Changes in High Density Lipoprotein Subfraction Lipids During Neutral Lipid Transfer in Healthy Subjects and in Patients with Insulin-Dependent Diabetes Mellitus

Mary C. Ritter and John D. Bagdade*

Department of Medicine, Rush Medical College, Chicago, Illinois 60612-3833

ABSTRACT: While it is known that the transfer of cholesteryl ester (CE) from high density lipoprotein (HDL) to the apo B-containing lipoproteins is increased in patients with diabetes, the extent to which the various lipoprotein fractions engage in neutral lipid exchange and the magnitude to which triglyceride (TG) is translocated is not known. To examine in greater detail neutral lipid net mass transfer in diabetes, the HDL subfractions and the apo B-containing lipoproteins were separated, and the net mass transfer of CE and TG was compared to that of control subjects. In both groups, bidirectional transfer of CE from HDL_3 to very low density lipoprotein (VLDL) + low density lipoprotein (LDL) and of TG from VLDL + LDL to HDL_3, took place, but this process was significantly greater ($P < .01$) in insulin-dependent diabetes mellitus (IDDM). In contrast, CE and TG accumulated in HDL_2 to a similar degree in normal and IDDM subjects. In recombination experiments with each of the apo B-containing lipoproteins, IDDM VLDL had a greater capacity to facilitate the exchange of core lipids from both IDDM and control HDL_3: on the other hand, LDL from IDDM and control subjects both donated TG and CE to HDL_2 and affected little change in HDL_3. These findings indicate that all the major plasma fractions normally participate in the trafficking of CE and TG among the lipoproteins during neutral lipid transfer and show that the principal perturbation in cholesteryl ester transfer in IDDM involves altered interaction between VLDL and the HDL_3 subfraction. *Lipids 31*, 1–7 (1996).

Specialized proteins in human plasma catalyze the transfer and exchange of cholesteryl ester (CE), triglyceride (TG), and phospholipids between lipoproteins (1–3). The reactions mediated by these lipid transfer proteins represent an important pathway in the intravascular metabolism of lipoproteins. Consequently, disturbances in transfer may not only adversely affect the composition of lipoproteins, but under certain circumstances they may also alter their metabolism. Plasma CE transfer protein (CETP) displays CE, TG, retinyl ester, and phospholipid transfer activities (2,4). Since it mediates all of the neutral lipid transfer activity in plasma, CETP plays a prominent role in the centripetal transport of CE from high density lipoprotein (HDL) to other lipoproteins and its reutilization by other tissues, and in its ultimate removal and excretion by the liver.

We have recently reported that both the net mass and isotopic transfer of CE from HDL to the apo B-containing lipoproteins is increased in plasma from normolipidemic insulin-dependent diabetes mellitus (IDDM) patients receiving conventional subcutaneous insulin treatment (5,6). While these studies implied that accelerated CET may be a previously unrecognized abnormality that increases cardiovascular risk in diabetes, they did not reveal the extent to which the HDL subfractions engaged in the transfer reaction and whether TG transfer also was increased. To obtain more detailed information about the roles played by the individual HDL subfractions and the behavior of very low density lipoprotein (VLDL) and low density (LDL) during CET in IDDM, we have studied the redistribution of HDL_2 and HDL_3 core lipids in intact plasma and in the presence of VLDL and LDL alone from control and IDDM subjects.

MATERIALS AND METHODS

Human subjects. Five IDDM patients (four female, one male) and five normolipidemic controls (three female, two male) were studied. The study protocol was approved by the Institutional Human Investigation Committee. Informed consent was obtained and the project was carried out according to the principles of the Declaration of Helsinki. Classification of these patients as having IDDM was based on clinical criteria only. Most had a prior history of ketoacidosis. All required insulin therapy to prevent ketosis. All patients followed a standard American Diabetes Association diet before study. None had renal disease manifested as proteinuria (Clinistix) or an elevated serum creatinine level, infection, was a vegetarian, cigarette smoker, an athlete, took drugs known to affect lipid metabolism, or had a history of ketoacidosis within six months prior to study. Control subjects were healthy, took no medications, and were matched for sex, approximate age, fasting lipid levels, weight, and level of physical activity. Blood for all studies was collected after an overnight fast in Na-EDTA-containing tubes, and plasma was separated promptly by low-speed centrifugation.

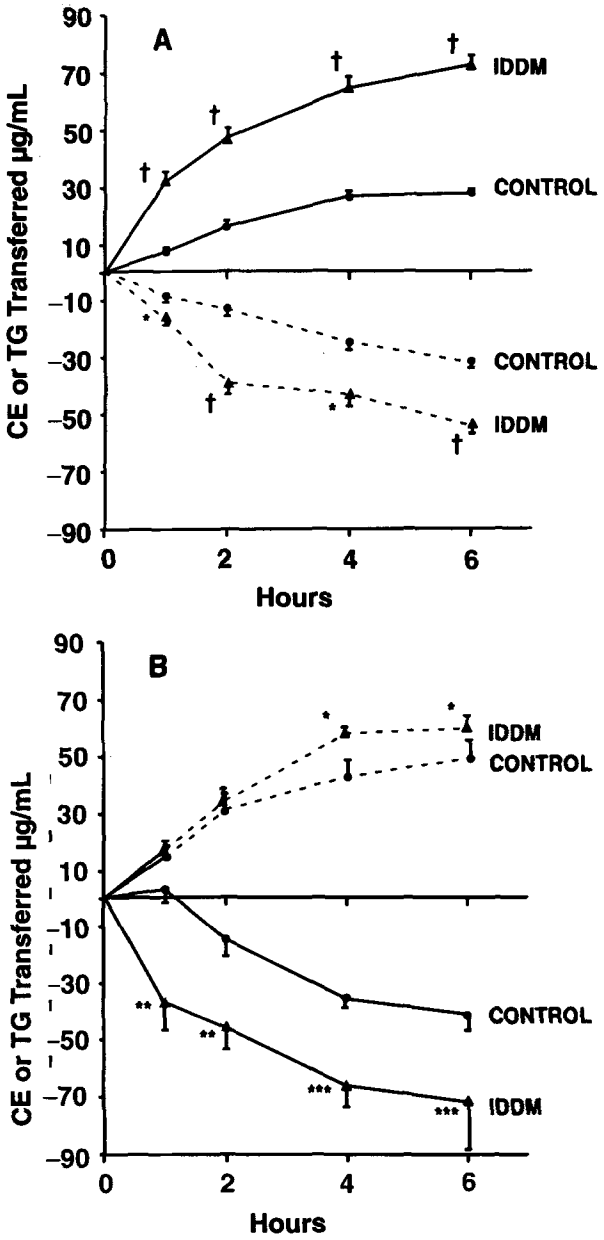

FIG. 1. Changes in the mass in cholesteryl ester (CE) and triglyceride (TG) of very low density lipoprotein (VLDL) + low density lipoprotein (A) and high density lipoprotein (HDL) (B) during transfer in intact plasma in five insulin-dependent diabetes mellitus (IDDM) and five control subjects; — CE; – – TG; *$P < .05$; **$P < .025$; ***$P < .01$; †$P < .001$.

CET. The mass transfer of CE, which measures the net transfer of preformed CE from HDL to VLDL + LDL in 1 mL of intact plasma, was measured during incubation at 37°C in a metabolic shaker in the presence 1.5 mM dithio-*bis*-5 dinitrobenzoic acid to inhibit lecithin cholesterol acyltransferase as previously described (7). Briefly, aliquots of plasma were removed prior to and after 1, 2, 4, and 6 h of incubation, chilled on ice, and then HDL_2 and HDL_3 were separated from VLDL and/or LDL by differential precipitation with dextran sulfate (8). At each sampling interval, the amounts of free and total cholesterol present in the supernatant were measured, and the amount of CE transferred into the apo B-containing lipoproteins was calculated from the difference between the two values.

Lipoprotein isolation. For the recombination studies, VLDL (d < 1.006 g/mL) and intermediate density lipoprotein (IDL)–LDL (d 1.006–1.063 g/mL) were isolated by sequential preparative ultracentrifugation at 8°C in a 40.3 rotor at 40,000 rpm for 18 h.

Analytical methods. Enzymatic kit procedures were employed to quantitate glucose (Boehringer-Mannheim, Indianapolis, IN), fructosamine (9), cholesterol (Boehringer-Mannheim), and TG (Sigma Chemical, St. Louis, MO). HDL–cholesterol was measured by a Standardized Lipid Research Clinic heparin/$MnCl_2$ precipitation procedure (10). Free cholesterol was estimated with the same components of the cholesterol kit except that CE hydrolase was omitted. CE was determined from the difference between total and free cholesterol.

Statistical methods. The means for each variable studied in diabetic and control subjects were compared by Student's *t*-test.

RESULTS

While fasting plasma lipids were similar in the two groups (Table 1), glucose and fructosamine were both significantly increased in the IDDM subjects. During the incubation of plasma, the extent to which IDDM VLDL + LDL acquired CE from HDL and donated TG to HDL (Fig. 1) was significantly increased. In both diabetic and control groups, the major interaction in plasma occurred between the apo B-containing lipoproteins and the HDL_3 subfraction (Fig. 2). Here too the magnitude of the bidirectional movement of core lipids differed in IDDM and control subjects. No striking sex difference was observed in the CET response within each small group. While CE declined with time in HDL_3 in both groups, it fell in IDDM HDL_3 more rapidly and to a significantly greater extent than in control HDL_3. At the same time, TG accrued at an increased rate and to a greater degree in IDDM HDL_3 than in controls. These changes together indicate that there was a greater net increment in TG and loss of CE in IDDM than in control HDL_3. In contrast, CE and TG both increased to a similar degree in their HDL_2 (Fig. 3).

Role of VLDL. To distinguish the contributions made by VLDL to these changes in the HDL subfractions, we performed a series of recombination experiments. Combining control VLDL with diabetic d > 1.063 g/mL fractions altered

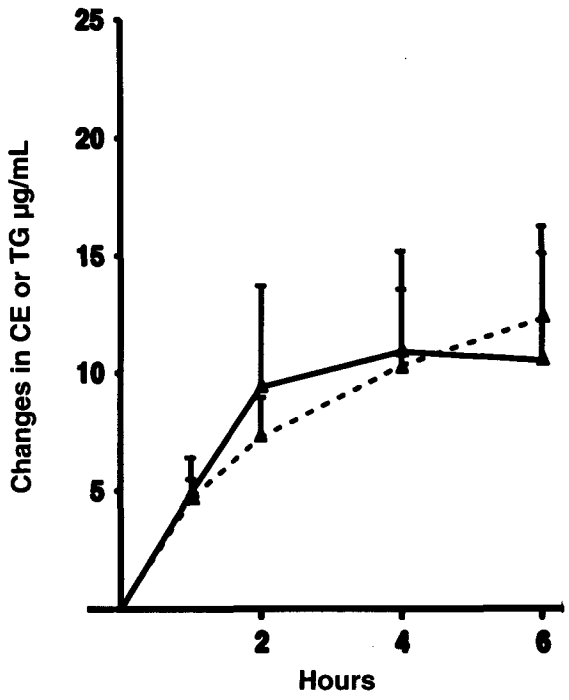
the VLDL core lipids in a manner identical to that observed when VLDL from two controls were added at the same TG concentration to their own d > 1.063 g/mL fractions (Fig. 4A). These data indicate that this IDDM HDL fraction had a normal capacity to stimulate neutral lipid transfer. In contrast, the change in IDDM VLDL core lipid content was virtually identical when it was combined with IDDM and control d > 1.063 g/mL fractions (Fig. 4B). This finding demonstrates that IDDM VLDL had an enhanced capacity to stimulate CET. In these experiments, TG and CE concentrations were similar in HDL_2 in the two groups (Table 2), suggesting that the abnormal interaction between IDDM VLDL and the d < 1.063 g/mL fraction involved only HDL_3. Indeed, a profile of net mass transfer was found in HDL_3 (Fig. 5) which was the reciprocal of that observed for VLDL (Fig. 4). This finding implies that the changes observed in CET in whole plasma largely reflected the interaction between VLDL and HDL_3.

Role of IDL–LDL. When added at the same concentration of cholesterol, both IDDM and control IDL–LDL donated CE and TG to HDL_2 though this property was somewhat greater in control than in IDDM IDL–LDL (Fig. 6). In contrast, little net mass transfer of either CE or TG was observed in HDL_3 when IDL–LDL from IDDM and controls were combined with d < 1.063 g/mL fractions (Table 3).



DISCUSSION

The HDL subfractions play a number of key roles in the centripetal movement of cholesterol from peripheral tissues to the liver (11). The smallest HDL, the prebeta-migrating fraction present in the HDL_3 density range, not only promote the efflux of cellular cholesterol, but they appear to be the major site for its esterification by lecithin cholesterol acyltransferase (12). In addition, data in the present study obtained in intact human plasma corroborate recent work performed in isolated and partially reconstituted experimental systems, showing that particles in the HDL_3 density range also are the main

reservoir in plasma from which esterified cholesterol (CE) is transferred to the apo B-containing lipoproteins (13). This central step in reverse cholesterol transport, designated CET (2–4), is mediated by the 74 kd protein CETP that has been shown to be closely associated with smaller HDL particles (14).

A number of different lines of evidence in humans and experimental animals suggest that, when CETP activity is increased, the atherogenicity of VLDL and LDL is enhanced because they become enriched with CE (3). The lipoprotein profile in pedigrees of families with CETP deficiency (in-

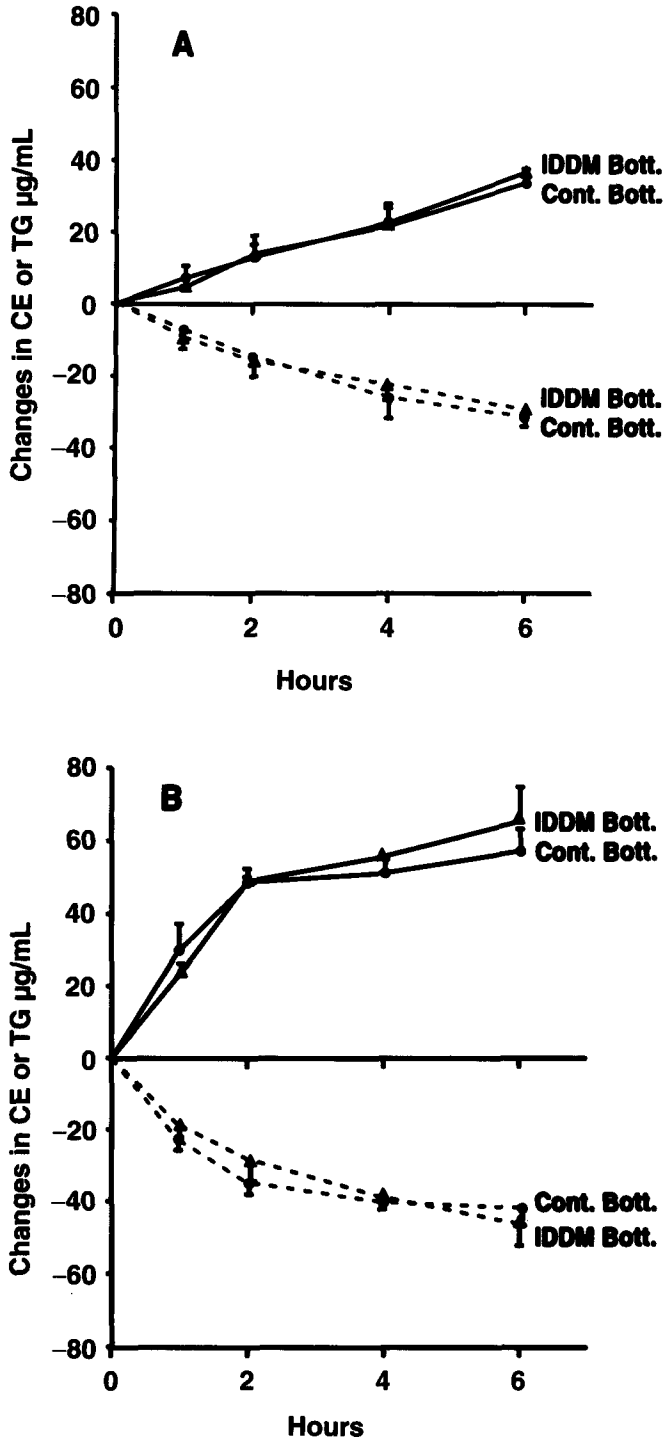

FIG. 5. Changes in the mass of CE and TG in HDL_3 when VLDL (d < 1.006 g/mL) from two control (A) and two IDDM (B) subjects were combined with d > 1.063 g/mL plasma fractions as indicated. See Figures 1, 2, and 4 for abbreviations and symbols.

creased HDL, a decrease in the CE content of the apo B-containing lipoproteins—VLDL, IDL, LDL, and decreased apo B) is typically one associated with resistance to atherosclerosis and some CETP-deficient families appear to experience longevity (15). Moreover, those animal species with low levels of CETP activity in plasma such as the rat, cow, and dog are resistant to dietary-induced atherosclerosis; those that have active CET such as rabbits, monkeys, and humans are highly susceptible (16). When mice, a resistant species, are made transgenic for simian CETP, they develop atherosclerosis in response to dietary fat (17). In contrast, those conditions in humans in which the rate of net transfer of CE is increased such as dysbetalipoproteinemia (18), and both IDDM (5,19) and noninsulin-dependent diabetes mellitus (20), all are associated with an acceleration of atherogenesis.

[a]Conditions: low density lipoprotein (LDL) from four IDDM and four control subjects were combined at plasma concentration with d 1.063 g/mL bottom fractions (ug/mL plasma). See Tables 1 and 2 for other abbreviations.

We have shown earlier that CE was transferred at an increased rate from HDL to VLDL and LDL in IDDM and noninsulin-dependent diabetes mellitus, and now again observe that altered behavior of VLDL was responsible for this disturbance. In our earlier studies we reported only the changes in CE and not in TG in the entire HDL fraction. Consequently, it was unclear to what extent HDL_2 and HDL_3 engaged in CET and the degree to which their respective core lipids were altered in the process. In the present study, we show for the first time that under the conditions of our assay there is a net increase in core lipids in HDL_2 and a net loss in HDL_3 during CET.

We confirm data obtained with reconstituted systems and demonstrate that the HDL_3 subfraction interacts predominantly with CETP and is not only the principal donor of CE to the apo B-containing lipoproteins, but also the primary acceptor of TG from VLDL. Moreover, our recombination studies demonstrate that the differences in CET in IDDM and control plasma are largely attributable to enhanced trafficking of

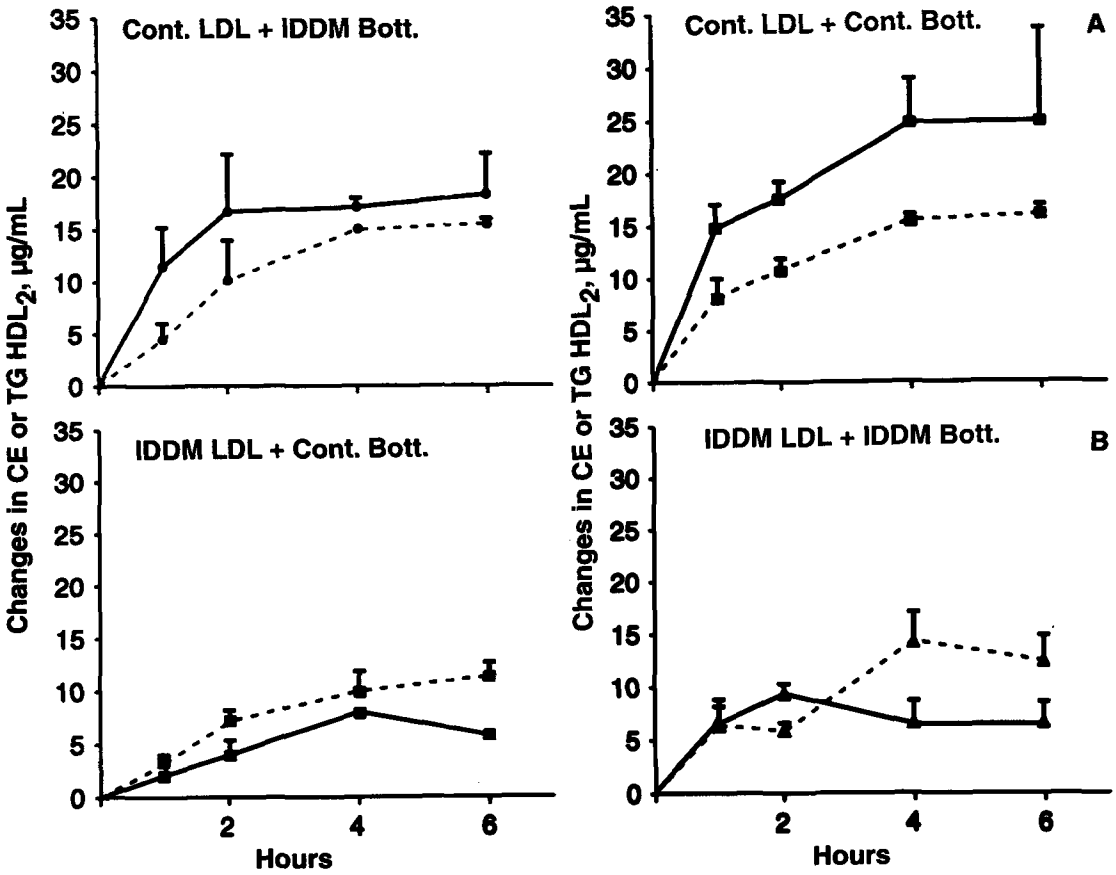

FIG. 6. Changes in the mass of HDL_2 core lipids when intermediate density lipoprotein (IDL)–LDL (d 1.006–1.063 g/mL) from two control (A) and two IDDM (B) subjects were combined with d > 1.063 g/mL plasma fractions as indicated. See Figures 1, 2, and 4 for abbreviations and symbols.

core lipids between VLDL and the HDL_3 subfraction. Since these experiments with VLDL were performed at the same TG concentration and the IDDM patients and controls were normolipidemic, it is unlikely that differences in particle number were responsible for the changes we found. Having not measured VLDL apo B, however, it is still possible that a small increase in VLDL particle number contributed to the increase in CET observed with this isolated fraction under these conditions. It seems more likely, however, that this behavior results from the presence of a subpopulation of lipoprotein particles in the IDDM VLDL fraction with distinctive alterations in lipoprotein composition likely accounting for this functional change. Although Morton (21) has shown that enrichment of lipoproteins with free cholesterol enhances their interaction with CETP and we have reported that this alteration manifested by an increase in the free cholesterol/lecithin ratio is present in diabetic VLDL and LDL (22), the precise cause of this altered behavior of VLDL during CET is still unclear.

Barter and co-workers (22) have shown in incubation studies performed with isolated HDL_3 that exposure to CETP resulted in the formation of populations of both larger and smaller particles. If an effect of this type occurred in the present studies, it could confound our results by altering the distribution of HDL particles in the HDL_2 and HDL_3 subfractions. This seems unlikely to have occurred, however, as later experiments from the same group showed, when apo B-containing particles were present (VLDL, LDL), the larger particles found in an isolated system did not form (22); instead, increased numbers of smaller particles were observed. If this latter effect of CETP occurred in incubated intact plasma in the present study, it would not affect our results because particles in HDL_3 that engaged in CET would remain in this fraction.

In contrast to the differences shown in the level of interaction of IDDM and control HDL_3 and VLDL, their HDL_2 subfractions functioned to the same degree as avid acceptors of both TG and CE. The propensity of the entire HDL fraction to accrue CE during the initial phase of CET in normal subjects was described earlier by VanTol and co-workers (23). Here we extend their observations: first, we show that the increase in CE mass involves the HDL_2 subfraction only; secondly, we find that the increment in CE is accompanied by a simultaneous parallel increase in TG.

Hydrocarbon Chain Distribution of Ether Phospholipids of the Ascidian *Halocynthia roretzi* and the Sea Urchin *Strongylocentrotus intermedius*

Bo Young Jeong[1], Toshiaki Ohshima*, and Chiaki Koizumi

Department of Food Science and Technology, The Tokyo University of Fisheries, Tokyo 108, Japan

ABSTRACT: The contents and compositions of the 1-*O*-alk-1'-enyl-2-acyl, 1-*O*-alkyl-2-acyl, and 1,2-diacyl glycerophospholipids in the muscle and viscera of the ascidian *Halocynthia roretzi*, and of the gonad of the sea urchin *Strongylocentrotus intermedius*, which are eaten to some extent in Alaska and in Asia, were analyzed by gas–liquid chromatography. 1-*O*-Alk-1'-enyl-2-acyl glycerophospholipids were found in all of the samples, accounting for 64.4–69.0% of the ethanolamine glycerophospholipid (EPL). By contrast, the levels of the 1-*O*-Alk-1'-enyl-2-acyl choline glycerophospholipids (CPL) were low (3.1–5.7%). CPL was rich in the 1-*O*-alkyl-2-acyl subclass amounting to 12.5–23.9% in the ascidian sample. The level of CPL in the sea urchin gonad was extremely high, amounting to 46.1%. The most prominent alkyl chains in the *sn*-1 position of CPL from the ascidian muscle were 16:0 (44.6%), 18:1 (26.5%), and 18:0 (10.7%), and of CPL from the sea urchin gonad were 18:0 (36.2%), 16:0 (33.0%), and 18:1 (17.8%). Unusually high levels of odd-numbered alkyl chains, e.g., 19:0 and *anteiso* 17:0, were detected in the CPL of all samples. The prominent alkenyl chains of EPL were 18:0 (69.4%), 16:0 (10.0%), and 18:1 (8.54%) (not counting the vinyl double bond) for the sea urchin gonad. Relatively high levels of 20:1 alkenyl chains were also present. The glycerol *sn*-2 positions contained high proportions of polyunsaturated fatty acids. Thus, 20:5n-3 (43.6%) and 22:6n-3 (20.1%) were most abundant in the alkylacyl CPL from the ascidian muscle and 20:5n-3 (54.9%) and 20:4n-6 (30.1%) in alkylacyl CPL from the sea urchin gonad. Despite a possible interconversion of the alkyl and alkenyl chains of each class of the ether phospholipids, they showed few features in common. *Lipids 31*, 9–18 (1996).

Marine invertebrates are rich sources of ether lipids, i.e., alkenylacyl glycerophosphocholines and glycerophosphoethanolamines (plasmalogens) and alkylacyl glycerophosphocholines and glycerophosphoethanolamines. Alkenylacyl choline glycerophospholipids (CPL) and ethanolamine glycerophospholipids (EPL) in marine invertebrates tissues are accompanied by a very significant amount of alkylacyl analogues (1). It has been found that EPL are richer in plasmalogens than are CPL, based upon the accumulated data on levels of alkenylacyl EPL and CPL of over 60 species of marine organisms (2,3). Among these organisms, ascidian and sea urchin are eaten to some extent by native populations in Alaska and on a large scale in Asia. Recent Japanese annual landings of sea urchin gonads exceed 300 metric tons. It is now accepted that the amount of ether-linked glycerolipids in rats can be easily increased with dietary supplementation of ether-linked lipids (4–6). Therefore, ether-linked glycerophospholipids in ascidian muscle and sea urchin gonads might be incorporated into human tissues and accumulated as membrane phospholipids. However, information on the fatty chain composition of alkenylacyl and alkylacyl subclasses of marine organisms, particularly on the fatty acid composition in the *sn*-2 position of marine invertebrates, has been relatively limited (7–12). In the present study, the contents and fatty chain compositions of alkylacyl and alkenylacyl choline and EPL in muscle and viscera of an ascidian, and in sea urchin gonads, were investigated in detail, with particular emphasis on comparing the alkyl and alkenyl chain structures within specific phospholipid subclasses to investigate the possibility of these organisms as a source of dietary exogenous ether-linked lipids.

MATERIALS AND METHODS

Samples. Ascidian *Halocynthia roretzi* (16 specimens, weighing an average of 318 g) were harvested at Ishinomaki Bay, near Sendai, Japan in July 1989. The samples were separated and pooled into muscle and viscera, and were subjected to lipid analyses. Sea urchin *Strongylocentrotus intermedius* (70 specimens with an average gonad weight of *ca.* 3 g) were collected at the coast of Abashiri, Hokkaido, Japan, in December 1989. The gonads were removed, pooled, and lipids were analyzed.

Lipid extraction and fractionation. Total lipids were extracted with a mixture of chloroform/methanol, according to the Bligh and Dyer procedure (13). The respective choline and ethanolamine phospholipids (CPL and EPL, respectively) were separated by silicic acid column chromatography, according to the method of Hanahan *et al.* (14).

Determination of lipid class contents. Total lipid content was determined gravimetrically. Phosphorus content in the total lipids (TL) was determined spectrophotometrically, according to Bartlett (15). The phospholipid content was obtained by multiplying the phosphorus content of the TL by 25 based on general phosphorus content in CPL. Phospholipid classes were separated by two-dimensional thin-layer chromatography (TLC) on a Silica Gel G plate (E. Merck, Darmstadt, Germany) and recovered by solvent extraction.

Analyses of alkenyl, alkyl, and acyl chain compositions. CPL and EPL fractions were each hydrolyzed with phospholipase C (*Bacillus cereus*; Boehringer Mannheim, Mannheim, Germany) to obtain the corresponding 1,2-diradyl glycerols. These were purified by preparative TLC on silicic acid and then acetylated (16). The acetylated derivatives were separated from each other by preparative TLC on Silica Gel G. The separated and purified acetylglycerol derivatives were saponified with 1 N KOH in ethanol at 85°C for 1 h. The 1-*O*-alk-1′-enylglycerols and 1-*O*-alkylglycerols thus obtained were extracted with diethyl ether and converted to their corresponding trimethylsilyl (TMS) ether derivatives, i.e., 1-*O*-alk-1′-enyl-2,3-TMS-glycerols and 1-*O*-alkyl-2,3-TMS-glycerols, respectively. The fatty acids released upon alkaline hydrolysis from the *sn*-1 and *sn*-2 positions of 1,2-diacylglycerol and from the *sn*-2 position of 1-*O*-alk-1′-enyl-2-acylglycerols and 1-*O*-alkyl-2-acylglycerols were extracted with diethyl ether and were, after methylation, analyzed by gas–liquid chromatography (GLC) under the conditions described below.

Determination of alkenylacyl, alkylacyl, and diacyl, and diacyl EPL, and CPL contents. The fatty acid contents of alkenylacyl, alkylacyl and diacyl EPL and CL in the TL were determined by GLC using 13:0 fatty acid (Sigma Chemical Company, St. Louis, MO) as an internal standard (17).

GLC and gas chromatography/mass spectrometry. The fatty chain compositions of 1-*O*-alk-1′-enyl-2,3-TMS-glycerols and 1-*O*-alkyl-2,3-TMS-glycerols derivatives were analyzed by GLC using a Shimadzu GC8APF instrument (Kyoto, Japan) equipped with a SUPELCOWAX-10 fused silica wall-coated open tubular column (30 m × 0.25 mm i.d.; Supelco Japan Ltd., Tokyo, Japan). The injector and the column were held at 250 and 210°C, respectively. Helium was used as carrier gas at a constant inlet pressure of 1.5 kg/cm^2.

TABLE 1
Lipid Contents of Ascidian and Sea Urchin Samples (wet wt%)

	Total lipids	Polar lipids	Nonpolar lipids
Ascidian *Halocynthia roretzi*			
Muscle	2.48	0.99	1.49
Viscera	3.35	0.94	2.41
Sea urchin *Strongylocentrotus intermedius*			
Gonad	4.09	1.35	2.74

Fatty acid compositions of the phospholipids were determined by GLC under similar conditions used for the analysis of the TMS ether derivatives, except that the column oven temperature was 195°C.

Mass spectrometric analysis of the TMS ether derivatives was carried out with a Shimadzu GC-MS 9020 DF instrument with a chemical ionization source to which the outlet of SUPELCOWAX-10 column (30 m × 0.25 mm i.d.) was connected directly. The column and injector temperatures were 230 and 250°C, respectively. The sample eluted from the GLC column was ionized in the chemical ionization mode by introducing *iso*-butane as a reagent gas at *ca.* 1 torr (18).

RESULTS

Lipid contents. As shown in Tables 1 and 2, the levels of TL, polar lipids (PL), and nonpolar lipids (NL) in the ascidian muscle were low. PL were predominantly composed of CPL, EPL, and sphingomyelin. There is a higher level of NL in the viscera; the level of the PL in the viscera was close to that of the muscle. The sea urchin gonad showed higher TL content compared to the ascidian samples. This is due to the higher level of both PL and NL in the sea urchin gonad than those of the ascidian samples. The sea urchin gonad PL were composed predominantly of CPL and EPL.

Contents of alkenylacyl, alkylacyl and diacyl CPL and EPL. The lipid subclass compositions of CPL and EPL are shown in Table 3. Of the ascidian muscle CPL, the diacyl subclass was the most prominent. The respective levels of alkylacyl and alkenylacyl subclasses were much lower. In the as-

cidian viscera CPL, the level of the diacyl subclass was lower, being offset by higher levels of alkylacyl and alkenylacyl subclasses, compared to those of the muscle CPL. Of the ascidian muscle EPL, the alkenylacyl subclass was most prominent. The levels of alkylacyl and diacyl subclasses were lower. The higher level of the alkenylacyl subclass (64.4%) was also noteworthy in the ascidian viscera sample.

In the sea urchin gonad CPL, the level of the alkylacyl subclass (46.1%) was much higher compared to the ascidian muscle and viscera CPL; however, the level of the diacyl subclass of the sea urchin gonad was lower. The level of alkenylacyl subclass was similar to that of the ascidian samples. Of the sea urchin gonad EPL, the most prominent subclass was alkenylacyl, followed by diacyl and alkylacyl subclasses in that order.

Based on the above data, it is possible to say that the most prominent lipid subclass of CPL was diacyl in the ascidian samples but was composed of both diacyl and alkylacyl subclasses in the sea urchin gonad. The alkenylacyl subclass of EPL was the most prominent in all of the samples submitted to the analyses of the present study.

Alkenyl, alkyl, and acyl chain compositions of CPL. The fatty acid and hydrocarbon chain compositions of alkenyla-

[d]NMID, nonmethylene-interrupted diene.

cyl, alkylacyl, and diacyl subclasses of the CPL in the ascidian muscle are shown in Table 4. 16:0, 18:0, and 18:1 alkenyl chains were prominent. The high level of 17:0 *anteiso* (10.7%) was unexpected. Although the prominent fatty acids in the *sn*-2 position of the alkenylacyl CPL were 20:5n-3 and 16:0, the levels of other acids were low, ranging from 1 to 7%.

The 16:0, 18:1, and 18:0 alkyl chains were prominent. Shorter alkyl chains, i.e., 14:0 and 15:0, were recognized. By contrast, the corresponding shorter alkenyl chains were not detected. The 20:5n-3 and 22:6n-3 fatty acids were prominent in the alkylacyl CPL.

The fatty acid and hydrocarbon chain compositions of alkenylacyl, alkylacyl, and diacyl subclasses of the CPL in the ascidian viscera are shown in Table 5. The compositions of the other alkenyl and alkyl chains were almost identical to those in the muscle CPL; however, the levels of the odd-numbered alkenyl chains, i.e., 17:0 and 19:0, were higher.

The fatty acid and hydrocarbon chain compositions of alkenylacyl, alkylacyl, and diacyl subclasses of the sea urchin gonad CPL are summarized in Table 6. The alkenyl chain

[a]The data are presented as the mean ± standard deviation of 6 (2 groups × 3) determinations.
[b]The position of the double bond applies to fatty acyl chains.
[c]The — denotes not detected.
[d]NMID, nonmethylene-interrupted diene.

compositions were quite simple; a subtotal of 18:0 and 16:0 alkenyl chains amounted to 66.7%. An unexpected amount of *iso* 17:0 alkenyl chain was included. The levels of polyunsaturated fatty acids, such as 20:5n-3 and 20:4n-6, were low among the fatty acids of the *sn*-2 position of the alkenylacyl subclass.

The alkyl chain composition was also simple; 18:0, 16:0, and 18:1 alkyl chains were prominent. By contrast, the levels of shorter alkyl chains, such as 16:0 and 14:0, were higher than those of the alkenyl chains with the same carbon chains. The levels of 20:4n-6 and 20:5n-3 in the *sn*-2 position were extremely high.

Alkenyl, alkyl, and acyl chain compositions of EPL. The fatty acid and hydrocarbon chain compositions of alkenylacyl, alkylacyl, and diacyl subclasses of EPL in the ascidian muscle are shown in Table 7. The 18:0, 16:0, and 18:1 alkenyl hydrocarbon chains were predominant. Among the fatty acids, 20:5n-3, 22:6n-3, and 20:4n-6 were prominent.

The 16:0, 18:0, and 18:1 alkyl chains were prominent. The 20:5n-3 and 22:6n-3 fatty acyl chains were linked selectively to the *sn*-2 position of the alkylacyl CPL.

Table 8 summarizes the fatty acid and hydrocarbon chain compositions of alkenylacyl, alkylacyl, and diacyl subclasses of the ascidian viscera EPL. The compositions of both the alkenyl chains and alkyl chains of the viscera EPL and of the muscle EPL closely resembled each other. In the acyl chain compositions of the alkenylacyl and alkylacyl subclasses, however, the levels of 20:5n-3 and 22:6n-3 of the viscera sample were lower than those of the muscle sample.

The fatty acid and hydrocarbon chain compositions of alkenylacyl, alkylacyl, and diacyl subclasses of EPL in the sea urchin gonad are summarized in Table 9. Although the locations of ethylenic bond in the alkenyl and acyl chains were not identified under the experimental conditions used in the present study, it is possible to separate the positional isomers from each other by GLC (8). Mass spectrometric data (not

shown) proved that these separated components on GLC were certain positional isomers of alkenyl and alkyl hydrocarbon chains: that is, 18:1 and 20:1 alkenyl chains and 18:1 and 20:1 alkyl chains.

DISCUSSION

Rapport and Alonzo (19) reported that 40–50% of EPL and 20–30% of CPL were plasmalogens in several marine invertebrates. More recent systematic survey of plasmalogen for more than 60 species of marine invertebrates established that these marine organisms are rich sources of plasmalogens (19.4 to 92.5% in the EPL fraction), and that EPL are richer in the levels of plasmalogens than are CPL (2). The level of the alkenylacyl glycerophospholipids of the ascidian muscle analyzed in the present study was lower than that reported previously, in which the alkenylacyl glycerophospholipids accounted for 74.8% of EPL (3). The levels of alkylacyl glycerophospholipids of the sea urchin gonad examined in this study were, however, higher compared to the results reported previously (2).

Vysotskii *et al.* (12) reported the composition of dimethylacetal released from the PL of ascidian. They found 18:0 (75.7%) and 16:0 (7.7%) as prominent dimethylacetals. Roots and Johnston (20) found that the major fatty aldehydes released from EPL of goldfish brain were 18:0, 18:1, and 16:0 alkenyl chains, and that from CPL was 16:0 alkenyl chain. Chacko *et al.* (21) found the major aldehyde composition of the garfish olfactory nerve EPL consisted of 18:1 (65.1%), 18:0 (18.0%), and 16:0 (8.8%) alkenyl chains. The major aldehydes released from CPL were 16:0 (56.1%), 18:1 (20.9%), and 18:0 (9.4%). Snyder *et al.* (22) analyzed phos-

pholipids of the starfish digestive reticulum and found that the major aldehydes of phospholipids were 18:0 (39%), 16:0 (31%), and 20:1 (13%). In our previous investigation on the bonito white muscle CPL (18), the alkyl and alkenyl chain compositions were 16:0 (55.5%) and 14:0 (11.5%), and 16:0 (75.4%) and 18:1 (4.0%), respectively. For the EPL of the bonito sample, 16:0 (47.8%), 18:0 (15.1%), and 18:1 isomers (10.8 and 6.0%) alkyl chains, and 16:0 (53.3%), 18:0 (19.4%), and 18:1 isomers (10.8 and 3.9%) alkenyl chains were prediminent. In the Japanese oyster wet tissues (8), the most prominent alkenyl and alkyl chains of CPL were 18:0 (63.3%) and 16:0 (44.0%), respectively. The most prominent alkenyl and alkyl chains of EPL were 18:0 (64.7%) and 18:0 (51.5%), respectively.

There have been few published studies on distribution of alkylacyl glycerophospholipids compared to those of alkenylacyl subclass. It is now accepted, however, that very significant amounts of alkylacyl glycerophospholipids exist in those marine organisms with high plasmalogen contents (21,23–25). This is believed, in the case of mammalian tissues, to be due to the biosynthesis of plasmalogens; alkylacyl subclass once formed can be converted directly to the corresponding alkenylacyl subclass by a certain enzyme system present in the microsomal fraction (26–28). Thompson (29) investigated the incorporation of ^{14}C-labeled feeds into phospholipids of the terrestrial slug *Arion ater* and concluded that the alkyl chain is converted to the alkenyl chain without cleavage of the ether bond. Other major studies *in vivo* with the tissue of tumor cells (30), rat brain (31), and a slime mold (32) revealed that alkenylacyl subclasses are produced by a direct α,β-desaturation of the corresponding alkylacyl subclasses in the biosynthesis of phospholipids. In our study, however, we did not find strong similarities between the alkyl and alkenyl chains within the ether lipid types isolated from

two different marine invertebrates. This is probably due to the differences in the rate of catabolism of alkenylacyl subclass; in the case of rat liver (33), a microsomal enzyme hydrolyzes the ether bond of lyso CPL plasmalogen but not that of intact CPL plasmalogen. In mammals, it is known that the 1′-alkenyl chain lengths are restricted to a narrow range by the substrate specificity of the acyl-CoA reductase (34) and also by the chain length specificity of the dehydrogenase which catalyzes conversion of 1-*O*-alkyl glycerophospholipids to 1-*O*-alk-1′-enyl glycerophospholipids (35).

Although the biological and physiological roles of alkenylacyl and alkylacyl glycerophospholipids still remain unresolved, almost complete absence of ether lipids in the tissues of patients suffering from Zellweger cerebrohepatorenal syndrome (36) is observed. It is now accepted that dietary alkyl glyceryl ethers are not only absorbed and converted to plasmalogens in intestinal tissues, but also transported to other organs where they are metabolized and deposited as membrane plasmalogens (37). The present results revealed that ascidian muscle and sea urchin gonads are rich sources of ether-linked glycerophospholipids and they might play a role as a source of the exogenous ether lipids for these patients (6).

ACKNOWLEDGMENT

This study was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan.

Dietary Modulation of Phospholipid Fatty Acid Composition and Lipoxygenase Products in Mouse Lung Homogenates

Hongjian Zhang and J. Bruce German*

Department of Food Science and Technology, University of California, Davis, California 95616

ABSTRACT: This study investigated the potential of dietary fats to modulate the arachidonic acid content of mouse lung phospholipids and the formation of lipoxygenase products from arachidonic and eicosapentaenoic acids. Prior to breeding, female mice were fed for five months diets with 10 wt% of either olive oil, safflower oil, fish oil, or linseed oil. The same diets were fed to the females during gestation and to the pups from day 18 to day 42 postpartum. On day 42, the phospholipids were extracted from fresh lung tissue and separated into classes [phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylcholine (PC), and phosphatidylinositol (PI)] by thin-layer chromatography. Methyl esters of phospholipid fatty acids and unesterified fatty acids were analyzed by gas chromatography. At comparable dietary n-3/n-6 ratios, arachidonic acid was reduced 85 and 75% in lungs from mice fed linseed oil and fish oil, respectively, compared to lungs of safflower oil-fed mice. Dietary fats affected the proportion of arachidonic acid in phospholipids in the order: PE > PC > PS > PI. Following incubation of homogenized lung tissue, the total amount of 12-lipoxygenase products was lowest in lungs from mice fed olive oil, and 12-hydroxyeicosatetraenoic acid was lowest in incubated lungs from mice fed linseed oil. Comparison of the amounts of lipoxygenase substrate fatty acids in the individual phospholipids with the lipoxygenase products suggested that the major substrate pool for the 12-lipoxygenase pathway in mouse lung homogenates was PC.

Lipids 31, 19–25 (1996).

The oxygenated metabolites synthesized from arachidonic acid are important mediators in a variety of biological processes (1). The suggestion has been made that excessive biosynthesis of these compounds is associated with physiological dysfunctions, such as thrombosis (2), cancer metastasis (3), inflammatory disease, asthma (4), psoriasis (5), and autoimmune diseases, such as rheumatoid arthritis (6). Lipoxygenases are enzymes that convert arachidonic acid into biologically-active compounds, such as leukotrienes, lipoxins, and an array of hydroxyl derivatives (1). In mammalian lungs, 12- and 15-lipoxygenases catalyze reactions that produce 12-hydroxyeicosatetraenoic (12-HETE) and 15-hydroxyeicosatetraenoic acid (15-HETE) from arachidonic acid (7,8). While the functions of some 5-lipoxygenase products have been well established, the physiological roles of the 12- and 15-lipoxygenases are not clearly understood. Although the association of several biological functions with 12- and 15-lipoxygenase pathways has been suggested (9), the involvement of the 12-lipoxygenase product 12-HETE in tumor cell metastasis is most striking (10). Studies have shown that 12-HETE promotes tumor-cell adhesion by increasing surface expression of alpha-v-beta-3 integrins on endothelial cells (11). Recently, a specific receptor for 12-HETE in Lewis-lung carcinoma cells was reported (12). Also, dietary maneuvers that enhanced arachidonic acid levels were associated with increased metastasis to the lung (13,14). These findings underline the potential importance of 12-lipoxygenase products in cellular activities, particularly in promoting the adhesion of tumor cells (10). Thus, it would be important to understand how the production of 12-lipoxygenase metabolites is regulated *in vivo*.

Considerable research has focused on understanding how dietary fatty acids are incorporated into cell membrane lipids and how this affects cell function. Changes in the fatty acid composition of tissue membrane lipids are routinely seen in response to dietary changes. Furthermore, biochemical studies show that specific changes in the fatty acyl composition of membrane phospholipids alter cellular and physiological processes, such as platelet aggregation, leukocyte chemotaxis, macrophage cytolysis, and tumor metastasis (15–17). Since these processes are frequently unbalanced in disease states, manipulation of membrane composition could result in important clinical benefits. Manipulation of fatty acids in membranes also alters synthesis of their oxygenated derivatives. Since different fatty acid oxygenation pathways show varying sensitivity to nutritional modulation, it is of interest to investigate how 12-lipoxygenase activity is regulated by dietary polyunsaturated fatty acids (PUFA).

Of particular interest are the n-3 family of PUFA and how they modulate tissue lipid composition, arachidonic acid metabolism, and eicosanoid production. Dietary supplementation with fish oil has been suggested to be beneficial in some

disease states that involve arachidonic acid metabolism (18). Although the mechanism by which n-3 PUFA in fish oil exert their effects is not completely understood, the putative beneficial effects may be derived from either modification of the arachidonic acid pool through n-3 PUFA replacement or the competition of n-3 PUFA-derived oxygenated metabolites (19,20). However, data are lacking to evaluate the ability of shorter-chain n-3 PUFA to modify arachidonic acid content in lung membrane phospholipids and to alter eicosanoid production.

The present study investigated differences in metabolism and incorporation of n-3 PUFA from two sources, linseed oil, which is rich in 18:3n-3, and menhaden fish oil, which is rich in 20:5n-3 and 22:6n-3, in comparison with oils rich in n-6 PUFA (safflower oil) and n-9 monounsaturates (olive oil). Previous studies with diets containing low n-3/n-6 ratios found that 18:3n-3 is a relatively inferior source in respect to the net accumulation of 20:5n-3 in tissues and the modulation of eicosanoid synthesis (21). In the present study, unsaturated fats were fed as both 18:3n-3, and 20:5n-3 plus 22:6n-3, at high n-3/n-6 ratio during the developmental period of mice. The mouse lung was chosen because: (i) previous work documents the differential incorporation of 18:3n-3 and fish oil n-3 PUFA (22), (ii) large quantities of this tissue are available for lipid analysis, and (iii) the organ releases a variety of lipid-derived bioactive compounds. The lung may be a good model for the study of lipoxygenase activities and functions (7,9,23).

MATERIALS AND METHODS

Animal and dietary protocols. Experimental animals were 42-day-old, pathogen-free Swiss Webster mice (Bantin & Kingman, Fremont, CA). The initial treatment, grouping, diet protocol, and breeding schemes of dams were previously described in detail (22). In brief, dams were divided into four groups and fed a nonpurified diet (Rodent Laboratory Chow no. 5001; Purina Mills, St. Louis, MO) for two weeks. The groups of mice were then fed one of four synthetic diets for a five-month period. Litters from each group were culled to ten pups/litter on day 3 postpartum. On day 18, the dams were removed from the cages. The pups were fed the synthetic diet continuously until day 42, when they were killed by CO_2 intoxication. Lipid analysis and eicosanoid production assays were conducted on lungs of the 42-day-old pups.

Synthetic diets consisted of fat-free AIN-76A powdered diets (Dyets, Bethlehem, PA) modified by addition of the following dietary fats at 10 g/100 g: safflower oil (Dyets), linseed oil (Spectrum Naturals, Petaluma, CA), olive oil (G. Sensat, Extra Virgin no. 5; Specialty Food and Beverage Sales, West Milford, NJ), or a 9:1 (w/w) mixture of menhaden oil (NIH Biomedical Test Materials Program, Bethesda, MD) and safflower oil. Safflower oil was added to the fish oil diet to ensure that the linoleic acid requirement was met and to achieve a 3:1 ratio of n-3/n-6. The fatty acid composition of each oil and ratios of n-3/n-6 are summarized in Table 1. Tocopherol (0.02 g/100 g oil) and *t*-butyl-hydroquinone (0.02 g/100 g oil) levels were constant across all of the dietary groups.

TABLE 1
Fatty Acid Composition of Oils Added to Experimental Diets[a]

Fatty acid	Safflower oil	Olive oil	Linseed oil	Fish oil
16:0	7[b]	14	6	16
18:0	2	3	4	3
18:1n-9	12	74	17	10
18:2n-6	78	7	16	7
18:3n-3	—[c]	0.6	57	1
20:5n-3	—	—	—	14
22:6n-3	—	—	—	12
n-3/n-6	<0.1	0.1	3	3

[a]Diets contained 10 wt% of either safflower oil, olive oil, linseed oil, or fish/safflower at 9:1 (w/w) ratio.
[b]Only key fatty acids are shown. Values are means of two determinations per oil and are expressed as mol%.
[c]Fatty acid concentrations were below 0.01 mol% of total fat.

Tissue lipid analysis. Tissue lipids were extracted in the presence of sodium dodecyl sulfate (24) with >90% recovery of total phospholipids. They were separated into classes by thin-layer chromatography on 10 × 10 cm pre-coated silica gel 60 plates (E. Merck, Darmstadt, Germany) developed in a solvent system consisting of chloroform/methanol/acetic acid/water (50.0:37.5:3.5:2.0, by vol) (25). Individual lipid classes were visualized with 8-hydroxyl-1,3,6-pyrenetrisulfonic acid trisodium salt (Eastman Kodak Co., Rochester, NY) (26). The bands containing phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI), and phosphatidylethanolamine (PE) were scraped, and the fatty acids were directly transesterified to methyl esters with 3 N methanolic HCl (Supelco, Bellefonte, PA) at 60°C overnight. Dipentadecanoyl PC was used as an internal standard to quantify recovery and yields and was added into each sample vial prior to methylation. Fatty acid methyl esters were extracted, and fatty acid composition of each phospholipid class was determined by gas chromatography on a Hewlett-Packard model 5890 gas chromatograph (Hewlett-Packard Co., Palo Alto, CA) equipped with a flame-ionization detector and a DB-23 25 m × 0.25 mm capillary column (J&W Scientific, Folsom, CA). Fatty acid methyl esters were identified by their retention time relative to known standards (Nu-Chek-Prep, Elysian, MN).

Unesterified fatty acids in fresh lung homogenates were extracted after 10 min incubation at 37°C in the same buffer as described above, in the presence of the 12-lipoxygenase specific inhibitor esculetin (10 μM) (27), methylated with ethereal diazomethane (27), separated from other lipid classes using solid-phase extraction columns (28) (Analytichem International, Harbor City, CA), and analyzed by gas chromatography as described (21,29).

Eicosanoid synthesis by lung tissue. To determine the effect of dietary modifications on the biosynthesis of eicosanoids, the lipoxygenase products generated by homogenized lung tissue were characterized. Mice were anesthetized and

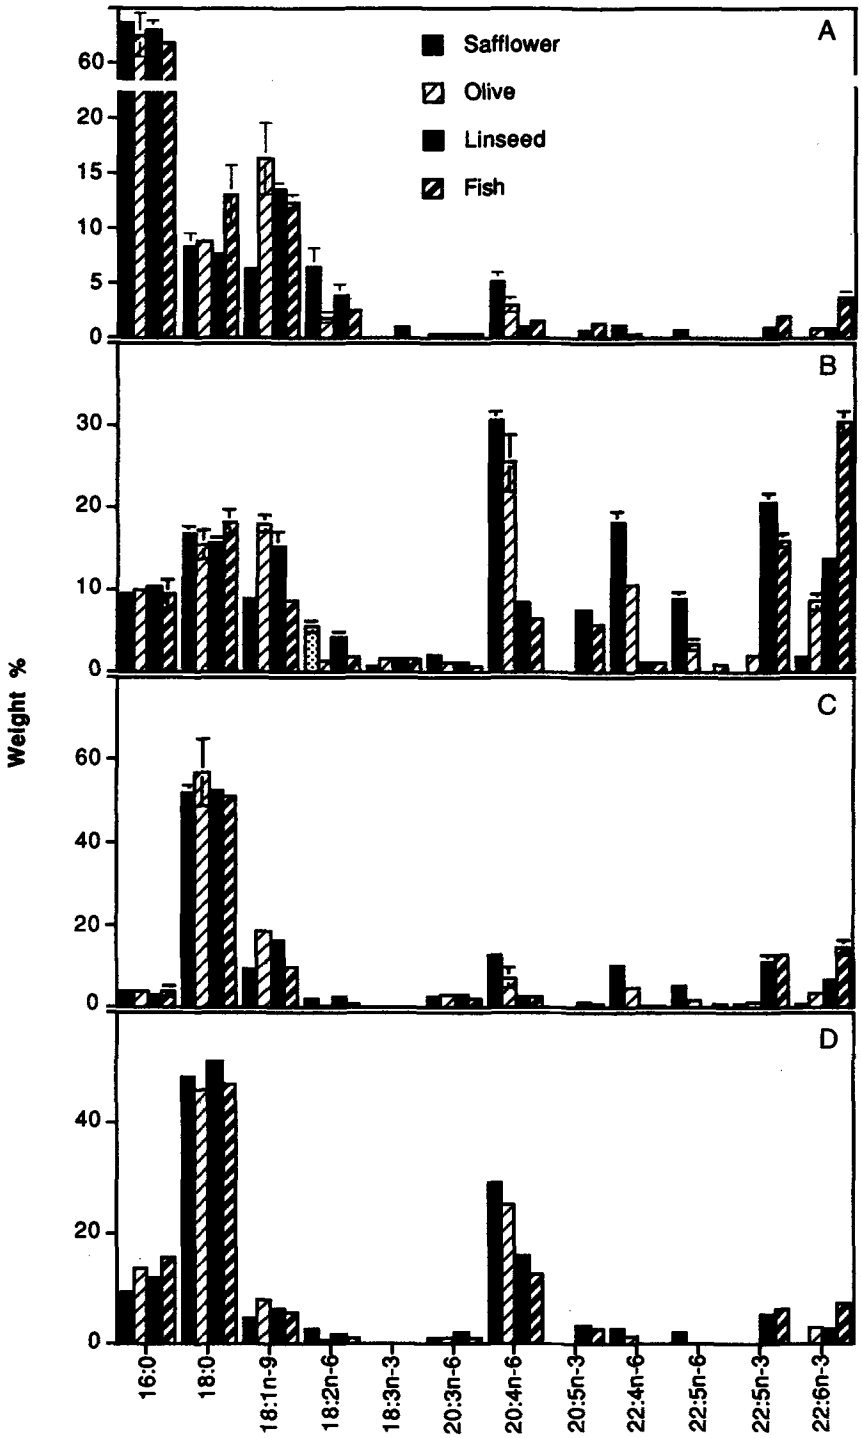

FIG. 1. Composition of major fatty acids in murine lung phospholipids after dietary fat modulation. Groups of animals were fed diets containing either safflower oil, olive oil, linseed oil, or fish oil. Values (n = 4) are expressed as mol%. A) phosphatidylcholine; B) phosphatidylethanolamine; C) phosphatidylserine; and D) phosphatidylinositol.

perfused with saline. The lungs were removed, rinsed with cold 0.05 M potassium phosphate buffer (pH 7.8), a buffer shown previously to be effective in assaying lipoxygenase activities, and homogenized in 5 vol of the same buffer. One-milliliter aliquots of the lung homogenates were incubated in a shaker-water bath at 37°C for 30 min. After incubation, the assay mixtures were acidified with 0.2 M acetic acid (pH 4.0) and lipid metabolites were extracted twice with 2 mL ethyl acetate. The extracts were evaporated to dryness under nitrogen, and lipoxygenase products were methylated with 200 μL

ethereal diazomethane. The methylated products were then separated and purified using silica solid-phase columns (Analytichem International) as previously described (28).

The analysis of hydroxy fatty acid methyl esters was carried out by reverse-phase high-pressure liquid chromatography using a Hewlett-Packard model 1090 high pressure liquid chromatograph with a 25 cm × 4.6 mm DB C-18 column (Supelco, Bellefonte, PA). The products were eluted isocratically using 75% methanol and 25% of a mixture of 5 mM ammonium acetate and 30% methanol containing 1 mM EDTA. The absorbance of eluted compounds at 234 nm was automatically recorded using a diode array detector (model 1040; Hewlett Packard, Bellefonte, PA). Lipoxygenase products were identified by comparing the retention times and/or ultraviolet spectra with those of authentic standards (7).

Statistical analysis. Data were analyzed using the *t*-test and analysis of variance (Microsoft® Excel; Microsoft Corporation, Redmond, WA).

RESULTS

Fatty acid composition of lung phospholipids. Figure 1 summarizes the fatty acid composition of individual phospholipids from the lungs of groups of mice fed weaning diets with either safflower oil, olive oil, linseed oil, or fish oil; 16:0 represented approximately 80% of the total fatty acids in the PC fraction from lungs of all dietary groups. Among the dietary groups, there were no differences in the amount of 16:0 in any of the individual phospholipid classes in spite of the highly varied intakes of long-chain PUFA during growth and development of the animals. Overall, for each of the dietary groups, the sum of saturated fatty acids was similar in PC, PS, PI, and PE; however, the proportions of C_{20} plus C_{22} unsaturated fatty acids were higher in the lung total phospholipids of mice fed safflower oil and fish oil than in those from mice fed linseed oil or olive oil ($P < 0.05$).

Arachidonic acid in lung PC in the safflower oil-fed mice (5.1%) was significantly different ($P < 0.05$) from that in the linseed oil-mice (1.0%), as shown in Figure 1A. Interestingly, the lower percentage of arachidonic acid in PC was accompanied by higher percentages of oleic acid (18:1n-9), eicosapentaenoic acid (20:5n-3), and docosahexaenoic acid (22:6n-3).

PE accumulated a high percentage of C_{20} and C_{22} PUFA, and the composition of these fatty acids was altered to a significant extent by n-3 dietary fatty acid modification (Fig. 1B) ($P < 0.05$). As a percentage of total fatty acids in PE, arachidonic acid was 30 and 6% in the safflower oil- and fish oil-fed groups, respectively, while 20:5n-3 and 22:6n-3 in these same groups were undetectable to 6% and 1.8 to 30%, respectively. The major difference between linseed oil and fish oil feeding was not in the relative quantity of 20:5n-3, but in the ratio of 22:5n-3 to 22:6n-3, which was approximately 1.5 in linseed oil-fed mice and 0.5 in fish oil-fed mice.

The major portion of the fatty acids in PS was 18:0, which represented approximately 50% of the total fatty acids. The relative compositional changes in PS PUFA were similar to those in PE, but PS in lungs from all dietary groups was uniquely enriched in 20:3n-6 (Fig. 1C). In fact, 20:3n-6 was the fatty acid least affected in each of the phospholipid classes examined.

The proportion of arachidonic acid in PE and PI was higher than in PC or PS (Fig. 1), and the dietary fats affected arachidonic acid content in PE to the greatest extent.

Lipoxygenase metabolites produced by homogenized lungs. The major metabolites formed by lung homogenates from all dietary groups were those of 12-lipoxygenase, 12-HETE and 12-HEPE derived from arachidonic acid and eicosapentaenoic acid, respectively. There was approximately 80 and 60% less 12-HETE produced by lung homogenates from linseed oil- and fish oil-fed mice, respectively, than by those from safflower oil-fed mice. The production of 12-HEPE was greater in the lung homogenates from linseed oil-fed (33-fold greater) and fish oil-fed (50-fold greater) groups than in those of the olive oil-fed group. Total 12-lipoxygenase products (12-HETE plus 12-HEPE) were lowest in the olive oil-fed group. The production of lipoxygenase metabolites as a function of dietary fats (Fig. 2) paralleled the fatty acid composition of the lung phospholipids (Fig. 3), with the association being most closely reflected by the levels of arachidonic acid and eicosapentaenoic acid in PC.

The variation in synthesis of 15-lipoxygenase products in response to dietary fat modification was different from that of 12-lipoxygenase. The 15-lipoxygenase product from arachidonic acid, 15-HETE, was relatively low in lungs of olive oil-, linseed oil-, and fish oil-fed mice, being about 15% of that produced in lungs of safflower oil-fed mice (Fig. 2), and the 15-lipoxygenase product from eicosapentaenoic acid (15-HEPE) was not detected under our experimental conditions.

Composition of fatty acids in homogenized lung tissues. Unesterified PUFA were measured in freshly homogenized

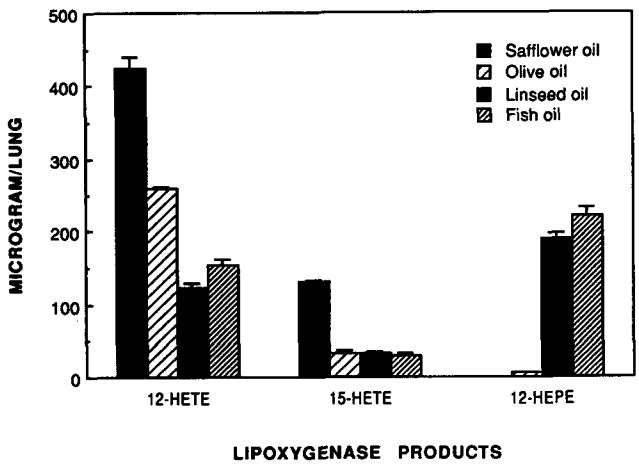

FIG. 2. Lipoxygenase products formed in incubated homogenates of lungs from mice fed diets varying in fat composition. Lipoxygenase products were extracted into ethyl acetate and methylated with diazomethane. After solid-phase extraction, the products were identified and quantified by reverse-phase high-performance liquid chromatography (n = 4). Bars are SD. 12-HETE, 12-hydroxyeicosatetraenoic acid; 15-HETE, 15-hydroxyeicosatetraenoic acid.

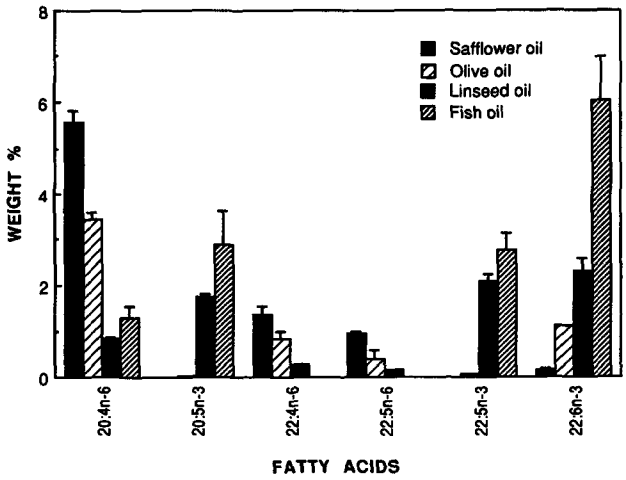

FIG. 3. Unesterified long-chain polyunsaturated fatty acids in homogenized lung tissue from mice fed diets varying in fat composition. Values are expressed as mol% of total free fatty acids (n = 4). Bars are SD.

lung tissue in the presence of the lipoxygenase inhibitor esculetin at 10 μM. Respectively, there was approximately 85 and 76% less arachidonic acid in lungs of linseed oil- and fish oil-fed mice than in lungs of safflower oil-fed mice, and 75- and 140-fold more eicosapentaenoic acid than in lungs of olive oil-fed mice (Fig. 3). Differences in unesterified arachidonic acid and eicosapentaenoic acid in fresh homogenized lung as a function of dietary fat source (Fig. 3) closely resembled their concentrations in isolated PC (Fig. 1A) and 12-lipoxygenase products in incubated homogenized lungs (Fig. 2).

Comparison of effects of dietary C_{18} and C_{20-22} n-3 PUFA. The shorter-chain and longer-chain dietary n-3 PUFA in linseed oil and fish oil, respectively, had similar effects on the modification of arachidonic acid content in phospholipids (Fig. 1). For mice fed linseed oil, which is rich in 18:3n-3, there was less arachidonic acid in PC (Fig. 1A), less unesterified arachidonic acid in fresh lung homogenates (Fig. 3), and less 12-HETE produced in incubated homogenized lung (Fig. 2) than for mice fed fish oil, which is rich in 20:5n-3 + 22:6n-3.

DISCUSSION

Experimental design. Previously, modification of tissue fatty acid composition and cell function in response to changes in dietary fatty acids was shown to be dependent on the quantity of other PUFA and total fat in the diet (21). Therefore, in the present study, the diets were varied solely in the type of unsaturated fatty acids and total fat was kept constant. As a consequence, total fat, total essential fatty acids and n-6/n-3 ratios were fixed relative to experimental conditions, and differences among dietary treatments solely reflected differences in the uptake and metabolism of the specific fatty acids.

Incorporation of n-3 PUFA and lung phospholipid composition. The fatty acyl composition of mammalian phospholipid membranes varies with tissue, cell type, and the composition of dietary fats (30). In lungs, dipalmitoyl PC is a major component of surfactant (31). Palmitic acid (16:0) represented approximately 80% of total fatty acids in the PC fraction of lungs from all animals used in this study, and there were no major differences among the dietary groups. This presumably reflects the low sensitivity of this phospholipid pool to modifications by dietary fatty acids. Thus, in spite of highly varied intakes of long-chain PUFA during growth and development, the accumulation of 16:0 in lungs was not affected.

The uptake of fatty acids into separate lipid classes and their subsequent metabolism are apparently regulated through a variety of pathways. Short-term modification of the diets of growing animals with structurally distinct fats enriched either in n-3, n-6, or n-9 PUFA exerts a significant effect on the composition of the membranes of animals (30). Dietary modification of membrane fatty acid composition has led to considerable interest in the possibility of modifying human diets for therapeutic or nutritional benefits. From this perspective, certain questions need to be addressed. Primarily, for therapeutic modulation, which fats should be included in diets? For example, is fish oil itself a uniquely effective component or do n-3 PUFA from other fat sources act equivalently? Previous studies in rodents (21) and humans (32) showed that diets rich in 18:3-n3 were less effective in modifying tissue concentrations of the longer-chain n-3 and n-6 PUFA than diets rich in 20:5n-3 and 22:6n-3, i.e., fish oils. This is clearly not due to an inability to metabolize 18:3n-3 into longer-chain products since the desaturases and elongases required are present in all animals examined (33). Therefore, it is possible that the differences in ability of shorter- (C_{18}) and longer- (C_{20-22}) chain n-3 PUFA to modify tissue PUFA concentrations are attributable to differences in the competition between n-3 and n-6 PUFA for metabolism to longer-chain products. That is, although 18:3n-3 can be metabolized efficiently to 20:5n-3 and 22:6n-3, this may not be realized if fluxes through the pathways are constant and the enzymes are simultaneously converting high levels of 18:2n-6. If true, such differences between shorter- and longer-chain n-3 PUFA potentially would be reversed if the shorter-chain n-3 PUFA were fed at higher levels and/or fed for longer time periods. The present study clearly demonstrated that the levels of arachidonic acid in lung phospholipids were responsive to n-3 dietary PUFA modification. At high and comparable n-3/n-6 ratios, linseed oil (rich in 18:3n-3) and fish oil (rich in 20:5n-3 and 22:6n-3) produced comparable effects on the modification of arachidonic acid contents in murine lung phospholipids. The higher 22:5n-3/22:6n-3 ratios observed in linseed oil-fed mice as compared to fish oil-fed mice suggest that the metabolism of 18:3n-3 by elongases and desaturases leads to the accumulation of longer-chain n-3 PUFA; however, the conversion of 22:5n-3 to 22:6n-3 by the pathway by which a Δ4 double bonds are introduced (34) seems to be limiting. In terms of lowering arachidonic acid levels during the developmental period of the animals, this suggests that shorter-chain and longer-chain PUFA have equivalent effects on murine lung phospholipids.

Arachidonic acid metabolism by 12-lipoxygenase. The potential role of 12-lipoxygenase metabolites in tumor cell adhesion and the possibility that enhanced arachidonic acid metabolism may account for a link between dietary n-6 PUFA metabolism and tumor metastasis led to this investigation of the relationships among dietary fat composition, lung lipid composition, and lipoxygenase products in lung tissue. The study confirmed that the majority of lipoxygenase products in lung were those of 12-lipoxygenase, i.e., 12-HETE from arachidonic acid and 12-HEPE from eicosapentaenoic acid (7–9). In addition, the data indicated that the formation of 12-lipoxygenase products was greatly affected by dietary n-3 PUFA modification. The shorter-chain n-3 PUFA (linseed oil) appeared to be more effective than longer-chain PUFA (fish oil) in decreasing 12-HETE production in incubated homogenized mouse lungs. This suggests that the production of 12-lipoxygenase products could be regulated by modification of fatty acyl composition of membrane phospholipids as a consequence of n-3 dietary PUFA manipulation. Although when 12-HETE was decreased by this means, a comparable increment in 12-HEPE was found. With respect to the involvement of 12-HETE in tumor cell adhesion, this could mean that manipulation of dietary fat is a nutritional approach to reduce the generation of this specific lipoxygenase metabolite *in vivo*; a net biological effect would depend upon differences in activity between 12-HETE and 12-HEPE.

Substrate pool(s) for lung 12-lipoxygenase. The complexity of oxygenase product formation *in vivo* can be attributed to various processes, including activation of specific phospholipases, release of arachidonic acid from discrete membrane phospholipids and conversion of arachidonic acid to metabolites by various oxygenases. Although release of arachidonic acid by phospholipases is believed to be the pivotal step in eicosanoid synthesis in many circumstances, it is not clear which phospholipids comprise the arachidonic acid pool in specific cell types of lung tissue. Distinct arachidonic acid pools may be used by different tissues or cells in response to particular stimulation *in vivo*, e.g., PE may be used in rat platelets (35) and PC and/or PI in mast cells (36). The present study compared fatty acid composition of lung phospholipids, lipoxygenase products in lung homogenates after 30 min of incubation, and composition of unesterified fatty acids in unincubated lung homogenates. These parameters were altered by modification of dietary PUFA. By comparing the extent in changes as a function of dietary fat, the data suggest that PC may serve as the major arachidonic acid pool for the 12-lipoxygenase pathway in mouse lung homogenates. As lung also expresses 15-lipoxygenase activity and as the response to diet for the 15-lipoxygenase in the mice differed, these two lipoxygenases may be controlled by different mechanisms. The physiological functions and differences in regulation mechanisms of mammalian lung lipoxygenases merit further investigation.

Separation and Quantitation of Mono-, Di-, and Triglycerides and Free Oleic Acid Using Thin-Layer Chromatography with Flame-Ionization Detection[1]

G. Peyrou, V. Rakotondrazafy, Z. Mouloungui*, and A. Gaset

Laboratoire de Chimie Agro-Industrielle-CATAR, Ecole Nationale Supérieure de Chimie, INP Toulouse, 31077 Toulouse, France

ABSTRACT: α-Monoolein was prepared from glycidol and oleic acid by the regioselective opening of glycidol in the presence of an anionic resin. During the reaction, the lipochemical synthesis medium becomes enriched in monoolein, the effective emulsifying agent. This mixture can be analyzed by thin-layer chromatography coupled with flame-ionization detection (FID). The products and reagents do not need to be derivatized. Diglyceride and triglyceride by-products affecting the selectivity of the reaction also could be detected using this technique. Cholesterol was used as an internal standard. The factors influencing the separation, including the hydrogen flow rate, scan speed, and the composition of the developing solvent, were investigated. The degree of separation is highly sensitive to the hexane/diethyl ether ratio of the developing solvent. Good separation of triglyceride, oleic acid, the two diglycerides, cholesterol, α-monoolein, and glycidol was obtained with the mixture hexane/diethyl ether/formic acid (65:35:0.04, by vol). Detector response, detection limits, and rod-to-rod variations also were examined. A range of rod loads giving a straightforward relationship between FID response and amount of compound loaded (relative to oleic acid and α-monoolein) was defined. The accuracy of the quantification was illustrated by analysis of a mixture of oleic acid and α-monoolein standards of known composition.

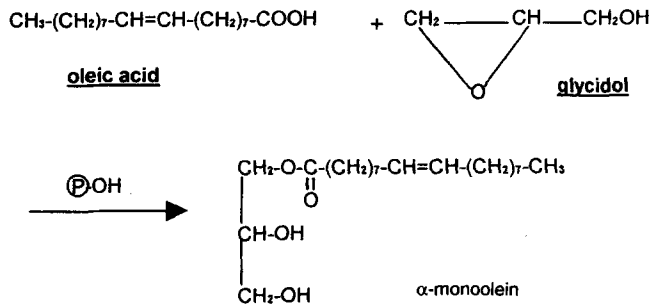
Lipids 31, 27–32 (1996).

Monoglycerides are used as additives for foods, feeds, cosmetics, coatings, and plastics (1–3). Stable oil-in-water or water-in-oil emulsions are produced under the action of those emulsifying agents. The normal reactions used to synthesize monoglycerides give rise to mixtures of mono-, di-, and triglycerides along with residual free fatty acids (1,4). The applications of these monoglycerides depend markedly on their overall content in the final product. The most commonly used methods for analysis of glycerides are gas-phase chromatography, thin-layer chromatography (TLC), and high-performance liquid chromatography (HPLC).

Prevot and Castille (5) analyzed monoglycerides by gas-phase chromatography on capillary columns. Although reproducible, this method requires derivatization of the hydroxyl groups on monoglycerides and fatty acids, and is also limited by the relatively short life-time of the column. Newer methods, including high-performance TLC (6) and high-performance size-exclusion chromatography (7), have been increasingly employed to separate and quantify partial glycerides in complex lipid mixtures.

TLC has the advantage of simplicity and flexibility in choice of operating parameters, although quantitation still presents problems. Amounts of products can be determined by densitometry, and, since the 1970s, coupling TLC with flame ionization has enabled single-step separation, identification, and quantification of each constituent of a complex lipid mixture.

Several workers have quantified the products of lipochemical reactions using TLC/flame-ionization detection (FID) (8,9). The partial glycerides from enzymatic hydrolysis of triolein (TO) have been determined by Tatara *et al.* (10) using boric acid-impregnated S-II chromarods (Iatron Laboratories, Tokyo, Japan) with a mobile phase of hexane/diethyl ether/acetic acid (70:30:1, by vol).



We propose a convenient method without requiring chemical derivatization of reagents or products with labile hydrogens, and without pretreatment of rods. It was developed using S-III (Iatron Laboratories) type rods. The mixtures to be analyzed were obtained by the condensation reaction of oleic acid with glycidol (GL) catalyzed by the anionic resin P-OH^- (Scheme 1) (11,12) in the absence of solvent. The α-monoolein (MO) was the main product formed in this fatty acid concentrated medium. By-products, such as diglycerides and triglycerides, formed in the reaction also were detected by this method. The TLC/FID analytical procedure was optimized using standard mixtures in order to assess the factors influencing the separation.

SCHEME 1

EXPERIMENTAL PROCEDURES

Reagents. Oleic acid (18:1) (>99%) was purchased from Fluka (L'Isle d'Abeau Chesnes, France). MO, TO, and cholesterol (CHO) of >99% purity were obtained from Sigma (L'Isle d'Abeau Chesnes, France). GL (>96%) was supplied by Aldrich (L'Isle d'Abeau Chesnes, France), and the anionic resin [Amberlyst A26 (OH^-)] was obtained from Rohm and Haas (Lauterbourg, France).

The lipochemical synthesis media resulted from the condensation of 18:1 with GL in a molar ratio of 18:1/GL (4:1, by mole). The reaction was carried out in the absence of solvent and was catalyzed by anionic resins. The reaction medium was thus referred to as a fatty acid concentrated medium. The amount of resin should correspond to a ratio 18:1/millliequivalent OH of the resin (50:5, by millimole). Initially, the resin was introduced into a flask fitted with stirrer and cooling system; 18:1 was then added to the resin and left for 15 min to adsorb at room temperature. GL was then added, and the reaction was continued for four hours at a temperature of 70°C. This produced 40% of MO in the final products. 1,2-Diolein (1,2-DO) and 1,3-diolein (1,3-DO) were obtained as by-products of the reaction. They were isolated from the synthesis media by column chromatography on Florisil (SDS, Peypin, France) with a hexane/diethyl ether mixture (50:50, vol/vol) as eluent (13).

Developing solvents. The solvent mixtures used for development contained X mL of hexane and 100-X mL of diethyl ether. Formic acid (0.04 to 1 mL) was added to 100 mL of the hexane/ether mixture. All solvents were HPLC grade.

Experimental procedure. Standards (TO, 18:1, 1,2-DO, 1,3-DO, CHO, MO, and GL) were dissolved as mixtures in HPLC-grade chloroform to obtain the desired concentrations. The concentration of the internal standard was fixed at 0.95 mg/mL for the assays.

A 1 mL of solution was spotted in fractions of 0.02 mL onto S-III chromarods with a model 3200/IS-01 autospotter (SES 3202; SES, Nieder-Olm, Germany). The S-III chromarods are reusable quartz rods coated with silica gel particles of uniform shape and size (14). Before spotting, the chromarods were scanned twice in the IATROSCAN (Iatron Laboratories, Tokyo, Japan; French distributor: BIONIS, Richebourg, France). Two sets of ten chromarods were simultaneously used in the experiments. After spotting, the set of chromarods was placed in the developing tank for 20 min. The rods were then dried in an oven at 120°C for 5 min, and then left in a vacuum dessicator for 5 min to reach room temperature. They were then transferred to the IATROSCAN and scanned.

Instrument and operating conditions. FID scans were performed using an IATROSCAN MK 5 analyzer connected to a 386 SX computer *via* an analog output. Data acquisition and analysis were carried out using Boreal software (JMBS Developments, Fontanil Cornillon, France).

The hydrogen and air flow rates of the FID were 160 and 1800 mL/min, respectively. The scanning speed was set at 3 corresponding to 35 s/rod. Other settings of hydrogen flow rate and scanning speed were only used in the experiments designed to study the influence of these two parameters.

RESULTS AND DISCUSSION

Influence of hydrogen flow rate. The response of the FID depends on the temperature of the flame, which is related to the hydrogen flow rate. Freedman *et al.* (15), working with S-II chromarods, chose a flow rate of 160 mL/min, which has been widely adopted by other authors (16–19). We experimented here with six different hydrogen flow rates over the range of 150–200 mL/min. The responses of 18:1 and MO at the different flow rates are shown in Figure 1. For these two compounds, hydrogen flow rates in the range of 160 to 180 mL/min gave the maximum response. However, high-flame temperatures may damage the silica coating of the rods, and so we selected a flow rate of 160 mL/min for the subsequent experiments.

Effect of scan speed. It has been reported that the response of some components increases with scan speed (20). However, complete burning may not be obtained at high scan speeds. Our normal scan speed was set at 3 corresponding to 35 s/rod. Two other scan speeds around this value were tested. As shown in Figure 2, only small alterations in the 18:1 and MO areas were observed between scan speeds 2 and 3, although a reduction was observed when the scan speed was

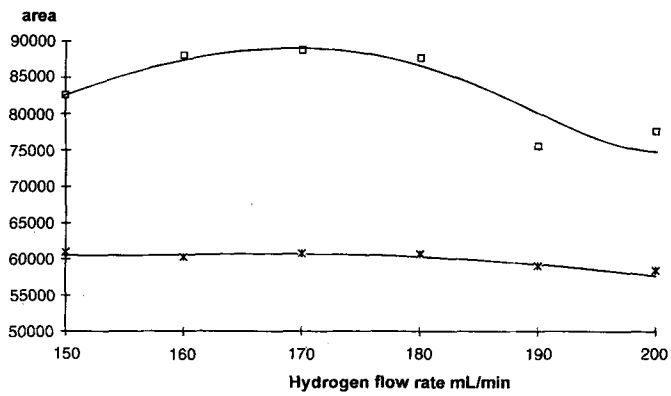

FIG. 1. Effect of hydrogen flow rate on response of oleic acid (18:1) (✳) and α-monoolein (MO) (□) spotted on S-III chromarods. 18:1 = 5 mg/mL, MO = 5 mg/mL; each point was the mean of values from ten rods.

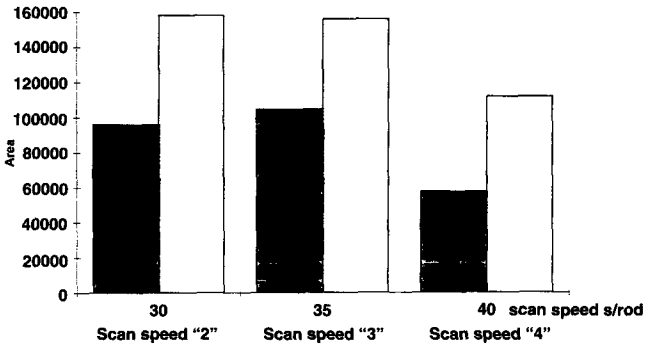

FIG. 2. Effect of scan speed on response of 18:1 (black bars) and MO (white bars). 18:1 = 5 mg/mL, MO = 5 mg/mL; each point was the mean of values from ten rods. Abbreviations as in Figure 1.

changed to 4. After spotting 5 mg of each component, no unburned sample was detected at any of these three scan speeds. A scan speed of 3 was thus selected for the subsequent experiments.

Effect of composition of developing solvent. The ternary mixture hexane/diethyl ether/formic acid is commonly used to analyze neutral lipid samples, containing fatty acids, tri-, di-, and monoglycerides (15), and good separations have been obtained using boric acid-impregnated S-II chromarods (10,21). However, the conditions described for the S-II rods are not directly applicable to the S-III chromarods, and pretreatment of the rods is not always required. Here, the optimum elution strength of the developing solvent mixture was optimized by adjusting the proportions of diethyl ether and formic acid. The effect of the hexane/diethyl ether ratio is shown in Figure 3.

As seen in Figure 3, the components can be considered in pairs—TO and 18:1, 1,2-DO and 1,3-DO, MO and GL. At low proportions of diethyl ether, TO and 18:1 were well resolved, but the 18:1 peak was broad. The two diglycerides were partially resolved, but MO and GL were not separated. Increasing the proportion of diethyl ether reduced the retention time of TO, 18:1, 1,2-DO, 1,3-DO, and MO without significantly influencing the retention time of GL. This enabled separation of MO and GL and improved the resolution of 1,2-DO and 1,3-DO without affecting the separation of TO and 18:1.

In another experiment, the hexane/diethyl ether ratio was kept constant, and different amounts of formic acid were added. The effect of formic acid is shown in Figure 4. Increasing the formic acid content enhanced the separation of MO and GL without affecting the separation of the other components. Peaks were sharper for 18:1, and especially for MO. The whole sample was well separated using hexane/diethyl ether (75:25, vol/vol) with various amounts of formic acid as developing solvent (Fig. 5A). However, with the internal standard (CHO), the 1,2-DO peak overlapped that of CHO (Fig. 5B).

More polar developing solvents were employed in an attempt to improve the separation of 1,2-DO and CHO. It was achieved with hexane/diethyl ether/formic acid (65:35:0.04, by vol) (Fig. 6). The diethyl ether content of the developing solvent may need to be altered slightly (±5% maximum) after several runs on the same rods if the quality of separation falls. This needs to be checked, especially when using new rods.

A complete separation of a mixture of TO, 18:1, 1,3-DO, 1,2-DO, MO, GL, and CHO was obtained in a single step without any chemical pretreatment of the chromarods, such as boric acid-impregnation. The S-III chromarods were found to give as good a separation as boric acid-impregnated S-II chromarods (10).

Calibration. The FID responses of 18:1 and MO were examined over a range of 0.08–20 μg of sample spotted, with hexane/diethyl ether/formic acid (75:25:0.04, by vol) as developing solvent. The detection limit was 0.01 μg for 18:1 and MO. In agreement with other investigators (20), we did not observe a linear relationship between the peak area and the amount of component spotted (Fig. 7). The FID response

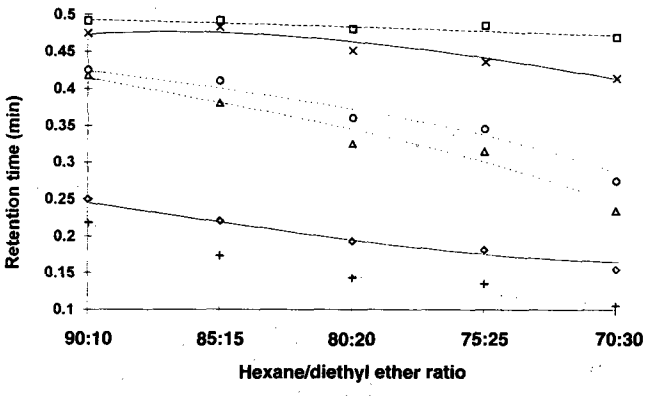

FIG. 3. Effect of hexane/diethyl ether ratio on the retention time of each component of the sample. Formic acid kept constant at 0.04 mL. Sample: triolein (TO) = 3 mg/mL, 18:1 = 3.2 mg/mL, 1,2-diolein (1,2-DO) and 1,3-diolein (1,3-DO) = 2 mg/mL, MO = 1.5 mg/mL, glycidol (GL) = 20 mg/mL (low response); 1 mL spotted; each point was the mean of values from six chromarods. Abbreviations as in Figure 1. TO, +; 18:1, ◇; 1,3-DO, △; 1,2-DO, ○; MO, ×; GL, □.

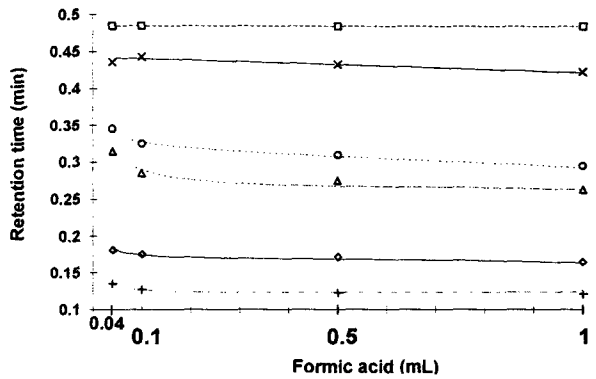

FIG. 4. Effect of formic acid on the retention time of each component of the sample hexane/diethyl ether ratio fixed at 75:25. Sample: TO = 3 mg/mL, 18:1 = 3.2 mg/mL, 1,2-DO and 1,3-DO = 2 mg/mL, MO = 1.5 mg/mL, GL = 20 mg/mL (low response); 1 mL spotted; each point was the mean of values from six chromarods. Abbreviation as in Figures 1 and 3, and key as in Figure 3.

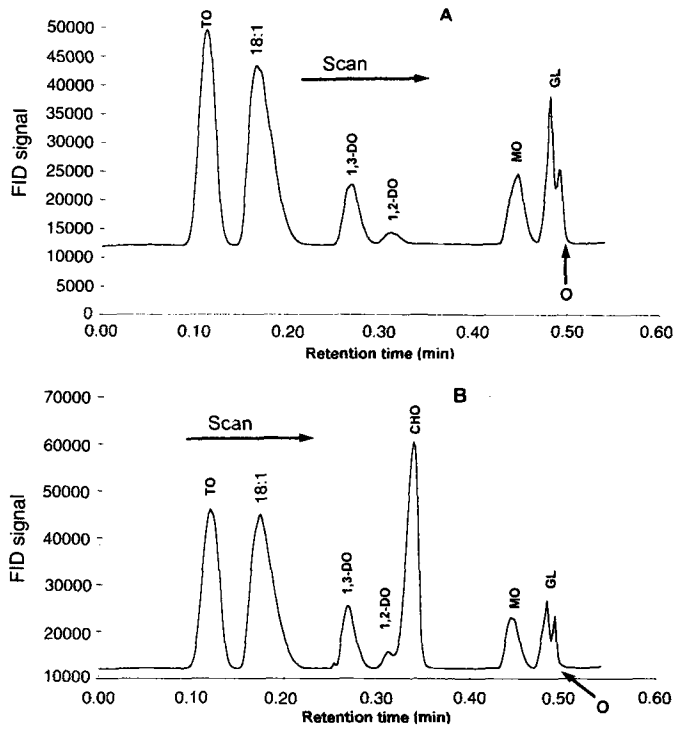

FIG. 5. Chromatograms of the sample developed with hexane/diethyl ether/formic acid (75:25:0.04). A: Without cholesterol (CHO); B: with CHO. Sample: TO = 3.2 mg/mL, 18:1 = 4.4 mg/mL, 1,2-DO and 1,3-DO = 1.5 mg/mL, MO = 1.5 mg/mL, GL = 18.6 mg/mL, CHO = 1 mg/mL; **O**: origin of sample application; GL produces a noisy signal close to the origin of sample application. Abbreviations as in Figures 1 and 3. FID, flame-ionization detection.

is in fact best fitted by power law equations: $Y = aX^b$ (20,22,23). The calibration curves of 18:1 and MO were approximated by the following equations: $Y = 8018X^{1.2204}$ (r^2 = 0.990) and $Y = 47819X^{0.5642}$ (r^2 = 0.880) for 18:1 and MO, respectively. A good correlation was found for 18:1 (r^2 = 0.990), but not for MO (r^2 = 0.880). The poor fit obtained for MO can be explained by a shift in the data over the range of 0.1 to 1 µg spotted (see zoom in Fig. 7). The data over the

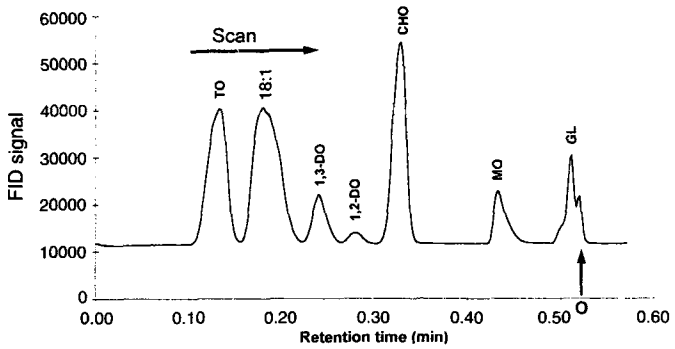

FIG. 6. Chromatograms of the sample developed with hexane/diethyl ether/formic acid (65:35:0.04). Sample: TO = 3.2 mg/mL, 18:1 = 4.4 mg/mL, 1,2-DO and 1,3-DO = 1.5 mg/mL, MO = 1.5 mg/mL, GL = 18.6 mg/mL, CHO = 1 mg/mL. Abbreviations as in Figures 1, 3, and 5.

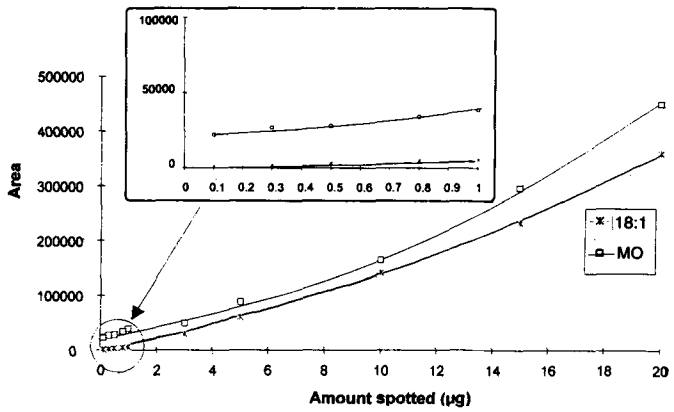

FIG. 7. Relationship between the peak area and the amount spotted for 18:1 and MO; 1 µL spotted; each point was the mean of values from ten rods. Abbreviation as in Figure 1.

range of 3–20 µg were well described by the equation $Y = 13626X^{1.1415}$ with a high correlation coefficient (r^2 = 0.992).

Fluctuations tended to occur and day-to-day reproducibility was not particularly good. This was accounted for by changes in room humidity. When the chromarods are exposed to the atmosphere, the silica gel coating quickly adsorbs moisture (24) and the percentage of water adsorbed influences the activity of the rod.

Sebedio and Juaneda (25) found that good results could be obtained by multilevel calibrations using an internal standard. The power law regression can be replaced by a linear regression over a defined range of component loads without affecting the correlation coefficient. As shown in Figure 8, interrod

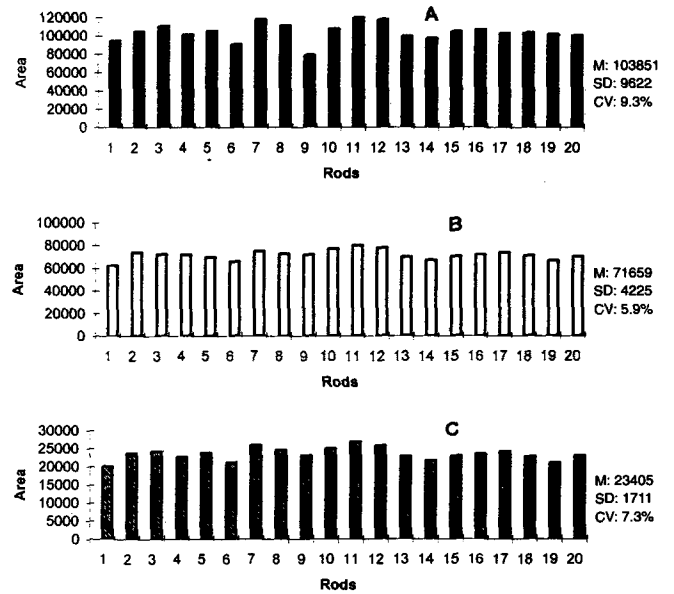

FIG. 8. Response of the two sets of ten chromarods. A: MO (4 µg spotted); B: 18:1 (4 µg spotted); C: CHO (0.95 µg spotted). M, mean of areas; SD, standard deviation; CV, coefficient of variation. Abbreviations as in Figures 1, 5, and 8.

variations were observed for 18:1 [coefficient of variation (CV) = 5.9%], MO (CV = 9.3%), and CHO (CV = 7.3%). Similar shapes were obtained for the three components 18:1, MO, and CHO over 20 chromarods. The use of an internal standard thus reduces interrod dispersion, and the responses of MO and 18:1 were normalized to the response of the internal standard (CHO) (Fig. 9), producing a significant reduction in the interrod variation. The CV was reduced from 9.3 to 6.3% for MO and from 5.9 to 2.5% for 18:1.

The relationships between the peak area and weight ratios were approximated by a linear regression over the range of 0.8 to 8 μg spotted for 18:1 and MO as governed by the following equations: $Y = 0.834X - 0.436$ with $r^2 = 0.996$ for 18:1 and $Y = 1.079X - 0.358$ with $r^2 = 0.995$ for MO. The high correlation coefficients indicated a good fit, and the plots are shown in Figure 10.

Analysis of a sample of known composition. A mixture of known composition of 18:1, MO, and CHO was prepared; 18:1 and MO were made up at concentrations of 4.6 mg/mL, and the internal standard at 0.95 mg/mL. Ten rods were used in the analysis of this model sample. The concentrations of 18:1 and MO were determined using the linear regressions established from the previous experiment, and the results are listed in Table 1.

The concentrations of 18:1 and MO were calculated from the means of the values from the ten rods. There was an adequate agreement between the observed results and the known concentrations of the components in the sample. However, the high CV observed for MO (10%) demonstrated that ten rods are required to achieve a relatively accurate determination. An analysis based on three rods would not be satisfactory.

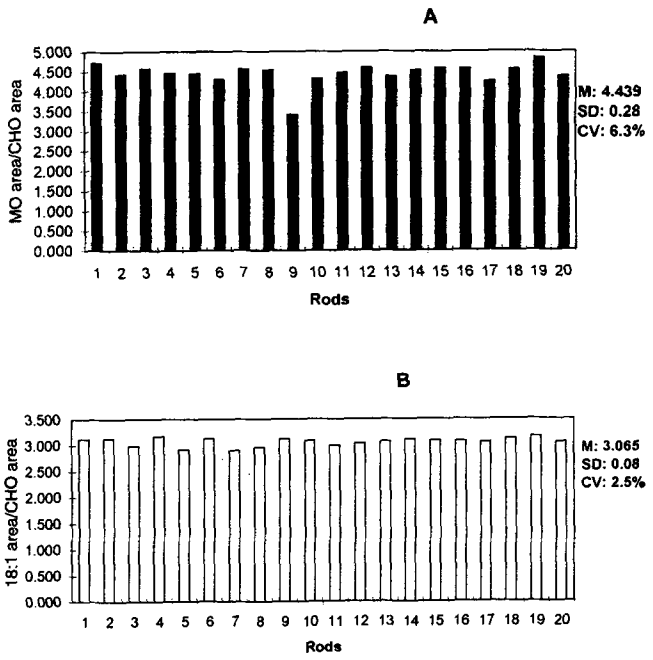

FIG. 9. Normalized response of the two sets of ten chromarods. A: MO/CHO; B: 18:1/CHO. Abbreviations as in Figures 1, 5, and 8.

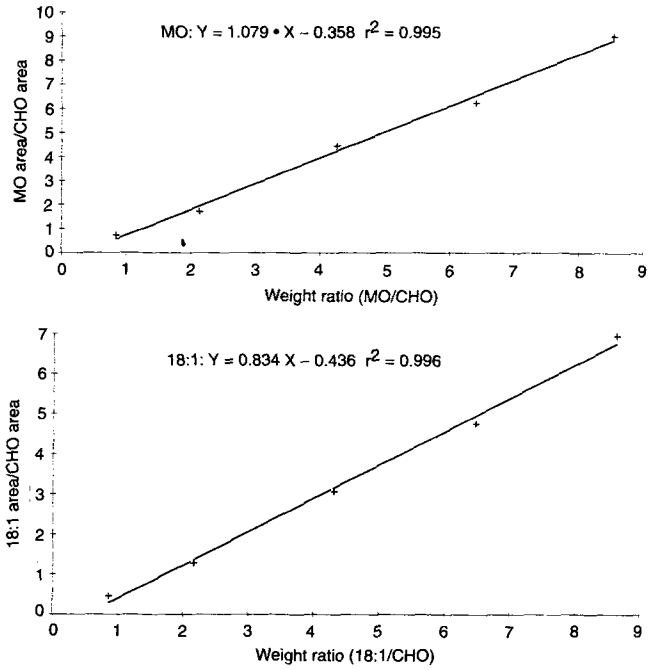

FIG. 10. The relationship between the peak area and weight ratios for MO and 18:1 with respect to the internal standard (CHO). Abbreviations as in Figures 1 and 5.

This analytical procedure using TLC/FID was found to be a rapid and efficient method for the analysis of the typical GL mixtures found in our synthesis media. Complete separation of the mixture was achieved in a single step without pretreatment of the chromarods and without derivatization of the sample. A hydrogen flow rate of 160 mL/min and a scan speed of 35 s/rod were found to be the optimum parameters for the IATROSCAN apparatus.

We obtained complete separation of the standards mixture (TO, 18:1, 1,2-DO, 1,3-DO, CHO, MO, and GL) using a developing solvent of hexane/diethyl ether/formic acid (65:35:0.04, by vol). However, for prolonged reuse of chromarods, the elution strength of the developing solvent may

need to be altered for optimum separation. An internal standard is needed for satisfactory reproducibility. Regular calibration with samples of known composition is also required.

The IATROSCAN MK-5 using S-III chromarods thus appears to be well suited for TLC/FID analysis of neutral lipids. It is noteworthy that this analytical technique requires relatively little maintenance, and several developments can be carried out using only 100 mL of solvent.

Optimization of the Mass Spectrometric Analysis of Triacylglycerols Using Negative-Ion Chemical Ionization with Ammonia

Päivi Laakso* and Heikki Kallio

Department of Biochemistry and Food Chemistry, University of Turku, FIN-20500 Turku, Finland

ABSTRACT: Conditions for the mass spectrometric analysis of triacylglycerols, *via* direct exposure probe, with ammonia negative-ion chemical ionization were optimized. Triacylglycerols were most favorably ionized, using the reactant gas pressure of approximately 8500 mtorr at the ion source temperature of 200°C with the instrumentation used. Abundant $[M - H]^-$ ions were produced under these conditions without the formation of $[M + 35]^-$ cluster ions, which would interfere with the molecular weight region of triacylglycerols in the spectra. A rapid desorption of the sample from the probe wire is recommended, using a relatively high heating rate (approximately 40 mA s^{-1}), to minimize thermal degradation of unsaturated molecules and the reducing effect of double bonds on the mass spectrometric response of triacylglycerols. Furthermore, the abundance of $[M - H]^-$ ion was enhanced by rapid heating, which we found to be important to improve the sensitivity. The appropriate amount of sample applied to the rhenium wire was in the region of 50–300 ng for one determination, i.e., only a few nanograms of a single triacylglycerol is required for production of a reliable spectrum. The reproducibility of the method was good as demonstrated with standards and a raspberry seed oil sample. The described mass spectrometric method is a fast and potentially useful tool for semiquantitative determination of triacylglycerol mixtures of various fats and oils. The discrimination, caused by differences in molecular size and unsaturation of triacylglycerols with 50 to 56 acyl carbons, was negligible under our optimized ionization conditions, thus, no correction factors were needed. These findings have not yet been verified with instruments in other laboratories. However, the present study shows how the analysis of triacylglycerols can be improved, regardless of the instrument, by optimization of the analytical conditions.

Lipids 31, 33–42 (1996).

The first mass spectrometric studies of triacylglycerols (TAG) in the 1960s were performed with electron ionization (EI) impact (1,2). In addition to fragment ions, the spectra consisted of $M^{+\bullet}$ and $[M - 18]^+$ ions at low abundance, which were used to determine the molecular weight distribution of TAG of several vegetable oils (3,4). As compared with EI spectra, a greater abundance of ions, consisting of the intact molecule, and less fragmentation are obtained by soft ionization methods, chemical ionization (CI) being used most often (5,6). TAG have been ionized using methane, isobutane, or ammonia as a reactant gas in the positive-ion mode to produce $[M + H]^+$ or adduct ions. Murata and Takahashi (7,8) ionized TAG with ammonia, which resulted in the formation of abundant $[M + NH_4]^+$ ions and $[M + H - RCO_2H]^+$ fragment ions useful for the determination of both molecular weights and combinations of fatty acids in TAG molecular species. Kuksis and colleagues (9,10) introduced the formation of prominent $[M + H]^+$ and $[M + H - RCO_2H]^+$ ions when TAG were separated by reversed-phase high-performance liquid chromatography (HPLC) combined with mass spectrometry (MS) using acetonitrile and propionitrile for elution and as reactant gases. The detection sensitivity was greatly improved by using negative-ion CI with dichloromethane, which yielded solely $[M + Cl]^-$ ions (11,12).

It has been shown recently by Kallio and Currie (13,14) that MS utilizing ammonia negative-ion CI is an efficient tool for the analysis of TAG. NH_2^- ion is a strong Brønsted base which is capable of deprotonating most organic molecules, including ketones and esters (15,16). TAG will be ionized to form deprotonated ions using ammonia as the reactant gas in negative ion mode. The *m/z* values of $[M - H]^-$ ions define unambiguously the number of acyl carbons and the number of double bonds present in the TAG of most fats and oils, and the abundance of $[M - H]^-$ ions determines the proportions of different molecular weight species. Similar data cannot be achieved with a single mode of either gas chromatography (GC) or HPLC, which are the most widely utilized techniques in lipid research. In addition, more detailed information on molecular species is obtained by collision-induced dissociation of a selected $[M - H]^-$ ion. The daughter-ion spectrum provides information on the fatty acid constituents and their distribution between *sn*-2 and *sn*-1,3-positions in TAG.

In this research, the conditions for mass spectrometric analysis of TAG of seed oils using ammonia negative-ion CI were optimized. Samples were introduced *via* a direct exposure probe into the ion source without chromatographic separation before MS. First of all, the effects of ion source temperature and reactant gas pressure, as well as the rate of probe heating on the quality of ammonia negative-ion CI mass spec-

tra of TAG, were studied. In addition, the reproducibility of the method and its applicability for quantitative analysis of TAG were investigated.

EXPERIMENTAL PROCEDURES

TAG standards and samples. Standards of both saturated and unsaturated TAG, listed in Table 1, were purchased from Sigma (St. Louis, MO). A stock solution of each compound (approximately 0.2–0.4 mg mL^{-1}) was prepared by dissolving the saturated TAG in dichloromethane and the unsaturated ones in hexane containing 0.02% (wt/vol) butylated hydroxytoluene (Sigma) to prevent oxidation. Individual components or mixtures of several standards were dissolved in hexane for mass spectrometric determinations. Lipids in the seeds of black currant (*Ribes nigrum*), lingonberry (*Vaccinium vitis-idaea*), and raspberry (*Rubus idaeus*), grown wild in Finland, were extracted with chloroform/methanol (2:1, vol/vol) using a modified Folch procedure (17) followed by purification of the TAG by elution from a short column of Florisil™ (Fluka Chemie AG, Buchs, Switzerland) with 10 mL hexane/diethyl ether (4:1, vol/vol) as the mobile phase. TAG were dissolved in hexane (approximately 1 mg mL^{-1}) for MS determinations. All solvents used were HPLC-grade supplied by Rathburn (Walkerburn, Scotland) and Merck (Darmstadt, Germany).

Mass spectrometric analysis. The mass spectrometric determinations were conducted with a Finnigan MAT TSQ-700 triple quadrupole instrument (San Jose, CA) with an ICIS II data system (Finnigan MAT). TAG were analyzed using negative-ion CI with ammonia (≥99.998%; Prax Air, Oevel, Belgium). The optimization of the ion source conditions was carried out with a mixture of four TAG standards at ammonia pressures of 3000, 5000, 7000, 8500, and 10000 mtorr at ion source temperatures of 120, 150, 180, 200, and 220°C. The ammonia pressure was monitored with a Convectron gauge (Phillips Company, Granville, OH) which was situated in the gas line before the flow-controller into the ion source. A volume of 0.5 μL of the sample was applied to the rhenium wire loop of the direct exposure probe (Finnigan MAT). The probe was introduced into the ion source after the solvent was evaporated, and the heating of the probe wire with the current was started to vaporize the sample. The desorption of TAG from the rhenium wire was optimized by testing heating rates between 2.5 and 100 mA s^{-1} both with mixtures of TAG standards and seed oil samples. The effect of concentration on the mass spectrometric response of TAG was tested with a mixture of 14 standards (mixture A, Table 1) with concentrations varying from 2.6 to 379.6 μmol L^{-1} of each compound. The concentration of the internal standard, *rac*-18:0-18:0-14:0, was constant (24.7 μmol L^{-1}) in each dilution. The repeatability and reproducibility of the mass spectrometric method was determined with TAG standards (mixture B, Table 1) and raspberry seed oil. Electron energy was 70 eV and filament current 400 μA throughout the experiment. The *m/z* range scanned was 250–950 during the optimization of the ion source conditions and that of the probe heating rate, and 700–1100 during the concentration, repeatability, and reproducibility experiments. Scans containing ions representing deprotonated TAG were averaged in each analysis. The abundances of the ions were corrected by ^{13}C isotope content, when necessary, before expressing the results as the mean of four analyses.

RESULTS AND DISCUSSION

Ammonia negative-ion CI of TAG yielded very simple mass spectra containing abundant $[M - H]^-$ ions. The *m/z* values and abundances of $[M - H]^-$ ions define the number of acyl

carbons and double bonds in TAG and the proportions of different molecular weight species. During this optimization study, more detailed information on the effects of different parameters on the analysis of TAG was considered important in order to expand the applicability of the method. The samples were introduced *via* a direct exposure probe into the ion source. The evaporation of different TAG does not occur simultaneously from the rhenium wire (18); therefore, the ion abundances obtained from the averaged spectra were used for further calculations.

Optimization of the ion source conditions. It is well known that ion source conditions may have a significant influence on the composition of the reactive CI gas plasma and, consequently, on the resulting mass spectra of sample molecules (16). The aim of the optimization was to find ion source conditions which will yield maximum sensitivity of deprotonated ions of TAG at minimum ion source pressure without formation of interfering cluster ions. The test mixture consisted of *rac*-1,2-distearoyl-3-palmitoyl-*sn*-glycerol, tristearoylglycerol, *rac*-dilinoleoyl-3-oleoyl-*sn*-glycerol, and trilinolenoylglycerol, each compound in the concentration of 0.15–0.17 $\mu g\ \mu L^{-1}$ in hexane, representing typical components in the seed oils of various plants, especially in the seeds of Northern wild berries. TAG containing 52, 54, and 56 acyl carbons with 1–9 double bonds are the most abundant constituents of several seed oils.

Ammonia negative-ion CI of TAG resulted in a spectrum which contained $[M - H]^-$ and $[M + 35]^-$ ions at various proportions, depending on the CI conditions in the ion source. In addition, only abundant RCO_2^- ions were produced with little structural significance and, therefore, are not discussed here. Figure 1A shows the abundance of $[M - H]^-$ ions originated from trilinolenoylglycerol at different ion source conditions. The ionization of *rac*-1,2-distearoyl-3-palmitoyl-*sn*-glycerol, tristearoylglycerol, and *rac*-1,2-dilinoleoyl-3-oleoyl-*sn*-glycerol were similar to that presented in Figure 1A. In general, the ionization efficiency decreased with increasing ion source temperature at constant CI gas pressure. At constant ion source temperature, the ionization efficiency of TAG increased with increasing reactant gas pressure up to 8500 mtorr. Some day-to-day variation existed in the ionization of the TAG, e.g., sometimes the ionization efficiency at 8500 and 10000 mtorr was nearly the same.

The proportion of the abundance of the cluster ion $[M + 35]^-$ from that of the corresponding $[M - H]^-$ ion originated from trilinolenoylglycerol is shown in Figure 1B. The formation of cluster ions during the analyses of *rac*-1,2-distearoyl-3-palmitoyl-*sn*-glycerol, tristearoylglycerol, and *rac*-1,2-dilinoleoyl-3-oleoyl-*sn*-glycerol at different ion source conditions resembled that shown in Figure 1B. Typically, the contribution of cluster ions decreased with increasing reactant gas pressure and increasing ion source temperature. For example, the proportions of cluster ions were more than 10% of the corresponding $[M - H]^-$ ion at the pressure of 3000 and 5000 mtorr at the ion source temperature of 120°C for each TAG studied. On the other hand, no cluster ions were observed at temperatures of 200 and 220°C when the intensities of the ions of interest were derived from the averaged scans.

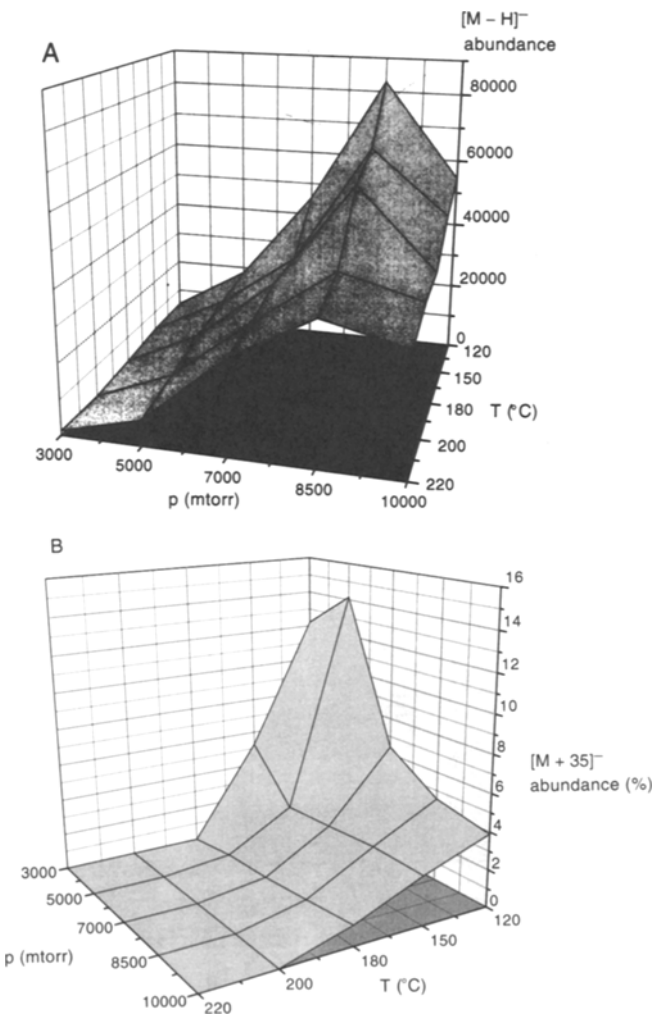

FIG. 1. A: The abundance of $[M - H]^-$ ion at different ion source conditions. B: The proportion of the abundance of the cluster ion, $[M + 35]^-$, from that of the corresponding deprotonated molecular ion at different ion source conditions. Sample: trilinolenoylglycerol; T, temperature; p, pressure.

Based on the ionization efficiency of TAG, the reactant gas pressure should be high and the ion source temperature low for maximal ionization. On the contrary, the formation of cluster ions is favored at low temperatures. Cluster ions disturb the molecular weight area of TAG in the spectra; thus, the formation of clusters should be eliminated with high enough ion source temperatures. TAG were most favorably ionized using the reactant gas pressure of approximately 8500 mtorr at the ion source temperature of 200°C with the instrument used, for the determination of molecular weight distribution of fats and oils. These conditions may serve as a guideline for optimization of the CI conditions for TAG, but, it may be necessary to make adjustments for these conditions depending on the sample and instrumentation. All experimental measurements described below were carried out at the optimized CI conditions.

Optimization of the probe heating rate. The effect of the heating rate of the rhenium wire of the direct exposure probe was studied with single standards (tristearoylglycerol, *rac*-1,2-dilinoleoyl-3-oleoyl-*sn*-glycerol, and trilinolenoylglycerol), a fifteen-component reference mixture (mixture B, diluted 1:9 with hexane, Table 1), black currant, and lingonberry seed oils. Unsaturated TAG are the most abundant constituents in most seed oils, containing even more than nine double bonds in their acyl chains. Therefore, it is of great significance to reduce thermal degradation or polymerization of these unsaturated molecular species during their desorption from the rhenium wire in the ion source. Heating rates from 2.5 to 100 mA s^{-1} were tested in this study. As an example, the influence of the probe heating rate on the proportions of RCO_2^-, $[M - RCO_2]^-$, and $[M - H]^-$ ions of the reference compound *rac*-1,2-dilinoleoyl-3-oleoyl-*sn*-glycerol is shown in Figure 2. We assumed that the proportions of RCO_2^- and $[M - RCO_2]^-$ ions would indicate the degree of thermal degradation of TAG. Surprisingly, the intensities of fragments resulting from the acyl loss of reference TAG, $[M - RCO_2]^-$, were very low, if found at all. The proportions of RCO_2^- and $[M - H]^-$ did not change significantly according to the rate of probe heating. However, the higher the heating rate the higher the abundance of $[M - H]^-$ ions. Such enhanced signal of the $[M - H]^-$ ions is essential to improve sensitivity. Very high heating rates resulted in bad peak shapes and high standard deviations because few data points only were acquired.

The effect of probe heating rate on the proportions of TAG of the fifteen-component reference mixture, according to the intensities of $[M - H]^-$ ions, is presented in Figure 3A. The proportions of unsaturated TAG with more than three double bonds were underestimated with a low heating rate of the probe. However, similar effect was not determined with the analyses of TAG of black currant seed oil (Fig. 3B) and lingonberry seed oil (Fig. 3C), although they contained around 62 and 82% TAG with six or more double bonds, respectively. An increase in the heating rate resulted in slightly reduced proportions of larger TAG, whereas those of smaller molecules increased. Overall, the heating rate of the probe did not significantly change the TAG distribution of the seed oils studied. It appears most appropriate to use a heating rate of around 40 mA s^{-1} of the direct exposure probe wire for the vaporization of TAG to obtain good sensitivity and reproducibility of the analysis and to minimize the discrimination of polyunsaturated TAG.

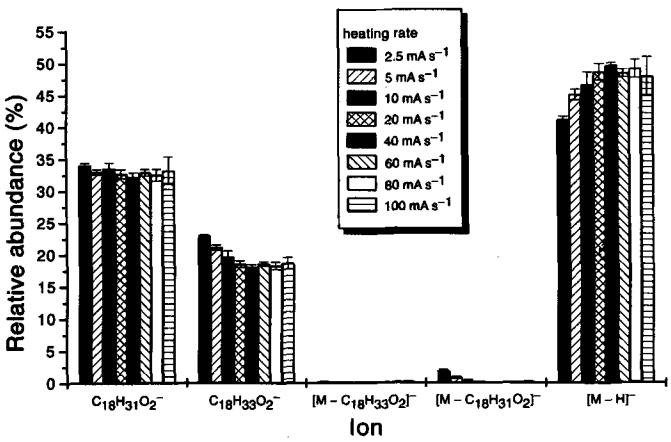

FIG. 2. The effect of the heating rate of the direct exposure probe on the proportions of RCO_2^-, $[M - RCO_2]^-$, and $[M - H]^-$ ions of *rac*-1,2-dilinoleoyl-3-oleoyl-*sn*-glycerol. Reactant gas pressure, 8500 mtorr; and ion source temperature, 200°C.

Effect of the sample amount. The effect of sample amount on the mass spectrometric response of TAG was tested with several dilutions of a mixture of reference components (mixture A, Table 1) concentrations varying from 2.6 to 379.6 μmol L^{-1} of each compound. A constant volume of a sample (0.5 μL) was applied to the rhenium wire; therefore, the amount of sample analyzed was changed by varying the concentration of the sample. An internal standard, *rac*-18:0-18:0-14:0, was added to each dilution (24.7 μmol L^{-1}) to eliminate inaccuracies in injection volumes.

The mass spectrometric response of the $[M - H]^-$ ions of TAG varied a lot as a function of the molecular size, with a slow probe heating (Fig. 4A). The response decreased with increasing molecular size, i.e., the total number of acyl carbons in TAG. As expected, the double bonds had a diminishing effect on the mass spectrometric response of unsaturated TAG (Fig. 4B). In addition to concentration, the effect of probe heating rate on the proportions of TAG was studied using slow (4 mA s^{-1}) and rapid (80 mA s^{-1}) heating (Fig. 5). Correction factors for each standard were calculated in relation to tripalmitoylglycerol (48:0) to determine the potential of this method for quantitative purposes (Table 2). When the sample was vaporized slowly, the proportions of unsaturated TAG were underestimated, being lower the more dilute the sample was. This resulted in large correction factors for unsaturated components (Table 2). The discrimination of polyunsaturated TAG can be eliminated by using rapid heating of a sample and a small sample amount. In this case, the correction factors of both saturated and unsaturated TAG were close to 1.0 (Table 2), i.e., the measured distribution of TAG was close to that of the composition of the mixture. The analysis of high-concentration samples using rapid heating of the probe resulted in increased proportions of smaller TAG and decreased proportions of larger molecules, as well as unsaturated components. Minor inaccuracies in the correction factors might be caused by sample preparation and impurities of the standards.

A few studies on the quantitative analysis of TAG with direct introduction inlet mass spectrometry have been published utilizing either EI (3) or ammonia CI (8,18). In these studies, the mass spectrometric response of TAG was reported to depend on the molecular structure, i.e., number of double bonds and molecular size; thus, correction factors had to be used for quantitative measurements. The results of the present study clearly show that the variation in the mass spectrometric response of TAG caused by differences in unsaturation and molecular size could be reduced, and nearly eliminated, by heating the probe wire very rapidly (Table 2), if the sample

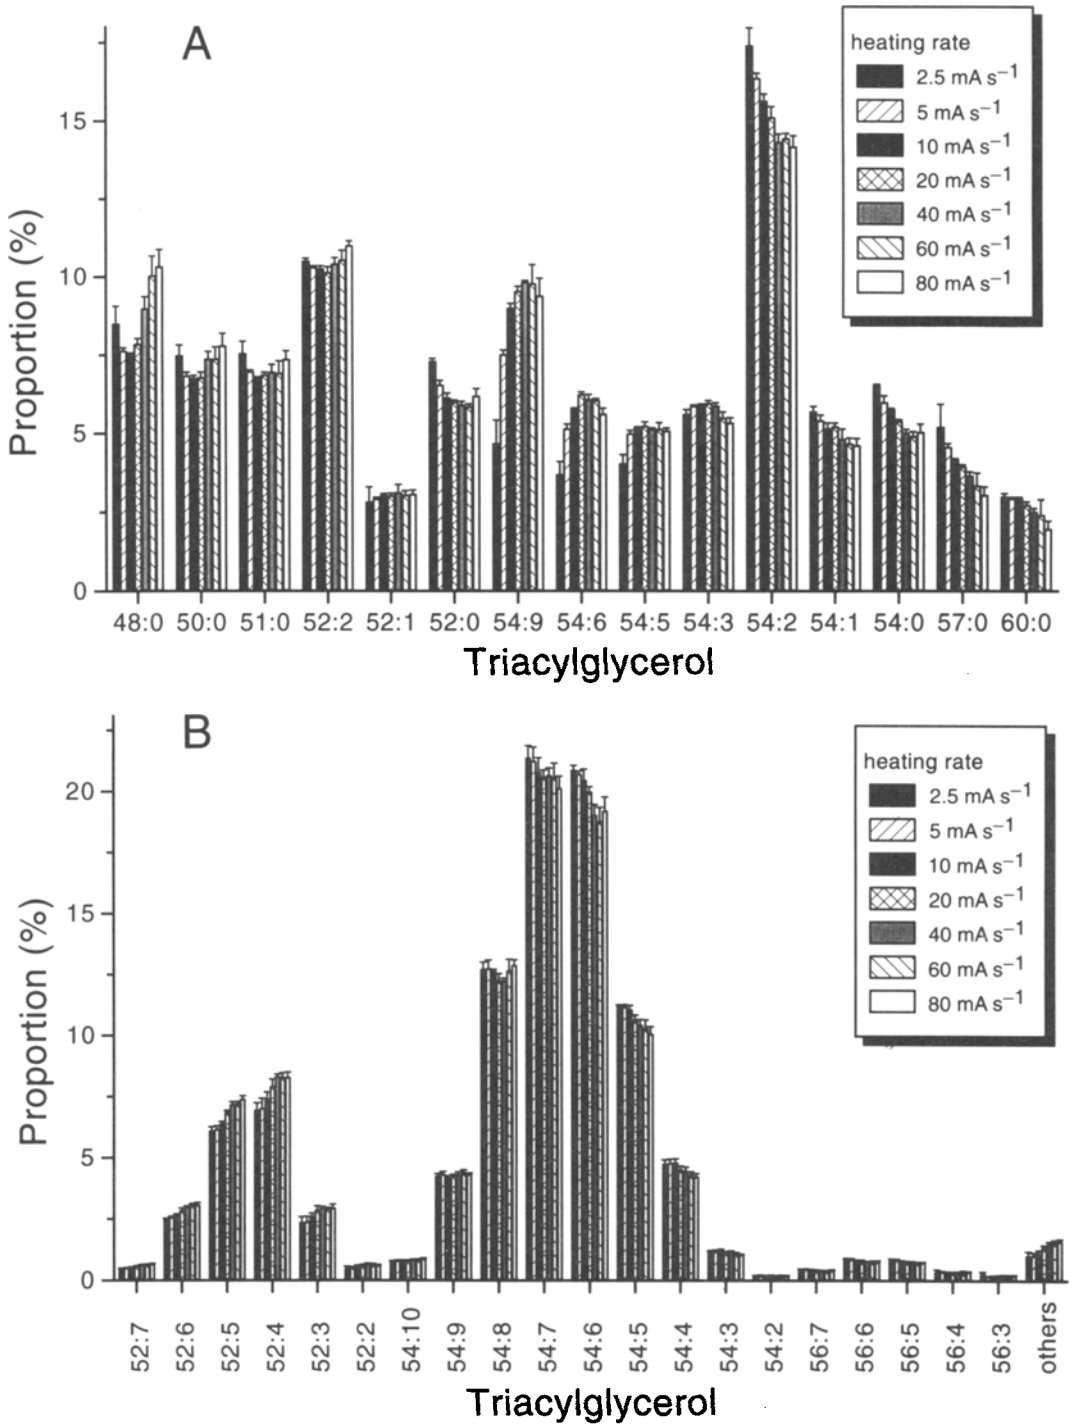

FIG. 3. The effect of the heating rate of the direct exposure probe on the distribution of triacylglycerols: A, reference mixture B (see Table 1), diluted 1:9 with hexane; B, black currant seed oil; and C, lingonberry seed oil. The proportions of triacylglycerols are based on the ^{13}C corrected abundances of $[M - H]^-$ ions of four analyses. Reactant gas pressure, 8500 mtorr; and ion source temperature, 200°C.

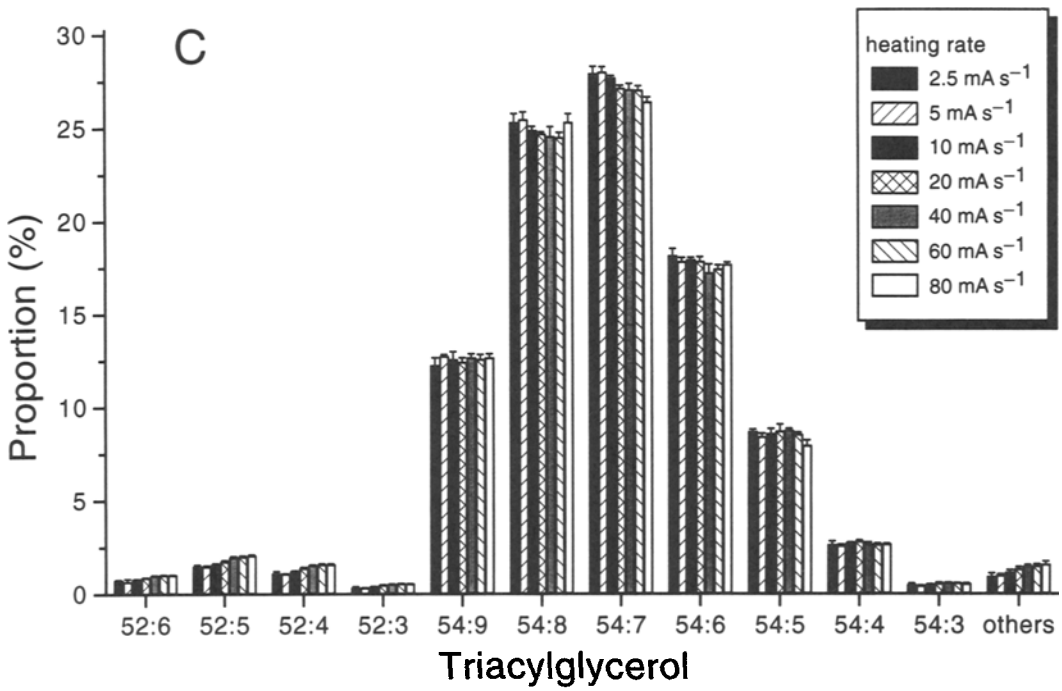
amount was small enough. Too small an amount of sample resulted in unacceptable standard deviation of the analysis. Based on the analysis of the TAG reference mixture, the appropriate concentration of the sample was approximately 100–600 ng μL^{-1}, i.e., 50–300 ng TAG per determination. In other words, only a few nanograms of a single TAG is required for production of a reliable spectrum. It is necessary to adjust the concentration of the sample to a range suitable for the analysis in order to avoid too large sample amounts. To compare TAG distributions, the concentration of each sample



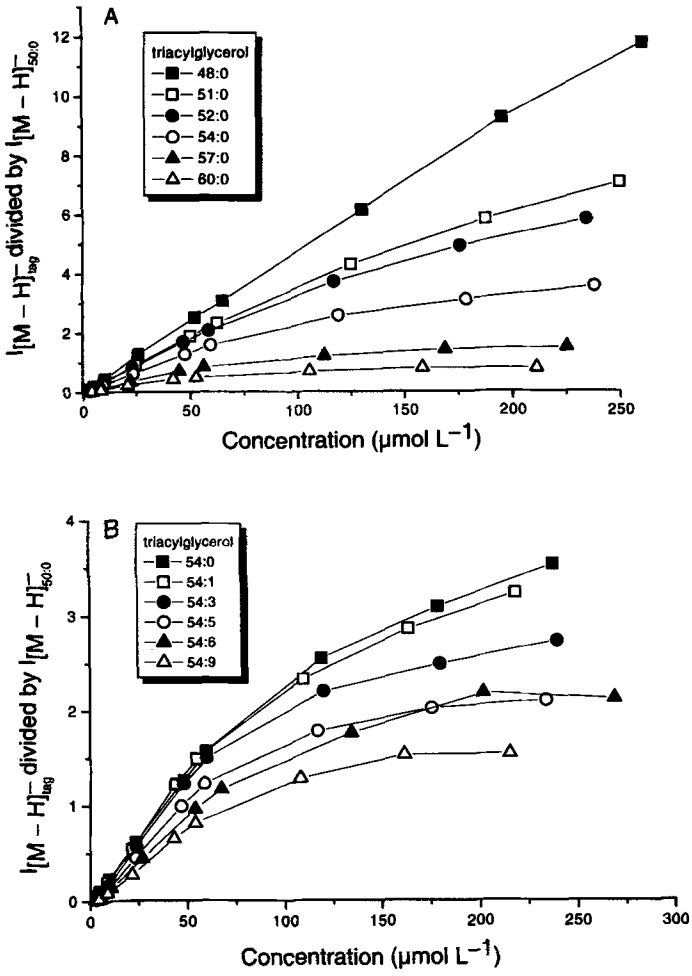


FIG. 3. (continued).

should be approximately the same to prevent mistakes in interpretation of the results caused by concentration differences. Under well-controlled conditions, the method is capable for semiquantitative determination of TAG mixtures of most fats and oils consisting of TAG with 50–56 acyl carbons without the use of correction factors.

Reproducibility of the analysis. The reproducibility of the mass spectrometric determination was studied with a mixture of fifteen TAG standards (mixture B, Table 1, Fig. 6A) and with the TAG isolated from the seeds of raspberry (Fig. 6B). The results are expressed as the mean of four analyses with error bars indicating the standard deviations. The coefficient of variation was typically less than 10% for the components comprising 1% or more of the total amount of TAG. In addition, the reproducibility of the determination from day to day and over longer periods was tested at different points of time. No major changes were observed in the molecular weight distribution of the TAG based on the averaged abundances of $[M - H]^-$ ions. The differences were more obvious with the fifteen-component mixture; nevertheless, reasonable reproducibility of the analysis was achieved in the *m/z* range, which covers the molecular weight area of TAG present in

FIG. 4. Response curves for the $[M - H]^-$ ions of A, the saturated triacylglycerols; and B, the unsaturated triacylglycerols having 54 acyl carbons (reference mixture A, see Table 1) with the addition of 24.7 μmol L^{-1} of *rac*-1,2-distearoyl-3-myristoyl-*sn*-glycerol as internal standard. A volume of 0.5 μL of the sample was applied to the rhenium wire of the direct exposure probe. Reactant gas pressure, 8500 mtorr; and ion source temperature, 200°C. The heating rate of the direct exposure probe was 4 mA s^{-1}; I = intensity; tag = triacylglycerol.

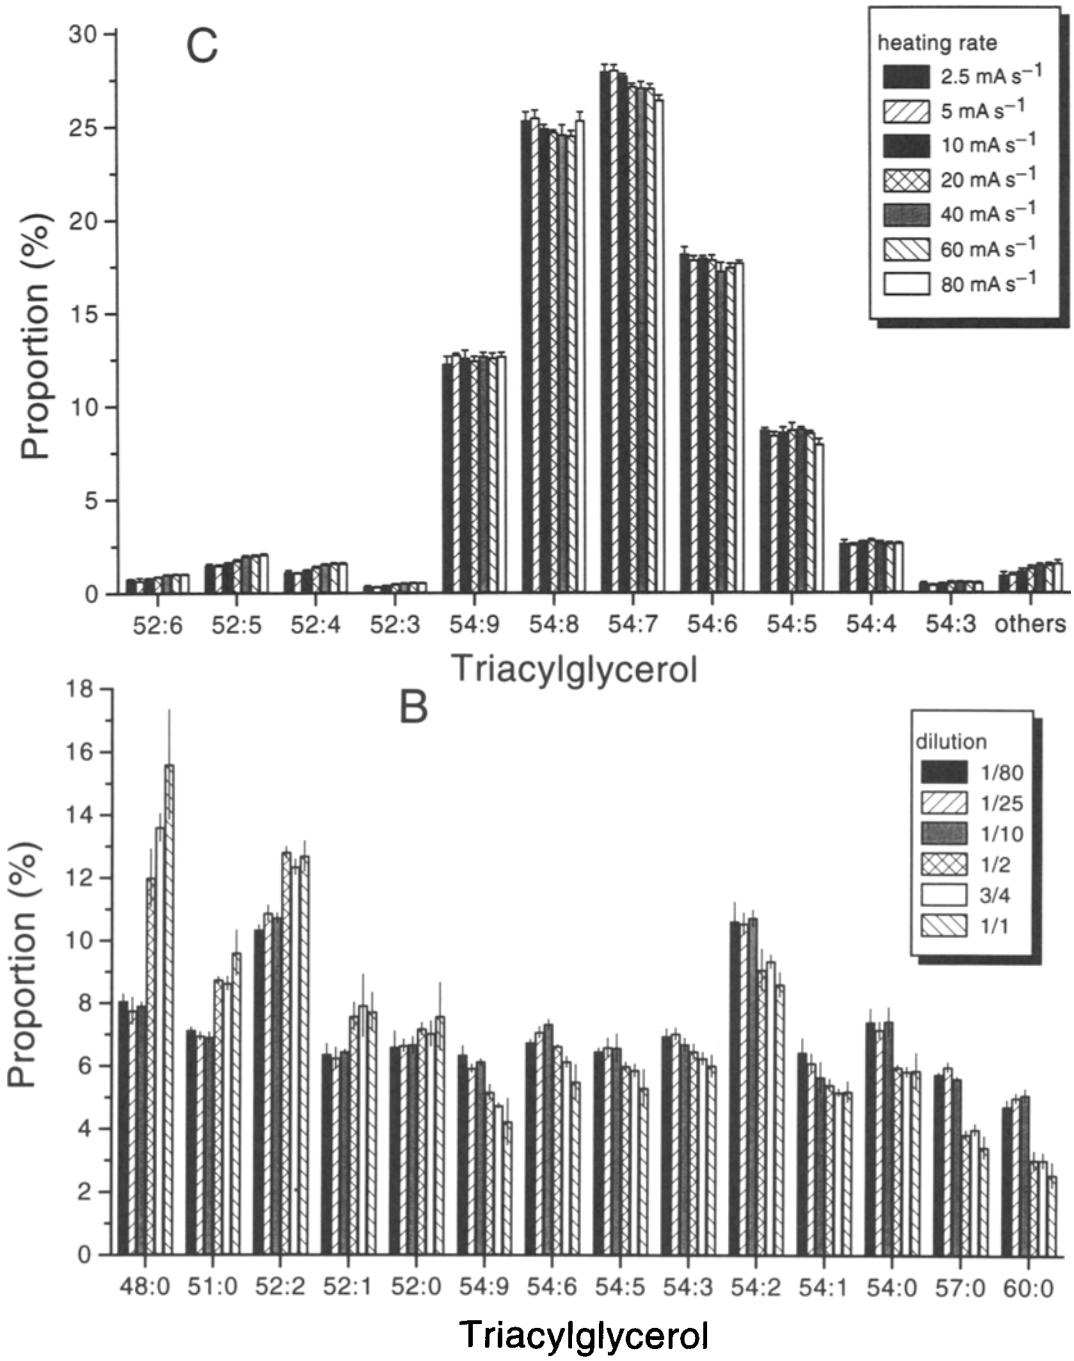

FIG. 5. The effect of concentration on the proportions of triacylglycerols of the reference mixture A (see Table 1) using A, a low (4 mA s^{-1}) and B, a high (80 mA s^{-1}) heating rate of the direct exposure probe. A volume of 0.5 µL of sample was applied to the rhenium wire of the direct exposure probe. The proportions of triacylglycerols are based on the ^{13}C corrected intensities of $[M - H]^-$ ions of four analyses. Reactant gas pressure, 8500 mtorr; and ion source temperature, 200°C.

most seed oils. Minor differences in the distribution may be explained by changes occurring in the sample as well as how the instrument has been tuned.

Mass spectrometric analysis of TAG using ammonia negative-ion CI is a fast and useful method to determine the molecular weight distribution of TAG. Information is obtained on both the number of acyl carbons and double bonds in TAG and the proportions of different molecular weight species. Although we have optimized the analytical conditions for the determination of TAG present in berry seed oils, the method can also be applied to other samples containing mainly TAG with 52, 54, and 56 acyl carbons. The analysis of more complex samples containing either a wide range of TAG with different molecular sizes, such as milk fat, or highly unsaturated

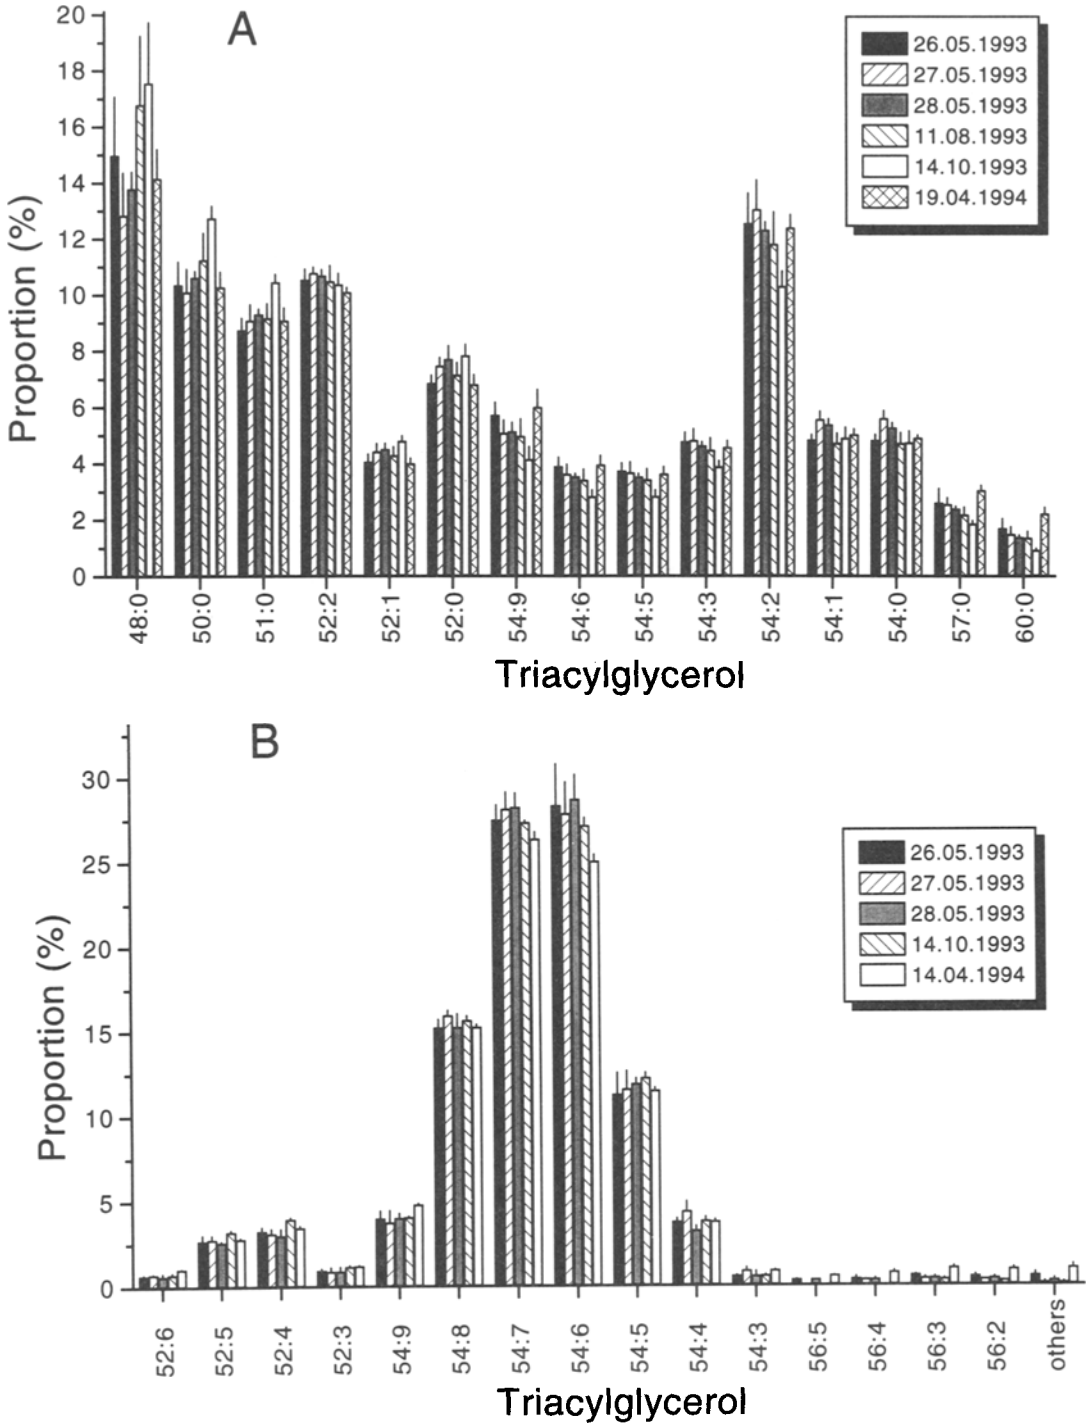

FIG. 6. The repeatability and reproducibility of the mass spectrometric determination for the molecular weight distribution of triacylglycerols: A, reference mixture B (see Table 1), and B, raspberry seed oil. The proportions of triacylglycerols are based on the ^{13}C corrected abundances of $[M - H]^-$ ions of four analyses. Reactant gas pressure, 8500 mtorr; and ion source temperature, 200°C.

components, such as fish oils, may require further optimization of the conditions. In the case of complex samples, it may be advantageous to separate or fractionate the samples, e.g., by chromatography prior to MS determination. This would facilitate the interpretation of the results. Compared with MS, unit resolution of TAG cannot be achieved with either GC or HPLC; GC is not suitable for the analysis of highly unsaturated TAG because of their thermal degradation and polymer-

TABLE 2
Correction Factors for Triacylglycerols in Relation to Tripalmitoylglycerol Using a Slow and Rapid Heating of the Direct Exposure Probe

	Correction factor[a]

[a]The ^{13}C corrected abundances of $[M-H]^-$ ions were corrected to correspond an equimolar amount of each triacylglycerol before calculating the correction factors as the abundance of $[M-H]^-$ ion of 48:0 divided by the abundance of $[M-H]^-$ ion of the analyte.
[b]Different dilutions (vol_{stock}/vol_{tot}) of the reference mixture A (see Table 1).

ization at the temperatures needed for analysis; and a problem with HPLC is the lack of universal detector without sample discrimination, although light-scattering detectors are useful for many applications. In addition, the mass spectrometric analysis of TAG *via* a direct exposure probe is a very fast method—one analysis takes only 2–3 min. In this study, we have demonstrated that the analysis of TAG, without discrimination according to molecular size or unsaturation, is possible under well controlled mass spectrometric conditions (optimized CI conditions, small enough sample amount). These findings have not yet been verified with other instruments in other laboratories. However, similar results should be achievable elsewhere with comparable instruments after optimization of the analysis of TAG. This technique allows rapid determination of TAG profile, which is very informative in addition to the fatty acid composition of the sample, for example for the needs of quality control in the food industry. Molecular species information could be valuable to improve technological properties of various products or to design products for special purposes, e.g., milk substitutes for infants. This technique may also allow rapid determination of adulterations of various fats and oils, if there are enough differences in the native TAG compositions of the different raw materials.

Vitamin E Protects Chick Tissues Against *ex vivo* Oxidation of Heme Protein

Haripriya T. Madabushi, Cathérine L.C. De Mulder, and Al L. Tappel*

Department of Food Science and Technology, University of California, Davis, California 95616

ABSTRACT: Protection by dietary vitamin E against *ex vivo* oxidation of heme proteins in liver and heart tissues of chicks was studied. A previously developed assay consisting of deconvoluting spectra obtained from tissue homogenates to measure oxidation of heme proteins proved successful. Compared to liver and heart from chicks fed the basal diet, the tissues from chicks receiving vitamin E exhibited less oxidation.
Lipids 31, 43–46 (1996).

Vitamin E is recognized as the major lipid antioxidant which is important in protecting tissues against oxidative damage and diseases (1). The purposes of this study were to study the protection against homogenate oxidative damage by dietary vitamin E; to test oxidation of heme proteins as a measure of oxidative damage; and to extend studies to another animal, the chick, which utilizes lipids and vitamin E differently than other laboratory animals, such as the rat.

The results of this study show protection by vitamin E of chick liver and heart homogenates against oxidative damage to heme proteins. The usefulness of the heme protein spectra analysis program (HPSAP), a recently developed method of measuring oxidized heme proteins, is confirmed.

MATERIALS AND METHODS

Animals and diets. Twelve male white leghorn day-old chicks were assigned to two groups fed either basal diet (Diet B) or Diet B plus vitamin E (B + E). Diet B, Dyets #13600 (Dyets Inc., Bethlehem, PA) was adequate for growing chicks in all nutrients except vitamin E. Diet B contained 200 g/kg diet soy protein, 4 g/kg DL-methionine, 424 g/kg corn starch, 200 g/kg dextrose, 50 g/kg cellulose, 50 g/kg tocopherol stripped corn oil, 60 g/kg salt mix #236001, 10 g/kg vitamin mix, and 2 g/kg choline bitartrate. For one group of chicks, Diet B was supplemented with 50 IU/kg vitamin E (Diet B + E). The chicks were on the experimental diets for a period of three weeks.

Preparation, oxidative reactions, and spectrophotometric measurement of tissue homogenates. Chicks were decapitated, and nonperfused liver and heart were dissected and frozen immediately. One gram of the frozen tissues was homogenized with 9 mL oxygenated Krebs-Ringer phosphate buffer containing glucose (10 mmol/L, pH 7.4) in a motor-driven tissue homogenizer. One and a half mL of tissue homogenate was incubated at 37°C in a gyratory water bath shaker (New Brunswick Scientific Co., Inc., New Brunswick, NJ) with continuous shaking (180 cycles/min).

After the incubation, 0.6 mL of tissue homogenate was mixed with 0.6 mL of glycerol. The sample was scanned from 500–640 nm, and the absorbance vs. wavelength at 5 nm intervals was automatically recorded by a scan program in a Beckman DU-50 spectrophotometer (Beckman Instruments, Inc., Fullerton, CA).

Absorbance spectra of the tissue heme proteins were analyzed with an HPSAP recently developed in this laboratory (2). The program contains literature values of micromolar extinction coefficients from 500 to 640 nm in 5 nm increments of heme compounds known to exist in liver and heart. The heme protein spectra included in the program are oxyhemoglobin, deoxyhemoglobin, methemoglobin, ferrylhemoglobin, and hemichrome. The corresponding myoglobin derivatives have essentially identical spectra. The program also contains the micromolar extinction coefficients for combined mitochondrial cytochromes and combined microsomal cytochromes. Micromolar extinction coefficients for reduced and oxidized mitochondrial and microsomal cytochromes are calculated according to the ratio of these compounds in chicken liver and heart. The HPSAP also contains a turbidity factor, which previous research has shown to be a linear function of wavelength, with a slope of −1.3 under the experimental conditions used in the study.

To determine micromolar concentrations of heme proteins, absorbance data were entered into the HPSAP. Quantitative determination of the heme compounds in the sample was achieved by a successive approximations fit between the experimental and calculated spectra. The calculated spectrum is based on the assumption that heme compounds closely obey Beer's law. The HPSAP records and subtracts from the absorbance of the sample any contribution due to turbidity in the sample and calculates the mole percent from the micromolar concentration of the individual heme compounds present in the sample.

Statistical analysis. The statistical package SAS (SAS Institute Inc., Cary, NC) was used to analyze all the experimen-

tal data. When significant F-values were obtained using analysis of variance, Duncan's least significant difference procedure was used to determine significant differences ($P < 0.05$) between treatment means.

The sum of squared differences (SSD) was used to evaluate the reliability of HPSAP in analyzing heme proteins in tissue homogenates by reconciling the experimental spectrum (as recorded by the spectrophotometer) and the calculated spectrum (determined with HPSAP). The SSD is calculated as follows: SSD = Σ (calculated absorbance − experimental absorbance) 2. The best fit is indicated as the SSD approaches zero.

RESULTS

Figures 1 and 2 show the data points for representative experimental spectra obtained at timed intervals during the oxidation of liver and heart homogenates from chicks fed basal diet (B) or basal diet supplemented with vitamin E (B + E). The experimental spectra typically have an absorbance of 1 of background turbidity due to absorbances of homogenate components other than the heme proteins. These experimental spectra are subjected to analytical deconvolution with HPSAP. Table 1 shows some representative analyses with HPSAP. The heme protein concentrations are calculated in μM, but because there are different concentrations in each sample from nonperfused tissue, the concentrations of individual and total heme proteins are normalized to mole percent.

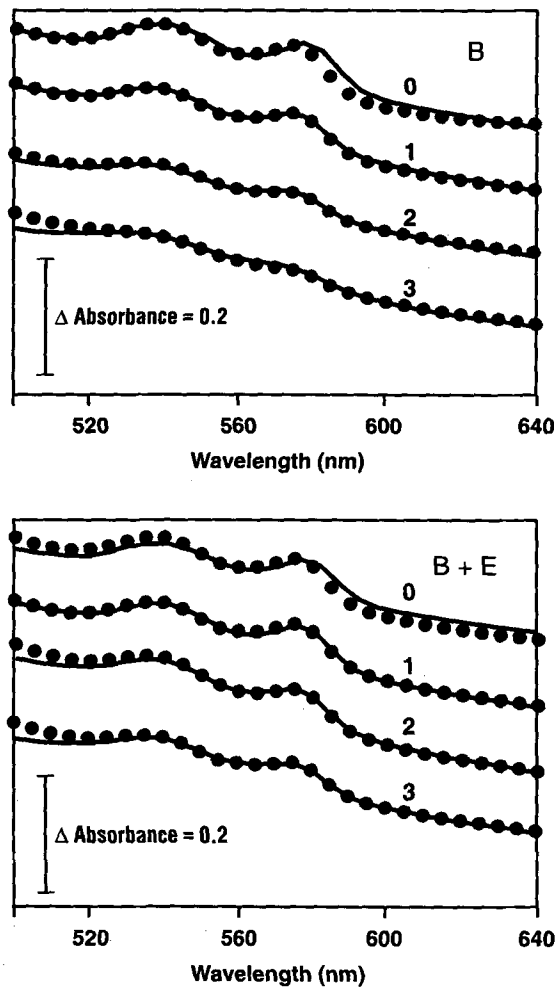

FIG. 1. Visible spectra of heme proteins in liver homogenates incubated at 37°C; 0 h (0); 1 h (1); 2 h (2); 3 h (3); •••, experimental data for spectra; ——, spectra calculated *via* heme protein spectra analysis program. Liver homogenates were from chicks fed basal Diet (B) or basal diet + vitamin E (B + E).

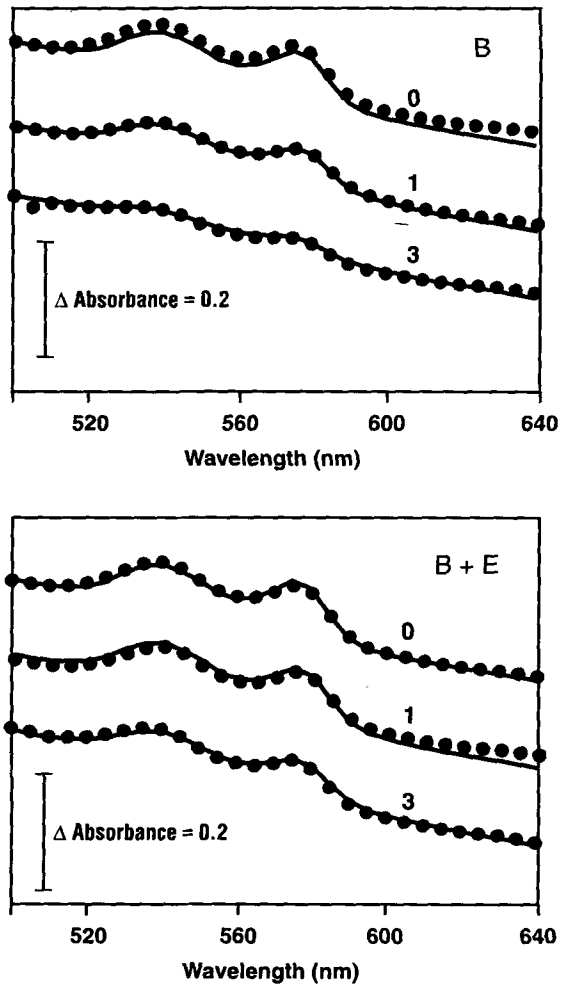

FIG. 2. Visible spectra of heme proteins in heart homogenates incubated at 37°C; 0 h (0); 1 h (1); 3 h (3); •••, experimental data for spectra; ——, spectra calculated *via* heme protein spectra analysis program. Heart homogenates were from chicks fed basal diet (B) or basal diet + vitamin E (B + E).

The low SSD values confirm the very good fits between the experimental spectral data and the calculated spectra, representing the sum of the spectra of the calculated heme proteins as shown in Table 1.

To further examine the correspondence between the experimental spectral data and the calculated spectra, the calculated spectra are superimposed on the experimental data as shown in Figures 1 and 2. The SSD was calculated for 90 spectra an-

TABLE 1
Heme Proteins Present in Liver and Heart Homogenates After Oxidation as Calculated with HPSAP[a]

	Liver				Heart

alyzed during the course of this work, and SSD values ranged from 0.00029 to 0.0170. Eighty percent of the SSD were below 0.0035, and 90% were less than 0.0055.

The experimental results of incubating liver and heart homogenates under oxidizing conditions can be seen in Figures 1 and 2 and Table 1. In the nonperfused liver, oxyhemoglobin from the blood is the dominant heme protein at 0 h. In the nonperfused heart, oxyhemoglobin and oxymyoglobin are the dominant heme proteins at 0 h. The spectra of both oxyhemoglobin and oxymyoglobin have the characteristic peaks at 545 and 577 nm. As the heme proteins in the homogenates oxidize with increasing incubation time, the spectra in Figures 1 and 2 and the analyses in Table 1 show the progressive formation of methemoglobin–metmyoglobin and hemichromes which have flatter spectra than oxyhemoglobin–oxymyoglobin.

The concentrations of α-tocopherol in liver tissue from chicks fed Diets B and B + E were <4 and 28 ± 5 μg α-tocopherol/g tissue, respectively. The concentrations of α-tocopherol in heart tissue from chicks fed Diets B and B + E were <4 and 18 μg α-tocopherol/g tissue, respectively (3).

The calculated heme proteins, for which Table 1 shows representative data, were totaled and averaged in Table 2 to show the mole percent oxidized heme proteins as a function of incubation time and vitamin E status. Table 2 records the decreased mole percent of oxidized heme proteins of liver and heart from chicks fed the Diet B + E compared to oxidized heme proteins from chicks fed only basal diet. These antioxidant effects were highly significant for liver homogenates ($P < 0.0006$) and heart homogenates ($P < 0.0014$). It is interesting to compare this data for the chick to similar data for the rat. The increase in percent oxidized heme proteins for liver from chicks on the basal diet compared to Diet B + E correlated with similar data from rats (4) with r = 0.99 ($P < 0.01$).

TABLE 2
Effects of Vitamin E on Total Oxidized Heme Proteins in Liver and Heart Homogenates

		Mole % oxidized heme proteins	
Tissue	Incubation time (h)	Basal diet	Basal diet + vitamin E
Liver	0	0	0
	1	44.4 ± 9.3	18.5 ± 11.0
	2	50.7.± 9.4	36.0 ± 20.7
	3	73.3 ± 11.9	43.2 ± 27.3
Heart	0	0	0
	1	27.7 ± 11.1	18.2 ± 15.0
	3	51.9 ± 11.4	29.6 ± 7.3

DISCUSSION

To understand damaging biological oxidative processes, it is necessary to quantify damage to proteins, lipids, and other cellular components. The quantitation of mixtures of heme proteins in biological systems has long been a problem. This is evidenced by the many spectra presented in the literature without quantitation. HPSAP has been developed (2) as a tool for multicomponent analysis using a full spectrum method. As shown in this research on chick tissues, this method is a powerful and versatile tool for analyzing heme proteins and their oxidative products. SSD is an appropriate statistical technique of evaluating the HPSAP. The low SSD values demonstrate that HPSAP is an accurate method for fitting spectra and thus for measuring oxidation of heme proteins.

HPSAP has been applied to spectra of mixtures of heme proteins from the literature including reflectance spectra of human skin *in vivo* and to laboratory preparations of these mixtures, including the complex spectra presented by tissue slices and homogenates, with equally good results (2).

This method is applicable to investigations of oxidative damage to animal tissues by toxic oxidants (4). HPSAP is also useful in studies of the protective effects of nutrient lipid antioxidants against oxidative damage to tissues (5,6).

Dietary vitamin E is known to be deposited in liver and heart of many animals (7). Vitamin E protects tissues against the major deteriorative processes, mainly lipid peroxidation. In a study of vitamin E protection against heme protein oxidation and lipid peroxidation in chicken liver slices, lipid peroxidation as measured by the production of thiobarbituric acid reacting substances has been found to correlate with heme protein oxidation (8).

The present study provides information on the protection by dietary vitamin E in the chick of liver and heart homogenates against heme protein oxidation. Because there is little information in the literature on comparative rates of tissue homogenate oxidations, it is significant to find the strong correlation between the rates of formation of oxidized heme proteins in chick and rat liver.

Protection by Multiple Antioxidants Against Lipid Peroxidation in Rat Liver Homogenate

Hao Chen[a] and Al Tappel[b,*]

[a]Department of Pharmacology, School of Medicine, University of Washington, Seattle, Washington and
[b]Department of Food Science and Technology, University of California, Davis, California

ABSTRACT: The purpose of this study was to test the hypothesis that multiple antioxygenic nutrients provide increased protection against lipid peroxidative damage to rat liver. Rats were fed diets (i) deficient in vitamin E and selenium (Diet 1), (ii) supplemented with vitamin E and selenium (Diet 2), (iii) supplemented with (ii) and in addition trolox C, *N*-acetylcysteine, coenzyme Q_0, and (+)-catechin (Diet 3), or (iv) supplemented with (iii) and in addition β-carotene, ascorbic acid palmitate, canthaxanthin, and coenzyme Q_{10} (Diet 4). Liver homogenates were obtained from three rats fed each of the diets for six weeks and were incubated at 37°C up to two hours with and without exogenous tertiary-butyl hydroperoxide (TBHP) or Cu^{2+}. Lipid peroxidation was determined by measurement of thiobarbituric acid substances. Diets 2 and 3 significantly protected against *in vivo* hepatic lipid peroxidation, and this protection was augmented by Diet 4. Diets 2, 3, and 4 were protective against mild oxidation induced by TBHP or Cu^{2+}. During incubations with exogenous TBHP and Cu^{2+}, there were only small differences between diets supplemented with antioxidants in inhibition of lipid peroxidation, indicating that diets supplemented with vitamin E and selenium (Diet 2) may have provided the maximal protection for liver. The possible mechanisms of protection provided by multiple antioxidants in diets were discussed. Protection by multiple antioxidants against lipid peroxidation may translate to prevention of peroxidative damage to human tissue, a factor in human disease.
Lipids 31, 47–50 (1996).

Lipid peroxidation, the major free radical reaction in cellular membranes, can cause serious oxidative damage to animal cells and tissues. Reactive oxygen species generated from lipid peroxidation rapidly interact with proteins, enzymes, and DNA molecules. Consequences of such interactions are involved in the development of various disease states such as atherosclerosis, cardiovascular disease, degenerative diseases, and cancer (1,2).

Vitamin E, ascorbic acid, thiol compounds, carotenoids, coenzyme Q, and flavonoids are potent antioxidants that can effectively inhibit lipid peroxidation and thus protect tissues against oxidative damage (3–5). Supplementary dietary antioxidants have shown beneficial effects in prevention of certain diseases. For example, some epidemiological studies have shown that dietary intake of high doses of vitamin E is associated with a reduced risk of heart disease (6).

If individual antioxidants can effectively inhibit lipid peroxidation both *in vitro* and *in vivo* as suggested by the above studies, it would be expected that a system containing multiple antioxidants could be more effective in protecting tissues against oxidative damage. First, multiple antioxidants in a system would provide complementary antioxygenic functions. A system containing both fat-soluble and water-soluble antioxidants will be more effective than a system containing only fat-soluble or water-soluble antioxidants because the former is capable of intercepting reactive oxygen species from both aqueous and lipid phases (3). Second, synergistic interaction could strengthen the functions of individual antioxidants. The antioxygenic functions of vitamin E can be augmented when ascorbic acid is present due to the participation of ascorbic acid in the regeneration of vitamin E (7). Third, addition of multiple antioxidants to diets would increase the total quantity of antioxidants. Recently, there have been studies of the effects of multiple antioxidants in cellular defense against oxidative damage (8–10).

The purpose of this study was to test the concept that diets containing multiple antioxidants would be more effective in protection of liver against lipid peroxidation. The diets were supplemented with vitamin E, trolox C (the water-soluble vitamin E analog), selenium, a thiol compound, carotenoids, coenzyme Q, ascorbic acid palmitate, and (+)-catechin, a flavonoid. There are three primary reasons for choosing these antioxidants. These antioxidants have shown strong protection against lipid peroxidation at least in *in vitro* systems. In addition, most of these antioxidants are present in human foods so that the results from this study would be applicable to people. Finally, effects of combinations of these dietary antioxidants have not been studied thoroughly. In this study, rats were fed either an antioxidant-deficient diet or diets containing multiple antioxidants for six weeks. To test the effectiveness of diets supplemented with antioxidants in protection against lipid peroxidation, liver homogenates were incubated at 37°C with and without the addition of the exogenous prooxidants tertiary-butyl hydroperoxide (TBHP) and Cu^{2+}.

TBHP is a representative toxic hydroperoxide, a class of compounds constantly formed in small amounts in normal metabolism. Cu^{2+} is a trace element which can initiate lipid peroxidation *in vivo*. Lipid peroxidation was measured as thiobarbituric acid-reactive substances (TBARS). The results from spontaneous lipid peroxidation provided information on the protection by multiple antioxidants against oxidative damage under conditions close to the *in vivo* situation. The results from lipid peroxidation induced by TBHP or Cu^{2+} showed the degree of effectiveness of multiple antioxidants in inhibition of lipid peroxidation initiated by specific prooxidants.

MATERIALS AND METHODS

Chemicals. The antioxidants and chemicals used in this study were (+)-α-tocopherol acid succinate (1210 I.U./g), sodium selenite (Alfa Inorganics, Beverly, MA), trolox C (Aldrich Chemical Co., Milwaukee, WI), coenzyme Q_0, coenzyme Q_{10}, (+)-catechin, dimethyl sulfoxide, β-carotene, ascorbic acid palmitate, *N*-acetylcysteine (Sigma Chemical, St. Louis, MO), canthaxanthin (Roche Vitamin and Fine Chemicals, Nutley, NJ), TBHP (Polysciences, Inc., Warrington, PA), and cupric chloride ($CuCl_2$) (Merck & Co. Inc., Rahway, NJ).

Animals and diets. Male Sprague-Dawley rats (Bantin & Kingman, Fremont, CA), weighing 40–60 g, were adapted for two days before being fed experimental diets. The basal diet (Diet 1) was deficient in vitamin E and selenium with 10% tocopherol stripped corn oil (Teklad Test Diet No. TD 77068, mineral mix No. 170911; Teklad Test Diets, Madison, WI). Animals were housed according to National Institutes of Health guidelines and had free access to deionized water and diets. Diets supplemented with antioxidants were divided into three groups: Diet 2, containing 25 mg vitamin E/kg diet and 0.3 mg selenium/kg diet; Diet 3, containing vitamin E, selenium, and the water-soluble antioxidants 50 mg trolox C/kg diet, 200 mg *N*-acetylcysteine/kg diet, 100 mg coenzyme Q_0/kg diet; and Diet 4, containing vitamin E, selenium, the water-soluble antioxidants and the fat-soluble antioxidants 30 mg coenzyme Q_{10}/kg diet, 45 mg β-carotene/kg diet, 45 mg canthaxanthin/kg diet, 100 mg ascorbic acid palmitate/kg diet. The (+)-catechin/kg diet (100 mg) was added to Diets 3 and 4 as a representative flavonoid. The rats were fed the experimental diets along with distilled water for six weeks.

Preparation of liver homogenates. The rats were decapitated, and livers were immediately dissected and immersed in ice-cold Krebs-Ringer phosphate buffer (pH 7.4). Livers were blotted with filter papers and stored at −22°C. Frozen livers were cut into 0.5 cm^3 cubes, and homogenates were prepared by homogenizing 1 g of liver with 9 mL of oxygenated buffer containing glucose (10 mmol, pH 7.4). A motor-driven tissue homogenizer was used.

Oxidation of homogenates and measurement of TBARS. Oxidation of tissue homogenates and measurement of TBARS followed the method described by Tappel and Zalkin (11) with some modifications. Two mL of homogenates were transferred to a 10-mL glass serum bottle containing 3 mL of oxygenated 0.9% NaCl. TBHP or Cu^{2+} for a final concentration of 0.1–1.0 mM, was added to the serum bottle immediately before the reaction began. The homogenates were incubated in the water-bath shaker at 37°C with continuous shaking (180 cycles/min). After incubation, the bottles were cooled with dry ice. Homogenates (2.5 mL) were transferred to a 10-mL centrifuge tube containing 2.5 mL of 10% trichloroacetic acid. The homogenates were centrifuged at 3000 rpm for 2 min at 4°C. After centrifugation, 4 mL of supernatant were reacted with 1.25 mL of 0.75% thiobarbituric acid (freshly prepared) at 100°C for 10 min. The resulting pink color was measured at 530 nm. TBARS were expressed as malondialdehyde equivalents per gram tissue.

The statistical package SAS (SAS Institute Inc., Cary, NC) was used to analyze all data. When significant F-values were obtained using analysis of variance, Duncan's least square means procedure was used to determine the significant difference ($P \leq 0.05$) between treatment means. Results were expressed as means ± standard deviation.

RESULTS

Time course of protection by antioxidants with or without prooxidants. Dietary treatments had no effect on the weight gained by the animals. No exogenous prooxidants were introduced to the incubation vessels during spontaneous lipid peroxidation (time 0). The concentrations of TBARS in liver homogenate from rats fed an antioxidant-deficient diet (Diet 1) rose substantially as incubation time increased (Fig. 1). Addi-

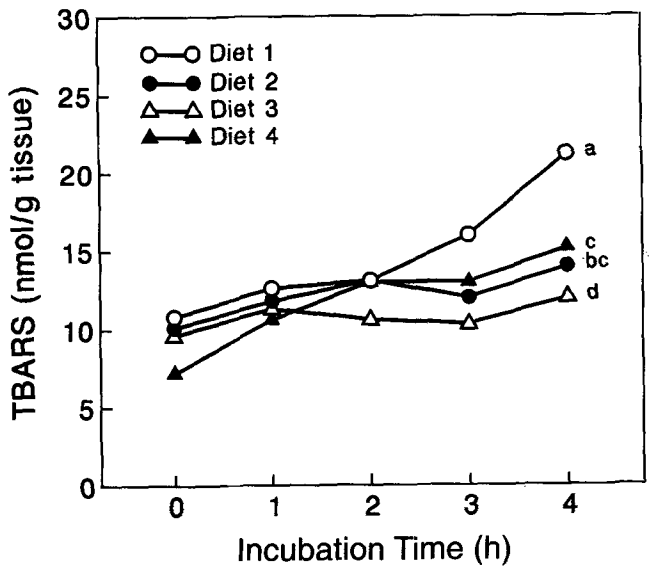

FIG. 1. Time course of spontaneous lipid peroxidation in liver homogenate showing protection by antioxidants; Diet 1 (basal diet). Liver homogenates were incubated at 37°C. Five timed measurements were taken from homogenates obtained from each rat. The values are expressed as mean for three rats. Curves not sharing a common letter are significantly different from each other at a 95% confidence level. The amounts of thiobarbituric acid-reacting substances (TBARS) are denoted by the alphabetic order with "a" as the largest and "d" as the smallest.

tional vitamin E and selenium (Diet 2) inhibited the formation of TBARS, particularly during the relatively long periods of incubation (3 and 4 h). Diets enriched with water-soluble antioxygenic nutrients (Diet 3) significantly augmented protection against lipid peroxidation provided by Diet 2. In the *in vivo* situation (incubation time 0), Diet 4, enriched with both water- and fat-soluble antioxidants, provided significantly better protection against lipid peroxidation than either Diets 2 or 3. As incubation proceeded, however, Diet 4 protected liver as effectively as Diet 2, but less effectively than Diet 3.

In the reactions induced by either TBHP or Cu^{2+}, dietary supplementation by vitamin E and selenium significantly lowered the production of TBARS only after 2 h and Cu^{2+} after 0.5 and 1.0 h (Fig. 2). Feeding Diet 4 markedly decreased *in vivo* lipid peroxidation compared to Diets 2 and 3. With additional antioxidants as incubation time progressed, there was no further decrease in the production of TBARS.

Protection by antioxidants against various concentrations of prooxidants. As the concentration of prooxidants increased in the incubated homogenates from the four dietary groups, the production of TBARS rose correspondingly in the systems induced by TBHP or Cu^{2+} (Fig. 3). When Cu^{2+} induced lipid peroxidation, the addition of vitamin E and selenium to the basal diet (Diet 2) suppressed the production of TBARS through 1.0 mM Cu^{2+}, and in the reaction initiated by TBHP Diet 2 suppressed TBARS through the 0.8 mM level of the inducer. Diet enriched with water-soluble antioxidants (Diet 3) improved the protection provided by Diet 2 for liver incubated with 0.8 and 1 mM TBHP but not with Cu^{2+}. In contrast, diet enriched with a full complement of antioxidants (Diet 4) appeared to offer no greater protection than that provided by Diet 2 for liver incubated with various concentrations of TBHP or Cu^{2+}.

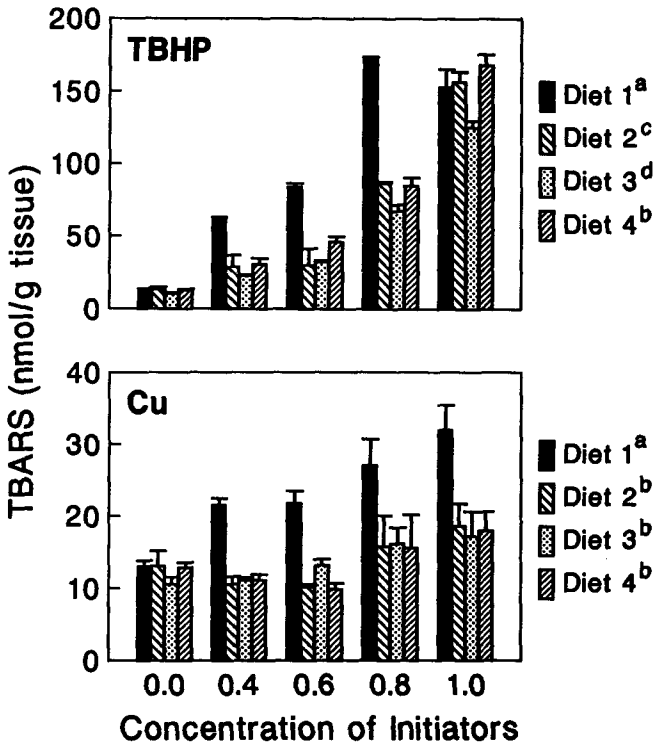

FIG. 3. Protection by antioxidants against lipid peroxidation of liver tissues induced by concentrations of TBHP or Cu^{2+} ranging from 0 to 1.0 mM. Liver homogenates were incubated at 37°C for 2 h. Five measurements were taken from homogenates obtained from each rat. The values are expressed as mean for three rats. TBARS of the concentration sequence of initiators not sharing common superscript letters are significantly different from each other at a 95% confidence level. The amount of TBARS is denoted by alphabetic order with "a" as the largest and "d" as the smallest. See Figures 1 and 2 for abbreviations.

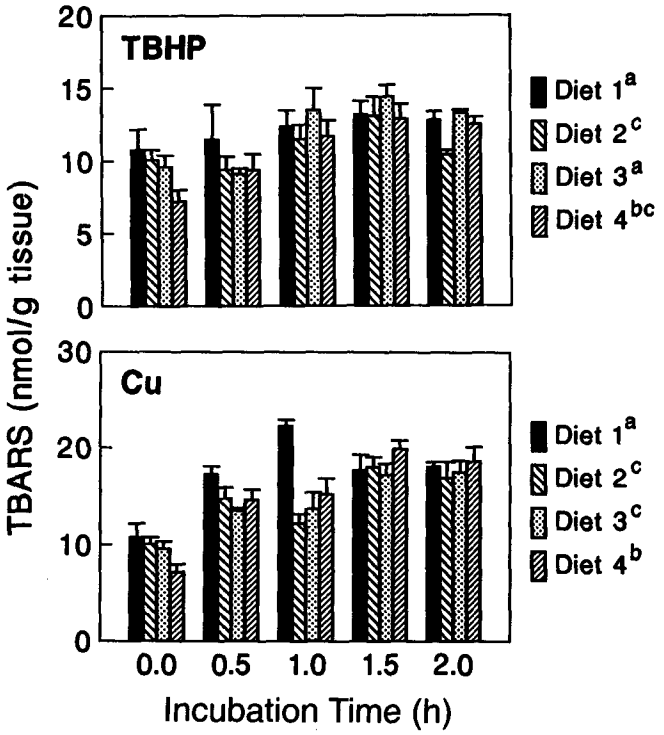

FIG. 2. Time-course study of the protection by antioxidants against lipid peroxidation of liver homogenates induced by tertiary-butyl hydroperoxide (TBHP) or Cu^{2+}. Liver homogenates were incubated at 37°C with 0.1 mM TBHP or Cu^{2+}. Five timed measurements were taken from homogenates obtained from each rat. The values are expressed as mean for three rats. The time sequence of TBARS not sharing a common superscript letter are significantly different from each other at a 95% confidence level. The amount of TBARS are denoted by the alphabetic order with "a" as the largest and "e" as the smallest. See Figure 1 for other abbreviation.

DISCUSSION

The antioxidants were chosen for this experimental study because there is a considerable amount of biochemical knowledge about each of them in the scientific literature: vitamin E, selenium, ascorbic acid palpitate, acetylcysteine, and coenzyme Q (1); trolox-C (12); β-carotene (2); and (+)-catechin (10). Previous studies have analyzed the deposition in vari-

ous tissues following dietary supplementation by vitamin E and selenium (8) and coenzyme Q (13), and β-carotene (14).

This research, using many antioxidants, is exploratory. Discussion of results is more empirical than mechanistic. The most important observation (Fig. 1) is that Diet 4 containing the most diverse antioxidants effected the lowest initial level of TBARS in the *in vivo* situation (incubation at 0 min). The superior performance of Diet 3 from 2–4 h and Diet 4 at 0 time may be attributed to the diversity of the antioxidants present in the diet, the level of concentration of the antioxidants, and synergistic effects among the antioxidants.

Antioxidants can inhibit lipid peroxidation either by reducing the rate of chain initiation (preventive antioxidants) or trapping free radicals (chain-breaking antioxidants) or both modes of action (1). Carotenoids, vitamin E, coenzyme Q, and flavonoids are excellent preventive antioxidants, due to their unusual ability to quench singlet oxygen (15–17). Vitamin E, ascorbate, and trolox C are potent chain-breaking antioxidants, due to their large rate constants for the reaction with peroxyl radicals. Apparently, the combination of preventive and chain-breaking dietary antioxidants, such as Diets 3 and 4, strengthens the protective effect against lipid peroxidation provided by Diet 2 that was supplemented with only vitamin E and selenium.

One important feature of Diets 3 and 4 is that they contain both lipid-soluble and water-soluble antioxidants. Even though lipid peroxidation occurs in the lipid phase, mainly in membranes, it can be accelerated by the attack from aqueous peroxyl radicals. Water-soluble antioxidants thus can inhibit lipid peroxidation by interacting with aqueous free radicals (1). For example, experiments have shown that ascorbate is the most effective antioxidant against lipid peroxidation in human blood plasma (17). In this study, the presence of both water- and lipid-soluble antioxidants in the diet also shows significant improvement of protection against *in vivo* lipid peroxidation compared to the diet supplemented only with water-soluble antioxidants.

During incubations with exogenous TBHP or Cu^{2+}, Diets 3 and 4 showed augmented protection over that of Diet 2 against *in vivo* lipid peroxidation in liver (Fig. 2), confirming the inhibition of *in vivo* spontaneous lipid peroxidation shown by Diets 3 and 4 (Fig. 1). With increased incubation times and concentrations of initiators, vitamin E and selenium (Diet 2) may have provided maximal protection against lipid peroxidation induced by TBHP and Cu^{2+} (Figs. 2 and 3). Further increase of quantity and variety of antioxidants offered very little or no improvement.

The results of the present study may be applicable to multiantioxidant protection of tissue and foods against oxidative damage.

ACKNOWLEDGMENT

We thank Roche Vitamin and Fine Chemicals for providing canthaxanthin for this study.

Dietary Fat and Neural Development

Robert A. Gibson[a], Maria Makrides[a], and Andrew J. Sinclair[b,*]

[a]Department of Paediatrics and Child Health, Flinders Medical Centre, Bedford Park, South Australia and [b]Department of Food Science, RMIT, Melbourne, Victoria, Australia

The concept that dietary fats are capable of not only altering the polyunsaturated fatty acid (PUFA) composition of neural tissue, but also can result in altered neural function is relatively new, and it is exciting research attention worldwide. For this reason we offered to organize a one-day symposium during the AOCS Annual Meeting & Expo at the Henry B. Gonzalez Convention Center in San Antonio, Texas, which took place May 7–11, 1995. This symposium was entitled "Dietary Fat and Neural Development." The meeting was designed to bring together the leading workers in the field under the auspices of a learned society (most meetings on this topic are organized by individual formula companies) in an environment that allowed for frank and open discussion. The format of the meeting was based on that developed by the organizers in 1992 at the 3rd International Congress of EFA and Eicosanoids, the proceedings of which were published by AOCS Press in 1993. The topics were organized into three main themes—animal studies, PUFA metabolism in humans, and randomized clinical trials involving human infants. Each of the themes was presented as three 20-minute talks followed by at least 40 minutes of discussion. Both the general topic and the discussion-based format seemed to appeal to participants, and despite this event being held on the final day of the AOCS meeting, the room was packed all day and discussion was intense. The level of interest was such that a whole meeting devoted to the difficulties in carrying out research in this area is being sponsored by AOCS in Barcelona, November 7–9, 1996, under the title "PUFA in Infant Nutrition: Consensus and Controversies."

The present issue of *Lipids* contains the papers presented at the symposium in San Antonio and includes reviews and original research articles. We wish to thank Dr. Howard R. Knapp, Editor-in-Chief of *Lipids*, for reviewing the papers and for his careful attention to detail. We are pleased that the papers from this symposium have appeared in print in less than nine months from the date of the meeting. Finally, we would like to thank AOCS, Wyeth-Ayerst, Mead Johnson, Martek Biosciences, Nestle, and Ross Laboratories for their support.

Retinal Fatty Acids of Piglets Fed Docosahexaenoic and Arachidonic Acids from Microbial Sources[1]

Margaret C. Craig-Schmidt[a,*], Kathryn E. Stieh[a], and Eric L. Lien[b]

[a]Department of Nutrition and Food Science, Auburn University, Auburn, Alabama 36849 and [b]Wyeth-Ayerst Laboratories, Nutrition Research Department, Philadelphia, Pennsylvania 19101

ABSTRACT: Docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) serve important roles in perinatal visual and neural development. A neonatal pig model was used to determine if dietary supplementation with DHA and AA at slightly greater concentrations than normally found in human milk would influence fatty acid accretion in retina. One-day-old piglets were assigned to one of four diets (n = 5/group): (i) STD, standard diet containing fat similar to infant formula; (ii) STD + DHA, 0.7% of fatty acids as DHA; (iii) STD + AA, 0.9% as AA; and (iv) STD + BOTH, 0.8% as DHA plus 1.0% as AA. After 25 d, fatty acids in retina phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were determined. Supplementation with DHA resulted in approximately twofold increases ($P < 0.05$) in PC–DHA (4.88% in STD vs. 10.03% in STD + DHA and 9.47% in STD + BOTH). Similarly, AA supplementation increased PC–AA 1.3–1.4-fold (4.47% in STD vs. 6.19% in STD + AA and 5.70% in STD + BOTH). For PE, supplementation with either fatty acid or in combination resulted in no significant increases, except for a 1.2-fold increase in DHA for STD + BOTH (32.66%) vs. STD (28.38%). Thus, PC responded to dietary supplementation, with addition of DHA, AA, or BOTH, resulting in increases in respective fatty acids; PE was less responsive, with only STD + BOTH resulting in increased DHA. No significant competition between DHA and AA in incorporation into phospholipids was observed. In conclusion, consumption of a combination of DHA and AA by neonatal pigs supported accretion of DHA in retina phospholipids, while simultaneously supplying the AA necessary for membrane phospholipids and eicosanoid biosynthesis.

Lipids 31, 53–59 (1996).

Docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) serve important roles in neural development in the perinatal period (1). Retina membrane phospholipids, particularly the phosphatidylethanolamine (PE) fraction, contain large amounts of DHA (2,3). Dietary deficiency in n-3 fatty acids is associated with visual abnormalities in rats (4), in nonhuman primates (5–7), in preterm infants (8–11), and in formula-fed term infants (12). During the perinatal period, AA accumulates in phospholipids and plays a vital role as a membrane component (1), as an eicosanoid precursor, and perhaps as a growth factor (13–16). Both DHA and AA are supplied to the developing infant by human breast milk. The concentration of AA is relatively constant in breast milk at about 0.5% of total fatty acids, whereas DHA concentrations vary from 0.2 to 1.9% of total fatty acids depending on the n-3 fatty acid content of the maternal diet (17–20). The higher concentrations are seen only in populations consuming large amounts of fish (21), or in lactating women whose diets are supplemented with fish oil (22). Typically, DHA concentrations would range from 0.2 to 0.6% of total fatty acids (23). Conventional infant formulas do not contain either of these long-chain polyunsaturated fatty acids.

In fully developed animals, the need for DHA and AA can be supplied by their shorter-chain precursors, α-linolenic acid (LNA, 18:3n-3) and linoleic acid (LA, 18:2n-6). However, in the preterm infant and perhaps in the term infant, formula containing only the shorter-chain precursors may be inadequate to meet the increased demands for long-chain polyunsaturated fatty acids with a chain length of 20 or more carbons (24–27). Various sources of preformed n-3 and n-6 polyunsaturated fatty acids have been added recently to some infant formulas. These include borage oil, evening primrose oil, and black currant seed oil as sources of γ-linolenic acid, egg yolk lipid as a source of AA, and marine lipids as a source of DHA (28). Microbial oils as concentrated sources of DHA and AA are currently available, but their efficacy has not been fully documented. Thus, in the current experiment, a neonatal pig model was used to determine if dietary supplementation with DHA and AA at concentrations only slightly greater than that found in human milk would influence fatty acid accretion in retina phospholipids.

Landrace sows bred to Duroc boars) piglets, weighing at least 1.36 kg at birth, were obtained from the Swine Nutrition Unit, Alabama Agricultural Experiment Station, Auburn University (Auburn, AL). At one day of age, one piglet from each of five litters was assigned randomly to one of four dietary treatments (n = 5/group) for 25 d: (i) STD, a standard diet containing a fat blend similar to that used in some commercial infant formulas; (ii) STD + DHA, standard diet modified to contain 0.7% of total fatty acids as DHA; (iii) STD + AA, standard diet modified to contain 0.9% of total fatty acids as AA; and (iv) STD + BOTH, standard diet modified to contain 0.8% of total fatty acids as DHA and 1.0% as AA. In addition, one piglet from each of the five litters was naturally-reared and was fed sow milk (SOW). The fatty acid composition of the experimental formulas and the sow milk as analyzed is shown in Table 1. The number of piglets remaining in each litter after allocation to formula-fed groups was adjusted by cross-fostering, if necessary, to maintain a constant litter size of five.

The piglets were allowed to suckle for 24 h after birth. Iron dextran injections were given on day 1, but all vaccinations were withheld. All piglets in the four formula-fed groups were housed at the Auburn University School of Veterinary Medicine in stainless-steel cages equipped with heat lamps. From day 1 to day 25, the piglets in the four formula-fed groups were bottle-fed a skim milk-based, sow-milk replacer formula (Pet Ag Inc., Elgin, IL) modified to contain either AA or DHA. Formula fat blends were adjusted to maintain relatively constant amounts of all fatty acids except AA and DHA. All formulas had an LA/LNA ratio of 9:1 (Table 1). Dietary antioxidant content, including β-carotene, was equalized for all formula-fed groups. During the first week, the piglets were fed to appetite five times a day, and after that four times a day. Feed consumption was recorded at each feeding.

The diet of the sows used for the naturally-reared group was a corn/soybean meal diet typically used by commercial swine producers in the United States and formulated to meet National Research Council (NRC) requirements for lactating sows (29). The sow diet was low in fat (2.8% by weight) and contained 1.54% 18:2n-6 and 0.03% 18:3n-3, with an LA/LNA ratio of 50:1. Milk collected from each of the five sows on day 12 of lactation had a LA/LNA ratio of 22:1 and a DHA content of 0.04% of total fatty acids (Table 1). The AA content of the sow milk was 0.7% of total fatty acids.

[a]Fatty acid composition of the standard diet with fatty acid composition similar to that of some current infant formulas (STD); STD + DHA, docosahexaenoic acid-supplemented; STD + AA, arachidonic acid-supplemented; STD + BOTH, DHA-and-AA supplemented; SOW, naturally-reared group fed sow milk.

Weight gain of the piglets was monitored every four days. All procedures involving animals were approved by the Auburn University Institutional Animal Care and Use Committee.

The pigs were euthanized after the 25-d feeding period. Retinas were removed, rapidly frozen in liquid nitrogen, and stored frozen under a blanket of argon gas at −80°C until preparation for fatty acid analysis.

Extraction of retina total lipids, separation of phospholipid classes, and fatty acid analysis. Procedures described by Marcheselli and Bazan (30) were used for homogenization of the tissue, extraction of total lipid, and separation of phospholipid classes. Samples were homogenized in chloroform/methanol (2:1, vol/vol) containing 50 mg/L butylated hydroxytoluene using a glass–glass Duall tissue homogenizer (Kontes Duall tissue grinder; Fisher Scientific, Pittsburgh, PA) (31). For completeness of extraction, the samples were sonicated for 30 min in a sonication bath prior to biphasic separation with the addition of 0.05% $CaCl_2$. The bidimensional thin-layer chromatographic procedure utilizes Silica Gel H plates containing 3% magnesium acetate as binder (Analtech Inc., Newark, DE) and solvent systems consisting of chloroform/methanol/concentrated ammonia (65:25:5, by vol) for the first dimension and chloroform/acetone/methanol/acetic acid/water (3:4:1:1:0.5, by vol) for the second dimension. Individual phospholipid fractions were visualized by spraying with a 0.005% methanolic solution of 2′,7′-dichlorofluorescein and viewing under ultraviolet light. Phospholipid classes were identified by comparison with standards (Matyrea, Inc., Pleasant Gap, PA).

Fatty acids in each phospholipid class were converted to fatty acid methyl ester (FAME) derivatives with 12% boron trifluoride in methanol (Supelco, Bellefonte, PA). Fatty acid composition of the individual phospholipids was determined by gas chromatography using a 30 m × 0.25 mm DB-225 fused silica capillary glass column (J&W Scientific, Folsom, CA). A Varian (Palo Alto, CA) 3400 gas chromatograph equipped with a flame-ionization detector and linked to a Varian 4400 integrator and a Varian autosampler were utilized. The injector and flame-ionization detector temperatures were maintained at 250 and 270°C, respectively. Helium was used as the carrier gas, with a column flow rate of 2.5 mL/s. The initial column temperature was set at 120°C. The column conditions were programmed such that the temperature increased from 120 to 170°C at a rate of 5°C per min, and from 170 to 225°C at a rate 1°C per min. FAME were identified by comparison of relative retention times with commercial FAME standards (Matyrea, Inc.) or with a secondary standard of menhaden oil obtained from NOAA Laboratory (Charleston, SC).

Statistical analysis. The data were analyzed using the general linear models procedure within SAS (32), following a randomized complete block model. Least significant difference was used for mean comparisons when significant treatment differences existed. Significant differences among means were determined at $P = 0.05$.

RESULTS

Initial body weights (mean, 1.79 kg) among the five dietary treatment groups were not significantly different. After 25 d of treatment, body weights for the four formula-fed treatment groups (mean, 10.05 kg) were heavier ($P < 0.05$) than that of the naturally-reared group (mean, 7.85 kg). No significant differences in formula consumption were observed among the four formula-fed groups.

The phosphatidylcholine (PC) fraction was responsive to dietary supplementation, with addition of DHA, AA, or BOTH resulting in increases in the added fatty acids relative to the STD (Fig. 1; Table 2). Supplementation with DHA resulted in twofold increases in percent of total fatty acids in PC–DHA with 4.88% of total fatty acids in STD compared with 10.03% in STD + DHA and 9.47% in STD + BOTH. (Fig. 1A). Other n-3 fatty acids in PC were not affected by addition of DHA or AA to the diet (Table 2). Supplementation with AA resulted in 1.3–1.4-fold increases in PC–AA, with 4.47% in STD compared with 6.19% in STD + AA and 5.70% in STD + BOTH (Fig. 1B). Significant increases in 22:4n-6 and 22:5n-6 were observed when the diet was supplemented with AA alone, but other n-6 fatty acids in PC were not affected by dietary treatment (Table 2). With respect to AA, the fatty acid profile of the naturally-reared group (SOW) was similar to that of the AA supplemented groups, i.e., AA in PC was similar in SOW, STD + AA, and STD + BOTH. The DHA in PC of the SOW was similar to that of STD + AA and STD + BOTH, but greater than the STD and

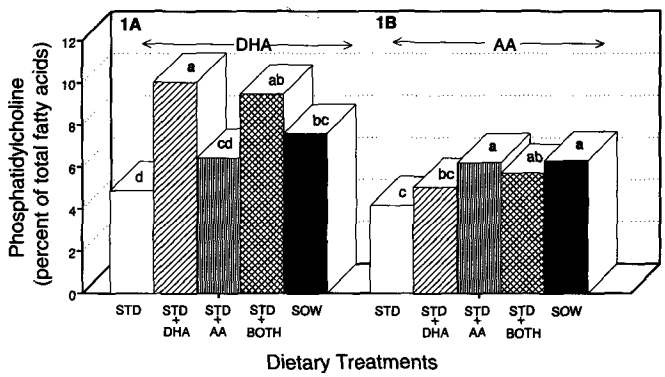

FIG. 1. DHA (1A) and AA (1B) in retina phosphatidylcholine of neonatal pigs in response to dietary treatments: STD, standard diet with fatty acid composition similar to that of some current infant formulas; STD + DHA, docosahexaenoic acid-supplemented; STD + AA, arachidonic acid-supplemented; STD + BOTH, DHA- and AA-supplemented; SOW, naturally-reared and fed sow milk. Treatment means (n = 5) not sharing a common letter are significantly different as determined by least significant difference; $P = 0.05$.

