ABSTRACT: Ganglioside GT1b and, to a lesser extent, GD3, enhanced phosphorylation of a 36 kDa protein (the substrate of protein kinase C) in the particulate fraction from bovine mammary gland. Sialic acids, asialogangliosides, and GM3 were without effect, and GD1a conversely inhibited phosphorylation of the 36 kDa protein. The enhanced phosphorylation by GT1b required the simultaneous presence of phosphatidylserine (PS) and Ca^{2+}. The 36 kDa protein reacted with anti-annexin I in Western blot analysis. Addition of purified annexin I to the reaction mixture containing the particulate fraction increased the extent of phosphorylated 36 kDa protein, and the phosphorylation was further enhanced by GT1b. The enhanced phosphorylation of annexin I by GT1b was also dependent on PS and Ca^{2+}. When annexin I was phosphorylated by purified protein kinase C, GT1b inhibited the annexin I phosphorylation. Addition of epidermal growth factor or insulin to the particulate fraction had little effect on the enhancement. These results suggest that an enzyme or enzymes other than protein kinase C, epidermal growth factor receptor kinase, or insulin receptor kinase is responsible for the GT1b- and GD3-enhanced phosphorylation of annexin I in the presence of PS and Ca^{2+}.
Lipids 31, 983–987 (1996).

Annexins belong to a family characterized by the ability to bind with membrane phospholipids in a Ca^{2+}-dependent manner, and are distributed in a wide variety of cells and tissues (1,2). Annexin I, best characterized in the family, is suggested to be implicated in the regulation of various biological processes, including exocytosis (2–4), eicosanoid production (5), and synthesis and secretion of prolactin (6). In the mammary gland, this protein is reported to be related to the mammary cell differentiation (7). Annexin I is the substrate for protein kinase C (PKC; 8), and phosphorylation by PKC suppresses the ability of this protein to aggregate phospholipid vesicles (3,4).

Gangliosides, localized mainly in the outer surface of the plasma membrane, modulate the activities of various protein kinases, including PKC. Gangliosides inhibit PKC activity when histone is used as the substrate, and the order of inhibitory capacity is dependent on the number of sialic acid residues (9). By comparison, in the case of endogenous protein phosphorylation, gangliosides act as inhibitors or stimulators for individual substrates. In bovine mammary gland, phosphorylation of most endogenous substrates for PKC is inhibited by the hydrophilic gangliosides such as GT1b, whereas some substrate phosphorylation is resistant to GT1b inhibition (10). In particular, phosphorylation of a 36 kDa protein present in the particulate fraction is enhanced by GT1b. In the present study, we show that phosphorylation of the 36 kDa protein, which was identified as annexin I, is enhanced by GT1b in the presence of phosphatidylserine (PS) and Ca^{2+}.

MATERIALS AND METHODS

Materials. Gangliosides and related compounds were purchased from Sigma Chemical Co. (St. Louis, MO). Monoclonal antibodies to bovine lung annexins I, II, IV, and VI were from Affiniti Research Products (Nottingham, United Kingdom). Recombinant human epidermal growth factor (EGF) was bought from Wako Pure Chemicals (Osaka, Japan). [γ-^{32}P]ATP was obtained from DuPont-New England Nuclear (Wilmington, DE). Cow mammary glands in the lactating state were collected from a local slaughterhouse.

Phosphorylation of total particulate fraction. The total particulate fraction from bovine mammary gland was prepared, and phosphorylation of endogenous proteins was carried out as described (11). Briefly, the standard assay mixture (0.2 mL) contained 25 mM *tris*(hydroxymethyl)aminomethane (Tris)-HCl (pH 7.5), 10 mM $MgCl_2$, 0.25 mM EGTA, 10 mM 2-mercaptoethanol, 50 μM [γ-^{32}P]ATP, and 20 μL of the particulate fraction (containing 40–50 μg of protein), in the absence or presence of 1-oleoyl-2-acetyl-*sn*-glycerol (OAG; 1 μg, 12.5 μM), PS (5 μg, 32 μM), and Ca^{2+} (1 μM). Gangliosides were sonicated in 20 mM Tris-HCl (pH 7.5), then incubated in the mixture. The reaction was initiated by the addition of ATP and continued for 5 min at 30°C. Phos-

phorylated proteins were separated by SDS–polyacrylamide gel electrophoresis, using 12 or 7.5% gels, then visualized by autoradiography.

Purification of annexin I. Annexin I from bovine mammary gland was purified essentially according to the method of Wang and Creutz (3). Briefly, the minced tissue (200 g) was homogenized using a Polytron for 1 min with 2 vol of buffer A (20 mM Tris-HCl, pH 7.5, 150 mM KCl, 0.12 TIU/mL aprotinin, 1 μg/mL leupeptin, 1 mM phenylmethylsulfonyl fluoride, 0.5 mM dithiothreitol, 1 mM benzamidine, and 4 mM iodoacetic acid), and centrifuged at 2,900 × *g* for 15 min. To the supernatant, $CaCl_2$ was added to a final concentration of 2 mM. The pellet obtained by centrifugation at 105,000 × *g* for 30 min was redissolved in buffer A (from which iodoacetic acid was deleted) containing 10 mM EGTA. Annexin I was further purified by sequential chromatographies with DEAE-Sephacel, hydroxylapatite, and Mono S. Annexin I thus obtained was homogeneous as revealed by SDS–polyacrylamide gel electrophoresis, but a faint additional band (33–34 kDa) was occasionally detected by Western blot analysis and autoradiography. In the blotting, both annexin I (36 kDa) and the 33–34 kDa protein reacted with anti-annexin I, but not with anti-annexins II, IV, and VI, thereby suggesting that the band was a breakdown product of annexin I.

Other methods. PKC was purified from the mammary gland by ammonium sulfate fractionation and DEAE-cellulose, Sephacryl S-200, and protamine-Sepharose 4B chromatographies, and phosphorylation of annexin I by PKC was done as described previously (11). Phosphorylation of the particulate proteins with annexin I added in the presence of EGF or insulin was performed as reported (12,13). All phosphorylation experiments were repeated using 2–5 mammary samples from different cows. Phosphoprotein patterns obtained using different samples were essentially similar, but individual variations of values obtained by densiometer scanning of autoradiograms were too large to analyze statistically. Autoradiograms were scanned using Bio-Profil (Vilber Lourmat, Marnelavalleé, France). Duplicate or triplicate scans were done for each lane, variations between scans being less than 10%. Protein was determined by the method of Bradford (14).

RESULTS

The total particulate fraction from bovine mammary gland contained several PKC substrates phosphorylated in the presence of the PKC cofactors OAG, PS, and Ca^{2+} (Fig. 1). These included 94 kDa, 91 kDa, 56 kDa, 42 kDa, and 36 kDa proteins. A 30 kDa protein, whose phosphorylation was independent of the cofactors, was casein. Although phosphorylation of these particulate substrates was relatively resistant to ganglioside inhibition, compared with that of cytosolic proteins (10), GT1b inhibited phosphorylation of the 91 kDa protein. Phosphorylation of the 36 kDa protein was inhibited by GD1a, but was enhanced by GD3 and in particular by GT1b. GM3 had little effect on the 36 kDa phosphorylation. *N*-acetylneuraminic acid, *N*-glycolylneuraminic acid, asialoGM1, and asialoGM2 also had little effect up to a 100 μM concentration (figure not shown). Sphingosine, like GD1a, inhibited the 36 kDa phosphorylation (11). Other than the 36 kDa protein, the 56 kDa protein phosphorylation was enhanced by GD3. However, phosphorylation of the 56 kDa and 42 kDa proteins was sometimes detected independent of the cofactors as shown in Figure 2.

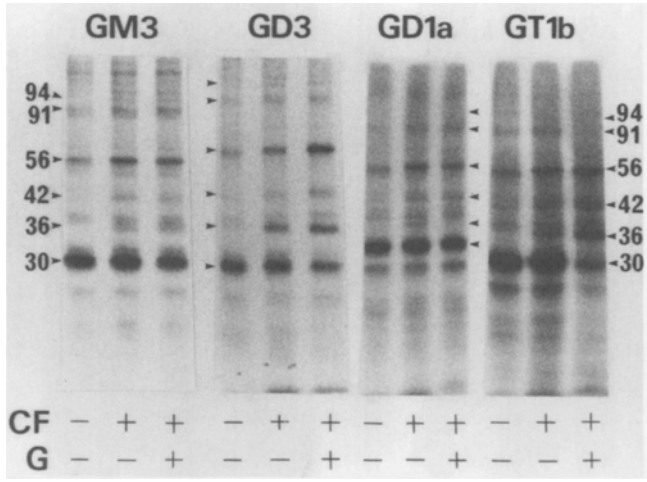

FIG. 1. Effects of gangliosides GM3, GD3, GD1a, and GT1b on phosphorylation of endogenous proteins from the total particulate fraction of bovine mammary gland. CF, protein kinase C cofactors (5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol, 25 μg/mL phosphatidylserine, and 1 μM Ca^{2+}); G, ganglioside (100 μM).

The enhanced phosphorylation by GT1b of the 36 kDa protein was dependent on the ganglioside concentrations (Fig. 2, lanes 1–5). The ED_{50} value was estimated to be approximately 10 μM GT1b. With 50 μM GT1b, 2.1- to 5.6-fold increases of the 36 kDa protein phosphorylation were observed by densitometer tracing (the results of five independent experiments). The enhanced effect of GD3 was less potent than that of GT1b (with 50 μM GD3, the increases were 1.3- to 1.8-fold).

Because of its molecular weight, its distribution in the particulate fraction and phosphorylation by PKC, the 36 kDa protein was assumed to be annexin I. Western blot analysis using anti-bovine annexin I revealed that the antibody reacted with the 36 kDa protein (Fig. 3). Antibodies to annexins II, IV, and VI did not react with the protein. Purified annexin I was included in the reaction mixture together with the particulate fraction. The phosphorylation of annexin I observed was dependent on the PKC cofactors (Fig. 2, lanes 6 and 7), and the phosphorylated annexin I band overlapped that of the 36 kDa protein. This result, taken together with that shown in Figure 3, indicated that the 36 kDa protein was annexin I. GT1b had little effect on the annexin I phosphorylation in the absence of the cofactors (Fig. 2, lane 8), but when present, GT1b further enhanced the phosphorylation (1.4- to 1.6-fold, lanes 7 and 9).GD3 also enhanced annexin I phosphorylation in the presence of the cofactors (figure not shown).

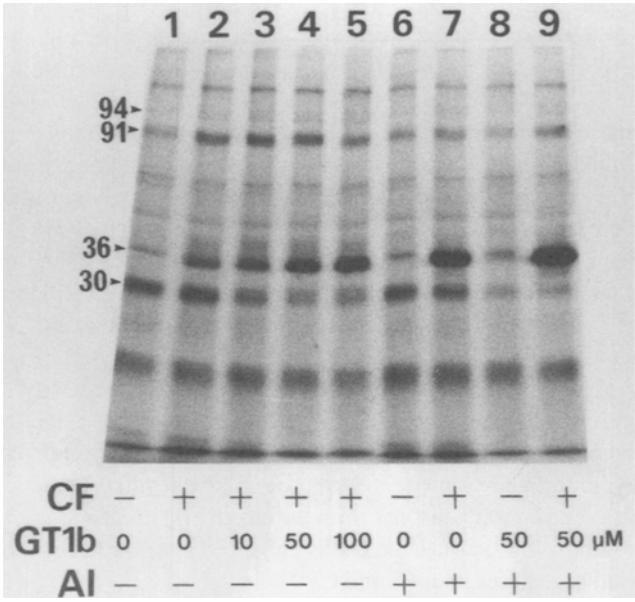

FIG. 2. Effect of GT1b on phosphorylation of the 36 kDa protein and added annexin I. Annexin I (AI, 4.76 μg) was included in the reaction mixture containing 20 μL of the particulate fraction, and phosphorylation was carried out in the absence or presence of the protein kinase C cofactors (CF; 5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol, 25 μg/mL phosphatidylserine, and 1 μM Ca^{2+}) and/or various concentrations of GT1b.

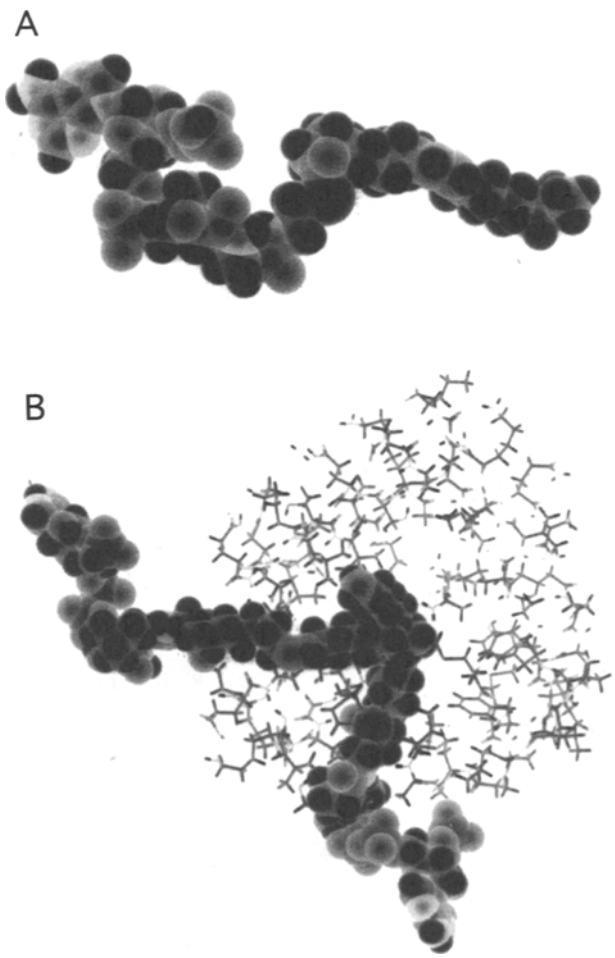

FIG. 3. Western blot analysis of the 36 kDa particulate protein using anti-annexin I. Lanes 1–2, autoradiography; lane 3, the blotting: CF, the protein kinase C cofactors (5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol, 25 μg/mL phosphatidylserine, and 1 μM Ca^{2+}).

Of the three PKC cofactors, the simultaneous presence of PS and Ca^{2+} was required for the enhanced phosphorylation by GT1b of annexin I (Table 1). OAG appeared not to be necessary for the GT1b-enhanced phosphorylation. PS and Ca^{2+}, used singly or in combination with OAG, showed little effect on the enhancement by GT1b. Higher concentrations of PS (250 μg/mL) or Ca^{2+} (250 μM), also added separately or in combination with OAG (50 μg/mL), had little effect (data not shown).

To identify the enzyme(s) responsible for the enhanced phosphorylation of annexin I by GT1b, purified annexin I was phosphorylated by PKC in the presence of GT1b (Fig. 4). Phosphorylation of annexin I in the presence of cofactors (lane 2) was inhibited by GT1b in a dose-dependent manner (lanes 3–5). The suppressed phosphorylation by GT1b was overcome by the addition of the higher concentration of PS, but not or only slightly by OAG or Ca^{2+} (lanes 6–8). GM3 and GD3 also inhibited the annexin I phosphorylation, and these inhibitions were similarly reversed by PS (figure not shown). Other than PKC, annexin I is phosphorylated by EGF receptor kinase (12) and insulin receptor kinase (13). The addition of EGF (100 ng/0.1 mL) or insulin (10^{-7} M) did not result in a change of the extent of annexin I phosphorylation in the absence or presence of the PKC cofactors and/or GT1b. Stimulation by these ligands of autophosphorylation of EGF receptor (170 kDa) and insulin receptor (95 kDa) was not clearly observed (figure not shown). GT1b, used singly or in combination with EGF or insulin, also showed little effect on the autophosphorylation.

[a]Annexin I (3.62 μg) was included in the reaction mixture (0.2 mL) containing 20 μL of the particulate fraction, and was phosphorylated in the absence or presence of the protein kinase C cofactors and/or GT1b as indicated. After autoradiography, the band corresponding to added annexin I plus the endogenous 36 kDa protein was scanned by a densitometer.

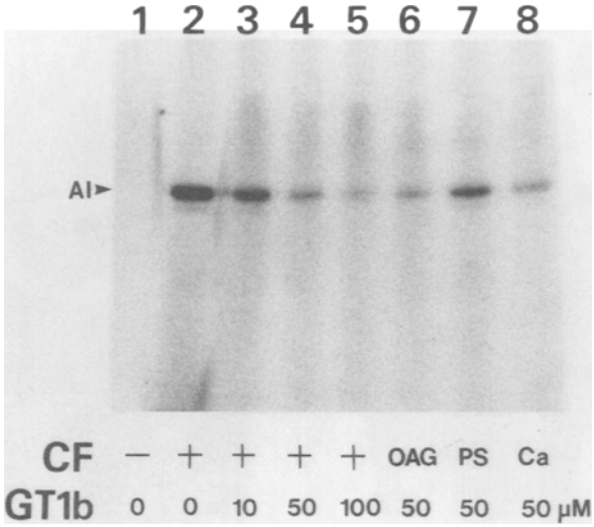

FIG. 4. Inhibition by GT1b of phosphorylation of annexin I by protein kinase C (PKC) and its reversal by the PKC cofactors. Annexin I (3.17 μg) was phosphorylated by PKC [9.7 U (pmol/min)] for 5 min at 30°C. CF, 5 μg/mL 1-oleoyl-2-acetyl-*sn*-glycerol (OAG), 25 μg/mL phosphatidylserine (PS), and 1 μM Ca^{2+}; OAG, 50 μg/mL OAG, 25 μg/mL PS, and 1 μM Ca^{2+}; PS, 250 μg/mL PS, 5 μg/mL OAG, and 1 μM Ca^{2+}; Ca, 250 μM Ca^{2+}, 5 μg/mL OAG and 25 μg/mL PS. Lane 1 contains PKC alone.

DISCUSSION

The present study indicated that phosphorylation of a 36 kDa PKC substrate in the particulate fraction from bovine mammary gland, identified as annexin I, was enhanced by GT1b. Of the gangliosides and the related compounds tested, GT1b and, to a lesser extent, GD3 enhanced annexin I phosphorylation, whereas GD1a and sphingosine inhibited it. Sialic acids, asialogangliosides, and GM3 showed little effect on the enhancement, suggesting that the enhanced phosphorylation was not simply caused by nonspecific binding of sialic acids, but was attributable to the interaction of protein kinase(s) or annexin I with the specific gangliosides, including GT1b and GD3.

The enzyme(s) responsible for the enhanced phosphorylation is unknown at present. Because PS and Ca^{2+} are required, PKC was initially postulated as a candidate. However, purified annexin I phosphorylation by PKC was inhibited by GT1b. Rat mammary gland contains PKC isozymes α, β1, β2, γ, and ζ, in which α is predominant (15). It is unlikely that ζ (atypical PKC) or new PKC are involved in the GT1b-enhanced phosphorylation of annexin I because these isozymes are Ca^{2+}-independent (16). Annexin I may be sequentially phosphorylated, i.e, initially phosphorylated by PKC, after which enhanced phosphorylation by GT1b is catalyzed by an enzyme or enzyme(s) such as Ca^{2+}/phospholipid-dependent protein kinase, which are reported to be distinct from PKC (17).

Annexin I is also the substrate for EGF receptor kinase (12) and insulin receptor kinase (13), and gangliosides modulate these tyrosine kinase activities (18,19). Phosphorylation of annexin I was not induced by EGF or insulin. Because bands corresponding to autophosphorylation of EGF and insulin receptors were not detected, these kinase activities may be defective in this tissue or the assay conditions might be inadequate for the kinases distributed in this tissue. In any case, EGF receptor kinase and insulin receptor kinase are suggested not to be involved in the GT1b-enhanced phosphorylation of annexin I. Tyrosine kinase activities of nerve growth factor receptor (20) and platelet-derived growth factor (PDGF) receptor (21) are also regulated by gangliosides. In the latter case, GT1b is one of the most effective gangliosides in inhibiting autophosphorylation of PDGF receptor (21). GT1b has been also shown to activate several protein kinase activities. Highly sialylated gangliosides, including GT1b, activate protein kinase activity in neuroblastoma cells in a Ca^{2+}-dependent manner (22). GT1b stimulates phosphorylation of several endogenous proteins in myelin by a Ca^{2+}-independent protein kinase (23). These kinases appear to be distinct from the enzyme(s) discussed in the present study, because the GT1b-enhanced annexin I phosphorylation requires both PS and Ca^{2+}.

Annexins I and II are secreted by a variety of cells (24,25). Extracellular annexins I and II are suggested to mediate the anti-inflammatory effect of glucocorticoids (5,25). Cell surface annexin II has been recently found to be a receptor for tanascin-C (26), which is prominently expressed in developing tissues. GT1b may enhance phosphorylation of annexin I on the external cell surface. The presence of extrinsic protein kinases, for example, PKC (27), has been already reported.

GT1b is the minor ganglioside species in bovine mammary gland, while GD3 is abundantly present (28,29). Because phosphorylation of annexin I is involved in membrane fusion processes (3,4), it is presumed in mammary gland that cell surface annexin I participates in the secretion of milk proteins, and that the secretory system may be regulated by phosphorylation by PKC, and further by GT1b- or GD3-modified phosphorylation. The GT1b-enhanced phosphorylation of annexin I is also implicated in the synthesis of milk proteins, because GT1b, GD3, and annexin I, as well as PKC, are found in the nuclear fraction from lactating bovine mammary gland (29–31), and also because rat mammary annexin I is involved in cell differentiation (7). Concentration changes of annexin I and gangliosides localized on cell surface and in nucleus have not yet been evaluated during the lactation cycle. Moreover, effects of steroid hormones and prolactin on their concentrations are not known. Studies along these lines should elucidate functional role(s) of the GT1b-enhanced annexin I phosphorylation in bovine mammary gland.

Sterol Composition of *Phaeodactylum tricornutum* as Influenced by Growth Temperature and Light Spectral Quality

Benoît Véron[a,*], Chantal Billard[a], Jean-Claude Dauguet[a], and Marie-Andrée Hartmann[b]

[a]Laboratoire de Biologie et Biotechnologies Marines, Université de Caen Basse-Normandie, 14032 Caen, France and [b]Institut de Biologie Moléculaire des Plantes, UPR CNRS 406, 67083 Strasbourg, France

ABSTRACT: In a detailed sterol analysis of the marine diatom *Phaeodactylum tricornutum,* free sterols as well as esterified and glycosylated conjugates were found. When the alga was grown under standard conditions (i.e., at 13°C under white light), 64% of total sterols were steryl glycosides. In all sterol classes, except steryl esters, (24*S*)-24-methylcholesta-5,22*E*-dien-3β-ol (epibrassicasterol) was the major (80 to 99%) sterol component. Eight other sterols were identified. Growth under different light spectral quality (red, blue, yellow, and green) at 13 and 23°C was examined. At 23°C, a dramatic decrease in total sterol content was observed, especially under blue light. The distribution of sterols between free and conjugated forms as well as sterol profile inside each class was found to be strongly dependent on the light spectral quality at both temperatures.

Lipids 31, 989–994 (1996).

Cultures of microalgae are extensively used as food for the commercial rearing of marine invertebrates such as oysters. Diatoms, which are abundant components of the phytoplankton, constitute a major nutritional source in aquaculture (1). As dietary polyunsaturated fatty acids and sterols are of great importance for growth and development of marine invertebrates, investigations have focused on these compounds. *Phaeodactylum tricornutum*, a marine pennate diatom (class Diatomophyceae), can satisfy these dietary requirements. Polar lipids of this diatom are characterized by a high content in C_{20}-polyunsaturated fatty acyl chains, mainly 20:5n-3, which is a major compound in stationary phase (2,3). The biosynthetic pathways of these polyunsaturated fatty acids in *P. tricornutum* have been recently investigated (4,5). Sterols are also an important aspect of lipids in marine nutrition. Bivalve mollusks are unable to synthesize *de novo* the sterols they need as membrane constituents and precursors of steroid derivatives (6), but are capable of using sterols from dietary sources such as phytoplankton (7). Few reports have dealt with sterols of *P. tricornutum* (3,8,9). The major sterol, which accounted for 91% of total sterols, was 24-methylcholesta-5,22-dien-3β-ol (3), with an α-oriented (or 24*S*) methyl group at C-24 of the side chain (i.e., epibrassicasterol) (8). The occurrence of 9% Δ7-sterols was reported (3), but has not been confirmed (9). We therefore decided to reinvestigate the sterol composition of *P. tricornutum*, with special emphasis on steryl conjugates. Moreover, since conditions of algal growth can affect its sterol composition (9 and references cited), we examined the influence of light spectral quality and temperature on the sterol profile of *P. tricornutum*. We show that this diatom contains free sterols (FS) as well as steryl esters (SE), steryl glycosides (SG), and acylated steryl glycosides (ASG). These different sterol classes were analyzed for their sterol composition. The nature of sugar(s) and fatty acyl chains of steryl conjugates was not determined. Our results indicate that profound alterations in the total amount as well as in the sterol profile of each sterol class of *P. tricornutum* occur in response to changes in both light spectral quality and culture temperature.

MATERIALS AND METHODS

Algal material and culture conditions. A unialgal culture of the diatom *P. tricornutum* Bohlin was obtained from the Culture Collection of the Laboratoire de Biologie et Biotechnologies Marines (University of Caen Basse-Normandie, France) (10). Under our growth conditions, this strain consists in colonial fusiform cells, with rare single or triradiate cells. A 150 mL-aliquot of stock culture was transferred in 2.5 L of enriched (soil extract and vitamins) sea water medium ES-Tris II (11) supplemented with 0.2 mM sodium metasilicate in 4-L flasks under aseptic conditions. Cultures were incubated at 13 or 23°C (±0.5) with a 12/12 h light/dark cycle provided from cool white, red, blue, yellow, and green 60 W lamps (Osram) at a light intensity of 100 $\mu E \cdot m^{-2} \cdot s^{-1}$ (12). All cultures were bubbled with 0.22 μm-filtered air. Cells were harvested at the beginning of stationary phase by centrifugation and lyophilized.

Sterol analysis. Sterols were extracted from dried samples with dichloromethane/methanol (2:1, vol/vol). After solvent evaporation, lipid extracts were applied to silica gel plates (0.25 mm, Durasil-25UV$_{254}$; Macherey-Nagel, Düren, Germany) to separate FS, SE, SG, and ASG (13). Sterols from SE, SG, and ASG were obtained as previously described (12,13). After acetylation, FS and sterols from conjugates were identified by gas chromatography (GC) using a chromatograph equipped with a flame-ionization detector and a glass fused silica capillary column (30 m × 0.32 mm) coated with a 0.25 μm film of CP-Sil5 (Chrompack, Middleburg, The Netherlands). Column was operated at head pressure of 10 psi of helium. The oven temperature was raised from 260 to 300°C at 2°C/min and held at 300°C for 10 min. Injector and detector temperatures were held at 310°C. Sterol identities were confirmed by GC/mass spectrometry (MS) (14,15) and quantified by GC using 5α-cholestane as an internal standard.

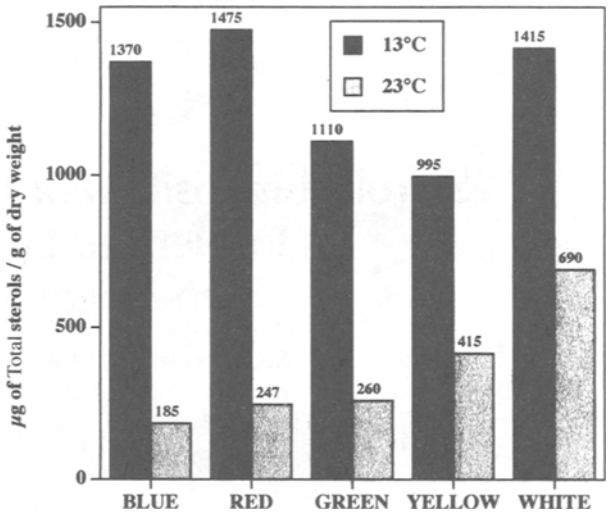

FIG. 1. Total sterol content in *Phaeodactylum tricornutum* grown at 13 and 23°C under different light spectral qualities.

RESULTS

Effects of light spectral quality and growth temperature on total sterol content. In Figure 1 are shown total sterol amounts of *P. tricornutum* grown at 13 and 23°C under different light spectral qualities. When expressed as μg/g dry weight, the total sterol content of cells grown at 13°C appears to be roughly similar (between 1100 and 1500) in all the illumination situations, with slightly lower amounts for cells grown under yellow and green light.

When grown at 23°C instead of 13°C, a dramatic decrease in total sterol amounts of cells was found, especially under blue light, with a 7-fold reduction. Such a temperature shift triggered a net inhibition of sterol biosynthesis, which was observed not to slow down the cell growth (data not shown). A similar but less important (1.4- to 3.7-fold) decrease in the total sterol content in cells of the chrysophyte *Ochromonas danica* was also reported to occur for growth temperature above 23°C (16).

Analysis of the different sterol classes. When grown at 13°C under white light, *P. tricornutum* was found to contain FS, but also SE, SG, and ASG. In contrast to most higher plant cells, FS were not the major compounds. The predominant sterol class was SG with 64% of total sterols (Table 1). FS represented 33% and ASG and SE together, only 3%. Such a repartition of sterols between the different classes was

found to be strongly dependent on the type of illumination. Whereas SG remained the main sterol conjugates under green and blue light, a marked increase in FS was observed under red light and in ASG under yellow light. In all situations, SE were minor forms of sterols.

When the culture temperature was raised to 23°C, a completely different distribution of sterols was observed. Under white light as well as under red and blue light, FS were the major compounds. SG were found to represent 50% of total sterols under yellow light and similar amounts of SG and SE (41 and 36%, respectively) were present in cells grown under green light.

Effects of light spectral quality and growth temperature on the sterol composition of each class. Sterol analysis. Nine sterols were identified in *P. tricornutum*. The major compound was by far 24-methylcholesta-5,22-dien-3β-ol (**4**) as already reported (3,9). The configuration at C-24 of this sterol was previously assigned to 24α (or 24*S*) (8); this compound therefore corresponding to epibrassicasterol. The second major sterol was found to be cholest-5-en-3β-ol (cholesterol) (**2**). Sterols with an ethyl group at C-24 such as (24ξ)-24-ethylcholest-5-en-3β-ol (**8**) and (24ξ)-24-ethylcholesta-5,22*E*-dien-3β-ol (**7**) were present in very low amounts, indicating that in *P. tricornutum* the enzyme involved in the second methylation step was not very active. Minor sterols, 5α-cholestan-3β-ol (cholestanol) (**3**), cholesta-5,22*E*-dien-3β-ol (22-dehydrocholesterol) (**1**), (24ξ)-24-methylcholesta-5,24(24^1)-dien-3β-ol (24-methylenecholesterol) (**5**), (24ξ)-24-methylcholest-5-en-3β-ol (**6**), and 24-ethylcholesta-5,24(24^1)*Z*-dien-3β-ol (isofucosterol) (**9**), were also identified in agreement with previous data (9). The C-24 stereochemistry was not determined in this work, but as *P. tricornutum* belongs to the order Pennales and contains both epibrassicasterol and isofucosterol, two sterols with a 24α-oriented alkyl group, all other 24-alkylsterols of this diatom likely have the same configuration (17). Diatoms from the order Pennales would be unique among algae, since most other algae contain sterols with a 24β-configuration (18).

Effects of light spectral quality at 13°C (Tables 2 to 6). Whatever the spectral nature of light illumination, epibrassicasterol (**4**) was the major compound of FS (between 68 and 95% of total FS). Cholesterol (**2**) accounted for only 2 to 5%, except for cells grown under red light (25%). Such cells were also found to contain 7% (24ξ)-24-ethylcholesta-5,22*E*-dien-3β-ol (**7**).

SE were characterized by a lower content in epibrassicasterol (**4**) compared to FS. Cholesterol (**2**) was the major sterol in SE for cells grown under white and blue light and 22-dehydrocholesterol (**1**), the major one under yellow and green light. Significant amounts of 24-ethylsterols were present under all light conditions.

SG and ASG were mainly constituted of epibrassicasterol (**4**), except for ASG from cells grown under red light in which cholesterol (**2**) was predominant. The C-24 alkylated sterols (**6**), (**7**), (**8**), and (**9**) were not detected as glycosylated conjugates, but other compounds with similar relative retention times have been found. They are designated as "unknown" in Tables 2 to 6. According to MS data, these compounds might correspond to hydroxylated derivatives of epibrassicasterol and cholesterol. However, conclusive determination of their structure requires nuclear magnetic resonance analysis.

Whatever the light spectral quality, 24-methylenecholesterol (**5**), a biosynthetic intermediate in the synthesis of epibrassicasterol (8), was never detected as a free compound.

Effects of light spectral quality at 23°C (Tables 2 to 6). In FS, epibrassicasterol (**4**) remained the major sterol, except for cells grown under green light. Cholesterol (**2**) was the second best represented compound.

Cholesterol (**2**) was present as the main sterol in SE. Significant amounts of 24-methylenecholesterol (**5**), were also detected.

The sterol composition of SG was dominated by epibrassicasterol in cells grown under white, red, green, and yellow light, but by cholesterol, under blue light. In ASG, epibrassicasterol (**4**), cholesterol (**2**), and 24-methylenecholesterol (**5**) were the major compounds.

DISCUSSION

Evidence is presented here that in *P. tricornutum,* as well as in higher plants (19) and in other types of algae (20), sterols occur as free, ester, and glycosylated forms. Under standard culture conditions (i.e., at 13°C under white light), free sterols are not the major compounds since 64% of total sterols are glycosylated. The occurrence of both SG and AGS suggests that an UDPG-sterol:β-Dglucosyltranferase and an SG:acyltransferase are likely involved in the synthesis of these compounds as demonstrated in the chlorophyte *Prototheca zopfii* (21).

Both the sterol profile inside each class and the distribution of sterols between free and conjugated forms were shown here for the first time to be closely dependent on illumination and growth temperature conditions. The temperature shift from 13 to 23°C was found to trigger a dramatic decrease in free and conjugated sterol biosynthesis. The slowing down of the biosynthesis was attested by the relative accumulation of 24-methylcholesterol (**5**) in SE, resulting in a lower flux of free precursors toward the synthesis of epibrassicasterol (**4**). Whatever the light conditions, an important increase in the relative percentage of cholesterol was also found in all forms of sterols, especially in SE, with a parallel decrease in the amount of epibrassicasterol, indicating a significant inhibition of the first methylation step at C-24.

Sterol glycosylation appears to be very sensitive to environmental changes. Thus, this process was found to be stimulated in cells grown at 13°C under red and blue light, but strongly inhibited at 23°C (a 100-fold decrease in SG under blue light and a 100-fold decrease in ASG under red light). SE synthesis appears to be much less sensitive to environmental changes.

Under blue light, the photosystems of *P. tricornutum* are expected to have their greatest efficiency in regard to carbon fixation and high amounts of chlorophylls *a* and *c* (22), in agreement with the life conditions of this temperate diatom in the euphotic zone of the ocean where blue light prevails. Such culture conditions under nonstressing light illumination could be used in order to study the physiological significance of drastic changes on sterol composition (i.e., shift from SG to FS and dominance of cholesteryl glycosides instead of epibrassicasteryl glycosides at 23°C), in particular their effect on properties of *P. tricornutum* membranes.

Although contents and proportions of algal fatty acids are considered the most important aspects of lipids in animal nutrition, dietary requirements for sterols in Bivalves and other marine invertebrates should be more closely investigated. Op-

timal amounts of sterols for animal growth and survival remain to be determined, but we have proven here that algal sterol contents, such as those exemplified by *P. tricornutum*, can be strongly modified by environmental factors. Whether or not sterol conjugates can satisfy the sterol requirement as efficiently as free forms has to be questioned. More suitable algal diets could therefore be provided in hatcheries by manipulating culture conditions.

ACKNOWLEDGMENTS

We wish to thank Olivier Lecurieux-Belfond for his assistance in extraction and purification of sterols. This research was supported by grants from the Syndicat Mixte pour l'Equipement du Littoral of the Conseil Général de la Manche and the Conseil Régional de Basse-Normandie and by a E.U. contract n°94/C 185/08.

A Simple Method for the Synthesis of Ceramides and Radiolabeled Analogues

Jasbir K. Anand*, Khalid K. Sadozai[1], and Sen-itiroh Hakomori[2]

The Biomembrane Institute, Seattle, Washington 98119-4237

ABSTRACT: A simple method has been developed for the coupling of amines to carboxylic acids. *N*-Fatty-acyl-sphingosine, cerebroside, and GM_3, as well as their respective [^{14}C] analogues, were synthesized using diethylphosphoryl cyanide as a potent coupling agent in the presence of triethylamine. The reaction procedure is rapid, racemization-free, and utilizes acids without derivatization. The desired ceramide products were obtained in 85–90% yield within one hour. The facile method presented here can also be used to synthesize [^{3}H]-*N*-acyl-labeled, as well as [^{14}C] [^{3}H] double-labeled, ceramides. *Lipids 31*, 995–998 (1996).

Ceramide (*N*-fatty acyl sphingosine) is the lipid moiety of sphingomyelin and all types of glycosphingolipids. It is considered the structural unit which anchors sphingolipids to biological membranes. It is the precursor as well as degradation product of sphingomyelin and glycosphingolipids (1). Recently, the functional role of ceramide as second messenger in transmembrane signaling has been the subject of great interest. When cells are stimulated by TNF-α, IL-1β, γ-interferon, dexamethasone, etc., ceramide content increases because of increased sphingomyelinase level and, consequently, activates ceramide-dependent kinases. This event leads to various phenotype changes, possibly through activation of transcription factors (see Refs. 2,3 for review). Ceramide can also be produced by hydrolysis of glucosyl- or galactosylceramide by β-glucosidase or β-galactosidase, as well as by endoceramidase (4,5).

The knowledge of the regulatory mechanisms for ceramide synthesis as a part of sphingolipid metabolism, and its degradation into sphingosine and fatty acid, is increasingly important. Thus the availability of [^{14}C]-labeled ceramide analogue, or preferably [^{14}C][^{3}H] double-labeled analogue, is highly desirable.

In order to study the effect of exogenous ceramides in cell growth and differentiation and to quantitate the ceramidase assay, we synthesized a variety of unlabeled, [^{14}C]-labeled, and [^{14}C][^{3}H] double-labeled ceramide homologues **3**, **5**, **8**, **10**, and **11** by a simple and convenient method.

Amides and ceramides are normally prepared using the acid anhydride (6,7), acid-halides (8,9) or by transacylation *via* fatty acid *N*-hydroxy succinimide (10,11) or by *p*-nitrophenyl esters (12,13). Alternative methods, using coupling agents as *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (14), dicyclohexylcarbodimide (15), or diphenyl phosphorazidate (16), have also been applied, but most of these reagents either require the removal of precipitated salts or result in unwanted side-products. These side-products adhere to the desired ceramides and cause interference in the biological assays. Some of these coupling agents have the tendency to inactivate at room temperature and some produce the undesired acid anhydrides, due to a rapid breakdown of the transition intermediate (17). Most of the reported procedures for the preparation of radiolabeled derivatives use the radioactive acids (acid derivatives) in large excess amount, as compared to amines, and thereby result in unnecessarily huge amounts of radioactive waste. In the procedure reported here, we used stoichiometeric amounts of the labeled acids, and we obtained the coupled products in almost quantitative yields.

MATERIALS AND METHODS

Sphingosine, **1**, was synthesized by the method of Herold (18). 1-[^{3}H]-Sphingosine, **4**, was generously supplied by Toyokuni *et al.* (19). Psychosine, **6**, was obtained by the alkaline hydrolysis of galactocerebroside isolated from bovine brain (20,21). *O*-(2-Methyl-5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-d-glycero-α-D-galacto-2-nonulopyranosylonate)-(2-3)-*O*-(2,4-di-*O*-acetyl-6-*O*-benzoyl-β-D-galactopyranosyl)-(1-4)-*O*-(3-*O*-acetyl-2,6-di-*O*-benzoyl-β-D-glucopyranosyl)-(1-1)-2S3R, 4E-3-*O*-pivolyl-2-amino-4-octadecene-1,3-diol (derivatised lyso-GM_3), **9**, was synthesized by the modified method of Murase *et al.* (22). Diethylphosphoryl cyanide (DEPC) was purchased from Aldrich Chemicals (Milwaukee, WI), sodium octonate [^{14}C] and [^{14}C] palmitic acid were purchased from ICN Chemicals (Cleveland, OH).

The ^{1}H nuclear magnetic resonance spectra were recorded on a Bruker (Karlsruhe, Germany) WM-500 spectrometer in

$CDCl_3$, $CDCl_3/CD_3OD$ (1:1), or dimethyl sulphoxide/D_2O (98:2). Thin-layer chromatography was performed on precoated silica gel plates (visualized by spraying with orcinol in H_2SO_4). Column chromatography was performed on silica gel. Fast atom bombardment–mass spectrometry was recorded on JEOL (Tokyo, Japan) JMS-10HX 110/DA-5000 mass spectrometer. Radioactivity was measured on a Beckman (Palo Alto, CA) LS 3801 liquid scintillation counter.

A representative procedure is as follows: Triethylamine (2.5 micromole) was added at 0°C to a stirred mixture of carboxylic acid (3 micromol), DEPC (6 micromole), and sphingoamine derivative (3 micromole) in a mixture of dimethylformamide and dichloromethane (2 mL, 1:3). The reaction mixture was stirred for 45 min at 0–30°C under argon, and progress of reaction was monitored by thin-layer chromatography with $CHCl_3/CH_3OH$ (18:2) solvent mixture. After the completion of reaction (45–60 min), the reaction mixture was evaporated under reduced pressure and the residue was subjected to column chromatography to isolate the desired ceramide derivatives with haxane, hexane/$CHCl_3$ (1:1), and $CHCl_3/CH_3OH$ (99:1).

Ceramides and cerebrosides: *N*-octanoyl-sphingosine **3a**, **3b**, and **5b** and *N*-palmitylpsychosine **8a** and **8b** were prepared, from sphingosine **1**, 1-[^{3}H]-sphingosine **4**, and psychosine **6**, respectively. *N*-Palmityl-GM_3 derivatives **10a** and **10b** were synthesized from the protected lyso-GM_3 **9** and later transformed into the unprotected derivatives **11a** and **11b** by treatment with $NaOCH_3$/NaOH.

Synthesis of all these ceramide derivatives was complete within one hour, as indicated by thin-layer chromatographic analysis of reaction mixtures. Prolongation of reaction time (up to 72 h) did not exhibit any appreciable increase in the yield of reaction.

The ^{1}H nuclear magnetic resonance and mass values of ceramides **3**, **5**, **8**, **10**, and **11**, were found to be in good agreement with the published data (Fig. 1).

Authentic samples of ceramides, *N*-octanoyl-sphingosine, psychosine, and GM_3 were compared with **3a**, **3b**, **5b**, **8a**, **8b**, **11a**, and **11b**, and found identical by thin-layer chromatographic co-spotting (Fig. 2), in addition to spectral data. The labeled ceramides **3b**, **5b**, **8b**, **10b**, and **11b** exhibited radioactive purity of 92–98%.

RESULTS AND DISCUSSION

We have synthesized ceramides (see Scheme 1): 2S, 3R, 4E-2-(*N*-octanoylamino-octadecene-1,3-diol (*N*-octanoyl-sphingosine), **3a**; 2S, 3R, 4E-1-*O*-(β-D-galactopyranosyl)-2-hexadecanoylamino-octadecene-1,3-diol [*N*-palmityl psychosine (cerebroside)], **8a**; and *O*-(5-*N*-acetylamino-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranosylonate)-(2-3)-*O*-(β-D-galactopyranosyl)-(1-4)-*O*-(β-D-glucopyranosyl)-(1-1)-2S, 3R, 4E-2-(*N*-hexadecanoylamino-4-octadecene-1,3-diol (*N*-palmityl GM_3), **11a**, as well as their [^{14}C]-labeled analogues, **3b**, **8b**, and **11b**, respectively. A double-labeled ceramide: *N*-[^{14}C]-octanoyl-1-[^{3}H]-sphingosine, **5b**, was also synthesized.

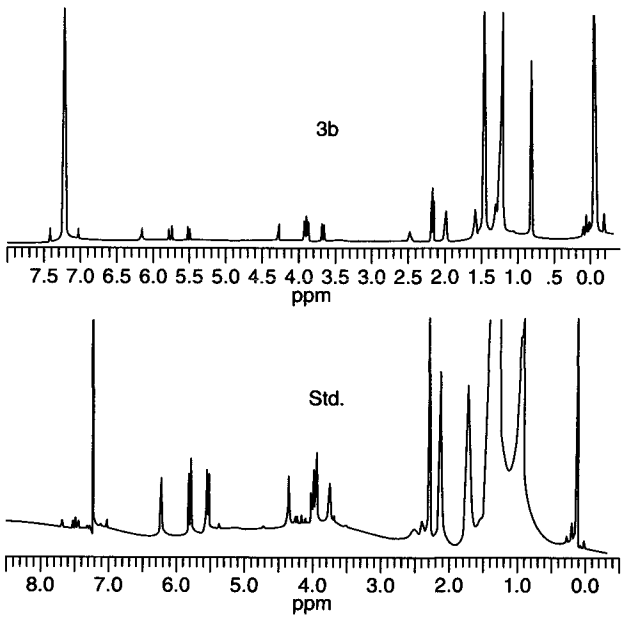

FIG. 1. The ^{1}H nuclear magnetic resonance spectrum of *N*-octanoyl-sphingosine **3b** and **std.** recorded in $CDCl_3$.

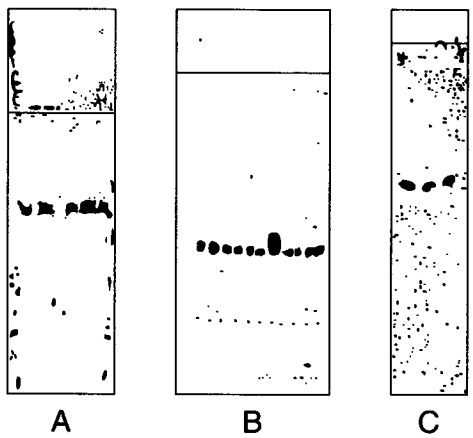

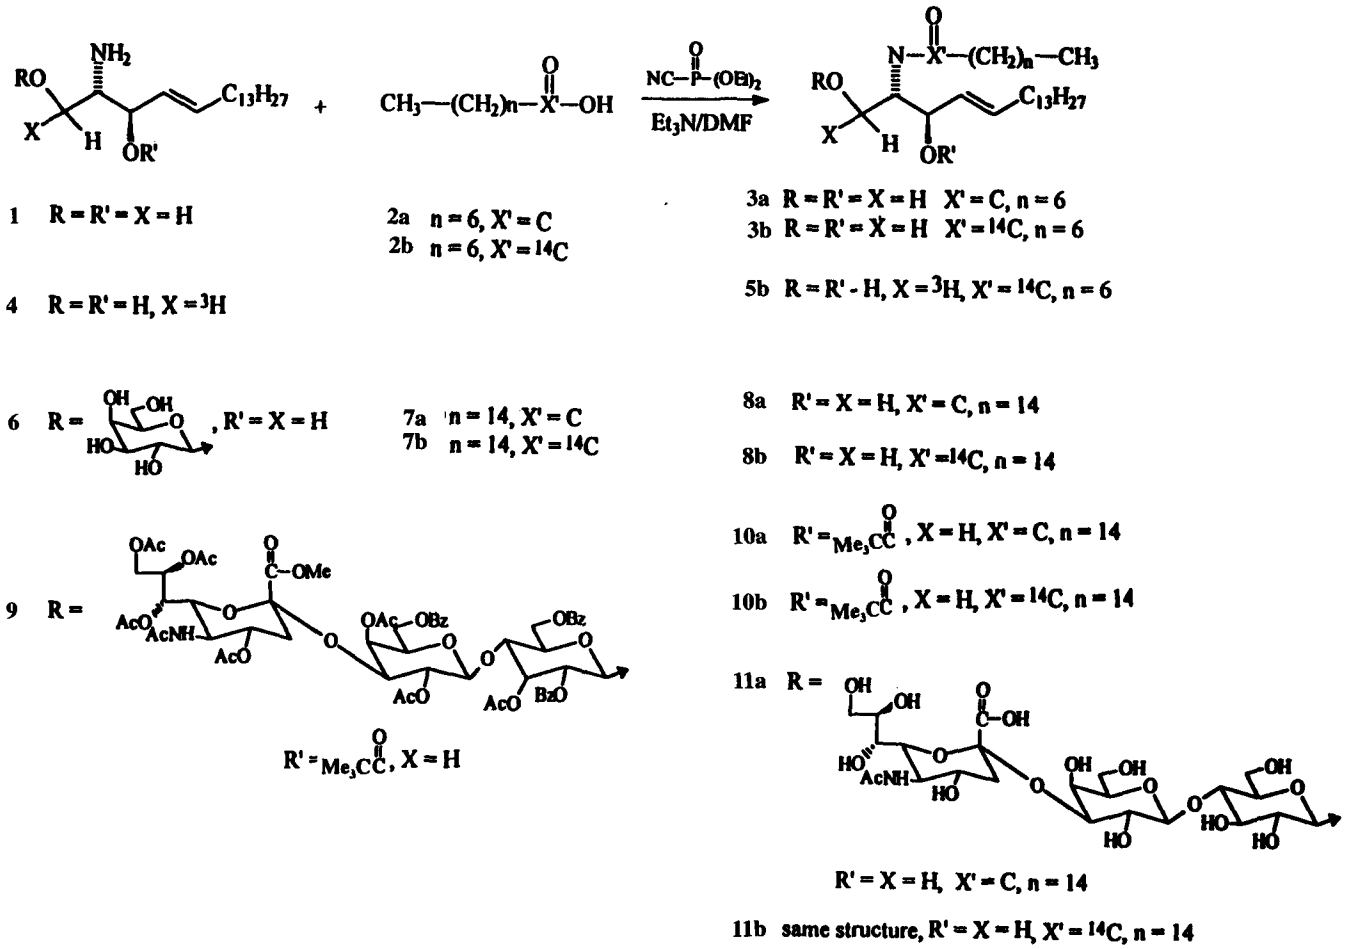

FIG. 2. Thin-layer chromatograms comparing the authentic samples with respective ceramide analogues. A : *N*-Octanoyl-sphingosine **3b**, **std.** and **5b** [$CHCl_3$:CH_3OH (18:2)]; B: *N*-Palmityl-psychosine **8b** and **std.** [$CHCl_3$:CH_3OH (17:3)] and C: *N*-Palmityl-GM_3 **11b** and **std.** [$CHCl_3$:CH_3OH (18:2)].

All of the above ceramides were obtained in 85–90% overall yields, using a facile synthetic procedure in which DEPC was used as a coupling agent. DEPC was first introduced by Yamada *et al.* (23,24) in 1973 as an efficient coupling agent for peptide synthesis. In their report the group also specified that the cyano intermediate formed after the action of DEPC can react with hydroxyl group, if left unprotected, to produce an ester derivative of the acid. However, during our synthetic studies, when we reacted different sphingoamines containing unprotected hydroxyl group with various carboxylic acids and

SCHEME 1

their [^{14}C] analogues, we obtained exclusively the desired ceramide products. Also, we did not obtain any esterified side-products due to the fatty acid and free hydroxyl group coupling.

The simple method described here is rapid, convenient, and 95% of the reaction takes place within the first 40 min, producing the desired ceramides with complete retention of configuration. During our isolation step, we have eliminated the aqueous work-up of the reaction mixture and thus reduced the extent of radioactive waste and exposure.

Bisallylic Hydroxylation and Epoxidation of Polyunsaturated Fatty Acids by Cytochrome P450

Ernst H. Oliw[a,*], Johan Bylund[a], and Ceil Herman[b]

[a]Division of Biochemical Pharmacology, Department of Pharmaceutical Biosciences, Uppsala University Biomedical Center, S-751 24 Uppsala, Sweden, and [b]Department of Biology, New Mexico State University, Las Cruces, New Mexico 88003

ABSTRACT: Polyunsaturated fatty acids can be oxygenated by cytochrome P450 to hydroxy and epoxy fatty acids. Two major classes of hydroxy fatty acids are formed by hydroxylation of the ω-side chain and by hydroxylation of bisallylic methylene carbons. Bisallylic cytochrome P450-hydroxylases transform linoleic acid to 11-hydroxylinoleic acid, arachidonic acid to 13-hydroxyeicosa-5*Z*,8*Z*,11*Z*,14*Z*-tetraenoic acid, 10-hydroxyeicosa-5*Z*,8*Z*,11*Z*,14*Z*-tetraenoic acid and 7-hydroxyeicosa-5*Z*,8*Z*,11*Z*,14*Z*-tetraenoic acid and eicosapentaenoic acid to 16-hydroxyeicosa-5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-pentaenoic acid, 13-hydroxyeicosa-5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-pentaenoic acid and 10-hydroxyeicosa-5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-pentaenoic acid as major metabolites. The bisallylic hydroxy fatty acids are chemically unstable and decompose rapidly to *cis-trans* conjugated hydroxy fatty acids during acidic extractive isolation. Bisallylic hydroxylase activity appears to be augmented in microsomes induced by the synthetic glucocorticoid dexamethasone and by some other agents, but the P450 gene families of these hydroxylases have yet to be determined. The fatty acid epoxides, which are formed by cytochrome P450, are chemically stable, but are hydrolyzed to diols by soluble epoxide hydrolases. Epoxidation of polyunsaturated fatty acids is a prominent pathway of metabolism in the liver and the renal cortex and epoxygenase activity appears to be under homeostatic control in the kidney. Many arachidonate epoxygenases have been identified belonging to the CYP2C gene subfamily. Epoxygenases have also been found in the central nervous system, endocrine organs, the heart and endothelial cells. Epoxides of arachidonic acid have been found to exert pharmacological effects on many cells.

Lipids 31, 1003–1021 (1996).

Cytochrome P450 (P450) designates a group of heme-thiolate proteins, which catalyze oxygenation of xenobiotics and endogenous compounds, e.g., fatty acids, lipid hydroperoxides, steroids, bile acids, retinoids, prostaglandins, leukotrienes, and cytokines (1–3). The mammalian P450 enzymes are formed from a gene superfamily presently comprising 14 gene families and 26 subfamilies (2,4). Over 400 P450 have been cloned and sequenced and about 200 of them are mammalian (e.g., 35 human, 48 rat, 29 mice, and 28 rabbit P450; Ref. 4).

According to recent work, the P450 gene superfamily has a long history of evolution (2). The ancestral gene may have existed 3.5 billion years ago. Many P450 can be induced by xenobiotics, often as part of a detoxification process, and the induction of P450 has attracted attention as an example of gene regulation by drugs (5). The evolution of P450 suggests that P450 gene regulation might have evolved as a metabolic regulatory pathway for endogenous compounds and among them, fatty acids.

The atomic, three-dimensional structure of a mammalian P450 has not yet been determined. P450 is also present in plants, fungi, and bacteria. The fatty acid monooxygenase P450BM-3 of *Bacillus megaterium*, P450cam of *Pseudomonas putida,* P450terp of a *Pseudomonas* species, and P450eryF of *Saccharopolyspora erythrea* have been crystallized and have provided three-dimensional structural and catalytic information on P450 (6–10,11). Reviews on the P450 gene superfamily with update on new sequences, gene mapping, and recommended nomenclature are published regularly (see Ref. 2), and recent information can also be conveniently obtained from the Internet (4,11).

OXYGENATION OF POLYUNSATURATED FATTY ACIDS

Arachidonic acid, linoleic acid, and other polyunsaturated fatty acids (PUFA) can be oxygenated by P450 in several

ways: (i) hydroxylations of the ω-side chain (ω1, ω2, ω3, etc.); (ii) hydroxylation of bisallylic carbons; (iii) epoxidation; (iv) hydroxylation of allylic carbons; (v) hydroxylation with double-bond migration.

The first three oxygenation mechanisms are quantitatively predominant. The oxygenation of arachidonic acid by bisallylic P450-hydroxylases and P450-epoxygenases is summarized in Figure 1. Many other PUFA can be oxygenated in the same way. Arachidonic acid has been intensively investigated due to its biological importance as a precursor of autacoids in mammals. Linoleic acid seems to have a corresponding function in lower organisms, algae and fungi, and in plants. Linoleic acid is also a major unsaturated fatty acid in the human diet. The present review will focus on bisallylic hydroxylations and epoxidations of PUFA, and in particular on linoleic, arachidonic, and eicosapentaenoic acids. As regards nomenclature, the recommendations on abbreviations (12) will be followed. Epoxyeicosatrienoic acid and the corresponding dihydroxyeicosatrienoic acid are often, and incorrectly, abbreviated to EET and to DHET by many investigators. We will use the abbreviations EpETrE and DiHETrE according to the standard nomenclature only to avoid confusion with other epoxides and diols of unsaturated eicosanoic fatty acids. We do so with some reluctance. EET is a widely recognized and obviously a more convenient abbreviation than EpETrE.

BISALLYLIC HYDROXYLATIONS

Early studies clearly demonstrated that arachidonic acid was converted enzymatically, and not by lipid peroxidation, to six *cis-trans* conjugated hydroxyeicosatetraenoic acids (HETE) by rat liver microsomes and NADPH (13–15). Steric analysis showed that five of the six *cis-trans* conjugated HETE were racemic or nearly racemic mixtures. One compound, 12*R*-hydroxy-5*Z*,8*Z*,10*E*,14*Z*-eicosatetraenoic acid (12*R*-HETE), was formed with stereoselectivity (81%) (16). The mechanism of biosynthesis was not determined. A hypothetical pathway for biosynthesis of 12*R*-HETE from 11,12-epoxy-5,8,14-eicosatrieonic acid (11,12-EpETrE) was proposed (see Ref. 17 for review). Many aspects of the biosynthesis of HETE by P450 remained conjectural, and it was unknown whether these HETE contained oxygen from air or water.

It is well established that the mechanism of ω2-hydroxylation of fatty acids by P450 involves hydrogen abstraction and insertion of the hydroxyl group with retention of configuration (18). More recently, the ω-hydroxylation of (1*R*)- and (1*S*)-[1-^{3}H, ^{2}H, ^{1}H;1-^{14}C]octane to 1-octanol by microsomes of rat liver and NADPH was investigated by Shapiro *et al.* (19). They found that the incoming hydroxyl assumed the configuration of the displaced hydrogen. However, there are exceptions to this rule. The incoming hydroxyl may also assume the opposite configuration (20). For this and other reasons, it

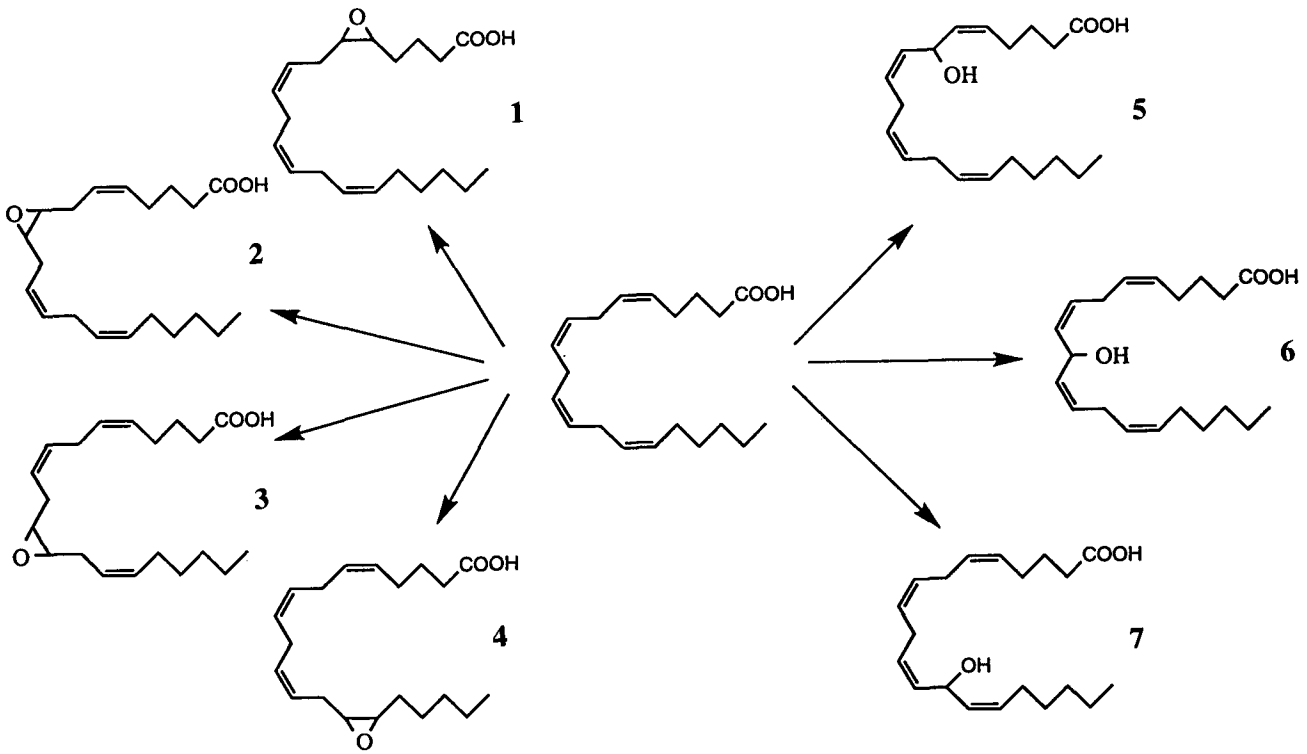

FIG. 1. Epoxidation and bisallylic hydroxylation of arachidonic acid by hepatic monooxygenases. The structures marked 1, 2, 3, and 4 designate the 5,6-, 8,9-, 11,12-, and 14,15-epoxides of arachidonic acid, respectively, while 5, 6, and 7 designate 7-hydroxyeicosa-5*Z*,8*Z*,11*Z*,14*Z*-tetraenoic acid (HETE), 10-HETE and 13-HETE, respectively.

seemed of interest to determine the mechanism of hydrogen abstraction and oxygenation during P450-catalyzed biosynthesis of *cis-trans* conjugated HETE. For simplicity, linoleic acid was chosen as a model substrate. The results were then extended to arachidonic and eicosapentaenoic acids.

Linoleic acid was metabolized by liver microsomes from untreated or phenobarbital-treated rats in the presence of NADPH to a large number of metabolites (21). Many metabolites had been previously identified as products formed by epoxidation and ω side-chain hydroxylations (22–24). Novel metabolites were 8-hydroxy-9,12-octadecadienoic acid (8-HODE), 11-HODE, and 14-HODE. In addition, two *cis-trans* conjugated hydroxy fatty acids, 9-HODE and 13-HODE, were detected. 11-HODE (59% *R*) was found to be a major metabolite, provided that the metabolites were extracted at pH 5–6 (21). Under these conditions, only small amounts of 13-HODE and 9-HODE were formed. Steric analysis revealed that 13-HODE and 9-HODE consisted mainly of the *R* enantiomers (>80%), while 11-HODE was almost racemic.

11-HODE was first identified by Hamberg *et al.* (25) in a red alga, *Lithothamnion corallioides*. These investigators found that 11-HODE was unstable in acidic media and converted to equal amounts of racemic 9-HODE and racemic 13-HODE (25). The latter contained oxygen from water. To avoid decomposition, the pH during extractive isolation of 11-HODE should be neutral or above pH 5.

Experiments under $^{18}O_2$ gas showed that 11-HODE was formed in liver microsomes by incorporation of oxygen from air (21). 13*R*-HODE and 9*R*-HODE also contained oxygen from air. The mechanism of biosynthesis of 9-, 11-, and 13-HODE was studied with stereospecifically deuterated linoleic acids. When [11*R*-^{2}H]linoleic and [11*S*-^{2}H]linoleic acids were used as substrates, the analysis showed a suprafacial relationship between oxygen insertion and hydrogen abstraction at C_{11} of the three enzymatic products, 11*R,S*-HODE, 9*R*-HODE, and 13*R*-HODE. A mechanism for the biosynthesis of these metabolites is proposed in Figure 2. 11-HODE was formed by hydroxylation of C_{11}, a process designated bisallylic hydroxylation. The two minor products, 8-HODE and 14-HODE, were formed by allylic hydroxylation, i.e., by hydroxylations of the allylic carbons C_8 and C_{14}, respectively. The experiments with stereospecifically deuterated linoleic acid indicated that 9*R*-HODE and 13*R*-HODE were formed by hydrogen abstraction at C_{11}, migration of the double bond, and suprafacial oxygen insertion at C_9 or C_{13} (Fig. 2). This sequence was designated hydroxylation with double-bond migration. To abstract hydrogen from the bisallylic methylene carbon requires about 10 kcal/mol less energy than abstraction of an allylic hydrogen and considerably less energy than abstraction of a methyl hydrogen (26).

In analogy with biosynthesis of 11-HODE from linoleic acid, arachidonic acid was found to be hydroxylated at C_{13},

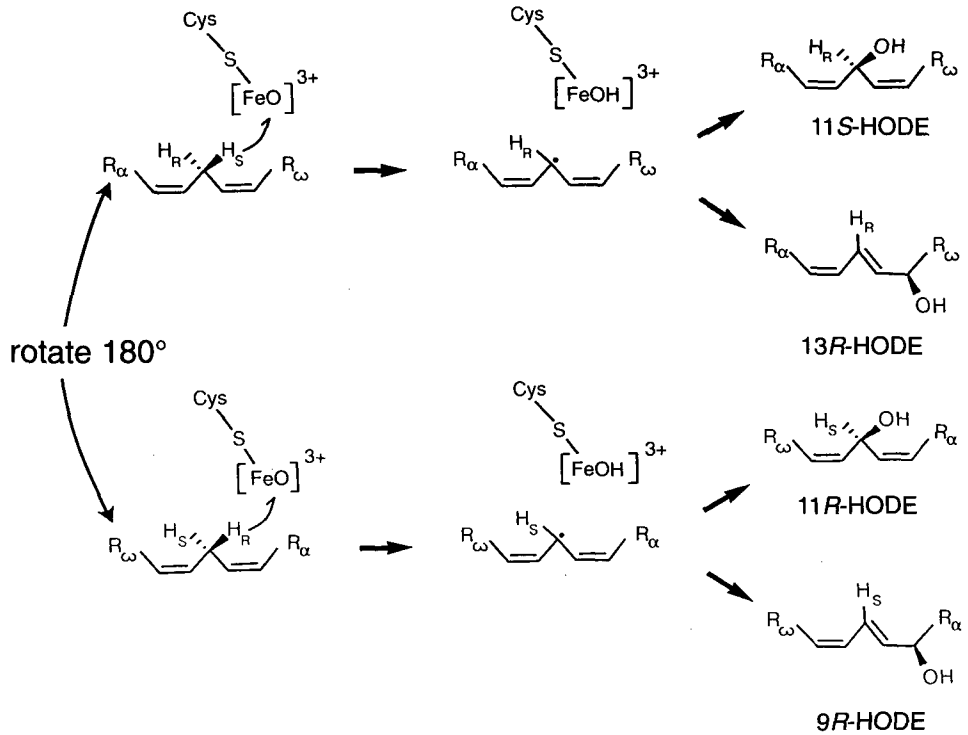

FIG. 2. A mechanism for the biosynthesis of 11-hydroxyoctadecadienoic acid (HODE), 13*R*-HODE, and 9*R*-HODE from linoleic acid. The substrate is rotated 180 degrees in the lower sequence. Top, biosyntheis of 11*S*-HODE and 13*R*-HODE *via* abstraction of the pro-*S* hydrogen. Bottom, biosynthesis of 11*R*-HODE and 9*R*-HODE *via* abstraction of the pro-*R* hydrogen. R_ω and R_α designate the terminal side chain and the carboxyl side chain, respectively.

the ω8 carbon, by monkey and human hepatic P450 to 13-HETE (27). Many other hydroxy metabolites were formed including 12*R*-HETE. The mechanism of biosynthesis of 12*R*-HETE is still enigmatic. It seems possible that 12*R*-HETE might be formed by hydrogen abstraction at C_{10}, double-bond migration and oxygen insertion at C_{12} in analogy with the biosynthesis of 13*R*-HODE from linoleic acid. This hypothesis should be tested with stereospecifically labeled arachidonic acid in position C_{10} and also with experiments under $^{18}O_2$ gas.

Brash *et al.* (28) investigated arachidonic acid metabolism by bisallylic hydroxylases of liver microsomes of phenobarbital-treated rats. Two novel metabolites were identified, 7-HETE and 10-HETE, as well as 13-HETE. The results showed that bisallylic hydroxylases may oxygenate all three bisallylic methylene carbons of arachidonic acid without positional selectivity. As described below, the major form of phenobarbital-induced P450 (CYP2B1) will epoxidize all four double bonds of arachidonic acid, while other epoxygenases show selectivity. Brash *et al.* (28) also made the unexpected observation that the bisallylic hydroxyl oxygen may, under certain conditions, be retained in the *cis-trans* conjugated products formed by acidic catalyzed decomposition of 13-HETE, 10-HETE, and 7-HETE.

11-HODE from linoleic acid and 13-HETE, 10-HETE, and 7-HETE from arachidonic acid were prominent metabolites of hepatic microsomes of phenobarbital-treated rats. 11-HODE and 18-HODE were formed in about equal amounts (21). The amounts of 13-HETE, 10-HETE, 7-HETE, 19-HETE, and 20-HETE were also of the same order of magnitude (28).

The bisallylic P450-hydroxylases have not been characterized with respect to their P450 gene families or subfamilies. Five different purified rat P450, i.e., CYP1A1, CYP2B1, CYP2B4, CYP2E1, and CYP4A1, and one rabbit P450 (CYP3A6) were investigated in a reconstituted system for bisallylic hydroxylase activity, but none of these formed significant amounts of [^{14}C]11-HODE from [^{14}C]linoleic acid (27). The negative results may partly be due to difficulties with reconstitution of the CYP3A subfamily (29).

Another approach was to study bisallylic hydroxylase activity by liver microsomes of treated rats. Drugs from five different classes of inducers of P450 were investigated (30), viz., β-naphthoflavone as an aromatic hydrocarbon-inducer (e.g., CYP1A), clofibrate as a peroxisome proliferator-inducer (CYP4A), the synthetic glucocorticoid dexamethasone as a steroid-inducer (CYP3A), phenobarbital as a prototype inducer (CYP2B), and acetone-starvation and isopropanol for CYP2E1. These agents may also induce many other P450 (5). CYP3A1 is also induced by phenobarbital and by ethanol or isopentanol (31,32).

All liver microsomes formed 18-HODE as a major metabolite while 11-HODE and 17-HODE were present in variable amounts. Liver microsomes of β-naphthoflavone-treated rats hydroxylated [^{14}C]linoleic acid at carbons 8, 11, 14, 16, 17, and 18. In addition, 9-HODE and 13-HODE were also formed. Microsomes of phenobarbital-treated rats formed essentially the same metabolites (21,28,30). 11-HODE was apparently formed without selectivity by liver microsomes of β-naphthoflavone and phenobarbital-treated rats. Liver microsomes of rats treated with acetone plus starvation or isopropanol also metabolized linoleic acid to 11-HODE along with large quantities of other hydroxy metabolites. These agents induce CYP2E1, which does not show bisallylic hydroxylase activity, as well as other P450, e.g., CYP3A1 (31). Clofibrate, which is a well-known inducer of ω1 hydroxylation (32,33), did not augment the biosynthesis of 11-HODE.

Liver microsomes of dexamethasone-treated Spague-Dawley and Fischer rats showed an augmented bisallylic hydroxylase activity (30). The two main metabolites of linoleic acid were 11-HODE and 18-HODE. Only small amounts of other hydroxy fatty acids were formed. Reverse phase–high-performance liquid chromatography (HPLC) analysis showed that dexamethasone treatment consistently increased formation of 11-HODE about tenfold in comparison with control rats (Fig. 3). Troleandomycin, an inhibitor of CYP3A (34), reduced the biosynthesis of 11-HODE (Fig. 3).

Bisallylic hydroxylations of arachidonic and eicosapentaenoic acids were also investigated (30). Microsomes of dexamethasone-treated rats formed mainly 13-HETE, 7-HETE, and 10-HETE, and only small amounts of 20-HETE and 19-HETE from [^{14}C]20:4n-6, while control microsomes formed 20-HETE, 13-HETE, and 19-HETE as the three major products. Microsomes of dexamethasone-treated rats converted [^{14}C]20:5n-3 to 13-hydroxyeicosapentaenoic acid (13-HEPE), 16-HEPE, and 10-HEPE as major bisallylic hydroxy metabolites and to 20-HEPE and 19-HEPE.

These results suggest that bisallylic hydroxylases for linoleic, arachidonic, and eicosapentaenoic acids could be induced by dexamethasone treatment of Sprague-Dawley and Fischer rats. Whether the bisallylic hydroxylases mainly belong to the CYP3A subfamily will await future studies with purified enzymes or expressed cDNA.

Bisallylic hydroxylases may be present in other gene families. Rifkind *et al.* (35) reported that five out of ten cDNA-

B, microsomes from dexamethasone-treated rats. C, microsomes from dexamethasone-treated rats incubated in the presence of 10 μM troleandomycin. The filled circle marks 11-HODE. See Figure 2 for abbreviations.

expressed human P450 in HepG2 cells converted arachidonic acid to significant amounts of *cis-trans* conjugated HETE (CYP2C9 20% of total metabolites; CYP1A2 15%; CYP2C8 6%; CYP2B6 6%; CYP3A4, 5%). Whether these HETE were formed enzymically, by lipid peroxidation or from acid-catalyzed decomposition of bisallylic hydroxy metabolites was not determined. The incubations were terminated by addition of 0.8 vol of glacial acetic acid, which would readily decompose any bisallylic hydroxy fatty acids present. It therefore seems promising to investigate the CYP1A, CYP2C, and the CYP3A subfamilies for bisallylic hydroxylases.

Whether bisallylic metabolites of arachidonic acid were formed by β-naphthoflavone-induced P450 has not been investigated. Purified hepatic P450 from β-naphthoflavone-treated rabbits and rats mainly formed 19-HETE (36–38), while more recent studies have demonstrated that C_{16} to C_{18} of arachidonic acid can be hydroxylated by microsomes of β-naphthoflavone, 3,4,5,3′,4′-pentachlorobiphenyl- or 3-methylcholanthrene-treated rats (39,40).

The tissue and species distribution of bisallylic P450-hydroxylases has not yet been studied systematically. Hepatic microsomes of several species contain bisallylic hydroxylase activity (27). It remains to be determined whether these enzymes are present in kidney cortex, the lung, or in other organs rich in P450.

Allylic and bisallylic hydroxy fatty acids are formed by lower organisms. 11*R*-HODE, 13-HETE, and 13-HEPE have been found in red algae, *L. corallioides et calcareum* (25,41), while 8*R*-HODE and its precursor hydroperoxy precursor, 8*R*-HPODE, are formed by two fungi, *Gaeumannomyces graminis* and *Laetisaria arvalis* (22,42–44). The fungal biosynthesis of 8*R*-HPODE is catalyzed by linoleic acid 8*R*-dioxygenase, which is a hemoprotein (45). The algae biosynthesize the bisallylic hydroxy fatty acids by incorporation of oxygen derived from water and thus by enzymes other than mono- or dioxygenases (25,46).

METABOLIC FATE

Fatty acid epoxides and their vicinal diol products are rapidly incorporated into phospholipids. Whether bisallylic hydroxy fatty acids can be incorporated into phospholipids has not been determined. It is unknown whether metabolites formed by bisallylic hydroxylations (11-HODE, 13-HETE, 10-HETE, 7-HETE, etc.) are of quantitative importance in the breakdown of linoleic and arachidonic acids. The bisallylic hydroxy fatty acids formed by liver microsomes of phenobarbital-treated rats are mainly racemic (21,28), which argues against a role as autacoids. More knowledge in this area is likely to follow in the near future.

EPOXIDATION

Epoxides of olefins were demonstrated in 1970 to be obligatory intermediates in the metabolism of olefins to 1,2-diols by rat liver microsomes (47). Epoxidation of oleic acid to *cis*-9,10-epoxystearic acid by liver microsomes, NADPH and molecular oxygen, with subsequent enzymatic hydrolysis to *threo*-9,10-dihydroxystearic acid, was reported by Watabe *et al.* (48,49).

The first structural analysis of mammalian P450 metabolites of arachidonic acid was performed in the rabbit kidney (50). Microsomes of rabbit renal cortex and NADPH were found to metabolize [^{14}C]arachidonic acid extensively to a large series of metabolites. Two of the major metabolites were identified as 14,15-dihydroxy-5,8,11-eicosatrienoic (14,15-DiHETrE) and 11,12-DiHETrE. Two epoxides, 14,15-EpETrE and 11,12-EpETrE, were postulated as intermediates in their biosynthesis. In addition, metabolites of arachidonic acid formed by ω1- and ω2-hydroxylation and by ω-oxidation were also identified.

The biosynthesis of the two diols by renal cortical microsomes required NADPH and it was not supported by NADH (50). Carbon monoxide inhibited the biosynthesis. Liver microsomes and NADPH catalyzed the same reaction, and the mechanism of biosynthesis of 14,15-DiHETrE and 11,12-DiHETrE were investigated in rabbit liver microsomes (51). Biosynthesis under an atmosphere of $^{18}O_2$ led to incorporation of only one ^{18}O atom into the diols. This suggested that the diols were formed from epoxides by hydrolysis, according to the established mechanism of diol formation (47–49). In addition to the diols, trihydroxy metabolites were also identified as polar metabolites in both rabbit renal cortex and in liver microsomes (51,52). These products were formed by ω1- and ω2-hydroxylation of 14,15-DiHETrE and 11,12-DiHETrE.

Three issues remained to be solved regarding the microsomal biosynthesis of diols. First, the postulated epoxide intermediates should be isolated in order to prove the oxygenation mechanism. Second, it should be determined whether these metabolites were formed by intact cells, whole organs, and *in vivo*. Third, the P450 gene families of constitutive P450-epoxygenases of arachidonic acid should be determined.

The first question was solved with isolation of the four epoxides of arachidonic acid. They were isolated either from microsomal preparations with little epoxide hydrolase activity, with the aid of epoxide hydrolase inhibitors, or from purified phenobarbital-induced rat and rabbit liver P450 (CYP2B1 and CYP2B4, respectively) in a reconstituted system (36). Two novel diols, 5,6-dihydroxy-8,11,14-eicosatrienoic acid (5,6-DiHETrE) and 8,9-dihydroxy-5,11,14-eicosatrienoic acid (8,9-DiHETrE), were also identified. Epoxides of arachidonic acid were converted by purified microsomal epoxide hydrolase to diols. Rabbit liver and renal cortical microsomes also formed small amounts of 5,6- and 8,9-DiHETrE (23). The isolation of epoxides formed from arachidonic acid by rat liver microsomes was also reported (53). Falck *et al.* (54) then determined the absolute configuration of epoxides formed by phenobarbital-induced, purified rat liver P450. With the exception of 5,6-epoxy-8,11,14-eicosatrienoic acid (5,6-EpETrE), the products were formed with significant stereoselectivity. For example, 14,15-EpETrE

consisted of 80% *R,S* and 20% *S,R*, while 8,9-epoxy-5,11,14-eicosatrienoic acid (8,9-EpETrE) and 11,12-EpETrE were almost enantiomerically pure (97% of the *R,S* and *S,R* enantiomers, respectively). These results were important, since racemic epoxides of fatty acids can be formed by nonenzymatic peroxidation (55).

Rat hepatocytes and renal cells were found to metabolize arachidonic acid to 14,15-DiHETrE and 11,12-DiHETrE (23). These diols were detected in rabbit liver and rabbit renal cortex and appeared to be formed endogenously. Epoxides of arachidonic acid were also detected in rabbit kidney (56), human urine (57), human plasma (58), rat liver (59), rat urine (60), and rat plasma (61). DiHETrE were also excreted in human urine (61). However, epoxides can also be formed nonenzymatically, and all these studies did not conclusively demonstrate enzymatic biosynthesis of epoxides *in vivo*.

Evidence for *in vivo* formation of epoxides of arachidonic acid in the liver and renal cortex was soon provided. Karara *et al.* (62) determined the absolute configuration of endogenous epoxides of the liver of untreated or phenobarbital-treated rats by chiral HPLC. The epoxides were derived from hepatic phospholipids by mild alkaline hydrolysis. 8,9-EpETrE and 11,12-EpETrE consisted mainly of the *S,R* enantiomers (79 and 63% of untreated and 99 and 83% in phenobarbital-treated livers, respectively) and 14,15-EpETrE of the *R,S* enantiomer (77 and 94%, respectively). Phenobarbital treatment thus had a large effect on the stereochemistry of the epoxides of hepatic phospholipids. This indicated *in vivo* biosynthesis. Except for the enantiomeric composition of 8,9-EpETrE, there was good agreement between the enantiomers in phospholipids and the enantiomers formed by phenobarbital-induced rat liver microsomes (54). Liver microsomes of untreated and phenobarbital-treated rats formed different enantiomers of 11,12-EpETrE *in vitro*. 11*R*,12*S*-EpETrE was the major enantiomer (81%) in control microsomes and 11*S*,12*R*-EpETrE the major product (83%) by phenobarbital-induced microsomes (33).

In the human kidney cortex (63), 8,9-EpETrE was racemic and the *R,S* enantiomers of 11,12-EpETrE and 14,15-EpETrE dominated (80 and 66%, respectively). 14,15-EpETrE was the major epoxide (44%), followed by 11,12-EpETrE (33%) and 8,9-EpETrE (23%). Karara *et al.* (64) also demonstrated an enantioselective preference for incorporation of 8*S*,9*R*-EpETrE, 11*S*,12*R*-EpETrE, and 14*R*,15*S*-EpETrE at *sn*-2 of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol of rat liver. These enantiomers were also identified after hydrolysis of phospholipids.

The third question was to identify the constitutive P450 gene families which contain arachidonic acid epoxygenases. This is still under investigation, and interesting results have emerged in the last years. The first approach was to examine purified P450 for epoxygenase activity in comparison with microsomes. The studies above showed that renal and hepatic microsomes of rats and rabbits predominantly oxygenated the 14,15 and 11,12 double bonds of arachidonic acid, while the 5,6 and the 8,9 double bonds were less prone to be oxygenated (50–52,54). Monkey liver microsomes yielded this pattern as well (65). In contrast, phenobarbital-induced liver microsomes and purified phenobarbital-induced P450 of rats (CYP2B1), rabbits (CYP2B4), and pigs oxygenated all four double bonds equally (36,53). Purified P450 from human livers of deceased with unknown drug histories were also found to epoxidize all double bonds of arachidonic acid (66). Only recently have P450 which differ from these patterns of oxygenation been found.

An arachidonic acid epoxygenase was purified from rabbit renal cortex and designated P450 2CAA (67). P450 2CAA formed 11,12-EpETrE (about 45% of total metabolites) and 14,15-EpETrE (about 30% of total metabolites) as the two major products. These results are interesting since they demonstrate some regiospecific oxygenation of the 11,12 double bond of arachidonic acid. Laethem and Koop (68) showed that rabbit CYP2C1, transiently expressed in COS-1 cells, catalyzed biosynthesis of 11,12-EpETrE, 14,15-EpETrE and 19-HETE (about 48, 16, and 13%, respectively), while rabbit CYP2C2 in the same system yielded only the two epoxides (11,12-EpETrE and 14,15-EpETrE) in a ratio of 2:1, respectively. P450 2CAA and CYP2C2 formed the epoxides with some stereoselectivity, 63 and 61% 11*S*,12*R*-EpETrE, respectively, and 72 and 62% 14*R*,15*S*-EpETrE, respectively (69). Purified P450 2CAA had a slightly larger molecular weight than CYP2C2 on polyacrylamide gel electrophoresis, but identical amino-terminal sequence. It seems likely that P450 2CAA and CYP2C2 are very similar but not identical isoforms (68).

The epoxygenases of the rat and human kidney cortex have been investigated (60,70). Rat kidney microsomal epoxygenase formed 8*R*,9*S*-, 11*R*,12*S*-, and 14*S*,15*R*-EpETrE with optical purities of 97, 88, and 70%, respectively. Inhibition studies with antibodies against P450 isoforms indicated that the epoxygenase belonged to the CYP2C gene family. The renal epoxygenase was cloned and found to be virtually identical with rat liver CYP2C23 (71). Expressed in COS-1 cells, the recombinant rat kidney epoxygenase formed the three epoxides with virtually identical optical purity with that of renal cortical microsomes (95, 85, and 75%, respectively). 11,12-EpETrE was the main product (54%), followed by 8,9- and 14,15-EpETrE (27% and 14%, respectively). In the human kidney cortex, CYP2C8 was identified as one of the P450-epoxygenase isoforms. Metabolism of arachidonic acid by recombinant CYP2C8 was both regio- and enantioselective for 11*R*,12*S*- and 14*R*,15*S*-EpETrE.

The identification of the CYP2C gene family as constitutive renal epoxygenases, which oxygenate the 11,12- and 14,15-double bonds with enantioselectivity, is of physiological interest. Rat renal cortical epoxygenase activity is induced by salt loading (60). Whether salt loading will induce epoxygenases in kidneys of other species is unknown, but this interesting finding in the rat suggests additional studies are necessary.

Site-directed mutants of CYP2B1 have been investigated

as epoxygenases of arachidonic acid (72). The substrate specificity of a P450 can be altered by an amino acid mutation at a few key positions in the substrate-heme pocket (73,74). CYP2B1 predominantly produced 14,15-EpETrE, but mutation of two important amino acids, Ile-114 or Gly-478, had profound effects on the biosynthesis of epoxides. For example, double mutation of CYP2B1 with Ala at these two positions yielded an active enzyme, which formed 8,9- and 5,6-EpETrE as the two main products. These elegant results suggest that Ile-114 and Gly-478 may change the orientation and oxygenation of the fatty acid in the active site. In regard to the mechanism of formation of epoxides, Groves *et al.* (75) have shown that epoxidation of propylene by CYP2B4 occurs with a concomitant, stereospecific hydrogen/deuterium exchange from the aqueous milieu. Epoxides of fatty acids could be expected to be formed in the same way, but this has not been determined.

An epoxygenase of arachidonic acid has also been purified from chick embryo livers after pretreatment with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin or β-naphthoflavone, both of which potently induce the epoxygenase activity (76–78). This P450 was immunologically different from the phenobarbital-induced arachidonic acid epoxygenase, but the catalytic properties were not investigated in detail. It should be noted that β-naphthoflavone induces ω2-hydroxylation of fatty acids (see above) in other species (13), while the chick epoxygenase apparently is induced by Ah receptor dependent inducers of P450 (76–78). Whether epoxides of arachidonic acid also mediate or modulate manifestation of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin toxicity, which has been suggested (76), remains to be established.

Liver microsomes of rats and rabbits can epoxidize a large number of different C_{18}–C_{22} unsaturated fatty acids. Epoxidation of oleic acid to *cis*-9,10-epoxystearic acid was described in 1971 (48). Linoleic acid, α-linolenic acid, 5,8,11-eicosatrienoic acid, 5,8,11,14,17-eicosapentaenoic acid, and docosahexenoic acid can be oxygenated to epoxides/diols (21,24,79,80). The double bond closest to the ω-end of many substrates has been readily oxygenated by liver microsomes of untreated animals.

Epoxidation of oleic, linoleic, α-linolenic, and γ-linolenic acids by CYP2C2 and CYP2CAA were reported recently (81). Linoleic and α-linolenic acids were converted to an equal mixture of all possible epoxides, while γ-linolenic acid was oxygenated at the 9–10 and 12–13 double bonds but not at the 6–7 double bond. Data on the epoxygenation of other unsaturated fatty acids by members of the CYP2C gene family is likely to follow. So far, the only strictly position-specific epoxygenase has been found in monkey seminal vesicles. In the presence of NADPH, microsomes of this tissue converted eicosapentaenoic acid into 17*S*,18*R*-epoxy-5,8,11,14-eicosatetraenoic acid (17*S*,18*R*-EpETE) and the corresponding diol, 17,18-dihydroxyeicosatetraenoic acid (65). Arachidonic acid was converted to 18*R*-HETE. It is possible that this seminal vesicle P450 could be identical with prostaglandin E 19*R*-hydroxylase (82).

P450-EPOXYGENASES AND BIOLOGICAL EFFECTS

EpETrE can affect cellular function in a wide variety of different tissues and cells. The mechanism behind these biological effects appears to be largely unknown. There appears to be little evidence for existence of specific receptors for EpETrE on cell membranes. In a few cases, the effects of EpETrE can be explained by inhibition of cyclooxygenase, by metabolism by cyclooxygenase, or by effects on other enzymes of the arachidonic acid cascade. When high micromolar concentrations of EpETrE are used, nonspecific membrane actions could contribute. Some investigators report effects at nanomolar concentrations, which might be of physiological relevance and deserve further attention. The hyperpolarizing action of EpETrE in certain cells is of considerable interest.

Liver. Not much is known about the biological effects of EpETrE on liver function. Most reports examine effects of micromolar concentrations. 14,15-EpETrE (10 to 50 μM) has been postulated to be involved in vasopressin-stimulated glycogenolysis in rat liver hepatocytes *via* an increase in phosphorylase a activity stimulated by cytosolic calcium increase (83). 14,15-EpETrE (1–10 μM) also stimulated ADP-ribosylation of a 52 kDa protein in rat liver cytosol, and its metabolite 14,15-DiHETrE was almost inactive (84). Whether these effects are stereospecific for one of the two enantiomers is unknown. Further information on biological roles of EpETrE on liver function may be obtained if studies are carried out in the presence and absence of clotrimazole and ketoconazole, which have been shown to be potent inhibitors of rat hepatic epoxygenase activity *in vitro* (85). Another unexplored area is the effects of P450 metabolites of arachidonic acid on the peroxisome proliferator-activated receptor (PPAR), the nuclear hormone receptor that regulate gene transcription in response to peroxisome proliferators. PPAR is activated by many eicosanoids, e.g., by PGA, PGD and PGJ compounds, and 8*S*-HETE (86).

Kidney. This research area has been summarized in excellent reviews by McGiff and collaborators (87,88), who emphasized that P450 metabolites of arachidonic acid are formed in critical nephron segments and may participate in receptor-mediated signal transduction as second messengers.

In many species, renal cortical epoxygenase activity is high and has been localized to specific cells of the nephron (89,90). Major products are 11,12- and 14,15-EpETrE in the rabbit (68) and 8,9-, 11,12-, and 14,15 EpETrE in the rat (60). As renal epoxygenase activity is of the same order of magnitude as in liver, the biological importance of EpETrE in the kidney needs to be determined. While suggested roles include modulation of the effects of renal hormones, regulation of blood flow, and of tubular function, a precise role in kidney physiology has not yet been defined (87). Roles of these metabolites have nevertheless been proposed in several models including experimental hypertension in the rat. However, there were no statistically significant differences in epoxygenase activity between normal and hypertensive rats at any age (91). In women with pregnancy-induced hyperten-

sion, increases in urinary 11,12- and 14,15-DiHETrE were observed (61).

Both racemic EpETrE and their dihydroxy metabolites inhibited the vasopressin-stimulated osmotic water flow in toad bladder *via* inhibition of adenylate cyclase, with 5,6- and 11,12-EpETrE being most potent. However, 10 μM concentrations were required for activity (92). Interestingly, 14,15-DiHETrE (0.1 μM) was as potent as PGE_2 in inhibiting the action of vasopressin on collecting ducts of the rabbit (93). 5,6-EpETrE (10 nM–1 μM) caused a transient increase in intracellular calcium of proximal tubular epithelium, mimicking the actions of angiotensin II (AII) and suggesting that P450 metabolites are involved in AII-induced calcium mobilization (94). In addition, racemic 14,15-EpETrE (1 μM) has been found to inhibit renin release from cortical slices of rat kidney (95). As 14*S*,15*R*-EpETrE is the major enantiomer of 14,15-EpETrE formed by renal microsomes and by the renal epoxygenases of rabbits and rats (60,68), it will be of interest to determine whether the effects on vasopressin and the renin-AII system are stereospecific.

Infusion of arachidonic acid into the rat renal artery causes vasoconstriction, which is blocked by inhibitors of PGH synthases, revealing a vasodilator response (96). This vasodilatation appeared to be dependent on endothelial cytochrome P450 as judged from the effects of inhibitors of P450 (96,97). In the isolated rabbit kidney, 5,6-EpETrE, 8,9-EpETrE, and 11,12-EpETrE induced vasodilatation, while 14,15-EpETrE induced vasoconstriction (98). The 5,6-epoxide was most potent and partly dependent on PGH synthases for vasoactivity (99,100). A recent detailed analysis showed that the effect of the 5,6-epoxide on the renal vasculature differed in the buffer and the blood perfused rat kidney model (101). In the latter, 5,6-EpETrE exerted vasoconstrictor effects, presumably due to metabolism by PGH synthase and thromboxane synthase of platelets to a vasoconstrictor substance. This action was antagonized by indomethacin. In the isolated rat kidney perfused with physiological buffer, the epoxide was a vasodilator and indomethacin was without effect on this response.

These observations thus suggested that epoxides may modulate renal function. The renal P450 system should be influenced by variations in salt and water balance or by other physiological means. Epidermal growth factor (30 nM) increased endogenous EpETrE levels fivefold within 10 min in primary cultures of rabbit proximal tubule cells and one epoxide, 5,6-EpETrE, augmented the effect of EGF on thymidine incorporation (102). The only physiological stimuli, which has been shown to increase renal epoxygenases, is salt loading, which results in a ten- to twelvefold increase in urinary excretion of arachidonic acid metabolites (EpETrE and DiHETrE) in rat urine (69). CYP2C23 appears to be the predominant, constitutive epoxygenase in the rat kidney while salt loading induces a yet unidentified CYP2C isoform that seems to be different from CYP2C23 (60,68,71,103).

Lung. There are species differences with respect to the production of epoxygenase metabolites by lung tissue. An early report indicated that rabbit lung tissue contained relatively little epoxygenase activity, forming only small amounts of 11,12-DiHETrE (23), in comparison with rabbit liver and kidneys. However, epoxygenase metabolites have been found in the rabbit and guinea pig lung, and CYP2B4 has been identified as a lung epoxygenase (104,105). The role of these metabolites in the lung is unclear. Methylated 5,6-EpETrE and 8,9-EpETrE relaxed guinea pig hilar bronchi *in vitro,* and epoxides could also be demonstrated in bronchoalveolar lavage fluid (105). Leukocytes in lung lavage from rats exposed to hyperoxia formed epoxides of linoleic acid, 12,13-epoxyoctadecenoic and 9,10-epoxyoctadecenoic acids, and these metabolites have been designated leukotoxin (106). Leukotoxin uncouples mitochondrial respiration and relaxes rat stomach smooth muscle at high concentrations (20–160 μM) (106). These products have also been identified in humans, but their biological significance is unknown (107). Induction of the cytochrome P450 system with β-naphthoflavone did not alter guinea pig pulmonary venule contractions induced by hypoxia or anoxia (108).

Platelets. The first report indicating a biological function of P450 metabolites of arachidonic acid appeared in 1976. Cinti and Feinstein (109) found that two inhibitors of P450 (metyrapone and CO) inhibited arachidonic acid induced platelet aggregation and the formation of aggregation factors from arachidonic acid by platelet microsomal P450. In spite of this report, it seems most unlikely that platelets can form EpETrE enzymatically. Convincing biosynthesis of EpETrE by platelets has not been demonstrated, but EpETrE have been identified in phospholipids of human platelets where they can be released by thrombin or platelet-activating factor (110). These EpETrE are either formed nonenzymatically or by other cells and taken up by platelets. EpETrE can affect platelet function. All EpETrE inhibited arachidonic acid-induced aggregation of washed platelets at 1–10 μM (see Ref. 17 for review). The antiaggregatory effects of EpETrE were recently attributed to selective inhibition of Ca^{2+} entry into platelets, as *cis*-14,15-EpETrE reduced both receptor-independent discharge by thapsigargin or receptor-dependent discharge by thrombin; however, these effects utilized high concentrations of *cis*-14,15-EpETrE (60 μM) (111). Interestingly, an analogue of 14,15-EpETrE, *cis*-4,15-episulfideeicosatrienoic acid, preferentially inhibited ionophore A23387-induced platelet aggregation, but did not inhibit aggregation induced by thrombin (112). 14,15-EpETrE (0.3 mg/kg i.v.) also inhibited platelet aggregation in mouse cerebral arterioles (113).

Platelets can also metabolize 5,6-EpETrE by PGH synthase-1 and thromboxane synthase. Balazy (112) demonstrated that human platelets metabolized 5,6-EpETrE into a number of metabolites, e.g. 5-hydroxy-6,9-epoxy-TXB_1, 5,6-epoxy-12-hydroxyheptadecadienoic acid, and 5,6-epoxy-12-hydroxyeicosatrienoic acid. It seemed likely that 5-hydroxy-6,9-epoxy-TXB_1 was formed from 5,6-epoxy-TXB_1 (and 5,6-epoxy-TXA_1) by intramolecular rearrangement in analogy with the formation of two isomers of 5-hydroxy-PGI_1 from 5,6-epoxy-$PGF_{1\alpha}$. Platelet aggregation was not induced by

5,6-EpETrE, although following preincubation, responsiveness to arachidonic acid was reduced. The author suggests that the platelet metabolites may be useful in assessing production of 5,6-EpETrE in humans (114).

The effects of other epoxides on platelet aggregation and thromboxane synthesis were recently investigated by VanRollins (115). In contrast to the arachidonic acid epoxides, all of the regioisomers of eicosapentaenoic and docosahexaenoic acid epoxides were found to inhibit platelet aggregation at much lower concentrations than those needed for blocking thromboxane biosynthesis. When eicosapentaenoic and docosahexaenoic acids are given as dietary supplements, platelet aggregation is impaired but thromboxane synthesis is unaffected. The author suggests that multiple circulating epoxides of these two fatty acids may contribute to platelet inhibition after eating fish oils.

Vascular tree. The effects of arachidonic acid and its P450 metabolites on the vasculature should be considered in the context of factors which mediate endothelium-dependent relaxation. In addition to prostacyclin and nitric oxide, which is the best characterized endothelium-derived relaxing factor, there may be at least one additional vasodilator substance, which has not yet been identified. This putative substance is designated endothelium-derived hyperpolarizing factor (EDHF), and it may be important for vasoregulation particularly of small resistance arteries (Refs. 116–118 for review). EDHF may be less reactive than nitric oxide and distinct from prostanoids. An increase in free calcium may release EDHF, which may increase conductance to potassium in smooth muscle cells. Some investigators suggest that EpETrE might be candidates of EDHF (119), while others remain skeptical (120).

Exogenous EpETrE and their vicinal diol products are rapidly taken up by arterial smooth muscle cells and by endothelial cells *in vitro* (121–123). The epoxides are partly hydrolyzed to vicinal diols and released to the medium. The metabolism of 11,12-EpETrE by arterial smooth muscle cells was recently studied by Spector and collaborators (124). The vicinal diol, 11,12-DiHETrE, and a novel metabolite, 7,8-dihydroxyhexadecadienoic acid were identified. The latter was apparently formed from 11,12-DiHETrE by two steps of β-oxidation. Interestingly, both metabolites (1–5 μM) caused vasorelaxation of precontracted porcine coronary artery rings.

Several investigators have found that arachidonic acid induced endothelium-dependent relaxation of the rabbit aorta (123), pulmonary rings (125), and coronary arteries (127). SKF 525A (a P450 inhibitor) blocked this effect (125–127), but it should be remembered that this inhibitor may have direct effect on potassium conductance (116).

5,6-EpETrE reduced vascular resistance of the isolated perfused rat caudal artery, the other epoxides being inactive (128). The biological activity of 5,6-EpETrE was dependent on PGH synthase in rat caudal artery and cerebral arterioles (128,129). It seems likely that the effects of 5,6-EpETrE were partly due to metabolism to epoxyprostaglandins. Carroll *et al.* (99) found that 5,6-EpETrE was converted to 5,6-epoxy-PGE_1 after circulating through the rabbit kidney. Authentic 5,6-epoxy-PGE_1 was equipotent to PGE_2 as a vasodilator in the isolated, perfused rabbit kidney. Metabolism by cyclooxygenase has also been implicated in the vasodilatory effects of 8,9-EpETrE and 11,12-EpETrE on intestinal serosal blood flow (130). 5,6-EpETrE may also be an important mediator of calcium influx in human and bovine endothelial cells (131). The vascular effects of 5,6-EpETrE and the other P450 metabolites of arachidonic acid have been reviewed (87,132). Systemic administration of EpETrE has virtually no effect on systemic or cerebral blood flow in the rat (133).

Epoxides of arachidonic acid may also affect vascular tone by PGH synthase-independent mechanisms. 8,9-EpETrE and 11,12-EpETrE caused transient dilatation of precontracted cerebral arteries at 50 μM and also increased the frequency of opening of K^+ channels at 5 μM (134). All four EpETrE (0.1–3 μM) increased the open-state probability of the Ca^{++}-activated K^+ channel (K_{Ca} channel) in cells from rabbit portal vein, rat caudal artery, guinea pig aorta, and porcine coronary artery (119,135). 11,12-EpEtTrE hyperpolarized and increased the open-state probability of a K_{Ca} channel in coronary smooth muscle cells (119). In renal vascular muscle cells 11*R*,12*S*-EpETrE (1–100 nM) increased the activity of the K_{Ca} channel (136). This enantiomer also relaxed small renal arteries preconstricted with phenylephrine. The vasodilator effect of some EpETrE may therefore involve activation of a K_{Ca} channel.

Vessels with injured endothelium due to artery stenosis synthesize 5,6-, 8,9-, 11,12-, and 14,15-EpETrE (137). The authors suggest that these metabolites may counteract the vasoconstriction action of thromboxane A_2 (137). 14,15-EpETrE ($2.5–5 \times 10^{-7}$ M) promotes adhesion of U937 cells to endothelium, suggesting that this compound may play a role in inflammation or atherogenesis (138). Rabbit aorta, isolated from animals with experimental hypercholesterolemia, was also found to generate all four EpETrE, but normal rabbit aorta failed to do so. All four regioisomers at concentrations from 10^{-8} to 10^{-5} M relaxed norepinephrine-precontracted aorta from normal and cholesterol-fed animals. However, only 14,15-EpETrE decreased the basal, but not the stimulated synthesis of 6-keto $PGF_{1\alpha}$ by aortas from normal rabbits (139).

Cultured bovine coronary artery endothelial cells form cyclooxygenase, lipoxygenase, and P450 metabolites of arachidonic acid (140). All four EpETrE were identified, and they may contribute to the endothelium-dependent relaxation caused by bradykinin and arachidonic acid. However, a recent study found that arachidonic acid metabolites were not involved in acetylcholine-induced endothelium-dependent hyperpolarization in guinea pig corotid artery (120). Further studies are needed to clarify the physiological role of P450 and EpETrE in the vascular wall.

Heart. The vasodilation of bradykinin on coronary arteries in the rat heart also seemed to be dependent on P450 metabolism of arachidonic acid (141). Effects of EpETrE on isolated hearts and ventricular myocytes have been reported (142).

