived by Fourier transformation of 1600 summed transients with a spectral accumulation time of ~14 min. Other NMR parameters were as follows: transient-acquisition time, 0.5 s; data size, 16 k; 43° pulse, duration 11.5 μs; pulse delay, 1 ms. For fully relaxed ^{31}P NMR spectra of phospholipid mixtures in sodium cholate, a 24.1 μs (90°) pulse with a 7-s relaxation delay (~5 T_1) was used. No line-broadening was used for processing of the free induction decays of the spectra that are shown here. For T_1 measurements, the sample consisted of 2.4 mM phospholipids, 200 mM sodium cholate, and 1 mM EDTA in D_2O, and the measurements were made by using an inversion recovery pulse sequence with 160 transients per spectrum.

Quantitative analysis of phospholipids. The concentrations of phospholipids were calculated from the spectra by comparing the peak areas (intensities) of phospholipid resonances with those obtained for known concentrations of authentic compounds. In this manner, standard samples were prepared by adding a known mass of lyso-PC in D_2O to the samples that were treated with sodium cholate. The effective molecular weight of lyso-PC was determined by the comparison of the peak area of lyso-PC with that of a known amount of inorganic phosphate (dried at 110°C overnight) in a fully-relaxed ^{31}P NMR spectrum. The T_1 values of various phospholipid standards in sodium cholate at 25°C were measured; the values obtained were very similar, and varied in the narrow range between 1.2 and 1.3 s. However, lyso-PC had a longer T_1 value than the other phospholipids (1.42 s), presumably due to its smaller molecular size. Due to the similarity of the T_1 values and nuclear Overhauser effects (20) of the various phospholipids in mixed micelles, the peak areas in the fully relaxed spectrum remained very similar to those in the spectrum acquired using the rapid-pulsing procedure. However, the ratio between the areas of the lyso-PC in the fully relaxed and rapid-pulsing spectra was 1.1:1; thus, for quantitative analysis of phospholipids, the peak area of lyso-PC was corrected by multiplying by this factor. For quantification of phospholipid concentrations in extracts, PC was used as an internal standard, the effective molecular weight of PC was determined in a similar way to that of lyso-PC. Peak areas were determined using automatic Lorentzian deconvolution

rather than integration, due to the overlapping phosphorus resonances of some of the phospholipids.

RESULTS

^{31}P NMR analysis of erythrocyte phospholipids. A ^{31}P NMR spectrum obtained from a sample of sodium cholate-treated human hemolysate is shown in Figure 1. It is evident that several resonances can be assigned to the various phospholipid classes in human erythrocytes, whereas these resonances are totally absent in the relevant section of the ^{31}P NMR spectrum of untreated human erythrocytes (not shown). The resonances in Figure 1 included those due to inorganic phosphate at 2.76 ppm, SPH at 0.493 ppm, ether-linked PE (alkenylacyl-PE and alkylacyl-PE) at 0.457 ppm, diacyl-PE at 0.431, PS at 0.217 ppm, phosphatidylinositol at –0.01 ppm, $PC_{s,m}$ (saturated and monounsaturated-diacyl PC) at –0.115 ppm and PC_p (polyunsaturated-diacyl PC) at –0.135 ppm. These assignments were confirmed: (i) by adding authentic phospholipids and phosphate to the sodium cholate-treated lysate sample and observing the increase in signal amplitude and intensity; and (ii) by selective hydrolysis of alkenylacyl (plasmalogen) and diacyl phospholipids with HCl and PLA_1, respectively. However, $PC_{s,m}$ and PC_p resonances were only tentatively assigned (21) (mol% of total phospholipids for $PC_{s,m}$ and PC_p were 18.8 ± 1.5 and 11.5 ± 0.9, respectively). Chemical shift assignments were "externally" referenced relative to 85% orthophosphoric acid at 0.000 ppm.

^{31}P NMR spectra of total lipid extracts from human erythrocytes (with an identical hematocrit to that of sodium cholatetreated erythrocytes) in $CDCl_3/CD_3OD$ (2:1, vol/vol) were also obtained (the spectra are shown in Fig. 1) in which only four classes of phospholipid resonances, including PC, PS, SPH, and PE (total), were resolved.

The molar concentrations of individual phospholipid classes of human erythrocytes determined from ^{31}P NMR

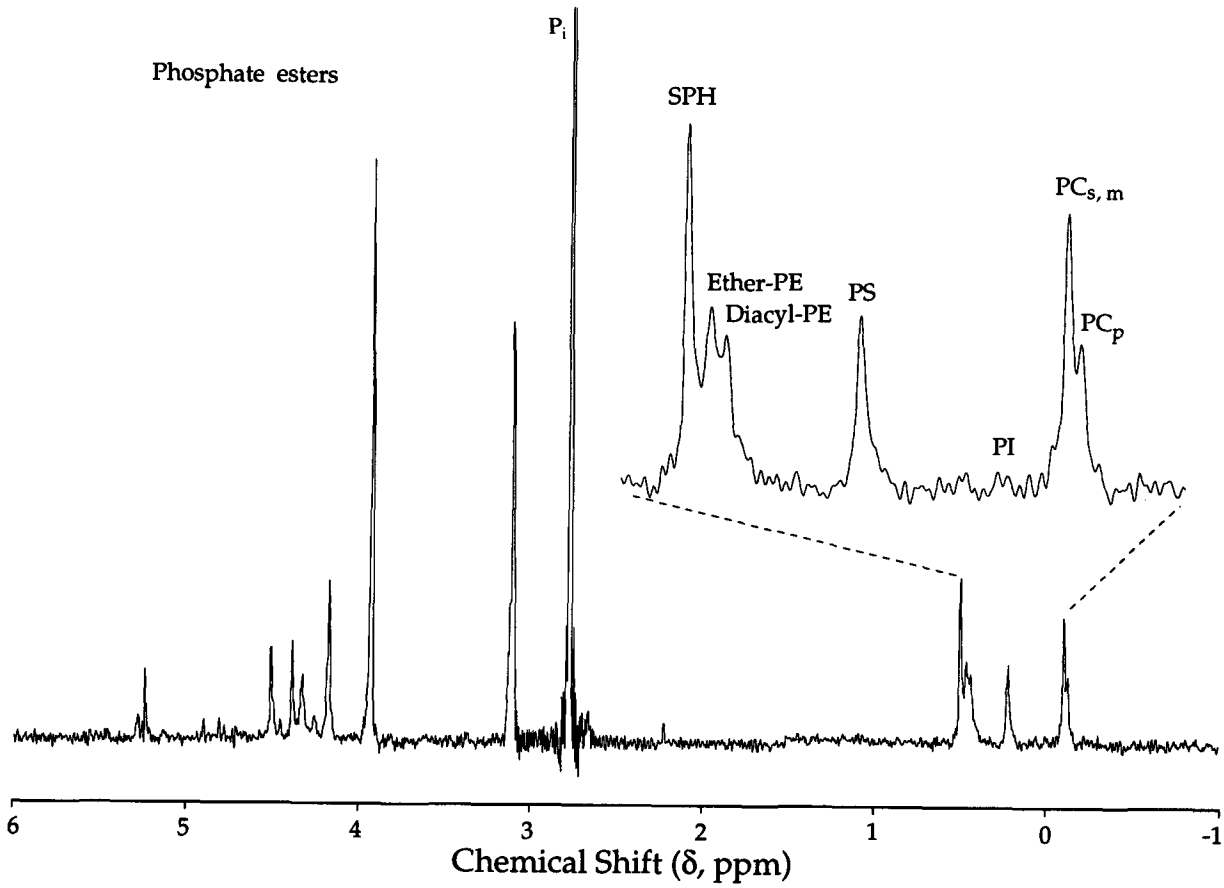

FIG. 1. ^{31}P Nuclear magnetic resonance (NMR) spectrum of sodium cholate-treated human hemolysate. Resonance assignments for the phospholipids indicated on the spectra were confirmed by adding authentic phospholipids to the NMR samples; and selective hydrolysis of alkenylacyl (plasmalogen) and diacyl phospholipids with HCl and phospholipase A_1, respectively. $PC_{s,m}$ and PC_p resonances were tentatively assigned. NMR parameters are given in the Materials and Methods section; pH of samples was ~8. PC_p, polyunsaturated-diacyl phosphatidylcholine; $PC_{s,m}$, saturated and monounsaturated-diacyl phosphatidylcholine; PS, phosphatidylserine; PE, phosphatidylethanolamine; SPH, sphingomyelin; and P_i, inorganic phosphate.

TABLE 1
Comparison of Concentration of Phospholipid Classes from Human Erythrocytes[a] Using Na Cholate Addition and Extraction Methods by ^{31}P Nuclear Magnetic Resonance

	Method		
Phospholipid[b]	Na cholate addition[c]	Rose extraction[d]	Bligh extraction[e]
SPH	689 ± 20 (100%)[f]	640 ± 18 (93%)	545 ± 15 (79%)
Total PE	1040 ± 80 (100%)	804 ± 64 (80%)	670 ± 50 (66%)
PS	446 ± 27 (100%)	326 ± 20 (673%)	165 ± 10 (37%)
Total PC	944 ± 9 (100%)	948 ± 10 (100%)	737 ± 8 (78%)
Total PL	3120 ± 60 (100%)	2720 ± 50 (87%)	2120 ± 40 (68%)

[a]Values are expressed in μmol (L packed erythrocytes)$^{-1}$ ± SD.
[b]SPH, sphingomyelin; PE, phosphatidylethanolamine; PS, phosphatidylserine; PC, phosphatidylcholine; PL, phospholipid.
[c]For details of the experimental procedure see the Materials and Methods section.
[d]Rose and Oklander (Ref. 14). Human erythrocytes were extracted using chloroform/isopropanol (7:11, vol/vol).
[e]Bligh and Dyer (Ref. 15). Human erythrocytes were extracted using chloroform/methanol (2:1, vol/vol).
[f]Relative recovery of phospholipid classes. Recoveries by the sodium cholate addition method were 100% and thus serve as the "standard."

spectra of extracts and sodium cholate-treated erythrocytes are given in Table 1. The recoveries of phospholipids from erythrocytes, assessed by using known amounts of added exogenous phospholipids and sodium cholate additions, were compared with those obtained from extracted erythrocytes. As is evident, the recoveries of the phospholipids were significantly greater with the detergent method.

Identification of ether-linked phospholipids. Figure 2A shows a ^{31}P NMR spectrum of an extract of erythrocytes treated with sodium cholate. The spectrum is virtually identical to that in Figure 1, with a slight improvement in the resolution of ether-linked PE resonances (resonances 2 and 3 belong to alkenylacyl-PE and alkylacyl-PE, respectively). When an acidic treatment by HCl fumes was carried out, only alkenylacyl-PE (resonance 2) disappeared from the spectrum (Fig. 2B); two additional resonances appeared and corresponded to lysophosphatidylethanolamine (lyso-PE) isomers (resonances 2a and 2b) due to the specific splitting of the 1-alkenyl bond. The assignment of the resonances was confirmed by HCl treatment of a mixture of 30% PE and 60% alkenylacyl-PE standard and observing the appearance of lyso-PE resonances. The areas of the alkenylacyl-PE resonance in Figure 2A, and those assigned to lyso-PE in Figure 2B, were also identical. The areas of other phospholipid resonances remained the same, both A and B of Figures. Upon PLA_1 treatments, all resonances assigned to PC, PS, and diacyl-PE disappeared (Fig. 1). The resonances corresponding to the lysoderivatives of most phospholipids were absent in the ^{31}P NMR spectra; this is because the water-miscible lysophospholipids were eliminated during the separation of the aqueous phase by using the Folch method. However, a small amount of lyso-PC was recovered, with the resonance appearing in the PE region of the spectrum, which was superimposed on the alkenylacyl-PE resonance. In order to identify those phospholipids that correspond to the 1-alkyl-2-acyl

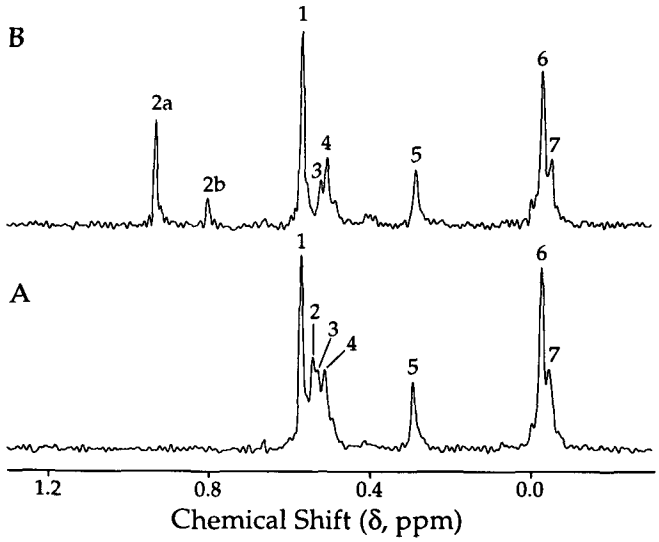

FIG. 2. ^{31}P NMR spectra of erythrocytes extract: A, treated with sodium cholate; B, treated by HCl fumes and then solubilized in sodium cholate. Assignments: 1, SPH; 2, ether-PE; 2a and 2b, lyso-PE isomers; 3, alkylacyl-PE; 4, diacyl-PE; 5, PS; 6, $PC_{s,m}$, 7, PC_p. Abbreviations as in Figure 1. Further experimental details are given in the Materials and Methods section.

species, experiments were also conducted where the samples were subjected to HCl hydrolysis after PLA_1 treatments (samples were freeze-dried overnight after treatment with PLA_1; see the Materials and Methods section). Apart from a resonance that appeared as a shoulder to the lyso-PC resonance in the ^{31}P NMR spectrum which was assigned to the alkylacyl-PE (Fig. 2), no other resonances in Figure 1 were detectable that could correspond to the 1-alkyl-2-acyl species of other phospholipids. Table 2 gives the content of PE of erythrocytes determined directly from ^{31}P NMR spectra of sodium cholate- treated erythrocytes (such as Fig. 1) and those ob-

TABLE 2
Phosphatidylethanolamine Composition (%)[a] of Human Erythrocytes, Obtained by ^{31}P Nuclear Magnetic Resonance (NMR) Analysis

Phosphatidylethanolamine	Determined by hydrolysis[b]	Determined directly[c]
Diacyl	13.2 ± 1.6	12.2 ± 1
Alkenylacyl (plasmalogen)	15.9 ± 0.6	—
Alkylacyl	2.5 ± 0.4	—
Ether-linked (alkenylacyl + alkylacyl)	18.4 ± 0.5	21.2 ± 1.7
Total	32 ± 1.8	33 ± 2.7

[a]Values are expressed as mol% ± SD of total phospholipids and are the average of three determinations on the same blood sample.
[b]Values were determined by hydrolysis of erythrocytes extract using HCl and PLA_1. For details of the experimental procedure, see the Materials and Methods section.
[c]Values were determined directly by dissolving erythrocyte lysates in detergent and acquiring ^{31}P NMR spectra.

tained from ^{31}P NMR spectra of erythrocyte extracts hydrolyzed with HCl (such as Fig. 2B). As can be seen, the values obtained for diacyl and ether-linked PE were similar.

DISCUSSION

Detergent was used in conjunction with ^{31}P NMR for the quantitative analysis of the phospholipid composition of human erythrocytes. The "detection levels" of phospholipids obtained with extraction of erythrocytes were significantly lower than those obtained by using the method of sodium cholate addition (Table 1). It has been shown by Eder *et al.* (13) that the recoveries of phospholipids from erythrocytes by using various extraction methods are influenced by the nature of the solvents, the duration of extraction, the temperature of extraction, and mechanical treatment of the sample. They also observed that recoveries of PC and SPH are not influenced by the conditions of extraction as much as those of PS and PE. It seems that this is related to the specific location of the phospholipids in the membrane; PC and SPH are located primarily in the outer leaflet of the bilayer, whereas PE and PS are located in the inner leaflet (13,22). A higher portion of saturated fatty acids in PC and SPH may be an additional factor influencing the higher extent of recovery of these phospholipids (13). Indeed, our present results show (Table 1) that by using extraction (chloroform/isopropanol, 7:11), only PC and SPH have high recoveries and these are comparable with those obtained by sodium cholate addition to the erythrocytes. The recoveries of PS and PE, on the other hand, were very poor by extraction (Table 1), especially using the Bligh and Dyer method (15) (chloroform/methanol, 2:1, vol/vol). Apart from differences in extraction conditions, the Bligh and Dyer method (15) requires filtration and phase separation, whereas in the Rose and Oklander method (14) (if NMR is used for analysis), the extract can be sampled directly without separation. For extraction of phospholipids from erythrocytes, Eder *et al.* (13) used ten binary and single-solvent systems with different extraction conditions. They concluded that, although the widely used methods gave incomplete extraction of all phospholipid classes from erythrocytes, hexane/isopropanol (3:2, vol/vol) is the most suitable solvent mixture for extraction of all phospholipids; and boiling of the sample during its processing is required for complete extraction of PE and PS. In the present study, for the comparison of recoveries of erythrocyte phospholipids (between detergent addition and extraction methods), we selected the most widely used extraction procedures (see the Materials and Methods section). Thus, we conclude that the extraction methods applied to erythrocytes may not reliably yield quantitative results of most erythrocyte phospholipid classes.

Although detergents such as Triton X-100 and sodium cholate have already been used for phospholipid analysis of human blood plasma (17,23,24) and amniotic fluid (21), the use of detergents for quantitative analysis of cell membrane phospholipids has not been reported by other workers (see our recent application to the analysis of animal red cell membranes; Ref. 25). The chemical shifts of phospholipids in Figure 1 are in good agreement with those reported by others for phospholipid micelles in detergent (21–23). The chemical shifts are also pH dependent, due to the state of ionization of the phosphate groups (24); however, between pH ~3 and ~9, they are unchanged (24). The narrow ^{31}P NMR line widths of erythrocyte phospholipids in sodium cholate (Fig. 1), which result from efficient averaging of chemical shift anisotropy and of dipolar interactions in small micelles (24), allow the individual phospholipid resonances to be at least moderately well resolved.

Although by acidic hydrolysis of alkenylacyl-PE, 2-acyl-lyso PE was expected to be the product, and we observed the appearance of two resonances (Fig. 2B) that were separated by 0.13 ppm. These two resonances also appeared with HCl treatment of standard alkenylacyl-PE. The rearrangement of lysophospholipids *via* acyl and phosphoryl migration has been reported (26). Plückthun and Dennis (26) by using ^{31}P NMR have shown that, at alkaline pH values, lysophospholipids can exist in the form of 1-acyl and 2-acyl isomers. At acidic pH values, however, several compounds were formed from 2-acyl PC, due to the hydrolysis of the choline group, acyl hydrolysis and migration, and phosphoryl migration. They were unable to identify all the migration products at acidic pH, partly because of some signal overlap and partly due to the complexity of the reactions. Our aim in this study was only to identify the plasmalogen content of PE by acidic hydrolysis; thus, we assigned the resonances in Figure 2B as lyso-PE isomers.

$PC_{s,m}$ and PC_p resonances in Figure 1 were tentatively assigned to saturated + monounsaturated and polyunsaturated acyl-PC, respectively. Pearce and Komoroski (21) have shown that the presence of double bonds in the acyl chains of phospholipids (dissolved in bile salts) induces small, but consistent, low frequency (upfield) shifts relative to the corresponding disaturated acyl phospholipid ^{31}P NMR signals. They proposed that the composite PC signal can be segre-

gated into three regions, starting at lower field-disaturated acyl PC, saturated–unsaturated acyl PC, and diunsaturated PC, with the resonances separated by 0.02 ppm from each other. PC_p resonates at 0.02 ppm to low frequency (upfield) from $PC_{s,m}$ (Fig. 1), with the percentages of PC_p and $PC_{s,m}$ to total PC being 62 and 38%, respectively. These values also were similar to those that had been reported by others (27,28). The fatty acid contents of $PC_{s,m}$ and PC_p in human erythrocytes are predominantly 16:0, 18:0, 18:1 and 18:2, 20:4, respectively (27,28). Except for a small amount of linoleic acid in position 1, all the polyunsaturated fatty acids are located in position 2 (28).

The resonances for diacyl PE (unlike those for diacyl PC) were unresolved (Fig. 1). This was probably because the acyl chains of PE (and of PS) in human erythrocyte membranes are highly unsaturated compared with those of PC (28). On the other hand, the effect of acyl unsaturation on the chemical shift of the diacyl PE resonance is smaller than that on the chemical shift of the diacyl PC resonance in detergent (21). However, the small overlapping resonances, to low frequency from diacyl PE and PS (Fig. 1), may belong to their polyunsaturated fatty acid species as these phospholipids contain high amounts of 20:4 fatty acids (28).

In conclusion, we present here a convenient ^{31}P NMR method for quantitative analysis of phospholipid classes in human erythrocytes using sodium cholate to bring about spectral resolution. The significant advantages of this method are its speed, accuracy, and simplicity. The method needs minimal sample handling and the whole spectral analysis can be done in a very short time (~14 min). These features make the method ideal for studying the individual phospholipid changes in erythrocytes from humans and other animals, and presumably also in other cells, and should be valuable in clinical investigations for diagnosis of various diseases, especially cardiovascular ones.

ACKNOWLEDGMENTS

The work was supported by a grant from the Australian NH&MRC to P.W.K., and The Royal Prince Alfred Hospital Research Fund to M.H.N.-S., P.W.K., and D.R.S. Prof. W.J. n-3 Polyunsaturated Fatty Acid-Induced Changes in the Molecular Species Composition of Diradylglycerol in Murine Peritoneal Macrophages Remain Stable During Incubation *ex vivo*

Paola A. Marignani and Rolf J. Sebaldt*

Department of Medicine, Faculty of Health Sciences, McMaster University, Hamilton, Ontario L8N 4A6, Canada

ABSTRACT: Three- to four-week-old C57BL/6 mice were maintained for four weeks on diets in which the 10% lipid component was the ethyl esters of either corn oil or n-3 polyunsaturated fatty acids (n-3 PUFA). Incubation of macrophages *ex vivo* for 14 h, a normal incubation time used for macrophage studies, in the absence of fetal calf serum, did not diminish the extent of incorporation of 20:5n-3 (eicosapentaenoic acid) and 22:6n-3 (docosahexaenoic acid) moieties into membrane phospholipids and into diradylglycerol (DG) relative to that after a very abbreviated incubation time. We conclude that studies examining the effects of dietary n-3 PUFA on DG formation and related physiological effects in macrophages can be performed after a normal *ex vivo* incubation of at least 14 h without experiencing a significant loss of incorporated n-3 PUFA.
Lipids 31, 771–776 (1996).

Humans are incapable of *de novo* synthesis of n-3 polyunsaturated fatty acids (PUFA) such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Incorporation of these PUFA into cell membrane lipids reflects their dietary intake (1–3). However, functional studies on lipid second messengers conducted *ex vivo* after manipulation of dietary PUFA content are potentially problematic because a rapid loss of the diet-induced changes in fatty acid composition might occur during the customary prolonged (12–16 h) incubation of adhered macrophage monolayers *ex vivo* (4–8). A number of physiological functions of macrophages require 8–16 h incubation *ex vivo* to reach stable basal levels (4), but the stability of phospholipid (PL) and diradylglycerol (DG) molecular species compositions over this prolonged interval is unknown. In the present study, we investigated to what extent previously described dietary n-3 PUFA-induced changes in PL and DG molecular species in murine peritoneal macrophages (3) remain stable after a customary prolonged incubation period *ex vivo* relative to a much more abbreviated incubation. Our results define a basis of validity on which functional studies of the effects of dietary n-3 PUFA may be performed *ex vivo*.

Abbreviations: AA, arachidonic acid; COEE, corn oil ethyl ester concentrate; DG, diradylglycerol; dfcs, heat-deactivated fetal calf serum; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PL, phospholipids; PMA, phorbol myristate acetate; PUFA, polyunsaturated fatty acids; n-3EE, n-3 fatty acid ethyl ester concentrate†.

MATERIALS AND METHODS

Animal care and diets. Ethyl ester concentrates were graciously supplied by the NIH/NOAA Fish Oil Test Materials Program (Charleston, SC). Pathogen-free 3–4-week-old C57BL/6 mice (4–5/cage) (Charles River Laboratory, Montreal, Quebec, Canada) were assigned to either corn oil ethyl ester concentrate (COEE) or n-3 fatty acid ethyl ester (n-3EE) diet groups for four weeks, as previously described (3), and allowed access to food and water *ad libitum*. Mice were individually weighed on day 0 and weekly thereafter to monitor growth.

Macrophage culture and stimulation. Mice were injected intraperitoneally with 1 mL brewer's thioglycollate (DIFCO, Detroit, MI). Macrophages were harvested and washed as described previously (3). For quantitative analyses of total DG mass, macrophage monolayers (2×10^6/9.62 cm^2 well) were adhered for 2 h, washed and cultured for an additional 2 h (abbreviated incubation) or 14 h (standard incubation). For DG and PL molecular species analyses, macrophage monolayers (15×10^6/16 cm^2 well) were similarly adhered and incubated. The culture medium was RPMI 1640 with (+dfcs) or without (–dfcs) 10% heat-deactivated fetal calf serum (dfcs), as indicated. Macrophage monolayers were then washed with Hank's Balanced Salt Solution containing 10 mmol/L HEPES, pH 7.4, and were stimulated for 10 min with either (PAF) (0.1 μM), ionomycin (10 μM), phorbol myristate acetate (PMA) (0.1 μg/mL), or HEPES-buffered Hank's Balanced Salt Solution control, as described previously (3). All conditions were repeated in duplicate or triplicate wells for each experiment.

Lipid analyses. Lipids were extracted by the Bligh and Dyer method (9). For total DG mass, DG was derivatized to

Copyright © 1996 by AOCS Press

phosphatidic acid, purified by thin-layer chromatography, and quantitated as described previously (3). For DG molecular species composition, DG was derivatized to dimethylphosphatidic acid and separated into molecular species fractions by argentation thin-layer chromatography as described (3). PL classes were separated and hydrolyzed to DG, then further analyzed as DG for molecular species fractions.

Statistical analysis. Results are expressed as mean ± SEM or as mean and range, as indicated. Statistical significance of differences between experimental conditions was tested by Student's two-tailed *t*-test using the Fig.P computer program (version 6.0c; Biosoft, Cambridge, United Kingdom).

RESULTS

Animal growth. Mice gained approximately 12 g after four weeks in both the n-3EE and COEE diet groups. Between diet groups, weights were not statistically significant at baseline or at weekly weighings.

The effects of incubation time, with and without fetal calf serum, on the total mass of DG. Mice were fed either n-3EE or COEE diets for four weeks, after which peritoneal macrophages were elicited, harvested, adhered for 2 h, and incubated *ex vivo* for an abbreviated (2-h) or a standard (14-h) duration, in either +dfcs or -dfcs medium. Macrophages were then left unstimulated to determine total basal DG mass or stimulated with PAF (0.1 μM) for 10 min. In the n-3EE diet group (Fig. 1A), basal DG mass was lower after the abbreviated than after the standard incubation time in both –dfcs medium (27.7 ± 1.7 pmol/10^6 macrophages compared to 31.9 ± 2.9, n.s.) and in +dfcs medium (30.5 ± 0.1 pmol/10^6 macrophages compared to 39.8 ± 0.9, $P < 0.05$). Similarly, after macrophage stimulation with PAF (Fig. 1A), DG mass was lower after abbreviated than after standard incubation time in both –dfcs medium (43.7 ± 5.4 pmol/10^6 macrophages compared to 45.6 ± 10.8, n.s.) and in +dfcs medium (66.5 ± 1.1 pmol/10^6 macrophages compared to 77.3 ± 8.1, $P < 0.05$). However, in the COEE diet group (Fig. 1B), both basal and PAF-stimulated DG mass were similar after abbreviated and standard incubation times in both -dfcs and +dfcs media.

The effects of incubation time, with and without fetal calf serum, on the molecular species composition of DG. Macrophages were prepared, incubated, and stimulated as described. Under both basal and PAF-stimulated conditions, our results (Fig. 2) generally show that the proportions of molecular species of DG after the standard incubation time did not differ significantly from the proportions present after only the abbreviated incubation time. Exceptions to this were seen only in +dfcs medium as follows: (i) In the n-3EE diet group (Fig. 2A), the fraction of basal DG with five double bonds (containing EPA) was 36.1–36.5 mol% after abbreviated incubation in +dfcs medium, but was lower by about 17% (30.7–30.9 mol%) after standard incubation (Fig. 2A,b). This difference was associated with a reciprocal change in DG species with four double bonds [containing arachidonic acid (AA)], whose proportion was 20.7–21.0 mol% after abbreviated incubation, but was 19% higher (26.6–28.7 mol%) after standard incubation (Fig. 2A,a). (ii) In the COEE diet group (Fig. 2B), the fraction of basal DG with four double bonds (containing AA) was 40.7–43.1 mol% after abbreviated incubation in +dfcs medium, but was 25% higher (54.2–57.4 mol%) after standard incubation (Fig. 2B,a). This difference was associated with a reciprocal change in the fraction of DG with six double bonds (containing DHA), which was 5.3–6.2

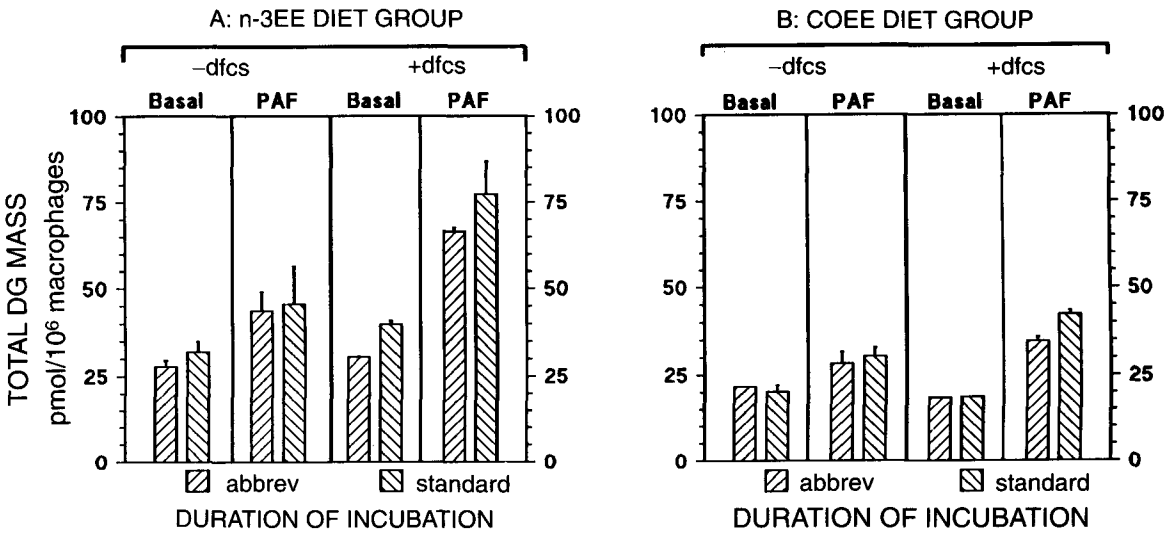

FIG. 1. The effects of incubation time in the presence and absence of heat-deactivated fetal calf serum (dfcs) on the total mass of diradylglycerol (DG) in murine peritoneal macrophages. Mice were fed diets containing either A: n-3 fatty acid ethyl ester concentrate (n-3EE) or B: corn oil ethyl ester concentrate (COEE) for four weeks. Macrophages were harvested, adhered for 2 h, incubated for an additional 2 (abbrev) or 14 (standard) h in either the absence (–dfcs) or the presence (+dfcs) of fetal calf serum in the culture media, and assayed for DG mass either under basal conditions or after a 10-min 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF) stimulation, as described in the Materials and Methods section. Results are expressed as pmol DG/10^6 macrophages, mean ± SEM ($n = 4$).

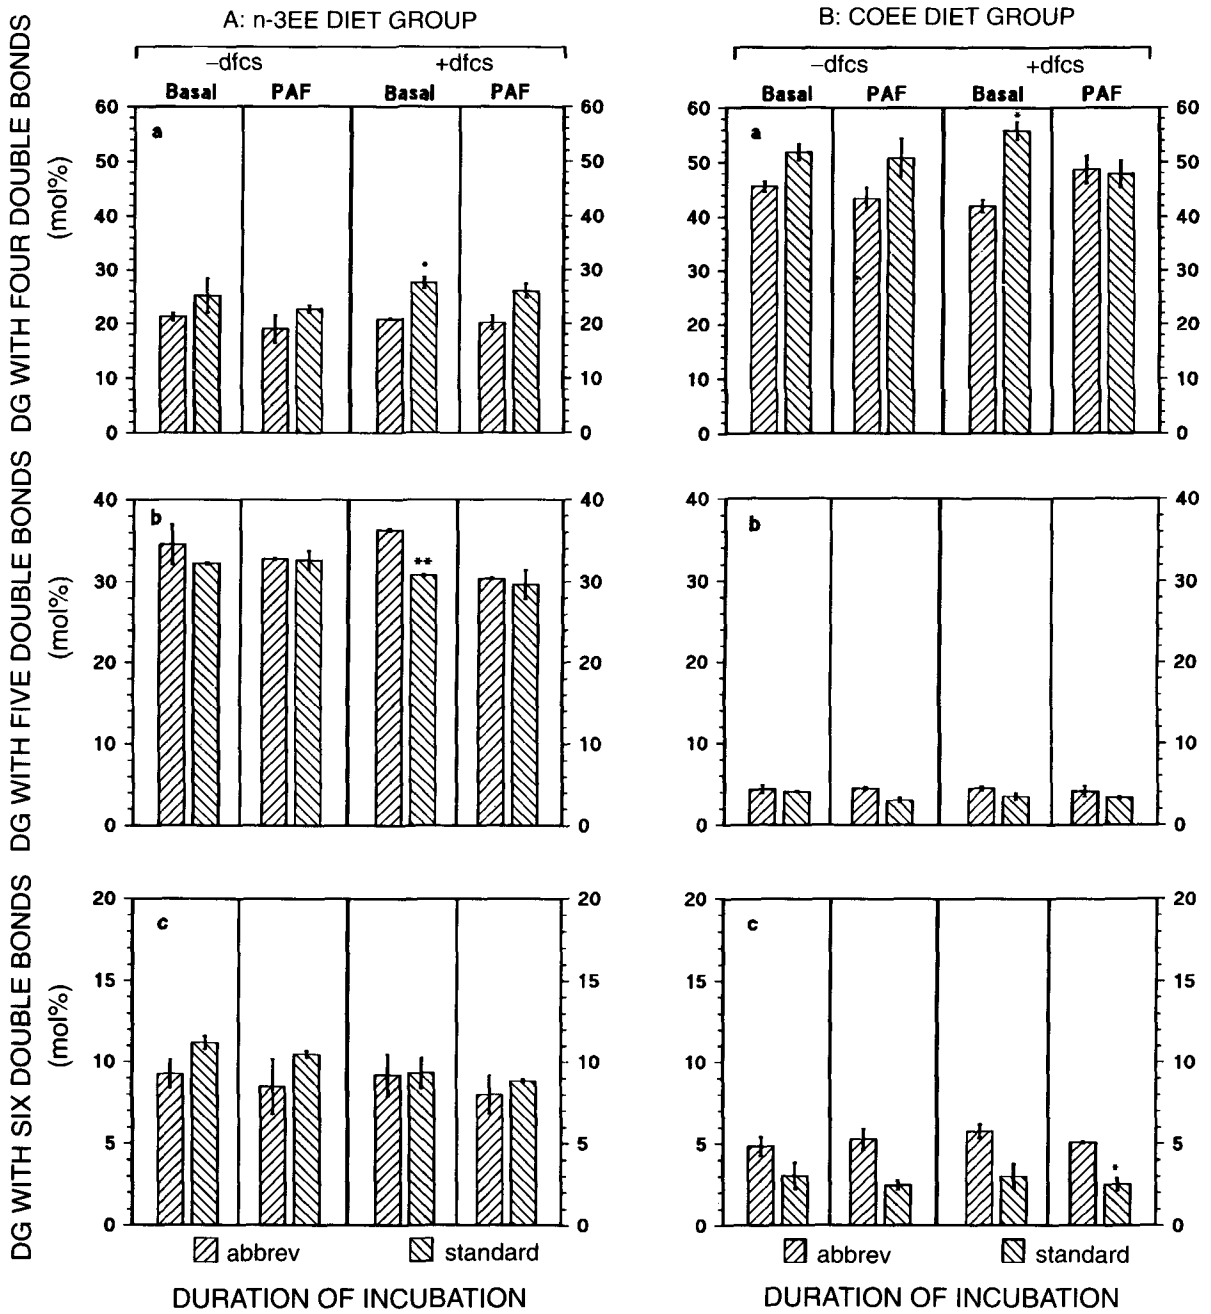

FIG. 2. The effects of incubation time in the presence and absence of dfcs on the molecular species composition of DG in murine peritoneal macrophages. Mice were fed diets containing either A: n-3EE or B: COEE for four weeks. Macrophages were prepared as in Figure 1 and assayed for DG molecular species composition, as described in the Materials and Methods section. Results for basal and for PAF-stimulated DG after 2 (abbrev) or 14 (standard) h of incubation without (–dfcs) or with (+dfcs) fetal calf serum are shown for molecular species fractions with (a) four, (b) five, and (c) six double bonds. Results are expressed as mol% of total DG, mean and range (n = 2). See Figure 1 for other abbreviations.

mol% after abbreviated incubation, but was lower by approximately 50% (2.3–3.8 mol%) after the standard incubation time (Fig. 2B,c). In summary, significant differences in the molecular species composition of DG were not found between abbreviated and standard incubation times unless dfcs was present in the culture media.

These results confirmed our concerns that supplementation of culture media with dfcs may alter the molecular species composition of DG that results from a diet with a controlled lipid content. The remaining experiments were therefore conducted using –dfcs medium. Our results (Fig. 3) show that within each diet group and for each macrophage stimulus, the distinctive proportions of DG molecular species with four, five, and six double bonds measured after standard incubation were not significantly different from those measured after abbreviated incubation. An isolated exception is the results with PMA stimulation in the COEE diet group (Fig. 3B,a), where the mol% of species with four double bonds

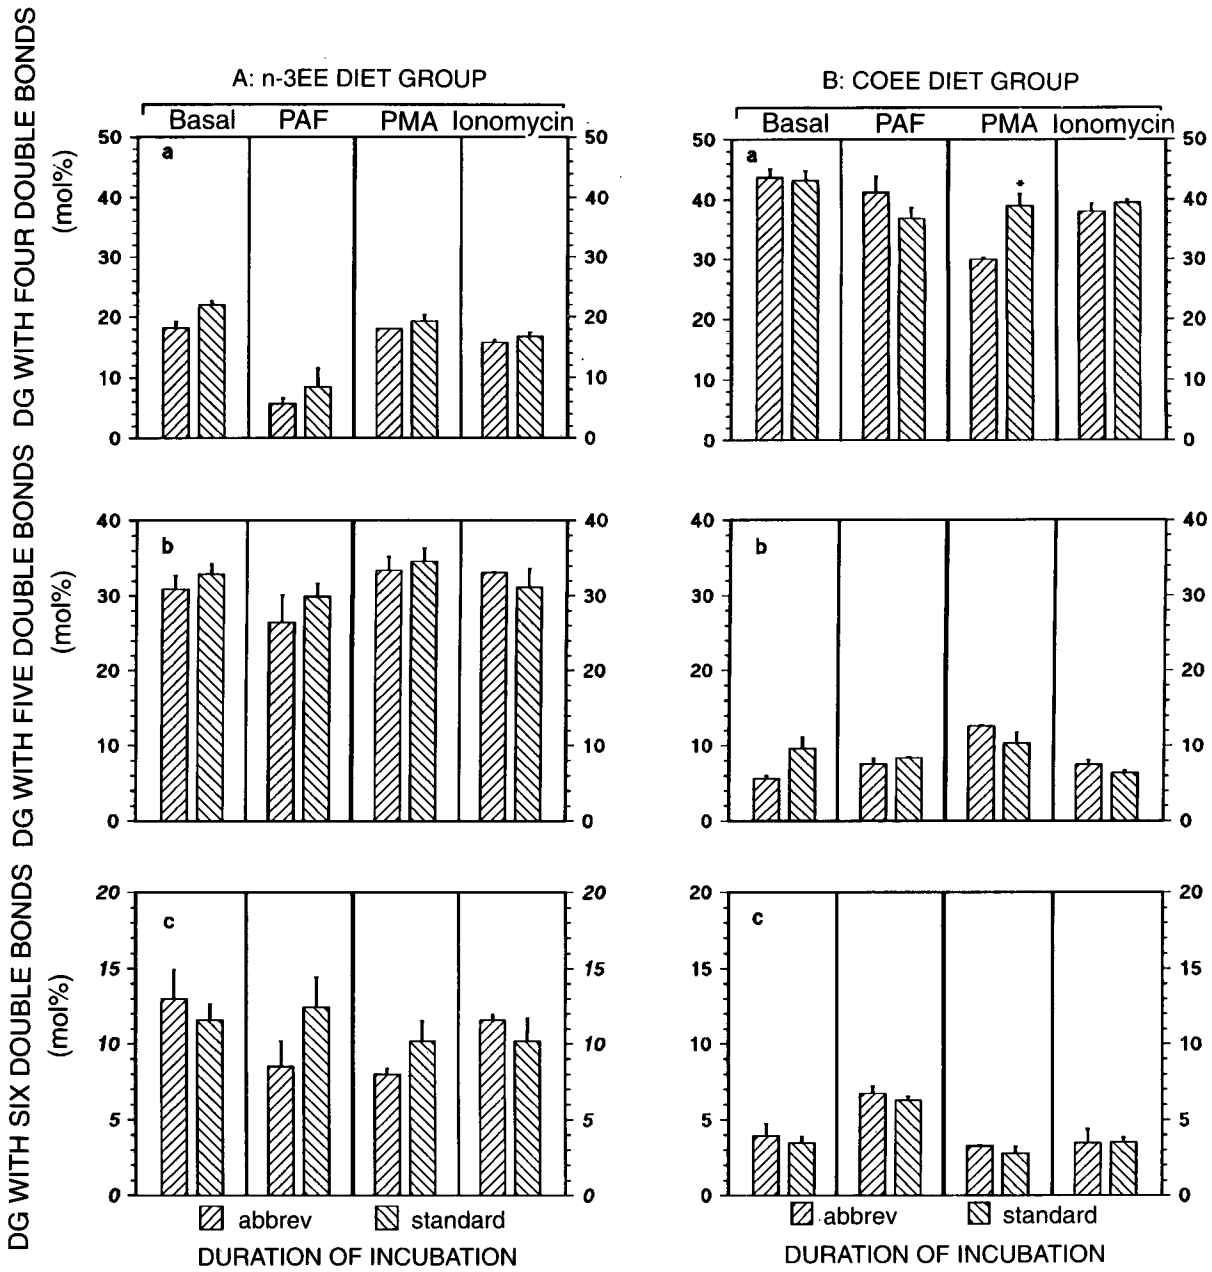

FIG. 3. The effects of incubation time on the molecular species composition of DG in variously stimulated murine peritoneal macrophages. Mice were fed diets containing A: n-3EE or B: COEE for four weeks. Macrophages were harvested, adhered for 2 h, incubated in media without dfcs for an additional 2 (abbrev) or 14 (standard) h and stimulated as described in the Materials and Methods section. Molecular species compositions of DG were analyzed as described in the Materials and Methods section. Results are shown for basal (n = 18) and agonist-stimulated conditions [PAF, 0.1 μM; phorbol myristate acetate (PMA), 0.1 μg/mL; and ionomycin, 10 μM; n = 6 each] for species with (a) four, (b) five, and (c) six double bonds. Results are expressed as mol% of total DG, mean ± SEM. *$P < 0.02$ relative to 2-h incubation. See Figure 1 for other abbreviations.

after abbreviated incubation (30 mol%) was lower than after standard incubation (40 mol%), the difference being due to a greater fraction of species with lesser degrees of unsaturation.

The effects of incubation time on the molecular species composition of PL classes. As DG is formed from membrane PL, and the results show a stability of DG molecular species composition over a period of standard incubation *ex vivo*, we wished to determine whether a corresponding stability of the dietary n-3 PUFA-induced changes in membrane PL also could be demonstrated.

Murine peritoneal macrophages were prepared after four weeks of either n-3EE or COEE diets, as described in the Materials and Methods section. After 2-h adherence and additional incubation *ex vivo* without dfcs for either an abbreviated (2-h) or a standard (14-h) duration, membrane PL classes phosphatidylcholine (n = 12), phosphatidylinositol (n = 8),

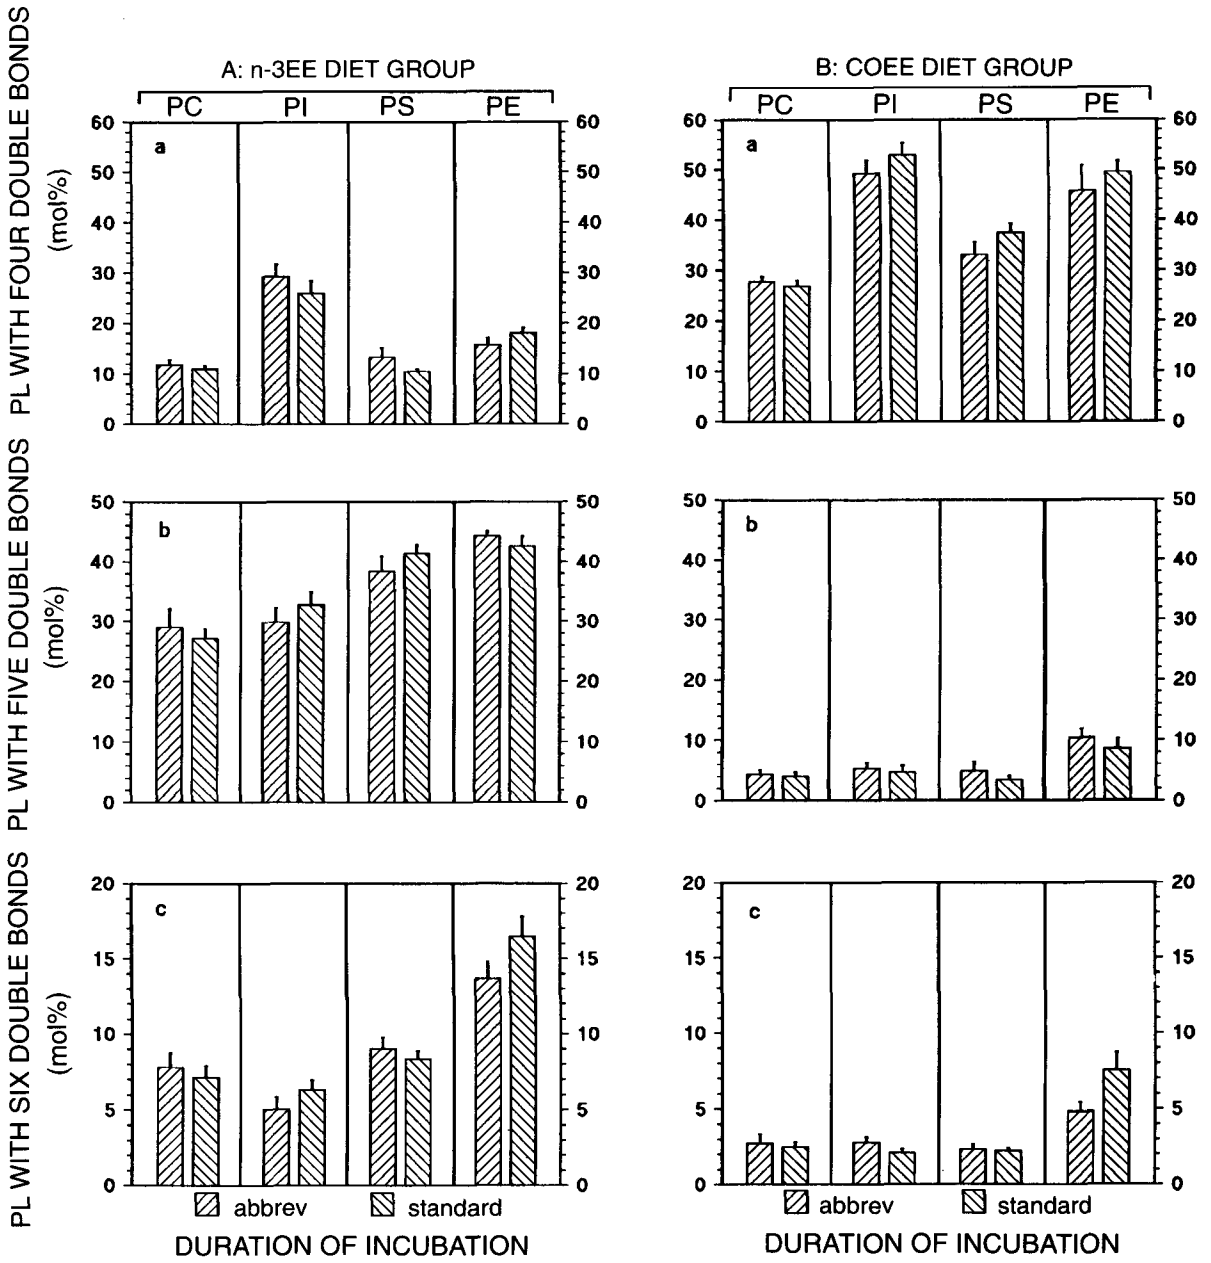

FIG. 4. The effects of incubation time on the molecular species composition of phospholipid (PL) classes in murine peritoneal macrophages. Mice were fed diets containing A: n-3EE or B: COEE for four weeks. Macrophages were prepared as in Figure 3 and incubated in media without dfcs for 2 (abbrev) or 14 (standard) h. PL classes were separated, and their molecular species compositions were analyzed as described in the Materials and Methods section. Results are shown for phosphatidylcholine (PC; $n = 12$), phosphatidylinositol (PI; $n = 8$), phosphatidylserine (PS; $n = 8$), and phosphatidylethanolamine (PE; $n = 10$) for species with (a) four, (b) five, and (c) six double bonds. Results are expressed as mol% of each PL, mean ± SEM. See Figure 1 for other abbreviations.

phosphatidylserine ($n = 8$), and phosphatidylethanolamine ($n = 10$) were extracted, separated, and analyzed for molecular species fractions (Fig. 4). Characteristic differences between the PL classes in their molecular species profiles are as previously described (3). For each PL class, however, the characteristic species distribution found after abbreviated incubation remained entirely preserved after standard incubation. No discernible trend over time was observed within any PL class in any molecular species fraction, in either the n-3EE (Fig. 3A) or the COEE (Fig. 3B) diet group. These results show that dietary n-3 PUFA-induced enrichment of macrophage membrane PL with EPA and DHA does not significantly degrade over the standard *ex vivo* incubation time.

DISCUSSION

It is a significant concern that cell membrane lipid modifications achieved by dietary changes *in vivo* might quickly be lost during incubation of cells in *ex vivo* experiments. In the current study, we characterized the effects of incubation time *ex vivo* on molecular species distributions of DG and PL.

We found that the total DG mass in macrophages in the n-3EE diet group tended to be greater after the standard than after the abbreviated incubation when dfcs was present in the culture media. It was stable under most other conditions (Fig. 1A). However, many other normal physiological functions of macrophages equilibrate only after several hours of incubation *ex vivo* (4). Our results (Fig. 1) suggest that total DG mass is similarly not yet stable after abbreviated incubation (2 h), particularly if dfcs is present in the culture media. For this reason, it is often important that macrophage monolayers not be studied *ex vivo* immediately after achieving adherence.

Molecular species of DG with EPA at the *sn*-2 position were diminished after standard incubation *ex vivo* in +dfcs medium, relative to abbreviated incubation, but this diminution was abolished in -dfcs medium (Fig. 2A,b). Furthermore, under both basal conditions and after stimulation of macrophages with either the physiological agonist, PAF, the tumor-promoting phorbol ester, PMA, or the divalent cation ionophore, ionomycin, we found that the proportions of DG molecular species studied in –dfcs medium were not different if the duration of *ex vivo* incubation was abbreviated to 2 h or was a standard 14 h (Fig. 3). Molecular species profiles of the PL classes phosphatidylcholine, phosphatidylinositol, phosphatidylserine, and phosphatidylethanolamine were similarly stable over the duration of the standard incubation (Fig. 4). In other words, there was no evidence of degradation of the lipid modifications that had previously been achieved *in vivo*. This PL stability presumably underlies the stability of the DG molecular species profiles discussed here.

We conclude that, at least under the conditions reported in this study, lipid modifications of macrophage membranes that are achieved *in vivo* after four weeks of dietary enrichment with n-3 PUFA are not lost *ex vivo* to any significant degree over the standard 14-h incubation time. These observations validate the use of *ex vivo* studies of macrophages to assess functional implications of dietary n-3 PUFA enrichment at the cellular level.

Phosphatidate Phosphatases of Mammals, Yeast, and Higher Plants

Michael G. Kocsis and Randall J. Weselake*

Department of Chemistry, University of Lethbridge, Lethbridge, Alberta T1K 3M4, Canada

ABSTRACT: Phosphatidate phosphatase (EC 3.1.3.4) catalyzes the hydrolysis of phosphatidate to yield *sn*-1,2-diacylglycerol and inorganic phosphate. In mammalian systems, forms of phosphatidate phosphatase involved in glycerolipid synthesis and signal transduction have been identified. Forms of the enzyme involved in signal transduction have been purified and partially characterized. In yeast, phosphatidate phosphatases associated with the endoplasmic reticulum and mitochondria have also been purified and partially characterized. Information on phosphatidate phosphatases from mammals and yeast is useful in characterizing the enzyme from plant systems. This review examines progress on the characterization of phosphatidate phosphatases from mammals, yeast, and higher plants. The purification and characterization of the phosphatidate phosphatase involved in glycerolipid synthesis in developing oilseeds may lead to the identification of the encoding gene. Increasing our understanding of the enzymes of lipid synthesis in developing seeds will aid in the development of biotechnological strategies for seed oil modification.
Lipids 31, 785–802 (1996).

Phosphatidate (PA) phosphatase (also called PA phosphohydrolase) (EC 3.1.3.4) catalyzes the hydrolysis of PA to generate *sn*-1,2-diacylglycerol (DG) and P_i (1). DG produced from the hydrolysis of PA is not only a direct precursor of triacylglycerol (TG), but also a substrate for the synthesis of membrane phospholipids (1,2). PA phosphatases involved in glycerolipid synthesis appear to exist in both soluble and particulate forms, with the distribution of these forms being affected by metabolic status (3,4). The intracellular translocation of PA phosphatase may help to regulate lipid metabolism (3). In mammalian systems, other forms of PA phosphatase have been identified which appear to be involved in signal transduction (5–7). The characterization of PA phosphatases from mammalian and yeast systems, however, is considerably more advanced than our understanding of forms of the enzyme in higher plant systems.

Developments in various areas of mammalian and microbial biochemistry often precede the development of our understanding of equivalent systems from plants. A major objective of this review is to integrate literature on eukaryotic PA phosphatases with the intention of providing a useful resource for plant lipid biochemists, physiologists, and biotechnologists involved in studying aspects of glycerolipid metabolism. We do anticipate, however, that the information in this review will also be useful to lipid biochemists in general. The properties of mammalian and yeast PA phosphatases are examined first, followed by a discussion of glycerolipid synthesis and PA phosphatases in higher plants.

MAMMALIAN PA PHOSPHATASES

PA phosphatase involved in glycerolipid metabolism. Extensive studies have been conducted on mammalian PA phosphatases involved in glycerolipid synthesis, but this review deals only with certain aspects of the literature. The microsomal form of PA phosphatase, which is mainly involved in glycerolipid metabolism, has been been referred to as PA phosphatase-1 (8,9). The enzyme translocates from the cytosol to the endoplasmic reticulum (ER) to become functionally active (8), has an absolute Mg^{2+} requirement (9), and is selectively inactivated by the thioreactive reagent, *N*-ethylmaleimide (NEM) (10). PA phosphatase-1 has not been purified to homogeneity from any mammalian source. PA phosphatase-1 activity, however, has been extensively characterized using several different tissues of mammalian origin (see Refs. 11–13 for reviews), including human adipose tissue (14).

Synthesis of the rat liver enzyme has been shown to be stimulated by glucagon, glucocorticoids, cAMP, and growth hormone (15–17); this action was antagonized by insulin (16). The level of PA phosphatase also seemed to be stabilized or maintained by glucagon, whereas insulin decreased the half-life of this activity (10,11). Humble and Berglund (18) have demonstrated that cytosolic PA phosphatase activity from rat liver could be influenced by a number of phospholipids when they were included with emulsions of PA. This suggested that

changes in the lipid environment may possibly play a role in modulating PA phosphatase activity *in vivo*. Berglund *et al.* (19) presented some evidence to support deactivation of PA phosphatase-1 by phosphorylation, but Butterwith *et al.* (20) were not able to confirm the findings.

The metabolic expression of PA phosphatase-1 activity is thought to be regulated by the ability of the cytosolic form to translocate to the ER, where its substrate is being generated (3,17,21). In rat liver, this intracellular movement seemed to be controlled mainly by the accumulation of fatty acids (22) and acyl-CoA esters (23) on the ER membranes. According to Hopewell *et al.* (21) and others (1,3,11), the binding of long-chain fatty acids and their CoA esters to the ER, as well as the accumulation of PA in this compartment, acts as a signal for more PA phosphatase to associate with the membranes, and thereby enhances the synthesis of glycerolipids, especially TG. It has been suggested that the translocation of PA phosphatase probably depends on the increased negative charge conferred to the ER membranes by these compounds (21), serving to activate PA phosphatase in order to match the rate of TG synthesis to the supply of fatty acids (3,17). Spermine also facilitated the association of PA phosphatase with the membranes of the ER (24), and its effect was synergistic with fatty acids in this respect (25). It appears that spermine may promote the association of hydrophobic proteins with lipids and membranes (21,26), possibly by forming complexes with acyl-CoA *in vivo* (24), and also by causing the aggregation of microsomal membranes *in vitro* (21). ADP, GDP, and CDP have been shown to activate rat liver phosphatase-1, whereas ATP was inhibitory (27). Short-term treatment with the amphipathic cationic drug, chlorpromazine, decreased the rate of TG and phosphatidylcholine (PC) biosynthesis in isolated rat hepatocytes, and decreased the rate of DG formation in a cell-free system of rat liver by displacing PA phosphatase from the microsomal membranes and also by preventing the soluble form of PA phosphatase from interacting with these membranes (21,28). Hopewell *et al.* (21) have indicated that chlorpromazine could oppose the intracellular translocation of PA phosphatase by donating a positive charge to the membranes. Additionally, there is some evidence that the regulation of PA phosphatase activity may be coordinated with that of CTP-phosphocholine cytidylyltransferase (EC 2.7.7.15), another translocatable enzyme involved in the glycerolipid metabolism of rat hepatocytes (29,30). Freeman and Mangiapane (31) have demonstrated that cytosolic rat liver PA phosphatase also translocates to the mitochondria and that mitochondrial PA could be converted to TG in rat hepatocytes (32).

The Mg^{2+}-dependent form of PA phosphatase from rat adipose tissue appears to have many characteristics in common with the enzyme from rat liver (13). The enzyme from rat adipose tissue, however, was not affected by the addition of ATP or ADP, suggesting that the enzymes from adipose tissue and liver may be regulated by different mechanisms, and may thus represent two different isoenzymes (33).

Besides the extensive studies on Mg^{2+}-dependent PA phosphatase from rat liver and adipose tissue, the enzyme has also been examined in a number of tissues from various mammalian species. For example, the enzyme has been studied in rod outer segments (34) and other subcellular fractions of bovine retina (35), as well as in pig (36) and mouse brain (37). PA phosphatase may play an important role in myocardial TG homeostasis, and the enzyme from rat heart shares many characteristics with the enzymes from rat liver and adipose tissue, including its stimulation by Mg^{2+} and oleate, and its regulation by subcellular translocation to the microsomal membranes in response to oleate (38). PA phosphatase from vertebrate lungs also functions in the production of pulmonary surfactant (12,39,40). The major component of pulmonary surfactant is the phospholipid, dipalmitoyl-PC (12), which is synthesized *via* the catalytic action of PA phosphatase in type II epithelial cells of the alveoli (39).

Further progress toward elucidating the mechanisms that control the PA phosphatase activity involved in glycerolipid metabolism, including its distribution in different cellular compartments, depends on the ability to purify and further characterize the Mg^{2+}-dependent enzyme. Butterwith *et al.* (15) have partially purified Mg^{2+}-dependent PA phosphatase from the cytosolic fraction of rat liver. Purification and characterization of Mg^{2+}-dependent PA phosphatases have been complicated by apparent aggregation of enzyme as observed during molecular sieve chromatography (41).

PA phosphatase involved in signal transduction. In addition to its pivotal role in glycerolipid metabolism, the PA phosphatase-catalyzed conversion of PA to DG is also important in signal transduction where DG serves as a second messenger (5–7). Recent studies also indicate that an important alternative route for the production of DG is through the breakdown of PC (8,9,42). The generation of DG can occur either directly as a result of phospholipase C activity or by the action of phospholipase D followed by PA phosphatase. The latter is an important route related to signal transduction DG liberation (43), and has been reported in rat liver (8,44), rat fibroblasts (5), Chinese hamster ovary cells (42), NG108-15 cells (6), porcine thymus (45), human neutrophils (42,46) and interleukin-1-stimulated human mesangial cells (47). PA may also be a potent second messenger involved in the modulation of protein kinase C, as well as several other processes (8,45). Therefore, it is most likely that PA phosphatase plays a role in destroying this signal while, at the same time, creating another through the formation of DG (42). The enzyme involved in cell signalling, which has been referred to as PA phosphatase-2 (5,8), is tightly bound to the plasma membrane (42), Mg^{2+}-independent (7,10), and insensitive to NEM (10,45).

PA phosphatases involved in signal transduction have been reported to have been purified from porcine thymus (45) and rat liver (48–50). Properties of highly purified preparations of these enzymes are summarized in Table 1. Solubilized PA phosphatase from porcine thymus membranes displayed a subunit molecular mass of 83 kDa based on SDS–polyacrylamide gel electrophoresis (PAGE) of the final enzyme preparation (45). A molecular mass of 218 kDa was determined by

TABLE 1
Properties of Phosphatidate (PA) Phosphatases Involved in Signal Transduction in Mammals[a]

PA phosphatase	Apparent molecular mass and charge	Kinetic and specificity properties	Activators and inhibitors	Other properties
Porcine thymus membranes (6,000–100,000 × *g*), Ref. 45	218 kDa (native) by gel filtration; 83 kDa (subunit) by SDS–PAGE (reducing and nonreducing)	K_m for bulk [PA] = 0.2 mM; K_m for surface [PA] = 0.3 mol%; specific activity (purified enzyme) = 15 μmol/min/mg protein; was inactive against LPA	Activators: Triton X-100, deoxycholate Inhibitors: Mn^{2+}, Ca^{2+}, Zn^{2+}, DG, sphingosine, chlorpromazine, NaF, propanolol	pH optimum 7–7.4; NEM-insensitive; Mg^{2+}-independent
Rat liver membranes (6,000–100,000 × *g*); PA phosphatase-2A (partially purified), Ref. 48	290–300 kDa (native) by gel filtration; 83, 54, and 34 kDa subunits detected by SDS–PAGE	Specific activity (partially purified enzyme) = 4.7 μmol/min/mg protein; accepted PA containing 6:0, 10:0, 14:0, 16:0, 18:0, 18:1, and 18:1-20:4; least active with 18:1–20:4-PA	Inhibitors: Mn^{2+}, Zn^{2+}, amphiphilic amines	NEM-insensitive
Rat liver membranes (6,000–100,000 × *g*); PA phosphatase-2B, Ref. 48	265 kDa (native) by gel filtration; 83 kDa (subunit) by SDS–PAGE (reducing and nonreducing)	K_m for bulk [PA] = 0.3 mM K_m for surface [PA] = 0.31 mol% V_{max} = 12.6 μmol/min/mg protein; specific activity (purified enzyme) = 10.7 μmol/min/mg protein accepted PA containing 6:0, 10:0, 14:0, 16:0, 18:0, 18:1, and 18:1–20:4; most active with 6:0-PA; dephosphorylated PA	Activators: Triton X-100, deoxycholate; Inhibitors: Mn^2, Zn^{2+}, Co^{2+}, DG, LPA, monoacylglycerol, spingosine, chlorpromazine, desipramine	pH optimum 6–7; NEM-insensitive; Mg^2-independent
Rat liver plasma membranes; cationic and anionic PA isolated; cationic form purified to homogeneity; Ref. 49	Cationic form 51 kDa by SDS–PAGE (reducing and non-reducing); anionic form about 53 kDa; pI cationic form = 9; pI anionic form < 4	Specific activities of cationic and anionic forms were 0.1 and 5.7 μmol/min/mg protein, respectively; both forms dephosphorylated LPA		NEM-insensitive; glycoproteins; the 2 forms appeared to be different sialated states of the same protein; immunochemical crossreactivity between anionic and cationic forms; anionic form a possible phosphoprotein
Rat liver membranes (34,500–235,000 × *g*), Ref. 50	186 kDa (native) derived from Stokes' radius and sedimentation coefficient; 31 kDa by SDS–PAGE			NEM-insensitive

[a]PAGE, polyacrylamide gel electrophoresis; LPA, lysophosphatidate; DG, *sn*-1,2-diacylglycerol; NEM, *N*-ethylmaleimide; pI, isoelectric point.

Superose 12 (Pharmacia Biotech, Uppsala, Sweden) gel filtration chromatography in the presence of 1% (wt/vol) Triton X-100 (Boehringer Mannheim GmbH, Mannheim, Germany), indicating a possible oligomeric structure for the enzyme. The enzyme was specific for PA, and was inhibited by the reaction product, DG.

Fleming and Yeaman (48) purified PA phosphatase-2 from a crude membrane fraction of rat liver. Gel filtration chromatography of the solubilized enzyme on Sephacryl S300 (Pharmacia) resulted in two major peaks of enzyme activity designated PA phosphatase-2A and 2B. The authors suggested that these may represent different isozymes of PA phosphatase-2. Each enzyme form was further purified independently by a series of chromatographic steps using buffers containing Triton X-100. Native PA phosphatase-2A eluted with an apparent molecular mass of 290-300 kDa during gel filtration chromatography on Superose 6. SDS–PAGE indicated that PA phosphatase-2A consisted of polypeptides with molecular masses of 83, 54, and 34 kDa. Futher purification failed to resolve these components. PA phosphatase-2B was purified to apparent homogene-

ity. Analytical gel filtration chromatography of PA phosphatase-2B using Superose 6 (Pharmacia) indicated an apparent molecular mass of 265 kDa. Analysis by SDS–PAGE resulted in detection of a polypeptide with molecular mass of 83 kDa, which was in agreement with results on porcine thymus PA phosphatase-2 (45). PA phosphatase-2A accepted a range of PA varying in fatty acyl chain length, but the enzyme was least active with arachidonyl-containing PA. PA phosphatase-2B also accepted a range of PA varying in acyl chain length, but it displayed a very strong preference for PA containing 6-carbon acyl chains. Fleming and Yeaman (48) further compared the properties of rat liver PA-phosphatase-2B to those of the porcine enzyme purified by Kanoh *et al.* (45). Both the porcine and rat liver enzymes were NEM-insensitive, and were inhibited by Zn^{2+}, Mn^{2+}, and amphiphilic amines. Neither enzyme was activated by fatty acids or phospholipids. The PA phosphatases from the two sources, however, differed in apparent native molecular mass. Rat liver PA phosphatase-2 also catalyzed the hydrolysis of lysophosphatidate (LPA) (48), the immediate precursor of PA (51).

In another report, Fleming and Yeaman (52) examined the subcellular distribution and some properties of NEM-sensitive and NEM-insensitive PA phosphatases in rat brain. NEM-sensitive PA phosphatase was associated with the cytosol and microsomes, whereas NEM-insensitive PA phosphatase was found in the synaptosomes. Translocation of cytosolic PA phosphatase was facilitated by oleate. NEM-sensitive PA phosphatase displayed increased specificity for PA with short acyl chains, whereas the NEM-insensitive form preferred both short acyl chains and long unsaturated acyl chains. NEM-insensitive PA phosphatase, however, was somewhat less effective in catalyzing the hydrolysis of arachidonyl-stearoyl-PA in comparison to dioleoyl-PA.

Waggoner *et al.* (49) purified a NEM-insensitive PA phosphatase from rat plasma membranes. The PA phosphatase was an integral membrane glycoprotein which appeared to be purified in two different sialated states. A cationic form [isoelectric point (pI) = 9] of the enzyme was purified to homogeneity, whereas an anionic form (pI < 4) was only partially purified. The apparent subunit molecular mass of the cationic form was 51 kDa based on SDS–PAGE. Antibodies raised against the cationic form were used to identify the anionic form in Western blots resulting from SDS–PAGE. The anionic form was about 2 kDa larger than the cationic form. Treatment of the anionic form with neuramindase generated a species with properties of the cationic form. Furthermore, treatment of both the cationic and anionic forms with *N*-glycanase F resulted in a 28 kDa band (based on SDS–PAGE and Western blot analysis). Treatment of anionic PA phosphatase with acid phosphatase altered the mobility of the enzyme based on analysis by SDS–PAGE and Western blotting, suggesting that anionic PA phosphatase was a phosphoprotein.

Recently, Siess and Hofstetter (50) identified a NEM-insensitive PA phosphatase following SDS–PAGE of enzyme which was partially purified from rat liver membranes. A denatured PA phosphatase with molecular mass of 31 kDa was detected on a nitrocellulose blot of the SDS-gel. Antiserum raised against partially purified enzyme was allowed to interact with the denatured enzyme followed by capture of native PA phosphatase from a solution containing active enzyme. The activity of the captured native enzyme was used to identify the position of the PA phosphatase subunit.

YEAST PA PHOSPHATASES

In *Saccharomyces cerevisiae*, the regulatory mechanisms and basic biosynthetic pathways involved in the formation of TG and other glycerolipids are very similar to those which occur in higher eukaryotes (53–55). Hosaka and Yamashita (55) demonstrated that PA phosphatase activity was associated with both membrane and cytosolic fractions from *S. cerevisiae*. They also partially purified and characterized the soluble form of PA phosphatase from this microorganism.

More recently, a microsomal PA phosphatase and another form of the enzyme present in both microsomes and mitochondria have been identified in *S. cerevisiae* (56,57). A 91-kDa form of the enzyme was purified to apparent homogeneity from the total membrane fraction of this yeast (58,59). Immunoblot analysis, using antibodies raised against this membrane-associated 91-kDa enzyme, showed that it was actually the proteolytic product of a 104-kDa form of microsomal PA phosphatase (57). Subsequently, using the same procedure employed to purify the 91-kDa protein, the 104-kDa form of the enzyme was purified from microsomes obtained from a strain of protease-deficient cells. The kinetic properties of the 104-kDa PA phosphatase were indistinguishable from the 91-kDa enzyme. Immunoblot analysis using antibodies specific for the 91-kDa enzyme also revealed the existence of a 45-kDa form of PA phosphatase, which was then purified to homogeneity from the mitochondrial fraction of *S. cerevisiae* (56,57). This was done by employing the same procedure initially used to purify the 91-kDa protein from the total membrane fraction. The 45-kDa form of the enzyme was shown to be associated with both the microsomal and mitochondrial fractions. The properties of purified PA phosphatases from *S. cerevisiae* are shown in Table 2.

The strictly microsomal, 91-kDa enzyme was monomeric, Mg^{2+}-dependent, stimulated by Triton X-100 and sensitive to thioreactive compounds (59). The apparent K_m for dipalmitoyl-PA and V_{max} were determined to be 50 μM and 30 μmol/min/mg, respectively (59). Kinetic analysis of purified 91-kDa PA phosphatase, using Triton X-100/PA mixed micelles, showed that enzyme activity was dependent on the bulk and surface concentrations of PA (60). This was consistent with a "surface dilution" kinetic scheme where PA phosphatase interacted with the mixed micelle surface before substrate binding and catalysis occurred. Based on kinetic constants, dicaproyl-PA was a better substrate than either dioleoyl-PA or dipalmitoyl-PA which, in relation to each other, were equally good substrates. The enzyme was inhibited by the phospholipid intermediate, cytidine diphospho-(CDP-)DG, and by the neutral lipids, DG and TG (59).

TABLE 2
Properties of Yeast PA Phosphatases[a]

PA phosphatase	Apparent molecular mass and charge	Kinetic and specificity properties	Activators and inhibitors	Other properties
Sacchromyces ceresisiae 91-kDa form purified from 1,500–100,000 × *g* fraction; Refs. 59, 60	93 kDa (native) by gel filtration; 91 kDa (subunit) by SDS–PAGE	K_m for bulk [PA] = 50 μM V_{max} = 30 μmol/min/mg protein; molecular activity = 2.7×10^3 min^{-1} specific activity (purified enzyme) = 29.5 μmol/min/mg protein; interfacial Michaelis constant (xK_m^B) for dioleoyl-PA = 0.14 mol fraction; specificity constants indicated that dicaproyl-PA was a better substrate than dipalmitoyl- or dioleoyl-PA (the latter two were equally good substrates); inactive against LPA; activation energy = 11.6 kcal/mol; assays conducted with Triton X-100/PA mixed micelles	Activators: Triton X-100 Mg^{2+}; Inhibitors: NEM, Hg^{2+}, *p*-chloromercuriphenyl-sulfonic acid, CDP-DG, DG, TG	pH optimum 7; degradation product of 104 kDa form, Ref. 136
S. cerevisiae 104-kDa form purified from microsomes of a protease-deficient strain; Refs. 57,61,62,64	104 kDa by SDS–PAGE	enzymological properties identical to the 91-kDa form	Activators: cardiolipin ($A_{0.5}^b$ = 1.9 mol%); CDP-DG ($A_{0.5}$ = 2.6 mol%); phosphatidylinositol ($A_{0.5}$ = 5.5 mol%) Inhibitors: phenylglyoxal (IC_{50} = 7.6 mM), propanolol (IC_{50} = 0.93 mM), ATP (IC_{50} = 1.3 mM), ADP (IC_{50} = 1.9 mM), CTP (IC_{50} = 1.1 mM), GTP (IC_{50} = 2.2 mM), UTP (IC_{50} = 1.3 mm), sphingosine (aK_i^c = 1.5 mol%), phytosphingosine (aK_i = 0.4 mol%), sphinganine (aK_i = 0.2 mol%),	pI = 6.0; located in microsomes
C. cerevisiae 45-kDa form purified from mitochondria; Refs. 57,61–64	45 kDa by SDS–PAGE	enzymological properties similar to 104-kDa form	Activators: Triton X-100; Mg^{2+}; anionic phospholipids Inhibitors: NEM, *p*-chloromercuriphenyl-sulfonic acid, phenylglyoxal (IC_{50} = 4.3 mM), propanolol (IC_{50} = 0.95 mM), nucleotides, sphingoid bases	pH optimum 6–7; pI = 8.3; located in mitochondria and microsomes; peptide fragments resulting from V8 proteolysis differ from the 104-kDa form; immunochemically related to 91-kDa and 104-kDa forms; induced by addition of inositol to growth medium; phosphorylated by cAMP-dependent protein kinase

[a]Abbreviations as in Table 1; TG, triacylglycerols. [b]$A_{0.5}$ = Concentration required for half-maximum activation (Ref. 62). [c]For aK_i, the term *a* takes in account an interaction factor for the inhibitor (Ref. 61).

The 45-kDa form of PA phosphatase was also Mg^{2+}-dependent and stimulated by Triton X-100 (56,57). Although the 45-kDa enzyme was associated with both the microsomal and mitochondrial fractions, the kinetic properties of this form of PA phosphatase were similar to those of the strictly microsomal enzyme when uniform mixed micelles containing Triton X-100 and PA were used. The 45-kDa and 91-kDa forms of the enzyme were also similar to each other with respect to their inhibition by various compounds and their temperature stability. The two forms of PA phosphatase, however, differed in their pI, and in the peptide fragments generated as a result of V8 proteolysis and cyanogen bromide cleavage.

A number of possible regulatory mechanisms for controlling lipid metabolism at the level of PA phosphatase have been investigated in *S. cerevisiae*. Evidence for possible *in vivo* regulation by certain sphingoid bases (61) and anionic phospholipids (62) has been presented. Wu *et al.* (61) demonstrated that the dependence of PA phosphatase activity on PA was cooperative in the absence or presence of sphingosine, phytosphingosine, and sphinganine, and that these compounds inhibited purified preparations of both the 104-kDa and 45-kDa forms of PA phosphatase in a dose-dependent manner. They also found that these sphingoid bases were parabolic competitive inhibitors of PA phosphatase activity, indicating that more than one inhibitor molecule contributed to the exclusion of PA from the enzyme, and that both phytosphingosine and sphinganine were inhibitory at near endogenous concentrations. More recently, both the 104-kDa and 45-kDa forms of PA phosphatase were shown to be activated by the anionic phospholipids cardiolipin, CDP-DG, and phosphatidylinositol (62). Enzyme activation followed positive cooperative kinetics and activation appeared to be caused by anionic phospholipids decreasing the K_m for PA. The anionic phospholipids were stimulatory near their endogenous concentrations.

Quinlan *et al.* (63) have shown that the 45-kDa enzyme from *S. cerevisiae* is probably regulated by a mechanism involving reversible cAMP-dependent protein phosphorylation. For example, cAMP-dependent protein kinase catalyzed the phosphorylation of pure 45-kDa PA phosphatase at a serine residue, which resulted in a 2.4-fold stimulation of PA phosphatase activity. Dephosphorylation of the pure 45-kDa enzyme was catalyzed by alkaline phosphatase, and resulted in a 1.3-fold inhibition of PA phosphatase activity. Purified 104-kDa PA phosphatase, however, was not phosphorylated by cAMP-dependent protein kinase, strongly suggesting that the two yeast enzymes were differentially regulated. These findings were corroborated by *in vivo* phosphorylation studies using *S. cerevisiae* mutants (*bcy 1* and *bcy 2*) defective in cAMP-dependent protein kinase activity.

Wu and Carman (64) examined the possible regulation of PA phosphatase from *S. cerevisiae* by nucleotides. Both the 104- and 45-kDa enzymes were inhibited by a number of nucleotides, with ATP and CTP being the most effective inhibitors. Further experiments with the 104-kDa enzyme indicated that the mechanism of inhibition was due to chelation of the Mg^{2+}, which serves as the enzyme's cofactor. The inhibitory effect of ATP was considered physiologically relevant as the inhibitor constant for ATP was in the range of its cellular concentration.

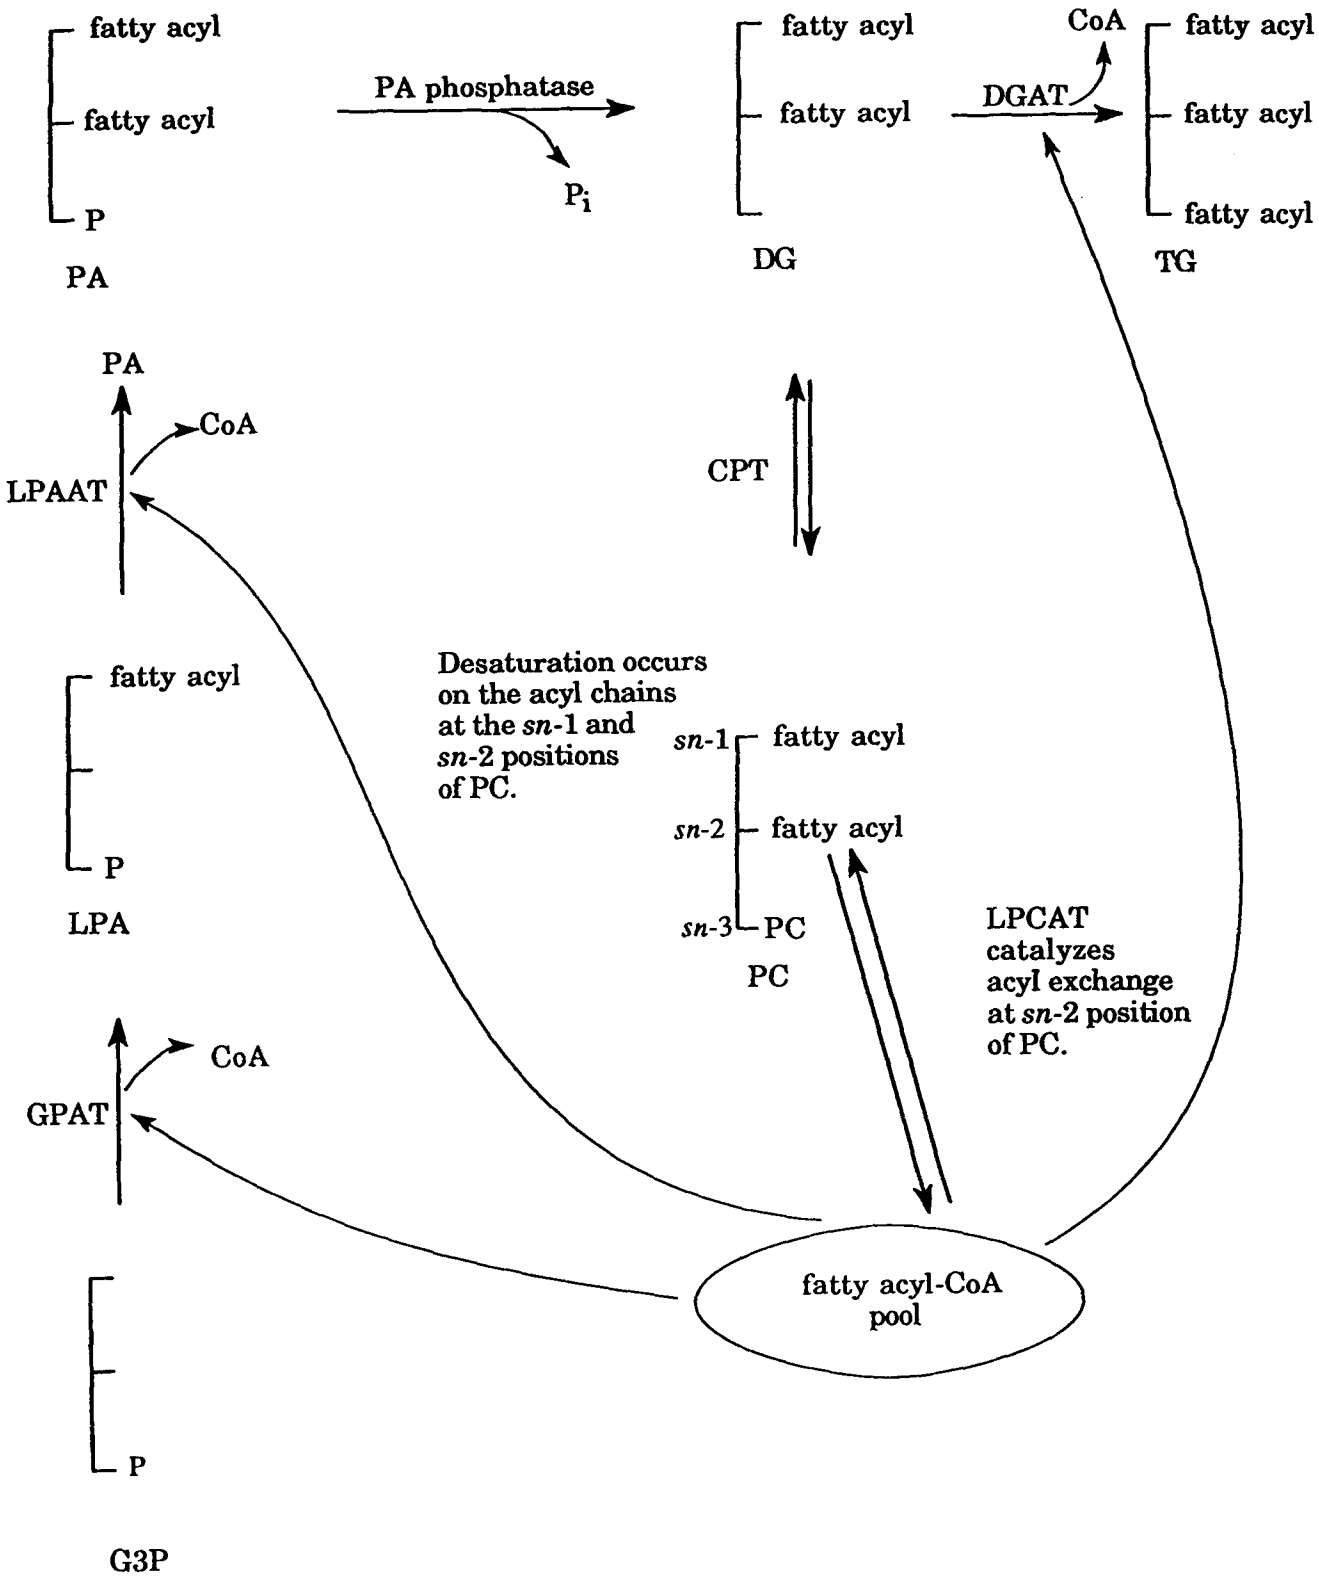
At the genetic level, certain factors regulate the expression of PA phosphatase in *S. cerevisiae*. It is not yet clear what the relative contributions of the 45-kDa and 104-kDa forms of PA phosphatase are to the overall TG and phospholipid synthesis rates in *S. cerevisiae*, but it has been found that PA phosphatase activity increases when wild-type cells are supplemented with inositol (65) and when cells enter the stationary phase of growth (53,65). CDP-DG synthase (CTP:phosphatidate cytidylyltransferase, EC 2.7.7.41) catalyzes the generation of CDP-DG and pyrophosphate from CTP and PA, and provides phosphatidyl moieties for the synthesis of major phospholipids (54). The 45-kDa form of PA phosphatase has been shown to be induced in the presence of inositol (57), and the activity of CDP-DG synthase was repressed (54). The activity of the 104-kDa PA phosphatase, however, was not affected by treatment with inositol (57). When yeast cells entered the stationary phase of growth, both the 104-kDa and the 45-kDa PA phosphatase were induced (57), and CDP-DG synthase activity was again repressed (54). The increase in PA phosphatase activity in response to inositol supplementation was correlated with an increase in phospholipid content at the expense of TG (57). In contrast, the increase in PA phosphatase activity observed during the stationary phase of growth correlated with an increase in TG content at the expense of phospholipid (53). Thus, in *S. cerevisiae*, the flux of acyl chains through DG and CDP-DG appears to be controlled by the relative activities of both forms of PA phosphatase, as well as by CDP-DG synthase.

GLYCEROLIPID SYNTHESIS IN HIGHER PLANTS

As indicated earlier in this review, one of our goals was to provide useful information for plant scientists studying PA phosphatases. In order to clarify the context in which plant PA phosphatases function, we briefly review TG biosynthesis as it relates to phospholipid metabolism in higher plants. The reader is also referred to other detailed reviews of plant lipid biosynthesis (66,67) and biotechnology (68,69).

The major pathway for the formation of TG was first elucidated using animal tissues through the work of Kennedy (51,70,71), Kornberg and Pricer (72), and others (73,74). Early evidence for Kennedy pathway activity in plants was based on experiments by Barron and Stumpf (75), which demonstrated that a particulate fraction from avocado mesocarp was capable of generating radiolabeled TG from [^{14}C]-*sn*-glycerol-3-phosphate (G3P). The formation of TG from G3P and fatty acyl-CoA precursors is known as the G3P or Kennedy pathway (51). The G3P dehydrogenase-catalyzed reduction of dihydroxyacetone phosphate, derived from cytosolic glycolysis and the pentose phosphate pathway, gives rise to G3P (76,77). In some cases, G3P may also be formed by the direct phosphorylation of glycerol, which is catalyzed by glycerol kinase (77,78).

De novo biosynthesis of fatty acids occurs within the plastids (79). Starting with acetyl moiety, the process involves several enzymes and a sequence of repeating reactions which results in the formation of fatty acids up to the level of 16:0, 18:0, and 18:1 (80,81). These fatty acids are generated as thioesters linked to acyl carrier protein (ACP), and are either used directly for plastidial glycero- and galacto-lipid biosynthesis or end up as fatty acyl-CoA in the cytoplasm (82). An acyl-ACP hydrolase may catalyze the hydrolysis of acyl-ACP liberating fatty acids for movement across the plastidial envelope (76). Fatty acyl-CoA are then generated by the action of an acyl-CoA synthetase, which is associated with the outer membrane of the plastid (76).



The Kennedy pathway enzymes (51,76), which are responsible for catalyzing TG bioassembly, are primarily associated with the ER. Strong evidence for this was provided by Stobart *et al.* (83), who demonstrated that microsomes from safflower seeds were capable of TG synthesis at rates comparable to the maximum *in vivo* (84) rate of TG deposition. Reactions involved in TG bioassembly in developing oilseeds are outlined in Scheme 1. The first enzyme of the Kennedy pathway, glycerophosphate acyltransferase (EC 2.3.1.15), catalyzes the acylation of G3P at the *sn*-1 position to form LPA. The second acyltransferase, lysophosphatidate acyltransferase (LPAAT; EC 2.3.1.51), is responsible for the *sn*-2 acylation of LPA to yield PA. It is the acyl specificity and selectivity properties of these two enzymes that govern the nonrandom distribution of fatty acid species at the *sn*-1 and *sn*-2 positions of PA and DG and the other glycerolipids which are subsequently derived from them (85,86). Recently, cDNA clones encoding LPAAT have been isolated and characterized for maize (87), *Limnanthes douglasii* (88), and immature coconut *(Cocos nusifera)* endosperm (89). PA phosphatase catalyzes the cleavage of PA to release P_i and the key intermediate in TG biosynthesis, DG. Diacylglycerol acyltransferase (DGAT; EC 2.3.1.20) is the enzyme responsible for the ultimate step in the biosynthesis of TG, and catalyzes the acylation of the *sn*-3 position of DG previously occupied by the P_i group. DGAT is partially responsible for regulating the fatty acid composition TG as it catalyzes the only step in the Kennedy pathway which is committed to TG biosynthesis (76). Identification of the remaining genes encoding the Kennedy pathway enzymes of the ER could contribute to the improvement of oilseed crops, but molecular genetic studies have been impeded by the difficulties experienced in the solubilization and purification of these enzymes (90–93).

The biosynthesis of membrane lipids share the same steps with the Kennedy pathway up to, and including, the point where DG is formed (78,94). These activities are localized in several compartments of the cell and are often collectively referred to as the Kornberg–Pricer pathway (95,96). In higher plants, a portion of DG derived from PC, synthesized in the ER, is directed to chloroplasts (80,82). Phosphatidylglycerol (PG) is the only product of plastidial lipid synthesis in many angiosperm families which have been designated 18:3 plants (67,80,82,97). In these 18:3 plants, other chloroplast lipids are synthesized using DG derived from the ER. The 18:3 plants contain galactolipids with substantial amounts of α-linolenic acid (67,82,97). In comparison, in some primitive angiosperms, such as *Arabidopsis* and spinach, both plastidial and extraplastidial DG contribute equally to the synthesis of galactolipids and sulfolipids (67,82,98). These latter species are designated as 16:3 plants because their leaf galactolipids are enriched in hexadecatrienoic acid (16:3n-3). For more detailed information on the pool of DG as it relates to synthesis of sulfolipids and galactolipids in plants, the reader is referred to Mudd and Kleppinger-Sparace (97) and Joyard *et al.* (99).

The acyl-CoA pool represents a complex collection of fatty acyl moieties in the developing seed (82). Desaturation-catalyzed reactions utilize PC as a substrate for the introduction of additional double bonds in the acyl chains at the *sn*-1 and 2 positions (76). The production of TG enriched in polyunsaturated fatty acids has been attributed to an acyl-exchange mechanism for releasing the desaturated products from the phospholipid back to the acyl-CoA pool (100) (see Scheme 1; adapted from Refs. 76 and 101). Acyl-CoA:lysophosphatidylcholine acyltransferase (LPCAT; EC 2.3.1.23) may catalyze the exchange of fatty acyl groups between 18:1-CoA and the polyunsaturated 18-carbon fatty acyl groups esterified to the *sn*-2 position of PC (76,101). The reaction is known to occur in reverse to facilitate entry of 18:2 and 18:3 into the acyl-CoA pool (101). In addition, LPCAT catalyzes the acylation of the *sn*-2 position of lysophosphatidylcholine to form PC (101). The combined effects of desaturation on PC and acyl exchange at the *sn*-2 position of PC lead to an acyl-CoA pool enriched in 18:2 and 18:3 moieties, which can then become substrates for the acyltransferases of the Kennedy pathway (76,78).

The production of TG enriched with polyunsaturated fatty acids has also been attributed to the flux of DG through the PC pool (76,80). DG generated through hydrolysis of PA by PA phosphatase in the Kennedy pathway is converted to PC by a freely reversible reaction catalyzed by CDP-choline 1,2-diacylglycerol cholinephosphotransferase (CPT) (EC 2.7.8.2) (2,25) (see Scheme 1). The acyl group at the *sn*-2 position of PC is capable of being rapidly desaturated as described above, but in this case the DG skeleton of PC is returned to the DG pool and converted into TG. Using microsomal preparations of cotyledons from developing safflower seeds, Stobart and Stymne (2) were able to demonstrate the rapid exchange of DG with PC, and Griffiths *et al.* (102) showed that DG equilibrated with the PC pool when the glycerol backbone, and associated acyl groups, flowed from PA to TG. Thus, the levels of DG used for TG biosynthesis are controlled through the activities of both PA phosphatase and CPT. Recently, a soybean (*Glycine max* L.) cDNA was was used to complement a CPT-deficient mutant of yeast (103).

The coordination of the Kennedy pathway enzymes with CPT, LPCAT, and oleate and linoleate desaturases is responsible for the synthesis of TG having 18:2 and 18:3 at the *sn*-2 position of the glycerol backbone (76,101). However, attempting to determine the relative contributions of CPT and

SCHEME 1

PA phosphatase in customizing the DG pool is difficult because PC and TG synthesis both appear to occur within the ER (82). In some developing seeds of oilseed plants the situation is further complicated by the fact that certain fatty acyl moieties are largely or completely excluded from the membrane lipids (78,104,105). Using homogenates obtained from the developing seeds of safflower, *Crambe abysinnica*, and *Cuphea wrightii*, Battey and Ohlrogge (106) demonstrated

that exogenously supplied medium- and long-chain fatty acids were targeted to TG and not to phospholipids.