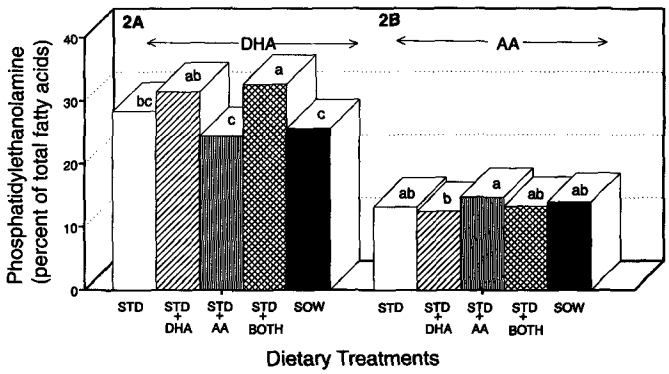

FIG. 2. DHA (2A) and AA (2B) in retina phosphatidylethanolamine of neonatal pigs in response to dietary treatments. Treatment means (n = 5) not sharing a common letter are significantly different as determined by least significant difference; $P = 0.05$. Abbreviations and diet definitions as in Figure 1.

less than the STD + DHA. No significant differences were observed among dietary treatments for any of the individual saturated fatty acids or the monoenes in PC.

For the PE fraction, supplementation with either DHA or AA alone or in combination did not result in significant increases, except for a 1.2-fold increase in DHA for STD + BOTH (32.66%) as compared with STD (28.38%) (Fig. 2; Table 3). The only other fatty acids in PE responding to dietary manipulation were 22:4n-6 and 22:5n-6, which were greater in STD + AA and SOW than in STD. Thus, under the conditions of the current experiment, retina PE was less responsive to dietary supplementation than PC.

DISCUSSION

Supplementation with DHA, AA, or BOTH clearly influenced the fatty acid profile of retina PC. Increases in accretion of these long-chain fatty acids in this phospholipid class were observed when preformed sources were provided in the diet. In contrast, the retina PE fraction, which is the phospholipid fraction containing DHA in particularly high concentrations, was less responsive to dietary supplementation of preformed C_{20-22} long chain fatty acids. The STD + BOTH treatment, but not the STD + DHA treatment, exhibited increased retina DHA in PE in response to supplementation. The changes observed for these two treatment groups compared to the STD were similar in magnitude (e.g., 31.47% for STD + DHA and 32.66% for STD + BOTH vs. 28.38% for STD), and it is possible that the small number of animals in each dietary treatment contributed to the lack of a statistically significant effect between the STD + DHA and the STD groups. Alternatively, the minimal response may be due to efficient mechanisms for acquisition and recycling of the DHA within the retina. Such mechanisms have been described by Anderson *et al.* (33) and Bazan *et al.* (34).

Innis and colleagues (35–37) have used the neonatal pig extensively to study questions similar to those addressed in the present study; however, preformed sources of AA and DHA were not used in any of these earlier studies. Hrboticky

et al. (35) showed that term-gestation piglets fed a vegetable oil-based formula with an LA/LNA ratio of 36.8 exhibited reduced DHA in retina total lipid, PC, and PE compared with piglets fed sow milk containing 0.1% DHA. Compensatory increases in 22:4n-6 and 22:5n-6 were observed in the retina of the formula-fed piglets. In subsequent studies (36,37), feeding formula with LA/LNA ratios ranging from 4 to 22 supported retina DHA accretion in PE in a manner similar to that of the SOW group with a DHA content of 0.1%; in contrast, feeding formula with an LA/LNA ratio of 30, but no preformed DHA, did not support comparable accretion of DHA in retina PE. When fish oil was used as a dietary source of DHA in a formula with 0.3% DHA and an LA/LNA ratio of 26 (36), retina PE–DHA was equivalent to that of the piglets consuming sow milk containing 0.1% DHA and having an LA/LNA ratio of 10. In the current experiment, the LA/LNA ratio of the formulas was held relatively constant at 9:1. If one uses the data of Innis and colleagues (35–37) as a frame of reference, formula containing an LA/LNA ratio of 9:1 but no added DHA should be adequate to support accretion of DHA in retina PE. This prediction is consistent with the observation that addition of preformed DHA alone did not result in significantly greater DHA in retina PE than in the piglets fed the unsupplemented formula. On the other hand, the increase in DHA in retina PE did reach statistical significance for the group fed DHA in combination with AA compared to STD. It is also noteworthy that in the SOW group, DHA in PC was significantly greater than in the STD in spite of the fact that the sow milk had an LA/LNA ratio of 22:1 and a DHA content of only 0.04% of total fatty acids.

[a]Data are presented as means. Means in the same row not sharing a common, nonitalicized superscript are significantly different as determined by least significant difference; $P = 0.05$.
[b]Fatty acid composition of the STD is similar to that of some current infant formulas.
[c]Pooled standard error of the mean based on n = 5, except for 22:1 and 18:3n-3.
[d]Includes 16:1n-9 and 16:1n-7.
[e]Includes 18:1n-9 and 18:1n-7.

In n-3 fatty acid deficiency, 22:5n-6 is increased, presumably to compensate for inadequate 22:6n-3. The ratio of DHA (22:6n-3) to docosapentaenoic acid (22:5n-6) is believed to be a more sensitive indicator of n-3 status than the relative percentages of either fatty acid (38). In the present study, the low DHA/docosapentaenoic acid ratios (4–6) observed for the STD + AA and the SOW treatments indicate that these diets were inadequate to support accretion of DHA in the retina comparable to that observed for the supplemented groups. Greater ratios (11–21) were observed in the DHA-supplemented groups for both PC and PE, but these ratios were not significantly different from those of the STD treatment group.

Because of the low DHA content of the sow milk in the current study, the naturally-reared group (SOW) should be considered a negative, rather than a positive, control with respect to DHA. However, even the very small amount of DHA in the sow milk may have played a physiological role as indicated by the fact that, in PC, DHA was greater in the SOW than in the STD. Fatty acid profiles of retina PC and PE for the SOW group were similar to those of the group supplemented with AA alone. This result can be explained by the similarities in the dietary fatty acid composition of the two groups (Table 1). In both the SOW and STD + AA groups, the DHA in the retina phospholipids was less than in the DHA-supplemented groups. These results may have implications for populations consuming large amounts of high linoleic vegetable oils and relatively little linolenic acid. Women in the United States have breast milk DHA concentrations on the low end of the spectrum compared with women in other countries (18), and it is speculated that maternal dietary supplementation of n-3 fatty acids or increased consumption of fish might be advisable.

In comparison to the retina, other tissues examined in the same study (Craig-Schmidt, M., Ping, L., Huang, M.C., Stainback, P., Mozaffar, S., and Johnson, J., unpublished data) exhibited greater fold-increases in both DHA and AA as a re-

sult of supplementation. For example, 4–6-fold increases were observed for DHA in lung and heart phospholipids, whereas the statistically significant changes in the retina were only 1–2-fold. The amount of DHA, however, is greater in the retina than in these other tissues, and because DHA is more highly conserved in the retina than in other tissues, it may be less susceptible to dietary manipulation. A lack of response to diet in retina DHA also has been observed in human infants. Makrides *et al.* (39) analyzed tissue DHA in infants undergoing postmortem examinations as a result of sudden death. Breast-fed infants had a greater proportion of DHA in their erythrocytes and brain cortex relative to those fed formula, but differences were not observed in the retina. Thus, there is some evidence that DHA in the retina may be maximized earlier than DHA in other tissues.

Carlson *et al.* (14,15) reported that preterm infants fed marine oil-supplemented formula exhibited a compromised AA status, presumably because of competition between n-6 and n-3 fatty acids. It is possible, therefore, that DHA added to formula could reduce AA in tissues. That competition exists between n-6 and n-3 fatty acids is well established (40,41), yet under conditions of the current dietary treatments, there appeared to be no significant inhibition of AA incorporation into retina phospholipid by the addition of DHA to the diet. Similarly, incorporation of DHA into retina phospholipid was not suppressed by addition of dietary AA. Retina PC was responsive to dietary supplementation, with addition of DHA, AA, or BOTH resulting in increases in these fatty acids when compared to animals fed the standard formula. Although retina PE was less responsive to dietary supplementation, addition of both DHA and AA resulted in an increase in DHA as compared to unsupplemented formula. On the basis of these results, it appears that a combination of DHA and AA in the diet can support accretion of DHA in retina phospholipids while simultaneously providing AA necessary for membrane phospholipids and eicosanoid biosynthesis.

ABSTRACT: The present study was designed to determine if dietary supply of long-chain fatty acid (LCFA, C20:4n-6, and/or C22:6n-3), reflecting levels that might be incorporated into infant formulas, influences the fatty acid composition of the visual cell membrane. The rod outer segment (ROS) of the retina was analyzed from rats fed diets varying in the ratio of 18:2n-6 to 18:3n-3 with or without 20:4n-6 [arachidonic acid (AA)] and 22:6n-3 (docosahexaenoic acid) from birth to six weeks of age. The level of very long chain fatty acids (VLCFA, C_{24}–C_{36}) was identified using gas chromatography and gas chromatography–mass spectrometry. In the ROS, the highest relative percent of AA was attained in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of animals fed 1% AA diet, whereas feeding 0.7% docosahexaenoic acid (DHA) diet significantly increased the DHA level in PC, phosphatidylserine, and phosphatidylinositol compared to feeding diets containing AA. VLCFA of n-6 and n-3 up to C_{36} were found in PC, with the most abundant fatty acids being C_{32} and C_{34}. In PC, phosphatidylserine and PE, the n-6 tetraenoic VLCFA level was highly increased in animals fed 1% AA compared to other dietary groups. This study suggests that dietary fat containing small amounts of AA or DHA is an important factor influencing membrane fatty acid composition of the visual cell during development.

Lipids 31, 61–64 (1996).

In recent years, it has become well established that alterations in dietary fat intake result in differences in the structural lipid composition and in functions of a wide variety of membranes (1). The fatty acid composition of membrane phospholipids seems to be especially sensitive to change in the animal's intake of essential fatty acids, and the balance between the n-6 and n-3 essential fatty acids fed (2,3). A few specialized cells contain very long chain essential fatty acids (VLCFA), having chain lengths of C_{24} to C_{34} (4,5). These VLCFA are present in the brain (6,7), testes (8,9), and in the rod photoreceptors of the retina (4,10,11). The physiological role of these essential fatty acids is unknown; however, the content of VLCFA in the rod outer segment (ROS) of the retina is increased or decreased, depending on the n-6 to n-3 fatty acid balance present in the diet fat fed (4).

During development, synaptogenesis, and photoreceptor biogenesis, deficiency of 22:6n-3 results in profound biochemical changes in membrane composition and membrane function of the ROS. In the preterm human infant, feeding 22:6n-3 seems to improve the delayed recovery of the dark-adapted electroretinogram and visual acuity (12–14). This suggests that n-3 fatty acids exert a functional role in the development of normal visual function that is dependent on the utilization of n-6 and n-3 fatty acids derived from the diet. Both 20:4n-6 and 22:6n-3 give rise to longer chain homologues in the ROS of the retina (4). This raises questions of what is the impact of dietary 20:4n-6 and 22:6n-3 content on the level of VLCFA homologues and the functional contributions of these fatty acids. Therefore, the present study was designed to determine if dietary supply of 20:4n-6 and 22:6n-3, reflecting levels that might be incorporated into infant formula, influences the fatty acid content of the major phospholipid components of the ROS in the retina.

MATERIALS AND METHODS

Animals and diets. Sprague-Dawley rats, obtained from the University of Alberta vivarium (Edmonton, Alberta, Canada), were housed individually, unless breeding. During breeding, three females and one male were housed together for a two-week "mating" period. Females were then moved to individual cages. Room conditions were maintained at 21°C with 12-h light and 12-h dark cycle. Water and food were supplied *ad libitum*. Experimental diets were fed to dams following delivery of the rat pups. All litters were culled to twelve animals within 24 h following parturition. Pups were sacrificed by decapitation in the light at three and six weeks of age. Animals

at three weeks of age received only maternal milk with no access to the chow fed the dam. Animals sacrificed at six weeks of age had been weaned at three weeks of age and were fed the same diet received by the dam.

Five semipurified experimental diets containing 20% fat (w/w) and varying in fat composition were fed (Table 1). Diet fats were formulated based on the fat composition of an existing infant formula providing an n-6/n-3 ratio of 7.3:1 (SMA; Wyeth-Ayerst Laboratories, Radnor, PA). Four experimental diets were formulated by the addition of various triglycerides to alter the composition of this basic fat formulation (Table 1). The arachidonic acid (AA) and docosahexaenoic acid (DHA) triglycerides utilized were obtained from single-cell oils (Martek Corporation, Columbia, MD).

Isolation of retina and ROS. All isolations were performed at 4°C. Retinas were isolated (15). Six retinas were pooled for separation of the ROS. ROS were isolated by discontinuous sucrose gradient centrifugation (16). Aliquots of ROS were evaluated by microscopy and polyacrylamide gel electrophoresis (17). In the gel, opsin with a molecular weight of 35000 daltons was present in ROS membranes. The purified ROS fraction contained only minor subcellular contamination by retinal debris.

Lipid analysis. Total lipids were extracted from the ROS (18). Phospholipids were separated from neutral lipids using silica G-plates (20 × 20 cm) and developed in a solvent system composed of petroleum ether/diethyl ether/acetic acid (80:20:1, by vol) and then eluted three times with 10 mL chloroform/methanol (1:1, vol/vol) containing 1 ppm ethoxyquin. Phospholipids were dried under nitrogen and redissolved in 0.2 mL hexane. Phospholipids were separated by spotting on hexane prewashed silica-gel H-plates (20 × 20 cm) developed in chloroform/methanol/2-propanol/0.25% (wt/vol)KCl/triethylamine (30:9:25:6:18, by vol) (19) for 1-1/2 h followed by chloroform/methanol/1-propanol/0.25% (wt/vol) KCl/triethylamine (30:9:25:6:18, by vol) for 1-1/2 h. With these two systems, phosphatidylcholine (PC) was separated from sphingomyelin. Thin-layer chromatography (TLC) plates were dried at room temperature for five minutes and visualized with 0.01% (wt/vol) Anilino Naphthalene sulfonic acid in water. Each phospholipid was recovered, and fatty acid methyl esters were prepared using BF_3/methanol reagent (20).

Analysis of fatty acid methyl esters. For separation of long-chain fatty acid (LCFA) and VLCFA, a Hewlett-Packard 5890 GLC (Palo Alto, CA) equipped with a Vista DS 654 data system (Varian Instruments, Georgetown, Ontario, Canada) was used. Chromatography utilized a BP × 70 column (25 m × 0.22 mm i.d.). The carrier gas was helium, at a flow rate of 2.2 mL/min and a split ratio of 20:1. The initial oven temperature was started at 110°C, increased to 320°C at a rate of 3°C/min and then held for five minutes. The injector temperature was 250°C. With these conditions, VLCFA up to 36 carbons in chain length were separated. Identification of the longer chain length fatty acids was based, in part, on retention times. Identification of the degree of unsaturation of the fatty acid was based on gas chromatography–mass spectrometry (GC–MS) analysis and prior separation of fatty acid methyl esters on the basis of a number of double bonds by argentation TLC.

Fatty acid methyl esters were injected into the BP × 70 column and analyzed by an electron ionization mass selective detector. The injector temperature was 250°C, and the GC–MS transfer line temperature was 300°C. The identification of VLCFA was performed using a Hewlett-Packard 5970 mass selective detector with a Hewlett-Packard comp 216 data system. The mass spectra of very-long-chain tetra, penta, and hexaenoic methyl esters from PC contained patterns similar to those published earlier (4). Argentation TLC was used to resolve fatty acid methyl esters on the basis of degree of unsaturation as described earlier (4).

Statistical methods. The effect of diet on fatty acid composition of phospholipid in ROS was assessed by analysis of variance procedures. Significant effects of treatment were defined utilizing Duncan's multiple range test (21). All data is expressed as mean ± standard error of the mean.

TABLE 1
Fatty Acid Composition of Diets Fed[a]

Fatty acid (wt% of fat)	n-6/n-3 7.3:1	n-6/n-3 4:1	1% AA	0.7% DHA	AA + DHA
12:0	9.6	7.0	7.3	10.2	7.9
14:0	5.8	5.1	4.8	6.2	5.7
16:0	12.7	14.6	15.7	14.7	15.9
18:0	7.7	8.1	9.3	7.3	8.9
18:1(n-7 + n-9)	40.7	40.4	38.9	38.3	38.8
18:2n-6	15.8	17.6	16.2	16.0	16.8

20:4n-6	—	—	1.2	—	1.2
20:5n-3	—	—	—	—	—
22:6n-3	—	—	—	0.8	0.7
n-6/n-3	7.3	4.1	7.1	6.9	7.5

[a]n-6/n-3, the ratio of 18:2n-6 to 18:3n-3; AA, arachidonic acid; DHA, docosahexaenoic acid.

RESULTS AND DISCUSSION

Diet treatment did not alter the weight gain of the animals in this experiment. In previous experiments, feeding n-3 fatty acids compared to low or deficient n-3 fatty acid intake in an n-6 to n-3 fatty acid unbalanced diet results in changes in the levels of n-3 fatty acids present in brain and retina. In the present study, however, a physiological level of intake of all fatty acids (22) was provided (Table 1). Inclusion of relatively small amounts of 20:4n-6 and 22:6n-3 in the postweaning diet increased the level of 20:4n-6 in PC and phosphatidylethanolamine (PE) (Fig. 1). It is also noteworthy that feeding 22:6n-3 is also associated with increases in the 20:4n-6 content of both phospholipids in the ROS compared to n-6/n-3 of 7:1 and 4:1 diet. This close association between the incorporation of 20:4n-6 and 22:6n-3 has been reported for brain phospholipids (23) and is highly suggestive that a diet induced increase in 22:6n-3 content in PC, and phosphatidylser-

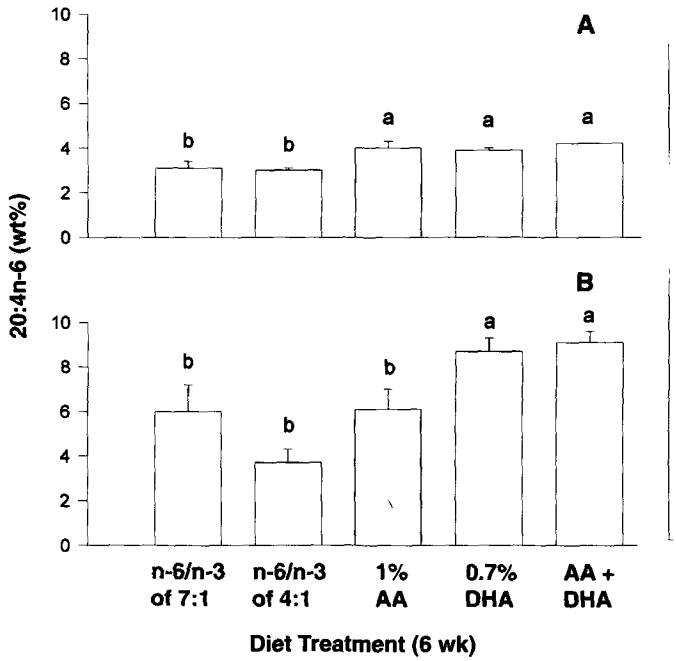

FIG. 1. Effect of diet fat on the content of 20:4n-6 in (A) phosphatidylcholine and (B) phosphatidylethanolamine. Values are mean ± SEM (wt%) with n = 3–5 for each group. Six retinas were pooled for each n. Significant effects of diet treatment were defined, utilizing Duncan's multiple range test at the level of $P < 0.05$ for a vs. b. Retinas were collected in the regular laboratory light; AA, arachidonic acid; DHA, docosahexaenoic acid.

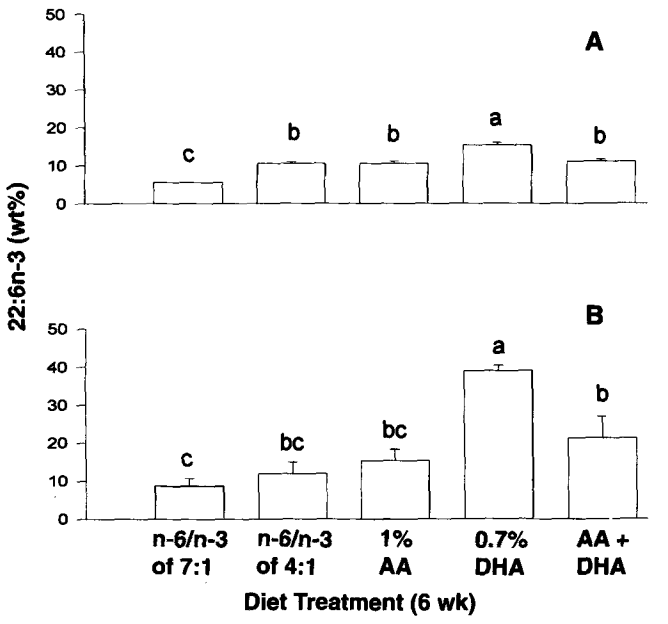

FIG. 2. Effect of diet fat on the content of 22:6n-3 in (A) phosphatidylcholine and (B) phosphatidylserine in the rod outer segment. Values are mean ± SEM (wt%) with n = 3–5 for each group. Six retinas were pooled for each n. Significant effects of diet treatments were defined, utilizing Duncan's multiple range test at the level of $P < 0.05$ for a vs. b vs. c. Retinas were collected in the regular laboratory light; see Figure 1 for abbreviations.

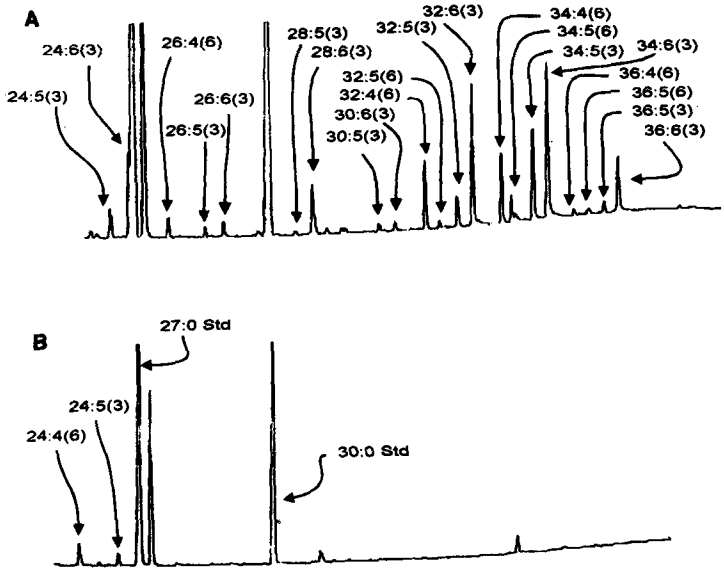

FIG. 3. Content of very long chain fatty acids of rod outer segment in phosphatidylcholine (A) and phosphatidylethanolamine (B). Identification of the each fatty acid peak was verified by gas chromatography–mass spectrometry. Phosphatidylcholine (A) contains very long chain fatty acids with up to 36 carbons in chain length, whereas phosphatidylethanolamine (B) contains up to 24 carbons. Std, standard.

ine (PS) in the ROS (Fig. 2) results in the synthesis of highly diunsaturated phospholipid species containing 20:4n-6 and 22:6n-3.

In the postweaning ROS, feeding of 22:6n-3 either alone or with 20:4n-6 increased phospholipid content of 22:6n-3 (Fig. 2). In PC, increasing the 18:3n-3 content of the diet resulted in an increase in the content of 22:6n-3. In PS, feeding 22:6n-3 increased the content of 22:6n-3 from 2.5- to 4-fold (Fig. 2).

In the ROS, only PC contains significant levels of VLCFA, with up to 36 carbons in chain length and having 4, 5, and 6 double bonds (Fig. 3). These observations are consistent with reports for bovine retina (24), human brain, and rat brain (6,25). Feeding 20:4n-6 in the diet was effective in increasing the level of n-6 tetraenoic VLCFA present in PC (Fig. 4), PE, and PS (data not shown), with concomitant reductions in n-3 VLCFA, which was vice versa with feeding 22:6n-3. The content of n-6 pentaenoic VLCFA was small, and the difference was not significant except C32:5n-6 in PC.

The present study provides experimental evidence indicating that small dietary amounts of 20:4n-6 and 22:6n-3 are important factors influencing membrane fatty acid composition of the visual cell during development. The data in this presentation has focused on the early postweaning period. However, our evidence indicates that analogous effects of diet also occur during the preweaning period. These effects of diet include significant alterations in LCFA and VLCFA in phospholipids as well as a reciprocal replacement of n-6 tetranoic VLCFA by n-3 pentaenoic VLCFA. These VLCFA of C_{24} to

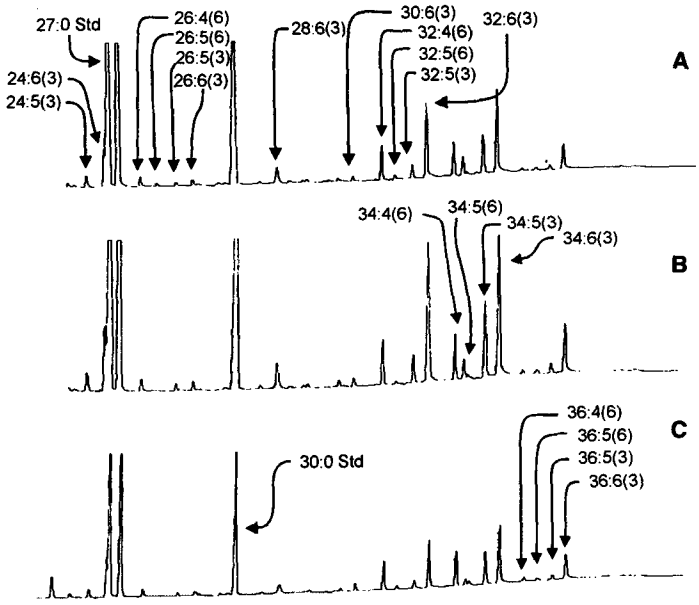

FIG. 4. Effect of feeding 20:4n-6 on the content of very long chain fatty acids in phosphatidylcholine in rod outer segment. Identification of each fatty acid peak was verified by gas chromatography–mass spectrometry. (A), The ratio of n-6/n-3 = 7.3:1; (B), (A) + 0.7% 22:6n-3 (DHA); (C), (A) + 1% 20:4n-6 (AA). See Figures 1 and 3 for abbreviations.

C_{36} carbon chain length are not of direct dietary origin and must be synthesized from shorter chain essential fatty acid precursors present in the diet fed. The functional roles for very long-chain n-6 and n-3 fatty acids in the ROS remain to be determined.

[b]Department of Food Science, Royal Melbourne Institute of Technology, Melbourne, 3000, Victoria, Australia

ABSTRACT: Docosahexaenoic acid (DHA), an n-3 polyunsaturated fatty acid, is found in consistently high concentrations in the retinae of mammals, yet its role in vision remains unclear. In this study, a mammalian model of variable retinal DHA concentration has been developed, such that the retinal phospholipids of guinea pigs contained between 2.5 and 30.8% DHA. Visual function was assessed using full-field flash electroretinography, over a range of exposure levels spanning six log units. Trend analysis indicated that retinal function was altered by the tissue DHA level, and was described by a second-order polynomial "inverted U-shaped" function. The results suggested that although some amount of DHA is essential for normal retinal function, increases in the DHA level past an optimal amount, found to be 19%, provided diminishing returns. In this study, manipulation of the retinal DHA level accounted for 21–35% of the electroretinographic variability.

Lipids 31, 65–70 (1996).

The most ubiquitous of the retinal n-3 polyunsaturated fatty acids (PUFA) is docosahexaenoic acid (DHA), which is contained in up to 60% of all structural phospholipid molecules, within the membranes of the photoreceptor outer segments (1). The prevalence and constancy of n-3 PUFA, particularly DHA (2,3), are clues that it plays an important role within the retina. Despite this, the function of DHA is still unclear.

Attempts to deplete mammals, such as rat and monkey, of retinal n-3 fatty acids by dietary manipulation, in an endeavor to elucidate the nature of DHA function, have had limited success (4,5). In these studies, complete depletion of DHA was not possible due to transplacental transport and other conservation mechanisms (6). Nevertheless, there is evidence to suggest that even DHA depletion to a level 60% or below control affects retinal function. In particular, n-3 deficiency has been shown to give rise to electroretinographic deficits (1,7–9), losses in visual acuity (1,10), and learning defects (11). In addition, n-3 deficiency has been shown to directly affect the function of the visual photopigment, rhodopsin (12), and a model for the role of DHA in modulation of rhodopsin function has been proposed (13).

The aim of the present study was to use an animal model of variable retinal DHA content (14) (ranging from negligible to very high) in order to assess the effect of this fatty acid on visual function.

MATERIALS AND METHODS

All experimental and surgical procedures were approved by the Animal Experimentation Ethics Committees of the Melbourne and Deakin universities and were conducted in accordance with the "Australian code of practice for the care and use of animals for scientific purposes."

Sixteen commercial diet-fed female Duncan-Hartley guinea pigs (in groups of four) were weaned onto a guinea pig commercial diet (LC—laboratory chow), or one of three semisynthetic diets based on a premixture described by Leat *et al.* (15). Various oils, providing a range of n-3 intakes, were added to this premixture to provide the sole source of lipid for each diet. The diet designed to result in depletion of retinal n-3 PUFA was the safflower oil (SO)-based diet, which utilized safflower seed oil as the only source of lipid. SO contains negligible amounts of n-3 and high amounts of n-6 fatty acids (n-6/n-3 = 72.0). Canola oil (CO) (n-6/n-3 = 2.5) was added to a second diet. The CO diet, like the LC diet (n-6/n-3 = 8.9) served as an n-3-sufficient diet. The third oil-supplemented diet contained a mixture of fish oil (FO), providing very high levels of n-3 fatty acids, particularly the longer chain n-3 PUFA, eicosapentaenoic acid, and DHA, plus CO and SO (n-6/n-3 = 2.5). The FO was added to the premixture in the form of cellulose-coated microcapsules to prevent oxidation (Dry n-3™ powder; Dano Chemo A/S, Norway). These oils were added in the ratio of fish/canola/safflower (25:45:30), and in all three synthetic diets this lipid comprised 100 g per 1 kg of diet mixture. Commercial chow was the fourth group, added as a standard reference, and all pellets originated from a single batch to ensure constancy throughout the experiment. All diets were supplemented with 10 g fresh carrots daily and water containing ascorbic acid (400 mg/L) *ad libitum*. The light environment was cycled (12 h light, 12 h dark) in the animal housing room and tempera-

ture was constant at 21°C. Fatty acid compositions of the four diets measured as described by Weisinger *et al.* (14) are given in Table 1.

Female guinea pigs were reared on these diets to four months of age, at which time they were joined with LC-fed males. Offspring (second generation guinea pigs) were weaned onto their respective diets at approximately 14 d. Second generation females were joined with LC-fed males. The offspring of this union (third generation, 4–6 litters giving n = 12 per diet group) were assessed at six to nine weeks of age, there being no significant difference between the ages of animals from different groups (mean age ± SD: SO, 7.0 ± 1.4; LC, 6.8 ± 0.9; CO, 6.5 ± 0.5; FO, 6.5 ± 0.9).

Following deep anesthesia (0.035 mL Ketamine and 0.025 mL Xyalzine/kg body weight) and mydriasis (Tropicamide 0.5%), full-field white flash electroretinograms (ERG) were recorded by placement of chlorided silver wire electrodes into the vitreous (active) and inferior cul de sac (inactive). Light flashes were delived *via* a fiber optic, positioned 6 mm from the cornea, at six light exposure levels, spanning the operational limits of both rod and cone receptor systems; the dimmest exposure was 1 lux.s. Exposure was raised in one log unit increments with the brightest flash being 10^5 lux.s. For each exposure, eight repeats were averaged to give the final waveform. The duration of each flash was 5 ms at the nominal exposure. The interstimulus interval was 15 s (between flashes). All animals were dark-adapted overnight (18 h) prior to the recordings.

Immediately following electroretinography, animals were sacrificed and their retinae removed under normal room light conditions. Lipids were extracted from the retinal tissue using chloroform/methanol, 2:1 (containing butylated hydroxytoluene antioxidant), and the phospholipids were separated from the neutral lipids by thin-layer chromatography (16). The methyl esters of the phospholipid fatty acids were formed by a saponification step using KOH followed by transesterification in BF_3 in methanol (16), and the fatty acid methyl esters were separated by capillary gas–liquid chromatography (DANI 6500 HR; ICI International, Melbourne, Australia) using a 50 m × 0.32 mm (i.d.) fused silica bonded phase column (BPX70; SGE, Melbourne, Australia). The column oven was programmed at 125°C for 3 min to 220°C at 8°C/min with helium as carrier gas at a flow rate of 43 cm/s. Fatty acids were identified by comparison with standard mixtures of fatty acid methyl esters, and the results were calculated using response factors derived from chromatographing standards of known composition (Nu-Chek-Prep, Elysian, MN).

The ERG is conventionally recognized by the measurement of two major changes in retinal polarity following light stimulation, the initial "negative" a-wave, and the ensuing "positive" b-wave. The a-wave strongly represents the activity within the photoreceptors, and the b-wave represents that of post-receptoral processes. The peak-to-peak amplitude is equivalent to the b-wave amplitude, taking into account the initial a-wave negativity and, hence, is a superior measure of the positive-polarity forces generated in the post-receptoral networks. Both peak-to-peak and a-wave amplitudes were measured, and the relationship between these electroretinographic waveforms, and the retinal DHA content was determined using trend analysis (17). The degree of correlation between these parameters was estimated using the Spearman statistic.

[a]The oil-supplemented diets (fish, canola, and safflower oils) were composed of 10% lipid (by weight); the laboratory chow diet contained 4.9% lipid.

RESULTS AND DISCUSSION

The results given in Table 2 indicate that the retinal fatty acid profile can be manipulated by dietary means by six to nine weeks of age in third generation animals. The retinal DHA content was found to be directly proportional to the dietary supply of precursory n-3 fatty acids (Fig. 1), consistent with, and extending, the earlier work of Leat *et al.* (15) on this species.

Both the n-6/n-3 ratio and total n-3 (by weight) were considered in the analysis of the diet–tissue DHA relationship. The n-6/n-3 ratio is considered a better index of dietary n-3 supply than the absolute quantity of added n-3 fatty acids. This is because n-6 and n-3 fatty acid families compete for the enzymes of desaturation (18). Therefore, a high total n-3 in the diet is less effective in increasing tissue n-3 PUFA (such as DHA) levels when the n-6 fatty acid content of the diet is also high. However, the usefulness of this index is reduced where the metabolic desaturation pathway is bypassed by direct supply of longer-chain PUFA. The FO diet, for example, supplies both eicosapentaenoic acid and DHA (in addition to α-linolenic acid), but contains an n-6/n-3 ratio nearly identical to that of the CO diet (2.54 and 2.51, respectively). As is shown in Table 2, animals in the FO group had greater levels of n-3 fatty acids in their retinae than those of the

canola group. Indeed, the retinal DHA content in the FO group was about 30% higher than the canola group.

In summary, these diet groups enabled the assessment of animals varying dramatically in terms of retinal DHA proportion, ranging from negligible amounts in the retinae of SO-supplemented animals to over ten times that proportion in the retinae of FO-supplemented animals. In agreement with the literature, the changes in retinal DHA concentration were inversely proportional with changes to the levels of docosapentaenoic acid (22:5n-6), and it appears that, biochemically, 22:5n-6 and DHA are interchangeable within the phospholipids of the retina. Together, DHA and 22:5n-6 comprise approximately 26–31% of the total retinal phopholipid fatty acid. The diets were very consistent in their effects on the fatty acid profile, with the standard deviation between animals in a given group rarely higher than 5%. For DHA content, the average standard deviation of the diet groups was 3.44%.

Other features of the retinal fatty acid profiles were that the diet with the highest n-6/n-3 (SO) had the highest levels of all n-6 PUFA ($P < 0.05$). The total n-6 level in the SO group was 44.04 and the n-3 level was 2.74%. As the proportion of the n-3 PUFA increased in the diet relative to the n-6 levels, the levels of n-3 PUFA increased in the retinal phospholipids. Thus, the total n-6 and total n-3 PUFA in commercial chow were 30.71 and 13.39%, respectively; in the CO diet the values were 21.08 and 23.15%, respectively; and for the FO group the values were 11.29 and 34.37%, respectively. Therefore, between 44 and 47% of the retinal phospholipid fatty acids were PUFA. The proportion of saturated fatty acids (16:0 and 18:0) and oleic acid (18:1) remained fairly constant between diet groups (see Table 2).

Figure 2 illustrates typical ERG recorded from four animals (representative of the four dietary groups) at the 10 lux.s exposure. Both a-wave and b-wave components are evident at this illumination level.

Table 3 gives the outcomes for the trend analysis between ERG amplitude and retinal DHA content. It shows the F-ratios for the zero order (constant), first order (linear), and second order polynomial when incorporated into the trend, as well as their applicability to the data. In modelling this data, a higher order polynomial was only included when the F-ratio was significantly ($P < 0.05$) greater than the preceeding lower order function.

Although there were significant differences in many of the other retinal PUFA (beside DHA and 22:5n-6), for example, a reduction in the arachidonic acid level in FO-fed animals, which may have contributed to the observed electroretinographic changes as a function of diet, these were not significantly correlated.

As is evident in Table 3, the second order regression provided the best fit to the data giving the (highest) F-ratio and r^2 values. We did not consider higher than second order polynomials as these were not statistically significant, and there is no postulated physiological basis for such a relationship. The results indicate that DHA serves a vital role in the normal function of the retina and that retinal DHA content forms a complex (nonlinear) relationship with the electroretinographic output. An inverted U-shaped trend (Scheme 1) was evident for the relationship between DHA content and the a-wave amplitude ($P < 0.02$) when the flash exposure was between 2.0 and 5.0 log lux.s and for the peak-to-peak amplitude ($P < 0.02$) at all intensities except 2.0 and 4.0 log lux.s. The most likely cause for the absence of any trend in the a-wave at the dimmest exposures is the low signal-to-noise ratio found at these levels. The implicit times of the a-wave and b-wave were measured, and no significant difference was found between any of the diet groups.

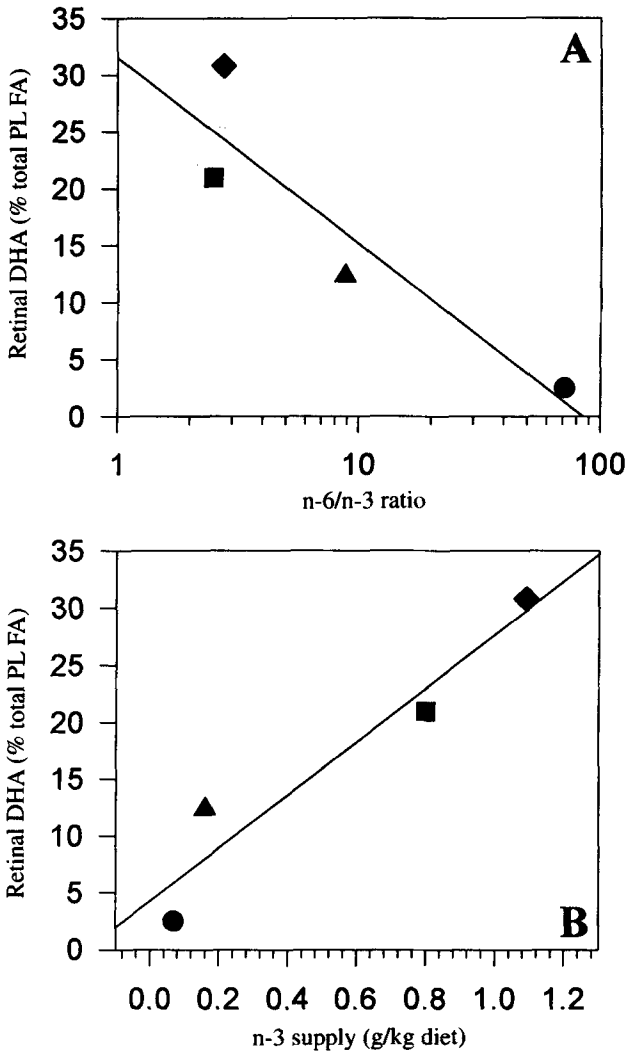

FIG. 1. A. Retinal docosahexaenoic acid (DHA) level as a function of dietary n-6/n-3 supply ratio. FIG. 2. Electroretinograms from a single animal taken at the 10 lux.s exposure level, representative of data obtained from the four diet groups (SO, safflower oil; CO, canola oil; FO, fish oil; and LC, laboratory chow).

The tissue–DHA level predicted to give optimal retinal function was determined by applying differential calculus to the second order polynomials to find the maximum for each light exposure level. The results indicate that a value of between 15–26% gives the optimal retinal DHA content (Table 4). The averages of 18.01 ± 1.89 (a-wave) and 20.74 ± 3.47 (peak-to-peak) suggest that a content of about 19% (corresponding to an n-3 supply of 0.64 g/kg of diet; n-6/n-3 ratio of 5.7, see Fig. 1) would give the best electroretinographic outcome. This value corresponds closely to those levels found in the LC- and CO-supplemented groups. Notably, the r^2 values obtained from this analysis indicate that between 21–35% of the variation in electroretinographic responses can be explained by a change in the retinal DHA content (see Table 3).

The mechanism by which alteration in retinal DHA content affects visual function is not known. It has been suggested that a reduced DHA content may directly impair the process of phototransduction (12), or perhaps synaptic transmission to the post-receptoral network (19). Notably, each rhodopsin molecule is surrounded by approximately 60 phospholipid molecules, most of which contain DHA as the major constituent (20). Hence, depletion of DHA could be expected to alter photoreceptor function. Such losses are observed despite the absence of structural damage to the retinal tissue (21) and an apparent increase in rhodopsin content within the outer segment disks (12). Interestingly, Watanabe *et al.* (22) found a decrease in the number of large phagosomes in the retinal pigment epithelium, but no structural change to the sensory retina. Landis *et al.* (23) observed an absence of photoreceptor disk shedding in animals fed a fat-free diet. These observations indicate that a reduction in retinal DHA content produces subtle inefficiencies in phototransduction and disk recycling mechanisms rather than morphological abnormalities. On the other hand, a high DHA content leads to oxidative stress. Receptor numbers become reduced, outer-seg-

SCHEME 2

ments are smaller, and post-receptoral physiology is disrupted by oxidative or phototoxic insult (24). This insult is likely to have occurred during rearing in room lighting conditions, as the experiments of Penn and Anderson (24) show that it can occur at normal room light levels (300 lux). Furthermore, our study determined no significant difference between the optimal DHA concentrations for high and low flash exposures (Table 4). If the primary effect of photic/oxidative insult was occurring during the flash exposure used in the experiment, a lower optimum DHA content would have been expected under conditions of high light exposure (Table 4). This is contrary to what was actually observed.

A model to describe the inverted U-shaped effect of DHA content on retinal physiology is shown in Scheme 1. This model proposes two opposing lipid-related factors influencing retinal function. The first factor is one that influences phototransductional light capture. The other involves oxidative damage. Furthermore, a scheme has been proposed to describe the electroretinographic findings in terms of receptoral (rhodopsin modulation) or post-receptoral (oxidative) involvement in Scheme 2. When the DHA content is low, reduced peak-to-peak and a-wave amplitudes are a result of photoreceptor dysfunction due to inefficiencies in light capture (Scheme 2, C). As discussed earlier in this chapter, this dysfunction probably arises from less efficient rhodopsin function (such as reduced "quantal catch") associated with the changes in membrane characteristics. When the content of DHA in the retinal phospholipid approaches 19%, retinal function peaks (Scheme 2, A). However, when the DHA content is raised above this optimal level, reduced amplitudes arise as a result of oxidative damage either at the photoreceptor level (Scheme 2, C) or both receptorally and post-receptorally (Scheme 2, B). This model is supported by our experimental data given in this paper and by the work of Penn and Anderson (24), who reported marked structural damage to the retinae of animals raised on high n-3 fatty acid diets in normal and in bright light conditions.

TABLE 4
Retinal Docosahexaenoic Acid (DHA) Content That Is Predicted by Trends to Give the Greatest Electroretinographic Peak-to-Peak at 10^2 lux.s and a-Wave

Flash exposure (log lux.s)	Optimal retinal DHA (% of total phospholipid fatty acids) a-Wave	Peak-to-peak
5.0	20.21	21.20
4.0	19.90	26.18
3.0	18.61	20.68
2.0	17.54	N/A[a]
1.0	16.03	18.60
0.0	15.79	17.04
Mean ± SD	18.01 ± 1.89	20.74 ± 3.47

[a]No sensible correlation was obtained for peak-to-peak at 10^2 lux.s.

The present study refutes the notion that a high content of DHA is necessary for optimal visual function as optimal retinal function occurred in the presence of moderate levels of DHA (19%). However, the retinal fatty acid profile of the guinea pig, in particular the proportion of DHA, appears different from that of other mammals. Whereas DHA comprises up to 60% of the retinal fatty acids in control diet-fed rats (25) and monkeys (19), the retinae of guinea pigs in this study contained half of this fraction (the FO group). However, we note that the high DHA levels were taken from rod outer segments rather than whole retinas as in the present study. The "control" groups, CO and LC, had DHA levels much lower than that of the FO group (see Table 2). This finding is in agreement with those of Leat *et al.* (15), who found similarly "low" DHA levels in chow-fed guinea pigs.

The fact that the guinea pig is the only mammal studied that can be completely depleted of retinal DHA suggests that it metabolizes n-3 fatty acids differently. Indeed, optimal retinal function is achieved in the guinea pig where the retinal DHA level is even lower than that of rats and monkeys raised on n-3–deficient diets. This apparently lowered demand for high tissue DHA levels is consistent with the lack of conservation of DHA in guinea pigs.

Two final points need to be raised. Our findings indicate that DHA plays a key role in the retinal function of the guinea

pig and that optimal retinal function is achieved in the presence of some 22:5n-6. It is also important to recognize that our study was limited to a single age group. Others have shown that there is an age dependency of the effect of n-3 deficiency on ERG function, with older animals showing little or no ERG anomalies (9).

Artificial Rearing of Infant Rats on Milk Formula Deficient in n-3 Essential Fatty Acids: A Rapid Method for the Production of Experimental n-3 Deficiency[1]

Glenn Ward, James Woods, Michelle Reyzer, and Norman Salem, Jr.*

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcoholism and Alcohol Abuse, Rockville, Maryland 20852

ABSTRACT: Research into the function of docosahexaenoic acid (DHA; 22:6n-3), the predominant polyunsaturated fatty acid (PUFA) in the central nervous system (CNS), is often hindered by the difficulty in obtaining dramatic experimental decreases in DHA in the brain and retina of laboratory rats. In this study, the artificial rearing procedure, whereby infant rats are removed from their mothers, gastrostomized, and fed synthetic formula, was used in an attempt to produce rapid changes in CNS levels of DHA. Female rats were raised, from day 4–5 of life, on one of two formulas—one containing the essential fatty acids of both the n-6 and n-3 series in proportions approximately equal to those of rat milk, and the other containing high levels of 18:2n-6 but very little n-3 fatty acid. At weaning, both groups were given AIN-76A diets modified so that the PUFA content resembled that of the preweaning formula. At eight weeks of age, the n-3-deficient group exhibited decreases of more than 50% in total DHA content in the brain, accompanied by increases in arachidonic acid (AA) (20:4n-6) and, especially, docosapentaenoic acid (22:5n-6). Other artificially-reared rats were mated and their offspring were also maintained on the respective diets. In spite of the fact that they had been reared artificially, the rats mated successfully and reared litters with no obvious abnormalities. At both ten days of age and again at eight weeks, offspring of the n-3-deficient mothers exhibited decreases of more than 90% in total DHA content. Again, the long-chain n-6 PUFA increased proportionately so that total PUFA levels in the brain were not lower. As these differences are greater than those commonly reported, even after 2–3 generations of normal dietary deprivation in rodents, this procedure may be an important tool in the study of the effects of n-3 deficiency on neural development and, subsequently, of the function of DHA in nervous tissue.

Lipids 31, 71–77 (1996).

A basic principle of nutritional research is that the determination of the essentiality of a nutrient requires the manipulation of tissue levels of that nutrient and the evaluation of appropriate functional endpoints. Specifically, this strategy requires that the following criteria be met: (i) the removal of the nutrient from the food source; (ii) the maintenance of the subject for an appropriate duration so that tissue levels decline to subnormal levels; and (iii) the evaluation of changes in structure or function of that tissue. In the case of the n-3 essential fatty acids (EFA), however, this approach has proven to be difficult. Although n-3 EFA can be removed from the food source either by providing, as the sole source of fat, oils such as safflower oil or through the use of specific purified fatty acids, the second criterion (the maintenance of the subject until tissue levels of n-3 EFA have been reduced sufficiently) has been difficult to meet. The member of the n-3 family which is of major interest, docosahexaenoic acid (DHA; 22:6n-3), is the predominant polyunsaturated fatty acid (PUFA) in the central nervous system (CNS) of mammals (1–4), and DHA in the brain of many species accrues mostly from mother's milk during the suckling period, when much of the brain is undergoing the most rapid stage of development. Furthermore, DHA is selectively retained by the brain, making depletion of brain stores difficult after weaning, when brain development is almost complete and the CNS has accumulated most of the adult concentration of 22:6n-3. The depletion of DHA, if begun after weaning, can take most of the lifetime of the animal, and major decreases often require a second or even third generation to be maintained on the diet. For example, in the rat, the usual procedure has been to place postweanling females on n-3-deficient diets throughout their lives and then evaluate their offspring, and although this technique has led to drastic reductions in 22:6n-3 in the brain in the second generation according to some reports (5,6), many studies have reported more modest decreases (7–9). Continuing the dietary n-3 deprivation for a third generation resulted in further decreases (10–13), but the time and resources required to carry out such studies may be prohibitive for many researchers.

One alternative approach has been to use animals, such as the nonhuman primate or the young piglet, which can be removed from the nursing mother shortly after birth and fed a

synthetic formula devoid of n-3 EFA throughout much of the brain development period. This method has been used successfully in a number of laboratories, producing major declines in CNS levels of DHA during early life in both monkeys (14–16) and piglets (17,18). Unfortunately, although the feeding of infant formula to monkeys and pigs provides a powerful model for the experimental production of n-3 deficiency, it has two practical limitations. Because of the considerable length of time required for these species to reach adulthood, and the space requirements for their housing and maintenance, use of these animals can require resources beyond the reach of many laboratories. Also, the common tests which would be used to evaluate functional changes in the CNS are less developed, and often more unwieldy, in these species than in common laboratory rodents.

The laboratory rat, on the other hand, is the subject of choice for most researchers. It is relatively easy and inexpensive to acquire and maintain, it reaches adulthood relatively quickly, and more is known about the behavioral capabilities of the rat than about any other nonhuman species. Furthermore, the relatively few reports of effects of n-3 deficiency suggest that DHA is required for normal retinal (12,19) and brain function (2,4,20). What is needed to facilitate further research into the nature of these effects is a method of producing rapid and dramatic declines in DHA in the rat brain.

Fortunately, there is a well-developed technique for raising infant rats on synthetic formula. The artificial rearing (AR) method for rats was developed a quarter century ago (21,22), and with subsequent advances in the development of appropriate rat-milk substitutes (23,24), it enables the researcher to make relatively precise manipulations of specific nutrients during a critical period of development (for review, see Ref. 25). AR has provided researchers with a powerful tool in such fields as early nutrition (24) and the effects of prenatal ethanol exposure (26). This paper describes the first attempt to use AR of infant rats to produce rapid decreases of DHA in the brain.

MATERIALS AND METHODS

Subjects. The first generation of rats were offspring of timed-pregnant Sprague-Dawley rats purchased from Taconic Farms (Germantown, NY). Upon arrival in our animal facility, the dams were individually housed in plastic cages on Bed o' Cobs bedding (Anderson Company, Maumee, OH) and maintained under a 12-h dark/light cycle at 21 ± 1°C. All offspring were housed, after weaning, in same-sex groups of up to five per cage.

Chow diets. Upon arrival, the pregnant dams were maintained on NIH-31 lab chow (Zeigler Brothers, Gardners, PA). After weaning, AR offspring were maintained first on modified AIN-76A powdered diets (BioServe, Frenchtown, NJ) and were eventually transferred to modified AIN-76A pelleted diets (Dyets, Inc., Bethlehem, PA). In both cases, the diet was modified in two ways: (i) the protein was comprised of vitamin-free casein, as we had determined that this protein source contained less fat than did casein; and (ii) the fat content was 5% by weight, and comprised of saturated fats in the form of distilled monoglycerides (Myverol 18-06 K; Eastman Chemicals, Inc., Kingsport, TN) and unsaturated fats in the form of ethyl esters of purified linoleate and linolenate (Nu-Chek-Prep, Elysian, MN), and docosahexaenoate (a kind gift from Professor Yasushi Tamura, Chiba University, Chiba City, Japan). The fatty acyl composition of the diets is shown in Table 1. In the control group, 12% of the fat was in the form of linoleic acid while 1% each was provided by linolenic acid and DHA. In the experimental group, there were almost no n-3 fatty acids, while 26% of the fat was in the form of linoleic acid.

Rat-milk substitute. The neonatal pups used in the AR treatment were fed a rat-milk substitute adapted from a protocol used elsewhere (J. Edmond, personal communication), and the composition is shown in Table 2. The rat-milk substitute consisted of a milk-protein substitute (provided as a gift by Professor John Edmond; UCLA, Los Angeles, CA) to which was added amino acids, carbohydrate, fat, vitamins, and minerals to approximate the composition of rat milk. During the first two days of AR, the diet was modified somewhat in that half the protein was in the form of soy protein (Supro Plus 675; Protein Technologies International, St. Louis, MO). This change was made after pilot work in our laboratory showed that partial substitution of soy protein for casein reduced mortality due to gastrointestinal bloat in the first few days of rearing. The fat content of the diet was composed of short- and medium-chain saturated fatty acids provided by medium-chain triglyceride (MCT) oil (Mead Johnson, Evansville, IN) and pure ethyl esters of the EFA linoleic and

α-linolenic acid, and the long-chain PUFA DHA. The fatty acid composition of the two diets is shown in Table 3.

Procedure. On day 4 or 5 after birth, pups were lightly anesthetized with isofluorane and implanted with gastrostomy tubes as described elsewhere (27,28). Briefly, six-inch-long Intramedic tubing (Clay Adams, Parsippany, NJ) (PE 10, 0.61 mm o.d.) was lubricated with MCT oil, inserted into the mouth, passed down the esophagus and out the lateral wall of the stomach. The pups were then housed on bedding in small plastic containers floating in heated water (36 ± 1°C). The milk substitute was delivered for 10 min every hour *via* PE 50 tubes attached to syringes mounted on infusion pumps (Harvard Apparatus, South Natick, MA). The total amount of food delivered each day was equal to 33% of the body weight of the pup for the first 3–4 d, and then gradually increased over the next week until it was 40% of body weight each day. Approximately equal numbers of pups from each litter were assigned to each experimental group. Pups were weaned on days 18–19 onto solid diets corresponding in PUFA content to the liquid diets. Some AR rats were killed at approximately eight weeks of age for lipid analysis, and others were allowed to reach sexual maturity and were mated beginning at 16 wk of age. Their offspring were allowed to suckle with their mothers and were removed and housed in same-sex groups on day 25 ± 1 d. They were then fed the diets fed to their mothers. Some pups were killed by decapitation on day 10 for fatty acid analysis, and others were killed by CO_2 exposure at eight weeks of age. In both cases, no more than one animal from each litter was used for biochemical analysis. All animal procedures were carried out in accordance with the guidelines set by the Animal Welfare Act and were done with the approval of the NIAAA Animal Care and Use Committee.

Biochemical analysis. Lipids were extracted from brain homogenates with chloroform and methanol by the method of Bligh and Dyer (29). Fatty acid methyl esters of total lipids were prepared with 14% (wt/vol) boron trifluoride and methanol according to the procedure of Morrison and Smith (30), and analyzed by a gas chromatograph (Hewlett-Packard 5890; Hewlett-Packard, Palo Alto, CA) equipped with a flame-ionization detector and a 30 m × 0.25 mm (i.d.) capillary column (J&W DB-FFAP; J&W, Folsom, CA). The conditions were as follows: 130°C initial temperature, no hold time, increase 4°C/min to 175°C, 1°C/min to 210°C, 30°C/min to 240°C, hold for about 15 min. Individual fatty acids were quantified by adding known amounts of the fatty acid 23:0 to the original homogenate before extraction, and the fatty acids were identified by comparison with known standards.

Statistical analysis. Data were analyzed as μg of fatty acid per gram of tissue by *t*-tests using the StatView statistical analysis package for the Macintosh computer. Significance level was set at $P < 0.01$.

RESULTS

The forebrain and cerebellar fatty acid composition of adult rats reared artificially from days 4–5 of life are shown in

[a]Data are expressed as the mean ± SEM for n = 5 animals each. Abbreviations as in Table 1.

Tables 4 and 5. At eight weeks of age, the levels of n-3 PUFA, particularly 22:6n-3, in both the forebrain and cerebellum declined considerably in the group reared on n-3-deficient rat-milk substitute neonatally and weaned onto deficient chow, and this decrease was accompanied by an increase in the amount of n-6 PUFA, particularly 22:5n-6 and, to a lesser extent, 20:4n-6 and 22:4n-6. The percentage decline of 22:6n-3 in the cerebellum was slightly greater than that in the forebrain (58% vs. 49%).

Most AR rats mated successfully and gave birth to live litters (15/16 in the adequate group vs. 12/15 in the deficient group). In several cases in both groups, all pups within a litter died within a few days of birth (five litters in the adequate group vs. three litters in the deficient group). Under visual examination, surviving pups appeared to be normal in both groups. Because the precise day of copulation was not known in these animals, it is not known if sexual responsiveness or gestation length differed between groups.

The fatty acid composition of brain regions of ten-day-old offspring of AR rats is shown in Tables 6 and 7. The n-3 PUFA declined by over 90% in both the forebrain and cerebellum of the n-3-deficient pups, and again, this drop was accompanied by increases in n-6 fatty acids. Similar declines of 22:6n-3 and associated increases in 22:5n-6 and other n-3 PUFA were also seen in the forebrain and cerebellum of eight-week-old offspring (Tables 8 and 9).

DISCUSSION

In this study, rats which had been fed n-3-deficient diets from day 4–5 of life and throughout development and adulthood exhibited losses of approximately 50% in n-3 fatty acids—particularly 22:6n-3—in the brain. Furthermore, their offspring exhibited losses of greater than 90% in 22:6n-3 in the brain both during the neonatal period and in early adulthood. These losses were offset by increases in long-chain n-6 fatty acids—primarily 22:5n-6, but also 20:4n-6 and 22:4n-6—so that the total PUFA content of the brain was maintained as described previously (31,32).

Although a recent study reported dramatic decreases in 22:6n-3 in the brains of offspring of guinea pigs fed n-3-deficient diets from weaning (33), the decreases found in the current study are of a much greater magnitude than those reported in rats or mice in most studies which rely on feeding of n-3-deficient laboratory chow beginning at weaning in the first generation. Although some early reports (5,6) described reductions of as much as 90–95% in phospholipid 22:6n-3 in the brain in the second generation, later studies generally have reported more modest decreases of approximately 50–75% (7–9). Even when the dietary n-3 deprivation was continued for a third generation, the resulting 22:6n-3 levels were still between one-half to one-quarter of those of n-3-adequate controls (10–13),

considerably higher than those of the second generation in this study.

When rats were given n-3-deficient diets beginning during the neonatal period, the losses of 22:6n-3 in the cerebellum exceeded those in the forebrain, and both structures exhibited similar losses when deficiency occurred throughout all stages of development. This may have been due to the fact that, in the rat, the cerebellum undergoes most of its development—and subsequent accrual of n-3 fatty acids—during the postnatal period while the forebrain has already undergone much of its development at the time of birth (34).

It has been reported in a number of studies (10,35,36) that n-3 deficiency is associated with increased frequency of reproductive failure, and n-3 fatty acids are reported to be necessary for the normal uterine development in the female rat (37). Some of the AR rats in the present study exhibited some difficulty in caring for their pups in the first few days after birth, but the frequency of this finding was approximately similar in both deficient and adequate dams. It is more likely that this problem was caused by the early removal of the rats from their own mothers and/or the AR experience itself. Future studies will address this issue in a quantitative fashion by evaluating maternal behavior in deficient and in adequate dams.

Earlier, the point was made that the determination of the essential nature of a nutrient required the removal of the nutrient from the food source, the maintenance of the subject for an appropriate duration so that tissue levels decline to subnormal levels, and the evaluation of any change in structure or function of that tissue. Because much of the DHA in the brain has accrued by weaning in most mammalian species, dietary n-3 deprivation beginning after this period may be relatively inefficient due to the time required to substantially reduce DHA levels in the brain. In species such as the primate or pig, feeding of n-3-deficient formulae can eliminate dietary n-3 EFA during brain development, but practical considerations make the use of these species difficult for many researchers. The rat, on the other hand, is an ideal experimental subject due to its relatively brief generation time, the relative ease with which it can be housed and maintained, and the vast amount of information available regarding its behavioral repertoire. In this study, through the use of the AR method, we have shown that the rat may also be an ideal subject for studies requiring dietary deprivation during much of the period of brain development. Future work in our laboratory will further address the precise nature of these biochemical changes at the level of the individual phospholipid classes and molecular species, and the question of functional changes in

Arachidonic Acid Supply and Metabolism in Human Infants Born at Full Term[1]

Berthold Koletzko*, Tamás Decsi, and Hans Demmelmair
Kinderpoliklinik, Ludwig-Maximilans-Universität, Munich, Germany

ABSTRACT: Infants need arachidonic acid (AA; C20:4n-6) for eicosanoid synthesis and deposition in growing tissues, including brain. Human milk supplies preformed AA in amounts considered to meet accretion in membrane-rich tissues, but vegetable oil-based infant formulas do not contain AA. We studied two groups of ten healthy infants, each fed human milk or formula, and analyzed plasma lipid composition. Percentage contributions of AA to plasma phospholipids were stable over two months after birth in breast-fed infants, but infants fed formula developed significantly ($P < 0.05$) lower levels at the ages of two weeks (formula 6.9% vs. breast 9.4%, w/w), one month (6.2 vs. 9.1%), and two months (5.7 vs. 8.4%). In a second trial, we randomized infants to receive (from birth to age four months) formula without or with both AA and docosahexaenoic acid (DHA; C22:6n-3) at levels typical for mature human milk. Infants fed conventional formula showed a continuous decrease of phospholipid AA over time, whereas feeding of formula supplemented with AA and DHA led to significantly higher AA levels, similar to those in breast-fed infants (two months: supplemented 9.6% vs. unsupplemented 7.1%; four months: 8.7 vs. 6.6%). In order to estimate infantile capacity for endogenous synthesis of AA, we fed four term neonates with newly diagnosed phenylketonuria (mean age 18 d) a formula with all fat contributed by corn oil, which has a higher natural ^{13}C-enrichment than European human milk or formula. Analysis of ^{13}C-enrichment in plasma fatty acids over four days allowed us to estimate infantile AA synthesis. We found an increased ^{13}C-value in plasma AA of all infants, which indicates that term neonates can synthesize AA. However, with a simplified isotope balance equation, we estimate that endogenous synthesis contributed only about 23% of total plasma arachidonic acid by day four. We conclude that full-term infants fed formula may require a dietary supply of some preformed AA if the biochemical status of breast-fed infants is to be achieved.
Lipids 31, 79–83 (1996).

Docosahexaenoic acid (DHA) is considered a conditionally essential nutrient for preterm infants, because its dietary supply was shown to be related to visual function in the first months of life and to cognitive development at a corrected age of one year (1–3). It is also generally agreed that DHA supply for preterm infants should not interfere with arachidonic acid (AA) status, as we and others found availability of AA related to growth (4–6). Therefore, it has been recommended in Europe that formula for low-birthweight infants should contain preformed elongation/desaturation products of both linoleic acid (LA) and α-linolenic acid (ALA) (7,8).

More recent results have raised the question whether healthy infants born at full term may also benefit from a dietary supply of preformed long-chain polyunsaturated fatty acids (LC-PUFA). Human milk (HM) provides considerable amounts of LC-PUFA (9,10), and formula based on vegetable oils does not (11,12). This difference in dietary intake is reflected by reduced DHA contents of structural brain lipids in formula-fed infants, as was shown by studies on tissue samples of deceased infants (13,14). Moreover, some studies using visual-evoked potential measurements found a lower visual acuity during the first months of life in formula-fed than in breast-fed babies (15,16), which has been correlated to DHA status (15), although other investigators did not find differences in visual function assessed with simple behavioral methods (17). However, a recent study with randomized feeding of formula without or with preformed DHA found a significant benefit of DHA on visual acuity as determined by evoked potentials (18). Less information is available on the metabolism and biological functions of AA in term babies. Some studies on formula-fed infants found lower AA values in plasma and red blood cell lipids than in breast-fed infants (19,20), while others did not (21,22). To shed some further light on this question, we studied AA metabolism and the effect of diet in full-term infants.

EXPERIMENTAL PROCEDURES

Subjects. In a first study, we followed 20 healthy infants born at full term, of which 10 were breast-fed and 10 fed a conventional infant formula based on cow's milk protein and vegetable fat (Pre-Aptamil; Milupa, Friedrichsdorf, Germany) from birth to age eight weeks (23). The formula used contained LA and ALA in amounts (13.2 and 1.0% w/w, respectively) comparable to those typical for mature HM in Europe (10), but no detectable AA and DHA. Blood samples for fatty

acid analyses were obtained at the ages of two weeks, one month, and two months.

In a second study, 22 apparently healthy, full-term, and appropriate for gestational age infants fed formula were randomly assigned (on day 5 of life) to be fed either with the same LC-PUFA–free formula used in the previous study (Pre-Aptamil; n = 10) or a formula with equal composition except for a different fat body enriched with egg lipids and evening primrose oil (Pre-Aptamil with Milupan; n = 12) with 0.2% (of fatty acids) γ-linolenic acid (GLA), 0.4% AA, and 0.3% DHA. Physical examinations, anthropometric measurements, and collections of venous blood samples were performed at the ages of 5 d and 1, 2, 3, and 4 mon (24).

In a third trial, we studied four full-term infants with newly diagnosed phenylketonuria detected by newborn screening, who thrived well and had no other apparent disturbance of health. The infants were studied at a postnatal age of 18 ± 3 days (M ± SD) with a normal body weight for age (3.3 ± 0.6 kg). Three infants had been fully breast-fed and one had been formula-fed. Blood samples were obtained before and at defined intervals over four days after the time of introduction of a therapeutic phenylalanine-free diet, in which all fat was contributed by corn oil. This diet provided an LA intake of 12–16 g per day, but no other n-6 PUFA. Corn oil has a slightly higher natural enrichment of ^{13}C than other dietary fats commonly used in Europe (25), including European HM or formula.

Analytical methods. For the analyses of plasma phospholipid fatty acids, lipids were extracted from plasma into chloroform/methanol, lipid classes were separated by thin-layer chromatography and fatty acids transesterified with methanol under acid catalysis as previously described (26). Fatty acid methyl esters were determined by high-resolution capillary gas–liquid chromatography with confirmation of peak identification by mass spectrometry, as reported in detail elsewhere (27). A gas chromatograph (HP 5890 A; Hewlett Packard, Palo Alto, CA) coupled *via* a combustion interface to an isotope ratio mass spectrometer (Delta S; Finnigan MAT, Bremen, Germany) was used for isotope ratio analyses of fatty acid methyl esters (28). ^{13}C-contents are expressed as $\delta^{13}C$-values relative to PeeDeeBelemnite carbonate as defined by Craig (29). The mean standard deviation for determination of $\delta^{13}C$-values of physiologically important fatty acid methyl esters from plasma samples was 0.5 per thousand (‰) (28). Minitab™ (Minitab Inc., State College, PA) was used for statistical analysis with unpaired and paired *t*-tests.

RESULTS

Plasma phospholipid ω6 PUFA in full-term infants fed human milk or LC-PUFA–free formula. There was no significant change of LA contributions to plasma phospholipids in breast-fed infants between the ages of two and eight weeks (Table 1). In contrast, LA values increased significantly in infants fed formula between the ages of two weeks and one month, and were significantly higher than in breast-fed infants both at the ages of one and two months. Values of GLA did not differ between the two groups throughout the study. After two weeks of age, dihomo-GLA (DGLA) values increased significantly in both groups; and breast-fed infants showed significantly higher DGLA values than infants fed formula at the age of two months (Table 1). AA values were significantly higher in infants fed human milk than in those receiving formula throughout the study. Breast-fed infants maintained relatively stable plasma phospholipid AA contents during the first two months of life, whereas percentage contributions of AA decreased significantly in infants fed formula between the ages of two weeks and two months. There was no difference between the groups in gains of weight and head and chest circumference, but longitudinal growth was significantly greater in formula-fed than in breast-fed infants (1.01 ± 0.22 vs. 0.74 ± 0.24 cm/wk, $P < 0.05$).

TABLE 1
ω6 Polyunsaturated Fatty Acids in Plasma Phospholipids of Full-Term Infants Fed Human Milk or Formula[a]

Age	Two weeks	One month	Two Months
Linoleic acid (C18:2n-6)			
Human milk	19.3 ± 1.66	16.52 ± 1.72[c]	17.25 ± 1.79[b]
Formula	20.76 ± 09.70[d]	22.91 ± 0.52[c,d]	23.45 ± 1.01[b]
γ-Linolenic acid (C18:3n-6)			
Human milk	0.08 ± 0.02	0.10 ± 0.02	0.15 ± 0.02
Formula	0.13 ± 0.03	0.11 ± 0.02	0.09 ± 0.01
Dihomo-γ-linolenic acid (C20:3n-6)			
Human milk	2.36 ± 0.15[d]	2.82 ± 0.17	3.40 ± 0.19[b,d]
Formula	2.66 ± 0.19[d]	3.13 ± 0.21[d]	2.77 ± 0.21[b]
Arachidonic acid (C20:4n-6)			
Human milk	9.39 ± 1.00[b]	9.06 ± 1.04[b]	8.41 ± 1.19[b]
Formula	6.91 ± 0.38[b,d]	6.16 ± 0.35[b]	5.74 ± 0.37[b,d]

[a]% w/w, mean ± SEM. Identical superscripts indicate significant differences: [b]= $P < 0.05$, [c]= $P < 0.01$ between groups (unpaired *t*-test); [d]= $P < 0.05$ between different time points within one group (paired *t*-test).

Plasma phospholipid ω6 PUFA in full-term infants fed formula without and with preformed dietary LC-PUFA. In both feeding groups, values of LA and GLA increased between the ages of five days and one month, whereas percentage contributions of AA decreased. At the ages of 1, 2, and 3 mon, percentage contributions of LA were significantly higher in infants fed LC-PUFA–free formula than in those receiving formula with preformed LC-PUFA (Table 2). Neither GLA nor DGLA values differed between the two groups throughout the study. From the age of one month onward, percentage contributions of AA were significantly higher in infants receiving formula enriched with LC-PUFA than in those fed LC-PUFA–free formula. Both formulas were well tolerated, and there was no difference between groups in gains of weight, length, and head circumference. Throughout the study, neither retinol nor α-tocopherol plasma concentrations differed between feeding groups (24).

Estimation of AA synthesis in full-term infants by using isotopic analyses. Analysis of HM samples from two of the three breastfeeding mothers revealed LA contents of 10.7 and 11.7% with δ^{13}C-values of −32.6 and −30.7 per thousand (‰), respectively, and the formula used contained 12.8% LA with a δ^{13}C-value of −29.8‰. In contrast, the corn oil used in the therapeutic diet of all infants contained 58.1% LA with a δ^{13}C of −16.4‰. Following the dietary change with introduction of corn oil, ^{13}C-enrichment of plasma LA increased rapidly in all infants (Fig. 1). The steepest increase was observed within the first 24 h after diet change, with a smaller rise of δ^{13}C over baseline thereafter. Although corn oil does not contain any appreciable DGLA and AA, there were also clear increases of ^{13}C-enrichment of plasma DGLA on days 1 and 4 and of plasma AA on day 4 (Fig. 1), but the change of δ^{13}C over baseline was clearly smaller in AA than in DGLA. These results indicate active endogenous synthesis of DGLA and AA in full-term infants in the first month of life. We used a simplified isotope balance equation described in detail elsewhere (28) to estimate the contribution of dietary LA to total serum LA and the contribution of AA synthesized from plasma LA to total plasma AA. The calculated proportions of serum LA contributed by dietary LA were 60.8 ± 7.4% (M ± SEM) on day 1 and 83.8 ± 4.0% on day 4. Proportions of serum AA contributed by endogenous LA conversion were 6.0 ± 6.0% on day 1 and 23.3 ± 4.3% on day 4.

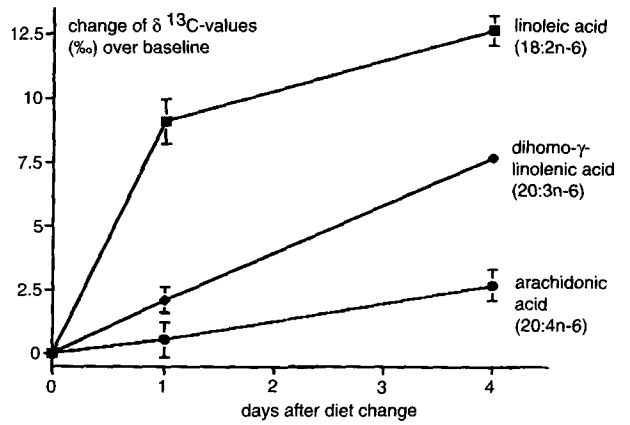

FIG. 1. Change of ^{13}C-enrichment [δ^{13}C over baseline, per thousand (‰), mean ± SEM] of plasma ω6 fatty acids in four newborn infants one and four days after dietary change from human milk or formula to a therapeutic formula with all fat contributed by corn oil, which has a higher natural ^{13}C-enrichment than most dietary fats in Europe. Values for dihomo-γ-linolenic acid represent means and SEM of only two infants. The increase of ^{13}C-enrichment of dihomo-γ-linolenic acid and arachidonic acid proves active endogenous synthesis *in vivo*.

DISCUSSION

The quality and composition of dietary fat supplied to infants has important structure and functional effects on their rapidly growing tissues (30). Among the many different aspects regarding the optimal lipid supply with HM and infant formulas, the dietary intake and metabolism of LC-PUFA receive increased attention. The results presented here indicate that full-term infants fed formula without AA and DHA are unable to match the AA status of infants fed HM for at least two months after birth, even though they receive a generous supply of the precursor fatty acids in amounts similar to HM. These data do not give any indication for a marked maturation of LC-PUFA synthesis activity in the first two months after birth. Compared to the breast-fed group, the formula-fed infants show a relatively less pronounced depletion of AA (at two months 68% of the mean of breast-fed infants) than of DHA (55%) (23), which may reflect the more complex synthesis of DHA and/or a difference in turnover rate.

It is conceivable that introduction of preformed LC-PUFA into infant formula similar to the biological model of HM

might be advantageous for the recipient infant (31). We have shown here that enrichment of an infant formula with preformed AA and DHA in amounts typical for mature HM improves AA status of full-term infants, and phospholipid AA values matching those of breast-fed infants are achieved up to the age of four months. Thus, LC-PUFA in the form used in this formula are effectively absorbed and metabolized. Although the enriched formula did contain 0.2% GLA, we did not find increased values of GLA and its elongation product, DGLA, in plasma phospholipids of the recipient infants. It appears that the contribution of relatively small amounts of dietary GLA to infantile phospholipid PUFA is minor. In these studies with a limited number of infants, there was no relation of AA supply and plasma lipid contents to clinical outcome parameters, such as growth. Hence, there are no data to address the question of a possible biological advantage of adapting dietary AA intake to that of breast-fed infants. No adverse side effects were observed, and there was no reduction of plasma levels of lipid-soluble antioxidant vitamins (24), which were in the reference range reported before for young infants (32).

In our stable isotope studies utilizing small natural variations of ^{13}C-enrichment in dietary lipids, gas chromatography combustion isotope ratio mass spectrometry proved to be a highly sensitive and precise tool for studying PUFA metabolism in infants. Our results demonstrate active AA synthesis in full-term neonates *in vivo*. These findings are in accordance with a previous report on demonstrable enzyme activities of Δ6 and Δ5-desaturases in liver microsomes of deceased neonates (33). However, the activity of synthesis is rather low, and apparently only about 6% of total plasma AA is renewed by this pathway per day. Whether this activity is sufficient to provide adequate amounts of AA to support rapid tissue growth with physiological composition remains highly questionable. Rather, full-term infants fed formula may require a dietary supply of some preformed AA if the biochemical status of breast-fed infants is to be achieved. Further studies are needed to explore the effects of variations in dietary composition on endogenous LC-PUFA synthesis, as well as possible clinical effects of variations in AA status. Such studies may contribute to establishing the n-6 and n-3 PUFA requirements of formula-fed, full-term infants.

A Randomized Trial of Visual Attention of Preterm Infants Fed Docosahexaenoic Acid Until Two Months[1]

Susan E. Carlson[a–c,*] and Susan H. Werkman[a,b]

Departments of [a]Pediatrics, [b]Obstetrics and Gynecology, and [c]Biochemistry, The University of Tennessee, Memphis, Memphis, Tennessee 38163

ABSTRACT: This was a randomized, double-blind trial to determine if a nutrient-enriched (preterm) formula supplemented with 0.2% docosahexaenoic acid (DHA, 22:6n-3) from a low eicosapentaenoic acid (0.06%) source of marine oil would enhance visual novelty preference and attention of preterm infants. Both the standard and experimental formulas contained 3% of total fatty acids as linolenic acid (18:3n-3) and were fed from approximately three days of age to two months past term. After two months, both diet groups were fed a commercially-available term formula with linolenic acid as the only source of n-3 fatty acid. At 12 mo visual recognition memory (novelty preference) and visual attention (number and duration of discrete looks) were determined with the Fagan Test of Infant Intelligence. The DHA-supplemented group compared with the control group had more and shorter duration looks in comparisons of familiar and novel stimuli, confirming earlier evidence that DHA can increase information processing speed of preterm infants who otherwise are receiving good intakes of linolenic acid. Because supplementation was stopped at two months and the effects seen at 12 mon, this study demonstrates for the first time that a relatively short period of DHA supplementation can produce significant effects on later visual attention.
Lipids 31, 85–90 (1996).

Earlier we tested the hypothesis that preterm infants fed an infant formula supplemented with a marine oil source of docosahexaenoic acid (DHA) would have enhanced visual and neural development compared with infants fed linolenic acid as their sole source of n-3 fatty acids. The DHA-supplemented group had higher preferential looking grating acuity at two and four months (1,2) and more (3,4) and shorter duration looks (4) during paired comparisons of novel and familiar stimuli at 6.5, 9, and 12 mon. Both higher visual acuity (5) and shorter look duration during paired comparisons of familiar and novel stimuli (6) are analogous to observations made in monkey infants with better DHA status, i.e., those fed linolenic acid-replete compared with linolenic acid-deficient diets. A major difference between the monkey infant studies and our randomized trial in preterm infants, however, was that the group of infants with poorer DHA status were fed good intakes of linolenic acid, i.e., 1.2 and 2.4% of energy intake before and after two months of age, respectively.

Although these data suggested that DHA was conditionally essential for normal visual and neural outcomes of preterm infants, growth, another planned outcome of the trial, was adversely affected by long-term DHA supplementation (7). DHA supplementation decreased plasma and red blood cell (RBC) phospholipid arachidonic acid (AA) (20:4n-6) (8), and plasma phosphatidylcholine AA, a marker of AA status, was highly correlated with first-year growth (9). The current trial provided the DHA-supplemented group with a lower eicosapentaenoic acid (EPA, 20:5n-3) source of marine oil DHA for a shorter period of time than our first trial (4), with the intent of minimizing the effect of n-3 long-chain polyunsaturated fatty acids on AA status and growth (10). As a result, the experimental group in this study received formula with the same amount of DHA (0.2%) but with only half as much long-chain n-3 fatty acid (0.26% instead of 0.5%). Infants were fed their assigned formulas until two months past term, and the effects of DHA supplementation on visual attention later in infancy are reported here.

EXPERIMENTAL PROCEDURES

Subject selection. Fifty-nine infants randomly assigned to treatment constituted the final study population in this, our second, double-blind study of the effects of DHA supplementation on preterm infants. The selection criteria for infants in the total sample have been reported in detail (10). Briefly, this was a group of infants weighing between 747 and 1275 g at birth who met the strict criteria for eligibility used in our earlier trial (4), except for having an incidence of bronchopulmonary dysplasia (BPD) or chronic lung disease of ~40%, typical of infants in this birth weight range. The diagnosis of BPD was based on a continuous requirement for supplemental oxygen at 28 d of age and the presence of characteristic radiologic signs of BPD. At 12 mon, a subset of 27 of these infants (12 control, 15 DHA-supplemented) received the same version of the Fagan Test of Infant Intelligence administered in our earlier trial. Their results are included in this report, and their neonatal/perinatal characteristics are shown in Table 1.

18:2n-6	21.2	21.2	34.3
18:3n-3	2.4	2.4	4.8
20:5n-3	—	0.06	—
22:6n-3	—	0.2	—

[a]The preterm formulas contained 812 kcal/L and were fed until two months past expected term when infants weighed ~4.8 kg. All infants received an unsupplemented term formula with 676 kcal/L from 2 until 12 mon past expected term. Abbreviation as in Table 1.

Experimental design. Consent for the study was obtained according to a protocol approved by the Institutional Review Board of The University of Tennessee, Memphis. Only parents who stated that they planned to feed infant formula were approached for permission to enroll their infant in this study. Infants were randomly assigned to a diet group by opening the next available envelope assigned to their gender. Each envelope contained a number identifying the formula, and the randomization was done in sequential series of eight. Each formula-gender appeared twice in each set of eight envelopes. The infants were enrolled when they were ready to start enteral feeding between two and five days of age. A preterm formula (Similac Special Care; Ross Products Division, Abbott Laboratories, Columbus, OH) was fed to the control group. The experimental formula was prepared by substituting a small amount of marine oil for an equivalent amount of the fat blend in the preterm formula. Otherwise, the experimental formula was identical to the commercially available preterm formula. Compared with most sources of marine oil, the source of marine oil added to the experimental formula had a relatively high ratio of DHA to EPA. The fatty acid composition of the two preterm formulas is shown in Table 2.

The preterm formula was designed especially for the higher nutrient needs of preterm as compared with term infants. Both diet groups received a low-iron version of the formula containing 24 kcal/oz (11) with or without a low EPA source of marine oil from enrollment until 2 mon past term. Infants received a daily supplement of 5 mg of iron from ferrous sulfate, beginning when they weighed 1.8 kg body weight and ending when they were two months past term. From 2 to 12 mon, infants from both groups were provided with a commercially-available formula (Similac with Iron) (11) designed for the nutrient requirements of infants born at term. The formulas were provided free to parents and without restriction. Compared with a group of ~60 term infants in the same hospital, the preterm infants in this study at 12 mon had slightly lower normalized weights but identical normalized lengths (12), evidence that they were well-nourished.

The gestational age of each infant was determined at birth by a combination of obstetric and pediatric assessments. The 52-wk (12 mon) Fagan Test was administered at 92 wk postmenstrual age (PMA) (12 mon) to all who returned for this visit.

Visual behavior testing. The method used to measure visual recognition memory and attention at 12 mon was the same as has been described (4). All tests were done by the same investigator, who was unaware of the infants' diets at the time of testing.

Statistical methods. This study was designed to test several hypotheses, including the hypothesis that visual novelty preference and attention of preterm infants during paired comparisons of novel and familiar stimuli would be enhanced by DHA supplementation. The power analysis for the trial was based on the number of infants needed to reject the null hypothesis for an effect of DHA supplementation on growth. Based on this analysis, 30 infants per group were planned.

At 12 mon, approximately half of the infants in each diet group were tested with a newer version of the Fagan Test that yielded data for look duration and number significantly different from the older version of the Fagan Test (Carlson, S.E., unpublished data). Because only the results obtained with the older version of the Fagan Test could be compared directly with those from our earlier study, only the scores of infants tested with that version are reported in Tables 3 and 4, where they are contrasted with results from that study. Many comparisons between diets (Table 4) suggest the null hypothesis

cannot be accepted because of Type II error that resulted from the unplanned loss of power.

The effects of diet on 12-mon visual attention were determined by Student's *t*-test. A *post hoc* two-way analysis of variance for diet and BPD was used to look for an effect of BPD, as well as diet. These analyses were done on a MacIntosh IIcx computer with StatView software (Abacus Concepts, Inc., Berkeley, CA). A P value of <0.05 was considered statistically different.

RESULTS

Age at test. The actual test ages in weeks from term (mean ± SD) and the numbers of infants tested with the original 52-wk version of the Fagan Test in each diet group were, respectively, 52.6 ± 1.2 (n = 12) for the control group and 52.4 ± 1.0 (n = 15) for the DHA-supplemented group. This age is described throughout the paper as 12 mon. The mean test age of the diet groups did not differ.

Neonatal and perinatal characteristics of the infants. The infants in each diet group are described in Table 1. The groups were similar in all respects except that the group fed DHA-supplemented formula had higher RBC phosphatidylethanolamine (PE) DHA at two months compared with the control group as a result of receiving a DHA-supplemented diet from birth until that age. After the DHA supplement was discontinued at two months, RBC PE DHA (g/100 g total fatty acid) declined progressively over the next few months. At 12 mon, the groups could not be distinguished from each other on the basis of their RBC PE DHA (10).

Effect of diet on visual attention during familiarization. During familiarization, infants in the two diet groups had similar numbers of looks at each study age, and the total number of looks was divided nearly equally between the infants' left and right (Table 3). Both the number of looks and look duration at 12 mon were similar to the results of our earlier randomized trial (Table 3).

Infants with BPD differed from those without BPD in that they had significantly fewer total looks during familiarization with the Fagan Test (Table 5, $P < 0.02$). Because all infants were required to look for the same amount of time during familiarization, a lower number of looks was directly related to a significantly longer look duration in infants with BPD compared with infants without BPD ($P < 0.01$).

Effect of diet on visual attention during paired comparisons. Both diet groups had a significant preference for the novel stimuli during paired comparison tests (Table 4), but DHA-supplemented compared with control infants had significantly more discrete looks to the familiar stimuli during paired comparison testing ($P < 0.05$). A comparison of the 12-month data from this trial with that from our earlier trial (shown in the last column of Table 4) indicates similar increases in the numbers of total looks, looks to novel, and looks to familiar with DHA supplementation, and remarkably similar looking times and novelty preferences. At 12 mon the average time/novel look (s) was lower in DHA-supplemented infants ($P < 0.05$), and the average time/look (s) tended in the same direction. Again, the average times/novel look for the control and DHA-supplemented infants in this study were practically the same as for their respective groups in our earlier study (Table 4).

At 12 mon, infants who developed BPD compared with those without BPD had a longer average time/look ($P < 0.03$),

average time/novel look ($P < 0.02$), and average time/familiar look ($P < 0.06$) (Table 5). Although the numbers in each diet-BPD group were small, longer look duration in infants with BPD appeared to be due to higher look duration in the BPD infants fed control formula because the means for the DHA-supplemented infants with and without BPD were similar. Novelty preference determined during paired comparison tests was not affected by BPD (Table 5).

DISCUSSION

While subjects of this study compared with our earlier study (4) had similar birth weights and gestational ages and were fed experimental and control formulas with the same amounts of DHA and linolenic acid, respectively, the studies also differed in several ways: (i) The source of marine oil was lower in EPA in the second compared with the first study (0.06 vs. 0.3%). (ii) The experimental formula with DHA was fed until two months instead of nine months past term. (iii) Infants in the second randomized trial were fed a nutrient-enriched, energy-concentrated (24 kcal/oz) preterm formula instead of a 20 kcal/oz term formula from 36 to 48 wk PMA. (iv) The infants in the second trial had a 40% incidence of BPD, usual for this weight range, whereas practically no infants with BPD were included in our first study (3 of 67) (7).

This study confirmed that preterm infants fed DHA have shorter look durations to novel stimuli on paired comparison tests compared with infants fed linolenic acid as their sole source of n-3 fatty acid. In addition, the outcomes for visual recognition memory and attention (number and duration of looks) of control and DHA-supplemented infants were numerically similar to the responses observed earlier despite the smaller than intended sample size and several differences in design that could have decreased the response of the experimental group (Table 4).

For example, the shorter period of DHA supplementation might have been expected to decrease or to eliminate the effect of DHA supplementation on number and duration of discrete looks during the test. This did not appear to happen.

Because the effects of DHA supplementation on visual attention were found ten months after DHA was removed from the diet, the data suggested that the early diet had a long-term effect on the neural pathways responsible for differences in look duration. The idea is plausible, given that human milk feeding, which provides DHA, has been shown to increase DHA in the central nervous system compared with DHA-free infant formulas (13,14).

What cannot be concluded from this study is whether or not this short interval of DHA supplementation interacted with the prolonged feeding of nutrient-enriched formula to produce the effects of short-term DHA feeding on 12-month look duration shown here. A comparison of the outcomes at 12 mon for control infants without BPD in this study (Table 5) with controls in our earlier study suggests, however, that prolonged use of a nutrient-supplemented formula in this trial neither enhanced novelty preference nor shortened look duration.

Among preterm infants, it is well known that those with BPD are at higher risk for poorer neurodevelopmental outcomes than those without BPD. The reasons for this are not entirely clear. Because novelty preference has predictive validity for performance on standardized intelligence tests in childhood (15,16), we might have anticipated that infants with BPD would have had a lower novelty preference than those without BPD. Instead, the infants with BPD in this study had the same visual recognition memory (novelty preference) as infants without BPD (Table 5).

Compared with infants without BPD, however, infants with BPD had longer looks during the paired comparison (novelty) tests. When the look durations to the novel stimuli and familiar stimuli were considered independently, BPD infants also had significantly longer duration looks to both novel stimuli and familiar stimuli. The data in Table 5 suggest that the higher look duration seen in the analysis of variance was due to a higher look duration among infants with BPD fed the control diet. Infants with BPD who received the DHA-supplemented diet appeared to have the same look du-

ration as DHA-supplemented infants without a history of BPD. Larger numbers of infants would need to be studied to determine if this is the case.

The familiarization interval for the Fagan Test is long and appears to be insensitive to known differences between groups of infants, e.g., the longer period of familiarization needed by preterm compared with term infants to demonstrate a novelty preference (17). Just as we found earlier (4), dietary DHA increased look number and decreased look duration during paired comparisons but not during familiarizations. Infants with BPD compared with those without BPD, however, had significantly fewer looks (and the reciprocal, longer look duration) during familiarizations, regardless of diet, suggesting poorer ability to shift attention.

In summary, the data from this randomized trial confirmed an earlier report (4) that preterm infants fed DHA have shorter look duration during paired comparison tests than infants fed linolenic acid as their sole dietary source of n-3 fatty acids. These data are analogous to those from monkey infants fed diets with, compared to without, adequate linolenic acid in that the group with better DHA status had a shorter look duration (6). Like novelty preference, shorter visual fixation in infancy is related to superior performance in infancy and childhood (18–20). Longer look duration has been suggested to be evidence of slower visual information processing (21,22), slower ability to disengage attention (23), or increased reactivity. If this is so, preterm infants fed DHA for only a short interval after birth may have more rapid visual information processing or more mature attention months after DHA is removed from their diet.

A Randomized Trial of Visual Attention of Preterm Infants Fed Docosahexaenoic Acid Until Nine Months[1]

Susan H. Werkman[a,b] and Susan E. Carlson[a,b,c,*]

Departments of Pediatrics[a], Obstetrics, Gynecology[b], and Biochemistry[c], The University of Tennessee, Memphis, Memphis, Tennessee 38163

ABSTRACT: This randomized, double-blind trial tested the hypothesis that the addition of 0.2% docosahexaenoic acid (DHA, 22:6n-3) from marine oil to commercially-available preterm and term formulas with ≥3% linolenic acid (18:3n-3) would enhance novelty preference and visual attention of preterm infants. Among preterm infants cared for in our center, study infants were a select group considered to be at lower risk for developmental delay. Study infants received their assigned diet (control, DHA-supplemented) from a mean postnatal age of 25 d until 9 mon past term. At 6.5, 9, and 12 mon past term, they were tested for visual recognition memory (novelty preference) and attention with the Fagan Test of Infant Intelligence. The effects of DHA supplementation were analyzed by repeated measures analysis of variance. In paired comparisons of novel and familiar stimuli, DHA-supplemented and control infants had the same novelty preference, but supplemented infants had more discrete looks to both novel ($P < 0.03$) and familiar ($P < 0.02$) stimuli and a shorter overall look duration ($P < 0.03$). These data are analogous to those from n-3–deficient and n-3–fed monkeys in that the group with better DHA status had shorter overall look duration. Because shorter look duration has been associated with more rapid information processing, preterm infants fed formulas with only linolenic acid may have had slower information processing than those fed DHA.
Lipids 31, 91–97 (1996).

The n-3 fatty acid-deficient diets are known to decrease docosahexaenoic acid (DHA) in retinal (1,2) and neural (2–4) tissues of developing animals. These decreases are associated with impaired retinal responses to light (1,2) and slower than normal visual acuity development (4). Diets that are deficient in n-3 fatty acids also cause behavioral changes on perceptual-cognitive tasks, which have been interpreted both as evidence of poorer discrimination learning (5–8) and as changes in sensory thresholds and maturation and arousal (9). Recently, rhesus monkey infants (10) fed n-3–deficient diets were reported to have increased look duration to both faces and patterns compared with n-3–fed infants, evidence of slower information processing (11,12), slower disengagement of attention (13), or increased reactivity.

Because the effect of an n-3 fatty acid-deficient diet on neural tissue of developing animals is reflected in erythrocyte phospholipid DHA (2,14), and because DHA accumulates rapidly during the last intrauterine trimester (15), low erythrocyte phospholipid DHA in preterm infants fed formula with linolenic acid led us to consider that DHA might be conditionally essential for visual and neural development of these infants (16). An earlier report from this study documented higher visual acuity in the DHA-supplemented group compared with infants fed linolenic acid at 2 and 4 mon (17) past term.

This same randomized, double-blind study also tested the hypothesis that the addition of 0.2% DHA to formulas with ≥3% linolenic acid would enhance novelty preference and visual attention (specifically, an increased number and an average decrease in duration of discrete visual fixations) in the first year of life. In a preliminary report of these data (18), DHA-supplemented infants compared with control infants fed linolenic acid as their sole source of n-3 fatty acids were shown to have an increased number of discrete visual attentions or looks during paired-comparison (novelty) testing but no difference in total looking time. One possible interpretation of these data was that the DHA-supplemented infants had more mature visual attention (19,20). However, the data could not be interpreted in the context of any known effect of n-3 fatty acid deficiency on visual attention. This situation changed with the report of Reisbick *et al.* (10) that n-3–deficient monkey infants had increased look duration compared with n-3–fed monkey infants. Their observation suggested further analysis of the data. The novelty preference and visual attention data from this trial are presented here.

EXPERIMENTAL PROCEDURES

Subject selection. The 67 study infants and their selection have been described in detail elsewhere (17). Their description is summarized in Table 1. Sixty-four of these infants remained in the study after 4 mon and were studied with the Fagan Test. Study infants weighed between 748 and 1398 g at birth and were eligible for the study when they had tolerated enteral intakes >462 kJ (100 kcal) • kg body wt^{-1} • d^{-1} for 5–7 d. Exclusion criteria included a need for mechanical ventilation at that time, intraventricular hemorrhage > grade

Maternal age (yr)	23 ± 6	23 ± 6
Gravida (cm)	2.5 ± 1.4	2.4 ± 1.3
Mother's formal education (yr)	11.4 ± 1.4	11.6 ± 1.6
Father's formal education (yr)	11.9 ± 1.8	11.6 ± 1.1
Ventilator (h)[c]	12 ± 7 (0–596)	6 ± 7 (0–352)
Total oxygen (h)[c]	58 ± 5 (0–830)	46 ± 5 (0–1570)
First formula (h)	78 ± 55	79 ± 54
Age at enrollment (d)	25 ± 10	24 ± 10
Weight at enrollment (g)	1304 ± 183	1330 ± 129

[a]Mean ± SD.
[b]Appropriate for gestational age (AGA)/small for gestational age (SGA). All SGA infants were between the fifth and tenth percentile of weight for age.
[c]Because ventilator and total oxygen were not normally distributed, the individual values were transformed to $\log_{10}$ to approximate a normal distribution. The log hours ($X \pm$ SD) were calculated for each dietary group and the antilog taken to reach $X \pm$ SD (h). The ranges of hours are in parentheses.

2 (21), retinopathy of prematurity > stage 2 (22), surgery for necrotizing enterocolitis, a weight less than the fifth percentile for gestational age, and a history of maternal substance abuse. These criteria were intended to eliminate potential confounding effects of uncontrolled variables such as intrauterine malnutrition, chemical insult, or chronic disease on the planned outcomes of the study.

Experimental design. The study was designed to test several hypotheses, including the hypotheses addressed in this paper, i.e., that novelty preference and visual attention would be enhanced by the addition of DHA to a formula that included the essential fatty acid, linolenic acid. The other planned outcomes of this study included biochemistry (23), visual acuity development (17), and growth (24). All growth and development measures were obtained and blood was drawn at the same follow-up visit. Blood was routinely drawn after all developmental assessments had been completed.

Consent for the study was obtained from a parent or parents according to a protocol approved by The University of Tennessee Institutional Review Board (Memphis, TN). Following this, infants were randomly assigned to a diet group by opening the next available envelope. Each envelope contained a number identifying the formula, and the randomization was done in sequential series of six. Each formula number appeared three times in each set of six envelopes. To produce the experimental formula, a small amount of marine oil was substituted for an equivalent amount of the fat blend in commercially available formulas designed for the nutrient needs of preterm infants (Similac Special Care; Ross Products Division) and term infants (Similac with Iron; Ross Products Division). The predominant fatty acids in the commercially-available formula (control) and the experimental formula (DHA-supplemented) are shown in Table 2. Study infants were fed their assigned preterm formula until discharge from the hospital at ~1.8 kg. After discharge from the hospital, they were fed their assigned term formula (control or DHA-supplemented) until 9 mon past term. Formula remained the infants' major source of nutrients and energy through at least 9 mon past expected term, but other foods were gradually added to the diet beginning at ~4 mon past term. From 9 to 12 mon most infants consumed a mixed diet that included whole cow's milk.

Visual behavior testing. The 29-wk (6.5 mon), 39-wk (9 mon), and 52-wk (12 mon) versions of the Fagan Test of Infant Intelligence (Infantest Corporation, Cleveland, OH) were administered to infants. These ages were calculated from the age the infant should have been 40 wk gestation (term). All tests were administered by the same individual (SHW) who received training by Infantest Corporation personnel in Cleveland, Ohio. She was not aware of the infants' diets at the time of testing. The version of the test used in this study was the one available from the Infantest Corporation in 1987. The test utilized a plastic viewing stage equipped with low voltage, individually housed lights with a magnifying lens attached permanently to the stage, and enclosed with a soft rubber eye cup on the side nearest the tester. The visual stimuli were black-and-white or color pictures of faces printed on washable Kimdura paper to prevent glare and to resist creases.

A Commodore 64 computer with accompanying monitor, keyboard, disk drive, and printer, and capability of accumulating real-time discrete looks of ≥0.1 s was used to record data from each discrete look during the familiarization and information processing portions of the test. The software was formatted so that time during looks to the infant's left side accumulated continuously throughout the time a "left look" key

[a]The preterm formulas contained 812 kcal/L and were fed until infants reached a weight of ~1.8 kg. All infants received their assigned term formula from 1.8 kg until 9 mon after term, calculated from the age they should have been 40 wk gestation. The term formula contained 676 kcal/L. See Table 1 for abbreviation.

was depressed, and time during looks to the right side accumulated continuously while a "right look" key was depressed. Each key depression/release was counted as a discrete look. A discrete look was defined as a look of ≥0.1 s duration. If an infant looked at a picture then looked away before returning his or her attention to the picture and each look was ≥0.1 s duration, two discrete looks were recorded. During the test the infant's mother was seated in a Naugahyde-covered chair with the infant on her lap. The chair was designed to comfortably hold mother and infant but narrow enough to fit between the side panels of the viewing stage. The tester was seated opposite mother and baby on a stool with a pneumatic height adjustment. The stage was placed between mother/baby and the tester and opened toward the tester so the stimuli could be placed rapidly and removed in synchrony with an audible cue from the computer.

The Fagan Test consisted of a series of familiarizations to visual stimuli (pictures of faces) followed by determinations of visual recognition memory in paired comparisons of familiar with novel stimuli. Information processing was determined from the number and duration of discrete looks during these paired comparisons. The Fagan Test has been standardized to take out age effects on novelty preference by manipulating familiarization and test times. Therefore, some age effects that depend upon familiarization criterion and available test times are meaningless or uninterpretable. As noted in the results, these include the number of looks during familiarization and the total time spent looking during paired comparisons. On the other hand, look duration automatically standardizes across various familiarization times and total looking times because it incorporates these times into the definition, so significant effects of age on look duration are meaningful.

During familiarization, infants were required to look for a fixed amount of time before proceeding to the paired-comparison (novelty) test. The time required was dependent upon the age of the infant. Younger infants (6.5 mon) were required to spend more time looking at the pictures during familiarization than older infants (9 and 12 mon). Entry of the infant's birthdate, gestational age at birth, and the date of the test automatically began the correct version of the Fagan Test. On three occasions, infants were shown two copies of the same picture simultaneously. On three other occasions, the same picture was shown on one side of the stage and then moved to the other side for accumulation of the required visual exposure. The discrete looks during these six familiarization periods were summed to equal the total number of looks during familiarization. The discrete looks to the infant's right and left sides, respectively, were also determined.

Following each familiarization, the familiar and a novel picture were placed on the stage together and the infant presented with both for a predetermined amount of time. A novelty preference score (%) was derived from the average percent of total time spent viewing the novel stimuli on ten discrete paired-comparison tests within the version of the Fagan Test administered at each age. Infants with an average score of >57% had a statistically significant novelty preference, i.e., their percent of time spent looking at the novel stimuli compared with the familiar stimuli was greater than chance. In contrast to familiarization, all infants were not required to spend the same total amount of time looking at the pictures during the paired comparisons. Instead, infants were given the opportunity to view the stimuli for a specific amount of time that was dependent on study age. Only a portion of the total time available beginning when the "left look" or "right look" key was depressed needed to be utilized for an infant to successfully complete each paired-comparison test.

Statistical methods. The power analysis for the study was based on the number of infants per group needed to reject the null hypothesis for an effect of DHA supplementation on growth, i.e., 30 infants/group. The effects of diet and study age on visual attention were determined using the General Linear Model procedure of SAS Version 6.0 (Cary, NC) (25) on the mainframe computer at The University of Tennessee, Memphis (Memphis, TN). The experimental design, involving repeated measures over time with each baby serving as its own control, may be called a split-plot or nested-factorial design (26). This analysis is particularly useful for clinical trials of the sort reported in this paper because it retains the advantages of a repeated measures analysis of variance (ANOVA), but neither estimates missing values nor excludes available data from subjects who are not tested at all ages.

Babies were nested within dietary treatments and repeatedly tested at 6.5, 9, and 12 mon. Because not all babies could be evaluated at each age, least-squares means (also called population marginal means or adjusted treatment means) were estimated for each treatment-time subclass (27). Missing values were treated as missing. Because only actual measurements were used in the analysis, the error term was probably larger than would be expected with analyses that allow estimation of missing data. At the same time, babies without assessments at every age were validly included in the analysis. The results reported here were based on 166 individual Fagan Tests: 24, 28, and 29 control infants and 27, 30, and 28 DHA-supplemented infants at 6.5, 9, and 12 mon, respectively. Of the 64 infants studied, 43 were tested at three ages, 16 at two ages, and 5 at one age. The majority of missing 6- and 9-mon values occurred in infants who reached test age before the test was available, while the majority of missing 12-mon values occurred because infants did not return for follow-up. Every available test was included in the analysis.

The specific hypotheses tested in this study were the following: (i) There is no difference in visual attention between the dietary treatments at 6.5, 9, or 12 mon. (ii) There is no change in visual attention over time for either of the two dietary treatments. To test these hypotheses, we subdivided the treatment-time sum of squares and degrees of freedom into separate contrasts and constructed F-tests. The pooled within-baby variance was used as the error term (or denominator) for F-tests of specific hypotheses at each of the time intervals and to assess changes within each dietary treatment group over time. A P value < 0.05 was considered evidence of a significant difference between compared groups.

RESULTS

Age at test. From term, the mean and SD for the actual test ages for these three versions of the Fagan Test were, respectively, 28.6 ± 2.2, 38.9 ± 1.9, and 53.0 ± 2.0 wk for the control group and 28.5 ± 2.7, 38.9 ± 2.2, and 52.7 ± 2.5 wk for the DHA-supplemented group. The mean test ages of the diet groups did not differ significantly at any study age. These study ages are described throughout this paper as 6.5, 9, and 12 mon, respectively.

Effect of diet and study age on visual attention during familiarization. During familiarization, infants in the two diet groups had similar numbers of discrete looks to pictures (Table 3). The total number of looks and the number of looks to the right and to the left were higher at 6.5 mon than at 9 and 12 mon ($P < 0.0001$), but this apparent effect of study age on numbers of looks may not be meaningful because younger infants were required to look at the pictures during familiarization for longer periods of time.

On the other hand, look duration during familiarization was significantly influenced by study age. This age effect is considered meaningful because look duration automatically standardizes across various familiarization times. Look duration decreased with age. Diet did not significantly influence look duration during familiarization, but there was a trend toward shorter look duration in DHA-supplemented infants compared with control infants (Table 3). An examination of the data shows a relatively equal distribution of total looks between the left and the right side at 6.5, 9, and 12 mon. Given the same opportunity to visually explore identical pictures on the left side and the right side of the stage, the infants as a whole did not have a preference for looking to one side or the other.

Effect of diet and study age on visual attention during paired comparisons. During novelty tests, both diet groups had a significant preference for novelty, i.e., they spent a significantly higher proportion of their total looking time viewing the novel stimuli. The ANOVA for the effects of diet and study age indicated that neither diet nor study age influenced overall novelty preference (Table 4); however, at 12 mon, DHA-supplemented infants had a lower novelty preference compared with the control group ($P < 0.05$).

On the whole, infants spent most of their available time during the tests engaged in attention to the pictures on the stage. Diet did not influence the total time spent looking at the visual stimuli during the novelty test, i.e., during the paired comparison between novel and familiar stimuli. Likewise, the actual times spent looking at novel pictures and familiar pictures were not influenced by diet (Table 4). Total looking time, the time spent looking only at novel stimuli, and the time spent looking at only familiar stimuli were higher at 6.5 mon than at 9 and 12 mon (Table 4), but this effect of study age shown by the ANOVA is meaningless given that the 6.5-mon version of the test allows more time for paired comparisons than do the 9- and 12-mon versions.

Diet influenced the number of discrete looks during the novelty test: the DHA-supplemented group had more total (novel and familiar) discrete looks compared with the control group ($P < 0.02$). This increase was also apparent when the number of looks to the novel stimuli ($P < 0.03$) and the number of looks to the familiar stimuli ($P < 0.03$) were considered independently. These increases in the number of total, novel, and familiar looks with DHA supplementation were significant at all study ages (Table 4). Because the DHA-supplemented group had more discrete looks within the same total time spent looking, they also had significantly shorter average look duration compared with the control group ($P < 0.03$). When the duration of looks to novel and familiar stimuli was considered independently, the average look duration to novel stimuli was significantly decreased by DHA supplementation ($P < 0.03$). Both diet groups had roughly similar proportions of looks to novel and familiar stimuli, so novelty

[d]The time allowed for the novelty preference assessment differed with study age. Because younger infants (6.5 mon) were allowed more time to look than older infants (9 and 12 mon), their higher times are a meaningless age effect.

preference was related to a shorter look duration to familiar compared with novel stimuli rather than to a smaller number of looks to familiar compared with novel stimuli.

At each study age, the total number of looks and the independent looks to novel stimuli and familiar stimuli were the same despite the increased time available for viewing the pictures accorded infants who received the 6.5-mon version compared with the 9- and 12-mon versions of the test. The reason for this is apparent following an examination of the effect of study age on the look duration (total, novel, and familiar) at 6.5 mon compared with 9 and 12 mon (Table 4). In each comparison, there was a progressive decrease in look duration with increasing age. The largest decrease occurred between the ages of 6.5 and 9 mon. In every case, the look duration to familiar stimuli during paired comparisons was ~60 to 70% of the look duration to novel stimuli.

DISCUSSION

When we designed this randomized trial in 1987, we asked if DHA was conditionally essential for optimal neural development of preterm infants. Novelty preference was chosen as one outcome. Following exposure to a stimulus (familiarization), primate infants spend more time attending to a novel stimulus (novelty preference) in a paired comparison of the familiar and novel stimuli (28). Novelty preference has been interpreted as an early measure of information processing capability (28). Under controlled conditions, novelty preference has significant, moderate predictive validity for performance on standardized intelligence tests in childhood (29,30). Novelty preference was assessed using a standardized test of novelty preference, the Fagan Test of Infant Intelligence (Fagan Test).

Shorter visual fixation or look duration in infancy has also been shown to be related to superior performance in infancy (31–33) and childhood (34). As noted earlier, short look duration has been interpreted as evidence of more efficient information processing (11,12) or enhanced ability to disengage from attended stimuli (13). At the suggestion of Dr. Susan Rose at Albert Einstein College of Medicine (personal communication), data for visual attention were also obtained. This was made possible because investigators associated with the Infantest Corporation shared software developed to measure looks and look duration during the Fagan Test. These aspects of visual attention rather than novelty preference were influenced by DHA supplementation during infancy.

Because infants were studied for fixed intervals of time at each age, more looks in DHA-supplemented compared with control infants (18) translated into significantly shorter look duration in the DHA-supplemented groups. The data reported here for look duration are, therefore, analogous to those from monkey infants (10) in that the group with better DHA status had a significantly shorter look duration during paired comparisons of novel and familiar stimuli. There was also a trend ($P < 0.12$) toward shorter look duration during familiarization in DHA-supplemented infants compared with control infants, suggesting that we would have found a similar effect during familiarization had larger numbers of infants been studied.

As shown in Table 4, there was no overall treatment (diet) effect on novelty preference with the Fagan Test, and both groups showed a significant novelty preference (the desired outcome) at all study ages. It is important to note that the Fagan Test was designed as a test of novelty preference that could screen for cognitive problems with sensitivity and identify normal cognitive function with specificity. Although effective for these purposes, the Fagan Test of novelty preference does not appear valid for identifying effects of better DHA status in normal infants.

The Fagan Test includes quite long familiarization intervals. If familiarization times are sufficiently long, they effectively ignore differences between groups in time required to habituate to a stimulus. For example, we find that preterm and term infants have a similar novelty preference on the Fagan Test (Carlson, S.E., unpublished data) even though preterm compared with term infants have not demonstrated a novelty preference in other tests with more restricted familiarization intervals (35,36). It is possible that the long familiarization times of the Fagan Test might also mask differences in novelty preference between DHA-supplemented and control infants.

We did find a lower novelty preference at 12 mon in the DHA-supplemented group compared with the group fed standard formula. This could be considered a negative finding (18); however, we do not consider this likely for several reasons. (i) The DHA-supplemented compared with the control group of infants had a similar 12-mon Bayley mental developmental index in this trial (37). (ii) The DHA-supplemented infants had a distinct novelty preference at all study ages, and their novelty preference at 12 mon did not differ from their novelty preference at 6.5 and 9 mon (the expected finding given that the Fagan Test was designed to eliminate age effects on novelty preference). (iii) Preterm infants fed DHA in this trial and a later trial (38) actually appeared to have a more mature pattern of visual attention than controls, processing information relatively more rapidly (11,12). Given long exposures in paired comparisons, infants with more mature visual information processing could habituate to the novel stimuli with a reduction in the percent of time spent viewing the novel stimulus. (iv) Little information is available about normal 12-mon novelty preference and visual behavior because studies relating these outcomes in infancy to later performance have typically involved infants between 3 and 7 mon of age.

This study confirmed that look duration decreases with age (11). We found this effect during both familiarizations and paired comparisons. Within paired comparisons, the decrease in look duration with age was seen for both novel stimuli and familiar stimuli. At each age, there was a remarkable similarity between the time/look during familiarization (when the stimulus was novel) (Table 3) and time/look to the novel stimuli during paired comparisons (Table 4).

In summary, infants fed DHA-supplemented compared with control formula until 9 mon past term had shorter look duration from 6 to 12 mon of age. Shorter look duration can now be included with higher visual acuity as a positive neural outcome of supplementing preterm infants with DHA. The relationship of DHA status to higher visual acuity and shorter look duration is analogous to those in monkey infants. Because preterm infants with the poorest DHA status received ≥3.0% linolenic acid, these data add support to earlier evidence from this randomized trial (17) that dietary DHA is conditionally essential for neural development of preterm infants.

ACKNOWLEDGMENTS

Supported by grants from the National Eye Institute (R01-EY08770), the National Institute of Child Health and Human Development (R01-HD31329), and a gift from Ross Products Division, Abbott Laboratories (Columbus, OH). The authors wish to thank Rosalind S. Griffin for assistance with publication of this manuscript, Dr. Sydney Reisbick for many helpful comments about the original version of the manuscript, and Dr. Elizabeth Tolley for assistance with the experimental design and statistical analysis.

ABSTRACT: It has been recognized that preterm infants have a more rapid development of visual acuity if fed human milk or a formula enriched with the long-chain polyunsaturated fatty acid (LCPUFA) docosahexaenoic acid (DHA) compared to a standard formula devoid of LCPUFA. Few studies have addressed whether the same is also true in term infants. The aim of the present study was to follow visual acuity and fatty acid composition in red blood cells (RBC) for the first 4 mon of life in 17 breast-fed and 16 formula-fed term infants. The formula used did not contain LCPUFA, but contained 1.7 wt% α-linolenic acid, and the linoleic/α-linolenic acid ratio was 8.5. The increase in visual acuity measured by Teller acuity cards developed more rapidly in breast-fed infants compared to formula-fed infants ($P < 0.001$). This was parallelled by a decrease in DHA of RBC in formula-fed infants, and with a significantly lower level at two and four months as compared to breast-fed infants. The content of DHA in milk from the breast-feeding mothers was high compared to other Western countries. The difference in visual acuity between the two feeding groups could be due to differences in DHA status as reflected by the RBC levels, but other explanations are possible. Intervention studies are required to verify if development of visual acuity in term formula-fed infants is dependent on the DHA level of formula.

Lipids 31, 99–105 (1996).

Docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) are rapidly incorporated into brain and retina lipids during the last trimester of pregnancy and the first year of life. Human milk contains DHA and AA, which is in contrast to most formulas presently on the market for term infants (1,2). Therefore, formula-fed infants depend on endogenous synthesis, particulary of DHA, by desaturation, elongation, and β-oxidation from the precursor α-linolenic acid (18:3n-3) (3,4). The synthesis of n-3 long-chain polyunsaturated fatty acids (LCPUFA) is influenced not only by the amount of α-linolenic acid, but also by the ratio of linoleic to α-linolenic acid in the diet, because of competition between these two essential fatty acids, during the formation of LCPUFA through elongation and desaturation (5). Preterm and term infants fed a standard formula with α-linolenic acid as the only n-3 fatty acid have lower levels of plasma and red blood cell (RBC) DHA than infants fed human milk or a formula supplemented with DHA (6–10).

Data indicate that preterm infants are not able to meet their DHA needs by endogenous synthesis, i.e., DHA is conditionally essential for preterm infants. This is supported by the finding that preterm infants randomized to receive formula supplemented with n-3 LCPUFA have a more rapid visual development than preterm infants fed standard formulas devoid of LCPUFA (11,12). Few studies have compared visual acuity in term breast-fed infants and infants fed a standard formula. In two studies, visual acuity was better in the breast-fed infants (13,14), while other studies reported no difference (15,16).

The aim of the present study was to follow the development of visual acuity and the fatty acid composition of RBC during the first four months of life in term infants. The infants were fed either human milk or a formula containing no DHA, but containing 14.4. and 1.7 wt% of total fatty acids as linoleic and α-linolenic acid, respectively, giving rise to a ratio of 8.5 between these two acids. This composition resembles that of human milk and meets current recommendations (17).

MATERIALS AND METHODS

Subjects. Healthy term infants were recruited through maternity departments or health visitors during the first month after delivery. The inclusion criteria were: gestational age 37–42 wk, uncomplicated pregnancy, birth weight between 2700–4500 g, Apgar score >7 after 5 min, and no neonatal diseases. Twenty-three breast-fed and 17 formula-fed infants were included. Six breast-fed infants were excluded; two be-

cause they only attended the first examination and four because the fatty acid analyses were unsuccessful.

Feeding regimen. Thus, in the breast-fed group, 17 infants were included in the analyses; one infant that received one formula meal (<150 mL/d) from three months of age was not excluded, while two infants receiving more than 500 mL of formula from the age of three months were excluded from the analyses of data from the four-month examination.

One formula-fed infant was excluded because he became ill at the age of two months. Among the remaining 16 formula-fed infants only three had never received breast milk. The median duration of breast feeding among the remaining infants was 1.5 wk (interquartile range: 3–17 d). All infants were weaned completely from the breast before the health visitor referred the mothers to us.

Small amounts of supplementary food (vegetable mashes and cereal-based gruel, not more than one meal a day) were introduced to one breast-fed and nine formula-fed infants from the age of three months.

Clinical examination and sampling of blood and milk. The infants were examined at 1, 2, and 4 mon of age. At the first visit, the parents were interviewed about pregnancy and delivery. At each visit, visual acuity, weight, length, and head circumference were measured, and a capillary blood sample was taken by a heel prick. A single milk sample (4 mL) was collected from each breast-feeding mother on all three visits, and was frozen at −80°C until analysis. Based on a review of the literature, Jensen (18) concludes that there are no differences in fatty acid composition of human milk, before and after nursing, from the right or left breast or during the day. Therefore, the mothers were asked to collect the sample at a time they found most convenient.

Fatty acid composition. RBC, obtained from 150–750 μL of blood from the infants, were subjected to lipid extraction based on the method by Folch *et al.* (19) modified for the minor amount of lipid present. Phospholipids were separated by thin-layer chromatography (20), and methyl esters were prepared from the phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions by saponification with 0.5 N NaOH in methanol followed by methylation of the fatty acids with 20% BF_3 in methanol as previously described (21). Methyl ester composition of PC and PE fractions from the infants was determined by gas–liquid chromatography (GC) on a Hewlett-Packard (Avondale, PA) 5890 instrument with on-column injection and a 50 m × 0.25 mm fused-silica capillary column coated with a 0.2 μm film of CP-Sil 88 (Chrompack, Middleburg, The Netherlands). The oven temperature was programmed from 90 to 160°C at a rate of 40°C/min and then to 200°C at 4°C/min, and finally, after 10 min to 220°C at a rate of 4°C/min.

Lipids from the milk were extracted (19), and methyl esters of the total lipids were prepared by direct methylation with KOH in methanol according to Christopherson and Glass (22). The fatty acid composition was determined on a Hewlett-Packard 5880A instrument with split injection and a 30 m × 0.32 mm fused-silica column with a 0.2 μm film of SP2380. The GC temperature program started from 80°C and was increased to 110°C at a rate of 30°C/min and then to 200°C at 4°C/min.

Visual acuity. Binocular acuity was measured by Teller acuity cards in half-octave steps. Infants were held by the parents and tested at 38-cm distance from the card behind a luminance matching grey screen as described by Teller *et al.* (23). The same observer (MHJ) tested all the infants at each examination. She was not blind to the feeding mode of the infants, as blinding was not possible due to practical limitations.

Statistics. Comparison between the feeding groups was done by Student's *t*-test, chi-square tests, or a two-way analysis of variance. Comparison within groups was done by using an analysis of variance. Tracking (i.e., the degree to which an infant with a high or low value at one examination adheres to a high or low value, respectively, at following examinations) was assessed using Pearson correlation coefficients.

RESULTS

There were no differences in basic characteristics (Table 1) or growth pattern (Table 2) when comparing breast-fed and formula-fed infants. Apgar scores after 5 min were ≥9 in all infants. Nor were there statistical differences between the groups with respect to mean age (SD) at the three examinations; the first examination (breast-fed vs. formula-fed) was after 24 (8.5) vs. 27 (8.7) d; the second examination after 63.5 (5.1) vs. 60 (4.8) d; and the third examination after 123 (3.1) vs. 124 (3.6) d.

Diet. The fatty acid compositions of the formula and human milk given are shown in Table 3. The formula contained only trace elements of LCPUFA and no DHA. The linoleic acid content was 14.4 wt%, slightly higher than that of human milk, and the linoleic/α-linolenic ratio was almost similar to that of the milk.

Visual acuity. Visual acuity increased over time in both feeding groups ($P < 0.001$) with a significantly higher increase in the breast-fed group ($P < 0.001$; Fig. 1). At two months, mean visual acuity was 2.6 vs. 1.8 cycles per degree (cy/degr), and at four months was 6.0 vs. 3.8 cy/degr in the breast-fed and formula-fed group, respectively.

There was no significant correlation between RBC DHA and visual acuity within the two feeding groups at four

TABLE 1
Characteristics of Infants According to Feeding Groups[a]

	Breast-fed (n = 17)	Formula-fed (n = 16)	Differences
Gestational age (wk)	40.2 (1.3)	39.8 (1.1)	n.s
Birth length (cm)	51.9 (1.9)	52.4 (2.1)	n.s
Birth weight (g)	3531 (458)	3645 (655)	n.s
Pregnancy weight gain (kg)	14.6 (4.1)	14.9 (6.4)	n.s
Maternal age (yr)	30.8 (3.8)	28.5 (3.8)	n.s
Caesarian (%)	31.3	12.5	n.s

TABLE 2
Anthropometric Data of the Two Feeding Groups[a]

		Breast-fed (n = 17)	Formula fed (n = 16)	Difference
Weight (g)	1 mon	4221.4 (587.2)	4218.9 (655.2)	n.s.
	4 mon	6827.5 (756.0)	7056.0 (976.4)	n.s.
	Weight gain (g/d)	25.9 (4.3)	28.7 (6.1)	n.s.
Length (cm)	1 mon	54.4 (1.7)	54.4 (2.7)	n.s.
	4 mon	63.9 (2.0)	64.8 (2.9)	n.s.
	Growth velocity (cm/d)	0.10 (0.02)	0.11 (0.01)	n.s.
Head circumference (cm)	1 mon	37.5 (1.1)	37.5 (1.4)	n.s.
	4 mon	42.8 (0.9)	42.6 (1.5)	n.s.
	Increase (cm/d)	0.05 (0.008)	0.05 (0.008)	n.s.

[a]Values are mean (SD); n.s., not significant.

months. However, when the two groups were combined, the correlation became significant (PC: r = 0.65, $P < 0.001$; PE: r = 0.48, $P = 0.01$).

RBC fatty acid composition. RBC DHA values were significantly higher in the breast-fed group in both the PC and PE fraction ($P < 0.001$ for both; Fig. 2). The change over time was different for the two feeding groups ($P = 0.006$ and $P < 0.001$ for PC and PE, respectively), with no change in the breast-fed group, and a significant fall in the formula-fed group for both phospholipid classes (both $P < 0.001$). At four months, the mean (SD) DHA levels in the PC fraction were 2.33 wt% (0.71) and 1.00 wt% (0.17), and in the PE fraction 8.26 wt% (2.18) and 4.20 wt% (0.63) in breast-fed and formula-fed infants, respectively.

With respect to changes over time in individual infants, the variation between infants was considerably less within the formula-fed group (Fig. 2). Tracking was also significantly higher in this group as compared with the breast-fed group. Comparing the first and the third examination for formula-fed infants, the Pearson correlation coefficient was 0.88 ($P < 0.001$) for PC and 0.67 ($P = 0.02$) for PE. For breast-fed infants there was no significant tracking.

The RBC eicosapentaenoic acid level in the PC fraction was significantly higher in the breast-fed group ($P < 0.001$), and there was no significant change over time ($P = 0.08$; Fig. 3). In the PE fraction, there was no overall difference between the feeding groups. However, the change over time was significantly different, with no change over time in the breast-fed group and a significant fall in the formula-fed group ($P = 0.009$).

In the PC fraction, RBC AA levels were significantly higher in the breast-fed group ($P < 0.001$, Fig. 3). There was a decrease over time ($P = 0.01$), mainly caused by a decrease in formula-fed infants. In the PE fraction, there was no significant difference between the feeding groups. There was no significant correlation between the AA levels and visual acuity.

Milk and formula fatty acid composition. The mean DHA in the breast milk was high at all ages (≥0.43 wt%), with no change over time (Table 3). Interestingly, two mothers devel-

TABLE 3
Fatty Acid Composition (wt%) of Milk from the Breast-Feeding Mothers and of the Formula Used[a]

	Human milk			
Fatty acid	1 mon (n = 16)	2 mon (n =17)	4 mon (n = 14)	Formula

oped very high relative concentrations during the study period. We have no explanation for this increase in DHA. These two mothers reported a fish intake of 2–3 times a week thoughout the study, which was also reported in eight other cases. They did not change their fish intake, nor did they take fish oil supplements, during the study. If these high values were excluded from the analysis, there was a significant decrease in milk DHA levels from one to two months ($P = 0.01$) and a trend for a decrease from one to four months ($P = 0.09$). Furthermore, there was significant tracking from one to two months (r = 0.66, $P = 0.01$), and a trend for tracking from one to four months (r = 0.59, $P = 0.09$).

DISCUSSION

It has been argued that plasma and RBC lipids may not reflect the concentration of these fatty acids in other tissues, e.g., the central nervous system (24). However, data from infants who died by cot deaths or dehydration showed that breast-fed infants have higher levels of DHA in the cerebral cortex than infants fed a formula devoid of DHA (25,26). Furthermore, it was shown that the level of DHA in cerebral cortex increases with duration of breast-feeding in contrast to formula-fed infants (26). However, no such difference was observed in the retina.

Because the concentration of DHA is particularly high in the synaptosomes of the central nervous system and the outer rod segment of the retina, it is to be expected that symptoms of deficiency should first appear from these tissues. Indeed, the first deficiency symptom in the human species reported was a decrease in visual function. In two randomized studies, preterm infants fed a formula supplemented with fish oil, providing DHA, was found to have a more rapid development of visual acuity as assessed by Teller cards (12) and visual evoked potentials (VEP) (11) than infants fed a controlled formula without DHA.

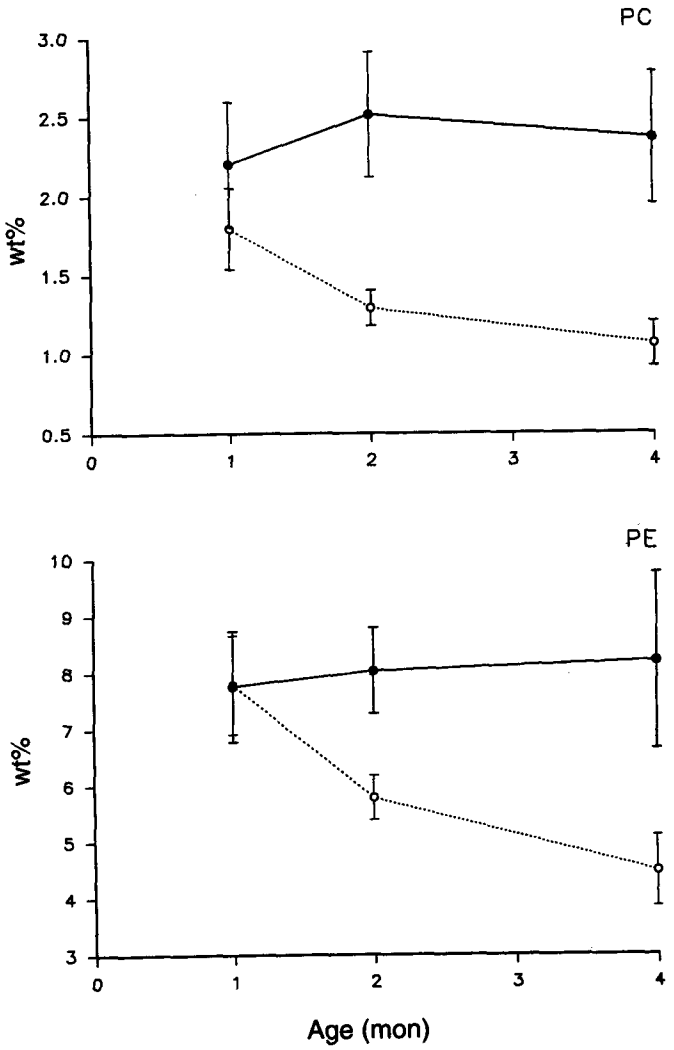

FIG. 2. Red blood cell phospholipid relative docosahexaenoic acid concentration in breast-fed and in formula-fed infants. Bars are ±1.96 SEM; ●—●, breast-fed; ○···○, formula-fed; PC, phosphatidylcholine; PE, phosphatidylethanolamine.

Makrides *et al.* (13), in a nonrandomized study, were the first to report a difference in visual acuity measured by VEP between breast-fed term infants and term infants fed a formula without DHA. On the other hand, Innis *et al.* (15) suggested that when term infants are fed a formula containing 2.1 wt% of the fatty acids as α-linolenic acid, there is no difference in visual acuity measured by Teller cards at three months of age between formula-fed and breast-fed infants. The formula used in the present study contained 1.7 wt% of the fatty acids as α-linolenic acid, which is close to the level used by Innis *et al.* (15), and with the same linoleic to α-linolenic acid ratio. In contrast to Innis *et al.* (27) and others (16), we found a highly significant difference in visual acuity at both two and four months of age (28).

The levels of linoleic and α-linolenic acids were chosen to resemble those of human milk from Danish mothers and to meet current recommendations of the European Society for Pediatric Gastroenterology and Nutrition (17). As the

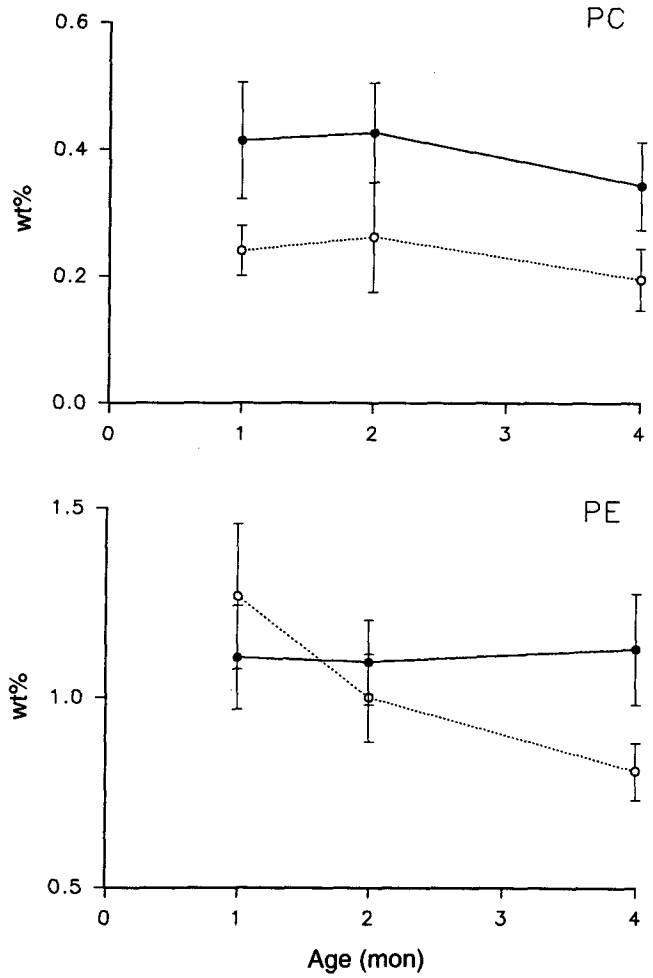

FIG. 3. Red blood cell phospholipid relative eicosapentaenoic acid concentration in breast-fed and in formula-fed infants. Bars are ±1.96 SEM; ●—●, breast-fed; ○···○, formula-fed; abbreviations as in Figure 2.

linoleic/α-linolenic fatty acid ratio is very similar to that used in the previously mentioned studies, it seems unlikely that differences in composition of the formulas could explain the observed differences with respect to visual acuity.

The hypothesis that the difference in DHA intake explains the difference in visual acuity in our term infants is supported in a recent study by Makrides *et al.* (29). They randomized term infants to feeding with a formula without DHA or one with 0.36 wt% DHA and compared with a breast-fed group. They found a higher visual acuity, measured by VEP in the breast-fed and in infants receiving the supplemented formulas, than in infants receiving the unsupplemented formula at 15 and 30 wk of age.

In agreement with others, we found that the relative concentration of RBC DHA decreased in formula-fed infants over time (9). This was true both for the PC and PE fractions of RBC. In contrast, in breast-fed infants, there was no significant decrease in DHA during the first four months of age. The main part of RBC AA was found within the PE fraction. We found no significant difference between the feeding groups in this fraction, although breast-fed infants had significantly higher values in the PC fraction.

In the study of Innis *et al.* (15), the relative concentrations of PC DHA, but not PE DHA, were lower both in breast-fed and in formula-fed infants compared to our study. We cannot explain this, nor do we know if this relates to differences in outcome. It is interesting to note, however, that we found considerably higher levels of DHA in breast milk than did Innis *et al.* (15). The medium levels in the present study, excluding the two mothers with the very high levels, were 0.49, 0.40, and 0.32 wt% at 1, 2, and 4 mon, respectively. In another study including Danish mothers, we found a level of 0.33 wt% (2). This is higher than the 0.2 wt% in the study by Innis *et al.* (15), and values reported from the United States of America, Australia, Germany, Hungary, and Sweden (29–32). This could explain the higher relative concentration in RBC phospholipids in our breast-fed infants.

We found a strong positive association between RBC DHA and visual acuity, which is in accordance with Makrides *et al.* (13). However, it is well known that DHA levels are different

in breast-fed and in formula-fed infants, and the positive association found when combining the two groups is therefore not a strong support that DHA status is important for visual acuity. When we analyzed the association between RBC DHA and visual acuity within each of the two groups separately, the associations were not significant. This could be due to the relatively low number of infants in the groups. In a randomized intervention study of term infants, Carlson *et al.* (33) found a difference in visual acuity at two months but not at four months of age when comparing two different formulas: one with a DHA level of 0.1 wt%, and the other being a standard formula without DHA. Thus, a small amount of DHA in the formula was associated with a transcient improvement in visual acuity, supporting a role for DHA. Furthermore, in the study by Makrides *et al.* (13), DHA was the only fatty acid that correlated to VEP acuity. Hence, it is tempting to speculate that the discrepancy with respect to effect on visual acuity in studies comparing breast-fed and formula-fed term infants could be explained by differences in DHA intake.

Finally, it should be noted that compositional differences between breast milk and formula other than the level of DHA or other polyunsaturated fatty acids might affect the development of visual acuity, compounds that are as yet unknown. The observer was not blinded to the feeding mode when testing visual acuity. Therefore we cannot exclude that the difference found was caused by observed bias. Furthermore, breast feeding *per se* might contribute to the outcome: one reason being that mothers who choose to breast feed may spend more time with their babies and by various means promote their development, including visual function.

ACKNOWLEDGMENTS

The study has been supported by grants from the Food Technology Research and Development Program (FØTEK), DanoChemo A/S, and the Swedish Medical Research Council (19x-05708). Beauvais A/S kindly supplied the formula used in the study.

ABSTRACT: Recent statements concerning linoleic (LA) and α-linolenic acid (LNA) intakes for infants include a desirable range of LA/LNA ratios. To evaluate several dietary LA/LNA ratios, the fatty acid patterns of plasma and erythrocyte phospholipid fractions, as well as plasma total lipid fractions, were determined shortly after birth and at 21, 60, and 120 d of age in term infants fed formula with 16% of fat as LA and either 0.4, 0.95, 1.7, or 3.2% as LNA (LA/LNA ratios of approximately 44, 18, 10, and 5). The content of all n-3 fatty acids in both plasma fractions was higher at all times in infants who received the highest LNA intake; however, the docosahexaenoic acid (DHA) content was only half that shortly after birth or reported in breast-fed infants of comparable ages. The LA content of plasma lipids of all groups was higher at all times than shortly after birth but did not differ among groups. The arachidonic acid (AA) content was higher in infants who received the lowest LNA intake, but only half that at birth or reported in breast-fed infants. In contrast, the DHA content of the erythrocyte phospholipid fraction did not differ among groups until 120 d of age when it was higher in those who received the highest LNA intake and the AA content of this fraction did not differ among groups at any time. These data demonstrate that dietary LA/LNA ratios between 5 and 44 do not result in plasma or erythrocyte lipid levels of DHA or plasma lipid levels of AA similar to those at birth or reported by others in breast-fed infants. However, the data indicate that the LA/LNA ratio of the formula is an important determinant of the amounts of DHA and AA required to achieve plasma and erythrocyte levels of these fatty acids similar to those of breast-fed infants.

Lipids 31, 107–113 (1996).

Docosahexaenoic acid (22:6n-3; DHA) and arachidonic acid (20:4n-6; AA) are important constituents of the structural lipids of membranes, particularly those of the retina and brain (1–4). Although both fatty acids are present in human milk, neither is present in infant formulas currently marketed in the United States. Consequently, the formula-fed infant must synthesize these fatty acids from their 18-carbon precursors, α-linolenic (18:3n-3; LNA) and linoleic acid (18:2n-6; LA), respectively. However, there is considerable evidence that formula-fed infants cannot synthesize sufficient DHA and AA to maintain plasma and erythrocyte levels of these fatty acids comparable to those of breast-fed infants (5–11). Recent postmortem studies (12–14) show that the brain content of DHA, but not AA, also is lower in formula-fed vs. breast-fed infants.

Since infants can synthesize some DHA and AA (15–17), the amounts of dietary LNA and LA, which compete with each other for desaturation and elongation, would be expected to affect endogenous DHA and AA synthesis. However, although a number of national and international advisory groups have recommended specific ranges of intakes of LNA and LA, including the ratio of the two (18–22), data concerning the effects of different dietary LA and LNA intakes and/or different dietary LA/LNA ratios on plasma and/or tissue DHA and AA levels of infants are limited. While ratios as low as four have been recommended (23), only one study, to our knowledge, has included infants fed a dietary LA/LNA ratio lower than seven (7).

The study reported here was designed to determine the effects of four LNA intakes, all accompanied by the same moderate intake of LA and, hence, the effects of four dietary ratios of LA/LNA on fatty acid patterns of plasma and erythrocyte lipid fractions of term infants. The data suggest that the LA/LNA ratio is an important determinant of the amount of DHA and/or AA that must be added to formulas to achieve the same plasma and/or erythrocyte lipid DHA and AA levels observed in breast-fed infants.

METHODS

Study population and study design. Eighty healthy term infants born after at least 37 weeks' gestation (mean gestational age, 39.6 ± 1.7 wk) with birth weights between the 5th and 95th percentiles of the National Center for Health Statistics standards (24) and whose mothers had elected not to breast-feed were assigned randomly and blindly to receive formulas

that differed only in LNA content as their sole source of nutrition from birth to 120 d of age. The fatty acid composition of the formulas and the oils comprising their fat content are shown in Table 1. LA comprised 15.6–17.6% of the total fatty acids of all formulas; LNA content varied from 0.4% in Formula 1 to 3.24% in Formula 4. The LA/LNA ratios of the formulas, which were manufactured by Mead Johnson Nutritionals (Evansville, IN), were 44.0, 18.2, 9.7, and 4.8; their total fat, protein, energy, carbohydrate, vitamin, and mineral contents were similar to those of the standard infant formula, Enfamil (Mead Johnson Nutritionals).

The assigned formula was started during the first day of life, and the intake of each infant throughout the first 120 d of life was estimated as described below. The fatty acid composition of the plasma total lipid fraction as well as the plasma and erythrocyte phospholipid fractions was measured within two days of birth (prior to hospital discharge) and within five days of 21, 60, and 120 d of age (see below).

The study was approved by the Clinical Investigation Committees of Baylor College of Medicine, Texas Children's Hospital, and Harris County Hospital District. Signed informed consent was obtained from at least one parent of all infants enrolled.

Formula intake. Intake of formula during the brief period of hospitalization was determined as the difference between pre- and postfeeding weights of each feeding unit offered. At discharge, at least one case of preweighed ready-to-feed formula was given to the parents at discharge, and additional preweighed cases were delivered to their homes as necessary thereafter (usually weekly or every other week). At each formula delivery, unused formula from the previous delivery was retrieved and weighed. Formula intake during the interval between deliveries was calculated as the difference between the weight of the case of formula delivered and that of the retrieved case. To facilitate calculation of intake during specific intervals (e.g., discharge to 21 d; 21 to 60 d, etc.), a fresh preweighed case of formula was always started immediately after each post-discharge evaluation.

Parents were instructed not to discard any unused formula but, rather, to replace the original lid on each bottle and return it to the case. Inspection of the returned cases indicated excellent compliance with this instruction.

Plasma and erythrocyte fatty acid patterns. Prior to hospital discharge and within five days of 21, 60, and 120 d of age, blood was obtained in EDTA-containing tubes for determining the fatty acid pattern of plasma and erythrocyte lipid fractions. Plasma and erythrocytes were separated immediately by centrifugation and stored separately at −70°C until analysis. For analysis, plasma and erythrocyte lipids were extracted by the method of Bligh and Dyer (25), and the phospholipid fractions of each were separated by one-dimensional thin-layer chromatography (Silica Gel G) using hexane/diethyl ether/glacial acetic acid (70:35:1, by vol). Methyl esters of the component fatty acids of the plasma total lipid and phospholipid fractions, as well as the erythrocyte phospholipid fraction, were prepared with boron trifluoride–methanol (26) and quantitated by gas–liquid chromatography (Varian 3500, Walnut Creek, CA) on a DB-225 capillary column (J&W Scientific, Folsom, CA) in the presence of 17:0 and 21:0 internal standards (27). The fatty acid patterns of the extracted lipid of the four formulas were determined by the same methods (Table 1).

Data analysis. All data are expressed as group means ± SD. Statistical significance of differences in means among groups at each time and differences within and/or among groups over time was tested by analysis of variance or covariance for repeated measures. The value of each fatty acid variable prior to hospital discharge was used as the covariate. Analyses of variance were followed, if indicated, with the Fisher least significance difference procedure for multiple comparisons of each paired group difference. A probability of 5% was assumed to represent statistical significance.

TABLE 1
Fatty Acid Composition (weight percent total fatty acids) of Study Formulas[a]

Fatty acid	Formula 1	Formula 2	Formula 3	Formula 4
8:0	1.3	1.2	1.3	1.2
10:0	0.9	0.9	1.0	1.0
12:0	9.7	9.6	9.6	9.5
14:0	4.7	4.6	4.6	4.6
16:0	23.6	23.3	23.4	23.2
18:0	4.5	4.5	4.5	3.7
20:0	0.3	0.3	0.3	0.3
16:1n-7	0.1	0.15	0.12	0.2
18:1n-9	36.5	36.9	36.6	36.6
22:1n-11	0.02	0.04	0.07	0.3
18:2n-6	17.6	17.3	16.5	15.6
18:3n-3	0.4	0.95	1.7	3.24
18:2n-6/18:3n-3	44.0	18.2	9.7	4.8

[a]The fat content of the formulas included canola, safflower, high-oleic sunflower, palm–stearin, and coconut oils: Formula 1, 3% canola, 15% safflower, 26% high-oleic sunflower, 30% palm stearin, and 26% coconut; Formula 2, 10% canola, 13% safflower, 22% high-oleic sunflower, 30% palm stearin, and 25% coconut; Formula 3, 20% canola, 10% safflower, 15% high-oleic sunflower, 30% palm stearin, and 25% coconut; Formula 4, 40% canola, 5% safflower, 30% palm stearin, and 25% coconut.

RESULTS

Subjects. Sixty-three of the eighty infants enrolled completed the study. Reasons for noncompletion included paternal disapproval (n = 4), unexplained decision to terminate participation (n = 4), maternal desire to attempt breast feeding (n = 2), dietary protein hypersensitivity (n = 2), and change of address (n = 5). The general characteristics of the four completed groups did not differ. Mean birth weights (kg ± SD) of Groups 1 through 4, respectively, were 3.38 ± 0.35 (n = 17), 3.20 ± 0.39 (n = 17), 3.15 ± 0.50, (n = 16), and 3.25 ± 0.48 (n = 13). Mean gestational ages (wk ± SD), respectively, were 39.8 ± 1.4, 39.6 ± 1.8, 39.6 ± 2.0, and 39.6 ± 1.5. Groups 1 and 2 included seven females and ten males; the female/male distribution of Groups 3 and 4 were 10:6 and 7:6. The Black/Hispanic/Caucasian distribution of the four completed groups

were: Group 1, 13:2:2; Group 2, 13:2:2; Group 3, 8:7:1; Group 4, 5:7:1.

The three postdischarge studies were performed at mean ages of 23.5 ± 4.5, 62.0 ± 5.3, and 124.4 ± 3.4 d in Group 1; 21.9 ± 1.5, 62.3 ± 4.7, and 123.4 ± 5.4 d in Group 2; 22.9 ± 3.1, 62.1 ± 2.1, and 122.2 ± 2.4 d in Group 3; and 22.0 ± 3.3, 60.2 ± 2.4, and 119.7 ± 3.1 d in Group 4.

Formula intake. There were no statistically significant differences in formula intake among groups either before hospital discharge or during any of the study intervals (data not shown). By history, none of the infants received foods other than the assigned formula before 120 d of age.

Plasma and erythrocyte fatty acid patterns. The mean mole percent of saturated and monounsaturated as well as individual n-3 and n-6 polyunsaturated fatty acids in the plasma phospholipids of all groups shortly after birth and at each postdischarge study are shown in Table 2. There were few statistically significant differences in the plasma phospholipid fatty acid patterns of individual groups at 21 vs. 60 vs. 120 d of age (i.e., group differences were apparent by 21 d of age and persisted through 120 d of age). However, the percentage of many fatty acids at these times differed from the percentage shortly after birth.

There were no statistically significant differences in the plasma phospholipid content of saturated or monounsaturated fatty acids among the formula groups at any time. At all times postdischarge, the percentages of 18:3n-3 (LNA), 20:5n-3, and 22:5n-3 were highest in the group that received the highest LNA intake (Group 4) and lowest in the group that received the lowest LNA intake (Group 1). The DHA (22:6n-3) content was lower than shortly after birth in all groups at all times postdischarge, but the content of Group 4 was significantly higher than that of the other three groups, the contents of which did not differ significantly.

The 18:2n-6 (LA) content of the plasma phospholipid fraction was higher than shortly after birth in all groups at 21, 60, and 120 d but did not differ among groups. The percentage of 20:4n-6 (AA) was significantly lower in all groups at 21, 60, and 120 d than shortly after birth, but, at all times, the percentage was higher in Group 1, which received the lowest LNA intake, than in Groups 2, 3, and 4. The percentages of both 22:4 n-6 and 22:5 n-6 were lowest at all times postdischarge in Group 4, which received the highest LNA intake, and highest in Group 1, which received the lowest LNA intake. The percentages of these fatty acids in Groups 2 and 3 were intermediate.

The mole percentages of most fatty acids in the plasma total lipid fraction (data not shown) differed quantitatively from the percentages in the plasma phospholipid fraction but the relative differences among groups and over time were similar to those observed in the plasma phospholipid fraction. Thus, these data and the fatty acid concentrations of the plasma phospholipid and total lipid fraction, which also did not provide additional information, are not shown (they can be obtained upon request from the authors).

The mean mole percent of total saturated and monounsaturated as well as selected n-3 and n-6 fatty acids of the erythrocyte phospholipid fractions of all groups at each time are shown in Table 3. For the most part, the fatty acid patterns of this fraction reflected the same relative differences among

TABLE 2
Fatty Acid Pattern of Plasma Phospholipid Fraction (mole percent) (from birth to 120 d of age)[a]

	Birth	21 Days	60 Days	120 Days
Total saturated fatty acids

[a]Statistically significant differences ($P < 0.05$) among groups at each time are indicated by different superscripts (a–d).

groups as the plasma phospholipid fraction. However, there were some important differences. The percentage of DHA in erythrocyte phospholipids at 21 and 60 d did not differ significantly from that shortly after birth in any group, and there were no statistically significant differences among groups; however, at 120 d, the percentage of DHA was lower in all groups than shortly after birth and significantly lower in Groups 1, 2, and 3 than in Group 4, which received the highest LNA intake. There were no statistically significant differences in the AA content of this fraction among groups at any time, and in all groups, the percentage at all times was from 18% (Group 2) to 50% (Group 1) higher than shortly after birth. The percentage of 22:4n-6 and 22:5n-6 did not differ among groups at 21 d but thereafter, the percentage of these fatty acids was lower, although not necessarily lower than shortly after birth, in Group 4 vs. Groups 1, 2, and 3.

DISCUSSION

As reported above and as expected, the highest LNA intake studied, or the lowest LA/LNA ratio resulted in higher plasma phospholipid and total lipid levels of DHA; the lowest LNA intake studied, or the highest ratio, resulted in higher AA levels. However, the DHA and AA contents of these plasma lipid fractions from 21 to 120 d of age were lower than shortly after birth and also lower than reported by others in breast-fed infants (8). Thus, no dietary LA/LNA ratio between 4.8 and 44 results in plasma lipid levels of either DHA or AA similar to those of breast-fed infants. Moreover, examination of the plasma phospholipid content of all n-3 and n-6 fatty acids suggests that this goal is unlikely to be achieved with either a lower or a higher dietary LA/LNA ratio.

The highest vs. the lowest LNA intake resulted in a severalfold greater plasma phospholipid content of LNA and EPA (20:5n-3), but only a modestly greater content of DHA. Similarly, this LNA intake resulted in a modestly lower plasma phospholipid content of AA but a markedly lower content of 22:5n-6. Similar but less marked effects also were observed by Clark *et al.* (7) in term infants fed formulas with 3.3 vs. 0.7% of fat as LNA (both with 13–14% of fat as LA). Ponder *et al.* (8) observed a higher eicosapentaenoic acid (EPA) content of plasma phospholipids in term infants fed formulas with 4.8 vs. 0.8% of fat as LNA (with 34 and 31% of fat, respectively, as LA) but no difference in the content of LNA, AA, or 22:5n-6. Marked increases in the LNA, EPA, and 22:5n-3 contents of the plasma phospholipid fraction and an actual decrease in DHA content were observed by Anderson *et al.* (28) in dogs that received a much higher intake of LNA and by Mantzioris *et al.* (29) in human volunteers who received 5.3% of energy intake as LNA and 3.3% as LA. The effect of the high LNA intake on n-6 fatty acids observed by Anderson *et al.* (28) in dogs and Mantzioris *et al.* (29) in human volunteers also was similar to the effect reported here, i.e., a modest decrease in plasma phospholipid AA but a more dramatic decrease in plasma phospholipid 22:4n-6 and 22:5n-6.

These effects of LNA intake on the content of long-chain, polyunsaturated n-3 and n-6 fatty acids in plasma lipids are difficult to explain totally by competition between LNA and LA for Δ^6-desaturation, respectively, to 18:4n-3 and 18:3n-6.

Mantzioris *et al.* (29) speculated that the inverse relationship between dietary LNA and the DHA content of phospholipids might represent displacement of DHA by EPA or by LNA itself. The effect also can be explained by competition of LNA, and possibly LA, with 24:5n-3 and 24:4n-6 for Δ^6-desaturation, respectively, to 24:6n-3 to 24:5n-6. These 24-carbon fatty acids are part of a pathway that was described recently in isolated hepatocytes (30,31) and has been shown to be involved in *in vivo* synthesis of 22:6n-3 by human infants (32,33). In this pathway, 22:5n-3 and 22:4n-6, rather than, and/or in addition to, undergoing Δ^4-desaturation to 22:6n-3 and 22:5n-6, respectively, are elongated to 24:5n-3 and 24:4n-6, which then undergo Δ^6-desaturation, and the products, 24:6n-3 and 24:5n-6, in turn, undergo β-oxidation, presumably in peroxisomes, to 22:6n-3 and 22:5n-6. Alternatively, or additionally, increased 22:5n-3 incident to the higher LNA intake could compete with 22:4n-6 for Δ^4-desaturation of 22:5n-3 to 22:6n-3 and 22:4n-6 to 22:5n-6. However, a Δ^4-desaturase has never been detected, and some believe that there may be no such enzyme (34,35).

Whatever the specific mechanism, the implications of the observed effects of LNA intake on n-3 and n-6 fatty acid metabolism are clear. If LNA, the precursor of DHA, interferes directly with synthesis of DHA as well as the corresponding n-6 polyunsaturated fatty acid (22:5n-6), an intake of LNA greater than the highest intake studied here, or a LA/LNA ratio lower than the lowest ratio studied, might reduce rather than increase the plasma phospholipid content of DHA, as observed by Anderson *et al.* (28) in dogs and Mantzioris *et al.* (29) in human volunteers.

Since the dietary LA/LNA ratio affects the plasma phospholipid content of both DHA and AA, it is clear that the intake of DHA and/or AA required to produce plasma lipid levels of these fatty acids similar to those of breast-fed infants will depend upon the LA/LNA ratio of the formula to which they are added. In other words, current recommendations to supplement infant formulas with the amounts of DHA and AA in human milk may only be appropriate for formulas with the same LA and LNA contents as human milk. Unfortunately, the LA and LNA, as well as the AA and DHA, contents of human milk are quite variable and dependent on maternal diet (36,37).

Despite differences in the DHA and AA content of plasma lipids incident to LNA intake, a statistically significant difference in the DHA content of erythrocyte phospholipid was not observed prior to 120 d of age, and the percentage of AA in this fraction at 120 d was higher in all groups than shortly after birth. This suggests that the early differences in plasma phospholipid contents of these fatty acids among groups may have limited physiological relevance, particularly if the fatty acid pattern of erythrocyte phospholipid more closely reflects the pattern of tissue lipids than the fatty acid pattern of plasma lipid as suggested by animal studies (38,39) as well as recent postmortem studies in infants (12–14,40).

The lack of difference in the AA content of the erythrocyte phospholipid fraction reported here is in agreement with the findings of Ponder *et al.* (8) in the erythrocyte phosphatidylcholine and phosphatidylethanolamine fractions of term infants fed LA/LNA ratios of 39 vs. 7 and Clark *et al.* (7) in the erythrocyte total lipid fraction of infants fed LA/LNA ratios of 19.2 vs. 3.8. In addition, postmortem studies have shown no difference in brain AA content of breast-fed vs. formula-fed infants (12–14). Taken together, these findings suggest that supplementing infant formulas with only DHA might result in an erythrocyte (and presumably other tissue) lipid fatty acid pattern, although not a plasma lipid pattern, similar to that of breast-fed infants. However, Auestad *et al.* (41) recently reported that addition of DHA (0.23% of total fatty acids) to a formula containing 20.7% of fatty acids as LA and 1.9% as LNA (LA/LNA = ~11) resulted in a decrease in the AA content of erythrocyte phosphatidylethanolamine.

Finally, although the study reported here did not directly address the issue of whether formulas for term infants should be supplemented with DHA and/or AA, the data reported contribute to the growing body of evidence, suggesting that supplementation with one or both fatty acids will be required to achieve plasma and tissue lipid contents of both DHA and AA similar to those of breast-fed infants. Equally important, the data suggest that the amounts of AA and/or DHA needed to achieve either goal will depend upon the relative amounts of the precursors of both fatty acids in the formula. It is important to emphasize that the LA/LNA ratios of the formulas evaluated in this study were achieved by altering only LNA content. Achieving the same intake ratios by altering only LA intake, theoretically, should produce the same results; however, this remains to be proven.

Is Dietary Docosahexaenoic Acid Essential for Term Infants?[1]

Maria Makrides, Mark A. Neumann, and Robert A. Gibson*

Department of Paediatrics and Child Health, Flinders Medical Centre, Adelaide SA 5042, Australia

ABSTRACT: There is a need to determine whether there is a dietary requirement for docosahexaenoic acid (DHA, 22:6ω3) by term infants to achieve their full developmental potential. Studies of brain fatty acid composition have demonstrated that infants who were breast fed have greater levels of cerebral cortex DHA than infants who were formula fed, suggesting that DHA in the cerebrum is dependent on a supply in the diet. Some physiological studies report that electrophysiological and behavioral assessments of visual function are improved in breast-fed infants relative to those fed formula, and that this is related to the level of DHA in their erythrocytes, whereas other studies demonstrate equivalent visual function between breast- and formula-fed infants. However, randomized studies of DHA supplementation of infant formula demonstrate that the visual function of formula-fed infants can be improved to breast-fed levels by adding DHA to formula. Further work is necessary to establish if there are long-term benefits of dietary DHA to the term infant.

Lipids 31, 115–119 (1996).

The definition of essential fatty acid (EFA) requirement in infancy is controversial. Classically, a nutrient requirement or recommended daily allowance (RDA) is defined as the daily intake of a specific indispensable nutrient that would prevent 98% of a healthy population from developing a deficiency syndrome that could only be reversed by the addition of that nutrient to the diet. Such dietary deficiency syndromes are severe and usually life-threatening. For example, the RDA for vitamin C is set to prevent the development of scurvy, and the RDA for thiamine (vitamin B_1) is set to protect against beriberi. For today's Western society, the relevance of such conservative estimates of dietary adequacy may be questionable as issues relating to intake of specific nutrients are more likely to revolve around the question of the intake necessary to fulfill full genetic potential. Such challenges are particularly pertinent to the field of fatty acid nutrition, as much controversy has surrounded the definition of EFA requirements in infancy.

Linoleic acid (LA; 18:2ω6) used to be considered the only EFA that must be supplied in infant diets to prevent functional abnormalities. The symptoms of classic EFA (LA) deficiency include scaly, dry skin lesions, failure to thrive, and growth retardation. Such cases of EFA (LA) deficiency have only been reported in patients maintained on lipid-free intravenous nutrition (1,2) or in infants consuming skim milk-based diets (3). In all cases, the deficiency symptoms were reversed by the addition of LA to the diet. Cuthbertson (4) argued that the minimum requirements for EFA (LA) were less than 1% of total energy. If one strictly defines a dietary requirement as a minimum level of intake to avoid the development of a deficiency syndrome (as in the RDA model), then Cuthbertson's (4) assertion is probably true.

In contrast to LA, α-linolenic acid (ALA; 18:3ω3) deficiency in humans has not been extensively documented, and most clues have come from the animal literature. For example, ALA deficiency produces alopecia and scaly dermatitis in Capuchin monkeys (5) and loss of visual acuity in young Rhesus monkeys (6). In humans, ALA deficiency has been described only in one six-year-old girl presenting with neurologic and visual symptoms (7), and in five adult patients presenting with cutaneous symptoms following either prolonged intravenous nutrition (8) or long-term gastric tube feeding (9). However, in all these cases, the ALA symptoms may be partly accounted for by other nutritional deficiencies: for example, low levels of vitamin E or total EFA deficiency. The authors estimate a daily ALA requirement corresponding to 0.3–0.5% of energy to avoid deficiency symptoms (7–9).

However, over the last decade, much research interest had focused on the longer chain products of LA and ALA metabolism, as it is these metabolites that are believed to be of physiological importance. For example, arachidonic acid (AA; 20:4ω6) and eicosapentaenoic acid (EPA; 20:5ω3) are needed as indispensable precursors for the synthesis of eicosanoids (prostaglandins, thromboxanes, and leukotrienes) that operate as regulators of various cell and tissue functions. Furthermore, during perinatal development, large amounts of long-chain polyunsaturated fatty acids (LCPUFA), such as docosahexaenoic acid (DHA; 22:6ω3) and AA, are incorporated into membrane phospholipids of all tissues (10–13). LCPUFA composition of membranes is of structural and functional importance as it contributes to the modulation of

membrane properties such as fluidity, permeability, and activity of membrane-bound receptors and enzymes (14). The highest LCPUFA concentrations are found in synaptosomal membranes and photoreceptors, and most of these LCPUFA are deposited in the last trimester of pregnancy and during early life (12,13). A number of animal studies have demonstrated a close association between perinatal EFA supply and ω3 LCPUFA contents of neural lipids, and to the development of visual function (6,15). A similar relation between ω3 LCPUFA and visual function also has been reported for preterm infants, resulting in expert nutrition committees recommending that preterm formulas be supplemented with LCPUFA (16,17), as LCPUFA, such as DHA and AA, occur in breast milk but are not contained in most formulas. Such recommendations are based on optimizing performance of preterm infants and, hence, defining a "sufficiency state" rather than preventing deficiency as unsupplemented infants manage to survive without major complications.

However, the definition of a sufficient state for the term infant is highly debatable. Recent studies comparing the fatty acid status and visual function of breast- and formula-fed term infants have reported mixed results (18–21), and there is an apparent reluctance to accept that the term infant may be as vulnerable as the preterm infant, especially as term infants grow and thrive on current formulas. The scope of this paper is to review and update the biochemical and physiological evidence that may implicate a role for DHA in the optimal development of the healthy, term infant.

Brain composition. It is perhaps not suprising that dietary fat composition has an effect on the fatty acids that are accumulated in brain tissue of human infants during the first year of life as the weight of the brain of infants is reported to increase by 750 g (22). Although much of this weight gain is thought to be due to myelination (thus chiefly involving the accumulation of saturated and monounsaturated fatty acids), a large degree of nerve cell proliferation also occurs involving cell membranes rich in LCPUFA. However, the results of early animal studies, particularly those with weanling rats, lead to a belief by some that young brains were impervious to change by dietary fats (23). More recent results (24) have highlighted the possibility that compositional change of brain tissue is only possible during a distinct period (or window) soon after birth.

We have previously reported that the lipids of the cerebral cortex taken from breast-fed infants were higher in DHA than in infants fed formula. These results have been confirmed by other investigators (22,25). We have continued to analyze samples of tissue as they became available (Fig. 1). Our current results confirm that accumulation of DHA in the cerebral cortex of breast-fed infants continues for at least 40 wk of life, increasing from a value of about 7.5 to about 10% of total fatty acids (Fig. 1A). Although our earlier results (26) indicated no change in birth levels of formula-fed infants, the increased sample size makes it clear that DHA also accumulates in formula-fed infants, but at a much reduced rate (from about 7 to about 8% total fatty acids in 40 wk) relative to breast-fed infants.

Levels of AA also change dramatically after birth, increasing in a curvilinear manner from approximately 9 to 12% of total fatty acids in the first 20 wk of life (Fig. 1B). Interestingly, these changes are independent of diet, indicating that either AA is aggressively accumulated, or that synthesis of AA from its 18 carbon precursor, LA, is sufficient to meet the requirement of the growing infant brain. Another way of phrasing this is that the dietary AA provided in breast milk may be redundant as far as the biochemistry of the brain is concerned, and that the lower AA levels in the blood of formula-fed infants may have limited relevance.

The percentage of LCPUFA does not increase in all areas of the brain in the first year of life. In the brain stem there is a continuous depletion in the proportions of both DHA (Fig. 1C) and AA (Fig. 1D) which is independent of diet. These results are consistent with the myelination that is known to occur in the brain stem during this period, and reflected by the increasing levels of monounsaturated fatty acids ($r^2 = 0.53$, $P < 0.001$).

It is important to stress that the infants from which brain samples were taken in both our studies and that were reported by Farquharson and co-workers (22,25) were all term infants. In particular, the infants in our studies all died suddenly and were apparently well immediately prior to death. Thus, the spectrum of fatty acids observed in these subjects is likely to reflect the pattern of the brains of living infants of equivalent ages. Even though term infants have presumably benefited from a full placental supply of LCPUFA, brain growth continues postnatally and the brain remains plastic to compositional change for at least 40 wk.

The fundamental importance of these results is that the level of DHA of the cerebrum is dependent on a supply of DHA in the diet. Providing only ALA in the diet, at least at the levels provided in current infant formulas, appears to be inadequate to support maximum deposition of DHA in the brain of the developing term infant. It is reasonable to postulate that these diet-induced changes in the brain cortex composition may have some physiological sequelae.

Breast vs. formula-fed infants. Our initial work suggested that there was a measurable functional difference between breast- and formula-fed infants (18). In this study (18), visual evoked potential (VEP) acuity was examined as a measure of neural maturity of the visual pathway of healthy term infants fed either breast milk or formula, along with their polyunsaturated fatty acid status. We observed that breast-fed infants had better VEP acuity than formula-fed infants, and that there was also a correlation ($r^2 = 0.42$, $P < 0.01$) between VEP acuity and erythrocyte DHA (marker of DHA tissue status). Thus, formula-fed infants had low DHA levels and reduced visual acuity, whereas breast-fed infants had high DHA levels and increased acuity.

Some other studies comparing breast and formula feeding have demonstrated comparable results (Table 1). Birch and co-workers (19) showed superior visual acuity as assessed by both VEP and forced choice preferential looking in breast-fed compared with formula-fed infants at four months of age. The

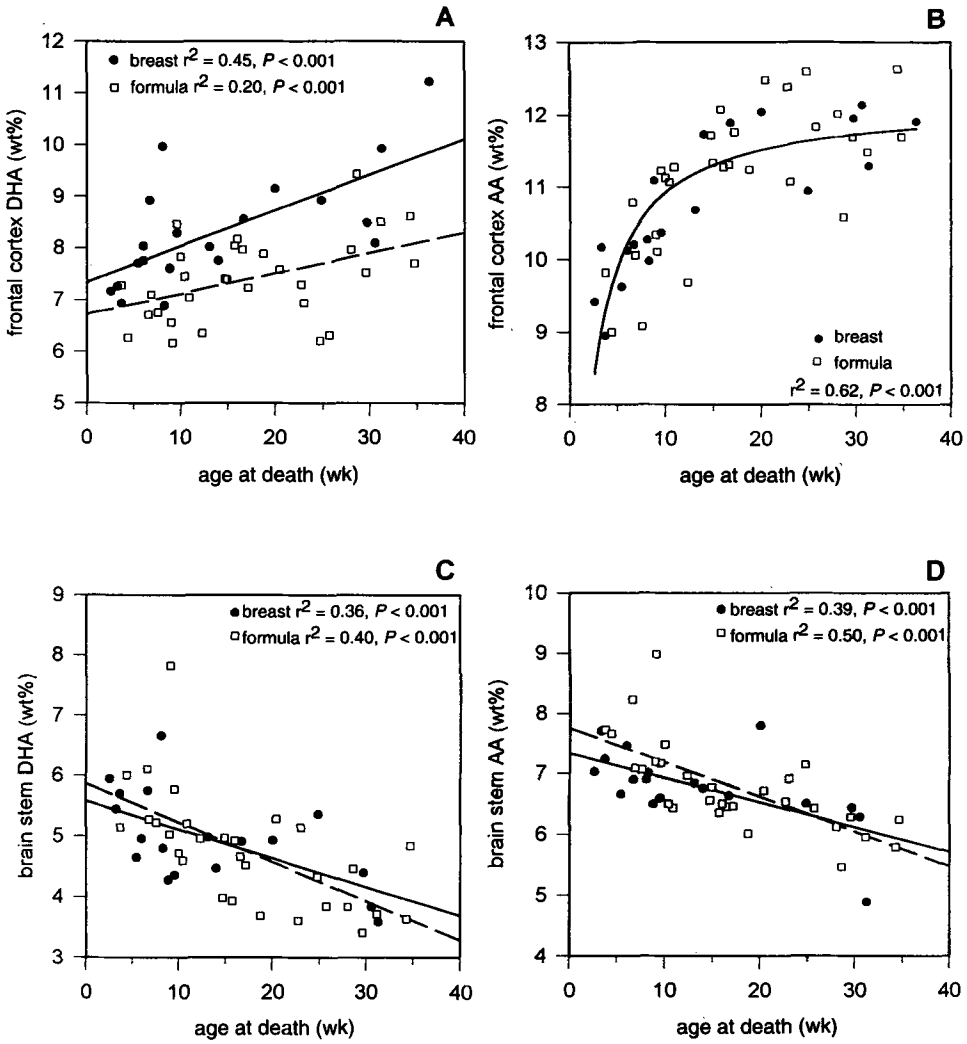

FIG. 1. Levels of docosahexaenoic acid (DHA; A,C) and arachidonic acid (AA; B,D) in brain frontal cortex (A,B) and brain stem (C,D) taken from term infants who died suddenly plotted as a function of age at death. Breast-fed infants (n = 21 frontal cortex; n = 19 brain stem) are defined as those receiving breast milk for ≥85% of their lives. Formula-fed infants (n = 30) are defined as those receiving breast milk for <30% of their lives.

mean VEP acuity of the breast-fed group was 0.51 log units compared with 0.62 log units for the formula-fed group ($P < 0.05$). Similarly, forced choice preferential looking acuity was also better in breast-fed rather than in formula-fed infants (0.73 vs. 0.81 log units, $P < 0.05$). These results were confirmed in a study by Jorgensen *et al.* (20) that demonstrated improved behavioral acuity at two and four months in exclusively breast-fed infants over those that were predominantly fed infant formula, despite the fact that the latter group were initially breast fed for some weeks (<4 wk). In contrast, Innis and co-workers (21) failed to detect any differences in visual acuity between breast- and formula-fed term infants at three months of age. It may be that the differences in these results will eventually be explained by variations in methodologies chosen to assess visual function. Relative to behavioral methods, VEP acuity has lower (better) acuity thresholds and tends to mature more rapidly (27,28). Alternatively, the disparity in the results may be explained by differences in the availability of ALA (the DHA precursor) in the various formula fat blends tested; or other confounding influences, such as gender, parental education, and socioeconomic status, none of which are accounted for in these studies.

However, the association between acuity or development and mode of feeding provides no evidence of causation. Randomized studies comparing the visual and neural development of infants fed formula supplemented with and without DHA are necessary for a causative link between dietary DHA and visual development in healthy, term infants to be established. Indeed, data from such studies are emerging from a number of research centers and are providing unique information regarding the potential role of DHA in a "complete and sufficient" diet for infants born at term.

Randomized studies of ω3 LCPUFA supplementation. Two randomized trials of ω3 LCPUFA supplementation of infant formula have been reported in term infants (see Table 2). In both studies, mothers who chose to formula feed their infants from birth were randomized to receive either a supplemented or placebo formula, and were compared with a reference group of breast-fed infants. In our study (29), VEP were performed under transient conditions at 16 and 30 wk, and VEP acuity was determined. Breast-fed infants and those supplemented with 0.36% DHA (in the form of a fish and evening primrose oil blend) had significantly better acuities than infants fed standard formula at both 16 ($P < 0.001$) and 30 ($P < 0.01$) weeks of age. These results provided no evidence of "catch-up" with age and are consistent with the visual loss observed in the rhesus monkey model of ω3 fatty acid deficiency (6). Carlson *et al.* (30) also demonstrated improved acuity, as assessed by the Teller method, in infants fed breast milk or DHA-supplemented formula compared with infants fed standard formula at two months of age. Unlike the results of our study, the effect of DHA supplementation was not evident in older infants. This may be explained by the different nature of the chosen assessments, or alternatively, by the differences in availability of ω3 fatty acids in the two test formulas.

In summary, both studies provide evidence for a functional role for dietary DHA in healthy, term infants. Interestingly, both studies measured effects on different aspects of visual function, with the VEP providing a visual sensory threshold measured at the occipital cortex and the behavioral (Teller) acuity requiring the integration of neural processes beyond the occipital (visual) cortex. Indeed, biochemical data on cerebral cortex fatty acid composition is consistent with the assertion that DHA is important for brain function. We sampled cerebral cortex tissue from the anterior frontal lobe (26), and Farquharson *et al.* sampled parietal lobe (22,25). Both these brain areas are associated with integrative neural processes and functions, suggesting that the dietary effects of DHA may not be limited to the visual pathway. Further study of fatty acid composition of specific brain loci may provide clues as to the types of physiological functions that may be affected. Such studies are necessary to complement and validate the results of randomized clinical trials in infants.

Since the preparation of this manuscript, two other randomized studies of LCPUFA supplementation of infant formula for term infants have been published (31,32). Agostoni

et al. (31) report that term infants fed a formula supplemented with DHA and AA from an egg phospholipid source have a higher developmental quotient than unsupplemented infants. Conversely, Auestad and co-workers (32,33) demonstrated no effect of LCPUFA supplementation on visual, mental, or psychomotor development of term infants.

REVIEW

Trans Unsaturated Fatty Acids in Bacteria

Heribert Kewelohᵃ,* and Hermann J. Heipieperᵇ

ᵃDepartment of Microbiology, University of Münster, D-48149 Münster, Germany and ᵇDivision of Industrial Microbiology, Department of Food Science, Wageningen Agricultural University, 6700 EV Wageningen, The Netherlands

ABSTRACT: The occurrence of *trans* unsaturated fatty acids as by-products of fatty acid transformations carried out by the obligate anaerobic ruminal microflora has been well known for a long time. In recent years, fatty acids with *trans* configurations also have been detected in the membrane lipids of various aerobic bacteria. Besides several psychrophilic organisms, bacteria-degrading pollutants, such as *Pseudomonas putida*, are able to synthesize these compounds *de novo*. In contrast to the *trans* fatty acids formed by rumen bacteria, the membrane constituents of aerobic bacteria are synthesized by a direct isomerization of the complementary *cis* configuration of the double bond without a shift of the position. This system of isomerization is located in the cytoplasmic membrane. The conversion of *cis* unsaturated fatty acids to *trans* changes the membrane fluidity in response to environmental stimuli, particularly where growth is inhibited due to the presence of high concentrations of toxic substances. Under these conditions, lipid synthesis also stops so that the cells are not able to modify their membrane fluidity by any other mechanism.
Lipids 31, 129–137 (1996).

OCCURRENCE OF *TRANS* FATTY ACIDS IN PROKARYOTES

In contrast to eukaryotic cells, bacteria usually do not have reserve fats in the form of triacylglycerols, and their fatty acids are only found as components of membrane lipids. If grown under standardized conditions, bacteria possess a constant fatty acid composition which is specific for a genus or even a species. Because membrane fatty acids can be extracted and measured with relatively simple methods (1,2), the identification of bacteria with the help of their fatty acid composition as a biochemical marker has become a routine method (3–7).

Whereas Archaebacteria mainly have isoprenoid compounds instead of fatty acids as constituents of their membrane lipids (8), the well-known spectrum of bacterial fatty acids comprises saturated, *cis*-monounsaturated, cyclopropane, and methyl-branched fatty acids. During the last years, two new fatty acid types have been found as membrane constituents of prokaryotes—polyunsaturated fatty acids (9–11) and a completely novel class of fatty acids, *trans* configurated unsaturated fatty acids. Even some years ago, the *trans* configuration of the double bond was described as an exception usually not found in unsaturated fatty acids of bacteria (12). One reason for this development may have been the introduction of capillary columns into gas-chromatographic techniques which led to a much better differentiation between fatty acid methyl esters (13,14).

It has long been known that the rumen and the feces of animals and humans contain high amounts of *trans* fatty acids. Apparently, hydrogenation of multiple unsaturated fatty acids from plant material by the ruminal and intestinal bacterial flora is responsible for this occurrence (15). It is well documented that bacteria like *Eubacterium lentum* reduce different unsaturated fatty acids, such as linolenic and linoleic acid, to yield largely stearic acid and some *trans* acyl derivatives (16,17). The physiological reasons for these fatty acid transformations in the anaerobic environment are still unknown. It has been reported that the polyunsaturated fatty acids are more toxic to the anaerobic bacteria than are the products of hydrogenation. Therefore, one function of bacterial fatty acid transformations may be to destroy growth-inhibiting substances (17). Another suggestion is that this process enables the strictly anaerobic bacteria to dispose excess reducing power (15). This bacterial activity is also responsible for the occurrence of *trans* fatty acids in cow's milk and milk products such as butter. Depending on the diet, milk fat has 2–9% total *trans* fatty acid isomers. Besides the consumption of artificially-derived fats as hydrogenated vegetable oils, the uptake of these bacterial transformation products leads to the presence of *trans* fatty acids in humans. The risk of dietary intake of *trans* isomers for human health, including coronary heart disease, is a matter of considerable controversy (18–24).

In several respects, the ruminal transformation process is different from the synthesis of *trans* monounsaturated fatty acids as membrane constituents by aerobic bacteria presented in the later part of this review. Differences in the enzymatic mechanism are also apparent, as the anaerobes always shift the position of the double bond during fatty acid conversion (25). Unesterified polyunsaturated fatty acids are the substrates of the hydrogenation, and the products of this process are fatty acids with free carboxyl groups. In minor amounts, these *trans* fatty acids are also found esterified in the membrane lipids of ruminal microorganisms. However, this is ap-

parently not caused by bacterial biosynthesis of fatty acids as phospholipid constituents. Ruminal bacteria often are auxotrophic and have growth requirements which are partially satisfied by fatty acids or lipids. The cells well-adapted to the steady supply of these compounds take up fatty acids, including *trans* unsaturated ones, from the ruminal fluid and incorporate them into their membrane lipids.

The first description of the occurrence of *trans* monounsaturated fatty acids in aerobic bacteria was in 1978 for methane-utilizing bacteria (13) and in 1981 for a marine bacterium (26). By now, *trans* fatty acids have also been described in some other groups of bacteria (Table 1). This overview shows that *trans* unsaturated fatty acids are dispersed in different and not necessarily related groups of the prokaryotes. They are, however, predominately found in Gram-negative bacteria.

The chloroplast membranes of higher plants and algae also contain some fatty acids with a double bond of *trans* configuration (43,44). *Trans* fatty acids can be detected in minor amounts in some marine animals; these occurrences may be caused by the input and incorporation of fatty acids of microbial or plant origin into membrane lipids.

The quantity of *trans* fatty acids in bacteria can often be greater than that of *cis* unsaturated fatty acids. Similar to other fatty acids in bacteria, the relative amounts of *trans* fatty acids strongly depend on the physiological condition of the cells such as growth rate, medium composition, or environmental factors.

BIOSYNTHESIS OF *TRANS* UNSATURATED FATTY ACIDS IN BACTERIA

Basic studies on biosynthesis and function of microbial fatty acids were done in *Escherichia coli* which, normally, does not have *trans* fatty acids. However, mutants defective in unsaturated fatty acid biosynthesis incorporated *trans* fatty acids in phospholipids when supplemented as growth factors (45–47). These observations were explained by the purely structural role of these membrane constituents in establishing a lipid bilayer with controlled fluidity parameters. Ingram (48) reported that membranes of *E. coli* containing *trans* unsaturated $C_{18:1}$ fatty acids were even more tolerant to toxic ethanol concentrations than were those with the *cis* isomers. However, for the utilization of *trans* unsaturated fatty acids, in contrast to *cis* isomers, a second mutational lesion with unknown function is required in *E. coli* (49). In these studies the *trans* unsaturated fatty acids were taken up from the growth medium by the fatty acid transport systems.

Many bacterial species can accumulate fatty acids by using acyl-chain unspecific active or passive transport mechanisms. The fatty acids are oxidized *via* β-oxidation or are incorporated into membrane lipids. In *E. coli* these two processes are regulated by a common regulation system (50). Due to the possibility of uptake from the growth medium, the presence of small amounts of a special fatty acid does not indicate the existence of a biosynthesis apparatus in the cells.

In 1987, Guckert *et al.* (27) demonstrated the biosynthesis of *trans* unsaturated fatty acids *in vivo* from acetate in *Pseudomonas atlantica,* but could not explain if or how these fatty acids were formed by the known biosynthetic routes of unsaturated fatty acids. Many obligate aerobic bacteria synthesize single, unsaturated fatty acids by the so-called aerobic pathway, which is also the usual way to produce these compounds in eukaryotic cells. Here, the *cis* double bond is subsequently introduced into the aliphatic acyl chains of saturated fatty acids by specific desaturases—electrons are transported from the saturated fatty acid *via* NADPH to O_2 using a

membrane-bound short electron chain (Fig. 1A). With bacteria, these systems act on phospholipids as substrates so that the cells can change the degree of saturation of their membrane fatty acids post-biosynthetically (51–53).

The second biosynthesis route, which does not depend on O_2 and therefore is called the anaerobic pathway, is the one which is present in the majority of prokaryotic cells, namely in anaerobic, facultatively anaerobic, and also some aerobic bacteria (40,50,54). In this pathway (Fig. 1B), which has been studied in detail in *E. coli*, unsaturated fatty acids are produced in an intermediate reaction of fatty acid biosynthesis: During the elongation cycle, a *trans* double bond is produced which can further be converted in two different ways. If it is further reduced, saturated fatty acids are formed. But, a specific hydratase, β-hydroxydecanoyl-acyl carrier protein-dehydratase, can isomerize the *trans* double bond in position 2,3 of the $C_{10:1}$ fatty acid into the *cis* form now in the 3,4 position. This product cannot be reduced, and the *cis* double bond remains intact during the subsequent elongation cycles. The final saturated and *cis*-unsaturated acyl chains are then incorporated into the membrane phospholipids of the cells. There is no post-biosynthetic modification of the degree of saturation of the fatty acids.

The positions of the double bonds of microbial C_{18}-fatty acids depend on the biosynthetic route by which they are produced; whereas during the anaerobic pathway a C_2-elongation of palmitoleic acid [$C_{16:1}(c9)$] leads to *cis*-vaccenic acid [$C_{18:1}(c11)$], the aerobic pathway produces oleic acid [$C_{18:1}(c9)$]. Therefore, the occurrence of *cis*-vaccenic acid or oleic acid in bacterial membranes gives an indication of the biosynthetic route of unsaturated fatty acids which is used by the organism. Studies with *Vibrio* ABE-1 forming *trans* fatty acids indicated that here even both pathways are present and are involved in biosynthesis of unsaturated fatty acids (40). Table 1 shows that the majority of *trans* fatty acids are formed by bacteria possessing the anaerobic route of biosynthesis. Apparently, organisms featured by the aerobic pathway are also able to form these compounds. From this it can be concluded that either different pathways are involved in the biosynthesis of *trans* unsaturated fatty acids, or that the mechanism is independent from the way of synthesis of *cis* unsaturated fatty acids.

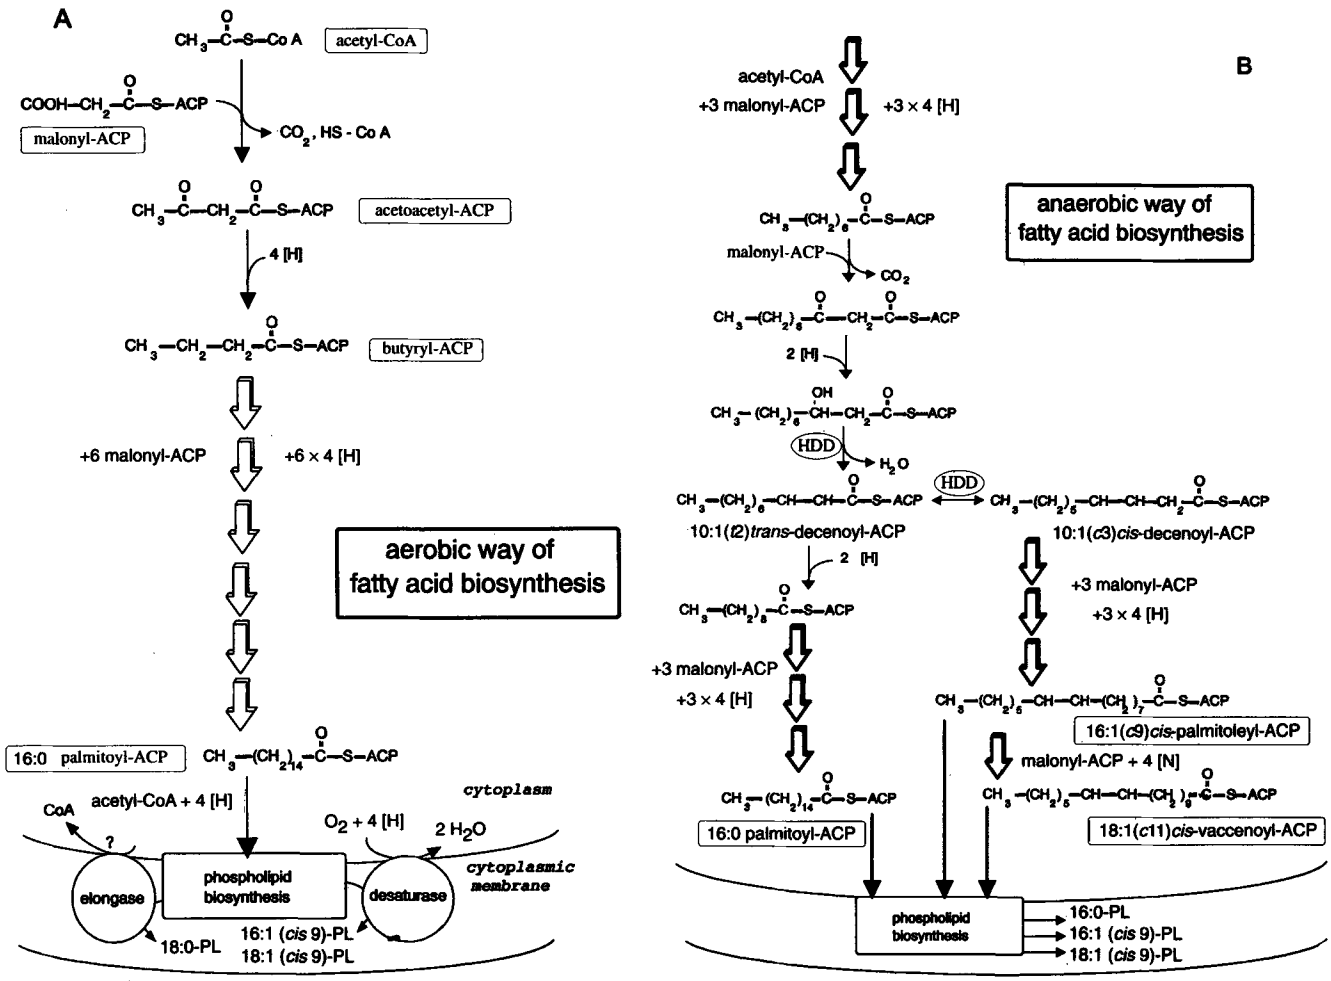

FIG. 1. Aerobic (A) and anaerobic (B) pathway of fatty acid biosynthesis and incorporation of fatty acids in phospholipids. PL, phospholipids; ACP, acyl carrier protein; HDD, β-hydroxydecanoyl-ACP-dehydratase.

Because of the position of the *trans* double bond in the intermediates of the anaerobic pathway [$C_{10:1}(t2)$], a further elongation of these acyl chains would lead to *trans* unsaturated fatty acids with double bonds in positions 8 (for $C_{16:1}$) or 10 (for $C_{18:1}$). Neither form of *trans* unsaturated fatty acids has been identified in bacteria. This indicates that *trans* fatty acids are not formed by a modification of the known anaerobic pathway. In all organisms studied up to now, the position of the *trans* double bond was identical with that of a *cis* one found in the same organisms.

TRANS UNSATURATED FATTY ACIDS ARE SYNTHESIZED BY A DIRECT ISOMERIZATION OF THE *CIS* FATTY ACIDS IN THE CELL MEMBRANE

The mechanism of synthesis of *trans* unsaturated fatty acids has been studied in detail with cells of *P. putida* and in the *Vibrio* strain ABE-1.

Growing cells of *P. putida* react to the addition of phenol or chlorinated phenols with a concentration-dependent increase in *trans* fatty acids and with a simultaneous decrease in the corresponding *cis* unsaturated fatty acids (29). The conversion also occurs in nongrowing cells where the ratio between saturated and unsaturated fatty acids and the total amount of *cis* and *trans* fatty acids cannot be changed due to the cessation of lipid biosynthesis. Moreover, the reaction takes place in cells in which fatty acid biosynthesis was totally inhibited due to the addition of cerulenin (28,30). The *cis–trans* conversion reaches its final *trans*-to-*cis* ratio about 30 min after the addition of a phenolic substance. The same rate of conversion was observed in the presence of chloramphenicol, indicating that the observed system is constitutively present and does not need a genetic induction (29,30).

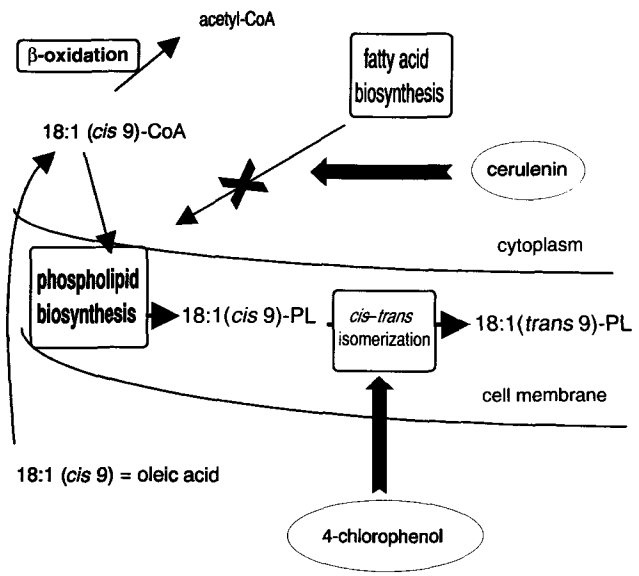

FIG. 2. *In vivo* formation of elaidic acid from oleic acid as proof of direct isomerization of *cis* to *trans* unsaturated fatty acids in *Pseudomonas putida* P8 induced by 4-chlorophenol. Abbreviation as in Figure 1.

Pseudomonas putida supplemented with oleic acid [$C_{18:1}(c9)$], which normally is not synthesized by this strain, incorporated it into the membrane lipids (Fig. 2). After adding 4-chlorophenol, which induced isomerization of fatty acids, oleic acid was converted into the *trans* isomer of this acid, elaidic acid [$C_{18:1}(t9)$]. These experiments were also done with radioactively-labelled oleic acid and in cells in which fatty acid biosynthesis was inhibited by cerulenin (55). The absence of other radioactive compounds in these experiments also indicated that oleic acid was not degraded or converted to other fatty acids. From these results, it can be concluded that *trans* fatty acids are synthesized by a direct isomerization of *cis*- to *trans*-unsaturated fatty acids without a shift in the position of the double bond. A similar observation has been made with marine psychrophilic *Vibrio* strains. Here the *cis–trans* isomerization was observed after an increase in the ambient temperature, and the position of the double bond was also not shifted (38,39,41). In experiments with isolated membrane fractions, the isomerization after addition of 4-chlorophenol was located in the inner membrane fraction, whereas those of the outer membrane were not active (55). These investigations showed that *trans* fatty acids are synthesized by a direct isomerization of the double bond of unsaturated fatty acids in the plasma membrane. Because the isomerization takes place in isolated membrane vesicles, the substrates for this reaction must be the acyl chain of the phospholipids. That means that the matrix of this still unknown system is also its substrate.

As in *P. putida,* the major phospholipids of the *Vibrio* strains were phosphatidylethanolamine and phosphatidylglycerol, both containing *trans* fatty acids. The positional distribution of these fatty acid components was also determined. They were located at both positions, but mainly at position *sn*-2 of the glycerol moiety (10,39,56).