These compounds did not affect cardiac or coronary functions in normal isolated guinea pig heart, but 11,12-EpETrE depressed recovery of the contractility after ischemia and elevated Ca_i of ventricular myocytes. The functional significance of the elevation of Ca_i remains to be determined. P4501A1 has been found in fish heart tissue (143). Recently, a novel arachidonic acid epoxygenase, designated P4502J2, was found in the human heart (144). This enzyme forms the 5,6-, 8,9-, 11,12-, and 14,15-EpETrE with little regioselectivity in the following amounts: 21, 24, 18, and 37%, respectively. The 8,9-, 11,12-, and 14,15-EpETrE could also be demonstrated in heart tissue (142).

Central nervous system and pituitary. P450 is present in many parts of the central nervous system (3,145), but only recently has biosynthesis of arachidonic acid epoxides been reported (146). Slices of mouse brain formed two epoxides, 14,15-EpETrE and 5,6-EpETrE, but their enantiomeric composition was not determined. Brain-synthesized 5,6-EpETrE caused transient cerebral arteriolar dilation similar to that caused by synthetic 5,6-EpETrE (15.6 μM), and the authors suggest it may have a role in cerebral microcirculation regulation (146). Microsomes of cat brain formed large amounts of 5,6-, 8,9-, and 11,12-EpETrE and small amounts of 14,15-EpETrE. 8,9-EpETrE and 11,12-EpETrE (50 μM) dilated serotonin-preconstricted, pressurized cerebral arteries, presumably through activation of K^+ channels (134). Rabbit cerebral arteries were dilated by 5,6-EpETrE (15.6 μM) while 8,9-EpETrE, 11,12-EpETrE, and 14,15-EpETrE were less active. The suggested mechanism was *via* cyclooxygenase metabolism of 5,6-EpETrE with formation of dilator oxygen radicals (129).

A series of recent papers have demonstrated that rat brain astrocytes in primary culture produce EpETrE (146–148). 11,12-EpETrE and 14,15-EpETrE were identified in one study as well as mRNA of P450 2C11 in the astrocytes (148). Ellis and collaborators (149) also report synthesis of 5,6-EpETrE and 14,15-EpETrE and the corresponding vicinal diols. These studies further emphasize that arachidonate epoxygenses are present in the brain, and that it is conceivable that EpETrE could modulate K_{Ca} channel activity in the cerebral microvessels.

Microsomes of rat hypothalamus oxygenated arachidonic acid to epoxides in the presence of NADPH (150). In addition, 5,6-EpETrE (2.5 μM) stimulated the release of somatostatin from the median eminence *in vitro*. These results were extended by demonstration and quantification of endogenous 8,9-, 11,12-, and 14,15-EpETrE in the rat hypothalamus. In contrast to 5,6-EpETrE, 8,9-EpETrE released somatostatin from the median eminence with an EC_{50} of only 5 pM (151). This profound bioactivity is remarkable, and it should therefore inspire further investigations.

P450 metabolism of arachidonic acid also occurs in the pituitary. Microsomes of rat anterior pituitary formed 20-HETE and at least three epoxides of arachidonic acid (5,6-, 11,12-, and 14,15-EpETrE) (152). These P450 metabolites affect anterior pituitary cells at relatively high concentrations. Inhibitors of P450 (SKF525A, piperonyl butoxide) blocked the release of corticotropins in response to a variety of secretagogues in mouse pituitary tumor cells (153). 5,6-EpETrE (1 μM) caused efflux of calcium and release of luteinizing hormone (154), stimulated release of prolactin from a rat anterior pituitary cell line, GH3 cells, at a concentration of 50 μM (155), and stimulated the release of growth hormone from pituitary cells in culture at a concentration of 20 μM (156). In addition, 5,6-, 8,9-, 11,12-, and 14,15-EpETrE (3 μM) all stimulated release of growth hormone from a population of enriched somatotrophs, with 5,6-EpETrE and 14,15-EpETrE more potent than the other two regioisomers (157).

Microsomes of the neural lobe of rat pituitary metabolized arachidonic acid to the major metabolites 8,9-, 11,12-, and 14,15-EpETrE which were produced in equal quantities and stimulated release of oxytocin and vasopressin over a concentration range from 10^{-8} to 10^{-6} M (158). These concentrations were 1.5 times greater than that of PGE_2 for similar effects on oxytocin and vasopressin release. 5,6-EpETrE was produced in lower quantities and was biologically inactive.

These studies demonstrated that epoxides of arachidonic acid were formed by mouse and cat brain, and by rat hypothalamus, pituitary, and astrocytes. Little is known about the stereochemistry of the products and the P450 isozymes catalyzing their biosynthesis. Because of the high concentrations used in some of these studies, the physiological function of arachidonic acid epoxides in regulation of hormone release from hypothalamus or the pituitary still remains to be established (see Ref. 159 for review).

Adrenals, pancreas, and ovaries. There are few reports on P450 metabolism of arachidonic acid by endocrine glands. EpETrE, HETE, and prostaglandins were identified as metabolites of arachidonic acid formed by rat adrenal glomerulosa cells (160), where they presumably have a role in aldosterone release (161). Epoxyeicosatrienoic acids have been shown to release insulin and glucagon from pancreatic islets (162). Human granulosa-luteal cells in culture and a human chorioncarcinoma cell line (BeWo) formed 14,15-EpETrE and 14,15-DiHETrE (163). Human granulosa cells of the ovary metabolized arachidonic acid to epoxides, and 14,15-EpETrE stimulated estradiol production at low concentrations (1–50 nM); however higher concentrations (10–50 μM) inhibited estradiol production and hCG-stimulated estradiol secretion. 14,15-EpETrE did not affect progesterone production at any concentration tested (164). 14,15-EpETrE is produced by human amnion, trophoblast, and umbilical vein tissues and may be involved in maintenance of vascular function (165).

Conclusion. A wide range of biological effects of epoxygenase metabolites of arachidonic acid and a few other fatty acids have been described in liver, kidney, lung, platelets, cardiovascular, nervous, and endocrine systems. Some studies have used micromolar concentrations of P450 metabolites, while other studies report effects in the nanomolar concentration range as P450 metabolites of arachidonic acid are present in low cellular concentrations, it remains to be determined

whether these metabolites are formed in high enough concentrations to be of physiological importance.

METABOLISM OF EPOXY AND BISALLYLIC HYDROXY FATTY ACIDS

Epoxide hydrolases. Epoxides of arachidonic acid were converted by epoxide hydrolases of hepatic microsomes to vicinal diols (36). Experiment with biosynthesis of epoxides using hepatic microsomes under $^{18}O_2$ gas showed that one ^{18}O atom was present in the diols. Gas chromatography–mass spectrometry (GC–MS) analysis showed that both ^{16}O and ^{18}O were found at the hydroxyl at C_{14} or at C_{15} of 14,15-DiHETrE and at the hydroxyl at C_{11} or at C_{12} of 11,12-DiHETrE (51). This indicated that oxygen from water or enzyme could be added to both carbons of the oxirane rings during the enzymatic hydrolysis.

Purified rat liver microsomal epoxide hydrolases were found to hydrolyze the four epoxides of arachidonic acid with V_{max} between 0.09 and 0.25 μmol/min/mg protein (36), but K_m values were rather high, e.g., 0.16 mM for 14,15-EpETrE. Corresponding figures for hydrolysis of these epoxides by purified mouse liver cytosolic epoxide hydrolase were between 0.07 and 1.26 μmol/min/mg protein, but the K_m value for 14,15-EpETrE was only 8 μM (166). Both microsomal and cytosolic epoxide hydrolases can thus hydrate the epoxides, but the cytosolic enzyme appeared to be more efficient (higher V_{max} and lower K_m). The fact that some investigators report biosynthesis of epoxides from [^{14}C]arachidonic acid by hepatic microsomes, while others mainly find the corresponding diols may be due to contamination with cytosolic epoxide hydrolases and to differences in the specific activity of the radiolabeled substrate.

The hydration of *cis*-epoxyeicosatrienoic acids by cytosolic epoxide hydrolases were investigated by Zeldin *et al.* (167), using chiral HPLC to separate the *S,S* and *R,R* enantiomers of the vicinal DiHETrE. Interestingly, acid-catalyzed hydration of the *cis*-epoxides did not always lead to equal formation of the *S,S* and *R,R* isomers; 14*S*,15*R*-EpETrE yielded a 3:1 ratio of these antipodes. Soluble epoxide hydrolase of rabbit liver hydrolyzed racemic 14,15-EpETrE to a 4:1 mixture of *R,R* and *S,S* enantiomers of 14,15-DiHETrE. Incubation with 14*S*,15*R*-EpETrE, the major enantiomer formed in the rat and rabbit kidney (60,168), yielded the *S,S* and *R,R* antipodes in a 3:1 ratio. 14*R*,15*S*-EpETrE, the major enantiomer of the liver and human kidney (62,63), was hydrated mainly to the *R,R* antipode of 14,15- DiHETrE (ratio 6:1). These results show that the oxirane ring was opened by cytosolic rabbit liver epoxide hydrolase mainly by addition of oxygen at C_{15}. Similarly, epoxide hydrolase selectively catalyzed addition of oxygen at C_9 of 8,9-EpETrE, while 11,12-EpETrE was hydrolyzed without regioselectivity. From these results, it seems likely that the *R,R* enantiomer of 14,15-DiHETrE is the major enantiomer in the liver and human kidney cortex, while *S,S* enantiomer is likely to predominate in the rabbit and rat kidney. The results were recently extended to studies with soluble epoxide hydrolase and a series of epoxides, their methyl esters, and hydrogenated compounds (169).

The catalytic mechanism of soluble epoxide hydrolases has been investigated in detail by Hammock and collaborators (170). *cis*-9,10-Epoxystearic acid was used as one of two model substrates. [^{18}O]Epoxystearic acid was enzymically hydrolyzed to the diol and ^{18}O was present at either C_9 (69%) or at C_{10} (31%). The other oxygen was found to be derived from the enzyme itself. When the unlabeled epoxide was incubated with excess enzyme for only one cycle in $H_2{}^{18}O$, the diol did not contain ^{18}O. Further analysis showed that the carboxylate anion of Asp-333 of the enzyme attacked the epoxide substrates and formed an α-hydroxyacyl-enzyme intermediate, which was hydrolyzed by "activated" water (postulated *via* a histidine) to the active enzyme and the diol.

PGH synthases. Soon after their discovery, EpETrE were found to affect many different organs and cells (17,82). It seemed possible that these effects could be either direct or indirect *via* modulation of prostaglandin biosynthesis. PGH synthases form prostanoids from eicosanoic fatty acids, which contain at least three double bonds, located at the 8,9, 11,12, and 14,15 positions (171–174). 5,6-EpETrE contains these double bonds.

5,6-EpETrE was found to be rapidly metabolized by PGH synthase-1 *in vitro* into epoxy prostaglandin endoperoxides, 5,6-epoxy-PGG_1 and 5,6-epoxy-PGH_1, which were isolated (175). These endoperoxides could be reduced to 5,6-epoxy-$PGF_{1\alpha}$ or could be enzymatically isomerized to 5,6-epoxy-PGE_1 (175–177). 5,6-Epoxy-$PGF_{1\alpha}$ is chemically unstable and can undergo intramolecular rearrangement with formation of 5-hydroxy-$PGI_{1\alpha}$ and 5-hydroxy-$PGI_{1\beta}$ (178,179). The latter are biologically inactive. McGiff and colleagues (99) have shown that exogenous 5,6-EpETrE is metabolized to a vasodilator, 5,6-epoxy-PGE_1, by the isolated perfused rabbit kidney.

The 8,9-, 11,12-, and 14,15-epoxides of arachidonic acid lack the necessary double bonds for prostaglandin biosynthesis. Some of them may undergo abortive PGH synthase reactions or can inhibit this enzyme. The *R,S* enantiomer of 14,15-EpETrE inhibits PGH synthase-1 of ram vesicular glands and platelets (176,180). It seems likely that some of the pharmacological effects of 14,15-EpETrE can be attributed to inhibition of PGH synthase (157). Recent studies show that 8,9-EpETrE can be oxygenated by PGH synthase to 8,9-epoxy-11*R*-hydroxyeicosatrienoic acid (181), which might contribute to the observed effects of 8,9-EpETrE on the renal circulation (182).

GSH transferases. Leukotriene A_4 (LTA_4) is an unstable allylic epoxide of arachidonic acid and an important intermediate in leukotriene biosynthesis. LTA_4 is conjugated with reduced GSH by LTC_4 synthase (183), leading to formation of LTC_4 and ultimately other peptidoleukotrienes with potent biological activities. It was therefore of interest to determine whether the homallylic epoxides formed by P450 could be conjugated with glutathione by glutathione *S*-transferases. This was found to be the case (184). 14,15-EpETrE was con-

jugated with glutathione, and the transferase isozymes 3-3 and 5-5 were most active with K_m values of about 10 μM and V_{max} values between 25 and 60 nmol conjugate/min/mg protein. The other epoxides were also substrates but were conjugated less efficiently.

Incorporation into phospholipids. Epoxides of arachidonic acid and other PUFA can be incorporated into phospholipids. 8*S*,9*R*-, 11*S*,12*R*-, and 14*R*,15*S*-EpETrE were, for example, demonstrated at the glycerol-*sn*-2 position of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol in the liver (64). Exogenous 14,15-EpETrE is rapidly incorporated into phospholipids of mastocytoma cells. The distribution of the epoxide in phospholipids was phosphatidylethanolamine>phosphatidylcholine>phosphatidylinositol (185). The rate of release of the epoxide from phosphatidylcholine and phosphatidylinositol was higher than the release of arachidonic acid from these phospholipids by phospholipase A_2 in agreement with previous reports (55, cf. Ref. 186).

EpETrE and DiHETrE were recently found to be incorporated into phospholipids of vascular endothelial cells (121,133), smooth muscle cells (122), endothelial cells (123), and astrocytes (148). These findings should be considered in the context of these metabolites as putative EDHF.

ANALYSIS OF EPOXIDES AND BISALLYLIC HYDROXY FATTY ACIDS

GC–MS and liquid chromatography–mass spectrometry (LC–MS) analyses. GC–MS has been the primary tool for structural identification of epoxides and other P450 metabolites of PUFA (see Ref. 187 for review). The mass spectra of epoxides of PUFA provide relatively little information on the position of the epoxide. Analysis of epoxides *via* 3-pyridinylmethyl esters are more informative (188). Conversion of the epoxides to diols or chlorohydrin adducts usually gives mass spectra with distinct fragmentation (189). A large and extremely useful collection of electron impact mass spectra of eicosanoids has been compiled by Pace-Asciak (190). Instruments for GC–MS analysis and interpretation of mass spectra of fatty acid derivatives and eicosanoids have been described by Murphy in an excellent monograph (191).

Methods for analysis based on deuterated or ^{18}O labeled internal standards have been used for quantification of epoxides or the corresponding diols by mass fragmentography (see Ref. 192 for details). Recently, EpETrE and their corresponding diols were identified in nanogram or picogram quantities using capillary GC–MS in election ionization as well as in the negative and positive ion-chemical ionization modes (121,193).

Yamane *et al.* (194) systematically studied epoxides of polyunsaturated eicsoanoic fatty acids and docosahexaenoic acid by LC–MS (thermospray). In addition, mass spectra of many of the corresponding diols were reported. So far LC–MS has not been used for analysis of bisallylic hydroxy fatty acids.

Steric analysis of hydroxy fatty acids. Enantiomers of *cis-trans* conjugated HETE and other *cis-trans* conjugated hydroxy fatty acids can be separated by chiral HPLC on *R*-(−)-*N*-(3,5-dinitrobenzyol)-α-phenylglycine columns as devised by Kühn *et al.* (195). After derivatization of the hydroxyl groups, the separation can be improved (196). Brash *et al.* (28) reported that bisallylic hydroxy metabolites of PUFA show increased end absorption at 220 nm in comparison with ω1 and ω2 hydroxy metabolites. This is convenient for monitoring these metabolites. Brash *et al.* (28) also reported that the enantiomers of 7-HETE, 10-HETE, and 13-HETE were at least partly resolved by chiral HPLC on Chiralcel OD (Diacel, Tokyo, Japan). Steric analysis of bisallylic hydroxy fatty acids can also be performed after partial hydrogenation of the double bonds, synthesis of (−)-menthoxycarbonyl derivatives and ozonolysis (21,25). Steric analysis of ω4-, ω3-, and ω2-hydroxy fatty acids can be performed by separation of diastereoisomeric *S*-phenylpropionic acid derivatives on GC (197). It is also possible to partly resolve the enantiomers of 18-HETE and 19-HETE on chiral HPLC (198).

Steric analysis of epoxy fatty acids. Chiral HPLC for separation of the enantiomers of all four epoxides of arachidonic acid was developed by Hammonds *et al.* (199), using Chiralcel OB and Chiralcel OD columns (Diacel). The epoxides were analyzed as methyl esters or as pentafluorobenzyl esters. The resolution was improved by hydrogenation. This valuable technique has now been used in many studies from this group. Whether these columns also can be used for steric analysis of epoxides of other fatty acids has not been determined. Cellulose derivatized with trisphenylcarbamate (Chiralcel OC, Diacel), for example, resolved the enantiomers of some epoxides of arachidonic, linoleic, and α-linolenic acids (168), but the enantiomers of the ω3 epoxides of eicosapentaenoic acid or linolenic acid were not separated. A general method for finding the suitable chiral HPLC column is lacking. There is a large selection of different chiral HPLC columns available (200), yet the choice of HPLC column is empirical, and, unfortunately, these HPLC columns with derivatized cellulose are very expensive.

A general method for steric analysis of *cis* and *trans* epoxides of fatty acids was developed by Fahlstadius and Hamberg (201). This method was based on hydrogenation and conversion of the epoxide to two regioisomeric allylic alcohols, followed by ozonolysis of (−)-menthoxycarbonyl derivatives and GC–MS analysis.

Steric analysis of vicinal diols. Vicinal *threo*-DiHETrE, formed by hydrolysis of EpETrE, can also be resolved by chiral HPLC as methyl ester derivatives using Chiralcel OC and Chiralcel OD columns (Diacel) (202). Resolution was improved by hydrogenation. The pentafluorobenzyl ester derivatives of the hydrogenated vicinal diols yielded better separation on the Chiralcel OD column (Diacel, and the elution times were shortened. The *R,R* enantiomers of the dihydroxyeicosanoic acids eluted before the *S,S* enantiomers. It would be useful if these results could be extended to other diols, e.g., to *threo*-17,18-dihydroxyeicosanoic and to *erythro*-17,18-dihydroxyeicosanoic acids.

CONCLUSIONS

PUFA can be oxygenated by P450 in many different ways. Epoxidation, hydroxylation of the ω-side chain, and bisallylic hydroxylation are quantitatively dominant. P450 is a ubiquitous enzyme (2,3). Some of these reactions have been found in other organs and tissues besides liver and kidney cortex. ω-Oxidation was discovered *in vivo* 60 years ago by Verkade *et al.* (203), and it was therefore expected that P450 would oxygenate arachidonic acid *in vivo* in man and in experimental animals.

Biological activities have been associated with many of the P450 metabolites of arachidonic acid. Epoxides of arachidonic acid have attracted the largest interest. Major advances in the last years have been the identification of the constitutive epoxygenases in the human, the rabbit, and the rat kidney. They belong to the CYP2C gene family. Much less is known about the bisallylic hydroxylases. Some of them may belong to the CYP3A family, which is induced by dexamethasone. The metabolic fate and importance of bisallylic hydroxy fatty acids have not yet been explored. The dietary intake of linoleic acid and other PUFA in the human diet is large. It may therefore be of interest to determine whether bisallylic metabolites are formed *in vivo* in humans. In contrast, ω1- and ω2-hydroxylation of saturated fatty acids have been extensively studied in man and many experimental animals. Considering their abundance, the bisallylic hydroxylases of PUFA and their possible biological functions deserve similar attention.

ACKNOWLEDGMENTS

We thank the reviewers for helpful suggestions and Dr. Arthur A. Spector for making unpublished material available. Supported by grants from the Swedish Medical Research Council (6523) and National Science Foundation (IBN-9318047).

Mechanism of Linoleic Acid Hydroperoxide Reaction with Alkali

Harold W. Gardner[a,*], Thomas D. Simpson[a], and Mats Hamberg[b]

[a]National Center for Agricultural Utilization Research, ARS, USDA, Peoria, Illinois 61604 and [b]Department of Medical Biochemistry and Biophysics, Karolinska Institutet, S-171 77 Stockholm, Sweden

ABSTRACT: Treatment of (13*S*,9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoic acid (13*S*-HPODE) with strong alkali resulted in the formation of about 75% of the corresponding hydroxy acid, (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoic acid (13*S*-HODE), and the remaining 25% of products was a mixture of several oxidized fatty acids, the majority of which was formed from (9*Z*,11*R,S*,12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid by Favorskii rearrangement (Gardner, H.W., *et al.* (1993) *Lipids 28*, 487–495). In the present work, isotope experiments were completed in order to get further information about the initial steps of the alkali-promoted decomposition of 13*S*-HPODE. **1.** Reaction of [hydroperoxy-$^{18}O_2$]13*S*-HPODE with 5 M KOH resulted in the formation of [hydroxy-^{18}O]13*S*-HODE and [epoxy-^{18}O](9*Z*,11*R,S*,12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid; **2.** treatment of a mixture of [U-^{14}C]13*S*-HODE and [hydroperoxy-$^{18}O_2$]13*S*-HPODE with KOH and analysis of the reaction product by radio-TLC showed that 13*S*-HODE was stable under the reaction conditions and did not serve as precursor of other products; **3.** reaction of a mixture of [U-^{14}C]13-oxo-9,11-octadecadienoic acid (13-OODE) and [hydroperoxy-$^{18}O_2$]13*S*-HPODE with KOH resulted in the formation of [U-^{14}C-epoxy-^{18}O](9*Z*,11*R,S*,12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid; **4.** treatment of a mixture of [hydroperoxy-$^{18}O_2$]13*S*-HPODE and [carboxyl-$^{18}O_1$]13*S*-HPODE with KOH afforded (9*Z*,11*R,S*,12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid having an ^{18}O-labeling pattern which was in agreement with its formation by intermolecular epoxidation. It was concluded that (9*Z*,11*R,S*,12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid is formed from 13*S*-HPODE by a sequence involving initial dehydration into the α,β-unsaturated ketone, 13-OODE, followed by epoxidation of the Δ^{11} double bond of this compound by the peroxyl anion of a second molecule of 13*S*-HPODE. Rapid conversion of hydroperoxides by alkali appeared to require the presence of an α,β-unsaturated ketone intermediate as an oxygen acceptor. This was supported by experiments with a saturated hydroperoxide, methyl 12-hydroperoxyoctadecanoate, which was found to be much more resistant to alkali-promoted conversion than 13*S*-HPODE.
Lipids 31, 1023–1028 (1996).

Frankel *et al.* (1) reported conversion by alkali of methyl linoleate hydroperoxides to their corresponding hydroxy fatty acids without explanation of possible mechanisms of transformation. Recently, this alkali transformation was investigated in more detail showing that (13*S*,9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoic acid (13*S*-HPODE) was converted to (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoic acid (13*S*-HODE) in about 75% yield without loss of regio- and stereoconfiguration (2,3). The majority of remaining 25% of products were proposed (3) to arise from Favorskii Rearrangement of intermediate (9*Z*,11*R,S*,12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid.

O'Brien (4), who reacted a number of "nucleophiles" with linoleic acid hydroperoxide obtained a similar conversion into hydroxyoctadecadienoic acid. Although O'Brien did not test alkali, he suggested that nucleophiles displaced the distal OH from the hydroperoxide group, and this seemed to be a plausible mechanism with the alkali transformation. However, it is difficult to reconcile how the nucleophilic hydroxyl anion could displace the distal hydroperoxide oxygen if the hydroperoxide group exists as a peroxyl anion in strong alkali.

In this communication we investigate the mechanism of alkali transformation of 13*S*-HPODE and compare its reaction with some other hydroperoxides. We show by labeling experiments that hydroperoxide oxygen is consumed by intermolecular epoxidation of a dehydration by-product, (9*Z*,11*E*)13-oxo-9,11-octadecadienoic acid (13-OODE). Evidence is presented to question the possibility of a nucleophilic displacement of the distal hydroperoxide oxygen.

MATERIALS AND METHODS

Materials. Bovine liver catalase 27,000 units/mg was from Sigma (St. Louis, MO). [U-^{14}C] linoleic acid was purchased from Amersham (Buckinghamshire, United Kingdom). $^{18}O_2$ of 99.4 atom % ^{18}O was from Isotec, Inc. (Miamisburg, OH). [Carboxyl-$^{18}O_1$]13*S*-HPODE (5) and [hydroperoxy-$^{18}O_2$]-

13*S*-HPODE (6) were prepared as described previously. Methyl 12-hydroperoxyoctadecanoate (12-HPO) was synthesized by the method of Bascetta and Gunstone (7) from methyl 12-hydroxyoctadecanoate from Nu-Chek-Prep (Elysian, MN). 13-OODE was prepared by oxidation of 13*S*-HODE with a CrO3-pyridine complex (8).

Reaction conditions. 13*S*-HPOD (2.3 mM) was treated with 5 M KOH at 35°C, and products were recovered as described previously (3). In certain KOH (always 5 M) treatments, the concentrations of some of the fatty acids or other reactants varied. Reaction of KOH was tested with (i) 0.75 mM uniformly ^{14}C-labeled [U-^{14}C]13*S*-HODE and 5.0 mM [hydroperoxy-$^{18}O_2$]13*S*-HPODE; (ii) 1.0 mM [carboxyl-$^{18}O_1$]13*S*-HPODE and 1.3 mM [hydroperoxy-$^{18}O_2$]13*S*-HPODE; (iii) 0.6 mM [U-^{14}C]13-OODE and 2.3 mM [hydroperoxy-$^{18}O_2$]13*S*-HPODE; (iv) 3.3 mM 12-HPO; and (v) 2.3 mM 12-HPO plus 2.3 mM 13*S*-HPODE.

Other methods. Other methods were essentially as described previously with few exceptions (3). Gas chromatography–mass spectrometry (GC–MS) was accomplished with the same equipment, except selected ion monitoring was utilized to determine isotopic compositions. Developing solvents for thin-layer chromatography (TLC) of methyl esterified products were hexane/ethyl acetate (8:2, vol/vol) and hexane/acetone (92:8, vol/vol). Products of 12-HPO were analyzed as methyl esters by high-performance liquid chromatography (HPLC) with a Microsorb silica column (250 × 4.6 mm, 5 μ spherical particle size; Rainin, Woburn, MA) using a Spectra-Physics (San Jose, CA) SP8800 pump. The isocratic solvent used for 12-HPO products was hexane/isopropanol (191:1, vol/vol) at a flow rate of 0.75 mL/min, and eluants were detected with a Varex (Rockville, MD) ELSD IIA detector (evaporative light-scattering detector) using a detector temperature of 73°C and a gas flow meter setting of 40 mm. Methyl 13*S*-HPODE and methyl 13*S*-HODE were separated with hexane/isopropanol (397:3, vol/vol) solvent at a flow rate of 0.6 mL/min. Detection was absorbance at 235 nm with a Spectra-Physics SP8490 detector.

H_2O_2 measurements. 13*S*-HPODE (385 mM) was incubated with 5 M KOH at 35°C, and 1 mL aliquots were taken at various times. The solution was adjusted to pH 4 with 2 M citric acid, and the aqueous layer was extracted with an equal volume of diethyl ether followed by hexane extraction to remove fatty acids. The extracted fatty acids were saved for analyses of the 13*S*-HODE/13*S*-HPODE ratios. The aqueous layer, containing H_2O_2, was adjusted to pH 6 (3.6 mL total), and a 2.4 mL portion was transferred to an O_2-electrode cell (Gilson Oxygraph, model 5/6H; Middleton, WI). O_2 evolution was measured after addition of 10 μL catalase solution [1 mg bovine liver catalase (27,000 units/mg from Sigma) per mL H_2O].

For determining the peroxide value of the aqueous layer, the same procedure as above was used, except the acidified reaction solution instead was extracted three times with a threefold volume of $CHCl_3$/methanol (2:1, vol/vol) to ensure complete removal of fatty acids in the $CHCl_3$ layer. The peroxide value of the H_2O–methanol layer was determined as described previously (9), except the thiosulfate used in titration was 1×10^{-4} N.

RESULTS AND DISCUSSION

Putative nucleophilic mechanism. One possible mechanism of fatty acid hydroperoxide conversion to fatty acid hydroxides by alkali would be nucleophilic attack at the distal OH of the hydroperoxide group affording fatty acid hydroxyl anion and H_2O_2. This mechanism was proposed by O'Brien (4) for the conversion of hydroperoxide fatty acid into its corresponding hydroxy fatty acid by a number of nucleophiles other than alkali. Previously, our laboratory could not detect a significant amount of H_2O_2 after 3 h of reaction (2). As shown in Table 1, these experiments were extended by (i) using higher concentrations of 13*S*-HPODE (385 mM), (ii) measuring H_2O_2 at a number of shorter times of reaction, and (iii) using two methods of H_2O_2 determination. Under these conditions, H_2O_2 could be detected, but the values were always fairly insignificant. During the first 30 min of reaction, a range of only 0.03–0.33% yield of H_2O_2 based on total 13*S*-HPODE was determined. Either H_2O_2 was a very transient intermediate or it was not formed in significant amounts. Considering alkali as a nucleophilic reagent, a severe constraint would appear to be presented by ionization of the hydroperoxide group to peroxyl anion under these very alkaline conditions, thus preventing attack by hydroxyl anion to form H_2O_2. The acid dissociation constant of the perhydroxyl (hydroperoxide) radical has a pK of 4.88 (10), which should not be much different for organic hydroperoxides. In addition, it was previously shown (2) that O_2 evolution could not be detected during the course of reaction as measured by a War-

60	0	n.d.	1:0.4

[a]13*S*-HPODE (385 mM) was reacted with 5 N KOH terminating the reaction at the times indicated by acidifying to pH 4, extracting the fatty acids, and then analyzing H_2O_2 in the aqueous layer as described in the Materials and Methods section; n.d., not determined.

[b]H_2O_2 was measured by determination of the O_2 released by O_2-electrode after treatment with catalase.

[c]H_2O_2 was measured by determination of peroxide value of the extracted aqueous layer by thiosulfate titration of I_2 released after treatment with acidic KI.

[d]The 13*S*-HODE/13*S*-HPODE ratio of extracted fatty acids was determined by high-performance liquid chromatography separation using ultraviolet detection at 232 nm. 13*S*-HODE, (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecenoic acid.

burg respirometer (a small amount of O_2 was consumed, 11% on a per mole basis). The lack of O_2 evolution was confirmed in this study by the inability to detect $^{18}O_2$ from the headspace of KOH treated [hydroperoxy-$^{18}O_2$]13*S*-HPODE by mass spectral analysis (data not shown). These data together suggest that nucleophilic displacement or O_2 elimination are probably not significant mechanisms.

Disposition of peroxide oxygen. A reaction mixture of [U-^{14}C]13*S*-HODE (0.75 mM) and [hydroperoxy-$^{18}O_2$]13*S*-HPODE (5 mM) in 5 M KOH at 35°C was sampled at 30, 60, and 90 min. The methyl esterified products were separated by TLC with hexane/ethyl acetate (4:1, vol/vol) and radioscanned. Samples obtained at each time showed a single radiolabeled peak due to the methyl ester of [U-^{14}C]13*S*-HODE. Spraying the plate with 8-anitino-1-naphthalenesulfonic acid (ANS) showed methyl esterified (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid and other products unlabeled with ^{14}C. This experiment showed that, once formed from 13*S*-HPODE, 13*S*-HODE is remarkably stable in alkali and that (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid and other by-products do not originate from 13*S*-HODE.

Reaction of [hydroperoxy-$^{18}O_2$]13*S*-HPODE (98+% isotopic purity) with 5 M KOH showed that product 13*S*-HODE retained one ^{18}O as expected as determined by the mass spectrum of its methyl ester/13-trimethylsilyloxy (OTMS) derivative: [*m/z* (percentage relative intensity, ion structure)] 384 (22, M^+); 313 (50, $[M - CH_3(CH_2)_4]^+$); 227 (23, $[M - (CH_2)_7COOCH_3]^+$); 73 [100, trimethylsilyl (TMS^+)]. Of significance to the mechanism, there was ^{18}O transfer to the other products. The important product (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid, intermediate to other compounds, was ^{18}O-labeled at the 11,12-epoxide. The 13-ketone was completely devoid of ^{18}O-label, presumably due to exchange with water. Compared with the same unlabeled fatty acid methyl ester (3), the important features of its mass spectrum were: 326 (28, M^+); 306 (28, $[M - H_2{}^{18}O]^+$); 295 (22, $[M - CH_3O]^+$); 266 (12); 223 (21, $[M - CH_3(CH_2)_4 - CH_3OH]^+$); 178 (61); 169 (43, $[M - (CH_2)_7COOCH_3]^+$); 140 (53); 99 (86, $CH_3(CH_2)_4CO^+$). The ^{18}O-labeling of Favorskii Rearrangement products derived from (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid, that is, 2-butyl-4-hydroxy-5-tetradecendioic acid and 2-butyl-3,5-tetradecadiendioic acid, were also examined by GC–MS. The mass spectrum of 2-butyl-3,5-tetradecadiendioic acid, dimethyl ester, was indistinguishable from the unlabeled compound previously reported (3) in agreement with its origin from the oxoepoxyene fatty acid with loss of the ^{18}O-labeled 11,12-epoxide. There are two isomers of product 2-butyl-4-hydroxy-5-tetradecendioic acid. One isomer (determined as its dimethyl ester/OTMS derivative) contained one ^{18}O-label as indicated by its *m/z* ion 398 (6, $[M - CH_3OH]^+$). Compared with its previously determined spectrum (3), the label was certainly not located on the most highly substituted carboxylate group as indicated by its *m/z* 371 (9, $[M - COOCH_3]^+$), but it was probably located at the 4-hydroxyl as indicated by its *m/z* 287 (100, $TMS^{18}OCH{-}CH{=}CH(CH_2)_7COOCH_3^+$). This result is in agreement with its origin from (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid with retention of the epoxide oxygen as a 4-hydroxyl. In contrast, the other isomer of 2-butyl-4-hydroxy-5-tetradecendioic acid had lost much of its ^{18}O-label as indicated by its *m/z* 285/287 ratio of 1:0.65. Evidently, this latter isomer may be more susceptible to forming the lactone observed previously (3), thus permitting exchange of oxygen. Also, the product, 11-hydroxy-9,12-heptadecadienoic acid (3), was labeled with one ^{18}O. Prominent features of its mass spectrum (methyl ester/OTMS derivative) were: 370 (23, M^+); 313 (25, $[M - CH_3(CH_2)_3]^+$); 213 (46, $[M - (CH_2)_7COOCH_3]^+$); 73 (100, TMS^+).

*Precursor to formation of (9Z,11*R,S,*12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid.* 13-OODE was a consistent, but low-yield, product in reactions of 13*S*-HPODE with alkali (3). It was postulated that this ketodiene fatty acid could be generated from 13*S*-HPODE by dehydration and subsequently act as an acceptor of peroxide oxygen to form (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid. This hypothesis was tested by reacting [U-^{14}C]13-OODE (0.6 mM) and [hydroperoxy-$^{18}O_2$]13*S*-HPODE (2.3 mM) with 5 M KOH at 35°C taking aliquot samples at 1 and 40 min. The esterified products were separated by TLC with hexane/acetone (92:8, vol/vol) solvent. Radioscanning of the 1-min sample showed one radiolabeled band due to unconverted [U-^{14}C]13-OODE. After spraying with ANS spray no fluorescent band due to the oxoepoxyene fatty ester was visible under ultraviolet (UV) light, but unconverted 13-OODE could be seen as a UV absorbing band. The 40-min products separated into a strongly radiolabeled band due to methyl (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoate (48,600 c.p.m.) and a faintly labeled band due to [U-^{14}C]13-OODE (2,944 c.p.m.). ANS spray and UV viewing revealed the two bands as the oxoepoxyene fatty ester (fluorescent) and 13-OODE (UV absorbing). GC–MS analysis showed the same prominent ions as described above for (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid derived from [hydroperoxy-$^{18}O_2$]13*S*-HPODE alone showing that it was labeled with one ^{18}O located at the 11,12-epoxide. This oxoepoxyene fatty acid was also generated from 13-OODE simply by incubation with H_2O_2 and 5 M KOH (data not shown). Therefore, (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid (OEOE in equation below) can be formed by epoxidation of 13-OODE in the presence of either 13*S*-HPODE or H_2O_2 and 5 M KOH as indicated by Equation 1:

$$\text{13-OODE} + \text{13}S\text{-HPODE (or } H_2O_2) + \text{KOH} \rightarrow \text{OEOE} + \text{13}S\text{-HODE (or } H_2O) + \text{KOH} \quad [1]$$

*Mechanism of oxygen transfer to (9Z,11*R,S,*12*S,R*)-13-oxo-11,12-epoxy-9-octadecenoic acid.* Intermolecular transfer of peroxide oxygen to the 11,12-double bond of 13-OODE in alkali is a reasonable assumption. This possibility was tested by reaction of [carboxyl-$^{18}O_1$]13*S*-HPODE (1.0 mM)

TABLE 2
Intermolecular Transfer of Hydroperoxide Oxygen to the 11,12-Epoxide of (9*Z*,11*R*,*S*,12*S*,*R*)-13-Oxo-11,12-epoxy-9-octadecenoic acid (OEOE)

Compound analyzed (as derivatives)	Isotopic composition
13*S*-HPODE reactant[a]	9% $^{18}O_0$; 42% carboxyl $^{18}O_1$; 49% hydroperoxide $^{18}O_2$
13*S*-HPODE recovered	10% $^{18}O_0$; 40% carboxyl $^{18}O_1$; 50% hydroperoxide $^{18}O_2$
13S-HODE	10% $^{18}O_0$; 42% carboxyl $^{18}O_1$; 48% hydroxy $^{18}O_1$
13-Oxo-9,11-octadecadienoate	23% $^{18}O_0$; 43% carboxyl $^{18}O_1$; 34% keto $^{18}O_1$
OEOE[b], found	29% $^{18}O_0$; 47% $^{18}O_1$; 24% $^{18}O_2$
OEOE, intermolecular reaction, calculated	29% $^{18}O_0$; 50% $^{18}O_1$; 21% $^{18}O_2$
OEOE, intramolecular reaction, calculated	9% $^{18}O_0$; 91% $^{18}O_1$; 0% $^{18}O_2$

[a]1 mM of [carboxyl-$^{18}O_1$]13*S*-HPODE (96% $^{18}O_1$; 4% $^{18}O_0$) and 1.3 mM [hydroperoxy-$^{18}O_2$]13*S*-HPODE (87% $^{18}O_2$; 13% $^{18}O_0$) was reacted with 5 M KOH at 35°C for 40 min. See Table 1 for other abbreviations.
[b]Under the conditions used, any ^{18}O-label at the C-13 keto oxygen of OEOE would have been lost because of exchange with water. This was proved in a separate experiment in which OEOE produced from [hydroperoxy-$^{18}O_2$]13*S*-HPODE was found to contain ^{18}O-label at the epoxide oxygen, but not at the keto oxygen.

and [hydroperoxy-$^{18}O_2$]13*S*-HPODE (1.3 mM) with 5 M KOH at 35°C for 40 min. The methyl esters of 13*S*-HODE, 13-OODE, and (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid were isolated by TLC after development with hexane/acetone (92:8, vol/vol). The isolates were analyzed by GC–MS using selected ion monitoring furnishing results consistent with intermolecular epoxidation in the formation of the oxoepoxyene fatty acid (Table 2).

Stability of saturated hydroperoxides. The availability of an activated double bond of 13-OODE seemed necessary in order to "reduce" 13*S*-HPODE into 13*S*-HODE. Thus, the fully saturated methyl 12-HPO was reacted with 5 M KOH. As expected, this hydroperoxide was resistant to alkali (Table 3). With extended times of incubation, 12-HPO was converted mainly into 12-oxooctadecanoic acid with only small amounts of 12-hydroxyoctadecanoic acid. 12-Oxooctadecanoic acid (methyl ester) was identified by its mass spectrum as follows: [*m/z* (percentage relative intensity, ion structure)] 312 (1.4, M^+); 281 (17, $M^+ - CH_3O$); 242 (22, $^+CH_2{=}COH(CH_2)_{10}COOCH_3$); 227 (17, $^+CO(CH_2)_{10}COOCH_3$); 185 (20); 167 (15); 153 (40); 128 (61, $CH_3(CH_2)_5COH{=}CH_2^+$); 113 (73, $CH_3(CH_2)_5CO^+$); 98 (80); 85 (57); 69 (70); 55 (100). 12-Hydroxyoctadecanoic acid was identified by its mass spectrum as its methyl ester trimethylsilyloxy derivative: [*m/z* (percentage relative intensity, ion structure)] 355 (2.4, $M^+ - CH_3O$); 339 (7, $M^+ - CH_3OH - CH_3$); 301 (59, $M+ - CH_3(CH_2)_5$); 187 (100, $CH_3(CH_2)_5CHOTMS^+$); 73 (49, TMS).

When 13*S*-HPODE was also included in the reaction with 12-HPO (Table 3), the conversion of 12-HPO was more rapid implying that the unsaturation provided by 13*S*-HPODE was responsible.

A proposed mechanism and other considerations. As shown in Figure 1, a mechanism is proposed that is consistent with the results. We propose that the first step is dehydration of 13*S*-HPODE to afford 13-OODE. Although 13-OODE is an intermediate that does not accumulate, 12-HPO in the presence of alkali was converted mainly to 12-oxooctadecanoic acid, inferring that conversion to the ketone is an important reaction with 13*S*-HPODE also. This ketodiene fatty acid provides the labile double bond that permits transfer of one distal oxygen from the peroxyl anion of 13*S*-HPODE to the 11,12-epoxide of (9*Z*,11*R*,*S*,12*S*,*R*)-13-oxo-11,12-epoxy-9-octadecenoic acid. As discussed previously (3), this oxoepoxyene fatty acid evidently undergoes Favorskii Rearrangement through an unobserved cyclopropanone intermediate to furnish 2-butyl-4-hydroxy-5-tetradecendioic acid and 2-butyl-3,5-tetradecadiendioic acid. It seems plausible that

TABLE 3
Conversion of Methyl 12-Hydroperoxyoctadecanoate (12-HPO) by Alkali with and without 13*S*-HPODE[a]

	12-HPO alone			12-HPO + 13*S*-HPODE		
Time (h)	Unreacted (mg)	12-HO[b] (mg)	12-OO[b] (mg)	Unreacted 12-HPO (mg)	Unreacted 13*S*-HPODE (mg)	12-HO + 13-HODE[c] (mg)
0	1.07	0.01	0	0.77	0.72	0.01
1	0.68	0.01	0.39	0.28	0.12	0.12
4	0.43	0.03	0.30			
6				0.10	0.02	0.31
12	0.39	0.04	0.45			

[a]The reaction was always 5 M KOH at 35°C. Incubations with 12-HPO alone was with 3.3 mM 12-HPO (1.09 mg 12-HPO/mL); with 12-HPO plus 13*S*-HPODE the concentration of both was 2.3 mM (0.76 mg 12-HPO/mL and 0.72 mg 13*S*-HPODE/mL). Material from 1 mL aliquots was analyzed as methyl esters. See Table 1 for other abbreviations.
[b]12-HO, methyl 12-hydroxyoctadecanoate; 12-OO, methyl 12-oxooctadecanoate.
[c]Methyl 12-hydroxyoctadecanoate and 13-HODE could not be separated by high-performance liquid chromatography, and thus, are tabulated together as a sum.

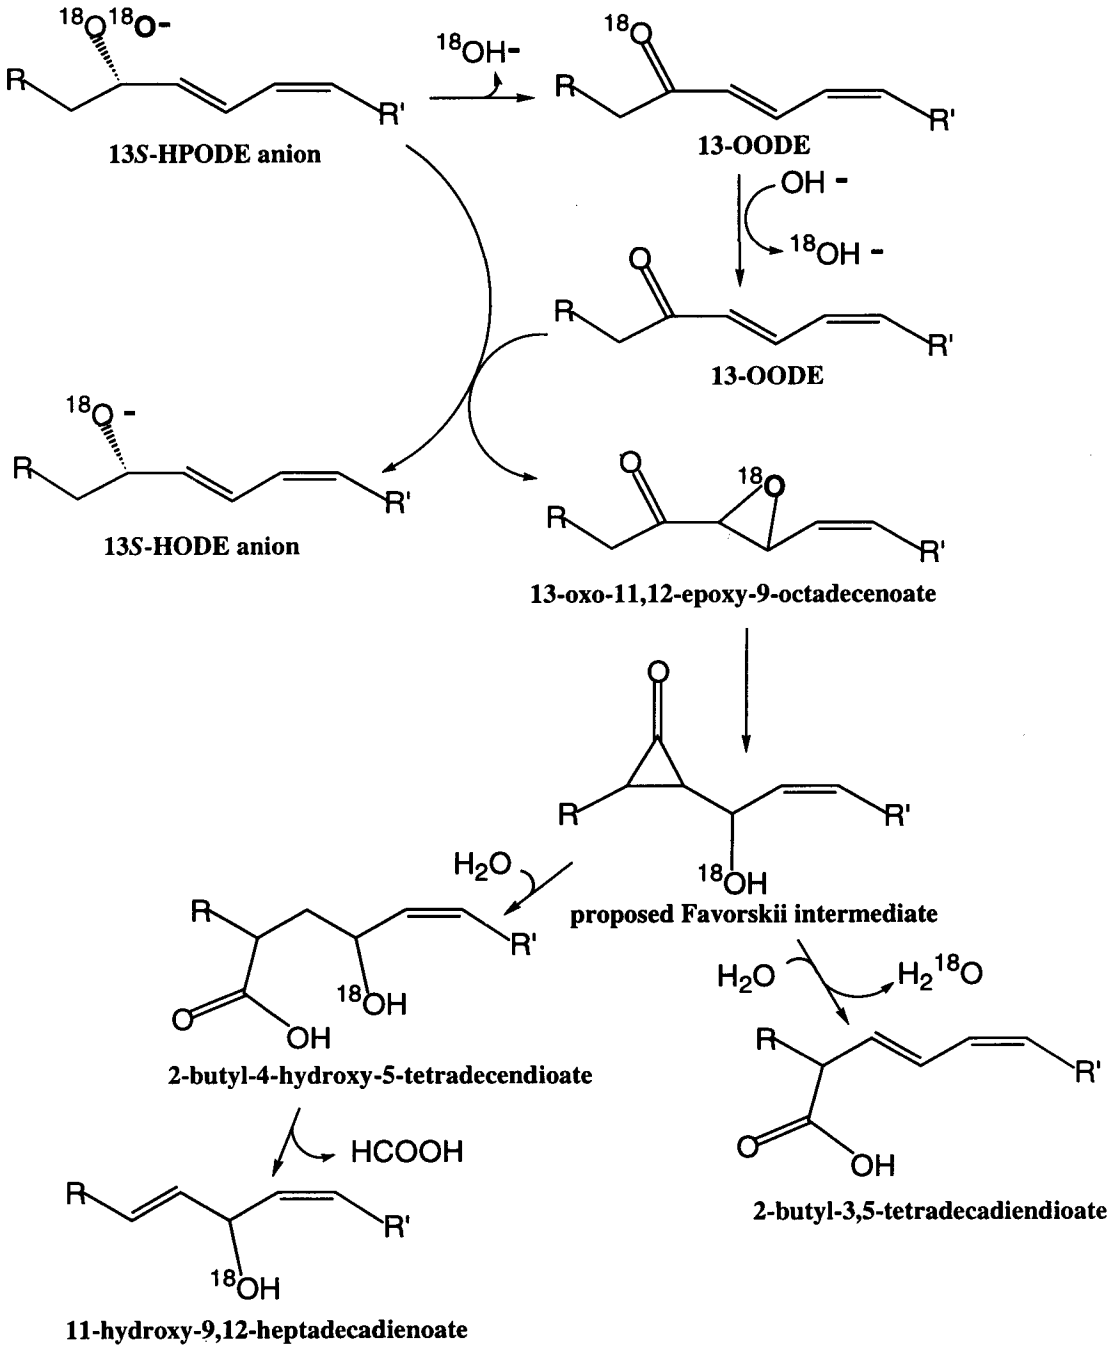

FIG. 1. Proposed reaction mechanism of (13*S*,9*Z*,11*E*)-13-hydroperoxy-9,11-octadecadienoate (13*S*-HPODE) by alkali into (13*S*,9*Z*,11*E*)-13-hydroxy-9,11-octadecadienoate (13*S*-HODE) and other fatty acids (as their K salts). 13-OODE, (9*Z*,11*E*)-13-oxo-9,11-octadecadienoate; R = $CH_3(CH_2)_3$-; R′ = $-(CH_2)_7COO^-K^+$; the bold ^{18}**O** indicates one oxygen transfer from hydroperoxy group to the epoxy group.

11-hydroxy-9,12-heptadecadienoic acid could arise from 2-butyl-4-hydroxy-5-tetradecendioic acid by elimination of formic acid, but the only evidence for this eventuality was a consistent ^{18}O-labeling pattern of the hydroxyl group.

Although the mechanism would seem to be completely assessed by our experiments, the stoichiometry of product formation is not balanced. If one considers that "dehydration" to 13-OODE is the origin of 25% of products other than 13*S*-HODE, then only 25% of the total serves as a sink for peroxide oxygen. Taken to completion, this would result in a 1:1 ratio of 13*S*-HODE to other products; whereas, the actual ratio was 3:1 (3). Obviously, there appear to be oxygen consumptive reactions unknown to us. For example, a number of minor products were short-chain dienedioc and monoenedioic acids, such as 3-hydroxy-4-tridecenedioic acid (3), and these compounds could arise from secondary oxidations not shown

in Figure 1. However, the minor quantity of short-chain compounds found gives reason to doubt that these potential oxidations would entirely account for the stoichiometric imbalance. One possibility is an oxygen consumption in the "dehydration" of 13*S*-HPODE to 13-OODE. A reaction incorporating such a feature is known as the "Russell Mechanism" which combines two peroxyl radicals of 13*S*-HPODE, yielding a molecule each of 13*S*-HODE and 13-OODE, as well as singlet oxygen (11). This would lead to a more realistic 2:1 ratio of 13*S*-HODE to other products. Evidentally, this reaction is not occurring because neither oxygen nor products of reaction between 13*S*-HODE and singlet oxygen were observed when [U-^{14}C]13*S*-HODE was incubated with 13*S*-HPODE.

Effects of Membrane Charges and Hydroperoxides on Fe(II)-Supported Lipid Peroxidation in Liposomes

Yoshiko Tampo and Masanori Yonaha*

Division of Environmental Hygiene, Hokkaido College of Pharmacy, Hokkaido 047-02, Japan

ABSTRACT: The processes in producing a lag phase in Fe^{2+}-supported lipid peroxidation in liposomes were investigated. Incorporation of phosphatidylserine (PS) or dicetyl phosphate (DCP) into phosphatidylcholine [PC(A)] liposomes, which have arachidonic acid, produced a marked lag phase in Fe^{2+}-supported peroxidation, where PS was more effective than DCP. Phosphatidylcholine dipalmitoyl [PC(DP)] with a net-neutral charge was still effective in producing a lag phase, though weak. Increasing concentrations of PS, DCP, and PC(DP) prolonged the lag period. Initially after adding Fe^{2+}, slight oxygen consumption occurred in PC(A)/PS liposomes including hydroperoxides, followed by a lag phase. An increase in the hydroperoxide resulted in a shortening of the lag period. The initial events of Fe^{2+} oxidation accompanied by oxygen consumption were dependent on the hydroperoxide content, but significant changes in diene conjugation and hydroperoxide levels at this stage were not found. The molar ratios of both disappeared Fe^{2+} and consumed O_2 to preformed hydroperoxide in liposomes with or without *tert*-butylhydroxytoluene were constant, regardless of the different amounts of lipid hydroperoxides. The antioxidant completely inhibited the propagation of lipid peroxidation in the lipid phase, following a lag phase. In a model system containing 2,2′-azobis (2-amidinopropane) dihydrochloride, Fe^{2+} were consumed. We suggest that Fe^{2+} retained at a high level on membrane surfaces play a role in producing a lag phase following the terminating behavior of a sequence of free radical reactions initiated by hydroperoxide decomposition, probably by intercepting peroxyl radicals.
Lipids 31, 1029–1038 (1996).

Lipid peroxidation in biomembranes is mediated by free radical reactions, including peroxidative fragmentation of phospholipids, leading to degeneration of the membranes associated with a variety of pathological events. Iron is known as an effective catalyst of lipid peroxidation (1). Iron-catalyzed lipid peroxidation is affected by the surface charges of membranes. For instance, Kunimoto *et al.* (2) observed that neutrally or negatively charged liposomes are more sensitive to ferrous ascorbate-supported peroxidation than to positively charged liposomes, and Fukuzawa *et al.* (3) showed that Fe^{2+}-catalyzed lipid peroxidation of linoleic acid in the presence of hydroperoxides was more effective in negatively charged micelles than in positively charged micelles. The Fe^{2+} complex is also effective in promoting lipid peroxidation of negatively charged liposomes in a nonenzymatic system (4) or in a reconstituted enzymatic system (5).

However, adding Fe^{2+} to mitochondria (6), microsomes (7,8), or phospholipid liposomes (2,9,10) produces a lag phase before the maximal rates of lipid peroxidation. The lag period is lengthened with an increase in added Fe^{2+}, and is shortened or eliminated by the coexistence of ferric iron (1,10), divalent, or trivalent metals without a redox capacity (8–10), or spermine (11). Alternatively, Yoshida *et al.* (12) reported that phosphatidylserine incorporated into phosphatidylcholine liposomes inhibits lipid peroxidation induced by ferrous-ascorbate. Similarly, Kogure *et al.* (11) showed that egg yolk phosphatidylcholine/bovine heart cardiolipin liposomes are resistant to ADP/Fe^{2+}-induced lipid peroxidation. These observations suggest that the net-negative surface charges of membranes in the appearance of the lag phase in lipid peroxidation may be important, in which case the lag phase could be produced by increased accumulation of Fe^{2+} on membranes (9). However, Fe^{2+}-supported lipid peroxidation in phosphatidylcholine liposomes also produces a lag phase (10), but it is unclear why the liposomes with the net-neutral charge are responsible for producing the lag phase.

Microsomes always contain traces of preformed lipid hydroperoxides (8). When liposomes are prepared by sonication, generation of traces of lipid peroxides is inevitable (8,13). Thus, obtaining peroxide-free lipid systems in biochemical experiments is difficult (8,14). The Fe^{2+} added to lipid systems with preformed hydroperoxides stimulate lipid peroxidation by decomposing hydroperoxides to free radicals leading to propagation reaction. Driomina *et al.* (9) observed that on adding Fe^{2+} an initial rise in malondialdehyde concentration before a lag phase was apparently associated with the decomposition of lipid peroxides. If alkoxyl and peroxyl radicals are generated during the process, the lag phase might reflect the duration of inhibition of lipid peroxidation.

The effect of membrane charge, as well as the behavior of Fe^{2+}, on producing a lag phase in lipid peroxidation is thus poorly understood; especially unclear are the molecular events in the processes leading up to propagation reaction. In this study, to clarify the mechanism producing a lag phase in Fe^{2+}-supported lipid peroxidation, we examined the effects of different surface charges of liposomes on the length of the lag phase and the chemical changes in the early stages before the lag phase, using phosphatidylcholine liposomes with different levels of lipid hydroperoxides. We show (i) the importance of anions on membrane surfaces in producing a lag phase, and (ii) the occurrence of Fe^{2+} oxidation accompanied by oxygen consumption in the early stages, is caused through free radical reactions, including hydroperoxide decomposition. We discuss the production of a lag phase in relation to redox cycling of iron on the membrane surfaces.

MATERIALS AND METHODS

Materials. L-α-phosphatidylcholine β-arachidonoyl γ-stearoyl [PC(A)], DL-α-phosphatidyl-L-serine dipalmitoyl (PS), L-α-phosphatidylcholine dipalmitoyl [PC(DP)], and dicetyl phosphate (DCP) were purchased from Sigma Chemical Co. (St. Louis, MO). All other chemicals used were of commercial reagent grade quality. Water processed with a Milli-Q system (Millipore, Milford, MA) was used to prepare all reagents. Ferrous ions were used as $FeSO_4$, dissolved carefully to avoid autoxidation in water purged with argon, and the solution (1.5 mM $FeSO_4$, pH 6.0) was kept under argon during the experiments. Under these conditions, no iron oxidation occurred. In this study, $FeSO_4$ below 150 μM was added directly to the reaction medium, including 25 mM Tris-HCl buffer at pH 7.5, as it produced no change in the pH of the buffer.

Preparation of lipid hydroperoxide. A solution of 100 mg PC(A) in 10 mL of chloroform/methanol (1:1, vol/vol) containing 5 mg methylene blue as a photosensitizer was placed in a beaker (diameter, 7 cm) and was stirred gently under photoirradiation for 3 h at 10°C. The light source, a 100 W tungsten proinjection lamp, was held at a 30-cm distance above the surface of the reaction mixture. The reaction mixture was passed through a column packed with Florisil (100–200 mesh) (Wako Chemicals, Tokyo, Japan) to remove methylene blue. The column was then washed with chloroform/methanol (1:2, vol/vol) followed by washing with methanol. After removing the solvents under argon, the lipids containing hydroperoxides were dissolved in chloroform. The hydroperoxide was determined by the method of Buege and Aust (15). Phosphorus in the lipids following oxidative degradation was estimated by the method of Fiske and Subbarow (16).

Preparation of liposomes. The PC(A), which has arachidonic acid at the β-position, was used as the substrate of lipid peroxidation, and PC(A) liposomes with different surface charges were prepared. A solution of 3.8 μmol of PC(A) and 0.38–1.15 μmol of PS, PC(DP), or DCP in chloroform were added to a small bottle, the chloroform was removed under argon, and the bottle was purged with argon after adding 1 mL of 0.1 M Tris-HCl at pH 7.5 containing 0.25 M NaCl, and then sealed. Unilamellar liposomes were prepared by sonication as we described previously (4). All operations were carried out under argon, and sonication was performed in ice-cold water. The hydroperoxide content of PC(A) in the liposomes after sonication was 2.9 ± 0.3 mol% (n = 20). Liposomes including hydroperoxides at higher concentrations were prepared as described above in this section, by adding different amounts of preformed hydroperoxides prepared by photoirradiation to PC(A) and PS dissolved in chloroform. When necessary, *tert*-butylhydroxytoluene (BHT) was also incorporated into the liposomes. The hydroperoxide levels of these liposomes after sonication were estimated and expressed as a liposomal concentration.

The stability of differently charged liposomes was compared by 5(6)-carboxyfluorescein- leakage (17). The proportion of the dye-leakage from 0.1 mM PC(A) liposomes after incubation in 0.15 M KCl and 25 mM Tris-HCl buffer (pH 7.4) at 37°C for 30 min was 6%, and incorporation of PC(DP), PS, or DCP at the concentrations used in this study caused no differences in leakiness. However, 11% releases were found by incorporating 20 μM stearylamine.

Lipid peroxidation. The incubation mixture contained phospholipid liposomes, Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5 in a final volume of 1.5 mL. After 2 min, with a temperature equilibration at 37°C, the reaction was started by adding 10–100 μL of 1.5 mM Fe^{2+}. Thiobarbituric acid-reactive substances (TBARS) were quantified by the method of Ottolenghi (18), using a value of the extinction coefficient at 535 nm of 156 $mM^{-1}cm^{-1}$, and the result was expressed as production of malondialdehyde. The background autoxidative activity (no incubation) of malondialdehyde production was subtracted in each experiment. Oxygen consumption was measured in a 1.5 mL cell at 37°C with a Clark electrode in a YSI Model 5300 Biological Oxygen Monitor (Yellow Springs Instruments, Yellow Springs, OH) and was calibrated by the method of Misra and Fridovich (19).

Assay of iron. The incubation mixture contained phospholipid liposomes, Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5 in a final volume of 1.5 mL. After 2 min, with temperature equilibration at 37°C, the reaction was started by adding 50 or 100 μL of 1.5 mM Fe^{2+}. The concentration of the remaining Fe^{2+} after incubation was determined colorimetrically using bathophenanthroline disulfonic acid disodium (BPS). An aliquot (1.0 mL) of the incubation mixture was added to 0.6 μmol of BPS in a final volume of 2.0 mL, and the absorbance at 534 nm was measured. An extinction coefficient of 22,140 $M^{-1}cm^{-1}$ for Fe^{2+}-BPS was used (20). The Fe^{3+} were monitored by recording an increase in absorbance at 310 nm at 37°C (21).

RESULTS

Figure 1 shows the profiles of Fe^{2+}-supported oxygen consumption in 100 μM PC(A) liposomes with different charges.

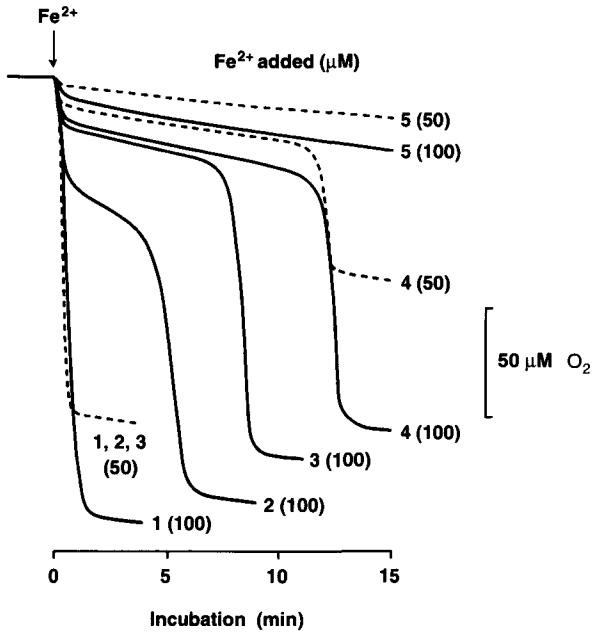

FIG. 1. Fe^{2+}-supported oxygen consumption of L-α-phosphatidylcholine β-arachidonoyl γ-stearoyl [PC(A)] liposomes with different surface charges. Phospholipid liposomes were prepared as described in the Materials and Methods section. The incubation mixtures contained 0.1 mM PC(A) liposomes, alone or including 20 μM of L-α-phosphatidylcholine dipalmitoyl [PC(DP)], dicetyl phosphate (DCP), or DL-α-phosphatidyl-L-serine dipalmitoyl (PS), 50 or 100 μM Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5. Oxygen consumption was monitored as described in the Materials and Methods section. The dotted lines indicate 50 μM Fe^{2+}, and the solid lines indicate 100 μM Fe^{2+}. 1, PC(A) alone; 2, PC(A)/PC(DP); 3, PC(A)/DCP; 4, PC(A)/PS; 5, without liposomes (Fe^{2+} autoxidation). The addition of Fe^{2+} is indicated by an arrow. This set of oxygraphs was one of three separate sets of experiments which showed essentially the same pattern.

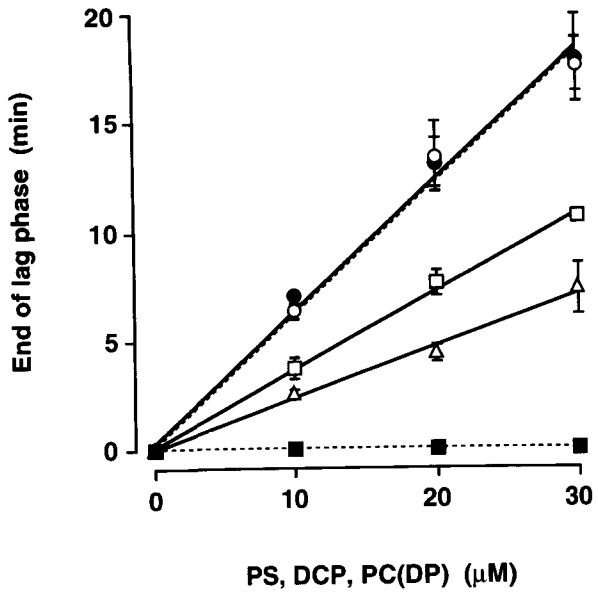

FIG. 2. Duration of the lag time of Fe^{2+}-supported oxygen consumption in PC(A) liposomes with different surface charges. Phospholipid liposomes were prepared as described in the Materials and Methods section. The composition of incubation mixtures is the same as in Figure 1, except that the liposomes, including PS, DCP, or PC(DP), at the indicated concentrations were used. The solid lines with open symbols indicate 100 μM Fe^{2+} addition: ○, PS; □, DCP; △, PC(DP), and the dotted lines with closed symbols indicate 50 μM Fe^{2+} addition: ●, PS; ■, DCP or PC(DP). Data represent the means ± SD of triplicate determinations. See Figure 1 for abbreviations.

With 50 μM Fe^{2+}, maximal rates of oxygen consumption occurred immediately after adding Fe^{2+} to PC(A) liposomes, and similarly, also in PC(A) liposomes incorporating either PC(DP) with a net-neutral charge or DCP with a negative charge. In contrast, in PC(A) liposomes containing PS with a net-negative charge, a small amount of oxygen was consumed initially after adding Fe^{2+}, followed by a period of slow oxygen consumption (lag phase), and, finally, a large amount of oxygen was quickly consumed. The same duration of lag phase was obtained with 100 μM Fe^{2+}, but a higher amount of oxygen was consumed after the lag. Similarly, in PC(A) liposomes containing PC(DP) or DCP, adding 100 μM Fe^{2+} produced a lag phase in oxygen consumption, but the length of the lag phase was different between both liposomes. It is noteworthy that a slight drop in each curve of oxygen consumption, in comparison with Fe^{2+} autoxidation, was always observed before the appearance of the lag phase. The lag periods of Fe^{2+}-supported oxygen consumption in PC(A) liposomes with PS, DCP, or PC(DP) at different concentrations were compared (Fig. 2). In all cases, except for DCP or PC(DP) with 50 μM Fe^{2+}, the lag periods lengthened linearly as a function of the concentrations of PS, DCP, or PC(DP). The ability of these compounds to prolong the lag period was in the order of PS>DCP>PC(DP). In PC(A) liposomes containing PS, the length of lag period at various concentrations of Fe^{2+} and the total oxygen consumption after the lag phase were estimated (Fig. 3). At all concentrations of Fe^{2+}, an increase in PS concentration lengthened the lag period. The length of the lag phase increased with increase in concentration of Fe^{2+} added up to 40 μM, but was constant above this concentration, which may reflect that the membrane surfaces are possibly saturated with Fe^{2+} at higher concentrations. At any concentration of PS, the total oxygen consumption after the lag phase constantly increased with an increase in Fe^{2+} concentrations, whereas the higher the concentration of PS, the lower was the oxygen consumption.

The changes in iron concentrations during Fe^{2+}-supported lipid peroxidation were monitored (Fig. 4). Generally, the oxygen consumption in either PC(A) liposomes or PC(A)/PS liposomes was accompanied by TBARS production, and these parameters correlated well with Fe^{2+} disappearance and Fe^{3+} formation in all processes of Fe^{2+}-supported lipid peroxidation, except that the initial consumption of oxygen in PC(A)/PS liposomes was not accompanied by TBARS production (the same level as without incubation). The rates of Fe^{2+} disappearance and Fe^{3+} formation during the lag phase

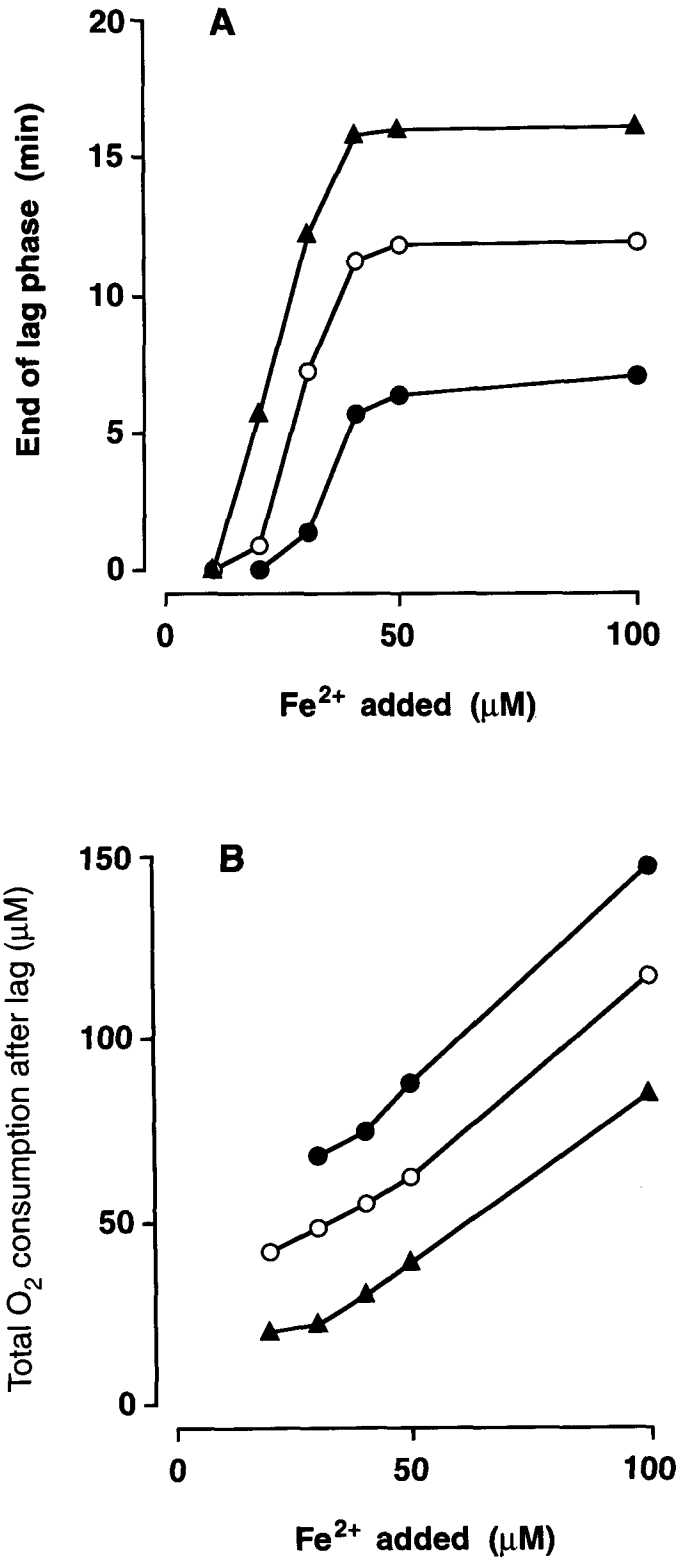

FIG. 3. Effects of Fe^{2+} at different concentrations on duration of lag time (A) and total oxygen consumption after lag (B) in PC(A)/PS liposomes. The composition of incubation mixtures is the same as in Figure 2, except that Fe^{2+} at the indicated concentrations was added. ●, 10 μM PS; ○, 20 μM PS; ▲, 30 μM PS. These data were one of two separate sets of experiments which showed essentially the same pattern. See Figure 1 for abbreviations.

were little changed compared with Fe^{2+} autoxidation without liposomes. After the lag phase, Fe^{2+} instantaneously disappeared with lipid peroxidation.

The effect of different levels of lipid hydroperoxides on oxygen consumption and Fe^{2+} oxidation in PC(A)/PS liposomes was examined (Fig. 5). All oxygen consumption curves in these systems showed a good correlation with Fe^{2+} oxidation. The lag periods in both parameters shortened with increased amounts of lipid hydroperoxides in the liposomes (lines 1 and 2), but lengthened with increased amounts of added Fe^{2+} (lines 2 and 3). The initial oxygen consumption and the accompanying oxidation of Fe^{2+} were affected by the hydroperoxide levels in liposomes (lines 1 and 2). Figure 6 shows that the lag periods in oxygen consumption in the presence of 50 μM or 100 μM Fe^{2+} varied inversely as the hydroperoxide content in the liposomes, and no lag period in the presence of 50 μM Fe^{2+} was produced at higher than the indicated hydroperoxide content. These results showed that the shortening of the lag phase is caused by preformed hydroperoxides *via* oxidation of Fe^{2+}.

In the early stages in Fe^{2+}-supported systems with preformed hydroperoxides, significant changes in the absorbance due to diene conjugation and the peroxide level were not found, while after the lag phase, rapid increases in these parameters reflected the propagation of lipid peroxidation (Fig. 7). The effect of BHT on Fe^{2+}-supported lipid peroxidation was examined (Fig. 8). Initially after adding Fe^{2+}, both oxygen consumption and Fe^{2+} oxidation between liposomes with or without BHT showed no differences, whereas BHT completely inhibited both lipid peroxidation and Fe^{2+} oxidation after the lag phase. In the early stages, Fe^{2+} disappeared and oxygen consumed were determined 1 min after incubation, using liposomes with different lipid hydroperoxide contents with or without BHT (Fig. 9). The disappearance of Fe^{2+} in the presence of 100 μM Fe^{2+} increased with increase in preformed hydroperoxides. No significant difference in Fe^{2+} disappearance was found between liposomes with or without BHT when two regression slopes or intercepts were compared by the Student's *t*-test. The molar ratio of disappeared Fe^{2+}/preformed hydroperoxide included in the liposomes was approximately three, while under argon without BHT, the ratio was two. Similarly, oxygen consumption depended on the content of preformed hydroperoxides, and BHT showed no significant influence on the oxygen consumption. About 2.5–2.8 moles of oxygen to a preformed hydroperoxide were consumed.

Coassin *et al.* (22) reported that Fe^{2+} is ineffective to inhibit crocin bleaching by peroxyl radicals, while iron is rapidly oxidized. The reactivity of Fe^{2+} with free radicals was examined in a model system containing 2,2′-azobis (2-amidinopropane) dihydrochloride (AAPH) (Fig. 10), which thermally decomposes to give two 2-amidinopropane radicals (A•), either recombining in a solvent cage or coupling with oxygen to give peroxyl radicals (23). In our study, Fe^{2+} were consumed depending on the amounts of AAPH under air (r = 0.995) or under argon (r = 0.988), but the consumption rate

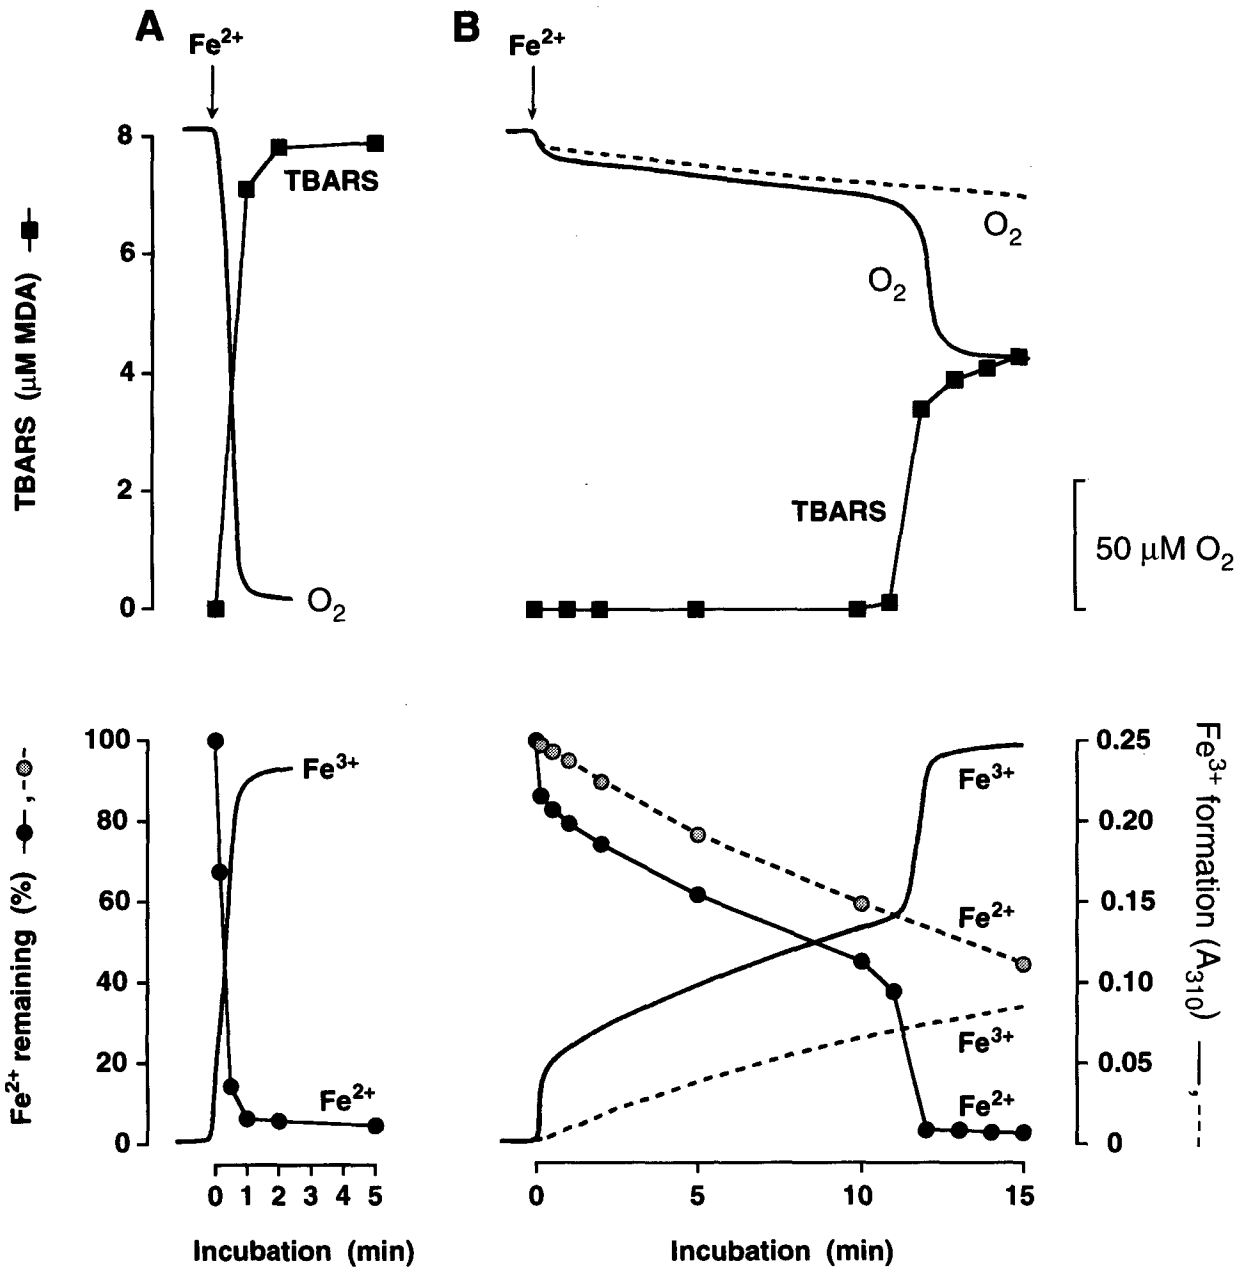

FIG. 4. Disappearance of Fe^{2+} during lipid peroxidation of PC(A) liposomes or PC(A)/PS liposomes. The incubation mixtures contained liposomes, 50 μM Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5. The concentration of PC(A) liposomes, alone (A) and including 20 μM PS (B), were 0.1 mM. Oxygen consumption, TBARS production, Fe^{2+} concentration, and Fe^{3+} formation were determined as described in the Materials and Methods section, and the dotted lines indicate autoxidation of Fe^{2+} without phospholipid liposomes. The addition of Fe^{2+} is indicated by an arrow. These data were one of two separate sets of experiments which showed essentially similar results. TBARS, thiobarbituric acid-reactive substances. See Figure 1 for other abbreviations.

in the absence of oxygen was markedly lower than in the presence of oxygen. This implies that the possibility of direct reaction of Fe^{2+} with AAPH may be ruled out. Under air, no oxygen consumption, compared with that of AAPH alone was influenced by Fe^{2+} at various concentrations (data not shown), suggesting that A• may react faster with oxygen than with Fe^{2+}. These results suggest that Fe^{2+} is capable of scavenging peroxyl radicals. It is likely that the low rate of Fe^{2+} disappearance in the absence of oxygen reflects possible scavenging of A• and latent reaction of A• dimerization.

DISCUSSION

All differently charged amphipathic compounds chosen to determine the effect of charges in this study had saturated acyl chains. The ability of these compounds to lengthen lag peri-

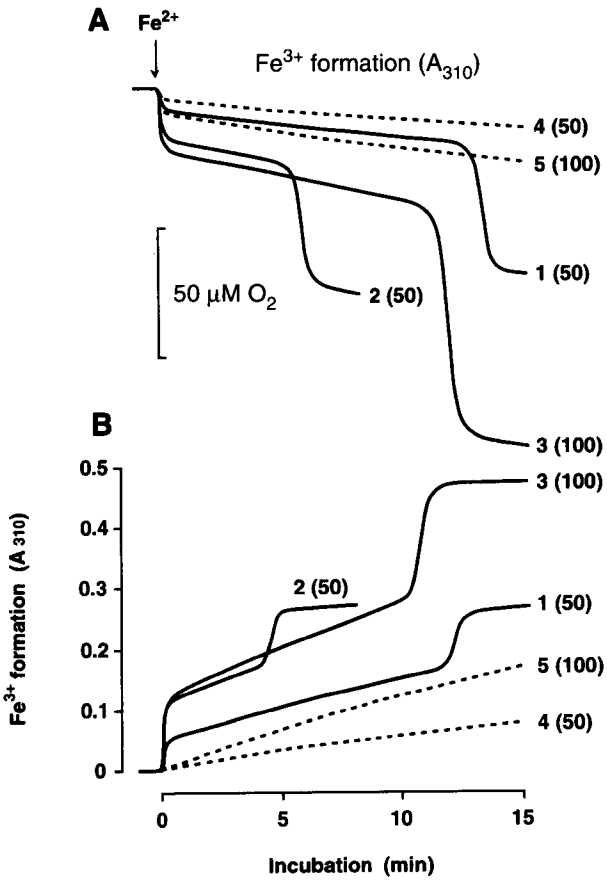

FIG. 5. Effect of lipid hydroperoxides on oxygen consumption (A) and Fe^{3+} formation (B) in Fe^{2+}-supported system containing PC(A)/PS liposomes. Liposomes, including preformed hydroperoxides, were prepared as described in the Materials and Methods section. The incubation mixtures contained 0.1 mM PC(A)/20 μM PS liposomes, including different amounts of hydroperoxides, 50 or 100 μM Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5. The concentrations of hydroperoxides and Fe^{2+} added were 1, 2.6 μM and 50 μM; 2, 5.4 μM and 50 μM; 3, 5.4 μM and 100 μM, respectively. Dotted lines 4 and 5 indicate the autoxidation of Fe^{2+} at 50 μM and 100 μM in the absence of liposomes, respectively. The addition of Fe^{2+} is indicated by an arrow. This set of oxygraphs was one of three separate sets of experiments which showed essentially the same pattern. See Figure 1 for abbreviations.

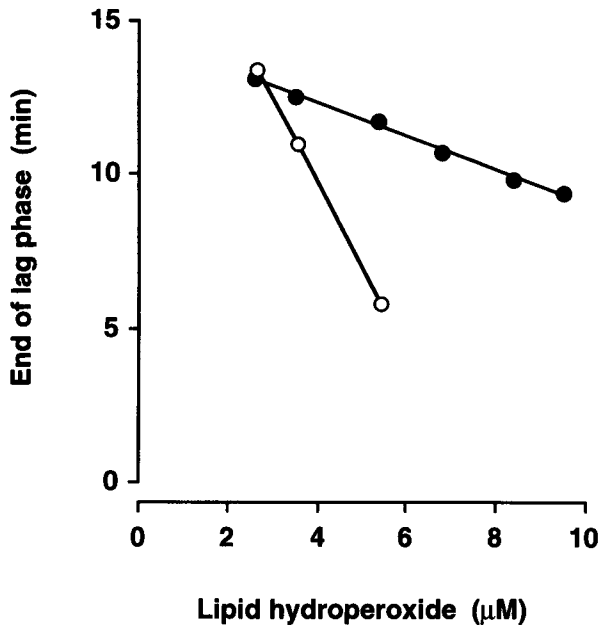

FIG. 6. Effect of lipid hydroperoxides on duration of the lag time in Fe^{2+}-supported system containing PC(A)/PS liposomes. Liposomes, including preformed hydroperoxides, were prepared as described in the Materials and Methods section. The composition of incubation mixtures is the same as in Figure 5, except that the concentrations of hydroperoxides included were 2.6, 3.5, 5.4, 6.8, 8.4, and 9.5 μM. ○, 50 μM Fe^{2+}; ●, 100 μM Fe^{2+}. Data represent the means of triplicate determinations. See Figure 1 for abbreviations.

ods in Fe^{2+}-supported oxygen consumption of PC(A) was in the order of PS>DCP>PC(DP). The effect of PS was predominantly superior to DCP, although the net-charge of these compounds is identical. One might imagine that the membrane instability of liposomes allows Fe^{2+} greater access to the internal lipid hydroperoxides resulting in differences in the lag phase. However, there were no differences in dye-leakiness among different liposomes used. Tadolini *et al.* (24) reported that phospholipid polar heads influence lipid hydroperoxide-dependent initiation of lipid peroxidation. Yoshida *et al.* (12) reported that saturated and unsaturated phosphatidylserine were similarly resistant to ferrous/ascorbate-supported lipid peroxidation, and they suggested the importance of their polar head groups in binding iron. Vile and Winterbourn (25) showed that iron also binds to the membrane of phosphatidylcholine liposomes. In our experiments, incorporation of 10–30 μM of PS, DCP, and PC(DP) into 100 μM PC(A) liposomes markedly produced lag periods, depending on their concentrations, regardless of the small amounts added. In addition, we postulated that the membrane surfaces might be saturated with Fe^{2+} at higher concentrations (Fig. 3). Hence, it is not plausible that prolongation of the lag period may largely depend on incorporation of saturated acyl chains into PC(A) liposomes. Our results appear to suggest that an increase in the anions on the liposomal surfaces affects the duration of the lag phase, supporting the view that liposomes with a net-negative surface charge are resistant to lipid peroxidation (11,12). However, the affinity of Fe^{2+} for the anions would be somewhat interfered with by the positive charges on the membrane surfaces. Indeed, the effect of PC(DP) on prolonging the lag period was poorer than that of DCP. In addition, the lag period (5 min) observed by adding a higher concentration (150 μM) of Fe^{2+} to PC(A) liposomes was significantly diminished by incorporating stearylamine (20 μM) with a positive charge into the liposomes (data not shown).

The total oxygen consumption after the lag phase clearly depended on the concentration of added Fe^{2+}, but inversely on PS concentrations. These observations suggest that the longer lag period leading to a decreased concentration of Fe^{2+}

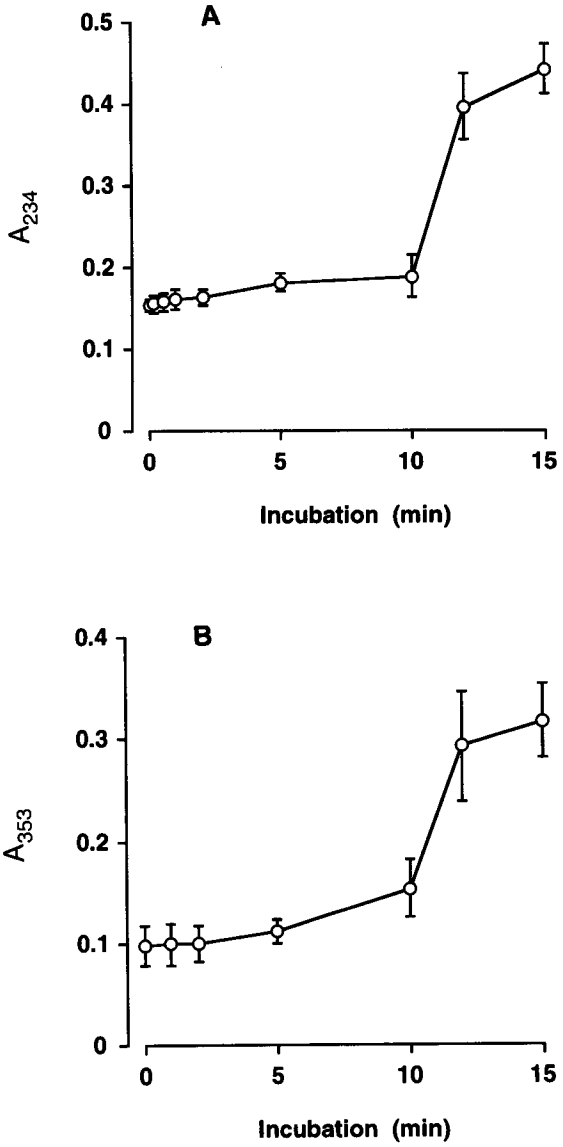

FIG. 7. Time-dependent changes of diene conjugation absorption (A) or hydroperoxide level (B) in PC(A)/PS liposomes with preformed hydroperoxides. Liposomes, including preformed hydroperoxides, were prepared as described in the Materials and Methods section. The incubation mixtures contained 0.1 mM PC(A)/20 μM PS liposomes including 5.7 μM hydroperoxides, 100 μM Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5. Diene conjugation absorption was monitored spectrophotometrically by recording separately the increase in absorbance at 234 and 310 nm at 37°C, because Fe^{3+} formation gave an additional increase in absorbance at 234 nm. After measuring the spectral change at 234 and 310 nm in Fe^{2+} autoxidation, the contribution of absorbance at 234 nm due to Fe^{3+} formation was subtracted. The absorbance (A_{234}) of phospholipid liposomes free from hydroperoxides was extrapolated to be 0.020 from calibration of phospholipid liposomes including different concentrations of hydroperoxides. Hydroperoxide was determined by the method of Buege and Aust (15), after the reaction was stopped with 0.57 mM bathophenanthroline. Data represent the means ± SD of triplicate determinations. See Figure 1 for abbreviations.

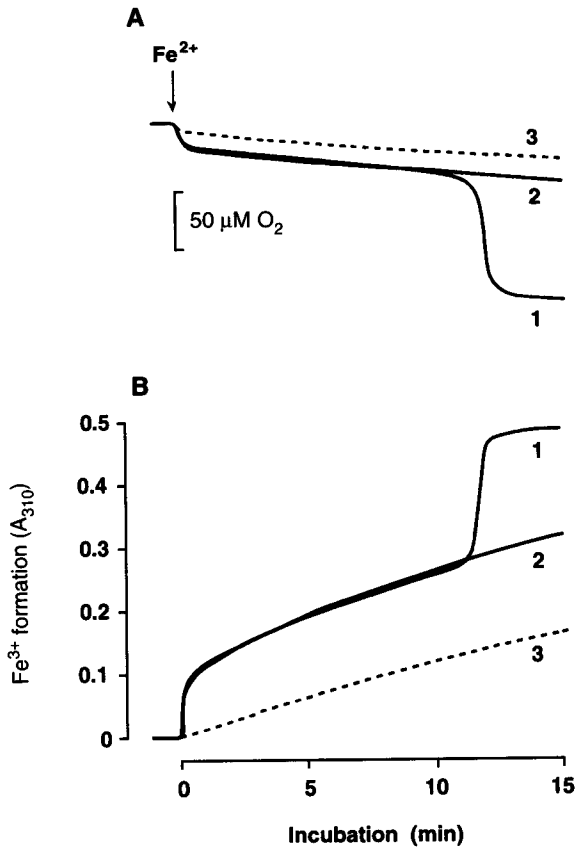

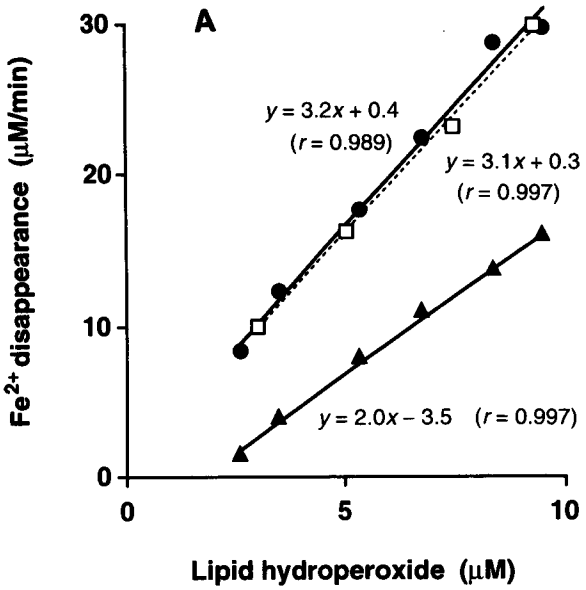

FIG. 8. Effect of *tert*-butylhydroxytoluene (BHT) in PC(A)/PS liposomes on Fe^{2+}-supported oxygen consumption (A) and Fe^{3+} formation (B). Liposomes, including preformed hydroperoxides, with or without BHT were prepared as described in the Materials and Methods section. The incubation mixtures contained 0.1 mM PC(A)/20 μM PS liposomes including 5.9 μM hydroperoxides, with or without 10 μM BHT, 100 μM Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5. 1, without BHT; 2, with BHT; 3, without liposomes (Fe^{2+} autoxidation). The addition of Fe^{2+} is indicated by an arrow. These tracings were selected from four separate sets of experiments which showed essentially the same pattern. See Figure 1 for other abbreviations.

due to autoxidation results in diminishing the magnitude of the chain propagation. Thus, massive lipid peroxidation after a lag phase appears to occur at a critical concentration of Fe^{2+} on the membrane surface, as suggested by Driomina *et al.* (9). Minimum concentrations of Fe^{2+} extrapolated from lag periods in PC(A) liposomes, including different concentrations of PS (Fig. 3), further suggest that the critical concentration of Fe^{2+} might be substantially altered by the binding capacity of the membrane surfaces.

Samokyszyn *et al.* (1) observed that ADP-Fe^{2+}-dependent lipid peroxidation is preceded by a lag phase diminished or eliminated by adding increasing concentrations of ADP-Fe^{3+}. They suggested that Fe^{3+} is important to initiate lipid peroxidation at a 1:1 ratio of Fe^{2+} and Fe^{3+}, and the lag phase represents the time to obtain sufficient levels of ADP-Fe^{3+} from ADP-Fe^{2+} autoxidation. In our experiments, about half of the added Fe^{2+} was lost by the end of the lag time (Fig. 4). However, apart from ferric iron, other metals without a redox capacity can also stimulate lipid peroxidation (8,9), and Aruoma *et al.* (8) suggested that Fe^{3+} may interfere with the inhibitory reactions of Fe^{2+} by displacing it from certain sites on membranes.

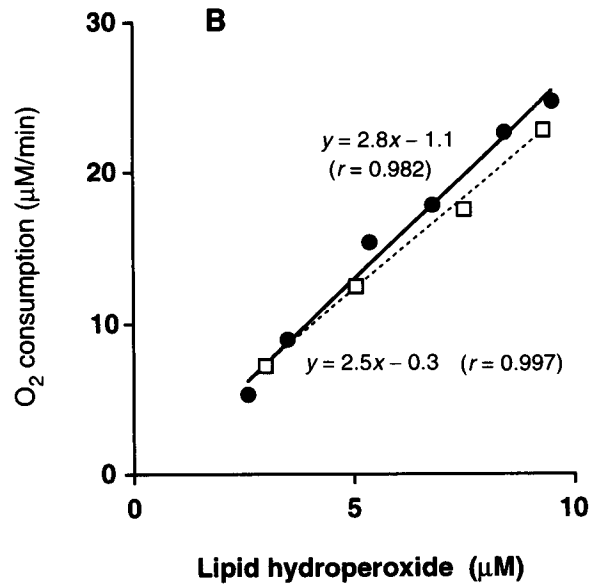

FIG. 9. Fe^{2+} disappearance (A) and oxygen consumption (B) in Fe^{2+}-supported system consisting of PC(A)/PS liposomes with different contents of lipid hydroperoxides. Liposomes, including preformed hydroperoxides, with or without BHT were prepared as described in the Materials and Methods section. The incubation mixtures contained 0.1 mM PC(A)/20 μM PS liposomes including different amounts of hydroperoxides, with or without 10 μM BHT, 100 μM Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5. The concentrations of hydroperoxides were 3.0, 5.1, 7.5, and 9.3 μM, when BHT was incorporated into the liposomes, but without BHT the concentrations were the same as in Figure 6. Fe^{2+} disappearance and oxygen consumption were determined 1 min after incubation. In aerobic conditions, each point indicates Fe^{2+} disappearance and oxygen consumption after subtracting the portion of Fe^{2+} autoxidation. ●, without BHT under air; □, with BHT under air; ▲, without BHT under argon. Data represent the means of triplicate determinations. See Figures 1 and 8 for abbreviations.

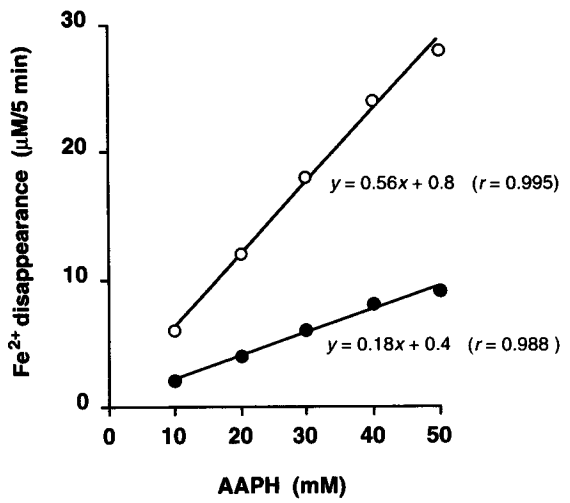

FIG. 10. Fe^{2+} disappearance promoted in the presence of 2,2′-azobis(2 amidinopropane)dihydrochloride (AAPH). The incubation mixtures contained AAPH at the indicated concentrations, 100 μM Fe^{2+}, 0.15 M KCl, and 25 mM Tris-HCl buffer at pH 7.5. The reaction was started by adding Fe^{2+} after preincubation for 1 min at 37°C. Under air, each point indicates Fe^{2+} disappearance after subtracting autoxidation of Fe^{2+}. ○, under air; ●, under argon. Data represent the means of triplicate determinations.

Driomina *et al.* (9) reported that an initial rise in malondialdehyde concentration accompanied by the fast flash of chemiluminescence occurred on adding Fe^{2+} to phospholipid liposomes. In this study, the initial disappearance of Fe^{2+} in Fe^{2+}-supported lipid peroxidation was also accompanied by oxygen consumption and was dependent on the lipid hydroperoxide content in the liposomes. Each molar ratio of either disappeared Fe^{2+} or consumed oxygen to preformed hydroperoxide in liposomes was constant, independent of the different amounts of lipid hydroperoxides. On the other hand, BHT incorporated into liposomes had no influence on the initial events of disappearance of Fe^{2+} and oxygen consumption. However, the results do not exclude the occurrence of free radical reactions on the membrane surface, because it is possible that the OH-group of BHT is located in membranes analogous to the location of α-tocopherol (26). Indeed, BHT completely inhibited the propagation of lipid peroxidation after the lag phase. These observations strongly support the results from the kinetics of Fe^{2+} oxidation in phosphatidylcholine liposomes, suggested by Garnier-Suillerot *et al.* (27), that hydroperoxide groups are localized at the aqueous interface and are decomposed by the subsequent binding of Fe^{2+} to the lipids. In Fe^{2+}-supported lipid peroxidation of PC(A)/PS liposomes with preformed hydroperoxides (10 μM), only 6% of 5(6)-carboxyfluorescein leaked by the end of the lag phase, while the propagation reaction was accompanied by the release of a great amount of dye (data not shown). These findings may suggest that a sequence of free radical reactions leading to the production of a lag phase preceding the propagation of lipid peroxidation in the lipid phase

occurs in the proximate region of the hydroperoxide group on the membrane surface of the liposomes.

Borg and Schaich (28,29) suggested that Fe^{2+} and Fe^{3+} at high concentrations can be expected to inhibit lipid peroxidation by the following radical scavenging reactions (Eqs. 1–3):

$$Fe^{2+} + LOO\bullet + H^+ \text{—fast} \rightarrow Fe^{3+} + LOOH \quad [1]$$

$$Fe^{2+} + LO\bullet + H^+ \text{—very fast} \rightarrow Fe^{3+} + LOH \quad [2]$$

$$Fe^{3+} + L\bullet \text{—fast} \rightarrow Fe^{2+} + L^+ \quad [3]$$

Equation 3 would be least important because of the short life time of L• except under severely hypoxic conditions (29). Our results from Fe^{2+} consumption in a model system, including AAPH, showed the possible involvement of Fe^{2+} in scavenging peroxyl radicals. However, whether Fe^{2+} has the ability to scavenge phospholipid peroxyl radicals remains unclear, as the redox potential of peroxyl radicals varies over a wide range (30).

The levels of diene conjugation and lipid hydroperoxides in Fe^{2+}-supported lipid peroxidation, did not change initially, regardless of a rise in oxygen consumption (Fig. 7). The lipid hydroperoxides used in this study were prepared by photooxidation. The oxidation of PC(A) with singlet oxygen produces eight hydroperoxide positional isomers, six (about 80%) of them having a conjugated diene (31). These conjugated dienyl hydroperoxides decompose through a series of reactions mediated by two moles of Fe^{2+} to form epoxy ketone and epoxy alcohol as major products (32,33). With regard to these reactions, Wilcox and Marnett (34) demonstrated that lipid alkoxyl radicals do not exist as reactive intermediates, since the intramolecular cyclization of lipid alkoxyl radicals into the adjacent site of unsaturation is instantaneous. Therefore, oxygen consumption, coupled with loss of conjugated dienes, results in epoxy peroxyl radical generation and subsequent formation of epoxy hydroperoxides (34). At the hydrogen abstraction stage, different types of compounds may compete. If epoxy peroxyl radicals abstract hydrogen from epoxy ketone and epoxy alcohol which still have a *bis*-allylic C-H bond in the molecule, the subsequent addition of oxygen generates new peroxyl radicals. During the sequence of these initial reactions in our study, three moles of Fe^{2+} and two moles of O_2 were consumed (Fig. 9). These results may be reconciled with assuming that Fe^{2+} scavenge the peroxyl radicals. When the above reactions are major reactions on the membranes, the levels of diene conjugation and hydroperoxide would not change significantly. The molar ratio of disappeared Fe^{2+} to preformed hydroperoxide contained in liposomes under argon was two. This ratio may be reasonable if Fe^{2+}, which could react with A• under argon, has the ability to scavenge epoxyallylic radicals that are more stable than alkoxyl radicals (34). Alternatively, both alkane radicals resulting from β-scission of alkoxyl radicals and lipid radicals generated by hydrogen abstraction from nonconjugated dienyl hydroperoxides might occur as minor (iron-independent) reactions at the oxygenation stage. The former reaction results in the loss of conjugated dienes, but the latter reaction is accompanied by conjugated diene formation.