Erucic acid (22:1) is one example of an unusual fatty acid that is channeled to reserve lipid. Several varieties of *Brassica napus* and *B. rapa* (syn. *campestris*) produce seed oil characterized by a large amount of erucic acid. Seed oils high in 22:1 are desirable as starting material for the production of high temperature lubricants, nylon, and plasticizers (107), and thus there is considerable interest in developing genetically manipulated *B. napus* which produces trierucoylglycerol (108–111). In high erucic acid rapeseed lines, this long-chain monounsaturated fatty acid is associated with the *sn*-1 and *sn*-3 positions of the TG molecules (112), but is essentially excluded from membrane constituents (106). Using *B. napus* microspore-derived (MD) embryos of the high erucic acid cultivar, Reston, Taylor *et al.* (108) demonstrated that [^{14}C]-erucoyl moieties from [^{14}C]-22:1-CoA were rapidly incorporated into TG, but were virtually excluded from complex polar lipids. Erucic acid is synthesized by the elongation of oleoyl-CoA (113,114) and the process does not involve, to any extent, a PC intermediate (80). Elongation occurs *via* two successive condensations in the presence of malonyl-CoA and reductant, resulting in 2-carbon extensions from 18:1-CoA *via* 20:1-CoA to 22:1-CoA, with retention of the relative ω-9-position of the double bond introduced during oleate synthesis in the plastid (113). Low erucic acid cultivars appear to simply lack elongase activity (75,115). Many *Brassica* species do not contain significant amounts of erucic acid at the *sn*-2 position (109). Thus, the theoretical breeding limit for 22:1 in *B. napus* seed oils was 66 mol% (110,111,115). Recently, a cDNA encoding LPAAT from developing seeds of meadowfoam *(Limnanthes alba alba)* was expressed in developing seeds of transgenic high-erucic acid *B. napus* (116). The transgenic seeds produced some trierucin, but the total erucic acid content was similar to the control seed. This work, however, constitutes a breakthrough in the genetic manipulation of acyltransferases to generate seeds oils with desired fatty acid compostion.

In other cases unusual fatty acids have been shown to be transiently incorporated into PC prior to their eventual accumulation as TG. In developing castor bean *(Ricinus communis)*, synthesis of ricinoleic acid (18:1-OH) was shown to occur by hydroxlyation of the oleoyl moiety while it was attached to the *sn*-2 position of PC (117). Oleate was released through the action of a phospholipase A_2 and was activated to ricinoleoyl-CoA which, in turn, served as substrate for the acyltransferases of the Kennedy pathway. In addition, PC containing oxidized acyl groups was more efficiently degraded by phospholipase then PC containing nonoxidized acyl groups (118). Thus, phospholipases may contribute to the exclusion of fatty acids containing oxidized acyl groups from membrane lipids (117,118). This may also serve as a mechanism for membrane repair (117). Ståhl *et al.* (119) have indicated that phospholipases specific for unusual acyl groups might also degrade PA. However, PA was a less efficient substrate than PC and represented a relatively small component of the total phospholipid pool in maturing oilseeds.

Petroselinic acid, the Δ-6 *cis* isomer of oleic acid, is another example of an unusual fatty acid (120). Cahoon and Ohlrogge (120) conducted time-course labeling and pulse-chase studies with [1-^{14}C]acetate using developing endosperm from the Umbelliferae species coriander (*Coriandrum sativum* L.) and carrot (*Daucus carota* L.). Radiolabeled petroselinic acid initially entered PC but accumulated in TG at a later time. Unlike ricinoleic acid, however, petroselinic acid was not further modified on PC.

Recently, Vogel and Browse (121) investigated the relative roles of CPT and DGAT in channeling unusual fatty acids into TG during seed maturation. In experiments with various oilseeds, CPT could not differentiate between DG molecular species containing 18:1 and those containing 10:0, 22:1, and 18:1-OH. Thus, CPT did not appear to be involved in the exclusion of unusual fatty acids from PC. DGAT from castor bean endosperm, however, displayed an enhanced preference for DG species containing two ricinoleic acid residues. CPT from the same plant did not exclude this fatty acid residue. Thus, it appeared that castor bean DGAT was involved in channeling ricinoleic acid into TG. The investigators suggested that there may be a number of mechanisms contributing to the exclusion of unusual fatty acids from membranes. These mechanisms may include the action of phospholipases specific for unusual acyl groups, the molecular species specificity of DGAT, and spatial separation of membrane lipid synthesis and TG bioassembly within the ER.

PLANT PA PHOSPHATASES

Although they have not been as well studied as the comparable enzymes in either mammalian tissues or yeast, PA phosphatase activities have been partially characterized in the plastids, microsomes, and soluble fractions of a number of plant tissues (for examples see Refs. 122–126). Kates (127) first showed that the 1,800–15,000 × *g* sediment from spinach leaf homogenate could catalyze the hydrolysis of PA to form P_i, but he generally employed PC as the substrate and followed the liberation of both choline and P_i. The formation of P_i was slower than that of choline and was preceded by a lag period, suggesting that PC was converted to PA and subsequently hydrolyzed to DG and P_i. In the same study, Kates (127) showed that the P_i could have arisen from either, or both, of the PC degradation products, PA or G3P, but not from LPA.

Leaf PA phosphatases. Königs and Heinz (128) investigated the subcellular distribution of PA phosphatase in broadbean *(Vicia faba)* leaves and partially characterized the enzyme. When the crude subcellular fractions obtained by the differential centrifugation of tissue homogenate were assayed at pH 5.6, PA phosphatase activity was almost exclusively associated with a 40,000 × *g* supernatant and a 600–15,000 × *g* sediment. About 80% of the total activity of the homogenate was found in the 40,000 × *g* supernatant. The cytosolic and particulate enzymes exhibited pH optima of 5.1 and 5.6, respectively, and both forms of PA phosphatase activity were

inhibited by Ca^{2+} ions. The enzyme in the 600–15,000 × *g* sediment was solubilized by sonciating in the presence Triton X-100.

The effect of herbicides on PA phosphatase and other enzymes involved in glycerolipid metabolism has been investigated in the leaves of groundnut *(Arachis hypogaea)*. Rajasekharan and Sastry (129,130) have shown that, although other enzyme activities involved in lipid metabolism were inhibited, both the plastidial and microsomal PA phosphatase activities from leaf disks of groundnut were insensitive to phenoxy, thiocarbamate, urea, and uracil herbicides.

The majority of research on leaf PA phosphatases has involved investigations of the plastidial enzyme. Studies have been conducted with nongreen starch-containing plastids from sycamore and cauliflower (125), as well as the chloroplasts of spinach (131,132) and pea (133). In plastids, DG is a source of acyl chains for galactolipids and sulfolipid (96,99). PA synthesized in plastids is metabolized into either DG or CDP-DG, and it is probably one of the major regulatory points for controlling the biosynthesis of plastidial membrane lipids and the final proportions of PG, galactolipids (monogalactosyldiacylglycerol and digalactosyldiacylglycerol), and sulfolipid (sulfoquinovosyldiacylglycerol) (96,99). The formation of DG occurs in the plastids as the result of a membrane-bound PA phosphatase (131,134), which is exclusively located on the inner envelope membrane (124,133). In contrast to plastids from 16:3 plants, those from 18:3 plants have a rather low PA phosphatase activity and cannot deliver DG fast enough to sustain maximal rates of galactolipid synthesis (99,135,136). These results explain why 18:3 plants contain only small amounts of galactolipids and sulfoquinovosyldiacylglycerol with 16-carbon fatty acids at the *sn*-2 position, but contain PG, which is synthesized from PA *via* CDP-DG. It is not known, however, whether the reduced level of plastidial PA phosphatase activity in 18:3 plants is due to a lower species-specific expression of the gene coding for the enzyme, or to the presence of regulatory molecules which control the activity of PA phosphatase in this compartment (99).

The PA phosphatase activity associated with plant plastids appears to exhibit a number of biochemical properties (95,132) which are clearly different from those described for the PA phosphatase activities involved in glycerolipid metabolism in the various cell fractions obtained from mammals and yeast. Excluding the cell-signalling form of PA phosphatase associated with the plasma membrane, all the PA phosphatase activities from yeast (57,59) and mammals (10,15,38,137) were Mg^{2+}-dependent, regardless of the cell fraction serving as the source of enzyme activity. Additionally, the PA phosphatase activities from yeast (55,56,58) and mammals (13,36) usually exhibited pH optima which were within one pH unit of neutrality. In marked contrast, the plastidial enzyme appeared not to need divalent cations, which, in fact, seemed to inhibit the enzyme, and plastidial PA phosphatase exhibited maximal activity at pH 9.0. This alkaline pH optimum appears to be physiologically relevant because Sauer and Heise (138) have shown that light-activated fatty acid synthesis in spinach chloroplasts was dependent on stromal pH, and that the optimum pH for fatty acid synthesis was close to 8.5. Therefore, it appears that plastidial glycerolipid metabolism may be linked to the biosynthesis of fatty acids, at least partly, through the effects of pH in this subcellular compartment. Feedback inhibition by DG probably plays a important role in the regulation of plastidial PA phosphatase which, in turn, would influence the rate of galactolipid and sulfolipid biosynthesis (95). Using isolated intact chloroplasts and envelope membranes from thermolysin-treated chloroplasts, Malherbe *et al.* (132) have shown that DG is a powerful competitive inhibitor of the spinach chloroplast enzyme. They determined an apparent K_i of 70 μM using *sn*-1,2-diolein, whereas the apparent K_m for *sn*-1,2-dioleoyl-PA was as high as 600 μM. When incubations were conducted in the presence of different molecular species of DG, at the same concentration as *sn*-1,2-diolein, PA phosphatase inhibition occurred in the same concentration range, but *sn*-1,3-dipalmitin had almost no inhibitory effect. It appears that the *in vivo* steady state activity of plastidial PA phosphatase is sensitive to the DG/PA molar ratio, as increasing this ratio resulted in a logarithmic increase in PA phosphatase inhibition. Because the apparent K_i value for DG was much lower than the apparent K_m for PA, it has been suggested that the rate of DG formation is closely related to the rate of its utilization by the plastidial enzymes involved in galactolipid and sulfolipid synthesis (96). Thus, feedback inhibition of PA phosphatase by DG would most likely lead to an accumulation of PA and would favor PG synthesis in the plastid envelope (132).

Recently, Malherbe *et al.* (139) reported the solubilization of PA phosphatase from spinach chloroplast envelope membranes using 3-[(3-cholamidopropy)-dimethylammonio]propanesulfonate (CHAPS). In the presence of CHAPS, 1 mg PG per mL of reaction mixture stimulated PA phosphatase activity by 2–4-fold, while the same concentration of PC inhibited the enzyme. Solubilized plastidial PA phosphatase was inhibited by Mg^{2+} and a number of other metal ions, and DG was a strong inhibitor. Solubilized PA phosphatase was fractionated by hydroxyapaptite chromatography into two major peaks of activity and one apparently minor component. Most of the enzyme activity passed through the column during sample application and washing. The specific activity of the unbound fraction was similar to that of the solubilized enzyme. The final peak of activity, which required the highest concentration of potassium phosphate for elution, represented about 15% of the initial activity applied to the column. This fraction exhibited a specific activity four to five times greater than that of the solubilized enzyme.

PA phosphatases from germinating seeds. Most of the research on PA phosphatases in seeds has involved extraplastidial forms of the enzyme. The cotyledons of fully imbibed or germinating mung beans *(Vigna radiata)*, which have been shown to contain at least two distinct PA phosphatase activities (140), are one example. In this case, an enzyme exhibiting a pH optimum of 7.5 was located on the ER, and a second

PA phosphatase with a pH optimum of 5.0 was found associated with the protein bodies. The PA phosphatase activity exhibiting the acidic pH optimum was very easily released into the soluble fraction during subcellular fractionation and could be partially separated from general acid phosphatase activity by chromatography. The apparent molecular mass of the acidic PA phosphatase was estimated to be about 37 kDa by gel filtration chromatography.

Moore *et al.* (141) examined the characteristics of PA phosphatase activity in subcellular fractions obtained from the endosperm of germinating seeds of castor bean. When enzyme assays were conducted at pH 7.4, PA phosphatase activity was found mainly in the microsomes with some activity in the soluble fraction. Later, when subcellular fractions were assayed under more acidic conditions (142), it was found that the cytosolic fraction contained most of the PA phosphatase activity. The ER-associated enzyme described by Moore *et al.* (141) was shown not to hydrolyze glucose 6-phosphate or *o*-carboxyphenyl phosphate, suggesting that the PA phosphatase activity in this fraction was not due to a nonspecific phosphatase. *p*-Nitrophenyl phosphate, however, was not tested as a possible substrate. The PA phosphatase activity associated with the endosperm from germinating castor beans is most likely not involved in TG biosynthesis, but instead probably plays a role in membrane formation and other processes involved in germination and seedling growth.

It has been demonstrated that microsomal PA phosphatase activity is involved in the degradation of membrane phospholipids in the cotyledons of germinating seeds of *Phaseolus vulgaris* (143). The activity of the enzyme was stimulated by Ca^{2+} and was calmodulin-dependent.

PA phosphatases from developing seeds. In developing oilseeds, the DG formed by the PA phosphatase-catalyzed hydrolysis of PA is not only a precursor of TG but is also a substrate used for the synthesis of membranes (144). Using the developing seeds from groundnut *(A. hypogaea)*, Sukumar and Sastry (145) showed that PA phosphatase was associated with both the microsomal and mitochondrial fractions. In contrast to plastidial PA phosphatase of leaf tissue (139), the enzyme activity from maturing groundnut seeds depended upon the inclusion of $MgCl_2$ in the homogenizing buffer. PA phosphatase activity was not found in the cytosolic fraction, and only a negligible amount (<1%) was associated with the fat fraction containing the oil bodies. Both the microsomal and mitochondrial PA phosphatase activities showed a significant increase in specific activity between 20 and 30 d after fertilization, with maximal specific activity occurring 30 d after fertilization.

The dephosphorylation of PA during TG formation by microsomal fractions obtained from the cotyledons of developing safflower seeds was demonstrated by Stymne *et al.* (100) using three cultivars differing in seed oil fatty acid composition. These cultivars included a high oleate (75% oleate, 16% linoleate) variety, a very high linoleate (6% oleate, 88% linoleate) variety, and a cultivar known as Gila (16% oleate, 75% linoleate). At the same time, an examination of the ability of different molecular species of acyl-CoA to be incorporated into phospholipids and acylglycerols in Gila and high oleate varieties gave some information about the substrate specificities of microsomal PA phosphatases (100). The results from this study strongly suggested that microsomal PA phosphatase did not show a marked substrate specificity. Ichihara (126) showed that the microsomal PA phosphatase in maturing seeds of safflower was specific and selective for unsaturated forms of PA, and when the different forms of PA were ranked, the order of selectivity was similar to that of the specificity. Additionally, in agreement with Stymne *et al.* (100), Ichihara (126) concluded that the broad selectivity for unsaturated PA species (*sn*-1,2-diunsaturated-PA and *sn*-1-saturated, 2-unsaturated-PA) indicated that the PA phosphatase reaction probably has little effect on the fatty acid composition of TG in the oil obtained from safflower. Furthermore, compared with the safflower microsomal enzyme, the chloroplast PA phosphatase of spinach leaves showed a broader specificity (126), which agreed with the selectivity profile indicated by labeling patterns of PA and DG synthesized from [^{14}C]-acetate previously demonstrated in spinach chloroplasts (94).

Griffiths *et al.* (102) showed that microsomal PA phosphatase from the developing seeds of safflower has an absolute Mg^{2+} requirement. This was confirmed by Ichihara *et al.* (122), who demonstrated that other divalent cations, such as Ca^{2+} and Mn^{2+}, could not be substituted for Mg^{2+}. Additionally, it was shown that the microsomal enzyme exhibited a pH optimum of 6.75 and was inhibited by the polyamines, spermidine and spermine, but not by putrescine, which is the diamine precursor of spermidine and spermine (122). It has been suggested that polyamines, which are ubiquitous in plant tissues, may affect the synthesis of TG in maturing oilseeds by modulating the enzyme activity of each step in the Kennedy pathway (122). The soluble form of the enzyme from developing safflower seeds has not been characterized, but has been suggested to be a functionally inactive cytosolic reservoir of the microsomal form of the enzyme (4). Thus, as in the mammalian system (3), it appears that in maturing safflower seeds PA phosphatase translocates between the cytosol and the ER in response to the fatty acid level in the cytosol (4). This may explain some of the conflicting reports resulting from studies using plant tissues, with some investigators believing PA phosphatase to be a membrane-associated enzyme and some claiming that it is soluble (123,144,146).

The combined and relative activities of the microsomal and cytosolic forms of PA phosphatase varied as function of safflower cotyledon development (4). Combined PA phosphatase activity in the tissue was highest during the period of rapid oil accumulation (13–15 d postanthesis), when the majority of the PA phosphatase was membrane-bound. At the initial and last stages of seed development, when TG synthesis was not significant, the majority of the enzyme was soluble. Additionally, palmitic, stearic and oleic acids, which are the fatty acid products formed in the plastids, caused the

translocation of PA phosphatase from the cytosol to the microsomes. Laurate and linoleate, which are not products of plastidial fatty acid biosynthesis, showed no effect. The intracellular translocation induced by oleate was reversed by its removal. The metabolically significant thioester, oleoyl-CoA, did not convert the soluble form of the enzyme into the membrane-bound form. The cytosolic form of PA phosphatase from safflower seeds could be induced to translocate to the microsomes prepared from the sunflower seeds, but not to the microsomes prepared from the seeds of oilseed rape or soybean.

PA has been shown to be a major product when microsomes obtained from developing safflower cotyledons were incubated with the Kennedy pathway precursors, fatty acyl-CoA and G3P (2). This suggested that PA phosphatase activity may have a rate-limiting role in TG biosynthesis. In contrast, Ichihara *et al.* (122) have indicated that the amount of PA phosphatase activity in developing safflower seeds was enough to account for the amount of TG being formed *in vivo*, and that DGAT may catalyze the rate-limiting step in TG biosynthesis. Previously, Ichihara *et al.* (147) reported that DGAT had the lowest specific activity of all the Kennedy pathway enzymes in particulate fractions obtained from developing safflower seed, suggesting a rate-limiting role for DGAT. More recently, Perry and Harwood (148,149) have shown that DG accumulates during the period of rapid TG accumulation in the zygotic embryos of *B. napus*, suggesting that DGAT exerts significant flux control over the Kennedy pathway.

The appearance of TG biosynthetic enzyme activities in developing oilseeds are coordinated with TG biosynthesis. Studies with developing seeds of *B. napus* have shown that the activities of the three acyltransferases of the Kennedy pathway increased greatly during the rapid phase of oil accumulation (150). Weselake *et al.* (151) have confirmed this observation for the developmental profile of DGAT activity during maturation of *B. napus* L. cv Westar seed. In developing safflower seeds, both PA phosphatase (4) and DGAT (151) activities increased during the rapid phase of oil accumulation and declined markedly as lipid levels reached a plateau. A similar relationship was reported earlier for microsomal PA phosphatase and DGAT activities in relation to oil accumulation in developing groundnut seeds (145).

A more detailed understanding of the biochemical and genetic regulation of the PA phosphatase involved in TG biosynthesis in developing seeds will be realized through further characterization and purification of the enzyme. One of the greatest difficulties in working with PA phosphatases, however, is reliably measuring the enzyme activity in homogenates and crude subcellular fractions. Plant biochemists should be aware of the enzyme assay problems that have been encountered in investigations with mammalian systems. In studies with microsomes from rat liver, Sturton and Brindley (152), have indicated that measurement of P_i overestimated PA phosphatase because phosphate was also produced from dephosphorylation of G3P derived from the deacylation of PA by phospholipases. In contrast, Ide and Nakazawa (153) found that measurement of P_i was more reliable in estimating PA phosphatase activity than monitoring the appearance of DG when using cytosolic and microsomal fractions from rat liver. In their studies, DG was rapidly deacylated by reactions catalyzed by acyl hydrolases. Thus, when embarking on the study of PA phosphatase in crude fractions, in addition to running the appropriate controls, it is also important to initially assay the enzyme using different procedures (10) and to examine the products generated when the enzyme assay is complete (153).

Microspore-derived embryos of *B. napus* accumulate TG in a fashion similar to zygotic embryos (154,155), and have proven useful in the characterization, solubilization, and partial purification of TG biosynthetic enzymes (91,93,108,111, 151,155,156). They are easy to manipulate in culture and large numbers of embryos at specific developmental stages can be readily obtained. Recent studies of TG biosynthesis and enzyme characterization have also been conducted using an embryogenic MD cell suspension culture of *B. napus* L. cv Jet Neuf (91,151). The cell suspension culture contained 3–4% TG on a dry weight basis under normal culture conditions (151). The TG content and the activity of DGAT, however, could be manipulated by altering the sucrose concentration of the growth medium (unpublished observations, Weselake, R.J., Byers, S.D., Davoren, J.M., Laroche, A., Hodges, D.M., Pomeroy, M.K., and Furukawa-Stoffer, T.L.). Therefore, this system may be potentially useful for identifying cDNA encoding enzymes of TG bioassembly through analyses of gene expression in cells grown under different sucrose concentrations.

Kocsis *et al.* (93) characterized PA phosphatase activity in soluble and microsomal fractions from developing seeds of *B. napus*. Soluble PA phosphatase activity may have been attributable to nonspecific acid phosphatase activity with a pH optimum of about 5, whereas microsomes displayed optimal activity in the range of pH 6–7. PA phosphatase was solubilized from microsomes of MD embryos using Tween 20. Gel filtration chromatography of the solubilized enzyme revealed a minimum molecular mass of about 40 kDa. The solubilized enzyme had a preference for dioleoyl-PA and palmitoyl-PA over distearoyl-PA. More recently, the PA phosphatase from microsomes of MD embryos of *B. napus* was found to be composed of both NEM-sensitive and NEM-insensitive activity, and part of the overall activity was also Mg^{2+}-dependent (unpublished observations, Furukawa-Stoffer, T.L., Weselake, R.J., and Pomeroy, M.K.). Therefore, it is possible that the membrane fractions from MD embryos of *B. napus* contained PA phosphatases involved in both glycerolipid biosynthesis and signal transduction.

In future research, it might be worthwhile to attempt photoaffinity labelling of the PA phosphatase involved in glycerolipid biosynthesis in developing seeds using a radiolabeled azido-derivative of PA. Photoaffinity labeling of the PA phosphatase polypeptide may serve as probe to facilitate enzyme purification. Ideally, labeling would have to be carried out

under conditions which minimized or eliminated the hydrolysis of azido-PA. Recently, the photoreactive substrate analogue, 12-[(4-azidosalicyl)amino]dodecanoyl-CoA, was found to be potentially useful in the purification of DGAT (157). This agent inhibited microsomal DGAT activity from MD embryos of *B. napus* and was used to label polypeptides in solubilized fractions containing DGAT activity. Alternatively, the genes encoding PA phosphatase and DGAT involved in glycerolipid biosynthesis in developing seeds may be identified through molecular genetic strategies. Indeed, mutants of lipid synthesis in plants have proven useful in the identification of genes encoding various enzymes involved in lipid metabolism (90).

A more complete picture of the biochemical regulation of PA phosphatase and DGAT in developing seeds awaits the identification of possible allosteric effectors which may modulate the activities of these enzymes. These enzymes may also be subject to phosphorylation/dephosphorylation mechanisms which are, in turn, dependent on other cellular conditions. As indicated previously, the 45-kDa form of yeast PA phosphatase is activated by phosphorylation catalyzed by a cAMP-dependent protein kinase (63). There is also compelling evidence that mammalian DGAT is regulated by reversible protein phosphorylation (158–160). It is possible that PA phosphatase and DGAT in the ER of the developing seed may interchange roles as rate-limiting enzymes depending on the metabolic status of their surroundings. The possible effects of oleate on promoting the interaction of solubilized PA phosphatase with microsomes may provide insights into the biochemical regulation of PA phosphatase and also contribute to the development of a procedure for reconstitution of PA phosphatase with membrane components.

Knowledge of the biochemical properties of PA phosphatase and DGAT may facilitate effective biotechnological strategies for increasing seed oil content and/or modifying the fatty acid composition of seed oil. Increasing PA phosphatase and/or DGAT production may lead to increased seed oil content. In addition, seed oil composition might be altered by modifying the genes encoding these enzymes. One might envision the development of a transgenic plant producing seeds which express a form of PA phosphatase which preferentially accepts specific species of PA. It may also be possible to modify potential regulatory sites on PA phosphatase so it responds to its metabolic environment in an altered fashion.

Role of PA phosphatase in phospholipid degradation and turnover. Besides its important role in glycerolipid synthesis, PA phosphatase is also involved in phospholipid degradation and phospholipid turnover in general. As previously discussed, microsomal PA phosphatase has been shown to be involved in the degradation of membrane phospholipids in germinating seeds (143). A similar mechanism also seems to be operative in the microsomal membranes from senescing carnation flowers (161,162). Additionally, the decrease in microsomal PA phosphatase activity, relative to the other enzymes involved in phospholipid degradation, has been implicated in chilling injury in tomato fruit (163). It appears that the chilling injury occurring during low temperature storage of tomato fruit may be the result of the accumulation of PA and other lipid degradation intermediates in the membranes due to the differential effects of reduced temperature on the activity of PA phosphatase and other lipid-degrading enzymes.

Highly purified preparations of NEM-insensitive PA phosphatases involved in signal transduction have been characterized in mammalian systems. Substantial progress has also been made in the characterization of purified forms of PA phosphatase from *S. cerevisiae*. It is clear from the literature that the study of PA phosphatases from mammals and yeast has had a significant impact on the design of experiments used in the characterization of plant PA phosphatases. No form of PA phosphatase, however, has been highly purified from any plant source. Identification of the gene encoding PA phosphatase involved in glycerolipid synthesis in developing oilseeds could contribute to the development of biotechnological strategies for increasing seed oil content and modifying the fatty acid composition of seed oil. Increasing seed oil content would be of great economic benefit. Modification of seed oil composition could contribute to product diversification, including production of nutritionally desirable oils and oils for the manufacturing industry.

ACKNOWLEDGMENTS

R.J.W. thanks the Natural Sciences and Engineering Research Council and Farming for the Future (Alberta Agricultural Research Institute) for supporting his research on the purification and characterization of triacylglycerol biosynthetic enzymes from oilseed rape. The authors thank Drs. D.M. Hodges, F.J. Lozeman, and D.C. Taylor for critical evaluations of the manuscript.

Specificity of Two Lipoxygenases from Rice: Unusual Regiospecificity of a Lipoxygenase Isoenzyme

Lian-Ying Zhang and Mats Hamberg*

Department of Medical Biochemistry and Biophysics, Division of Physiological Chemistry II, Karolinska Institutet, S-171 77 Stockholm, Sweden

ABSTRACT: The regio- and stereospecificity of two lipoxygenases from rice were investigated using arachidonic acid as the substrate. Rice seed lipoxygenase-2 (RSL-2) catalyzed oxygenation of arachidonic acid into a mixture of 5(*S*)-hydroperoxy-6,8,11,14-eicosatetraenoic acid [5(*S*)-HPETE] and 15(*S*)-hydroperoxy-5,8,11,13-eicosatetraenoic acid [15(*S*)-HPETE]. In addition, two double dioxygenase products, 5(*S*),15(*S*)-dihydroperoxy-6,8,11,13-eicosatetraenoic acid and 8(*S*),15(*S*)-dihydroperoxy-5,9,11,13-eicosatetraenoic acid, were obtained in a lower yield. The regiospecificity of the RSL-2-catalyzed oxygenation was pH-dependent. Thus, incubation at pH 6.7 led to the formation of 5(*S*)-HPETE and 15(*S*)-HPETE in a ratio of 52:48, and incubation at pH 9.8 strongly suppressed production of 5(*S*)-HPETE and led to formation of 5(*S*)-HPETE and 15(*S*)-HPETE in a ratio of 3:97. A pH-dependent orientation of arachidonic acid at the active site is proposed to explain these findings. Rice leaf pathogen-inducible lipoxygenase [Peng, Y.-L., Shirano, Y., Ohta, H., Hibino, T., Tanaka, K., and Shibata, D. (1994) *J. Biol. Chem. 269*, 3755–3761] catalyzed oxygenation of arachidonic acid into a single hydroperoxide isomer of high optical purity, i.e., 15(*S*)-HPETE (99.5% *S*).

Lipids 31, 803–809 (1996).

Presently, intense research is devoted to understand the molecular mechanisms involved in plant protection to microbial infection. Apart from being of biological interest, the agricultural and environmental protection aspects of such work is of obvious importance. In rice plants, a number of oxylipins, notably epoxy, hydroxy, epoxy-hydroxy, and trihydroxy derivatives of linoleic and α-linolenic acids, are produced in response to attack by the rice blast fungus (1–5). Levels of lipoxygenase and of enzyme(s) catalyzing degradation of hydroperoxides increase in rice leaves following infection with an incompatible race of the rice blast fungus (6,7). The nature of the hydroperoxide-decomposing enzyme activity in rice is not well established; however, it seems likely that at least part of this activity is due to the enzyme peroxygenase (8), which catalyzes reduction of fatty acid hydroperoxides with concomitant formation of epoxy- and epoxy-hydroxy fatty acids (9–11). Importantly, a number of oxygenated fatty acids produced from linoleic and α-linolenic acids in rice show antifungal activity. Thus, germination and germ tube elongation of spores of the rice blast fungus are inhibited by low concentrations (2–40 ppm) of the oxygenated fatty acids (12–14). Furthermore, when rice plants are grown in a nutrient solution supplemented with C_{18} epoxy acids and subsequently inoculated with rice blast fungus, the number of lesions appearing on leaves is dramatically reduced compared to that observed in the nonsupplemented controls (14).

Oxylipins derived from fatty acids other than linoleic and α-linolenic acids also can be important in plant defensive reactions against pathogens. For example, the fungus *Phytophthora infestans* elicits necrosis and accumulation of antimicrobial compounds in potato tubers. The causative agent in this process appears to be arachidonic acid, which is present in the fungal mycelia (but not in potato) (15). Arachidonic acid supplied from the fungus is converted into hydroperoxide derivatives by potato tuber lipoxygenase. The hydroperoxides and/or secondary metabolites formed from them appear to be of critical importance as elicitors, because the response reaction in the tuber tissue is blocked by lipoxygenase inhibitors (16,17).

The present paper is concerned with the structure and stereochemistry of products formed from arachidonic acid upon incubation with two rice lipoxygenases, i.e., rice seed lipoxygenase-2 (RSL-2) (18) and rice leaf pathogen-inducible lipoxygenase (RLIL) (19). Comparison of the specificities of oxygenations of arachidonic acid and linoleic acid is of general biochemical interest. Furthermore, although arachidonic acid is not present in rice, characterization of its lipoxygenase products is of potential biological importance in view of the possibility that arachidonic acid may be supplied to the rice plant by attacking fungi and insects.

EXPERIMENTAL PROCEDURES

Fatty acids and fatty acid hydro(pero)xides. Arachidonic and linoleic acids were purchased from Nu-Chek-Prep (Elysian,

MN). [1-^{14}C]Arachidonic and [1-^{14}C]linoleic acids were obtained from DuPont NEN (Boston, MA). 9(*S*)-Hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid [9(*S*)-HPOD] [enantiomeric composition: 9(*S*)/9(*R*), 98:2] and 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HPOD] [enantiomeric composition: 13(*S*)/13(*R*), 99:1] were prepared by incubations of linoleic acid with tomato lipoxygenase (20) and soybean lipoxygenase (21), respectively. 9(*S*)-HOD and 13(*S*)-HOD were prepared from the hydroperoxides by reduction with sodium borohydride in methanol. 9(*R,S*)-Hydroxy 10(*E*), 12(*E*)-octadecadienoic acid and 13(*R,S*)-hydroxy-9(*E*),11(*E*)-octadecadienoic acid were prepared by autoxidation of linoleic acid followed by reduction of the resulting hydroperoxides and isolation by high-performance liquid chromatography (HPLC) (22). 15(*S*)-Hydroperoxy-5(*Z*),8(*Z*),11(*Z*),13(*E*)-eicosatetraenoic acid [15(*S*)-HPETE] and 5(*S*)-hydroperoxy-6(*E*), 8(*Z*),14(*Z*)-eicosatetraenoic acid [5(*S*)-HPETE] were prepared by incubation of arachidonic acid with soybean lipoxygenase (21) and potato lipoxygenase (23), respectively. Aliquots of the hydroperoxides were treated with sodium borohydride to afford 15(*S*)-HETE and 5(*S*)-HETE. The methyl esters of 5(*R,S*)-HETE, 8(*R,S*)-HETE, 9(*R,S*)-HETE, 11(*R,S*)-HETE, 12(*R,S*)-HETE, and 15(*R,S*)-HETE were obtained by autoxidation of arachidonic acid followed by reduction, esterification, and isolation by straight-phase (SP) HPLC using a solvent system composed of 2-propanol/hexane (1.3:98.7, vol/vol).

Chemical methods. Catalytic hydrogenation (24), oxidative ozonolysis (25), and steric analysis of hydroxy acids (26) were performed as described.

Chromatographic and instrumental methods. Thin-layer chromatography (TLC) was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck (Darmstadt, Germany). Material was located by spraying with 2′,7′-dichlorofluorescein and viewing under ultraviolet (UV) light. Radioactivity on TLC plates was determined with a Berthold Dünnschichtscanner II (Berthold Analytical Instruments, Wildbad, Germany) interfaced with a Macintosh SE/30. SP-HPLC was performed using a column of Nucleosil 50-5 (200 × 4.6 mm) purchased from Macherey-Nagel (Düren, Germany). The solvent system used for isolation of monohydroxy esters was 2-propanol/hexane (1.3:98.7, vol/vol; flow rate, 1 mL/min), whereas 2-propanol/hexane (2.5:97.5, vol/vol; flow rate, 1.5 mL/min) was used for isolation of methyl dihydroxy- and dihydroperoxyeicosatetraenoates. The absorbancy and radioactivity of HPLC effluents were determined on-line using a Spectromonitor III (Laboratory Data Control, Riviera Beach, FL) and a liquid scintillation counter (IN/US Systems, Tampa, FL), respectively. Gas–liquid chromatography (GLC) was performed with a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm). Helium at a flow rate of 25 cm/s was used as the carrier gas. Gas chromatography/mass spectrometry (GC/MS) was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. UV spectra were recorded with a Hitachi (Tokyo, Japan) model U-2000 UV/VIS spectrophotometer. Infrared spectrometry was carried out using a Perkin-Elmer (Norwalk, CT) model 1650 FT-IR spectrophotometer. Radioactivity was determined with a Packard Tri-Carb model 4450 liquid scintillation counter (Packard Instruments, Downer's Grove, IL).

Expression of lipoxygenases. RSL-2 and RLIL were expressed in *Escherichia coli* BL21 (DE3) carrying pET3/RSL-2 (18) or pET3/RLIL (19) essentially as described. Briefly, *E. coli* cells were grown at 37°C to an A_{600} of 1.0–1.5 in 100 mL of Luria-Bertani medium (1% Trypton, 0.5% yeast extract and 1% sodium chloride) containing 50 μg/mL ampicillin. Isopropyl-thio-β-D-galactoside (0.4 mM) was added, and the culture was shaken at 15°C for 16 h. The cells were collected by centrifugation at 9300 × *g* for 15 min at +3°C and washed by resuspension in 100 mL of buffer A (10 mM sodium phosphate pH 6.8, 10% glycerol, 0.1% Tween 20, and 0.1 mM EDTA) followed by centrifugation. The pellet of washed cells was suspended in 50 mL of buffer A and sonicated at 0°C (4 periods of 15 s). Particulate material was removed by centrifugation, and the supernatant was used as the enzyme source. Protein was determined according to Bradford (27).

Lipoxygenase incubations. For assay of lipoxygenase activity, aliquots of the enzyme preparations obtained as described previously were added to 3 mL of 0.1 M potassium phosphate buffer pH 6.7, and arachidonic or linoleic acids (final concentrations, 50 μM) were added in 3 μL of ethanol. The A_{235} was followed vs. time. Preparative incubations were carried out at 23°C by stirring arachidonic or linoleic acids (100 or 300 μM as indicated) in 0.1 M potassium phosphate buffer, pH 6.7 (50–200 mL), in the presence of enzyme preparation. The reaction product was extracted with diethyl ether, and aliquots were esterified and analyzed by radio-TLC or radio-HPLC before and after reduction with sodium borohydride. The remaining part was reduced by treatment with sodium borohydride and esterified. Isolation of mono- and dihydroxyesters was carried out by SiO_2 open column chromatography followed by SP-HPLC.

RESULTS

Enzyme activity of preparations of RSL-2 and RLIL was assayed spectrophotometrically using arachidonic and linoleic acids as the substrates. As seen in Figure 1A, linoleic acid was a better substrate than arachidonic acid for RSL-2. A significant lag phase (approximately 1 min) was apparent with both acids. The progress of the oxygenations ceased at about 40% conversion (arachidonic acid) and 75–80% conversion (linoleic acid). This was probably due to inactivation of the enzyme because further conversion of the acids could be achieved by addition of a second aliquot of enzyme. The specific activities of RSL-2 in oxygenations of arachidonic and linoleic acids (measured at the point of maximum slope of the progress curves; ε = 26,000) were 0.27 μmol/min • mg protein and 0.61 μmol/min • mg protein, respectively. Arachidonic and linoleic acids were oxygenated at approximately the same rates upon incubation with RLIL (Fig. 1B). In this case, the lag phase was less pro-

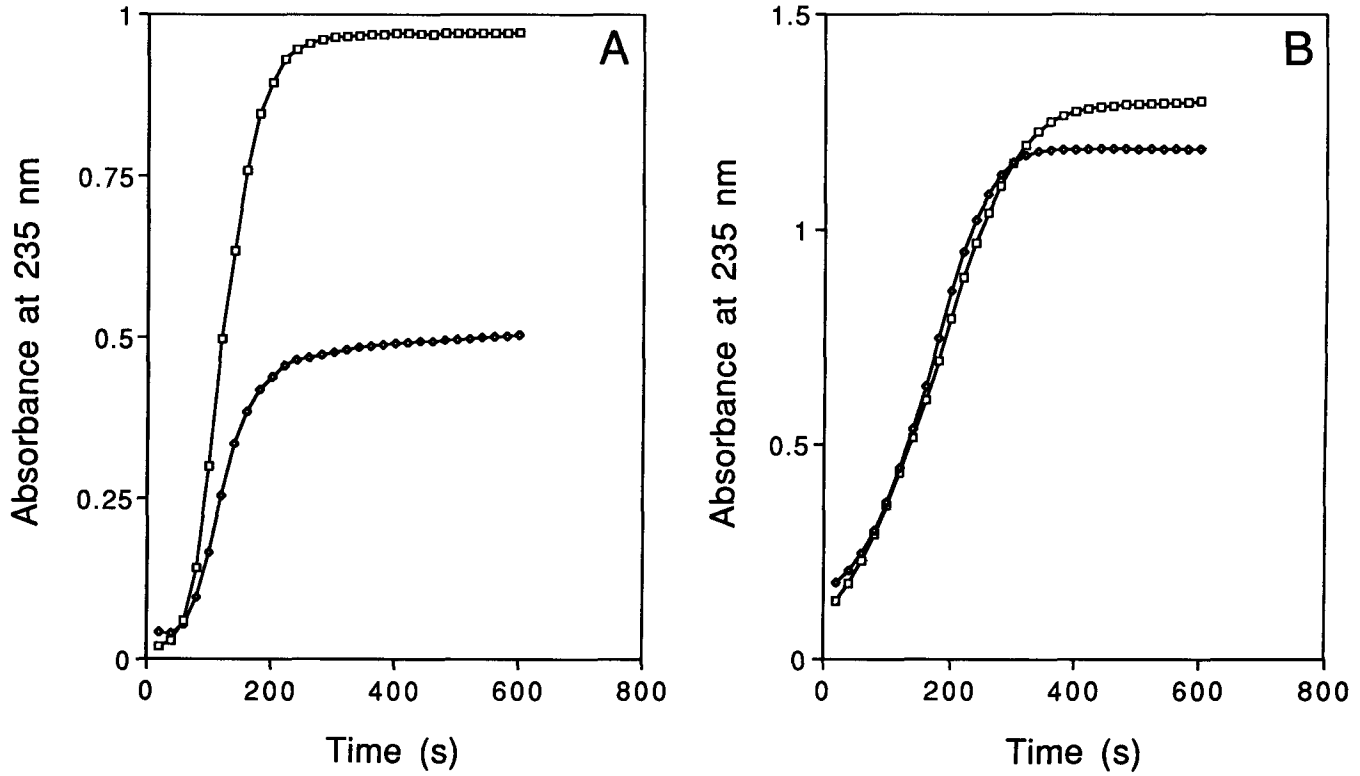

FIG. 1. Oxygenation of arachidonic and linoleic acids by rice seed lipoxygenase-2 (RSL-2) (A) and rice leaf pathogen-inducible lipoxygenase (RLIL) (B). The substrates (50 μM) were added dissolved in 3 μL of ethanol to preparations of RSL-2 (0.12 mg of protein in 3.2 mL of 0.1 M potassium phosphate buffer pH 6.7) or RLIL (0.03 mg of protein in 3.05 mL of 0.1 M potassium phosphate buffer pH 6.7). The absorbancy at 235 nm was followed vs. time. □, Linoleic acid; ◇, arachidonic acid.

nounced, and essentially complete conversions were observed. The specific activities of RLIL were 1.31 and 1.16 μmol/min • mg protein in oxygenations of arachidonic and linoleic acids, respectively.

Products formed from linoleic acid upon incubation with RSL-2. [1-^{14}C]Linoleic acid (300 μM) in 0.1 M potassium phosphate buffer pH 6.7 (100 mL) was stirred with enzyme preparation (3 mg of protein) for 20 min at 23°C. Material obtained by extraction with diethyl ether was subjected to SiO_2 open column chromatography. The column was eluted successively with diethyl ether/hexane (7:93, vol/vol; fatty acid fraction; less than 1% of the radioactivity applied), diethyl ether/hexane (20:80, vol/vol; hydroperoxide fraction; 86% of the radioactivity), and methanol (polar material; 14% of the radioactivity). Material present in the hydroperoxide fraction was reduced by treatment with sodium borohydride in methanol, esterified by treatment with diazomethane, and subjected to SP-HPLC. A main peak of material (retention volume, 7.6–8.1 mL) showing strong UV absorbance at 234 nm appeared. This compound was identified as the methyl ester of 13(*S*)-HOD by the following analyses (*cf.* Refs. 9,22): (i) cochromatography with authentic material on TLC and SP-HPLC; (ii) UV-spectrometry (λ_{max} = 234 nm, solvent ethanol); (iii) GC/MS analysis of the Me_3Si derivative using the same derivative of authentic material as reference; (iv) catalytic hydrogenation followed by GC/MS analysis of the Me_3Si derivative; and (v) oxidative ozonolysis performed on the propionyl derivative followed by coupling of the resulting 2-propionoxyheptanoic acid with L-phenylalanine methyl ester, and steric analysis of the resulting *N*-(propionoxyacyl)-L-phenylalanine-methyl ester (PAP) derivative by GLC (*cf.* Ref. 26). This last-mentioned analysis showed that the enantiomeric composition was 91% 13(*S*)-HOD and 9% 13(*R*)-HOD. In addition to 13(*S*)-HOD, three other hydroxyoctadecadienoates were observed upon SP-HPLC analysis. The identity of these compounds with the methyl esters of 9(*R,S*)-HOD [9(*R*)/9(*S*), 50:50; retention volume, 9.5–9.8 mL], 13-hydroxy-9(*E*),11(*E*)-octadecadienoic acid (8.7–9.0 mL), and 9-hydroxy-10(*E*),12(*E*)-octadecadienoic acid (10.4–10.8 mL) was established as described earlier using the respective authentic compounds as references. The composition of the hydroperoxide fraction obtained following incubation of linoleic acid with RSL-2 was: 13(*S*)-HPOD (87%), 9(*R,S*)-HPOD (8%), 9-hydroperoxy-10(*E*),12(*E*)-octadecadienoic acid (3%), and 13-hydroperoxy-9(*E*),11(*E*)-octadecadienoic acid (2%). A similar pattern of products was observed in incubations using a lower concentration (100 μM) of linoleic acid. That RSL-2 preferentially introduces oxygen at C_{13} when linoleic acid is used as the substrate has been previously reported (18).

Products formed from linoleic acid upon incubation with RLIL. [1-^{14}C]Linoleic acid (100 μM) was stirred with enzyme preparation (3 mg of protein) in 0.1 M potassium phosphate

buffer pH 6.7 (200 mL) at 23°C for 15 min. SiO_2 open column chromatography performed as described previously gave a hydroperoxide fraction that accounted for >90% of the radioactivity applied. Reduction with sodium borohydride followed by treatment with diazomethane and isolation by SP-HPLC afforded the methyl ester of 13-HOD (98%) and the methyl ester of 9-HOD (2%). Identification of the two compounds was performed by chemical and spectroscopical methods as described for the incubation of linoleic acid with RSL-2. The absolute configuration of the 13-HOD was found to be "*S*", i.e., 99.2% "*S*" and 0.8% "*R*." The configuration of the 9-HOD was not determined.

Products formed from arachidonic acid upon incubation with RSL-2. [1-^{14}C]Arachidonic acid (100 μM) in 0.1 M potassium phosphate buffer pH 6.7 (45 mL) was stirred with RSL-2 at 23°C. Three additions of enzyme preparation were made, i.e., 5 mL (3 mg of protein) at times 0, 10, and 20 min. After a stirring time of 30 min, the product was extracted with diethyl ether, reduced by treatment with sodium borohydride, and esterified. SiO_2 open column chromatography showed four main peaks of radioactivity, i.e., the methyl ester of arachidonic acid not converted [17%; eluted with diethyl ether/hexane (10:90, vol/vol)], methyl monohydroxyeicosatetraenoates [41%; eluted with diethyl ether/hexane (35:65, vol/vol)], methyl dihydroxyeicosatetraenoates (28%; eluted with ethyl acetate), as well as very polar material which was not further characterized (14%; eluted with methanol).

The methyl monohydroxyeicosatetraenoates were subjected to SP-HPLC (Fig. 2A). As seen, the methyl esters of 15-HETE (retention volume, 10.0–10.7 mL of effluent) and 5-HETE (22.4–23.7 mL of effluent) were obtained as the major compounds. In addition, small amounts of the methyl esters of 12-HETE, 11-HETE, 9-HETE, and 8-HETE, as well as the δ-lactone form of 5-HETE, appeared. The identities of the compounds were established by their retention volumes on SP-HPLC, by UV spectrometry, and by GC/MS analysis of the Me_3Si derivatives using the authentic compounds as references. In the cases of 5-HETE and 15-HETE, the absolute con-

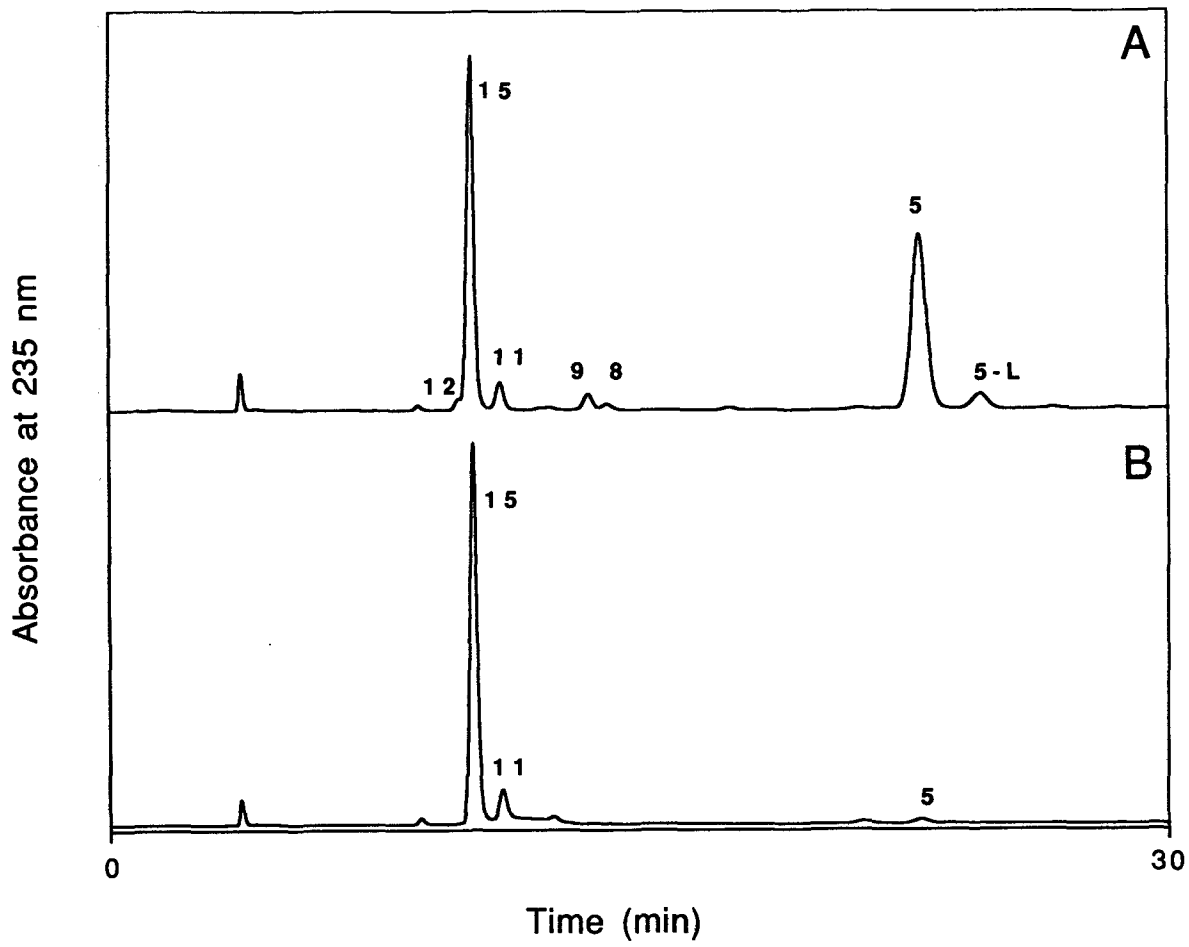

FIG. 2. High-performance liquid chromatography (HPLC) analysis of methyl monohydroxyeicosatetraenoates obtained following incubation of arachidonic acid with RSL-2 at pH 6.7 (A) and at pH 9.8 (B). The products of the incubations were reduced with sodium borohydride, esterified, and subjected to SiO_2 open column chromatography. Material present in the hydroxyester fraction (elution with diethyl ether/hexane, 35:65, vol/vol) was analyzed by straight-phase HPLC using a solvent system of 2-propanol/hexane (1.3:98.7, vol/vol) at a flow rate of 1 mL/min. 5-L, δ-lactone form of 5-HETE; 5, methyl ester of 5-HETE; 8, methyl ester of 8-HETE; 9, methyl ester of 9-HETE; 11, methyl ester of 11-HETE; 15, methyl ester of 15-HETE; 12, methyl ester of 12-HETE. See Figure 1 for other abbreviation.

figurations at C-5 and C-15, respectively, were determined. Thus, steric analysis of the PAP derivatives of 2-hydroxy-5-carbomethoxypentanoic acid (from the methyl ester of 5-HETE) and of 2-hydroxyheptanoic acid (from the methyl ester of 15-HETE) showed that the 5-HETE was due to 91% of the 5(*S*) enantiomer and 9% of the 5(*R*) enantiomer, whereas the 15-HETE was due to 90% of the 15(*S*) enantiomer and 10% of the 15(*R*) enantiomer.

The percentage composition of HPETE obtained following incubation of arachidonic acid with RSL-2 at pH 6.7 was: 12-HPETE, 2%; 15-HPETE, 43%; 11-HPETE, 4%; 9-HPETE, 3%; 8-HPETE, 1%; and 5-HPETE, 47% (Fig. 2A). Interestingly, the composition of HPETE obtained following incubation of arachidonic acid with RSL-2 was strongly pH-dependent. Thus, incubation at pH 9.8 afforded 15(*S*)-HPETE (88%) and 11-HPETE (9%). Formations of 5-HPETE (3%) and of 8-, 9-, and 12-HPETE, were almost completely abolished (Fig. 2B).

The methyl dihydroxyeicosatetraenoate fraction isolated by SiO_2 chromatography of the reduced and esterified product obtained following incubation of arachidonic acid with RSL-2 at pH 6.7 was subjected to radio-SP-HPLC. Two peaks of radioactivity appeared, i.e., Compound A (26.7–28.2 mL effluent; approximately 70% of the radioactivity) and Compound B (41.4–43.6 mL effluent; approximately 30% of the radioactivity). In a separate experiment, the sodium borohydride reduction was omitted. As expected, this resulted in two methyl dihydroperoxyeicosatetraenoates which eluted faster on radio-SP-HPLC, i.e., a major isomer corresponding to Compound A (18.0–19.1 mL effluent) and a minor isomer corresponding to Compound B (20.3–21.5 mL effluent).

The UV spectrum of Compound A showed λ_{max} (ethanol) = 243 nm, suggesting a 5,15-dihydroxyeicosatetraenoate having two pairs of conjugated *E,Z* double bonds (28). GC/MS analysis of the Me_3Si derivative showed a broad peak due to partial degradation on the capillary column. The mass spectrum showed prominent ions at *m/z* 479 (M – 15; loss of $\cdot CH_3$), 404 (M – 90; loss of Me_3SiOH), 394 (M – 100; rearrangement and loss of OHC-$(CH_2)_4$-CH_3), 203 [Me_3SiO^+=CH-$(CH_2)_3$-$COOCH_3$], 173 [Me_3SiO^+=CH-$(CH_2)_4$-CH_3], 129 (Me_3SiO^+=CH-CH=CH_2), and 73 (Me_3Si^+). The mass spectrum of the Me_3Si ether derivative of hydrogenated Compound A showed ions typical for a 5,15-dihydroxyeicosanoate, i.e., 487 (4%; M – 15, loss of $\cdot CH_3$), 431 [28; M – 71, loss of $\cdot(CH_2)_4$-CH_3], 402 [6; M – 100, rearrangement and loss of OHC-$(CH_2)_4$-CH_3], 401 [6; M – 101, loss of $\cdot(CH_2)_3$-$COOCH_3$], 341 [42; M – (71+90)], 311 [39; M – (101 + 90)], 203 [88, Me_3SiO^+=CH-$(CH_2)_3$-$COOCH_3$], 173 [74; Me_3SiO^+=CH-$(CH_2)_4$-CH_3], 129 (26; Me_3SiO^+=CH-CH=CH_2), and 73 (100; Me_3Si^+). Oxidative ozonolysis of the dipropionyl derivative of the methyl 5,15-dihydroxyeicosatetraenoate resulted in the formation of 2-propionoxy-5-carbomethoxypentanoic acid and 2-propionoxyheptanoic acid. Steric analysis of these compounds demonstrated that both chiral centers of the parent 5,15-dihydroxyeicosatetraenoate had the "*S*" configuration (C-5, 98.1% "*S*"; C-15, 97.9% "*S*"). This experiment also localized one double bond to the Δ^6 position and another double bond to the Δ^{13} position. On the basis of the data presented, Compound A was identified as methyl 5(*S*),15(*S*)-dihydroxy-6,8,11,13-eicosatetraenoate [methyl ester of 5(*S*),15(*S*)-diHETE].

The UV spectrum of Compound B showed λ_{max} (ethanol) 259, 268, and 279 nm, suggesting a conjugated triene structure (*cf.* Ref. 28). GC/MS analysis of the Me_3Si derivative showed a broad peak due to partial degradation. The mass spectrum showed prominent ions at *m/z* 423 [M – 71, loss of $\cdot(CH_2)_4$-CH_3], 394 [M – 100; rearrangement and loss of OHC-$(CH_2)_4$-CH_3), 243 [Me_3SiO^+=CH-CH_2-CH=CH-$(CH_2)_3$-$COOCH_3$], 173 [Me_3SiO^+=CH-$(CH_2)_4$-CH_3], and 73 (Me_3Si^+). The data mentioned suggested a 8,15-dihydroxyeicosatetraenoate, in which three of the four double bonds formed a conjugated triene. Catalytic hydrogenation afforded methyl 8,15-dihydroxyeicosanoate, as shown by the mass spectrum (Me_3Si derivative), which showed prominent ions at *m/z* 487 (5%; M – 15, loss of $\cdot CH_3$), 431 [14; M – 71, loss of $\cdot(CH_2)_4$-CH_3], 359 [13; M – 143, loss of $\cdot(CH_2)_6$-$COOCH_3$], 341 [38; M – (71 + 90)], 269 [29; M – (143 + 90)], 245 [94; Me_3SiO^+=CH-$(CH_2)_6$-$COOCH_3$], 216 [17; M – 286, rearrangement with loss of OHC-$(CH_2)_6$-CH($OSiMe_3$)-$(CH_2)_4$-CH_3], 173 [60; Me_3SiO^+=CH-$(CH_2)_4$-CH_3], and 73 (100; Me_3Si^+). Oxidative ozonolysis of the dipropionyl derivative of Compound B resulted in the formation of the propionyl derivatives of malic acid and of 2-hydroxyheptanoic acid. Steric analysis of the PAP derivatives of these compounds showed that C-8 and C-15 of the parent compound had both the "*S*" configuration (C-8, 99.0% "*S*"; C-15, 97.1% "*S*"). Furthermore, formation of the fragments mentioned, coupled with knowledge about the positions of the hydroxyl groups (at C-8 and C-15), and the presence of a conjugated tetraene structure, localized the four double bonds of Compound B to the Δ^5, Δ^9, Δ^{11}, and Δ^{13} positions. Accordingly, Compound B was identified as methyl 8(*S*),15(*S*)-dihydroxy-5,9,11,13-eicosatetraenoate [methyl ester of 8(*S*),15(*S*)-diHETE] (Fig. 3).

Products formed from arachidonic acid upon incubation with RLIL. [1-^{14}C]Arachidonic acid (100 μM) was stirred with enzyme preparation (3 mg of protein) in 0.1 M potassium phosphate buffer pH 6.7 (200 mL) at 23°C for 15 min. SiO_2 open column chromatography gave a hydroperoxide fraction accounting for approximately 90% of the radioactivity applied. The material was treated with sodium borohydride, and the esterified product was subjected to radio-SP-HPLC. A single peak due to the methyl ester of 15-HETE appeared (methyl ester of 11-HETE, less than 1%). Steric analysis of the 2-propionoxyheptanoic acid obtained following oxidative ozonolysis showed a high enantiomerical purity of the parent compound, i.e, 99.5% 15(*S*)-HETE and 0.5% 15(*R*)-HETE. Incubation of arachidonic acid with RLIL also was carried out at pH 9.8 and 5.2. In contrast to the results obtained with RSL-2, no pH-dependent change in regiospecificity could be observed. Thus, all incubations carried out in the pH range 5.2–9.8 led to the formation of 15(*S*)-HPETE with less than 3% of other HPETE isomers.

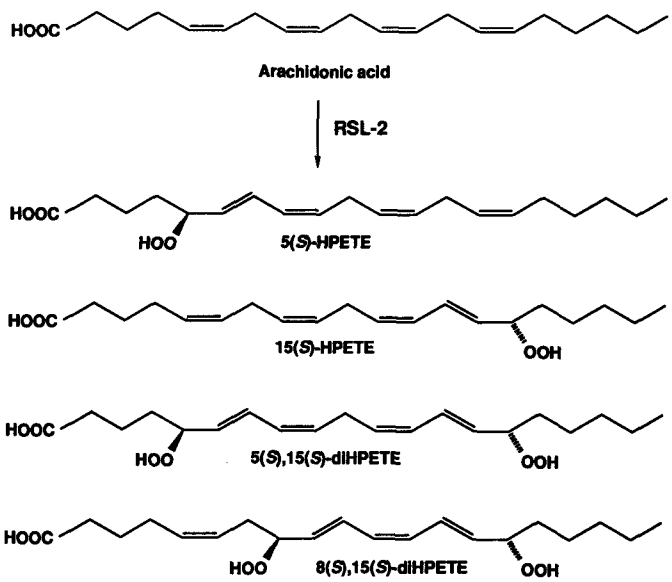

FIG. 3. Structures of mono- and dihydroperoxyeicosatetraenoates formed from arachidonic acid in the presence of RSL-2 at pH 6.7. See Figures 1 and 2 for abbreviations.

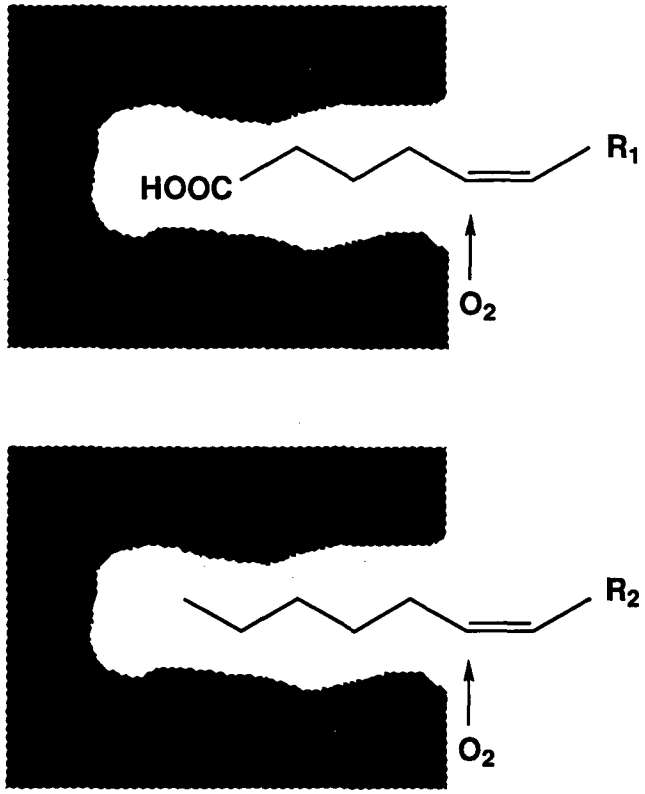

FIG. 4. Proposed head-to-tail orientations of the nonprotolyzed form of arachidonic acid at the active site of rice seed lipoxygenase-2 (RSL-2). Insertion of oxygen from a position above the plane of the carbon chain will result in the formation of 5(*S*)-HPETE when the substrate is oriented with its carboxyl end in the hydrophobic pocket (upper) and to 15(*S*)-HPETE when the orientation is reversed (lower). R_1, $(CH_2\text{-}CH{=}CH)_3\text{-}(CH_2)_4\text{-}CH_3$; R_2, $(CH_2\text{-}CH{=}CH)_3\text{-}(CH_2)_3\text{-}COOH$. See Figures 1 and 2 for abbreviations.

DISCUSSION

In agreement with previous work (18,19), RSL-2 and RLIL were found to catalyze oxygenation preferentially at the n-6 position of linoleic acid to provide 13(*S*)-HPOD as the major product. However, when arachidonic acid was used as substrate, the product profiles of the two enzymes differed. Thus, oxygenation of arachidonic acid in the presence of RLIL led almost exclusively to the formation of a single monohydroperoxide, i.e., 15(*S*)-HPETE. The enantiomerical purity of this compound was high (99.5% "*S*"). In contrast, catalysis by RSL-2 led to the formation of two major monohydroperoxides [5(*S*)-HPETE and 15(*S*)-HPETE] as well as significant amounts of two double dioxygenation products, [5(*S*),15(*S*)-diHPETE and 8(*S*),15(*S*)-diHPETE] (Fig. 3). Interestingly, the regiospecificity of RSL-2 was strongly pH-dependent. At pH 6.7, 5(*S*)-HPETE and 15(*S*)-HPETE were formed in a ratio of 52:48. Increasing the pH to 9.8 suppressed formation of 5(*S*)-HPETE and gave 15(*S*)-HPETE as the major product [ratio 5(*S*)-HPETE/15(*S*)-HPETE, 3:97]. In this context it is interesting to note that the regiochemistry of soybean lipoxygenase-1-catalyzed oxygenation of linoleic acid has been found to be pH-dependent (29), a phenomenon that is probably caused by alternate head-to-tail orientations of the substrate at the active site of the enzyme (29). It seems likely that the pH effect in arachidonic acid oxygenation observed in the present study can be explained in the same way, i.e., by the pH-dependent ionization of the carboxyl group coupled with the existence of a hydrophobic pocket in the active site of RSL-2. Thus, at an alkaline pH, the carboxyl group will exist as the charged carboxylate anion and, hence, only the ω-end of the arachidonic acid molecule can enter the hydrophobic pocket. In this situation, formation of one major HPETE [i.e., 15(*S*)-HPETE] will be predicted. On the other hand, at more acidic pH the carboxyl group will be protonated and therefore be able to enter the hydrophobic pocket. Two orientations of the substrate will thus be possible, leading to the formation of two major HPETE isomers [5(*S*)- and 15(*S*)-HPETE] (Fig. 4).

ACKNOWLEDGMENTS

This work was supported by the Swedish Medical Research Council (Proj. no 03X-05170). The authors are greatly indebted to Dr. D. Shibata, Mitsui Plant Biotechnology Research Institute, (Ibaraki, Japan), for generous gifts of *E. coli* carrying pET3/RSL-2 or pET3/RLIL.

cis/trans Isomerization of Unsaturated Fatty Acids as Possible Control Mechanism of Membrane Fluidity in *Pseudomonas putida* P8

Burkhard Loffeld and Heribert Keweloh*

Department of Microbiology, University of Muenster, D-48149 Muenster, Germany

ABSTRACT: Exponentially growing cells of *Pseudomonas putida* had an increased ratio of saturated to unsaturated fatty acids in response to increased growth temperatures. Resting cells in which fatty acid biosynthesis was stopped reacted to a thermal increase by converting *cis*-monounsaturated fatty acids to *trans* isomers. *cis/trans* Isomerization of up to 60% of the unsaturated fatty acids was also activated by alcohols of different chain length. Their effective concentrations apparently depended on the lipophilic character of the alcohols. Also, a salt shock caused by the addition of NaCl resulted in the production of *trans* fatty acids. However, cells that were adapted to growth media of high osmolarity synthesized cyclopropane fatty acids instead of *trans* fatty acids. Activity of *cis/trans*-isomerase was dependent on the growth phase and was significantly higher during logarithmic growth than during the stationary phase. The results of this study agree with the hypothesis that the isomerization of *cis* into *trans* unsaturated fatty acids is an emergency action of cells of *P. putida* to adapt membrane fluidity to drastic changes of environmental conditions.

Lipids 31, 811–815 (1996).

The fatty acid profile of microorganisms is a stable genetic trait and can be used for chemotaxonomic purposes. Bacteria have to be cultured under standarized conditions; otherwise the fatty acid composition of lipids may vary considerably with changes in environmental conditions, growth rate, or growth phase (1,2). Apparently, these lipid modifications enable vital membrane functions to continue if physical or chemical factors influence the stability of the cell membrane. Bacteria have different mechanisms to alter lipid composition and hence the fluidity of their membranes, in response to environmental changes, such as growth temperature. Many studies show that the most important way for bacteria to regulate membrane fluidity is to increase or decrease the proportion of saturated to *cis*-monounsaturated fatty acids (1–4).

Recently, *trans* unsaturated fatty acids were detected in bacterial lipids among the commonly found *cis* isomers (5–8). These unusual membrane constituents were identified in strains of *Pseudomonas putida* which can degrade toxic pollutants, such as phenol (9,10). Cells react to the addition of different aromatic substances or ethanol with the production of *trans*-unsaturated fatty acids (11,12). The increase in the amount of fatty acids with a double bond in a *trans* configuration is accompanied by an appropriate decrease of the corresponding *cis* isomers. Biosynthesis of *trans* fatty acids is located in the cytoplasmic membrane and is apparently performed by isomerization of *cis* unsaturated fatty acids to *trans* and not by *de novo* synthesis of fatty acids (13,14).

Thermal adaptation of the phenol-degrading bacterium *P. putida* P8 is normally done by modifying the degree of fatty acid saturation (11). Here we have studied if *cis/trans* isomerization of fatty acids is also involved in the regulation of membrane fluidity. Therefore, we observed the effects on the lipid composition of factors known to influence the membrane fluidity. The isomerization of *cis* unsaturated fatty acids to *trans* is apparently a general response of *P. putida* if the environmental conditions change and the membrane composition cannot be altered by conventional mechanisms.

METHODS

Growth conditions. Pseudomonas putida P8 isolated from phenol contaminated wastewater (15) was grown at 30°C in a minimal medium that contained: 0.6 g KH_2PO_4, 1.2 g K_2HPO_4, 1.0 g $(NH_4)_2SO_4$, 0.05 g $Ca(NO_3)_2$, 0.2 g $MgSO_4$, 0.01 g $Fe(NH_4)$ citrate, 1 mL of a trace element solution (16), and 4.0 g sodium succinate per L of deionized H_2O. The pH was adjusted to 7.0. Growth of cultures was measured by optical density.

Determination of bacteriostatic and bacteriocidal alcohol concentrations. The minimal inhibitory concentration of alcohols was defined as the concentration that completely blocked cellular growth. For determination different concentrations of the alcoholic compounds were added to exponentially growing cells of *P. putida* P8 and growth was monitored by measuring the absorbance (A_{560}) of cultures. To measure bactericidal concentrations (LD_{90}), cells of the logarithmic growth phase were incubated for three hours in the presence of different concentrations of the alcohols, after which a viable count measurement was carried out. The numbers of surviving cells

were determined, and the concentrations of alcohols needed for a tenfold reduction in cell number were calculated.

Lipid extraction and determination of fatty acid composition. Lipids were extracted with chloroform/methanol/water (1:1:1, by vol) as described by Bligh and Dyer (17). Fatty acid methyl esters were prepared by a 15-min incubation at 95°C in boron trifluoride/methanol using the method of Morrison and Smith (18). Fatty acid composition was determined using capillary gas chromatography of fatty acid methyl esters as described by Heipieper *et al.* (9). Replicate determinations indicated that the relative error (standard deviation/mean) × 100% of the values was 2–5%. The lipid fraction analyzed contained phospholipids to more than 95%.

Analysis of de novo *lipid synthesis.* Fatty acid biosynthesis was measured by studying the incorporation of labeled acetate in the lipid fraction. For this purpose 120 nCi of sodium [1-^{14}C]acetate (54 mCi/mmol; Hartmann Analytic, Braunschweig, Germany) were added to 1 mL of growing and nongrowing cells, respectively. After incubation for 2 h at 30°C, the cells were harvested and lipids were extracted as described previously. The radioactivity of the extracted lipids recovered in the chloroform layer was used as a measure of the incorporation of acetate in the fatty acids and was determined by liquid scintillation spectrometry.

Activity of cis/trans *isomerase.* Activity of *cis/trans* isomerase was measured after harvesting cultures at different times by sedimentation and resuspending cells in 50 mM potassium phosphate buffer, pH 7.0. Cells were harvested and lipids were extracted and analyzed before and after incubating with ethanol (10%, vol/vol) for 2 h at 30°C. The increase of the relative amounts of *trans* fatty acids during this activation period was defined as the *trans/cis* activity.

The *trans/cis* ratio was determined as the proportion of the sum of *trans* unsaturated to the sum of *cis* unsaturated fatty acids. The ratio of the relative amounts of saturated to unsaturated plus cyclopropane fatty acids was calculated as the degree of saturation. The experiments of this study were repeated at least three times and representative results were presented here.

RESULTS

Effect of temperature in growing cells. Membrane lipids of *P. putida* P8 cells harvested in the logarithmic growth phase contain palmitic acid (16:0) and the *cis* and the *trans* isomers of palmitoleic acid [16:1 (9)] and vaccenic acid [18:1 (11)] as main fatty acids. Additionally, myristic acid (14:0), stearic acid (18:0), and the cyclopropane fatty acids 17:0 cyc and 19:0 cyc usually occur in minor amounts (lower than 3% of total fatty acids, respectively). The lipids of these cells have a proportion of saturated to unsaturated fatty acids of about 0.6, which is increased slightly during the course of growth, and a *trans/cis* ratio below 0.1.

When the growth temperature was altered, the bacteria responded by changing the fatty acid composition and resulted in a modified degree of saturation (Fig. 1). Lipids of cells

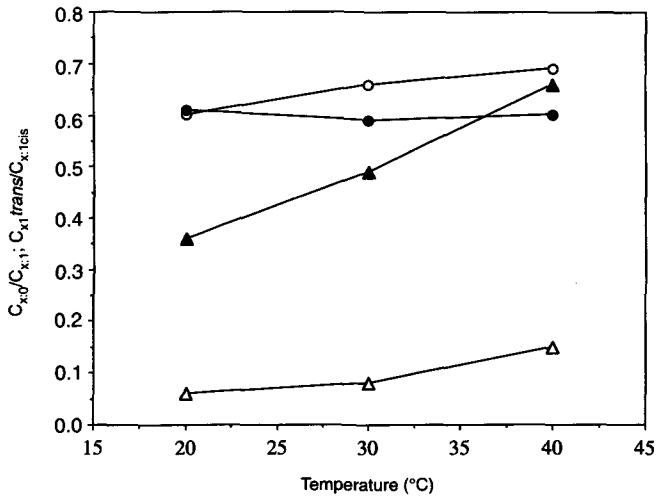

FIG. 1. Effect of temperature on the degree of saturation (circles) and the ratio of *trans* to *cis* unsaturated fatty acids (triangles) in the membrane lipids of cells of *Pseudomonas putida* P8. Exponentially growing cells were harvested by sedimentation and resuspended in growth medium (open symbols) or in 50 mM potassium phosphate buffer, pH 7 (closed symbols). After incubation for three hours at the temperature indicated, cells were harvested by sedimentation, washed with saline, and analyzed for fatty acids.

growing at the lower temperature of 20°C had a reduced degree of saturation compared with cells grown at higher temperatures. In growing cells, the ratio of *trans* to *cis* unsaturated fatty acids cells remained at a relatively low value and was only slightly increased at temperatures significantly higher than the optimal growth temperature of 30°C.

Effect of temperature in nongrowing cells. In contrast to growing cells, resting cells apparently did not use the conventional mode of thermal adaptation of lipids because they did not respond to increased temperatures with a change in the degree of saturation (Fig. 1). The cells grown at 30°C and resuspended in buffer at various temperatures converted the *cis* unsaturated fatty acids into *trans* isomers, mainly *cis* to *trans* 16:1. The increase in the *trans/cis* ratio of the unsaturated fatty acids depended on the ambient temperature and was highest at 40°C.

In the resting cells, the relative amounts of saturated fatty acids and of *cis* and *trans* unsaturated fatty acids together remained constant. Radioisotope tracer studies with sodium [^{14}C]acetate indicated that *de novo* biosynthesis of fatty acids did not occur in the nongrowing cells. Cells of *P. putida* P8 growing at 30°C in the minimal medium incorporated 13.0% of labeled acetate into lipids. Only 0.46% of the radioactivity was found in the lipid fraction after incubation with resting cells. Similiar amounts of activity were also detected in the chloroform layer during lipid extraction in control experiments without cells.

Effect of alcohols. Cis/trans conversion of up to 60% of the unsaturated fatty acids was also activated by the addition of organic chemicals, such as alcohols. These compounds were added to growing cells of *P. putida* P8. All alcohols used

were effective at different concentrations in this mode of fatty acid modification. Figure 2 shows that ethanol had to be added in a higher concentration to get the isomerization of *cis* to *trans*, while the long-chained alcohols butan-1-ol and hexan-1-ol were active in significantly smaller dosages. The effective concentrations corresponded to the length of the aliphatic moiety and thus the lipophilicity of the compounds.

The same alcoholic substance concentrations that caused maximal activation of *cis/trans* isomerization also completely inhibited cell growth (Fig. 2). At lower concentrations, the conventional mode of adaptation, i.e., change of degree of saturation was observed, and cell growth still continued. Bactericidal concentrations of alcohols used in these experiments were also measured. For ethanol (LD_{90}: 13% vol/vol) and butan-1-ol (3.0%) the lethal dose was in the range of the fatty acid modification. Either *cis/trans* isomerization was still possible in inactivated cells or conversion of unsaturated fatty acid preceeded the lethal event. In the case of hexanol (1.3%) the dose for a tenfold reduction in viable count was significantly higher than the range of concentrations inducing strong *cis/trans* isomerization of unsaturated fatty acids.

Effect of salt addition. We have studied the effect of an increase in salt concentration in the minimal medium by addition of NaCl. When cells of *P. putida* P8 were grown for several generations in the modified growth media (Fig. 3A), membrane lipids contained increased amounts of cyclopropane fatty acids, especially 17:0 cyc, while the content of the *cis* unsaturated fatty acids was diminished. The relative amounts of saturated and of *trans* fatty acids were not influenced.

The fatty acid composition of cellular lipids was modified in a completely different way if cells could not adapt to the increased salinity of the medium (Fig. 3B). In these experiments cells growing in minimal medium without salt were shocked by the addition of NaCl. These cells also responded to the increased salt concentration with a decrease of *cis* unsaturated fatty acids. In this case, a production of *trans* and not of cyclopropane fatty acids followed the change in medium composition.

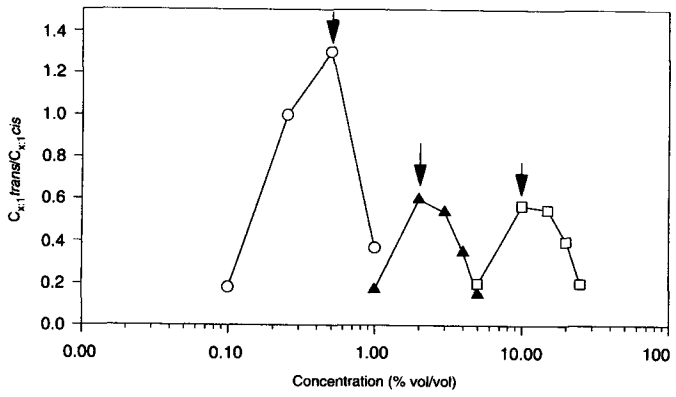

FIG. 2. Effect of ethanol (□), butanol (▲), and hexanol (○) on the ratio of *trans* to *cis* unsaturated fatty acids in the membrane lipids of cells of *Pseudomonas putida* P8. Alcohols were added to growing cells in the late log phase. After incubation for 3 h at 30°C cells were harvested, lipids were extracted and analyzed for fatty acids. Minimal inhibitory concentrations of the alcohols are indicated by an arrow above the plot of fatty acids.

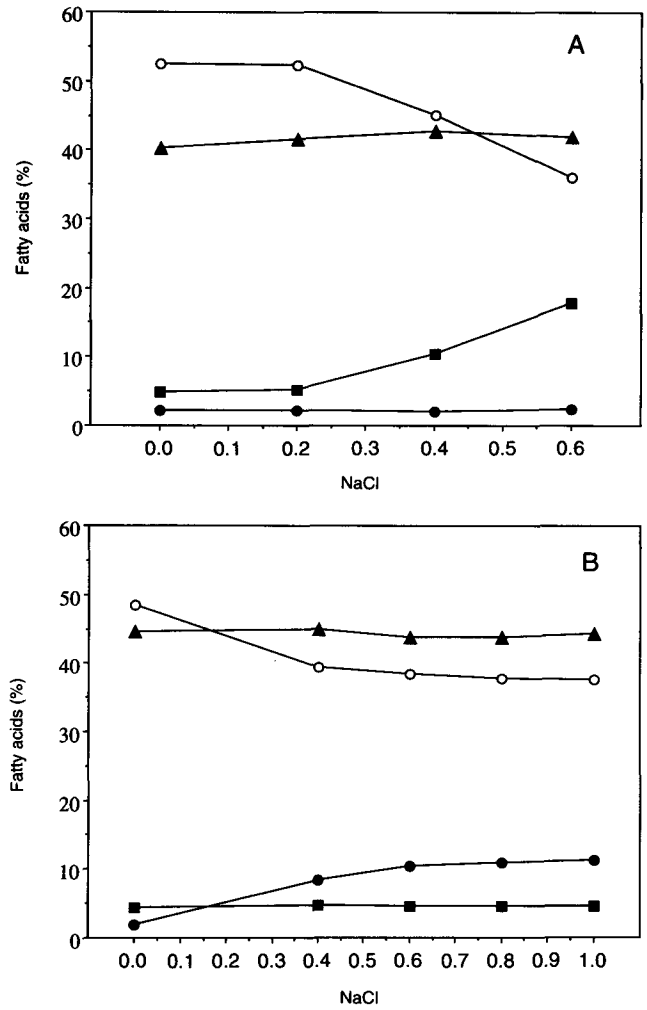

FIG. 3. Effect of salinity on fatty acid composition of salt-adapted and nonadapted cells of *Pseudomonas putida* P8: *trans* unsaturated (●), *cis* unsaturated (○), cyclopropane (■), and saturated fatty acids (▲). A, Salt-adapted cells were grown as overnight and main cultures in growth media with different salt concentrations. Cultures were harvested in the late-log phase and the bacterial lipids were analyzed. B, Cells were grown in a medium without NaCl and shocked by addition of concentrated salt solutions. Cells were sedimented 2 h later and analyzed for fatty acids.

Effect of growth phase. Pseudomonas putida cells at the stationary phase of cell growth were harvested and their lipids analyzed. They had a fatty acid composition significantly different from that of cells in the log growth phase (Fig. 4). The lower proportion of *cis* unsaturated fatty acids was mainly caused by an increase in the amounts of cyclopropane fatty acids. Simultaneously, the cells had a smaller content of *trans* fatty acids than the exponentially growing cells.

A conclusion about the activity of *cis/trans*-isomerase can be made by comparing the *trans* content of cells activated by ethanol with that of untreated cells. Figure 5 shows that this activity is dependent on the growth phase of the cells. Loga-

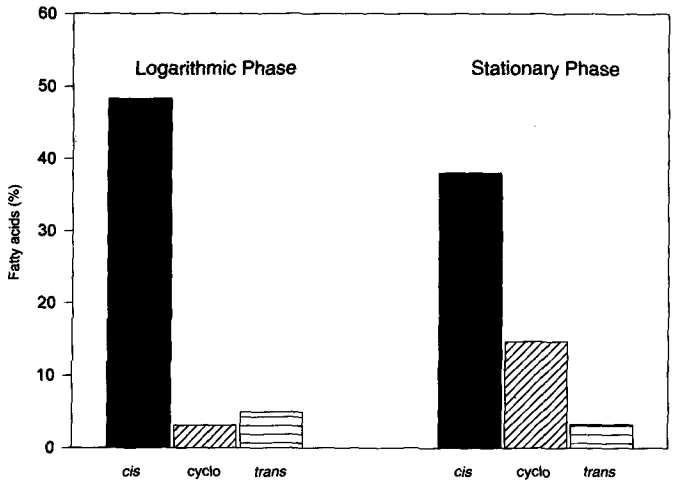

FIG. 4. Relative contents of fatty acids in cells of *Pseudomonas putida* P8 harvested in the mid-log phase (left three bars) or three hours after entry in the stationary phase (right three bars). Lipids were extracted and analyzed for *cis* unsaturated, cyclopropane (cyclo), and *trans* unsaturated fatty acids.

rithmically growing cells incubated with ethanol had a high activity of fatty acid conversion; a maximum was measured in the mid-log phase. Cells harvested in the late log phase showed a significantly decreased activity. In the stationary phase activity of *cis/trans*-isomerase dropped to a low level. Apparently, the isomerization of *cis* to *trans* fatty acids is not only influenced by environmental conditions, but also by intrinsic factors.

DISCUSSION

Fatty acid composition of bacterial lipids is affected by temperature (2,4,6–8,19), the presence of organic compounds such as aromatics or alcohols (20–23), or the osmolarity of the growth medium (24–26). Cells of *P. putida* P8 also respond to these membrane-active stimuli with commonly found membrane modifications, such as an increase in the degree of saturation of fatty acids or in the proportion of cyclopropane fatty acids. This study shows that the environmental factors, if applied under growth-inhibiting conditions, induce conversion of *cis* into *trans* unsaturated fatty acids in this bacterial strain. The isomerization of a large portion of *cis* into *trans* unsaturated fatty acids markedly decreases the membrane fluidity, as shown by different studies (8,10,27). Obviously, the reason for this is that the steric behavior of *trans* unsaturated fatty acids in membranes is similiar to that of saturated acyl chains. Both types of fatty acids possess a long extended conformation and a small molar volume as membrane constituents. In contrast to these acyl chains, *cis* unsaturated fatty acids have a rigid bend with an angle of 30°, and interrupt the highly ordered package of the acyl chains, leading to lower phase transition temperatures of the membrane.

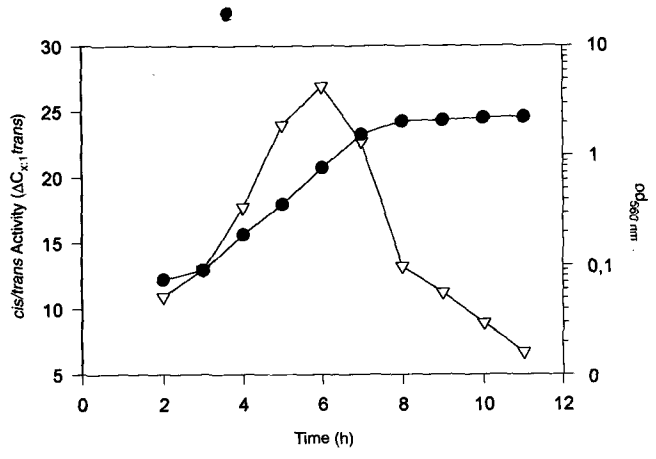

FIG. 5. Activity of *cis/trans* isomerase (▽) during growth (●) of *Pseudomonas putida* P8.

The regulation of membrane fluidity by modification of the ratio of saturated to monounsaturated fatty acids is probably restricted for growing cells in bacteria using the anaerobic way of fatty acid biosynthesis like *P. putida* and *Escherichia coli* (28). These bacteria, which lack membrane-bound desaturases, completely synthesize the saturated and unsaturated acyl chains of lipids in the cytoplasma. If cell growth ceases, lipid and fatty acid biosynthesis are immediately stopped and the degree of saturation cannot significantly be manipulated by the cells (29,30). Those bacteria that have the capacity of converting the double bond configuration possess a mechanism to change membrane fluidity, that is independent of growth. The mechanism is used whenever environmental conditions change so drastically that growth cannot continue.

An increase in the portions of cyclopropane fatty acids in cellular lipids is also frequently assessed when batch cultures enter the stationary phase of growth (1,28,31). The effect is apparently caused by the stringent response (32). Contrary to the activity of cyclopropane fatty acid synthetase, the activity of the *cis/trans* isomerase decreased significantly in *P. putida* P8 cells of the stationary phase. This observation is not in agreement with that of Guckert *et al.* (31). After long-term starvation of cells of *Vibrio cholerae* these authors measured increased amounts of *trans* unsaturated fatty acids. They explained this by a greater metabolic stability of the *trans* fatty acids than *cis* isomers in starving cells. However, cells of *Shewanella putrefaciens* and *Vibrio* sp. also showed a lower content of *trans* unsaturated fatty acids when their lipids were analyzed in the stationary growth phase (7,33). Therefore, there is more evidence that *cis/trans* isomerization is an emergency system of growing cells induced by threatening environmental conditions rather than a system that protects microbial lipids from degradation during nutritional deprivation.

Alterations in Cell Cholesterol Content Modulate Ca^{2+}-Induced Tight Junction Assembly by MDCK Cells

ABSTRACT: Transepithelial electrical resistance (TER), a measure of tight junction (TJ) barrier function, develops more rapidly and reaches higher values after preincubation of MDCK cells for 24 h with 2 μM Lovastatin (lova), an inhibitor of 3-hydroxy-3-methylglutaryl–CoA reductase. While this effect was attributed to a 30% fall in cholesterol (CH), possible effects of lova on the supply of prenyl group precursors could not be excluded. In the current study, strategies were devised to examine effects on TER of agents that simultaneously lower CH and increase the flux of intermediates through the CH biosynthetic pathway. Zaragozic acid, 20 μM, an inhibitor of squalene synthase known to increase the synthesis of isoprenoids and levels of prenylated proteins, lowered cell CH by 30% after 24 h, while accelerating development of TER in the same manner as lova. TER was also enhanced, despite a 23% increase in the rate of [^{3}H]acetate incorporation into CH, when total CH was reduced by 45% during a 2-h incubation with 2 mM methyl β-cyclodextrin (MBCD), an agent that stimulates CH efflux from cells. The fact that the rate of TER development was diminished when cell CH content was elevated by incubation with a complex of CH and MBCD is further evidence that this sterol modulates development of the epithelial barrier. Cell associated CH derived from the complex was similar to endogenous CH with respect to its accessibility to cholesterol oxidase. Lova's effect on TER was diminished when 5 μg/mL of CH was added to the medium during the last 11 h of incubation with lova.
Lipids 31, 817–828 (1996).

Movement of solutes and water from one compartment to another across an epithelial monolayer occurs *via* transcellular and/or paracellular pathways. Flux through the latter is determined by tight junctions (TJ), the most apical component of the epithelial junctional complex (1). Several proteins, including occludin, the first to have structural features and a subcellular distribution expected of a TJ protein (2), have been implicated in TJ assembly and function. The role of plasma membrane lipids in TJ biology is not as well understood. Early freeze fracture electron microscopy studies revealed striking similarities between TJ particles and structures formed after addition of Ca^{2+} to defined phospholipid mixtures (3–5). Based on these observations it was proposed that the TJ particles themselves might represent tubular, inverted, lipid micelles formed by fusion of the outer lipid bilayer of adjacent cells at points where they make contact. Although direct experimental support for this model is lacking, under certain conditions a lipid-soluble probe can be made to diffuse directly from the apical surface of one cell to that of another in a monolayer with established TJ (6,7).

Whether they constitute a structural element of the TJ or not, plasma membrane lipids are a diverse mixture of molecules which, if altered, can affect the activity of a variety of plasma membrane proteins (8,9), as well as more macroscopic events, such as the fusion of membranes (10). Directly or indirectly, therefore, plasma membrane lipids may affect TJ assembly and function. Attempts have been made to relate alterations in cell phospholipid composition to changes in transepithelial electrical resistance (TER), a commonly used measure of TJ function (11). Modifications in phospholipid fatty acyl group composition, for example, caused by the addition of exogenous fatty acids to the culture medium, altered the kinetics of Ca^{2+}-induced TJ assembly (12). Changes in phospholipid head group composition, on the other hand, had little effect on TJ (13). The compositional alterations produced in these studies were not confined to the plasma membrane, however, but were probably more global. In a recent study changes more localized to the cell surface lipid environment were induced by taking advantage of the observation that up to 90% of the cell's cholesterol (CH) is located in the plasma membrane (14,15). By incubating cells with Lovastatin (lova), an inhibitor of 3-hydroxy-3-methylglutaryl (HMG)–CoA reductase, most of any significant decline in total cell CH should occur in the plasma membrane pool. Decreasing CH by 30% in this fashion halved the time for initiating the development of TER and resulted in higher peak values when TJ were induced to form by addition of Ca^{2+} (16).

Because some of the intermediates derived from mevalonate are common precursors for biosynthesis of both CH and prenyl groups, the effects of lova on TER may not have been related solely to changes in CH content. In fact, among the proteins which undergo prenylation, rab 13, a small GTP binding protein, was recently shown to colocalize with the TJ associated protein zonula occludens-1 in polarized epithelial cells with formed TJ (17). Several observations, however, suggest that the fall in cell CH, rather than a decrease in the availability of precursors for prenyl group synthesis, is responsible for lova's effect on TER. The concentration of lova that produced accelerated Ca^{2+}-induced TJ assembly, for example, was considerably less (2 μM) than that commonly used to inhibit prenylation of proteins in a variety of cells (20–30 μM) (18–20). Furthermore, lova's effect on TER was overcome only at high concentrations of mevalonate (5 mM) that restored CH levels to control values, and not at lower levels (0.5 mM), which do not increase cell CH but do support prenylation of proteins (16,18,20). Although these data are consistent with the conclusion that TJ assembly is sensitive to the CH content of the plasma membrane, the possibility remains that lova's effect on TJ assembly might, at least in part, result from a decrease in the availability of intermediates required for protein prenylation.

In the present study strategies were employed to examine further the relationship between cell CH content and the development of TER. In one, zaragozic acid, a competitive inhibitor of squalene synthase known to increase the level of precursors utilized for isoprenoid synthesis (21,22), was substituted for lova and its effect on TER determined. As an alternative approach, instead of using CH synthesis inhibitors, a cholesterol binding agent, methyl β-cylcodextrin (MBCD), or a complex of CH and MBCD (CH-MBCD) was added to the medium to lower or raise, respectively, cell CH content. The data presented show that the CH taken up from the CH-MBCD complex is similar to endogenous CH with respect to its preferential accumulation in the plasma membrane. At low concentrations, exogenous CH (as CH-MBCD complex) overcomes, to a large extent, lova's effect on cell CH content and the development of TER.

METHODS AND MATERIALS

Reagents. Lova and zaragozic acid A were gifts from Merck Sharp and Dohme Research Labs (Rahway, NJ). Dulbecco's modified Eagle medium (DMEM), Ham's F-12 nutrient mixture, Earle's balanced salt solution (EBSS), and individual components to make low Ca^{2+} minimal essential medium (low Ca^{2+} medium) were from Gibco (Grand Island, NY). Newborn bovine calf serum (BCS) was from Hyclone Laboratories (Logan, UT), and trypsin was from Worthington Diagnostic Systems (Freehold, NJ). Trizma base, EDTA, sodium taurocholate, carbowax 6000, *p*-hydroxyphenylacetic acid, horseradish peroxidase (type VI; EC 1.11.1.7), *o*-dianisidine, CH-MBCD, MBCD, CH, and CH oxidase (*Streptomyces* species; 25 activity units per mg; EC 1.1.3.6) were obtained from Sigma Chemical Co. (St. Louis, MO). Radioactive reagents [^{3}H]acetic acid, sodium salt [specific activity (S.A.) 135.4 mCi/mmol], [4-^{14}C]CH (S.A. 54.0 mCi/mmol), and [methyl-^{3}H]thymidine (S.A. 84.2 Ci/mmol), were purchased from New England Nuclear Corp. (Boston, MA). Thin-layer chromatography (TLC) plates (Redi/Plate, Silica Gel G) and all organic solvents were from Fisher Scientific (Pittsburgh, PA). Two types of tissue culture inserts were used: Millicell-HA from Millipore (Bedford, MA) and Nunc 25-mm from Nunc Inc. (Naperville, IL). All chemical reagents were of analytical grade.

Cell culture. MDCK cells (CCL-34), obtained from the American Type Tissue Culture Collection (Rockville, MD), were used at passage levels 56–72. They were maintained in antibiotic-free DMEM/Ham's F-12 supplemented with 10% BCS and subcultured weekly at a split ratio of 1:6 using 0.05% trypsin in 0.02% EDTA in Ca^{2+}, Mg^{2+}-free EBSS, pH 7.2. Unless otherwise noted, cultures were kept at 37°C in a humidified atmosphere of 95% air and 5% CO_2; culture medium was changed at 2–3-d intervals. Stock cultures were routinely monitored for the presence of mycoplasma. Culture medium for experiments was supplemented with 500 U/mL penicillin and 0.5 mg/mL streptomycin (P/S).

Inhibitor stock solutions. Stock solutions of 6 mM lova (molecular weight 404.5) and 20 mM zaragozic acid (molecular weight 756) were freshly prepared in ethanol just prior to use.

"Ca^{2+} Switch" protocol. MDCK cells were plated at 1.5 times the number at confluence on inserts in DMEM/Ham's F-12, 10% BCS. Three hours later, floating cells were removed by rinsing with Ca^{2+} and Mg^{2+}-free phosphate-buffered saline (PBS), and adherent cells cultured in low Ca^{2+} medium, 1% BCS, P/S for 48 h. Assembly of TJ was then initiated by changing to Ca^{2+}-sufficient medium (low Ca^{2+} medium, 1% BCS, P/S supplemented with 1.8 mM $CaCl_2$) (23).

TER measurements. For repeated, sequential TER measurements on individual monolayers grown on 0.6-cm^2 Millicell-HA inserts, a Millicell-ERS volt-ohmmeter (World Precision Instruments, New Haven, CT) was utilized under temperature-controlled conditions at 37°C with electrodes reproducibly placed. Precautions were taken to maintain sterility during TER measurements. In our hands, the MDCK cells are well anchored to the Millicell-HA membrane and sample-to-sample variability in TER values is minimized (16,24).