In contrast to the system described here, all other known microbial or eukaryotic *cis–trans*-isomerases shift the position of the double bond during the isomerization reaction (25). In *E. lentum* the cytoplasmic isomerase converting *cis*- into *trans* unsaturated fatty acids during hydrogenation of fatty acids was characterized in detail. This system was inhibited by sulfhydryl reagents, e.g., *N*-ethylmaleimide (17,25). Experiments with *P. putida* S12 could show that the isomerization system in these cells is insensitive for *N*-ethylmaleimide (H.J. Heipieper, unpublished results). Obviously, the observed isomerization mechanism is a totally new enzymatic system. No biochemical or genetical characterization of the membrane system has been reported as yet.

PHYSIOLOGICAL FUNCTION OF *TRANS* UNSATURATED FATTY ACIDS IN BACTERIA

The first interpretation of the physiological function of *trans* unsaturated fatty acids was done by Guckert *et al.* (36). In long-term experiments with *Vibrio cholerae,* they showed that the amount of *trans* unsaturated fatty acids was increased in starving cells. The authors explained this by the greater sta-

bility of the *trans* fatty acids compared with the *cis* isomers. During starvation, the cells would metabolize their fatty acids, whereby the *cis*-fatty acids were better degraded than the *trans* isomers.Therefore, Guckert *et al.* (36) have suggested using a *trans/cis* ratio of greater than 0.1 in environmental samples as an index for starvation or stress. But this theory is not in agreement with results of studies with *P. putida* and *Shewanella putrefaciens*, where cells grown in batch cultures had a much lower content of *trans* unsaturated fatty acids when they were in the stationary growth phase (11,28). Therefore, the function of *trans* unsaturated fatty acids as a reserve for starvation seems to be unlikely.

Investigations concerning the toxic effects of organic compounds on cells of *P. putida* may help to elucidate the reason for *trans* unsaturated fatty acids occurring in these bacteria. The main target for the toxicity of organic solvents to bacterial and eukaryotic cells is the cell membrane (57–59). The compounds partition preferentially in membranes, causing an increase in membrane fluidity which is leading to a nonspecific permeabilization (57,58,60–64). For species of the genus *Pseudomonas,* it has often been observed that they are able to adapt to very high concentrations of inhibitory substances, leading to the ability to grow in the presence of organic solvent (65–67). The most important adaptative reaction of these bacteria against membrane active substances is changes in the fatty acid composition of membrane lipids. Figure 3 shows growth inhibition and membrane modifications of cells of *P. putida* in the presence of different concentrations of 4-chlorophenol. At concentrations up to 300 mg/L, which totally inhibits growth, the cells increase the degree of saturation of their membrane fatty acids. At higher concentrations, the cells do not use this mechanism but increase the content of *trans* unsaturated fatty acids. To explain this observation, the function and regulation of membrane fluidity in bacteria have to be described in more detail.

The physical properties of biological membranes, which can occur either in a highly ordered or a fluid crystalline phase state, are determined by the composition of the membrane lipids and fatty acids (47,68). The cellular barrier is simultaneously the matrix for enzymes, which depend on its fluidity conditions (62,63). On the other hand, some environmental factors, like temperature and organic solvents, have a strong influence on membrane fluidity and, therefore, on the physiological properties of a membrane. Microorganisms, however, can adapt to changes of their membrane fluidity; they react to externally dictated (occurring) changes in their environment by modifying their membrane to maintain a constant degree of fluidity. This mechanism is called "homeoviscosic adaptation" (52,62,69–72).

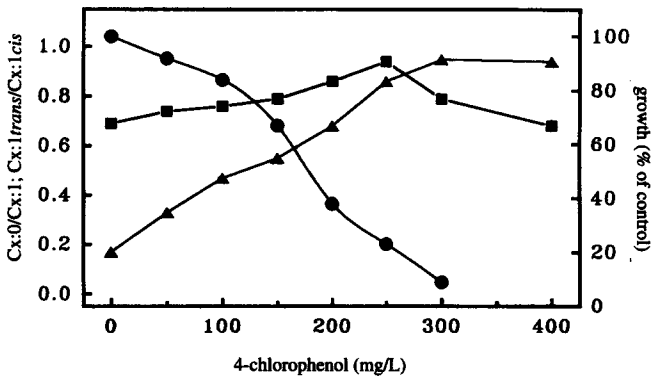

FIG. 3. Effect of 4-chlorophenol on cellular growth (●), degree of saturation (■), and *trans/cis* ratio (▲) of fatty acids of *Pseudomonas putida*.

Eukaryotic cells mainly regulate the fluidity of their membranes by changes of the cholesterol content. Bacteria, which normally do not possess steroids, have to use other mechanisms. Most bacteria regulate the fluidity of their membranes by varying the degree of saturation of their membrane fatty acids (51,69,73).

In membranes with a high content of saturated fatty acids, the acyl chains of the fatty acids produce the optimal hydrophobic interaction with each other which leads to a highly packed, rigid membrane. Due to the free rotation about the C–C bonds, saturated acyl chains can occupy an *all-trans* conformation, which allows the chain to be maximally extended. This conformation is preferred if the fluidity of a membrane is low. The temperature for the transition from the gel to the liquid-crystal membrane phase increases with an increasing ratio of saturated toward unsaturated fatty acids (degree of saturation). Contrary to this, the double bond of *cis* unsaturated fatty acids possesses a nonmovable bend with an angle of 30° in the acyl chain. Due to this bend, the highly ordered package of the acyl chains is disturbed, which leads to a lower phase transition temperature of these membranes (47). The transition temperature of a phosphatidylethanolamine bilayer decreases by about 42°C if only one saturated acyl chain per lipid molecule is replaced by a *cis* unsaturated one (39).

The *trans* configuration has a completely different effect on the fluidity of the phospholipid bilayer than the *cis* one (47,68,74). Figure 4 shows the structures of the two unsaturated fatty acids. *Trans* fatty acids can take up a long extended structure which is similar to that of saturated fatty acids. Membranes built of *trans* fatty acids can therefore form a more rigid package of the phospholipids than membranes with *cis* fatty acids. The measurement of phase transition temperatures of membranes built from identical phospholipids with *trans* instead of *cis* unsaturated fatty acids results in significantly higher transition temperatures(31,39,47). The replacement of one *cis* acyl chain by a *trans* fatty acid in phosphatidylethanolamine increases the transition temperature by 18–31°C, depending on the structure of the other acyl chain in the lipid molecule. Therefore, the conversion of *cis* unsaturated fatty acids into their *trans* configuration results in a significant reduction of the membrane fluidity which is, however, smaller as the replacement of *cis* by saturated fatty acids.

Bacteria such as *P. putida,* which possess the anaerobic pathway of fatty acid biosynthesis, can only change the de-

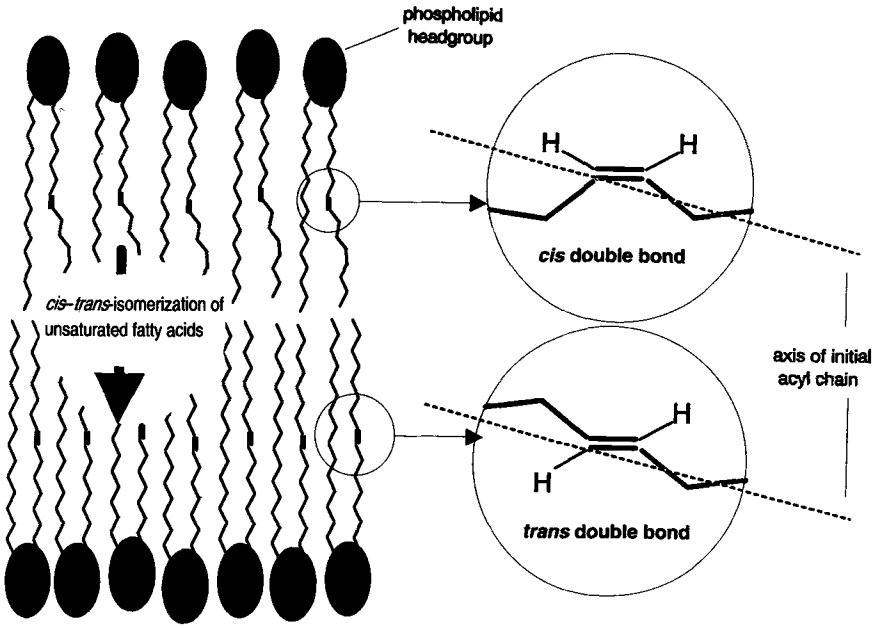

FIG. 4. *Cis-trans* isomerization of fatty acids and molecular packing of phospholipids with either *trans*- or *cis*-unsaturated fatty acids.

gree of saturation of fatty acids at the level of *de novo* synthesis. Bacterial lipids are stable cellular components, and the exchange of acyl groups of membrane lipids is very small. Fatty acid and lipid synthesis strongly correlate with cellular growth. In nongrowing cells, phospholipid synthesis is prevented by the "stringent control" and fatty acid synthesis is completely inhibited in the absence of lipid synthesis (54,75,76). Therefore, the cells are unable to change the degree of saturation of the membrane lipids, e.g., at concentrations of an inhibitor which totally prevents cellular growth (Fig. 3). Bacteria, however, which possess a system to isomerize the double bond of their unsaturated fatty acids, are still able to change the fluidity of their membranes under these adverse conditions.

The *cis–trans* isomerization is obviously an alternative mechanism of some bacteria to modify membrane fluidity. It would be of crucial importance when the regular mechanism of membrane adaption, the change in the degree of saturation, cannot be carried out due to the absence of lipid and fatty acid biosynthesis. Even when no energy substrate is available for the cells, a *cis–trans* isomerization of unsaturated fatty acids can be carried out without the high costs of energy and precursors. Another advantage of the mechanism is the speed of this direct fatty acid modification. Cells can react much faster to changes in their environment and can survive long enough so that they are able to subsequently react with long-term adaptative mechanisms.

POSSIBLE ECOLOGICAL ROLE OF *CIS–TRANS* ISOMERIZATION IN BACTERIA

This system modifying fatty acyl groups is obviously profitable to bacteria in which growth and energy-dependent adaptation mechanisms are insufficient when the physicochemical factors of their environment change. The ecological advantage for the marine psychrophilic *Vibrio* strains could be to react to changes in temperature with a system that is faster than one changing the degree of membrane saturation, because this reaction is related to the growth rates of the cells which are very slow at very low temperatures (38–40).

The other group of bacteria where the *cis–trans* isomerase was found are *Pseudomonas* strains, which play an important role as degraders of environmental pollutants. This system was found in *P. putida* strains which had the ability to degrade phenols (29), styrene (31), and toluene (31), and had the capacity to adapt to a wide range of organic compounds (66,77). Using the *cis–trans* isomerization system, the bacteria could adapt very quickly to toxic concentration of organic substrates. The cells can stabilize their membranes, allowing them to stay in physiologically acceptable condition in which they can activate (induce) other long-term adaptative mechanisms (58,73,78).

In *P. aeruginosa,* a content of *trans* unsaturated fatty acids of more than 40% could be found when these cells were grown with olive oil as carbon source (79). Olive oil possesses a high content of *cis* unsaturated fatty acids. Here the *cis/trans* isomerase seems to allow the cells to grow on this substrate, also incorporating the fatty acids from the olive oil in their membranes. Without the isomerization into the *trans* configuration, the high content of *cis* unsaturated fatty acids would markedly increase the fluidity of their membrane and the alternative, *de novo* synthesis of saturated fatty acids, is a very energy-dependent process.

A study on the effect of desiccation was carried out with a strain of *P. aureofaciens.* The cells significantly increased their ratios of *trans* to the corresponding *cis* fatty acids, whereas

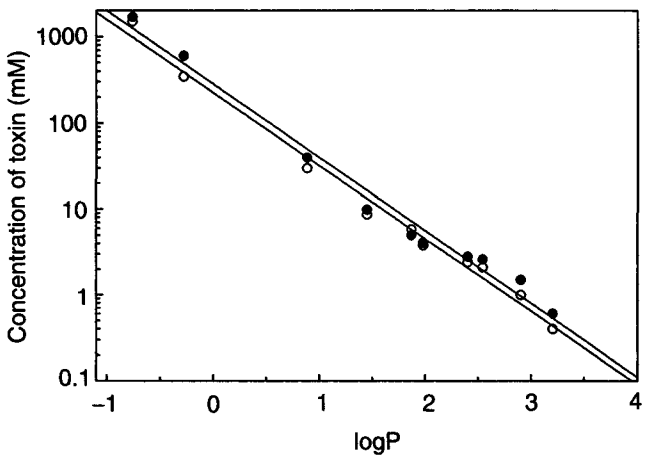

FIG. 5. Correlation between the hydrophobicity, given as the logP value of ten different organic compounds, growth inhibition, and *trans/cis* ratio of *Pseudomonas putida* cells. Growth inhibition (○) is presented as the LD 50 concentration. TC 50 (●) is the concentration of a specific organic compound at which the *trans/cis* ratio of unsaturated fatty acids is 50% of the maximal *trans/cis* value got by this inhibitor. The applied organic compounds are (in order of increasing logP values): methanol, ethanol, 1-butanol, phenol, 1-hexanol, p-cresol, 4-chlorophenol, toluene, 1-octanol, 2,4-dichlorophenol.

only a minor increase in the degree of saturation was observed as response on dry conditions (34). This may be another example where *cis–trans* isomerization substitutes the conventional mechanism of regulation of membrane fluidity if environmental conditions are adverse for the microorganisms.

Still unknown is the function of *trans* unsaturated fatty acids in methanotrophic bacteria, where they seem to be a common feature in all genera (3,4,13,14). The ecological function could be to react against high concentrations of methanol or formaldehyde, which are possible growth substrates or toxic intermediates in the oxidation of methane, and/or to adapt to other detrimental environmental influences.

PROSPECTS

In an extension of theoretical interest, the detailed assessment of the *cis/trans* fatty acid isomerase system will also have some possible applications. Potentially interesting reactions may be stereospecific transformations of unsaturated acyl compounds with the aim of synthesis of optically active hydroxy compounds. The conversion of *trans* configurated double bonds in dietary products for reasons of health or food technology is another promising application. Future research should clear up which substrates are accepted by the *cis/trans* isomerase. This may be an important question to be solved for the technical employment of the system.

In view of the characteristics of *cis/trans* isomerization affected by toxic substances, this system must be investigated for its ability to function as a toxicity test for organic environmental contaminations. Heipieper *et al.* (77) showed that a strong correlation exists between the hydrophobicity of organic solvents, their toxic potential to cells of *P. putida,* and their concentration activating the isomerization of *cis* to *trans* fatty acids (Fig. 5). From these results it may be anticipated that the isomerization of *cis* to *trans* unsaturated fatty acids in *P. putida* could function as an indicator for the toxicity of organic compounds. The development of such a test especially may have advantages in situations where growth-dependent tests cannot be performed, e.g., in natural habitats. The main field for an application of this indicator seems to be *in situ* bioremediation processes, where fatty acid profiles have importance as a marker for ecological investigations of the soil microflora (34,36,80–82). Therefore, the isomerization of *cis* to *trans* unsaturated fatty acids can be a relevant parameter for the physiological status of the microbial flora in the presence of toxic pollutants.

ABSTRACT: Growth hormone (GH) has many metabolic effects, but its mechanism(s) of action are not fully understood. We studied the short-term effects of endogenously produced GH on liver Δ6-desaturase activity and adipose and liver lipid fraction fatty acid composition in transgenic mice. MG101 transgenic mice ages 73–114 d received zinc to activate the ovine GH transgene for 7 d. Nontransgenic littermates, used as controls, also received zinc. Liver lipids were fractionated into phospholipids (PL), cholesteryl esters, and triglycerides (TG), and retroperitoneal adipose fractionated into PL and TG for fatty acid analysis. Liver microsomes were assayed for Δ6-desaturase activity. Animals expressing the ovine growth hormone transgene had a 2.5-fold higher liver Δ6-desaturase activity than controls. Arachidonate and docosahexaenoate were significantly higher in liver PL of GH transgenic animals compared to controls, but both were decreased in adipose PL in the GH animals. We conclude that increased production of GH affects both production and organ distribution of highly unsaturated fatty acids. The changes in arachidonate in various lipid pools following transgene expression may mediate the systemic actions of GH. *Lipids 31*, 139–143 (1996).

Transgenic animals carrying growth hormone (GH) genes can have increased lean body mass and growth, which is of potential benefit to meat production. However, most of these transgenic animal lines suffer from various side effects including arthritis and impaired immune and reproductive functions (1). The MG101 mouse carries the ovine GH (oGH) structural gene fused with the sheep metallothionein 1a (oMT1a) promoter (2). With this combination, the MG101 mice have a minimal level of basal expression of oGH, but high expression induced with 25 mM zinc in their drinking water (2). This strain of mice does not show apparent pathology after prolonged induction of GH. Nevertheless, these mice show marked enlargement of the liver and spleen (3) in addition to increased overall body size.

Recent studies suggest that GH stimulates hematopoiesis and modulates immune functions, although the mechanisms of these effects are unknown (4). Maddaiah and Clejan (5) reported that GH administration to hypophysectomized rats caused a rapid increase in the ratio of arachidonic acid (20:4n-6) to linoleic acid (18:2n-6) in phospholipids (PL) from liver microsomes and mitochondria. In a preceding study, 20:4n-6 in serum and liver PL was markedly increased in zinc-fed MG101 mice compared with control mice fed the same diet regimen (6). This alteration of fatty acid composition suggests an increased activity of hepatic Δ6-desaturase/elongase/Δ5-desaturase pathway utilized for 20:4n-6 synthesis. As arachidonic acid plays a key role in immune response by serving as a precursor of eicosanoids, the elevation of tissue 20:4n-6 could be in part responsible for the disorders of immune function seen in some GH transgenic animals.

Adipose tissue is another target tissue of GH, although the mechanism of action of GH on the adipocyte has not been fully elucidated. Transgenic animals expressing the GH gene generally become not only larger but leaner. This response is well documented in the MG101 transgenic mouse, which shows lower body fat when compared with controls with the same body weight (3,7). The effect of GH on adipocyte membrane fatty acid composition has not been investigated.

This study was undertaken to: (i) analyze activity of hepatic Δ6-desaturase, the rate-limiting enzyme of 20:4n-6 synthesis, and (ii) characterize the effects of GH expression in the MG101 mouse on fatty acid composition of lipid subfractions in liver and adipose.

MATERIALS AND METHODS

Animals and diets. Wild type F1 females (C57BL/6 × CBA) were mated with MG101 males hemizygous for the oMT1a-oGH fusion gene. At day 10, pups were individually identified by toe-notching, and characterized for presence of the transgene by polymerase chain reaction amplification of a unique transgene sequence from toe-notch lysate (8). The

oMT1a-oGH transgene is inherited in strict Mendelian fashion, and hemizygous progeny supplemented with zinc express the transgene due to dominant gene action. Therefore hemizygous transgenics and homozygous wild-type littermates (controls) were used as the two experimental groups. Animals were housed under conditions of 21°C, 55% humidity, and 14–10-h light–dark cycles. After weaning at day 21, the mice of both groups were fed Purina Rodent Chow 5001 (Purina Mills, St. Louis, MO) and water *ad libitum*. Groups of mature female mice (73 or 108 day-old transgenics, and 79 or 114 day-old controls) were given drinking water containing 25 mM zinc sulfate for 7 d. Upon stimulation by zinc, the plasma oGH concentration of the transgenic mouse rises to over 100 ng/mL from the unstimulated level of about 12 ng/mL, while control mice have 1–3 ng/mL (2,9). After 7 d of zinc supplementation, the animals were killed by cervical dislocation, and the liver and retro-peritoneal fat were quickly removed.

Isolation of microsomes. All processes were carried out under ice-cold conditions. The fresh liver sample, kept in ice-cold saline, was lightly blotted with a paper towel, weighed, and transferred to a Potter-Elvehjem homogenizer. After adding five times sample weight of homogenizing buffer (pH 7.5 at 4°C, 10 mM tris-HCl, 0.25 M sucrose), the liver was homogenized with ten up–down strokes. Five mL of the homogenate was centrifuged at 12,000 × *g* for 30 min to remove debris and the mitochondrial fraction. The remaining portion of the homogenate was saved and stored at −70°C for fatty acid analysis. The supernatant was then centrifuged at 110,000 × *g* for 60 min. The resulting microsome pellet was resuspended by adding 3 mL of incubation buffer (pH 7.4, 0.04 M phosphate buffer, 0.25 M sucrose, 0.15 M KCl, 0.70 mM *N*-acetylcysteine), and stored at −70°C until enzyme analysis.

Desaturase assay. The detailed assay for Δ6-desaturase activity has been described elsewhere (10). Desaturase activity was assayed in the incubation buffer with the final concentrations of 33 μM ^{14}C-linoleic acid as substrate, 1.3 mM ATP, 5 mM $MgCl_2$, 60 μM CoA, 870 μM NADH, 40 mM NaF, and 330 μM nicotinamide. The reaction was started by adding microsomes, and continued in a flat-bottom vial (25 mm diameter) in a Gyrotory Water Bath Shaker (New Brunswick, Edison, NJ) at 35°C and 110 cycles/min for 15 and 30 min. The reaction was stopped by adding 2 mL saponifying reagent (2 M KOH in methanol). All subsequent steps were performed under nitrogen with added butylated hydroxytoluene to prevent peroxidation of fatty acids. The acyl-CoA was saponified, acidified, and extracted by petroleum ether. Fatty acids were methylated by 5% acetyl chloride in methanol. Fatty acid methyl esters were separated on silver nitrate-impregnated thin-layer silica gel plates using a petroleum ether/diethyl ether solvent system. Separated substrate and product were eluted from the silica by xylene-based scintillation cocktail, and the radioactivity counted. Microsomal and cytosolic proteins were analyzed by a modified Lowry method (11).

Liver and adipose fatty acid analysis. The detailed procedure has been reported elsewhere (12). Briefly, tissue lipids were extracted with chloroform/methanol (2:1, vol/vol), and the extracted lipids were separated by thin-layer chromatography into three fractions, PL, triglyceride (TG), and cholesteryl esters (CE). Fatty acids from each lipid fraction were converted to methyl esters, and the relative quantities were determined by capillary gas chromatography. The absolute amount of each lipid fraction was measured by comparison to the respective heptadecanoate internal standard that was added at the extraction step. Statistical analysis consisted of two-tailed *t*-tests of the means of the two groups, as indicated in Tables 1–3.

RESULTS

As shown in Table 1, after 7 d of zinc feeding the body and liver weights of the transgenic mice compared to controls were 21 and 44% higher, respectively. Consequently, the liver/body weight ratio was higher in transgenic mice. Liver protein concentration did not differ between the two groups in either the homogenate or microsome fraction. Among liver lipids, the TG content was increased more than 3-fold, whereas PL and CE were unchanged. The activity of hepatic Δ6-desaturase for the transgenic mice was elevated more than 2.5-fold when the activity was expressed per mg microsomal protein and per gram liver. The difference became 3-fold when liver Δ6-desaturase activity was adjusted for body size (Table 1).

Table 2 shows the fatty acid profiles of the liver lipid fractions. The substrates of Δ6-desaturase, linoleic acid (18:2n-6), and α-linolenic acid (18:3n-3), were decreased in all three

TABLE 1
Body Weight, Liver Profile, and Δ6-Desaturase Activity[a]

	Control	Transgenic	Transgenic/ control

[a]Fatty acids expressed as weight %, mean ± SEM (n = 6 except n = 5 for cholesteryl esters of the control group). Means of the two groups significantly different by a two-tailed test: [b]$P < 0.01$, [c]$P < 0.001$, [d]$P < 0.05$.

lipid fractions of transgenic mice in comparison with the control group, although the reduction in linoleic acid in the CE did not reach statistical significance. On the other hand, 20:4n-6, the major product of the desaturase/elongase pathway for essential fatty acids, was elevated in all three liver lipid fractions of transgenic mice although it did not reach statistical significance in the TG fraction. The final product of n-3 essential fatty acids, 22:6n-3, was increased in the liver PL of transgenic mice, but decreased in the liver TG. Another final product of the same pathway, Mead acid (20:3n-9), was increased in the liver TG fraction of transgenic mice. Among the intermediates of the desaturase/elongase pathway, 20:3n-6 and 20:5n-3 were decreased in both PL and TG fractions in liver of transgenic mice, but 18:3n-6 was increased in the TG fraction (Table 2).

Saturated and monounsaturated fatty acids showed variable responses among liver lipid fractions. Palmitic acid (16:0) was unchanged in the liver PL and TG fractions between the transgenic and control groups, but was markedly increased in the CE fraction of transgenic mice. Stearic acid (18:0) was increased only in the liver PL of transgenic mice. Transgenic mice showed an increase in oleic acid (18:1n-9) in liver TG, but it was decreased in liver PL and CE (Table 2).

Table 3 reports the fatty acid content of adipose PL and TG. In adipose PL from transgenic mice, there was an increase in palmitic acid at the expense of significant decreases in 20:4n-6 and 22:6n-3 (which were relatively increased in the liver PL of transgenic mice). The adipose TG fatty acid composition was relatively unchanged, with the only significant differences being decreased 18:0 and increased 20:4n-6 in the transgenic mice.

DISCUSSION

The Δ6-desaturase, the gate keeper enzyme of the Δ6 desaturase/elongase/Δ5 desaturase pathway for 20:4n-6 synthesis, is subject to control by various hormones including steroid hormones, epinephrine, glucagon, and insulin. Most of these hormones suppress Δ6-desaturase activity, although insulin may stimulate the enzyme (13). In this study, we have demonstrated a marked increase in Δ6-desaturase activity in the transgenic mice following oGH induction for 1 wk with 25 mM zinc (Table 1). The increased Δ6-desaturase activity in the transgenic mice is reflected in the alteration of the fatty acid composition in liver PL, TG, and CE fractions, which showed decreased proportions of substrates (18:2n-6 and 18:3n-3) and increased final products (20:4n-6, 22:6n-3, and 20:3n-9) except for 22:6n-3 in the TG fraction (Table 2). However, as the total TG in the livers of the transgenic mice was increased approximately 3-fold, the absolute amount of 22:6n-3 in the TG fraction was actually increased despite its lower proportion.

Maddaiah and Clejan (5) reported that the 20:4n-6/18:2n-6 ratio in PL from liver microsomes and mitochondria of hypophysectomized rats was significantly elevated as early as 4 h after a single GH injection. This rapid change in PL fatty acid composition suggests that GH may also affect turnover and distribution of PL fatty acid *via* altering activities of enzymes such as phospholipases and lysophospholipid acyl transferases. The resultant effects of GH on adipose tissue

could be multifactorial. As GH has been shown to stimulate differentiation of preadipocytes to adipocytes both *in vitro* (14,15), and *in vivo* (16), it may play a role in adipose tissue development. Acute administration (20–30 min) of GH stimulated glucose uptake by adipocytes *via* the same mechanism as insulin (17), and inhibited epinephrine-stimulated lipolysis (18). Both of these effects would tend to increase adiposity. The other side of GH is its inhibitory effect on TG accumulation by adipose tissue. In humans, GH administration reduced fat and increased lean body mass of GH-deficient adults (19). GH also increased fat oxidation when administered to normal men (20). Contrary to its acute effect, chronic administration of GH increased hormone-sensitive lipase activity and glycerol release by cultured adipocytes (18). Schoenle *et al.* (21) reported that basal (no insulin stimulation) glucose transport was elevated to the insulin-stimulated level in adipocytes from GH-deficient patients, but it was suppressed to the normal level by GH treatment. Taken in combination, these observations point to the likelihood that chronic administration of GH to mature animals has an antilipogenic effect on adipose tissue.

The role of membrane 20:4n-6 in the function of adipose tissue has not been well defined. Gaillard *et al.* (22) showed that 20:4n-6 was required for the differentiation of a preadipocyte cell line, and this arachidonic acid effect appears to be mediated by prostaglandins (23). This observation has been reinforced by Serrero *et al.* (24), who observed that eicosanoids derived from arachidonate are involved in adipocyte differentiation. Pelikanova *et al.* (25) reported a positive correlation between insulin action and plasma 20:4n-6, and Borkman *et al.* (26) showed that the 20:4n-6 level in human muscle PL correlated with insulin sensitivity. Based on these studies, it is a logical extension that 20:4n-6 modulates insulin sensitivity in adipose tissue as well.

Altered availability of 20:4n-6 has also been documented to affect multiple other cellular functions, such as gene transcription of fatty acid synthase (27) and heat shock proteins (28), and it participates in the regulation of insulin secretion in part by inactivating protein kinase C (29). Arachidonate and other highly unsaturated fatty acids also modulate many processes affecting immune function (30,31).

Among the lipid fractions examined in this study, the adipose PL was the only fraction which showed a lower proportion of 20:4n-6 in the transgenic mice compared with the controls. This indicates that the fatty acid profile of adipose PL was not passively reflecting the production of highly unsaturated essential fatty acids in liver, but was subject to altered distribution by GH. The same response was seen with 22:6n-3, and these changes were parallel to those reported by Maddaiah and Clejan (5). If reduced, 20:4n-6 is associated with insulin resistance; then our observation of the reduced arachidonic acid in adipose PL could result in increased adipose lipolysis.

In summary, this study demonstrated that induction of an oGH transgene increased Δ6-desaturase activity and its resulting products including 20:4n-6 in liver lipids and adipose TG, but decreased 20:4n-6 and 22:6n-3 in adipose PL. The mechanism through which this GH effect alters adipose PL fatty acid composition is unknown at present. This complex alteration in the production and distribution of 20:4n-6 between tissues may be related to the effect of GH on energy balance, insulin sensitivity, immunity, and adipocyte functions.

ABSTRACT: ^{13}C magnetic resonance spectroscopy (MRS) is a noninvasive technique used in the study of lipids. We applied ^{13}C MRS to assess the effects of long-term dietary variation on adipose tissue composition in humans. *In vivo* ^{13}C MRS was used to analyze the fatty acid composition of adipose tissue in 88 healthy volunteers with significantly different diets (38 vegans, 11 vegetarians, and 39 omnivores) assessed by analysis of dietary records. Results were compared with the serum lipid profile. ^{13}C MRS revealed clear differences in the adipose tissue composition of vegans, which contained more unsaturated ($P < 0.01$) and fewer saturated fatty acids ($P < 0.01$) compared with omnivores and vegetarians. The vegan subjects had a significantly lower intake of saturated fatty acids and higher intake of polyunsaturated fatty acids than either the omnivore or the vegetarian groups ($P < 0.01$). These findings were associated with significantly lower levels of serum total cholesterol and low density lipoprotein-cholesterol in the vegan group compared with the omnivores. Our results demonstrate the use of ^{13}C MRS for the noninvasive study of adipose tissue composition and its application to the study of the interaction between long-term dietary and metabolic risk factors in humans.
Lipids 31, 145–151 (1996).

Coronary heart disease (CHD) remains a leading cause of death in the western world. Plasma cholesterol concentrations, central body fat distribution, and the dietary saturated fat content are recognized risk factors for CHD (1–4). Dietary unsaturated fatty acids have been shown to lower the concentration of plasma cholesterol (5,6) and are thought to reduce the risk of CHD. It has also been shown that adipose tissue fatty acids alter plasma lipid profiles and are correlated with potential risk of CHD (7). Screening subjects considered at risk of CHD is routinely performed by analyzing serum cholesterol and the lipoprotein profile (8–11). However, less attention has been directed to the contribution from adipose tissue composition.

Dietary fat is a major factor determining the fatty acid composition of adipose tissue, and the half-life of fatty acids in adipose tissue is around 600 d. The fatty acid profile of adipose tissue is therefore thought to reflect long-term dietary intake (12) and has been suggested as an alternative index of the habitual dietary fatty acid intake over the previous two to three years. Previously, studies of the fatty acid composition of adipose tissue from different regions of the body have been limited to gas–liquid chromatography (GLC) analysis of needle fat biopsies (13–21) or postmortem fat samples (13,22). Routine measurement of lipid composition by repeated biopsy in both healthy volunteers and patients invokes both ethical and practical difficulties. This has limited the number of serial studies looking at long-term dietary effects on adipose tissue composition. A noninvasive method of determining lipid composition is therefore required.

Magnetic resonance spectroscopy (MRS) is a technique that allows human biochemistry to be studied noninvasively. ^{13}C MRS has been successfully applied to the study of lipids *in vivo*, both in humans (23–25) and in animals (26–28). Although specific fatty acids cannot be assessed by ^{13}C MRS, measurements of the major classes of unsaturated and saturated fatty acids can be made (24). Furthermore, good correlation has been reported between GLC and ^{13}C MRS in both humans (24) and in animals (27,28). Animal studies suggest that *in vivo* ^{13}C MRS can detect changes in adipose tissue lipid composition arising from dietary manipulation (27,28). Beckmann (23) used ^{13}C MRS to noninvasively study the adipose tissue composition of human subjects on a standard and low-fat diet. MR spectra of adipose tissue were shown to reflect the subjects' diet (23).

In this study we assessed the use of *in vivo* ^{13}C MR spectroscopy to investigate the long-term effects of different diets on adipose tissue composition in healthy human volunteers. The results from this study are discussed in relation to dietary analysis and the lipid metabolic risk profile.

MATERIALS AND METHODS

Volunteer assessment. Written informed consent was obtained from all volunteers. Permission for this study was obtained from the ethics Committee of the Royal Postgraduate Med-

ical School, Hammersmith Hospital, London (REC 4096/93). Healthy volunteers were studied and were screened to exclude chronic illness, including diabetes and liver disease. Eighty-eight subjects were examined in total, and were divided into three age and sex-matched groups according to their dietary history: 38 vegans: 20–69 yr (35.1 ± 14.4) 21 males, 17 females; 39 omnivores: 20–74 yr (43.8 ± 16.9) 20 males, 19 females; and 11 vegetarians: 19–62 yr (34.2 ± 13.2) 6 males, 5 females.

The vegan diet excludes all forms of animal products. Ovo-lacto vegetarians do not consume meat or fish, but their diet does include dairy products. Volunteers were weight stable and had maintained their current diet for a minimum of three years.

Biochemical analysis. Fasting blood samples were drawn from each volunteer for serum lipid analysis, including total cholesterol, low density lipoprotein-cholesterol (LDL-c), high density lipoprotein-cholesterol (HDL-c), and triglycerides. Serum total cholesterol, HDL-c, and serum total triglyceride concentrations were determined enzymatically using standard methods (Boehringer, Mannheim, Germany). LDL-c was calculated from these values using the Friedewald equation. Repeated blood samples were obtained from six volunteers over a six-week period to assess the degree of variation in individual serum cholesterol levels. Screening tests also included full blood count and biochemical profile, including serum glucose, liver function tests, urea, and electrolyte estimates.

Dietary assessment. Each volunteer completed a seven-day dietary diary within one week of their *in vivo* ^{13}C MRS examination, using methodology validated by Bingham (29). Subjects were given a standard booklet containing written instruction on prospectively recording their food intake, and this written information was backed up by verbal advice. The diaries were then returned by mail, and the volunteers were contacted by telephone if clarification of intake was needed. Dietary analysis was carried out using a standard database (Microdiet, Salford University, Salford, United Kingdom) containing all data from current food tables (30). Validation was carried out by comparing the agreement (31) between estimated energy intakes from the diet diaries to estimate energy requirement from a standard formula (32). For subjects in energy balance, there should be good agreement between the two variables. The mean standard error of differences was −84 kcal, suggesting a slight underreporting with reasonable standard deviation for this type of comparison of ± 254 kcal. All volunteers included in this study fully completed their dietary records.

Anthropometric measurements. Anthropometric assessment was obtained on each subject by a trained observer. This included measurement of weight, height, waist, and hip circumference, and skinfold thickness from triceps, biceps, subscapular, and suprailiac regions. Body mass index, percentage body fat, and total body fat were calculated for each individual using standard methods (33).

^{13}C MRS. ^{13}C MR spectra were obtained from the adipose tissue of all 88 healthy volunteers. *In vivo* ^{13}C MR spectra were acquired on a 1.5 T Picker prototype system (Picker International, Cleveland, OH) using a 20-cm saddle transmitter coil and a 14-cm receiver coil, placed orthogonally to the left thigh of each subject. Fully relaxed coupled ^{13}C spectra were acquired using a 90° pulse, with eight averages and a repetition time of 30 s. The average time for each examination was 15 min.

Spectra were zero-filled to 4 K and Fourier transformed with no line broadening. Peaks were integrated using a curve-fitting computer model (NMR1;® New Methods Res., Inc., East Syracuse, NY). Six volunteers had ^{13}C MR spectra collected from various parts of their bodies, including thigh, waist, and buttocks, to determine possible regional variation in adipose tissue composition.

MRS data analysis. (i) Total fat analysis by ^{13}C MRS (Method A). Total unsaturated and saturated fatty acids were calculated (Table 1) as previously described by Moonen *et al.* (24), briefly: (see Fig. 1):

$$\% \text{ polyunsaturated} = \tfrac{1}{2}(I_{2b} + I_{3b})/I_1 \times 100 \quad [1]$$

$$\% \text{ monounsaturated} = \tfrac{1}{2}[(I_{2a} + I_{3a}) - (I_{2b} + I_{3b})]/I_1 \times 100 \quad [2]$$

$$\% \text{ saturated} = 100 - (\% \text{ polyunsaturated} + \% \text{ monounsaturated}) \quad [3]$$

This method allows direct comparison with literature values obtained by GLC (23,24). However, this method cannot be used accurately to determine proportions of monounsaturated and polyunsaturated fat present when fatty acids with more than two double bonds are present. The method of percentage carbon analysis as suggested by Barnard (27) was therefore also used.

(ii) Percentage carbon analysis by ^{13}C MRS (Method B). Most MRS methods for calculating polyunsaturated fatty acid content assume linoleic acid (18:2n-6) to be the principal polyunsaturated fatty acid present in human adipose tissue (85–90% in adults) (21,24). Here only two carbons would contribute to the resonances at 133.4 and 124.2 ppm in the coupled ^{13}C MR spectrum. If fatty acids with more than two double bonds are present, such as linolenic acid (18:3n-3) or arachidonic acid (20:4n-6), these assumptions will introduce large errors into the calculations, a particular problem in neonates (34–36) and vegans. We therefore calculated the percentage of total carbons (Table 2) in saturated or unsatu-

TABLE 1
Percentage Fat Determined by ^{13}C Nuclear Magnetic Resonance Spectroscopy (Method A)[a]

Diet type	% Total unsaturated	% Total saturated
Vegan	86.5 ± 0.9[b]	13.5 ± 0.9[b]
Omnivore	76.1 ± 0.6	23.9 ± 0.6
Vegetarian	78.9 ± 1.6[c]	21.1 ± 1.6[c]

[a]Mean ± SEM. Significant difference between vegans and omnivore controls, [b]$P < 0.01$; significant difference between vegans and vegetarians, [c]$P < 0.01$; no significant differences were found between vegetarians and omnivore controls.

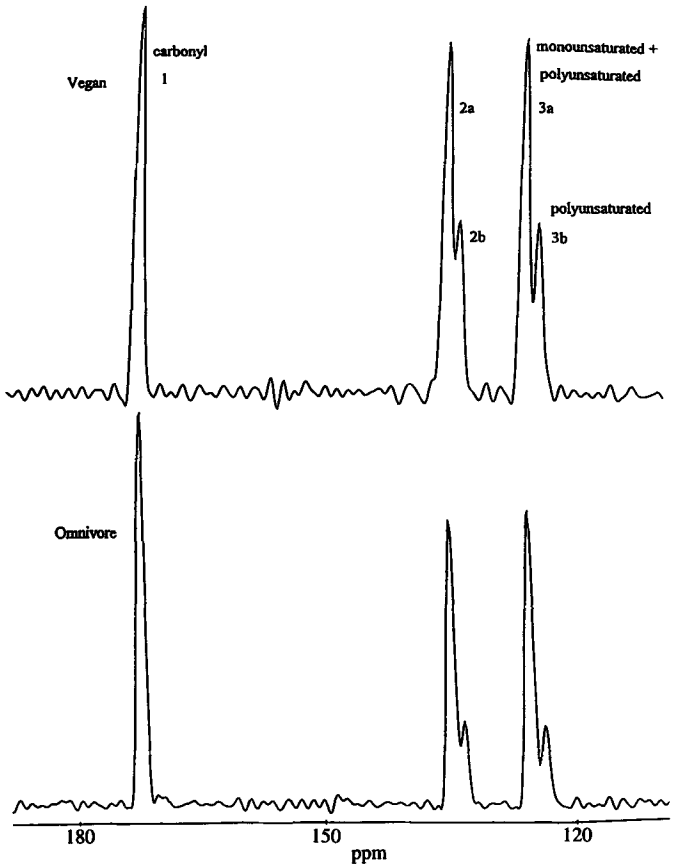

FIG. 1. ^{13}C Magnetic resonance spectra of human adipose tissue from a vegan and an omnivore expanded to show the unsaturated region (repetition time 30 s). Assignments: 1, carbonyl carbons (-C=O) 172.1 ppm; 2a and 3a, carbons in the monounsaturated and polyunsaturated position (-CH=CH- and -CH=CH-CH2-CH=CH-) 134.9 and 125.4 ppm; and 2b and 3b, polyunsaturated carbons only (-CH=CH-CH_2-CH=CH-) 133.4 and 124.2 ppm.

rated position in the fatty acid chain. This method is based on absolute data and makes no assumptions about the composition of the tissue under study (27).

Percentages of carbons in saturated and unsaturated position in the fatty acid chain were calculated from integrals of three regions of the ^{13}C MR spectrum—carbonyl at 165–175 ppm; unsaturated fatty acid carbons at 120–140 ppm; and saturated fatty acid carbons at 10–45 ppm.

$$\text{total carbon in fatty acid chain (A)} = I_{carbonyl} + I_{unsat} + I_{sat} \quad [4]$$

$$\text{percentage carbon in unsaturated position (B)} = (I_{unsat}/A) \times 100 \quad [5]$$

$$\text{percentage carbon in saturated position} = 100 - B \quad [6]$$

The unsaturated region has two pairs of resonances: (i) the larger peaks (I_{m+p}) 134.9 and 125.4 ppm from carbons in the monounsaturated and polyunsaturated position (-CH=CH= and -CH=CH=CH_2-CH=CH-) and (ii) the other peaks (I_p) 133.4 and 124.2 ppm from polyunsaturated fatty acid carbons (-CH=CH-CH_2-CH=CH-). Using peak height measurements or integrals of these peaks (obtained using a curve-fitting algorithm), the proportion of fatty acid carbons that were polyunsaturated or monounsaturated could be determined and used in the equations below:

$$\text{percentage carbon in a poly position} = I_p/(I_{m+p} + I_p) \times \% \text{ unsaturated (B)} \quad [7]$$

$$\text{percentage carbon in a mono position} = \% \text{ unsaturated} - \% \text{ polyunsaturated} \quad [8]$$

Statistical analysis. Statistical analysis was performed using Student's unpaired *t*-test. Correlation coefficients were calculated using the Pearson's test. All results presented are expressed as mean ± SEM.

RESULTS

Biochemical analysis. Results of the serum lipid analysis are shown in Table 3. Significantly lower concentrations of total cholesterol (4.41 ± 0.24 vs. 5.31 ± 0.24 mmol/L, $P < 0.01$) and LDL-c (2.46 ± 0.20 vs. 3.41 ± 0.23 mmol/L, $P < 0.05$) were observed in the vegan group compared with the omnivore population. No significant differences of triglycerides or HDL-c were observed in the vegans compared with the omnivores. The vegetarian group had significantly lower concentrations of LDL-c (2.65 ± 0.16 vs. 3.41 ± 0.23 mmol/L, $P < 0.05$) than the omnivores. However, no significant differences were observed between the lipid profiles of vegan and vegetarian groups.

[d]$P < 0.01$, [e]$P < 0.02$ difference between vegans and omnivore controls. [f]$P < 0.01$, [g]$P < 0.02$ difference between vegans and vegetarians. No significant differences were found between vegetarians and omnivore controls.

TABLE 3
Serum Lipid Profiles[a]

Diet	Cholesterol	LDL-c[b]	HDL-c[c]	Triglyceride
Vegan	4.41 ± 0.24[d]	2.46 ± 0.20[d]	1.35 ± 0.08	0.94 ± 0.09
Omnivore	5.31 ± 0.24	3.41 ± 0.23	1.44 ± 0.06	1.04 ± 0.09
Vegetarian	4.57 ± 0.38	2.65 ± 0.16[e]	1.38 ± 0.07	1.02 ± 0.12

[a]Mean ± SEM (mmol/L).
[b]LDL-c = low density lipoprotein-cholesterol.
[c]HDL-c = high density lipoprotein-cholesterol.
[d]Significant difference between vegans and omnivore controls; $P < 0.05$. No significant differences were found between vegans and vegetarians.

Dietary assessment. Dietary assessment of seven-day food records (Table 4) showed no significant differences in total calorific intake or the percentage total dietary fat intake between the three groups. As a whole group, the expected calorie intake was 2316 ± 54 kcal compared with 2231 ± 74 kcal reported calories.

The vegan population has a significantly higher intake of unsaturated fatty acids, particularly polyunsaturated fatty acids (37.9 ± 1.6 vs. 20.5 ± 1.2%, $P < 0.01$). They had a correspondingly lower intake of saturated fatty acids (22.3 ± 1.0 vs. 42.1 ± 1.2%, $P < 0.01$) in their diet than the omnivore groups. Vegans also have a significantly lower intake of saturated fatty acids than vegetarians (22.3 ± 1.0 vs. 41.7 ± 3.5%, $P < 0.01$). No significant differences in dietary fat content and composition were found between omnivores and vegetarians.

The vegan group also had a significantly higher dietary intake of carbohydrates than either omnivore or vegetarian groups (vegans 331.7 ± 23.2 g, omnivores 243.1 ± 9.4 g, vegetarians 230.8 ± 17.5 g, $P < 0.01$). There was no significant difference in carbohydrate intake between omnivores and vegetarians.

Anthropometric measurements. No significant differences were observed in the total percentage body fat present in either vegan, vegetarian, or omnivore groups. However, the vegan group had a lower body mass index (21.8 ± 0.5 vs. 23.6 ± 0.5 kg/m^2, $P < 0.05$) than the omnivore population (Table 5).

^{13}C MRS. Representative ^{13}C proton-coupled MR spectra obtained from the human thigh *in vivo* are shown in Figure 2. Resonances observed in these spectra arise solely from triglyceride molecules from adipose tissue (24). The peaks arise from the carbonyl, unsaturated, and saturated regions of the fatty acid chains and from the glycerol backbone. The unsaturated region is composed of resonances from monounsaturated fatty acids and polyunsaturated fatty acids. No regional variations were found in the spectra acquired from different areas of the body for individual subjects.

Differences between dietary groups. Expansions of the

[c]Significant difference between vegans and omnivore controls $P < 0.05$. No significant differences were found between vegans and vegetarians or vegetarians and omnivore controls.

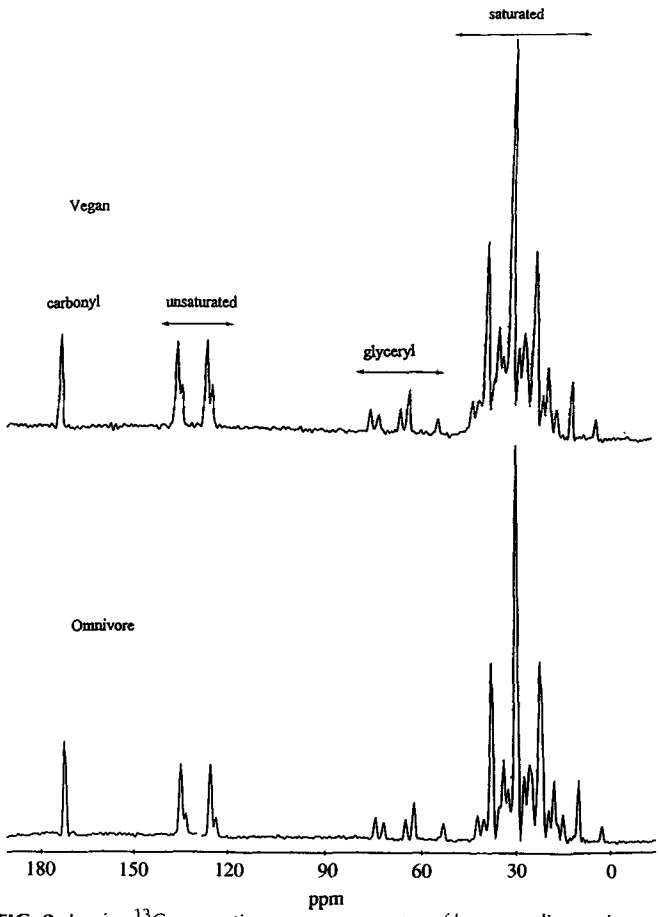

FIG. 2. *In vivo* ^{13}C magnetic resonance spectra of human adipose tissue from a vegan and an omnivore (repetition time 30 s). Resonances for the carbonyl, unsaturated, and saturated regions of fatty acid chains and from the glycerol backbone of the triglycerides may be observed. Assignments: carbonyl 170–175 ppm; monounsaturated and polyunsaturated fatty acid carbons 120–140 ppm; glycerol backbone 60–70 ppm; saturated fatty acid carbons 10–40 ppm.

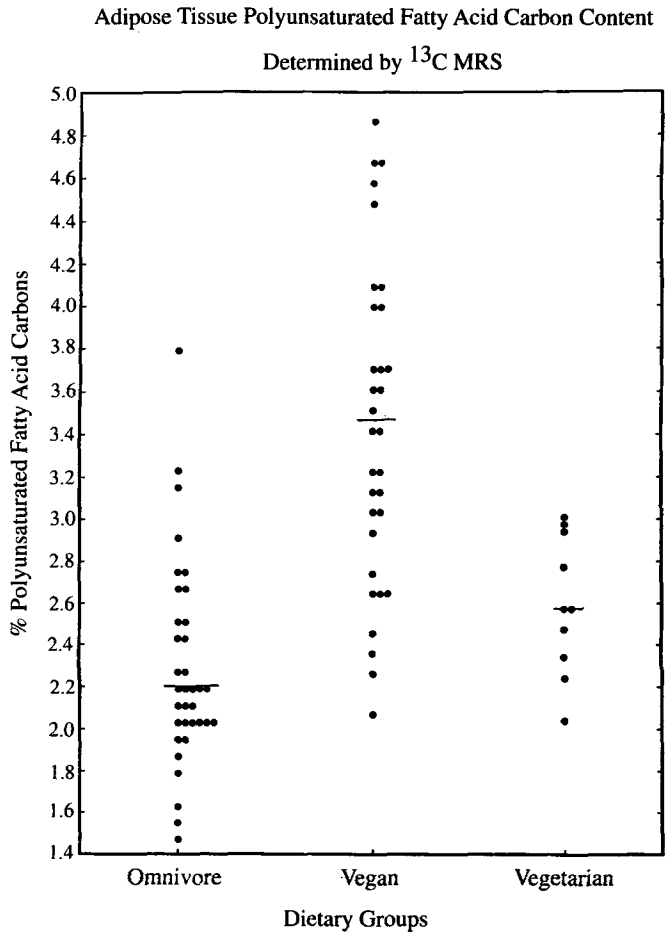

FIG. 3. Adipose tissue polyunsaturated fatty acid carbon content determined by ^{13}C magnetic resonance spectroscopy (MRS) for omnivore, vegan, and vegetarian dietary groups (Method B). This figure illustrates the increased mean polyunsaturated fatty acid content (—) in the vegan group, which showed a wide range of values and a marked increase in some subjects (maximum value 4.9%).

olefinic region of the ^{13}C MR spectra obtained from an omnivore and a vegan volunteer are shown in Figure 1. Significant differences in the relative intensity of resonances arising from unsaturated fatty acids can be observed. The vegan subjects have significantly more total unsaturated fat (86.5 ± 0.9%) than either vegetarian (78.9 ± 1.6%, $P < 0.01$) or omnivore groups (76.1 ± 0.6%, $P < 0.01$) (Method A) (Table 1).

Similarly, when the fatty acid content of adipose tissue is expressed as percentage carbon (Method B), these differences in saturated and unsaturated fatty acid carbons can again be observed (Table 2). Furthermore, this method allows us to assess the relative content of polyunsaturated and monounsaturated lipids without making assumptions as to the type of fatty acids present. Adipose tissue of vegan subjects had significantly more polyunsaturated fatty acid carbons (3.5 ± 0.1%) than either omnivore (2.3 ± 0.01%, $P < 0.01$) or vegetarians (2.6 ± 0.1%, $P < 0.01$) (Fig. 3). The relative content of monounsaturated fatty acids was similar in all groups. No significant differences in adipose tissue composition were found between the vegetarian and omnivore groups.

Correlation between MRS and dietary analysis. Significant correlations were found comparing dietary saturated fat intake with MRS measurement of both saturated ($r = 0.55$, $P < 0.01$) and polyunsaturated ($r = -0.64$, $P < 0.01$) fatty acid content of adipose tissue (Method B). A strong correlation was also found between the polyunsaturated/saturated ratio of dietary fat intake and the MRS measurement of polyunsaturated fatty acids in adipose tissue ($r = 0.61$, $P < 0.01$) (Method B). No correlations were found to exist between serum lipid levels and dietary intake, or between serum lipid levels and fatty acid content of adipose tissue, as determined by ^{13}C MRS.

DISCUSSION

In this study we have demonstrated that *in vivo* ^{13}C MRS can be used to assess the effects of diet on adipose tissue composition. Measurement of individual fatty acids, using natural abundance ^{13}C MRS, is not possible because of the limited

resolution of *in vivo* spectroscopy in humans. However, our results confirm that ^{13}C MRS offers a unique opportunity to noninvasively study dietary influences on adipose tissue lipid composition, allowing repeated measurements of the proportion of saturated and unsaturated fatty acids in adipose tissue (23,24). Significant differences were found in the relative levels of polyunsaturated and saturated fatty acids in the subcutaneous tissue of vegan volunteers compared with those on an omnivore diet.

Good agreement has previously been reported when directly comparing MRS and GLC analysis of adipose tissue composition (24,27,28). Overall reported values for the percentage of unsaturated fatty acids found in adipose tissue biopsies by GLC vary considerably (60–80%) (13–22). Subjects in these GLC studies had extremely different fat intake and our study has highlighted the dependence of adipose tissue composition on dietary fat content. Our results from omnivore subjects obtained using ^{13}C MRS were similar to these reported values, although in the upper part of this range (76.1 ± 0.6%). This can be explained by the fact that all three of our diet groups had a higher intake of dietary polyunsaturated fatty acids than in many other subject groups reported in the GLC literature.

Significant correlations between the MRS data and dietary assessment were obtained for saturated and polyunsaturated fatty acids, but not for monounsaturated fatty acids, a finding that agrees with previous studies (37). Dietary assessment of fat intake is dependent on the reliability of the individual dietary records. MRS may give a better indication of the long-term dietary history of a given subject, as it is not sensitive to short-term fluctuations in the amount and composition of the day-to-day diet. An interesting finding was the similarity between the vegetarian and omnivore groups in terms of diet and adipose tissue composition. It would appear that the vegetarians were replacing one form of saturated fat in their diet (meat) for another (dairy products), resulting in very little difference in the overall composition of their fat intake compared with an omnivore diet.

The levels of serum total cholesterol and LDL-c were shown to be significantly different in the vegans compared with omnivores. However, serum lipids were not strongly related to adipose tissue composition. This may arise from the large fluctuation of serum lipid levels (physiological/dietary related) known to occur, compared with the more stable composition of adipose tissue.

In vivo assessment of adipose tissue composition showed marked elevation in the levels of polyunsaturated and monounsaturated fatty acids in healthy subjects on a long-term vegan diet compared with healthy omnivores and vegetarians. This is an important finding, as it is thought that there is an inverse relationship between polyunsaturated fat in adipose tissue and the risk of CHD, though this is not fully understood (5).

In vivo ^{13}C MRS provides a unique opportunity to study lipid metabolism in humans. It provides a noninvasive method to study the fatty acid profile and may therefore become an important tool in large-scale or serial epidemiological studies. Determining the interactions between diet, adipose tissue, and serum lipids is an exciting future prospect.

Lipoprotein Composition and Serum Cholesterol Ester Fatty Acids in Nonwesternized Melanesians

Staffan Lindeberg[a,*], Peter Nilsson-Ehle[b], and Bengt Vessby[c]

[a]Department of Community Health Sciences, Lund University, S-223 54 Lund, Sweden, [b]Department of Clinical Chemistry, Lund University Hospital, S-22185 Lund, Sweden, and [c]Department of Geriatrics, Uppsala University, S-75185 Uppsala, Sweden

ABSTRACT: In this study, the relationships between dietary fat [as measured by serum cholesterol ester fatty acids (CE–FA)], age, smoking, body mass index, and serum lipids were analyzed in 151 subsistence horticulturalists, aged 20–86 yr, from Kitava, Trobriand Islands, Papua New Guinea. Their diet consists of tubers, fruit, coconut, fish, and vegetables with a negligible influence of western food and alcohol. Total fat intake is low [21% of energy (en%)], while saturated fat intake from coconuts is high (17 en%, mainly lauric and myristic acid). In multivariate analysis, 11–43% of the variation of the serum lipoprotein composition was explained by CE–FA, age, and smoking habits. The proportion of CE20:5n-3 explained much of the variation of triglycerides (TG, negative relation) and high density lipoprotein-cholesterol (HDL-C, positive) in both sexes and serum apolipoprotein A1 (ApoA1, positive) in the males. CE16:0 was positively related to TG and negatively related to HDL-C and ApoA1 in both sexes, and in males it related negatively to total cholesterol (TC) and low density lipoprotein-cholesterol (LDL-C). In males, negative relationships were present between CE18:2n-6 and TC and between CE14:0 and serum lipoprotein(a). Smoking was independently associated with lower ApoA1 in both sexes and with lower HDL-C and higher TG, TC, LDL-C, and apolipoprotein B in males. In conclusion, marine n-3 fatty acids and linoleic acid showed the same potentially beneficial relationships with lipoproteins and apolipoproteins as in western populations. The relations of palmitic acid to serum lipids may be explained in terms of endogenous fat synthesis at a low-fat intake, rather than reflecting its relative intake.
Lipids 31, 153–158 (1996).

The relations between serum lipoproteins and apolipoproteins and atherothrombotic cardiovascular disease are well established, both within and between westernized populations (1–3), with the possible exception of lipoprotein(a) [Lp(a)] (4). Increased total cholesterol (TC), low density lipoprotein-cholesterol (LDL-C), apolipoprotein B (ApoB), triglycerides (TG), and Lp(a) increase the risk, and increased high density lipoprotein-cholesterol (HDL-C) and apolipoprotein A1 (ApoA1) decrease it. Levels of serum lipoproteins and apolipoproteins are influenced by the composition of dietary fatty acids (FA) (5) which, in turn, are at least partly reflected by their relative presence in serum cholesterol esters (CE) (6–17).

In the island of Kitava, Trobriand Islands, Papua New Guinea, we have investigated a population of subsistence horticulturalists in whom stroke and ischemic heart disease (IHD) appear virtually absent despite high smoking rates (18). Diastolic blood pressure, body mass index (BMI; kg/m^2), and triceps skinfolds are very low as compared to healthy subjects from Sweden (where incidence rates of stroke and IHD are high), while systolic blood pressure and LDL-C are only slightly lower and in females only after 60 years of age (19).

The diet in Kitava is peculiar: total fat intake is low but saturated fat intake is high, and most of the dietary fat is derived from coconut and fish (20). The average level of physical activity is higher than in sedentary western populations, although not exceedingly high. The aim of the present study was to analyze the relationships between dietary FA, as reflected by serum CE–FA composition, and serum lipids, lipoproteins, and apolipoproteins in this particular population.

MATERIALS AND METHODS

A description of the Kitava study population and its lifestyle, our methods of age estimation, sampling procedures, and the examinations of nonattendants have been given previously (18). Ethical approval was given by the national Medical Research Advisory Committee of Papua New Guinea. The survey was also approved by other national and provincial bodies and at the community level by the inhabitants and their chiefs. One of us (SL) spent seven weeks in late 1990 with a local family while eating the typical food and closely observing the dietary habits of the host family and of more than 30 other inhabitants throughout the island. A diet history was

taken from five families, combined with weighing of constituents of ready-to-eat portions among three families. Study participants were interviewed about the amounts of modern foodstuffs consumed in the last 12 mon. Macronutrient composition was calculated from international food tables.

Ages were estimated by the use of historic events as reference. Fasting blood samples were obtained in the morning after an overnight fast from 129 males and 51 females aged 13–86 yr, 67% of which were randomly selected. Electricity for the centrifuge was provided by a petrol-powered generating set. Samples were kept at –130°C in a liquid nitrogen vessel (Air Liquide GT35; Air Liquide, Champigny, France) until storage at –70°C in Sweden. Blood pressure was recorded with subjects in the seated position. Age estimates, smoking status (no/yes), anthropometry, serum lipids, and CE–FA were available for 151 subjects.

The CE–FA were determined by using gas–liquid chromatographic methods as described earlier (21), and TC, HDL-C, and TG by using enzymatic methods (22). LDL-C was estimated according to Friedewald. The concentrations of apolipoprotein B100 (ApoB) and ApoA1 were determined by immunoturbidimetry in the Multistat III F/LS apparatus using monospecific polyclonal antibodies. Before assay, the serum samples were preincubated with TG lipase (23). Lp(a) was measured by the Pharmacia Apo(a) RIA method. This is based on the direct sandwich technique in which two monoclonal antibodies are directed against separate antigenic determinants on the Apo(a) in the sample. The concentration is expressed in units/L (U/L). One U of Apo(a) is approximately equal to 0.7 mg of Lp(a) according to the manufacturer. Serum analyses for TG, TC, and HDL-C were performed in one series, and CE–FA, ApoB, ApoA1, and Lp(a) in another series, all within 14 mon after sampling.

Statistical analyses were made separately for males and females. Each continuous variable was checked for or transformed into apparent normality by repeated use of normal probability plots (24). The only variables which appeared normally distributed without transformation in both sexes were CE18:2n-6 and ApoA1, BMI and HDL in males, and CE14:0 in females. After transformations, nine outliers were excluded which were all 3–6 standard deviations from respective means. Age trends were reasonably linear as assessed from bivariate scatter plots and from residual plots in the regression models.

Forward stepwise multiple linear regressions (MLR) were performed using Statistica software for the Macintosh (25). Age, smoking status (no/yes), and CE-FA were included as independent variables. Standardized regression coefficients (std β) are given to show the relative impact, in the final step, of each independent variable. The value of std β demonstrates how many standard deviations the (transformed) dependent variable changes when the (transformed) explanatory variable changes one standard deviation, given that the other entered variables are kept constant. Cumulative adjusted R squared are given to show, at each step, the percentage of variation of the dependent variable so far explained by the model.

RESULTS

Clinical characteristics. Kitavans were very lean and their diastolic blood pressure was low, while the prevalence of smokers was remarkably high (Table 1). Serum TC and LDL-C in males were similar to contemporary Japanese levels, whereas in young and middle-aged females they were at least as high as in Sweden.

Dietary pattern. Yam, sweet potato, fruit, fish, and coconut were dietary staples. Most notable was the virtual absence of dairy products, butter, margarine, lard, oils, refined sugar, alcohol, and cereals, foods which provide more than 70% of the dietary energy (en%) in Sweden. Saturated fat intake from coconut was high (mainly lauric and myristic acid), as well as carbohydrate intake from tubers and fruit, while the intake of total, monounsaturated and polyunsaturated fat was low (Tables 2 and 3). Alcohol was not available.

FA composition of CE. As is evident from Table 4, most CE–FA differed substantially from typical western populations. Palmitic (16:0) and palmitoleic acid (16:1n-7) were high. Linoleic acid and its derivatives were very low, and all n-3 polyunsaturated fatty acids (PUFA) were high. Lauric acid (12:0) was only detected in trace amounts despite a very high intake.

Associations between lipids/lipoproteins/apolipoproteins and CE–FA. In both sexes the CE–FA composition explained much of the variation of TG, HDL-C and ApoA1, but less of the variation of TC, LDL-C, ApoB, and Lp(a) (Tables 3, 5, and 6). Smoking was associated with lower ApoA1 in both sexes independently of CE–FA, and in males with lower HDL-C and higher TG, TC, LDL-C, LDL/HDL, ApoB, and ApoB/A1. BMI was univariately and multivariately related to several CE–FA, but not to lipids, lipoproteins, or apolipoproteins after adjustment for age, smoking, and CE–FA.

TABLE 1
Clinical Characteristics of Kitavans[a]

	Males (n = 102)			Females (n = 40)		
	Mean	(SD)	Range	Mean	(SD)	Range

[a]Percent of total fatty acids (FA) of serum cholesterol esters, means (SD). Comments refer to comparisons with Western populations.

DISCUSSION

In these traditional Pacific Islanders, who apparently escape atherothrombotic cardiovascular disease despite high smoking rates and partly unfavorable serum lipid levels, and despite a high intake of saturated fat, 11–43% of the variation of serum lipids, lipoproteins, and apolipoproteins was explained by age, smoking, and FA composition of CE.

[a]Significant independent variables, standardized regression coefficients (std β), and adjusted R squared (adj. R^2) in forward stepwise multiple regressions including age, smoking status, and 13 cholesterol ester fatty acids as independent variables. Abbreviations as in Table 1; TG, triglycerides; TC, total cholesterol. [b]$P < .05$. [c]$P < .01$. [d]$P < .001$.

The estimated FA intake was, to a certain degree, reflected in the CE–FA composition, with two possible exceptions—CE12:0 was only detected in trace amounts, despite a very high intake from coconut, and CE16:0 was high despite a very low intake. The latter finding is probably explained by a high rate of endogenous fat synthesis at low total fat intake. The proportion of n-3 PUFA was high and that of n-6 PUFA was low in consistency with the high intake of coconut and fish and the absence of oils, margarine, dairy products, and meat. The high level of CE14:0 agrees with the high amount of 14:0 in coconut.

[a]Significant independent variables, standardized regression coefficients, and adjusted R squared in forward stepwise multiple regressions including age, smoking status, and 13 cholesterol ester fatty acids as independent variables. Abbreviations as in Tables 1 and 4. $^bP < .05$. $^cP < .01$. $^dP < .001$.

Long-chain n-3 FA. In both sexes, CE20:5n-3 was negatively related to TG and positively related to HDL-C, and in males it was positively related to ApoA1. These relations are consistent with findings in a large number of dietary intervention trials and observational studies in western populations (26,27).

The second major FA reflecting fish intake, CE22:6n-3, behaved similarly to CE20:5n-3, although the association with lipoproteins and apolipoproteins reached significance only after excluding CE20:5n-3 as an independent variable (data not shown). When males and females were analyzed together in MLR, CE22:6n-3 was positively related to HDL-C even after adjustment for CE20:5n-3 (std $\beta = 0.32$; $P = 0.0036$). Recent reports have disputed this similarity between 20:5n-3 and 22:6n-3 in relation to serum lipids. In a coastal Norwegian population of males and females, HDL-C and ApoA1 were thus shown to be negatively related to 22:6n-3 in serum phospholipids (PL) and positively related to PL20:5n-3 (27). Furthermore, TG was not related to PL22:6n-3 in the same Norwegians, nor in French males (28). Contrasting findings suggest that fish oils rich in 22:6n-3 increase HDL-C to a greater degree than those rich in 20:5n-3 (29). A problem when interpreting cross-sectional findings is that 20:5n-3 and 22:6n-3 seem to differ in their time-course of incorporation into plasma lipids and in their affinity to lecithin:cholesterol acyl transferase, which is believed to form most of the CE present in plasma (30). Another problem is the possible confounding effect of alcohol intake, which was negatively associated with PL22:6n-3 and positively with PL20:5n-3 in French males (28), and which is known to raise HDL-C, ApoA1, and TG, and to lower LDL-C, at least in heavy drinkers (31). Alcohol intake was close to nil in Kitava.

Saturated fat. The negative association between CE16:0 and TC in males is at first sight surprising, as dietary 16:0 is positively related to LDL-C and TC, at least when the intakes of cholesterol and total fat are high or when the LDL receptor activity is otherwise compromised (32), and also because dietary 16:0 is positively related to CE16:0 at constant fat intake around 30 en% (10). However, when total fat intake is low, CE16:0 may preferentially reflect endogenous fat synthesis from carbohydrates rather than dietary intake of 16:0 (33). This may also explain the fact that CE16:0 in both sexes was positively related to TG and negatively to HDL-C, as TG is elevated, and HDL-C is reduced by an increased intake of carbohydrates (34), at least when dietary fat provides less than 25 en% and carbohydrates more than 60 en%, as is the case in Kitava. Similar negative relations between CE16:0 and HDL-C in healthy males from Finland (35) and France (36) suggest, on the other hand, that there may be additional explanations.

Myristic acid (14:0), which is the second most prevalent FA in coconut and probably the best marker of coconut intake in this survey, has repeatedly been shown to raise TC, LDL-C, and ApoB (37). Because the high intake of coconut is a probable cause of the fairly high TC, LDL-C, and ApoB in Kitavans, the absent relationship between CE14:0 and these variables is unexpected.

A diet high in 12:0 and 14:0 given to Danish men resulted in lower levels of Lp(a) (38), which may be beneficial in terms of IHD. It is therefore interesting that in Kitavans a univariate inverse relation was found between Lp(a) and CE14:0 in males. Nevertheless, despite a very high intake of 12:0 and 14:0 (and a negligible intake of *trans* FA), levels of Lp(a) were essentially the same as in Sweden (19), which is expected as much evidence has shown that Lp(a) is for the most part genetically determined (39).

Monounsaturated fat. In males CE16:1n-7 was positively related to TG, LDL-C, and ApoB. Similar relations were found in a large sample of middle-aged French males where, furthermore, CE16:1n-7 was positively associated with HDL-C and ApoA1 (36). These relationships were only significant in drinkers, and it was concluded that alcohol consumption was the probable cause, which agreed with other studies showing an association between alcohol consumption and 16:1n-7 in CE or PL in males (8,28,40). Alcohol intake is

negligible in Kitava, as already stated. Most of the 16:1n-7 appearing in CE in Kitavans is expected to be derived from 16:0, which would explain most of the behavior of CE16:1n-7 in multivariate analysis among males. However, CE16:1n-7 was not univariately related to CE16:0 in males or females. Rather, CE16:1n-7 was strongly and negatively related to CE18:2n-6, which explained 43 and 45% of the variation of CE16:1n-7 in stepwise MLR among males and females, respectively (data not shown), and this is partly in accordance with earlier findings (8,10).

n-6 FA. As expected, CE18:2n-6 was strongly and negatively associated with TC, but only in males. This agrees with consistent evidence that linoleic acid reduces LDL-C (41). The lack of relation to HDL-C and ApoA1 supports the notion that dietary 18:2n-6 has little effect on these two variables at realistic intakes (<10 en% in the West; <5 en% in Kitava) (42).

In females, CE20:3n-6 was positively associated with LDL/HDL, ApoB, and Lp(a), which is consistent with the higher levels of CE20:3n-6 in patients with IHD (21) or impaired glucose tolerance (43). Among French males, CE20:3n-6 was positively related to TG, TC, LDL-C, LDL/HDL, ApoB, and ApoB/A1, and negatively to HDL-C and ApoA1 (36). From dietary intervention trials, there is evidence of a strong inverse relationship between the intake of 18:2n-6 and its metabolite 20:3n-6 after two weeks (42), as well as after five months (10).

BMI. Contrary to what has been found in western populations, BMI was unrelated to lipoproteins and apolipoproteins after adjustment for age, smoking, and CE–FA, and the weak relations that tended to exist were opposite those generally expected in westerners (data not shown). This is not surprising as BMI in this very lean population probably reflects muscle mass rather than body fat.

Conclusions. In this population of subsistence horticulturalists, several relations were found between serum CE and serum lipoproteins and apolipoproteins, and it is inferred that this reflects the effects of dietary fatty acids. In earlier cross-sectional studies, mainly in westerners, significant correlations between the FA of human tissues and serum lipoproteins or apolipoproteins have often been weak and inconsistent, though less so for 18:2n-6 (9,13,16,28,32,36,44–50). The reasons for the unexpectedly large correlations in the present study are not evident. Partial explanations may be that the population is homogeneous and stable, and that important confounding factors of nutrition appear to be absent.

The findings also confirm that smoking is associated with raised TG, TC, LDL-C, and ApoB and with lowered HDL-C and ApoA1 (51), and that these relationships are largely independent of diet and alcohol.

Stearic Acid Unlike Shorter-Chain Saturated Fatty Acids Is Poorly Utilized for Triacylglycerol Synthesis and β-Oxidation in Cultured Rat Hepatocytes

Tonkun Pai and Yu-Yan Yeh*

Department of Nutrition, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT: Utilization of stearate as compared to various saturated fatty acids for cholesterol and lipid synthesis and β-oxidation was determined in primary culture of rat hepatocytes. At 0.5 mmol/L in the medium, stearate (18:0) adequately solubilized by albumin was less inhibitory to cholesterol synthesis from [2-^{14}C] acetate than myristate (14:0) and palmitate (16:0) (68% vs. 91 and 88% inhibition, respectively). The rate of incorporation into cholesterol from [1-^{14}C] stearate (3.0 ± 0.6 nmol/mg protein/4 h) was 37-, 1.8-, and 7.8-fold of that from myristate, palmitate, and oleate, respectively. Conversely, the rate of [1-^{14}C] stearate incorporation into total glycerolipids was 88–90% lower than that of labeled palmitate, myristate, and oleate. The rate of [1-^{14}C] stearate incorporation into triacylglycerol (3.6 ± 0.4 nmol/mg protein /4 h) was 6–8% of that from myristate, palmitate, oleate, and linoleate. The rate of stearate incorporation into phospholipids was the lowest among tested fatty acids, whereas the rate of mono-and diacylglycerol synthesis was the highest with stearate treatment. The rate of β-oxidation as measured by CO_2 and acid soluble metabolite production was also the lowest with [1-^{14}C] stearate treatment at 22.7 nmol/mg protein/4 h, which was 35–40% of those from other [1-^{14}C] labeled fatty acids. A greater proportion of stearate than other fatty acids taken up by the hepatocytes remained free and was not metabolized. Clearly, stearate as compared to shorter-chain saturated fatty acids was less efficiently oxidized and esterified to triacylglycerol in cultured rat hepatocytes.
Lipids 31, 159–164 (1996).

Even though the mortality from coronary heart disease has significantly decreased in the last two decades, the disease remains a major health problem and the leading cause of death in the United States (1,2). Coronary heart disease is a multifactorial disease, and high level of plasma cholesterol, especially low density lipoprotein (LDL) cholesterol, is one of the major risk factors that can be modified (2,3). Results from many animal, epidemiological, and clinical studies suggest that the amount and type of dietary fat affect plasma cholesterol concentrations (4–7). Unlike other shorter-chain saturated fatty acids [i.e., laurate (12:0), myristate (14:0), palmitate (16:0)] which are hypercholesterolemic, stearate (18:0) does not raise plasma cholesterol concentrations (5,8–14). Poor digestibility and bioavailability (15–18), absence of LDL receptor downregulation (19), and conversion of stearate to oleate (20,21) have been suggested as possible mechanisms underlying the neutral effect of stearate on plasma cholesterol. However, these mechanisms together do not fully explain the extent of the hypocholesterolemic nature of stearate. It is reasonable to assume that other mechanism(s) may also be involved in the regulation by stearate.

The poor understanding of cellular mechanism underlying the effect of dietary saturated fatty acids on plasma cholesterol concentration is attributed to its complexity of interaction among different fatty acids. Therefore, it is important to understand the mechanism regulating metabolism of individual fatty acids. By using primary culture of rat hepatocytes, the specific effects of fatty acids on lipid metabolism can be determined without the complications of others. The present study was conducted to determine the effects of different saturated fatty acids on cholesterol synthesis from acetate, and to determine utilization of different saturated fatty acids for cholesterol and glycerolipid synthesis, and for oxidation. The results showed that despite its high cholesterogenesity, the utilization of stearate for either oxidation or synthesis of glycerolipids, especially triacylglycerol, was markedly lower than other fatty acids.

MATERIALS AND METHODS

Animals and diets. Sprague-Dawley male rats (100–150 g body weight) were purchased from Harlan Sprague-Dawley (Indianapolis, IN) and fed *ad libitum* a rat chow from Ralston Purina Co. (St. Louis, MO). The rats were housed individually in stainless-steel cages at approximately 24°C and 50% relative humidity on a 12-h light/dark cycle (0600–1800) and had free access to water at all times. They were sacrificed between 0900 and 1000 on the day of hepatocyte isolation. The animal protocol was approved by The Pennsylvania State University Institutional Animal Care and Use Committee.

Preparation of rat hepatocytes. Hepatocytes were isolated from rats (225–250 g body weight) by the method of Berry and Friend (22) as modified by Seglen (23). As detailed elsewhere (24), the procedure involved collagenase perfusion *via* the hepatic portal vein, tissue mincing, filtration and centrifugation, and further purification by cell adherence. The isolated cells were resuspended in Dulbecco's modified Eagle medium (DMEM) supplemented with 5.6 mmol/L glucose, 10% fetal bovine serum (FBS), and antibiotics (penicillin, 100 units/mL and streptomycin, 100 μg/mL). The cell viability was determined by Trypan blue exclusion for each isolation. The cell preparations with 95% or higher viability were used throughout the experiments. A 2-mL aliquot of cell suspension ($0.7–0.8 \times 10^6$ cells/mL) was transferred to culture plates, each containing six wells (3.5 cm diameter), and incubated at 37°C under an atmosphere of 95% air and 5% CO_2. Six hours after incubation, cells that adhered to the flask were refed with the DMEM and incubated under the same conditions for 24 h. The adhered cells derived from the same liver were used for various fatty acid treatments in each experiment.

Hepatic capacity for cholesterol and lipid synthesis. The cultured cells obtained after 24 h incubation were washed three times with 2 mL of FBS-free DMEM. They were then incubated in the same medium with [2-^{14}C] acetate (specific activity, 36.96 MBq/mmol) and unlabeled acetate (1.0 mmol/L) in the presence of different fatty acids at 0.5 mmol/L. Fatty acids were provided as an albumin complex in a molar ratio of 5.6 (fatty acid/albumin). Stock solutions (100 mmol/L) were prepared from the sodium salt of each fatty acid. An aliquot of the stock solution was added to the DMEM containing 0.59% bovine serum albumin (BSA) followed by sonication prior to the incubation. At the end of 4 h incubation, the cells were harvested and lipids were extracted from the cells according to the procedure of Folch *et al.* (25). The extracted lipids were saponified and cholesterol was precipitated with digitonin solution (26). Fatty acids were extracted from the saponifiable fraction. Radioactivity of cholesterol and fatty acids derived from [2-^{14}C] acetate was measured using a liquid scintillation spectrometer (LS8100; Beckman instruments, Inc., Palo Alto, CA). The rate of cholesterol synthesis was expressed as nmol of acetate incorporated/mg protein/4 h. Cellular protein was determined by the method of Lowry *et al.* (27) from hepatocytes harvested from the culture treated without fatty acid and BSA during the 4-hr incubation.

Cholesterogenesity and lipogenesity of fatty acids. To evaluate the effects of individual fatty acids on the cholesterol and glycerolipid synthesis, the cultured cells obtained after 24 h incubation were washed three times with 2 mL of FBS-free DMEM followed by incubation in the same medium containing 0.5 mmol/L [9,10-^{3}H]myristate, [1-^{14}C]palmitate, [1-^{14}C]stearate or [1-^{14}C] oleate and corresponding nonlabeled fatty acid to yield a specific activity of 37 MBq/mmol. After 4 h incubation, the cellular lipids were extracted. For analysis of glycerolipids synthesized from the labeled fatty acids, the extracted cellular lipid was separated into phospholipid, triacylglycerol, diacylglycerol, monoacylglycerol, and free fatty acids on Silica Gel H plates using a solvent system consisting of hexane/ethyl ether/acetic acid (80:20:1) (28). Each lipid class was reextracted prior to radioactivity determination by liquid scintillation counting. The rate of synthesis was expressed as nmol of substrate incorporated/mg protein/4 h.

β-Oxidation of fatty acids. For measurement of β-oxidation capacity, the incorporation of [1-^{14}C] labeled fatty acid into $^{14}CO_2$ and acid soluble metabolites (ASM) was determined (29). ASM measured under the conditions were predominantly ketone bodies with Krebs'cycle intermediates and acetyl CoA as minor components (30). Cell treatments were identical to those in the cholesterol and lipid synthesis experiments described above except that culture flasks (25 cm^2) instead of the culture plates were used. Each culture flask was sealed with a rubber cap containing a center well. After 4 h incubation, 0.2 mL of 35% perchloric acid was injected to the medium to stop the reaction. To the filter paper in the center well, 0.1 mL of 1 M hyamine hydroxide solution was injected (30). The culture flasks were shaken for 1 h on ice to trap CO_2. For CO_2 measurement, the center well was placed in a scintillation vial and dried overnight. The radioactivity of CO_2 was determined by liquid scintillation counting. For measurement of ASM, the culture medium was centrifuged, and the supernatant was used for radioactivity determination. The rate of product formation was expressed as nmol of substrate incorporated/mg protein/4 h.

Fatty acid binding to albumin. The binding of fatty acids to BSA was determined by measuring the partitioning of [^{14}C] labeled fatty acids between heptane and DMEM (31,32). The binding of fatty acid at various fatty acid to BSA molar ratios (2:1, 5.6:1, 10:1) was tested. Fatty acid was maintained at 0.5 mmol/L in the medium. An aliquot of the stock solution of each fatty acid (100 mmol/L) was added to 20 mL of DMEM containing 1.65, 0.59, 0.33% BSA and [1-^{14}C]palmitate, [1-^{14}C]stearate, or [1-^{14}C]oleate with a specific activity of 3.7 MBq/mmol followed by sonication prior to the incubation. The mixture was then transferred to a 50-mL capped tube. A 2-mL portion of heptane was added, and the tubes were shaken at 20 strokes per minutes for 48 h to achieve equilibrium. After equilibration, the heptane fraction was transferred to scintillation vials and evaporated. The radioactivity was measured in a liquid scintillation spectrometer. The results expressed as percentage binding were calculated by subtracting the radioactivity in the heptane fraction from total radioactivity in the medium, dividing the value by total radioactivity in the medium and multiplying by 100.

Materials. Collagenase D was purchased from Boehringer Mannheim Co. (Indianapolis, IN). [2-^{14}C] Acetate, [9,10-^{3}H] myristate, [1-^{14}C] palmitate, [1-^{14}C] stearate, [1-^{14}C] oleate, and [1-^{14}C] linoleate were products of Amersham Co. (Arlington Heights, IL). Fatty acid-free BSA and sodium salts of myristate, palmitate, stearate and oleate were purchased from Sigma Chemical Co. (St. Louis, MO). DMEM, FBS, and antibiotics (penicillin and streptomycin) were provided by Life

Technologies, Inc. (Grand Island, NY). Silica gel H plates (20 × 20 cm, 250 μm layer thickness) were obtained from Alltech Associates, Inc. (Deerfield, IL).

Statistical analysis. Data were expressed as mean ± SD. The significant differences among various fatty acid treatments were analyzed by analysis of variance. Duncan's multiple range test was applied to identify significant differences between treatment group means (33). Probability values less than 0.05 were judged to be statistically significant.

RESULTS

Cholesterol synthesis. The rate of [2-^{14}C] acetate incorporation into cholesterol and fatty acid was measured in the presence or absence of 0.5 mmol/L myristate, palmitate, stearate, or oleate. All fatty acids tested were found to be inhibitory to cholesterol synthesis from [2-^{14}C] acetate when compared with the rate obtained from the cells incubated without exogenous fatty acid. Oleate and myristate were the most inhibitory (92 and 91%, respectively), followed by palmitate (88%) and stearate (68%) (Fig. 1). Clearly, stearate is less potent than shorter-chain saturated fatty acids and oleate in inhibiting cholesterol synthesis. Stearate was as effective as oleate and palmitate in inhibiting [2-^{14}C] acetate incorporation into fatty acid by 92–95%. Myristate inhibited the fatty acid synthesis by 73%. The experiments were then conducted to determine the rate of [9,10-^{3}H] myristate, [1-^{14}C] palmitate, [1-^{14}C] stearate, and [1-^{14}C] oleate incorporation into cholesterol. The rate of substrate incorporation into cholesterol, expressed as nmol/mg protein/4 h, were in decreasing order: stearate (2.98 ± 0.52) > palmitate (1.69 ± 0.24) > oleate (0.38 ± 0.14) > myristate (0.08 ± 0.008).

Glycerolipid synthesis. In view of the potential competition of cholesterol and glycerol lipid synthesis for the fatty acid substrate, the rates of fatty acid utilization for glycerol lipid production were determined. The rate of stearate incorporation into phospholipids was the lowest (2.9 ± 0.3 nmol/mg prot/4 h) among the tested fatty acids (Fig. 2). On the other hand, the rate of monoacylglycerol and diacylglycerol synthesis was the highest with stearate treatment. More strikingly, the rate of stearate incorporation into triacylglycerol (3.6 ± 0.4 nmol/mg protein/4 h) was only 6.3, 6.1, 5.6, and 7.5% of that of oleate, myristate, palmitate, and linoleate, respectively. Consequently, the highest rate of incorporation into glycerolipids (a sum of phospholipids, tri-, di- and monoacylglycerols) was noted for palmitate (72.4 ± 5.6 nmol/mg protein/4 h), followed by myristate (64.4 ± 3.0), oleate (62.7 ± 4.1), linoleate (55.1 ± 2.0), and stearate (6.5 ± 0.4 nmol/mg/4 h).

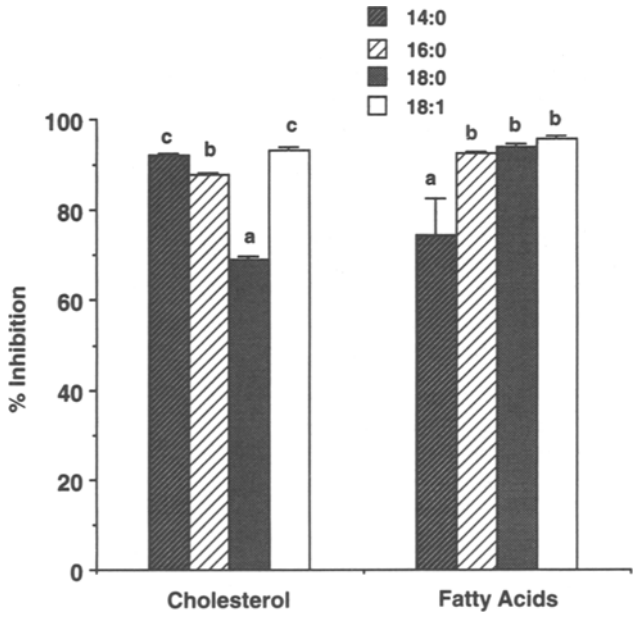

FIG. 1. Inhibition of [2-^{14}C] acetate incorporation into cholesterol and fatty acid by exogenous fatty acids in cultured rat hepatocytes. Values are mean ± SD for four samples. Values without a common letter are significantly different at $P < 0.05$. Percent inhibition is defined as the difference between the amount of [^{14}C]acetate recovered in cholesterol or fatty acids in the fatty acid treated hepatocytes and that in the hepatocytes without exogenous fatty acids divided by the amount of [^{14}C] acetate recovered in cholesterol or fatty acids in the hepatocytes without any fatty acid treatment multiplying by 100. The rate of acetate incorporation into cholesterol and fatty acid was 1.05 ± 0.03 and 0.26 ± 0.01 nmol/mg protein/4 h, respectively, for the control group. For the bars with unnoticeable error bars, the error bar is thinner than the bar frame. Myristate, palmitate, stearate, and oleate treatments are represented by 14:0, 16:0, 18:0, and 18:1, respectively.

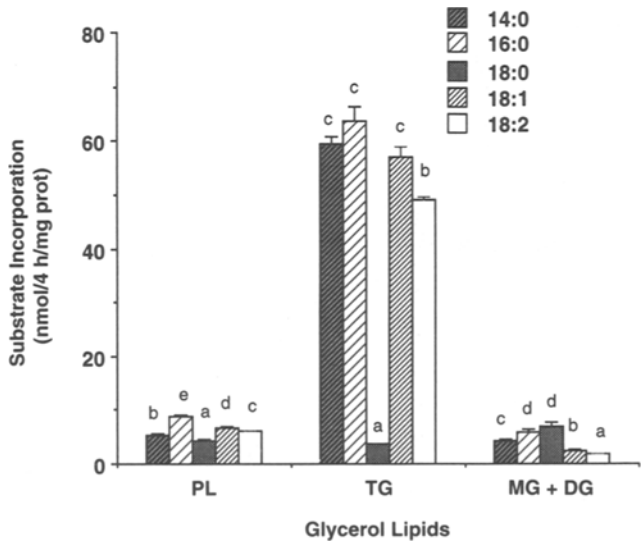

FIG. 2. Incorporation of [9,10-^{3}H] or [1-^{14}C] labeled fatty acids into various glycerolipids in cultured rat hepatocytes. Values are mean ± SD for four samples. Values without a common letter in the same cluster are significantly different at $P < 0.05$. Substrate incorporation is defined as nmol fatty acid incorporated into various glycerolipids for four hours per mg cellular protein. For the bars with unnoticeable error bars, the error bar is thinner than the bar frame. Myristate, palmitate, stearate, oleate, and linoleate treatments are represented by 14:0, 16:0, 18:0, 18:1, and 18:2, respectively. Abbreviations: PL, phospholipids; TG, triacylglycerols; MG + DG, monoacylglycerol and diacylglycerol.

TABLE 1
Utilization of [1-^{14}C] Labeled Fatty Acids *via* Mitochondrial β-Oxidation in Cultured Rat Hepatocytes[a]

Product	[^{14}C] Labeled			
	Palmitate	Stearate	Oleate	Linoleate
	(nmol/mg protein/4 h)			
$^{14}CO_2$	9.6 ± 4.1[d]	2.9 ± 0.47[c]	13.2 ± 2.1[d]	13.1 ± 1.2[d]
ASM	54.2 ± 12.9[d]	19.8 ± 3.37[c]	78.8 ± 15.2[e]	75.2 ± 11.4[e]

[a]Values are means ± SD for six to eight samples. Values without a common superscript in the same row are significantly different at $P < 0.05$. ASM, acid-soluble metabolites containing predominantly ketone bodies (Ref. 30).

Oxidation of fatty acids. The incorporation of [1-^{14}C] labeled fatty acid into CO_2 and ASM (29) was taken as a measure of β-oxidation capacity. The rates of CO_2 and ASM formation from [1-^{14}C] stearate were lowered than those from other [1-^{14}C] labeled fatty acids (Table 1). Thus, the sum of these two products derived from [1-^{14}C] stearate (22.7 nmol/mg protein/4 h) was 60–75% of that from other [1-^{14}C] labeled fatty acid.

The analysis of radiolabeled fatty acids accumulated in hepatocytes revealed that the amount of free fatty acid recovered in the cells was the highest with [1-^{14}C]stearate, followed by [1-^{14}C]palmitate, [1-^{14}C]oleate, [9,10-^{3}H]myristate, and [1-^{14}C]linoleate (Table 2). Specifically, the amount of the recovery of stearate, palmitate, oleate, myristate, and linoleate represented 8.5 ± 0.8%, 4.7 ± 0.8%, 0.7 ± 0.2%, 0.3 ± 0.001%, and 0.1 ± 0% of initial dose of the corresponding fatty acids (i.e., 1000 nmoles per incubation) in the incubation medium.

The sum of products (i.e., cholesterol, glycerolipids, β-oxidation metabolites, and free fatty acid) derived from [^{14}C] labeled fatty acids was then calculated. Of the initial dose of [1-^{14}C] fatty acids (1000 nmoles per incubation) provided in the medium, 12.5% (i.e., 124.7 ± 2.8 nmole/mg protein/4 h) of stearate as compared to 18.8% (i.e., 188.3 ± 5.0 nmol/mg protein/4 h) of palmitate and 16.3% (i.e., 162.5 ± 1.9 nmol/mg protein/4 h) of oleate were incorporated into all products.

Fatty acid binding. The different effects of fatty acids on lipid synthesis and β-oxidation led us to measure albumin binding capacity of fatty acids. The results showed that 99.84 ± 0.003% of stearate as compared to 99.45 ± 0.11% of palmitate and 99.94 ± 0.02% oleate was bound to BSA in the medium containing 2:1 molar ratio of fatty acid to BSA. Increasing the ratio to 5.6:1 and 10:1 did not alter the percentage of binding for stearate or palmitate, but slightly and significantly decreased oleate binding to 99.53 ± 0.22% and 96.54 ± 0.24%, respectively.

TABLE 2
Accumulation of [1-^{14}C] or [9,10-^{3}H] Labeled Free Fatty Acids in Cultured Rats Hepatocytes[a]

Substrate	Fatty acid accumulated (nmol/mg prot/4 h)
[9,10-^{3}H] Myristate	2.63 ± 0.01[c]
[1-^{14}C] Palmitate	47.04 ± 7.92[e]
[1-^{14}C] Stearate	84.60 ± 8.20[f]
[1-^{14}C] Oleate	6.75 ± 1.62[d]
[1-^{14}C] Linoleate	1.45 ± 0.00[b]

[a]Values are mean ± SD for six samples. Values without a common superscript in the same column are significantly different at $P < 0.05$. Free fatty acids were quantified by measuring cellular free fatty acids after 4 h incubation with [^{3}H] or [^{14}C] labeled fatty acids at 0.5 mM unlabeled fatty acid concentration.

DISCUSSION

Dietary fatty acids serve as precursors for cholesterol synthesis by producing acetyl-CoA *via* β-oxidation (34). They can also inhibit the cholesterol synthesis from other substrates such as acetate by diluting the acetyl-CoA pool. The rat liver plays important roles in controlling the plasma cholesterol concentration, because hepatic synthesis accounts for about 50% of whole animal cholesterol production (35). This together with the finding that stearate is as effective as oleate in reducing plasma cholesterol level (12) led us to speculate that stearate may impair hepatic cholesterol synthesis. Contrary to this speculation, we found that not only was stearate less inhibitory to cholesterol synthesis from acetate, but served as a preferred substrate over palmitate, myristate, and oleate for cholesterol synthesis. The most striking finding of the present study, however, is that the rate of stearate incorporation into triacylglycerol was markedly depressed to approximately 6–8% of that noted for myristate, palmitate, and oleate, suggesting a poor utilization of stearate for triacylglycerol synthesis (Fig. 2). The different rates of triacylglycerol synthesis from fatty acids have also been demonstrated previously by Nestel and Steinberg (36) and Kohour *et al.* (37). Consistent with the present study of hepatocytes, palmitate was incorporated into triacylglycerol at a rate that was 15–36% higher than that of linoleate incorporation in rat liver slices (36). Similarly, the output of triacylglycerol by the rat liver perfused with palmitate was the same as or higher than that perfused with oleate and linoleate (37). Interestingly, the rate of triacylglycerol output from stearate was not different or even higher than that from palmitate, depending on duration of the liver perfusion (37). The reason for the discrepancy in triacylglycerol synthesis from stearate observed between the cultured hepatocytes and perfused liver systems is not known. However, it is important to stress that maximal rate of triacylglycerol output by the liver perfused with stearate was accompanied by 480% increase in hepatic content of the fatty acid as compared to 46% increase of hepatocyte stearate in the present study (data not shown).

The mechanism underlying the marked impairment of triacylglycerol synthesis from stearate in cultured hepatocytes remains uncertain. Fatty acids present in the liver are either esterified to form glycerolipids or oxidized *via* β-oxidation (38,39). An alteration in one pathway can therefore inversely affect the other in metabolizing fatty acid. In fact, the inhibition of triacylglycerol synthesis by fish oil rich in n-3 fatty acids in rat liver and cultured hepatocytes (40,41) has been

attributed to increased CO_2 and ASM production, resulting in part from increased carnitine acyltransferase activity (41). Unlike the effect of n-3 fatty acid, the depressed rate of stearate incorporation into triacylglycerol could not be explained by enhanced ß-oxidation because the rates of CO_2 and ASM formation from [1-^{14}C] stearate were lower than those from other [1-^{14}C] labeled fatty acids (Table 1).

Triacylglycerol and phospholipid synthesis share common pathways and compete for fatty acids (42). Nonetheless, the impaired triacyglycerol synthesis from stearate was not a result of such a competition, since the rate of stearate incorporation into phospholipid was also decreased, although to a lesser extent. Dietary fatty acids are known to alter the activity of the enzymes involved in triacylglycerol synthesis: glycerol-3-phosphate acyltransferase, 1-acylglycerolphosphate acyltransferase, phosphatidate phosphohydrolase and 1,2-diacylglycerol acyltransferase (43). Our results showed that the rate of stearate incorporation into monoacylglycerol and diacylglycerol was similar to or higher than that of other fatty acids, suggesting that the activity of glycerol-3-phosphate acyltransferase and monoacylglycerol acyltransferase were not altered. It has been demonstrated in a feeding study that a markedly reduced plasma triacylglycerol concentration by fish oil was accompanied by approximately a 50% reduction in phosphatidate phosphohydrolase; however, the activity of diacylglycerol acyltransferase was not affected (43,44). Whether stearate inhibits phosphatidate phosphohydrolase and 1,2 diacylglycerol acyltransferase activity remains unclear.

In an attempt to further understand the possible mechanism, we found that the amount of exogenous stearate recovered as glycerolipids, cholesterol, β-oxidation products and free fatty acid in the hepatocytes was 25 and 35% lower than that derived from exogenous oleate and palmitate, respectively. Although β-oxidation was not determined in the experiment using [9,10- ^{3}H] myristate, the rate of myristate incorporation into the sum of glycerolipids and cholesterol (i.e., 64.5 nmol of myristate incorporated/mg protein/4 h) was 5.8-fold higher than that derived from stearate, indicating that similar to palmitate and oleate, myristate is more rapidly metabolized than stearate. It should be pointed out that the rate of myristate incorporation into the products may be underestimated due to potential exchange of [^{3}H] label of the fatty acid with water in the medium and cells. Taken together, the results of estimated recovery of cellular metabolites suggest that stearate uptake by the cells may be impaired. Although the reason for this impairment is obscure, the comparable albumin binding capacity of various fatty acids observed in the present study indicates that stearate was well solubilized in the medium. Nevertheless, the low substrate uptake alone could not fully account for greater than 90% reduction in triacylglycerol synthesis from stearate. It is intriguing that contrary to the low recovery of stearate in cellular metabolites, the amount of stearate remained free was the highest among all fatty acids. Of the total stearate taken up by the cells, more than 60% was free and not metabolized. Since activation of fatty acid is an essential step in its metabolism (45,46), the conversion of stearate to stearoyl CoA by fatty acyl CoA synthetase may be a limiting factor contributing to the impairment in stearate incorporation into triacylglycerol. This speculation is consistent with an earlier observation showing that the levels of fatty acyl CoA such as oleoyl CoA and linoleoyl CoA but not stearoyl CoA in liver and skeletal muscle reflected dietary fatty acids (47).

In summary, stearate is more cholesterogenic and less inhibitory to cholesterol biosynthesis from acetate than shorter-chain saturated and monounsaturated fatty acids. Most importantly, stearate is poorly utilized for triacylglycerol synthesis in cultured rat hepatocytes.

ABSTRACT: *Trans* polyunsaturated n-3 fatty acids are formed as a result of the heat treatment of vegetable oils. It was demonstrated previously that the 18:3 Δ9*cis*, 12*cis*, 15*trans* containing a *cis* Δ9 ethylenic bond was converted to a geometrical isomer of 20:5n-3, the 20:5 Δ5*cis*, 8*cis*, 11*cis*, 14*cis*, 17*trans*. In the present study, we have identified two new isomers of eicosapentaenoic acid, the Δ11 mono*trans* and the Δ11,17 di*trans* isomers in liver of rats fed a heated oil. These are formed as a result of the conversion of two of the main isomers of linolenic acid which are present in refined and frying oils, the 18:3 Δ9*trans*, 12*cis*, 15*cis* and the 18:3 Δ9*trans*, 12*cis*, 15*trans*.

Lipids 31, 165–168 (1996).

Trans C_{18} polyunsaturated fatty acids (PUFA) are formed during heat treatments (deodorization, frying) of vegetable oils (1–3). Linoleic acid is mainly isomerized to 18:2 Δ9*cis*, 12*trans*, and 18:2 Δ9*trans*, 12*cis*, whereas α-linolenic acid is isomerized to three major isomers which are 18:3 Δ9*cis*, 12*cis*, 15*trans*, 18:3 Δ9*trans*, 12*cis*, 15*cis* and 18:3 Δ9*trans*, 12*cis*, 15*trans*. The double bond at the Δ12 position is only isomerized to a low degree (4). These *trans* C_{18} PUFA are present in oils and fats, but also in different food products (5,6). Consequently, they are present in human tissues, including serum (7) and milk (8,9). It is now established that the *trans* isomers of linoleic and α-linolenic acids which contain a *cis* double bond at the Δ9 position are converted into isomers of arachidonic acid (10,11), eicosapentaenoic acid (EPA), and docosahexaenoic acid (12). The latter have been reported in human platelets (13), suggesting that humans are able to desaturate and elongate *trans* C_{18} precursors. Some physiological effects of 20- and 22-carbon *trans* n-3 PUFA have been reported on platelet function and metabolism (14,15) and electroretinography (16).

Only a few studies have been performed on the metabolism of fatty acids containing a *trans* double bond at the Δ9 position. The conversion of 18:2 Δ9*trans*, 12*cis* was reported in mice (11), indicating that when this fatty acid contains a *trans* double bond at the Δ9 position, it also may be desaturated and elongated into an isomer of arachidonic acid (11,17). Moreover, 18:2 Δ9*trans*, 12*cis* might also be elongated (11). Elaidic acid (18:1 Δ9 *trans*) has also been shown to be Δ5 desaturated (18). However, the possible conversion of the *trans* isomers of linolenic acid containing a *trans* double bond at the Δ9 position (i.e., 18:3 Δ9*trans*, 12*cis*, 15*cis*, and Δ9*trans*, 12*cis*, 15*trans*), which are present in refined oil, had not yet been studied. Indeed, four unknown peaks were reported after gas–liquid chromatography (GLC) of a 20:5 fatty acid methyl esters (FAME) fraction isolated from liver lipids of rats fed a heated linseed oil (19). These peaks labelled as X1, X2, X3, and X4 in the original publication were suspected to be other 20:5 *trans* isomers, but they were not clearly identified. Two geometrical isomers of EPA (i.e., 20:5 Δ5*cis*, 8*cis*, 11*trans*, 14*cis*, 17*cis*, and 20:5 Δ5*cis*, 8*cis*, 11*trans*, 14*cis*, 17 *trans*), which were recently synthetized (20), enable us to identify two new 20:5 isomers as being the metabolites of 18:3 Δ9*trans*, 12*cis*, 15*cis*, and 18:3 Δ9*trans*, 12*cis*, 15*trans*.

MATERIALS AND METHODS

Liver lipids were extracted (21) from Wistar rats fed for six weeks a diet containing 10% of linseed oil heated at 275°C for 12 h under nitrogen, as previously described (12). This represented a daily intake of about 2.3 g of oil. FAME were prepared using boron trifluoride in methanol (14% by vol), according to Morrison and Smith (22). Then, FAME were fractionated by reversed-phase high-performance liquid chromatography, as previously reported (9). Briefly, a Nucleosil (particle size: 5 μm) C_{18} column (25 cm × 4.6 mm i.d., Shandon, Eragny, France) was used and the mobile phase was a mixture of acetonitrile and acetone (9:1 by vol) at a flow rate of 4 mL/min^{-1}. The fraction corresponding to the 20:5 FAME was collected and then analyzed by GLC using two columns of different polarities. The first one was a 30 m × 0.25 mm i.d. DB Wax column (film thickness: 0.25 μm; J&W Scientific, Rancho Cordo, CA) installed on a Packard 438 gas chromatograph (Packard Instruments, Les Ulis, France). The oven temperature was 190°C and the injector and flame-ionization detector were maintained at 230 and 260°C, respectively. The

second column was a 50 m × 0.33 mm i.d. BPX 70 (film thickness: 0.25 μm; SGE, Melbourne, Australia) installed on a Hewlett-Packard 5890 series II gas chromatograph (Hewlett Packard, Les Ulis, France). The oven temperature was maintained at 170°C. The injector and detector were maintained at 250°C. Quantitative analyses were performed using a Chromjet SP 4490 integrator and Winer on Windows software (Thermo Separation Products, Les Ulis, France).

Additionally, the FAME were analyzed by gas-chromatographic–Fourier transform infrared (FTIR) using a CP Wax 57 CB column (50 m × 0.5 mm i.d.; Chrompack, Middelburg, The Netherlands) and a Bruker IFS 85 FTIR spectrometer (Bruker, Wissembourg, France) installed on a Carlo Erba (Milano, Italy) 5160 chromatograph. The conditions were the same as already described (12). Aliquots of the FAME were transformed into dimethyl oxazoline derivatives (DMOX) according to Fay and Richli (23). They were then analyzed by gas chromatography/mass spectrometry using a BPX 70 column as described previously and a Hewlett-Packard 5970 mass spectrometer. The temperature of the gas chromatographic oven was programmed from 60 to 170 at a rate of 20°C/min^{-1}.

RESULTS AND DISCUSSION

The FAME analysis of the 20:5 fraction from liver lipids of rats fed heated linseed oil showed six peaks as described previously (19). These compounds were not present in liver lipids from rats fed unheated linseed oil (24). The first one was identified some years ago as the 20:5 Δ5*cis*, 8*cis*, 11*cis*, 14*cis*, 17*trans* isomer of EPA (12), which was formed from 18:3 Δ9*cis*, 12*cis*, 15*trans*. Using the DB Wax column, EPA itself and four unknown peaks, which were called X1, X2, X3, and X4, are then eluted. Their respective equivalent chain length (ECL) values are presented in Table 1. The GLC–FTIR spectra obtained for X4 (Fig. 1) showed an absorption band at 966 cm^{-1}, which is characteristic of a *trans* ethylenic bond (25). X3 presented a similar FTIR spectrum, indicating the occurrence of at least one *trans* double bond on the carbon chain.

Figure 2 presents the mass spectra of the DMOX derivatives of EPA, X3, and X4. The fragmentation of EPA is the same as that described previously (23). Moreover, the three fragmentation patterns were similar, indicating that X3 and X4 are also 20:5 fatty acids, with their double bonds located at the Δ5, 8, 11, 14, and 17 positions (25). These gas-chromatographic–FTIR and gas chromatography/mass spectrometry results clearly indicate that X3 and X4 are *trans* isomers of EPA. Furthermore, comparisons of the ECL values on both types of liquid phase and the fragmentation pattern of X3 and X4 with those of the synthetized compounds (20) confirmed that X3 and X4 are 20:5 Δ5*cis*, 8*cis*, 11*trans*, 14*cis*, 17*trans*, and 20:5 Δ5*cis*, 8*cis*, 11*trans*, 14*cis*, 17*cis*, respectively.

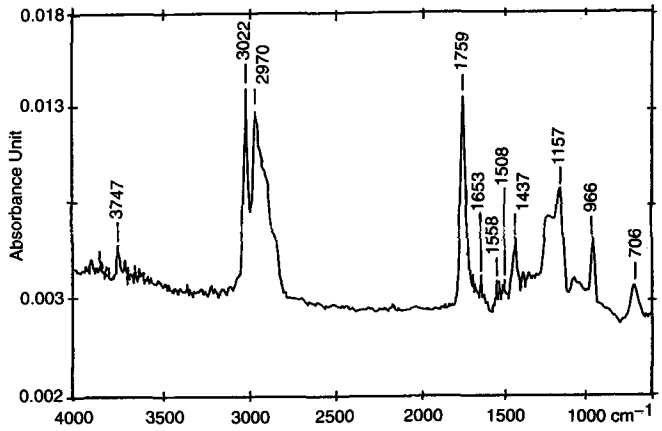

FIG. 1. Infrared spectrum of compound X4 obtained by gas-chromatographic–Fourier transform infrared. The chromatographic conditions are described in the Materials and Methods section.

Table 2 indicates the mean level of each 20:5 *trans* isomer in liver lipids of five rats fed heated oil for six weeks. Under these dietary conditions, the major 20:5 fatty acids were the Δ17 mono*trans* isomer and EPA (more than 80% of total 20:5 fatty acids). The 20:5 Δ11,17 di*trans* and Δ11 mono*trans* isomers represented about 5% of total 20:5 fatty acids. These are the desaturation and elongation metabolites of 18:3 Δ9*trans*, 12*cis*, 15*trans*, and of 18:3 Δ9*trans*, 12*cis*, 15*cis*, respectively. Both of these 18:3 isomers are present at significant levels in dietary oils (1,2,4,26). X1 and X2 might be other 20:5 *trans* fatty acids as suggested by Piconneaux (24). If so, they would be the metabolites of other 18:3 isomers (e.g., Δ9*cis*, 12*trans*, 15*trans*, and Δ9*cis*, 12*trans*, 15*cis*), which are minor constituents of some processed vegetable oils. Consequently, X1 and X2 are not of major human nutritional concern. Table 3 indicates the ratio between the 18:3 *trans* isomers in the diet and their respective 20:5 metabolites in the liver lipids of rats. These ratios probably indicate the rate of conversion of each *trans* 18:3 isomer into the corresponding *trans* 20:5 fatty acid. Both Δ9*cis* 18:3 isomers (Δ9*cis*, 12*cis*, 15*cis*, and Δ9*cis*, 12*cis*, 15*trans*) presented an accumulation (18:3/20:5) of about four. This might be related to the occurrence of the *cis* double bond at the Δ9 position, which was reported as helpful for the Δ6 desaturation (27). Both Δ9 *trans* isomers presented a lower rate of accumulation. However, the difference between the propensity for these two fatty acids (20.0 vs. 7.6) to accumulate is not clearly understood. The respective influ-

Chronic Administration of Eicosapentaenoic Acid and Docosahexaenoic Acid as Ethyl Esters Reduced Plasma Cholesterol and Changed the Fatty Acid Composition in Rat Blood and Organs

Livar Frøyland[a,*], Hege Vaagenes[a], Daniel K. Asiedu[a], Alexis Garras[a], Øyvind Lie[b], and Rolf K. Berge[a]

[a]University of Bergen, Department of Clinical Biology, Division of Biochemistry, Haukeland Hospital, N-5021 Bergen, Norway and [b]Directorate of Fisheries, Institute of Nutrition, N-5024 Bergen, Norway

ABSTRACT: Fish oils rich in n-3 fatty acids have been shown to decrease plasma lipid levels, but the underlying mechanism has not yet been elucidated. This investigation was performed in order to further clarify the effects of purified ethyl esters of eicosapentaenoic acid (EPA–EE) and docosahexaenoic acid (DHA–EE) on lipid metabolism in rats. The animals were fed EPA–EE, DHA–EE, palmitic acid, or corn oil (1 g/kg/d) by orogastric intubation along with a chow background diet for three months. At the end the animals were sacrificed. Plasma and liver lipids were measured, as well as lipid-related enzyme activities and mRNA levels. The fatty acid composition of plasma and different tissues was also determined. This study shows that, compared to the corn oil control, EPA–EE and DHA–EE lowered plasma cholesterol level, whereas only EPA–EE lowered the amount of plasma triacylglycerol. In liver peroxisomes, both EE preparations increased fatty acyl-CoA oxidase FAO activities, and neither altered 3-hydroxy-3-methylglutaryl (HMG)–CoA reductase activities. In liver microsomes, EPA–EE raised HMG–CoA reductase and acyl-CoAicholesterol acyltransferase activities, whereas DHA–EE lowered the former and did not affect the latter. Neither product altered mRNA levels for HMG–CoA reductase, low density lipoprotein-receptor, or low density lipoprotein-receptor related protein. EPA–EE lowered plasma triacylglycerol, reflecting lowered very low density lipoprotein secretion, thus the cholesterol lowering effect in EPA–EE-treated rats may be secondary to the hypotriacylglycerolemic effect. An inhibition of HMG–CoA reductase activity in DHA–EE treated rats may contribute to the hypocholesterolemic effect. The present study reports that 20:5n-3, and not 22:6n-3, is the fatty acid primarily responsible for the triacylglycerol lowering effect of fish oil. Finally, 20:5n-3 was not converted to 22:6n-3, whereas retroconversion of 22:6n-3 to 20:5n-3 was observed.
Lipids 31, 169–178 (1996).

The hypotriacylglycerolemic effect of marine oils containing very long-chain n-3 fatty acids, such as eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), has been extensively studied in humans and in different animal species and cultured cells (1–6). Fish oil lowers plasma triacylglycerol by reducing the hepatic production and secretion of lipoprotein particles rich in triacylglycerol, e.g., very low density lipoprotein (VLDL) (7–13) and by inhibiting the last enzyme in triacylglycerol biosynthesis, acyl-CoA:diacylglycerol acetyltransferase in rats (14). In addition to the effect on VLDL, fish oil affects nearly every major pathway of hepatic fatty acid metabolism (15,16). Evidence from *in vivo* and *in vitro* experiments in rats indicates that the instant hypotriacylglycerolemic effect observed after 20:5n-3 and fish oil administration could be attributed, at least in part, to a sudden increase in mitochondrial fatty acid oxidation (17–19). This may reduce the availability of fatty acids for lipid synthesis in the liver for export, e.g., in the form of VLDL (20). The changes of acyl-CoA:diacylglycerol acetyltransferase, however, could not explain the reduced availability of fatty acids for triacylglycerol biosynthesis (15,21). Recently, our group has reported (22,23) that 20:5n-3 and 22:6n-3 possess different metabolic properties, i.e., no triacylglycerol or cholesterol-lowering effects were observed in rats treated acutely and for up to 15 d with 22:6n-3, whereas 20:5n-3 decreased plasma cholesterol and triacylglycerol levels. These results are in agreement with results obtained by the isolated perfused rat liver (24).

The mechanism behind the cholesterol-lowering effect of polyunsaturated fat is at present not known in detail. n-3 Fatty acids have structural roles in glycerolipids of all cell membranes in the body, influencing membrane viscosity and permeability, and thereby possibly affecting the enzyme activity of membrane proteins. It has been reported that the hypocholesterolemic effect of fish oil feeding is accompanied by a significant inhibition of the microsomal 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase activity (17).

The rate-limiting enzyme in cholesterol formation, HMG–CoA reductase, is localized in the endoplasmic reticu-

lum and in intact peroxisomes (25,26). Both EPA–EE [EPA as ethyl ester (EE)] and DHA–EE [DHA as ethyl ester (EE)] treatment increased peroxisomal β-oxidation in the liver, as evaluated by measuring fatty acyl-CoA oxidase activity (FAO) (9,15,16). These observations led us to study the peroxisomal HMG–CoA reductase activity after long-term administration of EPA–EE and DHA–EE.

The degree of unsaturation of the fatty acyl chains may affect the fluidity of the lipid moiety of lipoproteins. Indeed, it has been suggested that polyunsaturated fat feeding may influence the structure of the low density lipoprotein (LDL) particle by changing the fluidity of its constituent lipids and thereby influencing the rate at which the particles can be catabolized (27).

The present study was conducted with a threefold purpose. First, we wanted to investigate whether DHA–EE and EPA–EE have a cholesterol-lowering effect after prolonged administration. Second, we addressed the question of whether cholesterol biosynthesis is regulated by the peroxisomal HMG–CoA reductase or by changes in the expression of LDL-receptor and LDL-receptor related protein (LRP-4) as denoted by their relative mRNA levels, both of which are thought to be important for the final catabolism of LDL and chylomicron remnants (28), respectively, by the liver. LRP-4 is composed completely of structural elements found in the LDL-receptor (29). Finally, we studied whether conversion of 20:5n-3 to 22:6n-3 and retroconversion of 22:6n-3 to 20:5n-3 occurs in rat plasma and organs (liver, heart, kidney, and epididymal fat) after prolonged feeding with EPA–EE and DHA–EE.

MATERIALS AND METHODS

Chemicals. EPA–EE and DHA–EE were obtained from Pronova Biocare AS (Oslo, Norway) and Norsk Hydro AS, Research Center (Porsgrunn, Norway). The purity of EPA–EE and DHA–EE used in the present study was 94 and 91%, respectively (Table 1). EPA–EE contained small amounts of stearidonic acid (18:4n-3) (1.1%) and DHA (22:6n-3) (1.8%), and the DHA–EE preparation contained some arachidonic acid (20:4n-6) (1.9%), eicosatetraenoic acid (20:4n-3) (1.0%), EPA (20:5n-3) (2.3%), and heneicosapentaenoic acid (21:5n-3) (4.6%). Corn oil was bought at the local store, and it contained linoleic acid (18:2n-6) (51.3%), oleic acid (18:1n-9), (33.6%), and palmitic acid (16:0) (10.1%).

Palmitic acid was obtained from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C]Palmitic acid (56 mCi/mmol), [^{14}C]acetyl-CoA (60 mCi/mmol), and $NaH^{14}CO_3$ (0.1 mCi/mmol) were purchased from the Radiochemical Centre (Amersham, England). [4-^{14}C]Cholesterol and [3-^{14}C]hydroxymethylglutaryl–CoA, with specific activities ranging from 55–60 mCi/mmol, were obtained from New England Nuclear (Boston, MA). All other chemicals were obtained from common commercial sources and were of reagent grade.

Animals. Male Wistar rats from Möllegaard Breeding Laboratory (Ejby, Denmark), weighing about 200 g, were housed

[a]Values are given as mean ± SD. Composition of diets (mol%). EPA–EE, eicosapentaenoic acid as ethyl ester; DHA–EE, docosahexaenoic acid as ethyl ester; R34-EWOS-ALAB, grover rat maintenance chow.

individually in metal wire cages and maintained at a 12-h light/dark cycle, at a temperature of 20 ± 3°C. The animals were acclimatized for one week under these conditions before the start of the experiment. The fatty acids were suspended in 0.5% CM-cellulose and administered by orogastric intubation once a day for three months at a dose of 1000 mg/d/kg body weight. Autooxidation of the stock suspensions was minimized by the addition of 0.5% (wt/vol) of α-tocopherol (vitamin E), flushing with N_2, and storing them at 0–4°C when not in use. All animals had free access to water and R34-EWOS-ALAB (12.5 MJ/kg) (Ewos, Sweden) grower rat maintenance chow. At the end of the experiment, the overnight-fasted (to avoid postprandrial values) animals were anaesthetized with Hypnorm (Janssen Pharmaceutica BV, Beerse, Belgium) Dormicum® (F. Hoffman-La-Roche Ltd., Basel, Switzerland) (fluanisone-fentanyl-midazolam) subcutaneously, and cardiac puncture was performed to obtain blood samples in EDTA (7.5%) containing vacutainers. Plasma was prepared from whole blood by centrifugation at 3000 rpm (1880 × *g*) for 10 min. The protocol was approved by the Norwegian State Board of Biological Experiments with Living Animals.

Preparation of subcellular fractions. The livers from individual rats were removed, weighed, and immediately chilled on ice. Portions of the livers were homogenized in ice-cold sucrose medium (0.25 M sucrose in 10 mM HEPES buffer and 1 mM EDTA, pH 7.4). Peroxisomal-enriched and microsomal fractions were prepared as previously described (15,16,22).

Enzyme assays. HMG–CoA reductase activity was assayed in the peroxisomal and microsomal fractions essentially as previously described (30). The samples were incubated for 15 min and terminated by addition of 25 µL 6 M HCl. Tritium-labeled mevalonic acid (0.01 µCi), together with 3 mg unlabelled mevalonic acid lactone, was added as internal standard. The incubation mixture was further lactonized, subjected to thin-layer chromatography, and analyzed for radioactivity (17).

Acyl-CoA:cholesterol acyltransferase (AcAT) activity was measured in the microsomal fraction (31), and activity was determined as previously described (15).

Analytical methods. Plasma free fatty acids were determined by an enzymatic colorimetric method (NEFAC; Wako Chemicals GmbH) as described previously (32). Protein was determined spectrophotometrically at 600 nm by the pyrogallol red-molybdate method (33) due to low protein concentrations. Phospholipids and cholesterol were analyzed using the enzymatic methods of bioMérieux (Marcy-l'Etoile, France) and Boehringer Mannheim (Mannheim, Germany), respectively.

Analysis of hepatic lipids was carried out by the Monotest cholesterol and phospholipid enzymatic kits (Boehringer Mannheim) and the Biopak triglyceride enzymatic kit (Biotrol, Paris, France). Protein was determined by the Bio-Rad assay kit (Bio-Rad Laboratories, Richmond, CA).

RNA purification. Livers were frozen in liquid N_2 immediately after dissection and stored at –80°C. Total cellular RNA was purified using the acid guanidinium thiocyanate-phenol method (34). The RNA concentrations were determined by measuring the ultraviolet absorbance at 260 nm.

Preparation of hybridization probes. The appropriate DNA fragments were excised from plasmids by restriction enzymes, and the purified fragments were ^{32}P-labeled using the oligo-labeling technique (35). The resulting specific activities ranged from $1–5 \times 10^9$ cpm/µg. The probes were purified fragments of cloned genes: rat LDL-receptor; 2.2 bp *Eco* RI inserted into pGEM7 (36), HMG–CoA reductase cDNA from baby hamster kidney cells; full-length *Eco* RI fragment of pDGS2, rat LRP-4; *Bam* HI fragment of a 3.6 kb cDNA inserted into pGEM4 (29), 28S rRNA; 1.4 kb *Bam* HI fragment of pA.

Hybridization and analysis of mRNA. Slot blotting of RNA onto nylon membranes was carried out as previously described (37). Hybridization to immobilized RNA was carried out in the presence of 50% formamide, 5 × SSC (0.75 M NaCl, 75 mM trisodium citrate dihydrate), 200 µg/mL heat-denaturated herring sperm DNA, 0.1% SDS, 25 µM sodium phosphate, (pH 6.4), 8.25% dextran sulphate at 42°C for 24–48 h (38). Filters were stringently washed twice in 0.2 × SSC, 0.1% SDS, 0.1% $Na_4P_2O_7$ at 65°C (or at 60°C for DNA probes not obtained from rats). When the filters were to be rehybridized, the bound probe was first stripped off by incubation of the filters in 0.1% SDS at 95–100°C for 7 min.

Kodak XAR 5 X-ray films were exposed to the membranes at –80°C in the presence of intensifying screens. Autoradiograms were analyzed by densiometric scanning using an LKB Ultrogel laser densiometer (Bromma, Sweden). The relative level of mRNA expression was estimated as the amount of radioactive probe hybridized to each sample of RNA relative to the level of 28S rRNA in each sample.

Statistical analysis. Results are reported as means ± SD from six animals. Treatment means were compared by one-way analysis of variance. Fisher's Least Square Difference was used to determine the significance of differences between the means at 95% confidence interval.

RESULTS

There were no significant changes in the body weight between the rats fed corn oil (control) and those of the other groups at the end of the experiment (data not shown).

As shown in Table 2, prolonged administration of EPA–EE to rats (maintained on a balanced pelleted diet) resulted in a lowering of plasma triacylglycerol, cholesterol, and phospholipid levels compared to corn oil-fed animals. Prolonged DHA–EE treatment did not affect the plasma triacylglycerol level but significantly lowered the concentration of plasma cholesterol as compared to control animals (Table 2). The plasma free fatty acids content (Table 2) and the hepatic triacylglycerol and phospholipid levels (Table 3) were not significantly changed after EPA–EE and DHA–EE treatment. The hepatic cholesterol concentration in EPA–EE treated rats was significantly higher than in controls (Table 3).

TABLE 2
Changes in Plasma Lipids in Rats After Prolonged Treatment (3 mon) with Palmitic Acid, EPA–EE, DHA–EE, and Corn Oil (control)[a]

Plasma lipids (mM)	Control	EPA–EE	DHA–EE	Palmitic acid
Triacylglycerol	1.81 ± 0.47[c]	1.05 ± 0.46[b]	1.74 ± 0.60[c]	1.51 ± 0.30[c]
Cholesterol	1.65 ± 0.22[c]	0.95 ± 0.14[b]	1.08 ± 0.23[b]	1.52 ± 0.37[c]
Phospholipids	1.71 ± 0.24[c]	1.13 ± 0.13[b]	1.44 ± 0.20[c]	1.54 ± 0.23[c]
Free fatty acids	0.46 ± 0.24[c]	0.42 ± 0.12[c]	0.34 ± 0.13[c]	0.56 ± 0.19[c]

[a]The plasma lipid values represent means ± SD from six animals in each experimental group. Means in a row with a different superscript are significantly different ($P < 0.05$). Abbreviations as in Table 1.

TABLE 3
The Effect of Prolonged (3 mon) EPA–EE, DHA–EE, Palmitic Acid, and Corn Oil (control) Feeding on Hepatic Lipids[a]

Hepatic lipids (μmol/g liver)	Control	EPA–EE	DHA–EE	Palmitic acid
Triacylglycerol	8.08 ± 1.54[c]	7.65 ± 1.55[c]	6.80 ± 1.52[c]	6.00 ± 1.00[c]
Cholesterol	3.20 ± 0.38[c]	4.20 ± 0.50[b]	3.36 ± 0.25[c]	2.91 ± 0.26[c]
Phospholipids	11.90 ± 1.39[c]	12.56 ± 1.49[c]	12.10 ± 0.90[c]	11.72 ± 0.70[c]

[a]The plasma lipid values represent means ± SD from six animals in each experimental group. Means in a row with a different superscript are significantly different ($P < 0.05$). Abbreviations as in Table 1.

Peroxisomal HMG–CoA reductase activity remained unchanged after EPA–EE and DHA–EE feeding, whereas the activity of the microsomal HMG–CoA reductase was higher and lower after EPA–EE and DHA–EE feeding, respectively, compared to control animals (Table 4). Rats treated with EPA–EE and DHA–EE did not affect HMG–CoA reductase mRNA levels as compared to control, whereas palmitic acid-fed animals revealed a higher HMG–CoA reductase mRNA level (Fig. 1 and Table 5). The activity of ACAT was higher after EPA–EE feeding compared to corn oil-fed animals (Table 4), whereas no change was observed in DHA–EE–treated rats.

When rats were treated with EPA–EE and DHA–EE, no evidence was found for lower LDL-receptor mRNA levels compared to control animals (Table 5). Moreover, the LRP-4 mRNA levels were constant in the different feeding regimes (Table 5).

Rats treated with EPA–EE, DHA–EE, and palmitic acid revealed higher levels of palmitic acid (16:0) and total saturated fatty acids in epididymal fat (Table 6) and lower levels of linoleic acid (18:2n-6) compared to controls (Table 7). In addition, EPA–EE and DHA–EE lowered the amount of oleic acid (18:1n-9) and total monoenes in epididymal fat as compared to corn oil-fed animals (Table 6). No such changes were observed in plasma, liver, heart, and kidney, except that the total saturated fatty acids was higher in plasma after palmitic acid administration, and EPA–EE treatment lowered the amount of vaccenic acid (18:1n-7) compared to controls (Table 6).

As shown in Table 7, DHA–EE and palmitic acid treatment lowered the amount of 18:2n-6 in the heart, whereas

[a]The values are given as means ± SD. Means in a row with a different superscript are significantly different ($P < 0.05$). Abbreviations as in Table 1; FAO, fatty acyl-CoA oxidase; HMG–CoA, 3-hydroxy-3-methylglutaryl–CoA; ACAT, acyl-CoA:cholesterol acyltransferase).

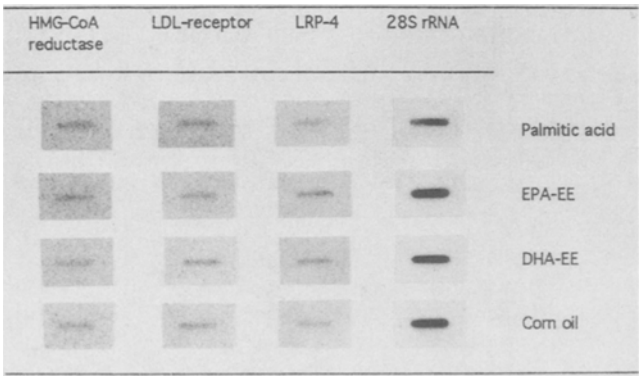

FIG. 1. mRNA expression of 3-hydroxy-3-methylglutaryl–CoA (HMG–CoA) reductase, low density lipoprotein (LDL)-receptor, LDL-receptor related protein (LRP-4), and 28S rRNA in liver of rats treated with eicosapentaenoic acid as ethyl ester (EPA–EE), docosahexaenoic acid as ethyl ester (DHA–EE), palmitic acid, and corn oil (control) for three months. One representative slot blot of a total of six is shown. The accumulated results from a complete experiment are given in Table 6. Total RNA was isolated from liver pieces of each animal in the different feeding groups. Samples of 1, 2, and 5 μg RNA were slot-blotted onto nylon membranes and hybridized to the probes indicated (see the Materials and Methods section).

EPA–EE treatment led to a higher level of α-linolenic acid (18:3n-3) in the kidney as compared to controls (Table 7).

EPA–EE and DHA–EE supplementation significantly lowered the amount of arachidonic acid (20:4n-6) in plasma, liver, heart, and kidney as compared to control animals, which led to a higher n-3/n-6 ratio in plasma and the different organs (Table 7). No significant differences in n-3/n-6 ratio between the two n-3 fatty acids were observed.

As shown in Table 7, prolonged EPA–EE feeding led to a higher amount of EPA (20:5n-3) in plasma, liver, heart, kidney, and epididymal fat by 11-, 17-, 36-, 11-, and 41-fold, respectively, as compared to controls. The amount of docosapentaenoic acid (22:5n-3) was also higher in plasma, liver, heart, kidney, and epididymal fat, by 5-, 5-, 4-, 5-, and 8-fold, respectively (Table 7). However, the levels of DHA (22:6n-3) were not higher after EPA–EE treatment, except for a 2-fold increase in epididymal fat (Table 7). DHA–EE treatment caused a less prominent elevation of DHA (22:6n-3) in plasma and organs than EPA–EE feeding, which increased 20:5n-3. The rise of 22:6n-3 levels by DHA–EE administration in plasma, liver, heart, kidney, and epididymal fat was 4-, 3-, 2-, 3-, and 11-fold, respectively, whereas a higher level of 22:5n-3 was only observed in kidney and epididymal fat.

It was noteworthy that, DHA–EE supplementation elevated the amount of 20:5n-3 in plasma, liver, heart, kidney, and epididymal fat by 5-, 8-, 6-, 7-, and 7-fold, respectively.

DISCUSSION

Plasma concentrations of EPA (20:5n-3) and DHA (22:6n-3) were significantly increased after pure EPA–EE (94%) and pure DHA–EE (91%) administration. The elongated product of 20:5n-3, docosapentaenoic acid (22:5n-3) was higher in plasma after EPA–EE administration compared to corn oil-treated rats, whereas no increased amount of 22:6n-3 was revealed. In the plasma of DHA–EE treated rats, however, 22:5n-3 remained unchanged, but the relative amount of 20:5n-3 was increased. Thus, DHA–EE treatment caused a less prominent increase in 22:6n-3 in the DHA–EE group than EPA–EE feeding, increased the amount of 20:5n-3 in the EPA–EE group in plasma and organs, respectively (Table 7). These results suggest that conversion of 20:5n-3 to 22:5n-3, but not to 22:6n-3, and retroconversion of 22:6n-3 to 20:5n-3 have occurred in tissues after n-3 fatty acid administration, as demonstrated in cultured hepatocytes (39–41).

The underlying assumption has long been that 20:5n-3 is elongated and desaturated directly to 22:6n-3. Recently Voss *et al.* (42) have shown in the rat that, although 20:5n-3 can be converted into 22:6n-3, it has to go through three steps, namely: first, being elongated to 24:5n-3-, second, Δ^6-desaturated to 24:6n-3; and finally, β-oxidized to 22:6n-3 (42). The results of our study argue against a direct conversion of 20:5n-3 to 22:6n-3 as the level of 22:6n-3 was unchanged in the liver, heart, and kidney after EPA–EE administration. As the amount of 22:5n-3 was increased in plasma and organs after EPA–EE supplementation (Table 7) and the peroxisomal β-oxidation was increased (Table 4), the unchanged level of 22:6n-3 could be due to a depressed Δ^6-saturation. Indeed, di-

TABLE 5
Expression of HMG–CoA Reductase, LDL-Receptor, and LRP-4 mRNAs in Liver of Rat Treated with Palmitic Acid, EPA–EE, DHA–EE, and Corn Oil (control) for Three Months[a]

Treatment	HMG–CoA reductase	LDL-receptor	LRP-4
Control	1.00 ± 0.10[c]	1.00 ± 0.20[c]	1.00 ± 0.17[c]

etary supplementation with n-3 fatty acids depresses rat liver Δ^6-desaturase activity (43), which is necessary for the second step of the conversion of 22:5n-3 to 22:6n-3.

Overall, our results argue against the direct conversion of 20:5n-3 to 22:6n-3, but are rather in favor of 22:6n-3 to 20:5n-3. Retroconversion of 22:6n-3 to 20:5n-3 has been reported in rat hepatocytes (39–41), rats (44,45), and humans (46,47). As 22:5n-3 is truly retroconverted to 20:5n-3, it will be difficult to study the unique effects of 22:6n-3 in rats as well as in humans as some of the 22:6n-3 will continuously be converted to 20:5n-3, and effects of 20:5n-3 may confound the search for the metabolic role of 22:6n-3, i.e., the secretion of VLDL triacylglycerol.

The present study reports that 20:5n-3, and not 22:6n-3, is the fatty acid primarily responsible for the triacylglycerol lowering effect of fish oil (Table 2). These effects are consistent with previous reports (15,44,48,49). Moreover, studies have shown that 20:5n-3 inhibits the triacylglycerol synthesis/secretion in rat (14,50), rabbit hepatocytes (51), HepG2 cells (11,52), and in perfused rat livers (10,24). Interestingly, at the second international congress of the International Society for the Study of Fatty Acids and Lipids (ISSFAL), held June 7–10, 1995, in Bethesda, Maryland, it was reported that 20:5n-3, and not 22:6n-3, appeared to be primarily responsible for the triacylglycerol lowering effect of fish oil in humans (living in Kansas City) (53). However, 22:6n-3 has also been reported to lower plasma triacylglycerol level in rats (45) and to lower triacylglycerol secretion from rat hepatocytes (3,54,55) in HepG2 cells (52) and perfused livers (10,12). These studies are relatively uniform in showing that 22:6n-3 as a substrate causes the cell to secrete reduced amounts of triacylglycerol. At the recent ISSFAL meeting (Grimsgaard, S., Bønaa, K.H., Hansen, J.B., Nordøy, A., and Ingelbretsen, O.C., unpublished data), it was reported that in the Tromsø study (Norway), 22:6n-3 was more efficient than 20:5n-3 in lowering plasma triacylglycerol concentration in humans. Moreover, in 1959 Worne and Smith (56) showed that 22:6n-3 reduced total serum lipids (triacylglycerol levels were not measured). In a more recent study (uncontrolled) by Hirai *et al.* (57), serum triacylglycerol levels were reduced after 22:6n-3 supplementation in Japanese Type IIb hyperlipidemia patients. These findings are in contrast to the human study reported at the 1995 ISSFAL meeting, intact animal data (15,22,44,48) (Table 2), and data from the perfused rat liver (24). The reason for this may be due to a higher basal level of 20:5n-3 and 22:6n-3 in humans from Norway and Japan compared to the people in Kansas City, as both Norwegians and Japanese probably consume more fish than the people living

TABLE 7
Changes in n-3 and n-6 Fatty Acids in Plasma Different Tissues of Rats Treated with EPA–EE, DHA–EE, Palmitic Acid (palm), and Corn Oil (corn) (control) for Three Months[a]

Fatty acid	Treatment	Fatty acid composition (mol%)				
		Plasma	Liver	Heart	Kidney	Epididymal fat

in Kansas City. The basal levels of 20:5n-3 and 22:6n-3 in our rats are also low. Whether the triacylglycerol-lowering effect by 22:6n-3 in human subjects from Norway and Japan could be ascribed to a conversion of 22:6n-3 to 20:5n-3, thereby increasing the level of 20:5n-3 (basal + retroconverted) should be considered. Jensen *et al.* (58), in an uncontrolled study, found no triacylglycerol-lowering effect with low doses of n-3, but did find a definite effect with a higher dose, confirming previous findings (59,60). Moreover, it has been shown that the more marked the triacylglycerol concentration at baseline, the greater its reduction by n-3 fatty acids (2,58,62–67), which may explain the striking response in hypertriacylglycerolemic patients (57,61,64).

In plasma the relative amount of 20:5n-3 and 22:6n-3 was almost identical (Table 7), indicating that the two n-3 fatty acids were equally well absorbed. However, in the liver and heart, the level of 20:5n-3 was less than half of the amount of 22:6n-3 (Table 7). The reason for this discrepancy could be ascribed to an increased β-oxidation of 20:5n-3 (68). Determining the effects of dietary 20:5n-3 and 22:6n-3 on hepatic fatty acid β-oxidation seems to be important to clarify the precise mechanism(s). Indeed, 20:5n-3 is reported to increase both the mitochondrial and peroxisomal β-oxidation (15,17–19,23), whereas 22:6n-3 increases peroxisomal β-oxidation (22).

An important finding in the present study was the observed decrease in plasma cholesterol level after prolonged EPA–EE and DHA–EE treatment (Table 2), and this is in agreement with previous reports (45,48,56,57). In perfused rat livers it has been shown that 22:6n-3 reduced the secretion of VLDL–cholesteryl esters similar to that with 20:5n-3, whereas only 20:5n-3 reduced the secretion of VLDL triacylglycerol (24). This study is in agreement with our plasma lipid data (Table 2).

Finally, in view of the cholesterol-lowering effect observed, we were able to explore how EPA–EE and DHA–EE treatments affected the enzymes in cholesterol and cholesterol–ester synthesis (HMG–CoA reductase and ACAT) and the transcription of the LDL-receptor and the LRP-4. HMG–CoA reductase is located mainly in endoplasmic reticulum, but the identification of the enzyme in peroxisomes, as

well as peroxisomal synthesis of dolichol and cholesterol, strongly supports the involvement of these organelles in intracellular lipid metabolism (39–41,65–67). It is well established that HMG–CoA reductase is rate-limiting in the synthesis of cholesterol under almost all experimental conditions (30,69). Prolonged administration of DHA–EE decreased the activity of microsomal HMG–CoA reductase, but had no effect on ACAT activity (Table 4). It is tempting to suggest that the observed hypocholesterolemic effect could be due to an inhibition of cholesterol biosynthesis.

LDL-receptor synthesis was probably unaffected after DHA–EE treatment to rats for three months as the LDL-receptor mRNA level was unchanged. Whether LDL-receptor activity was higher under the experimental conditions has not been addressed in this study. In a recent study by Spady (45), he found an induction in the LDL-receptor activity after both 20:5n-3 and 22:6n-3 supplementation, which is in contrast to a previous study by Roach *et al.* (70).

The underlying mechanisms for the observed decrease in plasma cholesterol are far from clear. Certain peroxisomal lipid metabolites have been implicated as inhibitors of sterol synthesis in cell cultures (71). In this study, peroxisomes seem to play a minor role in cholesterol biosynthesis during n-3 fatty acid treatments as peroxisomal HMG–CoA reductase activity remained unchanged (Table 4).

Prolonged feeding with pure EPA–EE, however, elevated the activities of ACAT and HMG–CoA reductase (Table 4) and raised the hepatic concentration of cholesterol (Table 3). This may be due to a compensatory effect in this long-term study, as the activities of these enzymes are suppressed during short-term EPA–EE treatment (Willumsen, N., Vaagenes, H., Asiedu, D.K., Lie, Ø., Rustan, A.C., and Berge, R.K., unpublished data). Because EPA–EE treatment lowered the plasma triacylglycerol (Table 2) and VLDL–triacylglycerol (data not shown) levels, the effect on cholesterol may be secondary to retarded triacylglycerol production. As VLDL is a precursor to LDL, it is conceivable that a reduction of VLDL secretion and of plasma VLDL levels will affect LDL formation, which might contribute to the cholesterol-lowering effect by EPA–EE treatment.

In summary, the present study suggests that 20:5n-3 and 22:6n-3 have different effects on hepatic synthesis and release of triacylglycerol and cholesterol and on some rate-limiting enzymes involved in these processes. EPA–EE feeding did not increase the amount of 22:6n-3, whereas DHA–EE increased the amount of 20:5n-3. The present study reports that 20:5n-3, and not 22:6n-3, is the fatty acid primarily responsible for the triacylglycerol-lowering effect of fish oil. Thus, this implies that it will be difficult to study the unique effects of 22:6n-3 as some of it will always be converted to 20:5n-3. Whether the effects were due to the 20:5n-3 generated from 22:6n-3, and not by 22:6n-3, must therefore be considered (41–50). The cholesterol-lowering effect after prolonged treatment with DHA–EE may, in part, be mediated by suppression of microsomal HMG–CoA reductase activity.

ACKNOWLEDGMENTS

The authors are obliged to Randi Sandvik, Kari Williams, Annbjørg Eliasson, and Svein Krüger for excellent technical assistance. Plasmids, encoding partial cDNA for hamster HMG–CoA reductase and rat LDL-receptor, were kindly provided by Dr. F. Leighton (Univeridad Catolica de Chile, Santiago de Chile) and rat LRP-4 was generously provided by Dr. O. Myklebost (The Norwegian Radiumhospital, Oslo, Norway). In addition, we are most grateful to Dr. I.L. Gonzales, who has made 28S rRNA available to us. This study was supported by The Research Council of Norway (research fellowship for Livar Frøyland), Pronova Biocare AS, The Norwegian Council on Cardiovascular Diseases (research fellowship for Daniel K. Asiedu), Astri og Edvard Riisøens Legat, Familien Blix Fond, and Bergen Heart Foundation.

Effects of Clofibrate on Lipids and Fatty Acids of Mouse Liver

G.L. Pennacchiotti, N.P. Rotstein, and M.I. Aveldaño*

Instituto de Investigaciones Bioquímicas de Bahía Blanca, Universidad Nacional del Sur and Consejo Nacional de Investigaciones Científicas y Técnicas, 8000 Bahía Blanca, Argentina

ABSTRACT: Clofibrate administration significantly altered the amount and fatty acid composition of lipids in mouse liver. The net content of phospholipids (PL) increased and that of triacylglycerols (TG) decreased concomitantly with liver enlargement in mice treated for two weeks with this drug (0.5% w/w in the food). The highest increase among PL was in phosphatidylcholine; other components either showed lower increases or, as in the case of sphingomyelin and the plasmalogens, decreased. In all lipid classes the treatment resulted in altered ratios between major saturates, between saturates and monoenes, and between major polyenes. Among these, 20:3n-6 and 22:5n-3 increased several-fold, and the 20:3n-6/20:4n-6 and 22:5n-3/22:6n-3 ratios increased due to a more active formation of the precursors than of the corresponding products. This change affected all glycerolipid classes. Liver sphingomyelin showed a relative enrichment in monoenoic fatty acids like 22:1 and 24:1, caused by a net decrease in the amount of saturates, particularly 22:0 and 24:0. The stimulated membrane proliferation imposed by clofibrate must increase phospholipid synthesis and, hence, the need for fatty acids. The results suggest that these demands are met mostly by TG acyl groups, either directly or after oxidation/desaturation processes. This was apparently the case for the polyenoic fatty acids of the n-6 and n-3 series. The longer chain (C_{22} and C_{24}) components decreased, suggesting that their oxidation was stimulated to provide part of the required (C_{20} and C_{22}) polyenes.
Lipids 31, 179–185 (1996).

Hypolipidemic drugs are used in the treatment of human hyperlipoproteinemias that are resistant to other therapeutic measures, such as diet manipulation, weight reduction, and exercise. The mechanism by which these drugs tend to lower elevated serum triglyceride and cholesterol levels has been an active research subject for years. Typical among these agents have been drugs belonging to the group of α-aryloxyisobutyric acids, such as clofibrate (1). This and other hypolipidemic chemicals have multiple actions at different loci in intact animals, their therapeutic use in humans being associated with many adverse reactions and undesirable effects.

Abbreviations: DPG, diphosphatidylglycerol; GLC, gas–liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipids; PUFA, polyunsaturated fatty acids; SM, sphingomyelin; TG, triacylglycerols.

In rodents, pharmacological doses of drugs like clofibrate and several structurally unrelated substances like herbicides and plasticizers are known to cause liver peroxisomes to proliferate in hepatic parenchymal cells (2). These "peroxisomal proliferators" cause induction of major peroxisomal enzymes, such as the ones that catalyze the β-oxidation of long- and very long chain fatty acids (3,4). Many studies on the physiological role of peroxisomes, their enzymes, and the molecular mechanisms of their induction have taken advantage of the use of peroxisomal proliferators as experimental tools to increase the yield of these organelles from rodent liver. The peroxisomal effect is but one of the changes effected by these chemicals in hepatocytes, however, as they also cause mitochondrial (5,6) and endoplasmic reticulum (1,2) proliferation and the activation of many enzymes known to be involved in the biosynthesis of lipids (see Ref. 7 and references therein). A nuclear protein receptor which is activated by peroxisomal proliferators, likely to mediate proliferator-induced gene expression, has been cloned from mouse (8) and rat (9), although its natural ligand has yet to be identified. In this study we have focused our interest on lipids, paying special attention to long- and very long chain polyunsaturated fatty acid (PUFA) components. We show that the administration of clofibric acid to mice under these conditions to induce peroxisome proliferation in rodents (10) leads to important modifications in the levels of major hepatic lipids, such as phosphatidylcholine (PC) and triacylglycerols (TG), affects the equilibrium between long- and very long chain (C_{24}) fatty acids in specific lipid classes like sphingomyelin (SM), and alters the proportions of relevant PUFA of the n-6 and n-3 series such as arachidonic (20:4n-6) and docosahexaenoic (22:6n-3) acids.

MATERIALS AND METHODS

Male albino mice of the BALB-C strain were used. Clofibric acid (Sigma Chemical Co., St. Louis, MO) was dissolved in acetone, food pellets (Nutrimentos, S.A., Buenos Aires, Argentina) were immersed in this solution for some time (0.5 g clofibric acid per 100 g pellets), and then the solvent was completely evaporated. Food from the same batch, used as control, was treated identically, except that it lacked the chemical. Control and experimental mice were allowed free access to

water and food for two weeks, after which the animals were killed by decapitation and their livers removed and weighed. The total body weight did not change significantly after the treatment (28.0 ± 1.0 and 27.6 ± 2.0 g in control and experimental animals, respectively). Lipid extracts were prepared and washed (11), and aliquots were taken for the determination of lipid phosphorus. Total phospholipids (PL) and TG were separated by thin-layer chromatography (TLC) on silica gel G using hexane/ether (80:20, vol/vol). For analytical and preparative purposes, the PL were resolved into classes using two-dimensional TLC. Solvents and procedures described by Rouser *et al.* (12) were used for PL analysis. The choline and ethanolamine glycerophospholipids were eluted from the silica (13), the solvents evaporated, and the samples subjected to a brief treatment with HCl in chloroform/methanol to attack the alk-1-enyl bond in plasmenylcholine and plasmenylethanolamine (14). After this treatment, the samples were subjected to further TLC to separate the diacylphospholipids, PC, and phosphatidylethanolamine from the corresponding, plasmalogen-derived, lysoPC and lysophosphatidylethanolamine. After TLC, all lipids were treated with BF_3 in methanol (15) to obtain the fatty acid methyl esters, which were analyzed by gas–liquid chromatography (GLC). Methyl esters were also subjected to argentation TLC in order to separate them according to unsaturation. This was performed using 20% $AgNO_3$ in silica gel G as adsorbent and chloroform/methanol (95:5, vol/vol) as solvent. This preseparation procedure facilitated the detection of PUFA that are minor components of mouse liver and circumvented the common problem of partial co-elution of some PUFA with other fatty acids from packed GLC columns, especially when analyzing total PL or total lipids. For GLC, N_2 at 30 mL/min as carrier gas and two 2 m × 2 mm glass columns packed with a polar stationary phase (15% SP2330 on Chromosorb WAW 100/120; Supelco Inc., Bellefonte, PA) were used. The columns were connected to flame-ionization detectors operated in the dual-differential mode. The column oven temperature was programmed at 5°C/min from an initial temperature of 160°C to a final one of 220°C. Injector and detector temperatures were 220 and 230°C, respectively. Peak quantitation was performed by electronic integration. The results presented in the tables and in the text are mean values ± standard deviations. Statistical analyses were carried out using the two-tailed Student's *t*-test. *P* values lower than 0.05 were considered significant.

RESULTS

Treatment of mice with clofibric acid resulted in a significant increase in the amount of phosphorus recovered in lipid extracts from liver (23.4 ± 5.5 and 36.4 ± 4.4 μmol/liver in controls and in treated animals, respectively). Because hepatic weight also increased (1.18 ± 0.11 to 1.64 ± 0.04 g, i.e., about 39%), the amount of lipid phosphorus per gram of tissue did not change significantly (20.9 ± 2.9 and 22.2 ± 2.4 μmol/g, respectively). The synthesis of the major phospholipid classes was stimulated at approximately similar rates in response to the growth demands imposed by the proliferator, as suggested by their composition (Table 1), which was not significantly modified. The separation into subclasses, however, showed that PC underwent the greatest increase, as it was the major component of a growing mass of PL. Some glycerophospholipids increased at slower rates than PC, and still others decreased, as in the case of the plasmalogens and SM.

In contrast to the abovementioned increase in PL, the content per gram of tissue of liver TG decreased as a consequence of clofibric acid administration (Table 2). The fall in TG was conspicuously greater than the net PL gain. On a μg/g basis, the acyl groups of TG contributed to the total lipid acyl groups of liver with 52.8 ± 1.9% and 34.6 ± 2.4% in control and clofibric acid-treated mice, respectively. The TG/PL mole ratio decreased from 0.738 ± 0.053 in controls to 0.378 ± 0.050 in drug-treated animals.

The fatty acid composition of total lipid, PL, and TG (Table 2) shows that clofibrate administration gave rise to altered proportions of relevant saturated acids, monoenoic acids, and PUFA. The most marked change occurred in TG, where the proportion of most polyenoic fatty acids decreased significantly. Because TG levels were substantially reduced by the drug treatment (Table 2), the PUFA components of TG decreased to larger extents than other acyl groups. This was the case with 18:2n-6, 18:3n-6, and 18:3n-3, as well as major products of their elongation and desaturation, namely 20:4n-6, 22:5n-6, and 22:6n-3. In PL, in TG, and in the total lipid of liver, the drug induced significant increases in the 18:1/18:0 ratio and decreases in the 18:3n-6/18:2n-6, 20:4n-6/20:3n6, 22:5n-6/22:4n-6, and 22:6n-3/22:5n-3 ratios.

The fatty acid composition of representative glycerophospholipid classes (Table 3) shows that the proportions of saturated, monoenoic, and polyenoic fatty acids were altered in membrane lipids. All of them showed significantly increased percentages of 18:1, 20:3n-6, and 22:5n-3, in-

18:0 such that the sum 18:0 + 18:1 was little affected, whereas the 18:1/18:0 ratio increased in all cases after clofibrate. In diphosphatidylglycerol (DPG), a lipid naturally poor in 18:0 and rich in 18:1, drug treatment resulted in a marked increase in 18:1 as well as in other monoenes. This occurred in the presence of an almost parallel decrease in the percentage of the major DPG component, 18:2n-6. Like the other constituents, DPG showed a decrease in the 20:4n-6/20:3n-6 and 22:6n-3/22:5n-3 ratios. DPG was the lipid to most clearly show a considerably diminished level of 20:3n-9 and a decreased 20:3n-9/20:2n-9 ratio. This is consistent with the decrease observed in the 20:4n-6/20:3n-6 ratio, as in both pairs of fatty acids the components are related *via* a 5-desaturation. The ratio 22:5n-6/22:4n-6 decreased in DPG as in most lipids, also in line with the decreases seen for 22:6n-3/22:5n-3, as the components of both pairs are related by a 4-desaturation.

SM differs from the glycerophospholipids in that it contains almost exclusively saturated and monoenoic fatty acids, being rich in very long chain components (Table 4). After clofibrate treatment, the percentage of all saturates of SM decreased (from 74.2 to 61.0%), whereas that of monoenes increased (from 25.8 to 39.0%), the saturate/monoene ratio changing from 2.87 to 1.56. The major saturated components of SM, 22:0 and 24:0, decreased; the major monoenes, 22:1 and 24:1, increased. Because the concentration of SM in liver was reduced with the drug (Table 1), it is clear from the results in Table 4 that the monoenes were much less affected than were the saturates.

The percentages of n-6 and n-3 PUFA in total lipid, PL, and TG are shown in Table 5. The changes induced by clofibrate in each of these groups are more clearly apparent here than in Table 2, where PUFA are together and their proportions are relatively minimized by the contribution of major saturated and monoenoic fatty acids. In controls, nearly half the fatty acids of TG and ~40% of those of PL were n-6 PUFA, whereas close to 9% of the fatty acids of TG and 16% of those of PL were n-3 PUFA (Table 5). Of the n-6 PUFA, as much as 90% of those of TG was made up of 18:2n-6, and ~95% of those of PL was accounted for by 18:2 and 20:4n-6. Of the n-3 PUFA, as much as 80% of those of TG was accounted for by 18:3n-3 and 22:6n-3, and the bulk (>90%) of those of PL was 22:6n-3. In controls, TG had larger basal proportions (Table 5) and concentrations than PL of all n-6 PUFA other than 20:3n-6 and 20:4n-6, and also of all n-3 PUFA other than 22:6 n-3.

The sum of n-6 and that of n-3 PUFA in liver PL was maintained at similar percentages with respect to other fatty acids in controls and clofibrate-treated animals, whereas in TG the proportion of n-6 and n-3 PUFA, but especially the latter, decreased substantially in relation to other fatty acids (Table 5). Among n-6 PUFA, the most remarkable effect of clofibrate on the total lipid composition was a large increase in the percentage of 20:3n-6, the metabolic precursor of 20:4n-6, with a concomitant decrease in that of 18:2n-6, 18:3n-6, and 24:5n-6. Among n-3 PUFA, the drug induced a large increase in the percentage of 22:5n-3, the metabolic precursor of 22:6n-3, with a concomitant decrease in that of 18:3n-3, 18:4n-3, and 24:6n-3. Taking into account the total amounts and the percentages of n-6 and n-3 PUFA (Table 5), it results that the significant decreases observed in the percentages of liver lipid 18:2n-6 and 24:4n-6 among n-6 PUFA, and in those of 18:3n-3 and 24:6n-3 among n-3 PUFA, were mostly, if not exclusively, contributed by TG. Conversely, the significant increases observed in the percentages of liver lipid 20:3n-6 and 20:4n-6 among n-6 PUFA, and of 22:5n-3 and 22:6n-3 among n-3 PUFA, were virtually exclusively contributed by PL. With the exception of 20:3n-6, all PUFA decreased in TG under the effects of clofibrate, whereas the concentrations of the major PUFA components of PL, 18:2n-6, 20:4n-6, and 22:6n-3, were preserved close to those of control conditions.

DISCUSSION

The data presented here show that the administration of clofibric acid to mice resulted in profound qualitative and quantitative modifications of hepatic lipids and their fatty acids. The major lipid effects were an increase in the amount of phospholipids and a decrease in that of TG, changes which are consistent with the well-known effect of clofibrate as plasma triglyceride-lowering agent. The proliferation of hepatic peroxisomes and mitochondria concomitantly with enzymes (10,16) that participate in fatty acid β-oxidation in both organelles is another of the typical biochemical responses of rodents to the challenges imposed by clofibrate and pharmacologically-related chemicals. In addition, drugs effecting peroxisomal proliferation in relatively high doses are well-known inducers of liver hypertrophy and hyperplasia (17,18).

[a]Fatty acid methyl esters were separated by means of argentation thin-layer chromatography to facilitate the detection of minor components. Values are percentages ± SD (n = 3–4 samples) of total n-6 (or n-3) polyunsaturated fatty acids (PUFA), calculated separately.
[b]Sum of all n-6 (or n-3) PUFA components in relation to the total fatty acids of each lipid (%).
[c]Ratios between the sums given in *b*.
[d]Amounts, in mg/g of tissue.
[e]Significant differences from control values, determined using the Student's *t*-test ($P < 0.05$).

An increased phospholipid biosynthesis to supply the cellular membranes required for this growth is consistent with the increase in liver weight and phospholipid mass (with virtually unchanged phospholipid levels per unit weight) observed here. Clofibrate-induced fatty acid oxidation, TG depletion, and PL formation are thus related. In rat liver (7) and kidney (19), it has been demonstrated that peroxisomal β-oxidation and microsomal 1-acylglycerophosphocholine acyltransferase are co-induced after administration of several peroxisomal proliferators. Other enzymes participating in hepatic lipid synthesis whose activity increase in response to these drugs are CTP:phosphocholine acyltransferase (20), acyl-CoA synthetase, 1-acylglycerophosphate acyltransferase (21), and fatty acid desaturases (22). The present results suggest that some of the fatty acids whose oxidation is stimulated by clofibrate in liver, from saturated to polyunsaturated, may originate in endogenous TG. The purpose of such fatty acid oxidation could be in part catabolic, as energy demands increase dramatically, and in part anabolic, as higher requirements for more fatty acids, including PUFA, are to be met. To sustain the stimulated synthesis of glycerophospholipids, remodelling of fatty acid pre-existing in the tissue could meet part of the requirements for important PUFA, such as 20:4n-6 and 22:6n-3.

The chain shortening of long-chain fatty acids which are poorly oxidized in mitochondria has been considered a physiologically relevant role of peroxisomal β-oxidation (23–25). In rodent liver, very long saturates like behenic, lignoceric, and cerotic acids, in the form of acyl-CoAs, are preferentially, if not exclusively, oxidized in peroxisomes (26–28), as mitochondria lack the necessary acyl-CoA (e.g., lignoceroyl CoA) ligase (29). The significant reduction of SM observed here, as it was concurrent with a decrease that selectively affected its very long saturated acyl chains, could be contingent upon stimulated oxidation of fatty acids in peroxisomes, this process consuming part of the substrates normally used for synthesizing SM (e.g., 24:0). Very long chain polyenoic fatty acids, such as those having 24 carbons, could also be chain-shortened in peroxisomes to give the major 20- and 22-carbon PUFA. Such oxidation, stimulated by peroxisomal proliferation, would explain the present observations of decreased levels of very long C_{24} PUFA in the liver of clofibric acid-treated mice. The novel observation we have made is that the TG account for most of this decrease.

In addition to directly affecting fatty acid oxidation, measured through $^{14}CO_2$ production, feeding clofibric acid and other structurally unrelated peroxisomal proliferators results in an accelerated conversion of [^{14}C]-labeled 18:2n-6, 18:3n-6, and 20:3n-6 to their desaturated and elongated metabolites, [^{14}C] 20:3n-6 and 20:4n-6 (22). This response was ascribed to induction of hepatic fatty acid desaturases, as it could be prevented by pretreatment of rats with cycloheximide. The increase observed here in 20:4n-6 content in liver PL agrees with these findings and interpretations. The disproportionate increase of 20:3n-6 with respect to 20:4n-6 suggests that: (i) the 20:4 newly formed was in part retroconverted, or (ii) even though stimulated, 5-desaturase synthesized less product than could have been made from the available substrate. The latter possibility is consistent with the fact that desaturases are rate-limiting steps in PUFA formation pathways (30). Our results show that under the influence of clofibrate, an analogous phenomenon affected the n-3 PUFA, as the proportion of 22:5n-3 increased more than that of the 4-desaturation product, 22:6n-3.

The observed accumulation in the total lipid of 20:3n-6 and 22:5n-3 with a concomitant net depletion of 18:2n-6 and 18:3n-3 on the one hand, and of 24:5n-6 and 24:6n-3 on the other hand, support the idea that elongation/desaturation of the 18 carbon precursors occurred at rates higher than normal in the presence of an accelerated chain-shortening of the longest n-6 and n-3 PUFA. Both mechanisms could contribute to meet the increased demands for the major 20:4n-6 and 22:6n-3 destined to phospholipids. The TG could be actively involved as donors of fatty acid precursors for both processes, as long-chain precursors (18 carbons) as well as very long chain products (24 carbons) decreased several-fold in TG under the effects of clofibrate without appearing as such in PL. The fact that in liver under basal conditions there were relatively larger amounts of most PUFA other than 20:4 and 22:6 in TG than in PL supports this possibility.

The changes induced by clofibric acid on mouse liver fatty acids agree with previous results in the rat (22) as far as n-6 PUFA are concerned. The corresponding PUFA of the n-3 series are shown here to be affected, even more drastically so than the n-6 polyenes. The relative effects on n-6 or n-3 PUFA could depend on the diet, in this case reflecting the relatively larger abundance of the former with respect to the latter in the standard rodent diet used, containing sunflower oil as the major source of fat (large n-6/n-3 ratio). Previous work has shown that the greater the proportion of n-3 PUFA in the diet, the lower the concentration of TG in plasma and the larger in liver (31). In rats fed a diet supplemented with a high amount of fish oil (31,32), or given separately the main constituents of fish oil, 20:5n-3 and 22:6n-3 (33), hepatic peroxisomal β-oxidation was stimulated. Because the effects of clofibrate on liver lipids, and consequently on blood lipids, could depend upon the type of polyenoic fatty acids (n-6, n-3, or n-9) fed to the animals, the effect of the simultaneous administration of hypolipidemic agents like clofibrate and hypolipidemic diets based on different types of dietary fatty acids deserves further investigation.

ABSTRACT: We investigated the influence of dietary fatty acid profile and triacylglycerol structure on the fatty acid profile and triacylglycerol structure of milk lipids in two generations of rats. Three groups of rats received diets containing 20% fat of which approximately 20% was n-3 fatty acids located in different positions of the triacylglycerol: a fish oil-based diet [docosahexaenoic acid (22:6n-3) predominantly in the *sn*-2 position], a seal oil-based diet (22:6n-3) predominantly in the *sn*-1/*sn*-3 position, or a plant oil-based diet [α-linolenic acid (18:3n-3) distributed evenly between the three positions]. This design allowed us to investigate (i) the effect of the triacylglycerol structure of the dietary fat; (ii) the effect of receiving the n-3 fatty acids as long-chain derivatives or as the precursor, 18:3n-3; and (iii) the long-term effects over two generations. The fatty acid profiles of the milk lipids largely reflected the diets, but in the second generation, the level of medium-chain fatty acids was higher ($P < 0.05$) in the milk from rats fed the fish oil diet (24%) compared with the other dietary groups (15 and 18%). This suggests an increased endogenous synthesis of fatty acids in the mammary glands of the fish oil-fed rats. The levels of long-chain n-3 fatty acids in milk were higher ($P < 0.05$) in rats fed marine oils (8–12%) compared with rats fed vegetable oil (1%) in both generations. The level of long-chain n-3 fatty acids was significantly higher in the milk from the fish oil-fed rats (12.3%) compared to the seal- oil fed rats (8.0%) in the first generation, but not in the second generation (8.9 vs. 9.1%). The general structure of milk triacylglycerols was maintained in the three experimental groups with 16:0 acylated in the *sn*-2 position and 18:1 in the *sn*-1/*sn*-3 positions. The triacylglycerol structure of mammalian milk appears to be conserved even during extreme dietary manipulation over two generations and an extensive enrichment with long-chain n-3 polyunsaturated fatty acids requires their presence in the diet.

Lipids 31, 187–192 (1996).

During the embryonic and early postnatal period, long-chain polyunsaturated fatty acids (PUFA), especially docosahexaenoic acid (22:6n-3), and arachidonic acid (20:4n-6), accumulate in the nervous system, including brain and retina. These fatty acids constitute up to 60% of the fatty acids in the photoreceptor outer segment membrane in the retina and in the synaptic membranes in the brain (1). The largest accretion of the PUFA in the nervous system takes place during the last trimester and the first 6–10 mon after birth in humans (2), and in the first 15 d after birth in the rat (3). The mammalian fetus receives the PUFA from the mother by placental transfer and the newborn mammal obtains them from the maternal milk.

We have demonstrated in a two-generation experiment that intake of fish oil, rich in eicosapentaenoic acid (20:5n-3) and 22:6n-3, compared to linseed oil, rich in 18:3n-3, is accompanied by elevated levels of 22:6n-3 in brain and heart phosphatidylethanolamine (4). We have also shown that the lymphatic absorption of a fatty acid is enhanced when this fatty acid is situated in the *sn*-2 position of dietary triacylglycerol (TAG) (5). About 75% of the long-chain PUFA in the *sn*-2 position in the dietary TAG are conserved during the absorption (6). Intravenously injected chylomicrons prepared from rats fed oils with different TAG structures are cleared at different rates (7). The TAG structure will therefore exert short-term effects on absorption, metabolism, and distribution of dietary fats in the organism. In the present long-term investigation, we examined whether the structure of maternal dietary TAG affects the structure and the fatty acid profiles of the milk TAG, with particular reference to n-3 PUFA. Differences in milk TAG could affect the absorption of fatty acids from the milk and the following tissue distribution in the suckling offspring.

MATERIALS AND METHODS

Animals and diets. The experiments were approved by the Danish Animal Experiments Inspectorate. Weanling female Wistar rats were purchased from Møllegård Breeding Centre A/S, Ll (Skensved, Denmark). They were housed in plastic cages and provided with tap water *ad libitum*. The temperature was maintained at 24°C, the relative humidity was 45%,

and the light/dark cycle was 12 h/12 h. The rats were divided into three groups of four rats, and received *ad libitum* diets composed of (in wt%): 40% starch, 20% fat, 20% casein, 10% sucrose, 5% salt mixture, 4% cellulose powder, 0.5% choline chloride, and 0.5% vitamin mixture (8). New batches were prepared every third week and stored at −40°C. In the fish oil diet, the fat component was 60% fish oil (Okholm olie; Thyborøn Andelsfiskeindustri, Thybøron, Denmark), 24% corn oil (FDB, Albertslund, Denmark), and 16% olive oil (Irma A/S, Rødovre, Denmark). In the seal oil diet it was 60% seal oil (made from seal blubber from Royal Greenland A/S, Greenland), 26% corn oil, 6% palm oil (Palmotex, Aarhus Oliefabrik A/S, Aarhus, Denmark), 6% olive oil, and 2% linseed oil (Nomeco A/S, Copenhagen, Denmark). The dietary oil in the vegetable oil diet was made from: 42% olive oil, 29% linseed oil, 15% palm oil, 10% corn oil, and 4% grape kernel oil (Dansk Supermarked A/S, Lyngby, Denmark). By these combinations of the oils, the amounts of polyunsaturated, monounsaturated, and saturated fatty acids in the three diets were similar (Table 1). The fish and seal oil diets differed mainly in the TAG structure, but it was not possible to make the fatty acid profiles completely similar due to the content of docosapentaenoic acid (22:5n-3) in the seal oil. The total amounts of n-3 fatty acids were nevertheless almost similar in all three diets, in the vegetable oil diet being 18:3n-3, whereas in the other diets it was 20:5n-3, 22:5n-3, and 22:6n-3 (Table 1). After five weeks, the rats were mated with male rats receiving ordinary chow diet. After approximately 20 d of pregnancy, the pups were delivered. Three weeks later the pups were separated from their mothers, and a minimum of seven females selected at random from each group were used in the succeeding part of the study. At approximately 14 wk of age, they were mated with male rats receiving an ordinary chow diet, and went through the same procedure as the first generation.

Collection of milk. The pups were separated from the mothers. After about four hours, the mothers received 0.2 mL Oxytocine intraperitoneally (10 IE/mL; Leo Vet, Ballerup, Denmark), and were sedated with 0.2 mL/100 g body weight of a mixture of Hypnorm (10 mg/mL fluanisonum, 0.2 mg/mL fentsnylum; Janssen, Oxford, United Kingdom):water (redestilled), 1:1, and Dormicum (Roche, Basel, Switzerland; 5 mg/mL)/water (redistilled), 1:1. The papillae were cleaned with ethanol, and the rats were milked manually with a yield of 1–2 mL of milk per rat per session. This was performed weekly for three weeks. The milk samples were stored at −20°C until analysis.

Analysis of milk lipids. The milk samples were extracted by the method of Folch *et al.* (9). The total fatty acid composition in the milk was determined by methylation with KOH in methanol (10), and the fatty acid methyl esters were analyzed by gas–liquid chromatography (GLC), using a Fisons Instruments HRGC Mega 2 series 8560 gas chromatograph with flame-ionization detection (Fisons Instruments, Milano, Italy), and a BPX-70 fused silica capillary column (25 m × 0.22 mm i.d.) (SGE, Victoria, Australia). On-column injection was used. Initial oven temperature was 40°C for 2 min, followed by a temperature gradient of 10°C/min until 150°C, followed by a gradient of 3°C/min until 215°C, followed by a gradient of 5°C/min, until a final oven temperature of 220°C, which was held for 3 min. The fatty acids were identified by

[a]Determined by gas–liquid chromatography (GLC) for triacylglycerols (TAG) or by regiospecific degradation followed by thin-layer chromatography and GLC as described in the text. Mean ± standard error of three determinations; PUFA, polyunsaturated fatty acids.
[b]Medium-chain fatty acids (MCFA) include $C_{6:0}$ to $C_{12:0}$.

comparison with authentic standards (Nu-Chek-Prep Inc., Elysian, MN).

Regiospecific analysis of TAG. Extracted lipid from milk samples or dietary oils were dissolved in diethyl ether in a 50-mL round-bottomed flask (11). While stirring with a magnetic stirrer, 0.2 mL allyl magnesium bromide was added, and the reaction was allowed to proceed for 60 s. Then 8 mL of acid buffer was added (0.27 M HCl in 0.4 M boric acid solution), both phases were transferred to a 30 mL test tube, and the water phase was removed. The ether phase was washed twice with 8-mL boric acid solution (0.4 M). The ether phase was dried with sodium sulphate, and the ether was evaporated under nitrogen. The glycerides were dissolved in 100 μL chloroform and separated into TAG, diacylglycerol, monoacylglycerols, and tertiary alcohol, using boric acid (0.4 M) impregnated thin-layer chromatography (TLC)-plates (E. Merck, Darmstadt, Germany) as described by Thomas *et al.* (12). The regiospecific analysis was based on the fatty acid profile of the *sn*-2 monoglyceride, in which the acyl migration of the fatty acids was <2% based on analysis of an actual standard (1,3-dioleoyl-2-palmitoyl-glycerol, 99%; Sigma, St. Louis, MO). The *sn*-2 monoglyceride band was scraped off the TLC-plate and extracted from the silica gel with 3 × 1 mL diethyl ether. The ether was evaporated under nitrogen, the glycerides dissolved in hexane, methylated, and analyzed by GLC as described above.

Statistics. All data were analyzed by analysis of variance. When significant differences were present, means were compared by Duncan's Multiple Range Test with a 5% level of significance.

RESULTS

The fatty acid profiles of the milk TAG were generally similar between the three dietary groups as well as first and second generation (Table 2). The medium-chain fatty acids, 6:0 to 14:0, were generally similar in the three groups of the first generation, but in the second generation significantly increased ($P < 0.05$) in the fish oil group and decreased ($P < 0.05$) in the vegetable oil group. The saturated fatty acids, 16:0 and 18:0, in the milk TAG did not appear to be affected by the dietary fat or the generations examined. The levels of the monounsaturated fatty acids showed diet differences. The major fatty acid in milk, 18:1n-9, was present at higher ($P < 0.05$) levels in milk from the vegetable oil-fed rats compared to the other groups and increased ($P < 0.05$) from first to second generation. The highest levels ($P < 0.05$) of palmitoleic acid (16:1n-7) and 20:1 were present in the seal oil group, where they appeared to accumulate, and the lowest ($P < 0.05$) levels were observed in the vegetable oil group. The concentration of the n-6 fatty acids, 18:2n-6 and 20:4n-6, were rather similar between diets and generations at approximately 12 and 0.5%, respectively. The n-3 fatty acids were markedly influenced by the diet. Linolenic acid (18:3n-3) was highest ($P < 0.05$) in the milk from the rats fed the vegetable oil diet compared with the other dietary groups, whereas the long-chain n-3 PUFA, 20:5n-3, 22:5n-3, and 22:6n-3, were found in greater concentrations in the marine oil-fed groups. The fish oil diet in the first generation resulted in higher ($P < 0.05$) levels of 20:5n-3 and 22:6n-3, and the seal oil diet resulted in the highest ($P < 0.05$) level of 22:5n-3. In the second generation, the levels of 20:5n-3 and 22:6n-3 in the milk from the seal and fish oil group were not different, but 22:5n-3 remained higher ($P < 0.05$) in the seal oil group.

The regiospecific distribution of fatty acids in the *sn*-2 position of milk TAG from the three dietary groups is shown in Table 3. Within each diet group, the TAG structures of the milk from the first and second generation were generally similar. Medium-chain fatty acids (MCFA) (8:0 and 10:0) and 18:1 were present in lower levels in the *sn*-2 position when

[a]For each fatty acid: Values (mean) not bearing the same superscript letter are significantly different at $P < 0.05$. If no superscript appears, values are not different; n ≥ 7, mole% calculated from GLC analysis of methyl esters. See Table 1 for abbreviations

compared with the total level in milk TAG (Table 2), whereas 14:0, 16:0, and 16:1 were present at higher levels in the *sn*-2 position. When present, 20:1 was mostly located in the *sn*-1/*sn*-3 positions. The contents of 18:2n-6 and 20:4n-6 were similar in the total TAG and in *sn*-2 position, and only small differences between diets and generations were found; 20:5n-3 was enriched ($P < 0.05$) in the milk from the marine groups, but it was mostly located in the *sn*-1/*sn*-3 positions, as seen from the low contents in the *sn*-2 position. On the other hand, 22:6n-3 appeared to be enriched in the *sn*-2 position in the second generation of the fish oil group, and in the seal oil group, 22:5n-3 was significantly enriched ($P < 0.05$) in the *sn*-1/*sn*-3 positions in the second generation.

DISCUSSION

Maternal milk TAG supply the infant with MCFA (13) for readily absorbable energy and n-6 as well as n-3 PUFA (14), which are important for membrane function and neural development. Furthermore, milk possesses a particular TAG structure with 16:0 mostly located in the *sn*-2 position (15). The fatty acids in milk have three different origins: the diet, adipose stores, and *de novo* synthesis in the mammary glands (16). In healthy women eating a Western diet, *de novo* synthesis accounts for 10–12% of the total fat in milk, and the diet for approximately 30% (16).

In this experiment we examined the effect of maternal dietary fatty acid profile and TAG structure on the fatty acid profile and the milk fat TAG structure in a two-generation experiment with rats. The diets were rich in n-3 PUFA, either from fish oil, from seal oil, or from vegetable oil, to elucidate the effect of dietary pre-formed 22:6n-3 vs. 18:3n-3 and the effect of dietary TAG structure. The two-generation model was used to study (i) if an adaptation to an intake of a high level of 18:3n-3 was followed by increased formation of 22:6n-3 and (ii) if a possible effect of TAG structure of the marine fat was increased or decreased in the second generation.

In rat milk we found up to 12% of long-chain n-3 PUFA following intake of marine fats, which is considerably higher than reported for chow-fed rats at about 1.2% (17) or human milk at about 3% (18). The milk from the rats fed the vegetable oil diet contained 7–8% 18:3n-3 and only a small amount (approximately 1%) of long-chain n-3 PUFA, indicating that although the desaturation and elongation of 18:3n-3 to 22:6n-3 in the liver are very active in the rat (19) this did not result in much higher levels of these n-3 PUFA in milk. Furthermore, the contents of 20:5n-3 and 22:6n-3 in the milk of the vegetable oil-fed rats did not increase from the first to the second generation as it did in the heart (4). Therefore, in order to obtain the higher levels of 22:6n-3 in the milk, this fatty acid needs to be included in the maternal diet.

The incorporation of n-3 PUFA into milk lipids (Table 2) showed some significant differences in content, but not positional distribution (Table 3), between the two marine oil groups in the first and second generation. A direct comparison between each of the n-3 PUFA was not possible, since there were differences between the two diets. However, the total n-3 PUFAs in the diets was more similar (fish oil 20.6%; seal oil 19.1%). The results clearly showed significantly higher incorporation ($P < 0.05$) of the n-3 PUFA into milk of fish oil-fed rats compared to seal oil-fed rats in the first generation (12.3 vs. 8.0%). This difference could not have occurred during absorption because the differences in TAG structure were previously shown not to affect the absorption of these two oils (20). A more probable explanation of these results may be at the level of chylomicron metabolism, since we have shown that the chylomicrons are cleared at different rates for these marine oils (7). In the second generation, there

were no significant differences in the n-3 PUFA between these two dietary marine groups (8.9 vs. 9.1%), which may suggest an adaptation. Certainly, there are strong trends to maintain a rather uniform fatty acid profile in milk fatty acid composition.

Furthermore, it is evident from these results that the positional distribution of fatty acids on dietary marine oil TAG was not preserved (Table 3) during milk synthesis as it is during fat absorption. The tailoring of TAG compared to the dietary TAG indicates that milk TAG are thus mostly synthesized *de novo* by the phosphatidic acid pathway, and the distribution of fatty acids in the milk TAG molecule, therefore, reflects the proportion of substrate fatty acids and specificity of the transacylases, and not the dietary TAG structure. In agreement with this, milk from seals eating large amounts of fish with 22:6n-3 in the *sn*-2 position of the TAG does not contain 22:6n-3 in the *sn*-2 position of the TAG (21,22).

The levels of total MCFA (6:0 to 14:0) in the milk ranged from 17 to 28% despite their absence in all the diets. Continued exposure to these diets into the second generation resulted in an increase in MCFA in the fish oil group and a decrease in the vegetable oil group. Previous studies of milk from rats fed chow diet (17) showed that MCFA (6:0 to 14:0) comprised approximately 20% in agreement with our vegetable oil group. The level of MCFA in human milk is between 5 and 10% (13,16,23). The majority of these are synthesized in the mammary gland, the synthesis being depressed by a fat-rich diet and increased by a carbohydrate-rich diet (24).

The contents of 20:4n-6 in the milk from the three groups were all similar and low (0.3–0.5%). Except for seal oil, which contained only 0.1%, none of the other diets contained 20:4n-6. The contents of 18:2n-6 (11–12%) indicated the availability of the precursor, but the higher level of 18:2n-6 in the vegetable oil did not result in elevated levels in the milk. This may suggest a regulation of the amount of long-chain PUFA, such as 20:4n-6 or 22:6n-3 in the milk, when these fatty acids are not directly available from the diet as also pointed out for human milk (14).

Palmitic acid is dominant in the *sn*-2 position and 18:1 in the *sn*-1/*sn*-3 position, and only 18:1 was affected by diet. This indicates that the TAG structure is strongly conserved throughout the two generations irrespective of diet. Milk TAG from several species (25), including humans (26), consistently show a similar pattern of 16:0 and 18:1 distribution. Palmitic acid in the *sn*-2 position was shown to be better absorbed than when present in the *sn*-1/*sn*-3 positions (15) which assures a more efficient transfer of 16:0 to the neonate.

Numerous studies have shown that the amount of n-3 fatty acids in the postnatal diet is very important for normal development of the central nervous system (1,27,28). The presence of 22:6n-3 seems especially vital, since the absence of this particular fatty acid in brain and retina has been correlated to reduced learning ability (29) and decreased visual acuity (30). Recent reports have questioned the necessity for preformed 22:6n-3 in the infant diet, indicating that term infants can convert 18:3n-3 into 22:6n-3 at a sufficient rate to support visual function (31). Others (32–34) found that 20:5n-3 and 22:6n-3 at 0.3 and 0.2% of dietary fatty acids in newborn infants secured an amount of long-chain n-3 fatty acids in the red blood cell phospholipids similar to what is found in human milk-fed infants. Infants given a supplement of n-3 fatty acids showed higher levels of 20:5n-3 and 22:6n-3 in the red blood cells at the expense of 20:4n-6 and accompanying growth retardation (32).

Our study has demonstrated that even under considerable manipulation of the maternal diet for two generations the structure of the milk TAG is highly conserved, and that the milk secretory system preserves the overall fatty acid profile and includes easily digested MCFA into the maternal milk. However, if a high level of long-chain n-3 fatty acids in the milk is desired, these fatty acids must be present in the maternal diet, since no adaptation to 18:3n-3 as a dietary source of long chain n-3 fatty acids was observed in this two-generation experiment.

ABSTRACT: In order to identify new structures and especially those involved as biosynthetic intermediates, the fatty acid composition of whole phospholipids from two Senegalese marine sponges from the order Axinellida, *Trikentrion loeve* and *Pseudaxinella* cf. *lunaecharta*, has been investigated by analytical gas chromatography and gas chromatography/mass spectrometry. Several new fatty acids were identified as methyl esters and *N*-acyl pyrrolidides, namely 16-eicosenoic, 11-tetracosenoic, 5-pentacosenoic, 11-hexacosenoic, 11-octacosenoic, 23-triacontenoic, 17,21-hexacosadienoic, 19,23-octacosadienoic, 9,23-triacontadienoic, 5,9,21-hexacosatrienoic, and 5,9,25-triacontatrienoic. *Trikentrion loeve* and *P.* cf. *lunaecharta* contain fifteen (25.7% of the total acid mixture) and thirteen (30.4%) Δ5,9 fatty acids, respectively. Based on gas chromatography/Fourier transform infrared experiments, the double bonds were assigned the (*Z*) configuration. Biosynthesis of dienoic and trienoic demospongic acids possessing an n-5 or an n-7 terminal double bond is discussed.
Lipids 31, 193–200 (1996).

As part of our continuing investigation of phospholipids from marine sponges of the Senegalese coast (1–5), we recently reported the occurrence of three new C_{30} unsaturated fatty acids in the sponge *Trikentrion loeve* Carter (3). The novel fatty acids 23-triacontenoic [**3**] and 9,23-triacontadienoic [**6**] are biosynthetic intermediates of the known 5,9,23-triacontatrienoic acid, whereas the novel isomeric acid 5,9,25-triacontatrienoic [**8**] involves an unusual pathway. Consequently, we undertook a more extensive study of this phospholipid fraction, together with an additional phospholipid fraction from the Senegalese sponge *Pseudaxinella* cf. *lunaecharta*, also belonging to the order Axinellida.

Since the findings of Litchfield and co-workers (6,7), sponge phospholipids have been known to contain high levels of very long-chain fatty acids (23–34 carbon atoms), including specific acids possessing unique 5(*Z*), 9(*Z*)-diunsaturation and sometimes an additional double bond near the chain terminus. The biosynthesis of these sponge fatty acids has been investigated, but a number of postulated intermediates have not yet been identified as natural products (8–10). The Senegalese sponge *Higginsia tethyoides* (order Axinellida, family Axinellidae) contains an unusually large amount (34.2%) of 5,9,23-triacontatrienoic acid and a new class of 2-methoxy fatty acids (11). In our search for Δ5,9 demospongic acids and their metabolic intermediates, we recently investigated the New Caledonian sponge *Cinachyrella* aff *schulzei*, which contained the largest number of Δ5,9 demospongic acids (15 acids) encountered to date in a marine sponge (4). In the latter sponge, we observed for the first time the occurrence of 27-methyl-5,9-octacosadienoic acid, which was also recently identified in two Caribbean sponges (12).

This report details the fatty acid composition of whole phospholipids from *T. loeve* and *P.* cf. *lunaecharta*, and describes the characterization of several new unsaturated demospongic acids presented in Figure 1.

EXPERIMENTAL PROCEDURES

Sponge material, extraction, and isolation of phospholipids. Specimens of *T. loeve* Carter and *P.* cf. *lunaecharta* were respectively collected by hand (scuba-diving) at Thiouri-Ba (40–45 m depth, off Dakar) and at Pointe Senti (100 km south of Dakar, ~1 m depth) in February of 1990. The sponges were washed in sea water, carefully cleaned, ground in a Waring blender with chloroform/methanol (1:1, vol/vol) and steeped twice in this solvent for 24 h at room temperature. The combined extracts yielded the crude total lipids. Phospholipids were separated from other lipids by column chromatography on silica gel (70–230 mesh) with hexane, chloroform, acetone, and methanol (phospholipid fraction) as successive eluents. The phospholipid mixture was analyzed by thin-layer chromatography (TLC) on silica gel (chloroform/methanol/water, 65:25:4, by vol). Standard phospholipid samples and normal, odd, and even (from C_{20} to C_{31}) fatty acids methyl esters (FAME) were purchased from the Sigma Chemical Co. (St. Louis, MO). The phospholipid mixture from *T.*

loeve also was studied by ^{31}P nuclear magnetic resonance (NMR) performed on a AC-400 Bruker NMR spectrometer (Karlsruhe, Germany) at 161.977 MHz. The phospholipid sample was dissolved in deuterated chloroform/methanol (2:1, vol/vol), and 85% phosphoric acid was used as external reference.

Gas–liquid chromatography (GC) and GC/mass spectrometry (GC/MS) analyses. The phospholipid fatty acids were converted to methyl esters by reaction (30 min under reflux) with methanolic hydrogen chloride, dissolved in hexane, and purified by column chromatography (silica gel, hexane/diethyl ether, 10:1, vol/vol). The resulting methyl esters were analyzed by GC. *N*-acyl pyrrolidide derivatives were prepared by direct treatment of methyl esters with pyrrolidine/acetic acid (10:1, vol/vol) under reflux (2 h) and purified by TLC (silica gel, hexane/diethyl ether, 1:2, vol/vol). FAME were hydrogenated by stirring (4 h) at room pressure and temperature in methanol with catalytic amounts of platinum (IV) oxide (Adam's catalyst; Sigma-Aldrich Chimie, Saint-Quentin-Fallavier, France). Methyl esters were analyzed by GC using a Carlo-Erba 4130 chromatograph (Milano, Italy) and a nonpolar OV-1 silica capillary column (25 m × 0.32 mm i.d., 0.40 μm phase thickness); hydrogen was used as carrier gas (50 kPa, split 5/100). The temperature was programmed at 3°C/min, from 180 to 300°C. Combined GC/MS was performed on a Hewlett-Packard HP-5890 chromatograph linked to an HP 9000/345 integrator (Palo Alto, CA). The GC column was a 30 m × 0.32 mm i.d. fused silica capillary column coated with DB-1 (0.25 μm phase thickness). The carrier gas was helium (0.5 bar, split 1/30). Column temperature was programmed from 180 to 310°C, at 3°C/min, for both derivatives (methyl esters and pyrrolidides).

GC/Fourier transform infrared (FTIR). GC/FTIR spectra were recorded with a 20SxB Nicolet spectrometer (Madison, WI), interfaced with a 5300 Mega Carlo Erba FID chromatograph equipped with a fused-silica capillary column (DB-1; 60 m, 0.32 mm i.d., 0.25 μm film thickness; J&W Scientific, Folson, CA). Oven temperature was programmed from 70 to 130°C (15°C/min) and from 130 to 290°C (4°C/min); isotherm steps of 2 min at 70°C and 40 min at 290°C were used. The carrier gas was helium (140 kPa). Pressure of hydrogen and air was 50 and 100 kPa, respectively. The light-pipe (infrared gas cell) was gold-coated, with dimensions of 160 × 1.2 mm. Temperature was maintained at 293°C for the experiments. Vapor phase infrared spectra were performed with 8 cm^{-1} resolution, and 16 data scans were collected and co-added per data file (2 s for each spectrum). Chromatogram reconstruction was performed with the Gram-Schmidt algorithm.

RESULTS

As determined by the chloroform/methanol extraction procedure, the sponge *P.* cf. *lunaecharta* (dry weight) yielded 2.3% of total lipids, and the sponge *T. loeve* yielded an unusual value of 8.0%. Phospholipids (215 mg) were recovered from 241 g (dry weight) of *P.* cf. *lunaecharta* (3.8% of total lipids), while 94 g of *T. loeve* (dry weight) yielded 192 mg (2.5%). As shown by TLC and ^{31}P NMR spectroscopy, the main phospholipid classes from *T. loeve* were phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylglycerol. As shown by TLC, the main phospholipid classes from *P.* cf. *lunaecharta* were phosphatidylethanolamine, phosphatidylserine, and phosphatidylglycerol. The only whole phospholipid fractions isolated by column chromatography (methanol-eluted fractions) were studied. The phospholipid fatty acid composition of both sponges is shown in Table 1, and the new demospongic acids are represented in Figure 1.

More than sixty fatty acids were identified in *T. loeve* or *P.* cf. *lunaecharta* by capillary GC of their methyl esters and GC/MS of their methyl esters and *N*-acyl pyrrolidides. Very

TABLE 1
Phospholipid Fatty Acids from Two Senegalese Marine Sponges of Order Axinellida[a,b]

Fatty acids	ECL	Abundance in weight (%) *Trikentrion loeve*	*Pseuchaxinella* cf. *lunaecharta*
Dodecanoic (12:0)	12.00	0.8	0.8
Tetradecanoic (14:0)	14.00	3.7	2.1
4,8,12-Trimethyltridecanoic (*br*-16:0)	14.52	12.4	3.1

[a]ECL, equivalent chain length (DB1); *i*, *iso*; *ai*, anteiso; *br*, branched; trace, <0.1%.
[b]Identified minor fatty acids (<0.2%): 10:0, *i*-19:0 (18.66), *ai*-19:0 (18.73), 20:4n-6 (19.20), *i*-20:0 (19.65), *ai*-20:0 (19.72), *ai*-21:0 (21.73), 23:0, *i*-27:0 (26.64), 27:0, 28:0, 30:0.
[c]First reported in phospholipids.
[d]Not previously found in nature.
[e]First reported in *T. loeve* (see Ref. 3).
[f]Detected Δ5,9 demospongic acids for which the location of the terminal double bond was not determined: Δ5,9,x-27:3 (26.32, trace) in *P.* cf. *lunaecharta*; Δ5,9,y-29:3 (28.27, 0.5%) and Δ5,9,z-29:3 (28.30, 0.5%) in *T. loeve*.

long-chain acids (>24 carbon atoms) accounted for about 34% in *T. loeve* and 52% in *P.* cf. *lunaecharta*. Most of the fatty acids compiled in Table 1 were identified as methyl esters by comparing their equivalent chain length (ECL) values with those of commercial standards and other known compounds. Capillary GC analysis of a hydrogenated aliquot also provided useful information for detection and identification of fatty acids. For many components, *N*-acyl pyrrolidide GC/MS data allowed us to confirm the structures and to determine the double bond and branching positions. GC retention times and mass spectral data of selected fatty acid pyrrolidides are as follows.

12-Methyloctadecanoic acid pyrrolidide [retention time (RT): 22.44 min]. Mass spectrum (MS) *m/z* (relative intensity): 351 (M^+, 1.2), 336 (0.7), 322 (0.3), 308 (0.8), 294 (0.3), 280 (1.2), 266 (1.2), 238 (1.6), 224 (0.8), 210 (0.8), 196 (0.9), 182 (1.6), 168 (2.3), 154 (1.3), 140 (2.5), 126 (14.8), 113 (100), 98 (9.4), 84 (4.7), 71 (12.5), 70 (12.1), 55 (17.2), 43 (23.4), 41 (11.0).

15-Methyloctadecanoic acid pyrrolidide (RT: 22.98 min). MS *m/z* (relative intensity): 351 (M^+, 0.6), 336 (0.2), 322 (0.4), 308 (0.7), 294 (<0.1), 280 (0.5), 266 (0.1), 252 (0.2), 238 (0.3), 224 (0.3), 210 (0.2), 196 (0.4), 182 (0.8), 168 (1.2), 154 (0.7), 140 (1.6), 126 (13.4), 113 (100), 98 (7.5), 84 (6.0), 71 (16.0), 70 (15.9), 55 (28.1), 43 (47.6).

14-Eicosenoic acid pyrrolidide (RT: 25.91 min). MS *m/z* (relative intensity): 363 (M^+, 9.9), 348 (1.1), 334 (3.4), 320 (3.3), 306 (4.8), 292 (4.6), 278 (3.5), 266 (6.3), 253 (4.3), 238 (2.4), 224 (2.8), 210 (2.1), 196 (4.3), 195 (5.3), 182 (4.2), 168 (4.5), 154 (4.3), 140 (6.0), 126 (33.9), 113 (100), 98 (43.5), 81 (95.0), 75 (95.0), 71 (55.0), 70 (55.0), 55 (100), 43 (96.0), 41 (100).