Under the liposomal conditions, each hydroperoxide group in preformed PC(A) hydroperoxides appears to be located on the membrane surfaces, with its adjacent site available for lipid peroxidation inside the membrane near the surfaces. The overall reaction of Fe^{2+}-supported lipid peroxidation may be considered as follows. After adding Fe^{2+}, the initial hydroperoxide decomposition catalyzed by Fe^{2+} leads to secondary peroxyl radical generation accompanied by oxygen consumption. Subsequent reactions of Fe^{2+} on the membrane surfaces show antioxidant behavior, which depends on competitive local concentration of Fe^{2+} and is largely stoichiometric. These reactions, including a lag phase, may be explained by assuming Equation 4.

$$Fe^{2+} + LOO\bullet + H^+ \rightleftarrows Fe^{3+} + LOOH \quad [4]$$

The assumption includes that the forward reaction is fast, while the reverse reaction is slow. This is reasonable from kinetic (29,35) and thermodynamic considerations (30). At high levels, Fe^{2+} can effectively quench chain-carrying radicals competitively (forward reaction in Eq. 4), by intercepting them before chain propagation. Within the reaction cage, there remains no Fe^{2+}, and therefore, the lag phase might represent a slow reaction of Fe^{3+} with LOOH (reverse reaction in Eq. 4). Thus, the equilibrium in Equation 4 would lie toward the right during the lag phase, eventually leading to steady-state (apparent inhibition) of lipid peroxidation. When the concentration of Fe^{2+} falls, the Fe^{2+} lose their antioxidant ability and convert from antioxidant to prooxidant behavior as a result of redox cycling at trace levels of Fe^{2+}. In this context, a slow initiation phase in the presence of low peroxide concentration in heme-catalyzed lipid peroxidation is followed by a fast propagative phase once a threshold concentration of hydroperoxide is achieved (13,36). This would be the case for our experimental conditions. Peroxyl radicals on membranes penetrate into the lipid phase, and the lengths of the chain grow, resulting in massive lipid peroxidation.

Manganese ions are radical scavengers with a potent antioxidant ability (22). A comparative study of Mn^{2+} with Fe^{2+} may provide further information on the antioxidant processes of these metals.

ABSTRACT: We describe a new concept implicating oxidized cholesterol derivatives and very long-chain fatty acids as possible factors in the development of corneal opacification after death. Corneal tissues, removed from both fresh and stale fish eyes, were examined for cholesterol derivatives and fatty acids after methanolysis of lipids. Cholesta-3,5-dien-7-one, cholest-4-en-3-one, hexacosanoic acid, and hexacosenoic acid were identified *via* gas chromatography/mass spectrometry in opacified corneas, but not in significant amounts in fresh ones. The present study confirmed the presence of lipid hydrolysis and a peroxidation process in the opacified cornea.
Lipids 31, 1039–1043 (1996).

It is a widely held belief that fish is fresh so long as the cornea of the fish is clear. Corneal opacification is used in forensic science to indicate the time of death. It appears about 10 to 12 h after death (1). Although the cause of this phenomenon has not been elucidated, it has long been considered to be the result of drying of the cornea and protein degeneration.

Ocular tissues are continuously exposed to light, especially ultraviolet light, and are very susceptible to reactive oxygen species and free radicals. There is increasing interest in the idea that reactive oxygen species and free radicals have important roles in cataract development (2) and retinal degeneration (3) and, related to this, opacification of the lens has been found to be partly due to membrane damage of the cell by lipid peroxidation. These results suggest that lipid peroxidation is actively involved in corneal opacification as a result of membrane damage. To prove this hypothesis we used fish cornea, because of their easy availability.

The present study examined the peroxidation of cholesterol from fish cornea by means of gas chromatography/mass spectrometry (GC/MS).

MATERIALS AND METHODS

Hentriacontanoic acid methyl ester (31:0), used as an internal standard, 2-hydroxyhexacosanoic acid (hydroxy 26:0) and hexacosanoic acid methyl ester (26:0) were purchased from Sigma (St. Louis, MO), hydrogen chloride (5%, wt/vol) in methanol was obtained from Nachalai Tesque, Inc. (Kyoto, Japan), cholesta-3,5-dien-7-one, cholest-5-ene-3β, 7α-diol, cholest-5-ene-3β, 7β-diol, 3β-hydroxycholest-5-en-7-one, and cholest-4-en-3-one were purchased from Steraloids, Inc. (Wilton, NH). *cis*-17-Hexacosenoic acid methyl ester (26:1) was synthesized as follows: According to the conventional synthetic method, cyclooctanone was first subjected to Bayer-Villiger oxidation to give 8-hydroxyoctanoic acid methyl ester, which was then tosylated. Coupling reaction of oleyl magnesium bromide, with the prepared tosylate in the presence of Li_2CuCl_4, gave the desired 26:1 as colorless oil. The structure, including geometry of *cis*-stereochemistry, was firmly determined from H-nuclear magnetic resonance (300 MHz) spectrum, which exhibited two signals due to *cis*-olefinic protons (δ 5.34 and 5.35, dt, J = 10 and 5 Hz) with the coupling constant of $J_{17,18}$ = 10 Hz. All other chemicals were of analytical grade.

Fresh and clear corneas were removed just after death from several sea bream that had been brought live to a fish market; these were used as controls. Opacified corneas were obtained from several additional sea bream which had been stored for two days in the refrigerator, but were still suitable for consumption. Corneal tissue was minced with scissors, homogenized on ice with chloroform/methanol (2:1, vol/wt) solution, ultrasonically disintegrated, and extracted followed by centrifugation at 3,000 rpm for 15 min. Chloroform was evaporated under a nitrogen stream. The crude membrane lipids were placed in a screwcock-sealed reactivial with hydrogen chloride in methanol and heated at 120°C for 1 h to convert fatty acids to their methyl esters. Methanol was evaporated under a nitrogen stream and chloroform was added. An aliquot of 1 μL chloroform solution was injected into the GC/MS.

In vitro *experiment.* A sample of approximately 0.5 mg of each of cholest-5-ene-3β, 7α-diol, cholest-5-ene-3β, 7β-diol, and 3β-hydroxycholest-5-en-7-one was heated in a screwcock-sealed reactivial with 1 mL of hydrogen chloride in methanol for 1 h at 120°C. Excess reagents were evaporated to dryness under nitrogen stream. The residue was then dissolved in 250 μL of chloroform. A 1-μL aliquot of the sample was injected into the GC/MS apparatus.

GC/MS. GC/MS was performed on a Shimadzu Qp-1000 (Shimadzu, Kyoto, Japan) and a JMS DX-300 GC-MS (JEOL, Tokyo, Japan) connected on-line with a DA 5000 mass data analyzer (JEOL) fitted with a DB-1 fused-silica megabore column (30 m × 0.53 mm i.d., film thickness 1.5 μm; J&W Scientific, Folsom, CA). Helium was used as the carrier gas. The flow rate was 30 mL/min. The mass scan range was 50–600 atomic mass units, with a scan time of 3 s. The gas chromatograph oven temperature was programmed to 220–310°C at 4°C/min. The injection temperature was 240 °C; separation and insertion temperature, 240°C; ion-source temperature, 240 °C ; ionization voltage, 70 eV; ionization current, 60 μA; and acceleration energy, 3.0 kV.

Selected-ion monitoring (SIM) analyses were performed. The following ions were monitored: *m/z* 382, M^+ ion of cholesta-3,5-dien-7-one; *m/z* 384, M^+ ion of cholest-4-en-3-one; *m/z* 376, fragment ion of 26:1; *m/z* 410, M^+ ion of 26:0; and *m/z* 480, M^+ ion of internal standard. Standard curves were prepared by SIM analyses of 50 and 100 μg/mL of cholesta-3,5-dien-7-one and cholest-4-en-3-one with 50 μg/mL internal standard as well as 20, 40, and 80 μg/mL of 26:0 and 26:1 with 50 μg/mL internal standard. Signal areas of ions monitored were measured from the selected ion current trace and ratios of signal areas for *m/z* 382/480, 384/480, 376/480, and 410/480 were computed for standards and for lipid extracts of specimens.

RESULTS

Figure 1 shows total ion chromatograms performed for both opacified and control corneas. Cholesterol, cholesta-3,5-diene, and cholesteryl methyl ether were present in both samples. Many signals appeared in the opacified cornea. Electron impact (EI) mass spectra of signals A, B, C, and D are shown in Figure 2.

The signals A and B, appearing at a retention time (Rt) of 13.2 and 13.9 min, had a molecular ion at *m/z* 366 and a fragment ion at *m/z* 211. After methanolysis of standard cholest-5-ene-3β, 7α-diol and cholest-5-ene-3β, 7β-diol *in vitro,* we observed three cholestatrienes (cholesta-2,4,6-triene, cholesta-3,5,7-triene, and unknown) with a molecular ion at *m/z* 366 and a fragment ion at *m/z* 211. Two signals in the analysis of each of three cholestatrienes were consistent with signals A and B from the opacified cornea. Electron impact mass spectra of standard cholesta-3,5-dien-7-one and cholest-4-en-3-one are also shown in Figure 2. After methanolysis of standard 3β-hydroxycholest-5-en-7-one, we observed one signal being consistent with standard cholesta-3,5-dien-7-one. The mass spectrum of signal C in Figure 2 (Rt, 16.6 min) was consistent with that of standard cholesta-3,5-dien-7-one (*m/z* 382, 174), and the mass spectrum of signal D (Rt, 17.1 min) was consistent with that of standard cholest-4-en-3-one (*m/z* 384, 124).

Mass chromatograms that were monitored at *m/z* 366, 382, and 384 are shown in Figure 3. Thus, signal C was identified as cholesta-3,5-dien-7-one and signal D as cholest-4-

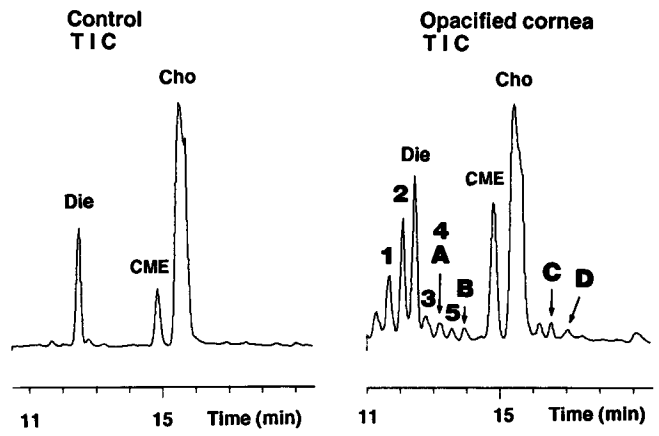

FIG. 1. Total ion chromatograms (TIC) for control and opacified cornea. Die, cholesta-3,5-diene; CME, cholesteryl methyl ether; Cho, cholesterol. A, B, unidentified but may be cholesta-2,4,6-triene and cholesta-3,5,7-triene; C, cholesta-3,5-dien-7-one; D, cholest-4-en-3-one; 1, 2-hydroxytetracosenoic acid (h24:1); 2, 2-hydroxytetracosanoic acid (h24:0); 3, hexacosenoic acid (26:1); 4, hexacosanoic acid (26:0); and 5, 2-hydroxypentacosanoic acid (h25:0).

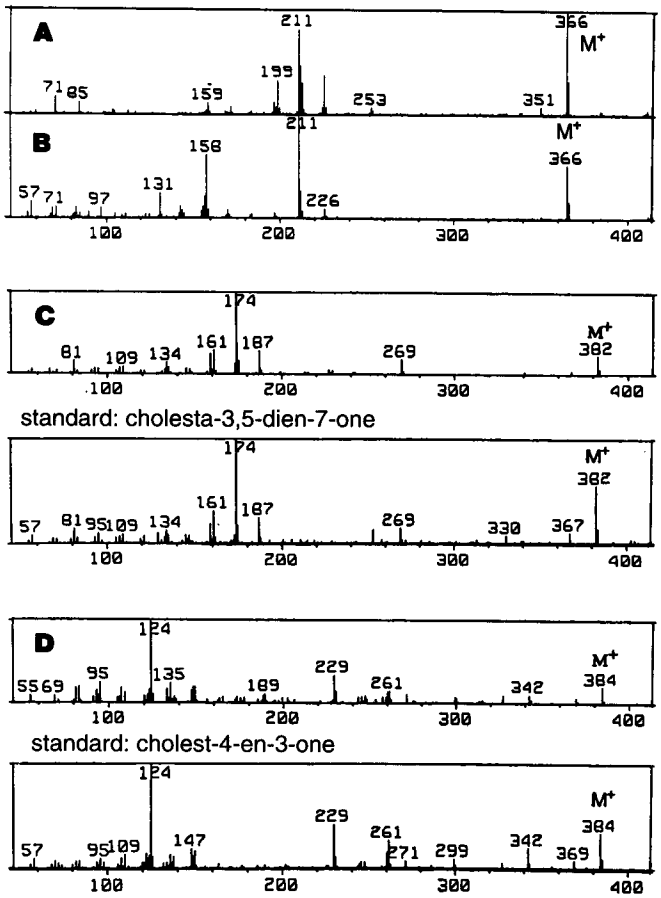

FIG. 2. Electron impact mass spectra of standard cholesta-3,5-dien-7-one and cholest-4-en-3-one, and for signals A, B, C, and D.

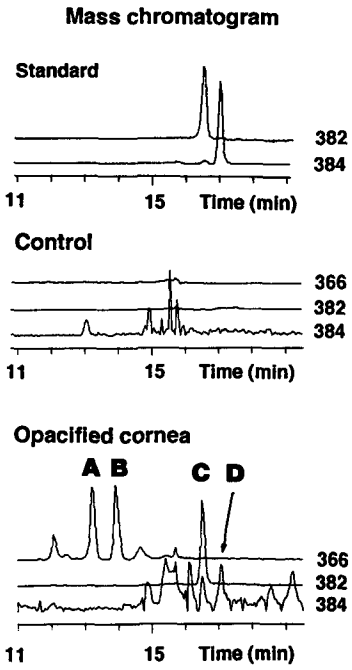

FIG. 3. Mass chromatograms with monitoring at *m/z* 366, 382, and 384 for standard cholesta-3,5-dien-7-one and cholest-4-en-3-one, control cornea and opacified cornea.

en-3-one by both mass spectra and mass chromatograms. Many unidentified signals appeared by monitoring at *m/z* 384 for the opacified cornea samples in Figure 3. Of these, the left signal of C (Rt, 16.1 min) might be cholest-5-en-3-one, but we failed to get a clear mass spectrum of it. The levels of cholesta-3,5-dien-7-one and cholest-4-en-3-one were 4.8 ± 0.2 μg/mg fat and 4.5 ± 0.1 μg/mg fat in the opacified cornea (n = 5); they were not detected in significant amounts in the control cornea.

Next, EI mass spectra of signals 1, 2, 3, 4, and 5 in Figure 1 are shown in Figures 4 and 5. The mass spectrum associated with signal 1 was consistent with 2-hydroxytetracosenoic acid methyl ester (*m/z* 337, 396), signal 2 was consistent with 2-hydroxytetracosanoic acid methyl esters (*m/z* 339, 398), and signal 5 was 2-hydroxypentacosanoic acid methyl ester (*m/z* 353, 412). The signals originating from

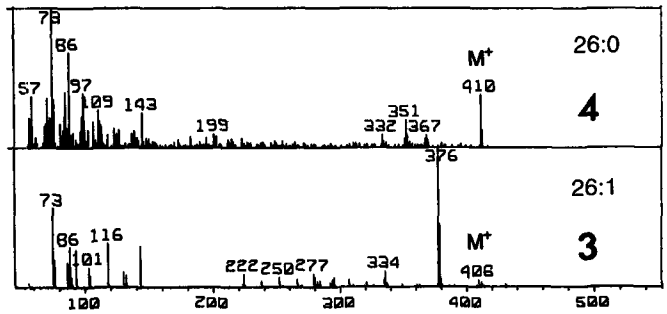

FIG. 5. Electron impact mass spectra of 26:0 for signal 4 and 26:1 for signal 3 in Figure 1.

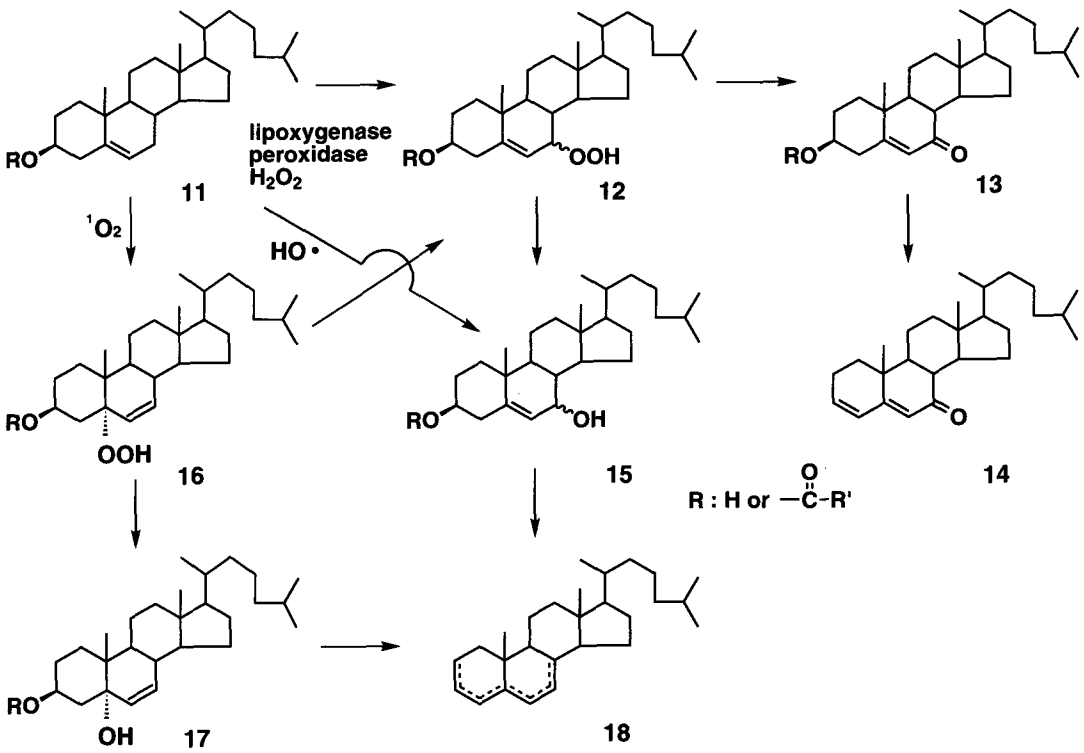

methyl esters of standard *cis*-17-26:1 and 26:0 were seen at Rt of 12.8 and 13.1 min, respectively. The mass spectrum of signal 3 (Rt, 12.8 min) was consistent with *cis*-17-26:1 (*m/z* 408, 376), and signal 4 (Rt, 13.1 min) was consistent with 26:0 (*m/z* 410, 367), as shown in Figure 5. The levels of 26:0 and 26:1 were 3.0 ± 0.1 and 6.2 ± 0.2 μg/mg fat in the opacified cornea (n = 5); they were not detected in significant amounts in the control cornea.

DISCUSSION

The results of the present study show for the first time that the opacified cornea of fish contained significant amounts of cholesta-3,5-dien-7-one, cholest-4-en-3-one, and cholestatrienes, whereas these compounds were essentially absent from the normal cornea of fish. The structures were confirmed by their mass spectra on GC/MS.

Many authors have written biological effects of oxysterols such as cytotoxicity, atherogenicity, sterol metabolism interference, mutagenicity, and carcinogenicity (4–7). Analyses of lipids of erythrocyte membrane (8) and fatty liver (9) of alcoholic patients revealed a significant accumulation of cholesta-3,5,-dien-7-one. In addition, elevated cholester-5-ene-3β, 7β-diol was seen in human atheroma (10) and 7-hydroperoxycholest-5-en-3β-ol was recognized in oxidized human low density lipoprotein (11).

An outline of oxidized cholesterol formation is shown in Scheme 1. The first step may be a peroxidation of cholesterol [11] to 7-hydroperoxycholesterol [12] in a microsomal lipid oxidizing system or by lipoxygenase and peroxidase, or cholesterol [11] to 5α-hydroperoxycholest-6-en-3β-ol [16] by singlet oxygen followed by rearrangement to 7-hydroperoxycholesterol [12]. This [12] might be oxidized to 3β-hydroxycholest-5-en-7-one [13], followed by dehydration to cholesta-3,5-dien-7-one [14], or might be reduced to cholest-5-ene-3β,7α-diol [15] and cholest-5-ene-3β,7β-diol [15]. These [15] might be dehydrated to cholestatrienes [18] during the acid methanol treatment. In contrast, [16] might be reduced to cholest-6-ene-3β, 5α-diol [17], followed by dehydration to cholestatriene [18]. Hydroxyl radical generated by Fenton reaction may form cholest-5-ene-3β, 7α and 7β-diol [15]. Cholest-5-ene-3β, 7β-diol and 3β-hydroxycholest-

SCHEME 1

5-en-7-one appeared at Rt of 18 and 19.7 min, respectively; however, we failed to detect these signals in Figures 1 and 3 because of acid methanol treatment.

In contrast, Cenedella *et al.* (12) detected cholesta-3,5-diene in an opacified dog cornea without the use of saponification. Detecting more than five peaks by GC/MS after heating cholesta-3,5-dien-7-one at 70°C for 30 min, we adopted methanolysis. However, a recent kinetic study on 3β-hydroxycholest-5-en-7-one stability during saponification clearly showed that 3β-hydroxycholest-5-en-7-one destruction occurred rapidly at 65 and 75°C (13). We should have used "cold" saponification at 45°C as a preliminary experiment to avod formation of artifacts. Because we detected cholesta-3,5-diene, as well as cholesteryl methyl ether, even in the control specimen under methanolysis conditions, and these steroids may not have been present in the initial extract before methanolysis, it is not clear whether cholesta-3,5-diene is present in the opacified cornea or not.

Next, we considered the incidence of lipid peroxidation in the cornea after death. In general, superoxide dismutase and reduced glutathione must act as agents of a radical scavenging system, whereas catalase scavenges hydrogen peroxide. Aldehyde dehydrogenase in mammalian lens has been reported to have a role in preventing cataract formation (14). Moreover, corneal alcohol dehydrogenase and aldehyde dehydrogenase isozymes were also identified as having a role in the detoxification of lipid peroxidation (15). When the lens was incubated *in vitro,* using xanthine oxidase as a superoxide generating system, cataract formation was suppressed by adding vitamin E (16). In contrast, reduced glutathione concentration, as well as reduced glutathione activity in the lens, has been shown to cause senile cataracts (17,18). We suggest that the activity of various radical scavenging systems decreases rapidly after death and, consequently, lipid peroxidation cannot be prevented, contributing to corneal opacification.

In the present study, an overlap of signal A, the elimination reaction product, with methyl ester of fatty acid (26:0), unfortunately was observed as the other instance of overlap of cholesta-3,5-diene with fish fatty acids (19). Although this study revealed the elevation of not only very long chain fatty acids but 2-hydroxy fatty acids, the implication of 2-hydroxy fatty acid generation on corneal opacification was not be elucidated clearly, however, hydrolysis of esterified fatty acids to their free form occurs under these post-mortem conditions.

As very long-chain fatty acids are degraded by the peroxisomal β-oxidation system, peroxisomal disorders such as Zellweger syndrome have been reported to cause the accumulation of these acids in plasma or tissue (20). Thus, the accumulation of 26:0 and 26:1 in the opacified cornea suggests the occurrence of peroxisomal disorders at the early stage of death.

The signal originating from methyl ester of 2-hydroxyhexacosanoic acid (hydroxy 26:0) (*m/z* 426, 367) appeared at Rt of 15.2 min; however, we failed to get this signal in Figure 1 because of an overlap with cholesterol so that it is not clear whether the opacified cornea had hydroxy 26:0.

[a]Bay Zoltán Foundation for Applied Research, H-6701 Szeged, Hungary, [b]Institute of Biochemistry, Biological Research Centre, Hungarian Academy of Sciences, H-6701 Szeged, Hungary, and [c]School of Fisheries, University of Washington, Seattle, Washington 98195

ABSTRACT: Fluorescence anisotropy parameter of [p-(6-phenyl)-1,3,5-hexatrienyl]phenyl–propionic acid (DPH–PA) and 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene (TMA–DPH) embedded in synaptic plasma membranes prepared from brains of cold (5°C) and warm (22°C) adapted fish (*Cyprinus carpio* L.), rat *(Rattus norvegicus)* and bird *(Branta canadensis)*, was studied. Fatty acid composition of total lipids as well as molecular species composition of diacyl phosphatidylcholines and phosphatidylethanolamines was also determined. The amount of long-chain polyunsaturated fatty acids decreased with increasing body temperature. There was a near-complete compensation of membrane structural order for environmental/body temperature over the evolutionary scale as seen by DPH–PA. Using TMA–DPH, the compensation was partial with rat and bird. Since DPH–PA and TMA–DPH differ in their charges, it is proposed, that the former reported membrane regions rich in cationic or zwitterionic (neutral) phospholipids and the latter, membrane regions rich in negatively charged phospholipids in the synaptic plasma membranes. Many different molecular species (20–25) of diacyl phosphatidylcholines and diacyl phosphatidylethanolamines were identified. The level of 16:0/22:6 phosphatidylcholine decreased while disaturated phosphatidylcholines increased with increase of environmental/body temperature from the fish through the bird. Level of 1-monoenoic, 2-polyenoic phosphatidylethanolamines also decreased with an increase in environmental/body temperature. Experiments using vesicles made of mixed synthetic phosphatidylcholine vesicles (16:0/16:0, 16:0/18:1, 16:0/22:6 in various proportions) showed that increase in disaturated phosphatidylcholine species does not explain the observed complete adjustment of membrane structural order in synaptic plasma membranes. Change in level of 1-monoenoic, 2-polyenoic phosphatidylethanolamines might be one of the factors involved in controlling the biophysical properties of the membrane according to the temperature.
Lipids 31, 1045–1050 (1996).

Convincing evidence has been presented that vertebrates possess the ability to adjust the fluidity of their membranous structure to environmental/body temperature in order to maintain their structural and functional integrity (1). Biological membranes are assemblies of lipids and proteins (2), and the lipid component is regarded to be responsible for controlling the physical properties of these structures. Although the motional properties of the hydrocarbon chains of the component polar lipids define the actual "fluidity" of membranes, the precise role of the individual membrane lipid constituents is not completely understood. Accumulation of polyunsaturated fatty acids in structural lipids during adaptation to reduced temperatures has repeatedly been demonstrated (3–5), but they may not be entirely responsible for the increase of fluidity since the physical properties of phospholipids are not linear functions of the number of double bonds present (6,7). Indeed, a number of data show no increase in fluidity in membranes of intact cells (8–11) or subcellular membranes (12,13) rich in polyunsaturated fatty acids. Earlier we observed the accumulation of 1-monounsaturated, 2-polyunsaturated phosphatidylethanolamine molecular species in livers and brains of freshwater and marine fish (14,15) and shrimp (16) species evolutionary or seasonally adapted to their thermal environment and concluded that not the gross amounts of polyunsaturated fatty acids but their combination with monounsaturated fatty acids in certain structural lipids play a role in controlling membrane physical properties in response to changes of body/environmental temperature. The synaptic membrane fraction of vertebrate brains has been shown to exhibit an almost perfect compensation for the temperature over the evolutionary scale (17). It seemed plausible to compare the molecular species composition of the two major diacyl phosphoglycerides, phosphatidylcholines, and phosphatidylethanolamines, with its biophysical properties in representative

species of fish, adapted to summer and winter temperatures, as well as of warm-blooded animals, such as mammalians and birds.

MATERIALS AND METHODS

Animals. Winter- (5°C) and summer adapted (22°C) carp (*Cyprinus carpio* L.) weighing 1–1.5 kg, collected from a local fish farm in the course of years 1994–1996; male Wistar rats (160 g); and wild geese *(Branta canadensis),* hunted near Pasco Washington, were used for preparation of brain synaptic membranes. Brains were removed immediately after killing the animals by decapitation or hunting and placed into liquid nitrogen until processed. Pooled brain probes of ten carps, five rats, and five birds were used for the investigations.

Synaptic plasma membrane fraction was prepared according to Szücs and Coscia (18). Briefly, the brains (6–7 g) were homogenized in 0.32 M sucrose containing 1 mM $MgCl_2$ 1 mM EDTA, 50 mM Tris HCl, and pH 7.1 using a Teflon homogenizer, ten passes. The homgenate was centrifuged at $1000 \times g$ for 10 min. The supernatant was sedimented at $13000 \times g$ for 30 min and resuspended in sucrose solution and spun again at $10800 \times g$ for 20 min followed by a further supension and centrifgation at $14000 \times g$ for 20 min. Then, the pellet was suspended by a Dounce homogenizer and lyzed at 0°C for 30 min. Finally the membranes were overlaid to a sucrose gradient consisted of a 10, 28.5, and 34% sucrose and centrifugated using a Beckman SW 27 rotor (Beckman Instruments, Fullerton, CA) for 60 min. The synaptic membranes were harvested at the interface of 28.5 and 34% sucrose and stored at −70°C. Electron microscopy showed formation of sealed vesicles free of mitochondrial contamination.

Analysis of lipids. Lipids were extracted from synaptic plasma membranes according to Folch *et al.* (19). Lipid extracts were further fractionated by thin-layer chromatography on precoated silica gel plates (Silica Gel G 60; E. Merck, Darmstadt, Germany) according to Fine and Sprecher (20). For preparation of choline and ethanolamine phosphoglycerides the spots were visualized by spraying with 0.5% 1-anilino,8-naphthalene sulphonic acid (Sigma, St. Louis, MO) in 50% methanol and viewed under ultraviolet light. They were then removed and extracted with chloroform/methanol 2:1, or used directly for derivatization to determine their molecular species compositions. Molecular species composition was determined according to Takamura *et al.* (21). Separation of purified dinitrobenzoyl derivatives of the diacylglycerols, obtained by phospholipase C (*Bacillus cereus*, Sigma) was performed on a Hypersyl column (5 μ, 250 × 4.6 mm) using a Merck-Hitachi 6220 high-performance liquid chromatography (HPLC) instrument.

Membrane fluidity. The synaptic plasma membranes or phosphatidylcholine vesicles were labeled either with 1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene (TMA–DPH) or 3-[p-(6-phenyl)-1,3,5-hexatrienyl]phenyl–propionic acid (DPH–PA) or DPH–PA, respectively, 15 min prior to starting the measurements. Steady-state fluorescence anisotropy parameter, R_{ss}, was determined between 2 and 30°C at 2°C intervals or at the respective body temperatures of the animals using a computer-controlled Hitachi MPF 2A spectrophotofluorimeter in heating mode (1°C/min) (22). Steady-state fluorescence anisotropy parameter was calculated according to Equation 1:

$$R_{ss} = I_{(vv)} - Z \cdot I_{(vh)} + Z \cdot I_{(vh)} \quad [1]$$

where $I_{(v)}$ and $I_{(h)}$ are the vertically and horizontally polarized light intensities, respectively, while $Z = 0.92$ and was calculated according to the formula: $Z = I_{(vh)}/I_{(hh)} \cdot R_{ss}$ primarily reflects the degree of hindrance to free rotation of the probe in its environment (23). Higher values represent more ordered, less fluid structures. Each data point is the average of ten readings.

Chemicals. DPH–PA and TMA–DPH were from Molecular Probes, Inc. (Eugene, OR). 1-palmitoyl, 2-palmitoyl phosphatidylcholine (16:0/16:0) (DPPC), 1-palmitoyl, 2-oleoyl phosphatidylcholine (16:0/18:1) (POPC), and 1-palmitoyl, 2-docosahexaenoyl phosphatidylcholine (16:0/22:6) (PDPC) were from Avanti Polar Lipids, Inc. (Birmingham, AL). All reagents were of analytical or HPLC grade.

RESULTS

Table 1 lists the fatty acids present in total lipids of brain synaptic plasma membranes of warm- and cold-adapted fish, rat, and goose. There is a clear tendency of diminishing the level of 22:6, with increasing environmental/body temperature.

[a]WA: warm-adapted (n = 3, mean ± SD), CA: cold-adapted (n = 4, mean ± SD).

Tables 2 and 3 give the molecular species composition of diacyl-phosphatidylcholines and ethanolamines in the synaptic membranes. Species of 16:0/18:1 dominated the diacyl-phosphatidylcholine fraction in the cold-adapted fish followed by 16:0/22:6. 16:0/16:0, and 18:0/22:6 were represented by low values compared to animals with warmer body/environmental temperatures. An increasing tendency was observed in the level of 16:0/16:0 phosphatidylcholines from cold-adapted fish through bird (from 5 to 27%). Parallel to this, the level of 16:0/22:6 decreased from 14.5 to 3.5% in cold-adapted fish to rat (Table 2).

[a]See Table 1 for abbreviations.

In diacyl-phosphatidylethanolamine fraction of cold-adapted fish 18:0/22:6, 18:1/22:6, and 16:0/22:6 were the major species. Increase in environmental/body temperature was accompanied by an increase in the level of 18:0/22:6 and a decrease in 18:1/22:6, 18:1/20:4, and 16:0/22:6 (Table 3). Proportion of 16:0/20:4 was almost identical in the different vertebrate classes while the level of 18:0/20:4 showed an abrupt increase with type of control of body temperature, that is the shift from poikilotherm to homeotherm (Table 3). Dipolyunsaturated (22:6/22:6, 20:4/20:4) molecular species were detected only in fish probes being the cold-adapted ones more rich in them than the warm-adapted fish.

Table 4 the steady-state anisotropy parameters (R_{ss}) of DPH–PA and TMA–DPH embedded in brain synaptic plasma membranes of the representative vertebrate classes is compared at their respective body temperatures. As seen, DPH–PA reported identical fluidities at the respective body temperatures, indicating a perfect compensation of membrane structural order for the environmental/body temperature. In contrast, TMA–DPH gave a different response and reported more fluid structures with rat and bird than expected on the basis of results obtained by DPH–PA.

Figure 1 shows the effects of different phosphatidylcholine species, showing the most characteristic changes during the thermal evolution, on structural order of fatty acids in phospholipid vesicles. Three vesicle populations were prepared from PDPC, POPC and DPPC, one representing the fish (PDPC/POPC/DPPC, 53:35:12%) the other one the rat (PDPC/POPC/DPPC, 35:45:20%), and the third one the bird (PDPC/POPC/DPPC, 28:37:35%) synaptic plasma membranes. Since phosphatidylcholine is one of the major constituents of these structures, it was expected that the results obtained will partially clarify the biological significance of the observed changes shown in Table 4. As seen, the "fish-like" phosphatidylcholine combination gave the least ordered, more fluid vesicles, and the "bird like" combination the most ordered, less fluid, structures at low measuring temperatures. At high measuring temperatures, this difference is reduced.

TABLE 4
Steady-State Fluorescence Anizotropy Parameter, R_{ss}, of 1-(4-Trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene (TMA–DPH) and 3-[p-(6-Phenyl)-1,3,5-hexatrienyl]phenyl–propionic acid (DPH–PA) Embedded in Synaptic Plasma Membranes of Representative Vertebrate Species Measured at Their Body Temperatures[a]

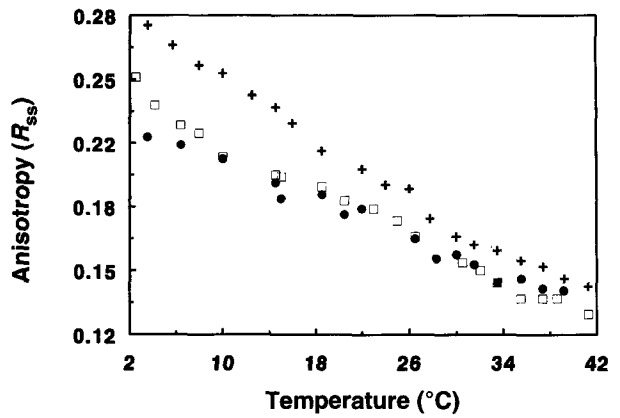

FIG. 1. Temperature dependence of fluorescence anizotropy parameter, R_{ss}, of DPH–PA embedded in "fish-like" (DPPC/POPC/PDPC, 12:35:53%); "rat-like" (DPPC/POPC/PDPC, 20:45:35%); and "bird-like" (DPPC/POPC/PDPC, 35:37:28%) phosphatidylcholines. ●: "fish-like," □: "rat-like," +: "bird-like" phosphatidylcholine vesicles. Each data point is the average of ten readings.

DISCUSSION

The experiments presented in Tables 1 and 4 confirm the observation of Cossins and Prosser (24) and Behan-Martin *et al.* (17) showing an adaptation of fatty acid composition and biophysical properties of brain synaptic membranes to environmental/body temperature over the evolutionary scale. In our experiments the extent of adjustment of fluidity was different with the two probes used. The anisotropy parameters measured by DPH–PA were almost identical at the respective body temperatures of the investigated species. Using TMA–DPH, similar anisotropy parameters were seen only with fish adapted to summer and winter temperatures, but with rat and bird nearly identical anisotropy parameters were obtained at 20 and 10°C, respectively. The above authors used DPH to describe the fluidity of these structures. This probe distributes randomly into the hydrophobic core of the membranes and thus reports the overall fluidity relationships. DPH–PA and TMA–DPH anchor to the lipid water interface (25,26). A major difference between DPH–PA and TMA–DPH is in their charges: the former is negatively and the latter is positively charged. R_{ss} values (Table 4) obtained for TMA–DPH were consistently lower than those for DPH–PA. TMA–DPH probes the membrane at the segment C_{8-10} while DPH–PA at the segment C_{10-12} (27). Since it is known that disorder increases toward the methyl end of fatty acyl chains (28) and DPH–PA reported more ordered structures than TMA–DPH, it is unlikely that this difference would come from the different vertical locations of the probes. Moreover it has been shown that both probes give identical R_{ss} values in identical environment (29). Thus it can be concluded, that TMA–DPH, due to its cationic nature, reported membrane regions rich in negatively charged phospholipids while DPH–PA, being repelled from this environment, reported regions where only neutral or positively charged phospholipids were present. Schroeder *et al.* (30) found that TMA–DPH reported more fluid structures in mice brain SPM and concluded that the outer leaflet is more fluid than the inner one reported by DPH–PA. Since DPH–PA and TMA–DPH reported idential fluidities in fish SPM, it is also possible that fish and mammalian synaptic plasma membranes differ in this respect.

In general, choline-containing glycerophospholipids make up 35-40% of phospholipids in synaptic plasma membranes (31–34) and dominate the outer leaflet (31). Over 90% of choline phosholglycerides is present in diacyl form. Diacyl phoshatidylethanolamines make up only 45–55% of the ethanolamine glycerophosholipids and the rest is present in alkyl-, or alkenylacyl form in vertebrate brains (35).

It is conceivable that alterations seen in composition of diacyl choline phosphoglycerides during the thermal evolution are at least partially involved in controlling membrane fluidity according to the temperature in certain regions of the synaptic plasma membranes. It can be expected that changes in disaturated components are one of the factors affecting the fatty acyl chain order and contribute to perfect compensation of membrane order for environmental/body temperature. An increase in disaturated species with increasing temperatures might render the membranes more ordered. Indeed, Hazel *et al.* (36) reported that mixing various amounts of 16:0/16:0 phosphatidylcholine to 16:0/22:6 phosphatidylcholine made the vesicles more ordered. Figure 1 shows that varying the proportion of 16:0/16:0 phosphatidylcholine in vesicles brought about a similar trend of alterations in structural order of fatty acyl chains as seen with native synaptic plasma membranes in the course of thermal evolution/adaptation at low measurement temperatures. However, the compensation of structural order in these artificial membranes was far below 100% observed for native synaptic plasma membranes. Since the R_{ss} vs. temperature curves were overlapping in case of "fish-like" (12% DPPC) and "rat-like" (20% DPPC) vesicles above 10°C, it is probable that DPPC alone, below a critical concentration, may not be involved in compensation of membrane structural order for temperature. The vast difference between the degree of compensation between the intact and artificial membranes made of synthetic phospholipids raises the question as to whether some other membrane components are involved in the observed homeoviscous response. Earlier, investigating the response by intact nerve cells given to changes of temperature under *in vitro* conditions using a spin labelled fatty acid, we found that a high degree of compensation was seen only with the intact cells and not with vesicles made of the extracted phospholipids (15).

The level of disaturated diacyl ethanolamine phosphoglycerides is low and does not change either seasonally in fish or during thermal evolution of vertebrates; thus this species might not be involved in controlling the biophysical properties of the membranes. The observation that the proportion of 1-monounsaturated, 2-polyunsaturated phosphatidylethanolamines decreases with increasing environmental/body temperature in synaptic plasma membranes is in line with our earlier observations on molecular species composition of livers

and brains of fish seasonally or evolutionarily adapted to contrasting temperatures (14–16). In a previous study we concluded that these phosphatidylethanolamines might play a role in the control of physical properties of membranes during thermal adaptation in fish liver (37). In fact we presented evidence showing that 18:1/22:6-, in contrast to 16:0/18:1 phosphatidylethanolamine, mixed to 18:0/22:6 phosphatidylcholine effectively decreased the acyl chain order in phospholipid vesicles using different *N*-(9-anthroyloxy) fatty acids and lowered the thermotropic phase transition temperature determined by electron spin resonance spectroscopic technique using 5-SASL (37). The ratio of 16:0/18:1 or 18:0/22:6 to 1-monounsaturated, 2 polyunsaturated phosphatidylethanolamines, increased from 0.19 and 0.95 in cold-adapted fish to bird, respectively, and from 0.96 and 13.46 in cold-adapted fish to bird, respectively, (Table 2). Thus a proper balance between certain molecular species in synaptic plasma membranes might contribute to the control of physical state according to environmental/body temperature.

ABSTRACT: We extended our previous data regarding the modulation of human platelet-activating factor receptor (hPAF-R) expression on human B cell lines as well as normal B cells. First, we showed that hPAF-R mRNA was present in B cell lines expressing membrane hPAF-R, but was absent from cell lines devoid of hPAF-R. Second, enhanced hPAF-R membrane expression induced in IM9 line by IL4 was preceeded by hPAF-R mRNA accumulation that was detectable by 8 h and which peaked at 24 h. Similar results were observed for 10 nM platelet-activating factor treatment, which increased hPAF-R mRNA content up to 120% at 48 h, whereas hPAF-R membrane expression was up-regulated by 130%. Third, our data indicate that functional hPAF-R are expressed on resting, as well as on activated, B cells and that B cell activation is required for maintaining hPAF-R membrane and mRNA expression. Thus, in normal B cells, as well as in B cell lines, transcriptional regulation and/or messager stability control hPAF-R expression.

Lipids 31, 1051–1058 (1996).

Platelet-activating factor (PAF) is a potent phospholipid mediator of inflammatory, allergic, thrombotic, and shock reaction (1–3). Produced at the site of agression, PAF recruits and stimulates neutrophil, eosinophil, and macrophages. Accumulating data suggest that PAF may also act on lymphocytes and regulate their activation. Using 1-*O*-[^{3}H]octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine [^{3}H]PAF binding, we and others have demonstrated that several B cell lines expressed human platelet-activating factor receptor (hPAF-R) (4,5). We have also demonstrated that membrane hPAF-R expression is specifically enhanced by IL4 and by PAF itself (5). In addition, our data indicated that hPAF-R was expressed on resting as well as activated B cells, but was only present on activated T cells (5,6). Recently, cDNA cloning from various sources revealed that hPAF-R belongs to the β-adrenergic receptor family (7–10). hPAF-R displays a number of features that may characterize a new family of serpentine receptors (11). Using antibodies directed against two different parts of the extracellular region of human hPAF-R, two groups have definitively established hPAF-R expression in monocytes, granulocytes, neutrophils, and eosinophils (12,13). In contrast, they obtained conflicting results regarding hPAF-R expression on lymphocytes.

In the present work, we extended our previous data on B cell lines, showing that hPAF-R mRNA correlated with hPAF-R membrane expression. On normal B cells, the expression of functional membrane hPAF-R, as well as its modulation during cell activation, was analyzed.

MATERIALS AND METHODS

B cells and cell cultures. The final medium for cultures consisted of RPMI 1640 supplemented with 10% heat-inactivated fetal calf serum (FCS), 100 U/mL penicillin, 100 μg/mL streptomycin, 2 mM L-glutamine, 1 mM sodium pyruvate, and 10 mM HEPES (Biochrom KG, Berlin, Germany). For culture in the presence of PAF, heat-inactivated FCS was depleted from acetylhydrolase activity by a brief acidic treatment as described previously (14,15). Cells were cultured in an humidified atmosphere containing 5% CO_2 in air at 37°C.

Nalm 6, Daudi, Raji, Ramos, and IM9 were obtained from the American Type Culture Collection (ATCC) (Rockville, MD). Rj2.2.5 and RM3 (two DR-deficient mutants of Raji) were provided by R. Accola (Verone, Italy) and A.F. Calman (San Franscico, CA), respectively (16,17). EBV1 and COR (a gift from B. Lisowska-Grospierre, Paris, France) cell lines were established by Epstein-Barr virus infection of normal peripheral B cells using the B95.8 (Epstein-Barr virus-producing Marmoset lymphoblastoid cell line) supernatant. Cell density was adjusted at 2–3 × 10^5 cells/mL, three times a week.

Human mononuclear cells were obtained from tonsils removed from children with chronic tonsillitis. Resting B cells were isolated from the E^- fraction by percoll gradient separation, as previously described (15). Normal resting B cells (1 × 10^6 cells/mL) were stimulated for 48 h by Staphylococcus Aureus Cowan 1 (SAC; 1:10^4, vol/vol; Calbiochem Corp., San Diego, CA), phorbol 12,13-dibutyrate (PDB; 1 ng/mL;

Sigma Chemical Co., St. Louis, MO) and ionomycin (800 ng/mL), phorbol 12-myristate 13-acetate (PMA; 5 ng/mL; Sigma), IL4 (400 U/mL, Genzyme, Cambridge, CA), or the combination of CD40 Ab (18) (from G28-5 hybridoma provided by E.A Clark, Seattle, WA) (1 μg/mL), and IL4. Cell count and viability (by trypan blue exclusion) were assessed at the time of the assay.

Binding assay of radiolabeled PAF. Synthetic PAF C_{18} (1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine) and lyso-PAF (1-*O*-octadecyl-*sn*-glycero-3-phosphocholine) (Bachem, Bubendorf, Switzerland) were dissolved at 10 mM in ethanol (60%). The solutions were evaporated under nitrogen, redissolved at 100 mM in 0.9% NaCl containing 2.5 mg/mL fatty acid free–human serum albumin (HSA; Biomerieux, Lyon, France) and stored at −20°C. For further dilutions, the concentration of 2.5 mg/mL Fatty acid free–HSA was maintained. [^{3}H]PAF (sp. act. 9.25 MBq/mmol) was purchased from Amersham (Les Ulis, France).

[^{3}H]PAF binding to B cell lines was performed as previously described (5). In brief, cells (5×10^6 cells/mL) were incubated for 2 h at 4°C with [^{3}H]PAF (0.325–10 nM) with or without unlabelled PAF (500 nM). B cell associated-radioactivity was then measured on GF/C filters (Millipore, Ferrière, France) after vacuum filtration as described. The average number of hPAF-R/cell and the dissociation constant were quantified by Scatchard plot analysis of the specific binding data (5).

cDNA probes and Northern blot analysis. A 0.7 kb EcoRI cDNA fragment of hPAF-R (previously described in Ref. 12) was used as specific probe, whereas a 1.5 kb EcoRI cDNA probe of ribosomal RNA 18S (ATCC, Rockville, MD) was used for control hybridization. Probes were radiolabelled to a specific activity $>1 \times 10^8$ cpm/mg with [α^{32}P]dCTP (sp. act. >3000 Ci/mmol; Amersham) using a multiprime DNA labelling kit (Amersham).

Total RNA was extracted from cell preparations by guanidium isothiocyanate-phenol chloroform technique according to Chomczynski and Sacchi (19). Twenty μg of total RNA were electrophoresed through a 1% formaldehyde–agarose gel and blotted onto Hybond N^+ nylon membrane (Amersham). Specific hybridization was performed as previously described (19). Membranes were exposed to X-ray films (Hyperfilm MP; Amersham) with intensifying screens at −80°C for 48 h. Membranes were rehybridized with an 18*S* probe as control. Quantification of signal intensity was performed by a STARWISE image processing system (IMSTAR, Paris, France)

Immunofluorescence analysis. IOB4 (IgG1, CD19), ROM2 (IgG2a, CD14) monoclonal antibodies, FITC-conjugated goat $F(ab')_2$ anti-mouse IgG or FITC-conjugated goat $F(ab')_2$ anti-rabbit IgG were purchased from Immunotech (Marseille, France). Polyclonal hPAF-R antibody (12) was used at 1:500 dilution as defined by preliminary experiments. A polyclonal keyhole limpet hemocyanin antibody was used as control. Membrane hPAF-R expression was assessed by flow cytometry as previously described (5). Cell labelling was analyzed using a FACScan flow cytometer (Becton Dickinson, Mountainview, CA) using logarithmic scale for fluorescence. At least 5,000 events were analyzed after gating on viable cells for each histogram.

Measurement of $[Ca^{2+}]_i$ by flow cytometry. $[Ca^{2+}]_i$ mobilization was determined in B cell lines and normal B cells using fluorescent dye Indo-1 AM (Sigma) as previously described (13). Briefly, cells were washed twice in RPMI 1640, resuspended at 3×10^6 cells/mL in RPMI 1640 plus 10% FCS and loaded with 10 μM Indo-1 AM for 30 min at 37°C. Cells were washed twice in RPMI 1640 and allowed to equilibrate for an additional 30 min at 37°C. Cells were pelleted, resuspended at 2×10^6 cells/mL in Hank's balanced salt solution without Ca^{++} supplemented with 10 mM Hepes, and protected against light until use. Ca^{++} concentration was brought to 1.5 mM and cell suspensions were prewarmed at 37°C for 15 min prior to the assay. At the time of assay, PAF, lyso–PAF or Nacl–HSA were added to one mL of cell suspension and fluorescence signals recorded in an EPICS Prolile flow cytometer (Coulter, Hialeh, FL). Results are expressed as peak mean fluorescence intensity (MFI) (*y*-axis, linear scale) recorded every 60 s (*x*-axis).

RESULTS

Expression of membrane and mRNA hPAF-R in B cell lines. Binding of [^{3}H]PAF on several B cell lines is depicted in Figure 1A. As shown, Raji and IM9 expressed high numbers of hPAF-R, whereas no binding site was detected on Daudi and Nalm 6. Two HLA DR class II-deficient mutants of Raji, RM3 and Rj2.2.5, exhibited 3- and 10-fold less [^{3}H]PAF binding sites than did Raji. Compared to RM3, Ramos displayed similar number of sites. By contrast, two lymphoblastoid cell lines established from normal peripheral B cells were devoid of binding site. Scatchard analysis revealed, in all positive cell lines, a single class of high affinity hPAF-R with a kd value ranging from 1 to 4.5 nM (data not shown).

Northern blot analysis, (Fig. 1B) showed that hPAF-R mRNA was expressed as a single 3.8-4 kb transcript in Raji, IM9, RM3, and Rj2.2.5 cell lines, whereas no hPAF-R mRNA was detected in Daudi and Nalm 6. hPAF-R mRNA signal intensity was similar in B cell lines exhibiting high (Raji and IM9) or low number (Rj2.2.5 and RM3) PAF binding sites. This suggests that, in cell lines, hPAF-R membrane expression is regulated at transcriptional and post-transcriptional levels.

PAF modulation of hPAF-R mRNA expression. We next examined whether modulation of membrane hPAF-R expression induced by PAF itself (5) was regulated at a transcriptional level. Thus, IM9 B cells were cultured in 10% FCS acetylhydrolase-free medium with or without PAF for defined periods of time. An important increase of hPAF-R mRNA accumulation was observed with 10 and 100 nM PAF, and vehicle (NaCl–HSA) had no effect (Fig. 2A). For short-time exposure (6 h), 100 nM induced a maximal increase (87%) of hPAF-R mRNA level (Fig. 2B). For longer-time exposure, 10 nM was more efficient than 100 nM PAF in modulating hPAF-R mRNA level. For instance, at 48 h, the increase in mRNA content was 73 and 120% for 100 and 10 nM PAF, re-

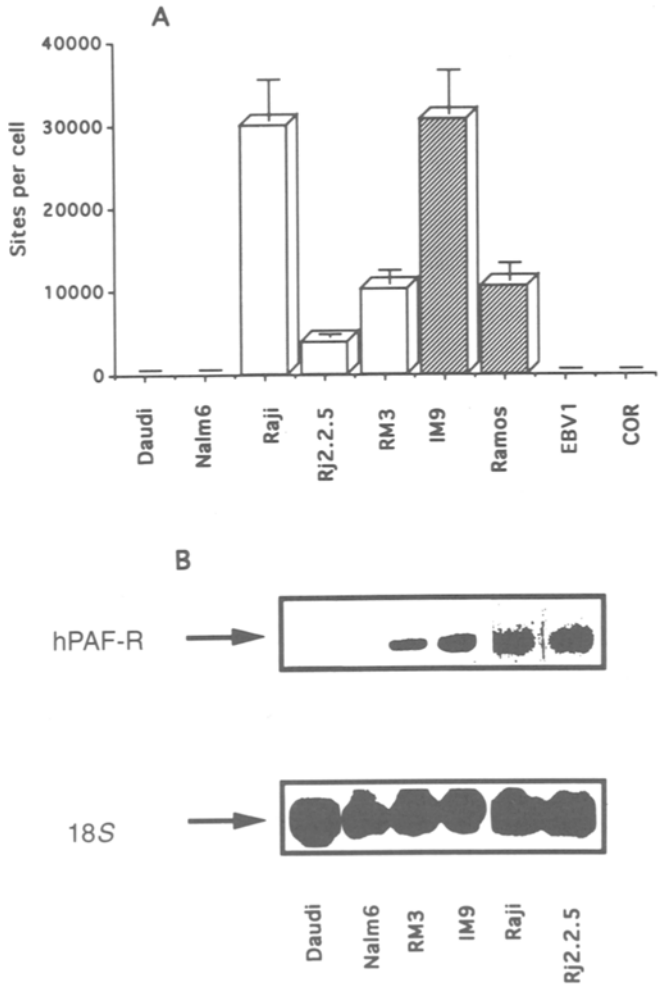

FIG. 1. Human platelet-activating factor receptor (hPAF-R) expression in human B cell lines. (A), binding on various B cell lines. Results are expressed as mean number of sites ± SD as determined by scatchard analysis. (B), Northern blot using ^{32}P-hPAF-R or ^{32}P ribosomal RNA 18*S* probes (20 µg/lane) (ATCC, Rockville, MD). One representative experiment out of six is shown.

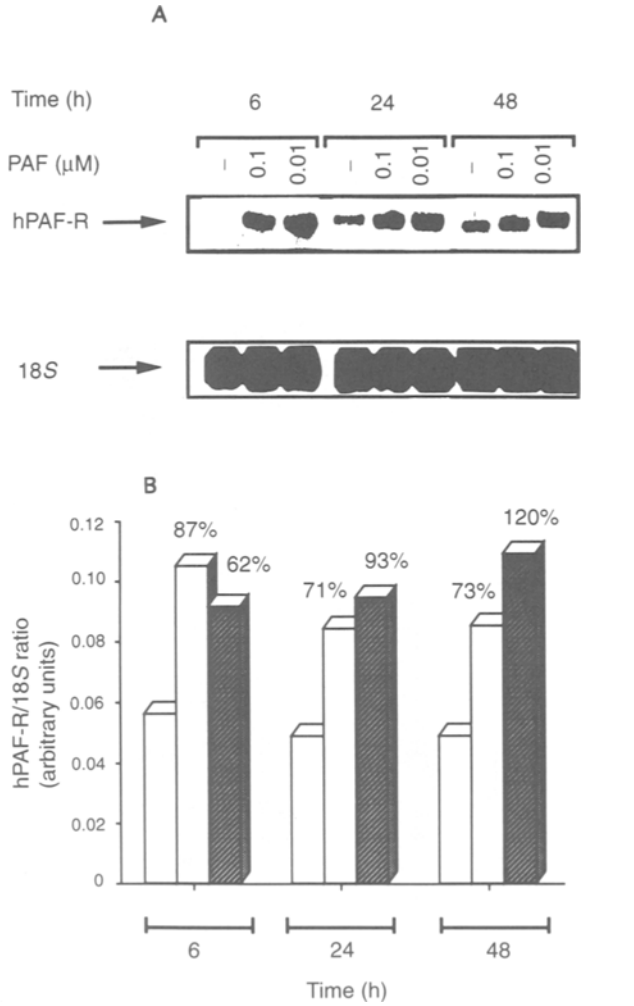

FIG. 2. hPAF-R mRNA expression is modulated by platelet-activating factor (PAF). IM9 cells (0.2×10^6/mL) were cultured for 6, 24, or 48 h in acetylhydrolase-free medium with 10 to 100 nM PAF or vehicle. (A), Northern blot analysis using ^{32}P-hPAF-R or ^{32}P ribosomal RNA 18*S* probes (20 µg/lane). Densitometric analysis of the blot is plotted in (B). One representative experiment out of three is shown. See Figure 1 for abbreviation and company source.

spectively. The increase in hPAF-R mRNA fits well with our previous observation, showing that treatment of IM9 cells with PAF (10 or 100 nM) up-regulated the membrane expression of its own receptor by about 130% (5).

IL4 modulation of hPAF-R mRNA expression. We have previously reported that IL4 up-regulated by about 150% the number of hPAF-R sites, without affecting the affinity (5). Here, kinetic studies on hPAF-R mRNA expression were performed after addition of IL4 (400 U/mL) or medium (Fig. 3). hPAF-R mRNA expression increased by 130% after 8 h, reached a maximum by 24 h (210%), and decreased thereafter (110 and 0% at 48 and 72 h, respectively).

Expression of hPAF-R mRNA in normal human B cells. We next investigated hPAF-R mRNA expression in normal B cells. Northern blot analysis was performed on RNA extracted from fresh resting B cells (resting) or from B cells cultured for 48 h with medium (none), SAC, IL4, PMA, or PDB plus ionomycin. Results in Figure 4A show that resting, but not medium-treated (48 h), B cells expressed hPAF-R mRNA. In activated B cells, hPAF-R mRNA level was similar (PDB plus ionomycin, IL4) or twofold higher (PMA, SAC) than that observed in resting B cells (Fig. 4B).

Resting and activated B cells express membrane hPAF-R. Using a polyclonal hPAF-R antibody, we also investigated membrane expression on normal B cells. Preliminary experiments indicated that this antibody stained IM9 and Raji, but not Daudi cell lines (data not shown). Figure 5 shows that all B cell populations were more than 91% $CD19^+$ and less than 3% $CD14^+$. hPAF-R expression recovered in 40 to 50% resting B cells (Fig. 5A) was lost after 48 h of culture in medium (data not shown). Stimulation with IL4 (Fig. 5B) increased the percentage of hPAF-R positive cells to 73% without changing the staining intensity (MFI equal to 64 vs. 52). Stimulation by SAC (Fig. 5C) or PDB plus ionomycin (Fig. 5D) had little effect on the percentage of positive cells (55

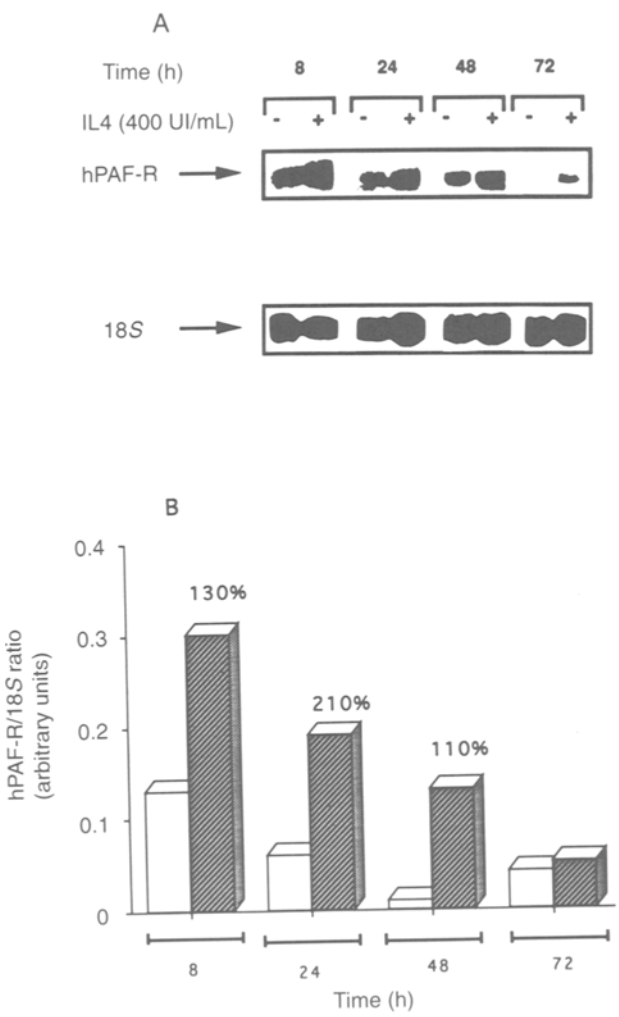

FIG. 3. hPAF-R mRNA expression is modulated by IL4. IM9 cells (0.2 × 10^6/mL) were cultured with IL4 (400 U/mL) or with medium for defined periods of time. (A), Northern blot analysis using using ^{32}P-hPAF-R or ^{32}P ribosomal RNA 18*S* probes (20 µg/lane). Densitometric scanning of the blot is computed in (B), One representative experiment out of two is shown. See Figure 1 for abbreviation and company source.

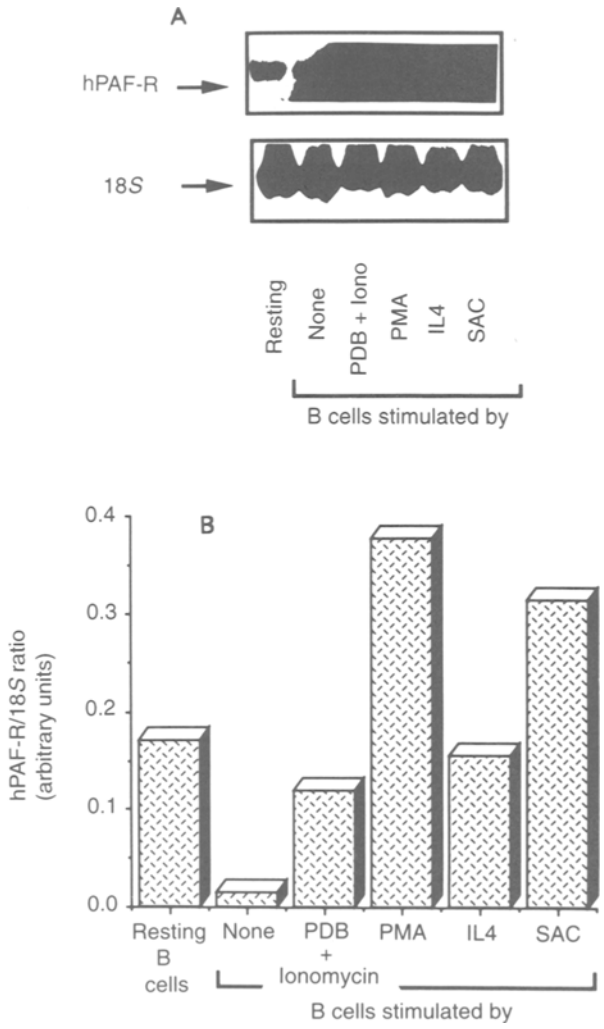

FIG. 4. hPAF-R mRNA expression in normal human B cells. B cells (1 × 10^6/mL) were cultured in medium (none) or stimulated with Staphylococcus Aureus Cowan (SAC) (1:10^4, vol/vol), IL4 (400 U/mL), 12-phorbol myristale 13-acetate (PMA) (5 ng/mL), or phorbol 12,13-dibutyrate (PDB) (1 ng/mL) plus ionomycin (Iono) (800 ng/mL) for 48 h before RNA extraction. RNA from fresh resting B (resting) cells was also extracted. (A), Northern blot analysis (20 µg/lane) using ^{32}P-hPAF-R or ^{32}P ribosomal RNA 18*S* probes. Densitometric scanning of the blot is computed in (B). One representative experiment out of three is shown. See Figure 1 for additional abbreviation and company source.

and 61% vs. 40%), but enhanced the staining intensity (MFI equals to 115 and 84 vs. 52, respectively). With PMA (Fig. 5E), both the percentage of positive cells and the staining intensity increased by twofold. Because B cell stimulation may also lead to a shift of CD19 MFI, we tried to quantify variations in hPAF-R expression by comparing the ratio between hPAF-R and CD19 MFI. The ratio for IL4-or PDB plus ionomycin-treated B cells was not different from that of resting B cells (0.26 and 0.27 vs. 0.25). For SAC- and PMA-treated B cells, the ratio increased up to 0.35 and 0.44, respectively.

Resting and activated B cells express functional hPAF-R. To investigate whether changes in membrane hPAF-R expression correlated with functional modifications, B cell populations activated by various agents were submitted to Ca^{2+} flux measurement. Results in Figure 6 show that both resting and activated B cells mounted a specific calcium response. Similar maximum values of MFI, ranging from 495 to 548, were obtained for B cells stimulated with SAC (Fig. 6C), PDB plus ionomycin (Fig. 6D) and PMA (Fig. 6E). For B cells cultured with IL4 alone (Fig. 6B) or CD40 antibody plus IL4 (Fig. 6F), the Ca^{2+} flux increased more rapidly and reached a maximum at 650 and 817 respectively. Resting (Fig. 6A) and IL4-treated B cells exhibited similar reactivity (maximum MFI equal to 614 and 650, respectively). As expected, addition of lyso-PAF did not induce Ca^{2+} fluxes.

DISCUSSION

Paf is a potent phospholipid mediator of inflammation produced by and acting on numerous cells. Accumulating data showed that monocytes and lymphocytes are important targets for PAF. On monocytes, PAF up-regulates the production of several cytokines

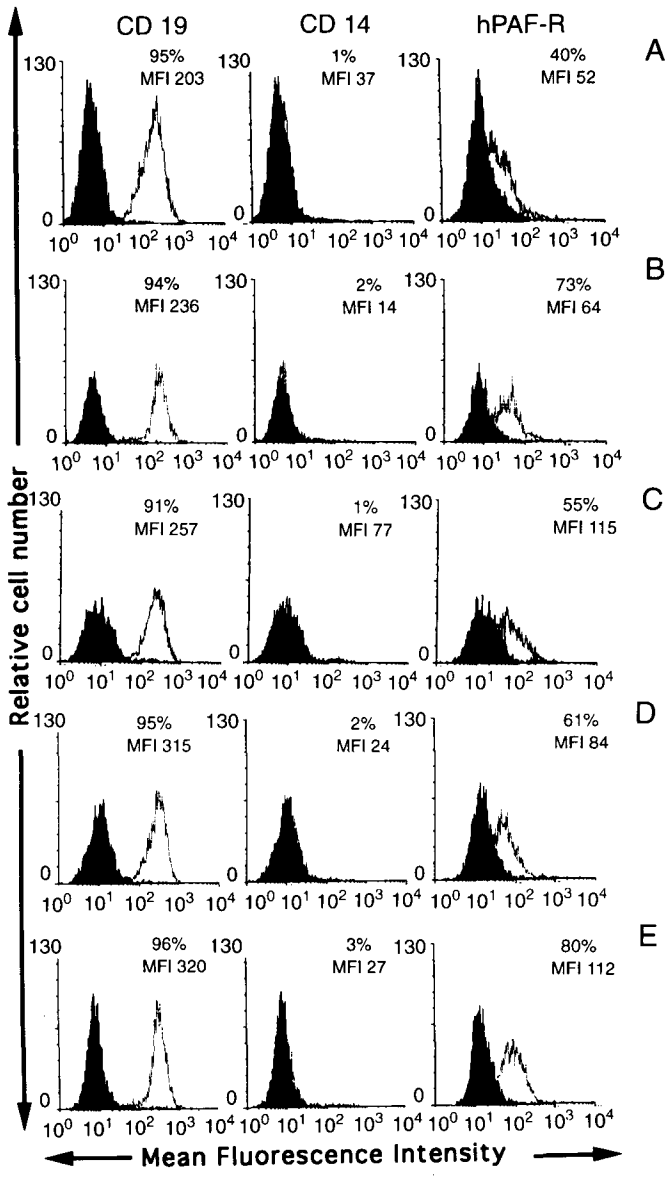

FIG. 5. Membrane hPAF-R expression on human B cells. B cells (1×10^6/mL) stimulated with IL4 (400 U/mL) (B), SAC (1:10^4, vol/vol) (C), PDB (1 ng/mL) plus ionomycin (800 ng/mL) (D), or PMA (5 ng/mL) (E), for 48 h were stained with CD19, CD14 mAbs, and polyclonal hPAF-R, as described in the Materials and Methods section. Fresh resting B cells were also analyzed (A). Mouse IgG and keyhole limpet hemocyanin polyclonal antibody were used as controls (dark histogram). Percent positive cells and mean fluorescence intensity (MFI) are indicated for each panel. One representative experiment out of two is shown. See Figure 1 for additional abbreviation.

(19–24) and PAF receptor expression is modulated by IFN_γ or PAF (25,26). On T lymphocytes, paf decreases CD2 and CD3 expression and differently regulates CD2- and CD3-mediated T cell activation (27–29). In addition, several investigators have demonstrated that PAF regulates important steps of human B cell activation, proliferation, and immunoglobulin production (30–34). hPAF-R expression is well established in B cell lines, but remains controversial on normal B lymphocytes (5,12,13).

In this report, we have shown that hPAF-R mRNA was present in B cell lines expressing membrane hPAF-R, but was absent from cell lines devoid of hPAF-R. By contrast, Raji 2.2.5 and RM3 expressed 3- and 10-fold less PAF binding sites than Raji without any difference in hPAF-R mRNA contents. Moreover, IL4 or exogenous PAF modulated hPAF-R mRNA levels in IM9 and Raji cell lines, but not in Nalm 6 or Daudi. After IL4-treatment of IM9 cells, hPAF-R mRNA increased by 130% at 8 h and maximal expression was observed by 24 h (210%). At 24 h, a 150% increase of membrane hPAF-R number occurs upon IL4 treatment (5). Thus, IL4 may control IgE production in B cells by two mechanisms: directly, by controling isotype switching; and indirectly, by favoring hPAF-R expression and thus, responsiveness to PAF. On monocytes, IFNγ also upregulated hPAF-R mRNA and membrane expression (25).

In addition to IL4, PAF itself also enhanced hPAF-R mRNA expression on IM9 cells. Although hPAF-R mRNA accumulation induced by 10 and 100 nM PAF followed different kinetics, a marked increase from 73 to 120% was observed at 48 h. At that time, 10 nM PAF induced an increase of similar magnitude for hPAF-R membrane and mRNA expression (130 and 120%, respectively). Up-regulation of hPAF-R expression, following exposure to PAF, contrasts with homologous desensitization of hPAF-R previously reported, for instance, in human platelets (35,36) or Kupffer cells (37). Depending on the nature of cell target, different mechanisms, including hPAF-R loss, conformational changes, or uncoupling of the receptor, have been envisioned for explaining desensitization (38,39). Additionally, hPAF-R up- or down-regulation may be dependent on the concentration of PAf used. In this regard, we previously observed dual biological effects of PAF on normal activated B cells—1 and 100 nM PAF increased cell proliferation, whereas 1 to 10 μM inhibited it. In Raji cells which express 10- to 20-fold more hPAF-R than normal B cells, 1 μM PAF increased cell proliferation and [^{3}H]PAF binding (5). In human monocytes, which constitutively express more hPAF-R membrane than B cells (12), 10 nM to 1 μM PAF also induced a twofold increase in hPAF-R mRNA expression (26). At the present time, the biological relevance of the PAF-mediated upregulation of its own receptor remains open to discussion. One likely and interesting possibility is that triggering of hPAF-R by its ligand may lower the threshold for PAF responsiveness. The modulation of hPAF-R expression may be relevant to the regulation of the immune response by providing a dynamic and on-demand regulation of various cellular responses, depending on local PAF concentration.

Low levels of [^{3}H]PAF binding on normal B cells led us to examine membrane, as well as mRNA hPAF-R expression. All resting B cells tested expressed 10- to 20-fold lower PAF mRNA than IM9 (data not shown). The loss of hPAF-R mRNA signal after 48 h of culture in medium alone suggests that B cell activation was required for maintaining its expression. By immunofluorescence, membrane hPAF-R expression was detected on 40 to 50% of resting B cells. After activation,

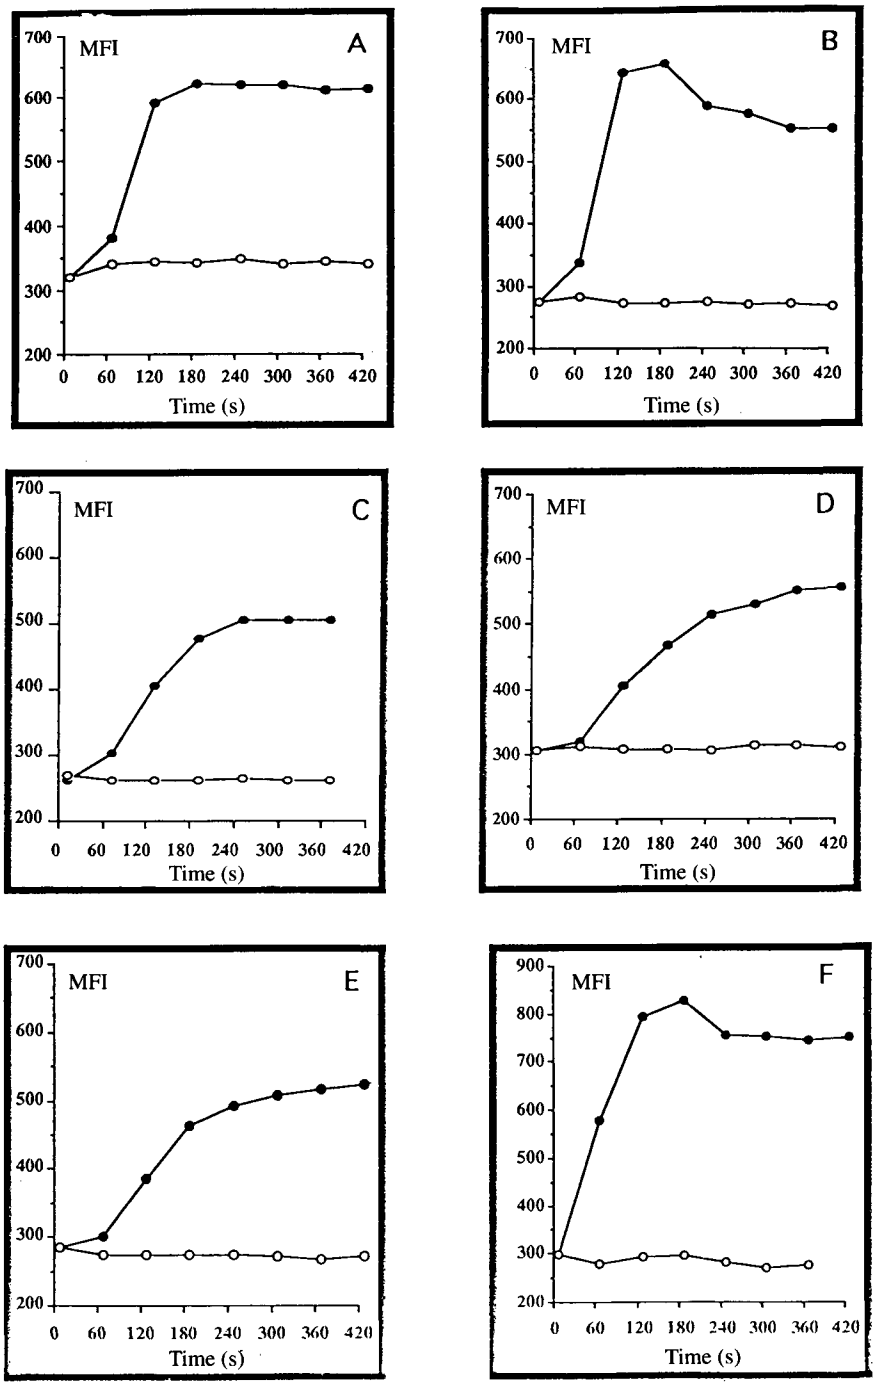

FIG. 6. PAF induces $[Ca^{2+}]_i$ mobilization in resting and activated B cells. B cells were activated for 48 h with IL4 (400 U/mL) (B), SAC (1:10^4, vol/vol) (C), PDB (1 ng/mL) plus ionomycin (800 ng/mL) (D), PMA (5 ng/mL) (E), or CD40 (1 μg/mL) plus IL4 (400 U/ml) (F), Resting (A) and activated B cells were loaded with Indo-1/AM. Changes in $[Ca^{2+}]_i$ were recorded by flow cytometry. Results are expressed as change in MFI (linear scale) after stimulation with PAF (●) or lysoPAF (○). One representative experiment out of two is shown. See Figures 2 and 5 for abbreviations.

the percentage of positive cells and/or the staining intensity increased with a maximal induction observed in the presence of PMA or SAC. Reactivity of resting or activated B cells was not due to residual monocytes as similar results were obtained using B cells purified with CD19 dynabeads (data not shown). Thus, these results indicate that B cell activation plays a major role in expression and conformational changes of the hPAF-R. By contrast to our study and the one by Müller *et al.* (12), Simon *et al.* (13) reported the lack of hPAF-R on human resting B cells. It is worth mentioning that we did use an anti-

body directed against residues 164 to 173, which included a part of the second extracellular loop of the hPAF-R. This region which also contained the unique *N*-glycosylation site and one of the two conserved cystein residues is required for stability of ligand binding pocket (33). In contrast, Simon *et al.* (13) used an antibody raised against the NH2-terminal region, not essential for ligand binding. As both antibodies detected the presence of hPAF-R in IM9 and Ramos, one can speculate that apparent differences in hPAF-R expression is due to a special conformation of the receptor on resting B cells.

Although most stimuli increased transcription and sustained hPAF-R expression in B cells, some of them also favored functional responses. Indeed, stimulation with CD40 antibody plus IL4 raised up the capacities of B cells to respond to PAF. This result is particularly important as IL4 and the signal delivered through CD40/CD40L interactions play major roles in IgE production and memory B cell generation (40, 41). Whether CD40 triggering acts directly on hPAF-R expression, conformation, or indirectly favors PAF response through TNFα production and/or NF-KB activation remains to be established.

In summary, ours results showed that: (i) spontaneous hPAF-R expression in B cell lines seems essentially regulated at a transcriptional level; (ii) IL4 and PAF control hPAF-R expression by acting at a transcriptional level and/or by stabilizing hPAF-R mRNA; (iii) functional hPAF-R are expressed on resting and activated B cells and (iv) B cell activation may regulate hPAF-R expression, conformation, and function. The latter data and the observation that PAF regulates cytokine production suggest that PAF is an important modulator of B cell response and differentiation.

The Effects of Lidocaine and Hypoxia on Phospholipid Biosynthesis in the Isolated Hamster Heart

Jason T. Wong, Ricky Y.K. Man[1], and Patrick C. Choy*

Department of Biochemistry and Molecular Biology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba R3E 0W3, Canada

ABSTRACT: In this study, the effects of lidocaine and hypoxia on the biosynthesis of phospholipids in the hamster heart were examined. Hamster hearts were perfused with [1,3-^{3}H]glycerol under normal and hypoxic conditions, and in the absence or presence of 0.5 mg/mL lidocaine. After perfusion, the radioactivity incorporated into the various phospholipid fractions was determined. With the exception of phosphatidylcholine, the synthesis of phospholipids was generally stimulated by lidocaine perfusion. In contrast, hypoxia caused a general decrease in phospholipid biosynthesis which was partially restored by lidocaine. ATP and CTP levels were severely reduced under hypoxic conditions, but their levels were not restored by lidocaine treatment. The activities of enzymes for phospholipid synthesis were determined under the various perfusion conditions. The activity of phosphatidic acid phosphatase was elevated by lidocaine and decreased by hypoxic treatment. The activity of CTP:phosphatidic acid cytidylyltransferase was increased under hypoxia, with or without lidocaine. Despite the reduction in phosphatidylcholine biosynthesis, no change in the activity of cytidine diphosphocholine (CDPcholine):diacylglycerol cholinephosphotransferase was detected following lidocaine or hypoxic perfusion. However, enzyme activity was inhibited by the presence of lidocaine in the assay mixture. Our results indicate that the reduction in phospholipid biosynthesis under hypoxic conditions was caused mainly by diminishing high-energy nucleotide levels. The enhancement of phospholipid biosynthesis by lidocaine appeared to be mediated in part by modulation of enzyme activities.

Lipids 31, 1059–1067 (1996).

Phospholipids are the major lipid component of biological membranes (1). In mammalian tissues including the heart, the appropriate content and composition of phospholipids are important for the maintenance of cellular integrity and proper membrane function. In addition, alterations in membrane phospholipids may affect the conduction of electrical signals across the cardiac membrane (2). Hence, the biosynthesis and catabolism of phospholipids are under rigid control. The pathways for the synthesis of the major phospholipids in the heart have been largely elucidated (3,4), but the mechanisms controlling these metabolic pathways have not been fully explored.

Perfusion of the hamster heart *ex vivo* in the Langendorff mode is a useful model to study the control of phospholipid metabolism in the isolated organ. When the hamster heart was perfused under hypoxic conditions or in the presence of amphiphilic compounds such as lidocaine or methyl-lidocaine, alterations in phospholipid biosynthesis were detected (5–7). Perfusion under hypoxia caused a large reduction of the ATP and CTP levels in the heart, with a concomitant decrease in the incorporation of radioactive choline into phosphatidylcholine (5). However, the effects of hypoxia on other phospholipid groups were not known. When the hamster heart was perfused with lidocaine, increases in the synthesis of lysophosphatidic acid, phosphatidic acid, phosphatidylethanolamine, phosphatidylserine and phosphatidylinositol were observed (7). In contrast, the synthesis of phosphatidylcholine was decreased under identical conditions. Further investigation revealed that the activities of key enzymes responsible for phospholipid biosynthesis were modulated by lidocaine. Because lidocaine has been employed routinely as a therapeutic agent for the treatment of cardiac arrhythmias, it would be of interest to study its action on phospholipid biosynthesis under hypoxic conditions. In the present study, the effect of hypoxia on the biosynthesis of phospholipids in the heart and the effect of lidocaine on phospholipid biosynthesis during hypoxia were examined.

MATERIALS AND METHODS

Materials. Lidocaine hydrochloride was obtained from Astra Pharmaceutical Products (Mississauga, Ontario, Canada). [1,3-^{3}H]Glycerol (3.1Ci/mmol), [1-^{14}C]oleoyl-coenzyme A (CoA) (54 mCi/mmol), [1-^{14}C]palmitoyl-CoA (47.8 mCi/mmol), [5-^{3}H]CTP (58 mCi/mmol), *myo*-[2-^{3}H]inositol (18.2 Ci/mmol), and [^{3}H]acetic anhydride (0.5 Ci/mmol) were

obtained from Amersham International (Oakville, Ontario, Canada). Cytidine diphosphocholine (CDP[methyl-^{14}C]choline) (58 mCi/mmol) and cytidine diphosphoethanolamine (CDP[1,2-^{14}C]ethanolamine) (97 mCi/mmol) were obtained from the NEN Division of Dupont Co. (Dorval, PQ, Canada). All lipid products were obtained from Serdary Laboratories (London, Ontario, Canada). BCl_3-methanol reagent was obtained from Supelco Canada (Mississauga, Ontario, Canada). All other chemicals, solvents, and biochemicals were of reagent grade and were obtained from the Canlab Division of Baxter Company (Winnipeg, Manitoba, Canada) or Sigma Chemical Company (St. Louis, MO).

Perfusion of the isolated hamster heart. Syrian Golden hamsters weighing 120 ± 20 g were used throughout the study. Isolated hearts were perfused for 60 min in the Langendorff mode (cannulation *via* the aorta) with Krebs-Henseleit buffer containing 1.0 mM [1,3-^{3}H]glycerol (3 μCi/μmol), saturated with a gas mixture composed of 5% CO_2 and either 95% O_2 (control) or 95% N_2 (hypoxia). In some experiments, 0.5 mg/mL lidocaine was added to the perfusate. The viability of the heart during perfusion was monitored by electrocardiac recording. An electrode was placed on the aorta and another electrode was immersed in the buffer solution bathing the apex of the heart. Perfusion of the heart under hypoxic conditions from 30 to 60 min caused some electrophysiological and morphological changes that were reversible upon reoxygenation (data not shown). Hypoxic exposure of the heart in excess of 60 min caused irreversible damage to the cardiac tissue (5).

Determination of uptake and incorporation of radioactive glycerol. After perfusion, 10 mL of fresh Krebs-Henseleit buffer was injected through the cannula to remove residual radioactive perfusate. The hearts were homogenized in 20 mL chloroform/methanol (1:1, vol/vol), and the insoluble material was sedimented by centrifugation. An aliquot of the supernatant was taken for determination of radioactivity by scintillation counting. A 0.25 M KCl solution and chloroform were added to the supernatant to cause phase separation, and samples of the aqueous and organic phases were taken for radioactive determination. The extraction efficiency of labeled phospholipids by this method was 88–90% and was not affected by lidocaine. The phospholipid and neutral lipid classes in the organic phase were separated by thin-layer chromatography (TLC) in the following solvent systems. Phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylserine fractions were separated in a solvent containing chloroform/methanol/15 M aqueous NH_3/water (35:15:2:1, by vol). The solvent used for the separation of phosphatidic acid and lysophosphatidic acid contained chloroform/methanol/HCl (87:13:0.2, by vol) (8). Cytidine diphosphate (CDP-)diacylglycerol was separated in a solvent containing chloroform/methanol/acetic acid/water (52:20:7:3, by vol) (9). The solvent for the separation of diacylglycerol contained light petroleum (bp 35–60°C)/diethyl ether/acetic acid (60:40:1, by vol). After visualization by iodine staining, the bands on the TLC plate corresponding to authentic standards were scraped into scintillation vials and their radioactivities were determined.

Lipid determinations. The major phospholipids separated by TLC were quantified by lipid phosphorus determination according to the procedure of Bartlett (10). For the determination of phosphatidylinositol and phosphatidylserine, the procedure of Rouser *et al.* (11) was used. For the determination of lysophosphatidic acid and phosphatidic acid, the procedure of Zhou and Arthur (12) was employed. Using phosphatidylcholine as a standard, the result obtained by the procedure of Rouser *et al.* (11) or Zhou and Arthur (12) was found to be comparable to that obtained by the Bartlett method (10). Diradylglycerol, of which 90% is in diacyl form (13), was isolated from the lipid extract by TLC, and the acyl groups were converted to the respective methyl esters by reaction with BCl_3-methanol (14). The fatty acid methyl esters were quantified by gas–liquid chromatography using a Shimadzu (Tokyo, Japan) Mini-2 gas–liquid chromatograph equipped with 15% DEGS (on 80/100 Chromosorb W/AW) columns. Heptadecanoic acid methyl ester was used as a standard for quantification.

Determination of ATP and CTP levels. ATP and CTP levels in the heart were determined as described earlier (5). After perfusion, hearts were stored temporarily in liquid nitrogen, and then homogenized in 6 mL chloroform/methanol (2:1, vol/vol). A small amount of labeled CTP was added to the homogenates for the calculation of yield. Water (3 mL) was added to the homogenate to cause phase separation. The aqueous phase was removed and the organic phase was re-extracted twice with 3 mL of water. The pooled aqueous phase extract was concentrated by evaporation under reduced pressure, and the nucleotide content in each sample was analyzed by high-pressure liquid chromatography using an Ultrasphere-ODS reversed-phase column (Beckman, Mississauga, Ontario, Canada). Nucleotides were eluted from the column with 0.03 M KH_2PO_4 containing 0.02 M tetrabutylammonium phosphate in 19% acetonitrile, pH 2.65.

Determination of cytidine diphosphocholine levels. Samples were prepared in the same manner as those used for the analysis of ATP and CTP. The recovery of CDPcholine was calculated from a small amount of CDP-[methyl-^{14}C]choline added to the tissue homogenate. The concentrated aqueous sample was dissolved in 10 mL water and applied to a Dowex AG1-X8 (Sigma-Aldrich Canada, Mississauga, Ontario, Canada) (OH^- form) column (1 cm × 30 cm). Choline was removed from the column by 60 mL methanol/water (1:1, vol/vol) followed by 10 mL water, and CDPcholine and phosphocholine were co-eluted with 200 mL 0.4 M NH_4HCO_3. The fraction containing the CDPcholine and phosphocholine was evaporated under reduced pressure and redissolved in 5 mL water. The sample was applied to a Norite A (Sigma-Aldrich Canada)/celite (1:1, vol/vol) column (1 cm × 5 cm). Phosphocholine was eluted from the column with 20 mL water and 15 mL 2% ethanol, and CDPcholine was eluted with 30 mL 40% ethanol containing 1% NH_4OH. The CDPcholine fraction was treated with 10 units of alkaline phos-

phatase and 10 units of *Crotalus adamanteus* phosphodiesterase (type III) to yield choline. The choline in this sample was purified by extraction into 3 mL heptan-3-one containing tetraphenylboron (10 mg/mL). The choline in the heptan-3-one was back-extracted with 0.5 mL 0.4 M HCl followed by a second extraction with 3 mL 1.0 M HCl. The HCl extracts were combined and lyophilized, and the choline was determined by the quantitative conversion of choline into [γ-^{32}P]phosphocholine (15).

Determination of enzyme activities. After perfusion, hearts were homogenized in a buffer containing 0.25 M sucrose and 10 mM Tris/HCl (pH 7.4). The postnuclear fraction was obtained by centrifugation at 2000 × *g* for 10 min. The postmitochondrial fraction was obtained by centrifugation of the postnuclear fraction at 12,000 × *g* for 15 min. The cytosolic and the crude microsomal fractions were obtained by centrifugation of the postmitochondrial fraction at 100,000 × *g* for 60 min. The resulting supernatant was designated as the cytosolic fraction, while the microsomal pellet was suspended in 10 mM phosphate buffer (pH 7.4). The protein contents of the various fractions were determined by the method of Lowry *et al.* (16). Enzyme activities were assayed in the subcellular fractions as described in the following sections.

Acyl-CoA:glycerol-3-phosphate and acyl-CoA:lysophosphatidic acid acyltransferases. The activities of acyl-CoA:glycerol-3-phosphate and acyl-CoA:lysophosphatidic acid acyltransferases were determined in the postnuclear fraction by the procedure of Batenburg *et al.* (17). For the acylation of glycerol-3-phosphate, the assay mixture consisted of 100 mM Tris/HCl (pH 7.5), 1.5 mM glycerol-3-phosphate, 90 mM sucrose, 0.5 mg of bovine serum albumin, 1 mM dithiothreitol, 40 μM [1-^{14}C]oleoyl-CoA (4000 dpm/nmol) and approximately 0.2 mg protein in a volume of 500 μL. The reaction was initiated by addition of the postnuclear fraction, incubated at 30°C for 30 min, and terminated by addition of 3 mL chloroform/ methanol (2:1, vol/vol). A solution containing 0.5 M NaCl was then added to the mixture to cause phase separation. The presence of a high salt concentration in the aqueous phase facilitated the recovery of lysophosphatidic acid in the organic phase. The lipid fractions in the organic phase were separated by TLC, and the distribution of radioactivity in the lipid fractions was scanned by a Bioscan System 200 Imaging Scanner (Interscience Inc., Markham, Ontario, Canada). The vast majority (>85%) of the labeling was found in the lysophosphatidic acid fraction. The radioactivity in this fraction was determined by scintillation counting.

For the acylation of lysophosphatidic acid, the reaction was carried out under the same conditions, except that *sn*-glycerol-3-phosphate was replaced with 0.2 mM 1-palmitoyl-*sn*-glycerol-3-phosphate (17). The labeled phosphatidic acid formed in the reaction was separated by TLC and the radioactivity in that fraction was determined.

Phosphatidic acid phosphatase assay. Phosphatidic acid phosphatase activity was assayed in the cytosolic and microsomal fractions by determining the production of 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycerol from the corresponding phosphatidic acid (18). The labeled phosphatidic acid was obtained from 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycerophosphocholine by phospholipase D hydrolysis (19). The assay mixture (total volume 100 μL) contained 100 mM Tris/HCl (pH 7.4), 1 mM dithiothreitol, 0.2 mg bovine serum albumin, 0.6 mM 1-palmitoyl-2-[^{14}C]oleoyl-*sn*-glycerol-3-phosphate (2000 dpm/nmol), 0.4 mM phosphatidylcholine, 1 mM $MgCl_2$, 1 mM EGTA, 1 mM EDTA, 0.75 mM oleic acid, and approximately 50 μg protein. The phosphatidic acid and phosphatidylcholine substrates were dispersed by sonication prior to their addition to the assay mixture. The cytosolic fraction was preincubated with oleic acid for 20 min at 37°C prior to the assay. The reaction was initiated by the addition of the appropriate subcellular fraction to the assay mixture and incubated at 37°C for 60 min. The reaction was terminated by the addition of 2 mL chloroform/ methanol (2:1, vol/vol). After phase separation, the labeled diacylglycerol in the organic phase was separated by TLC and the radioactivity in that fraction was determined.

CDPcholine:1,2-diacylglycerol cholinephosphotransferase and CDPethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase assays. CDPcholine:1,2-diacylglycerol cholinephosphotransferase and CDPethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase activities were assayed in the microsomal fraction by determining the transfer of CDP-[^{14}C]choline or CDP-[^{14}C]ethanolamine, respectively, to diacylglycerol (20,21). The reaction mixture for the cholinephosphotransferase assay (200 μL) contained 10 mM Tris-HCl, 10 mM $MgCl_2$, 1 mM EDTA, 0.4 mM CDP-[^{14}C]-choline (1.0 μCi/μmol), 0.2 mM diacylglycerol (prepared in 0.015% Tween 20), final pH 8.5, and 50 μg protein. The reaction was initiated by the addition of labeled CDPcholine, and the mixture was incubated at 37°C for 15 min. The reaction was terminated by the addition of 3 mL chloroform/methanol (2:1, vol/vol), and water was added to cause phase separation. The phosphatidylcholine in the organic phase was separated by TLC and the radioactivity in that fraction was determined.

The reaction mixture for ethanolaminephosphotransferase (200 μL) contained 10 mM Tris-HCl (pH 8.5), 10 mM $MnCl_2$, 1 mM EDTA, 0.2 mM CDP-[^{14}C]ethanolamine (1.0 μCi/μmol), 0.2 mM diacylglycerol (prepared in 0.015% Tween 20), final pH 8.5, and 50 μg protein. The reaction was initiated by the addition of labeled CDPethanolamine, and the mixture was incubated at 37°C for 15 min. The reaction was terminated by the addition of 3 mL chloroform/methanol (2:1, vol/vol), and water was added to the mixture to cause phase separation. The phosphatidylethanolamine in the organic phase was separated by TLC and the radioactivity in that fraction was determined.

CTP:phosphatidic acid cytidylyltransferase assay. CTP:phosphatidic acid cytidylyltransferase activity was assayed in the microsomal fraction using [5-^{3}H]CTP and phosphatidic acid as substrates (22). The reaction mixture contained 50 mM Tris/maleate (pH 6.5), 20 mM $MgCl_2$, 15 mM

Triton X-100, 1.0 mM [5-^{3}H]CTP (10,000 dpm/nmol), 0.5 mM phosphatidic acid, and 50 μg protein. The reaction was initiated by addition of the microsomal fraction and the mixture was incubated at 37°C for 15 min. The reaction was terminated by the addition of 2.5 mL 0.1 M HCl in methanol. After cooling, 5 mL chloroform was added to the mixture. The chloroform/methanol mixture was washed three times with 10 mL 2 M $MgCl_2$ (23), and the total radioactivity in the organic phase was determined. TLC analysis of the organic phase showed that over 98% of the radioactivity was located in the CDP-diacylglycerol fraction.

Phosphatidylinositol synthase assay. Phosphatidylinositol synthase activity was assayed in the microsomal fraction by determining the transfer of *myo*-[^{3}H]inositol to CDP-dipalmitoylglycerol (24). The reaction mixture (total volume 100 μL) contained 100 mM Tris-HCl (pH 7.5), 1 mM EGTA, 3 mM $MgCl_2$, 3 mM $MnCl_2$, 0.2% Triton X-100, 0.1 mM CDP-dipalmitoylglycerol, 0.1 mM *myo*-[^{3}H]inositol (5×10^5 dpm/nmol), and 50 μg protein. The reaction mixture was incubated at 37°C for 30 min, and the reaction was terminated by addition of 1 mL chloroform/methanol/HCl (100:100:1, by vol) and 0.4 mL 0.9% KCl. After phase separation, the labeled phosphatidylinositol in the organic phase was separated by TLC and the radioactivity in that fraction was determined.

Serine base exchange enzyme assay. Serine base exchange enzyme activity was assayed in the microsomal fraction by determining the production of radioactive phosphatidylserine from [^{3}H]serine and phosphatidylethanolamine (25). The reaction mixture (total volume 250 μL) contained 10 μM *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (pH 7.3), 0.8 μmol phosphatidylethanolamine, 20 nmol [^{3}H]serine (78,000 dpm/nmol), 6 μmol $CaCl_2$, 50 μg bovine serum albumin, and 50 μg protein. The reaction was carried out at 37°C for 15 min, and terminated by 2 mL chloroform/methanol (2:1, vol/vol). After phase separation, the phosphatidylserine in the organic phase was separated by TLC and the radioactivity in that fraction was determined.

Statistical analysis. Statistical significance was determined by analysis of variance, followed by two-tailed independent Student's *t*-tests. The level of significance was defined as $P < 0.05$.

RESULTS

Perfusion of hamster hearts. Hamster hearts were perfused with Krebs-Henseleit buffer containing 1 mM [1,3-^{3}H]glycerol. The buffer was saturated with either 95% O_2/5% CO_2 or 95% N_2/5% CO_2 prior to and during perfusion. Analysis of oxygen content in the perfusate showed that the $_PO_2$ in the oxygen-saturated buffer (for controls) was over 500 mm Hg, whereas the $_PO_2$ in the N_2-saturated buffer (for hypoxic perfusion) was less than 40 mm Hg. The $_PCO_2$ in all buffers was 35–40 mm Hg, which produced a pH value of 7.40 ± 0.05. The uptake of labeled glycerol by the hamster heart was found to be linear under normoxic and hypoxic conditions for up to 60 min of perfusion (6,7, and unpublished data). Hearts perfused under hypoxic conditions for 60 min displayed an abnormal electrocardiogram which was readily reversible upon re-oxygenation (5). Some degree of mitochondrial swelling at 60 min of hypoxic perfusion was observed by electron microscopy, and the swelling was found to be reversible upon re-oxygenation (5). Hypoxic exposure beyond 60 min caused irreversible electrophysiological and morphological damage (26,27). Hence, hearts were perfused under hypoxic conditions for 60 min or less in all experiments.

Modulation of phospholipid biosynthesis by lidocaine and hypoxia. In this study, hamster hearts were perfused under normoxic or hypoxic conditions in the absence or presence of 0.5 mg/mL lidocaine. After perfusion, the heart was homogenized and the total uptake of labeled glycerol was determined. The uptake of glycerol was markedly increased (88%) when the heart was perfused with 0.5 mg/mL lidocaine under normoxic conditions, and the majority of the increase in radioactivity was found in the organic phase (Fig. 1). Analysis of the organic phase by TLC revealed that there were increases in the labelings of lysophosphatidic acid (181%), phosphatidic acid (135%), CDP-diacylglycerol (153%), phosphatidylinositol (75%), phosphatidylserine (90%), phosphatidylethanolamine (157%), and diacylglycerol (258%) (Fig. 2). In contrast, the labeling of phosphatidylcholine was significantly decreased (40%).

When the heart was perfused under hypoxic conditions, the uptake of labeled glycerol was reduced (47%), and the majority of the reduction in radioactivity was confined to the organic phase (Fig. 1). Analysis of the organic phase by TLC showed general reductions in radioactivity associated with all lipid fractions (Fig. 2). When 0.5 mg/mL lidocaine was present in the hypoxic buffer, the reduction in total glycerol uptake became less severe (24%). This partial restoration of labeled glycerol uptake was also reflected in radioactivity found in the organic phase. Analysis of labelings of lipid fractions by TLC revealed that all phospholipid fractions except phosphatidylcholine were restored to their control values by lidocaine (Fig. 2). The reduction of radioactivity incorporated into phosphatidylcholine during hypoxic perfusion was not altered by the presence of lidocaine.

Alterations in the labeling of the lipid fractions might arise from changes in the pool sizes of any labeled glycerol-containing lipid precursors. Hence, the pool sizes of phospholipid and diacylglycerol fractions in the heart perfused under hypoxic conditions or in the presence of lidocaine were determined. As depicted in Table 1, phospholipid and diacylglycerol contents in the heart were not affected by hypoxic perfusion or lidocaine treatment. We have shown previously that the pool of CDP-diacylglycerol in the heart was not affected by lidocaine treatment (7). Recently, the cardiac CDP-diacylglycerol pool was found to remain unchanged under hypoxia (28). Thus, the observed alterations in the labeling of the cardiac phospholipids did not appear to arise from changes in their pool sizes or those of their precursors.

Effect of hypoxia on nucleotide contents. Because ATP and CTP are required for the synthesis of all phospholipids,

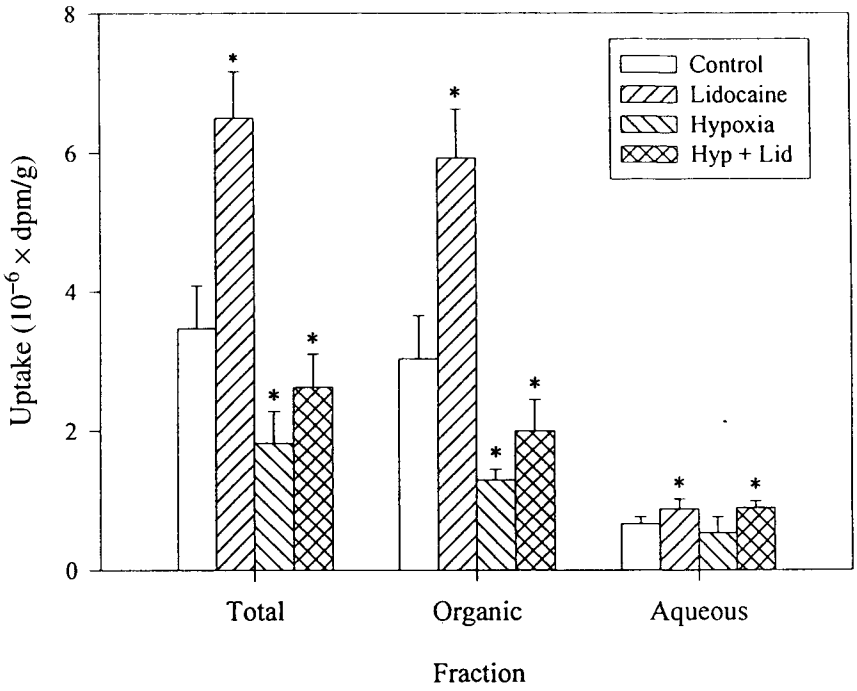

FIG. 1. The effects of lidocaine and hypoxia on the uptake of labeled glycerol in the hamster heart. Hamster hearts were perfused with Krebs-Henseleit buffer containing 1.0 mM [1,3-^{3}H]glycerol (3 μCi/μmol) for 60 min. The buffer was saturated with either 95% O_2 (control) or 95% N_2 (hypoxic), and contained either 0 or 0.5 mg/mL lidocaine. Tissue extraction and phase separation were performed as described in the Materials and Methods section, and samples were taken for determination of radioactivity. The results are expressed as means ± SD. The number of experiments was as follows: control, $n = 13$; lidocaine, $n = 11$; hypoxia, $n = 4$; hypoxia + lidocaine, $n = 3$. *$P < 0.05$ compared with control.

changes in levels of these nucleotides may affect the rate of phospholipid biosynthesis. Hence, the levels of ATP and CTP in the hamster heart perfused under hypoxia or with lidocaine were determined. As shown in Table 2, the levels of ATP and CTP were not affected by lidocaine perfusion, but were significantly reduced in the hypoxic heart. The presence of lidocaine during hypoxic perfusion did not cause any significant change in the levels of these nucleotides.