Thymidine uptake studies. One hour before and at various times after the addition of Ca^{2+}, lova-treated and control cells were radiolabeled for 1 h with 1.0 μCi/mL [^{3}H]thymidine. Monolayers were washed to remove residual [^{3}H]thymidine and incubation in nonradioactive medium continued until the assay was terminated on day four. To collect the radioactive DNA, monolayers were rinsed six times with ice-cold PBS and lysed with 1 mL of 0.1% SDS for 15 min at 37°C. Lysates were collected and aliquoted as follows—200 μL for protein determination and 800 μL for trichloroacetic acid (TCA) precipitation. Ten mL of ice cold 5% TCA was added to the lysate for 10 min. The TCA precipitates were collected on AA 0.8-

μm filters (Millipore) using a manifold (Millipore), washed twice with cold 5% TCA, air-dried, and transferred to scintillation vials. Three mL of Ultima Gold (Packard, Middletown, CT) was added and the samples were counted in a 2200CA Tri Carb Liquid Scintillation Analyzer (Packard).

Metabolic labeling of endogenous CH. Cells were cultured on Nunc 25-mm tissue culture inserts in DMEM/Ham's F-12, 10% BCS; after 3 h the medium was replaced with low Ca^{2+} medium, 1% BCS, P/S supplemented with 1.0 μCi/mL [^{3}H]acetate or 0.025 μCi/mL [^{3}H]acetate for double labeling experiments. The Nunc inserts were chosen for two reasons—first, they are transparent and therefore allow the monolayer to be monitored by phase microscopy and, second, the substratum, which is resistant to organic solvents, can be readily removed and monolayer lipids extracted directly. Although there was more variation in TER measurements from insert to insert, CH measurements, as well as the overall time-course for Ca^{2+}-induced TJ formation and final steady-state TER values, were similar to those made on Millicell-HA inserts.

Preparation of CH-MBCD in cell culture medium. For cell culture applications an aqueous solution of CH-MBCD was prepared as recommended by Sigma Chemical Co. (25). Briefly, an aqueous stock solution of CH-MBCD equivalent to 5 mg/mL CH (0.109 g complex/mL) was filtered in a sterile manner and stored at 4°C. An aliquot of the stock solution was diluted with cell culture medium to obtain the desired final concentration of CH. The final molar ratio of CH to MBCD was 1:6.2, and the concentration of MBCD used during supplementation with cholesterol varied from 0.02–0.09 mM.

Preparation of radioactive CH-MBCD. A mixture containing 15 mg CH in ethanol and 5 μCi of ethanolic [^{14}C]CH was dried under a stream of N_2 and then heated under vacuum for 20 min at 50°C to remove all traces of solvent. The radioactive CH was moistened with a few drops of 45% MBCD in 0.9% NaCl and mixed with a glass rod until a paste-like slurry was formed. The total volume of 45% MBCD added to the slurry was adjusted to 1.0 mL and the mixture stirred overnight at room temperature. The next day it was transferred to an Eppendorf tube and microfuged for 5 min; the supernatant containing the water-soluble radioactive complex was stored at 4°C until needed (26–28). Working solutions were prepared by diluting the stock solution to a desired final concentration in cell culture medium. The resulting specific activity of the prepared inclusion complex was 561 dpm/μg CH and the molar ratio of CH to MBCD was 1:8.6.

Oxidation of CH in intact MDCK cell monolayers. Monolayers were fixed *in situ* with 1% glutaraldehyde in mannitol/Tris/$CaCl_2$ (300:12:0.5 molar ratio), pH 7.4 (mannitol buffer), for 15 min at 4°C. After fixation, they were rinsed three times with mannitol buffer, and 5 U/mL of CH oxidase at 37°C was added to the apical, the basolateral, or to both sides of the monolayers. Based on preliminary experiments which showed that oxidation of CH reached a plateau between 4 and 6 h of incubation at 37°C, samples for analysis were harvested for up to 6 h. At each time point the enzyme reaction was terminated by washing the monolayers twice with ice-cold mannitol buffer (29), removing the substratum and adherent monolayer from the insert and transferring it to a glass conical centrifuge tube containing the solvent mixture for lipid extraction.

Lipid extraction. Monolayers attached to the Nunc support were extracted three times with isopropanol/hexane (2:3, vol/vol). Extracts were dried with a stream of N_2 and the lipids redissolved in 1.0 mL of chloroform/methanol (2:1, vol/vol). A 20-μL aliquot of each sample was transferred to a scintillation vial to obtain total lipid radioactivity. CH, CH ester, and cholestenone standards were added to the samples to facilitate their visualization on the chromatography plate. The samples were dried under N_2 and dissolved in 60 μL of chloroform/methanol for transfer to a TLC plate (29).

TLC. Samples were applied to silica gel TLC plates which had been activated by heating for 45 min at 104°C. Lipids were separated using hexane/ether/acetic acid (80:20:1, by vol) as the developing solvent. Lipid spots were detected by lightly spraying the TLC plate with 0.1% aqueous 8-anilino-1-naphthalene-sulfonic acid while viewing under ultraviolet light at 366 nm. Spots corresponding to CH, CH ester, and cholestenone were scraped and transferred to scintillation vials. Ultima Gold (2 mL) was added and the samples counted. The percent oxidation was calculated as: dpm cholestenone/(dpm cholestenone + dpm CH) × 100.

CH determination. Cell monolayers were lysed and CH content determined enzymatically on a measured aliquot as previously described (16,30).

Protein determination. Protein content of cell lysates was assayed using the micro bicinchoninic acid method (Pierce, Rockford, IL) according to the manufacturer's instructions.

CH oxidase assay. Determination of CH oxidase activity in culture media was adapted from a method described by Sigma Quality Control, which was based on patent to Eastman Kodak Company (Rochester, NY) (31). Briefly, in a 1.5-mL reaction mixture with 500 μL of sample, the final concentrations of reagents are 0.009% *o*-dianisidine, 0.017% (wt/vol) CH, 0.33% (vol/vol) Triton X-100, and 10 units of horseradish peroxidase. The increase in absorbance at 500 nm was recorded for 5 min where ΔA_{500}/min was determined at the maximum linear rate.

RESULTS

Reducing cell CH using inhibitors of its synthesis: Lova. Development of TER following the addition of Ca^{2+} to Ca^{2+}-deficient monolayers of MDCK cells previously incubated for 24 h with 2 μM lova, an inhibitor of HMG–CoA reductase, occurs more rapidly than in control cells (Fig. 1A). Three hours after Ca^{2+} addition, TER rose to values approximately three times greater than control monolayers. In both experimental and control cultures, peak TER was achieved 8–10 h after addition of Ca^{2+}; however, the peak TER values attained by lova-treated monolayers were 1.5-times greater than controls. TER approached control values (90–100 $\Omega \cdot cm^2$) by 48 h. Parallel sets of control and lova-treated monolayers har-

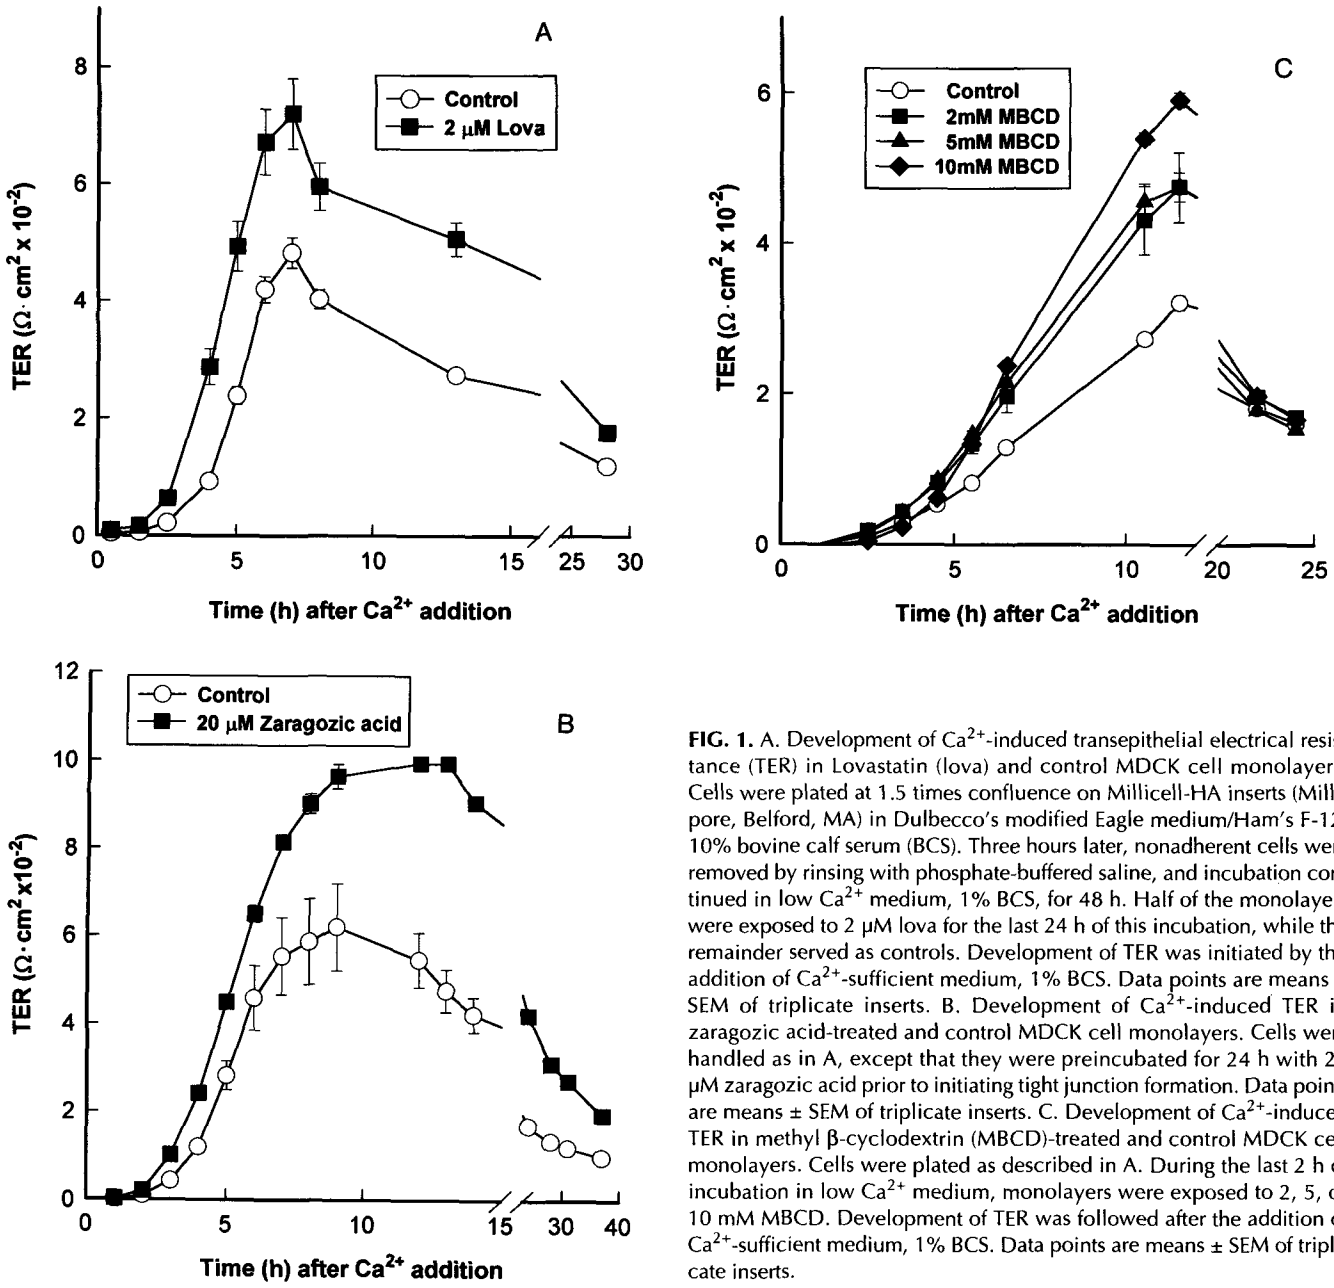

FIG. 1. A. Development of Ca^{2+}-induced transepithelial electrical resistance (TER) in Lovastatin (lova) and control MDCK cell monolayers. Cells were plated at 1.5 times confluence on Millicell-HA inserts (Millipore, Belford, MA) in Dulbecco's modified Eagle medium/Ham's F-12, 10% bovine calf serum (BCS). Three hours later, nonadherent cells were removed by rinsing with phosphate-buffered saline, and incubation continued in low Ca^{2+} medium, 1% BCS, for 48 h. Half of the monolayers were exposed to 2 μM lova for the last 24 h of this incubation, while the remainder served as controls. Development of TER was initiated by the addition of Ca^{2+}-sufficient medium, 1% BCS. Data points are means ± SEM of triplicate inserts. B. Development of Ca^{2+}-induced TER in zaragozic acid-treated and control MDCK cell monolayers. Cells were handled as in A, except that they were preincubated for 24 h with 20 μM zaragozic acid prior to initiating tight junction formation. Data points are means ± SEM of triplicate inserts. C. Development of Ca^{2+}-induced TER in methyl β-cyclodextrin (MBCD)-treated and control MDCK cell monolayers. Cells were plated as described in A. During the last 2 h of incubation in low Ca^{2+} medium, monolayers were exposed to 2, 5, or 10 mM MBCD. Development of TER was followed after the addition of Ca^{2+}-sufficient medium, 1% BCS. Data points are means ± SEM of triplicate inserts.

vested at T_0, when Ca^{2+} was added, were analyzed for their CH and protein content. CH levels in the lova-treated cells were reduced by approximately 30%, and the protein content was unaffected (Table 1).

Zaragozic acid. If lova's effect on TER is more closely related to a fall in CH than to a decreased supply of prenyl group precursors, then zaragozic acid, which elevates the level of those precursors but depresses CH content (21,22,32), should also increase TER. The data in Figure 1B and Table 1 show that zaragozic acid induced a 32% fall in CH and affected the development of TER by monolayers in a manner similar to that observed with lova.

MBCD reduces cell CH by stimulating its efflux. To eliminate nonspecific effects associated with long-term exposure of cells to inhibitors of CH synthesis, another agent, MBCD, was employed to decrease cell CH. Using this cell impermeant CH binding agent at 2, 5, or 10 mM to stimulate CH efflux, CH content was diminished by 46–78% within 2 h (Table 1). The effect of MBCD on TER was virtually the same as that obtained when lova or zaragozic acid was employed (Fig. 1C). After 11 h in Ca^{2+}-sufficient medium, peak TER values attained by monolayers treated with MBCD were 1.5–1.8 times greater than controls. Lowering cell CH by stimulating efflux would be expected to stimulate production of mevalonate and endogenous cholesterol (21,22). Indeed, although the rate of [^{3}H]acetate incorporation into CH by cells incubated for 24 h with lova decreased below control values, that of cells treated with MBCD for 2 h actually increased (Fig. 2).

Raising cell CH content depresses the ability of MDCK cell monolayers to develop TER. The uptake of [^{14}C]CH (5

TABLE 1
Protein and Cholesterol Content of MDCK Cell Monolayers Following the Administration of Agents That Reduce Cell Cholesterol (CH) Content[a]

Agent	Incubation time (h)	Protein (mg/insert)	CH (μg/insert)	μg CH/mg protein
0	24	0.52 ± 0.02	10.09 ± 0.03	19.53 ± 0.74
2 μM Lovastatin	24	0.52 ± 0.01	7.86 ± 0.24	15.08 ± 0.25
0	24	0.44 ± 0.02	9.95 ± 0.32	22.61 ± 0.95
20 μM Zaragozic acid	24	0.46 ± 0.01	7.16 ± 0.06	15.56 ± 0.29
0	2	0.56 ± 0.01	10.60 ± 0.75	19.08 ± 1.12
2 mM MBCD	2	0.58 ± 0.01	5.91 ± 0.24	10.18 ± 0.39
5 mM MBCD	2	0.55 ± 0.01	3.04 ± 0.35	5.53 ± 0.58
10 mM MBCD	2	0.55 ± 0.01	2.36 ± 0.17	4.27 ± 0.32

[a]Data are expressed as the mean ± SEM of triplicate inserts. MBCD, methyl β-cyclodextrin.

μg/mL) from a complex of [^{14}CH]-MBCD (final [MBCD] = 0.02 mM) by MDCK cells was half maximum at 5 h and peaked between 12 and 24 h (Fig. 3). The effect of increasing cell CH content on development of TER was examined by exposing monolayers to three different concentrations of CH (as the CH-MBCD complex) for either the last 11 or 24 h of a 48-h period that preceded the addition of Ca^{2+} to initiate TJ assembly. Cells from one set of inserts were subsequently analyzed for CH and protein content, whereas those on another received 1.8 mM Ca^{2+}; TER was monitored until values approached steady state. Within each of these two experiments the increase in CH content, after exposure to increasing concentrations of exogenous CH, semiquantitatively correlated with a lowering in TER values. A greater increase in CH content is associated with a larger fall in TER (Fig. 4). Interestingly, after 11 h of incubation, the data suggest that cell CH had reached a maximum of *ca.* 30 μg/mg of protein (Table 2). Evidence that the cells may have become saturated with free

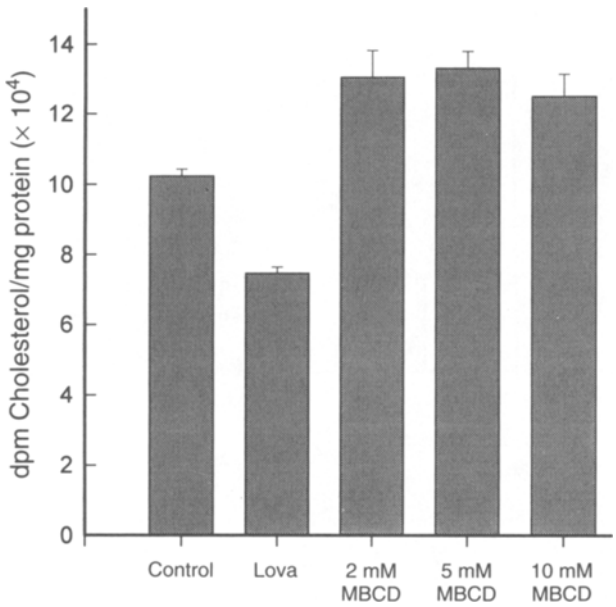

FIG. 2. [^{3}H]Acetate incorporation into cholesterol (CH) of control, lova-, and MBCD-treated cells. Cells were plated at confluence in Dulbecco's modified Eagle's medium/Ham's F-12, 10% BCS. Three hours later, they were transferred to low Ca^{2+} medium, 1% BCS. One day after plating one set of inserts received 2 μM lova while the remainder had their medium changed. On the third day after plating, other sets of monolayers were exposed either to 2, 5, or 10 mM MBCD for 2 h. At the end of that time all sets were pulse-labeled for 15 min with 1.0 μCi/mL [^{3}H]acetate. Lipids were extracted and [^{3}H]CH was isolated by thin-layer chromatography and its radioactivity assayed. Data are means ± SEM of triplicate inserts. See Figure 1 for abbreviations.

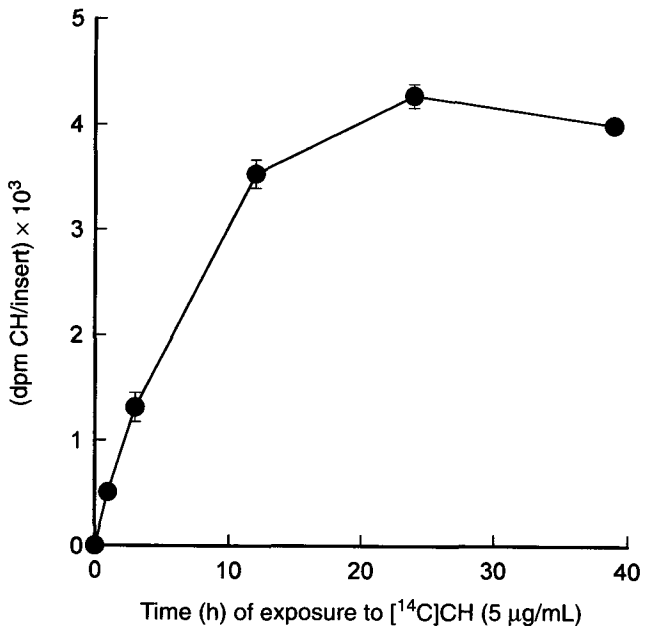

FIG. 3. Rate of [^{14}C]CH uptake by MDCK cells supplemented with [^{14}C]CH-MBCD. Cells were plated on inserts in Dulbecco's modified Eagle's medium/Ham's F-12, 10% BCS. Three hours later, nonadherent cells and medium were removed and low Ca^{2+} medium, 1% BCS, added. Three days after plating the cells were incubated with 5 μg/mL [^{14}C]CH. Lipids were extracted from cells harvested 1, 3, 12, 24, and 39 h later after extensive rinsing with phosphate-buffered saline to remove excess [^{14}C]CH-MBCD. CH was isolated by thin-layer chromatography and its radioactivity assayed as described in the Methods and Materials section. Data points are means ± SEM from six inserts. See Figures 1 and 2 for abbreviations.

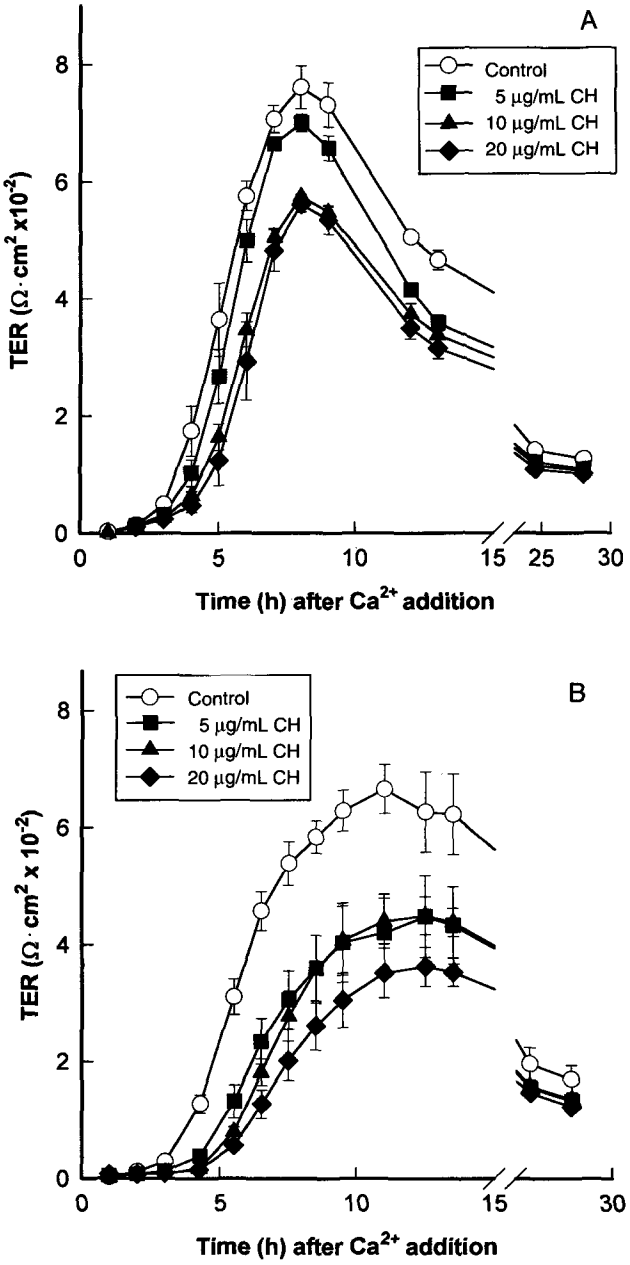

FIG. 4. Effect of exogenous cholesterol on the development of TER. Cells were plated on Millicell-HA inserts as described in the legend to Figure 1. A: Eleven hours before the addition of Ca^{2+}, medium was changed to one containing 0, 5, 10, or 20 µg/mL CH as CH-MBCD complex. B: Cells were treated as in A, except that monolayers were exposed to CH 24 h before the addition of Ca^{2+}. After addition of Ca^{2+}-sufficient medium, to all monolayers, measurements of TER were made. Data points are means ± SEM of triplicate inserts. See Figures 1 and 2 for abbreviations.

CH at this point is suggested by the fact that the fraction of exogenous CH in the form of CH ester was elevated *ca.* 3.5-fold when the exogenous CH was raised from 5 to 10 µg/mL (Fig. 5, hatched bars). Exposure of cells to CH-MBCD for 24 h resulted in greater suppression of TER than that observed at 11 h, despite a similar elevation in CH content (Fig. 4B).

[a]Data are expressed as the mean ± SEM of triplicate inserts. See Table 1 for abbreviations.

The cell-associated CH derived from exogenous CH-MBCD equilibrates with endogenous CH and is localized primarily to the plasma membrane. To compare the fraction of exogenous CH localized to the cells' surface with that of

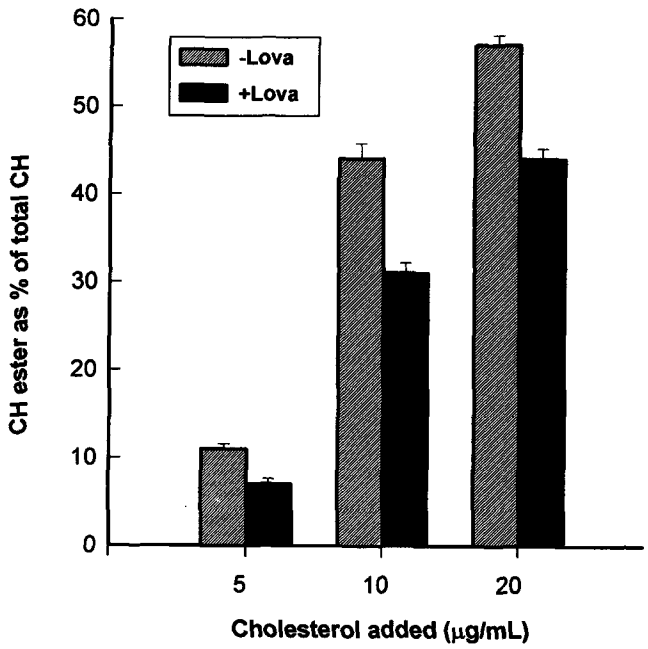

FIG. 5. CH ester synthesis from exogenous CH supplied to control and lova-treated MDCK cells. Cells were plated at confluence on inserts in Dulbecco's modified Eagle's medium/Ham's F-12, 10% BCS. Three hours later, they were transferred to low Ca^{2+} medium, 1% BCS, for 48 h. Half the monolayers were exposed to 2 µM lova for the last 24 h of this incubation while the remainder served as controls. At 37 h after plating the cells were incubated with 5, 10, or 20 µg/mL [^{14}C]CH as the CH-MBCD complex. Eleven hours later Ca^{2+}-sufficient medium, supplemented with the same concentration of [^{14}C]CH, was added. After 24 h of further incubation, monolayers were washed four times with phosphate-buffered saline, their lipids extracted, separated by thin-layer chromatography, and the radioactivity of the [^{14}C]CH and [^{14}C]CH ester spots were quantitated by liquid scintillation counting. Percent CH ester was calculated as: dpm [^{14}C]CH ester/(dpm [^{14}C]CH ester + dpm free [^{14}C]CH) × 100. Data are means ± SEM of triplicate inserts. See Figures 1 and 2 for abbreviations.

endogenous CH, CH oxidase, a probe for plasma membrane associated cholesterol, was employed (14,29). Monolayers in low Ca^{2+} medium (no formed TJ), that had been doubly labeled with [^{3}H]acetate (to label endogenous CH) and [^{14}C]CH from the MBCD complex, were incubated with CH oxidase after fixation with glutaraldehyde, and the fraction converted to radiolabeled cholestenone determined. When monolayers were not fixed with glutaraldehyde prior to incubation with CH oxidase, only 13% of the ^{3}H and ^{14}C in cell-associated CH was converted to cholestenone; pretreating with 1% glutaraldehyde increased this value to *ca.* 85% (Fig. 6). These data suggest that both endogenous CH and that taken up from the medium were equally accessible to CH oxidase. Further evidence that the added CH was an integral component of the plasma membrane was obtained by exposing mature monolayers, with formed TJ, to [^{14}C]CH-MBCD, added either to the apical or basolateral medium. Eleven hours later, the accessibility of the incorporated [^{14}C]CH to a solution of CH oxidase added to the opposite surface was determined. Within one hour of incubation at 37°C, approximately one-third of the incorporated [^{14}C]CH was oxidized to [^{14}C]cholestenone (Table 3), regardless of the cell surface that had been exposed to CH-MBCD or enzyme solution. This figure increased to 96% after six hours. That the TJ had retained their barrier function during the incubation was demonstrated by assaying the apical and basolateral solutions for CH oxidase activity one and six hours after addition of enzyme. No activity was detected after one hour, and at six hours the concentration of enzyme in the apical solution was only 5% of that in the basolateral solution.

The effect of exogenous CH on TER development by lova-treated monolayers may be mediated by mechanisms that compromise monolayer integrity. Cells were incubated with 5 μg/mL of CH during the last 11 h of a 24-h incubation with lova to determine the extent to which the time course for development of TER could be restored to that of controls. During the first five hours after addition of Ca^{2+} to the monolayer, the curve was only slightly below that of cells that had received only lova; beyond five hours, however, they diverged (Fig. 7A). By 12 h the TER values of monolayers incubated with both lova and CH overlapped those of controls and continued to do so for the remainder of the experiment. Raising the concentration of exogenous CH to 10 or 20 μg/mL diminished the rate and extent to which TER developed to well below that of controls, despite the fact that cell CH content did not increase beyond 30 μg/mg protein (Table 4). The protein content of these monolayers was virtually identical and no morphological differences between the monolayers was apparent upon examination by phase microscopy. If the incubation with lova and CH was extended to 24 h, virtually no

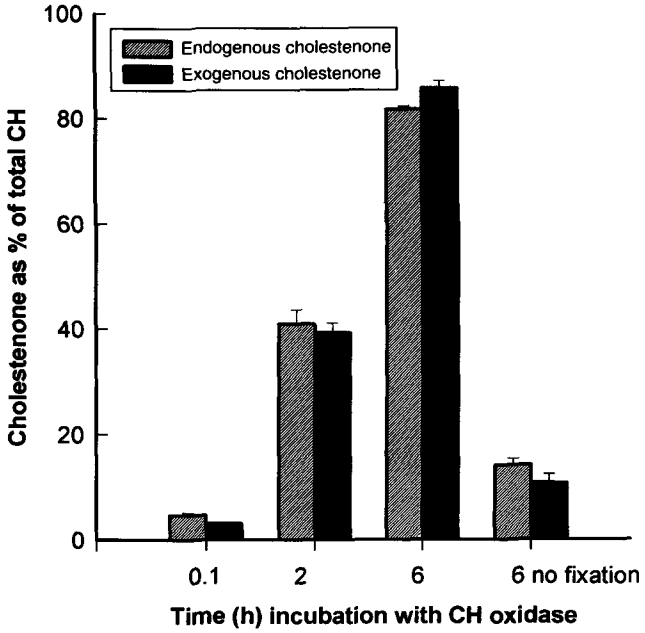

FIG. 6. Oxidation of cell-associated exogenous and endogenous CH to cholestenone with CH oxidase. Cells were plated at confluence on inserts at T_0 in Dulbecco's modified Eagle's medium/Ham's F-12, 10% BCS. Three hours later, they were incubated in low Ca^{2+} medium, 1% BCS, with 0.025 μCi/mL [^{3}H]acetate to label endogenous CH. After 37 h medium was changed to one containing 5 μg/mL [^{14}C]CH. Eleven hours later, monolayers were rinsed three times with mannitol buffer and all but one set fixed with 1% glutaraldehyde in mannitol buffer at 4°C for 15 min. Fixative was removed by rinsing three times with mannitol buffer. CH oxidase, 5 U/mL, was then added to both sides of the monolayer for 0.1, 2, and 6 h. Lipids were extracted and radiolabeled CH and cholestenone were isolated after separating them by thin-layer chromatography. Incorporated ^{3}H and ^{14}C were quantitated by liquid scintillation counting. Percent cholestenone was calculated as: dpm cholestenone/(dpm cholestenone + dpm CH) × 100. Data are means ± SEM of triplicate inserts. See Figures 1 and 2 for abbreviations.

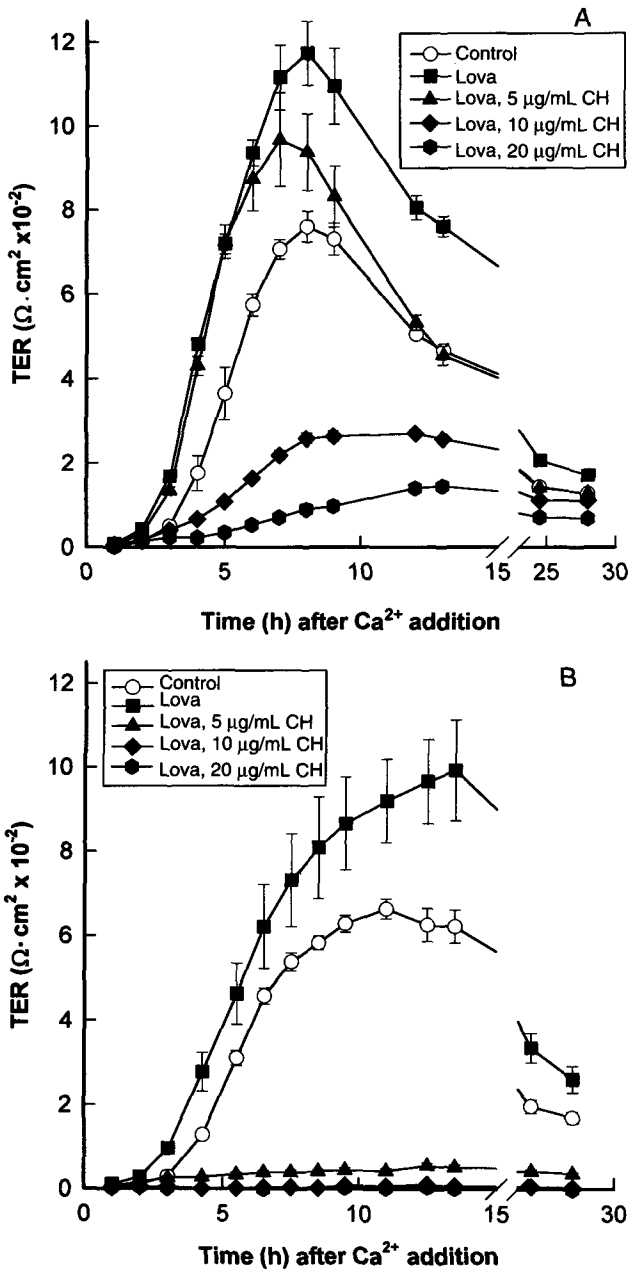

FIG. 7. Effect of exogenous CH on the development of TER in lova-treated cells relative to controls. Cells were plated on inserts as described in the legend to Figure 1. A: Twelve hours after addition of 2 µM lova, medium was changed to one containing the same concentration of lova and either 5, 10, or 20 µg/mL CH as the CH-MBCD complex. The same components were in the Ca^{2+}-sufficient medium, 1% BCS, used to initiate tight junction (TJ) formation. B: Cells were treated as in A, except that monolayers were exposed to 2 µM lova and 5, 10, or 20 µg/mL CH simultaneously 24 h before the addition of Ca^{2+}. TJ formation was initiated as described in A. Data points are means ± SEM of triplicate inserts. See Figures 1 and 2 for abbreviations.

TER developed after addition of Ca^{2+}, even at the lowest concentration of CH tested (Fig. 7B). In contrast to cultures incubated with either lova or CH alone, microscopic examination of these monolayers revealed that there were a greater number of cells floating, empty patches had formed, and the remaining adherent cells had become more round in appearance. Measurements of TER on such monolayers are not a valid measure of TJ formation. Such morphological changes have been observed in MDCK cells and other cell types exposed to much higher concentrations of lova (16,18–20). It is conceivable that exogenous CH down-regulated HMG–CoA reductase (22,33,34) and, by doing so, was acting in concert with lova to effectively reduce the level of intermediates between mevalonate and CH to a point that isoprenoid synthesis was impaired.

TABLE 4
Protein and Cholesterol Content of Control and Lovastatin-Treated MDCK Cell Monolayers Following the Administration of CH-MBCD[a]

CH added (µg/mL)	CH incubation time (h)	Protein (mg/insert)	CH (µg/insert)	µg CH/mg protein

DISCUSSION

In an earlier study it was shown that exposing MDCK cells to 2 µM lova for 24 h resulted in a more rapid Ca^{2+}-induced development of TER, an index of TJ assembly (16). Several observations from that and other published studies suggested that lova's effect on TER were more closely related to changes in cell CH content than to changes in the level of prenyl group precursors. For example, the concentration of lova required to inhibit prenyl group synthesis is generally 10–15 times greater than that used in the current studies (18–20). Furthermore, only high concentrations (5 mM) of mevalonate were capable of overcoming lova's effects on TER; at 0.5 mM—a concentration of mevalonate which, in other cells, supports biosynthesis of isoprenoids (16,18,20)—lova's effects on TER were unaffected. This indirect evidence notwithstanding, there may be variations from one cell type to another in the sensitivity of isoprenoid biosynthesis to lova. One indirect measure of this variability, based on observations that indicate a role for isoprenoids in the regulation of cell growth (35), is the incorporation of [methyl-^{3}H]thymidine into DNA. Although 20–30 µM lova is required to interfere with protein prenylation in many cell types, it was recently shown that as little as 1 µM lova inhibited radiolabeled thymidine incorporation into DNA of kidney mesangial cells by mechanisms that involved depleting the intermediates required for prenyl group biosynthesis (36).

In the studies presented here, the relationship between cell CH content and development of TER were re-examined using

strategies that altered CH levels in a given direction by means that in some cases increased, and in others decreased, the flux of intermediates through that part of the pathway common to CH and isoprenoid biosynthesis. Zaragozic acid, by competitively inhibiting squalene synthase, decreased cell CH content and stimulated development of Ca^{2+}-induced TER to an extent similar to that caused by lova. This occurred despite the fact that, unlike lova, zaragozic acid has been shown to actually increase levels of intermediates required for prenyl group biosynthesis. After treatment of Hep G2 cells with zaragozic acid, for example, label from mevalonate accumulated in farnesyl pyrophosphate (32). In addition, labeling of prenylated proteins by [^{3}H]mevalonolactone was increased in livers from zaragozic acid-treated rats (21). The fact that both lova and zaragozic acid decreased cell CH and accelerated development of TER despite having opposing effects on the level of prenyl group intermediates, strongly suggests that their effects on TER are mediated by a fall in CH content. It should also be noted that in contrast to mesangial cells, any reduction in the level of prenylated proteins that might have been caused by lova were not sufficient to affect [methyl-^{3}H]thymidine incorporation into DNA. Control cultures and those incubated with 2 μM lova incorporated 5980 ± 330 DPM/mg protein and 6080 ± 20 DPM/mg protein, respectively.

To avoid prolonged incubation of cells with enzyme inhibitors altogether, MBCD, a water-soluble cyclodextrin that has been used for studies *in vivo* and *in vitro* to solubilize a variety of hydrophobic molecules, including CH (25,37), was employed. In a recent study cyclodextrins were shown to stimulate efflux of CH from fibroblasts and hepatoma cells (38). In the current study, MBCD at 2.0 mM stimulated sufficient CH efflux from MDCK cells to decrease cell CH to a degree similar to that achieved during longer incubations with lova or zaragozic acid. As was the case with those two inhibitors, monolayers treated with MBCD developed TER, after Ca^{2+} addition, more rapidly than the untreated controls. Reducing cell CH is known to increase HMG–CoA reductase activity (21,22,39) and should, therefore, maintain or even increase the flux of intermediates through that part of the CH biosynthetic pathway that supplies intermediates for prenyl group biosynthesis. This was confirmed by showing that [^{3}H]acetate incorporation into cell CH under these conditions was elevated by about 20% (Fig. 2). These data contrast with the effect of 2 μM lova, which decreased [^{3}H]acetate incorporation into CH by 27%. Interestingly, the increased incorporation of labeled acetate into CH caused by MBCD appears to be an adaptive response to the CH efflux. The CH mass after 2 h of incubation with 2 mM MBCD was reduced by 46%; after 24 h the cells had synthesized enough CH so that the mass was only 15% less than that of controls. Together these results suggest that it is the fall in cell CH and not a decrease in the availability of intermediates for prenyl group biosynthesis that accelerates the rate at which TER develops after Ca^{2+} addition.

If decreasing CH accelerates the rate at which TER develops in the confluent MDCK monolayer, then increasing cell CH might be expected to suppress it. This prediction was tested by incubating cells with a water-soluble complex of CH-MBCD. Incubation of cells for 11 h with 5, 10, and 20 μg/mL of CH as the CH-MBCD complex slowed the rate at which TER developed; the degree of decline was correlated with the increase in cell CH. A similar relationship between development of TER and increased cell CH was observed after a 24-h exposure of cells to CH-MBCD as well. At the lowest concentration of exogenous CH tested, only a small fraction of the CH taken up was converted to CH ester during 11 h of incubation. At 10 and 20 μg/mL this fraction increased markedly, indicating that the added CH was entering intracellular compartments and that the plasma membrane may be approaching saturation at relatively low levels of exogenous CH. A similar trend in CH ester formation was noted when lova-treated cells received exogenous CH. That there was a smaller percentage of the exogenous CH esterified by lova-treated cells is consistent with published data demonstrating that lova is an inhibitor of acyl-CoA:cholesterol acyltransferase (40). It should be noted that at the highest concentration of CH-MBCD used to increase cell CH, the total concentration of MBCD in the medium was only one-twentieth (0.09 mM) of that used to stimulate efflux. At that low concentration, in the presence of 1% BCS, there was no measurable decrease in cell CH, and the time course for development of TER was unaffected.

That the effects of incubation with CH-MBCD on TER are associated with incorporation of exogenous CH into the lipid bilayer of the plasma membrane is suggested by the following observations: (i) More than 85% of the cell CH, whether derived from endogenous or exogenous sources, was accessible to CH oxidase, a cell impermeant probe commonly employed in studies on the subcellular distribution of CH (29,41). (ii) Prior to fixation only 10–15% of the endogenous and exogenous CH pools were accessible to CH oxidase, a figure that agrees well with the accessibility of endogenous CH reported for fibroblasts (42) and LLC-PK1 cells (29). After fixation, on the other hand, 85–90% of both pools were enzymatically oxidized to cholestenone. The kinetics of the enzyme-catalyzed reaction were similar for both populations of radiolabeled CH. Although fixation with glutaraldehyde is necessary when CH oxidase is used as a probe (14,29,41), the chemical basis for this requirement is not known. It has been suggested, however, that glutaraldehyde, by reacting with amino groups of membrane components, may alter the organization of the cell surface, allowing greater access of the enzyme to its substrate (29). The fact that the enzymatic oxidation of both endogenous and exogenous CH pools is sensitive to glutaraldehyde suggests that the CH taken up from the CH-MBCD complex is not merely adsorbed to the cell surface, but is as integral to the membrane structure as endogenous CH. If it had been nonspecifically adsorbed to the cell surface, its accessibility to the enzyme would not be expected to increase after glutaraldehyde treatment. That 96% of the radiolabeled [^{14}C]CH taken up from one side of a mature mono-

layer with intact TJ was converted to cholestenone by CH oxidase added to the opposite compartment also supports the notion that once incorporated into one membrane domain (e.g., the apical surface), CH can move, by diffusional or transcytotic mechanisms, to the other (e.g., basolateral), where it is accessible to the enzyme.

Using CH-MBCD as a means of overcoming lova's effect on TER yielded data that were difficult to interpret. Exposing cells to CH at 5 μg/mL for 11 h did nothing to change lova's effect on TER development during the first five hours following Ca^{2+} addition. Beyond that time, the curve approached that of the untreated controls and overlapped it 12 h after Ca^{2+} addition. At higher concentrations of CH, under the same conditions, the time course was depressed well below that observed when only CH was added. None of the monolayers exposed to CH-MBCD for the entire 24 h of incubation with lova developed TER. Based on protein determinations and observations of those cultures by phase microscopy, however, it was clear that many cells had detached from the substratum and those that remained had become more rounded in appearance. Technically such changes would interfere with measurements of TER. It is not clear to what extent similar but more subtle changes in cell shape or monolayer integrity might have contributed to the results obtained after 11 h of incubation with both lova and CH-MBCD. Whatever the mechanism, it appears that exogenous CH, by raising cell CH, acts synergisticlly with lova, an agent that lowers it. This paradox may best be explained by focusing on how exogenous CH and lova each affect HMG–CoA reductase activity. Elevation of CH may down-regulate this enzyme (22,33,34) enough to slow CH synthesis without adversely affecting prenylation of proteins. When lova is also present simultaneously, however, any remaining activity is inhibited and mevalonate production slowed to such an extent that both CH synthesis and prenylation of proteins is decreased. Consistent with this explanation are data which show that as a percent of total lipid radioactivity, [^{3}H]acetate incorporation into CH declined from 47% (untreated) to 28, 16, and 7% in cultures that had been exposed for 24 h to 2 μM lova, 5 μg/mL CH, or both simultaneously. The rounding and detachment of cells that was observed in cultures incubated with both agents for 24 h was indistinguishable from that observed when cells were treated with 20–30 μM lova alone (16,18–20).

To summarize, measures that severely limit the availability of precursors required for prenylating proteins (e.g., incubations with both lova and CH) yield changes in monolayer integrity that make it difficult or technically impractical to use TER as a means of studying the formation of TJ. The data presented here do not rule out a role for prenylated proteins in TJ assembly, however, they do demonstrate that changes in cell CH can effectively modulate Ca^{2+}-induced TJ assembly by mechanisms that are independent of changes in the supply of intermediates required for protein prenylation.

How the Ca^{2+}-triggered assembly of TJ is modulated by CH is not clear. However, both CH and Ca^{2+} are known to affect the organization of membrane phospholipids as well as the activity of a variety of surface proteins (43–46), and the initial interaction with Ca^{2+} apparently occurs at a point on, or very close to, the plasma membrane (47). A change in CH, among other things could: (i) Affect the generation of signals from the plasma membrane that initiate TJ assembly (11,48); (ii) alter membrane fusion events (10) and, as a consequence, the traffic of surface components needed for TJ; (iii) promote or retard the interactions between the plasma membrane and cytoskeletal elements (49,50) or between membrane proteins of adjacent cells. This latter possibility is of particular interest in view of a recent study which indicates that removal of plasma membrane CH causes a reduction in bilayer thickness and, conversely, addition of CH increases its thickness (51). It is possible that homotypic interactions between surface elements (e.g., occludin) leading to TJ assembly between adjacent epithelial cells are facilitated when membrane width decreases by removal of CH or hampered if it increases upon CH incorporation. Additional studies are in progress to determine which of the many events linking Ca^{2+} binding at the cell surface to assembly of TJ are sensitive to changes in CH content.

ABSTRACT: n-9 Eicosatrienoic acid (ETrA), also known as Mead acid, is a minor fatty acid in essential fatty acid (EFA)-sufficient healthy subjects but is found at increased levels in EFA deficiency. This study examined the influence of dietary ETrA from a biological source on plasma and tissue ETrA. A synthetic fat-free diet was prepared to which was added Mut 48 oil which contains 19% ETrA (wt%) as well as other n-9 fatty acids. Blends of vegetable oils were used to achieve overall diets with 5% fat (wt%) and varying amounts of ETrA at two different dietary levels of linoleic acid (LA), approximately 4.4 and 19% of total fatty acids. These diets were fed to 5-week-old Dark Agouti rats for four weeks. Plasma lipid fractions and liver, spleen, and peritoneal exudate (PE) cells were analyzed for fatty acid composition. ETrA was present at up to 20% total fatty acids in plasma triglyceride, cholesterol ester, and phospholipid fractions. ETrA also accumulated to substantial levels in phospholipids of liver and spleen (up to 15% of total fatty acids) and PE cells (up to 11%). ETrA was found in plasma and tissue phospholipids in proportion to the amount of ETrA present in the diet. The incorporation was reduced in diets with higher LA content compared to diets containing similar amounts of ETrA but lower LA. All rats remained apparently healthy, and histological survey of major organs revealed no abnormality. While the long-term implications for health of ingestion of diets rich in ETrA remain to be established, rats appear to tolerate high levels of dietary ETrA without adverse effects. Dietary enrichment with ETrA warrants further investigation for possible beneficial effects in models of inflammation and autoimmunity, as well as in other conditions in which mediators derived from n-6 fatty acids can affect homeostasis adversely.
Lipids 31, 829–837 (1996).

Dietary n-6 polyunsaturated fatty acids (PUFA) are present in the Western diet at levels far in excess of essential requirements (1). As a result, arachidonic acid (AA; 20:4n-6) is the dominant substrate for eicosanoid-forming enzymes which are pivotal in platelet-vascular homeostasis and control of inflammation. Consequently, the balance of eicosanoids produced is prothrombotic and proinflammatory as evinced by the antithrombotic and antiinflammatory effects of agents such as aspirin, which inhibit prostaglandin H synthase. These effects of n-6 eicosanoids can be reduced by dietary fortification with the n-3 homologue of AA, eicosapentaenoic acid (EPA; 20:5n-3). This fatty acid competes for eicosanoid-forming enzymes, and is metabolized to products, which on balance, reduce risk for thrombotic events and modulate inflammation.

Dietary fortification with the n-9 homologue of AA and EPA, eicosatrienoic acid (ETrA; 20:3n-9), also can antagonize n-6 eicosanoid formation (2). However, the lack of a suitable biological source of ETrA has been a barrier to experimental feeding studies. The present study examines the effects of Mut 48 oil, an ETrA-rich oil derived from a strain of the fungus *Mortierella alpina*, on the fatty acid composition of plasma lipid fractions and cellular phospholipids in rats. Because accumulation of EPA in plasma and cell phospholipids is reduced by dietary linoleic acid (LA; 18:2n-6), ETrA accumulation was assessed at two levels of dietary LA (3). ETrA is a normal metabolite which is typically present at low levels in plasma and cells, except in the setting of n-6 essential fatty acid (EFA) deficiency when levels increase. Evidence for signs of the EFA deficiency syndrome (coat changes and growth retardation) were, therefore, sought in rats fed the ETrA-fortified diets.

METHODS

Materials. Mortierella alpina oil was obtained from Suntory Ltd. (Osaka, Japan). Sunflower oil and Sunola™ were obtained from Meadow Lea Foods Ltd. (Sydney, Australia). Sunola is an oil obtained from a sunflower strain which yields an oil with a low LA content (~4.4% total fatty acids) compared to regular sunflower oil which contained approximately 70% LA.

[a]Expressed as percentage of total fatty acids as determined by gas–liquid chromatography analysis.
[b]The test diets are designated according to the ratios of their approximate content of linoleic acid and n-9 eicosatrienoic acid.

Diets. A set of oil mixtures containing approximately 12, 8, or 4% (wt%) of ETrA in combination with LA at levels of 4.4 and 19% (wt%) were prepared by using varying amounts of sunflower, Sunola and *M. alpina* oils. In a further preparation, *M. alpina* oil was blended with a small amount of sunflower oil to yield an oil mix containing 16.5% (wt%) of ETrA and 4.4% (wt%) of LA. In addition, Sunola alone and a blend of Sunola with sunflower oil were used to achieve oils with undetectable ETrA and 4.4 or 19% (wt%) of LA, respectively. These preparations were mixed with a fat-free diet which was based on the AIN-76 diet, as published previously (4). The total fat content of the final diet was 5% (wt%). The salient details of the test diets in relation to fatty acids of interest are detailed in Table 1. The full fatty acid analysis is detailed elsewhere (5).

Rats. Female Dark Agouti rats were used with groups of four rats being fed the test diets from five weeks of age for four weeks. The rats were observed and given fresh food daily, and weighed weekly. Peritoneal exudates (PE) were induced with peptone 3% (g/100 mL) four hours prior to sacrifice as described previously (4).

Collection of samples. Rats were sacrificed by cervical dislocation under halothane/nitrous oxide anesthesia. Blood samples were taken by cardiac puncture. PE cells were obtained by lavage as described (4). The liver, spleen, kidney, heart, and skin specimens were excised. The study was

approved by the Animal Ethics Committee of the Institute of Medical and Veterinary Science (Adelaide, Australia) where the animals were housed.

Fatty acid analyses. Lipids were extracted from plasma or homogenized tissue samples with chloroform/methanol (7:3), and extracts were evaporated to dryness under nitrogen. The residues were dissolved in chloroform/methanol (9:1) and stored at −70°C prior to fatty acid analysis. Plasma triglycerides, cholesterol esters, and phospholipids and tissue phospholipid fractions were separated by thin-layer chromatography (6). The samples were then hydrolyzed and methylated in 1% H_2SO_4 and methanol at 70°C for three hours. The resulting methyl esters were separated and quantified by gas–liquid chromatography as described previously (7). All organic solvents contained butylated hydroxyanisole 0.005% (g/100 mL).

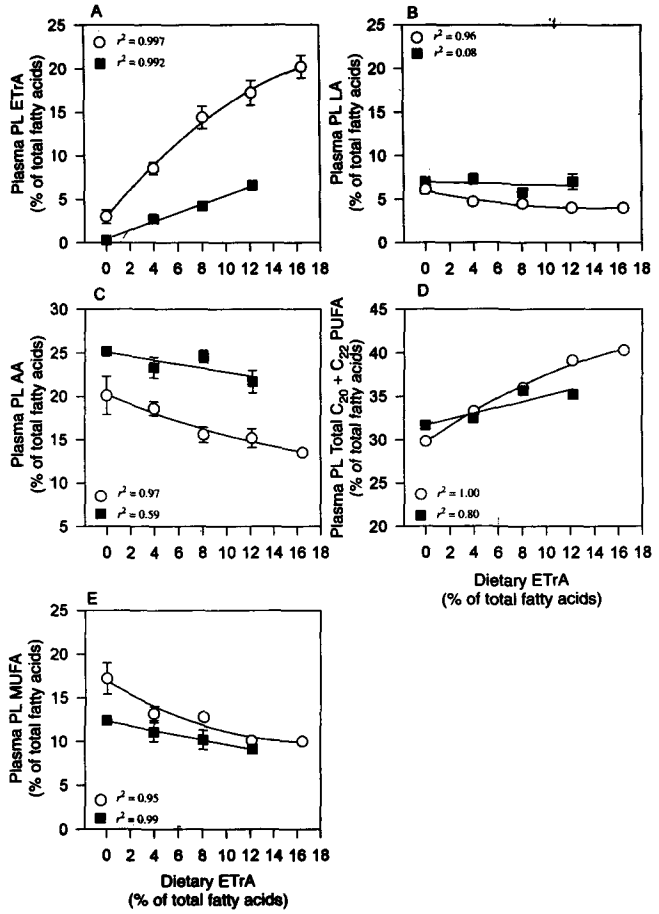

FIG. 1. Plasma phospholipids (PL): Levels of selected fatty acids in plasma lipid fractions from rats fed for four weeks diets containing linoleic acid (LA) at 4.4 % of total fatty acids (O----O) or LA at 19% of total fatty acids (■-----■) and increasing amounts of n-9 eicosatrienoic acid (ETrA). A, ETrA; B, LA; C, arachidonic acid (AA); D, total C_{20} + C_{22} polyunsaturated fatty acids (C_{20} +C_{22} PUFA); E, monounsaturated fatty acids (MUFA).

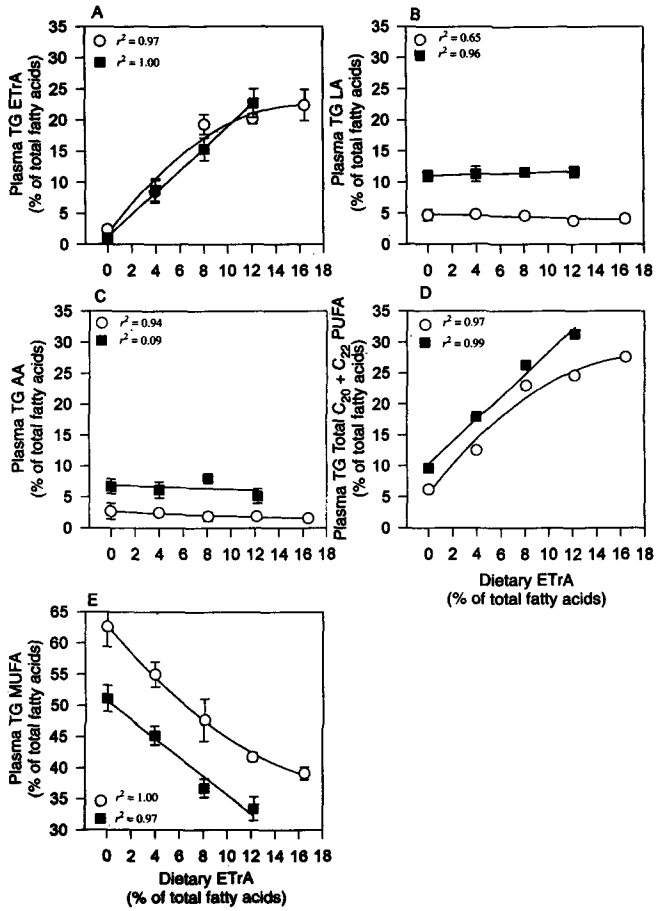

FIG. 2. Plasma triglycerides (TG): See Figure 1 caption for data.

Histological survey. Formalin fixed sections of liver, spleen, kidney, skin, and heart were stained with haematoxalin and eosin and examined by light microscopy.

RESULTS

Fatty acid composition of plasma lipid fractions (Tables 2–4 and Figs. 1–3). With the diets containing the lower level of LA (4.4% total fatty acids), ETrA attained levels of ~20% total fatty acids in all of the plasma lipid fractions, and incorporation was curvilinear in relation to dietary ETrA. Within the ambit of levels attained when the diets contained the higher level of LA (19% total fatty acids), incorporation of ETrA was essentially linear. In the phospholipid and cholesterol ester fractions, but not the triglycerides, ETrA accumulation was reduced substantially by dietary LA.

Accumulation of LA was greater with the higher LA diets than with the lower LA diets, although the differences were modest, except in the triglycerides. By contrast, AA accumulation was strongly influenced by dietary LA in the case of the plasma phospholipids and cholesterol esters. The levels of LA were modestly affected or unaffected by dietary ETrA. However, with increasing dietary ETrA, dose-dependent reductions of AA were seen in all fractions with the exception of the triglycerides where AA levels were low. With increasing dietary ETrA, total C_{20} and C_{22} PUFA increased by up to 10% in the phospholipids and by more than 20% in the triglycerides (with reciprocal displacement of monounsaturates) but were unchanged in the cholesterol esters.

Fatty acid composition of cellular phospholipids (Tables 5–7 and Figs. 4–6). The effects of dietary ETrA and LA on the levels of ETrA, LA, and AA in liver, spleen, and PE cell phospholipids resembled broadly the pattern seen in plasma phospholipids. Compared with liver and plasma phospholipids, spleen and PE cell phospholipids were distinctive in displaying significant accumulations of 22:3n-9, a metabolite of ETrA absent or present in trace amounts only in the diets. With increasing dietary ETrA, there was an overall increase in C_{20} and C_{22} PUFA as a proportion of total fatty acids, with an increment of ~10% of total fatty acids for spleen and PE cells and ~5% of total fatty acids for liver. In liver and spleen, but not PE cells, monounsaturates decreased with increasing dietary ETrA.

General observations and growth. All rats appeared normal in terms of general behavior and condition. Growth was

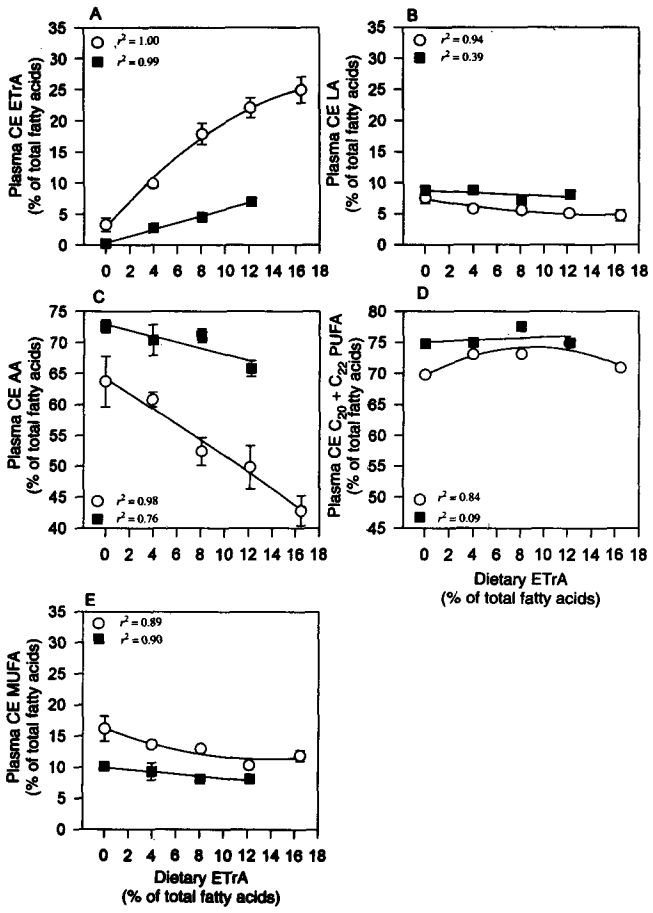

FIG. 3. Plasma cholesterol esters (CE): See Figure 1 caption for data.

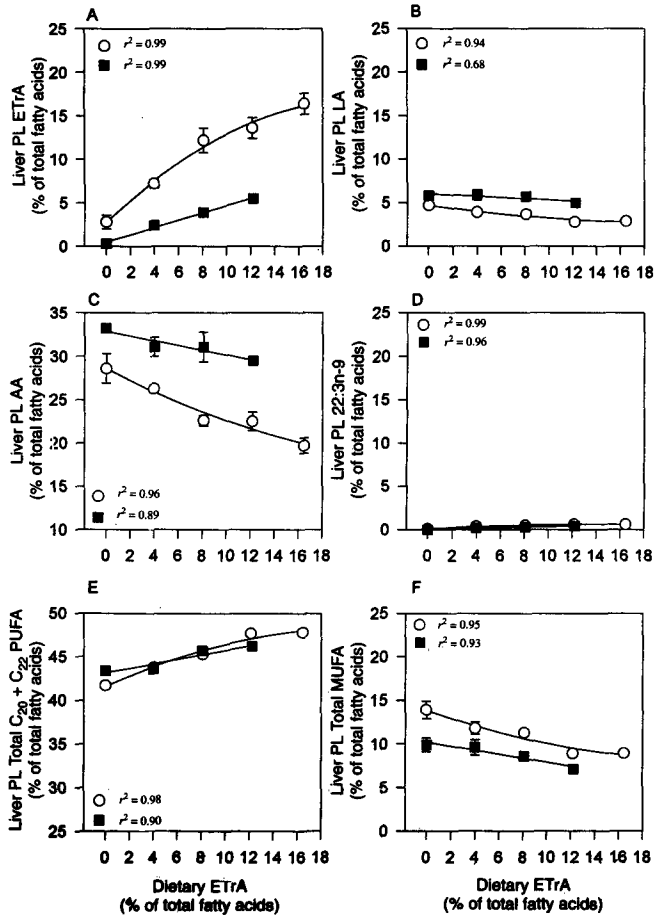

FIG. 4. Liver: Levels of selected fatty acids in tissue and cell phospholipid extracts from rats fed for four weeks diets containing LA at 4.4 % of total fatty acids (O----O) or LA at 19% of total fatty acids (■-----■) and increasing amounts of ETrA. A, ETrA; B, LA; C, AA; D, n-9 docosatrienoic acid (22:3n-9); E, total C_{20} + C_{22} PUFA; F, MUFA. See Figure 1 for abbreviations.

accelerated in rats receiving ETrA relative to rats receiving the diets with no ETrA, regardless of the LA content. There appeared to be a direct relationship between dietary ETrA and weight gain (Fig. 7).

Histological survey. All organs and tissues examined histologically (liver, spleen, kidney, heart, and skin) displayed normal appearances.

DISCUSSION

These investigations show that dietary ETrA appears prominently in plasma lipid fractions and that it is incorporated efficiently into cellular phospholipids in a dose-dependent manner. Levels of ETrA attained 20% of total fatty acids in each of the plasma fractions and 11–16% in PE cell, spleen, and liver. Our data suggest that both plasma fractions and cell membrane phospholipids are saturable in relation to ETrA. The facility with which ETrA accumulates suggests that it competes favorably with potential fatty acid competitors for enzymes responsible for acylation of fatty acids into cell membranes and plasma phospholipids.

Dietary LA had an important negative effect on incorporation of dietary ETrA into plasma lipid fractions and membrane phospholipids. For a given dietary intake of ETrA, levels of ETrA in phospholipids from rats fed the higher LA diets were only 25 to 30% of the values attained with the lower diets. We have reported similar effects of dietary LA on incorporation into plasma lipid fractions and cell membranes of EPA, the n-3 homologue of ETrA (3).

The major n-9 PUFA incorporated into all the plasma fractions and tissues examined was ETrA despite the fact that the diets contained a range of n-9 PUFA. In particular, 18:2n-9 (~14%) was only slightly less abundant in the Mut 48 oil than 20:3n-9 (~16%). That the level of 18:2n-9 only once exceeded 2% total fatty acids in any fraction tested suggests that metabolism of this species occurs readily. One possible route of metabolism of 20:2 n-9 is desaturation by δ5 desaturase to ETrA, which, in contrast to δ6 desaturase, does not appear to be rate-limiting in relation to desaturation of PUFA (8).

In rats, ETrA can be metabolized further to 22:3n-9 (2). This fatty acid was present in only trace amounts in the Mut 48 oil-containing diets and was found in only small amounts (<1% fatty acids) in the plasma fractions and liver phospholipids. By contrast, more substantial accumulation of 22:3n-9

[a]Expressed as percentage of total fatty acids; mean ± SD, $n = 4$ rats in each group. [b]n-9 Eicosatrienoic acid/linoleic acid in diet expressed as percentage of total fatty acids. [c]n.d. = Not detected.

was observed in spleen and PE cell. This accumulation displayed a highly significant ($r^2 > 0.99$) second-order correlation with dietary ETrA with apparent saturation at levels of 4% for spleen and ~7% for PE cells. Reciprocal depression of the n-6 homologue 22:4n-6 was seen. Metabolism of dietary ETrA differs from EPA (and to a lesser extent AA) with regard to the lack of evident accumulation of the n-9 homologue of n-3 docosahexaenoic acid (DHA) in PE cells (2).

The accomodation of ETrA within plasma phospholipids and cell membranes was achieved by combinations of displacement of AA and monounsaturates and expansion of the sum contribution of C_{20} and C_{22} fatty acids. The differences in the patterns of accumulation of ETrA and other fatty acids between different plasma lipid fractions highlight the shortcomings of analyses confined to total plasma lipids. For example, in the cholesterol esters, an essentially reciprocal relationship between ETrA and AA levels was seen without the increase of $C_{20} + C_{22}$ fatty acids seen with the plasma phospholipids and triglycerides. As discussed above, with spleen and PE cell phospholipids, the ETrA metabolite C22:3n-9

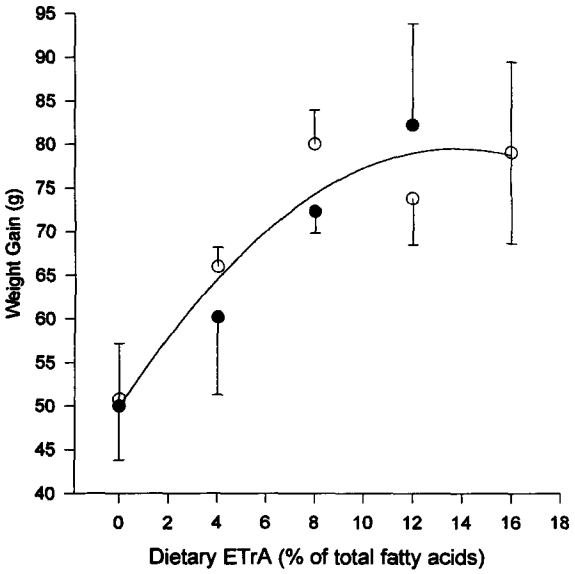

FIG. 7. Mean weight gain (g) observed in groups of rats ($n = 4$) during a four-week period of feeding with diets containing LA at 4.4% of total fatty acids (O----O) or LA at 19% of total fatty acids (■-----■) and increasing amounts of ETrA. See Figure 1 for abbreviations.

also accumulated. The accumulations of ETrA and 22:3n-9 in cells appeared to be potentially saturable as evinced by the observed hyperbolic relationships with dietary ETrA.

With the exception of the plasma cholesterol ester fraction, plasma and cellular AA were only partially displaced by dietary ETrA (as discussed above). This is similar to changes seen in EFA deficiency where AA levels are relatively conserved in the presence of LA depletion and ETrA accumulation (9). The ETrA-rich diets were associated with a modest reduction in LA in some, but not all, fractions or tissues. With the exception of the plasma triglycerides, dietary LA had little effect on LA accumulation in the various fractions, thus establishing the EFA-sufficiency of the lower LA diets. The salient biochemical point of distinction between the effects of ETrA-rich diets and EFA deficiency is the profound LA depletion in plasma and cells seen only in the latter. This is an important difference since the loss of cutaneous barrier function seen in EFA deficiency has been attributed directly to LA depletion (10).

The positive effect on growth of the ETrA-rich diets suggests that ETrA, or some other factor within Mut 48 oil, possesses general metabolic effects. However, only group data with large variation are available from this experiment, and further investigation on weight gain in individual rats is needed to confirm this apparent finding. Nevertheless, the present studies at least establish that dietary ETrA has no negative effects on growth *per se*, in contrast to the reported effects of EFA deficiency.

The very substantial incorporation of ETrA from the diet into cells observed raises questions as to the effects of this incorporation on cell metabolism. As a C_{20} PUFA, ETrA is a potential substrate competitor with AA for eicosanoid-forming enzymes. However, ETrA cannot be converted to a cyclic eicosanoid, such as a thromboxane or prostaglandin, because it lacks the n-6/δ14 double bond. Nevertheless, ETrA could influence eicosanoid synthesis through displacement of AA at the *sn*-2 position of phospholipids, resulting in reduced release of AA by phospholipases. This effect would be analogous to that seen with long-chain n-3 fatty acids where the antiinflammatory effects of purified EPA and DHA ethyl esters in a model sensitive to cyclooxygenase inhibition (carrageenan-induced paw oedema in the rat) correlated with the extent of reduction of AA as a proportion of total C_{20} and C_{22} PUFA in leucocyte phospholipids (11).

In a separate component of the present study, we analyzed the effects of the test diets on leukotriene B_4 (LTB_4) production by rat PE cells stimulated *in vitro*. Dietary ETrA inhibited LTB_4 production in a dose-dependent manner, and the effect was attributable to dose-dependent inhibition of LTA hydrolase (5). These observations confirm and extend our earlier studies into the effects of dietary supplementation with synthetic ETrA on LTB_4 production by leucocytes in rats (2), and are also consistent with *in vitro* studies into the effects of exogenous ETrA on LTB_4 production (9,12). The substantial incorporation of ETrA seen in spleen cells raises the possibility that dietary fortification of ETrA may have other important immunomodulatory effects. It is also possible that 22:3n-9, which accumulates in spleen and PE cell phospholipids, could also have immunomodulatory actions.

A clue to possible beneficial effects of ETrA may be found in the homology between ETrA and EPA, a constituent of fish oils which has been shown to have antiinflammatory effects (13,14). Conceivably, future investigations could be undertaken to assess the effects of ETrA in animal models of human diseases and, in particular, diseases in which there is an immunological pathogenesis or an important inflammatory component. The expected greater stability of ETrA-rich oils relative to n-3 fatty acid-rich oils, which have immunomodulatory effects, makes dietary ETrA fortification potentially a more acceptable and perhaps more effective strategy. If ETrA proves to be nontoxic and useful in reducing the incidence and/or severity of inflammatory diseases in susceptible animals, dietary studies could be undertaken in humans, involving, in the first instance, those with immunoinflammatory disorders or those identified as being at increased risk.

ABSTRACT: Previous research has linked hyperlipidemia with increased serum concentrations of lipid peroxidation products; however, a specific association between diet-induced oxidative stress and hyperlipidemia has not been studied. In the present study, the relationship between tissue lipid peroxidation and hyperlipidemia induced by ingestion of fish oil was examined. In Experiment 1, male Golden Syrian hamsters were fed semi-purified diets composed of 1.6 wt% safflower oil plus 15.0 wt% of either butterfat (BF), safflower oil (SAFF), or high-cholesterol menhaden oil [MHO(H-CHOL)] semipurified diets for 27 d. The cholesterol contents of the diets were adjusted to 0.088%. The MHO(H-CHOL)-fed hamsters exhibited higher serum concentrations of total cholesterol, triglycerides, apolipoprotein B, and lipid peroxides when compared to the BF and SAFF diet groups. In a further study (Experiment 2), hamsters were fed for 27 d three dietary treatments: (i) MHO(H-CHOL) with no vitamin E content; (ii) a low-cholesterol menhaden oil containing high concentrations of vitamin E (2.5 mg tocopherol/g oil or dietary concentrations of 375 mg/kg) [MHO(L-CHOL) + E]; and (iii) the MHO(L-CHOL + E) with added cholesterol (595 mg/kg) [MHO(L-CHOL) + CHOL + E] to match the cholesterol content of the MHO(H-CHOL). The MHO(L-CHOL) + E and MHO(L-CHOL) + CHOL + E diet groups showed lower concentrations of serum cholesterol, triglycerides, and hepatic lipid peroxides than the MHO(H-CHOL)-treated group. Moreover, in contrast to the hypercholesterolemia caused by the MHO(H-CHOL) feeding, the MHO(L-CHOL)+ E and MHO(L-CHOL) + CHOL + E diets did not show a serum cholesterol-elevating action. This study supports the hypothesis that oxidative stress in the Syrian hamster could play a causal role in dietary-induced hyperlipidemia which can be inhibited by high vitamin E intake.
Lipids 31, 839–847 (1996).

Lipid peroxidation and oxidative stress have been associated with the occurrence of hypercholesterolemia and atherosclerosis both in humans and experimental animals (1–5). Despite associations of oxidative stress with hyperlipidemia, a possible relationship between diet-induced oxidative stress and diet-induced hyperlipidemia has not been closely examined.

Fish-oil feeding generally results in reductions in plasma triglyceride and very low density lipoprotein concentrations (6), but there does exist conflicting research. Investigations have shown elevated serum triglycerides in the New Zealand rabbit (7) and the Golden Syrian hamster (8) following fish-oil feeding. In addition, the fish oil-fed Syrian hamster had an elevated apolipoprotein B/apolipoprotein AI ratio (8), which may be correlated with an increased risk of atherosclerosis and may be a better predictor of coronary heart disease than plasma lipid concentrations *per se* (9). Fish-oil concentrates given to hypercholesterolemic men have caused increased plasma total and low density lipoprotein (LDL) cholesterol concentrations (10).

Fish oils rich in n-3 polyunsaturated fatty acids (PUFA) that are efficiently incorporated into tissue membrane phospholipids displacing n-6 PUFA, and membranes enriched in n-3 fatty acids are likely to be more susceptible to oxidative disruption (11). Dietary fish-oil consumption has been shown to increase aortic lesions in rabbits and cause higher plasma levels of lipid peroxidation products as measured by the production of thiobarbituric acid reactive substances (TBARS) (12). In addition, oxidative stress generated by fish-oil consumption is known to increase the requirement of vitamin E (12). As lipid peroxidation (1) and a low body content of tocopherol (5) have been shown to increase tissue cholesterol concentrations, the accompanying increase in oxidative stress could play a causal role. Indeed, the ability of fish oil to decrease plasma triglyceride concentrations in the normolipidemic human has been shown to be markedly enhanced by high supplemental intake of vitamin E (13). Haglund *et al.* (13) suggested that the antioxidant effect of vitamin E was involved through efficient inhibition of fatty acid peroxidation, thereby allowing larger amounts of active n-3 fatty acids in fish oils to exert triglyceride-lowering effects.

In the present study, two experiments were performed with the Syrian hamster. In Experiment 1, the relationship between tissue concentrations of lipid peroxidation products and serum lipid concentrations was investigated among menhaden

oil-, butterfat (BF), and safflower oil (SAFF)-based diets. In contrast to fish oils, SAFF feeding was not expected to increase tissue lipid peroxidation as tissue concentrations of lipid peroxidation products have previously been shown not to be increased by high n-6 PUFA intake as compared to high-saturated fatty acid intake (14). Dietary studies comparing the effects of different fat sources on blood cholesterol metabolism have typically not balanced for the vitamin E content nascent in each fat. Hence, in the initial experiment, the effects of the different fat sources on blood cholesterol metabolism and lipid peroxidation were assessed without balancing for the vitamin E content as this could inhibit the effects of fish oil on lipid peroxidation and on blood lipid concentrations. In a second experiment, we tested whether a high intake of vitamin E could modify the dietary cholesterol-induced hyperlipidemia and tissue lipid peroxidation associated with fish oil-based diets.

MATERIALS AND METHODS

Experimental design. In Experiment 1, hamsters were fed semipurified diets containing 1.6 wt% SAFF and 15 wt% of either BF, SAFF, or a high cholesterol (5.76 mg cholesterol/g of oil) menhaden oil [MHO(H-CHOL)] (Table 1). In experiment 1, the effects of these different fat sources on blood cholesterol metabolism and lipid peroxidation were examined without matching for vitamin E content as additional vitamin E might have compromised effects of MHO(H-CHOL) on lipid peroxidation and on blood lipid concentrations. The MHO(H-CHOL) and BF had nondetectable concentrations of vitamin E, whereas SAFF contained 0.42 g vitamin E/g oil (Table 1). Sufficient vitamin E (6.1 mg vitamin E/kg diet) was added to the BF and MHO(H-CHOL) semipurified diets to meet the National Research Council (NRC) requirements for adequate vitamin E intake for the hamster (15). As BF con-

TABLE 1
Composition of Experimental Diets (g/kg)[a]

Ingredients	BF	SAFF	MHO(H-CHOL)	MHO(L-CHOL) + E + CHOL	MHO(L-CHOL) + E

Vitamin mix[f]	14	14	14	14	14
Mineral mix[g]	80	80	80	80	80

[a]BF = butterfat; SAFF = safflower oil, MHO(H-CHOL) = high cholesterol (5.76 mg cholesterol/g oil) menhaden oil; MHO(L-CHOL) + CHOL + E = low cholesterol (1.9 mg cholesterol/g oil) MHO with high vitamin E content (2.5 mg vitamin E/g oil) and added cholesterol (595 mg/kg); MHO(L-CHOL) + E = low cholesterol (1.9 mg cholesterol/g oil) MHO with high vitamin E content (2.5 mg vitamin E/g oil).

[b]Nondetectable concentrations of vitamin E in BF. Fatty acid composition of BF is as follows (mg%): 4:0, 3.3%; 6:0, 2.3%; 8:0, 1.6%; 10:0, 3.9%; 12:0, 4.0%; 14:0,12.5%; 14:1, 1.2%; 16:0, 33.1%; 16:1n-9, 1.7%; 18:0, 11.6%; 18:1n-9, 21.0%; 18:2n-6, 3.8%.

[c]In Experiments 1 and 2, all diets contained a minimum of 1.6 wt% SAFF to prevent essential fatty acid deficiency. Vitamin E concentration of SAFF is 0.42 g/g oil. Fatty acid composition of SAFF is as follows (mg%): 14:0, 0.3%; 16:0, 11.9%; 18:0, 2.3%; 18:1n-9, 14.1%; 18:2n-6, 70.9%; 18:3n-3, 0.5%.

[d]Nondetectable concentrations of vitamin E in MHO(H-CHOL) and 2.5 mg vitamin E/g oil in MHO(L-CHOL). Fatty acid composition of H-CHOL MHO is as follows (mg%): 14:0, 15.2%; 16:0, 22.3%; 16:1n-9, 12.7%; 18:0, 3.9%; 18:1n-9, 10:0%; 18:2n-6, 2.8%; 18:3n-3, 1.1%; 18:4n-3, 4.5%; 20:1n-9, 1.4%; 20:4n-6, 0.5%; 20:5n-3, 12.7%; 22:1n-9, 1.3%; 22:4n-6, 0.5%; 22:5n-3, 1.5%; 22:6n-3, 9.6%. Fatty acid composition of MHO(L-CHOL) is as follows (mg%): 14:0, 7.8%; 16:0, 14.7%; 16:1n-9, 0.2%; 18:0, 2.7%; 18:1n-9, 5.2%; 18:2n-6, 1.4%; 18:3n-3, 0.9%; 18:4n-3, 2.5%; 20:1n-9, 0.8%; 20:4n-6, 0.8%; 20:5n-3, 13.6%; 22:1n-9, 0.2%; 22:4n-6, 0.2%; 22:5n-3, 2.5%; 22:6n-3, 10.2%.

[e]Cholesterol United States Pharmacopeia (USP) was added to the oil, BF, and MHO(L-CHOL) diets at 880, 440, and 595 (mg/kg diet), respectively. No cholesterol was added to the MHO(H-CHOL) diet because it naturally contains 5.76 mg cholesterol/g of oil. BF naturally contains 2.39 mg cholesterol/g BF, MHO(L-CHOL) contains 1.9 mg cholesterol/g oil, and SAFF contains no cholesterol.

[f]Vitamin mix supplied the following (mg/kg diet): niacin, 135; calcium pantothenate, 60; riboflavin, 22.5; pyridoxine, 9; thiamin, 30; folic acid, 3; biotin, 0.9; cyanocobalamine, 0.015; menaquinone, 6; choline, 6000; α-tocopheryl acetate (1350 IU/g), 6.1; cholecalciferol (400,000 IU/g), 9.32; vitamin A palmitate (250,000 IU/g), 40.2. Only 18.5 mg/kg of vitamin A palmitate (250,000 IU/g) was provided to the BF diets since vitamin A occurs naturally in BF at a level of 30.07 IU/g.

[g]Mineral mix supplied the following (mg/kg diet): calcium carbonate, 22.48; potassium phosphate, 25.16; sodium chloride, 5.72; magnesium sulfate, 4.46; cupric carbonate, 0.0045; cobalt chloride, 0.0666; sodium fluoride, 0.00008; potassium iodate, 0.0040; ferric sulfate, 1.045; manganous carbonate, 0.0115; sodium selenite, 0.00033; zinc carbonate, 0.0265.

tained 2.39 mg cholesterol/g and SAFF contained no cholesterol, United States Pharmacopeia (USP) cholesterol was added to the SAFF and BF diets at 880 and 440 mg (mg/kg diet), respectively, to match levels in the MHO(H-CHOL). In Experiment 2, hamsters were fed one of three semipurified diets which consisted of: (i) the high-cholesterol MHO(H-CHOL); (ii) a low-cholesterol menhaden oil which also contained high amounts of vitamin E (2.5 mg vitamin E/g oil) equivalent to a dietary concentration of 375 mg/kg [MHO(L-CHOL) + E]; and (iii) the low-cholesterol MHO(L-CHOL) + E oil (2.5 mg vitamin E/g oil) which was supplemented with USP cholesterol (595 mg/kg diet) [MHO(L-CHOL) + CHOL + E] to match the high-cholesterol content found in MHO(H-CHOL).

Animals and diets. Male Syrian hamsters, weighing 110–120 g, were purchased at seven weeks of age from Charles River Inc. (St-Constant, Quebec, Canada). The animals were fed a commercial nonpurified diet (Mouse Chow; Purina, Montreal, Quebec, Canada) upon arrival. After an adaptation period of three weeks, the hamsters received semipurified diets for 27 d in two separate experiments. Thirty-six hamsters were weighed and randomly assigned to three semipurified diet groups in Experiment 1, whereas in Experiment 2, twenty-one hamsters were weighed and allocated randomly to three semipurified diet groups. In Experiments 1 and 2, all diets contained minimally sufficient vitamin E (6.1 mg vitamin E/kg diet) to meet the NRC requirements of vitamin E for the hamster (15). In all diets, butylated hydroxytoluene was added to dietary fat sources at a level of 0.1% of lipid weight to protect fats from oxidation. The MHO(H-CHOL) was purchased from U.S. Biochemical Corporation (Cleveland, OH), and the MHO(L-CHOL) was a gift from the Fish Oil Biomedical Test Material Program of the National Marine Fisheries Service (Washington, D.C.). The differences in fatty acid content between the MHO(L-CHOL) and MHO(H-CHOL) oils as indicated in Table 1 were minimal, i.e., total n-3 content (mg %) = 29.4 [MHO(L-CHOL)] and 29.7 [MHO(H-CHOL)]; n-6/n-3 ratio = 0.09 [MHO(L-CHOL)] and 0.12 [MHO(H-CHOL)]; unsaturation indices = 167 [MHO(L-CHOL)] and 184 [MHO(H-CHOL)]; eicosapentaenoic acid (20:5n-3)/arachidonic acid (20:4n-6) ratio = 17 [MHO(L-CHOL)] and 25.4 [MHO(H-CHOL)]; 20:5n-3/docosahexaenoic acid (22:6n-3) ratio = 1.3 [MHO(H-CHOL)] and 1.3 [MHO(L-CHOL)]. Based on previous literature, the magnitude of the differences in fatty acid composition would not be expected to impact upon serum lipid concentrations (16,17). Unused fresh diets were kept in plastic bags at 4°C, and bags were flushed with nitrogen after each opening during the trial. Samples of stored semipurified diet were measured for TBARS on a weekly basis throughout the experiment to obtain an index of dietary lipid peroxidation by a modification (18) of the method of Dahle *et al.* (19). Analysis of all semipurified diets yielded nondetectable values of TBARS, e.g., below 20 nmol of reference standard (malondialdehyde *bis*diethyl acetal). Suitable vitamin and mineral mixes for hamster needs were developed following the NRC requirements (15) and were given at 1.5 times the requirements to ensure an adequate intake of those nutrients. BF (Lactancia, Victoriaville, Quebec, Canada) contained 18.4% water (manufacturer's specifications). This factor was taken into account in the formulation of the BF diet (e.g., 177.6 g/kg of BF was added into the diet instead of 150.0 g/kg of lipid that was added in the other diets) in order to make the diets isoenergetic.

The animals were housed individually in plastic bottom wired top cages and kept in a temperature-controlled room (23–25°C) with a 12-h automatically maintained light-dark cycle (light cycle 0700 to 1900). They were allowed access to food and water *ad libitum*. Fresh diets were fed to the animals daily, and uneaten food was discarded. Body weight was measured every second day, and food intake was recorded daily. Care and handling of the animals conformed to the guidelines of the McGill University Animal Care Committee and Canadian Council of Animal Care (20).

Tissue sampling and preparation. On day 1 and day 27, blood was collected using heparinized capillary tubes by retro-orbital sinus puncture, from 14-h fasted hamsters anesthetized with CO_2. On day 27, the hamsters were killed by decapitation under CO_2 anesthesia. Hearts and livers were excised and cleaned of blood with ice-cold saline, and the tissues were weighed. The hearts were fixed on corks for histological examination. Livers were freeze-clamped in liquid nitrogen and stored at −80°C until analyses. Aliquots of blood samples were allowed to clot at room temperature, centrifuged at 6000 × *g* for 10 min, and stored at 4°C until they were analyzed within two days for total cholesterol, total triglyceride, and high density lipoprotein cholesterol (HDL-C) content. The remaining serum was stored at −20°C for determination of serum apolipoprotein A-I, apolipoprotein B, alanine aminotransferase, and lipid peroxides at a later date.

Biochemical analysis. Serum measurements of cholesterol, triglyceride, and HDL-C were obtained by automated enzymatic methodology with the Abbott VP Super System (Abbott, Irving, TX) using Abbott enzymatic reagent kits (Abbott kit 6095 for cholesterol, 6097 for triglycerides, and 6039 for HDL-C). Serum alanine aminotransferase was measured *via* an enzymatic assay (Sigma kit 59 for aminotransferase; Sigma Chemical Co., St. Louis, MO) as an index of possible liver damage. Apolipoproteins A-I and B were measured using enzymatic assays (356 for apolipoprotein A-I and 357 for apolipoprotein B; Sigma Chemical Co.). The serum alanine aminotransferase, apolipoproteins A-I and B enzymatic assays were analyzed using the Abbott VP Super System. Serum and liver were thawed and analyzed for lipid hydroperoxides using an adaptation of a lipid hydroperoxide kit assay (Kamiya Biomedical, Thousand Oaks, CA) based on the method of Oshishi *et al.* (21). The lipid was extracted by the method of Folch *et al.* (22) and reconstituted in different quantities of isopropranol (different dilutions) due to the variable amounts of lipids in each sample. The absorbance of the sample was determined at 620 nm using a microplate reader (Titertek Multiskan Plus MKII; ICN Biomedicals, Cleveland,

OH) using a 620 nm filter. The concentration of TBARS in livers was assayed as described previously (18). Concurrent measurements of lipid hydroperoxides and TBARS were made, as previous research has indicated that concentrations of these indices appear to peak at different time points in hepatic tissues in relation to the induction of the oxidative stress (23). The cholesterol content of the dietary fats was determined by gas–liquid chromatography by the method of Heuck *et al.* (24). The fatty acid composition of the dietary fats was determined by gas–liquid chromatography following fatty acid methyl esters formation and has been described previously (25).

Histopathology. The heart was sectioned midway through the atria, and the aorta was cut distally to the sinus valves and fixed on a cork. Cryostat frozen sections, 10 μm thick, were cut at three different levels and stained with oil red O and counterstained with haematoxylin. The sections were examined microscopically, and a similar section of each aorta was scored from 0 to 10 according to a modification of the method of Roberts and Thompson (26). Aorta were examined for the presence of foam cells and lesions in the aortic sinus wall. The histology was done on 50% of hearts, taken *via* random allocation, in each diet group (i.e., six hearts per dietary treatment).

Statistical analysis. Statistical analysis of the data was performed using the Statistical Analysis System for personal computers (Version 6.04, 1992; SAS Institute, Cary, NC). Two-way analysis of variance was used to determine the influence of time and dietary treatment on parameters measured at the beginning and end of the experiment (body weight, triglycerides, cholesterol, HDL-C). In Experiment 1, for serum lipid measures, body weight change was used as a covariate in the statistical model of two-way analysis of variance (ANOVA). One-way ANOVA was used to determine whether there was a main effect of diet on cumulative food intake, liver weight, serum alanine transferase, apolipoproteins A-I and B, apolipoprotein A-I/B, serum liver lipid peroxides, and liver TBARS. In Experiments 1 and 2, when a significant difference occurred among the main effects of diet and time in two-way ANOVA analyses or when a significant main effect of diet was observed *via* one-way ANOVA, mean differences among treatment groups were identified by least significant means for *a priori* comparisons. In Experiment 1, the following *a priori* comparisons were done to determine the effect of dietary source of fat on serum lipoprotein and tissue lipid peroxidation concentrations: (i) BF vs. SAFF, (ii) SAFF vs. MHO(H-CHOL), and (iii) BF vs. MHO(H-CHOL). Pearson's correlations between serum lipids and apolipoproteins and serum measures of oxidative stress (lipid peroxides and TBARS) were performed. In Experiment 2, the specified comparisons were: (i) MHO(H-CHOL) vs. MHO(L-CHOL) + E, (ii) MHO(H-CHOL) vs. MHO(L-CHOL) + CHOL + E , and (iii) MHO(L-CHOL) + E vs. MHO(L-CHOL) + CHOL + E. Cumulative food intake in Experiment 2 was put as a covariate in the statistical model of two-way ANOVA for serum lipid measures. The values were expressed as means ± SE for all parameters measured. In all comparisons, $P < 0.05$ was considered as the minimum level of significance.

RESULTS

Experiment 1. Food intake, weight gain, and tissue weight. There were no significant differences in cumulative food intakes among the BF (170.9 ± 3.7 g), SAFF (163.0 ± 3.7 g), and MHO(H-CHOL) (155.1 ± 3.2 g) diets. Body weight change from day 0 to day 27 was significantly higher ($P < 0.05$) in the BF (+4.4 ± 2.1 g) and the SAFF (+5.3 ± 1.8 g) groups as compared to the MHO(H-CHOL) group (−1.9 ± 1.4 g). No differences in the magnitude of body weight change were found between the BF group and the SAFF group. Liver weight as a percentage of body weight, however, was lower ($P < 0.05$) in the BF (6.35 ± 0.11%) and the SAFF (6.08 ± 0.07%) groups as compared to fish oil-fed (6.70 ± 0.12%) group suggesting an association between fish-oil feeding and hepatomegaly. The BF and SAFF groups were not different from each other in terms of liver weight as a percentage body weight. Liver weights were not different among the dietary treatments (data not shown).

Serum cholesterol, triglycerides, and apolipoproteins. Because significant differences were observed in terms of body weight change, body weight change was included as a covariate in the two-way ANOVA statistical analyses for serum lipid analyses. Body weight as a covariate, however, did not statistically influence serum lipid concentrations. In general, for total serum cholesterol concentrations, significant main effects of diet ($P < 0.0001$), time ($P < 0.0001$), and a significant diet × time ($P < 0.0001$) interaction were observed (Table 2).

In terms of the changes in total serum cholesterol, a significant main effect of diet ($P < 0.0001$) was observed. As would be expected from the high-saturated fat content of BF, the BF group showed a significantly higher final concentration of serum cholesterol and a larger increase in total serum cholesterol than did hamsters fed the polyunsaturated SAFF diet (Table 2). The MHO(H-CHOL) hamsters had significantly higher final levels of serum cholesterol than did the hamsters fed either the SAFF and BF diets. In addition, hamsters fed the MHO(H-CHOL) diet had greater change in total serum cholesterol concentrations over the 27-d feeding period than the BF and the SAFF groups (Table 2), indicating a hypercholesterolemic action of MHO feeding relative to the other lipid-based diets.

For serum triglycerides measured on day 0 and day 27, significant main effects of diet ($P < 0.05$), time ($P < 0.005$), and a significant interaction of diet × time ($P < 0.05$) were observed. The change from day 0 to day 27 in serum triglyceride concentrations also demonstrated a significant main effect of diet ($P < 0.001$). The MHO(H-CHOL) group demonstrated higher final concentrations of triglycerides than either the BF or SAFF groups. The change (day 0–27) in triglyceride concentrations in the MHO(H-CHOL) hamsters was also significantly greater than in the BF- and SAFF-fed animals, indicating a hypertriglyceridemic effect of fish-oil intake. No differences were observed in either final serum triglyceride concentrations or change (day 0–27) in serum triglyceride concentrations between the BF and SAFF diets.