16-Eicosenoic acid pyrrolidide (RT: 26.01 min). MS *m/z* (relative intensity): 363 (M^+, 5.7), 348 (0.2), 334 (2.7), 320 (2.7), 306 (2.2), 295 (2.2), 294 (0.8), 281 (4.6), 280 (0.8), 266 (4.1), 253 (2.1), 252 (2.1), 239 (1.3), 238 (1.4), 224 (2.7), 210 (2.3), 196 (3.1), 195 (2.9), 182 (2.9), 168 (4.0), 154 (1.8), 140 (5.3), 126 (38.4), 113 (100), 98 (19.2), 84 (21.3), 75 (85.0), 72 (38.6), 70 (40.3), 55 (100), 43 (84.9).

*5-Pentacosenoic acid pyrrolidide [**2**] (RT: 36.07 min).* MS *m/z* (relative intensity): 433 (M^+, 2.7), 418 (2.0), 404 (0.1), 390 (0.7), 376 (0.6), 362 (1.5), 348 (0.9), 336 (0.7), 334 (0.9), 320 (1.4), 306 (1.2), 292 (1.4), 278 (1.6), 264 (1.9), 250 (3.6), 236 (3.9), 222 (3.2), 208 (3.2), 196 (2.3), 194 (2.6), 182 (4.8), 180 (5.1), 166 (3.6), 164 (3.0), 154 (1.8), 152 (7.8), 140 (4.7), 126 (35.9), 113 (100), 98 (20.3), 85 (9.4), 83 (9.2), 72 (29.7), 70 (28.6), 69 (25.0), 55 (42.2), 43 (31.2), 41 (21.9).

*11-Hexacosenoic acid pyrrolidide [**1b**] (RT: 38.36 min).* MS *m/z* (relative intensity): 447 (M^+, 6.8), 432 (0.3), 418 (0.5), 404 (1.0), 390 (0.3), 376 (0.3), 362 (0.4), 348 (0.5), 346 (0.4), 334 (0.5), 320 (0.7), 306 (0.9), 292 (1.2), 278 (1.7), 264 (2.4), 250 (4.1), 236 (4.5), 224 (2.4), 210 (2.1), 196 (2.0), 194 (1.6), 182 (6.2), 180 (5.3), 168 (4.3), 154 (2.0), 140 (4.7), 126 (39.1), 113 (100), 98 (17.2), 85 (7.8), 72 (28.1), 70 (17.1), 55 (31.3), 43 (29.7), 41 (15.6).

*11-Octacosenoic acid pyrrolidide [**1c**] (RT: 41.92 min).* MS *m/z* (relative intensity): 475 (M^+, 3.0), 460 (0.2), 446 (0.2), 443 (0.1), 432 (0.1), 418 (0.2), 404 (0.3), 390 (0.2), 376 (0.5), 362 (0.3), 348 (0.8), 334 (0.7), 320 (1.2), 306 (1.5), 292 (1.3), 278 (2.8), 265 (1.6), 264 (2.7), 250 (1.9), 238 (1.4), 236 (1.6), 224 (1.6), 222 (1.4), 210 (3.0), 209 (2.2), 196 (2.5), 182 (3.6), 168 (3.8), 155 (2.2), 154 (2.5), 140 (3.1), 126 (28.1), 113 (100), 98 (17.2), 85 (7.8), 81 (7.2), 72 (25.8), 70 (25.2), 55 (31.2), 43 (31.2).

17,21-Hexacosadienoic acid pyrrolidide [4]. (RT: 38.60 min). MS *m/z* (relative intensity): 445 (M^+, 12.0), 430 (0.2), 416 (0.8), 402 (1.4), 388 (1.6), 376 (0.7), 374 (0.9), 362 (1.6), 360 (0.8), 348 (4.7), 334 (4.4), 322 (3.0), 320 (6.5), 308 (4.5), 306 (4.3), 294 (2.5), 280 (2.0), 266 (2.1), 252 (2.2), 238 (2.3), 224 (2.2), 210 (2.1), 196 (2.2), 182 (3.5), 180 (3.4), 168 (3.6), 155 (1.7), 154 (1.9), 140 (4.0), 127 (8.0), 126 (35.9), 113 (100), 98 (18.0), 84 (10.9), 81 (7.8), 72 (43.7), 70 (57.8), 55 (46.1), 43 (31.2), 41 (23.4).

19,23-Octacosadienoic acid pyrrolidide [5]. (RT: 42.21 min). MS *m/z* (relative intensity): 473 (M^+, 6.4), 459 (<0.1), 444 (0.5), 430 (0.8), 416 (0.9), 402 (0.7), 390 (0.9), 388 (0.8), 376 (3.9), 362 (2.7), 348 (1.4), 336 (1.2), 322 (2.1), 308 (1.6), 294 (1.8), 280 (2.2), 266 (2.2), 252 (2.0), 238 (2.2), 224 (2.0), 210 (2.2), 196 (2.7), 182 (3.3), 180 (3.9), 168 (3.7), 155 (1.8), 154 (2.3), 140 (4.3), 126 (32.8), 113 (100), 98 (20.3), 84 (7.8), 81 (12.5), 72 (43.7), 70 (57.8), 55 (42.2), 43 (28.1), 41 (18.7).

26-Methyl-5,9-octacosadienoic acid pyrrolidide (RT: 42.87 min). MS *m/z* (relative intensity): 487 (M+, 0.9), 473 (0.4), 458 (0.3), 452 (0.4), 448 (0.8), 430 (0.7), 417 (0.3), 360 (0.6), 350 (0.3), 276 (1.6), 266 (0.6), 250 (1.7), 234 (1.3), 226 (0.8), 207 (2.0), 196 (0.3), 194 (0.3), 192 (0.9), 180 (24.5), 166 (4.1), 152 (1.8), 140 (3.6), 126 (19.9), 113 (100), 98 (27.0), 85 (11.2), 71 (13.2), 55 (27.2), 43 (26.8).

5,9,21-Hexacosatrienoic acid pyrrolidide [7] (RT: 37.15 min). MS *m/z* (relative intensity): 443 (M^+, 3.1), 434 (0.2), 428 (0.1), 414 (0.2), 400 (0.2), 386 (0.3), 372 (0.5), 360 (0.3), 346 (0.2), 332 (0.2), 318 (0.6), 304 (0.2), 290 (0.4), 276 (0.3), 262 (0.4), 260 (0.7), 248 (0.7), 247 (0.5), 234 (1.1), 220 (0.9), 206 (0.5), 194 (0.5), 180 (18.0), 166 (0.8), 152 (1.0), 140 (1.6), 126 (14.8), 113 (100), 98 (14.1), 85 (7.0), 72 (16.4), 71 (16.1), 70 (8.2), 55 (25.0), 43 (18.8), 41 (12.5).

Saturated fatty acids. In *P.* cf. *lunaecharta*, a relatively short-chain acid was readily identified as its methyl ester showed an ECL value of 18.42 and a molecular ion (GC/MS) at *m/z* 312 accompanied by major common fragmentation ions at *m/z* 74 (base peak) and *m/z* 87, indicating a branched nonadecanoic structure. This compound remained unchanged upon catalytic hydrogenation. The MS of the corresponding pyrrolidide confirmed a nonadecanoic structure (19:0), showing a molecular ion peak at *m/z* 351. Enhanced peaks at *m/z* 280 (C_{14} fragment) and *m/z* 308 (C_{16}), and a very low fragmentation ion at *m/z* 294 (C_{15}) indicated a methyl branch at C-15. Thus, we characterized the 15-methyloctadecanoic acid previously found only in total lipids from the sponge *Dysidea fragilis*, but not described in detail (13). In the same manner, the unusual 12-methyloctadecanoic acid known since 1975 and recently described from *Agelas conifera* (14) was identified. Both MS of the pyrrolidide derivatives are given here. Two isoprenoid fatty acids were readily identified as methyl esters from GC and GC/MS data, namely 4,8,12-trimethyltridecanoic (4,8,12-TMTD) and 3,7,11,15-tetramethylhexadecanoic (3,7,11,15-TMHD, phytanic acid) (15,16).

Monoenoic fatty acids. Several new phospholipid long-chain monoenoic acids were identified in these sponges. 23-Triacontenoic acid **[3]**, characterized in our previous study (3) and found in *T. loeve*, is the longest monoenoic acid yet isolated from a sponge. Another unusual acid detected in *P.* cf. *lunaecharta* was readily identified as its methyl ester and had an ECL value of 24.53 and a molecular ion peak at *m/z* 394, indicating a 25:1 acid structure. The pyrrolidide derivative gave a molecular ion peak at *m/z* 433, indicating a 25:1 structure, and this peak disappeared upon catalytic hydrogenation. Key fragmentation ions at *m/z* 140 (C_4 fragment) and *m/z* 152 (C_5) indicated Δ5 unsaturation. Thus, we identified 5-pentacosenoic acid **[2]**, to our knowledge not previously described in any phospholipid fraction. Both new monoenoic short-chain acids, 16-eicosenoic in *T. loeve* and 14-eicosenoic in *P.* cf. *lunaecharta*, were also identified. As their methyl esters, these acids had ECL values of 19.90 and 19.80, respectively, and their MS displayed a molecular ion peak at *m/z* 324, suggesting a 20:1 acid structure. Both GC peaks disappeared upon catalytic hydrogenation and both MS of their pyrrolidides exhibited a molecular ion peak at *m/z* 363 (20:1 structure). Key fragments at *m/z* 294 (C_{15}) and *m/z* 306 (C_{16}) indicated Δ16 unsaturation for the first acid, whereas those at *m/z* 266 (C_{13}) and *m/z* 278 (C_{14}) indicated Δ14 unsaturation for the second acid. Furthermore, a series of Δ11 monoenoic acids was found in *P.* cf. *lunaecharta*, namely Δ11-20:1, Δ11-22:1, and the unusual Δ11-24:1, Δ11-26:1, and Δ11-28:1. These acids were readily identified *via* their methyl esters and pyrrolidides, whose MS contained the expected molecular ion peaks. The MS of all their pyrrolidides showed a difference of 12 amu between key fragments at *m/z* 224 (C_{10}) and *m/z* 236 (C_{11}), which was clearly indicative of Δ11 unsaturation.

Dienoic fatty acids. Two new dienoic long-chain fatty acids were identified in *P.* cf. *lunaecharta*. The methyl ester of the first acid was eluted just after the well-known Δ5,9-26:2 acid methyl ester (ECL 25.70); its MS had a molecular ion peak at *m/z* 406, suggesting a 26:2 acid structure. The structure was confirmed by the disappearance of the corresponding GC peak upon catalytic hydrogenation and by a molecular ion peak at *m/z* 445 for the corresponding pyrrolidide, as given previously. This acid did not possess typical Δ5,9 unsaturation because it lacked prominent fragmentation ions at *m/z* 81 (for methyl ester) and *m/z* 180 (for pyrrolidide). Both double bonds were readily located by differences of 12 amu between homologous ions at *m/z* 308 (C_{16}) and *m/z* 320 (C_{17}) for the first one, and at *m/z* 362 (C_{20}) and *m/z* 374 (C_{21}) for the second, indicating Δ17 and Δ21 unsaturations, respectively. Thus, the new fatty acid 17,21-hexacosadienoic **[4]** was identified. In the same way, a new octacosadienoic acid was identified because its methyl ester presented an ECL value of 27.66 (eluted after the known Δ5,9-28:2 acid methyl ester) and a molecular ion peak at *m/z* 434; these data suggested a 28:2 acid structure confirmed by the disappearance of the corresponding GC peak upon hydrogenation. The corresponding pyrrolidide displayed a molecular ion peak at *m/z* 473, confirming a 28:2 structure (see above). Differences of 12 amu between homologous ions, first at *m/z* 336 (C_{18}) and *m/z* 348 (C_{19}), and then at *m/z* 390 (C_{22}) and *m/z* 402 (C_{23}), readily indicated Δ19 and Δ23 unsaturations, respectively.

Thus, we identified the new fatty acid 19,23-octacosadienoic [5], which is a homologue of acid [4].

A rare Δ5,9-nonacosadienoic acid, first reported from two Caribbean sponges (12), also was characterized using the same strategy as described previously. The methyl ester was eluted just after 27-methyl-5,9-octacosadienoic acid methyl ester (*iso*-Δ5,9-29:2), recently found in *C.* aff *schulzei* (4). The pyrrolidide of this acid showed a molecular ion peak at *m/z* 487, confirming a 29:2 structure, and a major ion at *m/z* 180 arising from double allylic cleavage between C_7 and C_8, which is typical of Δ5,9 acid pyrrolidides. Methyl branching at the C_{26} position was indicated readily by significant homologous fragmentation ions at *m/z* 431 (protonated C_{25} fragment) and *m/z* 458 (C_{27}), and by the absence of C_{26} fragment at *m/z* 444. Thus, 26-methyl-5,9-octacosadienoic acid (*anteiso*-Δ5,9-29:2) was identified.

Trienoic fatty acids. In our recent report (3), we described the identification of a new Δ5,9 trienoic acid with an n-5 terminal double bond, namely 5,9,25-triacontatrienoic [**8**]. Another new trienoic acid was identified in *P.* cf. *lunaecharta*. Its methyl ester had an ECL value of 25.24, and displayed a molecular ion peak at *m/z* 404 and a major peak at *m/z* 81 typical of Δ5,9 unsaturated acids, suggesting a Δ5,9,n-26:3 structure. These data were consistent with the presence of a molecular ion peak at *m/z* 443 (26:3) and a prominent peak at *m/z* 180 in the MS of its pyrrolidide. A terminal double bond was readily located between the C_{21} and C_{22} atoms because of an interval of 12 amu between the homologous ions at *m/z* 360 (C_{20}) and *m/z* 372 (C_{21}). Thus, the new demospongic acid Δ5,9,21-26:3 [**7**] was characterized.

Three long-chain Δ5,9 trienoic acids also were detected, but the exact position of the third double bond could not be assigned due to the very small amounts available. *Psadaxinella* cf. *lunaecharta* contained a Δ5,9,x-27-3 acid as traces, whereas *T. loeve* contained two minor, different Δ5,9 nonacosatrienoic acids. The latter two isomers were successively eluted as methyl esters (RT, 29.97 min, ECL 28.27; and RT, 30.07 min, ECL 28.30) and showed almost identical MS. Both methyl ester MS displayed the molecular ion peak at *m/z* 446 and the typical fragment at *m/z* 81, which is indicative of a 5,9-nonacosatrienoic structure. Both these peaks disappeared upon catalytic hydrogenation. The corresponding pyrrolidide derivatives were also distinctly eluted (RT, 43.09 and 43.17 min, respectively) and yielded MS that displayed a molecular ion peak at *m/z* 485, indicating a 29:3 structure and an appreciable peak at *m/z* 180 typical of Δ5,9 unsaturation. Both spectra possessed the logical sequence with 14 amu differences until the $C_{20:2}$ fragment at *m/z* 360. Both spectra also possessed this same logical sequence following the ion peak at *m/z* 400 ($C_{23:3}$ fragment). Thus, the third double bond was located between the carbon C_{20} and C_{23} in the two isomeric Δ5,9,y-29:3 and Δ5,9,z-29:3 acids. In the unsaturated fatty acids, all double bonds were of (*Z*) configuration, as the GC/FTIR spectra showed absorptions near 3010 and 700 cm^{-1}, but no absorption near 960 cm^{-1} (17).

DISCUSSION

Of particular interest was the co-occurrence of two phospholipid isoprenoid fatty acids in both sponges, namely 4,8,12-TMTD and phytanic acid (3,7,11,15-TMHD). These fatty acids are frequent in marine environments, but it was previously suggested that these acids do not occur together in the same sponge (18), although they have been found together in the total lipids of *D. fragilis,* in which they are minor components (13). We recently also reported the co-occurrence of the common 4,8,12-TMTD and the not widespread 5,9,13-trimethyltetradecanoic from several marine sponges belonging to the genus *Cinachyrella* (order Spirophorida) originating along the Senegalese coast or in the New Caledonian lagoon (2,4,5). These findings led us to analyze all sponges from there specifically for isoprenoid acids. Thus, we found 4,8,12-TMTD and 3,7,11,15-TMHD together in the Senegalese sponge *P.* cf. *lunaecharta* (order Axinellida, family Axinellidae), which is closely related to *P. lunaecharta,* which also contains both these acids (15). GC/MS single-ion monitoring experiments indicated no trace of 5,9,13-trimethyltetradecanoic acid in these three Axinellida sponges.

The new sponge phospholipid 5-pentacosenoic acid [**2**] identified in *P.* cf. *lunaecharta* has already been found in mycobacteria, as noted by Rezanka (19). We recently reported the first occurrence of 5-octacosenoic acid in phospholipids of *C.* aff *schulzei* (4), and acids Δ5-20:1, Δ5-22:1, Δ5-23:1, and Δ5-26:1 were recently found in freshwater sponges (20). These findings suggest that Δ5 desaturation could arise as a first desaturation step after chain elongation in sponges. It has been demonstrated by incorporation experiments that synthetic 5-hexacosenoic acid is a biosynthetic precursor of 5,9-hexacosadienoic acid (10). The rare fatty acids Δ11-24:1 [**1a**], Δ11-26:1 [**1b**], and Δ11-28:1 [**1c**] found in *P.* cf. *lunaecharta*, in addition to the known Δ11-20:1 and Δ11-22:1, show that a Δ11-desaturase may be operative in this sponge. The acids Δ11-26:1 and Δ11-28:1 were previously found in mycobacteria (19).

Apart from methylene-interrupted polyunsaturated acids, long-chain polyunsaturated acids in sponges almost always possess a Δ5,9 unsaturation pattern. Both new acids Δ17,21-26:2 [**4**] and Δ19,23-28:2 [**5**] represent a new class of long-chain unsaturated fatty acids. Previously, the lower homologous acid Δ11,15-20:2 was identified from a Caribbean sponge (21). As demonstrated by various incorporation experiments, marine sponges are able to synthesize the Δ5,9 demospongic acids by elongation of short-chain saturated or monoenoic fatty acids, followed by desaturation (8–10,22). Thus, the hypothetical Δ21-26:1 and Δ23-28:1 intermediate acids can arise from exogenous 11-hexadecenoic, as previously suggested (23), but subsequent desaturation, such as Δ17 or Δ21 positions, respectively, do not likely occur in a sponge. The lack of Δ19 desaturase activity in a marine sponge was demonstrated (10,22). Furthermore, it is known that the Δ5,9 unsaturation can also be introduced into shorter fatty acids beginning at either the Δ5 or Δ9 position (22).

Thus, myristic acid (14:0) is the shortest acid amenable to chain elongation (22). The Δ9-14:1 acid was described in three marine sponges, which also contained the Δ5,9-18:2 acid (24). The lower homolog Δ5,9-16:2 acid was a major fatty acid of *Chondrilla nucula* (25) and was present in *Chondrosia reniformis* (12). The freshwater sponges *Baicalospongia bacillifera* and *B. intermedia* also contained the Δ5,9-16:2 acid together with the Δ9-14:1, Δ5-16:1, and Δ9-16:1 acids (20).

Therefore, one can likely assume the occurrence of a dienoic short-chain precursor, such as the Δ5,9-14:2 acid, from which the known active homologation enzyme system of the sponges could be operative as follows:

Δ5,9-14:2 → → Δ11,15-20:2 → → Δ17,21-26:2 → Δ19,23-28:2

Also noticeable in *T. loeve* phospholipids was the occurrence of fifteen Δ5,9 long-chain acids accounting for 25.7% of the total mixture, including 5,9,23-triacontatrienoic acid which was the major component (14.8%). Such a large number of Δ5,9-long-chain acids was first observed in *C.* aff *schulzei*, in which they accounted for 30% of the total mixture (4). *Pseudaxinella* cf. *lunaecharta* contained thirteen such acids (30.4%), 5,9-hexacosadienoic acid being the major component (20.3%).

The only known biosynthetic pathway to Δ5,9,n trienoic demospongic acids involves homologation in the n-7 even-chain monoenoic fatty acid series, followed by Δ5 and Δ9 desaturation, as previously demonstrated by incorporation studies in the case of the Δ5,9,19-26:3 from *M. prolifera* (8,10). Palmitoleic acid (Δ9-16:1) incorporated into the sponge *Aplysina fistularis* led to Δ5,9,23-30:3 (9). This sponge was able to homologate short-chain precursors, such as the exogenous acid Δ9-16:1 up to the Δ19-26:1 acid. A further desaturation yielded Δ9,19-26:2, which also occurs in *M. prolifera* (8,10). Such a pathway is involved in the biosynthesis of the relatively frequent Δ5,9,23-30:3 acid (as depicted in Fig. 2A), but the former postulated intermediates, Δ23-30:1 and Δ9,23-30:2 acids (7,23), were not found as natural products in sponge phospholipids before their identification in *T. loeve* (3). Thus, Δ5 desaturation appeared to be a last step in *T. loeve*, but also can occur as a first desaturation in marine sponges.

One of the most interesting results of this work was finding two new trienoic demospongic acids with an n-5 terminal double bond, namely Δ5,9,21-26:3 [7] in *P.* cf. *lunaecharta* and Δ5,9,25-30:3 [8] in *T. loeve*, in addition to the already encountered Δ5,9,23-28:3 acid (4,19,23). In a similar manner as previously mentioned, these trienoic acids most likely arise from short precursors, such as the Δ11-16:1 acid, by chain elongation in the n-5 monoenoic series (23), and by subsequent Δ5,9 desaturation (Fig. 2B). Despite the lack of postulated n-5 monoenoic intermediates in our sponges (acids in brackets), it should be noted that several lower homologs acids have been reported from some sponges, namely Δ11-16:1 (23,26,27), Δ13-18:1 (6), Δ15-20:1 (13), Δ17-22:1 (26), and Δ19-24:1 (21,23,26–28).

In summary, these two Axinellida sponges are of particular interest as they contain several new long-chain unsaturated

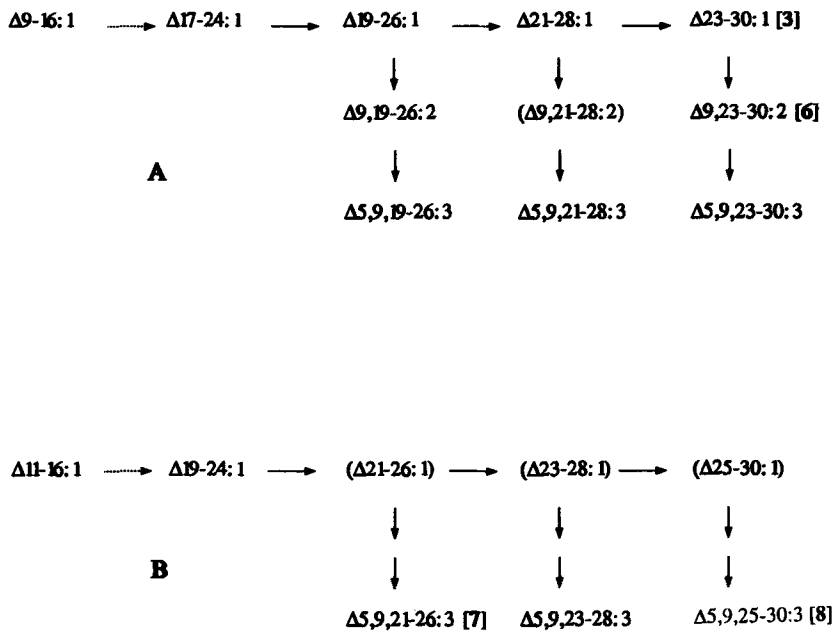

FIG. 2. Proposed biosynthetic pathways for Δ5,9,n demospongic acids with an n-7 (A) or n-5 (B) terminal double bond. All fatty acids were identified in *Trikentrion loeve* or *Pseudaxinella* cf. *lunaecharta* apart from the Δ11-16:1 and Δ19-24:1 acids found in several sponges (see Discussion section) and the Δ9,19-26:2 acid found in *M. prolifera* (Refs. 8,10). Postulated intermediates (in brackets) have not yet been identified as natural products so far.

acids involving unusual biosynthetic possibilities that likely include an n-5 monoenoic chain-elongation step. Nevertheless, much biosynthetic work is needed to demonstrate the origin of these new fatty acids.

ACKNOWLEDGMENTS

We wish to thank Dr. Robert Faure, Laboratoire de Spectroscopie and Emile M. Gaydou, Université d'Aix-Marseille III, for NMR measurements; Nicole Boury-Esnault, Centre d'Océanologie de Marseille, Station Marine d'Endoume, for the identification of *Pseudaxinella* cf. *lunaecharta* and Haïdar El Ali, Head of the Scuba Diving Club Oceanium de Dakar, for organizing the dives. This is part 6 in the series "Sponge Fatty Acids" (see Ref. 1 for part 5).

An Unusual Fatty Acid Pattern in *Eranthis* Seed Oil

K. Aitzetmüller*

Institut für Chemie und Physik der Fette, BAGKF, D-48147 Münster, Germany

ABSTRACT: The current discussion on "renewable resources", and the possibility of gene transfer into rapeseed, has led to many investigations into the biosynthetic pathways leading to industrially useful fatty acids. The various tribes and genera of the plant family *Ranunculaceae* contain a large variety of unusual fatty acids. Seed fatty acid patterns differ considerably from genus to genus and are chemotaxonomically significant indicators. *Eranthis* seed oil has now been found to contain a fatty acid pattern that deviates significantly from the eleven different fatty acid patterns that had been described in this plant family. The main fatty acid (up to 57%) is 13-*cis*,16-*cis*-docosadienoic acid. Other, minor fatty acids found are Δ5-*cis*-monoenoic, -dienoic, and -trienoic fatty acids that had already been reported to be constituents of the genus-specific seed oil fatty acid patterns of various genera from this plant family. Capillary gas–liquid chromatographic retention data indicate that 22:3Δ5*cis*,13*cis*,16*cis* is probably also present. Seed fatty acid chemotaxonomic evidence thus points to a different position of *Eranthis* within the tribes of this plant family. These findings again indicate that the plant family *Ranunculaceae* would be an ideal object to study fatty acid biosynthesis and phylogenetic evolution, because in other genera of this family other types of desaturation and chain elongation mechanisms predominate.
Lipids 31, 201–205 (1996).

The current discussion on renewable resources in the oils and fats field, and the possibility of gene transfer from wild species into agronomically developed crops such as rapeseed, has sparked a large number of investigations into the biosynthetic pathways leading to unusual and industrially useful fatty acids (1, 2). Recent research on seed oils and fatty acids of the plant family *Ranunculaceae* has shown that this plant family contains a large number of different fatty acids, and seed oil fatty acid patterns, that may relate to phylogenetic evolution (3, 4). So far, eleven distinctly different fatty acid patterns have been described in this family (4). The fatty acid composition found in seed oils from mature seeds indicates that in developing seeds of members of this plant family, a variety of desaturation mechanisms and chain elongation mechanisms must be operative that deserve to be studied in more detail (3).

Abbreviations: ECL, equivalent chain length; GC/MS, gas chromatography/mass spectrometry; GLC, capillary gas–liquid chromatography; RRT, relative retention time.

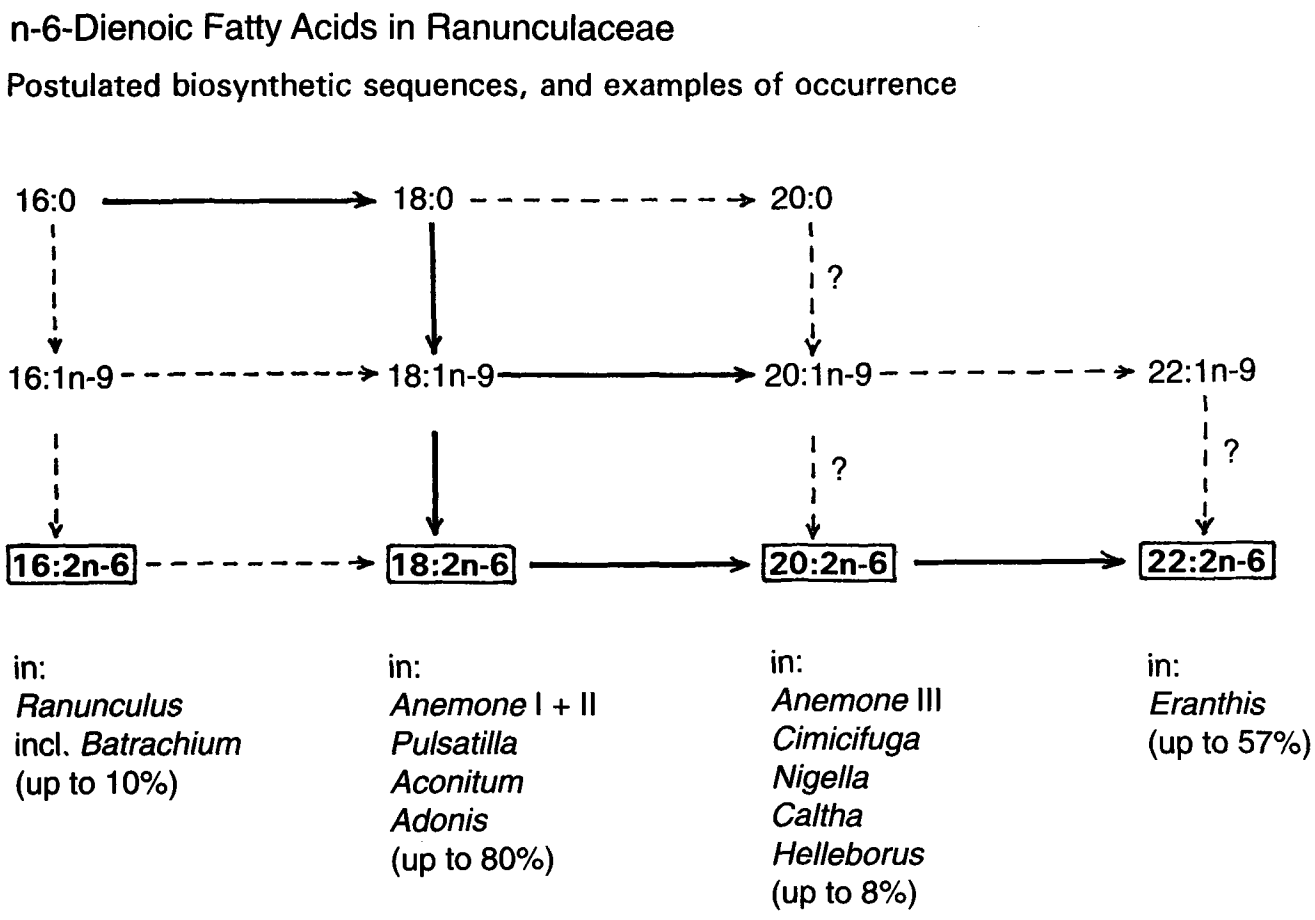
It seems that in the phylogenetic evolution of the extant members of this plant family from ancient angiospermous predecessors, several steps or mutations must have occurred that influenced or changed enzymes required for fatty acid biosynthesis. Desaturation between carbon atoms 4 and 7, which we had called "front-end"-desaturation in an earlier paper (3), may have changed several times (perhaps by stepwise or independent mutations of the amino acid sequence of the desaturases involved). In some species, chain lengths end at C_{18}, in others at C_{20}. In a number of genera, various combinations exist of "front-end"-desaturation and chain elongation beyond C_{18}. In other genera, both these features were apparently lost during the course of evolution (4). Because of these observations, and provided that the family is indeed monophyletic, the members of this plant family would make an ideal object to study the phylogenetic evolution of seed fatty acid biosynthesis (3,4,5–11).

To test this hypothesis, a number of key species were investigated for seed fatty acid composition where this was previously unknown (4). The findings with *Eranthis hyemalis* are reported in this paper.

EXPERIMENTAL PROCEDURES

Seeds of *E. hyemalis* were kindly provided by Prof. U. Jensen (Department of Botany, University of Bayreuth, Germany) and by M. Payer (St. Pölten, Austria). The seeds were crushed and extracted with hexane as described previously (12). After saponification and removal of the unsaponifiable, fatty acid methyl esters were prepared using the Deutsche Gesellschaft für Fettwissenschaft-BF_3-method (13). Capillary gas chromatography of fatty acid methyl esters and the evaluation of the obtained "fingerprint" patterns was carried out using Hewlett-Packard (Avondale, PA) GLC equipment and a Silar 5 CP column (Chrompack, Middelburg, The Netherlands) as described previously (5,6). To obtain additional fatty acid structural information, the following alternative capillary gas–liquid chromatography (GLC) conditions of different selectivity were used: CP-SIL-88 (Chrompack): 50 m × 0.32 mm; film thickness 0.25 μm; carrier gas He, 1.25 mL/min; temperature program, from 100 to 220°C at 1.5°C/min; 20 min isothermal; Injector and detector at 250°C; split 1:100; 1 μL solution was injected. BPX (SGE, Weiterstadt, Germany): 50 m × 0.22 mm; film thickness 0.25 μm; carrier gas N_2, 0.69 mL/min; temperature program, from 100 to 240°C at 2°C/min;

Copyright © 1996 by AOCS Press



32 min isothermal; injector at 260°C; detector at 240°C; split 1:80; 1 μL solution was injected.

Unusual fatty acids were identified by chromatography on three columns of different polarity and by co-chromatography with standards and samples of known fatty acid composition (6), including 22:2n-6 standards from Nu-Chek-Prep (Elysian, MN) and Larodan (Malmö, Sweden). Dimethyl disulfide adducts of fatty acid methyl esters and fatty acid 4,4-dimethyloxazoline derivatives were prepared and analyzed by gas chromatography/mass spectrometry (GC/MS) as described (14–16).

RESULTS AND DISCUSSION

Several n-6 dienoic fatty acids had been observed before in various genera of the plant family *Ranunculaceae* (Scheme 1). Hexadecadienoic acid (16:2n-6) is a chemotaxonomically significant constituent (at levels of 2–10% of total seed oil fatty acids) of most, if not all, of the species belonging to the genus *Ranunculus* L. incl. subgenus *Batrachium* L. (3,4). Linoleic acid (18:2n-6) is the end product of fatty acid biosynthesis, for example, in "*Anemone* II" (4), and in *Pulsatilla*, *Adonis*, and *Aconitum*, as in many conventional oilseeds (7,8). Eicosadienoic acid (20:2n-6) is found at levels of 7–8% in "*Anemone* III" (3, 4). It is also found, although at lower levels, in *Cimicifuga*, *Helleborus*, *Actaea* and *Caltha* (4). Its presence is highly significant in *Nigella*, where 20:2 is a much larger peak than 20:1 (4).

Seed fatty acid fingerprints (5) show that in the plant family *Ranunculaceae* there are genera where 20:1Δ11*cis* is the most significant peak, while the levels of the corresponding n-6 desaturation product, i.e., 20:2Δ11*cis*,14*cis*, are very low (for example, *Delphinium* and *Consolida*). This ratio is reversed in genera such as *Nigella*, where 20:2 > > 20:1. In still other genera, for example in *Caltha* (9), as well as in *Anemone* III (4) and *Cimicifuga* (Aitzetmüller, unpublished data), 20:2 is apparently further desaturated at Δ5, i.e., at the "front end" closer to the COOH group, to yield 20:3Δ5*cis*, 11*cis*,14*cis*, which is a major fatty acid in *Caltha* (3, 4, 9). Other C_{16}, C_{18}, and C_{20} fatty acids—with the highly significant exception of 18:2n-6—are apparently also desaturated at Δ5 in a number of genera, for example in *Caltha*, *Cimicifuga*, *Actaea* and *Anemone* III (4), leading to a whole range of various Δ5*cis* fatty acids. In view of this, it is rather surprising that an 18:3 polyenoic fatty acid with a *cis* double bond in position Δ5 has not yet been observed in this plant family. However, the corresponding *trans*-fatty acid, 18:3Δ5*trans*,9*cis*, 12*cis*, is prominent in *Aquilegia* and *Thalictrum* (10,11) and

SCHEME 1

may indeed be a chemotaxonomic marker (3,4) of the subfamily *Thalictroideae* (14) or *Isopyroideae* (15). The fatty acid 18:4Δ5*trans*,9*cis*,12*cis*,15*cis* has recently been tentatively identified as a minor acid in *Isopyrum* (4), and 18:4Δ5*cis*,9*cis*,12*cis*,15*cis* is apparently a minor acid present in both *Caltha* and *Cimicifuga* (4).

Fatty acid methyl esters obtained from *E. hyemalis* seed oil gave a totally different fatty acid pattern in capillary GLC (Fig. 1). The main fatty acid (up to 57%) was 22:2n-6 (or 22:2Δ13*cis*,16*cis*). This was identified *via* its relative retention times (RRT) and equivalent chain length (ECL) values on three different gas chromatographic columns of different selectivity (6), including direct comparison and co-chromatography with suitable reference standards and other seed oils where it occurs (5). The observed ECL value for the 22:2n-6 standard on Silar 5CP was 22.86, and the same ECL value was found for the major *Eranthis* fatty acid. Likewise the ECL values on CP-SIL-88 and BPX were 23.32 and 23.00, respectively. Co-chromatography of *Eranthis* methyl esters with authentic 22:2n-6 yielded only one peak in the 22:2n-6 region of the chromatogram. GC/MS of the methyl ester gave the molecular ion of 350 as expected for 22:2. GC/MS of the dimethyl disulfide adduct indicated fragmentation compatible with a 22:2n-6 structure (major diagnostic fragments at *m/e* 265 and 155). GC/MS of the 4,4-dimethyloxazoline derivative also confirmed the 22:2n-6 structure (major diagnostic fragments at m/e 252, 264, 292, and 304).

However, *Eranthis* apparently also contained a whole range of Δ5*cis* desaturation products as minor seed oil fatty acids (Table 1). Most of these were identified by comparison with *Caltha*, *Actaea*, and *Cimicifuga* (4) fatty acids on three GLC columns of different selectivity. They were identical with those fatty acids whose presence had already been established in *Caltha* (9). Most significantly, and again as in *Caltha*, *Actaea*, *Cimicifuga*, and "*Anemone* III" (4), the Δ5*cis*-desaturation product of linoleic acid (i.e., pinolenic acid, 18:3Δ5*cis*,9*cis*,12*cis*) was missing also in the *Eranthis* seed oil fatty acid pattern. Apart from these fatty acids, *Eranthis* apparently also contained the Δ5*cis* desaturation product of 22:2n-6, i.e., the fatty acid 22:3Δ5*cis*,13*cis*,16*cis*—a fatty acid hitherto not yet described and a homologue of the main fatty acid of *Caltha* (9). This identification, however, is based solely on GLC column selectivity, RRT and ECL considerations (17,18) and therefore should be considered as tentative—no reference material for co-chromatography was available. The same applies to another noticeable peak, which is

[b]Austrian sample.
[c]Identification tentative [by gas–liquid chromatography (GLC)].

most likely 20:2Δ5*cis*,11*cis*—a fatty acid so far found only in low amounts in other *Ranunculaceae*. This too was identified by extrapolation of the GLC (RRT and ECL) data of other Δ5 acids in the *Ranunculaceae*, as well as by a direct comparison with the equivalent minor fatty acid peaks present in *Caltha* (3,5,6,9,19). *Eranthis* seeds obtained from two different sources in Germany and in Austria showed essentially the same fatty acid pattern (Table 1).

The results described here support the position of *Eranthis* as a separate tribe or subtribe within the *Ranunculaceae* (20, 21). Moreover, Jensen (22) had observed a serologically closer relationship between *Eranthis* and the *Actaea–Cimicifuga* group. This, too, is supported by the present results, which indicate the presence of a similar set of Δ5 fatty acids in *Eranthis*, compared with those found in *Actaea* and *Cimicifuga* (cf. Table 3 in Ref. 4).

Apparently, in *Eranthis* still another major fatty acid biosynthetic pathway, different from those postulated before in other *Ranunculaceae* genera (3) is operative. Fatty acid biosynthesis in *Eranthis* does not stop at 20:1 (as in *Consolida*) or at 20:2 (as in *Nigella*), and it is not deviated to the main production of 20:3Δ5*cis*,11*cis*,14*cis* [as in *Caltha* (Ref. 9)]. Also, Δ5*trans* fatty acids (10,11,19) as in the subfamily *Isopyroideae* (20) were not observed. Instead, apparently further chain elongation occurs and leads to the accumulation of 22:2Δ13*cis*,16*cis* as the major end product of fatty acid biosynthesis (up to 57%). Presumably, 20:2Δ11*cis*,14*cis* is the predecessor [4]. However, a whole range of Δ5*cis* fatty acids—similar to those found in *Caltha*, *Cimicifuga*, and *Actaea*—is also present in *Eranthis* as minor fatty acids, accompanying the predominant 22:2n-6 (Table 1).

The phylogenetic relationships between members of the family *Ranunculaceae* have recently been the subject of much discussion (cf. Refs. 20,21,23, and references quoted therein). If the *Ranunculaceae* are indeed monophyletic, the findings on *Eranthis* presented here again support the view (3, 4) that the members of this plant family are ideal study objects for the phylogenetic evolution of seed fatty acid biosynthesis and the enzymes involved in this. It would certainly be interesting to find out more about the activities and specificities, and the amino acid sequences, of the various desaturases and elongases required to produce all these different unusual fatty acids. The presence of these enzymes in the seeds may have contributed significantly to the earlier serological findings of Jensen (22) when, in contrast to his later work, antibodies against total seed proteins were used. During the evolution of this plant family, stepwise changes in the primary amino acid sequences of the enzymes involved here may have occurred by way of mutation. From a better understanding of these evolutionary developments, important conclusions could be drawn with regard to genetic engineering of enzymes that may be involved in the biosynthesis of industrially useful fatty acids with unusual double bond positions. Eventually, such work may lead to new and improved technical oil crops as renewable resources (1,2,24), for future decades when petroleum resources are depleted.

ACKNOWLEDGMENTS

The author is indebted to Prof. Dr. U. Jensen, Dept. of Botany, University of Bayreuth, Germany, and to M. Payer, St. Pölten, Austria, for providing seeds of *Eranthis hyemalis*, to G. Werner for skillful experimental work, and to Dr. K. Vosmann from this institute for GC/MS structural confirmation of 22:2n-6. Dr. L. Brühl and Dr. N. Tsevegsüren of this institute provided GLC data on CP-SIL-88 and BPX.

ABSTRACT: Six oils of marine, algal, and microbial origin were analyzed for stereospecific distribution of component fatty acids. The general procedure involved preparation of *sn*-1,2-(2,3)-diacylglycerols by partial deacylation with ethylmagnesium bromide or pancreatic lipase, separation of X-1,3- and *sn*-1,2(2,3)-diacylglycerols by borate thin-layer chromatography, resolution of the *sn*-1,2- and *sn*-2,3-enantiomers by chiral phase high-performance liquid chromatography following preparation of dinitrophenylurethane derivatives, and determination of the fatty acid composition by gas chromatography. Unexpected complications arose during a stereospecific analysis of triacylglycerols containing over 33% of either 20:4 or 22:6 fatty acids. The *sn*-1,2(2,3)-diacylglycerols made up of two long-chain polyunsaturated acids migrated with the X-1,3-diacylglycerols and required separate chiral phase resolution. Furthermore, the enzymatic method yielded *sn*-1,2(2,3)-diacylglycerols, overrepresenting the polyenoic species due to their relative resistance to lipolysis, but prolonged digestion yielded correct composition for the 2-monoacylglycerols. The final positional distribution of the fatty acids was established by pooling and normalizing the data from subfractions obtained by normal- and chiral-phase separation of diacylglycerols. The molecular species of X-1,3-, *sn*-1,2- and *sn*-2,3-diacylglycerol dinitrophenylurethanes were identified by chiral-phase liquid chromatography/mass spectrometry with electrospray ionization, which demonstrated a preferential association of the paired long-chain acids with the *sn*-1,2- and *sn*-2,3-diacylglycerol isomers.

Lipids 31, 207–215 (1996).

Knowledge of the stereospecific distribution of fatty acids in natural fats is of interest because of the positional specificity of the lipolytic enzymes (1–3), the intestinal absorption, and reesterification of intact 2-monoacylglycerols (MAG) (4,5), and the desirability to reproduce the structure of certain scarce natural fats and oils (6,7) by blends of natural or synthetic fats and oils. Recently specialty or designer oils rich in n-6 and/or n-3 polyunsaturated C_{20} and C_{22} fatty acids have been introduced for dietary supplementation (8), but the triacylglycerol (TAG) structure of these oils has not been determined. In fact, application of conventional methods of stereospecific analyses to such oils has proved difficult due to isolation of nonrepresentative diacylglycerol (DAG) intermediates (Myher, J.J., Kuksis, A., and Park, P.W., 1994, unpublished results). We have traced this problem to the overlap of long-chain *sn*-1,2(2,3)-DAG with short- and medium-chain X-1,3-DAG during the boric acid thin-layer chromatography (TLC) used for the preliminary resolution of the *sn*-1,2(2,3)- and X-1,3-DAG. Usually natural oils contain only one long-chain polyunsaturated fatty acid per TAG molecule and borate TLC yields representative *sn*-1,2(2,3)-DAG from Grignard degradation (5,9). The present study demonstrates that valid stereospecific analyses of the oils enriched in polyunsaturated fatty acids can be obtained provided special care is taken in the isolation and identification of the enantiomeric DAG intermediates.

Abbreviations: DAG, diacylglycerol; DNPU, dinitrophenylurethane; ECN, equivalent carbon number; ELSD, evaporative light-scattering detection; GC, gas chromatography; HPLC, high-performance liquid chromatography; LC/MS, liquid chromatography/mass spectrometry; MAG, monoacylglycerols; PN, partition number; TAG, triacylglycerol; TLC, thin-layer chromatography.

EXPERIMENTAL PROCEDURES

Materials. Six polyunsaturated oils of marine (tuna) (B), microalgal (*Chrypthecodinium cohnii*) (C and D) and microbial micelia (*Mortierella alpina*) (A, E, and F) origin were available in the laboratory. Three were rich in arachidonic acid (A, E, and F), and three were rich in docosahexaenoic acid (B, C, and D). Reference *sn*-1,2- and *sn*-2,3-DAG dinitrophenylurethane (DNPU) derivatives prepared from standard TAG were available in the laboratory from previous studies (10,11). The 3,5-dinitrophenylisocyanate was purchased from Sumitomo Chemical Co. (Osaka, Japan). Ethylmagnesium bromide and boric acid were obtained from Aldrich Chemical Co. (Milwaukee, WI). Pancreatic lipase was obtained from Sigma Chemical Co. (St. Louis, MO).

Purification of TAG. Five drops of each oil were dissolved in 1 mL of chloroform, and 250 μL of the solution was applied to a 20 × 20 cm TLC plate coated with a 250-μm thin-layer of Silica Gel H (Merck, Darmstadt, Germany). The plate was developed with hexane/ethyl acetate (88:11, vol/vol) (12). The TLC bands corresponding to standard steryl ester, TAG, and phosphatidylcholine were scraped off and eluted

Copyright © 1996 by AOCS Press

with chloroform/methanol (2:1, vol/vol) and the solvents evaporated under nitrogen. Care was taken in collecting the TAG fraction to avoid loss of short- and long-chain TAG that might have trailed or preceded the bulk of species. The TAG fraction was subjected to immediate stereospecific analysis, while the other fractions were saved for later analyses. Aliquots were taken for nonpolar capillary gas chromatography (GC) of fatty acids and reversed-phase high-performance liquid chromatography (HPLC) of the intact lipid esters (see below).

Partial deacylation of TAG. Ten mg of the purified TAG were dissolved in dry diethyl ether (1 mL), freshly diluted 0.5 M ethyl magnesium bromide in dry ethyl ether (250 μL) was added, and the mixture was shaken for 1 min before glacial acetic acid (6 μL) in hexane (5 mL) and water (2 mL) were added to stop the reaction (5). The organic layer was washed twice with water (2 mL) and dried over anhydrous sodium sulfate. After evaporating the solvent in a stream of nitrogen at room temperature, the mixture of deacylation products was separated by borate TLC (13) using chloroform/acetone (88:12, vol/vol). The *sn*-1,2(2,3)- and X-1,3-DAG were separately recovered. Alternatively, the TAG were partially deacylated by digestion with pancreatic lipase using another established procedure (14). The digestion was performed in presence of gum arabic for 30 s and the digestion products extracted with diethyl ether. The *sn*-1,2(2,3)- and X-1,3-DAG and 2-MAG, were resolved by boric acid TLC and separately recovered as described above. For preparation of representative 2-MAG the digestion was prolonged to 2–3 min. After taking aliquots of the DAG fractions for fatty acid analyses, the remainder of the X-1,3- and *sn*-1,2(2,3)-DAG were converted into the DNPU derivatives for chiral phase HPLC resolution (see below).

Preparation of 3,5-DNPU. The X-1,3- and the *sn*-1,2(2,3)-DAG (1 mg) were dissolved in dry toluene (400 μL) containing 40 μL of dry pyridine and about 2 mg of 3,5-dinitrophenylisocyanate and allowed to stand for 1 h at room temperature (5). The partly overlapping long-chain *sn*-1,2(2,3)-DAG and the short-chain X-1,3-DAG were converted to the DNPU derivatives together, while the short-chain *sn*-1,2(2,3)-DAG and the long-chain X-1,3-DAG were derivatized separately. The resulting 3,5-DNPU derivatives were purified by TLC on a silica gel plate (Kodak, Rochester, NY). Prior to use, the plate was activated at 110–120°C for 1 h. The reaction mixture, dissolved in 400 μL of chloroform, was spotted on the plate and developed up to 15 cm using petroleum ether/1,2-dichloroethane/ethanol (40:10:3, by vol) as the developing solvent. Bands were located under ultraviolet and the 3,5-DNPU fractions (R_f = 0.5–0.6) were scraped off the plate. The pure 3,5-DNPU were recovered from the adsorbent by extraction with diethyl ether.

Chiral phase HPLC. The enantiomeric *sn*-1,2- and *sn*-2,3-DAG in the *sn*-1,2(2,3)- and in the X-1,3-DAG fractions were resolved using the chiral (R)-(+)-1-(1-naphthyl)ethyl-amine phase bonded to silica (YMC Pack A-KO_3; YMC Inc., Kyoto, Japan) and installed in a Hewlett-Packard (Palo Alto, CA) Model 1090 liquid chromatograph, as previously described (10,11). The analysis was performed isocratically at 23°C using hexane/1,2-dichloroethane/ethanol (40:10:1, by vol) as the mobile phase at a constant flow rate of 0.5 mL/min. Peaks were monitored at 254 nm using a variable wavelength detector. The corresponding *sn*-1,2- and *sn*-2,3-DAG from the two separations were collected and combined for fatty acid analysis.

GC of fatty acids. The fatty acid composition of the purified TAG and their deacylation products was determined following transmethylation with 6% H_2SO_4-MeOH as described (12). The methyl esters were resolved by polar capillary GC and the component acids were quantitated by flame-ionization detection (12).

HPLC of TAG. Intact TAG were resolved by reversed-phase HPLC as previously described (15). The eluted peaks were monitored and quantitated by an evaporative light-scattering detector (ELSD).

Liquid chromatography/mass spectrometry (LC/MS). LC/MS with on-line electrospray of the DAG DNPU was performed using the YMC Pack A-KO_3 column installed in a Hewlett-Packard Model 1090 liquid chromatograph. The separations of X-1,3-, *sn*-1,2- and *sn*-2,3-DAG were obtained with hexane/dichloromethane/ethanol (40:10:1). After post-column mixing with 0.3 mL/min isopropanol/1% aqueous ammonia, mass spectra of eluting peaks were acquired by negative mode nebulizer assisted electrospray interfaced with a Hewlett-Packard MS Engine Quadrupole mass spectrometer (16).

Calculations. The mole % fatty acid composition of the *sn*-1, *sn*-2 and *sn*-3 positions of the TAG molecules were calculated by subtraction of the mole % fatty acid compositions as follows (5):

$$sn\text{-}2 = (\text{2-MAG}), \text{ from pancreatic lipase deacylation} \quad [1]$$

$$sn\text{-}1 = 2 \times (sn\text{-}1,2\text{-DAG}) - (sn\text{-}2\text{-MAG}) \quad [2]$$

$$sn\text{-}3 = 2 \times (sn\text{-}2,3\text{-DAG}) - (sn\text{-}2\text{-MAG}) \quad [3]$$

Alternatively, the positional fatty acid distribution was calculated as follows:

$$sn\text{-}1 = 3 \times (\text{total TAG}) - 2 \times (sn\text{-}2,3\text{-DAG}) \quad [4]$$

$$sn\text{-}3 = 3 \times (\text{total TAG}) - 2 \times (sn\text{-}1,2\text{-DAG}) \quad [5]$$

The final composition of the *sn*-1 and *sn*-3 positions was obtained by averaging the results of the two calculations.

RESULTS AND DISCUSSION

Preliminary characterization. TLC of the oil samples in a neutral solvent system revealed the presence of a large TAG band preceded by a faint band corresponding to steryl esters and small amounts of polar material left at the origin of the plate. There was evidence for the presence of trace amounts of free sterols or free DAG in the E and F, and C and D oil samples. Table 1 gives the fatty acid composition of the purified TAG

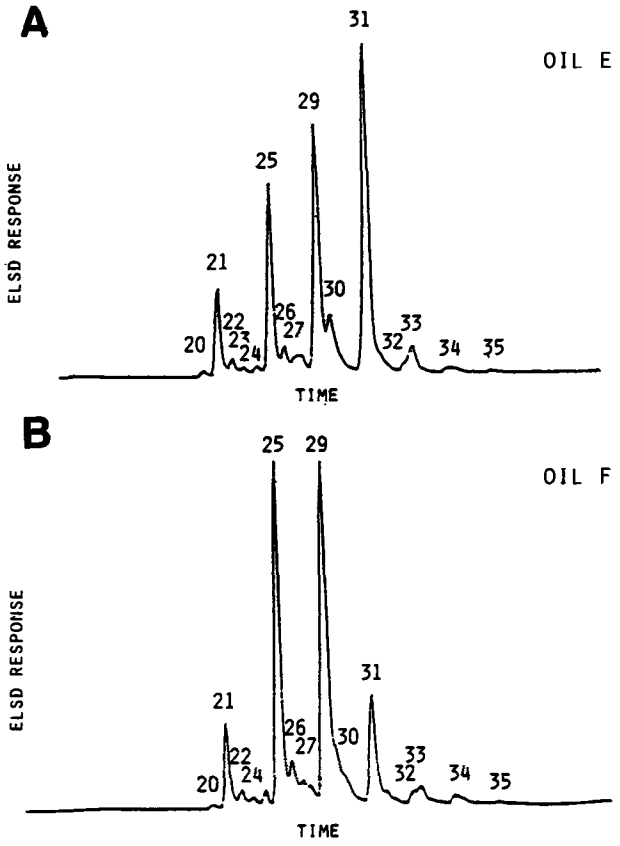

FIG. 1. Reversed-phase high-performance liquid chromatography (HPLC) profiles of E and F polyunsaturated oils as obtained with light-scattering detector. HPLC conditions: Hewlett-Packard Model 1050 liquid chromatograph (Palo Alto, CA) equipped with a Supelcosil LC-18 column (25 × 0.46 cm. i.d.) coupled to a Varex evaporative light-scattering detection (ELSD) II light scattering detector. Solvent: linear gradient of 10–90% isopropanol in acetonitrile at 25°C over a period of 70 min (1 mL/min). Peak identification by fractional equivalent chain-length number is given in Table 2.

fractions. It is seen that the TAG samples can be arranged in three groups on the basis of the major fatty acid content. Thus, samples E and F are characterized by a high content of 20:4, which averages about 50% of total. In contrast, samples C and D are characterized by a high content of 22:6, which averages about 40%. The C sample also contained a significant amount of 20:4 (6.5%). Finally, samples A and B contain mixed polyunsaturates as major components. Thus, sample A contains both 18:2 (21%) and 20:4 (25%) as polyunsaturates, while sample B contained 20:5 (7.1%) and 22:6 (29.9%) as the polyunsaturates. Sample B also contained 16:1 (5.0%) and was by far the most complicated of all the oil samples.

Figures 1–3 show the reversed-phase HPLC elution profiles of the purified TAG as monitored by the ELSD. Sample C oil gives excellent separation with almost complete baseline resolution (often complete resolution), despite the high content of 22:6 in these samples. The resolution of the E sample is poorer, and poor resolution appears to be due mainly to the higher content and greater variety of the unsaturated acids. Less than perfect separation was obtained also for the other 20:4-rich TAG oil, sample A. There was an abundance of double peaks. Likewise, double peaking was present in the B sample, although extensive resolution was still obtained.

Tables 2 and 3 give the quantitative composition of the TAG peaks by equivalent carbon number (ECN) as estimated by HPLC with ELSD. The reversed-phase HPLC resolves TAG by partition or ECN, where one double bond decreases the retention time equivalent to shortening the carbon chain by two methylene units. However, fractional ECN numbers also may be calculated to accommodate slight differences in retention time due to differences in location of the double bond in the fatty chain and of the fatty acid in the TAG molecule. In the present instance, the ECN values range from 38 to 54. Although a tentative identification of the major TAG species can be calculated from statistical consideration of the composition and positional distribution of the fatty acids, exact identification requires MS (see below). Thus, sample D would be expected to contain 14:0-22:6-22:6 (58:12 = PN 34), 16:0-22:6-22:6 (60:12 = PN 36) and 14:0-16:0-22:6 (52:6 = PN 40), where PN is the partition number (the acyl carbon number minus two times the number of double bonds), and major peaks can be found corresponding to these structures in the elution pattern. The identity of the major species can be confirmed and the identity of others established by on-line MS, which, however, was not completed on all samples as it was not considered necessary for stereospecific analysis of the positional distribution of the fatty acids.

Deacylation of TAG. Accurate stereospecific analysis depends on the precise execution of each one of the multistep

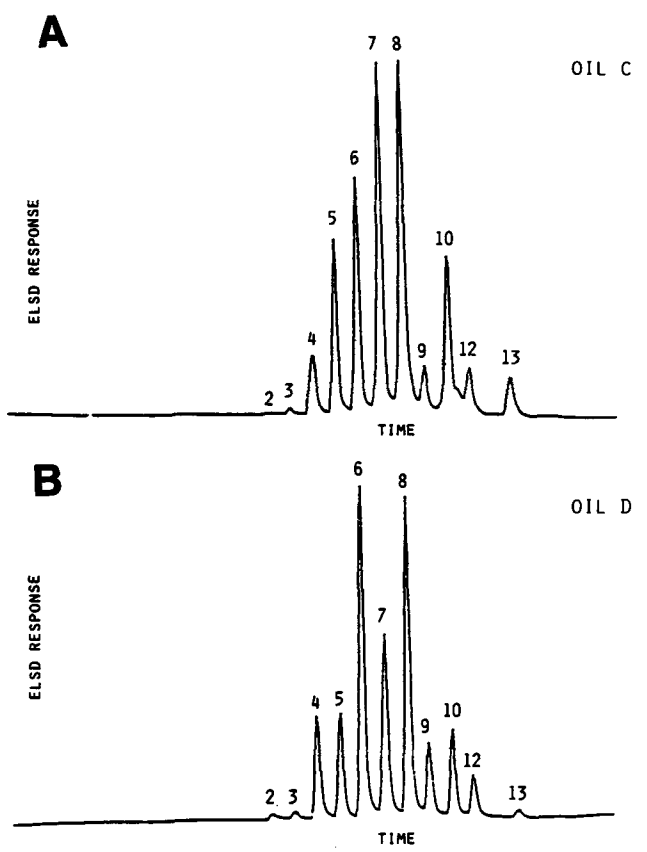

FIG. 2. Reversed-phase HPLC profiles of C and D polyunsaturated oils as obtained by light-scattering detector. HPLC conditions as given in Figure 1. Peak identification as given in Table 2. See Figure 1 for abbreviations.

procedure and frequent reconstitutions must be made to ascertain that each step has been adequately completed. Of critical importance is the formation of representative (random) *sn*-1,2(2,3)-DAG. In this study, neither the Grignard reaction nor pancreatic lipase yielded representative *sn*-1,2(2,3)-DAG, as isolated by borate TLC. This was due to the faster TLC migration of the long-chain polyunsaturated *sn*-1,2(2,3)-DAG, which led to an overlap with the X-1,3-DAG. Only after chiral-phase HPLC of the X-1,3-DAG was it recognized that the long-chain polyunsaturates in this fraction were due to contamination with *sn*-1,2(2,3)-DAG (see below). Because of the chain-length segregation and background contamination, it was also difficult to obtain representative samples from the small 2-MAG fraction produced during the Grignard reaction. However, representative 2-MAG could be recovered by prolonged pancreatic lipolysis, which yields 2-MAG as the final reaction products. In this case the TLC band was so strong that a representative 2-MAG fraction was readily obtained without contamination and undesirable segregation based on chain length. Pancreatic lipase is known to discriminate against the long-chain polyunsaturated fatty acids during brief digestion periods leading to nonrepresentative formation of the DAG intermediates. Table 4 shows the fatty acid composition of the original and reconstituted TAG for the D oil, along with corrected and calculated composition of the *sn*-1,2(2,3)-DAG obtained by Grignard deacylation, and of 2-MAG recovered from pancreatic and Grignard deacylation. There is reasonably good agreement between the corrected experimental *sn*-1,2(2,3)-DAG and the *sn*-1,2(2,3)-DAG calculated from the original TAG and the 2-MAG derived from pancreatic digestion. Thus, it became necessary to correct the *sn*-1,2- and *sn*-2,3-DAG compositions for loss of the polyunsaturated species in the X-1,3-DAG fraction in all the oils enriched in polyunsaturated long-chain acids. The need for such corrections was minimal in case of the A and B oils, the *sn*-1,2(2,3)-DAG of which showed only limited overlap with the X-1,3-DAG.

Stereospecific analyses. Figure 4 shows the chiral-phase HPLC separation of the *sn*-1,2- and *sn*-2,3-DAG derived from two of the TAG samples, one rich in 20:4 (F) and the other rich in 22:6 (D) fatty acid. Both show excellent resolution of the *sn*-1,2- and *sn*-2,3-enantiomers, with the latter emerging last. The X-1,3-isomers not removed by borate TLC emerge just ahead of the *sn*-1,2-enantiomers. There is considerable resolution of molecular species within the *sn*-1,2- and *sn*-2,3-enantiomers. The species were identified by chiral-phase LC/MS with electrospray. As noted above, during borate TLC, the long-chain *sn*-1,2(2,3)-DAG were observed to mi-

grate with the short-chain X-1,3-DAG. Figure 5 shows the chiral-phase LC/MS elution patterns for the selected ions representing the mass of the 22:6-22:6 species. Peaks of comparable intensity are seen to be eluted in the *sn*-1,2- and *sn*-2,3-enantiomer regions of the chiral chromatogram. Similar separations were necessary for the oils rich in 20:4 acid. In this instance, the *sn*-1,2-enantiomers would be expected to show higher intensity than the *sn*-2,3-enantiomers.

Tables 5–7 give the corrected fatty acid composition of the *sn*-1, *sn*-2, and *sn*-3 positions of the six oils. It is seen that the 20:4 in E and F (Table 5) is found in the *sn*-1 position in double the concentration in the *sn*-3 position, with an intermediate value in the *sn*-2 position. The *sn*-3 position contains the bulk of 16:0 and 18:0, while the 18:1 and 18:2 are largely found in the *sn*-2 position. In contrast the 22:6 in C and D (Table 6) was found mainly in the *sn*-2 position, with the *sn*-1 position containing about half as much and the *sn*-3 position an intermediate value of this acid (especially in D). While 18:1 again was preferred for the *sn*-2 position, the saturated fatty acids 14:0 and 16:0 were about equally divided between the *sn*-1 and *sn*-3 positions with much less found in the *sn*-2 position. The 22:6 distribution in B (Table 7) again was confined largely to the *sn*-2 and *sn*-3 positions, with about one quarter of each in the *sn*-1 position. Interestingly, in this instance the 18:1 was divided nearly equally between the *sn*-1 and *sn*-3 positions, with much smaller amounts in the *sn*-2 position. The saturated acids, 14:0 and 16:0, were found primarily in the *sn*-1 and *sn*-2 positions, while 18:0 was found primarily in the *sn*-1 position. The 20:4 distribution in A (Table 7) was characterized by nearly equal proportions of the acid in all three positions of the TG, while the other major unsaturated acids, 18:1 and 18:2, were found in the *sn*-2 position in approximately twice the proportions found in *sn*-1 and *sn*-3 positions, which were about equal. The 16:0 was found in high proportions in *sn*-1 and *sn*-3 positions, while 18:0 was

[a]From data in Table 6, reconstituted triacylglycerols (TAG) = (position 1 + position 2 + position 3)/3.
[b]Calc. 1,2(2,3)diacylglycerols (DAG) = (3 × TAG + *sn*-2-MAG)/4.
[c]*sn*-2-Monoacylglycerols (MAG) from pancreatic lipolysis.

preferentially associated with the *sn*-3 position, with smaller amounts in *sn*-1 position. In contrast, the modest amounts of 24:0 were divided nearly equally between the *sn*-1 and *sn*-3 positions, with very little in the *sn*-2 position. Although the B and A oils are more complex in the composition and positional distribution of the fatty acids, it appears that they conform to the distribution of the polyunsaturated and saturated fatty acids established for the simpler oils (E and F, and C and D series).

Significance. It is difficult to compare the results of this work with published literature because natural oils containing over 33% of long-chain polyunsaturated fatty acids have not been previously subjected to stereospecific analyses. Analyses of TAG of human milk have shown that the 20:4n-6 and

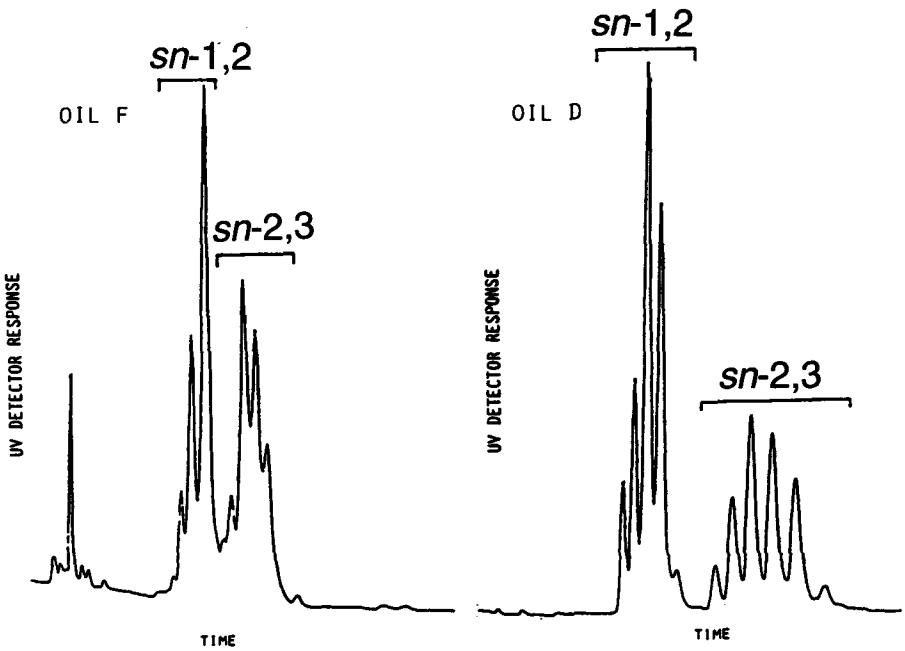

FIG. 4. Chiral-phase HPLC of the diacylglycerol dinitrophenyl urethane derivatives of F and D polyunsaturated triacylglycerols. *sn*-1,2-, *sn*-1,2-diacylglycerols (DAG); *sn*-2,3-, *sn*-2,3-DAG. Chiral-phase HPLC conditions: Hewlett-Packard Model 1090 liquid chromatograph equipped with a chiral column (25 cm × 4.6 mm i.d.) containing R-(+)-1-(1-napthtyl)ethylamine polymeric phase chemically bonded to 300 Å wide-pore spherical silica (YMC-Pack A-KO_3; YMC Inc., Kyoto, Japan). Solvent system: isocratic system of hexane/dichloromethane/ethanol 40:10:1, by vol, at 0.5 mL/min at an oven temperature of 23°C. Ultraviolet detector at 254 nm. See Figure 1 for abbreviations and company source address.

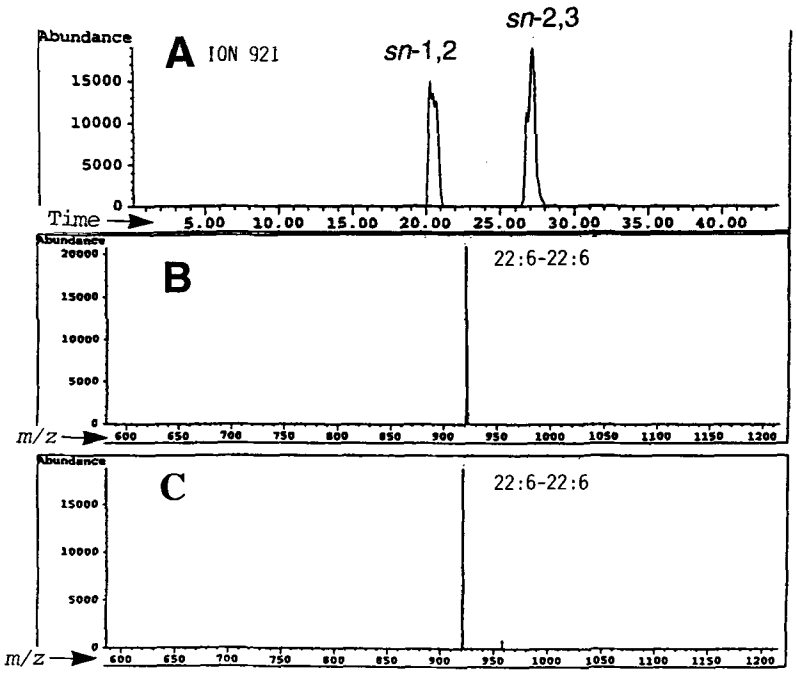

FIG. 5. Chiral-phase liquid chromatography/mass spectrometry (LC/MS) of the dinitrophenylurethane derivatives of oil C polyunsaturated *sn*-1,2- and *sn*-2,3-DAG recovered in the X-1,3-DAG fraction during borate thin-layer chromatography. Chiral-phase HPLC conditions as in Figure 4. LC/MS conditions as given in Experimental Procedures section. A, selected ion [*m/z* 921] profile corresponding to 22:6-22:6 species of DAG; B, total ion spectrum of peak corresponding to *sn*-1,2-enantiomers; C, total ion spectrum of peak corresponding *sn*-2,3-enantiomers. See Figures 1 and 4 for other abbreviations.

22:6n-3 acids are located mainly in the *sn*-2 and *sn*-3 positions (17,18), with the *sn*-1 position being relatively deficient in these acids (17). These findings have led to the observation that the fish oil and mother's milk on digestion would provide polyunsaturated 2-MAG, which would promote the recovery of these acids in the chylomicron TAG (19). On this basis, the oils rich in 20:4 (E and F) and 22:6 (C and D) would also yield high proportions of n-3 and n-6 polyunsaturated 2-MAG. In contrast to mother's milk, the present oils contain also high proportions of polyunsaturated fatty acids in the *sn*-1 position of the glycerol molecule. The metabolic significance of the location of the polyunsaturated fatty acids in the *sn*-1 position of the glycerol molecule is not known. Sample A oil is unusual in the content of comparable proportions of 20:4 in all three positions of the glycerol molecule. It would probably resemble the E and F in its metabolic fate.

These oils enriched in 20:4 and 22:6 acids also possess the unusual feature of containing significant amounts of TAG with two polyunsaturated long-chain fatty acids per molecule. In short-term incubations, pancreatic lipase discriminates against polyunsaturated long-chain fatty acid esters (20,21), but it is not known if this discrimination is more serious when two or three long-chain acids are present in a TAG molecule. During the present stereospecific analyses, there was a clear evidence for discrimination against the polyunsaturated TAG at early times, while at later times 2-MAG of representative composition were obtained.

The positional location and molecular association of long-chain polyunsaturated fatty acids may be pertinent to the resistance of these oils to peroxidation. Recent work has suggested (22) that a polyunsaturated fatty acid in the 2-position is more vulnerable to peroxidation than a similar fatty acid in the primary position. Assuming a fork shape for the TAG molecule, polyunsaturated fatty acids in the primary positions were thought to interact for mutual protection against oxidation. These observations are contradictory to earlier findings, showing that polyunsaturated acids in the primary positions were more vulnerable to peroxidation (23,24). Perhaps the protective interaction between the polyunsaturates in the primary positions is observed only when both are present in the same TAG molecule. The effect of the structural features of these unusual oils upon intestinal digestion and absorption, and upon peroxidation are subject to experimental determination and correlation with the positional distribution of the fatty acids.

Quantitative High-Performance Liquid Chromatography Analysis of Plant Phospholipids and Glycolipids Using Light-Scattering Detection

G.A. Picchioni[a,*], A.E. Watada[b], and B.D. Whitaker[b]

[a]Department of Agricultural Sciences, Technology, and Education, Louisiana Tech University, Ruston, Louisiana 71272 and [b]Horticultural Crops Quality Laboratory, Beltsville Agricultural Research Center, U.S. Department of Agriculture, Beltsville, Maryland 20705

ABSTRACT: Application of the evaporative light-scattering principle to quantitative high-performance liquid chromatography (HPLC) analyses of plant membrane lipids has received little study. Light-scattering detection response curves were generated for nine classes of plant membrane phospholipid and glycolipids. Quantitative results obtained by HPLC/light-scattering detection and conventional lipid analytical methods (thin-layer chromatography and lipid-P assay) were in close agreement, confirming the reliability of HPLC/evaporative light-scattering detection (ELSD) analyses. Only three of the nine plant lipid classes gave linear detector response functions above 10 μg injected lipid mass. This finding contradicts earlier precepts involving light-scattering detection of lipids. At a given mass, appreciable variation in ELSD signal intensity and detection limit was found to exist among the various plant membrane lipid classes. The variation in detector response among plant lipid classes is an important consideration in achieving accurate quantitative results in plant lipid analyses.
Lipids 31, 217–221 (1996).

The availability of an efficient method to quantify plant phospholipid and glycolipid classes would aid in our understanding of the vital functions that these membrane structural components fulfill in plant tissues. Traditionally, thin-layer chromatography (TLC) has been used to isolate and quantify complex lipids, but quantification may be time-consuming, tedious, and labor-intensive (1,2).

High-performance liquid chromatography (HPLC) has become an important tool for the separation and analysis of phospholipids and glycolipids. Since total plant lipid extracts are diverse, gradient elution procedures are necessary to achieve effective separations (3), and this may present detection difficulties in quantitative analyses. These problems have been discussed in detail, particularly regarding ultraviolet, refractive index, and fluorescence detection of lipids (4,5). The recent introduction of evaporative light-scattering (ELS) detectors, which are largely unaffected by changes in mobile phase composition, has surmounted these difficulties and offers new opportunities for quantitative lipid class analyses (6).

Several applications of HPLC/ELS detection in quantitative analyses of neutral and polar lipid classes from animal tissues are available (5,7,8). More recent accounts of HPLC separation and ELS detection have included the analysis of phospholipids from seed oils (6,9) and of both phospholipids and glycolipids from wheat flour (10). Such reports reveal major differences in lipid class profiles between these sources and higher plant tissues. Quantitative data for phospholipid and glycolipid classes in plant tissues obtained by using ELS detection are unavailable. Moreau (11) demonstrated that this detection technique may be useful in neutral lipid, glycolipid, and phospholipid separation of plant tissues, but this report did not provide quantitative analyses.

It has been demonstrated that ELS detector sensitivity may vary among characteristic animal lipid classes (5). This finding could have an important bearing on quantification of plant lipid classes, particularly those present in low concentrations in tissue. The objectives of this study were to evaluate possible variation among plant phospholipid and glycolipid classes in ELS detector response, and to compare quantitative analyses of plant membrane lipid classes between HPLC/ELSD and conventional lipid analytical procedures.

MATERIALS AND METHODS

Plant material and sample preparation. Carrots (*Daucus carota* L. "Apache") were purchased from a local produce distributor and mature apple fruit (*Malus domestica* Borkh. "Red Delicious" and "Golden Delicious") were obtained from a nearby orchard.

Peeled and shredded carrots, and the outer 2–3 mm of cortical tissue of apple fruit (obtained after peeling the fruit) were frozen in liquid N_2 and lyophilized. Total lipid extracts were obtained from dried, powdered subsamples (200 mg for

carrot, 500 mg for apple) which were homogenized in 10 mL chloroform/meth-anol (2:1, vol, vol), then washed using the methods of Folch *et al.* (12). The total lipid extract was separated into glycolipid and phospholipid fractions using solid-phase extraction, and these fractions were prepared for HPLC analyses as described previously (13,14).

HPLC system. Component classes in glycolipid and phospholipid fractions were separated by normal-phase HPLC using a 10 cm × 3 mm, 5-μm ChromSep LiChrosorb Si 60 silica cartridge (Chrompak, Raritan, NJ). Samples (100 μL) were introduced using a WISP 712 programmable injector (Waters, Milford, MA). The injector also served to initialize a Waters 600E solvent delivery system and personal computer for data acquisition at the beginning of each analysis. Maxima 820 software (Dynamics Solutions, Millipore Corp., Ventura, CA) was used for peak integration, generation of calibration curves and regression coefficients, and the determination of plant lipid class concentrations.

The mobile phases for glycolipid and phospholipid elutions were modified from the ternary gradient systems developed by Moreau *et al.* (15) and Letter (16) using 2-propanol, hexane, and water, with the elution schemes described previously (13,14). All solvents were continuously sparged with He (20 mL/min), and the solvent mixture was maintained at a flow rate of 0.5 mL/min.

Lipid classes were detected using a Varex IIA ELS detector (Varex Corp., Burtonsville, MD). The N_2 flow rate was maintained at 2.5 L/min, and the drift tube temperature was held at 90°C throughout all analyses. Calibration curves were generated by injecting a concentration series of authentic lipid class standards. Calibration data were log-transformed, and comparisons of the slopes and intercepts from the various lipid classes were made using the method of Snedecor and Cochran (17) on MSTAT-C, version 2.11 (Michigan State University, East Lansing, MI).

Solvents and lipid calibration standards. Phospholipid standards [phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylcholine (PC), lysophosphatidylcholine (LPC), and phosphatidic acid (PA)] were obtained from Sigma Chemical Co. (St. Louis, MO) and were derived from soybean, except for PA which was derived from egg yolk lecithin. Preliminary analyses on HPLC confirmed that the commercial source of PA coeluted with PA isolated from plant tissue by TLC.

Glycolipid standards [monogalactosyldiacylglycerol (MGDG), digalactosyldiacylglycerol (DGDG), sterol glycoside (SG), and acylated sterol glycoside (ASG)] were purchased from Matreya (Pleasant Gap, PA) and were of plant origin (plant species unknown). MGDG and DGDG were completely hydrogenated (saturated acyl groups). Preliminary comparisons with highly unsaturated MGDG and DGDG (isolated from plant tissue by TLC) showed that HPLC separation and quantification of MGDG and DGDG were unaffected by fatty acid unsaturation.

HPLC-grade solvents (2-propanol and hexane) were from Mallinckrodt Specialty Chemicals, Inc. (Paris, KY). Water was purified using a Nanopure II system (Barnstead, Boston, MA), then passed through a 0.22-μm Nitroplus cellulose filter (Micron Separations, Inc., Westboro, MA) before use.

TLC and lipid-P analyses. Quantitative tissue analyses of HPLC and one-dimensional TLC analyses were compared for ASG, SG, and MGDG. Aliquots of glycolipid fractions were loaded onto 10 × 20 cm TLC plates coated with a 0.25-mm thickness of silica gel 60 (EM Science, Cherry Hill, NJ). Glycolipids were separated using a solvent mixture of chloroform/ethyl acetate/methanol/acetic acid/water (120:20:40:20:4, by vol). All TLC solvents were HPLC-grade and were obtained from Burdick and Jackson (Muskegon, MI). Spots were identified, eluted from the gel, and the lipids quantified as described by Whitaker (18).

Total lipid-P was determined on duplicate, 20-μL aliquots of the plant phospholipid fractions by the method of Ames (19). The total phospholipid mass in each sample was then calculated using an average molecular weight of 750.

Results obtained from TLC (glycolipid fractions only) and total lipid-P determinations were compared with quantitative HPLC results using student's *t*-tests and linear regression, respectively.

RESULTS AND DISCUSSION

Relationship between lipid class and ELS detector response. Second-order polynomial or linear regression calibration curves provided regression coefficients (r^2) of 0.98 or greater for all lipid classes (data not shown), but detector response varied between classes (Figs. 1 and 2). At masses greater than approximately 10 μg, linear response functions were obtained only for PI, PC, and DGDG. The remaining lipid classes (PE, LPC, PA, MGDG, SG, and ASG) produced exponential functions at masses up to 80 μg. Although we could find no prior documentation of calibration curves for each of these lipid classes in a single report, this finding contradicts the generalization that ELS detectors provide linear responses for lipids at masses of 10 μg and above (4,10,16).

Log-transformed data of Figures 1 and 2 provided linear functions for each lipid class, but the slopes were not parallel (Table 1). The lipid classes yielding exponential curves above 10 μg had greater slopes on log/log plots than did lipid classes giving linear curves above 10 μg. The greater slopes for PA and ASG were the result of relatively low detector sensitivity for these classes at low injected masses as compared to the other lipid classes in their respective groups (see insets in Figs. 1 and 2). This is further indicated by the low y-intercept values for PA and ASG. Peak areas of PA and ASG never reached the levels of their counterpart lipid classes even with 80-μg injections, indicating relatively low detector sensitivity for these lipid classes.

Variation in ELSD response among lipid classes at equivalent masses may partly result from differences in lipid-specific particle sizes which result in different amounts of light scattering (16). Such variation should be expected when considering the large molecular size variation among the lipid

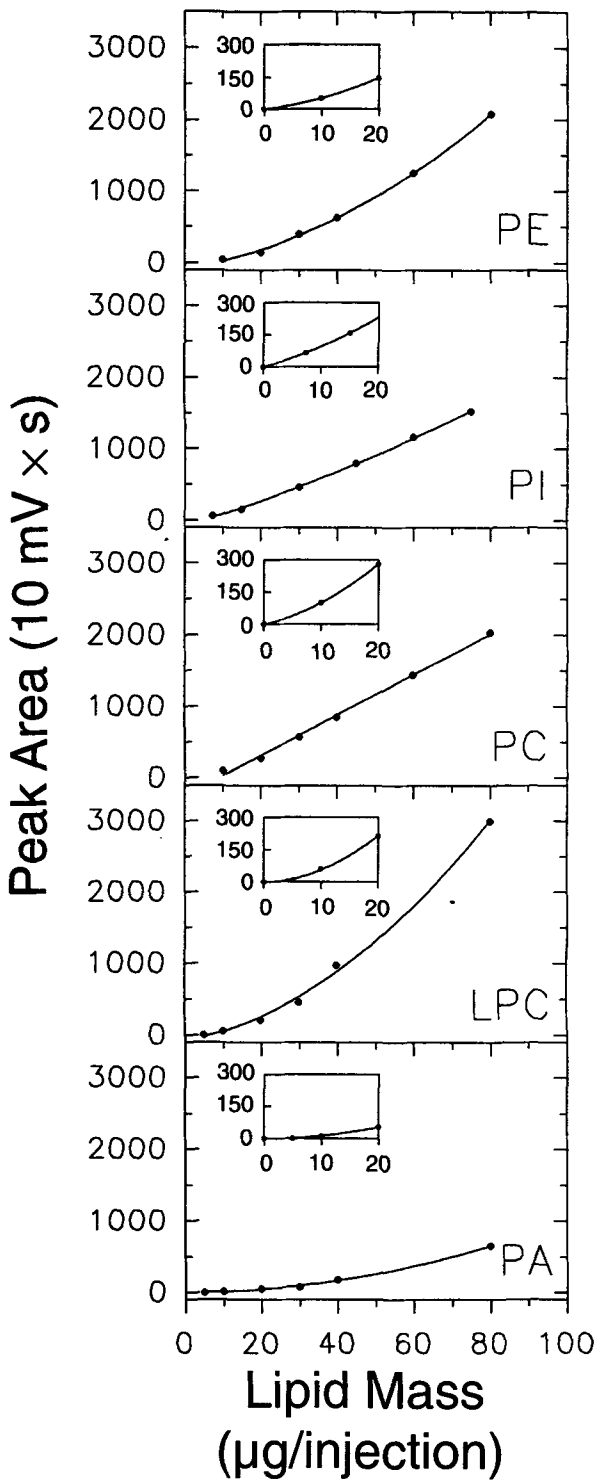

FIG. 1. Phospholipid class calibration curves of mass injected vs. detector response. Each point represents the mean of duplicate injections. Insets are expanded portions of the curves below 20 µg. classes analyzed in our study (up to 45% differences in formula weights).

Detection limits for PE, PI, PC, LPC, DGDG, MGDG, and SG ranged between 250 and 500 ng. However, the detector showed reduced sensitivity and lower peak height/background ratios for PA and ASG, and we were unable to obtain reliable detection below 1 µg for these two classes. Lower limits of lipid detection with ELSD have been documented (5,16), but these reports included analyses of neutral lipid classes. Neutral lipids elicit greater ELSD responses than polar lipids (8); thus these studies did not fully assess the potential of ELS detection for the variety of plant lipid classes used in our study.

Lipid quantification by HPLC/ELSD and conventional procedures. Quantitative HPLC results for glycolipids were

[a]Values within columns and lipid class groups with the same letter are not significantly different by F-test ($P \leq 0.05$). PI, phosphatidylinositol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; LPC, lysophosphatidylcholine; PA, phosphatidic acid; DGDG, digalactosyldiacylglycerol; MGDG, monogalactosyldiacylglycerol; SG, sterol glycoside; ASG, acylated sterol glycoside.

TABLE 2
Glycolipid Class Concentrations of "Red Delicious" Apple Fruit Determined After One-Dimensional TLC and After HPLC[a]

Glycolipid class	Glycolipid concentration (mg/100 g dry tissue weight) HPLC	TLC
ASG	6.7 ± 0.5 (7.5)	7.7 ± 1.6 (20.7)
SG	29.7 ± 1.5 (5.1)	26.4 ± 3.3 (12.5)
MGDG	20.2 ± 1.3 (6.4)	19.0 ± 3.6 (18.9)[b]

[a]Values are the mean ± standard deviation of three determinations on separate fruit, each representing a paired analysis of the same tissue sample. Means between columns are not significantly different by *t*-test at the 5% level. Numbers in parentheses refer to coefficient of variation (%). HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography. See Table 1 for other abbreviations.
[b]Mass determined by multiplying molar values obtained following spectrophotometric assay (Ref. 18) by a molecular weight of 772.

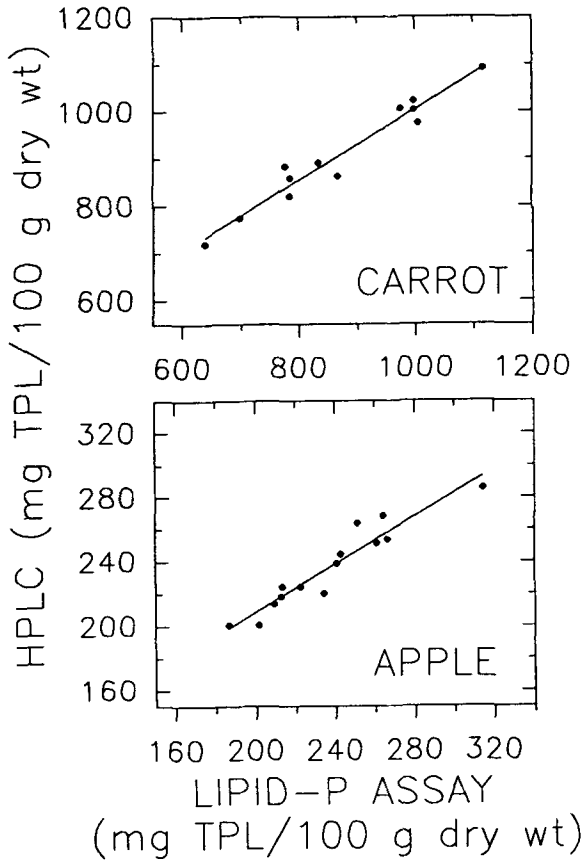

FIG. 3. Total phospholipid mass (TPL) of "Apache" carrot and "Golden Delicious" apple tissues determined by lipid-P assay and by summation of individual phospholipid masses determined by high-performance liquid chromatography (HPLC) peak integration. Regression equations as follows: $y = 256 + 0.75x$, $r = 0.97$, $N = 12$ (carrot); $y = 61 + 0.74x$, $r = 0.95$, $N = 14$ (apple). Each point represents a paired analysis of the same tissue sample.

in close agreement with one-dimensional TLC analyses (Table 2). Method averages did not differ significantly ($P \leq 0.05$), but variability was 2.5 to 3 times greater for the TLC averages. The increased variability with TLC probably resulted from the greater number of sources of systematic error, such as in the quantitative scraping and eluting of silica gel and in the subsequent spectrophotometric assay.

Total phospholipid values obtained by conventional lipid-P analyses and by summation of individual phospholipid masses by HPLC peak integration were closely correlated (Fig. 3). The total mass of phospholipid determined by lipid-P analysis (as compared with HPLC analysis) averaged 95.6 ± 5.3% for carrot tissue and 100.1 ± 4.7 for apple tissue. The wide ranges of total phospholipid concentrations in both tissues were the result of endogenous phospholipid increases which occurred during previous experiments (13,14).

Quantitative HPLC data were reproducible, with coefficients of variation ranging from 1 to 5% during automated analyses lasting up to 48 h. Phillips *et al.* (20) reported a close correlation between HPLC/FID and TLC quantitative analyses of animal lipid classes. However, FID systems are more expensive and require more maintenance than ELSD (11). In addition, a new version of the Varex ELS detector (Model III) may provide greater detection sensitivity over FID detectors as well as the version used in our study (21; R. Moreau, personal communication).

In conclusion, results of this study confirm the usefulness of ELS detection in the quantitative analyses of plant membrane phospholipid and glycolipid classes. For most of the plant lipid classes evaluated, detection is a nonlinear function above approximately 10 to 20 μg of lipid mass. Also, ELS sensitivity and detection limits appear to vary ELSD among plant lipid classes. These findings, which have been largely overlooked to date, are important considerations in achieving accurate quantitative results in plant lipid analyses.

ACKNOWLEDGMENTS

Appreciation is extended to Williard Douglas and Arthur Reyes for their technical assistance, and to Robert Moreau for helpful comments. Use of a company or product name by the U.S. Department of Agriculture does not imply approval or recommendation of the product to the exclusion of others which may also be suitable.

Phosphatidylglycerol Molecular Species of Photosynthetic Membranes Analyzed by High-Performance Liquid Chromatography: Theoretical Considerations

Yinong Xu and Paul-André Siegenthaler*

Laboratoire de Physiologie Végétale, Université de Neuchâtel, rue CH-2007 Neuchâtel, Switzerland

ABSTRACT: A reversed-phase high-performance liquid chromatography technique was developed to separate, identify, and quantify individual phosphatidylglycerol (PG) molecular species in thylakoid membranes isolated from higher plant leaves. PG was first separated by thin-layer chromatography; then the dinitrobenzoyl derivatives of diacylglycerols produced after phospholipase C hydrolysis of PG were separated by a C_{18} reversed-phase column and detected at 254 nm. A linear response of the detector was observed in the range of 0.025 to 12 nmol of PG molecular species. It was established that there was an excellent correlation (r = 0.996) between the carbon and double-bond number in the aliphatic residues and the relative retention time of dinitrobenzoyl derivatives. A new equivalent carbon number value (ECN*) which takes into consideration the number of *cis*-(n_c) and *trans*-(n_t) double bonds per molecular species was defined as ECN* = CN − $2n_c$ − n_t, where CN is the number of carbon atoms in the aliphatic residues. The logarithm of the retention time increased linearily as a function of ECN* value. However, in this type of correlation, it may happen that two molecular species of PG having distinct relative retention times had the same ECN* value. In this case, the two molecular species can be identified by the linear correlation (r = 1) existing between the reciprocal of the relative retention time and the number of double bonds ($0 \leq n \leq 3$) in the separate 18:n/Δ3-*trans*-hexadecenoic acid [16:1(3*t*)] and 18:n/16:0 molecular species series. The advantages of this method are good separation, short elution time, quantitative precision, and predictable retention times of PG molecular species from chloroplast membranes. The method has been used routinely to identify the ten PG molecular species of thylakoid membranes in squash, potato, lettuce, and spinach leaf: 18:3/16:1(3*t*), 18:3/16:0, 18:2/16:1(3*t*), 18:2/16:0, 18:1/16:1(3*t*), 18:1/16:0, 18:0/16:1(3*t*), 18:0/16:0, 16:0/16:1(3*t*), and 16:0/16:0.

Lipids 31, 223–229 (1996).

Phosphatidylglycerol (PG) represents about 10 mol% of the total acyl lipids in thylakoid membranes of higher plants (1). In spite of its small proportion, this lipid is characterized by several unique and important features. First, PG is thought to be the only anionic phospholipid in higher plant thylakoid membranes (2). It is asymmetrically distributed across the membrane with a significant enrichment (69 mol%) in the outer monolayer (3). It also contains a special fatty acid, the Δ^3-*trans*-hexadecenoic acid [16:1(3*t*)], which is always linked to the glycerol molecule at the *sn*-2 position (4,5): There is evidence that 16:1(3*t*)-containing PG is involved in the molecular organization of the LHCII receptor complex (6). We have recently found that the phospholipid population which is located in the inner monolayer sustains most of the uncoupled noncyclic electron flow activity (3,7). Finally, because of its high-melting point fatty acids [16:0, 18:0, and 16:1(3*t*)] in plants sensitive to chilling, PG can form a gel phase in the membrane at cold temperatures and, consequently, induce chilling damage (8,9).

Thus far, most of the information about PG concerns its fatty acid composition. However, molecular species may be even more important than total fatty acid composition in the structure/function relationship of this lipid. Subtle differences in molecular species composition significantly may affect the physical properties and physiological activities of a membrane (10).

In order to separate, identify, and quantify the molecular species of PG, several methods have been proposed in the literature, e.g., thin-layer chromatography (TLC) on $AgNO_3$ in silica gel (5,11), capillary column gas chromatography using volatile derivatives and coupled gas chromatography/mass spectrometry (12). However, the argentation method cannot be used to resolve certain PG molecular species such as PG 16:0/16:0, 16:0/16:1(3*t*), 18:0/16:0, and 18:0/16:1(3t) (5). Kito *et al.* (13) have developed a sensitive method for the quantitative analysis of phospholipid molecular species by high-performance liquid chromatography (HPLC). Diacylglycerols (DAG) were prepared from phospholipids by phospholipase C (PLC) treatment and converted to the corresponding dinitrobenzoyl (DNB) derivatives which were detected at 254 nm. This method has been successfully used to analyze the molecular species of phosphatidylcholine and phosphatidylethanolamine extracted from animal cells (14).

Using the method described by Kito's group (13,14), we report here on the quantitative separation of PG molecular species in thylakoid membranes isolated from plant leaves. Based on the relationship between the number of carbon atoms as well as of double bonds and the relative retention time (RRT) of PG DNB derivatives, the corresponding molecular species of PG can be identified.

EXPERIMENTAL PROCEDURES

Chemicals. PLC, EC. 3.1.4.3 (grade 1, from *Bacillus cereus*) was from Boehringer Mannheim (Rotkreuz, Switzerland). Pyridine and 3,5-DNB chloride were provided by Fluka Chemie AG (Buchs, Switzerland), and diethyl ether extra pure, acetonitrile, and 2-propanol (gradient grade) were from Merck (Darmstadt, Germany). All other solvents were of reagent grade.

Plant material. Squash (*Cucurbita pepo* L. cv Quintal), potato (*Solanum tuberosum* L. cv Granola), and spinach (*Spinacia oleracea* L. cv Nobel) plants were grown in a growth chamber under the following conditions: 12 h of light (350 μmol • s^{-1} • m^{-2})/22°C/50% relative humidity and 12 h darkness/18°C/60% relative humidity. For squash plants, the two first leaves were harvested when the third leaf appeared (about two weeks after germination). For potato and spinach plants, mature leaves were harvested after about one month of growth. Lettuce (*Latuca sativa* L. cv Laitue Romaine de Morges) leaves were from the local market.

Preparation of thylakoid membranes. Deribbed leaves (about 30 g) were ground in a Waring Blender for 5 s in 160 mL of a grinding medium containing 330 mM sorbitol/30 mM 4-morpholinopropanesulfonic acid–KOH (pH 7.8)/2 mM. The mixture was filtered through six cheesecloth layers; then the filtrate was spun down at 1910 × *g* for 1 min. The supernatant was discarded by aspiration while the intact chloroplast pellet was resuspended in a lysis medium containing 10 mM *N*-Tris[hydroxymethyl]methylglycine–KOH (pH 7.8) first in 4 mL with a smooth brush, then in 30 mL. After 1 min, isomolarity was restored by adding 4 mL of 3 M sorbitol. The mixture was spun down at 4300 × *g* for 2 min. After discarding the supernatant by aspiration, thylakoids were resuspended in a washing medium containing 300 mM sorbitol/10 mM *N*-Tris[hydroxymethyl]methylglycine–KOH (pH 7.8) then sedimented for 2 min at 4300 × *g*. The thylakoid pellet was resuspended in the same washing medium and adjusted to 1 to 2 mg chlorophyll/mL. The chlorophyll concentration was determined according to Bruinsma (15).

Lipid extraction. To 1 mL of thylakoid suspension (1 to 2 mg chlorophyll/mL), 4 mL of chloroform/methanol (1:1, vol/vol) and 0.8 mL of 100 mM KCl were added. The mixture was centrifuged (1300 × *g* for 5 min). The lower phase was collected and dried under N_2. The pellet was resuspended in chloroform/methanol (8:2, vol/vol).

PG separation. The acyl lipids contained in the chloroform/methanol extract were separated by two-dimensional TLC on silica gel 60 plates (pre-coated silica gel plates, Merck 5626). The total lipid extract corresponding to 0.15 mg chlorophyll was spotted on the plate using an automatic sample applicator (Linomat IV; Camag, Switzerland). TLC plates were developed in acetone/toluene/water (91:30:8,by vol). After drying in an N_2 atmosphere, TLC were developed in the second dimension with a mobile phase consisting of chloroform/methanol/25% NH_3/water (65:35:2:3,by vol). Lipids were revealed with 0.01% primuline in acetone/H_2O (60:40, vol/vol) and the band corresponding to PG was scrapped and introduced into a glass tube. After the addition of 30 μg of distearoyl phosphatidylcholine as internal standard, the mixture was washed twice with chloroform/methanol (1:1, vol/vol) to eliminate silica gel then dried under N_2.

PLC treatment and preparation of DNB derivatives. The removal of the polar head groups of PG was achieved by treatment with the PLC and the preparation of the 3,5-DNB derivatives of PG was carried out according to the method of Kito *et al.* (13), however, with some modifications. The purified PG was resuspended by sonication in 1.25 mL of 10 mM Tris–HCl (pH 7.5) containing 30 mM H_3BO_3, 1 mM $ZnSO_4$, and 5 mM $CaCl_2$. After the addition of ten units of PLC (5 μL) and 2 mL of water-saturated diethyl ether, the tubes were shaken at 30°C for 60 min. The diethyl ether layer containing DAG was collected, whereas the remaining aqueous phase was washed twice with 2 mL of water-saturated diethyl ether. The diethyl ether fractions were then dried under N_2.

HPLC analysis of 3,5-DNB derivatives. HPLC was performed on a Kontron HPLC-system 400 with detection at 254 nm. The column used was the KS250/6/4/nucleosil 100-5C_{18} mounted with a guard column KS 11/6/4/nucleosil 120-7C_{18} from Macherey-Nagel (Düren, Germany). Elution was achieved isocratically with acetonitrile/2-propanol (80:20, vol/vol).

Fatty acid analysis. Each HPLC peak corresponding to 3,5-DNB PG derivative molecular species was collected and dried under N_2 flow. The fatty acid constituents of each PG derivative were transesterified with 5% H_2SO_4 in methanol at 85°C for 1 h under N_2 (1). The extraction of the methyl esters was achieved with 1.5 mL pentane after addition of 1 mL water. The extract was evaporated to dryness with N_2, taken up in 150 μL hexane and injected (5 μL) automatically into the gas chromatograph Hewlett-Packard 5890 (Palo Alto, CA) mounted with a capillary column Hewlett-Packard free fatty acid phase (30 m; i.d. 0.53 mm). The column was isothermically run at 190°C with helium as carrier (14.8 mL/min) while the detector (flame-ionization detector) was held at 230°C. Retention times of fatty acid methyl esters were compared with those of standard methyl esters of 18:0, 18:1, 18:2, 18:3, 16:0, and 16:1(3*t*), allowing the identification of the fatty acids contained in each HPLC peak. The quantification of fatty acids was carried out by adding a known amount (30 μg) of arachidic acid (20:0) in each sample, just before the transesterification step.

RESULTS AND DISCUSSION

Molecular species of thylakoid membrane PG in four plant species. Figure 1 shows the HPLC profile of 3,5-DNB deriv-

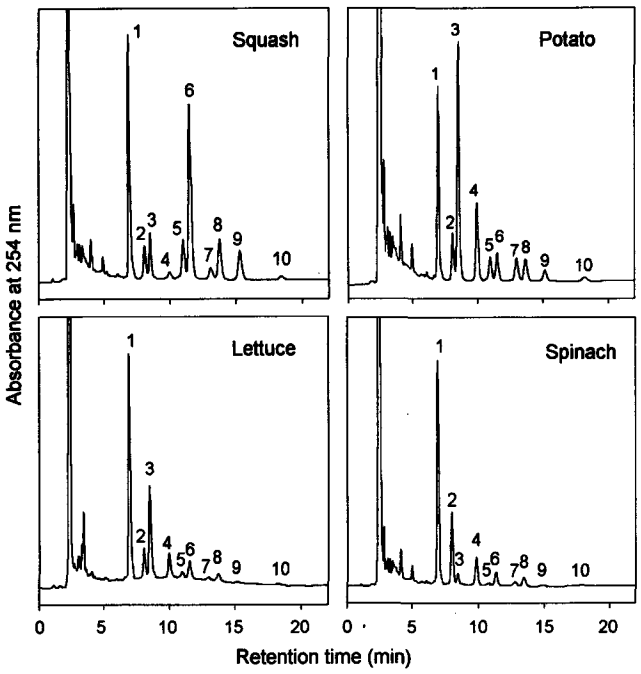

FIG. 1. High-performance liquid chromatography profile of 3,5-dinitrobenzoyl derivatives of phosphatidylglycerol isolated from thylakoid membranes of squash, potato, lettuce, and spinach. Peak numbers correspond to those in Tables 1 and 2. The retention time of the internal standard (3,5-dinitrobenzoyl derivative of 18:0/18:0 phosphatidylcholine) was 25.02 min (data not shown).

atives of DG isolated from thylakoid membranes of four plant species. All thylakoid membranes were characterized by ten HPLC peaks numbered from 1 to 10. It is noteworthy that, under our experimental conditions, all compounds were eluted from the HPLC column during 20 min only. The peaks appearing during the first 7 min were not due to lipid derivatives since an HPLC profile of a control sample (e.g., without added PG DNB derivatives) gave exactly the same profile as those illustrated in Figure 1 (results not shown). In addition, no methyl esters of fatty acids were detected by gas chromatography in the first fractions of the HPLC eluate. As an example, the composition in fatty acids of each HPLC peak from squash thylakoid PG (Fig. 1) is shown in Table 1. Each peak included two main fatty acids, except peak 8, which contained essentially 16:0. Within experimental errors, the amount of these two fatty acids was the same. However, each peak included small amounts of fatty acid contaminants due to manual collection of the eluted sample. In our hands, contaminants never exceeded 0.8 mol% of total PG (e.g., the contamination by 18:1 in peak 6). This indicates that each peak corresponded to one DNB–DAG molecular species. Table 1 also shows that each HPLC peak always contained either 16:0 or 16:1(3*t*) as one of the main fatty acids, the other one being a fatty acid in the C_{18} series, in agreement with the finding of Roughan (5). However, there are two exceptions to this general rule, i.e., peak 6 containing both 16:0 and 16:1(3*t*) and peak 8 containing essentially 16:0 (in double amount). Several authors have reported that in leaf PG of higher plants, the *sn*-1 position is occupied either by a fatty acid of the C_{18} series or by 16:0, whereas the *sn*-2 position always contains a fatty acid of the C_{16} series. This last finding has been verified by hydrolyzing the ester bond of PG at the position *sn*-2 with snake venom phospholipase A_2 according to Chapman and Barber (16). Moreover, when present, 16:1(3*t*) is always located at the *sn*-2 position (4,5,8,17). On the basis of these findings, it was possible to assign a PG molecular species to each of the HPLC peak, as illustrated in Table 1. It can be seen that about 50 mol% of PG in squash (a plant sensitive to chilling) thylakoid membranes contained highly saturated molecular species [e.g., 16:0/16:1(3*t*), 16:0/16:0, 18:0/16:1(3*t*), 18:0/16:0]. In contrast, the PG from potato, and even more from lettuce and spinach (chilling-resistant plants) thylakoid membranes, was characterized by much more unsaturated molecular species [e.g., 18:3/16:1(3*t*), 18:2/16:1(3*t*); see Fig. 1]. These results are qualitatively in agreement with earlier observations (12,18). However, Sekiya *et al.* (19) have reported that in leaves of various *Citrus* species, there are also additional mol-

[b]The *sn* position of fatty acids was not determined but assumed from other reports (see text); 16:1(3*t*), Δ^3-*trans*-hexadecenoic acid.
[c]The underlined numbers correspond to the main fatty acids in each peak.

ecular species, such as 18:3/18:3 and 18:2/18:3. These species are likely to originate from other leaf membranes.

Determination of the DNB–DAG molecular species by their HPLC retention time. Figure 2 shows the relationship between the logarithm of the retention time of 3,5-DNB derivatives of PG isolated from squash thylakoid membranes and the equivalent carbon number (ECN) value of each PG molecular species. The ECN value, which was thoroughly discussed by Christie (20), is defined as the actual number of carbon atoms in the aliphatic residues (CN) less twice the number of double bonds (n) per molecule (the carbons of the glycerol moiety are not counted for this purpose), i.e., ECN = CN – 2n. Though the ECN value was applied to triacylglycerol molecular species (for a review, see Christie, Ref. 20), we found that this relationship also applied to 3,5-DNB derivatives of phospholipids, provided that the influence of *trans*-double bonds, which are frequent in PG molecular species, is considered in a special manner. Based on the results shown in Table 2 and Figure 1, we propose a new formula expressing the actual number of carbon atoms: ECN* = CN – $2n_c - n_t$, where n_c and n_t correspond to the number of *cis*- and *trans*-double bonds per molecular species, respectively. For example, in the 18:3/16:1(3*t*) PG molecular species, ECN* = 34-6-1 = 27. Table 2 also shows that the retention time increased exponentially as a function of the ECN* values. Consequently, the logarithm of the retention time increased (apparently) linearily as a function of ECN* values as illustrated in Figure 2A (y = 0.059 × – 0.748; r = 0.996). However, two molecular species of PG [e.g., 18:1/16:1(3*t*) and 16:0/16:1(3*t*)] presented the same ECN* value (ECN* = 31) but were characterized by two different retention times. Similarly, two other species (18:1/16:0 and 16:0/16:0) also differing by their retention time, had the same ECN* value (ECN* = 32). This similarity can be explained by the fact that the retention time value is a precise experimental data while the ECN* value is an estimation of the ECN for which it was assumed that one *cis*- and one *trans*-double bond corresponded to two and one carbon, respectively. Thus, the two pairs of molecular species which have distinct retention time presented the same ECN* value.

As can be seen in Table 1, the ten PG molecular species, except 16:0/16:0 and 16:0/16:1(3*t*), can fit into the two series:

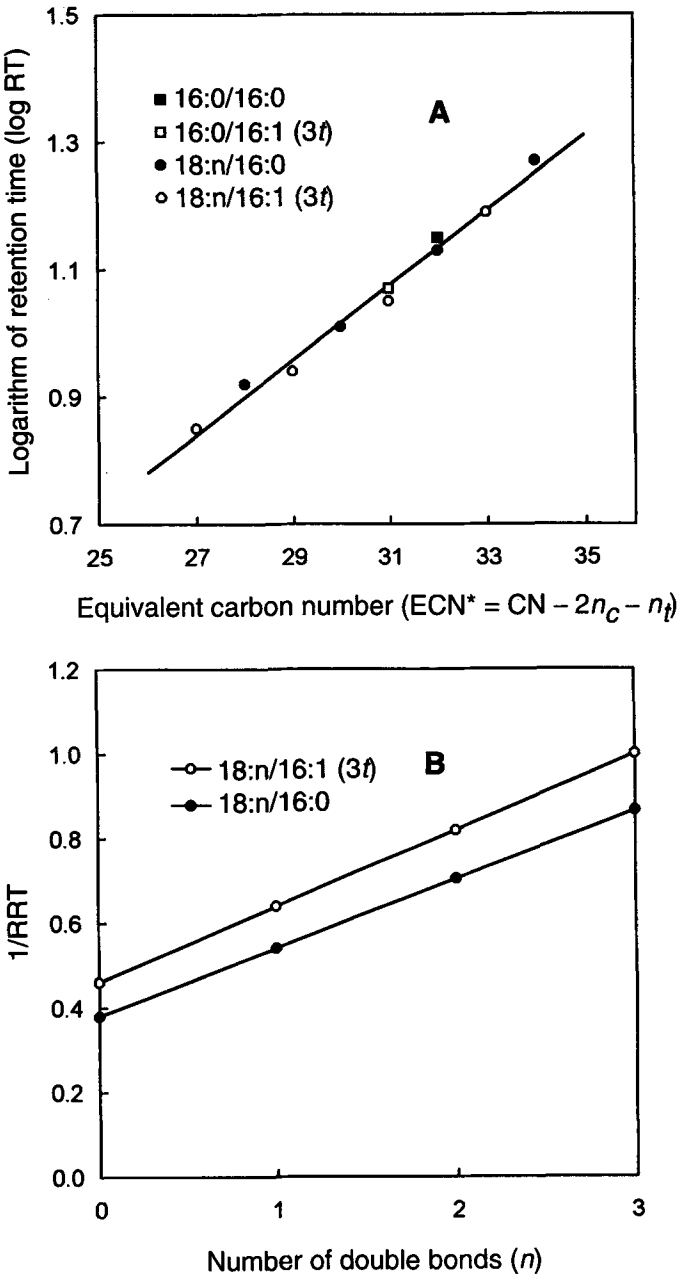

FIG. 2. A: Correlation between the logarithm of the retention time expressed in min (log RT) and the corrected equivalent carbon number (ECN*) in phosphatidylglycerol molecular species of squash thylakoid membranes. ●, 18:n/16:0; ○, 18:n/Δ^3-*trans*-hexadecenoic acid [16:1(3*t*)], ■, 16:0/16:0; □, 16:0/16:1(3*t*). B: Correlation between the reciprocal of the relative retention time (1/RRT) and the number of double bonds (n) in 18:n/16:0 (●) and 18:n/16:1(3*t*) (○) molecular species of phosphatidylglycerol.

TABLE 2
Relationship Between the ECN of PG Molecular Species and the Retention Time of 3,5-Dinitrobenzoyl Derivatives of PG Isolated from Squash Thylakoid Membranes

Peak number[a]	Molecular species	ECN*[b]	Retention time (min)	RRT[c]	1/RRT
1	18:3/16:1(3*t*)	27	7.03	1.00	1.000
2	18:3/16:0	28	8.10	1.15	0.868
3	18:2/16:1(3*t*)	29	8.60	1.22	0.817
4	18:2/16:0	30	9.94	1.41	0.707
5	18:1/16:1(3*t*)	31	11.09	1.58	0.634
6	16:0/16:1(3*t*)	31	11.62	1.65	0.605
7	18:1/16:0	32	12.94	1.84	0.543
8	16:0/16:0	32	13.45	1.91	0.523
9	18:0/16:1(3*t*)	33	15.35	2.18	0.458
10	18:0/16:0	34	18.47	2.63	0.381

[a]Peak numbers correspond to those indicated in Figure 1.
[b]A new equivalent carbon number (ECN*) value has been defined (see text).
[c]The relative retention time (RRT) was calculated in terms of the retention time of the first eluted component [i.e., 18:3/16:1(3*t*)]. See Table 1 for other abbreviations.

18:n/16:1(3*t*) and 18:n/16:0 where $0 \leq n \leq 3$. In each series, the characteristics of the molecular species are determined by the number of double bonds of the C_{18} -fatty acid at the *sn*-1 position. Figure 2B shows that for each of the above molecular species series, the reciprocal of the RRT and the number of double bonds in the two C_{18} series were linearly correlated, with a correlation coefficient (r) of 1. The general equation of the straight line is $1/RRT = an + b$, where n is the number of double bonds in the C_{18}-fatty acid series, b the reciprocal of the relative retention time of 18:0/16:1(3*t*) in the 18:n/16:1(3*t*) series and of 18:0/16:0 in the 18:n/16:0 series, and a the slope of the straight line. Based on the data shown in Table 2, one can calculate the equation of each straight line:

$$\text{for the 18:n/16:1(3}t\text{) series: } 1/RRT = 0.181n + 0.456 \quad [1]$$

$$\text{for the 18:n/16:0 series: } 1/RRT = 0.162n + 0.381 \quad [2]$$

The slope (a) of the straight line characterizing the 16:1(3*t*)-containing series is greater than that of the 16:0-containing series. This indicates that the two lines are not parallel and that the presence of a *trans*-double bond at the *sn*-2 position resulted in the decrease of the RRT of the corresponding DNB derivative molecular species in the HPLC reversed-phase column (see Fig. 2A). This observation suggests that the interactions of 16:1(3*t*) or 16:0 at the *sn*-2 with the other fatty acid partners (e.g., C_{18}:*n*) of a same PG molecular species toward the stationary phase of the HPLC column are different. Thus, different relative interactions between the double bonds may explain why two molecular species having the same ECN* value but a different number of double bonds can be easily separated in the HPLC reversed column, e.g., 18:1/16:1(3*t*) and 16:0/16:1(3*t*) as well as 18:1/16:0 and 16:0/16:0 (Table 2). In addition, two molecular species having the same ECN* value and the same double-bond number but a different distribution of the double bonds in the *sn*-1 and *sn*-2 position can also be separated in the HPLC column, e.g., the 18:2/18:2 and 18:3/18:1 molecular species of phosphatidylcholine (data not shown). The former species had a RRT smaller than that of the latter species. Thus, Figure 2B allows one to predict with great accuracy the composition of any PG molecular species having 18:n/16:0 or 18:n/16:1(3*t*) configuration ($0 \leq n \leq 3$).

Verification of the validity of the method. The above method which allows the separation and identification of 3,5-DNB derivatives of PG molecular species requires two critical steps. First, the removal of the polar head group (phosphoglycerol) by the hydrolysis of PG in the presence of PLC has to be complete. Figure 3 shows that with increasing concentrations of PLC there was a concomitant decrease in PG and an increase in DAG content up to a concentration of 160 mU of PLC/about 70 nmol of PG. Beyond this minimal concentration, the hydrolysis reaction was complete. In the method described, we propose to use 1 to 10 units of PLC/70 nmol PG. In comparison, Kito *et al.* (13) have reported that 200 units of PLC/0.5 mg (about 700 nmol) phosphatidylcholine were required in spite of the fact that phosphatidylcholine is a better substrate than PG for the PLC from *B. cereus* (21). Second, the transformation of the resulting DAG molecules into 3,5-DNB DAG also has to be complete without any modification of the fatty acid composition. Kito *et al.* (13) have demonstrated that under conditions identical to ours, 98.8% of the DAG are converted to 3,5-DNB–DAG. Furthermore, we have verified that the products of the enzymatic (DAG) and chemical (DNB–DAG) reactions have the same fatty acid composition as that of the initial phospholipid (PG) as illustrated in Figure 4.

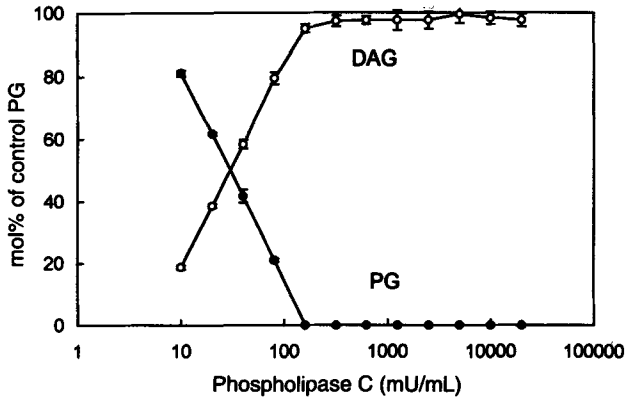

FIG. 3. Dependence of the formation of diacylglycerol (DAG; ○) from phosphatidylglycerol (PG; ●) on the concentration of phospholipase C. The results are presented as means ± standard deviation of triplicate samples.

Finally, it was necessary to verify that the areas of the HPLC peaks obtained at 254 nm are not affected by the differences in the structure of the PG molecular species. To this end, five samples of DNB–DAG corresponding to 2.5 (12.5 μg chlorophyll), 5 (25 μg), 10 (50 μg), 20 (100 μg), and 40 (200 μg) nmol were injected in the HPLC column. Figure 5

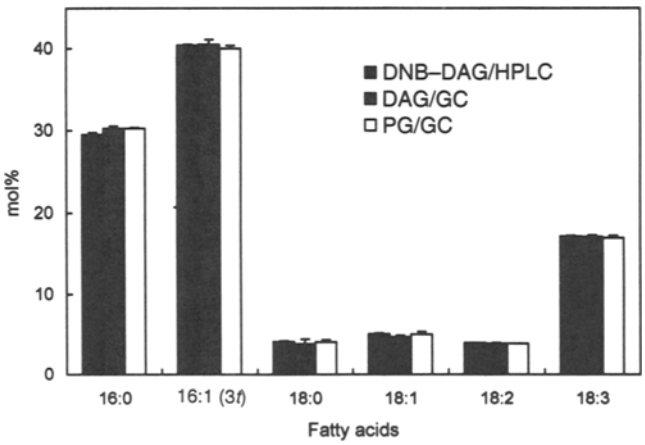

FIG. 4. Comparison of the fatty acid composition of PG, DAG obtained after phospholipase C treatment, and 3,5-dinitrobenzoyl–diacylglycerol (DNB–DAG) molecules obtained after derivatization. The fatty acid content in PG and DAG was measured by gas chromatography as described in the Experimental Procedures section. The fatty acid composition of DNB–DAG was calculated on the basis of the molecular species obtained by high-performance liquid chromatography (HPLC) (see Table 1). See Figure 3 for other abbreviations.

shows that the amount of DNB–DAG injected in the HPLC was linearly correlated with the peak area. This was true for the ten PG molecular species encountered in the thylakoid membranes of squash. From these data and those reported in Table 1, one can calculate the range limits within which the peak areas were proportional to the amounts of DNB–DAG. The upper limit (see arrow in Fig. 5) was found for the DNB–DAG [16:0/16:1(3*t*)] which corresponded to about 12 nmol (i.e., 40 nmol of DNB–DAG injected × 31 mol% of total PG/100 = 12.4 nmol). The lower limit (see arrow in Fig. 5) was obtained for the DNB–DAG (18:0/16:0) which corresponded to 0.025 nmol (i.e., 2.5 nmol of DNB–DAG injected × 1 mol% of total PG/100 = 0.025 nmol). Though not shown in Figure 5, the detection limit of DNB–DAG (18:0/16:0) can be lowered to 6 pmol, an amount which is generally sufficient for characterizing the PG molecular species in higher plants. When higher sensitivities are needed, new techniques such as electrospray mass spectrometry (22) or HPLC/mass spectrometry using electrospray ionization (23) allow the quantification of phospholipid molecular species as low as approximately 0.5 pmol (23).

Conclusions. The fact exists that PG molecular species encountered in photosynthetic membranes from higher plants contain, in addition to *cis*-double-bond fatty acids, one *trans*-double bond in 16:1(3*t*), required a new theoretical approach on the relationship between the HPLC experimental data (e.g., retention time or its reciprocal) and the structural characteristics of each molecular species (carbon and double-bond number). A new ECN value $ECN^* = CN - 2n_c - n_t$, where CN corresponds to the number of carbon atoms in the aliphatic residues and n_c and n_t to the number of *cis*- and *trans*-double bond per molecular species. Moreover, the ten PG molecular species, except 16:0/16:0 and 16:0/16:1(3*t*), fit into the two series: 18:n/16:1(3*t*) and 18:n/16:0 ($0 \leq n \leq 3$) where the characteristics of the molecular species are determined by the number of double bonds of the C_{18}-fatty acid at the *sn*-1 position. The reciprocal of the retention time and the number of double bonds in the two C_{18} series are linearly correlated (r = 1).

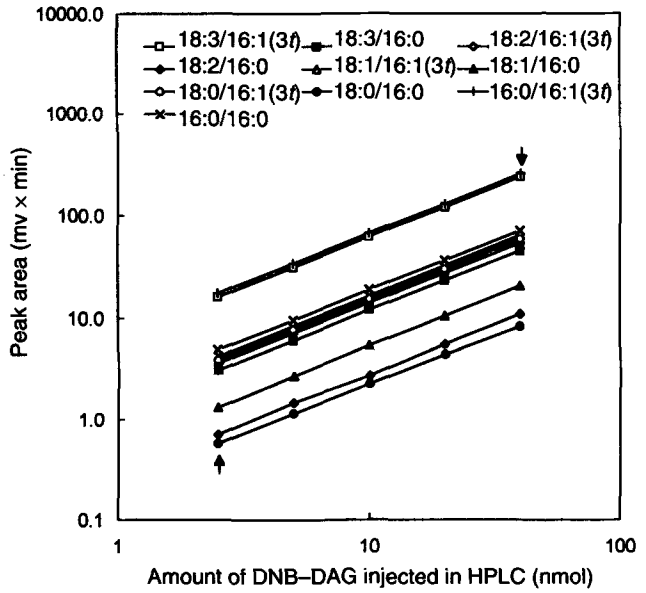

FIG. 5. Proportionality between the amounts of DNB–DAG injected in the HPLC column and the peak areas of each DNB–DAG molecular species. For further explanation, see the text. See Figures 3 and 4 for abbreviations.

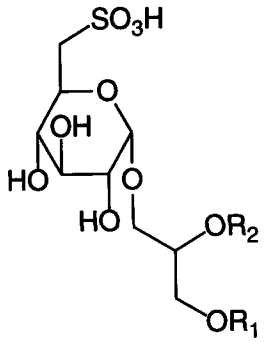
The Use of Nicotinates and Sulfoquinovosyl Monoacylglycerols in the Analysis of Monounsaturated n-3 Fatty Acids by Mass Spectrometry



Michael Keusgen[1], Jonathan M. Curtis, and Stephen W. Ayer*

Institute for Marine Biosciences, National Research Council of Canada, Halifax, Nova Scotia B3H 3Z1, Canada

ABSTRACT: Fatty acyl groups (16:1 and 16:0) liberated from purified sulfoquinovosyl diacylglycerols produced by the unicellular marine microalga, *Heterosigma carterae* (formerly *H. akashiwo*), were converted to either the corresponding alcohols or methyl esters. Nicotinate derivatives of the alcohols were examined by combined gas chromatography/mass spectrometry, and the methyl esters were examined by nuclear magnetic resonance (NMR) spectroscopy after separation by high-performance liquid chromatography. Three different hexadecenoyl fatty acyl groups were identified, one of which was *cis* 13-hexadecenoyl (16:1n-3). Both the configuration and the n-3 position of the double bond in the *cis* 13-hexadecenoyl moiety were unequivocally established by NMR analysis of the corresponding methyl ester. The nicotinate derived from the alcohol of the 16:1n-3 fatty acyl moiety gave a characteristic fragmentation series in the electron impact mass spectrum which, by careful interpretation, was consistent with, but not unambiguous for, the assigned location of the double bond. Tandem mass spectrometry experiments on a sulfoquinovosyl monoacylglycerol containing the *cis* 13-hexadecenoyl group in the *sn*-2 position, using negative-ion liquid secondary ion mass spectrometry, also gave a fragmentation pattern which was consistent with the positional assignment of the double bond.

Lipids 31, 231–238 (1996).

Due to their activity against the human immunodeficiency virus, sulfoquinovosyl diacylglycerols (SQDG) have attracted considerable attention in the past few years (1). SQDG are widely distributed in nature, occurring in most higher plants, algae, and in a purple nonsulfur bacterium. Because of the difficulties in separation and purification of the naturally-occurring mixtures of SQDG (for a general structure see Scheme 1), which differ only in the length and/or degree of unsaturation of the fatty acyl substituents, a practical and rapid method for the structural analysis of these substances has been elusive (2). As part of a program to develop such a general method, we have examined the complex mixture of unusual SQDG produced by *Heterosigma carterae* (formerly *H. akashiwo*) (3), a fish-killing microalga (4). One of the acyl groups liberated from the SQDG produced by *H. carterae* was identified as *cis* 13-hexadecenoyl, the structure determination of which is reported herein.

SCHEME 1

In the past, 13-hexadecenoic acid (16:1n-3) has been identified in lipids by gas chromatographic techniques (5–7). However, the fatty acid structural assignments were not always confirmed by nuclear magnetic resonance (NMR) techniques, nor by gas chromatography/mass spectrometry (GC/MS) experiments (i.e., preparation and analysis of suitable derivatives which could confirm the assumed structure by a specific fragmentation). In recent years, picolinyl ester derivatives of fatty acids and nicotinates of long-chain alcohols were found to be suitable for the positional determination of double bonds by mass spectrometry, and were tested for a number of standard compounds (8–12). However, because monounsaturated n-3 fatty acids or the analogous alcohols are not commercially available, these derivatization techniques have not been fully evaluated for such compounds (12). After submission of this report, it came to our attention that *cis* 15-octadecenoic acid (18:1n-3) is now available from Sigma Chemical Company (St. Louis, MO). In preliminary experiments, it was found that the fragmentation pattern in the electron impact (EI) mass spectrum of the nicotinate ester derivative of one of the three SQDG 16:1 acyl groups pro-

duced by *H. carterae* was ambiguous with respect to the double bond position (either n-3 or n-4). Furthermore, due to the lack of commercially-available standard fatty acids and alcohols, it was not possible to make the distinction between n-3 and n-4 monounsaturated nicotinates on the basis of their gas chromatography (GC) retention times. Thus, a simple interpretation of the EI mass spectra of nicotinate derivatives of n-3 and n-4 monounsaturated fatty alcohols may result in the wrong assignment—a problem which, to our knowledge, has not been previously reported. To overcome this problem, we have investigated, in detail, the fragmentation pattern for the nicotinate derivative of the *cis* 13-hexadecenoyl moiety liberated from *H. carterae* SQDG, and, more importantly, we unequivocally established the n-3 position of the double bond by NMR analysis of the corresponding methyl ester.

We have also utilized the sulfoquinovosyl moiety as a "natural derivative," which acts by localizing the negative charge at the sulfonic acid moiety, and hence might be suitable for the assignment of the double bond position in the attached fatty acyl group by MS. Although SQDG can potentially yield the required information *via* negative-ion tandem mass spectrometry (MS/MS), in experiments using liquid secondary ion mass spectrometry (LSIMS) ionization, the interpretation of the spectra in terms of the double bond positions is difficult because there are two fatty acyl chains involved in the SQDG structure (13). For this reason, an SQDG which contained the *cis* 13-hexadecenoyl moiety in the *sn*-2 position was converted to the corresponding sulfoquinovosyl monoacylglycerol (SQMG) by an enzymatic reaction (lipase type XI, specific for hydrolysis the *sn*-1 acyl moiety). The negative-ion LSIMS MS/MS spectrum of the resulting SQMG was compared with that of an SQMG containing the hexadecanoyl group in the *sn*-2 position. This latter substance was derived from SQDG isolated from the brown macroalga *Alaria esculenta*. It was shown that SQMG are suitable for the assignment of the double bond position in n-3 fatty acids.

MATERIALS AND METHODS

Extraction and isolation of (SQDG) from H. carterae *and* A. esculenta. Wet cell material of *H. carterae* (160 g, strain 102-R, cultivated in natural sea water) was extracted with 1 L of MeOH/$CHCl_3$ (7:3, vol/vol) for 30 min at 7°C. The mixture was bubbled with nitrogen and sonicated. The extract was filtered, and the residue was washed three times with 150 mL of MeOH/$CHCl_3$ (7:3, vol/vol). The combined filtrates were evaporated to dryness under reduced pressure to yield 8.4 g of crude extract. The extract was loaded on a silica gel column (30 mm i.d., 100 g silica gel) and the SQDG were eluted using a gradient consisting of the following steps: (i) 200 mL *n*-hexane/$CHCl_3$ (2:1, vol/vol); (ii) 250 mL $CHCl_3$; (iii) 250 mL $CHCl_3$/MeOH (3:1, vol/vol); (iv) 250 mL $CHCl_3$/MeOH (1:1, vol/vol); and (v) 500 mL MeOH. The separation was monitored by thin-layer chromatography (TLC). A total of 850 mg SQDG was isolated. The ^1H and ^{13}C NMR spectra of this mixture of SQDG were in accordance with published results (1,14).

The crude SQDG fraction was separated on a Nova-Pak C_{18} high-performance liquid chromatography column (7.8 mm i.d. × 300 mm; Waters Limited, Milford, MA) using a linear gradient from MeOH/H_2O (7:3, vol/vol) to 100% MeOH (3 mL/min; two Waters M6000 pumps combined with a gradient controller; Ultraviolet-detection at 215 nm with a Waters 484 UV-detector) to give 101 mg of SQDG, which contained the 16:1/16:0 fatty acyl pair (retention volume 113 mL). The identities of these fatty acyl moieties were confirmed by LSIMS. The resultant LSIMS MS/MS fragmentation was in accordance with published results (13).

The brown alga *A. esculenta* (275 g wet weight) was collected at Herring Cove near Halifax, Nova Scotia, Canada, in June 1994. Immediately after collection, the tissues were frozen in liquid nitrogen, ground in a blender in a frozen state, and then extracted with 1 L of MeOH/$CHCl_3$ (7:3, vol/vol). The crude extract was fractionated in the same way as described previously to yield 360 mg of a mixture of SQDG.

Reductive cleavage of SQDG (16:1/16:0 fatty acyl pair) from H. carterae: *Preparation of alcohols.* One hundred milligrams of $LiAlH_4$ were carefully added to diethyl ether (3 mL) and stirred until hydrogen evolution stopped. A solution of 15 mg SQDG (16:1/16:0 fatty acyl pair) in 1,4-dioxane (0.5 mL) was then added, and the mixture was stirred for 30 min under reflux. After cooling, the reaction mixture was carefully added to 10 mL ice-cold deionized water. The water layer was acidified to pH 1 with dilute sulfuric acid and then extracted five times with 20 mL of hexane. The combined hexane layers were dried over anhydrous Na_2SO_4, filtered, and evaporated under reduced pressure. The resulting colorless oil (5 mg) was examined by TLC (Merck Kieselgel 60 F_{254}, 0.25 mm layer; Merck, Darmstadt, Germany) and ^1H NMR (Bruker AMX 500; Bruker, Ontario, Canada). The TLC plates were developed with *n*-hexane/diethyl ether (3:1, vol/vol). After dipping in *p*-anisaldehyde/sulfuric acid/acetic acid/ethanol (2.7:3.3:1.1:93.0, by vol), and heating the plate, a single blue spot at $R_f = 0.21$ was observed. The ^1H NMR spectrum ($CDCl_3$) of this material shows, in addition to the typical signals for long-chain alkyl groups, a methylene triplet at δ 3.62 ppm, indicative of the newly formed mixture of 16:1/16:0 alcohols.

Conversion of nicotinic acid to the acid chloride. Two hundred milligrams of nicotinic acid (BDH Chemicals Ltd., Poole, Dorset, United Kingdom) and 0.5 mL of SO_2Cl_2 (Aldrich Chemical Co., Inc., Milwaukee, WI) were combined in a reaction vial and tightly sealed. The mixture was heated to 100°C for 10 min. After cooling, the remaining SO_2Cl_2 was removed with a stream of nitrogen. The final product formed colorless needles and sublimed easily. It was found to be suitable for the esterification reaction without recrystallization or sublimation.

Synthesis of the nicotinates. This procedure is based on the synthesis developed by Vetter and Meister (11). The mixture of 16:1 and 16:0 long-chain primary alcohols (5 mg) were dissolved in 0.5 mL anhydrous pyridine (Aldrich Chemical Co., Inc.) in a reaction vial. Nicotinyl chloride hydrochloride

(25 mg) was added and, after flushing with nitrogen, the vial was tightly sealed. The mixture was stirred at 100°C for 10 min. The resulting clear, slightly yellow solution was then added to an aqueous saturated NaCl solution (10 mL), and extracted five times with 10 mL of *n*-hexane. The combined hexane layers were dried over anhydrous Na_2SO_4. After filtration, the solvent was evaporated under reduced pressure to give 3 mg of a slightly yellow oil which was examined by ^1H NMR ($CDCl_3$). The methylene triplet (δ 3.62 ppm) had now shifted downfield to δ 4.37 ppm, indicating the successful formation of the nicotinate ester derivatives. The pyridine moieties of the formed nicotinates showed signals at δ 7.54, 8.45, 8.81, and 9.25 ppm. The crude mixture of 16:1 and 16:0 nicotinates was directly analyzed by GC/MS without further purification. The nicotinate derivatives of 16:1n-3 (100%), 16:1n-5 (20%), 16:1n-7 (20%), and 16:0 (130%) fatty alcohols were detected (ratios were determined from the total ion chromatogram peak areas, with the peak area for the 16:1n-3 nicotinate normalized to 100%). The individual nicotinates were not isolated.

Enzymatic cleavage of SQDG (16:1n-3/16:0 fatty acyl pair): Preparation of 16:1n-3 SQMG. The enzymatic digestion is based on the procedure described by Fischer, *et al.* (15). A portion of the SQDG sample (75 mg) containing the 16:1/16:0 fatty acyl pair isolated from *H. carterae* was separated into seven fractions on the Nova-Pak C_{18} column using a 30-min, 3 mL/min gradient consisting of MeOH/H_2O (9:1, vol/vol) isocratic for 5 min, then a linear increase to 9.4:0.6 MeOH/H_2O (vol/vol) over 15 min, then a linear increase to 9.5:0.5 (vol/vol) over 5 min, followed by a linear gradient over 5 min to 100% MeOH, and monitoring absorption at 215 nm. The fraction highly enriched in the SQDG with the 16:1n-3/16:0 fatty acyl pair (retention volume 62.1 mL) was identified by ^1H and ^{13}C NMR analysis, including ^1H–^1H COSY, heteronuclear multiple quantum correlation, and heteronuclear multiple bond correlation. A total of 3 mg of this fraction was dissolved in MeOH (0.5 mL), containing 1 mg of Triton X-100 (Union Carbide, Toronto, Ontario, Canada). The solvent was removed under a stream of nitrogen. The residue was dissolved in Tris buffer (0.5 mL, pH 7.4 at room temperature), and 5 mg of lipase solution (lipase type XI from *Rhizopus arrhizus*; Sigma Chemical Co., St. Louis, MO) was added. The mixture was stirred at 37°C for 15 min. The reaction was stopped by adding isopropanol (15 mL), and the solvent was evaporated to dryness under reduced pressure. The residue was loaded onto a flash column (8 mm i.d.) packed with 2.5 g of C_{18} derivatized silica gel (Baker, Toronto, Ontario, Canada) and eluted with water (25 mL) followed by MeOH (25 mL). The methanol fraction containing the 16:1n-3 SQMG was analyzed by LSIMS MS/MS.

Enzymatic cleavage of SQDG from A. esculenta: *Preparation of SQMG.* The crude mixture (3 mg) of SQDGs from *A. esculenta* was hydrolyzed in the same manner as described previously. The methanol fraction containing the SQMG was analyzed by LSIMS MS/MS.

SQDG: Preparation of fatty acid methyl esters. Fifteen

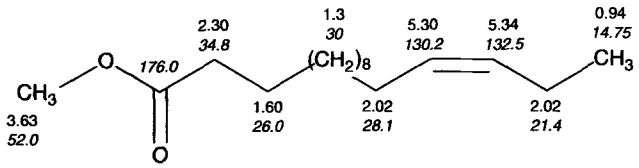

FIG. 1. Proton and ^{13}C assignments for *cis* 13-hexadecenoic acid methyl ester (CD_3OD). ^{13}C chemical shifts are in *italics*. The nuclear magnetic resonance (NMR) assignments were confirmed by two dimensional NMR experiments.

milligrams of the SQDG (16:1/16:0 fatty acyl pair) isolated from *H. carterae* were dissolved in absolute MeOH (5 mL) and a few drops of trifluoroacetic acid were added. After 5 min, the solvent was evaporated under reduced pressure, and the mixture was separated on the Nova-Pak C_{18} column using a 20 min linear gradient system of acetonitrile/H_2O (7:3, vol/vol) to 100% acetonitrile (3 mL/min), and compound detection was done at 215 and 230 nm with a Waters 994 diode array detector (the ratio of the peak intensities between 215 and 230 nm yields some information about the degree of unsaturation in the fatty acid methyl esters). A total of 2.2 mg of hexadecenoic acid methyl esters, comprised of about 70% *cis* 13-hexadecenoic acid methyl ester, was isolated (retention volume 81.6 mL). Further purification of this material by separation on a Zorbax R_X-C18 column (10 mm i.d. × 250 mm; MAC-MOD Analytical, Inc., Brockville, Ontario, Canada) using a linear gradient (3–17 min, 3.5 mL/min) from MeOH/H_2O (8:2, vol/vol, 0–3 min, 3.5 mL/min) to MeOH/H_2O (9:2, vol/vol, 17–30 min, 4.0 mL/min) gave 0.7 mg of *cis* 13-hexadecenoic acid methyl ester (retention volume 95 mL). The NMR assignments for this substance, obtained using COSY, heteronuclear multiple quantum correlation, and heteronuclear multiple quantum correlation and heteronuclear multiple bond correlation experiments, are given in Figure 1. The two remaining 16:1 fatty acid methyl esters were identified as the methyl esters of palmitoleic acid (*cis* 16:1n-7) and 11-hexadecenoic acid (16:1 n-5) (Keusgen, M., Curtis, J.M., and Ayer, S.W., unpublished data).

MS. All MS experiments were performed using a VG ZAB-EQ mass spectrometer (Fisons Instruments, Manchester, United Kingdom) controlled by the VG Opus software. All GC/MS experiments were done with a Hewlett-Packard (Avondale, PA) 5890 Series II gas chromatograph and on-column injector. A 30-m DB225 capillary column (J&W Scientific, Folsom, CA) with an i.d. of 0.25 mm and a film thickness of 0.25 μm was used. The gas chromatograph was operated in constant flow mode at a rate of 50 cm/s of He carrier gas. The temperature program was as follows: initial temperature 70°C for 1 min, ramp at 20°C/min to 180°C, ramp at 3°C/min to 240°C, and oven hold for 20 min. EI experiments were performed at an ion source temperature of 200°C and an ionizing electron energy of 70 eV. LSIMS experiments used a 20 keV beam of Cs^+ ions and a matrix of triethanolamine. MS/MS experiments were performed in the first field-free region by a linked scan at constant B/E using Ar collision gas

at a pressure which attenuated the ion beam by 50% and at a collision energy of 8 keV.

RESULTS AND DISCUSSION

Vetter and Meister (11) first described the use of nicotinates as derivatives for the structure elucidation of long-chain alcohols. Induced by a hydrogen transfer to the pyridine nitrogen, a fairly regular fragmentation series results due to remote-site radical-induced cleavages along the chain. Harvey (10) described a very similar fragmentation for picolinyl esters obtained from fatty acids. For the investigation of SQDG fatty acyl groups, reductive cleavage of the ester bonds and conversion of the formed alcohols into nicotinates was found to be the best procedure [use of the picolinyl ester methodology gave poor recovery of the polyunsaturated fatty acid derivatives (Keusgen, M., Curtis, J.M., and Ayer, S.W., manuscript in preparation)]. A major alcohol liberated in the investigated SQDG fraction from *H. carterae* was identified as *cis* 13-hexadecenol, as described later. The corresponding fatty acid is *cis* 13-hexadecenoic acid (*cis* 16:1n-3). The n-3 position and *cis* configuration of the carbon–carbon double bond were determined by NMR analysis of the methyl ester of this acid. In a ^{1}H NMR decoupling experiment, irradiation of the multiplet at δ 2.02 ppm (CD_3OD) furnished an AB spin system for the olefinic protons, with a coupling constant of J_{AB} = 10.8 Hz, a value typical for olefinic protons in the *cis* configuration (16). In the same experiment, the signal for the terminal methyl group collapsed to a singlet, a result which allowed unambiguous assignment of the n-3 position for the double bond. Additionally, the ^{1}H–^{1}H COSY spectrum of this methyl ester (Fig. 2) clearly shows cross peaks for correlation of the resonance for the terminal methyl group (δ 0.94 ppm) with the allylic protons resonating at δ 2.02 ppm. The ^{13}C NMR spectrum shows signals at δ 130.2 and 132.5 ppm, which are also characteristic for olefinic carbons in monounsaturated fatty acid methyl esters bearing olefinic protons in the *cis* configuration (Fig. 1) (17,18).

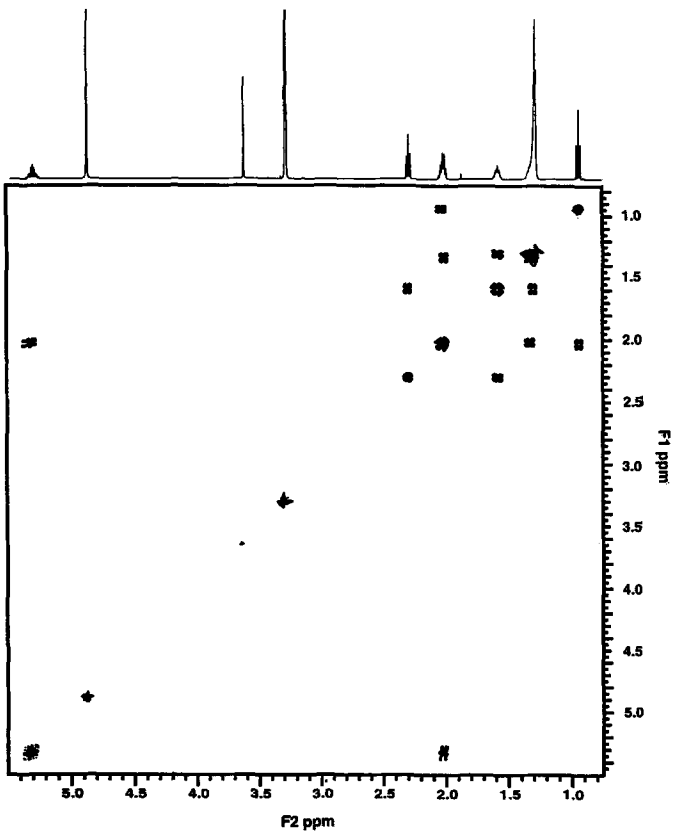

FIG. 2. Proton–proton COSY nuclear magnetic resonance (NMR) spectrum of *cis* 13-hexadecenoic acid methyl ester (CD_3OD) with the one-dimensional proton NMR spectrum positioned at the top of the COSY spectrum.

For the determination of the double bond position in monounsaturated fatty acids, a direct comparison between the derivatives of a saturated and monounsaturated fatty acids with the same number of carbons is helpful (e.g., 16:0, 16:1n-7, and 16:1n-3). Figure 3 shows mass spectra of the nicotinate esters of hexadecanol (Fig. 3A) and *cis* 9-hexadecenol (Fig. 3B), and Figure 4 shows the mass spectrum for the nicotinate ester of *cis* 13-hexadecenol. These nicotinates were resolved by GC (retention times of 22.6, 23.4, and 24.0 min, respectively), and were obtained after liberating the corresponding alcohols from the SQDG purified from extracts of *H. carterae*. For the nicotinate ester of hexadecanol, an ion at *m/z* 332, due to the loss of the terminal methyl group ($[M–CH_3^•]^+$), and an additional fragment ion at *m/z* 318, resulting from the loss of the terminal ethyl group ($[M–CH_3CH_2^•]^+$), are clearly visible. The spectrum also shows a remarkably distinct series of CH_2 losses from *m/z* 318 to 178, arising from remote-site radical-induced cleavages further along the alkyl chain. Note that the fragment ion at *m/z* 332 has a significantly lower intensity than the following ones (*m/z* 318 to 178). Below *m/z* 178, rearrangement processes reflecting hydrogen transfer onto the pyridine ring dominate. This results in the ions at *m/z* 165, 151, and 137 rather than at one amu lower as would be expected for simple remote-site radical-induced cleavages. The base peak ion at *m/z* 124 is characteristic for the nicotinates. Its formation can be rationalized by transfer of two hydrogen atoms and loss of the alkyl chain to give the *N*-protonated nicotinic acid (11).

It is well known that when the alkyl chain also contains a double bond, this pattern of peak intensities is changed (10–12). The published spectra of picolinyl and nicotinate ester derivatives of monounsaturated fatty acids and long chain alcohols, respectively [e.g., *cis* 9-octadecenoic acid (10) and *cis* 9-octadecenol (11)], clearly show that the fragment ions arising from the formal cleavage of the double bond (e.g., between a and a′, Fig. 3B) or vinylic cleavages (e.g., between a and b, or between a′ and b′, Fig. 3B) give weak signals. In contrast, peaks representing cleavages at the allylic positions (e.g., between b and c, or between b′ and c′, Fig. 3B) are clearly visible in the published spectra. In addition, the fragment ions resulting from cleavage on the distal side of the double bond (e.g., between b′ and c′, or c′ and d′, Fig. 3B), are significantly enhanced in intensity (10–12).

When there is a double bond in the n-3 position, as for the

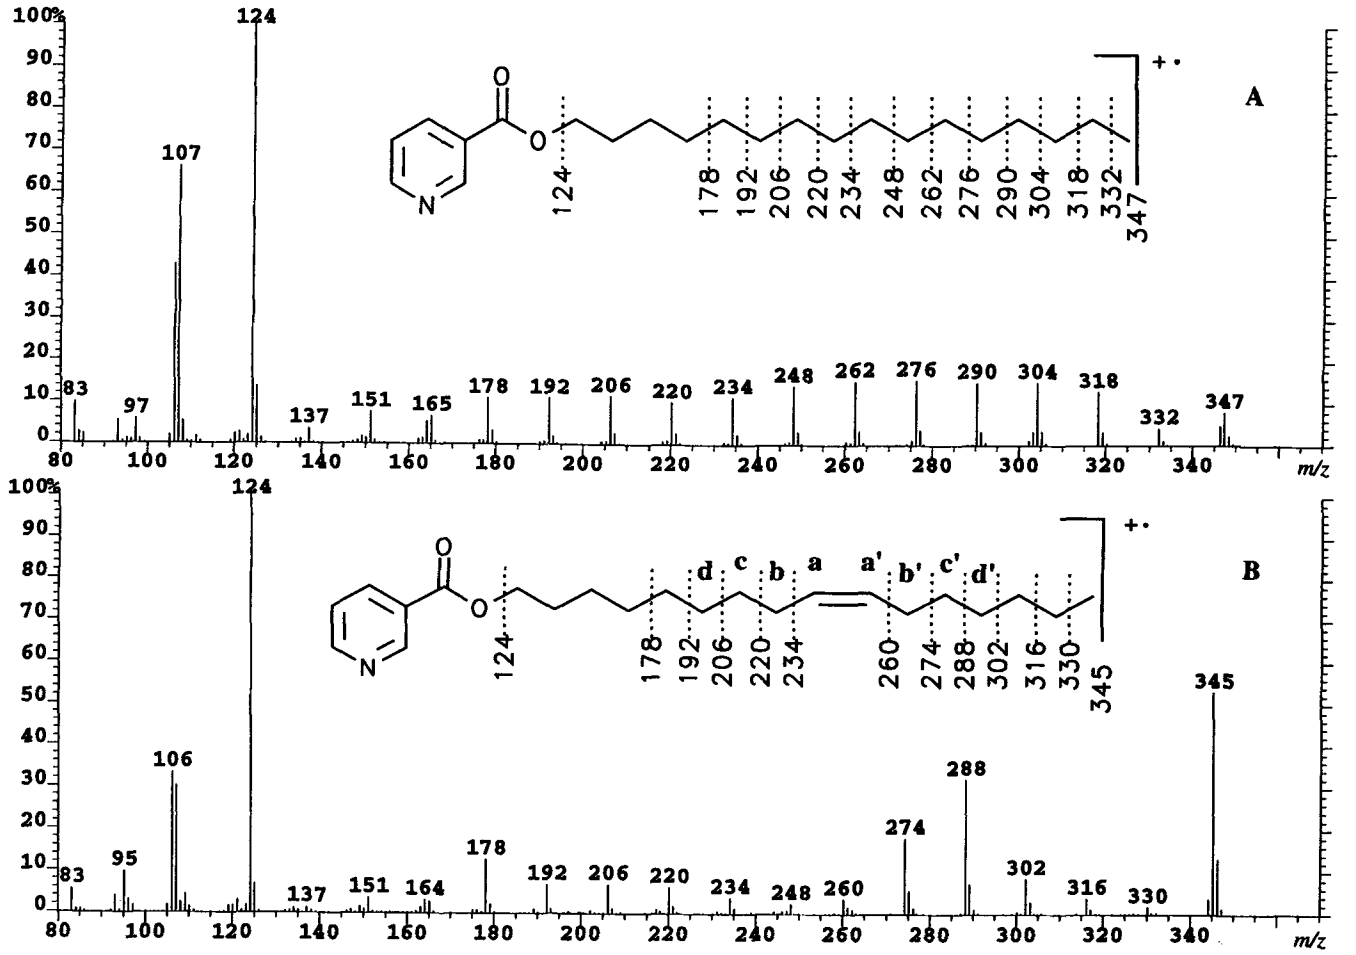

FIG. 3. The gas chromatography/mass spectrometry election impact mass spectra of the nicotinate derivatives obtained from (A) hexadecanol, and (B) *cis* 9-hexadecenol, by reductive cleavage of a sulfoquinovosyl monoacylglycerol followed by esterification.

nicotinate derivative of *cis* 13-hexadecenol, the results are less clear (Fig. 4). In this case, there are two superimposed effects on the relative fragment ion intensities which must be considered:—(i) for saturated alkyl chains, a relatively weak signal results from the loss of the terminal methyl group, while the signal coming from the loss of the terminal ethyl group is much stronger; and (ii) the fragment intensities resulting from cleavages at the isolated double bond, as described previously. From interpretation of the spectrum shown in Figure 4 based on literature precedent (8–11), and in comparison to Figure 3B, it would appear that the double bond is located at the n-4 position. Formal cleavage of the double bond would correspond to the low relative intensity cluster of fragment ions at *m/z* 290–288, and the relatively intense fragment ion at *m/z* 302 would correspond to a distal vinylic cleavage. In the present case, however, the nicotinate derivative is known to be that of an n-3 monounsaturated fatty alcohol (i.e., by interpretation of the NMR data for the *H. carterae* SQDG 16:1n-3 fatty acyl methyl ester derivative), and the correct interpretation could possibly be made by considering the regular fragmentation series from *m/z* 276–178, and the relative intensities of the *m/z* 330 and 316 fragment ions. If the double bond had been located in the n-4 position, the peak at *m/z* 276 would be expected to have a significantly weaker intensity than the following ones (*m/z* 262—178), as it would represent cleavage at a vinylic position. Additionally, Figure 4 shows that the peak at *m/z* 330, which represents the loss of the terminal methyl group, has nearly the same intensity as the peaks between *m/z* 276 and 178 (compared with the relative intensities of the analogous fragment ions at *m/z* 330, and between *m/z* 220 and 178, for the nicotinate derivative of the 16:1n-7 SQDG acyl moiety as shown in Fig. 3B). This enhanced relative intensity can be explained by the fact that the terminal methyl group is in an allylic position. In an analogous way, the fragment ion at *m/z* 274 in Figure 3B, which represents cleavage at the distal allylic position for the nicotinate ester of the 16:1n-7 SQDG fatty acyl group, also shows enhanced intensity. The signal at *m/z* 316 in Figure 4 represents a formal cleavage at the distal vinylic position. This type of fragmentation usually produces weak signals, but, in the case of the nicotinate ester of *cis* 13-hexadecenol, this signal has a high relative intensity, a result which is consistent with the EI mass spectral data reported for the picolinyl ester derivative of *cis* 15-octadecenoic acid

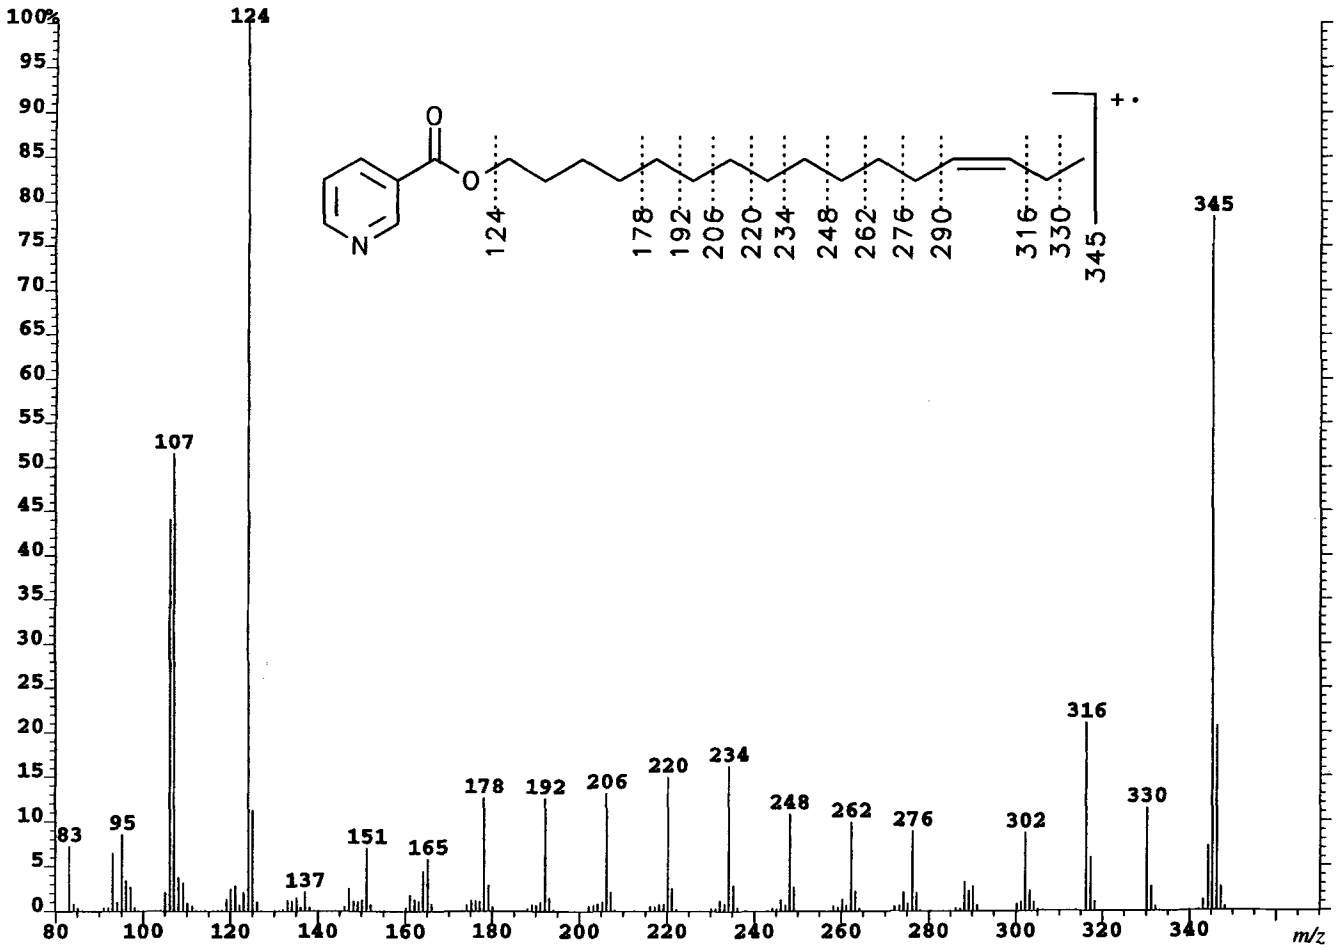

FIG. 4. The gas chromatography/mass spectrometry election impact mass spectrum of the nicotinate derivative obtained from *cis* 13-hexadecenol by reductive cleavage of a sulfoquinovosyl monoacylglycerol followed by esterification.

(18:1n-3) (12). The intensity of the fragment ion representing the distal vinylic cleavage may be expected to be weak for nicotinates with the double bond further up the chain. The ambiguous ions at *m/z* 290 or 288 are interpreted as arising as a result of cleavage at the interior vinylic position (expected to be of low relative intensity), and the ion at *m/z* 302 is interpreted as arising from cleavage of the double bond. The relative intensity of *m/z* 302 ion is certainly anomalous. In results for picolinyl ester and nicotinate derivatives of fatty acids which have been fully reported to date, the relative abundance of fragment ions resulting from cleavage of the double bond are usually the smallest of any neighboring fragment ions (8–11).

In summary, for the determination of the double bond location in nicotinates derived from monounsaturated fatty alcohols, it is essential to consider the relative peak intensities, in addition to the actual *m/z* values of the fragment ions. The identification of a mass difference of 26 amu, without considering the peak intensities, is not sufficient to unambiguously locate the carbon–carbon double bond position in the nicotinate ester of *cis* 13-hexadecenol. Of course, the ideal experiment would be comparison with the nicotinate of a standard fatty alcohol of the expected structure but, as stated previously, in the case of n-3 monounsaturated fatty acids and alcohols, these compounds are not commercially available. After submission of this report, it came to our attention that *cis* 15-octadecenoic acid (18:1n-3) is now available from Sigma Chemical Company (St. Louis, MO).

We have also evaluated an alternative approach to the identification of the n-3 unsaturated fatty acyl groups present in the SQDG isolated from *H. carterae*. Fischer *et al.* (15) described a reaction with a lipase produced by *Rhizopus arrhizus* which specifically catalyzes the removal of the fatty acid at the *sn*-1 position of SQDG to yield an SQMG. The fatty acid liberated by the enzyme also can be recovered and analyzed, if this is required, to complete the structural determination of the SQDG. This selective lipase reaction was applied to the SQDG isolated from *H. carterae* which contained the *cis* 13-hexadecenoic/hexadecanoic acid pairing. The mass spectrum of the resulting SQMG, obtained by LSIMS in the negative-ion mode using a triethanolamine matrix, showed a deprotonated molecular ion at *m/z* 553, indicating that the *cis* 13-hexadecenoic acid is attached to the *sn*-2 position of the glycerol moiety. The analogous SQMG with hexadecanoic acid at the *sn*-2 position was obtained from the SQDG fraction of the brown alga *A. esculenta* (*m/z* 555 for $[M - H]^-$).

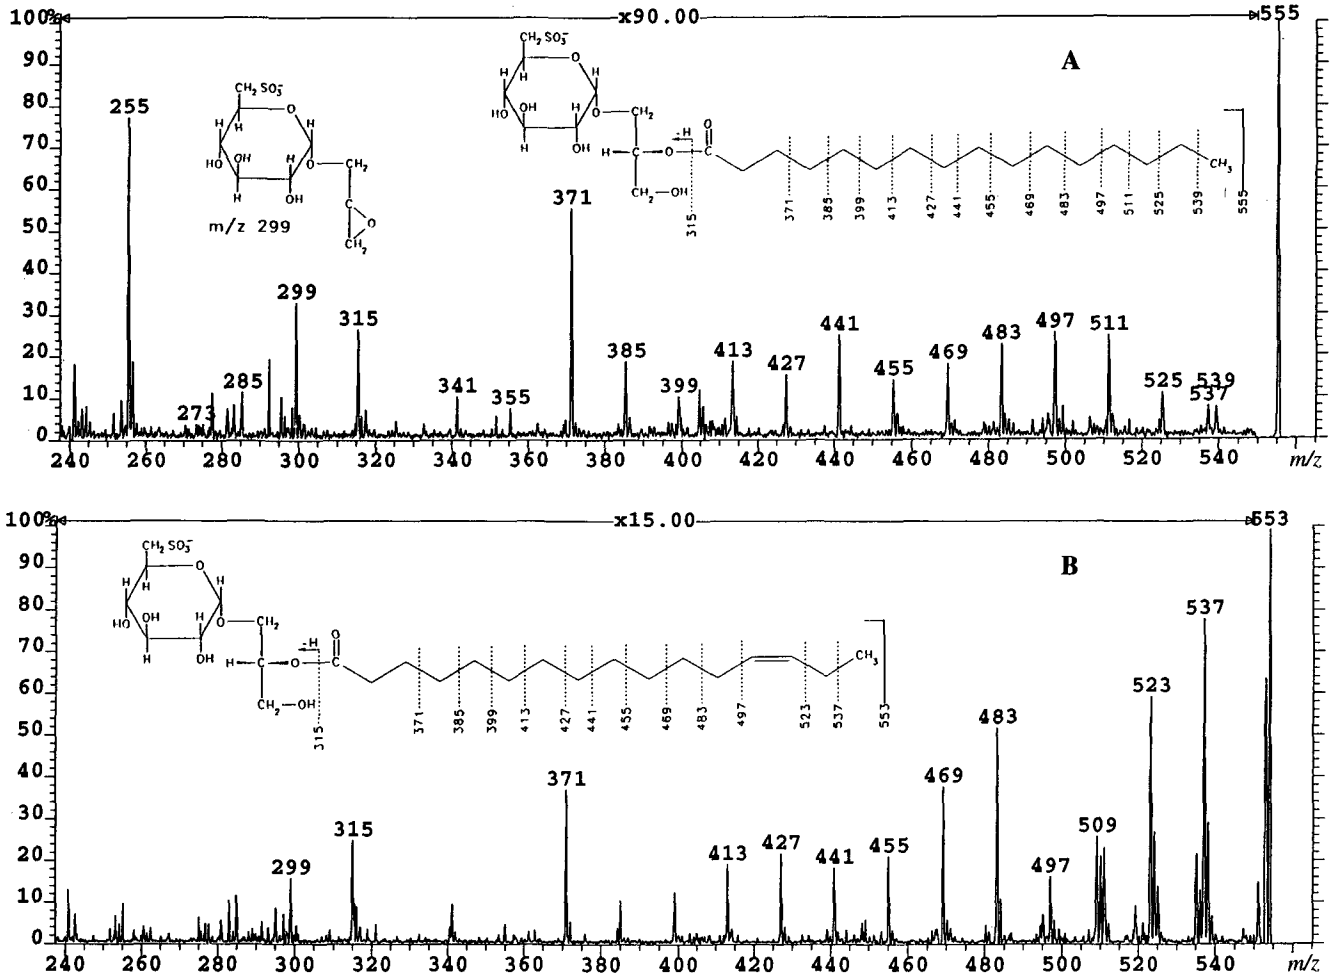

FIG. 5. The fragment ion mass spectra (liquid secondary ion tandem mass spectrometry) of a sulfoquinovosyl monoacylglycerol(SQMG) containing (A) hexadecanoyl, or (B) *cis* 13-hexadecenoyl, in the *sn*-2 position. The SQMG were obtained from the respective sulfoquinovosyl diacylglycerol by a lipase catalyzed reaction.

Because LSIMS produces little fragmentation and, hence, little structural information, it was necessary to induce fragmentation *via* collisionally-activated dissociation and record the fragment-ion spectrum (MS/MS). Due to the fact that the negative charge is localized on the sulfonic acid group, charge-remote fragmentation occurs along the alkyl chain (Fig. 5) in an analogous way to the remote-site radical-induced fragmentation observed in the positive-ion EI mass spectra of the nicotinates (Fig. 3). For SQDG, this type of fragmentation was first described by Gage *et al.* (13). However, without using the *sn*-1 deacylation, the resulting MS/MS spectra are very complex.

Figure 5A shows the negative-ion LSIMS MS/MS of the SQMG, which contains hexadecanoic acid. Starting from *m/z* 555 (the deprotonated molecular ion), a series of fragment ions is clearly visible. For a saturated fatty acyl chain this series can be explained by the loss of C_nH_{2n+2} (19,20). Thus, the loss of the terminal methyl group is manifested as a loss of CH_4 rather than $CH_3^{\bullet}$. The fragmentation of the acyl chain is fairly regular down to *m/z* 371. The spectrum also shows a significant peak at *m/z* 537, which can be explained by the formal loss of H_2O, and formation of a double bond at the glycerol backbone. Theoretically, a fragmentation series from this ion down to *m/z* 353 (signal at *m/z* 371 minus 18 amu) should be visible, but the intensities of the corresponding signals are very low. The fragment ion at *m/z* 299 has been proposed to arise from the formation of an epoxide ring (13).

Figure 5B shows the negative-ion LSIMS MS/MS of the SQMG containing *cis* 13-hexadecenoic acid. Starting from *m/z* 553, a series of fragment ions is also clearly visible. The loss of 26 amu rather than 28 for two methylene groups, and a perturbation in the fragment-ion intensity pattern, indicates the site of a double bond. In general, the peak pattern for the acyl chain fragmentation is analogous to that following EI ionization of the corresponding nicotinate (Fig. 4). The formal cleavage of the double bond yields somewhat ambiguous signals between *m/z* 509–511, but the following peak at *m/z* 497 shows a difference of 26 mass units to the peak at *m/z* 523 and indicates that the double bond is located at the n-3 position. Note that the cleavage adjacent to the double bond

(vinylic cleavage) results in a decreased ion intensity for the fragment ion at *m/z* 497 (Fig. 5B) in a similar way to that observed in positive-ion EI mass spectrum for the nicotinate derivative. From *m/z* 497, a series of fragment ions corresponding to the formal elimination of successive methylene groups is visible down to *m/z* 371, a series analogous to that shown in Figure 5A, and indicating a straight chain saturated alkyl group.

This work indicates the difficulties in assigning the double bond position in n-3 fatty acyl moieties, by MS alone, in the absence of standards. The assignments can only be achieved by careful attention to fragment-ion mass-to-charge ratios, and relative signal intensities within a series of remote-site radical-induced or charge-remote fragmentations. Even then, the distinction between n-3 and n-4 monounsaturation is difficult, and must be confirmed by NMR analysis. Mass spectral analysis of SQDG n-3 monounsaturated fatty acyl groups has been demonstrated using two distinct methods of analysis, namely GC/MS analysis of nicotinates using EI ionization, and negative-ion LSIMS MS/MS for SQMG obtained from the corresponding SQDG by selective enzymatic cleavage. The latter procedure also greatly simplifies the MS/MS spectrum over that of the native SQDG. The analysis of SQMG by negative-ion LSIMS MS/MS is an alternative method for determination of carbon–carbon double bond positions in the *sn*-2 fatty acyl chain of SQDG.

ACKNOWLEDGMENTS

We gratefully acknowledge Tony Windust for providing cultures of *H. carterae* and collecting *A. esculenta*, Carolyn Bird for the identification of *A. esculenta*, Mei Hong for technical assistance, and Dr. John A. Walter and Ping Seto for obtaining the NMR spectra. We thank Dr. Judy Needham and Dr. Archie McCulloch for critically reviewing the manuscript, and an anonymous reviewer for giving us many valuable comments and suggestions. This is NRCC publication number 38118.

REVIEW

n-3 Fatty Acids and Lipoproteins: Comparison of Results from Human and Animal Studies

William S. Harris*

Lipoprotein and Nutrition Research Laboratory, Department of Medicine, University of Kansas Medical Center, Kansas City, Kansas 66160-7418

ABSTRACT: The impact of n-3 fatty acids (FA) on blood lipoprotein levels has been examined in many studies over the last 15 yr in both animals and humans. Studies in humans first demonstrated the potent triglyceride-lowering effect of n-3 FA, and these were followed up with animal studies to unravel the mechanism of action. This paper reviews the reported effects of n-3 FA on blood lipoproteins in 72 placebo-controlled human trials, at least 2 wk in length and providing 7 or less g of n-3 FA/day. Trials in normolipidemic subjects (triglycerides <2.0 mM; 177 mg/dL) were compared to those in hypertriglyceridemic patients (triglycerides ≥2.0 mM). In the healthy subjects, mean triglyceride levels decreased by 25% ($P < 0.0001$), and total cholesterol (C) levels increased by 2% ($P < 0.009$) due to the combined increases in low density lipoprotein (LDL)-C (4%, $P < 0.02$) and high density lipoprotein (HDL)-C (3%, $P < 0.008$). In the patients, triglyceride levels decreased by 28% ($P < 0.0001$), LDL-C rose by 7% ($P < 0.0001$), but neither total C nor HDL-C changed significantly. Although the effect on triglyceride levels is also observed in rats and swine, it is rarely seen in mice, rabbits, monkeys, dogs, and hamsters. Whereas n-3 FA have only a minor impact on lipoprotein C levels in humans, they often markedly lower both total C and HDL-C levels in animals, especially monkeys. These differences are not widely appreciated and must be taken into account when studying the effects of n-3 FA on lipoprotein metabolism.
Lipids 31, 243–252 (1996).

Fish oils rich in n-3 fatty acids (FA) have long been known to lower serum triglyceride levels in humans, but their effects on individual lipoprotein classes (low and high density lipoproteins, LDL and HDL, respectively) have been less clear. In 1989, a review appeared examining these questions based on the literature then available (1). In the ensuing years, more fish oil studies have been published which generally used lower intakes of n-3 FA for longer periods of time in larger groups of subjects. In the 1989 review (1), all studies were included regardless of whether or not they were placebo controlled and regardless of n-3 FA intakes or study durations. This present review incorporates the newer studies in a more critical analysis of only placebo-controlled trials using "practical" amounts of n-3 FA. This approach eliminated studies in which significant reductions in saturated FA accompanied the switch to the fish oil diet, potentially confounding the results (1). Also considered is the role of control oils (e.g., olive oil) as "placebos" vis-à-vis their impact on lipid and lipoprotein levels.

In addition to summarizing the most recent and well-designed human studies, it seemed appropriate to compare and contrast the results reported in humans with those found in experimental animals. It is the author's belief that significant confusion has crept into this field by the frequent (and often unconscious) extrapolation of animal data to the human situation. Animal experiments can obviously be useful in sorting out mechanisms of action, but when the effects seen in humans cannot be reproduced in the animal model, the significance of the animal data to human metabolism is unclear. If the effect elicited in humans does not occur in the animal model, it is inappropriate to use the latter to explore mechanisms underlying the former.

HUMAN STUDIES

The studies included in this summary were required to meet the following criteria: placebo-controlled with either crossover or parallel designs; no more than 7 g of eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA) per day; study durations of at least two weeks; supplementation (not whole food substitution) studies; effects on triglyceride levels given; data from baseline as well as placebo and intervention periods reported; all types of subjects included (normals, hyperlipidemics, hypertensives, diabetics, and patients with coronary heart disease or renal disease); and English language articles. Although placebo-control was one of the criteria, two studies were included that were not placebo-controlled, Eritsland *et al.* (2) and Dehmer *et al.* (3). These were allowed because they included parallel, untreated control groups; they studied large numbers of patients (511 and 82, respectively) for relatively long periods of time (9 and 3 mon, respectively). Including these trials, there were 72 data sets taken

from 60 separate publications (2–61). Approximately 70 studies with "before-and-after" designs were excluded.

In summarizing the lipid and lipoprotein data, the reported findings were weighted by study size in order to give the larger trials more influence. Briefly, the absolute change from baseline was calculated for placebo and fish oil treatments in each study. This change was multiplied by the number of subjects in the study to get an aggregate change for the whole study population. The aggregate lipid concentration at baseline (and after placebo) for all subjects was calculated by multiplying the number of subjects times the baseline (and placebo) lipid concentration (in mM). Then, these aggregates (both for lipid levels and for the changes) were summed across all studies. The overall, weighted, percentage changes were then calculated by dividing the aggregate change by the aggregate baseline (or placebo) value. This method was used for the crossover trials. For parallel group studies, the "baseline" lipid values were taken to be the average baseline for both treatment groups; otherwise the weighting procedure was the same as for the crossover trials.

Changes in lipid and lipoprotein levels from baseline to the end of the placebo, and the n-3 FA periods were compared by paired *t*-test. Dose-response relationships between n-3 FA intakes and fractional changes in triglyceride, and LDL-cholesterol (C) levels were determined by regression analysis. Both analyses were done using Microsoft Excel version 5.0.

Effects of n-3 FA vs. placebo on serum lipid and lipoprotein levels. The weighted percentage changes in lipids and lipoproteins according to patient type (normolipidemic vs. hypertriglyceridemic) across all studies are given in Figure 1. Mean intakes of n-3 FA were 3.7 g/d in the normals and 4.0 g/d in the patients. Triglyceride levels were reduced by 25–30% in both groups of subjects ($P < 0.0001$), and there was no significant difference between the change relative to

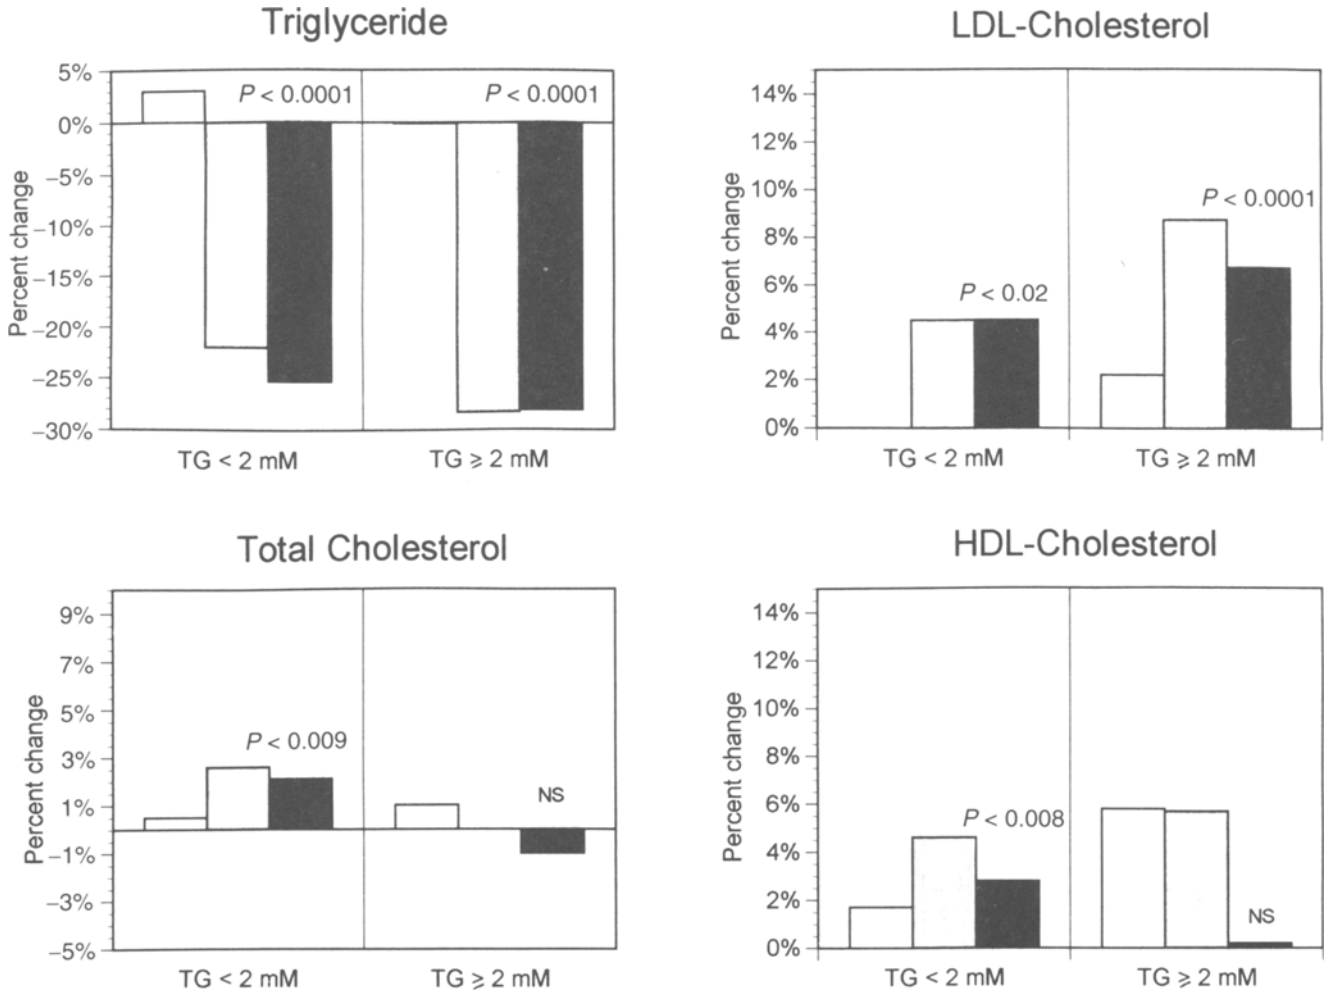

FIG. 1. The effects of n-3 fatty acids (FA) on serum lipids and lipoproteins in normotriglyceridemic (TG < 2 mM) and hypertriglyceridemic (TG ≥ 2 mM) subjects. [An average triglyceride (TG) molecular weight of 885 g/mol was used to calculate molarity, thus, 2 mM = 177 mg/dL]. Results from 72 placebo-controlled data sets in which over 1700 subjects were fed between 1 and 7 g of n-3 FA daily for at least two weeks are summarized. Percentage changes were calculated from weighted data allowing larger studies to contribute more to the mean effects. The three columns on each side of each graph show the change from baseline to placebo (open bars), the change from baseline to n-3 FA (gray bars), and the net difference between placebo and n-3 FA periods (black bars). *P* values are for the latter comparison; LDL, low density lipoprotein; HDL, high density lipoprotein.

baseline vs. that relative to placebo. Total C levels were slightly increased (about 2% vs. placebo, $P < 0.009$) in the studies with normolipidemic subjects, but were unaffected in the hyperlipidemics. Contributing to the rise in total C levels was the 4% rise in LDL-C in the normals ($P < 0.02$) and the 7% rise in patients ($P < 0.001$), respectively, and the 3% rise in HDL-C levels ($P < 0.008$) in the normals only; HDL-C levels were not affected in the patient studies. To find no rise in HDL-C in the face of an almost 30% reduction in very low density lipoprotein (VLDL) levels was unexpected in view of the relatively tight, inverse relationship between serum triglyceride and HDL-C levels (62). This finding suggests that n-3 FA may interrupt the metabolic connection between these lipoprotein fractions.

The inclusion of placebo groups was most helpful in deciphering the effects of n-3 FA on HDL-C levels in the patient studies because placebo "treatment" had the same effect as n-3 FA treatment, a 5–6% increase from baseline. Thus, the effect attributable to n-3 FA was nil. This finding calls into question the commonly held belief that polyunsaturated vegetable oils lower HDL-C levels (63); it appears that small amounts taken as supplements may do the opposite.

This exercise afforded the opportunity to ask if olive oil (the most commonly used placebo in these trials) was truly neutral vis-à-vis circulating lipid levels. In the 33 data sets that used olive oil (or its ethyl esters) (5,7,9,12,16–20,23, 25,27,31,33,34,36,37,40,42,44–47,49,51–55,57,59,61), the mean percentage changes (vs. baseline) in cholesterol, triglyceride, LDL-C, and HDL-C levels were –0.3, 2.3, –1.2, and 3.2%, respectively. Thus, about 10 g of olive oil per day had negligible effects on most lipoprotein fractions, with the possible exception of HDL-C. The similarity between these results for olive oil and those for all placebo oils combined (Fig. 1) suggests that polyunsaturated vegetable oils in general can be used as placebos in studies such as these. Furthermore, the relative neutrality of the placebos suggests that the reported changes in serum lipid levels in the over 70 "before-and-after" studies rejected from this analysis probably do reflect the true effects of n-3 FA (except possibly for HDL-C). Finally, the neutrality of the placebos supports the inclusion here of the Eritsland and Dehmer studies (2,3), which included parallel untreated control groups.

Although mean triglyceride levels decreased in 68 of the 72 data sets, the decreases were not always statistically significant. Triglycerides were reduced significantly in 73% of the studies in hypertriglyceridemic patients (2,3,15–18,20, 22–26,28–30,47,49–52,55,56,58), and in about 50% of studies with healthy subjects (4,5,7,8,10,11,13,32,36,39,43–45, 59,61). Thus, it was not uncommon for the decrease in blood triglyceride levels to not reach statistical significance, especially in studies in normolipidemic subjects. It should be noted, however, that often studies are not specifically sized to detect changes in triglyceride levels, especially studies designed to examine the effects of n-3 FA on nonlipid endpoints. In addition, smaller intakes of n-3 FA produce less triglyceride lowering (see below). Significant LDL-C increases were reported in 18% of the studies in normals (6,7,35,43,64) and 32% of the studies in patients (3,15–18, 22–24,29,52,55). LDL-C levels never decreased significantly vs. placebo in any trial. HDL-C rose significantly in 3% of studies (35,65) and never declined.

An important point from both therapeutic and regulatory standpoints is whether the triglyceride-lowering effect of n-3 FA is dose-related (66). Figure 2 shows that there is a statistically significant, inverse relationship between n-3 FA intakes and percentage triglyceride lowering both in volunteers ($r = 0.35$, $P < 0.001$) and in patients ($r = 0.50$, $P < 0.001$). Therefore, supplementary EPA + DHA (at least up to 7 g/d) lowers triglyceride levels in a dose-dependent manner. It is clear from these figures, however, that significant differences in

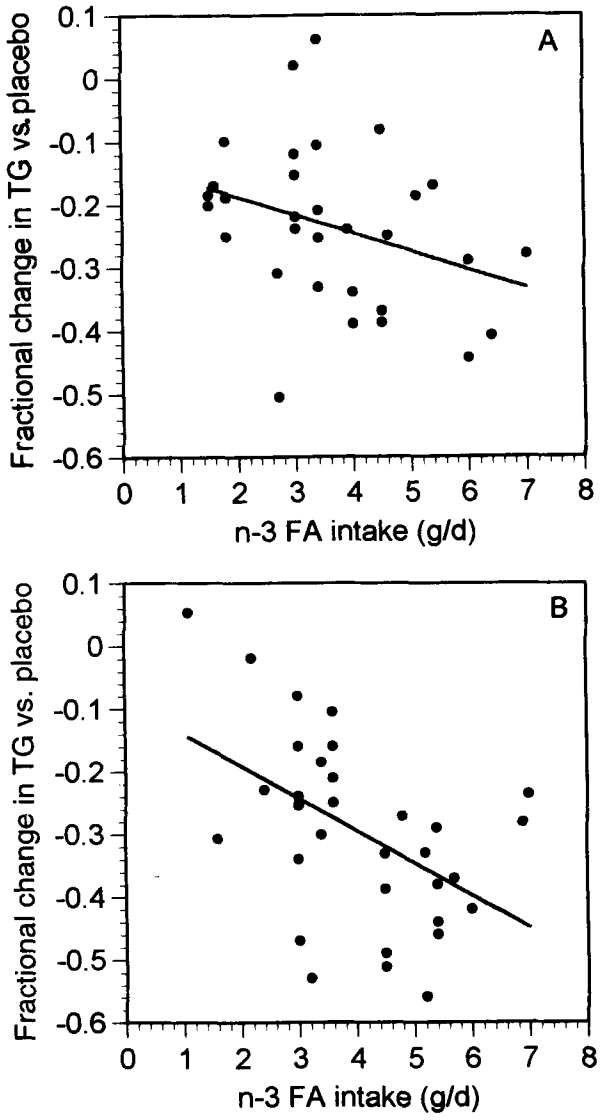

FIG. 2. Fractional changes (vs. placebo) in serum triglyceride levels as a function of n-3 FA intakes from studies in healthy subjects (A) and hypertriglyceridemic patients (B). Significant relationships were seen in both normals ($r = 0.35$, $P < 0.001$) and patients ($r = 0.5$, $P < 0.0001$). Abbreviations as in Figure 1.

response to the same dose were frequently observed (e.g., between 3 and 4 g/d in patient responses ranged from −5 to −52%).

There have been concerns that the hypotriglyceridemic effect may diminish with time (67). Figure 3 illustrates the percentage change in triglyceride levels over time for all studies combined. In order to "visually weight" each study, the points are drawn as a "bubbles," with the area of the bubble being proportional to the number of subjects studied. In this manner, the reader can immediately see not only the spread of the data but also the size of the studies from which results were obtained. From Figure 3 it is obvious that most studies have lasted 10 wk or less. The two largest studies (2,50) lasted 26 and 36 wk and provided 6.8 and 3.4 g of n-3 FA daily, respectively. Their results strongly suggest that the effect persists as long as supplementation continues. In the longest controlled trial, Sacks *et al.* (59) treated normolipidemic, coronary artery disease patients with n-3 FA or placebo for 112 wk. The n-3 FA group (n = 31) received 4.8 g of EPA + DHA daily, whereas the control group (n = 28) received 12 g of olive oil as a placebo. The fish oil produced small and nonsignificant increases in total, LDL-C, and HDL-C levels, and triglyceride levels were lowered by 30%. In an uncontrolled study providing about 3.3 g n-3 FA per day, Saynor and Gillott (68) reported that triglyceride reductions were maintained even after seven years of therapy. There can be little doubt that with continued supplementation, the hypotriglyceridemic effect persists.

Unlike the hypotriglyceridemic effect, the LDL-C raising effect does not appear to be dose-dependent. Figure 4 illustrates for patient studies only (where LDL-C most often increased) that there was no relationship between n-3 FA intake and percentage change in LDL-C levels ($r = 0.13$, nonsignificant). There was even a suggestion from the study of Leaf

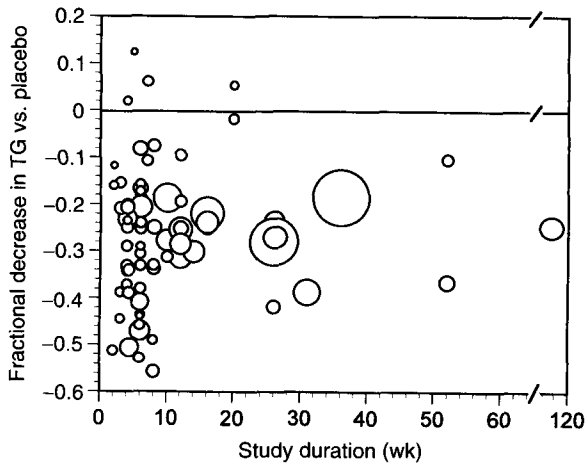

FIG. 3. A comparison of study duration to fractional triglyceride (TG) lowering in all data sets. Each set is represented by a "bubble," the area of which is proportional to the number of subjects in that data set. The largest "bubble" represents a study of 511 patients (Ref. 2). The 20–30% reduction in triglyceride levels persisted even in the longest study (28 mon) reported to date (Ref. 59).

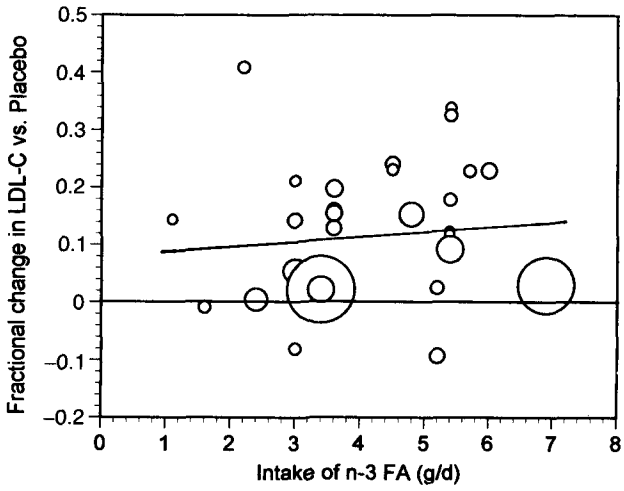

FIG. 4. Relationship between n-3 FA intake and fractional change in LDL-C in studies with hypertriglyceridemic patients. No relationship to dose is evident ($r = 0.13$, NS), with the largest studies showing no more than a 5% increase, even with 6.8 g of n-3 FA/d. See Figure 3 legend for a description of the data presentation, and Figure 1 for abbreviations; C, cholesterol.

et al. (50) that at LDL-C is not increased after six months of a large dose (6.8 g/d). Is this because the effect on LDL-C resolves with time? In the studies with normals (Fig. 5A), those lasting less than 10 wk showed a more consistent LDL-C response than those lasting more than 10 wk. In the study by Sacks *et al.* (59), there was no significant effect on LDL-C after 28 mon of 4.8 g of n-3 FA daily. In the patient studies (Fig. 5B), there was a fairly consistent rise in LDL-C levels of up to 30% in the shorter-term studies (<10 wk), but in most of the 6–12-mon studies (2,50,53), only a small and statistically insignificant 5% increase in LDL-C was noted. Germane to this question is the recent study by Morgan *et al.* (69), in which 7.5 g/d of n-3 FA increased LDL-C (vs. corn oil) at 6 wk, but not at 12 wk in 20 noninsulin-dependent diabetes mellitus patients. These findings suggest the LDL-C raising effect of n-3 FA supplementation may not persist as long as the hypotriglyceridemic effect.

One other interesting observation may be made from these studies in regard to effects of oil supplementation on body weight. Sacks *et al.* (59) gave their subjects an additional 12 g of oil daily for 28 mon, providing an extra 90,700 kcalories. This caloric load should have increased body weights by 11.8 kg, but only a 2 kg increase was noted. Smaller doses given for six (50) and nine (2) months should have increased body weights by 2 and 1.3 kg, respectively, but no change was found. It appears that either unconscious reductions in energy intake or increases in energy utilization accompanied oil (placebo or fish oil) supplementation.

In summary, using data derived only from placebo-controlled trials in which subjects were given less than 7 g of n-3 FA daily, the hypotriglyceridemic effect was substantial, it persisted over time, and was dose-dependent. LDL-C levels increased significantly in the short term, but appeared to

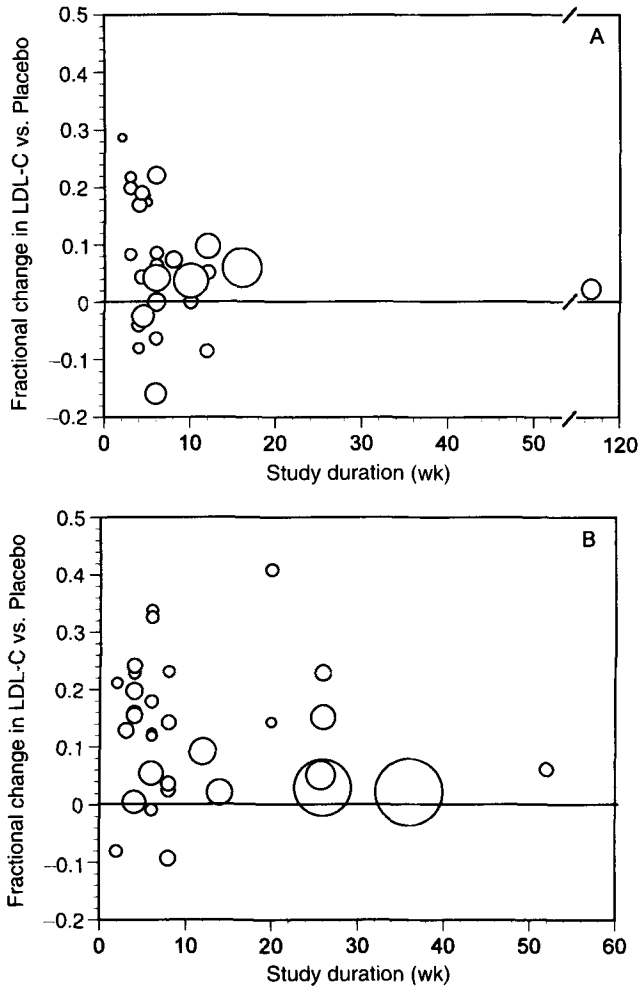

FIG. 5. Effect of study duration on LDL-C levels. For both normals (A) and patients (B), the net fractional change (vs. placebo) in LDL-C is given. Most of the larger studies reported minimal changes in LDL-C levels, especially those of longer duration. See Figure 3 legend for a description of the data presentation, and Figures 1 and 4 for abbreviations.

return toward baseline with time. Although there was no unique effect of n-3 FA on HDL-C levels, supplementation with any polyunsaturated oil would be expected to produce small increases compared to no supplementation.