Because CDPcholine is a key metabolite for the synthesis of phosphatidylcholine, its level in the heart perfused under hypoxic conditions or in the presence of lidocaine was determined. Our results show that the CDPcholine content in the

[a]Hamster hearts were perfused with Krebs-Henseleit buffer containing 1.0 mM glycerol for 60 min. The buffer was saturated with either 95% O_2 (control) or 95% N_2 (hypoxic), and contained either 0 or 0.5 mg/mL lidocaine. After perfusion, the lipid fractions were separated by thin-layer chromatography, and the amount of lipid in each fraction was determined as described in the Materials and Methods section. The results are expressed as means ± SD for n sets of experiments, unless indicated otherwise in parentheses.
[b]Diacylglycerol content is expressed as μmol glycerol/g wet weight.

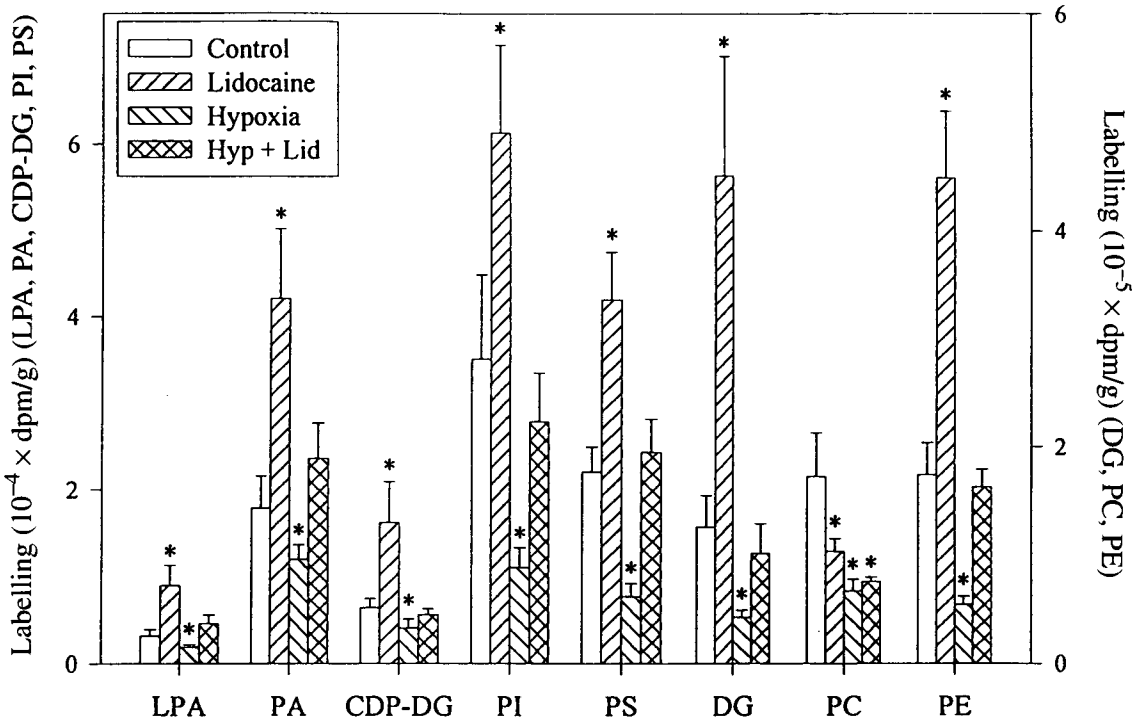

FIG. 2. The effects of lidocaine and hypoxia on the labeling of phospholipids and neutral lipids in the hamster heart. Hamster hearts were perfused as described in Figure 1. After perfusion, lipid fractions were separated by thin-layer chromatography (TLC) as described in the Materials and Methods section, and the radioactivity in each fraction was determined. The results are expressed as means ± SD. The numbers of experiments were as in Figure 1. Left axis corresponds to results for lysophosphatidic acid (LPA), phosphatidic acid (PA), CDP-diacylglycerol (CDP-DG), phosphatidylinositol (PI), and phosphatidylserine (PS). Right axis corresponds to results for diacylglycerol (DG), phosphatidylcholine (PC), and phosphatidylethanolamine (PE). *$P < 0.05$ compared with control.

hamster heart was not changed by hypoxic perfusion or lidocaine treatment, or by lidocaine under hypoxia.

Effects of lidocaine and hypoxia on phospholipid biosynthetic enzymes. Changes in the labeling of the cardiac phospholipids might arise from changes in activities of the enzymes responsible for their biosynthesis. Hence, the activities of the phospholipid biosynthetic enzymes in the hamster heart were determined subsequent to perfusion under hypoxia or with lidocaine. Specifically, hearts were perfused under the defined conditions for 60 min with Krebs-Henseleit buffer containing 1.0 mM glycerol. After perfusion, subcellular fractions were prepared and enzyme activities were determined as described in the Materials and Methods section. The activity of phosphatidic acid phosphatase was elevated (26%) in the microsomal fraction after lidocaine perfusion (Fig. 3). This effect was abolished when the microsomal fraction was incubated with 4.0 mM *N*-ethylmaleimide (NEM) prior to the assay of enzyme activity (data not shown). The increase in microsomal enzyme activity was accompanied by a 30% decrease in cytosolic enzyme activity. Perfusion under hypoxia decreased the activity of this enzyme in both microsomal and cytosolic fractions. The presence of lidocaine during hypoxic perfusion did not result in any beneficial effect on the phosphatidic acid phosphatase activity (Fig. 3).

The activity of CTP:phosphatidic acid cytidylyltransferase (for the formation of CDP-diacylglycerol) was not affected by lidocaine under normoxic conditions (Fig. 3). However, its activity was increased (52%) under hypoxia, and the presence of lidocaine in the hypoxic buffer caused a further increase (170%) above the control activity.

The activities of the other phospholipid biosynthetic enzymes examined were not significantly affected by various experimental treatments (Fig. 3). Although the labeling of phosphatidylcholine was decreased by lidocaine, the activity

TABLE 2
The Effect of Lidocaine on Nucleotide Levels in Normoxic and Hypoxic Hamster Hearts[a]

	Nucleotide level (% of control)		
Nucleotide	Lidocaine	Hypoxia	Hypoxia + lidocaine
ATP	112 ± 11	23 ± 18[b]	29 ± 10[b]
CTP	106 ± 10	48 ± 10[b]	35 ± 8[b]
CDPcholine	103 ± 14	105 ± 9	96 ± 11

[a]Hamster hearts were perfused for 60 min with Krebs-Henseleit buffer with or without 0.5 mg/mL lidocaine under normoxic or hypoxic conditions. After perfusion, ATP, CTP, and CDPcholine levels in the heart were determined as described in the Materials and Methods section. Results are expressed as percentage of control and values represent means ± SD for three sets of experiments. Control values were: ATP, 2.54 ± 0.16 μmol/g heart; CTP, 11.49 ± 2.24 nmol/g heart (5); CDPcholine, 94 ± 6 nmol/g heart.
[b]$P < 0.05$ compared with controls.

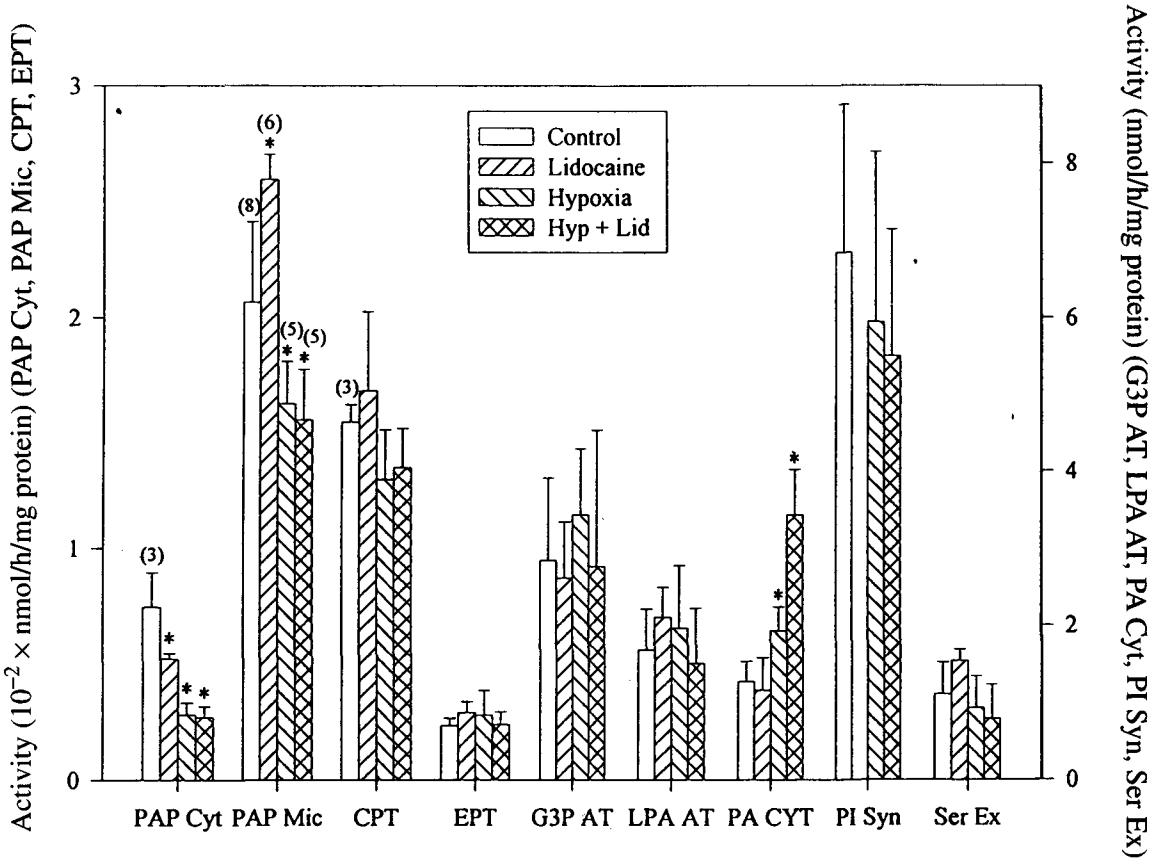

FIG. 3. The effects of lidocaine and hypoxia on the activities of lipid biosynthetic enzymes in the hamster heart. Hamster hearts were perfused for 60 min with Krebs-Henseleit buffer containing 1.0 mM glycerol. The buffer was saturated with either 95% O_2 (control) or 95% N_2 (hypoxic), and contained either 0 or 0.5 mg/mL lidocaine. After perfusion, subcellular fractions were prepared and enzyme activities were assayed as described in the Materials and Methods section. Results are expressed as means ± SD. The number of experiments was as follows, unless otherwise indicated in parentheses: control, $n = 6$; lidocaine, hypoxia, and hypoxia + lidocaine, $n = 3$. Left axis corresponds to results for phosphatidic acid phosphatase in the cytosolic fraction (PAP Cyt); and phosphatidic acid phosphatase (PAP Mic), CDP-choline:1,2-diacylglycerol cholinephosphotransferase (CPT), and CDPethanolamine:1,2-diacylglycerol ethanolaminephosphotransferase (EPT) in the microsomal fraction. Right axis corresponds to results for acyl-CoA:glycerol-3-phosphate acyltransferase (G3P AT), acyl-CoA:lysophosphatidic acid acyltransferase (LPA AT), CTP:phosphatidic acid cytidylyltransferase (PA CYT), phosphatidylinositol synthase (PI Syn) (activity not determined for lidocaine perfusion), and serine base exchange enzyme (Ser Ex) in the microsomal fraction of the heart. *$P < 0.05$ compared with control.

CDPcholine:1,2-diacylglycerol cholinephosphotransferase, which catalyzes the incorporation of the diacylglycerol into phosphatidylcholine, was not changed following perfusion with lidocaine (Fig. 3). However, the direct addition of lidocaine to the assay mixture caused a decrease in the cholinephosphotransferase activity in both normoxic and hypoxic hearts, regardless of whether lidocaine was present in the perfusate during perfusion (Table 3). The direct addition of lidocaine to enzyme assays did not cause any significant change in the activities of phosphatidic acid phosphatase or CTP:phosphatidic acid cytidylyltransferase (data not shown).

TABLE 3
The Effect of Lidocaine on CDPcholine:Diacylglycerol Cholinephosphotransferase Activities[a]

Microsomal fraction	CDPcholine:diacylglycerol cholinephosphotransferase activity (nmol/h/mg protein)
Unperfused hearts	164 ± 20
Perfused control	159 ± 26
Perfused control + 0.5 mg/mL lidocaine	90 ± 14[b]
Perfused with lidocaine	165 ± 36
Perfused with lidocaine + 0.5 mg/mL lidocaine	94 ± 33[b]
Hypoxic perfusion	138 ± 26
Hypoxic perfusion + 0.5 mg/mL lidocaine	88 ± 23[b]

[a]Hamster hearts were perfused for 60 min with Krebs-Henseleit buffer containing 0 or 0.5 mg/mL lidocaine under normoxic or hypoxic conditions. After perfusion, microsomal fractions were isolated by differential centrifugation. Cholinephosphotransferase activities in the microsomal fractions were determined in the absence or presence of 0.5 mg/mL lidocaine. Results are expressed as means ± SD for four separate experiments.
[b]$P < 0.05$ compared with controls.

DISCUSSION

The objective of the present study was to investigate the effect of lidocaine on phospholipid biosynthesis under hypoxic conditions. We have shown earlier that a higher than therapeutic dose of lidocaine (for the treatment of cardiac arrhythmia; initial dose of 200 mg administered over 15 min) is required for a general stimulation of phospholipid biosynthesis

in the hamster heart (7). In this study, hypoxia was found to cause a general decrease in phospholipid biosynthesis. We have also shown that a high level of lidocaine has the ability to partially restore the decrease in phospholipid biosynthesis produced by hypoxia.

Because both ATP and CTP are required for the formation of phospholipids, changes in their levels during hypoxia would affect the labeling of phospholipids. The reduction in the levels of high energy nucleotides during hypoxia has been documented (5,29) and was confirmed in this study. The reduction of the high energy nucleotides would be coupled with increases in the monophosphonucleotides and diphosphonucleotides. The higher levels of these nucleotide species might further reduce the rate of phospholipid biosynthesis either through product inhibition or enhancement of the backward reaction. Interestingly, lidocaine has the ability to partially restore phospholipid synthesis during hypoxia without any significant effect on the reduced ATP and CTP levels.

CTP:phosphatidic acid cytidylyltransferase is the rate-determining enzyme for the synthesis of CDP-diacylglycerol, a precursor of phosphatidylinositol (30,31). The enhancement of its activity during hypoxia may be regarded as a compensatory mechanism to maintain the proper level of CDP-diacylglycerol at low CTP concentrations. This is not surprising because a similar compensatory increase in the activity of CTP:phosphocholine cytidylyltransferase has been previously observed (5). Alternatively, the ability of lidocaine to stimulate the enzyme activity only under hypoxic conditions is intriguing, and further studies are required to characterize the mechanisms for the observed increases in the enzyme activity.

Phosphatidic acid phosphatase catalyzes the conversion of phosphatidic acid to diacylglycerol and is regarded as a key enzyme in regulating the supply of diacylglycerol for the synthesis of phosphatidylcholine, phosphatidylethanolamine and triacylglycerol (for review see Ref. 32). There are two distinct forms of this enzyme. One form is located in the plasma membrane and is involved in signal transduction, while the other is found in the cytosolic and microsomal fractions and is involved in glycerolipid synthesis when bound to membranes (33,34). The latter form is characterized by its sensitivity to inhibition by the thio-reactive agent NEM, whereas the former is insensitive to NEM. The enhancement of the microsomal (NEM-sensitive) phosphatidic acid phosphatase activity by lidocaine may provide an explanation for the observed increase in the labeling of diacylglycerol. The increase in the microsomal enzyme activity might arise from the translocation of the enzyme from the soluble to the membrane compartment during lidocaine perfusion. Intriguingly, hypoxic perfusion caused a decrease in the enzyme activity in both cytosolic and microsomal fractions which was not reversible by lidocaine. Therefore, the restoration of diacylglycerol labeling by lidocaine under hypoxia might be caused by the enhanced synthesis of its metabolic precursors. Although no changes in the activities of acyl-CoA:glycerol-3-phosphate and acyl-CoA lysophosphatidic acid acyltransferases were detected when these enzymes were assayed after perfusion, their activities were stimulated by the direct addition of lidocaine to the assay mixtures (7). We postulate that the direct action of lidocaine on these enzymes might not be detectable when assayed after perfusion of the heart in the presence of lidocaine due to extensive dilution of the drug during the homogenization process.

The synthesis of phosphatidylcholine was distinct from the other phospholipids because it was inhibited by lidocaine. Our results indicate that CDPcholine:1,2-diacylglycerol cholinephosphotransferase plays a major role in the synthesis of phosphatidylcholine. During lidocaine perfusion, the labeling of phosphatidylcholine decreased under normoxia and remained depressed under hypoxia despite the lidocaine-induced increase or restoration, respectively, in the labeling of diacylglycerol. In addition, the CDPcholine pool was not changed by lidocaine or hypoxic perfusion. Thus, the *in situ* activity of the cholinephosphotransferase appears to be inhibited by lidocaine under both normoxic and hypoxic treatment. This notion is supported by the fact that the enzyme activity was shown to be inhibited by the direct addition of lidocaine to the assay mixtures. In contrast to phosphatidylcholine, the labeling of phosphatidylethanolamine correlated proportionately with the labeling of diacylglycerol under all perfusion conditions. Although diacylglycerol is the common precursor of phosphatidylcholine and phosphatidylethanolamine, it is clear that there are distinct and independent controls for the biosynthesis of these two phospholipids in the hamster heart.

Laboratoire des Maladies Métaboliques et Micronutriments, INRA de Clermont-Ferrand/Theix, 63122 St-Genés-Champanelle, France

ABSTRACT: Amylase-resistant starch (RS) represents a substrate that can be administered in substantial amounts in the diet, in contrast to gel-forming polysaccharides, such as guar gum (GG). The aim of this work was thus to compare the effects of GG and RS on cholesterol metabolism in rats adapted to 0.4% cholesterol diets, using dietary GG or RS levels (8 or 20%, respectively) that led to a similar development of fermentations, as assessed by the degree of enlargement of the cecum. The RS diet elicited a marked rise in the cecal pool of short-chain fatty acids, especially acetic and butyric acid, whereas the GG diet favored high-propionic acid fermentations. Both polysaccharides markedly altered the cholesterol excretion, from 50% of ingested cholesterol in controls, up to about 70% in rats adapted to the RS or GG diets. With these diets, the fecal excretion of bile acids was enhanced (67 and 144% with the RS and GG diets, respectively). RS and GG diets were effective in lowering plasma cholesterol (about −40%) and triglycerides (−36%). There was practically no effect of the diets on cholesterol in d > 1.040 lipoproteins (high density lipoproteins), whereas RS (and to a larger extent, GG) were very effective to depress cholesterol in d < 1.040 lipoproteins (especially in triglyceride-rich lipoproteins). Fermentable polysaccharides counteracted the accumulation of cholesterol in the liver, especially cholesterol esters. In parallel, liver acyl CoA:cholesterol acyltransferase was depressed in rats fed the RS or GG diets, whereas only the GG diet counteracted the downregulation of 3-hydroxy-3-methylglutaryl–CoA by cholesterol. These data suggest that RS may be practically as effective as a gel-forming gum, such as GG, on steroid excretion and on cholesterol metabolism.

Lipids 31, 1069–1075 (1996).

There has been a great deal of interest in the cholesterol-lowering properties exhibited by some dietary fibers. Most of these hypocholesterolemic fibers are viscous materials that are fermentable within the large intestine. Guar gum (GG; a gel-forming galactomannan polysaccharide) has been extensively investigated in this respect, and the hypocholesterolemic effect of this gum is apparently connected to: (i) its ability to elevate the viscosity in the small intestine, thus depressing cholesterol absorption (1,2) and the subsequent delivery of cholesterol to the liver *via* chylomicron remnant; (ii) its bile acid-binding capacity, which increases the catabolism of cholesterol through conversion to bile acids in the liver (3–5). Soluble fibers are generally broken down by the large intestine microflora, and the resulting production of short-chain fatty acids (SCFA) may be involved in the metabolic effects of fibers (6), besides modification in the secretion of gastrointestinal hormones, insulin, and glucagon (7,8). These last effects are certainly prevailing with fermentable carbohydrates which are devoid of ion-exchange or viscous properties, such as oligosaccharides or resistant starches (RS) (9–11), although it has been proposed that the helical structures in starch could act as binding sites for bile salts (12). In this view, it has been reported that, in the absence of fermentations in the large intestine, a high rate of bile acid excretion is not always sufficient to elicit a plasma cholesterol-lowering effect (13,14).

In this work, it was thus decided to compare the effects of GG and an RS (crude potato starch) on cholesterol metabolism by using levels in the diet leading to a similar development of fermentations, as assessed by the degree of enlargement of the cecum. The results indicate that, when given at a relatively low level in the diet, a gel-forming compound, such as GG, is effective on cholesterol metabolism, probably because of its capacity to influence most of the potential sites controlling this metabolism. A nonviscous fermentable polysaccharide, such as RS, is also effective to alter the digestive balance of neutral and acidic steroids, and could be tolerated at a higher dietary level than GG.

MATERIALS AND METHODS

Animals and diets. Three groups of eight male Wistar rats (IFA-CREDO, l'Arbresle, France) weighing 160 g, were housed two per cage (wire-bottomed to limit coprophagy) and

fed a semipurified diet that contained the following (by dry weight): 14% casein (L. François, Saint-Maur, France), 14% peanut oil (CIO, Genay, France), 0.4% cholesterol (Sigma, St. Louis, MO), 6% mineral mixture (UAR, Villemoisson/Orge, France), and 1% vitamin mixture (UAR). In the control diet, the carbohydrate supply was 64.6% wheat starch (L. François), whereas in the experimental groups, a part of wheat starch was replaced by 20% crude potato starch (L. François) or by 8% GG (Sigma). The rats were housed in a temperature-controlled room (22°C) with the dark period from 2000 to 0800 h for 21 d. The daily food consumption and body weight were recorded, and the feces were collected and weighed over three consecutive days (to study bile acid excretion and neutral sterol balance) at the end of the adaptation period (starting at day 18). Animals were handled according to the recommendations of the Institutional Ethic Commitee (Clermont-Ferrand University, Clermont-Ferrand, France).

Sampling procedures. Rats were sampled at the end of dark period (between 0800 and 0900 h), when cecal fermentations were still very active. They were anesthesized (sodium pentobarbital, 40 mg/kg) and maintained on a warming plate at 37°C. An abdominal incision was made and blood was withdrawn from the cecal vein and the abdominal aorta. The blood was placed in microfuge tubes containing heparin and centrifuged at 10,000 × *g* for 2 min. Plasma samples were kept at 4°C for lipid and lipoprotein analysis.

A portion of liver was freezed-clamped and stored at −80°C for the measurement of lipid contents. Hepatic microsomes were prepared as described previously (14) and stored at −80°C until measurement of 3-hydroxy-3-methylglutaryl–CoA reductase (HMGR) and acyl CoA:cholesterol acyltransferase (ACAT) activities. The protein content of the microsomes was determined using the Pierce BCA reagent kit (Interchim, Montluçon, France).

At the same time, the cecum was removed and weighed. Duplicate samples were collected into 2-mL microfuge tubes that were immediately frozen and stored at −20°C. Before SCFA analysis, supernatants were obtained by centrifuging one of these two microtubes at 20,000 × *g* for 10 min at 4°C.

Analytical procedures. SCFA were measured on aliquots of cecal supernatants by gas–liquid chromatography as described previously (15). Bile acids and neutral sterols were extracted from feces by dispersion using a Polytron homogeneizer (Luzern, Switzerland) in 10 vol of ethanolic KOH (0.5 M); after an additional extraction step, the dispersed samples were warmed at 80°C for one hour and then centrifuged at 8,000 × *g* for 5 min. Bile acids concentration was measured on this extract using the reaction catalyzed by 3 α-hydroxysteroid dehydrogenase (EC 1.1.1.50; Sigma) (16); cholesterol concentration was enzymatically determined on this same extract using a kit purchased from BioMérieux (Charbonnières-les-Bains, France). Liver lipids were extracted with chloroform/methanol (2:1, vol/vol) according to the method described by Folch *et al.* (17). Triglycerides (Biotrol, Paris, France), total cholesterol, and free cholesterol (Boehringer, Meylan, France) were determined by enzymatic procedures as described by Mazur *et al.* (18). Hepatic cholesteryl ester concentrations were calculated by difference between total and free cholesterol.

Plasma lipoproteins were separated by density gradient ultracentrifugation (19), using pooled samples. After centrifugation in a TST 41.14 swinging-bucket rotor at 100,000 × *g* for 24 h at 18°C, the gradient was divided into 24 × 500 µL fractions and kept at 4°C for lipid analysis. Due to the low level of low density lipoprotein (LDL) and the relative overlapping of high density lipoprotein (HDL)1 and HDL2 fractions in rat plasma, it was decided to present data on the $d < 1.040$ fraction [chiefly triglyceride-rich lipoprotein (TGRLP), with a minor contribution of LDL] and on the $d > 1.040$ fraction (essentially HDL), as previously effected (20).

Triglycerides (Biotrol), cholesterol, and phospholipids (BioMérieux) were determined in plasma and lipoprotein fractions by enzymatic procedures. The protein concentration of isolated lipoproteins was determined using the Pierce BCA reagent kit.

The activity of liver microsomal HMGR was measured as described by Wilce and Kroone (21): labeled mevalonolactone was separated from unreacted HMG–CoA by columm chromatography, using AG1-X8 resin (200-400 mesh; Biorad, Paris, France). The activity was expressd in pmol of [^{14}C]HMG–CoA transformed in [^{14}C]mevalonolactone per minute per milligram of microsomal protein. ACAT activity was measured on liver microsomes using the method described by Erickson *et al.* (22). Endogenous microsomal cholesterol was esterified in presence of [^{14}C]oleyl-CoA, and the resulting cholesteryl-[^{14}C]oleate was isolated after extraction by chloroform/methanol (2:1,vol/vol) followed by thin-layer chromatography. ACAT activity was expressed in nmoles of oleyl-CoA incorporated in cholesteryl oleate per minute per milligram of microsomal protein.

Statistical analysis. Values are given as the means ± SEM and, where appropriate, significance of the difference between mean values was determined by analysis of variance coupled with the Student-Newman-Keuls multirange test. Values of $P < 0.05$ were considered significant.

RESULTS

Effects of diets on animals and their digestive tract. The different diet conditions had no influence on the body weight gain (Table 1), but the daily food intake was slightly higher in rats fed the RS diet than in those fed the control or the GG diets (25.9 vs. 24.0 g/d, respectively). In rats fed the RS and GG diets, the caecum was markedly heavier (+130%) than in control rats. The cecal pH was 7.22 in rats fed the control diet; it was more acidic (6.21) in rats adapted to the RS diet, as well as in those adapted to the GG diet (5.91). RS diet led to a rise in the total SCFA concentration, compared to controls (from 82 to 153 mM), as well as in the total SCFA pool (from 149 to 674 µmoles). This rise was lesser in rats fed the GG diet (total SCFA 118 mM, corresponding to a cecal SCFA pool of 479 µmoles). There was a striking difference between the

molar SCFA ratio in the cecum: RS diet led to high acetic/butyric acid fermentations, whereas GG diet rather promoted high propionic acid (42% of total SCFA) fermentations.

Effects of diets on the the fecal excretion of neutral and acidic steroids. As shown in Table 2, the daily cholesterol intake in rats fed the control or GG diet was about 220 μmoles/d, except in rats adapted to the RS diet (243 μmoles/d) due to the greater food intake in this diet group. The cholesterol fecal excretion in controls (109 μmoles/d) corresponded to 50% of the daily food supply. This excretion was markedly elevated in rats adapted to the fiber diet (55%), and it corresponded to 70% (RS diet) or 74% (GG diet) of the daily cholesterol intake. Both RS and GG diets elicited a significant rise in the cecal bile acids pool (54 and 110%, respectively), whereas the cecal bile acids concentration was rather depressed, especially in rats adapted to the RS diet. The daily fecal excretion of bile acids was 67% greater than in controls in rats fed the RS diet and 144% greater in those fed the GG diet.

Effects of RS or GG on plasma lipids and lipoprotein profile, and on liver lipids. Rats fed the RS or GG diets had a significantly lower plasma cholesterol and triglycerides concentration than control rat (Table 3), but the cholesterol-lowering effect was more pronounced in rats adapted to the GG diet. Analysis of the plasma lipoprotein profile (Fig. 1) shows that cholesterol in the $d < 1.040$ kg/L fractions, in rats adapted to the control cholesterol diet, accounted for 68% of total lipoprotein cholesterol. There was a drastic reduction of cholesterol in this fraction (particularly in TGRLP, data not shown) in rats fed the RS or GG diets (GG being the most potent). In contrast, there was no significant change in the $d > 1.040$ cholesterol (essentially HDL) in rats adapted to the RS or GG diets. The triglyceride concentration in the TGRLP fraction was also significantly depressed by RS and GG (−22 and −28%, respectively).

Both fermentable polysaccharides displayed a significant effect on liver pool of cholesterol and triglycerides, but the GG diet appeared more potent in this respect than the RS diet (Table 3). There was no significant effect of the diets on the liver-free cholesterol, and the lowering of liver cholesterol essentially affected the esterified fraction; as a result, the percentage of esterified cholesterol declined from 70% to about 50%.

Effects of RS or GG on the liver HMGR and ACAT activity. As shown in Figure 2, the microsomal HMGR activity was practically suppressed (18 pmoles · min^{-1} · milligram protein^{-1}) in rats fed the control 0.4% cholesterol diet, and it was not significantly modified in those adapted to the RS diet. In contrast, the HMGR activity was markedly higher (71

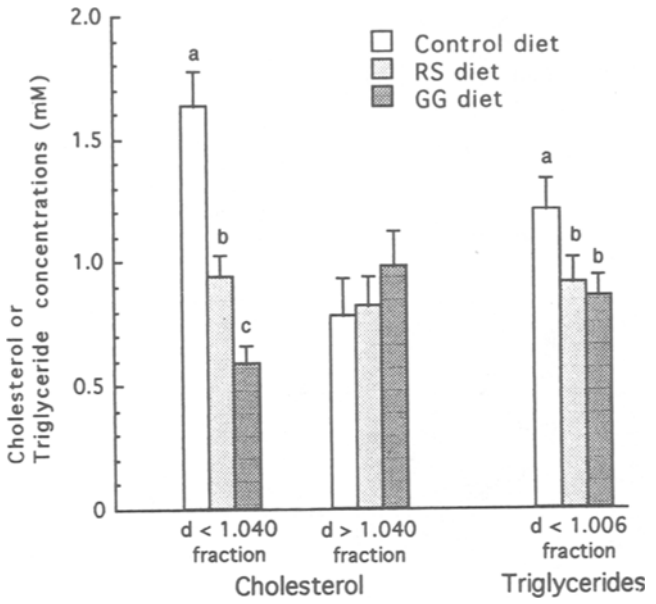

FIG. 1. Histograms showing the repartition of cholesterol and triglycerides in the various plasma lipoprotein fractions in rats adapted to the control, resistant starch (RS), or guar gum (GG) diets. Each value is a mean ± SEM of a triplicate analysis of a pool of eight plasmas. The fractions with a density lower than 1.040 kg/L corresponded chiefly to triglyceride-rich lipoproteins, with a minor contribution of low density lipoproteins. The fractions with a density higher than 1.040 kg/L corresponded essentially to high density lipoproteins. Values not sharing a common letter are significantly different ($P < 0.05$).

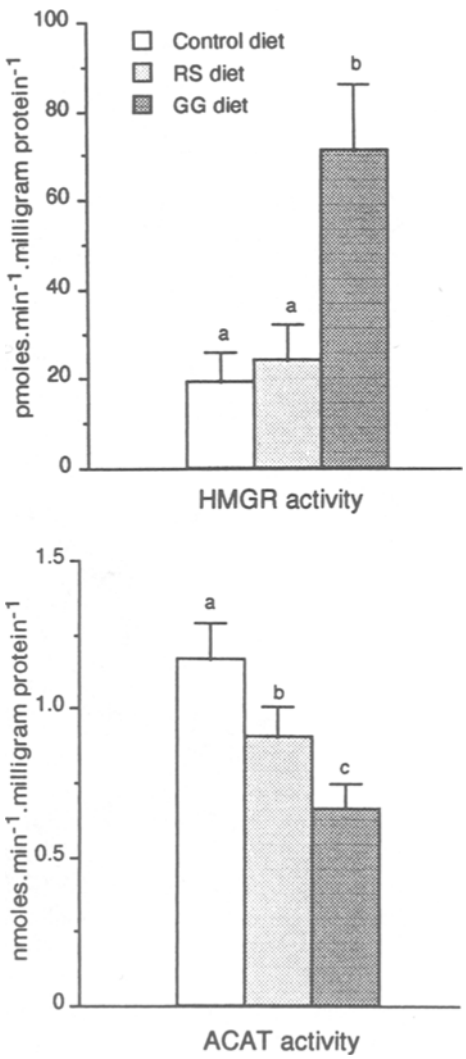

FIG. 2. Histograms showing the effects of diets on the hepatic activity of 3-hydroxy-3-methylglutaryl–CoA reductase (HMGR) and acyl CoA:cholesterol acyltransferase (ACAT). Each value is a mean ± SEM for eight rats. Values not sharing a common letter are significantly different ($P < 0.05$). See Figure 1 for abbreviations.

pmoles · min^{-1} · milligram $protein^{-1}$) in rats adapted to the GG diet. The basal ACAT activity present at a relatively high level (1.15 nmoles · min^{-1} · milligram $protein^{-1}$) in rats fed the fiber-free/cholesterol diet; ACAT activity was slightly lowered in rats fed the RS diet, but it was strongly depressed (about –45%) in those adapted to the GG diet.

DISCUSSION

The RS or GG diets led to a considerable increase in cecal weight, a general feature of fermentable carbohydrates in rats (23). However, the availability of polysaccharide for microbial degradation could be somewhat higher with the RS than with GG diet (although there was no difference in the cecal weight), as the cecal SCFA pool was 40% higher in rats adapted to the RS diet. RS promoted high-SCFA fermentations, characterized by a large proportion of butyric acid, whereas GG favored high-propionic acid fermentations. As a result, the cecal pool of propionate was 70% higher in rats adapted to GG than to the RS diet. Fermentable carbohydrates may alter the energetic fuel available for liver metabolism, corresponding to a partial substitution of glucose by SCFA, especially with RS (8). Furthermore, the time course of glucose absorption could be prolonged by the presence of GG but also when a significant part of starch is resistant to pancreatic hydrolysis. Only a small percentage of absorbed glucose is removed and utilized by the liver (8), whereas SCFA are essentially taken up by the liver, especially propionic and butyric acid (6). This is accompanied by a lowering of the basal insulinaemia and of the daily fluctuations of plasma insulin (8).

There was an unequivocal hypocholesterolemic effect of GG or RS in the present study performed on rats fed 0.4% cholesterol diets. The cholesterol-lowering effect of RS was less apparent with low fat/no cholesterol diets (8,14). Accordingly, soluble fibers, such as GG or pectin, more effectively depressed plasma cholesterol with cholesterol diets (1,2,23). With the present cholesterol diets, the first consequence of polysaccharides intake seems to be a reduced effectiveness of cholesterol absorption. With the GG diet, the high viscosity of the intestinal content may slow down triglycerides digestion, shifting intestinal fatty acids absorption toward more distal sites (24). In contrast to glycerides, only a part of dietary cholesterol is absorbed, especially when it is present in

relatively high quantities in the diet. It is noteworthy that RS appeared as effective as GG to enhance the fecal excretion of cholesterol.

More than 60% of crude potato starch escapes to pancreatic hydrolysis (25), and thus its helical structure could be available as binding sites for steroids (12), but it is still unclear whether cholesterol is as effectively trapped as bile salts in these structures. Accumulation of bile acids in the cecum is probably a reflection of impaired reabsorption in the small intestine, especially the ileum. Thus, it appears that GG is very effective in enhancing the appearance of bile acids in the large bowel, but RS is also effective in this respect. Gel-forming properties of GG have been frequently invoked; some data indicates that GG actually binds bile acids, but not phospholipids, suggesting that its trapping properties are relatively specific (26). It must be kept in mind that, due to the hydrolysis and absorption of most nutrients, the digestive content in the distal jejunum and the ileum should be strongly enriched into nonavailable carbohydrates, together with endogenous materials. This could explain why compounds with low (or devoid of) bile acids binding capacities are liable to affect bile acids reabsorption. It has also been suggested that, proportionately, bile acids sequestrants may have a greater effect in the colon than in the upper portion of the gastrointestinal tract (27).

In the cecum, bile acids are extensively deconjugated and converted to secondary bile acids by bacterial 7α-dehydroxylation. A passive absorption of bile acids takes place in the large intestine, but the fact that their fecal excretion is enhanced indicated that absorption in the large intestine (which may be enhanced with soluble fibers, Ref. 23) fails to compensate for a reduce absorption in the small intestine. Secondary bile acid absorption is likely to be depressed, because of (i) inhibition of 7α-dehydroxylase activity at acidic pH (28), (ii) depressed bile acid solubility due to acidic conditions, especially as insoluble calcium salts (29). Furthermore, bacterial proliferation is itself a factor of bile acids insolubilization because bile acid binding possibilities by colonic microorganisms have been reported (30,31).

The present data suggests that the digestive absorption of cholesterol could be lowered from 50% in control rats down to 26–30% in rats fed the RS or GG diets, as reported for GG in guinea pig (2). Using retrograded starch (RS3 type), Verbeek *et al.* (32) actually found a stimulation of fecal bile acid excretion, but a lowered excretion of neutral steroids. It must be kept in mind that this balance is not a direct reflection of intestinal absorption as it is also affected by changes in the endogenous secretion of cholesterol. Nevertheless, the drastic lowering of cholesterol in the $d < 1.040$ fraction (apoprotein B-rich lipoproteins) of rats adapted to the RS or the GG diets (triglyceride-lowering was less effective) is consistent with a reduced rate of absorption from the digestive tract, although other factors (involved in the control of the peripheral clearance of TGRLP) also have an influence (33). Addition of soluble fibers to the diet has been shown to decrease plasma LDL cholesterol concentrations in species in which cholesterol was transported by LDL (34–36). A large part of the plasma cholesterol in rats is associated with HDL. With cholesterol-free diets, it has been observed that soluble fibers exert a cholesterol-lowering effect in all lipoprotein fractions, including HDL (4,10,14). The presence of a large part of plasma cholesterol in TGRLP in rats fed cholesterol could be due to a reduced rate of chylomicrons clearance, together with a high rate of cholesterol appearance (from digestive origin). Furthermore, it has been reported that cholesterol-enriched diets are liable to stimulate triglyceride synthesis and to depress the oxidation of fatty acids in the liver (37). It is noteworthy that fermentable carbohydrates, particularly GG, were very effective to depress cholesterol in the $d < 1.040$ fraction. This could result from an impaired intestinal absorption of cholesterol, altered concentrations of circulating apolipoproteins (4,38), or from an accelerated rate of lipoprotein removal by tissues (18,39,40). Furthermore, the increase in bile acid synthesis (as reflected by the rate of fecal bile acid excretion) could also represent a mechanism to explain the reduction of cholesterol in the TGRLP.

The liver is the major organ involved in cholesterol homeostasis, because it exhibits capacities to *de novo* synthesize, to oxidize, or to esterify cholesterol. Hepatic ACAT activity is generally elevated when the cholesterol delivery to the liver is enhanced (40,41). In the present study, RS and GG diets elicited a lowering of liver cholesterol, particularly the esterified fraction. This was accompanied by a noticeable decrease in ACAT activity, as reported elsewhere (2,40,41). A depressed esterification of cholesterol may correspond to a decrease in the amount of enzyme or to the influence of regulating intracellular factors. It could also be related to changes in the substrates pools (cholesterol and fatty acyl-CoA). Free cholesterol was slightly depressed in the liver of rats adapted to the GG diet, but not in those fed the RS diet. A decrease in the microsomal cholesterol concentration may account for a diversion of the intracellular pool of cholesterol from the ACAT sites to the cholesterol 7α-hydroxylase sites, which have been inducted with GG diets (3,4). This should reduce the pool of cholesterol esters destined to the core of the very LDL, hence an improved vascular catabolism of these particles (33). GG intake was more efficient than RS in lowering plasma cholesterol and the free-cholesterol fraction in the liver; accordingly, only GG counteracted the repression of HMGR caused by dietary cholesterol. With cholesterol-free diets, the loss of bile acids induced by RS feeding is generally sufficient to elicit an induction of liver HMGR (14). Bile acid elimination is certainly enhanced by fibers, and they have recently been described as upregulators of ACAT, with little effect on HMGR activity (42).

The question arises whether SCFA, particularly propionate, potentiate the consequences of an enhanced fecal steroid excretion. A putative role of this SCFA to mediate the cholesterol-lowering effect of fiber has been proposed (43), probably in relation with the inhibition of the metabolism of the major lipogenic precursors, such as acetate or lactate (8,44). A relatively low insulinemia has been observed in rats

fed RS, in parallel to a high rate of SCFA absorption while glucose absorption was lower than in fiber-free controls; taken together, these factors may account for a depressed lipid synthesis (9). The relationship between SCFA availability and cholesterol metabolism is certainly complex as, in the present study: (i) an RS diet which yields acetic/butyric acid fermentations was effectively hypocholesterolemic, (ii) a GG diet which yields high-propionic acid fermentations was even more effective, although there was an upregulation of HMGR.

In conclusion, the study indicates that both nonviscous (RS) or viscous (GG) nonavailable polysaccharides may exhibit a cholesterol-lowering effect in animals adapted to a cholesterol diet. The commited mechanisms are certainly complex and affect different processes—absorption in the small intestine, large bowel fermentations, hepatic and extrasplanchnic metabolism. Compounds like GG are difficult to administer in relatively large quantities, and it appears that, in this respect, RS represent an interesting alternative and/or complement for maximal effects on cholesterolemia.

Influence of a Subinhibitory Dose of Antifungal Fatty Acids from *Sporothrix flocculosa* on Cellular Lipid Composition in Fungi

M. Benyagoub[a], C. Willemot[b], and R.R. Bélanger[a,*]

[a]Department of Plant Science, Faculty of Agriculture and Food Science and [b]Horticulture Research Centre, Envirotron, Laval University, Quebec, G1K 7P4, Canada

ABSTRACTS: Antifungal fatty acids produced by the biocontrol fungus *Sporothrix flocculosa* were studied on the basis of their effect on growth and cellular lipid composition of three fungi, *Cladosporium cucumerinum, Fusarium oxysporum,* and *S. flocculosa,* whose growth was decreased by 51, 33, and 5%, respectively, when exposed to 0.4 mg fatty acid per ml. The sensitivity to fatty acid antibiotics from *S. flocculosa* was related to a high degree of unsaturation of phospholipid fatty acids and a low proportion of sterols. The major responses of sensitive fungi to sublethal doses of antifungal fatty acids from liquid culture of *S. flocculosa* were: (i) a decrease in total lipid; (ii) an increase in the degree of fatty acid unsaturation (18:1 > 18:2 > 18:3); (iii) an increase in free fatty acids and phosphatidic acid and a decrease in total phospholipids; and (iv) an increase in sterol/phospholipid ratio. These modifications in lipid composition led to an increase in membrane fluidity in sensitive fungi, as demonstrated by assessment of fluoresence anisotropy using liposomes and 1,6-diphenyl-1,3,5-hexatriene probe. This alteration in the physical state of lipids appears to be responsible for the previously demonstrated alteration of membrane structure and function in fungi confronted to *S. flocculosa.*
Lipids 31, 1077–1082 (1996).

Sporothrix flocculosa Traquair, Shaw and Jarvis, is an antagonist fungus which has biocontrol potential against powdery mildew diseases (1–4). Microscopic and ultrastructural observations revealed that the antagonist induced a collapse of host conidia and mycelium without hyphal penetration (3,5). These results suggested that *S. flocculosa* killed its hosts by means of antibiosis (5,6). Chemical analysis of the culture filtrates confirmed this hypothesis and led to the isolation of three molecules with antimicrobial properties (7,8). They were identified as 4-methyl-7,11-heptadecadienoic acid, 9-heptadecenoic acid, and 6-methyl-9-heptadecenoic acid. When tested *in vitro,* these molecules exhibited a spectrum of activity against several fungi, but were not active against *S. flocculosa* itself (6,7). Additional work indicated that these metabolites induced the release of intracellular ions and proteins from treated fungi (6). Theses results combined with cytochemical observations (5) suggested that these antibiotics produced by *S. flocculosa* caused a disruption of the properties and function of the cytoplasmic membrane.

The antifungal properties of fatty acids have received considerable attention over the years (9–12). From previous work, it is known that unsaturated fatty acids can inhibit the activity of several membrane proteins, such as α-mannosyltransferase (13), chitin-synthase (14), valyinyl-tRNA synthetase (15), and (1,3)-β-glucan synthase (16). However, little is known about the mechanisms by which these fatty acids interfere with the activity of these proteins. The interaction between exogenous fatty acids and membrane lipids has been proposed as a key factor to explain the observed inhibitory effects (16), but Kabara *et al.* (11) suggested that the fluidity of the cell membrane can be disturbed maximally by lipophylic compounds of particular chain lengths or unsaturation.

In this study, we have attempted to elucidate the molecular basis underlining the mechanisms by which *S. flocculosa* antibiotics altered membrane permeability. Considering the importance of lipids in maintaining the physiological properties of cell membrane, it was hypothesized that the antimicrobial fatty acids interfered with lipid composition in the target fungi. In this context, the objectives of this study were twofold—to compare and to analyze the lipid composition of three fungi, *Cladosporium cucumerinum, Fusarium oxysporum,* and *S. flocculosa,* reported to be sensitive, moderately sensitive, and resistant, respectively, to the antibiotics; and to compare changes in lipid composition following an exposure to a subinhibitory level of antibiotics.

MATERIALS AND METHODS

Fungal material. Sporothrix flocculosa was maintained on yeast malt agar containing 3 g yeast extract/L, 3 g malt extract/L, 5 g peptone extract/L, 10 g dextrose/L, and 15 g bactoagar/L. *Fusarium oxysporum* f. sp. *radicis-lycopersici* (FORL) Jarvis and Shoemaker was obtained from P. Thibodeau (MAPAQ, Quebec, Canada) and *C. cucumerinum* Ellis and Arth from the Centre for the Land and Resources Research (Ottawa, Canada). FORL and *C. cucumerinum* were maintained on potato/dextrose agar.

Extraction of antifungal fatty acids from liquid culture of S. flocculosa. Antibiotics were extracted as described previously (7,8). Briefly, the liquid medium was separated from the biomass through filter paper (Whatman No. 1) and the mycelium discarded. The filtrates were further extracted with chloroform. The organic fraction was dried under vacuum and the residue was redissolved in chloroform before analysis by thin-layer chromatography (TLC). Chromatograms were developed in ethyl acetate/hexane (1:4, vol/vol) and spots were viewed under ultraviolet radiations at 254 and 366 nm. To localize zones of antifungal activity, silica gel plates were seeded with a sporal suspension of *C. cucumerinum,* as described previously (17). In addition, both oleic and linoleic acids were bioassayed at concentrations of 1, 10, 100, and 1000 μg to serve as controls and to assess specificity of the antifungal fatty acids. The chloroform extracts from the filtrates were applied to a silica gel column and flash-chromatographed by elution with hexane, diethyl ether, and methanol. The active fractions were purified with a combination of preparative TLC and high-performance liquid chromatography with C_{18} reverse-phase columns (8 × 10 cm; Millipore-Waters Ltd., Mississauga, Ontario, Canada). Identification of the active fractions was performed by Fourier transform infrared spectra, nuclear magnetic resonance magnetic spectroscopy (^1H, ^{13}C, 2-D, and Hector) and gas chromatography/mass spectrometry.

Effect of antibiotics on fungal growth. Conidia from tested fungi were suspended in 100 mL of yeast malt peptone dextrose broth medium at 10^6 cells/mL. The three antifungal fatty acids, in a ratio 1:1:1 (by vol) were tested at a concentration (0.4 mg/mL) which reduced the dry weight growth of *C. cucumerinum* by approximately 50% (Table 1). This relatively high concentration was necessary to achieve the desired effect because of the low solubility of the fatty acids in a water-based medium. The antibiotics were added to the sterile medium as a methanol solution. Growth was quantified by dry weight measurement after four days. A comparable quantity of methanol was added to the culture media to serve as control.

Extraction of lipids. Fungal cells were collected by centrifugation, washed with water, and dried by lyophilization. Lyophyllized cells were suspended in 50 mL methanol and homogenized with a Polytron (Kinematica, Brinkman Instruments, Ontario, Canada) for one minute. Chloroform and water were then added to the suspension to give a ratio of 2:2:1 (by vol) chloroform/methanol/water. The suspensions were placed on a rotary shaker at 150 rpm in the dark for 12 h. The cells were collected by centrifugation (8000 × *g*) and the extraction procedure was repeated with a ratio of 4:2:1 (by vol) of methanol/chloroform/water. After 24 h the combined extracts were dried with anhydrous Na_2SO_4 and the organic phases were taken to dryness on a rotary evaporator and the residue immediately dissolved in chloroform/methanol (2:1, vol/vol) and concentrated under nitrogen gas. The oil residue constituted the total lipid extract. It was kept at 4°C until use.

Analysis of lipids. Polar lipids, mainly phospholipids, and neutral lipids were separated by precipitation in acetone as described by Kates (18). Individual phospholipids were separated by TLC on Silica Gel 60 (0.5-mm thick) (VWR Scientific, London, Ontario, Canada) using a solvent system of chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1; by vol). Phospholipid classes were located by exposing plates to iodine vapor. Individual phospholipids were identified by reference to standards (Sigma Chemicals, St. Louis, MO) run simultaneously. Using this procedure, phosphatidylinositol and phosphatidylserine were not completely separated. The silica gel bands corresponding to each compound were scraped from the plates and washed by neutral Bligh-Dyer solvent as described by Kates (18). Phospholipid classes were quantified by the phosphorus assay as described by Marinetti (19).

Neutral lipids were separated by TLC in hexane/diethyl ether/acetic acid (7.8:2:0.4, by vol). All neutral lipid classes were visualized on the plates with iodine vapor and identified by comparison of R_f values with authentic standards (Sigma).

Total fatty acids and sterols were obtained by alkaline hydrolysis (0.8 mL, 33% wt/vol, KOH in 8 ml EtOH, 2 h at 90°C). The nonsaponifiable fraction containing sterols was obtained by washing the hydrolysate three times with 15 mL hexane. The hydrolysate was then brought to pH 1–2 with 6 M HCl, and the saponifiable fraction containing the fatty acids was obtained by washing it three times with pentane. Fatty acids obtained in this manner were converted to their fatty acid methyl ester (FAME) derivatives using 14% BF_3/MeOH reagent (Sigma) at 90°C for 60 min under nitrogen. FAME were also prepared directly from phospholipids (obtained from TLC plates, as described previously) by transesterification using sodium methoxide in methanol. FAME were analyzed by gas–liquid chromatography (GLC) (model 5890 series II, Hewlett Packard, Mississauga, Ontario, Canada) on a 30–m capillary DB-225 column (J&W Scientific, Rancho Cordova, CA). The oven temperature program was initially 100°C, then raised at 20°C min^{-1} to 200°C, held for 5 min, then raised at 10°C min^{-1} to 240°C and held for 5 min. H_2 injector and flame-ionization detector temperatures were 230 and 250°C, respectively. FAME were identified by comparison of their retention times with those of authentic standards (Sigma), and quantified using methylnonadecanoate as an internal standard. Peaks were integrated with an HP model 3392A.

TABLE 1
Mycelial Dry Weight of Four-Day-Old Liquid Cultures of *Cladosporium cucumerinum, Fusarium oxysporum* f. sp. *radicis-lycopersici* (FORL), and *Sporothrix flocculosa* Grown in Absence (control) or Presence (treated) of Antifungal Fatty Acids Produced by *S. Flocculosa*

Fungus	Control[a] (mg)	Treated (mg)	% Inhibition
C. cucumerinum	913	446	51
FORL	1065	712	33
S. flocculosa	836	796	5

[a]Values are means of three different cultures.

The degree of unsaturation was determined as previously described (20) where:

$$\Delta/\text{mole} = [\%18{:}1 + 2\,(\%18{:}2) + 3\,(\%18{:}3)]/100 \quad [1]$$

Sterols were estimated by the method of Zlatkis *et al.* (21), using ergosterol (Sigma) as standard.

Preparation of liposomes. Liposomes were prepared according to the method of Alving *et al.* (22). Briefly, total lipids extracted from *S. flocculosa* and *C. cucumerinum* were dissolved separately in chloroform/methanol (2:1; vol/vol) and transferred to round-bottom flasks. Under a gentle flow of nitrogen, the solvent was evaporated to dryness to form a thin lipid film on the walls of the flasks. Liposomes were prepared by dispersing the lipids in 10 mM Tris-HCl buffer, pH 7.4, containing 145 mM NaCl, followed by vortexing for 10 min in the presence of glass beads. To the final liposome preparation, 1,6-diphenyl-1,3,5-hexatriene (DPH) was added to give 1 mM.

Fluorescence anisotropy. Fluorescence measurements were taken with a SLM spectrofluorimeter (Aminco; SLM instruments, Urbana, IL) equipped with Glan-Thompson polarization optics with excitation and emission wavelengths of 360 and 430 nm, respectively. Anisotropy values (r) were determined as described earlier (24) where $r = I_H - I_V/I_H + 2\,I_V$; I_H and I_V being the intensity of horizontal (parallel) and vertical (perpendicular) polarized light, respectively. The standard deviation of polarization values was 0.02.

RESULTS

General effects on growth. As previously reported (8), all three fatty acids exhibited antifungal activity on the TLC-bioassay when an equivalent of roughly 7.5 μg of each molecule was spotted on the plates. By contrast, only a faint zone of activity was detected with oleic acid when 1000 μg were spotted.

The three fungi used in this study varied considerably in their sensitivity to the fatty acids. For instance, at the concentration used in this study (0.4 mg/mL), the antibiotics inhibited the growth of *C. cucumerinum* and *F. oxysporum* by 51 and 33%, respectively, whereas growth of *S. flocculosa* was only slightly inhibited (Table 1).

Total lipid composition. Separation of total lipids by TLC revealed no qualitative differences in lipid classes among the fungi tested (Table 2). However, quantitative comparison of total lipids indicated that *C. cucumerinum* had a lower relative cellular lipid content than *S. flocculosa* or FORL. After treatment with the antifungal fatty acids, the total lipids in *C. cucumerinum* and FORL were decreased by 18 and 11%, respectively, although they remained unchanged in *S. flocculosa* (Table 2).

Effects on sterols and individual phospholipids. The total sterol content in *C. cucumerinum* was much lower than in *S. flocculosa* or FORL controls (Table 2). Although there was no major effect of antibiotics on the total sterol content in the three fungi, cellular phospholipids decreased by 30 and 19% in *C. cucumerinum* and FORL, respectively (Table 2). In *S. flocculosa*, no apparent effect on total phospholipids was detected. For the sterol/phospholipid ratio (S/P), it increased to a higher extent in both *C. cucumerinum* and FORL than in *S. flocculosa* (Table 2).

The proportion of individual phospholipids varied among the three fungi (Table 3). In *S. flocculosa* and *C. cucumerinum* phosphatidylcholine (PC) and phosphatidylethanolamine (PE) together represented more than 70% of total phospholipids. Nevertheless, the PC/PE ratio in *C. cucumerinum* was much higher (3.1) than in *S. flocculosa* (1.7). In FORL the proportion of phosphatidylinositol and phosphatidylserine was higher compared to the other two fungi (Table 3). Finally, the cardiolipin content was considerably higher in *C. cucumerinum* (Table 3).

After treatment with the antifungal fatty acids, the most important quantitative differences were a 4- and 2-fold increase in phosphatidic acid (PA) in *C. cucumerinum* and in FORL, respectively (Table 3). Comparatively, the differences between levels of each phospholipid were negligible between control and treated *S. flocculosa*.

Effect on fatty acid composition. As shown in Table 2, free fatty acid contents were five and three times higher in *C. cucumerinum* and FORL, respectively, following treatment with antifungal fatty acids. In *S. flocculosa*, the amount of cellular free fatty acids was slightly increased.

Among phospholipid fatty acids, palmitic and oleic acids were the most prevalent saturated and unsaturated fatty acids,

respectively, in the three fungi used in this study (Table 4). The degree of unsaturation (Δ/mole) was higher in *C. cucumerinum* than in FORL and *S. flocculosa* controls (Table 4). After treatment with the antibiotics the degree of unsaturation remained stable in *S. flocculosa*, and it increased in *C. cucumerinum* and FORL by 22 and 13%, respectively (Table 4). Accordingly, the ratio was considerably reduced in *C. cucumerinum* and FORL following treatment, due to the decreased proportion of 18:1 and increased 18:2 and 18:3, respectively. In the case of phospholipids from *S. flocculosa*, the ratio was unchanged in response to the treatment (Table 4).

Fluorescence polarization. The effect of fungitoxic fatty acids on lipid fluidity was investigated using DPH, an intrinsic fluorescent probe located deep within the hydrophobic core of the membrane bilayer of liposomes. The fluorescence anisotropy or *r* value is taken as an index of membrane fluidity, with decreasing *r* values indicating increases in lipid fluidity. Anisotropy values from lipids built with lipids of *C. cucumerinum* were lower than the ones recorded with liposomes from *S. flocculosa* lipids (Table 5). Additionally, the fungitoxic fatty acids caused dose-dependent decreases in anisotropy (*r*) values in *C. cucumerinum*, thus increasing lipid fluidity by more than 100% at the highest concentration tested (0.5 mg/mL). By contrast, *r* values in liposomes from lipids of *S. flocculosa* only indicated a 17% increase in lipid fluidity at the same concentration (Table 5).

TABLE 5
Fluidity (*r*) of Liposomes Prepared with Lipids Extracted from Liquid Cultures of *Cladosporium cucumerinum* and *Sporothrix flocculosa* Grown in the Presence of Increasing Concentrations of Antifungal Fatty Acids Produced by *S. flocculosa*

	$r^{a,b}$	*r*
Concentrations (mg/mL)	*C. cucumerinum*	*S. flocculosa*
0	0.19 ± 0.03	0.28 ± 0.03
0.2	0.15 ± 0.01	0.29 ± 0.07
0.4	0.11 ± 0.02	0.27 ± 0.03
0.5	0.09 ± 0.01	0.24 ± 0.04

[a]Values are means ± SD of three different preparations of liposomes.
[b]*r* represents anisotropy values where $r = I_H - I_V / I_H + 2\ I_V$; I_H and I_V being the intensity of horizontal and vertical polarized light, respectively.

DISCUSSION

Lipids are major components of the cell membrane and many metabolic reactions occur in association with these membranes. The physical properties of lipids and the dynamic nature of membrane have important effects on the function of

many membrane-associated proteins. The modification of the lipidic environment in membranes may therefore be harmful to cell viability (24,25). Several antimicrobial molecules have been found to interfere with lipid metabolism or directly with specific lipid molecules (26,27). Recently, new fatty acids with antifungal activity were isolated and characterized from liquid cultures of the biocontrol agent *S. flocculosa* (6,7). Cytochemical and physiological studies revealed that these antibiotics induced a dysfunction of the cytoplasmic membrane. Because these antifungal molecules seem to have a differential effect on fungi, three fungi, with different sensitivity to antibiotics, were selected for the purpose of this study: *C. cucumerinum*, sensitive, FORL, moderately sensitive, and *S. flocculosa*, resistant (5,6). The analysis of lipid composition among the three fungi, both before and after treatment with antibiotics, revealed some important differences which appear to be related to their level of sensitivity.

Firstly, *C. cucumerinum* had a much lower lipid content than the two other fungi. This low concentration of lipids had been previously reported with another species of *Cladosporium* (25), and may be related to the sensitivity of this fungus to the antifungal fatty acids. Additionally, *C. cucumerinum* contains less sterols than FORL or *S. flocculosa*. This factor could also play a role in its greater sensibility to the antibiotics, because it is well established that the presence in a lipid bilayer of sterols tends to buffer the bilayer against stress-induced fluctuation in fluidity (28). Another interesting observation was the degradation of phospholipids in both sensitive fungi (*C. cucumerinum* and FORL) following treatment. This breakdown of phospholipids was correlated with a drastic increase in free fatty acid contents. Free fatty acids are known to be toxic in high concentrations (26), and the increase observed as a result of exposure to the antibiotics may explain their higher sensitivity. The accumulation of these fatty acids could not only be attributed to an increase in breakdown of acyl lipid, but also to a reduction in fatty acid incorporation into acyl lipids and/or a stimulation of *de novo* synthesis, as a consequence of the disparity between fatty acid synthesis and utilization.

For the individual phospholipids, further differences were noted between the three fungi before and after treatment, and sometimes with a correlation to sensitivity to antifungal fatty acids. It is well known that head groups, charge and structure of phospholipids, and the fluctuation in their levels may alter membrane permeability and membrane-associated functions (29,30). Indeed, previous studies have shown that PE molecules are more closely packed than PC molecules (31). In the sensitive fungus (*C. cucumerinum*), the PC/PE ratio was much higher than in *S. flocculosa*. In addition, *C. cucumerinum* contains a high quantity of cardiolipin in its lipids. This phospholipid has the highest transition temperature of all lipids at neutral pH (32). However, it cannot be directly involved in the alteration of plasma membrane function as this lipid is characteristically located in the inner membrane of mitochondria. The increases of PA molecules in sensitive fungi, following treatment, is therefore probably correlated with a degradation of phospholipids.

Another feature shared by *C. cucumerinum* and FORL was their higher level of phospholipid unsaturated fatty acids compared to *S. flocculosa*. This higher level, combined with an increase in unsaturation following treatment with antibiotics, could be involved in the alteration of plasma membrane function in sensitive fungi, as previously reported (6). Indeed, changes in the degree of unsaturation of phospholipids will alter the fluidity of the membrane, i.e., the degree of mobility of the phospholipid fatty acyl chains in the bilayer. Changes in unsaturation have also been reported to affect the activity of membrane-bound enzymes and proteins (33). The involvement of the desaturase activities in the increase of unsaturation of fatty acids has been previously demonstrated (34). These desaturases are lipophilic microsomal enzymes; their activities are modulated by the fluidity of the membrane in which they are embedded (35).

The results concerning the degradation of phospholipids, the differences in head groups of phospholipids, and the increases in unsaturation of phospholipid fatty acids suggest an alteration in membrane environment. To address this question, the effects of antifungal fatty acids on lipid fluidity were determined by fluorescence anisotropy measurement using liposomes and the probe DPH. The low value of anisotropy of liposomes built with lipids from untreated *C. cucumerinum* could be explained by a constitutive high degree of unsaturation of phospholipid fatty acids, a low quantity of sterols, and the presence of a high proportion of cardiolipin, as described previously. The drastic decrease in anisotropy values in liposomes prepared with lipids from treated *C. cucumerinum* was consistent with modifications observed such as the increase in phospholipid fatty acids unsaturation and the degradation of phospholipids. In addition, the increase in lipid fluidity reflects an increase in membrane lipid disorder, which is coherent with the reported deterioration of cell membranes and enhanced permeability induced by metabolites from *S. flocculosa* (6).

In conclusion, fungal sensitivity to fatty acid antibiotics from *S. flocculosa* appears to be related to a high degree of unsaturation of phospholipid fatty acids and a low proportion of sterols. The major responses of sensitive fungi to sublethal doses of antifungal fatty acids from liquid culture of *S. flocculosa* were: (i) a decrease in total lipid; (ii) an increase in the degree of fatty acid unsaturation (18:1 > 18:2 > 18:3); (iii) an increase in free fatty acids and PA, and a decrease in total phospholipids; and (iv) an increase in S/P ratio. These modifications in lipid composition led to an increase in membrane fluidity, which is responsible for the previously demonstrated alteration of membrane structure and function in fungi confronted to *S. flocculosa* (5) and its toxic metabolites (6).

Ultrasound-Assisted Synthesis of Santalbic Acid and a Study of Triacylglycerol Species in *Santalum album* (Linn.) Seed Oil

Marcel S.F. Lie Ken Jie[a,*], Mohammed Khysar Pasha[a], and Fasih Ahmad[b]

[a]Department of Chemistry, The University of Hong Kong, Hong Kong and [b]Department of Biochemistry, Faculty of Life Sciences, Aligarh Muslim University, Aligarh, India - 202002

ABSTRACT: Methyl ricinoleate (**1**) was treated with bromine and the dibromo derivative (**2**) was reacted with ethanolic KOH under ultrasonic irradiation to give 12-hydroxy-octadec-9-ynoic acid upon acidification with dil. HCl. The latter compound was methylated with BF_3/methanol to give methyl 12-hydroxy-octadec-9-ynoate (**3**). Compound **3** was treated with methanesulfonyl chloride in the presence of triethylamine in CH_2Cl_2 to give methyl 12-mesyloxy-octadec-9-ynoate (**4**). Reaction of methyl 12-mesyloxy-octadec-9-ynoate with aqueous KOH under ultrasonic irradiation (20 kHz) gave (11*E*)-octadecen-9-ynoic acid (**5**, santalbic acid, 40%) and (11*Z*)-octadecen-9-ynoic acid (**6**, 60%) on acidification with dil. HCl. These isomers were separated by urea fractionation. The ^{13}C nuclear magnetic resonance (NMR) spectroscopic properties of the methyl ester and the triacylglycerol (TAG) esters of these enynoic fatty acid isomers were studied. The carbon shifts of the unsaturated carbon nuclei of the methyl ester of the *E*-isomer were unambiguously assigned as 88.547 (C-9), 79.287 (C-10), 109.760 (C-11), and 143.450 (C-12) ppm, while the unsaturated carbon shifts of the (*Z*)-enynoate isomer appeared at 94.277 (C-9), 77.561 (C-10), 109.297 (C-11), and 142.668 (C-12) ppm. In the ^{13}C NMR spectral analysis of the TAG molecules of type AAA containing either the (*Z*)- or (*E*)-enyne fatty acid, the C-1 to C-6 carbon atoms on the α- and β-acyl positions were differentiated. The unsaturated carbon atoms in the α- and β-acyl chains were also resolved into two signals except that of the C-11 olefinic carbon. Sandal *(Santalum album)* wood seed oil (a source of santalbic acid) was separated by silica chromatography into three fractions. The least polar fraction (7.2 wt%) contained TAG which had a random distribution of saturated and unsaturated fatty acids, of which oleic acid (69%) was the predominant component. The second fraction (3.8 wt%) contained santalbic acid (58%) and oleic acid (28%) together with some other normal fatty acids. Santalbic acid in this fraction was found in both the α- and β-acyl positions of the glycerol "backbone." The most polar fraction (89 wt%) consisted of TAG containing santalbic acid only. The distribution of the various fatty acids on the glycerol "backbone" was supported by the results from the ^{13}C NMR spectroscopic analysis.

Lipids 31, 1083–1089 (1996).

The chemistry of conjugated long-chain fatty alcohols and esters containing an enyne system is of current interest for the synthesis of biologically active compounds such as pheromones, leukotrienes, and prostaglandins (1,2). The seed oil of *Santalum album* (Sandalwood) contains a significant level of (11*E*)-octadecen-9-ynoic acid (commonly known as santalbic or ximenynic acid) (79 wt%) (3). Sandal seed oil is used in the treatment of skin diseases and shows antiviral and diuretic activities (4). The plant *Ixiolaena brevicompta*, which contains acetylenic fatty acids, is reported to be responsible for causing acute muscular degeneration and mortalities in sheep. These mortalities have been linked to the inhibitory effects of acetylenic acids on cyclooxygenase, lipoxygenase, and phospholipase A_2 activities (5–7). Spitzer *et al.* (8) have also reported the occurrence of santalbic (ximenynic) acid in the seed oil of *Curupira tefeensis* (Fam. Olacaceae). Pasha and Ahmad (3) have recently described the preparation of various oxygenated fatty acid esters from the methyl ester of natural santalbic acid.

The total synthesis of santalbic acid has been described by Crombie and Jacklin (9) from acetylenic intermediates, which required seven steps. Gunstone and Said (10) have reported a mixture of methyl santalbate (38%) and a methylene-interrupted enyne derivative [viz. methyl (12*E*)-octadecen-9-ynoate] (57%) as the main products when methyl 12-mesyloxy-octadec-9-ynoate is refluxed with NaOMe in methanol. Despite the abundant occurrence of triacylglycerols (TAG) containing acetylenic acids in many seed lipids, little work has been carried out to analyze their molecular species. The only information on the distribution of a methylene-interrupted enyne fatty acid [viz. crepenynic acid, (9*Z*)-octadecen-12-ynoic acid] has been reported for the seed oil of *Crepis rubra* (11). In this seed oil, crepenynic acid is found to be mainly esterified to the glycerol at the *sn*-2 and *sn*-3 positions with saturated acids occupying mainly the *sn*-1 position.

In this paper we describe (i) an efficient ultrasound-assisted synthesis of santalbic acid and its (*Z*)-isomer starting from ricinoleic acid [12-hydroxy-(9*Z*)-octadecenoic acid] *via* the mesyloxy derivative of an acetylenic intermediate (methyl 12-hydroxy-octadec-9-ynoate) and (ii) the analysis of TAG molecular species in Sandalwood (*Santalum album*) seed oil by ^{13}C nuclear magnetic resonance (NMR) spectroscopy.

MATERIALS AND METHODS

The matured seeds of *S. album* (Sandalwood) were supplied by Sandal Research Centre (Bangalore, India). Analytical grade reagents and adsorbents (silica gel GF_{254}) for thin-layer chromatography (TLC) and column chromatography were obtained from E. Merck (Darmstadt, Germany). Porcine pancreatic lipase was purchased from Sigma Chemical Co. (St. Louis, MO). Gas–liquid chromatographic (GLC) and ^1H and ^{13}C NMR spectroscopic analyses were conducted by methods described elsewhere (12). Extraction of the seed oil, transmethylation, and pancreatic lipase hydrolysis followed by methylation for the determination of the fatty acid composition were performed according to the methods described by Pasha and Ahmad (3,13). Ultrasonication was carried out using a 20 kHz (53 W/cm^2) ultrasound horn (Undatim Ultrasonic S.A., Louvain-la-neuve, Belgium) with the reaction mixtures contained in a water-cooled cell at 20°C. The preparations of TAG of type AAA using santalbic acid or its (*Z*)-isomer were conducted as described by Ziegler and Berger (14).

EXPERIMENTAL PROCEDURES

Preparative TLC fractionation of Sandalwood seed oil. The seed oil (200 mg) was dissolved in *n*-hexane (20 mL), and the solution was applied on 10 silica gel coated TLC plates (0.3 mm thick). The plates were developed four times each (multiple developments) in a mixture of *n*-hexane/diethyl ether/acetic acid (85:15:5, vol/vol) at 5°C. The plates were viewed under ultraviolet light and bands corresponding to retardation factor (R_f) = 0.6 (fraction A), 0.5 (fraction B), and 0.3–0.4 (fraction C) were scraped off. The combined bands of each fraction of silica were extracted with diethyl ether (4 × 20 mL) to give fractions A (14.4 mg), B (7.6 mg), and C (176 mg). The isolated samples of TAG fractions were stored under nitrogen in *n*-hexane at 0–5°C.

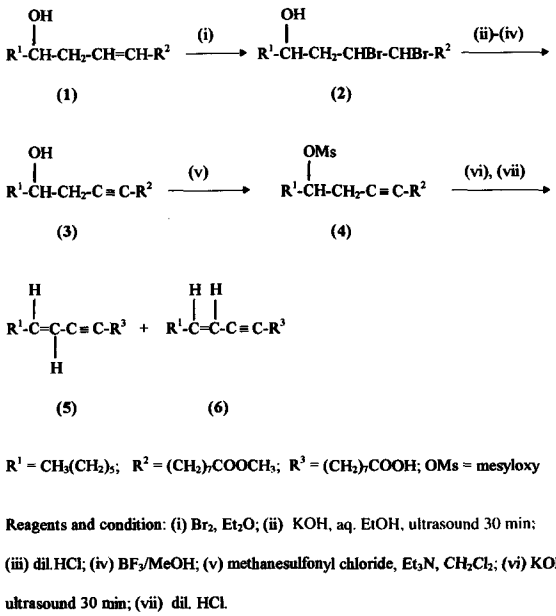
*Methyl 9,10-dibromo-12-hydroxyoctadecanoate (**2**).* Bromine (5.6 g, 3.5 mmol) was added to a solution of methyl ricinoleate (**1**, 2.0 g, 6.4 mmol) in diethyl ether (30 mL) and stirred for 15 min. The reaction mixture was successively washed with aqueous sodium thiosulfate solution (5%, 10 mL), water (20 mL), and dried over anhydrous sodium sulfate. The ethereal mixture was filtered and the filtrate evaporated to give crude methyl 9,10-dibromo-12-hydroxyoctadecanoate (**2**, 3.0 g, 100%) as a viscous liquid. TLC, R_f 0.6 (petroleum ether/diethyl ether, 7:3, vol/vol); infrared (IR) (cm^{-1}): 3450 (*br*), 1740(*s*), 840(*m*), 760 (*m*), and 720(*s*); ^1H NMR ($CDCl_3$, δ) 0.88(*t*, 3H, CH_3), 1.2–1.8 (*m*, 20H, CH_2), 1.9-2.1(*m*, 4H, CH_2), 2.2(*s*, 1H, CH-O*H*), 2.3(*t*, 2H, 2-*H*), 3.6(*s*, 3H, $COOCH_3$), 3.8(*m*, 1H, C*H*-OH), and 4.6(*m*, 2H, C*H*-Br).

*Methyl 12-hydroxy-octadec-9-ynoate (**3**).* A mixture of compound **2** (3.0 g, 6.3 mmol), ethanol (95%, 30 mL), and KOH (5.3 g, 9.5 mmol) was sonicated for 30 min using a 20 kHz horn at 20°C. The reaction mixture was acidified with HCl (6M, 20 mL) and extracted with diethyl ether (3 × 30 mL). The ethereal extract was washed with water (30 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated, and the residue was refluxed with borontrifluoride/methanol (14%, w/w, 5 mL) in absolute methanol (30 mL) for 10 min. Water (50 mL) was added and the reaction mixture was extracted with diethyl ether (2 × 50 mL). The solvent was evaported, and silica column chromatographic purification of the residue using a mixture of petroleum ether and diethyl ether (85:15, vol/vol) as eluent gave pure methyl 12-hydroxy-octadec-9-ynoate (**3**, 1.3 g, 66%). TLC, R_f 0.5 (petroleum ether/diethyl ether, 7:3, vol/vol); IR (cm^{-1}): 3450 (*br*), 1740(*s*), 1460(*m*), 1435(*m*), 1360(*m*), and 1170(*m*); ^1H NMR ($CDCl_3$, δ): 0.88 (*t*, 3H, CH_3), 1.2–1.6 (*m*, 20H, CH_2), 2.04 (*s*, 1H, CH-O*H*), 2.2 (*m*, 4H, 8-*H* and 11-*H*), 2.3 (*t*, 2H, 2-*H*), 3.66 (*s*, 3H, $COOCH_3$), and 3.96 (*m*, 1H, C*H*-OH); ^{13}C NMR ($CDCl_3$, ppm): 14.1 (C-18), 18.7 (C-8), 22.6 (C-17), 24.9 (C-3), 25.2 (C-14), 27.7 (C-11), 28.6 (C-7), 28.9, 29.3, 31.8 (C-16), 33.9 (C-2), 36.2 (C-13), 51.4 ($COOCH_3$), 70.3 (C-12), 76.2 (C-10), 83.1 (C-9), and 174.3 (C-1)

*Methyl 12-mesyloxy-octadec-9-ynoate (**4**).* A mixture of compound **3** (1.0 g, 3.2 mmol), methanesulfonyl chloride (0.8 g, 7.0 mmol), triethylamine (1.0 mL) and dichloromethane (10 mL) was stirred at 0–5°C for 30 min. The reaction mixture was diluted with dichloromethane (50 mL) and successively washed with dilute HCl (2M, 5 mL), water (20 mL), and dried over anhydrous sodium sulfate. The mixture was filtered and the filtrate evaporated to give crude methyl 12-mesyloxy-octadec-9-ynoate (**4**, 1.2 g, 95%) as a viscous oil. TLC, R_f 0.4 (petroleum ether/diethyl ether, 1:1, vol/vol), IR (cm^{-1}): 1735 (*s*), 1440 (*m*), 1460 (*m*), 1360 (*s*), 1170 (*s*), and 910 (*s*); ^1H NMR ($CDCl_3$, δ) 0.88 (*t*, 3H, CH_3), 1.2–1.6 (*m*, 18H, CH_2), 2.1 (*t*, 3H, 8-*H*), 2.3 (*t*, 2H, 2-*H*), 2.6 (*d*, 2H, 11-*H*), 3.05 (*s*, 3H, CH_3 of OMs); 3.7 (*s*, 3H, $COOCH_3$), and 4.7 (*quintet*, 1H, C*H*-OMs); ^{13}C NMR ($CDCl_3$, ppm) 14.1 (C-18), 18.6 (C-8), 22.5 (C-17), 24.8 (C-3), 24.9, 25.2 (C-14), 28.6 (C-7), 28.7, 28.8, 28.9, 29.0, 31.6 (C-16), 33.9, 34.0 (C-2), 38.7 (CH_3 of OMs), 51.4 ($COOCH_3$), 74.6 (C-10), 81.5 (C-12), 83.3 (C-9), and 174.2 (C-1).

*(11E)-Octadecen-9-ynoic acid (**5**) and (11Z)-octadecen-9-ynoic acid (**6**).* A mixture of methyl 12-mesyloxy-octadec-9-ynoate (1.0 g, 2.6 mmol), KOH (1.2 g), and water (20 mL) was placed in a water-cooled cell (20°C) and sonicated (20 kHz) for 30 min. The reaction mixture was acidified with dilute HCl (6M, 20 mL) and extracted with diethyl ether (3 × 50 mL). The ethereal extract was washed with brine (30 mL) and dried over anhydrous sodium sulfate. The filtrate was

evaporated to give crude enynoic acids (0.70 g, 97%). Gas chromatography (GC) analysis of the methyl esters of this mixture showed (11*E*)-octadecen-9-ynoic acid (**5**, santalbic acid) and its (*Z*)-isomer (**6**) in the ratio of 2:3.



The mixture of the crude acids (0.7 g), urea (3.0 g), and methanol (9 mL) was warmed to dissolve the urea crystals. The solution was allowed to cool to room temperature and was kept at 5°C for 4 h. The solution was filtered to recover the solid urea adduct. The collected urea adduct was dissolved in dilute HCl (2M, 25 mL). The acidic solution was extracted with diethyl ether (3 × 30 mL). The organic extract was washed with water (30 mL) and dried over Na_2SO_4. The filtrate was evaporated and the residue was twice refractionated (collecting the urea adduct each time) by using urea (1 g) and methanol (3 mL), which yielded in pure santalbic acid (**5**, 0.24 g, m.p. 39°C., lit. (15) 39–40°C).

The mother liquor from the first fractionation process was acidified with dilute HCl (2M, 10 mL). The solution was extracted with diethyl ether (3 × 30 mL). The ethereal extract was washed with water (30 mL) and dried (Na_2SO_4). The filtrate was evaporated and repeated (twice) urea fractionation of the mother liquors with urea (1 g) and methanol (3 mL) gave pure (11*Z*)-octadecen-9-ynoic acid (**6**, 0.36 g) as a viscous oil.

*Cleavage oxidation of (11*E*)-octadecen-9-ynoic acid.* A mixture of (11*E*)-octadecen-9-ynoic acid (25 mg, 0.09 mmol), glacial acetic acid (18 mL), water (2 mL), and KMnO4 (0.2 g, 1.3 mmol) was sonicated for 15 min at 20°C. The reaction mixture was diluted with water (20 mL) and extracted with diethyl ether (3 × 10 mL). The ethereal extract was washed with water (20 mL) and dried over anhydrous sodium sulfate. The filtrate was evaporated to give a residue (20 mg). The residue was refluxed with borontrifluoride/methanol (14%, w/w, 2 mL) in absolute methanol (10 mL) for 5 min. Water (20 mL) was added and the reaction mixture was extracted with *n*-hexane (2 × 10 mL). The organic extract was washed with water (5 mL) and dried over anhydrous sodium sulfate. The solvent was evaporated and the resulting methyl esters were analyzed by GLC. GLC analysis showed the esterified products as methyl heptanoate and dimethyl nonanedioate by reference to authentic samples.

RESULTS AND DISCUSSION

*Synthesis and properties of santalbic acid (**5**) and its (Z)-isomer (**6**).* We have made successful use of ultrasound as an energy source in chemical transformations involving various fatty acid molecules (12,16–18 and Lie Ken Jie, M.S.F., and P. Kalluri, submitted for publication). The synthesis route for the preparation of santalbic acid and its (*Z*)-isomer is presented in Scheme 1. The ultrasound-assisted dehydrobromination reaction of methyl 9,10-dibromo-12-hydroxy-octadecanoate (obtained by bromination of methyl ricinoleate) using ethanolic KOH gave 12-hydroxy-octadec-9-ynoic acid (**3**) in high yield (12). The latter compound was esterified and mesylated. Reaction of methyl 12-mesyloxy-octadec-9-ynoate

$R^1 = CH_3(CH_2)_5$; $R^2 = (CH_2)_7COOCH_3$; $R^3 = (CH_2)_7COOH$; OMs = mesyloxy

Reagents and condition: (i) Br_2, Et_2O; (ii) KOH, aq. EtOH, ultrasound 30 min; (iii) dil.HCl; (iv) BF_3/MeOH; (v) methanesulfonyl chloride, Et_3N, CH_2Cl_2; (vi) KOH, H_2O, ultrasound 30 min; (vii) dil. HCl.

SCHEME 1

(**4**) with aqueous KOH under ultrasound (30 min) furnished in almost quantitative yield a mixture of santalbic acid (**5**, 40%) and its (*Z*)-isomer [**6**, (11*Z*)-octadecen-9-ynoic acid, 60%] as determined by GLC. Gunstone and Said (10), however, reported in a similar reaction the isolation of methyl santalbate (38%) and a mixture of the methylene-interrupted methyl (12*Z/E*)-octadecen-9-ynoate isomers, when the same mesyloxy intermediate was refluxed with NaOMe in MeOH. To verify Gunstone's results, the reaction was repeated by refluxing methyl 12-mesyloxy-octadec-9-ynoate(**4**) with NaOMe in MeOH for 4 h. Analysis of the isolated products showed the presence of a mixture of methyl (*E/Z*)-octadecen-9-ynoate (20%), methyl 12-methoxy-9-octadecynoate (5%), and unreacted methyl 12-mesyloxy-9-octadecynoate. No methylene-interrrupted enyne fatty esters [i.e., methyl (12*E/Z*)-octadecen-9-ynoate] were detected in the isolated product mixture. The same reaction, when conducted under ultrasound (15 min), gave a mixture of methyl (*E/Z*)-octadecen-9-ynoate in low yield (20%). We were therefore unable to reproduce the reaction as reported by Gunstone and Said (10). In considering the stability of the two possible enyne systems obtainable from this elimination reaction involving compound **4**, we would expect the conjugated enyne isomer to be preferentially formed over the methylene-interrupted enyne isomers.

The separation of the obtained mixture of enynoic acids (**5,6**) into pure components was achieved by repeated urea fractionation. Pure santalbic acid (**5**, 34 wt%) was isolated after three urea fractionations. The mother liquor yielded pure (11*Z*)-octadecen-9-ynoic acid (**6**, 51 wt%) after three urea fractionations. The position of the enyne system in santalbic acid and its (*Z*)-isomer was determined by a newly developed ultrasound-assisted oxidative cleavage procedure as described elsewhere (Lie Ken Jie, M.S.F., and P. Kalluri, sub-

mitted for publication). This procedure involved the reaction of santalbic acid or its (*Z*)-isomer with $KMnO_4$ in acetic acid/water (9:1, vol/vol) under ultrasonic irradiation (20 kHz) for 15 min. The isolated oxidation products were methylated, and the methyl ester derivatives were identified by GLC analysis as methyl heptanoate and dimethyl nonanedioate. This result confirms the position of the enyne system in compounds **5** and **6**.

The results of the ^1H and ^{13}C NMR analysis of methyl santalbate (**5**) and its (*Z*)-isomer (**6**) are presented in Table 1. The ^1H NMR spectrum of the synthetic methyl santalbate showed the characteristic doublet at δ 5.47 and a multiplet at δ 6.04 for the shifts of the 11-*H* and 12-*H* ethylenic protons, respectively. The multiplet at δ 2.05 was assigned to the shift of the 13-*H* protons, as confirmed by double irradiation technique. The shift of the methylene protons (8-*H*) adjacent to the acetylenic bond appeared at δ 2.26. This signal merged with the triplet of the 2-*H* protons (δ 2.31). In the ^{13}C NMR spectrum of methyl santalbate, the shifts of the C-11 and C-12 ethylenic carbon atoms appeared at δ 109.76 and 143.45, respectively. These chemical shifts were confirmed from the results of the ^1H-^{13}C COSY spectrum. In order to assign the shifts of the acetylenic carbon atoms unequivocally, it was necessary to run a long-range ^1H-^{13}C heteronuclear correlation spectrum optimized at $J_{C\text{-}H}$ 10 Hz. This technique allowed interconnections up to three nuclei to be established. From these results, the shifts of the C-9 and C-10 carbon atoms were confirmed as δ 88.55 and 79.29, respectively. The presence of the (*E*)-enyne system was confirmed by the signal at δ 19.33 for the shift of the C-8 methylene carbon atom and by the signal at δ 32.98 for the shift of C-13.

The ^1H NMR spectrum of methyl (11*Z*)-octadecen-9-ynoate differed significantly from that of the (*E*)-isomer (methyl santalbate) in that the 12-*H* olefinic proton appeared as a distinct double triplet at δ 5.83, while the signal for the 11-*H* protons remained as a doublet at δ 5.44(d). The ^{13}C NMR spectrum of the (*Z*)-isomer showed a significant shift difference for one of the acetylenic carbon atoms. The shift of the C-9 acetylenic carbon (δ 94.28) was comparatively more deshielded than the similarly positioned acetylenic carbon atom of methyl santalbate. The effect of the (*Z*)-enyne system caused the shift of the methylene carbon atom (C-13) adjacent to the (*Z*)-double bond to appear at δ 30.04. This shift value was much higher than that expected of the shift of a methylene carbon atom adjacent to an isolated (*Z*)-double bond, which normally appears at *ca.* δ 27.0 from TMS.

From this study of the NMR analysis of methyl santalbate and its (*Z*)-isomer, we were able to determine unambiguously the shifts of the unsaturated carbon atoms of the enyne system in these fatty ester isomers. In view of our successful qualitative and semi-quantitative analysis of saturated and unsaturated TAG (19–22), the ^{13}C NMR spectral properties of the corresponding TAG of type AAA composed of santalbic acid or its (*Z*)-isomer were studied as presented in Table 2. In both TAG containing the (*E*)-enynoic (**7**) or (*Z*)-enynoic (**8**) acids, the shifts of the C-1 to C-6 carbon atoms in the α- and β-position of the glycerol "backbone" were clearly differentiated into individual signals and were readily identified by referring to carbon chemical shifts reported elsewhere (Lie Ken Jie, M.S.F., and P. Kalluri, submitted for publication). The shifts of the acetylenic carbon atoms were also differentiated where the shift value of the C-9 carbon atom in the α-acyl chain appeared higher than that of the C-9 in the β-acyl chain. However, the shift of the acetylenic C-10 carbon shift in the β-acyl chain was higher than that of the α-acyl chain. The olefinic carbon atoms at C-11 in the α- and β-acyl chains were not differentiated, but the C-12 olefinic carbons in the α- and β-acyl chains were separated into two distinct signals. It was therefore of interest to note that in such TAG molecules containing an enyne system, the olefinic carbon atom immediately adjacent to the acetylenic bond remained undifferentiated. This particular observation should be borne in mind when mixtures of TAG containing such conjugated enyne systems were to be analyzed by ^{13}C NMR spectroscopy.

Analysis of the TAG species in sandalwood seed oil. The total fatty acid composition of the TAG of sandalwood seed oil is presented in Table 3, which shows oleic acid (18%) and santalbic acid (79%) as the major fatty acid components by

[a]TAG, triacylglycerols.
[b]Fatty acid composition at β-position was determined by lipolysis with pancreatic lipase; fatty acid composition at α-position was calculated from the total fatty acid composition at α- and β-positions.

GLC analysis of the methyl esters. The oil (a mixture of TAG) was separated by preparative silica TLC into three fractions (A–C). Fraction A (7.2%, w/w) was the least polar fraction, which was followed by fractions B (3.8%, w/w) and C (89%, w/w). The total fatty acid composition and that of each fraction (A–C) are given in Table 3 by GLC analysis of the methyl esters.

Fraction A was composed of saturated fatty acids and 18:1 (69%), 18:2 (6%), and 18:3 (8%). This fraction contained no santalbic acid. The ^{13}C NMR spectrum of fraction A showed a rather random distribution of saturated and unsaturated acyl moieties on the glycerol "backbone" as indicated by the shifts of the C-1 to C-3 and the unsaturated carbon atoms (Table 4). From the intensities of the signals of the unsaturated carbon atoms (C-9 and C-10), the amount (in terms of molar equiva-

18:2(9*a*,11*E*) (α,β)	C-11	109.782	29.98
18:2(9*a*,11*E*) (α)	C-12	143.415	92.92
18:2(9*a*,11*E*) (β)	C-12	143.422	69.48

lent) of the oleic acid in the β-position appeared to be about twice that present in the α-acyl chain. This rather random distribution of saturated and unsaturated fatty acids on the glycerol "backbone" was confirmed by the results from the pancreatic lipase hydrolysis of fraction A (Table 3).

The fatty acid analysis of fraction B by GLC of the methyl esters showed a large amount of santalbic acid (58%) and oleic acid (28%). From the intensities of the C-1 signals in the ^{13}C NMR spectrum of the TAG (Table 5), the distribution of santalbic acid appeared to be higher in the α-position than in the β-position (in a ratio of about 3:2 based on the intensity ratios of the C-1 carbon signals). This relative distribution of santalbic acid on the glycerol "backbone" was also supported by the intensities of the signals for the shifts of the carbon atoms of the enyne system, which appeared at 88.490 (C-9, α-acyl), 79.299 (C-10, α-acyl), 143.415 (C-12, α-acyl), 88.461 (C-9, β-acyl), 79.311 (C-10, β-acyl), and 143.422 (C-12, β-acyl) ppm. The lipase hydrolysis of this fraction showed a mixture of santalbic and oleic acid in the ratio of about 3:2 in the β-acyl position as the two main components.

Fraction C consisted of TAG containing santalbic acid moieties only as indicated by the ^{13}C NMR spectrum. The carbon shifts of the various carbon atoms were identical to those exhibited by the synthetic TAG of type AAA containing santalbic acid moieties (**7**) as described in Table 2. The exclusive presence of santalbic acid in this most polar fraction was further confirmed by GLC analysis of the methyl esters.

It can be concluded from these results, that ^{13}C NMR analysis of TAG fractions of seed oils provides an insight of the distribution and types of fatty acids present in the TAG mixture of a seed oil.

ABSTRACT: A high-performance liquid chromatographic method, using post-column detection with diphenyl-1-pyrenylphosphine (DPPP), was developed for the quantitative and qualitative determination of isomeric lipid hydroperoxides (OOH). The OOH eluted from a normal-phase column were passed through a photodiode array detector and then mixed with DPPP solution in a reaction coil heated at 80°C. DPPP oxide formed by the reaction with OOH was determined by monitoring the fluorescence intensity at 380 nm and excitation at 352 nm. The conjugated diene OOH (13-*cis,trans*- and 9-*cis,trans*-OOH) and nonconjugated OOH (12-*cis-trans*- and 10-*cis,trans*-OOH) from photosensitized oxidation of methyl linoleate were determined in a molar ratio of 31:29:19:21, respectively. However, only the two conjugated hydroperoxides were detected by ultraviolet absorption at 234 nm. Further applications were carried out for the determination of OOH of methyl oleate and methyl linolenate. This method proved to be useful for the determination of the OOH containing both conjugated and nonconjugated diene structures.

Lipids 31, 1091–1096 (1996).

A normal-phase column high-performance liquid chromatography (HPLC) method has been applied successfully to separate positional isomers of hydroperoxides (OOH) formed as primary oxidation products of fatty acid esters (1). Ultraviolet (UV) light absorption at 234 nm due to conjugated dienes has been used to detect separated OOH isomers. However, the UV measurement at 234 nm is not specific to OOH (1,2), nor is it suitable for determination of nonconjugated OOH (3). One solution to this problem involves HPLC separation of lipid OOH with post-column chemiluminescence detection based on luminol or isoluminol oxidation during a reaction of hydroperoxides and cytochrome C (4,5). Some applications to biological systems have also been reported (6–8). Generally, nonpolar solvent systems based on *n*-hexane are used in HPLC for separation of OOH positional isomers (1). However, a post-column reaction of luminol to luminol oxide progresses only under aqueous alkaline conditions (6). Therefore, the number and type of organic solvents used for mobile phase are relatively limited, as hydrophilic nonpolar solvent mixtures do not mix well with hydrophobic luminol reagents in a post-column reaction coil.

Diphenyl-1-pyrenylphosphine (DPPP) is a recently developed fluorescent reagent which reacts specifically with various lipid OOH to form DPPP oxide even though in the presence of lipid alcohol. The DPPP oxide is excited with UV light at 352 nm and gives the emission wavelength at 380 nm (9). This reaction progresses in many different types of solvents (9), and therefore not only a reversed-phase, but also a normal-phase HPLC separation mode are useful for the DPPP fluorescence post-column detection. A few applications of this system have already been reported for analyses of OOH of triacylglycerol, cholesterol, cholesterol esters, and phospholipids in biological systems (10–12). This study was aimed at applying the DPPP fluorescence detection HPLC system to the study of lipid hydroperoxide positional isomers and their structures.

In this paper, autoxidized and photosensitized-oxidized unsaturated fatty acid methyl esters (FAME) were used as model lipids. To evaluate the efficiency of the present methology, results were compared to previous studies based on gas chromatography/mass spectrometry (GC/MS) and HPLC with UV detection.

MATERIALS AND METHODS

Lipid standard. Methyl oleate, methyl linoleate, and methyl linolenate of >99% purity were purchased from Nu-Chek-Prep. Inc. (Elysian, MN). These esters were purified by pas-

sage through a Sep-Pak silica cartridge (Waters Associates, Milford, MA) just before use (13).

Chemicals. DPPP was kindly donated by the Tosoh Company (Tokyo, Japan). Methylene blue trihydrate and $NaBH_4$ (Wako Pure Chemicals, Osaka, Japan) were of reagent grade. *n*-Hexane of HPLC grade was used after glass-distillation. Diethyl ether of reagent grade was purified by a combination of the first washing with ferrous sulfate–sulfuric acid solution to remove peroxide impurities followed by distillation in glass. Methanol, 1-butanol, and acetone (all HPLC grade) were used as purchased.

Autoxidation of lipids. One hundred mg of FAME were dissolved in *n*-hexane and placed into a glass test tube (10 mm × 13 mm). *n*-Hexane was flushed out with a nitrogen stream. Autoxidation of FAME was carried out in air at 35°C in the dark. The autoxidized FAME was dissolved in *n*-hexane and separated by HPLC.

Photosensitized oxidation of lipids. The oxidation of FAME was sensitized with methylene blue (1 mg/g ester) in a methanol solution with continuous gentle stirring in a jacketed flask cooled to 3°C. The solution in the flask was exposed to a 1000-watt tungsten light source through a 3-cm layer of water to filter out infrared radiation (14). Methanol was evaporated under a nitrogen stream in the dark and the residual photosensitized-oxidized lipid was dissolved in 25% diethyl ether in *n*-hexane. The solution was passed through a Sep-Pak silica cartridge to remove the photosensitizer. The eluent was made up to 10 mL with *n*-hexane and 20 µL solution was injected to the HPLC column.

The HPLC system. A schematic of the HPLC system used is shown in Figure 1. The mobile phase passed through an HPLC column with an HPLC pump (model 1050; Hewlett-Packard, Boise, ID). The eluant from the column was then passed through a diode array detector (HP 1040A) and subsequently to a stainless-steel reaction coil (0.5 mm i.d. × 10 m). At the inlet of the reaction coil, a DPPP reagent solution was pumped (HPLC pump, model 45; Waters Associates) and mixed with the eluent in a T-connector. The reaction coil was immersed in a water bath heated at 80°C. The eluent from the coil was cooled to room temperature by passing through a stainless steel coil (0.5 mm i.d. × 5 m), immersed in a water tank, and led to a fluorescence photospectrometer (model 650-40; Perkin Elmer, Norwark, CO). The intensity of the fluorescence signal was integrated with a chromatographic integrator (Hewlett-Packard model 3390A).

Separation and detection of OOH. A normal-phase column (Supelcosil LC-Si, 2.1 mm i.d. × 250 mm, 5 µm; Supelco, Bellefonte, PA) was used to separate positional isomers of fatty ester OOH. A mixture of 500 mL of *n*-hexane and 34 mL of diethyl ether was pumped at a rate of 0.6 mL/min. The DPPP solution (3 mg in a mixture of 200 mL 1-butanol and 200 mL methanol) was pumped at a flow rate of 0.6 mL/min.

Lipid OOH eluted from the column were passed through the dioide array detector and the absorption due to conjugated dienes was monitored at 234 nm (1). The fluorescence intensity of the DPPP oxides formed by reacting lipid hydroperoxides and DPPP was monitored at 380 nm with excitation at 352 nm (9).

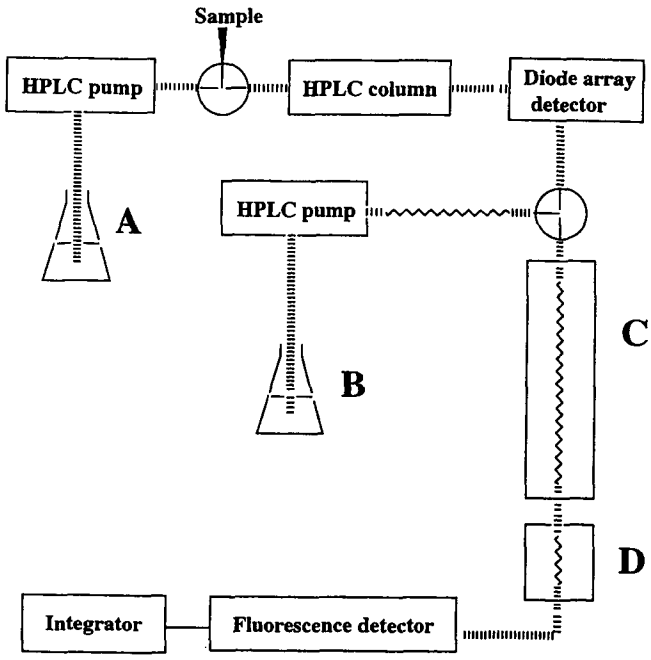

FIG. 1. Diagram of the diphenyl-1-pyrenylphosphine (DPPP)-fluorescence detection high-performance liquid chromatography (HPLC) system. A, HPLC pump for a mobile phase; B, HPLC pump for the DPPP solution; C, reaction coil; D, cooling coil.

GC/MS. OOH positional isomers separated by the HPLC column and monitored with the diode array detector were fractionated before mixing with the DPPP solution by disconnecting the flow tubing at the inlet of the T-connector behind the column. Butylated hydroxyanisole (200 ppm) was added to suppress formation of secondary oxidation products. The hydroperoxides were reduced to the corresponding hydroxy esters with $NaBH_4$ (15), followed by hydrogenation to avoid rearrangement of hydroperoxides, and subsequently converted to trimethylsilyl (TMS) ether derivatives by adding hexamethyldisilazane and trimethylchlorosilane (14).

The TMS derivatives were separated with a gas chromatography (model GC 17A; Shimadzu, Kyoto, Japan) equipped with a Supelcowax-10 fused silica open-tubular column (0.25 mm i.d. × 25 m, 0.25 µm; Supelco Japan Ltd., Tokyo, Japan).

The outlet of the column was connected directly to an electron impact ion source of a quadrupole mass spectrometer (Shimadzu model QP 5000). The column oven temperature was programmed from 150 to 220°C at 1°C/min. Injection port temperature was 250°C. Helium was used as carrier gas. Mass spectra were acquired using 3 KV accelerating energy, 70 eV electron beam energy, and a source temperature of 260°C by using a computer system (Shimadzu Class-5000).

RESULTS

Separation of positional isomers of methyl linoleate OOH. Photosensitized-oxidized methyl linoleate showed four peaks

by HPLC with post-column DPPP fluorescence detection (Fig. 2A). However, only two peaks were shown by UV at 234 nm (Fig. 2B). MS (data not shown) confirmed the identity of the positional isomers as follows: 13-*cis,trans*-, 12-*cis,trans*-, 9-*cis,trans*-, and 10-*cis,trans*-hydroperoxy methyl linoleates based on the literatures (15,16).

Typical chromatograms of autoxidized methyl linoleate OOH detected by fluorescence at 380 nm and absorption at 234 nm (Fig. 2, C and D). Four peaks, including methyl linoleate 13-*cis,trans*-, 13-*trans,trans*-, 9-*cis,trans*-, and 9-*trans,trans*-hydroperoxy isomers, were identified by MS of the corresponding TMS derivatives of hydroperoxides separated by HPLC (data not shown).

Separation of other fatty acid methyl ester OOH. Peak assignment was confirmed for every peak component fractionated by HPLC (data not shown). Although methyl 10-*cis,trans*- and 9-*cis,trans*-hydroperoxy monoene hydroperoxides could not be detected by UV absorption at 234 nm (Fig. 3B), the isomers were detected by DPPP-fluorescence (Fig. 3A). For photosensitized-oxidized methyl linolenate, the peaks due to 13-*cis,trans*-, partially separated 16-*cis,trans*- and 12-*cis,trans*-, 15-*cis,trans*-, 9-*cis,trans*-, and 10-*cis,trans*-methyl linolenate OOH were readily measured by DPPP-fluorescence detection (Fig. 3C). The nonconjugated hydroperoxide isomers, 15-*cis,trans*- and 10-*cis,trans*-methyl linolenate hydroperoxy, were not detected by UV absorption at 234 nm (Fig. 3D).