TABLE 2
Effects of Dietary Fats on Serum Concentrations of Total Cholesterol, Triglycerides, HDL-C, and Apolipoproteins A-I and B in Hamsters (Experiment 1)[a]

	BF	SAFF	MHO(H-CHOL)
Total cholesterol (mg/dL)			
Day 0	(12) 108.87 ± 5.73	(12) 97.29 ± 6.58	(12) 100.58 ± 4.49
Day 27	(12) 154.67 ± 7.54	(12) 101.62 ± 5.81[a]	(12) 183.86 ± 6.97[b,c]
Change	(12) 45.81 ± 8.81	(12) 4.33 ± 8.72[a]	(12) 83.28 ± 7.68[b,c]
Total triglycerides (mg/dL)			
Day 0	(12) 230.33 ± 10.19	(12) 205.80 ± 11.61	(12) 200.03 ± 14.15
Day 27	(12) 233.96 ± 21.35	(12) 222.35 ± 15.90	(12) 303.95 ± 26.65[b,c]
Change	(12) -6.37 ± 22.25	(12) 16.56 ± 10.36	(12) 103.92 ± 20.06[b,c]
HDL-C (mg/dL)			
Day 0	(10) 59.12 ± 2.33	(10) 54.52 ± 2.68	(10) 54.29 ± 2.00
Day 27	(12) 71.38 ± 3.86	(10) 76.17 ± 8.18	(12) 83.04 ± 8.80
Change	(10) 6.05 ± 2.65	(10) 6.62 ± 3.18	(10) 10.87 ± 5.52
Apo A-I (mg/dL)	(5) 64.50 ± 2.04	(5) 62.80 ± 1.53	(5) 61.50 ± 2.32
Apo B (mg/dL)	(12) 16.35 ± 1.57	(12) 15.21 ± 1.20	(12) 37.85 ± 2.33[b,c]
Apo A-I/Apo B	(5) 5.32 ± 0.43	(5) 5.10 ± 0.88	(5) 1.77 ± 0.17[b,c]

[a]Values are means ± SE. Number in parentheses equals number of hamsters. Hamsters were fed BF, SAFF, and MHO(H-CHOL)-based semipurified diets for 27 d. See Table 1 for other abbreviations. Means within each row with superscript letters indicate the following comparisons are significantly different ($P < 0.05$) by least significant means: [a]BF vs. SAFF; [b]SAFF vs. MHO(H-CHOL); [c]BF vs. MHO(H-CHOL). Body weight change (day 0–27) was used as a covariate in the statistical model of two-way analysis of varriance (ANOVA). Significance of main effects of two-way ANOVA for total serum cholesterol (diet: $P < 0.05$; time: $P < 0.005$; diet × time: $P < 0.05$), total serum triglycerides (diet, $P < 0.0001$; time: $P < 0.0001$; diet × time: $P < 0.0001$), serum high density lipoprotein-choleserol (HDL-C), (diet: nonsignificant; time: $P < 0.0001$; diet × time: nonsignificant). Significant main effects of one-way ANOVA for serum cholesterol change ($P < 0.0001$), serum triglyceride change ($P < 0.001$), serum apo B ($P < 0.0001$), serum apolipoprotein (Apo) A-I/Apo-B ($P < 0.001$).

ANOVA showed no significant diet or time effects on serum HDL-C concentrations. On the other hand, the MHO(H-CHOL) animals had concentrations of apolipoprotein B that were greater than hamsters fed the BF and SAFF diets. In addition, hamsters fed the MHO(H-CHOL) diet had significantly lower ratios of apolipoprotein A-I/apolipoprotein B than the other two diets.

Serum and liver lipid oxidation products. The source of fat influenced the levels of serum lipid peroxides as animals fed the MHO(H-CHOL) diet had significantly higher serum levels of lipid peroxides than the hamsters fed the SAFF and BF diets (Table 3). Liver lipid peroxide and TBARS levels were not affected by the source of fat. When all dietary treatments were grouped together, correlations were observed between serum lipid peroxides and a number of serum indices including total serum cholesterol (change) ($r = 0.42$; $P < 0.004$), total serum triglycerides (change) ($r = 0.47$; $P < 0.0009$), serum apolipoprotein B ($r = 0.69$; $P < 0.0001$), and the serum apolipoprotein A-I to apolipoprotein B ratio ($r = -0.72$; $P < 0.0004$).

Serum alanine aminotransferase and histopathology. There were no significant differences observed among the treatment groups in terms of serum alanine aminotransferase levels (data not shown). Morphometric evaluation of the histologic sections showed the absence of foam cells. No atherosclerotic lesions in the aortic sinus wall and no significant differences in intimal thickness were observed among dietary treatments (data not shown).

Experiment 2. Food intake, weight gain, and tissue weight. There were no differences in cumulative food intake between the MHO(H-CHOL) (161 ± 6 g) group and either the MHO(L-CHOL) + CHOL + E (148 ± 5 g) or the MHO(L-CHOL) + E (167 ± 5 g) groups; however, food intake was significantly lower ($P < 0.05$) in the MHO(L-CHOL) + CHOL + E group when compared with the MHO(L-CHOL) + E group. Although total weight gain did not differ among the dietary treatments (data not shown), liver weight at day 27 was significantly higher ($P < 0.05$) in the MHO(H-CHOL)-fed group (6.14 ± 0.37 g) as compared with the MHO(L-CHOL) + E (4.82 ± 0.21 g) and MHO(L-CHOL) + CHOL + E (5.14 ± 0.21 g) groups. Similarly, liver weight as a percentage of body weight was significantly higher in the MHO(H-CHOL)-fed animals (4.50 ± 0.20%) relative to the MHO(L-CHOL) + E (3.60 ± 0.07%) and MHO(L-CHOL) + CHOL + E (4.00 ± 0.20%) groups, indicating that the hepatomegaly associated with MHO feeding in Experiment 1 could be alleviated by high vitamin E intake. The MHO(L-CHOL) + E and MHO(L-CHOL) + CHOL + E diet groups were not significantly different from each other in terms of liver weight or liver weight as a percentage of body weight.

Serum cholesterol and triglycerides. Since significantly different amounts of diets were consumed, food intake was included as a covariate for the two-way ANOVA for assessing the statistical comparisons of serum lipid values in Experiment 2. However, differences in cumulative food intake did not contribute to significant changes in plasma lipid con-

TABLE 3
Effects of Dietary Fats on Serum and Liver Lipid Peroxides (LPO) and Liver Thiobarbituric Acid Reactive Substances (TBARS) in Hamsters (Experiment 1)[a]

TBARS			
Liver (nmol/mg fat)	(12) 8.98 ± 2.02	(11 9.71 ± 3.38	(11) 10.78 ± 1.82

[a]Values are means ± SE. Number in parentheses equals number of hamsters. See Table 1 for other abbreviations. Hamsters were fed BF, SAFF, and MHO(H-CHOL)-based semipurified diets for 27 d. Means within each row with superscript letters indicate the following comparisons are significantly different ($P < 0.05$) by least significant means: [a]BF vs. SAFF; [b]SAFF vs. MHO(H-CHOL); [c]BF vs. MHO(H-CHOL). Significance of main effect of one-way ANOVA for serum LPO ($P < 0.0001$).

centrations. In general, for total serum cholesterol concentrations, significant diet ($P < 0.001$), time ($P < 0.01$), and diet × time ($P < 0.005$) interactions were observed (Table 4). A significant diet ($P < 0.05$) effect was observed for change (day 0–27) in serum cholesterol concentrations. For the MHO(H-CHOL) group, serum cholesterol increased significantly ($P < 0.05$) from baseline after 27 d of feeding. On the other hand, no significant differences were observed for the MHO(L-CHOL) + CHOL + E and the MHO(L-CHOL) + E groups with respect to the comparison of cholesterol concentrations on day 27 with baseline values. The MHO(H-CHOL)-fed hamsters also had significantly higher final concentrations of total serum cholesterol than did either the MHO(L-CHOL) + E or the MHO(L-CHOL) + CHOL + E groups (Table 4). Vitamin E, however, did not completely overcome the hypercholesterolemic effect of cholesterol as no significant differences were observed between the MHO(H-CHOL) and the MHO (L-CHOL) + E + CHOL groups when the change in serum cholesterol between day 0 and day 27 was measured. The change in serum cholesterol over the 27-d feeding period was significantly lower in the MHO(L-CHOL) + E animals as compared with the other groups (Table 4). Overall, these data suggest that the hypercholesterolemic action of MHO was partially inhibited by high vitamin E intake.

A significant diet ($P < 0.001$) effect was observed in terms of total serum triglycerides, and a significant diet ($P < 0.05$) effect was observed for change (day 0–27) in serum triglyceride concentrations. After the 27-d feeding, the serum

Day 27	(6) 65.47 ± 6.04[a,b]	(7) 50.69 ± 3.17	(7) 49.32 ± 2.56
Change	(6) −38.16 ± 10.00	(7) −31.18 ± .63	(7) −41.01 ± 8.60

[a]Values are means ± SE. Number in parentheses equals number of hamsters. See Tables 1 and 2 for abbreviations. Hamsters were fed for 27 d one of three semipurified diets which consisted of: (i) a high-cholesterol MHO(H-CHOL); (ii) a low-cholesterol MHO which also contained high amounts of vitamin E (2.5 mg vitamin E/g oil) equivalent to a dietary concentration of 375 mg/kg [MHO(L-CHOL) + E]; and (iii) the low-cholesterol MHO(L-CHOL) + E oil (2.5 mg vitamin E/g oil) which was supplemented with United States Pharmacopeia cholesterol (595 mg/kg diet) [MHO(L-CHOL) + CHOL + E] to match the high-cholesterol content found in MHO(H-CHOL). Means within each row with superscript letters indicate the following comparisons are significantly different ($P < 0.05$) by least significant Means: [a]MHO(H-CHOL) vs. MHO(L-CHOL) + CHOL + E; [b] MHO(H-CHOL) vs. MHO(L-CHOL) + E; [c]MHO(L-CHOL) + E vs. MHO(L-CHOL) + CHOL + E. Means within each column with the supercript letter [d]indicate that the comparison of day 0 vs. day 27 is significantly different ($P < 0.05$) by least significant means. Cumulative food intake (day 0–27) was used as a covariate in the statistical model of two-way ANOVA. Significance of main effects of two-way ANOVA for total serum cholesterol (diet: $P < 0.001$; time: $P < 0.01$; diet × time: $P < 0.005$), total serum triglycerides (diet, $P < 0.001$; time, nonsignificant; diet × time: nonsignificant), serum HDL-C (diet: $P < 0.0001$; time: $P < 0.0001$; diet × time: $P < 0.0001$). Significance of main effect of one-way ANOVA for serum cholesterol change ($P < 0.05$) and serum triglyceride change ($P < 0.05$).

triglyceride concentrations were higher in the MHO(H-CHOL)-fed animals relative to the other diet groups, suggesting that the hypertriglyceridemia produced by MHO feeding was inhibited by the supplemental vitamin E. In addition, a hypertriglyceridemic effect of dietary cholesterol occurred as total serum triglyceride concentrations were significantly higher in the MHO(L-CHOL) + CHOL + E group as compared with the MHO(L-CHOL) + E animals. Also, when the change between initial and final triglyceride concentrations was compared, the MHO(H-CHOL) group had a significantly greater change in triglyceride concentrations as compared with both the MHO(L-CHOL) + E and the MHO(L-CHOL) + CHOL + E groups.

For serum HDL-C, significant diet ($P < 0.0001$), time ($P < 0.0001$), and diet × time interaction ($P < 0.0001$) effects were observed. All three diet groups showed a significant ($P < 0.0001$) drop in serum HDL-C values from baseline after the 27-d feeding. Serum HDL-C at day 27 was significantly higher in the MHO(H-CHOL) group than in either the MHO(L-CHOL) + E group or the MHO(L-CHOL) + CHOL + E group, but no significant differences were observed among all treatments when changes in HDL-C concentrations were analyzed.

Liver lipid peroxides. Livers from hamsters fed the MHO(H-CHOL) diet had significantly higher ($P < 0.05$) lipid peroxide concentrations (0.29 ± 0.05 nM/mg protein) as compared with either the MHO(L-CHOL) + E (0.15 ± 0.02 nM/mg protein) group or the MHO(L-CHOL) + CHOL + E (0.15 ± 0.03 nM/mg protein) group supporting the idea that supplemental vitamin E produced an inhibitory effect on MHO-mediated hepatic lipid peroxidation. The MHO(L-CHOL) + E animals did not differ significantly in terms of liver peroxide concentrations from the MHO(L-CHOL) + CHOL + E hamsters.

DISCUSSION

A possible etiological role of oxidative stress in hyperlipidemia has been suggested from animal studies showing that a deficiency of vitamin E, an important antioxidant that protects cell membranes against oxidative damage and lipid peroxidation, increases tissue cholesterol (5). The administration of fish oils to animals has previously been indicated to cause a low body content of vitamin E due to enhanced *in vivo* lipid peroxidation of n-3 fatty acids (27), and supplementation of vitamin E well above normal physiological requirements was needed in both mice (28) and primates (29) to normalize tissue vitamin E concentrations. Moreover, induction of oxidative stress in rats by administration of xenobiotic compounds, such as phenobarbital, has been demonstrated to increase total cholesterol and LDL-cholesterol (30). Conversely, supplementation of vitamin E at a level of 2000 mg vitamin E/kg diet has been shown to decrease plasma cholesterol concentrations in the Watanabe heritable hyperlipidemic rabbit (31). The findings of the present study lend further support for the concept that oxidative stress could play a significant role in disrupting cholesterol metabolism which can be ameliorated *via* high intakes of vitamin E.

Our findings show that the hyperlipidemic response in the hamster to a high intake of fish oil is related to the oxidative challenge induced by this diet. Experiment 1 showed that intake of MHO was associated with increased serum lipid peroxidation relative to hamsters fed either BF or SAFF-based diets. This observation is consistent with findings of higher serum concentrations of lipid peroxidation products observed in humans (13) and experimental animals such as rabbits (10) and rats (12) following fish oil supplementation. It is well established that polyunsaturated fats increase the requirement for vitamin E by increasing the susceptibility of cell membranes to oxidative degradation (32). As observed previously with n-6 PUFA diets (14), levels of tissue lipid peroxidation products were not increased by high n-6 fatty acid intake as compared with the high saturated fatty acid intake *via* the BF diet.

The high concentrations of serum lipid peroxides in the MHO(H-CHOL)-fed animals suggest that the body content of vitamin E was not adequate to protect highly oxidizable n-3 PUFA from oxygen-free radical attack. In support of this concept, the fish oil diets with a high vitamin E content in Experiment 2 were associated with lowered tissue lipid peroxidation. In the second experiment, fish oils with a high tocopherol content were associated with a serum cholesterol-lowering action even when matched for the higher cholesterol content of the hyperlipidemic MHO. The highly significant correlations between serum levels of lipid peroxidation and various apolipoprotein and lipoprotein fractions also suggest that the increased levels of oxidative stress could contribute to the adverse MHO(H-CHOL)-induced apolipoprotein and lipoprotein profiles. The results thus present the interesting possibility that depletion of tissue vitamin E and lipid peroxidation could be involved in the hyperlipidemic response of the hamster to fish oils. Human studies support the concept that supplemental vitamin E could affect the serum lipid-lowering effects of fish oil as subjects receiving vitamin E demonstrated a more marked fish oil-induced decrease in blood triglyceride concentrations than those receiving fish oil alone (13). As blood cholesterol concentrations were unaffected by vitamin E supplementation in the presence of fish oil intake, Haglund *et al.* (13) suggested that triglyceride synthesis might be more disrupted by peroxidation of fatty acids than cholesterol synthesis. The present study does not support this hypothesis in the hamster as both blood components were adversely affected by the MHO(H-CHOL) treatment. Moreover, both the cholesterol and triglyceride serum fractions showed lower concentrations (Table 4) in the presence of high intake of vitamin E when fish oil was given in Experiment 2. Differences in fish oil metabolism between the human and the hamster could account for the differential results observed in terms of serum cholesterol concentrations between the two studies.

In spite of increases in lipid peroxidation induced by the fish oil supplement, lipid peroxidation did not exert athero-

genic effects over the 27-d study period. This result does not discount the possiblity that atherogenic lesions may have occurred at a later period in the feeding study as aortic lesions were visible in fish oil-fed rabbits after five months of feeding (11). Although fatty streaks and foam cells have previously been reported in the Golden Syrian hamster after a four-week feeding (33), the atherogenic effects were caused by feeding 15% BF in the presence of much higher levels of cholesterol (3%) than was used in the present study (0.088%).

A major confounding effect between the two types of MHO oils was the higher cholesterol content of the MHO(H-CHOL). Despite the addition of matching levels of cholesterol to the MHO(L-CHOL), however, significant differences existed in terms of concentrations of serum cholesterol and triglycerides between the two oils. Moreover, only the MHO(H-CHOL) group experienced a significant rise in serum cholesterol concentrations from baseline values (Table 4). In Experiment 2, the serum lipid concentrations of MHO(L-CHOL) + CHOL + E were intermediary between those of the other two groups, thereby indicating that the high cholesterol content of MHO(H-CHOL) was partially responsible for the hyperlipidemic effect of the MHO(H-CHOL) oil. The minimal differences in fatty acid content between the MHO(H-CHOL) and the MHO(L-CHOL) oils were not likely responsible for the observed differences in serum lipid concentrations from the feeding of these two oils. Data from animal feeding studies that have compared fish oils with different fatty acid compositions with dietary levels of cholesterol adjusted to be the same. These studies have shown that the dietary ratios of 20:5n-3 to 20:4n-6 (16) and 20:5n-3 to 22:6n-3 (17) were the variables that caused differences in the hypolipidemic action among fish oils from different species. In particular, a hypolipidemic action was associated with fish oils with more than threefold higher dietary 20:5n-3/20:4n-6 ratios in contrast to fish oils that showed no hypolipidemic effect (16). In the present study, however, the differences in these dietary ratios were small between the two oils (Table 1). In fact, the trends in these ratios observed in the two MHO, deviated in the opposite direction. Hence, in terms of hypolipidemic action the hyperlipidemic MHO without added vitamin E had a higher 20:5n-3/20:4n-6 ratio (25.4) as compared to the hypolipidemic MHO with a high vitamin E content which had a ratio of 17. Four- to tenfold differences in the 20:5n-3 to 22:6n-3 ratio among fish oils have been indicated to result in differential decreases in plasma concentrations of total cholesterol, LDL, and HDL (17). The dietary 20:5n-3 to 22:6n-3 ratio, however, was identical in the two MHO, 1.3. These data support the claim that difference in the vitamin E content of the oils rather than the fatty acid composition was the major factor involved in the observed differences in lipid-lowering action between the two oils.

An increase in the serum triglyceride concentrations and a decrease in the apolipoprotein A-I/apolipoprotein B ratio have all been previously observed in the Golden Syrian hamster following feeding of a fish oil-based semipurified diet (8). In contrast to the present experiments, however, Hayes *et al.* (8) did not observe the hypercholesterolemic response to fish-oil feeding. The contrasting results in terms of serum cholesterol observed between our two studies could be accounted by differences in strain of Syrian hamster. Although the source of Syrian hamster was not indicated in the Hayes *et al.* study, a variability has been noted among Syrian hamsters from different commercial sources with respect to their lipidemic responses to dietary parameters (34).

Fish-oil intake in our study resulted in an increase in the liver weight/body weight ratio as in other studies (35). However, unlike other work (36), no increase in serum alanine aminotransferase was observed with fish-oil intake. Some investigators have suggested that the hepatomegaly could be related to the peroxisomal proliferation induced by fish-oil feeding and that the peroxisomal proliferation was a cause of the reduced synthesis and secretion of very low density lipoprotein triglyceride (37). Although peroxisomal proliferation was not measured, the fish oil-induced hepatomegaly in both Experiments 1 and 2 was associated with serum triglyceride-raising rather than triglyceride-lowering effects of fish oil, suggesting that the hepatomegaly may be dissociated from triglyceride-lowering effects of fish oil. As the hepatomegaly and hepatic lipid peroxidation were decreased in the presence of vitamin E supplementation, it is possible that fish oil-induced hepatomegaly could be related to oxidative stress at the hepatic level.

The present study shows that dietary vitamin E can modulate fish oil-induced changes in blood lipid metabolism and that a diet containing high amounts of fish oil induces an oxidative challenge. Lipid peroxidation and tocopherol depletion could be involved in the hyperlipidemic response of the hamster to fish oils since high vitamin E intake was associated with the production of hypolipidemic effects when MHO was fed. The highly significant correlations between serum levels of lipid peroxidation and various apolipoprotein and lipoprotein fractions lend further support to a role of lipid peroxidation in the diet-induced alterations in serum lipoprotein metabolism. Additional studies are needed in the hamster to investigate the extent to which fish oil consumption increase the requirement for antioxidant nutrients. Overall, the present studies indicate that the relationship between diet-induced oxidative stress and hyperlipidemia has been largely overlooked and is deserving of further study to fully evaluate its importance.

ACKNOWLEDGMENTS

Grant support from the National Sciences and Engineering Research Council of Canada (to S. Kubow) and the Dairy Farmers of Canada (to S. Kubow, S. Kermasha, K.G. Koski, and J.-S. Phillips) is gratefully acknowledged. The authors thank the excellent technical assistance of Susan Smith and Aghdas Zamani. The gift of MHO(L-CHOL) from the Fish Oil Biomedical Test Material Program of the National Marine Fisheries Service in Washington, D.C., is appreciated.

A Diet Containing Myristoleic Plus Palmitoleic Acids Elevates Plasma Cholesterol in Young Growing Swine

Dana R. Smith*, Darrell A. Knabe, H. Russell Cross, and Stephen B. Smith

Department of Animal Science, Texas A&M University, College Station, Texas 77843-2471

ABSTRACT: The objective of this study was to test the effect of a novel fatty acid mixture, enriched with myristoleic and palmitoleic acids, on plasma lipoprotein cholesterol concentrations. Weanling pigs were assigned to one of six groups and each group received a diet differing in fatty acid composition. Diets were fed for 35 days and contained 10 g added cornstarch/100 g (to provide baseline data) or 10 g added fatty acids/100 g. For those diets containing added fatty acids, extracted lipids contained 36% myristoleic plus palmitoleic acid combined (14:1/16:1 diet), 52% palmitic acid (16:0 diet), 51% stearic acid (18:0 diet), 47% oleic acid (18:1 diet), or 38% linoleic acid (18:2 diet). With the exception of the cornstarch diet, all diets contained approximately 30% myristic acid. There were no significant differences in weight gain across treatment groups ($P = 0.22$). All diets caused a significant increase in triglycerides and in total, low density lipoprotein, high density lipoprotein, and very low density lipoprotein cholesterol. The increase in total plasma cholesterol from pretreatment values was greatest in pigs fed the 14:1/16:1 and 18:1 diets. However, the increase in low density lipoprotein cholesterol from the pretreatment concentration was greatest in the 14:1/16:1-fed pigs. Increases in very low density lipoprotein cholesterol above pretreatment concentrations were lowest in 16:0-fed pigs and greatest in 18:1-fed pigs. Dietary fatty acids elicited changes in plasma fatty acids which generally were reflective of the diets, although the 18:0 diet did not alter plasma fatty acid concentrations and the 16:0 diet increased plasma 16:0 only at the end of the study. These results demonstrated that the combination of myristoleic plus palmitoleic acids increased plasma cholesterol in young pigs, suggesting that fatty acid chain length, rather than degree of unsaturation, is primarily responsible for the effects of fatty acids on circulating lipoprotein cholesterol concentrations. *Lipids 31*, 849–858 (1996).

In the United States, coronary heart disease is a leading cause of debilitating illness and death. Among several factors contributing to the increase in coronary heart disease, plasma lipid and lipoprotein cholesterol levels are the most highly correlated. The usefulness of these biochemical measures in predicting risk has been demonstrated by the findings of such epidemiological studies as the Framingham Heart Study (1). Dietary recommendations for reducing the risk of heart disease include those by the National Institutes of Health (2) and the National Cholesterol Education Program (3). Generally, the recommendations are for dietary fat to be limited to 30% of total energy or less and for saturated fatty acid intake to be limited to 10% or less of total energy.

Recommendations to reduce saturated fatty acid intake are based on research or epidemiological investigations comparing diets high in saturated, monounsaturated, or polyunsaturated fats (4). Typically, diets high in saturated fatty acids are enriched with lauric (12:0), myristic (14:0), or palmitic acid (16:0), whereas diets high in unsaturated fatty acids contain elevated concentrations of oleic (18:1), linoleic (18:2), or linolenic acid (18:3) (5,6). Thus, previous studies that addressed the effect of fatty acid saturation generally did not concurrently control fatty acid chain length.

More recent investigations have addressed the effects of fatty acid chain length (7–9). In nonhuman primates (7), a diet containing lauric plus myristic acids elicited greater concentrations of total and low density lipoprotein (LDL) cholesterol, and a similar effect was observed in humans fed diets enriched with either a synthetic high-lauric acid oil or palm oil (8). However, an investigation with piglets fed infant formulas (9) indicated that fatty acid positional distribution confounds the effects of fatty acid chain length on plasma cholesterol concentrations.

To our knowledge, no previous investigation has compared the effects of both chain length and degree of unsaturation on lipoprotein cholesterol concentrations. The current study takes advantage of the availability of a fatty acid mixture containing myristoleic acid combined with palmitoleic acid to compare the effects of shorter monounsaturated fatty acids (the myristoleic/palmitoleic acid mixture) to the more common 18-carbon oleic acid. Within this investigation, the effects of these monounsaturated fatty acids on lipoprotein cholesterol concentrations also were compared to the effects of the saturated fatty acids, palmitic and stearic acid, and the polyunsaturated fatty acid, linoleic acid.

Phosphorus	0.65	0.65
Energy density (kcal/100 g as fed)	391	441

[a]Diet exceeds all National Research Council requirements.
[b]Composition of the vitamin mix; retinyl palmitate, 2.3 mg/kg; cholecalciferol, 6.4 μg/kg; all-*rac*-α-tocopheryl acetate, 44 mg/kg; menadione sodium bisulfate, 2.8 mg/kg; riboflavin, 7.7 mg/kg; *d*-pantothenic acid, 30 mg/kg; niacin, 33 mg/kg; choline, 287 mg/kg; and cyanocobalamin, 44 μg/kg.
[c]Contributed the following mg per kg of diet: Cu, 10; Fe, 100; I, 0.3; Mn, 15; Zn, 100; Se, 0.3.
[d]Provided 55 mg carbodox/kg of diet.

were approved by the Texas A&M University Animal Care Committee.

Each treatment group contained seven pigs. The pigs were weaned at about 28 d of age. Weanling pigs were fed a sorghum-based diet containing neither added fat nor cornstarch for one week postweaning (Table 1) and then were allotted to one of six treatments groups. One of six littermates from each of seven sows was assigned to each diet group. Five groups received test diets containing 10 g added fatty acids/100 g (by wet weight); one group received the soybean meal diet containing corn starch substituted by weight for the added fatty acids. The cornstarch-fed group was included to provide baseline data, and to allow for the evaluation of production effects that were independent of dietary fatty acids.

Fatty acids or corn starch were mixed with the other dietary components weekly in a food mixer. The pigs were allowed free access to the food, and fresh water was available at all times. Diets were fed for 35 d, and pigs were weighed weekly.

The added fatty acids contained approximately 45% myristoleic plus palmitoleic acid combined, 95% palmitic, 95% stearic, 78% oleic, or 63% linoleic acid, as determined by fatty acid analysis in our laboratory (Table 2). Because the myristoleic/palmitoleic acid mixture also contained approximately 33% myristic acid, myristic acid (Sigma Chemical Co., St. Louis, MO) was added to all diets containing added fatty acids. The fatty acids were obtained from the Henkel Corporation (Cincinnati, OH). The myristoleic/palmitoleic

[a]Composition of fatty acid mixtures as received.
[b]Measurement not applicable.
[c]nd = Not detectable.
[d]Fatty acid composition of the total lipids of the diets (as fed). The baseline diet (with no added fat) was calculated to contain 2.5% lipids, whereas the other diets contained 12.5% (2.5% endogenous lipids plus 10% added lipids). Myristic acid was added to the 16:0, 18:0, 18:1, and 18:2 diets to equal the amount of 14:0 observed in the 14:1/16:1 diet (approximately 33%).

acid mixture (provided without charge) was Emery 889, a nonfood-grade fatty acid mixture. Palmitic, stearic, oleic, and linoleic acids were Emersol food grade fatty acids, 6343, 6353, 6321, and 315, respectively.

After mixing the fatty acids with the basal diet, the fatty acid composition of each diet was as indicated in Table 2. The enrichment of the diets containing added myristic acid was apparent. The cornstarch diet contained a high percentage of oleic and linoleic acids; however, because the cornstarch diet contained only 2.5% total lipid, the actual amounts of oleic and linoleic acid were less than 0.6 and 1.1 g/100 g diet, respectively. In contrast, the oleic and linoleic acid diets contained 5.7 g oleic acid/100 g diet and 4.6 g linoleic acid/100 g diet, respectively (calculated from the data in Tables 1 and 2). Although the fatty acid mixtures used to enrich the diets were not pure, only the primary fatty acids (and the added myristic acid) contributed significantly to the fatty acid composition of each diet.

Plasma sample collection. Blood samples were obtained by vena caval puncture 7 d prior to the feeding trial and at weeks 1, 3, and 5. This schedule allowed two-week intervals between sampling times. The animals were allowed access to food prior to the first sample and were deprived of food approximately 16 h prior to obtaining the subsequent blood samples. Samples were collected and added to tubes containing EDTA (50 g/L final concentration), and then centrifuged at 2,500 × *g* for 15 min to isolate the plasma.

Plasma analyses. Total cholesterol was quantified with Sigma Diagnostics cholesterol reagent, which measures cholesterol enzymatically and is a modification of the method of Allain *et al.* (10). Lipoprotein cholesterol concentration was measured utilizing the LipoPhor System (Quantimetrix, Hawthorne, CA). By this system, lipoproteins were separated according to their molecular size and shape by discontinuous gel electrophoresis on polyacrylamide gels. The plasma sample was applied to the polyacrylamide gel tube with a loading gel solution containing Sudan Black B, which binds proportionally to the relative amount of cholesterol in each lipoprotein fraction. After electrophoresis was completed, the percentage of each of the separated lipoproteins was quantified with a Beckman DU-7 spectrophotometer with scanning and integrating software (Beckman Instruments, Irvine, CA). The relative amounts of very low density lipoprotein (VLDL), high density lipoprotein (HDL), and LDL cholesterol were calculated by factoring the percentage of each fraction by the total cholesterol of the plasma sample. Scans of control human plasma supplied by the manufacturer and from the pigs indicated nearly identical rates of migration of each lipoprotein cholesterol fraction (data not shown). In the human plasma samples, LDL cholesterol accounted for 52% of the total cholesterol, whereas in the porcine sample LDL cholesterol accounted for less than 40% of the total cholesterol, and HDL cholesterol was the predominant cholesterol fraction.

Quantitative triglyceride determination of 10 μL plasma utilized a modified procedure by Bucolo and David (11) and employed a triglyceride reagent (Sigma Chemical Co.). Briefly, triglycerides were hydrolyzed by microbial lipoprotein lipase. The liberated glycerol was converted to glycerol-3-phosphate by glycerol kinase and was subsequently oxidized to dihydroxyacetone phosphate by glycerol-3-phosphate dehydrogenase. The resulting NADH + H^+ reduces 2-(*p*-iodophenyl)-3-*p*-nitrophenyl-5-phenyltetrazolium chloride to formazan in the presence of microbial diaphorase. Formazan has an absorbance at 500 nm, and the reaction is linear for the range of triglycerides observed in plasma.

Fatty acid analysis. Fatty acid composition of 5 mL plasma from weeks 1 and 5 was measured by gas–liquid chromatography. Samples of the dietary fats (100 mg) and the actual diets (5 g) also were analyzed for fatty acid composition. The diet samples were obtained weekly, pooled within treatment, and subsampled for fat extraction. Lipid extraction was according to Folch *et al.* (12), and the extracted lipids were methylated by the Morrison and Smith (13) procedure, except that boron triflouride was increased to 7.2 g/sample. Subsequently, the fatty acid methyl esters were analyzed using a Packard Chrompack gas chromatograph (Model 437a; Chrompack Inc., Claritan, NJ) with a stainless steel column (3 mm × 10 m) packed with Chromasorb W-Aw 80/100. Injector and detector temperatures were 225 and 215°C, respectively. Oven temperature was 180°C initially. After 8 min (following the appearance of methyl palmitoleate), the oven temperature was increased by 10°C/min to a final temperature of 210°C. The flow rate of the carrier gas, nitrogen, was 22 mL/min. To each sample, 5 mg of an internal standard (methyl laurate) were added immediately prior to injection. A mixture of 20 mg each of trimyristin, tripalmitin, tristearin, and triarachidin was extracted, saponified, and methylated to calculate lipid recovery during the extraction process (approximately 80%). Another standard of known composition was run to verify the identity of the fatty acids in the samples. Fatty acid peaks determined by gas chromatography were then used to calculate the amount of fatty acids (mmol/L) according to the calculations described by Slover and Lanza (14).

Statistical analyses. For animal weights, differences from the initial values (7 d prior to the feeding trial) were calculated, and the data were analyzed using the general linear models procedure of the Statistical Analysis System (15). The model included diet, time, diet × time, and animal within diet.

Plasma measurements also were analyzed by the general linear models procedure (14) in two manners. Plasma values for pigs fed added fatty acids were compared to respective values from the cornstarch-fed group. Also, mean differences from initial (pretreatment) values over the course of the study were calculated within each treatment group, and the mean differences were compared across treatment groups. The model for both analyses included diet, time, diet × time, and animal within diet. Means were separated with Scheffe's multiple-comparisons test using a predetermined significance of $P < 0.05$ for all comparisons.

RESULTS

Animal growth. There were no significant differences across treatment groups in weight gain ($P = 0.22$) (Fig. 1A); average daily gains generally increased throughout the study (data not shown in tabular format). Because feed intake was based on pen averages, it was not possible to analyze this measure statistically. Average daily intake was low initially, and increased progressively until week 4 (Fig. 1B). The low rate of gain and intake during the first week of the study may have been caused by the young age at which these animals received dietary treatments (one week postweaning). Aversion to the diets was not apparent because intakes were similar in all treatment groups, particularly during the first four weeks of the study. By week 4, average daily intake appeared to decline in several groups, including the cornstarch-fed group (Fig. 1B). This experiment terminated on July 31, and the apparent decline in average daily intake may have been in response to the elevated ambient temperature.

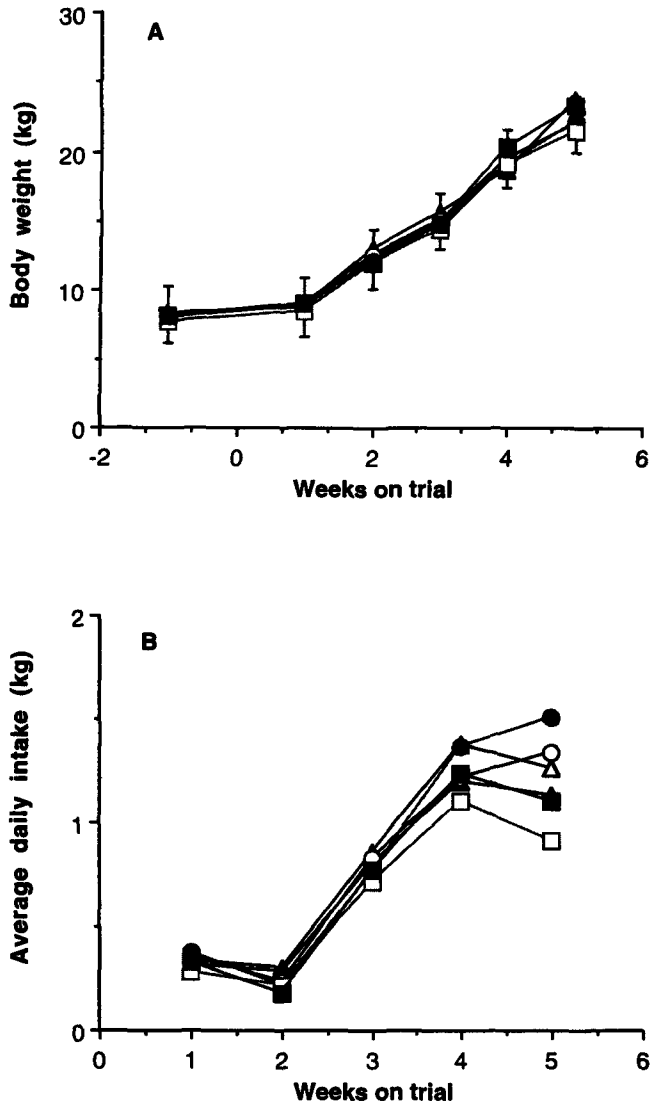

FIG. 1. Body weights and average daily feed intake of pigs fed diets varying in specific fatty acids. A, Body weight; B, average daily intake. Each data point represents a pen average for seven animals per pen. △, Cornstarch diet; ▲, 14:1/16:1 diet; ○, 16:0 diet; ●, 18:0 diet; □, 18:1 diet; ■, 18:2 diet.

Plasma cholesterol fractions and triglycerides. Plasma cholesterol concentrations were comparable to those reported by others for piglets and growing pigs (9,16,17), and HDL cholesterol constituted approximately 50% of total cholesterol (Fig. 2). In the cornstarch-fed pigs, average total cholesterol (2.78 mmol/L) was approximately one-half the value observed in humans (6,8,18) and nonhuman primates (5,7).

After one week of treatment, total cholesterol had risen in all groups, including the cornstarch-fed group (Fig. 2A). There was a signficant diet × time interaction for total ($P = 0.003$), LDL ($P = 0.006$), and HDL ($P = 0.04$) cholesterol concentrations, indicating that the changes with time varied among treatment groups. The pigs receiving the added myristoleic plus palmitoleic acid had the highest plasma total cholesterol throughout the study. At weeks 1 and 3, plasma cholesterol also was significantly elevated in pigs fed the added oleic acid, and at week 3, total cholesterol was elevated in pigs fed the linoleic acid diet. Total cholesterol declined markedly between weeks 3 and 5; this same pattern was observed in all cholesterol fractions (Fig. 2).

The LDL cholesterol concentrations for all groups were the same initially and followed the same general pattern as total cholesterol throughout the study (Fig. 2B). Throughout the study, LDL cholesterol concentrations were higher in pigs fed the myristoleic/palmitoleic acid diet than in the cornstarch-fed pigs. Diets containing oleic acid (weeks 1 and 3) and linoleic acid (week 3) also caused elevated LDL cholesterol concentrations (Fig. 2B). An identical pattern was observed for HDL cholesterol (Fig. 2C). There was not a significant diet × interaction for plasma concentrations of VLDL cholesterol (Fig. 2D). Lipoprotein cholesterol concentrations in pigs fed the palmitic or stearic acid-enriched diets were not affected by the inclusion of fatty acids in the diets. Plasma triglycerides also were unaffected by dietary fatty acids (Fig. 2E).

Overall means for differences from initial (pretreatment) concentrations for each of the cholesterol fractions (pooled across time) are listed in Table 3. There was a significant diet effect for total, LDL, and VLDL cholesterol. Total and LDL cholesterol differences from initial values were greatest in pigs fed the myristoleic/palmitoleic acid diet, whereas VLDL cholesterol was greatest in the oleic acid-fed pigs. Pigs fed stearic acid exhibited the lowest plasma total, LDL, and HDL cholesterol concentrations.

Plasma fatty acid composition. The groups receiving fatty acid-enriched diets exhibited markedly higher plasma myristic acid relative to the cornstarch-fed group (Fig. 3A), reflecting the addition of myristic acid to these diets. Plasma myristoleic (Fig. 3B) and palmitoleic acid (Fig. 3D) increased ($P <$ 0.0005) in pigs fed the myristoleic plus palmitoleic acid-en-

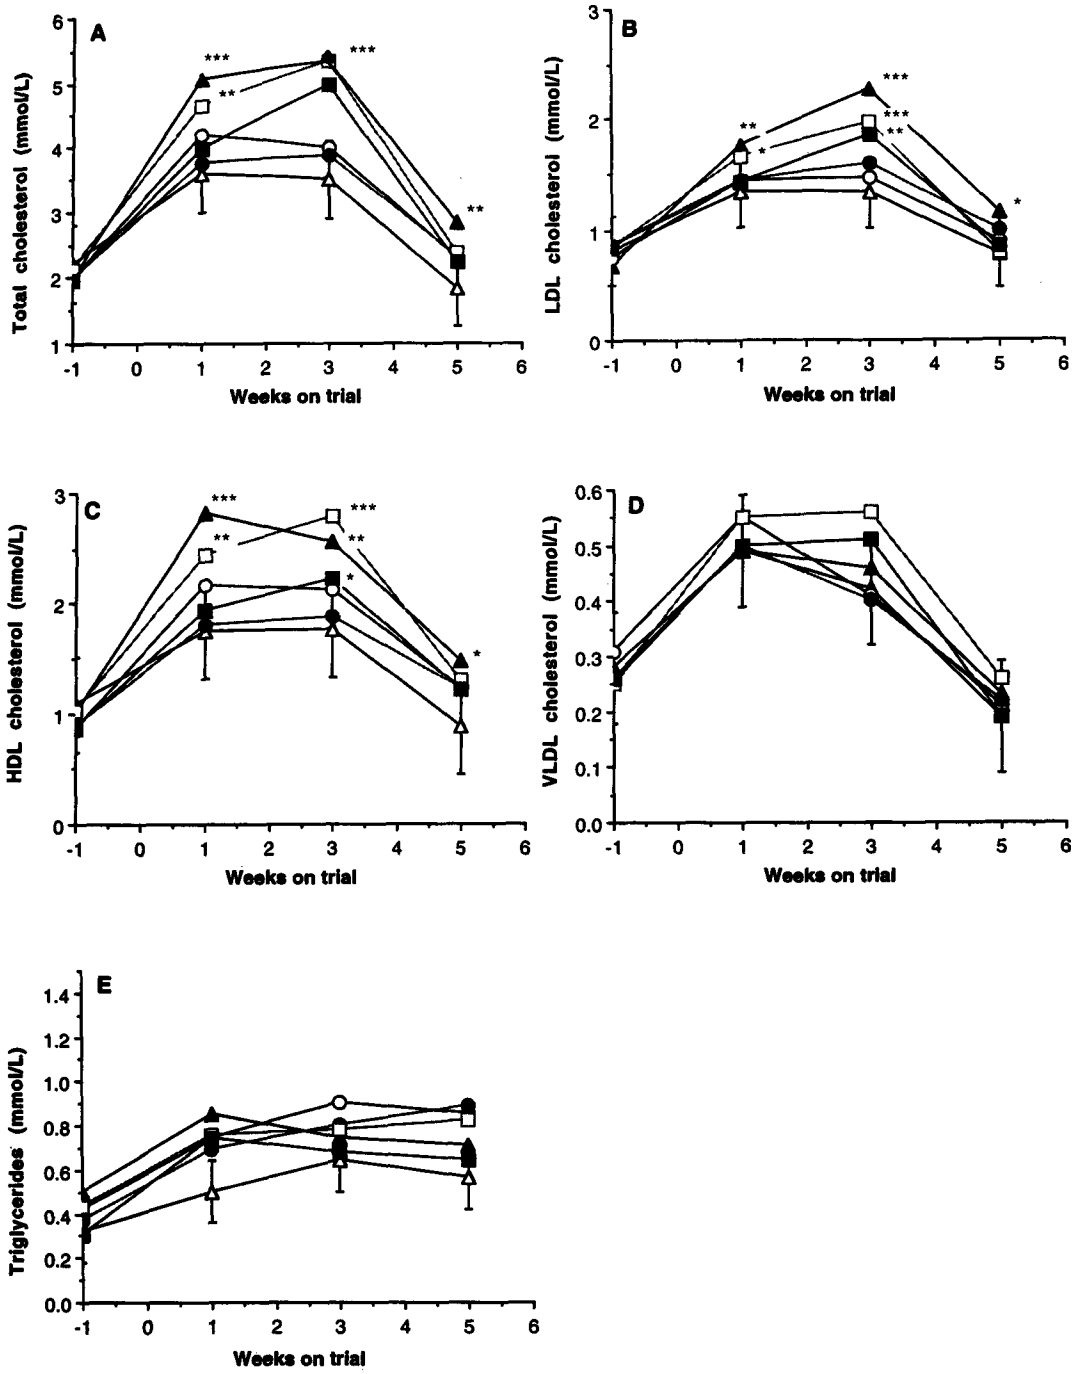

FIG. 2. Plasma lipoprotein cholesterol and triglyceride concentrations in pigs fed diets varying in specific fatty acids. Each data point is the mean for seven animals per treatment group. The vertical bars affixed to the points for the cornstarch-fed group represent the pooled standard deviation. A, Total cholesterol; B, low density lipoprotein (LDL) cholesterol; C, high density lipoprotein (HDL) cholesterol; D, very low density lipoprotein (VLDL) cholesterol; E, triglycerides. $^{*}P < 0.05$; $^{**}P < 0.005$; $^{***}P < 0.0005$. Each data point represents a pen average for seven animals per pen. △, Cornstarch diet; ▲, 14:1/16:1 diet; ○, 16:0 diet; ●, 18:0 diet; □, 18:1 diet; ■, 18:2 diet.

riched diet. By week 5, pigs fed added palmitic acid exhibited elevated plasma palmitic acid (Fig. 3C).

Plasma stearic acid increased with time in all groups, but was unaffected by diet (Fig. 4A). None of the treatment groups exhibited greater plasma oleic acid than the cornstarch-fed group (Fig. 4B). By week 5, plasma linoleic acid was elevated in all treatment groups except those fed added stearic acid, relative to the cornstarch-fed group (Fig. 4C). In pigs fed the linoleic acid diet, plasma linoleic acid was elevated relative to the cornstarch-fed group by week 1. Neither

[a]Data are least square means for each set of seven pigs, pooled across all measurement time periods. Abbreviations: LDL, low density lipoprotein; HDL, high density lipoprotein; VLDL, very low density lipoprotein; D, significant diet effect ($P < 0.05$); T, significant time effect; D × T, significant diet × time interaction, as determined by analysis of variance. When analysis of variance indicated a significant diet effect, means were separated by Scheffe's multiple comparison test. Means in a row without a common superscript are different ($P < 0.05$).

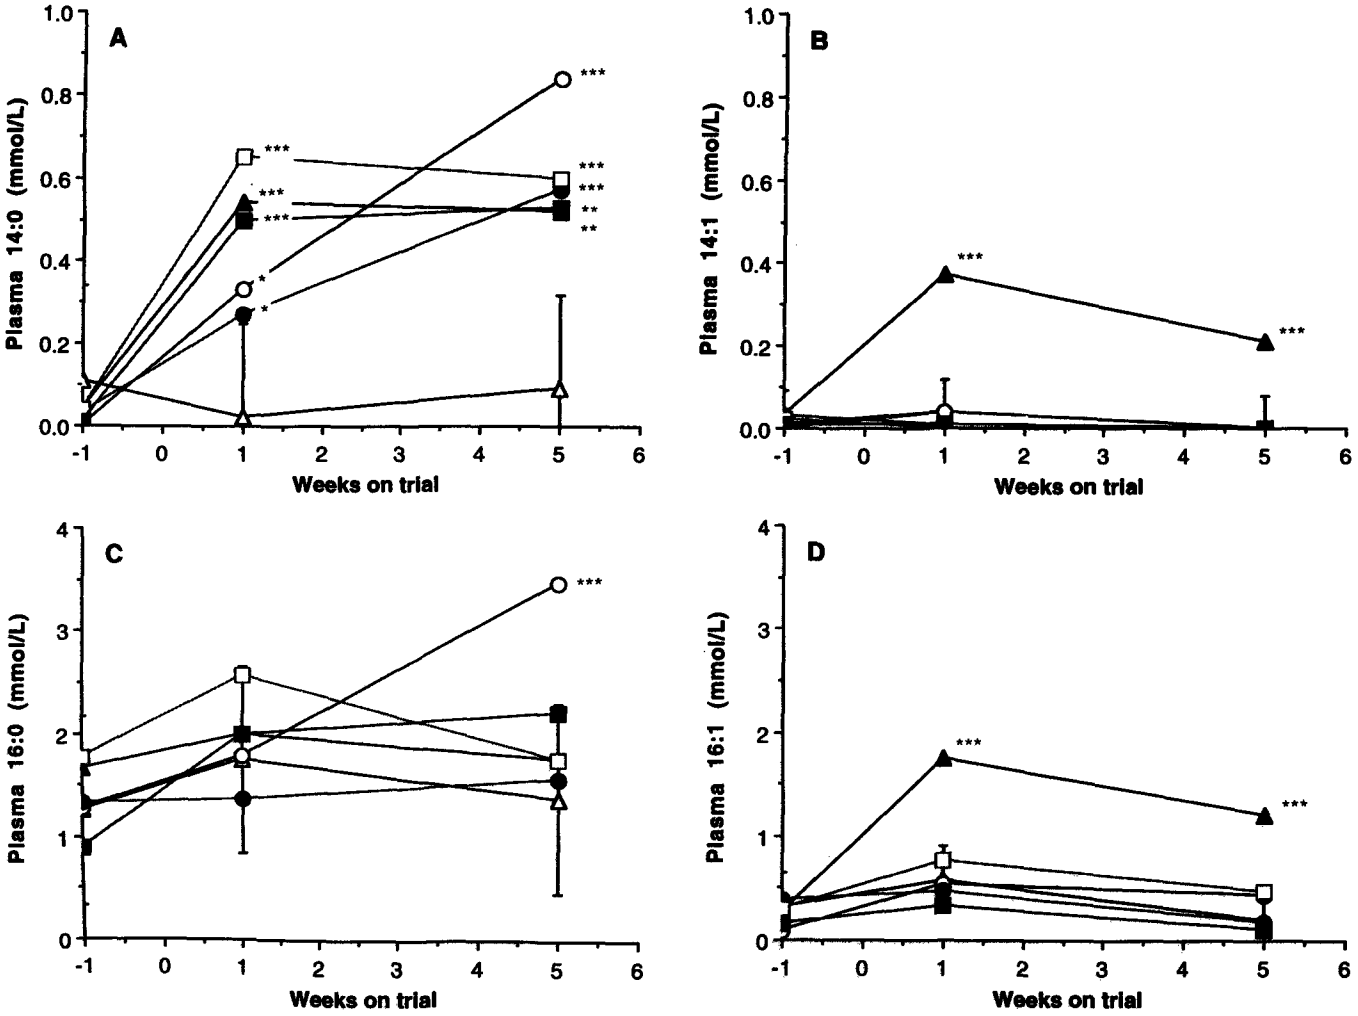

FIG. 3. Plasma 14- and 16-carbon fatty acid concentrations in pigs fed diets varying in specific fatty acids. Each data point is the mean for seven animals per treatment group. The vertical bars affixed to the points for the cornstarch-fed group represent the pooled standard deviation. A, Plasma myristic acid; B, plasma myristoleic acid; C, plasma palmitic acid; D, plasma palmitoleic acid. $*P < 0.05$; $**P < 0.005$; $***P < 0.0005$. Each data point represents a pen average for seven animals per pen. △, Cornstarch diet; ▲, 14:1/16:1 diet; ○, 16:0 diet; ●, 18:0 diet; □, 18:1 diet; ■, 18:2 diet.

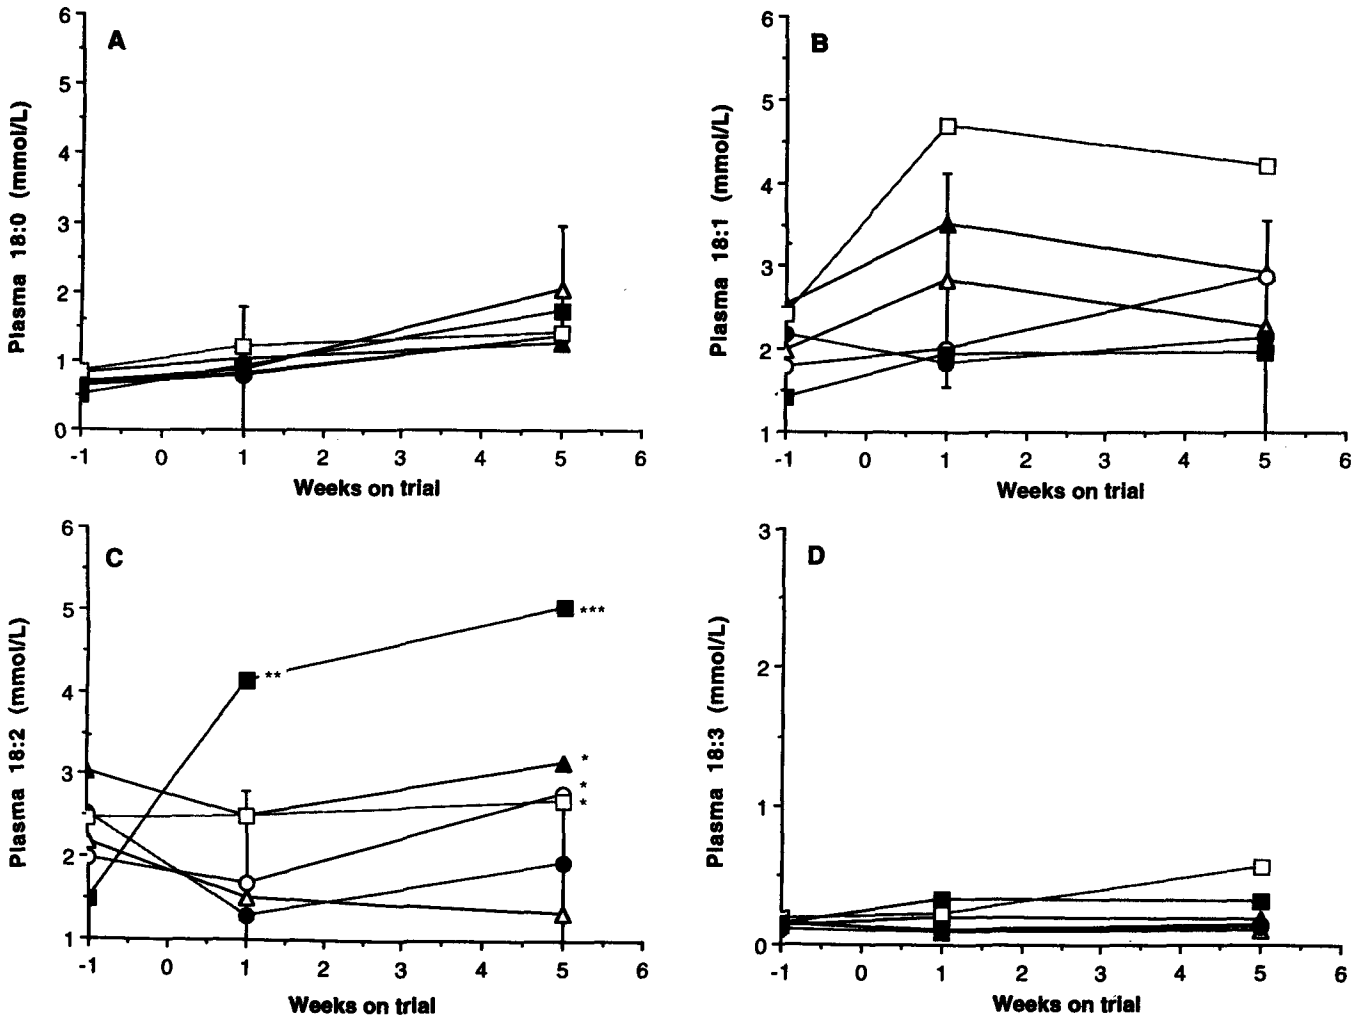

FIG. 4. Plasma 18-carbon fatty acid concentrations in pigs fed diets varying in specific fatty acids. Each data point is the mean for seven animals per treatment group. The vertical bars affixed to the points for the cornstarch-fed group represent the pooled standard deviation. A, Plasma stearic acid; B, plasma oleic acid; C, plasma linoleic acid; D, plasma linolenic acid. $^{*}P < 0.05$; $^{**}P < 0.005$; $^{***}P < 0.0005$. Each data point represents a pen average for seven animals per pen. △, Cornstarch diet; ▲, 14:1/16:1 diet; ○, 16:0 diet; ●, 18:0 diet; □, 18:1 diet; ■, 18:2 diet.

plasma linolenic (Fig. 4D) nor arachidonic acid (data not shown) was affected by dietary treatment or time.

Overall means for differences from initial (pretreatment) concentrations for each of the plasma fatty acids (pooled across time) are listed in Table 4. Plasma myristic acid increased an average of approximately 0.25 mmol/L in those pigs fed diets containing added fatty acids; this represented a fivefold increase from initial values in plasma myristic acid. The marked increases in plasma myristoleic and palmitoleic acid (Figs. 3B and 3D) in pigs fed the myristoleic plus palmitoleic acid-enriched diet were evident in the mean changes from initial values (Table 4). It is unusual in that the palmitic acid and linoleic acid-enriched diets caused similar mean increases in plasma palmitic acid concentrations (approximately 0.8 mmol/L).

As indicated in Figure 4A, plasma stearic acid increased with time, but there was neither a diet effect ($P = 0.76$) nor a diet × time interaction ($P = 0.96$). Plasma oleic acid increased with time in several of the treatment groups (Fig. 3B), so the diet × time interaction was not significant ($P = 0.50$). However, the greatest mean increase from initial concentrations in plasma oleic acid was elicited by the oleic acid-enriched diet (Table 4). The largest increase from initial values for any plasma fatty acid was observed for plasma linoleic acid (2 mmol/L) in pigs fed diets enriched with this fatty acid. In the stearic acid-fed pigs, the plasma linoleic acid concentrations declined with time. Plasma linolenic and arachidonic acids were affected by neither diet nor time (Table 4).

DISCUSSION

Studies of the cardiovascular system of swine and the characteristics of their lipoproteins have established the pig as a model for the investigation of metabolic diseases in humans. High-fat and/or high-cholesterol diets in swine induce atherosclerosis (19,20). Swine, like humans, have a genetically di-

TABLE 4
Overall Means for Differences from Initial Values for Plasma Fatty Acid Concentrations (mmol/L) in Pigs Fed Diets Varying in Specific Fatty Acids[a]

	Diet group

[a]Data are least square means for each set of seven pigs, pooled across all measurement time periods. Abbreviations as in Table 3. When analysis of variance indicated a significant diet effect, means were separated by Scheffe's multiple comparison test. Means in a row without a common superscript are different ($P < 0.05$).

verse propensity within their species to develop atherosclerosis, which has made possible many investigations of the interaction between nutrition and genetic background in the etiology of cardiovascular disease (21). One limitation of swine is that HDL cholesterol constitutes 50% or more of their total cholesterol (Fig. 2; Ref. 22). However, because both humans and swine have similar anatomy of the coronary arterial system and similar LDL receptors on liver membranes, and because both display a high correlation between aortic cholesterol and serum LDL-cholesterol levels (21), swine are considered useful models for the study of human cardiovascular disease. With this in mind, this investigation sought to document the effects of a diet enriched with 14- and 16-carbon monounsaturated fatty acids on lipoprotein cholesterol concentrations in young swine. The ultimate goal was to clarify the relative importance of fatty acid chain length and unsaturation in determining the effects of fatty acids on serum cholesterol in humans.

The marked elevation, and subsequent decline by week 5, in cholesterol fractions in all groups (including the cornstarch-fed group) was unexpected. In a previous study (22), mature pigs were fed diets containing high oleic acid (80%) sunflower oil or beef tallow at a level of 10% of the diet by weight. Plasma total cholesterol rose during the first four weeks (from 1.4 to 2.7 mmol/L in both groups). However, after eight weeks, plasma cholesterol had declined only marginally in the mature pigs (to 2.4 mmol/L), unlike the large decline observed in the young pigs of the present study. Food intake declined in all but the stearic acid-fed group during the last week of this investigation, which may have been responsible for the reduction in plasma cholesterol concentrations.

In spite of an apparent lack of a steady state during the course of this investigation, there was a consistent response of LDL cholesterol to the diet containing myristoleic plus palmitoleic acids. Reiser (23) asserted that the hypercholesterolemic effect of fatty acids was in part due to relative absorption of fatty acids, rather than degree of unsaturation. Correspondingly, plasma concentrations of myristoleic and palmitoleic acids were elevated markedly in pigs fed the diet enriched with these fatty acids. These data are insufficient to indicate relative absorption of the various dietary fatty acids. However, adding myristoleic and palmitoleic acids to the diet profoundly increased the availability of those fatty acids in plasma.

Previous research demonstrated that oils containing myristic acid increased plasma total cholesterol (24,25). The inclusion of myristic acid in the fatty acid-enriched diets increased plasma myristic acid to over 0.5 mmol/L by the end of the current study, which may have contributed to the hypercholesterolemic effects of the myristoleic/palmitoleic acid diet.

One primary objective of this investigation was to compare the effects of an 18-carbon monounsaturated fatty acid (i.e., oleic acid) to the effects of shorter chain monounsaturated fatty acids on cholesterol concentrations. In humans, enriching diets with oleic acid results in lower total cholesterol than diets enriched with saturated fatty acids (17,26–28); the same has been observed in nonhuman primates (5). Oleic acid-enriched diets do not decrease LDL cholesterol in rats; nor do they affect HDL cholesterol (29). In the current investigation, the oleic acid-enriched diet increased total cholesterol from pretreatment values nearly to the extent of the myristoleic/ palmitoleic acid-enriched diet. However, the primary effect of the oleic acid-enriched diet was to increase the concentration of VLDL (and to some extent HDL) cholesterol whereas, as stated previously, the myristoleic/palmitoleic acid diet increased both HDL and LDL cholesterol.

There are several mechanisms by which the myristoleic plus palmitoleic acid-enriched diet could have increased LDL cholesterol. Oleic acid stimulates rat hepatic cholesterol synthesis by activating hydroxy-methylglutaryl–CoA reductase (30), and other monounsaturated fatty acids may have the same effect. In guinea pigs, oleic acid slows LDL turnover by altering LDL composition (31), and the shorter chain monounsaturated fatty acids may have increased the concentration of LDL cholesterol by this mechanism.

Saturated fatty acids have been shown to block LDL cholesterol receptors (32,33), due primarily to impaired LDL re-

ceptor-mediated catabolism (34). It is unlikely that the myristoleic/palmitoleic-enriched diet worked *via* this mechanism, because neither added myrisitic acid nor palmitic acid increased LDL-cholesterol. Replacing dietary lauric and myristic acids with palmitic acid decreased total and LDL cholesterol in nonhuman primates, and concurrently decreased the apo B/apo A-I ratio (7). The myristoleic/palmitoleic-enriched diet may have increased total and LDL cholesterol in pigs *via* increased apo B production.

Another specific objective of this investigation was to demonstrate that 14- to 16-carbon fatty acids are hypercholesterolemic, whereas 18-carbon fatty acids are hypocholesterolemic, regardless of the degree of unsaturation. However, cholesterol concentrations in pigs fed diets enriched with either palmitic or stearic acid were not different; nor were they different from cholesterol concentrations in pigs fed linoleic acid.

The design of this experiment did not allow statistical comparison of food intake; however, average daily intake by week 5 was greatest in pigs fed diets enriched with stearic acid. Thus, feeding saturated fatty acids, particularly stearic acid, as free fatty acids may have resulted in poor absorption. Although Bonanome and Grundy (26) provided evidence for absorption of dietary stearic acid in humans, Ockner *et al.* (35) demonstrated that dietary saturated fatty acids, once released from triacylglycerols, are absorbed more slowly than unsaturated fatty acids. This has been confirmed by several recent investigations. Monsma and May (36), Renaud *et al.* (37), and Brink *et al.* (38) indicated that stearic acid in the *sn*-1,3 positions of dietary triacylglycerols is poorly absorbed, particularly in the presence of elevated dietary calcium (38). A recent study in piglets (9) indicated that this also applies to palmitic acid in the *sn*-1,3 position.

Our data suggest that dietary palmitic acid was absorbed more effectively than was dietary stearic acid: the plasma palmitic acid concentration (and increase from pretreatment levels) was greatest in pigs fed the palmitic acid-enriched diet; and, like all other dietary fatty acids except stearic acid, the palmitic acid diet increased HDL cholesterol. The lack of effect a significant effect of the stearic acid-enriched diet on any of the cholesterol fractions is taken as further evidence for poor absorption of dietary stearic acid in this study.

We also had predicted that the diet high in stearic acid would increase the plasma concentration of oleic acid. Bonanome and Grundy (39) suggested that absorbed stearic acid would be desaturated to form oleic acid. Stearoyl-CoA desaturase is active in porcine liver, adipose tissue, muscle, and intestinal mucosa (22), so the potential for desaturation exists at several porcine tissue sites. However, plasma oleic acid was not elevated in pigs fed the stearic acid-enriched diet in the present study; nor is dietary stearic acid readily interconverted to oleic acid in rat liver (36).

Unlike the diets containing saturated fatty acids, the linoleic acid-enriched diet elicited consistent and predictable results. The overall changes in total and LDL cholesterol were low, especially when compared to the increase elicited by the myristoleic/palmitoleic-enriched diet. Thus, for those diets enriched with unsaturated fatty acids, we observed three distinct responses: the myristoleic/palmitoleic acid diet caused marked elevations in LDL cholesterol; the oleic acid diet caused the greatest increase in VLDL cholesterol; and the linoleic acid diet increased neither. The singularly hypercholesterolemic nature of the myristoleic/palmitoleic acid diet leads us to conclude that fatty acid chain length, rather than degree of unsaturation, is responsible for the effects of dietary fatty acids on the plasma concentration of LDL cholesterol in young swine. Total and LDL cholesterol were much higher in pigs fed the myristoleic/palmitoleic diet and in those fed the 16-carbon, palmitic acid-enriched diet, which suggests that myristoleic acid was more hypercholesterolemic than the 16-carbon palmitoleic acid. Similar studies in humans await the availability of a food-grade source of myristoleic and palmitoleic acids.

Fatty Acid Composition of Late Embryonic and Early Postnatal Rat Brain

Pnina Green and Ephraim Yavin*

Department of Neurobiology, The Weizmann Institute of Science, 76100 Rehovot, Israel

ABSTRACT: The fatty acid (FA) composition and distribution in a variety of phospholipids (PL) and neutral lipids (NL) at two discrete stages during the embryonic rat brain development were investigated. Over 96% of the FA were acylated into fetal brain PL at embryonic day 17 after the peak of neuronal proliferation and at embryonic day 20, one day prior to delivery. Phosphatidylcholine constituted approximately 60% of the total PL pool, phosphatidylethanolamine (PE) 30%, phosphatidylserine (PS) 6%, and phosphatidylinositol (PI) 4%. The diacylglycerols and triacylglycerols constituted 1–2% of the fetal brain lipids. α-Linolenic acid (18:3n-3) and linoleic acid (18:2n-6) were found in very low amounts in all fetal brain PL and NL. The percentage of the n-6 polyunsaturated FA, consisting of arachidonic acid (AA), 22:4n-6 and 22:5n-6, remained unchanged in all the fractions, except in PI, in which the proportion of AA increased. The concentration of docosahexaenoic acid (DHA) increased with age in all the fractions, with the bulk of accumulation accounted for by its increase in PE and, to a lesser extent, in PS. This finding suggests a "DHA accretion spurt" during the last three days of pregnancy.

Lipids 31, 859–865 (1996).

Docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) are the major polyunsaturated fatty acids (PUFA) in the adult mammalian brain (1,2), and can be locally synthesized from their corresponding dietary precursors, α-linolenic acid (LNA, 18:3n-3) and linoleic acid (LA, 18:2n-6), respectively (3,4).

In a recent publication we have shown that the prenatal rat brain is also able to convert both LNA and LA into the higher long-chain polyunsaturated homologs (5). In the course of this study, it became apparent that only scant information exists on the fatty acid (FA) composition of the rat brain during the prenatal life. Sinclair and Crawford (6) studied the FA composition of the total brain in mid-term fetal and newborn rats, and Cunnane and Chen (7,8) performed a quantitative analysis of the FA composition of phosphatidylcholine (PC), phosphatidylethanolamine (PE), and triacylglycerols (TG) in the postnatal, but not prenatal, rat brain. More recently, a detailed description of the FA composition of PC and PE in the prenatal guinea pig brain has been documented (9,10). There is practically no knowledge concerning the FA composition of the less abundant brain lipids, i.e., phosphatidylinositol (PI), phosphatidylserine (PS), or neutral lipids (NL), such as diacylglycerols (DG) and TG. Several of these quantitatively minor lipid fractions now have well established roles in cell function and signal transduction (11–13).

The present study was undertaken in order to provide detailed information on the FA composition of most abundant lipid fractions of the fetal rat brain at 17 and 20 d of gestation. The first time point selected represents the stage of cessation of neuronal proliferation, and the second time point reflects the FA status prior to delivery. The data obtained were compared to the FA composition of the lactating (postnatal day 8, P8) rat brain. The data herein suggest that during the late intrauterine life a major accumulation of brain DHA occurs, mainly in PE and PS lipids.

EXPERIMENTAL PROCEDURES

Animals and surgery. Pregnant Wistar (250–300 g body weight) rats (WIS Animal Breeding Center, Rehovot, Israel) were fed *ad libitum* chow containing 5 g lipid/100 g with the following FA composition: 13% 16:0, 4% 18:0, 24% 18:1, and 52% 18:2n-6, and 5% 18:3n-3. At days 17 and 20 of gestation (E17 and E20), dams were anesthetized by intramuscular injection of 50 mg ketamine (Parke Davis, Pontypool, Wales, United Kingdom) and 7 mg xylizine HCl (Bayer, Leverkusen, Germany) per kg body weight (0.2 mL/300 g body weight of a 1:1 mixture of 2% xylizine HCl-Rompun and 0.1 g/mL ketamine). An abdominal midline incision was performed, the two uterine horns were exposed, and the fetal brains were immediately placed in liquid nitrogen upon removal. The time elapsed between the incision of the fetal neck in preparation for brain removal (and thus causing fetal death), and the placement of the brain into liquid nitrogen was never more than 10 s. Similarly, approximately 200-mg portions of P8 rat brains also were removed.

Lipid extraction and analysis. After weighing, the brains were homogenized in 2 mL hexane/isopropanol (3:2, vol/vol) containing 5% butylated hydroxytoluene, using a Polytron ho-

mogenizer (Kinematica, Luzern, Switzerland), according to Hara and Radin (14). A known amount of the internal standard heneicosanoic acid (21:0) was added to each sample before homogenization in order to quantitate the total brain FA content. The organic layer containing the lipid extract was separated from the residual tissue by low-speed centrifugation.

Nonpolar and polar lipids were separated by thin-layer chromatography on washed and preactivated silica gel G plates (Merck, Darmstadt, Germany). The solvent system used to separate DG and TG from free FA consisted of a freshly prepared mixture of hexane/ether/acetic acid (40:60:2.3, by vol) (15). Standard lipid mixtures (Sigma Chemical Co., St. Louis, MO) were run for identification of spots. The major phospholipids (PL)—PC, PE, PI, and PS—were separated by a mixture of chloroform/methanol/methylamine (40%) (130:70:30, by vol) (16). All the solvents were of high-performance liquid chromatographic grade.

Lipid spots resolved on thin-layer chromatography using the solvent mixture hexane/ether/acetic acid (40:60:2.3, by vol) were visualized under ultraviolet light after spraying with 0.2% dichlorofluorescein in ethanol. Individual spots were identified and scraped into glass tubes to which known amounts of heneicosanoic acid were added. Each sample was transmethylated, and total FA was quantitated based on the internal standard as described previously (17). The sum of TG, DG, free FA, and PL (the latter resided at the origin) accounted virtually for all the FA content present in the extract. The percentage weight of FA in each individual fraction was estimated, and the results are means ±1 SE in each individual fraction. Determinations were done on six E17 samples (each sample of three pooled brains), seven E20 samples (each sample of two pooled brains), and four P8 brains.

FA accretion rates were calculated as follows: for the intrauterine period up to E17, the brain FA content at E17 was divided by 17; for the next 3 d of fetal life, the difference between the FA content at E20 and E17 was divided by 3; finally, the difference between the FA content at P8 and E20 divided by 9 resulted in the accretion rate of the FA during the early postnatal period. Lipid phosphorus was determined according to Bartlett (18).

Statistical analysis. Analysis of the data was performed by the general linear model provided by the statistical analysis system for analysis of variance with repeated measures, nested design, where fetuses were nested within mothers. Specific differences between the developmental stages were determined by Tukey's procedure, with the α level set at 0.05. Values of various developmental periods designated by the same letters were not significantly different.

RESULTS

The changes in the brain weight and brain total FA content from E17 through E20 and up to P8 are depicted in Figure 1. Most of the increase in brain weight during this period was from day E20 to P8, but FA accumulation was maximal before birth.

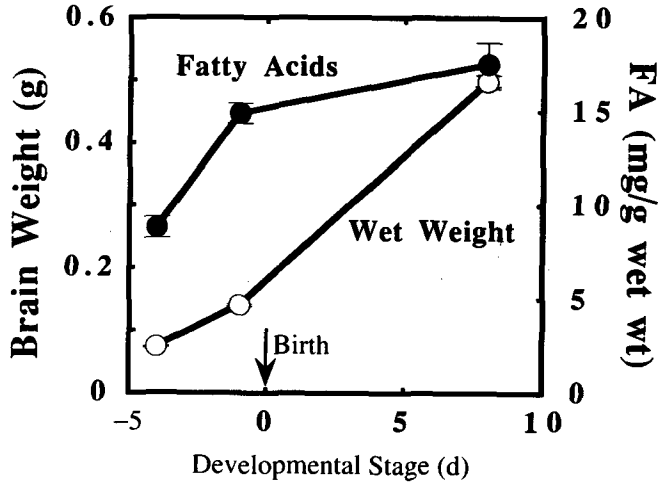

FIG. 1. Changes in the brain weight and total fatty acid (FA) content. Total brain weight (○) and brain FA concentration (●) during development. Values of brain weight are means ± SE of 69, 58, and 18 brains from embryonic day 17 (E17), embryonic day 20 (E20), and postnatal day 8 (P8) animals, respectively. FA concentrations are means ± SE of 12 E17 samples (each sample of three pooled brains), 10 E20 samples (each sample of two pooled brains), and 16 P8 brains.

The majority (96%) of the brain FA was associated with the PL pool (Table 1). The NL pool, consisting mainly of DG, TG, and free FA, accounted for the remaining 4% of the total brain FA. No differences were observed in the relative size of either pool during the developmental time points examined. Within the PL pool, PC and PE were the major fractions, constituting approximately 60 and 30% of total PL, respectively. PS and PI comprised approximately 6 and 4% of total PL, respectively.

The FA composition of the total brain lipids is shown in Table 2. The proportion of the saturated FA and the n-6 PUFA remained relatively constant. The percentage of the monounsaturated FA decreased by nearly 35% between E17 and P8. This decrease was accounted for by decreases in both 16:1 and 18:1. The n-3 PUFA almost doubled during this period, with most of the increase accounted for by changes in the amount of DHA.

The average daily accretion rates calculated for the major FA are depicted in Figure 2. On a semilog scale, DHA was

TABLE 1
Major Fatty Acids (FA) Containing Lipid Pools During Perinatal Stages of the Rat Brain[a]

Lipid	Weight percentage of FA		
	E17	E20	P8
Phospholipid	96.23 ± 0.87	96.16 ± 0.57	95.68 ± 0.47
Diacylglycerol	1.22 ± 0.36	0.87 ± 0.12	1.83 ± 0.10
Triacylglycerol	1.80 ± 0.14	1.91 ± 0.44	1.53 ± 0.50
Free FA	0.73 ± 0.46	1.06 ± 0.17	0.98 ± 0.09

[a]Results are means ± SE of the percentage of the fraction, determined by the weight of the FA in each as described in the Materials and Methods section. Determinations were done on six E17 (embryonic day 17) samples (each sample of three pooled brains), seven E20 (embryonic day 20) samples (each sample of two pooled brains), and four P8 (postnatal day 8) brains.

[a]Results are mean weight % ± SE of FA from six E17 samples (each sample of three pooled brains), eight E20 samples (each sample of two pooled brains), and five P8 brains. DMA, dimethylacetal; Σ Sat, sum of saturated FA (14:0, 16:0, and 18:0); Σ MUFA, sum of monounsaturated FA (MUFA) (16:1 and 18:1); Σ n-6 PUFA, sum of the n-6 family of polyunsaturated FA (PUFA) (18:2, 20:3, 20:4, 22:4, and 22:5); Σ n-3 PUFA, sum of the n-3 family of PUFA (18:3, 22:5, and 22:6). Values not bearing the same superscript (b–d) are significantly different. Abbreviations as in Table 1.

the most pronounced PUFA to accumulate prior to birth. The average daily accumulation rate of DHA increased almost fivefold between E17 and E20 (from 39 μg/g/d to 187 μg/g/d), whereas that of AA increased only 1.3-fold (from 85 μg/g/d at E17 to 113 μg/g/d at E20). After birth, the daily acquisition rate of DHA decreased while that of AA remained constant.

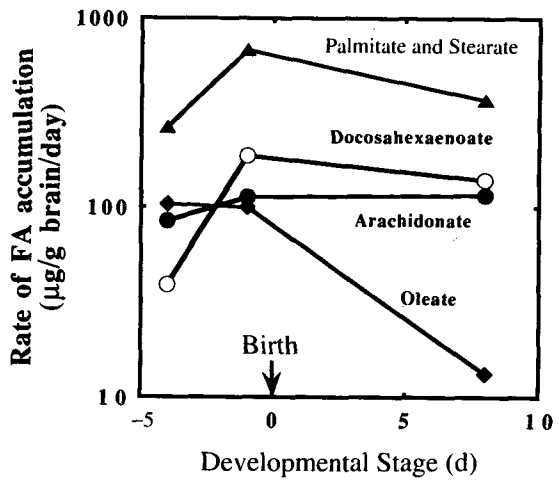

FIG. 2. Values are average daily accretion rates of the respective FA calculated for the following periods: up to E17 (day 4), between E17 and E20 (day 1), and between E20 and P8. DHA, docosahexaenoic acid; AA, arachidonic acid; OA, oleic acid; Sat., saturated acid. See Figure 1 for other abbreviation.

The FA composition of the major brain lipids is shown in Tables 3 and 4. The largest component of esterified FA was saturated. PE was the least saturated PL, mainly because this fraction included alk-1-enyl bonds (plasmalogen), which constituted approximately 40% of the total PE pool at E20 (Green, P., and Yavin, E., unpublished data). Although the total saturated FA were found in similar concentrations in most of the lipid fractions (Table 3), the types of saturated FA differed widely (Table 4). Thus, the major saturated FA in PC was 16:0, and in PI and PS it was 18:0. In PE, 16:0 and 18:0 were found in almost equal proportions. Most of the monounsaturated FA was comprised of 18:1 (Table 4), and was most abundant in PC (Table 4). The proportion of this FA group decreased in all the lipid fractions from E17 to P8, the most pronounced changes being observed in PS and PE.

The major long-chain PUFA were AA and DHA (Table 4). In PS and PE, 22:4n-6 and 22:5n-6 also were found in substantial proportions. At all the developmental points, PE contained most of the brain PUFA, both n-6 and n-3 forms (Table 3). Thus, although the percentage of n-3 PUFA was highest in PS, their absolute amount was severalfold greater in PE. Similarly, even though AA was the major PUFA in PI, amounting to 39.4–45.2% of the total FA in this fraction (Table 4), PE contained 3.4-, 3.8-, and 11.9-fold more AA on a weight basis than PI at E17, E20, and P8, respectively.

PS and PE were relatively enriched in DHA (Table 4) and contained most of the DHA esterified into the total brain PL (78.8, 84.2, and 91.5% at E17, E20, and P8, respectively, calculated from Figure 1, Table 4, and the relative amounts of the various PL). Moreover, most of the increase in total brain DHA observed during this period was accounted for by the increases of this FA in PE and PS. DHA also increased substantially in TG and DG (Table 4), but total esterified DHA in these NL fractions was less than in PC because of their small amount (Table 1).

Concomitantly with the increases in DHA described here, significant decreases in the proportion of 22:5n-6 were observed in all the lipid fractions (Table 4).

DISCUSSION

In this study we provide detailed information on the quantitative aspects of FA composition and accretion in the lipid fractions of the early developing rat brain. This information was deemed important because, in contrast to abundant data on the FA composition in the adult rodent brain (2,19–22), much less is known about the FA in the brain lipid fractions during fetal development (6,9,23). Furthermore, the changes of the FA in the various PL classes at these critical stages of the developing rat brain are still not complete. A detailed quantitative analysis of the PC and PE molecular species in the guinea pig fetal brain was recently reported (10), but data on the FA composition of PI and PS, as well as of the NL, were not provided. These latter lipids, although minor quantitatively, are

essential for such cellular functions as enzyme activation (13) and second-messenger formation (11). For example, it has been demonstrated that PS is a necessary component in the activation of several protein kinase C isoforms (12). Moreover, it appears that the fatty acyl composition of PS is one of the regulatory factors in enzyme activation (24).

The bulk of weight increase of rat brain occurs postnatally, with the growth spurt paralleling myelinogenesis (25), whereas neuronal proliferation and differentiation are nearly complete by birth. Thus, neuronal membrane PL formation and FA accretion should be substantial at this period. Therefore, failure to acquire sufficient and appropriate PUFA at such critical periods in fetal development may have harmful and irreversible consequences for postnatal growth and function. In this study we show that FA accumulation is steeper than brain weight gain before birth; weight gain is more rapid while during the early postnatal period. The latter relationship between brain weight gain and FA accretion persists up to the fifth postnatal week (6). Thus, intrauterine life constitutes an important period of brain FA deposition.

The changes in the quantity of the long-chain PUFA are of special interest, as they, or their precursor FA, LA, and LNA, have to be obtained from the diet. In a previous developmental study, it has been shown that the bulk of the rat brain PUFA accumulates postnatally (6). Furthermore, in several species, during brain growth n-6 PUFA accumulation predated that of n-3 PUFA accumulation (26). In these reports, however, detailed analysis of fetal brain FA was not performed. The increase in the amount of the n-3 PUFA demonstrated in the present study was mainly due to the prominent accretion of DHA (Table 2). Actually, the strikingly accelerated rate of DHA accretion during the last three days of pregnancy (Fig. 2) constitutes a "DHA accretion spurt," analogous to the traditional concept of "brain growth spurt" coined by Dobbing (25). A similar period of prenatal rapid DHA accumulation was observed between day 25 and day 35 of gestation in the guinea pig (9). An increasing ratio of DHA to AA has been documented in the human fetal brain after 30 wk of gestation (27). However, in contrast to our results in the rat fetal brain (Table 2), the enhanced accumulation of DHA in the human fetal brain was accompanied by decreasing proportions of AA.

The sources of the long-chain PUFA in the fetal brain are mostly maternal (6), although it has been shown both *in vitro* (28) and *in vivo* (5) that the fetal rat brain has the ability to form long-chain PUFA from their precursors. The ability of

[a]Abbreviations and statistics as in Tables 1 and 2. ND, not detected.

early postnatal rat brains to elongate-desaturate deuterium-labeled LA and LNA to their longer chain desaturated products has been demonstrated recently (29). Although the fetal liver does not supply long-chain PUFA to the fetal guinea pig brain (9), it does so in the postnatal developing mouse brain (30), the early postnatal rat (29), and in domestic felines (31).

The very low proportion of the precursor essential FA as compared to their long-chain products in the developing brain (Tables 2 and 4) suggests preferential uptake of the long-chain PUFA from the blood (32), local elongation-desaturation by the brain (5), or both. The low levels of brain LA and LNA were not due to dietary deficiency, because high proportion of these FA, especially of LA, were found in the 20-d fetal liver (Green, P., and Yavin, E., data not shown). The proportions of LA and LNA in the brain lipid do not change substantially during development, as adult rat (22) and mouse (33) brains also contain very low levels of these FA.

Provided adequate dietary conditions prevail, the FA composition of the individual brain PL in the adult rat and mouse is highly characteristic (2,19–21). In our study, this distinctive pattern of brain PL acyl chain composition was already evident (Table 4), implying that the mechanisms responsible for the final PL shaping (34) are present and active in the fetal brain. Some of them have been demonstrated in our previous study (5).

Two points of interest should be mentioned regarding the fetal accumulation of the PUFA in the brain PL between E17 and E20. First, the percentage of AA increased only in PI (Table 4), that of 22:4n-6 and 22:5n-6 remained almost unchanged in all the PL, but the concentration of DHA increased in all of them (Table 4). Second, the bulk of brain DHA accretion from E17 to E20 was accounted for by its increase mainly in PE and, to a lesser extent, in PS.

In the first postnatal week, a steep decrease in the proportion of 22:5n-6 was observed in all the fractions (Table 4). Because elevation of brain 22:5n-6 has been associated with dietary deficiency of n-3 FA (35), it may be postulated that during intrauterine life, a relative n-3 FA deficiency exists. Indeed, major increases in the proportion of DHA in most lipid fractions were observed between E17 and P8 (Table 4).

The FA composition of DG and TG was more variable than that of the PL (Table 4). The FA composition of the TG partially reflects that of their precursors, the DG (Table 4). It has been postulated by Cook (28) that the brain TG pool is important for the transfer of long-chain FA to PL. In the present study, a steep increase in the proportion of DHA occurred in TG (Table 4). In addition, even though the amounts of DG and TG in the fetal brain were negligible relative to the PL (Table 1), a very brisk turnover of labeled AA and DHA in these fractions was demonstrated (Green, P., and Yavin, E., unpublished data). Taken together, these data tend to confirm Cook's assumption (28).

In summary, substantial brain FA accumulation occurs during late gestation, with the accretion of DHA being most prominent. The bulk of DHA accumulation is accounted for by its increase in PE, and to a lesser amount, in PS. Because the fetus is totally dependent upon the maternal supply of nutrients for the acquisition of its FA (36), the "DHA accretion spurt" described in this study underscores the need for adequate maternal nutrition and an intact and functioning placental-fetal unit.

The Effects of 3-Hydroxy-3-Methylglutaryl–CoA Reductase Inhibition on Tissue Levels of Carnitine and Carnitine Acyltransferase Activity in the Rabbit

Jalaluddin Bhuiyan* and David W. Seccombe

Department of Pathology, University of British Columbia, Division of Clinical Chemistry, Department of Pathology and Laboratory Medicine, Vancouver Hospital & HSC, Vancouver, V5Z 1M9, Canada

ABSTRACT: Recently, a new class of lipid lowering agents [3-hydroxy-3-methylglutaryl (HMG)–CoA reductase inhibitors] was introduced into clinical practice. The use of these agents could lead to a secondary deficiency in carnitine, which may manifest clinically as a myalgia/myositis—a side effect that is occasionally seen with this class of drugs. In the present study, we examined the effect of an HMG–CoA reductase inhibitor (lovastatin) on serum and tissue levels of carnitine and carnitine acyltransferase activities in the rabbit. Rabbits (n = 6) were fed chow containing lovastatin (30 mg/d) for 16 wk. Blood was collected and tissues (liver, heart, and skeletal muscle) harvested at sacrifice. Free and total carnitine were measured in serum and tissues by a radioenzymatic method. Carnitine acetyltransferase and carnitine palmitoyltransferase (CPT) activities were determined and expressed relative to DNA. Serum free (24.0 ± 2.6 vs. 29.4 ± 3.1 μM) and total (35.1 ± 4.7 vs. 52.8 ± 8.8 μM) carnitine levels increased significantly with 16 wk of treatment. This increase in total carnitine was mainly due to an increase in the levels of serum acylcarnitine (12.7 ± 3.1 vs 26.5 ± 5.7 μM). Tissue levels of total carnitine were significantly decreased by the treatment. Carnitine acetyltransferase was unaffected by the treatment, whereas there was a significant increase in the activity of CPT in the liver and heart.

Lipids 31, 867–870 (1996).

High concentrations of plasma low density lipoprotein cholesterol are believed to be a major risk factor in the development of atherosclerosis and coronary heart disease (1). With the advent of inhibitors of 3-hydroxy-3-methylglutaryl (HMG)–CoA reductase activity (the rate-limiting step in cholesterol biosynthesis), the treatment of hypercholesterolemia has improved considerably (2,3). Lovastatin is one of the more widely prescribed agents among the different HMG–CoA reductase inhibitors (2,3). Development of diffuse muscle pain and myositis, which occasionally progresses to frank rhabdomyolysis, is a rare side effect that can be seen with the use of these agents (4,5). Because these drugs inhibit the rate-limiting enzyme for cholesterol synthesis, their use would lead to an increase in the acyl-CoA/free CoA ratio within the liver cell. Under these circumstances, there may be a higher than normal carnitine requirement for the buffering of these acyl-CoA moieties through an esterification reaction yielding acylcarnitine and free CoA. Theoretically, under these circumstances, some patients may develop a secondary deficiency in muscle carnitine. Clinically, this may manifest as a myalgia/myositis.

Carnitine is found in virtually all cells of higher organisms. The primary function of this molecule is to transfer long-chain acyl-CoA across the inner mitochondrial membrane for β-oxidation (6). Carnitine may also function in other metabolic processes including the modulation of the acyl-CoA/CoASH ratio in mammalian cells (7). Ninety-eight percent of the total body carnitine store is in muscle; the remaining is present in extracellular fluid, liver, and other tissues existing in free and acylated forms. Carnitine acyltransferases (CAT) catalyze the formation of acylcarnitines from acyl-CoA. CAT and carnitine palmitoyltransferase (CPT) are two important enzymes involved in these reactions (8). Carnitine has been suggested to activate fatty acid oxidation and to prevent the accumulation of potentially toxic levels of cytosolic and mitochondrial acyl-CoA (9).

In this study, we examined the effect of 16 wk of administration of an HMG–CoA reductase inhibitor (lovastatin) on carnitine and acylcarnitine concentrations in chow-fed rabbits. In addition, we studied the effect of this drug on the activity of two carnitine related enzymes—CAT and CPT. Our results indicate that treatment of rabbits with an HMG–CoA reductase inhibitor for 16 wk alters their carnitine status.

MATERIALS AND METHODS

Animals. Female New Zealand white rabbits (2.0–2.5 kg) were used. They were divided into two groups: a control group (n = 6) fed Purina rabbit chow (Purina Mills, St. Louis, MO), and the experimental group (n = 6) fed a rabbit chow diet containing lovastatin (30 mg/d; Ralston Purina Canada Inc., Mississauga, Ontario, Canada) for 16 wk. Lovastatin was mixed with ethanol (2 mL) and rabbit chow (200 g). The control diet was prepared similarly without adding lovastatin.

The animals were housed in individual metabolic cages, allowed free access to water and fresh diet, and maintained on a 12-h lights on/off cycle throughout the study.

At sacrifice, serum was collected and tissues (liver, heart, and skeletal muscle) immediately harvested into liquid nitrogen and stored at −70°C until analyzed.

Analyses. Serum free, acyl, and total carnitine were determined by a radioenzymatic method as described by Parvin and Pande (10). Tissues (liver, heart, and skeletal muscle) were prepared for carnitine (free, acyl, and total) and CAT activities determined as previously described (11,12). Carnitine was measured according to Paryin and Pande (10). Tissue carnitine results were expressed relative to DNA. DNA was determined according to the method of Labarca and Paigen (13).

CAT assay. The CAT activities were measured in 10% tissue (liver, heart, and muscle) homogenates by monitoring the conversion of [1-^{14}C]acetyl-CoA (50 μM) in the presence of carnitine (5 mM) to [1-^{14}C]acetyl-carnitine as described previously (10,14).

CPT assay. The activity of CPT was assayed in 10% tissue homogenates at 30°C with 50 μM [1-^{14}C]octanoyl-CoA as substrate in the presence of 5 mM carnitine according to Murthy and Pande (15). [1-^{14}C]Octanoyl-CoA was synthesized and purified as previously described (16).

Statistical analysis. The Student's *t*-test for unpaired data was used. Differences were considered significant at $P < 0.01$ for a two-tailed test.

RESULTS

Effect of HMG–CoA reductase inhibition on serum carnitine levels. Sixteen weeks of drug treatment significantly increased the serum free (24.0 ± 2.6 vs. 29.4 ± 3.1 μM), acyl (12.7 ± 3.1 vs. 26.5 ± 5.6 μM), and total (35.1 ± 4.7 vs. 52.8 ± 8.8 μM) carnitine concentrations in rabbit serum (Table 1).

Effect of HMG–CoA reductase inhibition on tissue carnitine levels. Sixteen weeks of feeding a diet containing lovastatin significantly decreased the tissue levels of carnitine in liver, heart, and skeletal muscle (Table 2). Among the tissues studied, skeletal muscle showed the greatest decrease in carnitine content.

Effects of HMG–CoA reductase inhibition on CAT and CPT activities in liver, heart, and skeletal muscle. The effects of drug treatment on the activities of CAT and CPT in liver, heart, and skeletal muscle are presented in Table 3. Treatment for 16 wk significantly increased the activities CPT in liver and heart (0.35 ± 0.09 vs. 0.50 ± 0.02 and 0.84 ± 0.22 vs. 1.33 ± 0.13 nmol · min^{-1} · g^{-1} DNA, respectively). Treatment had no effect on the activities of this enzyme in skeletal muscle. The CAT activity was unaffected by the treatment.

DISCUSSION

The pathogenic mechanisms underlying the myopathy and rhabdomyolysis that is occasionally seen with the use of HMG–CoA reductase inhibitors are unknown. Sixteen weeks of drug treatment in the rabbit significantly increased the serum levels of total carnitine. This increase was most evident in the concentrations of serum carnitine esters (Table 1). Of particular interest was that treatment significantly decreased the content of total carnitine in liver, skeletal muscle, and heart (Table 2). This observation may have implications

with respect to the pathogenesis underlying the reported side effect of myalgia/myositis that occasionally occurs with this class of agents. Conceivably, over time, carnitine may be released from these tissues in the form of acylcarnitine as a mechanism by which the cells rid themselves of potentially toxic acyl-groups that may be accumulating as a by-product of mitochondrial metabolism. The continued release of acylcarnitine from the tissues may lead to a secondary carnitine deficiency over time. Carnitine is an important intracellular buffer for maintaining the acyl-CoA/CoASH ratio within cells (7,17,18).

Skeletal muscle is particularly sensitive to a deficiency state involving carnitine. Deficiency impacts type 1 fibers most markedly. Lipid is a major energy source of this fiber type both at rest and during prolonged exercise (19). As a carnitine deficiency develops, muscle long-chain acyl-CoA esters will divert to esterification reactions rather than oxidation. Depending upon the severity of the deficiency, this may result in the deposition of lipid droplets in muscle, giving rise to a lipid storage myopathy. In a less severe state, one might see a myositis and impaired muscle function secondary to the accumulation of acyl-CoA moieties and a decreased availability of free CoA for other reactions. Lipid storage myopathies secondary to carnitine deficiency have been reported with inherited deficiencies of different chain length acyl-CoA dehyrogenases (20–22), respiratory chain defects (23), methymalonic aciduria (24), and others. In all of these cases, the excretion of acylcarnitine increases with a concomitant rise in the [acylcarnitine]/[carnitine] ratio in plasma. Coincident with this, tissue levels of total carnitine decrease (25). A similar pattern was evident in the current study (Tables 1 and 2).