ANIMAL STUDIES

Clearly there is a substantial body of consistent human data describing the effects of n-3 FA on serum lipid and lipoprotein levels. There is, likewise, a large body of animal data addressing this question, but as will be briefly described below, it is far less consistent, not only among, but also within, genera. Animal experimentation is frequently used to answer questions of ultimate relevance to humans. If the intervention used in an animal model does not produce the same effect as it does in humans, then the value of the model must be questioned. (It should be recalled here that the model is not only the species utilized, but also the experimental conditions employed, e.g., intake of n-3 FA, other dietary components, species-specific nutrient needs, duration of supplementation, period of fasting, etc.) Explorations of lipid-lowering mechanisms in such models may teach us little about how n-3 FA affect lipid metabolism in humans.

Triglycerides. Among laboratory animal species, only rats (70–72) and swine (73–75) generally responded to n-3 FA feeding with triglyceride lowering. Mice (76), rabbits (77–79), monkeys (80–82), and hamsters (83,84) usually did not exhibit a hypotriglyceridemic effect, and in dogs n-3 FA did not change any serum lipid parameter whatever (85–87). Interestingly, in African green monkeys, triglyceride levels rose during the n-3 FA feeding period compared to a lard diet (82,88), but did not change when compared to safflower oil (89).

LDL. LDL-C has not often been measured in animal studies, partly because in several commonly-used species (rats, mice, rabbits, dogs, hamsters), LDL is not the major C transporting lipoprotein; in these species, HDL seems to serve this function. When LDL-C was measured in swine fed fish oil, it usually was unaffected (90,91) or rose (73,92). In rabbits, LDL-C levels have been reported to go in all directions in response to fish oil feeding (93–95), and the most common effect noted in monkeys has been a significant LDL-C lowering (80,81,88), a response never noted in placebo-controlled humans.

HDL. Swine (73,96), monkeys (80–82,88,97,98), hamsters (83,84), and rats (99–101) most often responded to n-3 FA feeding with a substantial reduction in HDL-C whereas levels were generally unchanged in other species. Such a reduction stands in marked contrast with the neutral to positive effect on HDL-C levels noted in humans.

The reasons for this incomparability between animal and human responses to n-3 FA feeding are likely to be due to several factors. First, there are marked differences in lipoprotein metabolism among species (102), with (Westernized) humans being relatively unique with respect to their high ratio of LDL-C to HDL-C. Differences in susceptibility to oxidative stress (103), coupled with the failure of some investigators to provide adequate antioxidant protection (104), may have also played a role. In addition, the C contained in many n-3 FA preparations was often not balanced in the control diet, and this has been shown to have a significant impact on the n-3 FA response (84). Finally, the frequent use of very high intakes of n-3 FA in animal studies probably also contributed to the differences in response. A survey of animal experiments reporting the effects of fish oils on a wide variety of conditions (not just serum lipids) well illustrates this point (Fig. 6). When intakes were adjusted according to body surface area (105) and compared to a reasonable intake of 3 g/d in humans, then the prevalence of potential "overdosing" becomes evident. The effects in animals of "human equivalent" intakes of n-3 FA on lipid (or any other area of) metabolism have not been systematically investigated. Until they are, it will be difficult to produce pertinent animal models and to conduct meaningful mechanistic investigations to determine how n-3 FA impact human lipid metabolism.

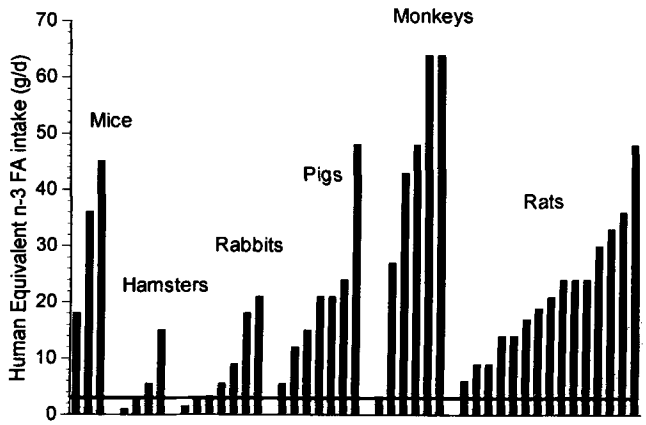

FIG. 6. Comparison of "human equivalent intakes" of n-3 fatty acids (FA) used in animal trials to the target intake of 3 g/d in humans (solid horizontal line). Reported intakes in animal studies were corrected for differences in body surface area according to Freiderich *et al.* (Ref. 105) in order to estimate the human equivalent intake.

Atherosclerosis. Although the focus of this review has been on fish oils and serum lipoprotein levels, the goal of many of the animal studies reviewed here was to determine the effects of n-3 fatty acids on arteriopathy [See Sassen *et al.* (106) for review]. Atherosclerosis (or surrogate phenomena such as intimal proliferation or monocyte adhesion to endothelial cells) has usually been inhibited by n-3 FA in swine (73,75,107,108), monkeys (81,82,88), and dogs (85–87,109). (Monkeys and swine are often considered to be the best models for human atherosclerosis.) In rabbits, neutral (77,79,93, 110,111), protective (94,95,112–115), and adverse (116–118) effects have all been reported. In the only mouse study reported, an antiatherosclerotic effect of n-3 FA was found (76).

In humans, there is significant (119–122), although not universal (123), epidemiological support for an antiatherogenic effect of n-3 FA. But there is only one prospective intervention study (124) in which the ability of fish oils to reduce cardiac morbidity and mortality was tested. In that trial, 2,033 men who had survived one heart attack were randomly assigned either to be given advice to eat two meals of oily fish per week or not. After two years, the fish advice group had a statistically significant 29% reduction in overall mortality. Both this study and the positive trials in swine and monkeys should compel us to mount a large-scale, secondary prevention trial with n-3 FA in humans.

It is important to note that in the animal studies, there was often a great discrepancy between the impact of n-3 FA on the extent of atherosclerosis and on blood lipoprotein levels. Less arterial disease in the presence of increased LDL-C and/or decreased HDL-C levels was commonly reported. The studies of Weiner *et al.* (73) in swine and Davis *et al.* (81) in rhesus monkeys are illustrative. In the former study, pigs were fed an atherogenic diet with or without 30 mL of cod liver oil for eight months. Thus, saturated fat intake was not reduced to make room for the fish oil; the latter was simply added to the diet (a vegetable oil control group would have been most helpful here as would a source of n-3 FA not rich in fat-soluble vitamins). Nevertheless, in this study, coronary arteriopathy was markedly reduced by fish oil feeding, and mean LDL-C levels increased from 300 mg/dL to nearly 400 mg/dL, and mean HDL levels decreased from 130 to 80 mg/dL, changes that would hardly be considered antiatherogenic. In the monkeys (81), the addition of fish oil (or the removal of coconut oil?) lowered HDL-C levels from 49 to 20 mg/dL, and yet the extent of disease was significantly reduced. In addition to having antiplatelet effects (125,126), n-3 FA treatment has also been reported to reduce macrophage uptake of monkey VLDL particles (127), reduce adhesion of leukocytes to hamster endothelium *in vivo* (128), and reduce the expression of adhesion molecules in vascular endothelial cells (129). Thus, these FA appear to have significant antiatherogenic potential independent of (despite?) their effects on lipid risk factors. It would be unfortunate indeed if future research with fish oils was hampered by paying more attention to their effects on surrogate risk factors than on atherosclerosis itself.

Conclusion. In humans, n-3 FA exert a significant hypotriglyceridemic effect which is dose-dependent and persistent. Effects on other lipoprotein fractions are relatively minimal and possibly transient. No animal model has yet been developed which mimics these effects. Accordingly, extreme care must be taken in order to avoid inappropriate extrapolations of animal findings to humans.

ARTICLE

Study of the Δ12-Desaturase System of *Lipomyces starkeyi*

Anne Lomascolo, Eric Dubreucq*, and Pierre Galzy

Ecole Nationale Supérieure Agronomique, Institut National de la Recherche Agronomique, 34060 Montpellier Cédex, France

ABSTRACT: The specific activity of the microsomal Δ12-desaturase system, which transforms oleic acid into linoleic acid, was about 16 pmol/min/mg protein. However, most of the total activity was nonsedimentable even after a 200000 × *g* centrifugation for 100 min. The study of various physicochemical parameters showed that this enzymatic complex, functioning optimally between pH 7 and 8, had low thermal stability. Ca^{2+}, which may cause an aggregation of the microsomes, and Hg^{2+} completely inhibited the activity, whereas Mg^{2+}, Mn^{2+}, and Zn^{2+} were activators. The Δ12-desaturase system was relatively specific toward oleic acid, though isomers of this fatty acid also had an action, either as substrates or as competitive inhibitors, on the activity of the system. The study of the effect of the exogenous oleoyl-CoA and elaidoyl-CoA on the specific activity of the Δ12-desaturase system showed a preference toward oleoyl-CoA.

Lipids 31, 253–259 (1996).

We have previously shown (1) that the lipids from yeast species belonging to the related genera *Lipomyces* and *Waltomyces* contain notable amounts of essential long-chain fatty acids (linoleic and α-linolenic acids), which are precursors of very long-chain polyunsaturated fatty acids such as dihomo-γ-linolenic and arachidonic acids found as traces. In this paper, we have also shown that oleic acid was the most abundant fatty acid in the lipids (40% of total fatty acids) of *Lipomyces* and *Waltomyces* and that its desaturation produced a relatively important amount of linoleic acid (19% of total fatty acids).

Although desaturases are key enzymes in the regulation of unsaturated fatty acid biosynthesis, studies dealing with the desaturation enzymatic complexes of microorganisms are not numerous, and most of the literature concerns the desaturases contained in rat liver microsomes. Among the microbial desaturase systems studied are those of *Bacillus* species (2), *Mortierella alpina* (3,4), *Mucor* sp. INMI (5), *Saccharomyces cerevisiae* (6), *Yarrowia lipolytica* (7,8), and *Cryptococcus curvatus* (9).

In the present work, we have studied the influence of various physical and chemical parameters on the specific activity of the microsomal Δ12-desaturase system of *Lipomyces starkeyi* CBS 1807 responsible for the formation of linoleic acid from oleic acid. The activity of the Δ6 desaturase system, which may desaturate oleic acid into $C_{18:2n-9}$, has not been studied here because this latter fatty acid was not detected in the fatty acid composition of the strain *L. starkeyi* CBS 1807 (1) nor in that of the microsomes prepared from the cells of this yeast.

MATERIALS AND METHODS

Microorganisms. Lipomyces starkeyi CBS 1807 was obtained from the Centraal Bureau voor Schimmelcultures (Delft, The Netherlands).

Biochemicals. [1-^{14}C] Oleic acid (58 mCi/mmol) was obtained from Amersham (Amersham France, Les Ulis, France). It was diluted with cold oleic acid to a 10 mCi/mmol specific activity. Coenzyme A and ATP were purchased from Sigma (Sigma Chimie, Saint-Quentin Fallavier, France), and NADH was provided by Boehringer (Boehringer Mannheim, Meylan, France).

Culture medium and growth conditions. The strain was grown in medium G as described by Lomascolo *et al.* (1). Cultivation was conducted at 28°C for 15 h. At the end of the exponential growth phase, cells were harvested by centrifugation (7000 × *g* for 10 min) at 4°C and washed twice with a cold pH 7.5 buffered solution (buffer A) containing 0.05 M potassium phosphate, 0.65 M sorbitol, 1 mM EDTA, 1 mM DTT, and 1 mM $MgCl_2$.

Preparation of microsomes. The washed cells were suspended in 25 mL of buffer A and ground for 3 min in a CO_2 cooled Braun MSK bead grinder (Braun, Melsungen, Germany). The homogenate was then centrifuged at 25000 × *g* for 40 min, and the resulting supernatant fluid was centrifuged at 105000 × *g* for 100 min. The pellet, consisting in the microsomal fraction, was finally suspended in 2 mL of buffer A. This corresponded to 4.0 to 6.5 mg of protein per mL determined according to the procedure of Lowry *et al.* (10). Microsomes were used immediately for assays of desaturase activity. Aliquots of microsomes were kept at −20°C for 24 h before the determination of NADH:cytochrome *c* reductase (EC 1.6.2.1), succinate:cytochrome *c* reductase (EC 1.3.99.1), and glucose-6-phosphate dehydrogenase (EC 1.1.1.49) activities.

Fatty acid extraction and analysis. Fatty acid methyl esters were obtained as follows. The assay reaction mixture (1.1 mL), added with 0.7 mL of an ethanolic solution of 4 M KOH, was saponified at 80°C for 1 h in sealed ampules. For the analysis of the microsomal fatty acid composition, 1.1 mL of a suspension of microsomes was used instead of the reaction medium. After removal of unsaponified substances with hexane, the mixture was acidified with 0.8 mL of 4 M HCl, and free fatty acids were extracted three times with 2.5 mL of hexane. After evaporation of the solvent using a flow of N_2, the residue was methylated in the presence of 0.75 mL of 12.5% boron trifluoride in methanol for 2 min at 90°C in sealed ampules. After cooling in ice, 0.75 mL of distilled water was added to decompose the excess of BF_3, and the fatty acid methyl esters were extracted three times with 1.5 mL of hexane. The solvent was then evaporated, and the samples were kept in 0.1 mL of hexane at −20°C under N_2. Fatty acid methyl esters were analyzed by gas chromatography as described by Lomascolo *et al.* (1).

Assays of NADH:cytochrome c *reductase, succinate:cytochrome* c *reductase, and glucose-6-phosphate dehydrogenase activities.* All assays were carried out at 30°C in a Uvikon 930 UV/Visible spectrophotometer (Kontron Instruments, Zürich, Switzerland). (i) NADH:cytochrome *c* reductase: the reaction mixture contained in a final volume of 1.5 mL: 50 mM Tris HCl buffer pH 7.2, 0.06 mM NADH, 0.06 mM ferricytochrome *c*, 3 mM NaN_3, and 0.05 mL of a suspension of microsomes. The reaction was started by the addition of microsomes, and the reduction of cytochrome *c* was followed by recording the absorbance increase at 550 nm. The millimolar extinction coefficient used for cytochrome *c* was 29 $L.mmol^{-1}.cm^{-1}$. (ii) Succinate:cytochrome *c* reductase: the reaction mixture for this enzyme assay was the same as above, except that NADH was replaced with disodium succinate. (iii) Glucose-6-phosphate dehydrogenase: the reaction mixture contained in a final volume of 1.5 mL: 100 mM Tris HCl buffer pH 7.5, 1 mM glucose-6-phosphate, 0.15 mM NADP, 20 mM $MgCl_2$, and 0.1 mL of microsomes. The reaction was started by the addition of microsomes, and the reduction of NADP was followed by recording the absorbance increase at 340 nm. The millimolar extinction coefficient used for NADP was 6.22 $L.mmol^{-1}.cm^{-1}$.

Assay of Δ12-desaturase activity. The reaction mixture (final volume, 1.1 mL) contained: 0.1 M potassium phosphate buffer, pH 7.2, 0.65 M sorbitol, 1 mM DTT, 5.5 mM $MgCl_2$, 6.5 mM ATP, 0.5 mM CoA, 0.7 mM NADH, 18–20 μM [1-^{14}C] oleic acid (in 5 μL of ethanol, i.e., 0.2 μCi), and 0.15 mL of microsomes (0.6–1 mg protein).

The reaction was started by the addition of [1-^{14}C] oleic acid and was performed for 10 min at 40°C (except for the study of the effects of temperature on activity) with constant shaking in air. The reaction was stopped by adding 0.7 mL of 4 M KOH in ethanol. For the study of the influence of cations, the assay reaction medium (potassium phosphate buffer pH 7.2, sorbitol, DTT, $MgCl_2$, ATP, CoA and NADH, microsomes and cation) was preincubated for 10 min before adding [1-^{14}C]. The preincubation time was 2 min for the study of the influence of chemical amino reactive reagents. After saponification and methylation of fatty acids as described above, fatty acid methyl esters were separated by argentation thin-layer chromatography using toluene/acetonitrile (97:3, vol/vol) as mobile phase. Plates of Silica gel 60G (Merck, Darmstadt, Germany) were impregnated with 10% silver nitrate according to Wilson and Sargent (11). Commercial standards of $C_{18:0}$, $C_{18:1}$, and $C_{18:2}$ were cochromatographed on each plate. Following their visualization using 2′-7′-dichlorofluoroscein, the spots corresponding to saturated, monounsaturated, and biunsaturated fractions were separately scraped off the plates. The silica gel containing the fractions was suspended in Packard Instagel Plus scintillation liquid (Packard, Rungis, France) added with 77% (by vol) of distilled water in vials protected from light in order to prevent the formation of silver oxide. Radioactivity was counted after one hour in a 1600 TR Liquid Scintillation Analyzer (Packard Instruments S.A., Rungis, France). From the amount of radioactivity found in the diene fraction vs. the radioactivity recovered from the monoene fraction, the enzyme activity could be determined and expressed as picomoles of oleic acid converted to linoleic acid per min and per mg of microsomal proteins.

For each activity value given in this paper, at least two microsomal preparations obtained from different cultures were used, with at least three independent measurements made on each preparation. The activity value given was the mean of these six or more determinations.

The diene fraction obtained by thin-layer chromatography after 0 and 10 min of reaction at 40°C (standard conditions) has been identified as linoleic acid ($C_{18:2n-6}$) by gas chromatography by comparison of the retention time of the resulting peak with that of a commercial sample of pure linoleic acid.

RESULTS AND DISCUSSION

Localization of Δ12-desaturase system activity. Little activity (<2%) was associated with the mitochondrial fraction (25000 × *g* pellet). Table 1 shows that only a part of the activity of the Δ12-desaturase system was contained in the microsomal 105000 × *g* pellet. Total Δ12-desaturase system activity was 30 times higher in the 25000 × *g* supernatant (which contained microsomes plus cytosol) and 16 times higher in the 105000 × *g* supernatant than in the 105000 × *g* pellet. The specific activity measured on microsomes obtained by a 200000 × *g* centrifugation was the same as that found in microsomes contained in the 105000 × *g* pellet (16 pmol/min/mg protein).

The measurement of NADH:cytochrome *c* reductase, succinate:cytochrome *c* reductase, and glucose-6-phosphate dehydrogenase activities verified the nature of the pellet obtained after centrifugation at 105000 × *g*. A rotenone-insensitive NADH:cytochrome *c* reductase is also a characteristic enzyme from the endoplasmic reticulum in rat liver (12), and of the microsomes of mammalian and plant cells in which

TABLE 1
Distribution of Δ12-Desaturase System Activity

Cell fraction	Protein content (mg)	Formation of linoleic acid: Total activity (nmol/min^{-1})	Formation of linoleic acid: Specific activity[a] (pmol/min/mg protein)
Supernatant at 25000 × *g*	40	4.8 (100%)	131.1 ± 11
Microsomes, pellet at 105000 × *g*	9	0.2 (4%)	20.8 ± 1
Supernatant at 105000 × *g*	37	2.9 (60%)	74.1 ± 14

[a]Values of specific activity are given as mean ± SEM (n = 3).

it is linked to cytochrome b_5 and is involved in the fatty acid desaturation (13). Desaturases in the microsomal electron transport system occur together with NADH:cytochrome b_5 reductase and cytochrome b_5. Our results show that the activity of NADH:cytochrome *c* reductase measured in 105000 × *g* pellet extracts which had been frozen at –20°C was the same with or without rotenone (7.5 µL of a 1 mg.mL^{-1} ethanolic solution): 0.021 µmol cytochrome *c* reduced/min/mg protein ±0.004 (n = 9). On the other hand, the succinate:cytochrome *c* reductase, characteristic of mitochondrial activities (14), did not have any activity in the microsomal pellet, whereas the specific activity of this enzyme was 9 nmol cytochrome *c* reduced/min/mg protein in the 25000 × *g* pellet (i.e., in the mitochondria). Finally, glucose-6-phosphate dehydrogenase, characteristic of the microsomes plus cytosol fraction (15) was present in the microsomal pellet and the supernatant of the 105000 × *g* centrifugation (0.1 ± 0.02, n = 4 and 0.37 ± 0.13, n = 4 µmol NADP/min/mg protein, respectively). The 105000 × *g* pellet was thus effectively composed of microsomes and free of mitochondria. Unless otherwise specified, this pellet was used in all the subsequent studies.

Fatty acid composition of microsomes. The long-chain fatty acid composition of microsomes is given in Table 2: oleic acid, linoleic, and palmitic acids represented more than 80% of total fatty acids. This composition was similar to that of the whole cells of *L. starkeyi* (1).

Δ12-Desaturase system specific activity in standard conditions. We have verified that the specific activity (16 pmol/min/mg protein ± 4, n = 10) was proportional to the reaction time when measured after up to 10 min in the standard reaction conditions described in the Materials and Methods section. This specific activity was the same when the microsomal protein amount in the reaction mixture was doubled.

The specific activity was in the same range as that found in *M. alpina* under similar conditions (3). On the other hand, it was threefold lower than that of *Mucor* sp. INMI (5) and sixfold lower than that of *Y. lipolytica* (7). Culture conditions, particularly aeration and temperature, may influence the production or the activity of the Δ12-desaturase system. The different procedures used for the obtention of microsomes may also result in differences of activity. Notably, as most of the Δ12-desaturase activity was found as a nonsedimentable form in the 105000 × *g* and 200000 × *g* supernatants, i.e., not in the standard microsomal fraction, the procedures for disruption may influence the activity found in the microsomes. A high proportion of Δ12-desaturase activity was also observed in 160000 × *g* and 200000 × *g* supernatants of microsomal preparations from *Y. lipolytica* (7).

Effects of temperature and pH on the specific activity of the Δ12-desaturase system: (i) Influence of temperature: the reaction was performed in the same conditions as described for the standard reaction but for different temperatures. The results given in Figure 1 show that the optimal temperature was 40°C for 10 min of reaction. The study of the thermal denaturation of the Δ12-desaturase system was realized by incubating the microsomal extracts for 15 and 30 min at various temperatures (30 to 45°C) before adding labelled oleic acid. After this treatment, the enzyme activity was determined in the standard conditions (Fig. 2A). Above 45°C, the Δ12-desaturase system did not show activity after 10 min. This sensitivity to temperatures higher than 40°C is likely to be due to the low apparent activation energy of the thermal denaturation of the enzyme complex (31 kJ.mol^{-1} ± 19, n = 3), determined using an Arrhenius plot (Fig. 2B). (ii) Influence of pH: the reaction was realized as described for the standard reaction but for pH values varying from 5 to 9. The buffers used were citric acid/disodium phosphate 0.1 M (pH 5), potassium phosphate 0.1 M (pH 6–8), and Tris HCl 0.1 M (pH 9). The enzymatic system functioned optimally when microsomes were placed in a reaction medium with a pH between 7 and 8 (Fig. 3), corresponding to the usual intracellular pH range. It is to be noted that the pH at the active sites of the Δ12-desaturase system in the

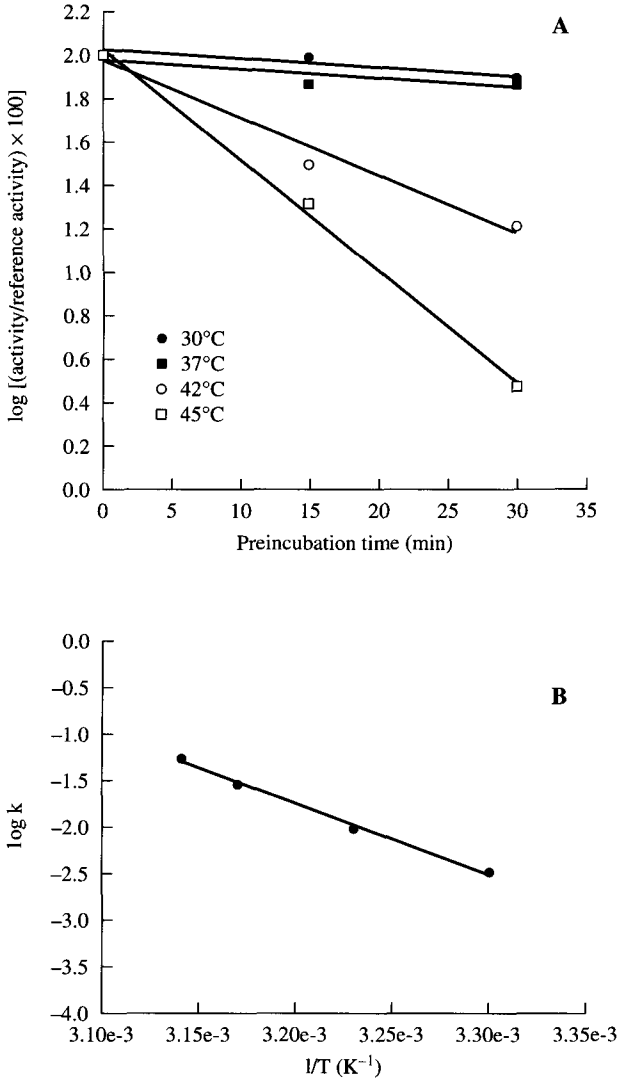

FIG. 2. (A) Thermal denaturation. Residual specific activity of the Δ12-desaturase system after 15 and 30 min of preincubation at different temperatures (30, 37, 42, and 45°C). The reference activity was measured in the standard reaction conditions (10 min at 40°C). (B) Thermal denaturation of the Δ12-desaturase system (Arrhenius plot).

microsomes may be different from the pH of the reaction medium.

Apparent K_m. By varying the concentration of labelled oleic acid in the reaction mixture, an apparent K_m value of 50 μM (±9, n = 3) was determined from the Lineweaver-Burk plot represented in Figure 4. It was in the same range as that found for *Y. lipolytica* (7).

Influence of effectors. Table 3 indicates the relative Δ12-desaturase specific activity (%) in the presence of different cations in the reaction mixture, compared to a reference realized in standard conditions. The activity was completely inhibited by Hg^{2+}. Among the other cations, Ca^{2+} presented the most important effect since it inhibited 80% of the activity. However, it is to be noted that this cation was employed in the protocol of Käppeli *et al.* (16) in order to precipitate the microsomal fraction, recovered by a rapid centrifugation at 15000 × *g*. It may thus mean that in the presence of Ca^{2+} in the reaction mixture, microsomes formed aggregates of lower specific activity. The fact that EDTA (Table 4), which is a metal chelating agent, inhibited 60% of activity indicated that a cationic ion is necessary to the functioning of the Δ12-desaturase system. Mg^{2+} is generally used in desaturase assays. In our case, the activity in the presence of 3 mM Mg^{2+} was 30% lower than in the standard conditions (5.5 mM). However, Zn^{2+}, and more especially Mn^{2+} had, at the concentration of 3 mM, a same or higher activating effect as 5.5 mM Mg^{2+}.

Table 4 gives the relative activity (%) of the Δ12-desaturase complex in the presence of effectors reacting with peculiar amino acid residues and of EDTA. An inhibitory effect was observed in the presence of *N*-ethylmaleimide (100%), iodine (90%), Woodward reagent K (i.e., *N*-ethyl-5-phenyl-

TABLE 3
Influence of Different Cations at 3 mM on the Activity of the Δ12-Desaturase System

Cations (chloride salts)	Relative Δ12-desaturase system activity[a] (%)
Mn^{2+}	123 ± 6
Zn^{2+}	106 ± 3
Hg^{2+}	0
Mg^{2+}	71 ± 2
Co^{2+}	59 ± 2
Cu^{2+}	97 ± 3
Ca^{2+}	19 ± 2

[a]This percentage was the ratio between the activity obtained in presence of each cation and the activity measured in the standard conditions (16 pmol/min/mg protein). Values are given as mean ± SEM (n = 3). Each cation was incubated 10 min with microsomes before adding oleic acid.

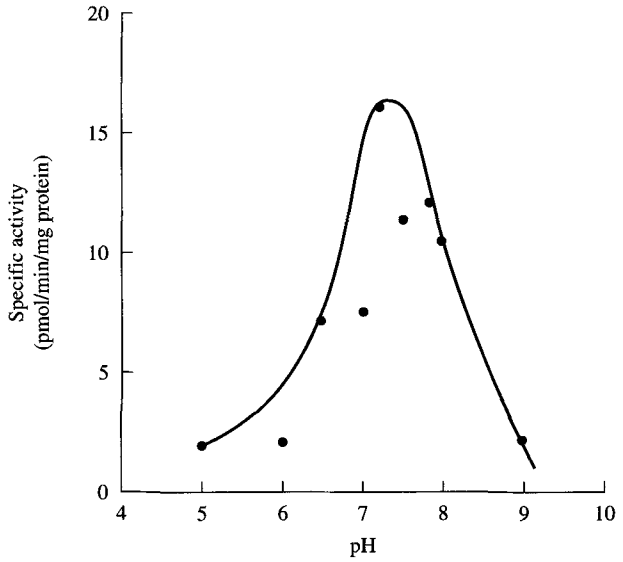

FIG. 3. Influence of pH on the specific activity of the Δ12-desaturase system.

isoxazolium 3′-sulfonate, 90%), *N*-bromosuccinimide, and iodoacetic acid (50–60%). Cystein (characterized by *N*-ethylmaleimide and iodoacetic acid), tyrosine (iodine and *N*-bromosuccinimide), aspartic and glutamic acids (the Woodward reagent K), and histidine (iodoacetic acid and *N*-bromosuccinimide) thus seem to be necessary to the reaction. It is to be noted that the inhibitory effect of iodine may also be due to a reaction with the double bonds of the unsaturated fatty acids involved in the reaction.

[b]Woodward reagent K: *N*-ethyl-5-phenylisoxazolium 3′-sulfonate. Each effector was incubated 2 min with microsomes before adding [^{14}C] oleic acid.

Effect of isomers of oleic acid and of oleoyl-CoA and elaidoyl-CoA. In our conditions of determination of the activity of the Δ12-desaturase system, at least two activities are involved: in a first step, acyl CoA synthetase catalyzes the formation of oleoyl-CoA from oleic acid and CoA, then oleoyl-CoA is desaturated into linoleoyl-CoA (we have verified that no desaturation occurred when CoA was absent in the reactant medium). In an attempt to evaluate the substrate specificity of the Δ12-desaturase system, the desaturation of oleic acid into linoleic acid was measured in the presence of equimolar quantities (0.02 mM) of labelled oleic acid and cold isomers of this fatty acid (Table 5). The Δ12-desaturase activity was about 25% inhibited in the presence of petroselinic, petroselaidic, and *cis*-vaccenic acids. Elaidic acid had a slightly higher inhibitory effect, whereas *trans*-vaccenic acid inhibited the reaction by only 10%. If the system had the same affinity toward these isomers as toward oleic acid, the activity would be 50% inhibited. There is thus at least one enzyme in the desaturase complex which presents a higher affinity toward oleic acid than its isomers. This enzyme may be the acyl-CoA synthetase, the Δ12 desaturase, or an intermediary enzyme, such as an oleoyl-CoA acyl transferase responsible for the formation of 1-acyl 2-oleoyl-*sn*-3-phospholipids as suggested by Ferrante *et al.* (7). It is to be noted that mammalian liver and *Bacillus* acyl-CoA synthetases are known to be very nonspecific (17).

In a second set of experiments, we have studied the influence of the addition of cold oleoyl-CoA or elaidoyl-CoA to the reaction mixture containing microsomes (105000 × *g* pellet) or the 105000 × *g* supernatant. Inhibition of the microsomal desaturase complex by 0.02 mM oleoyl-CoA and elaidoyl-CoA, which were supposed to compete with the [^{14}C] oleoyl-CoA produced by the acyl-CoA synthetase, was only 12 and 3%, respectively (Table 5). This was lower than expected, as cold oleoyl-CoA should have reduced the mea-

TABLE 5
Influence of the Addition of Different Isomers of Oleic Acid and of Oleoyl-CoA and Elaidoyl-CoA on the Activity of the Δ12-Desaturase System in the Presence of 0.02 mM [^{14}C] Oleic Acid

Fatty acids and acyl-CoA	Final concentration (mM)	Percentage of residual Δ12-desaturase system activity[a]
Cold oleic acid (*cis*-9)[b]	0.02	51 ± 4
Elaidic acid (*trans*-9)[b]	0.02	70 ± 4
Petroselenic acid (*cis*-6)[b]	0.02	78 ± 6
Petroselaidic acid (*trans*-6)[b]	0.02	76 ± 5
cis-Vaccenic acid (*cis*-11)[b]	0.02	77 ± 2
trans-Vaccenic acid (*trans*-11)[b]	0.02	88 ± 3
Oleoyl-CoA[b]	0.02	88 ± 1
Elaidoyl-CoA[b]	0.02	97 ± 1
Oleoyl-CoA[b]	0.20	0
Elaidoyl-CoA[b]	0.20	0
Oleoyl-CoA[c]	0.02	45 ± 4
Elaidoyl-CoA[c]	0.02	51 ± 2

[a]This percentage was the ratio between the activity obtained in presence of each isomer of oleic acid or of each molecule of acyl-CoA and the activity measured in the standard conditions. Values are given as mean ± SEM (n = 3).
[b]Reactions were realized with microsomes (105000 × *g* pellet).
[c]Reactions were realized with the 105000 × *g* supernatant.

sured activity by at least 50% by simple dilution of the [^{14}C] oleoyl-CoA. This indicates that the concentration of exogenous oleoyl-CoA at the active site of the desaturase complex was about ten times lower than that of the [^{14}C] oleoyl-CoA produced from the 0.02 mM [^{14}C] oleic acid. The access of exogenous acyl-CoA to the desaturase complex, probably located at the inner side of the microsomal membrane, was thus a limiting step, certainly due to the hydrophilic properties of acyl-CoA. When oleoyl-CoA and elaidoyl-CoA were added at a higher concentration (0.2 mM), a full inhibition of the measured activity was observed. In this case, the inhibition was much stronger than expected from the results obtained with 0.02 mM: if the concentration of exogenous acyl-CoA were 10-fold higher at the active site of the Δ12-desaturase, the measured activity should have been at least 50% of the reference activity. Two hypotheses could explain the 100% inhibition that was observed: (i) an inhibition of acyl-CoA synthetase by acyl-CoA, which would reduce the amount of radioactive acyl-CoA produced from [^{14}C] oleic acid; and (ii) the presence of a transport system for acyl-CoA functioning for acyl-CoA concentrations higher than 0.02 mM.

In the absence of integral microsomes, in the 105000 × *g* supernatant, the inhibition by 0.02 mM acyl-CoA was about 50%. This indicates that the access of acyl-CoA to the desaturation system is probably more direct in the supernatant fraction, which is consistent with the hypothesis that the supernatant contains finely dispersed fragments of endoplasmic reticulum (too small to form microsomes), or a solubilized form of the desaturation system: in both cases, the limiting step of the susbstrate penetration in or through the microsomal membrane is absent. This faster access to the enzymatic system also applies to oleic acid, which could partly explain the high desaturase activity of the supernatant compared to microsomes.

The influence of the concentration of exogenous oleoyl-CoA or elaidoyl-CoA on the activity of desaturation of [^{14}C] oleic acid is shown on Figure 5. The experimental data concerning oleoyl-CoA were in quite good agreement with the model according to which the exogenous oleoyl-CoA simply dilutes the [^{14}C] oleoyl-CoA produced from [^{14}C] oleic acid by the acyl-CoA synthetase. The data concerning elaidyl-CoA were also in agreement with the dilution model, but the activities were always higher than in the presence of oleoyl-

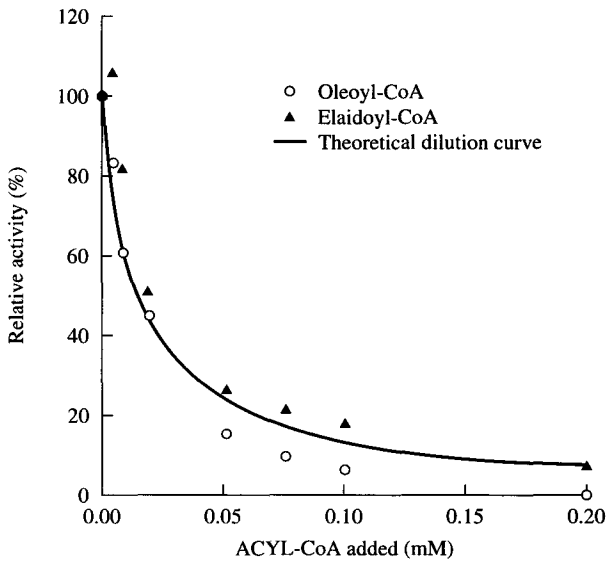

FIG. 5. Influence of the addition of cold oleoyl-CoA (○) or elaidoyl-CoA (▲) on the activity of desaturation of 0.02 mM [^{14}C] oleic acid. The dotted line represents the theoretical reduction of this activity by dilution of the intermediate [^{14}C] oleoyl-CoA with the cold oleoyl-CoA added.

CoA. This probably reflected a higher affinity of the Δ12 desaturase, or of an intermediary enzyme such as an oleoyl-CoA acyltransferase, for oleoyl-CoA than for its *trans* isomer. The study of the substrate specificity of the Δ12 desaturase system is difficult due to the involvement of numerous enzymes. However, the use of the 105000 × *g* supernatant seems to facilitate this study.

Lipolysis and Heterogeneous Catalysis. A New Concept for Expressing the Substrate Concentration

Christine Bernard[1], Jean Buc[2], and Gérard Piéroni*

Centre de Biochimie et de Biologie Moléculaire, Centre National de la Recherche Scientifique, 13402 Marseille Cedex 09, France

ABSTRACT: A new concept is proposed for quantifying the substrate concentration during heterogeneous catalysis of the kind which occurs during lipolysis. The number of molecules of protein (enzyme) adsorbable to the lipid substrate interface per unit of volume was evaluated and defined as a volumetric concentration of protein (enzyme) binding site (PEBS). Using porcine pancreatic lipase (EC 3.1.1.3) as a model enzyme, the maximal PEBS concentration was measured under various assay conditions by determining the saturation of the lipid substrate with the enzyme. Abacuses correlating the lipid substrate concentration (M) with the PEBS concentration (M) under each experimental conditions were used to express the kinetic data in terms of a volumetric concentration of PEBS. Comparisons could thus be made between data obtained with various enzymes and lipid interfaces because they were expressed with the same unit. In the case of pancreatic lipase, using triolein and tributyrylglycerol as substrates, K_m values of 2.7 and 7.5 nM PEBS were obtained, respectively, and K_D values ranging around 9 nM PEBS were also obtained from Scatchard plots. In addition, the average superficial density of PEBS was found to be 10×10^{11} molecules • cm^{-2}, which is a value commonly obtained with structural proteins and enzymes adsorbed to an acylglyceride–water interface, this finding supports the idea that the PEBS concept represents the room in which the protein molecule adsorbs at the lipidic interface.

Lipids 31, 261–267 (1996).

Lipolytic enzymes are characterized by their action at oil–water interfaces where their substrate is present. In situations of this kind, which are typical of heterogeneous catalysis, it is difficult to evaluate the kinetic parameters, particularly the affinity of the lipolytic enzymes for their lipidic substrates. The difficulties are due primarily to the fact that the lipidic substrate can generally be only poorly described in terms of quantitative and qualitative parameters.

Benzonana and Desnuelle (1) were the first to demonstrate that there exists a relationship between the "surface concentration" of the lipidic substrate and the lipolytic activity; in addition they pointed out that the intrefacial area in a volume unit was not the only significant variable in the process: this finding helped to focus attention on these other variables such as the nature of the lipidic surface. Monolayer studies at the air–water interface, in situations in which the area of the surface formed by the lipidic substrate is known with precision, have highlighted the variability of the protein (enzyme)–lipid interactions which can occur with the same amount of surface of the same lipid, depending on the lipid packing, for example (2–4). As the result of this variability, it is still difficult to compare kinetic data obtained under different experimental conditions, and no dissociation constant, K_D, or thermodynamic values have been published to date which might facilitate the making of comparisons between the interactions involving various enzymes and substrates and give better insight into the biological and physicochemical processes underlying these interactions.

The aim of the present study was to propose a convenient means to express the "substrate concentration" in heterogeneous catalysis which would allow, at the same time, to take into account the parameter "surface concentration" and the qualitative parameters of the protein (enzyme)–lipid interaction. Under each type of assay conditions, the maximal capacity of the lipid substrate to bind the enzyme molecules was evaluated from saturation curves, and the corresponding concentration of adsorbable molecules was taken to be the true substrate concentration. This transformation facilitates the treatment of the kinetic data and permits more satisfactory comparisons between (i) various Michaelis constants, K_m, measured on various lipidic substrates, and (ii) the K_D of various proteins at a given lipidic interface.

MATERIALS AND METHODS

Assay of lipase activity. Lipase activity was assayed potentiometrically using a pHstat apparatus (Radiometer, Copenhagen, Denmark). Assays were carried out at pH 8.0 and at 25°C with emulsified glycerol tributyrate (Fluka, Buchs, Switzerland) or preemulsified triolein (10%, vol/vol) in gum arabic (10%, wt/vol in water). The aqueous phase consisted

of 2.5 mM Tris-HCl buffer pH 8.0 containing 5 mM $CaCl_2$ and 10 mM NaCl. The total volume of the assay medium, including the lipid, was 25 mL. The hydrolysis was measured for 3–5 min after addition of the enzyme. The activity was calculated from the slope of this curve and expressed in katal.

Enzyme. Two preparations of pure porcine pancreatic lipase (triacylglycerol acyl-hydrolase, EC 3.1.1.3.) were used during this study. They were a gift from Dr. M. Rovery (Marseilles, France) and were prepared as described in (5). Sample A, which was kept in concentrated solution (4.8 mg/mL), showed a lipase activity of 213 microkatal (μkat)/mg, whereas sample B, which was more diluted (1.49 mg/mL), had an activity of 84 μkat/mg: both activities were measured against tributyrylglycerol emulsion.

Determination of particle size of emulsified lipids: (i) triolein emulsion. The distribution of lipid droplet sizes was determined using the particle size distribution analyzer Capa-700 (Horiba, Kyoto, Japan). Capa-700 is based on a liquid-phase dispersive sedimentation method (gravity and centrifugal force) whereby measurements are made by means of an optical transmission method at 560 nm (photosedimentometry). The validity of the method has been evaluated recently (6), and the data obtained here with the Capa-700 were checked using calibrated microparticles in the size range 0.2–100 μm (polystyrene size standard kit; Polysciences, Warrington, PA). The mean discrepancy between the expected and measured median diameters of the microparticles was ±10.3%. Measurements were performed on aliquots of the triolein emulsion diluted in distilled water up to an optical density of between 0.5 and 1.0 at 560 nm. The results were expressed in the form of droplet size distributions. The median size values were calculated with the particle analyzer software from the droplet size distribution. By varying the mixing time of the oil–gum arabic-water mixture, a series of triolein emulsions in gum arabic were prepared. Increasing the mixing time from 30 s to 60 s, 120 s, 180 s, and 300 s decreased the median diameter of the lipid droplets from 1.75 μm to 1.67 μm, 1.24 μm, 1.08 μm and 0.84 μm, respectively. With mixing time of 30 s, the average median diameter of the lipidic droplets was found to be 1.84 μm ± 0.10 μm (n = 3). *(ii) tributyryl glycerol emulsion.* Due to its instability, tributyrylglycerol emulsion was not analyzed using the particle size distribution analyzer. The lipid emulsion was diluted ten times with water, and a droplet rapidly examined under a microscope and photographed. The average diameter of the smallest droplets, which were assumed not to have undergone any coalescence, was taken to be representative of the size of the oily phase during the assay: 30 ± 10 μm.

Recovery of unbound enzyme. The distribution of lipase between the aqueous and oily phases of tributyrylglycerol was determined as previously described by Borgström (7). In a lipase assay system, the enzyme was added to 25 mL of the aqueous phase containing 0.5 mL of tributyrylglycerol under stirring. After recording the hydrolysis for 5 min, the aqueous phase was aspirated with a syringe and filtered through a single-use hydrophilic filter unit with a porosity of 0.45 μm (Minisart NML, 2.5-cm diameter; Sartorius, Göttingen, Germany). The filtrate was then measured to determine the lipase activity.

Analysis of data. All of the calculations were performed on a personal computer. The experimental data were fitted to various equations using a Newton-Gauss algorithm (8). The quality of the fit was evaluated using standard methods, such as those described in the review by Mannervick (9).

RESULTS

Lipolytic activity as a function of the enzyme concentration. Figure 1A gives a classical plot of enzymatic activity as a function of the substrate concentration. The specific activity

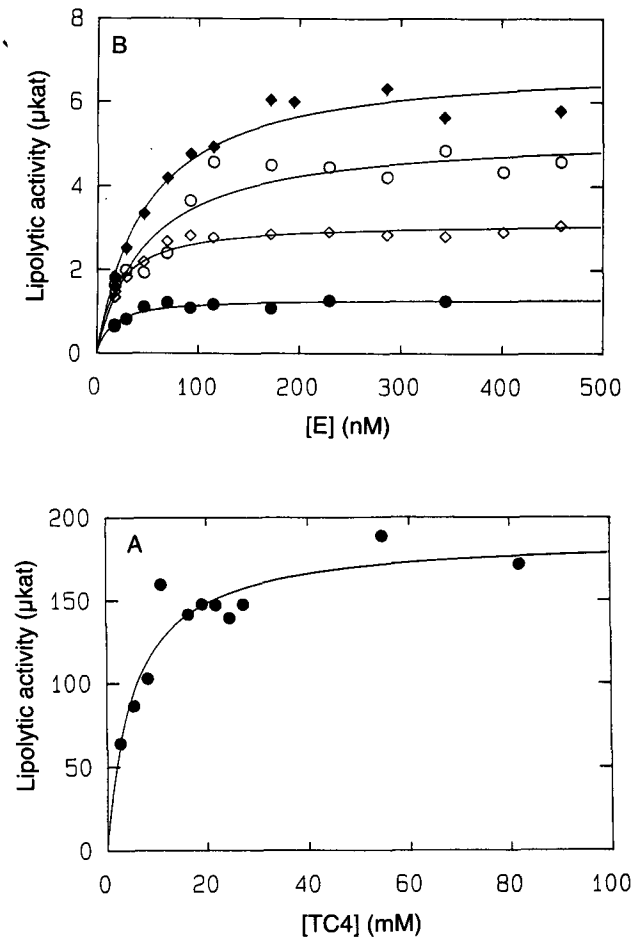

FIG. 1. (A) Lipolytic activity of porcine pancreatic lipase (2.2 μg), sample B, as a function of the tributyrylglycerol concentration [TC4], pH 8.0. Fitting the data to a hyperbola using a Newton-Gauss algorithm gave a V_{max} = 186 nkat, corresponding to a specific activity of 84 μkat/mg and a $K_{m\ apparent}$ = 5.4 mM. (B) Lipolytic activity of porcine pancreatic lipase, sample B, as a function of the concentration of added enzyme [E], with different amounts of tributyrylglycerol present in the assay, pH 8.0: ●, 125 μL; ◇, 250 μL; ○, 375 μL; ◆, 500 μL. Fitting the data to a hyperbola using a Newton-Gauss algorithm gave the following V_{max} values: 1.31, 3.14, 5.26, and 6.95 μkat as well as the $K_{m\ apparent}$ values: 15, 20, 50, and 47 nM (average value: 33 ± 18 nM).

of lipase, sample B, 4368 kat • mole^{-1}, was obtained after fitting the data to a hyperbola, and a $K_{m\ apparent}$ value of 5.4 mM was obtained.

Figure 1B gives the lipolytic activity of pancreatic lipase as a function of the enzyme concentration at the various tributylglycerol concentrations used in the assay. At small enzyme concentration values, the curve giving the lipolytic activity as a function of the enzyme concentration was almost linear for substrate concentrations over 250 µL, and the specific activity of the enzyme (kat/kg of protein) as well as the molar turnover (kat/mole of enzyme) could be calculated as usual. After adjusting the curves in Figure 1B to a hyperbola using the Newton-Gauss algorithm, the maximal lipolytic activity values were obtained at infinite enzyme concentrations at various substrate concentrations. Values of 1.31, 3.13, 5.26, and 6.94 µkat were obtained for 125, 250, 375, and 500 µL of tributyrylglycerol, respectively, added to the assay medium. In addition, the values corresponding to pseudo-K_m averaged to 33 ± 18 nM.

Assessment of the specific activity of pancreatic lipase at high enzyme concentrations. The adsorption of lipases to interfaces generally fits the Langmuir adsorption isotherm (1,10), which supports the fact that each molecule of lipase probably interacts with the interface independently of the others. The hypothesis was tested that every molecule of enzyme works independently, under conditions in which the lipidic interface is close to saturation with enzyme. Several assays were conducted with 2.4 µg (a catalytic amount far from the saturation conditions) and 200 µg of pancreatic lipase (an amount of enzyme leading to 80% saturation of the lipidic interface). These assays involved filtering the lipidic emulsion to differentiate between the enzyme bound to the oily phase, which was retained by the filter, from the free enzyme in the solution. The results are presented in Table 1. In those cases in which 2.4 µg (1.84 nM) of enzyme (138.7 µkat/mg) was used, 100% of the enzymatic activity was accounted for after filtering the lipid emulsion, whereas the bound enzyme ranged around 95%. In those cases in which 200 µg (154 nM) of enzyme (198.2 µkat/mg) was involved, the activity recovered accounted for 85% of the activity involved in the assay. Only 19% of the injected enzyme activity was measured under these assay conditions; 29.7% was found to be unbound. The identified losses amounted to 36.2%; they were attributed mainly to nonspecific adsorption during the filtration process and to the rapid decrease in specific activity of the enzyme stock solution after dilution. Within less than 10 min, a decrease from 198.2 to 125 µkat/mg was measured (data not shown). Assuming that all of the nonrecovered activity (15%) corresponded to adsorbed but nonactive enzyme, the specific activity of the adsorbed lipase must therefore have been at least [19/(19 + 15)]100 = 56% of that measured at the beginning of the saturation curve.

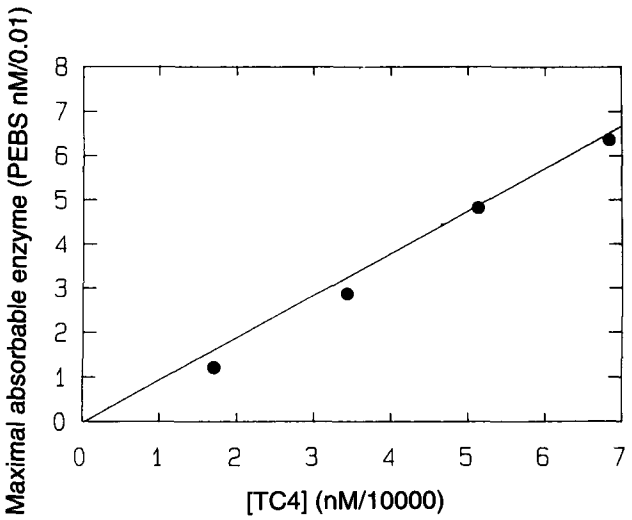

FIG. 2. Maximal adsorbable enzyme, expressed in protein (enzyme) binding site (PEBS) concentration, as a function of the substrate concentration [TC4]. The V_{max} values in Figure 1B were divided by the specific activity determined from Figure 1A leading to amounts of maximal adsorbable enzyme under the assay conditions, 25 mL, expressed in terms of PEBS concentration, which were plotted vs. the corresponding tributyrylglycerol concentrations. The data were fitted to a line forced through the origin: $y = \alpha$ [Tributyrylglycerol, M] + β; the fit gave: $\alpha = 0.957 \times 10^{-6}$ and $\beta = 2.17 \times 10^{-9}$; $r = 0.994$.

The protein (enzyme) binding site (PEBS). Assuming that every molecule of adsorbed enzyme works independently, it was possible to express the lipolytic activity in terms of the concentration of adsorbed lipase molecules. This was done by dividing the lipolytic activity per of volume unit (kat • volume^{-1}), taking into account the volume of the assay, by the molar turnover (kat • mole of enzyme^{-1}). Hence, the maximal values of the lipolytic activity measured in the presence of various concentrations of lipidic substrate, as obtained from Figure 1B, were transformed into a concentration of adsorbable molecules of lipase at the saturation of the lipidic interface. Figure 2 shows that abacus giving the maximal concen-

TABLE 1
Partition of Pancreatic Lipase Between the Lipidic and Aqueous Phases

Amount of enzyme added (total activity added)	Activity measured, nkat (% of total activity)	Activity recovered from the aqueous phase, nkat (% of total activity)	Identified losts, nkat (% of total activity)	Accounted activity, nkat (% of total activity)
2.4 µg (330 nkat)	323 ± 16 (96.8)	20.8 ± 7.5 (6.4)	3.7 (0.01)	347 (103.2)
200 µg (39600 nkat)	7600 (19.0)	11800 (29.7)	14400 (36.2)	33700 (85.0)

tration of adsorbable molecules of lipase, measured under our specific assay conditions, with respect to the concentration of tributyrylglycerol. A linear relationship between the concentration of substrate (mole · liter^{-1}) and the maximal concentration of adsorbable molecules of lipase (mole · liter^{-1}) ($y = \alpha$ [Tributyrylglycerol, M] + β, with $\alpha = 0.957 \times 10^{-6}$; $\beta = 2.17 \times 10^{-9}$ and $r = 0.994$) was observed. The slope of this curve (0.957×10^{-6}) indicates the efficiency of the assay system in terms of the "room" (mole · liter^{-1}) for lipase adsorption created by a concentration of one mole per liter of tributyrylglycerol. The inverse of the slope (1.04×10^{6}) gives the number of molecules of tributyrylglycerol needed to create the "room" for adsorbing one molecule of lipase. We propose to use the concept of PEBS as a means of expressing this "room" for the adsorption of one molecule of lipase in this particular case.

Using the abacus in Figure 2, we converted a lipid substrate concentration, reflecting only the proportions of the components of the heterogeneous mixture (x mL of lipidic phase + y mL of aqueous phase) into a PEBS concentration which can be used to express the true volumetric concentration of substrate (dimension: mole · liter^{-1}). Hence the kinetic data can be written as follows according to the Michaelis-Menten model:

$$\begin{aligned} &\text{Enzyme (solution)} + \text{PEBS (solution)} \xleftrightarrow{k1/k2} \\ &\text{Enzyme} \approx \text{PEBS (solution)} \xrightarrow{k3} \\ &\text{Enzyme} \approx \text{PEBS*} \text{ (solution)} + \text{Products} \end{aligned} \qquad [1]$$

This formula made it possible to use the PEBS concentration as if it stood for the concentration of the substrate in homogeneous catalysis, and thus to calculate a K_m value expressed as a volumic PEBS concentration. Table 2 gives the K_m values calculated in the case of porcine pancreatic lipase under various conditions involving tributyrylglycerol emulsion as substrate as well as a coarse emulsion of triolein in gum arabic and various pancreatic lipase preparations. The results ranged around 7.5 ± 2.0 nM PEBS ($n = 4$) regardless of the assay conditions (fast or slow stirring) when tributyrylglycerol was used as substrate, and 2.7 nM PEBS when triolein was used as the substrate. Very fine triolein emulsions were not suitable in this case because their hydrolysis was too fast and therefore not compatible with the capacities of the pHstat apparatus.

Calculation of the K_D. In the Michaelis-Menten model presented above, the species Enzyme ≈ PEBS and Enzyme ≈ PEBS*, differing, in our case, by a single molecule of tributyrylglycerol out of 1.04×10^{6} molecules, can be taken to be identical. For this reason, k3 presumably had a negligible effect on the equilibrium concentration of the Enzyme ≈ PEBS complex.

If one writes the initial concentrations of enzyme and PEBS as follows: $[E]_0$ and $[PEBS]_0$, and if at time t: [E] and [PEBS], assuming a stoichiometry of n between the enzyme and the PEBS (the value $n = 1$ was assumed at the beginning of the study), the concentration of free sites at time t, can be written as follows:

$$[\text{PEBS}] = n\,[\text{PEBS}]_0 - [\text{Enzyme} \approx \text{PEBS}] \qquad [2]$$

and:

$$K_D = \frac{[\text{E}]\,\{n[\text{PEBS}]_0 - [\text{Enzyme} \approx \text{PEBS}]\}}{[\text{Enzyme} \approx \text{PEBS}]} \qquad [3]$$

which gives

$$\frac{[\text{Enzyme} \approx \text{PEBS}]}{[\text{PEBS}]_0} = \frac{n[\text{E}]}{K_D + [\text{E}]} \qquad [4]$$

Figure 3A gives the data in Figure 1B, after transformation according to the abacus in Figure 2, and plotted to illustrate the latter relationship. After fitting the data using a Newton-Gauss algorithm, the values $K_D = 9.08 \pm 1.51$ nM and $n = 0.81 \pm 0.02$ were obtained. The same data were also plotted on a Scatchard plot. Figure 3B gives these results, which have been presented for convenience with a normalized abscissa. Values of $K_D = 9.03 \pm 2.66$ nM and $n = 0.84 \pm 0.10$ were obtained.

Determination of the surface PEBS density. Using the total area measurements obtained on the lipidic substrate as described in the Materials and Methods section, it was possible to calculate the superficial PEBS density (molecules · surface^{-1}) available for adsorption to pancreatic lipase molecules. As shown in Table 2 with lipase sample A, these values ranged between $10 \pm 6.2 \times 10^{11}$ and $14 \pm 0.7 \times 10^{11}$ molecules · cm^{-2} in the case of tributyrylglycerol–water interface and triolein–water interface, respectively, and plateaued at $4.5 \pm 2.7 \times 10^{11}$ molecules · cm^{-2} with lipase sample B.

TABLE 2
Pancreatic Lipase: Kinetic and Physicochemical Parameters

Substrate	$K_{m\ apparent}$ Triacylglycerol, mM	$K_{m\ apparent}$ Enzyme, nM	K_m PEBS, nM	K_d PEBS, nM	Maximal surface density PEBS, molecules · cm^{-2}
Tributyrylglycerol (lipase, sample A)[a]	29 ± 6	21	7.5 ± 2.0	—	$10.4 \pm 6.2 \times 10^{11}$
Tributyrylglycerol (lipase, sample B)[a]	5.4	—	7.5	—	$4.5 \pm 2.7 \times 10^{11}$
	—	33 ± 18	—	9.1 ± 1.5	—
Triolein, gum arabic (lipase, sample A)[a]	1.5	169	2.7	—	$14.0 \pm 0.7 \times 10^{11}$

[a]Enzymes; PEBS, protein (enzyme) binding site.

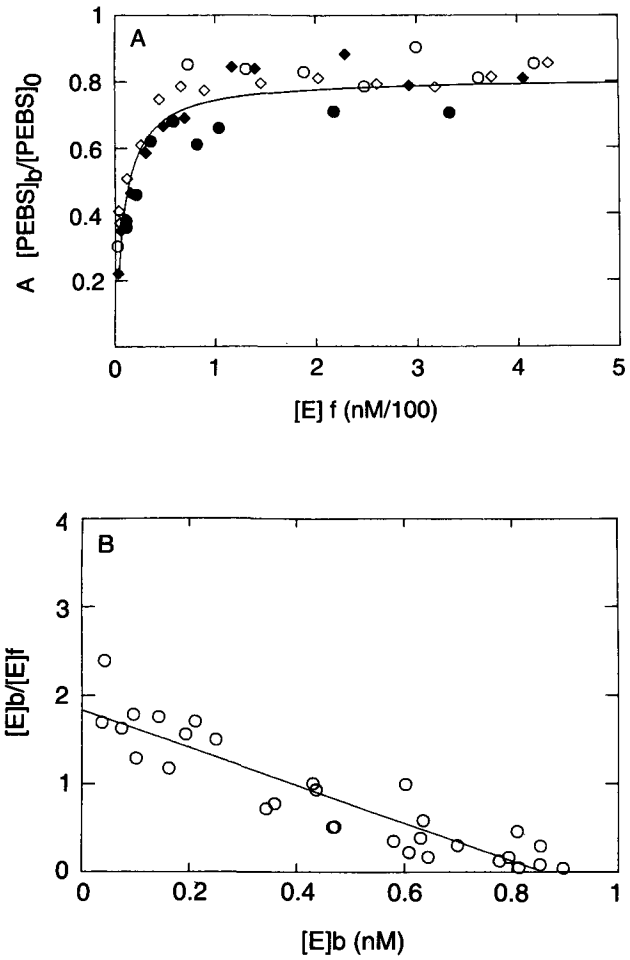

FIG. 3. (A) Plot of kinetic data from Figure 1B after transformation according to the abacus in Figure 2 in terms of the molar fraction of bond over initial PEBS species, $[PEBS]_b/[PEBS]_0$, as a function of the concentration of free enzyme, $[E]_f$. Fitting the data to a hyperbola using the Newton-Gauss algorithm gave: K_D = 9.08 ± 1.51 nM and n = 0.809 ± 0.022. (B) Scatchard plot of enzyme species after normalization of the abscissa for the various tributyrylglycerol concentrations used. K_D = 9.03 ± 2.66 nM and n = 0.844 ± 0.100. See Figure 2 for abbreviation.

DISCUSSION

The aim of the present study was to tackle the old problem of expressing the substrate concentration in heterogeneous catalysis, with special emphasis on lipolysis. Figure 1 and Table 2 show how ambiguous the determination of the kinetic constant K_m can be in heterogeneous catalysis, depending on the choice of the variable: the lipid substrate concentration or the enzyme concentration; values differing by six orders of magnitude were obtained for the same kinetic constant K_m of the same reaction. This strongly supports the need to use the qualitative term "apparent," which is often associated with the K_m values determined on the basis of lipid concentrations. A new concept is presented here for expressing the substrate concentration in heterogeneous systems such as those involved in the lipolysis of triacylglycerol emulsions by pancreatic lipase.

According to this concept, it is postulated that a stoichiometry of one exists between the protein (enzyme) that binds the lipidic interface and the "room" available for it to bind, which implies that under saturating conditions the concentration of bound protein (enzyme) is equal to the amount of "room." Hence, the amount of "room" existing in a heterogeneous system, under given conditions, can be calculated from the saturation curve of this system with the protein (enzyme) under study through the basic relation: one molecule of bound protein (enzyme) per liter corresponds to one unit of "room" per liter. This "room" or PEBS, to which no specific properties have been attributed, is taken to be the substrate involved in homogeneous catalysis.The interaction between the soluble protein (enzyme) and the lipidic emulsion is described in terms of an interaction with PEBS as follows:

$$\begin{aligned} &\text{Enzyme (solution)} + \text{PEBS (solution)} \xleftrightarrow{k1/k2} \\ &\text{Enzyme} \approx \text{PEBS (solution} \xrightarrow{k3} \\ &\text{Enzyme} \approx \text{PEBS* (solution)} + \text{Products} \end{aligned} \qquad [5]$$

The ratio between the PEBS concentration and that of the hydrophobic phase (substrate) present in a volume unit of the aqueous phase of the assay (a ratio between two volumetric concentrations of molecules, dimensionless) was evaluated. This ratio was given by the slope of the abacus of Figure 2, $\alpha = 0.957 \times 10^{-6}$. This value serves as an index to the efficiency of the assay system at binding the protein (enzyme) under study. Its inverse gives the number of molecules of hydrophobic phase (substrate) needed to bind one protein (enzyme) molecule, i.e., the number of molecules of lipid constituting an oligomer (PEBS). The smaller this number, the more efficient the hydrophobic phase in the binding of the protein will be. In our case, Enzyme ≈ PEBS is a complex consisting of one molecule of enzyme with 1.04×10^6 molecules of tributyrylglycerol, and Enzyme ≈ PEBS* is the same complex, containing one molecule less of tributyrylglycerol. Consequently, one may take the two enzymatic complexes Enzyme ≈ PEBS and Enzyme ≈ PEBS* to be identical and, in the K_m equation, neglect the term k3, so that it is possible to identify K_m and K_D. It is worth noting that the pseudo-K_m value of 33 ± 18 nM, as obtained from Figure 1B with pancreatic lipase, ranges around the protein (enzyme) concentrations values giving 50% saturation of the lipidic interface (K_D): 132 and 40 nM, for bovine serum albumin and β-lactoglobulin, respectively. as calculated from Reference 13. In addition, it is worth noting that the value of this pseudo-K_m (33 ± 18 nM) calculated for the enzyme ranged with the K_m calculated using the PEBS concentration (7.5 nM), conversely to that of the apparent K_m calculated for the triacylglycerol which ranged six orders of magnitude greater (29 ± 6 mM, Table 2).

According to this model, the PEBS should be viewed as an oligomer of lipid molecules devoid of cooperativity. In a way, this is the opposite situation to that of an oligomeric enzyme acting on a monomeric substrate in homogeneous catalysis. This transformation can be used to describe the binding

and kinetic data obtained on heterogeneous systems with the same formality as that used with homogeneous systems, and to calculate the Michaelis-Menten K_m values as well as the Scatchard K_D values in terms of the PEBS concentrations. It is worth mentioning that the PEBS concentration (molecules · volume^{-1}) takes into account both the "surface concentration" of the lipid emulsion (surface · volume^{-1}), a quantitative parameter, and the PEBS surface density (molecules · surface^{-1}) at saturation of the lipidic-water interface, which is a qualitative parameter, in the form of the product of these two factors. The PEBS surface density values obtained (see Table 2) were comparable to the maximal surface density values obtained with of human gastric lipase (10.6×10^{11} molecules · cm^2), bovine serum albumin (11×10^{11} molecules · cm^{-2}), and β-lactoglobulin (14×10^{11} molecules · cm^{-2}) adsorbed to a lipid monolayer of dicaprin at 35 dyn · cm^{-1} (11–13), as well as with porcine pancreatic lipase (29.5×10^{11} molecules · cm^{-2}) and porcine pancreatic carboxylester lipase (21×10^{11} molecules · cm^{-2}) obtained by a different technique on different lipid interfaces (14,15). In addition, the maximal superficial PEBS concentration value was found to amount to 20% of the surface coverage of the lipid interface, assuming that a lipase molecule occupies 2000 Å^2 at the interface.

According to Scatchard, the answer to complicated binding problems of this kind will depend on the answers to the simpler questions "How many?" and "How tightly bound?" (16). It is very likely that in our case the surface density of PEBS available for protein (enzyme) adsorption may answer the question "How many?", and that on the other hand, the K_D values calculated in terms of the PEBS concentration give the strength of the interaction and may answer the question "How tightly bound?", if one uses the relation: $\Delta G = -RT \text{ Log } K_D$ (10 kcal, in our case), thus opening the way to a thermodynamic approach to the interaction.

There exist many different ways of studying the adsorption of a protein to a lipidic interface. In the present study, the catalytic activity of pancreatic lipase was taken as an example for evaluating the maximal amount of protein capable of adsorbing to various lipidic emulsions. To transform a lipolytic activity into an amount of adsorbed enzyme, the assumption that the specific activity of the lipase was constant along the whole saturation curve had to be made. Table 1 shows data which are consistent with the conclusion that the specific activity of the enzyme was at least 56% of that measured at the beginning of the saturation curve, assuming that in the least favorable case, all of the unrecovered enzyme was bound, but that its activity was weak at the lipidic interface when almost 80% of the interface saturation was reached. If the specific activity of the lipase had not been constant along the whole saturation curve, this would have introduced an error in evaluating the maximal amount of bound enzyme. The magnitude of this error was assessed from its effects on the Scatchard plot, and a value of $n = 0.844$ was obtained, which is not very different from $n = 1$, the theoretical value; a clear-cut linear response was obtained (Fig. 3B). The effects of any changes in the specific activity of the lipase would therefore be very limited in our case. It is worth noting that this bias, which possibly affects the constancy of the specific activity of the enzyme when the ratio of enzyme to substrate was high, is also to be found in situations in which the enzymatic activity is recorded as a function of the substrate concentration, as shown in Figure 1A, at the low lipidic substrate concentrations. Furthermore, in the latter situation, a classical plot of the data according to Lineweaver and Burk (17) increases the bias, because the experimental points corresponding to the range of concentrations where the constancy of the specific activity of the enzyme is the least dependable, weigh heavily on the slope of the curve and hence on the value of the $K_{m\ apparent}$. On the other hand, determining the mass of adsorbed protein (enzyme) using physicochemical methods would have introduced another bias, because no proof is available when using this technique, that only the molecular species corresponding to completely intact protein (enzyme) is giving off a significant signal. This situation is illustrated in Table 2, where two different samples, A and B, of pure lipase, differing in their specific activity by a factor of 2.53 (213 μkat · mg^{-1} over 84 μkat · mg^{-1}), lead to two different surface densities of active enzyme differing by a factor of 2.31 (10.4×10^{11} molecules · cm^{-2} over 4.5×10^{11} molecules · cm^{-2}). These data are consistent with the possibility that the inactive or weakly active molecules of lipase included in the lipase sample B preparation may have adsorbed to the lipidic interface. Under these conditions, the surface density of the lipase molecule species in sample A or B is probably the same, but the molecules adsorbed in sample A will be 2.5 times more active than those in sample B.

The K_m (K_D) values expressed as a PEBS concentration ranged around 10 nM (Table 2). The lowest value was measured on triolein emulsion. These values differed by six orders of magnitude from the $K_{m\ apparent}$ determined using the classical method. It is interesting to make a parallel with the K_D values of the pancreatic lipase obtained in the presence of colipase adsorbed to a lipidic interface, which also ranged around nM (18–20). When expressed in terms of a PEBS concentration, the kinetic and binding data correlate well, therefore, with physical parameters measured using various other techniques. The use of the PEBS concept might help to achieve a deeper insight into protein–lipid interactions.

Stimulation of Microsomal Cholesterol Ester Hydrolase by Glucagon, Cyclic AMP Analogues, and Vasopressin in Isolated Rat Hepatocytes

María L. Hernández, María J. Martínez, José I. Ruiz, and Begoña Ochoa*

Department of Physiology, University of the Basque Country Medical School, E-48080-Bilbao, Spain

ABSTRACT: Short-term activation of microsomal cholesterol ester hydrolase by glucagon, cAMP analogues, and vasopressin in isolated rat hepatocytes is described. Glucagon led to a dose- and time-dependent activation of cholesteryl oleate hydrolysis, but values returned to basal levels within 120 min. Exposure of isolated hepatocytes to 0.5 mM concentrations of dibutyryl-cAMP or 8-[4-chlorophenylthio]-cAMP, or 25 μM forskolin caused persistent activation of cholesterol ester hydrolase activity after a lag period of 30 min. The three agents resulted in early marked intracellular accumulation of cAMP that declined progressively, and moderate and sustained reductions in the diacylglycerol content. The actions of glucagon on hepatocytes were inhibited by pretreatment of cells with 10 nM [8-arginine] vasopressin. Vasopressin elicited a consistent and sustained increase in cholesterol ester hydrolase activity and diacylglycerol without affecting cAMP while reducing the effect of glucagon on cAMP. Furthermore, the effects of glucagon and vasopressin on the activation of cholesterol ester hydrolase were not additive despite the similarity of their stimulation of diacylglycerol formation. Blockade of vasopressin-mediated activation of cholesterol ester hydrolase and diacylglycerol content were induced by excess prazosin. These data suggest that stimulation of microsomal cholesterol ester hydrolase in isolated liver cells may involve at least two signal transduction systems.

Lipids 31, 269–276 (1996).

Cholesterol esters in the liver are subject to a constant cycle of synthesis and hydrolysis reactions. Two neutral cholesterol ester hydrolases (EC 3.1.1.13.) (CEH) located in cytosol and microsomes (1–5) are responsible for the release of cholesterol from the cholesterol ester stores and, as such, are potential points for regulation of cholesterol homeostasis in the body. Whereas cytosolic CEH has been purified and is fairly well characterized (6–8), little information is available about the biochemistry, the physiological role, and the regulation of the microsomal form of this esterase. Microsomal CEH is thought to have a role in determining the partitioning of cholesterol toward the bile canaliculi or the bloodstream and in maintaining the balance between free and esterified cholesterol in endoplasmic reticulum. The activity of neutral microsomal CEH was found to be different from that of hormone-sensitive lipase (9), neutral retinyl ester hydrolase, and acid CEH also located in microsomes (10). Microsomal CEH from rat liver is located in the luminal side of the rough membranes (11), shows a circadian rhythm unrelated to the feeding status of animals (12), and is inhibited by a cytosolic protein (13). The cytosolic inhibitor was reported to be very active in the female liver and to respond to changes in the hormonal and the nutritional status of female rats (14).

Reversible protein phosphorylation has been implicated as a common mechanism for the short-term regulation of cholesterol metabolism. The inhibition of β-hydroxy-β-methylglutaryl-CoA reductase activity in its phosphorylated form is well established (15–17). Contradictory results have appeared about the regulation of acyl-CoA:cholesterol acyltransferase (18–21) and bile acid synthesis (22–24) by second messenger-mediated processes. Much evidence has accumulated supporting the concept that cytosolic CEH is activated by cAMP-dependent phosphorylation in steroidogenic and other nonhepatic tissues. Whether or not liver-soluble CEH is regulated by phosphorylation mechanisms is open to question. Evidence for activation of cytosolic CEH by cAMP- and Ca^{2+}-mediated processes has been presented in rat liver (6), while findings suggesting inactivation by phosphorylation were presented in hepatocyte suspensions (25). The evidence currently available for the involvement of second messengers in the regulation of the microsomal CEH is scant. An *in vitro* cell-free study from our laboratory has revealed marked stimulation of microsomal CEH by cAMP-dependent protein kinase or Ca^{2+}/calmodulin, whereas enzyme inactivation was dependent on phosphatase action (26). This led us to suggest for the first time that, in the rat liver, microsomal CEH may be regulated by reversible phosphorylation, with the phosphorylated form of the enzyme being the more active form. More recently, we found that okadaic acid, a potent and specific inhibitor of cellular protein phosphatases 1 and 2A, caused early and sustained inhibitions of microsomal CEH in hepatocyte suspensions (27). In addition, the inhibitory effect of

okadaic acid was found not to be related to the dibutyryl cAMP (db-cAMP)-promoted stimulation of esterase activity (27). Hoang *et al.* (21) reported stimulation of neutral CEH activity by cAMP analogues and glucagon in the post-mitochondrial supernatant of cultured hamster hepatocytes, but there are no systematic studies on the effects of these compounds on the neutral microsomal cholesterol ester hydrolysis in isolated rat hepatocytes.

The present study was aimed at determining whether changes in neutral microsomal CEH activity are related to changes in the cellular content of cAMP in isolated rat hepatocytes. We used the hormone glucagon, forskolin, a potent activator of adenylate cyclase, the cell-permeable cAMP analogues db-cAMP and 8-[4-chlorophenylthio]-cAMP (CPT-cAMP) to elevate the cAMP content in hepatocytes. Vasopressin pretreatment was used to reduce the subsequent glucagon-stimulated cAMP production. Further, we examined the effects of these interventions on the cellular content of 1,2-diacylglycerol (DAG), which is taken to be an indirect measure of the protein kinase C branch of the phospholipase C-dependent signal transduction pathway.

EXPERIMENTAL PROCEDURES

Chemicals. Cholesterol [1-^{14}C]oleate (59.5 mCi/mmol) and the cAMP radioimmunoassay kit were from Amersham (Aylesbury, Bucks, United Kingdom). Collagenase and CPT-cAMP were obtained from Boehringer Mannheim GmbH (Mannheim, Germany). Bovine serum albumin (essentially fatty acid-free), glucagon, [8-arginine], vasopressin, forskolin, prazosin, db-cAMP, and soybean trypsin inhibitor were obtained from Sigma Chemical Co. (St. Louis, MO). 8-Chloro-cAMP (8-Cl-cAMP) was kindly supplied by Dr. Y. S. Cho-Chung (National Cancer Institute, Bethesda, Maryland).

Isolation of hepatocytes and sampling for enzyme activity. Female Sprague-Dawley rats (180–200 g), housed in temperature- and light-controlled rooms and maintained on a standard diet *ad libitum* with free access to water, were used for the experiments at 0830. Hepatocytes were isolated by collagenase digestion as previously described (28). Cell viability was assessed by the Trypan blue exclusion test and by determining lactate dehydrogenase retention (29), both measurements showing routinely 90–95% viability. Liver cells (0.5 g) were suspended in Krebs-Henseleit solution, pH 7.4, containing 2.5 mM $CaCl_2$, 10 mM glucose, and 2.5% bovine serum albumin, to give a cell density of 4–5 $\times$ 10^6 cells/mL. Hepatocytes were maintained in suspension by rotary shaking and were incubated at 37°C for 30 min prior to addition of the desired compound. The cells were continuously gassed with O_2/CO_2 (19:1). Glucagon was added in 20 µL of 3 mM HCl and forskolin in pure dimethylsulfoxide at a 0.2% final concentration in the medium. All other compounds were dissolved in distilled water. The control cells received the solvent only. At the end of the incubation, two 1 mL aliquots containing 50 mg cells were taken, and the cell pellets were rapidly frozen in liquid N_2 and stored at –20°C until they were processed to measure cAMP and DAG. The remaining incubates (0.4 g cells in 8 mL medium) were diluted 2.5-fold in ice-cold 20 mM Tris-HCl buffer, pH 7.4, containing 200 mM sucrose, 50 mM NaF, and 10 mM EDTA, and then centrifuged. The cell pellets were homogenized in 4 vol of the above buffer and submitted to cell fractionation (1,000 $\times$ *g*, 10 min; 22,000 $\times$ *g*, 10 min; 105,000 $\times$ *g*, 60 min, twice). Microsomes were resuspended in 1 vol of 20 mM Tris–HCl buffer, pH 7.4, containing 250 mM sucrose, and further assayed for CEH activity.

Assay of CEH. Microsomal CEH activity was measured as described before (26). In brief, the assay mixture contained 0.3 mg of microsomal protein in a 0.4 mL solution containing 100 mM imidazole-HCl buffer, pH 6.8, and 40 nmol cholesterol [1-^{14}C]oleate (specific activity 6.25 mCi/mmol) presented as mixed micelles of cholesterol oleate, lecithin, and sodium taurocholate in a 1:4.4:2.5 molar proportion (30). The incubation was stopped and the labeled free fatty acids released were measured as described by Martínez *et al.* (26). One Unit of CEH corresponds to the hydrolysis of one pmol cholesterol oleate per min at 37°C.

Measurement of the cellular content of cAMP and DAG. The absolute mass of cAMP in hepatocytes was determined by a commercial radioimmunoassay kit in ethanolic extracts of the cells (50 mg cells in 0.5 mL of 1% 1N HCl in ethanol) conducted following the manufacturer's instructions. For measuring the cellular DAG level, lipids were extracted exhaustively twice (31), separated by thin-layer chromatography in *n*-heptane/diisopropyl ether/acetic acid (70:30:2, by vol) and charred (32). The DAG bands were quantified by densitometry with an image analyzer BioImage (Millipore, Milford, MA) using dioleylglycerol as standard.

Chemical and statistical analysis. The protein concentrations were determined by the dye-binding technique of Bradford (33) using bovine serum albumin as standard. Statistical significance of results was assessed by the unpaired Student's *t*-test.

RESULTS

The results in Table 1 show that exposure of isolated rat liver cells to glucagon led to moderate, though consistent, dose-dependent activations of microsomal CEH and, as expected, to increases in cellular cAMP. The temporal relationship between the activity of CEH in the microsomal fraction and the content of cAMP in hepatocytes exposed to 100 nM glucagon was analyzed. Figure 1 shows the parallel changes in these parameters. Glucagon caused an immediate elevation of enzyme activity, that remained enhanced for at least 60 min and returned to the basal value 120 min after the hormone addition (Fig. 1A). The extent of increase was consistently around 30%. Concomitantly, a 4-fold increase was seen in the cAMP concentration after a 5-min incubation with the hormone. The cAMP then declined gradually, and by 120 min no intracellu-

TABLE 1
Dose-Dependent Effect of Glucagon on the Microsomal Cholesterol Ester Hydrolase (CEH) Activity and on the Intracellular cAMP Content in Isolated Hepatocytes[a]

Glucagon (nM)	Microsomal CEH (% of control)	cAMP (% of control)
0	100 ± 2	100
1	96 ± 1	135
10	122 ± 3[b]	282
100	134 ± 2[c]	310
200	141 ± 7[c]	ND

[a]The hepatocytes were incubated for 10 min with glucagon, and samples were then collected to measure the microsomal CEH activity and the cellular cAMP content. Parameters are expressed as the percentage of the value found in the absence of glucagon (100%), which was 44.8 ± 0.94 Units/mg protein for CEH activity (mean ± SE of four independent experiments) and 132 pmol/g cell wet weight for cAMP (mean of two experiments). Statistical significance of the difference in values in each column with respect to the control is: [b]$P \leq 0.05$; [c]$P \leq 0.01$; ND, not determined.

lar accumulation of this cyclic nucleotide was detected (Fig. 1B).

The temporal relationship between the neutral microsomal CEH activity and the cAMP level was further investigated in hepatocytes exposed to two types of cAMP-elevating agents that act independently of the glucagon receptor(s): the cell-permeable cAMP analogues db-cAMP and CPT-cAMP and the potent and selective adenylate cyclase activator forskolin. The kinetics of the enzyme stimulation by the cAMP analogues were found to be different from that induced by glucagon, and they are plotted in Figure 2A. Increases in CEH activity were observed after an initial lag period of 30-min exposure to a 0.5 mM concentration of either analogue and activity remained stimulated substantially within the 120-min exposure tested. Figure 2B shows that both db-cAMP and CPT-cAMP led to a drastic increase in the cellular content of cAMP shortly after its addition, after which it declined gradually. The reported different rate of metabolism of these analogues (34) was reflected in the magnitude and pattern of stimulation of cAMP and CEH activity. CPT-cAMP induced cellular accumulation of cAMP to a lesser extent at the beginning, but the effect persisted for a longer period than that seen with db-cAMP, and a similar profile of activation was seen in CEH. The cell permeable compound 8-Cl-cAMP has been reported to bind specifically to the regulatory subunit of the cAMP-dependent protein kinase type II in cancer cell lines (35). We found that 8-Cl-cAMP raised microsomal CEH activity and the increase in enzyme activity exhibited the same temporal pattern to that seen with the other site-selective analogue CPT-cAMP (results not shown). Raising intracellular cAMP levels by direct stimulation of adenylate cyclase with the diterpene forskolin gave the maximum increase in cAMP (5-fold) within 10 min incubation, and there was also a lag of 30 min before any increase in microsomal CEH activity was detected (Fig. 3). Again, the change in cAMP preceeded that of the enzyme activity.

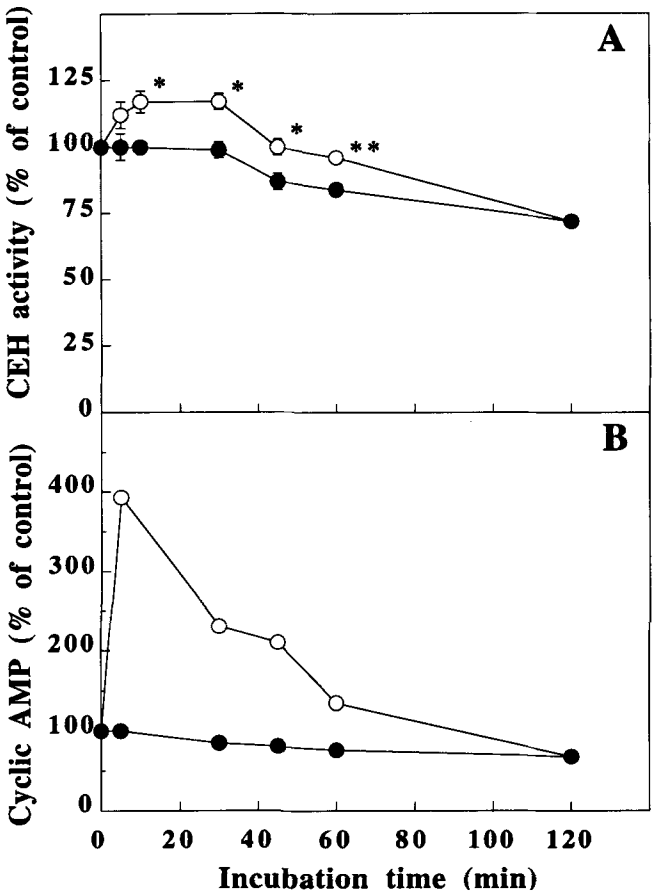

FIG. 1. Time-course of glucagon-mediated increases in microsomal cholesterol ester hydrolase (CEH) activity and in cellular cAMP content in isolated hepatocytes. The hepatocytes were incubated for 5 to 120 min with 100 nM glucagon (○), and the control cells (●) were exposed to the vehicle alone. Cell samples were collected at the indicated times and assayed for microsomal CEH activity (A) and cellular cAMP (B). Values shown are means ± SE of four different experiments for CEH activity and means of two for cAMP levels. Vertical bars not shown lie within the symbols. Parameters are expressed as the percentage of the value found in the control cells at the zero time (100%), which was 43.89 ± 2.49 Units/mg microsomal protein for CEH activity and 196 pmol/g cell wet weight for cAMP. Statistical significance of the difference in values with respect to the control is: *$P \leq 0.025$; **$P \leq 0.005$.

As a further analysis of the factors hypothetically relevant to the regulation of CEH activity in liver microsomes, we also measured the cellular concentration of DAG, one of the signals that mediate α-adrenergic responses *via* protein kinase C. Figure 4 shows changes in content of DAG in hepatocytes incubated over 5 to 120 min with the cAMP-elevating agents already mentioned: glucagon (100 nM) and forskolin (25 μM) in A, and db-cAMP (0.5 mM) and CPT-cAMP (0.5 mM) in B. The results show an overall decreasing trend. A gradual lowering of cellular DAG was caused by glucagon and forskolin. The response of this parameter to the cAMP analogues was similar in magnitude and shape. DAG were rapidly reduced and maintained between 25–30% below the

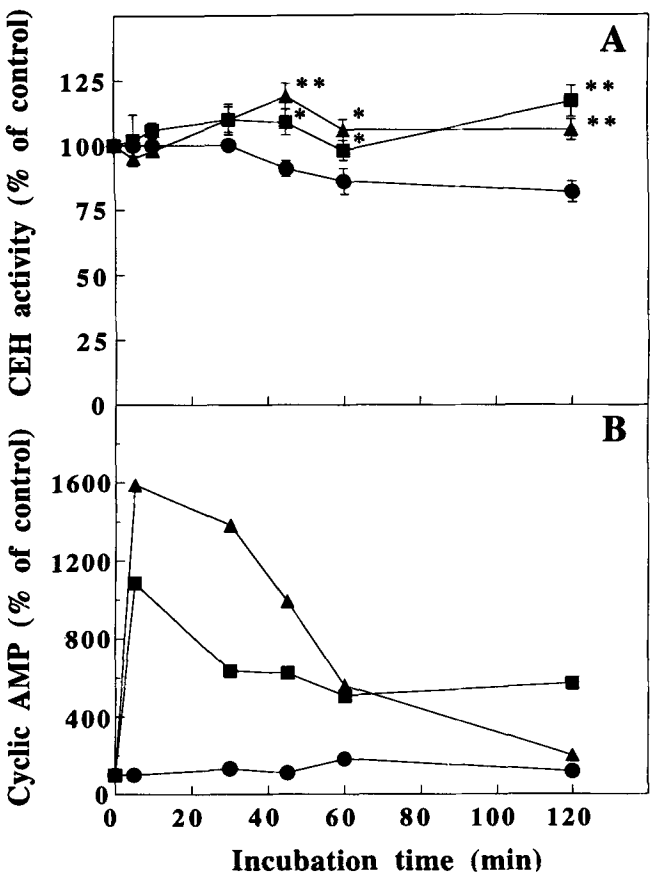

FIG. 2. Time-course of dibutyryl cAMP (db-cAMP)- or 8-[4-chlorophenylthio]-cAMP (CPT-cAMP)-mediated increases in microsomal cholesterol ester hydrolase (CEH) activity and in cellular cAMP content in isolated hepatocytes. The hepatocytes were incubated for 5 to 120 min with 0.5 mM db-cAMP (▲) or 0.5 mM CPT-cAMP (■), and the control cells (●) were exposed to the vehicle alone. Cell samples were collected at the indicated times and assayed for microsomal CEH activity (A) and cellular cAMP (B). Values shown are means ± SE of four different experiments for CEH activity and means of two for cAMP. Vertical bars not shown lie within the symbols. Parameters are expressed as the percentage of the value found in the control cells at the zero time (100%), which was 39.89 ± 2.11 Units/mg microsomal protein for CEH activity and 207 pmol/g cell wet weight for cAMP. Statistical significance of the difference in values with respect to the control is: $^{*}P \leq 0.05$; $^{**}P \leq 0.01$, at least.

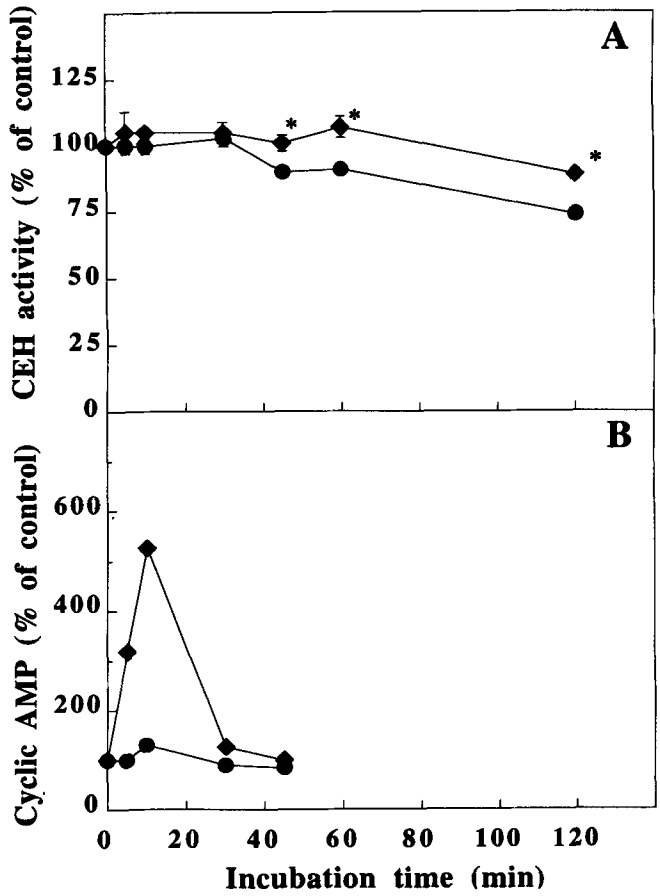

FIG. 3. Time-course of forskolin-mediated increases in microsomal cholesterol ester hydrolase (CEH) activity and in cellular cAMP content in isolated hepatocytes. The hepatocytes were incubated for 5 to 120 min with 25 mM forskolin (◆), and the control cells (●) were exposed to the vehicle alone. Cell samples were collected at the indicated times and assayed for microsomal CEH activity (A) and cellular cAMP (B). Values shown are means ± SE of four different experiments for CEH activity and means of two for cAMP. Vertical bars not shown lie within the symbols. Parameters are expressed as the percentage of the value found in the control cells at the zero time (100%), which was 45.89 ± 3.71 Units/mg microsomal protein for CEH activity and 188 pmol/g cell wet weight for cAMP. Statistical significance of the difference in values with respect to the control is: $^{*}P \leq 0.05$.

level in resting cells, except with a 60-min incubation, where DAG were essentially as they were in the controls.

Consistent with the fact that glucagon and β-adrenergic responses become desensitized by vasopressin exposure (36), Figure 5A shows that prior treatment of hepatocyte suspensions with 10 nM vasopressin for 5 min partially prevented the cAMP accumulation induced by 100 nM glucagon. The longer the cells were incubated with glucagon after vasopressin was added the less complete was the inhibition. Interestingly, exposure of cell suspensions to vasopressin alone gave a rapid and sustained activation of microsomal CEH without significantly affecting cAMP and, under these conditions, glucagon was unable to enhance further cholesterol esterase activity (Fig. 5B). Panel C of this figure shows the sustained 50–60% increase in cellular DAG induced by vasopressin either in the absence or in the presence of glucagon throughout the observation time. Though not shown, preincubation of cells with excess propranolol (150 μM) for 5 min did not produce any significant change in the concentration-dependent increase of CEH activity and cAMP level by glucagon.

Table 2 shows that simultaneous treatment of hepatocytes with both glucagon and vasopressin resulted in a nonadditive activation of CEH, an increase of cAMP lower than that due to glucagon, and an increase of DAG similar to that of vasopressin. Finally, the ability of the α_1-adrenergic agonist prazosin to modify vasopressin-mediated activation of CEH was examined. A 5-min pretreatment with excess prazosin (100

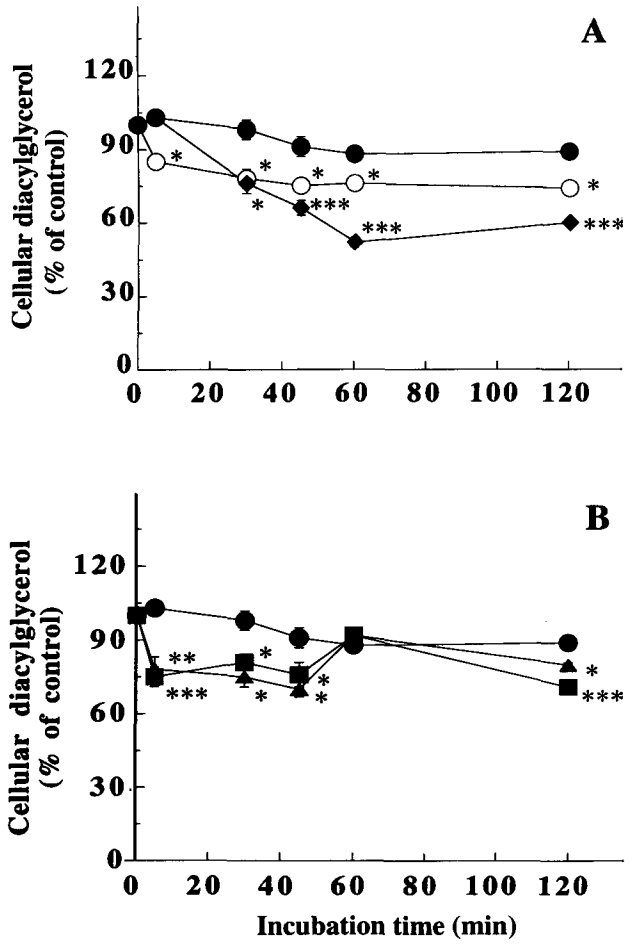

FIG. 4. Time-course of glucagon, forskolin, dibutyryl cAMP (db-cAMP), and 8-[4-chlorophenylthio]-cAMP (CPT-cAMP) to decrease the cellular content of diacylglycerol (DAG) in isolated hepatocytes. The hepatocytes were incubated for 5 to 120 min with 100 nM glucagon (○), 25 mM forskolin (◆), 0.5 mM db-cAMP (▲), or 0.5 mM CPT-cAMP (■). The control cells (●) were exposed to the vehicle alone. Cell samples were collected at the indicated times and assayed for DAG as described in the Experimental Procedures section. Values shown are means ± SE of four different experiments and are expressed as the percentage of the value found in the control cells at the zero time (100%), which was 4.12 ± 0.66 nmol/mg cell protein. Vertical bars not shown lie within the symbols. Statistical significance of the difference in values with respect to the control is: $*P \leq 0.025$; $**P \leq 0.01$; $***P \leq 0.005$.

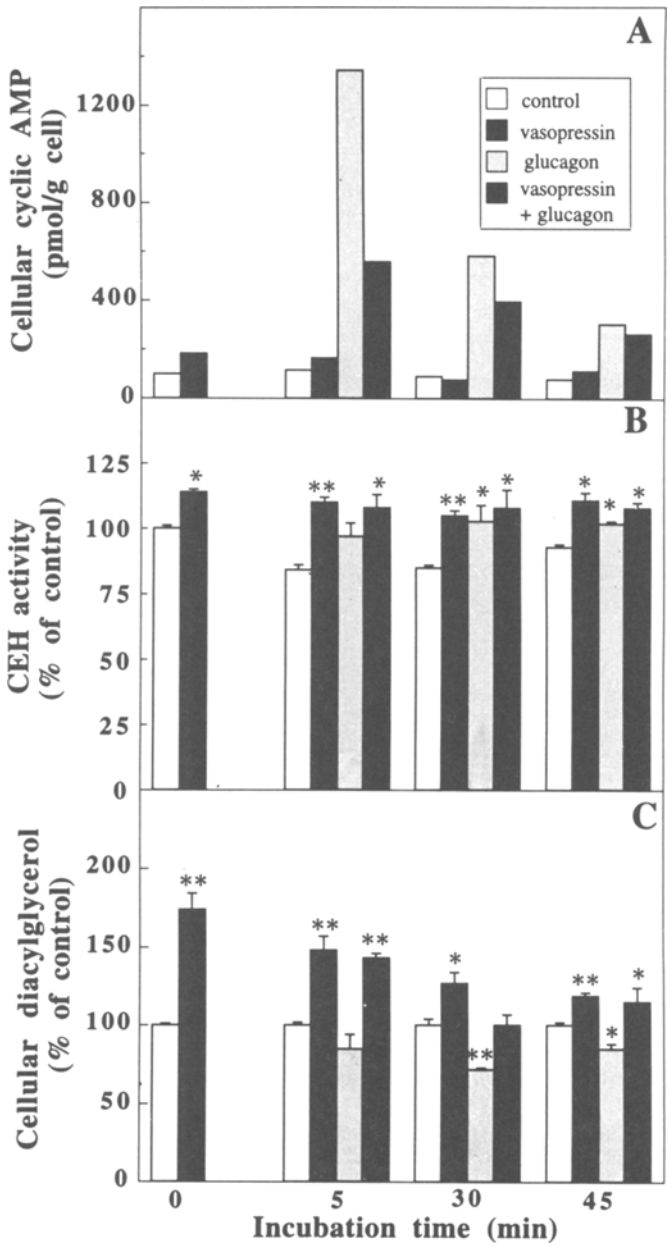

FIG. 5. Effect of prior exposure to vasopressin on glucagon-mediated changes in microsomal cholesterol ester hydrolase (CEH) activity and in cellular cAMP and diacylglycerol (DAG) levels. The hepatocytes were incubated for 5, 30, or 45 min with 100 nM glucagon subsequent to cell exposure to 10 nM vasopressin for 5 min. The control cells were pretreated with the vehicle alone. Cell samples were collected at the indicated times and assayed for microsomal CEH activity (A) and for cellular cAMP (B) and DAG content (C) as described in the Experimental Procedures section. Values shown are means ± SE of four different experiments except for cAMP (n = 2). Parameters are expressed as the percentage of the value found in the control cells at the 5 min time (100%), which was 40.9 ± 1.0 Units/mg microsomal protein for CEH activity and 4.36 ± 0.05 nmol/mg cell protein for DAG. Statistical significance of the difference in values with respect to the control is: $*P \leq 0.05$, minimun; $**P \leq 0.005$.

μM) was able to prevent vasopressin, alone or in combination with glucagon, from causing the increase in microsomal CEH activity, whereas activation of CEH by glucagon alone was still found. Table 2 also depicts that the changes in DAG due to the hormones were blocked by prazosin, while those in cAMP were unaffected.

DISCUSSION

The data presented herein provide evidence that exposure of rat hepatocytes in suspension to the hormones glucagon and/or vasopressin, or to compounds that increase intracellular cAMP, causes the rate of cholesterol oleate hydrolysis by microsomal CEH to be enhanced. The results suggest the involvement of several different mediators in this regulation. These findings agree with those we reported in a previous

TABLE 2
Effect of Prazosin on Glucagon and/or Vasopressin-Mediated Changes in the Microsomal Cholesterol Ester Hydrolase (CEH) Activity and in the Cellular cAMP and Diacylglycerol (DAG) Content in Isolated Hepatocytes[a]

	Microsomal CEH (Units/mg prot)	cAMP (pmol/g cell)	DAG (nmol/mg cell prot)
Control	41.61 ± 1.74	86	5.46 ± 0.37
Glucagon	56.58 ± 1.22[c]	232	4.64 ± 0.14[b]
Vasopressin	53.67 ± 2.00[b]	106	7.17 ± 0.16[b]
Glucagon + vasopressin	57.49 ± 1.35[c]	178	7.05 ± 0.88[b]
Prazosin	44.29 ± 1.94	119	5.51 ± 0.41

[a]The hepatocytes were exposed to 100 μM prazosin for 5 min before addition of 100 nM glucagon and/or 10 nM vasopressin. After 30 min, cell samples were collected to measure the microsomal CEH activity and the intracellular cAMP and DAG content. Values shown are means ± SE of four independent experiments except for the measurement of cAMP (n = 2). Statistical significance of the difference in values in each column with respect to the control is: [b]$P \leq 0.05$; [c]$P \leq 0.005$. CEH activity in the presence of prazosin plus glucagon was significantly different ($P \leq 0.05$) from that in the presence of prazosin alone.

study with cell-free systems, in which stimulation of neutral microsomal CEH was seen after treatment of rat liver microsomes with a cAMP-dependent protein kinase or with Ca^{2+}/calmodulin (26), and with a recent report by Hoang *et al.* (21), indicating stimulation of neutral CEH activity by cAMP analogues and glucagon in the post-mitochondrial supernatant of cultured hamster hepatocytes.

We have found in this study with rat hepatocyte suspensions that the hormone glucagon, the cell permeable cAMP analogues db-cAMP, CPT-cAMP, and 8-Cl-cAMP, and the adenylate cyclase activator forskolin stimulate microsomal CEH activity. Comparison of the kinetics of CEH activity and cellular cAMP levels is consistent with a causal relationship. On one hand, the glucagon-induced stimulation in enzyme activity was approximately constant from 10 to 60 min of incubation, as was the induction of cAMP. Furthermore, increases in CEH activity and cAMP were parallel between 45 and 120 min after the addition of either cAMP analogue. However, at shorter incubation periods, when cAMP was at its maximum level, there was a lack of response in CEH activity. A similar temporal pattern was observed with forskolin, as the stimulation of the rate of cholesterol ester hydrolysis lagged behind the peak rise in cAMP. This was found to be the case for all the cAMP-elevating agents that act independently of the glucagon receptor(s). The effectiveness of the nonspecific cAMP analogue db-cAMP and the two site-selective analogues CPT-cAMP and 8-chloro-cAMP in activation of CEH were rather similar and higher than that of forskolin. As mentioned above, the greatest difference is that CPT-cAMP and 8-Cl-cAMP provoked marked activations at the longest incubation period tested. This may reflect different balances between penetration of the cell by each analogue, degradation within the cell and ability to activate target enzymes (37). These findings, taken together, suggest that cAMP may play a role in the stimulation of CEH activity. Whether or not cAMP exerts its effect *via* phosphorylation of the enzyme or by some other mechanism will be difficult to ascertain until the enzyme has been purified and can be studied at the molecular level.

In contrast to the cAMP-related agents discussed above, glucagon caused an immediate activation of CEH, suggesting that glucagon acts through a mechanism different from that of forskolin and cAMP analogues, at least in the initial stages of altering CEH activity. Glucagon is known to induce numerous actions in hepatocytes that appear to occur independently of any increase in cAMP and may be due to activation of lipid signalling pathways (36,38–41). Short-term effects of this hormone include stimulation of glycogenolysis, gluconeogenesis and fatty acid oxidation, and inhibition of fatty acid synthesis (42). In addition to glucagon (36,38–40), db-cAMP and the adenylate cyclase activator forskolin have also been reported to induce variations in the concentrations of cellular DAG and cytoplasmic free calcium (36,40,43). Our experiments show immediate reductions in DAG in cells treated with all the cAMP-elevating agents used in this work. Therefore, although it is likely that the effect of glucagon on CEH activity is mediated in part by increasing the intracellular concentration of cAMP, the change in the DAG content and the reported induction of calcium mobilization (36) may play a role in the early regulatory mechanism. This idea is further supported by the finding (not shown) that, although the glucagon-mediated increase in cAMP is potentiated by 3-isobutyl-1-methyl-xanthine, glucagon action on CEH is not affected by it. Conversely, when the glucagon-mediated increase in cAMP is reduced by pretreatment of hepatocytes with vasopressin, the glucagon action on CEH is not seen. Indeed, it is almost axiomatic to say that most receptors couple to multiple signalling pathways and that the product of one pathway can have feedback effects on the other signalling pathways, or activation of one receptor can modulate the response of another. The fact that the β-adrenergic blocker propranolol was without effect on glucagon actions, whereas vasopressin inhibited the ability of glucagon to stimulate cAMP content (36) and CEH activity, suggests that glucagon is acting *via* its own receptor(s).

In the liver, vasopressin is well known to produce marked changes in the phosphorylation state of diverse proteins through phosphoinositide-derived metabolites because hepatocytes contain a large number of vasopressin receptors, higher than those for angiotensin II or related Ca^{2+}-mobilizing hormones (44,45). Vasopressin treatment, alone, activated microsomal CEH activity without varying cAMP. The elevation in intracellular DAG found in vasopressin-treated hepatocytes was maintained when glucagon was added simultaneously. The magnitude and the time-dependence of vasopressin-induced DAG accumulation were in the range of previously reported data (44). In this situation, CEH remained activated at its maximum extent (about 35%), but there were

no observed synergistic effects. In addition, excess prazosin prevented the activation of CEH elicited by vasopressin, as expected from a role for DAG/Ca^{2+} in the activation. This indicates that the neutral microsomal CEH is consistently activated by occupancy of not only glucagon but also vasopressin receptors. It is not clear why there is no activation of CEH in cells exposed to vasopressin and glucagon following prazosin treatment. Under these conditions, it is assumed that prazosin is preventing vasopressin but not glucagon from activating CEH. Thus, whereas the increases in CEH activity and cAMP levels are seen, the glucagon-mediated decrease in DAG is abolished by prazosin. It is possible that the binding of glucagon to a DAG/Ca^{2+}-related receptor is disturbed by the α_1-adrenergic agonist, which in turn could affect in some way the response of CEH to the cAMP signal.

It is of interest to note that the magnitude of the effects on the neutral microsomal CEH activity caused by phosphorylating agents in the intact hepatocyte is much smaller than those found in cell-free systems (26). As a matter of fact, large effects on the microsomal cholesterol esterase, unlike the cytosolic CEH, are often not seen in studies with intact animals or isolated liver cells. A possible explanation is that microsomal CEH, as other enzymes involved in cholesterol homeostasis, is controlled by a variety of mechanisms besides phosphorylation that may be interconnected or acting simultaneously, this having the power to attenuate the effects of phosphorylation. Neither can we rule out that microsomal CEH has a maximum level for activation, once the phosphorylation cascades are switched on by occupancy of glucagon and/or vasopressin receptors. Whether the phosphorylation of an enzyme *in vivo* is finally expressed as a change of its activity depends on the concentration of substrate and effectors within the cell (46), parameters that can be altered when cells are exposed to agonists.

This study provides the first evidence that triggering the phosphorylation cascades by cAMP-dependent and Ca^{2+}-linked hormones in isolated rat hepatocytes correlates with increased activity of the neutral microsomal CEH. Whether the changes in this esterase activity have a real impact in the cholesterol flux inside the hepatocyte is presently under study.

A Protein Tyrosine Kinase Associated with the ATP-Dependent Inactivation of Adipose Diacylglycerol Acyltransferase

T.E. Lau and M.A. Rodriguez*

University of Ottawa, Department of Biochemistry, Ottawa, Ontario, K1N 6N5 Canada

ABSTRACT: The activity that has been previously reported to reversibly inactivate adipose glycerolphosphate acyltransferase (GPAT) and diacylglycerol acyltransferase (DGAT) *in vitro* in the presence of ATP is shown here to be partially purified from adipose tissue with an apparent molecular weight of 68 kDa. The activity responsible for inactivating DGAT is associated with a kinase activity as determined by phosphate incorporation both into microsomal proteins and into a synthetic tyrosine-containing peptide as substrate for protein tyrosine kinase. Two microsomal polypeptides of 53 and 69 kDa are major substrates of this kinase. Both DGAT inactivating and kinase activities assayed from the purified sample have been found to be insensitive to the Ser/Thr kinase inhibitor H-7 while being sensitive to genistein and tyrphostin-25. A crude protein phosphatase preparation from liver was capable of reversing the effects of both activities. The purified sample was also shown to inactivate GPAT in the presence of ATP. These results suggest that a protein tyrosine kinase, in concert with a protein tyrosine phosphatase, may regulate the activities of DGAT and GPAT by a phosphorylation–dephosphorylation mechanism.
Lipids 31, 277–283 (1996).

Simultaneous triacylglycerol synthesis and lipolysis allows adipose tissue to rapidly respond to changes in peripheral tissue requirements for fatty acids. Moreover, phospholipids and diacylglycerols are essential components of cell membranes and are mediators of hormone action. However, the regulation of glycerolipid synthesis is not yet well understood. There have been conflicting reports about the regulatory roles of hepatic diacylglycerol acyltransferase (DGAT) and phosphatidate phosphatase (PAP) (1–3). At present, a rate-limiting step in adipocyte triacylglycerol (TAG) synthesis has not been established. Rather, all enzymes appear to be functioning below saturation to allow multistep regulation. In this way, the steady-state triglyceride synthesis could increase without a rise in levels of phosphatidate and lysophosphatidate, which can potentially pose a threat to membrane stability and function (4).

Although it is well established that fatty acid incorporation into adipose tissue triglycerides is under hormonal control (4), the precise molecular events involved in the regulation of synthesis have yet to be elucidated. Whereas only glycerolphosphate acyltransferase (GPAT) has been found to be activated by insulin (5), catecholamines have been previously reported to decrease the activity of GPAT (6), PAP (7), and DGAT (6). However, in a more recent report (8), it was proposed that norepinephrine does not directly regulate TAG synthesis in adipocytes. *In vitro* experiments suggest that TAG synthetic enzymes, including GPAT (9,10), PAP (11), and DGAT (12,13) from various tissues, may be regulated by a phosphorylation-dephosphorylation mechanism. However, different kinases have been implicated with conflicting reports on their effects on the enzymes (11–16).

We have previously described the presence of an enzyme activity in adipose tissue which, in the presence of ATP, reversibly inactivates GPAT (17) and DGAT (18). We have also shown that this activity could not be replaced by different preparations of protein kinase C (PKC) and protein kinase A (PKA) (18). In the present report, we describe the partial purification of this enzyme activity from the adipose cytosol and demonstrate its association with a protein tyrosine kinase activity.

MATERIALS AND METHODS

Materials. Oleic acid, oleoyl-CoA, diolein (1,2-dioleoyl-*sn*-glycerol), L-glycerol-3-phosphate, ATP, CoA, DL-dithiothreitol (DTT), ethylenediaminetetraacetate (EDTA), fatty acid-free bovine serum albumin (BSA), 4′,5,7-trihydroxyisoflavone (genistein), 1-(5-isoquinolinylsulfonyl)-2-methylpiperazine (H7), [3,4,5-trihydroxybenzylidene]-malononitrile (tyrphostin-25), tyrosine kinase synthetic substrate peptide (Arg-Arg-Leu-Ile-Glu-Asp-Ala-Glu-Tyr-Ala-Ala-Arg-Gly), Reactive Blue 2-Sepharose, S-Sepharose, Sephacryl S-200, DEAE-Sepharose CL-6B, polyethylene glycol compound (MW 15,000–20,000), SDS, acrylamide, Brilliant Blue G colloidal, and molecular weight standards were obtained from the Sigma Chemical Co. (St. Louis, MO). Filters (0.22 μm pore size) were obtained from Millipore (Bedford, MA). Phospho-

cellulose paper (Whatman P-81) was obtained from Canadawide Scientific (Ottawa, Ontario, Canada). [9,10-^{3}H]Oleic acid (7.4 Ci/mmol) and L-[2-^{3}H]glycerol-3-phosphate (10.6 Ci/nmol) were obtained from Du Pont Canada Inc. (Mississauga, Ontario, Canada). [9,10-^{3}H]Oleoyl-CoA (100 Ci/mol) was prepared from the radioactive fatty acid following the method of Bishop and Hajra (19) as previously described (20). ^{32}P-γ-ATP (3 Ci/mmol) was obtained from Amersham (Oakland, Ontario, Canada). Universol (liquid scintillation cocktail) was from ICN Biomedicals (Mississauga, Ontario, Canada).

Preparation of microsomes. Epididymal adipose tissue microsomes from male Sprague Dawley rats (Charles River Canada Inc., St. Constant, Quebec, Canada) were prepared by differential centrifugation of the homogenized tissue as previously described (17). When indicated, to remove any endogenous kinase, the microsomes were washed with a buffer containing 200 mM Tris-HCl (pH 9.0), 1 M NaCl, 1 mM EDTA, 0.25 M sucrose, and 1 mM DTT. Amounts of microsomes used in the experiments are indicated throughout this paper as the mass of microsomal protein.

Purification of DGAT inactivating activity. The activity responsible for DGAT inactivation was purified by fractionation of 50 mL of the 100,000 × *g* supernatant from homogenized adipose tissue, with the fractions of the purification sequence being tested for DGAT inactivation with washed microsomes (8 μg) as shown below. The cytosol was first mixed with solid ammonium sulfate to reach 55% ammonium sulfate saturation and the mixture was stirred at 4°C for one hour. After centrifugation the pellet containing the DGAT inactivating activity was resuspended in TED buffer [50 mM Tris-HCl (pH 7.5), 1 mM EDTA, and 2 mM DTT] and applied to a 20 mL Blue-Sepharose column followed by elution with TED buffer containing 0, 0.3, and 1 M NaCl. The protein peak which eluted at 0.3 M NaCl contained the higher capacity for DGAT inactivation. It was dialyzed against TED buffer and applied to a 20 mL S-Sepharose column, which was eluted with 0.5 M NaCl in TED buffer. The pooled fractions containing the activity were dialyzed against TED buffer, applied to a 7 mL DEAE Sepharose column and eluted with 1 M NaCl in TED buffer. Fractions containing the activity were pooled, concentrated with polyethylene glycol (Sigma) and applied to a 45 cm Sephacryl S-200 column equilibrated with TED buffer. The final pooled fractions containing the activity were made to 20% (vol/vol) with respect to glycerol and stored at –20°C.

Protein phosphatase preparation. Protein phosphatase was partially purified from rat liver up to the ethanol precipitation step of the method of Brant *et al.* (21) as previously described (17).

GPAT assay. GPAT assay was performed at 37°C in a final volume of 0.5 mL containing 0.1 M Tris-HCl (pH 7.5), 2 mM DTT, 10 mM $MgCl_2$, 25 μM BSA, 0.1 mM oleoyl-CoA, 1 mM [^{3}H]glycerol-3-phosphate (1.2 Ci/mol), and microsomes (5–10 μg). After a 4-min incubation, the reaction was stopped by vortexing with 1 mL of butanol saturated with water. The butanol phase was washed three times with 1.5 mL of water saturated with butanol, and a 0.5 mL aliquot was counted in 7 mL Universol in a beta counter.

DGAT assay. DGAT was assayed as previously described (18) with minor changes by incubating 5–10 μg of microsomes for 5 min at 37°C in 0.5 mL of Tris-HCl (pH 7.5) containing 1 mM DTT, 10 mM $MgCl_2$, 5 μM BSA, 20 μM [^{3}H]oleoyl-CoA (7.5 Ci/mol), and 150 μM 1,2-diolein (delivered in 5 μL acetone). The reaction was stopped with 1.5 mL of isopropanol/hexane (1:1, vol/vol), and the hexane phase was washed three times with 0.75 mL of isopropanol/hexane (4:1, vol/vol) and 0.75 mL of 0.05% KOH. A 0.75-mL amount from the hexane phase was counted in 7.5 mL Universol in a beta counter.

DGAT/GPAT inactivating activity assay. ATP-dependent GPAT and DGAT inactivation was determined by performing the corresponding enzyme assays with 8 μg of microsomes (unless otherwise mentioned) and the indicated sample, in the presence and absence of 0.5 mM ATP. Inactivating activity was expressed as the percentage decrease in the rate of DGAT or GPAT activity caused by the addition of ATP as previously described (17,18). Since no linear dependence of DGAT/GPAT inactivation with time could be obtained in most of our assay conditions (18), our measurements of DGAT or GPAT inactivation are not rates but rather levels of inactivation which, in most cases, correspond to the maximum level observable with our microsomes preparation.

Protein kinase assay. Kinase activity was assayed by measuring the incorporation of ^{32}P from ^{32}P-γ-ATP into either microsomes or the tyrosine kinase synthetic-peptide substrate. Phosphorylation of microsomes was carried out in 0.1 mL of TMD buffer [50 mM Tris-HCl (pH 7.5), 10 mM $MgCl_2$, 1 mM DTT] containing 0.5 mM ^{32}P-γ-ATP (40 Ci/mol) and 30 μg of microsomes. The reaction was initiated by addition of the kinase sample or, in the case of microsomes containing the endogenous kinase, by the addition of the ^{32}P-γ-ATP. After a 5 min incubation at 37°C, a 75 μL aliquot of the incubation mixture was applied to a 0.22-μm pore size filter (2-cm diameter) which was prewashed with 0.5 mL of 50 mM phosphate. The reaction was terminated by passing 2.5 mL of 50 mM phosphate through the filter disc under suction. Discs were dried and counted in 7 mL of Universol (ICN).

Phosphorylation of the synthetic peptide was carried out as described by Pike *et al.* (22) with some minor modifications. The incubation was carried out at 37°C in 20 μL of TMD buffer containing 1 mM synthetic peptide and 0.5 mM ^{32}P-γ-ATP (40 Ci/mol). The reaction was initiated by the addition of the kinase sample and terminated after five minutes by the addition of 30 μL of 5% trichloroacetic acid. After centrifugation, the supernatant was blotted on phosphocellulose paper (2 cm^2) and washed three times with 75 mM phosphoric acid. After drying, the paper was counted in 7 mL of Universol.

Protein assay. Protein concentrations were measured by the dye-binding assay of Bradford (24) using bovine serum albumin as the standard.

Electrophoresis. SDS–polyacrylamide gel electrophoresis (SDS–PAGE) was carried out in a mini-protein gel electrophoresis apparatus (Bio-Rad), under reducing conditions using the discontinuous system of Laemmli (23), with 7.5 and 4.5% acrylamide resolving and stacking gels, respectively. Gels were stained with Brilliant Blue G colloidal (Sigma), dried and, when indicated, exposed to Fuji NIF-RX X-ray film. The following molecular weight markers (Sigma) were used: carbonic anhydrase (29 kDa), ovalbumin (45 kDa), bovine serum albumin (66 kDa), phosphorylase b (97.4 kDa), and β-galactosidase (116 kDa).

RESULTS

Incubation of microsomes from rat adipose tissue with 0.5 mM ATP resulted in the partial inactivation of DGAT (33 ± 1%) as shown in Figure 1. These microsomes also contained an endogenous kinase activity that catalyzed the incorporation of ^{32}P from ^{32}P-γ-ATP into microsomes. Washing the microsomes with a high salt, high pH buffer caused the removal of both the ATP-dependent DGAT inactivating activity and the kinase activity (Fig. 1). The adipose tissue cytosolic fraction was able to restore both activities when added to the washed microsomes (Fig. 1), which is in agreement with previous results showing that the cytosol stimulated the ATP-dependent inactivation of microsomal DGAT (18).

Partial purification of the DGAT inactivating activity. The activity responsible for the ATP-dependent inactivation of DGAT was partially purified from the cytosol by a sequence of steps involving protein precipitation with ammonium sulfate as well as Blue Sepharose, S-Sepharose, DEAE-Sepharose, and Sephacryl S-200 chromatographies, as described in the Materials and Methods section. The activity bound to Blue Sepharose, S-Sepharose, and DEAE-Sepharose and coeluted with the protein peaks at NaCl concentrations of 0.3, 0.5, and 1.0 M, respectively (Fig. 2). In the case of the gel filtration column, the protein eluted in two overlapping peaks corresponding to 82 and 44 kDa, with the activity centered at 67 kDa (Fig. 2). Aliquots from the pooled fractions containing 1.2 μg of protein caused 46 ± 4% inactivation of DGAT in the presence of ATP. The final fraction containing the activity represented 0.1% of the starting protein (Table 1). SDS–PAGE of the purified fraction showed a major band at about 68 kDa (Fig. 3).

Phosphorylation of a tyrosine containing peptide. Consistently through the purification steps, the pooled fractions with DGAT inactivating activity were found to phosphorylate the synthetic peptide Arg-Arg-Leu-Ile-Glu-Asp-Ala-Glu-Tyr-Ala-Ala-Arg-Gly (Table 1) which is a specific substrate of protein tyrosine kinases (22). Thus, a protein tyrosine kinase activity seemed to co-purify with the ATP-dependent DGAT inactivating activity. About 90% of the total cytosolic tyrosine kinase activity was lost at the salt precipitation step resulting in a 50% drop in specific activity. However, more than 50% of the remaining activity was recovered, with a purification factor of about 120-fold, through the last four chromatographic steps (Table 1).

Our purified kinase was also able to phosphorylate microsomes at a rate of 0.24 ± 0.08 μmol Pi · min^{-1} · mg^{-1}, which represents a 400-fold increase over the cytosolic specific activity (Table 1).

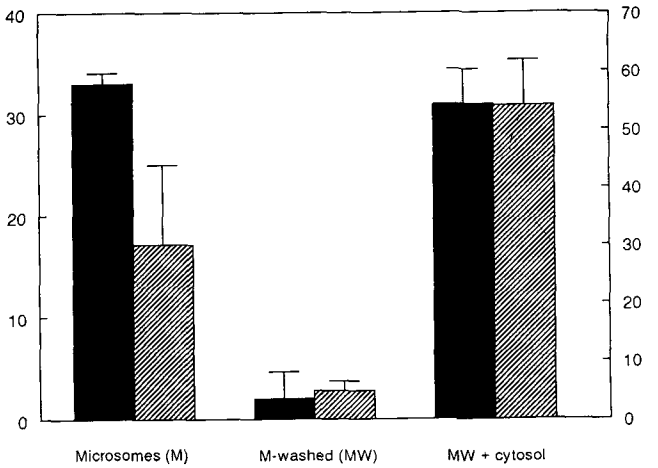

FIG. 1. Localization of the activity responsible for diacylglycerol acyltransferase (DGAT) inactivation. Microsomes (M) and washed microsomes (MW) were assayed for ATP-dependent DGAT inactivation in the presence and absence of cytosol (120 μg). For microsomal phosphorylation, 30 μg of microsomes with and without 60 μg cytosol were assayed for the incorporation of ^{32}P-phosphate from ^{32}P-γ-ATP into microsomes. Results are given as mean ± SEM (n = 5). Solid bar, ATP-dependent DGAT inactivation (%); ruled bar, microsomal phosphorylation (pmol Pi/min).

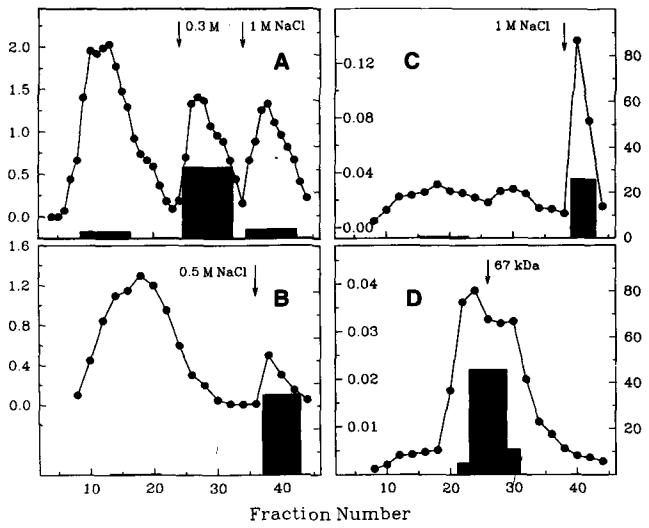

FIG. 2. Purification of DGAT inactivating activity. Elution profiles for the Blue Sepharose column (a), the S-Sepharose column (b), the DEAE-Sepharose column (c), and the Sephacryl S-200 column (d) are given (from Sigma Chemical Co., St. Louis, MO). Fractions were assayed for protein content. Pools were made of the protein peaks, as indicated by the bars, and 50 μL aliquots were assayed for DGAT inactivating activity. Fraction volume was either 1 mL (A) or 0.5 mL (B, C, and D). ●, Protein concentration (mg/mL); ■, DGAT inactivation (%). Abbreviation as in Figure 1.

TABLE 1
Purification Sequence of the Kinase Associated with DGAT Inactivation[a]

Purification step[b]	Total protein (mg)	DGAT inactivating activity	Microsome phosphorylation (nmol/mg/min)	Tyrosine kinase activity (nmol/mg/min)
Cytosol	150.0	+	0.62 ± 0.1 (4)	0.20 ± 0.03 (8)
Ammonium sulfate	37.5	+	n.d.[c]	0.10
Blue Sepharose	9.38	+	n.d.	0.56
S-Sepharose	0.57	+	n.d.	3.52
DEAE-Sepharose	0.29	+	n.d.	6.36
Sephacryl S-200	0.14	+	240 ± 80 (4)	11.7 ± 0.4 (8)

[a]Pooled fractions testing positive for the presence of diacylglycerol acyltransferase (DGAT) inactivating activity (Fig. 2) were assayed for protein content, for microsome phosphorylation, and for kinase activity with the tyrosine containing peptide. Where indicated, values given are means ± SEM (number of determinations).
[b]All from Sigma Chemical Co. (St. Louis, MO).
[c]n.d., Not determined

Effect on GPAT. Since we have previously shown that microsomal GPAT is also reversibly inactivated by an ATP-dependent activity in rat adipose cytosol (17), we determined whether or not the activity purified from the cytosol could inactivate GPAT *in vitro*. Addition of 1.2 µg of partially purified kinase preparation and 0.5 mM ATP to the incubation mixture of the GPAT assay resulted in 34 ± 3% inactivation, which is similar to the 38 ± 5% GPAT inactivation obtained with 120 µg of cytosol.

Effect of various protein kinase inhibitors. We have previously shown that DGAT inactivating activity in the cytosol could be inhibited by EDTA, but it was insensitive to inhibitors of serine/threonine kinases such as H7 and the protein inhibitor of PKA (18). We have now found that these two latter inhibitors decreased the level of microsome phosphorylation with cytosol by nearly 50% (data not shown), suggesting the presence of cytosolic serine/threonine kinases acting on microsomal proteins unrelated to DGAT activity. As shown in Figure 4, our kinase preparation showed a relatively lower sensitivity to inhibition of microsome phosphorylation by H7, indicating that a good part of the cytosolic serine kinase activity had been removed. By contrast, two tyrosine kinase inhibitors, tyrphostin-25 and genistein, were effective in blocking both the microsome phosphorylation and the DGAT inactivating activities of our purified fraction (Fig. 4).

Phosphorylation of microsomal proteins. Figure 5 shows the autoradiograph of ^{32}P-phosphorylated microsomal proteins run on SDS–PAGE. Two major bands at 53 ± 1.3 and 69 ± 1.1 kDa (four gels) were visible, as well as a third one at the top of the resolving gel which may represent an aggregate of proteins (lane 1). Other minor bands were also apparent in

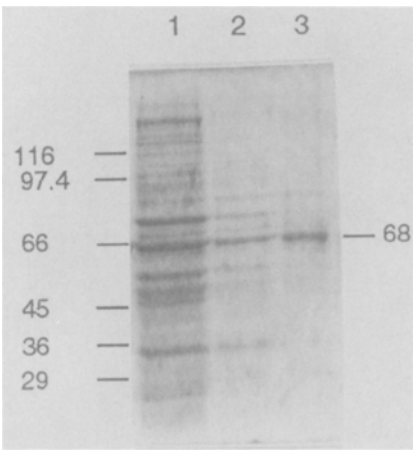

FIG. 3. Electrophoresis of the purified activity. SDS–polyacrylamide gel electrophoresis was run with 80 µg of the 55% ammonium sulfate pellet (lane 1), 20 µg of the 0.3 M NaCl pool from Blue Sepharose column (lane 2), and 10 µg of the Sephacryl S-200 pool (lane 3). The gel stained for protein with Brilliant Blue G colloidal. The molecular weight markers (kDa) (left) and the purified protein (right) are indicated. Company source as in Figure 2.

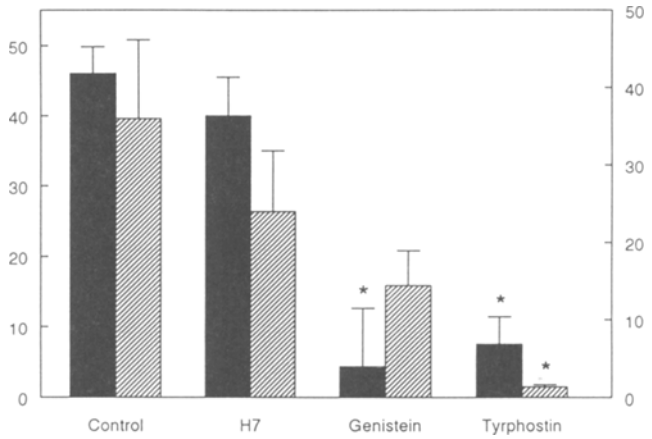

FIG. 4. Effect of kinase inhibitors on the purified activity. Washed microsomes (8 µg) were assayed for DGAT inactivation and phosphorylation of microsomes in the presence of the purified activity (2.4 µg/mL) and 0.2 mM of different inhibitors (H7, genistein, and tyrphostin-25). Results are given as mean ± SEM (n = 4). Significant inhibition ($P < 0.05$) was estimated by a paired *t*-test with the control (no inhibitor) as reference, and is indicated by *. Solid bar, ATP-dependent DGAT inactivation (%); ruled bar, microsomal phosphorylation (pmol Pi/min). Abbreviation as in Figure 1.

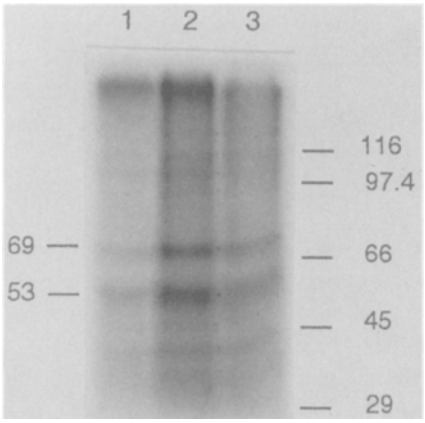

FIG. 5. Phosphorylation of microsomal proteins. Phosphorylation of microsomes was carried out by incubating washed microsomes (20 µg) in 40 µL of 50 mM Tris-HCl (pH 7.5)/10 mM $MgCl_2$/1 mM DL-dithiothreitol buffer with ^{32}P-γ-ATP (0.4 mM, 1 Ci/mmol) in the absence (lane 1) and presence (lanes 2 and 3) of 0.5 µg of the purified kinase for 5 min at 37°C. The reaction was stopped by the addition of 20 µL electrophoresis sample buffer (3-fold concentration) and then heated at 95°C for 4 min. A 50 µL aliquot was applied to each lane. Gels were stained, dried, and exposed to Fuji NIF-RX film for three days. Values correspond to molecular weight (kDa) of markers (right) and major phosphopolypeptides (left). Lane 1, control (microsomes alone); lane 2, kinase added; and lane 3, kinase and tyrphostin-25 (0.2 mM) added.

TABLE 2
Reactivation of DGAT by Protein Phosphatase

Addition	DGAT reactivation[a] (% ± SEM)	p^b
None	92 ± 9	—
Okadaic acid (0.1 µM)	88 ± 9	n.s.
NaF (40 mM)	26 ± 4	<0.001
Phosphate (10 mM)	12 ± 15	<0.01
EDTA (1 mM)	6 ± 11	<0.01
Vanadate (2 mM)	45 ± 9	<0.05

[a]Microsomes (1 mg/mL) were pretreated for 10 min at room temperature with cytosol (2.4 mg/mL) and ATP (0.5 mM) in 50 mM Tris-HCl (pH 7.5)/10 mM $MgCl_2$/1 mM DTT buffer. Aliquots of treated microsomes (10–15 µg) were incubated for 10 min at 37°C in the same buffer with and without a crude preparation of liver protein phosphatase (0.7 mg/mL) in the presence of the indicated inhibitors and 20 µM of carried over ATP, and then assayed for DGAT activity. DGAT reactivation in the presence of each inhibitor was estimated from the relative increase in DGAT activity of pretreated microsomes caused by incubation with the phosphatase. DTT, DL-dithiothreitol; see Table 1 for other abbreviation.

[b]From a paired *t*-test using the results without inhibitor (92 ± 9%) as reference; n.s., not significant.

the regions of 40 and 100 kDa. The addition of our purified kinase to the incubation medium (lane 2) resulted in the increased phosphorylation of all bands, and this effect was largely prevented when the inhibitor tyrphostin-25 was present in the incubation (lane 3). The fact that the addition of the kinase and the inhibitor did not change the pattern of phosphorylated bands in the microsomes suggested that the endogenous kinase activity remaining in our microsomal preparation was largely the tyrosine kinase which was demonstrated to be present in our purified fraction. By contrast, when the purified kinase was incubated with ^{32}P-γ-ATP and run on SDS–PAGE followed by autoradiography (not shown), no phosphorylated bands were apparent, suggesting that the enzyme does not autophosphorylate.

Reversion of protein phosphorylation and DGAT inactivation with a crude protein phosphatase preparation. We have previously reported that cytosol/ATP dependent inactivation of microsomal GPAT (17) and DGAT (18) activities could be reversed by incubating the inactivated microsomes with a partially purified protein phosphatase from rat liver in the absence of ATP. The reactivation of DGAT from ATP/cytosol-treated microsomes by the phosphatase preparation was now found to be Mg^{++} dependent and could be inhibited by phosphate, NaF, and vanadate, but not by the protein phosphatase inhibitor okadaic acid (Table 2).

Reversibility of microsome phosphorylation by the liver phosphatase preparation was investigated by pretreatment of washed microsomes with the purified kinase and ATP, which resulted in phosphorylation of the microsomes and a 46% decrease in DGAT activity (Fig. 6). Upon removal of the ATP by filtration, incubation of the treated microsomes with the crude protein phosphatase preparation restored DGAT activity while removing most of the microsomes bound ^{32}P (Fig. 6).

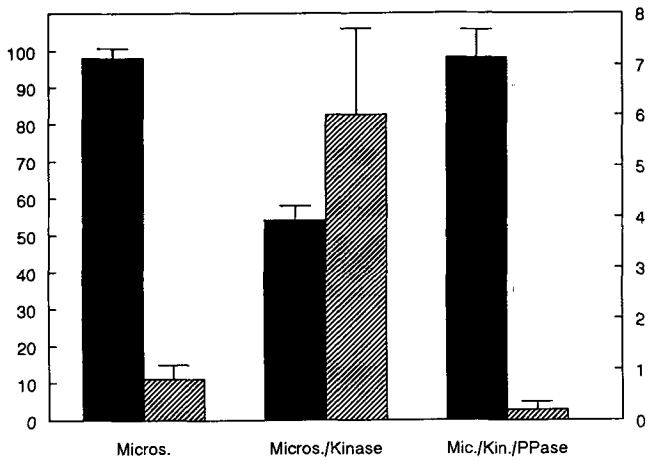

FIG. 6. Reversibility of DGAT inactivation and microsomal phosphorylation. Microsomes (0.3 mg/mL) were incubated at room temperature for 5 min in 50 mM Tris-HCl (pH 7.5)/10 mM $MgCl_2$/1 mM DL-dithiothreitol buffer with the purified kinase (2.4 µg/mL) and (0.5 mM) ATP followed by filtration through an Amicon P30 membrane to remove the ATP. The microsomes retained on the filter were resuspended in 0.1 mL of TMD buffer containing 100 µg of the crude phosphatase from liver and incubated for 10 min. Aliquots of this incubation mixture, as well as of the untreated microsomes and the kinase/ATP treated microsomes, were assayed for DGAT activity. Alternatively, ATP was substituted by ^{32}P-γ-ATP (40 Ci/mol) and aliquots corresponding to the untreated, the kinase-treated, and the kinase/phosphatase-treated microsomes were removed for determination of the amount of [^{32}P]phosphate bound to microsomes. Controls were run in parallel in which the kinase and the phosphatase were omitted from the incubations. Results are expressed as percentages of these controls ± SEM (n = 4). Solid bar, DGAT (% control); ruled bar, microsomal [^{32}P]phosphate (nmole Pi/mg). Abbreviation as in Figure 1.

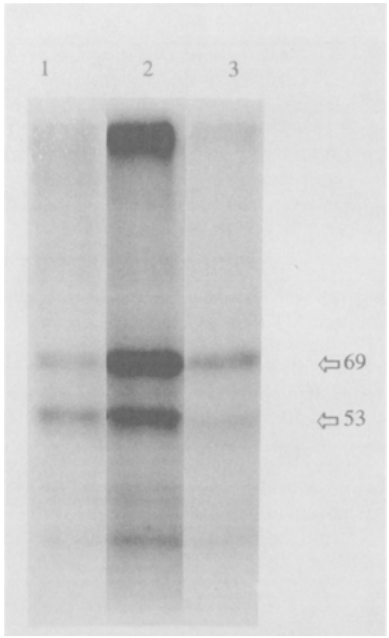

FIG. 7. Phosphatase treatment of phosphorylated microsomal proteins. Washed microsomes were phosphorylated with ^{32}P-γ-ATP in the presence (lanes 2 and 3) and absence (lane 1) of the purified kinase as described in Figure 5. For lane 3, the kinase treated microsomes were filtered on an Amicom P30 membrane, resuspended in TMD buffer, and incubated with crude phosphatase (1 mg/mL) as described in Figure 6. Reactions were stopped by adding electrophoresis sample buffer, and aliquots (20 μg microsomal protein) from the incubation mixtures were applied to the gel. Following electrophoresis, the gel was stained, dried, and exposed to Fuji NIF-RX film for five days. Molecular weight values (kDa) of the major phosphoproteins labelled are indicated. Lane 1, microsomes alone; lane 2, kinase-treated microsomes; and lane 3, kinase/phosphatase-treated microsomes.

Figure 7 shows the dephosphorylation of phosphoproteins from the kinase/ATP-treated microsomes. Treatment with the kinase (lane 2) stimulated the level of ^{32}P-phosphate incorporation into microsomal polypeptides as in Figure 5. Treatment with the liver phosphatase (lane 3) reversed the level of phosphorylation close to control levels (lane 1).

We have observed that if both the purified kinase and liver phosphatase were present in excess with microsomes in the presence of 1 mM ATP, the kinase was able to overcome the phosphatase resulting in net inactivation of DGAT and microsomal phosphorylation (4.5 nmol phosphate/mg microsomes), although not to the level achieved by the purified kinase alone (6.0 nmol phosphate/mg microsomes).

DISCUSSION

The present results confirm our previous findings of an ATP-dependent activity present in the cytosol of adipose tissue, which reduces both microsomal GPAT and DGAT activities *in vitro* (17,18). We have now partially purified that activity. Since we could not measure rates of DGAT inactivation, we were unable to determine the degree of purification of the activity. According to protein recovery in the final pool, the degree of purification attained is on the order of 1000-fold. Considering that this is a regulatory enzyme, higher purification is probably required in order to achieve homogeneity. The purified activity ran at about 67 kDa on a gel filtration column, and showed a single 68 kDa polypeptide band on SDS–PAGE, suggestive of a monomeric enzyme. However, it is possible that a minor component of our purified fraction, not even visible on the SDS gel of Figure 3 but containing the activity, could run at 67 kDa on gel filtration due to interactions with either the gel or with other proteins.

Our results suggest that the activity responsible for DGAT inactivation in the presence of ATP is a protein kinase. This hypothesis is supported by the following observations: (i) DGAT inactivation did not occur when ATP was substituted by β,γ-methylene-ATP (18), (ii) the kinase activity expressed as the phosphorylation of a synthetic peptide was associated with the DGAT inactivating activity through the purification steps, (iii) when endogenous microsomal activity responsible for DGAT inactivation was removed by appropriate washing of microsomes, the microsomal phosphorylating activity was concomitantly lost, (iv) both activities required Mg^{2+} and were inhibited by EDTA, (v) both activities were sensitive to the tyrosine kinase inhibitors genistein and tyrphostin-25, and (vi) both activities could be reversed by treatment with a crude preparation of protein phosphatase from rat liver. In addition, the putative DGAT kinase appeared to be a tyrosine kinase, both because of its sensitivity to established tyrosine kinase inhibitors (genistein and tyrphostin-25) and because of its ability to phosphorylate a synthetic peptide which is used as a general artificial substrate of protein tyrosine kinases. Moreover, the specific activity of the tyrosine kinase increased with the sequential purification steps of the DGAT inactivating activity.

Although a cytosolic enzyme, our protein kinase was associated strongly with the microsomal membranes. Two microsomal polypeptides of 53 and 69 kDa seemed to be substrates of our protein kinase. At this point we cannot assign any of the phosphorylated bands either to the DGAT or GPAT enzymes. However, studies by radiation inactivation of rat liver DGAT suggest that a unit of 68–76 kDa comprising one or more polypeptides is required for activity (25). More recently, rat liver DGAT has been purified to near homogeneity and shown to comprise at least a 60 kDa polypeptide (26).

Furthermore, it has been suggested that a 54 kDa microsomal polypeptide, which is labelled by radioactive iodoacetate but is not phosphorylated by PKA, is a component of adipose GPAT (15). This band may correspond to one microsomal substrate (53 kDa) of our kinase. However, *Escherichia coli* GPAT comprises a single polypeptide of 83 kDa (27) and murine mitochondrial GPAT has been recently identified as a 90 kDa polypeptide (28).

Dephosphorylation of both phosphorylated polypeptides by treatment with a crude protein phosphatase preparation from rat liver was concomitant with the reactivation of DGAT and GPAT activities from microsomes treated with our puri-

fied kinase and ATP, suggesting the involvement of those polypeptides in the said microsomal activities.

Since our previous results indicated that the DGAT enzyme in our microsomal preparations is already in a partially inactivated form (18), the combined effect of kinase inactivation and phosphatase activation should result in a change of rates of triacylglycerol synthesis much higher than the 30-40% change in DGAT and GPAT activities observed in our *in vitro* experiments.

One of the effects of insulin is an increase in adipocyte TAG synthesis, which is not secondary to its effects on lipoprotein lipase, glucose uptake, or fatty acid synthesis (4). The implication of a protein tyrosine kinase in the regulation of two key triglyceride synthetic enzymes, GPAT and DGAT, suggests that in concert with a tyrosyl phosphatase, the kinase could regulate this metabolic pathway. Insulin stimulation of adipose TAG synthesis could be mediated by activation of the phosphotyrosyl phosphatase and inactivation of the putative DGAT/GPAT kinase.

The Influence of a Fish Oil-Enriched Diet on the Phospholipid Fatty Acid Turnover in the Rabbit Red Cell Membrane *in vivo*

ABSTRACT: The influence of the polyunsaturated fatty acid (PUFA) composition of the diet on the rate of fatty acid turnover of individual phospholipids in the erythrocyte membrane *in vivo* was studied. Following modification of the fatty acid composition of the membrane phospholipids by the use of a fish oil or a linoleic acid enriched diet, phospholipids—labelled in the unsaturated fatty acid at the 2-position of the glycerol moiety—were introduced into the membrane of freshly isolated rabbit erythrocytes. Thereafter, the labelled erythrocytes were reinjected into the bloodstream of the animal. It appears that, with the exception of 1-palmitoyl,2-linoleoyl phosphatidylcholine, all other phosphatidylcholines disappear faster from the erythrocytes of fish oil-fed rabbits than from the red cells of linoleic acid-fed rabbits. Another parameter, which possibly influences the turnover rates of PUFA containing phospholipids, can be peroxidation. An attempt was made to measure peroxidative damage of lipids *in vivo* by the introduction of 1-palmitoyl,2-*cis*-parinaroyl phosphatidylcholine (PnPC)—a probe to measure oxidative stress—into the membrane of freshly isolated erythrocytes, in the same way as is described for the radioactive phospholipids. The data demonstrate that the fluorescent signal from the PnPC decreases at a fast rate which is independent of the dietary conditions.

Lipids 31, 285–293 (1996).

In the last decennia, diets rich in polyunsaturated fatty acids [PUFA, mainly linoleic acid ($C_{18:2n-6}$)] have been recommended for treatment and prevention of atherosclerosis and heart disease, because n-6 PUFA are claimed to have plasma cholesterol-lowering capacities (1–3). More recently n-3 PUFA [eicosapentaenoic acid ($C_{20:5n-3}$) and docosahexaenoic acid ($C_{22:6n-3}$)], present in fish oil, have been recognized as being even more potent than linoleic acid (1,4); n-3 PUFA have a marked triglyceride lowering effect (1,3,5).

However, the beneficial effects of a fish oil-enriched diet seem to be in contradiction with the fact that, as a result of the increased PUFA intake, membranes may accumulate relatively high amounts of PUFA-containing phospholipids (with more than three double bonds) and become more vulnerable to peroxidative damage (6,7). Lipid peroxidation may result in membrane damage and has been correlated with disorders occurring during aging and several diseases including cancer, coronary heart disease, and atherosclerosis (7–12).

Both the composition of the diet, as well as peroxidative damage, can modify the fatty acid composition of membranes. It is not known, however, to what extent the composition of the diet or peroxidative damage will influence the rate of phospholipid fatty acid renewal in the erythrocyte membrane *in vivo*. We have tried to clarify these questions by using a method which enables us to measure the *in vivo* turnover of individual phospholipid species in the erythrocyte membrane (13,14).

First the fatty acid composition of membrane phospholipids is modified *in vivo* by the use of different diets. A fish oil-enriched diet has been compared with a linoleic acid-enriched diet. Then, using a phospholipid transfer protein, trace amounts of radiolabelled and well-defined phospholipids were introduced into the membrane of freshly isolated rabbit erythrocytes. After reinjection of those labelled cells into the animal, the *in vivo* decay of the radiolabel was followed by analyzing the erythrocytes in blood samples that were taken at timed intervals.

Recently, a new method has been described which can be used to measure oxidative stress (*in vitro*) in model membrane systems, erythrocyte membranes, and intact erythrocytes with a naturally occurring fluorescent vegetable fatty acid, parinaric acid [PnA, 9,11,13,15-octadecatetraenoic acid ($C_{18:4}$), 15,16]. The basis for this fluorescent peroxidation assay is provided by the special structure of the PnA molecule, its conjugated double bond system giving rise to the fluorescent properties as well as susceptibility to peroxidation. PnA and parinaric acid containing phosphatidylcholine (PnPC) can be

used as probe molecules to detect lipid peroxidation because peroxidation and decrease in fluorescence are coupled. Applying small amounts of this probe in the abovementioned method can be expected to give information about the occurrence of lipid peroxidation and its influence on phospholipid fatty acid turnover *in vivo*.

Finally, the ability of α-tocopherol to influence lipid peroxidation and phospholipid fatty acid renewal, in particular the protection of PUFA, is examined by varying the vitamin E concentrations in the various diets and applying both approaches described above.

MATERIALS AND METHODS

1-Palmitoyl,2-[1-^{14}C]-oleoyl-*sn*-glycero-3-phosphocholine ([^{14}C]16:0,18:1PC), 1-palmitoyl,2-[1-^{14}C]-linoleoyl-*sn*-glycero-3-phosphocholine ([^{14}C]16:0,18:2PC), and 1-stearoyl,2-[5,6,8,9,11,12,14,15-^{3}H]-arachidonoyl-*sn*-glycero-3-phosphocholine ([^{3}H]18:0,20:4PC) were purchased from Amersham (Buckinghamshire, United Kingdom). 1-Palmitoyl,2-[1-^{14}C]arachidonoyl-*sn*-glycero-3-phosphoethanolamine ([^{14}C]16:0,20:4PE) was obtained from NEN (Du Pont de Nemours, Bad Homburg, Germany).

Corresponding nonradioactive phospholipids, 1-palmitoyl,2-*cis*-parinaroyl phosphatidylcholine (PnPC), 1-palmitoyl,2-oleoyl-*sn*-glycero-3-phosphocholine (16:0,18:1PC), and 1-stearoyl,2-arachidonoyl-*sn*-glycero-3-phosphocholine (18:0,20:4PC) were obtained from Avanti Polar Lipids (Alabaster, Alabama). Egg-yolk PC, cholesterol, and phosphatidic acid were obtained from Sigma (St. Louis, MO). All other chemicals and solvents used were of analytical grade or LiChrosolve grade.

Animals. Thirty-two female Dutch SPF rabbits (HsdPOC.Dutch, 10–11 weeks old) were purchased from Harlan Porcellus (Blackthorn, United Kingdom). They were fed a linoleic- or fish oil (menhaden oil; Oil Milling Division, Rotterdam, The Netherlands) enriched semisynthetic diet (25% Hope Farms RG grains + 75% semisynthetic diet; Hope Farms RG, Woerden, The Netherlands) containing 40 energy% fat. Animals were adapted to the diet by starting with Hope Farms RG and changing the diet every two weeks by replacing 25% Hope Farms with 25% semisynthetic diet. The basal diet contained in g/1000 kJ: calcium caseinate, 14.6; mineral mix, 5.5; vitamin mix, 0.5; fat, 10.8; maizena, 27.1; sawdust, 14.3 and grassflour, 1.4. Two groups received a linoleic acid-enriched semisynthetic diet with different amounts of vitamin E: 187 (group I) or 300 (group II) α-TE/kg diet (1 TE = 1 mg R,R,R-α-tocopherol acetate). Group III and IV received a fish oil-enriched semisynthetic diet with respectively 187 or 300 α-TE/kg diet. The fat content in Group I and II was in energy% 11.4 sunflower seed oil high in linoleic acid, 8.3 sunflower seed oil high in oleic acid, 8 cocoa butter, and 12.3 hydrogenated coconut oil. In Group III and IV, the fat contained (in energy%) 19 fish oil, 3 sunflower seed oil high in linoleic acid, 6.5 sunflower seed oil high in oleic acid, 1 cocoa butter, and 10.5 hydrogenated coconut oil. Diets were prepared in large quantities, subsequently divided in small aliquots and stored frozen at –20°C. The animals were given fresh diets every day. All oils were analyzed for oxidation stability prior to diet preparation and peroxide values were less than 0.1%. The fatty acid composition of the semisynthetic diets is shown in Table 1. The animals were fed the semisynthetic diet for at least four weeks.

Experimental outline. Before starting the *in vivo* experiments, small amounts of blood were taken from the animals for the analyses of the fatty acid and phospholipid compositions as well as the vitamin E contents of serum and erythrocytes. Thereafter, phospholipid turnover was studied as follows. From an animal, a small amount of blood was taken and the erythrocytes were isolated, washed, and incubated with phospholipid vesicles and phospholipid transfer protein as described below. After loading the erythrocyte membrane this way with a radioactive or fluorescent phospholipid, the cells were collected, washed to remove the excess of lipids and protein, and reinjected into the same animal. Thereafter, small blood samples were taken at timed intervals during the next 7 d and analyzed for residual radioactivity or fluorescence present in the erythrocytes.

Preparation of erythrocytes for lipid and vitamin E analysis. Venous blood (7 mL) was obtained from rabbits, using acid–citrate–dextrose (ACD) as anticoagulant. Erythrocytes were pelleted by centrifugation for 10 min at 750 × *g* and washed three times with 4 mL 155 mM NaCl. The buffy coat was carefully removed by aspiration after each wash. After

[a]Data represent the major fatty acids as present in the linoleic acid- (Group I and II) and fish oil-enriched (Group III and IV) diets. SAFA: saturated fatty acids; MUFA: monounsaturated fatty acids; :2, :3, >:3: polyunsaturated fatty acids with 2, 3, and more than 3 double bonds, respectively.

the last wash and resuspension in 155 mM NaCl, the haematocrit of the erythrocyte suspension was determined.

Lipid analysis. Erythrocyte samples were extracted according to a modification of the protocol of Rose and Oklander (17). In short, 400 µL packed cells were lysed by adding 400 µL 1 mM EDTA while vortexing. After 15 min at room temperature under nitrogen, 3.2 mL isopropanol containing 0.1 mM butylhydroxy toluene (BHT; Sigma) was added while vortexing. The suspension was vortexed for 90 s under nitrogen. After addition of 2.0 mL dichloromethane (again while vortex-mixing), vortexing was again continued for 90 s. Following centrifugation for 5 min at 1000 × *g*, the supernatant was kept at –20°C under nitrogen until analysis.

Lipids were extracted from 1 mL serum with 4.0 mL isopropanol containing 0.1 mM BHT and 2.5 mL dichloromethane using the above described procedure.

Fluorescence measurements were carried out by transferring 2 mL of the lipid extracts to a thermostated cuvette (T = 25°C) equipped with a magnetic stirring device and using a SLM Aminco SPF 500 Spectrofluorometer (SLM Instruments, Inc., Urbana, IL). The emission wavelength was set at 413 nm with slit width 20 nm; excitation was scanned from 260–360 nm with slit width 2 nm.

For radioactivity measurements, part of the lipid extracts were transferred to scintillation vials and, after evaporation of the organic solvent, radioactivity was determined in a Packard Tri-Carb 1500 Liquid Scintillation Analyzer using Emulsifier Scintillator 299 (Packard, Meriden, CT).

To determine the fatty acid composition of the red cells and serum, total phospholipid extracts were dried under nitrogen, and fatty acid methyl esters were prepared using BF_3 as described previously (18). Analyses were performed on a Perkin Elmer 8500 gas chromatograph (Buckinghamshire, United Kingdom) equipped with either a CP Sil 88, or CP-Wax 52 CB capillary column (both Chrompack, Middelburg, The Netherlands).

To determine the fatty acid composition of the individual phospholipids, extracts of about 500 µL packed cells or 1 mL serum were dried under nitrogen and redissolved in 100 µL chloroform/methanol (1:2, vol/vol). Phospholipids were separated by two-dimensional thin-layer chromatography according to the protocol of Broeckhuyse (19), on thin-layer plates covered with silica 60 (Merck, Darmstadt, Germany). Lipid spots were visualized by fluorescein and scraped off under nitrogen. Phospholipids were extracted from the silica using the method of Bligh and Dyer (20) and subsequently used for analysis of the fatty acid composition.

Vitamin E analysis. To 2 mL of a 20–50% haematocrit cell suspension, 4 mL of ethanol containing 1% vitamin C (Merck), and 0.01% pyrogallol (May and Baker) were added as antioxidants, while vortexing. The apolar fractions were extracted under vortexing with 3 mL of hexane, containing 2.0 µg/mL α-tocopherylacetate (Sigma) as internal standard and 4.4 µg/mL BHT as antioxidant. Thereafter, the mixture was extracted once again with 3.0 mL of hexane. The hexane extracts were stored under nitrogen in the dark at –20°C until analysis.

To determine the vitamin E content of the erythrocyte membrane, extracts were dried under nitrogen and redissolved in 125 µL methanol; 100 µL was injected into the high-performance liquid chromatograph (Gilson, Villiers-le-Bois, France). Vitamin E analysis was performed on an Ultrasphere ODS reversed-phase column (Beckman Instruments, Inc., San Ramon, CA) (250 × 4.6 mm i.d.) and ultraviolet detection (287 nm). Methanol was used as effluent at 1.0 mL/min.

Preparation of erythrocytes for incorporation of phospholipids. From rabbits, adapted to the semisynthetic diet, blood was collected from the ear vein (8 mL/kg bodyweight) in ACD. Erythrocytes were isolated by centrifugation for 10 min at 1000 × *g* and washed two times with 20 mL phosphate buffered saline containing 150 mM NaCl, 5.4 mM Na_2HPO_4, 1.3 mM KH_2PO_4, and 1 mM EDTA (pH 7.4). For phosphatidylethanolamine (PE) incorporation, the cells were washed with "sucrose buffer," containing 280 mM sucrose, 10 mM NaCl, 20 mM glucose, 1 mM EDTA, and 10 mM Tris-HCl (pH 7.4). The buffy coat was carefully removed after each wash.

Preparation of donor vesicles. Vesicles were prepared from two different mixtures of lipids. In a number of experiments, various unlabelled synthetic PC species were used, mixed with 40 mol% of cholesterol, 5 mol% of PA, and trace amounts of [^{14}C]16:0,18:1PC and [^{3}H]18:0,20:4PC, both at a final concentration of 1.0 nCi/nmol phospholipid. The PC-fraction consisted of PnPC, 16:0,18:1PC, and 18:0,20:4PC in a molar ratio of 1:0.25:0.25. The mixture also contained 6 mol% BHT to prevent oxidation.

Alternatively, vesicles were prepared from egg-yolk PC, mixed with an equimolar amount of cholesterol, 6 mol% of PA, and trace amounts of [^{14}C]16:0,18:2PC at a final concentration of 1.1 nCi/nmol PC. The above lipid mixtures were dried under nitrogen, resolved in ethanol (5 µmol PC/mL), and kept under nitrogen at –20°C until further use within one week. Vesicles were prepared in phosphate-buffered saline using the ethanol injection method as described by Batzri and Korn (21).

For studies involving the introduction of labelled PE into the cells, a different method of vesicle preparation was used. Egg-yolk PC was mixed with 40 mol% of cholesterol, 5 mol% of PA, 2.5 mol% BHT, and trace amounts of [^{3}H]18:0,20:4PC and [^{14}C]16:0,20:4PE, both at a final concentration of 0.75 nCi/nmol phospholipid. The lipid mixture was dried under nitrogen and dispersed in sucrose buffer (nitrogen saturated) at a final concentration of 1 µmol phospholipid/mL and vortexed in the presence of a few glass beads. The lipid dispersion was subsequently sonicated under nitrogen for two min, using a Branson (Danbury, CT) sonifier set at 50 W. Vesicle suspensions were stored at 4°C under nitrogen until used (within a few days).

Preparation of transfer proteins. The PC specific transfer protein (PC–TP) was purified from bovine liver (22) and stored at a concentration of 700 µg/mL in 50% glycerol at –20°C. The nonspecific lipid transfer protein (nsL–TP) was also purified from bovine liver (23) and stored at a concentration of 800 µg/mL at –20°C in 50% glycerol. Before use, glycerol was removed by overnight dialysis of the protein so-

lution against a 100-fold volume of phosphate-buffered saline or sucrose buffer (in the case of nsL–TP) at 4°C. The PC–TP solution was used as such, but the nsL–TP protein solution was first concentrated against flake polyethylene glycol (Aquacide III; Calbiochem, La Jolla, CA).

Incorporation of labelled phospholipids into erythrocytes. A 30% (vol/vol) suspension of cells was incubated at 37°C during 60 min (in closed tubes) in a slowly shaking waterbath in the presence of labelled donor vesicles and 2.5 μM PC–TP in phosphate-buffered saline. The ratio of erythrocyte phospholipid to vesicle phospholipid was 50 (the ethanol concentration was less than 0.5%). Cells were isolated by centrifugation at 1000 × *g* for 10 min, and the residual vesicles and PC–TP were removed by one additional wash with an excess of 155 mM sterile NaCl.

For the incorporation of radiolabelled PE, erythrocytes were incubated at 37°C during 60 min in a slowly shaking waterbath with nsL–TP (1.2 mg/mL packed cells) and radiolabelled vesicles. The ratio of erythrocyte phospholipid to vesicle phospholipid was 20. After incubation, the erythrocyte suspension was diluted twice with sucrose buffer, and the cells were subsequently isolated by centrifugation at 1000 × *g* during 10 min. The residual vesicles and nsL–TP were removed by two additional washes with an excess of 155 mM sterile NaCl.

In vivo *fatty acid renewal of various phospholipid species and lipid peroxidation.* The labelled erythrocytes were resuspended in 155 mM sterile NaCl and reinjected into the ear vein of the rabbit. After one hour, and thereafter at timed intervals during one week, 3 mL blood samples were taken. Lipids were extracted from erythrocytes, and the residual radioactivity or fluorescence was determined following the above described procedures. The measured radioactivity or fluorescence is plotted semilogarithmically against time and the half-time values of the various PC-species and PnPC are calculated using the formula:

$$y(t) = A \cdot e^{-\delta t} \quad [1]$$

in which $y(t)$ = the amount of label at time t, A is a constant factor and δ = rate of loss of radioactivity or fluorescence.

RESULTS

Fatty acid composition of serum and serum PC. The fatty acid composition of serum for the different dietary groups is given in Table 2. The fish oil-enriched diet causes drastic changes in the fatty acid pattern of serum of rabbits, compared to the linoleic acid-enriched diet, characterized by large increases in n-3 PUFA, eicosapentaenoic acid ($C_{20:5}$), docosapentaenoic acid ($C_{22:5}$), and docosahexaenoic acid ($C_{22:6}$), in combination with decreased $C_{18:2n-6}$ concentrations. The use of different diets results also in differences in fatty acid composition of serum PC (Table 2).

Fatty acid composition of total phospholipids and the individual phospholipid classes PC and PE in the erythrocyte membrane. The fatty acid composition of the erythrocyte membrane (Fig. 1) of rabbits fed a linoleic acid-rich diet is similar to that of serum (Table 2). The rabbit erythrocyte membrane contains $C_{18:2n-6}$ (35%) as major fatty acid, and this amount is somewhat lower than that of serum. Feeding fish oil to rabbits resulted in drastic changes in the fatty acid pattern of their red cell phospholipids. There is a large accumulation of n-3 PUFA, $C_{20:5}$ (9%), $C_{22:5}$ (7%), and $C_{22:6}$ (8%) in combination with lower $C_{18:2n-6}$ concentrations (14%). Surprising is the low amount of $C_{20:5}$ and the high amount of $C_{22:5}$ when compared to the situation in serum. The amount of $C_{20:4n-6}$ is not changed by the use of fish oil. The almost constant level of $C_{20:4n-6}$ in erythrocytes is in agreement with previously published data on rabbits (24), but not with those of monkeys (25).

20:5	—	—	18.5	10.0
22:5	—	—	3.2	2.2
22:6	—	—	8.1	5.9

[a]Rabbits were fed a linoleic acid-rich (Group I) or a fish oil-rich (Group III) semisynthetic diet, both supplemented with 187 α-TE/kg diet, for at least four weeks. Total lipid extracts of serum and serum phosphatidylcholine (PC) were analyzed for their fatty acid composition as described in the Materials and Methods section. Data presented are the averages of values obtained from duplicate analyses of serum and serum PC from two different animals and are expressed as percentage of the total major fatty acids. A dash (—) indicates a value of less than 0.5%.

The total PUFA content, including C18:2n-6, did not change by the diet; it remained 43–44% of the total fatty acid composition of the membrane, while the double bond index (mean number of double bonds per fatty acid) is increased from 1.2 for erythrocytes of linoleic acid-fed rabbits to 2.0 for erythrocytes of fish oil-fed animals. A theoretical lipid peroxidation susceptibility index (6) for the erythrocyte, based on PUFA oxidation susceptibility indices of 1, 3, 4, and 5 for 18:2, 20:4, 20:5/22:5, and 22:6, respectively, is increased from 63 (group I) to 135 (group III). These oxidation related membrane characteristics indicate that the PUFA-enriched erythrocytes are expected to be more susceptible to lipid peroxidation.

The use of fish oil also results in characteristic differences in fatty acid composition of the individual phospholipid classes PC and PE (Fig. 2). In both these classes, 60–70% of the C18:2n-6 is replaced by n-3 PUFA (C20:5, C22:5, and C22:6). Interestingly, the decrease in the relative amount of 18:1 as observed in the total red cell fatty acids in fish oil-fed rabbits (Fig. 1, III), comes to the exclusive account of a change in the fatty acid composition of the PE (Fig. 2B).

In vivo *turnover and lipid peroxidation in the erythrocyte membrane.* The fish oil-enriched diet drastically changed the

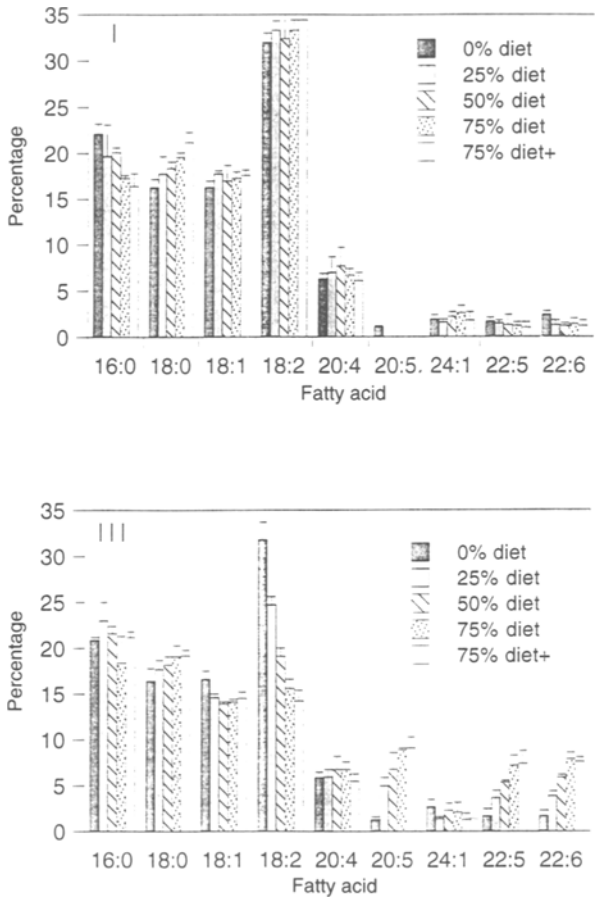

FIG.1. Fatty acid composition of rabbit erythrocyte membranes during adaptation to the diet. Rabbits were fed a linoleic acid-rich (Group I) or a fish oil-rich (Group III) semisynthetic diet both supplemented with 187 α-TE/kg diet. Animals were adapted to the diet by starting with Hope Farms RG (Woerden, The Netherlands) and changing the diet every two weeks by replacing 25% Hope Farms with 25% semisynthetic diet: 25, 50, and 75% semisynthetic diet. Just before the turnover experiments started, an additional analysis was done. Total lipid extracts of erythrocytes were analyzed following the procedures described in the Materials and Methods section and data presented are the average of values obtained from duplicate analyses of erythrocytes from four or eight rabbits. Fatty acids corresponding to less than 0.5% are not indicated.

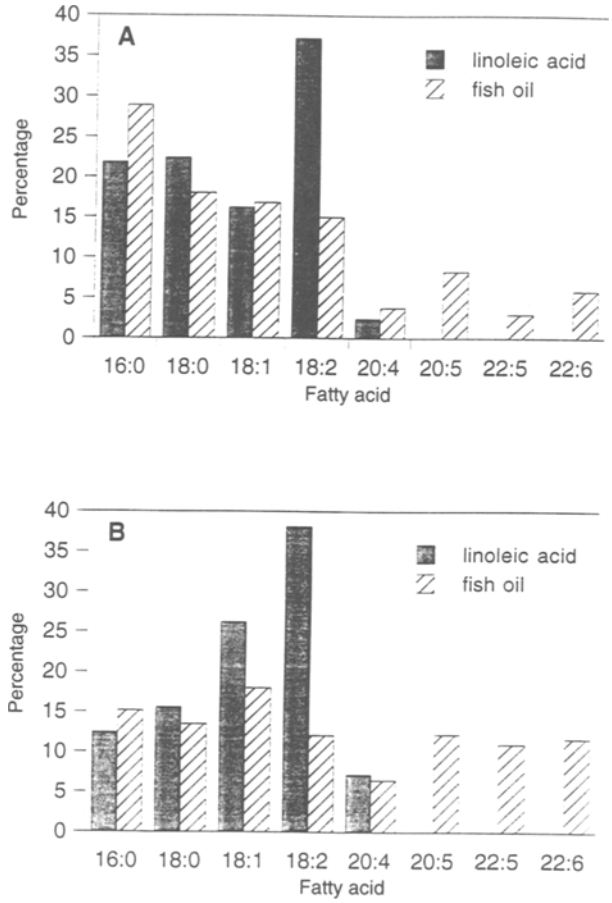

FIG. 2. Fatty acid composition of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) in rabbit erythrocyte membranes. Rabbits were fed a linoleic acid-rich or a fish oil-rich semisynthetic diet, both supplemented with 187 α-TE/kg diet for at least four weeks. The individual phospholipids (PC, PE) were separated and analyzed for their fatty acid composition as described in the Materials and Methods section. Data are the average of values obtained from duplicate analyses of PC and PE of erythrocytes from two rabbits. Fatty acids corresponding to less than 0.5% are not indicated. A and B: fatty acid composition of PC and PE, respectively.

fatty acid composition of the rabbit erythrocyte membrane. Those membranes contain high quantities of n-3 PUFA (group III) in contrast to the other group which contains n-6 PUFA (group I). Both types of modified red cells have been used to investigate the influence of the PUFA composition of the diet on the *in vivo* turnover of various phospholipid fatty acids.

Small amounts of radiolabelled phospholipids were introduced into the membrane of freshly isolated erythrocytes in such a way that less than 1% of the native PC or PE in the erythrocyte was replaced by the radiolabelled markers. As documented extensively in previous studies, such a low amount of replacement does not affect the structural and functional characteristics of the erythrocyte membrane nor the overall cellular properties to any measurable extent (13). Erythrocytes, containing the radioactive phospholipids, were reinjected into the animals and at various time points thereafter small samples were taken and analyzed for residual radioactivity present in the total phospholipid extracts. The actual half-time values for the loss of the different phospholipid species from circulation have been calculated using the formula as shown in the Materials and Methods section and are presented in Table 3. As discussed previously (14), the observed half-time values for the disappearance of the label from circulation need to be corrected for the contribution of cell sequestration, in order to obtain information of the actual fate of the probe molecules in the circulating erythrocytes. The average half-time value for red cell survival in rabbits on a linoleic acid-rich diet has been determined to be 12 d (13), but it is not known whether this parameter changes as a consequence of the fish oil-rich diet. However, the observation that the half-time values for the *in vivo* survival of both the

[a]Rabbits were fed a linoleic acid-rich semisynthetic diet with 187 (Group I) or 300 α-TE/kg diet (Group II) or a fish oil-enriched semisynthetic diet with 187 (Group III) or 300 α-TE/kg diet (Group IV). The observed (obs) and corrected (cor) half-time values on the removal of individual species from the circulating cells are calculated from the formulas as shown in the Materials and Methods section and the Results section, respectively. The asterisk (*) indicates the position of the label. Data marked ** are obtained with radiolabelled phospholipids which were introduced into the erythrocytes with the nonspecific lipid transfer protein, whereas the others are obtained using the PC specific transfer protein. The data are the average of values obtained from analyses of decay of radioactivity and fluorescence, respectively, of erythrocytes from two or three rabbits; each time point is analyzed in duplo; n.d. is not determined; PnPC, 1 palmitoyl, 2-*cis*-parinaroyl PC. See Table 2 for other abbreviations.

TABLE 4
***In vivo* Daily Replacement of Rabbit Erythrocyte Membrane Phospholipids[a]**

	Daily replacement (% of total erythrocyte PC/PE)			
Phospholipid	Group I	Group II	Group III	Group IV
16:0,18:2* PC	24.8	24.0	10.0	9.5
16:0,18:1* PC	3.1	3.8	4.0	3.8
18:0,20:4* PC	0.4	0.5	0.9	0.9
18:0,20:4* PC**	0.5	n.c.	1.0	n.c.
16:0,20:4* PE**	0.5	n.c.	0.8	n.c.

[a]Rabbits were fed a linoleic acid-rich semisynthetic diet with 187 (Group I) or 300 α-TE/kg diet (Group II) or a fish oil-enriched semisynthetic diet with 187 (Group III) or 300 α-TE/kg diet (Group IV). The daily replacement of each species can be estimated on the basis of the turnover data and the abundance of each species (Fig. 2) and are expressed as % of the total phosphatidylcholine (PC) or phosphatidylethanolamine (PE) complement of the erythrocyte membrane (n = 2–3). The asterisk (*) indicates the position of the label. Data marked ** are obtained with radiolabelled phospholipids which were introduced into the erythrocytes with the nonspecific lipid transfer protein, whereas the others are obtained using the PC specific transfer protein; n.c., not calculated.

16:0,18:2PC and PnPC do not, if at all, experience any appreciable changes, strongly indicates that the change in diet does not affect the lifetime of the circulating erythrocytes. Hence, the observed half-time values for the *in vivo* disappearance of radiolabel and fluorescence signal, respectively, can be corrected for the contribution of cell sequestration (Table 3) by using the previously applied formula:

$$y(t) = A \cdot e^{-(\delta - \delta ery)} \quad [2]$$

in which $y(t)$ = amount of radiolabel at time t, A = a constant, δ = rate of loss of radioactivity or fluorescence, and δery = rate of removal of erythrocytes from circulation. The data for the fish oil-fed rabbits (groups III and IV) show that differences do occur in the rates at which the individual species disappear from the circulating cells. With the exception of 16:0,18:2PC, all other phospholipids that had been introduced into the erythrocytes of fish oil-fed rabbits showed a (slight) decrease in the half-time values of their *in vivo* survival.

Taking the half-time values presented in Table 3, the fatty acid analysis data in Figure 2 (for instance, $C_{20:4n-6}$ comprises 2.4% of the total fatty acids of the PC) and making the assumption that the majority of the PUFA occupy the 2-position in the phospholipid molecules, it is possible to estimate the amounts of various individual PC and PE species which are replaced per day. Thus, 18:0,20:4PC represents at most 4.8% of the total PC pool, and using the half-time value for its *in vivo* survival in the linoleic acid fed rabbits of 5.6 d (Table 3), it follows that the removal of 18:0,20:4PC from circulation contributes to 0.4% of the total red cell PC per day only. But still, this is an overestimation because part of $C_{20:4n-6}$ will be present in combination with C16:0 instead of $C_{18:0}$, which means that the relative amount of 16:0,20:4PC will in fact be less than 4.8% of the total PC. Similar estimations for the other species have been made, and the results are shown in Table 4. It is obvious that a somewhat higher PC turnover takes place in the fish oil-fed group, with the exception of the 16:0,18:2 species. This supports the idea that direct exchange of intact PC molecules between serum and erythrocytes plays an important role, because the supply of 16:0,18:2PC from the serum and the amount in the erythrocytes are less in the fish oil group than in the linoleic acid-fed group. The opposite effect is seen for 18:0,20:4PC, which is increased in both serum and erythrocytes of fish oil-fed rabbits and, as a consequence, its contribution to the turnover of the entire PC pool in the erythrocytes increases by about 100%.

Another parameter which possibly influences the turnover rates of phospholipids can be found in the process of lipid peroxidation. To investigate this effect, small amounts of PnPC, a probe to measure oxidative stress, were introduced into the membrane of freshly isolated erythrocytes in the same way as is described for the radioactive phospholipids. Erythrocytes, containing the PnPC, were reinjected into the animals, and at various time points thereafter, small samples were taken and analyzed for residual fluorescence present in the total phospholipid extracts. The half-time value found for PnPC in erythrocytes from fish oil-fed rabbits is 1.4 d and differs not from that found in erythrocytes from linoleic acid-fed rabbits (1.3 d).

Vitamin E levels in the rabbit erythrocyte membrane. Figure 3 gives the results of vitamin E analyses of rabbit erythrocytes as a function of the diet. Although both linoleic- and fish oil-enriched diets contain equal amounts of vitamin E (187 α-TE/kg diet), the α-tocopherol content of rabbit erythrocytes is drastically lowered in fish oil-fed rabbits (group III), be it still somewhat higher than the starting values. Supplementation of the linoleic acid-enriched diet with 300 α-TE/kg diet (group II) increases drastically the vitamin E lev-

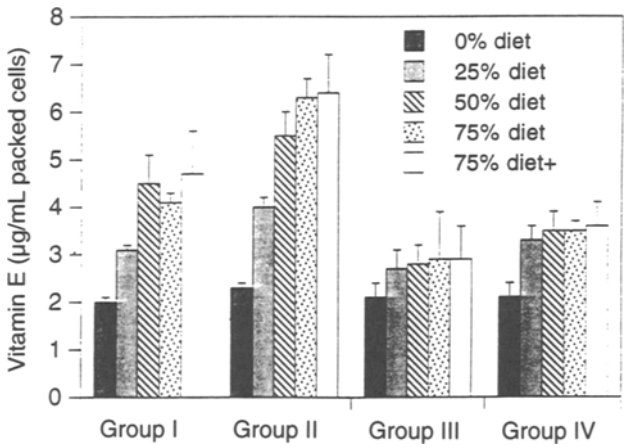

FIG. 3. The effect of the diet on vitamin E levels in the rabbit erythrocyte membrane. Rabbits were fed a linoleic acid-rich semisynthetic diet with 187 (Group I) or 300 α-TE/kg diet (Group II) or a fish oil-rich semisynthetic diet with 187 (Group III) or 300 α-TE/kg diet (Group IV). Animals were adapted to the diet by starting with Hope Farms RG and changing the diet every two weeks by replacing 25% Hope Farms with 25% semisynthetic diet: 25, 50, and 75% semisynthetic diet. Just before the turnover experiments started, an additional analysis was done. Erythrocyte membrane extracts were analyzed for their vitamin E levels as described in the Materials and Methods section. Data presented here are the average of values obtained from duplicate analyses of erythrocytes from four or eight rabbits. Company source as in Figure 1.

els of the rabbit erythrocyte membrane. On the other hand, supplementation of fish oil-enriched diet with extra vitamin E (300 α-TE/kg diet, group IV) has only a small positive effect on those levels in the erythrocyte, and the vitamin E concentration remains still below that in the group fed a linoleic acid-rich diet with 187 α-TE/kg diet.

The serum and erythrocyte lipid fatty acid patterns of the rabbits supplemented with 300 α-TE/kg diet closely resemble the 187 α-TE/kg diet fatty acid patterns (data not shown) and are in agreement with previously published data (24).

The extra addition of vitamin E to the diet has no influence on the turnover values of red cell PC fatty acids in fish oil-fed rabbits and a small turnover enhancing effect on red cell PC fatty acids in linoleic acid-fed rabbits (Table 3). Similarly, it has neither an effect on the phospholipid replacement per day (Table 4), nor on the half-time value of the disappearance of PnPC fluorescence (Table 3).

DISCUSSION

The data presented here demonstrate that the fish oil-enriched diet causes profound changes in the phospholipid fatty acid pattern of serum and erythrocyte membranes of rabbits. Feeding fish oil to rabbits results in a high amount of n-3 PUFA ($C_{20:5}$, $C_{22:5}$, and $C_{22:6}$) in the phospholipids of both serum and red cell membranes, and these data are in agreement with previously published results on rabbits (24,25), monkeys (26), rats (27,28), and humans (29,30). It is not known, however, to what extent the composition of the diet will influence the rate of fatty acid renewal of individual phospholipids in the erythrocyte membrane *in vivo*. To study this in more detail, we introduced phospholipids, labelled in the unsaturated fatty acid at the 2-position, in the rabbit erythrocyte membrane as described recently (14). Only trace amounts of PC and/or PE are introduced into the red cell membranes which will be diluted in the regular PC/PE pools (13,31) *via* transbilayer redistribution (32–34). After reinjection of the labelled cells into the rabbit, decay of radioactivity was measured in time, and the renewal rate of the phospholipid fatty acids in the red cell membrane was calculated. It appears that the fatty acid composition of the diet affects the rate of renewal of individual phospholipids. The labels from 16:0,18:1PC, 18:0,20:4PC, and 16:0,20:4PE disappear faster from the erythrocytes of fish oil-fed rabbits than from the red cells of linoleic acid-fed rabbits (Table 3). An exception is observed for the disappearance of the radiolabel from 16:0,18:2PC. The half-time value of this species did not change by the use of a fish oil-enriched diet. This observation might be explained by the fact that the rate of renewal of this phospholipid is already extremely high (half-time value is 1.5 d), and therefore small differences are not noticeable anymore.

Another way of looking at the influence that the composition of the diet may have on the renewal of the phospholipids in the red cell is by calculation of the replacement of these phospholipids in the erythrocyte membrane per day (Table 4). It shows that in erythrocytes of fish oil fed rabbits an increase in replacement of 18:0,20:4PC by about 100% per day is found compared to erythrocytes of linoleic acid-fed rabbits. If we consider the fact that in the serum of fish oil-fed rabbits more PC with arachidonic acid at the 2-position is present, and assuming that the total phospholipid content remains constant throughout (5), the conclusion might be drawn that the replacement of individual PC species depends on the amount of these species in the serum. The observation that the fatty acid composition of the PC present in the serum resembles that of the erythrocytes, to a large extent, suggests that direct exchange of intact PC molecules between erythrocyte and serum may play a role. The data on 16:0,18:2PC support this conclusion, because the concentration of this PC is lower in serum and erythrocytes of fish oil-fed rabbits, thus resulting in a lower contribution of this species to the daily exchange of the entire PC pool. On the other hand, loss of radioactivity from the reporter molecules can also be due to a process of de-/reacylation, since the radiolabel was present in the fatty acid residue at the 2-position of the phospholipids and unlabelled fatty acid, free, or esterified to other complex lipids is present in excess. However, previous results (14) suggest that the loss of molecular species of PC from the circulating red cell is due to the exchange of intact PC molecules to the serum.

Due to the preferred localization of PE in the inner membrane layer of the rabbit erythrocyte [18:82, out/in (13,31)], exchange of erythrocyte PE with serum PE might play a minor role. Therefore, the observed higher turnover of 16:0,20:4PE in fish oil-fed rabbits (Table 3) could be due to an increase in metabolic turnover (35,36).

Whatever mechanism of renewal is operative, the total amounts of both phospholipids in the red cell membrane remain fairly constant throughout (5,29). This implies that the loss of a phospholipid from the erythrocyte membrane has to be compensated for by the uptake of a molecule with an identical polar headgroup from the serum pool or by uptake of a lysophospholipid from the serum followed by reacylation with fatty acid at the inner membrane layer of the red cell, as suggested by the experimental evidence presented by Renooij *et al.* (35–38).

Another factor which may influence the turnover of PUFA containing phospholipids can be peroxidation. As a result of an increased PUFA intake due to the fish oil diet, an accumulation of n-3 PUFA containing phospholipids in the erythrocyte membrane appears, and these red cells become more vulnerable for peroxidative damage.

An attempt was made to measure peroxidative damage of lipids *in vivo* by using parinaroyl PC [PnPC(n-3)]. The data demonstrate that the fluorescent signal from the PnPC decreases at a fast rate (Table 3) which is independent of the dietary conditions. Assuming that this loss of fluorescent signal is not due to exchange of the PnPC with serum PC, because an equivalent phospholipid is not present in the serum, peroxidation may be responsible for the decay. This seems in contradiction with the increase in the peroxidation susceptibility index from 63 for erythrocytes of linoleic acid-fed rabbits to 135 for erythrocytes of fish oil-fed rabbits, since in the latter case a higher half-time value for the disappearance of this probe might have been expected as a consequence of the higher buffering capacity of the high amount of n-3 PUFA to cope with the radicals formed. On the other hand, the fluorescent PnA is very sensitive to peroxidation (39), and the assumption seems justified that it has a higher sensitivity toward peroxidation than the other naturally occurring n-3 fatty acids. One possible explanation could be that in both cases the PnPC will be the first phospholipid to be peroxidized, which is in agreement with *in vitro* results published by van den Berg *et al.* (26).

Finally, the ability of α-tocopherol, the major lipid-soluble chainbreaking antioxidant in the erythrocyte membrane (40), to influence lipid peroxidation and phospholipid fatty acid renewal *in vivo* is examined. Although both diets contain equal amounts of vitamin E (187 α-TE/kg diet), the α-tocopherol content of rabbit erythrocytes was drastically lowered in fish oil-fed animals when compared to linoleic acid-fed rabbits, and these results are in agreement with data from Nair *et al.* (41).

The low amount of vitamin E in the red cell of fish oil-fed rabbits may be a result of the low amount of this antioxidant in the plasma, because (i) vitamin E can exchange between plasma and erythrocytes (42), (ii) its concentration is related to the concentration of plasma lipids (43), and (iii) in humans the ratio between plasma and the red cell vitamin E appears to be constant (approximately 3:1), irrespective of large differences in vitamin E intake (40). Indeed, in plasma of fish oil-fed rabbits, a reduction in α-tocopherol concentration is observed in comparison with linoleic acid-fed rabbits, the levels being 14.0 and 17.8 μg α-tocopherol/mL serum, respectively, although it remains as yet unknown whether this change is due to a reduced lipid content in the plasma of fish oil-fed rabbits. However, this decrease in α-tocopherol content is in agreement with data published for men (41).

On the other hand, this decrease in circulating plasma α-tocopherol in fish oil-fed rabbits could be a reflection of the increased demand for antioxidants as result of the increased PUFA intake. However, in the erythrocytes of either linoleic acid- or fish oil-fed rabbits supplementation with extra α-tocopherol did not result in a slower turnover of phospholipid fatty acids or in a decreased lipid peroxidation. This could indicate that the vitamin E level in the red cells of either rabbit is already sufficiently high, even without extra supplementation. This view is supported by the observation that (i) the erythrocyte phospholipid fatty acid pattern was similar irrespective of feeding rabbits with either 187 or 300 α-TE/kg of vitamin E, which is in agreement with observations in monkey erythrocytes (25) and (ii) the lowest concentration of dietary vitamin E already provides a level of approximately one molecule of vitamin E per 1000 lipid molecules in the red cells (40).

Concluding, it appears that the fatty acid composition of the diet affects the rate of phospholipid fatty acid renewal in the erythrocyte membrane *in vivo*.

ACKNOWLEDGMENTS

We are grateful to J. Westerman for the purification of PC specific transfer protein and nsL-TP and to the collaborators of the Animal Care Department and W.G.L. van Nielen of Diet and Health Research (Unilever Research Laboratory Vlaardingen, The Netherlands) for their technical assistance. ABSTRACT: The role of phospholipids in biliary cholesterol solubilization and crystallization has only recently begun to be appreciated. Phospholipid vesicles are believed to be the metastable carrier from which cholesterol nucleates. Cholesterol crystallization is influenced by the phospholipid species in bile. Feeding rats and hamsters with diets enriched in phospholipids or their precursors, especially ethanolamine, resulted in reduced cholesterol saturation of bile. Although whole phospholipids are normal dietary constituents, the effects and safety of phospholipid components have not been tested in humans. In the present study, we have evaluated the effects of a dietary phospholipid mixture, enriched with phosphatidylethanolamine, on human bile and red blood cell membrane lipid composition. Five ambulatory volunteers having a chronic indwelling T-tube, with an intact enterohepatic circulation, were investigated. Thirty-six grams of phospholipids (54% phosphatidylethanolamine, 54% linoleyl acyl chains) were added to their daily diet for fourteen days. Biliary nucleation time, cholesterol carriers, as well as plasma, red blood cell membrane, and bile lipid compositions, were monitored. Following phospholipid supplementation, the proportion of linoleyl chains (18:2) in biliary phospholipids increased significantly from 31.1 ± 1.2 to 37.7 ± 5.3%, while that of oleyl chains (18:1) decreased from 11.4 ± 1.6 to 9.6 ± 1.1%. These changes were accompanied by an increase of linoleate and its metabolite, arachidonate, in red cell membranes. Phospholipid feeding did not cause any side effects, and no significant changes in biliary nucleation time, cholesterol, phospholipid, or bile salt concentrations, or in the distribution of cholesterol within micelles or vesicles. We conclude that phospholipid feeding is safe, and can be effective as a vehicle for lecithin fatty acyl chain modulation of bile and lipid membranes. These findings may provide a basis for a controlled modulation of biliary phospholipids to increase cholesterol solubility in bile.

Lipids 31, 295–303 (1996).

The water-insoluble cholesterol is secreted into bile in association with phospholipids, in the form of vesicles (1,2). Bile salts are secreted separately, and subsequently form (together with phospholipids) various cholesterol solubilizing aggregates. The presence of micelles, phospholipid vesicles, and liquid crystals is widely accepted. The presence of additional lamellar structures is controversial (3,4). Phospholipids are essential components in all these aggregates (except simple micelles). Bile salts were at the forefront of biliary research for over two decades. The role of phospholipids and their various molecular forms has only recently begun to be appreciated.

First it was demonstrated that phospholipid vesicles were the metastable carrier from which cholesterol nucleated, particularly when their cholesterol/phospholipid ratio was high (5,6). Subsequently, it was shown that the addition *in vitro* of minute amounts of phospholipids, particularly those with saturated acyl chains, normalized the nucleation time of lithogenic biles (7). The addition of equivalent amounts of bile salts had no effect on nucleation. It was demonstrated that changes in the head group or fatty acyl chains of phospholipids, without any change in their concentration, had major effects on cholesterol carriers and the nucleation time in model and in human biles (8). The process of cholesterol crystallization is also significantly influenced by the phospholipid species in bile (9,10).

All these results stimulated the interest in the qualitative and quantitative modulation of biliary phospholipids. The phospholipids in bile are composed primarily of a mixture of lecithin molecular species having palmitic or stearic acid in the *sn*-1 position with more unsaturated acyl chains in the *sn*-2 position (11,12). Experimental (13–16), as well as clinical, studies (17,18) demonstrated that biliary phospholipid secretion and composition can be modulated by dietary means. Feeding diets enriched in phospholipids and their components to rats and hamsters revealed that ethanolamine administration markedly reduced cholesterol concentration and the cholesterol saturation index (CSI) of bile (19). The effects and safety of some phospholipid components have not been tested in humans, although whole phospholipids are normal dietary constituents (in eggs, soybean, etc.). In the present study, we have evaluated the effects of a dietary phospholipid mixture,

enriched with phosphatidylethanolamine (PE), on human bile and red blood cell (RBC) membrane lipid composition.

MATERIALS AND METHODS

Subjects. Six experiments were carried out in five ambulatory volunteers having a chronic indwelling T-tube, with an intact enterohepatic circulation. One subject was studied twice. All patients had undergone cholecystectomy, choledochotomy, and T-tube placement for gallstones—four had cholesterol and one (Patient OA; see Table 1) pigment stones. The study was approved by the local ethical committee, and informed consent was obtained from all participants. The demographic and clinical data are presented in Table 1. All patients were well nourished and their hepatic, renal, and thyroid functions were within normal limits. They had no evidence of obesity (>125% ideal body weight), recent weight loss (>10% during six past months), hypercholesterolemia (cholesterol >250 mg/dl), or diabetes mellitus, nor were they receiving any medication (including oral contraceptives) which could affect the parameters studied.

Study protocol. To ensure an intact enterohepatic circulation, the T-tube had been clamped for a minimum of 10 d before initiating the study. Patients were kept on a constant diet designed to be nutritionally adequate, consisting of 25% protein, 30% fat, 45% carbohydrates, and a total of 1600–2000 kcal per day, from the clamping day and throughout the study period. After ten days on this diet, 36 g of phospholipids (Lecithin granules; Lucas Meyer, Hamburg Germany; for composition see Table 2) were added in three divided doses to this diet for fourteen days. Thereafter, the subjects were switched back to the basic diet for another fourteen days. Bile was collected by gravity from the T-tube for 30 min at predesignated times. In between sampling, the T-tube was kept clamped throughout the study period. Blood and bile samples were obtained after an overnight fast at two-week intervals, each time on two consecutive days. The first pair of samples (sample A) was obtained two days before addition of the lecithin granules to the diet (day 0, day 1), the second (sample B) on the last two days of the lecithin-supplemented diet (day 14, day 15), and the third (sample C) on the last two days of the basic diet alone (day 28, day 29). Blood samples were collected for analysis of plasma lipids, as well as for RBC membrane lipids and fatty acid composition. Bile samples were used for determination of lipids, nucleation time, cholesterol carriers, and fatty acid composition of biliary phospholipids. Stone composition was determined after drying, pulverization, and dissolution in isopropanol as previously described (20).