Quantitative analyses. Tables 1, 2, and 3 summarize peak area ratios of OOH of methyl oleate, linoleate, and linolenate photosensitized-oxidized to different peroxide values. Previously reported results show that the ratios of isomeric OOH formed from photosensitized-oxidized methyl esters were 47.7–51:52.3–49 for methyl oleate (14, 15,17). For 13-*cis,trans*-, 12-*cis,trans*-, 9-*cis,trans*-, and 10-*cis,trans*-hydroperoxides, the previously reported ratios were 34.5–35.0, 17.0–17.0, 31.9–32.0, 16.7–17.0 (14,15).

Reproducibility of the determination of hydroperoxides by this HPLC system was evaluated (Table 4). For the hydroperoxides from methyl oleate and from methyl linoleate, good reproducibility in determination of peak areas was obtained. However, for the methyl linolenate OOH, the peak areas of 10-*cis,trans*-hydroperoxy methyl linolenate were not reproducible due to miss integration of peak area. The use of peak height for quantification may resolve this problem.

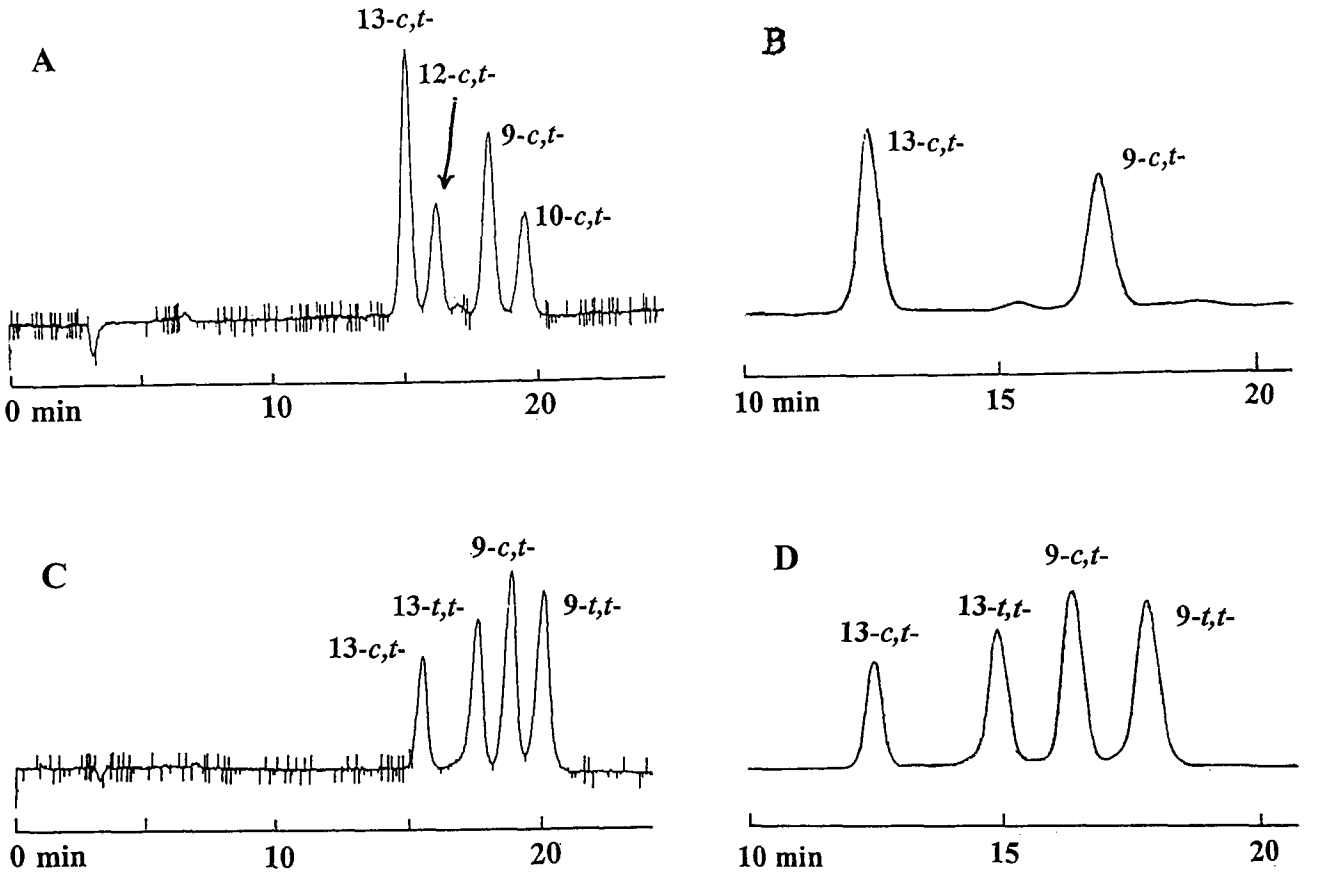

FIG. 2. Typical chromatograms of methyl linoleate isomeric hydroperoxides. Photosensitized-oxidized methyl linoleate detected by the DPPP-fluorescence detection (A) and by ultraviolet (UV) absorption at 234 nm (B). Autoxidized methyl linoleate detected by the DPPP-fluorescence (C) and by UV light absorption at 234 nm (D). See Figure 1 for abbreviations; *c,t-, cis,trans-*.

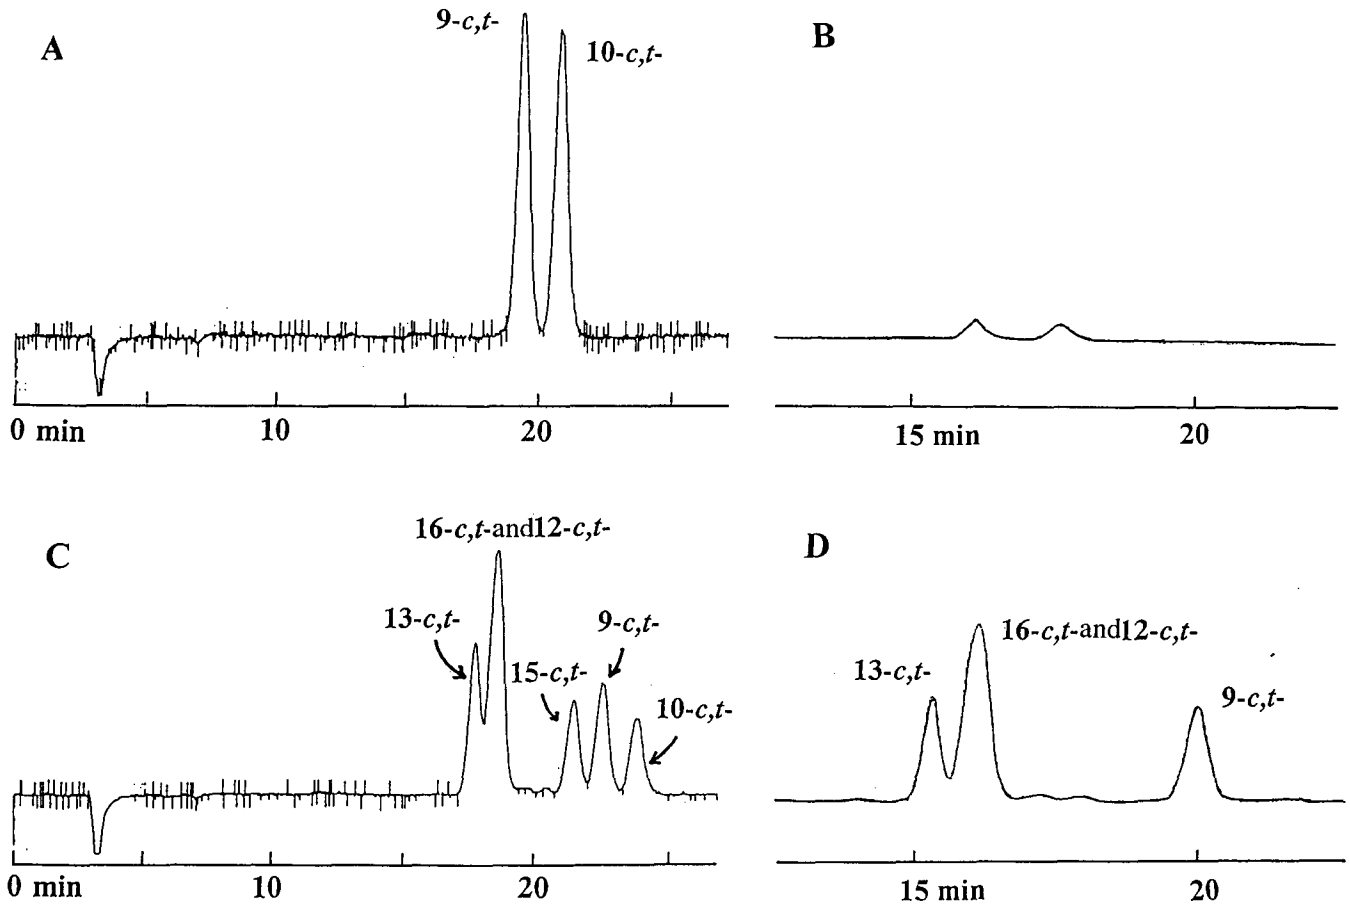

FIG. 3. Typical chromatograms of methyl oleate and methyl linolenate isomeric hydroperoxides. A and C, photosensitized-oxidized methyl oleate and methyl linolenate hydroperoxides, respectively, detected by DPPP-fluorescence; B and D, detected by absorption at 234 nm. See Figures 1 and 2 for abbreviations.

DISCUSSION

This study showed that the DPPP fluorescence detection coupled with HPLC is a simple and accurate method to determine the distribution of OOH isomers of methyl oleate, linoleate, and linolenate. Autoxidation of methyl linoleate produced four conjugated positional isomers of monohydroperoxides, i.e., 13-*cis,trans*-OOH, 13-*trans,trans*-OOH, 9-*cis,trans*-OOH, and 9-*trans,trans*-OOH, which can be analyzed by UV light absorption (1).

However, the nonconjugated singlet oxygen oxidation products of methyl linoleate, 12-*cis,trans*-OOH and 10-*cis,trans*-OOH, are not detectable by UV light absorption. These nonconjugated hydroperoxides are detectable by the DPPP fluorescence detection system, because DPPP is directly oxidized by hydroperoxides to form a fluorescent DPPP oxide. However, in the chemiluminescence detection, several kinds of oxygen radicals and excited oxygens oxidize luminol (5). In the chemiluminescence detection, nonconjugated OOH isomers of methyl linoleate and methyl linolenate were detectable in HPLC, however, separation between certain isomers was not completed (18). Nonlipid components such as sugar, amino acids and ascorbic acid contaminated into a methanol-aqueous layer in a stage of lipid extraction interfere with the accurate analysis of hydroperoxides by causing quenching of the chemiluminescence (5).

It is well accepted that oxidation by singlet oxygen takes place at both ends of the C=C bond (17). Therefore, photosensitized oxidation of methyl oleate forms only two isomers, i.e., 9-*cis,trans*-OOH and 10-*cis,trans*-OOH (13–15,17). The ratios of 9-*cis,trans*-OOH to 10-*cis,trans*-OOH reported little variation; 50:50 by GC/MS (17), 47.7:52.3 by GC/MS (14), and 51:49 by HPLC (13).

A number of previous studies on measurement of lipid hydroperoxide have been carried out by GC/MS. Derivatizations of OOH, including reduction and hydrogenation of hydroperoxy group to the corresponding hydroxy group and subsequent conversion to TMS ether group, are required before GC/MS analysis (14,19–21). These derivatizations are usually time-consuming and can possibly form artifacts during treatment of a sample OOH as well as unsaturated lipids. In contrast, the DPPP fluorescence detection system requires no derivatization of the sample.

It was also possible to determine monohydroperoxides at

Difficulties in the Assay of Phosphatidate Phosphohydrolase Activity. Influence of Ionic Strength, Detergent, and Selection of Substrate

Margareta Stark and Elisabet Humble*

Karolinska Institute, Department of Medical and Laboratory Sciences and Technology, Division of Clinical Chemistry, Huddinge University Hospital, S-141 86 Huddinge, Sweden

ABSTRACT: In the present paper, problems in connection with assay of the activity of magnesium-dependent rat liver phosphatidate phosphohydrolase (PAP) are discussed. PAP activity is usually measured by following the production of diacylglycerol or inorganic phosphate from the substrate phosphatidate. These two methods may give widely different results due to a number of factors that may affect the assay. One such factor is the composition of the substrate. Higher apparent enzyme activity was observed with dioleoyl-phosphatidate than with dipalmitoyl-phosphatidate. This substrate-dependent difference in apparent PAP activity was 2–2.5-fold in the absence and 10-fold in the presence of Triton X-100, respectively. Triton X-100 reduced the activity as measured with the dipalmitoyl-phosphatidate substrate. In contrast, the activity of PAP as measured with dioleoyl-phosphatidate was stimulated by Triton X-100. The stimulatory effect of Triton was reduced or abolished when the ionic strength in the assay mixture was increased. Assays based on ^{32}P-labeled substrate are rapid and sensitive. It is shown here that ^{33}P can be used as an alternative. This radionuclide has a longer half-life and also emits particles with lower energy, thus posing less potential health hazards for the user.
Lipids 31, 1097–1102 (1996).

Phosphatidate phosphohydrolase (PAP; EC 3.1.3.4.) catalyzes the dephosphorylation of phosphatidate, producing diacylglycerol and inorganic phosphate. This reaction occurs at an important branch-point in glycerolipid metabolism. Diacylglycerol is the immediate precursor for triacylglycerol and is also used for the synthesis of the major phospholipids phosphatidylcholine and phosphatidylethanolamine. PAP is considered to play an important role in controlling the rate of synthesis of liver glycerolipids, in particular that of triacylglycerols (1–3). Two forms of PAP activity that differ from each other in various respects have been identified (4,5). One form, the activity of which is independent of magnesium ions and insensitive to inhibition by *N*-ethylmaleimide (NEM), is present predominantly in the plasma membrane. This enzyme is thought to play a role in cell-signalling by changing the local concentrations of the second messengers phosphatidate and diacylglycerol. The other enzyme form, present in cytosolic and microsomal fractions, is magnesium-dependent and NEM-sensitive and is regarded as a metabolic form, operative and with regulatory functions in glycerolipid synthesis.

PAP activity is generally measured by following the formation of diacylglycerol or the release of inorganic phosphate. It is often difficult to compare results obtained by different assay protocols since the enzyme activity could be affected by a number of factors, such as the composition of the phosphatidate substrate, presence of detergents, etc. In the present paper, attempts are made to define some of these different factors and evaluate their importance for the apparent enzyme activity. Furthermore, the use of ^{33}P as an alternative to ^{32}P in the phosphate determination assay method is described.

MATERIALS AND METHODS

Enzyme preparation. Microsomal and cytosolic fractions were prepared from the livers of male 200 g Sprague-Dawley rats fed ordinary laboratory chow *ad libitum* (6). PAP was purified from the cytosolic fractions by hydroxylapatite chromatography (7). In order to induce PAP activity, the rats received an intraperitoneal injection of ethanol 16–18 h before they were killed (7–9).

Preparation of radioactively labeled substrates. ^{32}P-labeled phosphatidate was prepared by incubation of γ-^{32}P-ATP (DuPont NEN, Boston, MA) and diolein with *Escherichia coli* diacylglycerol kinase (Calbiochem, La Jolla, CA) as described by Day and Yeaman (5). ^{33}P-phosphatidate was prepared from diolein and γ-^{33}P-ATP (DuPont NEN) using the same procedure. Phosphatidate was separated from water-soluble substances by extraction and was used in the assay without further purification (as described in Ref. 5). The amount of diolein carried over with the nonpurified radioactive substrate would give a diolein concentration of about 10 μM in

the assay. Addition of diolein to the purified (thin-layer chromatography, see below) and nonpurified substrate in amounts corresponding to 10 μM (and even 50 μM) final concentration of diolein in the assay mixture did not affect the enzyme activity measured in the absence and in the presence of Triton X-100 (Sigma Chemical Corporation, St. Louis, MO) using the assay system described below. The enzyme activity measured in control experiments with purified radioactively labeled dioleoyl-phosphatidate substrate in the absence and in the presence of Triton X-100 and at low and high (up to 200 mM) concentrations of potassium phosphate was the same as with the nonpurified radioactive substrate. Dioleoyl-phosphatidate was stored in chloroform solution at –20°C under argon. Prior to use, nonradioactive phosphatidate (L-α-phosphatidic acid, dioleoyl; Sigma) was added to the radioactive phosphatidate to a specific radioactivity of 1000–2000 cpm/nmol, the solvent was evaporated under a stream of argon, and 10 mM Tris/HCl buffer, pH 7.4, containing 3 mM EDTA and 4 mM EGTA was added. The phosphatidate was either sonicated for one min in 15-s bursts or solubilized by the addition of Triton X-100. Sonicated phosphatidate was slightly turbid while the addition of the detergent produced a clear solution.

In some experiments ^{32}P- or ^{33}P-labeled phosphatidate was prepared from dipalmitin instead of diolein. This phosphatidate substrate was purified before use (thin-layer chromatography, same as for [^{14}C]phosphatidate, see below), since the incorporation of phosphate into dipalmitin was much lower than into diolein. The radioactive dipalmitoyl-phosphatidate was stored in chloroform/methanol (2:1) at –20°C under argon. Prior to use, the solvent was evaporated, and nonradioactive phosphatidate (L-α-phosphatidate, dipalmitoyl; Sigma), dispersed by sonication in 10 mM Tris/HCl buffer, pH 7.4, was added. Labeled and unlabeled phosphatidate was then sonicated together or solubilized with Triton as described above. In order to obtain a clear solution, the dipalmitoyl-phosphatidate/Triton mixture had to be heated (2–3 min at 55°C). When cooled to room temperature, this solution was still clear.

[^{14}C]phosphatidate was prepared by incubation of rat liver microsomes with glycerol-3-phosphate and [1-^{14}C]palmitic acid or [1-^{14}C]oleic acid, extracted with chloroform and purified by thin-layer chromatography (10).

Enzyme assay. (i) Phosphate determination method. Unless otherwise specified PAP activity was measured for 10 min at 37°C by following the release of water-soluble ^{32}P or ^{33}P from 0.5 mM ^{32}P- or ^{33}P-labeled phosphatidate in 50 mM Tris/HCl buffer, pH 7.0, containing 2.5 mM $MgCl_2$, 0.2 mg bovine serum albumin (fatty acid free, Sigma) per mL, 1 mM EDTA, 1 mM EGTA and 1 mM dithiothreitol, in the presence or absence of 5 mM Triton X-100.

When Triton X-100 was present, it was mixed with the phosphatidate substrate at a molar ratio of 10:1 before it was added to the assay system. In control experiments with microsomal and cytosolic (crude and purified by hydroxylapatite chromatography) PAP, the concentration of Triton X-100 was varied from 2.5 mM to 15 mM (in 2.5 mM steps) at 0.5 mM dioleoyl-phosphatidate and 0–2.5 mM potassium phosphate in order to ensure that 10:1 was an optimal detergent:phosphatidate ratio.

Total volume of the incubation mixture was 0.1 mL. The reaction was terminated by the addition of 0.5 mL of 0.1 M HCl in methanol. Chloroform (1 mL) and 1 M $MgCl_2$ (1 mL) were then added. After thorough mixing, the phases were allowed to separate and a 1 mL aliquot of the aqueous layer was transferred to a scintillation vial and radioactivity determined in 8 mL of Lumasafe (LUMAC LSC B.V., Groningen, The Netherlands), using a liquid scintillation counter (1217 Rackbeta; LKB-WALLAC, Stockholm, Sweden).

(ii) Diacylglycerol determination method. Unless otherwise specified, PAP activity was measured in 0.8 mL incubation mixtures for 10 or 15 min at 37°C by following the production of [^{14}C]diacylglycerol from (a) 0.625 mM [^{14}C]phosphatidate in 75 mM Tris/maleate buffer, pH 6.9, containing 2 mM $MgCl_2$, 0.25 mM EDTA, and 0.05–0.1 mM dithiothreitol or (b) 0.5 mM [^{14}C]phosphatidate in 50 mM Tris/HCl buffer, pH 7.0, containing the same additives as described above for the phosphate determination method. The reaction was terminated by the addition of five volumes of chloroform/methanol (2:1, vol/vol). In order to identify the reaction products, the chloroform phase was subjected to thin-layer chromatography, and the chromatoplates were scanned for radioactivity using a computerized radioscanner (for more details see Refs. 7,10).

(iii) Treatment with NEM. In experiments performed to test the effect of NEM on PAP activity, the samples were preincubated for 10 min at 37°C with or without 4.2 mM NEM prior to assay.

RESULTS AND DISCUSSION

For several years, the diacylglycerol detection method, a in the Materials and Methods section under paragraph (ii), has been our standard method for measuring magnesium-dependent NEM-sensitive PAP activity in rat and other mammalian tissues. By the convenient technique with radioscanning of the chromatoplates, diacylglycerol is identified and the relative amounts of substrate remaining and product formed are calculated. This method also offers the possibility to detect other labeled products that might be formed as the result of other contaminating enzyme activities.

Although giving reproducible results, the diacylglycerol determination method bears the disadvantages of being time-consuming and not sufficiently sensitive for all purposes. In some experiments we have, therefore, chosen to assay PAP activity using the faster and more sensitive method with determination of ^{32}P-phosphate released.

As discussed in e.g., References 11–13, interference by other enzyme activities present in different amounts in different tissues and cellular fractions can create problems. Thus, the presence of diacylglycerol lipase would underestimate PAP activity determined by measuring the formation of dia-

cylglycerol. Lipase activity can be inhibited by diisopropylfluorophosphate (4,12), tetrahydrolipstatin (4), and, at least partially, by phenylmethylsulfonyl fluoride (14). When the activity of lipase is high, it might be more convenient to assay PAP activity by measuring the release of water-soluble phosphate. On the other hand, this latter method can be invalid in the presence of phospholipases, degrading phosphatidate to glycerol-3-phosphate (that also can be further degraded by various phosphatase activities), thus leading to overestimation of the activity of PAP. Consequently, it is advantageous to include both diacylglycerol and phosphate determination techniques in the methodological arsenal, at least when working with PAP in crude systems.

^{33}P as an alternative to ^{32}P. The short half-life (14.3 d) and the high energy of the radiation emitted (maximum of 1.709 MeV) from the ^{32}P isotope can be considered disadvantageous in many cases. Recently, ^{33}P-ATP has been introduced as an alternative to ^{32}P-ATP. This radionuclide (i.e., ^{33}P) has a longer half-life (25.4 d) and emits particles with much lower energy (maximum 0.249 MeV). Thus, the PAP substrate with radioactive phosphate does not have to be prepared as often using ^{33}P compared to ^{32}P, and, both as a result of this, and because of the shorter range of ^{33}P-radiation, the hazard for the experimentator is reduced. We have prepared ^{33}P-phosphatidate and found the results when testing PAP activity with this substrate to be comparable to those obtained with ^{32}P-phosphatidate. Due to the low energy of the radiation, ^{33}P has to be counted in a scintillator. A ^{32}P-channel can be used, as proposed by NEN (^{33}P-Nucleotide Applications Guide obtained from NEN), but the energy spectrum of the radiation more closely resembles that of ^{14}C. Using a ^{14}C- or a ^{33}P-channel gives higher readings and should be preferred. Alternatively, as also proposed by NEN, a wide open channel can be used. Comparing the readings obtained in different channels, we found that the relative radioactivity of γ-^{33}P-ATP samples was 100% in the wide open channel, 98% in the ^{33}P- and ^{14}C-channels, and 61% in the ^{32}P-channel, respectively.

Phosphatidate species. Differences in apparent PAP activity observed when comparing results obtained with the two assay methods (i.e., determination of diacylglycerol or phosphate) may be due to differences in the composition of the assay mixture. When PAP activity is measured as formation of labeled diacylglycerol, the assay generally involves use of a phosphatidate substrate with palmitoyl acyl chains. In contrast, release of inorganic ^{32}P-phosphate is usually measured with a substrate containing oleoyl acyl chains. In the former case, in which the substrate is labeled with the long-lived ^{14}C(or ^{3}H)-isotope, it seems practical to use chemically stable saturated acyl chains. In addition, [1-^{14}C]palmitic acid that is used for preparation of the substrate is less expensive than [1-^{14}C]oleic acid. When the release of inorganic radiolabeled phosphate is measured, an isotope with a short half-life is used, and thus there is less need for long chemical stability. In addition, at least in our hands, the diolein used for preparation of the substrate, and the unlabeled dioleoyl-containing phosphatidate used to dilute the radioactive substrate are more easily dispersed than the corresponding palmitoyl species. Furthermore, the activities of some isozymes of PAP have been reported to be higher when measured by determination of phosphate released from dioleoyl-phosphatidate as compared to dipalmitoyl-phosphatidate (e.g., 15–18). Confirming this, using both the diacylglycerol- and the phosphate determination method, we have found the activity of rat liver cytosolic PAP, purified by hydroxylapatite chromatography, to be 2–2.5-fold higher with dioleoyl-phosphatidate than with the dipalmitoyl substrate. In contrast, with membrane-bound substrate, the soluble rat liver PAP has been reported to display higher activity with dipalmitoyl- than with dioleoyl-phosphatidate (19). This discrepancy might result from differences in the physical states of membrane-bound and sonicated/solubilized substrate or from interference by some component(s) in the membranes.

There was a good correlation between the diacylglycerol- and phosphate-determination methods as exemplified by the experiment on rat liver cytosolic PAP illustrated in Figure 1 and also when testing the effect of pravastatin treatment on the activity of PAP in rat liver microsomes. Treatment of rats with pravastatin has recently been shown to increase the activity of liver PAP, as measured by the diacylglycerol determination method (a in the Materials and Methods section) (6), and this increase was found to be of the same magnitude when the activity was assayed by measuring the release of phosphate (not shown).

Influence of Triton X-100 and ionic strength. Some investigators measure PAP activity in the presence of Triton X-100. The detergent is often added, together with the substrate, in a mixed micelle at a molar ratio of Triton X-100 to phosphati-

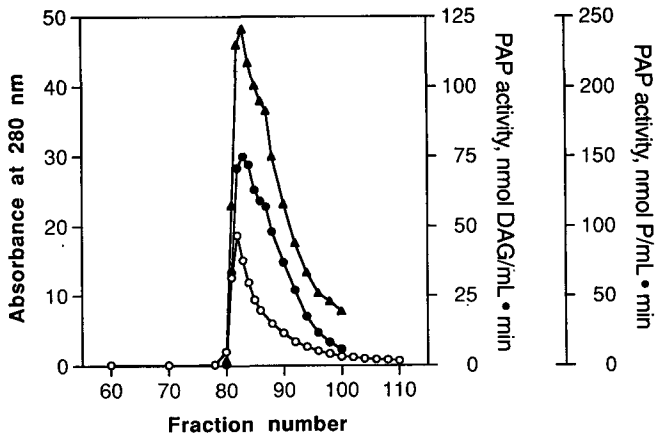

FIG. 1. Hydroxylapatite chromatography of rat liver cytosol as described in Ref. 7. The enzyme was eluted with 400 mM potassium phosphate, pH 7.4, containing 30% (vol/vol) glycerol, 1 mM EDTA, and 0.1 mM dithiothreitol. Absorbance at 280 nm (○); activity measured as ^{14}C-diacylglycerol (DAG) formed from [^{14}C]dipalmitoyl-phosphatidate (●) and as water-soluble ^{33}P-phosphate (P) released from ^{33}P-labeled dioleoyl-phosphatidate (▲). In both cases the assay mixture contained 0.625 mM phosphatidate, 75 mM Tris/maleate buffer, pH 6.9, 2 mM $MgCl_2$, and 0.25 mM EDTA. Triton was not present; PAP, phosphatidate phosphohydrolase.

date of 10:1 (e.g., 5,20). The NEM-sensitive, magnesium-dependent and the NEM-insensitive, magnesium-independent forms of rat liver PAP are reported to be differently affected by Triton X-100. The activity of the NEM-insensitive PAP in crude subcellular fractions is stimulated by Triton X-100 (4,5). The activity of the NEM-sensitive form has been reported to be stimulated (although to a lesser degree) by Triton when assayed in the absence of phosphatidylcholine (5). However, in the presence of phosphatidylcholine, Triton has an inhibitory effect on the activity (4).

We have earlier reported that partially purified magnesium-dependent rat liver PAP assayed in the absence of phosphatidylcholine and with [^{14}C]dipalmitoyl-phosphatidate as the substrate is inhibited by several detergents (octylglucoside, sodium cholate, and Tween 20; Ref. 7). In the present investigation, we have found that the enzyme is inhibited also in the presence of Triton X-100 when assayed with dipalmitoyl-phosphatidate as the substrate using either the phosphate- or the diacylglycerol determination method. The inhibitory effect was observed irrespective of whether the enzyme was assayed at low concentration of potassium phosphate (2.5 mM; Fig. 2) or at higher (100 mM; not shown) concentration of potassium phosphate and irrespective of whether the dipalmitoyl-phosphatidate/Triton substrate used was slightly turbid or clarified by warming (as described in the Materials and Methods section).

However, when assayed with dioleoyl-phosphatidate as the substrate, the enzyme activity was stimulated in the presence of 5 mM Triton X-100, provided that the concentration of potassium phosphate in the assay was not too high (Fig. 3A). Also the presence of higher concentrations of Tris/HCl buffer reduced the stimulation obtained by Triton. The stimulatory effect of 5 mM Triton on the activity of the purified enzyme was not due to the presence of magnesium-

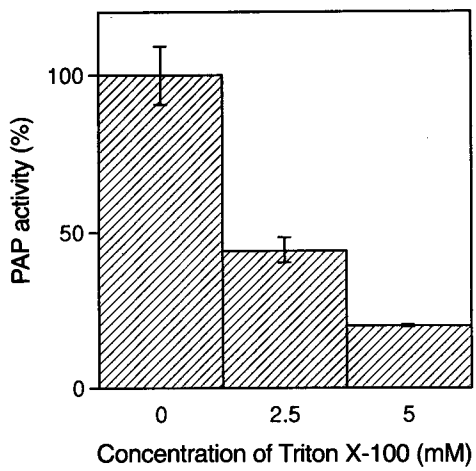

FIG. 2. Activity in the absence and in the presence of Triton X-100 of rat liver cytosolic PAP purified by hydroxylapatite chromatography. The figure shows mean and range of triplicate determinations of the activity using the phosphate determination assay method with ^{33}P-dipalmitoyl-phosphatidate as the substrate. The final concentration of potassium phosphate in the assay was 2.5 mM. See Figure 1 for abbreviation.

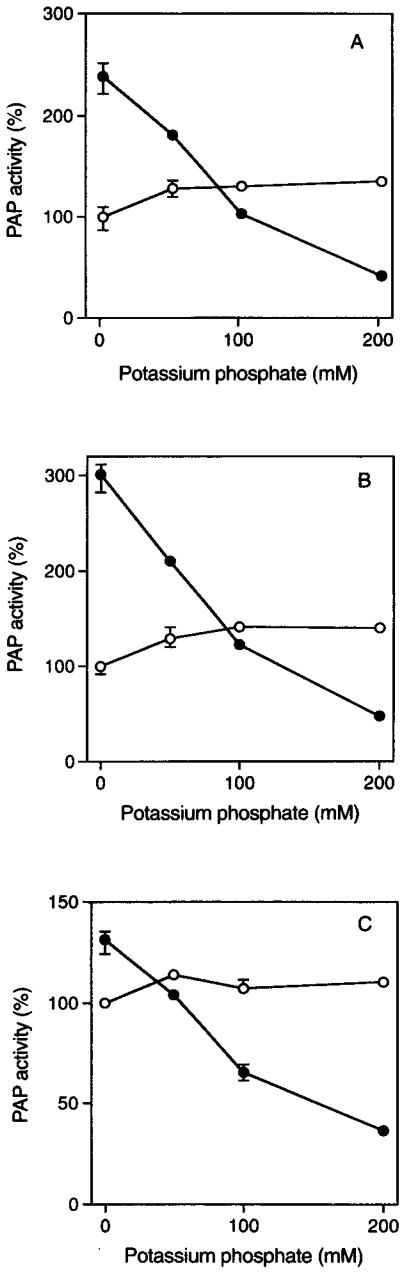

FIG. 3. Effect of increasing concentrations of potassium phosphate on PAP activity. Microsomal and cytosolic (crude and purified by hydroxylapatite chromatography) PAP activity in the absence (○) and in the presence (●) of 5 mM Triton X-100. The figure shows mean and range of triplicate determinations of the activity using the phosphate determination assay method with ^{33}P-dioleoyl-phosphatidate as the substrate. Where no error bars are shown, the variation was small enough to be contained within the area of the symbol. The enzyme sample constituted one-fourth of the total incubation volume. Prior to assay, the microsomal and cytosolic fractions were diluted with the buffer used for homogenization of the livers (i.e., 10 mM Tris-HCl, pH 7.4, 0.25 M sucrose, 1 mM EDTA, and 0.2 mM dithiothreitol), and the purified enzyme (OH-ap pool) was diluted with 10 mM potassium phosphate buffer, pH 7.4, containing 30% (vol/vol) glycerol, 1 mM EDTA, and 0.2 mM dithiothreitol. The potassium phosphate concentration (final concentrations in the assay are given) was adjusted by adding potassium phosphate buffer, pH 7.0, to the assay mixtures. A: OH ap pool; B: cytosol; C: microsomes. See Figure 1 for abbreviation.

independent PAP since no activity could be detected in the absence of magnesium. Concentrations of Triton higher than 5 mM were inhibitory. For comparison, the effect of 5 mM Triton on the activity of PAP in the cytosolic and microsomal fractions of rat liver is also shown (Fig. 3B and C). PAP activity in the cytosolic fraction was also very low in the absence of magnesium (not exceeding 5% of the activity in the presence of magnesium). The contribution of the NEM-insensitive, magnesium-independent PAP activity to the total microsomal PAP active on dioleoyl-phosphatidate in the absence of potassium phosphate and in the presence of 100 mM potassium phosphate was estimated by analyzing samples preincubated with or without NEM. It was found that the NEM-insensitive activity amounted to about 10% of the total activity in the absence and about 20% in the presence of Triton X-100.

Increasing concentrations of NaCl and KCl produced stimulation and inhibition of the enzyme activity similar to but not as pronounced as that shown in Figure 3 for potassium phosphate. Sodium phosphate (200 mM) was as effective in these respects as potassium phosphate (200 mM). Exchanging 10 mM Tris/HCl for 10 mM potassium phosphate or 0.25 M sucrose for 30% glycerol in the buffer used for dilution of the enzyme prior to assay did not affect the results obtained with low and high (100 mM) potassium phosphate (other salts and concentrations were not tested in this respect).

Concluding remarks. Thus, in conclusion, when assayed in the presence of Triton X-100, the apparent activity of the magnesium-dependent rat liver PAP differed up to at least tenfold, depending on whether dioleoyl- or dipalmitoyl-phosphatidate was used as the substrate. The enzyme showed higher activity when assayed with dioleoyl-phosphatidate than with dipalmitoyl-phosphatidate. Triton X-100 stimulated the former activity and inhibited the latter activity. The stimulatory effect of Triton was, however, reduced or abolished when the ionic strength in the assay mixture was increased. An interpretation of the stimulating effect of Triton X-100 might be that the dioleoyl-phosphatidate/Triton X-100 mixed micelle mimics the natural substrate more closely than does dioleoyl-phosphatidate alone. However, salts were interfering. Increasing salt concentrations stimulated the enzyme activity in the absence and inhibited the activity in the presence of the detergent. This was particularly obvious with potassium and sodium phosphate. Whether the salts act by interfering with the organization of the mixed micelles or with the binding of the enzyme to the substrate/detergent micelle is unclear at present.

On the basis of the results obtained in this investigation, it could thus be concluded that it is important to take differences in ionic strength, Triton X-100 concentration, and phosphatidate species into account when comparing PAP activities measured by different assay protocols, to investigate the influence of these factors when setting up an assay for PAP, and to be aware that salts and detergents could be carried over into the assay with enzyme preparation or substrate in amounts large enough to affect the results. γ-^{33}P-ATP could be used instead of γ-^{32}P-ATP in order to prepare a substrate for PAP with longer radioactive half-life and less potential health hazard.

Comparison of the Structural and Functional Effects of Monomeric and Dimeric Human Apolipoprotein A-II in High Density Lipoprotein Particles

Sissel Lund-Katz*, Yvette M. Murley, Errol Yon, Kristin L. Gillotte, and W. Sean Davidson

Biochemistry Department, MCP•Hahnemann School of Medicine, Allegheny University, Philadelphia, Pennsylvania 19129

ABSTRACT: High density lipoprotein (HDL) is thought to play a significant role in the process of reverse cholesterol transport. It has become clear that the apolipoprotein (apo) composition of HDL is important in determining the metabolic fate of this particle. The major proteins of human HDL are apoAI and APOAII; the latter protein is a disulfide-linked dimer in humans and higher primates but monomeric in the other species. The consequences of the apo Cys6-Cys6 disulfide bridge in apoAII for human HDL structure and function are not known. To address this issue, the influence of the Cys6-Cys6 disulfide bridge on the interaction of human apoAII with palmitoyl–oleoyl phosphatidylcholine has been studied. The size and valence of a series of homogeneous discoidal complexes containing either monomeric (reduced and carboxymethylated) or dimeric apoAII have been determined, and their ability to remove cholesterol from rat Fu5AH hepatoma cells grown in culture has been compared. The apoAII dimer and monomer form discoidal complexes of similar size, with twice as many of the latter molecule required per disc. Removal of the disulfide bond influences the stability of the helical segments around the edge of the disc as seen by a decrease in α-helix content of the monomeric protein. The discoidal particles containing the monomeric form of apoAII are somewhat more effective than particles containing either dimeric apoAII or apoAI in removing cellular cholesterol. Overall, reduction of the disulfide bridge of apoAII probably does not have a major effect in the determination of HDL particle size *in vivo*. It follows that the evolution of the Cys6-Cys6 disulfide bond in higher primates probably has not had a major effect on the function of the apoAII molecule.
Lipids 31, 1107–1113 (1996).

High density lipoprotein (HDL) particles function *in vivo* as a carrier of cholesterol in the reverse cholesterol transport pathway by which cholesterol is transported from the periphery to the liver for excretion (for reviews see Refs. 1 and 2). Consequently, increased plasma concentrations of HDL tend to prevent atherogenesis and are inversely correlated with the incidence of premature coronary artery disease (3). The major proteins of human HDL are apolipoproteins (apo) AI and AII. There are subspecies of HDL comprising particles that variously contain either apoAI (LpAI) or apoAII (LpAII) alone, or a mixture of both proteins (LpAI + AII) (1–4). It seems that apoAII interferes with the function of apoAI in reverse cholesterol transport because expression of high levels of apoAII (either mouse or human) does not prevent formation of atherosclerotic lesions in transgenic mice (5,6). Studies with mice transgenic for human apoAII indicate that this protein participates in determining HDL particle size (7); this effect may be the reason for the apparent modulation by apoAII of reverse cholesterol transport in these animals. Results from cell culture experiments using either natural or reconstituted HDL particles show that LpAI, LpAII, and LpAI + AII can sustain cellular cholesterol efflux (8,9); depending upon the cell type, LpAII can be somewhat less effective than LpAI (9). In summary, the current view of the function of apoAII is that it seems not to be essential in HDL metabolism but that it affects HDL functional states and probably contributes to atherogenesis (10).

In humans, amino acid 6 of apoAII is cysteine whereas this is not the case in other mammals including monkeys (10). Consequently, plasma apoAII is a disulfide-linked dimer of two 77-amino acid chains in humans but monomeric in the other species. This raises the question of the role of the apoAII Cys6-Cys6 disulfide bridge in human HDL structure and function. Dimeric apoAII (apoAII-D) binds well to phospholipid and, in fact, with higher affinity than apoAI perhaps because apoAII is more hydrophobic (11). Consistent with the enhanced binding affinity, dimeric apoAII can displace apoAI from HDL particles (12–15). It has been shown that reduction and carboxymethylation of the Cys residues in apoAII to form monomeric apoAII (apoAII-M) does not prevent binding to phospholipid and formation of complexes (16). However, lipid-free monomeric apoAII binds less well than dimeric apoAII to plasma membranes from either rat liver

cells or bovine aortic endothelial cells (17). Consistent with this, monomeric apoAII can exchange more rapidly than the dimeric molecule between phospholipid vesicles (18). A comparison of the effects of adding HDL containing monomeric and dimeric apoAII to plasma preparations showed that the dimers inhibit formation of small HDL particles (19). However, despite these isolated observations, there has been no systematic comparison of the lipid interactions of monomeric and dimeric apoAII. Given recent developments in understanding how apoAI forms discrete subpopulations of particles when reconstituted with phospholipid (20–22), it is of interest to know how the monomer and dimer forms of apoAII participate in this process.

In this study, the influence of the Cys6-Cys6 disulfide bridge on the interaction of apo AII with palmitoyl–oleoyl phosphatidylcholine (POPC) is investigated. In addition, the abilities of the reconstituted monomer and dimer LpAII particles to function as acceptors of cellular cholesterol are compared. The results show that elimination of the disulfide bridge to form monomeric apoAII molecules does not affect the size distribution of the reconstituted HDL particles but has some effect on their ability to remove cellular cholesterol. The α-helical segments of apoAII are less stable when the Cys6-Cys6 disulfide bond is broken.

EXPERIMENTAL PROCEDURES

Materials. Sodium cholate was purchased from Sigma (St. Louis, MO). Egg yolk phosphatidylcholine, 1-palmitoyl 2-oleoyl phosphatidylcholine (POPC), and dimyristoyl phosphatidylcholine (DMPC) were purchased from Avanti Polar Lipids (Birmingham, AL). Guanidine HCl was obtained from Bethesda Research Laboratories (Bethesda, MD). Essentially fatty acid-free bovine serum albumin (BSA) was purchased from Sigma (St. Louis, MO). Dimethyl suberimidate was purchased from Pierce (Rockford, IL). All other reagents were analytical grade.

Methods. Isolation and purification of apolipoprotein AII. Human HDL was isolated from fresh plasma from normolipidemic subjects by a modification of the polyanion precipitation method of Burstein *et al.* (23). For every 1 vol of plasma, 0.1 vol of 4% (wt/vol) sodium phosphotungstate in water were added to precipitate low density lipoprotein and very low density lipoprotein. The precipitate was pelleted by centrifugation at 4°C for 10 min at 1800 rpm. The density of the supernate was adjusted to 1.21 g/mL with dry potassium bromide, and the solution was ultracentrifuged at 50,000 rpm in a Beckman 50.2 Ti rotor for 24 h. The total HDL fraction was dialyzed extensively against 4 L of saline in water [0.9% (wt/vol) NaCl and EDTA (2 mM)] and then against dilute saline in water [0.09% (wt/vol) NaCl and EDTA (2 mM)] at 4°C. After concentration to 20–40 mg protein per mL in a filtration cell (Amicon, Beverly, MA) with a molecular weight cut-off of 100 kDa, the HDL was delipidated with ethanol–diethyl ether as described by Scanu and Edelstein (24). ApoAII was isolated from the apo HDL by anion exchange chromatography on Q-Sepharose (25) and stored in lyophilized form at −70°C. Prior to use, purified apoAII was resolubilized in 6 M guanidine HCl and dialyzed extensively against a 10 mM Tris buffer that contained 150 mM NaCl (pH 8.0).

Reduction and carboxymethylation of ApoAII. In human plasma, mature apoAII (17 kDa) exists as a homodimer with each subunit being about 8 kDa connected by a disulfide linkage. Monomeric apoAII was prepared by a modification of the method of Jackson *et al.* (26). Briefly, lyophilized, lipid-free apoAII (20 mg) was dissolved in Tris buffer containing 3 M guanidine HCl and 0.02 M dithioerythritol at pH 8.6. This mixture was incubated at 30°C for 6 h under nitrogen. The reduced form of the protein was then carboxymethylated by the addition of iodoacetic acid (50 mg) and incubation under the same conditions for 1 h. The mixture was then desalted on a Bio-Gel P-2 column (Bio-Rad Laboratories, Hercules, CA) (1.5 × 30 cm) in 0.1 M ammonium bicarbonate buffer. Those fractions found to contain protein by absorbance at 280 nm were pooled and lyophilized. Analysis by SDS–polyacrylamide gel electrophoresis (PAGE) showed that the reduced and carboxymethylated apoAII contained <1% unreacted apoAII dimer. As with the dimeric form of apoAII, the monomeric form was resolubilized in 6 M guanidine HCl and dialyzed extensively against Tris buffer before use.

Preparation and characterization of reconstituted HDL (rHDL) particles. All POPC-containing discoidal particles were reconstituted using the cholate removal method originally described by Bonomo and Swaney (27) and modified by Sparks *et al.* (28). The desired amount of POPC in chloroform (see Table 1) was added to a 15 mL borosilicate tube and dried under nitrogen. Tris buffer was added to give a POPC concentration of 20 mM and vortexed. Enough sodium cholate was added to achieve a molar ratio of POPC/cholate of 0.74 followed by vortexing. The resulting solution was incubated at 37°C and vortexed every 15 min for 1.5 h. The desired amount of either apoAI [isolated as described previously (25)] or apoAII (see Table 1) was added, and the mixture was diluted to 1 mg protein per mL and then incubated for 1 h at 37°C. The sodium cholate was removed by incubation with hydrated Biobeads (1 g of Biobeads/2 mg sodium cholate) for 3 h at 4°C. The Biobeads were then removed by filtration through a 0.22 μm filter. The resulting complexes were concentrated to about 1–2 mg protein per mL in Centricon 30 concentrators (Amicon) and stored at 4°C for no more than 2 wk.

DMPC-containing discoidal particles were prepared by mixing lipid and protein directly at the desired ratio. DMPC was dried from a chloroform solution under nitrogen to a thin film on the walls of a test tube. Traces of remaining solvent were removed by drying for 1 h under vacuum. The proteins in Tris buffer were added to the lipid film and bath-sonicated for 5 min at the gel to liquid crystal transition temperature of the lipid (24°C). The DMPC and the apo formed characteristic discoidal complexes. In a typical experiment, DMPC and protein were dispersed to give 2.5:1 (w/w) DMPC–protein discoidal complexes.

The size and homogeneity of the particles were estimated

[b]Determined from SDS–polyacrylamide gel electrophoresis of dimethylsuberimidate crosslinked complexes.
[c]Hydrodynamic diameter determined from nondenaturing gradient gel electrophoresis using reference globular proteins. Analysis by unpaired *t*-test indicated that the particle diameters for each type of complex were not significantly different except that the apoAI D1 particle was significantly ($P < 0.05$) smaller than the other D1 particles and the apoAI D4 particle was significantly larger ($P < 0.001$) than the other D4 particles. POPC, 1-palmitoyl, 2-oleoyl phosphatidylcholine.

by electron microscopy and nondenaturing PAGE. Negative stain electron microscopy was performed at 80 K magnification as described by Forte and Nordhausen (29). Mean particle dimensions of 100 particles were determined from each negative. The hydrodynamic diameters of discoidal rHDL particles were estimated by Phast electrophoresis using precast 8–25% polyacrylamide gels (Pharmacia, Biotech Inc., Piscataway, NJ) under nondenaturing conditions (28). The particle migrations into the gel were determined to within 0.1 mm by digitizing the gel with a Mustek 105 hand scanner (Mustek, Taiwan) followed by computer image analysis (Sigma Scan/Image; Jandel Scientific, San Rafael, CA). Intact rHDL particles were chemically analyzed where appropriate using the Markwell modification of the Lowry protein assay (30) while phospholipids were determined as inorganic phosphorus by the method of Sokoloff and Rothblat (31). The number of protein molecules per particle was determined by crosslinking the apoAII with dimethyl suberimidate as reported by Swaney (32). The electrophoretic mobilities of HDL particles were measured on Beckman (Fullerton, CA) Paragon preformed 0.5% agarose gels, and the net number of negative charges per complex (valence) was calculated as described by Sparks and Phillips (33). The average α-helix content of either lipid-bound or lipid-free apoAII was determined by circular dichroism spectroscopy using a Jasco J41A spectropolarimeter (Jasco Inc., Easton, MD). Spectra were measured at 25°C in a 0.1-cm path length quartz cuvette as described previously (22). The percentage α-helix was determined from the molar ellipticities at 222 nm (34). The effect of guanidine HCl on the α-helix content of the rHDL particles was used to obtain the free energy of unfolding of apoAII as described previously (22).

Interaction of proteins with phospholipids: (i) monolayers. The relative affinities of the dimeric and monomeric apo AII for the lipid–water interface were investigated using a surface balance technique. Employing published procedures (21,22,35), an insoluble monolayer of egg yolk PC was spread at the air–water interface in a circular Teflon dish containing 80 mL of phosphate-buffered saline (pH 7.0) at room temperature. The surface pressure (π) was monitored by the Wilhelmy plate technique using a mica plate connected to a Cahn RTL recording electrobalance (Cahn Instruments, Inc., Cerritos, CA). Sufficient egg yolk PC was spread from 9:1 (vol/vol) hexane/ethanol solution to give an initial surface pressure (π_i) in the range 5–30 dynes/cm. Proteins dissolved in the above buffer containing 1.5 M GdnHCl were injected into the subphase to give an initial concentration of 5×10^{-5} g/dL; a small Teflon tube which projected through the monolayer into aqueous subphase was used for this injection so that the egg yolk PC monolayer was not disrupted. The presence of GdnHCl ensured that the protein molecules were initially present as random coil monomers. The protein molecules renatured in the subphase as the GdnHCl was diluted to a final concentration of ≤1mM. The solution was stirred continuously with a magnetic stirrer, and the increase in surface pressure ($\Delta\pi$) with time was recorded until a steady-state value of $\Delta\pi$ was obtained. The steady-state $\Delta\pi$ values were plotted as a function of π_i. A linear extrapolation to $\Delta\pi = 0$ dyn/cm gave the exclusion pressure, or the value of π_i (±1 dyn/cm) at which the proteins were no longer able to penetrate into the egg yolk PC monolayer.

(ii) Multilamellar liposomes. DMPC in chloroform was dried in borosilicate tubes under nitrogen and then under vacuum for 1 h. Tris buffer (0.01M Tris, 1.0 mM EDTA and 0.15 M NaCl, pH 8.2) was added to give a lipid concentration of 10 mg/mL and vortexed to form a turbid suspension of multilamellar liposomes. The abilities of the proteins to solubilize the DMPC liposomes into small discoidal particles were examined by monitoring the optical density at 400 nm. An aliquot of a 10 mg/mL solution in 1 M guanidine-HCl of the apoAI or apoAII preparations was added to the DMPC liposomes to attain a weight ratio of 2.5:1 DMPC/protein. The guanidine-HCl was present to prevent self-association and to ensure that all of the apoproteins were in a common physical state. Tris buffer was added quickly to give a final volume of

1.4 mL and a final guanidine-HCl concentration of 70 mM. After mixing, the absorbance of the mixture at 400 nm was recorded as a function of time on a Varian DMS90 spectrophotometer (Palo Alto, CA). All solutions were maintained at 24° ± 0.2°C. The absorbance of DMPC liposomes (2.5 mg/mL), containing 70 mM guanidine-HCl in a final volume of 1.4 mL, was recorded as a control.

Efflux of cellular cholesterol. Rat Fu5AH hepatoma cells were used to monitor the unesterified (free) cholesterol (FC) efflux efficiencies of discoidal complexes of DMPC and various apoproteins. The methods for the efflux assay as well as the post experiment work-up were as previously reported (35) with the following exceptions. The Fu5AH cells were plated 6 d prior to the experiment in 12-well cell plates (22 mm) at 75–100 × 10^3 cells per well. 2 μCi/well [^{3}H]-FC in bicarbonate-buffered MEM with 3% fetal calf serum was used for the cell labeling procedure. After a brief wash, the efflux measurements were initiated by the application of 1.0 mL/well of the test medium containing 0.5% BSA and the acceptor particle present at 100 μg protein/mL. Typical cell protein values were between 250 and 300 μg protein per well. The fractional release of cellular FC determined experimentally was analyzed as described in detail for these systems previously (35). The fractional efflux at any time was corrected for the efflux observed to control medium that did not contain any added acceptor particles. The kinetic analysis to derive the apparent rate constant (k_e) for the efflux process assumed a closed system in which FC exists in one of two kinetic pools, either the cellular FC pool or the acceptor FC pool. The halftimes ($t_{1/2}$) for efflux was derived from the relationship ($t_{1/2} = \ln 2/k_e$).

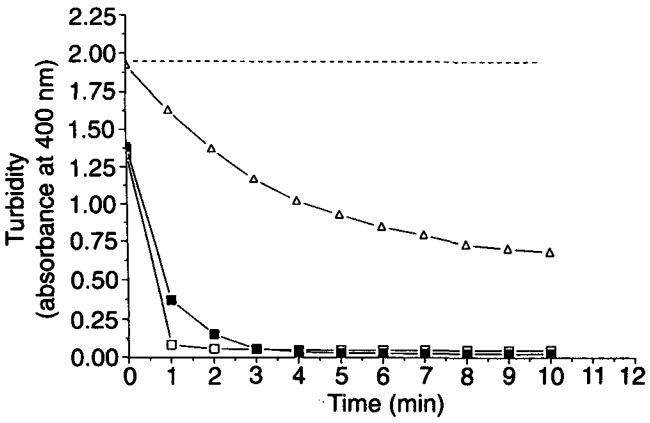

FIG. 1. Comparison of the abilities of apoAI, AII-D, and AII-M to solubilize DMPC liposomes. The absorbance at 400 nm of control dimyristoyl phosphatidylcholine (DMPC) liposomes [(----), 2.5 mg in 1.4 mL buffer] at 24°C was measured every minute up to 10 min; 1 mg apoAI (△), 1 mg apoAII-D (■), or 1 mg apoAII-M (□) were added to 2.5 mg DMPC liposomes, final volume 1.4 mL, and the absorbance was measured for up to 10 min.

RESULTS

Characterization of the lipid binding affinity of apoproteins. The lipid binding affinities of apoAI, apoAII-D, and apoII-M were compared by studying the changes in turbidity of suspension of DMPC multilamellar liposomes as a function of time (Fig. 1). The rates of interaction of the apoproteins with the DMPC liposomes were in the order: apoAI < apoAII-D, apoAII-M. The exclusion pressures for penetration into an egg PC monolayer for apoAI, apoAII-D and apoAII-M were 34, 36, and 34 dyn/cm, respectively. These values confirm that because of its higher hydrophobicity apoAII-D is slightly more surface-active than apoAI (cf. 11). However, disruption of the disulfide bond in apoAII to form apoAII-M slightly reduces the lipid affinity of apoAII-D.

Characterization of the size and composition of rHDL particles. A series of well defined complexes of POPC and apoAI, apoAII-D, or apoAII-M were prepared (Table 1). These particles were designed to contain different numbers of protein molecules. Electron microscopy showed these rHDL particles to be highly homogeneous and discoidal in appearance. Table 1 shows clear increases in particle hydrodynamic diameter in the range 7–13 nm for apoAI-containing particles and 8–10 nm for the apoAII-containing particles, as the rHDL phospholipid to protein ratio was increased. Chemical cross-linking of the protein molecules showed that all the discoidal complexes contained two molecules of apoAI/particle except for the 12.8 nm particle which probably contained three molecules (36). In contrast, in the apoAII-D and apoAII-M-containing complexes, the D1 and D2 particles contained four and eight protein molecules, respectively. The D3 and D4 complexes had a protein content of four or eight molecules apoAII-D and apoAII-M per particle, respectively. The particles appeared homogeneous on native polyacrylamide gradient gel electrophoresis (PAGGE), each exhibiting a single, discrete band (data not shown). Agarose gel electrophoresis was used to determine the effect of reducing the disulfide bond of the dimeric apoAII on the charge of the particles. The particle valences varied between −5.6 and −8.6e for the apoAII-D and apoAII-M particles (Table 2). Previous studies have shown that variations in apoAI-containing rHDL particle valences of up to 2e can be caused by a change in particle size [cf. Table 1 and (22)]. It is apparent from Table 2 that there is a similar effect of particle size on the charge of the particles for the discs containing either apoAII-M or apoAII-D. The fact that the valences of apo AII-M and apoAII-D in equivalent discoidal complexes are generally similar (Table 2) indicates that the removal of the disulfide bridge does not alter the net charge of the protein molecule. Furthermore, the differences in secondary structure of apoAII-D and apoAII-M in the discs (see below) do not affect the overall ionization of the charged amino acid sidechains.

ApoAII secondary structure and conformational stability. CD was used to determine the average α-helix content of both free and lipid-bound apoAII-D and apoAII-M. In this study, the α-helix contents of lipid-free apoAII-D and apoAII-M were considerably lower, 37 and 18%, respectively, than the value reported for lipid-free apoAI (46%, 22). When compared to apoAI complexed with POPC, the apoAII/POPC

TABLE 2
Physical Characteristic of Discoidal POPC/apoAI, POPC/apoAII-Dimer, and POPC/apoAII-Monomer Particles with Increasing Phospholipid to Protein Molar Ratio

	% α-helix[a]			Valence (e)[b]		
Complex	AI	AII-D	AII-M	AI	AII-D	AII-M
D1	62	51	39	−5.8 ± 0.2	−5.6 ± 0.2	−5.9 ± 0.2
D2	67	58	47	−7.7 ± 0.4	−6.3 ± 0.3	−6.3 ± 0.3
D3	82	61	51	−7.7 ± 0.4	−6.6 ± 0.3	−6.2 ± 0.3
D4	84	63	61	−10.9 ± 0.0	−8.6 ± 0.2	−7.5 ± 0.3

[a]Values calculated from the molar ellipticity at 222 nm ± 5% (SD).
[b]The number of excess negative charges per particle in electronic units derived from migration in a 0.5% agarose gel at pH 8.6. Analysis by unpaired *t*-test indicated that the valences of apoAII-D and apoAII-M were not significantly different in the D1–D3 complexes but were different ($P < 0.01$) in the D4 particles. See Table 1 for abbreviations.

discs had generally lower α-helix contents (Table 2). However, in all cases there was an increase in α-helix content directly related to increases in POPC content and particle diameter (Table 2). It is apparent that the smaller apoAII-M-containing particles had lower α-helix contents than the equivalent apoAII-D particles. The stabilities of the α-helices in apoAII-M and apoAII-D were monitored in the presence of increasing concentrations of GdnHCl. The particles containing apoAII-D were progressively denatured by GdnHCl, and the process was complete at approximately 5 M whereas equivalent discoidal complexes made with apoAII-M required about 3 M GdnHCl to fully denature (data not shown). The free energies of denaturation of apoAII-D increased from 2.4 ± 0.22 to 3.5 ± 0.21 kcal/mol as the discoidal complexes increased in size from D1 to D4. Such an increase in helix stability with increasing POPC/apoAI disc size has been reported previously (from 1.4 ± 0.2 to 3.0 ± 0.2 kcal/mol) (22). The equivalent values for the apoAII-M discs were 0.7 ± 0.2 to 1.4 ± 0.1 kcal/mol; this indicates that disruption of the disulfide bond in apoAII-D tends to destabilize the α-helical segments of the molecule, presumably due to reduced interaction between amphipathic α-helices.

Efflux of cellular cholesterol to ApoA-containing rHDL particles. The abilities of the discoidal D3 DMPC/apoA particles (Table 1, described in Methods) to act as acceptors of cell plasma membrane cholesterol at 100 μg phospholipid per mL were compared using rat Fu5AH hepatoma cells that had been labeled with [^{3}H]FC. Figure 2 demonstrates that the DMPC/apoAII-M particles display an enhanced ability to accept cellular FC relative to the DMPC/apoAI or DMPC/apoAII-D particles. The $t_{1/2}$ for FC efflux from Fu5AH to the rHDL made with apoAI, apoAII-D, and apoAII-M were 9.6 ± 0.5, 10.3 ± 1.5, and 3.8 ± 0.3 h, respectively. Analysis by unpaired *t*-test indicates that the $t_{1/2}$ for apoAI and apoAII-D are not significantly different whereas the $t_{1/2}$ for apoAII-M is significantly lower ($P < 0.005$) than either of the prior values. The FC efflux efficiency of the apoAI-containing particles is consistent with that seen in previous studies (37).

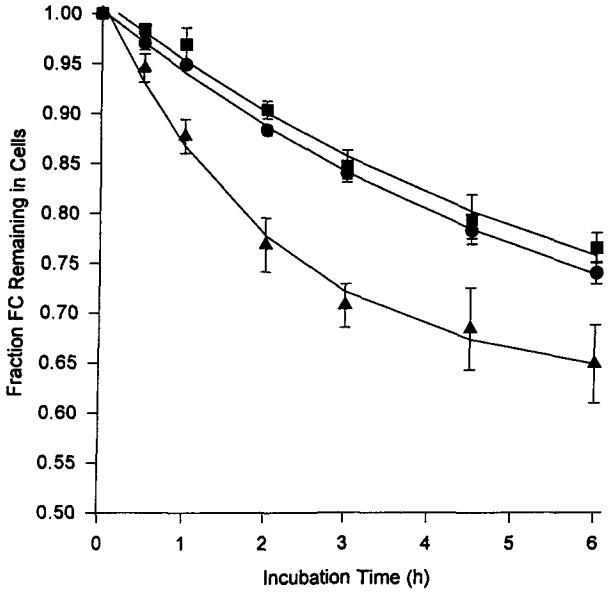

FIG. 2. Time course of [^{3}H]free cholesterol efflux from rat Fu5AH hepatoma cells to discoidal reconstituted high density lipoprotein (rHDL) containing various apoproteins. Rat Fu5AH hepatoma cells that had been trace-labeled with [^{3}H]free cholesterol in 22-mm tissue culture wells were incubated for 6 h at 37°C in a humidified incubator (5% CO_2) with 1.0 mL of test medium containing 0.5% bovine serum albumin and the rHDL containing the indicated apoprotein at 100 μg of protein/mL. The rHDL particles (D3 complexes, Table 1) were: DMPC/apoAI (●), DMPC/apoAII-dimer (■), and DMPC/apoAII-monomer (▲). The vertical axis indicates the fraction of initial labeled free cholesterol (FC) that remained in the cell at the designated times. Each point represents the mean of three cell wells. The error bars represent 1 SD. All curves were obtained by fitting the entire time course to the model for tracer equilibration between two pools. See Figure 1 for other abbreviation.

DISCUSSION

This study examined the effects of reducing the apoAII Cys6-Cys6 disulfide bridge on the structure of rHDL and also on the function of this particle in cholesterol efflux. These two effects are discussed in turn below.

(i) Structure. Spontaneous clearing of DMPC liposomes by direct addition of protein, in an aqueous solution, occurs more rapidly for apoAII than for apoAI (Fig. 1). This is in agreement with previously published data from this laboratory showing apoAII-D to have a higher surface activity than apoAI (11). The faster rate of reaction of the monomeric apo A-II compared to dimeric apo A-II (Fig. 1) is presumably due to its expected higher diffusion coefficient. Also, binding to lipid–water interfaces, as measured by monolayer exclusion pressure, is slightly less for the dimeric protein. Apo AI, apoAII-M, and apoAII-D can all form discoidal complexes of similar size with POPC; these discoidal particles are organized with the amphipathic, α-helical, segments of the apoprotein molecules covering the POPC acyl chains at the disc edge (20–22). Table 1 shows clear increases in the particle hydrodynamic diameter as the rHDL phospholipid to protein ratio increases for these complexes. For any particle of

given size, twice the number of apoAII-D molecules, compared to apoAI, are required to achieve particle stability. This suggests that the amphipathic α-helices present in two molecules of apo AII-D can cover as many PC acyl chains at the disc edge as the helices present in one apoAI molecule. This is consistent with the observation that two apo AII-D molecules can displace one apoAI molecule from either discoidal or spherical HDL particles (12,13). Since two times as many apoAII-M as apoAII-D molecules can form discs of the same size with POPC (Table 1), it is apparent that HDL particle size is not affected by the presence of the disulfide bridge. It follows that the role of apoAII in determining HDL particle size *in vivo* (7) is independent of the Cys6-Cys6 disulfide bond.

However, although equal masses of apoAII-M and apoAII-D can form rHDL particles of the same size, the information on secondary structure (α-helix content) and conformational stability (free energy of denaturation) indicates that removal of the disulfide bond influences the packing of the apoAII molecule around the edge of the POPC disc. The only major structural effect of reducing the apoAII disulfide bridge is on the stability of the helical segments. This effect presumably arises from the reduced opportunity for intramolecular helix-helix interactions in the monomeric molecule. It is likely that these helical segments, which are less resistant to denaturation by GdnHCl in apoAII-M than in apoAII-D, are more loosely packed around the edge of the disc (see below). The greater exchangeability of apoAII-M molecules compared to apoAII-D molecules (19) is consistent with this concept.

(ii) Function. The difference in helical packing between POPC discs containing apoAII-M and apoAII-D might be expected to influence the abilities of these particles to accept cellular cholesterol because a dependence of efflux on rHDL structure has been demonstrated (34). There is general agreement that the plasma membrane pool of cholesterol leaves the cell *via* the aqueous diffusion mechanism (37–40). Transfer by this mechanism occurs by a two-step process that involves the desorption of a cholesterol molecule from the membrane and subsequent diffusion through the aqueous phase until it incorporates into a phospholipid-containing acceptor particle. At low acceptor particle concentration (≤100 μg POPC/mL), the rate of cellular cholesterol transfer to an extracellular HDL particle depends upon the rate constants for (i) desorption from the plasma membrane and (ii) collision and incorporation of the desorbed cholesterol molecule into the HDL particle. The second term is affected by the diffusion coefficient of the acceptor particle and the fraction of HDL-cholesterol molecule collisions that result in incorporation of a cholesterol molecule into the HDL particle. For various acceptor particles of the same size but different structure, only the fraction of successful collisions can differ because their diffusion coefficients are the same. It follows that the greater rate of efflux of cellular cholesterol to the POPC/apoAII-M disc depicted in Figure 2 must occur because of such an effect. Presumably, the looser arrangement of the α-helices around the edge of this disc relative to either the apoAI/POPC or apoAII-D/POPC disc leads to a greater fraction of the collisions with cholesterol molecules diffusing in the extracellular aqueous phase resulting in successful incorporation of the cholesterol molecule into the disc. The observation that the POPC/apoAI and POPC/apoAII-D discs have similar capabilities of removing cellular cholesterol is consistent with prior comparisons of LpAI and LpAI + AII isolated from human plasma (8).

Conclusion. Overall, reduction of the disulfide bridges in apoAII seems not to have a major effect. Discoidal particles of similar size can be made with apoAII-D and apoAII-M with twice as many of the latter molecules required. The ability of apoAII to modulate HDL particle size is not affected by the presence or absence of the Cys6-Cys6 disulfide bond. This conclusion is consistent with studies of the effects on HDL of overexpression of apoA-II in transgenic mice. Thus, overexpression of either dimeric human apoA-II (7) or monomeric human apoA-II where Cys6 was mutated to Ser (41) has no significant effect on either the levels or particle size of the major HDL species. In contrast, overexpression of mouse apoA-II leads to increases in both HDL levels and particle diameter (42). These results indicate that while removal of the Cys6-Cys6 disulfide bond in apoA-II has no effect on HDL metabolism in mice, variations elsewhere in the amino acid sequences of the human and murine proteins lead to significant variations in function.

With regard to the initial step in the reverse cholesterol transport process, the data in the paper suggest that a discoidal particle containing apoAII-M is somewhat more effective than either apoAI- and apoAII-D containing particles in removing cellular cholesterol. However, overall it seems that the evolution of the Cys6-Cys6 disulfide bridge in higher primates probably has not had a major effect on the function of the apoAII molecule.

ABSTRACT: The nuclear hormone receptors NUC-1 (PPARδ) and PPARα are members of the peroxisome proliferator-activated receptor (PPAR) family. The members of this receptor family are activated by agents that stimulate peroxisome proliferation, free fatty acids, prostaglandin J2 metabolites, and agents considered for the therapy of insulin-independent diabetes mellitus. To identify putative physiological agents that activate NUC-1, we tested the ability of acetone extracts of various rat tissues to activate the transcription of an MMTV-luciferase reporter gene, *via* a GR/NUC-1 hybrid receptor. GR/NUC-1 contains the ligand binding region of the NUC-1 receptor and the DNA binding domain of the glucocorticoid receptor. Using this assay, we found stimulatory activity in the pancreas, which upon purification and characterization was identified as methyl-palmitate, known to be enriched in pancreatic lipids. In addition, we determined that ethyl esters of palmitic and oleic acids are also potent activators of this receptor. Thus, fatty acid ester formation may control the cellular concentrations of fatty acids, and acyl-ester formation may play a role in the control of metabolic pathways and the activation of the PPAR.
Lipids 31, 1115–1124 (1996).

The nuclear hormone receptor NUC-1 (PPARδ) is a member of the steroid hormone receptor superfamily and a member of the peroxisome proliferator-activated receptor (PPAR) family that we cloned from the human osteosarcoma SAOS/B10 cells (1,2). The PPAR family contains the three mammalian receptors PPARα, PPARγ and NUC-1 (PPARδ) (1–3), and three xenopus receptors xPPARα–γ (4). Based on amino acid sequence similarity, NUC-1 belongs to this family of receptors, but its amino acid sequence is not close enough to xPPARβ to be the mammalian homologue of this receptor. The members of the PPAR family are activated by molecules that induce peroxisome proliferation (1–4). Several of these synthetic molecules, which include WY-14643, nafenopin and clofibric acid, are used for the therapy of hyperlipidemia. It was also shown that free fatty acids, such as linoleic, arachidonic, and oleic acid can specifically activate the mPPARα and the NUC-1 receptors (2,4–9). Thus, both the fatty acids and drugs for the treatment of hyperlipidemia can induce peroxisome proliferation and lower the levels of triglycerides in the blood. mPPARα, which is abundant in the liver, has therefore been proposed to participate in the regulation of fatty acid metabolism. Moreover, it was demonstrated that the PPARγ and PPARα and their ligands play a key role in adipocyte differentiation (10,11). Recently, it was shown that prostaglandin J2 metabolites bind and preferentially activate the PPARγ subtype (12,13). Furthermore, it was shown that thiazolidinedione antidiabetic agents that improve glucose sensitivity in noninsulin-dependent diabetes mellitus activate the members of the PPAR family (12–14).

In order to find putative physiological agents that modulate transcription *via* the NUC-1 receptor, we tested the ability of acetone powders of various rat tissues to activate the transcription of the MMTV-luciferase reporter gene, driven by the GR/NUC-1 hybrid receptor that contains the ligand binding region of the hNUC-1 receptor and the DNA binding domain of the glucocorticoid receptor (GR). We found that acetone powders of rat intestine and pancreas contain a substance that specifically activates the transcription mediated by the GR/NUC-1 receptor. We identified this substance as the methyl ester of palmitic acid. In addition, we show that the NUC-1 receptor can mediate the transcription from a reporter gene that is under the control of the peroxisome proliferator-responsive regulatory element of the rat Acyl-CoA oxidase gene promoter (4).

MATERIALS AND METHODS

Chemicals. Acetone powders of various rat tissues and the various fatty acids were obtained from Sigma (St. Louis,

MO). WY-14643 (4-chloro-6-(2,3-xylidino)-2-pyrimidinylthio) acetic acid was obtained from Medicinal Chemistry Laboratories (Merck Frosst, Quebec, Canada).

Plasmids. The reporter gene MMTV-luciferase was the plasmid pJA358, in which the firefly luciferase gene is regulated by an MMTV promoter that contains tandem repeats of the glucocorticoid hormone response element (2,8). The reporter plasmid MMTV\PPRE-luciferase is similar to the above MMTV-luciferase reporter gene in which glucocorticoid hormone response element was replaced with the peroxisome proliferator responsive region found in the acyl-CoA oxidase gene (PPRE) and is identical to the PPRE in the 2A-GST-CAT reporter gene (8). Plasmid pJ3NUC-1 is an expression vector containing the cDNA of the NUC-1 receptor (2,8). Expression plasmid pSV2wrec contains the native mouse GR (2). The expression vector pJ3GR/NUC-1 was the chimeric receptor in which the DNA binding domain of GR was fused with the ligand binding domain of NUC-1 receptor (2,8). Expression vector pJ3GR/PPARα contains the chimeric receptor in which the DNA binding domain of GR was fused to the ligand binding domain of mPPARα (8). Expression vector pJ3NER contains the cDNA for the native NER steroid hormone receptor (15). Expression vector pJ3GR/NER contains the hybrid receptor in which the DNA binding domain of the GR was fused to the ligand binding domain of NER receptor.

Ligand-dependent transcription assays. Ligand-dependent screening assays were as previously described (2). The reporter gene MMTV-luciferase was co-expressed with plasmids containing cDNA for the steroid hormone receptors in COS-7 cells. Ligands were added 30 min after addition of the calcium phosphate–DNA co-precipitate. After 18 h, the cells were washed and fresh ligands were added. Twenty-four hours later, cell extracts were prepared and assayed for luciferase activity. In some experiments, transfection was performed in 150-mm tissue culture dishes. After 18 h, cells were washed and seeded into 24 well plates. After attachment of the cells, the ligands were added and luciferase activity was tested two days later. All compounds were dried and dissolved in ethanol or DMSO and added to the assays at 500–1000-fold dilutions of concentrated stock solutions. The data is presented as the mean of triplicate or tetraplicate samples with the standard deviation shown for each data point. Each assay was repeated at least three times with similar results obtained for each experiment.

Purification of methyl ester of palmitic acid. Acetone powders, acetone insoluble material, of various rat tissues were obtained from Sigma. The powder (50 g) was dissolved in 1000 mL of a chloroform/water/ethanol mixture (50:50:1). After vigorous mixing for 10 min, the phases were separated by centrifugation at 5000 × *g*. The chloroform phase which contained 90% of the activity was dried under vacuum. The residue was dissolved in hexane and loaded onto a silica gel column followed by elution with hexane, chloroform, ethyl acetate, propanol, and ethanol. The hexane phase contained most of the agonistic activity and was further purified on semi-preparative C_{18} high-performance liquid chromatography (HPLC) and C_4 HPLC columns employing linear gradients of 40% acetonitrile/60% water to 90% acetonitrile/10% water and monitoring the ultraviolet 200 nm.

The activity of the various fractions was tested after evaporation of the solvents. The materials were dissolved in ethanol and tested in the ligand screening assays for activity. The final concentration of ethanol did not exceed 0.2% of the cell culture medium.

Identification of methyl palmitate. The structure of the purified compound that activated the GR/NUC-1 chimeric receptor was analyzed by nuclear magnetic resonance (NMR). Proton and carbon NMR spectra were recorded at room temperature on a Varian VXR-500S NMR spectrometer (Palo Alto, CA) operating at a proton frequency of 500 MHz and a carbon frequency of 125 MHz. The material present in fractions 41–47 (pool 2, Fig. 4) of the C_4 (HPLC) column was dissolved in 100 atom percentage D CD_3CN (Merck Isotopes, Darmstadt, Germany). Chemical shifts are referenced to internal tetramethylsilane.

RESULTS

Activation of NUC-1 receptor by acetone powders of rat organs. To identify the putative natural ligand for the NUC-1 receptor, we prepared a ligand-dependent transcription assay that has been successfully used for the identification of ligands for members of the steroid hormone receptor superfamily (1,2,16–18). The ligand binding domain of the NUC-1 receptor was fused to the DNA binding domain of the GR as previously described (1,2,8). The recombinant GR/NUC-1 receptor was then co-transfected with the MMTV-Luciferase reporter gene into COS-7 cells, and the effect of potential ligands on expression levels of luciferase enzyme was monitored as described in the Materials and Methods section. Since most of the ligands for members of the steroid hormone receptor superfamily are hydrophobic, we tested the ability of acetone powders from various rat tissues to activate the GR/NUC-1 chimeric receptor. We found that acetone powders of intestine and pancreas produced the largest stimulation of luciferase activity (Fig. 1A). Acetone powders of muscle, intestinal mucosa, and kidney had lower activity while no significant stimulation of the luciferase activity was observed in acetone powders of liver, heart, lung, placenta, spleen, and adrenal cortex. In order to test the activation specificity of GR/NUC-1 by these acetone powders, we tested their effects on the ligand-dependent transcription assays mediated by the GR/NER chimeric receptor. This receptor is the fusion product of the amino terminal region, including the DNA binding domain, of the GR and the ligand binding domain of NER, a nuclear receptor that is not related to the PPARα family, and for which no ligand has been identified (15). In these experiments, none of the acetone powders exhibited stimulation of the MMTV-Luciferase reporter gene (Fig. 1B), suggesting that the pancreas and intestine acetone powders activate specifically the GR/NUC-1 chimeric receptor.

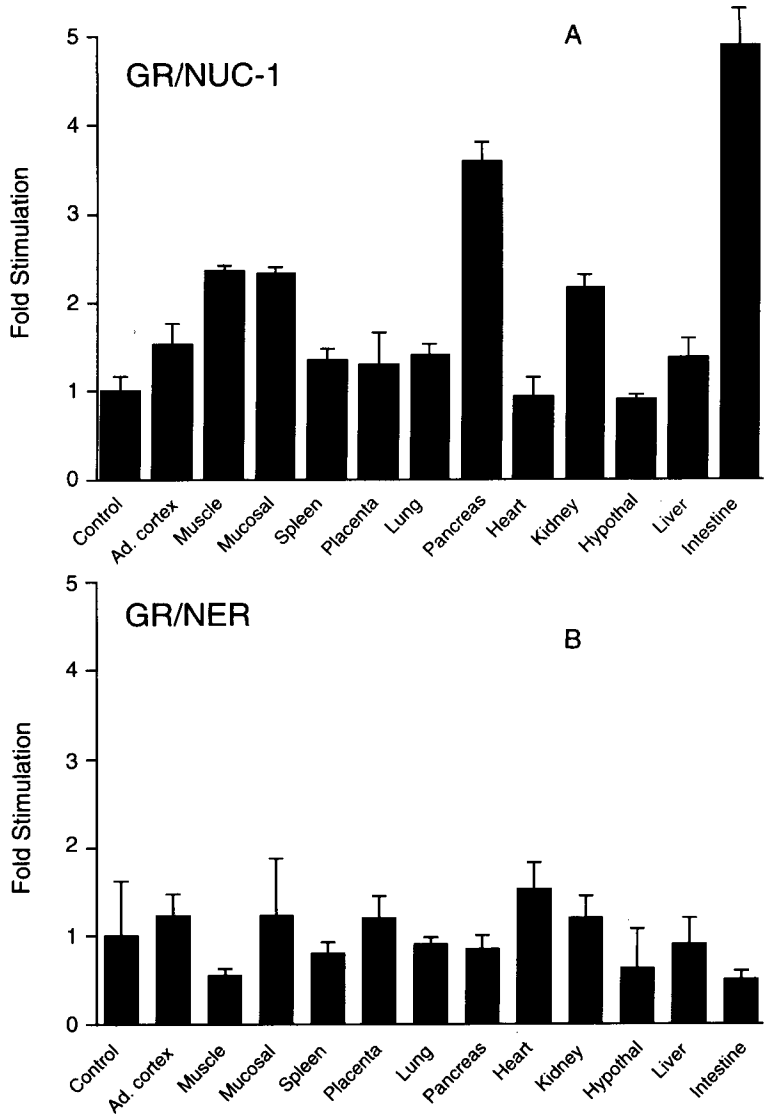

FIG. 1. Activation of GR/NUC-1 and GR/NER chimeric receptors by acetone powders of rat tissues. Acetone powders of various rat tissues were dissolved in dimethylsulfoxide (20 mg/mL) and cleared by centrifugation. Samples were added to the ligand-dependent transcription assays mediated by the chimeric receptors in cells transfected with GR/NUC-1 (A) or GR/NER (B). The abbreviations are: Ad. cortex, adrenal cortex; Mucosal, intestinal mucosa; Hypothal, hypothalamus.

Methyl palmitate is the active agent that stimulates NUC-1-dependent transcripion. We next examined the chloroform/water partition of the active component found in the acetone powders. The active material was added to a mixture of water and chloroform (1:1). After mixing, the two phases were separated by centrifugation and each phase was evaporated under vacuum. The subsequent residues were then dissolved in DMSO and tested for activity. We found that the chloroform phase contained 90% of the stimulatory activity present in the original acetone powder (Fig. 2). About 10% of the activity was present in the water phase. The chloroform-soluble material retained its specificity for activation of the GR/NUC-1 receptor. Neither the acetone powder nor the water-soluble material stimulated transcription mediated by the chimeric receptor GR/NER or by the wild-type GR (Fig. 2). The stimulation of GR/NUC-1 by acetone powders of intestine and pancreas was similar in magnitude and receptor specificity to that of 100 μM WY-14643. Furthermore, addition of the chloroform or acetone extracts to a transcription assay that contained only the MMTV-luciferase reporter gene produced no stimulatory activity (not shown).

To further purify the active ingredient, the chloroform-soluble material of the acetone powder was dissolved in hexane, loaded onto a silica gel column, and eluted with hexane, chloroform, ethanol, and methanol. The solvents were evaporated, samples of the residues were dissolved in DMSO and tested in the ligand-dependent transcription assay. Most of the activity was in the hexane fraction, although some activity was

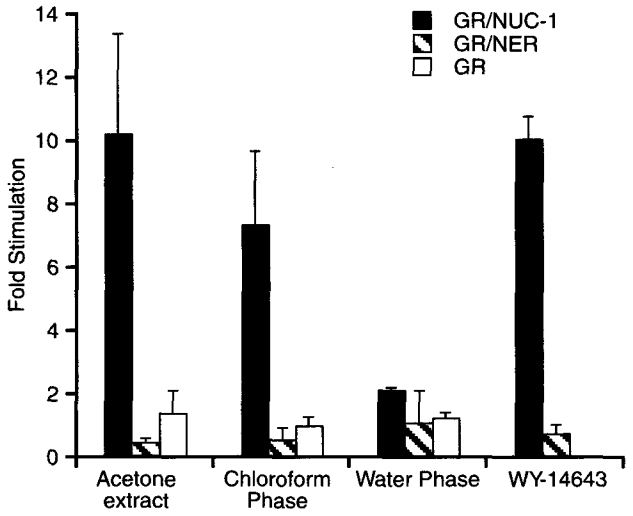

FIG. 2. Partition of GR/NUC-1-stimulation activity between acetone and water. One gram of pancreas acetone powder was added into a mixture of 50 mL water/chloroform (1:1). After mixing and vortexing, the two phases were separated by centrifugation and the separated water and chloroform phases were dried and dissolved in dimethylsulfoxide. Samples were added to the transfection assays as described in methods.

observed in other fractions. The hexane fraction was subjected to HPLC purification on a C_{18} column (Fig. 3A). Testing the C_{18} column fractions in the GR/NUC-1 ligand transcription assay, we found the highest activity was concentrated at fractions 61 to 68 which corresponded to the area of a major ultraviolet peak of fractions eluted at 44 to 48 min (Fig. 3). The active fractions, which on an analytical C_4 HLPC column exhibited similar ultraviolet absorption profile, were pooled and were further purified by HPLC on a C_4 column (Fig. 4A). The fractions 3–40, 41–47, and 48–69 were pooled, and the activity was found to be concentrated in pool 2 (fractions 41–47, Fig. 4B). The activity found in pool 2 was similar in magnitude to the activity found in the peak fraction (fraction 63) of the C_{18} column. HPLC analysis of the material in pool 2 fraction revealed that this material was relatively pure (Fig. 5A). Analysis of the proton NMR spectrum showed resonances characteristic of a saturated, straight-chain fatty acid (Fig. 5B). The 3-proton singlet at 3.6 ppm suggested that the fatty acid was esterified with a methyl group. The length of the fatty acid chain was obtained from integration of the proton resonances (NMR data are in the legend of Fig. 5B). A proton-decoupled carbon spectrum of the sample was found to be identical with that of an authentic sample of methyl palmitate (Fig. 5B). Thus the molecular structure of this compound was determined to be the methyl ester of palmitic acid. Since pool 2 fraction is of a pure material, the calculated concentration of methyl palmitate (from pool 2) in the transcription assay in Figure 4B was 52 μM and gave transactivation of GR/NUC-1 chimeric receptor (5.1-fold, Fig. 4) that was comparable to the stimulation magnitude of an authentic sample of 50 μM methyl palmitate (3.3-fold, Fig. 6).

To confirm that methyl palmitate is indeed capable of activating the GR/NUC-1 receptor, we tested commercially obtained methyl palmitate in the ligand-dependent transcription assay. Indeed, 99.9% pure methyl palmitate activated transcription mediated by the GR/NUC-1 receptor about threefold (Fig. 6A). Moreover, methyl ester of oleic acid was an equally potent agonist of the GR/NUC-1 receptor, whereas the free form of palmitic acid was less potent in the ligand-dependent transcription assay. In contrast, the free form of oleic acid was a potent activator. Furthermore, we found that an ethyl ester of oleic acid was also a potent activator in this assay (Fig. 6A). Similar results were observed with the chimeric receptor GR/PPARα which contains the ligand binding domain of the PPARα. The GR/PPARα was activated by methyl palmitate, ethyl palmitate, and the various forms of oleic acid (Fig. 6B). No such stimulation was observed when these molecules were added to ligand-dependent transcription assays mediated by other receptors with their cognate hormone response element such as GR/NER, GR, or retinoic acid receptors (not shown). We concluded, therefore, that the free fatty acids or their esters could specifically activate the proteins that belong to the PPAR subfamily.

Methyl palmitate activates the normal NUC-1 receptor. The PPAR family can recognize a specific DNA sequence within the promoter of the acyl-CoA oxidase gene that codes for a key enzyme in the metabolism of fatty acids. Therefore, we examined whether methyl palmitate can activate the transcription mediated by native NUC-1 receptor through the same DNA sequences (4,7,16). We replaced the glucocorticoid hormone response element found in the MMTV promoter with the PPAR hormone response element, thus forming a luciferase reporter gene that is under the control of the NUC-1 receptor. Co-expression of the wild-type NUC-1 receptor with this reporter gene resulted in a ligand-dependent stimulation of luciferase expression (Fig. 7). Either methyl palmitate or palmitic acid increased luciferase expression. In control experiments, addition of methyl palmitate or palmitic acid to cells cotransfected with the reporter gene containing the glucocorticoid hormone response element did not show ligand-dependent stimulation by NUC-1 receptor (Fig. 7). Moreover, methyl palmitate did not stimulate the luciferase expression mediated by the glucocorticoid receptor (not shown).

DISCUSSION

PPARα and NUC-1 belong to the steroid hormone receptor superfamily. They are activated by drugs for the treatment of hyperlipidemia and by fatty acids. Furthermore, these receptors stimulate transcription of reporter genes *via* response elements identified in promoters of genes that code for the enzymes that participate in peroxisomal fatty acid β-oxidation (4,8,9,19). These observations suggest that PPARα and NUC-1 play a role in the physiological regulation of fatty acid metabolism (1–4). We report here the identification of a putative natural activator of the members of the PPAR family. By testing acetone powders of various rat tissues in ligand-de-

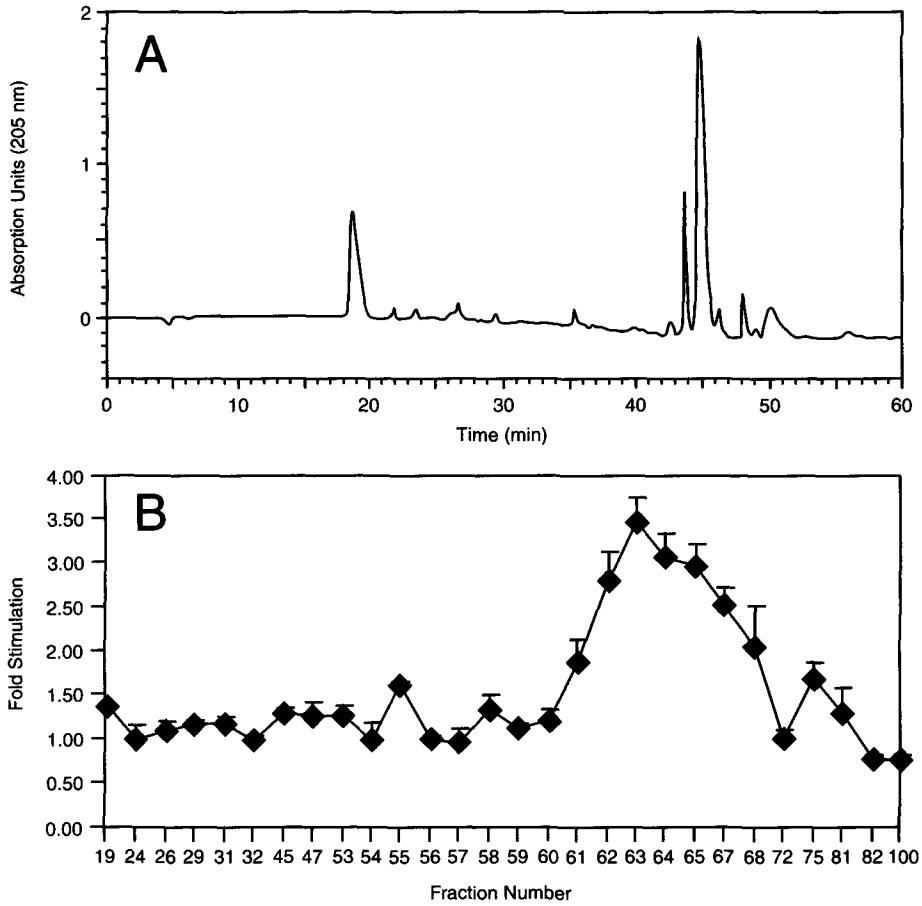

FIG. 3. Activation of GR/NUC-1 chimeric receptor by C_{18} high-performance liquid chromatography (HPLC) fractions of the pancreas powders. A 100-mg portion of the hexane fraction eluted from the silica gel column was dissolved in ethanol and was chromatographed on Vydac C_{18}, 10 μ, 300Å, 22.5 mm × 250 mm HPLC column employing a 40% acetonitrile/60% water to 90% acetonitrile/10% water linear gradient over 60 min at 5 mL/min flow rate (A). The various fractions were tested for the stimulation of transcription mediated by the GR/NUC-1 chimeric receptors (B). Column fractions were tested individually or as pool of fractions indicated in the figure as the number of the last fraction in the pool (1–19, 20–24, 25–26, 27–29, 30–31, 33–34, 35–45, 46–47, 48–53, 69–72, 73–75, 76–81, and 82–100) for further purification on C_4 HPLC column.

pendent transcription assays mediated by the GR/NUC-1 hybrid receptor, we discovered that intestine and pancreas powders contain substances that specifically stimulate the transcription *via* the NUC-1 ligand binding domain. The agonist specificity was reflected in the lack of stimulation of transcription mediated by the native GR or hybrid receptor GR/NER which have ligand binding domains different than that of PPAR. Moreover, the native NUC-1 that does not recognize the MMTV reporter gene did not transactivate transcription by the extracts. After purification, we identified the major active material in acetone powder of rat pancreas as the methyl ester of palmitic acid. This finding was confirmed by the ability of synthetic methyl palmitate to specifically activate both GR/NUC-1, the related GR/PPARα hybrid receptors, and the native NUC-1 receptor. Further experiments showed that the ethyl ester of palmitic acid was an equally potent activator of these receptors. Moreover, we found that the methyl- and ethyl esters of oleic acid were also potent activators of the PPARα and NUC-1 receptors. These observations are supported by the reports that synthetic methyl-ester compounds such as methyl clofenapate and LY-171883 were found to be potent activators of the members of the PPAR family (1,5). These compounds lack the carboxylic group that characterizes the various compounds that activate these receptors. These findings suggest that a free carboxylic group may not be required for the activation of these receptors, and that esters of the fatty acid may also act as activators of the PPAR family.

The natural occurrence of fatty acid methyl esters was reported only in few publications since, in most cases, fatty acid composition is analyzed after transmethylation of the organic extracts. However, there are confirmed reports in the literature of the isolation of fatty acid methyl esters from various human and animal cells and tissues (20–27). Moreover, the biochemical pathway for methyl-ester formation was determined to be the carboxyl methylation of fatty acids by

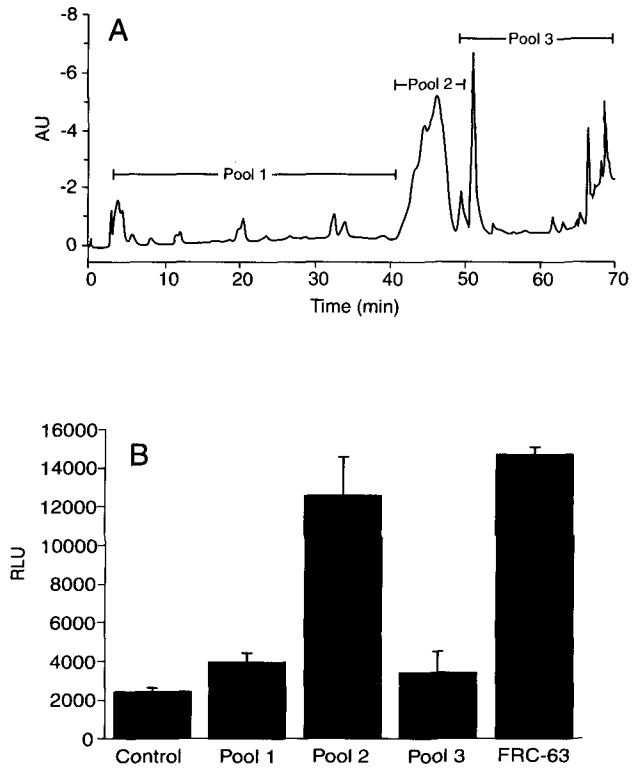

FIG. 4. Activation of GR/NUC-1 chimeric receptor by C_4 HPLC column fractions of the pancreas powders. Fractions 61–68 that corresponded to the C_{18} elution at 44 to 48 min were pooled. After evaporation, 16-mg portion was dissolved in 250 μM ethanol and was chromatographed on Vydac C_4 (Phenomenex, Torrance, CA), 5 μ, 300Å, 10 mm × 250 mm HPLC column employing a 40% acetonitrile/60% water to 90% acetonitrile/10% water linear gradient over 60 min at 5 mL/min flow rate, ultraviolet 200 nm (A). The various fractions were pooled as illustrated in part A, dried under vacuum, dissolved in ethanol (pool 1, 500 μg/150 μL; pool 2, 1010 μg/150 μL; pool 3, 390 μg/150 μL). Fraction 63 (FRC-63) represents a fraction from the peak activity eluted from the C_{18} HPLC column (45 min). See Figure 3 for company source and abbreviation.

S-adenosylmethionine (24–26). The formation of methyl esters of fatty acids was demonstrated in both cells and tissues, as well as membrane preparations incubated with a radioactive methyl group on methionine or *S*-adenosylmethionine. Furthermore, enzymatic activity that catalyzes the methyl hydrolysis was also described (27). Interestingly, the pancreas, from which we purified methyl palmitate, is one of the organs with the highest enzymatic activity for the production of fatty acid methyl esters (21,22,26).

The biochemical pathway for the formation of fatty acid ethyl esters has also been documented both *in vivo* and *in vitro* (28–32). Fatty acid ethyl esters are the end product of a nonoxidative pathway for ethanol metabolism in a variety of tissues from several species, including humans (28–31). The enzyme that catalyzes this reaction, fatty acid ethyl ester synthase, was identified in several tissues including lung, liver, and pancreas (28–32). It was shown that tissues that are most commonly damaged by alcohol abuse contain high levels of the fatty acid ethyl ester synthase (28). Moreover, the pancreas that was the source for our isolation of methyl palmitate is also rich in fatty acid ethyl ester synthase (30,33, 34). Interestingly, it was observed that palmitic acid increases the insulin release that was potentiated by a high glucose concentration from pancreatic β-cells (35). This effect appeared to be through an unknown glucose-dependent mechanism that is not mediated by the β-oxidation pathway.

An effort to isolate the natural activators of the members of the rat PPARα from human plasma led to the identification of palmitic acid, oleic acid, linoleic acid, and arachidonic acid (36). In our studies, the silica gel fractions obtained with solvents more polar than hexane, i.e., chloroform through methanol, contained compounds that activated the NUC-1 receptor. These fractions probably contain the free acid forms of the various fatty acids described above. Therefore, we elected to purify the compound(s) from the hexane fraction because of their higher specific activity.

It is of interest that methyl palmitate rather than the free acid form, which is the major fatty acid (over 50%) in mammals, was the PPAR family agonist purified from pancreas powders. The incorporation of the free acids into glycerol esters and fatty acid metabolism may reduce their effective concentration and reduces the pool of free fatty acids. Although there is no data in that matter, one may speculate that the formation of methyl ester of fatty acids will slow down the fatty acid metabolism and increase their cellular concentration and therefore increase the availability of fatty acids to the PPAR. Therefore, other cellular components such as uptake, cellular metabolism, or binding proteins may be the limiting factors in determining the response to the concentrations of exogenous methyl palmitate and palmitic acid. Further studies are needed to evaluate the *in vivo* effects of the esters of fatty acids. It was shown that administration of methyl palmitate suppresses the reticuloendothelial system and strongly inhibits the function of Kupffer macrophages in rats (37). It was also shown that methyl palmitate prevents liver damage mediated by the activation of Kupffer cells, after reperfusion that followed liver hypoxia (38). Treatment of rats with methyl palmitate also improved survival after orthotopic liver transplantation, probably by inhibiting the activity of Kupffer cells (39). It remains to be examined if the immunosuppressive effects of methyl palmitate are related to the activation of PPAR-type receptors. In this context, it is noteworthy that clofibrate, another PPARα ligand, improved psoriatic lesions (40).

Further studies aimed at the identification of selective agonists and antagonists of the members of the PPAR family, and the potential of the biological role of methyl palmitate in the pancreas are needed.

ACKNOWLEDGMENTS

We thank Drs. Dwight Towler and Zoran Zimolo for helpful discussions and advice, Dr. Carl Bennett for his outstanding cooperation in the preparation of oligonucleotides, and Jacquelyn C. Rees for the preparation of the manuscript. Special thanks to Jeff Campbell for the preparation of the art work.

Kinetics of Formation of Fluorescent Products from Hexanal and L-Lysine in a Two-Phase System

Henrik Stapelfeldt and Leif H. Skibsted*

Department of Dairy and Food Science, Royal Veterinary and Agricultural University, Rolighedsvej 30, DK-1958 Frederiksberg C, Denmark

ABSTRACT: Kinetics of formation of fluorescent condensation products from hexanal and L-lysine (or its *N*-acetylated forms) including mass-transfer has been studied in a two-phase system consisting of lysine (or lysine derivative) in an aqueous phosphate buffer and a 1-octanol solution of hexanal as model for formation of fluorophores between protein and carbonyl compounds in peroxidizing biological systems. The initial rate of formation of fluorescent products in the aqueous phase was found to be proportional to the concentration of hexanal and lysine and to increase in both phases with increasing pH in the aqueous phase, in contrast to a higher-order dependence on hexanal in the octanol phase. At pH = 6.8, the temperature dependence of the appearance of fluorescent products corresponds to apparent energies of activation of 63 kJ · mol^{-1} and 87 kJ · mol^{-1} in the aqueous phase and the octanol phase, respectively. Fluorescent condensation products appeared faster in the octanol phase. However, by a kinetic analysis, the fluorescent products were shown to be formed in the aqueous phase, corresponding to the lower energy of activation and to the simple second-order kinetics, and subsequently distributed between the aqueous phase and the octanol phase. L-Lysine reacted faster than N_α-acetyl-L-lysine which reacted faster than N_ε-acetyl-L-lysine. Using fluorescence quantum yields, determined to be $1.4 \cdot 10^{-2}$ in octanol and $8 \cdot 10^{-3}$ in water at pH 6.8, an apparent partition coefficient of 17 (octanol/water) was determined for the condensation product of L-lysine. The steady-state fluorescence in the octanol phase was attributed to two components with fluorescence lifetimes at 25°C of 0.7 ± 0.05 ns and 5.1 ± 0.2 ns, assigned to hexanal and the condensation product, respectively. The emission spectra were resolved in the two components using phase-sensitive detection, and the condensation product had emission maximum at 405 nm.

Lipids 31, 1125–1132 (1996).

During peroxidation of unsaturated fatty acids or lipids, various volatile carbonyl compounds are formed as the result of carbon-carbon cleavage of alkoxyl radicals formed by homolytic cleavage of hydroperoxides. These carbonyl compounds are able to react with amino groups (1), as those present in lysine residues in proteins, to yield fluorescent condensation products [cf. (2)], and fluorescence measurements have been demonstrated (3,4) to yield excellent indices of lipid peroxidation in biological materials (5). Fluorescence is also frequently used for the assessment of lipid oxidation in meat products where good correlation is found with the sensory impression of rancidity (6).

In order to mimic the conditions in the living cell and in food systems with aqueous phases containing the proteins and lipid phases in which the secondary lipid peroxidation products originate, a two-phase system was developed with a phosphate buffer as the aqueous phase with lysine derivatives as the reactive amine, and 1-octanol as the lipophilic phase, which with its similar polarity mimics the carbon chain of phospholipids (7). Hexanal, originating from breakdown of 13-hydroperoxy linoleic acid, 13-hydroperoxy γ-linolenic acid, and 15-hydroperoxy arachidonic acid (8), is the volatile compound found in the largest amounts in the headspace of peroxidizing tissue and was therefore used as a model for reactive carbonyl volatiles in the present study.

The reaction between lipid peroxidation products and amines is also of interest in relation to the *in vivo* formation of lipofuscin-like compounds during aging. The fluorescence of lipofuscin is not caused by a single fluorophore, as the colors of the emission range from blue to orange [cf. (9)]. Results from *in vitro* studies of formation of fluorophores related to lipofuscin, which notably showed only violet or blue fluorescence (10–12), have accordingly been questioned as being of relevance as lipofuscin models (13). A more detailed photophysical characterization of the involved fluorophores is not available. A comparison of the fluorophores formed *in vitro* and *in vivo* is expected to be more conclusive when based on fundamental photophysical parameters such as fluorescence quantum yields and emission lifetimes (14,15). Such information is also essential in order to distinguish between extracted fluorescent oxidation products and co-extracted fluorophores which are not related to lipid oxidation.

MATERIALS AND METHODS

Materials. 1,4-*Bis*(4-methyl-5-phenyl-oxazolyl)benzene (dimethyl-POPOP) scintillation grade was purchased from Fluka (Buchs, Switzerland). Rhodamine 101 laser grade was from Exciton (Dayton, OH). L-lysine monohydrochloride

biochemical grade and hexanal (>98% purity) was from Merck (Darmstadt, Germany), N_ε-acetyl-L-lysine and N_α-acetyl-L-lysine was from Sigma (St. Louis, MO). All other reagents were of analytical grade. Water was purified through a Millipore Milli-Q unit (Milford, MA), and only glassware was used for the experiments.

The pH was measured with a combination glass electrode (Ingold type 405) in conjugation with a Metrohm (Herisau, Switzerland) 605 pH meter. The electrode was standardized against titrated aqueous solutions of hydrochloric acid in 0.16 M NaCl, employing the definition pH = $-\log [H^+]$ throughout.

Two-phase model system. Hexanal was dissolved in 20 mL 1-octanol, and the L-lysine salt or derivative was dissolved in 50 mL 0.050 M aqueous phosphate buffer adjusted with NaCl to yield an ionic strength of 0.16. The aqueous phase was sterile filtered (0.22 μm filter) prior to use in order to prevent microbial growth. The two phases were constantly mixed in closed 300 mL gas-washing bottles by stirring with Teflon-coated magnetic stir bars in a thermostatted water bath.