Rat liver HMG–CoA reductase and the fatty acid oxidation enzyme, CPT, are closely interlinked on a metabolic basis (26). It has been reported that chronic feeding of rats with an HMG–CoA reductase inhibitor increases the activities of liver outer mitochondrial CPT. More recently, it was observed that the rate of hepatic palmitate oxidation and the production of acid-soluble by-products were significantly increased with lovastatin treatment of rat hepatocytes (27). It was suggested that the underlying mechanism for this increase in fatty acid oxidation was due to an induction of hepatic CPT activity by the drug. The main acid-soluble product formed during the oxidation of palmitic acid by rat liver and muscle mitochondria is acetyl-CoA, which is readily esterified to carnitine forming acetylcarnitine. This esterification reaction is catalyzed by CAT (28). Once formed, acetylcarnitine is transported from the tissues to the plasma, where it is either metabolized or excreted unaltered by the kidneys. Our results of a significant increase in CPT activities in rabbit liver and heart after sixteen weeks of lovastatin treatment (Table 3) confirmed these findings. We did not see an effect of this drug on CAT activity. This may be due to the high activities of this enzyme that are already present in these tissues, making further induction unlikely. It is of interest to note that tissue levels of carnitine were decreased in all of the tissues studied, and CPT activity was increased in all those tissues, except in the case of skeletal muscle. The activity of CPT in skeletal muscle is not readily inducible under normal circumstances other than through exercise training; whereas in the liver and heart, the activity of this enzyme tends to respond more acutely to metabolic challenges.

In summary, we have shown that 16 wk of treatment with an HMG–CoA reductase inhibitor significantly alters the carnitine status in the rabbit. Further studies are necessary to establish whether or not these changes are functionally significant.

Dietary Sunflower Oil Reduces Plasma and Liver Triacylglycerols in Fasting Rats and Is Associated with Decreased Liver Microsomal Phosphatidate Phosphohydrolase Activity

Lucie Frémont* and Marie-Thérèse Gozzelino

Laboratoire de Nutrition et Sécurité Alimentaire I.N.R.A., Jouy-en-Josas Cedex, France

ABSTRACT: Plasma and liver lipids were studied in male weanling rats fed diets containing moderate levels of fat (6% by weight) as sunflower oil (SF diet, rich in linoleic acid), salmon oil (SM diet, rich in long-chain n-3 fatty acids), or a blend of peanut and rapeseed oil (PR diet, rich in oleic acid). After nine weeks of feeding, the fasting plasma cholesterol concentrations were 49 and 24% lower in groups SM and SF, respectively, as compared to group PR. Both dietary salmon oil and sunflower oil lowered the triacylglycerol concentration of plasma and liver but, unexpectedly, the response was higher with sunflower oil. Indeed, in group SM the values were 15 and 30% lower in plasma and liver, whereas in group SF, they were 24 and 53% lower, respectively. As compared to group PR, liver triacylglycerols and microsomes contained 2.5- and 2.3-fold less oleic acid, respectively, in group SF, and they were 9.2- and 3.2-fold enriched in n-3 fatty acids, respectively, in group SM. The liver triacylglycerol concentrations were correlated with changes in the microsomal Mg^{2+}-dependent phosphatidate phosphohydrolase activity ($r = 0.47$, $P < 0.01$). As oleic acid, unlike long-chain n-3 fatty acids, is considered to promote the triacylglycerol synthesis and secretion, our findings suggest that changes in the membrane fatty acid composition could affect the triacylglycerol content of liver and plasma. Moreover, the availability within the liver, of oleic acid, predominantly incorporated into triacylglycerols, might limit the triacylglycerol production in SF-fed rats.

Lipids 31, 871–878 (1996).

In a recent study (1) we observed that in rats fed moderate levels of fats, dietary sunflower oil (SF) efficiently reduced fasting serum triacylglycerol levels, whereas salmon oil (SM) lowered serum cholesterol but had no significant reducing effect on triacylglycerols. These findings contrasted with numerous data showing that, in rats as well as in humans, fish oils rich in long-chain n-3 polyunsaturated fatty acids (PUFA) were the most active dietary fats to lower serum triacylglycerol levels (2–8). It has been demonstrated that the response was largely mediated by the inhibition of membrane-bound enzymes involved in triacylglycerol synthesis. Actually, long-chain n-3 PUFA reduce hepatic glycerophosphate acyltransferase (9–11), diacylglycerol acyltransferase (12–14), and phosphatidate phosphohydrolase (PAP) (15–19) activities. In contrast, oleic acid enhances the hepatocyte triacylglycerol synthesis and secretion (20–22). This effect may be explained by the capacity of oleic acid to activate the hepatic PAP (23,24) and to be preferentially utilized for triacylglycerol synthesis (22). Therefore, n-3 PUFA and oleic acid play a major role in the hepatic production of triacylglycerols by controlling the activity of PAP, which is a key enzyme of the synthetic pathway. In our previous study (1) oleic acid accounted for less than 10% of serum fatty acids in SF-fed rats. The concomitant alterations in membrane fatty acid composition suggested that the reduction of oleic acid in SF-fed rats, as well as the enrichment in long-chain n-3 PUFA in SM-fed rats, could contribute to lowering serum triacylglycerol levels by changing the activity of membrane-associated enzymes. Therefore, we have undertaken the present study to compare the responses of plasma and liver lipids to either dietary SF or SM. We have examined whether the reduction also concerned liver fractions, especially triacylglycerols, and whether dietary fats altered their oleic acid content. We have also determined whether fatty acid compositional modifications of a microsomal-enriched fraction were associated with changes in the Mg^{2+}-dependent PAP (EC 3.1.3.4) activity.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (IFFA CREDO, L'Arbresle, France) bred in our laboratory were randomly distributed into three groups of ten rats just after weaning (21-day-old). Animals were maintained at 22 ± 1°C with a 12-h light/dark cycle. During the following nine weeks, rats were fed *ad libitum* purified diets prepared in the laboratory, containing 6% by weight (about 13% of total calories) of different types of lipids.

The experimental groups received either: (i) a mixture of peanut oil and rapeseed oil containing high levels of oleic acid and providing the required levels of PUFA (PR diet: n-6/n-3 = 5.2); (ii) SF (SF diet: n-6/n-3 = 664); (iii) SM (SM diet: n-6/n-3 = 0.10). The fatty acid composition of each diet is shown in Table 1.

The other dietary components were (w/w): 22% casein, 43.2% cornstarch, 21.6% sucrose, 4% mineral mixture, 1% vitamin mixture, 2% cellulose, and 0.16% methionine.

The mineral mixture contained (g/kg): Ca $HPO_4 \cdot 2\ H_2O$, 380; $K_2\ HPO_4$, 240; $CaCO_3$, 180; Mg $SO_4 \cdot 7\ H_2O$, 90; NaCl, 69; MgO, 20; $FeSO_4 \cdot 7\ H_2O$, 8.6; Zn $SO_4 \cdot H_2O$, 5; Mn $SO_4 \cdot H_2O$, 5; Cu $SO_4 \cdot H_2O$, 1; NaF, 0.8; CrK $(SO_4)_2 \cdot 12\ H_2O$, 0.5; KI, 0.04; $CoCO_3$, 0.02; $Na_2\ Se\ O_3 \cdot 5\ H_2O$, 0.02.

The vitamin mixture contained (g/kg triturated in sucrose): retinyl acetate (500 000 IU /g), 1; cholecalciferol (250 000 IU/g), 2.5; all-*rac*-α-tocopherol (500 IU/g), 10; menadione, 0.1; thiamin HCl, 1; riboflavin, 1; nicotinic acid, 4.5; calcium pantothenate, 3; pyridoxine HCl, 1; inositol, 5; D-biotin, 0.02; folic acid, 0.2; cyanocobalamin, 0.00135; ascorbic acid, 10; *p*-aminobenzoic acid, 5; choline chloride, 75.

After an overnight fast, rats were weighed and killed by decapitation without anesthesia and exsanguinated. Blood samples collected on EDTA (1 mg/mL) were centrifuged at low speed. Plasma was stored at −80°C after adding sodium azide (0.02%). Livers were rapidly removed, rinsed with ice-cold 150 mmol/L NaCl, blotted, and weighed. Aliquots were freeze-clamped and stored at −80°C.

Analytical procedures. Aliquot samples of thawed liver (corresponding to about 100 mg of fresh tissue) were homogenized in 4 mL of ice-cold buffer (150 mmol/L NaCl, 10 mmol/L Tris-HCl, pH 7.4) using a loose-fitting Dounce homogenizer (Bioblock Scientific, Illkirch, France) with six up-and-down passes of the pestle. The protein content was determined according to Bradford (25) using the Biorad Protein assay (Biorad, Richmond, CA) with bovine serum albumin (fraction V) as standard. Lipids were extracted according to Folch *et al.* (26) using 6 mL of chloroform/methanol (2:1, vol/vol) for 1.5 mL homogenate. After two washes, the lower chloroform phase was dried under nitrogen and resolubilized in 0.25 mL of 2-propanol. Triacylglycerols and cholesterol (total and free) were quantified by enzymatic colorimetric tests (644200 and 1442341; Boehringer Mannheim, Meylan, France). The phospholipid content was estimated by the phosphorus content (P × 25) determined by the method of Bartlett (27).

Triacylglycerol and cholesterol concentrations were measured directly in plasma. High density lipoprotein (HDL)-cholesterol was estimated after precipitation of very low density lipoprotein (VLDL) and low density lipoprotein (LDL) by the dextran sulfate Mg^{2+} procedure of Warnick *et al.* (28) adapted for rat plasma (29).

Preparation of liver membranes and metabolic assays. Liver tissue was rinsed with ice-cold NaCl 0.15 M, minced with scissors, and homogenized in 5 vol of buffer (250 mmol/L sucrose, 10 mmol/L Tris-HCl, pH 7.5, 1 mmol/L EDTA, 0.5 mmol/L dithiothreitol). After filtration through nylon gauze, the preparation was centrifuged at 20,000 × *g* for 20 min at 4°C. The supernatant (below the floating fat layer) was collected and centrifuged at 105,000 × *g* for 60 min at 4°C. The supernatant was collected as the cytosolic fraction (termed "cytosol") and the pellet as the microsomal enriched fraction (termed "microsomes").

The Mg^{2+}-dependent PAP activity was assayed by the method of Walton and Possmayer (30) with slight modifications. Liposomes were obtained by sonication (Labsonic 1510 Braun fitted with a microprobe; Labsonic Braun, Melsungen, Germany) in NaCl 150 mmol/L of equimolar (2 mmol/L) of Lα-phosphatidate (PA) and dimyristoylphosphatidylcholine (DMPC) (Sigma, St. Louis, MO).

The reaction mixture contained 0.5 mmol/L PA–DMPC liposomes, 1.5 mmol/$MgCl_2$ (16), and 50–100 μg microsomal protein in a final volume of 0.2 mL. The mixture was incubated at 37°C for 20 min. The reaction was terminated according to Mavis *et al.* (31) by adding 0.8 mL of a solution containing 0.13% SDS, 1.25% ascorbic acid, 0.32% ammonium molybdate, 4 H_2O, and 0.75 N H_2SO_4. The phosphomolybdate color was developed at 45°C for 20 min, and absorbance was measured at 820 nm. Cytosol was treated as described by Berglund *et al.* (32) using 0.23 g ammonium sulfate per mL solution for 10 min at 4°C. The precipitate was isolated after centrifugation at 10,000 × *g* for 10 min. The surface was gently washed with 50 mmol/L Tris-HCl pH 7.5, 230 mmol/L sucrose. It was then dissolved in the same buffer, and the PAP activity was determined.

Preliminary studies showed that the assays were linear with respect to both time of incubation and amount of protein.

[b]mg/100 g Diet.

Fatty acid composition of liver lipids. Liver lipids were extracted according to Folch *et al.* (26) in the presence of butylated hydroxytoluene (0.02% wt/vol). Phospholipids were separated from neutral lipids on a silica cartridge (SEP-PACK; Waters Associates, Milford, MA) by successive elutions with chloroform, acetone, and methanol (33). Lipids were saponified in 15% KOH at 37°C for 5 h. The fatty acids were esterified by methanol containing 3% HCl and 4% 2,2 dimethoxypropane at 70°C for 35 min and analyzed by gas–liquid chromatography. The Carlo Erba model 4180 (Milan, Italy) chromatograph included an automatic injector on the column, a flame-ionization detector, and a CP wax 52 CB (carbowax 20 M) bonded fused silica capillary column (50 m × 0.3 mm i.d.). The assays were carried out with programmed oven temperature rises of 3°C/min from 54 to 200°C. Hydrogen was the carrier gas at a pressure of 0.8 bar. Peak areas were measured with an integrator connected to a microcomputer which expressed the data automatically. Peaks were identified by comparing their equivalent chain lengths with those of authentic fatty acid methyl esters.

Analysis of data. Data are expressed as the mean ± SD. Differences between dietary groups were determined by analysis of variance. Comparisons were made using Fisher's least significance difference test at the $P < 0.05$ level of significance.

RESULTS

There were no significant differences between groups for the mean final body weight (group PR 245.5 ± 14.3g ; group SF 231.9 ± 24.6 g; group SM 246.6 ± 22.4 g). Likewise, the liver protein contents were not altered by dietary treatments. The mean values ranged from 128 to 132 mg/g fresh liver. Table 2 shows the effect of dietary fatty acids on fasting plasma and liver lipids. SM, as well as SF feeding, significantly reduced plasma triacylglycerol concentrations compared with PR feeding. However, the effect was higher in group SF (–24%) than in group SM (–15%). Plasma cholesterol levels were significantly lowered, but more markedly in group SM (–49%) than in group SF (–24%). Nevertheless, dietary 18:2n-6 and long-chain n-3 PUFA had similar effects on plasma cholesterol vehicled either in VLDL + LDL or in HDL, as the HDL-cholesterol to total cholesterol ratio was not altered (0.80–0.83 range).

The triacylglycerol concentrations were also lowered in liver. Actually, both dietary sources of PUFA were very effective in significantly reducing the values, but the response was higher with SF (–53%) than with SM (–30%). The other lipid classes were moderately or not affected by dietary PUFA. Only SM significantly reduced phospholipids (–15%). Both SF and SM diets lowered liver cholesterol in the same proportion (10–12%), but they did not significantly change the unesterified to total cholesterol ratio (0.86–0.88 range). The fatty acid distribution in liver lipid classes is reported in Table 3. The major changes concerned monounsaturated and PUFA. The oleic acid content of triacylglycerols was lowered by 59% in group SF and by 47% in group SM compared to group PR. As expected, the triacylglycerols from SF-fed rats were enriched in n-6 PUFA, 18:2 (2.4-fold), and 20:4 (2.8-fold), whereas n-3 PUFA accounted for only 0.6% of total fatty acids. The response to dietary SM was also very pronounced. The 2.6-fold reduction of n-6 PUFA affected both 18:2 and 20:4 at similar extents, whereas the levels of long-chain n-3 PUFA were 9.2-fold higher than in group PR, with more than half of them as 22:6. Liver phospholipids were less affected than triacylglycerols. It is noticeable that SF feeding did not alter the proportion of 20:4n-6, whereas it increased that of 22:5n-6 by 14-fold. The increase in the n-6 pentaene to n-3 hexaene ratio likely reflected an n-3 deficiency (34). Conversely, SM feeding enhanced the long-chain n-3 PUFA content by 2.7-fold. This was compensated by the fall of n-6 PUFA (about threefold). A very minor fraction of liver acyl chains was used to esterify cholesterol. The major part of acyl chains consisted of palmitic acid (25–31%) and oleic acid (22–41%). Cholesteryl esters from SF-fed rats which did not contain long-chain n-3 PUFA were enriched by more than twofold in 18:2n-6. In SM-fed rats, the lowered content of

[a]Data are expressed as mol per 100 mol of the total fatty acids and are means ± SD (n = 10). For any lipid class, means with no common superscript are significantly different at $P < 0.05$. Abbreviations as in Table 1; nd, not detected or lower than 0.1%.

n-6 PUFA was replaced mainly by 20:5n-3 rather than 22:6. In contrast, 22:6 was the predominent n-3 PUFA in the other ester classes.

Figure 1 represents the liver content of fatty acyl chains incorporated in the three classes of esterified lipids. None of the fatty acids present in hepatic cholesteryl esters exceeded 0.3 μmol/g. Accordingly, almost all liver fatty acids were distributed between phospholipids and triacylglycerols. Irrespective of dietary fats, liver phospholipids from the three groups had similar amounts of saturated and monosaturated fatty acids, which could originate from both endogenous and exogenous sources. Palmitic acid was distributed in the three classes, whereas stearic acid was almost entirely found in phospholipids. Irrespective of dietary treatments, phospholipids contained more than 12 μmol 18:0/g liver vs. 0.2–0.4 and 0.04–0.07 in triacylglycerols and cholesteryl esters, respectively. Oleic acid was the major fatty acid of triacylglycerols. The highest content, obtained with the PR diet, reached 6.4 μmol/g liver. The values were 2.7- and 5.2-fold lower in groups SM and SF, respectively. Because of the lowering effect of dietary SF on liver triacylglycerol levels, the amounts of 18:2n-6 incorporated in liver triacylglycerols were only scarcely higher in group SF than in group PR (2.7 vs. 2.4 μmol/g liver, respectively). The phospholipid content of liver was not influenced by SF feeding. Accordingly, both PR and SF groups incorporated similar amounts of 20:4n-6 in this lipid class. The value, 21 μmol/g liver, represented about 96% of 20:4n-6 present in the liver-esterified lipids. More than 70% of 20:4n-6 was replaced by 20:5 and 22:6n-3 in phospholipids from group SM. The amounts reached 4.6 and 11.4 μmol/g liver, respectively.

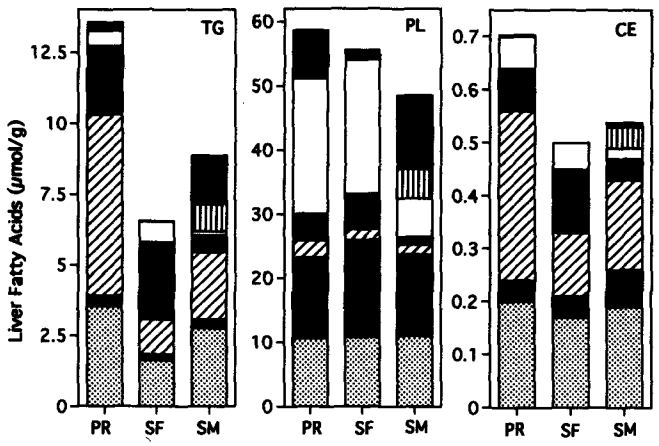

FIG. 1. Amounts of fatty acids in liver-esterified lipids (μmol/g fresh weight). Values were calculated using data from Tables 2 and 3. Triacylglycerols (TG), phospholipids (PL), and cholesteryl esters (CE) contained 3, 2, and 1 mol fatty acid/mol ester, respectively. Esterified cholesterol was total cholesterol minus free cholesterol. Dotted bar, 16:0; black bar, 18:0; white cross-hatched bar, 18:1n-9; grey bar, 18:2n-6; white bar, 20:4n-6; vertically striped bar, 20:5n-3; and gray cross-hatched bar, 22:6n-3; PR, a blend of peanut oil and rapeseed oil; SF, sunflower oil; SM, salmon oil.

The fatty acid composition of the microsomal fractions resembled that of total phospholipids, with more 18:1n-9 and 18:2n-6 and less 22:6n-3 in the three dietary groups (Table 4). The mean values from all the three groups showed a significant positive correlation between the liver triacylglycerol concentrations and the percentage of oleic acid in either liver triacylglyc-

[a]Data are as described in Table 3; mol/100 mol. Abbreviations as in Table 1; UI (unsaturation index) = sum $(a \times b)/S$ where a is the relative percentage of each unsaturated fatty acid, b is the number of double bonds for that particular fatty acid, and S is the percentage of total saturated fatty acids.

TABLE 5
Effects of Dietary Lipids on Mg^{2+}-Dependent Phosphatidate Phosphohydrolase (PAP) Activity in Rat Liver[a]

Pap activity	PR diet	SF diet	SM diet
Cytosol	7.77 ± 1.31[a]	6.47 ± 1.29[b]	4.92 ± 0.95[c]
Microsomes	5.38 ± 0.64[a]	4.21 ± 0.94[b]	4.3 ± 0.74[b]
% Of total in microsomes	41 ± 5[a]	39 ± 5[a]	47 ± 6[b]

[a]The PAP activity in either cytosol or microsomes was estimated by the release of inorganic phosphate from phosphatidate-dimyristoylphosphatidylcholine liposomes in the presence of 1.5 mmol/L Mg^{2+}. Data are as described in Table 2; nmol/min/mg protein. Abbreviations as in Table 1.

erols ($r = 0.97$; $P < 0.05$) or in liver microsomes ($r = 0.97$; $P < 0.05$).

The activity of liver Mg^{2+}-dependent PAP (Table 5) was greater in cytosol than in microsomes. Feeding PUFA decreased the activity in both fractions, but the values differed between groups SF and SM only in cytosol, as the activities were lowered by 17 and 37%, respectively. Pooled data from the three groups showed a significant and positive correlation between liver triacylglycerol concentrations and microsomal PAP activity ($r = 0.47$; $P < 0.01$) (Fig. 2). There was no correlation between plasma triacylglycerol concentrations and phosphatidate hydrolysis.

DISCUSSION

The present results confirm our recent data showing the higher capacity of SF as compared to SM to lower plasma triacylglycerol levels in fasting rats (1). The same protocol was used for both experiments, but in the present study neither plasma nor liver samples were pooled. They were treated individually in order to obtain a more accurate response to dietary treatments. This may explain that, unlike previous results, the difference between plasma triacylglycerols levels from groups PR and SM was significant.

The response of plasma cholesterol to dietary PUFA partially depends on that of plasma triacylglycerols. Indeed, a fraction of cholesterol is delivered to plasma in VLDL, the triacylglycerol-rich particles further converted into LDL. However, other mechanisms might explain the reduction of HDL-cholesterol as this fraction represented at least 80% of total plasma cholesterol. Our results agree with those of Balasubramaniam *et al.* (3) showing that, in rats, fish oil was more efficient than safflower oil in decreasing the total plasma cholesterol levels. These authors suggested that n-3 and, to a lesser extent, n-6 PUFA increased the secretion of cholesterol into bile. They hypothesized that the effects could be related to an accelerated uptake of lipoproteins by the liver, possibly due to alterations in the plasma membrane of liver cells.

The phosphatidate hydrolysis was different in the three dietary groups. However, neither total nor soluble PAP activity

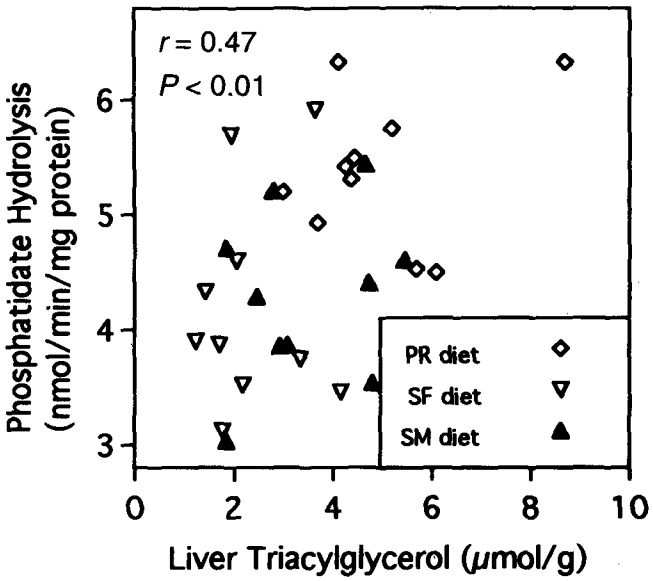

FIG. 2. Correlation between microsomal Mg^{2+}-dependent phosphatidate phosphohydrolase activity and triacylglycerol concentrations of liver in rats fed different dietary lipids for nine weeks (n = 10/dietary group). Values from Table 5 are plotted vs. those from Table 2. See Figure 1 for abbreviations.

was correlated with plasma or liver triacylglycerol levels. The 24% lower cytosolic PAP activity in group SM compared to group SF was of the same magnitude as that obtained in three-week-old rats fed diets containing either fish oil or SF (18). It is recognized that long-chain fatty acids control the expression of PAP (23). In rat hepatocytes, oleate increases the PAP activity by promoting the translocation of the enzyme from the cytosol to the endoplasmic reticulum (24). This was not observed in this work as the fraction of total activity in microsomes was not higher in group PR than in the other groups. Likewise, no change was observed either in a study using rat liver perfused with either oleic acid or long-chain n-3 PUFA (16), or in feeding experiments comparing responses to vegetable and fish oils (17,35). The values found for microsomal activity were probably overestimated because inorganic phosphate was produced *via* phosphatidate deacylation and dephosphorylation (36). Moreover, plasma membranes present in the microsomal fraction contain a PAP not involved in triacylglycerol synthesis (37).

Anyway, the positive correlation of liver triacylglycerol concentrations with phosphatidate hydrolysis in the microsomal fraction of liver supports the hypothesis that dietary-induced changes in the microsomal fatty acid distribution could alter the expression of the bound PAP. Our data showing the reducing effect of dietary long-chain n-3 PUFA on the Mg^{2+}-dependent microsomal PAP activity are consistent with results obtained in rats (15) and Syrian hamsters (19). *In vitro* studies on liver (12) and intestinal (14) cells showed that microsomal membranes enriched in eicosapentaenoic acid synthesized less triacylglycerols than membranes enriched in oleic acid. Hence the difference between responses to PR, SF, and SM diets might be due partly to changes in the eicosapentaenoic and oleic acid contents of liver microsomes. In this study, liver microsomes contained less oleic acid in group SF than in group SM. In contrast, Balasubramaniam *et al.* (3) found the same proportion of oleic acid (9%) in liver microsomes of weanling rats fed either fish oil or safflower oil, but only fish oil lowered plasma triacylglycerol levels. This might be linked to the higher intake of oleic acid than in our study (2 g/100 g diet). The 57% lower microsomal proportion of oleic acid in group SF compared with group PR was partly due to the inhibitory effect of linoleic acid on the desaturation of stearic acid as shown by other authors. In weanling Wistar rats, replacing dietary olive oil by corn oil lowered the oleic acid content of liver microsomes by 66%. This corresponded to opposite changes in Δ6 and Δ9 desaturase activities (38). Like in our experiment, the value of unsaturation index was practically unchanged. This contributed to maintaining the homeostasis of membranes (38,39).

Another cause of the reduced triacylglycerol levels in liver might be the lowering of the pool of oleic acid available for esterification. This assumption is supported by the positive correlation found between the percentage of oleic acid in liver triacylglycerols and the triacylglycerol content of liver. Moreover, we previously observed that serum lipids incorporated less oleic acid in group SF than in group SM (9 vs. 16), despite a higher intake (1).

Although a fraction of oleic acid has an endogenous origin, the amounts present in liver may be restricted because dietary PUFA have the capacity to reduce the hepatic synthesis of fatty acids (40,41) and to stimulate the mitochondrial oxidation of long-chain fatty acids. The latter effect has been demonstrated for the n-3 series (10,11,19) but not for the n-6 series. Moreover, fish oil can induce a reduction in plasma free fatty acids which contributes to lowering of hepatic triacylglycerols (42). Few studies showing the more potent reducing effect of diets rich in fish oil compared to diets rich in vegetable oil on plasma triacylglycerol levels report the responses of liver triacylglycerol levels. Yeo and Holub (43) found lower amounts in fish oil- than in SF-fed rats. The discrepancy with our study could be related to the higher intake of fats (10%), which provided higher amounts of oleic acid for triacylglycerol synthesis. This assumption is supported by the presence of equivalent high proportions (21%) of oleic acid in liver triacylglycerols from both dietary groups. Similar differences between liver triacylglycerol levels were observed in rats fed 15% (9) and 20% (35) lipid diets. The response to diets rich in fish oil was also due to the stimulation of peroxisomal fatty acid oxidation.

In contrast with our study, Rustan *et al.* (35) showed much higher amounts of monoenes in liver triacylglycerols with a sunflower oil diet (2.52 instead of 1.52 μmol/g liver) than with a fish oil diet (1.79 instead of 3.34 μmol/g liver). This could reflect a higher rate of triacylglycerol synthesis in SF-fed rats because diets provided high amounts of oleic acid, preferentially incorporated into triacylglycerols. The effect of SF cannot be assigned to n-6 PUFA because 18:2n-6 only possesses a weak hy-

potriglyceridemic activity, whereas 20:4n-6 may elevate circulating triacylglycerols (44). We observed that SM, but not SF, reduced liver phospholipids. Indeed, the replacement of decreased 20:4n-6 is limited (45) despite the high capacity of long-chain n-3 PUFA to be incorporated into phospholipids (14,19,22).

In summary, the present study shows that under our experimental conditions dietary SF had a tendency to be more efficient than dietary SM to lower both plasma and liver triacylglycerols. In particular, intake of dietary lipids was lower than in many other studies. It is obvious that several mechanisms are involved in the responses to dietary PUFA. Among them, our data underlines the role of membrane fatty acids in the rate of hepatic phosphatidate hydrolysis. The lack of stimulation by oleic acid, as well as the inhibition by long-chain n-3 PUFA of the esterification pathway, might contribute to the hypotriglyceridemic effect of SF and SM, respectively. The concomitant reduction of oleic acid in liver triacylglycerols and microsomes suggests that the availability of oleic acid might limit the triacylglycerol production in SF-fed rats.

ABSTRACT: This study was designed to elucidate the effect of the synthetic androgen, methyltestosterone, on bile flow and biliary lipid secretion in female hamsters. Animals were divided into four groups and fed the following diets: group 1, lithogenic diet for three weeks; group 2, lithogenic diet + 0.05% methyltestosterone for three weeks; group 3, lithogenic diet for six weeks; group 4, lithogenic diet + 0.05% methyltestosterone for six weeks. At the end of each experimental period, the hamsters were operated on to establish external biliary fistulas. During the depletion of the endogenous bile acid pool (for two hours), the basal bile flow of group 4 was significantly smaller than that of group 3. Basal bile acid output was significantly lower in the methyltestosterone-fed groups 2 and 4 than in control groups 1 and 3. In contrast, groups 2 and 4 secreted more cholesterol than groups 1 and 3. Group 4 had a higher ratio of cholesterol output to phospholipid output than group 3. Increasing doses of taurocholate were infused after the bile acid depletion period, and it was found that methyltestosterone did not change the bile acid independent bile flow. The increments in cholesterol or phospholipid output induced per increment of bile acid output (linkage coefficients) were analyzed by linear regression. The methyltestosterone-fed groups (groups 2 and 4) had a higher linkage coefficient of cholesterol output to bile acid output than the control groups (groups 1 and 3). The linkage coefficients of phospholipid output to bile acid output of groups 2 and 4 were also higher compared to groups 1 and 3. The linkage coefficient of cholesterol output to phospholipid output of group 2 was higher than that of group 1. These results suggest that methyltestosterone stimulated the cosecretion mechanism of cholesterol and phospholipid in bile associated with an increasing ratio of cholesterol to phospholipid. In conclusion, the synthetic androgen, methyltestosterone, caused a decrease in basal bile flow and bile acid secretion, and an increase in basal cholesterol secretion and the biliary cholesterol-to-phospholipid ratio. These findings explain, in part, how methyltestosterone intensifies the formation of cholesterol gallstones in female hamsters. *Lipids 31*, 879–886 (1996).

In humans, the incidence of cholesterol gallstones is about twice as high in females as in males (1). Oral contraceptives (2,3) and estrogen therapy in postmenopausal women (4), as well as prostate cancer treatments (5), raise the risk of developing gallstones in these subjects. Such observations strongly suggest that, in humans, female sex hormones promote gallstone formation, but the mechanism of this effect is not understood. The effects of male sex hormones on gallstone disease have not been studied in detail. In previous studies, we found that, unlike humans, male hamsters from Sasco fed a lithogenic diet (LD, containing 4% butterfat and 0.3% cholesterol) had a high incidence of cholesterol gallstones (up to 90%), while females of the same "strain" formed no stones even when palmitic acid was substituted for butterfat to enhance the lithogenic stimulus (6–8). However, when these female hamsters were fed the LD containing 0.05% methyltestosterone (MeT), a synthetic androgen, they developed cholesterol gallstones as readily as the males (9). MeT administration to female hamsters increased the biliary cholesterol saturation index, raised the proportion of biliary cholesterol carried in vesicles, and changed the biliary bile acid composition to that of the males (9). The male hormone appeared to stimulate the formation of lithogenic bile and cholesterol gallstones; it is unclear whether MeT exerted this effect by stimulating biliary cholesterol secretion, inhibiting bile acid secretion, or modifying phospholipid secretion. In order to elucidate the mechanism of action of MeT, we fed an LD containing this androgen to female hamsters and studied bile flow and biliary lipid secretion.

MATERIALS AND METHODS

Animals and diets. Fifty-eight female golden Syrian hamsters (42–56 g) were purchased from Sasco, Inc. (Omaha, NE). The hamsters were divided into four groups and fed the LD with or without MeT (Dyets, Inc., Bethlehem, PA) and water *ad libitum* for three or six weeks prior to surgery: group 1 ($n = 11$), LD for three weeks; group 2 ($n = 15$), LD + 0.05% MeT for three weeks; group 3 ($n = 16$), LD for six weeks; and group 4 ($n = 16$), LD + 0.05% MeT for six weeks. The LD contained 43.6% corn starch, 20.0% casein, 14.6% dyetrose (soluble starch), 10.0% fiber (cellulose), 5.0% salt mix (modified U.S.P. XIV salt mix No. 200951), 4.0% butterfat, 2.0% corn oil, 0.5% vitamin mix (No. 300000), and 0.3% cholesterol.

Surgical procedures. The hamsters were anesthetized by intraperitoneal injection of 20 mg/100 g body weight of ketamine (Ketaset; Fort Dodge Laboratories, Inc., Fort Dodge, IA) at the end of each feeding period. Additional intramuscular injections of ketamine (10 mg) were used to maintain anesthesia. A polyethylene catheter (PE-10, 0.28 mm i.d., Clay Adams, Parsippany, NJ) was inserted into the femoral vein, and 0.9% saline was infused at a rate of 1.13 mL/h using a Harvard syringe pump (Harvard Apparatus, Millis, MA). After laparotomy, the cystic duct was ligated with a hemostatic clip and the common bile duct was cannulated using polyethylene tubing (PE-10). Saline infusion was maintained for two hours to deplete the endogenous bile acid pool. Sodium taurocholate (TC) (Sigma Chemical Co., St. Louis, MO) was then infused at increasing rates of 1 and 6 μmol/h/100 g body weight together with trace amounts of 24-^{14}C-labeled TC (Amersham Life Science, Arlington Heights, IL); each dose of TC was infused for two hours. In the six-week groups, TC infusion was increased up to 18 μmol/h/100 g body weight to evaluate a potential cholestatic effect of MeT on bile acid secretion. Bile samples were collected every 20 min in preweighed vials and stored at −20°C until analyzed. At the end of the experiment, the gallbladder was removed and examined for gallstones.

Analytical procedures. The presence of cholesterol gallstones and crystals in the gallbladder was confirmed by polarizing light microscopy (Olympus MCHAP microscope; Olympus Corp., Lake Success, NY). For measurement of the recovery of [^{14}C]TC, 10 μL of hepatic bile was counted in a Beckman LS 3801 liquid scintillation system (Beckman Instruments, Fullerton, CA) with automatic quench correction, using Aquasol-2 (NEN Research Products, Boston, MA) as the scintillation fluid. Bile volumes were determined gravimetrically, and the samples were divided into aliquots for analysis of the biliary lipids. Total bile acid concentration was measured enzymatically using a commercial kit (# 450-A; Sigma Chemical Co.); the bile acid composition was further analyzed by gas–liquid chromatography after preparation of the methyl ester acetate derivatives, as previously reported (10). The phospholipid concentration was determined enzymatically (Wako Pure Chemical Industries, Ltd., Osaka, Japan). The cholesterol concentration was measured by gas–liquid chromatography after formation of the trimethylsilylether derivative (11).

Calculations and statistics. The differences in the incidence of cholesterol gallstones and biliary cholesterol crystals were calculated by the Fisher exact test (12). Bile flow was expressed as microliters per minute per kilogram body weight; biliary lipid output was expressed as micromoles per minute per kilogram body weight. The basal bile flow and the biliary lipid output during depletion of the endogenous bile acid pool were calculated using the data of the 60–120 min period before TC infusion. We excluded the data of the initial 0–40 min, as bile flow and biliary lipid secretion were unstable during the first 40 min. The data are presented as the mean ± SD. The means were compared by analysis of variance to determine the F statistic. Student's t-test was then used for values for which the F statistic was significant ($P < 0.05$) (12). The relationships between bile flow and bile acid output, cholesterol output and bile acid output, phospholipid output and bile acid output, and cholesterol output and phospholipid output were analyzed by linear regression for the period of bile acid depletion and TC infusion (1 to 6 μmol/h/100 g body weight). The regression lines were plotted; the y-intercepts and slopes were calculated. The linkage coefficient (LKC) is defined as the slope of the regression line, that is, the increment in cholesterol or phospholipid output induced per increment of bile acid output, and the incremental ratio of cholesterol output to phospholipid output (13–15). Comparisons were made between the slopes and intercepts of the groups receiving the LD vs. LD + MeT (group 1 vs. group 2, group 3 vs. group 4) by using SAS/STAT software (version 6.10; SAS Institute Inc., Cary, NC) (16,17). The groups fed LD + MeT for three and six weeks were also compared (group 2 vs. group 4). A difference was considered significant at $P < 0.05$.

RESULTS

The hamsters gained weight and remained healthy during administration of the experimental diets. Table 1 summarizes the incidence of cholesterol gallstones and crystals at the end of three and six weeks. No stones were found in groups 1 and 3, which received the LD without MeT. The addition of MeT to the diet induced cholesterol gallstones: at the end of three weeks, two hamsters (13%) had gallstones and four hamsters (27%) had biliary cholesterol crystals (group 2), while at the end of six weeks, 13 hamsters (81%) had gallstones and crystals (group 4).

TABLE 1
Incidence of Cholesterol Gallstones and Cholesterol Crystals at Sacrifice[a]

Group	Diet	Feeding period (wk)	Cholesterol gallstones [no. of animals (%)]	Cholesterol crystals [no. of animals (%)]
1	LD	3	0/11 (0)	0/11 (0)
2	LD + MeT	3	2/15 (13)	4/15 (27)
3	LD	6	0/16 (0)	1/16 (6)
4	LD + MeT	6	13/16[b,c] (81)	13/16[b,c] (81)

[c]Differs from group 3; $P < 0.01$.

At the end of the feeding periods, surgery was performed to establish a biliary fistula and insert the femoral vein cannula. TC was infused i.v. at increasing doses after depletion of the endogenous bile acid pool. When the maximum dose (6 μmol/h/100 g body weight for the 3-wk groups and 18 μmol/h/100 g body weight for the 6-wk groups) was infused, the recovery of TC was 102.6 ± 4.5, 102.7 ± 6.8, 98.7 ± 6.6%, and 98.0 ± 19.6% for groups 1–4, respectively. There were no significant differences between the control group and the MeT group for both feeding periods. Figure 1 illustrates the time course of bile flow at the end of three weeks (A) and at the end of six weeks (B). Groups 2 and 4, which were fed LD + MeT, secreted less bile than the corresponding groups on LD (groups 1 and 3) during the 120-min bile acid depletion period. During TC infusion, there were no significant differences in bile flow between the control groups and the hormone-treated groups (group 1 vs. 2, group 3 vs. 4). The time course of biliary bile acid secretion in each group paralleled the rate of bile flow (data not shown). Figure 2 illustrates the time course of biliary cholesterol secretion. At the end of three weeks (Fig. 2A), the animals fed MeT (group 2) secreted more cholesterol during depletion of the bile acid pool; this difference ceased after TC infusion. At the end of six weeks (Fig. 2B), the MeT group (group 4) had a consistently higher cholesterol output than the control group (group 3) for the entire period.

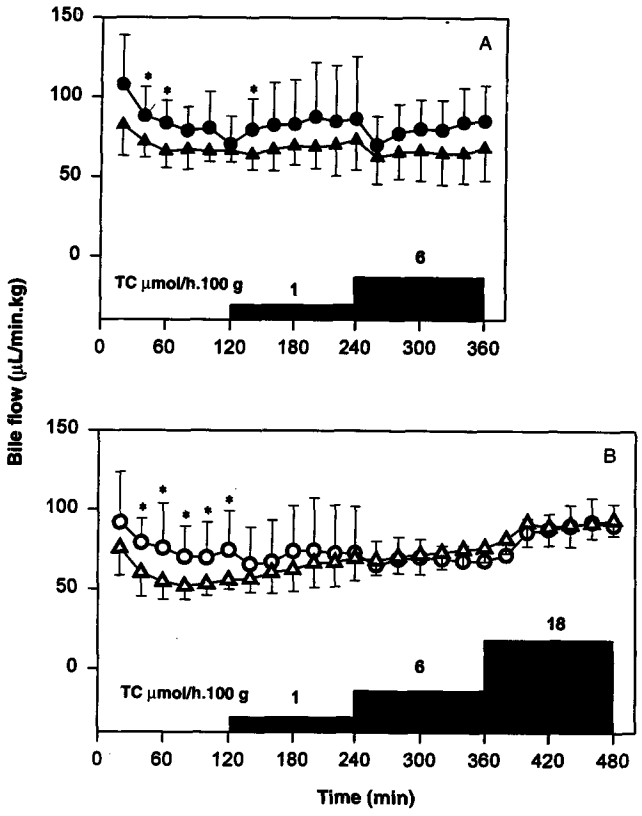

FIG. 1. Time course of bile flow during bile acid depletion and taurocholic acid (TC) infusion periods. A: group 1, lithogenic diet (LD) for three weeks (●) and group 2, LD + 0.05% methyltestosterone (MeT) for three weeks (▲). B: Group 3, LD for six weeks (○) and group 4, LD + 0.05% MeT for six weeks (△). Values represent the means ± SD. *Significant differences were determined by Student's *t*-test, $P < 0.05$.

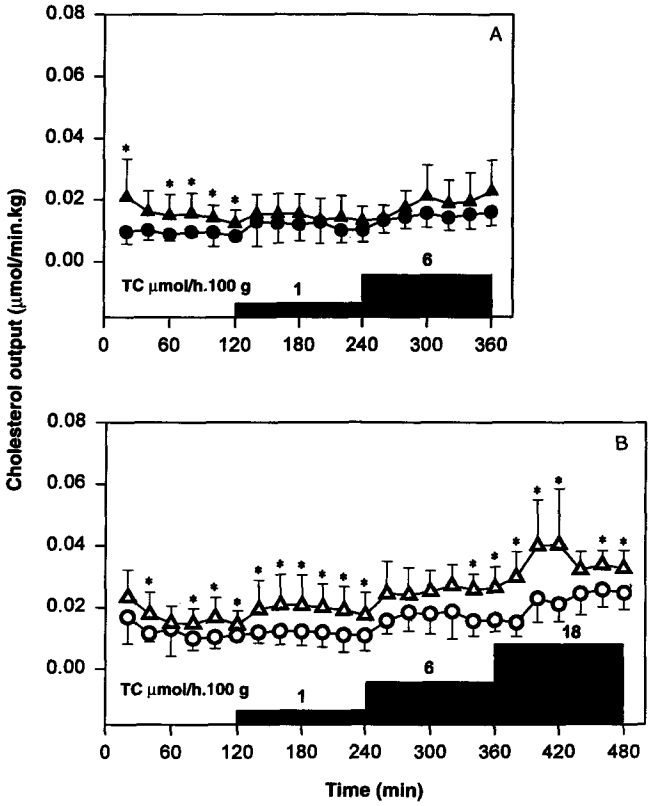

FIG. 2. Time course of cholesterol output during bile acid depletion and TC infusion periods. A: Group 1, LD for three weeks (●) and group 2, LD + 0.05% MeT for three weeks (▲). B: Group 3, LD for six weeks (○) and group 4, LD + 0.05% MeT for six weeks (△). Values represent the means ± SD. *Significant differences were determined by Student's *t*-test, $P < 0.05$. See Figure 1 for abbreviations.

Bile acid analysis of the hepatic bile before TC infusion showed that the administration of MeT altered the bile acid composition. The percentage of cholic acid (CA) in the MeT-fed groups was significantly lower than in the LD controls. At the end of three weeks, the percentage of CA was 50.5 ± 1.8% in group 1 and 40.6 ± 4.1% in group 2 ($P < 0.02$). At the end of six weeks, the percentage of CA was 43.8 ± 4.6% in group 3 and 29.1 ± 2.0% in group 4 ($P < 0.01$). As a result, the ratio of CA/chenodeoxycholic acid (CDCA) was lower in the bile of the MeT-treated animals (3.2 ± 1.0 vs. 1.4 ± 0.4, group 1 vs. group 2, $P < 0.05$; and 2.0 ± 0.6 vs. 0.8 ± 0.1, group 3 vs. group 4, $P < 0.01$). During TC infusion (at a rate of 6 μmol/h/100 g body weight), CA accounted for about 90% of biliary bile acids in all groups. The CA/CDCA ratio was 48.4, 26.2, 42.1, and 28.7 for groups 1–4, respectively.

Table 2 summarizes basal bile flow, biliary lipid output, and the ratio of cholesterol output to phospholipid output during depletion of the endogenous bile acid pool. The six weeks MeT-treated group (group 4) had the smallest bile flow. In the three weeks groups, basal bile flow of group 2 was less than group 1, but this difference was not statistically significant.

TABLE 2
Basal Biliary Lipid Secretion During Depletion of the Endogenous Bile Acid Pool[a]

Group number	Bile flow (μL/min/kg)	BA output (μmol/min/kg)	CH output (μmol/min/kg)	PL output (μmol/min/kg)	Ratio of CH output/PL output
1	78.4 ± 17.5	0.281 ± 0.083	0.009 ± 0.003	0.084 ± 0.068	0.291 ± 0.314
2	66.5 ± 9.1	0.194 ± 0.075[b]	0.014 ± 0.005[b]	0.120 ± 0.060[b]	0.133 ± 0.046
3	72.8 ± 23.0	0.287 ± 0.128	0.011 ± 0.005	0.096 ± 0.073	0.407 ± 0.466
4	54.1 ± 8.2[c,d]	0.171 ± 0.057[d]	0.015 ± 0.005[d]	0.055 ± 0.060[c,d]	0.956 ± 0.871[c,d]

[a]Data were used for the 60–120-min period before taurocholate infusion. See the Materials and Methods section for details of statistical analysis; BA, bile acid; CH, cholesterol; PL, phospholipid.

[c]Differs from group 2; $P < 0.01$.
[d]Differs from group 3; $P < 0.02$.

Basal bile acid output was significantly lower in the hormone-treated animals as compared to the control animals (group 2 vs. group 1, group 4 vs. group 3). In contrast, cholesterol secretion was significantly higher in the MeT-fed animals as compared to the control animals. Phospholipid output was variable in each animal; the MeT-treated animals showed an increase after three weeks, but a decrease at the end of six weeks. The ratio of cholesterol output to phospholipid output increased significantly at the end of six weeks in the MeT-treated hamsters (group 4 vs. group 3).

Table 3 summarizes the coefficients of the linear regression equations describing the relationships between bile flow and biliary lipid outputs. The effect of MeT on the relationship between bile flow and bile acid output is also shown in Figure 3. The *y*-intercept is defined as the bile acid independent bile flow, and the slope represents the bile acid dependent bile flow (μL/μmol of bile acid) (18). MeT appeared to decrease the bile acid dependent bile flow (slope) after three and six weeks, but these values were not statistically significant (Fig. 3, Table 3). In the MeT-fed animals, the bile acid independent bile flow (intercept) decreased after a longer feeding period (group 2 vs. group 4). There were no differences between intercepts of control groups and MeT groups (group 1 vs. group 2, group 3 vs. group 4). The relationship between cholesterol output and bile acid output was altered by MeT (Fig. 4, Table 3). At the end of three weeks, LD + MeT (group 2) caused a greater increment of cholesterol output per 1 μmol of bile acid output, (LKC, slope), than LD alone (group 1). After six weeks, the stimulatory effect of MeT on cholesterol output remained; the LKC of group 4 was higher than that of group 3. MeT feeding exerted a similar relationship for phospholipid output and bile acid output. The LKC of phospholipid output to bile acid output of groups 2 and 4 was higher than that of groups 1 and 3, respectively (Table 3). The LKC of cholesterol output to phospholipid output in group 2 was higher than that in group 1 and decreased after six weeks (group 4) (Table 3).

DISCUSSION

In previous studies, we observed a relationship between gender and stone formation in the hamster, but the mechanism by which this occurred was not clear (8,9). We postulated that a hormone produced changes in the secretion of one or more of the three biliary lipids. In the present study, we used the female hamsters fed LD with or without MeT in an attempt to elucidate the mechanism(s) involved. Bile acid infusion to replace the endogenous bile acids allowed us to probe for relationships between bile flow, cholesterol secretion, phospholipid secretion, and bile acid secretion. In humans (19,20), dogs (20), and rats (21,22), a hyperbolic relationship was reported between cholesterol output and bile acid output, and between phospholipid output and bile acid output. However, Gurantz and Hofmann (14) and Berr *et al.* (15) showed that in the hamster, under the conditions employed, these relationships appeared to be almost linear. In our study, the relationships between the secretion of the three biliary lipids were also compatible with linear functions; consequently, we ana-

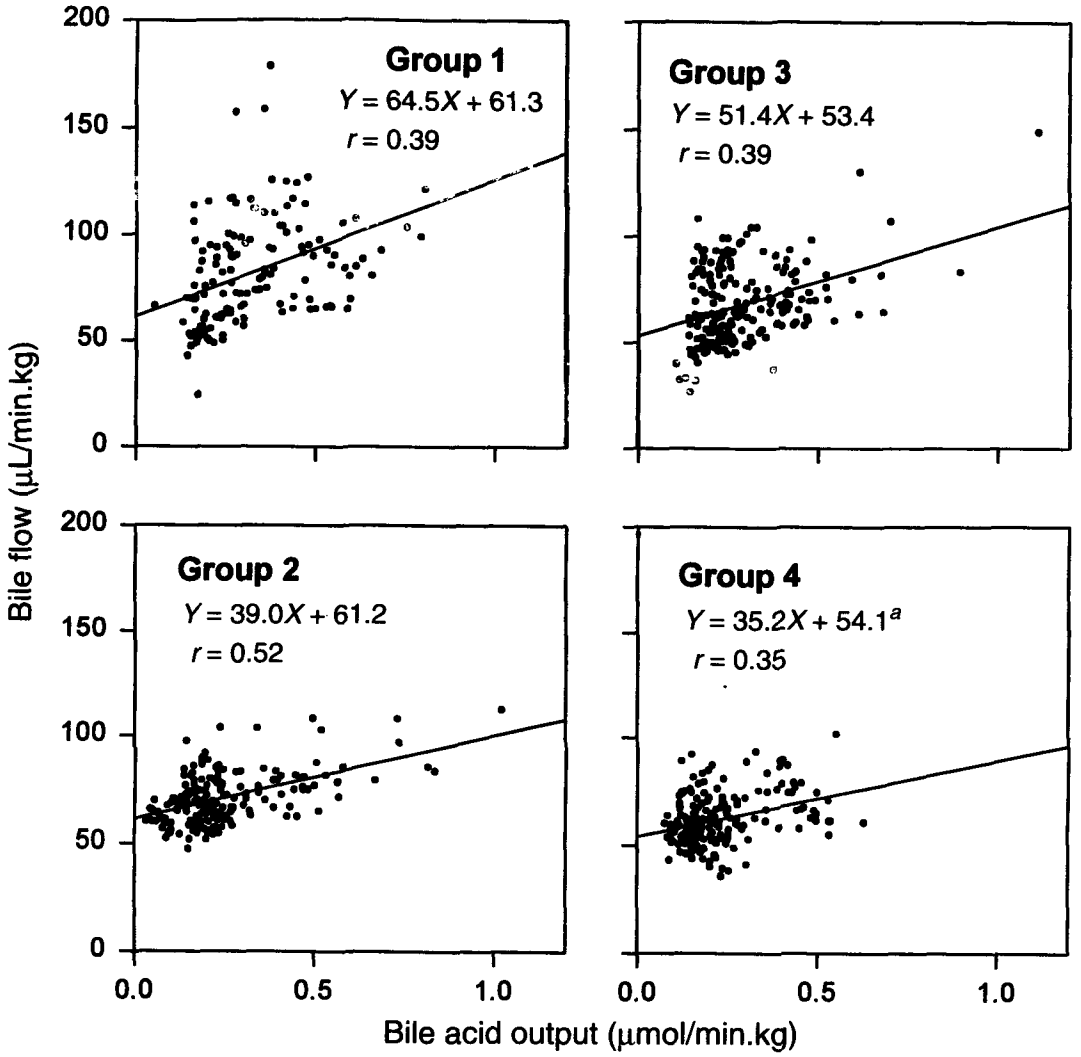

FIG. 3. Relationships between bile flow and bile acid output during bile acid depletion and TC infusion periods (1–6 µmol/h.100 g body weight). Group 1, LD for three weeks; group 2, LD + 0.05% MeT for three weeks; group 3, LD for six weeks; group 4, LD + 0.05% MeT for six weeks. Coefficients of the linear regression equations were compared among pertinent groups (group 1 vs. group 2, group 3 vs. group 4, and group 2 vs. group 4). [a]Differs from group 2; $P < 0.02$. See Figure 1 for abbreviations.

lyzed the relationships by linear regression (Figs. 3, 4; Table 3). Apparently, there are species differences in the mechanism of biliary lipid secretion.

We examined, for the first time, the effects of a synthetic androgen on bile flow and biliary lipid secretion. MeT reduced basal bile flow during depletion of the bile acid pool (Fig. 1; Table 2). However, this androgen did not inhibit the excretion of radiolabeled TC at the maximum rate of TC infusion (6 and 18 µmol/h/100 g body weight after 3 and 6 wk, respectively). There were no differences in the bile acid independent bile flow between control groups and MeT groups. These results showed that MeT was less cholestatic than certain estrogens; the latter have been reported to decrease bile acid independent bile flow (23–26). MeT seemed to decrease basal bile flow by reducing basal bile acid secretion. TC infusion restored bile acid secretion and bile flow in group 4 to the level of those of the control group (group 3) (Fig. 1). MeT might reduce the secretion of bile acids by decreasing bile acid synthesis, as it did not inhibit the recovery of labeled TC (greater than 98%). Davis *et al.* (27) showed that ethinylestradiol (EE) reduced the activity of cholesterol 7α-hydroxylase, the rate-limiting enzyme of bile acid synthesis, by increasing the viscosity of the microsomal membrane. Similar studies using androgens have not been reported.

MeT altered biliary lipid secretion. This hormone decreased the basal output of bile acids and increased cholesterol output (groups 2 and 4). The LKC of cholesterol output to bile acid output and phospholipid output to bile acid output increased in the hamsters fed MeT. These changes resulted in the production of lithogenic bile and formation of cholesterol gallstones. There are several possible explanations for the effects of MeT on biliary lipid secretion. First, changes in the

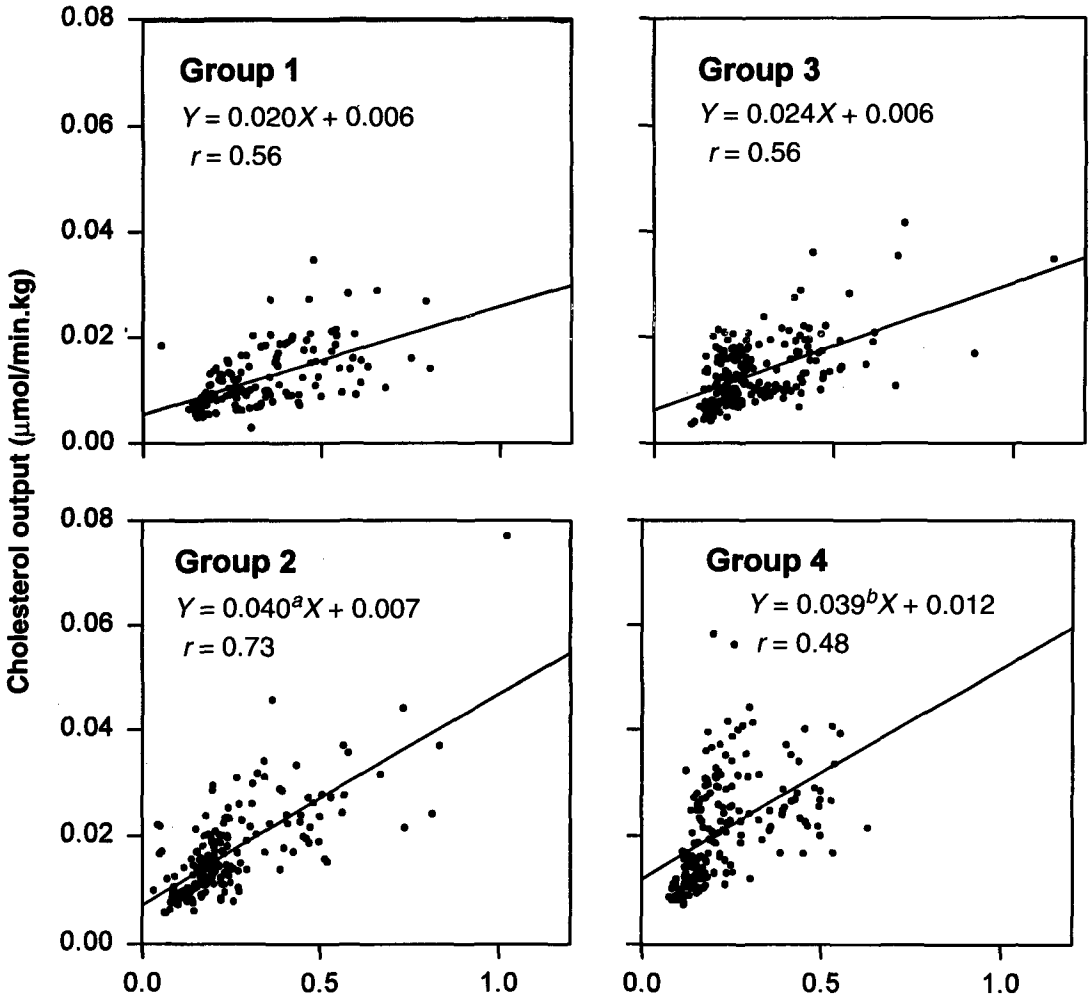

FIG. 4. Relationships between cholesterol output and bile acid output during bile acid depletion and TC infusion periods (1–6 μmol/h.100 g body weight). Group 1, LD for three weeks; group 2, LD + 0.05% MeT for three weeks; group 3, LD for six weeks; group 4, LD + 0.05% MeT for six weeks. Coefficients of linear regression were compared among pertinent groups (group 1 vs. group 2, group 3 vs. group 4, and group 2 vs. group 4). [a]Differs from group 1; $P < 0.025$, [b]differs from group 3; $P < 0.01$. See Figure 1 for abbreviations.

biliary bile acid composition by the hormone could alter the secretion of cholesterol and phospholipid in bile. MeT decreased the CA/CDCA ratio in bile. It was previously observed that there was a sex difference in bile acid composition in the hamster (8,9,28). It is possible that MeT inhibited 7α-hydroxy-4-cholesten-3-one 12α-hydroxylase, thus reducing the ratio of CA/CDCA. In hamsters, CDCA was found to be more effective in stimulating the secretion of biliary cholesterol than CA (14). The change in the CA/CDCA ratio could be partly responsible for the increase in cholesterol secretion in the female hamsters fed MeT. However, this interpretation may only partially explain the stimulatory effect of MeT on cholesterol secretion. Hamsters fed MeT secreted more cholesterol than the control groups, even during a high dose infusion of TC (when the proportion of CA in bile was 90% in both groups) (Fig. 2). Second, hormones have been shown to produce a change of cholesterol distribution in the hepatocyte which might lead to an increase in biliary cholesterol secretion. The female sex hormone, EE, increased membrane cholesterol, resulting in reduced membrane viscosity (24,25,29,30). Another female hormone, progesterone, inhibited acyl coenzyme A/cholesterol acyltransferase and increased free cholesterol in the biliary cholesterol precursor pool, resulting in an increased secretion of cholesterol (21,23,31). Presumably, MeT may have increased the amount of cholesterol in the canalicular membrane or altered the free cholesterol compartment of the biliary cholesterol precursor pool to induce high cholesterol secretion in bile. Third, MeT may directly affect a presently unknown mechanism of biliary lipid secretion. Berr *et al.* (15) reported that EE increased cholesterol and phospholipid secretion without increasing bile acid output or changing the bile acid composition, possibly by this unknown mechanism of cholesterol secretion.

It is postulated that cholesterol and phospholipid are secreted together in vesicular form into the canaliculi (32,33). In the present study, the LKC of cholesterol to bile acid and phospholipid to bile acid were higher in the LD + MeT groups than in the LD groups. The LKC of cholesterol to phospholipid was also higher on LD + MeT at the end of three weeks. MeT increased the ratio of cholesterol output to phospholipid output during basal secretion at six weeks. These data suggested that MeT stimulated a cosecretion mechanism with an increasing ratio of cholesterol to phospholipid. A similar effect was reported for EE, which increased the secretion of cholesterol and phospholipid at a constant cholesterol/phospholipid ratio (15).

In conclusion, the synthetic androgen, MeT, decreased basal bile flow and bile acid secretion, stimulated basal cholesterol secretion, and raised the ratio of cholesterol to phospholipid in the bile of female hamsters. These changes led to the formation of cholesterol gallstones. The mechanism of gallstone formation is complex; a variety of factors besides biliary lipids must be considered. It is possible that MeT affected gallbladder motility, mucin production, nucleating/antinucleating proteins, the structure of the gallbladder epithelium, and/or phospholipid transfer protein(s) (34–38). However, the detailed mechanism whereby MeT induces changes in biliary lipid metabolism is still unknown.

ACKNOWLEDGMENTS

We wish to acknowledge the help of Qiuhu Shi, Dr. Ilene Wilets, and Dr. Jose S. Victoria in carrying out the statistical analyses. This research was supported in part by USPHS grants R01 DK-43204 from the National Institute of Diabetes and Digestive and Kidney Disease (BIC), R37 HL-24061 from the National Heart, Lung, and Blood Institute (EHM), and a grant from the Hellman Fund.

Salivary Lipid Profiles of the Leech (*Hirudo medicinalis*)

Joseph L. Rabinowitz*

The Veterans Administration Hospital, and the Department of Biochemistry School of Dental Medicine, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT: Saliva was collected from sixteen leeches (*Hirudo medicinalis*). The saliva was analyzed for its total lipid content (3.26 ± 0.31 mg of total lipids per 100 mL saliva). The lipids were separated into polar and nonpolar by chromatographic techniques. The neutral fraction was approximately 2/3 of the total, and the polar fraction was approximately 1/3 of the total lipids. Thin-layer chromatography was used to obtain the individual profiles of the polar and nonpolar lipids. Of the identified lipids, phosphatidic acids and free fatty acids represented the largest percentage. These results suggest that the leech contains a unique lipid distribution, and that some of these components may be potent phospholipases and lipases that probably are present in its saliva for the purpose of preventing plugging or healing of the wound in the attacked organism.
Lipids 31, 887–888 (1996).

Although some nonlipid components of the saliva of leeches (*Hirudo medicinalis*) have been reported, no information is available concerning the lipid profile of this important medicinal species. It was felt that the lipid content and composition may yield information that may be helpful in explaining the anticoagulatory properties found in leeches. Many leech products are currently used and many more are being investigated (1,2).

MATERIALS AND METHODS

Sixteen leeches (*H. medicinalis*) were purchased from commercial sources, and the salivary fluid was obtained by established methods (3–10). All lipids or solutions containing lipids were kept under nitrogen at all times. When stored, lipids were kept under nitrogen at −20°C in the presence of approximately 5 μg of butylated hydroxytoluene per mg of lipid. Lipid standards and plates were purchased from Applied Sciences (State College, PA). Each batch of saliva was individually extracted five times, one hour each time (one extraction followed the others) with 4 mL of chloroform/methanol (2:1, vol/vol) at 0°C. One aliquot of this abstract was subjected to silicic acid column chromatography to separate phospholipid (by methanol elution) from neutral lipids (by chloroform elution). Individual lipid families were obtained from the separated neutral lipids and phospholipids by chromatography on thin-layer plates, and each was individually identified and assayed. Silica Gel-G glass plates with petroleum ether/ethyl ether/acetic acid (90:10:1, by vol) was used for the nonpolar lipids. Silica Gel-H with chloroform/methanol/acetic acid/water (200:120:25:15, by vol) was used for the polar lipids (3,4).

*Address correspondence at the Veterans Administration Hospital, 39th and Woodland Avenue, Philadelphia, PA, 19104.

RESULTS AND DISCUSSION

The results from the lipid profiles were obtained from 16 individual analyses of leeches (Table 1). The lipid composition is very different from that observed in other species, and may be unique for this invertebrate. The total lipid content observed was approximately 3 mg per 100 mL of saliva. This is about half of the total lipids found in the saliva of many vertebrates. Although most vertebrates show a high content of phosphatidylcholine (4–7), the content of lecithin in the leech was exceedingly small. The content of phosphatidylserine and phosphatidylinositol was small and very similar to that of most species. The large amounts of phosphatidic acids found

TABLE 1
Lipid Analysis of Leech Saliva (16 specimens)

Total lipids (mg/100 mL)	3.26 ± 0.31[a]
Percentage of total lipid	
Neutral lipids	66.67 ± 12.4
Polar lipids	33.33 ± 7.8
Neutral lipid families	
Mono- + diglycerides	4.97 ± 2.1
Cholesterol	9.25 ± 2.3
Free fatty acids	17.02 ± 3.7
Triglycerides	13.47 ± 3.5
Methyl esters	8.09 ± 4.7
Cholesterol esters	10.71 ± 5.9
Unidentified	8.16

may indicate that the saliva of the leech contains very active phospholipases. These results also suggest that the leech must have various powerful lipases that could help hydrolyze any clots formed after the leech has attached itself to the skin. This ability is essential so that the leech may be able to prevent coagulation that would stop the loss of blood flow from the attacked individual (11,12).

The percentage of other minor components (sphingomyelin, lysolecithin, cardiolipin, etc.) of the polar lipid group is within the range found in most other species. The total polar lipid amount as a percentage of the total lipid content is a little above that of most other species. Nonpolar lipids in the leech represent approximately 2/3 of the total lipid content, which is a smaller amount than that found in most species. The percentage of cholesterol and cholesterol esters found represent a very small amount of lipid compared to that found in human saliva. The amount of mono- and diglycerides represent almost 5% of the total lipids recovered. This is a value much higher than the percentage observed in the other species examined (5–9). This may occur due to high nonpolar lipase activity in the saliva of the leech, which would be understandable considering the high phospholipase activity that was also observed.

These results suggest that the saliva of the leech has a lipid profile that is compatible with and necessary for its functions. These functions permit the easy flow of blood and of other nutritional products from the attacked individual and may help prevent the closing of the wound or coagulation that would impede the flow of fluids to the leech (13–15).

ABSTRACT: The physiological role of long-chain fatty acyl-CoA is thought to be primarily in intermediary metabolism of fatty acids. However, recent data show that nM to μM levels of these lipophilic molecules are potent regulators of cell functions *in vitro*. Although long-chain fatty acyl-CoA are present at several hundred μM concentration in the cell, very little long-chain fatty acyl-CoA actually exists as free or unbound molecules, but rather is bound with high affinity to membrane lipids and/or proteins. Recently, there is growing awareness that cytosol contains nonenzymatic proteins also capable of binding long-chain fatty acyl-CoA with high affinity. Although the identity of the cytosolic long-chain fatty acyl-CoA binding protein(s) has been the subject of some controversy, there is growing evidence that several diverse nonenzymatic cytosolic proteins will bind long-chain fatty acyl-CoA. Not only does acyl-CoA binding protein specifically bind medium and long-chain fatty acyl-CoA (LCFA-CoA), but ubiquitous proteins with multiple ligand specificities such as the fatty acid binding proteins and sterol carrier protein-2 also bind LCFA-CoA with high affinity. The potential of these acyl-CoA binding proteins to influence the level of free LCFA-CoA and thereby the amount of LCFA-CoA bound to regulatory sites in proteins and enzymes is only now being examined in detail. The purpose of this article is to explore the identity, nature, function, and pathobiology of these fascinating newly discovered long-chain fatty acyl-CoA binding proteins. The relative contributions of these three different protein families to LCFA-CoA utilization and/or regulation of cellular activities are the focus of new directions in this field.
Lipids 31, 895–918 (1996).

HISTORICAL PERSPECTIVE

Long-chain fatty acyl-CoA (LCFA-CoA) are the CoA thioesters of fatty acids (Fig. 1A) and represent the "activated state" of fatty acids necessary for metabolism. Early studies of CoA derivatives of long-chain fatty acids focused on their function(s) as intermediates in fatty acid metabolism. More recent data suggesting potential roles of LCFA-CoA in cellular signalling and in gene regulation have rekindled interest in these established lipidic molecules. Despite this impor-

tance, very little is known regarding the intracellular trafficking, targeting, and presentation of LCFA-CoA to enzymes and DNA regulatory binding proteins. LCFA-CoA may move through the cytoplasm either spontaneously or by protein mediated intracellular movement. The latter mechanism is particularly appealing since it offers a means of specific intracellular targeting for LCFA-CoA. Nearly two decades ago it was reported that the cytosol contained LCFA-CoA binding activity, subsequently identified as fatty acid binding proteins (FABP) (1–5). However, the identity of FABP as being responsible for cytosolic LCFA-CoA binding has recently been questioned (6–8). What then is(are) the cytosolic LCFA-CoA binding protein(s) and what is(are) their physiological function(s)? Without attempting to be exhaustive, the remainder of this article is focused on examining the identity, tissue distribution, binding characteristics, function, molecular biology, structure, regulation, and pathobiology of the cytosolic, nonenzymatic, LCFA-CoA binding proteins.

THE LIGAND: LCFA-CoA

Tissue content and distribution of LCFA-CoA. LCFA-CoA are present in the cell in high amounts. Although the majority of studies quantitating LCFA-CoA have focused on liver, heart, and lung, significant amounts also have been found in brain, kidney, muscle, and adipose tissues (Table 1). The data have been difficult to compare, largely because LCFA-CoA levels have been reported in many different units. For example, liver concentration of LCFA-CoA has been expressed on the basis of tissue wet weight (15–83 nmol/g wet weight; with most values centered near 40 nmol/g wet weight), dry weight (94–219 nmol/per g dry weight), protein (108–248 nmol/g cell protein), and as μM (110–152 μM in liver cytosol). Heart LCFA-CoA levels are in the same range as those of liver (10–70 nmol/g wet weight; with most values centered near 50 nmol/g wet weight). Tissues such as lung, brain, and kidney have intermediate levels near 24–31 nmol/g wet weight. In contrast, muscle and adipose LCFA-CoA concentrations are up to 5- to 35-fold lower than liver or heart (Table 1). The high levels of LCFA-CoA in liver and heart are consistent with the role of these tissues in LCFA-CoA metabolism: glyceride and cholesteryl ester synthesis in the liver and fatty acid oxidation in the heart. Thus, it seems surprising that adipose tissue has extremely low levels of LCFA-CoA. This suggests that other factors (e.g., LCFA-CoA thiolase, acyl transferase enzyme activity, LCFA-CoA binding proteins) must play a role in determining tissue LCFA-CoA content.

TABLE 1
Tissue Long-Chain Fatty Acyl-CoA Content

Tissue	Content	Units	Reference

Compartmentalization of LCFA-CoA. In most tissues LCFA-CoA is generally present in highest concentration in mitochondria and microsomes (Table 2). This would be expected due to the presence of enzymes involved in β-oxidation and fatty acid synthesis in these locations. In contrast, cytosolic LCFA-CoA levels may be relatively low or undetectable. For example, two studies reported that LCFA-CoA were not detected in cytosol of rat liver and rat heart (9,10). In contrast, LCFA-CoA content of rat lung homogenate, microsomes, and cytosol was 16.8 ± 7.6, 14.4 ± 7.9, and 2.3 ± 0.3 nmol/mg protein, respectively (11). Furthermore, assuming that about 20% of cellular protein is cytosolic, then only 2.7% of lung LCFA-CoA is cytosolic. In contrast, a similar calculation for lung alveolar type II cells (11) reveals that in these cells about 21% of cellular LCFA-CoA is cytosolic. Other reports also indicate that cytosolic LCFA-CoA content may be substantial. For example, if one assumes that cytosol represents about 20% of cell protein, two reports (12,13) indicate that about 17 and 60% of LCFA-CoA may be cytosolic in rat liver and heart, respectively (Table 2). The reasons for the discrepancies between these reports on the low or absence vs. significant levels of LCFA-CoA in liver and heart cytosol are not known.

The subcellular distribution of LCFA-CoA can be modulated by the oxygenation state of the tissue. For example, hypoxia resulted in a 4.5-fold increase in LCFA-CoA levels of rat heart cytosol (13). Concomitantly, hypoxia increased

TABLE 2

LCFA-CoA levels 6- to 7-fold in rat heart and liver mitochondria (10).

Effect of drugs and disease on tissue LCFA-CoA. The level of LCFA-CoA in the cell is not a constant parameter but is highly dependent on a number of other factors. LCFA-CoA levels are modulated over a 20-fold range by nutrition, drugs, oxygenation, and endocrine status, resulting in increased LCFA-CoA levels severalfold in liver and/or heart (Table 3). For example, administration of long-chain fatty acids such as palmitate and drugs such as peroxisome proliferators doubled liver LCFA-CoA content (14). Starvation increased liver LCFA-CoA content nearly 4-fold (15–17). Furthermore, ischemia and hypoxia increased heart LCFA-CoA levels up to 1.6- to 3.1-fold (10). In contrast, valproate induced hepatotoxicity decreased liver LCFA-CoA content nearly 5-fold (18) (Table 3).

Function of LCFA-CoA. LCFA-CoA have long been recognized as being important intermediates in the *de novo* biosynthesis of fatty acids (endoplasmic reticulum) as well as fatty acid oxidation (mitochondria and peroxisome), membrane biogenesis (phospholipids), and lipid storage (triglycerides and cholesteryl esters) of exogenously derived fatty acids in the cell (Table 4). Equally important, LCFA-CoA feedback inhibit several enzymes in fatty acid synthesis and metabolism [e.g., fatty acid synthetase and acyl CoA synthetase (19–23)]. In view of the importance of these lipids in atherosclerosis, diabetes, and other lipid disorders alone, LCFA-CoA occupy an important place in biology.

Less well understood is the role of fatty acyl-CoA as regulatory molecules in signaling pathways. For example, LCFA-CoA modulate neutrophil superoxide generation (24), intracellular Ca^{++} (25), glucose-stimulated insulin release (26), protein acylation (27–29), and protein phosphorylation (30,31) (Table 4). Equally important, exciting recent reports from bacterial systems indicate that LCFA-CoA have additional roles in regulating gene transcription (33,34) (Table 4).

Mechanism of LCFA-CoA modulation of protein function. Despite the demonstrated impacts on regulation of cellular function *in vitro*, there has been some concern that regulatory effects of LCFA-CoA may be based on nonspecific and artifactual detergent activity of these highly surface-active molecules (35). Some support for this concern comes from early studies that used dye-binding techniques to measure the critical micellar concentration of LCFA-CoA, near 3–4 μM (reviewed in Ref. 35). If this technique correctly measures the LCFA-CoA critical micellar concentration, then one must conclude that in the 100–150 μM range of cellular LCFA-CoA concentrations, these molecules could form micellar structures. Such micelles could act as potent detergents to disrupt the structure of membrane lipids and/or to directly solubilize/disrupt protein structure (reviewed in Ref. 35). This would elicit potent deleterious effects on membrane-bound or soluble proteins and enzymatic processes (reviewed in Ref. 35). However, three sets of evidence are inconsistent with the above conclusion.

First, the dye-binding techniques used to measure the critical micellar concentrations for LCFA-CoA yield critical micellar concentrations that are several orders of magnitude too low. A wide variety of more recent studies with fluorescence, spin-label, ultrastructural, and gel permeation techniques showed that the critical micelle concentration of LCFA-CoA was two orders of magnitude higher, between 60–200 μM (reviewed in Ref. 35), than obtained with the dye-binding technique. Thus, under normal physiological conditions, adipose, muscle, kidney, brain, and lung tissue levels of total cellular LCFA-CoA (about 2–70 μM) are considerably less than the LCFA-CoA micellar concentration range (Table 1). Although the proportion of cytosolic LCFA-CoA in most of these tis-

sues is unknown, lung has only about 3% of its LCFA-CoA in the cytosol. Likewise, although liver or heart LCFA-CoA concentrations are about 70–210 μM (Table 1), generally less than one-fifth of this LCFA-CoA is cytosolic (Table 2). These considerations indicate that cytosolic LCFA-CoA concentrations in a variety of tissues are in the range of 0 to 42 μM, clearly below the critical micellar concentration of LCFA-CoA.

More importantly, under a variety of conditions [starvation, diabetes, peroxisome proliferators, fatty acid feeding, ischemia, hypoxia (Table 3); pathological conditions (see last section of this article)], liver and heart LCFA-CoA levels are as much as 4-fold higher and well above the range of LCFA-CoA critical micellar concentration in most tissues reported. Unless substantial quantities of LCFA-CoA are specifically bound by cytosolic LCFA-CoA binding proteins or nonspecifically bound by membrane lipids, these levels of LCFA-CoA would be toxic due to nonspecific binding to and subsequent inhibition of enzymes vital to cell function.

In addition, the intracellular level of free (not bound to protein or membranes) LCFA-CoA levels in the cell is much lower because of intracellular binding by membrane lipids and binding to cytosolic long chain acyl CoA binding proteins. LCFA-CoA will partition between membrane phospholipids and cytosolic proteins, depending on their respective relative affinities and capacities for LCFA-CoA binding. Since phospholipid membranes can bind up to 15 mol% LCFA-CoA without disruption, they have a large capacity for binding the levels of LCFA-CoA found in cells (36,37). In addition, liver cytosolic lipid binding proteins bind about 450 nmole/g cytosolic protein. Liver LCFA-CoA levels are 108–248 nmole/g total protein in fed and fasted rats (39). If one takes 20% of cellular LCFA-CoA to be cytosolic and assumes that cytosolic protein accounts for about 20% of cellular protein, one can estimate that about 5–10% of the available cytosolic protein LCFA-CoA binding sites are normally occupied by LCFA-CoA. This estimate is in agreement with one recent study reporting the LCFA-CoA pool sizes in lung type II cells (11): whole cells, 31 ± 11; microsomes, 93 ± 8; cytosol, 33 ± 6 nmol/mg protein (11). Thus, even if the cytosolic LCFA-CoA content increases 4–5-fold as in ischemia (Table 3), the available cytosolic protein LCFA-CoA binding sites would still not be saturated with LCFA-CoA.

The remaining noncytosolic LCFA-CoA appears bound to membrane lipids and/or proteins. The LCFA-CoA acyl chain composition of cytosolic and microsomal fractions of the lung type II cells was identical, with 16:0 (49–54%), 18:0 (20–21%), and 18:1 (14–16%) acyl CoA predominating (11). This would suggest that the membranes and cytosolic LCFA-CoA binding proteins (as a group) display similar affinity profiles for a variety of LCFA-CoA. However, other data obtained with individual purified LCFA-CoA (see below) indicate that significant differences in LCFA-CoA acyl chain preferences may exist.

Since the membrane lipids provide a huge reservoir of additional nonspecific LCFA-CoA binding sites, it is likely that there exists very little cytosolic free-unbound LCFA-CoA. The above observations certainly are consistent with this prediction. The following calculation provides an estimate of the free-unbound cytosolic LCFA-CoA. Since cytosolic proteins represent about 20% of total cell protein, the above data may be used to estimate that 74% of LCFA-CoA is bound nonspecifically to membranes as compared to 20% in cytosol [free + cytosolic protein bound]. Because liver has 108–248 nmol LCFA-CoA/g protein and if 20% is cytosolic, then 22–50 nmol LCFA-CoA/g cytosolic protein is present in cytosol. Cytosolic long-chain fatty acyl-CoA binding proteins specifically bind up to 446 nmol LCFA-CoA/g cytosolic protein in liver, therefore exceeding the LCFA-CoA concentration by 9- to 20-fold. Since the K_d of the LCFA-CoA binding proteins are in the 0.08–10 μM range (see Table 8 below), cytosolic LCFA-CoA are probably 95% bound to the LCFA-CoA binding proteins. The level of cytosolic free-unbound LCFA-CoA is estimated to be in the range 1–4 μM, based on the above calculations. However, depending on the tissue type, this level of free-unbound LCFA-CoA would depend on the type, quantity, and relative affinities of the cytosolic LCFA-CoA protein(s) present.

Finally, the level of LCFA-CoA necessary to modulate the function of enzymes and functions *in vitro* (Table 4) are generally 0.5–10 μM. Clearly, these levels are not only below the critical micellar range of 60–200 μM, but they are in the estimated range of cytosolic free-unbound LCFA-CoA near 1–4 μM (see above). It should be noted that enzymes such as mitochondrial ATP/ADP translocase (ANT) and acetyl CoA carboxylase (ACC) are both inhibited by nanomolar concentrations of fatty acyl CoA (22,23,40). Likewise, inhibition of transcription factor proteins (e.g., FadR) occurs at low concentration, 12 nM (33,34). Furthermore, the effects of LCFA-CoA appear to be specific since they are not observed upon addition of short-chain acyl-CoA (33,34). Thus, not only the cytosolic levels of free-unbound LCFA-CoA, but also their subcellular distribution (peroxisomes, mitochondria, nucleus, cytosol), are important in the regulation of cellular function. In summary, the levels of free-unbound LCFA-CoA eliciting regulatory effects are 3–4 orders of magnitude lower than the critical micellar concentration. They are, however, in the range potentially influenced by the cytosolic LCFA-CoA binding proteins.

IDENTITY AND TISSUE DISTRIBUTION OF MAMMALIAN LCFA-CoA BINDING PROTEINS

Although albumin binds LCFA-CoA and is found in liver (37), it is primarily an extracellular serum protein and will not be considered further here. At least three different types of cytosolic LCFA-CoA binding proteins have been discovered: FABP, acyl CoA binding protein (ACBP), and sterol carrier protein-2 (SCP-2) (Table 5).

Cytosolic FABP. Perhaps the first intracellular proteins recognized as fatty acyl CoA binding proteins were the cytosolic FABP from liver and heart (2–5,41,42) (Table 5). Seventeen

TABLE 5
Cytosolic Fatty Acyl-CoA Binding Protein Families

Family	Protein	Acronym[a]
Fatty acid binding protein	Liver fatty acid binding protein	L-FABP
	Heart fatty acid binding protein	H-FABP
	Intestinal fatty acid binding protein	I-FABP
	Brain fatty acid binding protein	B-FABP
	Adipocyte lipid binding protein	ALBP
Acyl-CoA binding protein	Acyl-CoA binding protein	ACBP
Sterol carrier protein-2	Sterol carrier protein-2	SCP-2
	Nonspecific lipid transfer protein	nsLTP
	Sterol carrier protein-x	SCP-x

[a]FABP, fatty acid binding protein (L-, liver; H-, heart; I, intestinal; B, brain); ALBP, adipocyte lipid binding protein; ACBP, acyl-CoA binding protein; SCP-2, sterol carrier protein-2 (13-2 kDa); SCP-x, sterol carrier protein-x (58 kDa).

members of this intracellular FABP family have been identified (42,43). The FABP are 14–16 kDa clam-shaped proteins present in high concentration in the cell (2–5% of cytosolic protein), and their properties are reviewed in References 42–45. Within the cell, FABP are primarily cytosolic, with highest concentrations near the endoplasmic reticulum and lower levels localized in mitochondria and nucleus (46,47). Although the individual FABP appear unique in regard to sequence and antigenic specificity, their ligand specificities are generally broad and overlapping and include fatty acids, lysophosphatidic acid, prostaglandins, cholesterol (in some cases), bile acids, azo dyes, carcinogens, etc. (reviewed in Refs. 44,45,48). Twenty years ago, the first FABP shown to bind LCFA-CoA was the native L-FABP isolated from rat liver (1,2,4). This observation was later followed by reports that native heart FABP (H-FABP) (3,5,44), native adipocyte lipid binding protein (ADLP) (42), recombinant intestinal-FABP (I-FABP; Jolly, C., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication), brain recombinant brain-fatty acid binding protein (B-FABP) (49), and brain recombinant H-FABP (49) also bound LCFA-CoA (Table 5). However, the results from LCFA-CoA binding studies obtained with native FABP isolated from liver, heart, and adipose tissues were recently questioned (7) when a new LCFA-CoA binding protein, acyl-CoA binding protein (ACBP), was isolated from the liver (6). It was suggested that early preparations of FABP isolated from native tissues did not resolve low molecular weight proteins such as ACBP. Thus, it seemed possible that ACBP co-purifying with the native FABP might account for the LCFA-CoA binding properties of these preparations (7). This dilemma was resolved by the use of recombinant liver-FABP (L-FABP) (41). Bacteria do not contain acyl-CoA binding protein (ACBP), and therefore this mammalian protein cannot be a cross contaminant in recombinant L-FABP preparations. Furthermore, when the recombinant L-FABP was subjected to Tricine (Fisher, Pittsburgh, PA) SDS–polyacrylamide gel electrophoresis capable of resolving 10 kDa ACBP from 14 kDa L-FABP, no bands were detected at 10 kDa. Finally, several assays including a modified Lipidex 1000 (Sigma, St. Louis, MO) assay (41), a fluorescent *cis*-parinaroyl CoA binding assay (41), *cis*- and *trans*-parinaroyl CoA lifetime, limiting anisotropy, and rotations (Frolov, A., and Schroeder, F., submitted for publication), and L-FABP intrinsic tyrosine fluorescence (Jolly, C.A., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication) clearly demonstrated LCFA-CoA interaction with recombinant L-FABP.

ACBP. The second LCFA-CoA binding protein family has been the subject of considerable interest and controversy. Thus far, only one member of this family has been reported, but with two very different designations and/or potential functions. It was first discovered in 1983 in the brain and designated as a diazepam binding inhibitor (DBI) protein (50). Initially DBI was thought to function as a potential neurotransmitter which displaced benzodiazepines from GABA receptors in the central nervous system (50,51). It is identical in amino acid and cDNA sequence to ACBP, isolated from bovine liver three years later (6,52). Although this LCFA-CoA binding protein is variously designated as ACBP, DBI, or ACBP/DBI for simplicity's sake, only the ACBP designation will be used in this review. ACBP is a highly conserved protein found in a wide range of animals including yeasts, insects (tobacco hornworm, Drosophila), frogs, trout, tortoise, birds, and mammals (rat, mouse, rabbit, dog, pig, cow, and human) as well as plants (6,19,51,53–66). ACBP has been identified in all mammalian tissues tested to date (19,51,53, 67–77).

ACBP is primarily a cytosolic protein that appears localized in highest concentrations in specialized cells. Immunohistochemistry has been used to resolve ACBP localization in tissues. ACBP is immunodetected primarily in cells having secretory function such as hepatocytes, steroid producing cells of the adrenal cortex and testis, cells in islets of the pancreas, tubular epithelial cells of the kidney, small intestinal epithelial cells, bronchiolar epithelial cells, etc. (70,71). In the brain, ACBP has been localized primarily to ependymal and glial cells, with low levels in neurons in some species (78–81). However, within the neuron ACBP appears to be

[a]Reference 51. See Table 5 for abbreviation. [b]Reference 68. [c]Reference 19. [d]nmol/g wet weight (Ref. 146). [e]408 nmol/g liver protein (Ref. 19). [f]nmol/g wet weight (Ref. 51).

concentrated in the synaptosomal nerve ending (82). Mouse brain synaptosomal cytosol ACBP concentration is high at 3.1 μg/mg (0.31 nmol/mg) cytosolic protein (82). This level observed in neuronal nerve endings (synaptosomes) is as high as that reported for liver or intestine, organs with highest reported levels of ACBP (Table 6). These observations with neurons and nerve endings suggest that, although ACBP is primarily cytosolic, its distribution within the cytosol may not necessarily be uniform.

Sterol carrier protein-2 (SCP-2). The third long-chain fatty acyl-CoA binding protein, SCP-2, is the newest member of the LCFA-CoA binding proteins (Frolov, A., Cho, T.-Y., Billheimer, J.T., and Schroeder, F., submitted for publication) (Table 5). Tissue levels of SCP-2 are in the range of 0.01 to 0.10% of cytosolic protein (83–85). SCP-2 is alternately known as nonspecific lipid transfer protein, nsLTP, a designation based on its broad ligand specificity for phospholipids (85), glycolipids (84), cholesterol (86), fatty acids (87), and fatty acyl-CoA (see below) (Frolov, A., Cho, T.-Y., Billheimer, J.T., and Schroeder, F., submitted for publication). Two immunodetectable SCP-2 forms have been demonstrated with the 13.2 kDa SCP-2 generally being present in 10-fold greater amount than the 58 kDa SCP-x. More importantly, the subcellular distribution of these SCP-2 forms differs dramatically. The 13.2 kDa SCP-2 protein is present in cytosol, mitochondria, peroxisomes, and near endoplasmic reticulum, while the 58 kDa SCP-x form is localized exclusively in peroxisomes (88).

Relative concentrations of FABP, acyl-CoA binding protein, and SCP-2 within tissues. The data provided in the above sections allow direct comparisons of the relative concentrations of the three LCFA-CoA binding protein families in a variety of tissues. For example, L-FABP levels are generally in the range of 3–5% of cytosol protein (2.2–3.6 nmol/mg cytosol protein) (3,44). Liver ACBP levels are found in the range from 0.06 to 0.64 nmol/mg cytosol protein (on average about 0.33 nmol/mg cytosol protein) (19,68). Liver levels of SCP-2 are about 0.10% of cytosolic protein (0.07 nmol/mg cytosol protein) (83–85). Thus, the overall pattern of the relative molar ratio of these proteins (L-FABP/ACBP/SCP-2) reported in liver cytosol appears to be approximately 40:5:1. These ratios are also reflected in some tissues high in all three proteins, i.e., intestine, but not in many other tissues such as brain. In mouse brain, the relative molar ratio of FABP/ACBP/SCP-2 calculated from reported values (49,82) is approximately 3:1:1, very different from that observed in liver. Taken together with their somewhat different subcellular distributions (see above), this would suggest that the relative importance of FABP, ACBP, and SCP-2 in LCFA-CoA metabolism and/or regulation of cellular function may be highly dependent on the specific tissue and cell type within that tissue.

MOLECULAR BIOLOGY OF CYTOSOLIC LCFA-CoA BINDING PROTEINS

As shown in Table 5, the cytosolic LCFA-CoA binding proteins belong to at least three different families. Within a specific family there is considerable amino acid and cDNA sequence homology/identity. In contrast, there is very little if any identity/homology in amino acid or cDNA sequence between FABP (reviewed in Refs. 44,45), acyl-CoA binding proteins (reviewed in Refs. 19,54–60), and SCP-2 (reviewed in Refs. 90,91).

Cytosolic FABP. The molecular biology of the FABP family has been extensively reviewed previously (42–45) and will not be reiterated here. Suffice it to say that nearly half of the reported seventeen members of this family have been cloned and sequenced with their amino acid sequence homology within a species ranging from 18–67% (reviewed in Ref. 43). Sequence homology of a given FABP among several species is, of course, considerably greater. Exons III and IV are thought to be related to the differences in ligand specificities between members of the protein family or to targeting of specific enzymes or membranes with which they interact.

ACBP. In contrast to the FABP family, a single gene appears to code for a single protein, ACBP, which appears to be present in all tissues tested. Comparisons of the ACBP amino acid sequence of different organisms shows high sequence homology with most observed differences represented by conservative changes (58,92). The ACBP gene, comprised of four exons and three introns, has been cloned and characterized in the rat (60,65), human (93), duck (58), and yeast (59). The rat ACBP has one expressed gene, localized on chromosome 2, and four processed pseudogenes. ACBP gene transcription is initiated at two major and multiple minor initiation sites. The promoter region displays several potential tissue-specific *cis*-acting elements that may regulate the level of tissue-dependent ACBP expression. Alternative RNA splicing in the ACBP gene is not observed. The ACBP gene shows characteristics of a typical housekeeping gene (60,65).

SCP-2. The SCP-2 proteins of rat, mouse, human, and chicken have been cloned and sequenced (reviewed in Refs. 84,94,95). The chicken SCP-2 is 88% identical to its mammalian homologs, consistent with a high degree of evolutionary conservation (94). SCP-2 cloned from a mouse brain library is 99.9% identical in cDNA and amino acid sequence to SCP-2 cloned from a liver cDNA library, indicating that a single gene encodes for SCP-2 (82). The SCP-2 gene is located on human chromosome 1p32 and consists of 15 exons and 15 introns (95). Multiple transcription start sites have been identified. The presence of two unique initiation sites and a leader sequence (post-translationally cleaved) in the SCP-2 gene results in the expression of two proteins of different molecular weight, 15 kDa (pro-SCP-2) and 58 kDa (SCP-x) (90,91). Alternative RNA splicing in the SCP-2 gene has been suggested to give rise to a 29 kDa SCP-2 (96). This suggestion appears consistent with Western blots of liver cytosol showing cross reactivity of anti-SCP-2 with a protein near 29 kDa. However, work from our laboratory in which the 29 kDa protein was isolated from rat liver indicated no similarity to SCP-2 or the putative 29 kDa SCP-2 suggested to arise by alternative RNA splicing (Pu, L., and Schroeder, F., manuscript in preparation). Likewise, higher molecular weight proteins cross reactive with anti-SCP-2 have also been revealed by Western blots of yeast (97), but these proteins either did not function in lipid transfer (97) or, when isolated and/or cloned, were unrelated to SCP-2 or the putative 29 kDa SCP-2 suggested to arise by alternative RNA splicing (Tahotna, D., Ossendorp, B., Schroeder, F., Daum, G., and Hapala, I., manuscript in preparation). Thus, it would seem that the SCP-2 gene codes only for two transcripts transcribed as 58 kDa SCP-x and 15 kDa pro-SCP-2. The 15 kDa pro-SCP-2 is rarely detected in tissues because its presequence is rapidly post-translationally cleaved to yield the 13.2 kDa SCP-2 protein (90,91). The 58 kDa SCP-x and 13.2 kDa SCP-2 proteins share a common 13.2 kDa C-terminus. The 13.2 kDa SCP-2 is reported localized to cytosol, mitochondria, peroxisomes, and near endoplasmic reticulum while the 58 kDa SCP-x is found exclusively in peroxisomes (88).

REGULATION OF THE LCFA-CoA BINDING PROTEINS

Cytosolic FABP. The influence of physiological conditions, nutrition, development, sex, diurnal rhythm, and drugs on FABP expression has been reviewed previously and will not be reiterated here (44,98–104). Suffice it to say that under these conditions, FABP levels range from up to 6-fold decreases to 3-fold increases, depending on the type of FABP and tissue examined.

ACBP. The influence of nutrition on ACBP levels has been examined in rat liver, kidney, and heart. In one study, fasting for 24 to 48 h resulted in elevation of long-chain acyl-CoA esters, decreased liver ACBP mRNA levels, and no significant change in ACBP protein levels measured by an ELISA assay (105). In a second study, ACBP tissue levels, especially in liver, responded acutely to changes in diet (106). Fasting for 24 to 48 h resulted in decreased liver ACBP levels (from 66.5 ± 13.1 to 39.5 ± 6.2 pg/ng DNA) but had no effect on kidney and heart levels. Feeding of a high-fat diet resulted in an approximately 1.5- to 2-fold increase in liver ACBP levels by 48 h and levels remained elevated as long as the high-fat diet was fed. Kidney and heart showed a mild increase in ACBP levels after prolonged feeding of the high-fat diet (by 7 and 28 d, respectively) (106).