Bile analysis. An aliquot (1 mL) of the collected hepatic bile was frozen immediately at −70°C for subsequent lipid analysis, performed within four weeks. The remaining bile was ultracentrifuged at 192,000 *g* for one hour at 25°C to remove cell debris. Samples of the supernatant bile were used to determine the nucleation time and the distribution of biliary cholesterol between the vesicular and micellar carriers by gel filtration chromatography as described elsewhere (6,21,22). Bile lipids were extracted by the method of Folch *et al.* (23). Bile acid concentration was determined enzymatically (24), cholesterol was determined by the method of Abbell *et al.* (25), and phospholipids as described by Bartlett (26). The CSI was calculated using the critical tables of Carey (27). Phosphatidylcholine (PC) and PE were separated by chromatography on a column of silicic acid (28). All samples were tested for purity after the separation by thin-layer chromatography (Silica gel 60, 0.25 mm; Merck, Darmstadt, Germany) employing chloroform/methanol/acetic acid/H_2O (100:20:12:4, by vol). Aliquots (5 µL) of the fresh bile incubated at 37°C were examined daily under polarized light. Nucleation time was defined as the time at which at least three cholesterol crystals were observed and found again in the next day's sample (22). The samples were observed up to 30 d. The gross appearance and chemical analysis of the stones, as well as the presence or absence of cholesterol monohydrate crystals in the sediment, were used to classify stone composition (29).

Plasma lipid analysis. Ten mL of venous blood drawn into glass tubes containing EDTA (1 mg/mL of blood) were transferred to the laboratory in iced water for immediate separation by low-speed refrigerated centrifugation (1000 *g*, 4°C) for ten minutes. Sodium azide (1 mg/mL plasma) was added, and the plasma was then kept at 4°C for up to five days prior to determination of total plasma lipids by enzymatic colorimetric testing. Triglycerides were determined with a kit from Sigma Co. (St. Louis, MO), and phospholipids, were determined with total and free cholesterol (FC) by kits from Boehringer Mannheim GmbH (Ingelheim, Germany).

Preparation and chemical analysis of RBC membrane lipid extracts. After plasma separation, the erythrocytes were washed three times with three volumes of a cooled isotonic solution containing 0.15 M NaCl, 10^{-5} M EDTA. The buffy coat was removed by aspiration after each wash. Finally, the

[a]From Lucas Meyer (Hamburg, Germany). Lipids were extracted with chloroform/methanol (23). Phospholipids were separated by thin-layer chromatography as described in the Materials and Methods section. The phospholipids spots were collected, and the phosphorus content was determined (26). Fatty acids composition was determined as described in the Materials and Methods Section.

packed erythrocytes were kept up to four weeks at –20°C for lipid analysis. RBC concentration was determined by a coulter counter (H*1 Analytical console assay; Technicon Instrument Corporation, Tarrytown, NY). Two 0.5 mL aliquots of the packed RBC were taken for lipid extraction. The RBC membrane lipids were extracted according to the method described by Rose and Oklander (30), which demonstrated complete recovery of both FC and phospholipids. FC in the lipid extracts was analyzed enzymatically (Boehringer Mannheim GmbH). Inorganic phosphate in the lipid extracts was eliminated by washing with 0.2 vol of 0.05 M KCl. The washed lipid extracts were then analyzed for phospholipid phosphorus by the method of Bartlett (26).

Analysis of bile and RBC phospholipid fatty acid composition. Aliquots of bile and RBC membrane lipid extracts were saponified with 0.5 M methanolic–KOH at 50°C, and the fatty acids were recovered after acidification by hexane extraction. The fatty acids were methylated with diazomethane and separated by gas–liquid chromatography on a 25 M fused silica column cross-linked with methylsilicone (0.52 mm film thickness) at a temperature range of 180–240°C, employing a Hewlett-Packard (Avondale, PA) 5790A gas-chromatograph equipped with a flame-ionization detector (31). The relative composition of a fatty acid mixture was calculated by a Hewlett-Packard 3390A integrator. For quantitative analysis, heptadecanoic acid was added as internal standard, assuming that the response of the detector for all methyl-fatty acids was identical.

Statistical analysis. In order to compare mean values of bile and plasma lipid concentrations, as well as fatty acid compositions at the various time points, analysis of variance was performed using the multiple comparisons option of Duncan. Because of sample size limitations, a nonparametric test of Kruskal-Wallis was also done. P values equal or less than 0.05 were considered significant.

RESULTS

The biliary lipid composition of the patients throughout the study period is presented in Table 3. Phospholipid supplementation did not cause significant changes in the concentration of the biliary lipid constituents, nor in the distribution of cholesterol between micelles and vesicles. The nucleation time of all samples was long (>10 d) and remained so, irrespective of the diet. Liver function tests of the patients remained within normal limits throughout the study and the follow-up.

The mean plasma phospholipid, cholesterol (free and esterified), and triglyceride levels were 237 ± 40, 50 ± 5, 225 ± 35, and 168 ± 68 mg/dl, respectively, at baseline. These values remained unaffected by phospholipid supplementation (244 ± 44, 50 ± 7, 213 ± 27, and 176 ± 58 mg/dl, respectively).

[a]Sample definitions as in Table 3.

The main seven biliary phospholipid fatty acyl species are detailed in Table 4 and in Figures 1 and 2. In all five patients, phospholipid supplementation resulted in a significant ($P = 0.05$) enrichment of the bile with linoleic acid (18:2). In Figure 2, which depicts the relative increase/decrease of the means, a marked increase in 18:2 (from 31.1 ± 1.2 to 37.7 ± 5.3%), accompanied by a decrease in 18:1 (from 11.4 ± 1.6 to 9.6 ± 1.1%) can be seen. However, the fatty acid composition started to return to baseline levels when feeding was discontinued. None of the other fatty acyl groups were affected by the treatment. As expected, the total fatty acid concentration remained unchanged. In addition, the relative proportion of PC and PE in bile remained unchanged—the PC/PE ratio in bile was 65.8 ± 25.6 on day 0, 60.6 ± 24.9 on day 14, and 93.4 ± 68.2 on day 28 ($P > 0.4$).

The mean RBC membrane FC and phospholipid concentrations (g/10^{12} cells) were 0.11 ± 0.01 and 0.18 ± 0.04 before, and 0.11 ± 0.00 and 0.21 ± 0.05 after phospholipid sup-

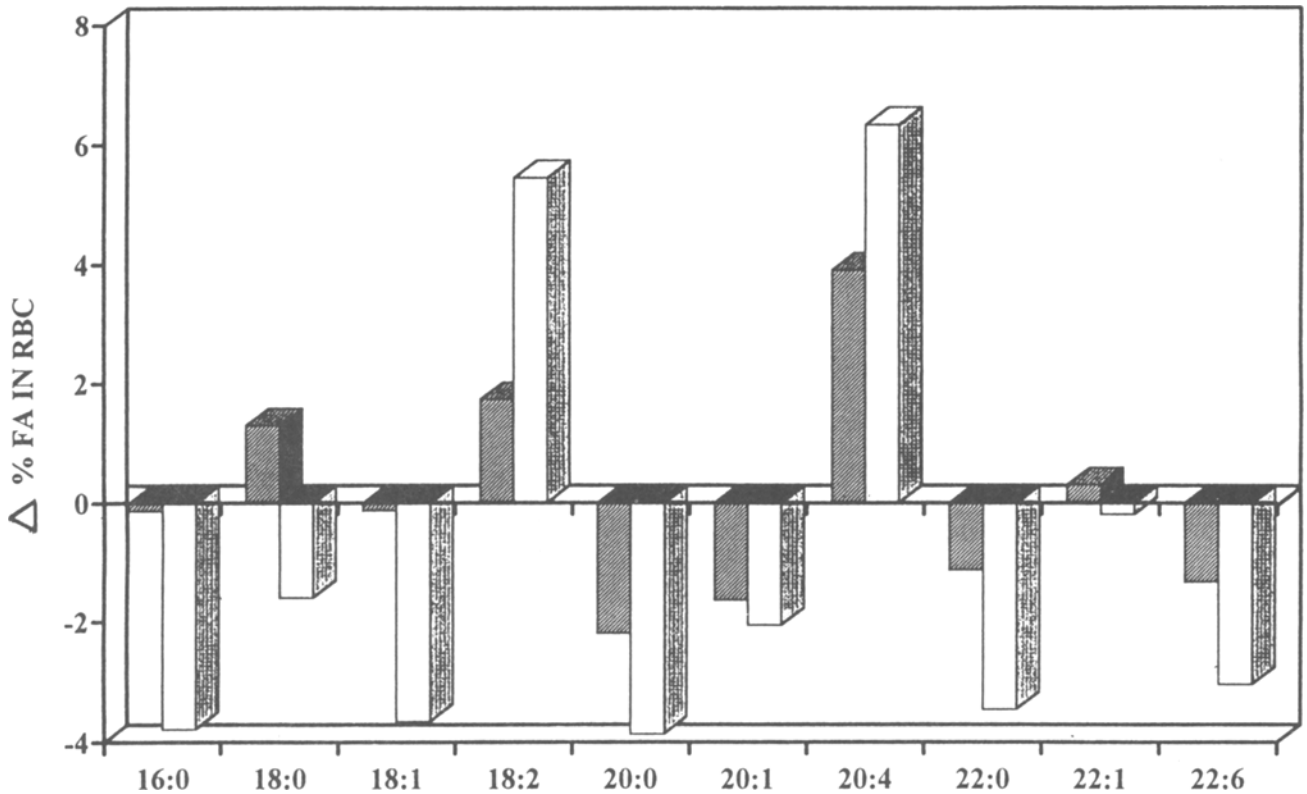

FIG. 3. Relative changes (Δ) in fatty acyl composition of red blood cell membrane phospholipids. The hatched bars represent changes between the basal diet and phospholipid supplementation. The open bars represent changes between basal diets at the beginning and at the end of the follow-up, i.e., two weeks after phospholipid supplementation. FA, fatty acids.

plementation, respectively. Thus, no changes in RBC membrane lipid concentrations or in their relative ratios were detected. The effect of phospholipid supplementation on RBC membrane lipid composition in two patients is detailed in Table 5 and in Figure 3. It can be seen that phospholipid supplementation resulted in marked increases in linoleate (18:2) and arachidonate (20:4) concentrations (from 6.2 to 12.0%, and from 4.3 to 14.0%, respectively). Concomitantly, a slight decrease in the minor fatty acyl species (20:0, 20:1, 22:0, and 22:1) was seen. These effects persisted in patient XJ throughout the prolonged study period, and continued to increase after feeding was discontinued (Fig. 3).

DISCUSSION

Experimental data in humans have revealed differences in biliary lecithin molecular species in gallstone patients as compared to controls. Ahlberg *et al.* (32) found more 16:0–18:1–PC and less 16:0–18:2–PC, whereas others have found increased levels of unsaturated PC acyl chains (especially 20:4) in gallstone patients (33,34). Hay *et al.* (12), on the other hand, failed to find any consistent pattern of lecithin molecular species in cholesterol gallstone patients. Nevertheless, based on experimental evidence, the modulation of phospholipid composition of bile could have very beneficial results. Increasing the relative concentration of phospholipids in human bile retards cholesterol nucleation (7). Changes in phospholipid head groups or in their fatty acyl chains, without any changes in concentration, can produce similar results (8). Unsaturated lecithins accelerate cholesterol crystallization while saturated lecithins retard the process (9,35).

Modulation of biliary phospholipid composition has been accomplished experimentally in laboratory animals (13–16,36), but was insufficiently studied in humans. Feeding a diet rich in legumes reduced the biliary phospholipid concentration in young Chileans (17), whereas dietary fish oils were found to decrease cholesterol saturation in gallstone patients (18). Modulation of biliary phospholipid composition could, in theory, be achieved by changing their hepatic metabolism or their dietary intake. While feeding various phospholipid components to rats and hamsters, it was noted that ethanolamine supplementation resulted in a considerable decrease of cholesterol concentration in bile (19). Bile salts and phospholipids were not significantly affected and the CSI decreased.

About two decades ago, shortly after the introduction of oral bile acid therapy, there were attempts to feed phospholipids to reduce the lithogenicity of bile, but the results were variable and, on the whole, disappointing. Tompkins *et al.* (37) fed 17 patients with 10 g of soybean lecithin for 5–10 d, and collected hepatic bile daily from an open T-tube, begin-

ning on the third post-operative day. They found a significant increase in the phospholipid/cholesterol ratio during phospholipid feeding. However, the relevance of these findings is questionable, because unlike our study, theirs was done with a disrupted enterohepatic circulation. Holan *et al.* (38) fed patients having radiolucent gallstones with 4.5 g of lecithin for three weeks, and examined their duodenal biles at the beginning and the end of the study. They found no significant changes in biliary lipid composition or cholesterol saturation. They did, however, note an increase in 18:2 and, to a lesser extent, in 20:4 fatty acyl chains of phospholipids in their aspirates, suggesting an effect on bile. These early data are consistent with the findings of our study, which examined the effects of phospholipid feeding sequentially in pure bile, under strictly controlled conditions. The efficacy and safety of various phospholipid components in humans were not sufficiently tested. We started our investigation with whole phospholipids, which are normal dietary constituents. The preparation used (Lecithin granules) has been used as a food supplement for many years in several European countries and in Israel. We chose this preparation because of its high PE content (approximately 54%) and record of safety. The amount used, 2 tablespoons three times in day with meals (36 g/d), is considerably larger than that used in previous studies (37,38), and is close to the maximal dose compatible with patient compliance over a period of weeks. All patients had an intact and stable enterohepatic circulation with easy access to repeated bile sampling, due to a chronic indwelling, closed, T-tube. This permitted repeated sampling over a period of several weeks on a fixed diet with and without phospholipid supplementation. In this initial study, we chose to investigate T-tube rather than gallbladder bile, because the former provides a more controlled system. Using T-tube bile, the subjects can serve as their own controls, and the effects of gallbladder function, as well as variations in bile sampling, are avoided (39,40). Moreover, it has recently been shown that metastability and lithogenicity can also be measured in hepatic bile (41).

In our study, the nucleation time, as well as the proportion of cholesterol in phospholipid vesicles, were not altered by the diet. Caution should, however, be exercised in interpreting the results of cholesterol carriers, the quantitation of which is prone to artifacts (42). To overcome some of the possible artifacts, Donovan *et al.* (43) have recently suggested the use of an elution buffer containing the intermicellar concentration of bile salts. However, despite the theoretical justification of this concept, its superiority over the widely used constant bile salt concentration has not been proven when studying human bile. We therefore used the commonly applied and repeatedly tested method of a constant (10 mM NaTC) buffer. This approach was further supported by the fact that the biliary lipid concentrations remained unchanged in each individual patient (who served as their own control) during the study period. Together with the unaffected CSI, our findings of unaltered cholesterol carriers suggest that the diet had no effect on lithogenicity of the bile. One should yet remember that the nucleation time of hepatic bile (as opposed to that of gallbladder bile) may not be a sensitive measure of lithogenicity (41), whereas the CSI certainly is not (44). Phospholipid supplementation did, however, cause a relative enrichment of linoleic acid within biliary phospholipids. This can be explained by the fact that linoleic acid was the main acyl chain (54%) present in the supplementary diet. Whether this enrichment reflects enrichment of the overall phospholipid body pool or maybe more specifically of liver cell membranes is difficult to assess.

The proportion of the essential fatty acid linoleic acid (18:2) increased in bile as well as in RBC. As this fatty acid is not synthesized in the body and its proportion in the ingested phospholipids was high, this result may be expected. Moreover, because 18:2 is rapidly converted to arachidonic acid (20:4), the associated increase in 20:4 can be readily explained. The life span ($T_{1/2}$) of RBC is long (*ca.* 120 d) and they have a limited synthetic capacity after release into the circulation. Because new RBC replace old cells, it is quite logical that the proportion of linoleic acid in RBC increased during dietary supplementation. Furthermore, exchange of membrane phospholipid fatty acids by hydrolysis and reacylation is expected. These increased levels of fatty acids persisting after supplementation were stopped and rose further during a second period of supplementation. In contrast, in the highly labile bile which is secreted *de novo,* the proportion of linoleic acid increased during dietary supplementation and fell rapidly thereafter.

Thus, in the present study, phospholipid, and in particular PE dietary supplementation, failed to change lipid concentrations or lithogenicity of bile. Nevertheless, phospholipid feeding was found to be effective as a vehicle for fatty acyl chain modulation of bile as well as RBC membranes. The pathophysiological relevance of these effects is presently unclear. However, combining the experimental data on the effects of phospholipid species on cholesterol crystallization with the fact that phospholipid species can be enriched in bile prompt further study in this direction. Additional attempts to regulate biliary phospholipids should probably also be directed toward the feeding of phospholipid components or influencing their metabolism in the liver.

ACKNOWLEDGMENTS

This work was performed in partial fulfillment of the requirements for a Ph.D. degree for Ronit Pakula at Sackler Faculty of Medicine, Tel-Aviv University, Israel. Supported in part by the Minerva Center for cholesterol gallstones and lipid metabolism in the liver, Tel-Aviv University, and a research grant (FMK) from the Chief Scientists Office, Israel Ministry of Health, Jerusalem.

Long-Chain Polyunsaturated Fatty Acids in Plasma Lipids of Obese Children

Tamás Decsi[a], Dénes Molnár[a], and Berthold Koletzko[b,*]

[a]Department of Paediatrics, University Medical School of Pécs, Pécs, H-7623 Hungary, and [b]Kinderpoliklinik, Ludwig-Maximilians University, Munich, D-80336, Germany

ABSTRACT: Fatty acid composition of plasma phospholipids (PL), triglycerides (TG), and sterol esters (STE) was determined by high-resolution capillary gas–liquid chromatography in 22 obese children (age: 13.7 ± 1.4 y, body weight relative to normal weight for height: 170 ± 24%, mean ± SD) and compared with data obtained in 25 age-matched healthy controls. There were no differences in the levels of linoleic acid (LA, $C_{18:2n-6}$) in any of the plasma fractions from the obese children and the controls. Obese children exhibited significantly higher values of arachidonic acid (AA, $C_{20:4n-6}$) than controls both in PL (12.6 [2.4] vs. 8.3 [1.4], % wt/wt, [median (interquartile range)], $P < 0.001$) and STE (7.3 [1.8] vs. 6.0 [1.1], $P < 0.05$). Similarly, obese children showed higher values than controls for dihomo-γ-linolenic acid (DHGLA, $C_{20:3n-6}$) in PL (4.0 [0.5] vs. 3.0 [0.6], $P < 0.001$), TG (0.4 [0.1] vs. 0.2 [0.1], $P < 0.001$), and STE (0.9 [0.1] vs. 0.7 [0.1], $P < 0.01$), and for γ-linolenic acid ($C_{18:3n-6}$) in STE (1.1 [0.2] vs. 0.8 [0.2], $P < 0.001$). The AA/LA ratios were higher in obese children than in controls in PL (0.68 [0.16] vs. 0.42 [0.09], $P < 0.0005$) and STE (0.16 [0.04] vs. 0.12 [0.02], $P < 0.05$), whereas the AA/DHGLA ratios were lower in TG of obese children than in controls (3.40 [0.64] vs. 5.10 [1.75], $P < 0.005$). Plasma glucose concentrations were inversely related to AA in TG ($r = 0.53$, $P < 0.05$), and plasma TG concentrations were inversely related to AA in PL and STE ($r = -0.49$, $P < 0.05$ and $r = -0.48$, $P < 0.05$) and to the AA/DHGLA ratios in PL ($r = -0.57$, $P < 0.01$), TG ($r = -0.56$, $P < 0.01$), and STE ($r = -0.56$, $P < 0.01$). We conclude that the significantly higher values of n-6 long-chain polyunsaturated fatty acids (LCP) in plasma lipids of obese children than in age-matched controls may be caused by an enhanced activity of Δ6-desaturation, and we speculate that elevated fasting immunoreactive insulin seen in obese children (19.4 ± 8.0 μU/mL) may stimulate synthesis of n-6 LCP fatty acids.

Lipids 31, 305–311 (1996).

Obesity is characterized by excessive expansion of adipose tissue mass and multiple derangements of carbohydrate and lipid metabolism. Because disturbances of lipid metabolism are associated with increased risks of morbidity and mortality in obesity, lipid metabolism has been studied extensively in obese subjects. Awareness of the importance of long-chain polyunsaturated fatty acid (LCP) metabolism in obesity has increased considerably in recent years, and fatty acid composition of plasma lipid classes has been investigated in obese adults (1–4). The primary aim of these studies was to examine the effect of weight reduction on fatty acid composition of plasma lipids; however, the most striking finding was a low percentage contribution of the principal n-6 LCP fatty acid, arachidonic acid ($C_{20:4n-6}$, AA), to plasma phospholipids (PL) in untreated obese adults on omnivorous diets (3). Because restriction of dietary fat intake is a cornerstone in the treatment of obesity, alterations of essential fatty acid (EFA) metabolism in obese subjects prior to any dietary intervention raised important questions about the adequacy of weight reduction diets in obesity.

Childhood obesity carries not only an increased risk of lasting morbidity, but also physical and psychosocial burdens, particularly around puberty when many obese children embark on dietary treatment in parallel with the peripubertal growth spurt. If obese children have reduced long-chain polyunsaturated fatty acids (PUFA) prior to dietary treatment, as reported for obese adults (3), dietary reduction of fat intake might worsen EFA status during a time of increased need for EFA for tissue storage and growth. In preterm infants, low n-6 LCP fatty acid values have been associated with reduced growth (5–7).

Controversial results have been reported on the efficacy of n-6 LCP fatty acid synthesis in obese animals. In genetically obese Zucker rats (*fa/fa*), contributions of arachidonic acid to PL in serum, liver, kidney, and heart were lower than in lean (*Fa/-*) animals (8). In contrast, an increase in conversion of linoleic acid (LA, $C_{18:2n-6}$) to AA has been reported in genetically obese mice (9). It is not known whether these animal models represent the pathophysiology of childhood obesity, and whether data obtained in obese adults reflect fatty acid metabolism in childhood obesity. Because we were unable to find data on PUFA in obese children in the published literature, we investigated fatty acid composition of plasma lipid classes in children with untreated obesity.

MATERIALS AND METHODS

The investigations were carried out in 22 obese children (11 girls and 11 boys) referred to a consultant pediatrician (D.M.) at the Department of Pediatrics, University Medical School of Pécs (Pécs, Hungary), because of their weight. The children were free of other known illnesses, were not dieting, and were not participating in physical training programs. The study was carried out in accordance with the Declaration of Helsinki II and with approval of the ethics committee of the University Medical School of Pécs. Informed parental consent was obtained for each child before enrollment in the study.

Anthropometric measurements were carried out by the same investigator. Body weight was determined to the nearest 0.5 kg with the child dressed only in underwear and wearing no shoes. Height was measured to the nearest 0.1 cm by a Holtain stadiometer (Holtain Limited, Crymich, Dyfed, Britain). Body fat was estimated according to Parizková and Roth (10) from five skinfold thicknesses measured on the left side of the body three consecutive times with the help of a Holtain caliper. Lean body mass was calculated by subtracting body fat from actual body weight. Relative body weight was calculated as the ratio between actual body weight and the ideal body weight for age, gender, and height (11). The waist and hip circumferences were measured with the subject in the supine position. The pubertal stage of the children was determined according to Tanner (12).

Blood samples were taken from the antecubital vein in the fasting state early in the morning. Blood was collected into tubes containing 2 mg/mL EDTA for triglyceride, cholesterol, plasma glucose, and insulin determinations, and into another tube for fatty acid analysis. The samples were centrifuged immediately at 4°C and plasma was stored at –20°C until analysis. Plasma samples were thawed only once.

Laboratory analyses, except for fatty acid determinations, were carried out at the Department of Pediatrics, Pécs. Plasma glucose concentrations were determined by the glucose oxidase method (13). Plasma insulin concentrations were measured with commercially available radioimmunoassay kits (Isotope Institute of the Hungarian Academy of Sciences, Budapest, Hungary). With this method, the upper limit of the normal range (mean + 2SD) for immunoreactive insulin levels in 100 healthy control children was found to be 20 μU/mL. Triglyceride and cholesterol were determined with an enzymatic kit (Boehringer, Mannheim, Germany).

Fatty acid analysis was carried out at the Kinderpoliklinik of the University of Munich (Munich, Germany). Plasma lipids were extracted from 0.25 mL plasma with chloroform/methanol (14) after addition of internal standards. Lipid classes were separated on silica gel plates (Nr. 5721; E. Merck, Darmstadt, Germany) with one 18-cm run of petroleum ether/ether/acetic acid (75:25:1, by vol), then 5-cm run of chloroform/methanol/water (65:25:4, by vol) (15). Fatty acids in plasma PL, triglycerides (TG), and sterol esters (STE) were transesterified with methanol and hydrochloric acid (16) and analyzed by high-resolution capillary gas–liquid chromatography.

A Hewlett-Packard 5890 (series II) gas chromatograph, equipped with a Sil 88 cyanopropil column of 50-m length (Chrompack, Middelburg, The Netherlands), was used to identify the fatty acid methyl esters. The running conditions for these determinations were: initial temperature, 60°C, followed by an increase (20°C/min) to 190°C for 1 min, followed by another increase (25°C/min) to 230°C for 31 min. The column head pressure was 1.5 bar. Identification of fatty acids was verified by comparison with authentic standards (Nu-Chek-Prep, Elysian, MN) and mass spectrometry (Hewlett-Packard Series 5971 MSD). Fatty acid results were expressed as percentage (w/w) of all fatty acids detected with a chain length between 12 and 22 carbon atoms.

The normal plasma fatty acid composition values used for comparison in this study were taken from a previously published study involving a sizable cohort (n = 115) of healthy children (17). From this data pool, data of the subgroup of children aged 10 to <15 years (n = 25, 13 males and 12 females, mean age: 12.9 ± 1.6 yr, mean ± SD) were used for comparison. These children were investigated either because of symptoms presumably not related to fatty acid metabolism, or because of planned elective surgery calling for general anesthesia. One of the inclusion criteria in the study was body weight between the 3rd and 97th centiles. Fasting plasma was obtained from these subjects and analyzed for fatty acid composition with procedures identical to those described above.

Results were evaluated with Minitab for Windows, Release 9 (18). All data except fatty acids were compared by Student's unpaired *t*-test. The fatty acid data are presented as median and interquartile range values; because skewed distributions were found, especially present at low concentrations, Mann-Whitney's two-sided rank test was used for intergroup comparison of fatty acid profiles. Differences were regarded as statistically significant at $P < 0.05$.

RESULTS

The subjects' characteristics are shown in Table 1. All subjects were markedly obese; the extent of overweight expressed as a percentage of ideal body weight ranged from 31 to 131%. Age, body weight, relative body weight, height, and body mass index did not differ significantly between boys and girls, though girls tended to be slightly heavier and somewhat shorter than boys (Table 1). Body fat content was significantly higher in girls than in boys. Consequently, lean body masses tended to be higher in boys than in girls; however, the differences did not reach statistical significance. The waist to hip ratio of males was significantly higher than that of females, a finding indicative of a tendency to abdominal adiposity in males. Girls were sexually more mature than boys; median Tanner's stages of public hair/breast development in girls were 5:5, whereas median stages of public hair/genital development in boys were 2:3.

Plasma TG, cholesterol, glucose, and immunoreactive insulin (IRI) concentrations are shown in Table 1. Average TG concentrations were only slightly elevated; when considered individually, seven subjects (4 girls and 3 boys) exhibited hy-

TABLE 1
Characteristics of the Subjects[a]

	Girls (n = 11)	Boys (n = 11)	All (n = 22)
Age (y)	13.9 ± 1.4	13.6 ± 1.5	13.7 ± 1.4
Weight (kg)	89.7 ± 20.3	88.3 ± 22.2	89.0 ± 20.8
RBW (%)	177 ± 25	166 ± 11	170 ± 24
Height (cm)	161 ± 8	166 ± 11	164 ± 10
BMI (kg/m^2)	34.2 ± 5.2	31.7 ± 5.2	32.9 ± 52
BF (%)	43.1 ± 3.0[c]	35.0 ± 4.0[c]	39.1 ± 5.4
LBM (kg)	50.9 ± 11.4	57.0 ± 13.9	54.0 ± 12.8
Waist/hip ratio	0.80 ± 0.08[b]	0.90 ± 0.06[b]	0.85 ± 0.08
Triglyceride[b] (mmol/L)	1.59 ± 0.55	1.69 ± 0.84	1.64 ± 0.70
Cholesterol (mmol/L)	4.11 ± 0.61	4.35 ± 0.60	4.24 ± 0.60
Glucose (mmol/L)	4.11 ± 0.58	4.29 ± 0.76	4.20 ± 0.67
IRI (μU/mL)	21.0 ± 7.8	17.8 ± 8.2	19.4 ± 8.0

[a]Values are mean ± SD. Means in a row sharing a common superscript (b,c) are significant different ([b]$P < 0.005$, [c]$P < 0.0001$) using Student's unpaired *t*-test; RBW, relative body weight; BMI, body mass index; BF, body fat content; LBM, lean body mass; IRI, fasting immunoreactive insulin.
[b]Cutoff points of hypertrigliceridemia and hypercholesterolemia in children were set by the Hungariank Lipid-Consensus Conference as 1.6 and 5.2 mmol/L, respectively.,

pertriglyceridemia with serum TG concentrations > 1.6 mmol/L (range: 1.8–3.9 mmol/L). Plasma cholesterol concentrations were not markedly elevated; the maximal value was 5.3 mmol/L. In spite of normoglycemia (range of plasma glucose concentrations: 2.3–5.0 mmol/L), basal plasma IRI concentrations exceeded the value for normal children in nine subjects (5 girls and 4 boys; range: 21–39 μU/mL). Basal plasma immunoreactive insulin concentrations tended to be higher in girls than in boys; the mean value for the IRI levels in the obese girls was greater (by 1 μU/mL) than the upper limit of normality (mean + 2 SD) reported for healthy females.

The fatty acid composition of plasma lipid classes in the obese children is compared with values of age-matched controls in Table 2. There were no significant differences between boys and girls in percentage contributions of fatty acids to plasma PL, TG, and STE either in the present investigation, or in a previous study on healthy children (18); therefore, pooled values for both sexes are shown in Table 2. Percentage contributions of palmitic acid ($C_{16:0}$) in the TG and STE fractions and stearic acid ($C_{18:0}$) in the STE fraction were significantly higher in the obese children compared with the controls. Total saturated fatty acids were significantly higher in TG and STE of obese children than in controls. In plasma PL, however, only stearic acid ($C_{18:0}$) values were elevated in the obese subjects, whereas levels of myristic ($C_{14:0}$) and palmitic ($C_{16:0}$) acids were highest in the control group. Total saturated fatty acids in PL did not differ between the two groups. Octadecenoic acids, that is, oleic ($C_{18:1n-9}$) plus vaccenic ($C_{18:1n-7}$) acid, in the PL fraction and total monounsaturated fatty acids in the PL and TG fractions were significantly lower in obese than in the control children.

Percentage contributions of the n-6 precursor essential fatty acid LA, as well as percentage contributions of eicosadienoic acid ($C_{20:2n-6}$), did not differ between the two groups. In contrast, obese children had significantly higher levels of

[a]Values are % w/w [median (interquartile range)], obese: n = 22, control: n = 25, ND denotes not detectable. Medians in a row sharing a common superscript (b,c,d) are significantly different ([b]$P < 0.05$, [c]$P < 0.01$, [d]$P < 0.001$) using Mann-Whitney's two-sided rank test.
[b]Total n-6 long-chain polyunsaturated fatty acid (LCP) denotes ($C_{20:2n-6} + C_{20:3n-6} + C_{20:4n-6} + C_{22:4n-6}$).
[c]Total n-3 LCP denotes ($C_{20:5n-3} + C_{22:5n-3} + C_{22:6n-3}$).

TABLE 3
Product/Substrate Ratios of n-6 Long-Chain Polyunsaturated Fatty Acid Biosynthesis in Plasma Lipid Classes of Obese Children and Age-Matched Controls[a]

Ratio	Phospholipids		Triglycerides		Sterol esters	
	Obese	Control	Obese	Control	Obese	Control
$(C_{18:3n-6} + C_{20:3n-6})/C_{18:2n-6}$	0.21 (0.06)[d]	0.15 (0.04)[d]	0.04 (0.01)	0.03(0.01)	0.04 (0.01)[a]	0.03 (0.01)[d]
$C_{20:4n-6}/C_{20:3n-6}$	3.08 (0.56)	2.85 (0.71)	3.40 (0.64)[c]	5.10 (1.75)[c]	8.41 (1.70)	9.05 (1.81)
$C_{20:4n-6}/C_{18:2n-6}$	0.68 (0.16)[d]	0.42 (0.09)[d]	0.08 (0.02)	0.07 (0.01)	0.16 (0.04)[b]	0.12 (0.02)[b]

[a]Values are [median (interquartile range)], obese: n = 22, control: n = 25. Medians in a row sharing a common superscript (a,b,c,d) are significantly different ([b]$P < 0.05$, [c]$P < 0.005$, [d]$P < 0.0005$) using Mann-Whitney's two-sided rank test.

the metabolites of Δ6-desaturase, γ-linolenic acid (GLA, $C_{18:3n-6}$) in the STE fraction, dihomo-γ-linolenic acid (DHGLA, C20:3n-6) in all of the plasma fractions, AA in the PL and STE fractions and adrenic acid ($C_{22:4n-6}$) in the PL and TG fractions than the controls (Table 2).

Percentage contributions of the n-3 precursor essential fatty acid, α-linolenic acid ($C_{18:3n-3}$), were significantly lower in all of the plasma fractions in obese children than in controls. There were no differences between the two group in the percentage contributions of the principal n-3 LCP fatty acid, docosahexaenoic acid ($C_{22:6n-3}$), but total n-3 LCP fatty acids were significantly lower in TG of obese than in controls.

Product/substrate ratios for n-6 LCP fatty acid biosynthesis in obese subjects are compared with data of controls in Table 3. The ratios of GLA plus DHGLA to LA, i.e., the product/substrate ratios reflecting the Δ6-desaturase enzyme activity, were higher in both PL and STE in obese subjects than in controls. In contrast, the ratios of AA to DHGLA ($C_{20:4n-6}/C_{20:2n-6}$) were significantly lower in TG of obese children than in controls, whereas no differences in PL and STE were seen. The ratios of AA to LA ($C_{20:4n-6}/C_{18:2n-6}$) were significantly higher in both PL and STE of obese subjects than in controls. No significant differences were found when the product/substrate ratios calculated for girls were compared with those calculated for boys.

The twelve characteristics of the subjects (age, weight, height, relative body weight, body fat content, lean body mass, body mass index, waist to hip ratio, plasma glucose, IRI, cholesterol, and TG concentrations) were used as predictive variables in multiple linear regression analyses, whereas percentage contributions of AA and the AA/LA and AA/DHGLA ratios in plasma lipid classes were entered as responding variables. Significant inverse correlations were seen between plasma TG concentrations and percentage contributions of AA in plasma PL ($r = -0.45$, $P = 0.04$) and STE ($r = -0.48$, $P = 0.03$). A significant inverse correlation existed between plasma glucose concentrations and the percentage contribution of AA in plasma TG ($r = -0.53$, $P < 0.05$). Similarly, the ratios of AA to LA in TG ($C_{20:4-6}/C_{18:2n-6}$) were inversely correlated with plasma glucose concentrations ($r = -0.61$, $P < 0.005$). In both PL and STE, the AA/LA ratios were inversely related to plasma TG concentrations (r −0.51, $P < 0.05$; $r = -0.48$, $P < 0.05$). Body heights were significantly correlated with the AA/LA ratio in STE ($r = 0.44$, $P < 0.05$). The ratios of AA to DHGLA ($C_{20:4n-6}/C_{20:3n-6}$), i.e., the substrate/product ratios for Δ5-desaturase enzyme were inversely related to the plasma TG concentrations in all three lipid classes investigated (PL: $r = -0.57$, $P < 0.01$; TG: $r = -0.56$, $P < 0.01$; STE: $r = -0.56$, $P < 0.01$).

Amounts of substrate ($C_{20:3n-6}$) and product ($C_{20:4n-6}$) of the Δ5-desaturase and the $C_{20:4n-6}/C_{20:3n-6}$ ratio in obese children with plasma TG concentrations > 1.6 mmol/L) were compared with the values from children with plasma TG concentrations ≤1.6 mmol/L (Table 4). In all lipid classes investigated, percentage contributions of DHGLA ($C_{20:3n-6}$) were similar in the two groups, but children with hypertriglyceridemia tended to have lower AA ($C_{20:4n-6}$) values than children with <1.6 mmol/L plasma TG concentrations. The AA/DHGLA ratios were significantly lower in the children with plasma TG concentrations >1.6 mmol/L than in those with ≤1.6 mmol/L plasma TG concentrations (Table 4).

No significant differences were found in percentage contributions of n-6 LCP fatty acids and their product/substrate ratios in children with and without basal hyperinsulinemia (IRI concentrations > 20 μU/mL) (data not shown).

DISCUSSION

In the present study, we compared the fatty acid composition of plasma lipid classes in obese children with the corresponding values obtained in a sizable cohort of healthy children, and the fatty acid data were analyzed in relation to parameters characterizing the obese subjects. In contrast to previous observations in obese adults compared with nonobese controls (3,19), we found that percentage contributions of n-6 LCP fatty acids to plasma lipid classes were higher in obese children than in age-matched control subjects. This finding raises the question of determining which mechanisms may have contributed to enhanced n-6 LCP fatty acid values in obese children.

High percentage contributions of n-6 LCP fatty acids to plasma lipid classes may arise as the result of at least five different factors: (i) a high dietary intake of preformed n-6 LCP; (ii) a high dietary intake of LA ($C_{18:2n-6}$); (iii) enhanced rate of the synthesis of n-6 LCP fatty acids from LA; (iv) diminished rate of n-6 LCP fatty acid utilization (for incorporation into tissues, eicosanoid synthesis and oxidation); and 5) increased liberation of stored LCP fatty acids from body pools (mainly from adipose tissues).

We have no detailed information on the diet of the children

TABLE 4
Percentage Contributions of n-6 Substrate ($C_{20:3n-6}$) and Product ($C_{20:4n-6}$) of Δ5-Desaturase in Obese Children with and without Plasma Triglyceride Concentrations >1.6 mmol/L[a]

Plasma triglyceride	>1.6 mmo/L	≤1.6 mmoll/L
	(n = 7)	(n = 15)
Plasma triglyceride concentration (mmol/L, mean ± SD)	2.43 + 0.68[a]	1.25 ± 0.20[a]
Fatty acids [(% w/w, median (interquartile range)]		
Plasma phospholipids		
$C_{20:3n-6}$ (% w/w)	3.99 (0.88)	3.81 (0.59)
$C_{20:4n-6}$ (% w/w)	10.78 (1.21)	13.69 (1.72)
$C_{20:4n-6}/C_{20:3n-6}$	2.60 (0.50)[b]	3.47 (0.67)[b]
Plasma triglycerides		
$C_{20:3n-6}$ (% w/w)	0.44 (0.07)	0.39 (0.10)
$C_{20:4n-6}$ (% w/w)	1.02 (0.21)	1.36 (0.25)
$C_{20:4n-6}/C_{20:3n-6}$	2.67 (0.74[b]	3.58 (0.68)[b]
Plasma sterol esters		
$C_{20:3n-6}$	1.00 (0.07)	0.85 (0.17)
$C_{20:4n-6}$	6.12 (1.28)	8.45 (1.53)
$C_{20:4n-6}/C_{20:3n-6}$	6.03 (1.30)[b]	9.07 (1.50)[b]

[a]Means in a row sharing a common superscript are significantly different ([a]$P < 0.005$) using Student's unpaired *t*-test. Medians in a row sharing a common superscript are significantly different ([b]$P < 0.05$) using Mann-Whitney's two-sided rank test.

prior to the study; however, enhanced dietary intake of fatty acids (either LCP or precursor) seems to be an unlikely explanation for the elevated n-6 LCP values observed in the obese children. In a previous study in obese children from this same population, it was found that they did not consume more fat than nonobese controls, either when fat intake is expressed as g/kg body weight or g/kg lean body mass (20). Furthermore, there are few foods in which AA constitutes more than 2–6% of the total fatty acids by weight, and these foods, including such items as egg yolk, beef liver, mackerel, and whale oils (21), are unlikely to contribute substantially to the diet of young teenagers. Consequently, the fact that the obese children originated from a geographically different population than the controls could not have a major influence on dietary intake of preformed n-6 LCP such as AA. A high dietary intake of LA would have been reflected also in high percentage contributions of LA to plasma lipid classes, but LA values in obese children did not differ from those measured in controls (Table 2).

In spite of the similar values for LA ($C_{18:2n-6}$), percentage contributions of GLA ($C_{18:3n-6}$), DHGLA ($C_{20:3n-6}$), and AA ($C_{20:4n-6}$) were significantly higher in the obese children than in the controls. This pattern is consistent with an enhanced conversion of LA to the other n-6 LCP fatty acids. The finding that percentage contributions of eicosadienoic acid ($C_{20:2n-6}$), a direct elongation product of LA, did not differ between the obese and nonobese groups, supports the hypothesis that chain-elongation was unaffected but desaturase activity was enhanced in the obese children. The product/substrate ratios calculated for the enzymes of n-6 LCP fatty acid synthesis support this concept further.

The substrate/product ratios for the Δ6-desaturase ($[C_{18:3n-6} + C_{20:3n-6}]/C_{18:2n-6}$) were significantly higher in both PL and STE of obese children than in controls. In plasma TG, this ratio did not differ significantly between the two groups. The substrate/product ratios for the Δ5-desaturase ($C_{20:4n-6}/C_{20:3n-6}$) did not differ between the two groups in PL and STE; at the same time, obese children exhibited significantly lower values in TG. In conclusion, our data are consistent with the hypothesis that enhanced activity of the Δ6-desaturase contributed to higher AA and n-6 LCP fatty acid values in plasma lipids in obese children. This hypothesis is further supported by the absence of other known pathophysiological mechanisms, such as diminished n-6 LCP utilization or increased liberation of n-6 LCP from body stores in nondieting obese teenagers.

There are several nutritional and hormonal factors that play a role in the regulation of essential fatty acid desaturation (22,23) and which may have figured in the enhanced Δ6-desaturase activity seen in the obese children in this study. In animal experiments Δ6-desaturase is stimulated by protein and energy intakes (24,25), and low Δ6-desaturase activity has been suggested as the mechanism for the low AA and n-6 LCP fatty acid values seen in children with protein-energy malnutrition (26–28).

Insulin has been reported to be a potent activator of Δ6-desaturase (24,29,30,31), and the insulin secreted by obese individuals has full biological activity (32). Even though we found no significant correlation between insulin concentrations and LCP fatty acid values, and fatty acids in children with basal hyperinsulinemia did not differ, we still consider that the action of insulin may explain at least in part the high n-6 LCP fatty acid values observed in the obese children. This hypothesis is further supported by the absence of other known

pathophysiological mechanisms, such as diminished n-6 LCP utilization or increased liberation of n-6 LCP from body stores in nondieting obese teenagers.

There are several nutritional and hormonal factors that play a role in the regulation of essential fatty acid desaturation (22,23) and which may have figured in the enhanced Δ6-desaturase activity seen in the obese children in this study. In animal experiments Δ6-desaturase is stimulated by protein and energy intakes (22,24,25), and low Δ6-desaturase activity has been suggested as the mechanism for the low AA and n-6 LCP fatty acid values seen in children with protein-energy malnutrition (26–28).

Insulin has been reported to be a potent activator of Δ6-desaturase (24,29,30,31), and the insulin secreted by obese individuals has full biological activity (32). Even though we found no significant correlation between insulin concentrations and LCP fatty acid values, and fatty acids in children with basal hyperinsulinemia did not differ, we still consider that the action of insulin may explain at least in part the high n-6 LCP fatty acid values observed in the obese children in the present study. Mean basal IRI concentrations were high in the obese children, and 9 of the 22 subjects showed biochemical hyperinsulinemia. The observed inverse relation between plasma glucose concentrations and AA values in plasma TG seems also to support the hypothesis of a relation of insulin to the high n-6 LCP fatty acid values found in obese children. Hyperinsulinemia increases with the duration of obesity in children with a negative family history for diabetes mellitus (33), and the antilipolytic effect of insulin seems to be preserved in obese subjects with marked resistance to its glucoregulatory effect (34). In healthy humans, insulin sensitivity assessed as metabolic clearance rates of glucose during euglycemia clamp studies was found to be positively related to the percentage of arachidonic acid in phospholipids in serum (35) as well as in skeletal muscle (36). The lack of a significant correlation of fatty acid results in this study may be due to the fact that fasting IRI does not reflect total insulin effects, including postprandial secretion.

Our results in obese children contrast with findings of reduced n-6 LCP in obese adults (3). However, low n-6 LCP fatty acid values were not a unanimous finding in obese adults; Rössner and co-workers (1) reported significantly higher AA values in plasma cholesterol esters in obese adults than in controls. It is possible that differences in the study populations may have contributed to the varying results. Some of the pertinent factors analyzed in the present study (particularly glucose and insulin concentrations) were not reported in investigations on obese adults (1,3). Hyperlipidemia is a common finding in advanced obesity, and significant inverse relations of plasma triglyceride concentrations to product/substrate ratios of enzymes of n-6 LCP synthesis were seen in this study. Cunnane *et al.* (37) reported a similar phenomenon, i.e., an inverse correlation of the percentage contribution of AA in liver triacylglycerols to total triacylglycerol concentrations in rats, hamsters, guinea pigs, and monkeys. Increased AA values are a consistent observation during weight reduction in obese adults (1,3,4) and were also reported in parallel with significant reductions of plasma TG concentrations (1).

In the present study, the product/substrate (AA/DHGLA) ratio was significantly lower in TG of obese children than in controls, which is in agreement with the observation of Guesnet and co-workers (8), who recently reported significantly lower AA/DHGLA ratios of plasma and tissue samples in obese than in lean female Zucker rats.

We hypothesize that the higher n-6 LCP fatty acid values found in obese children are due to an enhancement of the Δ6-desaturase enzyme activity, whereas the Δ5-desaturase activity appeared lower in the obese children than in the controls. Our data provide evidence that the risk of an EFA deficiency is not increased when diets low in the n-6 LCP fatty acids are consumed during the treatment of obesity is adolescents.

Changes in the Size and Docosahexaenoic Acid Content of Adipocytes During Chick Embryo Development

Klára Farkas, Iain A.J. Ratchford, Raymond C. Noble, and Brian K. Speake*

Department of Biochemical Sciences, Scottish Agricultural College, Ayr, KA6 5HW, United Kingdom

ABSTRACT: The development of adipose tissue in the chick embryo was investigated using two groups of fertile eggs which differed by 1.7-fold in their initial yolk lipid levels. The triacylglycerol content of the subcutaneous adipose depot in both groups increased dramatically from day 12 of the 21-day embryonic period, attaining a maximal value just prior to hatching. During this period, the amount of triacylglycerol deposited in the adipose tissue was very highly correlated with the amount of lipid transferred from the yolk. The triacylglycerol content of the depot was also dependent on the initial yolk lipid content. During the hatching period, the amount of adipose triacylglycerol remained approximately constant in the group with the higher initial yolk lipid content but, in the case of the group with the lower initial yolk lipid levels, decreased by approximately 25%. The size distribution of adipocytes isolated from the tissue was determined by computerized image analysis microscopy. The mean adipocyte diameter increased from approximately 6 to 35 μm between days 12 and 19, irrespective of the initial yolk content, although development within the eggs with the lower initial yolk content resulted in a decrease in cell size over the hatching period. Both the triacylglycerol and phospholipid fractions of the isolated adipocytes contained substantial proportions (approximately 6%, w/w) of docosahexaenoic acid (DHA) at days 12 and 14, and lower levels of this fatty acid at the later stages. The amount (mg/depot) of DHA in adipose triacylglycerol decreased dramatically over the hatching period. The amount (mg/brain) of DHA in brain phospholipid increased by more than 5-fold between day 12 of development and hatching. A possible explanation for the data may be that DHA is preferentially mobilized from adipose tissue in order to deliver the fatty acid to the developing neural tissues in a form suitable for uptake. *Lipids 31*, 313–321 (1996).

The final week of the 21-d embryonic period of the chicken is characterized by the rapid transfer of lipid components from the yolk to the embryo (1). Current evidence indicates that yolk lipids are taken up by the yolk sac membrane where they are assembled into lipoprotein particles for release into the embryonic circulation (1,2). The action of lipoprotein lipase, located at various tissue sites, on the plasma lipoproteins results in the uptake and utilization of the constituent fatty acids by the embryonic tissues (3). The resultant lipoprotein remnants are taken up by the embryonic liver, with the consequent accumulation of large amounts of cholesteryl ester in this tissue (4,5).

The intensity of the lipid transfer process, the predominance of lipid metabolism in the embryonic tissues, and the fact that the embryo develops as a self-contained system free from contemporaneous maternal influences (1) are factors which favor the suitability of the chick embryo as a model system for studying various aspects of lipid utilization during development. The present study encompasses the relationship between two such aspects; namely, the development of adipose tissue and the delivery of essential long-chain polyunsaturated fatty acids, in particular docosahexaenoic acid (DHA; 22:6n-3), to the embryonic tissues.

Subcutaneous adipose tissue can be detected in the chick embryo from around day 12 of development, and the tissue then grows rapidly during the final week of embryogenesis (3,6). The fact that rates of lipogenesis from carbohydrate precursors are extremely low in this system (7), coupled with the observation that very high levels of lipoprotein lipase activity are expressed in the embryo's adipose tissue (3), suggests that the growth of the tissue is dependent largely on the uptake of fatty acids hydrolyzed from yolk-derived plasma lipids. The sensitivity of the adipocytes to lipolytic agonists increases toward the end of the embryonic period (8), suggesting that one of the functions of adipose tissue in this system may be to provide a store of triacylglycerol which can be partially mobilized for energy purposes during hatching.

High levels of DHA are incorporated into the phospholipids of the brain and retina of the chick embryo (9,10) and of most other vertebrates (11) during development, and an adequate supply of this fatty acid is deemed to be essential for the optimal functional maturation of these tissues (11). Previous studies from our laboratory have shown that the transport of DHA from the yolk to the embryonic tissues is characterized by a series of unique features, including the preferential uptake of DHA-containing phospholipids from the yolk by the yolk sac membrane (1), the specific transfer of yolk-derived DHA into the triacylglycerol fraction of plasma lipoproteins (3,12), and the incorporation of large proportions of this fatty acid into the triacylglycerols of the liver and adipose tissues (1,3). In the present study, changes in adipocyte size dis-

tribution and in the DHA content of the adipose tissue lipids were evaluated from the time of the initial formation of the tissue until the end of the embryonic period. Changes in the DHA content of brain phospholipid during the same period are also reported.

MATERIALS AND METHODS

Embryos. Fertile eggs of the Ross 1 broiler-breeder strain were obtained from Ross Poultry Ltd. (Inverurie, United Kingdom) and incubated at 37.8°C and 60% relative humidity in a forced-draught incubator with automatic egg turning. Hatching occurred after 21 d of incubation, and the chicks were maintained in the incubator at 37.8°C and 60% relative humidity for one day after hatching, with free access to drinking water but with no food provision. In order to compare the effects of differences in the lipid provision from the yolk on the development of adipose tissue in the embryo, two experiments were performed using batches of eggs which differed in their initial yolk lipid content. The initial egg weights (g) for the two batches were 48.4 ± 0.7 and 62.2 ± 0.7 (means ± SEM, measured on 20 eggs from each batch), and the initial lipid contents of the yolks (g total lipid/yolk) were 3.4 ± 0.1 and 5.7 ± 0.1 (means ± SEM, measured on 8 eggs from each batch). The respective DHA contents (mg/yolk) of the initial yolk lipid samples were 67.4 ± 2.2 and 94.3 ± 4.1 (means ± SEM measured on 4 eggs from each batch). At the appropriate developmental stages, embryos were excised from the eggs, and the subcutaneous adipose tissue was quantitatively dissected from the upper thigh area and along the sides of the abdomen and thorax. The combined tissue from these sites from both sides of a single embryo is hereafter referred to as a depot. Other, more diffuse sites of adipose tissue, such as those in the neck region, were not included in this study. On each sampling day, 4 replicate portions of adipose tissue, each derived from between 2 and 10 embryos, depending on the developmental stage, were prepared. The pooling of tissue samples from several embryos was necessary in order to provide sufficient material for the subsequent measurements, particularly at the earlier developmental stages. The intact yolk complexes (i.e., yolk plus yolk sac membrane) were also excised from the eggs and stored at –20°C for up to 2 wk to await lipid analysis. Brains were also dissected from the embryos at various developmental stages and stored at –20°C for up to 2 wk prior to lipid analysis.

Adipocyte preparation. Each replicate portion of adipose tissue was weighed and then minced with scissors to give small pieces of approximately 2 mm^3. A weighed sub-portion (200–400 mg) obtained by random selection of the small pieces was subjected to chloroform/methanol extraction in order to determine the triacylglycerol content of the depot (see below). A further sub-portion (200–400 mg) was incubated in 3 mL of Dulbecco's Modified Eagle's Medium buffered with 25 mM HEPES and containing bovine serum albumin (1%, wt/vol) and collagenase (1 mg/mL) for 1 h at 37°C in a stoppered polypropylene tube with rapid shaking. All constituents of the digestion medium were obtained from Sigma Chemical Co. (Poole, United Kingdom) The digested tissue was gently filtered through a polyester fine mesh (Boots PLC, Nottingham, United Kingdom), and after centrifugation at 300 × *g* for 4 min the infranatant and pellet were carefully removed from beneath the floating fat cell layer with a syringe. The cells were washed twice with 3 mL of Dulbecco's Modified Eagle's Medium containing HEPES (25 mM) and bovine serum albumin (1% wt/vol) and finally resuspended in 1 mL of the same medium. At all stages of cell preparation prior to microscopic analysis, the cells were maintained in medium at 37°C; polypropylene vessels were used throughout.

Measurement of cell size distribution. Adipocytes were examined microscopically using an Olympus Varox (Olympus Optics, United Kingdom) fitted with a combined Nomarski differential interference contrast/phase contrast/brightfield, 1.4NA, aplanatic, achromatic condenser. Brightfield images were obtained using a long working distance plan X10, 0.55NA objective with an X3.3 eyepiece. Images were obtained using a Panasonic CCD camera (Model number WL-CL700/B) (Optivision, Osset, Yorkshire, United Kingdom) mounted vertically on the microscope. The images were analyzed by Bio Scan OPTIMAS software v3.01 (Datacell, Maidenhead, United Kingdom) running on a 25 MHz 386 DX SVGA computer operating with 4 Mb memory, maths coprocessor present, MSDOS 6.2, MS Windows 3.1 with a 20 Mb permanent swap file on a 200 Mb fast hard disk. The main OPTIMAS program and all macro routines were run from a RAM drive created in memory to increase image handling speed and data processing.

Cell measurements were made using a macro coded C++ program specifically written in house for the acquisition/manipulation of the image and the processing of the data. Details of this program are available on request. The image settings for brightfield microscopy were Contrast 220 and Brightness 200. Images were corrected for background distortions and nonuniformity by division of the same image in a blank field. Irregularities created by interference in the color signal from the camera were removed using a color and motion stabilizer. Intact adipocytes were clearly distinguished from oil droplets or debris, and the program exported the cell diameter data as ASC11 code for statistical analysis. Measurements were performed on between 100 and 150 cells examined at random from each replicate sample of adipocytes, giving a total of 400–600 measurements at each developmental stage.

Lipid analysis. Samples were homogenized in a suitable excess of chloroform/methanol (2:1, vol/vol), lipid extracts were prepared, and the amounts of total lipid present were determined gravimetrically (13). Lipids were separated into their major classes by thin-layer chromatography on silica gel G (Merck, Darmstadt, Germany) in a solvent system of hexane/diethyl ether/formic acid (80:20:1, by vol). Following transmethylation (14), the fatty acid compositions of the relevant lipid classes were determined by gas–liquid chromatography using a capillary column system (Carbowax, 30 m × 0.25 mm, film thickness 0.25μ; Alltech, Carnforth, United

Kingdom) in a CP9001 instrument (Chrompack, Middleburg, The Netherlands). The amounts and relative proportions of the fatty acids present were quantified using an EZ Chrom Chromatography Data System (Scientific Software Inc., San Jose, CA). The identities of the peaks were verified by comparison with the retention times of standard fatty acid methyl esters (Sigma Chemical Co.).

RESULTS

Relationship between yolk lipid transfer and adipose tissue development. The results in Figure 1 illustrate the relationship between the amount of total lipid transferred from the yolk complex and the accumulation of triacylglycerol in the adipose depot during development, using two groups of eggs which differed by 1.7-fold in their initial yolk lipid content. In both cases, a relatively small proportion (approximately 9%) of the initial amount of yolk lipid was utilized during the first 12 d of the 21-d embryonic period, and no detectable deposition of adipose triacylglycerol occurred during this time. By contrast, the rapid transfer of the lipid from the yolk from day 12 onward was accompanied by an intensive deposition of triacylglycerol in the adipose tissue which was maintained up to the time of hatching (Fig. 1, A and B). The amount of triacylglycerol that accumulated in the depot was consistently greater for the experiment using eggs with the larger initial level of yolk lipid. For example, by day 19, the triacylglycerol content of the depot and the amount of lipid transferred from the yolk were, respectively, 1.42- and 1.43-fold greater when development was supported by an initial yolk lipid content of 5.7 g as opposed to 3.4 g. For both groups of eggs, the level of adipose tissue triacylglycerol at each time point between days 12 and 19 inclusively was very highly correlated with the amount of lipid transferred from the yolk by that stage ($r = 0.99$, $y = 0.118x - 61.5$, and $r = 0.98$, $y = 0.119x - 46.7$, for the large and small egg experiments, respectively, where x represents mg lipid transferred from the yolk, and y indicates mg triacylglycerol/depot). The relative proportions of triacylglycerol and phospholipid in the yolk remained essentially constant, at approximately 72 and 20 (wt% of total lipid), respectively, throughout incubation.

Between days 19 and 22 (i.e., the period spanning the hatching process), the previously linear relationship between yolk lipid transfer and adipose tissue development completely disappeared. Whereas a considerable proportion (approximately 30%) of the total yolk lipid transfer occurred during this time, no further increase in the amount of adipose triacylglycerol was observed. For the experiment based on the higher initial yolk lipid content, the amount of triacylglycerol in the depot remained approximately constant over the hatching period. However, when development was based on the lower initial yolk lipid level, a significant ($P < 0.01$) decrease

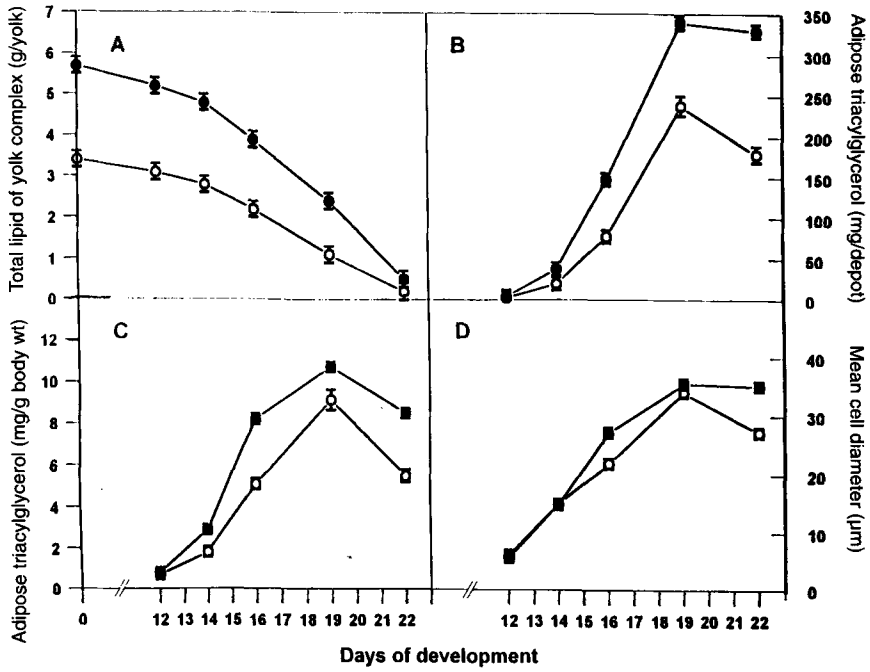

FIG. 1. Relationship between yolk lipid transfer and adipose tissue development. The amount of total lipid present in the yolk complex (A), the amount of adipose tissue triacylglycerol expressed as mg/depot (B) or mg/g body weight (C), and the mean adipocyte diameters (D) are shown during development using two groups of eggs which initially contained either 5.7 ± 0.1 (●) or 3.4 ± 0.1 (○) g total lipid per yolk (means ± SEM, measured on eight eggs from each batch). The results depicted in the figures are the means ± SEM of measurements on four replicate samples at each developmental stage. Day 22 is equivalent to one day after hatching.

of approximately 25% in the amount of adipose triacylglycerol occurred between days 19 and 22.

The size of the embryos and newly-hatched chicks were dependent on the initial egg size and yolk lipid content. For example, the fresh weight (g) of the hatchlings at day 22 were 39 ± 4 and 34 ± 2 (means ± SEM, measured on 4 chicks from each experimental group) for the experiments using the larger and smaller eggs, respectively. However, the lower levels of adipose triacylglycerol in the latter situation were not simply a reflection of the general reduction in embryonic growth since the differences were still apparent when expressed on a body weight basis (Fig. 1C)

Changes in adipocyte size during development. The frequency distributions of adipocyte diameters at different stages of development are depicted by the histograms in Figure 2, in which the values from the 4 replicate samples at each stage are combined. In general, the distributions of cell sizes were relatively symmetrical about the means, approximating to a Gaussian pattern. The changes in the distribution profiles during development were clearly indicative of a continuous increase in cell size within the adipocyte population taking place between days 12 and 19. The pattern of change was very similar irrespective of the initial yolk lipid content. The standard deviation of the sizes within the cell population also increased continuously during development (e.g., from SD = 2.1 μm at day 12 to SD = 8.0 μm at day 19, for the experiment depicted in Fig. 2A), thereby illustrating that adipose tissue growth was accompanied by a greater range of cell sizes. Between days 19 and 22 (i.e., over the hatching period), there was very little change in the adipocyte size profile in the experiment using eggs containing the larger initial amount of yolk lipid (Fig. 2A). In contrast, the experiment based on the lower initial yolk lipid content was characterized by a clear shift in the cell size profile to give a population exhibiting significantly smaller diameters (Fig. 2B).

The developmental changes in mean cell diameter are depicted in Figure 1D, showing the average values of the 4 replicate samples at each stage. The negligible differences between the replicate samples, as indicated by the very low SEM values, reflect the effectiveness of the randomized selection of cells for measurement, and justify combining the values obtained from the replicates to provide a population of sufficient size to produce the histograms shown in Figure 2. Prior to hatching, the mean cell diameters were very similar for the two experiments in spite of utilizing eggs of different initial yolk lipid contents, increasing in both cases from approximately 6 μm at day 12 to approximately 35 μm at day 19; a significant difference ($P < 0.001$) between the two experiments was only observed at day 16. However, whereas the mean adipocyte diameter remained relatively constant over the hatching period following development within the larger eggs, a significant ($P < 0.001$) decrease in cell size over this period, to approximately 27 μm by day 22, was observed following development within the smaller eggs.

Fatty acid composition of adipocyte lipids. Triacylglycerol comprised more than 97% (w/w) of the total lipid from the adipocytes at all stages. The fatty acid composition of adipocyte triacylglycerol for the experiment based on the lower initial yolk lipid content is shown in Table 1. Very similar results were obtained for the experiment based on the higher initial yolk lipid content (not shown). Relatively high proportions of DHA (>6%) were present in the adipocyte triacylglycerol at days 12 and 14, but this proportion decreased considerably by the later developmental stages, so that, in the one-day-old chick, DHA comprised less than 1% of the triacylglycerol fatty acids. The fatty acid composition of the triacylglycerol of the isolated adipocytes was essentially identical to that of the intact tissue at all developmental stages (data not shown). The phospholipid fraction, which at all stages comprised less than 2% (w/w) of the total lipid content of the isolated adipocytes, exhibited proportions of DHA which were very similar to the corresponding triacylglycerol values (Table 2). Thus, the level of DHA in adipocyte phospholipid was 6–7% at days 12 and 14, decreasing to less than 1% in the day-old chick.

Expression of the levels of the individual fatty acids in the triacylglycerol fraction of the intact adipose tissue in terms of mg/adipose depot indicated a unique pattern of change for the

[a]Wt% of total fatty acids. Only fatty acids comprising more than 0.5% are shown. Values are means ± SEM of four replicate adipocyte preparations at each stage, from the experiment based on the initial yolk lipid content of 3.4 g.

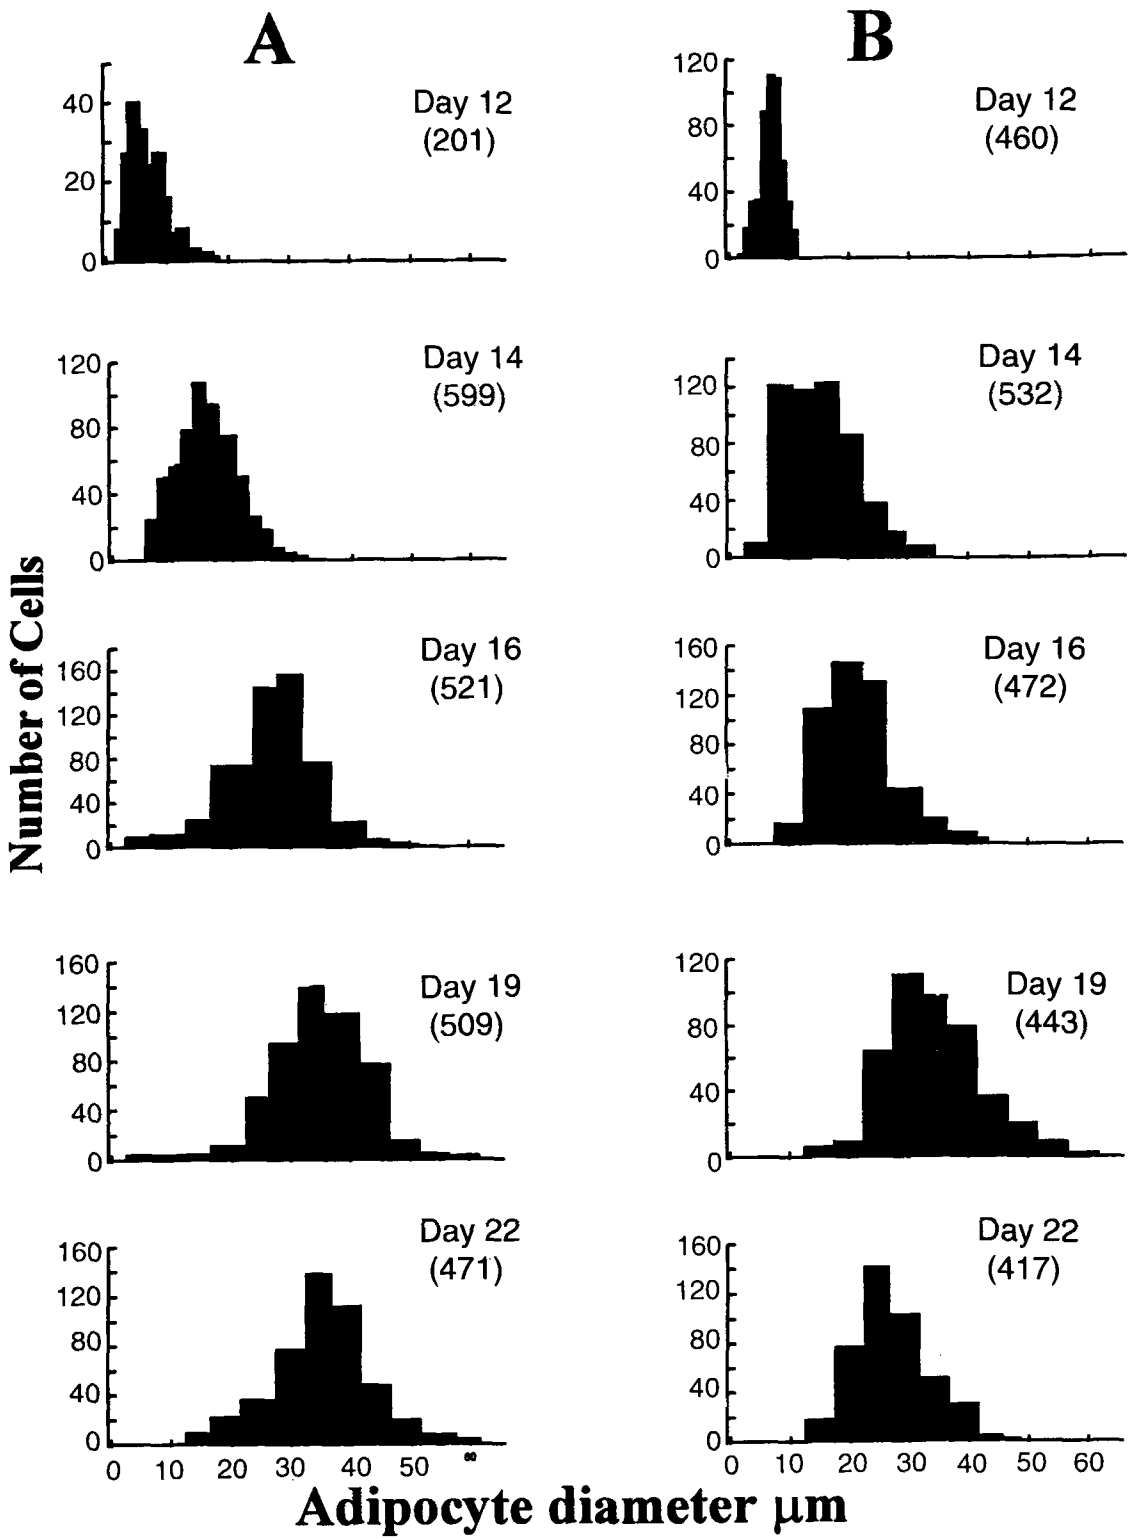

FIG. 2. Frequency distributions of adipocyte diameters during development. The histograms represent the frequency distributions of the adipocyte diameters (μm) in which the measurements from the four replicate samples at each stage are combined. Panels A and B refer to the experiments based on initial mean yolk lipid contents of 5.7 and 3.4 g, respectively. The numbers of cells examined are indicated in the parentheses.

amount of DHA in comparison with the profile for the other major fatty acids (Fig. 3). For example, the amounts of 18:1n-9 (Fig. 3A) and 16:0 (Fig. 3B) in the triacylglycerol fraction of the adipose depot increased continually from day 12 to 19 and thereafter either remained approximately constant (experiment using eggs initially containing 5.7 g yolk

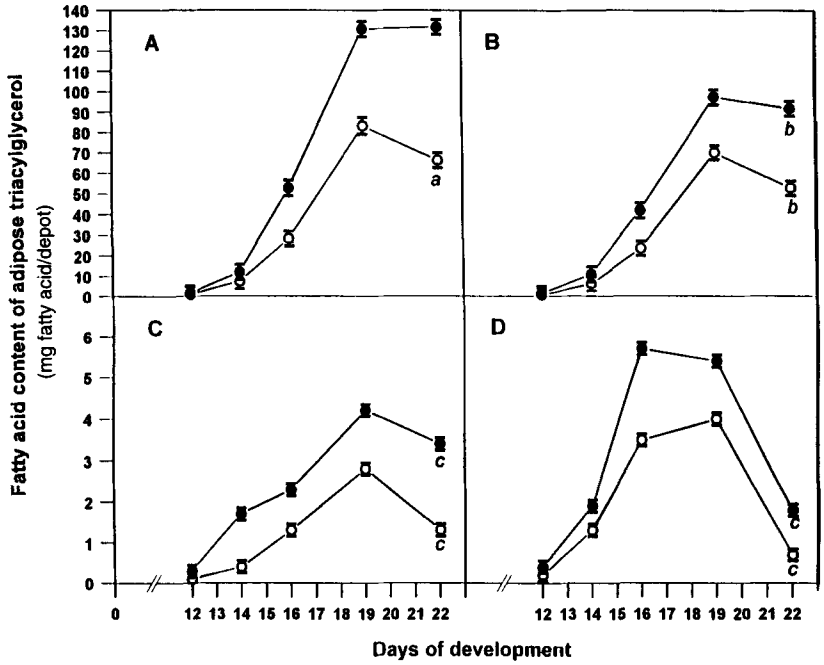

FIG. 3. Amounts (mg fatty acid/depot) of 18:1n-9 (panel A), 16:0 (panel B), 20:4n-6 (panel C), and 22:6n-3 (panel D) in adipose tissue triacylglycerol. The means ± SEM of the four replicate samples at each developmental stage are shown for the experiments based on initial mean yolk lipid contents of 5.7 (●) and 3.4 (○) g. Comparison between day 22 and day 19: $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$.

lipid) or decreased slightly (experiment using eggs initially containing 3.4 g yolk lipid) over the hatching period. In contrast, the amount of DHA (Fig. 3D) remained approximately constant between days 16 and 19, but then decreased dramatically over the hatching period. Thus, whereas the amount of 18:1n-9 between days 19 and 22 decreased by 0 and 20% in the two experiments, the corresponding decreases in the levels of DHA were 67 and 83%. Prior to day 19, the changes in the amount of arachidonic acid (Fig. 3C) followed a similar profile to that exhibited by 18:1n-9 and 16:0. However, over the hatching period, the amount of arachidonic acid also decreased by a greater extent (19 and 54% in the two experiments) than the changes observed for 18:1n-9 and 16:0. The amounts of 18:0, 18:2n-6, and 18:3 n-3 are not shown in Figure 4, but the pattern of change of these fatty acids followed very similar profiles to those exhibited by 18:1n-9 and 16:0.

Accumulation of DHA in the developing brain. The amount of DHA present as a component of the phospholipid fraction of the brain was determined at various stages of development in the experiments using the two batches of eggs which differed by 1.7-fold in their initial yolk lipid contents. In both experiments, the DHA content of the brain increased continuously during the period between day 12 of incubation and day 1 after hatching (Fig. 4); in both cases, the scale of the increase in brain DHA over this period was 5- to 6-fold. In spite of the difference in the initial amount of yolk lipid and the 1.4-fold difference in the initial yolk lipid DHA content between the two experiments (see the Materials and Methods section), the levels of DHA in brain phospholipid were very similar in the two cases. For example, at day 19 and day 22, there were no significant differences in brain DHA content between the two experiments.

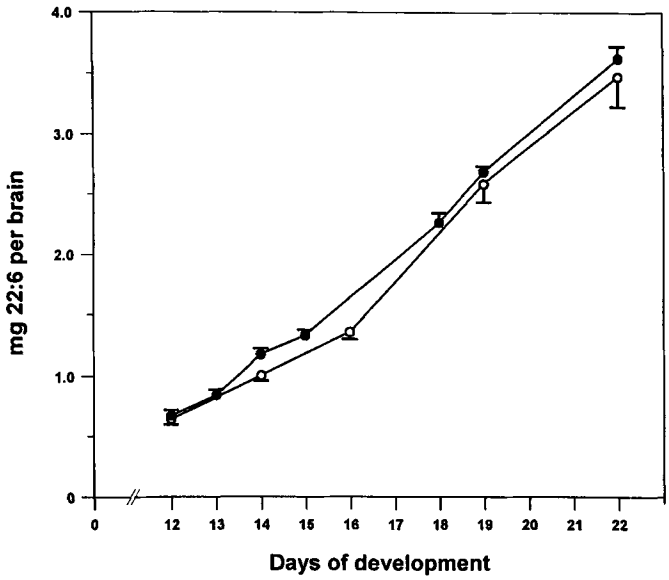

FIG. 4. Accumulation of docosahexaenoic acid (DHA) in brain phospholipid. The amounts of DHA present in the phospholipid of the embryonic brains (mg DHA/brain) during incubation of eggs with initial yolk lipid contents of 5.7 (●) and 3.4 (○) g. Results are the means ± SEM of four brains at each developmental stage.

DISCUSSION

Prior to about day 12 of the chicken's 21-d embryonic period, the rate of transfer of lipid from the yolk to the embryo is relatively low, and subcutaneous adipose tissue cannot be detected (Fig. 1). Thus it is likely that the lipid components which are transferred during this early phase of development are almost entirely utilized for energy purposes or incorporated into the cell membranes of the growing tissues. However, the period around day 12 marks a phase of major metabolic change in this system, characterized by a transition to a state of very intensive transfer of lipid from the yolk to the embryonic tissues (1). The development of subcutaneous adipose tissue is one consequence of this transition, and triacylglycerol accumulates in the tissue at a high rate from day 12 until hatching as indicated in Figure 1B; this is consistent with previous studies (3,6).

Inspection of the data presented in Figure 1 indicates that the amount of triacylglycerol deposited in the adipose tissue between days 12 and 19 is highly correlated with the amount of lipid transferred from the yolk. Furthermore, this linear relationship applies not only to the different stages of development within an experiment, but also to comparisons between batches of eggs containing different initial amounts of yolk lipid. Thus, development within larger eggs, supported by a greater initial amount of yolk lipid, results in the accumulation of increased levels of triacylglycerol in adipose tissue, whether expressed on the basis of mg triacylglycerol per depot or per g body weight (Fig. 1, B and C). Since neither the *de novo* synthesis of lipid from carbohydrate (7), nor the mobilization of lipid from the adipose stores (8), apparently occurs to any significant extent during the period between days 12 and 19, it is likely that the supply of lipid from the yolk in the form of plasma lipoproteins, and the capacity of the tissue to utilize this lipid source mediated by the expression of lipoprotein lipase activity (3) are the key determinants of the rate of adipose tissue growth, during this period. Thus, assuming the level of lipoprotein lipase activity is not limiting, it may be surmised that the growth of the adipose depot will be a function of the amount of lipid transferred from the yolk. The results of the present study (Fig. 1, A and B) are clearly consistent with such a view.

The hatching period marks another major metabolic transition (1) which, in the case of adipose tissue, is typified by a complete breakdown of the previously linear relationship between lipid transfer from the yolk and the accumulation of triacylglycerol in the tissue. Although the intensity of yolk lipid transfer is maintained over this time, with some 30% of the total transfer occurring between days 19 and 22, the growth of the tissue was found to cease completely during this period, and in the case of the experiment based on the lower initial yolk lipid level, the amount of adipose triacylglycerol significantly decreased (Fig. 1). These changes may reflect a combination of a reduced ability of the tissue to obtain lipid from plasma sources due to the reduction in adipose tissue lipoprotein lipase activity which occurs at this time (3), together with an increase in the sensitivity of the tissue to lipolytic hormones (8).

The chick embryo system provides an opportunity to study the characteristics of adipose development from the time of the initial formation of the tissue. A major feature of this process, as shown in Figures 1D and 2, is the marked increase in adipocyte size during the period of rapid lipid deposition. Thus, the mean cell diameter was found to increase from approximately 6 μm at day 12 to about 35 μm by day 19 (Fig. 1D). The adipocyte size frequencies shown in Figure 2 approximate to a Gaussian distribution about the mean value, with no indication of any bimodal distribution of cell sizes which have been associated with increased fat deposition in cattle and pigs (15). Although the use of eggs of different sizes revealed that the triacylglycerol content of the adipose tissue was highly dependent on the initial yolk lipid content (Fig. 1, A and B), the mean adipocyte diameter and cell size distribution from days 12 to 19 were not markedly affected by differences in the initial level of yolk lipid (Figs. 1B and 2). However, small differences in adipocyte diameter can reflect much larger differences in cellular lipid content since cell volume is proportional to the cube of the diameter. Also, the changes in adipocyte number during development were not measured in this study, and so the effects of the initial yolk lipid levels on adipose tissue hyperplasia remain to be evaluated. It should also be noted that the demarcation between adipocytes and preadipocytes is essentially one of methodology, i.e., defined by the accumulation of sufficient lipid within the cell to enable isolation by flotation. It is possible that in the period under study, characterized by the initial genesis and rapid development of the tissue, a significant proportion of tissue lipid may be present in preadipocytes at various stages of differentiation and therefore excluded from the cell size measurements. There is evidence that differential proliferation rates of preadipocytes are associated with differences in fatness between lines of chickens (16).

The triacylglycerol fraction of the isolated adipocytes contained relatively high proportions of DHA (approximately 6%) at days 12 and 14, but with significantly lower proportions at the later stages (Table 1); this is consistent with previous results obtained from analysis of the intact adipose tissue (3). In addition, the results in Table 2 indicate that the adipocyte phospholipids, although quantitatively a minor component and generally displaying a distinct fatty acid composition, contained proportions of DHA which were very similar to those of the corresponding triacylglycerol fraction. Thus the decrease in the proportion of DHA in the triacylglycerol fraction from day 14 onward was paralleled by similar changes in the composition of the adipocyte phospholipid. Previous studies from our laboratory have revealed that the transfer of DHA from the yolk lipids to the embryonic tissues displays a range of unique features not shown by the other major fatty acids. For example, DHA-containing phospholipid species are preferentially taken up from the yolk by the yolk sac membrane at around day 12 (1,12). Moreover, within the yolk sac membrane, DHA is apparently transferred from the yolk phospho-

lipid to triacylglycerol during the assembly of lipoprotein particles for release into the circulation (3,12). The high levels of lipoprotein lipase activity in the adipose tissue (3) of the chick embryo and the fact that lipoprotein triacylglycerol is the preferred substrate for this enzyme (17) are therefore consistent with the uptake of significant levels of DHA by the adipocytes during the period from days 12 to 14.

Expression of the levels of the different fatty acyl components of adipose triacylglycerol in terms of the amount (mg) of each fatty acid per intact depot (Fig. 3) reveals an additional unique feature relating to DHA transfer in the embryo. The amounts of the major C_{16} and C_{18} fatty acids in the tissue increased continuously from day 12 to day 19 and then remained relatively constant or decreased slightly over the hatching period, i.e., parallel to the changes in triacylglycerol content (Fig. 3, A and B). In contrast, the amount of DHA remained relatively constant in the tissue between days 16 and 19 and then decreased precipitously over the hatching period (Fig. 3D). The amount of arachidonic acid in the depot also decreased significantly during hatching, but to a lesser extent than observed for DHA (Fig. 3C).

A possible explanation for these results may be that DHA is preferentially mobilized from the tissue. This may apply not only to the hatching phase but also to the preceding period between days 16 and 19 where the relatively constant levels of DHA in the tissue could reflect a balance between uptake from plasma lipoproteins and mobilization from the adipose triacylglycerol. The existence of such a process would be of considerable relevance to the delineation of the route by which DHA supply is maintained to the brain and retina. The form in which DHA is delivered from the plasma to the developing neural tissues is not known but, as a result of studies on mammalian systems, a range of possibilities has been suggested including the nonesterified fatty acid (18,19), lysophospholipid (20), lipoprotein phospholipid secreted by the liver (21,22), and distinct plasma phospholipid species (23,24). The absence of lipoprotein lipase activity in the brain of the chick embryo (3) precludes the possibility of direct uptake into this tissue following the localized hydrolysis of lipoprotein triacylglycerol. However, the possibility that DHA may be preferentially mobilized from adipose tissue to release the free fatty acid form into the plasma would be consistent with the evidence of Dhopeshwarkar and Mead (18) and Anderson and Connor (19) that polyunsaturated fatty acids are delivered to the brain as the nonesterified form in the plasma.

The period encompassed by the development of subcutaneous adipose tissue in the embryo is also characterized by a marked accumulation of DHA in the phospholipid of the brain (Fig. 4). Although this observation is compatible with a role for adipose tissue in the supply of DHA to the brain, further studies are required to provide a direct test of this concept. It is, however, clear that the amounts of DHA mobilized from the adipose depot between days 19 and 22 are more than adequate to supply the demands of the brain for this fatty acid over the hatching period (Fig. 3D cf Fig. 4).

It is of interest that several studies on human development have implied a role for adipose tissue in the supply of DHA to the neural tissues. For example, it is recognized that maternal adipose stores are extensively mobilized during the second half of pregnancy, providing a supply of polyunsaturated fatty acids to the fetus (25). In addition, the results of Farquarson *et al.* (26) indicate that DHA is selectively depleted from the adipose tissue of the human infant during the first 20 wk of neonatal life. Further studies are needed to assess whether the evidence from the present investigation, suggesting that DHA is preferentially mobilized from the adipose tissue of the chick embryo, can provide insights into the mechanism by which polyunsaturated fatty acids are delivered to the neural tissues during mammalian development.

Application of 2-Hydroxypropyl-β-Cyclodextrin in the Assay of Acyl-CoA:Cholesterol Acyltransferase and Neutral and Acid Cholesterol Ester Hydrolases

Mariana Liza, José R. Romero, Yolanda Chico, Olatz Fresnedo, and Begoña Ochoa*

Department of Physiology, University of the Basque Country Medical School, E-48080-Bilbao, Spain

ABSTRACT: The utility of 2-hydroxypropyl-β-cyclodextrin for increasing the sensitivity of assays for the microsomal acyl-CoA:cholesterol acyltransferase, and the acid lysosomal and the neutral microsomal and cytosolic cholesterol ester hydrolase activity was studied in rat hepatocytes. Enzyme assays, at optimal concentrations of cyclodextrin, were validated by assessing: (i) linearity of product formation with incubation time and protein amount, and saturation with substrate, and (ii) the effect of treatments of cells or of subcellular fractions on enzyme activities. Delivery of cholesterol dissolved in 2-hydroxypropyl-β-cyclodextrin to the acyl-CoA:cholesterol acyltransferase assay mixture raised the enzyme activity more than 8-fold and was twice that measured when cholesterol was added in Triton WR-1339. 2-Hydroxypropyl-β-cyclodextrin itself was partially effective, apparently by making endogenous cholesterol more accesible to the enzyme. Inclusion of 2-hydroxypropyl-β-cyclodextrin in cholesterol ester hydrolase assays using standard micellar substrates doubled the activity estimated in lysosome and microsome preparations and enhanced the cytosolic cholesterol esterase activity by about 50%. Differences in the catalytic activity of acyl-CoA:cholesterol acyltransferase and cholesterol ester hydrolases caused by treatment of hepatocytes with compound 58-035 or 25-hydroxycholesterol, or of subcellular fractions with NaF, were maintained when enzymes were assayed with cyclodextrin. The results indicate that 2-hydroxypropyl-β-cyclodextrin is a suitable vehicle for delivering cholesterol to acyl-CoA:cholesterol acyltransferase and enhances the sensitivity of standard assays of the enzymes governing the intrahepatic hydrolysis of cholesteryl esters.

Lipids 31, 323–329 (1996).

The substituted glucopyranose ring structure, 2-hydroxypropyl-β-cyclodextrin (HPBCD), shows a remarkable ability to form aqueous-soluble inclusion complexes with a variety of hydrophobic drugs due to the lipophilic cavity of its seven glucopyranose units (1–3). In particular, HPBCD has been used to prepare stable aqueous solutions of cholesterol, bile acids, and other sterols for both cell culture and *in vivo* studies (4). This has been extended to its use in the assay of cholesterol 7α-hydroxylase and in the 7α-hydroxylation of 27-hydroxycholesterol in microsomal preparations from hamster liver and HepG2 cells (5), and in the synthesis of 27-hydroxycholesterol in rat liver mitochondria (6). The convenience offered by these methods prompted us to investigate the utility of HPBCD in the assay of the intracellular enzymes involved in maintaining the balance of cholesterol between its free and esterified forms within the liver.

The esterification of cholesterol is catalyzed by the enzyme acyl-CoA:cholesterol acyltransferase (ACAT), which is a membrane-bound enzyme localized in the RNA-rich endoplasmic reticulum of the cell (7,8). Standard methods for the radioactive assay of ACAT are based on the incorporation of [1-^{14}C]oleoyl CoA into cholesteryl esters using as substrate the microsomal endogenous cholesterol, which is suboptimal, or a saturating cholesterol concentration. In the latter case, cholesterol is added normally in liposomes (8) or as an aqueous dispersion in Triton WR-1339 (Sigma, St. Louis, MO) (9). The hydrolysis of cholesteryl esters is brought about by the catalytic action of at least three cholesterol ester hydrolases (CEH). The acid lysosomal CEH (lCEH) breaks down cholesteryl esters derived from lipoproteins internalized into cells by receptor-mediated endocytosis, whereas the two neutral forms of CEH activity in microsomes (mCEH) and cytosol (cCEH) catalyze the release of free cholesterol from stores of cholesteryl esters present in cytoplasmic lipid droplets. CEH are commonly measured in terms of the release of labelled oleic acid from a cholesterol [1-^{14}C]oleate micellar preparation, which gives estimates of activity higher than when cholesteryl oleate is suspended in ethanol or acetone. The micellar preparation described by Brecher *et al.* (10) is the most frequently used in the CEH assay and that reported by Hajjar *et al.* (11) in the two neutral CEH assays. Evidence has been obtained in the present work indicating the usefulness of HPBCD for assaying the activity of the microsomal acyl-CoA:cholesterol acyltransferase, with or without added cholesterol as substrate, and for enhancing the sensitivity of standard assays of the acid and the two neutral CEH in subcellular preparations of rat hepatocyte suspensions.

MATERIALS AND METHODS

Chemicals. Cholesteryl [1-^{14}C]oleate (59.5 mCi/mmol), [1-^{14}C]oleic acid (57 mCi/mmol), and [1-^{14}C]oleoyl CoA (56 mCi/mmol) were from The Radiochemical Centre (Amersham, United Kingdom). Cholesteryl [^{3}H]oleate (47 Ci/mmol) was from Du Pont New England Nuclear (Boston, MA). Bovine serum albumin (essentially fatty acid-free), HPBCD, Triton WR-1339, egg lecithin, sodium taurocholate, cholesterol, cholesteryl oleate, 25-hydroxycholesterol, oleic acid, and oleoyl CoA were obtained from Sigma.

Isolation of hepatocytes and sampling for enzyme activities. Female Sprague-Dawley rats (180–200 g), housed in temperature- and light-controlled rooms and maintained on a standard diet *ad libitum* with free access to water, were used for the experiments. Hepatocytes, isolated by collagenase digestion as previously described (12), were suspended in Krebs-Henseleit solution, pH 7.4, containing 2.5 mM $CaCl_2$, 10 mM glucose, and 2.5% bovine serum albumin, to give a cell density of 6–7 $\times$ 10^6 cells/mL. Hepatocytes were maintained in suspension by horizontal shaking, incubated for 30 min prior to addition of the desired compound, and continuously gassed with O_2 /CO_2 (19:1). At the end of the incubation, cells were pelleted and washed twice in ice-cold 20 mM Tris-HCl buffer, pH 7.4, containing 250 mM sucrose, and then centrifuged. The cell pellets were homogenized in 4 vol of the above buffer containing 2 mM EDTA, 10 μM leupeptin, 1 mM benzamidine, and 0.5 mM dithiothreitol, and submitted to differential centrifugation as in Refs. 13 and 14. The lysosome-enriched fraction was resuspended in 250 mM sucrose solution at a protein concentration of 1 mg/mL and microsomes in 20 mM Tris-HCl buffer pH 7.4 containing 250 mM sucrose at a protein concentration of 5 mg/mL. Frozen preparations retained full enzyme activity for at least two weeks.

Assay of ACAT. After the studies that revealed the usefulness of HPBCD, the standard assay mixture contained, in a final volume of 250 μL, 200 μg protein, 80 μM of fatty acid-free bovine serum albumin, 2 mM glutathione, 250 μM cholesterol, 6 mM HPBCD, and 120 μM [1-^{14}C]oleoyl CoA (1000 dpm/nmol) in 100 mM potassium phosphate buffer, pH 7.4. Cholesterol was added as a solution in 10 μL of 45% HPBCD in water, which was prepared as described by De Caprio *et al.* (4). All components except oleoyl CoA were preincubated for 10 min; the reaction was initiated by the addition of oleoyl CoA and was run for 3 min. Enzyme blanks were run in parallel. The reaction was stopped with 5 mL chloroform/methanol (2:1, vol/vol) and cholesterol [^{3}H]oleate (30,000 dpm) was added to each tube to assess recovery. After separation into two layers by the addition of 1.25 mL of 0.88% (wt/vol) KCl, the chloroform layer was removed and dried. The lipids were separated by thin-layer chromatography using *n*-heptane/diisopropyl ether/acetic acid (70:30:2, by vol). Radioactive bands corresponding to cholesteryl oleate were delimited (Multitracemaster analyzer; Berthold, Wildbad, Germany), scraped into vials, and counted for radioactivity by liquid scintillation spectrometry. ACAT activity was expressed as pmol cholesterol esterified per min (1 unit) per mg of protein at 37°C.

Assay of lysosomal, microsomal, and cytosolic CEH activity. CEH activity was determined in terms of release of labelled oleic acid from a cholesteryl [1-^{14}C]oleate micellar substrate. The optimal assay conditions were as follows. For the acid CEH assay, the reaction mixture contained in a final volume of 200 μL, 15 μg of protein, 250 μM of cholesteryl [1-^{14}C]oleate (7000 dpm/nmol), and 15 mM HPBCD in 10 mM acetic acid/Na acetate buffer, pH 4.6. Substrate was prepared basically according to Brecher *et al.* (10) with double concentrations of cholesteryl oleate and lecithin. All components except cholesteryl oleate were preincubated for 10 min; the reaction was initiated by the addition of cholesteryl [1-^{14}C]oleate and was run for 4 min. For the CEH assay, the reaction mixture contained in a final volume of 200 μL, 100 μg of protein, 15 mM HPBCD, 100 μM of cholesteryl [1-^{14}C]oleate (7000 dpm/nmol) incorporated in mixed micelles of egg lecithin and sodium taurocholate (11), and 100 mM imidazole-HCl buffer, pH 6.8. All components except the substrate were preincubated for 10 min; the reaction was initiated by the addition of cholesteryl [1-^{14}C]oleate and was run for 45 min. CEH activity in the cytosol was measured as described for the microsomal form of CEH except that 200 μg of protein, 250 μM of cholesteryl [1-^{14}C]oleate, and 5 mM HPBCD in a final volume of 300 μL solution containing 100 mM imidazole-HCl buffer, pH 6.8, were used, and that the reaction was run for 30 min. In all CEH assays, protein blanks were run in parellel. The released oleic acid was separated from the nonhydrolyzed cholesteryl oleate by adding 5 mL of *n*-heptane/chloroform/methanol/oleic acid (1:1.25:1.4:10^{-4}, by vol) and 1 mL of 50 mM NaOH, H_3BO_3, Na_2CO_3 buffer, pH 11.5. The mixture was shaken and centrifuged to separate the organic layer and the aqueous phase. Aliquots of 1.5 mL of the upper phase were counted for radioactivity. The average efficiency (87%) of extraction of released oleic acid was estimated by running assays using micelles prepared in the same way as the substrate, except that [1-^{14}C]oleic acid was used instead of cholesteryl [1-^{14}C]oleate. The specific activities of all CEH are expressed as units corresponding to hydrolysis of one pmol cholesteryl oleate minute mg protein at 37°C.

Chemical and statistical analysis. Proteins were measured by the dye-binding technique of Bradford (15) using bovine serum albumin as standard. The cholesterol content of microsomal preparations was quantified by high-performance liquid chromatography as described earlier (16), after an exhaustive extraction of the lipids, essentially by the method of Folch *et al.* (17). Statistical significance of results was assessed by the unpaired Student's *t*-test.

RESULTS

The potential utility of HPBCD was first investigated using microsomal, lysosomal, and cytosolic preparations of rat liver cells assayed for ACAT and acid and neutral CEH activities

under the conditions reported to be the optimal in References 9, 10, and 14, respectively. To address this, increasing amounts of HPBCD, as a 45% HPBCD solution (wt/vol) in water (4), were added to enzyme assay mixtures. Cholesteryl oleate exhibited a very low solubility in HPBCD. Following the method referenced above to prepare sterol inclusion complexes, we found that the maximum solubility for cholesteryl oleate at 20°C was 0.9 nmol/mL of a 45% HPBCD solution. A standard CEH assay requires between 20 and 50 nmol cholesteryl oleate for saturation, concentration that one could never reach using the HPBCD solution for presenting cholesteryl oleate to esterases. In the assay of ACAT with added cholesterol, increasing amounts of HPBCD were used to dissolve cholesterol, instead of the detergent Triton WR-1339 (600 μg, as in Ref. 9). Figure 1 shows a similar trend in the effects of HPBCD on ACAT activity whether assayed with endogenous cholesterol, referred to as basal ACAT, or with added exogenous cholesterol. The maximum increases in the cholesterol esterifying activity were seen with 6 or 12 mM cyclodextrin. Activity declined progressively at higher concentrations, so that at 48 mM the activities of both basal ACAT and ACAT dropped below those found in the absence of the solubilizer. However, the magnitude of the effects differ in that basal ACAT activity was increased 3–4-fold by the addition of HPBCD, whereas ACAT activity was doubled by substituting HPBCD for Triton WR-1339 to dissolve cholesterol. A moderate maximum of CEH activity was found with 5 mM HPBCD, and activity diminished progressively above this concentration. As the concentration of HPBCD increased, there was a concomitant increase in the estimated rate of cholesteryl oleate hydrolysis by the lCEH and mCEH, their specific activities being almost tripled by 15–60 mM HPBCD. In the experiments depicted in Figure 1, the reactions were started by adding the substrate after preincubating the enzyme source with HPBCD at 37°C for 10 min, the earliest time point tested. Though not shown, we found that longer preincubation periods resulted in either no further rises or even moderate decreases in activity, i.e., preincubation of microsomes with 250 μM cholesterol in 6 mM HPBCD for 30 min yielded an ACAT activity (2506 ± 127 units/mg protein) lower than that with a 10-min preincubation (3193 ± 30 units/mg protein). In subsequent experiments, HPBCD was included in the assay mixture of ACAT, cCEH, lCEH, and mCEH at 6 mM (10 μL), 5 mM (5 μL), 15 mM (10 μL), and 15 mM (10 μL), respectively, by adding the volume given in parentheses as a 45% HPBCD solution in water.

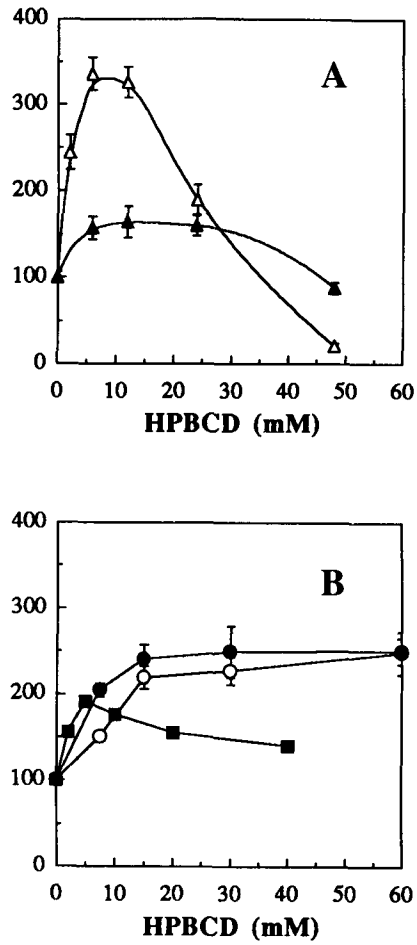

FIG. 1. Effect of increasing concentrations of 2-hydroxypropyl-β-cyclodextrin (HPBCD) on acyl-CoA:cholesterol acyltransferase (ACAT) and the lysosomal, microsomal, and cytosolic cholesterol ester hydrolase (CEH) activity. The activities of (A): ACAT (% of control), with the microsome endogenous cholesterol (27 ± 3 mM) (△) or added 250 μM cholesterol (▲) as substrate, and (B) the lysosomal (○), microsomal (●), and cytosolic (■) CEH (% of control) were measured as described in the Results section in the presence of increasing concentrations of HPBCD. Data are expressed as the percentage of the activity measured without HPBCD that averaged: basal ACAT, 601 ± 49; ACAT, 2031 ± 201; lysosomal CEH: 5813 ± 298; microsomal CEH: 52.5 ± 5.1; and cytosolic CEH: 48.9 ± 6.0 units/mg protein. Values are mean ± SE for three separate experiments. Vertical bars not shown lie within symbols.

The kinetic properties of the enzymes under study were analyzed in the presence or absence of HPBCD. Figure 2 shows the dependence of ACAT activity with the incubation time, protein amount, and exogenous cholesterol. The maximal rate of synthesis of cholesteryl esters was reached by the addition of 6 mM HPBCD preloaded with 250 μM cholesterol, resulting in a neat saturation curve. The rate was about twice that achieved when 250 μM cholesterol was delivered in 600 μg Triton WR-1339 as in Reference 9. The assays contained 120 μM oleoyl CoA and 80 μM bovine serum albumin, which were found to saturate the reaction (data not shown). Under these conditions, the formation of cholesteryl esters was linear with time up to 5 min and with added protein up to 1.2 mg/mL, and the estimated ACAT activity was routinely increased 2-fold by adding cholesterol in HPBCD. Greater percentual increases were found when endogenous cholesterol was esterified. Thus, HPBCD enhanced basal ACAT 3–4-fold. Comparison of the data in Figure 2 indicates that the progress of cholesterol esterification with time and protein amount in microsomes to which only HPBCD was added is close to that observed in microsomes to which cholesterol in Triton WR-1339 had been added.

Figure 3 depicts the dependence of the acid lysosomal, neutral microsomal, and neutral cytosolic CEH activities on

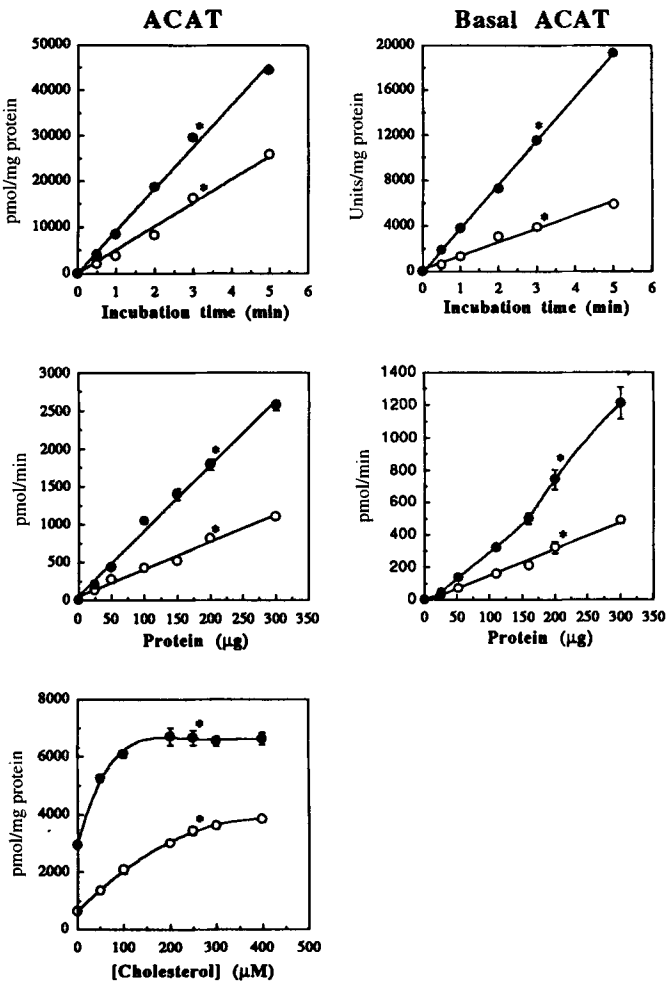

FIG. 2. Dependence of ACAT activity with the incubation time, protein amount, and exogenous cholesterol in the presence or absence of HPBCD. Basal ACAT activity was measured in microsomal preparations with increasing incubation time and protein amount using as substrate endogenous cholesterol (29 ± 4 μM) as described in the Results section in the presence (closed symbols) or absence of 6 mM HPBCD (open symbols). To estimate ACAT under saturation conditions, 250 μM cholesterol was added in 600 μg Triton WR-1339 (Sigma, St. Louis, MO) (open symbols) or 6 mM HPBCD (closed symbols), and these concentrations of Triton WR-1339 and HPBCD were kept constant when ACAT was assayed in the presence of increasing amounts of cholesterol. Values are mean ± SE for three separate experiments. Vertical bars not shown lie within symbols. Asterisks indicate the values used in those experiments where the effect of other variable was tested. Abbreviations as in Figure 1.

incubation time, protein amount, and substrate concentration. Measurements were done with the parameters indicated by asterisks using the micellar substrate described by Brecher *et al.* (10) for the acid and by Hajjar *et al.* (11) for the neutral CEH activities. Addition of optimal concentrations of HPBCD to enzyme assays doubled the lCEH and mCEH activities and enhanced the estimated cCEH activity by about 50%. The reaction rates of the three enzymes showed saturation and were linear with the incubation time and proportional to the protein in the assay. This generalized enhancement of sensitivity enabled us to optimize new conditions for measuring cholesterol esterase activity. They are detailed under the Materials and Methods section, in addition to those to measure ACAT activity. Yet, amounts of enzyme protein much lower than indicated may be used in those studies in which a small amount of enzyme is available.

Preliminary data suggested that HPBCD may also enhance the sensitivity of assays for the mCEH and the lCEH, though not for the cCEH, when cholesteryl oleate is presented as an ethanol solution. We used the optimal assay conditions for the micellar assays, including the corresponding micellar lipids, with the exception that cholesteryl oleate was added in 10 μL ethanol. The presence of 15 mM HPBCD in the assay increased the lCEH activity from 2741 ± 138 to 3403 ± 160 and the mCEH activity from 34.0 ± 3.5 to 65.6 ± 6.8 units/mg/protein (mean ± SE for three experiments). However, 5 mM HPBCD decreased drastically the cCEH activity: from 45.0 ± 3.2 to 16.8 ± 4.8 units/mg protein (mean ± SE for three experiments). The marked ability of cyclodextrin to form inclusion complexes with bile salts (4) may lead to a decreased availability of functional bile salts, which are required to estimate optimally the neutral CEH activity in the cytosol (18). Thus, the addition of HPBCD to a cCEH assay containing bile salts in a nonmicellar form seems unsuitable. Nevertheless, it must be noted that concentrations of HPBCD and assay conditions other than those used here may be required to estimate maximally the acid and neutral CEH activities when cholesteryl oleate is dissolved in ethanol.

As part of the validation of our assays using HPBCD, we evaluated the effect of treatments of cells or subcellular fractions on ACAT and CEH activities. For this purpose, hepatocyte suspensions were treated with compound 58-035 or 25-hydroxycholesterol, which are known to inhibit (19) and to activate (20) ACAT, respectively. As shown in Table 1, 58-035 produced a drastic, dose-dependent inhibition of cholesterol esterification; thus, 0.1 mg/mL 58-035 decreased ACAT activity to 9% and 1 mg/mL to 2.5% of that found in control cells. Differences in catalytic activity persisted when measured in the absence of HPBCD. The synthesis of cholesteryl esters in microsomes from cells exposed to 25-hydroxycholesterol was higher than that in control cells. When ACAT activity was assayed under saturation conditions, the extent of increase was around 36% with both methods. However, the increase in basal ACAT caused by 25-hydroxycholesterol was higher with the HPBCD method (from 39 to 65%). Control cells and cells exposed to 58-035 or 25-hydroxycholesterol exhibited rather constant acid and neutral cholesterol esterase activities regardless of the method used. Further analysis of the potential interaction of HPBCD with enzyme reactions was done with cell-free extracts assayed for enzyme activities in the presence of NaF, a nonspecific inhibitor of esterase activity (Table 2). With HPBCD in the assay, the marked fall in the rate of the three hydrolytic processes was slightly accentuated over that measured in the absence of the solubilizer. With both assay methods, NaF was found to elevate ACAT activity with saturating cholesterol by about 22%, but this was not the case when cholesterol was not added.

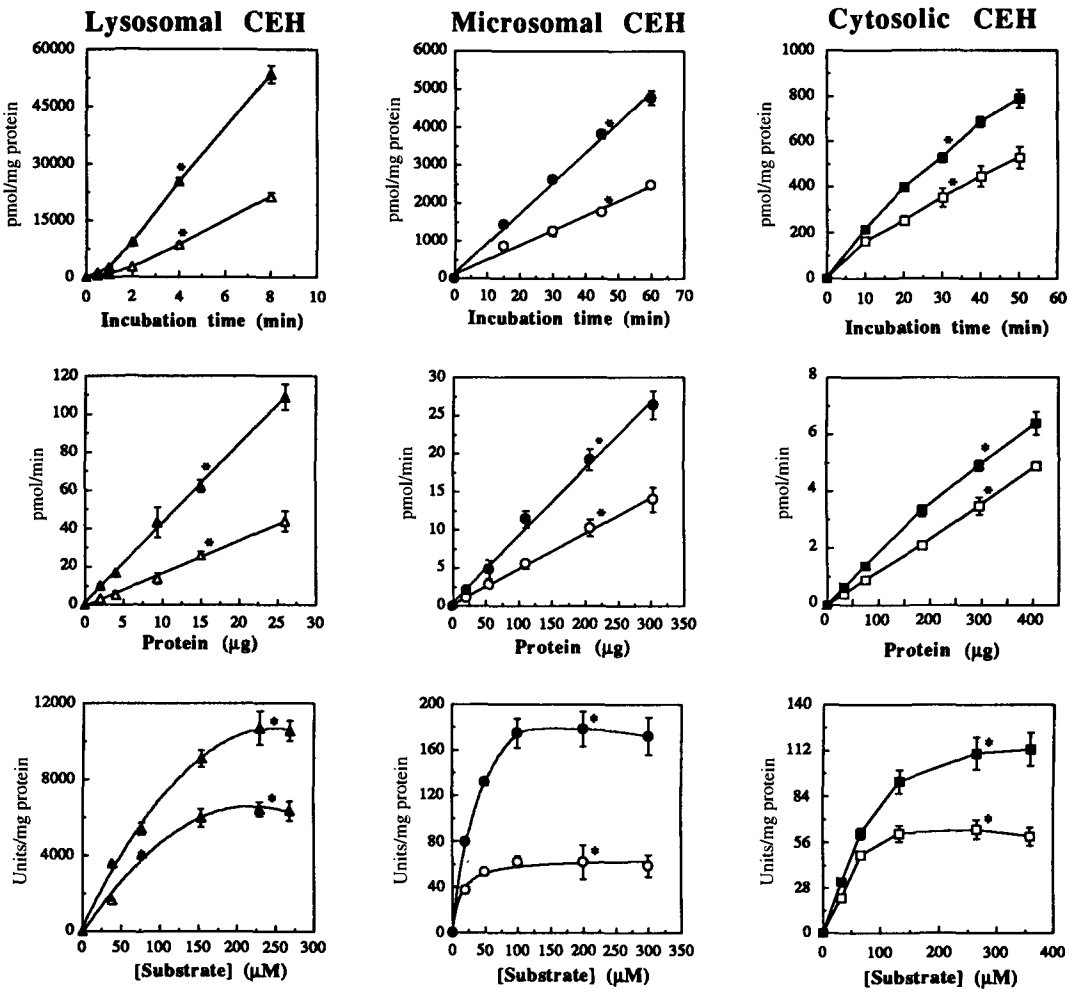

FIG. 3. Effect of HPBCD on the dependence with the incubation time, protein amount, and substrate concentration of the lysosomal, microsomal, and cytosolic CEH activity. CEH activity was measured in lysosomal (▲), microsomal (●), and cytosolic (■) preparations with increasing time of incubation, protein amount, and substrate concentration as described in the Results section with (closed symbols) and without (open symbols) 15, 15, and 5 mM HPBCD, respectively. Values are mean ± SE for three separate experiments. Vertical bars not shown lie within symbols. Asterisks indicate the values used in those experiments where the effect of other variable was tested. Abbreviations as in Figure 1.

TABLE 1
Effect of Treatment of Hepatocyte Suspensions with Compound 58-035 or 25-Hydroxycholesterol on ACAT and the Lysosomal, Microsomal, and Cytosolic CEH Activity[a]

Enzyme (units/mg)	HPBCD	Control (DMSO)	58-035 (1090 μg/mL)	58-035 (1 mg/mL)	Control (ethanol)	25-OH-cholesterol (50 μg/mL)
Basal ACAT	6 mM	2940 ± 104	235 ± 14[c]	69 ± 5[c]	3712 ± 194	6125 ± 186[c]
	—	635 ± 53	59 ± 10[c]	17 ± 4[c]	717 ± 91	997 ± 54[b]
ACAT	6 mM	4590 ± 265	477 ± 25[c]	121 ± 9[c]	6005 ± 245	8174 ± 324[c]

cCEH	5 mM	118.9 ± 6.3	123.0 ± 9.4	128.4 ± 10.3	91.2 ± 6.5	90.6 ± 7.2
	—	78.3 ± 7.9	77.9 ± 5.6	80.2 ± 8.0	62.8 ± 8.6	61.4 ± 5.1

[a]Liver cells were incubated for 2 h with 0.1 or 1 mg/mL 58-035 added in 10 μL dimethylsulfoxide (DMSO) or 50 μg/mL 25-hydroxycholesterol added in 10 μL ethanol. Controls were incubated with the same volume of the corresponding solvent alone. Cells were homogenized and submitted to subcellular fractionation, and acyl-CoA:cholesterol acyltransferase (ACAT) and cholesterol ester hydrolase (CEH) activities were determined as described in the Materials and Methods section in the presence or absence of 2-hydroxypropyl-β-cyclodextrin (HPBCD). lCEH, lysosomal CEH; mCEH, microsomal CEH; cCEH, cytosolic CEH; 25-Hydroxycholesterol (Sigma, St. Louis, MO); Compound 58-035, Dr. J. Heider (Bando Z. Research Institute, Basel, Switzerland). Comparison between control and treated cells: $^{b}P \leq 0.05$; $^{c}P \leq 0.001$.

TABLE 2
Effect of the Presence of NaF in the Assay Mixture on the Activity of ACAT and the Lysosomal, Microsomal, and Cytosolic CEH[a]

Enzyme (units/mg protein)	HPBCD	Control	50 mM NaF
Basal ACAT	6 mM	3764 ± 236	3499 ± 210
	—	848 ± 65	864 ± 53
ACAT	6 mM	4892 ± 257	5937 ± 298[b]
	—	2220 ± 163	2719 ± 132[b]
lCEH	15 mM	11941 ± 934	1337 ± 108[b]
	—	4155 ± 335	947 ± 79[c]
mCEH	15 mM	197.9 ± 12.9	48.5 ± 7.0[c]
	—	82.4 ± 10.1	28.7 ± 4.6[c]
cCEH	5 mM	88.6 ± 7.3	13.7 ± 1.5[c]
	—	61.7 ± 6.8	14.5 ± 1.8[c]

[a]Control untreated hepatocytes were homogenized and submitted to cell fractionation, and acyl-CoA:cholesterol acyltransferase (ACAT) and cholesterol ester hydrolase (CEH) activities were determined as described in the Materials and Methods section in the presence or absence of 2-hydroxypropyl-β-cyclodestrin (HPBCD); 50 mM NaF was added to assays in 50 μL of the corresponding buffer. Data represent mean ± SE for four experiments done in duplicate. Comparison between control and treated cells: [b]$P \leq 0.05$; [c]$P \leq 0.001$.

DISCUSSION

Endogenous cholesterol is known to be insufficient to saturate ACAT (7–9,20) so that, under nonsaturating conditions, the measurement of activity is substrate limited. When HPBCD is used, all hydrophobic compounds experience a substantial shift into the aqueous phase because of complexation of the molecules with HPBCD (3). Therefore, the fact that the inclusion of cyclodextrin alone in the assay raises ACAT activity about 4-fold suggests that it increases the availability or solubility of cholesterol to the enzyme. Preloading the solubilizer with cholesterol further augmented the rate of cholesterol esterification, to a maximum twice that elicited when ACAT was assayed with cholesterol dissolved in Triton WR-1339. Previous studies indicated that, unlike other vehicles, including detergents, sterols remain in solution within the cavity of the cyclodextrin after subsequent dilutions in aqueous medium (4). It is therefore likely that the aqueous-soluble inclusion complex of cholesterol with HPBCD ensures a more efficient and complete supply of substrate to the site where the enzyme reaction takes place. It has been suggested that regulation of ACAT activity by free cholesterol is due not only to changes in substrate availability, but also to nonsubstrate modulation of enzyme activity (8,21). This is supported by our observation that similar ACAT activities were measured in microsomes with 250 μM cholesterol added in Triton WR-1339 and in microsomes with an HPBCD-enhanced availability of the endogenous substrate, in which cholesterol could reach no more than 22 ± 3 μM, assuming that 80% microsomal free cholesterol is solubilized within 10 min as reported in Reference 5. A part of the activating effect of cyclodextrin might be related to its amphiphilic properties (2). Thus, HPBCD may act as spacer molecules, facilitating the intramembrane movement of cholesterol to the active site of ACAT, or perhaps mimicking an endogenous cholesterol transport system. By this mechanism, high concentrations of HPBCD (i.e., 48 mM) could disturb the endoplasmic reticulum membranes as well as selectively inhibit the activity of the enzymes asymmetrically inserted therein. This is supported by our finding that the enzyme ACAT, whose active site faces the cytoplasm (7), is nearly inactivated by 48 mM HPBCD whereas CEH activity, which resides on the luminal side of the endoplasmic reticulum (22), is not affected. As we found for ACAT, 6 mM HPBCD was also found to be the optimal concentration for assaying the 7α-hydroxylation of cholesterol and 27-hydroxycholesterol in microsomal preparations from hamster liver and HepG2 cells (5). Inasmuch as the enhancement of ACAT activity with endogenous cholesterol by extracellular 25-hydroxycholesterol is higher when the enzyme activity is measured with HPBCD, the availability of the second substrate, 25-hydroxycholesterol (20), for esterification in microsomes also may be increased.

There is considerable evidence that the activities of various CEH are markedly affected by the manner in which the substrate is presented to the enzyme. Cholesteryl esters are insoluble in aqueous media, and the substrate is usually presented either as a solution in ethanol or acetone or suspended in a mixed micelle with bile salts and phospholipids. In consequence, cholesterol esterases act at a lipid–water interface. We use in this work the micellar substrates reported in References 10 and 11 because of the inability of HPBCD to form inclusion complexes with cholesteryl oleate at the concentrations required to saturate CEH assays, and we report here that HPBCD, at optimum concentrations, increases the sensitivity of lysosomal, microsomal, and cytosolic CEH assays. The interpretation of the mode of action of HPBCD is based on the fact that CEH activity is modulated by both qualitative and quantitative changes in the accessibility of the substrate. It is likely that HPBCD activates CEH indirectly, affecting the interfacial quality of the substrate so that the efficiency with which cholesteryl oleate is presented to the enzyme is enhanced. This is supported by the finding that HPBCD increases CEH activity regardless of the mode of presentation of the substrate. In addition, HPBCD may contact the micelle and facilitate the substrate shift from the core toward the surface as well as its interaction with the enzyme. On the other hand, the different degrees and trends of activation caused by HPBCD on the three esterases may be attributable to their different subcellular location. Compared to the soluble enzyme, greater increases of activity were observed in particulate enzymes that reside within the organelle lysosome or on the luminal side of the rough endoplasmic reticulum (22). In both cases the micellar substrate must overcome a physical barrier to reach the enzyme. As mentioned above, the lipophilic properties of HPBCD would lead to its partitioning in cellular membranes, which might facilitate the penetration of the bilayer by cholesteryl oleate. A partial sequestration of micellar bile salts by HPBCD might also be related to the low increase of sensitivity found for the cytosolic CEH assay.

In conclusion, the cyclic oligosaccharide HPBCD at a certain concentration may be used to potentiate substantially the estimation sensitivity of ACAT and the acid and neutral CEH activity. Our assays are useful for testing effects of treatments of cells or of subcellular fractions on the enzymes governing the cholesteryl ester cycle within the hepatocyte.

ABSTRACT: Positional isomers (1-butyryl-2*X*-3*Y*-*rac*-glycerol and 2-butyryl-1*X*-3*Y*-*rac*-glycerol; *X,Y* = long-chain acyls) of saturated triacylglycerols (TAG) with 34 and 40 acyl carbons were shown to separate in two chromatographic peaks on immobilized phenyl(65%)methylsilicone column by gas–liquid chromatography, and on reversed-phase ODS-1 column by high-performance liquid chromatography. The analysis of 500-MHz ^{1}H nuclear magnetic resonance (NMR) spectra showed distinct differences between 2-butyryl-1*X*-3*Y*-*rac*-glycerol and 1-butyryl-2*X*-3*Y*-*rac*-glycerol isomers in the resonance signals of methylene and methine protons of glycerol backbone, and carbon-2 methylene of acyl groups, and methyl protons of butyryl group. The ^{1}H NMR spectra of three interesterified mixtures of three monoacid TAG containing saturated butyrate and caproate TAG and unsaturated butyrate TAG showed that triplets of methyl protons of butyryl groups at *sn*-1(3)- and *sn*-2-positions in saturated and unsaturated TAG had similar chemical shifts and that the chemical shift of caproyl methyl protons was different from those of butyryl methyl protons. The positional distribution of butyryl groups in isolated positional isomers of butyrate TAG, interesterified TAG mixtures, and natural and interesterified butteroil can be determined by integration of these signals.

Lipids 31, 331–336 (1996).

The determination of positional distribution of acyl groups between *sn*-1(3) and *sn*-2 positions in the molecular species of triacylglycerols (TAG) or TAG mixtures can be carried out by pancreatic lipase deacylation (1), by Grignard degradation with allyl magnesium bromide (2), and by mass spectrometric methods (3). Low-resolution ^{1}H nuclear magnetic resonance (NMR) spectra with lanthanide chemical shift reagents have been shown to differentiate the positional isomers of dipalmitoyloleoylglycerol (4) and those of unusual monoisovaleroyldipalmitoylglycerol and di-isovaleroylpalmitoylglycerol (5). ^{1}H NMR spectra at 220 MHz with chiral chemical shift reagents have been used to show the absolute configuration of a monobutyryl TAG fraction of hydrogenated butterfat to be 1,2-diacyl-3-butyryl-*sn*-glycerol (6). Differences in the chemical shifts of carbon-2 (7), olefinic carbon (8), carbonyl carbon (9), and n-3 carbons of saturated TAG isomers (10) in the ^{13}C NMR spectra have been used to deduce the position of acyl groups. The acyl distribution and acyl positional distribution in vegetable oils have been examined by quantitative high-resolution ^{13}C NMR (11). Recently, ^{1}H-^{13}C correlated NMR spectroscopy has been used to assist quantitative one-dimensional ^{1}H and ^{13}C evaluation of positional isomers of an interesterified TAG mixture (12). Our aim was to study the possibility to determine the distribution of short-chain acyl groups between primary and secondary positions in TAG of natural fats by high-resolution gas–liquid chromatography (GLC) and high-resolution ^{1}H NMR. To achieve this objective and to reveal the reliability of the determination, interesterified mixtures of TAG of known composition, isolated short-chain acyl TAG isomers, and interesterified and natural butteroil were studied.

MATERIALS AND METHODS

Three equimolar mixtures of three monoacid TAG [tributyrin, trilaurin, tristearin; tricaproin, tripalmitin, tristearin; and tributyrin, tristearin, triolein (Fluka AG, Buchs, Switzerland)] and butteroil were interesterified at 90°C using 1% sodium methoxide as catalyst. The TAG of the reaction mixtures were isolated on silica gel thin-layer chromatography (TLC) plate as described by Christie (13), or on a 5-cm × 2-cm silica gel column, which was eluted with mixture of hexane/diethyl ether (95:5, vol/vol). For the assignment of ^{1}H chemical shifts, 2-butyryl-1,3-distearoylglycerol was synthesized according to the principles reported by Jensen and Pitas (14) as follows: 1,3-distearoylglycerol (Nu-Chek-Prep, Elysian, MN) (40 μmol), butanoyl chloride (60 μmol), and pyridine (60 μmol) in chloroform (0.6 mL) were stirred at 25°C for 7 d.

TAG of the reaction mixture were isolated by TLC on a silica gel plate (Merck, Darmstadt, Germany) using hexane/diethyl ether/ formic acid 80:20:2 as developing solvent (13).

TAG were analyzed on a Carlo Erba gas chromatograph (Milan, Italy) with an on-column injector, a flame-ionization detector, and a constant pressure/constant flow cp-cf 516 module. The chromatograms were run on a 25-m 0.25-mm i.d. immobilized phenyl(65%)methylsilicone column (Quadrex, New Haven, CT) with 0.1-μm film thickness. Injection was made with a constant carrier gas (hydrogen) pressure as described by Kemppinen and Kalo (15). Immediately after injection, the cp-cf module was changed to constant flow mode (linear velocity 62 cm/s). Temperature program was: After 3 min at 180°C, the column temperature was increased at 10°C/min to 310°C, 0.5°C/min to 320°C, and further 2°C/min to 360°C (hold 4 min).

TAG isomers were isolated by reversed-phase high-performance liquid chromatography (HPLC) using a Hewlett-Packard 1090 series II liquid chromatograph with an effluent splitter (split ratio 1:1) and an evaporative light-scattering detector (Cunow Model DDL 21; Cunow, Cergy Saint-Christophe, France). The detector was operated at 54°C with air pressure of 1.1 bar. The isolation was performed on a 25-cm × 0.46-cm Spherisorb S5ODS1 column (PhaseSep, Deeside, United Kingdom) with 5 μm particle size, 8 nm pore diameter, and 7% carbon coverage using a linear gradient of 1–70% isopropanol in acetonitrile and a flow rate of 1 mL/min (90 min).

^{1}H NMR spectra were recorded in $CDCl_3$ with Varian Unity 500 (11.74T) spectrometer (Palo Alto, CA) and referenced to internal tetramethylsilane (TMS) (0.00).

RESULTS AND DISCUSSION

In gas chromatographic analyses, the polarizable phenylmethylsilicone columns have been proven to separate TAG isomers with different acyl chains in the acyl carbon number range 24–42 due to polarity differences of these isomers (16). When the interesterified equimolar mixture of tributyrin, trilaurin, and tristearin was analyzed on such column, each of the TAG with 28, 34, and 40 acyl carbons eluted in two peaks with ratios 1.84:1, 1.92:1, 1.98:1, respectively (Fig. 1). The ratios were close to the expected random ratio 2:1. We concluded that 2-butyryl-1*X*-3*Y*-*rac*-glycerol (*X,Y* = long-chain acyls) isomers were separated from 1-butyryl-2*X*-3*Y*-*rac*-glycerol isomers. To identify these isomeric TAG, we studied the possibility of isolating them using reversed-phase HPLC column. The ODS-1 column separated TAG with 34 and 40 acyl carbons in two peaks, when a linear gradient of 1–70% isopropanol in acetonitrile was used (Fig. 2). Despite numerous attempts, complete separation of TAG 28 isomers could not be achieved by modification of gradient. Relative to gas chromatographic separation, the TAG isomers eluted in the reverse order, which was expected for the separation on a reversed-phase column. This is consistent with polarity differences of TAG isomers. A *ca.* 6 mg sample of interesterified mixture was subjected to a preparative separation of TAG 34 and TAG 40 isomers on the analytical HPLC column used.

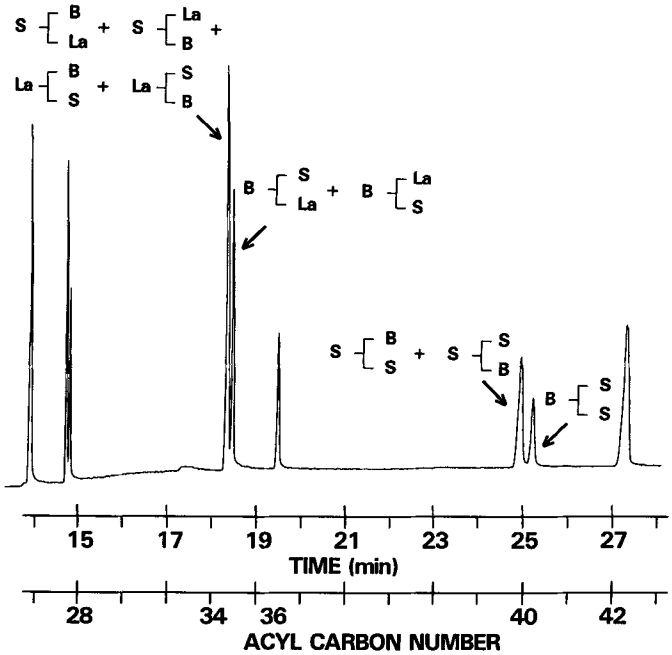

FIG. 1. Separation of triacylglycerols of interesterified mixture of tributyrin, trilaurin, and tristearin on a 25-m 0.25-mm i.d. immobilized phenyl(65%)methylsilicone column with 0.1-μm film thickness using cold on-column injection, and hydrogen as carrier gas (linear velocity 62 cm/s). Abbreviations: B = butyryl, La = lauroyl, and S = stearoyl.

The ^{1}H NMR spectrum of the TAG 40.1 (Fig. 2) collected from the HPLC separation and that of the synthesized 2-butyryl-1,3-distearoylglycerol were identical (Fig. 3, A and B), and both were similar to the spectrum of TAG 34.1 (Table 1). The ^{1}H NMR spectra of TAG 40.2 and TAG 34.2 were almost similar, but they differed markedly from those of TAG 40.1 and TAG 34.1 in the resonance signals of methylene and methine protons of glycerol backbone, the C-2-methylene protons of acyl groups, and the methyl protons of butyryl group (Table 1; and Fig. 3, A, B, and C). The ^{1}H spectrum of the TAG 40.1 (and TAG 34.1) showed AB part of an ABX system of methylene and methine protons of glycerol backbone at δ 4.161 (4.162) ppm and 4.306 (4.307) ppm, and X part at δ 5.28 ppm; and coupling constants J_{AX} 5.9 Hz, J_{BX} 4.2 (4.4) Hz, and J_{AB} 11.9 Hz (Table 1). The ^{1}H spectrum of the TAG 40.2 (and TAG 34.2) showed two overlying ABX systems of methylene and methine protons of glycerol backbone (Table 1; Fig. 3C). The δ-values for A_IB_I methylene protons were 4.160 and 4.305 ppm, and those for $A_{II}B_{II}$ 4.164 and 4.309 (4.308) ppm, δ_X 5.28 ppm and coupling constants J_{AIX} = 5.9 Hz, J_{AIIX} = 6.0 Hz, J_{BIX} = 4.2 (4.3) Hz, J_{BIIX} = 4.4 Hz, and $J_{AIBI} = J_{AIIBII}$ = 11.9 Hz (Table 1). The ^{1}H NMR spectra of the TAG 40.1 and TAG 34.1 showed two overlying triplets of C-2 methylene protons of acyl groups at δ 2.318 and 2.320 ppm (Table 1; Fig. 3, A and B). Three overlying triplets of C-2 methylene protons were at δ-values 2.327, 2.320, and 2.312 ppm in the spectra of TAG 40.2 and TAG 34.2 (Table 1; Fig.

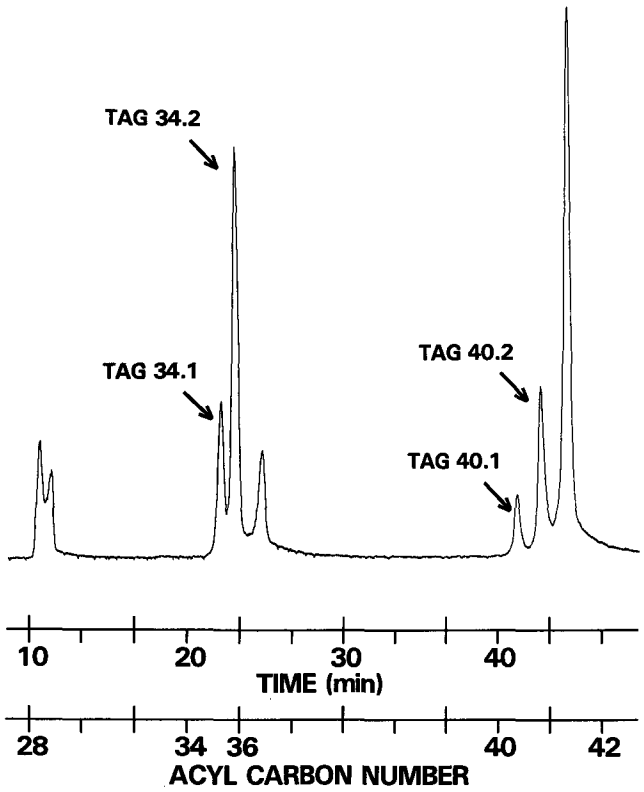

FIG. 2. Reversed-phase high-performance liquid chromatography chromatogram of triacylglycerols (TAG) of interesterified mixture of tributyrin, trilaurin, and tristearin on a 25-cm × 0.46-cm ODS-1 column using linear gradient of 1–70% isopropanol in acetonitrile.

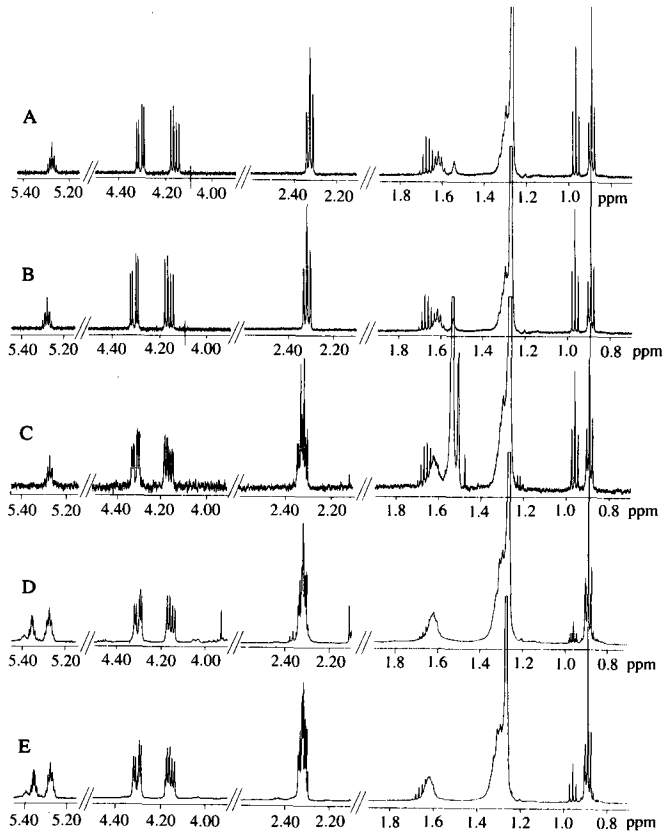

FIG. 3. 500-MHz ^{1}H nuclear magnetic resonance spectra of synthesized 2-butyryl-1,3-distearoylglycerol (A), isolated 2-butyryl-1,3-distearoylglycerol (B), 1-butyryl-2,3-distearoyl-*rac*-glycerol (C), interesterified butteroil (D), and natural butteroil (E). Chemical shifts are referenced to tetramethylsilane (0.00).

3C). The spectra of TAG 40.2 and TAG 34.2 showed that the two methylenes of glycerol backbone, and the C-2 methylenes of acyl groups, are in different environment.

The ^{1}H NMR spectrum of the TAG 40.1 (and TAG 34.1) showed a triplet of methyl protons of 2-butyryl group at δ 0.967 (0.966) ppm, and a triplet of long-chain acyl protons at δ 0.892 ppm (Table 1; Fig. 4, A and B). The δ-value of the triplet of methyl protons of 1(3)-butyryl group of TAG 40.2 (and TAG 34.2) was 0.960 ppm differing from the δ-value of the methyl protons of 2-butyryl group of TAG 40.1 (and TAG 34.1) 0.007 (0.006) ppm (Table 1; and Fig. 4C).

In addition, ^{1}H NMR spectra of all TAG isomers showed a sextet of C-3 methylene of butyryl group within δ 1.6–1.7 ppm partially overlying with signals of C-3 methylenes of long-chain acyls, and an intense signal of methylene protons of long-chain acyl groups at δ 1.266 ppm (Table 1; and Fig. 3, A, B, and C).

The integration of the signals of synthesized 2-butyryl-1,3-distearoylglycerol showed ratios of protons of glycerol methine/glycerol methylene/C-2 methylene of acyl groups/methyl of butyryl group/methyl of stearoyl group 1:3.98:5.73:2.73:5.81, which are consistent with the structure. The spectra of TAG 34.1, TAG 40.2, and TAG 34.2 are consistent with the structures of 1-lauroyl-2-butyryl-3-stearoyl-*rac*-glycerol, 1-butyryl-2,3-distearoyl-*rac*-glycerol, 1-butyryl-2-lauroyl-3-stearoyl-*rac*-glycerol and 1-butyryl-2-stearoyl-3-lauroyl-*rac*-glycerol, respectively.

To reveal the possibility of determining the distribution of butyryl groups between *sn*-1(3)- and *sn*-2-positions in TAG mixtures, the NMR spectra of three interesterified equimolar mixtures of three monoacid TAG were recorded. The ^{1}H NMR spectrum of the interesterified mixture of tributyrin, trilaurin, and tristearin containing *ca.* 63% butyrate TAG showed two triplets at δ 0.957 and δ 0.964 ppm representing resonance signals of methyl protons of butyryl groups at *sn*-1(3)-positions and at *sn*-2-position, respectively (Fig. 4D). The intensity ratio of the most intense signals was 1.96:1, and that of the sum of the triplet signals 1.85:1, which agreed with the ratio of theoretical value of 2:1 and those of the isomers of TAG with 28, 34, and 40 acyl carbons of GLC analysis (1.84:1–1.98:1).

The ^{1}H NMR spectrum of the interesterified mixture of tricaproin, tripalmitin, and tristearin revealed that the signals of methyl protons of caproyl groups in the range 0,907–0,921 ppm do not disturb the determination of positional distribution of butyryl groups (Fig. 4E).

The ^{1}H NMR spectrum of the interesterified mixture of tributyrin, tristearin, and triolein containing saturated, monoene, and diene butyrate TAG showed two triplets at δ 0.960 ppm and at δ 0.966 ppm of methyl protons of butyryl groups

at *sn*-1(3)-positions and at *sn*-2-position, respectively (Fig. 4F). Integration of signals revealed distribution of buturyl groups between *sn*-1(3)- and *sn*-2-position in the ratio 1.77:1 according to the most intense signals and in the ratio 1.74:1 according to the sum of the triplet signals.

The ^{1}H NMR spectra of the three interesterified mixtures of three monoacid TAG revealed that positional distribution of butyryl groups in the mixtures of saturated, monoene, and diene TAG can be determined on the basis of triplets of methyl protons. The ^{1}H NMR spectra of natural and interesterified butteroil were recorded to prove the applicability of the method in analyzing natural fats. The spectrum of interesterified butteroil showed the triplets of methyl protons of butyryl groups at the *sn*-1(3)-position and at *sn*-2-position at δ 0.959 and δ 0.965 ppm, respectively, in the ratio 1.82:1 of most intense signals and in the ratio 1.71:1 of the sum of signals, which agree with the random ratio 2:1 (Fig. 4G). In the spectrum of natural butteroil, only one triplet of methyl protons of buturyl group at δ 0.958 ppm was observed, indicating that butyric acid is entirely esterified with primary hydroxyls (Fig. 4H). This is in accordance with the results of stereospecific analysis using Grignard degradation and enzymatic deacylation (17–19), and ^{1}H NMR spectroscopy with chiral shift reagent of monobutyryl TAG fraction of hydrogenated butterfat (6), which indicated that butyric acid is predominantly esterified at the *sn*-3-position, and the results of regiospecific analysis using ^{13}C NMR spectroscopy, which demonstrated the primary isomeric positioning of butyryl groups (>97%) (7).

The spectra of interesterified mixtures of tributyrin, trilaurin, and tristearin; and tributyrin, tripalmitin, and triolein, showed several overlying ABX systems of methylene and methine protons of glycerol backbone around δ 4.16 ppm (A) and 4.30 ppm (B) and δ 5.28 ppm (X) and the spectrum of interestrified mixture of tricaproin, tripalmitin, and tristearin only one ABX-system. In the spectra of butteroils, the expected overlying ABX systems were poorly resolved (Fig. 3, D and E). On the contrary, to the isolated positional isomers of butyryl TAG, the signals of glycerol backbone protons of TAG mixtures and butteroils cannot been used in identifying the position of butyryl groups. Spectra of all interesterified mixtures and both butteroils showed overlaying triplets of C-

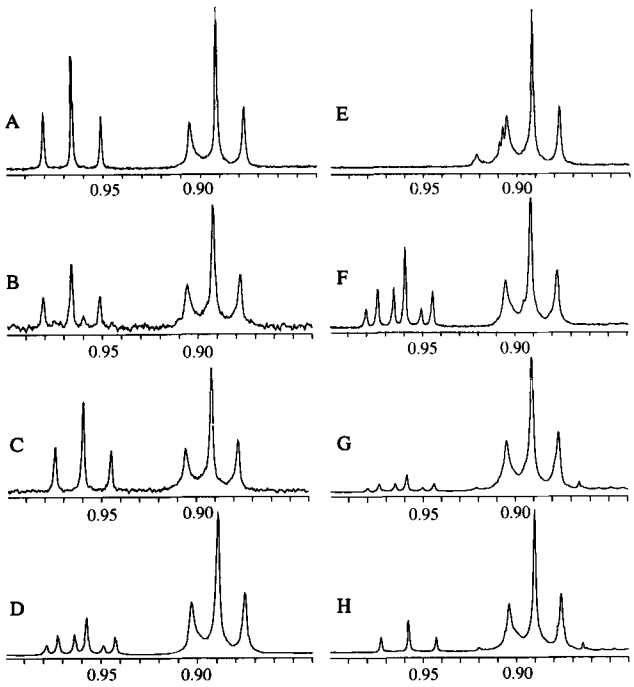

FIG. 4. Resonance signals of the methyl protons of butyryl group of synthesized 2-butyryl-1,3-distearoylglycerol (A), isolated 2-butyryl-1,3-distearoylglycerol (B), 1-butyryl-2,3-distearoyl-*rac*-glycerol (C), interesterified equimolar mixtures of tributyrin, trilaurin, and tristearin (D); tricaproin, tripalmitin, and tristearin (E); tributyrin, tristearin, and triolein (F), interesterified butteroil (G), and natural butteroil (H).

2 methylene protons around δ 2.3 ppm, signals of C-3 methylene protons of butyryl groups around δ 1.65 ppm (except the spectrum of caproyl TAG), signals of C-3 methylene protons of long-chain acyl groups around δ 1.62 ppm and signals of other methylenes of long-chain acyls in the range δ 1.2–1.3 ppm and a triplet of methyl protons of long-chain acyls around δ 0.89 ppm. The spectra of interesterified mixture of tributyrin, tristearin, and triolein, and both butteroils showed signals of olefinic protons at δ 5.35 ppm and allylic methylene protons at δ 2.02 ppm (20).

In the present study, the polarizable phenyl(65%)methylsilicone column showed equal or better separation efficiency of positional isomers of butyrate TAG than reported recently for unspecified short-chain TAG isomers (21). The resolving power of these columns is sufficient to be used in the determination of positional distribution of butyric acid in the simple mixtures of butyrate TAG. It is likely that also positional isomers of other short-chain TAG, at least caproates, can be separated by GLC. Work is in progress to study to which extent GLC can be used in the determination of positional distribution of short-chain TAG in simple mixtures and natural fats. The determination of positional distribution of butyryl groups by ^{1}H NMR spectroscopy can be done without any other treatments than drying of a fat sample and from much smaller sample than by ^{13}C NMR (7). ^{1}H NMR spectra can be easily recorded from a sample below one milligram. The method is thus useful in the structural analysis of molecular species of butyrate TAG isolated by combined chromatographic techniques.

In conclusion, the results clearly demonstrated the resolving power of polarizable phenylmethylsilicone (GLC) column and reversed-phase ODS-1 (HPLC) column in separation 2-butyryl and 1(3)-butyryl isomers of saturated TAG. We showed that the 500-MHz ^{1}H NMR spectra differentiated 2-butyryl and 1(3)-butyryl isomers, and that the determination of positional distribution of butyryl groups in simple mixtures of saturated, monoene, and diene butyrate TAG and in isolated positional isomers of butyrate TAG can be done by GLC or ^{1}H NMR spectroscopy. We showed also the applicability of ^{1}H NMR spectroscopy in determining the positional distribution of butyryl groups between *sn*-1(3)- and *sn*-2-positions in TAG of milkfat by direct measurement of dried milkfat samples.

Mechanism of Lower Oxidizability of Eicosapentaenoate Than Linoleate in Aqueous Micelles

Kazumasa Yazu[a], Yorihiro Yamamoto[b,*], Koji Ukegawa[a], and Etsuo Niki[b]

[a]Department of Energy Resources, National Institute for Resources and Environment, Ibaraki 305, Japan, and
[b]Research Center for Advanced Science and Technology, University of Tokyo, Tokyo 153, Japan

ABSTRACT: The aerobic oxidation kinetics of methyl eicosapentaenoate (20:5n-3) and methyl linoleate (18:2n-6) were compared in homogeneous chlorobenzene solution and in Triton X-100 aqueous micelles at 37°C. The rate of disappearance of 20:5n-3 was two times faster than that of 18:2n-6 in chlorobenzene, while the former was five times slower than the latter in aqueous micelles. It was also observed that ΔO_2 = Δ18:2n-6 and ΔO_2 = 2 Δ20:5n-3 in aqueous micelles. In the oxidation of a 1:1 mixture of 20:5n-3 and 18:2n-6 in micelles, the rate of disappearance of 20:5n-3 was 3.6 times faster than that of 18:2n-6, and the rate of total substrate disappearance was reduced by a factor of 5 as compared with 18:2n-6 oxidation. These data suggest that the peroxyl radical derived from 20:5n-3 is more polar than that from 18:2n-6, and the former is likely to diffuse from the core to the micelle surface. This lowers the oxidizability for 20:5n-3 in aqueous micelles by enhancing the termination reaction rate for peroxyl radicals and by reducing the rate of propagation since there may be more 20:5n-3 peroxyl radicals at the surface than in the micelle core.
Lipids 31, 337–340 (1996).

Polyunsaturated fatty acids (PUFA) are particularly susceptible to oxidation since they have chemically labile, bisallylic hydrogen substituents (1–4). Therefore, the oxidizability of PUFA should be dependent on the number of bisallylic positions available for oxidation. This has been confirmed for the oxidation in homogeneous solution (1–4). On the contrary, it has been recently reported that the oxidizability of PUFA in aqueous micelles decreased with an increasing number of bisallylic sites available for oxidation, although the rate of free radical production was not controlled (5). Similar phenomenon was observed in photooxidation of PUFA in aqueous micelles (6). However, the reason for this reversed relationship in reactivity has not been adequately explained (5,6). In order to answer this question, we compare the oxidation kinetics of methyl eicosapentaenoate (20:5n-3) and methyl linoleate (18:2n-6) both in homogeneous chlorobenzene solution and in aqueous micelles using both water- and lipid-soluble azo initiators to obtain a constant rate of free radical production. Consumption of substrates was determined by gas chromatography (GC). Substrates were extracted from aqueous micelles with hexane/methanol (5:1, vol/vol) and condensed under reduced pressure prior to the injection.

When 200 mM 20:5n-3 and 18:2n-6 were independently oxidized with 10 mM lipid-soluble initiator, 2,2'-azobis(2,4-dimethylvaleronitrile) (AMVN) in chlorobenzene, the rate of consumption of 20:5n-3 was about two times faster than that of 18:2n-6 as shown in Figure 1. On the other hand, the rate of disappearance of 20:5n-3 was about five times slower than that of 18:2n-6 when 1.6 mM 20:5n-3 and 18:2n-6 were independently oxidized with 2 mM AMVN in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 (Fig. 2). This was also the case when the oxidation in aqueous micelles was initiated with water-soluble initiator, 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH). These data confirm the

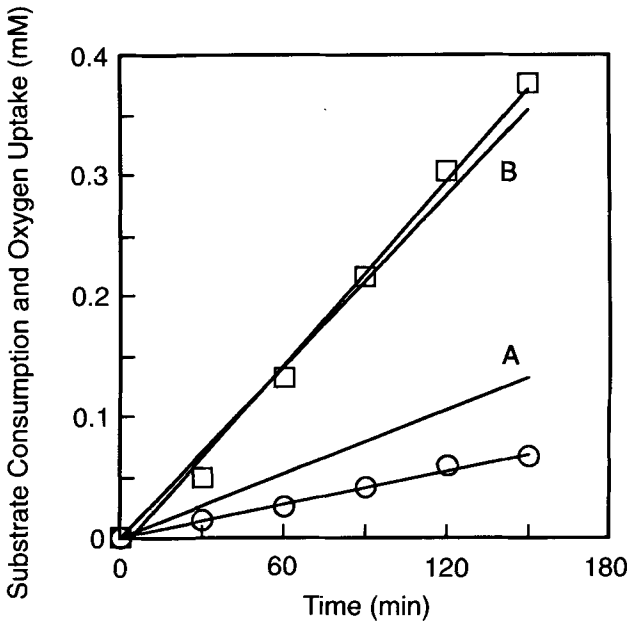

FIG. 2. Substrate consumption in 2.0 mM 2,2′-azobis(2,4-dimethylvaleronitrile)-initiated, aerobic oxidation of 1.6 mM 20:5n-3 (○) and 1.6 mM 18:2n-6 (□) in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 at 37°C. Oxidations were conducted separately. Lines A and B show oxygen uptake by 20:5n-3 and 18:2n-6, respectively, during the oxidations in the same conditions.

reported observation (5) that in aqueous micelles the oxidizability of PUFA is inversely correlated with the number of bisallylic positions available for oxidation.

The oxidation of substrate (*LH*) initiated with an azo initiator (*A-N=N-A*) proceeds by the following mechanism (2–4):

initiation:

$$A\text{-}N{=}N\text{-}A \xrightarrow{k_d} 2eA\bullet + (1-e)A - A + N_2 \quad [1]$$

$$A\bullet + O_2 \rightarrow AOO\bullet \quad [2]$$

propagation:

$$AOO\bullet + LH \xrightarrow{O_2} AOOH + LOO\bullet \quad [3]$$

$$LOO\bullet + LH \xrightarrow{k_p} LOOH + L\bullet \quad [4]$$

$$L\bullet + O_2 \rightarrow LOO\bullet \quad [5]$$

termination:

$$2\,LOO\bullet \xrightarrow{k_t} \text{nonradical products} \quad [6]$$

where k_p and k_t are the rate constants for propagation and termination Reactions 4 and 6, respectively. The rate of chain initiation, R_i, is given in Equation 7 where k_d is the rate constant for the decomposition of azo initiator and e is the efficiency of free radical production. The rate of substrate consumption, $-d[LH]/dt$, is expressed by Equation 8.

$$R_i = 2e \cdot k_d[A\text{–}N{=}N\text{–}A] \quad [7]$$

$$-d[LH]/dt = kp(R_i/2k_t)^{1/2}[LH] + R_i \quad [8]$$

R_i in Equation 7 is determined by measuring the induction period (t_{inh}) due to the addition of the chainbreaking antioxidant, 2,6-di-*tert*-butyl-4-methylphenol and is calculated from Equation 9 (2–4,7). The $e \cdot k_d$ values at 37°C for AAPH and AMVN when 1.6 mM substrate was dissolved in 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM Triton X-100 are 3.5×10^{-7} s^{-1} and 2.5×10^{-7} s^{-1}, respectively. These values were the same, irrespective of the lipid substrates, 20:5n-3 or 18:2n-6. We have used $e \cdot k_d$ value, 2.2×10^{-6} s^{-1}, for AMVN in chlorobenzene obtained previously (8).

$$R_i = 2[\text{2,6-di-}tert\text{-butyl-4-methylphenol}]/t_{inh} \quad [9]$$

The rate of substrate consumption was proportional to the substrate concentration and to the square root of R_i (data not shown), indicating that Equation 8 holds. The oxidizability values, $k_p/(2k_t)^{1/2}$, are given in Table 1 which summarizes the kinetic data. The oxidizability at each bisallylic site for 18:2n-6 is about two times larger than that for 20:5n-3 in chlorobenzene. On the other hand, in aqueous micelles, the oxidizability at bisallylic site for 18:2n-6 is about 20 times larger than that for 20:5n-3, indicating 20:5n-3 is less susceptible to oxidation than 18:2n-6. It is noteworthy that the oxidizability for each substrate was almost the same when the oxidation was initiated with either water- or lipid-soluble initiators. The oxidizability at bisallylic site for 18:2n-6 increased by a factor of 2 on going from chlorobenzene to micelles. Similar results were reported by the comparison of the oxidation kinetics of linoleic acid in chlorobenzene and in sodium dodecyl sulfate micelles (9). However, the oxidizability at each of bisallylic sites for 20:5n-3 decreased by a factor of 5 in comparison to chlorobenzene and micelles, indicating that the reactivity of peroxyl radical derived from 20:5n-3 changed substantially in aqueous micelles (see later discussion).

The oxidations of 20:5n-3 and 18:2n-6 were also followed

by measuring oxygen uptake using an oxygen electrode in aqueous micelles. Figure 2 shows that the rates of oxygen uptake and substrate consumption were the same in the AMVN-initiated oxidation of 18:2n-6 in micelles. On the other hand, the ratio of the rate of oxygen uptake to that of the substrate consumption is about 2 in the oxidation of 20:5n-3. These data indicate that the oxidation of 20:5n-3 may proceed by a more complicated mechanism which includes the intramolecular cyclization of peroxyl radicals (10). This intramolecular reaction was shown to be evident in the oxidation of PUFA having more than three double bonds (10–12).

The peroxyl radical derived from 20:5n-3 should contain two molecules of absorbed oxygen. Therefore, this peroxyl radical is likely to be more polar than the peroxyl radical from 18:2n-6 having absorbed only one molecule of oxygen. Therefore, it is expected that the peroxyl radical derived from 20:5n-3 may diffuse from the hydrophobic region of the micelles to the polar surface region of the micelles as first suggested by Barclay and Ingold (13). This results in a decrease in the rate of propagation reaction since there may be more 20:5n-3 peroxyl radicals located at the surface as compared with the internal lipophilic region. Although Barclay *et al.* (9,14) reported a decrease in termination reactions for 18:2n-6 in micelles compared to organic solution, it is possible that 20:5n-3 peroxyl radicals may be more inclined toward termination reactions by their propensity to condense as polar groups at the surface layer of the micelles. Both changes would cause a decrease of oxidizability for 20:5n-3 in aqueous micelles as expected from Equation 8.

This interpretation was confirmed by the results of the oxidation of a 20:5n-3 and 18:2n-6 mixture (total 1.6 mM) in aqueous micelles. Table 2 shows that the relative reactivity of 20:5n-3 and 18:2n-6 toward peroxyl radical is about 3.5:1 (see (–*d*[20:5n-3]/*dt*/-*d*[18:2n-6]/*dt*)/([20:5n-3]/[18:2n-6]) values). This number is close to the ratio (4:1) of bisallylic sites for 20:5n-3 and 18:2n-6, suggesting 20:5n-3 is more prone to oxidation than 18:2n-6 even in aqueous micelles. However, the replacement of 18:2n-6 by 20:5n-3 (18:2n-6 to 20:5n-3 ratios of 1:7, 1:4, 1:1, and 0:1) reduced the rate of total substrate disappearance by factors of 3, 4, 5, and 5, respectively (Table 2). If the peroxyl radical derived from 20:5n-3 has similar reactivity in propagation and termination reactions as the peroxyl radical derived from 18:2n-6 in aqueous micelles as is observed in homogeneous solution, such a great reduction in the rate of total substrate disappearance should not be seen. Therefore, the results shown in Table 2 strongly suggest that the peroxyl radical derived from 20:5n-3 resides at a different location from where the peroxyl radical derived from 18:2n-6 is located in aqueous micelles. It is likely to be at the surface of the micelles since the peroxyl radical derived from 20:5n-3 is more polar than that from 18:2n-6. This would explain the reduction of oxidizability for 20:5n-3 in aqueous micelles by enhancing the rate of chain termination reaction of peroxyl radical and by reducing the rate of propagation since there may be more 20:5n-3 peroxyl radicals at the surface than in the micelle core.

Effects of Dietary Triacylglycerol Structure on Triacylglycerols of Resultant Chylomicrons from Fish Oil- and Seal Oil-Fed Rats

Michael Søberg Christensen* and Carl-Erik Høy

Department of Biochemistry and Nutrition and Center for Food Research, Technical University of Denmark, DK-2800 Lyngby, Denmark

ABSTRACT: We investigated the influence of the intramolecular fatty acid distribution of dietary triacyl-*sn*-glycerols (TAG) rich in n-3 polyunsaturated fatty acids (PUFA) on the structure of chylomicron TAG. Fish oil and seal oil, comparable in fatty acid compositions but with different contents of major n-3 PUFA esterified at the *sn*-2 position (20:5n-3, 46.6%, and 5.3%; 22:6n-3, 75.5%, and 3.8%, respectively), were fed to rats. Mesenteric lymph was collected and the chylomicrons were isolated by ultracentrifugation. The fatty acid composition of chylomicrons largely reflected the fatty acid composition of the oils administered. The intramolecular fatty acid distributions of the TAG fed were reflected in the chylomicron TAG as the fraction of the total contents observed in the *sn*-2 position of 20:5n-3 were 23.6 and 13.3%, and of 22:6n-3 were 30.6 and 5.4% for resultant chylomicrons following fish oil and seal oil administration, respectively. Thus, after seal oil administration, significant higher load of n-3 PUFA was esterified in the *sn*-1,3 positions of chylomicron TAG compared with fish oil administration ($P < 0.05$).

Lipids 31, 341–344 (1996).

Long-chain n-3 polyunsaturated fatty acids (PUFA), e.g., eicosapentaenoic (20:5n-3) and docosahexaenoic (22:6n-3) acids, are of interest in general public health (1), as well as in enteral nutrition for hospital patients (2). *In vitro* studies have demonstrated that n-3 PUFA may exhibit resistance toward hydrolysis in the gastrointestinal tract (3,4), and it has thus been speculated that fish oil may not be efficiently digested and absorbed. The intestinal digestion of triacyl-*sn*-glycerol (TAG) is achieved mainly by the *sn*-1,3 specific pancreatic lipase. The 2-monoacyl-*sn*-glycerols (2-MAG) and free fatty acids formed are absorbed by the enterocytes and, once entering, are reacylated to TAG primarily by the 2-MAG pathway during fat absorption. Åkesson *et al.* (5) demonstrated that during absorption of 1,2-dilauryl-3-oleyl-*sn*-glycerol, lauric acid was maintained in the *sn*-2 position, and during absorption of menhaden oil, in which PUFA dominate in the *sn*-2 position, 85% of the fatty acids of the MAG obtained from the enterocytes were maintained in the TAG of chylomicrons (6). The intramolecular distributions of fatty acids in TAG from marine mammals and fish are different. In the seal oil, the n-3 PUFA are esterified in the *sn*-1,3 positions of the TAG, whereas in fish oils the PUFA are mostly esterified in the *sn*-2 position (4). This different distribution of fatty acids in the TAG may affect the intestinal absorption and distribution of the n-3 PUFA in humans (7). However, we have previously demonstrated that the absorption of n-3 PUFA from native oils, fish and seal oils, was affected by the intramolecular fatty acid distribution only to a minor degree in the rat (8). The intramolecular fatty acid distribution of TAG in chylomicrons may influence their metabolism in the systemic circulation, as the TAG are degraded by lipoprotein lipase which is an *sn*-1,3 specific lipase. Findings with chylomicrons produced during absorption of fish and seal oils demonstrated different metabolism, seal oil chylomicrons being removed faster from the plasma than fish oils chylomicrons (9). In the present paper, we investigated how the intramolecular distribution of n-3 PUFA in dietary TAG affects the intramolecular fatty acid distribution of TAG of chylomicrons.

MATERIALS AND METHODS

Male Wistar rats (specific-pathogen–free) were obtained from Møllegaard Laboratory (Ll. Skensved, Denmark). The rats were caged in pairs at 25°C at a relative humidity of 45%. Standard chow diet (standard chow diet/Altromin no. 1324; Chr. Pedersen, Ringsted, Denmark) and drinking water were provided *ad libitum*. The rats weighed 250–300 g at the time of surgery.

The surgical procedure and the experiment were approved by the Danish Committee on Animal Experiments. The rats were anesthetized with pentobarbital (7 mg/100 g body weight, i.p.), and a cannula was inserted into the main mesenteric lymph duct essentially as described by Bollmann *et al.* (10). Following surgery, the rats were placed in individual restraining cages in a quiet room (25°C) with free access to tap

water. The rats were hydrated by infusion of physiological saline (0.15 M NaCl, 2 mL/h) through a gastric feeding tube placed at the time of surgery. The following day, 0.3 mL of either fish oil (Okholms fish oil, a product for human consumption; Thyborøn Andelsfiskeindustri, Thyborøn, Denmark) or seal oil (Greenlandic seal, *Pagophilus graenlandicus)*, followed by 0.5 mL of physiological saline (0.15 M NaCl), was administered through the feeding tube and the infusion of saline was continued. The lymph was discarded for the first 45 min, as no significant amount of dietary fat is transported through the lymphatics within that period, and then collected for eight hours. The chylomicrons were isolated by ultracentrifuge flotation using a discontinuous gradient (9,11), and the total lipid fraction extracted (12). The lipid extracts were applied to thin-layer chromatography plates (Merck art. no. 5721; Merck, Darmstadt, Germany) and developed in hexane/diethylether/acetic acid (80:20:1, by vol). The bands were visualized by spraying with 2,7-dichlorofluorescein, and the TAG band and application point containing the phospholipids were scraped off for fatty acid analysis. The fatty acids were methylated using KOH in methanol (13), and the fatty acid methyl esters analyzed by gas–liquid chromatography as previously described (9).

The intramolecular fatty acid distribution in TAG of dietary oils and chylomicrons was determined by Grignard degradation of the TAG using allylmagnesium bromide followed by analysis of the *sn*-2 MAG (14). This procedure eliminated the possible discrimination of n-3 PUFA due to slow hydrolysis previously reported for pancreatic lipase (3).

RESULTS

In the fish oil (Table 1), the major sources of n-3 PUFA were 20:5n-3 and 22:6n-3. The 22:6n-3 was concentrated in the *sn*-2 position of the TAG, whereas the 20:5n-3 was more evenly distributed between the *sn*-2 and the *sn*-1,3 positions of the TAG molecules. The 18:1, 20:1, and 22:1 were mainly esterified in the *sn*-1,3 positions, as reduced levels were found in the *sn*-2 position compared with the TAG, whereas approximately one-third of the saturated fatty acids were acylated in the *sn*-2 position. The intramolecular structure of seal oil TAG (Table 2) was significantly different from that of the fish oil TAG. The saturated and monounsaturated fatty acids with 14–18 carbons were mostly esterified in the *sn*-2 position, whereas 20:1 and 22:1 were esterified in the *sn*-1,3 positions. The PUFA, which mainly consisted of 20:5n-3 and 22:6n-3, were specifically esterified in the *sn*-1,3 positions, as only 5.3 and 3.9% of 20:5n-3 and 22:6n-3 of the total content in TAG, respectively, were found in the *sn*-2 position.

The fatty acid composition of the TAG and the phospholipids of chylomicrons and the intramolecular fatty acid distribution of the TAG following administration of oils were examined (Tables 1 and 2). The fatty acid composition of chylomicron TAG resembled the composition in the dietary oil. The ratio between mol% of n-3 PUFA in the chylomicron TAG and the oil administered was similar for the two oils

[a]The data for the seal oil analyses represent average of three determinations for both the TAG and *sn*-2 MAG. Abbreviations as in Table 1.
[b]Chylomicrons were collected from seven animals and the lipid fractions were extracted. Following separation on thin-layer chromatography, the TAG and PL fractions were analyzed for fatty acid composition by gas–liquid chromatography. Data represent mean ± SEM.
[c]The fatty acid composition of the 2-MAG of the fish oil and the chylomicron TAG were determined by Grignard degradation followed by isolation and analysis of the *sn*-2 MAG. The fatty acid composition in the *sn*-1,3 position can be calculated using the equation: mol% in *sn*-1,3 = (3 × mol% in TAG – mol% in *sn*-2 MAG)/2.

(~ 0.65 and ~0.80 for 20:5n-3 and 22:6n-3, respectively). The contents of 16:0, 18:2n-6, and 20:4n-6 in the chylomicron TAG were augmented compared with the content in the dietary oil, probably reflecting a contribution of fatty acids from the bile (15,16). The structural analysis of the chylomicron TAG showed that significantly more n-3 PUFA were esterified in the *sn*-1,3 positions after seal oil administration compared with fish oil administration ($P < 0.05$, Student's *t*-test).

Similarly, in the *sn*-2 position of the TAG from fish oil chylomicrons, a greater amount of n-3 PUFA was esterified compared with seal oil chylomicrons. The fatty acid composition of the chylomicron phospholipids reflected contribution of fatty acids of endogen origin as the contents of stearic acids (18:0, 17.6 ± 0.4, and 17.6 ± 0.5), linoleic acid (18:2n-6, 17.8 ± 0.5, and 18.4 ± 0.4), and arachidonic acid (20:4n-6, 16.7 ± 0.8, and 15.1 ± 0.5) in mol% following fish oil and seal oil administration, respectively, were high, whereas these fatty acids only were present in the oil in very low amounts. The fatty acids composition of the phospholipids from the two populations of chylomicrons was similar.

DISCUSSION

There has been no previous study comparing the effect of different intramolecular fatty acid distributions of n-3 PUFA in dietary TAG on the intramolecular fatty acid distribution of TAG of chylomicrons. Our data demonstrate that the ratio of n-3 PUFA esterified in the *sn*-2 vs. the *sn*-1,3 positions of chylomicron TAG depends on the oil administered. Following administration of seal oil, the n-3 PUFA were mainly esterified in the *sn*-1,3 positions of the chylomicron TAG, however, with an increase in the relative amount esterified in the *sn*-2 position from 5 mol% in the seal oil to 7.5 mol% the TAG of the chylomicrons. The n-3 PUFA from the fish oil were evenly distributed between the *sn*-2 and the *sn*-1,3 positions in chylomicron TAG. About one-third of the n-3 PUFA were esterified in the *sn*-2 position, compared with 57.5% in the oil administered. This agrees with the studies of Yang *et al.* (6,17), who observed a reduction in the percentage of the n-3 PUFA esterified in the *sn*-2 position of chylomicrons TAG compared to the menhaden oil administered. In contrast, Chernenko *et al.* (18) found that the positional distribution of fatty acids in the total lymph lipid fraction was similar to that in the fish oil (MaxEPA) administered. This discrepancy may reflect the use of total lymph and pancreatic lipase for structural analysis by Chernenko *et al.* (18). Alternatively, differences in the fatty acid composition of MaxEPA, 20:5n-3/22:6n-3 ~1.5, and the fish oil used in the present study, 20:5n-3/22:6n-3 ~0.9, may result in different metabolism of the n-3 PUFA.

A partial retailoring of the TAG during absorption reflects a contribution from the phosphatidic acid pathway in mucosa (19), the action of intestinal hydrolases (20), or a concerted action of lipases in the lumen (21), resulting in a total hydrolysis of some TAG to free fatty acids and glycerol. The similar fatty acids composition of chylomicron phospholipids following fish oil and seal oil administration and the similarities between the oils administered and the chylomicron TAG indicate that the phosphatidic pathway mainly contributed to phospholipid synthesized, whereas the TAG were synthesized by the MAG pathway. A reduction in long-chain fatty acids (20–22 carbon fatty acids) of the MAG from enterocytes compared with those recovered from the micellar phase of the lumen following digestion of menhaden oil (22) may reflect a total degradation of these MAG within the enterocytes or a special utilization of monoacylglycerols containing n-3 PUFA.

The predominant fatty acids in the phospholipids of chylomicrons were fatty acids of "endogenous?" origin, and the phospholipids seemed to transport the n-3 PUFA of dietary origin to a minor degree, especially when the amount of phospholipid (6–8 wt%) relative to TAG (90 wt%) in chylomicrons (23) was taken into consideration. The high levels of 20:5n-3 and 22:6n-3 found in the TAG of chylomicrons following fish oil and seal oil administration indicated that the n-3 PUFA were well absorbed under the present experimental conditions.

Our study demonstrates that n-3 PUFA are esterified at different positions within the TAG of chylomicrons following administration of different polyunsaturated oils, such as fish and seal oils. Extensive studies with model TAG, such as 1,2-dioleyl-3-stearyl-*sn*-glycerol and 1,3-dioleyl-2-stearyl-*sn*-glycerol, have demonstrated that the TAG structure affects the clearance of TAG and the removal of chylomicron remnants (24–26). Previously, we have demonstrated different metabolism of fish oil chylomicrons compared with seal oil chylomicrons. These findings may be explained by differences in the intramolecular fatty acid distribution of TAG due to either different hydrolysis rates of TAG by lipoprotein lipase or by different surface properties of the resultant 2-MAG affecting the metabolism of chylomicron particles.

Dietary Long-Chain Polyunsaturated Fatty Acids Modify Heart, Kidney, and Lung Fatty Acid Composition in Weanling Rats

A. Suárez, M.J. Faus, and A. Gil*

Department of Biochemistry and Molecular Biology, University of Granada, 18071 Granada, Spain

ABSTRACT: The fatty acid composition of heart, kidney, and lung was studied in weanling rats fed three diets differing in their polyunsaturated fatty acid content for 0, 2, and 4 wk. The first group had a 10% w/w fat semipurified diet which consisted of a mixture of olive oil (62.5%), soybean oil (11.1%), and refined coconut oil (26.4%) and provided 18:1n-9, 18:2n-6, and 18:3n-3 in similar amounts to a maternal human milk (diet HO). The second group received 7% of HO fat and 3% fish oil (0.4% 20:4n-6 and 5% 22:6n-3 of total fatty acids) (diet FO), and the third group was fed 7% HO fat, 1.5% of the same fish oil, and 1.5% of a purified pig brain phospholipid concentrate (0.6% 20:4n-6 and 3.5% 22:6n-3 of total fatty acids) (diet FO + BPL). The experimental diets increased tissue monounsaturated fatty acids in comparison with rats at weaning. Tissue lipid content of 20:4n-6 was increased and 22:6n-3 decreased in Group HO compared with weanling rats, whereas opposite changes were observed in Group FO. Feeding diet FO + BPL increased 22:6n:3 in tissue lipids compared with diet HO, and increased 20:4n-6 content in relation to diet FO. Our results indicate that rat heart, kidney, and lung are highly responsive to dietary n-3 and n-6 long-chain polyunsaturated fatty acids during postnatal life.
Lipids 31, 345–348 (1996).

Deficient tissue 22:6n-3 accretion has been linked to abnormal electroretinograms in premature human infants (1), monkeys (2), and rats (3). Diets supplemented with n-3 long-chain polyunsaturated fatty acids (LC-PUFA) increase 22:6n-3 content in tissue lipids, and may affect visual function in infants (1) and learning ability in rats (4). However, prolonged feeding with n-3 LC-PUFA–supplemented formulas has been associated with lower head circumference in premature infants (5), reduced pup brain weight in rats (4), and decreased plasma and erythrocyte membrane 20:4n-6 in both neonates (6) and rats (7). In addition, a direct correlation between 20:4n-6 status of preterm infants and growth has been described (8). Feeding formulas supplemented with animal fat blends containing n-6 and n-3 LC-PUFA promoted acceptable levels of 20:4n-6 and 22:6n-3 in plasma and erythrocyte lipids in neonates (9) and in rats (10,11). However, the degree to which dietary 20:4n-6 and 22:6n-3 modify fatty acid composition of other tissues, such as heart, kidney, and lung, is unknown.

The aim of this study was to compare the fatty acid composition of heart, kidney, and lung in weanling rats fed on diets supplemented with preformed 20:4n-6 and 22:6n-3. Results on fatty acid composition of plasma lipids, erythrocyte membrane lipids, liver microsome phospholipids, and brain lipids have been previously described (10).

EXPERIMENTAL PROCEDURES

Animal experiments. Male Wistar rats at weaning (21 d) were purchased from Interfauna Iberica S.A. (Barcelona, Spain). Animals had no access to solid food. Seven rats were killed under anesthesia by terminal bleeding and used as control animals at weaning. The rest were randomly divided into three groups of 14 rats each. Rats received a 10% w/w fat semipurified diet and had free access to water. Group HO fat consisted of a mixture of olive oil (62.5%), soybean oil (11.1%), and refined coconut oil (26.4%) (devoid of LC-PUFA); group FO received 7% of group HO fat and 3% deodorized Spanish sardine oil (0.4% 20:4n-6 and 5.0% 22:6n-3 of total fatty acids); group FO + BPL was fed 7% group HO fat, 1.5% of the same fish oil concentrate, and 1.5% of a purified pig brain phospholipid concentrate rich in both 20:4n-6 and 22:6n-3 (0.6% 20:4n-6 and 3.5% 22:6n-3 of total fatty acids). The detailed composition of the diets has been previously described (10). Diets were prepared by the Research & Development Department of PULEVA S.A. (Granada, Spain).

After two and four weeks of feeding, seven animals from each group and feeding period were fasted for 24 h, anesthetized, and killed. Heart, kidney, and lung tissues were excised and processed immediately for extraction of total lipids (12). Fatty acids were methylated and separated by capillary gas chromatography as previously described (9).

Statistics. To evaluate the effect of three diets and two feeding periods, a two-way analysis of variance and a posteriori comparisons of means were done using the Bonferroni test (13). Comparisons with the baseline group were done

with the Dunnest test (13). The level of statistical significance was determined at $P < 0.05$.

RESULTS AND DISCUSSION

Tables 1 to 3 show the proportions of selected LC-PUFA and the sum of saturated fatty acids (SAT), monounsaturated fatty acids (MONO), and n-6 and n-3 LC-PUFA in heart, kidney, and lung lipids, respectively. No major differences were observed for SAT among groups and feeding periods except for group HO, which had significantly lower levels of SAT in heart at two and four weeks of feeding and in lung at two weeks in relation to weanling rats and group FO + BPL. Consistent with previous studies by our group of rats at weaning (10), the significant increases in MONO in heart, kidney, and lung lipids in all experimental groups compared with values at weaning are related to the relatively high content of 18:1n-9 in the diets, as it occurs in maternal human milk (14). Previous reports showed that high monounsaturated diets increased the levels of 18:1n-9 and MONO in erythrocyte membrane phospholipids in term infants (15) and in erythrocyte membrane phospholipids and liver microsomal phospholipids in rats at weaning (16).

After four weeks, group HO, which received a diet with an 18:2n-6/18:3n-3 ratio of 6:1 and devoid of LC-PUFA, had significantly lower total n-3 and total n-6 LC-PUFA values in heart, lung, and kidney lipids than rats at weaning. Within LC-PUFA, 20:4n-6 and 22:6n-3 were the major affected LC-PUFA in tissue lipids in group HO. These results suggest that the exclusive supply of 18:2n-6 and 18:3n-3 may not be sufficient to maintain tissue levels of 20:4n-6 and 22:6n-3 during postnatal life. The addition of fish oil to diet (group FO) significantly increased tissue 20:5n-3, 22:6n-3, and total n-3 LC-PUFA levels, whereas 20:4n-6 decreased in relation to diet HO and weanling rats.

The most interesting findings were that diet FO + BPL, which had a higher 20:4n-6 content than diet FO, increased not only heart, kidney, and lung 20:5n-3 and 22:6n-3, but also 20:4n-6 as compared with diet FO. Thus, a reduction of 22:6n-3/20:4n-6 ratio from 12.5 (diet FO) to 5.8 (diet FO + BPL) favored efficient 20:4n-6 incorporation to tissue lipids. Reduction of n-3 LC-PUFA content in diet FO + BPL could also result in a lower inhibition of 20:4n-6 synthesis from 18:2n-6 and incorporation into tissue lipids. Although our data do not allow us to make a conclusive statement on the beneficial or detrimental effects of dietary supplementation with n-3 and n-6 LC-PUFA on organ function during postnatal development, these results suggest that the level and type of dietary n-3 and n-6 fatty acids significantly modify tissue LC-PUFA in rats at weaning during postnatal life, and that incorporation of LC-PUFA to infant formulas should be carefully evaluated.

Reaction of Lipids Containing Hydroxy Groups with Trimethylsulfonium Hydroxide: Formation of *O*-Methyl Derivatives

Klaus Vosmann[a], Erhard Schulte[b], Erika Klein[c], and Nikolaus Weber[c,*]

[a]Institut für Chemie und Physik der Fette, BAGKF, D-48147 Münster, [b]Institut für Lebensmittelchemie der Universität, D-48147 Münster, and [c]Institut für Biochemie und Technologie der Fette, H.P. Kaufmann-Institut, BAGKF, D-48147 Münster, Germany

ABSTRACT: Base-catalyzed transesterification of acyl lipids with trimethylsulfonium hydroxide (TMSH) is an easy and convenient method for the preparation of fatty acid methyl esters (FAME) for gas chromatography (GC) analyses. We have found, however, that lipids containing hydroxy groups are partially converted to the corresponding *O*-methyl ether derivatives which may interfere with FAME in GC separations. For example, long-chain alcohols are found to be converted to alkyl methyl ethers, *rac*-1-*O*-alkylglycerols to the corresponding 2-*O*- and 3-*O*-monomethyl ethers, as well as 2,3-di-*O*-methyl ethers, hydroxy fatty acids to methoxy FAME, and cholesterol to cholesteryl 3β-methyl ether. From our results, it is obvious that TMSH derivatization method is not recommended without limitation for lipids containing hydroxy groups; it may be, however, of some diagnostic value for the analysis of such lipids by GC/mass spectrometry.

Lipids 31, 349–352 (1996).

Fatty acid methyl esters (FAME) are the most common derivatives for the analysis of fatty acids by gas chromatography (GC) (1,2). Recently, a very convenient method has been described for the derivatization of acyl lipids to FAME by using trimethylsulfonium hydroxide (TMSH) as the reagent (2–5). This method is based on earlier publications which have drawn attention to the advantage of this mild methylation reagent for the preparation of FAME for GC analysis (6,7). It was also shown that FAME are formed by base-catalyzed transesterification of acyl lipids such as triacylglycerols, whereas unesterified fatty acids are methylated by pyrolytic decomposition of the corresponding TMSH salts (7). Here we report about the limitations of the use of TMSH in derivatization of lipids for GC analyses in the case that appreciable proportions of lipids containing hydroxy groups are present in the sample.

Abbreviations: FAME, fatty acid methyl esters; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; TMSH, trimethylsulfonium hydroxide.

MATERIALS AND METHODS

Chemicals. Long-chain alcohols, cholesterol, and methyl methanesulfonate were purchased from E. Merck (Darmstadt, Germany). Hydroxy and epoxy fatty acids, as well as cholesteryl 3β-methyl ether, were products of Sigma-Aldrich (Deisenhofen, Germany). TMSH reagent (0.2 M TMSH in methanol) was a product of Macherey-Nagel (Düren, Germany). Monomethylethers of *rac*-1-*O*-alkylglycerols were obtained from Calbiochem-Novabiochem (Bad Soden, Germany) and Berchtold (Bern, Switzerland).

Preparation of standards. FAME were prepared by the reaction of free fatty acids with diazomethane (8). *rac*-1-*O*-Alkylglycerols, *rac*-1-*O*-alkyl-2,3-di-*O*-methylglycerols, and methyl ethers of long-chain alcohols were prepared according to the procedure of Baumann and Mangold (9) by the use of alkyl methanesulfonates or methyl methanesulfonate. Methoxy FAME were prepared from the corresponding hydroxy FAME by the reaction with diazomethane in the presence of silica gel (10).

Derivatization for GC. To a solution of 0.8 mg lipid containing hydroxy groups in 40 μL *t*-butyl methyl ether, 20 μL TMSH reagent were added. The derivatization mixture was used immediately for GC.

GC. GC of was carried out using a Hewlett-Packard (Böblingen, Germany) HP-5890 Series II gas chromatograph fitted with a flame-ionization detector. *O*-Methyl ether derivatives of lipids were separated on a 0.15 μm FFAP-CB fused silica capillary column (Macherey-Nagel), 25 m × 0.25 mm i.d. The alkyl methyl ethers were separated using nitrogen as carrier gas (linear velocity 20 cm/s) initially at 160°C for 6 min, followed by linear programming from 160 to 240°C at 4°C per min. The final temperature was kept constant for 10 min. The split ratio was 1:10; the injector as well as flame-ionization detector temperature was 270°C. GC peaks were assigned by comparison of their retention times with those of known standards. Methoxy FAME as well as *O*-methyl derivatives of *rac*-1-*O*-alkylglycerols were separated under similar conditions using a linear temperature program from 160 to 240°C at 8°C per min. The final temperature was kept constant for 20 min. Cholesteryl 3β-methyl ether was separated isothermically at 240°C.

GC/mass spectrometry (MS). GC/MS of *O*-methyl derivatives was performed at electron impact mode (70 eV) and chemical ionization mode (230 eV; methane as reagent gas, 160 Pa) on a Hewlett-Packard instrument Model 5890 Series II/5989 A (Palo Alto, CA). The GC instrument was equipped with a 0.23 μm Permabond OV-1 fused silica capillary column (Macherey-Nagel) 25 m × 0.32 mm i.d. The carrier gas was He at a flow rate of 1.0 mL/min. The column temperature was initially kept at 150°C for 5 min and then programmed from 150 to 270°C at 4°C/min; the final temperature was held for 5 min. Other operating conditions were split/splitless injector in splitless mode (temperature 300°C), interface temperature 280°C, and ion source temperature 200°C. Structural assignments were made for purchased genuine methoxy lipid standards and methoxy derivatives prepared from authentic samples by established procedures. Peaks of methoxy derivatives of hydroxy lipids obtained by the reaction with TMSH were assigned a structure if ions corresponding to all the important mass fragments of Table 1 were present, and no other high mass ions were detected.

RESULTS AND DISCUSSION

Single compounds or mixtures of lipids containing hydroxy groups, such as long-chain alcohols, alkylglycerols, hydroxy fatty acids, and cholesterol, were reacted with TMSH under pyrolytic conditions in order to study the possible formation of artefactual derivatives which may interfere with the GC analysis of FAME.

Figure 1 shows the gas chromatogram of the reaction products of a mixture of 1-hexadecanol and 1-octadecanol with TMSH. Obviously around 30% of the alcohols were transformed to the corresponding 1-*O*-methyl ethers, i.e., hexadecyl methyl ether and octadecyl methyl ether, which were

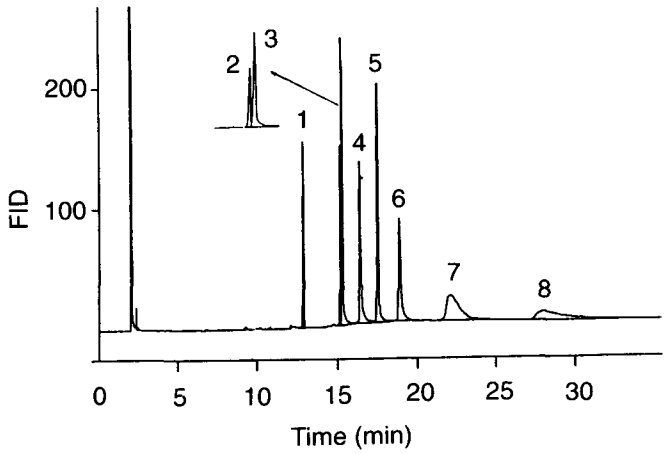

FIG. 2. Gas chromatogram of the reaction products of a mixture of *rac*-1-*O*-hexadecylglycerol and *rac*-1-*O*-octadecylglycerol with trimethylsulfonium hydroxide (1, *rac*-1-*O*-hexadecyl-2,3-di-*O*-methylglycerol; 2, *rac*-1-*O*-octadecyl-2,3-di-*O*-methylglycerol; 3, *rac*-1-*O*-hexadecyl-3-*O*-methylglycerol; 4, *rac*-1-*O*-hexadecyl-2-*O*-methylglycerol; 5, *rac*-1-*O*-octadecyl-3-*O*-methylglycerol; 6, *rac*-1-*O*-octadecyl-2-*O*-methylglycerol; 7, *rac*-1-*O*-hexadecylglycerol, not reacted; 8, *rac*-1-*O*-octadecylglycerol, not reacted); see Figure 1 for abbreviation.

identified by comparison with standards as well as by GC/MS (Table 1). The most important mass fragments for the structural assignment of the primary long-chain alcohols were the $[M\text{-}CH_3OH]^+$ ions which are typical of the *O*-methyl ether structure. Other structurally important intense ions have not been found. These observations are consistent with the literature (11). Molecular weight was determined in all samples, i.e., alkylmethyl ethers, alkylmethylglyceryl ethers, methoxy FAME, and cholesteryl 3β-*O*-methyl ether, by chemical ionization MS.

The gas chromatogram of the reaction products formed from a mixture of *rac*-1-*O*-hexadecylglycerol and *rac*-1-*O*-octadecylglycerol with TMSH is shown in Figure 2. The six reaction products observed in addition to the nonreacted alkylglycerols were identified by comparison with authentic standards as well as by GC/MS (Table 1) as the isomeric 2-*O*-methyl and 3-*O*-methyl 1-*O*-alkylglycerols, respectively, and the corresponding 2,3-di-*O*-methyl ether derivatives. In most electron impact spectra, small proportions of $[M + 1]^+$ ions have been observed. Earlier studies have also shown $[M + 1]^+$ ions for saturated long-chain alcohols (11), whereas $[M + 1]^+$ peaks have not been detected for alkylglyceryl ethers (12). Fragments with two, three, or four carbon atoms were found to be typical cleavage products of the glycerol backbone of alkyl(methyl)glyceryl ethers (Table 1) which is consistent with the literature (13). It is interesting to note that the 3-*O*-methyl derivatives are formed in higher proportions than the 2-*O*-methyl derivatives (ratio around 1:0.8; yield of mono- plus dimethyl derivatives around 80%), suggesting that different sterical effects are operative in the *O*-methylation at positions 2 and 3 of 1-*O*-alkylglycerols.

Figure 3 shows the gas chromatogram of the reaction products of a mixture of 12-hydroxystearic acid and ricinoleic acid with TMSH. Obviously, the free fatty acids were converted completely to the methyl esters. In addition, small proportions of methyl 12-methoxystearate and methyl 12-methoxyoleate (around 3 to 5%, each) are formed as confirmed by comparison with standards as well as by GC/MS (Table 1). The loss of CH_3OH fragments is typical of lipids containing methyl ether and methyl ester groups (14); the fragments at *m/e* 243, 211, 197, and 97 clearly show the position of the methoxy group at the acyl backbone. Surprisingly, both methyl *erythro*- and *threo*-9,10-dihydroxyoctadecanoates were con-

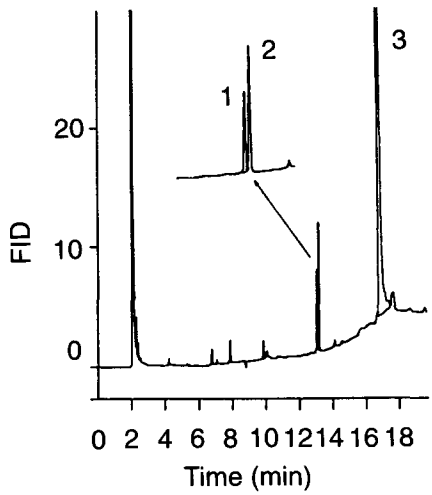

FIG. 3. Gas chromatogram of the reaction products of a mixture of 12-hydroxy stearic acid and ricinoleic acid with trimethylsulfonium hydroxide (1, 12-methoxy stearic acid methyl ester; 2, 12-methoxy octadec-9-enoic acid methyl ester; 3, 12-hydroxy stearic acid methyl ester plus ricinoleic acid methyl ester); see Figure 1 for abbreviation.

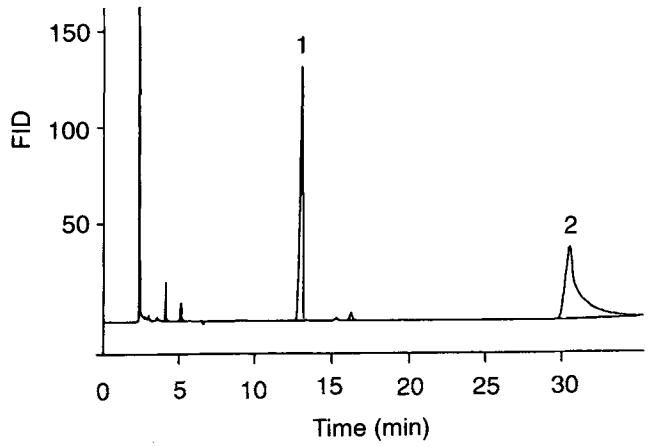

FIG. 4. Gas chromatogram of the reaction products of cholesterol with trimethylsulfonium hydroxide (1, cholesteryl 3β-*O*-methyl ether; 2, cholesterol, not reacted). See Figure 1 for abbreviation.

verted to the monomethoxy plus dimethoxy derivatives to an extent of around 60% (data not shown), demonstrating a positive effect of the vicinal hydroxy groups on *O*-methyl ether formation. A similar effect was observed for the vicinal hydroxy groups of 1-*O*-alkylglycerols.

It is evident from Figure 4 that cholesteryl 3β-*O*-methyl ether is formed in high proportions (around 40%) by reacting cholesterol with TMSH. The 3-*O*-methyl derivative was identified by comparison with an authentic standard as well as by GC/MS (Table 1). In addition, mass spectrum of cholesteryl 3β-*O*-methyl ether agreed with that given in the literature (15).

In conclusion, our data clearly show that *O*-methyl ether derivatives are formed, in part, from lipids containing hydroxy groups during pyrolytic reaction conditions in the GC injector, whereas the hydroxy groups do not react with the TMSH reagent at room temperature (data not shown). In GC, peaks of the *O*-methyl derivatives may interfere partially with peaks of FAME and, therefore, lead to erroneous results. The use of TMSH is not generally recommended, therefore, for the analysis of lipids containing hydroxy groups. It can be of some diagnostic value, however, for the detection of these lipids in samples. In contrast to lipids with hydroxy groups, epoxy fatty acids such as *cis*- and *trans*-9,10-epoxystearic acids are converted to the corresponding FAME without further derivatization (data not shown).

Studies are in progress concerning methods which enable us to circumvent the disturbing effects of *O*-methyl ether formation on FAME analyses of, e.g., wax esters, hydroxy fatty acids, and animal lipids with high proportions of ether glycerolipids.

Effect of α-Tocopherol and Trolox on the Decomposition of Methyl Linoleate Hydroperoxides

Anu Hopia[1], Shu-Wen Huang, and Edwin N. Frankel*

Department of Food Science and Technology, University of California, Davis, California 95616

ABSTRACT: To clarify the mechanisms of antioxidant action, the effect of α-tocopherol and its water-soluble carboxylic acid derivative, Trolox, was studied on the decomposition of methyl linoleate hydroperoxides (MeLoOOH). Decomposition rate and the distribution of autoxidation products formed from MeLoOOH were followed by analyzing the volatile and nonvolatile products by static headspace gas chromatography and normal-phase high-performance liquid chromatography, respectively. Both α-tocopherol and Trolox markedly inhibited the decomposition of MeLoOOH in a concentration-dependent way. In the absence of antioxidants, MeLoOOH was completely decomposed after incubation for 48 h at 60°C, and in the presence of equal molar concentration of antioxidants only 6–7% of initial MeLoOOH was decomposed even after 280 h of incubation. MeLoOOH produced 1.2% methyl linoleate hydroxy compounds (MeLoOH) in the presence of α-tocopherol and 3.8% in the presence of Trolox. Both antioxidants inhibited the formation of volatile decomposition products and the formation of ketodiene compounds. The hydroxy compounds may be formed by the reaction of alkoxy radical and hydrogen donating antioxidants. Conversion of MeLoOOH into stable MeLoOH demonstrated that the antioxidants α-tocopherol and Trolox trap alkoxyl radicals by H-donation.