Fluorescence measurements were carried out with an SLM 48000S multifrequency, phase-modulation spectrofluorometer (SLM Instruments Inc., Urbana, IL) with a 450-W Xe arc lamp, SLM MC200 excitation and MC320 emission monochromator mounted with Hamamatsu R928P photomultiplier tube at right angle to the line of illumination. Emission spectra reported were corrected for instrument sensitivity characteristics, and excitation spectra were corrected for lamp spectral characteristics by the method of ratio recording (16) using a solution of rhodamine 101 (3 g/L ethylene glycol) as quantum counter. Measurements were made in thermostatted quartz cells with right angle observation at the center. Air-saturated solutions were used for the measurements, except where otherwise noted. Fluorescence emission intensities were measured relative to an 0.10 mg/L solution of quinine sulphate in 0.50 M H_2SO_4.

Fluorescence quantum yield. The absorption of the products formed was measured in cuvettes with 50-mm light pathway in a Shimadzu UV-2101 PC spectrophotometer (Shimadzu, Duisburg, Germany). The fluorescence quantum yield (Φ_f) was determined by the optically dilute concept (17) using a solution of quinine sulfate in aqueous 0.5 M H_2SO_4 as fluorescence quantum yield reference [$\Phi_f = 0.546$ (18)] and correction for refractive indices [$n_{D,25}$(octanol) = 1.4276, $n_{D,25}$(water) = 1.3325; both values from (19)].

Emission lifetimes. The fluorescence lifetimes were determined by the multifrequency phase and modulation technique using an Omnichrome Series 2074 continuous wave He-Cd laser (Omnichrome, Chino, CA) as a light source (Schott UG11 325nm bandpass filter) in the SLM 48000S spectrofluorometer with the intensity of the exciting light sinusoidally modulated by means of a Pockel's cell. The instrument was set up at "magic angle" conditions, and emission was collected through a Schott KV 389-cut-on filter. Phase and modulation lifetimes (τ_p and τ_m) were calculated according to (20):

$$\tau_p = \frac{\tan\phi}{\omega} \qquad \tau_m = \frac{\sqrt{(1/m^2)-1}}{\omega} \qquad [1]$$

where ϕ is the phase shift in degrees, m the relative modulation, and ω the angular modulation frequency ($\omega = 2\pi \times$ frequency). Dimethyl-POPOP dissolved in absolute ethanol was used as a fluorescence lifetime standard [1.45 ns (21)]. At each frequency, the phase difference and demodulation were taken as the average of ten measurements.

Frequency-domain data analysis. As described in detail in Reference 22, calculated phase ($\phi_{c\omega}$) and modulation ($m_{c\omega}$) were estimated from the measured phase (ϕ_ω) and modulation (m_ω) values, the estimated uncertainties in the phase ($\sigma_{\phi\omega} = 0.5°$) and modulation ($\sigma_{m\omega} = 0.005$), and evaluated by the reduced chi-square χ^2_R:

$$\chi^2_R = \frac{\chi^2}{\nu} = \sum_\omega \frac{1}{\sigma^2_{\phi\omega}}(\phi_\omega - \phi_{c\omega})^2 + \sum_\omega \frac{1}{\sigma^2_{m\omega}}(m_\omega - m_{c\omega})^2 \qquad [2]$$

For the present analysis, we made measurements at 16 frequencies, with $\nu = 2(16) - 3 = 29$ degrees of freedom for fitting to a two-component decay (three repetitions).

Phase-sensitive detection of emission spectra. The steady-state emission spectrum, $F(\lambda,\phi_D)$, at detector phase, ϕ_D, from a sample containing two fluorophores, A and B with lifetimes $\tau_A < \tau_B$, using modulated light and phase-sensitive detection is (23)

$$F(\lambda,\phi_D) = F_A(\lambda)m_A\cos(\phi_D - \phi_A) + F_B(\lambda)m_B\cos(\phi_D - \phi_B) \qquad [3]$$

$F_A(\lambda)$ and $F_B(\lambda)$ are intensities of components A and B at wavelength λ, ϕ_A and ϕ_B are the phase angles, as calculated by Equation 1 using modulation frequency of 30 MHz. The steady-state spectrum of the unsupressed fluorophore was obtained by selecting the detector phase to be out of phase, $|\phi - \phi_D| = 90°$, with the emission of the other component.

RESULTS

Upon reaction in the two-phase system with hexanal dissolved in the octanol phase and L-lysine dissolved in the aqueous phase, a weak fluorescence was accumulating with a structureless emission spectrum in both phases with $\lambda_{em,max}$ at 420 nm for the aqueous phase (independent of excitation wavelength for 330–370 nm excitation) originating in a structureless excitation spectrum with maximum at 350 nm. The fluorophore formed was distributed between the aqueous phase and the octanol phase with $\lambda_{em,max}$ blue-shifted 5 nm (24) in the less polar octanol phase. The reaction was accompanied by the release of protons, as demonstrated in preliminary experiments with unbuffered solutions, but in experiments carried out in deoxygenated solutions (N_2-flushing), the rate of condensation was found not to depend on O_2 thus excluding hexanal oxidation as source of H^+, in accordance with Reference 25, and experiments were consequently performed with air-saturated solutions. The reaction order for the

reactants was determined using the method of initial rates [flooding of one of the reactants (26)]. In the pH region studied (5.3 to 6.8), as may be seen in Figure 1A for experiments with a constant concentration of L-lysine and varying hexanal concentration, and in Figure 1B for experiments with a constant concentration of hexanal and varying L-lysine concentration, the rate of formation of fluorescent products was in aqueous solution proportional to the concentration of both reactants at low concentrations in agreement with the overall rate law

$$\frac{dI}{dt} \propto \frac{d[\text{fluorophore}]}{dt} = k[\text{hexanal}][\text{L-lysine}] \qquad [4]$$

For both types of experiments, the rate of appearance was higher in the octanol phase compared to the aqueous phase, and in the experiment with (large) excess of hexanal, a significant curvature was noted for the appearance of fluorescence in the octanol phase. The results presented in Figure 1 are from the high-pH experiment (pH = 6.8), at lower pH the curvature was less significant (data not shown).

In order to investigate whether the higher rate observed for appearance of fluorescence in the octanol phase compared to the aqueous phase and the noted deviation from second-order reaction in the octanol phase was due to (i) a partitioning phenomenon, (ii) a lower fluorescence quantum yield in the aqueous phase compared to the octanol phase, or (iii) a faster rate of reaction in the octanol phase, the fluorescence quantum yield of the fluorophore(s) was determined in each phase. In a series of experiments at pH = 6.8 at 37°C with 1 M hexanal in the octanol phase, the fluorescence was followed in each phase for varying concentrations of L-lysine in the aqueous phase. As may be seen from Figure 2, the fluorescence intensity relative to a quinine standard reaches constant values in the aqueous phase after approximately 7 d for each L-lysine

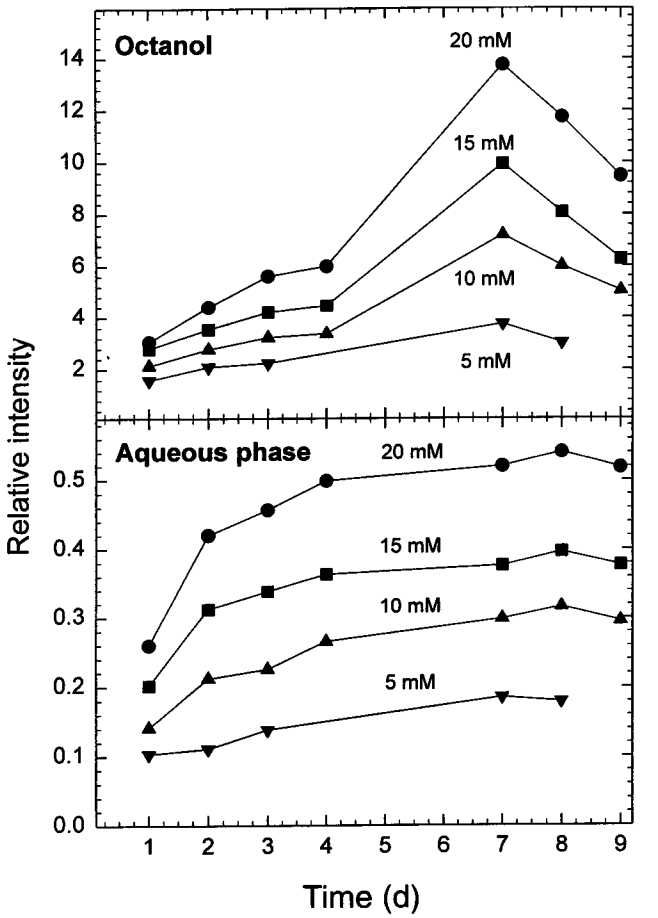

FIG. 2. Time course of formation of fluorescence in each phase of a two-phase system with 1 M hexanal in 1-octanol (20 mL) and varying concentration of L-lysine, as marked in the figure, in the aqueous phase (50 mL of 50 mM phosphate buffer, pH 6.8, $I = 0.16$) at 37.0 ± 0.5°C. Fluorescence intensity is measured relative to a 0.10 mg/L solution of quinine sulphate in 0.5 M H_2SO_4.

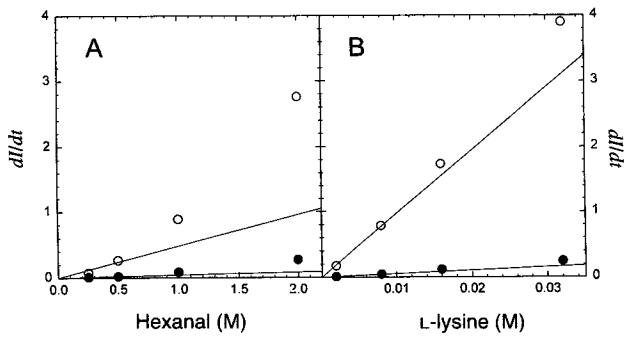

FIG. 1. Initial rate of formation of fluorescent products at 37.0 ± 0.5°C in the aqueous phase (●) and the octanol phase (○) of a two-phase system where *dI/dt* is the change in the relative intensity of emitted light at 410 nm with time for the first 2800 min of reaction. A, fixed concentration (10 mM) of L-lysine in the aqueous phase (50 mL of a 50 mM phosphate buffer, pH 6.86, $I = 0.16$) and varying concentrations of hexanal in the 1-octanol phase (20 mL). B, fixed concentration (1.0 M) of hexanal in the 1-octanol phase (20 mL) and varying concentrations of L-lysine in the aqueous phase (50 mL of a 50 mM phosphate buffer, pH 6.74, $I = 0.16$).

concentration. The relative fluorescence intensity is linearly dependent on the L-lysine concentration as may be seen in Figure 3, showing that a single fluorophore (or fluorophores in a constant ratio) are formed from L-lysine. From the fluorescence intensity and the absorbance of the solution for the 20 mM L-lysine solution measured in a 5-cm cell, the quantum yield was calculated (17) to yield $\Phi_{f,w} = 8 \cdot 10^{-3}$ (in water). The results were more complex for the formation of the fluorophore in octanol, since the intensity decreased after 7 d of reaction, suggesting further reactions. However, the maximum intensity obtained after 7 d in the octanol phase also depends linearly on the L-lysine concentration (Fig. 3), and applying a similar analysis as for the aqueous phase, yielded $\Phi_{f,o} = 1.4 \cdot 10^{-2}$ (in octanol). These results are lower limits since a slight turbidity developed in the solutions used for absorbance measurements. It should be noted that the quantum yields at the low concentrations employed inherently are corrected for partition reaction between the two phases, since the calculations are independent of the actual

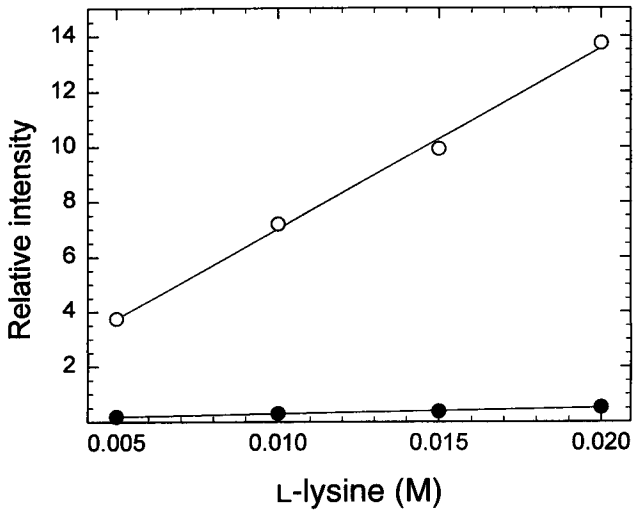

FIG. 3. Relative fluorescence intensity (measured relative to a 0.10 mg/L solution of quinine sulphate in 0.5 M H_2SO_4) after 7 d in aqueous phase (●) and octanol phase (○) for 1 M hexanal in octanol reacting with L-lysine in the aqueous phase, cf. Figure 2.

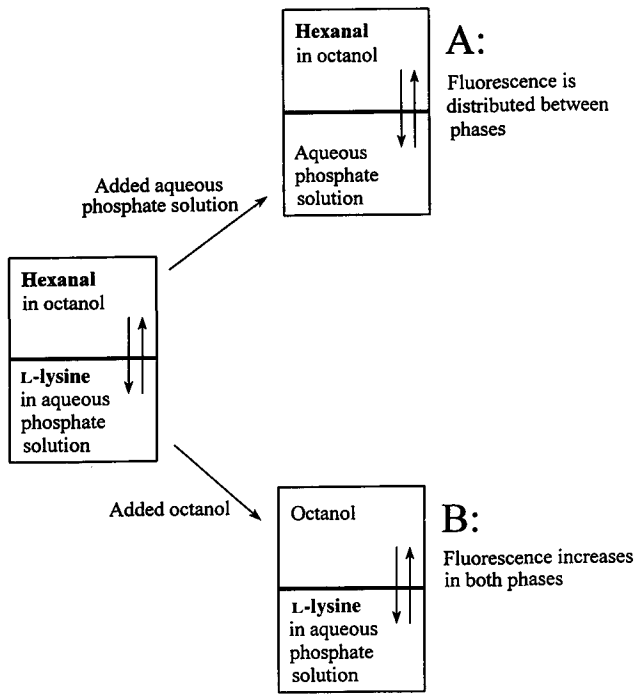

FIG. 4. Design of the reactant-removal experiment. After 7 d of reaction at 37.0 ± 0.5°C of a two-phase system with 20 mM of L-lysine in the aqueous phase (50 mL of a 50 mM phosphate buffer, pH 6.82, I = 0.16) and 1 M hexanal in the 1-octanol phase (20 mL), the phases were separated into two new bottles. The 1-octanol phase was transferred to bottle A and added the original volume of the pure phosphate buffer while the aqueous phase was transferred to bottle B and added the original volume of pure 1-octanol.

concentration of the fluorophore and only depend on the fluorescence intensity relative to the absolute quinine standard and on the absorbance. However, the fluorophore is distributed between the phases:

$$\text{fluorophore (aq)} \rightleftarrows \text{fluorophore (o)} \qquad [5]$$

for which the partition constant is defined and further related to the observed fluorescence intensity by:

$$K_p = \frac{[\text{fluorophore (o)}]}{[\text{fluorophore (aq)}]} \approx \frac{I_o}{I_w} \times \frac{\Phi_{f,w} \cdot \varepsilon_w \cdot n_w^2}{\Phi_{f,o} \cdot \varepsilon_o \cdot n_o^2} \qquad [6]$$

Accepting the further approximation, that the product of the molar absorptivity at the wavelength of excitation (ε) and the squares of the refractive index (n) is independent of the solvent, the experimental data (Fig. 3) yields K_p = [(14 − 1.8)/(0.52 − 0.1) × (8 · 10^{-3}/1.4 · 10^{-2})] = 17. The fluorophore is thus clearly more soluble in the lipohilic phase compared to the aqueous phase, suggesting that, if the fluorophore is formed in the aqueous phase, it is subsequently transferred to the octanol phase. In order to investigate the kinetics in further details, the following experiment, outlined in Figure 4, was designed: After 1 wk of reaction at 37°C in the two-phase system with 1 M hexanal in 20 mL of octanol and 20 mM L-lysine in 50 mL of aqueous phosphate buffer (0.050 M, pH 6.82, I = 0.16), the octanol phase was removed and mixed with pure phosphate buffer in another bottle (A), and the remaining aqueous phase was mixed with pure octanol (B). The fluorescence intensities of the two phases in the two separate bottles were then measured regularly during the next week. In both bottles the originally formed fluorophores were distibuted between the two phases within a few hours, but in contrast to bottle A, the fluorescence intensity increased in both phases of bottle B after the initial distribution of the fluorophores due to continued reaction between lysine and dissolved hexanal. Our findings are consistent with a mechanism where the aldehyde of the octanol phase dissolves in the aqueous phase in which the reaction takes place, and the fluorophores formed are subsequently distributed between the two phases (insert in Fig. 5). This mechanism is supported by the far higher solubility of hexanal in water [56 mM at 30°C (27), and a partition coefficient of $10^{1.78}$ (24)] than for lysine in octanol [0.08 mM, based on water solubility of 2.3 M and a partition coefficient of $10^{-4.44}$ (28)], and is in accordance with our observation of an interruption of fluorophore formation in the octanol phase of bottle A after removal of the aqueous phase containing lysine. The better linear dependence observed for the rate of appearance of fluorescence in the water phase on the concentration of excess of lysine (Fig. 1B), compared to the dependence for the rate of appearance of fluorescence in the octanol phase on the concentration of excess of hexanal (Fig. 1A), is in further support of this conclusion. However, the observed rates of appearance are only approximately 20 times larger [average value from Fig. 1 (A and B)] than in the aqueous phase, cf. Equation 4:

$$\frac{\left(\frac{dI}{dt}\right)_o}{\left(\frac{dI}{dt}\right)_w} = 20 = \frac{k_o[\text{hexanal}]_o[\text{lysine}]_o}{k_w[\text{hexanal}]_w[\text{lysine}]_w} \qquad [7]$$

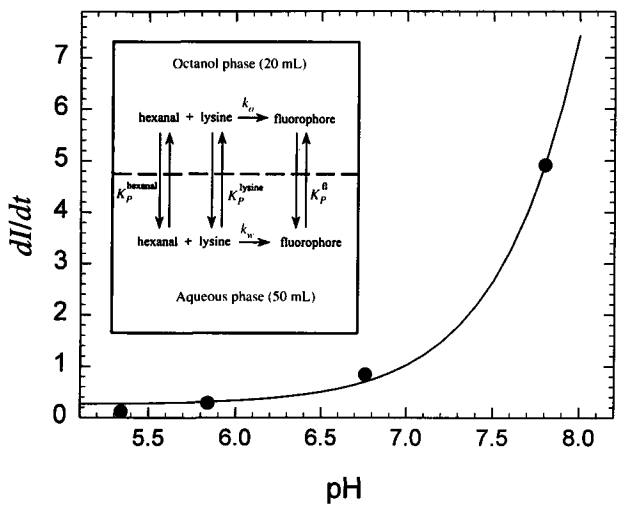

FIG. 5. Effect of pH in the aqueous phase on rate of formation of fluorescent products at 37.0 ± 0.5°C in the aqueous phase of a two-phase system consisting of 50 mL aqueous phase (10 mM L-lysine in 50 mM phosphate buffer with $I = 0.16$) and 20 mL octanol phase (1.0 M hexanal). *dI/dt* is the change in the relative intensity of emitted light at 410 nm with time for the first 2800 min of reaction. The full line is the best fit of the data to Equation 9 describing two parallel reactions of lysine in acid/base equilibrium with its protonated form (pK_a = 9.08 at 37°C and $I = 0.16$). Regression analysis yields $v_{R\text{-}NH_2} = (9.4 \pm 0.3) \cdot 10^{-5}$ and $v_{R\text{-}NH_3^+} = (2.5 \pm 0.7) \cdot 10^{-7}$ for the two relative rates, making the reaction of the protonated amine not significantly different from zero at a 5% level. Insert: kinetic model for the two-phase system.

and the ratio between the rate constant in octanol and in water accounting equally well for the observed appearance of fluorescence is:

$$\frac{k_o}{k_w} = \frac{dI_o}{dI_w} \times \frac{[\text{hexanal}]_w[\text{lysine}]_w}{[\text{hexanal}]_o[\text{lysine}]_o} = \frac{dI_o}{dI_w}\left(K_P^{\text{hexanal}} \cdot K_P^{\text{lysine}}\right)^{-1}$$

$$= 20 \cdot 10^{-1.78} \cdot 10^{4.44} = 9 \cdot 10^3 \qquad [8]$$

where K_p^{hexanal} and K_p^{lysine} are the partition coefficients between water and octanol for hexanal and lysine, respectively (24,27). It may thus be concluded that the rate constant for the octanol phase should be 9000 times the rate constant for the water phase to account equally well for the observed rate. The temperature dependence of the appearance of fluorescent products analyzed according to the Arrhenius equation for both phases yields further information. For the three temperatures investigated at pH 6.68 ± 0.05, a linear plot was observed both for the aqueous phase ($r^2 = 0.999$) and for the octanol phase ($r^2 = 0.998$), and apparent energies of activation $E_a = 63 \pm 2$ kJ · mol^{-1} for the aqueous phase and $E_a = 88 \pm 4$ kJ · mol^{-1} for the octanol phase were calculated. It appears unlikely that the significantly larger rate constant required to account for the reaction in the octanol phase compared to the aqueous phase has a significantly higher energy of activation.

The rate of reaction in both phases was found to be very dependent on the pH of the aqueous solution, and as shown in Figure 5, the rate of reaction increased more than an order of magnitude, when solution pH increases in the biologically relevant interval from 5.35 to 7.80. The rate of appearance of fluorescence at different pH was analyzed according to

$$\frac{dI}{dt} = \frac{[H^+]}{[H^+]+K_a} \times v_{R\text{-}NH_3^+} + \frac{K_a}{[H^+]+K_a} \times v_{R\text{-}NH_2} \qquad [9]$$

in agreement with parallel reactions in the aqueous phase of the protonated form of lysine (rate $v_{R\text{-}NH_3^+}$) and the non-protonated form of lysine (rate v_{NH_2}) in (rapid) equilibrium with each other with an acid dissociation constant, K_a, of $8.31 \cdot 10^{-10}$ (28). The reaction of the protonated form was by regression analysis found to be nonsignificant, and it can therefore be concluded that the condensation is a reaction between the free amino group of lysine and hexanal in the aqueous phase.

The relative reactivity of the two amino groups of lysine was studied by a comparison of the rate of reaction of the *N*-acetylated forms of lysine. The rate of reaction was found to be in the order L-lysine > N_α-acetyl-L-lysine > N_ε-acetyl-L-lysine, and the rate of formation of condensation products was highest in the octanol phase for all three forms of lysine (Fig. 6). The results show that hexanal is capable of reacting with both the ε-amino groups in proteins as well as the *N*-terminal amino group. Moreover, the higher reactivity of N_α-acetyl-L-lysine compared to N_ε-acetyl-L-lysine suggests that steric factors are important, since pK_a is 9.08 for the ε-amino group and 10.69 for the α-amino group (29). As may be seen from Figure 6, the octanol phase is slightly fluorescent prior to reaction. Hexanal is very weakly absorbing having ε = 4 M^{-1}cm^{-1} in 1-octanol at the absorption maximum 288 nm due to a symmetry-forbidden n→π* transition (30). The fluo-

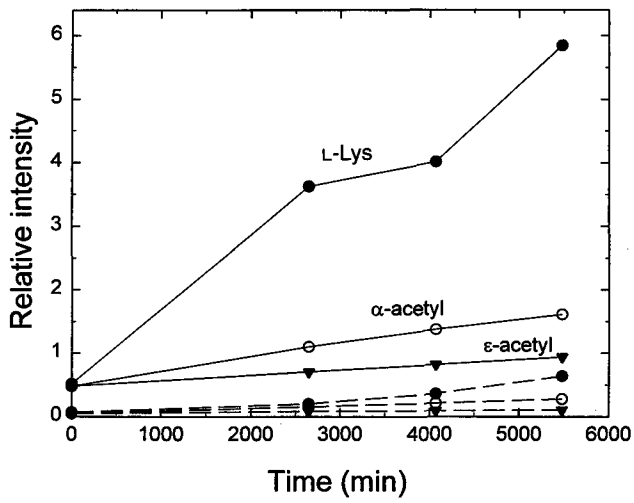

FIG. 6. Time course of formation of fluorescent products in the aqueous phase (broken line) and octanol phase (solid line) of a two-phase system consisting of 50 mL aqueous phase (10 mM of L-lysine (●), N_α-acetyl-L-lysine (○) and N_ε-acetyl-L-lysine (▼), respectively, in 50 mM phosphate buffer with pH = 6.86, $I = 0.16$) and 20 mL octanol phase (1.0 M hexanal). Emission intensity at 410 nm measured relatively to a 0.10 mg/L solution of quinine sulphate in 0.50 M H_2SO_4.

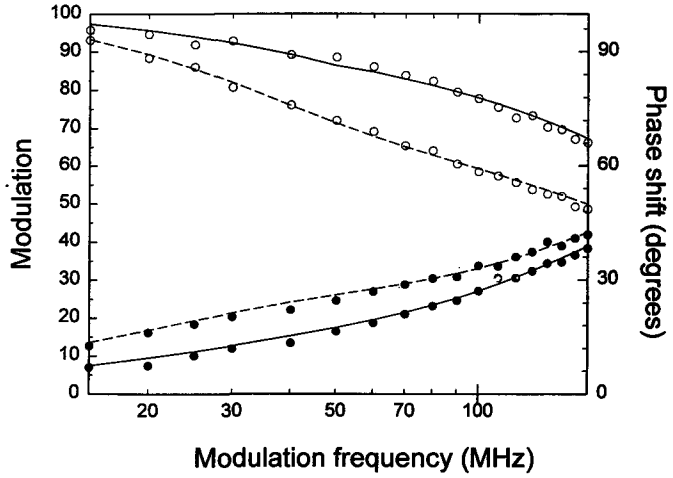

FIG. 7. Multifrequency phase and modulation data for the octanol phase of the reaction mixture (50 mL of 20 mM L-lysine in 50 mM aqueous phosphate buffer, $I = 0.16$, pH 6.83, and 20 mL of 1.0 M hexanal in 1-octanol), at 37.0 ± 0.5°C after 23 h of reaction (solid line) and 71 h of reaction (dashed line). The lines are a common best fit to the experimental data for both reaction times (●, measured phase shift; ○, modulation) using Equation 1 and Equation 2 with two exponential components with $\tau_1 = 0.7 \pm 0.05$ ns and $\tau_2 = 5.1 \pm 0.2$ ns, respectively.

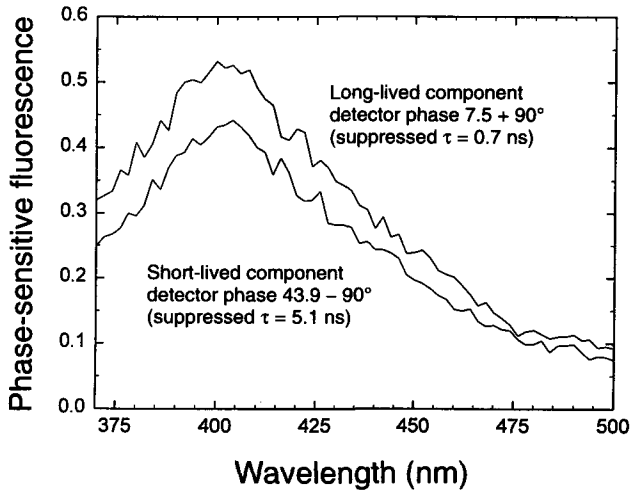

FIG. 8. Phase-sensitive emission spectra for the two components in the octanol phase of the reaction mixture described in legend to Figure 7, using 30 MHz modulation frequency.

rescence quantum yield is very low [$7 \cdot 10^{-4}$ in cyclohexane (31)]. In order to resolve the background fluorescence of hexanal from the condensation product, the phase and demodulation technique was used. Multifrequency phase and modulation data were best fitted to a bi-exponential decay function, and addition of a third component was not statistically justified. The fit yielded two fluorophores with lifetimes 0.7 and 5.1 ns, see Figure 7 for day 1 and 3. From the increased phase shift and lower modulation at all modulation frequencies, a larger contribution from the long-lived component to the fluorescence decay constant was found with time (fraction of 0.20 after 1 h of reaction to 0.48 after 123 h), and this component was accordingly assigned as the condensation product. Based on the two fluorescence lifetimes, the steady-state emission spectra were resolved using phase-sensitive detection. The similarity of these spectra (Fig. 8, for day 4 at pH 6.83) suggests that the fluorophore of the condensation product(s) is closely related to the parent carbonyl compound, as further evidenced by the partition coefficient.

DISCUSSION

In a two-phase model system with mass-transfer, we have shown that monofunctional aldehydes are able to react with L-lysine to yield fluorescent compounds under conditions of relevance for biological systems, as previously demonstrated by Kikugawa and Sawamura (32) in a solubilized system. Alkanals also react with proteins, and hexanal has been shown to react with polylysine (33), with erythrocyte ghosts (34), and eye lens α-crystallin (35), to yield fluorescent protein cross-links. Suyama and Adachi (36) proposed that the reaction proceeds through an α,β-unsaturated aldimine, which could be formed as an intermediate in amine-catalyzed aldol condensation or condensation of α,β-unsaturated aldehydes with amines. The formation of both 2-ethyl-2-hexenal and a tetrameric dialdehyde during reaction between butanal and benzylamine in a solubilized system (37) is further of support for this mechanism.

The demonstrated increase in rate of formation of fluorophores with increased pH is in accordance with the results of Fukuzawa *et al.* (38) on the reaction of 12-keto-oleic acid with glycine in a system consisting of 20% ethanol and 0.1 M phosphate buffer. It may thus be speculated that reaction depends on an initial aldol condensation to form an α,β-unsaturated aldehyde together with a deprotonization of the amino group to yield a stronger nucleophile. The aldol condensation has been shown to be catalyzed by amino acids or by phosphatidylethanolamine (36). The demonstrated partitioning of the alkanals between water and octanol, corresponding to partioning between membrane and serum, suggests a mechanism, in which peroxidation of the phospholipids in membranes yield alkanals, which are converted to α,β-unsaturated aldehydes in the lipid/water interface catalyzed by phosphatidylethanolamine in the membranes, after which these are able to react with available amino groups to form fluorescent condensation products. In this context, it is interesting to note that the fluorescent condensation product has a partition coefficient of 17, which is more similar to the partition coefficient of hexanal than lysine. Hexanal reacts with both the α-amino group, corresponding to the *N*-terminal of proteins, and the ε-amino group of lysine, and since the rates of formation of fluorescent products are not very different, it may be concluded that the ε-amino group plays the major role in the reaction of proteins due to the higher number of these groups. Moreover, alkanals constitute an important source for formation of α,β-unsaturated aldehydes also capable of reaction with sulphydryl groups of proteins (39), resulting in forma-

tion of a thioether linkage from a protein to C-3 of the aldehyde. The unreacted carbonyl group of this conjugate could further react with an amino group forming an unconjugated imine resulting in severe protein damage through a nonfluorescent cysteine-lysine cross-link. In fact, the high reactivity of α,β-unsaturated carbonyls toward thiols, such as glutathione and *N*-acetyl-cysteine, has been demonstrated to block the formation of fluorescent conjugates in mixtures with glycine and 12-keto-oleic acid giving only rise to nonfluorescent products (38). Although less reactive than alkenals and 4-hydroxy-alkenals, the importance of alkanals in the formation of fluorescent products and protein cross-links cannot be neglected as they are formed in significantly higher concentrations during the course of peroxidation of unsaturated lipids.

In conclusion, the present study has shown that the rate of formation of fluorophores from amino groups and aldehydes increases with pH and that the condensation is taking place in the serum phase and that fluorophores subsequently are "extracted" back to the lipid phase, indicating that the formation of blue fluorescent extractables would be tissue-dependent. The fluorescence of extracts is consequently expected to be very heterogeneous, and a complete understanding of the nature of extractable fluorescent lipid oxidation products and lipofuscin fluorescence will depend on a photophysical characterization of the fluorophores involved. When future research has provided this knowledge, it would be possible to analyze for specific fluorophores originating in oxidative transformations and thereby significantly improve the specificity of the fluorescence assay for evaluation of oxidative status.

ACKNOWLEDGMENTS

This research was sponsored by the FØTEK programme through the LMC Center for Advanced Food Studies. The spectrofluorometer was available through a grant from the Danish Technical Research Council, The Danish Agricultural and Veterinary Research Council, and Direktør Ib Henriksens Fond. The authors are grateful to Marianne Olsen and Christina Duedahl for excellent technical assistance.

ABSTRACT: The enzymatic hydrolysis of frying used vegetable oils with different degrees of alteration were measured using porcine pancreatic lipase (acylglycerol acylhydrolase EC 3.1.1.3). Successive frying of potatoes significantly increased the level of total polar lipid content in the palm olein from 9.3 ± 0.1 mg/100 mg oil to 26.4 ± 0.3 mg/100 mg oil after 90 fryings, and from 4.0 ± 0.1 mg/100 mg oil to 27.7 ± 0.3 mg/100 mg oil in sunflower oil after 60 fryings. Triacylglycerol polymers, triacylglycerol dimers, and oxidized triacylglycerols also increased 37-, 7.9-, and 7.5-times in palm olein, respectively, and 56-, 22-, and 4.7-times in sunflower oil, respectively. However, diacylglycerols and free fatty acid levels related to hydrolytic alteration did not increase with the number of fryings in both oils. The substrate concentration in the reactor was determined by calculating the molecular weight of each oil showing a different degree of alteration. We compared the methodology used by us and that used by other authors. The results show that the methods are reproducible and that the values obtained are in concordance with theoretical values. The kinetic parameters apparent Michaelis-Menten constant (K_M^{app}) and apparent maximum velocity of hydrolysis (V_{max}^{app}) were different in unused palm olein (5.1 ± 0.7 and 166 ± 7.6, respectively) than in sunflower oil (2.2 ± 0.3 and 62 ± 2.2, respectively). However, changes in K_M^{app} and V_{max}^{app} were not related to the degree of alteration of the oils.
Lipids 31, 1133–1139 (1996).

Pancreatic lipase—triacylglycerol acylhydrolase (EC 3.1.1.3)—is a key enzyme for the intraluminar digestion of dietary fats. It hydrolyzes long-chain triacylglycerol derivatives into more polar fragments, mainly monoacylglycerols and free fatty acids, which are subsequently absorbed (1,2).

This enzyme shows fatty acyl specificities for chainlength, position, and geometry of double bonds (3). However, little is known about the kinetic behavior of pancreatic lipase toward the thermoxidized fatty acyl components in triacylglycerol molecules.

Deep-fat frying is an important method for preparing food that has become more common in the past few years. Nevertheless, during deep-fat frying the fat employed for this purpose is exposed to agents that cause drastic structural changes in it. Moisture from foodstuffs causes hydrolytic alteration; atmospheric oxygen entering the oil gives rise to oxidation, and the temperature (180°C) at which the operations take place accelerates chemical changes involving the formation of complex reaction products such as triacylglycerol polymers, triacylglycerol dimers, and oxidized triacylglycerols (4–7).

In order to know whether the digestion process of culinary fats is influenced by these collateral products developed during frying, it would be interesting to study whether pancreatic lipase activity is affected by the presence of these alteration products.

Edible oils which have been heated in the presence of air are well known to have less nutritive value than the corresponding fresh oils (8,9). This negative effect has been attributed to the presence of polymers. However, López-Varela *et al.* (10) have shown a similar fat absorption in rats fed a diet containing a high level of thermoxidized sunflower oil than in rats fed the unused oil. At present, it is not well known whether the lower absorption of heated fat is due to deficiencies in the step of enzymatic hydrolysis to reduce molecular weight (MW) of complex glycerides or to difficulties in the absorption of complex fatty acids released by the action of pancreatic lipase. Results obtained on oxidized triacylglycerol monomers indicate that hydroperoxides undergo hydrolysis to the same extent as normal triacylglycerols (11). However, results of Márquez Ruiz *et al.* (12) clearly demonstrate that enzymatic hydrolysis depends on the MW of the glycerides being slower as alteration compound MW increases.

In order to know whether the digestion process of culinary fats is influenced by these collateral products developed during frying, it would be interesting to study whether pancreatic lipase activity is affected by the presence of these alteration products.

Recently, a marked increase in the consumption of palm olein (containing approximately 43% oleate) for frying purposes has been described in Mediterranean countries (13). Economic reasons and the high oxidative stability of palm olein, as described by Gupta (14), are responsible for the use of palm olein for frying and for snack foods.

As far as we know, no work has been done studying the kinetic parameters of thermoxidized palm olein. For this reason, the aims of the present work were (i) to study the thermoxidative alteration of palm olein and sunflower oil (two culinary fats that differ in their fatty acid composition) and (ii) to determine the kinetics of the enzymatic hydrolysis of used frying vegetable oils with different degrees of alteration by porcine pancreatic lipase *in vitro* in order to elucidate the effect of the complex reaction products arising during frying on lipolysis.

MATERIALS AND METHODS

Palm olein was provided by AGRA S.A. (Bilbao, Spain). Refined sunflower oil Koipesol (Córdoba, Spain) and potatoes (Kennebec variety; Galicia, Spain) were purchased at a local store. Silica gel 60 F_{250} (63–200 μm) for column chromatography and silica gel 60 (20 × 20 cm, 0.2 mm layer thickness) for thin-layer chromatography were obtained from E. Merck (Darmstadt, Germany). Triolein, diolein, monoolein, oleic acid, and lipase (EC 3.1.1.3) from porcine pancreas (Type II) were obtained from Sigma Chemical Co. (St. Louis, MO). Polyethylene glycols of different MW (3000, 1500, 1000, 400, and 200) were obtained from Fluka Chemie AG (Buchs, Switzerland). All other chemicals used were of the purest degree available. Aqueous solutions were made with double-distilled water.

Frying performances. The deep-fat frying operations were carried out in domestic electric fryers that contained 3 L of oil. The oil was heated to 180°C (20 min), and then 500 g of potatoes (slices *ca.* 2 mm thick) were fried for 8 min. A total of 90 fryings with palm olein and 60 fryings with sunflower oil, at a rate of 10 fryings per day were carried out. The overall time that the oils were heated throughout the whole experimental period can be estimated as 30 h, in the case of palm olein, and 20 h for sunflower oil. No fresh oil was added at any time. Extensive details of the frying method and the temperature changes have been described previously (7).

Aliquots of 50 mL of the unused oil and the corresponding used oil from different fryings were taken for analysis. All samples were kept at –20°C under an atmosphere of nitrogen until analysis.

Analytical determinations. (i) *Determination of the fatty acid composition of unused oils.* Unused palm olein and sunflower oil were saponified with 0.5 N sodium hydroxide and then methylated following the method suggested by the IUPAC (15). The fatty acid methyl esters of the oils were then analyzed by gas chromatography on a Hewlett-Packard (Palo Alto, CA) 5890 Series II chromatograph fitted with a flame-ionization detector (FID). Analyses were effected on a steel column packed with 10% Supelcoport 2330 (Supelco, Bellefonte, PA) on 100/120 Chromosorb WAW 2 m × 1/8 in. The temperature of the column was held for 8 min at 170°C and then increased to 240°C at 2°C/min. The temperature of the injector was 250°C and that of the detector 280°C. Sample size was 1 μL. The peak areas were measured using a Hewlett-Packard 3396 Series II integrator.

(ii) Oil sample analysis. Oil samples were analyzed throughout the frying operations by a combination of adsorption and size exclusion chromatography, which includes: (a) determination of polar compounds by silica column chromatography, following the method of Waltking and Wessels (16), using a modified proportion of hexane/diethyl ether to fill the column and to elute the nonpolar fraction (7). The efficacy of the separation was then checked by thin-layer chromatography to guarantee the absence of unaltered triacylglycerols in the polar lipid fraction. (b) Distribution of polar compounds by high-performance size-exclusion chromatography (HPSEC). Following the method of Dobarganes *et al.* (6), polar compounds were analyzed in a Waters 501 chromatograph (Milford, MA) with a 20 μL sample loop. A Waters 410 refractive index detector and two 0.01 and 0.05 μm (5 μm particle size) pL gel (polystyrene–divinylbenzene) columns (7.5 × 300 mm) (Hewlett-Packard) connected in series and operated at 40°C were used. High-performance liquid chromatography (HPLC)-grade tetrahydrofuran (THF) served as the mobile phase with a flow of 1 mL/min. Sample concentrations were between 10 and 15 mg/mL in THF. All eluents and samples were precleaned by passing them through a 2 μm filter. The quantity of each compound was calculated as previously described (17).

Determination of average MW of oils. The average MW of unused oils and of the corresponding oils used in different fryings were calculated by a calibration curve using HPSEC (18), which is a valuable technique in providing information about sample complexity, accurate MW, and their distribution patterns. In a size exclusion chromatography column, the analytes are eluted in accordance with their molecular sizes, i.e., hydrodynamic volume in a mobile phase solvent.

HPSEC retention times of standard acylglycerides (triolein, diolein, monoolein, and oleic acid) on two 0.01 and 0.05 μm (5 μm particle size) pL gel (polystyrene–divinylbenzene) (Hewlett-Packard) columns were determined by injecting individual samples with THF as the eluent at a flow rate of 1 mL/min. Calibration curves were fitted with the SIMFIT statistical package (19).

Sample preparation for enzyme assays. The substrate was prepared by emulsifying 7.5 mL oil (palm olein or sunflower oil) and 7.5 mL Tris-HCl buffer 0.01 M (pH 8.3) with 35 mL of emulsifying reagent (20) using an ultrasonic generator (sonifier 450; Branson Ultrasonics Corp., Danbury, CT) equipped with a 10-mm probe. The probe was placed in the bulk of the solution to be emulsified and its output activated at 80 watts for 3 min. The preparation was then left to stand for 1 min. This operation was repeated twice. The emulsifying reagent (1 L) contained glycerol (540 mL), arabic gum

(10 g), NaCl (17.9 g), KH_2PO_4 (0.41 g) and twice distilled water.

Enzyme assays. Titrimetric assay was employed to determine lipolytic activity (21). The acid released in the hydrolysis was continuously titrated at pH 8.3 with the aid of a Metrohm Ltd. pH-stat [Impulsomat 614, Dosimat 665 (with microstirrer) and pH-meter 691] (Herisau, Switzerland). Several NaOH solutions (5 to 50 mM) were used as titrating agents.

The reaction mixture consisted of different amounts of substrate emulsion (10–150 μL), 1 mL of lipase solution (10 mg/mL), and 0.01 M Tris-HCl buffer (pH 8.3) up to 10 mL total volume. In a typical experiment, Tris-HCl buffer (pH 8.3) and substrate emulsion were placed in the 37°C-thermostated cuvette of the pH-stat. The mixture was shaken vigorously for 10 min at 37°C. Stirring rate was adjusted to approximately 1300 rpm. Then, 1 mL of lipase solution (10 mg/mL) in Tris-HCl buffer (pH 8.3) was added. The reaction time was 10 min.

In all cases, lipase activity was measured as initial reaction rates in order to avoid the possible inhibition that might take place due to the appearance of reaction products. The slopes of the initial linear stretch of the kinetic curves were determined graphically. Experiments were performed in triplicate, and relative standard errors were less than 5%. Specific lipase activity was defined as the μmol of free fatty acids released per minute and per mg of crude enzyme.

Statistical analysis. Data from the different oils were compared by one-way analysis of variance of repeated measures, followed by multiple-range analysis.

Curve fitting and statistical treatment of the data from enzyme assays were performed using the SIMFIT package (19). Kinetic behaviour of used and unused oils were considered not statistically different when their confidence limits are to a certain extent overlayed.

RESULTS AND DISCUSSION

Composition of unused and repeatedly fried oils. The total polar lipid contents from palm olein and sunflower oil are shown in Table 1, as a representative measurement of the total alteration in the oils together with the contents of different groups of altered products. In both cases, the results were obtained from unused oil and the corresponding oil used in different fryings.

As may be seen in Table 1, the polar lipid content of used palm olein showed a linear increase throughout the successive fryings of potatoes from 9.3 ± 0.1 mg/100 mg unused oil to 26.4 ± 0.3 mg/100 mg oil after ninety fryings. According to Fedeli (22), the speed of degradation is proportional to temperature and the frying time. Accordingly, the total polar lipid content of sunflower oil increased during frying from 4.0 ± 0.2 mg/100 mg unused oil to 27.7 ± 0.3 mg/100 mg oil after sixty fryings (Table 2).

When the alteration levels produced by frying in both cooking oils were compared (Table 1), despite the higher percentage of total polar lipid content in unused palm olein with respect to fresh sunflower oil, a higher increase in the total alteration percentage was observed in sunflower oil as compared to palm olein (60 fryings vs. 90 fryings, respectively) for a similar polar content to be reached (approximately 27%).

Sunflower oil has a higher unsaturated fatty acid content than palm olein, as may be observed in Table 2. These results are in agreement with those reported by other authors (23).

In this sense the lower alteration in palm olein as compared to sunflower oil after a similar number of fryings, in accordance with several authors (24–26), indicates that alterations in used frying fats are related to their degree of unsaturation as well as the heat treatment. The results show that palm olein exhibits a unique stability in frying applications.

The polar fraction of unused and used palm olein was further examined by HPSEC to investigate thermooxidative and hydrolytic alterations in the frying oil.

Quantitation of the different groups of alteration compounds in palm olein and sunflower oil, respectively, is shown in Table 1. As can be seen, triacylglycerol polymers, triacylglycerol dimers and oxidized triacylglycerols, which involve thermooxidative alteration, increased throughout the fryings in both culinary oils, reaching higher contents in sunflower

[a]Values are means of three samples ± SD expressed in mg/100 mg oil. Values in the same column bearing a common letter are not significantly different. TG, triacylglycerols; DG, diacylglycerols; MG, monoacylglycerols; FFA, free fatty acids; ANOVA, analysis of variance; NS, not significant.

TABLE 2
Major Fatty Acid Composition (%) of Unused Palm Olein and Sunflower Oil[a]

Fatty acids	Palm olein	Sunflower oil
$C_{14:0}$	1.10 ± 0.04	—
$C_{16:0}$	38.60 ± 0.40	6.76 ± 0.02
$C_{18:0}$	4.02 ± 0.01	3.71 ± 0.07
$C_{18:1}$	44.90 ± 0.20	32.52 ± 0.04
$C_{18:2}$	10.30 ± 0.40	55.55 ± 0.09

[a]Mean of three samples ± SD.

oil. This is due to the higher content of unsaturated fatty acids in sunflower oil as compared with palm olein (see Table 2) and it is responsible for higher stability in palm olein when heated or oxidized.

Furthermore, hydrolytic reactions did not increase during consecutive fryings of potatoes in palm olein as shown in Table 1, because diacylglycerols, monoacylglycerols, and free fatty acids remained at similar levels throughout the fryings. However, the diacylglycerol content in sunflower oil increased slightly; by contrast, free fatty acid contents remained unchanged throughout the successive fryings (Table 1).

The above results clearly indicate that in deep-fat frying of potatoes thermooxidative reactions take place preferentially over hydrolytic reactions. It can be also concluded that, in general, discontinuous and successive fryings of potatoes increase the degree of polymerization of culinary fats. These results are in agreement with those reported by several authors (27,28).

Average MW of unused and repeatedly heated frying oils. In order to carry out a study on the pancreatic lipase activity in several unused and used frying oils, we needed to establish in some way the substrate concentration in the reactor. We therefore addressed the problem of calculating the MW of each unused and fried oils showing a different degree of alteration. The method used was to perform calibration curves with standards on HPSEC.

The calibration curves of retention times (r_t) vs. log MW are shown in Figure 1.

The corresponding equation for standard acylglycerols was:

$$\log MW = 6.87 - 0.30\, r_t \qquad [1]$$

with a correlation coefficient of $r = -0.998$. However, the lack of acylglycerol standards with a higher MW than triacylglycerols (>900) prevents the use of this equation to calculate the MW of the compounds with different degrees of polymerization after frying. Consequently, a calibration curve (Fig. 1) was made up using polyethylene glycol (PEG) standards of various MW (3000, 1500, 1000, 400, and 200) (18). The corresponding equation was:

$$\log MW = 6.53 - 0.26\, r_t \qquad [2]$$

with a correlation coefficient of $r = -0.999$. When this calibration Equation 2 was applied to confirm the MW of the acylglycerol standards, significant differences were observed; these were higher than the expected values. This suggests that a certain interaction must take place between the mobile phase and the acylglycerols (18). Therefore, Equation 2 may not be applied when calculating the MW of acylglycerols due to their different chemical properties with respect to PEG, which induces slight differences in their r_t. This was demonstrated by statistically comparing Equation 1 and Equation 2 which proved to be significantly different (ANOVA of regression coefficient; $P < 0.001$). Accordingly, calculation of the MW of the different compounds with different degrees of polymerization by extrapolation to Equation 1 affords a lower error than Equation 2 for the above indicated reasons. Equation 1 was therefore applied to calculate the MW of the compounds of the thermooxidized oils.

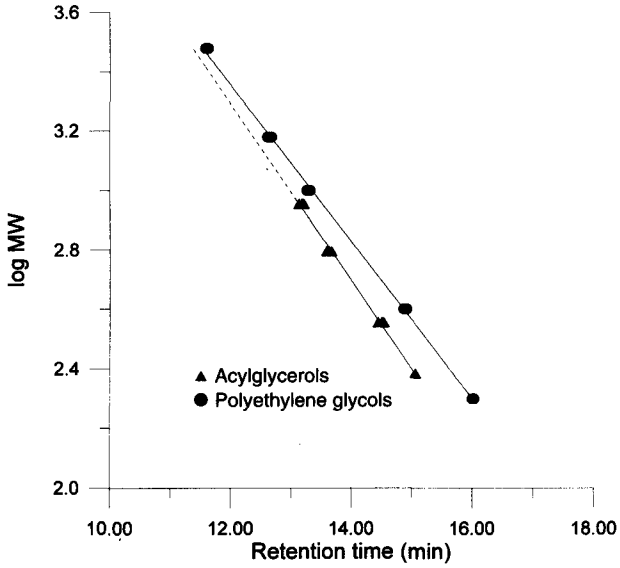

FIG. 1. Determination of molecular weights (MW) of oils. Calibration graph using acylglycerols (▲) and polyethylene glycols (●) as standards. (—) corresponds to computer fitting of the data to linear equation. (---) corresponds to the estimated linear equation for acylglycerols with MW between 900 and 3000.

Table 3 gives the estimated average MW of unused palm olein and sunflower oil as 855 and 865, respectively. Likewise, Table 3 offers the estimated average MW of each of the different samples of palm olein and sunflower oil after frying employed as substrates for porcine pancreatic lipase. As can be seen in this table, the average MW of culinary fats increased throughout the different fryings. This might be related to the formation of high MW compounds, such as triacylglycerol dimers and polymers.

Activity of pancreatic lipase against unused and repeatedly fried oils. To establish whether the alteration products arising during the frying process might affect pancreatic lipase activity among its natural substrates, enzymatic activity was measured in sunflower oil and palm olein from different fryings. In an attempt to quantify whether the kinetic behav-

TABLE 3
Average Molecular Weights of Palm Olein and Sunflower Oil, Unused and After Fryings, Determined by High-Performance Size-Exclusion Chromatography

	Number of fryings	Average molecular weight
Palm olein	0	855
	60	905
	90	951
Sunflower oil	0	865
	30	943
	60	1005

ior is influenced by frying, $v - [S]$ studies where $v - [S] = v$ vs. $[S]$; where v is the initial velocity in μmol/min · mg enzyme and $[S]$ is substrate concentration is mM were performed and the corresponding kinetic parameters were calculated. As an example, the corresponding study to palm olein and sunflower oil after sixty and thirty fryings both showing a similar degree of alteration [around 18% (Table 1)] is shown in Figure 2.

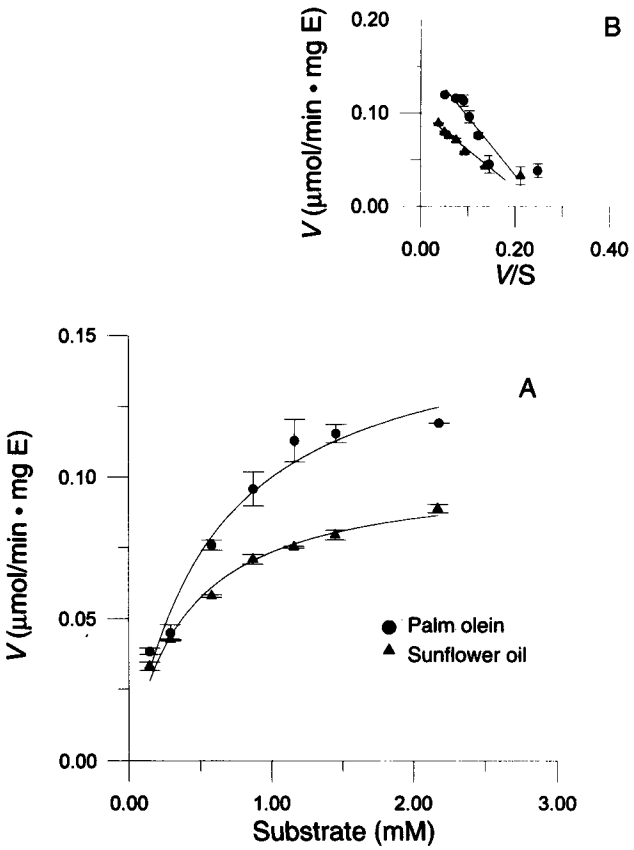

FIG. 2. (A) Activity of pancreatic porcine lipase toward palm olein (●) and sunflower oil (▲) both with approximately 18% of polar compounds (after sixty and thirty fryings, respectively). Conditions were: substrate ranging from $1.5 \cdot 10^{-1}$ mM to 2.2 mM, Enzyme = 1 mg/mL, 0.01 M Tris-HCl buffer (pH 8.3), T = 37°C. Solid line corresponds to computer fitting of the data to the Michaelis-Menten equation, and error bars refer to 95% confidence limits using the corresponding Student's t. (B) The same results under the Eadie-Hofstee plot.

Figure 2A shows that in both cases hydrolysis corresponds to a Michaelis-Menten saturation kinetic behavior, in agreement with the straight line observed in the Eadie-Hofstee plot (Fig. 2B). Each data set was fitted to the Michaelis-Menten equation by nonlinear regression and the corresponding V_{max}^{app} and K_M^{app} were estimated.

With a view to comparing the effect of the frying process of oils on the Michaelis-Menten parameters, Table 4 was constructed with the respective parameters.

As can be seen in Table 4 for palm olein, the K_M^{app} and V_{max}^{app} values did not show a clear relationship with the number of fryings, and therefore with the content of alterated compounds in the oils. Results of K_M^{app}/V_{max}^{app} suggest that within the range of our study, the enzymatic hydrolysis catalyzed by porcine pancreatic lipase in palm olein is not deeply modified by compounds of higher polarity (oxidized triacylglycerols) or high MW (triacylglycerol dimers and polymers). The new compounds yielded in oils during the culinary processes induced changes that did affect interphase quantity and quality.

Hydrolysis of alteration products by porcine pancreatic lipase has already been described by other authors. In this sense, Miyashita *et al.* (11) showed that porcine pancreatic lipase is not inactived in the presence of monohydroperoxides and that the hydrolysis preferentially takes place in monohydroperoxide fatty acids instead of nonoxidized fatty acids located in the same triacylglycerol position. Later, Henderson *et al.* (29) concluded that the high MW polymers of triacylglycerols present in oxidized fish oils can be hydrolyzed by pancreatic lipase *in vitro*. By contrast, authors such as Yoshida and Alexander (30) report that the lower the degree of enzymatic hydrolysis, the higher the complexity of the isolated fraction. Similarly, Márquez-Ruiz *et al.* (12) have demonstrated that the enzymatic hydrolysis of olive oil heated at 180°C depends on the MW of the glycerides, being slower as the MW of alteration compounds increases. Furthermore, it has been shown (31) that the polymers formed in fried oils have surfactant properties. Consequently emulsions with higher surfactant contents are more stable and their interphase surface is larger.

According to the above results, the alterations obtained after frying in palm olein induce different effects which may enhance or interfere with enzymatic hydrolysis. The possibility of which all these effects are balanced could be responsible for not clear and relevant changes on the kinetic parameters when studying various palm olein and sunflower oil samples presenting diverse alteration degrees, as it has been observed in this work (Table 4). Using sunflower oil as a substrate for porcine pancreatic lipase, although significant, no relevant changes in the kinetic parameters K_M^{app} and V_{max}^{app} of the catalytic process were induced by the increased alteration resulting from successive fryings (Table 4). These results are thus in agreement with these obtained for palm olein (Table 4).

On comparing the kinetic parameters obtained in the hydrolysis of palm olein and sunflower oil (Table 4), both K_M^{app}

TABLE 4
Kinetic Parameters for the Hydrolysis of Unused Palm Olein and Sunflower Oil and After Being Used in Successive Fryings of Potatoes Catalyzed by Pancreatic Porcine Lipase[a]

Oil	Number of fryings	K_M^{app} (mM) · 10	V_{max}^{app} (μmol/min · mg E) · 10^3	K_M^{app}/V_{max}^{app}
Palm olein	0	5.1 ± 0.7[a]	166 ± 7.6[a]	3.07 ± 0.56[a,b]
	60	5.9 ± 1.0[a]	159 ± 9.7[a]	3.71 ± 0.85[a]
	90	5.3 ± 0.9[a]	226 ± 14[b]	2.35 ± 0.54[b]
Sunflower	0	2.2 ± 0.3[a,b]	62.0 ± 2.2[a,b]	3.55 ± 0.61[a,b]
	30	3.9 ± 0.4[b,b]	102.0 ± 3.0[b,b]	3.82 ± 0.50[a]
	60	2.1 ± 0.4[a,b]	76.1 ± 3.2[c,b]	2.76 ± 0.64[b]

[a]Kinetic values for the same oil bearing different letter are significantly different.
[b]Significant respect to palm olein from the same number of fryings.

and V_{max}^{app} were higher in palm olein than in sunflower oil, regardless of the degree of alteration. The lower K_M^{app} value obtained with sunflower oil points to the higher enzymatic affinity of pancreatic lipase for this substrate as compared to palm olein, although the higher V_{max}^{app} value with palm olein showed a higher efficiency in hydrolyzing this oil. These differences are due to the different fatty acid composition in both culinary fats since all assays were performed under identical experimental conditions. Table 3 shows the fatty acid composition of both oils. Palm olein has a higher content of palmitic acid ($C_{16:0}$) and oleic acid ($C_{18:1}$) but a lower content of linoleic acid ($C_{18:2}$) as compared to sunflower oil. The differences in hydrolysis could be due to the oleic acid content since several authors have concluded that oleic acid is released with the highest relative speed (32).

To summarize, in the deep-fat frying of potatoes, thermooxidative reactions preferentially take place over hydrolytic reactions and consequently the degree of polymerization of culinary fats is increased. This originates an increase in the average MW of these oils. The methodology proposed by us is appropriated for calculating the MW of heat-oxidized oils. The alteration products arising during the frying process would not greatly affect the enzymatic hydrolysis, given by the apparent K_M and V_{max} values, of the triglycerides in oils.

Chronic Free Fatty Acid Infusion in Rats Results in Insulin Resistance But No Alteration in Insulin-Responsive Glucose Transporter Levels in Skeletal Muscle

[a]Laboratoire de Physiopathologie de la Nutrition, CNRS U 307, Université Paris 7, 75251 Paris Cedex 05, France and [b]Harvard Thorndike Laboratory of Beth Israël Hospital, Harvard Medical School, Boston, Massachusetts 02215

ABSTRACT: To investigate the mechanism by which free fatty acids (FFA) affect glucose uptake, we studied the effect of chronic elevation (24 h) of plasma FFA in rats on whole body glucose disposal and glucose utilization index (GUI) in the basal state and under a euglycemic hyperinsulinemic clamp in relation to the amount of insulin-responsive glucose transporter (IRGT, i.e., GLUTU) protein in different muscles (oxidative and glycolytic) and adipose tissue. Infusion of Intralipid in the basal state led to a ~40% increase in whole body glucose uptake and a ~250% increase in GUI in adipose tissue as compared to control rats. There was no change in the amount of IRGT protein in any of the muscle types whereas in fat depots it was either unchanged or decreased. Under moderate or supraphysiological hyperinsulinemia, increment of whole body glucose disposal was significantly lower in Intralipid perfused rats when compared to controls (~110 μU/mL: 0.7 ± 0.1 vs. 1.3 ± 0.1 mg/min, $P < 0.02$; ~1000 μU/mL: 3.0 ± 0.2 vs. 3.9 ± 0.4 mg/min, $P < 0.02$). Under moderate hyperinsulinemia stimulation, GUI was significantly reduced in different muscles and adipose tissue as compared to controls. We conclude that peripheral insulin resistance which occurs after elevation of plasma FFA levels does not seem to be explained by changes in the amount of IRGT protein in either oxidative or glycolytic skeletal muscle. Thus fatty acid infusion appears to be associated with a defect in IRGT translocation to the plasma membrane, fusion with the membrane, or intrinsic activity.
Lipids 31, 1141–1149 (1996).

Over 25 years ago, Randle and his associates (1) demonstrated an inhibitory effect of free fatty acids (FFA) on glucose uptake in the perfused rat heart. Recently several groups have examined glucose-fatty acid interactions in humans (2–7) and rabbits (8) during hyperinsulinemia when most of the glucose uptake occurs in muscle (8). Some found inhibitory effects of lipid on whole body glucose uptake (5,6,9) but others did not (2–4,7). It was also observed that high FFA concentrations can even stimulate glucose uptake in the presence of hyperinsulinemia and euglycemia in rat skeletal muscle (10). Discrepancies between these studies could partly be explained by methodological differences. For example it was found that, in humans, the metabolic competition between FFA and glucose is very much time-dependent (4).

Assuming that FFA could interfere with glucose utilization, several investigators have attempted to explain the cellular mechanism by which FFA inhibit glucose uptake in skeletal muscle *in vivo* and *in vitro*. In humans, it was shown that lipid infusion reduced glucose uptake by interfering with glycogen synthesis, but it failed to increase citrate and glucose-6-phosphate concentrations (11). This latter observation does not support the Randle hypothesis. When the effect of FFA had been studied *in vitro*, it was shown that palmitate inhibited insulin-stimulated glucose transport only in fibers with a high respiratory capacity (9). It was suggested that palmitate could have a direct effect on the plasma membrane and could exert its inhibitory effects *via* alteration of the activity of the insulin-sensitive glucose transporter (IRGT, i.e., glucose transporter 4). Thus the interaction between FFA and glucose appears complex and seems to depend on the experimental conditions.

As previous experiments failed to demonstrate an inhibitory effect of fatty acids on insulin-mediated glucose uptake over a short period of time (2–4 h), we investigated whether a prolonged elevation (24 h) of FFA levels, which is often encountered in physiological or physiopathological situations, could solve the controversy over the issue of FFA/glucose interaction in rats. Furthermore we attempted to clarify which step of glucose uptake could be affected during hyperlipidemia by studying possible changes in expression of IRGT protein in oxidative and glycolytic muscle fibers.

MATERIALS AND METHODS

Animals. Three-month-old female Wistar rats weighing 200–220 g were used. They had free access to water and laboratory chow pellets (UAR 113, Villemoisson, France) containing 7% palmitic acid, 0.5% palmitoleic acid, 3% stearic

acid, 15% oleic acid, and 20% linoleic acid (calorific value 5 Kcal/kg). The technique for long-term infusion in unrestrained rats was used as described previously (12). The infusion period started on day 3 after surgery and lasted 24 h. Circulating concentrations of FFA were initially raised by a priming bolus of heparin (100 U) followed by a constant infusion of a mixture of a 10% triglyceride emulsion (Intralipid KabiVitrum, Helsingborg, Sweden; 2000 Kcal/L; 10% soybean oil containing 10% palmitic acid, 4% stearic acid, 23% oleic acid, 53% linoleic acid, 8% linolenic acid, 0.60 g lecithin, and 1.25 g glycerol per 100 mL and heparin 20 U/mL) at a rate of 50 μL/min/kg (=Intralipid rats). Control rats were infused with a saline solution. Basal state was defined as the end of saline or Intralipid infusion period (Fig. 1).

Glucose turnover rate. Measurements were performed at time 24 h while maintaining saline and Intralipid infusion (i.e., in the basal state) and during a euglycemic hyperinsulinemic clamp (protocol 1; Fig. 1). Rats were deprived of food for 4 h, i.e., under conditions of negligible glucose delivery by the gut (13). Rats were anesthetized with pentobarbital sodium (50 mg/kg i.p.). A catheter was inserted into the left carotid artery for blood sampling. Infusions (insulin, labeled and unlabeled glucose) were carried out using butterfly needles that were inserted in the saphenous veins.

Experiments consisted of a tracer ([3-^{3}H] glucose) equilibration period (−50 to −15 min), a basal period (−15 min to 0 min), and a euglycemic clamp study period (0 to 90 min). A priming dose of [3-^{3}H] glucose (4 μCi) was injected through the saphenous vein at −50 min followed by a continuous infusion at a rate of 0.2 μCi/min throughout the study. In Intralipid rats, Intralipid infusion was maintained throughout the study period (−50 to 90 min). Blood samples were drawn at −15, −10, and 0 min during the basal period and at time 70, 80, and 90 min during the steady-state euglycemic clamp for glucose disposal rate evaluation.

Euglycemic clamp. Before insulin infusion, two sets of blood samples were drawn for determinations of basal blood glucose, plasma insulin, and plasma FFA levels. A priming dose of insulin (20 mU; pork monocomponent insulin; Novo, Copenhagen, Denmark) dissolved in isotonic saline was injected through a saphenous vein followed by a continuous infusion of insulin (either 0.4 or 3 U/kg/h) at a constant rate of 20 μL/min.

During the glucose clamp, blood was sampled every 5 min to determine arterial glycemia and to adjust the rate of unlabeled glucose infusion to maintain the blood glucose concentration at the level measured in the basal state (i.e., 24 h after saline or Intralipid infusion). The euglycemic clamp was attained within 30–40 min and maintained for 60 min thereafter. Steady-state specific glucose radioactivity and plasma glucose and insulin concentrations were determined during the last 20 min of the clamp. Two additional blood samples were drawn for FFA determinations.

At completion of the euglycemic insulin clamp, animals were killed after i.p. administration of pentobarbital (150 mg/kg). The soleus (oxidative), gastrocnemius (glycolytic and oxidative separately), and tibialis anterior (glycolytic) muscles as well as white adipose tissue (periovarian and inguinal) and brown adipose tissue (interscapular site) were obtained for quantification of glucose transporter, IRGT. These muscles and the liver were also used for glycogen content determinations. All these parameters were also studied in the basal state (animals were killed prior to starting the euglycemic clamp). All tissues were immediately frozen at −80°C.

Glucose utilization index (GUI). GUI is defined as the amount of 2-deoxy glucose uptake by an individual tissue per unit of time. To determine the GUI, a tracer dose of 2-deoxy [1-^{3}H] glucose (25 Ci/mmol; 25 μCi/rat; CEA, Saclay, France) was injected in 100 μL of 0.9% NaCl as a bolus through a saphenous vein in animals submitted or not to an Intralipid infusion during 24 h (protocol 2; Fig. 1). At 1, 3, 5, 10, 20, 40, and 60 min after the injection, blood was sampled *via* the arterial catheter for determination of 2-deoxy [1-^{3}H] glucose radioactivity and blood glucose concentrations. Rats were killed by cervical dislocation 60 min after the 2-deoxy [1-^{3}H] glucose injection, and tissues were immediately removed and their 2-deoxy [1-^{3}H] glucose-6-phosphate contents were determined as described previously (14). Glucose utilization was then calculated, except that the value was not corrected by the discrimination factor (lumped constant) for 2-deoxyglucose in glucose metabolic pathways. Therefore the results are expressed as an index of glucose utilization.

Analytical methods. Blood glucose was determined by the glucose oxidase technique using a glucose analyzer (YSI, Yellow Springs, OH). For the assay of [3-^{3}H] glucose radioactivity, blood samples were deproteinized with $Ba(OH)_2$ and $ZnSO_4$, and the supernatant was evaporated to dryness at 50°C to remove tritiated water. The dry residue was dissolved in 0.5 mL water to which 10 mL scintillation solution were added (Aqualuma plus; Lumac, Arnhem, The Netherlands), and radioactivity was determined in a Packard Tri-Carb 460C liquid scintillation system. Plasma insulin concentrations were determined by a radioimmunoassay kit (SB-INSI-ORIS, Gif-sur-Yvette, France). FFA concentrations were measured using an enzymatic assay (NEFA-C test; Wako Chemicals, Neuss, Germany). Protein was assayed by Lowry's method

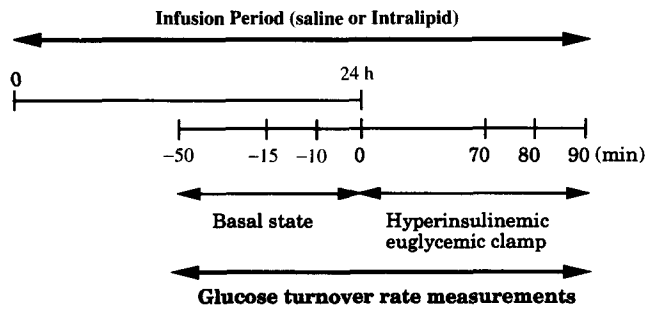

FIG. 1. Design of studies of measurements of glucose turnover rate (protocol 1) and glucose utilization index (protocol 2) in basal state and during the euglycemic/hyperinsulinemic clamp in rats.

(15), and glycogen concentrations in the liver and muscles were determined according to the technique of Roehrig and Allred (16). Muscle glycogen determinations required a previous digestion of the tissue (~50 mg) in NaOH (1 N) at 60°C for 1 h.

Homogenates from hindlimb muscles and adipose tissue. Each muscle was first homogenized with a Polytron (Janke & Kunkel, Staufen, Germany) in ice-cold phosphate-buffered saline (PBS; 0.9% NaCl, 20 mM KCl, 0.1 M phosphate buffer, pH 7.4) containing 1% Triton X-100 (Warren, MI). Homogenization was then completed with a glass homogenizer (Kontes, Hayward, CA) by 30 strokes. White and brown adipose tissue were homogenized in ice-cold 1 mM EDTA, 20 mM Tris/HCl, and 0.25 mM sucrose (pH 7.4).

Quantification of glucose transporter protein by immunoblotting. Equal amounts of proteins (100 µg) were solubilized in Laemmli buffer and subjected to a 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis. The proteins were then electrophoretically transferred to nitrocellulose membranes (BA 85; Schleicher and Schuell, Dassel, Germany). Protein markers (Rainbow; Amersham, Bucks, United Kingdom) were used as molecular weight standards and also to assess the efficiency of the transfer. The membranes were blocked with nonfat dry milk (Carnation, Los Angeles, CA) in Tris (hydroxymethyl) aminomethane (Tris)-buffered saline (pH 7.6) with 0.1% Tween 20 tris buffer saline Tween 20 (TBST) and incubated at the recommended dilution of antibodies in the same solution washed three times in TBST, and reacted with ^{125}I-anti-mouse IgG (Amersham, Bucks, United Kingdom) for 1 h. The filters were again washed three times with TBST and exposed to Hyperfilm MP (Amersham) then quantified by scanning densitometry (connected to a Macintosh microcomputer; Hoeffer, San Francisco, CA). The antibody used was 1F8 (East-Acres Biological, Wilmington, MA) which is specific for the IRGT-protein.

Calculations. Glucose kinetics. In the basal steady state, the rate of glucose appearance (Ra, endogenous glucose production) was equal to the glucose disposal rate (Rd, glucose utilization). Rd was calculated according to the formula Rd = Ra = [3-^{3} H] glucose infusion rate [disintegrations per minute (dpm/min)] divided by blood glucose specific activity (dpm/mg), during the last 20 min of the glucose clamp (50–70 min after the onset of insulin infusion).

Results are given as means ± SE. Statistical analyses were performed with the unpaired Student's *t*-test.

RESULTS

During the lipid infusion, the mean food intake was significantly decreased compared with controls (11.8 ± 1.2 vs. 18.3 ± 2.3 g/day $P < 0.001$). In the Intralipid group, the daily energy intake was about 52.2 Kcal (14.4 and 37.8 Kcal from lipid and chow pellets, respectively). In control rats it was about 57.6 kcal. Total energy intake did not differ significantly between groups. The daily lipid intake was about 0.8 and 2.0 g in control and Intralipid rats, respectively.

It should be emphasized that a third group of rats was studied in postabsorptive state without previous saline infusion, i.e., 4 h after the food was withheld. All the parameters studied were not statistically different from those measured in the control group, thereby showing the absence of effect of saline infusion (data not shown).

Glucose, insulin, and FFA levels. In the basal state, i.e., 24 h after saline or lipid infusion, arterial blood glucose concentrations were 100 ± 1.6 and 102 ± 1.7 mg/dL, and insulin levels were 23.6 ± 1.6 and 24.7 ± 2.6 µU/mL in control and Intralipid rats, respectively. During the glucose clamp study, plasma insulin concentrations were raised to 107.1 ± 8.3 and 139.5 ± 15.0 µU/mL [nonsignificant (NS)] with a rate of 0.4 U/kg/h and to 1105 ± 115 and 1018 ± 124 µU/mL (NS) with a rate of 3 U/kg/h in control and Intralipid rats, respectively.

In the basal state, the arterial concentration of FFA was significantly higher in Intralipid than in control rats (Fig. 2). During hyperinsulinemia (0.4 U/kg/h), FFA levels in Intralipid rats remained similar to that measured in the basal state (0.76 ± 0.08 mM) whereas they were significantly lower (0.36 ± 0.03 mM $P < 0.001$) when infusing 3U/kg/h. In control rats, FFA concentrations were significantly decreased at both infusion rates of insulin (0.4 U: 0.23 ± 0.04 mM $P < 0.05$ and 3 U: 0.12 ± 0.02 mM $P < 0.001$) compared with basal state.

Glucose disposal rate. In the basal state, the glucose disposal rate was significantly higher in Intralipid than in control rats (Fig. 3A). During moderate hyperinsulinemia (~100 µU/mL), increment in glucose utilization was significantly lower in Intralipid than in controls (Fig. 3B). Under marked hyperinsulinemia (~1000 µU/mL), increment in glucose utilization averaged 3.0 ± 0.2 and 3.9 ± 0.4 mg/min ($P < 0.02$; Fig. 3B) in Intralipid and control groups, respectively.

Figure 4 depicts changes in glucose infusion rates during the glucose clamp. Under moderate (Fig. 4A) or marked (Fig. 4B) hyperinsulinemia, and over the time interval 30–90 min, the rate of glucose infusion was significantly lower in Intralipid rats than in controls. At completion of the two glucose clamp studies, the hepatic glucose production was totally suppressed in controls whereas it was decreased by ~50% in Intralipid rats (data not shown).

GUI. In a first group of rats, we measured glucose transport in individual tissues in order to know which ones had decreased glucose utilization after Intralipid infusion. In the basal state, i.e., after completion of saline and Intralipid infusions, the GUI of oxidative muscles (soleus and oxidative gastrocnemius) as well as glycolytic muscles (tibialis anterior and glycolytic gastrocnemius) were similar both in control and Intralipid rats (Fig. 5). In contrast, the GUI in white adipose tissue was more than two times higher ($P < 0.001$) in Intralipid than in control rats both in subcutaneous (inguinal fat pad) and profound (periovarian fat pad) locations. Note that GUI in brown adipose tissue was about five times higher than that measured in white adipose tissue, and it was unaffected by Intralipid infusion.

In a second group of rats, a euglycemic clamp was performed after 24 h while maintaining the Intralipid infusion.

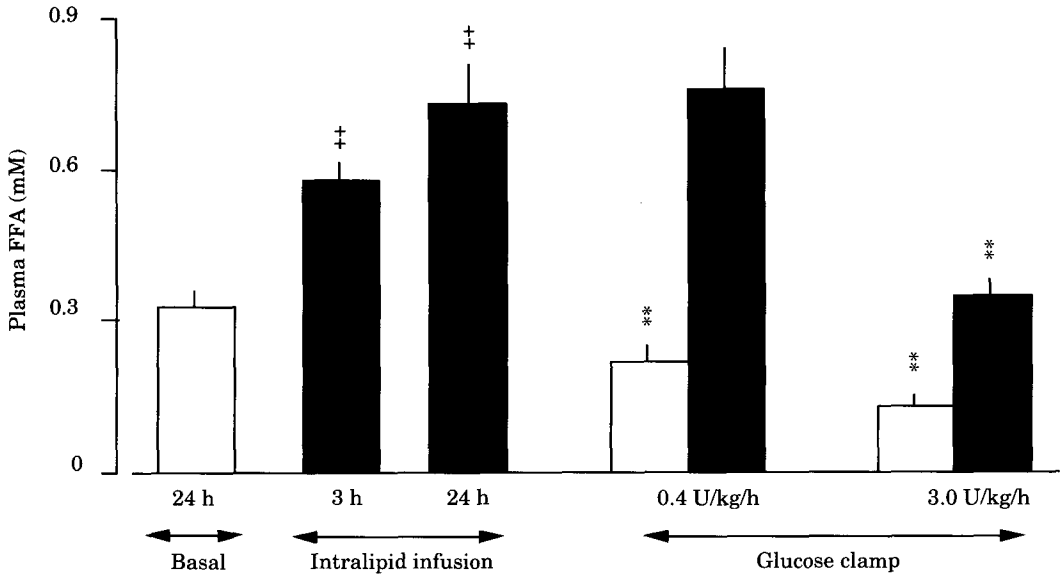

FIG. 2. Plasma free fatty acid concentrations in rats in the basal state, after saline (□, $n = 15$) or 24 h of Intralipid infusion (■, $n = 12$) and after a euglycemic hyperinsulinemic clamp performed at the end of infusion period. The rate of insulin infusion was either 0.4 or 3.0 U/kg/h, corresponding to plasma insulin levels of ~100 and 1000 μU/mL, respectively. $^{++}P < 0.001$ (Intralipid vs. control in the basal state); $^{**}P < 0.001$ (glucose clamp vs. basal state).

In control rats there was a 2–5-fold stimulation of glucose utilization by insulin in all muscles and fat depots. In contrast, in Intralipid rats, GUI was not significantly increased by insulin either in muscles (oxidative and glycolytic) or adipose tissue when compared to the basal state, indicating that insulin resistance took place in these tissues. With respect to the brown adipose tissue, it displayed a marked stimulation of glucose utilization in both groups, but it was less pronounced in Intralipid rats than in controls (46 ± 8 vs. 176 ± 18 ng/min/mg tissue).

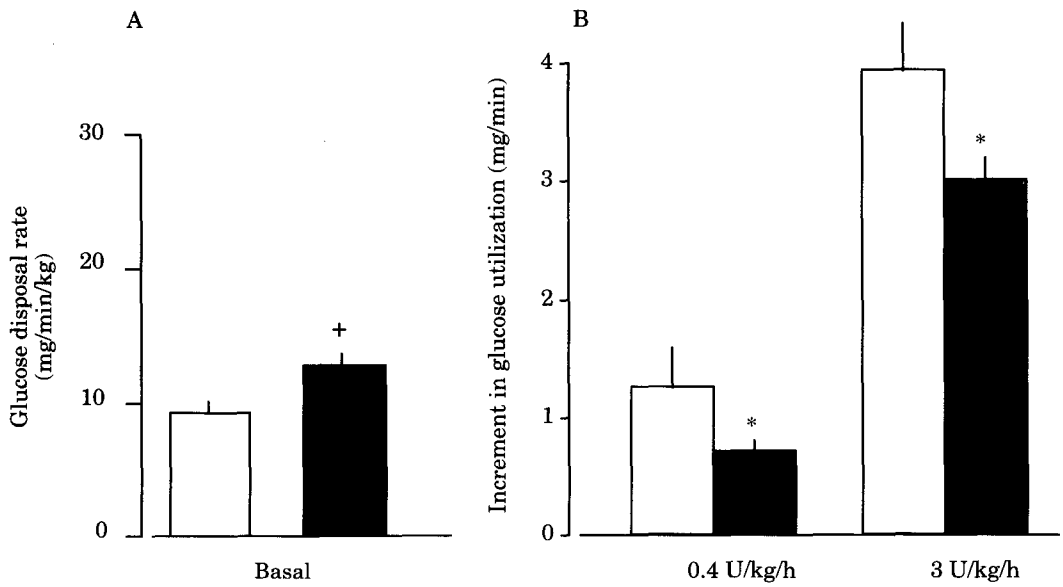

FIG. 3. Glucose disposal rate in rats, in the basal state (A) and increment in glucose utilization after a euglycemic hyperinsulinemic clamp (B). Saline (□, $n = 15$) or 24 h Intralipid infusion (■, $n = 12$). The rate of insulin infusion was either 0.4 or 3.0 U/kg/h, corresponding to plasma insulin levels of ~100 and 1000 μU/mL, respectively. A) $^{+}P < 0.01$ (Intralipid vs. control in the basal state); B) $^{*}P < 0.01$ (Intralipid vs. control after the glucose clamp).

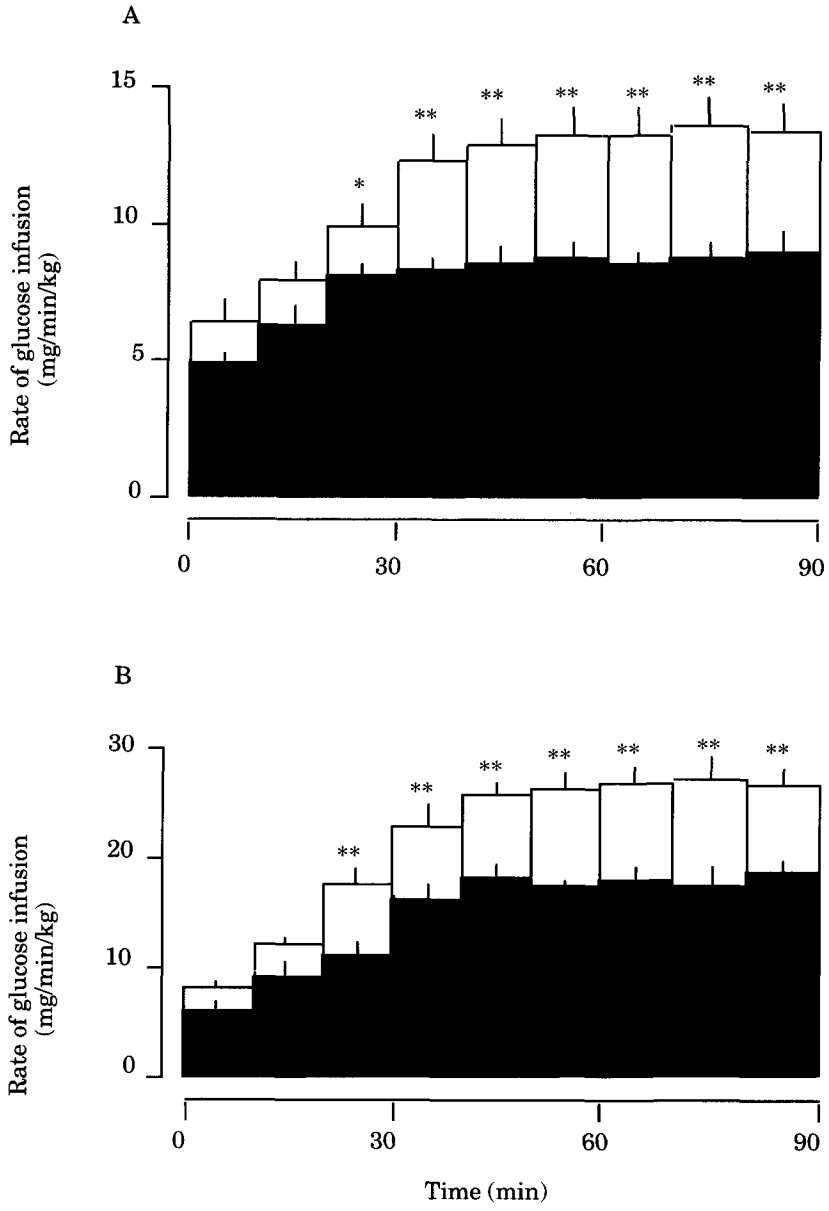

FIG. 4. Rates of glucose infusion during a euglycemic hyperinsulinemic clamp, in control rats (□, $n = 15$) and 24 h after Intralipid infusion (■, $n = 12$). The rate of insulin infusion was either 0.4 U/kg/h (A) or 3.0 U/kg/h (B), corresponding to plasma insulin levels of ~100 and 1000 μU/mL, respectively. $^{*}P < 0.01$, $^{**}P < 0.001$ (control vs. Intralipid).

Muscle and hepatic glycogen content. Lipid infusion significantly lowered hepatic glycogen content (Table 1). In contrast, it did not affect muscle glycogen content, and it was of the same order of magnitude (~4.5–5.0 mg/g) both in glycolytic and oxidative muscles. However when rats were given 11 g of food (restricted) which represents the intake of Intralipid group, without lipid infusion, muscle glycogen content was decreased by about 30% both in glycolytic and oxidative muscles when compared to Intralipid group.

Glucose-transporter concentration. Quantification of IRGT protein by densitometry showed that lipid infusion (basal state) did not affect the amount of transporters in each skeletal muscle type (Fig. 6A and 6B) as well as after moderate or marked hyperinsulinemia (data not shown). It also should be pointed out that the expression of IRGT in oxidative muscles (soleus and oxidative gastrocnemius) was much greater than in glycolytic muscles (tibialis anterior and glycolytic gastrocnemius). The highest expression of IRGT being in the soleus. In white and brown adipose tissue, lipid infusion did not affect the amount of IRGT except in the perirovarian fat pad in which it was significantly decreased ($P <$ 0.001 vs. control, Fig. 6C).

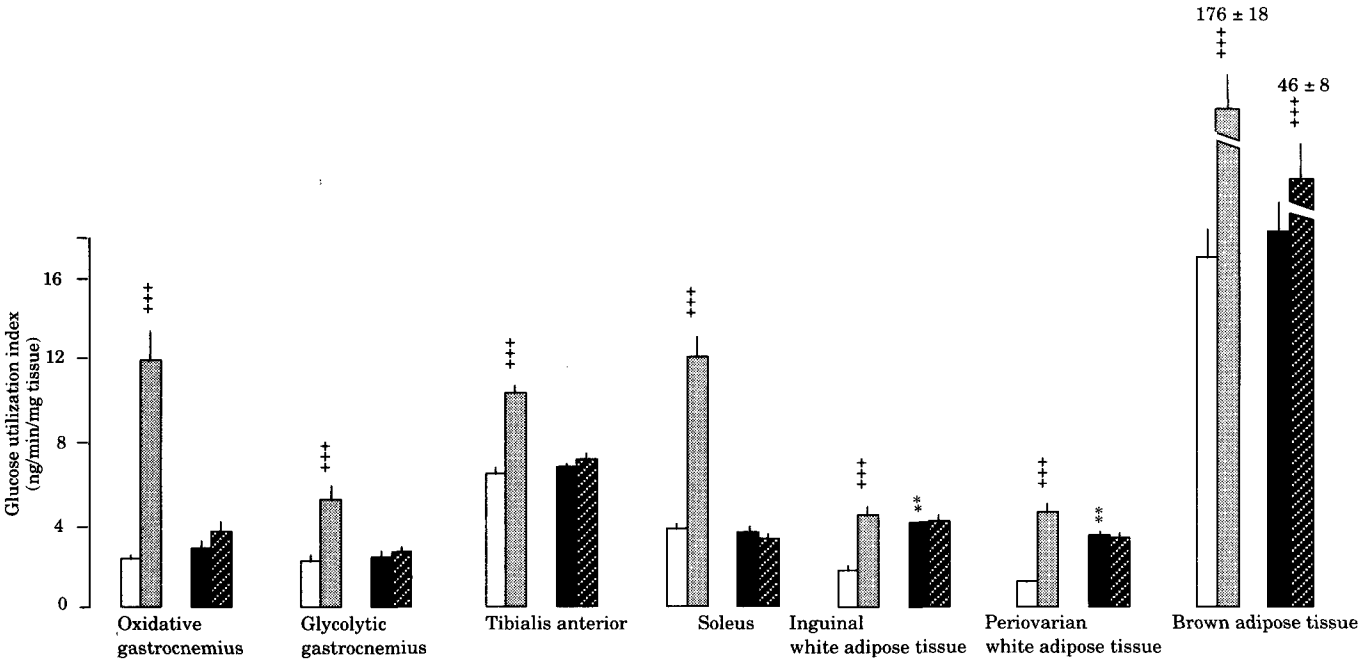

FIG. 5. Glucose utilization index in the basal state, i.e., at the end of saline or Intralipid infusion period (, control rats, $n = 8$; , Intralipid rats, $n = 7$) and during a glucose clamp performed after the end of saline or intralipid infusion period (, control rats, $n = 8$; , Intralipid rats, $n = 9$). $^{**}P < 0.001$ (control vs. Intralipid in the basal state); $^{+++}P < 0.001$ (glucose clamp vs. basal state).

DISCUSSION

The present work demonstrates that chronic elevation (24 h) of plasma FFA levels in rats results in an impaired insulin stimulation of GUI in skeletal muscles and adipose tissue. This defect cannot be attributed to changes in the amount of IRGT protein in skeletal muscles. However, since we measured total amount of IRGT protein (i.e., IRGT localized at the level of plasmic membrane and intracytosolic pool), we cannot rule out that FFA may interfere either with insulin by reducing the recruitment of functional IRGT or with IRGT function once translocated. It is also possible that glucose uptake was affected at a distal site. These unresolved issues need further investigation.

TABLE 1
Liver and Skeletal Muscle Glycogen Content (mg/g of tissue)[a]

	Control	Intralipid	Restricted
Muscles			
Oxidative gastrocnemius	5.01 ± 0.20	4.48 ± 0.30	3.50 ± 0.20*
Glycolytic gastrocnemius	4.77 ± 0.36	4.62 ± 0.30	3.40 ± 0.15*
Tibialis anterior	4.33 ± 0.25	4.76 ± 0.28	3.45 ± 0.20*
Soleus	4.90 ± 0.07	4.67 ± 0.30	3.41 ± 0.10*
Liver	56.30 ± 5.10	4.82 ± 1.13**	—

[a]Animals were perfused with saline (control), triglycerides (Intralipid) or were given 11 g of food which represent the intake of Intralipid group, without lipid infusion (restricted). Liver glycogen content was not measured in restricted rats.
*$P < 0.01$ food-restricted vs. Intralipid.
**$P < 0.01$ Intralipid vs. control.

In vivo and in the postabsorptive state (basal glucose and insulin levels), it seems that interactions between lipid and glucose metabolism operate under a restricted range of experimental conditions since it would be dependent upon FFA concentrations. Thus, in rats, inhibition of muscle glucose uptake occurs in the presence of physiological (moderate) and acute elevation in FFA levels (10). In contrast, it was found that supraphysiological concentrations of plasma FFA stimulate glucose utilization in rat skeletal muscle (10) and in human forearm tissues (17). In the present study, chronic elevation of FFA concentrations within a physiological range significantly increases whole body glucose disposal rate in the basal state.

During Intralipid infusion, enhanced glucose disposal rate occurs without change in blood glucose level. It implies an increase in hepatic glucose production, and it is mainly attributable to the increased gluconeogenesis since the liver is almost depleted in glycogen stores. *In vivo* studies have shown that the rates of FFA/lipid oxidation are positively correlated with the rate of hepatic glucose production (18). *In vitro* studies also demonstrated that the addition of palmitate to hepatocytes stimulates gluconeogenesis (19) and partially inhibits glycolysis (20). Furthermore, increased fat oxidation provides the stimulus for the activation of the key enzymes of gluconeogenesis (21). Taken together these factors may account for most of the increased hepatic glucose production.

In the basal state, FFA increased rather than decreased glucose disposal rate. This is inconsistent with the operation of the glucose–fatty acid cycle. Using the 2-deoxyglucose technique, we showed that the uptake of glucose by different mus-

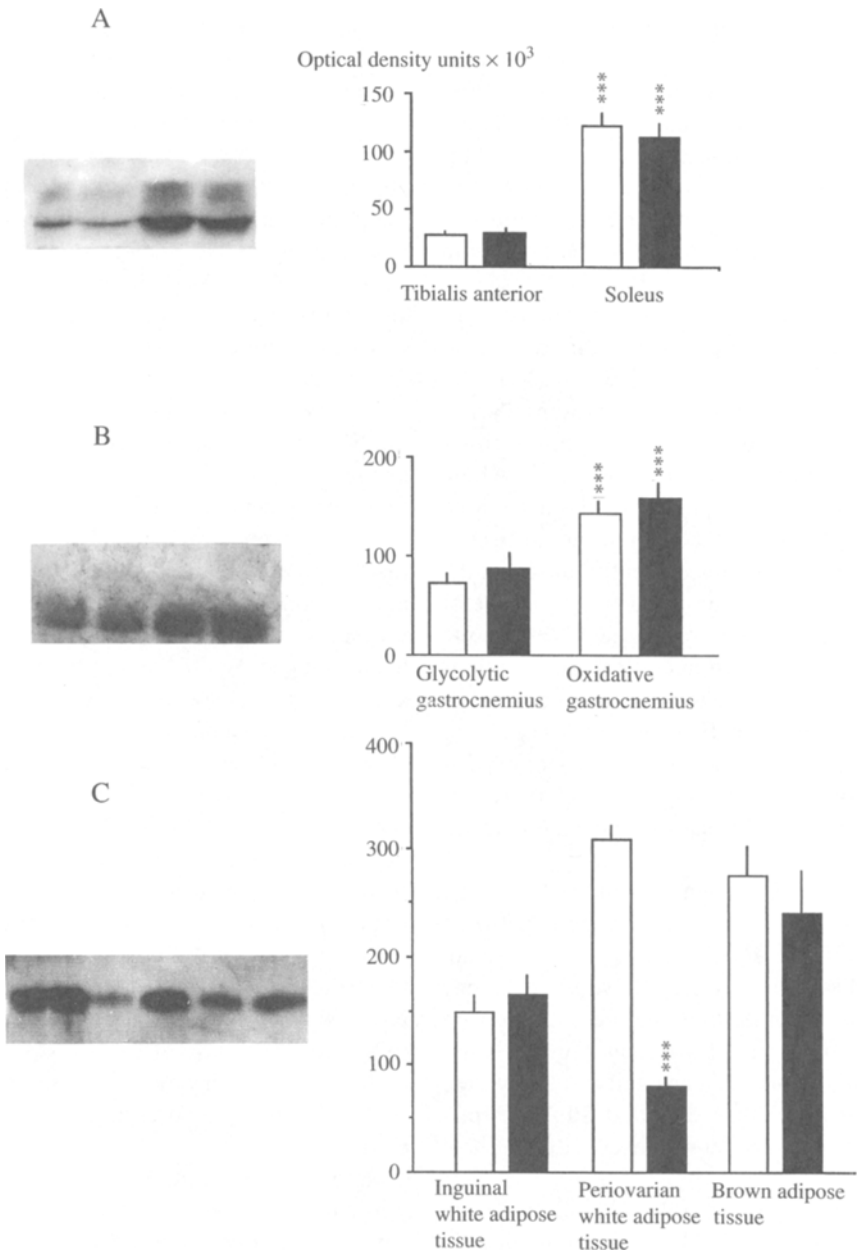

FIG. 6. Effect of Intralipid infusion (basal state) on the amount of IRGT protein in different muscles of the hindlimb and adipose tissue in control (□, $n = 5$) and in Intralipid (■, $n = 5$) rats in the basal state. IRGT protein was determined using a Western blotting protocol and detection of IRGT using a specific anti-serum. (A): ***$P < 0.001$ (soleus vs. tibialis anterior) (B): ***$P < 0.001$ (oxidative gastrocnemius vs. glycolytic gastrocnemius). (C): ***$P < 0.001$ (control vs. Intralipid rats).

cle types was unchanged. This observation implies that other tissues should augment their glucose utilization. Adipose tissue would be a potential candidate because FFA at physiological concentrations have been reported to increase basal glucose transport in isolated rat adipocytes (9,22,23) and *in vivo* when acutely increasing the circulating FFA concentrations in rats (10). In the present study we also found an increased glucose uptake in white adipose tissue (subcutaneous and profound) in Intralipid group as compared to control rats. From these previous studies (9,10), a greater uptake of glucose for reesterification in the face of increased FFA influx would seem the logical explanation for the increase in glucose disposal rate. However a rough estimate of the increment in GUI in white adipose tissue (Fig. 5) indicates that it cannot account for the totality of the increase in glucose disposal rate (Fig. 3). Consequently, it seems logical to suggest that some non-insulin-sensitive tissues also increased their glucose uptake.

Under euglycemic hyperinsulinemic conditions, we con-

firmed that the stimulation of whole body glucose uptake is markedly impaired in the presence of elevated plasma FFA concentrations (3,6,8). These data could be of clinical relevance, particularly in view of the recent demonstration that elevation of blood FFA concentration produced peripheral insulin resistance in healthy volunteers (24) and in noninsulin-dependent diabetic patients (25). Using the 2-deoxyglucose technique, we emphasize that insulin resistance takes place in all insulin-sensitive tissues studied, i.e., both muscles (glycolytic and oxidative) and adipose tissue (white and brown). Similarly, studies carried out on isolated rat adipocytes also demonstrated that prolonged treatment with saturated fatty acids induced insulin resistance (22). In the present work it was unexpected to note that under moderate hyperinsulinemia there was a modest but significant increment in whole body glucose disposal rate whereas there was no detectable stimulation of 2 deoxyglucose uptake in individual tissues studied. Such a discrepancy remains currently unexplained. We can only hypothesize that the discrimination factor (lumped constant) for 2-deoxyglucose in glucose metabolic pathways is lower in Intralipid than in control rats. Previous studies showed that in VMH obese rats the lumped value in white adipose tissue was significantly lower in VMH as compared to control rats (26). If it applies to the present experiment it would mean that insulin stimulation of the 2-deoxyglucose uptake by individual tissues is underestimated in the Intralipid group.

With respect to the muscle glycogen content, we found that elevated FFA level seems to have a "glycogen sparing effect." Thus, in another group of food restricted rats which were not infused with Intralipid but which were allowed to consume 11 g of food as in the Intralipid group, the muscle glycogen content declined by ~30%. Although we cannot precisely determine the mechanism(s) which can account for this finding one can however postulate that elevated FFA inhibits glycogenolysis as has been shown during exercise in skeletal muscle (27).

In parallel with the changes in whole body glucose disposal we studied the amount of IRGT protein in glycolytic and oxidative muscles in the basal state (i.e. after saline and lipid infusion). After saline infusion, expression of IRGT is much greater in oxidative muscles (soleus and oxidative gastrocnemius) than in glycolytic muscles (tibialis anterior and glycolytic gastrocnemius) which is in keeping with previous work (28). When lipid was infused both the expression of IRGT and the GUI did not change in each type of muscle when compared to controls in spite of an increase in whole body glucose uptake. This is in keeping with a recent study that showed that palmitate does not affect glucose transport in either the soleus or epitrochlearis *in vitro* in the absence of insulin (9). Consequently, other tissue(s) could significantly enhance their glucose uptake. White adipose tissue would be involved since its 2-deoxyglucose uptake is increased after Intralipid infusion. However, it is not accompanied by parallel changes in IRGT expression because the amount of transporter is either unchanged (inguinal adipose tissue) or decreased (periovarian tissue). It has been demonstrated that increased glucose transport does not necessarily imply changes in the amount of IRGT in the plasma membranes. Thus, in isolated rat adipocytes, both palmitate and oleate stimulate glucose transport but only palmitate increases the amount of IRGT in the plasma membranes (9,23). This finding points out that the stimulatory effect of oleate on glucose uptake in adipocytes may be mediated by changes in the intrinsic activity of IRGT. In the present work the same conclusion could be extended to the white adipose tissue. However it is also possible that the amount of glucose transporter 1 was increased.

The role of IRGT in the insulin resistance phenomenon has not been clearly established yet. In humans, when inducing an insulin-resistant state by infusion of lipid, there is no relationship between glucose uptake and the content of IRGT in skeletal muscle during 3 h of euglycemia and hyperinsulinemia as well as in the postabsorptive state (29). In animal models it seems that variations in the amount of IRGT protein depends on the way the insulin-resistant state has been induced as well as the type of muscle studied. Thus a four-day hyperinsulinemia imposed on normal rats in the presence of moderate hypoglycemia produced an insulin-resistant glucose transport in several muscles (30) as well as a decrease of the glucose transporter protein in the tibialis (glycolytic muscle) (31). When hyperinsulinemia and hyperglycemia coexist for three days in rats, there is no change in IRGT protein in hindlimb muscle, which suggests that impaired insulin action was probably due to decreased intrinsic activity of the transporter (32). Finally, the insulin-resistance glucose uptake characteristic of obesity and NIDDM cannot be attributed to altered expression of IRGT (33,34).

In summary, chronic elevation of plasma FFA levels results in (i) an impaired insulin stimulation of the GUI in muscle and adipose tissue and (ii) unchanged amount of IRGT protein in different muscle types (glycolytic and oxidative). These results are consistent with changes in IRGT functional activity and/or compartmentalization or a defect at the level of intracellular glucose metabolism.

ABSTRACT: The effects of dietary highly hydrogenated soybean oil (HSO) upon the changes caused by dietary polychlorinated biphenyls (PCBs) were examined in rats. Six groups of rats were fed the following diets for 30 d: a 20% soybean oil-containing diet (control diet), a diet in which a half of soybean oil was substituted with HSO (HSO-A diet), a diet in which cellulose powder was replaced with HSO (HSO-B diet) and these diets supplemented with 100 ppm PCBs (control + PCBs, HSO-A + PCBs and HSO-B + PCBs diets). Hepatic concentration of PCBs and relative liver weight were markedly decreased in rats fed with the HSO-A + PCBs diet compared with those fed with the other diets containing PCBs. Liver lipids and liver cholesterol were considerably decreased with a reciprocal increase in fecal sterol excretion by rats fed the HSO-A + PCBs and the HSO-B + PCBs diets compared with those fed with the control + PCBs diet. The fatty acid composition in hepatic phospholipids showed an independent increase of the saturated fatty acid content induced by dietary HSO and PCBs. Dietary PCBs also caused decreases in the amounts of monounsaturated and n-3 polyunsaturated fatty acids. These results suggest that dietary HSO prevents accumulation of PCBs in the liver and promotes the excretion of lipids stimulated by PCBs, accompanied by a change in fatty acid metabolism.
Lipids 31, 1151–1156 (1996).

Polychlorinated biphenyls (PCBs) are worldwide environmental pollutants. Because of a variety of physicochemical properties depending upon the degree of chlorination, commercial PCBs have been used for a wide range of purposes, for example, as heat transfer fluids, dielectric fluids for transformers and capacitors, organic diluents, lubricants, etc. Although the total amount of PCBs in the world was estimated in the past at about 1.5 million tons (1), there is no information about the amount of PCBs which have leaked from various facilities or products into the environment. In Japan these compounds have not been produced for many years, but they still persist in the environment and food. PCBs in the environment have therefore been transported and accumulated into living organisms, which have experienced various undesirable effects. Recently nonortho-chlorine substituted (coplanar) PCBs have been recognized as toxic as polychlorinated dibenzo-*p*-dioxins (2), and these findings have caused a new awareness of the risk of PCBs.