Like FABP, ACBP is regulated by peroxisome proliferators. Several peroxisome proliferators have been shown to induce increased expression of rat hepatic ACBP RNA and protein levels approximately 1.5- to 2-fold within 24 to 48 h of exposure *in vitro* and ACBP protein levels by seven days *in vivo* (105,107). *In vivo*, ACBP mRNA and protein levels increased in a time- and dose-dependent fashion. ACBP mRNA increased by 24 h post exposure and protein levels increased 1.5- to 1.7-fold by 3–14 d of exposure (14). The induction of long-chain acyl-CoA hydrolase activity increased in parallel to the ACBP increase and may be due to peroxisome proliferator induced sustained accumulation of total long-chain acyl CoA esters (14).

L-FABP and I-FABP stimulate the formation of glycerides from LCFA-CoA, while neither L-FABP nor I-FABP (intestinal FABP) stimulates formation of LCFA-CoA by LCFA-CoA synthase (41; Jolly, C.A., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication). I-FABP expression in transfected CaCo-2 cells decreased L-FABP expression (89). Therefore it seems possible that cellular L-FABP and/or I-FABP levels could modulate the expression of ACBP. The effect of L-FABP and I-FABP levels on expression of ACBP was examined in transfected L-cell fibroblasts. L-cells transfected with either L-FABP or I-FABP differentially affect the uptake of fatty acids and the synthesis of phospholipids vs. triglycerides (108). However, neither L-FABP nor I-FABP expression affected the expression of ACBP in L-cells (Fig. 2): untransfected L-cells, LM-cells (derived from L-cells), transfected L-cells with 0.4% of cytosol protein as L-FABP, and transfected L-cells expressing about 0.35% of cytosol protein as I-FABP were 0.83 ± 0.15, 0.72 ±

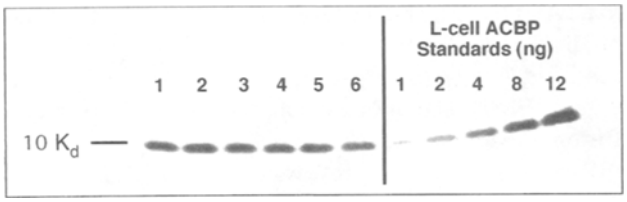

FIG. 2. Acyl-CoA binding protein (ACBP) levels in transfected L-cell fibroblasts expressing other long-chain fatty acyl-CoA binding proteins. The derivation of liver fatty acid binding protein (L-FABP) (151,229), intestinal-FABP (I-FABP) (108), and sterol carrier protein-2 (SCP-2) (126) expressing cell lines, SDS–polyacrylamide gel electrophoresis, and Western blotting procedures are described therein. Immunoblotting was performed with rabbit anti-L-cell ACBP polyclonal primary antibody; biotinylated goat anti-rabbit IgG as secondary antibody; avidin biotin-alkaline phosphatase, and visualization with Vector black substrate (Vector, Burlingame, CA). Blots were photographed with an IS-500 computerized gel documentation system (Alpha-Innotech, San Leandro, CA). From each image, protein bands of cell samples in each lane were quantitated by comparing to known amounts of ACBP protein standards loaded on the same blot using the public domain program, NIH Image V.I.G. (written by Wayne Rasband and is available by anonymous FTP from zippy.nimh.nih.gov.) on a Power MacIntosh 8100/80AV computer (Apple Corp., Cupertino, CA). ACBP protein was expressed as ng/μg sample. The amount of ACBP in the six cell lines analyzed was not significantly different ($P > 0.05$) and ranged from 0.50 to 0.83 ng/μg protein. A representative immunoblot is shown. Lanes 1–6 were loaded with 10 μg protein of cell homogenate while lanes 7–11 were loaded with 1, 2, 4, 8, and 12 ng of purified L-cell ACBP. Lane 1, untransfected L-cells. Lane 2, untransfected LM cells (a cell line derived from L-cells). Lane 3, transfected L-cells expressing 0.4% of cytosolic protein as L-FABP. Lane 4, transfected L-cells expressing 0.35% of cytosolic protein as I-FABP. Lane 5, transfected L-cells expressing 0.036% of cytosolic protein as 13 kDa SCP-2. Lane 6, transfected L-cells expressing 0.03% of cytosolic protein as 15 kDa pro-SCP-2. Lanes 7–11, ACBP standards of 1, 2, 4, 8, and 12 ng, respectively.

0.04, 0.61 ± 0.01, and 0.73 ± 0.05 ng ACBP/10 μg homogenate protein, respectively. This is also consistent with studies on chronic ethanol administration, which results in fatty infiltration of the fatty liver. Chronic ethanol administration increases liver L-FABP expression (109) (Myers-Payne, S.C., Hubbell, T., Wood, W.G., and Schroeder, F., manuscript in preparation), without affecting liver ACBP expression (Myers-Payne, S.C., Hubbell, T., Wood, W.G., and Schroeder, F., manuscript in preparation) in the mouse. These studies suggest that cellular ACBP levels are not regulated by expression of L-FABP or I-FABP.

SCP-2. Although an early report indicated that total immunoreactive liver SCP-2 was relatively unresponsive to cholesterol feeding or lipid-lowering agents (83), more recent data show mRNA and SCP-2 levels vary over a 10- to 30-fold range under different development, hormonal, or lipid-lowering agent treatments (84,110–117). Expression is regulated at three levels: transcription of the gene (84,110–117), post-translational modification (118,119), and possibly alternative mRNA splicing (90,118,120). SCP-2 gene expression is developmentally regulated (113,117) and is modulated translationally and/or post-translationally by lipid-lowering agents (113,115). In addition, expression of the various molecular weight forms of SCP-2 appears differentially responsive depending on organs and subcellular organelle type. For example, in steroidogenic cells trophic hormones and steroids stimulated differential expression of mRNA transcripts and increased mitochondrial SCP-2 3-fold (110,112).

The observation that SCP-2 stimulates the formation of cholesteryl esters (84,121–125) and binds LCFA-CoA (Frolov, A., Cho, T.-Y., Billheimer, J.T., and Schroeder, F., submitted for publication) suggests that cellular SCP-2 levels could modulate the expression of ACBP. The effect of 13 kDa SCP-2 and 15 kDa pro-SCP-2 expression on expression of ACBP was examined in transfected L-cell fibroblasts. In L-cells transfected with cDNA encoding either 13 kDa SCP-2 or 15 kDa pro-SCP-2, only the 13 kDa SCP-2 protein is detectable in Western blots (126). This is due to the rapid post-translational cleavage of the amino terminal 20 amino acid leader sequence of the 15 kDa pro-SCP-2 protein. L-cells transfected with either 13 kDa SCP-2 or 15 kDa pro-SCP-2 differentially affect the uptake of cholesterol (126) and fatty acids (Murphy, E.J., Barhoumi, R., Frolov, A., Burghardt, R., and Schroeder, F., submitted for publication). However, neither 13 kDa SCP-2 nor 15 kDa pro-SCP-2 expression significantly altered ACBP expression in transfected L-cells (Fig. 2). ACBP levels in untransfected L-cells, LM-cells (derived from L-cells), transfected L-cells with 0.036% of cytosol protein as 13 kDa SCP-2, and transfected L-cells with 0.03% of cytosol protein as 15 kDa pro-SCP-2 were 0.83 ± 0.15, 0.72 ± 0.04, 0.64 ± 0.05, and 0.50 ± 0.05 ng/10 μg homogenate, respectively. This lack of significant difference is also consistent with studies on chronic ethanol administration where increases in mouse brain SCP-2 expression did not affect ACBP expression (82). These studies suggest that cellular ACBP levels are not regulated by expression of SCP-2.

STRUCTURE OF THE LCFA-CoA BINDING PROTEINS

Cytosolic FABP. The intracellular FABP are small, 14–16 kDa, cytosolic proteins. The tertiary structure of the FABP family has been extensively reviewed previously and will not be reiterated here (43). The common structural motif of these proteins consists of ten antiparallel beta strands oriented to form two sheets making up a slightly elliptical barrel. The beta strands of one sheet are perpendicular to those of the other sheet with the strands connected by two short helixes or by tight turns. This gives the FABP an overall three-dimensional clam shape. Although a gap exists between beta strands D and E, it apparently does not constitute the ligand entry portal. The interior of the beta barrel contains a hydrophobic ligand binding cavity. However, there are some charged amino acid residues and water molecules present in the binding cavity. X-ray crystallography indicates that fatty acid ligands are oriented with the fatty acid carboxyl bound deep within the binding pocket *via* a salt bridge to Arg residues and by hydrophobic interactions as well. Competition studies between long-chain fatty acids and LCFA-CoA indicate that these lig-

ands compete for the same binding sites in the liver FABP (41; Frolov, A., and Schroeder, F., submitted for publication). However, the orientation of LCFA-CoA bound to FABP is not known. Because of the size and polarity of the CoA portion of LCFA-CoA, this would preclude the entry of this portion of the molecule into the hydrophobic binding pocket (see section on ligand binding below). Based on Silicon Graphics (Mountain View, CA) computer modeling and the known structure of related FABP (127), a proposed structure of L-FABP and orientation of two LCFA-CoA in the binding sites have been developed (Fig. 1B). As shown, the CoA portion of the LCFA-CoA is too large and polar to be accomodated in the binding sites of L-FABP. Instead, the hydrophobic fatty acid alkyl chains of the LCFA-CoA are oriented with the methyl end of the fatty acyl groups buried deep in the L-FABP binding pockets.

ACBP. ACBP is a small protein, with 86 amino acids and a molecular weight of approximately 10 kd (19,68,92). The three-dimensional structure of ACBP from bovine liver and recombinant bovine ACBP expressed in *Escherichia coli* in solution (Fig. 3) has been elucidated using multi-dimensional nuclear magnetic resonance (NMR) spectroscopy (128). ACBP forms four alpha helixes, designated A1 through A4 (129–131). A2 forms the central point and has nonpolar contacts to the other three helices (131). A1 and A4 run antiparallel to A2 while A3 runs almost parallel to A2 (129–131). Hydrophobic interactions (hydrogen bonds) between the four alpha helices form a three-dimensional structure with the appearance of a "shallow bowl" or groove (130,131). The center outer and inner surfaces of the bowl are composed primarily of a cluster of hydrophobic amino acid residues while the rim of the bowl and upper outside surface contain a large number of charged amino acid residues from the N-terminal portions of A2 and A3 and the hydrophilic residues of A1 and A4 (130,131). The binding site for acyl-CoA esters involves the cluster of hydrophobic residues located in the bottom inner surface of ACBP of which the amino acid sequence from Asp^{21} to Asp^{38} appears to be important (132) (Fig. 3). This portion of the hydrophobic ligand binding domain in the second alpha helix (amino acid residues, 23–28) is highly conserved from yeasts to humans. The only charged amino acid residues in the ligand binding site are Lys 13 and Lys 32 on the inside surface and His 30 on the outside bottom (130). The binding site is arranged so that only LCFA-CoA esters can bind strongly (131) (Fig. 3). The fatty acyl chain, pantetheine, and Cys parts of the ligand fit into the binding site of ACBP by forming a combination of electrostatic and hydrogen bonds so that the nonpolar portions of the ligand are hidden and the polar portions are on the surface (131). The 3'phosphate group of the CoA portion of the ligand is essential for binding to ACBP (133). It forms salt bridges with the lysine residues and hydrogen bonds to tyrosine 28. Therefore, binding depends upon the nonpolar interactions between the ACBP binding site and the acyl chain, methyl groups, and pantetheine portions of the ligand as well as polar and nonpolar binding of the CoA to ACBP which protects the nonpolar portions of the ligand from solvent (131).

FIG. 3. Nuclear magnetic resonance (NMR) structure of recombinant bovine ACBP with bound LCFA-CoA. Silicon Graphics model based on previously published NMR data (129–131). The image was produced with a program developed by Jon A. Christopher in 1996, "SPOCK: the Structural Properties Calculation and Observation Kit" Program Manual, The Center for Macromolecular Design (Texas A&M University, College Station, TX). See Figure 2 for other abbreviation. See Figure 1 for company source.

SCP-2. The tertiary structure of the SCP-2 family is perhaps the least understood of the intracellular LCFA-CoA binding proteins. Only a single report on the NMR structure of the human 13.2 kDa SCP-2 holoprotein has appeared (139). Three alpha-helixes and a five-stranded beta-sheet, arranged in antiparallel fashion, constitute the polypeptide backbone of SCP-2. Deletion of either the amino-terminal amphipathic alpha-helix or deletion of the carboxyl terminal beta-sheet inactivates SCP-2 in terms of sterol and phospholipid transfer (90). Amino acid substitutions at Asn^{104} or near Cys^{71} also abolished SCP-2 sterol and phospholipid transfer activity (90). SCP-2 binds fatty acids (87). Forster energy transfer data indicate the SCP-2 fatty acid binding site, located on the opposite side of SCP-2 as the single tryptophan residue, may coincide with the SCP-2 site associated with sterol and phospholipid transfer (Frolov, A., Billheimer, J.T., and Schroeder, F., submitted for publication). Since LCFA-CoA compete for the same site as fatty acid binding to SCP-2 (Frolov, A., Cho, T.-Y., Billheimer, J.T., and Schroeder, F., submitted for publication), this would suggest that the LCFA-CoA may also coincide with the above activities. The effect of these mutations in SCP-2 on fatty acid or LCFA-CoA binding has not been examined. There are no reports on the tertiary structure of holo-SCP-2 with any bound ligand. Likewise the orientation of LCFA-CoAs bound to SCP-2 is not known. However, the size and polarity of the CoA portion of LCFA-CoA would preclude the entry of this portion of the

molecule into what appears to be a very hydrophobic fatty acid binding pocket in the 13.2 kDa SCP-2 (87). Nothing is known of the structural characteristics of the 58 kDa SCP-x.

LCFA-CoA BINDING CHARACTERISTICS OF MAMMALIAN LCFA-CoA

FABP. Although endogenous bound fatty acids have been reported in native FABP isolated from tissues and recombinant FABP isolated from bacteria, the presence of endogenous bound LCFA-CoA in these FABP preparations has not been documented (3,44). However, many early studies of native FABP from liver and heart demonstrated LCFA-CoA binding *in vitro* (1–5,44). L-FABP bound palmitoyl and oleoyl CoA with high affinity, K_d near 0.14–2.8 μM, depending on the specific LCFA-CoA and the assay used (Table 7). There is apparent disagreement on the stoichiometry of LCFA-CoA binding to L-FABP with the early studies with native L-FABP indicating 1:1 stoichiometry (1,2,41) while a later study with recombinant L-FABP showed stoichiometry of 2:1 (41). This apparent discrepancy was resolved by the finding that, due to the type of protein assay used, the early studies overestimated L-FABP by 1.7-fold (41,140,141). Native H-FABP isolated from human or rat heart also bound LCFA-CoA with high affinity, K_ds near 0.5 μM, but with less than molar stoichiometry (5). In contrast, the native adipocyte adipocyte lipid binding protein (ALBP) bound LCFA-CoA more weakly, with K_d near 10 μM, than either native L-FABP or native H-FABP (42) (Table 7).

The above observations using the Lipidex-1000 assay with native L-FABP, H-FABP, and ALBP isolated from liver, heart, and adipose tissues, respectively, to demonstrate LCFA-CoA binding were recently questioned on the basis of two issues (7). First, it was suggested that early preparations of native FABP were impure and cross-contaminated with ACBP such that copurified ACBP, but not FABP, accounted for LCFA-CoA binding ability of these FABP. Second, it was shown that LCFA-CoA binding to L-FABP (but not to ACBP) was highly dependent on the ratio of ligand/protein/Lipidex-1000 in the assay. In fact, with a modified Lipidex-1000 assay no binding of LCFA-CoA to L-FABP was demonstrated (7). This controversy was resolved through the use of recombinant L-FABP (41) and H-FABP (49). Since *E. coli* do not contain ACBP, there is no possibility of cross-contamination with this protein. The recombinant L-FABP bound both oleoyl CoA (Lipidex-1000 assay) and *cis*-parinaroyl CoA (fluorescence assay) with K_d in the range of 3–13 μM (41). The fluorescence assays are not a competition assay and therefore do not suffer from the problems intrinsic with a competition assay like the Lipidex-1000 assay. Furthermore, L-FABP has two fluorescent fatty acid binding sites (140,141) that are competitively displaced by oleoyl-CoA (41; Frolov, A., and Schroeder, F., submitted for publication; Jolly, C.A., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication). In addition, the K_d for binding of recombinant bovine L-FABP to oleoyl-CoA was determined to be 1 μM by titration microcalorimetry (142). The ability of recombinant H-FABP to bind LCFA-CoA was confirmed in a displacement assay where oleoyl CoA was able to displace bound fatty acid from recombinant H-FABP (49). These data clearly show that the recombinant L-FABP and H-FABP both bind LCFA-CoA, and suggestions that the native L-FABP and H-FABP do not bind LCFA-CoA are most likely due to the type of assay used.

Additional evidence indicates that several other members of the FABP family also bind LCFA-CoA (Table 7). The ability of recombinant brain FABP (B-FABP) to bind LCFA-CoA was confirmed in a displacement assay where oleoyl CoA was able to displace bound fatty acid from the recombinant B-FABP (49). Previously all reports on native and recombinant I-FABP ligand interaction concluded that I-FABP, unlike

TABLE 7
Fatty Acid Binding Proteins That Also Bind Fatty Acyl-CoA[a]

Protein	Source	Assay	Fatty acyl CoA	K_d (μM)	Stoichiometry (mole/mole)	Reference
			Fatty acid-binding protein family

[a]See Table 5 for abbreviations. [b]Jolly, C.A., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication.

the other members of the FABP family, had a strict ligand specificity for long-chain fatty acids. Consistent with this and in contrast to L-FABP, an initial report showed negligible increase in fluorescence intensity upon addition of *cis*-parinaroyl CoA to recombinant I-FABP (41). However, more recent data using intrinsic I-FABP, tryptophan, and acrylodated-I-FABP fluorescence assays showed that oleoyl-CoA bound to I-FABP with high affinity, K_d near 0.2–2.3 μM, depending on the assay used (Jolly, C.A., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication). The reason for the discrepancy with the earlier study is that I-FABP appears to have a unique LCFA-CoA binding site in which the *cis*-parinaroyl group of *cis*-parinaroyl CoA does not enter deeply into the hydrophobic portion of the ligand binding pocket (Jolly, C.A., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication). Additional supportive evidence for LCFA-CoA binding to I-FABP was obtained by phase and modulation resolved fluorometry. Oleoyl-CoA significantly decreases the lifetime of I-FABP tryptophan by 17% ($P < 0.05$), decreases the limiting anisotropy of I-FABP tryptophan by 28% ($P < 0.02$), but does not change the hydrodynamic radius of I-FABP (Frolov, A., and Schroeder, F., submitted for publication).

In summary, at least five members of the FABP family (L-FABP, H-FABP, ALBP, B-FABP, and I-FABP) bind LCFA-CoA with μM dissociation constants and (with the exception of L-FABP which binds two LCFA-CoA per molecule of protein) with binding stoichiometries of 1:1 (Table 7). As mentioned above, these high affinities as well as the near millimolar cytosolic concentration of FABP (ranging from 1–6% of cytosolic protein) makes the FABP important potential contributors to LCFA-CoA binding in cytosol of tissues such as liver, heart, adipose, and intestine.

ACBP. ACBP isolated with an endogenous bound LCFA-CoA has not been reported. However, numerous studies *in vitro* demonstrate LCFA-CoA binding to a single binding site on ACBP (Table 8). NMR studies indicate that apo-ACBP and holo-ACBP (containing bound palmitoyl CoA) are structurally almost identical (128). Therefore, ligand binding does not induce a significant change in the tertiary structure of ACBP. However, the presence of ligand in the binding site results in a decrease in flexibility of the ACBP protein backbone within the binding site (128). Additional evidence indicates that ACBP specifically binds acyl CoA esters and not free fatty acids, free CoA, ATP, NADH, NADPH, GABA, palmitoyl carnitine, or cholesterol (8,19,68,143). The 3′ phosphate group on the ribose moiety of the acyl CoA ester is essential for binding since 3′-dephospho-hexadecanoyl-CoA does not displace 12-doxylstearoyl-CoA (143). Also, 3′-dephospho-doxylstearoyl-CoA does not bind recombinant bovine ACBP when analyzed by electromagnetic spin resonance spectroscopy (143). Therefore, both the CoA portion of the ligand as well as the acyl chain are involved in binding of LCFA-CoA to ACBP.

ACBP binds acyl-CoA esters with an acyl chain length of 8–22 carbons with high affinity, but binding affinity has been reported to be greatest for long-chain acyl-CoA esters with acyl chains of 14–22 carbons (19,143). The affinities of ACBP for a variety of LCFA-CoA is highly dependent on the type of assay used to determine binding. With the Lipidex 1000 binding assay, it was reported that bovine and rat ACBP bound acyl-CoA esters with a K_d near 0.13–0.27 μM (Table 8). [It should be noted that under the Lipidex-1000 assay conditions used therein, binding of LCFA-CoA to liver or heart FABP was not observed (8).] ACBP binds to acyl-CoA esters with equimolar stoichiometry (8,19). The fluorescent *cis*-parinaroyl CoA assay yielded a K_d of 0.2 μM (Table 8). The latter assay is not a competition assay and not subject to the same potential artifacts as the Lipidex-1000 assay. In contrast to the μM K_d reported with the Lipidex 1000 and fluorescence assays, other assays suggest that ACBP binds LCFA-CoA with 10^2- to 10^7-fold lower K_d. One study reported that the binding affinity of ACBP to long-chain acyl CoA esters is so high that no free ligand is detected, and therefore no dissociation constant can be determined by electromagnetic spin resonance spectroscopy (143). Another report using titration microcalorimetry showed K_d values for binding of hexadecanoyl CoA to

TABLE 8
Acyl CoA-Binding Protein (ACBP) Ligand Affinities

Type	Ligand	Technique	K_d (M)	B_{max}	Reference
Rat liver	Palmitoyl-CoA	Lipidex	0.27×10^{-6}	0.95	8

recombinant bovine ACBP to be in the range 0.45–0.2 × 10^{-13} M (144). In addition, two yeast ACBP homologues which bind LCFA-CoA with high affinity have been characterized and the K_d determined by titration calorimetry was 0.55 × 10^{-10} (145). These picomolar K_d obtained by microcalorimetry differ by 2–7 orders of magnitude from those obtained with the Lipidex-1000 (0.1–0.2 μM) or *cis*-parinaroyl CoA (0.2 μM) assays (Table 8). Although the Lipidex-1000 assay does not give accurate binding constants for ACBP since it can extract acyl-CoA esters bound to Lipidex, it is difficult to imagine that ACBP could serve as a LCFA-CoA donor *in vivo* if such high affinities obtained by titration microcalorimetry actually reflect the *in vivo* situation. Further work will be necessary to resolve the differences obtained with the various methods.

SCP-2. Of all the intracellular lipid binding proteins, perhaps the most difficult one for demonstrating ligand binding has been the SCP-2. Endogenous bound LCFA-CoA has not been reported. Even *in vitro* studies are few and subject to problems. This issue has been at least partly resolved by the recent discovery that SCP-2 ligand interactions are very sensitive to the solvent vehicle used to add the ligand *in vitro* (87). The latter work clearly demonstrated that, in the absence of solvent 12-*N*-methyl-(7-nitrobenz-2-oxa-1,3-diazol)amino stearate (NBD-stearic acid) bound to SCP-2 with high affinity, K_d near 0.2 μM. NBD-stearic acid is poorly fluorescent in aqueous buffer. However, in the presence of SCP-2, NBD-stearic acid fluoresces strongly (Fig. 4, top curve). As indicated by decreased fluorescence of bound NBD-stearic acid, addition of oleoyl-CoA results in displacement of bound NBD-stearic acid (Fig. 4, bottom curve). More direct evidence for LCFA-CoA binding to SCP-2 was obtained with *cis*-parinaroyl CoA. *Cis*-parinaroyl CoA is poorly fluorescent in aqueous buffer. However, when bound to SCP-2, it fluoresces strongly and a saturation binding curve may be constructed (Fig. 5). Analysis of the binding curve for SCP-2 binding to *cis*-parinaroyl CoA yields a K_d of 0.08 μM (Table 7).

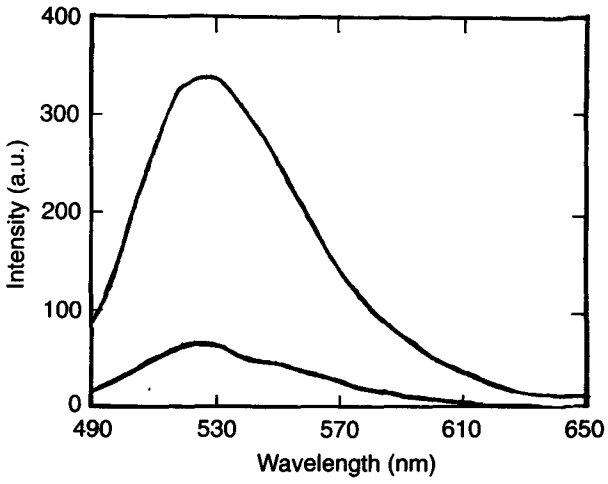

FIG. 4. Displacement of sterol carrier protein-2 (SCP-2) bound NBD-stearic acid by oleoyl CoA. All spectroscopic measurements were as described elsewhere (Frolov, A., Cho, T.-Y., Billheimer, J.T., and Schroeder, F., submitted for publication). NBD-stearic acid (0.1 μM) was added to SCP-2 (0.1 μM) (top curve). Thereafter, oleoyl-CoA (5 μM) was added (bottom curve). In both curves a blank, low fluorescence intensity of NBD-stearic acid in pH 7.4 phosphate buffer was subtracted. Excitation wavelength was 466 nm. Fluorescence intensity was determined at 22°C.

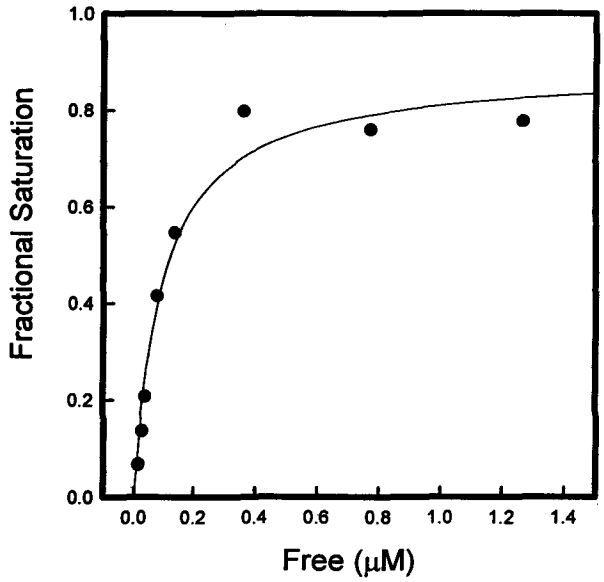

FIG. 5. *Cis*-parinaroyl CoA binding to SCP-2. All spectoscopic measurements were as described elsewhere (Frolov, A., Cho, T.-Y., Billheimer, J.T., and Schroeder, F., submitted for publication). Increasing SCP-2 was added to 0.3 μM *cis*-parinaroyl CoA in phosphate buffered pH 7.4 saline. Excitation was at 313 nm and fluorescence emission intensity was measured at 420. See Figure 4 for abbreviation.

Relative distribution of LCFA-CoA among the cytosolic FABP, ACBP, and SCP-2. At least three types of nonenzymatic cytosolic proteins interact with LCFA-CoA: FABP, ACBP, and SCP-2. Using the *cis*-parinaroyl CoA fluorescence binding assay, a rank order of K_d may be constructed as follows: FABP, 13 μM; ACBP, 0.2 μM; and SCP-2, 0.08 μM (Tables 7 and 8). LCFA-CoA binding to SCP-2 has not been determined by the Lipidex-1000 assay or titration microcalorimetry. However, both of these assays indicate that the rank order of K_d is still maintained for FABP and ACBP (Lipidex-1000: FABP = 0.14–3.6 μM and ACBP = 0.12–0.27 μM; Titration microcalorimetry: FABP = 1 μM and ACBP = 0.24 × 10^{-6} to 0.45 × 10^{-13} M) (Tables 7 and 8).

As pointed out in the preceeding sections, four factors will influence the amount of LCFA-CoA bound to the three types of LCFA-CoA binding proteins in the cell: (i) the concentration and subcellular distribution of LCFA-CoA; (ii) the concentration and subcellular distribution of LCFA-CoA binding proteins; (iii) the LCFA-CoA binding affinities of the three LCFA-CoA binding protein families; and (iv) the LCFA-CoA chain length specificity of each binding protein. This creates difficulty in accurately predicting the proportion of LCFA-

CoA bound to the individual members. For example, the preceding sections pointed out that the majority of LCFA-CoA is membrane-bound and the remaining LCFA-CoA is almost all bound to cytosolic proteins. Among these proteins, the FABP have the highest concentration in the cell cytosol [5- to 15-fold higher than ACBP in liver; 2- to 51-fold higher than ACBP in heart (19,146)]. Although "cytosolic" ACBP and SCP-2 concentrations appear in the same range, the preceding sections pointed out that SCP-2 is largely membrane-associated and may be very concentrated in peroxisomes where SCP-x appears located in the peroxisomal matrix while the SCP-2 may be localized on the cytofacial leaflet of the peroxisome. In addition, there is a lack of agreement between microcalorimetric and other methods reporting K_d for LCFA-CoA binding to the three proteins. Finally, the LCFA-CoA chain length specificity is not documented for all of these binding proteins. ACBP has highest affinities for long-chain LCFA-CoA. The chain length preferences of SCP-2 and L-FABP for long-chain fatty acids would also suggest that the LCFA-CoA would bind better than the short- or medium-chain fatty acyl-CoA. Nevertheless, one may estimate the range of relative distribution of protein-bound LCFA-CoA among the three species (FABP, ACBP, and SCP-2) in the cell cytosol. If the higher cellular content of FABP over ACBP and SCP-2 is considered to be offset by the higher affinity of the latter two proteins for LCFA-CoA, then all three protein fractions may contain roughly similar quantities (but at different occupancies of available binding sites) of LCFA-CoA. At least one study suggests that both the FABP and ACBP play a role in acyl-CoA binding *in vivo* in liver and heart (8). If the microcalorimetrically determined affinites (seven orders of magnitude higher affinities for LCFA-CoA) are assumed correct, then essentially all of the cytosolic LCFA-CoA would be bound by ACBP. Indeed, under some assay conditions *in vitro,* it has been reported that ACBP can bind all acyl CoA in the presence of FABP (8).

FUNCTION OF CYTOSOLIC LCFA-CoA BINDING PROTEINS

Cytosolic FABP. There is no evidence obtained *in vivo* for the physiological role of FABP binding LCFA-CoA. However, a number of studies *in vitro* show that FABP alters the activities of a variety of lipid synthetic and oxidative enzymes that utilize LCFA-CoA as substrates (Table 9). For example, L-FABP enhances or inhibits microsomal fatty acyl-CoA synthase (1,44,147) and stimulates phosphatidic acid biosynthesis *in vitro* (1,147–150). Although early data with unwashed microsomes suggested that I-FABP did not stimulate phosphatidic acid synthesis (41), more recent data from our laboratory using washed microsomes indicate that I-FABP does stimulate phosphatidic acid biosynthesis (Jolly, C.A., Hubbell, T., Behnke, W.D., and Schroeder, F., submitted for publication). Apparently the unwashed liver microsomes contain enough LCFA-CoA binding proteins to raise the baseline enzymatic activity and obscure effects of I-FABP. As pointed out above, the suggestion that the lipid synthetic stimulatory activities in early preparations of native FABP may have been due to copurified ACBP is unlikely. This issue was clearly resolved in several recent studies demonstrating that recombinant L-FABP stimulates incorporation of LCFA-CoA into phosphatidic acid *in vitro* (41), into phospholipids in intact transfected cells expressing L-FABP (108), into cholesteryl esters *in vitro* (151), and into cholesteryl esters in intact transfected cells expressing L-FABP (151). Likewise, recombinant I-FABP stimulated incorporation of fatty acids into triglycerides and cholesteryl esters in intact transfected cells expressing I-FABP (152,153).

In addition to stimulating enzymes using LCFA-CoA as substrates, the FABP alter fatty acid synthesis and other proteins whose activities are regulated by LCFA-CoA (Table 10). In only one case was inhibition observed, e.g., fatty acid synthetase is inhibited by FABP (6). In contrast, several lipogenic

enzyme activities were stimulated by L-FABP, Lu-FABP, or P-FABP (Table 10). For example, free LCFA-CoA esters are potent inhibitors of specific enzymes within the cell such as acetyl-CoA carboxylase (ACC) and adenine nucleotide translocase (ANT) which are of vital importance for cellular function. LCFA-CoA esters inhibit ANT and therefore suppresses mitochondrial respiration and ATP synthesis while inhibition of ACC suppresses fatty acid synthesis. *In vitro* examination of the effects of L-FABP upon LCFA-CoA inhibition of ACC showed that in the presence of LCFA-CoA the ACC and ANT activities were stimulated by L-FABP (12,154).

ACBP. The physiological function of ACBP is not known. However, a number of studies both *in vitro* and *in vivo* show that ACBP is involved in lipid metabolism and in the regulation of long-chain acyl CoA levels within the cell (Table 9). In support of this potential role of ACBP in basal cellular metabolism, the gene encoding this protein has features of a housekeeping gene such as: the promoter region located in a CpG island, lack of a TATA box, and the presence of processed pseudogenes (65). Additional support of the role of ACBP as a housekeeping protein is its stability in several cell lines *in vitro*. The half-life of the ACBP protein within 3T3-L1 and 3T3-C1 mouse embryo fibroblasts, H-4-11-E rat hepatoma cells, and HepG2 human hepatoma cells *in vitro* are approximately 25–53 h (155). Recent evidence has proven that a major function of ACBP in yeast is to maintain a pool of bound intracellular LCFA-CoA. Recombinant bovine ACBP transfected into yeast *(Saccharomyces cervisiae)* increased the total ACBP and resulted in an increase in the pool of long-chain acyl CoA esters, possibly *via* the mechanism of binding LCFA-CoA and decreasing feedback inhibition of yeast fatty acid synthetase and LCFA-CoA synthetase (156). In addition, overexpression of yeast ACBP *(S. carlsbergensis)* resulted in subsequent expansion of the intracellular acyl-CoA pool (145).

ACBP from bovine liver was first discovered to induce the synthesis of medium-chain fatty acyl-CoA esters by goat mammary gland fatty acid synthetase *in vitro* by binding to acyl CoA esters (6). Research involving the *in vitro* effects of ACBP upon other enzymes involved in lipid metabolism within the cell has shown that ACBP stimulates the synthesis of LCFA-CoA esters by mitochondrial LCFA-CoA synthetase (12). Newly synthesized LCFA-CoA were removed from the mitochondrial membrane by ACBP and therefore reduced the negative feedback of LCFA-CoA esters upon the enzyme (12). However, saturation of ACBP with long-chain acyl CoA esters abolished the stimulatory effect of ACBP upon acyl CoA synthetase (12). In addition, ACBP increases the activity of outer mitochondrial carnitine palmitoyl transferase, the enzyme which is involved in fatty acid oxidation in the mitochondria (157). The enzyme, carnitine palmitoyltransferase, is located on the outer mitochondrial membrane facing the cytosol and is particularly sensitive to the effects of micromolar concentrations of free LCFA-CoA esters such as palmitoyl-CoA. Bhuiyan and Pande (157) showed that various carnitine palmitoyl transferase preparations *in vitro* are able to use palmitoyl-CoA bound to ACBP in a near physiologic molar ratio of 1:1. Results of these experiments suggest that ACBP binds LCFA-CoA esters to prevent their inhibition of carnitine palmitoyl transferase, and at the same time ACBP facilitates removal of the acyl carnitine product from the enzyme so as to decrease feedback inhibition by the product. The latter suggestion is puzzling in view of other data (see above), indicating that ACBP does not bind palmitoyl carnitine. In addition, ACBP may sequester LCFA-CoA esters and facilitate their transport to the catalytic site of selected enzymes. Studies which support the potential role of ACBP in acyl-CoA transport have shown that ACBP can extract LCFA-CoA from phosphatidylcholine membranes immobilized on nitrocellulose and, subsequently, the ACBP–LCFA-CoA complex was able to transport and donate the LCFA-CoA to mitochondria or microsomes in suspension for fatty acid β-oxidation or glycerolipid synthesis (144).

Both cytoplasmic and microsomal membranes contain high levels of acyl-CoA hydrolases. Upon addition of LCFA-CoA to microsomal membranes followed by an incubation period at 37°C, only 10% of LCFA-CoA could be recovered in the absence of ACBP. In the presence of ACBP, the recovery of LCFA-CoA under the same conditions was 86% of added LCFA-CoA (12). Clearly ACBP protected LCFA-CoA from hydrolysis under these conditions. In contrast, L-FABP was not able to prevent LCFA-CoA hydrolysis under the same conditions (12). This would suggest that ACBP, but not L-FABP, may protect long-chain acyl-CoA esters from hydrolysis *in vitro*. It is important that this observation may not necessarily extend to other types of FABP.

ACBP is present in human red blood cell cytosol but not in the erythrocyte membrane (72). It appears to form a cytosolic reserve pool of LCFA-CoA for acylation of membrane phospholipids by lysophospholipid acyltransferase. ACBP-bound LCFA-CoA is preferred over free LCFA-CoA as a sub-

strate and therefore is important in the cellular distribution and utilization of LCFA-CoA as well as in phospholipid turnover in red blood cells (72).

As pointed out above, free LCFA-CoA esters are potent inhibitors of specific enzymes within the cell such as ACC and ANT which are of vital importance for cellular function. LCFA-CoA esters inhibit ANT and therefore suppress mitochondrial respiration and ATP synthesis while inhibition of ACC suppresses fatty acid synthesis. *In vitro* examination of the effects of ACBP upon LCFA-CoA inhibition of ACC showed that ACC and ANT activity were unaffected by LCFA-CoA esters as long as the molar ratio of LCFA-CoA ester to ACBP was less than 0.8 (12). In addition, ACBP has a higher affinity for LCFA-CoA esters because addition of ACBP to ACC bound to LCFA-CoA restored the activity of ACC (12). Due to the high binding affinity of ACBP for acyl-CoA esters and the high hydrolytic activity in cytosol and membranes, ACBP maintains a pool of acyl-CoA, and the intracellular free LCFA-CoA concentration *in vivo* is very low so as to maintain the activity of important enzymes such as ACC and ANT.

Free long-chain acyl-CoA esters readily partition into the phospholipid bilayer of membranes or bind membrane proteins and may therefore contribute to membrane damage by a detergent effect. ACBP, not FABP, prevented the binding of long-chain acyl-CoA ester to heat denatured microsomal membranes *in vitro* (8). These results suggest that ACBP may play a role in protecting membranes against damage by long-chain acyl CoA esters.

In addition to its role in relationship to acyl-CoA metabolism (see above), ACBP has been shown to effect a variety of other processes within cells. There has been considerable controversy regarding the function of ACBP in the brain. Two distinct types of benzodiazepine receptors have been identified in the brain. Central benzodiazepine receptors are present primarily in neurons and associated with GABA adrenergic ($GABA_A$) receptors which are ligand-gated chloride channels (158). Benzodiazepines such as diazepam and clonazepam bind these receptors with high affinity (158,159). ACBP has been shown to modulate this receptor in a fashion which can be blocked by antagonists and therefore was first thought to be a neurotransmitter (7,92,158). However, this question has not been fully resolved because actual direct binding of ACBP to the $GABA_A$ receptor has not been proven, purified ACBP from bovine liver does not have DBI activity in the brain, ACBP is present in very low levels in neurons, and micromolar concentrations of ACBP are required for inhibition of benzodiazepine binding when most neutrotransmitters are active at nanomolar concentrations (67,78,92,159,160).

The second type of benzodiazepine receptor, peripheral benzodiazepine receptors (PBR), are found in the brain and most peripheral tissues and are localized primarily in the outer mitochondrial membranes in many cells although other locations have been identified (161–164). These receptors mediate some of the pharmacologic effects of benzodiazepines, and are often abundant in steroid-producing tissues such as brain, adrenal cortex, and testis. Extensive work has identified the importance of these receptors in steroid biosynthesis.

ACBP undergoes posttranslational proteolytic cleavage resulting in biologically active cleavage products having varying effects in the brain and other tissue types (50,73,74, 165–167). Two peptide cleavage products of ACBP are octadecaneuropeptide (ODN), composed of amino acids 33–50 and triacontatetraneuropeptide (TTN), consisting of amino acids 17–50 (166). ODN appears to be involved primarily in modulation of GABA receptors in various tissue, and it also inhibits glucose-induced insulin secretion in the pancreas with a potency similar to intact ACBP (73,168). ACBP and its proteolytic cleavage products have been identified in tissues involved in steroid biosynthesis and have been shown to modulate steroid synthesis in the brain, adrenal gland, and testis (134–137,169,170) and regulate glucose-induced insulin secretion (73,133,168). It is still unclear whether intact ACBP, its processing products, or both are involved in modulation of PBR. Work in our laboratory indicates that an 8 kDa fragment of ACBP lacking the carboxy terminus did not affect the binding of ligand to the PBR (Gossett, R.E., and Schroeder, F., manuscript in preparation). However, ACBP and/or other proteolytic processing products of ACBP may be important in modulation of PBR in mitochondrial steroidogenesis. One study demonstrated that binding (chemical crosslinking) of purified, radiolabeled ACBP to mitochondrial PBR protein occurred in rat Leydig R2C cells and promoted constitutive steroidogenesis (170). In addition, ACBP depletion by treatment of the cells with cholesterol linked deoxynucleotide antisense to ACBP suppressed the expression of ACBP to undetectable levels by immunoblotting and resulted in a dramatic decrease in steroid synthesis (171). Both ODN and ACBP were detected in these cells, but which protein(s) bound PBR was not determined. Further work will be necessary to more fully characterize the role of ACBP and its cleavage products in modulation of PBR in various tissues.

SCP-2. The function of SCP-2 in LCFA-CoA metabolism or regulation is not well known at this time (Tables 9 and 10). However, there is strong indication that SCP-2 stimulates microsomal acyl CoA/cholesterol acyltransferase *in vitro* (Table 9). Whether it does so by enhancing incorporation of sterol or of LCFA-CoA or both remains to be resolved. There are some suggestions that SCP-2 may also be involved in peroxisomal β-oxidation of fatty acids. As pointed out in preceding sections, the 13.2 kDa form of SCP-2 binds LCFA-CoA and is found in high content in peroxisomes as well as other organelles. The 58 kDa SCP-x is found exclusively in peroxisomes (88). Furthermore, the 58 kDa SCP-x is a thiolase that binds and hydrolyzes long-chain 3-oxoacyl CoA, an intermediate in fatty acid β-oxidation (172).

PATHOBIOLOGY OF LCFA-CoA BINDING PROTEINS

FABP. The effect of disease on expression of FABP has been reviewed earlier and will not be covered in depth here (44).

Briefly, FABP expression is generally decreased in starvation, diabetes, and hepatitis depending on tissue type and type of FABP being examined. In contrast, FABP levels are increased in ischemia and chronic alcoholism. Interestingly, FABP is markedly reduced in several liver (44) and intestinal tumors (173) as well as transformed cell lines in culture: hepatomas (44,174,175), L-cells (151), Caco-2 (89,176,177). Furthermore, at least one FABP isolated from mammary gland and milk is closely related to H-FABP and has been identified as a potent mammary tumor inhibitor (178,179). Finally, liver L-FABP has been postulated to be involved in gene regulation and carcinogenesis (48,174,175,180,181).

ACBP. ACBP has been shown to be increased in a number of different disease states affecting the central nervous system. Increased ACBP concentrations have been detected in the cerebrospinal fluid of humans with chronic hepatic encephalopathy, and in patients with depression and schizophrenic behavior (182–184). In addition, there may be an association of ACBP levels with the development of alcohol dependence and withdrawal symptoms. Injections of ACBP into the lateral ventricles of rats elicited behavioral changes similar to those of alcohol withdrawal, and the expression of ACBP mRNA increased in mice inhaling ethanol vapor for eight days as well as up to three days after withdrawal of ethanol (51,185). Perhaps ACBP and/or a proteolytic peptide derived therefrom may by acting as a benzodiazepine receptor antagonist in these studies. Nicotine exposure for 24 h resulted in a dose-dependent increase in ACBP expression in mouse primary cultured cerebral cortical neurons (186). This effect lasted for approximately 48 h and was abolished by a nicotine acetylcholine receptor antagonist.

Increased ACBP expression has been demonstrated in a number of different tumor types *in vivo* such as astrocytomas, glioblastomas, and medulloblastomas with the highest expression occurring in the most anaplastic tumors (187,188). ACBP levels were low to undetectable in normal brain and benign brain neoplasms such as meningiomas and pituitary adenomas (187,188). In addition, PBR are low to undetectable in normal brain and low-grade astrocytomas whereas malignant tumors expressed high levels. In both astrocytomas and gliomas as well as cultured primary astrocytes and C-6 glioma cells, many cells expressing ACBP also expressed PBR (187,188). Other tumor cells in which ACBP has been identified include L cells (Fig. 2), ras or sre transformed immortalized rat colon cell lines (Gossett, R., Schroeder, F., Roths, J., Gunn, J.M., and Kier, A., manuscript in preparation), human prostatic adenocarcinoma cell lines, Leydig cell-derived tumor cell lines, rat insulinoma cell line, dimethylbenz(x)anthracene-induced mammary tumors in the rat, and in the supernatant from a metastatic human malignant melanoma cell line (77,138,170,189,190). The mechanistic basis for this association of ACBP expression with malignancy is, however, unclear at this time. Further work will be necessary to determine if ACBP is involved in the regulation of cell growth possibly *via* interaction with PBR. Alternately increased ACBP levels may be secondary to increased acyl CoA turnover in more rapidly growing cells.

SCP-2. SCP-2 expression is dramatically modulated in several disease states. Diabetic rat liver has a 4.5-fold higher 58 kDa SCP-2 (peroxisomal) and 60–90% lower 13.2 SCP-2 (cytosolic/peroxisomal) (114,116). In contrast, diabetes increased intestinal 13.2 kDa SCP-2 3- to 4-fold (116). Transformed cells had 10-fold lower SCP-2 levels than corresponding normal tissue (125,151,191). In addition, adrenal carcinomas exhibit decreased expression of SCP-2 mRNA compared to normal adrenal tissue (192). SCP-2 levels are also markedly reduced in peroxisomal deficiency (reviewed in Refs. 193–196) and other diseases (reviewed in Refs. 110,197).

CONCLUSIONS AND FUTURE DIRECTIONS

The ligand specificity and function of the LCFA-CoA binding proteins (FABP, ACBP, SCP-2) represent a controversial area of investigation. Much of the difficulty lies in the type of ligand binding assays used as well as the differential susceptibility of these proteins to the effects of assay conditions, i.e., different Lipidex-1000 assay conditions, the presence of solvents, etc. Further contributing to the confusion is the potential for mutual cross-contamination of these small proteins whose molecular weights are in the range of 10–15 kDa. Finally, the relationship of ACBP's ability to bind LCFA-CoA and influence LCFA-CoA metabolism to its putative interactions with benzodiazepine receptors and GABA receptors remain to be clarified.

What has been clearly established, however, is that mammalian cytosol contains at least three distinct families of LCFA-CoA binding proteins (FABP, ACBP, and SCP-2) and that members of all three families bind LCFA-CoA. Equally important, potential functions of this LCFA-CoA binding by individual members of these families have begun to be investigated. Because of the potential for many early preparations of FABP being cross-contaminated with ACBP, early reports of FABP functions in LCFA-CoA metabolism, and regulation of protein function need to be viewed with caution and should be re-evaluated. The use of recombinant L-FABP, however, has clearly shown that this protein binds LCFA-CoA and stimulates microsomal glycerophosphate acyltransferase and acyl CoA/cholesterol acyltransferase. Because of the newness of the discovery that SCP-2 binds LCFA-CoA, the role(s) of SCP-2 in LCFA-CoA metabolism and function are largely unknown. However, both native and recombinant SCP-2 stimulate microsomal acyl CoA/cholesterol acyltransferase.

While much work needs to be done delineating the functions of FABP and SCP-2 in LCFA-CoA metabolism, considerably more progress has been made in our understanding of ACBP function in LCFA-CoA metabolism. ACBP has been shown to specifically bind only LCFA-CoA esters and function as an LCFA-CoA pool former (6–8,19,68,92,143,145). Therefore, ACBP appears to play a key role in LCFA-CoA sequestration, transport, and utilization within cells by regulating the size of the intracellular LCFA-CoA pool, acyl CoA ester transport to and from enzymes involved in lipid metabolism, protection of enzymes whose activity is inhibited by

free LCFA-CoA esters, prevention of the breakdown of LCFA-CoA esters by intracellular hydrolases, and protection of cellular membranes.

Although no evidence exists at this time, by virtue of binding LCFA-CoA the FABP, ACBP, and SCP-2 may also play a regulatory role in the cell. LCFA-CoA esters are important for reactions involving protein acylation/deacylation while specific LCFA-CoA esters (myristoyl-CoA and palmitoyl-CoA) are involved in signal transduction via myristoylated and palmitoylated proteins, binding to and regulation of transcription factors, and in formation of secretory vesicles.

The fact that there exist three separate classes of lipid-binding proteins which can bind acyl CoA exemplifies the complexity and perhaps functional redundancy often encountered in the regulation of various LCFA-CoA processes within the cell. To date ACBP, which does not appear to bind ligands other than LCFA-CoA, may be specific for its actions involving LCFA-CoA molecules in the cytosol. The fact that the FABP and SCP-2 also bind and modulate LCFA-CoA at first glance may represent overlapping and multiplicity of functions of these proteins. Yet, their differing subcellular distributions argue against all three proteins functioning identically in the cell. In tissues and cells containing ACBP, SCP-2, and FABP, all three protein families may contribute to LCFA-CoA utilization. At the same time the broad ligand specificity of the FABP and SCP-2 allows the regulation of a variety of other cellular processes involving fatty acid metabolism, cholesterol transport, etc. In liver, the concentration of L-FABP is an order of magnitude higher than ACBP. Both proteins can bind LCFA-CoA, but ACBP exhibits a binding affinity one or more orders of magnitude higher than that of L-FABP. Therefore, in liver, ACBP may be more important under conditions of low levels of LCFA-CoA while L-FABP may contribute additional functions under conditions in which LCFA-CoA levels exceed the binding capacity of ACBP. The potential contribution of SCP-2 remains to be determined, but its high concentration in peroxisomes (which apparently do not contain L-FABP and ACBP) suggests an important role of SCP-2 in LCFA-CoA metabolism in this organelle. Future work will also need to focus on investigating the interactions of ACBP, FABP, and SCP-2 with regulatory molecules within cells as well as determining their function both *in vitro* and *in vivo*. Essential will be studies comparing the three LCFA-CoA binding proteins to ascertain their relative contribution in various functions involving LCFA-CoA.

ACKNOWLEDGMENTS

The helpful technical assistance of Timothy Hubbell was much appreciated. This work was supported in part by the USPHS National Institutes of Health Grant DK41402.

Quantitative Analysis of Triglycerides Using Atmospheric Pressure Chemical Ionization–Mass Spectrometry

Wm. Craig Byrdwell*, Edward A. Emken, William E. Neff, and Richard O. Adlof

FQS, NCAUR, ARS, USDA, Peoria, Illinois 61604

ABSTRACT: Atmospheric pressure chemical ionization–mass spectrometry (APCI–MS) was used for quantitative analysis of triglycerides (TG) separated by reverse-phase high-performance liquid chromatography. APCI–MS was used for analysis of mono-acid TG standards containing deuterated internal standard, of a synthetic mixture of heterogeneous TG, of randomized and normal soybean oils and of randomized and normal lard samples. Quantitation of the TG by four approaches based on APCI–MS were compared, and these were compared to quantitation obtained using liquid chromatography (LC) with flame-ionization detection (FID). The APCI–MS methods were based on (i) calibration curves from data for mono-acid TG standards, (ii) response factors obtained from a synthetic mixture of TG, (iii) response factors calculated from comparison of randomized samples to their statistically expected compositions, and (iv) response factors calculated from comparison of fatty acid (FA) compositions calculated from TG compositions to FA compositions obtained by calibrated gas chromatography (GC) with FID. Response factors derived from a synthetic mixture were not widely applicable to samples of disparate composition. The TG compositions obtained using APCI–MS data without application of response factors had average relative errors very similar to those obtained using LC–FID. Numerous TG species were identified using LC/APCI–MS which were undetected using LC–FID. Two quantitation methods, based on response factors calculated from randomized samples or on response factors calculated from FA compositions, both gave similar results for all samples. The TG compositions obtained using response factors calculated from FA compositions showed less average relative error than was obtained from LC–FID data, and were in good agreement with predicted compositions for the synthetic mixture and for randomized soybean oil and lard samples.

Lipids 31, 919–935 (1996).

Early (1) and recent (2) reviews have summarized the use of several types of two-dimensional detection methods for analysis of triglycerides (TG) using high-performance liquid chromatography (HPLC). These methods have included refractive index, ultraviolet-vis spectrophotometric, moving belt flame-ionization (FID), and evaporative light-scattering (ELSD) detection. While each of these detection methods has its strengths and weaknesses with regard to solvent compatibility, sensitivity, and other factors, the accuracy of the quantitative data of all these methods is dependent on the quality of the chromatographic resolution of the TG species. In complex mixtures which contain numerous species with the same equivalent carbon numbers, complete, or even partial, resolution of chromatographically overlapped species may not be possible. To solve this problem several types of mass spectrometric detection have been successfully applied to the identification and quantitation of molecular species of TG mixtures. Several interface types, such as fast atom bombardment, thermospray, direct inlet, and electrospray have been used, and these applications have been recently reviewed (3). One of the simplest, yet effective, ionization interfaces for use in a chromatographic system has been the direct inlet interface.

We have reported results that demonstrated that atmospheric pressure chemical ionization (APCI) is similarly a simple, versatile ionization source for analysis of TG. Our recent publications (4,5) described the application of APCI–mass spectrometry (MS) to the qualitative analysis of simple homogeneous (mono-acid) TG and genetically modified soybean oils (SBO) separated using reverse-phase HPLC (RP-HPLC). We showed that the mass spectra of TG obtained using APCI–MS were relatively simple and consisted primarily of diglyceride (DG) ions, $[M - RCOO]^+$ or $[DG]^+$, and protonated molecular ions, $[M + 1]^+$. The degree of unsaturation was the primary factor in determining the amount of DG vs. TG ions formed. The mass spectra of TG containing more than four sites of unsaturation contained protonated TG ions as base peaks. DG fragments were the base peaks in spectra of TG containing less than three sites of unsaturation. Mass spectra of TG with three or four sites of unsaturation contained either DG fragments or protonated TG ions as base peaks, depending on the fatty acid (FA) distribution within the TG. No TG protonated molecular ion (only DG) was observable from TG containing only saturated FA. Thus, the utility of APCI–MS for qualitative analysis of TG has been well demonstrated, but the potential for quantitative analysis using this ionization technique has not been explored.

Reported here is the extension of APCI–MS to the quantitative analysis of several model and natural TG samples. We report the quantitative analysis of a synthetic mixture containing homogeneous (mono-acid) TG with d_{12}-tripalmitin as internal standard, of a synthetic mixture of thirty-five TG with randomly distributed FA, of randomized and normal SBO and of randomized and normal lard samples. Comparison of quantitative results based on several approaches is presented: (i) construction of calibration curves from mono-acid TG standards, (ii) response factors obtained from a synthetic mixture of heterogeneous (mixed-acid) TG, (iii) response factors calculated from the comparison of randomized samples to their statistically expected compositions, and (iv) response factors calculated from comparison of compositions calculated from TG compositions to compositions obtained by calibrated gas chromatography (GC) with FID detection.

MATERIALS AND METHODS

TG. TG standard mixture "HPLC #G-2" was obtained from Nu-Chek-Prep (Elysian, MN). The TG standard mixture contained equal weights of the following mono-acid TG: tripalmitin (PPP), tripalmitolein (PoPoPo), tristearin (SSS), triolein (OOO), trilinolein (LLL), and trilinolenin (LnLnLn), where P is palmitic acid, S is stearic acid, O is oleic acid, L is linoleic acid, and Ln is linolenic acid. A stock solution of "HPLC #G-2" was used to prepare solutions containing: 30 μg/μL, 15 μg/μL, 6 μg/μL, 3 μg/μL, 0.6 μg/mL, 0.3 μg/μL, and 0.06 μg/μL total TG. This resulted in solutions containing the following amounts of individual TG standards: 5 μg/μL, 2.5 μg/μL, 1.0 μg/μL, 0.5 μg/μL, 0.1 μg/μL, 0.05 μg/μL, and 0.01 μg/μL. d_{12}-PPP was added to each standard solution at a concentration of 1.01 μg/μL as internal standard. The d_{12}-PPP was prepared in our laboratory by reduction of methyl *cis*-9-hexadecenoate-13,13,14,14-d_4 [prepared in a similar manner as the methyl 9-*cis*-octadecenoate analogue (6)] with Wilkinson's Catalyst (7) and hydrogen to the saturated fatty acid methyl ester (FAME), methyl palmitate-d_4. The FAME was converted to the FA with alcoholic KOH and reacted with glycerol and *p*-toluenesulfonic acid to yield d_{12}-PPP (8).

Synthetic mixture of TG from FA. FA (all >99% pure) were purchased from Nu-Chek-Prep. Five FA were used: P, S, O, L, and Ln. The mixed FA TG standard was prepared by the *p*-toluenesulfonic acid-catalyzed esterification of glycerol with an equimolar mixture of the FA (8). Glycerol and *p*-toluenesulfonic acid (Fisher Scientific Co., Fair Lawn, NJ) were used as received. All solvents were HPLC quality and were used without further purification.

Natural samples. Refined, bleached, and deodorized SBO was obtained from PVO Foods, Inc. (St. Louis, MO) and was randomized using the sodium-catalyzed interesterification method of List *et al.* (9). Refined and deodorized native lard was obtained from Colfax (Pawtucket, RI.) The lard was randomized by Nabisco Foods (Indianapolis, IN) using a similar method for randomization (interesterification).

GC. FAME were analyzed using a Varian 3400 (Palo Alto, CA) gas chromatograph equipped with a Supelco (Belefonte Park, PA) SP2380 30 m × 0.25 mm i.d. capillary column. The conditions were: inlet temperature = 240°C; detector temperature = 280°C; initial temperature = 150°C; initial time = 35 min; ramp to 210°C at 3°C/min. Methyl esters were made by the sodium methoxide esterification according to the method of Glass (10).

Liquid chromatography (LC). Solvents were purchased from Aldrich Chemical Co. (Milwaukee, WI) or EM Science (Gibbstown, NJ). Solvents were HPLC grade or the highest available quality and were used without further purification. The HPLC pump used for LC/APCI–MS was an LDC 4100 MS (Thermo Separation Products, Schaumburg, IL) quaternary pump system with membrane degasser. The columns used were an Adsorbosphere C18 (Alltech Associates, Deerfield, IL), 25 cm × 4.6 mm, 5 μm (12% carbon load) in series with an Adsorbosphere UHS C18 25 cm × 4.6 mm, 10 μm (30% carbon load). The flow rate throughout was 1 mL/min. A gradient solvent program with propionitrile (PrCN), dichloromethane (DCM), and acetonitrile (ACN) was used to separate the mixture of homogeneous TG containing d_{12}-tripalmitin as internal standard. The gradient used was as follows: initial—PrCN/DCM/ACN (45:20:35, by vol); linear from 15 to 20 min to PrCN/DCM/ACN (45:25:30, by vol), held until 35 min; linear from 35 to 40 min to PrCN/DCM/ACN (45:30:25, by vol), held until 95 min. Separations incorporating PrCN provided slightly better peak shapes than those without, but due to variations in lot-to-lot solvent quality, the change was made to a DCM/ACN system. APCI source temperature and gas flows were optimized to minimize the amount of undesirable adduct formation.

Separations of the synthetic randomized mixture of heterogeneous TG and of the randomized and normal SBO and lard samples were accomplished using gradient elution as follows: initial—ACN/DCM (65:35, vol/vol); linear from 20 to 25 min to ACN/DCM (60:40, vol/vol), held until 35 min; linear from 35 to 40 min to ACN/DCM (55:45, vol/vol), held until 50 min; linear from 50 to 60 min to ACN/DCM (55:45, vol/vol), held until 85 min 5 μL of each sample solution was injected. The column effluent was split so that ~850 mL/min went to an ELSD and ~150 μL/min went to the APCI interface. ELSD data were used only to confirm proper operation of the LC system; these data are not presented. The ELSD was an ELSD MKIII (Varex, Burtonsville, MD). The drift tube was set at 140°C, the gas flow was 2.0 standard liters per minute. High purity N_2 was used as the nebulizer gas.

The quantitative analysis by RP-HPLC with FID detection used a linear gradient of ACN/DCM 70:30 to 40:60 vol/vol over 120 min. Columns and conditions were as previously described (11). The gradient used for LC–FID could not be used for APCI–MS analysis because the mass spectrometer's LC software did not allow gradient runs over 99 min in length.

MS. A Finnigan MAT (San Jose, CA) SSQ 710C mass spectrometer fitted with an APCI source was used to acquire mass spectral data. The vaporizer was operated at 400°C, and

the capillary heater was operated at 265°C. The corona voltage was set at 6.0 μA throughout. Auxiliary and sheath gases were set to 35 psi and 5 mL/min, respectively. Spectra were obtained from *m/z* 400 to *m/z* 1000 or *m/z* 1100, with a scan time of 1.75 to 2.0 s. Preliminary data showed no substantial ions below *m/z* 400. Chromatograms were processed using three-point smoothing for graphical output, but no smoothing was applied during quantitation of extracted ion chromatograms. All mass spectra shown represent an average of spectra over the breadth of a chromatographic peak. Nominal masses, shown in mass spectra, were obtained by application of a mass defect of 0 mmu @ 0 amu to 700 mmu @ 1000 amu.

Lipase hydrolysis. Positional isomers were determined using lipase hydrolysis as previously described (12). Briefly, lipase (EC 3.1.1.3) was used to cleave the FA at glycerol 1,3 carbons, and the lipolysis products were separated using solid phase extraction. The FAME of the lipolysis products were analyzed using GC–FID, and the composition obtained was compared to the FAME composition obtained for the intact samples.

Calculations. The expected composition of the synthetic mixture was calculated from the FA composition. If FA are esterified with glycerol, the number of possible TG molecular species, excluding isomers, can be calculated from the equation (13):

$$\text{number of TG molecular species} = \frac{n^3 + 3n^2 + 2n}{6} \quad [1]$$

where n is the number of FA. When 5 FA are used, 35 TG molecular species are possible. The 5 FA would be randomly distributed between all possible molecular species. Formulas for calculating the composition of a randomly distributed mixture of TG were derived from probability theory (14). The following equations were used to calculate the percentages of TG containing one (Eq. 2), two (Eq. 3), or three (Eq. 4) different FA:

$$\text{TAG\%} = \frac{\text{FA\%} \cdot \text{FA\%} \cdot \text{FA\%}}{10{,}000} \quad [2]$$

$$\text{TAG\%} = \frac{(\text{FA1\%} \cdot \text{FA1\%} \cdot \text{FA2\%}) \cdot 3}{10{,}000} \quad [3]$$

$$\text{TAG\%} = \frac{(\text{FA1\%} \cdot \text{FA2\%} \cdot \text{FA3\%}) \cdot 6}{10{,}000} \quad [4]$$

These equations also were used to calculate the theoretical compositions of the randomized SBO and lard samples from their FA compositions determined by calibrated GC–FID.

The percent relative errors for TG were calculated by subtracting the statistically expected amount from the determined amount, multiplying by 100, and then dividing by the statistically expected amount. The percent relative errors for the most abundant TG in a sample were averaged to give the average relative error. TG present at low levels had higher percent relative errors, so these were not included in calculation of the average relative error for a sample. Similarly, the percent relative errors for the FA was calculated by comparison of the FA composition calculated from the TG composition to the FA composition determined by calibrated GC–FID. The individual FA relative errors were averaged to give the average relative error for the FA composition.

RESULTS

Homogeneous mixture. Seven concentrations of a six-component homogeneous TG standard mixture were prepared, and raw quantitative data were obtained by summing the areas under the $[DG]^+$ and $[M + 1]^+$ peaks. The total areas under the $[DG]^+$ and $[M + 1]^+$ peaks were obtained from extracted ion chromatograms (EIC), in which a chromatogram was produced by selectively extracting the appropriate $[DG]^+$ and $[M + 1]^+$ *m/z* for each TG from the total, or reconstructed ion chromatogram.

Calibration curves were constructed by referencing the total peak areas for each TG to the area obtained for the deuterated d_{12}-PPP internal standard $[d_8\text{-DG}]^+$ peak having *m/z* = 559.5. Example calibration curves for three of the homogeneous TG standards are shown in Figure 1. The sensitivities (line slopes) and intercepts are given in slope/intercept form for the six components as follows: LnLnLn $y = 0.1201\,x + 0.05481$; LLL $y = 0.1199\,x + 0.05297$; OOO $y = 0.1471\,x + 0.05605$; SSS $y = 0.1337\,x + 0.06286$; PoPoPo $y = 0.2382\,x + 0.04958$; PPP $y = 0.1957\,x + 0.04113$, where y is the ratio of the area of the analyte peak to the area of the internal standard peak and x is the amount, in μg, actually injected. The correlation coefficients were LnLnLn =.9986, LLL = .9964, OOO = .9993, SSS = .9966, PoPoPo = .9987, PPP = .9998. As expected, the fit of the calibration curves was improved by decreasing the concentration ranges in the calibration curves. If only the lower four concentrations were used (0.01 μg/μL, 0.05 μg/μL, 0.10 μg/μL, and 0.50 μg/μL), the correlation coefficients became: LnLnLn = .9992; LLL = .9999; OOO = 1.0000; SSS = .9999; PoPoPo = 1.0000; PPP = 1.0000. PPP and PoPoPo had correlation coefficients of 1.0000 if the point obtained for 1.0 μg/μL was also included.

Of the 0.01 μg/μL solution, 5 μL contained 50 ng of each TG. This amount was the approximate detection limit of tristearin under these chromatographic conditions. The detection limit of tripalmitin was lower. Use of a micro flow chromatographic system with no splitting of the effluent stream would likely result in lower limits of detection.

35-Component synthetic TG mixture. An FID chromatogram and an annotated MS total ion chromatogram of the synthetic mixture of heterogeneous TG are shown in Figure 2. Although different gradients of ACN/DCM were used on the two systems, the chromatograms gave similar peak patterns. The shorter gradient run on the LC/APCI–MS system produced less resolution than the longer gradient used for the LC–FID run. The heated capillary interface between the atmospheric pressure and high vacuum regions of the ionization interface also resulted in a slight loss in peak resolution. In spite of higher resolution in the FID chromatogram, several peaks were present which contained unresolved overlapped TG. The TG which were unresolved in

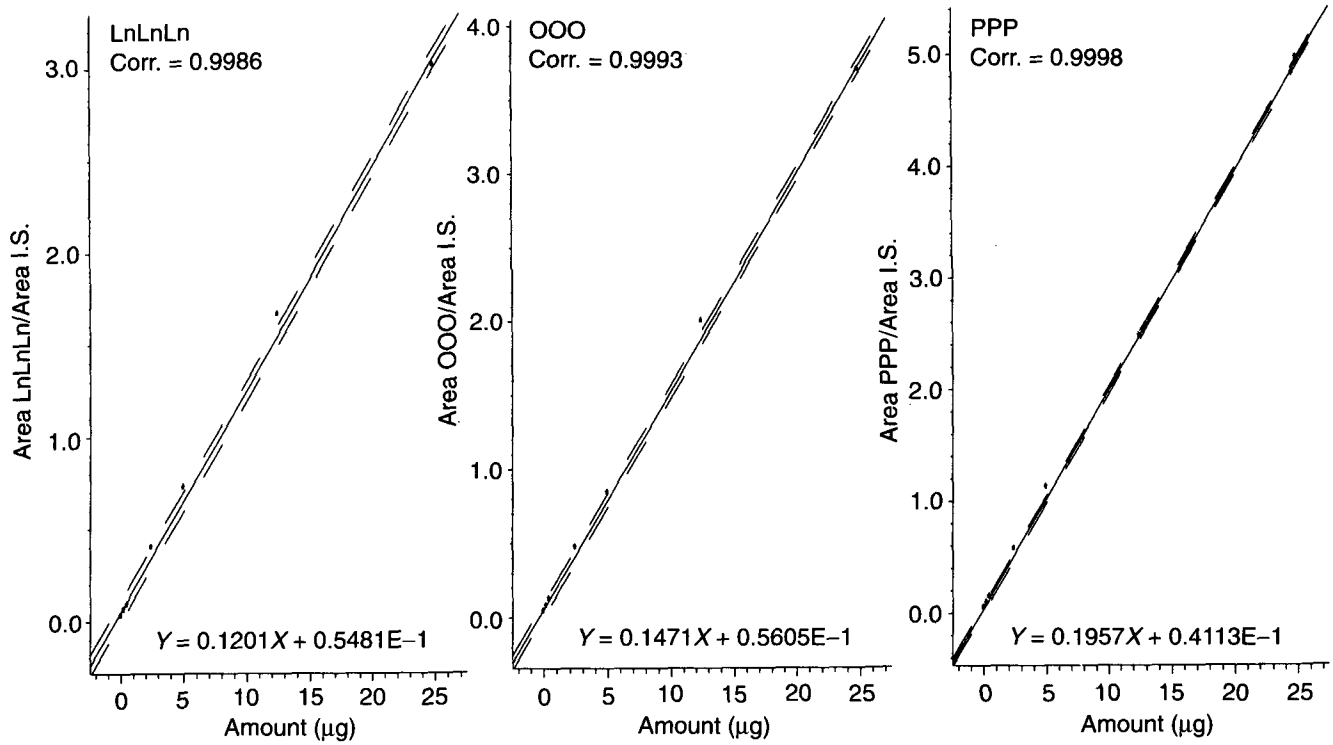

FIG. 1. Calibration curves for LnLnLn, OOO, and PPP where Ln is linolenic acid, O is oleic acid, and P is palmitic acid. Plots represent the total area for each triglyceride divided by the area of the internal standard peak, d_{12}-PPP, vs. the amount of each triglyceride injected. Line equations are given in slope/intercept form.

FID chromatograms were readily resolved by their different *m/z* in EIC. Because each TG produced up to three DG fragments, unresolved peaks in one EIC were resolved in other EIC of $[DG]^+$ arising from the same TG. The appearance of peaks in several EIC which all arose from one TG greatly facilitated the qualitative identification of individual TG in complex mixtures.

EIC of $[DG]^+$ *m/z* are shown in Figure 3. Each EIC showed an elution pattern which was based on the equivalent carbon number of the fatty acyl chains attached to the DG. The areas under the peaks in the $[DG]^+$ EIC were summed with the areas under peaks in EIC for $[M + 1]^+$ ions to provide a total area for each TG. The composition calculated from the combination of "raw" $[DG]^+$ and $[M + 1]^+$ ion areas for each TG in the EIC of the APCI–MS data is shown in Table 1. The composition determined by LC with FID detection is also given in Table 1. Positional isomers of the TG were not distinguished, so the abbreviations given in Table 1 identify molecular species without respect to the positional arrangement of the FA. Peaks in the EIC of *m/z* 603.5, arising from $[OO]^+$ and $[SL]^+$, were only partially resolved, so they were manually integrated to give the best approximation of appropriate peak areas. This partial overlap resulted in some variability, however, as demonstrated by the largest standard deviation in Table 1 shown by OLS. In the EIC of *m/z* 601.5, an unresolved overlap occurred between the "P" peak of $[OL]^+$ (#1) and the "O" peak of $[SLn]^+$ (#2). The ratios of the "Ln_1," "L_1," and "S_1" peaks to the "Ln_2," "L_2," and "S_2" peaks were used to apportion the overlapped peak, so that O_1/O_2 and P_1/P_2 were in the same proportion as $[(Ln_1 + L_1 + S_1)/(Ln_2 + L_2 + S_2)]$. Again, however, these individual peak areas represent only one of several peaks which contribute to the total area for a given TG molecular species.

The FA composition of the heterogeneous calibration mixture was determined (as the FAME) by GC with FID. The FAME mole percent composition was Ln = 18.5%; L = 19.8%; O = 20.2%; S = 20.6%; P = 20.9%. Using the above equations to calculate the randomly distributed TG percentage composition gave the statistical percentage composition shown in Table 1. The data in Table 1 demonstrate that the APCI–MS data require response factors to adjust the raw percentages to agree with the expected percentages. The areas under peaks attributable to the TG species (and the percentage composition) were dependent on the acyl chain length and on the fragmentation behavior of the TG, which was dependent on the number of sites of unsaturation in the TG species. Trisaturated TG produced virtually only $[DG]^+$ ion, with no $[M + 1]^+$ ion observed. Since the $[DG]^+$ ions, having lower *m/z*, were propagated through the MS system more efficiently than larger ions, they gave larger response than was observed for those TG which gave significant $[M + 1]^+$ ions. Conversely, TG containing polyunsaturated fatty acyl chains gave $[M + 1]^+$ ions as base peaks and showed less signal response. Other methods of mass spectrometric quantitation of TG have reported similar effects from unsaturation and/or chain length (15–19). Thus, Table 1 indicates that SSS was overrepresented, or gave a percentage composition larger than

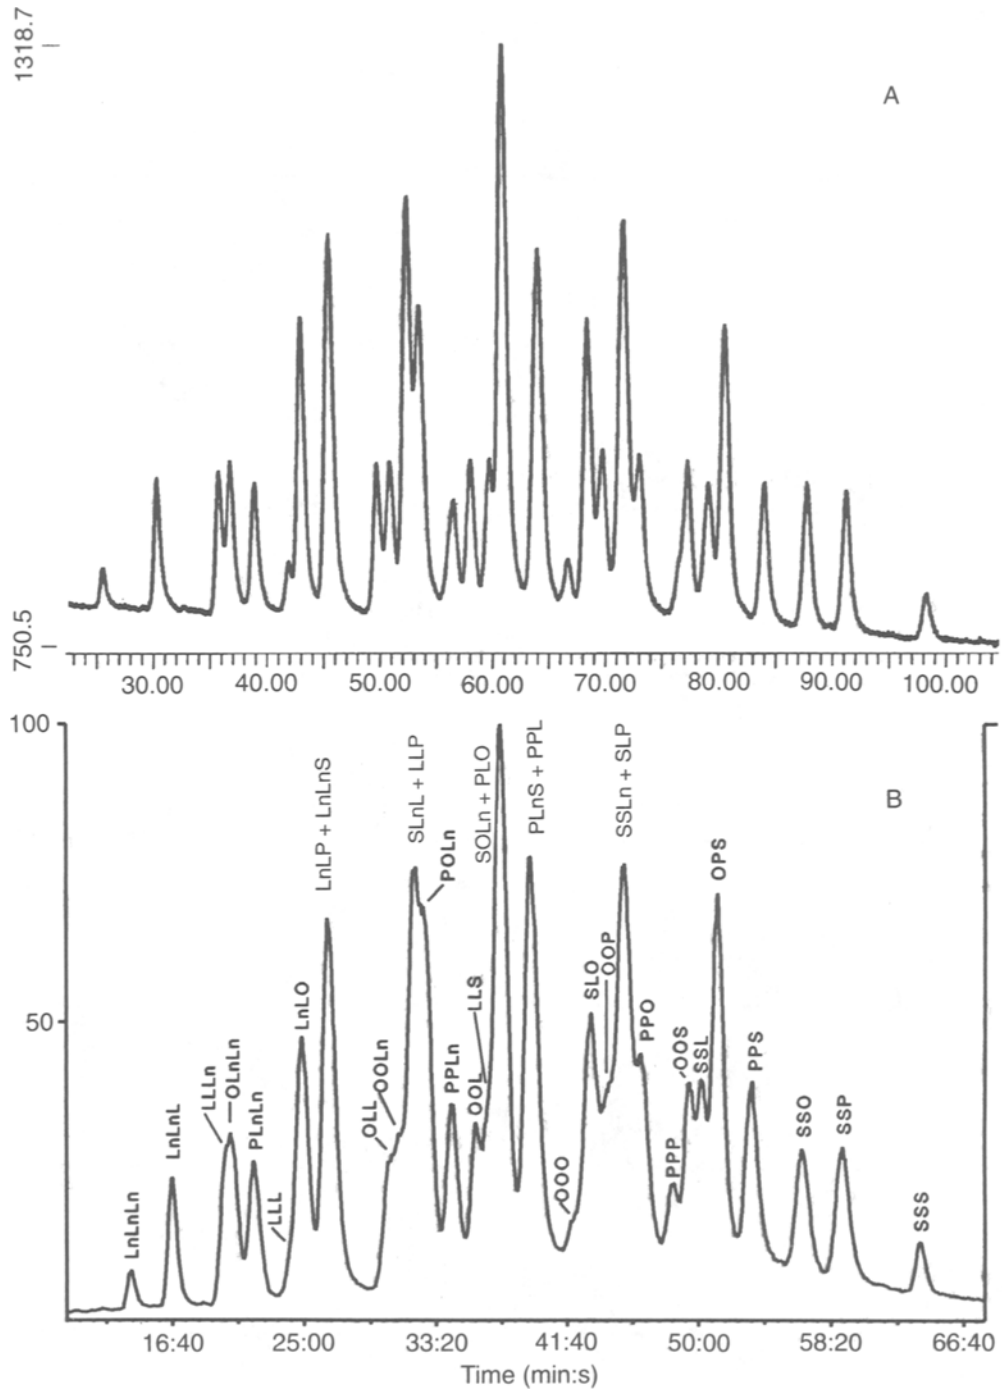

FIG. 2. A) Liquid chromatography–flame-ionization detection and B) liquid chromatography/atmospheric pressure chemical ionization–mass spectrometry chromatograms of a synthetic mixture of 35 triglycerides containing five randomly distributed fatty acids. Peak labels identify individual triglyceride molecular species. See Figure 1 for abbreviations; S, stearic acid; L, linoleic acid.

the calculated amount, while LnLnLn was underrepresented, or gave a percentage composition less than the calculated amount. PPP was overrepresented the most, as it had shorter acyl chains in addition to saturated acyl chains. Though not directly correlated, the same trend in dependence of the quantitative peak areas on the qualitative appearance of the spectra was seen in the sensitivities (slopes) of the calibration curves presented above. The sensitivity of the PPP calibration curve was larger than that for the SSS calibration curve, which was larger than that for the LnLnLn calibration curve. However, TG containing monounsaturated fatty acyl chains gave higher sensitivities than tri-saturates in the calibration curves.

Example mass spectra of four TG species are shown in

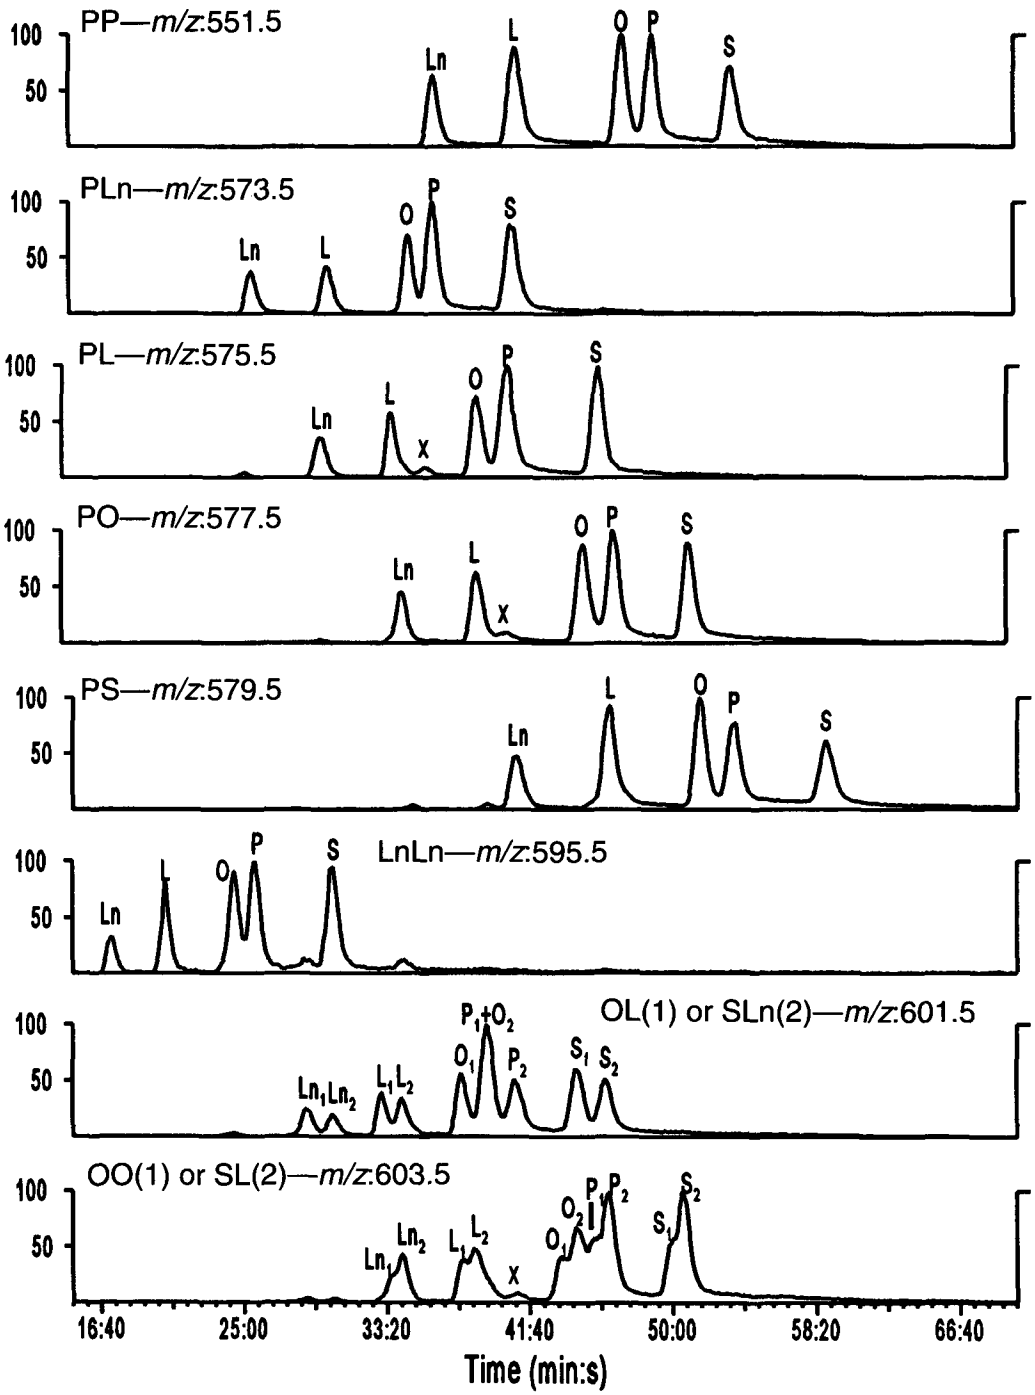

FIG. 3. Extracted ion chromatograms of [diglyceride (DG)]$^+$ *m/z* from a synthetic mixture of 35 triglycerides. [DG]$^+$ identity and *m/z* are given in the upper left of each chromatogram. The peaks are labeled with the identity of the fatty acid which, in combination with the [DG]$^+$, make each of the triglyceride molecular species. See Figures 1 and 2 for other abbreviations.

Figure 4. These spectra demonstrate that, as previously reported, spectra of TG containing more than four sites of unsaturation had [M + 1]$^+$ ions as base peaks, while spectra of TG containing less than three sites of unsaturation had [DG]$^+$ ions as base peaks. Though conditions were optimized to minimize the amount of PrCN adducts formed, these spectra showed distinct PrCN adduct ions. The separations carried out using only ACN/DCM gradients resulted in spectra containing virtually no adduct ions.

One method to produce response factors was to calculate a set of empirical factors for each TG which, when multiplied by the raw MS composition, gave the statistical composition.

[a]Abbreviations as in Table 1.
[b]FA composition calculated from the TG composition determined by LC/MS from the sum of $[DG]^+$ and $[TG + 1]^+$ peaks.
[c]FA composition calculated from the adjusted TG composition which was obtained by application of response factors derived from the ratio of FA compositions of the raw MS data and GC–FID data.
[d]FA composition calculated from the TG composition determined using LC with FID detection.

This set of response factors for each TG could then be applied to other TG mixtures containing a similar set of TG. Response factors obtained from the synthetic mixture were applied to the randomized SO sample presented below.

A second method for producing response factors was to compare the FA composition calculated from the TG composition to the FA composition determined by calibrated GC–FID. The FA compositions determined by GC–FID and calculated from the "raw" MS data are given in Table 2. The amount of palmitic acid calculated from the TG composition was larger than the amount determined by GC–FID, as was the amount of stearic acid. The amount of linolenic acid calculated from the TG composition was less than that determined by GC–FID. Response factors for each FA were calculated by dividing the FA composition determined by calibrated GC with FID detection by the FA composition calculated from the TG composition given from the "raw" APCI–MS data. These numbers were then normalized to the smallest value to produce a set of factors: P = 1.00; S = 1.12; O = 1.20; L = 1.19; Ln = 1.29. Response factors for each TG were calculated by simply multiplying the appropriate FA response factors together. For example, the response factor for PPP was $1.00 \cdot 1.00 \cdot 1.00 = 1.00$, while that for LLL was $1.19 \cdot 1.19 \cdot 1.19 = 1.68$. Application of the response factors calculated from the GC–FID FA composition gave the TG composition listed in Table 1.

It can be seen that the TG composition adjusted using the GC–FID-derived response factors agrees more closely with the calculated composition than does the composition determined by LC–FID, which is accepted for use for quantitation without response factors (20). The average relative error for the GC–FID-adjusted APCI–MS TG composition was 7.4% per TG compared to the predicted composition. The average relative error of the TG composition determined by LC–FID was 17.4% per TG compared to the predicted composition. The composition determined by LC–FID had an average relative error very similar in magnitude to the "raw" APCI–MS composition. The FA composition resultant from the response-factor-adjusted APCI–MS TG composition, Table 2, had an average relative error of 1.7% per FA compared to the FA composition determined by GC–FID. The FA composi-

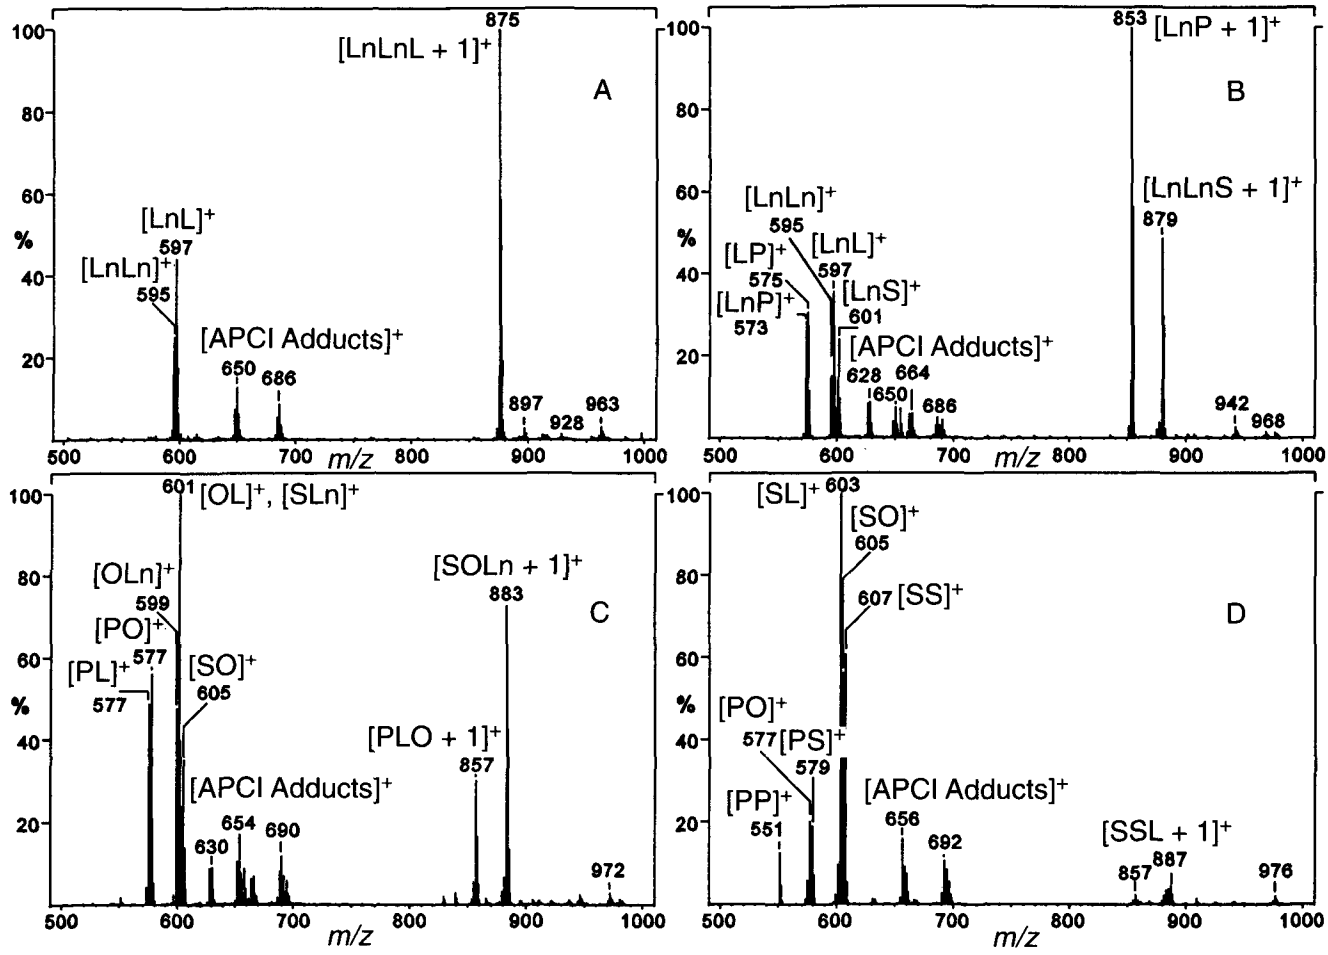

FIG. 4. Mass spectra of A) LnLnL (8 sites), B) LnLP and LnLnS (5 and 6 sites), C) PLO and SOLn (3 and 4 sites), and D) SSL with smaller amounts of OOS and OPS (2, 1 sites). Adducts formed were the $[DG + 53]^+$ and $[DG + 89]^+$ ions derived from addition of propionitrile [molecular weight (MW) = 55 amu)] and from addition of propionitrile plus acetonitrile (MW = 38 amu). See Figures 1, 2, and 3 for abbreviations; APC1, atmospheric pressure–chemical ionization.

tion resultant from the TG composition obtained from the LC–FID data had an average relative error of 4.0% per FA.

Randomized SBO. Chromatograms of randomized SBO obtained using LC–FID and LC/APCI–MS are shown in Figure 5. These two methods gave very similar peak patterns and comparable visible resolution. EIC were used to quantitate the $[DG]^+$ and $[M + 1]^+$ peak areas as described above. Example EIC are shown in Figure 6. Example mass spectra are shown in Figure 7. Because the chromatographic separation used an ACN/DCM gradient, these spectra did not show significant adduct formation. Only small amounts of ACN adducts were formed. The "raw" TG composition calculated from the sum of $[DG]^+$ and $[M + 1]^+$ peaks is given in Table 3, as is the composition determined by LC–FID. The theoretical TG composition of the randomized SBO was calculated using the FA composition determined by calibrated GC–FID, given in Table 4. The calculated TG composition is given in Table 3. The FA composition at carbon 2 of the TG determined by GC–FID of the products of lipase hydrolysis is given in Table 4, and may be compared to the composition at carbon 2 of normal SBO. The change in composition at carbon 2 toward that of the total FA composition indicated that randomization was mostly, but not absolutely, complete.

Response factors were produced by comparison of the FA composition calculated from the "raw" LC/APCI–MS data to the FA composition determined by GC–FID. The normalized response factors for the FA were as follows: P = 1.13; S = 1.00; O = 1.36; L = 1.87; Ln = 1.07. As above, these FA response factors were multiplied together to give TG response factors for each of the TG molecular species. The adjusted TG composition obtained using the FA-derived response factors is given in Table 3. These response factors generally reflected the qualitative fragmentation behavior discussed above except for the response factor for linolenic acid. Based on the considerations mentioned above, it was expected that this FA would be underrepresented and require a response factor greater than those for oleic and linoleic acids. In this SBO sample, in contrast to the synthetic mixture, linoleic acid

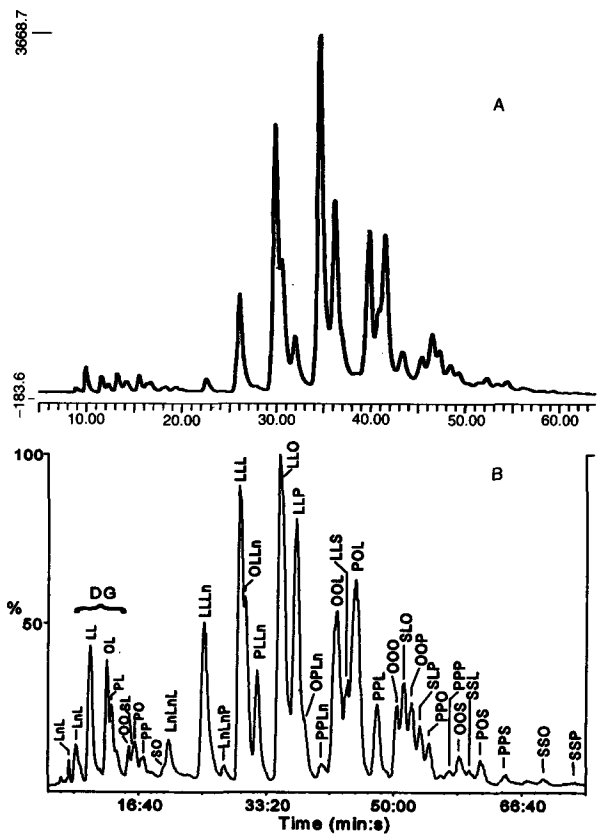

FIG. 5. A) Liquid chromatography–flame-ionization detection and B) liquid chromatography/atmospheric pressure chemical ionization–mass spectrometry chromatograms of randomized soybean oil. Peak labels identify individual DG and triglyceride molecular species. DG, formed during the randomization, eluted first. See Figures 1, 2, and 3 for abbreviations.