Lipids 31, 357–365 (1996).

Major focus of the research on antioxidants has been directed on their ability to inhibit hydroperoxide formation (1–3), but less attention has been given on their effectiveness to inhibit the decomposition of lipid hydroperoxides. Phenolic antioxidants, such as tocopherols, not only inhibit the formation of lipid hydroperoxides, but also are known to have an effect on the decomposition of hydroperoxides. At high concentration, α-tocopherol can suppress further reactions of methyl linoleate (MeLo) and linolenate monohydroperoxides by donating hydrogen to peroxyl radical, thus inhibiting formation of *trans,trans* monohydroperoxide isomers in MeLo and cyclic hydroperoxides in methyl linolenate (4,5). α-Tocopherol (6) and other phenolic antioxidants (7) modify the proportions of volatile decomposition products of methyl linoleate hydroperoxides (MeLoOOH) and reduce the total amount of volatile decomposition products. During autoxidation of corn oil, α-tocopherol reduced the formation of hexanal derived from linoleate hydroperoxides (8). Previous research on the effect of tocopherols on the decomposition of hydroperoxides is conflicting, and this may be due to different experimental conditions and concentration of antioxidants. In 2.5 mM aqueous solution of free linoleic acid, the addition of 0.625 μM–0.625 mM of α-, γ-, and δ-tocopherols increased the stability of linoleic acid hydroperoxides (9). However, addition of 7 μmoles α-tocopherol to MeLoOOH in benzene solution (75 μmoles in 30 mL representing 2.5 mM solution) did not influence the amount decomposed by Cu(II) ions (10). Previous work on hydroperoxide decomposition was performed mainly using metal or radical catalysts (10,11), or on fatty acids (9,12–15). Very little work has been reported on the effects of antioxidants on thermal decomposition of hydroperoxides. Because the secondary decomposition products are mainly responsible for causing rancidity in foods, as well as damage in biological material, it is also of high importance to study the effect of antioxidants on decomposition of hydroperoxides and the formation of secondary decomposition products.

The aim of this work was to clarify the mechanisms of α-tocopherol and its water-soluble derivative, Trolox, in inhibiting the formation of volatile and nonvolatile decomposition products from MeLoOOH. The formation of selected volatile and nonvolatile decomposition products was followed by static headspace gas chromatography (GC) and by normal-phase high-performance liquid chromatography (HPLC), respectively.

MATERIALS AND METHODS

Materials. MeLo was supplied by Nu-Chek-Prep, Inc. (Elysian, MN), hexadecane and α-tocopherol by Sigma Chemicals Co. (St. Louis, MO), and Trolox by Aldrich Chemical Company, Inc. (Milwaukee, WI). Hexane and diethyl ether were purchased commercially (Fisher Scientific, Fairlawn, NJ). All the solvents were HPLC grade.

Preparation of MeLoOOH. Hydroperoxides of MeLo were prepared from autoxidized MeLo by chromatography (16) (Sep-pak silica cartridge; Waters Chromatography Division, Milford, MA). The hydroperoxide fraction was shown to be

pure by thin-layer chromatography and had an absorptivity of 24,000 at 234 nm.

Decomposition of MeLoOOH. MeLoOOH or a 1:1 mixture of unoxidized MeLo and MeLoOOH (20 mM each) was dissolved in hexadecane solution in the absence or in the presence of 2 and 40 mM α-tocopherol or Trolox. MeLoOOH and α-tocopherol were soluble in hexadecane, but Trolox was only slightly soluble, and formed cloudy suspensions. Lipid solutions were incubated at 60°C for up to 282 h with continuous shaking. Sample aliquots for HPLC and GC analyses were taken at regular intervals.

HPLC analysis. Nonvolatile autoxidation products were analyzed by normal-phase HPLC, by a modified method of Tokita and Morita (17), using a Hewlett-Packard (Palo Alto, CA) model HP 1090 system equipped with a diode array detector. Particle size of the silica column was 5 μm (Supelco 25 cm × 2.1 mm; Bellefonte, PA). The solvent system was hexane/diethyl ether (85:15, vol/vol) with a flow rate of 0.3 mL/min. Ethanol used to stabilize diethyl ether was removed by silica column chromatography prior to the HPLC analysis. Autoxidation products were monitored at 233 nm (conjugated dienes), 210 nm (ester bond), and 268 nm (ketodienes). Tocopherols were monitored at 295 nm.

GC analysis of volatile decomposition products. Hexadecane solution (100 mg of 40 mM lipid solution) was weighed into 6-mL headspace vials. The hexanal formed was analyzed by static headspace capillary GC (16). The results were calculated as millimoles hexanal per kilogram hexadecane solution.

RESULTS

HPLC analysis of MeLoOOH decomposition products in the presence of α-tocopherol and Trolox. The main advantage of the HPLC method was the possibility of simultaneously monitoring MeLoOOH and formation of two important groups of decomposition products. The decomposition rate of hydroperoxides and formation of hydroxy compounds were monitored as total areas of four peaks (Fig. 1). Formation of ketodiene compounds was monitored as total areas of the two peaks in the chromatogram (Fig. 1A, peaks 1 and 2) having an absorption maximum at 268 nm in this solvent system (Fig. 2, spectrum 3), which is characteristic for ketodiene compounds (18). Total peak areas of these compounds were converted to percentage of the initial content of hydroperoxides by using the extinction coefficient of 28,600 for hydroperoxides (19), 27,200 for hydroxy compounds (19), and 28,000 for ketodiene compounds (18).

Elution order of the identified compounds was as follows: peaks 1 and 2, ketodienes; peaks 3–6, 13-*cis,trans* MeLoOOH, 13-*trans,trans* MeLoOOH, 9-*cis,trans* MeLoOOH, 9-*trans,trans* MeLoOOH; peaks 7–10, 13-*cis,trans* MeLoOH (methyl linoleate hydroxy compounds), 13-*trans,trans* MeLoOH, 9-*cis,trans* MeLoOH, 9-*trans,trans* MeLoOH (Fig. 1). Tentative identification of the MeLoOOH isomers was based on the ultraviolet spectra of the compounds (Fig. 2, spectras 1 and 2) and on the elution order reported in the literature (17,19). Retention times of the hydroxy compounds were confirmed with a reference sample prepared by reducing MeLoOOH mixture with $NaBH_4$. α-Tocopherol eluted before ketodienes (Fig. 1D, peak 11). Trolox could also be monitored by HPLC (Fig. 1C, peak 12). However, as it was only sparingly soluble in hexadecane, Trolox could not be measured quantitatively.

Effect of antioxidants on the decomposition of pure MeLoOOH. Both α-tocopherol and Trolox significantly inhibited the decomposition of MeLoOOH (Fig. 3). In the absence of antioxidants, 94% of initial MeLoOOH decomposed during the first 48 h at 60°C, whereas only 0–6% decomposed in the presence of antioxidants. After 282 h of incubation, MeLoOOH decomposed only 8.4% in the presence of 40 mM α-tocopherol and 11% in the presence of 40 mM Trolox. α-Tocopherol at 2 mM inhibited MeLoOOH decomposition up to 48 h, but Trolox was as effective at 2 mM as at 40 mM in inhibiting this decomposition for 282 h.

Antioxidants were detected in the samples until MeLoOOH started to decompose (Fig. 3). α-Tocopherol at 2 mM decomposed completely after 48 h incubation, and at 40 mM approximately 20% decomposed after 282 h incubation (Fig. 3B). Trolox was detected in the samples at 2 mM and 40 mM level, and samples also contained nonsolubilized Trolox after 282 h of incubation.

In the presence of antioxidants, the hydroxy derivatives (MeLoOH) produced represented 1.2–3.5% of initial MeLoOOH (Fig. 4A). Formation of MeLoOH was highest in the presence on 40 mM Trolox (3.5% of initial MeLoOOH), followed by 2 mM Trolox sample (2.1%) and 40 mM α-tocopherol (1.2%). With 40 mM Trolox, 1.5% MeLoOH was present initially after sample preparation. In the control sample, MeLoOH increased up to 0.5% during the first 20 h. However, the concentrations of MeLoOH compounds decreased rapidly in this sample during further incubation.

Ketodiene compounds were formed simultaneously with the rapid decomposition of hydroperoxides (Fig. 4B). In the control sample, ketodiene compounds increased from 0.3% of the initial MeLoOOH up to 4% after the first 20 h of incubation, and then decreased to 1.8% after 120 h of incubation. In the presence of α-tocopherol and Trolox, the formation of ketodiene compounds was inhibited together with the stabilization of hydroperoxides. Thus, after 282 h of incubation, 1.1% of ketodienes was formed in the presence of 40 mM Trolox, 0.9% in the 2 mM Trolox sample, and 1.6% in the 40 mM α-tocopherol sample (Table 1). In the presence of 2 mM α-tocopherol, the formation of ketodienes was inhibited during the first 48 h, increased rapidly to 2.8% when hydroperoxides started to decompose, and then decreased to 1.0% after 282 h of incubation.

Hexanal is a major volatile decomposition product of linoleate hydroperoxides (6,7). Both antioxidants inhibited hexanal formation effectively (Fig. 4C). Hexanal content increased initially in the control sample. In the presence of 2 mM α-tocopherol, hexanal increased simultaneously with

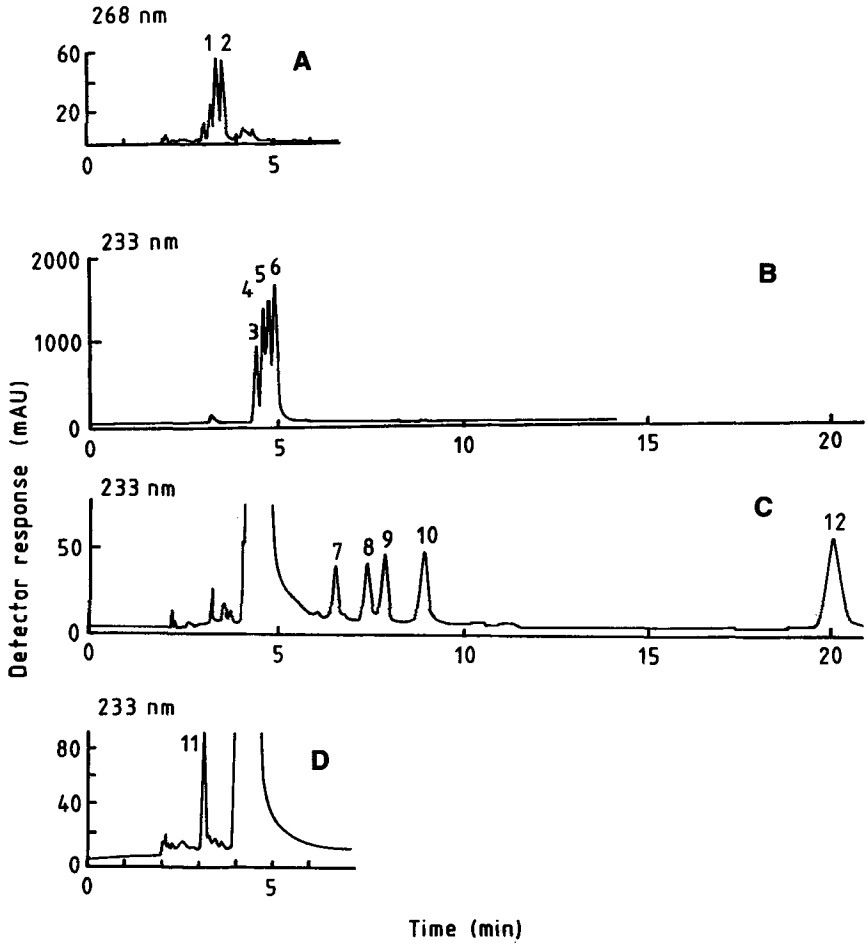

FIG. 1. High-performance liquid chromatographic (HPLC) chromatogram of oxidation products in the presence of antioxidants. Chromatographic conditions: silica column (5 μm, 25 cm × 2.1 mm), hexane/diethyl ether (85:15, vol/vol), flow rate of 0.3 mL/min. Autoxidation products were monitored at 233 nm (conjugated dienes) and 268 nm (ketodienes), and tocopherols and Trolox at 295 nm. Elution order of oxidation products: A, peaks 1 and 2, ketodienes; B, peaks 3–6, 13-*cis,trans* methyl linoleate hydroperoxides (MeLoOOH), 13-*trans,trans* MeLoOOH, 9-*cis,trans* MeLoOOH, 9-*trans,trans* MeLoOOH; C, peaks 7–10, 13-*cis,trans* methyl linoleate hydroxy compounds (MeLoOH), 13-*trans,trans* MeLoOH, 9-*cis,trans* MeLoOH, 9-*trans,trans* MeLoOH. Elution order of antioxidants: C, peak 12, Trolox; D, peak 11, α-tocopherol.

MeLoOOH decomposition after a lag period of 48 h. Hexanal formation was completely inhibited in the presence of 2 mM Trolox or 40 mM α-tocopherol and Trolox. After 282 h incubation, only 0.06 to 0.13 mmol/kg of hexanal was formed in the presence of 40 mM α-tocopherol or Trolox, compared to 2.24 mmol/kg after 48 h incubation in the absence of antioxidants.

Effect of antioxidants on the MeLo/MeLoOOH (1:1) mixture. The influence of unsaturated fatty acids as competitive hydrogen donors on the secondary reactions of hydroperoxides was investigated by decomposing MeLoOOH in the presence of unoxidized MeLo. In a mixture of MeLo (20 mM) and MeLoOOH (20 mM), changes in the rate of MeLoOOH decomposition, as well as formation of hexanal, MeLoOH, and ketodiene were similar, but lower than in pure MeLoOOH. After 282 h incubation, the amount of undecomposed MeLoOOH was 90.6% with 40 mM α-tocopherol, 88.9% with 40 mM Trolox, and 83.3% with 2 mM Trolox (Table 1). Oxidation of MeLo occurred in the sample containing 40 mM α-tocopherol, and the hydroperoxide content increased from 100% initially up to 123% during the first 114 h of incubation (Fig. 5A). α-Tocopherol apparently had a prooxidant effect at the 40 mM level. In the presence of 2 mM α-tocopherol, the hydroperoxides started to decompose after 114 h, and after 282 h of incubation only 15% of initial MeLoOOH was left undecomposed. Also, α-tocopherol was consumed after 120 h (Fig. 5B).

As with pure MeLoOOH, in the presence of MeLo, MeLoOH was produced in the presence of α-tocopherol and Trolox (Fig. 6A). After 330 h incubation, 3.17% MeLoOH

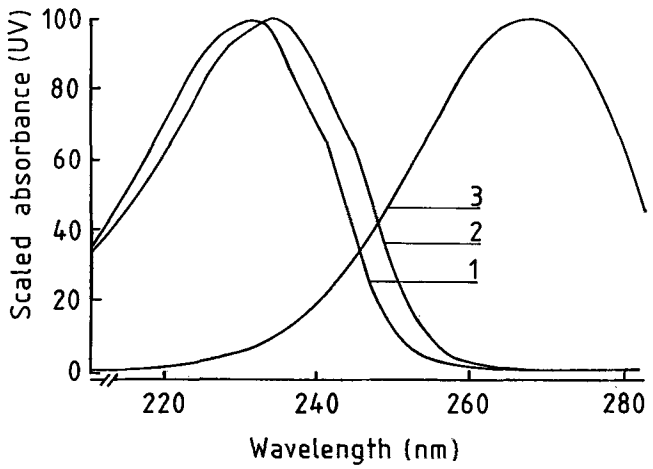

FIG. 2. Ultraviolet (UV) spectra of *trans,trans* (spectrum 1, combined peaks 4 and 6 in Fig. 1B) and *cis,trans* (spectrum 2, combined peaks 3 and 5 in Fig. 1B) hydroperoxides with absorption maximum of 230 and 235 nm, respectively, and ketodiene compounds (spectrum 3, combined peaks 1 and 2 in Fig. 1A) with absorption maximum at 268 nm.

was formed with 40 mM Trolox, 1.55% with 2 mM Trolox, and 0.54% with 40 mM α-tocopherol. In the presence of 2 mM α-tocopherol, MeLoOH content increased up to 0.54% after 282 h, but decreased after 330 h of incubation. Also in the MeLoOOH/MeLo mixture, the formation of ketodienes (Fig. 6B) and hexanal (Fig. 6C) increased together with MeLoOOH decomposition. Thus, ketodiene formation was highest in the control sample, reaching a maximum value of 5.6% after 48 h and 5.26% in the presence of 2 mM of α-tocopherol after 282 h of incubation. Ketodiene compounds were not formed initially in the presence of 40 mM α-tocopherol, 40 mM Trolox, or 2 mM Trolox. After 282 h incubation, 2.0% ketodiene compounds were formed in the presence of 40 mM α-tocopherol, 2.0% in 40 mM Trolox, and 1.5% in the presence of 2 mM Trolox (Fig. 6B).

[a]MeLOOH, methyl linoleate hydroperoxides; MeLoOH, methyl linoleate hydroxy compounds; MeLo, methyl linleate. [b]Percentage of initial MeLOOH content. [c]All conversion products identified.

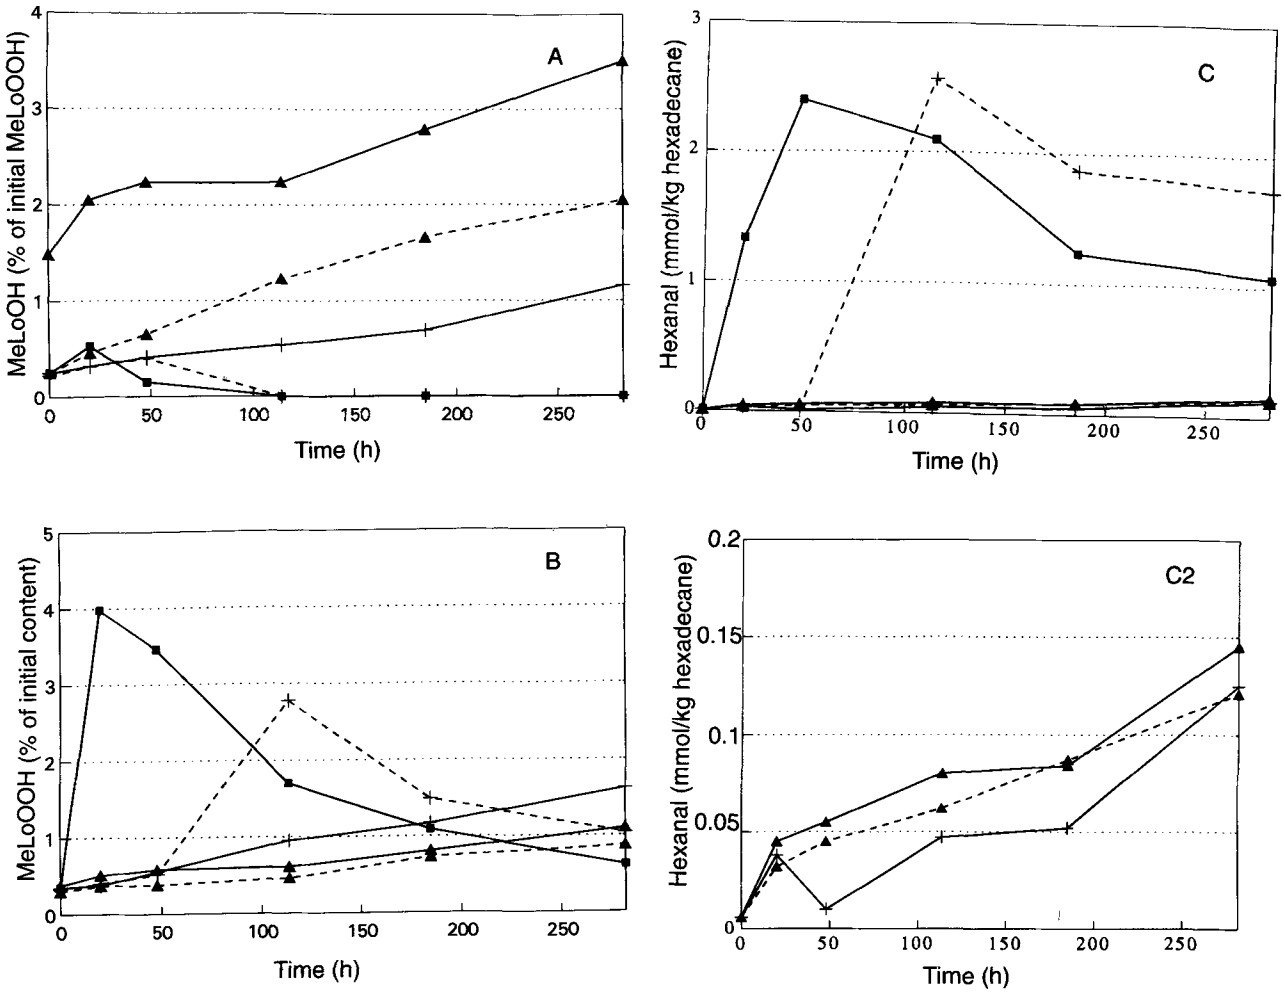

FIG. 4. A, Formation of hydroxy compounds; B, ketodiene compounds; C, hexanal, during decomposition of methyl linoleate hydroperoxides with or without antioxidant; C2, (C) with expanded y-axis. Samples in hexadecane solution. Legend as in Figure 3.

In the samples containing 40 mM α-tocopherol or Trolox and 2 mM Trolox, MeLoOH and ketodiene compounds were the major decomposition products of MeLoOOH, whereas in the highly decomposed samples a major part of the decomposition products was not detectable by the HPLC method used (Table 1). Thus, the conversion products that remained unidentified were 67% with 40 mM α-tocopherol, 99% with 2 mM α-tocopherol, 58% with 40 mM Trolox, and 54% with 2 mM Trolox (Table 1). More work is needed to further identify decomposition products other than hydroxy and ketodiene compounds.

DISCUSSION

The literature on decomposition of hydroperoxides deals mostly with lipids in the absence of antioxidants (10–15, 20,21). However, the pathways of decomposition would be expected to be markedly affected by the presence of hydrogen donating antioxidants. Decomposition of MeLoOOH leads to the same major products, such as ketodienes, hydroxy, epoxy and dimeric compounds, but in different ratios depending on whether the reaction proceeds through alkoxyl or peroxyl radical intermediates (10). Decomposition pathways of MeLoOOH depend markedly on the reaction conditions, and several mechanisms for lipid hydroperoxide decomposition have been suggested. According to the bond dissociation energies, the thermal decomposition of MeLoOOH may occur mainly through alkoxyl radical (44 kcal/mol) rather than through peroxyl radical (90 kcal/mol). However, the presence of transition metal ions may greatly affect the decomposition pathways. Peroxyl radicals may be produced by metal catalysts in their higher valence state, and alkoxyl radicals may be produced by metals in their lower valence state (22). MeLoOOH also have been shown to rearrange and decompose through pentadienyl radical (23). In this study no metal catalyst was added, but traces of metals are expected to be present in the reaction mixtures that would accelerate the decomposition of MeLoOOH at 60°C. Therefore, decomposition through alkoxyl radical is considered to be an important pathway.

The results of this study indicate that the phenolic antioxidants α-tocopherol and Trolox at high concentrations effi-

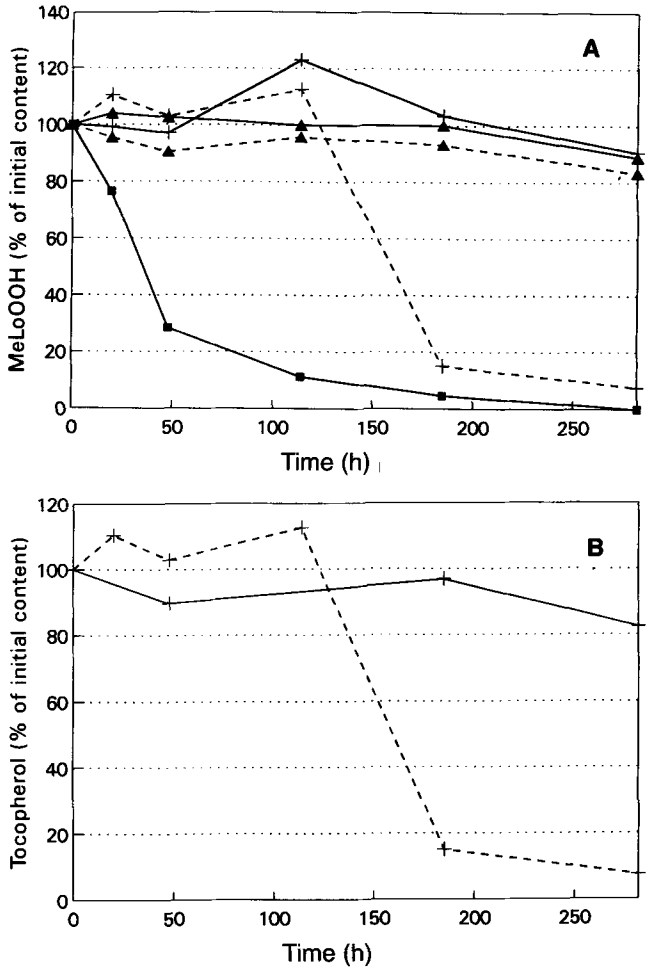

FIG. 5. Decomposition of methyl linoleate (MeLo) hydroperoxides (MeLoOOH) (A), and α-tocopherol (B), at 60°C. MeLoOOH/MeLo (20 mM each, 1:1) in hexadecane solution with or without antioxidants. Legend: —■— = 20 mM each of MeLoOOH and MeLo; —+— = 20 mM each of MeLoOOH and MeLo + 40 mM α-tocopherol; ---+--- = 20 mM each of MeLoOOH and MeLo + 2 mM α-tocopherol; —▲— = 20 mM each of MeLoOOH and MeLo + 40 mM Trolox; ---▲--- = 20 mM each of MeLoOOH and MeLo + 2 mM Trolox.

ciently inhibit the decomposition of MeLoOOH. This effect of α-tocopherol has been reported previously (6,9), but not for Trolox. This study provides, for the first time, evidence for the strong stabilizing effect of Trolox on lipid hydroperoxides. α-Tocopherol has been shown to inhibit decomposition of hydroperoxides in corn oil (8) and linoleic acid (9). Frankel and Gardner (6) observed that α-tocopherol at high concentrations decreases the total volatile products of MeLoOOH formed by thermal decomposition. They suggested that α-tocopherol at high concentration inhibits β-scission of alkoxyl radical (Eq. 1), leading to formation of aldehydes and hydrocarbons, by hydrogen donation.

$$R_2CH\text{–}O^{\bullet} \rightarrow RCHO + R^{\bullet} \quad [1]$$

Donation of the readily available hydrogen of α-tocopherol to alkoxyl radical would lead to formation of hydroxy compound (Eq. 2), through the following mechanism postulated by Bell *et al.* (24) and later by Hamberg (13) and Gardner (14):

$$RO^{\bullet} + RH \rightarrow ROH + R^{\bullet} \quad [2]$$

Because the oxy radical of an alkoxy is allylic and the oxy radical is located at a secondary carbon, straight abstraction of hydrogen (Eq. 2) is considered to be fairly insignificant in the absence of strong hydrogen donors (25). β-Scission (Eq. 1) producing aldehydes and intramolecular rearrangements producing epoxy compounds and dimers, as well as disproportionation, are considered more probable reaction pathways (25,26). However, strong hydrogen donors, such as α-tocopherol and Trolox, may markedly affect the reaction pathway involving alkoxy radical, and the conversion of MeLoOOH into MeLoOH would be favored, as observed in this study. Previously, Schieberle and Grosch (10) observed that the decomposition of MeLoOOH was inhibited by ascorbyl palmitate with the simultaneous formation of MeLoOH. Formation of MeLoOH was also detected during autoxidation of MeLo in the presence of ascorbyl palmitate (27).

In the present study, the decomposition of MeLoOOH was effectively inhibited by Trolox and α-tocopherol with the simultaneous formation of MeLoOH and no hexanal formation. These results support the hypothesis that in the presence of the strong hydrogen donors α-tocopherol and Trolox, hydrogen abstraction by alkoxyl radicals (Eq. 2) becomes more favorable than β-scission of alkoxyl radicals (Eq. 1), resulting in effective inhibition of hexanal formation. Because MeLoOH formation also increased in the presence of unsaturated fatty acid, which is a competitive hydrogen donor in lipid systems (28), the hydrogen source in the reaction is mainly the antioxidant (AH) (Eq. 3) rather than the unsaturated lipid (RH) (Eq. 2).

$$RO^{\bullet} + AH \rightarrow ROH + A^{\bullet} \quad [3]$$

Thus, the conversion of MeLoOOH into MeLoOH shown in this study may provide a pathway to explain the antioxidant mechanism of α-tocopherol and Trolox in inhibiting the decomposition of hydroperoxides.

Ketodiene compounds, 13- and 9-oxo octadecadienoic acids are one major group of products known from the homolytic decomposition of linoleic acid hydroperoxides (10–13,29). Ketodienes were the main breakdown products formed during the aerobic breakdown of MeLoOOH in the presence of copper through alkoxy radical intermediate (10). Proposed mechanisms for ketodiene formation include the disproportionation of peroxyl radicals through a tetroxide intermediate in which hydrogen atom is transferred from one radical to another (30) (Eq. 4), the elimination of hydrogen from a tetroxide intermediate in which only ketodiene compounds are formed (10) (Eq. 5), and the elimination of hydrogen from an alkoxyl radical (13,14) (Eq. 6).

$$2\,R_2CHOO^{\bullet} \rightarrow R_2\text{–}CH\text{–}OOOO\text{–}HCR_2 \rightarrow R_2CHOH + R_2C{=}O + O_2 \quad [4]$$

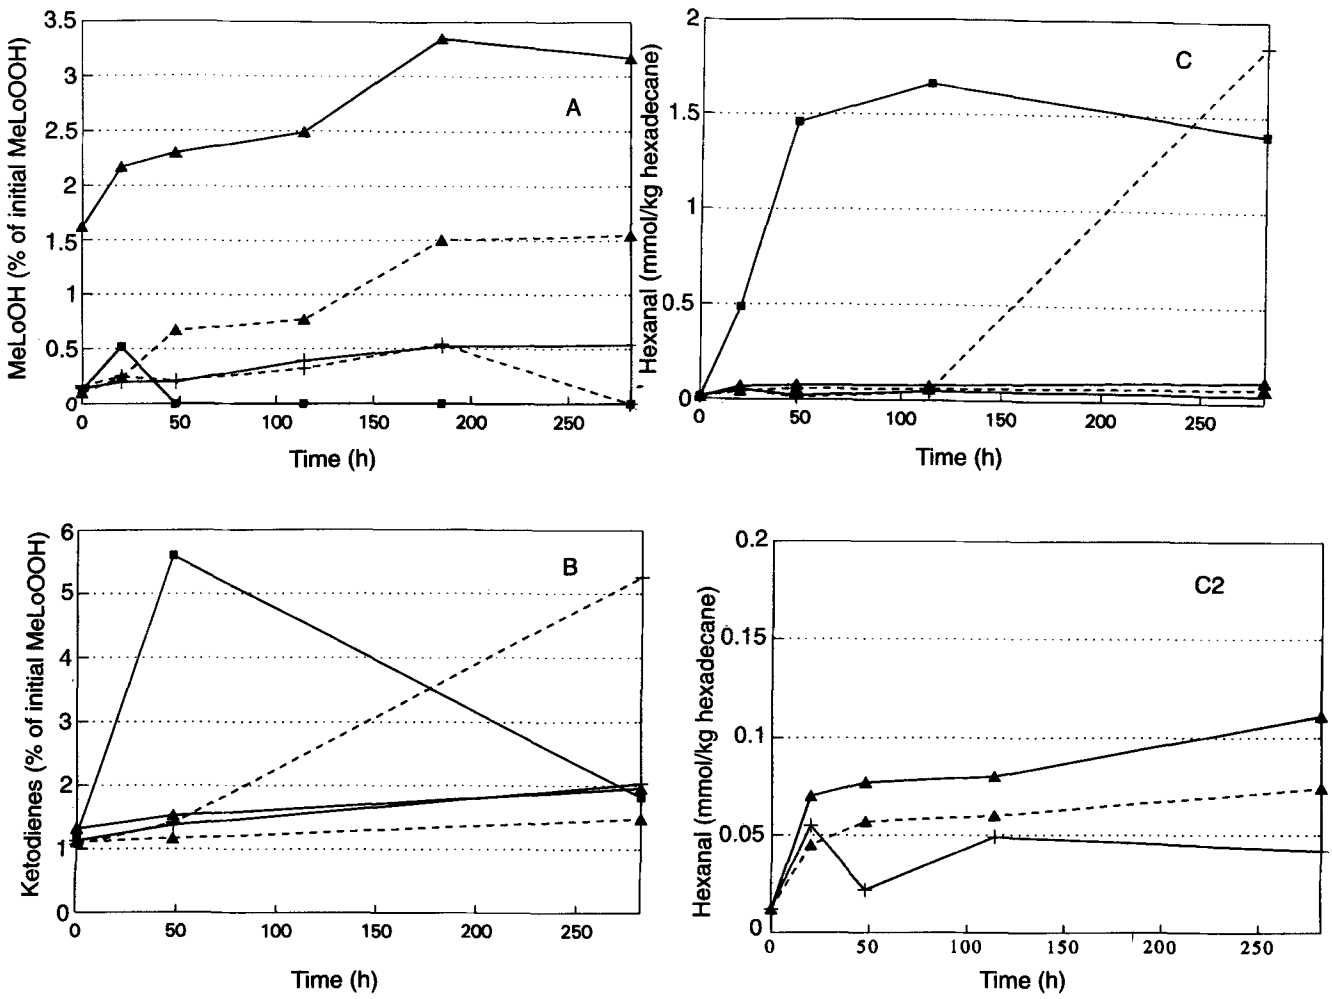

FIG. 6. A, Formation of hydroxy compounds; B, ketodiene compounds; C, hexanal, during decomposition of MeLoOOH with or without antioxidants; and C2, (C) with expanded y-axis. 40 mM solution of MeLoOOH/MeLo (1:1) in hexadecane solution. Legend and abbreviations as in Figure 5.

$$2\,R_2CHOO^{\bullet} \rightarrow R_2\text{–}CH\text{–}OOOO\text{–}HCR_2 \xrightarrow{-2H} 2\,R_2C{=}O + O_2 \quad [5]$$

$$R_2CHO^{\bullet} + X^{\bullet} \rightarrow R_2C{=}O + XH \quad [6]$$

Disproportionation of alkoxy radical (Eq. 4) would be expected to produce equal amounts of hydroxy and ketodiene compounds by the Russell mechanism (30). However, as discussed by Gardner (26), this pathway was not considered to be important.

In this work, antioxidants were shown to decrease the formation of keto dienes and increase the formation of hydroxy dienes. With Trolox, the ratio of hydroxy to ketodiene compounds was higher than with α-tocopherol. Therefore, hydrogen donating antioxidants can greatly influence the reaction pathways leading to stable hydroxy compounds.

Although the hydrophilic Trolox was only slightly soluble in hexadecane, it was more effective in inhibiting MeLoOOH decomposition than the lipophilic α-tocopherol. This phenomenon has not been previously reported for the decomposition of pure hydroperoxides, but it is consistent with our previous observations that these antioxidants have different effects on hydroperoxide and hexanal formation during autoxidation of corn oil (8). In a bulk corn oil system, even though the hydrophilic antioxidants Trolox and ascorbic acid were not completely soluble, they were more effective than the lipophilic antioxidants α-tocopherol and ascorbyl palmitate. However, in the corresponding corn oil-in-water emulsion system, the lipophilic antioxidants were more effective than their hydrophilic analogues in inhibiting hydroperoxide formation and decomposition. In emulsions, the higher protection of lipophilic antioxidants was explained by their higher affinity toward the oil–water interface. In bulk oils, the better protection of hydrophilic antioxidants was explained by their preferential orientation in the air–oil interface. This interfacial phenomenon supports our finding that the hydrophilic Trolox is more effective than the lipophilic α-tocopherol in inhibiting hydroperoxide decomposition in the nonpolar hexadecane solution. In our previous study (8), we also observed that α-tocopherol was more effective in inhibiting hydroperoxide formation at 232 than at 1161 μM, but the reverse trend was observed in inhibiting hydroperoxide decomposition based on hexanal determination. These results

support our previous study (6), showing that α-tocopherol is an effective inhibitor of the β-cleavage (Eq. 1) responsible for hexanal formation.

This study was limited to the formation of three groups of decomposition products formed at 60°C—hexanal, hydroxy, and ketodiene compounds, which can be formed *via* alkoxyl radicals by β-scission (Eq. 1), hydrogen abstraction (Eq. 2), and hydrogen elimination (Eq. 6). However, other reactions of lipid alkoxyl radicals may be significant under different conditions (25). During Fe(II)-induced decomposition of the 13-hydroperoxide of linoleic acid in methanol solution in the presence of a vitamin E model compound (2,2,5,7,8-pentamethyl chromanol-6-ol), under either aerobic or anaerobic conditions, the formation of epoxy compounds through epoxyallylic radicals, formed by rearrangement of alkoxyl radicals, was suggested as a possible pathway of decomposition (31). In another study (32), the decomposition of 13-MeLoOOH in air in the presence of equal molar concentrations of Fe(III) acetylacetonate and α-tocopherol in benzene solution at 37°C, produced mixtures of peroxy-α-tocopherones, epoxy-hydroperoxy-α-tocopherones, and tocopherol dimers. Under these conditions, the formation of both peroxyl and alkoxyl radicals, rearranging into allylic epoxy-hydroperoxyl radical intermediates, may account for the lipid–tocopherol adducts identified. Further research is under way to clarify the effect of antioxidants on the formation of other nonvolatile compounds, including polymeric products and epoxides, from the thermal decomposition of lipid hydroperoxides.

Physicochemical Characterization of ATP Binding to Human 5-Lipoxygenase

Masato Noguchi*, Masashi Miyano[1], and Takashi Matsumoto

Life Science Research Laboratory, Japan Tobacco Inc., Yokohama, Kanagawa 227, Japan

ABSTRACT: Human 5-lipoxygenase requires ATP as a stimulatory factor. At the two preferred concentrations of the free Ca^{2+}, 0.02 μM with a resting cell and 20 μM with a stimulated cell, Scatchard analysis revealed that 5-lipoxygenase has one affinity ATP binding site with a K_d of 4.6 μM at the low Ca^{2+} concentration but has two affinity ATP binding sites with a higher K_d of 4.4 μM and a lower K_d of 14.5 μM at the high Ca^{2+} concentration. In contrast, in a Tween 20 reaction system, 5-lipoxygenase had similar activation coefficients for ATP at both Ca^{2+} concentrations; these were 12.7 μM at the low Ca^{2+} concentration and 12.0 μM at the high Ca^{2+} concentration. These results showed that 5-lipoxygenase has an ATP binding site and suggest that self-association of 5-lipoxygenase in 20 μM Ca^{2+} may affect ATP binding affinity as measured by Scatchard analysis.

Lipids 31, 367–371 (1996).

5-Lipoxygenase (EC 1.13.11.34) is responsible for the first two steps in the formation of leukotrienes, which exhibit biological activities related to inflammatory and allergic responses (1,2). These two steps are the oxygenation of free arachidonate to form 5*S*-hydroperoxy-6-*trans*-8,11,14-*cis*-icosatetraenoic acid (5-HPETE) by 5-HPETE synthetase activity and the subsequent dehydration of 5-HPETE to form 5,6-*trans*-oxido-7,9-*trans*-11,14-*cis*-icosatetraenoic acid (LTA_4) by LTA_4 synthetase activity. LTA_4 is further converted to 5*S*,12*R*-dihydroxy-6,14-*cis*-8,10-*trans*-icosatetraenoic acid (LTB_4), a chemotactic factor, and to the peptidoleukotrienes known as the slow-reactant substance A. Thus, the production of LTA_4, initiated by 5-lipoxygenase, is the first step in the synthesis of leukotrienes, which are of great significance in the pathophysiology of inflammation and anaphylaxis.

5-Lipoxygenase has been purified from several sources such as human leukocytes (3,4), porcine leukocytes (5), rat basophilic leukemia cells (6,7), and mouse mastocytoma cells (8). The enzyme activity is modulated by calcium (9), ATP, and detergents (3,4,8,10). Experiments with partially purified enzyme from guinea pig neutrophils showed that ATP stimulates 5-lipoxygenase activity more than GTP, UTP, AMP, and cAMP (11). 5-Lipoxygenase cDNA has been isolated from human placenta (12), dimethyl sulfoxide-differentiated HL-60 cells, and rat basophilic leukemia cells (13). Although these sequence studies of the enzyme could not reveal any known ATP binding sequence motif in the enzyme, ATP-sepharose affinity chromatography was first applied to purify 5-lipoxygenase from rat basophilic leukemia cells (14), and a successful purification of the enzyme by this method was reported recently for a recombinant enzyme (15). This suggests that 5-lipoxygenase may have an ATP binding site(s). However, it is still unknown how many ATP molecules bind to 5-lipoxygenase and how its binding affinity is. In this report, we describe the stimulatory effects of ATP on purified human 5-lipoxygenase.

MATERIALS AND METHODS

Materials. Arachidonate (>99%) was purchased from Caymen (Ann Arbor, MI) and purified with the CC-4 column method described elsewhere (4). The resulting solution containing arachidonate was concentrated under argon gas. The concentrated arachidonate was diluted with ethanol in which oxygen was substituted with argon gas to avoid air oxidization. Polyoxyethylene sorbitanmonolaurate (Tween 20) containing less hydroperoxide, adenosine 5′-(α-thio)triphosphate (α-S-ATP) and adenosine 5′-(γ-thio)triphosphate (γ-S-ATP) were from Calbiochem (San Diego, CA). Other nucleotides were from Sigma (St. Louis, MO). Inorganic triphosphate was a gift from Professor Junichiro Mukai of the Graduate School of Genetic Resources Technology, Kyushu University. [γ-^{32}P]-ATP (110 TBq/mmol) was obtained from Amersham (Arlington Heights, IL). Other reagents were of the highest grade available.

Enzyme purification. Human recombinant 5-lipoxygenase was expressed and purified as described previously (10).

Enzyme assays by spectrophotometrical and continuous monitoring. The standard assay for 5-HPETE synthetase/LTA_4 synthetase activities in the purified enzyme was performed in

0.5 mL of a 0.1 M HEPES buffer (pH 8.0) containing Ca^{2+}-nitriotriacetic acid (NTA) buffer, various concentrations of ATP, 0.5 mM DTT, 0.1 mM arachidonate, and 0.01% Tween 20. Arachidonate-Tween 20 mixed micelles were added to the reaction mixture after arachidonate was vigorously mixed with Tween 20.

After 1 min of preincubation in cuvettes (1 cm light path) at 30°C, the reaction was initiated by adding 6 μg of the enzyme. The progress of the reaction was followed spectrophotometrically by monitoring the absorbance at 236 nm for 5-HPETE and at 280 nm for the two LTB_4 isomers derived from the nonenzymatic degradation of LTA_4 using a Shimadzu (Tokyo, Japan) spectrophotometer model UV-2200. Molar absorption coefficients of 23 mM^{-1} cm^{-1} (16) at 236 nm for 5-HPETE and 39.5 mM^{-1} cm^{-1} (17) at 280 nm for the two LTB_4 isomers were used.

5-Lipoxygenase has two activities, the initial synthesis of 5-HPETE and the subsequent conversion to LTA_4. Therefore, we assumed the true velocity of 5-HPETE to be the summation of the 5-HPETE and LTA_4 velocities.

Tween 20 was used in this study because, as shown in previous studies, a clear reaction mixture could be obtained and a higher 5-HPETE synthetase activity could be observed with Tween 20 than with the other detergents (10). We prepared a fresh Tween 20 solution for each experiment to avoid peroxidation.

Binding assay. 5-Lipoxygenase (6 μg) was mixed with [γ-^{32}P]-ATP in 0.1 M HEPES buffer (pH 8.0) containing Ca^{2+}-NTA buffer, 0.5 mM DTT and incubated at 30°C for 5 min in a final volume of 100 μL. The incubation was terminated by the addition of 20 μL of 0.5% gamma globulin and 250 μL of ice-cold 30% polyethylene glycol 6000. This mixture was centrifuged for 5 min at 15,000 × *g*, 4°C. The radioactivity of the precipitate was measured by liquid scintillation spectrometry. Nonspecific binding was measured in the presence of 100 mM ATP.

Calculation of free calcium concentrations. The free Ca^{2+} concentration of the calcium ion buffer was calculated according to the formula that uses a pK_d of 6.5 for calcium-NTA at pH 8.0 (18).

Miscellaneous. Protein concentrations were determined by the Bradford method using a Bio-Rad Protein Assay kit (Richmond, CA) with bovine serum albumin as the standard. The protein concentration of the purified 5-lipoxygenase was determined by using a molar extinction coefficient of 1.2 × 10^5 M^{-1} cm^{-1} at 280 nm (12,13).

All experiments were repeated at least three times and all data are shown as the average values of the experiments.

RESULTS

Activation coefficients of ATP to the 5-HPETE activity. The effects of ATP on two representative Ca^{2+} concentrations were investigated. In our previous paper (10), little activity was detected at less than 0.1 μM Ca^{2+}; 5-lipoxygenase and LTA_4 synthetase activities attained their maxima over 5 μM Ca^{2+} as determined by the binding of the enzyme to phosphatidylcholine liposomes (19). Based on those results, we established Ca^{2+} concentrations of 0.02 and 20 μM as our representative low and high concentrations for determining the effects of ATP under different free Ca^{2+} concentrations in the Ca^{2+}-NTA system (18). As shown in Figure 1, the addition of ATP to 0.02 μM Ca^{2+} achieved a ninefold increase of 5-HPETE synthetase activity, whereas the addition of ATP to 20 μM Ca^{2+} caused only a threefold increase of activity. The maximum activity of the enzyme at 0.02 μM Ca^{2+} was approximately 80% of the maximum activity at 20 μM Ca^{2+}. Regardless of the Ca^{2+} concentration, the activation coefficients of 5-HPETE synthetase in the presence of ATP were similar when the activation coefficients were calculated from a double-reciprocal plot of the steady-state velocity (K_a = 12.0 μM at the high Ca^{2+} concentration and 12.7 μM at the lower).

Binding of ATP to 5-lipoxygenase. To determine how many ATP molecules bind to a 5-lipoxygenase molecule, the

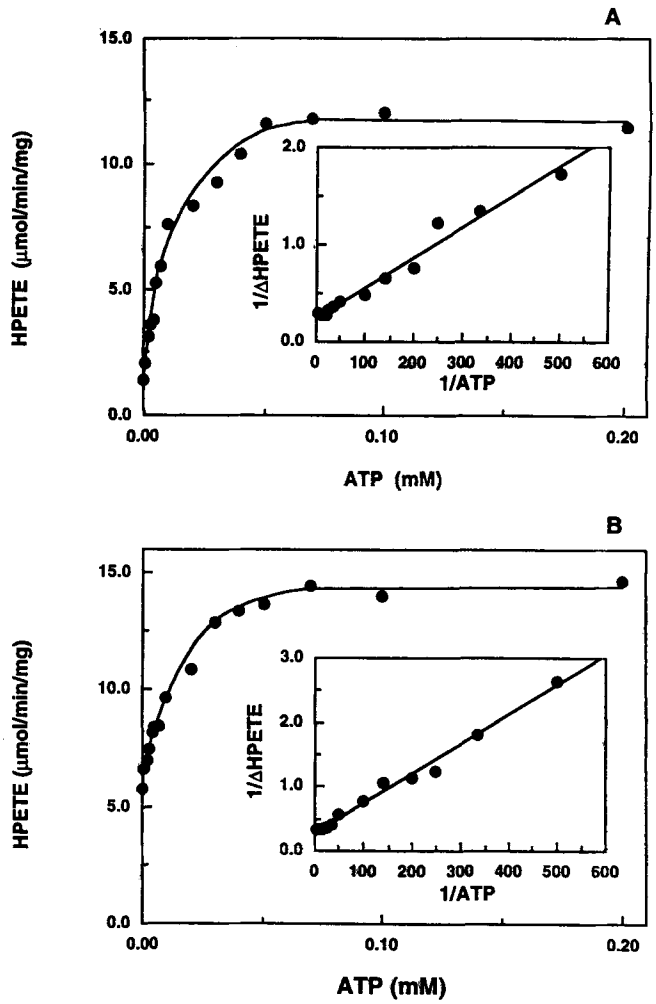

FIG.1. Enhancement of 5*S*-hydroperoxy-6-*trans*-8,11,14-*cis*-isosatetraenoic acid (5-HPETE) synthetase activity by ATP concentration at 0.02 (A) and 20 μM (B) free Ca^{2+}. Free Ca^{2+} concentrations were controlled by the calcium ion buffer. The velocities were fitted to the double-reciprocal analysis.

purified 5-lipoxygenase was subjected to Scatchard analysis of [γ-^{32}P]-ATP binding to the enzyme without any detergent. Scatchard analysis indicated one ATP binding site per 5-lipoxygenase molecule at either the low or the high Ca^{2+} concentration (n = 1.0 at 0.02 μM Ca^{2+} and n = 1.2 at 20 μM Ca^{2+}, Fig. 2). A simple ATP binding with a K_d of 4.6 μM was observed at the low Ca^{2+} concentration. On the other hand, the two different slopes at the high Ca^{2+} concentration showed that 5-lipoxygenase had two affinity sites for ATP with a higher K_d value of 4.4 μM (n = 0.6) and a lower K_d value of 14.5 μM (n = 0.6).

ATP requirement of 5-HPETE synthetase activity and effects of other nucleotides on 5-HPETE synthetase activity. Among the tested nucleotides, γ-S-ATP most effectivly stimulated the activity of 5-HPETE synthetase (Table 1). In this reaction system, α-S-ATP was somewhat less effective than ATP, the effect of dATP was approximately 60% of ATP, and ADP and AMP were less effective than dATP. Other triphosphate nucleotides, adenosine, adenine, and inorganic pyrophosphate, seemed to have no stimulative or inhibitory effect on 5-HPETE synthetase activity. Previously, we found that phosphatidylcholine liposomes increased the conversion ratio of 5-HPETE to LTA_4 (19); however, in this study, none of the nucleotides tested were found to enhance LTA_4 synthetase activity of the enzyme.

TABLE 1
Effects of Various ATP Analogues on 5-HPETE Synthetase Activity[a]

Additions	Enzyme activity (μmol/min/mg)	Relative activity (%)
None	2.65	100.0
ATP	12.80	483.2
ADP	6.15	232.2
AMP	3.71	140.0
cAMP	3.24	122.2
α-S-ATP	11.00	415.1
γ-S-ATP	15.99	603.6
ITP	3.66	138.1
GTP	2.62	98.9
CTP	3.41	128.9
dATP	8.04	303.4

[a]Enzyme was incubated in the assay mixture containing 80 μM Ca^{2+}, 100 μM arachidonate, and 0.01% Tween 20 with various nucleotides at 0.1 mM. Enzyme activities are expressed as initial velocities. 5-HPETE, 5*S*-hydroperoxy-6-*trans*-8,11,14-*cis*-isosatetraenoic acid.

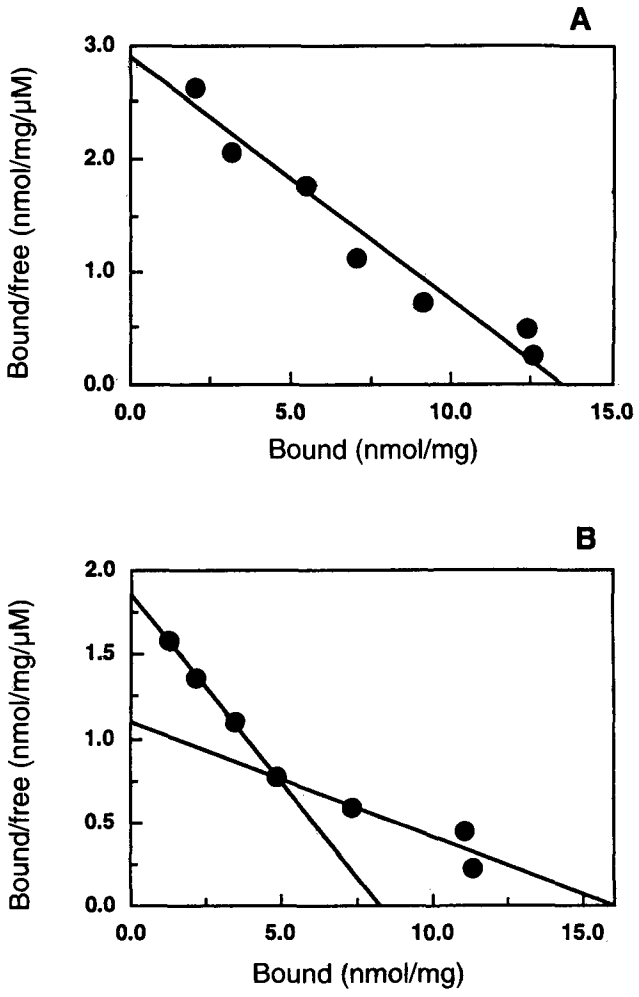

FIG. 2. Scatchard analysis of [γ-^{32}P]-ATP binding to purified 5-lipoxygenase at 0.02 μM (A) and 20 μM (B) free Ca^{2+}. Free Ca^{2+} concentrations were controlled by the calcium ion buffer.

DISCUSSION

Kinetic analysis showed that in the presence of Tween 20 and 0.02 μM Ca^{2+}, ATP enhances 5-HPETE synthetase activity with Ka = 12.7 μM and that in the presence of Tween 20 and a higher Ca^{2+} concentration of 20 μM, ATP enhances 5-HPETE synthetase activity with K_a = 12.0 μM; the 5-lipoxygenase activation coefficients for ATP at the different Ca^{2+} concentrations were similar (Fig. 1). In the absence of Tween 20, however, Scatchard analysis revealed a single binding site of 5-lipoxygenase with a K_d of 4.6 μM at the low Ca^{2+} concentration, and two binding sites with K_d of 4.4 and 14.5 μM at the high Ca^{2+} concentration (Fig. 2); this indicated that in the absence of Tween 20 the binding mode of ATP to 5-lipoxygenase at the low Ca^{2+} concentration differed from the binding at the high Ca^{2+} concentration. In the presence of high Ca^{2+}, 5-lipoxygenase translocates to phosphatidylcholine liposomes due to a conformational change (19). In the absence of detergent, the conformation of the enzyme changes as it binds Ca^{2+} and reveals a hydrophobic region that may allow it to self-associate through hydrophobic interactions. Tween 20 is used extensively to solubilize membrane-associated proteins while maintaining their activities. When Tween 20 is present, after Ca^{2+} binds 5-lipoxygenase, the detergent may cover the newly exposed hydrophobic portion of the enzyme that might otherwise interact with phosphatidylcholine liposomes or with other 5-lipoxygenase molecules. This model is consistent with the similar K_a values we obtained irrespective of Ca^{2+} concentration in the enzyme assay with Tween 20 (Fig. 1). On the other hand, our binding assay system did not contain phosphatidylcholine liposomes, to which 5-lipoxygenase translocates when it is activated at the

TABLE 2
Effects of Adenosine, Inorganic Pyrophosphate (PPi), and Inorganic Triphosphate (PPPi) on 5-HPETE Synthetase Activity[a]

Additions	Enzyme activity (μmol/min/mg)	Relative activity (%)
None	2.65	100.0
Adenosine	3.53	133.3
PPi	3.33	125.5
PPi	3.52	132.9
Adenosine + PPi	4.02	151.6
Adenosine + PPPi	2.79	105.4

[a]Enzyme was incubated in the assay mixture containing 80 μM Ca^{2+}, 100 μM arachidonate, and 0.01% Tween 20 with adenosine, PPi, and PPPi at 0.1 mM. Enzyme activities are expressed as initial velocities. Abbreviation as in Table 1.

high Ca^{2+} concentration, thus the binding affinity of ATP to 5-lipoxygenase should be lower in our system because of enzyme self-association in the absence of detergents. One interpretation of these results is that a 5-lipoxygenase molecule may have an ATP binding site with a binding affinity to ATP that is constant, irrespective of the presence of Ca^{2+}.

The value of K_d at the low Ca^{2+} concentration and the value of K_a for ATP differed (Figs. 1 and 2). Tween 20 may affect the conformation of the enzyme so that the value of K_a for ATP is much lower than what might be predicted by the K_d of the binding assay. Such a conformational change of the enzyme also may occur in the absence of Tween 20 when 5-lipoxygenase molecules associate with each other at the high Ca^{2+} concentration, and may account for the lower K_d comparable to the K_a value for ATP.

It has been reported that ATP stimulated the 5-lipoxygenase activities more than the other ATP analogues (11). In this report, we have shown that γ-S-ATP stimulated 5-HPETE synthetase activity more than ATP (Table 1). α-S-ATP resulted in less activity than ATP. These results showed that the γ-phosphate moiety of ATP is important for the stimulation. Because ADP and the other nucleotides with triphosphate were less effective than ATP, the charges on the adenine and γ-phosphate moieties may cooperatively affect the enzyme activity. dATP affected ~60% of ATP on 5-HPETE synthetase enhancement. Differences in the ribose moiety of these nucleotides affected the activity of the enzyme less than the difference in the base. The ribose ring may work as a spacer which arranges the relative positions of base and triphosphate. The mixture of both adenosine and these free inorganic phosphates did not enhance the enzyme activity as significantly as the addition of adenosine alone (Table 2), therefore, the conformation of both the adenine-base and the phosphate moieties appears to be essential for the activation of 5-lipoxygenase. Unexpectedly, the addition of adenosine and inorganic pyrophosphate to the reaction mixture showed more effective enhancement than the addition of adenosine and inorganic triphosphate. We obtained the same results as above on LTA_4 synthetase (data not shown).

Finally, 5-lipoxygenase did not show any ATP-hydrate activity or any self-phospholylation (data not shown). These results were consistent with stimulations of the enzyme activity by γ-S-ATP and α-S-ATP; thus, it is concluded that ATP, like Ca^{2+}, acts as a co-factor of 5-lipoxygenase activity.

ACKNOWLEDGMENT

Sterol Specificity of the *Saccharomyces cerevisiae ERG6* Gene Product Expressed in *Escherichia coli*

Mylavarapu Venkatramesh, De-an Guo, James G. Harman, and W. David Nes*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409

ABSTRACT: The *ERG6* gene from *Saccharomyces cerevisiae* has been functionally expressed in *Escherichia coli*, for the first time, yielding a protein that catalyzes the bisubstrate transfer reaction whereby the reactive methyl group from (*S*)-adenosyl-L-methionine is transferred stereoselectively to C-24 of the sterol side chain. The structural requirements of sterol in binding and catalysis were similar to the native protein from *S. cerevisiae*. Inhibition of biomethylation was observed with fecosterol and ergosterol which suggests that ergosterol may function in wild-type yeast as a feedback regulator of sterol biosynthesis.
Lipids 31, 373–377 (1996).

The (*S*)-adenosyl-L-methionine:$\Delta^{24(25)}$-sterol methyl transferase (SMT: EC 2.1.1.41) synthesized by *Saccharomyces cerevisiae* catalyzes the stereoselective transfer of the (*S*)-adenosyl-L-methionine (AdoMet) methyl group to the 24,25-double bond of the sterol side chain (Fig. 1). The crucial role of this enzyme in regulating production of ergosterol, which functions as the fungal membrane insert, has stimulated considerable interest in the kinetic properties, stereochemistry, and mechanism of the transfer reaction (1–4), and in the design of inhibitors of SMT activity which may be used clinically or agrochemically as antifungal agents (5,6). The putative gene encoding the SMT from *S. cerevisiae* has been cloned and sequenced (7–9); however, there is no enzymological evidence to demonstrate that *ERG6* encodes an SMT enzyme. The purpose of this communication is to report for the first time enzymological evidence that *ERG6* is the yeast SMT structural gene and the sterol substrate specificity of the gene product.

MATERIALS AND METHODS

Media, strains, and plasmids. Escherichia coli AG-1 cells were used in transformation experiments. Plasmid pBR322 (10) was used as the cloning vector. Plasmid pRG458 (7) was provided by Dr. Martin Bard (Dept. of Biology, Indiana University, Indianapolis, IN) and used as the source of *ERG6* DNA. Cells were routinely maintained on Luria broth medium (11). Lucia broth medium was supplemented with ampicillin at a final concentration of 50 μg/mL when culturing cells that contained plasmid DNA. Cells were made competent using a solution of 50 mM $CaCl_2$ (11). SOB medium (12) was used for cell recovery following transformation with plasmid DNA.

Subcloning and DNA sequence analysis. DNA fragments generated by digestion of pRG458 with *Dra* I and *Nhe* I to isolate the open reading frame (ORF) were separated by agarose gel electrophoresis. The 1281 base pair fragment was eluted from the gel, extracted twice with an equal volume of phenol/chloroform/isoamyl alcohol (25:24:1), precipitated in ethanol, dried, and dissolved in *tris*-EDTA buffer (11). The DNA was made blunt-ended by incubation with T4 DNA polymerase and deoxynucleoside triphosphates and ligated into *Eco*R V-linearized, dephosphorylated pBR322. Protocols for plasmid and DNA fragment isolation, restriction endonuclease digestion, ligation, and transformation were either standard (11) or were those recommended by the manufacturer. Shrimp alkaline phosphatase was purchased from Ambion (Austin, TX). Restriction enzymes were purchased from U.S. Biochemicals (Amersham, Arlington Heights, IL) and Promega Corporation (Gaithersburg, MA). Reagents for the preparation of blunt-ended *ERG6* fragment and ligation reactions were purchased as kits from Panvera Corporation (Madison, WI). Dideoxynucleotide sequencing of plasmid DNA clones was performed by the chain termination method (13) using the reagents and protocol from a Sequenase II kit purchased from U.S. Biochemicals. Oligonucleotides used to prime the sequencing reactions were synthesized at the Texas Tech University Biotechnology Institute Core Facility (Lubbock, TX).

Expression of SMT activity and measurement of enzyme kinetics. Escherichia coli cells that contained pSMTy23 were cultured at 37°C to a culture A_{600} of 0.8 to 1.0. The cells were harvested by centrifugation (4,000 × *g* for 10 min). The resulting pellet was resuspended in 5 mL of buffer (50 mM Tris-HCl, pH 7.5, 2 mM $MgCl_2$, 2 mM 2-mercaptoethanol) and ruptured using a French Press (SLM Instruments, Urbana, IL). The cell debris was removed by centrifugation (12,000 × *g* for 15 min), and the supernatant fraction (batch enzyme) was used as the source of material for the SMT assay system (14). SMT assays were performed on 0.5 mL batch enzyme in reactions that contained 50 μM zymosterol and 50 μM [*methyl*-$^3H_3$]AdoMet as described elsewhere with constant agitation at 55 rpm on a shaker bath at 30°C for 45 min

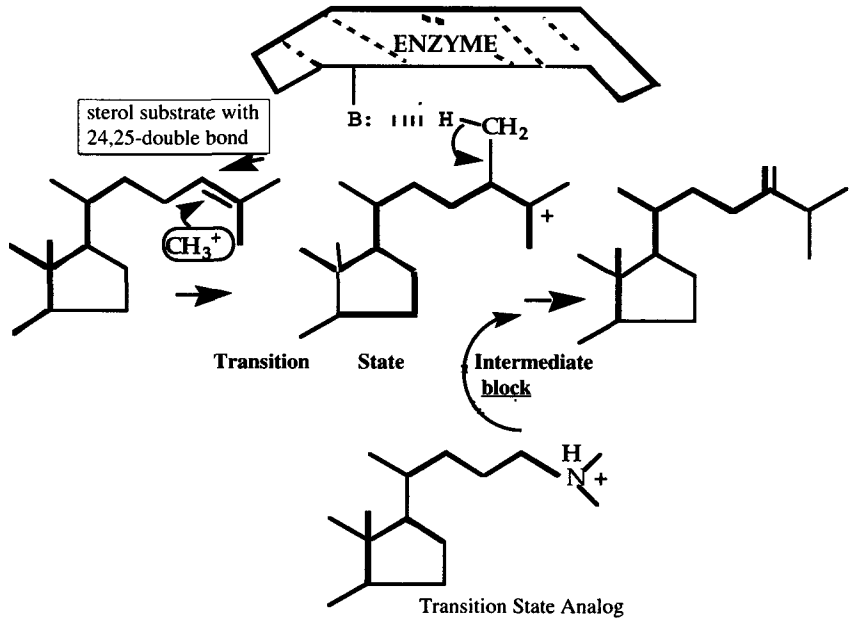

FIG. 1. Mechanism of the (*S*)-adenosyl-L-methionine: $\Delta^{24(25)}$-sterol methyl transferase-catalyzed transmethylation of sterol and (*S*)-adenosyl-L-methionine to yield a 24(28)-methylene sterol. The sterol nomenclature system used in this paper follows the *Nes* rules discussed in Reference 19 and references cited therein. Thus the exocyclic methylene carbons are numbered C-24-C-28, not 24(24').

(15,16). Reactions were terminated by adding 10% methanolic KOH. Nonsaponifiable lipids were extracted from the reaction mixtures with diethyl ether and the organic-soluble sterols and radioactivity analyzed as described (15,16). Inhibitor studies were performed using batch enzyme in the presence of 5 to 100 μM zymosterol and 50 μM [*methyl*-$^3H_3$]AdoMet, and inhibitor concentrations were tested over the range of 1 nM to 100 μM. Inhibition type and K_i values were determined by standard graphical procedures (15,16) for which computer-assisted linear regression analysis afforded

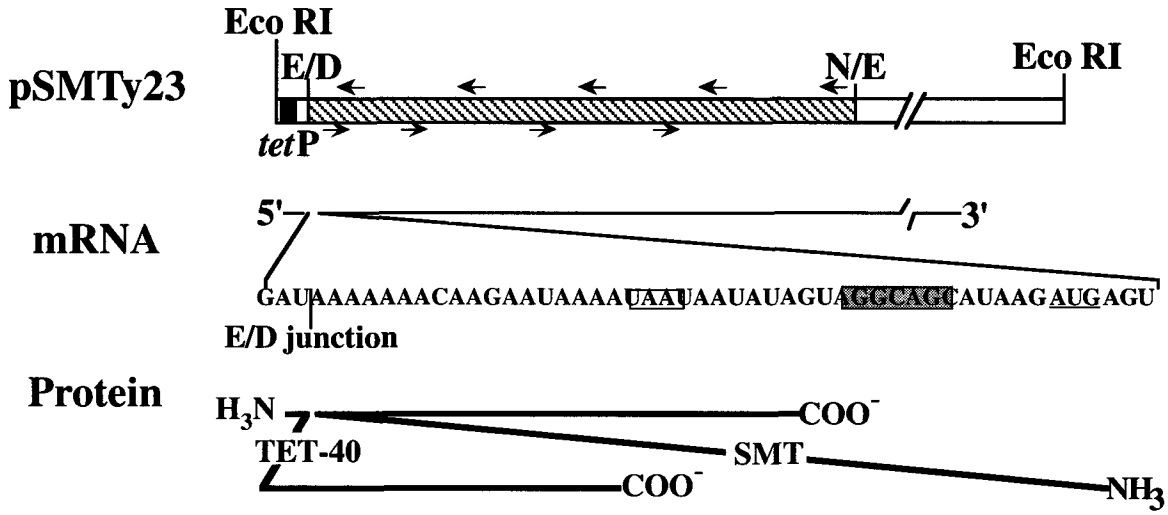

FIG. 2. Cloning, sequencing, and organization of pSMTy23; pSMTy23 DNA is shown as an *Eco*R I linearized plasmid. The *Eco*R V/*Dra* I (E/D) and *Nhe* I/*Eco*R V (N/E) junctions flank the DNA, derived from pRG458, that contains the *ERG6* structural gene (hatched region). The approximate positions and orientation of the oligonucleotide primers used to sequence the pSMTy23 insert are represented by arrows. The pBR322 tetracycline resistance promoter (*tet*P) is represented as a black box. The mRNA that originates from *tet*P has an open reading frame that encodes a truncated (40 amino acid, TET-40) form of the tetracycline resistance gene product whose translation terminates as the result of an in-frame UAA (boxed) located in the cloned DNA fragment. A purine-rich sequence (shaded box), which may serve as a ribosome binding site for (*S*)-adenosyl-L-methionine: $\Delta^{24(25)}$-sterol methyl transferase (SMT) translation, is located six bases upstream of the putative SMT initiator codon (underlined).

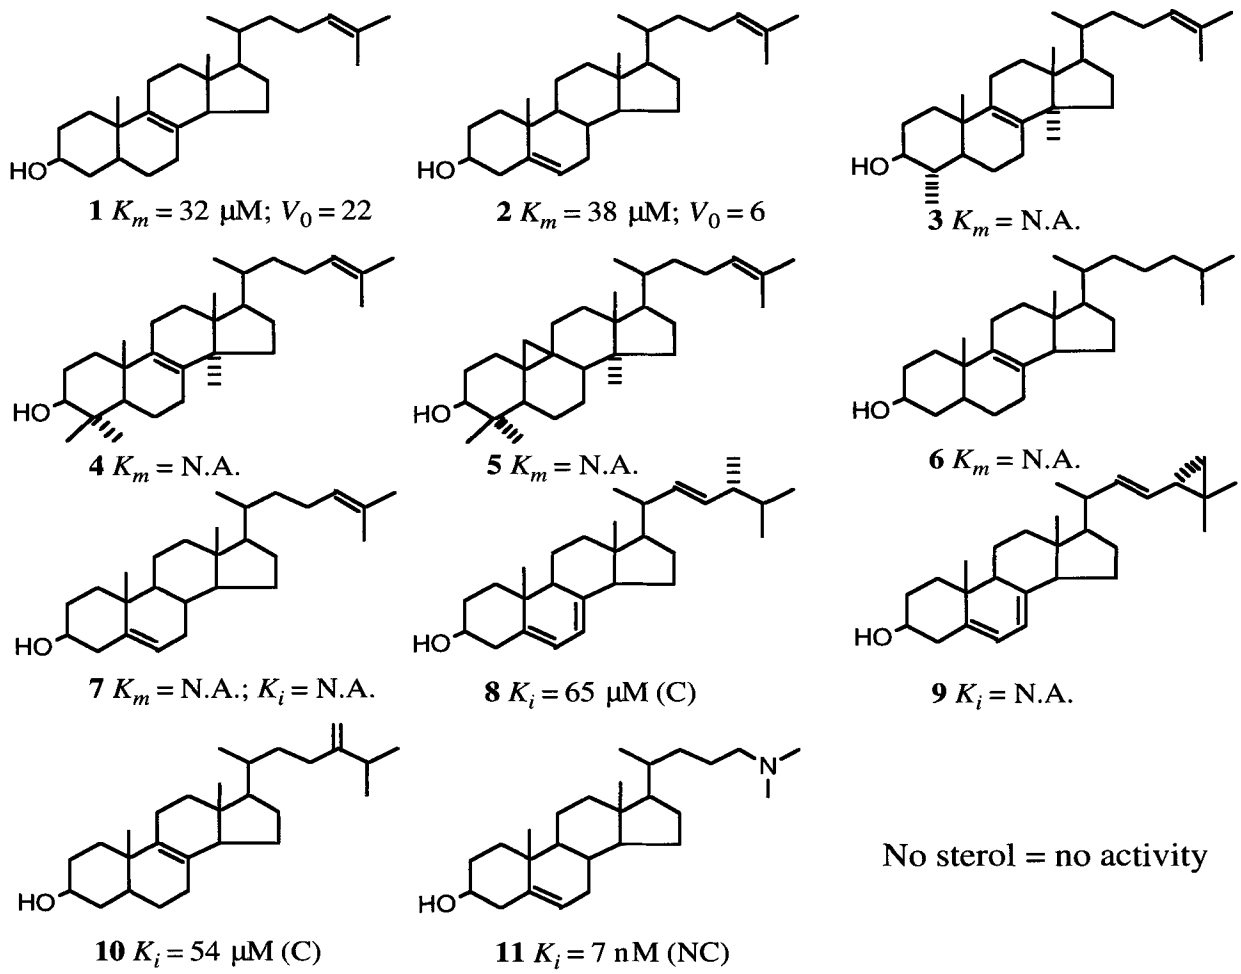

FIG. 3. Sterol substrate specificity and inhibitors of (*S*)-adenosyl-L-methionine: $\Delta^{24(25)}$-sterol methyl transferase enzyme expressed in *Escherichia coli.*

correlation coefficients greater than 0.98 in all trials (n = 3). Products of the SMT reactions were analyzed by high-performance liquid chromatography (HPLC)-radiocounting and gas chromatography/mass spectrometry (GC/MS) (15,16). Protein was determined as described (17). Source of compounds was described elsewhere (15,16; Nes, W.D., and Guo, D., unpublished data). Attempts to overexpress the *ERG6* gene in *E. coli* using plasmid vector, e.g., pLEX (P_L expression system from Invitrogen, San Diego, CA) were impeded by the nonavailability of a restriction site which was appropriate for cloning.

RESULTS AND DISCUSSION

Our initial efforts were directed to the cloning and sequencing of the putative open reading frame (ORF) of *ERG6*. The purpose of these experiments was to confirm that the *ERG6* DNA used in this study was identical to *SED6*, the gene claimed by Hardwick and Pelham (8) to be *ERG6*. *Escherichia coli* has been found to lack the capacity to synthesize sterols (18). For this reason, *E. coli* was chosen as the expression system of the *ERG6* gene. The *SED6* gene sequence published by Hardwick and Pelham (8) was analyzed using the program GeneJockey (Biosoft) to determine that *Dra* 1 and *Nhe* 1 were appropriate restriction enzymes for subcloning the ORF from the plasmid pRG458. The 1.3 kilobase pair fragment obtained by digesting pRG458 with *Dra* 1 and *Nhe* 1 was subcloned into the *Eco*R V site of pBR322. Two unique clonal types, pSMTy23 and pSMTy10, were obtained (Fig. 2). Restriction enzyme digestion patterns of the plasmids determined that these clones differed in the orientation of the insert. DNA sequence analysis of pSMTy23 confirmed that this clone contained a sequence identical to the putative *ERG6* gene published by Hardwick and Pelham (8).

Batch enzyme preparations from cells that contained either pSMTy23 or pSMTy10 were analyzed for SMT activity as described in the Materials and Methods section. Preparations from cells that contained pSMTy23 were found to contain SMT activity, whereas preparations from cells that contained pSMTy10 did not. Our rationale for the basis of SMT

enzyme expression from pSMTy23 in *E. coli* is that *ERG6* mRNA was synthesized in a transcript which originated at the tetracycline resistance determinant promoter of the vector. The bacterial-expressed recombinant protein from this vector system is likely to give rise to the native protein rather than a fusion protein. A purine-rich sequence located upstream of the putative SMT start codon is predicted to serve as a ribosome binding site for translation (Fig. 2).

The functional importance of precise structural and electronic features of the methyl acceptor molecule in supporting SMT activity was first examined in reactions that contained either cholest-8-enol or cholesta-8,24-dienol (zymosterol) as substrate. Methyl transfer occurred only in those reactions that contained zymosterol, demonstrating the importance of the 24,25-double bond in the sterol side chain for catalysis (Fig. 3). HPLC-radiocounting was performed on Whatman reversed-phase C_{18}-columns designed to separate substrate from 24(28)-methylene product and related 24-alkene isomers (19). As shown in Figure 4, zymosterol was stereoselectively biomethylated to fecosterol. To obtain sufficient quantities of biomethylated product for chemical identification, 20 assays were performed, and approximately 4 μg of chromatographically pure sterol was collected from the HPLC column. The sterol was identifed as fecosterol by comparison of its chromatographic behavior in thin-layer chromatography (R_f 0.3, analytical plates developed twice in 85:15 benzene/ether), HPLC (0.77, α_c on Whatman C_{18}-column (Maidstone, England) eluted with MeCN/i-PrOH (9:1) at 1 mL/min at ambient temperature, and gas–liquid chromatography (1.31, retention time relative to cholesterol on 3% SE-30 packed column operated isothermally at 245°C), and by its fragmentation pattern in mass spectroscopy (*m/z*, M^+ 398 amu and other diagnostic ions at 383, 365, 341, 314, 327, 299, 285, 271, 245), with that of an authentic specimen (19).

Several naturally occurring sterols with the 24,25-double bond were tested as substrates; zymosterol and desmosterol were found to function as methyl acceptors in the SMT reaction, whereas lanosterol, cycloartenol, and 31-norlanosterol did not serve as substrates for SMT (Fig. 3). Greater catalytic competence (measured as V_{max}/K_m, 15) was observed with zymosterol than desmosterol. Sterol specificity for SMT catalysis exhibited by the protein expressed from pSMTy23 was similar to that of the native enzyme of *S. cerevisiae* (20,21). In contrast to the plant SMT (15), the yeast sterol-SMT complex was found to be sensitive to steric interference from the C-4 methyl group(s) (20). The isosteric transition state analog for the biomethylation reaction, 24β,25-cyclopropyl ergosta-5,7,(*E*)22-trienol, was not an inhibitor of SMT activity, due to the modification at C-24. However, the isoelectronic transition state analog, 25-azacholesterol (at which physiological pH is protonated) (16) was a potent inhibitor of SMT activity, results consistent with previous reports that 25-azacholesterol and related side-chain ammonium-containing sterols are potent inhibitors of yeast SMT activity (4,5,21).

The SMT from pSMTy23 exhibited a competitive-type inhibition by fecosterol, which is consistent with kinetics from

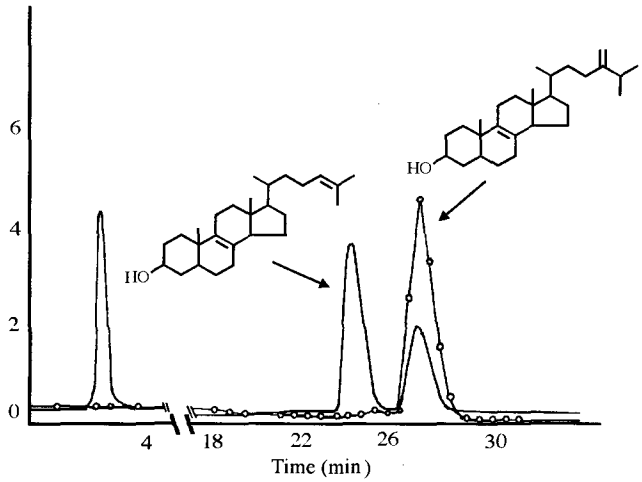

FIG. 4. High-performance liquid chromatography-radiocount chromatogram [Whatman C_{18}-reversed phase column (Maidstone, England) eluted with acetonitrile/isopropanol, 9:1; the ultraviolet detector was set at 205 nm] showing the mass and radioactivity associated with sterols isolated from the thin-layer chromatography-purified nonsaponifiable lipids (NSF) fraction. The NSF was diluted with 50 μg of nonradioactive fecosterol. The sample was obtained from reactions that contained zymosterol and [$^3H_3$-methyl](*S*)-adenosyl-L-methionone as substrates and batch enzyme prepared from pSMTy23-containing cells; O—O, ^3H-radioactivity (dpm x 104); —, detector response (205 nm). Abbreviation as in Figure 2.

product inhibition. When ergosterol and cholesterol were paired as inhibitors, only ergosterol inhibited SMT activity (Fig. 1). This result is expected since cholesterol does not possess a 24-alkyl group. Thus, ergosterol may regulate its synthesis under normal physiological conditions through control of post-lanosterol transformation events as proposed by Moore and Gaylor (20). The inability of others to observe product inhibition by fecosterol (4,5) may be due to the high level of endogenous ergosterol in microsome preparations from wild-type cells (21).

Hydropathy analysis of the SMT enzyme (Fig. 5), based on the predicted amino acid composition from the *ERG6* gene sequence, indicates that the enzyme is moderately hydrophilic with no obvious membrane-localizing elements. For some experiments, batch enzyme was processed by centrifugation at 100,000 × *g* for 90 min to sediment a microsomal fraction (14,22). Microsomal pellets were found to contain 80% of the original SMT activity of the sample, suggesting that the SMT produced in *E. coli* is membrane-associated. Emulphogen-solubilized microsomes released SMT activity with 50% recovery. These observations are consistent with the demonstration that the yeast SMT is loosely bound to the endoplasmic reticulum and distributes into several alternate membrane fractions and into a "floating lipid layer" upon fractionation (14,22).

In this report we demonstrate that the *ERG6* gene expressed from pSMTy23 in *E. coli* produces a protein that mediates biomethylation of zymosterol. The product of the reaction was unambiguously identified as fecosterol using a combination of radiochemical, chromatographic, and spectral

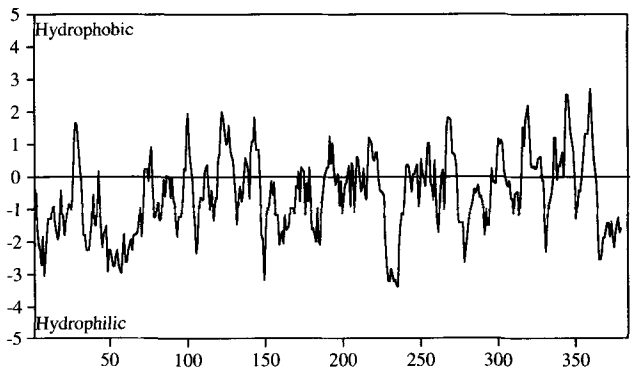

FIG. 5. Hydropathy plot of predicted (*S*)-adenosyl-L-methionine: $\Delta^{24(25)}$-sterol methyl transferase amino acid sequence (Ref. 8).

methods. Down-regulation of the SMT enzyme activity from pSMTy23 by select 24-alkyl sterols shows metabolic specificity for the structure of the side chain. These results confirm that *ERG6* is the structural gene for SMT in yeast and that ergosterol may function to regulate its own synthesis under normal physiological conditions in yeast.

ABSTRACT: A lipase was isolated from *Penicillium* sp. strain UZLM-4 and characterized. This lipase has a molecular weight of 27,344 (determined by mass spectrometry) and hydrolyzes triglycerides in preference to mono- and diglyceride substrates. Among various triglyceride substrates, tributyrin is hydrolyzed about four times faster than any other tested. The lipase has a preference for hydrolysis at the 1,3 positions of the lipids and shows a weak stereoselectivity for the S enantiomer. Unlike most other lipases, this lipase is stable and has a high activity at low surface pressures (5–10 mN/m).
Lipids 31, 379–384 (1996).

Commercial applications of lipases have been investigated for many years. The present and potential uses of lipases span a wide variety of industries, including production of flavor esters for various foods (1), production of surfactants (2), transesterifications for production of various oils, and, more recently, in chiral syntheses (3–5). Among the enzymatic properties which might be important for any given application are the thermal stability, the substrate specificity for both chain length and position, stereoselectivity, and stability in organic solvents.

In addition to the commercial interest in lipases, a great deal of academic interest has been focused on these enzymes. The physical and enzymatic properties of many lipases from a wide variety of sources have been investigated, and in the past few years a number of three-dimensional structures have been reported (6–12). Many microbial lipases including those from *Rhizomucor* (13), *Pseudomonas* (14), *Candida* (15), *Geotrichum* (16,17), *Aspergillus* (18,19), *Rhizopus* (20), and *Penicillium* (21–28) have been isolated and characterized. In this report we describe the purification and characterization of a lipase from *Penicillium* sp. which displays some novel enzymatic properties.

Abbreviations: HPLC, high-performance liquid chromatography; PDMS, poly(dimethylsiloxane).

MATERIALS AND METHODS

Identification and culture of strain. The strain of *Penicillium* sp. (UZLM-4) was isolated from soil and characterized at the Microbial Enzymes Laboratory of the Uzbekistan Academy of Sciences (Tashkent, Uzbekistan). Screening for the lipase-producing clone of *Penicillium* was done by spreading a suspension of spores on agar-fat plates (a lower layer of animal fat overlaid with 2.0% nutrient agar). The colonies producing the strongest clearing zones were selected. The organism was cultured in 30-L fermenters for 72 h at 25–27°C on a medium containing 5% malt extract, 0.5% sucrose, 0.7% cotton oil, 0.2% $NaNO_3$, 0.1% $CaCO_3$, 0.05% KCl, 0.02% $MgSO_4$, and 0.001% $FeSO_4$ adjusted to pH 5.8–6.0. The cells were removed by filtration. The lipase was found in the culture filtrate, and the crude enzyme preparation was obtained by precipitation with 4 vol of isopropanol. The precipitate was air-dried and stored at −20°C.

Purification of lipase. Ten grams of the crude lipase preparation was redissolved in water (2.5%) and fractionated with acetone. The precipitate obtained at 33–75% acetone (vol/vol) was removed by centrifugation at 3000 × *g* for 20 min at 4°C and was redissolved in 200 mL of 20 mM sodium phosphate buffer, pH 8.5. The enzyme was partially purified batchwise on 50 mL of Q-Sepharose (Pharmacia, Uppsala, Sweden) equilibrated with the same buffer. The material which flowed through the Q-Sepharose in 20 mM buffer without binding was adjusted with saturated ammonium sulfate solution to 10% saturation and applied to a butyl-Sepharose column (Pharmacia) (2.5 × 5 cm) equilibrated with 10% saturated ammonium sulphate. After thoroughly washing unbound material from the column with 10% saturated ammonium sulfate, the enzyme was eluted with a gradient to water. Fractions containing lipase were pooled, concentrated on a YM 3 Amicon membrane (Amicon, Inc., Beverly, MA) (3000 MW cutoff), and diafiltered with 20 mM sodium phosphate buffer, pH 8.5. Concentrated semipurified lipase preparation (10 mL) was applied on a Mono Q FPLC column (1.2 × 10.8 cm) (Pharmacia) equilibrated with 20 mM phosphate buffer, and the enzyme was eluted with a 0–0.2 M NaCl gradient in phosphate buffer,

[a]Protein concentration was determined with modified Lowry method (Ref. 40).
[b]Lipase activity was determined titrimetrically as described in the Materials and Methods section.
[c]Preparation concentrated on YM 3 Amicon membrane (Amicon, Inc., Beverly, MA).

pH 8.5. The summary of the lipase purification is shown in Table 1.

Gel electrophoresis. SDS gel electrophoresis was done on a Phastsystem (Pharmacia, Uppsala, Sweden) using 10–15% gradient gels according to the manufacturer's instructions. Protein bands were stained with Coomassie blue.

Amino acid analysis. Purified protein (50 µg) was hydrolyzed by using the acid vapor technique (27), and the hydrolysate was analyzed on a Beckman System 6300 High Performance Amino Acid Analyzer (Beckman Instruments, Fullerton, CA).

N-*Terminal sequencing. Penicillium* lipase (1–2 µg) was separated on an SDS gel, and the doublet was electroblotted onto a polyvinylidene fluoride membrane (Immobilon; Millipore, Milford, MA) according to the procedure described by Matsudaira (29). The *N*-terminal sequence was determined on an Applied Biosystems (Foster, CA) model 470A gas-phase protein sequenator (30).

Mass spectrometry. The purified protein was dialyzed into 5% acetic acid (vol/vol) for mass spectrometry. The protein mass was determined on an ion spray mass spectrometer (API III Biomolecular Mass Analyzer, Perkin-Elmer Sciex Instruments, Thornhill, Ontario, Canada) calibrated using lysozyme and polyethyleneglycol standards. The molecular weight was calculated from a set of simultaneous equations of the form

$$m/z = \frac{MW + n}{n} \quad [1]$$

where m/z is the measured mass/charge ratio, MW is the molecular weight, and n is the number of protons giving the protein its charge. Successive peaks in the spectrum differ by one proton so that if $m/z(1) < m/z(2)$, then

$$m/z(1) = \frac{MW + n}{n} \quad \text{and} \quad m/z(2) = \frac{MW + n - 1}{n - 1}$$

A series of peaks then provides a set of simultaneous equations from which the value MW can be derived.

Determination of lipase activity. (i) Plate assay. Lipase activity in column fractions was estimated by a rhodamine–triglyceride–agarose plate assay according to the procedure developed in our laboratory (31).

(ii) Titrimetric assay. All lipid substrates were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Initial velocity was measured using a titrimetric assay according to a recently described procedure (32). An emulsion was prepared by sonicating a mixture of di- or triglyceride (5 mM) and poly(dimethylsiloxane) (PDMS) in 2% (wt/vol) arabic gum solution and 1% $CaCl_2$. The mixture was sonicated for two minutes at 50% power output on a W-375 sonicator (Heat Systems Ultrasonics Inc., Farmingdale, NY). The enzymatic reaction was initiated by addition of 1–10 µg of enzyme to the emulsion. Throughout the assay the pH was maintained at pH 7.0 by titration with 50 mM NaOH by pH-stat (RTS822 Recording Titration System; Radiometer, Copenhagen, Denmark). Lipase activity was expressed in µmoles of fatty acid released per mg of enzyme at 25°C.

(iii) High-performance liquid chromatography (HPLC) measurements. The reaction mixture totalling 5 mL composed of 50 mM phosphate buffer, pH 7.1, and a suspension of 150 mM triolein or diolein was placed in the scintillation vial and stirred with a 12 mm stirring bar at 700 rpm. The 40 µL samples were withdrawn periodically and diluted with 800 µL of acetone, filtered through 0.2 µ HV Millipore filter and the reaction products were analyzed by reverse-phase HPLC (Waters, Milford, MA) on a C18 column (CSC-S ODS2, 25 × 0.46 cm, 5 µm; Supelco, Missassuaga, Ontario, Canada) using acetone/acetonitrile (1:1, vol/vol) as the mobile phase (33). The peak areas of the various reaction products were integrated using the Baseline 810 software (Waters) and compared to respective standards.

(iv) Monolayer measurements. The chloroform solutions of 1,2- or 1,3-dicaprin were spread over 400 cm^2 of 10 mM Tris-HCl, pH 7.0, in 100 mM NaCl containing 22 mM $CaCl_2$ and 1 mM EDTA placed in the "zero-order" trough (34). The surface pressure of the monolayer was controlled by a barostat (KSV Instruments, Helsinki, Finland) equipped with a Wilhelmy plate connected to the electromicrobalance. Lipase (approximately 0.1 µg) was injected under the monolayer film in the "enzyme" compartment of the trough, and the progress of the reaction was monitored by the data station equipped with the software provided by the barostat's manufacturer. Enzyme activity was expressed in µmoles of substrate hydrolyzed per µmol of lipase per minute per cm^2 of the interface at 25°C [µmoles $(DC_{10}) \cdot cm^{-2} \cdot min^{-1} \cdot \mu mol^{-1}$ (E)].

RESULTS

Purification. The isopropanol extraction of the culture filtrate typically gave a twofold purification of the lipase with about 80% recovery of the lipase activity in the resulting dried powder. Table 1 shows the results of a typical purification of the lipase from this crude dried powder. The yield of enzyme purification was typically 20–30% of the activity present in the crude enzyme preparation. The acetone precipitation produced two fractions with lipase activity. The major activity

was purified further to the lipase described in this paper and will be referred to as UZLM-A. No attempts have been made to pursue the other activity because of the low yield. The substrate profile of the second lipase fraction was somewhat different than that of the major fraction, but since we were unable to purify the second fraction to homogeneity, no extensive characterization and comparison were possible.

The acetone precipitation resulted in a loss of some lipase activity and a drop in the specific activity (Table 1). This rather harsh treatment of the enzyme was nonetheless necessary, as with no acetone precipitation the recovery of the lipase in subsequent chromatographic steps was drastically reduced. This parallels results obtained with other lipases produced by fermentation from media containing high concentrations of lipids (Ziomek, E., unpublished results). Although we have no direct evidence of lipid binding to the lipase, we suspect that complexation with lipids or lipopolysaccharides alters the chromatographic behavior of the enzymes and makes recovery difficult. The acetone treatment solubilizes the vast majority of lipids from the mixture and separates the enzyme from the lipids. The Q-Sepharose purification step resulted in a large increase in activity and a recovery of more than 100% (see Table 1). This indicates that at this stage of the purification the enzyme was separated from some inhibitory factors which have not been identified.

Biochemical characterization The MW of the purified lipase estimated from SDS gels is ~28,000. Immediately following purification, a doublet with estimated MW of 28,000 and 26,000 was observed on the SDS gels. The doublet was blotted from the gel and *N*-terminal sequencing of the first 22 residues showed a single strong signal, indicating that the two bands of the doublet must be either identical or closely related proteins. The mass of the enzyme measured by ion spray mass spectrometry is 27,334 ± 1.2 daltons, consistent with the MW estimated from SDS gels (Fig. 1). Small peaks in the mass spectrum suggest the presence of components of about 25,000 and 26,000 MW, consistent with the appearance of the doublet on SDS gels. Since only one sequence was observed from the doublet, these components must be either trace amounts of C-terminally truncated forms of the major lipase activity or closely related lipases. Upon storage of the enzyme preparation at 4°C, some precipitate was observed. After centrifugation to remove the precipitate, a single band at 28,000 MW was observed on SDS gels. No further characterization of the precipitate was done, but the lipase remaining in solution appeared to be homogeneous.

TABLE 2
Comparison of *N*-Terminal Sequences of Some *Penicillium* Lipases[a]

Microbial source	*N*-terminal sequence	Reference
P. sp. UZLM-4	ATAATAAFPDLNXAAKLXXAAY--	—
P. expansum	AVAASAAFPDLXRAAKLSSAVY--	28
P. camembertii	DVSTSELDQFEFWVQYAAASYY--	36

[a]X = unidentified residue.

Comparison of the *N*-terminal sequence shown in Table 2 with those of other known lipase sequences reveals striking similarity to the *N*-terminal sequence of a lipase from *P. expansum* (28). A search of the SWISS-PROT database (35) revealed no other significant sequence similarities. There is weak similarity of the N-terminal sequences of UZLM-A and *P. expansum* lipase to residues 149-170 of *P. camembertii* lipase (28,36). Within this 22-residue stretch, there are two "identities" spanning three residues and one of two residues. However, one must introduce insertions or deletions to align these three "identical" stretches simultaneously. This suggests that the similarities of the UZLM-A and *P. expansum* sequences with this region of *P. camembertii* are fortuitous and of no functional significance.

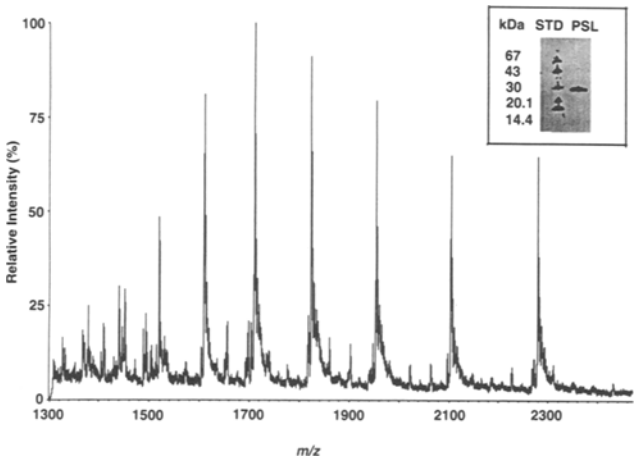

FIG. 1. Mass spectrometric analysis of the purified UZLM-A lipase. The mass calculated from the series of major peaks in this spectrum is 27,344 daltons. The inset shows the SDS–polyacrylamide gel electrophoresis of *Penicillium* sp. UZLM-A lipase. Lane 1, Bio-Rad (Bio-Rad Labs, Richmond, CA) low molecular weight standards. Lane 2, purified *Penicillium* sp. UZLM-A lipase, 0.5 μg.

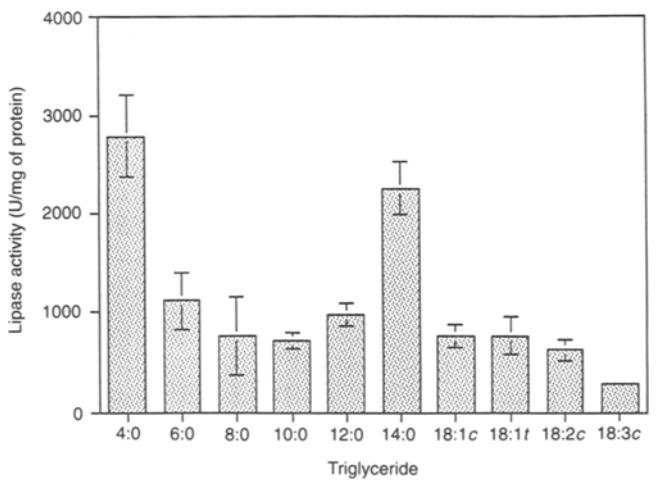

FIG. 2. Substrate profile of *Penicillium* sp. UZLM-A lipase. Activities were measured using the titrimetric assay, and the specific activities are reported in units/mg protein where one unit is 1 μmole fatty acid produced per minute.

TABLE 3
***Penicillium* sp. UZLM-A Lipase Activity Against Diglycerides**

Glyceride	Units/mg	% of the reactive triglyceride activity[a]
Triolein	778	100.0
Diolein (90% 1,3-DO)	160	20.6

Tripalmitin	25	100.0
1,3-Dipalmitin	7	28.0

[a]Lipase activity determined titrimetrically as described in the Materials and Methods section.

Substrate specificity. Comparison of initial hydrolysis rates of various lipid substrates shows that this enzyme strongly prefers tributyrin to any other lipid tested (Fig. 2). Most other substrates ranging from $C_{6:0}$ to $C_{18:2}$ are hydrolyzed at about 25% of the rate observed for tributyrin. One exception is trimyristin ($C_{14:0}$), whose initial rate of hydrolysis is more than twice that of most of the other substrates and two-thirds that of tributyrin. The hydrolysis of tricaprylin ($C_{8:0}$) rapidly stops about 15–30 s after the reaction is initiated, making measurement of the initial rate difficult. The reason for this behavior is uncertain. Although unlikely, the substrate may contain an impurity which inhibits the lipase. Another possibility is that the enzyme is rapidly inhibited by the products of the hydrolysis as discussed below.

Initial hydrolysis rates of diglyceride substrates are roughly one quarter or less of the rate of hydrolysis of the corresponding triglyceride (Table 3). HPLC analysis of reaction products also shows that hydrolysis of triolein leads to accummulation of diolein and monoolein, indicating slower hydrolysis of both diglyceride and monoglyceride (Fig. 3).

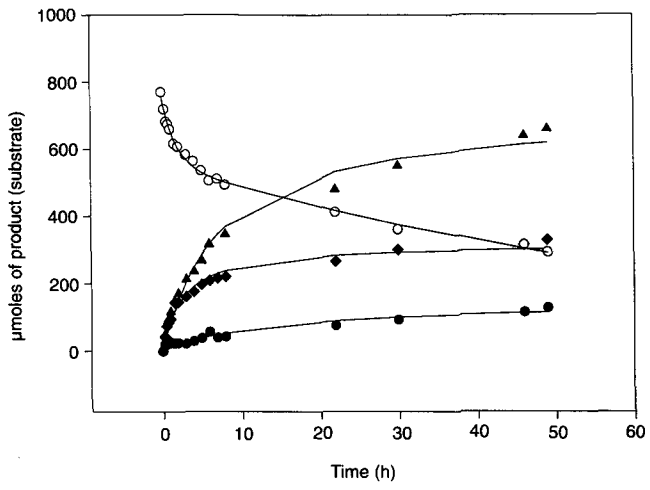

FIG. 3. Hydrolysis of triolein by *Penicillium* sp. UZLM-A lipase. The course of the reaction was followed by high-performance liquid chromatography analysis of a small aliquot of the reaction mixture at various time points. Triolein is represented by open circles, diamonds represent diolein, closed circles represent monoolein, and triangles represent oleic acid.

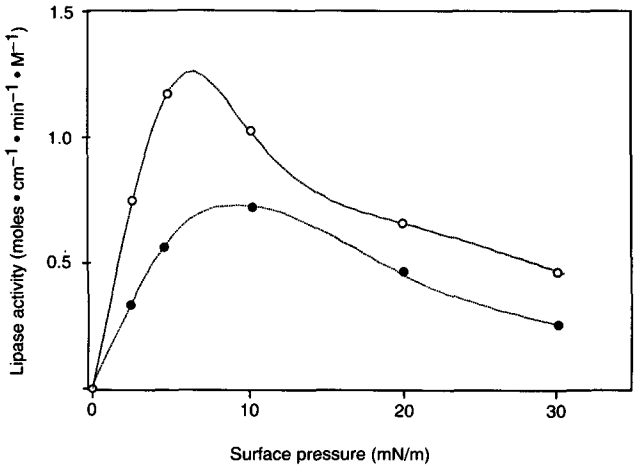

FIG. 4. Surface pressure profile of *Penicillium* sp. UZLM-A lipase determined by the monolayer method. Open circles represent curve for 1,2-dicaprin (S) as the substrate and closed circles represent 2,3-dicaprin (R) as the substrate.

1,2-Diolein is produced in about 5-fold excess over 1,3-diolein, indicating that this lipase shows a strong preference for hydrolysis of the acyl chains at the 1,3 positions.

The monolayer studies using dicaprin as a substrate show a rather unusual property of UZLM-A lipase (Fig. 4). Most lipases show their highest activities at surface pressures of 20–40 mN/m and lose their activity when exposed to the interface at a low surface pressure (5 mN/m) (37). In contrast, the *Penicillium* lipase prefers a low density monolayer film. This lipase also showed a weak S (1,2-dicaprin) over R (2,3-dicaprin) enantiomeric preference (Fig. 4) and strong 1,3-positional selectivity. Monolayer studies using other synthetic lipids as substrates confirmed the strong 1,3-positional selectivity and the weak S stereoselectivity. The enantiomeric selectivity was mainly observed at low interfacial surface pressure, similar to the properties of other lipases reported by Rogalska *et al.* (37).

The preference of UZLM-A for triglycerides and low interfacial pressures suggests an explanation for the rapid loss of activity against tricaprylin. The inhibition might result from accumulation of reaction products which increases the surface pressure at the interface. In the lipase assay used in this study, PDMS was used as a carrier for the triglycerides and the emulsions of the triglyceride–PDMS complex were used as the lipase substrate. In this type of emulsion, triglycerides and products of the lipolysis desorb only slowly from the surface of the emulsion droplet. The desorption rate is inversely proportional to the hydrocarbon chain length and is higher for fatty acids, mono- and diglycerides than for triglycerides. At least transiently, however, mono- and diglycerides could accummulate to create a high interfacial surface pressure. The surface pressures exerted by mono- and diglycerides are known to be higher than for monolayers of triglycerides and could inhibit UZLM-A, which shows a preference for low surface pressure interfaces. Perhaps the dicaprylin–PDMS complex forms the most impenetrable interface and accumulation of dicaprylin in

the course of the lipolysis produces a reaction profile typical of product inhibition.

DISCUSSION

A number of different lipases have been purified from various strains of *Penicillium*. Some of the properties of lipase UZLM-A are similar to other *Penicillium* lipases. Like UZLM-A, many *Penicillium* lipases have reported MW in the 25,000–32,000 range. The MW of 27,344 determined for the lipase UZLM-A is the most similar to the MW of 27,000 estimated from gel filtration of lipase A from *P. cyclopium* Westring (22). Interestingly, these two lipases also share similarities in their substrate preferences. In both cases, tributyrin is hydrolyzed faster than any other triglycerides tested. Lipases with preferences for tributyrin have also been described from *P. crustosum* (MW 32,000) (21) and from *Penicillium citrinum* (no MW estimate provided) (26). The lipase from *P. expansum* (MW 25,000) also reportedly hydrolyzes triglycerides faster than other substrates (28). The similarity of the *N*-terminal sequences of *P. expansum* lipase and UZLM-A strongly suggests that they are similar enzymes. No sequence information is available for the *P. cyclopium* and *P. citrinum* enzymes, but based on the similarities to UZLM-A and *P. expansum* lipase cited above, one might also also expect sequence similarities. Cloning and expression of the lipase described here are underway and should soon provide a complete amino acid sequence.

In contrast to the similarities to some *Penicillium* lipases, there are also striking differences between UZLM-A and other *Penicillium* lipases. One lipase from *P. cyclopium* M1 and one from *P. simplicissimum* are considerably larger than other *Penicillium* lipases, 54,000 and 56,000 MW, respectively (24,27). *Penicillium cyclopium* M1, *P. cyclopium* Westring, and *P. camembertii* produce enzymes which hydrolyze mono- and diglycerides and monoacyl esters significantly faster than they hydrolyze triglycerides (23,25), the opposite of the preferences described here. The *N*-terminal sequence of *P. camembertii* lipase bears no resemblance to that of UZLM-A and *P. expansum* lipase. Despite some similarity of the *N*-terminal sequence of our lipase to a region in the middle of *P. camembertii* lipase, there is probably no functional significance to the similarity, and they probably represent truly different lipases. *Penicillium cyclopium* M1 and *P. cyclopium* Westring produce both lipases that prefer triglycerides and lipases that prefer mono- and diglycerides, and complete hydrolysis of triglycerides to fatty acids and glycerol requires the presence of both lipases (23). A similar situation is likely to exist in many other *Penicillium* strains as well.

One of the most interesting features of lipase UZLM-A is its activity and stability at low surface pressures. This type of behavior could explain why this enzyme prefers liquid triglycerides (oils) over solid fats which exert a higher surface pressure. The affinity of UZLM-A lipase to low surface pressure interfaces could also explain its low activity against di- and monoolein. The surface pressures exerted by both diglycerides and monoglycerides are 2–3 times higher than the maximal surface pressure of the triglyceride (38). The lipase from *P. camembertii*, in contrast to UZLM-A, maintains its activity at surface pressures above 20 mN/m, consistent with its high activity on mono-and diglycerides (39). The surface properties and stereoselectivities of other *Penicillium* lipases have not been reported and possibly have not been extensively investigated. The three-dimensional structure of *P. camembertii* lipase has been reported (11). Crystal structure analysis of UZLM-A is currently underway. Comparison of these structures should provide important insight into the substrate selectivities of lipases.

Sphingomyelin Metabolism Is Linked to Salt Transport in the Gills of Euryhaline Fish

Mohammed El Babili, Gérard Brichon, and Georges Zwingelstein*

Institut Michel Pacha, Université Claude Bernard Lyon I, 83500 La Seyne sur Mer, France

ABSTRACT: By *in vivo* and *in vitro* studies of L-(3-^{3}H)serine and [9,10(n)-^{3}H]palmitic acid incorporation into phospholipids, we show a change in the renewal of the ceramide moiety of sphingomyelin in the gills of euryhaline fish (sea bass and eels) when the animals were subjected to abrupt alterations in environmental salinity. *In vivo*, decrease of the salinity from sea water (salinity 3.7%) to diluted sea water (salinity 1%) induced an increase of label incorporation into gill sphingomyelin. The same was true when gills from sea water-adapted sea bass or sea water-adapted eels were incubated in diluted sea water. A decrease in free ceramides synthesis was also observed in the gills of sea water-adapted sea bass when the salinity of the incubation medium was reduced. Direct inhibition of Na^+/K^+-ATPase activity with ouabain decreased the sphingomyelin synthesis in the gills of sea bass during *in vitro* incubation in diluted sea water, whereas treatment with furosemide stimulated sphingomyelin synthesis in the same gills incubated in sea water. These findings indicate that changes in Na^+ fluxes modify the sphingomyelin turnover and control the production of free ceramides and sphingosine in gill cells of euryhaline fish. In view of the well-known effects of these sphingomyelin degradation products on isolated tumor cell differentiation, we suggest that they play a very important role in modulating chloride cell distribution and metabolism of fish gills during abrupt changes in environmental salinity.

Lipids 31, 385–392 (1996).

Sphingomyelin (SPH) is found in all fish and crab tissues as a component of cell membranes (1–4). There is a greater percentage of SPH in gill phospholipids than in those of other tissues (2,4), and sea water (SW) adaptation increases this percentage in the gills of euryhaline crabs (5). The biosynthetic pathway for SPH appears to be very active in the gills of teleosts and crustaceae (6,7). This pathway involves ceramide synthesis from long-chain bases followed by transfer of a phosphocholine moiety catalyzed by phosphatidylcholine (PC)-ceramide cholinephosphotransferase (8). Factors influencing SPH turnover include serine and acyl-CoA availability, and the relative activities of key enzymes in the synthesis and degradation pathways. The first step in degradation involves the removal of the head-group by sphingomyelinase, an enzyme found in gill cells (2).

In addition to their respiratory function, the gills of euryhaline fish and crabs participate in osmoregulation (9,10). The gills are the site of active NaCl transport and the direction of active salt transport is correlated with external salinity. In gills of *Anguilla anguilla* and *Platichthys flesus*, two euryhaline teleosts, active NaCl absorption begins during adaptation to fresh water (FW) (11,12). The branchial epithelium of SW-adapted fish show a much larger population of chloride cells than that of FW-adapted fish (13). These cells are the site of chloride transport and possess enzymatic characteristics of electrolyte-transporting epithelia (13,14). In gill epithelium, most of the Na^+/K^+-ATPase activity is found in chloride cells, and cell density depends directly on the external salinity (13,14). In both teleosts and crabs, changes in chloride cell density are accompanied by an alteration of phospholipid metabolism (5,15). It has been reported (8) that SPH concentration is different in gills of FW- and SW-adapted crabs (*Eriocheir sinensis*). Changes in the concentration of this major phospholipid may reflect modification of its turnover rate. Moreover, SPH catabolism liberates ceramide and/or free sphingosine, potential second messengers which could modulate cell function (16,17). The recent discovery that these intermediates play an important role in controlling cell growth, differentiation and oncogenesis (17–20) has motivated this study of SPH metabolism during abrupt salinity changes in fish gills.

MATERIALS AND METHODS

Two different species of euryhaline fish were used in this study, a marine fish: sea bass (*Dicentrarchus labrax*) and a freshwater fish: yellow European eel (*A. anguilla*). Sea bass (*D. labrax*) averaging 75 g were originally obtained from a sea farm (Centre de production aquacole IFREMER, Palavas les Flots, France) and were kept in indoor tanks with continuously flowing Mediterranean SW (salinity 3.7%) at 14–15°C for 4 wk. Eels averaging 100 g were originally obtained from the Rhône river and were acclimated to continuously flowing

FW or SW at 14–15°C for 4 wk. Sea bass were fed a standard diet and eels were starved.

In vivo *L-3(^{3}H)-serine incorporation.* Sea bass acclimated to SW received 100 μCi of L-3(^{3}H)-serine (29 Ci /mmol; Amersham, Les Ulis, France) per 30 g wet weight by intraperitoneal injection and were randomly divided in two groups: (i) SW (salinity 3.7%) and (ii) diluted SW (salinity 1%) at a controlled temperature of 17°C. After 16, 24, and 36 h, the animals were killed by a blow on the head, and gills were isolated and weighed. Lipid extraction and purification were performed on the fresh tissue by the method of Folch *et al.* (22), modified by Chapelle *et al.* (23). The phospholipid classes were resolved by two-dimensional thin-layer chromatography (TLC) on precoated silica-gel G-60 plates (Merck, Darmstadt, Germany) as previously described by Portoukalian *et al.* (24). Phospholipids were detected with a specific spray reagent (25) and quantified by determining the phosphorus content in each spot as previously described (5,24). For the radioactive determination, phospholipid spots revealed on the TLC chromatograms were counted in the presence of silica gel, by scraping into a scintillation vial and resuspending in 3 mL water/ethanol (1:1, vol/vol) and 8 mL Picofluor 30 (Packard, Downers Grove, IL) (26).

In vitro *L-3(^{3}H)-serine incorporation.* Gills from SW-adapted sea bass were cut at their bases, and each pair transferred to ultra-filtered Mediterranean SW or diluted SW, rinsed and blotted on paper. Then, one gill of each pair was placed in SW and the other in diluted SW containing 0.3 μM L-3(^{3}H)-serine (29 Ci/mmol; Amersham) or 0.2 μM [9,10(n)-^{3}H]-palmitic acid (40–60 Ci/mmol; Amersham) and incubated at 15°C for the indicated time. Lipids were extracted and analyzed as described above.

Analysis of long-chain bases in SPH. Phospholipids were separated by one dimensional TLC on precoated silica-gel G-60 plates in chloroform/methanol/water (65:35:6, by vol). The SPH spots, visualized with iodine, were scraped into tubes, eluted with a mixture of chloroform/methanol/acetic acid/water (50:39:1:10, by vol) and washed as described by Arvidson (27). Some lipid extracts were subjected to mild alkaline methanolysis (28) before purification of SPH by TLC. SPH was first enzymatically hydrolyzed using 10 units/mL phospholipase C (Type 1 from *Clostridium perfringens*; Sigma, St. Louis, MO) in 1 mL of Tris pH 7.4, 30 mM $CaCl_2$ mixed with 1 mL diisopropyl ether for 18 h at 20–25°C to obtain the ceramides (29). Diisopropyl ether was evaporated in a stream of nitrogen before the addition of 4 mL chloroform/methanol (1:1, vol/vol) and 1.8 mL water. Ceramides were extracted in the chloroform phase, followed by centrifugation. Aliquots of the water and chloroform soluble extracts were counted. Under these conditions of hydrolysis, TLC of the chloroform extract on silica gel in chloroform/methanol/water (65:35:6, by vol) showed the total disappearance of SPH. The ceramides were acid hydrolyzed in teflon-lined screw-capped tubes in concentrated HCl/water/methanol (1:2:6, by vol) for 18 h at 80°C (30). The samples were taken to dryness with added methanol and benzene to eliminate HCl and water. The residues, redissolved in 0.5 mL of chloroform/methanol (2:1, vol/vol) and diluted with standards (mixture of SPH, ceramides, sphingosine, fatty acids, and esters), were separated by one-dimensional TLC on precoated 10 × 5 cm TLC plates. The plates were first developed to 5 cm in chloroform/methanol/water (100:42:6, by vol) and then, after drying, in chloroform/methanol (50:3, vol/vol) to the 10-cm length. The fatty acids and esters, ceramides, sphingosine, and SPH spots were visualized with iodine and scraped into scintillation-counting vials and counted. Under these conditions, all of the radioactivity initially found in the ceramide was distributed between sphingosine and fatty acids, according to the radioactive precursor.

Determination of radioactivity in free ceramides of gills. For free ceramide measurements, lipids were subjected to mild alkaline hydrolysis (28) in 0.4 M methanolic NaOH at 37°C for 1 h. Concentrated HCl was added to obtain a final concentration of 0.4 N acid, and hydrolysis was continued for 1 h at the same temperature. After extraction with chloroform, the resulting extracts were diluted with solutions of purified ceramides and separated by one-dimensional TLC on 10 × 5 cm precoated silica-gel plates by two successive developments, as described above. SPH and ceramides were visualized with iodine, scraped, and counted. The ceramide radioactivity in tissue, in dpm/100 mg wet gills, was calculated from SPH radioactivity found on the plate.

Statistics. Means for individual phospholipid radioactivity were compared using one-way analysis of variance. Percentages were arcsine transformed. If test for normality failed, then a nonparametric Kruskal-Wallis one-way analysis of variance on ranks was used. All values presented are means ± SEM.

RESULTS

In vivo incorporation of L-(^{3}H)serine into gill lipids of the sea bass during abrupt change in salinity from SW (3.7%) to diluted SW (1.0%) is summarized in Table 1. During this 36-h experimental period, 90% of lipid radioactivity in the gills was present in phospholipids, and this stayed relatively constant [from 7318 ± 293 (4) dpm/100 mg wet gills at 16 h to 8031 ± 250 (4) at 36 h in SW and 6143 ± 288 (4) to 7655 ± 774 (4) in diluted SW]. When the distribution of the radiolabel among lipid species was determined (see Table 1), radioactivity was significantly lower ($P < 0.01$) in SPH of the gills of fish in SW than in those of fish transferred to diluted SW. No major variations for the other lipids were observed. The gross distribution of radioactivity in PC, phosphatidylserine (PS), and phosphatidylethanolamine (PE) appeared to be independent of salinity. In these same experiments, phospholipid composition showed the same general pattern in the gills of both animals, with SPH representing 11.5 ± 0.2% of total lipid phosphorus [PC: 46.0 ± 0.3%, PS: 6.4 ± 0.2%, phosphatidylinositol (PI): 4.4 ± 0.2%, and PE: 17.2 ± 0.5%]. To determine whether the differences in SPH metabolism during the abrupt decrease in salinity resulted from a direct effect on

TABLE 1
***In vivo* Distribution of L(3-^{3}H)Serine into Gill Lipids of the Sea Bass During an Abrupt Change from Sea Water (SW, salinity 3.7%) to Diluted Sea Water (salinity 1%)[a]**

Lipid	SW	Diluted SW

gill SPH turnover, we have carried out *in vitro* experiments, looking at the effect of medium salinity on the incorporation of L-(^{3}H)serine into phospholipids of isolated gills from SW-adapted fish. As shown in Table 2, there was a marked increase (+43%) in SPH radioactivity (from 11.6 to 16.4%) in phospholipids extracted from gills incubated in diluted SW. Low salinity resulted in a decrease (−13%) in PS radioactivity without modifying PC and PE label percentage.

To confirm the effect of abrupt change in external salinity on gill SPH metabolism in another euryhaline fish, we have analyzed the *in vitro* incorporation of L-(^{3}H)serine into the phospholipids of gills obtained from SW- and FW-adapted eels. In these experiments, gills were incubated in a synthetic medium with an osmotic pressure and ionic composition similar to eel plasma. There was a large difference between the incorporation of the radiolabel into SPH of gills from SW- or FW-adapted eels (Fig. 1). There were no major differences between the other phospholipids, except for a small increase of the label in PC of gills from SW-adapted eels.

The distribution of the label in SPH isolated from gills after *in vivo* radioactive serine incorporation revealed that

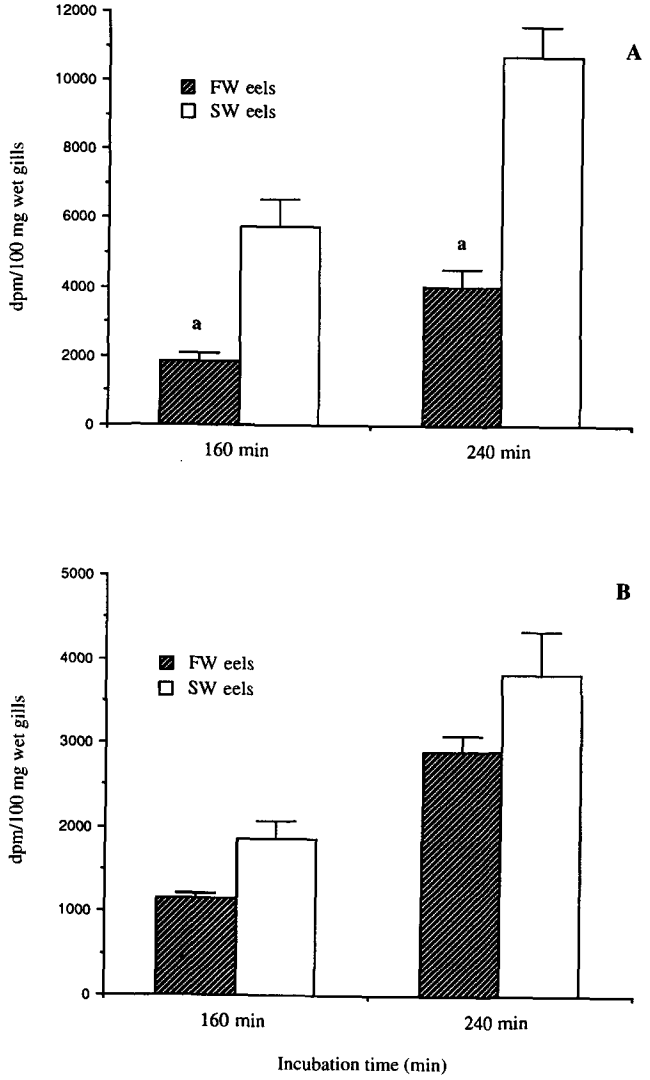

FIG. 1. *In vitro* incorporation of L-(U^{14}C)serine into gill sphingomyelin (A) and phosphatidylcholine (B) of salt water (SW)- and fresh water (FW)-adapted eels. Gills from SW- or FW-adapted eels were incubated for 160 and 240 min at 17°C in a synthetic medium of NaCl, 147 mM; KCl, 2.66 mM; $CaCl_2$, 2.17 mM; $MgCl_2$, 2.34 mM; HNa_2PO_4, 8.1 mM; and H_2NaPO_4, 1.9 mM, containing 0.35 µCi L-(U^{14}C)serine/mL. Values are means ± SEM of four animals. a, Values statistically different ($P < 0.01$) between gills from SW- and FW adapted eels.

TABLE 2
Influence of the Salinity of *in vitro* Incubation Medium on the Distribution of L-(3-^{3}H)Serine into Gill Phospholipids of Sea Bass[a]

	Incubation medium	
Lipid	SW	Diluted SW
SPH	11.56 ± 0.19[b]	16.40 ± 0.06[c]
PC	4.48 ± 0.27	5.20 ± 0.06
PS	48.03 ± 1.32	41.58 ± 0.79[d]
PE	9.87 ± 0.76	10.79 ± 0.35

[a]Gills from SW-adapted sea bass were incubated for 4 h at 17°C in SW (salinity 3.7%) or diluted SW (salinity 1%) containing 5 µCi L-(3-^{3}H)serine/mL.
[b]Values are expressed as dpm% of the total dpm in the lipid extracted from the gills and are the means ± SEM of six animals. Values statistically different: [c]$P < 0.01$, [d]$P < 0.05$, between SW and diluted SW. See Table 1 for abbreviations.

about 80–85% of total radioactivity was found in the sphingosine moiety. The fatty acids and choline isolated during enzymatic and acid treatments contained 10–15% of the radioactivity. After *in vitro* incubation, 90–95% of the radioactive label was found in the sphingosine moiety of the purified SPH. These results were consistent with the sphingosine biosynthetic pathway, in which the first stage is a condensation of serine and palmitoyl-CoA followed by an acylation to ceramide. To form SPH, the phosphorylcholine head-group seems to be transferred from PC to ceramide (6). To determine if the rate of the acylation step in the SPH biosynthesis was altered by the salinity change, we have measured the incorporation of (^{3}H)palmitic acid into gill SPH under the same

in vitro conditions. Results of these experiments with gills from sea bass are summarized in Figure 2. The salinity of the incubation medium had a large effect on the rate of radioactive palmitic acid incorporation into gill SPH. For the other lipids, no differences between SW and diluted SW were observed except after 2 h of incubation in PC. In these experiments, 27% of the radiolabel was located in sphingosine and 73% in the acyl moiety of the SPH isolated after SW or diluted SW incubation.

The above results demonstrate an effect of external salinity on the rate of SPH synthesis in gills of sea bass and eels. However, they give only an imperfect picture of the biochemical changes due to salinity variations. For this reason, it was

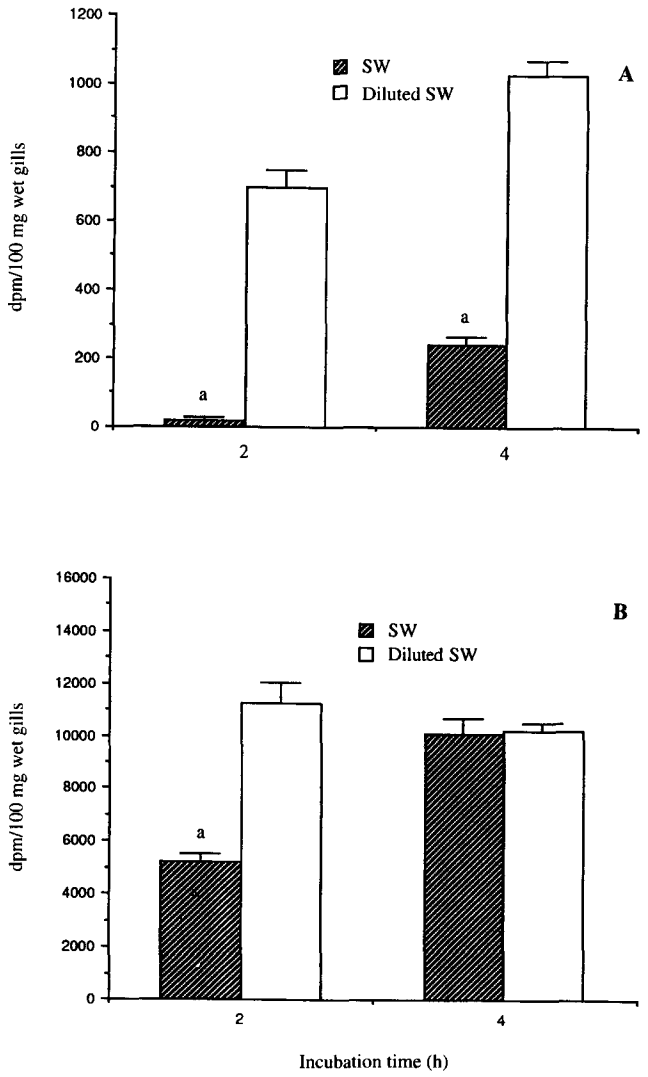

FIG. 2. Influence of medium salinity on the incorporation of [9,10(n)-^{3}H]palmitic acid into (A) gill sphingomyelin and (B) phosphatidylcholine of sea bass. Gills from SW-adapted sea bass were incubated for 2 and 4 h at 17°C in a SW or diluted SW medium containing 5 μCi (^{3}H)palmitic acid/mL. Values are means ± SEM of four animals. a, Values statistically different ($P < 0.01$) between gills from SW (salinity 3.7%) and diluted SW (salinity 1%) incubation medium. See Figure 1 for abbreviation.

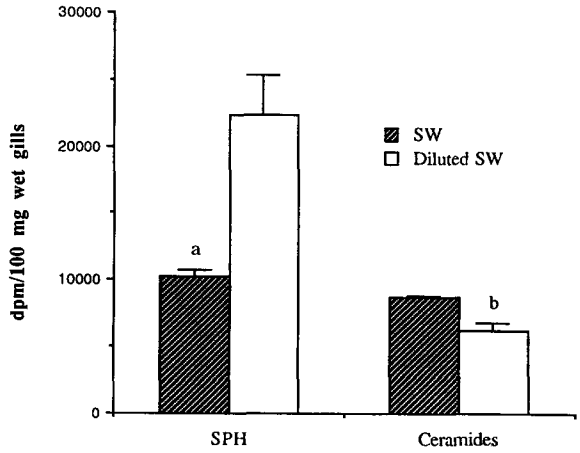

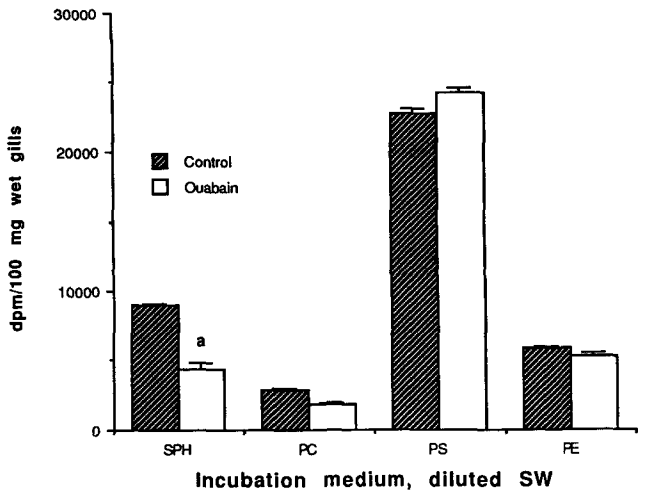

FIG. 3. Sphingomyelin and ceramide radioactivities in gills from SW-adapted sea bass after 4 h of incubation at 17°C in SW or diluted SW containing 15 μCi (^{3}H)serine/mL. Values are means ± SEM of four animals. Values statistically different: a, $P < 0.01$ and b, $P < 0.05$, between gills from SW and diluted SW incubation media; SPH, sphingomyelin. See Figure 1 for other abbreviation.

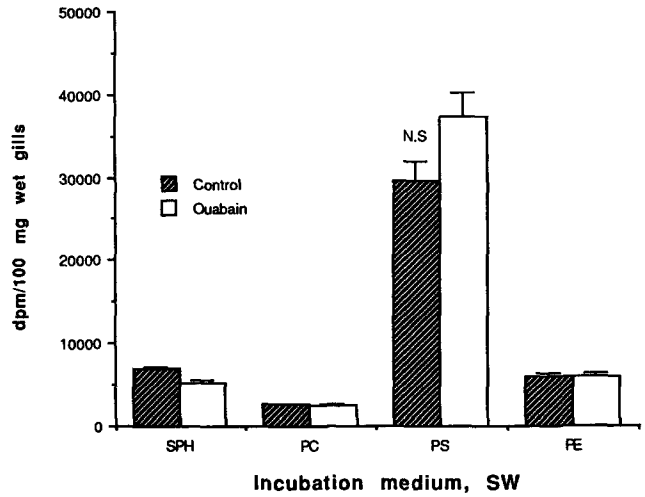
of interest to measure radioactivity incorporated into free ceramide, an intermediate of SPH metabolism. Figure 3 shows the activity of SPH and ceramides in the gills of sea bass after 4 h of incubation in diluted SW or SW containing 15 μCi (^{3}H)serine/mL. We observed an effect of external salinity on the incorporation of radiolabel into free ceramides and SPH. Diluted SW caused a decrease in label incorporation into tissue free ceramides (essentially with nonhydroxylated fatty acids) together with an increase in incorporation into SPH.

To test the hypothesis that the increase in SPH biosynthesis is linked with the change of Na^+ flux in branchial cells during salinity changes, we have studied the effect of Na^+ transport modulators on *in vitro* incorporation of L-(^{3}H)serine into SPH of sea bass gills. The effect of ouabain on L-(^{3}H)serine incorporation into gill phospholipids of sea bass incubated in diluted SW is summarized in Figure 4. Ouabain (1 mM) decreased the incorporation of the label into gill SPH (from 16.4 ± 0.5 to 11.9 ± 0.9%) after 4 h of incubation. In the same medium, neither 1 mM N-amidino-3,5-diamino-6-chloropyrazinecaarboxamide (amiloride), nor 1 mM 5-[aminosulfonyl]-4-chloro-2-[2-furanylmethyl)-amino] benzoic acid (furosemide) affected the SPH synthesis. Under the same conditions, however, furosemide strongly increased the incorporation of the label into PC (see Fig. 5). During incubation in SW, only furosemide increased the incorporation of the radiolabel into SPH from 7.6 ± 0.3 to 10.6 ± 0.5%; the other Na^+ modulators had no effect (Fig. 5).

DISCUSSION

This study shows that an abrupt decrease in salinity causes a marked increase in SPH turnover in the gills of euryhaline fish. However, this effect is probably transient because maximal changes appear to occur within 6–48 h. The same pattern



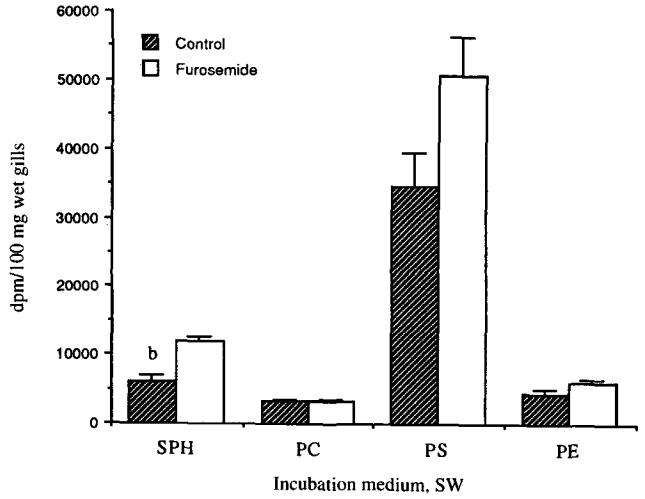


FIG. 4. Effect of 1 mM ouabain on L-(3-^{3}H)serine incorporation into gill phospholipids of sea bass during a 4-h *in vitro* incubation in diluted SW. Values are means ± SEM of four animals. a, Values statistically different ($P < 0.01$) between control and ouabain-treated gills; N.S., not significant. See Figure 1 for other abbreviation.

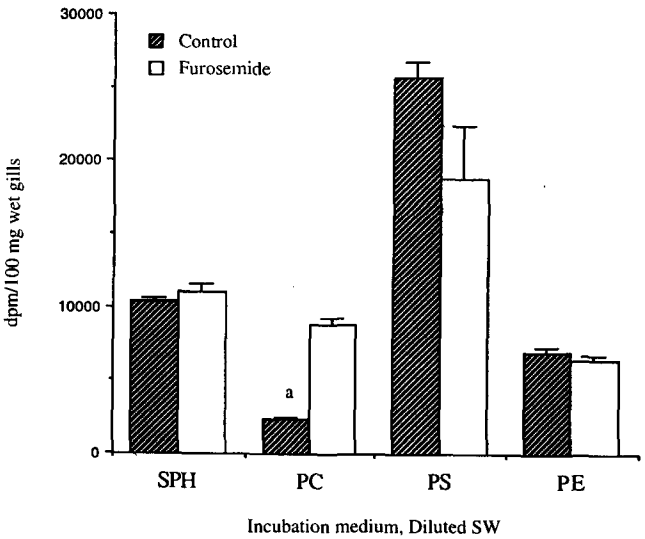

FIG. 5. Effect of 1 mM 5-[aminosulfonyl]-4-chloro-2-[(2-furanylmethyl)-amino] benzoic acid (furosemide) on L-(3-^{3}H)serine incorporation into gill phospholipids of sea bass during a 4-h *in vitro* incubation in SW or diluted SW. Values are means ± SEM of four animals. Values statistically different: a, $P < 0.01$ and b, $P < 0.05$, between control and furosemide-treated gills; PC, phosphatidylcholine; PS, phosphatidylserine; PE, phosphatidylethanolamine. See Figures 1 and 3 for other abbreviations.

is observed in SW- or FW-adapted eels (2). However, 16–36 h after the transfer of SW-adapted sea bass to diluted SW, the percentage of radioactivity incorporated into SPH increases by 24%. Four hours after the salinity change *in vitro*, radioactivity incorporation increases by 110% for SPH and decreases by 36% for free ceramide, an intermediate metabolite. These results demonstrate that an alteration in ceramide metabolism induced by an abrupt change of salinity takes place in the gills of euryhaline fish and that it may mediate some of the cellular rearrangement known to occur after an osmotic shock. Indeed, the number of chloride cells in the gills of euryhaline fish transferred from FW to SW and of hyperosmotic crab transferred from SW to FW increases (13,31).

Relatively little is known about the control of proliferation and distribution of the mitochondria-rich chloride-transporting cells in gills. The induction of the differentiation program of these cells is started by an unknown mechanism. In murine erythroleukemia cells, Kiss *et al.* (32) have shown that treatment with phorbol esters at concentrations sufficient to induce cell differentiation significantly increased the rate of SPH synthesis. In the same cells, the drop of intracellular Na^+ induced by dimethylsulfoxide appears as an early event of cell differentiation (33), and the decrease in Na^+/K^+ pump activity measured by Mayer and Bernstein (34) is probably one of the multiple factors inducing the differentiation program. Similarly, amiloride (a specific inhibitor of Na^+/H^+ exchange) interferes with 12-0-tetradecanoylphorbol 13-acetate (TPA)-induced differentiation of HL-60 cells (35).

We have shown that SPH biosynthesis *in vitro* by gills from SW-adapted sea bass, can be rapidly elevated by incubation in diluted SW. A similar effect has been noted by Girard *et al.* (36) for chloride cells from the gills of SW- compared with FW-adapted eels, in a study of the effect of adrenalin on ^{32}P incorporation into phosphatidic acid and PI.

Under our experimental conditions, the use of different inhibitors of Na^+ transport allowed additional observations. In FW or diluted SW, the pump transporting K^+ from the extracellular space into the cell is ATP dependent and Na^+ coupled (37). This Na^+/K^+ pump is inhibited by ouabain which acts on the basolateral membrane of the transporting cells (38,39). This ouabain-inhibited Na^+/K^+-ATPase is present in the gills of fish, and its activity is strongly enhanced by adaptation to SW in euryhaline fish (40). On the other hand, in FW, the active Na^+ uptake in trout gills is also inhibited by amiloride or furosemide, a second group of Na^+ transport modulators (41). These diuretics inhibit the active transfer of Na^+ on the apical membrane of the ion-transporting cells (42). With SW-adapted sea bass, 1 mM amiloride has no effect on the activation of SPH synthesis observed during *in vitro* incubation in diluted SW medium. It is interesting to note that amiloride has practically no effect on the cellular sodium movements under these conditions (42). Concentration of the Na/K pump inhibitor ouabain, which causes a reduction in sodium efflux (38), has an inhibitory effect on the radiolabel incorporation. Furosemide, another loop diuretic, activates the SPH synthesis in SW but has no effect in diluted SW.

The transient increase in SPH synthesis observed in the gills of euryhaline animals during a sudden decrease of salinity probably corresponds to the increased turnover of a second messenger provided by SPH metabolism in some specialized cells of the gills. This is the first time that the modulation of SPH metabolism in a specialized organ has been linked directly with environmental changes.

Lavie *et al.* (43) have shown in various cultured cell types that the replacement of cell-conditioned medium by HEPES-buffered saline causes a rapidly increase in the levels of endogenous sphingoid bases. In both isolated fish gills and cultured cells, activation or inhibition of the SPH cycle may also be triggered pharmacologically or by changing medium conditions. At least three components of this cycle act as biological signals in cells: ceramides, sphingosine, and sphingosine-1-phosphate (44). The biochemical targets of these intermediates in synthesis or degradation pathways of SPH are unknown; however, ceramides and sphingoid bases act as modulators of protein kinase C activity (45), and these compounds have been shown to regulate cell growth, cell differentiation, programmed cell death and eicosanoid production (17,18).

SPH turnover is influenced by the availability of precursors and by the relative activities of key enzymes in the synthesis and degradation pathway. The synthesis is dependent on the activity of sphingomyelin synthase which transfers the phosphorylcholine head group from PC to ceramide, yielding SPH and diacylglycerol (6,46). The degradation pathway is influenced by the activity of pH-sensitive sphingomyelinase, an enzyme found in plasma membranes and in lysosomes (47), which catalyzes the removal of the SPH head-group to give ceramides. In view of our results, we can hypothesize that the activity of these enzymes in the gills of euryhaline fish may be modulated by changes in intracellular Na^+ or pH induced by variation in external salinity. If this is the case, the increase of SPH turnover (caused by the activation of SPH synthase and/or sphingomyelinase during transfer to diluted SW) may control the levels of intermediate compounds such as sphingoid bases, ceramides or diacylglycerol. In turn, these intermediates would act as signals controlling protein kinase C activity, thereby initiating the activation or inhibition of chloride cell differentiation. The report by Kolesnick (48), in which sphingomyelinase prevents the morphologic changes associated with TPA-induced conversion to the macrophage phenotype in HL-60 cells, supports this hypothesis. However, in HL-60 sensitive-cells, Okazaki *et al.* (49) found that 1-α,25-dihydroxyvitamin D_3 activates a sphingomyelinase that increases SPH turnover and causes the formation of intracellular ceramides, which then induce cell differentiation to the monocytic phenotype. These observations do not allow identification of the intermediate of the SPH pathway, which controls chloride cell proliferation in the gills of euryhaline fish during abrupt changes in salinity.

ACKNOWLEDGMENTS

We thank Prof. J.M. Weber for discussions on the experiments and for critical reading of the manuscript during a stay at Animal Energetics Laboratory (University of Ottawa).

[a]Department of Biochemistry and Molecular Biology, Faculty of Sciences, University of Granada, Granada 18001, Spain and [b]Department of Clinical and Basic Psychobiology, University of Almería, Almería, Spain

ABSTRACT: We have studied the synthesis of phospholipids in hepatocytes isolated from chronically ethanol-treated rats by using isotopically labelled serine, ethanolamine, and choline as exogenous precursors. Our results demonstrate that ethanol induces specific effects on the biosynthesis of phosphatidylethanolamine and phosphatidylcholine *via* CDP-derivatives and also on the synthesis of phosphatidylserine *via* the Ca^{++}-dependent base-exchange reaction. Thus, the synthesis of phosphatidylethanolamine from [^{3}-H]ethanolamine and the incorporation of [^{3}H]serine into phosphatidylserine were clearly higher in hepatocytes from ethanol-treated rats compared to controls. The synthesis of phosphatidylcholine from [methyl-^{14}C]choline, on the other hand, decreased markedly, suggesting a specific inhibition of cholinephosphotransferase activity. We have also demonstrated that the phosphatidylcholine levels are markedly decreased in hepatocytes isolated from chronically ethanol-treated rats as a consequence of the lower phosphatidylcholine biosynthesis. The decrease in the incorporation of radioactivity from choline to betaine, which we also found, is interpreted as being the result of a higher use of betaine as methyl donor instead of methionine to maintain the hepatic *S*-adenosylmethionine levels in chronic alcoholism.
Lipids 31, 393–397 (1996).

Phospholipids are basic components of cell membranes, acting mainly as regulators of membrane-bound enzymes and in the membrane transport processes. The pathways of glycerophospholipid biosynthesis in the mammal liver are well established (1), and their regulation is becoming understood in considerable detail (1,2).

It is also widely recognized that chronic ethanol administration produces two major disturbances in lipid metabolism, fatty liver, and hyperlipidemia. Fatty liver develops as a consequence of alterations in the regulation of several metabolic pathways in the liver while hyperlipidemia can develop from alterations in metabolic pathways in hepatic and extrahepatic tissues (reviewed in Refs. 3 and 4). As far as fatty liver is concerned, it has been consistently demonstrated that ethanol induces triacylglycerol synthesis and its accumulation in the liver after both acute and chronic treatment (5). Fatty acids accumulate because of various different alterations and from several sources: enhanced hepatic lipogenesis, decreased lipoprotein release, increased mobilization of peripheral fat, and decreased fatty-acid oxidation as a consequence of reduced citric-acid-cycle activity (for review see Ref. 6).

As mentioned above, hepatic triacylglycerol accumulation has been consistently described in chronic alcoholism; however reports on the effects of ethanol on the biosynthesis of phospholipids are scarce and contradictory. Castro *et al.* (7) reported that acute ethanol administration stimulates the synthesis of phospholipids in rat hepatocytes, while other authors have indicated a marked decrease in the biosynthesis of phosphatidylcholine in alcoholic rat liver (8). This reduction in phosphatidylcholine synthesis is consistent with the decrease found by Lieber *et al.* (9) in the hepatic phosphatidylcholine levels after chronic ethanol treatment. In spite of the physiological importance of phospholipids, the mechanism by which ethanol interferes with their metabolic pathways has not been adequately studied. Thus, we have made a comparative study into the effects of ethanol on the specific biosynthetic pathways of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine by using radiolabelled serine, ethanolamine, and choline as exogenous precursors.

EXPERIMENTAL PROCEDURES

L-[3-^{3}H]serine, [1-^{3}H]ethanolamine, and [methyl-^{14}C]choline were purchased from Amersham International (Amersham, Bucks, United Kingdom). Fatty acid-free bovine serum albumin (BSA) and collagenase (Type A from *Clostridium histolyticum*) were supplied by Boehringer Mannheim (Barcelona, Spain). Thin-layer chromatography (TLC) plates were from Sigma (Madrid, Spain) and Percoll was supplied by Pharmacia (Uppsala, Sweden). All the other reagents used were of analytical grade.

Male Sprague-Dawley rats (150–170 g initial body weight) were fed for 31 d on the Miller *et al.* (10) liquid diet. In the ethanol-fed liquid diet, the caloric contribution of proteins, fats, carbohydrates, and ethanol was 23, 12, 29, and 36%, respectively. A pair-fed group received an isocaloric mixture with maltose–dextrin instead of ethanol.

The rats were housed in a controlled temperature and humidity chamber with a 12 h light/dark cycle. The rats were starved overnight when the hepatocytes were to be isolated.

The hepatocytes were isolated by Seglen's collagenase perfusion procedure (11) with minor modifications. Isolated hepatocytes were suspended in Krebs-Henseleit buffer, pH 7.4, supplemented with 1.5% BSA and 10 mM glucose. Their viability, determined by Trypan blue exclusion, was always higher than 90% in all the preparations used.

The hepatocytes were incubated at 37°C in a shaken water bath (80 oscillations/min) in Krebs-Henseleit buffer, pH 7.4, containing 1.5% BSA and 10 mM glucose, under an atmosphere of carbogen (95% O_2:5% CO_2). The incubations contained 5×10^6 cells in a final volume of 2.5 mL of incubation medium. The reactions were initiated by the addition of 125 nmol of methionine and L[3-^{3}H]serine (125 nmol; 150960 dpm/nmol) or [1-^{3}H]ethanolamine (100 nmol; 119920 dpm/nmol) or [methyl-^{14}C]choline (125 nmol; 32667 dpm/nmol). The incubations were carried out for 30 min at 37°C under an atmosphere of carbogen and stopped by the addition of 7.5 mL of ice-cold Krebs-Henseleit. The cells were washed twice in Krebs-Henseleit medium at $50 \times g$ for 5 min, and the pellet was collected to be used for the analysis of lipid and water-soluble metabolites.

Lipids were extracted from the cell pellet according to the procedure of Folch *et al.* (12). The chloroform layer was dried by evaporation under a stream of nitrogen, while the water–methanol phase was collected and used to determine water-soluble metabolites. The lipid residue was dissolved in chloroform, and the different phospholipids were separated on silica gel 60 G TLC plates, as indicated by Higgins (13). Silica gel bands corresponding to the individual phospholipids were scraped and used for phosphorous determination. Silica gel does not interfere with the colorimetric assay and the recovery by this procedure was higher to 90%. The levels of individual phospholipids were quantified by Bartlett's method (14) in control and ethanol-treated hepatocytes before being incubated in the presence of the different radioactive substrates.

Phosphatidyl-*N*-monomethylethanolamine and phosphatidyl-*N,N*-dimethylethanolamine were isolated from the chloroform fractions by TLC on silica gel H plates, using chloroform/methanol/acetic acid (70:30:4, by vol) as solvent, according to Marino *et al.* (15).

The water-soluble intermediates, ethanolamine phosphate and CDP-ethanolamine, were separated from the aqueous fractions by Wang and Moore's method (16), using silica gel G TLC plates and a solvent system composed of 96% ethanol/3% NH_4OH (1:2, vol/vol). Betaine and the water-soluble phosphatidylcholine precursors, choline phosphate and CDP-choline, were separated from the aqueous fractions according to Vance *et al.* (17) using silica gel G TLC plates and methanol/0.6% ClNa/28% NH_4OH (50:50:5, by vol) as solvent.

The spots corresponding to each compound were visualized by exposing the plates to iodine vapors, then scraped and transferred to scintillation vials to measure the radioactivity with a Beckman 6000-TA liquid scintillation counter (Madrid, Spain).

The results are expressed as means ± SEM, as indicated in the legends to the tables. Statistical significance was determined by Student's *t*-test.

RESULTS AND DISCUSSION

We have analyzed the influence of chronic ethanol ingestion on the biosynthetic pathways of phospholipids in hepatocytes isolated from rat liver. The synthesis of phospholipids takes place *via* specific pathways; phosphatidylcholine and phosphatidylethanolamine can be synthesized in microsomes *via* CDP-derivatives while serine is incorporated into the headgroup of phosphatidylserine in a microsomal Ca^{++}-dependent base-exchange reaction. The phosphatidylserine is further decarboxylated in the mitochondria to give phosphatidylethanolamine *via* phosphatidylserine decarboxylase, and this phosphatidylethanolamine can be methylated to phosphatidylcholine by three enzymatic steps, which take place in the endoplasmic reticulum.

Firstly, to determine the effects of ethanol treatment on the levels of the individual phospholipids, they were isolated and quantified. The results in Table 1 demonstrate that the treatment produces a significant decrease in the amounts of phosphatidylcholine while the levels of the other phospholipids are similar in the control and ethanol-treated groups. These results are in accordance with those previously reported by other authors in both human (9) and primate (18) livers, suggesting a specific interference of ethanol on the phosphatidylcholine metabolism in different animal species.

It has been accepted that changes in the endogenous pools of intermediates may in some situations be responsible for the differences found in experiments in which the radiolabel incorporation is used as an index of biosynthetic processes. However, recent evidence has demonstrated the existence of different intracellular nonuniformly mixing metabolic inter-

TABLE 1
Effect of Chronic Ethanol Consumption on the Phospholipid Levels in Isolated Rat-Hepatocytes[a]

	Control	Ethanol
Phosphatidylcholine	3.05 ± 0.13	2.04 ± 0.16[a]
Phosphatidylethanolamine	2.14 ± 0.16	1.78 ± 0.17
Phosphatidylserine	0.84 ± 0.07	0.76 ± 0.09
Phosphatidylinositol	1.05 ± 0.07	0.99 ± 0.11

[a]Results are expressed as μg of lipid phosphorous/10^6 cells and are means ± SEM for six determinations. Statistical significances of differences from the control are indicated by [a]$P \leq 0.015$.

mediates pools in the phosphatidylcholine biosynthetic pathway (19,20). So, Kent *et al.* (20) have demonstrated that when electropermeabilized cells are incubated with radiolabeled phosphocholine or CDP-choline there is no incorporation of radioactivity into phosphatidylcholine, therefore there is no mixing with the endogenous pool of these metabolic intermediates. This indicates that all three water-soluble reaction intermediates of phosphatidylcholine biosynthesis are not freely diffusible in the cell, but are channeled in some maner, resulting in a functional linkage between the individual steps in phosphatidylcholine biosynthesis. Thus, assuming that exogenous and endogenous precursors are not uniformly mixed, in the present study we have used exogenous substrates such as isotopically labelled serine, ethanolamine, or choline in order to analyze the individual steps in the biosynthesis of the different phospholipids.

With regard to the incorporation of serine into phospholipids, the results in Table 2 show that in control hepatocytes the label from this amino acid is found in phosphatidylserine, phosphatidylethanolamine, and phosphatidylcholine, while no detectable radioactivity exhibited sphingomyelin or phosphatidylinositol. Interestingly, in chronically ethanol-treated hepatocytes, an increase in the radioactivity associated with the three phospholipids can be seen, the increase being clearly higher in phosphatidylserine. Our results therefore indicate that chronic ethanol consumption markedly enhances the synthesis of phosphatidylserine from serine, producing an increase in the radioactive label in phosphatidylserine and consequently in the other phospholipids synthesized from it.

Phosphatidylserine is synthesized in mammals exclusively from a base-exchange reaction catalyzed by phosphatidylserine synthase, and it has indeed been reported that free fatty acids exert a marked activator effect on this enzyme activity in both liver (21) and brain (22) microsomes. Since cytosolic fatty acids significantly increase in the liver as a consequence of ethanol metabolism (6), they could be responsible in part for the increase in the phosphatidylserine synthase activity and thus in the synthesis of all serine-derived phospholipids found in this study. In addition, it has been consistently demonstrated in our (23) and other (24) laboratories that ethanol ingestion induces marked changes in the lipid composition and fluidity of hepatic microsomal membranes in chronic alcoholism, and since phosphatidylserine synthase is an enzyme located in the endoplasmic reticulum, it is possible that the modifications induced by ethanol in this membrane may also be responsible for the alterations in this enzyme activity.

Similarly to that found in phosphatidylserine synthesis, hepatocytes from chronically ethanol-treated rats exhibit a higher capacity to synthesize phosphatidylethanolamine from exogenous ethanolamine (Table 3). In fact, in the alcoholic group, the incorporation of ethanolamine was three times higher than that found in control hepatocytes. As a consequence of this increase, phosphatidylcholine and the methylated intermediates, phosphatidyl-*N*-monomethylethanolamine, and phosphatidyl-*N,N*-dimethylethanolamine also show a higher radioactive label in ethanol-treated hepatocytes. An increase in the lipogenic activity in rat livers after ethanol administration has been observed by different authors, and it has been related to an increase in phosphatidate phosphohydrolase activity (25,26). Thus, the enhancement in the synthesis of phosphatidylethanolamine found in our study is consistent with an activation in phosphatidate phosphohydrolase activity, which could produce an increase in the availability of diacylglycerol substrate necessary for the last step in phosphatidylethanolamine biosynthesis catalyzed by the enzyme ethanolamine phosphotransferase. In addition, it is interesting to note that the increase in the synthesis of phosphatidylethanolamine is accompanied by a significant decrease in the radioactivity of the metabolic intermediates, ethanolamine phosphate and CDP-ethanolamine (Table 3).

As far as the influence of ethanol consumption on the biosynthesis of phosphatidylcholine *via* CDP-choline is concerned, the results shown in Table 4 indicate that in hepatocytes isolated from chronically ethanol-treated rats the incorporation of choline into phosphatidylcholine decreases very significantly, although neither choline phosphate nor CDP-choline shows any alteration in their radioactive labels. Thus, this inhibition of phosphatidylcholine biosynthesis may be attributed to the specific action of ethanol on choline phosphotransferase activity, involved in the final step of phosphatidylcholine synthesis. Other authors have also found a significant decrease in phosphatidylcholine synthesis in the livers of chronically ethanol-treated rats (8), suggesting that this effect might be due to an acute depletion of the levels of the diacyl-

Phosphatidylcholine	97.28 ± 2.3	573.49 ± 1.43[b]

[a]Results are expressed as pmol/min × 10^6 cells and are means ± SEM for four determinations. Statistical significances of differences from the control are indicated by [a]$P \leq 0.001$; [b]$P \leq 0.0001$.

glycerol substrate required for phosphatidylcholine biosynthesis. Nevertheless, both phosphatidylcholine and phosphatidylethanolamine synthesis *via* CDP-derivatives requires diacylglycerol, and so a reduction in the diacylglycerol levels should affect these pathways similarly. Since as mentioned above (Table 3), the radioactive label of phosphatidylethanolamine from [1-^{3}H]ethanolamine is clearly enhanced after ethanol treatment while that of phosphatidylcholine is significantly reduced, it is evident that the changes in the diacylglycerol levels cannot be responsible for the decrease in the phosphatidylcholine biosynthesis, at least under our experimental conditions.

To sum up, the comparative analysis of the biosynthesis of both phosphatidylcholine and phosphatidylethanolamine *via* CDP-derivatives allows us to demonstrate that ethanol ingestion exerts a differential effect on the Kennedy pathway, an increase in phosphatidylethanolamine synthesis, and a decrease in the biosynthesis of phosphatidylcholine. In any case, the lower phosphatidylcholine synthesis is consistent with the reduction in the level of this phospholipid found in our study. The increase in the phosphatidylethanolamine and phosphatidylserine synthesis observed in alcoholic rats when ethanolamine or serine is used as exogenous precursor does not suppose an increase in the levels of these phospholipids after 31 d of ethanol ingestion (Table 1). This could be explained as a result of a higher methylation of phosphatidylethanolamine, synthesized from exogenous serine or ethanolamine, to give phosphatidylcholine in order to compensate its decrease by the CDP-choline pathway.

On the other hand, it can also be observed in Table 4 that the radioactivity from choline appears as well in betaine, the end-product of their oxidation by choline oxidase. Remarkably, in the ethanol group, the radioactivity in betaine is clearly lower than that found in control hepatocytes. Although this reduction could be explained as the result of a specific inhibition of choline oxidase, there is experimental evidence in chronic alcoholism to suggest an enhancement in the use of betaine (27). In fact, the decrease in the radioactive label of betaine found in our study after chronic ethanol ingestion is consistent with a compensatory mechanism by which betaine is preferably used as methyl donor in situations of impairment in the methionine synthesis to allow the maintenance of the hepatic *S*-adenosylmethionine levels. So, other authors have demonstrated an increase in the betaine–homocysteine methyltransferase activity in chronic alcoholism (28), which agrees with our data. These results support the notion that betaine exerts a hepatoprotective effect due to its ability to stimulate the formation of *S*-adenosylmethionine in the liver.

All these results are of a great physiological interest because phosphatidylcholine and phosphatidylethanolamine are structural and/or functional components of membranes and lipoproteins and thus their formation and/or metabolism is required for signal transduction, membrane formation, and lipoprotein synthesis. Clearly any change in their metabolism could alter these processes contributing to the pathology associated with alcoholism.

Dietary Eritadenine-Induced Alteration of Molecular Species Composition of Phospholipids in Rats

Kimio Sugiyama* and Akihiro Yamakawa

Department of Applied Biological Chemistry, Faculty of Agriculture, Shizuoka University, Shizuoka 422, Japan

ABSTRACT: The effect of dietary eritadenine, a hypocholesterolemic compound found in the mushroom *Lentinus edodes*, on the fatty acid and molecular species profiles of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) in the plasma and liver microsomes was investigated in relation to the hypocholesterolemic action of the compound in rats. Animals were fed the control or eritadenine-supplemented (50 mg/kg diet) diet for 14 d. Eritadenine supplementation significantly decreased the plasma concentrations of cholesterol and phospholipids, but not triglycerides. The PC/PE ratio of liver microsomes, but not plasma, was also markedly decreased by eritadenine. Eritadenine supplementation was found to increase the proportion of 18:2n-6 and, inversely, to decrease the proportion of 20:4n-6 and 22:5n-6 in plasma PC and liver microsomal PC and PE, indicating that eritadenine depressed the metabolism of linoleic acid. The effect of eritadenine on the profile of n-3 fatty acids was dissimilar in PC and PE. These changes in fatty acid composition were selectively reflected in the molecular species composition of both PC and PE; the extent of increase in 16:0-18:2 molecular species or decrease in 18:0-20:4 molecular species was apparently greater than that of other molecular species containing 18:2 or 20:4 in the sn-2 position. These results suggest that, in addition to the decrease in liver microsomal PC/PE ratio, the alteration of plasma PC molecular species composition might also participate in the hypocholesterolemic action of eritadenine.

Lipids 31, 399–404 (1996).

The mushroom *Lentinus edodes* (Shiitake in Japanese) has a potent hypocholesterolemic action when fed to rats (1), and eritadenine [2(R),3(R)-dihydroxy-4-(9-adenyl)-butyric acid] was isolated from the mushroom as a hypocholesterolemic factor (2,3). Eritadenine also exists in another mushroom *Agaricus bisporus* (champignon) to a lesser extent (4). To date, a number of studies have reported on the mechanism by which *L. edodes* or eritadenine exerts its hypocholesterolemic action, but the detailed mechanism is not yet fully elucidated.

Recently, we provided evidence that the hypocholesterolemic action of *L. edodes* (5) or eritadenine (6,7) might be elicited through a decrease in the ratio of phosphatidylcholine (PC) to phopshatidylethanolamine (PE) in liver microsomes of rats. This eritadenine-induced alteration of hepatic phospholipid class profile was found to arise primarily from the depression of PE *N*-methylation (6). However, it is still unclear how the decreased PC/PE ratio of liver microsomes is associated with the reduction of plasma cholesterol. One of the interesting reports concerned with the relationship between phospholipid metabolism and the regulation of plasma cholesterol is that the difference in the molecular species of plasma high density lipoprotein (HDL) PC could largely influence the uptake of HDL cholesterol by tissues (8,9). These findings led us to postulate a working hypothesis that eritadenine may elicit its hypocholesterolemic effect not only by decreasing the PC/PE ratio of liver microsomes, but also by altering the molecular species composition of plasma lipoprotein PC. However, no information currently exists concerning eritadenine's ability to modify the molecular species composition of plasma lipoprotein PC.

In this study, therefore, the effect of dietary eritadenine on the profiles of fatty acids and molecular species of plasma and liver microsomal major phospholipids (PC and PE) was investigated with the aim of clarifying the mechanism of the hypocholesterolemic action of eritadenine in rats.

MATERIALS AND METHODS

Animals. Twelve male 5-wk-old rats of the Wistar strain were received at 90–100 g body weight from Japan SLC (Hamamatsu, Japan). The rats were individually housed in hanging stainless-steel wire cages kept in an isolated room at a controlled temperature (23–25°C) and humidity (40–60%). Lights were maintained on a 12-h cycle (lights on from 0600 to 1800 h). For 5 d, animals were fed the powdered laboratory stock diet, which resembled the control diet described below except that sucrose and lactose were replaced by starch and 2 g/kg diet of choline chloride was added. Then, they were divided into two groups of six rats each with similar mean weights (~121 g) and allowed free access to the experimental diets and water for 14 d.

Diets. Two diets, control and eritadenine-supplemented, were utilized in this study. The control diet consisted of the following (g/kg): casein (Nacalai tesque, Kyoto, Japan), 250;

cornstarch (Fuji-seifun, Shimizu, Japan), 450; sucrose (Fuji-seito, Shimizu, Japan), 200; corn oil (Honen, Tokyo, Japan), 50; AIN-76 mineral mixture (Oriental Yeast, Tokyo, Japan), 35; AIN-76 vitamin mixture (Oriental), 10; choline chloride (Wako Pure Chemical, Osaka, Japan), 4; lactose (Wako), 1. Eritadenine, which was isolated from dried *L. edodes* mushroom according to the method of Tokita *et al.* (10), was fully mixed with lactose and added to the diet at a level of 50 mg/kg diet at the expense of lactose. This dose level was proven to be sufficient to elicit maximal hypocholesterolemic effect (6). Choline chloride was introduced into the diet at a relatively high level (4 g/kg) because lower levels of dietary choline led to the development of fatty livers (7). The fatty acid composition of corn oil used was as follows (wt%): 16:0, 12.2; 18:0, 1.8; 18:1n-9, 32.8; 18:2n-6, 51.4; and 18:3n-3, 1.6.

Tissue collection and fractionation. At the end of the feeding period, rats were killed by decapitation under light anethesia with diethyl ether between 1100 and 1200 h and without prior food deprivation. Plasma was separated from heparinized whole blood by centrifugation at 2000 × *g* for 20 min at 4°C. An aliquot of the plasma was stored at 4°C until subsequent analyses for plasma lipid concentrations, and the residual plasma was stored at −80°C until analyses for phospholipids. After collection of blood, the whole liver was quickly removed, rinsed in ice-cold saline, blotted on filter paper, and cut into two portions. One portion of the liver was quickly frozen in liquid nitrogen and stored at −30°C until analyses for liver lipid concentrations. The other portion was homogenized in 4 vol (vol/wt) of an ice-cold 10 mM Tris-HCl buffer (pH 7.4) containing 0.15 M KCl. The homogenates were centrifuged at 10,000 × *g* for 10 min at 4°C, and the resultant supernatants were further centrifuged at 105,000 × *g* for 60 min at 4°C to obtain the microsomal fraction as a precipitate. The microsomes obtained were resuspended in the homogenizing buffer and stored at −80°C until analyses for phospholipids.

Lipid analysis. The plasma concentrations of total cholesterol, HDL-cholesterol, free cholesterol, triglycerides, and phospholipids were measured enzymatically with kits (Wako). The difference between total cholesterol and HDL cholesterol or free cholesterol was assumed to be very low density lipoprotein (VLDL) + low density lipoprotein (LDL) cholesterol or esterified cholesterol, respectively. The lipids of liver, liver microsomes and plasma were extracted by the method of Folch *et al.* (11). The cholesterol, triglycerides and phospholipids in the extract of liver were measured by the methods of Zak (12), Fletcher (13), and Bartlett (14), respectively. For the determination of phospholipid class composition, the phospholipids in the extracts of liver microsomes and plasma were separated into each class by thin-layer chromatography (TLC) on Silica Gel 60 (E. Merck, Darmstadt, Germany) using chloroform/methanol/water (65:25:4, by vol) as a developing solvent. The bands of each phospholipid class were visualized in iodine vapor, scraped off the plate, and analyzed directly for inorganic phosphorus (14). For the determinations of fatty acids and molecular species, PC and PE were similarly separated by TLC, visualized with dichlorofluorescein, scraped off the plate and extracted with chloroform/methanol (1:1, vol/vol). Aliquots of PC and PE were treated with 14% (wt/wt) BF_3/methanol reagent (Wako) (15), and fatty acid methyl esters formed were analyzed by gas–liquid chromatography (GLC) on a Model GC-17A (Shimadzu Seisakusho, Kyoto, Japan), equipped with a TC-FFAP capillary column (0.25 mm × 30 m; GL Sciences, Tokyo, Japan). Other aliquots of PC and PE were converted to diacylglycerol benzoates according to the method of Blank *et al.* (16). The diacylglycerol benzoates were separated into each molecular species by high-performance liquid chromatography (HPLC) on a Model LC-6A system (Shimadzu), equipped with an ODS column (4.6 × 250 mm; Lichrosorb RP-18; E. Merck), essentially according to the method of Blank *et al.* (16). Identification of molecular species was made by both comparison with the elution times of some authentic molecular species and fatty acid analysis of eluents by GLC. Because some peaks consisted of two molecular species, the ratio of two molecular species was estimated by the analysis of fatty acids by GLC. Figure 1 shows a typical HPLC chromatogram.

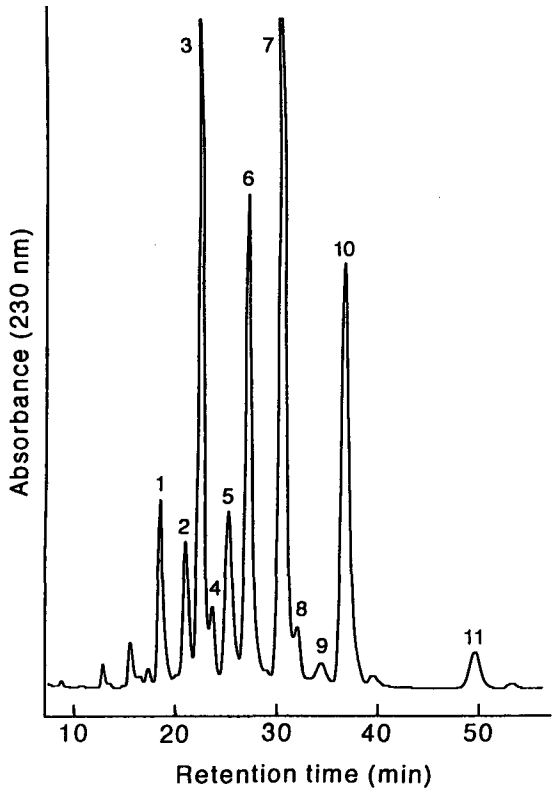

FIG. 1. A typical high-performance liquid chromatography chromatogram of liver microsomal phosphatidylcholine molecular species in rats. Peak numbers 1–11 indicate the following molecular species: 1, 16:0-22:6; 2, 18:1-20:4; 3, 16:0-20:4; 4, 16:0-22:5; 5, 18:1-18:2 + 18:0-22:6; 6, 16:0-18:2; 7, 18:0-20:4; 8, 18:0-22:5; 9, 18:1-18:1; 10, 16:0-18:1 + 18:0-18:2; 11, 18:0-18:1.

Statistical analysis. Data were expressed as mean ± SEM for six rats. Student's *t*-test was used to examine the signifi-

cance between control and eritadenine-supplemented groups. Simple correlation between variables was calculated by linear regression analysis.

RESULTS

The body weight gain, food intake and relative liver weight of rats were not significantly different between the two dietary groups (Table 1).

Liver and plasma lipid concentrations. The concentrations of cholesterol, triglycerides, and phospholipids in the liver were slightly, but significantly, increased by eritadenine supplementation. The plasma cholesterol concentrations of total, VLDL + LDL, HDL, free, and esterified were all significantly decreased by eritadenine supplementation. Although the plasma phospholipid concentration was also significantly decreased, the plasma triglyceride concentration was unaffected by eritadenine.

Phospholipid class composition. Table 2 shows the effect of dietary eritadenine on the phospholipid class composition of both liver microsomes and plasma. Eritadenine supplementation significantly decreased the proportion of PC and, inversely, increased the proportion of PE in liver microsomes. Consequently, the PC/PE ratio was significantly decreased by eritadenine. In contrast, there was no difference in the concentration of total phospholipids in liver microsomes between the control and eritadenine-supplemented groups (405 ± 12 vs. 416 ± 9 nmol/mg protein). In the plasma, the proportion of PC was slightly decreased by eritadenine supplementation, but neither the proportion of PE nor the PC/PE ratio was significantly affected by eritadenine.

Fatty acid composition of phospholipids. Table 3 shows the effect of dietary eritadenine on the fatty acid composition of plasma PC and liver microsomal PC and PE. Eritadenine supplementation significantly increased the proportion of 18:2n-6 and, inversely, decreased the proportion of 20:4n-6 and 22:5n-6 in both PC and PE. Consequently, the ratio of 20:4n-6 + 22:5n-6 to 18:2n-6 was markedly decreased by eritadenine. Eritadenine supplementation also significantly increased the proportion of 16:0 and decreased the proportion of 18:0 in plasma and liver microsomal PC, although these changes were relatively minor in liver microsomal PE. Eritadenine supplementation significantly increased the proportion of n-3 fatty acids in liver microsomal PE, unlike in plasma and liver microsomal PC.

Molecular species composition of phospholipids. Table 4 shows the effect of dietary eritadenine on the molecular species composition of plasma PC and liver microsomal PC and PE. The proportion of 16:0-18:2 PC was markedly increased by eritadenine supplementation, whereas the proportion of 18:0-18:2 PC or 18:1-18:2 PC was only slightly affected by eritadenine. Similarly, the eritadenine-induced decrease in 20:4n-6 of PC was more prominently reflected in the decrease in 18:0-20:4 PC than in the decrease in 16:0-20:4 PC or 18:1-20:4 PC. The eritadenine-induced alteration of 16:0-18:2 and 18:0-20:4 molecular species was also observed in liver microsomal PE, although the extent of the change was smaller than that in PC.

TABLE 1
Effect of Dietary Eritadenine on Plasma and Liver Lipid Concentrations in Rats[a]

	Dietary group	
	Control	+Er
Body weight gain (g/14 d)	81 ± 2	82 ± 1

DISCUSSION

Effect on phospholipid class composition. It has been shown that eritadenine is a potent inhibitor of *S*-adenosylhomocysteine (SAH) hydrolase (17) and consequently increases the concentration of SAH in isolated hepatocytes (18) and intact

livers (6) of rats. This increase in hepatic SAH concentration caused by eritadenine was thought to bring about a depression of PE *N*-methylation. Actually, the *in vivo* incorporation of the labeled methyl group of methionine into plasma and liver microsomal PC was almost completely inhibited in rats fed a diet supplemented with eritadenine (50 mg/kg diet) (6). These results, together with results on the analysis of hepatic phospholipid precursors, indicated that dietary supplementation with eritadenine led to a decrease in the liver microsomal PC/PE ratio primarily through depressed PE *N*-methylation and secondarily through increased PE biosynthesis *via* the CDP-ethanolamine pathway (6,7). The present study confirmed that eritadenine can markedly decrease the PC/PE ratio of liver microsomes. In contrast, the PC/PE ratio of plasma was found not to be affected by eritadenine, supporting the idea that the phospholipid class composition of plasma is resistant to dietary manipulation compared with that of liver microsomes (19).

Effect on fatty acid and molecular species composition. The present study clearly demonstrated that dietary supplementation with eritadenine could cause a drastic alteration of fatty acid composition and molecular species composition not only of liver microsomal PC, but also of plasma PC. The results of fatty acid analysis of phospholipids indicate that the metabolic conversion of 18:2n-6 to 20:4n-6 or 22:5n-6 was largely depressed in rats fed the eritadenine-supplemented diet. Although the activity of enzymes participating in the metabolism of fatty acids was not measured in the present study, another study by our laboratory showed that the Δ6-desaturase activity of liver microsomes was markedly depressed in eritadenine-treated rats (unpublished observation). This suggests that eritadenine depresses the metabolism of linoleic

acid by decreasing the activity of Δ6-desaturase, a rate-limiting step for linoleic acid metabolism (20). Further, there are lines of indirect evidence that the decrease in liver microsomal PC/PE ratio may be associated with the decrease in Δ6-desaturase activity. In addition to eritadenine, certain hypocholesterolemic substances such as PE (21), ethanolamine (21,22), glycine (22), and some dietary proteins including soybean protein (19) have been shown to decrease the PC/PE ratio of liver microsomes in rats. Of these substances, PE or ethanolamine (23) and soybean protein (24) were shown to bring about a decrease in the 20:4/18:2 ratio of plasma and liver microsomal PC accompanying a decrease in the activity of microsomal Δ6-desaturase. Further, it was shown that a decrease in the PC/PE ratio caused by choline deficiency (25) or vitamin B_6-deficiency (26) was coupled with a decrease in the activity of Δ5- or Δ6-desaturase, respectively, in liver microsomes of rats. These results indicate that the phospholipid class profile of liver microsomes, as represented by the PC/PE ratio, is one of the factors which affect the activity of desaturases (27,28). Taking these findings into consideration, it is possible that the depression of fatty acid metabolism by eritadenine is also mediated by a decrease in the PC/PE ratio of liver microsomes.

It seems reasonable to consider that the molecular species composition of plasma PC reflects, to some extent, that of liver microsomal PC, because the greatest part (*ca.* 80%) of plasma PC is derived from the liver (29). In fact, as a whole, there was a similarity of PC molecular species composition between plasma and liver microsomes when analyzed using values listed in Table 4 ($r = 0.842$, $P < 0.001$), although there was an apparent divergence in the proportion of specific molecular species such as 16:0-18:2 and 18:0-20:4. This divergence may be accounted for in part by the fact that certain molecular species, e.g., 18:0-20:4, were relatively not secreted from the liver as a lipoprotein component (30). Further, plasma HDL phospholipids are known to undergo deacylation by lecithin:cholesterol acyltransferase with a substrate specificity for molecular species. It is thought that phospholipid molecular species composition is regulated by a complex mechanism, e.g., biosynthesis of whole phospholipid molecule *via* different pathways, and subsequent remodeling by deacylation-reacylation. In addition, the depression of linoleic acid metabolism appears to contribute to the eritadenine-induced alteration of phospholipid molecular species which contain n-6 fatty acids in the *sn*-2 position, although this cannot account for the selective alteration of molecular species composition. In the rat liver, PC is deduced to be synthesized *via* the CDP-choline pathway by 60–80% and *via* the PE *N*-methylation pathway by 20–40% (31). In contrast, it is thought that PC biosynthesis *via* the latter pathway is largely inhibited in rats fed a eritadenine-supplemented diet. Thus, eritadenine modifies the relative dependency of PC biosynthesis on the two major pathways in the liver. However, it is unlikely that the cessation of PC biosynthesis *via* the PE *N*-methylation itself is a main cause of eritadenine-induced selective alteration of PC molecular species composition because eritadenine increased 16:0-18:2 molecular species and decreased 18:0-20:4 molecular species in both liver microsomal PC and PE. It is unclear how eritadenine affects the remodeling of phospholipids.

The present study demonstrated that the level of n-3 fatty acids in liver microsomal PE were increased, whereas those in PC were decreased by eritadenine. This is other evidence that *N*-methylation of PE in the eritadenine-treated rats was not active, although the mechanism for the differential effect of eritadenine is currently unclear. Contrary to the results presented here, Samborski *et al.* (32) showed that the inhibition of PE *N*-methylation by 3-deazaadenosine, another inhibitor of SAH hydrolase, did not affect the PC or PE molecular species composition of cultured rat hepatocytes. One of the reasons for this discrepancy may be the difference in the experimental conditions employed, i.e., *in vivo* or cells in culture, and relatively long-term (14 d) or short-term (up to 12 h) treatment of the inhibitors. The data on the time-dependent *in vivo* effect of dietary eritadenine on the molecular species composition of phospholipids should help to explain the discrepancy.

Mechanism of hypocholesterolemic action. Previous studies have suggested that eritadenine exerts its hypocholesterolemic action through depressed secretion of lipoprotein cholesterol from the liver into the blood circulation and/or increased uptake of plasma lipoprotein cholesterol by tissues (33,34). *Lentinus edodes* mushroom or eritadenine indeed causes, in many cases, fat accumulation in the liver with overall decreases in plasma lipids in rats. However, this eritadenine-induced fatty liver and a decrease in plasma triglyceride concentration could be effectively prevented by elevating the level of dietary choline without diminution of the hypocholesterolemic action of eritadenine (7). This suggests that the essential hypocholesterolemic action of eritadenine cannot be ascribed to the depressed secretion of triglyceride-rich lipoprotein (VLDL) from the liver. In support of this, the present study also showed that eritadenine supplementation can significantly decrease the plasma concentrations of cholesterol and phospholipids without concomitant decrease in plasma triglyceride concentration.

In contrast, little information is available concerning the effect of eritadenine on the uptake of plasma lipoproteins by tissues. It is widely accepted that the uptake of plasma lipoproteins is regulated mainly by a receptor-mediated mechanism. On the other hand, it has been shown that the uptake of HDL by tissues was promoted by the hydrolysis of HDL phospholipids by hepatic lipase (35). Further, Kadowaki *et al.* (9) demonstrated that the uptake rate of cholesterol ester of reconstituted HDL by perfused rat livers was largely influenced by PC molecular species used for the reconstitution of HDL. They showed that the uptake of HDL cholesterol was most stimulated by 16:0-18:2 PC of five PC molecular species tested (16:0-18:2, 16:1-16:1, 18:0-18:2, 18:1-16:0, and 20:1-20:1). These findings suggest the possibility that certain types of hypocholesterolemic treatment to increase the proportion of specific PC molecular species, e.g., 16:0-18:2, of plasma HDL bring about a reduction of plasma cholesterol,

at least in part, through increased uptake of HDL cholesterol by tissues. This assumption, together with the results presented here that eritadenine supplementation drastically increased the proportion of 16:0-18:2 PC in the plasma, appears to support the idea that eritadenine might also exert its hypocholesterolemic action through the alteration of plasma PC molecular species composition. The direct evidence for this hypothesis, however, is yet to be presented.

ABSTRACT: Adult male rats were surgically given a drainage catheter in the main mesenteric lymph duct. After an overnight fast, five groups of rats received intragastrically, in one bolus, butter, corn oil (CO), cod liver oil (CLO), menhaden oil (MO), or ethyl esters of eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids (K80). Intestinal lymph was collected in these conscious animals, each hour during the first 6 h and in a single sample for the next 18 h. The absorption peak appeared earlier after MO and CO than after CLO administration. The quantities of triglycerides recovered during the first 6 h were significantly lower after butter (91 mg) and K80 (54 mg) administration than for the other three oils. No difference was observed between the vegetable oil and the two marine oils (CO = 173 mg, CLO = 148 mg, MO = 180 mg). The total triglyceride recovered in 24 h was highest after CLO (410 mg) and lowest with K80 (146 mg). An increase in the weight percentage of some characteristic fatty acids of the lipid mixtures was observed: oleic acid for butter, oleic and linoleic acids for CO, EPA and DHA for CLO, MO, and K80. Chylomicrons were the largest with CO, more numerous and smaller with CLO, and the smallest with K80. Results obtained illustrated the relation between gastrointestinal hydrolysis, enterocyte biochemical events, and lymph triglyceride absorption profiles as related to the composition and distribution of triglyceride fatty acids.

Lipids 31, 405–414 (1996).

Intestinal absorption (1–4) of dietary triglycerides, major lipid constituents of the lipid diet, is decisive for the biological availability of fatty acids of oils and fats. Intestinal bioavailability is a consequence of the fatty acid carbon number, of the degree of unsaturation and of reciprocal influences of the different fatty acids at different levels of the intestinal tract (2). The stomach is the site of an important action of a preduodenal lipase (5) and the initiation of emulsification (6,7). In the proximal small intestine, hydrolysis by the pancreatic lipase occurs, in association with the mixture of bile salts and pancreatic colipase. Whatever the hydrolysis rate, the specificity of lipases and the distribution of fatty acids on the glycerol backbone are decisive parameters (8,9), including the nature of the fatty acid, with the possibility of a slower hydrolysis of some polyunsaturated fatty acids (10,11). This point may explain some of the differences previously observed in intestinal absorption of triglycerides with similar fatty acid compositions but from varied origins, for example, land or marine animals (12,13). Mixed micelle formation follows and is obligatory for diffusion across the unstirred water layer to occur. Uptake of monomers of fatty acids and monoglycerides by enterocytes, although thought to be a passive diffusion process, might be facilitated by membrane fatty acid binding proteins (FABP) such as FABPpm (14) and a fatty acid translocase (15). In the enterocytes, I-FABPc and L-FABPc might facilitate the intracellular transport (16) and the activation and reesterification of fatty acids that precede the formation and exocytosis of chylomicrons and very low density lipoprotein (VLDL). Conflicting results in the literature relating to absorption recoveries of vegetable oils, land mammal fats, or marine oils might be reconciled on the basis of different experimental conditions, particularly modalities and/or level of administration (2,17–19,20–22).

The aim of this work is to compare intestinal absorption processes of four fats or oils representative of a spectrum of fatty acids, to understand some of the variations in intestinal absorption due to different fatty acid compositions. We chose butter, corn oil (CO), and cod liver oil (CLO) and menhaden oil (MO), two cold-water marine fish oils. In addition, we studied intestinal absorption of K80, a mixture of ethyl esters of eicosapentaenoic (EPA) and docosahexaenoic acid (DHA). For this purpose, we investigated recoveries and profiles of mesenteric lymph triglycerides and intestinal lymph lipoproteins, especially their morphological aspects and fatty acid composition.

MATERIALS AND METHODS

Animals. Official French regulations (n° 87848) for the care and use of laboratory animals were followed (n° 03056). Male Wistar rats weighing 180–250 g were obtained from Centre d'élevage Dépré (Saint Doulchard, France). They were housed for one week before the study in a controlled environment, with constant temperature and humidity and a dark period from 2000 to 0800 h. They were fed the standard nonpurified diet AO4 containing 3.5 g/100 g lipid (UAR Villemoisson sur Orge, Epinay sur Orge, France), and had free access to tap water.

Surgical procedure. A laparotomy was performed under ether anesthesia. Mesenteric lymph duct cannulation was performed using a heparinized polyethylene catheter (n°1, i.d. 0.3, o.d. 0.7; Biotrol, Paris, France) (23). Immediately after the surgery, rats were placed in restraining cages in an air-conditioned room (25°C). They did not receive solid food but had free access to a water solution containing sodium chloride (7 g/L) and potassium chloride (2 g/L).

Experimental procedures. The morning after surgery, basal lymph of fasting rats was collected for 1 h in tubes placed inside Dewar flasks containing ice, immediately before lipid administration. Then, 0.65 mL of slightly heated butter (above its melting point of 29°C), or 0.5 mL of the oils, or of K80 was administered intragastrically. The lymph was separately collected each hour during the first 6 h and in a single sample for the next 18 h from the conscious animals. According to the time period during lipid absorption, the lymph flow rate was two to three times as high as in the fasting state. In all cases, the animals whose lymph flow had not increased in this range were discarded (24). The samples were immediately treated for both morphological study of lipoproteins and lipid extraction followed by phospholipid, triglyceride, and fatty acid analysis.

Butter and oils. Table 1 shows the distribution of the major fatty acids of the butter and the three oils studied as measured by gas–liquid chromatography (GLC). Butter is particularly rich in medium-chain saturated fatty acids (C12:0, C14:0, and C16:0 represent 45% wt%). CO is characterized by the presence of C18 unsaturated fatty acids, especially oleic and linoleic acids, which represent 82.4% (wt%) of fatty acids. Marine fish oils constitute natural sources of n-3 polyunsaturated fatty acids. However, wide variations are recorded according to the species. While CLO contains monounsaturated very long chain fatty acids such as gadoleic (C20:1n-9) and cetoleic acids (C22:1n-11), MO provides only small traces of them, and is significantly enriched in both EPA (C20:5n-3, 16.4%) and DHA (C22:6n-3, 7%). In contrast to the fatty acid composition of butter and CO, the two marine oils span a wide range of fatty acids chain lengths from C_{14} to C_{22}. In some experiments with butter, 1.7×10^4 Bq of [1-^{14}C] oleic acid (specific activity: 2.1 GBq/mmol) was added before its gastric administration.

Lipids were purchased from Nu-Chek-Prep (Elysian, MN) or SIGMA-France (Saint Quentin Fallavier, France). The labeled fatty acid was provided by CEA (Gif sur Yvette, Saclay, France). Butter and CO were purchased at a local store. CLO was purchased at a local pharmacy, and MO was donated by the Zapata Protein Co. (Reedville, VA). Ethyl esters of EPA and DHA, K80, were generously supplied by Norsk Hydro, s.a. (N-0203; Oslo, Norway).

[a]Fatty acids of butter, corn oil, cod liver oil, and menhaden oil are in triglyceride chemical form. K80 is composed of ethyl esters.

Lipid analysis. Phospholipids and triglycerides were determined in lymph samples using enzymatic kits (Test-Combination Phospholipides-Test Peridichrom Triglycerides GPO-PAP; Boehringer, Mannheim, Germany). Lipids from the lymph of fasting rats (collected during the hour before the infusion of the lipids) and the intestinal lymph samples were extracted by dimethoxymethane–methanol (4:1, vol/vol) (25), dehydrated with absolute ethanol and then dissolved in chloroform. If necessary, the radioactivity of the total lipid extracts was determined when indicated using a liquid scintillation spectrophotometer (Packard Prias PLD Tricarb; Packard Instruments, Downers Grove, IL).

GLC analysis. The analysis of butter fatty acids was performed according to Gresti *et al.* (26); the analysis of K80 fatty acids was performed by Norsk Hydro. After extraction, CO, MO, and CLO fatty acids and fatty acids of collected lymph samples were methylated in the presence of boron trifluoride (27), with heptadecanoic acid as internal standard. Methyl esters were extracted using hexane and separated by GLC. These studies were carried out with a Packard chromatograph (model 417; Packard Instruments) and a capillary column (CP wax 52 CB 50 m; Chrompack, Les Ulis, France). Fatty acid analysis of lymph samples collected in fasting rats

or in rats after oil administration was performed at a constant temperature of 200°C with helium as a carrier gas. For butter experiments, the initial oven temperature was 130°C, followed by a temperature increase of 4°C/min until 225°C was reached. The peak areas were measured by an integrator (Chromjet; Spectra-Physics, San Jose, CA) and normalized to give the values as weight percentages of total fatty acids (g/100 g total fatty acids).

Microscopic observation of lymph particles. Lymph was defibrinized by gauze filtration and 10 µL fixed with 200 µL of osmium tetroxide (0.2 g/L) for 1 h at 4°C. One drop of fixed suspension was placed on a collodion carbon grid. After complete evaporation of the fixing solution, the particles were shadowed with gold-palladium at a 50° angle with an Edwards E12E vacuum evaporator (Edwards High Vacuum Limited, Crawlay, Sussex, United Kingdom) (28). Two or three grids of each lymph fraction were examined using a Hitachi HU 11E transmission electron microscope (Hitachi, Ltd., Tokyo, Japan). At least 1,000–2,000 shadowed particles for each lymph fraction were counted and classified by size.

Statistics. Results were expressed as micromole equivalents of labeled fatty acid when oleic acid was added in butter, using the specific activity of the labeled fatty acid added, and in milligrams of triglyceride or phospholipid for butter, oil and ethyl ester absorption studies. Values, expressed as means ± SEM, were examined by analysis of variance and significant differences between means from different fats or oils and across time within each fat or oil were tested by Student's *t*-test for an independent variable.

RESULTS

Mesenteric lymph triglyceride output. In the fasting state, mesenteric lymph triglycerides reached 21.2 ± 1.0 mg for a 6-h time period in the 26 rats of the experiments, and no significant difference was recorded between the lymph flows of the various groups (0.6 ± 0.1 mL/h). After lipid infusion, the lymph flow increased twofold, 1.1 ± 0.1 mL/h, regardless of the lipid type, with a maximum at the absorption peak of 1.74 ± 0.2 mL/h that was threefold higher than the fasting state. Table 2 summarizes lymph flows and lymph triglyceride outputs observed after intragastric administration of 0.65 mL of butter, 0.5 mL of CO, CLO, MO, or ethyl esters of EPA and DHA (K80).

The first 6 h of digestion and absorption after the intragastric administration of butter were accompanied by a lymph triglyceride output significantly lower ($P < 0.01$) than for the the three oils. No significant difference was observed in mesenteric lymph triglyceride outputs between the vegetable oil and the two marine oils. In the case of EPA and DHA in ethyl ester form, the amount of mesenteric lymph triglycerides was significantly lower than for the oils ($P < 0.001$) or in comparison with butter ($P < 0.001$).

Considered over a time period of 24 h, a significant difference was maintained between the amount of mesenteric lymph triglyceride output with the feeding of butter and CO, whereas all significant differences disappeared between the amounts of mesenteric lymph triglycerides recovered after the feeding of butter and the two marine oils. The lowest lymph triglyceride output was observed after administration of K80 ethyl esters.

TABLE 2
Lymph Flows and Lymph Triglyceride (TG) Outputs After Intragastric Administration of Different Lipids[a]

	Lymph flows[b]		TG outputs[c]	
Lipids studied	Fasting state (mL/h)	Absorption peak (mL/h)	TG, 0–6 h (mg)	TG, 0–24 h (mg)
Butter ($n = 6$)	0.65 ± 0.1[a]	1.1 ± 0.2[a]	91 ± 2[c]	346 ± 9[c]
Corn oil ($n = 4$)	0.70 ± 0.01[b]	2.0 ± 0.4[b]	173 ± 20[d]	282 ± 32[d]
Cod liver oil ($n = 6$)	0.30 ± 0.03[b]	1.3 ± 0.3[b]	148 ± 14[d]	410 ± 62[c,d]
Menhaden oil ($n = 6$)	0.70 ± 0.5[a]	2.2 ± 0.4[a]	180 ± 12[d]	347 ± 21[c,d]
K80 ($n = 4$)	0.75 ± 0.1[a]	2.1 ± 0.5[a]	54 ± 6[e]	146 ± 26[e]

[a]Values are means ± SEM for number of rats per group.
[b]Values are expressed in milliliters per hour for lymph flows in the fasting state and at the absorption peak and are horizontally significantly different ([a]$P < 0.05$, [b]$P < 0.025$).
[c]Values are expressed in milligrams for TG outputs. For the first 6 h of the experiments, means assigned different superscript letters (c,d,e) are vertically significantly different at $P < 0.01$ and at $P < 0.05$ for the following 18 h.

At all time periods, phospholipids represented only a minor contribution to the lymph lipids, i.e., of 6, 8, 12, 12, and 17% of the total in butter, CO, CLO, MO, and ethyl ester experiments, respectively.

Evaluated in triglyceride amounts vs. the quantities recovered over the time period of 24 h, 26 ± 1% and 32 ± 2% were recovered during the first 6 h in butter and ethyl ester experiments, while 62 ± 8% and 52 ± 6% were recovered with CO and MO experiments, respectively, and only 36 ± 6% with the CLO set of experiments.

Mesenteric lymph triglyceride profiles. The lymphatic triglyceride flux, expressed as milligrams per hour of triglycerides, was followed hour after hour during the first 6 h after lipid administration and then in a block from the 6th to the 24th hour (Fig. 1A). The lymphatic flux of CLO was observed to increase to a peak at 4.5 h and decline, whereas that of CO had reached a peak by the first measurement at 2 h and that of MO peaked prior to 1.5 h and ended by 6 h. Thus the maximum amount in lymph appeared early, as soon as the second hour, with butter and MO, the lipids richest in medium chain fatty acid triglycerides (49 and 43%, respectively, of $C_{12:0}$, $C_{14:0}$, $C_{16:0}$, and $C_{16:1}$). CO exhibited a large peak amount in lymph which was spread over 3 h. In the case of CLO, rich in monounsaturated very long chain fatty acid triglycerides, the peak lymphatic absorption was delayed and narrow compared with those of the other two oils.