Commercial PCBs (Aroclor, Kanechlor, or Clophen) have a broad spectrum of toxicity that depends upon the chlorine content of the mixture, animal species, and exposure duration to the mixture. The toxic effects of PCBs included acute lethality, hepatomegaly, fatty liver, porphyria, dermatological aberrations, immunotoxicity, carcinogenesis, and neurotoxicity. Hepatotoxicity, in relation to lipid metabolism, is the general response observed in diverse laboratory animal species including rats, mice, rabbits, guinea pigs, monkeys, and minks. For example, toxic responses including metabolic abnormality of lipid metabolism in liver were observed in rats (3) and a monkey (4) exposed to low levels of chronic PCBs. Besides these direct effects, dietary PCBs also affect several nutritional events. Horio *et al.* (5,6) have shown that ascorbic acid levels in the liver and plasma are reduced by feeding PCBs to rat mutants unable to synthesize ascorbic acid, whereas ascorbic acid formation in normal rats is markedly enhanced by dietary PCBs (7,8). Other antioxidants such as β-carotene (9) or tocopherols (10) are also decreased significantly by PCBs in laboratory animals. According to Kato and Yoshida (11), feeding PCBs to rats causes cholesterol accumulation in the plasma and liver with an increase in its biosynthesis. We have also reported the effects of dietary cholesterol, ubiquinone-10, or powdered green tea on the metabolic responses to dietary PCBs (12–14).

On the other hand, we found that highly hydrogenated soybean oil (HSO), considered to be hardly digested and poorly absorbed, also prevented cholesterol accumulation in the liver and promoted its rapid excretion in rats (15). These results indicate that HSO might also prevent the absorption of certain xenobiotics and reduce their adverse effects, at least in part.

In this paper, therefore, we studied how dietary HSO affected the altered lipid distribution, including cholesterol transport, caused by dietary PCBs.

MATERIALS AND METHODS

Animal experiments. Male Wistar rats (Japan SLC Inc., Hamamatsu, Japan), weighing an average of 80 g, were housed individually in cages with a wire screen bottom and were provided with a commercial nonpurified diet (CLEA Japan Inc., Tokyo, Japan) and tap water *ad libitum* before the experiment for 5 d. A room temperature was maintained at 22–24°C on a 12-h light/dark cycle with light from 1300–0100. At the end of the experiment, feces were collected for 48 h just before fasting. After fasting overnight, rats were anesthetized with diethyl ether and sacrificed between 0700–0800. Blood was collected from the abdominal aorta, using a plastic syringe containing heparin, for plasma cholesterol analysis. Immediately after the livers were removed, weighed and cooled on ice, they were frozen at –70°C until assay.

All aspects of the animal experiments were approved by the animal policy and welfare committee in our Institute.

The composition of experimental diets and that of fatty acids in dietary fats are shown in Tables 1 and 2, respectively. The diet in which 50% of soybean oil was replaced with highly HSO was named HSO-A and that in which cellulose powder was completely replaced by HSO was named HSO-B. To prepare diets containing PCBs, Kanechlor 500 (Kaneka Co. Ltd., Osaka, Japan) was added to each diet at a concentration of 100 ppm. The composition of PCB congeners in Kanechlor 500 was similar to Arochlor 1254 which contains 54% of chlorine (w/w).

Analysis. PCBs were determined by the method of Ukawa *et al.* (16) using a gas–liquid chromatograph with an electron capture detector (HP5890 series II; Hewlett-Packard Co., Palo Alto, CA) with SPD-1 (Sperco Inc., PA). Total cholesterol and high density lipoprotein (HDL)-cholesterol in plasma obtained from blood centrifuged at 1500 × *g* for 10 min were measured using commercially available kits (Cholesterol C-test and HDL-cholesterol C-test; Wako Pure Chemical Industries, Ltd., Osaka, Japan). Liver lipid extracted by the method of Folch *et al.* (17) was determined gravimetrically. Fecal lipid was extracted by modified method of Folch *et al.* (17) in which the extraction process was performed using warm chloroform–methanol solution. Lipid in the freeze-dried feces was extracted by warm Folch solution containing a small amount of water (60°C, 1 h). After being dried under an N_2 stream, the residue was dissolved in 25 mL petroleum ether with anhydrous Na_2SO_4. Twenty mL of petroleum ether phase was transferred to a receptacle which was weighed in advance, and evaporated under a stream of N_2 followed by drying in an oven (100°C, 1 h). Lipid was determined by the difference between the initial and final weight of the receptacle. After mild saponification of the lipids, liver cholesterol was extracted and determined by the method of Grundy *et al.* (18). Fecal sterols were extracted by the method of Yamanaka *et al.* (19). Fecal neutral sterols were assayed by the procedure of Grundy *et al.* (18). The concentration of total fecal acidic steroids was assayed by the method of Forman *et al.* (20). After separation from other lipids with thin-layer chromatography (21), hepatic phospholipid was methylated with 5% HCl–methanol at 100°C for 3 h, and the fatty acid composition was determined by the procedure of Kawai and Nakayama (22) with the slight modification of using a slower temperature gradient program in capillary gas chromatography (4°C/min from 100 to 230°C). Urinary ascorbic acid was assayed by the method of Okamura (23). Hepatic cytochrome P-450 was determined by the procedure of Omura and Sato (24). Frozen liver slices were stained with Oil Red for the histochemical observation according to the procedure of Lillie (25).

[a]SFA and UFA, saturated fatty acid and unsaturated fatty acid, respectively. See Table 1 for other abbreviation.

RESULTS

Body weight gain during the experiment (30 d) was similar among rats fed with any of the three diets regardless of the addition of PCBs (control: 141 ± 4.4 g, control + PCBs: 140 ± 5.8 g, HSO-A: 139 ± 6.1 g, HSO-A + PCBs: 140 ± 5.2 g, HSO-B: 139 ± 3.8 g, HSO-B + PCBs: 138 ± 2.4 g). Food consumption was about 20% greater in rats given the HSO-A diet (HSO-A: 501 ± 16.8 g, HSO-A + PCBs: 502 ± 16.0 g) than in those given the other two diets with or without PCBs (control: 413 ± 7.9 g, control + PCBs: 420 ± 8.6 g, HSO-B: 405 ± 6.7 g, HSO-B + PCBs: 413 ± 7.0 g). The effects of dietary HSO and PCBs on liver weight, lipids, and plasma cholesterol are shown in Table 3. Addition of PCBs to the diets increased the relative liver weight of rats, but the increase was least in the HSO-A + PCBs diet group among the three. The concentration of liver lipid was increased by the addition of

TABLE 3
Effects of Dietary PCBs and Highly Hydrogenated Soybean Oil on Relative Liver Weight, Plasma and Liver Lipids in Rats[a]

	Control	Control + PCBs	HSO-A	HSO-A + PCBs	HSO-B	HSO-B + PCBs
Relative liver wt (g/100 g b.w.)	3.9 ± 0.08[a]	5.9 ± 0.12[b]	3.9 ± 0.07[a]	5.0 ± 0.05[c]	3.9 ± 0.07[a]	5.8 ± 0.13[b]
Liver lipid (mg/liver/100 g b.w.)	448 ± 27.3[a]	636 ± 46.6[b]	359 ± 28.7[c]	425 ± 32.8[a]	422 ± 14.4[a]	528 ± 34.9[d]
Liver cholesterol (mg/liver/100 g b.w.)	7.9 ± 1.69[a]	53.2 ± 0.82[b]	6.5 ± 0.24[c]	22.2 ± 1.75[d]	9.3 ± 1.02[a]	24.5 ± 1.99[d]

Plasma HDL-cholesterol (mg/dl)	32 ± 2.0[a]	52 ± 3.4[b]	34 ± 2.5[a]	51 ± 2.6[b]	32 ± 1.2[a]	50 ± 2.5[b]

[a]Each value shows mean ± SEM, $n = 6$. In each experiment, values on the same line across without common superscript letters denote significant differences ($P < 0.05$). PCBs, polychlorinated biphenyls; HDL, high density lipoprotein. See Table 1 for other abbreviation.

PCBs to the diet, but this accumulation of liver lipid was prevented by the concomitant ingestion of HSO, especially by the HSO-A + PCBs diet. Moreover, under PCB-free conditions, the concentration of liver lipid was lower in rats fed with the HSO-A diet than in rats fed with the other two diets. A considerable increase in liver cholesterol level caused by supplementary PCBs was markedly prevented by HSO. Effects of dietary HSO and PCB on fecal weight and sterols are shown in Table 4. Rats fed HSO-A excreted more than twice the sterols of that by the other groups. As shown in Table 4, fecal total neutral sterols, cholesterol and coprostanol, were kept low and at similar levels among rats fed with the three diets without PCBs, but were increased considerably by supplementing with PCBs. Moreover, HSO ingestion changed the composition of neutral sterols in feces. Coprostanol was excreted at considerable levels into the feces of rats given the control diet with or without PCBs, whereas it was undetectable in the feces of animals given HSO regardless of PCBs supplement. Rats given the PCB-containing diets had higher total plasma cholesterol and HDL-cholesterol than those given the corresponding PCB-free diets (Table 2), with no significant difference among the groups given PCB diets. The amounts of urinary ascorbate and the level of hepatic cytochrome P-450 increased by dietary PCBs were not affected by HSO ingestion (ascorbic acid shown by mg/day/100 g body weight in control, control + PCBs, HSO-A, HSO-A + PCBs, HSO-B, HSO-B + PCB were 0.08 ± 0.003, 8.46 ± 0.794, 0.10 ± 0.014, 7.35 ± 0.702, 0.09 ± 0.010, and 8.01 ± 0.585, respectively, and cytochrome P-450 shown by nmol/mg protein in control, control + PCBs, HSO-A, HSO-A + PCBs, HSO-B, HSO-B + PCB were .0.5 ± 0.12, 2.0 ± 0.19, 0.5 ± 0.02, 1.8 ± 0.09, 0.7 ± 0.07, and 2.1 ± 0.13, respectively).

The effect of dietary HSO on PCB accumulation in rat liver are shown in Figure 1. Although a considerable amount of PCBs accumulated in the livers of rats given PCBs-containing diets, the PCB level was about half in rats on HSO-A + PCBs diet compared with those on the other two diets with PCBs. PCBs were undetectable in the livers of rats on the PCB-free diets.

Figure 2 shows the typical photomicrographs of liver sections stained with Oil Red from rats given the control and experimental diets. The panlobular region was evenly stained with Oil Red in rats given the control diet. However, in the presence of HSO, the staining was limited to only the midlobular region between the periportal and perivenous region in rats given especially the HSO-A diet. By the addition of PCBs to the diets, the staining profile was distinctly changed around the central vein. Similar, but less apparent changes were evident in rats given the HSO-A + PCBs diet.

Table 5 shows the fatty acid composition of hepatic phospholipids in rats given the control and the HSO-A diet with or without PCBs. HSO intake increased total saturated fatty acids, especially 18:0, though it decreased polyunsaturated fatty acids, mainly 18:2. Addition of PCBs to the diets also increased saturated fatty acids, especially 18:0, whereas it decreased 18:1 and n-3 polyunsaturated fatty acids with changes in the n-6 polyunsaturated fatty acids, namely an increase in the 20:4 n-6 and a decrease in the 18:2n-6. Consequently, dietary HSO and PCBs had additional effects on the 18:0 content of liver phospholipid. The ratio of n-6/n-3 was increased by dietary PCBs, but not by HSO.

DISCUSSION

There was no apparent difference in body weight gained, but food consumption was significantly greater in rats given the HSO-A diet than in those given the other two diets (Table 3). By analysis of the HSO used in our experiment, 57% of the triacylglycerol in HSO was tristearoylglycerol and most of

TABLE 4
Effects of Dietary PCBs and Highly Hydrogenated Soybean Oil on Fecal Dry Weight and Fecal Sterols in Rats[a]

	Control	Control + PCBs	HSO-A	HSO-A + PCBs	HSO-B	HSO-B + PCBs
Fecal dry weight (g/day/100 g b.w.)	0.59 ± 0.023[a]	0.62 ± 0.025[a,c]	1.33 ± 0.028[b]	1.36 ± 0.033[b]	0.54 ± 0.006[a]	0.66 ± 0.025[c]
Fecal cholesterol (mg/day/100 g b.w.)	0.5 ± 0.03[a]	4.8 ± 0.32[b]	2.1 ± 0.16[c]	5.1 ± 0.21[b]	2.5 ± 0.12[c]	7.4 ± 0.48[d]

the remainder distearoylmonoacylglycerols (15). As the HSO-A diet contained a greater amount of tristearoylglycerol which is considered to be difficult to digest (26), rats given the HSO-A diet would have to eat more food to obtain a sufficient growth rate and hence excreted more in the feces as shown in Table 5. Rats on the HSO-A + PCBs diet had the lowest relative liver weight and PCBs accumulation in the liver among rats on the three diets containing PCBs (Fig. 1). The indigestibility and low absorptivity of HSO which induces the suppression of the diffusion of PCBs through the intestinal wall and their rapid passage through the bowels appeared to prevent the absorption of dietary PCBs.

HSO did not prevent the increase in plasma total cholesterol caused by dietary PCBs. The effect of dietary HSO on the transport of endogenous cholesterol might differ from that of exogenous cholesterol. A different type of lipoprotein metabolism might be involved, but details were unclear from the present experiment.

The histochemical results showed that the shape and arrangement of hepatocytes in the perivenous region were al-

[a]Each value shows mean ± SEM, $n = 6$. In each experiment, values in the same line without common superscript letters denote significant difference ($P < 0.05$). n.d. = not detected. The abbreviations, SFA, MUFA, and PUFA mean saturated fatty acid, monounsaturated fatty acid and polyunsaturated fatty acid, respectively. P/S means PUFA/SFA. See Tables 1 and 3 for other abbreviations.

tered along the distribution of lipids stained by Oil Red (Fig. 2). This indicated that dietary PCBs injured the area around the central vein. A decrease in the level of liver lipids by dietary HSO would be in concert with the lack of Oil Red staining in livers from rats on the HSO diets.

The changes of fecal neutral sterols, namely the disappearance of coprostanol, were observed in the feces in rats given the HSO diet (Table 4), suggesting a shift in enterobacteria, for example, a decrease in the population of bacteria such as *Eubacterium* having a specific enzyme that reduces cholesterol to coprostanol (27), although we did not perform bacteriological examinations.

As shown in Table 5, HSO ingestion increased the 18:0 content of hepatic phospholipid, suggesting that 18:0 in HSO was partly absorbed and contributed to the increase in the proportion of saturated fatty acid content. Actually, about 43% of triacylglycerol in HSO was distearoylmonoacylglycerol whose absorption was considered relatively easy. PCB ingestion also increased the 18:0 proportion of the fatty acid content in hepatic phospholipid. These findings might be the result of the activation of fatty acid synthesis, because dietary PCBs are known to increase lipid synthesis (28). The supply of 18:0 by dietary HSO and the increase of this fatty acid by PCBs were independent, and caused a 7% increase in the stearic acid ratio and a 4.6% increase in total saturated acid in the hepatic phospholipids of rats given HSO-A + PCBs compared with controls. The increased saturated fatty acid proportion seemed to affect other physiological situations like the fluidity of membrane lipids.

In contrast to 18:0, 18:1 was reduced by about 2% by dietary PCBs, but not by dietary HSO. According to Leikin and Brenner (29), Δ^9-desaturase is stimulated by dietary cholesterol, which also increases the 18:1 ratio accompanied with a decrease in the proportion of saturated fatty acids. This mechanism was explained by an altered fluidity of membrane lipids. Whether the alteration of Δ^9-desaturase activity is associated with a specific response to PCBs or the different origin of the cholesterol supply remains to be ascertained.

With respect to the n-6 polyunsaturated fatty acid levels, the concentration of 18:2 decreased, with a reciprocal increase of the 20:4 proportion in rats given PCBs regardless of HSO in the diet. Borlakoglu *et al.* (30) observed the increase of fatty acid desaturation in rat hepatic microsomes at 5 d after intraperitoneal injection of PCBs. Similarly, dietary PCBs might stimulate the Δ^6- and Δ^5-fatty acid desaturases to alter the ratio of 18:2 and 20:4. As 20:4 is relevant to inflammation, PCBs-mediated increase of this fatty acid content in hepatic phospholipid might cause some undesirable physiological or pathological situations. We have shown in this study that insofar as those situations are concerned, dietary HSO would not be effective because it cannot prevent the increase of the 20:4 content. Also, dietary HSO could modify some PCBs-mediated physiological changes including the alteration of liver and fecal lipids, and the accumulation of PCBs in the liver.

Dietary Docosahexaenoic Acid Has Little Effect on Peroxisomes in Healthy Mice

Dirk De Craemer*, Marina Pauwels, and Christiane Van den Branden

Menselijke Anatomie & Embryologie, Vrije Universiteit Brussel, Laarbeeklaan 103, 1090 Brussels, Belgium

ABSTRACT: NMRI mice were fed diets supplemented with 0.05, 0.2, or 2% (w/w) docosahexaenoic acid (DHA), a polyunsaturated fatty acid present in fish oil, for 3 d, 3 wk, or 3 mon. The doses of DHA were chosen to supply the mice with concentrations of DHA which approximate those that have been reported to be beneficial to patients with peroxisomal disease. Diets containing 0.05 or 0.2% DHA did not change hepatic, myocardial, and renal catalase (EC 1.11.1.6) activity except for a slight but significant increase (to 120%) in myocardial catalase activity in mice treated with the 0.05% DHA diet for 3 mon. A diet with 2% DHA induced myocardial catalase activity to 150% after both 3 d and 3 wk of administration. In the liver of mice fed this diet for 3 wk, hepatic catalase activity was increased to 140% while no induction of palmitoyl-CoA oxidase (EC 1.3.99.3), urate oxidase (EC 1.7.3.3), and L-α-hydroxyisovalerate oxidase (EC 1.1.3.a) was observed. With the light microscope, no changes in peroxisomal morphology were visually evaluated in catalase stained sections of liver, myocardium, and kidney of mice fed either diet. Our results show that in healthy mice a low dietary DHA dose (<0.2%; this corresponds to a dose prescribed to peroxisomal patients) has no effect on several hepatic peroxisomal H_2O_2-producing enzymes, including the rate-limiting enzyme of the peroxisomal fatty acid β-oxidation. This may indicate that such a DHA dose will not add a strong load on the often disturbed fatty acid metabolism in the liver of patients with peroxisomal disorders.

Lipids 31, 1157–1161 (1996).

Peroxisomes are cell organelles characterized by the presence of H_2O_2-producing oxidases and high amounts of catalase, a H_2O_2-scavenging enzyme (1). These and other peroxisomal enzymes take part in several metabolic processes, thus playing a variety of critical roles in cellular metabolism. A deficiency of only one peroxisomal enzyme may already induce a spectrum of severe clinical symptoms (2). Today there exists no established therapy for patients with a deficiency of one or more peroxisomal enzymes.

Based on the finding that patients with several peroxisomal disorders show too low levels of docosahexaenoic acid (DHA) in several organs (3,4), it has been suggested to supplement this polyunsaturated fatty acid in the diet of peroxisomal disorder patients (5,6). While in some clinical trials fish oil is added to the diets of patients with peroxisomal disorders (7), others recommend the use of purified DHA (5,8). Clinical improvement of patients treated with dietary DHA supplementation was recently reported (5,8).

We previously studied the effect of different doses of a fish oil extract on the peroxisomes in liver, myocardium, and kidney of healthy mice (9,10). The investigated fish oil doses were chosen in such a way that the daily amount of DHA administered to the mice approximated the doses which were beneficial to patients with a peroxisomal disease. An increase in peroxisomal β-oxidation and catalase activity in liver and myocardium was observed but only when doses higher than the doses used in clinical settings were administered (9–11).

The aim of this study was to investigate the effect of dietary supplementation of purified DHA on peroxisomes in mice. The studied DHA doses were identical to the DHA doses previously selected in the fish oil experiments (9–11). As this study was being completed, data on the effect of DHA supplementation to rats were published (12,13). Preliminary results have been reported during the Sixth Belgian Week of Gastroenterology; Knokke, Belgium, March 16–18, 1994 (14).

MATERIALS AND METHODS

Adult male NMRI mice (35–40 g) were randomly assigned into groups of at least five animals. They were fed a standard laboratory meal (A04; UAR, Epinay, France) supplemented with 0.05% DHA ethyl ester for 3 d, 3 wk, and 3 mons or with 0.2 or 2% DHA ethyl ester for 3 d and 3 wk. Ethyl DHA was obtained from Sigma (Bornem, Belgium). DHA is a polyunsaturated fatty acid present as a main compound in fish oil extracts. The composition of the standard laboratory meal has previously been given (10). The dietary DHA doses were chosen to approximate the daily oral dose of 250 mg DHA ethyl ester administered in a clinical setting to children with generalized peroxisomal disorders (5,8). We considered the body surface area as reference point to convert doses from man to mouse (15). To express a mg/kg dose in any given species as the equivalent mg/m^2 dose, the dose has to be multiplied by the appropriate ratio between surface area and body weight. This ratio is 3 for the mouse and is 25 for a child of 20 kg

(15). We calculated that a dose of 250 mg/d given to a child with a maximum body weight of 20 kg (which is in fact a daily intake of 12.5 mg/kg body weight) corresponds to a daily intake of 12.5 × 25/3 = 104 mg/kg body weight in the mouse. The mean intake of DHA by the mice on a diet with 0.05, 0.2, or 2% DHA was 87, 350, and 3500 mg/d/kg body weight, respectively, being slightly smaller to approximately 3.5- and 35-fold the clinical dose. The time control groups received the A04 meal only. All animals had free access to food and water. The appetite of the animals under DHA treatment was not different from control animals.

The activities of peroxisomal fatty-acyl CoA oxidase (EC 1.3.99.3), urate oxidase (EC 1.7.3.3), L-α-hydroxy acid oxidase (EC 1.1.3.a) and D-amino acid oxidase (EC 1.4.3.3) were assayed in liver homogenates of mice treated with the highest DHA-supplemented diet (2%) for 3 wk using the method of Osumi and Hashimoto (16) with the following substrates: palmitoyl-CoA, urate, L-α-hydroxyisovalerate, D-alanine, and D-proline, respectively. Catalase (EC 1.11.1.6) activity was assayed in homogenates of liver, heart, and kidney cortex according to Baudhuin (17,18).

Histological analysis (after diaminobenzidine staining for catalase) of the peroxisomes in liver, myocardium, and kidney were performed as previously described (19). Results are given as the mean ± SD. For statistical analysis, the Mann-Whitney test was used (20). Significance was obtained when $P < 0.05$.

RESULTS

The DHA diet was well accepted by the mice. At the end of the experiment, body weight of DHA-treated animals was similar to the weight of control animals. No hepatomegaly was observed. Liver, heart, and kidney weights expressed as percentages of body weight were not changed (results not shown). The time control groups showed no differences in catalase activity and histological appearance of the peroxisomes and, therefore, were pooled into one control group.

Hepatic catalase activity was not altered in mice fed a diet supplemented with 0.05 or 0.2% DHA when compared to the activity in control mice (76 ± 6 U_B/g liver) (Fig. 1). A significant increase in catalase activity (to 140%) was observed in mice fed the highest DHA dose for 3 wk. Treatment for 3 d had no effect on catalase activity (Fig. 1). In myocardium of mice fed a diet supplemented with 0.05% DHA, only the prolonged treatment of 3 mon induced a slight but significant increase in catalase activity (to 120%) when compared to control animals (1.26 ± 0.10 U_B/g myocardium) (Fig. 2). Feeding diets with 0.05 or 0.2% DHA for 3 d or 3 wk had no effect on myocardial catalase activity. An increase to ± 150% of control catalase activity was found in mice fed 2% DHA-supplemented diet for 3 d and 3 wk (Fig. 2). Renal catalase activity was not altered in mice fed a DHA-containing diet for up to 3 wk (2% DHA-diet) or for up to 3 mon (0.05% DHA-diet) (Fig. 3).

The activities of several H_2O_2-generating peroxisomal oxidases were assayed in the liver of mice with a significant increase in hepatic activity of the H_2O_2-scavenging peroxisomal enzyme, catalase. Palmitoyl-CoA oxidase, urate oxidase, and L-α-hydroxyisovalerate oxidase activities were not changed in animals fed the 2% DHA-diet for 3 wk (Table 1). No activity of D-amino acid oxidase using D-proline and D-alanine as a substrate was detected in both mice fed a control or a DHA-containing diet.

Light microscopic study of diaminobenzidine-stained sections of liver, myocardium, and kidney revealed the presence of peroxisomes in both control and DHA-treated mice. In the liver, peroxisomes were observed throughout the parenchyma. No alterations in staining intensity, size, number, or distribution of the peroxisomes in DHA-treated animals were observed (Fig. 4). Myocardial peroxisomes revealed a heterogeneous distribution in all investigated samples being apparently absent

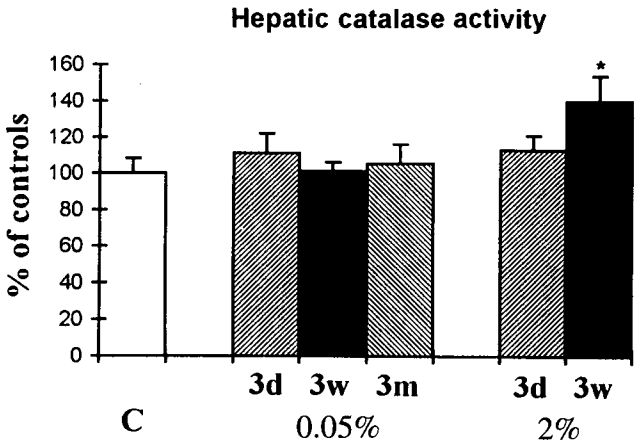

FIG. 1. Catalase activity in liver homogenates of mice treated with 0.05% DHA and 2% DHA for up to 3 mon. Significant increases from control data (C) (76 ± 6 U_B/g liver = 100%) are indicated with *.

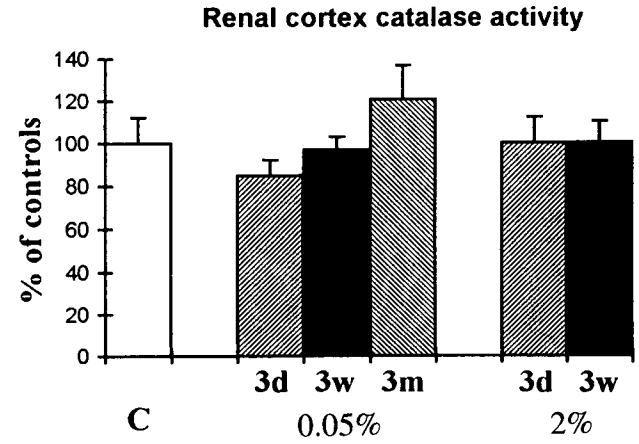

FIG. 2. Catalase activity in renal cortex homogenates of mice treated with 0.05% DHA and 2% DHA for up to 3 mon. No significant changes from control data (C) (33 ± 2 U_B/g kidney cortex = 100%) are observed.

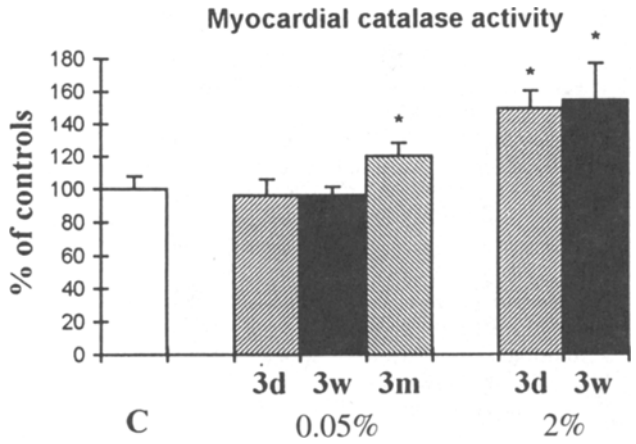

FIG. 3. Catalase activity in myocardium homogenates of mice treated with 0.05% DHA and 2% DHA for up to 3 mon. Significant increases from control data (C) (1.26 ± 0.10 U_B/g myocardium = 100%) are indicated with *.

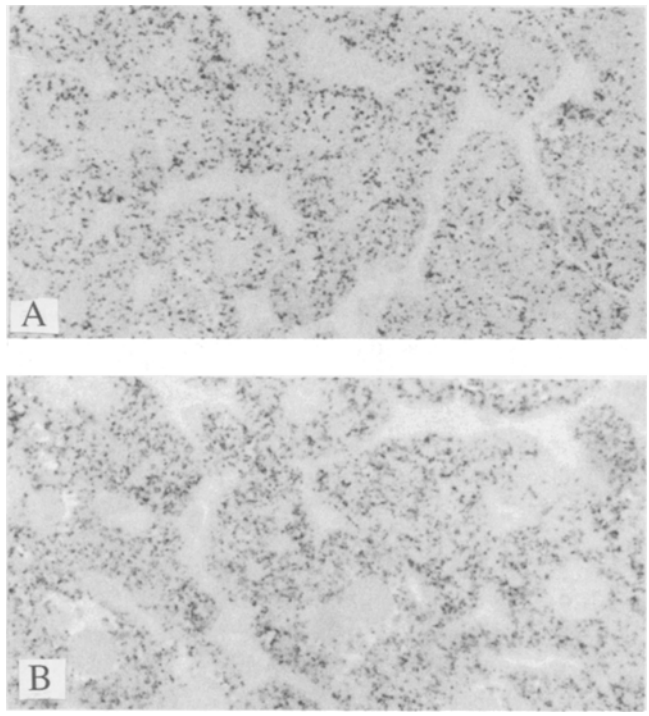

FIG. 4. Light micrographs of liver of mice treated with a control diet (A) or a diet with 2% DHA (B). Liver sections were stained for catalase activity. Catalase reaction product is found in the peroxisomes which are recognized as dots in the cytoplasm. No changes in size, shape, and distribution of the peroxisomes are observed. Catalase cytochemistry. X 500.

Control	5	1.221 ± 0.201	1.371 ± 0.456	0.848 ± 0.055
DHA	5	1.391 ± 0.244	1.110 ± 0.290	0.818 ± 0.081

[a]Enzyme activities are expressed as nmol H_2O_2/min/mg liver; DHA, docosahexaenoic acid.

in some fibers and numerous in adjacent fibers. This characteristic made it difficult to visually evaluate changes in number and distribution of the peroxisomes. In DHA-treated mice, size and staining intensity of myocardial peroxisomes were similar to those observed in control mice. Renal peroxisomes were predominantly observed in the epithelium of proximal tubules. No differences in morphological characteristics of the peroxisomes in proximal tubules between DHA-treated and control mice were observed. A few small peroxisomes were infrequently observed in the glomeruli, distal tubules, and collecting tubules in all investigated renal sections.

DISCUSSION

We found that a 3 wk administration of 2% DHA (which corresponds to a daily uptake of 3500 mg DHA/kg body weight) induced catalase activity in mouse liver while no induction of three peroxisomal oxidases (fatty acyl-CoA oxidase, urate oxidase, and L-α-hydroxyacid oxidase) was provoked. Lower doses (corresponding to a daily uptake of 87 and 350 mg DHA/kg body weight) enclosing the doses prescribed to patients with peroxisomal diseases did not change hepatic catalase activity. In rats that received 1000 mg DHA/d/kg body weight by gastric intubation for 3 mon, a significant induction of hepatic catalase activity (to 118%) was observed (13). This dose corresponds to 500 mg DHA/d/kg body weight in the mouse when the body surface area is considered as reference point to convert doses between rats and mice (15). In contrast to our results, a significant increase in peroxisomal fatty acyl-CoA oxidase activity (to 164%) was observed in these rats; this effect was also obtained in rats treated with 500, 1000, and 1500 mg DHA/d/kg body weight by gastric intubation for 10 d (12). The discrepancy in results may be ascribed to differences in DHA administration, type of animals used, and composition of the diets.

Mice fed the 2% DHA diet for 3 wk revealed a three-times smaller induction of hepatic catalase activity when compared to mice of the same strain, age, and sex fed the 10% fish oil diet that contains the same final concentration of DHA (9). In addition peroxisomal β-oxidation was increased at least 6.6-fold in the mice fed 10% fish oil while no induction was found in mice treated with 2% DHA diets. These data suggest that in mice the induction of peroxisomal enzymes in the liver can mainly be ascribed to the high concentration of fatty acids in the fish oil diet. This assumption also holds true for the inducing effects of other high-fat diets which often have a composition totally different from fish oil (9).

Myocardial catalase activity was induced in mice fed the 2% DHA-containing diet. We previously reported a stronger

induction of catalase activity in mice fed a 10% fish oil diet (in which the concentration of DHA is 2%) (9,10). This suggests that part of the catalase activity induction observed in myocardium of mice treated with dietary fish oil may be ascribed to the presence of DHA. No data on catalase activity in myocardium of treated rats are available (12,13).

To our knowledge, data on the effects of dietary supplementation of DHA, alone or as part of a fatty acid mixture other than fish oil, on the functions and morphology of renal peroxisomes are lacking. We found no changes in catalase activity, in intensity of peroxisomal catalase staining, and in size, shape, and distribution of peroxisomes in the kidney of mice fed either diet. This is in line with our previous findings made in mice fed fish-oil supplemented diets (9,10).

The increases in catalase activity observed in liver and myocardium are not reflected in an enhanced staining intensity of the individual peroxisomes. This indicates that the intensity of the oxidized diaminobenzidine in sections cytochemically stained for catalase is little susceptible to the observed changes in activity of this enzyme.

Our results indicate that dietary supplementation of DHA in doses approximating the daily amount of DHA prescribed to patients with peroxisomal disorders has little effect on the peroxisomal compartment in healthy mice. Only myocardial catalase activity was increased in long-term (3 mon) treated animals and suggests the need for an increased H_2O_2-scavenging activity. However, in liver of mice treated with 2% DHA, the increased catalase activity was not related to an induction of three H_2O_2-producing enzymes including peroxisomal fatty acyl-CoA oxidase. An increased H_2O_2 pool may be brought on by other peroxisomal oxidases or by the import of extraperoxisomal H_2O_2 as the peroxisomal membrane is permeable for small solutes (21). A strong increase in peroxisomal β-oxidation without an as strong induction of catalase activity is a general phenomenon observed in rodents treated with peroxisome proliferators, a heterogeneous group of drugs and chemical substances (22). Several members of this group of products show an increased incidence of hepatic tumors in long-term treated rodents. This characteristic has been ascribed to the disturbed equilibrium between H_2O_2-generating and H_2O_2-scavenging pathways.

We conclude that DHA doses which gave clinical improvement to patients with generalized peroxisomal disorders are low enough not to be a burden for β-oxidation in liver and kidney of healthy mice. Only the unknown immediate cause for induction of catalase activity in myocardium of mice treated for 3 mon with the low dose of DHA could be a source of concern and needs further investigation.

Modification of Membrane Fatty Acid Composition, Eicosanoid Production, and Phospholipase A Activity in Atlantic Salmon *(Salmo salar)* Gill and Kidney by Dietary Lipid

J. Gordon Bell*, Bruce M. Farndale, James R. Dick, and John R. Sargent

N.E.R.C. Unit of Aquatic Biochemistry, Department of Biological and Molecular Science, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

ABSTRACT: Atlantic salmon post-smolts were fed diets containing either fish oils (Fosol, FO and Marinol, MO) rich in long-chain n-3 polyunsaturated fatty acids (PUFA), or plant oils rich in 18:2n-6 (sunflower oil, SO) or 18:3n-3 (linseed oil, LO) for 12 wk. The major PUFA in individual phospholipids from gill and kidney were related to the dietary lipid intake. Levels of n-6 PUFA were highest while levels of n-3 PUFA were lowest in fish fed SO. Fish fed LO generally had lower levels of 20:4n-6 compared to the other treatments while fish fed SO generally had the highest levels of 20:4n-6. In all phospholipid classes except phosphatidylinositol (PI) 20:5n-3 was greatest in fish fed MO followed by FO, LO, and SO. In PI, 20:5n-3 was also highest in fish fed MO but those fed LO contained more 20:5n-3 than those fed FO. This resulted in the ratio of the eicosanoid precursors, 20:4n-6/20:5n-3, being significantly greater in fish fed SO, for all phospholipid classes, compared to fish fed the other three dietary oils. The activity of gill phospholipase A was greatest in fish fed FO and was lowest in fish fed SO. The concentration of $PGF_{3\alpha}$ was significantly increased in gill homogenates from fish fed MO compared to the other three treatments while $PGF_{2\alpha}$ was significantly increased in fish fed SO compared to those fed LO. The concentration of PGE_3 was significantly reduced in kidney homogenates from fish fed SO compared to the other three treatments while PGE_2 was significantly increased in fish fed SO compared to those fed either FO or LO.
Lipids 31, 1163–1171 (1996).

Considerable evidence now exists to suggest that overproduction of 2-series eicosanoids, derived from arachidonic acid (20:4n-6, AA), is fundamental in increased occurence of a number of chronic inflammatory diseases in humans, particularly cardiovascular and autoimmune conditions (1,2). Evidence that the long-chain n-3 polyunsaturated fatty acids (PUFA) present in fish oils, namely eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA), have an ameliorating effect on the above conditions is well documented (3,4). EPA can be metabolized by both lipoxygenase and cyclooxygenase to yield a range of eicosanoids although their biological efficacy is generally reduced compared to their AA-derived analogues (5). Additionally, both EPA and DHA, and α-linolenic acid (18:3n-3) can inhibit cyclooxygenase activity and thus reduce production of eicosanoids derived from AA (6,7).

The rate and type of eicosanoid synthesis, at the cellular level, depend on the size and composition of the available precursor pool which consequently can be modulated by dietary PUFA intake (8). At least three enzymes, Δ6- and Δ5-desaturase (9) and phospholipase A_2 (10), are involved in supply of precursor PUFA for eicosanoid synthesis, and the reactions they catalyze can be influenced by a number of nutritional and physiological factors (9,11). Thus, in addition to their ability to inhibit eicosanoid production directly, n-3 PUFA can, by inhibition of linoleic acid desaturation and elongation, further reduce the synthesis of 2-series eicosanoid production (12).

Fish offer a useful model system for investigating the synthesis and interaction of eicosanoids of the 2- and 3-series since their tissues are naturally abundant in both EPA and DHA (13,14). However, despite the apparent excess of EPA over AA in their phospholipids, fish do produce considerable quantities of AA-derived eicosanoids (15), and a number of studies suggest that AA is the preferred substrate for cyclooxygenase in plaice neutrophils, turbot gills, and brain astroglial cells in culture (16–18). In previous studies, Atlantic salmon given diets containing 18:2n-6 or 18:3n-3 have shown increased levels of AA and EPA, respectively, which have influenced the production of AA-derived eicosanoids (19, 20). The ability of the lipoxygenase product 12-hydroxy-5,8,10,14-eicosatetraenoic acid (12-HETE) to modulate the activity of ion channels has been observed in mammals (21), and clearly this activity would be important in gills which,

along with the posterior kidney are vital in osmoregulation in fish. The ability of fish gill and kidney to synthesise prostaglandins has been known for some time although their functions were originally not clear (22,23). More recently prostaglandin E (PGE_2) and PGE_1 have been identified as active antidiuretic agents in trout and eel kidney (24,25) while PGE_2 inhibits ion transport in gill epithelia (26). Clearly diet-induced changes in gill and kidney eicosanoid products might affect the ability of salmon to osmoregulate effectively which would compromise their ability to adapt to the marine environment when undergoing parr-smolt transformation.

In the present experiment, four groups of Atlantic salmon were given diets enriched in either 18:2n-6 (sunflower oil), 18:3n-3 (linseed oil), or 20:5n-3 (Marinol, southern hemisphere fish oil) which were compared to a control group fed a northern hemisphere fish oil (Fosol). The phospholipid fatty acid compositions of gill and kidney were determined along with concentrations of prostaglandins PGE and PGF of the 2- and 3-series and gill phospholipase A activity.

MATERIALS AND METHODS

Fish and husbandry. Four hundred Atlantic salmon S1 smolts of mean weight 54 g were obtained from the Scottish Office Agriculture Environment and Fisheries Department (S.O.A.E.F.D.) Fish Cultivation Unit (Aultbea, Wester Ross, Scotland) and distributed randomly into four tanks of 2000 L each, and supplied with nonrecirculated seawater at a rate of 26 L/min. The fish were subject to natural photoperiod, and the water temperature during the experimental period (August–November) varied from 15–9°C. Diets were supplied by automatic feeders which were adjusted to supply 30 g/kg biomass per day, until the average fish weight reached 100 g, and thereafter this was reduced to 20 g/kg biomass for the remainder of the experiment. The feeding trial was conducted for a period of 3 mon, and fish were weighed individually at the start and finish of the trial and weighed in bulk at 28-d intervals after which the ration was adjusted accordingly. The experiment was conducted in accordance with British Home Office guidelines regarding research on experimental animals.

Diets. The composition of the basal diet has been described in detail previously (27) and utilized a low-temperature fishmeal as protein source. The lipid component of 100 g/kg was either Fosol (FO), a Northern hemisphere fish oil derived from pelagic fish, mainly herring, capelin and sand eel (Seven Seas Ltd., Hull, United Kingdom), sunflower oil (SO) (Tesco Ltd, Cheshunt, United Kingdom), linseed oil (LO) (Omega Nutrition Inc., Vancouver, Canada), or Marinol (MO), a Southern hemisphere fish oil derived from sardines, pilchards, and anchovies (Fishing Industry Research Unit, Rosebank, 7700 Republic of South Africa). An antioxidant mix was added to the oils before mixing with the dry ingredients (27). The diets were formulated to satisfy the nutritional requirements of salmonid fish (28) and contained 46% crude protein and 16% lipid. The fatty acid compositions of the four experimental diets are shown in Table 1.

[a]Includes 15:0, 17:0, and 20:0.
[b]Includes 18:3n-6 and 22:4n-6.
[c]Polyunsaturated fatty acids include 16:2, 16:3, and 16:4; trace value <0.05%; — = not detected. Fosol is a Northern hemisphere fish oil derived from pelagic species, herring, capelin, and sand eel. Marinol is a Southern hemisphere fish oil derived from sardine, pilchard, and anchovy.

Extraction and analysis of lipids. Intact gill arches and posterior kidney samples were dissected from four fish per dietary treatment and immediately frozen in liquid nitrogen. Samples were stored at –40°C prior to lipid extraction. Total lipid was extracted from gill, kidney, and diet samples by the method of Folch *et al.* (29). The details of extraction, separation of phospholipid classes, and preparation of fatty acid methyl esters have been described in detail previously (27). The fatty acid methyl esters were separated and quantified by gas–liquid chromatography (Carlo Erba Vega 6000; Fisons Ltd., Crawley, United Kingdom) using a 50 m × 0.22 mm capillary column (free fatty acid phase, S.G.E. Ltd., Milton Keynes, United Kingdom). Hydrogen was used as carrier gas and temperature programming was from 50 to 160°C at 39°C/min and then to 225°C at 2°C/min. Individual methyl esters were identified by comparison to known standards and by reference to published data (30).

Extraction, separation, and enzyme immunoassay of PGE and prostaglandin F (PGF) isomers. Gill and kidney samples were dissected out, weighed, and immediately homogenized

in 3 mL of Hank's balanced salt solution containing 15% ethanol (vol/vol) and 0.15 mL of 2M formic acid. Homogenates were frozen in liquid nitrogen and stored at −20°C until the eicosanoids were extracted. The frozen homogenates were thawed and centrifuged (1000 × *g*, 5 min) to precipitate cell debris. The supernatants were extracted using octadecyl silica (C18) Sep-Pak minicolumns [Millipore (United Kingdom), Watford, United Kingdom)] by the method of Powell (31) and as described in detail by Bell *et al.* (18). The final extract was dissolved in 0.1 mL of methanol prior to HPLC. The isomers were separated by reverse phase high-performance liquid chromatography (HPLC) largely as described in Bell *et al.* (18). An isocratic solvent system was employed containing 17 mM phosphoric acid/acetonitrile (70:30, vol/vol) at a flow rate of 1 mL/min. The elution times of the two PGE and two PGF standards were determined by ultraviolet (UV) detection at 196 nm using a Pye-Unicam LC-UV detector. Fifty μL of the eicosanoid homogenate extract was injected onto the column and 1 mL fractions were collected using an LKB 2112 Redirac. Fractions corresponding to each PGE isomer were pooled and extracted as follows. The pooled fractions were applied to a C18 Sep-Pak which had been pre-washed with 5 mL methanol and 10 mL distilled water. The column was then washed with a further 10 mL of distilled water, and then the PGE eluted in 5 mL ethyl acetate. Samples were dried under nitrogen and redissolved in immunoassay buffer. The remaining 50 μL of the eicosanoid extract was injected onto the column, and fractions corresponding to the two PGF isomers were collected and concentrated as described for PGE isomers. Measurement of PGE and PGF isomers of the 2- and 3-series was performed using enzyme immunoassay kits for PGE_2 and $PGF_{2\alpha}$ according to the manufacturers' protocols (SPI-Bio, Massy, France). Cross reactivity of PGE_3 for the PGE_2 antibody and of $PGF_{3\alpha}$ for the $PGF_{2\alpha}$ antibody was 100% in both cases.

Determination of phospholipase A activity. Phospholipase A activity was assayed with endogenous substrate largely as described by Szymanska *et al.* (32). Gill filaments were dissected from the gill arch and homogenized in 2 mL of 50 mM Tris-HCl (pH 8.5) containing 200 mM KCl and $CaCl_2$. One mL was removed and the lipid extracted immediately by the method of Folch *et al.* (29), 0.1 mL was removed for protein determination and the remaining homogenate placed in a shaking water bath at 18°C. After 2 h, the reaction was terminated by addition of 5 mL of chloroform/methanol (2:1, vol/vol) containing 0.05% butylated hydroxytoluene and the lipids extracted as described above in the *Extraction and analysis of lipids* section. Free fatty acids, phosphatidylethanolamine (PE), and phosphatidylcholine (PC) in 0- and 2-h samples were separated by double-development high-performance thin-layer chromatography (HPTLC) as described by Bell *et al.* (19) and quantified by scanning densitometry using a Shimadzu CS-9000 (Tokyo, Japan) dual wavelength TLC scanner and DR-13 recording integrator.

Materials. TLC plates (20 × 20 cm × 0.25 mm) and HPTLC plates (10 × 10 cm × 0.25 mm) pre-coated with silica gel 60 were obtained from Merck (Darmstadt, Germany). All solvents were HPLC grade and were obtained from Rathburn Chemicals Ltd. (Walkerburn, United Kingdom). Hank's balanced salt solution was obtained from Flow Ltd. (Rickmansworth, United Kingdom).

Statistical analysis. Significance of difference ($P < 0.05$) between dietary treatments was determined by analysis of variance (ANOVA). Analyses were performed using a Statgraphics (system 3.0) computer package (Statistical Graphics Corporation, Rockville, MD). Data which were identified as nonhomogeneous (using Bartlett's test) were subjected to either arcsine square root or log transformation before ANOVA. Differences between means were determined by Tukey's test.

RESULTS

The fatty acid compositions of gill phospholipid classes are shown in Tables 2–5. In PC (Table 2) the level of total monoenoic fatty acids was significantly reduced in fish fed SO compared to those fed FO. Linoleic acid content was significantly different for each dietary treatment with the highest level in SO-fed fish and the lowest in those fed MO. Levels of 20:2n-6, 20:3n-6, and total n-6 PUFA were all significantly greater in fish fed SO compared to those fed LO which, in turn, had significantly higher levels than in either the FO- or MO-fed fish. AA was significantly higher in gill PC from fish fed SO compared to those fed any of the other diets but was significantly lower in fish fed LO compared to those fed FO. α-Linolenic acid, 18:3n-3, 20:3n-3, and 20:4n-3 were significantly increased in salmon fed LO compared to the other

[a]Values are weight % of total fatty acids. Values are means ± SD for four samples per dietary treatment. SD < 0.05 are tabulated as 0.0. Values in the same row with different superscript letters are significantly different ($P < 0.05$); trace value <0.05%. See Table 1 for abbreviations.

three treatments. EPA levels were significantly different in each dietary treatment with the highest value in fish fed MO followed by FO, LO, and lastly SO-fed fish. Levels of 22:5n-3 were significantly greatest in fish fed MO with those fed FO and LO having similar 22:5n-3 levels, while SO-fed fish had the lowest level. DHA levels were significantly greater in fish fed MO and FO compared to those fed SO or LO while total n-3 PUFA were significantly lower in SO-fed fish. Total PUFA were significantly greater in fish fed SO compared to those fed FO or MO and significantly greater in fish fed LO than fish fed FO. The n-3/n-6 PUFA ratio in fish fed FO and MO was significantly higher than in fish fed LO which was, in turn, significantly greater than those fed SO. The 20:4/20:5 eicosanoid precursor ratio was significantly greater in fish fed SO compared to the other three treatments.

The fatty acid compositions of gill PE are shown in Table 3. The level of total saturated fatty acids was significantly greater in fish fed MO compared to those fed LO. The levels of total monoenoic fatty acids were significantly different for each dietary treatment with the highest level in fish fed FO and the lowest in fish fed SO. The dietary induced changes in 18:2n-6, 20:2n-6, 20:3n-6, 22:5n-3, 20:4/20:5 ratio and total n-6 PUFA, in gill PE, were similar to those in PC, but AA was significantly elevated only in fish fed SO. α-Linolenic acid was significantly different in all dietary treatments with the highest level in fish fed LO and the lowest in fish fed SO while 20:3n-3 and 20:4n-3 were significantly increased only in fish fed LO. EPA was significantly increased in fish fed MO compared to all other treatments while FO- and LO-fed fish had significantly more EPA than those fed SO. Fish fed FO contained significantly more DHA than those fed MO, and both were significantly higher than those fed SO. Total n-3 PUFA were significantly greater in fish fed LO compared to all other treatments while those fed FO or MO contained significantly more n-3 PUFA than those fed SO. However, fish fed SO contained significantly more total PUFA than any other treatment, and LO-fed fish contained significantly more PUFA than either FO or MO-fed fish. The n-3/n-6 PUFA ratio was significantly different in all treatments with the highest value in MO-fed fish and the lowest in SO-fed fish. Total DMA were significantly greater in fish fed LO and MO compared to those fed SO and FO.

The fatty acid compositions of gill PI are shown in Table 4. Total saturates were significantly lower in fish fed FO compared to fish fed any of the other treatments. The level of 18:2n-6 was significantly greater in fish fed SO and significantly lower in those fed MO compared to all other treatments. The level of 20:2n-6 in gill PI was significantly greater in fish fed SO compared to those fed FO or MO. The level of 20:3n-6 was significantly greater in fish fed SO compared to the other three treatments and was significantly greater in fish fed LO compared to fish fed FO and MO. Total n-6 PUFA were significantly greater in fish fed SO compared to all other treatments. α-Linolenic acid and 20:3n-3 were significantly greater in gill PI from fish fed LO compared to the other three treatments while 20:3n-3 in fish fed MO was greater than in those fed FO or SO. The level of 20:4n-3 in fish fed LO was significantly greater than in fish fed SO or MO. EPA in gill PI was significantly greater in fish fed LO or MO compared to both other treatments while EPA was significantly lower in

fish fed SO compared to those fed FO. DHA was significantly reduced in fish fed SO compared to fish fed FO. Total n-3 PUFA were significantly lower in fish fed SO compared to the other three treatments. The 20:4/20:5 eicosanoid precursor ratio was significantly higher in fish fed SO compared to all other treatments while the ratio in fish fed FO was significantly higher than in fish fed LO or MO.

The AA and EPA composition and AA/EPA in PC, PE, and PI of salmon kidney are shown in Figures 1–3. In kidney PC (Fig. 1), AA was significantly reduced in fish fed LO compared to the other three treatments. EPA was significantly different for each dietary treatment with the highest value in fish fed MO and the lowest in those fed SO. The AA/EPA ratio was significantly greater in fish fed SO compared to the other three treatments. In kidney PE (Fig. 2), AA was significantly reduced in fish fed LO compared to fish fed FO or SO and was significantly greater in fish fed SO compared to the other three treatments. EPA was sigificantly reduced in SO-fed fish compared to the other three treatments and was significantly increased in fish fed MO compared to the other three groups. As with kidney PC, the AA/EPA ratio was significantly increased in fish fed SO compared to the other three treatments. In kidney PI (Fig. 3) AA was significantly reduced in fish fed LO compared to the other three treatments while AA was significantly lower in fish fed MO compared to those fed SO. EPA was significantly reduced in fish fed SO compared to the other three treatments and was significantly increased in fish fed MO compared to those fed FO. The AA/EPA ratio was significantly greater in fish fed SO compared to the other three treatments and was significantly greater in fish fed FO compared to those fed LO or MO.

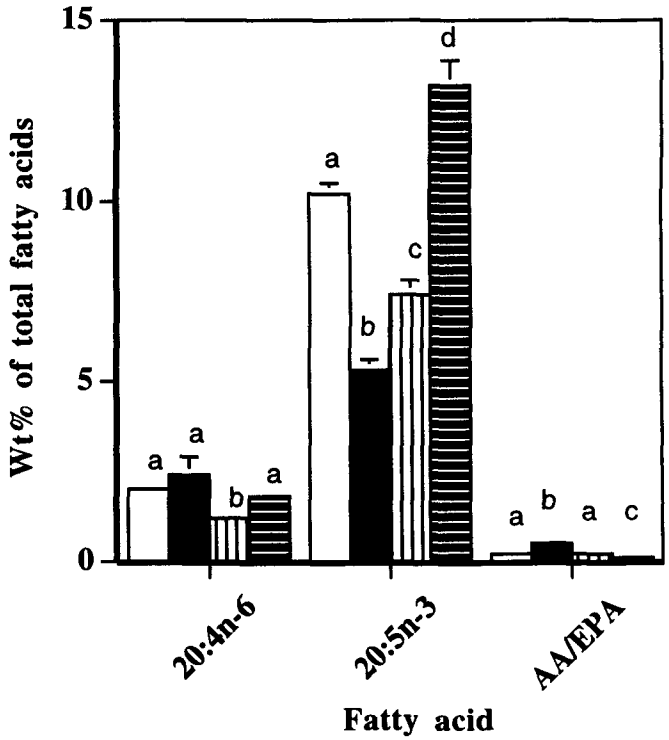

FIG. 1. Levels of 20:4n-6, 20:5n-3, and the ratio of arachidonic acid/eicosapentaenoic acid (AA/EPA) in kidney phosphatidylcholine from salmon fed diets containing either Fosol fish oil (open bars), sunflower oil (filled bars), linseed oil (vertical bars), or Marinol (horizontal bars). Values are means ± SD for four fish per treatment. Values for each fatty acid having a different column letter are significantly different ($P < 0.05$).

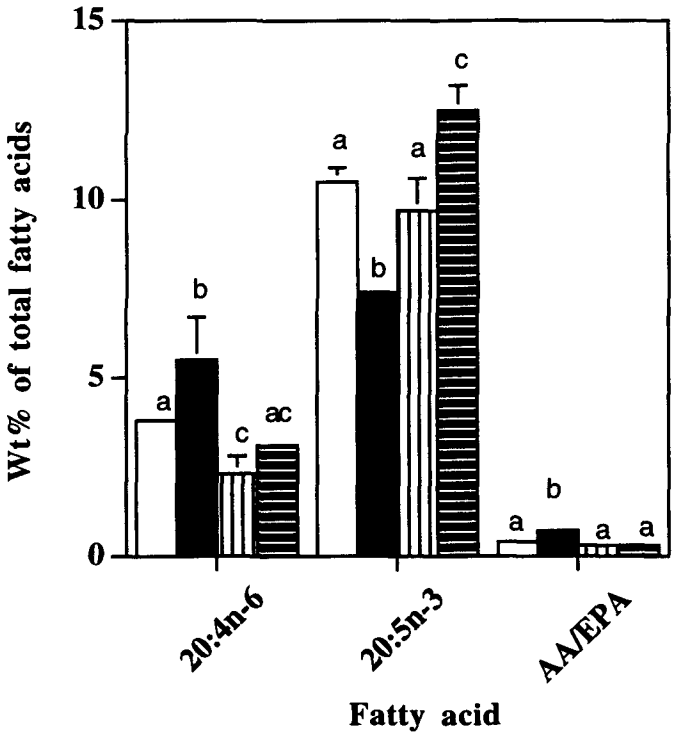

FIG. 2. Levels of 20:4n-6, 20:5n-3, and the ratio of AA/EPA in kidney phosphatidylethanolamine from salmon fed diets containing either Fosol fish oil (open bars), sunflower oil (filled bars), linseed oil (vertical bars), or Marinol (horizontal bars). Values are means ± SD for four fish per treatment. Values for each fatty acid having a different column letter are significantly different ($P < 0.05$).

The activities of gill phospholipase A, measured with endogenous substrate, are shown in Table 5. Results are calculated either as accumulation of free fatty acid or hydrolysis of PC and PE/h per mg protein. In terms of liberation of free fatty acid, the fish fed FO had significantly higher phospholipase A activity compared to the other three treatments with the activity in SO-fed fish being significantly lower than those fed LO. In terms of hydrolysis of PC and PE, the highest mean activity was again in fish fed FO, although this was not significantly different from those fed MO, and the lowest value was in fish fed SO which was significantly lower than in fish fed either FO or MO.

The concentrations of PGE and PGF isomers, of the 2- and 3-series, in gill homogenates are shown in Table 6. $PGF_{3\alpha}$ concentration was significantly greater in gills of fish fed MO compared to the other three treatments. $PGF_{2\alpha}$ concentration was significantly increased in fish fed SO compared to fish fed LO. The ratio of $PGF_{2\alpha}/PGF_{3\alpha}$ was significantly greater

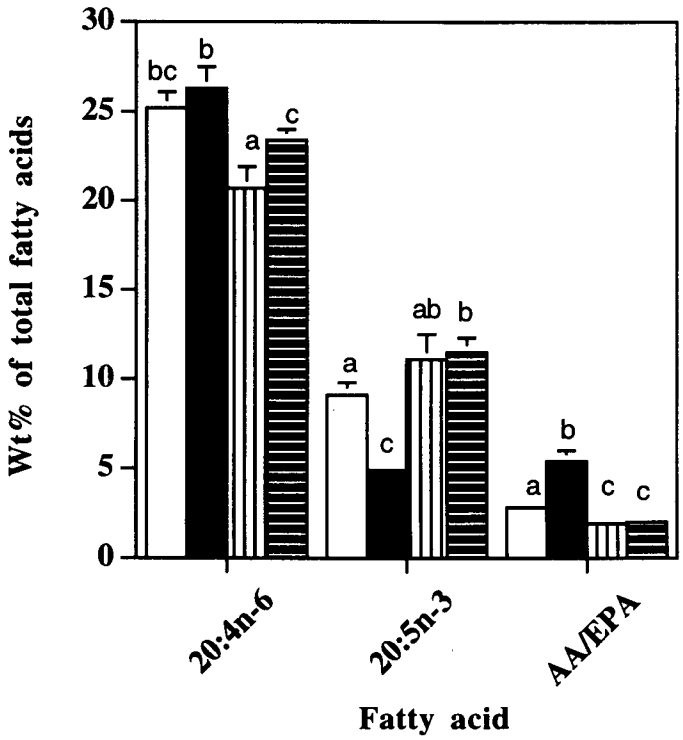

FIG. 3. Levels of 20:4n-6, 20:5n-3, and the ratio of AA/EPA in kidney phosphatidylinositol from salmon fed diets containing either Fosol fish oil (open bars), sunflower oil (filled bars), linseed oil (vertical bars), or Marinol (horizontal bars). Values are means ± SD for four fish per treatment. Values for each fatty acid having a different column letter are significantly different ($P < 0.05$).

in fish fed SO compared to all other treatments. The concentrations of PGE and PGF isomers, of the 2- and 3-series, in kidney homogenates are shown in Table 7. PGE_3 concentration was significantly reduced in kidney of fish fed SO compared to the other three treatments while PGE_2 was significantly increased in fish fed SO compared to those fed FO and LO. Consequently, the PGE_2/PGE_3 ratio was significantly greater in fish fed SO compared to the other three treatments.

TABLE 5
Phospholipase A Activities in Gills of Salmon Fed Diets Containing FO, SO, LO, or MO[a]

Phospholipase A activity	FO diet	SO diet	LO diet	MO diet
nmol fatty acid liberated/hour per mg protein	89.5 ± 10.5[a] (100%)	43.2 ± 5.3[b] (48%)	62.8 ± 3.1[c] (70%)	52.5 ± 4.5[b,c] (59%)
nmol PC and PE hydrolyzed/hour per mg protein	28.9 ± 3.5[a] (100%)	9.8 ± 2.5[b] (34%)	17.2 ± 6.8[b,c] (60%)	22.8 ± 3.7[a,c] (79%)

[a]Values in brackets are percentage of maximum activity. Values are means ± SD for four fish per dietary treatment. Values in the same row with different superscript letters are significantly different ($P < 0.05$); PC, phosphatidylcholine; PE, phosphatidylethanolamine. See Table 1 for other abbreviations.

TABLE 6
Concentrations of PGE_3, PGE_2, $PGF_{3\alpha}$, and $PGF_{2\alpha}$ in Homogenates of Gill from Salmon Fed Diets Containing Either FO, SO, LO, or MO[a]

Prostaglandin	FO diet	SO diet	LO diet	MO diet
PGE_3	11.4 ± 1.3	14.9 ± 2.3	19.4 ± 5.2	16.7 ± 0.5
PGE_2	14.3 ± 1.5	16.1 ± 0.5	11.1 ± 3.9	14.5 ± 4.1
PGE_2/PGE_3	1.3 ± 0.2	1.1 ± 0.3	0.6 ± 0.4	0.9 ± 0.3
$PGF_{3\alpha}$	0.15 ± 0.02[a]	0.10 ± 0.03[a]	0.10 ± 0.01[a]	0.39 ± 0.10[b]
$PGF_{2\alpha}$	0.27 ± 0.09[a,b]	0.44 ± 0.14[a]	0.10 ± 0.02[b]	0.32 ± 0.06[a,b]
$PGF_{2\alpha}/PGF_{3\alpha}$	1.8 ± 0.6[a]	3.5 ± 0.7[b]	1.0 ± 0.2[a]	0.9 ± 0.4[a]

[a]Values are pg/mg tissue and are means ± SD from four samples per dietary treatment. Values in the same row having different superscript letters are significantly different ($P < 0.05$). PGE, prostaglandin E; PGF, prostaglandin F. See Table 1 for other abbreviations.

DISCUSSION

The fatty acid compositions of gill and kidney from fish fed the two fish oils, FO and MO, were largely similar except that fish fed MO incorporated more EPA (up to 42%), and its elongation product 22:5n-3, into membrane phospholipids. This was reflected in a slight reduction in the AA/EPA eicosanoid precursor ratio in most phospholipid classes, although this change was only statistically significant in kidney PC and PI. The concentration of 22:6n-3 was similar or slightly less in phospholipids of fish fed MO compared to those given FO indicating that little of the increased EPA was converted to 22:6n-3 and probably indicated that both diets supplied sufficient 22:6n-3 to satisfy requirements. Fish fed the two plant-derived oils, SO and LO, accumulated increased levels of the principal dietary C_{18} PUFA, 18:2n-6, and 18:2n-6 and 18:3n-3 respectively, into tissue phospholipids. In addition, both treatments had significantly increased levels of 20:2n-6 and 20:3n-6, the products of elongation and of Δ6 desaturation and elongation, in membrane phospholipids compared to fish fed fish oils. However, while fish fed SO had increased levels of AA (the product of Δ5 desaturation) in tissue phospholipids, fish fed LO had AA levels which were significantly less than or equal to the values in fish fed fish oils. It is apparent that LO, which is rich in18:2n-6 but which also contains an abundance of 18:3n-3, has an inhibitory effect on the Δ5 desaturase responsible for conversion of 20:3n-6 to AA.

TABLE 7
Concentrations of PGE_3, PGE_2, $PGF_{3\alpha}$, and $PGF_{2\alpha}$ in Homogenates of Kidney from Salmon Fed Diets Containing Either FO, SO, LO, or MO[a]

Prostaglandin	FO diet	SO diet	LO diet	MO diet

[a]Footnotes as described for Table 7. SD <0.05 are tabulated as 0.0. See Tables 1 and 6 for abbreviations.

While the abundance of 18:2n-6 in SO-fed fish allows conversion to AA to proceed unhindered, the presence of competing n-3 PUFA, both 18:3n-3 and C_{20}, in LO-fed fish prevents the same conversion of 18:2n-6 to AA in the latter fish. Thus, in fish fed LO there is competition between 18:2n-6 and 18:3n-3 at the Δ6 desaturase and also between 20:3n-6 and 20:4n-3 at the Δ5 desaturase which results in an overall inhibition of AA production. The ability of diets rich in 18:3n-3 to inhibit conversion of 18:2n-6 to AA has been recorded previously in mammals (9,33), and in fish (20).

The fish fed SO and LO received similar levels of EPA from the diet yet phospholipids from fish fed LO contained significantly more EPA compared to fish fed SO and suggests appreciable conversion of 18:3n-3 to EPA in LO-fed fish. The ability of salmon parr, during the freshwater period of the salmon life cycle, to convert 18:3n-3 to DHA has been recorded previously (13) but as with the fish given pre-formed EPA in the form of MO those given LO did not have increased 22:6n-3 compared to fish fed FO. In general, the reduced EPA and increased AA in SO-fed fish and the increased EPA and reduced AA in LO-fed fish resulted in the former having a significantly higher AA/EPA ratio in tissue phospholipids compared to the latter. In LO-fed fish the EPA formed from 18:3n-3 appeared to be incorporated specifically into PI where the mean EPA values were in excess of those in fish fed FO in both kidney and gill. This further supports previous suggestions that PI may provide a source of precursors for eicosanoid production (34,35).

The fatty acid composition of phospholipids can influence the physical properties of cell membranes which, in turn, can influence the activities of membrane-associated proteins and enzymes (36), including those involved in phospholipid metabolism. Recent studies with rats have shown that an increased dietary n-3/n-6 PUFA ratio, resulting from feeding fish oil, caused increased activity of phospholipase A_2 in gastric mucosa (37) but reduced phospholipase A activity in liver and cardiac myocytes (38,39). In salmon fed a reduced n-3/n-6 PUFA ratio, resulting from feeding SO, the phospholipase A activity was increased in cardiac tissue compared to those fed FO (20). In the present study, fish fed FO had the highest phospholipase A activity followed by those fed MO and LO with the lowest activity in fish fed SO. Clearly the increased incorporation of n-6 PUFA and/or the reduced incorporation of long-chain n-3 PUFA was effective in reducing the activity of phospholipase A in salmon gill. This result explains the reduced production of lipoxygenase metabolites in salmon fed increasing levels of dietary linoleic acid (19). These results demonstrate the importance of phospholipid fatty acid composition in modifying the membrane microenvironment of the phospholipase enzyme which thereby can influence the catalytic activity of the enzyme. The precise mechanism of this process remains unclear, but two hypotheses could be appropriate in this case. Firstly, alterations in membrane PUFA composition could alter the physical characteristics of the membrane, including curvature, viscosity and fluidity, such that association of phospholipase with the membrane phospholipid substrate was altered allowing subsequent changes in phospholipase activity (40). Secondly, phospholipase A_2 is activated by peroxidized fatty acids, and since membranes enriched with long-chain n-3 PUFA have a higher unsaturation index, they may be more susceptible to peroxidation than membranes containing fewer unsaturated bonds (41). In addition to the above influences, PGE_1, derived from 20:3n-6, is known to inhibit release of AA from membrane phospholipids by phospholipases (42). Although PGE_1 concentrations were not measured in the present study, the percentage of 20:3n-6 was increased up to 18-fold, in fish fed SO, and up to 7-fold in fish fed LO, compared to fish fed either of the fish oils.

In addition to their respiratory activity, the gills of euryhaline fish are also involved in osmoregulation. The gills are involved in active transport of Na^+ and Cl^- with the direction of transport determined by external salinity. In euryhaline teleosts, the uptake of Na^+ and Cl^- is activated during adaptation to freshwater to maintain plasma concentrations of the above electrolytes at 120–150 mM (43). In seawater adapted teleosts, the branchial epithelium has an increased population of chloride cells, which are the site of active chloride transport, and also contain most of the Na^+/K^+-ATPase activity found in gill epithelia (44). The teleost kidney in fish adapted to freshwater produces large amounts of very dilute urine while after seawater adaptation, small quantities of very concentrated urine are produced. Kidney water and electrolyte regulation are controlled jointly by hormonal and eicosanoid messengers (15).

Prostaglandins E and F of the 2- and 3-series, derived from AA and EPA, respectively, were measured in homogenates from gill and kidney. Both tissues showed changes in the concentration and ratio of the 2- and 3-series of prostanoids which could be attributed to dietary fatty acid intake. In general, fish fed EPA-rich MO had the highest levels of the 3-series prostanoids, and in some instances these were matched by fish fed LO, while the lowest levels of 3-series prostanoids were in fish fed SO. Apart from gill PGE, the ratio of 2-series/3-series was increased in fish fed SO compared to the other treatments. Thus, the ratio of prostaglandins produced broadly reflected the ratio of precursor PUFA in the tissue phospholipids although comparison of the ratios did not clearly identify one phospholipid as the precursor source.

Although the ability of fish kidney and gill to synthesize prostaglandins has been identified for some time, the precise physiological functions were largely unknown (22,23). In more recent studies the effect of prostaglandins and hydroxy fatty acids, the latter being lipoxygenase metabolites, on osmoregulatory processes have been identified (21,25). Prostaglandins are modulators of fluid and electrolyte balance in fish kidney (45,46) and in gill and opercular membranes (26). PGE_2 and other prostanoids are known to operate in conjunction with prolactin, a hyperosmoregulatory hormone in teleost fish, to control electrolyte balance across gill epithelial membranes (47).

In the present study we have demonstrated that feeding di-

etary lipids with varying amounts of n-3 and n-6 PUFA, derived from fish and vegetable oils, can affect the fatty acid composition, and in particular the incorporation of C_{20} eicosanoid precursors, in salmon gill and kidney. We have also demonstrated the effects of these membrane PUFA alterations on phospholipase A activity and the production of AA- and EPA-derived prostanoids. While mammalian studies suggest that eicosanoids derived from EPA are generally of lower biological potency compared to their AA-derived homologues (48), this may not be true in fish where prostaglandins and leukotrienes derived from EPA and AA appear to have similar functions and efficacy with regard to a number of immunoregulatory activities (49). Clearly, the spectrum of eicosanoids produced by a particular cell is dependent on a more complex mechanistic process than the concentration or ratios of substrate fatty acids esterified in membrane phospholipids alone. The importance of the dietary induced changes described in this study to the physiological functions of osmoregulatory tissues in teleost fish is an area of continuing investigation.

ACKNOWLEDGMENT

We would like to thank all S.O.A.E.F.D. personnel involved in running the Fish Cultivation Unit, Aultbea, Scotland, for their expertise and assistance with fish husbandry.

ABSTRACT: The effects of growth temperature on the fatty acid compositions of the phosphatidylcholine (PC), phosphatidylethanolamine (PE), and total lipid (TL) fractions of the free-living nematode *Caenorhabditis elegans* were investigated. A reduction in growth temperature from 25 to 15°C caused the proportions of eicosapentaenoic acid (20:5n-3) to increase from 23.6 to 32.5% in the PC, from 7.4 to 10.8% in the PE, and from 12.9 to 19.9% in the TL fractions. Conversely, the levels of dihomo-γ-linolenic acid (20:3n-6) and arachidonic acid (20:4n-6) in these phospholipid fractions and the TL fraction both decreased with decreasing growth temperature. Analysis of the positional distribution of fatty acids in the PC fraction revealed that the change in the composition of C_{20} polyunsaturated fatty acid was obvious in position *sn*-2. Lowering the growth temperature induced an increase in the level of the diacyl subclass of PE from 58% at 25°C to 71% at 15°C, with a concomitant decrease in the levels of the alkylacyl and alkenylacyl subclass of PE of *C. elegans*. These changes observed in the phospholipids of *C. elegans* might be one mechanism for adaptation to low temperature.

Lipids 31, 1173–1178 (1996).

The free-living nematode *Caenorhabditis elegans* has been the subject of a number of recent biochemical studies such as investigations of behavioral genetics and experimental gerontology. Because of its small size and the fact that it is a self-fertilizing hermaphrodite, *C. elegans* can be easily grown under laboratory conditions with *Escherichia coli* as food. Using monoxenic culture conditions, there is no possibility for involvement of intermediate organisms between the nematodes and their food. This offers an advantage in the study of lipid metabolism of this multicellular organism.

Previously, we examined the phospholipid composition and fatty acid compositions of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of *C. elegans* and found that the nematode contained both n-3 and n-6 series polyunsaturated fatty acid (PUFA), and that eicosapentaenoic acid (EPA) (20:5n-3) was the most abundant fatty acid in the PC fraction (1). The abundance of EPA in the total lipids of *C. elegans* was also shown by Hutzell and Krusberg (2). In addition, the free-living nematode species *Turbatrix aceti* and the entomopathogenic nematode *Steinernema carpocapsae* have been shown to contain EPA and to have the ability to synthesize PUFA *de novo* (3–5).

Several lower classes of organisms have been reported to produce EPA *de novo* and accumulate a large amount of EPA to adapt to a decrease in environmental temperature. Shimizu *et al.* (6) showed that several fungal microorganisms produced a large amount of EPA only when grown at low temperature. The increased level of EPA at lower growth temperature was also observed in the *Vibrio* species of bacterium isolated from fish intestine (7) and the nematode *S. carpocapsae* (5).

In the present study, we examined the effects of temperature on the fatty acid compositions and subclass compositions of phospholipids of *C. elegans*. The results showed that the levels of EPA, the most abundant and the most unsaturated fatty acid in *C. elegans*, were increased in the PC, PE, and total lipid (TL) fractions when the nematodes were cultured at low temperature. Furthermore, lowering the growth temperature induced an increase in the level of the diacyl subclass of PE of *C. elegans*.

MATERIALS AND METHODS

Materials. Agar, peptone, tryptone, and yeast extract were obtained from Difco Laboratories (Detroit, MI). Glycerol and precoated thin-layer plates (Silica gel 60) were from Merck (Darmstadt, Germany). Silic AR (100–200 mesh) was the product of Mallinckrodt (Paris, KY). Phospholipase A_2 (EC 3.1.1.4, from *Crotalus adamanteus* venom) was from Sigma Chemical Co. (St. Louis, MO).

Growth of E. coli *and lipid extraction. Escherichia coli* (OP50 strain) was grown in a phosphate buffer (pH 7.4) with tryptone, glycerol, and yeast extract at 37°C. *Escherichia coli* from late-logarithmic cultures was centrifuged at 5,000 × *g* for 10 min. The pelleted *E. coli* was resuspended in S. medium (8) and stored at 4°C until use. For lipid analysis,

E. coli which had been stored at 4°C was homogenized by grinding in a mortar with a pestle in a small amount of chloroform/methanol mixture (1:2, vol/vol). The lipids were extracted from the homogenate according to the method of Bligh and Dyer (9).

Growth of C. elegans. The standard wild-type strain N2 of *C. elegans* was grown at temperatures (±0.5°C) of 15, 20, and 25°C on 90-mm nematode growth medium (NGM) agar plates seeded with *E. coli* as described previously (1). NGM agar plates were prepared as follows: NaCl, 3 g; agar, 17 g; peptone, 5.0 g; cholesterol (5 mg/mL in ethanol), 1 mL and H_2O, 975 mL were mixed, then autoclaved, and 1 M $CaCl_2$, 0.5 mL; 1 M $MgSO_4$, 1 mL and 1 M potassium phosphate (pH 6.0), 25 mL were mixed. The $CaCl_2$, $MgSO_4$, and potassium phosphate solutions were autoclaved separately before addition. Upon observation under the microscope, the worms on plates rich with adult worms were washed off the plates with M9 buffer (8). The suspension of bacteria and nematodes was centrifuged at 170 × *g* for 2 min to pellet the nematodes. The supernatant solution was discarded and the pelleted nematodes were repeatedly washed with M9 buffer. The packed worms were suspended with a small amount of M9 buffer, layered over 35% sucrose solution and centrifuged at 1,800 × *g* for 5 min. *Escherichia coli* and dead worms were sedimented, whereas live *C. elegans* floated on the sucrose layer. The live *C. elegans* was withdrawn and repeatedly washed with M9 buffer to remove sucrose. In another experiment, *C. elegans* was cultured at 25°C until the plates were rich with adult worms on NGM agar plates with *E. coli*. Half of the nematodes were then exposed to 15°C for 5 h before harvesting, and the other half of the nematodes were harvested without low temperature treatment. This shift in temperature was achieved within 30 min.

Lipid extraction and fractionation. Purified live *C. elegans* was homogenized by grinding in a mortar with a pestle in a small amount of chloroform/methanol mixture (1:2, vol/vol). TL were extracted from the homogenate according to the method of Bligh and Dyer (9) as described previously (1). The lipid extracts were fractionated into the neutral lipid fraction and the phospholipid fraction using silic AR column chromatography (1). The PC and PE fractions were prepared from the phospholipid fraction by preparative thin-layer chromatography (TLC) using the solvent system chloroform/methanol/H_2O (65:35:6, by vol). The triglyceride (TG) fraction was prepared from the neutral lipid fraction by TLC using the solvent system petroleum ether/diethyl ether/acetic acid (80:30:1, by vol). Detection was done with 0.01% primuline (in acetone/H_2O, 4:1, vol/vol) under ultraviolet light. The relative amounts of the PC and PE subclass were determined by successive degradation of the phospholipids with mild alkali and acid, respectively (10). Lipid phosphorus was determined by the method of Bartlett (11). The amount of TG was determined by gas chromatography (GC) with arachidic acid (20:0) as the internal standard.

Positional distribution of fatty acid in the PC and PE fraction. PC or PE (1 μmol) of *C. elegans* was dissolved in 3 mL of diethyl ether and 0.4 mL of 25 mM Tris-HCl buffer (pH 6.9) containing 5 mM NaCl and 55 mM $CaCl_2$. The reaction was started by adding 100 units of phospholipase A_2. The reaction mixture was stirred vigorously at room temperature for 2 h. After evaporation of the ether phase under a stream of N_2 gas, 2 mL of a chloroform/methanol mixture (1:1, vol/vol) and 0.5 mL of H_2O were added for phase separation. Lipids were recovered from the chloroform phase and subjected to silic AR column chromatography. Released fatty acids were recovered from the chloroform/methanol mixture (95:5, vol/vol) eluate, and phospholipids were recovered from the methanol eluate. Lysophospholipid was purified from the methanol eluate by preparative TLC. The released fatty acids and fatty acids esterified to lysoPC and lysoPE were subjected to transmethylation, and the resulting fatty acid methyl esters were analyzed by GC as described below. Unhydrolyzed PC and PE were both less than 2% compared to lysoPC and lysoPE, respectively. The hydrolysis of the *sn*-2-esterified fatty acid of PC by phospholipase A_2 was evaluated using 1-palmitoyl-2-[1-^{14}C] linoleoyl-GPC (12).

Fatty acid analysis. Fatty acyl residues of PC, PE, and TG of the *C. elegans* were converted to fatty acid methyl esters with 5% methanolic HCl and analyzed by GC (Shimadzu 14A; Shimadzu, Kyoto, Japan) equipped with a capillary column fused with a 0.25 μm film of polar CBP20 (0.22 mm × 30 m; Shimadzu). The temperature of both the injector and the flame-ionization detector was 250°C. The initial column temperature was set at 170°C and then raised to 225°C at 5°C/min. The fatty acid methyl esters obtained from the total lipid extracts of *C. elegans* were purified before GC by TLC using the solvent system petroleum ether/diethyl ether/acetic acid (80:30:1, by vol) to remove unsaponifiable materials. Fatty acid methyl esters were identified by comparing their retention times with those of authentic standards as described previously (1).

RESULTS

Effects of growth temperature on fatty acid composition of C. elegans. Because the standard wild-type strain N2 of *C. elegans* can be grown at temperatures between 12 and 25°C monoxenically on *E. coli* as a food source (8), we chose temperatures of 15, 20, and 25°C for growth of *C. elegans* in this study. The culture times of nematodes were 9–10 d, 7–8 d, and 6–7 d at 15, 20, and 25°C, respectively. The fatty acid compositions of the PC, PE, and TL fractions of *C. elegans* grown at these temperatures are shown in Table 1. Growth temperature affected the proportions of C_{20} PUFA in the PC, PE, and TL fractions of *C. elegans*. In the PC fraction, the level of EPA was increased from 23.6% at 25°C to 32.5% at 15°C. Conversely, dihomo-γ-linolenic acid (DGLA) (20:3n-6) and arachidonic acid (AA) (20:4n-6) in the PC fraction of *C. elegans* were both decreased with lowered growth temperature. Although the extent of the changes was smaller than that in the PC fraction, the increased level of EPA and the decreased level of AA were also observed in the PE and

[a]Values are weight percentage, as mean values ± SD (four, five and five harvests of nematodes grown at 15, 20, and 25°C, respectively and three harvests of *E. coli* grown at 37°C). Significantly different from *C. elegans* grown at 25°C as determined using the Student's *t*-test ([b]$P < 0.005$, [c]$P < 0.05$). [d]DMA, dimethylacetal. [e]N.D., Not detected; PC, phosphatidylcholine; PE, phosphatidylethanolamine; TL, total lipid.

TL fractions when the nematodes were cultured at low temperature. The proportions of saturated acids such as palmitic acid (16:0) and stearic acid (18:0) in the PC and TL fractions of the nematodes grown at 15°C were significantly lower than those in the nematodes grown at 25°C. Growth temperature also affected the levels of C_{18} unsaturated fatty acids in *C. elegans*. In the PC, PE, and TL fractions, the levels of oleic acid (18:1n-9) were decreased and the levels of linoleic acid (18:2n-6) were increased with lowering of the growth temperature.

Effects of growth temperature on the positional distribution of fatty acids in the PC and PE fraction of C. elegans. The positional distributions of fatty acids in the PC and PE fraction of *C. elegans* grown at 15 and 25°C were investigated (Table 2). The proportions of C_{20} PUFA located at the *sn*-2 position of PC were higher than those at the *sn*-1 position, but substantial proportions of C_{20} PUFA were present at the *sn*-1 position. The effects of growth temperature on the fatty acid composition of the PC fraction were more obvious in position *sn*-2 than in position *sn*-1. The reduction of growth temperature caused the proportion of EPA at the *sn*-2 position to increase from 34.2 to 42.9%. Although the level of AA esterified at the *sn*-1 position was not significantly affected by growth temperature, its level at the position *sn*-2 was lower at 15°C than that of 25°C (4.9% vs. 8.2%). The proportions of the C_{18} fatty acids and fatty alcohol (detected as dimethylacetal (DMA)) at the *sn*-1 position of PE were markedly influenced by growth temperature. The proportion of 18:0 DMA derived from the predominant alkenyl chain of PE of *C. elegans* (1) was decreased from 20.7% at 25°C to 6.2% at 15°C, in agreement with the results of analysis of PE subclass (see below). Conversely, the levels of stearic acid and *cis*-vaccenic acid (18:1n-7) in position *sn*-1 of PE were both increased with decreasing growth temperature.

Effects of short-term exposure of C. elegans *to low temperature on EPA content in the PC, PE, and TG fractions.* Next, we examined whether short-term exposure of *C. elegans* to low temperature affected the levels of EPA in the PC and PE fractions of the nematodes. In this experiment, we also investigated the change in the content of EPA in the TG fraction to examine the possibility that EPA esterified to TG was transferred to phospholipids as an emergency response to the reduced temperature. The amount of TG was almost equal to that of PC of *C. elegans* (molar ratio) and the proportion of EPA in the TG fraction of nematodes grown at 25°C was around 7%. When the nematodes grown at 25°C for 6–7 d were treated at 15°C for 5 h, the EPA level in the TG fraction was not affected. In contrast, the EPA level in the PC fraction was significantly increased compared to the *C. elegans* maintained at 25°C (Fig. 1). These results indicated that recruitment of EPA from TG to PC would not contribute to the increase in the EPA level in the PC fraction in these experimental conditions.

Effects of growth temperature on subclass composition of PC and PE of C. elegans. As described previously, PE of *C. elegans* contained substantial proportions of the alkylacyl

and alkenylacyl subclass (1). These subclasses of PE were both decreased with lowered growth temperature. Conversely, the content of the diacyl subclass of PE was increased from 58% at 25°C to 71% at 15°C (Fig. 2). In contrast to the PE fraction, a large portion of PC was accounted for by the diacyl subclass (93.5% at 25°C and 95.3% at 15°C), irrespective of the growth temperature.

DISCUSSION

Under the monoxenic culture conditions used in this study, *E. coli* was the food for *C. elegans*. Despite the fact that the fatty acids which comprised the *E. coli* lipids were saturated, cyclopropane-ringed and n-7 series monoenoic fatty acids (Table 1), *C. elegans* contained n-3 and n-6 series PUFA. This indicates that *C. elegans* has the ability to synthesize these highly unsaturated fatty acids *de novo*, as in the nematodes *T. aceti* (4) and *S. carpocapsae* (5). Although higher animals have been considered unable to synthesize linoleic acid *de novo*, some insect species (13,14), the land slug (15), the garden snail (15), and protozoan amoeba (16), have recently been reported to have ω6 desaturase activity. Both ω6 and ω3 desaturase activities must be present in the multicellular animal *C. elegans*, because the nematodes contain n-6 and n-3 series PUFA. Furthermore, the presence of EPA and AA in *C. elegans* also indicates that this nematode has the ability to desaturate the Δ-6 and Δ-5 positions of fatty acid like higher animals.

Lowering the growth temperature has been shown to induce alterations in membrane fatty acid compositions in various organisms. The nematode *C. elegans* tested here showed an increase in EPA levels and decrease in AA and DGLA levels in the PC and PE fractions when cultured at low temperature. These changes in the composition of C_{20} PUFA in response to a decreased growth temperature agree with similar results in *S. carpocapsae* (5). The increase in the level of EPA and the decrease in the levels of DGLA and AA with lowered growth temperature observed in the PC fraction of *C. elegans* was more obvious in position *sn*-2 than *sn*-1. It appears that the amounts of EPA synthesized *de novo* are increased at lower temperature, because the elevated level of EPA was also observed in the TL fraction of *C. elegans*. A possible explanation of this phenomenon is that the activities of the ω3 and Δ-6 desaturase (both of which deasaturate linoleic acid) were differently affected by the growth temperature. At lower growth temperature, amounts of linoleic acid metabolized by ω3 desaturase might be increased to form more abundant α-linolenic acid. This change might lead to the elevated level of EPA with depressed levels of n-6 series PUFA such as AA. It should be mentioned that an ω3 desaturase activity which produced EPA from AA was present in certain lower fungi (6,17) and the free-living nematode *T. aceti* (4). Further investigations are necessary to elucidate the details of the mechanism underlying the increase in the EPA level in response to a decreased growth temperature in the nematodes.

When the nematodes grown at 25°C for 6–7 d were exposed to 15°C for 5 h, the level of EPA in the PC fraction was significantly increased. In this experiment, the content of EPA in the TG fraction was not affected. Therefore, EPA was rapidly synthesized in response to thermal fluctuations to adapt to low

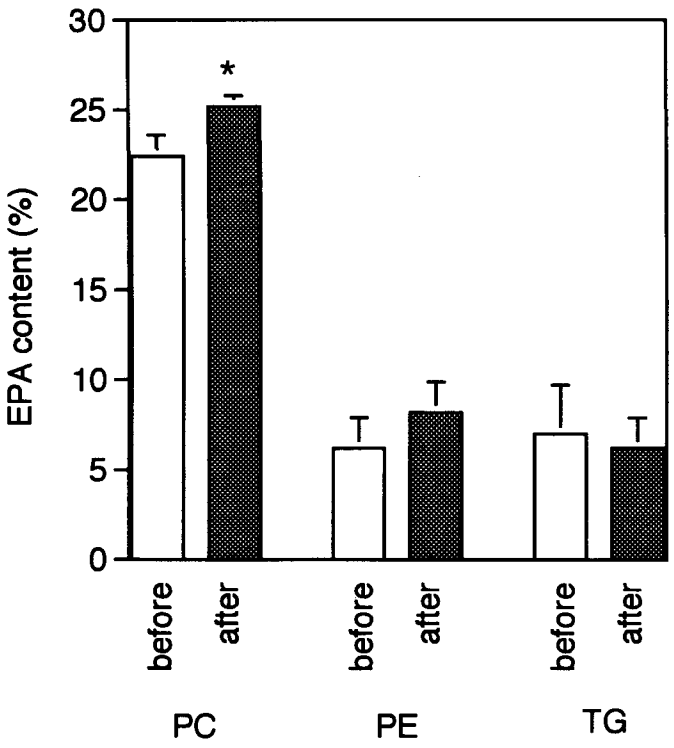

FIG. 1. Effects of short-term exposure of *Caenorhabditis elegans* to low temperature on eicosapentaenoic acid (EPA) content in various lipid classes. Values are weight percent, as mean values ± SD (three harvests of nematodes). *Caenorhabditis elegans* was cultured at 25°C for 6–7 d. Half of the nematodes were then harvested, and the other nematodes were exposed to 15°C for 5 h before harvesting. *Significantly different from the proportion of EPA of *C. elegans* without low temperature treatment as determined using the Student's *t*-test ($P < 0.05$); open bar, before temperature shift; shaded bar, after temperature shift; PE, phosphatidylethanolamine; PC, phosphatidylcholine; TG, triglyceride.

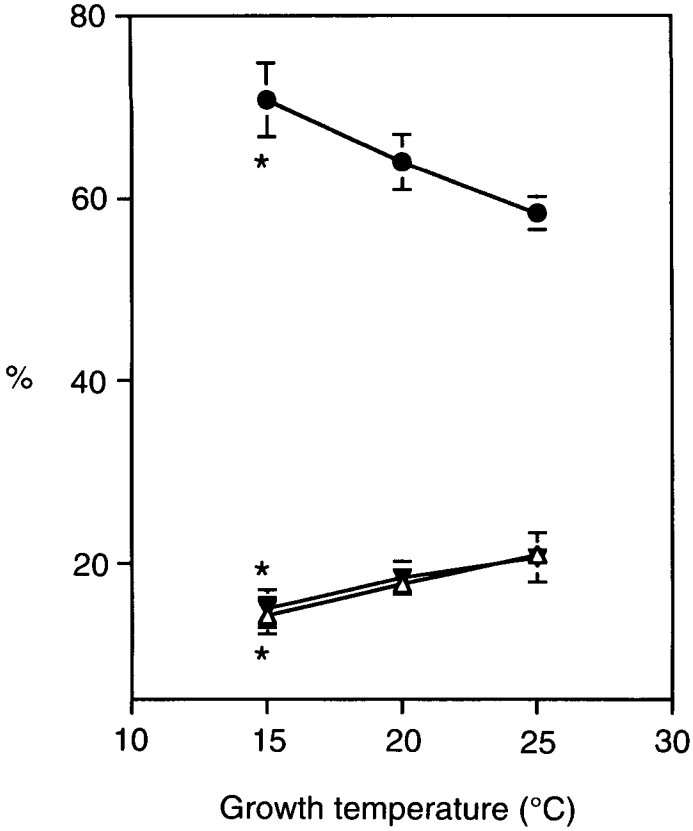

FIG. 2. Effects of growth temperature on the subclass composition of PE of *Caenorhabditis elegans*. *Caenorhabditis elegans* was grown at temperatures of 15, 20, and 25°C. Values are mean ± SD (four, five, and five harvests of nematodes grown at 15, 20, and 25°C, respectively). *Significantly different from the proportion of the corresponding PE subclass of *C. elegans* grown at 25°C as determined using the Student's *t*-test ($P < 0.005$); —●—, diacyl; —△—, alkylacyl; —▼—, alkenylacyl.

temperature rather than through recruitment of EPA from TG to PC.

Growth temperature affected the subclass composition of the PE fraction. At lower growth temperature, the levels of stearic acid and *cis*-vaccenic acid in position *sn*-1 of PE were markedly increased with a concomitant decrease in the level of 18:0 DMA, indicating that the depressed level of alkylacyl and alkenylacyl subclasses of PE were compensated for by the increase in levels of diacylPE containing these C_{18} fatty acids in position *sn*-1. Judging from experiments with monolayers and bilayers, ether bonding has been considered to be less polar than carbonyl ester bonding (18,19). Moreover, PE containing monoenoic acid at position *sn*-1 have been shown to have a disordering effect on biomembranes (20,21). Therefore, the increase in the proportion of PE molecular species with a monoenoic acid in position *sn*-1 might increase the membrane fluidity.

In conclusion, lowering the growth temperature induced the increased level of EPA in the PC, PE, and TL fractions of *C. elegans*. The proportion of the diacyl subclass of PE was also increased with lowered growth temperature. Such changes observed in the phospholipids of *C. elegans* might be one mechanism for the adaptation to low temperature.

ABSTRACT: *Lagenidium giganteum,* a facultative parasite of mosquito larvae, cannot synthesize sterols, and requires an exogenous source of these lipids in order to enter its reproductive cycle. This parasite grows vegetatively in the absence of sterols, but requires cholesterol or structurally related compounds to produce motile zoospores, which are the only stage capable of infecting mosquitoes. Sterols structurally related to cholesterol and some steryl esters inhibited the activity of *L. giganteum* phospholipase A_2 (PLA_2), an enzyme that hydrolyzes fatty acids from the *sn*-2 position of glycerophospholipids. Sterols that induce reproduction inhibited *L. giganteum* PLA_2 activity, while sterols and steroids that do not support sporulation had minimal effect. Most steryl esters had no effect on enzyme activity, but cholesteryl arachidonate (CA) was a potent inhibitor of parasite PLA_2. Not all enzymes partly purified using a DEAE-Sephacel column were affected by these lipids, demonstrating selective inhibition of specific enzymes. Potency was enhanced by up to several orders of magnitude if epoxy fatty acids were esterified to the cholesterol nucleus. The steryl ester pool was dynamic during morphogenesis, and the fatty acid composition of the steryl esters did not mimic total cell or membrane (glycerophospholipid) fatty acid composition as *L. giganteum* proceeded through its growth cycle. Synthesis of CA and monoepoxy CA by the parasite was confirmed using electrospray mass spectrometry and collision-induced dissociation. Steryl derivatives selectively inhibited PLA_2 enzymes from bovine pancreas, snake venom, and human cytoplasmic 85-kDa PLA_2.
Lipids 31, 1179–1188 (1996).

Three decades ago it was discovered that sterol auxotrophic Oomycetes found in the genera *Pythium* and *Phytophthora*, which include primarily plant parasites, require an exogenous source of sterols in order to complete their sexual cycle (1–3). It was subsequently found that a third member of this group, *Lagenidium giganteum* (Oomycetes: Lagenidiales), a facultative parasite of mosquito larvae, also requires exogenous sterols structurally related to cholesterol to enter its asexual (4) and sexual (5) cycles. These Oomycetes, a group classically regarded as fungi but now recognized as being allied with diatoms and other chromist algae (6,7), grow vegetatively in the absence of sterols. Although the subject of numerous investigations over the last 30 years (reviewed in Refs. 8–10), the physiological bases of sterol-mediated morphogenesis of these Oomycetes are not known. Most investigations have focused on structure–activity studies reiterating the dual structural and regulatory roles of sterols that had previously been documented in other organisms (11–13).

Oosporogenesis, the production of sexual propagules, can be initiated in the absence of sterols in species of *Phytophthora* and *Pythium* (but not by *L. giganteum*) especially when growth media are supplemented with glycerophospholipids containing unsaturated fatty acid moieties (14). Viable oospores, however, could not be produced without minimal levels of sterol supplementation (15). The most interesting finding regarding sterol-mediated morphogenesis of these auxotrophs was the pivotal role of the ring and side-chain structural features during the onset of meiosis (16). Abortion of oospores not supplemented with cholesterol occurred during the early stages of meiosis, usually soon after fusion of male and female gametangia.

Phospholipases A_2 (PLA_2) are a family of enzymes that hydrolyze fatty acids in the *sn*-2 position of glycerophospholipids, resulting in release of a free fatty acid and a lysophospholipid (17,18). These widespread enzymes have a variety of physiological roles including digestion, membrane synthesis and remodeling, as major components of snake and bee venom, and in providing free arachidonic acid (20:4n-6) for subsequent metabolism by lipoxygenase, cyclooxygenase, and other fatty acid oxygenase enzymes. Oxygenated fatty acids, especially arachidonic acid derivatives collectively known as eicosanoids, are lipid mediators of many inflammatory and allergic reactions. The search for selective inhibitors of PLA_2, therefore, is the focus for much research in both academic and pharmaceutical laboratories (19–21).

Recently we showed that log growth phase cultures of *L. giganteum* growing on defined media supplemented with

cholesterol had over four times as much PLA_2 activity as comparable cultures grown in the absence of sterol (22), possibly due to increased rates of membrane synthesis or remodeling. This difference disappeared when enzyme activities in stationary phase cultures were compared. Subsequent *in vitro* assays demonstrated that cholesterol and related sterols added to cell homogenates directly affected PLA_2 activity. Assays for screening PLA_2 inhibitors are fraught with difficulty because of interfacial activation (enzyme activity for micellar and other aggregates can be up to three orders of magnitude greater than that for monomeric substrates) and related complications associated with the composition, concentration, and availability of substrate (23–25). Many PLA_2 inhibitors added at millimolar or high micromolar concentrations act simply by denying the enzyme access to the substrate rather than by specifically interacting with the enzyme (26). Taking these potential complications into consideration, this report extends our initial observations to the effect of steryl esters and hydroxy and epoxy derivatives of steryl esters on enzyme activity. Selective inhibition of PLA_2 from different organisms by various compounds belonging to this new class of inhibitor, including a human enzyme implicated in inflammation, is demonstrated.

MATERIALS AND METHODS

Materials. Enzymes, cold substrate, and other chemicals were obtained from Sigma (St. Louis, MO) or Aldrich Chemical Company (Milwaukee, WI) unless otherwise noted. The cholesteryl esters of cholesteryl-9-hydroxy-10,12-octadecadienoic acid (9-HODE) and cholestery-13-hydroxy-9,11-octadecadienoic acid (13-HODE) were from Cayman Chemical (Ann Arbor, MI). Radiolabelled glycerophospholipids were from New England Nuclear (Boston, MA).

Source and maintenance of the parasite. Cultures of the California isolate of *L. giganteum* (ATCC 52675) were maintained on two types of media. Defined medium designated DM2 (43) consisted of (gram/liter distilled water): 4 glucose, 2 glutamic acid monosodium salt, 1 asparagine, 0.036 $MnCl_2 \cdot 4\ H_2O$, 0.01 $ZnSO_4 \cdot 7H_2O$, 0.063 H_3BO_3, 0.008 $CuSO_4 \cdot 5\ H_2O$, 0.01$(NH_4)_6Mo7O_2 \cdot 4\ H_2O$), 0.017 $CoCl_2 \cdot 6\ H_2O$, 0.012 $Fe(NO_3)_3 \cdot 9\ H_2O$, 0.05 EDTA, 0.05 KH_2PO_4, 0.05 K_2HPO_4, 0.1 thiamine HCl, 0.1 KNO_3, 0.05 methionine, 0.1 $MgSO_4 \cdot 7\ H_2O$), 0.15 $CaCl_2 \cdot 2\ H_2O$, pH 7.0. Reproductively competent cultures were grown on PB2 medium (gram/liter distilled water): 2 Proflo cottonseed extract (Traders Protein, Memphis, TN), 1.5 glucose, 0.5 lactalbumin hydrolysate, 1.0 egg yolk, 0.225 $CaCl_2 \cdot 2\ H_2O$, 0.3 $MgCl_2 \cdot 6\ H_2O$, 0.008 $Fe(NO_3)_3 \cdot 9\ H_2O$, 0.1 fish peptone, pH 7.5. DM2 cultures were grown in 1 L of media in 2800 mL Fernbach flasks (Scientific Products, McGaw Park, IL), and PB2 cultures were maintained in 200 mL of media in 1 L flasks, on a gyrotary shaker for two to seven days.

Homogenization and column chromatographic separation of phospholipase fractions. Cells harvested by filtration on Whatman filter paper (Maidstone, England) were homogenized in lysing buffer (50 mM Tricine, 1 mM EDTA, 1 mM EGTA, 1 mM phenylmethylsulfonyl fluoride dissolved in ethanol, pH 8.5) in a stainless-steel cup with a Virtis (Lab-Line Instruments, Melrose Park, IL) homogenizer for 6–8 min, with liquid nitrogen added approximately every 2 min. Cell disruption was confirmed microscopically. The mycelial homogenate was centrifuged at 10 K × *g* for 30 min and stored at –20°C until use.

Fractions containing PLA_2 activity were obtained by homogenate separation on a 23 × 120-mm DEAE-Sephacel column (Pharmacia) using a NaCl salt step gradient (27). Homogenate containing approximately 15 mg protein (Bio-Rad protein assay; Richmond, CA) was layered on the column and fractionated with eluting buffer (10 mM KCl, 1 mM DTT, 100 mM Tris-HCl, pH 8.0) with 0, 100, 500, and 800 mM NaCl (100 mL of each). Ten mL aliquots were collected, and these were then stored in 1–1.5 mL aliquots at –70°C until use. Fractions were screened for PLA_2 activity with and without cholesterol. Selected fractions exhibiting sterol-mediated enzyme activity were used in subsequent assays.

PLA_2 assay. Radiometric PLA_2 assays were performed using L-α-1-*O*-hexadecyl-2-[5,6,8,9,11,12,14,15-^{3}H]-arachidonoyl phosphatidylcholine (*ca.* 55 mCi/mmol; New England Nuclear) as substrate, following a slight modification of methods developed by Gronich *et al.* (28) and Ghomaschi *et al.* (29). For all enzymes except for the human 85 kDa cytoplasmic PLA_2, the reaction mixture consisted of 4 μL of 30 mM $CaCl_2 \cdot 2\ H_2O$, 3 μL substrate dissolved in DMSO (final substrate concentration of 9.9 μM), and 34 μL enzyme solution. For the 85 kDa enzyme, the buffer in which the enzyme was shipped was driven off by nitrogen, and the enzyme resuspended in 0.5 mL of 80 mM glycine containing 200 μM Triton X-100 (Sigma), 5 mM $CaCl_2 \cdot 2\ H_2O$, 250 μg fatty acid-free bovine serum albumin mL^{-1}, 70% (vol/vol) glycerol, pH 9.0 (30). The reactions were carried out in 1.5 mL glass vials in a shaking water bath for 30 min at 30°C. Enzyme concentrations were adjusted so that in control assays approximately 40–50% of the substrate was metabolized. (The theoretical maximum is approximately 50% substrate hydrolysis.) Stock solutions of steroids, sterols, and steryl esters in hexane were dried under N_2 in reaction vials, and their effects on PLA_2 activity were assessed following 15-min preincubation with shaking at 30°C in the absence of substrate. The reaction was stopped with 370 μL of $CHCl_3/CH_3OH/HCl$ (200:100:1, by vol), followed by sequential addition of 460 μL of $CHCl_3/CH_3OH/H_2O$ (1:2:0.8, by vol), 240 μL $CHCl_3$, 240 μL H_2O, and 10 μL of a carrier solution (stock solution consisting of 400 μL arachidonic acid plus 600 μL of 50 μg/mL 2,6-di-*tert*-butyl-4-methylphenol in DMSO). After vortexing, the top layer was removed, and the bottom layer collected. The concentrated bottom layer was applied to a silica gel column (5–6 cm) in a Pasteur pipet. Free fatty acids were eluted with *ca.* 3.5 mL hexane/diethyl ether/HOAc (70:30:1, by vol) into 4 mL Wheaton Omnivials. The eluent was evaporated under N_2 and suspended in aquasol from New England Nuclear (Wilmington, DE) for liquid scintillation counting analysis.