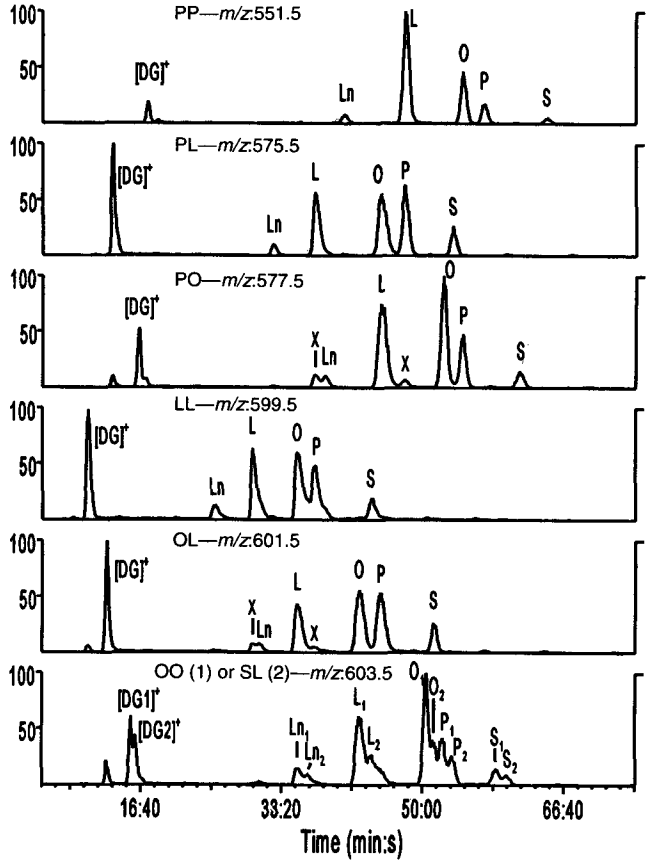

FIG. 6. Extracted ion chromatograms of $[DG]^+$ *m/z* from randomized soybean oil. $[DG]^+$ identity and *m/z* are given in the upper left of each chromatogram. The peaks are labeled with the identity of the fatty acid which, in combination with the $[DG]^+$, make each of the triglyceride molecular species. See Figures 1, 2, and 3 for abbreviations.

was present in a much larger percentage than was linolenic acid. Because of the elution patterns in the EIC, the "L" peak in one EIC gave a ^{13}C isotope peak, for molecules containing two ^{13}C atoms, at nearly the same chromatographic position as the "Ln" peak in the EIC for a DG having one less site of unsaturation (for instance, the "L" peak of the $[PL]^+$ EIC at *m/z* 575.5 gave an isotope peak at the same location as the "Ln" peak in the *m/z* 577.5 EIC of $[PO]^+$). The molecules which contained two ^{13}C isotopes therefore contributed peak area to the peaks in the EIC of the DG having one less site of unsaturation. When linoleic acid was present in a much larger amount than linolenic acid, the contribution of peak area from the isotope-containing molecules caused overestimation of the amount of linolenic acid-containing species. Imperfect chromatographic overlap of the peaks and some small variability in isotope ratios made subtraction of a calculated isotope area impractical. The response factors calculated from the FA composition or from the statistical composition effectively compensated for this overestimation.

The adjusted TG composition obtained using FA-derived response factors was in fair agreement with the composition calculated for a random distribution of the FA. The average relative error for the twenty most abundant molecular species was 8.6% per TG for the TG composition obtained from the GC-adjusted APCI–MS data, compared to the composition expected from a random distribution. The average relative error for the most abundant TG molecular species was 23.9% for the TG composition obtained by LC with FID detection, compared to the TG composition expected from a random distribution. TG molecular species which were not detected using LC–FID, which had relative errors of 100%, were not included in the calculation of the average percent relative error. The FA compositions calculated from the TG compositions obtained from the GC-adjusted MS data and the LC–FID data are given in Table 4. The FA composition calculated from the TG composition obtained from the GC-adjusted MS data had an average relative error of 2.2% per FA compared to the FA composition obtained by GC–FID. The FA composition calculated from the TG composition obtained by LC–FID had an average relative error of 6.5% per FA.

Quantitation based on response factors calculated from the synthetic mixture was also performed. Relative response factors for each TG were calculated by dividing the percentage expected from the random distribution of FA by the TG per-

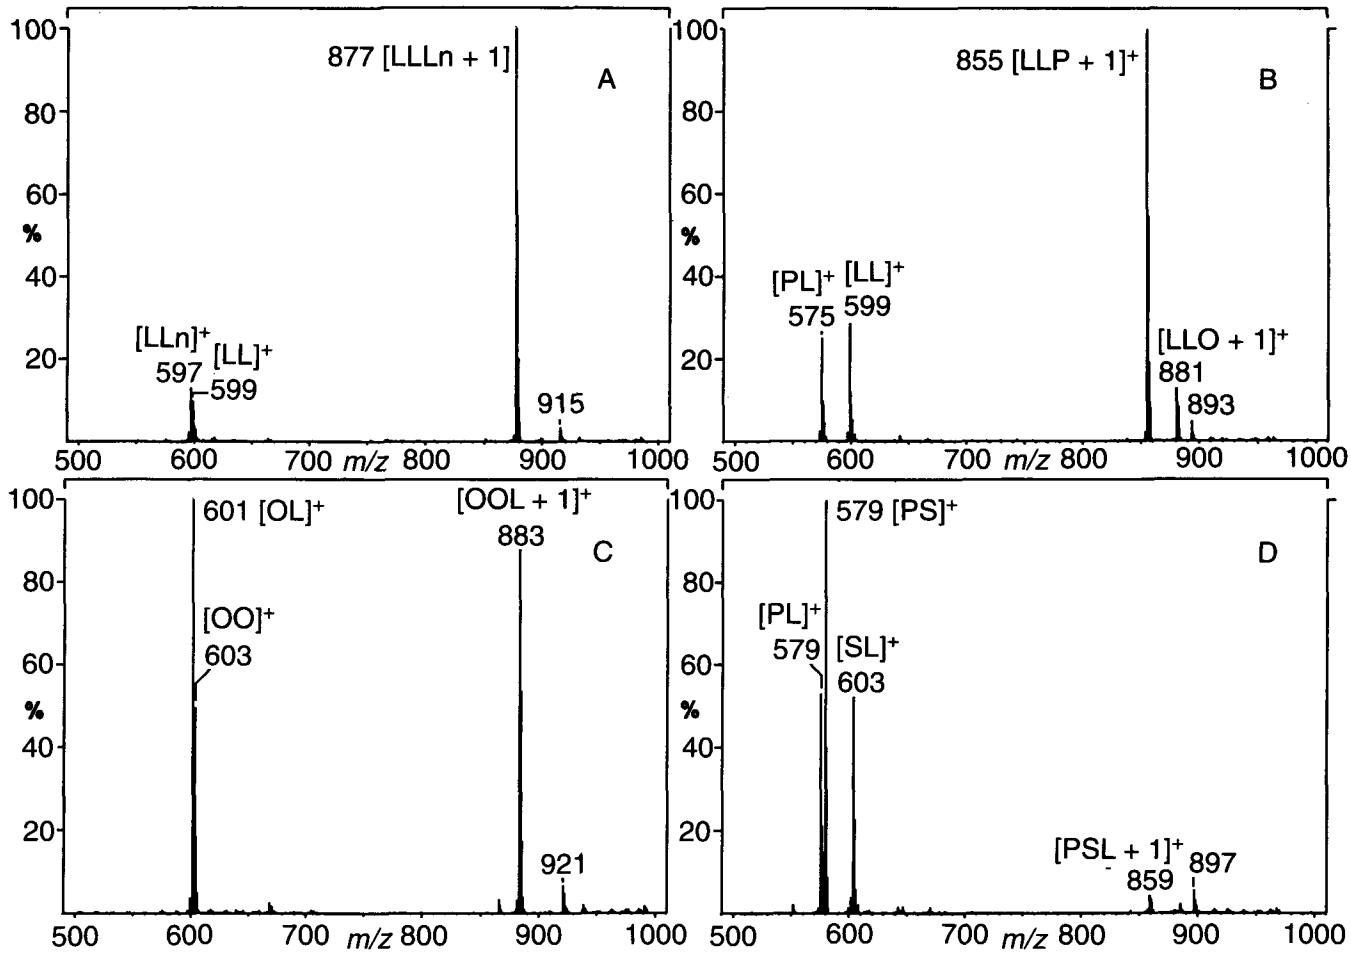

FIG. 7. Mass spectra of A) LLLn (7 sites), B) LLP with a small amount of LLO (4 sites), C) OOL (4 sites), and D) PSL (2 sites). Small amounts of [DG + 38]$^+$ adduct ions derived from addition of acetonitrile (MW = 38 amu) were formed. See Figures 1, 2, and 3 for abbreviations.

centage obtained by APCI–MS. Application of response factors thus obtained to the randomized SBO resulted in the TG composition given in Table 3. The poor agreement of the calculated composition with the expected composition indicated that relative response factors calculated from a sample with a significantly different percentage composition were not useful. The concentration dependence of the relative response factors necessitated use of response factors derived from mixtures of similar composition. The FA composition calculated from the TG composition obtained using response factors obtained from the synthetic mixture had an average relative of 26.7% per FA. Because of the demonstrated lack of utility, the use of response factors calculated from the synthetic mixture was not pursued further.

Normal SBO. A chromatogram obtained using LC with APCI–MS detection is shown in Figure 8. The TG composition obtained from this chromatogram is given in Table 5, listed as "raw" APCI–MS data. The TG composition determined by LC–FID is also given in Table 5. Quantitation using response factors derived from the FA composition determined by GC–FID was performed as described above. The FA composition calculated from the "raw" MS data and the FA composition determined by GC–FID are given in Table 6. The response factors calculated by comparison of the MS to the GC–FID data were: P = 1.12; S = 1.12; O = 1.44; L = 2.03; Ln = 1.00. Response factors for individual TG molecular species were calculated as described above. The TG composition which resulted from application of the response factors thus derived is given in Table 5, referred to as "GC–FID RF Adjusted %."

The FA composition obtained from the TG composition calculated using response factors derived from GC–FID data is given in Table 6. This FA composition showed an average relative error of 4.5% per FA, compared to 19.8% average relative error from the "raw" APCI–MS data and 9.2% average relative error per FA from the LC–FID data.

Quantitation was also performed using response factors calculated from the randomized SBO. Response factors for each of the TG molecular species were calculated by dividing the statistically expected composition for the randomized

[b]FA composition at glycerol carbon 2 determined by GC–FID analysis of the products of lipase hydrolysis. Perfect agreement with the total FA composition determined by GC–FID indicates complete randomization.

sample by the raw APCI–MS percentage composition. The response factors thus obtained were applied to the raw APCI–MS data for the normal SBO. The resultant TG composition is given in Table 5. The TG composition agrees very well with the TG composition obtained using response factors calculated from the GC–FID composition determined for the normal SBO. The FA composition calculated from the randomized-SBO-normalized TG composition, shown in Table 6, exhibited an average relative error of 6.5% per FA. This compares favorably with the results obtained from the GC–FID-derived response factor normalized data.

Despite the close similarity in the results obtained using response factors derived from randomized SBO vs. GC–FID data, the methods used to obtain the response factors were very different. The randomized SBO-derived response factors were dependent only on the GC–FID composition and statistical distribution determined for the randomized SBO sample, with no dependence on the GC composition actually determined for the normal SBO. On the other hand, the GC–FID-derived response factors had no dependence on the randomized SBO sample or on any statistical calculation, but depended only on the GC–FID data for the normal SBO. That the two approaches resulted in very similar TG compositions, and yielded similar calculated FA compositions indicated that both quantitation methods may be used to produce results which provide less average relative error than LC–FID results.

Randomized lard. An LC/APCI–MS chromatogram of randomized lard is shown in Figure 9. The TG composition determined from this chromatogram is given in Table 7, as is the composition determined by LC–FID. Because this was a ran-

domized sample, the theoretical composition could be calculated from the statistical distribution of FA. The FA composition determined by calibrated GC–FID used for calculation of the statistically expected TG composition is given in Table 8. The expected TG composition calculated from the FA composition is given in Table 7. Comparison of the FA composition at carbon 2 of the TG of the randomized lard to the total FA composition, Table 8, indicated that the lard was well randomized, in contrast to the FA composition at carbon 2 for the normal lard. The FA composition calculated from the "raw" TG composition determined by APCI–MS is given in Table 8. The FA composition determined by calibrated GC–FID was divided by the FA composition calculated from the "raw" TG composition to produce the following response factors for each of the FA: M = 1.66; Po = 1.00; P = 1.80; L = 1.90; O = 2.01; S = 1.73. Response factors for each of the TG molecular species was obtained by multiplying the appropriate FA response factors together, as described above. The TG composition resultant from application of the TG response factors derived from these FA response factors is given in Table 7. Because of the small amounts of linolenic acid and C_{20} fatty acids distributed throughout possible TG molecular species, these were not quantitated in the EIC for the lard samples, but several molecular species were identified by their fragments and pseudo-molecular ions. The average relative error for the 35 components which made up 99.6% of the quantitated composition was 10.1% per TG for the GC–FID-adjusted composition, compared to 31.4% per TG and 28.9% per TG for compositions determined by unadjusted APCI–MS data and LC–FID data, respectively. TG species which were not identified by LC–FID, and so had 100% relative error, were not included in the calculation of the average relative error for that detection method. Numerous species present at near 1% in composition were not identified in the LC–FID chromatograms because they eluted undetected under larger peaks. Many such species were conclusively identified from APCI–MS data, using EIC.

The FA compositions which were calculated from the TG compositions reported in Table 7 are shown in Table 8. As was the case for all samples discussed above, the average relative error for the FA composition calculated from the GC–FID-adjusted TG composition showed the least average relative error of the quantitation methods. The FA composition calculated from the LC–FID TG composition exhibited lower amounts of myristic and palmitoleic acids present than were determined by calibrated GC–FID. This is a result of the inability of the LC–FID detector to resolve the many minor components containing these FA which coeluted with components present in larger amounts. The EIC obtained from the APCI–MS data allowed ready identification, by $[DG]^+$ and $[M + 1]^+$ *m/z*, of numerous myristic and palmitoleic acid-containing species which coeluted with major species. This re-

sulted in excellent agreement between the response factor-adjusted APCI–MS data and the GC–FID data.

Normal lard. A chromatogram obtained by LC/APCI–MS of normal lard is shown in Figure 10. The TG composition determined from this chromatograms is given in Table 9. As in the case of normal SBO, two methods for calculation of response factors were used for quantitation of normal lard. Response factors were calculated by comparison of the FA composition determined by GC–FID, given in Table 10, to the FA composition calculated from the TG composition, and response factors were calculated from comparison of the theoretical composition of randomized lard to the composition determined by APCI–MS. The FA response factors calculated by dividing the FA composition calculated from the TG composition determined by APCI–MS by the FA composition determined by GC–FID, normalized to the smallest, were: M = 1.79; Po = 1.00; P = 1.84; L = 1.92; O = 1.91; S = 1.50. Response factors for each of the TG molecular species were obtained by multiplication of the appropriate FA response factors. The resultant response factor-adjusted TG compositions are given in Table 9. The adjusted APCI–MS compositions are in good agreement with each other, in contrast to the composition obtained using LC–FID. As with the randomized lard, numerous TG species present in amounts as high as 1.5% were not identified by LC–FID because they eluted undetected under larger chromatographic peaks. As with the randomized lard, this resulted in a FA composition calculated from the LC–FID TG composition which contained smaller amounts of myristic and palmitoleic acids than determined by GC–FID. The FA compositions calculation from the response-factor-adjusted APCI–MS data showed good agreement with the FA composition determined by calibrated GC–FID.

DISCUSSION

The analysis of the mono-acid TG presented above demonstrated that, for individual TG of interest, calibration curves having good correlation coefficients could be constructed. Even simple natural fats and oils, however, contain enough TG molecular species that it becomes impractical to construct calibration curves for all species of interest. Thus, alternative quantitation approaches were necessary which were targeted at more complicated samples. The trends observed in the slopes of the calibration curves, in correlation with the trends observed in the MS fragmentation patterns of TG with varying amounts of unsaturation, demonstrated that the quantitation of TG is distinctly related to the qualitative appearance of the spectra obtained using APCI–MS.

Quantitation of a complex sample generally depends on

analysis of samples of known composition containing all species of interest. It was hoped that a complex synthetic mixture could be produced which, by nature of the method of its synthesis, would have a known composition, which could then be used as a calibration mixture. Toward this end, the mixture of 35 TG derived from five FA was produced. However, as the results in Table 3 showed, it quickly became apparent that there was sufficient concentration dependence in the response of the TG that such a universal calibration mixture was not adequate. Examination of the calibration curves confirmed that there was a noticeable change in slope of the points at lower concentration vs. those at higher concentration, which resulted in a concave appearance of the curves. Thus, while overall the calibration curves indicated linear responses over a broad concentration region, within different regions of the curves enough difference in slope was present to indicate that there was potential for problematic effects in calculation of percentage composition in mixtures containing TG present in disparate percentages.

Another method for production of a complex mixture of known composition was necessitated. Just as the composition of the synthetic mixture was given by the statistical distribution of the FA used for the synthesis, the composition of a completely randomized sample is given by the statistical distribution of its FA composition. Thus, the FA composition determined by calibrated GC–FID could be used to determine the composition of a completely randomized sample. This approach has the advantage that, if the randomized sample was used for calibration of a similar nonrandomized sample, the FA composition should be the same, so that the concentration differences between TG species arising from those FA in the two samples would not be great. However, unlike the synthetic mixture, for which there was no theoretical reason to believe that a random distribution was not achieved, a randomized fat or oil sample depends on dissociation and then reassociation of FA from/to the glycerol backbone, so independent steps had be taken to confirm that randomization occurred. Lipase hydrolysis has become a commonly used tool for determination of the positional distribution of FA within TG species, by differentiating between FA at the carbon 1,3 positions vs. the carbon 2 position. While not perfect, this approach is generally considered useful to indicate the degree of randomization achieved. For a completely randomized sample, the composition determined for the FA at carbon 2 equals the total FA composition. This is in distinct contrast to most natural fats and oils, which show distinct preferential placement of FA, depending on the type of fat or oil. The differences in FA placement in normal vs. randomized oils is seen by comparison of the lipase data for randomized vs. normal SBO in Tables 4 and 6, respectively. Normal SBO showed much less palmitic acid in the carbon 2 position vs. the total FA composition, but more linoleic acid in this position vs. the total FA composition. In contrast, the randomized sample showed much better agreement between the total FA

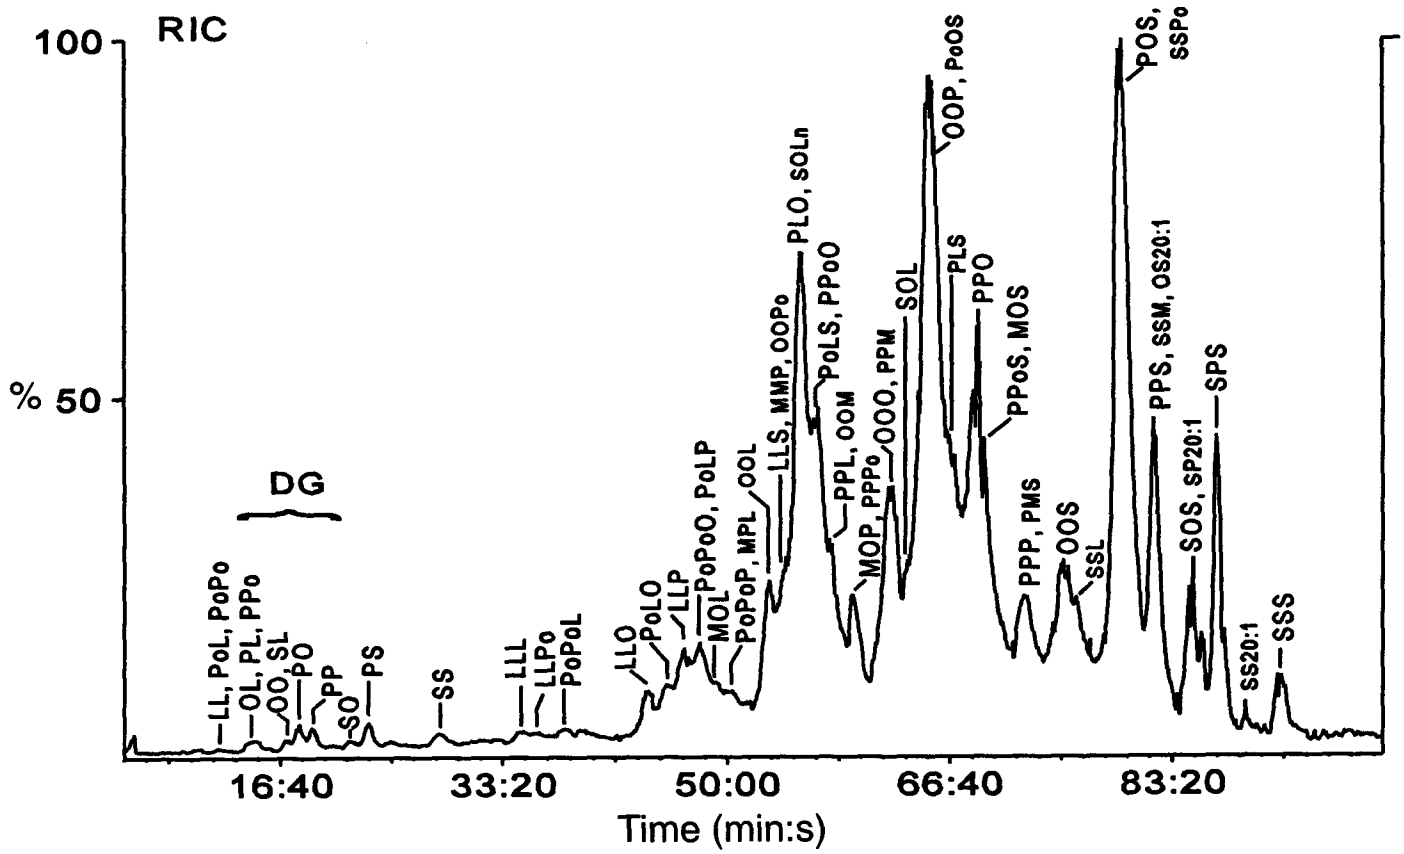

FIG. 10. Liquid chromatography/atmospheric pressure chemical ionization–mass spectrometry chromatogram of normal lard. Peak labels identify DG or triglyceride molecular species. See Figures 1, 2, 3, and 8 for abbreviations.

composition and the composition at carbon 2, though the agreement was not absolute, indicating that the randomization was not absolute. Opposite trends were observed in the lipase data for randomized vs. normal lard. Palmitic acid was preferentially incorporated into the 2-position of normal lard vs. randomized lard, shown in Tables 8 and 10, respectively, while less of oleic and linoleic acids appeared in the 2-position. More importantly, there was excellent agreement between the FA composition at the 2-position vs. the total FA composition, indicating a high degree of randomization.

The lipase data indicated that calculation of the TG composition of the randomized samples from the statistical distribution of the FA composition was expected to provide a good representation of the TG composition of the sample. Then, using the calculated TG composition to calculate response factors for each TG resulted in an adjusted TG composition equal to the random distribution. When the response factors thus derived were applied to the nonrandomized samples, good agreement was obtained between this method and another quantitation method, which used response factors based on FA. Importantly, the FA composition of the normal samples calculated from the TG composition obtained by application of the response factors calculated from the randomized samples showed excellent agreement with the FA composition obtained by calibrated GC–FID of the normal samples. The agreement with the GC–FID FA composition was better than that obtained from the TG composition determined by LC–FID, which was also in good agreement with the GC–FID results. However, the LC–FID detector did fail to identify numerous TG components. In the lard samples, most of these unidentified species contained myristic and palmitoleic acids, so these FA produced large relative error in the FA composition.

The response factors calculated using the synthetic mixture and the randomized samples all reflected the dependence of the qualitative behavior of the response factors on the fragmentation behavior of the TG, in combination with practical complications such as isotope peaks chromatographically coeluted with certain FA. The FA compositions calculated from the TG composition determined by APCI–MS also showed the same trends. Thus it seemed reasonable to use the FA composition for calculation of response factors to compensate for overrepresented and underrepresented FA. Several approaches were tried, but the best results came from simple multiplication of individual FA response factors together to produce TG response factors. The results obtained for all samples using this simple approach were in good agreement with calculated results, and the FA compositions calculated from the adjusted TG compositions were also in good agreement with the GC–FID results. Like the approach

which used response factors calculated from randomized samples, this approach gave composition information for many species which were undetected by LC–FID. This approach had an advantage over the use of response factors derived from the randomized samples: it was equally applicable to randomized and to normal samples alike. The response factors were calculated based on the net over- or under-response of the FA, with no dependence on statistical distribution. Thus, whether a sample has been completely randomized or not was irrelevant, because the FA composition was determined using GC–FID. Response factors produced from the randomized mixtures were dependent on the statistical distribution of the FA, so lipase hydrolysis, or other method for confirmation of the randomization, was necessary.

Two methods for quantitation of TG composition using LC/APCI–MS data have been presented which provided good agreement to each other and to expected results. They both yielded FA compositions which were in good agreement with FA compositions obtained using GC–FID analysis. The choice of which method is most appropriate for a particular use depends on the goals of the total analytical scheme being employed. Simple analyses of fat and oil TG composition may make use of the simplicity of calculation of response factors with only GC–FID data required. On the other hand, some analyses, such as studies of genetically modified seed oils or dietary studies, often require the use of additional techniques, like lipase hydrolysis, as routine aspects of the analytical approach, so this information should be used, if available. Both of the methods described yielded results which showed less relative error than the commonly used quantitation method of LC–FID analysis. Although the FA compositions calculated from the TG compositions obtained using LC–FID were in good agreement with the FA compositions obtained by GC–FID (except for FA present at moderately low levels), the TG composition obtained by LC–FID contained numerous omissions of TG species which were conclusively identified using LC/APCI–MS. The two-dimensional nature of the FID, as well as ELSD and other detectors, imposes inherent limitations on their ability to fully characterize complex fat and oil samples. A simple and versatile analytical method like LC/APCI–MS makes mass spectrometric detection an attractive alternative for complete qualitative and quantitative characterization of complex TG mixtures.

Department of Biochemistry and Food Chemistry, University of Turku, FIN-20014 Turku, Finland

ABSTRACT: The changes in the triacylglycerol (TAG) composition of colostrum fat of three cows were studied. In addition to the determination of fatty acid composition by gas chromatography, the distribution of TAG according to the acyl carbon number (ACN) and molecular weight was analyzed utilizing both supercritical fluid chromatography (SFC) and ammonia negative-ion chemical ionization mass spectrometry (MS). Colostrum TAG contained substantially less stearic and oleic acids and more myristic and palmitic acids than the normal Finnish milk fat. The major trends in the changes of fatty acids and TAG were similar for each cow, although clear differences between individuals were found. During the first week of parturition, the proportions of short-chain fatty acids (C_4–C_{10}) typically increased as well as those of stearic and oleic acids, whereas the relative amounts of C_{12}–C_{16} acids decreased, especially those of myristic and palmitic acids. Distinct changes occurred also in TAG distributions: the proportions of molecules with ACN 38–40 increased and those with ACN 44–48 decreased. Although there were distinct differences between individuals shortly after delivery, both the fatty acid compositions and TAG distributions of the milk samples of the cows started to resemble each other after one week. The theoretical profiles of colostrum TAG calculated based on the fatty acid compositions differed clearly from the ACN distributions analyzed by SFC and MS. Thus, the analysis of TAG is essential, because the changes in molecular species composition of colostrum TAG cannot be estimated according to the fatty acid analysis alone. *Lipids 31*, 937–943 (1996).

The composition of milk fat triacylglycerols (TAG) has been extensively studied. However, most often information on the fatty acid composition, produced by gas chromatography (GC), has been found to be adequate. More specific information about milk fat has been achieved by analyzing the intact TAG by chromatographic methods, such as GC on both nonpolar (1,2) and polar stationary phases (3–5), and by high-performance liquid chromatography (HPLC) on reversed-phase columns (2,6–9) and ion-exchange columns loaded with silver ions (7,8,10–12). Furthermore, supercritical fluid chromatography (SFC) has been proved to be a useful technique for the analysis of TAG of various samples, including milk fat (13). In addition, milk fat TAG have been analyzed utilizing mass spectrometry (MS) in different modes usually in combination with chromatographic separation techniques (4,6,8,9,14–16). Chromatography prior to MS improves the interpretation of the results of complex mixtures. For some purposes, ammonia negative-ion chemical ionization MS, without chromatographic separation, has been found to be a rapid and sensitive technique for the analysis of TAG (17,18).

The colostrum of various species differs clearly from the mature milk. Some studies have been focused on the determination of fatty acid composition in cow colostrum and changes in the proportions of fatty acids after parturition (19–23). However, the TAG composition of colostrum has not been studied extensively. The present study was designed to provide information on the changes occurring in the composition of cow colostrum during the first week after parturition. The fatty acid compositions were determined by GC, and the TAG were separated according to the acyl carbon numbers (ACN) by SFC on a nonpolar column. In addition, molecular weight species of TAG were analyzed by ammonia negative-ion chemical ionization MS. The theoretical ACN distribution of TAG was calculated based on the fatty acid compositions and compared with that obtained on SFC and MS.

EXPERIMENTAL PROCEDURES

Materials. Milk samples were received from three cows, two of which were Ayrshires (cow 1, cow 2) and one Frisian (cow 3). Cow 2 was a descendant of cow 1. The cows were bred in Finland on the same farm and kept on the same diet consisting of oat meal, silage, concentrate, dry hay (*ad libitum*), minerals, and vitamins. The cows calved during a 10-d period in February 1993. Cow 1 had its fourth parturition, whereas cow 2 had its first and cow 3 its fifth calving. The milk samples were collected after every 12 h during the first week after parturition and stored at −20°C until the fat was separated by centrifugation and phase-exchange using sodium sulphate. TAG were purified from the total lipids by elution from short columns of Florisil™ with 10 mL of *n*-hexane/diethyl ether (4:1, vol/vol). Purified TAG fractions of 1 mg were dissolved in 1 mL of *n*-hexane for mass spec-

trometric analyses and for preparation of fatty acid methyl esters. An aliquot of the total lipid fraction was diluted in dichloromethane for supercritical fluid chromatographic analyses. All solvents were of HPLC-grade and were supplied by Merck (Darmstadt, Germany) or Rathburn (Walkerburn, Scotland).

GC. Fatty acid methyl esters of the TAG were prepared by sodium methoxide-catalyzed transesterification as described elsewhere (7). The analyses were obtained on a Hewlett Packard 5890 gas chromatograph (Palo Alto, CA), equipped with a split injector (split ratio 35:1) and a flame-ionization detector (FID). An OV-351 column (25 m × 0.20 mm i.d. with 0.20 μm film; HNU-Nordion Instruments Ltd., Helsinki, Finland) was used for GC with a three-step temperature programming initialized at 35°C with a 3-min isothermal period followed by a linear temperature increase at 10°C min^{-1} from 35 to 160°C, 2°C min^{-1} from 160 to 190°C, and 5°C min^{-1} from 190 to 230°C. The injector and detector temperatures were 225 and 240°C, respectively. Helium was used as a carrier gas with a column flow rate of 30 cm s^{-1} measured with propane at the initial conditions of the chromatographic program. Fatty acids were identified by reference to three standard mixtures of fatty acid methyl esters (ME61, ME68, and BR1; Larodan Fine Chemicals AB, Malmö, Sweden). The response correction factor for each fatty acid methyl ester, used for the conversion of percentage peak area to mol%, was determined by analyzing the reference mixture ME61.

SFC. The SFC analyses were conducted with a Lee Scientific Series 600 supercritical fluid chromatograph (Dionex, Salt Lake City, UT) equipped with an FID. The temperature of the FID was held at 340°C, and nitrogen was used as a make-up gas. An electrically and pneumatically controlled Valco switching valve (Valco Instruments Co. Inc., Houston, TX) with an internal loop volume of 1.0 μL was used for timed split/dynamic split injections with a loop-open time of 0.6 s. Frit restrictors (30 cm × 50 μm i.d.; Dionex) were installed both at the dynamic split outlet and at the detector end of the analytical column. SFC-grade CO_2 (Scott Specialty Gases, Plumsteadville, PA) was used as a carrier fluid with a column flow rate of 0.37 mL min^{-1} measured with propane at the initial conditions of the chromatographic program. An SB-Octyl-50 column (10 m × 50 μm i.d. with 0.25 μm film; Dionex) was used with linear density programming of CO_2 from 0.140 g mL^{-1} with a rate of 0.010 g mL^{-1} min^{-1} at a constant temperature of 140°C for the elution of TAG. Samples of 40 mg were dissolved in 1 mL of dichloromethane. The ACN distributions of TAG in the figures were means of three determinations without applying response factors.

MS. Ammonia negative-ion chemical ionization of TAG was obtained on a Finnigan MAT (San Jose, CA) TSQ-700 triple quadrupole instrument with a direct exposure probe for sample introduction (17,18). An aliquot of 1.0 μL of TAG dissolved in *n*-hexane was applied to the rhenium wire of the direct exposure probe. The probe was introduced into the ion source after the sample solvent was evaporated at ambient temperature. The sample was vaporized in the ion source by heating the rhenium wire with the current rate of 40 mA s^{-1}. The pressure of ammonia (≥ 99.998%; Prax Air, Oevel, Belgium) was 8500 mtorr, and the ion source temperature was 200°C. The electron energy applied was 70 eV and the filament current 400 μA. The *m/z* values were scanned from 450 to 950 with a scanning time of 0.5 s. Ammonia negative-ion chemical ionization MS of TAG yielded simple spectra containing abundant $[M - H]^-$ ions only in the scanned molecular weight region. Scans containing ions representing deprotonated TAG were averaged in each analysis. The abundance of the $[M - H]^-$ ions in the averaged spectrum was corrected according to the ^{13}C and ^{18}O isotopes, before expressing the results as the mean of four analyses. No corrections were made according to the mass spectrometric response factors of TAG.

RESULTS AND DISCUSSION

Fatty acid compositions. The changes in the fatty acid composition of colostrum TAG during the first week after parturition were determined by GC as fatty acid methyl esters. Altogether 26 fatty acids were separated and identified from the colostrum fat samples. The most abundant fatty acids were butyric acid, myristic acid, palmitic acid, stearic acid, and oleic acid, together representing more than 75 mol% of the total fatty acids in each sample. Compared with the composition of normal Finnish milk fat (8), the colostrum TAG were substantially lower in stearic and oleic acids, and richer in myristic and palmitic acids.

The major trends in the changes of the proportions of fatty acids were similar for each cow, although variation between individuals was found (Fig. 1). The proportions of the short-chain fatty acids, from C_4 to C_{10}, increased after parturition with the exception of cow 1. The relative amounts of fatty acids with 12–16 acyl carbon atoms typically decreased, especially those of myristic acid and palmitic acid. Furthermore, the proportions of stearic acid, oleic acid, and *cis*-vaccenic acid (data not shown) increased after parturition with the exception of cow 2. The relative amounts of linoleic acid and α-linolenic acid (data not shown) were less than 2 and 0.6 mol%, respectively, in each sample, and only minor changes in their proportions were observed. In general, the proportions of different fatty acids started to resemble each other more and approached the composition of normal Finnish milk fat after one week, even though there were great differences between individuals shortly after delivery. For example, the proportion of $C_{18:1}$ fatty acids in the milk samples of the three cows approached the value of 20 mol% which is typical for Finnish winter milk.

Our results are in good accordance with those reported by Senft and Klobasa (20) and Baše *et al.* (22). There are also contradictory results as reviewed by Christie (24) and Hawke and Taylor (25): the proportion of palmitic acid has been reported to remain relatively constant or increase slightly, and the relative amounts of stearic acid and oleic acid have been found to diminish after calving. During early lactation, the fatty acids are mobilized extensively from the adipose tissue

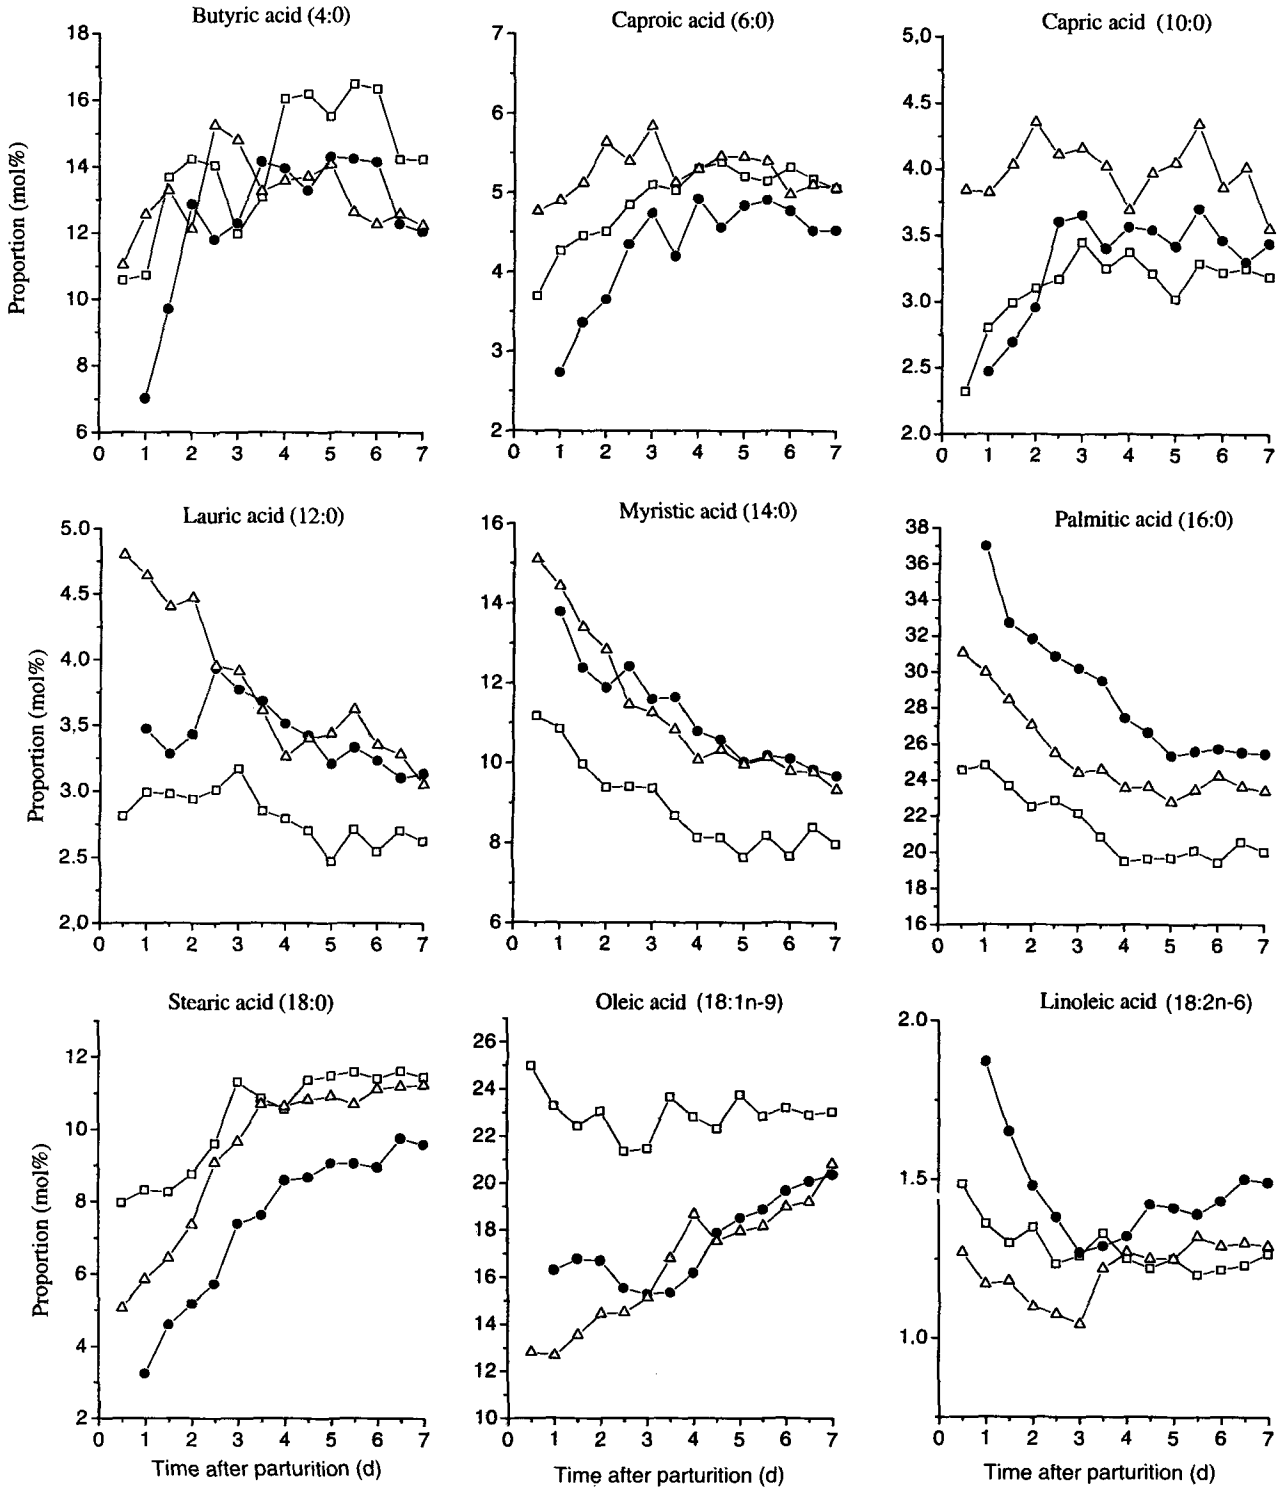

FIG. 1. Changes in the proportions (mol%) of fatty acids in the milk fat triacylglycerols of three Finnish cows (△ = cow 1, □ = cow 2, ● = cow 3) during the first week after parturition. The most abundant fatty acids of groups representing C_4–C_{10} acids, C_{12}–C_{16} acids, and C_{17}–C_{18} fatty acids are presented. The method for the analysis of fatty acids is described in the Experimental Procedures section.

for milk fat synthesis. A decline in the proportions of C_{18} fatty acids has been assumed to reflect the drop in the extent of lipid mobilization from the adipose tissue after parturition (24). The most abundant fatty acids in the tallow of Finnish cows are palmitic, stearic, and oleic acids. Thus, the diminished mobilization of storage lipids would partially explain the decrease in the proportion of palmitic acid, but not the observed increase in the proportions of stearic acid and oleic acid in the present study. The high content of myristic acid in the milk TAG shortly after delivery and the increase in the proportions

of short-chain fatty acids indicate distinct changes in the *de novo* synthesis of fatty acids after parturition.

Although significant changes in the proportions of individual fatty acids occurred during the first week after parturition, the proportions of total saturates (approximately 70 mol%) and unsaturates (approximately 30 mol%) were nearly constant. In general, the most distinct changes in fatty acids occurred during the first four days, after which the composition slowly approached that of normal milk fat. The fatty acid compositions, however, did not provide information concerning changes at the molecular level, thus, other techniques were required.

TAG distributions. The TAG compositions of the colostrum samples were measured with both SFC and MS. SFC separated TAG mainly according to the combined number of acyl carbons on a nonpolar stationary phase (Fig. 2). Colostrum TAG were separated into groups representing molecules with 26–54 acyl carbons. The presence of isobaric TAG, differing substantially in the chainlength of the fatty acyl residues, resulted in a partial separation within most of the ACN-groups. For example, 1,3-dipalmitoyl-2-butanoyl-*sn*-glycerol eluted well-separated after trilauroylglycerol as tested with reference compounds. In addition to the molecular association of fatty acids, the steric interactions between the fatty acid moieties and the stationary phase have an effect on the retention. The differences in unsaturation of the analytes were less important on the separation, causing only slight broadening of the chromatographic peaks. Figure 2 shows that the distribution of TAG changed clearly after parturition. For example, a decline in the proportions of molecules having from 42 to 48 acyl carbons was found. The repeatability of the analysis was acceptable, the coefficient of variation typically being less than 3% for the components corresponding to more than 1% of the total.

The advantage of MS was the unit resolution that made it possible to achieve information on the molecular species composition of TAG. The *m/z* values of the $[M - H]^-$ ions characterized the combined number of acyl carbons and double bonds in the acyl chains of TAG, and the abundances of the $[M - H]^-$ ions defined the proportions of different molecular weight species of TAG. In addition to the ACN distribution, the analysis of colostrum TAG by ammonia negative-ion chemical ionization MS produced information on the saturated, monoenoic, dienoic, and polyenoic TAG consisting of fatty acids with even or odd numbers of carbon atoms without chromatographic separation. TAG containing *cis*- or *trans*-fatty acids could not be separated with the method used.

Information on the ACN distribution of TAG was achieved from both SFC and MS determinations. Figure 3 shows as an example the measured ACN distributions of the TAG of the milk samples of cow 1. The proportions of different ACN-groups, analyzed either by SFC or MS, differed to some extent, which was due to the differences in molecular discrimination of the analytical techniques. Nevertheless, both methods provided similar trends for the changes of colostrum TAG, and therefore, are useful for biological screening purposes.

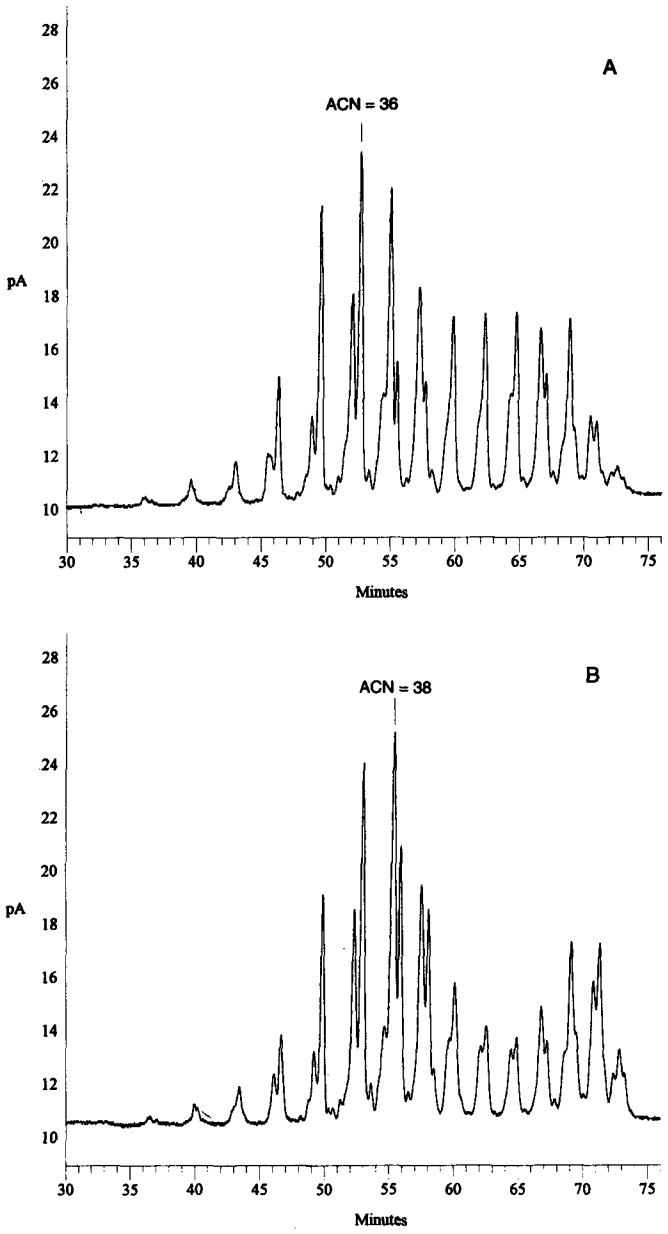

FIG. 2. Supercritical fluid chromatographic separation of the triacylglycerols of the colostrum samples: A, 1 d after parturition; and B, 7 d after parturition of the cow 1 on an SB-Octyl-50 column (10 m × 50 μm i.d. with 0.25 μm film; Dionex, Salt Lake City, UT). ACN, acyl carbon number.

The differences in the TAG profiles between the cows studied were marked; however, similarities were also found. The general distribution profile of TAG of each sample was bimodal. TAG with ACN 36–40 were the most abundant components among the molecules, which may contain butyric acid. The maximum of the TAG, which do not contain butyric acid, was in the region of ACN 46–52. The composition changed substantially during the first week after parturition: the proportions of TAG with ACN 38–40 increased and those with ACN 44–48 decreased. The alterations in the proportions of molecules with 50–54 acyl carbons varied from cow

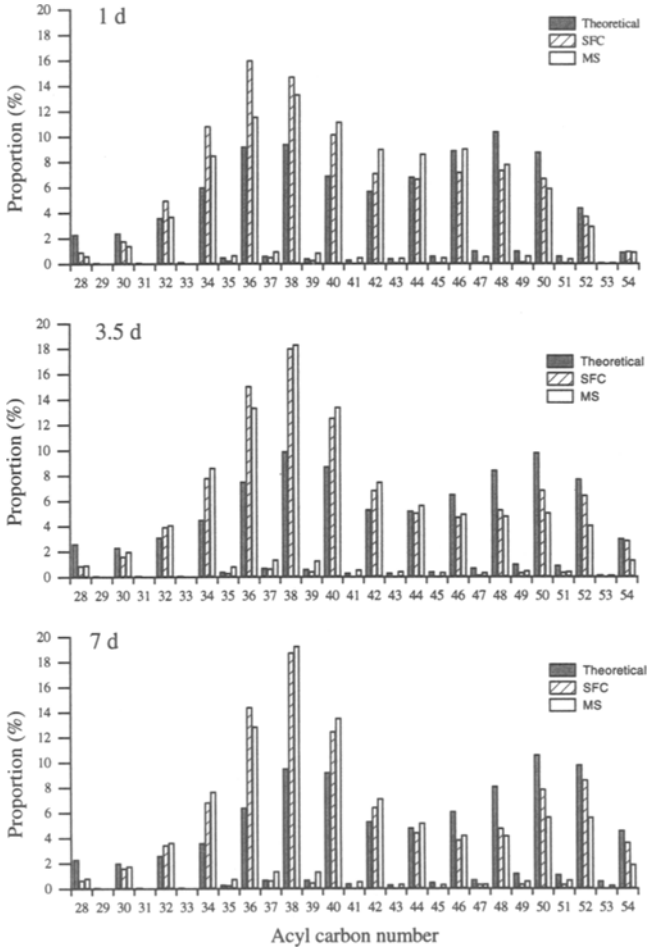

FIG. 3. Acyl carbon number (ACN) distribution of milk fat triacylglycerols 1, 3.5, and 7 d after parturition of the cow 1 determined by supercritical fluid chromatography (SFC) and mass spectrometry (MS). The theoretical ACN distribution of triacylglycerols is calculated according to the fatty acid compositions, assuming a 1,2,3-random distribution of fatty acids.

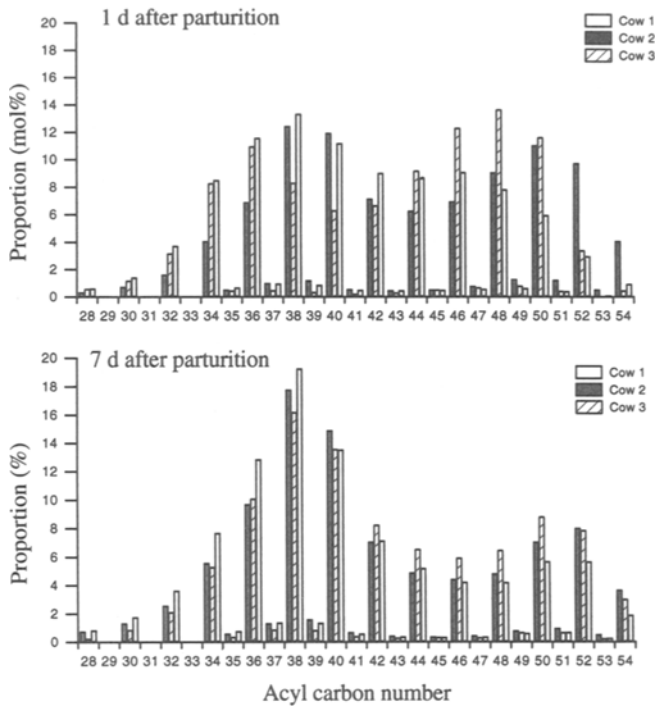

FIG. 4. Acyl carbon number distribution of milk fat triacylglycerols of three Finnish cows 1 and 7 d after parturition. The results are based on the mass spectrometric data.

to cow and may be explained by the great differences in the proportions of $C_{18:1}$ fatty acids between individuals (Fig. 1). Figure 4 presents the TAG distributions, based on MS-data, of the colostrum of each cow collected 1 d and 7 d after parturition. The TAG profiles showed distinct differences between individual cows shortly after delivery. After one week, the changes between the cows were clearly diminished and the compositions of milk TAG were much alike.

For comparison, the distribution of the TAG of each colostrum sample was calculated according to the fatty acid composition, assuming a 1,2,3-random distribution of fatty acids. The theoretical distributions of TAG clearly differed from those measured by SFC and MS (Fig. 3): the proportions of TAG with ACN 34–42 were underestimated and the proportions of TAG with ACN 28 and 46–52 overestimated. The nonrandom structure of TAG of mature milk is well known (26,27), and similar deviations from the random distribution have been reported elsewhere (9,28). The molecular association of fatty acids during the biosynthesis of milk fat TAG is not a random process; therefore, it is not possible to estimate the changes occurring in molecular species composition of TAG based on the fatty acid analysis alone.

In addition to ACN distributions obtained on SFC and MS, the mass spectrometric analysis provided information on differently unsaturated molecular species of TAG. The proportions of saturated, monoenoic, dienoic and trienoic TAG in the colostrum of the three cows studied are presented in Table 1. The differences in the TAG composition of the milk samples after 1 d of parturition of each cow were distinct. After one week of parturition, the TAG compositions were more alike; 32–44 mol% saturated TAG, 41–45 mol% monoenes, 12–19 mol% dienes, and 2–4 mol% trienes. This kind of composition of the TAG is typical for Finnish winter butter fat (8).

As an example, the changes in the distribution of saturated and monoenoic TAG in the milk samples of cow 1 are shown in Figure 5. The most abundant saturated components were 34:0, 36:0, and 38:0. The proportion of 38:0 increased after parturition in the colostrum of each cow, whereas the proportions of 44:0–48:0 declined. The changes in the relative amounts of 28:0–36:0 varied from cow to cow. The profiles of monoenoic TAG were bimodal, closely resembling the ACN profiles. The most abundant monoenoic TAG were 36:1, 38:1, 40:1, 46:1, 48:1, and 50:1. Typically, the proportions of TAG 28:1–40:1 increased and those of TAG 44:1–50:1 decreased after parturition.

The data presented in this study, i.e., changes in the fatty acid compositions and TAG profiles, improves our under-

TABLE 1
Changes in the Proportion (mol%) of Triacylglycerols, Differing in the Degree of Unsaturation, in the Milk Samples of Three Finnish Cows During the First Week After Parturition[a]

Triacylglycerols	Time after parturition (d)	Proportion (mol%) Cow 1	Cow 2	Cow 3
Saturated	1	51.6	27.4	41.6

	7	0.3	0.4	0.6

[a]Results calculated from mass spectrometric data.

standing of biological changes in colostrum TAG. Apparent differences between individuals were found, which may be due to genetic factors including the breed of a cow, the age, and the time of delivery. Changes in the fatty acid composition of the milk samples determined by capillary GC did not provide adequate information about the changes in TAG compositions. Comparisons of the ACN distributions of colostrum TAG, measured by SFC and MS, with the theoretical ones, based on the fatty acid compositions, clearly showed that the molecular association of fatty acids during the biosynthesis of milk fat is not a random process. Both SFC and MS are convenient techniques for the analysis of TAG. The ACN distribution of TAG is achieved directly from the SFC data sheet, whereas MS data providing more detailed information require extensive calculations. Therefore, sophisticated computer programs for the handling of MS data would be advantageous in routine analysis. The present study clearly showed that it was not possible to estimate the changes in the molecular species composition of colostrum TAG according to the fatty acid analysis alone. Instead, both SFC and MS analyses provided valuable information about TAG compositions in the colostrum.

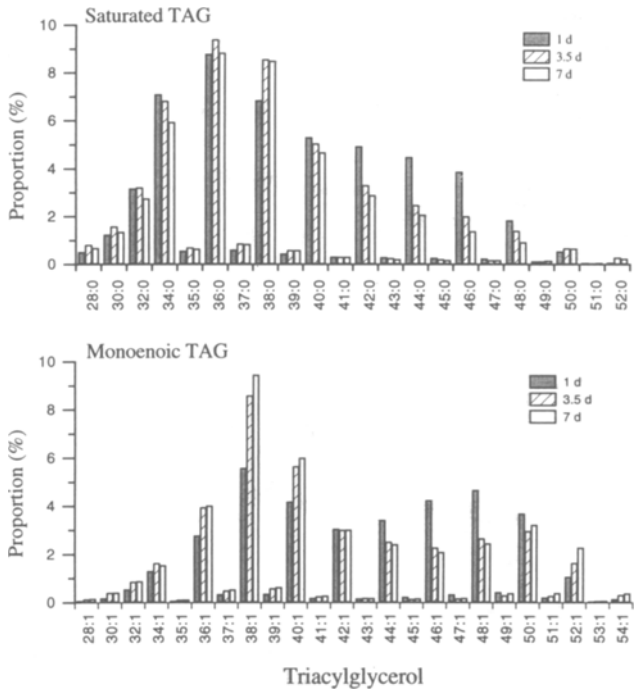

FIG. 5. Changes in the distribution of saturated and monoenoic triacylglycerols (TAG) in the milk fat of cow 1 during the first week after parturition (1, 3.5, and 7 d).

Departments of Surgery, Beth Israel Medical Center, New York, New York
and the Albert Einstein College of Medicine, The Bronx, New York

ABSTRACT: This study examined the effect of castration and dietary hormonal supplementation on cholesterol cholelithiasis in male hamsters. Animals fed a standard lithogenic diet developed cholesterol gallstones (17%) after 6 wk, while castrated hamsters did not form any stones. Addition of a synthetic androgen, methyltestosterone, to the lithogenic diet induced cholelithiasis in castrated animals (50%). The biles of normal and castrated-hormone supplemented hamsters had cholesterol saturation indices of 1.0 and 1.1, respectively, while the bile of the castrated animals remained unsaturated (0.6). The ratio of cholic acid/chenodeoxycholic acid in bile increased after castration, but returned to normal levels following hormonal supplementation. Biliary cholesterol carriers were separated by ultracentrifugation. Animals in the stone-forming groups (normal and castrated-hormone treated) had a significant proportion of their biliary cholesterol in vesicles (44 and 46%, respectively); castrated hamsters had less cholesterol in vesicle form (9%). The molar ratio of cholesterol/phospholipid in vesicles was reduced after castration (0.93 vs. 0.42) and increased by hormonal supplementation (1.89). In conclusion, when compared to normal male hamsters fed a standard lithogenic diet, castration reduced the cholesterol saturation of bile, lowered the vesicular/micellar ratio in bile, and inhibited cholesterol cholelithiasis. Dietary androgen supplementation increased the lithogenicity of bile, resulting in stone formation in castrated animals.
Lipids 31, 945–948 (1996).

Generally, it is believed that sex hormones influence the incidence of cholesterol cholelithiasis in man (1–4). We have previously shown that male hamsters formed cholesterol gallstones when fed a lithogenic diet (LD), whereas female hamsters fed the identical diet were completely resistant to stone formation (5–7). Dietary administration of the synthetic androgen, methyltestosterone (MeT), to female hamsters induced cholelithiasis to levels observed in males (7). However, the role of the male hormone in gallstone formation remained unclear.

Castration of the male hamster is a surgical procedure which allowed us to evaluate whether male hormones affect cholelithiasis. The dietary addition of the sex hormone to the castrated animal can then be used to study gallstone induction. In this report, we evaluated, for the first time, the effect of (i) castration and (ii) castration with dietary MeT supplementation on biliary lipids, cholesterol carriers in bile, and cholesterol cholelithiasis.

MATERIALS AND METHODS

Animals and diets. Thirty-five male golden Syrian hamsters (four weeks old, 60–74 g) were purchased from Sasco, Inc. (Omaha, NE). The animal protocols were approved by the Institutional Committee on Scientific Activities. Twenty-three hamsters were castrated under anesthesia using an intramuscular injection of ketamine (20 mg/100 g body weight) (Fort Dodge Laboratories, Inc., Fort Dodge, IA). A sham operation was performed on 12 hamsters used as controls. After the operation, the animals were given water and rodent chow *ad libitum* for one week prior to feeding the experimental diets. The animals were fed the following diets for 6 wk: group 1 (control, $n = 12$), lithogenic diet (LD); group 2 (castrated, $n = 11$), LD; group 3 (castrated, $n = 12$), LD + 0.05% MeT. The LD contained 43.6% corn starch, 20.0% casein, 14.6% dyetrose (soluble starch), 10.0% fiber (cellulose), 5.0% salt mix (modified U.S.P. XIV salt mix No. 200951), 4.0% butterfat, 2.0% corn oil, 0.5% vitamin mix (no. 300000), and 0.3% cholesterol (Dyets, Inc., Bethlehem, PA). At the end of the feeding period, the hamsters were fasted overnight and anesthetized by intramuscular injection with 20 mg/100 g body weight of ketamine. After laparotomy, gallbladder bile was aspirated and aliquoted for analysis of biliary lipids and separation of cholesterol carriers. The gallbladder was removed and examined for gallstones.

Analytical procedures. The presence of cholesterol gallstones and crystals in the gallbladder was confirmed by polarizing light microscopy (Olympus MCHAP microscope; Olympus Corp., Lake Success, NY). Bile acids were analyzed by gas–liquid chromatography as the methyl ester acetate derivatives as previously reported (8). The total phospholipid concentration was determined enzymatically (Wako Pure

Chemical Industries, Ltd., Osaka, Japan). The cholesterol concentration was determined by gas–liquid chromatography as the trimethylsilylether derivative (9).

The cholesterol carriers were separated by sucrose linear density gradient ultracentrifugation (Ayyad, N., Cohen, B.I., Ohshima, A., and Mosbach, E.H., submitted for publication). Fresh gallbladder bile was centrifuged at 5,000 rpm for 30 min. The supernatant solution was incubated with [1α, 2α (n)-^{3}H] cholesterol and 1-palmitoyl-2-[1-^{14}C] oleoyl phosphatidylcholine (Amersham Life Science, Arlington Heights, IL) under N_2 for one hour at 37°C with shaking. Sucrose (772 mg/mL bile) was dissolved in 50 μL of labeled bile and placed at the bottom of an OptiSeal centrifuge tube (Beckman Instruments Inc., Palo Alto CA). A sucrose linear density gradient (0–46%, 5 mL) was layered on top of the bile sample. The samples were placed in a NVT 90 near vertical rotor (Beckman Instruments Inc., Fullerton, CA) and centrifuged in a L-60 ultracentrifuge (Beckman Instruments Inc.) at 50,000 rpm for one hour. Fractions (total, 30–32) were collected from the bottom of the tube. Twenty μL of each fraction was counted in a Beckman LS 3801 liquid scintillation system with automatic quench correction, using Aquasol-2 (NEN Research Products, Boston, MA) as the scintillation fluid.

Calculations and statistics. Differences in the incidence of cholesterol gallstones were calculated by chi-square (10). The cholesterol saturation index (CSI) was determined as previously reported (11,12). All data are presented as the mean ± SD. The means were compared by analysis of variance to determine the F statistic; Student's *t*-test was applied to those values for which the F statistic was significant ($P < 0.05$) (10).

RESULTS

All hamsters were healthy and gained weight during the experimental feeding period. Table 1 summarizes the incidence of cholesterol gallstones and biliary lipid composition in male hamsters at sacrifice. Sham operated animals (controls, group 1) had a gallstone incidence of 17%. Castrated hamsters formed cholesterol stones only when MeT was added to the diet (group 2 vs. group 3, 0 vs. 50%). Castration decreased biliary cholesterol (group 1 vs. group 2, 6.6 vs. 3.0 mol%) and total biliary lipids (group 1 vs. group 2, 8.5 vs. 5.8 g/dL); these values were restored by MeT supplementation to levels found in the sham group (group 3, cholesterol, 7.4 mol%; total lipids, 9.4 g/dL). In contrast, biliary bile acid was significantly higher in group 2 than groups 1 and 3. Consequently, the CSI in group 2 was significantly lower (0.6) than groups 1 and 3 (1.0 and 1.1, respectively). Table 2 shows the biliary bile acid composition at sacrifice. Chenodeoxycholic acid (CDCA) and lithocholic acid (LCA) were lower in the castrated hamsters (group 2) than in the controls (group 1) and the MeT-supplemented animals (group 3); cholic acid (CA) and deoxycholic acid (DCA) were higher in group 2 than groups 1 and 3. The ratio of CA metabolites to CDCA metabolites in group 2 was significantly higher (3.4) than groups 1 and 3 (1.1 and 1.6, respectively).

Table 3 summarizes cholesterol carriers in bile and the molar ratio of cholesterol to phospholipid in each carrier. Groups 1 and 3 had a higher proportion of vesicles than group 2 (44 and 46% vs. 9%, respectively). Vesicles and micelles in groups 1 and 3 had a significantly higher cholesterol/phospholipid ratio than those in group 2.

DISCUSSION

In the present study, we deprived male hamsters of the sex hormone *via* castration and studied gallstone formation. In contrast to normal males, the bile of castrated hamsters remained unsaturated and no stones developed. Dietary administration of MeT to the castrated animals increased cholesterol saturation and induced stone formation. We have previously showed that the male sex hormone plays an important role in cholesterol cholelithiasis in female hamsters (7). These results indicated that the castrated male and the normal female hamster responded similarly to dietary MeT. We have also found that in the female hamster, dietary administration of MeT increased the secretion of biliary cholesterol while decreasing bile acid secretion and bile flow; these alterations induced lithogenic bile (Ohshima, A., Cohen, B.I., Ayyad, N., and Mosbach, E.H., submitted for publication). In the castrated male hamster, MeT appeared to have a similar effect on the secretion of biliary lipids as observed in the female. Other sex hormones also affect biliary lipid secretion and cholelithiasis: the female hormone, ethinylestradiol (EE), increased the cosecretion mechanism of cholesterol and phospholipid (13) and stimulated the formation of gallstones (14). Another female hormone, progesterone, also increased the secretion of biliary cholesterol (15) and induced cholesterol crystals when admin-

istered with EE (16). Sex hormones (androgen, estrogen, and gestagen) might have similar stimulatory effects on biliary cholesterol secretion and stone formation.

The biliary bile acid composition differed in male and female hamsters: females had a higher CA/CDCA ratio than males (17). In a previous study, MeT altered the bile acid composition of female hamsters to that found in males (7). We found that castration increased CA metabolites and decreased CDCA metabolites in the bile of male hamsters; MeT supplementation restored the bile acid composition to that of the control males. Androgens might decrease the activity of the hepatic steroid 12α-hydroxylase, which determines the ratio of CA/CDCA (17). Since CDCA stimulates biliary cholesterol secretion more than CA in hamsters (18), the change in bile acid composition (decreased CA/CDCA ratio) could be responsible, at least in part, for the increase of biliary lithogenicity in normal male or androgen supplemented animals.

Castration reduced the proportion of vesicles in bile and prevented stone formation, while MeT increased this cholesterol carrier to control levels and stimulated lithiasis. These results support the hypothesis that vesicle formation precedes cholesterol gallstone formation (19–21). The amount of vesicles in the control and the castrated-MeT treated hamsters were similar; however, the cholesterol/phospholipid ratio of these vesicles was higher in the MeT treated group (0.93 vs. 1.89, respectively). Vesicles having a higher cholesterol/phospholipid ratio tend to be less stable and form cholesterol crystals more rapidly (20–22). In our experiment, castrated-MeT treated hamsters formed more stones than the control animals; even though the CSI of both groups was similar and above unity. There is a general agreement that cholesterol supersaturation is necessary but not sufficient for cholesterol gallstone formation (6,22–26). These results suggest that the cholesterol/phospholipid ratio of vesicles may be a more rigorous parameter to predict cholelithiasis than the CSI.

TABLE 3
Distribution of Cholesterol Between Its Carriers in Bile[a]

Group (*n*)[a]	Vesicles % CH	Micelles % CH	CH/PL in vesicles	CH/PL in micelles

[b]Differs from group 1, $P < 0.03$.
[c]Differs from group 2, $P < 0.04$.

In conclusion, castration resulted in unsaturated bile, reduction of total biliary lipids, and inhibition of cholesterol cholelithiasis in male hamsters. Dietary supplementation with MeT resulted in elevation of biliary lithogenicity and gallstone formation. The proportion of cholesterol in vesicles as well as the cholesterol/phospholipid ratio in vesicles was markedly reduced by castration but increased after hormonal supplementation. These results suggest that there is a strong relationship between hormonal factors and cholesterol gallstone formation.

Dietary Fat Alters Biliary Lipid Secretion in the Hamster

Departments of Surgery, Beth Israel Medical Center, New York, New York
and the Albert Einstein College of Medicine, The Bronx, New York

ABSTRACT: Dietary fat has been found to alter the incidence of cholesterol gallstones in hamsters: butterfat intensifies while safflower oil reduces lithiasis. We now report how dietary fat affects bile flow and biliary lipid secretion in this model. Male hamsters were fed one of three experimental diets: a control diet (containing 0.3% cholesterol); control diet + 4.0% butterfat; or control diet + 4.0% safflower oil. After three weeks, bile samples were collected *via* an external biliary fistula. The endogenous bile acid pool was depleted for 120 min followed by increasing rates of taurocholate infusion for 160 min. Basal secretion of biliary lipids was measured during the bile acid depletion period. Basal bile flow and bile acid output were not significantly different in the three groups. Dietary butterfat increased basal cholesterol output compared to the control diet (0.037 vs. 0.025 μmol/min · kg, respectively); safflower oil did not change cholesterol output (0.027 μmol/min · kg). Hamsters fed butterfat or safflower oil secreted more phospholipid (0.171 and 0.178 μmol/min · kg, respectively) than controls (0.131 μmol/min · kg). The cholesterol/phospholipid output ratio of the butterfat group was higher than the safflower oil group (0.220 vs. 0.153, respectively). Effects of dietary fat on several relationships between bile flow and biliary lipid secretion were analyzed by linear regression using the data for the entire bile collection period (bile acid depletion and taurocholate infusion). Butterfat and safflower oil did not change either bile acid dependent or bile acid independent bile flow. Hamsters fed butterfat had a higher linkage coefficient (slope) of cholesterol vs. bile acid output than the safflower oil group (0.023 vs. 0.009, respectively). The linkage coefficient of phospholipid vs. bile acid output of the butterfat group was higher than the controls (0.278 vs. 0.185, respectively). In summary, butterfat induced a high cholesterol and phospholipid secretion with a high cholesterol/phospholipid output ratio; safflower oil induced a high phospholipid secretion with a low cholesterol/phospholipid output ratio. Butterfat and safflower oil have different effects on biliary lipid secretion. These differences in biliary lipid secretion may explain, in part, how butterfat and safflower oil differ in affecting gallstone formation in hamsters.

Lipids 31, 948–954 (1996).

It has been shown that different nutrients affect cholesterol cholelithiasis (1). In our laboratory, we have found that dietary fat and fatty acids alter the incidence of cholesterol gallstones in hamsters (2–4). Addition of 4.0% butterfat to a purified diet containing 0.3% cholesterol increased the incidence of cholesterol gallstones after 6 wk (63–84%); 4.0% safflower oil reduced cholelithiasis (13–22%) (3,5–7). Values observed for the biliary cholesterol saturation indices (greater than unity) and the amount of biliary cholesterol in vesicles were similar and could not explain the differences in stone formation (5–7). Biliary lipid secretion is a dynamic measurement of the output of cholesterol, phospholipid, and bile acids (8,9), which may enable us to explain some of the early events of cholelithiasis. We now report, for the first time, the effects of dietary butterfat or safflower oil on bile flow and biliary lipid secretion in our hamster model.

MATERIALS AND METHODS

Animals and diets. Male golden Syrian hamsters (50–55 g) were purchased from Sasco, Inc. (Omaha, NE). The animal protocols were approved by the Institutional Committee on Scientific Activities. The hamsters were divided into three groups and fed the experimental diets and water *ad libitum* for three weeks prior to surgery: group 1 ($n = 6$), purified diet + 0.3% cholesterol (control diet); group 2 ($n = 5$), control diet + 4.0% butterfat; group 3 ($n = 5$), control diet + 4.0% safflower oil. The purified diet contained 45.6% corn starch, 20.9% casein, 15.3% dyetrose (soluble starch), 10.4% fiber (cellulose), 5.2% salt mix (modified U.S.P. XIV salt mix No. 200951), 2.1% corn oil (source of essential fatty acids), and 0.5% vitamin mix (no. 300000) (Dyets, Inc., Bethlehem, PA).

Surgical procedures. At the end of the feeding period, the hamsters were anesthetized by intraperitoneal injection of 20 mg/100 g body weight of ketamine (Ketaset; Fort Dodge Laboratories, Inc., Fort Dodge, IA). Additional intramuscular injections of ketamine (10 mg) were used to maintain anesthesia. A polyethylene catheter (PE-10, 0.28 mm i.d.; Clay Adams, Parsippany, NJ) was inserted into the femoral vein, and 0.9% saline was infused at a rate of 1.13 mL/h using a Harvard syringe pump (Harvard Apparatus, Millis, MA). After laparotomy, the cystic duct was ligated with a hemostatic clip, and the common bile duct was cannulated using poly-

ethylene tubing (PE-10). Saline infusion was maintained for two hours in order to deplete the endogenous bile acid pool. Sodium taurocholate (TC) (Sigma Chemical Co., St. Louis, MO) was then infused at increasing rates of 6 and 18 μmol/h/100 g body weight together with trace amounts of [24-^{14}C] TC (Amersham Life Science, Arlington Heights, IL); each dose of TC was infused for 80 min. Bile samples were collected every 20 min in preweighed vials for the entire period (280 min). Each sample was weighed, divided into aliquots, and analyzed for biliary lipids. At the end of the experiment, the gallbladder was removed and examined for gallstones using polarizing light microscopy (2).

Analytical procedures. Bile volumes were determined gravimetrically. The recovery of [24-^{14}C]TC in 10 μL of each hepatic bile sample was quantitated using a Beckman LS 3801 liquid scintillation system (Beckman Instruments, Fullerton, CA) with automatic quench correction (5). Total bile acids, cholesterol, and phospholipids were each measured enzymatically using commercial kits (bile acid, # 450-A and cholesterol, # 352-20; Sigma Chemical Co.; phospholipid, Wako Pure Chemical Industries, Ltd., Osaka, Japan) (2).

Calculations and statistics. Bile flow is expressed as microliters per minute per kilogram body weight; biliary lipid output is expressed as micromoles per minute per kilogram body weight. Since bile flow and biliary lipid secretion were variable during the first 40 min, the basal bile flow and biliary lipid output during depletion of the endogenous bile acid pool were calculated using the data for the 40–120 min period before TC infusion (three to four samples per animal). The data are presented as the mean ± SD. The means were compared by analysis of variance to determine the F statistic; Student's *t*-test was applied to those values for which the F statistic was significant ($P < 0.05$) (10). The relationships between bile flow vs. bile acid output, cholesterol output vs. bile acid output, phospholipid output vs. bile acid output, and cholesterol output vs. phospholipid output were analyzed by linear regression for the bile acid depletion and TC infusion periods (ten to twelve samples per animal) (8,9). The regression lines were plotted, and the slopes and *y*-intercepts were calculated. The linkage coefficient (LKC) is defined as the slope of the regression line, that is, the increment in cholesterol or phospholipid output induced per increment of bile acid output, or the incremental ratio of cholesterol output to phospholipid output (8,9). Comparisons of slopes or *y*-intercepts were made using SAS/STAT (version 6.10; SAS Institute Inc., Cary, NC) (11,12). A difference was considered significant at $P < 0.05$.

Some hamsters had normal bile flow, bile acid output, and cholesterol output, but their phospholipid output was significantly lower than normal. In these animals, the ratio of cholesterol/phospholipid output was considerably higher (1.0–10.0) than in normal hamsters (0.1–0.3) during both the bile acid depletion and TC infusion periods. Consequently, data obtained from these animals were excluded from the analyses (one hamster from group 1, two from group 2, and one from group 3). There were a sufficient number of samples to compare the results statistically, since we collected as many as twelve samples per animal.

RESULTS

All hamsters remained healthy and gained weight during the experiment. At the end of the feeding period, surgery was performed to establish a biliary fistula and to insert a femoral vein cannula. TC was infused i.v. at increasing doses after depletion of the endogenous bile acid pool. When the maximum dose of TC (18 μmol/h/100 g body weight) was infused, the recovery of labeled TC was 98.5 ± 4.4%, 96.8 ± 5.4%, and 91.4 ± 10.1% for groups 1–3, respectively. After bile collection, the gallbladder was examined for the presence of cholesterol gallstones. No stones were detected in any of the animals after 3 wk.

Table 1 summarizes basal bile flow, biliary lipid output, and the ratio of cholesterol output to phospholipid output during the depletion of the endogenous bile acid pool. Basal bile flow and bile acid output did not differ among the three groups. Dietary safflower oil did not change basal cholesterol output (group 1 vs. group 3, 0.025 vs. 0.027 μmol/min · kg); butterfat induced a higher basal cholesterol output (group 2, 0.037 μmol/min · kg) than the control and safflower oil diet. Butterfat and safflower oil increased basal phospholipid output (groups 2 and 3, 0.171 and 0.178 μmol/min · kg) as compared to the control diet (group 1, 0.131 μmol/min · kg). Group 2 had a higher ratio of cholesterol output to phospholipid output than group 3 (0.220 vs. 0.153, respectively).

Table 2 lists the coefficients of the linear regression equations for several relationships between bile flow and biliary lipid outputs. The regression line of bile flow vs. bile acid output showed that both dietary butterfat and safflower oil did not change either bile acid-dependent (slope) or bile acid-independent (*y*-intercept) bile flow. The relationship between cholesterol vs. bile acid output showed that butterfat induced a higher LKC than safflower oil (group 2 vs. group 3, 0.023 vs. 0.009) (Fig. 1). The LKC for controls (group 1) was 0.017; this value was increased 35% by butterfat and decreased 47% by safflower oil. The LKC of phospholipid vs. bile acid output was also altered by dietary fat (Fig. 2): the slope of phospholipid vs. bile acid was 50% higher in the butterfat group than the control group (group 2 vs. group 1, 0.278 vs. 0.185). The LKC for safflower oil (group 3, 0.224) was intermediate between groups 1 and 2. The LKC of cholesterol vs. phospholipid output for group 1 (0.117) was higher than that for groups 2 and 3 (0.081 and 0.064, respectively); the *y*-intercept for group 1 (0.005) was lower than those of groups 2 and 3 (0.018 and 0.012, respectively).

DISCUSSION

The incidence of cholesterol gallstones has been found to change with the type and amount of dietary fat (2–4). In some cases, animals with or without stones had supersaturated bile as well as a significant portion of biliary cholesterol in cholesterol/phospholipid vesicles (5–7). It appeared that supersaturation of bile as well as the presence of cholesterol-rich vesicles are necessary, but are not the only conditions for cholesterol gallstone formation (13–15). The reason for the differences in the incidence of cholelithiasis remained unclear. Measurements of biliary lipid secretion may be useful to examine the early stages of cholelithiasis (16). The precise relationship between dietary fat, biliary lipid secretion, and gallstone formation are not known in our model. Consequently, we now examined the effect of dietary butterfat or safflower oil on bile flow and biliary lipid secretion in bile fistula hamsters. Our standard gallstone induction period is 6 wk (3–7). A 3-wk feeding period was used in this study to examine changes in biliary lipid secretion prior to gallstone formation.

Dietary butterfat increased both basal cholesterol and phospholipid outputs and resulted in a higher cholesterol/phospholipid output ratio compared to controls. Safflower oil stimulated basal phospholipid output and resulted in a lower cholesterol/phospholipid output ratio relative to controls. These results suggested that the reduced lithiasis observed after 6 wk with safflower oil could be related to a lower cholesterol/phospholipid output ratio during the first 3 wk. Butterfat raised the LKC for cholesterol vs. bile acid while safflower oil reduced it relative to controls. Butterfat increased the LKC for phospholipid vs. bile acid; safflower oil also increased this LKC but to a lesser extent. It is generally accepted that cholesterol and phospholipid are secreted together as vesicles from the canalicular membrane of hepatocytes (15,17,18). These results also suggest that fat may affect the secretory relationship between cholesterol and phospholipid.

The dietary fats used in this study had a different fatty acid composition. Butterfat is rich in saturated fatty acids (palmitic acid, 16:0, 27%); safflower oil contains mostly unsaturated fatty acids (linoleic acid, 18:2, 78%) (19). We have reported that palmitic acid and linoleic acid affect cholesterol gallstone incidence in a manner similar to butterfat and safflower oil, respectively (3,4,20). The changes observed in biliary lipid secretion in the present study might be related to the fatty acid composition of the dietary fat.

It has been found that a high-fat diet can stimulate biliary lipid secretion (21). In our experiment, animals fed either butterfat or safflower oil (total fat 6%) secreted more phospholipid than the controls (total fat 2%). However, cholesterol secretion was stimulated only in the butterfat group. Theoretically, dietary fat could affect the biliary cholesterol/phospholipid output ratio by changing one or more of the following factors: (i) secretion or composition of biliary bile acids, (ii) bile acid independent bile flow, and/or (iii) biliary phospholipid composition. First, it has been shown that biliary cholesterol and phospholipid secretions were stimulated by bile acids in a dose-dependent manner; this increase was dependent on the structure of the administered bile acid (9,22). However, in the current experiment, butterfat and safflower oil did not alter biliary bile acid secretion; neither fat changed

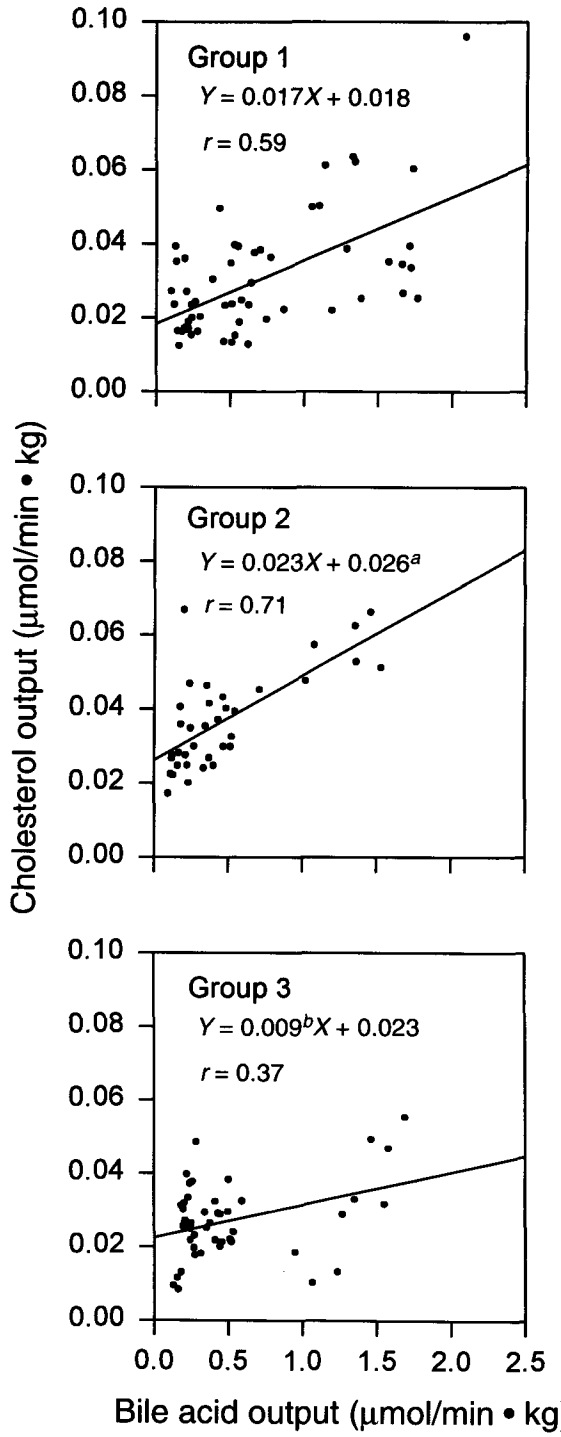

FIG. 1. Relationship between cholesterol output and bile acid output during bile acid depletion and sodium taurocholate infusion periods (6–18 µmol/h · 100 g body weight). Group 1, purified diet + 0.3% cholesterol (control diet); group 2, control diet + 4.0% butterfat; group 3, control diet + 4.0% safflower oil. the composition of biliary bile acids (Ref. 5; Ayyad, N., Cohen, B.I., Ohshima, A., and Mosbach, E.H., submitted for publication). Thus, secretion and composition of biliary bile acids were not factors in changing the cholesterol and phospholipid output. Second, it is known that the bile acid independent bile flow was another regulatory factor that could af-

fect the biliary secretion of cholesterol and phospholipid: a lower bile acid independent bile flow induced a more effective secretion of these lipids (23). In our study, butterfat or safflower oil did not change the bile acid independent bile flow, suggesting that this factor was not responsible for the changes in the biliary lipid secretion. Third, it was shown that the fatty acid components of the biliary phospholipids reflected the composition of the exogenous fat (7,20,24,25). We have previously found that dietary safflower oil and 18:2 increased the 16:0–18:2 phosphatidylcholine molecular species in bile by approximately 25% (20). Robins *et al.* (26) showed that the various molecular species of biliary phosphatidylcholine altered the amount of cholesterol transported into bile. It is possible that the changes we observed in biliary phospholipids may also alter the cholesterol/phospholipid output ratio. Furthermore, the changes observed in the phosphatidylcholine molecular species could also affect the stability of vesicles from which cholesterol crystals nucleate: unsaturated fatty acids stabilize vesicles to a greater extent than saturated fatty acids (27–30).

Many studies have examined the effects of unsaturated fat on bile and plasma cholesterol levels (24,25,31,32). It was reported that safflower oil caused an increase in biliary cholesterol secretion (24,25,31,32). This result was opposite from that reported in the present study. However, we cannot compare these experiments to our study because of major differences in the experimental design. These earlier studies employed a significantly lower level of exogenous cholesterol (0.02%) to maintain normal cholesterol synthesis; our experiments used 0.3% cholesterol to induce gallstones, a dose which eliminated endogenous cholesterol synthesis (33). The amount of exogenous cholesterol appears to modify the effect of dietary fat on biliary cholesterol secretion.

In conclusion, dietary administration of butterfat or safflower oil had different effects on the secretion of biliary cholesterol and phospholipid which could explain, in part, their role in cholesterol cholelithiasis in hamsters.

Effects of Dietary Heated Fats on Rat Liver Enzyme Activity

Courdjo Lamboni and Edward G. Perkins*

Burnsides Research Laboratory, Department of Food Science, University of Illinois at Urbana–Champaign, Urbana, Illinois 61801

ABSTRACT: The objective of this study was to evaluate the effects of dietary heated fats from a commercial deep-fat frying operation on rat liver enzyme activity. The fats, partially hydrogenated soybean oil (PHSBO) used for four days and for 7 days (7-DH) for frying foodstuffs in a commercial restaurant, were fed to rats in either free access to food or by pair-feeding graded doses. All diets were isocaloric and contained 15 g/100 g of diet. Experiments were conducted with control rats fed nonheated (NH) PHSBO diet. Animals fed 7-DH diet in each set of experiments had larger amounts of cytochromes P_{450} and b_5 and greater activity of NADPH-cytochrome P_{450} reductase when compared to controls. The activities of carnitine palmitoyltransferase-I and isocitrate dehydrogenase were significantly lower in rats fed test diets in comparison to controls. A significantly depressed activity of glucose 6-phosphate dehydrogenase was also noticed for these animals when compared to those fed NH. In addition, liver and microsomal protein concentrations were significantly greater in rats fed the used oils in comparison to controls, and liver glycogen was significantly lower.

Lipids 31, 955–962 (1996).

Deep-fat fried foods, such as French fries, fried chicken, fried fish, or potato chips, are typical fast foods served in restaurants. The heated fat from a deep-fat fryer is absorbed into the fried foods, and are eventually ingested through that food. In the deep-fat frying process, the temperature of the oil is at least 180°C and the oil is used repeatedly, with many cooling and reheating cycles. It has been noted in the literature (1–3) that during deep-fat frying, moisture and air are mixed into the hot fat and that intermittent heating is more damaging to the fat than continuous heating. Under these conditions, both thermal and oxidative deterioration of the fat takes place during the heating process.

Other studies (3–5) have reported many adverse biological effects of heated and oxidized fats, such as retarded growth, enlargement and/or fatty necrosis of the liver, hair loss, and dermatitis when such fats are fed to rats. It also has been reported (3,6,7) that during deep-fat frying many toxic compounds are formed in the heated oil which may cause the deleterious effects observed when ingested by rats. Among the toxic compounds generated during deep-fat frying are carbonyl, cyclic monomer, and dimer derivatives (8,9).

Even though previous studies have focused on biochemical indices and histopathological evaluations (4,5,10), little attention has been paid to the effects of fats used for frying foodstuffs under restaurant conditions on the activity of several metabolic enzymes in rat liver.

Andia and Street (11) reported increased activity of the enzyme S-adenosylmethionine:phosphatidylethanolamine methyltransferase when thermally oxidized oil was fed to rats. Yoshioka *et al.* (12) reported low activities of thiokinase and succinate dehydrogenase when autoxidized safflower oil was fed to rats. They associated the observed metabolic effects with elevated carbonyl values of the oxidized oils.

The present study focused on the effects of partially hydrogenated soybean oil (PHSBO) that had been used for four days (4-DH) or seven days (7-DH) for frying foodstuffs. In addition, rats were pair-fed diets containing graded dose of the 7-DH oil to evaluate the effects of the amounts of used oil ingested by animals on their liver enzyme activity. The oil was obtained from a commercial fast food restaurant deep-fat frying operation producing French fries, fried fish, and fried chicken (Table 1). The following rat liver enzymes were investigated: carnitine palmitoyltransferase-I (CPT-I), isocitrate dehydrogenase (ICDH), glucose 6-phosphate dehydrogenase (G 6-PDH), and NADPH-cytochrome P_{450} reductase. The observed effects from the experimental groups of rats were compared with those of control groups of animals (in free access to food and by pair-feeding) fed diets containing nonheated (NH) PHSBO.

MATERIALS AND METHODS

The oils used in this study were obtained from a fast food restaurant which served French fries, deep fried chicken, fried fish, onion rings, mushrooms, and hush puppies (Table 1). The control was NH PHSBO and the used oil fed was taken from fryers at 4 days (4-NH) and 7 days (7-NH). The 4-NH oil was about halfway through its useful life and the 7-NH oil, although near the throwaway point, still produced good quality fried food. The oils were filtered through a paper filter

daily to remove particulate material. Analytical values describing the oils are given in Table 1.

Animals, diets, and procedures. Male Sprague–Dawley weanling rats (50–60 g) were purchased from Harlan Sprague Dawley Inc. (Indianapolis, IN) and were maintained on nonpurified diet for one week in steel wire mesh cages. All animals were then assigned to three groups of 10 rats each by complete randomization using a random number table (13). One of the groups was considered the control group and was fed the 15% NH diet. Another group was fed the 15% of 4-DH diet while the last group was fed the15% 7-DH diet.

In a pair-feeding experiment, three groups of 10 rats each were fed diets containing 5, 10, and 15% of the 7-DH oil. A control group was designed identical to the previous control rats in this pair-feeding experiment. The composition of the diets fed to animals is described in Tables 2 and 3.

Procedures. All diets were prepared weekly in 1.5-kg batches and the stock diets stored in capped plastic containers under nitrogen in a 4°C cold room. Animals were then switched to their respective diets and were provided with free access to 20 g of food every day for 10 wk. The rats also had free access to tap water. Animal weights and feed intake were recorded daily. At the end of the feeding period, a total of 6–8 rats per day were randomly chosen from each of the different groups and were killed by decapitation after CO_2 inhalation for a short time. Blood was collected under heparin for plasma and the liver was quickly excised and weighed. Two-gram portions of liver were introduced into the appropriate cooled buffer (kept in ice) for the purpose of enzyme activity

assay and the rest of the liver was frozen by liquid nitrogen and stored at −70°C for future analyses.

Preparation of liver microsomes. Liver microsomes were obtained according to the method described by Lake (14), quickly frozen in liquid nitrogen, and stored at −70°C until enzyme assay the following week.

Measurement of cytochrome P_{450} ($Cyt.P_{450}$), cytochrome b_5 ($Cyt.b_5$), and NADPH-$Cyt.P_{450}$ reductase (EC 1.6.2.4) activity. $Cyt.P_{450}$, $Cyt.b_5$ contents, and NADPH-$Cyt.P_{450}$ reductase (EC 1.6.2.4) activity were determined in liver microsome fractions according to Lake (14).

CPT-I (EC 2.3.1.21) activity. CPT-I activity was assayed according to the "assay II" and using "Method C" described by McGarry *et al.* (15).

G 6-PDH (EC 1.1.1.49) and ICDH (EC 1.1.1.42) activities. About 2 g of fresh liver tissue were homogenized in about 0.04 mL/mg wet weight physiological saline solution containing 0.66 mol/L EDTA, and the enzyme activities determined according to Löhr and Waller (16).

Protein determination. The protein contents of rat liver microsomes, the 31000 × *g* supernatant fluid, and that of liver tissue were determined according to the method described by Lowry *et al.* (17).

Lipid analyses. Lipids were extracted from liver tissue according to the Folch *et al.* (18) method and the total liver lipid content was obtained by gravimetry as described by Lamboni (19). Fatty acid profiles of liver lipids were performed by gas–liquid chromatographic analyses of fatty acid methyl esters prepared according to AOCS Official Method Ce 2-66 (20). Fatty acid profiles were obtained using a model 5730 Hewlett-Packard (Palo Alto, CA) gas chromatograph equipped with a flame-ionization detector. The column used was an Omegawax 250 capillary column (30 m by 0.25 mm with a 0.25-mm film plus a 5-m guard column) (Supelco, Bellefonte, PA). The conditions were: column temperature programmed from 100°C (with a 0 time hold) to 220°C (with an 8-min hold) at a rate of 4°C/ min. The carrier gas was hydrogen at 2–4 psig with a column split ratio of 32:1. The injection temperature was 250°C and the detector temperature was 300°C.

Gel-permeation (size-exclusion) chromatography. Free fatty acids, mono-, di-, and triacylglycerols, and polymeric material were determined by gel-permeation chromatography using a Waters HPLC system with two columns of Ultrastyragel 500 Å pore size, 30-cm in length (Waters Inc., Milford, MA). A mobile phase of tetrahydrofuran at 0.7 mL/min was employed, and the detector was a Waters model 410 differential refractometer.

Glycogen determination. Glycogen content of liver tissue was obtained according to the method described by Siu Lo (21) and modified by Lamboni (19).

Statistical analysis of data. Data were analyzed by analysis of variance for a completely randomized design using StatView statistical software package (StatView SE + Graphics; 1988 Abacus Concepts, Inc., Berkeley, CA). When a significant ($P < 0.05$) F test was detected, pairwise comparisons of means between groups were performed by Fisher's protected least significant difference.

RESULTS

Weight gain, feed efficiency, and liver weight/body weight ratio. No significant differences were found in weight gain, feed efficiency, and liver/body weight ratios in the groups fed the control, 4-DH, and 7-DH diets. Data from studies with both pair feeding and free access to food also showed no significant differences (Table 4).