In accordance with triglyceride outputs, for the three oils, the rise in the lymphatic triglyceride flux gave equivalent amounts of triglycerides at the absorption peak (43.2 ± 4.2,

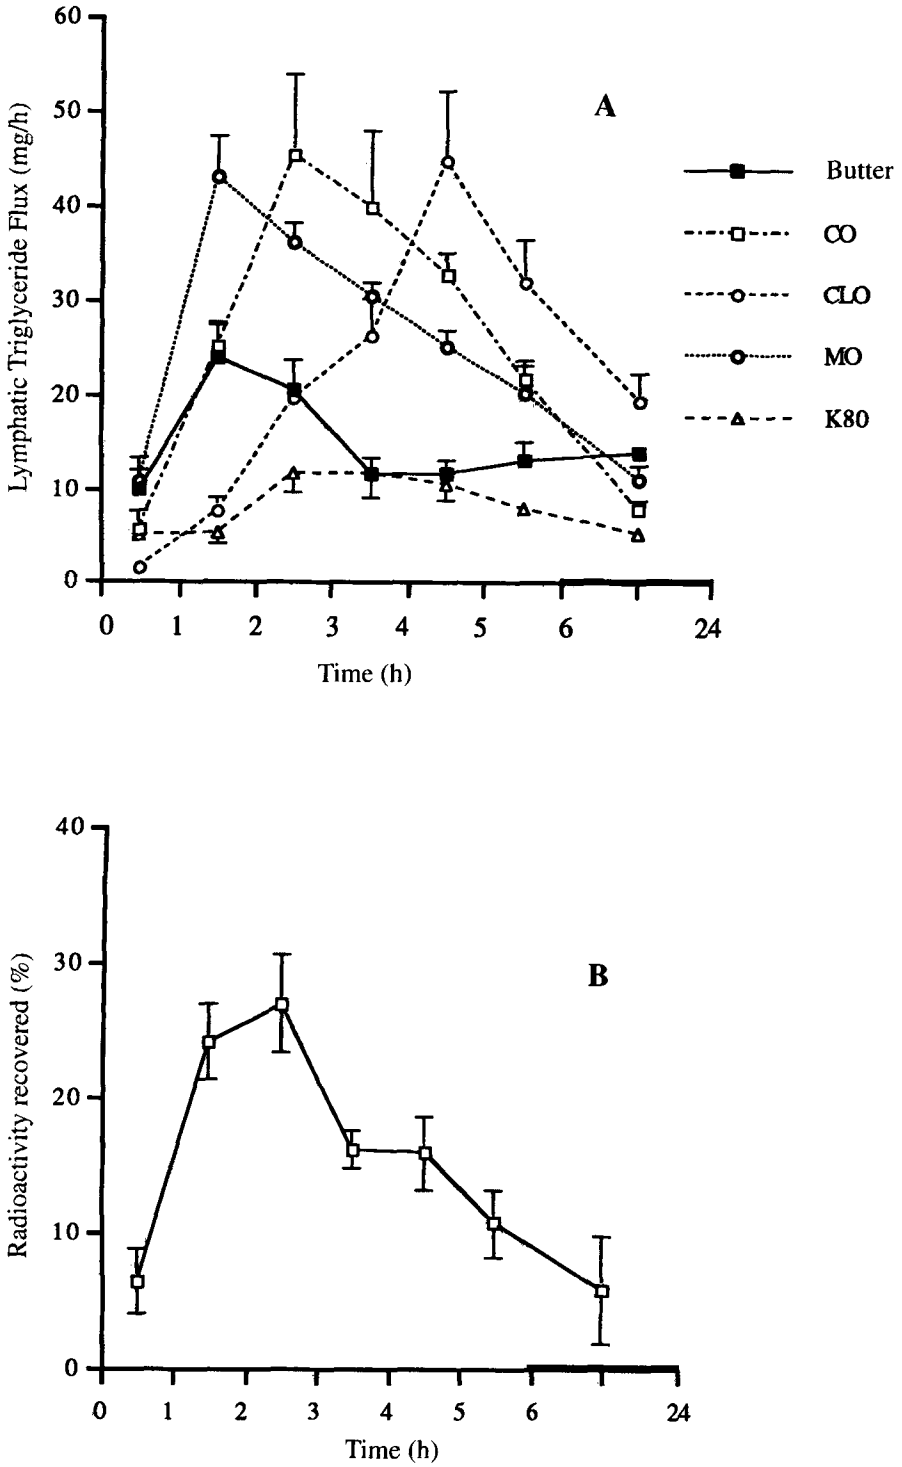

FIG. 1. A. Lymphatic triglyceride flux (mg/h) in rat mesenteric lymph following intragastric feeding. Values are means ± SEM (bars), $n = 6$, except for corn oil, $n = 3$. B. Time course recovery of radioactivity after intragastric feeding with butter and labeled oleic acid. Values are means ± SEM (bars), $n = 6$. Abbreviations: CO, corn oil; CLO, cod liver oil; MO, menhaden oil.

45.3 ± 8.6, and 44.7 ± 7.6 mg for MO, CO, and CLO, respectively). With butter, this value fell to 24.0 ± 3.3 mg, half as much as with the oils; for K80, the absorption peak was discrete and spread, with the highest triglyceride output one-fourth that of the other oils.

When labeled oleic acid was added to butter (Fig. 1B), of

the radioactivity recovered over the first 24 h, 75% was recovered over the first 6 h and 51% during the second and the third hours (24.1 ± 2.8 and 26.9 ± 3.6%) of intestinal absorption.

Time course appearance of some characteristic exogenous fatty acids in rat mesenteric lymph. An increase of the weight percentages of some characteristic fatty acids of the lipids ad-

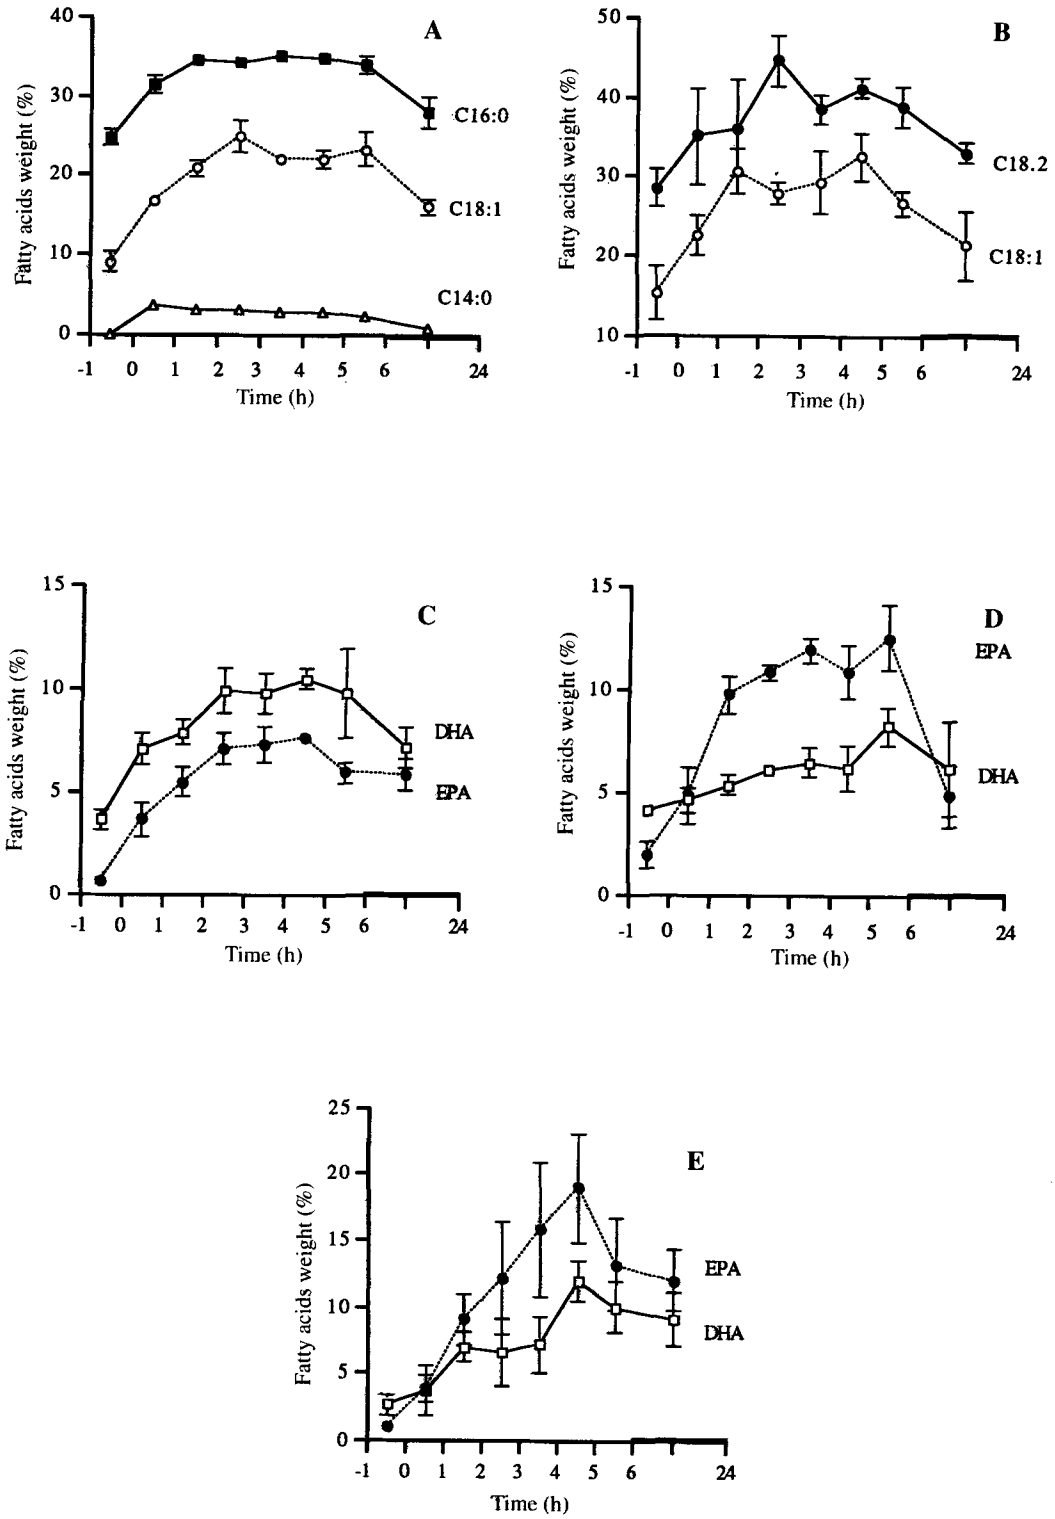

FIG. 2. Time course appearance of some characteristic fatty acids of butter, oils, or K80 in rat mesenteric lymph following intragastric feeding. Values are percentages of weight of fatty acids ± SEM (bars) $n = 4–6$; A, butter; B, corn oil; C, cod liver oil; D, menhaden oil; E, K80; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid..

ministered was observed as soon as the absorption process took place: oleic acid and butter feeding, oleic and linoleic acids and corn oil feeding, and particularly EPA and DHA and either the two marine oil feeding or EPA and DHA ethyl ester feeding. In fact, Figure 2 shows a more or less steady state of appearance in mesenteric lymph for these exogenous fatty acids, with comparison to the fasting state. For example, EPA and DHA were present in high percentages after the absorption peak and even beyond the first 6 h of absorption with the CLO and K80 experiments.

Usually, the fatty acid pattern of administered lipids was maintained in mesenteric lymph at the absorption peak. However, although the ratio of EPA to DHA was equal to 1.06 and 2.4 in CLO and MO, respectively, it was always lower in mesenteric lymph, even during the active absorption period. Thus, this ratio was equal to 0.7 and 1.8 with CLO and MO experiments, respectively, at the absorption peak. With K80 feeding, this ratio was sometimes larger or smaller than 1.6, the ratio of the mixture administered.

The weight percentage of the characteristic fatty acids recovered in mesenteric lymph was in parallel to the increased amounts of triglycerides measured in these same mesenteric lymph samples. However, the contribution of endogenous fatty acid to the formation of mesenteric lymph lipoprotein was also clearly apparent during exogenous lipid absorption processes.

Absorption of EPA and DHA appeared more efficient in marine oils than in the K80 experiments, taking into account their weight percentages in the two marine oils and ethyl esters K80 studied. The intestinal supply of EPA and DHA was higher in absolute value for the two marine oils compared with K80, with an average of 3.4–4.5 mg vs. 2.2 mg for EPA, and 4.3–4.5 mg vs. 1.5 mg for the DHA.

Mesenteric lymph lipoproteins. The absorption of butter, the three oils, or the ethyl esters of EPA and DHA administered to rats resulted in mesenteric lymph chylomicrons (Fig. 3). A correlation was noted between the amount of triglycerides recovered and the percentage and size of lipoproteins of diameter ≥0.1 μm. This correlation was particularly identified with CLO feeding ($r = 0.97$, $P < 0.005$). For this oil, chylomicrons were numerous but their size was often smaller than that observed with MO and CO feeding, in which the ab-

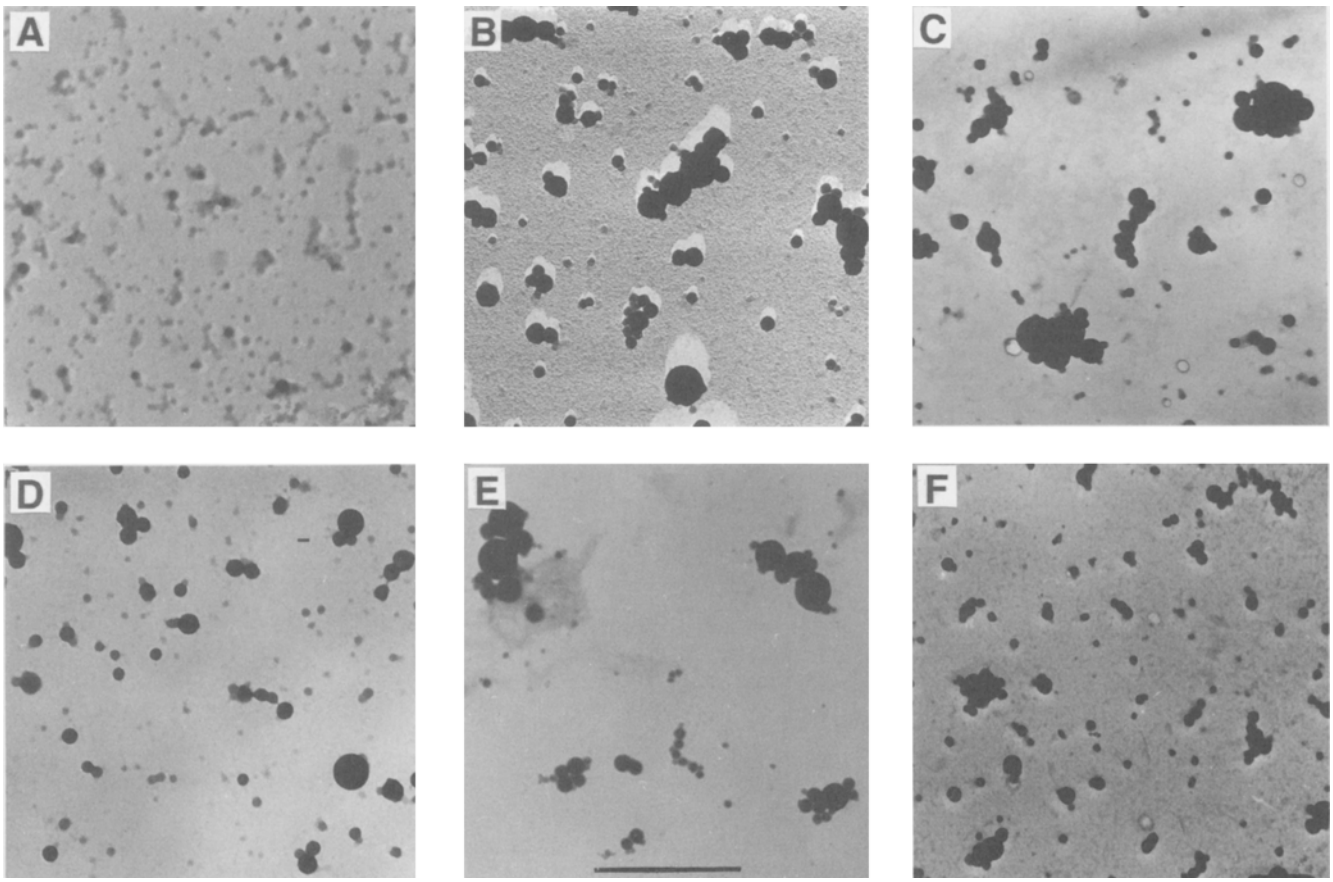

FIG. 3. Electron micrographs of lipoprotein particles of rat mesenteric lymph collected at the peak of absorption after intragastric administration of 0.65 mL of (B) butter, (C) 0.5 mL of corn oil, (D) cod liver oil, (E) menhaden oil, or (F) ethyl esters of eicosapentaenoic acid and docosahexaenoic (K80). Compared with mesenteric lymph of (A) fasting rats, absorption of lipids was followed by a scarce VLDL presence and a particular increase in enlarged chylomicrons especially after corn oil and menhaden oil absorption. Conversely, after absorption of K80, chylomicrons remained relatively small in agreement with biochemical results. Scale bar = 1 μm.

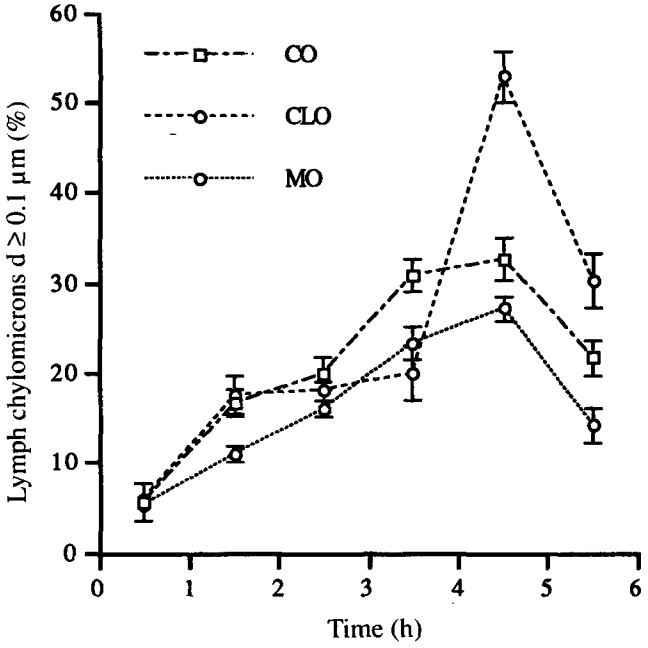

FIG. 4. Distribution of mesenteric lymph lipoproteins. Relative proportion of lipoproteins of a diameter ≥0.1 µm, in various time periods of mesenteric lymph collection after corn oil (CO), cod liver oil (CLO), or menhaden oil (MO) feeding (see the Materials and Methods section).Values are means ± SEM (bars).

sorption peaks occurred earlier (Fig. 1A). For these three oils, the amount of triglycerides carried by mesenteric lymph lipoproteins was equivalent at the absorption maximum and chylomicrons were observed with CO and MO. Consequently, the percentage of these large chylomicrons was higher with CLO feeding (Figs. 3 and 4). Whatever the calculation method used, all lymph particles or particles of a diameter larger than either 0.07 or 0.1 µm, the lymph particles after the feeding of ethyl ester of EPA and DHA were always smaller than after intragastric administration of butter or the three oils (Fig. 4).

DISCUSSION

In the fasting state, lymph flows of the rats were similar to those seen in previous studies carried out in comparable experimental conditions, and their rise during lipid absorption showed no significant difference regardless of the fat or oil given (17,24).

In agreement with Chernenko *et al.* (20), during the first 6 h or the following 18 h after either vegetable or marine oil feeding, there was no significant difference in lymph absorption. Because Chen *et al.* (29) added albumin to their lipid emulsion, which is known to decrease both fatty acid intestinal uptake and lymph flow (30), the discrepancy of our data with the observations of these authors might be explained by differences in experimental techniques. Indeed, intragastric administration, as used in the present study, seemed to allow lingual lipase hydrolysis, particularly at the *sn*-3 position of the triglycerides, and favored the start of lipid emulsification (6,31). Nelson and Ackman (2) emphasized the importance of the beginning of triglyceride hydrolysis in the stomach, and Harris and Williams (7), in human studies, demonstrated the very rapid and intensive absorption of emulsified fish oils.

Nelson and Ackman (2), believed that the rate of lipolysis could affect the route by which the liberated fatty acids enter the circulation. After butter feeding, the release of medium-chain fatty acids by lingual lipase activity during the stomach step, increased their portal absorption and explained the lower lymph triglyceride outputs in comparison with the oil experiments. Furthermore, this effect of the stomach on butter absorption could also explain differences with the results of Kalegoris and Story (22,32), who used intraduodenal butter administration. Such a practice delayed both emulsification and hydrolysis. Consequently, the absorption of fatty acid triglycerides was delayed, and endogenous fatty acid participation in lymph lipoproteins might have been increased (33).

In case of the oils, the faster the processes of absorption occurred during the first 6 h after feeding, the lower the amounts of lymph triglyceride required during the following 18 h of lymph collection. Such observations were to be linked with the involvement of endogenous fatty acid (33) which was maintained over a longer time period and, in the same way, might explain the high lymph triglyceride output obtained from the 7th to the 24th hour after CLO ingestion.

The slight increase in phospholipids in whole mesenteric lymphs observed with the two marine oils in comparison with the vegetable oil might be attributed to the n-3 fatty acids in these oils. This has been observed in previous studies, for example, between oleic acid and EPA (34–36).

EPA and DHA given as 80% of total fatty acids in ethyl esters were recovered in lymph samples at a level of 1% in accordance with previous reports (18,19,21,37,38); when given in the form of marine oils, peak values were 5–16%. This difference in absorption may reflect differences in emulsification, hydrolysis, and absorption. Previous reports have demonstrated in both rats and humans that ethyl esters are as well absorbed as triglycerides (18,19,21,38,39).

When n-3 polyunsaturated fatty acids were administered alone in ethyl ester form, in the absence of monoglycerides, their enterocyte esterification by the phosphatidic pathway was less efficient than with the monoglyceride pathway in accordance with the lower efficiency of lumenal hydrolysis (38,40). Indeed, Lawson and Hughes (19) showed that the absorption of fatty acid ethyl esters was highly dependent on the amount of co-ingested fat, a source of monoglycerides. As suggested by Ackman (12,13), it is necessary to point out that in the case of ethyl esters, transport in phospholipid form both by mesenteric lymph and portal blood is possible. This was confirmed by Hamasaki *et al.* (41), who observed a high incorporation of EPA administered as ethyl esters in plasma phospholipids and, in the present work, by the highest enrichment in phospholipids being in lymph after K80 feeding. In agreement with some observations by Yang and Kuksis (34) on CO and its fatty acid methyl esters, the absorption of EPA

and DHA in the form of ethyl esters *via* the glycerophosphate pathway released smaller lipoproteins in mesenteric lymph compared with those obtained with the three oils studied.

High percentages of short-chain (<16) fatty acids, particularly with butter and MO, were linked to an early appearance of triglycerides in mesenteric lymph. Conversely, the presence of very long-chain monounsaturated fatty acids in the CLO, such as gadoleic and cetoleic acids, delays and sometimes impairs the absorption of other fatty acids (21,28,42), thus delaying the lymph triglyceride absorption peak.

Taking into account the fatty acid distribution on the glycerol of the CO and MO triglycerides (21,43), the slight delay in the appearance of the absorption peak with CO might involve a more rapid hydrolysis of shorter-chain fatty acids of MO accompanied by a consecutive rapid enterocyte uptake of monoglycerides, rapidly available for triglyceride reesterification through the monoglyceride pathway. These results were in agreement with the high release of myristic, palmitoleic, and oleic acids observed by Yang *et al.* (38) studying MO lipolysis. Differences in mesenteric lymph triglyceride output profiles were in accordance with the size of mesenteric lymph lipoproteins. The size of the chylomicrons was dependent upon the amount of triglycerides absorbed and transported (44) and on the fatty acid composition of exogenous lipids (28,34). In our experimental conditions of lymph fixation and lipoprotein shadowing, distortions of the lipoprotein shapes were never observed. As previously shown (28), chylomicrons formed at the peak of absorption were larger than those formed at the beginning and toward the end of the absorption period. When absorption peaks were spread over a long period of time, a longer length of small intestine involved in absorption processes may explain an increase in chylomicon number. When the absorption peak was obtained over a shorter time period, for an equivalent triglyceride amount recovered in lymph, an increase in chylomicron size was observed (45). Such illustrations were consistent with the effect of the degree of unsaturation of triglyceride fatty acids. A certain degree of absorptive efficiency clearly appeared in a comparison of both the triglyceride output profiles and the morphological aspect of chylomicron formation and was confirmed especially after MO and CLO feeding, in agreement with previous studies (21,28,46) and as shown by Kalogeris and Story (22) after butter and CO feeding.

Aside from the consequences of the differential activity of preduodenal and pancreatic lipases according to the nature of fatty acid located at the *sn*-1 and *sn*-3 positions of triglycerides, fatty acid absorption is influenced by the triglyceride structure and is increased for fatty acids located in the *sn*-2 position, taking into account the preferential triglyceride synthesis *via* the 2-monoglyceride pathway (8,9,12,13,20,47).

Scrutiny of the time course appearance of some characteristic exogenous fatty acids illustrates these absorption modalities. The distribution of palmitic and oleic acids on the *sn*-1, *sn*-2, and *sn*-3 positions of the butter triglycerides was as follows: 31, 32.3, 5.4 for palmitic acid and 30.0, 18.9, 23.1 for oleic acid *sn* positions, respectively (48). Figure 1B shows the time course of mesenteric lymph appearance of butter containing labeled exogenous oleic acid, while in Figure 2, both endogenous and exogenous oleic acid were considered. Examination of the two profiles shows that oleic acid preferentially distributed in the *sn*-1 and *sn*-3 positions of butter triglycerides was consequently rapidly released and taken up by enterocytes and recovered in mesenteric lymph. Moreover, while the respective percentages (w/w) were 29 and 25% for the butter containing palmitic and oleic acids, palmitic acid absorption seemed to be favored by its preferential location in the *sn*-2 position.

Despite the preponderance of linoleic acid in the *sn*-2 position and the random distribution of oleic acid for the CO triglycerides (43), preferential lymph output of linoleic acid appeared only during the first 3 h of absorption.

Mesenteric lymph appearance profiles of n-3 polyunsaturated fatty acids in the present work were similar to those reported in the literature (20,49). Although great variation was seen, depending on the fish species and the area of fishing, DHA was often enriched at the *sn*-2 position of marine oil triglycerides, particularly for the CLO in which EPA is more randomly distributed. Thus, if the distribution of EPA and DHA on the *sn*-1, *sn*-2, *sn*-3 positions of CLO triglycerides was 2, 12, 13 and 1, 20, 6, respectively (11), the results obtained would be in accordance with the structure of marine oil triglyceride, and might explain that although there were percentages of 9 and 9.6% (w/w) of DHA and of EPA, respectively, in CLO, increased mesenteric absorption of DHA was observed after the feeding of this oil, in the same way as MO (38). Such results might provide evidence of a higher intestinal availability of DHA compared with EPA at the initial time period of absorption. Investigations are currently being carried out to attempt to link some of these intestinal events with the gastrocolic localization of acyltransferases and binding proteins involved in lipid intestinal absorption processes of lipids.

ACKNOWLEGMENTS

The authors wish to extend their thanks particularly to Pr. H. Carlier for many helpful discussions, M.C. Monnot for her skillful technical assistance, and J. Gresti, a member of the Faculté des Sciences Mirande, Dijon, France, for his expert help in conducting the GLC butter analysis.

Comparative Hypocholesterolemic Effects of Six Vegetable Oils in Cholesterol-Fed Rat

Michihiro Fukushima, Shiori Akiba, and Masuo Nakano*

Department of Bioresource Chemistry, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, Hokkaido 080, Japan

ABSTRACT: The hypocholesterolemic efficacies of various polyunsaturated fatty acids were compared in rats given cholesterol-enriched diets. *Oenothera biennis* Linn oil (OBLO, linoleic + γ-linolenic), sunflower oil (linoleic), palm oil (PLO, oleic + linoleic), soybean oil (linoleic + α-linolenic), high-oleic safflower oil (oleic + linoleic), or mixed oil (linoleic + α-linolenic) was added to the diet at 200 g/kg (20% groups). OBLO was also added at 100 g/kg diet (10% group). The serum total and very low density lipoprotein + intermediate lipoprotein + low density lipoprotein cholesterol concentrations of the 10 and 20% OBLO groups were consistently lower than those in the other groups. The liver cholesterol concentration in the PLO group was lower in all groups. The liver cholesterol concentrations in the 10 and 20% OBLO groups were also lower than in the other groups. There were no significant differences in the fecal neutral sterol and bile acid extraction among groups.
Lipids 31, 415–419 (1996).

Dietary linoleic acid (LA, 18:2n-6) serves as a precursor for biosynthesis of arachidonic acid (20:4n-6), the substrate for eicosanoid synthesis through activity of the enzymes cyclooxygenase and 5-lipoxygenase. It has long been accepted as having hypocholesterolemic effects (1,2). More recently, linoleic acid derivatives, particularly γ-linolenic acid (GLA), were found to be even more potent in reducing blood cholesterol in humans and rats (3–6). Richard *et al.* (7) also reported that a dietary intake of 4–5.8 mmol GLA per day is more efficient in reducing serum total and low density lipoprotein (LDL) cholesterol levels than dietary LA in humans. However, natural sources of GLA are quite limited.

Evening primrose oil usually contains about 9% GLA. This oil has been shown to have greater hypocholesterolemic activity than safflower oil (SAFO) or soybean oil (SBO) at the 10% level in the diet (8,9). Suzuki *et al.* (10) have found that several genera of molds can produce lipids containing about 10% GLA. However, the mold oil contains less LA and more oleic and palmitic acids. Thus, the mold oil does not have greater hypocholesterolemic activity than SAFO (11). *Oenothera biennis* Linn seed oil (OBLO) (evening primrose) contains about 71% LA and 14% GLA. The purpose of the present study is to investigate the effect of OBLO on lipid metabolism in rats in comparison with several other plant oils.

MATERIALS AND METHODS

Animals and diets. Male F344/jcl rats (4 wk old) were purchased from Japan CLEA Co. Ltd. (Tokyo, Japan). Thirty-five animals were housed individually in cages in a room controlled for temperature (23 ± 1°C), humidity (60 ± 5%), and light (12-h light/dark cycle). The composition of the experimental diet was as follows (wt%): casein, 20; fat, 10 or 20; cornstarch, 15; cellulose powder, 5; DL-methionine 0.3; mineral mixture, 3.5 (AIN-76) (12); vitamin mixture, 1 (AIN-76) (12); choline bitartrate, 0.2; cholesterol, 1; sodium cholate, 0.25; and sucrose to 100. OBLO was extracted from seeds collected in fields around the city of Obihiro (Hokkaido, Japan) using an oil mill (MKZA10-15; Masuko Sangyo Co., Ltd., Saitama, Japan). Sunflower oil (SFO) was a generous gift from the town of Hokuryu (Hokkaido, Japan). Palm oil (PLO), perilla oil, high-oleic SAFO, and SBO were purchased from Asahi Electric Industry Co. (Tokyo, Japan), Kanto Chemical Co. Inc. (Tokyo, Japan), Ajinomoto Co. (Tokyo, Japan), and Fuji Oil Co. (Osaka, Japan), respectively. Mixed oil (MIXO) was a mixture of PLO, high-oleic SAFO, and perilla oil (6:3:1, by vol) (13). The lipid class of each oil was as follows: OBLO was composed of 79% triacylglycerol (TG), 6% diacylglycerol (DG), 9% sterol, and other components; SFO was composed of 73% TG, 3% DG, 9% sterol, and other components; PLO was composed of 78% TG, 5% DG, 9% sterol, and other components; SAFO was composed of 84% TG, 2% DG, 9% sterol, and other components; SBO was composed of 80% TG, 1% DG, 13% sterol, and other components; MIXO was composed of 85% TG, 2% DG, 4% sterol, and other components. Sitosterol comprised about 81–91% of the sterol concentration in each oil.

TABLE 1
Fatty Acid Composition of Dietary Fats

Dietary fats	Fatty acids (wt%)						
	16:0	18:0	18:1	18:2n-6	18:3n-3	18:3n-6	P/S[a]
Oenothera biennis							
Linn oil	7.2	1.4	6.2	71.0	—	13.7	11.7
Sunflower oil	6.6	3.6	25.1	63.5	—	—	9.6
Palm oil	48.8	0.4	33.9	16.9	—	—	0.4
Soybean oil	11.3	2.8	25.0	51.3	8.9	—	5.3
Safflower oil[b]	6.8	1.8	40.0	50.3	0.3	—	7.5
Mixed oil[c]	30.1	2.9	36.7	22.8	6.6	—	1.0

[a]Polyunsaturated/saturated ratio (P/S) = (18:2 + 18:3)/16:0.
[b]High-oleic safflower.
[c]The dietary fat was a mixture of palm oil, high-oleic safflower oil, and perilla oil (6:3:1, by vol).

Table 1 shows the fatty acid compositions of the dietary fats. All animals were fed a fat- and cholesterol-enriched diet containing 200 g of PLO and 10 g cholesterol/kg for 4 wk as a preliminary diet to create hypercholesterolemic rats. The rats (8 wk old) were divided into seven groups of five animals each. Rats were allowed free access to experimental diets and water for 6 wk; body weight and food consumption were recorded every other week. To avoid autooxidation, each diet was stored at −20°C and freshly prepared each day. All animal procedures described conformed to certain principles (see Ref. 14).

Analytical procedures. Blood samples (2 mL) were collected weekly between 0800 and 1000 h from the jugular veins of fed rats. The samples were taken into tubes without anticoagulant; after the samples stood at room temperature for 2 h, serum was prepared by centrifugation at 1500 × *g* for 20 min. At the end of the experimental period of 6 wk, all fecal excretion during one day was collected; fecal dry weights did not differ among groups. The rats were killed by ether inhalation, and the livers quickly removed, washed with cold saline (9 g NaCl/L), blotted dry on filter paper, and weighed before freezing for storage.

Chemical analysis. Total cholesterol, high density lipoprotein (HDL)-cholesterol, and TG concentrations in the serum were determined enzymatically using commercially available reagent kits (assay kits for the TDX system; Abbott Laboratory Co., Irving, TX). The very low density lipoprotein (VLDL) + intermediate lipoprotein (IDL) + LDL-cholesterol concentration was calculated as follows: VLDL + IDL + LDL-cholesterol = total cholesterol − HDL-cholesterol.

Total lipids were extracted from serum, liver, and feces by a mixture of chloroform/methanol (2:1, vol/vol) (15). The serum and liver phosphatidylcholine (PC) were separated by two-step single-dimensional thin-layer chromatography on a silica gel plate; the solvents were chloroform/methanol (one-step: 95:5, vol/vol) and chloroform/acetone/methanol/acetic acid/water (two-step: 50:20:15:10:5, by vol). The fatty acids of the PC fraction were esterified in HCl–methanol (5 mL/L) for 2 h at 125°C (16) and analyzed using gas–liquid chromatography (GLC; Shimadzu 14A, Kyoto, Japan) with a 10% DEGS packed column (2 mm × 2.6 m, support shimalite w; Shimadzu) with nitrogen as the carrier gas. Neutral sterols in feces and liver obtained by saponification were acetylated (17) and analyzed by GLC with a DB17 capillary column (0.25 mm × 30 m; J&W Scientific, Folsom, CA). Acidic sterols in feces were measured by GLC following the method of Grundy *et al.* (18).

Statistical analysis. Data are presented as means and standard deviations. The mean and standard deviation for serum total cholesterol, HDL-cholesterol, VLDL + IDL + LDL-cholesterol, and TG for each time point were calculated. The significance of differences between treatment groups was determined by general liner models with Duncan's multiple-range test (SAS Institute, Cary, NC). Results were considered significant at $P < 0.05$.

RESULTS

Feed intake, rat growth, and liver weight. The results are summarized in Table 2. The dietary MIXO tended to increase the body weight gain significantly more than the other dietary fats except for dietary SBO. The liver weight in the 10% OBLO group was the lowest of all groups, and there were no significant differences in the food intake among the groups.

Tissue lipid concentration. The serum total, VLDL + IDL + LDL-cholesterol, HDL-cholesterol, and TG concentrations are shown in Table 3. The total and VLDL + IDL + LDL-cho-

TABLE 2
Body Weight Gain, Food Intake, and Liver Weight in Rats Fed Dietary Fats for Six Weeks[a]

Component	Diet

10% OBLO	0.8 ± 0.3	1.5 ± 0.6^{a}	1.3 ± 0.3^{a}
20% OBLO	1.2 ± 0.5	0.7 ± 0.3^{b,c}	0.6 ± 0.3^{b}
SFO	1.1 ± 0.6	0.4 ± 0.3^{c}	0.5 ± 0.1^{b}
PLO	1.0 ± 0.5	1.2 ± 0.5^{a,b}	1.5 ± 0.8^{a}
SBO	1.0 ± 0.5	0.5 ± 0.3^{c}	0.5 ± 0.2^{b}
SAFO	0.7 ± 0.3	0.6 ± 0.4^{c}	0.6 ± 0.3^{b}
MIXO	0.9 ± 0.2	0.9 ± 0.5^{b,c}	0.6 ± 0.2^{b}

[a]Values are expressed as means ± standard deviations for five rats. Means within the same columns bearing different superscripts are significantly different ($P < 0.05$); VLDL, very low density lipoprotein; IDL, intermediate lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein. See Table 2 for other abbreviations.

lesterol concentrations in the 10 and 20% OBLO groups were significantly lower than those in the other groups. Although HDL-cholesterol concentrations in the 10 and 20% OBLO groups were significantly lower than those in the PLO group, there were no significant differences among all groups except for dietary PLO. The serum TG concentrations in the 10% OBLO and PLO groups were significantly higher than those in the other groups at 6 wk.

Table 4 illustrates the cholesterol concentrations in the livers of rats at the end of the 6-wk feeding period. Dietary SFO increased liver cholesterol concentration significantly among all groups, whereas dietary PLO and 10% OBLO groups showed a significant decrease. The dietary 20% OBLO, SAFO, and MIXO groups also showed lower liver cholesterol concentration than the SFO and SBO groups.

Fatty acid composition of the tissue. The fatty acid composition of PC in the serum and liver is shown in Table 5. The level of 18:2n-6 in the serum of the 20% OBLO group was significantly higher than that in the PLO, SBO, SAFO, and MIXO groups. The level of 20:3n-6 in the 10% OBLO group was the highest among all groups. The level of 20:4n-6 showed a greater increase in the serum of the SFO groups than that in the SBO and MIXO groups.

The level of 18:2n-6 in the liver of the 20% OBLO and SBO groups increased significantly compared with the PLO and MIXO groups. The level of 20:3n-6 in the 10 and 20% OBLO groups was significantly higher than in the other groups.

Fecal lipid concentration. Table 6 shows the effects of the dietary fat on fecal neutral sterol and bile acid concentrations in rats at the end of the experimental period. There were no significant differences in the fecal neutral sterol concentrations among the groups.

The excretion of lithocholic acid increased in the PLO group, and the excretion of cholic acid decreased in the SAFO and MIXO groups. However, there were no significant differences in the fecal total bile acid concentrations among the groups.

DISCUSSION

This study indicated that dietary OBLO at a level of ~190 mg 18:3n-6/d is more efficient in lowering serum total cholesterol than are SFO or SAFO which contains abundant LA, or MIXO with n-6/n-3 ratios of approximately 3.5 and a polyunsaturated/saturated ratio of approximately 1.0 (13). These results agree with those of previous studies (3–9). There were no significant differences in the fecal neutral sterol and total bile acid concentrations among all groups. These results show that the cholesterol-lowering effect of their polyunsaturated oils is not due to increased fecal excretion of neutral and acidic sterols. Huang *et al.* (8) reported that evening primrose oil (Efamol) lowered the plasma cholesterol concentration and increased the levels of LA and arachidonic acid in phospholipids of

plasma and liver more than hydrogenated coconut oil and SAFO. However, there were no significant differences in the liver cholesterol concentration among the three oils (8). Their results were similar to our data. However, the liver cholesterol concentrations in the groups fed diets containing more polyunsaturated fatty acids (PUFA) were higher than those in rats fed the dietary PLO. The low level of liver cholesterol in the PLO group may be attributable to the reduced hepatic LDL receptor activity, due to feeding fats containing less PUFA and more saturated fatty acid (19).

The reduction of the VLDL + IDL + LDL-cholesterol concentration was similar to that reported by Richard *et al.* (7). Ishikawa *et al.* (20) observed significant changes in plasma lipids after administration of 300 mg/d of GLA to hypercholesterolemic patients over an 8-wk period. The total cholesterol, LDL-cholesterol, and apo B concentrations were decreased in patients without hypertriglyceridemia. The effects on blood cholesterol therefore appeared to be clearly related to the dose of GLA administered, as judged by feeding 200–400 mg of GLA in this experiment. The high levels of serum total, HDL-, and VLDL + IDL + LDL-cholesterol in the PLO group were similar to those reported by Nicolosi *et al.* (21). They indicated that the high degree of dietary fatty acid saturation such as that found in coconut oil induced greater changes in plasma lipoprotein (apo B and apo A-I levels) and LDL metabolism (21). Dietary PLO increased the HDL-concentration among all groups. Sugano *et al.* (9) reported that olive oil containing less PUFA and more saturated

fatty acid reduces the HDL-cholesterol concentration. Grundy and Denke (22) reported that LA lowers the level of apo A-I, which is the major protein component of circulating HDL (23).

In conclusion, the results of this study demonstrate that the OBLO decreases the serum total cholesterol and VLDL + IDL + LDL-cholesterol concentrations in the presence of excess cholesterol in the diet.

A Rapid Method for Separation of Plasma Low and High Density Lipoproteins for Tocopherol and Carotenoid Analyses

Silke Vogel, John H. Contois[1], Sarah C. Couch, and Carol J. Lammi-Keefe*

Department of Nutritional Sciences, University of Connecticut, Storrs, Connecticut 06269

ABSTRACT: Ultracentrifugation (UC) is the method most often employed for separation and quantification of lipoproteins. Because this procedure requires expensive laboratory equipment, a large volume of fresh sample and an inordinate amount of time, it may not be ideal for routine clinical/experimental use. The aim of the current study was to evaluate a method which combines selective precipitation (HDL–P) and immunoseparation (LDL–I) for the rapid and reliable isolation of high density lipoproteins (HDL) and low density lipoproteins (LDL) specifically for vitamin E and carotenoid determination within these fractions. Cholesterol and triacylglycerol concentrations within the HDL and LDL were also determined to enable expression of vitamin E and carotenoid concentrations per gram of lipid. Isolation of lipoproteins by UC was used as the reference method (HDL–UC/LDL–UC). There were no significant differences between methods for α- and γ-tocopherol in LDL and HDL. Carotenoids measured in HDL and LDL were comparable between the methods. The exception was higher lutein/zeaxanthin concentration in HDL–P and LDL–I compared to HDL–UC and LDL–UC, respectively. Additionally, lycopene concentration was significantly lower in LDL–I compared to LDL–UC. In comparing vitamin E and carotenoid values in lipoproteins separated from fresh and frozen plasma by the direct method, there was no difference in α-tocopherol or the majority of carotenoids measured. In conclusion, a combination of selective precipitation and immunoseparation of fresh or frozen plasma for subsequent α- and γ-tocopherol analyses provides an accurate and reliable alternative to lipoprotein separation by UC. Additionally, carotenoid concentrations in HDL separated by selective precipitation and analyses of α- and β-carotenes and β-cryptoxanthin in LDL separated by immunoseparation are also reliable, while lycopene and lutein/zeaxanthin concentrations in LDL–I are not readily comparable to LDL–UC.

Lipids 31, 421–426 (1996).

Studies of the metabolism and transport of lipids and lipid-soluble nutrients rely on the ability to separate and quantify plasma lipoproteins. Further, an accurate and precise measurement of lipoprotein constituents is dependent on the separation technique employed. Ultracentrifugation (UC) is the technique traditionally used for separation and quantification of lipoproteins on the basis of hydrated density (1). This method requires expensive equipment and significant sample volume. It is also time-consuming, requiring several days. Additionally, fresh plasma and serum must be utilized for the separation to obtain optimal results. These aspects of the UC methodology clearly limit its utility for routine laboratory analyses.

Alternative methods have been developed for lipoprotein separation. Column chromatography, high-performance liquid chromatography (HPLC), and electrophoresis are not applicable for routine analyses as they are time-consuming, and accuracy is not always satisfactory (1). For the routine separation and subsequent cholesterol determination of high density lipoproteins (HDL), selective precipitation of apolipoprotein B containing particles is now widely used in routine analyses (2). This method has the advantages of being fast, reliable, and inexpensive. Chemical precipitation and affinity chromatography have been proposed and used for the isolation of low density lipoproteins (LDL) (3,4). While these methods are also inexpensive and efficient, LDL cannot be separated from very low density lipoproteins (VLDL) and chylomicrons. Also, only fasting blood samples and samples with low to normal triacylglycerol (TG) concentrations can be separated with accuracy. Recently a new method was developed by Genzyme Corporation, Diagnostics Division (Cambridge, MA) and is now commercially available from Sigma Diagnostics (St. Louis, MO). That methodology permits the direct separation of LDL particles from other lipoproteins by immunoseparation. Chylomicrons, VLDL, and HDL are selectively removed and retained on a filter by specific antibodies immobilized on polystyrene microspheres that allow only LDL to pass through the filter. In a recent study that compared immunoseparation against ultracentrifugation in 115 serum samples, McNamara *et al.* (5) concluded that immunoseparation is an accurate and reliable method for LDL cholesterol measurement.

The objective of this study was to evaluate a method which permits fast and reliable isolation of HDL and LDL for subsequent accurate analyses of tocopherols and carotenoids in these lipoproteins. For this purpose, analyses of carotenoids and α- and γ-tocopherols in LDL separated by immunoseparation (LDL–I) and HDL isolated by selective precipitation (HDL–P) (herein referred to as direct methods) were compared to those in lipoproteins isolated by sequential UC (LDL–UC and HDL–UC). In addition, the effect of sample freezing (–80°C) on carotenoid and tocopherol concentrations following lipoprotein separation by LDL–I and HDL–P assays was assessed.

MATERIALS AND METHODS

Subjects. Twenty healthy, normolipidemic volunteers, eleven men and nine women, participated in the study. Fasting blood samples were drawn from each subject into vacutainers containing EDTA (0.15%). Plasma was separated by low-speed centrifugation for 20 min at 1,500 × *g* at 4°C. Lipoprotein separation procedures were started within an hour after blood sampling. Figure 1 summarizes the protocol for lipoprotein separation and vitamin analyses. All subjects received a description of the study protocol and signed informed consent forms. This study was approved by the University of Connecticut Human Subject Approval Committee.

Ultracentrifugation. The lipoprotein fractions (VLDL, LDL, and HDL) were isolated using two sequential ultracentrifugation steps. In brief, plasma (5 mL) was transferred to quickseal tubes (Beckman Instruments, Palo Alto, CA) and centrifuged for 18 h at 39,000 rpm, 4°C in a 40.3 Ti fixed-angle rotor ultracentrifuge (Beckman). The 1.006 g/mL top fraction (VLDL) was brought back to a volume of 2.5 mL with saline (0.85%). The bottom fraction was adjusted to a relative density of 1.063 with KBr and centrifuged for 18 h at 39,000 rpm to obtain the LDL (top) and the HDL (bottom) fractions. The HDL fraction was not further separated from the lipoprotein free fraction. Preliminary studies demonstrated that no carotenoids and tocopherols were associated with this fraction (Vogel, S., Contois, J.H., and Lammi-Keefe, C.J., unpublished observation).

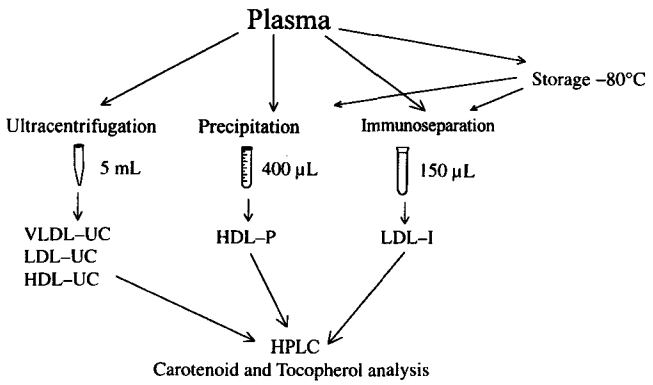

FIG. 1. Protocol for lipoprotein separation and vitamin analyses; HPLC, high-performance liquid chromatography; VLDL–UC, very low density lipoprotein isolated by sequential ultracentrifugation; LDL–UC, low density lipoprotein isolated by sequential ultracentrifugation; HDL–UC, high density lipoprotein isolated by sequential ultracentrifugation; HDL–P, high density lipoprotein isolated by selective precipitation; LDL–I, low density lipoprotein isolated by immunoseparation.

Immunoseparation. A commercially available reagent (Genzyme Corporation) was used to separate LDL from plasma by immunoseparation. This method uses specific antibodies immobilized on polystyrene microspheres to selectively remove HDL, chylomicrons, and VLDL, which are excluded by a filter. LDL passes through the filter and is present in the filtrate. For our purpose, we first pipetted 334 µL of the reagent into separation tubes (Genzyme Corporation), added 50 µL plasma, vortexed the tubes immediately, and allowed them to incubate for 10 min at room temperature. LDL particles were drawn through the filter with subsequent centrifugation at full speed in a microfuge at 12,000 × *g* for 10 minutes. Because of the approximate sevenfold dilution of the LDL, three filtrates for each sample were pooled to ensure adequate sample size for the detection of tocopherols and carotenoids in the LDL fraction.

Selective precipitation. HDL were isolated from plasma according to Warnick *et al.* (6), using Dextran Sulfate-Mg^{2+} chloride as the precipitation reagent. Plasma (400 µL) was transferred to microtubes, and 40 µL reagent added to each tube. The tubes were immediately vortexed. After a 10-min incubation at room temperature, the samples were centrifuged for 30 min at 1,500 × *g*. The supernate containing the HDL particles was then removed and kept at 4°C until further analyses.

Lipid determination. Cholesterol and TG concentrations in plasma and lipoproteins were measured using enzymatic test kits (Sigma Diagnostics). Lipids in HDL–P were determined in 12 subjects.

Vitamin analyses. The α- and γ-tocopherols and carotenoids in plasma and lipoprotein fractions were analyzed using the reversed-phase HPLC method described by Barua *et al.* (7). Prior to extraction, retinyl hexanoate and β-apo-8′-carotenyl myristate in methanol were added to each sample as internal standards for tocopherols and carotenoids, respectively. After precipitation of proteins with methanol, all samples were extracted twice with hexane. No additional extraction with ethylacetate was performed. Preliminary analyses showed recovery was not improved with the ethylacetate extraction (Contois, J.H., and Lammi-Keefe, C.J., unpublished observation). The hexane extracts were transferred to test tubes and the hexane subsequently evaporated under a gentle stream of nitrogen. The residues were redissolved in 60 µL of a dichloromethane/mobile phase (1:5) mixture, and 40 µL were used for HPLC analyses. The mobile phase consisted of acetonitrile/methylenechloride/methanol/*n*-butanol with 0.1% ammonium acetate (90:15:10:0.1,by vol). The HPLC system included a Waters pump (flow rate 1.5 mL/min), a 5 µm C_{18} stainless-steel Waters (Milford, MA) resolve column, an autosampler (Millipore, Milford, MA), two absorbance detectors connected in series, and a dual channel integrator. The detectors were set at 300

TABLE 1
Carotenoid and Tocopherol Concentrations in Lipoproteins Used for Precision Determinations (μmol/L)[a,b]

Vitamin	HDL–P[c]	LDL–I[c]
Lutein/zeaxanthin	0.23 ± 0.03	0.21 ± 0.02
β-Cryptoxanthin	0.03 ± 0.003	0.03 ± 0.01
Lycopene	0.07 ± 0.01	0.22 ± 0.08
α-Carotene	0.02 ± 0.003	0.03 ± 0.01
β-Carotene	0.03 ± 0.002	0.10 ± 0.03
α-Tocopherol	7.76 ± 1.07	7.62 ± 0.68
γ-Tocopherol	2.37 ± 0.41	1.21 ± 0.11

[b]Precision for analyses of lipoprotein isolated by direct methods only.
[c]Low density lipoprotein isolated by immunoseparation (LDL–I) and high density lipoprotein isolated by selective precipitation (HDL–P) refer to separation by immunoseparation and precipitation, respectively.

nm (Thermo Separation Products, Fremont, CA) to monitor retinol and tocopherols and at 450 nm (Varian 2550; Varian, Palo Alto, CA) to monitor carotenoids. The analyte peaks were identified by retention times and quantified using standard curves of external standards for each analyte.

Analyses of frozen samples. Samples of plasma from 12 subjects were stored for 6 mon at −80°C. After thawing of samples at room temperature, the LDL fraction was separated by immunoseparation and HDL by selective precipitation, as described above. Cholesterol, TG, and vitamin concentrations were determined for plasma and all lipoprotein fractions.

Statistical analyses. Concentrations of lipids (TG and cholesterol) and vitamins in the lipoprotein fractions separated by UC vs. the direct methods and concentration in fresh vs. frozen/thawed specimens were compared using paired *t*-tests (SAS Institute, Cary, NC).

RESULTS

Precision. To evaluate the applicability of the direct methods for the analyses of carotenoids and tocopherols, the variability was determined for the analyses of carotenoids and tocopherols in LDL and HDL isolated using the direct methods. Precision exceeding 95% was achieved for duplicate analyses of all HDL carotenoids and tocopherols. Precision for α- and γ-tocopherols in LDL was 99% and for carotenoids 86–97%. Table 1 shows lipoprotein concentrations of the carotenoids and tocopherols in the lipoproteins that were analyzed.

During separation, the LDL fraction was diluted approximately sevenfold, resulting in low carotenoid concentrations. Low carotenoid concentrations resulted in high variability associated with their detection by HPLC. We found that the use of LDL–I isolated from 300 μL plasma instead of 150 μL plasma decreased variability and increased precision to 95% for all carotenoids in the LDL fraction.

Comparison of direct methods and ultracentrifugation for separating LDL and HDL: TG and cholesterol. The mean plasma TG and cholesterol concentrations for 20 subjects were 86.6 ± 39.4 and 173.4 ± 33.4 mg/dL, respectively. There were no significant differences between the methods for LDL. The mean LDL cholesterol concentrations were 119.1 ± 45.1 and 110.3 ± 35.7 mg/dL, and the mean LDL–TG concentrations were 36.6 ± 40.8 and 24.3 ± 15.0 mg/dL for LDL–I and LDL–UC, respectively. In contrast, HDL lipid concentrations in 12 subjects were significantly different between the methods. HDL–TG concentrations (18.2 ± 6.4 vs. 13.4 ± 2.5 mg/dL, HDL–P vs. HDL–UC) and HDL cholesterol concentrations (51.1 ± 15.8 vs. 48.3 ± 13.9 mg/dL, HDL–P vs. HDL–UC) were significantly higher in HDL–P compared to HDL–UC.

Carotenoids and tocopherols. Mean carotenoid and tocopherol concentrations for LDL and HDL isolated from both separation methods are shown in Table 2. All values are expressed as μmol/g total lipid measured for the corresponding lipoprotein.

There were no significant differences between methods for α- and γ-tocopherol concentrations within either LDL or HDL. In LDL fractions, there were no differences for α-carotene, β-carotene, and β-cryptoxanthin concentrations between separation methods. In contrast, lycopene concentrations determined in LDL–I were significantly lower than those measured in LDL–UC, while lutein/zeaxanthin concentrations were significantly higher in LDL–I. There was very good comparability between methods for the majority of the carotenoids in the HDL fraction. Lutein/zeaxanthin was the exception with a significantly higher concentration in HDL–P.

Effect of storage on separation of LDL and HDL by the direct methods. In addition to comparing two lipoprotein separation methods, this study also investigated whether selective precipitation and immunoseparation could be applied to samples that had been previously frozen (−80°C) and then thawed.

TABLE 2
Carotenoid and α- and γ-Tocopherol Concentrations in LDL–I and HDL–P vs. LDL–UC and HDL–UC (μmol/g total lipid)[a]

Vitamin	N	LDL–I	LDL–UC	*P* value	HDL–P	HDL–UC	*P* value
Lutein/zeaxanthin	20	0.20 ± 0.12	0.14 ± 0.07	$P < 0.05$	0.37 ± 0.18	0.30 ± 0.11	$P < 0.05$
β-Cryptoxanthin	20	0.08 ± 0.07	0.10 ± 0.08	N.S.	0.12 ± 0.09	0.11 ± 0.08	N.S.
Lycopene	20	0.30 ± 0.21	0.43 ± 0.22	$P < 0.05$	0.15 ± 0.09	0.15 ± 0.08	N.S.
α-Carotene	20	0.04 ± 0.03	0.06 ± 0.05	N.S.	0.03 ± 0.02	0.03 ± 0.03	N.S.
β-Carotene	20	0.13 ± 0.08	0.17 ± 0.14	N.S.	0.08 ± 0.06	0.08 ± 0.07	N.S.
α-Tocopherol	20	7.00 ± 3.37	6.08 ± 2.75	N.S.	7.34 ± 5.19	6.91 ± 4.88	N.S.
γ-Tocopherol	20	1.68 ± 0.98	1.42 ± 0.69	N.S.	2.42 ± 1.71	2.22 ± 1.23	N.S.

[a]Values are expressed as μmol/g total lipid determined in the lipoprotein (mean ± SD); N.S., not significant; abbreviations as in Table 1; HDL–UC and LDL–UC, high and low density lipoprotein separation by ultracentrifugation.

TABLE 3
Carotenoids, α- and γ-Tocopherol Concentration in Whole Plasma: Fresh vs. Frozen Samples (μmol/g total plasma lipids)[a]

Vitamin	Fresh $n = 12$	Frozen[a] $n = 12$	*P* Value
Lutein/zeaxanthin	0.23 ± 0.14	0.19 ± 0.12	$P < 0.05$
β-Cryptoxanthin	0.11 ± 0.07	0.10 ± 0.05	N.S.
Lycopene	0.26 ± 0.13	0.31 ± 0.20	N.S.
α-Carotene	0.04 ± 0.03	0.06 ± 0.05	N.S.
β-Carotene	0.13 ± 0.09	0.15 ± 0.12	N.S.
α-Tocopherol	7.84 ± 2.48	8.78 ± 1.01	N.S.
γ-Tocopherol	2.04 ± 1.01	1.26 ± 0.53	$P < 0.01$

[a]Plasma samples were stored at −80°C for six months and thawed prior to analyses. Concentrations expressed as mean ± SD. Abbreviation as in Table 2.

Mean cholesterol concentration in the LDL–I was unchanged after storage of plasma samples (99.9 ± 26.7 vs. 102.1 ± 23.6 mg/dL, fresh vs. frozen). Mean cholesterol concentration in the HDL–P was significantly increased (51.1 ± 15.9 vs. 56.2 ± 14.4 mg/dL, fresh vs. frozen, respectively), and TG concentrations in HDL–P and LDL–I were increased (18.2 ± 6.4 and 20.7 ± 9.3 mg/dL vs. 25.2 ± 7.0 and 27.1 ± 14.5 mg/dL, fresh vs. frozen, respectively). Further, there was a significant increase in TG but not cholesterol in whole plasma.

Freeze/thawing of whole plasma had no effect on α-tocopherol and most carotenoids. Lutein/zeaxanthin and γ-tocopherol concentrations were greater in fresh whole plasma (Table 3).

A freeze/thaw effect similar to the effect observed for whole plasma was seen for LDL–I and HDL–P (Table 4). Lutein/zeaxanthin and γ-tocopherol were significantly lower in both fractions after freeze/thawing. Lycopene was decreased in LDL–I but not in HDL–P. There were no differences for other carotenoids and α-tocopherol.

DISCUSSION

Our goal in this study was to evaluate a method that permits fast and reliable plasma lipoprotein separation with subsequent accurate analyses of tocopherols and carotenoids in those fractions. To achieve this goal, immunoseparation and selective precipitation were used to isolate LDL and HDL, respectively. The traditional separation method, UC, was used as the reference.

To express lipid-soluble vitamins per gram lipid within each lipoprotein fraction, cholesterol and TG concentrations were determined after LDL and HDL separation. LDL cholesterol and LDL–TG concentrations were not different between the separation methods. This is consistent with the findings of McNamara *et al.* (5) who demonstrated that immunoseparation is appropriate for separation of LDL and subsequent cholesterol analyses. While immunoseparation has only recently been made commercially available, selective precipitation for the purpose of subsequent HDL–cholesterol determination has been used for many years in clinical laboratories as an alternative to UC (2). Selective precipitation in the present study was achieved with a medium molecular weight (M_r 50,000) dextran sulfate preparation, as introduced by Warnick *et al.* (6). Although this method previously has not been compared to UC, it was shown to compare well to precipitation with heparin–Mn^{2+}, a method demonstrated to have comparable accuracy to UC (6). The significantly higher HDL-P cholesterol and TG concentrations therefore remain unexplained. The higher lipid concentrations could be due to incomplete precipitation of apolipoprotein B particles or to higher recovery achieved with the precipitation method compared to UC. The fact that no turbidity, an indicator for insufficient apolipoprotein B precipitation, was observed in any supernate, argues against the former explanation.

The tocopherol concentrations in lipoproteins separated with the direct methods were comparable with UC separation. Therefore, we conclude that immunoseparation and selective precipitation is an appropriate method for the determination of α- and γ-tocopherols in LDL and HDL. There are few reports for tocopherol concentrations in lipoproteins separated by methods other than UC. Carcelain *et al.* (8) used selective precipitation to determine α-tocopherol in HDL. Those investigators redissolved the remaining precipitate for analyses of tocopherol in the VLDL–LDL fraction. They demonstrated that α-tocopherol concentrations in lipoproteins separated by precipitation were not significantly different compared to lipoprotein separation by UC. In a study by Clevidence and Lehman (4), HDL and VLDL–LDL fractions were separated using heparin affinity chromatography. Results were not directly compared to UC methods, but combined α-tocopherol and γ-tocopherol of HDL and VLDL–LDL fractions com-

TABLE 4
Carotenoid and α- and γ-Tocopherol Concentrations in LDL–I and HDL–P: Fresh vs. Frozen (μmol/g lipid)[a]

	LDL–I $n = 12$			HDL–P $n = 12$		
	Fresh	Frozen[a]	*P* value	Fresh	Frozen	*P* value

γ-Tocopherol	2.14 ± 0.92	1.20 ± 0.51	$P < 0.05$	2.95 ± 1.96	1.78 ± 0.71	$P < 0.05$

[a] Plasma samples were stored at −80°C for six months and thawed prior to lipoprotein separation. See Table 2 for abbreviations. Concentrations expressed as mean ± SD.

pared well to whole serum concentrations. In contrast to the methodologies of those studies (4,8), the combined use of precipitation and immunoseparation has the advantage that the precipitate does not have to be redissolved (8). Further, only LDL and not combined LDL–VLDL fractions, which is the case in precipitation or affinity column methods, is obtained with immunoseparation. The importance of this is that immunoseparation can be used with elevated TG levels and nonfasting samples, while high TG or postprandial concentrations of chylomicrons will interfere with the other separation methods (4,5,8).

Carotenoid concentrations in HDL separated by selective precipitation have not been reported previously. Results from the present study indicate that separation by precipitation presents a quick and efficient alternative for analyses of carotenoids in HDL. With the exception of lutein/zeaxanthin, carotenoid concentrations were not different between the methods. The reason for significantly higher lutein/zeaxanthin concentrations in HDL–P and LDL–I is not clear.

Similar to the situation for HDL, analyses of carotenoids in LDL have been performed in lipoproteins separated mainly by UC. Immunoseparation compared favorably to UC as an alternative method for subsequent carotenoid analyses in LDL. The two hydrocarbon carotenoids, α- and β-carotenes, and the hydroxycarotenoid, β-cryptoxanthin, were similar *via* the two methods.

Although desirable, analyses of fresh plasma samples are not always feasible. Instead, plasma samples may need to be frozen and stored for future analyses. It is therefore important to ensure that analytical procedures are adequate for samples previously frozen. We evaluated the effect of plasma storage at –80°C for 6 mon on the performance of the direct methods with subsequent lipid, carotenoid, and tocopherol analyses.

TG and cholesterol concentrations were significantly increased in HDL–P of frozen/thawed plasma samples. Results described in the literature regarding selective precipitation procedures applied to frozen/thawed samples are equivocal, suggest no change, a decrease or an increase in HDL–cholesterol concentrations after freezing (9–14). Bachorik *et al.* (14), using heparin–Mn^{2+} as precipitation reagent, showed an effect that was dependent on the initial HDL–cholesterol concentrations. Samples with low cholesterol concentrations (comparable to concentrations in the present study) tended to be higher, while samples with high HDL–cholesterol concentrations tended to be lower, after freeze/thaw. Increases after freeze/storage were reported for samples that were precipitated using phosphotungstic–$MgCl_2$ (13). In that study, interassay variability may have accounted for the effect (13). In the one study that has reported on the same precipitation reagent that we have employed, it was demonstrated that HDL–cholesterol was increased after storage in samples with plasma TG over 200 mg/dL, due to inadequate precipitation of apolipoprotein B particles (12).

In this study LDL–cholesterol concentrations in frozen samples were not different than cholesterol concentrations in fresh samples. This contrasts with the results of McNamara *et al.* (5) who reported a decrease in LDL cholesterol separated by immunoseparation after storage. Storage of plasma samples at temperatures of –70°C reportedly has no negative impact on carotenoid and tocopherol concentrations (15–18). Our results corroborate those findings for the majority of carotenoids and α-tocopherol in whole plasma. However, lower concentrations were observed for lutein/zeaxanthin and γ-tocopherol in whole plasma. These lower concentrations were apparently due to lower concentrations of these analytes in both HDL and LDL after storage (Table 4). Lycopene in LDL was decreased after storage. The remaining carotenoids and α-tocopherol in the LDL–I and HDL–P were not affected by freeze/thaw. While carotenoid stability in lipoproteins during storage has not previously been reported, the stability of α-tocopherol in LDL and HDL in the current study corroborates an earlier report (19).

In conclusion, the combined use of immunoseparation for LDL separation and selective precipitation for HDL isolation is an attractive accurate and reliable alternative to separation by UC for subsequent vitamin E and carotenoid analyses. Advantages of the combined method are that only a small sample volume is required, separation can be achieved within a short time, previously frozen plasma samples can be analyzed, and initial costs are minimal.

The present study included only normolipidemic subjects. Hypertriglyceridemia was previously associated with a positive bias for cholesterol measured in LDL separated by this immunoseparation technique (5). The impact of high plasma triglyceride concentrations on tocopherol and carotenoid analyses in LDL–I has not been evaluated in the present study.

Finally, it is important to note that although UC is often considered the "gold standard" for lipoprotein separation, UC lacks the necessary accuracy and precision to be considered a true reference method. UC is labor-intensive and time-consuming, and the method is also skill-dependent. There is a large margin for error resulting in imprecision and bias. Therefore, although we would like to see close agreement between the direct methods and UC, it is not absolutely necessary to validate a newer method against UC. In fact, with labile compounds, such as carotenoids, the faster, direct methods may, in fact, provide more accurate measurement of these analytes. Our data for LDL tocopherol and carotenoid concentrations represent a "worst case" scenario where measurements were made close to the detection limits of the assay. Still, the method provides good reproducibility and accuracy.

Estimation of Polyunsaturated Fatty Acid Content in Lipids of Aquatic Organisms Using Thin-Layer Chromatography on a Plain Silica Gel Plate[1]

Takashi Nakamura*, Masahiro Fukuda, and Ryusuke Tanaka

Laboratory of Fisheries Technology, Faculty of Agriculture, Kyushu University, 6-10-1, Hakozaki, Fukuoka 812-81, Japan

ABSTRACT: We have designed a rapid method for the separation of polyunsaturated fatty acids (PUFA, ≥ trienes) from non-PUFA, and for estimation of total amounts of PUFA in lipids of aquatic organisms. Lipids from thirty-one species, including marine and fresh water fishes, shell fishes, marine algae, and other aquatic animals, and from terrestrial organisms, were transesterified with sodium methoxide in methanol. The resulting fatty acid methyl esters were separated by thin-layer chromatography on commercially available plain silica gel plates with a developing solvent of *n*-hexane/ethyl ether/acetic acid (95:5:1, by vol). All of the methyl esters from aquatic organisms tested separated into two spots, whereas those from terrestrial sources, except for linseed oil, showed a single unresolved spot. The upper and lower spots were scraped separately from the plate, and their fatty acid compositions were determined by gas–liquid chromatography. The lower spot was composed of PUFA having more than two double bonds, whereas components of the upper spot were saturated, monoenoic, and the greater part of the dienoic fatty acids. When the spots on the silica gel plate were stained with Coomassie brilliant blue, the amounts of PUFA in aquatic organisms could be estimated satisfactorily using a scanning densitometer.

Lipids 31, 427–432 (1996).

The physiological and nutritional importance of n-3 polyunsaturated fatty acids (PUFA, ≥ trienes) has been recognized in humans (1,2) and in other organisms (3–5). Icosapentaenoic acid, 20:5n-3 acid, reduces blood pressure and cholesterol levels in plasma (6,7), suppresses the production of eicosanoids of the 2 series, and increases the formation of eicosanoids of the 3 series (8–10). Docosahexaenoic acid, 22:6n-3 acid, is particularly high in content in mammalian tissues such as brain, retina, and sperm; the functional roles and biological essentiality of this acid have been elucidated (11–13). There is now a growing demand for marine oils, the main source of n-3 PUFA, for use in human foods, pharmaceuticals, and in industrial intermediates. Thus, there is a need for simple and adequate analytical methods for separation, identification, and evaluation of the resource oils.

Abbreviations: GLC, gas–liquid chromatography; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography.

Gas–liquid chromatography (GLC) and high-performance liquid chromatography are potent tools for separation of complex mixtures of natural fatty acids (14). Thin-layer chromatography (TLC) is widely used for identification or preparation of fatty acids and their derivatives. Mangold and Kammereck (15) and Wolfe *et al.* (16) demonstrated that acetoxymercurimethoxy derivatives of fatty acids can be resolved by TLC according to their degree of unsaturation. A more popular method is argentation TLC. Unsaturated fatty acids with both normal and substituted chains are clearly separated on a silica gel TLC plate impregnated with silver nitrate, which retards the migration of the more unsaturated species in relation to that of the more saturated ones (17,18). In these techniques, however, the procedure for the derivatization is tedious and the preparation of silver nitrate plates is expensive. Using ordinary and high-performance silica gel plates, Shantha and Ackman (19) demonstrated good separations of PUFA methyl esters from the saturates, monounsaturates, and diunsaturates.

We also made use of conventional TLC on plain silica gel and intended to design a simple and rapid method for differentiating lipids of aquatic organisms from those of terrestrial sources and for subsequent quantification of PUFA in the lipids by densitometry.

MATERIALS AND METHODS

Materials. Five marine fish: *Trachurus japonicus* (horse mackerel), *Chrysophrys major* (red sea bream), *Sardinops melanosticta* (sardine), *Limanda yokohamae* (mud lab), *Nibea mitsukurii*; seven freshwater fish: *Carassius carassius cuvieri* (crucian carp), *Tribolodon hakonensis* (dace), *Oncorhynchus mykiss*, *Anguilla japonica*, *Cyprinus carpio*, *Plecoglossus altivelis*, *Carassius carassius langsdorfii*; two shellfish: *Paphia undulata* (little clam), *Solen Gouldi* (razor clam), and meat tissues used for this experiment were purchased mainly from local retail stores. Seven algae: *Undaria pinnatifida* (wakame), *Ulva pertusa* (green laver), *Porphyra yezoensis*, *Ishige okamurai*, *Hizikia fusiformis*, *Colpomenia sinuosa*, and *Sargassum muticum*, were collected from the intertidal zone of northern Fukuoka. The lipids were extracted by homogenizing the tissue with chloroform/methanol (2:1, vol/vol) according to the procedure of Folch *et al.* (20). Plant

seed oils were purchased from Wako Pure Chemical Industries (Osaka, Japan). Squid liver oil and other oils were donated by Dr. M. Furuichi, Laboratory of Fisheries Research Station, Kyushu University (Fukuoka, Japan).

Methylation. The lipid sample (~15 mg) in a screw-capped test tube was dissolved in benzene (0.5 mL) and 0.5 M-methanolic sodium methoxide (1 mL), and transmethylated at 80°C for 20 min (21).

TLC and densitometry. The fatty acid methyl esters from various organisms were spotted on the silica gel TLC plates which had been purchased from the E. Merck Co. (Darmstadt, Germany), Macherey-Nagel (Neumann-Neander-Strasse, Germany), Whatman Paper Ltd. (Maidstone, England), and Wako Pure Chemical Industries. The plates were activated at 110°C for 1 h before use, and developed with *n*-hexane/diethyl ether/acetic acid (95:5:1, by vol). The plates were sprayed with 50% (vol/vol) sulfuric acid and charred on a hot plate. Another set of plates dried by air-blowing were dipped into a staining solution consisting of 0.02% Coomassie brilliant blue (Fluka Chemicals AG, Buchs, Switzerland) in 20% methanol (22). After 30 min, the plates were removed from the staining solution, immersed in 20% methanol, and allowed to stand for 3 min with gentle agitation. The plates were removed from the stain removal solution, air dried, and spot intensities were measured using a scanning densitometer (CS-9300PC chromatoscanner; Shimadzu Co., Kyoto, Japan) at 600 nm of reflectance mode, subtracting blank readings from adjacent positions on the plate.

GLC. The TLC-spots or bands marked under ultraviolet light on the plate (Silica gel 60 F254; E. Merck Co.) were scraped off separately. The gel was extracted with chloroform/methanol (2:1, vol/vol), and the solvent was removed under reduced pressure. The resulting residue was analyzed by GLC, using a gas chromatograph (Shimadzu GC-14A; Shimadzu Co.) equipped with a flame-ionization detector and a capillary column (HR-SS-10, 30 m × 0.25 mm i.d.; Shinwakako Co., Kyoto, Japan). The column temperature was programmed for a linear increase of 4°C/min from 150 to 220°C. The methyl esters on the chromatograms were identified by conventional methods using the retention times of standards and the equivalent chain lengths, and by gas chromatography/mass spectrometry (QP-5000; Shimadzu Co.). Standard fatty acid methyl esters, 14:0, 16:0, and 18:0 were purchased from Wako Pure Chemical Industries, 20:0 and 22:0 were from GL Science Co. (Tokyo, Japan), 18:2n-6, 18:3n-3, and 20:4n-6 were from Sigma Chemical Co. (St. Louis, MO), and 20:5n-3 and 22:6n-3 were donated by Idemitsu Petro Chemical Co. (Tokyo, Japan). All of the reagents used in these experiments were of analytical grade.

RESULTS

Separation properties of fatty acid methyl esters on TLC. The fatty acid methyl esters prepared from various origins were separated on plain silica gel TLC plates. A typical chromatogram is shown in Figure 1. All of the esters from aquatic

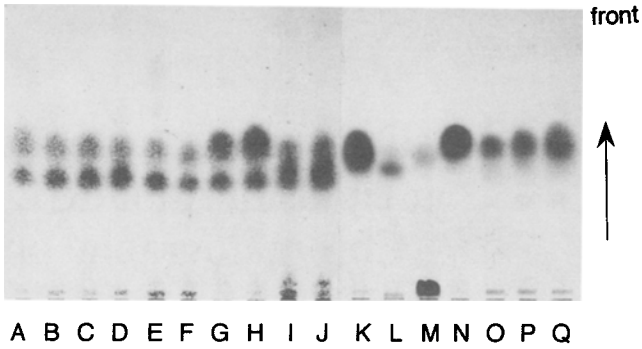

FIG. 1. Separation of fatty acid methyl esters prepared from lipids of aquatic and terrestrial organisms by thin-layer chromatography (TLC) on a plain silica gel plate. Conditions: TLC plate, Silica gel 60 F254 (E. Merck, Darmstadt, Germany); developing solvent, *n*-hexane/diethyl ether/acetic acid (95:5:1, by vol). The plate was sprayed with 50% (vol/vol) sulfuric acid and charred on a hot plate. A: horse mackerel, B: red sea bream, C: crucian carp, D: dace, E: little clam, F: razor clam, G: sea lion oil, H: sea snake oil, I: wakame, J: green laver, K: soybean oil, L: linseed oil, M: castor oil, N: olive oil, O: beef, P: pork, and Q: chicken.

organisms tested, including marine and freshwater fish, shell fish, marine algae, and some other aquatic animals such as sea snake and sea lion, were separated into two spots, whereas those from terrestrial organisms, including plant oils and meat tissues, showed one spot except for the ambiguous spots of linseed oil (Fig. 1L). These findings were confirmed using all of the commercially available silica gel plates used in this experiment.

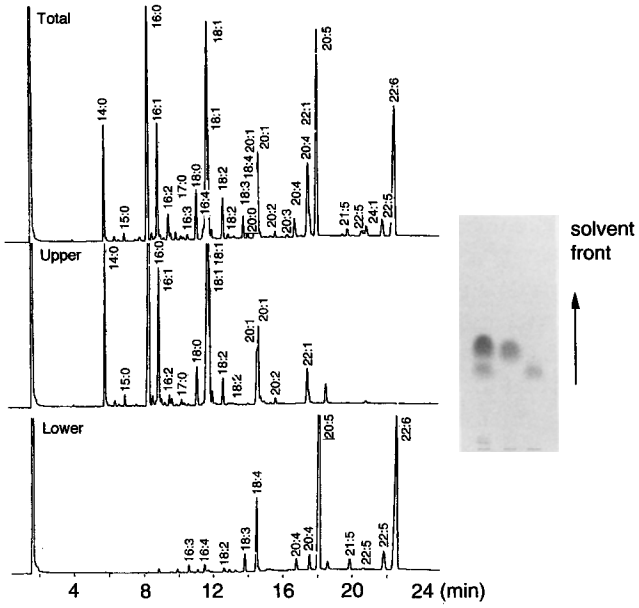

FIG. 2. Fatty acid analysis of the upper and lower spots on thin-layer chromatography (TLC) plates at methyl esters of squid liver oil by gas–liquid chromatography. Conditions: column, HR-SS-10 (0.25 mm × 30 m; Shinwa-kako, Kyoto, Japan); column temperature, 150 to 220°C (4°C/min); detector, flame-ionization detector. Conditions of TLC were as described in Figure 1. The plate was stained with 0.02% Coomassie brilliant blue. T: total methyl esters, U: upper spot, L: lower spot.

The upper and lower spots or bands marked under ultraviolet light on TLC plates were scraped off separately and analyzed on a capillary gas chromatographic column. As shown in the case of squid liver oil (Fig. 2), the upper spot consisted mainly of methyl esters of saturated and monoenoic acids, whereas the lower spot consisted of polyunsaturated acid esters which have more than two double bonds such as 16:4n-3, 18:3n-3, 18:4n-3, 20:4n-3, n-6, 20:5n-3, 21:5n-3, 22:5n-3, and 22:6n-3 acids. Fatty acids with two double bonds seemed to be distributed mainly in the upper spot with a part present in the lower spot.

The fatty acid compositions of organisms illustrated in Figure 1 are shown in Table 1. Aquatic animals have large amounts of long-chain PUFA such as 22:6n-3, 22:5n-3, 21:5n-3, 20:5n-3, and 20:4n-3, n-6 acids. Algae, wakame, or *Undaria pinatifida* contained relatively large amounts of 20:4n-6 and 20:5n-3 acids, but not 22:6 acid, and green laver *Ulva pertusa* contained large amounts of 18:3n-3, 18:4n-3, and small amounts of long-chain PUFA. On the contrary, only trace amounts of these PUFA were present in terrestrial animals and plant oils: the main components of the former were medium-chain, saturated, and monoenoic fatty acids such as 16:0, 16:1, 18:0, and 18:1 acids, and the latter comprises 16:0, 16:1, 18:1, 18:2, and 18:3 acids. Consequently, depending upon the composition and contents of PUFA, the methyl esters from aquatic organisms are separated clearly into two

[a]PUFA, polyunsaturated fatty acids.

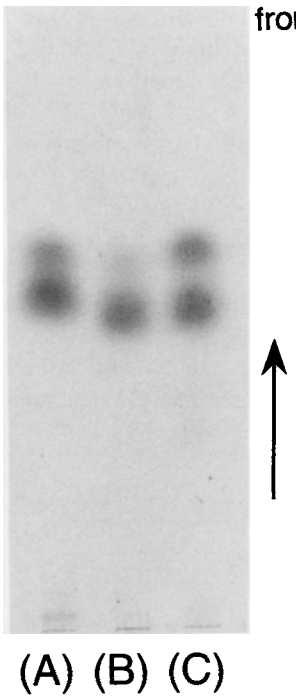

FIG. 3. Separation behaviors of fatty acid methyl ester from linseed oil on a silica gel thin-layer plate. Conditions were as described in Figure 1. (A): methyl ester of linseed oil, (B): same weight mixture of (A) and methyl docosahexaenoate, (C): same weight mixture of (A), methyl docosahexaenoate, and methyl oleate.

spots on the TLC plate, whereas fatty acid methyl esters from terrestrial organisms which have little PUFA showed only the one upper spot. The esters from the algae are less separable because they had little 22-carbon PUFA. The separation behaviors of the fatty acid esters of linseed oil, which has a high content of 18:3n-3 acid (62.6%) and little of long-chain PUFA, were studied in further detail. As shown in Figure 3, the total fatty acid esters were separated into very close double spots (Fig. 3A). By addition of an equal amount of 22:6n-3 acid ester, the lower spot of 18:3n-3 acid ester showed less mobility and formed one spot with 22:6n-3 acid ester (Fig. 3B). A same weight mixture of the linseed oil, 22:6n-3, and 18:1n-9 esters showed clear subfractionation (Fig. 3C), similar to that found on aquatic organisms in Figure 1.

Densitometric analysis of PUFA. As described above, the methyl esters of PUFA of aquatic organisms, especially of fish and fish oils, are clearly separated from more saturated ones. Using this characteristic, the content of PUFA in aquatic organisms was estimated following staining with Coomassie brilliant blue. The results of grouping analyses of fatty acids by densitometry are summarized in Table 2. The amounts obtained were in good agreement with those obtained by GLC, though lower amounts of PUFA in fish lipids and higher amounts of PUFA in algae than those determined by GLC were estimated by densitometry. The amount of PUFA can be roughly estimated by eye after conventional charring with sulfuric acid on a hot plate. However, this charring method could not be applied for densitometric determination, because the charring intensities of the lower spot (PUFA) and the upper spot were quite different; the upper spot resisted charring with sulfuric acid.

DISCUSSION

As shown in Table 1, the fatty acid compositions of lipids of aquatic organisms are complex. Factors including season, water temperature, nature of fats in their diets, maturity, and gender affect the makeup of the distribution patterns. As a result, the composition and contents of the fatty acids may vary not only from species to species, but to an even greater extent from one fish to another even of the same species. However, because aquatic organisms constitutionally contain relatively large amounts of long-chain PUFA, their fatty acid methyl esters are separated into two spots on the plain silica gel plate, as seen in Figure 1. Thus, using the characteristic behavior on the TLC plate, one can distinguish fish oils from terrestrial oils containing little PUFA, and can apply the method to the preparation and estimation of PUFA containing more than two double bonds. Shantha and Ackman (19) recommended use of their TLC method for enrichment of PUFA in foods and marine lipids. They detected amounts down to 1% or less of PUFA spot or band on the TLC plate, although the distribution behaviors of the trienes such as linolenate were different from those of our method. They reported that the dienes distributed to the upper and the trienes to both the upper and lower spots.

TABLE 2
Grouping Analyses of Fatty Acids in Aquatic Organisms by Densitometry and GLC[a]

	TLC		GLC		
Lipids	Upper spot non-PUFA (%)	Lower spot PUFA	Dienes+ non-PUFA (%)	≥ Triene PUFA	Lipid content (%)
Sardine	57.1 ± 0.6	42.9 ± 0.6	55.3 ± 0.4	44.7 ± 0.4	2.2
Horse mackerel	82.1 ± 0.8	17.9 ± 0.8	74.7 ± 0.9	25.4 ± 0.6	6.1
Squid liver oil	74.7 ± 2.4	25.3 ± 2.4	68.1 ± 0.9	31.9 ± 0.9	—
Crucian carp	69.8 ± 2.9	30.2 ± 2.8	62.9 ± 0.6	37.1 ± 0.6	3.5
Dace	67.2 ± 1.1	32.8 ± 1.1	63.3 ± 1.1	36.7 ± 1.1	1.0
Wakame	59.0 ± 1.1	41.1 ± 1.1	61.4 ± 1.0	38.7 ± 1.0	2.2
Green laver	56.0 ± 3.5	44.0 ± 3.5	62.7 ± 1.6	37.3 ± 1.6	1.3

[a]The results are expressed as the mean value with standard deviation for triplicate determinations, TLC, thin-layer chromatography; GLC, gas–liquid chromatography. See Table 1 for other abbreviation.

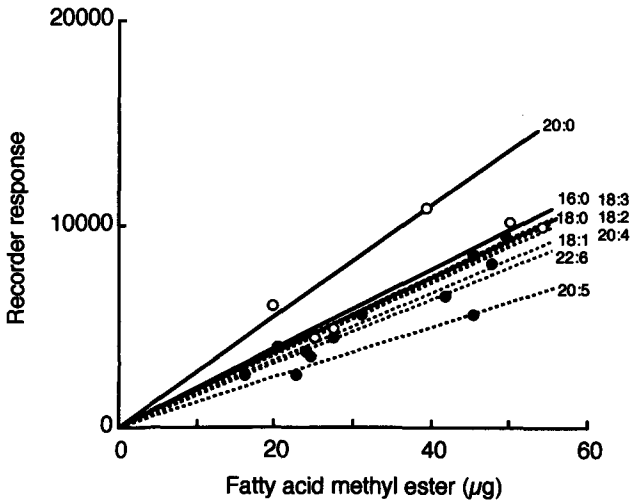

FIG. 4. Staining intensities of authentic fatty acid methyl esters. After thin-layer chromatographic separation under the same conditions as described in Figure 1, the spots were stained with 0.02% Coomassie brilliant blue in 20% methanol for 30 min. See text for details; —○—, saturated ester; – –●– –, unsaturated ester.

Staining with Coomassie brilliant blue is a practical technique. Some discrepancy of analytical values between GLC and densitometry in Table 2 may be reflected in the fundamental difference of the analytical principles of the two methods. Another reason may be attributed to the intrinsic stainability of esters by Coomassie brilliant blue (Fig. 4). Generally, the longer the fatty acid chain and the fewer the double bonds, the more intense is the stainability. However, because the main fatty acids in lipids of aquatic organisms have a similar stainability, the method can be used for estimation of PUFA contents in aquatic organisms.

Oshima *et al.* (23) studied chromatographic behavior or free fatty acid on Iatroscan TLC-FID Chromarods. They observed similar separation of free PUFA from non-PUFA. If the method is applicable to separation of fatty acid methyl esters, better agreement of the measured value with those of GLC may be expected.

Increased Hepatic Synthesis and Accumulation of Plasma Apolipoprotein B100 in Copper-Deficient Rats Does Not Result from Modification in Apolipoprotein B mRNA Editing

ABSTRACT: Experimentally induced copper deficiency in the rat results in increased plasma apolipoprotein B100 (apo B100) concentration in association with increased hepatic apo B100 synthesis. This enhancement of apo B100 synthesis and plasma accumulation accounts for the rise of plasma low density lipoprotein in these animals. In the present study, we have investigated if the selective increase in hepatic apo B100 synthesis is accounted for by changes in apo B mRNA editing. Reverse transcription coupled with polymerase chain reaction amplification and primer extension analysis of apo B cDNA revealed no differences in apo B mRNA editing in either the liver or small intestine between control and copper-deficient rats. We speculate that the increase in apo B100 synthesis in the liver of copper-deficient rats reflects posttranslational alterations in gene expression accompanying changes in very low density lipoprotein assembly and secretion.
Lipids 31, 433–436 (1996).

Dietary copper is often low in the Western diet, and dietary copper deficiency has been speculated to be involved in the etiology of atherosclerosis (1). Studies in copper-deficient rats have pointed to several potential mechanisms whereby copper deficiency may contribute to atherosclerosis susceptibility (1). It has been shown, for example, that copper deficiency induces hypercholesterolemia (2), affects oxidative defense (1), increases the susceptibility of lipoproteins to peroxidation (3), and impairs prostaglandin metabolism (4). The hypercholesterolemic effects of copper deficiency in various experimental animal models is well documented (2), and has been suggested to arise from an increased rate of hepatic cholesterol synthesis (5). It has been proposed that this increased cholesterol synthesis may be due to the elevated hepatic glutathione and in turn elevated 3-hydroxy-3-methyl-glutaryl CoA reductase activity (6). Copper deficiency-induced hypercholesterolemia is also associated with changes in lipoprotein distribution and composition (7–9). This hypercholesterolemia mainly results from an increase in cholesterol concentration in high density lipoprotein and low density lipoprotein fractions in conjunction with increased plasma apolipoprotein (apo) E and apo B concentrations (9,10). In addition, density gradient ultracentrifugation and immunoblot analysis of isolated lipoproteins showed an increase in apo B100 abundance in copper-deficient rats as compared to controls (10).

In regard to the sources of apo B containing lipoproteins in mammals, it is well established that there is organ-specific production of two distinct forms (apo B100 and apo B48), which are products of a common gene (11). In humans, apo B100 is synthesized in the liver, and apo B48 in the small intestine. In rats, both forms of apo B are synthesized and secreted by the liver. Apo B48 mRNA is produced from apo B100 mRNA by a unique mechanism known as RNA editing. Apo B mRNA editing involves a site-specific C to U cytidine deamination reaction which is mediated by an enzyme complex containing a catalytic subunit, apobec-1 (11–13). In view of the finding that copper deficiency selectively increases hepatic apo B100 synthesis (10), the present study was designed to determine whether this effect is mediated through alterations in apo B mRNA editing.

MATERIALS AND METHODS

Animals and diets. Weanling male Wistar rats (IFFA-Credo, L'Arbresle, France) were randomly divided into copper-deficient and control groups. Rats were housed in wire-bottomed cages in a temperature-controlled room (22°C) with 12 h light–dark cycle and were pair-meal-fed the indicated diet for 6 wk. The appropriate weight of food (as determined below) was delivered to each group of animals at regularly spaced, timed intervals, three times each day. Food consumption was determined directly by weighing the residual from each feeding cycle and continuously adjusting the amount delivered to ensure that both groups consumed identical portion sizes. The semipurified diet contained (g/kg) casein 200, sucrose 650, corn oil 50, alphacel 50, DL-methionine 3, choline bitartrate

2, modified AIN-76 mineral mix 35, and AIN-76 A vitamin mix 10 (ICN; Biomedicals, Orsay, France). Cupric carbonate was omitted from the AIN-76 mineral mix in the copper-deficient diet. The copper concentrations of the diets were 0.4 mg/kg (deficient) and 6 mg/kg (control). Animals were anesthetized with sodium pentobarbital (40 mg/kg body weight) 15 h following the last meal and were then exsanguinated. The final body weight of rats was 287 ± 3 and 246 ± 5 g (n = 6 per group; $P < 0.001$) for the control and copper-deficient groups, respectively. Reduced plasma copper concentrations, assessed by atomic absorption spectrometry (Perkin Elmer 560; Perkin Elmer, Norwalk, CT) were found in copper-deficient rats as compared to control animals (0.6 ± 0.1 vs. 14.2 ± 0.5 μmol/L).

Analysis of apo B isomorph distribution. Lipoprotein fractions (d < 1.063 g/L) were isolated from plasma by ultracentrifugation 18 h at 100,000 × g. Samples of isolated lipoproteins were submitted to 4–20% SDS–polyacrylamide gel electrophoresis (Biorad, Ivry Sur Seine, France). The samples were subsequently electroblotted to nitrocellulose membranes (Hybond C Super; Amersham, Bucks., England). Immunodetection was performed using a rabbit antirat low density lipoprotein antibody and enhanced chemiluminescence (Amersham). Parallel analyses were performed on these aliquots using a rabbit antirat apo E antiserum. Quantification of signals was performed by laser densitometry.

Analysis of apo B mRNA editing. Total cellular RNA from liver and small intestine was isolated using the guanidinium/phenol/chloroform method (14). RNA integrity was assessed by agarose gel electrophoresis and visualization of 18S and 28S ribosomal RNA by ethidium bromide staining. Aliquots of total RNA (2 to 10 μg) were DN-ased as described (15) and approximately 100 ng used for reverse transcriptase–polymerase chain reaction (RT–PCR). Reverse transcription was performed at 70°C for 15 min using a downstream rat apo B antisense primer (ND3) and 5u rTth (# N808-0097; Perkin-Elmer, Cetus, CT) (15,16). Following reverse transcription, 80 μL (final volume) of PCR buffer was added along with a rat apo B sense primer (ND1) (15). PCR was performed for 30 cycles of 30 s at 95°C, 1 min at 55°C, 1.5 min at 72°C, with a final 10-min extension. For each RNA sample, a negative control was run to check for DNA contamination using rTth and leaving the sample on ice during reverse transcription. Additionally, each reaction contained a tube with all above buffers and enzymes but without RNA to exclude PCR product contamination. Reaction material (15–20 μL) was analyzed by agarose electrophoresis to demonstrate the expected 275 base pair apo B cDNA amplification product. RT–PCR products were purified using spin columns and apo B cDNA editing assayed by primer extension using an end-labeled oligonucleotide antisense primer (BT7) and T7 DNA Polymerase, as detailed previously (15). The dried gel was exposed to Kodak XAR film (Rochester, NY) at –80°C with enhancing screens. Autoradiographs at comparable exposures were scanned using a laser densitometer. We have previously validated the linearity of this assay between 1 and 99% editing of a synthetic RNA template (15).

Statistical analysis. Results were expressed as mean ± SEM. The statistical significance of differences between means was assessed by Student's t- and Mann-Whitney tests.

RESULTS AND DISCUSSION

Previous studies from our group have shown that experimentally-induced copper deficiency in the rat results in an increased apo B100 concentration in the plasma in association with increased hepatic apo B100 synthesis (10). The present work confirms these findings as evidenced by the increased ratio of apo B100/apo B48 in plasma of copper-deficient rats as compared to their pair-meal fed controls (Fig. 1A). Additionally, as inferred by Western blot analysis, apo E abundance was increased in the d < 1.063 g/L fraction (Fig. 1B), findings which confirm our previous demonstration of increased plasma apo E concentrations in copper-deficient rats (9). Since a selective increase in hepatic apo B100 synthesis was demonstrated in copper-deficient rats, we determined whether changes in apo B mRNA editing in the liver could explain this modification. The data reveal no significant differences in the extent of apo B mRNA editing in either the liver or small intestine (Table 1 and Fig. 2).

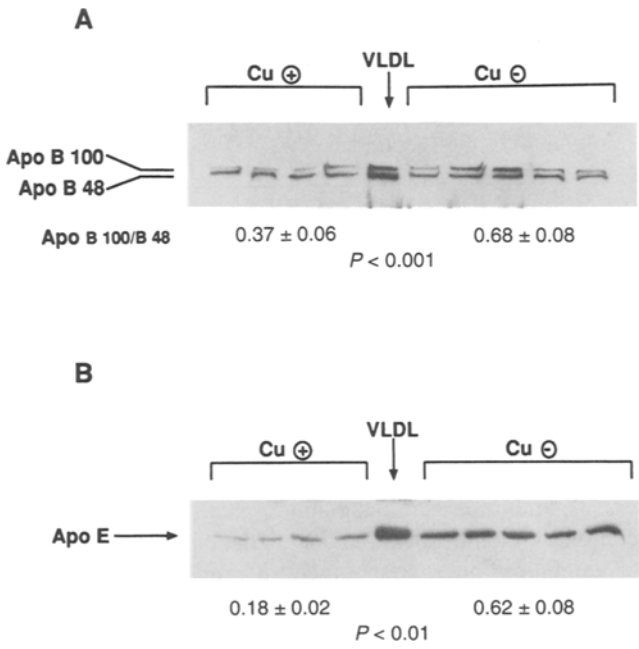

FIG. 1. Immunoblot analysis of plasma (A) apolipoprotein (apo) B isoforms and (B) apo E. Aliquots of lipoprotein fractions (d < 1.063 g/L) isolated from control and copper-deficient rats were electrophoresed through a 4–20% SDS–polyacrylamide gel electrophoresis slab gel and transferred to nitrocellulose membrane. Immunodetection was performed using either a rabbit anti-rat (A) low density lipoprotein or (B) anti-apo E antibody and enhanced chemiluminescence; VLDL, very low density lipoprotein.

TABLE 1
Apolipoprotein B mRNA Editing (%TAA) in the Liver and Small Intestine of Control and Copper-Deficient Rats[a]

	Experimental group	
	Control	Copper-deficient
Liver	73 ± 6	66 ± 8
Jejunum	92 ± 1	95 ± 1
Ileum	95 ± 1	96 ± 1

[a]Results are given as means (±SEM) of three to four individual measurements per group. There was no significant differences between the two groups of rats ($P > 0.05$); TAA = the proportion of edited apolipoprotein B cDNA.

Regulation of apo B synthesis and secretion can theoretically occur at a number of levels, including changes in apo B mRNA abundance, apo B mRNA editing, and modifications in intracellular degradation of newly synthesized apo B (16–20). Our previous studies (10,21), taken together with the present work, show that copper deficiency affects apo B synthesis without modification in either apo B mRNA abundance or posttranscriptional RNA editing. Thus, we speculate that the increase in apo B100 synthesis in the liver of copper-deficient rats reflects posttranslational alterations in apo B gene expression, presumably including intracellular degradation and secretion, associated with the changes in very low density lipoprotein assembly and secretion. Previous work has shown that copper deficiency enhances the hepatic synthesis of cholesterol (5), fatty acids, and phospholipids (22), suggesting that these alterations may lead to an increased secretion of triglyceride-enriched hepatic very low density lipoprotein. Nevertheless, the precise mechanism by which copper deficiency selectively enhances apo B100 synthesis remains to be elucidated.

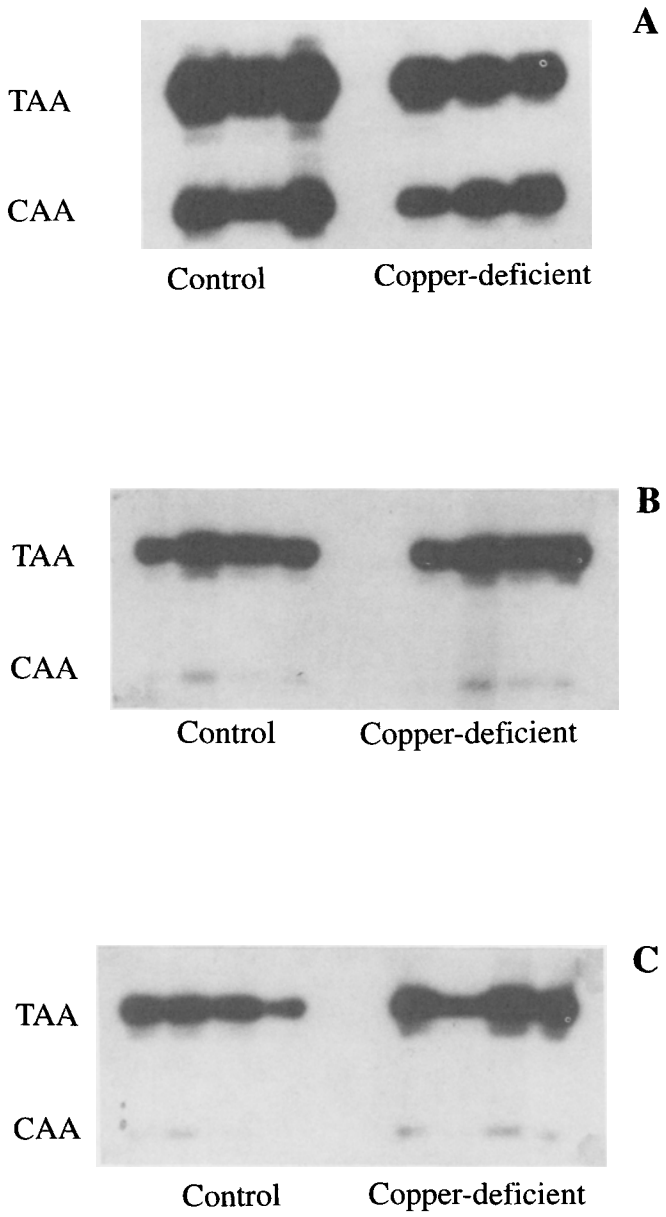

FIG. 2. Apolipoprotein (apo) B mRNA editing in control and copper-deficient rats, determined by reverse transcriptase–polymerase chain reaction (PCR) and primer extension analysis. Purified PCR products were subjected to primer extension analysis to demonstrate the proportion of edited (TAA) vs. unedited (CAA) apo B cDNA: (A) liver, (B) jejunum, (C) ileum.

Postnatal Changes in Activation of Polyunsaturated Fatty Acid, Acylation of Lysophosphoglyceride, and Phosphorylation of Diacylglycerol in Cortical Gray Matter of Rat Cerebrum

Ayako Kanazawa*, Yukari Watanabe, and Kenshiro Fujimoto

Department of Applied Biological Chemistry, Faculty of Agriculture, Tohoku University, Sendai 981, Japan

ABSTRACT: Activation of polyunsaturated fatty acid, acylation of lysophosphoglyceride, and phosphorylation of diacylglycerol in postnatal developing rat cerebrum were studied *in vitro*, using cortical gray matter homogenates. The rate of n-3 and n-6 fatty acid activation was maximal at ten days after birth and minimal at adulthood. Acylation of lysophosphoglyceride was most active at the neonatal stage and gradually decreased with age. In addition, the amount of phosphatidic acid formed from 1, 2-dioleoyl-glycerol was also maximum at the neonatal stage, and then gradually decreased. These results suggest that the specific activity of glycerolipid synthesis in cortical gray matter declines during postnatal development.

Lipids 31, 437–440 (1996).

During development, the brain actively accumulates long-chain polyunsaturated fatty acids (PUFA) in many species (1), and the amount of phospholipid increases with age (2). Long-chain PUFA is preferentially located in the *sn*-2 position of glycerophospholipid and plasmalogen (3,4). This selective incorporation of long-chain PUFA to the *sn*-2 position of glycerophospholipid is known to be regulated by a deacylation–reacylation mechanism (5,6). Acyl-CoA synthetase and acyl-CoA:lysophosphoglyceride (LPG) acyltransferase catalyze CoA + ATP-dependent acylation, which is one of three types of reactions related to deacylation–reacylation in the brain (7). Previous studies on the acylation of LPG in the developing brain (8,9) have not addressed PUFA. In this study, acyl transfer by acyl-CoA:LPG acyltransferase in the cortical gray matter of developing rat cerebrum was investigated, in addition to PUFA-activation by acyl-CoA synthetase.

Changes in diacylglycerol (DG) kinase activity in cortical gray matter were also investigated. The brain contains several times more phosphatidic acid (PA) than the liver or retina, and the PA content in mouse adult brain is much greater than that in neonatal brain (10). The formation of PA by DG kinase in rat cerebral cortex occurs at a much greater rate than the acylation of *sn*-glycerol-3-phosphate (11). It has been suggested that DG kinase makes a considerable contribution to the biosynthesis of PA in the brain. Both PA and DG are intermediates in glycerophospholipid synthesis (12). PA is converted to phosphatidylinositol through cytidine diphosphate DG, and DG is a substrate for the synthesis of phosphatidylcholine (PC), phosphatidylethanolamine (PE), and triacylglycerol. It has been suggested that DG kinase might regulate the levels of DG and/or PA. Currently, there is no evidence that DG kinase activity changes during development.

MATERIALS AND METHODS

Animals. Female and male Wistar rats (Funabashi Farm, Funabashi, Chiba, Japan) were fed a semipurified diet containing 10% soybean oil (13), and mated at 12 wk of age. Pups were weaned at 3 wk of age and maintained *ad libitum* on the same diet until they were 26-weeks-old. Cerebral cortices were obtained from newborn, 10-day-old, 20-day-old, 30-day-old, 16-week-old, and 26-week-old rats soon after decapitation, and kept at −80°C until use.

Materials. [1-^{14}C]Linoleic acid (2.0 GBq/mmol), [1-^{14}C]-linolenic acid (2.0 GBq/mmol), [1-^{14}C]arachidonic acid (2.0 GBq/mmol), [1-^{14}C]eicosapentaenoic acid (1.9 GBq/mmol), [1-^{14}C]docosahexaenoic acid (1.9 GBq/mmol), and [1-^{14}C]-arachidonyl-CoA (2.1 GBq/mmol) were purchased from New England Nuclear (Boston, MA). [γ-^{32}P]ATP (110 GBq/mmol) was purchased from Amersham (Amersham, United Kingdom). Radio-labeled fatty acids and ATP were diluted with unlabeled fatty acids (Funakoshi, Tokyo, Japan) and ATP (Oriental Yeast, Tokyo, Japan). Bovine serum albumin (BSA; essentially fatty-acid free, Fraction V) was obtained from Sigma (St. Louis, MO). 1,2-Dioleoyl-*sn*-glycerol (18:1/18:1 DG), 1-stearoyl-2-arachidonoyl-*sn*-glycerol (18:0/20:4 DG),

lysophosphatidylcholine (LPC) (porcine liver), and lysophosphatidylethanolamine plasmalogen (LPEP) (bovine brain) were purchased from Funakoshi. Other chemicals were purchased from Wako Pure Chemical (Osaka, Japan).

Preparation of homogenates. Gray matter, obtained from the cerebral cortex, was homogenized in 0.15 M KCl/20 mM Tris-HCl buffer solution (pH 7.4) and centrifuged at 700 g for 5 min. The supernatant was used for the enzyme assays. The protein content of the supernatant was determined using a Bio-Rad protein assay kit (Bio-Rad, Hercules, CA).

Enzyme assays. Fatty acid activation was assayed according to the procedure of Reddy and Bazan (14). The acylation of LPG was measured by a modification of the procedure described by Fisher and Rowe (15). A final volume of 150 μL of 100 mM Tris-HCl buffer solution (pH 7.4) contained 2 nmol 20:4n-6-CoA (4.2 kBq) [or 2 nmol 22:6n-3 (1.0kBq), 200 nmol ATP, 50 nmol $CoANa_3$, 4 μmol $MgCl_2$, 7.5 μmol $NaHCO_3$, and 4 nmol BSA], 15 nmol LPC (or LPEP), and 100 μg homogenate protein. The reaction was started by adding homogenate solution and stopped by adding 3.65 mLof chloroform/methanol/0.1 N HCl (100:200:65, by vol) after incubation at 37°C for 1–3 min. A blank assay was carried out without LPG. Lipid extract was obtained from the reaction mixture using the method of Bligh and Dyer (16), and applied to thin-layer chromatography (17). The PC or PE on Silica Gel 60 aluminum plate (Merck, Darmstadt, Germany) viewed under iodine vapor was cut out, transferred to a scintillation vial containing scintillation fluid, and counted in an Aloka LC903 (Aloka, Tokyo, Japan). The phosphorylation of DG was assayed according to the procedure of Kanoh and Ohno (18).

Statistical analysis. Differences between groups were analyzed by the Mann-Whitney U-test when the P value in the Kruskal-Wallis test was less than 0.05.

RESULTS AND DISCUSSION

Reddy and Bazan (14) reported that the activation of saturated fatty acid (16:0) and PUFA (18:2n-6, 20:4n-6, and 22:6n-3) occurred at a maximum rate in mouse whole brain at 15 d of age. We also observed that PUFA-activation in rat brain was enhanced in the middle of the suckling period. Table 1 shows the amounts of acyl-CoA formed from n-6 fatty acids by whole brain homogenates. The specific activities of both 18:2n-6 and 20:4n-6 CoA synthetase in newborns were significantly lower than those in 10-day-old rats, while no significant differences were observed between newborns and 30-day-old and 26-week-old rats. Furthermore, a rapid increase in the rate of PUFA-activation up until 10 d after birth was observed in cortical gray matter (Table 2), which contains a high concentration of PUFA (19). The amount of acyl-CoA formed was maximum at 10 d, and minimum at 16 and 26 wk after birth, regardless of the substrate fatty acid. PUFA-activation in adult rats occurred at a considerably slower rate than that in younger rats, although the decline in PUFA-activation observed in whole brain was not remarkable. The specific activity of acyl-CoA synthetase in cortical gray matter changed drastically with age. The results of this study suggest that the use of PUFA in cortical gray matter is less active in adult rats than younger rats.

TABLE 1
Activation of n-6 Fatty Acids by Whole Brain Homogenates[a]

Fatty acid	0 d	10 d	30 d	26 wk
	(nmol/min/mg of protein)			
18:2n-6	3.82 ± 0.22[a]	4.93 ± 0.67[b]	4.73 ± 0.93[a,b]	4.06 ± 0.29[a,b]
20:4n-6	3.48 ± 0.44[a]	4.64 ± 0.49[b]	3.76 ± 0.57[a,b]	2.90 ± 0.41[a]

[a]Values (means ± SD of five litters or five rats) with different superscript letters (a,b) are significantly different ($P < 0.05$).

It has been demonstrated that acyl-CoA:LPG acyltransferase in rat brain microsomes shows an acceptor preference in the descending order of 1-acyl-glycero-3-phosphocholine, 1-acyl-glycero-3-phosphoethanolamine, and 1-alk-1′-enyl-glycero-3-phosphoethanolamine (plasmalogen type), and seems to be acylated by 18:1n-9 and 20:4n-6 rather than by 22:6n-3 (7). We also observed that the rate of transference of 20:4n-6 to LPEP (1-alkenyl) was considerably lower than that of LPC (1-acyl) by cortical gray matter homogenates. It has been shown that the remodeling of ether-linked phospholipid is catalyzed by direct transfer of a fatty acid between two molecules of glycerophospholipid rather than by acyl-CoA:LPG acyltransferase (5,7). In inflammatory cells, 20:4n-6 is initially incorporated into PC and subsequently transferred to PE plasmalogen (5). In the present study, the rate of the transference of 20:4n-6 to both LPC and LPEP was maximum in newborns (Table 3), and the radioactivity of the PC fraction was also maximum in newborns in an assay with-

22:6	LPEP	0.10 ± 0.008[a]	0.10 ± 0.01[a,b]	0.09 ± 0.01[a,b]	0.08 ± 0.006[a,b]	0.07 ± 0.02[b]

[a]Values (means ± SD of five litters or five rats) with different superscript letters (a–c) are significantly different ($P < 0.05$); LPC, lysophosphatidylcholine; LPEP, lysophosphatidylethanolamine plasmalogen.

out exogenous LPG (data not shown). Furthermore, the activity of acylation showed an age-dependent decrease, regardless of whether 20:4n-6-CoA or 22:6n-3 was used as a substrate. The incorporation of 22:6, which is catalyzed by acyl-CoA synthetase and acyl-CoA:LPG acyltransferase, also occurred at a maximum rate in newborns and was hardly affected by the change in the activity of acyl-CoA synthetase with age. It has been shown that PC is formed from 18:1 and LPC at a maximal rate by cortical gray matter homogenates of rhesus monkey at the neonatal stage (8). In rat whole brain, the activity of acylating lyso-PE (1-acyl, 1-alkyl, and 1-alkenyl), in the absence of exogenous acyl-CoA, increases with development (9), and this enhancement may be influenced by increasing myelin lipid.

Table 4 shows the amount of PA formed from DG by cortical gray matter homogenates. The specific activity of 18:1/18:1 DG kinase was significantly higher in newborns and 10-day-old rats than in 16-week-old and 26-week-old rats. The rate of phosphorylation of 18:1/18:1 DG seemed to decline with age during postnatal development. The active phosphorylation of 18:1/18:1 DG at the neonatal stage might have been induced by the enhanced synthesis of glycerolipid. However, the activity for 18:0/20:4 DG, which is a typical DG species produced from phosphatidylinositol, did not change. The different effects of age on the phosphorylation of 18:1/18:1 DG and 18:0/20:4 DG might be due to the existence of several DG kinase species in the brain. Lemaitre *et al.* (20) investigated the distribution of 20:4-specific and nonspecific isozymes of DG kinase in baboon tissues, and observed high activities of both isozymes in the brain. The results of this study suggest that the specific activity of glycerolipid synthesis in cortical gray matter declines as the rat cerebral cortex matures.

Neutral Sterols of Sawflies (Symphyta): Their Relationship to Other Hymenoptera

Nathan M. Schiff and Mark F. Feldlaufer*

Bee Research Laboratory, ARS, USDA, Beltsville, Maryland 20705

ABSTRACT: To investigate sterol utilization in sawflies, the neutral sterols of four species of sawflies were determined by gas–liquid chromatography and mass spectrometry, and compared to the respective dietary plant material. Cholesterol was the predominant (55–76%) sterol in all species and stages of sawflies examined. Host plants, however, contained primarily sitosterol (50–88%), along with other 24-alkylsterols and only 0.5–5.9% cholesterol, indicating that the sawflies examined are capable of dealkylating the C_{28} and C_{29} phytosterols in their diet to cholesterol. Comparative sterol metabolism in Hymenoptera is discussed.

Lipids 31, 441–443 (1996).

Insects require a dietary source of sterol for normal growth, development, and reproduction; a considerable amount of literature exists on the utilization and metabolism of dietary sterols by insects. It appears that although many plant-feeding insects are capable of converting dietary C_{28} and C_{29} phytosterols to cholesterol, other insects are incapable of this conversion, and their tissues contain little or no cholesterol (1–4). The orders Hemiptera (true bugs) and Hymenoptera (ant, bees, wasps) are interesting in this regard. Omnivorous or predaceous members of these taxa contain predominantly cholesterol, presumably because cholesterol is a major dietary sterol (5,6). However, other members of these groups that have developed phytophagy secondarily contain little cholesterol, and apparently do not possess the ability to dealkylate their dietary phytosterols. Included in this latter category are milkweed bugs (*Oncopeltus fasciatus*), cotton stainers (*Dysdercus fasciatus*), honey bees (*Apis mellifera*), several solitary bees, and certain phytophagous ants (7–13).

The exception to this pattern appears to be the Symphyta, a suborder of Hymenoptera generally referred to as "sawflies." All sawflies are primary plant-feeders, the only exception being the Orussidae, a single family that is predaceous or parasitic on wood-boring insects (14). Schaefer *et al.* (15) demonstrated that the Virginia pine sawfly *Neodiprion pratti* (Dyar) was able to dealkylate sitosterol, and three other species of sawflies, including *Dolerus nitens* Zaddach, *Xiphydria maculata* Say, and *Aneugmenus flavipes* (Norton), were shown to contain predominantly either cholesterol or 7-dehydrocholesterol, indicative of their ability to dealkylate plant sterols (16).

We have been able to acquire four additional sawflies species, including several of economic importance, and have compared the tissue sterols of these insects with their respective host plants in an effort to obtain the broadest picture of sterol utilization in this group of primitive phytophagous hymenopterans.

MATERIALS AND METHODS

Adults of *Macroxyela ferruginea* (Say) (f. Xyelidae) were collected on elm (*Ulmus* sp.) trees in Beltsville, Maryland. Adults of the red-headed pine sawfly *N. lecontei* (Fitch) (f. Diprionidae) were reared from larvae collected from pine (*Pinus* sp.) in Howard Co., Maryland, by trimming infested branches. Wheat stem sawfly *Cephus cinctus* Norton (f. Cephidae) adults were collected by sweep net from wheat near Three Forks, Montana, and adult *Atomocera decepta* Rohwer (f. Argidae) were reared from larvae collected in Beltsville, Maryland, on hibiscus (*Hibiscus moscheutos*). All insects and representative host plant samples were stored in MeOH at 4°C until workup. All laboratory analyses were done in triplicate; these analyses were conducted on pooled insect and pooled plant samples. Many of the insects only can be collected at specific times of the year, and then only for short periods. At these times, we collect as many insects as possible, then pool the sample. Therefore, we are basing our results, not on an individual or two, but rather a pooled population.

The MeOH from individual samples was decanted and reserved, and all samples were homogenized in $CHCl_3$/MeOH (2:1, vol/vol), filtered, and reextracted in fresh solvent. Combined filtrates, including the decanted methanol, were taken to dryness under vacuum. Residues were saponified by refluxing for 3 h using 6% KOH in a solution of EtOH/benzene/water (10:1:1, by vol). After cooling, the mixture was diluted with three volumes of water, acidified with 6 N HCl, and extracted three times with hexane. The hexane extracts were dried (overnight) over Na_2SO_4 and then taken to dryness under vacuum. The residues from all samples were fractionated on 60–100 mesh Florisil (5 g; Fisher Scientific, Fair Lawn, NJ) in a diethyl ether/hexane system as previously de-

scribed (17). Neutral sterols were analyzed initially by capillary gas–liquid chromatography (GLC) at 245°C on a Shimadzu GC-9A gas chromatograph (Columbia, MD) equipped with a DB-1 fused silica column (15 m × 0.25 mm, 0.25 μm film; J&W Scientific, Folsom, CA), and identifications confirmed by GLC/mass spectrometry. Mass spectra were obtained on a Finnigan 4500 (Finnigan Corp., Sunnyvale, CA) fitted with a J&W DB-1 fused silica column (30 m × 0.32 mm, 0.25 μm film) and temperature programmed from 230 to 255°C (5°C increase/min). Electron impact data were collected at 70 eV and a source block temperature of 150°C.

RESULTS

The neutral sterols detected in the four species of sawflies examined along with the sterol composition of their dietary plant material were determined by GLC/mass spectrometry by comparison to known standards (summarized in Table 1). Cholesterol was the predominant sterol in all sawfly species and stages, ranging from over 55% in *N. lecontei* larvae to almost 76% in *M. ferruginea* adults. Other C_{27} sterols isolated from sawfly tissue included 7-dehydrocholesterol, desmosterol, lathosterol, and cholesta-5,22,24-trien-3β-ol. In contrast, the respective dietary plant material of these sawflies contained only relatively small amounts of cholesterol, ranging from 0.6% in pine needles to 5.9% in wheat stems. The predominant sterol in all host plants was sitosterol (50.2 to 83.5%), with lesser (and varying) amounts of stigmasterol, isofucosterol, and 24-methylcholesterol, depending on the particular plant species examined.

DISCUSSION

The high levels of cholesterol present in sawflies in this study, along with the relatively low proportions of cholesterol found in their respective dietary plant material, are indicative of an ability in these insects to dealkylate C_{28} and C_{29} phytosterols. The levels of desmosterol found in two of the sawfly species (*M. ferruginea* and *N. lecontei* adults) are also indicative of an ability to dealkylate, as desmosterol has been shown in radiolabeled studies to be an intermediate in the conversion to cholesterol by several insect species that dealkylate (1). Our present study, along with two previous studies (15,16), demonstrate that all eight species of sawflies examined to date can convert dietary phytosterols to cholesterol. Because these species represent four superfamilies and six families of the Symphyta, the ability to dealkylate is probably characteristic of the entire suborder, the one possible exception being members of the family Orussidae, which apparently have either a parasitic or predaceous association with wood-boring beetles (14).

The ability of sawflies to dealkylate phytosterols is different from phytophagous members belonging to the other suborder of Hymenoptera, the Apocrita comprising the bees, ants, and wasps. Ritter *et al.* (11) showed that brain and whole body extracts of the leaf-cutting ant *Atta cephalotes* (L.) contained only 24-methylene- and methylsterols and no cholesterol, indicating that the ant could not dealkylate the 24-methylsterols in its diet. Based on a comparison of dietary and tissue sterols, another fungus-feeding ant, *Acromyrmex octospinosus* (Reich), was also thought to be unable to dealkylate 24-alkylsterols (12). The honey bee *A. mellifera* was neither able to convert radiolabeled C_{28} and C_{29} sterols nor ^{14}C-desmosterol to cholesterol (10,18), and the solitary cactus bee *Diadasia rinconis* contained less than 0.1% cholesterol in its tissues (13). Interestingly, all of these plant (fungus or pollen)-feeding hymenopterans are secondarily phytophagous, having evolved from predaceous ancestors. Although strictly predaceous species of ants and wasps have been shown to contain primarily cholesterol (6), this may be more a function of a diet rich in cholesterol than an inherent ability to dealkylate C_{28} and C_{29} sterols. Examining orussids, the

Identification of a Novel all-*cis*-5,9,12-Heptadecatrienoic Acid in the Cellular Slime Mold *Polysphondylium pallidum*[1]

Tamao Saito* and Hiroshi Ochiai

Division of Biological Sciences, Graduate School of Science, Hokkaido University, Sapporo, 060 Japan

ABSTRACT: The all-*cis*-5,9,12-heptadecatrienoic acid was identified in the cellular slime mold *Polysphondylium pallidum*. The structural elucidation was accomplished by capillary gas chromatography, argentation thin-layer chromatography, and gas chromatography/mass spectrometry. This fatty acid has not been reported previously.
Lipids 31, 445–447 (1996).

Cellular slime molds provide an excellent model system for the study of cell-cell interactions. By starvation, the cells are triggered to enter a developmental cycle: over the course of a few hours, the cells begin to undergo chemotactic migration followed by the formation of multicellular aggregates.

Knowing the fatty acid composition is the first step in obtaining information with membrane fluidity in relation to cell-cell interactions. The fatty acid composition of the cellular slime mold *Dictyostelium discoideum* has been reported previously on both bacterially grown NC-4 and axenically grown Ax2 (1–3). Those compositions agreed well, and it was found that the total amount of unsaturated fatty acids was extremely high, comprising 75–90% of the total fatty acids of the organism and the membrane. Moreover, there was no clear difference between the fatty acid compositions prepared from the growth and aggregation phases in *D. discoideum*.

In the related species, *Polysphondylium pallidum*, there has been no previous report on the fatty acid composition. To determine the membrane components of the cells involved in cell-cell interaction, we have analyzed the fatty acids of *P. pallidum*.

We report here the occurrence of a novel fatty acid, all-*cis*-5,9,12-heptadecatrienoic acid, which, to our knowledge, has not been observed in nature before.

EXPERIMENTAL PROCEDURES

Polysphondylium pallidum strain WS320 was cultured as described previously (4). Total lipids were extracted from cells of the vegetative growth and aggregation competent phases by the method of Bligh and Dyer (5). The extracted lipids were subjected to methanolysis with 10% acetylchloride in methanol for 3 h at 90°C. The fatty acid methyl esters (FAME) were separated by thin-layer chromatography (TLC) on silica gel (E. Merck AG, Darmstadt, Germany) with hexane/diether ether/acetic acid (90:10:1, by vol) as solvent. After the plate was developed, it was dried and sprayed with a 0.01% primulin in a mixture of acetone and water (4:1, vol/vol). The spots on silica gel were detected under ultraviolet light, and one spot corresponding to FAME was recovered. The total FAME in the spot were extracted with hexane/methanol/500 mM NaCl in water (2:1:1, by vol), dried, and then redissolved in hexane. The total FAME were then separated by argentation TLC (AgTLC) on silica gel with hexane/diether ether (2:3, vol/vol) according to the degree of unsaturation. The FAME were analyzed with a Hitachi gas–liquid chromatograph (Model 263-30; Tokyo, Japan) equipped with a flame-ionization detector and capillary column (CPS-1; 50 m × 0.25 mm, i.d., 0.25 mm film; Quadrex, New Haven, CT). The separated FAME were identified by comparing their retention times with those of authentic standards as described previously (6). The positions of double bonds in the FAME were determined by the pyrrolidine method (7). For the further analysis of the positions of double bonds, trienoates were reduced partially with hydrazine and subjected to AgTLC with hexane and diether ether (80:20, vol/vol) as developing solvent. The monoenoate band corresponding to authentic methyl *cis*-monoenoates was scraped off and extracted with hexane. The purified monoenoate fraction was subjected to the I_2-catalyzed reaction for the formation of the adducts with dimethyl disulfide (DMDS) according to a minor modification (8) of the procedure of Shibahara *et al.* (9). Pyrrolidine derivatives and DMDS adducts were analyzed on an HP-5 column (30 m × 0.32 mm, i.d.; Hewlett-Packard, Palo Alto, CA) in a Hewlett-Packard HP-5890 gas chromatograph coupled to a JMS-AX500 (JEOL, Tokyo, Japan) mass spectrometer. The column temperature was programmed to increase

from 260 to 300°C and from 230 to 280°C at a rate of 2°C/min for pyrrolidine derivatives and DMDS adducts, respectively.

RESULTS AND DISCUSSION

The FAME mixture was fractionated by AgTLC according to the degree of unsaturation. In the analysis on the AgTLC, we detected saturated, monoenoic, dienoic, and trienoic fatty acids in the total lipids of *P. pallidum* (data not shown). In the trienoate fraction, two peaks appeared in an analysis by gas–liquid chromatography (Fig. 1). Because no report on the presence of the trienoate in the cellular slime molds grown in nature exists to our knowledge, we tried to identify the peaks.

To ascertain the positions of double bonds in both of the peaks, a part of the trienoate fraction was subjected to pyrrolididation. Two peaks in the trienoate fraction were identified as heptadecatrienoic acid (peak 1) and octadecatrienoic acid (peak 2) as described later. Figure 2 shows the mass spectrum of the pyrrolidine corresponding to peak 1. These results indicate that the fatty acids, peaks 1 and 2, seem to be a novel 5,9,12-heptadecatrienoic acid and a 5,9,12-octadecatrienoic acid (data not shown), respectively.

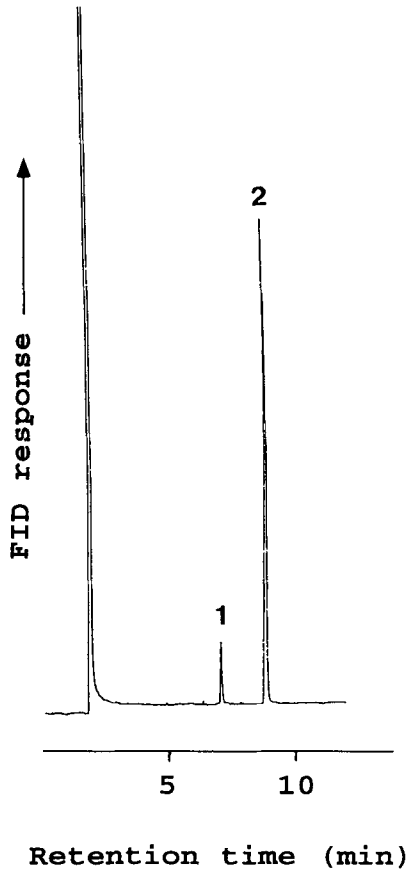

FIG. 1. Capillary gas chromatogram of fatty acid methyl esters of the trienoate fraction prepared from the aggregation-phase cells. Peak identifications are described in the text; FID, flame-ionization detector.

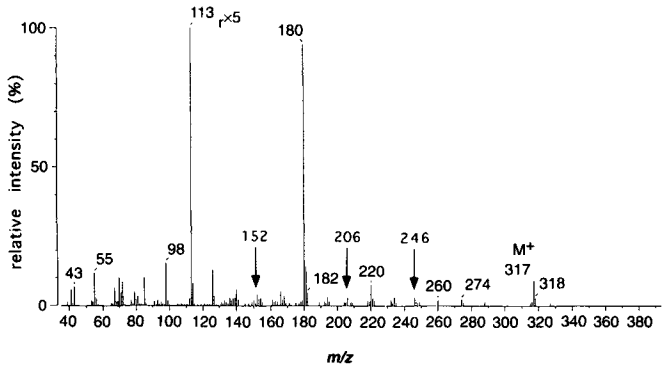

FIG. 2. Mass spectrum of heptadeca-5,9,12-enoylpyrrolidine. Arrows indicate the positions that differ by 12 mass units.

To confirm the results obtained, we used DMDS derivatives for analysis by gas chromatography/mass spectrometry. A part of the trienoate fraction was partially reduced with hydrazine; in the reduced products, a *cis*-monoenoate fraction was recovered by AgTLC, but no band corresponding to a *trans*-monoenoate was observed (data not shown). The DMDS adducts of the monoenoates were analyzed by gas chromatography/mass spectrometry. Figure 3 shows the mass spectra of the DMDS adducts recovered from the monoenoic FAME. The presence of DMDS adducts of 17:1(5), 17:1(9), and 17:1(12) methyl esters was confirmed, based on the detection of sets of the key fragmentation ions at *m/z* 215, 161, and 129 (Fig. 3A), at *m/z* 159, 217, and 185 (Fig. 3B), at *m/z* 227, 259, and 117 (Fig. 3C), respectively. The presence of the DMDS adducts of 18:1(5), 18:1(9), and 18:1(12) methyl esters was confirmed in the same manner by means of mass spectrometry (data not shown). The three types of 17:1 and 18:1 methyl esters recovered from the *cis*-monoenoate fraction were formed from 17:3 methyl ester and 18:3 methyl ester, respectively, by partial reduction with hydrazine, which is known to reduce double bonds without geometrical or positional isomerization of the remaining double bonds (8). Consequently, peaks 1 and 2 could be identified as all-*cis*-17:3(5,9,12) and all-*cis*-18:3(5,9,12), respectively; 18:3(5,9,12) has already been identified in the seed oil of a gymnosperm (10,11).

To the best of our knowledge, all-*cis*-17:3(5,9,12) identified here in *P. pallidum* has not been found previously in nature. The amount of trienoic fatty acids increased more in the aggregation competent phase than in the growth phase, concomitant with the decrease in the amounts of monoenoic and saturated fatty acids. This transition may provide the membrane with sufficient fluidity; under such conditions, the organism may be able to attain its morphogenesis at temperatures below 25°C. This heptadecatrienoic acid occupies about 1.5–2.0% of total fatty acids, whereas octadecatrienoic acid is a major component (17–27%) in the same acids. The composition analysis of the complete fatty acids should be undertaken as the next step of this study.

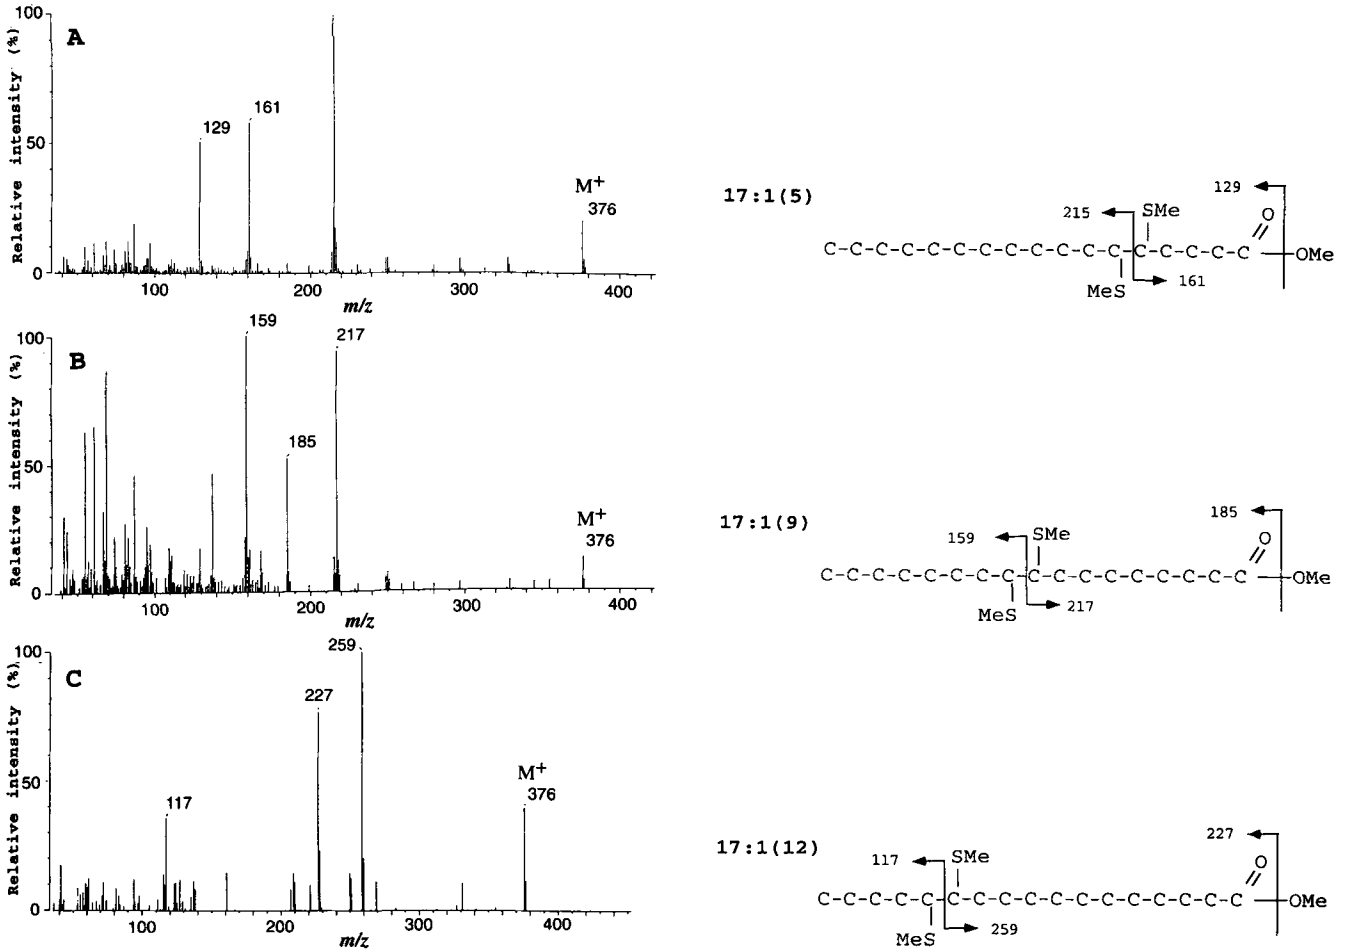

FIG. 3. Mass spectra of dimethyl disulfide adducts of total 17:1 methyl esters derived by partial hydrazine-reduction of the trienoate fraction. The schemes show fragmentation patterns of the individual dimethyl disulfide adducts of the methyl esters. Spectra A, B, and C are measured at different scan numbers on mass chromatograms.

ANNOUNCEMENTS

SPECIAL *LIPIDS* SUPPLEMENT—PROCEEDINGS OF THE ISSFAL 2ND INTERNATIONAL CONGRESS

Extra copies of the March *Lipids* Supplement—"Fatty Acids and Lipids from Cell Biology to Human Disease," the Proceedings of the 2nd International Congress of the ISSFAL (International Society for the Study of Fatty Acids and Lipids)—which includes 57 full manuscripts from participants in oral presentations at the Congress (332 total pages), are available for individual purchase at $60 each.

CALENDAR

May 1996

XVIth Washington International Spring Symposium on Frontiers in Bioactive Lipids—'96, May 6–9, 1996, Washington, D.C., USA. Information: Dr. Jack Y. Vanderhoek, Chair—Symposium '96, Dept. of Biochemistry and Molecular Biology, The George Washington University, 2300 Eye St., N.W. RN 5530, Washington DC 20037-2337 USA (Phone: 202-994-2929; Fax: 202-994-8974; E-mail: jyvdh@gwis2.circ.gwu.edu.). Deadline for submission of abstracts: February 1, 1996.

June 1996

Symposium on Diet, Nutrition and Health: An Update, University of Western Ontario from June 16–19, 1996, sponsored by the Royal Society of Canada. Sessions on Diet and Cardiovascular Disease, Diet and Cancer, Diet and Selected Health Problems, Including Hypertension, Diabetes, Obesity, Kidney Disease, Osteoporosis and Alcohol Abuse, as well as Diet and Health Maintenance in People at Various Stages of Life, Including the Elderly. Information: The Centre for Human Nutrition, The University of Western Ontario, London, ON N6A 5C1, Canada (Phone: 519-661-3096; Fax: 519-661-4006).

July 1996

European Thrombosis Research Organisation and the International Society for the Study of Fatty Acids and Lipids in cooperation with Summer University of Maastricht, July 10–12, 1996, University of Maastricht, The Netherlands, presents "Lipids, Membranes and Thrombosis (fundamental basis of cardiovascular disease and its prevention)." Information: Gerard Hornstra, Department of Human Biology, P.O. Box 616, 6200MD Maastricht, The Netherlands (Phone: +31-43-88 16 25; Fax: +31-43-67 09 76; E-mail: G. Hornstra @ HB.RuLimburg.NL).

September 1996

37th International Conference on the Biochemistry of Lipids, Antwerp, Belgium, Sept. 4–7, 1996. Themes: enzymes and transfer proteins related to lipoprotein metabolism, aspects of protein lipidation, and peroxisomal lipid metabolism. Poster communications may relate to the three conference themes or any other area of lipid metabolism. Information: Dr. P. van Dyck, Secretariat 37th ICBL, Department of Biochemistry, Physiology and Genetics, Division of Human Biochemistry, State University Centre Antwerp, Groenenborgerlaan 171, B2020 Antwerp, Belgium (Phone: 32 3 218 0329; Fax: 32 3 218 0326).

7th International Congress on Phospholipids, Sept. 9–11, 1996, Brussels, Belgium. Program topic areas include Growth, Death and Cancer; Choline, Choline Phospholipids and the Brain; Importance of Phospholipids in Health and Disease. Information: AOCS Meetings Department, P.O. Box 3489, Champaign, IL 61826-3489 USA (Fax: 1-217-351-8091).

IV. International Dermatology Symposion Berlin, Sebaceous Gland and Its Disorders, Basic and Clinical Research, Clinical Entities and Treatment, Sept. 13–15, 1996, University Medical Center Benjamin Franklin. Information: Docent Dr. Ch. C. Zouboulis, Department of Dermatology, University Medical Center Benjamin Franklin, The Free University of Berlin, Hindenburgdamm 20, D-12200 Berlin, Germany (Phone: 49-30-8445-2808; Fax: 49-30-8445-4262).

October 1996

Frontiers in Lipid and Lipoprotein Research: Basic Science, Analytical, Clinical, and Public Health Applications, Oct. 4–6, 1996, Stouffer Renaissance Hotel, Dallas, Texas. Sponsored by the Lipids and Lipoproteins Division of the

American Association for Clinical Chemistry, the Centers for Disease Control and Prevention, and the American Heart Association. An integrated review of relevant recent advances in basic science, measurement technology, epidemiological and clinical research, and public health issues will be presented. This review will help define state-of-the-art techniques for understanding and preventing morbidity and mortality due to heart disease. Information: Paula M. Steiner, Medical Research Laboratories, 2 Tesseneer Dr., Highland Heights, KY 41076 (Phone: 606-781-8877, Extension 252; Fax: 606-781-9310; E-mail: lipf@cehehll.em.cdc.gov).

Certification Board for Nutrition Specialists, Oct. 11, 1996, San Francisco, California. Certifying examination for nutritionists and dieticians with advanced degrees. Information: CBNS, 1562 First Avenue, Box #258, New York, NY 10028 (Phone: 212-332-0774 (leave message); Fax: 212-777-1103).

American College of Nutrition, 37th Annual Meeting, Oct. 11–13, 1996, San Francisco, California (Phone: 212-777-1037; Fax: 212-777-1103).

Seminar: Interconversion of Polyunsaturated Fatty Acids, and Their Functions in Membranes, Oslo, Norway, Oct. 11–12, 1996. Information: Georg Lambertsen, Secretary, Lipidforum, Breistølen 1, N-5035, Bergen, Norway (Phone: 4755 + 32 89 56; Fax: 47 55 + 32 57 24).

November 1996

AOCS Conference on PUFA in Infant Nutrition: Consensus and Controversies, Nov. 7–9, 1996, Barcelona, Spain. Information: Susan E. Carlson (E-mail: scarlson@utmem1.utmem.edu); Robert A. Gibson (E-mail: rgibson@paed_nnu.fmc.flinders.edu.au); Berthold Koletzko (Fax: 49-89-5160-4733); or AOCS Meetings Department, P.O. Box 3489, Champaign, IL 61826-3489 USA (Fax: 1-217-351-8091).

June 1997

The 19th Nordic Lipid Symposium, Ronneby, Sweden, June 15–18, 1997. Information: Georg Lambertsen, Secretary, Lipidforum, Breistølen 1, N-5035, Bergen, Norway (Phone: 47 55 + 32 89 56; Fax: 47 55 + 32 57 24).

July–August 1997

Fourth International Congress on Essential Fatty Acids and Eicosanoids, July 27–August 1, 1997, Edinburgh, Scotland. Information: Secretariat, c/o Meeting Makers, 50 George St., Glasgow G1 1QE, Scotland, United Kingdom.

ARTICLE

Phospholipid Composition of Neonatal Guinea Pig Liver and Plasma: Effect of Postnatal Food Restriction

Alan N. Hunt, Graham C. Burdge, and Anthony D. Postle*

Child Health, University of Southampton, Southampton SO16 6YD, United Kingdom

ABSTRACT: Preterm guinea pigs were delivered on day 65 of gestation (term = 68 d) and were allowed either free or restricted access to food for the subsequent 48 h. Plasma phosphatidylcholine (PC) concentration increased postnatally from 190 (range 144–307) to 751 (426–1039) and 883 (758–977) μM for fed and starved pups, respectively. Plasma PC composition in both groups of pups was characterized by selective and equivalent relative increases to individual molecular species containing 18:0 at the *sn*-1 position. Hepatic PC concentration increased from 6.75 (5.41–8.20) to 8.65 (6.54–10.63) and 9.23 (8.18–10.17) μmol/g for fed and starved pups, respectively, and, under all conditions, hepatic PC molecular composition closely mirrored that of plasma PC. These results support the hypothesis that the molecular species composition of plasma PC for the guinea pig in the immediate postnatal period is determined largely by the composition of the hepatic PC pool destined for lipoprotein secretion. Hepatic PC composition and concentration of the starved neonatal guinea pig were maintained independently of any dietary nutrient intake, at the expense of mobilization of extra hepatic lipid reserves. While this adaptive mechanism has inherent limited survival potential in neonatal starvation, it has implications for studies measuring plasma phospholipid fatty acid compositions as biochemical markers of dietary fat intake in preterm infants.

Lipids 31, 489–495 (1996).

Adequate supply of both n-3 and n-6 essential fatty acids (EFA) from the maternal circulation to the fetus and neonate is essential for optimal perinatal growth and development (1). A restricted capacity of fetal liver to desaturate and elongate the dietary EFA [linoleate (18:2n-6) and α-linoleneate (18:3n-3)] contributes to a requirement for the mother to supply long-chain polyunsaturated fatty acid (PUFA) products, arachidonate (20:4n-6) and docosahexaenoate (22:6n-3), respectively (2). The association between impaired neurological development and inadequate acquisition of 22:6n-3 in brain phospholipid has stimulated considerable research into the dietary PUFA content that is required to support optimal brain maturation, particularly in preterm infants (3,4). In general, these studies have concluded that improved neurological function in preterm infants can be achieved by balanced supplementation of infant formulas with 20:4n-6 and 22:6n-3 (5,6).

One major problem in human studies has been the lack of suitable biochemical markers to use in the evaluation of responses to changes in dietary formula fatty acid compositions. In this context, plasma phosphatidylcholine (PC) and erythrocyte PC and phosphatidylethanolamine (PE) fatty acid compositions have been regularly measured as surrogate markers of tissue phospholipid compositions (1,3–6). These measurements are not ideal, because plasma PC composition is dependent principally on the composition of hepatic PC (7), and erythrocyte phospholipid compositions are maintained by cell-specific acylation mechanisms (8). We have previously demonstrated, by analysis of the synthesis and secretion of hepatic and plasma PC molecular species in the rat (9) and guinea pig (10), that specificity of hepatic PC synthesis largely determines the composition of plasma PC. One major implication of this conclusion is that any dietary-associated changes to the composition of plasma PC must be mediated through corresponding adaptations to hepatic phospholipid metabolism.

In the present study, we have examined whether this hypothesis is supported by the changes to liver and plasma phospholipid composition that accompany the transition from placental to enteral nutrition at birth, using a neonatal guinea pig model. The guinea pig is in many respects an appropriate model to study perinatal changes to human infant lipid metabolism. In common with human infant development, the guinea pig exhibits a substantial accumulation of lipid in late gestation (11), its milk has a relatively low fat content (4%) (12), and it has a reduced capacity for ketone synthesis in the immediate postnatal period (13). In the present study, guinea pig pups were delivered 3 d preterm, and were either starved for 48 h or allowed to suckle freely for the same time period. Analysis of plasma PC and of hepatic PC and PE molecular species by high-performance liquid chromatography (HPLC) demostrated compositional and concentration changes that were substantially independent of postnatal dietary intake.

MATERIALS AND METHODS

Materials. HPLC grade methanol and trifluoroethanol (TFE) were obtained from Rathburn Ltd. (Walkerburn, Scotland). Chloroform and choline chloride were purchased from Merck Ltd. (Lutterworh, Leicestershire, United Kingdom). ATP, NADP, α-amylogycosidase (EC 3.2.1.3), glucose-6-phosphate dehydrogenase (EC 1.1.1.49), and hexokinase (EC 2.7.1.1) were purchased from Boehringer Mannhein UK (Lewes, East Sussex, United Kingdom). All other reagents and lipid standards were from Sigma (Poole, Dorset, United Kingdom).

Animal procedures. Female Dunkin-Hartley guinea pigs of known gestational age were obtained from our own colony as described previously (10,14). A total of twelve litters (32 pups) were delivered by Caesarian section, nine at day 65 gestation and three at day 67. Pups delivered on day 65 were randomly assigned to one control and two experimental groups, each containing animals from at least three litters. Pups in the control group were killed immediately at delivery, as were pups in a second control group which were delivered at day 67 of gestation. One group of pups delivered at day 65 was fed normally by being placed with lactating surrogate mothers for 48 h before being killed. The other group of pups delivered at day 65 were starved for 48 h by being placed with nonlactating adult female guinea pigs and allowed access to water, but not to solid food or edible bedding materials. Nonlactating dams were removed for 1 h each day and allowed free access to normal maintenance diet. All animals were killed by pentobarbitone injection. Whole-body weights were recorded for each pup at delivery, and also after 48 h for fed and starved animals. Blood was collected by cardiac puncture using EDTA as an anticoagulant. Plasma was separated from blood cells by centrifugation, and livers were removed and weighed rapidly before freezing in liquid nitrogen. All samples were stored at −20°C until analysis.

HPLC analysis of phospholipid molecular species. Liver PC and PE for HPLC analysis were prepared from 100-mg aliquots of liver tissue. Internal standards, 100 nmol PC14:0/14:0 in 25 μL TFE and 100 nmol PE14:0/14:0 in 100 μL chloroform were added, and homogenates in saline (0.8 mL) were extracted by chloroform/methanol as described previously (14). Plasma samples were extracted according to Bligh and Dyer (15) with the following modifications. Plasma (200 μL) was added dropwise with continual stirring to ice-cold methanol (2 mL) followed by addition of internal standard (20 nmol PC14:0/14:0 in 5 μL TFE), saline (600 μL), chloroform (2 mL), and water (1 mL). PC and PE were sequentially purified by solid-phase extraction using disposable BondElut aminopropyl cartridges (Phenomenex, Macclesfield, United Kingdom) (10,14); PC was eluted using chloroform/methanol (60:40, vol/vol) wash and PE using a subsequent methanol wash. Intact phospholipid molecular species were resolved by HPLC on a 3 μm, 25 cm × 4.6 mm APEX I ODS reverse-phase column (Jones Chromatography, Hengoed, Mid-Glamogan, UK) using a mobile phase of methanol/water (930:70, vol/vol) containing 40 mM choline chloride at a flow rate of 0.8 mL/min (16). Mass of eluted molecular species was quantified by postcolumn derivatization with 1',6-diphenyl-1,3,5-hexatriene and fluorescence detection (17). Individual molecular species were identified by retention time relative to the internal standard. Identities of species were further confirmed by reference to authentic standards, by the ratio of mass to ultraviolet absorption at 205 nm, and by gas-chromatographic analysis of fatty acid methyl esters derived from phospholipid species eluted from the HPLC (18).

Plasma cholesterol and triglyceride. Total plasma cholesterol and triglyceride concentrations were determined by cholesterol esterase (EC 3.1.1.13) or lipase (EC 3.1.1.3) hydrolysis followed by enzymatic/colorimetric assays linked to either cholesterol oxidase (EC 1.1.3.6) or glycerol phosphate oxidase (EC 1.1.3.21), respectively, using an RA2000 autoanalyzer (Bayer, Basingstoke, Hampshire, United Kingdom).

Liver glycogen. Liver glycogen from 100-mg aliquots of liver was determined as described by Keppler and Decker (19). Free glucose and total glucose, released by hydrolysis of glycogen in tissue homogenates by amyloglucosidase, were quantified separately in linked enzymatic assays (hexokinase/glucose-6-phosphate dehydrogenase) coupled to an increase in NADPH absorbance at 340 nm. The difference between the determinations represented the glycogen-specific glucose concentration.

Liver water. Liver water content was determined in accurately weighed (1 g) samples of liver which were lyophilized overnight in clean, dry, preweighed tubes, then oven-dried to constant weight.

Fecal lipid analysis. The fatty acid composition of total fecal lipid was determined by gas-chromatographic analysis of methyl fatty acids. Feces (1 g) were extracted using chloroform and methanol (2:1, vol/vol), saponified with methanolic KOH, and derivatized using boron trifluoride and methanol.

Statistical analysis. Statistical analysis was carried out using the Mann-Whitney U-test. All results are presented as median values, with ranges indicated.

RESULTS

Carcass and liver weights. The carcass and liver weights of animals delivered at day 65 and day 67 and killed immediately were essentially the same (Table 1). Similarly, these parameters were unchanged compared with birth weights for pups fed for 48 h after delivery. In contrast, starved animals showed a 20.7% fall in carcass weight compared with their birth weights, and a 24.7% decrease in liver weight compared with control pups delivered on day 65 (Table 1). The possibility that part of the fall in starved liver weight might have been due to dehydration was discounted by determination of liver water content in both fed and starved animals. There was no difference in the liver dry weights of starved or fed neonatal animals (Table 1). The possibility that starved animals may have received significant nutrition by coprophagic ingestion of fecal material from the surrogate mothers was addressed

TABLE 1
Neonatal Guinea Pig Carcass and Liver Weights[a]

	Day 65, killed at delivery (n = 9)	Day 67, killed at delivery (n = 9)	Pups fed for 48 h after delivery (n = 7)		Pups starved for 48 h after delivery (n = 7)	
			At delivery (day 65)	After delivery (48 h)	At delivery (day 65)	After delivery (48 h)
Body weight (g)	82.2 [74.7–97.8]	78.1 [70.1–95.2]	90.2 [77.9–104.6]	84.3 [78.2–100.8]	88.6 [67.1–119.3]	70.3 [57.0–90.6][b,c]
Liver wet weight (g)	3.59 [2.68–5.68]	3.48 [2.66–5.13]	ND	3.67 [3.10–5.00]	ND	2.62 [1.77–3.54]
Liver water (%)	62.3 [61.8–66.1]	61.7 [58.6–64.8]	ND	72.8 [71.4–76.8][b]	ND	71.1 [63.5–73.4][b]
Liver dry weight (g)	1.29 [1.01–2.07]	1.30 [1.02–2.10]	ND	0.98 [0.79–1.36][d]	ND	0.81 [0.50–0.94][d]

[a]Results of carcass weights, liver weights, and percentage liver water determinations in preterm guinea pigs. Values are expressed as medians with ranges; ND = not determined.
[b]Result significantly ($P < 0.05$) different from animals killed at delivery on day 65.
[c]Result significantly ($P < 0.05$) different from birth weight on day 65.
[d]Result significantly ($P < 0.0005$) different from animals killed at delivery on day 65. Values which were significantly different from animals killed on day 65 were also significantly different from values for animals killed at birth on day 67. All other comparisons between groups did not show a significant difference.

and largely discounted. There was no visually detectable material in the stomach lumens of starved animals. Moreover, fatty acid analysis of total lipid extracts of fecal material could detect only saturated and monounsturated fatty acids, principally palmitate, stearate, and oleate, and these were present at low concentration. Quantities of EFA, linoleate and linoleneate, and of their elongation and desaturation products were negligible.

Liver glycogen content. Liver glycogen concentration increased by 55% from 46.7 (17.7–52.9) mg/g wet wt on day 65 to 72.3 (41.2–105.3) mg/g wet wt on day 67 *in utero*. Liver glycogen in fed animals [44.2 (39.6–53.2) mg/g wet wt] was unchanged compared with the value at day 65, but was drastically reduced in starved animals to 2.0 (1.6–9.1) mg/g, $P < 0.001$.

Plasma PC and hepatic PC and PE concentrations. The concentration of PC in plasma increased slightly by 51% between day 65 and day 67 *in utero* ($P < 0.05$), but was subsequently more significantly elevated both in fed (4.0-fold, $P < 0.01$) and starved (4.6-fold, $P < 0.01$) neonatal guinea pigs (Table 2). Hepatic concentrations of PC (Table 3) and PE (Table 4) were the same for control newborn animals delivered on day 65 or day 67 of gestation. In contrast, hepatic PC concentration was elevated to a similar extent by 2 d of age in both fed (28.1%) and starved animals (36.7%) compared with values at birth for animals delivered on day 65 (Table 3). Liver PE concentration was increased only in fed (41.7%) animals (Table 4).

Plasma PC molecular species compositions. The seven molecular species detailed in Table 2 accounted for over 95% of total plasma PC. The distributions of plasma PC species were equivalent for newborn animals delivered on day 65 or day 67. The increased plasma PC total concentration between animals born on day 65 and day 67 was accounted for by general increased concentrations of all individual PC species, with the increases for PC16:0/22:6, PC16:0/20:4, PC18:0/22:6, and PC18:0/18:2 being significant at the 5% level. In contrast, the considerably greater elevated plasma

Total	6.75 [5.41–8.20]	7.29 [6.18–8.39] (8)	8.65 [6.54–10.63] (28)[b]	9.23 [8.18–10.17] (37)[c]

[a]Results of high-performance liquid chromatography analyses of hepatic PC molecular species compositions of preterm guinea pigs killed at birth, or delivered at 65 d gestation and either fed or starved for 48 h. Values are median concentrations with ranges and median percentage change compared with animals killed at delivery on day 65. See Table 2 for abbreviation. There was no significant difference in hepatic PC molecular species composition between fed and starved animals. Values which were significantly different for animals killed on day 65 were also significantly different from newborn animals killed on day 67 ($P < 0.05$).
[b]Values significantly ($P < 0.05$) different from animals killed at birth at 65 days gestation.
[c]Values significantly ($P < 0.01$) different from animals killed at birth at 65 days gestation.

PC concentration for both fed and starved postnatal animals was due to more significant increases in all PC species. The changes observed were essentially identical for both fed and starved animals. For both groups of postnatal animals, this increase in plasma PC concentration was more pronounced for species containing 18:0 rather than 16:0 at the *sn*-1 position. For fed and starved animals the mean percentage concentration increases for plasma *sn*-1 16:0 species were 161 and 207%, while corresponding values for *sn*-1 18:0 species were greater at 426 and 487%.

Hepatic PC molecular species compositions. For all groups of animals, the composition of hepatic PC (Table 3) closely resembled that of the corresponding plasma PC samples (Table 2), with the additional resolution of PC16:0/16:0. The eight major PC species reported (Table 3) consistently represented more than 88% of total hepatic PC. At delivery, the hepatic concentration of PC16:0/18:1 decreased slightly between day 65 and day 67, while that of PC18:0/18:2 increased (Table 3). In contrast, by comparison with compositions on day 65, the increased concentrations of liver PC in both fed and starved postnatal animals were characterized by more selective increased concentrations of individual molecular species. Strikingly, similar changes to hepatic PC composition were observed for both starved and fed neonatal guinea-pig pups (Table 3). In general, PUFA-containing PC species with 18:0 at the *sn*-1 position increased in concentra-

[b]Result significantly ($P < 0.01$) different from animals killed at delivery on day 65.
[c]Result was significantly different between animals either fed or starved for 48 h after birth.

tion, while little change was observed for the corresponding species containing *sn*-1 16:0. The concentration increases for fed and starved pups were 54.5 and 75.3% for PC18:0/22:6, 60.5 and 86.0% for PC18:0/20:4 and 49.0 and 44.6% for PC18:0/18:2, respectively. There were smaller but still significant increases for PC16:0/20:4 (41.1%) and PC16:0/18:1 (42.5%) in livers from starved but not fed animals.

Hepatic PE molecular species compositions. Six major PE species are reported (Table 4) which comprise more than 95% of hepatic PE. The only differences in PE molecular species composition between pups delivered on day 65 and day 67 were decreased concentrations of the arachidonoyl-containing species PE16:0/20:4 and PE18:0/20:4 on day 67. As with both plasma and liver PC, the major changes observed by two days after delivery were similar for both fed and starved pups (Table 4). The concentration increases for fed and starved animals were 47.4 and 11.4% for PE18:0/22:6, 40.5 and 41.7% for PE18:0/20:4 and 85.7 and 60.4% for PE18:0/18:2, respectively. In contrast, for *sn*-1 16:0 PE species, the concentrations of PE16:0/20:4 and PE16:0/18:2 decreased by 23.7 and 42.1%, respectively, in livers from starved pups compared with corresponding values at delivery on day 65 (Table 4).

Plasma cholesterol and triglyceride concentration. Total plasma cholesterol and triglyceride concentrations (Table 5) showed no significant change *in utero* between day 65 and day 67. However, plasma cholesterol increased in fed (3.0-fold) and starved (3.8-fold) animals. Plasma triglyceride concentration was significantly elevated in the starved group (56.5%) compared with fed animals, but the starved animals also displayed a large range with one outlying lipemic value of 5.28 mmol/L.

DISCUSSION

The results from this study have demonstrated clearly that, in the preterm guinea pig, the postnatal changes to plasma PC composition observed in milk-fed pups were also apparent in pups subjected to acute, severe food restriction for 48 h. Not only was the overall increase in plasma PC concentration identical in fed and starved animals, but the detailed changes to PC molecular species compositions were also very similar (Table 2). Our observation agrees closely with studies on plasma phospholipid fatty acid concentration in human preterm infants who were either fed milk formula or who received lipid-free parenteral nutrition postnatally (20). By three days of age, total plasma phospholipid had almost doubled for both groups of infants, and no deficiency of long-chain PUFA was apparent for infants who did not receive any lipid nutrition.

We have previously demonstrated, by detailed metabolic studies of hepatic phospholipid metabolism in the rat (9) and guinea pig (10), that the composition of plasma PC is determined principally by the molecular specificity of hepatic PC synthesis. Comparison of the molecular species compositions of liver PC from stillborn infants and cord plasma PC suggested that a similar relationship holds for the human infant (21). In the present study, analysis of the molecular species compositions of plasma PC (Table 2) and liver PC (Table 3) was consistent with a similar mechanism acting in the postnatal guinea pig. For all experimental groups, the distribution of plasma PC species closely reflected that of the corresponding liver samples. There were relatively minor changes to the fractional compositions of both liver and plasma PC between day 65 and day 67 *in utero*, compared with the more significant and equivalent changes to both parameters for animals delivered on day 65 and killed 2 d later, which in turn were independent of the establishment of postnatal nutrition. The differential increases in both liver and plasma for PC species containing 18:0 at the *sn*-1 position were intriguing. We have previously reported that PC was synthesised *de novo* in perinatal guinea pig liver from CDP:choline principally as molecular species with *sn*-1 16:0, and *sn*-1 18:0 species were formed largely by acyl remodeling (10). The relative postnatal increase of *sn*-1 18:0 PC species in both liver and plasma could possibly be due to more rapid turnover of *sn*-1 16:0 species associated with increased acitivity of acyl remodeling pathways.

It is clear from the compositional analyses (Tables 3 and 4) that the major adaptations to hepatic phospholipid metabolism that occurred over the first two postnatal days were substantially independent of dietary input. Any contribution of coprophagic feeding by starved animals to these changes can be discounted because fecal material contained no n-6 or n-3 fatty acids that could have been precursors for the increased concentrations of polyunsaturated phospholipid species. The

similar extent of the increase in postnatal concentrations of plasma PC (Table 2) and plasma cholesterol (Table 5) suggests that a postnatal increased rate of hepatic lipoprotein secretion may also have been independent of food intake. These conclusions are supported by previous reports that, in other situations, the compositions of liver and exported lipoprotein phospholipid are sensitive to nondietary, hormonal influences. For example, the elevated 20:4n-6 content of hepatic PC in the female compared with the male rat is due principally to estrogen action (22), while specific increases of hepatic or plasma PC16:0/22:6 concentrations in human (21), rat (9), and guinea pig (14) at defined time points in gestation were independent of any change to the n-3 fatty acid intake of the maternal diet. While the hormonal factors regulating postnatal adaptations of hepatic phospholipid metabolism have not been investigated, our results are consistent with a previous implication of a central role for modification of plasma cortisol concentration (23).

Comparison of postnatal changes to circulating phospholipid composition and concentration in different animal species showed both similarities and significant differences. Total plasma phospholipid concentration increased in the initial days after birth for the preterm human infant (20,24) as well as for the guinea pig (Table 2). In contrast, the associated changes to plasma PC molecular species composition differed markedly between animal species and were possibly associated with the developmental timing of PUFA supply that is essential for brain maturation (25). For instance, assimilation of 22:6n-3 into brain phospholipid and neuronal maturation are initiated in mid-gestation for the human infant and continue for at least six months postnatally (26–28), but are both largely postnatal events for the rat (29). Consistent with the particularly high demand for PUFA to support human fetal brain development, fetal human plasma PC is selectively enriched in PUFA *in utero*, followed by a large increase in the content of 18:2n-6 after the establishment of enteral feeding (20,30). In contrast, the PUFA content of rat plasma PC increases only postnatally (31). Our analysis of plasma PC in the perinatal guinea pig, which showed no dramatic selective change to the content in PC species containing 22:6n-3 or 20:4n-6 compared with 18:2n-6 (Table 2), was compatible with previous reports that acquisition of 22:6n-3 into brain PE (18) and neuronal differentiation (32) are both essentially complete at term in this animal species.

Evidently, all EFA-containing phospholipid species in both the fetal and neonatal guinea pigs must have been derived from the maternal diet, either through placental transport or from milk. Presumably, mobilization of adipose tissue lipid reserves deposited *in utero* provided sufficient substrate to sustain postnatal changes to guinea pig plasma PC for at least two days in fasted animals, but obviously would be of limited use in the longer term. At the very least, however, it is clear from this response in starved guinea pig pups that the fatty acid composition of milk lipid cannot be the sole determinant of postnatal changes to plasma PC composition. A substantial contribution to such changes must come from adaptations to neonatal lipid metabolism that are essentially independent of postnatal dietary lipid input.

Dietary Triacylglycerol Structure and Saturated Fat Alter Plasma and Tissue Fatty Acids in Piglets

Sheila M. Innis[a,*], Roger Dyer[a], Paul T. Quinlan[b], and Deborah Diersen-Schade[c]

[a]Department of Paediatrics, University of British Columbia, Canada, [b]Unilever Research, Colworth Laboratory, Sharnbrook, United Kingdom, and [c]Mead Johnson Research Center, Evansville, Indiana

ABSTRACT: Human and pig milk triacylglycerols contain a large proportion of palmitic acid (16:0) which is predominately esterified in the 2-position. Other dietary fats contain variable amounts of 16:0, with unsaturated fatty acids predominantly esterified in the 2-position. These studies determined if the amount or position of 16:0 in dietary fat influences the composition or distribution of liver, adipose tissue, lung, or plasma fatty acids in developing piglets. Piglets were fed to 18 d with sow milk or formula with saturated fat from medium-chain triglyceride (MCT), coconut or palm oil, or synthesized triacylglycerols (synthesized to specifically direct 16:0 to the 2-position) with, in total fatty acids, 30.7, 4.3, 6.5, 27.0, and 29.6% 16:0, and in 2-position fatty acids, 55.3, 0.4, 1.3, 4.4, and 69.9% 16:0, respectively. The percentage of 16:0 in the 2-position of adipose fat from piglets fed sow milk, palm oil, and synthesized triacylglycerols were similar and higher than in piglets fed MCT or coconut oil. Thus, the amount, not the position, of dietary 16:0 determines piglet adipose tissue 16:0 content. The effects of the diets on the plasma and liver triacylglycerols were similar, with significantly lower 16:0 in total and 2-position fatty acids of the MCT and coconut oil groups, and significantly higher 16:0 in the plasma and liver triacylglycerol 2-position of piglets fed the synthesized triacylglycerols rather than sow milk or palm oil. The lung phospholipid total and 2-position 16:0 was significantly lower in the MCT, coconut, and palm oil groups, but similar in the synthesized triacylglycerol group and sow milk group. The lung phospholipid total and 2-position percentage of arachidonic acid (20:4n-6) was significantly lower in all of the formula-fed piglets than in milk-fed piglets. The physiological significance of this is not known.
Lipids 31, 497–505 (1996).

Intraluminal hydrolysis of dietary triacylglycerols by gastric and pancreatic lipase releases fatty acids from the 1 and 3 positions to form 2-monoacylglycerols and unesterified fatty acids, which are then absorbed and reassembled to triacylglycerols (1). Available estimates suggest that about 75% of fatty acids absorbed as 2-monoacylglycerols are conserved in the same 2-position as in the diet fat during this reassembly (2,3). Clearance of plasma triacylglycerols is mediated by lipoprotein lipase (LPL; EC 3.1.1.34) in the capillary beds. LPL activity increases dramatically in the rat and pig in the early postnatal period (4–6). This increase in LPL activity coincides with the rapid postnatal adipose tissue growth which occurs in many species, including pigs and humans. LPL can hydrolyze fatty acids from the 1- and 3-positions of triacylglycerols, but has restricted activity with fatty acids at the 2-position (7). Unesterified fatty acids released by LPL may be taken up by adipose tissue and re-esterified, or enter the circulation (8). Partial glyceride products may be further hydrolyzed by hepatic lipase, or possibly taken up by the liver in remnant lipoproteins. The 2-monoacylglycerol products could also be taken up by adipose tissue and reesterified *via* the monoacylglycerol pathway, or hydrolyzed by monoacylglycerol lipase (9).

The composition of human and pig milk, and the milk of several other animals is unusual in that palmitic acid (16:0) is preferentially esterified at the 2-position of the triacylglycerols (10,11). Pig adipose tissue, in contrast to humans and most other animals, also shows this unusual fatty acid distribution with the 2-position of the triacylglycerols largely occupied by 16:0 (12–15). Pig adipose tissue triacylglycerols, and pig and human milk fat, have been reported to have about 72–78, 58, and 55% 16:0, respectively, in fatty acids esterified at the 2-position (10,12,16). This specific positioning of 16:0 in the 2-position suggests that triacylglycerol synthesis in pig adipose tissue and human and pig mammary glands proceeds *via* the α-glycerophosphate pathway. Pig liver, in contrast, has a fatty acid distribution similar to other species with predominately oleic acid (18:1) and linoleic acid (18:2n-6) in the triacylglycerol 2-position (13). Recent studies have shown higher amounts of 16:0 in the 2-position of postprandial plasma triacylglycerols from breast-fed infants (17) and piglets fed sow milk (16) than in infants or piglets fed formula with 16:0 esterified to the triacylglycerol 1- or 3-positions. Whether the plasma triacylglycerol fatty acid distribution influences fatty acid delivery or distribution to adipose tissue, liver, or lung, for example, is unclear. The studies reported here determined if the distribution of fatty acids in milk or formula triacylglycerols influences the composition of fatty acids at the 2-position of adipose and liver triacylglycerols in piglets. Analysis of lung phospholipid fatty acids was included because of the possibility that 16:0 in the 2-po-

sition of dietary fat could contribute to dipalmitoyl phosphatidylcholine in the growing lung.

METHODS

Animals and diets. Four ready-to-use liquid formulas were prepared by Mead Johnson (Evansville, IN) to contain similar levels of total saturated fatty acids, oleic acid (18:1), linoleic acid (18:2n-6), and linolenic acid (18:3n-3). Three formulas were prepared using high-oleic sunflower oil, sunflower oil and canola oil with saturated fatty acids added as medium-chain triglyceride (MCT) (8:0 plus 10:0), coconut oil (12:0 plus 14:0), or palm, mid-fraction (16:0). The formula containing MCT, and the formulas containing coconut or palm oil had a fat blend similar to that in some preterm and term infant formulas, respectively. The other formula contained synthesized triacylglycerols with the tradename Betapol^R. The synthesized triacylglycerols were made by interesterifying a tripalmitin-rich fraction of palm oil with sunflower and canola oils (16). The palm oil formula had 27.0% 16:0 with 4.4% 16:0 in the fatty acids esterified to the triacylglycerol 2-position, whereas the formula with synthesized triacylglycerols had 29.6% 16:0 with 69.9% 16:0 in the 2-position fatty acids (Table 1). The formulas were all low in cholesterol (<5 mg/dL) and devoid of carbon chain 20 and 22 n-6 and n-3 fatty acids. Complete details of the formula composition have been published (16).

Newborn, male piglets (Peter Hill Holdings, Langley, British Columbia, Canada), birthweight >1 kg were randomly assigned to the formulas and bottle-fed or left with the natural mother, six piglets per group. Littermates were not assigned to the same diet group. Passive immunity was provided to the bottle-fed piglets by addition of lyophilized immunoglobulins (La Belle Associates Inc., Bellingham, WA) to the formula for the first 72 h after birth (18).

At 18 d of age, and 10–12 h after the last feed, the piglets were anesthetized by intramuscular injection with ketamine/rompun (37.5/3.75 mg/kg; MTC Pharmaceuticals, Cambridge, Ontario, Bayvet Division, Chemagro Ltd., Etobicoke, Ontario, Canada). Fasting blood was used to allow study of predominately endogenous rather than absorbed triacylglycerols in plasma. Blood was drawn by cardiac puncture into tubes containing EDTA (150 mg EDTA/L in 9 g NaCl/L) as the anticoagulant, and plasma was prepared by centrifugation. Liver, abdominal subcutaneous tissue, and lung were quickly excised, blotted, weighed, homogenized, frozen in liquid nitrogen, then maintained at –80°C until analyzed. The procedures involving the piglets were approved by the Animal Care Committee of the University of British Columbia and conformed to the guidelines of the Canadian Council on Animal Care.

Biochemical analyses. Plasma and tissue total lipids were extracted, and the plasma and liver triacylglycerols and lung phospholipids were then separated from the other lipid classes by thin-layer plate chromatography (16,19). The composition of fatty acids at the 2-position of plasma, liver, and adipose tissue triacylglycerols and in the milk and formula fat as analyzed based on the methods of Kuksis (20) and Christie (21) as described elsewhere (16,17). Fatty acids were converted to their respective methyl esters using methanolic HCl (1:5 vol/vol) 100°C × 5 min for lung phospholipids and 14% boron trifluoride in methanol/benzene/methanol (25:20:25, by vol) 100°C × 30 min for triacylglycerols and 2-monoacylglycerols. Fatty acid methyl esters were separated using a Varian 3400 gas–liquid chromatograph equipped for analysis with capillary columns and quantitated using a Varian Star data system (Varian Canada Inc., Georgetown, Ontario, Canada) (17).

Statistical analysis. Results were compared among the groups of piglets fed formula and between each group of piglets fed formula and the group fed sow milk using analysis of variance. Formal tests for significant difference used Fisher's least significant difference and were done only for analysis of variance results with $P < 0.05$. The level of statistical significance was adjusted, using the Bonferroni correction,

[a]The fatty acids are given as a percentage relative to the total fatty acids. Other details of the formula composition are in Innis and Dyer (Ref. 16).
[b]The sow milk also contained 1.1% carbon chain length 20 + 22n-6, including 0.7% 20:4n-6, and 0.7% carbon chain length 20 + 22n-3 fatty acids, including 0.2% 22:6n-3. The source of fat in the sows' diet was canola oil.
[c]MCT, medium-chain triglycerides; TG, triacylglycerols.

for the number of comparisons made, and was set at $P < 0.0125$ for comparisons among the groups fed formula and at $P < 0.008$ for comparisons between the groups fed formula and the group fed sow milk. All calculations were performed using the General Linear Models procedure in the Number Cruncher Statistical System, version 5.01 (Kaysville, Utah).

RESULTS

The sow milk and formula fatty acids all contained about 36–41% saturated fatty acids, but the levels of 8:0, 12:0, and 16:0, and the position of 16:0 in the triacylglycerols differed among the diets (Table 1). The formula with MCT had 22.2% 8:0 with 4.3% 16:0, and the formula with coconut oil 19.1% 12:0 with 6.5% 16:0. In contrast, the formula with palm oil or synthesized triacylglycerols, and the sow milk all had 27.0–30.7% 16:0. The sow milk and the formula with synthesized triacylglycerols had 55.3 and 69.9% 16:0, respectively, in fatty acids esterified at the 2-position. The formula with MCT, coconut and palm oil, however, had only 0.4–4.4% 16:0 in the 2-position fatty acids, and this was accompanied by higher levels of 18:1 (40–60% 2-position fatty acids), 18:2n-6 (22–25%), and 18:3n-3 (5.2–5.5%). The sow milk had 18.7% 18:1, 4.9% 18:2n-6, and 0.3% 18:3n-3; the formula with synthesized triacylglycerols had 13.7% 18:1, 6.5% 18:2n-6, and 0.8% 18:3n-3 in fatty acids esterified at the 2-position (Table 1).

The body weight of the piglets at 18 d of age was (mean ± SE) 5.1 ± 0.2, 4.4 ± 0.4, 4.3 ± 0.3, 4.4 ± 0.4, and 4.2 ± 0.4 kg for piglets fed sow milk, or the formula with MCT, coconut oil, palm oil, or the synthesized triacylglycerols, respectively. Body weight gain per liter of formula intake was not different among the four groups of formula-fed piglets: (mean ± SE) 293 ± 13, 292 ± 10, 274 ± 9, and 284 ± 3 g gain/L, respectively. The intake of sow milk could not be measured. The plasma cholesterol concentration of piglets fed sow milk was 4.47 ± 0.26 mmol/L and was significantly higher than the plasma cholesterol concentration of piglets fed the formula with MCT, 1.91 ± 0.10 mmol/L; coconut oil, 2.07 ± 0.10 mmol/L; palm oil, 2.17 ± 0.10 mmol/L; or synthesized triacylglycerols, 2.56 ± 0.18 mmol/L. The liver triacylglycerol concentration was significantly higher in piglets fed sow milk (mean ± SE 126 ± 3 μg/g liver) than in piglets fed the formula with palm oil (114 ± 2 μg/g) or synthesized triacylglycerols (103 ± 6 μg/g), but was not different from that of piglets fed the formula with MCT (123 ± 2 μg/g) or coconut oil (112 ± 7 μg/g). The liver triglyceride concentration of piglets fed the formula with MCT was also significantly higher than that of piglets fed the formula with palm oil or synthesized triacylglycerols.

The composition of the triacylglycerol total and 2-position fatty acids in the piglet plasma, liver, and adipose tissue, together with that of the diets, is shown in Figures 1 and 2. Arachidonic acid (20:4n-6) and 22:6n-3 were not present in the formulas, and because levels were low in all of the triacylglycerol fractions, data for these fatty acids are not included. The difference in the saturated fatty acid composition of the milk and formula diets resulted in similar differences in the saturated fatty acid composition of the piglet plasma, adipose tissue, and liver triacylglycerols. Piglets fed the formula with MCT or coconut oil, containing 8:0 or 12:0, respectively, as the major saturated fatty acid, had significantly lower levels of 16:0 in plasma, adipose tissue, and liver triacylglycerol total fatty acids than piglets fed sow milk or the formula with 16:0 from palm oil or synthesized triacylglycerols (Fig. 1). The fasting plasma triacylglycerol percentage of 16:0 was not significantly different between the piglets fed sow milk and those fed the formula with palm oil or synthesized triacylglycerols, although values for piglets fed the formula with palm oil were lower than values for piglets fed the formula with synthesized triacylglycerols. Similarly, the adipose tissue and liver triacylglycerol percentage of 16:0 was similar in piglets fed the formula with synthesized triacylglycerols and piglets fed sow milk, and significantly higher in both of these groups than in piglets fed the formula with palm oil. The higher percentage of 16:0 in the adipose tissue and liver of piglets fed milk or the formula with synthesized triacylglycerols could be due to improved absorption of 16:0 when present in the 2-position, rather than the 1 or 3-position of the dietary triacylglycerols (1,22,23). However, the slightly lower proportion of 16:0 in the palm oil than in the synthesized triacylglycerol formula or the sow milk (Table 1) could also explain these results. The significant differences in 12:0 and 14:0 in the piglet plasma and adipose tissue, and in 14:0 in liver among the groups (Fig. 1) may also be attributable to the differences in levels of these fatty acids in the diets. The very low amounts of 8:0, 10:0, and 12:0 in the liver triacylglycerols is probably explained by rapid, carnitine-independent oxidation and low activity of acyltransferases with medium-chain fatty acids (24,25).

Despite similar levels of 39–41% 18:1 in the milk and formula fatty acids, the differences in the formula saturated fatty acid compositions resulted in differences in 18:1, and to a smaller extent 18:2n-6 and 18:3n-3, in the piglet plasma, adipose tissue, and liver triacylglycerols. Levels of 18:1 and 18:2n-6 were significantly higher in liver, plasma, and adipose tissue triacylglycerols, and 18:3n-3 was significantly higher in plasma and adipose tissue of all piglets fed formula rather than sow milk. The higher 18:2n-6 and 18:3n-3 in piglets fed formula is probably explained in part by the higher formula content of 18:2n-6 and 18:3n-3 than that found in the milk (15.5–16.4% 18:2n-6 and 3.1–3.4% 18:3n-3 in the formulas and 8.2% 18:2n-6 and 0.8% 18:3n-3 in the sow milk). Piglets fed the formula with MCT oil had a significantly higher percentage of 18:1 in plasma, adipose tissue, and liver triacylglycerols than piglets fed the other formulas (Fig. 1). Levels of 18:1 in the plasma and liver triacylglycerols of piglets fed the formula with coconut oil were also significantly higher than those of piglets fed the formula with palm oil or synthesized triacylglycerols. Differences in 18:2n-6 and 18:3n-3 among piglets fed the different formulas were smaller, but generally followed a similar pattern to 18:1, with

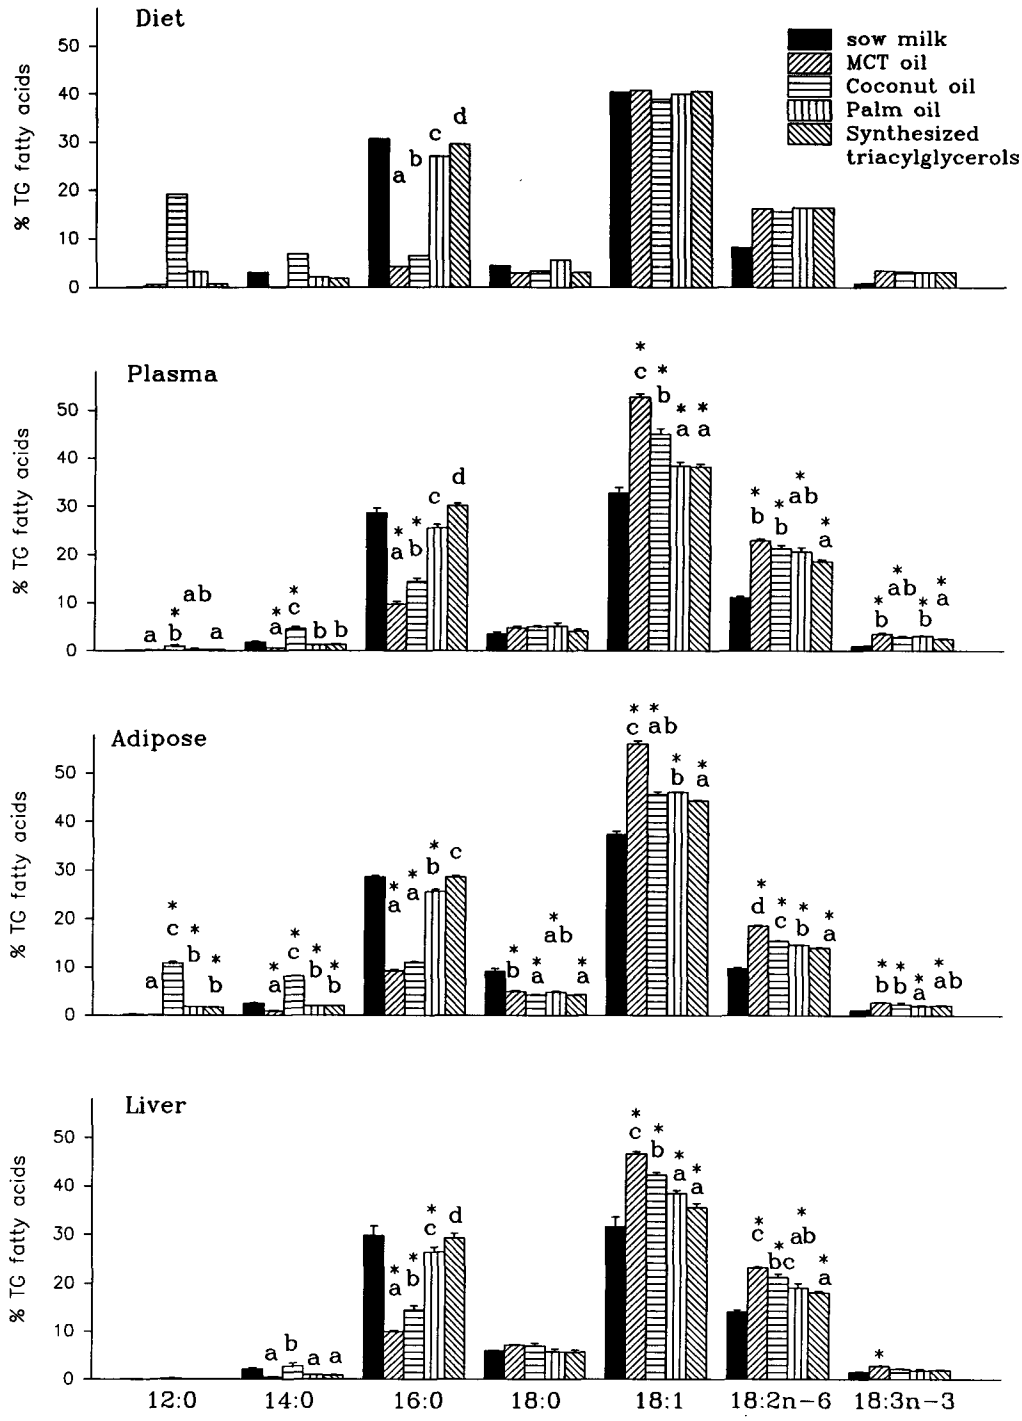

FIG. 1. Major fatty acid components (% total) of the diet, and of fasting plasma, adipose tissue, and liver triacylglycerols (TG) of piglets fed sow milk, or formula with medium-chain triglycerides (MCT) oil, coconut oil, palm oil, or synthesized TG from birth to 18 d of age. Values for plasma and tissue fatty acids are means ± SEM; *value significantly different from group fed sow milk, $P < 0.008$; ^{abcd}values for groups fed formula with a different letter are significantly different, $P < 0.0125$.

values for piglets fed the MCT > coconut oil > palm oil > synthesized triacylglycerol formula (Fig. 1).

The composition of fatty acids at the 2-position of the milk and formula fat also had a clear effect on the plasma, adipose tissue, and liver triacylglycerol 2-position fatty acids, with remarkably similar effects in the plasma and liver (Fig. 2). Piglets fed the formula with synthesized triacylglycerols had a significantly higher percentage, and piglets fed the formula

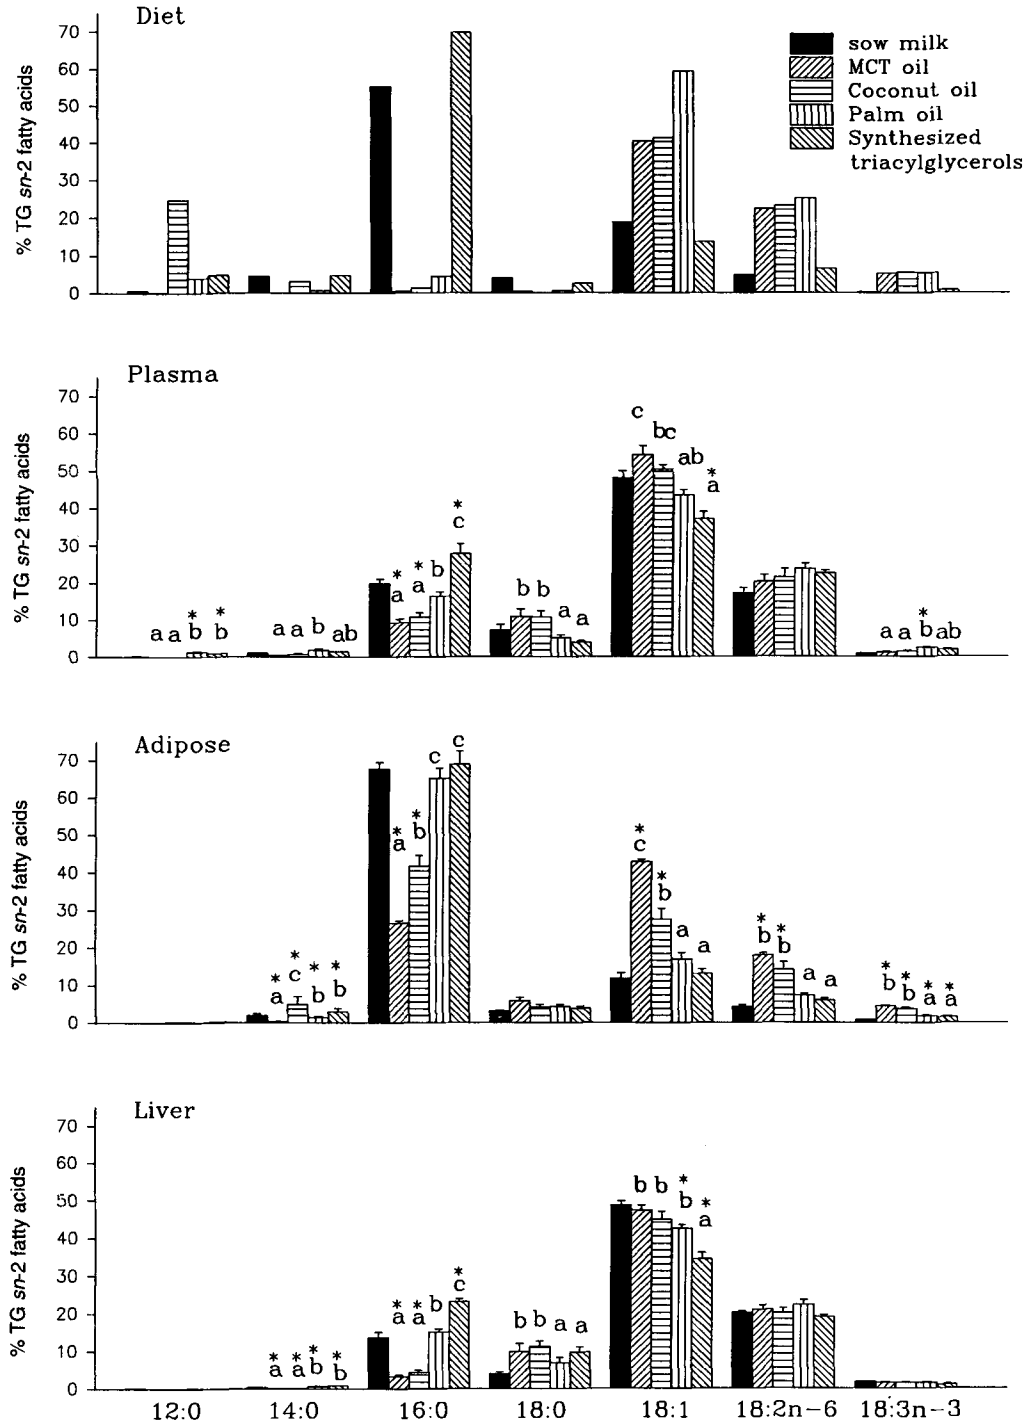

FIG. 2. Major fatty acid components (% total) esterified to the 2-position of the diet, and of fasting plasma, adipose tissue, and liver TG of piglets fed sow milk, or formula with MCT oil, coconut oil, palm oil, or synthesized triacylglycerols from birth to 18 d of age. Values for plasma and tissue fatty acids are means ± SEM; *values significantly different from group fed sow milk, $P < 0.008$; ^{abcd}values for groups fed formula with a different letter are significantly, $P < 0.0015$. Abbreviations as in Figure 1.

with MCT or coconut oil had a significantly lower percentage of 16:0 in plasma and liver triacylglycerol 2-position fatty acids than piglets fed sow milk or the formula with palm oil. In contrast, the percentage of 16:0 in the adipose tissue 2-position fatty acids was not different among piglets fed the formula with palm oil or synthesized triacylglycerols, and piglets fed sow milk.

The percentage of 18:1 in the 2-position of the plasma, adi-

pose tissue, and liver triacylglycerols showed a consistent pattern among the formula groups with piglets fed MCT > coconut oil > palm oil > synthesized triacylglycerols (Fig. 2). The differences among groups fed the MCT, coconut oil, and palm oil formulas are clearly not explained by differences in the percentage of 18:1 in the 2-position of the formula fat (Table 1). The percentage of 18:1 was significantly higher in the plasma and liver of piglets fed the formula with MCT, coconut oil, or palm oil, and in the adipose tissue of piglets fed the formula with MCT or coconut oil than in piglets fed the formula with synthesized triacylglycerols. The percentage of 18:1 in the 2-position fatty acids of adipose tissue from piglets fed the formula with MCT or coconut oil, in liver triacylglycerols from piglets fed the formula with palm oil, and in liver and plasma triacylglycerols from piglets fed the formula with synthesized triacylglycerols was lower than in piglets fed sow milk. Despite differences in the diets, there were no significant differences in the percentage of 18:2n-6 in the 2-position fatty acids of plasma or liver triacylglycerols, or in the percentage of 18:3n-3 in the liver triacylglycerols among piglets fed the different diets. In contrast, the percentages of 18:2n-6 and 18:3n-3 in the adipose tissue triacylglycerol 2-position fatty acids were significantly higher in piglets fed the formula with MCT or coconut oil than in piglets fed sow milk or the other formulas. The percentage of 18:3n-3, but not 18:2n-6, was also significantly higher in the adipose tissue of piglets fed the formula with palm oil or synthesized triacylglycerols than in piglets fed sow milk.

The major fatty acid components of lung phospholipid fatty acids, however, were significantly influenced by both the dietary saturated fatty acid composition and positional distribution (Table 2). Piglets fed the formula with MCT, coconut, or palm oil had significantly lower levels of 16:0 in lung phospholipid total and 2-position fatty acids than piglets fed sow milk. Values for piglets fed the formula with synthesized triacylglycerols, on the other hand, were not significantly different from that of the sow milk group. The percentages of 18:1 and 18:2n-6 in lung total and 2-position fatty acids were significantly higher, but 20:4n-6 was lower in all groups of piglets fed formula than in the group fed sow milk. The percentage of 20:4n-6 in total and 2-position fatty acids was also significantly lower in lung phospholipids from piglets fed the formula with MCT than in piglets fed the other formulas. No significant differences in lung phospholipid 18:2n-6 were found among the formula groups, or in 22:6n-3 among the milk or formula groups.

DISCUSSION

These studies show that the composition and distribution of dietary saturated fatty acids determine in part the composition and distribution of fatty acids in liver and adipose tissue, as well as in fasting plasma triacylglycerols of young piglets. The composition of adipose tissue fatty acids in piglets (26), pigs (13,15), human adults and infants, and other species (12,14,27–29) is known to correlate with the fatty acid composition of the diet. The 2-acyl group of adipose tissue triacylglycerols in most species, like that of plasma and other tissues, is usually an unsaturated fatty acid. The explanation for a specific positional distribution of adipose tissue fatty acids, other than a belief that lysophospholipid acyltransferase or remodeling reactions are specific for unsaturated fatty acids, is not clear. The adipose tissue from several species of the pig family, however, is unusual and different from that of humans and most other animals in that 16:0 is preferentially positioned at the 2 rather than the 1,3-positions (12–15). Thus un-

TABLE 2
Composition of Lung Phospholipid Total and 2-Position Fatty Acids from Piglets Fed Sow Milk or Formula[a]