Protein, lipid, and glycogen. Animals fed 7-DH diet showed a greater ($P < 0.0001$) liver protein content (Table 4) than the control group of rats fed NH diet. The increased content observed when animals were fed 4-DH diet was not significantly different from that of control rats. In comparison to the 4-DH diet group of rats, the increased protein content noticed for the 7-DH diet group was highly significant.

The group of rats fed 10% 7-DH diet in the pair-feeding experiment had a significantly greater liver protein content when compared to the control group. The difference observed in liver protein content when animals were fed 15% 7-DH diet was highly significant when compared to the control group of rats (Table 4).

Liver microsomal protein (Table 4) of rats fed the 7-DH diet was significantly increased ($P < 0.0001$) compared to the control animals fed the NH diet. When rats were fed the 4-DH diet, no significant difference was observed in comparison with a control group of rats fed the NH diet. However, when the 4-DH diet group of rats was compared to the 7-DH diet group, the increased content of microsomal protein measured in the latter group was highly significant.

After 10 wk of pair-feeding rats with 15 or 10% 7-DH diet, liver microsomal protein content was significantly increased compared to the control animals (Table 4).

Liver lipid content of animals fed the 7-DH diet was significantly increased compared to the control group fed the NH diet. The slight increase of liver lipid in rats compared to controls was not significant.

In the pair-feeding experiment, the level of lipid in livers of rats fed the 15% 7-DH diet was greatly increased compared to the control animals fed NH diet. Feeding rats 10% of the

[a]Values are means ± SEM. Free Acc. Fo. = free access to food; see Table 1 for other abbreviations.
[b]$P < 0.0001$ when compared to the NH group of rats.
[c]$P < 0.0001$ when compared to the group of rats fed diet containing PHSBO used 4 d (4-NH) for frying foodstuffs.
[d]Nonsignificant when compared to the 4-NH group of rats.
[e]$P < 0.05$ when compared to the control group.
[f]$P < 0.01$ when compared to the control group.

7-DH diet resulted in a significant increase of liver lipid content in comparison to the control animals (Table 4). There were no significant differences in the liver lipid or fatty acid composition, regardless of the diet fed.

The lipid/protein ratio (Table 4) of rats fed the 7-DH diet was significantly lower ($P < 0.0001$) than that of the control animals. The low ratio observed when animals were fed the 4-DH diet was not significantly different from the ratio noticed for the control group of rats fed NH diet. However, when the 4-DH diet group of rats was compared to those fed the 7-DH diet, the lowest ratio observed for the latter group was significantly different ($P < 0.0001$) from that of the former group of animals.

Pair-feeding rats with graded doses of 7-DH diets showed that the 15% 7-DH diet induced the lowest lipid/protein ratio with $P < 0.01$, while groups of rats fed 5 or 10% 7-DH diets did not show any significant decrease when compared to the control animals.

Liver glycogen content (Table 4) when rats were fed the 7-DH diet was significantly decreased ($P < 0.0001$) compared to the liver glycogen of those fed the NH diet. When the 4-DH diet group of rats was compared to the 7-DH diet group, the decreased content of liver glycogen observed in the latter group of rats was significantly ($P < 0.05$) different from the liver glycogen content noticed in the former group.

In the pair-feeding experiment, the decreased values of liver glycogen observed for groups fed 10 or 15% 7-DH diets was significantly different ($P < 0.0001$) from the control animals (Table 4).

Microsomal Cyt.b_5 and Cyt.P_{450}. The 7-DH diet induced a significant increase in Cyt.b_5 content in liver microsomes in comparison with a control group of rats fed NH diet (Table 5). The increased content of Cyt.b_5 observed in animals fed the 4-DH diet was also significantly different from the content of Cyt.b_5 measured for the control group. However, the increased content of Cyt.b_5 observed for the 7-DH diet group of rats was significantly different from the level recorded for the group of rats fed 4-DH diet.

Rats pair-fed graded doses of 7-DH diets showed a highly significant increase in Cyt.b_5 when animals were fed the 15%

[a]Values are means ± SEM. See Tables 1 and 4 for abbreviations.
[b]$P < 0.01$ compared to the control group of rats fed diet containing NH PHSBO.
[c]$P < 0.0001$ compared to the NH group of rats.
[d]$P < 0.0001$ compared to the group of rats fed diet containing PHSBO used 4 d (4-DH) for frying foodstuffs.
[e]$P < 0.001$ compared to the 4-DH diet group of rats.

7-DH in comparison with the control group of rats fed the NH diet. When the 10% 7-DH was fed, the increased value was significant at $P < 0.01$ when compared to the control animals (Table 5).

Cyt.P_{450} content in liver microsomes of rats fed 7-DH diet was highly increased (Table 5) compared to the control group fed the NH diet. The group of animals fed 4-DH diet also had an increased liver Cyt.P_{450} content ($P < 0.01$). Rats fed the 4-DH diet compared to those fed the 7-DH diet exibited the greatest content of Cyt.P_{450} in the latter group, which was significantly different from that noted in the former group of animals.

In the pair-feeding experiment where rats were fed graded doses of the 7-DH diets, the content of liver microsomal Cyt.P_{450} for the group of rats fed 15% 7-DH diet was highly increased compared to the control group of rats fed 15% NH diet. When 10% 7-DH diet was fed to animals, the increase observed was significantly different from the control group (Table 5).

NADPH-Cyt.P_{450} reductase. The activities of NADPH-Cyt.P_{450} reductase (EC.1.6.2.4) measured in liver microsomes of rats fed 4-DH or 7-DH diets were increased when compared to the control group of rats fed NH diet. The increase was significant when animals were fed the 7-DH diet (Fig. 1). A significant increase was also observed when rats were fed the 4-DH diet. The greatest activity measured for the group of rats fed the 7-DH diet was significantly different from that of animals fed the 4-DH diet.

The enzyme NADPH-Cyt.P_{450} reductase (EC 1.6.2.4) when rats were pair-fed with graded doses of 7-DH diets showed an increased level of activity compared to the control group of animals fed the 7-NH diet. The increase was highly significant ($P < 0.0001$) for the 10 and 15% 7-DH diet groups of rats. It was also significant at $P < 0.001$ when rats were fed 5% 7-DH diet in comparison to the control group (Fig. 1).

CPT-I. The activity of CPT-I (EC 2.3.1.21) in liver mitochondrial membrane of rats fed 7-DH diet was significantly decreased ($P < 0.01$) in comparison with a control group of rats fed NH diet (Fig. 2).

A significant decreased activity ($P < 0.01$) of the enzyme CPT-I (EC 2.3.1.21) was observed in the pair-feeding experiment when rats were fed the 7-DH diet in comparison with the control animals. Feeding 5 or 10% 7-DH diets did not result in any significant difference when compared to the control group of rats. (Fig. 2).

ICDH. The activity of isocitrate/NADP-oxidoreductase (EC 1.1.1.42) (decarboxylating) was decreased in liver mitochondria when rats were fed either 4-DH or 7-DH diets in comparison with a control group of rats fed NH diet (Fig. 3). The decreased activity observed for the 7-DH diet group of rats was significantly different from the control group at $P < 0.05$. However, the decreased activity observed when animals were fed 4-DH diet was not significant when compared to the control group. The lowest activity measured for the 7-DH diet group of rats was not significantly different from that of animals fed the 4-DH diet.

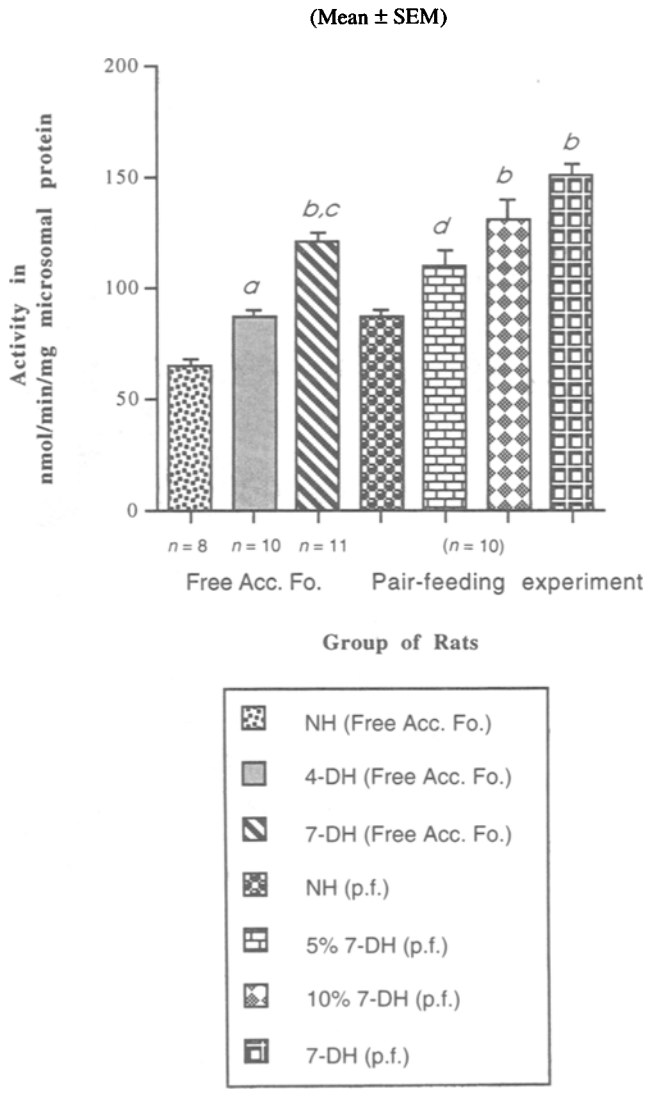

FIG. 1. NADPH-cytochrome P_{450} reductase activity in liver microsomes of rats fed NH, 4-DH, and 7-DH diets. NH, control group of rats fed diet containing nonheated (NH) partially hydrogenated soybean oil (PHSBO); 4-DH, group of rats fed diet containing PHSBO used 4 d (4-DH) for frying foodstuffs; 7-DH, group of rats fed diet containing PHSBO used 7 d (7-DH) for frying foodstuffs. $^{a}P < 0.001$ when compared to the control group of rats fed the NH diet. $^{b}P < 0.0001$ when the 7-DH diet group of rats was compared to the NH group of rats. $^{c}P < 0.0001$ when compared to the 4-DH diet group of rats. Free Acc. Fo., free access to food; p.f., pair-feeding.

In the pair-feeding experiment, the decreased activity of the enzyme ICDH (EC 1.1.1.42) observed when rats were fed 15% 7-DH diet was significantly different from the control animals. Feeding 5 or 10% 7-DH diets did not show any significant difference when compared to the control group of rats. (Fig. 3).

G 6-PDH. The activity of (EC 1.1.1.49) D-glucose 6-phosphate/NADP-oxidoreductase measured in the liver of rats fed either 4-DH or 7-DH diets was depressed when compared with a control group of rats fed NH diet (Fig. 4). When rats

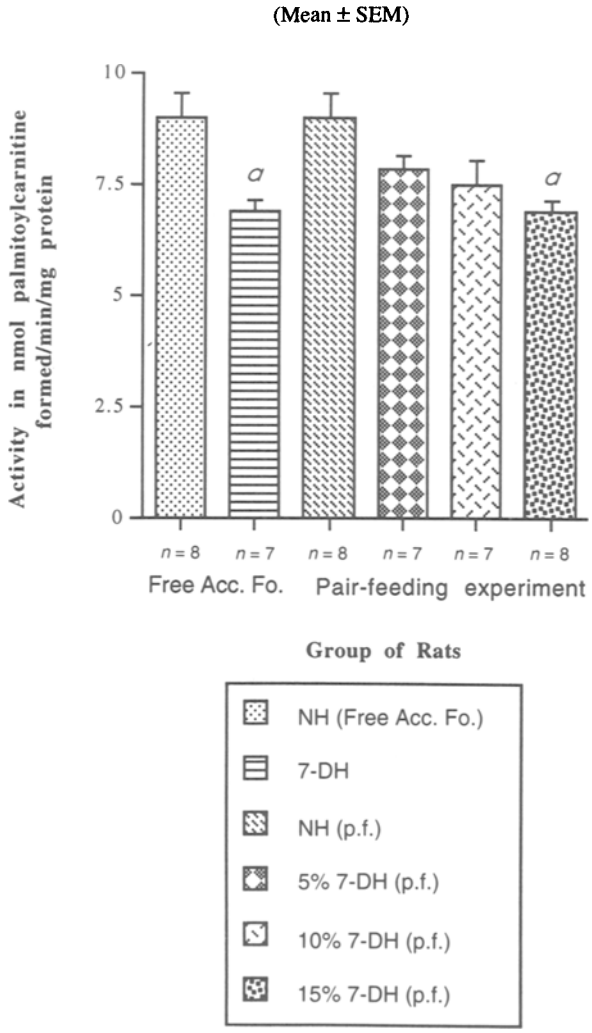

FIG. 2. Carnitine palmitoyltransferase-I activity in liver mitochondria of rats fed NH and 7-DH diets. Abbreviations and legend descriptions as in Figure 1. $^aP < 0.01$ compared to the control group of rats fed the NH diet.

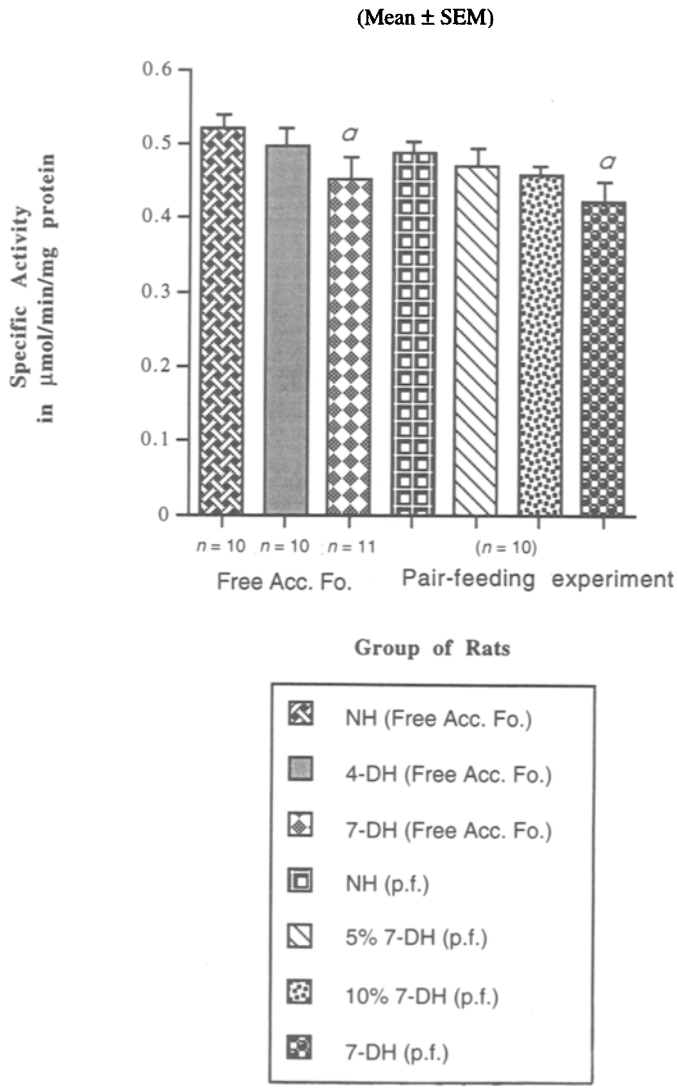

FIG. 3. Isocitrate dehydrogenase activity in liver of rats fed NH, 4-DH, and 7-DH diets. $^aP < 0.05$ when the 7-DH diet group of rats was compared to the NH group of rats. See Figure 1 for abbreviations and legend descriptions.

were fed the 7-DH diet, the depressed activity observed for the enzyme was highly significant when compared to the control group. Although a depressed activity was observed when animals were fed the 4-DH diet, the difference was not significant when compared to the control group of rats. The lowest activity of G 6-PDH measured for the group of rats fed the 7-DH diet was significantly different from that observed for the group of animals fed the 4-DH diet.

When rats were pair-fed graded doses of the 7-DH diets, a depressed activity of the oxidoreductase (EC 1.1.1.49) was noticed when compared with a control group of rats fed the NH diet. Animals which were fed the 15% 7-DH diet displayed the significantly lowest activity among groups in comparison to the control group. When 10% 7-DH diet was fed to animals, the activity of G 6-PDH was significantly depressed when compared to the control group of rats. Feeding 5% 7-DH diet led to a depressed activity at $P < 0.05$ compared to the control animals (Fig. 4).

DISCUSSION

The weight gain data showed trends that were noted by previous researchers (22–24) who worked with laboratory heated fats. In these studies, feeding rats with commercially heated fats led to growth depression, suggesting that the heated oils may contain substances that prevent animals fed such fats from growing properly. The weight gain declined after 35 d of feeding such a diet to animals. This may suggest that the accumulated deleterious compounds generated during the commercial deep-fat frying process must be ingested at certain levels to exert the adverse nutritional effects of such fats when fed to rats.

Feed efficiency data were not significantly different among groups fed either diets in the free access to food or by pair-feeding experiments, suggesting that the effects observed in

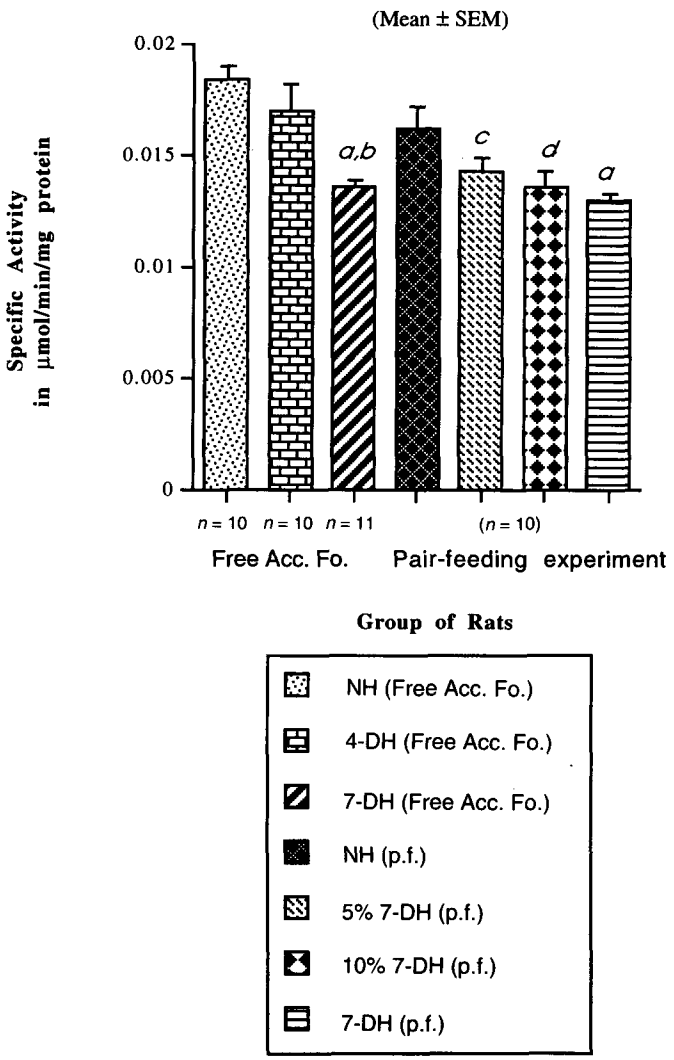

FIG. 4. Glucose 6-phosphate dehydrogenase activity in liver of rats fed NH, 4-DH, and 7-DH diets. See Figure 1 for abbreviations and legend descriptions. [a]$P < 0.0001$ when the 7-DH diet group of rats was compared to the NH group of rats. [b]$P < 0.0001$ when the 7-DH diet group of rats was compared to the NH group of rats. [c]$P < 0.0001$ when compared to the 4-DH diet group of rats. [d]Nonsignificant when compared to the 4-NH group of rats.

this study cannot be attributed to the amount of diet ingested by the rats and may simply reflect the content of the oils fed to animals.

When rats were fed the 7-DH diet, their liver weight/body weight ratio (Table 3) was not significantly higher than those fed either NH or 4-DH diets, but did suggest an increase in liver size. In addition, the increased level of protein or lipid content in the liver may have contributed to the abnormal liver weight of animals fed the used oils. Pair-feeding rats with the 7-DH diet led to similar results. The increased content of liver protein observed in this study when rats were fed the used oil either *ad libitum* or by pair-feeding agrees with the findings of Miller and Landes (25), who reported an increased content of liver protein when rats were fed laboratory thermally oxidized fats.

The significantly increased level of hepatic lipid obtained when rats were fed the 7-DH diet either in a pair-feeding or free access to food experiment suggests an accumulation of liver lipids in these animals in comparison with the control group of rats fed the diet containing the NH PHSBO. This is probably due to the developing fatty liver previously reported (10). In addition, the lipid/protein ratio (Table 3) of animals fed the 7-DH diet in a pair-feeding or free access experiment clearly confirms the excessive amount of protein being retained or produced when compared to that of lipid in liver tissue of the same group of rats. The ratio was significantly lower in the group of rats fed the 7-DH diet when compared to the control animals fed the NH diet than it was in the group of rats fed the 4-DH diet. A similar lipid/protein ratio was noted in the pair-feeding experiment when the 7-DH diet group of rats was compared to the control group of animals fed the 15% NH diet.

With regard to the effect of the amount of protein on the activity of liver microsomal mixed-function oxidase system (26–28), the highly significant increased content of Cyt.P_{450} (Table 4) in animals fed the 7-DH diet clearly demonstrates an effect of the components generated in the used oil. Rats fed the 4-DH diet also showed an increased level of Cyt.P_{450} in the microsomal fractions at $P < 0.01$. These enzyme systems increase in activity in the presence of xenobiotic materials.

The significantly decreased activity of ICDH observed when rats were fed the 7-DH diet (Fig. 3) suggests an impairment of the trichloroacetic acid cycle enzyme activity. This may have resulted in an accumulation of citrate, which was transferred through the mitochondrial membrane under passive diffusion and regenerated the cytosol with acetyl-CoA under ATP-citrate lyase (EC 4.1.3.6) activity. The excess of acetyl-CoA in the cytosol could then have undergone fatty acid synthesis. The complementary NADPH required for fatty acid synthesis could be supplied by L-malate/NADPH oxidoreductase (malic enzyme) (EC 1.1.1.40). Because a control group of rats was fed the same level (15%) of the NH PHSBO, the decreased activity of ICDH measured in the experimental groups of rats may have other origins that might be attributed to effects of secondary degradation products, such as carbonyl compounds or cyclic fatty acid monomers generated during frying.

ACKNOWLEDGMENTS

We thank the Illinois Agricultural Experiment Station for partial support of this study. Thanks are also given to the Fulbright committee for their financial support of Courdjo Lamboni's graduate career toward Ph.D. degree at the University of Illinois, Urbana–Champaign.

ABSTRACT: Guinea pigs were fed for five weeks with three diets containing different levels of vitamin E: LOW (but nondeficient, 15 mg of vitamin E/kg diet), MEDIUM (150 mg/kg diet), and HIGH (1,500 mg/kg diet). Dietary vitamin E supplementation did not change oxidative stress indicators in the hydrophilic compartment but increased liver α-tocopherol in a dose-dependent way and strongly decreased sensitivity to nonenzymatic *in vitro* liver lipid peroxidation. This last effect was already observed in group MEDIUM, and no further decrease in *in vitro* lipid peroxidation occurred from group MEDIUM to group HIGH. The protective effect of vitamin E against *in vitro* lipid peroxidation was observed even though an optimum dietary concentration of vitamin C for this animal model was present in the three different vitamin E diets. Both HIGH and LOW vitamin E decreased percentage fatty acid unsaturation in all phospholipid fractions from membrane origin in relation to group MEDIUM. The results, together with previous information, show that both vitamin E and vitamin C at intermediate concentrations are needed for optimal protection against lipid peroxidation and loss of fatty acid unsaturation even in normal nonstressful conditions. These protective concentrations are higher than those needed to avoid deficiency syndromes.
Lipids 31, 963–970 (1996).

Many studies suggest the involvement of oxidative damage in the etiology of important diseases such as cancer and arteriosclerosis. There is increasing epidemiological evidence (1,2), supported by some longitudinal prospective human studies (3,4), indicating that antioxidants like vitamin E and C are protective against the development of those diseases. This is probably due to their capacity to reduce oxidative damage to lipids (5,6) and other cellular macromolecules (7). Thus, there is great interest in obtaining a better knowledge about the *in vivo* effects of different dietary doses of these vitamins on tissues. Vitamin E or C is suitable for increasing antioxidant capacity safely and easily, because they are susceptible to dietary manipulation, whereas supplementation with antioxidant enzymes or GSH (which is under feedback cellular control) is not feasible in humans.

Vitamin E is considered the principal antioxidant defense against lipid peroxidation in cell membranes in mammals. Lipid peroxidation is a degradative chain reaction of oxygen radicals with unsaturated fatty acids. The most important role of vitamin E in tissues seems to be the protection of membrane polyunsaturated fatty acids (PUFA) against the deleterious effects of oxygen radicals. Specific effects of α-tocopherol that do not involve its antioxidant properties and act upon the architecture of membranes by controlling their lipid profile also have been suggested (8,9). Recent reports have also shown that vitamin E can work as a prooxidant when present in high concentrations *in vitro* (10,11); presumably *via* effects of tocopheroxyl radical.

The notion that the optimum levels of vitamins E and C to protect against *in vivo* oxidative stress are substantially higher than the recommended dietary allowance (RDA) needed to avoid deficiency syndromes is gaining experimental support. The guinea pig is the ideal laboratory animal model to perform diet-controlled *in vivo* experiments since (like higher primates) it cannot synthesize either ascorbate or α-tocopherol. We have recently shown that optimum dietary vitamin C levels in the guinea pig for protection against endogenous oxidative stress in liver are much higher than the minimum daily requirement of this animal, whereas vitamin C megadoses do not bring about further protection and are even detrimental for membrane PUFA (12). We study here the effect of three very different doses of vitamin E—from low but nondeficient levels to a very high dose—using the same guinea pig model. The study was performed at the optimum dose of vitamin C found previously (12) in order to test the efficacy of vitamin E over an adequate vitamin C background. Oxidative stress was studied both for mainly hydrophilic [glutathione redox ratio (GSH/GSSG) and protein oxidation] and lipid-dependent parameters (lipid peroxidation and fatty acid composition). Similar to what was found for vitamin C (12), intermediate dietary levels of vitamin E, sixfold higher than the minimum daily requirement,

protect against *in vitro* liver lipid peroxidation, whereas further supplementation to high levels do not bring additional protection. Relative percentage reduction of fatty acid unsaturation in all kinds of membrane phospholipids was found both in animals receiving low or high vitamin E dietary levels compared with those receiving the medium level.

MATERIALS AND METHODS

Animals, diets, and vitamin E. Dunkin-Hartley male guinea pigs weighing 200–250 g were obtained from IFFA-CREDDO (Lyon, France). Three diets differing in vitamin E content were prepared by U.A.R. (Perpignan, France) by adding d,l-α-tocopherol acetate to the standard guinea pig diet (diet 114; U.A.R.). The vitamin E dietary content was 1,500 mg of vitamin E per kg diet (group HIGH), 150 mg vitamin E/kg (group MEDIUM), or 15 mg vitamin E/kg (group LOW). These vitamin E contents were confirmed after analysis by high-performance liquid chromatography (HPLC). Briefly, tissue samples (20–40 mg) were saponified in the presence of 0.2 mL of 15% ascorbic acid, 2 mL of ethanol containing 0.025% butylated hydroxytoluene, and 1 mL of 40% potassium hydroxide. Tocopherol was then extracted with hexane containing 0.025% butylated hydroxytoluene, the hexane was removed with N_2, the residue was redissolved in 0.5 mL ethanol, and 20 μL were injected in the HPLC. Mobil phase was 100% methanol, and the column was a C_{18} reverse phase Machery Nagel (Duren, Germany) 4.6 × 100 mm, 7 μm. The system was composed of a Waters 510 pump (Millipore Corporation, Milford, MA), a Gilson ultraviolet detector (Middleton, WI) set at 292 nm, and a Spectraphysics integrator (San Jose, CA). The basal diet contained 18.5% protein, 2.9% fat, 46.9% carbohydrates, 8.4% mineral mix, 1.4% vitamin mix, 11% humidity, and 10.9% nonnutritive bulk. The content of minerals and vitamins per kg of diet was: phosphorus, 8.6 g; calcium, 10.6 g; potassium, 12.0 g; sodium, 3.45 g; magnesium, 3.13 g; manganese, 100 mg; iron, 320 mg; copper, 26 mg; zinc, 85 mg; cobalt, 1.61 mg; vitamin A, 19,000 I.U.; vitamin D_3, 2,031 I.U.; thiamine, 22.5 mg; riboflavin, 21 mg; pantothenic acid, 123 mg; pyridoxine, 10.7 mg; menadione, 55 mg; niacin, 193 mg; folic acid, 7.3 mg; biotin, 0.275 mg; choline, 1,740 mg; myo-inositol, 250 mg; vitamin B_{12}, 0.054 mg; *p*-aminobenzoic acid, 10 mg; and vitamin C, 660 mg. This amount of dietary vitamin C was found to be optimal from the point of view of oxidative stress and fatty acid composition in a previous study (12) in the liver of male guinea pigs of the same age than those used here.

The animals were fed for five weeks the three experimental diets, and they were maintained inside aseptic air positive-pressure animal cabinets (A 130 SP; Flufrance, Cachan, France) equipped with an HEPA air filter (99.999% for particles >0.3 μm) at the inlet. At the end of the dietary regimen, the animals were sacrificed by decapitation and liver samples were immediately excised and stored at –80°C.

Nonenzymatic in vitro *lipid peroxidation.* Sensitivity to nonenzymatic *in vitro* lipid peroxidation was estimated by incubating supernatants of liver samples, obtained by centrifugation at 3,500 × *g* of liver homogenates (prepared in 50 mM phosphate buffer pH 7.4), in the presence of 0.4 mM ascorbate and 0.05 mM $FeSO_4$ for 0, 90, and 180 min at 37°C. At the end of the incubation period, the thiobarbituric acid (TBA) assay was performed by a method specially adapted to tissue extracts (13). MDA (malondialdehyde–bisdimethyl acetal; Merck, Darmstadt, Germany) was used as a standard. The results were expressed as nanomoles of MDA equivalents produced per min per g tissue and represent the sensitivity of liver lipids to an oxygen radical induced oxidative stress.

Oxidative stress in the hydrophilic compartment. In order to estimate the GSH/GSSG ratio, liver samples were homogenized in 5% trichloroacetic acid (TCA) with 0.01 N HCl, and total glutathione was measured by the spectrophotometric recycling assay (14) in the presence of 5,5′-dithiobis (2-nitrobenzoic acid), NADPH, and glutathione reductase at 412 nm. GSSG was assayed by the same method by direct derivatization of GSH homogenizing another sample from the same tissue in the presence of 12.5 mM *N*-ethylmaleimide, followed by alkaline hydrolysis of *N*-ethylmaleimide (15). GSH values were obtained after subtracting GSSG from total glutathione.

Protein carbonyl content was determined spectrophotometrically according to the 2,4-dinitrophenylhydrazine (DNPH) method (16) as previously described (12). Briefly, liver samples were treated during 15 min with 0.1% digitonin, 1 mM EDTA, phenylmethanesulfonyl fluoride (40 μg/mL), and protease inhibitors, centrifuged, the DNA was removed with 1% streptomycin (15-min incubation), and samples were centrifuged again. The supernatants were divided into two portions which were treated with 2 M HCl or 10 mM DNPH in 2 M HCl. Proteins were precipitated with 20 and 10% TCA and the pellets were washed three times with ethyl acetate/ethanol. Pellets were dissolved in 6 M guanidine hydrochloride in 20 mM potassium phosphate (pH 2.3). Each DNPH sample was scanned from 320 to 410 nm against the HCl corresponding sample, and the peak absorbance was used to calculate protein carbonyls (extinction coefficient 22,000 M^{-1} cm^{-1}). The protein concentration was read at 280 nm in the HCl sample using 6 M guanidine hydrochloride as a blank.

Fatty acid analyses. Liver fatty acids were analyzed as previously described (17). Lipids were extracted with 2-propanol that was then evaporated with N_2. The lipid fractions were separated by thin-layer chromatography on silica gel plates. The phospholipid composition was studied using chloroform/methanol/acetic acid/water (50:25:8:4, by vol) and visualized with 10% $CuSO_4$ in 8% H_3PO_4. Lipids were transesterified with 5% HCl in methanol at 75°C. The esters were extracted with *n*-pentane and saturated NaCl, evaporated under N_2 and redissolved in CS_2. Fatty acid methyl esters were analyzed on a gas chromatograph equipped with a fused silica capillary column (Supelcowax TM 10; 30 m × 0.53 mm; Supelco, Inc., Bellefonte, PA). Chromatographic conditions: carrier gas, N_2, at 60 mL/min; flame-ionization

detector with H_2 at 50 mL/min and air at 500 mL/min; injector and detector temperature, 250°C; column temperature was increased from 135 to 195°C: increase of 4° per min; from 195 to 215°C: increase of 1° per min; from 215 to 235°C: increase of 2° per min. Identification of esters was made by comparison with authentic standards (Sigma, St. Louis, MO).

Statistical analysis. Comparisons between the three vitamin E groups were analyzed by one-way analysis of variance (ANOVA). After the ANOVA, the Fisher's least significant difference test was used to analyze significance between paired groups when necessary. *In vitro* lipid peroxidation was analyzed by two-way ANOVA (for time and vitamin E group) and by one-way ANOVA (as a function of incubation time). The 0.05 level was selected as the point of minimal statistical significance in every comparison.

RESULTS

Vitamin E supplementation. Vitamin E supplementation did not affect the growth rate of the animals after either 3 or after 5 wk of treatment (data not shown). The same was true for food ingestion (data not shown). Vitamin E dietary supplementation effectively led to very different hepatic levels of vitamin E in the three groups after 5 wk of supplementation. Increasing vitamin E dietary content one order of magnitude from group LOW to group MEDIUM resulted in a 129% increase in liver α-tocopherol concentration (from 11.9 ± 1.9 to 27.2 ± 3.2 μg/g of tissue). When dietary vitamin E was further increased another order of magnitude from group MEDIUM to group HIGH, the liver α-tocopherol concentration increased an additional 196% (from 27.2 ± 3.2 to 80.4 ± 5.6 μg/g). The hepatic α-tocopherol content of the group LOW (11.9 μg/g) showed that these animals were not vitamin E-deficient.

Sensitivity to in vitro *lipid peroxidation.* No differences in lipid peroxidation were observed between the three vitamin E groups at time 0 (Fig. 1). Incubation in the presence of Fe^{++}-ascorbate significantly increased the production of lipid peroxidation products in the three groups. The rate of increase in lipid peroxidation was significantly higher in group LOW than in the other two groups showing higher liver α-tocopherol levels (Fig. 1). No significant differences between group MEDIUM and group HIGH were found at any incubation time.

We have previously shown (12) that vitamin C supplementation also decreases nonenzymatic *in vitro* lipid peroxidation in the guinea pig liver under the same experimental conditions used here (Fig. 2A). The optimum intermediate level of vitamin C supplementation found in that work, 660 mg of vitamin C/kg of diet, is the one used in the present experiment in all the vitamin E groups. Similar degrees of lipid peroxidation were observed in both works at LOW E plus MEDIUM C (Fig. 2: second bar in A and first bar in B). Although optimum vitamin C levels were used here in the three vitamin E groups, group LOW E showed higher *in vitro* lipid peroxidation values than groups MEDIUM E and HIGH E (Fig. 2B).

Oxidative stress in the hydrophilic compartment. Two indexes of oxidative stress were measured in the hydrophilic compartment, GSH/GSSG ratio, and protein carbonyls. The results obtained for both indexes were highly consistent since no significant changes were observed as a function of vitamin E dietary and hepatic concentration in any group (Table 1).

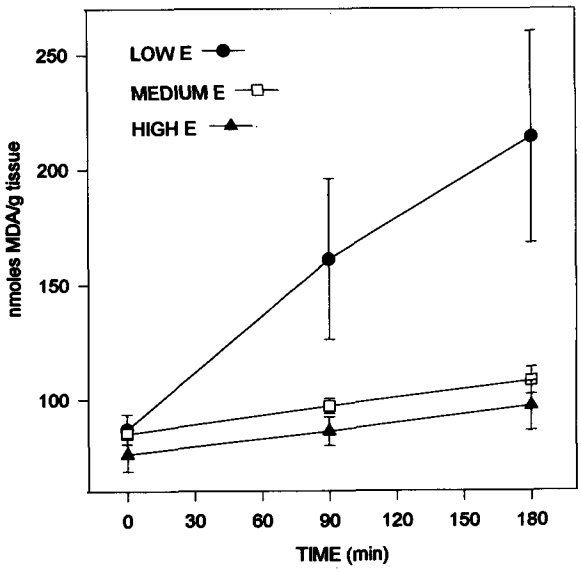

FIG. 1. Sensitivity to *in vitro* nonenzymatic (Fe^{++}-ascorbate) lipid peroxidation in the liver of guinea pigs fed with diets containing 15 (LOW E), 150 (MEDIUM E), or 1,500 (HIGH E) mg of vitamin E/kg during five weeks. Values are means ± SEM and are expressed as nmoles of malondialdehyde (MDA) equivalents/g tissue; n = seven animals per point. *In vitro* lipid peroxidation increased significantly in the three groups as a function of time [one-way analysis of variance (ANOVA); $P < 0.01$ in LOW E; $P < 0.001$ in MEDIUM E and HIGH E]. The rate of increase of liver peroxidation was significantly higher in LOW E than in the other two groups (two-way ANOVA; $P < 0.05$).

Fatty acid analyses. In the phosphatidylethanolamine fraction of liver lipids, significant changes were observed between groups MEDIUM and HIGH. Both unsaturated/saturated ratio (U/S) and the unsaturation index (UI; which takes into account the number of double bonds of each polyunsaturated fatty acid) decreased in group HIGH in relation to group MEDIUM (Table 2 and Fig. 3). This was mainly due to significant decreases in the percentage of α-linolenic (18:3n-3), arachidonic (20:4n-6), n-6 PUFA, and n-3 PUFA and to a significant increase in 16:0. The group LOW only showed a decrease in total n-6 PUFA and no significant changes were detected in any particular fatty acid. PUFA n-6 were maximum in group MEDIUM, and both HIGH and LOW vitamin E levels led to decreases in unsaturated fatty acids.

Phosphatidylcholine showed significant changes of similar character to those observed for phosphatidylethanolamine. The main changes observed occurred again in the group HIGH. n-3 PUFA, U/S ratio, UI, and linolenic acid decreased and saturated 12:0 increased in group HIGH in relation to group MEDIUM (Table 3 and Fig. 3). The unsaturated 20:2 n-6 decreased from group MEDIUM to group LOW.

In the sphingomyelin fraction, the UI, U/S ratio, n-6

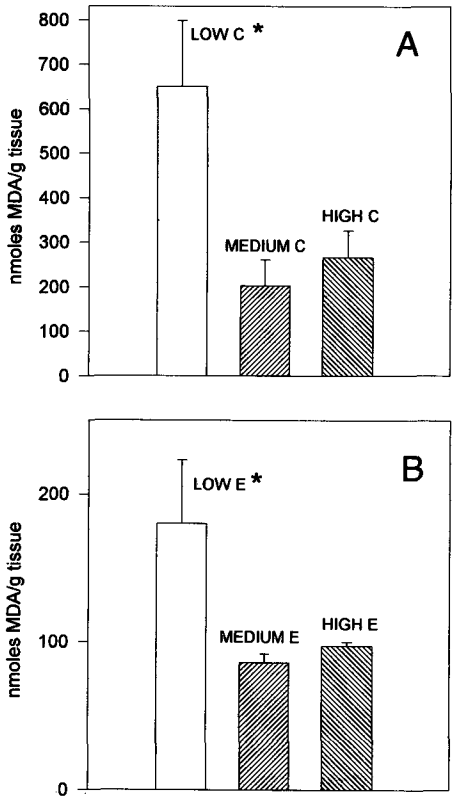

FIG. 2. Comparison of the effects on sensitivity to lipid peroxidation in the liver due to different dietary vitamin C levels in guinea pigs receiving LOW vitamin E (A) with those due to different vitamin E levels in guinea pigs receiving MEDIUM vitamin C in the diet (B). Optimum protection is obtained with the simultaneous presence of intermediate levels of both vitamins (second bar in B). Vitamin E (mg/kg) was: 15 (LOW), 150 (MEDIUM), and 1,500 (HIGH); and vitamin C (mg/kg) was: 33 (LOW), 660 (MEDIUM), and 13,200 (HIGH). Values in (B) come from Barja *et al.* (Ref. 12). Both in A and B the species, strain, body sizes, time of vitamin C or E supplementation, and lipid peroxidation conditions (90 min in the presence of ascorbate-Fe^{++}) were the same. Values are expressed as nmoles of MDA equivalents/g tissue; * = significant difference in relation to the other two groups, $P < 0.05$. See Figure 1 for abbreviation.

18:3n-3	2.19 ± 0.81		2.93 ± 0.67	*	1.78 ± 0.86
20:3n-6	0.37 ± 0.03		0.41 ± 0.08		0.44 ± 0.22
20:4n-6	13.05 ± 1.13		13.35 ± 1.20	*	11.39 ± 2.13
22:5n-3	1.05 ± 0.12		0.99 ± 0.14		0.95 ± 0.14
22:6n-3	0.88 ± 0.10		0.93 ± 0.18		0.89 ± 0.16
SFA	44.92 ± 1.32		43.73 ± 1.55		45.80 ± 2.31
PUFA n-6	45.70 ± 1.70	*	47.74 ± 1.61	*	45.78 ± 1.63
PUFA n-3	4.13 ± 0.91		4.85 ± 0.61	*	3.63 ± 0.92
MUFA	6.95 ± 0.60		6.31 ± 0.55		6.56 ± 0.83
U/S	1.21 ± 0.06		1.28 ± 0.08	*	1.18 ± 0.09
UI	3.06 ± 0.19		3.26 ± 0.24	*	2.92 ± 0.30
Chain length	18.06 ± 0.16		18.12 ± 0.10		18.06 ± 0.16

[a]Values are means ± SEM from seven animals per group. U/S is the ratio between Σmol% of unsaturated and Σmol% saturated fatty acids. The unsaturation index (UI) corresponds to the ratio: (Σmol% of unsaturated fatty acids × number of double bonds of each unsaturated fatty acid)/Σmol% of saturated fatty acids (SFA), PUFA n-6: Polyunsaturated fatty acids n-6; (Σmol% 18:2 + 20:3 + 20:4 + 22:4). PUFA n-3: Polyunsaturated fatty acids n-3; (Σmol% 18:3 + 22:5 + 22:6). MUFA: Monounsaturated fatty acids (Σmol% 16:1 + 18:1). Average chain length = $[(\Sigma\%Total_{14} \times 14) + (\Sigma\%Total_{16} \times 16) + (\Sigma\%Total_{18} \times 18) + (\Sigma\%Total_{20} \times 20) + (\Sigma\%Total_{22} \times 22)]/100$. Asterisks between columns describe differences between LOW E and MEDIUM E or between MEDIUM E and HIGH E. * = $P < 0.05$.

PUFA, arachidonic and linoleic acid decreased in group HIGH in relation to group MEDIUM (Table 4 and Fig. 3). Even though 16:0 was decreased in group HIGH in relation to group MEDIUM, this was more than compensated by an increase in 18:0, and saturated fatty acids (SFA) did not differ between the two groups. The only changes observed between groups MEDIUM and LOW were a decrease in n-6 PUFA and a decrease in the U/S ratio. Thus, again both low and high vitamin E levels caused a reduced percentage of unsaturated fatty acids, and the changes were more marked in HIGH than in LOW (but nondeficient) vitamin E animals.

More significant and quantitatively greater changes were observed for lysophosphatidylcholine, in which alterations followed the same pattern as in the rest of membrane phospholipid fractions. Group HIGH showed very significant decreases in n-6 PUFA, U/S ratio, UI, and arachidonic acid and important increases in 18:0 in relation to group MEDIUM (Table 5). The increase in 18:0, similarly to what was observed for sphingomyelin, compensated for the decrease in 16:0 and in this case the increase in the percentage of SFA in group HIGH reached statistical significance. Decrease in vitamin E from MEDIUM to LOW groups resulted in highly significant decreases in UI, n-6 PUFA, and arachidonic acid, and in increased 18:0, decreased 16:0, and increased total SFA. When both increases or decreases were considered, the changes observed with HIGH and LOW vitamin E levels in relation to group MEDIUM pointed always in the same direc-

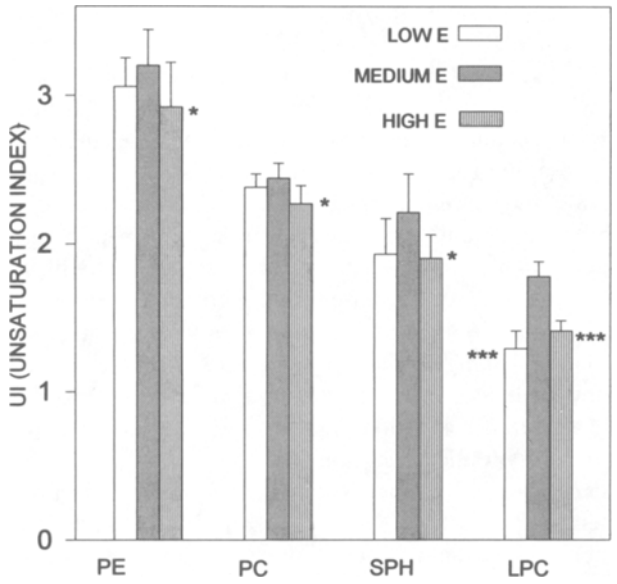

FIG. 3. Decreases in fatty acid unsaturation with both LOW and HIGH vitamin E dietary supplementation in liver guinea pig phospholipids. Vitamin E (mg/kg) was: 15 (LOW), 150 (MEDIUM), and 1,500 (HIGH). PC = phosphatidylcholine; PE = phosphatidylethanolamine; SPH = sphingomyelin; LPC = lysophosphatidylcholine; UI = unsaturation Index (see Tables 2–5). Asterisks: significant differences respect to group MEDIUM (* = $P < 0.05$; *** = $P < 0.001$).

tion: decreases in the degree of total fatty acid unsaturation (Fig. 3).

The changes observed in the triglyceride fraction were totally different from those observed for phospholipids mainly derived from membrane fractions. Group HIGH showed increases in 14:0 and 16:0 and a decrease in 18:0 in relation to group MEDIUM, and an increase in the percentage of SFA in relation to group LOW (Table 6). Group LOW showed higher 18:2 n-6 and n-6 PUFA and lower 18:0 than group MEDIUM. Neither the U/S ratio nor the UI showed changes as a function of vitamin E levels (Table 6).

The mean chain length was not modified in any lipid fraction as a result of vitamin E treatment.

DISCUSSION

In the present study, we have used three different levels of vitamin E in the diet to obtain guinea pigs with three different hepatic concentrations of vitamin E. Animals in the LOW vitamin E group ingested 0.6–0.75 mg of vitamin E per day, a dose very close to the minimum daily vitamin E requirement for long-term maintenance of the growing guinea pig, 1 mg/d (18,19). Animals in this group LOW have low tissue vitamin E levels, but they cannot be considered vitamin E-deficient. Animals in group MEDIUM are in the normal range used for routine maintenance of guinea pig, receiving an amount of vitamin E more than sixfold higher than the minimum daily requirement. Finally, group HIGH was designed to clarify the effects of supplementing the diet with levels of vitamin E 65-fold higher than the minimum daily requirement on hydrophilic and lipid oxidative stress markers and fatty acid profiles in the guinea pig liver.

In spite of the presence of widely different hepatic α-tocopherol contents, neither GSH/GSSG ratio or protein carbonyls varied. The reduced and oxidized forms of glutathione are present in the hydrophilic compartment, and the same is true for a great part of tissue proteins. That result is consistent with the function of vitamin E as an important antioxidant in membranes but not in the hydrophilic cellular compartment.

Contrasting with this lack of effect in the hydrophilic compartment, the increase in liver α-tocopherol from group LOW to group MEDIUM strongly inhibited nonenzymatic (induced by Fe^{++}-ascorbate) *in vitro* lipid peroxidation. This is consistent with an important antioxidant role of vitamin E in the membrane cellular compartment. Further increases in liver α-tocopherol to group HIGH did not afford additional protection in our system, perhaps because under these conditions ascorbate eventually becomes limiting. Some reports have shown similar results for laboratory rodents. A diet with 180 mg of vitamin E/kg decreased lipid peroxidation in relation to a diet with 86 mg/kg in rat liver after almost one month, whereas 1,400 mg/kg did not bring further protection (20). Vitamin E dietary supplementation also decreased susceptibility to lipid peroxidation in rat liver (21,22), and peroxidation of rat liver microsomes induced by Fe^{++}-ascorbate (23). No decreases in liver peroxidation were described in mice treated for 7 wk with 200 mg of vitamin E/kg vs. a deficient diet, but tissue vitamin E levels were not measured (24). The reason for the lack of differences in *in vitro* lipid peroxidation between groups MEDIUM and HIGH is not known, but the possibility exists that most ascorbate is consumed during the first part of prolonged incubation. It is possible that the amount of oxidative stress generated by our incubation system was not high enough to produce a vitamin E depletion which could discriminate between MEDIUM and HIGH vitamin E levels.

Previous work from our laboratory showed that vitamin C supplementation decreases nonenzymatic *in vitro* lipid peroxidation in LOW E guinea pig liver under the same experimental conditions used here. In the present work, we show that vitamin E protects from *in vitro* lipid peroxidation in spite of the use—in the three vitamin E groups—of the optimum (intermediate) vitamin C concentration found in our earlier work (12). Thus, optimum protection from hepatic *in vitro* lipid peroxidation in the guinea pig needs the simultaneous supplementation with both vitamins (C and E) at intermediate levels. This is consistent with the proposal of a cooperation between both vitamins *in vivo*, vitamin C reducing α-tocopheroxyl radical back to vitamin E (25,26).

Unsaturated fatty acids are highly sensitive molecules to free radical damage in cells. This sensitivity increases as a function of the number of double bonds of each individual fatty acid (27). Few works have addressed the problem of the possible effects of dietary vitamin E on tissue fatty acid profiles (28), as we have here in liver, and to our knowledge none has been performed in guinea pigs. A decrease in fatty acid unsaturation in liver microsomes of rat pups fed a vitamin E-deficient diet during 9 mon, the mothers receiving the same diet during gestation, has been recently described (29). In this work, liver vitamin E decreased to levels much lower than in our work (0.8 μg/g liver) and decreases in unsaturated 16:1, 18:1, 18:2, 20:3, and increases in 18:0 and total SFA were found in the vitamin E-deficient group. No group supplemented with vitamin E megadoses was included in that study. Other authors also have found decreases in unsaturation in liver microsomes and mitochondria in vitamin E-deficient rats

(30). At the other end of the spectrum, 2,000 mg of dietary vitamin E/kg diet during 6 wk decreased UI, 20:4, and 22:6 and increased 18:2 in the liver of spontaneously hypertensive rats (31). No group with low E levels was included in this work, only phosphatidylcholine was studied, and SFA were not measured. Other authors did not find changes in fatty acid unsaturation in rat tissues after feeding low vitamin E diets (32). Problems in study design may explain differences in results reported. As an example, no changes in liver PUFA were found after feeding Swiss mice diets with 0, 50, or 150 mg of vitamin E/kg, but no changes in liver vitamin E were found among the three dietary groups (33). Clearly, the lack of effect on PUFA in this study was associated with a lack of change in liver vitamin E.

In our present work, we have shown that both LOW and HIGH dietary and hepatic vitamin E levels were associated with a significantly lower fatty acids percentage of unsaturated, and maximum unsaturation occurs at intermediate vitamin E levels (Fig. 3). The LOW E effect is observed even in animals in which tissue vitamin E concentrations have not fallen to deficiency levels. Quantitatively greater effects were observed at HIGH than at LOW dietary vitamin E. When significant changes were observed, they occurred in the same direction in all the lipid fractions except for the triglycerides, indicating that the protective antioxidant role of vitamin E at intermediate levels operates mainly in membrane lipids. Triglycerides are deposited in hepatic cells surrounded by other molecules like phospholipids or cholesterol. This may afford them protection against oxidative stress, thus explaining their minor changes after vitamin E supplementation in comparison with those shown by phospholipids. The changes observed in phospholipids always occurred in the same direction from the group MEDIUM to the other two groups: decreases in the percentage of unsaturated fatty acids.

The decrease in unsaturation at low vitamin E levels could be predicted from prior work on the antioxidant role of this vitamin in the lipid membrane environment. Concerning the relative reduction of unsaturation at high vitamin E doses, various possibilities arise. It has been shown that α-tocopherol can have a prooxidant effect in chemical (10) and low density lipoprotein systems (11) *in vitro*. The prooxidant effect has been attributed to the reaction of tocopheroxyl radical (the oxidized free-radical form of vitamin E) with unsaturated lipids and lipid hydroperoxides, forming alkyl and peroxyl lipid radicals (10). This prooxidant effect does not occur if sufficiently high concentrations of antioxidants like vitamin C or ubiquinol-10, which reduce tocopheroxyl radical to vitamin E, are present in the *in vitro* system (11). This explanation would be consistent with our *in vitro* results, since the dietary vitamin E level of the group HIGH (1,500 mg/kg) surpassed that of vitamin C (660 mg/kg) in the present work. Nevertheless, no increases in oxidative stress markers (GSH/GSSG and protein carbonyls) were found in group HIGH. Furthermore, only percent, not absolute, fatty acid values were measured. Thus, the decreases in percent unsaturated fatty acids can be due to increases in SFA instead of to decreases in absolute amounts of unsaturates. Other alternatives are also possible. Effects of vitamin E on the synthesis of unsaturated fatty acids cannot be discarded since it has been shown that Δ-9 desaturase activity is decreased both by vitamin E-deficient and by vitamin E- supplemented diets in rat liver microsomes (34) and that high vitamin E concentrations (20-fold the control level) decrease Δ-6 desaturase in rat liver (35). Finally, the decrease in unsaturation in group HIGH also can be due to an inhibitory effect of high doses of α-tocopherol on phospholipase activity (36). This would decrease the elimination from the membranes of lipid hydroperoxides, known propagators of lipid peroxidation. In any case, the results show decreases in the percentage of unsaturated membrane fatty acids at both too low and too high dietary vitamin E doses in the liver *in vivo*.

A decrease in liver fatty acid unsaturation with both too low (33 mg/kg) and too high (13,200 mg/kg) dietary vitamin C levels has been found in our laboratory in the same guinea pig model used here, and higher unsaturation was observed again at intermediate (660 mg/kg) vitamin C dietary levels (12). These intermediate ascorbate levels were also enough to protect against lipid peroxidation. For both antioxidant vitamins (E and C), an intermediate dietary vitamin level exists at which protection from lipid peroxidation and a percentage of unsaturated higher fatty acids is observed in the liver. That level is 40- (vitamin C) or 6-fold (vitamin E) higher than the minimum daily requirement needed to avoid deficiency syndromes. This is consistent with the idea that optimum dietary levels of vitamin E and C are probably higher than the current RDA, whereas megadose levels can alter membrane fatty acid profiles in the same direction as marginal antioxidant vitamin deficiency.

ACKNOWLEDGMENTS

This work was financially supported by grant n°93/0145E from the National Research Foundation of the Spanish Ministry of Health (FISss). Predoctoral fellowships were received by C. Rojas and S. Cadenas (F.P.I., Ministry of Education) and a postdoctoral fellowship by R. Pérez-Campo (FISss).

ABSTRACT: *Trans* fatty acids from hydrogenated vegetable and marine oils could be as hypercholesterolemic and atherogenic as saturated fatty acids. Hence, it is important to know the fatty acid composition in major food contributors, e.g., margarines and shortenings. In 1992 margarines were examined, and in 1995 brands covering the entire Danish market were examined. Significant amounts of *trans*-18:1 were found only in hard margarines (mean: 4.2 ± 2.8%) and shortenings (mean: 6.8 ± 3.1%), whereas the semisoft and soft margarines contained substantially less *trans*-18:1 in 1995 than in 1992. Where marine oils had been used to a larger degree the mean *trans*-monoenoic content was about 15%, of which close to 50% was made up of long-chain (C_{20} and C_{22}) *trans* fatty acids. A noteworthy decrease in the content of *trans*-18:1 had occurred for the semisoft margarines, from 9.8 ± 6.1% in 1992 to 1.2 ± 2.2% in 1995. Calculated from sales figures, the supply of *trans*-18:1 plus saturated fatty acids from margarines has decreased over this three-year period by 1.4 g/day, which has been replaced by *cis* monounsaturated and polyunsaturated fatty acids.

Lipids 31, 971–975 (1996).

Trans fatty acids (TFA) are formed in small amounts in ruminant animals and will appear in the meat and milk (1). Consequently, TFA have always been part of the human diet. However, an additional and a more recent intake is derived from industrially hydrogenated vegetable and marine oils used in the manufacturing of margarines and shortenings, where mainly *trans*-octadecanoic acid is found. The position of the double bond is more or less normally distributed from the n-2 to the n-12 position with n-7, n-8, and n-9 being the most abundant (2).

Recently, the contribution of dietary TFA to plasma lipid and lipoprotein profiles (3–10) and risk of coronary heart disease (11–13) has attracted much scientific interest. Although experts have differed somewhat in their interpretation of the scientific evidence, and how the evidence should influence dietary advice to the public (14–16), many would admit that products high in TFA are unnecessary and could be harmful.

Thus, in Denmark the margarine industry has been put under pressure to manufacture products with lesser contents of TFA. Furthermore, it might be feared that TFA in margarines have been replaced by atherogenic saturated fatty acids, primarily lauric (LA; C_{12}), myristic (MY; C_{14}), and palmitic acid (PA; C_{16}) (6,17,18). From a public health perspective this would be an unfortunate development. To get more insight into the changing fatty acid pattern in Danish margarine products, we decided to examine the fatty acid composition of available margarines in 1995, and compare it to a similar examination performed in 1992.

EXPERIMENTAL PROCEDURES

All Danish margarine brands available on the retail market in the autumn of 1992 and 1995 were analyzed. Furthermore, in 1995 all Danish manufactured shortening brands intended for use in the baking industry were analyzed (in Denmark, shortenings are sold only for industrial purposes). One package of 400–500 g of each brand was taken at random directly from the production line.

In 1992 three factories produced margarine in Denmark, namely Vejle Margarinefabrik (Vejle, Denmark), Dragsbæk Margarinefabrik (Thisted, Denmark), and Van den Bergh Foods (Sønderborg, Denmark). In 1995 one more factory, Grønvang Margarinefabrik (Vejen, Denmark), was in existence. From 1992 to 1995 large changes in product types and brand names of margarines had occurred.

There was only minimal import of margarine and shortening in 1992 and 1995, so the sampling covers the entire Danish market for the retail outlet and the baking industry.

A total of 117 samples was drawn consisting of 74 brands of margarines (40 margarines in 1992 and 34 margarines in 1995) for the retail market, and 43 brands of shortenings for the baking industry.

The fatty acids were determined by boiling the fat in methanolic potassium hydroxide, methylation by boiling with methanol and boron trifluoride, and extraction of the fatty acid methyl esters with isooctane, followed by gas–liquid

chromatography (GLC) (PE 8500; Perkin Elmer Corp., Norwalk, CT) on a 50-m, capillary column, CP Sil 88, 0.32-mm i.d. (Chrompack International, Middelburg, The Netherlands) with flame-ionization detection. C_{17} is used as an internal standard for quantification of the fatty acids (19). Temperature program was: start temperature, 120°C; iso time, 0.0; ramp rate, 2.0°C; oven temperature, 220°C; iso time, 2.0 min; detector temperature, 350°C; programmed temperature, vaporizer injection system from 40 to 300°C. With this temperature program and column, there is good separation between *cis*- and *trans*-18:1, but there is still a minor overlap between some of the isomers, tending to underestimate the *trans* content a little. However, the overlap is negligible for *trans*-18:1 amounts below 10% of the fatty acids (20). *Cis*-20:1 elutes before 18:3, so the *trans*-20:1 does not interfere with 18:3.

All analyses were carried out as double determinations, and the results were ascertained by making the so-called R-charts over the deviation on the double determination of the fatty acids PA (16:0), stearic (18:0), oleic (*cis*-18:1n-9), and linoleic (LI; *cis*-18:2n-6). As reference materials are used and in-house material of margarine, certified BCR reference material CRM 162 Soya-maize oil (Community Bureau of Reference, Brussels, Belgium) and Nu-Chek-Prep standards GLC 68 and 17A[1] (Nu-Chek-Prep, Inc., Elysian, MN).

The long-chain (LC) TFA from hydrogenated fish oils cannot be sufficiently separated to be quantified by GLC on a 50-m polar capillary column. To quantify these TFA, the fatty acid methyl esters were separated by thin-layer chromatography by application in a spot on Kieselgel plates (Merck, Darmstadt, Germany) impregnated with a solution of 5% silver nitrate and eluted with petroleumether/diethyl ether. The spots were visualized by spraying with dichlorfluorescin, scraped off and eluted with diethyl ether (21). The spots with saturated fatty acids and TFA were combined. The fatty acids were then determined as described previously, again using C_{17} from the spot with saturated fatty acids as internal standard for the determination of TFA.

Statistical analysis was performed with the Student's unpaired *t*-test. Two-sided *P*-values less than 0.05 were considered statistically significant. Values are given as mean ±1 SD unless otherwise indicated.

RESULTS

For presentation, the margarines for the retail market are divided into three categories based on their LI content: (i) margarines with less than 20% (wt% of total fatty acids) LI (these are hard margarines used mainly for frying); (ii) margarines containing 20–40% LI (these are semisoft margarines used mainly as spreads on bread); (iii) margarines with more than 40% LI. These are soft margarines also used as spreads.

The contents (mean, range) of individual fatty acids in margarines and shortenings are given in Table 1. *Trans*-18:2 or conjugated 18:2 are not present in Danish margarines in any significant amounts (<0.2% of total fatty acids).

A nonsignificant fall in *trans*-18:1 from 1992 to 1995 in hard margarines, from 5.8 ± 3.2 to 4.2 ± 2.8% ($P = 0.2$), was demonstrated. Three hard margarine products (15%) were "*trans*-free" (containing less than 1%) in 1995 as opposed to none in 1992. Total saturated fatty acids were higher in 1992 than in 1995 (41.9 ± 2.8 and 34.6 ± 11.2%, respectively), even though not significantly ($P = 0.07$). The saturated fatty acids LA, MY, and PA, suspected to have a high atherogenic potential, were almost unchanged in 1992 compared to 1995 (29.4 ± 4.0 and 26.5 ± 8.5%, respectively). Total monounsaturated fatty acids—chiefly oleic acid—were 29.9 ± 7.5% in 1992, significantly lower than

TABLE 2
***Trans* Monoenoic Fatty Acids (wt% of total fatty acids) in Danish Margarines and Shortenings**

	Mean ± SD	Variation
Trans-16:1	2.4 ± 1.4%	0–5.4%
Trans-18:1	5.7 ± 1.9%	2.6–10.0%
Trans-20:1	4.0 ± 2.2%	0.1–7.6%
Trans-22:1	2.9 ± 2.1%	0–6.1%
Σ*Trans*-monoenoic	15.1 ± 4.9%	8.2–22.2%

40.1 ± 10.8% in 1995 ($P < 0.05$). LC were present in amounts of less than 1% of total fatty acids in none of the brands in 1992, compared to seven brands (35%) in 1995.

In margarines with 20–40% LA, a significant fall in *trans*-18:1 was demonstrated between 1992 and 1995. Mean values were 9.8 ± 6.1% in 1992 and 1.2 ± 2.2% in 1995 ($P < 0.001$). Six brands (75%) contained less than 1% *trans*-18:1 in 1995 compared to only one margarine brand (6%) in 1992. Saturated fatty acids showed no changes (20.1 ± 5.2 and 21.3 ± 6.9%, respectively), and polyunsaturates were significantly higher in 1995 compared to 1992 (28.6 ± 5.9 and 35.8 ± 7.3%, respectively; $P < 0.05$). LC, usually in small amounts, were demonstrated in seven products (41%) in 1992 and in three products (38%) in 1992.

Trans-18:1 was very low in soft margarines in 1992, as well as in 1995. All but four margarine brands (71%) were "*trans*-free" in 1992, and all but two (67%) in 1995. Total saturated fatty acids were significantly higher in 1995 compared to 1992 (21.0 ± 2.3 and 27.4 ± 8.0%, respectively; $P < 0.05$), due entirely to a higher content of LA, MY, and PA (13.6 ± 2.4 and 19.6 ± 4.3%, respectively; $P < 0.001$). LC were not used to any significant degree in the soft, and semisoft, margarines.

The content of saturated LA, MY, and PA was not significantly different ($P = 0.3$) in "*trans*-free" margarines (27.8 ± 11.9%) compared to margarines with >1% *trans*-18:1 (24.2 ± 7.7%).

All shortenings for the baking industry contain less than 20% LI. A lower *trans*-18:1 content was demonstrated in the hard margarines (1995) compared to the shortenings. Mean values in shortenings were 6.8 ± 3.1%, significantly higher than in margarines ($P < 0.005$). Only three (7%) brands of shortenings were "*trans*-free." The higher *trans* content was mainly compensated for by a lower content of polyunsaturated fatty acids.

A total of 13 shortenings and hard margarines contained more than 5% LC. These brands had an average of about 15% total *trans*-monoenoic fatty acids, of which close to 50% were made up of *trans*-LC (20:1 and 22:1) (Table 2). n-3 Polyunsaturated fatty acids are not present in significant amounts (<0.2% of total fatty acids) after hardening of the fish oils.

DISCUSSION

Discussions about the health effects of TFA were intensified in 1990 when TFA were reported to increase low density lipoprotein-(LDL) and decrease high density lipoprotein-(HDL) cholesterol concentrations in the blood of healthy normocholesterolemic subjects (5). Later studies indicated that TFA might also increase plasma triglyceride (4) and lipoprotein(a) concentrations (3,7), both considered to be risk factors for coronary heart disease. The significance of these findings was supported by recent prospective epidemiological studies showing association between the intake of TFA and subsequent coronary heart disease (11–13). Recently, however, several reviews have critically examined the scientific evidence linking the intake of TFA to premature atherosclerosis (14,15,22,23). The conclusions from these reviews are that TFA increase plasma concentrations of total- and LDL-cholesterol when substituted for oleic acid, but decrease cholesterol concentrations when substituted for saturated fatty acids (butter or PA), and that the effects on HDL-cholesterol and lipoprotein(a) concentrations are ambiguous. Also, in some epidemiological studies, the association between intake of TFA and coronary heart disease could not be demonstrated (24,25). Studies on the implications for human health of TFA are still quite few, especially if compared to the wealth of data linking intake of saturated fatty acids to the development of coronary heart disease.

Although data supporting the relation between the intake of TFA and coronary heart disease are sparse, there has, for the last five years, been a public pressure on margarine producers to reduce TFA in their products. In Denmark, the pressure during recent years has been increased further due to the recommendations from the Danish Nutrition Council to reduce the content of TFA in all margarines (16), and the contemplations of the Danish National Food Agency concerning legislation on maximum content of TFA in margarines and other hydrogenated oils (26).

Three saturated fatty acids in the diet—LA, MY, and PA—are involved in raising cholesterol levels as much or more than *trans*-18:1 (6,17,18), whereas the saturated stearic acid almost certainly is biologically neutral (27). From a public health aspect, it would not be appropriate to substitute the *trans* content in margarines with vegetable fats with high contents of LA, MY, and PA, e.g., coconut or palm oil.

This does not seem to be the case for Danish margarines. In the margarines with the most noteworthy reduction in *trans*-18:1 content (from 9.8 to 1.2%), i.e., the semisoft spreads, TFA were largely substituted by polyunsaturated fatty acids—primarily LI. Soft margarines seemed to have a higher "cardiac risk profile" in 1995 than in 1992, because of a higher content of saturated fatty acids, primarily LA and MY. Soft margarines contained insignificant amounts of *trans*-18:1 in both 1992 and 1995.

A gradual decrease in TFA in margarines has been observed since the mid-1960s in many Western countries, mainly because of improved processing conditions (28). A decline also can be demonstrated for Danish margarines. A total of 30 different Danish margarines, which did not cover the entire retail market, was analyzed in 1985 (29). Margarines with <20% LA, 20–40% LA, and >40% LA had *trans*-18:1 contents of 7.1, 9.8, and 4.1%, respectively. Our

study showed that *trans*-18:1 had decreased to considerably lower levels in 1992, and that a further decrease had occurred in 1995. Compared to the *trans*-18:1 content in 1985, average decreases of 40–90% were seen in margarines analyzed 10 yr later.

A recent study of French tub margarines (semisoft and soft margarines) also demonstrated a decline in *trans*-18:1 content, from a mean of 13% of total fatty acids in 1991 to 3.8% in 1995 (30). In that study, four of the 12 margarines examined were "*trans*-free" (<2% TFA), whereas four years earlier none were "*trans*-free." Incidentally, the French study found extremely high *trans* contents (more than 50% of total fatty acids) in two of the three examined shortenings, much higher than the contents seen in Danish manufactured shortenings.

Shortenings used in the baking industry have a higher *trans* content than comparable (solid) margarines. It is claimed by the margarine manufacturers that the present *trans* content is necessary in shortenings to give the product "unique" physical properties, such as satisfactory mouthfeel and distinctive texture which, to a large extent, characterizes the final food product (e.g., snacks, cakes, biscuits, confectionery). The truth of this claim is, however, scientifically unproven.

Danish shortenings and hard margarines—as is the case for margarines and shortenings produced in the United Kingdom and in other Nordic countries—often contain significant amounts of partially hydrogenated marine oils. Marine oils do not seem to be present at all in margarines with medium and high levels of LI.

The hydrogenation of both vegetable oils and marine oils results in a number of isomers, of which *trans*-monoenoic acids dominate (28). So far, most studies on the effects of TFA have been conducted with partially hydrogenated vegetable oils. A recent study has shown that high intake of TFA (about 20 g/day) from partially hydrogenated marine oils increases total- and LDL-cholesterol and decreases HDL-cholesterol compared to the intake of the same amount of TFA from partially hydrogenated soybean oil (3).

This study showed a sizable reduction from 1992 to 1995 in the use of marine oils in solid margarines, reflected in the reduced content of LC. Shortenings contained a similar amount of LC, about 7% of total fatty acids. A substantial amount of LC was present in the form of *trans*-monoenoic acids (*trans*-20:1, *trans*-22:1). The mean content of *trans*-monoenoic acids from LC constituted almost half of total TFA in shortenings and margarines. Thus, because long-chain *trans*-monoenoic acids are suspected to be atherogenic, there is good reason to urge the margarine industry to continue lowering the content of partially hydrogenated marine oils in shortenings and margarines.

Based on Danish sales figures for margarines and shortenings in 1995 (from the Association of Danish Margarine Manufacturers, which include factories supplying close to 100% of the Danish market), total sale for the Danish market corresponds to a daily per capita supply of 30 g, of which 10 g is made up from shortenings, and 14, 4, and 2 g from hard, semisoft, and soft margarines, respectively. It can be calculated that the average per capita supply of *trans*-18:1 from margarines and shortenings is about 1.5 g daily for every Dane. On the assumption that the sale of margarines was similar in 1992 and 1995, the supply of *trans*-18:1 from margarines has decreased by 0.7 g/day. This decrease has occurred at the same time as saturated fatty acids decreased by 0.7 g/day. This decrease of 1.4 g/day has been replaced by 1.0 g/day of *cis* monounsaturated fatty acids and 0.4 g/day of polyunsaturated fatty acids.

However, it must be remembered that compared to a national average saturated fat intake of 40 g/day (31), the intake of *trans*-18:1 from hydrogenated vegetable oils is indeed very low. Although *trans* content of margarines and shortenings should be minimized, dairy products, margarine, and meats are still the major contributors of saturated fatty acids to the diet and should continue to be the focus of dietary change. Compliance with this recommendation will also appreciably lower dietary TFA.

Polyunsaturated Fatty Acids Exert Antiarrhythmic Actions as Free Acids Rather Than in Phospholipids

ABSTRACT: Previous studies have shown that exogenous free n-3 polyunsaturated fatty acids (PUFA) can prevent tachyarrhythmias caused by specific agents in isolated cardiac myocytes. However, the question as to whether incorporation of the n-3 PUFA into membrane phospholipids has the same immediate protective effects remained to be answered. To answer this question, we increased the content of n-3 PUFA in the phospholipids of cultured neonatal rat myocytes by growing them 2–3 d in a culture to which eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) in 15 μM concentration was added. Analysis of the fatty acid composition of membrane phospholipids revealed a significantly higher level of EPA and DHA (from 0.2 to 7.6% and from 1.2 to 6.5%) in cells supplemented with EPA or DHA, respectively. The responses of the myocytes grown in normal media or in media enriched with the PUFA to arrhythmogenic agents were examined after free fatty acids were removed from the medium and the cells. The arrhythmogenic agents used were the β-adrenergic agonist isoproterenol or an elevated extracellular concentration of calcium. The results showed that there was no significant difference in the induction of tachyarrhythmias by isoproterenol or by elevated $[Ca^{2+}]_o$ in cells grown in media enriched with PUFA, as compared with cells grown in normal media in the absence of the free PUFA. Under the conditions of this study, only the unesterified PUFA were able to protect the cardiomyocytes against induced arrhythmias. There was no antiarrhythmic effect due to an increased fraction of EPA or DHA in membrane phospholipids.

Lipids 31, 977–982 (1996).

Sudden cardiac death constitutes a major portion (50–60%) of mortality from acute myocardial infarctions, some 250,000 deaths annually in the United States alone (1). Malignant arrhythmias such as ventricular tachycardia and ventricular fibrillation are thought to be main factors causing sudden cardiac death. There are several studies which indicate a role for long-chain n-3 fatty acids in the prevention of fatal ventricular arrhythmias. In experiments with rats and marmosets, McLennan *et al.* (2–4) showed that feeding tuna fish oil, in contrast to saturated animal fat or olive oil, prevented the animals from fatal rhythm disturbances following an experimental myocardial infarction. Similar feeding studies on rats by Hock *et al.* (5) confirmed these results. Billman *et al.* (6) reported that an intravenous infusion of an emulsion comprised largely of eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) as their free fatty acids can prevent ischemia-induced ventricular fibrillation in conscious exercising dogs. The animals were prepared by a surgically induced myocardial infarction and placement of a hydraulic cuff around the left circumflex artery, which enabeled subsequent induction of ischemia during exercise. Our earlier studies have shown that free long-chain polyunsaturated fatty acids (PUFA) at 2–15 μM can prevent the arrhythmias induced by ouabain (0.1 mM), high extracellular calcium (7 mM), lysophosphatidylcholine (2–10 μM), acylcarnitine (2-10 μM), or the β-adrenergic agonist isoproterenol (ISO) (2-10 μM) in isolated neonatal rat cardiac myocytes (7–11). In humans a randomized clinical trial has reported a significant reduction in sudden cardiac death in patients whose diets were supplemented with long-chain n-3 fatty acids (12). Another human study showed a reduction in mortality from coronary heart disease without a reduction in heart attacks in patients eating fish, which also suggests a reduction in sudden death (13).

Our previous studies indicate that it is the unesterified free fatty acid which prevents the arrhythmias (7–11). However, it is still unclear—especially with respect to the dietary studies—whether n-3 PUFA in membrane phospholipids can also exert a protective effect. So far, most studies analyzing changes in cell behavior due to effects mediated by the fatty acids focus on the fatty acid composition of the phospholipids in cell membranes. This suggests that some workers feel that it is the resulting enrichment of membrane phospholipid content with the fatty acids that accounts for the changes in cellular functions. In this context, it seemed important to assess whether the antiarrhythmic effect of n-3 PUFA, like EPA and DHA, is based only on effects of their free fatty acid form or if the effect is dependent on incorporation of these fatty acids

into membrane phospholipids. Because dietary feeding studies cannot discern between effects of increased concentrations of PUFA in membrane phospholipids or in the free nonesterified fatty acids, since both increase simultaneously, this study uses isolated multicellular cardiac myocyte cultures to examine the effects of EPA or other n-3 PUFA as a constituent of membrane phospholipids on the inducibility of arrhythmias by isoproterenol (ISO) or high extracellular calcium concentrations. We show that there is no prompt protective effect due to an enrichment of membrane phospholipids with n-3 fatty acids, and that the protective effect of these n-3 PUFA against arrhythmias is only a function of the free, unesterified fatty acid.

METHODS

Cell culture. Cardiac myocytes were isolated from one-day-old rats using the Neonatal Cardiomyocyte Isolation System (Worthington Biochemical Corp., Freehold, NJ). This system is based on that described by Toraason *et al.* (14), in which minced tissue is incubated overnight with trypsin in the cold. The isolated cells were placed on 15-mm glass coverslips in petri dishes. Cells were cultured at 37°C in air with 5% CO_2 added and 98% relative humidity in a tissue culture incubator (Model 3123; Forma Scientific, Marietta, OH); the medium contained 5% fetal calf serum and 10% horse serum. The culture medium was changed every other day. After 48 h in culture, the myocytes had attached to the coverslips and formed multicellular colonies of regularly and spontaneously beating cells. Cells were used for experiments after 3–5 days of culture.

Fatty acid composition analysis. The fatty acid composition of cellular phospholipids was analyzed as described previously (15). Lipid was extracted with chloroform/methanol (2:1, vol/vol). Samples were sealed under nitrogen and stored at –20°C until thin-layer chromatography (TLC) was performed. For TLC, the samples were dried under nitrogen and reconstituted in 80–100 µL chloroform. TLC plates were activated at 90–100°C for 1 h, and chromatography was run using petroleum ether/ethyl ether/acetic acid (80:20:1, by vol) as the solvent. Bands were made visible with 0.01% 8-anilino-1-naphthalenesulfonic acid, and gel scrapings of the phospholipid fraction were collected for methylation. To obtain fatty acid methyl esters, 1.5 mL borontrifluoride in methanol (14%) and 2 mL hexane were added to the gel scrapings and then heated for one hour at 100°C. After this procedure 1 mL of water was added and mixed vigorously. Tubes were allowed to stand for at least 30 min before removing the hexane phase. Samples were then dried under nitrogen and reconstituted in 100 µL isooctane of which 2 µL were analyzed by gas–liquid chromatography. An Omegawax™ column (30 m; Supelco, Bellefonte, PA) was used in a Hewlett-Packard 5890A gas chromatograph (Hewlett-Packard, Avondale, PA). Carrier gas was hydrogen (2.39 mL/min), injected with a split ratio of 1:31. The initial temperature was 165°C for 5 min; then temperature was increased to 195°C at 2.5°C/min and from there to 220°C at 5°C/min. Temperature was held for 10.5 min and then decreased to 165°C at 27.5°C/min. Peaks were identified by comparison with fatty acid standards (Nu-Chek-Prep, Elysian, MN), and area percentage for all resolved peaks was analyzed using a Perkin-Elmer M1 integrator (Perkin-Elmer, Norwood, CT).

Measurement of cell contraction. Changes in amplitude of contraction and beating rate of cultured cardiomyocytes were determined using a phase contrast microscope and video-monitor edge-detector (Crescent Electronics, Salt Lake City, UT) as described previously (7). A glass coverslip with attached cultured myocytes was brought to a chamber which was continuously superfused during contractility measurements with a HEPES buffered-saline solution (in mM: 140 NaCl, 5 KCl, 1.0 $MgCl_2$, 1.2 $CaCl_2$, 1.0 Na_2HPO_4, 5.0 HEPES, 10 glucose; pH was adjusted to 7.4 with NaOH). In the experiments using high Ca^{2+} concentrations in the perfusion fluid, Na_2HPO_4 was omitted from the buffer to prevent precipitation of calcium salts. The chamber was placed on the stage of a Zeiss Axiovert 10 inverted microscope (Zeiss, Oberkochen, Germany) and was surrounded by a temperature-controlled lucite box heated to 37°C. A four-way manifold controlled the inlet to the perfusion system delivered by two syringe pumps (Harvard Apparatus Inc., South Natick, MA), so that the coverslip could be sequentially superfused with different solutions. The flow rate was 20 mL/h, and the cells were magnified with a 32x objective. Plastic beads added to the cell cultures on day two were used as markers for myocyte motion. The image was monitored with a CCD videocamera (Javelin Electronics, Los Angeles, CA) and displayed on a monitor. A video motion detector system recorded motion along a selected raster line and transferred these data to a Grass 79D strip chart recorder (Grass Instrument Co., Quincy, MA). After 3–5-min equilibration period while perfusing with HEPES buffer, different solutions could be added while observing the contraction behavior of the cells. Changes in amplitude and rate of cell contractions were used to assess the effects of different perfusates on cell contractions.

Statistical analyses. The results of the arrhythmia-induction experiments were analyzed using X^2-test with two degrees of freedom, using 0.05 as level of significance. No corrections were used. The data from the fatty acid analyses are shown as means ± SE, rounded off to the nearest significant figure.

Materials. Neonatal Cardiomyocyte Isolation System Kit was purchased from Worthington Biochemical Corp. ISO was obtained from Elkins-Sinn, Inc. (Cherry Hill, NJ). Fatty acids were obtained from Sigma Chemical Co. (St. Louis, MO). Fatty acids were dissolved weekly in ethanol at the concentration of 10^{-2} M and stored under a nitrogen atmosphere at –20°C. The final concentration of ethanol was negligible and had no effect on myocyte contraction. TLC plates were purchased from Fisher Chemicals (Pittsburgh, PA), as were the standard solvents used in the analysis of fatty acids.

RESULTS

Our goal was to test if there is any change in response of cardiac myocytes to arrhythmogenic agents due to a change in cellular phospholipid content of n-3 PUFA. Therefore, we increased the membrane phospholipid composition of the myocytes with n-3 PUFA. The enrichment of cells with n-3 PUFA was obtained by growing myocytes for at least 48 h in media containing these fatty acid in a concentration of 15 μM. To confirm that an enrichment of phospholipids with n-3 PUFA was achieved, the fatty acid composition of phospholipids was analyzed, as described. The results are shown in Table 1. The analyses revealed a significant increase in the content of EPA from 0.2 ± 0.2 to 7.6 ± 1.0% and in the elongated EPA derivative docosapentaenoic acid (DPA, 22:5n-3) from 2.5 ± 0.9 to 13.1 ± 1.2% in controls vs. EPA-supplemented cells. Cells cultured with DHA showed an increase of DHA in phospholipid from 1.2 ± 0.4 to 6.5 ± 0.3%.

These cells were then used in contractility studies similar to those previously reported (7–11). ISO, as well as a high extracellular calcium concentration, induce spasmodic tachyarrhythmic events in cultured cardiomyocytes, making these cells a suitable model for studying cardiac arrhythmias. The cells, when grown in nonenriched media, show a slowing of contraction rate in response to perfusion with n-3 PUFA (5–15 μM), normally within 3 to 12 min. Perfusion with these fatty acids is able to stop arrhythmias induced by ISO (Fig. 1A) or by an elevated extracellular calcium concentration (Fig. 2A). We compared the response of those cells with that of cells having a higher phospholipid content of long-chain n-3 PUFA (Fig. 1B). After establishing a baseline of contraction while perfusing with HEPES-buffer (3–5 min), 2 mg/mL delipidated bovine serum albumin (BSA) was added to the superfusate for 3 min. Delipidated BSA binds free fatty acids tightly, which removes the free fatty acids carried over from the culture medium and the myocytes. Thereby, an environment essentially free of nonesterified fatty acid was created for the cells.

The cells were then perfused with ISO (3–10 μM) to induce arrhythmias. In both cell groups, controls and PUFA-enriched, we found the induction of arrhythmias by ISO. Of 51 nonenriched cells tested, 26 (51%) developed arrhythmias while perfused with ISO, in comparison to 47 of 107 (44%) EPA-enriched cells and 6 of 13 (46%) DHA-enriched cells. Chi-square tests applied to these data show that there were no significant differences between the two cell groups in terms of induction of arrhythmia by ISO ($X^2 = 0.69$, $P > 0.1$).

In experiments performed with high extracellular Ca^{2+} concentration (7 mM) instead of ISO as arrhythmogenic agent, we induced arrhythmia in 16 of 20 (80%) nonenriched cells tested as compared to 10 of 14 (71%) EPA-enriched cells and 4 out of 6 (67%) cells enriched with DHA ($X^2 = 0.58$, $P > 0.1$). These results indicate that there was no protective effect due to the increased n-3 fatty acids in phospholipid. In all cases tested, perfusion with free EPA or DHA (15 μM) terminated the arrhythmias induced by ISO, both in unenriched controls ($n = 8$) as well as in enriched cells ($n = 23$). When 7 mM extracellular Ca^{2+} was used as arrhythmogenic agent, there was a reversal of arrhythmias by perfusion of EPA or DHA in 10 controls ($n = 12$) as well as in 9 enriched cells ($n = 10$). These data further indicate that the n-3 PUFA in phospholipids had no antiarrhythmic effect in this study. Representative examples for the induction of arrhythmias by ISO and their termination by EPA-perfusion are given for both cell groups in Figure 1. Corresponding data are shown for Ca^{2+}-induced arrhythmias in Figure 2.

These findings show that despite a large enrichment of the n-3 PUFA content in membrane phospholipids of the myocytes, no antiarrhythmic protection was afforded in the absence of free n-3 PUFA. Only free n-3 PUFA were protective against arrhythmias in this study; the same n-3 fatty acids when only present in the membrane phospholipids were not antiarrhythmic.

TABLE 1
Comparison of Phospholipid Fatty Acid Composition in Control Cells and Cells After Growth in Media Containing EPA or DHA (15 μM)[a]

	Phospholipid fatty acid composition (wt%)		
Fatty acid	Control ($n = 5$)	EPA-enriched ($n = 10$)	DHA-enriched ($n = 3$)
16:0	8.8 ± 1.5	7.8 ± 1.4	11.6 ± 0.8
18:0	19.7 ± 2.7	16.2 ± 2.4	15.0 ± 0.9
18:1n-9	9.6 ± 1.2	8.4 ± 0.6	7.8 ± 0.5
18:2n-6	9.9 ± 1.4	9.0 ± 0.9	8.1 ± 0.5
20:3n-6	0.3 ± 0.2	0.4 ± 0.2	1.0 ± 0.0
20:4n-6	13.9 ± 2.3	13.5 ± 1.2	7.7 ± 0.5[b]
20:4n-3	3.7 ± 1.0	2.6 ± 0.4	0.4 ± 0.1
20:5n-3	0.2 ± 0.2	7.6 ± 1.0[b]	1.5 ± 0.1
22:0	0.4 ± 0.4	0.3 ± 0.1	0.5 ± 0.0
22:4n-6	2.1 ± 0.7	1.1 ± 0.4	0.7 ± 0.2
22:5n-3	2.5 ± 0.9	13.1 ± 0.2[b]	1.3 ± 0.1
22:6n-3	1.2 ± 0.4	0.5 ± 0.2	6.5 ± 0.3[b]

[a]Data were obtained by gas chromatography. Values are means ± SE: [b]$P < 0.01$. The minor fatty acids are not included, so the total percentages do not add up to 100; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

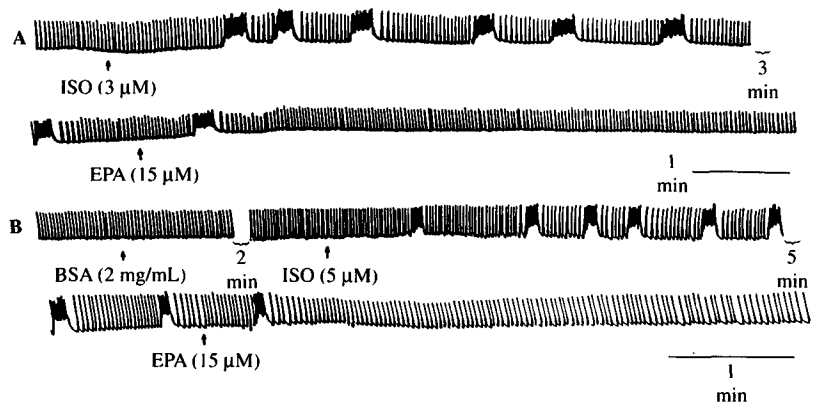

FIG. 1. A. Response of control cells to isoproterenol (ISO). Perfusion with ISO-induced arrhythmias, which could be terminated by subsequent addition of eicosapentaenoic acid (EPA). B. Response of cells enriched with EPA to ISO. Cells were first perfused with buffer, then with bovine serum albumin (BSA) to remove free fatty acids. Perfusion with ISO induced arrhythmia. This arrhythmia could be terminated by additionally perfusing with 15 μM EPA.

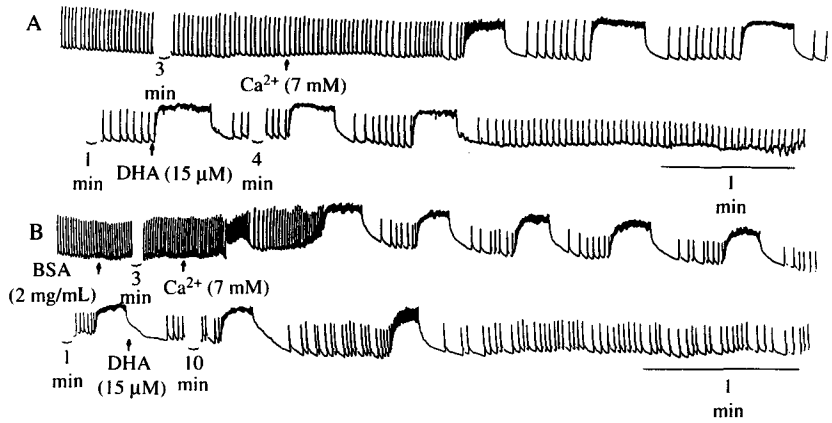

FIG. 2. A. Response of control cell to stimulation with 7 mM extracellular Ca^{2+}. Induced arrhythmias were terminated by subsequent addition of docosahexaenoic acid (DHA) (15 μM). B. Cells cultured in 15 μM DHA showed induction of arrhythmia by 7 mM extracellular Ca^{2+}. Arrhythmia was reversible with perfusion with DHA (15 μM). See Figure 1 for other abbreviation.

DISCUSSION

Many studies examining the effects of fatty acids on myocardial cell function have focused on changes in the fatty acid content of the phospholipids. It seems to be widely assumed that changes in cell functions associated with an increase or reduction of the intake of specific fatty acids result from enrichment or depletion of these fatty acids in cellular phospholipids. This assumption has been implicit in the interpretation of dietary studies that found a correlation between the antiarrhythmic action of n-3 PUFA and their enrichment in membrane phospholipids of cardiac myocytes (2–4). However, these studies do not permit discrimination between a direct effect of the free n-3 PUFA or a direct effect when incorporated in membrane phospholipids, since in animal feeding experiments the free fatty acid levels and the PUFA incorporation in membrane phospholipids both increase simultaneously. The goal of this study was to test the effects of those alternatives separately.

The cell system used consists of an isolated, cultured, spontaneously beating neonatal rat ventricular myocyte preparation with cell-cell communications. These cells respond to ISO stimulation or to stimulation with high extracellular calcium concentrations with development of tachyarrhythmias and chaotic fibrillatory beating activity, thereby showing an arrhythmic profile resembling that recorded from the isolated or *in vivo* heart (16–18). EPA or DHA (5–15 μM) is able to prevent or terminate these arrhythmias when added

to the perfusate (10). Both n-3 and n- 6 PUFA as their free acids are able to exert antiarrhythmic action, in contrast to saturated and monounsaturated fatty acids which have no antiarrhythmic effects (7,10,11) and do not block sodium channels (19) or bind to the channel protein (20) as do the free PUFA. However, the n-6 PUFA arachidonic acid showed induction of arrhythmias in one-third of the experiments (7). This is due to arrhythmogenic cyclooxgenase metabolites derived from arachidonic acid, not to the arachidonic acid *per se*. By using only n-3 PUFA in these experiments, we exclude this possibility, as these PUFA have not been found to be arrhythmogenic in our previous experiments (7,10,11).

An increase in content of n-3 PUFA in phospholipids was established by growing neonatal cardiomyocytes in medium containing EPA or DHA, and these cells were used to test if there is a protective effect arising from n-3 PUFA in membrane phospholipids. By culturing myocytes with or without EPA or DHA added to the medium and then superfusing them with delipidated BSA to remove free EPA or DHA from the medium and the myocytes (7,10), we could test the effect of just the EPA and DHA incorporated into cellular phospholipids in contrast to experiments using the intact animal. Despite the higher content of EPA + DPA (3 vs. 20% in control vs. enriched cells) or of DHA (1 vs. 6.5%) in the phospholipid fraction, there was no protective effect from this enrichment of phospholipids with n-3 PUFA. Furthermore, arrhythmias induced in these cells could be terminated in the same way as observed for cardiomyocytes grown in the absence of the PUFA when the myocytes were subsequently perfused with free EPA (10–15 μM). In this study we saw only a rate of arrhythmia-induction by ISO of 51%, as compared to 100% in a previous study (10), though we have been unable to discern the explanation for this difference.

The observation that it is only free PUFA which has an antiarrhythmic effect is supported by other findings. Studies with Billman showed that intravenous administration of fatty acid emulsions exerted a rapid protective effect against malignant ventricular arrhythmias in dogs without detectable incorporation of the infused n-3 PUFA into plasma phospholipids (Billman, G.E., Kang, J.X., and Leaf, A., unpublished data). Our previous experiments have shown that perfusion of spontaneously beating cardiac myocytes with free n-3 PUFA can terminate arrhythmias in a few minutes, while ethyl esters or triglycerides of these fatty acids fail to do so (6,7). Additionally it was shown that the electrical excitability of the cardiomyocytes can be suppressed by exposing them to free n-3 PUFA for just 2–5 min (19), and in whole-cell voltage clamp studies blocking effects on the sodium current are seen within seconds after the PUFA are applied directly onto the myocytes (21). It has also been shown that PUFA bind specifically to the sodium channel protein (20). In these studies, no comparable effects of the monounsaturated oleic acid or of saturated fatty acids has been noted. Charnock *et al.* (22) have determined the fatty acid composition in normoxic rat hearts. They found that elevating the dietary intake of n-3 fatty acids increased the content of nonesterified fatty acids toward a greater amount of n-3 PUFA in the myocardium. However, because the n-3 PUFA increased in both the nonesterified, free fatty acid fraction and in the phospholipid fraction of the myocardium, they were unable to distinguish in which fraction the n-3 PUFA were exerting their antiarrhythmic action.

When the myocytes are enriched in their phospholipid content of n-3 PUFA, conditions that will activate cellular phospholipases may liberate the PUFA as free fatty acids. The PUFA esterified in phospholipids could thus contribute indirectly and secondarily to an antiarrhythmic effect. This study does not test this possibility. This study does, however, indicate that it is only the free PUFA which exerts a protective effect against arrhythmias. The alternative that the effect of PUFA against arrhythmias is a direct effect of their incorporation into phospholipids can be excluded. It is only the free PUFA partitioning nonconvalently among the membrane lipids of cardiac myocytes which exert an antiarrhythmic effect.