Data are reported as mean ± 1 SD ($n \geq 3$), and have been normalized to controls.

Synthesis and thin-layer chromatography (TLC) of epoxy fatty acid steryl esters (SE). Epoxide derivatives of cholesteryl arachidonate, cholesteryl linoleate, and cholesteryl linolenate were synthesized using the method of Falck *et al.* (31). Ten mg of the SE was dissolved in 2.61 mL ice cold CH_2Cl_2 and 6.33 mg of 3-chloroperoxybenzoic acid slowly added. Following incubation for 12–15 h at 0°C, 16.67 µL of methyl sulfide was added and the mixture held for 20 min at room temperature. After dilution with 5 mL CH_2Cl_2, the epoxy derivatives were washed in a separatory funnel three times with 5 mL H_2O and then once with 5 mL NaCl-saturated H_2O. The bottom (organic) layer was dried under N_2, the residue resuspended in $CHCl_3/H_2O$ (1:1, vol/vol), the H_2O layer discarded, and the organic layer dried. The epoxides were weighed and stored in MeOH at −70°C. A portion of the mixture was separated on silica gel G plates using hexane/diethyl ether/acetic acid (70:30:1, by vol). A prescored portion of the plate was broken off and the epoxides visualized by exposure to I_2 vapor. Individual bands were eluted from the plate with MeOH and the fractions stored in the same solvent at −70°C. Epoxides were hydrolyzed into polyols by suspension in tetrahydrofuran/H_2O/perchloric acid (18:8.5:0.175, by vol) and stirred for 8 h at room temperature. The reaction was terminated by adding 20 mL H_2O followed by extraction with CH_2Cl_2 (32). The organic layer was dried and the derivatives stored at −70°C until use.

Whole cell, SE, and glycerophospholipid fatty acid analysis. Cultures of the parasite were grown in liquid shake culture on PB2 medium, and separate flasks harvested during log growth phase (15-h post-inoculation), at the time of initiation of oosporogenesis (35-h post-inoculation), and during stationary growth (4-d post-inoculation). Following collection by filtration, total cell lipids were extracted by standard Folch extraction (33). Glycerophospholipids were eluted just above the origin, and the SE fraction collected from near the solvent front following TLC using the system described for the SE epoxides. Fatty acid methyl esters (FAME) were obtained using acetyl chloride following the one-step transesterification procedure of Lepage and Roy (34). FAME were analyzed on a Hewlett-Packard 5890 Series II gas chromatograph (Palo Alto, CA) using a 30 m DB-23 column (J&W Scientific, Folsom, CA). The initial temperature of 120°C was held for 2 min then raised at 4°C per min up to 240°C and held for 10 min. Using He as a carrier gas at 2 mL/min and the constant flow mode of gas chromatography (GC) operation, splitless sample injection was at 200°C and the detector held at 280°C. FAME were identified by comparison with retention times of standards. Fatty acid composition for *L. giganteum* grown in PB2 had previously been confirmed by GC–mass spectrometry (MS) and electrospray (ESI)–MS.

ESI–MS. ESI–MS and tandem mass spectrometry (collision-induced dissociation, ESI–MS/MS) was performed using a triple quadrupole Sciex API III instrument (Thornhill, Ontario, Canada). Samples were dissolved in 5 mM ammonium acetate in methanol, and infused into the electrospray source *via* a 50 µM silica transfer line using a Harvard Apparatus pump at 2–3 µL/min. Positive ion ESI–MS and ESI–MS/MS used an orifice voltage of 65–75 V and an interface temperature of 52°C. For ESI–MS/MS precursor ions were selected with the first of three quadrupoles (Q1) for collision-induced dissociation with argon in the second quadrupole (Q2). The third quadrupole (Q3) was scanned with a mass step of 0.20 Da and 1 ms per step. Precursor ion transmission and related parameters were adjusted so as to achieve slightly better than unit resolution (35). Spectra were collected and analyzed using proprietary software from Sciex.

RESULTS

Enzyme stability and endogenous inhibition. Lagenidium giganteum PLA_2 activity in 10 K × *g* supernatant was stable for several months at −20°C; however, after separation on the DEAE-sephacel column, enzyme activity was rapidly lost if the fractions were stored at less than −70°C. Individual column fractions lost activity if they were thawed more than 2–3 times. Potent endogenous PLA_2 inhibitors were removed during the column chromatographic separation. These compounds could be extracted from 10 K × *g* supernatant with methylene chloride, and two inhibitory fractions were obtained following TLC—one that comigrated with phospholipid standards and a second with an R_f value similar to SE. These inhibitors were not further characterized.

Sterol and steroid regulation of PLA_2 activity. At a concentration of 600 µM, sterols that induce *L. giganteum* oosporogenesis, including ergosterol, 7-dehydrocholesterol, 5-cholestene 3β, 4β-diol, and cholesterol, inhibited PLA_2 activity of crude 10 K homogenates by 55–65% (Fig. 1). Cholestane, desmosterol, cholesterol-5α,6α-epoxide, and ecdysteroids (insect molting hormones), which do not promote reproduction, were found to have minimal effect. Sterols that have some biological activity but that cannot induce appreciable numbers of viable oospores, such as lanosterol and epicholesterol, were found to have an intermediate effect (*ca.* 40–50% inhibition). There was not a well-defined correlation between oospore induction and PLA_2 inhibition in all cases. Ergosterol, which is very effective in inducing *L. giganteum* sporulation if care is taken to minimize degradation of the conjugated ring system during medium preparation, was not significantly more effective than compounds such as epicholesterol and lanosterol that induce minimal reproduction (Fig. 1). There was some variability in the relative effect of sterols on PLA_2 activity in homogenates from different *L. giganteum* cultures, probably due to small differences in the production and activation of at least eight different enzymes capable of hydrolyzing fatty acyl esters in the *sn*-2 position (43), some of which were unaffected by sterols. Cholesterol at the same concentration (600 µM) did not have a significant effect on the activity of two commercially available enzymes, bovine pancreas and *Naja naja* venom PLA_2 (Sigma).

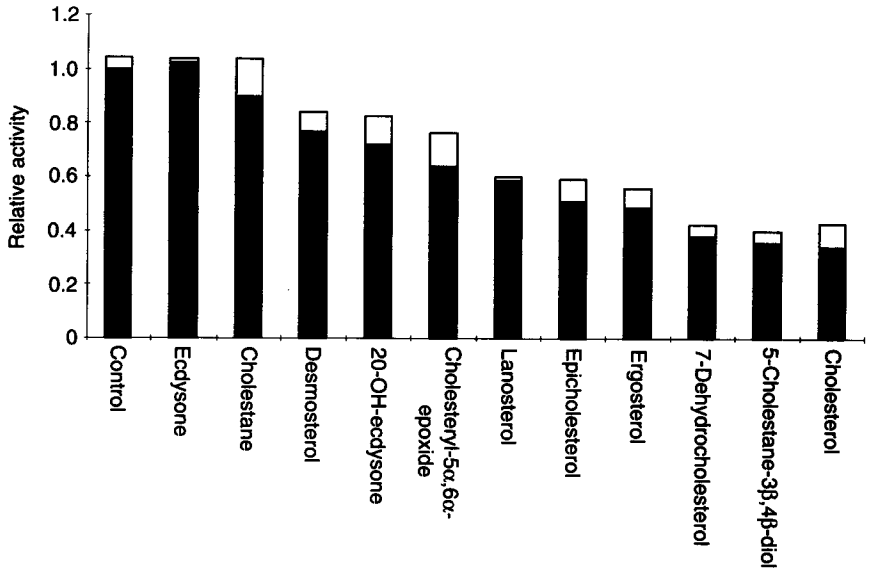

FIG. 1. Effect of sterols (600 μM) on phospholipase A_2 (PLA_2) activity of 10 K × *g* homogenates from *Lagenidium giganteum*. Data is expressed relative to control activity (mean ± SD, $n \geq 3$).

SE. SE were found to have variable effects. Tested on two active *L. giganteum* fractions from a DEAE-Sephacel column that were inhibited by cholesterol (100 mM NaCl/fraction 5 and 800 mM NaCl/fraction 2), cholesteryl palmitate and cholesteryl linoleate, and a number of short-chain esters were not inhibitory at 600 μM (Fig. 2), but cholesteryl arachidonate inhibited PLA_2 activity by 88% at the same concentration.

Cholesteryl-9-HODE and cholesteryl-13-HODE were found to have variable effects on different enzymes. When tested against *L. giganteum* enzymes at 600 μM, the cholesteryl ester of 9-HODE inhibited substrate hydrolysis by about 53%, while the 13-HODE derivative gave no significant inhi-

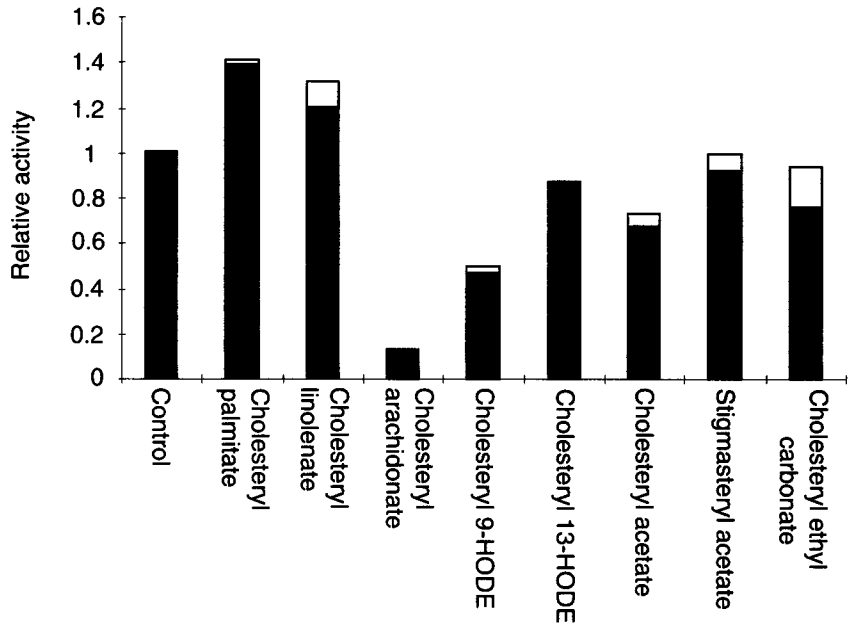

FIG. 2. Effect of steryl esters (600 μM) on PLA_2 activity of 10 K × *g* homogenates from *Lagenidium giganteum*. Data is expressed relative to control activity (mean ± SD, $n \geq 3$). See Figure 1 for abbreviation.

bition (Fig. 2). When tested at the same concentration against the PLA_2 from *Naja naja* venom, both the 9-HODE and 13-HODE cholesteryl esters were found to be extremely inhibitory, with 90 and 92% inhibition, respectively. Human recombinant 85 kDa cytoplasmic PLA_2 was inhibited by over 75% by cholesteryl-13-HODE.

Except for a role in lipid transport, SE are largely considered to be metabolically inert storage compounds. Following separation of SE and glycerophospholipid (GPL) fractions from other lipids using TLC, cycling of the fatty acyl constituents during *L. giganteum* morphogenesis was followed by GC of the FAME. For some fatty acids, e.g., palmitic acid (16:0), there were minor changes in the mol% fatty acyl composition of the SE fraction as the parasite proceeded from log growth, to the initiation of sexual reproduction, and then to stationary phase growth (Table 1). There were significant changes in the mol% fatty acyl composition of other species, especially involving oleic (18:1n-9) and linoleic (18:2n-6) acids (Table 1). Whole cell and GPL fatty acid composition (relative mol%) also changed during morphogenesis, but did not necessarily match the SE fatty acyl composition. This was especially true for arachidonic acid (20:4n-6) where there were very great increases in this polyunsaturated fatty acid during the transition from log growth to later stages in morphogenesis in the whole cell and GPL fractions that was not mirrored by increases in the SE fraction (Table 1).

Positive ion ESI–MS and ESI–MS/MS were used to analyze the SE fraction from a stationary phase culture of the parasite. It was determined that *L. giganteum* synthesized cholesteryl arachidonate and the monoepoxy derivative of this ester (see spectra below). It was not possible to determine the specific epoxy isomer synthesized by the parasite using this spectrometric method.

[b]Trace—<0.1 mol%. There were at least a dozen other minor fatty acids present. Cell, whole cell fatty acid methyl esters (FAME) extract; GPL, FAME of glycerophospholipids; SE, FAME of steryl esters.

Epoxy SE. Of all compounds tested, the mix of cholesteryl arachidonate epoxides (CAE) was the most potent *L. giganteum* PLA_2 inhibitor, with over 90% inhibition of 10 K × *g* supernatant enzyme activity at 630 μM, and inhibition of over 80% of some of the partly purified *L. giganteum* enzymes at concentrations as low as 6 nM. Note that here and in following sections where we are dealing with mixtures of epoxide or polyol isomers, the approximate mid-range molecular weight of the mixtures, e.g., that corresponding to the diepoxy linolenate derivative, was used to generate approximate inhibitor molarities. ESI–MS and ESI–MS/MS examination of the CAE revealed a mixture of mono-, di-, tri-, tetra, and pentaepoxide isomers (Fig. 3).

A preliminary separation of the mixture was done using normal-phase TLC plates with a mobile phase of hexane/ether/glacial acetic acid (70:30:1, by vol). ESI–MS/MS analysis of the TLC fractions revealed that the tetra- and pentaepoxides remained near the origin, with mono- and diepoxides migrating close to the solvent front. When tested for their effects on the activity of an active fraction eluted from a DEAE-sephacel column (100 mM NaCl/fraction 5), most of the epoxide isomers were found to be inhibitory. TLC fractions 1 and 2 (monoepoxides), 5–7 (triepoxides), and 9 and 10 (tetra- and pentaepoxides) were found to be significantly inhibitory at 60 μM (Table 2). When added at 6 μM, the effect on PLA_2 activity of some of the epoxide TLC fractions was reversed, with activity increasing. Lower concentrations of the different fractions were not evaluated.

The activity of human recombinant 85 kDa PLA_2 was significantly increased by preincubation with the CAE mix from concentrations of 6 nM to 60 μM. Because of the inhibition found with cholesteryl-13-HODE (18-carbon hydroxy fatty acid moiety), we synthesized epoxy derivatives of cholesteryl linoleate (18:2n-6 fatty acid) and cholesteryl linolenate (18:3n-3). Both mixtures of epoxide isomers inhibited the 85 kDa enzyme at a concentration of 50 μM, but had no effect on *L. giganteum* PLA_2. The mixture of epoxylinolenate de-

[a]The number of epoxy groups in each thin-layer chromatography (TLC) fraction was determined using positive ion electrospray tandem mass spectrometry (ESI–MS/MS).

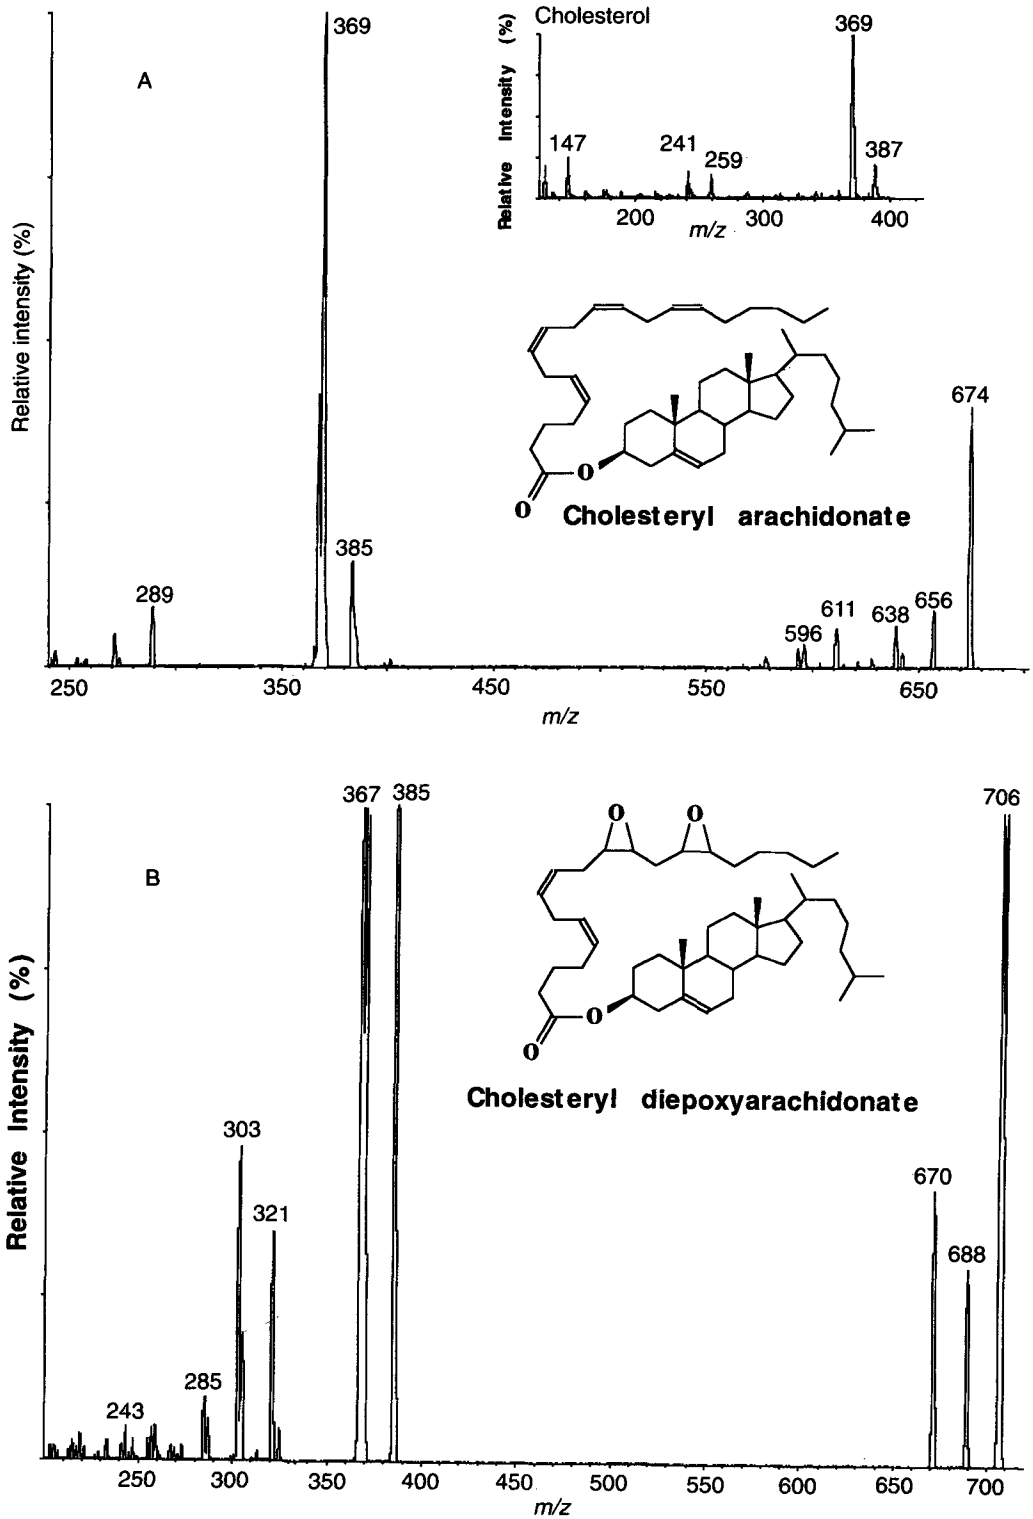

FIG. 3. A. Positive ion electrospray tandem mass spectrum of cholesterol (inset) and cholesteryl arachidonate. B. Positive ion electrospray tandem mass spectrum of diepoxy cholesteryl arachidonate. There are a number of positional and geometric isomers contributing to this spectrum, the structure of only one of which is depicted.

rivatives was most active against the human enzyme, with 500 nM inhibiting substrate hydrolysis by almost 80%.

Cholesterol, cholesteryl arachidonate, CAE, and CA polyols [CAE hydrolyzed by the method of Nourooz-Zadeh *et al.* (32)], were tested to determine their lowest inhibitory concentrations against *L. giganteum* PLA_2 and eluted from the DEAE-Sephacel column (100 mM NaCl/fraction 5 and 800 mM NaCl/fraction 2). The mixture of CAE was by far the most potent inhibitor, with >70% inhibition at levels as low as 6 nM. Inhibition comparable to that found using CAE was obtained using cholesterol, cholesteryl arachidonate, and the mixture of cholesteryl arachidonate diols (obtained by chemical hydrolysis of the CAE mixture) at concentrations of 600 μM, 70 μM, and 600 μM, respectively. The polyol mixture inhibited the activity of bovine pancreas PLA_2 by over 90% at a concentration of 3 μM.

DISCUSSION

We have demonstrated a correlation between ability of certain sterols to induce oosporogenesis and selectively inhibit *L. giganteum* PLA_2 enzymes. Lack of effect by sterols on some enzymes was expected since this parasite, which completely digests its mosquito larval hosts, must have a variety of lipolytic enzymes. Some of these would be constitutively expressed, nonspecific lipases, while others—those more likely to be under regulatory control—would be involved in specific developmental processes. Using mouse fibroblast cell membranes as substrates, it had previously been shown that sterol depletion enhanced metabolism of phosphatidylcholine (but not phosphatidylethanolamine) by PLA_2 present in β-bungarotoxin (36), but we found no effect of cholesterol on the activity of enzymes from bovine pancreas or snake venom.

This report is the first to show *in vitro* sterol regulation of a specific class of enzyme since sterol induction of reproduction by *Pythium and Phytophthora* was first described over three decades ago (2,3,37). Showing a physiological role for sterols and steryl derivatives in regulating PLA_2 and (a)sexual reproduction by this parasite would require a concerted research effort, that would include determination of: substrate specificity of acyltransferases, epoxidases (cytochromes P450), and epoxide hydrolases; developmental regulation of SE and PLA_2 synthesis; and subcellular colocalization of SE and specific PLA_2 that are subject to (epoxy) SE regulation.

The SE FAME composition of *L. giganteum* did not mimic either the whole cell or membrane composition. This preliminary observation suggests that this lipid class, generally considered to be metabolically inert (38,39), may have physiological functions in addition to storage and lipid transport.

Interfacial activation of PLA_2, and most other enzymes involved in lipid metabolism, are operationally defined as enzyme activity directed toward substrates at an organized interface (40). In addition to enzyme and substrate concentrations, kinetic analysis (and screening for inhibition) of these enzymes must also consider the organization of the lipid aggregate and related factors that affect enzyme binding to the interface (24,41,42). At least for pharmacologically and biochemically useful compounds, only active site-directed inhibitors are desirable. Compounds that act by restricting access of enzyme to substrate by binding to the vesicle surface are of little interest.

It is possible that the effects on *L. giganteum* PLA_2 of cholesterol and other sterols and steroids listed in Figure 1 were due to this type of nonspecific interference. This conclusion is based on the relatively high concentration of steroid needed to inhibit substrate hydrolysis. It is generally assumed that structural features of sterols necessary for them to interact with phospholipids include a planar ring sytem, a hydrophobic side-chain with or without a C-24 alkyl substituent, and a free 3β-OH group (43). Interpretation of our results is complicated by the fact that our assay used a DMSO-based vesicle system. It is likely that all of the steroids and sterols examined were solubilized by DMSO, although it could be argued that only those compounds meeting the structural criteria listed above associated with the GPL substrate per se. Inactive compounds such as cholestane and cholesteryl epoxide could preferentially partition into DMSO-rich areas of the vesicles, having minimal effect on enzyme access to substrate. This interpretation, however, does not explain why desmosterol, which also meets the criteria for interacting with GPL, was ineffective in inhibiting parasite PLA_2. Partitioning of the relatively hydrophilic ecdysteroids during the PLA_2 assays is difficult to predict, but these compounds were inactive both in the induction of oosporogenesis and in PLA_2 inhibition. In any case the high concentration of sterol needed for inhibition does not preclude a physiological role for cholesterol and related sterols in regulating this enzyme *in vivo*, since in some membranes cholesterol can make up over 50 mol% of total lipid.

The case for specific interaction with the enzyme becomes stronger as the results with the SE are considered. First, since all the compounds we examined had fatty acids in the C-3 position, the requirement for a free 3β-OH group is not met. As before, it is probable that DMSO-based vesicles will incorporate many classes of lipids, including SE, but preferential association of the inhibitors with the glycerolipid substrate is not likely. Second, we documented specific inhibition of enzymes from different biological sources by different steroids. If these compounds were acting primarily by binding to vesicles and thereby interfering with enzyme access to substrate, it would be expected that all PLA_2 would be similarly affected. It is difficult to explain why, for example, cholesteryl arachidonate but not cholesteryl linolenate inhibited *L. giganteum* PLA_2 if these compounds were only acting by nonspecific interference with enzyme binding to vesicles. Third, as we proceeded to evaluation of the steryl epoxy fatty acid derivatives, inhibition (or in some cases activation) of substrate hydrolysis occurred using nanomolar concentrations of these compounds. Since the substrate concentration is nearly 10 μM, it is not likely that nanomolar inhibitor concentrations would have the observed effects on enzyme activity. Kinetic analyses of PLA_2 are best performed using

assays in the scooting mode and monitored by the pH-stat method (44). Our radiometric assay is not amenable to this type of analysis, so we cannot support our conclusions with kinetic data.

Triterpenoids isolated by Jain *et al.* (24) from peppercorn berries that inhibit PLA_2 activity bear the closest structural resemblance of any described inhibitors to the steryl derivatives described here. The two inhibitory compounds that they describe, which have either a hydroxyl or a carbonyl group at C-3, are characterized by a terminal carboxyl group on the alkyl moiety attached to C-17, which appeared to be in contact with the catalytic site. Unlike those compounds, the SE evaluated in this investigation are not amphipathic. As concluded by Jain *et al.* (24), who used x-ray crystallographic data generated for native enzymes and those bound to various inhibitors (45–47), it is possible that the rigid tetracyclic nucleus of these lipids interacts with the hydrophobic region bordering the cavity that leads to the active site. In order to explain the specificity of inhibition demonstrated in this investigation, it must be assumed that the fatty acyl moiety interacts directly with the catalytic site. The size of the active site pocket in the different classes of PLA_2 has been invoked as the explanation for specificity or lack thereof for hydrolysis of certain fatty acids (48), and may explain preferential inhibition of enzymes from different organisms by different steryl derivatives. Activation of the human 85 kDa enzyme by CAE is complemented by preferential hydrolysis of arachidonic acid in GPL by this enzyme. Since none of the steryl epoxy fatty acids were completely purified, it is not possible to delineate the precise structural features required for inhibition.

Introduction of epoxide or hydroxyl groups into the esterified fatty acyl chain greatly enhanced their inhibitory activity. This is in apparent contrast to the increased activity of PLA_2 enzymes from several organisms documented when the phospholipid substrate included peroxidized lipids (49–52). The structure of the oxidized moieties was not examined in those studies, although it is probable that at least some hydroxyl and epoxide groups were produced by nonenzymatic dehydration of the hydroperoxides.

Lipoxygenase or related fatty acid oxygenase activity has been demonstrated to regulate sexual reproduction by *L. giganteum* (53) and related Oomycetes (54–56). We have documented synthesis of cholesteryl epoxy arachidonate by *L. giganteum*, and oxygenation of SE could be involved in regulating growth and reproduction by these organisms.

Several useful observations emerged from this investigation of sterol-mediated PLA_2 activity. SE may not be as metabolically inert as previously assumed, and the length of the fatty acyl moiety differentially regulates PLA_2 activity. Epoxidation of fatty acid SE can significantly alter biochemical activity of these compounds. The discovery of a new class of inhibitor for these enzymes, with selective activity against PLA_2 from different organisms, has possible implications for treatment of inflammatory diseases.

ACKNOWLEDGMENTS

This work was supported in part by grants from the National Institutes of Health (AI 22993 and AI 34339), and by the Bosack Kruger Charitable Foundation, Redmond, Washington. Genetics Institute, Cambridge, Massachusetts, kindly provided recombinant human 85 kDa PLA_2. Lanosterol was obtained from W.D. Nes (Texas Tech University, Lubbock, TX) and ecdysone from M.J. Thompson (U.S. Department of Agriculture, Beltsville, MD).

Alk-1-enylacyl, Alkylacyl, and Diacyl Subclasses of Native Ethanolamine and Choline Glycerophospholipids Can Be Quantified Directly by Phosphorus-31 NMR in Solution[1]

Barbara Malewicz and Wolfgang J. Baumann*

Membrane Chemistry and Biology Section, The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

ABSTRACT: We show that phosphorus-31 nuclear magnetic resonance spectroscopy can be used to distinguish and to quantify the alk-1-enylacyl, alkylacyl, and diacyl glycerophosphoethanolamine (GPE) subclasses, and the respective glycerophosphocholine (GPC) subclasses, in their native form without prior degradation or derivatization, provided the phospholipids are observed in the nonaggregated state. Monomeric phospholipid distribution is ascertained by recording the spectra, after removal of metal ions, on $CDCl_3/CD_3OD/D_2O$ (50:50:15, by vol) solutions. The utility of this approach is exemplified for the ethanolamine glycerophospholipids (EPL) from bovine brain and the choline glycerophospholipids (CPL) from bovine heart. Sharp and well-resolved resonances are obtained for alkylacylGPE (+0.395 ppm; re 1% H_3PO_4), alkenylacylGPE (+0.353 ppm), and diacylGPE (+0.315 ppm), and for alkylacylGPC (–0.383 ppm), alkenylacylGPC (–0.436 ppm) and diacylGPC (–0.451 ppm). Integrated peak areas are shown to closely correlate with dose. Accurate quantitation of EPL and CPL subclasses at submicromolar levels can further be facilitated by use of synthetic dialkylGPE (+0.602 ppm) and dialkylGPC (–0.196 ppm) as internal standards. The method is simple, rapid, sensitive and reproducible, and permits the complete resolution and direct quantitation of all ethanolamine and choline glycerophospholipid subclasses quite independent of fatty chain length and degree of unsaturation.
Lipids 31, 1189–1195 (1996).

Phosphatidylethanolamines (PE) and phosphatidylcholines (PC) from natural sources often contain the respective alk-1-enylacyl and alkylacyl subclasses in addition to the diacyl species (for reviews, see Refs. 2–4). In fact, in some tissues, including brain (5–8), nerve (9) or heart (5–7, 10,11), the alk-1-enylacyl glycerophosphoethanolamine (GPE) or glycerophosphocholine (GPC) species can be more abundant than diacylGPE or diacylGPC. However, it has generally not been possible either to separate the native alk-1-enylacyl, alkylacyl and diacyl ethanolamine glycerophospholipid (EPL) or choline glycerophospholipid (CPL) subclasses from each other, or to quantitate the intact subclasses in the presence of each other.

Current procedures for the analysis of the alkenylacyl, alkylacyl, and diacyl GPE and GPC subclasses in biological samples typically involve acidic, alkaline or phospholipase-catalyzed hydrolysis (5,10,12–15), acid-catalyzed transmethylation (16), or $LiAlH_4$ reduction (17,18) followed by characterization of the long-chain moieties by gas chromatographic techniques (for a review, see Ref. 19). Alternatively, the EPL and CPL subclasses can be resolved as the respective diradylglycerol derivatives which are obtained by phospholipase C catalyzed removal of the polar phosphobase headgroup (14,20,21) and by replacing it with a less polar acetyl (8,14,20,22), benzoyl (23,24), or 3,5-dinitrobenzoyl (25–28) function. The nonpolar diradylglycerol derivatives can then be resolved by thin-layer chromatography (TLC; Refs. 14,20,23), gas–liquid chromatography (22), or high-performance liquid chromatography (8,23–28), and further assayed or characterized by spectroscopic techniques (15,23,29).

We present here an alternative experimental approach by which the native alk-1-enylacyl, alkylacyl and diacyl GPE and GPC subclasses can be distinguished from each other and can be quantified directly on natural EPL and CPL fractions without prior degradation or derivatization. The method is based on the observation that phosphorus-31 nuclear magnetic resonance (NMR) gives distinct and well-resolved signals for each of the EPL and CPL subclasses, provided that intermolecular interactions are minimized through appropriate choice of the solvent medium.

MATERIALS AND METHODS

Materials. Solvents used were freshly distilled from a glass apparatus. Deuterated solvents were purchased from Cam-

bridge Isotope Laboratories (Andover, MA). EPL from bovine brain (brain PE fraction) and CPL from bovine heart (heart PC fraction) were obtained from Avanti Polar Lipids (Alabaster, AL). 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine used as standards were also from Avanti. Ether lipid standards were synthesized in our laboratory following established procedures (30,31). *rac*-1,2-Di-*O*-octadecylglycero-3-phosphoethanolamine used as dialkylGPE standard was synthesized from dioctadecyl glycerol ether (32) using the Hirt and Berchtold (33) phosphorylation procedure; *rac*-1,2-di-*O*-hexadecylglycero-3-phosphocholine used as dialkylGPC standard was prepared from dihexadecyl glycerol ether (32) according to Hansen *et al.* (34). All standards used were pure as judged by TLC (see below), and their structures were verified by ^{13}C NMR on $CDCl_3/CD_3OD/D_2O$ (50:50:15, by vol) solutions (35) and comparison with published data (34,36,37).

Chromatography and sample preparation . Phospholipids were resolved by TLC on 0.5-mm layers of Silica Gel H (Merck, Darmstadt, Germany) using $CHCl_3/CH_3OH/H_2O$ (65:35:8, by vol) as developing solvent. TLC plates were predeveloped in methanol, dried, and activated at 120°C for 15 min prior to applying the lipid samples. For analytical purposes, fractions were made visible by spraying with concentrated sulfuric acid/CH_3OH (1:1, vol/vol) followed by charring at 190°C. In preparative work, lipid fractions were localized by gently blowing iodine vapors (by means of a Pasteur pipette containing a few iodine crystals) over the lanes of suitable standards that were typically run along both edges of the plate. Residual iodine was removed under a stream of nitrogen, and lipid bands were immediately scraped off the plate. Phospholipids were eluted with $CHCl_3/CH_3OH/H_2O$ (50:40:10, by vol), and the adsorbent was separated by filtration through a 0.45-μm Acrodisc (13CR; Gelman Sciences, Inc., Ann Arbor, MI) and washed two to three times with fresh solvent. To remove metal ions (38) from the combined eluates, the solvent ratio was adjusted to arrive at a Folch mixture (39) in which $CHCl_3$ and CH_3OH were present at a 2:1 (vol/vol) ratio with the water phase (20% of $CHCl_3/CH_3OH$ volume) consisting of 10 mM EDTA in 2 mM Tris buffer (pH 8), and the mixture was vortexed for 30 s. Upon separation of the layers, the upper phase was reextracted with the appropriate amount of fresh Folch lower phase, and the combined lower phase lipid extracts were evaporated under a stream of nitrogen prior to NMR analysis. Total phospholipid contents were determined by inorganic phosphorus assay (40).

Phosphorus-31 NMR measurements. ^{31}P NMR spectra were recorded at 121.42 MHz on a Varian Unity 300 instrument (Varian Associates, Palo Alto, CA) using a 5-mm variable temperature probe. Standard single-pulse experiments entailed a 90° pulse of 10 μs, an acquisition time of 3.2 s, and a pulse delay of 16 s (T_1 ~3 s), with the decoupler gated *on* during acquisition only. The spectral width was 430 Hz, and 2752 datapoints were collected. The number of transients ranged from 16 to 3200, depending on the phospholipid concentration. Data were zero-filled and Fourier-transformed without applying exponential linebroadening which permitted a spectral resolution of 0.1 Hz. Spectra were referenced relative to 1% H_3PO_4 which was sealed into a 1-mm i.d. glass capillary that was concentrically placed in the NMR sample tube to serve as external standard. The 1% H_3PO_4 standard (0.00 ppm) was chosen in lieu of the more common 85% H_3PO_4 reference (–0.48 ppm) to keep the signal intensity of the standard commensurate with the phospholipid signal intensities observed on the small analytical samples used. Spectra were recorded at 25 ± 0.1°C on freshly prepared samples dissolved in $CDCl_3/CD_3OD/D_2O$ (50:50:15, by vol), using $CDCl_3$, CD_3OD, and D_2O that had been purged of dissolved oxygen by a stream of nitrogen to minimize linebroadening. Peak assignments were verified based on alkenylacyl/alkylacyl conversion by hydrogenation and on acid-catalyzed hydrolysis of the alkenylacyl species, and were aided by the use of synthetic alkylacyl and diacyl phospholipid standards. Peak areas were measured by digital integration.

RESULTS

Figure 1 shows the high-resolution phosphorus-31 NMR spectra (121.42 MHz) which we obtained on a PE fraction from bovine brain (Fig. 1, left panel) and on a PC fraction from bovine heart (Fig. 1, right panel). Spectra were recorded after isolating the ethanolamine and the choline glycerophospholipid fractions by TLC, removing metal ions by EDTA treatment, and upon dispersing the samples in deuterated chloroform/methanol/water (50:50:15, by vol). Sharp and well-resolved resonances are seen for alkylacylGPE (+0.395 ppm), alkenylacylGPE (+0.353 ppm), and diacylGPE (+0.315 ppm), with all the signals located downfield from 1% H_3PO_4, and for alkylacylGPC (–0.383 ppm), alkenylacylGPC (–0.436 ppm), and diacylGPC (–0.451 ppm), with all the signals located upfield from 1% H_3PO_4.

Figure 1 demonstrates that useful spectra can be obtained within a reasonable time (64 transients; ~20 min) on lipid samples of moderate size (10 μmol; ~7 mg). The spectra could easily be improved by increasing sample size or total acquisition time. Although the signal-to-noise ratios of these spectra were not optimized, the resonances are actually quite sharp with apparent linewidths at halfheight ($\nu_{1/2}$) of about 1.7 to 1.8 Hz for the EPL signals, and about 0.5 to 0.6 Hz for the CPL signals. The somewhat greater apparent linewidths at halfheight of the EPL signals can be attributed to minute chemical shift differences between respective diradylGPE species bearing saturated and unsaturated aliphatic chains. Such "finesplitting" is not indicated for the CPL signals (Malewicz, B., and Baumann, W.J., unpublished data).

Because the chemical shift differences between the alkylacyl, alkenylacyl, and diacyl GPE signals are quite small (i.e., 0.038-0.042 ppm; ~5 Hz), and are even smaller between alkenylacylGPC and diacylGPC (0.015 ppm; ~1.8 Hz), it is crucial that phosphorus linewidth is minimized and signal

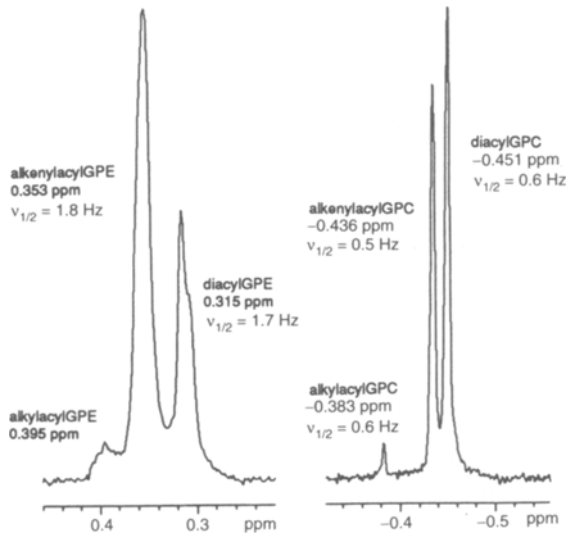

FIG. 1. ^{31}P nuclear magnetic resonance spectra (121.42 MHz) of the ethanolamine glycerophospholipids (EPL) from bovine brain (left panel) and the choline glycerophospholipids (CPL) from bovine heart (right panel). The EPL and CPL fractions were isolated by silicic acid thin-layer chromatography, using $CHCl_3/CH_3OH/H_2O$ (65:35:8, by vol) as developing solvent, and eluted from the adsorbent with $CHCl_3/CH_3OH/H_2O$ (50:40:10, by vol). Metal ions were removed by EDTA treatment, and spectra were recorded on samples (10 μmol each, 64 transients) dissolved in $CDCl_3/CD_3OD/D_2O$ (50:50:15, by vol). Chemical shifts are given in ppm relative to 1% H_3PO_4 (0.0 ppm) which served as external standard. Well-resolved narrow signals ($\nu_{1/2}$ 0.5–1.8 Hz) are observed for each of the alkylacyl, alkenylacyl and diacyl EPL and CPL subclasses.

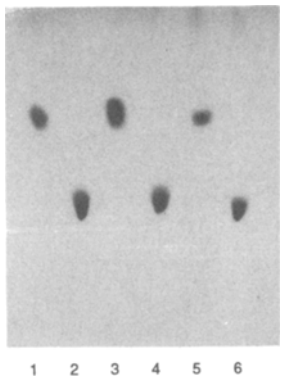

FIG. 2. Thin-layer chromatogram illustrating the relative migration rates of various ethanolamine and choline glycerophospholipids on Silica Gel H using $CHCl_3/CH_3OH/H_2O$ (65:35:8, by vol) as developing solvent. The fractions are designated as: **1**, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine; **2**, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine; **3**, ethanolamine glycerophospholipid fraction from bovine brain; **4**, choline glycerophospholipid fraction from bovine heart; **5**, *rac*-1,2-di-*O*-octadecylglycero-3-phosphoethanolamine; and **6**, *rac*-1,2-di-*O*-hexadecylglycero-3-phosphocholine. Phospholipid fractions were made visible by charring after spraying with sulfuric acid/CH_3OH (1:1, vol/vol).

resolution optimized by observing the phospholipid molecules in the nonaggregated state.

For practical purposes, phospholipid subclass analyses by ^{31}P NMR are best done on isolated ethanolamine and choline glycerophospholipid fractions as they are readily obtained, for example, by silicic acid chromatography on a TLC plate. Figure 2 illustrates the migration rates in TLC of the brain EPL fraction (**3**) and the heart CPL fraction (**4**) relative to 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (**1**) and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (**2**) with chloroform/methanol/water (65:35:8, by vol) as the developing solvent. Recording the spectra on isolated ethanolamine and choline glycerophospholipid fractions ensures that the respective EPL and CPL subclass resonances are observed without possible interference from other phospholipid signals. This is particularly important for the analysis of the EPL subclasses because the phosphatidylserine signal, for example, can overlap with the diacylGPE resonance (data not shown). However, if so desired, the EPL and CPL subclasses can reliably be assayed in the presence of each other.

Quantitative information can be obtained from the spectra by simple integration of peak areas. Because the phospholipids under consideration here each contain only a single phosphate group, the ratios of integrated peak areas do directly translate into mole percentages. No corrections need to be made for variations in chain length or degree of unsaturation.

Thus, digital integration of the EPL subclass resonances (Fig. 1, left panel; $n = 3$) showed that the ethanolamine glycerophospholipid fraction from bovine brain consisted of 64.0 ± 1.2 mol% alkenylacylGPE, 31.8 ± 0.5 mol% diacylGPE, and 4.2 ± 1.3 mol% alkylacylGPE, which is in good agreement with the data obtained by Blank *et al.* (63.5 ± 1.2, 30.6 ± 1.3, and 5.9 ± 1.2 mol%, respectively; see Ref. 23) who analyzed the EPL subclasses as diradylglycerol benzoates upon phospholipase C hydrolysis of bovine brain EPL. Similarly, integration of the CPL subclass resonances (Fig. 1, right panel; $n = 3$) showed that the choline glycerophospholipid fraction from bovine heart consisted of 55.5 ± 1.3 mol% diacylGPC, 40.9 ± 1.0 mol% alkenylacylGPC, and 3.6 ± 0.4 mol% alkylacylGPC, which compares well with the data obtained by Pugh *et al.* (57, 39, and 3.6 mol%, respectively; see Ref. 10) upon acid-catalyzed and alkaline hydrolyses of bovine heart CPL. If, in addition, total phospholipid phosphorus (40) is assayed, the relative mole percentages obtained by digital integration of peak areas can then, of course, also be converted into absolute concentrations.

Absolute subclass quantitation can directly, and more conveniently, be achieved, however, by phosphorus NMR by use of quantitative internal standards. The synthetic dialkyl glycerol ether analogs of PE and PC, i.e., dialkylGPE and dialkylGPC, lend themselves particularly well for this purpose. Both, dialkylGPE and dialkylGPC give rise to distinct signals in phosphorus NMR, with the dialkylGPE resonance appearing at 0.602 ppm (see Fig. 3, insert, **St**), well separated from alkylacylGPE (**1**), alkenylacylGPE (**2**), and diacylGPE (**3**), and the dialkylGPC resonance appearing at −0.196 ppm (see Fig. 4, insert, **St**), well separated from alkylacylGPC (**1**), alkenylacylGPC (**2**), and diacylGPC (**3**). This makes it possi-

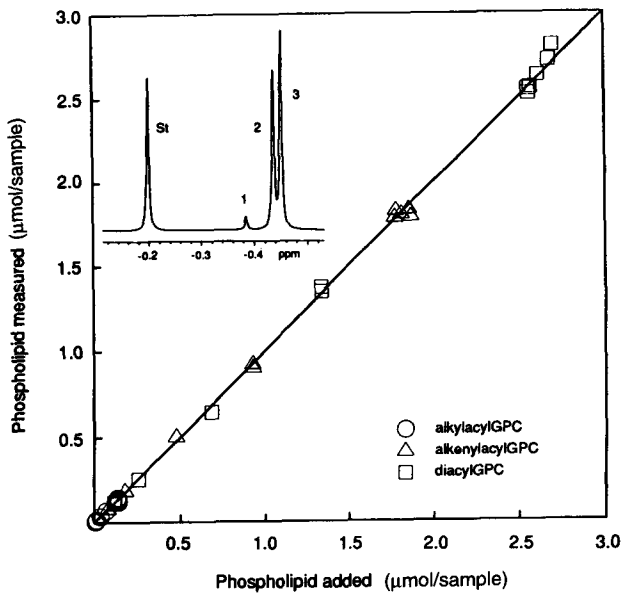

FIG. 3. Quantitation by ^{31}P nuclear magnetic resonance spectroscopy of the alkylacyl, alkenylacyl, and diacyl ethanolamine glycerophospholipid subclasses illustrated for bovine brain EPL. The spectral insert shows the resolved resonances of alkylacylGPE (**1**), alkenylacylGPE (**2**), and diacylGPE (**3**) relative to *rac*-1,2-di-*O*-octadecylglycero-3-phosphoethanolamine which was added as quantitative internal standard (**St**) prior to thin-layer chromatographic isolation of the EPL fraction (see the Materials and Methods section). The plot illustrates the excellent correlation that exists between EPL dose, as measured by inorganic phosphorus assay, and the respective EPL subclass levels determined by phosphorus NMR based on integrated peak areas relative to the dialkylGPE standard (500 nmol).

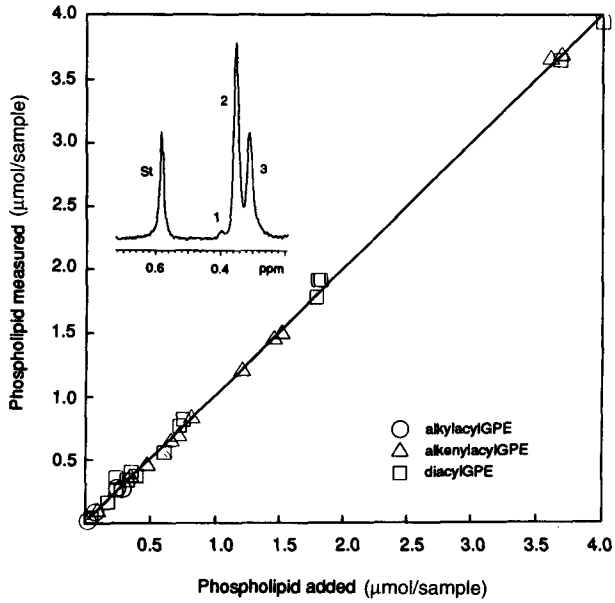

FIG. 4. Quantitation by ^{31}P nuclear magnetic resonance spectroscopy of the alkylacyl, alkenylacyl, and diacyl choline glycophospholipid subclasses illustrated for bovine heart CPL. The spectral insert shows the resolved resonances of alkylacylGPC (**1**), alkenylacylGPC (**2**), and diacylGPC (**3**) relative to *rac*-1,2-di-*O*-hexadecylglycero-3-phosphocholine which was added as quantitative internal standard (**St**) prior to thin-layer chromatographic isolation of the CPL fraction (see the Materials and Methods section). The plot illustrates the excellent correlation that exists between CPL dose, as measured by inorganic phosphorus assay, and the respective CPL subclass levels determined by phosphorus NMR based on integrated peak areas relative to the dialkylGPC standard (500 nmol).

ble to quantitate each EPL and CPL subclass by direct comparison of its integrated peak area with that of the respective internal diether phospholipid standard.

The accuracy and sensitivity of the assay are illustrated for alkylacylGPE (**1**), alkenylacylGPE (**2**), and diacylGPE (**3**) relative to dialkylGPE (**St**) in Figure 3, and for alkylacylGPC (**1**), alkenylacylGPC (**2**), and diacylGPC (**3**) relative to dialkylGPC (**St**) in Figure 4. The plots show the excellent correlation that exists over a wide range of concentrations between phospholipid dose, as measured by inorganic phosphorus assay, and the respective phospholipid subclass levels as determined by phosphorus-31 NMR based on integrated peak areas relative to those of dialkylGPE and dialkylGPC (500 nmol) used as quantitative internal standards. Low micromolar quantities of phospholipid subclass can be assayed rapidly (64–640 transients) with an error of less than ±5%. Given sufficient acquisition time (3200 transients), even samples as small as 10 nmol of CPL subclass or 50 nmol of EPL subclass can be quantitated with an error of less than ±10%.

Use of the diether glycerophospholipids as internal standards has the additional advantage that dialkylGPE (**5**) and dialkylGPC (**6**) migrate in silicic acid chromatography together with the respective alkenylacyl, alkylacyl, and diacyl ethanolamine (**3**) and choline (**4**) glycerophospholipids (see Fig. 2). Hence, when added to a lipid extract, the diether analogs are isolated together with the respective natural EPL and CPL fractions and thus can also account for any losses that occur in the course of phospholipid isolation (see Figs. 3 and 4).

DISCUSSION

Observance of isotropic phospholipid phosphorus resonances that can be interpreted in quantitative terms requires that line-broadening is minimized by measuring the spectra on phospholipids in the nonaggregated state. Yet, most phospholipids because of their amphiphilic nature resist true solubilization in polar or in nonpolar solvents where they form molecular aggregates, such as liposomes or reverse micelles. We have previously shown that nonaggregation of phospholipids in a given medium is indicated in carbon-13 NMR by the observance of maximal two-bond and three-bond carbon–phosphorus couplings (J_{CP}; Ref. 36), and in the case of choline phospholipids by the appearance of well-defined ^{13}C-^{14}N couplings (J_{CN}) and by the magnitude of the ^{14}N quadrupolar relaxations (^{14}N T_1; Ref. 35). Based on these criteria, chloroform/methanol/water (50:50:15, by vol) has evolved as the medium of choice in which a wide range of natural phospholipids can be observed in the nonaggregated state (34–37). We

have utilized this observation in the present study to resolve and to analyze by phosphorus NMR all alkenylacyl, alkylacyl, and diacyl subclasses of ethanolamine glycerophospholipids from bovine brain and choline glycerophospholipids from bovine heart.

Two different approaches have previously been used to characterize phospholipid dispersions by phosphorus NMR. By the first approach, phospholipids are dispersed as mixed micelles with bile acids or other detergents (41,42). Although good resolution between phospholipid class and species resonances can be achieved with defined compounds on model systems (41–43), the detergent mixed micelle approach has not been proven practical for the actual analysis of more complex natural phospholipid mixtures (41,44,45). The resolution of alkylacyl, alkenylacyl, and diacyl GPC or GPE subclass resonances has not been accomplished using the detergent micelle technique (44). By the second approach, phospholipids are dispersed in a two-phase, Folch-like solvent mixture (39) supplemented with chelating agent and monovalent ions (e.g., chloroform/methanol/0.2 M aqueous cesium or potassium EDTA, 10:4:1, by vol), and the spectra are recorded on the organic lower phase in the presence of the aqueous upper phase (46). However, in the two-phase system, signal separations and chemical shifts can vary substantially with the make-up of the lower phase, dependent on lipid source and lipid concentration, which makes peak assignments tenuous (47–49). Particular confusion exists in the literature in regard to the resolution and assignment of alkylacyl, alkenylacyl, and diacyl GPC and GPE resonances in spectra obtained on complex phospholipid mixtures. Although it was first suggested that the alkenylacylGPC and diacylGPC resonances can be resolved by the two-phase approach (46), others have later shown that the initial claim was based on the mistaken identification of alkylacylGPC as alkenylacylGPC (49,50). Yet, misassignment of alkylacylGPC as alkenylacylGPC is still prevalent in the literature (e.g., 51–53), and alkenylacylGPC and diacylGPC have still not been resolved. Moreover, in the two-phase system the alkenylacylGPE and diacylGPE resonances do frequently overlap with each other and with other phospholipid signals (49), and the alkylacylGPE resonance has not been identified (e.g., 49,54,55).

The present study has shown that phosphorus NMR can resolve all native alkenylacyl, alkylacyl and diacyl glycerophosphoethanolamine and glycerophosphocholine subclasses if monomeric phospholipid distribution is ensured by use of a single-phase chloroform/methanol/water (50:50:15, by vol) system as the solvent medium. Characteristic and narrow phosphorus resonances are thus obtained ($\nu_{1/2}$ 0.5–1.8 Hz) for each of the ethanolamine and choline glycerophospholipid subclasses irrespective of lipid source and lipid concentration, and essentially independent of fatty chain length and degree of unsaturation. Simple integration of peak areas gives relative molar subclass concentrations. Absolute concentrations can directly be measured by use of the respective diether phospholipids, dialkylGPE and dialkylGPC, as quantitative internal standards. The method is simple, rapid, sensitive, and reproducible and permits the complete resolution and direct quantitation of all ethanolamine and choline glycerophospholipid subclasses without prior degradation or derivatization.

Phospholipid subclass quantitation by NMR has, of course, the further advantage that the lipid samples are conserved and thus can still subsequently be used for molecular species and fatty chain analyses, if so desired.

ABSTRACT: This study evaluated the effect of storage on the quantitation of lipoprotein (Lp)(a) in 25 serum samples. Aliquots of serum were stored for up to three years at either −20°C or −70°C and Lp(a) subsequently analyzed using an enzyme-linked immunosorbent assay kit. Concentrations of Lp(a) declined during storage, and the temperatures employed elicited significantly different ($P < 0.05$) values within 12 mon which further diverged during three years of storage. Compared to baseline values, significant decreases ($P < 0.05$) in Lp(a) levels were evident after six months of storage at −20°C with apparent losses (geometric mean) reaching 36.9% (95% confidence interval: 30.9%, 42.9%) after three years. Similarly, significantly lower ($P < 0.05$) Lp(a) values were recorded after six months of storage at −70°C and at three years the decrease (geometric mean) was 19.1% (95% confidence interval: 14.3%, 24.0%). The losses, after three years, in terms of the arithmetic mean were 53.5 and 26.2% at −20 and −70°C, respectively. Phenotype analysis suggested that large isoforms are more susceptible to degradation than smaller moieties. This may be related to the observation that apparent losses are reduced in samples containing over 8 mg/dL Lp(a). Nevertheless, Lp(a) levels in stored samples retained a strong correlation with the baseline values. These results must be considered specific for the storage conditions and analytical procedures employed.
Lipids 31, 1197–1203 (1996).

Lipoprotein (Lp)(a) is a predominantly cholesterol-rich lipoprotein similar in structure to low density lipoprotein but possessing an apolipoprotein (apo)(a) moiety linked to $apoB_{100}$ *via* a disulfide bridge (1,2). A triglyceride-rich Lp(a) particle containing apoE also occurs but represents only 10 to 20% of total plasma Lp(a) (3,4).

Apo(a) exists in over 30 isoforms which range in molecular weight from 200 to 838 kDa (5,6). Each isoform contains one kringle 5 moiety, so named because of its 85% homology with the corresponding domain in plasminogen. The isoforms differ in their number of kringle 4s moieties. The kringle 4s can be further classified into ten distinct forms (types 1 to 10). One copy each of type 1 and of types 3 to 10 occurs in all isoforms but variable numbers of the type 2 moiety accounts for the heterogeneity of apo(a) (5,7,8). The large number of isoforms complicates development of a standardized assay procedure for Lp(a) and hinders evaluation of its physiological role (9).

Serum Lp(a) concentrations range from less than 1 mg/dL to over 100 mg/dL. These quantities are highly skewed toward high values in Caucasians and Asians but less so in Blacks who tend to have higher levels of Lp(a) (10–12). An inverse relationship exists between apo(a) isoform size and Lp(a) concentration (13,14).

Study of Lp(a) is prompted by reports suggesting an association between Lp(a) levels and vascular disease independent of other lipoproteins and risk factors (15–22). The action of Lp(a) is suggested to involve both atherogenic and thrombotic mechanisms (23,24). Nevertheless, several studies question the association between Lp(a) concentrations and vascular disease (25–28). Various suggestions have been offered to account for these dissenting observations, including sample storage, group size, population differences, allele distribution, and duration of follow-up.

In this study, the effect of sample storage on Lp(a) measurements was evaluated. Samples were stored for up to three years, at either −20 or −70°C, prior to analysis using an ELISA. These results are needed for critical evaluation of long-term prospective and retrospective data.

EXPERIMENTAL PROCEDURES

Subjects. The study group consisted of 25 consecutive healthy employees (13 males, 12 females) of the University of Pittsburgh ranging in age from 25 to 43 yr.

Laboratory. Subjects were instructed to fast after 9:00 pm on the night before blood collection, which occurred between 8:30 and 11:00 a.m. Blood samples were collected into 15 mL plain red-top vacutainers (Becton Dickinson, Rutherford, NJ) and held at ambient temperature for 45 min. Serum was sepa-

rated by centrifugation at 1500 × *g* for 15 min at 4°C. The serum was then divided into 14 aliquots of 0.5 mL and placed into 2-mL polypropylene screw-top 0-ring tubes (Sarstedt, Newton, NC). Seven 0.5 mL aliquots from each subject were stored at −20 and −70°C. No additives were added to the aliquots prior to storage, and no freezer breakdowns occurred during this study.

Lp(a) was measured using a commercially available ELISA kit (Strategic Diagnostics, Newark, DE; previously Terumo) that reports Lp(a) particle as mg/dL. In brief, serum (10 μL) with 2 mL of diluent containing protein stabilizers and thimerosal were incubated (60 min at room temperature) and rotated (120 rpm) in a covered (Laboratory Wrap; Fisher, Pittsburgh, PA) multicell plate containing monoclonal anti-apo(a) antibody bound to the well surfaces. This antibody reacts with an apo(a) Kringle 4-like epitope in all 33 isoforms tested (29). Unbound antigen was removed by washing with a buffered solution containing thimerosal and detergent. There were four washes in total, and the plate was rotated 180° after the second aspiration. Subsequently, a second incubation with a polyclonal anti-apo(a) antibody conjugated with horseradish peroxidase was undertaken (20 min at room temperature) with rotation (120 rpm) and covering (Laboratory Wrap). The plate was then washed, as above, and color development started by adding a fresh (<20 min) solution (100 μL) of hydrogen peroxide and 0-phenylenediamine. The reaction 10 min at room temperature with rotation at 120 rpm was stopped by adding 2 N sulfuric acid (50 μL) and the absorbance at 490 nm read within 15 min. Standards (0 to 80 mg/dL), pre-diluted controls, a laboratory pooled control, and duplicate samples were run with each assay. No edge effects were observed. The coefficient of variation between runs was 8%. The assay exhibits no cross-reactivity with plasminogen (100 mg/dL), low density lipoprotein (LDL) (200 mg/dL), high density lipoprotein (HDL) (400 mg/dL), or very low density lipoprotein (VLDL) (170 mg/dL). The analyses over the three-year period required the use of kits with different lot numbers (see legends to Tables 1 and 2). This was considered an unavoidable complication due to the lability of the kits. The standards, human plasma in a buffered solution with protein stabilizers and thimerosal, are reported to be stable during storage at 4°C for 20 mon. Strategic Diagnostics tests each lot number with nine serum and three plasma (EDTA) samples ranging in Lp(a) concentration from one to sixty mg/dL. For the lot number to be released for use, all values obtained must fall within two standard deviations of the accumulative mean. This procedure has been ongoing since 1989 and entails storage of the test samples at −80°C. The Strategic Diagnostics standard contains two isoforms, S_1 and S_3, that give bands of equal intensity on immunoblots (29). This nomenclature is based on that of Utermann *et al.* (13) and the S_1 and S_3 isoforms are assigned molecular masses of 520 kDa and 640 kDa, respectively. Additional documentation of the response of these two isoforms to the antibody is unavailable. Standardization of the assay is further complicated by the occurrence of over 30 isoforms (5,6), and Taddei-Peters *et al.* (30) report that this assay underestimates the concentration of the smaller isoforms. These limitations, however, do not affect the comparison of Lp(a) concentrations in the same groups of samples stored for different periods of time and at different temperatures, although it complicates attempts to interpret the influence of isoform size. An ELISA involving a monoclonal anti-apo(a) capture antibody and a polyclonal anti-apo lipoprotein β detection antibody has been reported to be insensitive to variation in apo(a) isoform size when reporting the data as moles/L (31).

Phenotype analysis of the apo(a) isoforms was done using SDS–agarose gel electrophoresis as described previously (32).

Statistical analysis. All statistical tests and calculations of rates of degradation were based upon the natural logarithm of the observed data. The percentage decline on the geometric scale refers to the difference between the mean of the logs at each time point and the mean of the log at baseline. This was done to correct for the highly skewed nature of the data. Statistical significance of observed temperature effects was assessed by running paired *t*-tests at each time point. Overall time effects and rates of degradation between time points were calculated by utilizing the Analysis of Variance and Covariance module of the BMDP Statistical Software package (BMDP Statistical Software, Inc., Los Angeles, CA). The difference in means of the transformed data and their 95% confidence intervals were calculated with a Bonferroni adjustment factor for multiple comparisons. It should be noted that this is a very conservative method which produces very wide confidence limits when calculation of degradation rates is performed. Confidence limits for the percentage decrease in the arithmetic means are not reported as the assumption of normally distributed data at each time point is clearly violated. Pearson correlation coefficients were calculated for the 1-, 2-, and 3-year data as related to the fresh samples.

RESULTS

Analysis of the 25 fresh samples indicated they had a mean Lp(a) concentration of 20.0 ± 21.6 (SD) mg/dL and a median of 9.6 mg/dL. The range was from 1.0 to 73.7 mg/dL, and twelve of the 25 subjects had plasma Lp(a) levels of over 10 mg/dL. Analysis of stored samples indicated that values declined during storage at both −20 and −70°C, and the decrease was significantly greater at the former temperature ($P < 0.05$) after one, two, and three years (Table 1). The differences between the −20 and −70°C results illustrate the effect of temperature as magnified by time and the distribution of the percentage decreases after three years (Fig. 1) emphasizes the greater losses observed at −20°C. Inspection of mean Lp(a) levels at each time point revealed an increase at three months. Although an apparent rise in Lp(a) concentration is possible, we believe that this elevation is due to analytical variation (see below). All results were evaluated with and without the three-month results, but for the ANOVA data reported in this paper the three month values were excluded. At both temper-

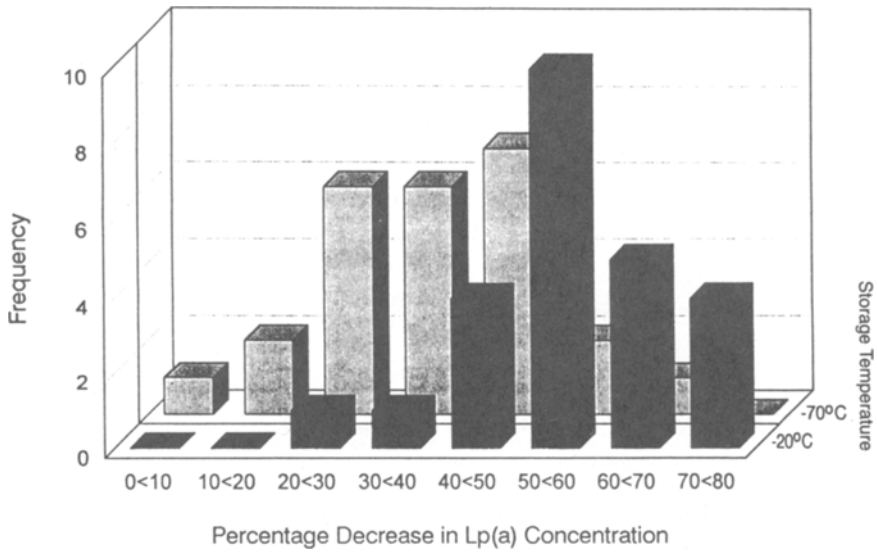

FIG. 1. Distribution of percentage decreases in lipoprotein (Lp)(a) concentration after storage for three years at either –20 or –70°C.

atures the first significant decrease from the baseline values was observed at the six-month time point. After three years the percentage decrease in the arithmetic mean was 53.5 and 26.2% for the –20 and –70°C samples, respectively. As noted in the methodology, confidence limits for the percentage decrease in the arithmetic means are not reported. At three years the percentage decrease in the geometric mean was 36.9% (95% CI: 30.9%, 42.9%) at –20°C and 19.1% (95% CI: 14.3%, 24.0%) at –70°C. Although absolute values decreased during storage, the values for stored samples retained a strong correlation with the concentrations of the baseline samples: r = 0.970 and 0.987 for the three years, –20 and –70°C, samples respectively (Fig. 2).

Although the 25 consecutive samples analyzed demonstrate the skewed distribution typical of general populations, the presence of specimens with low Lp(a) values complicates interpretation of the data. The precision of the analysis becomes a major consideration at low concentrations. Consequently the statistical analyses were repeated for the 15 samples with Lp(a) levels exceeding 8 mg/dL. The results (Table 2) indicate that the percentage decline in Lp(a) concentrations is less than that for the total sample. The decreases are not significant until one year and two years at –20 and –70°C, respectively. The effect of temperature is significant at all time points, except at six months.

DISCUSSION

Stability of the analyte is always a concern during studies involving analysis of stored samples. Loss of integrity may lead to spurious conclusions whereas stability promotes long-range prospective and retrospective studies. The literature involving Lp(a) stor-

[d]Confidence intervals not computed for three months time point (see text).

age emphasizes short-term studies (<6 mon), and the conclusions are variable. The results are influenced by the storage conditions employed and by the method used to quantitate Lp(a).

At 4°C, Sgoutas and Tuten (33) in a study involving serum samples observed a significant decrease of 30% (ELISA, Standard Diagnostics) and 12% (immunourbidimetric) in Lp(a) values after 16 d at 4°C. Cazzolato *et al.* (34) also using serum but with EDTA and NaN_3 added noted that Lp(a) concentrations were stable after 2 mon if measured by nephelometry but, if analyzed by Laurell electrophoresis the areas increased after 2 mon. In contrast, four studies storing plasma for up to 10 wk at 4°C noted no significant change in Lp(a) values. Albers and Hazzard (35) employing radial immunodifusion (RID) and Albers *et al.* (36) using a radioimmunoassay method noted that Lp(a) levels in EDTA plasma samples containing NaN_3 were unaffected by four and ten weeks of storage, respectively. Similarly, Fless *et al.* (31) and Taddei-Peters *et al.* (30), both analyzing filter sterilized EDTA plasma by an ELISA, reported no change in Lp(a) levels after one week and one month, respectively.

At –20°C, three studies report that Lp(a) in serum is stable during storage. Jauhiainen *et al.* (26) employing an immunoradiometric (IRMA) method reported that the serum concentration of a population with Lp(a) levels of over 20 mg/dL was unaffected by storage for 8.5 yr, but their results indicated considerable fluctuation among the values for individual samples with time. Similarly, Gaubatz *et al.* (37) using an electroimmunoassay reported that Lp(a) was stable for one year in serum samples. Cazzolato *et al.* (34) analyzing serum samples fortified with EDTA and NaN_3 noted no change in

Lp(a) concentration after 6 mon of storage. Both electrophoresis and nephelometry gave similar results although the authors emphasize that an initial freeze/thaw causes a 10 to 12% decline in Lp(a) concentrations. In contrast to these results, Craig *et al.* (38) using RID noted that Lp(a) concentrations in serum declined by 46% within 6 mon. Our ELISA results indicate that serum Lp(a) values diminish during storage at −20°C, but the decreases (arithmetic mean): 9.2% at 6 mon and 53.3% at 3 yr are at a slower rate than that noted by Craig *et al.* (38). This discrepancy is magnified if we compare our results for samples with over 8 mg/dL of Lp(a) to the Craig *et al.* (38) data who also used the 8 mg/dL cut off point. As both studies used serum samples with no additives, the clearest distinction between the two reports is that this investigation employed an ELISA (Standard Diagnostics) and Craig *et al.* (38) used RID to quantitate Lp(a). However, our rates of Lp(a) loss are similar to those noted by Kronenberg *et al.* (39) who studied plasma (EDTA) samples. Using an ELISA (Boehringer), they observed a 13% decline in Lp(a) concentration after two years. Albers and Hazzard (35) using RID noted that four weeks of storage had no effect on Lp(a) levels in plasma (EDTA, NaN_3) samples. In contrast, Usher *et al.* (29) also analyzing plasma (EDTA, NaN_3, Trasylol) samples and using two ELISA procedures (Standard Diagnostic, Boehringer) observed an apparent elevation of 8% in Lp(a) values after storage for four to six weeks at −20°C.

At −70°C, Craig *et al.* (38) (serum) reported that losses at −70°C were not significantly different from the extensive decreases observed at −20°C (see above). Our −70°C data (arithmetic mean) noted a 17.1 and 26.2% decline in Lp(a) values after two and three years' storage, respectively. Again our data for loss of Lp(a) are closer to those reported by Kronenberg *et al.* (39) for plasma (EDTA) samples: 7% after two years at −80°C as measured by ELISA (Boehringer). Fless *et al.* (31) and Taddei-Peters *et al.* (30) both studying filter sterilized EDTA plasma and using ELISA employing apo(a) capture and apoB detection antibodies reported that Lp(a) was stable for at least one month and one year, respectively.

The results for Lp(a) storage documented above are highly variable. This partly reflects the different storage conditions and analytical techniques utilized. As expected, losses are more apparent in serum than in plasma samples. The wide number of techniques involved makes comparison of the various methodologies difficult. However, as noted above, Sgoutas *et al.* (33) analyzing serum samples noted that an ELISA (Standard Diagnostics) is more sensitive to apparent losses than nephelometry. The high losses observed by Craig *et al.* (38) were obtained using RID.

Apparently discrepant results may also reflect differences in isoform frequency between the populations studied. Consequently, we analyzed the apo(a) phenotypes of our stored samples and results are available for 22 specimens. The three samples that gave inconclusive results contained low concentrations of Lp(a): 1.0, 1.1, and 3.7 mg/dL. Using apo(a) isoform 15 as the cutoff point, the population could be divided into three groups: both isoforms ($n = 7$) of small size (low); both isoforms ($n = 9$) of large size (high) and a third group ($n = 6$) with a combination of small and large isoforms (medium). We made the assumption that all single-banded samples (nine) were homozygous for the product detected, i.e., no null gene present. Statistical analysis indicated that at −20°C the effect of isoform size was of marginal significance ($P = 0.064$) but at −70°C, when the apparent loss is much less, the effect of isoform size was significant ($P = 0.024$). If only the high and low groups were compared, then the result at −20°C was similar but at −70°C the P value was now <0.005. At both temperatures the percentage decrease in Lp(a) concentration after storage for three years was greatest for the high molecular weight group. After stratifying the apo(a) isoforms based on size, the groups become small but the data suggest that stability of Lp(a) during storage is influenced by isoform size.

Inspection of our results (Table 1) indicates a strong linear component to the decreases in Lp(a) concentration, emphasizing the effect of storage time, and minimizing the influence of the time periods between collection and freezing and between thawing and analysis. However, the values obtained at three months are an exception. At this timepoint the Lp(a) concentrations had apparently increased (arithmetic mean) by 18.7 and 9.0% at −20°C and −70°C, respectively. It is possible for lipoprotein levels to ostensibly increase during storage as was noted for Lp(a) by Usher *et al.* (29). The epitope of the Lp(a) may change resulting in enhanced interaction with antibodies. It is questionable, however, whether this effect would only be manifested at the three-month measurement. Evaporation of samples may also cause an apparent increase in Lp(a) concentration, and care was taken to avoid this problem. It should also be noted that the −20 and −70°C samples were handled as separate batches; although both groups exhibited an apparent rise in Lp(a) concentration at three months, this was not observed at any other time point. An alternative explanation notes that in addition to any effects of storage, superimposed on the analyses is an analytical variation. Both the −20 and −70°C samples at three months were assayed using the same lot number kit (NM 1081), and the other time points involved several different lot numbers (Table 1).

Kronenberg *et al.* (39) have reported that degradation of Lp(a) at −20 or −80°C occurs predominantly during the first month of storage, but our studies failed to confirm this observation. Kronenberg *et al.* (39) also noted loss of Lp(a) in samples stored at −20 or −80°C was associated with one or three freeze/thaw cycles. Similarly, Sgoutas and Tuten (33) noted loss of Lp(a) in samples stored at −20°C after one (ELISA) or two (ITA) freeze/thaw cycles. If the samples were stored at −80°C, then loss of Lp(a) was noted after two (ELISA) or three (ITA) freeze/thaw cycles. We do not have information on one or two freeze/thaw cycles, but we have data indicating that the values for Lp(a) are not affected by three to eight freeze/thaw procedures prior to analysis (40).

Although it must be emphasized that our results are specific for the storage conditions used and the analytical proce-

dures employed, the apparent decline in Lp(a) during storage stresses the need to minimize potential losses. Specific procedures employed must bear in mind the analyses that are subsequently to be performed, but several precautions can be considered. It is known that collection of samples into EDTA reduces degradation resulting from autoxidation and enzymatic activity by chelating heavy metal ions (41). Correction must then be made for the osmotic effect of EDTA which causes an artificial fall in lipoprotein concentration (42). In addition, protease inhibitors such as aprotinin may be added to the samples to minimize proteolytic activity arising from native or bacterial enzymes (43). Finally, an antibacterial agent such as Thimerosal can be included (44).

In conclusion, our results indicate that after storage of serum samples at −20 and −70°C for three years the values observed for Lp(a) are decreased (geometric mean) by 36.9 and 19.1% and (arithmetic mean) by 53.5 and 26.2%, respectively. Nevertheless, the concentrations of Lp(a) in stockpiled samples remain closely correlated with baseline values indicating that although absolute values change, stored samples can still be used for comparisons. However, the duration the aliquots have been stored at −70°C should not vary more than six months between samples. In addition, samples stored at −70°C for three or more years should be matched for apo(a) isoform size.

The Sterols of *Cucurbita moschata* ("calabacita") Seed Oil

Juan B. Rodriguez, Eduardo G. Gros*, María H. Bertoni, and Pedro Cattaneo

Departamento de Química Orgánica (Orientaciones Química Orgánica y Bromatología y Tecnología de Alimentos), Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria, 1428 Buenos Aires, Argentina

ABSTRACT: From the sterol fraction of seed oil from commercial *Cucurbita moschata* Dutch ("calabacita") Δ^5 and Δ^7 sterols having saturated and unsaturated side chain were isolated by chromatographic procedures and characterized by spectroscopic (^{1}H and ^{13}C-nuclear magnetic resonance, mass spectrometry) methods. The main components were identified as 24*S*-ethyl 5α-cholesta-7,22*E*-dien-3β-ol (α-spinasterol); 24*S*-ethyl 5α-cholesta-7,22*E*,25-trien-3β-ol (25-dehydrochondrillasterol); 24*S*-ethyl 5α-cholesta-7,25-dien-3β-ol; 24*R*-ethyl-cholesta-7-en-3β-ol (Δ^7-stigmastenol) and 24-ethyl-cholesta-7,24(28)-dien-3β-ol ($\Delta^{7,24(28)}$-stigmastadienol).

Lipids 31, 1205–1208 (1996).

In previous works the general chemical composition of the fruit pulp, the acidic composition of crude seed oil, and the chemical composition of the seed defatted meal flour from *Cucurbita moschata* Dutch ("calabacita") (1) were evaluated (2–4). Continuing with the study of the lipids from the same seed oil, the sterols were isolated from the unsaponifiable fraction and analyzed by chromatographic and spectroscopic methods. We report now the sterol composition, including the absolute configuration at C-24 of the major components, of the natural occurring Δ^5 and Δ^7 *C. moschata* sterols. In contrast to previous studies finding epimeric mixtures at C-24 (5–7), we detected single stereoisomers.

MATERIALS AND METHODS

Cucurbita moschata Dutch was harvested at Buenos Aires and Mendoza provinces, Argentina. Ground whole seeds (715 g) were extracted with hexane (Soxhlet) yielding 222 g of crude oil (33.2% on dry basis). Saponification of 14 g of oil afforded unsaponificable fraction (250 mg) from which the sterol fraction was obtained by preparative thin-layer chromatography. ^{1}H nuclear magnetic resonance (NMR) spectra were recorded in a Bruker AC-200 (Karlsruhe, Germany) and in a Bruker AM-500 spectrometers. Chemical shifts are listed in δ (ppm) relative to tetramethylsilane employed as internal standard. Coupling constants (*J*) are presented in Hz. ^{13}C NMR spectra were full decoupled. Gaschromatography–mass spectrometry (GC–MS) analyses were performed on a VG TRIO-2 (Manchester, United Kingdom) instrument. High-resolution mass spectra (HRMS) were registered in a VG-ZAB BEQ spectrometer. Preparative high-performance liquid chromatography (HPLC) was carried out in a Micromeritics chromatograph (Norcross, GA) with a solvent delivery system model 750, a Thermo Separation Products refractive index detector model refractoMonitor® IV (Fremont, CA), and a Beckman Ultrasphere ODS-2 column (250 × 10 mm, 5 μm) (Fullerton, CA) eluting with absolute methanol at a flow rate of 3.0 mL/min.

Abbreviations: GC–MS, gas chromatography–mass spectrometry; HPLC, high-performance liquid chromatography; HRMS, high-resolution mass spectrometry; NMR, nuclear magnetic resonance.

RESULTS AND DISCUSSION

The unsaponificable fraction from a hexane extract of seed oil from *C. moschata* Dutch was separated by preparative thin layer chromatography (8). The sterol fraction was isolated and analyzed by GC and GC–MS methods. These analyses were conducted on free sterols as well as on their trimethylsilyl ether and acetyl derivatives. The mixture contained Δ^5 and Δ^7 derivatives with saturated and unsaturated side chains. The mass spectra of the derivatives allowed unequivocal assignments of Δ^5 and Δ^7 sterols. The latter were characterized by the presence of molecular ions for acetates and the absence of M-129 and 129 fragments for the silylated derivatives (data not shown) (9).

Table 1 shows the 11 components detected in the sterol fraction together with their percentage in the mixture, GC–relative retention time data and the main fragments of their respective mass spectrum registered for the free sterols and for the respective acetylated derivatives.

The sterols were also separated by preparative HPLC, and the major members corresponding to the single peaks were further analyzed by NMR spectrometry and MS. The ^{1}H NMR analysis also indicates the presence of a Δ^7 double bond according to the chemical shift of angular methyls, 0.54 for H-18 and 0.80 ppm for H-19 (10,11) and to the chemical shift of the vinyl proton (H-7) at 5.16 ppm. The presence of a Δ^7 series was clearly confirmed by ^{13}C NMR spectra in which signals corresponding to C-7 and C-8 are observed at around 117 and 139 ppm, respectively (12–14).

24S-Ethyl 5α-cholesta-7,22E-dien-3β-ol (α-spinasterol) (**7**). HPLC retention time 26.7 min. HRMS: Calc'd 412.3705.

24R-Ethyl-cholesta-7-en-3β-ol (**10**). HPLC retention time 29.9. HRMS: Calc'd 414.3862. Found 414.3862. ^{1}H NMR (Cl_3CD): δ 0.54 (*s*, 3 H, H-18), 0.80 (*s*, 3 H, H-19), 0.928 (*d*, *J* = 6.1, 3 H, H-21), 3.60 (*m*, 1 H, H-3), 5.17 (*m*, 1 H, H-7).

24-Ethyl-cholesta-7,24(28)-dien-3β-ol (**11**). HPLC retention time 24.6. HRMS: Calc'd 412.3705. Found 412.3795. ^{1}H NMR (Cl_3CD): δ 0.54 (*s*, 3 H, H-18), 0.80 (*s*, 3 H, H-19), 0.98 (*d*, *J* = 6.9, 6 H, H-26 and H-27), 3.60 (*m*, 1 H, H-3), 5.08 (*m*, 1 H, H-3), 5.08 (*m*, 1 H, H-28), 5.16 (m, 1 H, H-7).

The most abundant components, all belonging to the Δ^7 series, were 24*S*-ethyl 5α-cholesta-7,22E-dien-3β-ol (spinasterol, the 24α-epimer) (**7**) being the principal one accounting for almost 34% of the total mixture, 24*S*-ethyl 5α cholesta-7,22*E*,25-trien-3β-ol (25-dehydro condrillasterol, the 24β-epimer) (**8**) (10%) and 24*S*-ethyl-cholesta-7,25-dien-3β-ol (24β-epimer) (**9**) (19%). Δ^7-Stigmastenol (24α-epimer) (**10**) (10%) and $\Delta^{7,24(28)}$-stigmastadienol (**11**) (8%) were also present as important components.

It is interesting to point out that previous works dealing with 24-ethyl-Δ^7-sterols indicated co-occurrence of carbon-24 epimeric mixtures although with predominance of 24-α epimers (5–7). In the present case, we undoubtedly detected C-24 single stereoisomers. This assertion is based on the careful analysis of the NMR spectra and chromatographic behavior of the purified compounds.

The absolute configuration at C-24 were assigned by comparison of published NMR data from sterols of other species of the Cucurbitacea family (6–7). The structures of these sterols are presented in Scheme 1.

Epoxy Allylic Carbocations as Conceptual Intermediates in the Biogenesis of Diverse Marine Oxylipins

William H. Gerwick

College of Pharmacy, Oregon State University, Corvallis, Oregon 97331

ABSTRACT: Marine organisms, especially marine algae, are extremely rich in a diversity of novel oxylipin structures. Many of these oxylipins contain functionalities and rings of a type and location unknown in mammalian systems. In this perspective reviewing marine oxylipins, a proposal is formulated for the central intermediacy of an epoxy allylic carbocation in the biogenesis of these diverse structures. This proposal is strengthened by the relatively large number of examples which are consistent with this type of mechanistic transformation.
Lipids 31, 1215–1231 (1996).

In the last 20 years, virtually all classes of marine organisms have yielded unusual oxylipin structures, collectively identifying marine creatures as the richest source for structural diversity in this chemical class (1). Structural motifs particularly noteworthy among marine oxylipins, because of their abundance and structural uniqueness, include unusual positions of oxidation (1,2) incorporation of halogen atoms (3,4), and carbocycles involving positions not usually involved in ring formation in mammalian prostaglandins (5). Coincident with the unusual structures of these metabolites is a range of intriguing biological properties, some with medical application (e.g., antiproliferative) (6) and some with profound ecological roles (4,7). However, appreciation of the chemistry, biochemistry, and ecology of marine oxylipin production is still very much in its infancy, and there are many more cases wherein these features remain concealed than known.

In formulating this review, I have considered this surprisingly diverse array of marine oxylipins, many of which my laboratory has discovered over the past 10 years, with an aim of uncovering potential points of commonality in their structure and biogenesis (Fig. 1). In this regard, I hoped to find features which would make these structures, individually as well as collectively, more comprehensible in terms of their chemistry and biochemistry, and perhaps even their evolutionary origins.

Abbreviations: 2D, two-dimensional; CD, circular dichroism; EAC, epoxy allylic carbocation; GC, gas chromatography; HEPE, hydroxyeicosapentaenoic acid; HETE, hydroxyeicosatetraenoic acid; HODTA, hydroxyoctadecatetraenoic acid; HOTE, hydroxyoctadecatrienoic acid; HpEPE, hydroperoxyeicosapentaenoic acid; HpETE, hydroperoxyeicosatetraenoic acid; HpODTA, hydroperoxyoctadecatetraenoic acid; LO, lipoxygenase; MC, (−)-menthoxycarbonyl; MS, mass spectrometry; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography.

Marine organisms are characteristically rich in polyunsaturated fatty acids, particularly those of the ω3 class (8). Many of these fatty acids are substrates for diverse lipoxygenase enzymes which stereospecifically oxidize these to diene-hydroperoxides. Fatty acids of various chain lengths (e.g., C_{18}, C_{20}, and C_{22}) are often acceptable substrates for a particular oxidation pathway and give rise to homologous series of oxylipins (9–11). As a group, marine organisms are also rich in the diversity of sites in the carbon chain to which lipoxygenases (LO) show specificity. [The convention followed in this review is that the positional specificity of lipoxygenases acting on C_{20}-derived fatty acids is identified relative to the carboxyl terminus (e.g., 5-lipoxygenase, 8-lipoxygenase), whereas their specificity on C_{18} acids is identified relative to the methyl terminus (e.g., ω6 lipoxygenase).] Marine oxylipins which likely derive from action of 5-, 8-, 9-, 11-, 12-, 15- (1,2), or "ω3" lipoxygenases (12) have been reported (1,2). With only a few exceptions (13–15), mechanistic and enzymological features of this wealth of marine LO have gone unstudied. Nevertheless, either through direct product isolation or inference, the same general mechanism for conversion of a 1,4-diene to a conjugated diene hydroperoxide is postulated and seems reasonable (16). This review's attempt to identify unifying features of marine oxylipin biogenesis focuses on steps subsequent to the LO-initiated metabolism of endogenous polyenoic fatty acids to hydroperoxides, as this initiating step has already been identified as being in common to many marine oxylipins (2). The ensuing steps involve reaction and rearrangement chemistry of this hydroperoxide.

For example, tissues and life stages of various higher plants, especially the seeds and seedlings of cereals, as well as lower plants and some animals such as coral, contain an enzymatic activity which catalyzes the dehydration of the LO-derived hydroperoxides to allene oxides (17). This activity is due to allene oxide synthase (hydroperoxide dehydrase), a membrane-bound enzyme that in plants is associated with chloroplasts (18). It was purified to homogeneity from flaxseed and characterized as a 55 kD hemoprotein of the cytochrome P-450 class (19). Recent insight into the mechanism of allene oxide formation (Fig. 2) was obtained through fortuitous isolation of a series of epoxyalcohols when an alternative substrate was provided to the enzyme (20). Consistent with the mechanism and activity of cytochrome P-450, the

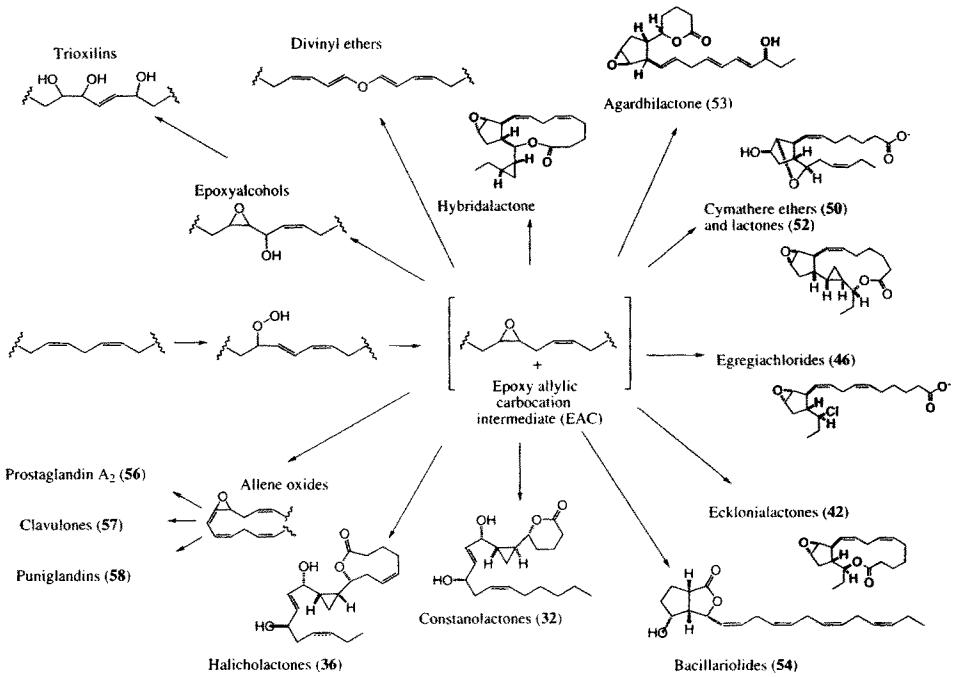

FIG. 1. Overview of the proposed central intermediacy of epoxy allylic cations (EAC) in the biogenesis of diverse marine oxylipins.

hydroperoxide is proposed to be homolytically cleaved, and the resulting allylic alkoxyl radical then cyclizes to an epoxide, thus forming a carbon-centered radical. Under normal processing by the enzyme, and in analogy to mechanisms worked out for the prostacyclin and thromboxane synthases (21), a one electron oxidation by the iron-oxo complex leads to an epoxy allylic carbocation (EAC) which upon proton loss gives an allene oxide, the precursor to phytodienoic and jasmonic acids in higher plants (22), and presumably, diverse prostaglandin structures in marine corals (Fig. 2) (23,24).

It is the contention of this review that all of the steps in this mechanism, except the last, are in operation in the formation of a diversity of marine oxylipins, as an EAC is in fact an ideal conceptual intermediate in the biogenesis of diverse marine oxylipin structures (Fig. 1). Such an intermediate has been previously proposed in the biosynthetic pathway for

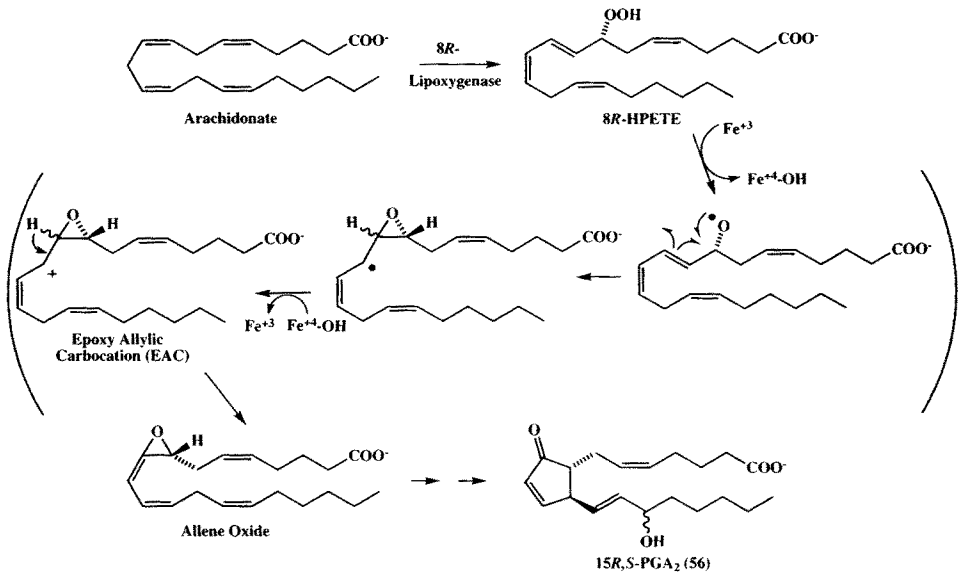

FIG. 2. Allene oxide biosynthesis involving an intermediate alkoxyl radical and epoxy allylic cation (adapted with modifications from Ref. 20). In marine corals such as *Plexaura homomalla,* this biosynthetic pathway has been postulated to lead to PGA_2 (**56**) production.

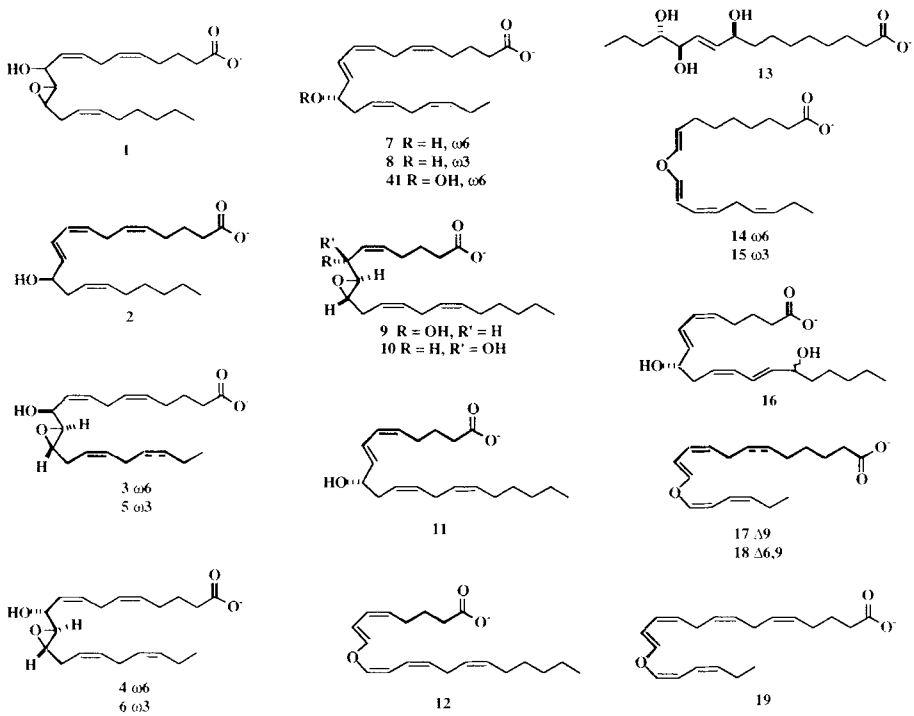
epoxyalcohols (25), α- and γ-ketols (26), allene oxides (20,27,28), divinyl ethers (29), and a number of marine-derived carbocyclic oxylipins (30–32). This proposal not only gives potential insight into the mechanism of marine oxylipin formation, but also into the enzymology and evolutionary relationship of this biosynthetic process in diverse marine creatures. Finally, while it is beyond the scope of this review to describe alternative hypotheses for each oxylipin metabolite, it should be acknowledged that for many discussed herein, alternative biogeneses can be proposed that are mechanistically and biochemically rational. It is precisely this uncertain origin which makes their structures so fascinating, and points out the necessity for biosynthetic experimentation in this area.

CENTRALITY OF EPOXY ALLYLIC CARBOCATIONS IN THE BIOGENESIS OF DIVERSE OXYLIPINS



Those marine oxylipins which potentially arise through a hydroperoxide-epoxy allylic carbocation manifold are arranged in the following sections, first into acyclic products and then into carbocyclic products. This latter section is further subdivided into cyclopropyl and cyclopentyl oxylipins. Collectively, this large number of metabolites (greater than 50) which is envisioned to arise *via* an EAC intermediate provides an abundance of support to the idea that this is a general metabolic feature of oxylipin formation in marine organisms. In the ensuing sections, the structure and methods of structural analysis are first presented, and are then followed in each case by biogenetic hypotheses.

OXYLIPINS WITHOUT CARBOCYCLES

1. Epoxyalcohols

The occurrence of epoxyalcohols in the lipid extracts of marine organisms was first reported from the tropical red algae, *Platysiphonia miniata* and *Cottoniella filamentosa*, in 1990 (33). Hepoxilin B_3 (**1**) (see Scheme 1—compound structures 1–19,41) was found as a minor metabolite of both of these algae and co-occurred with the well recognized LO metabolite, 12-hydroxyeicosatetraenoic acid (12-HETE, **2**). From *P. miniata*, the hydroxyacid was characterized as the *S* stereoisomer (**7**). While the epoxide was shown to be *trans* in both isolates of hepoxilin B_3, in neither case were other features of the stereochemistry determined.

Subsequently, both the *erythro* and *threo* isomers of hepoxilin B_3 (**3**,**4**) and hepoxilin B_4 (**5**,**6**) were isolated from another tropical red alga, *Murrayella periclados* (34). The relative stereochemistry of these two pairs of C-10 epimers was deduced from consideration of their relative polarity on thin-layer chromatography (TLC) as well as the H10 ^{1}H nuclear magnetic resonance (NMR) chemical shift and H10-H11 coupling constant (35). Absolute stereochemistries in the *erythro* isomer of hepoxilin B_3 and the *threo* isomer of hepoxilin B_4 were determined by derivatization and cleavage to form the (−)-menthoxycarbonyl (MC) derivative of dimethyl 2*S*-hydroxyundecane-1,11-dioate (from *erythro* B_3, **3**) and the (−)MC derivative of dimethyl 2*R*-hydroxyundecane-1,11-dioate (from *threo* B_4, **6**)(35). These were compared with authentic standards and defined the algal metabolites as *erythro*-11*S*,12*S*-epoxy-10*S*-hydroxy-5*Z*,8*Z*,14*Z*-eicosatrienoic acid

SCHEME 1

(**3**) and *threo*-11*S*,12*S*-epoxy-10*R*-hydroxy-5*Z*,8*Z*,14*Z*,17*Z*-eicosatetraenoic acid (**6**), respectively. The co-occurrence of the 12-LO metabolites 12*S*-HETE (**7**) and 12*S*-HEPE (**8**) supports the contention that the hepoxilin derivatives derive in these algae from rearrangement of putative 12*S*-HpETE (**46**) or 12*S*-HpEPE precursors (36).

Two new epoxyalcohols also have been obtained from the lipid extract of the Oregon red alga *Polyneura latissima* (37). These structures are unique in that the epoxide is located at C_8-C_9 and the alcohol (of both stereochemistries) is at C_7 [8*S**,9*S**-epoxy-7*S**-hydroxy-5*Z*,11*Z*,14*Z*-eicosatrienoic acid (**9**) and 8*S**,9*S**-epoxy-7*R**-hydroxy-5*Z*,11*Z*,14*Z*-eicosatrienoic acid (**10**)]. As these co-occurred with 9*S*-HETE (**11**), it is reasonable to propose the activity of a 9-LO in this seaweed which results in a 9-hydroperoxy intermediate. This is then either reduced (**11**), rearranged to epimeric epoxyalcohols (**9** and **10**), or rearranged to a novel divinyl ether (**12**, see below).

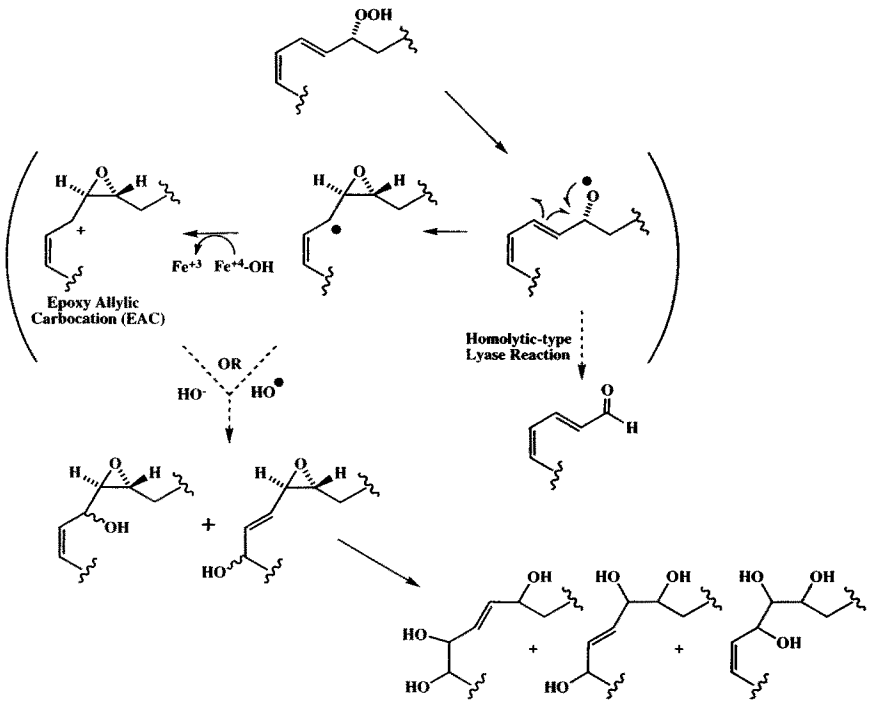
As shown in Figure 3, all of the above epoxyalcohols could conceptually arise *via* an EAC intermediate which in turn would derive from a dienyl hydroperoxide. The resulting EAC could be trapped with water to form the corresponding epoxyalcohols. However, it has been proposed that 1,2-epoxides with a 3-hydroxy or 5-hydroxy group (the "1" position is defined as the site of initial hydroperoxidation) are formed *via* radical processes (hydroperoxide dehydrase) while only epoxyalcohols of the 1-hydroxy-2,3-epoxy or 1-hydroxy-4,5-epoxy are formed *via* ionic mechanisms (hydroperoxide isomerase) (17). In this case, it is possible that in algae and other marine organisms the carbon-centered radical formed en route to an EAC (Fig. 2) is quite often trapped through an "oxygen rebound-type" mechanism to form the abundance of epoxyalcohols described above.

2. Trioxilin from *Lyngbya majuscula*

The marine cyanobacterium (blue-green alga) *L. majuscula* is a source of the hepoxilin-type hydrolysis product 9*S*,12*R*,13*S*-trihydroxy-10*E*,15*Z*-octadecadienoic acid (**13**)(38), and hence, is related to the homologous trioxilin of mammalian occurrence (39). The C_{20} homologs of these triols have been isolated from various mammalian tissues and have been shown to derive from hepoxilin epoxide hydrolase opening of hepoxilin A_3 (Fig. 3) (40). However, these same metabolites have also been isolated as hepoxilin A_3 hydrolysis artifacts, a process promoted under acidic conditions (40). In this study of *L. majuscula* chemistry (38), a nonacidic extraction and workup were used which favor the triol metabolite as the true natural product. Inherent in this biogenetic proposal for the formation of **13** is the intermediacy of 12*S*,13*S*-epoxy-9*S*-hydroxy-10*E*,15*Z*-octadecadienoic acid, itself formed *via* the rearrangement of 13*S*-hydroperoxy-9*Z*,11*E*,15*Z*-octadecatrienoic acid (Fig. 3). In turn, the hydroperoxide likely originates from action of an ω6-lipoxygenase (C_{13} oxygenation) on α-linolenic acid.

3. Divinyl Ethers from Red and Brown Algae

While divinyl ethers [e.g., colneleic (**14**) and colnelenic acids (**15**)] were first found as metabolites of a terrestrial plant



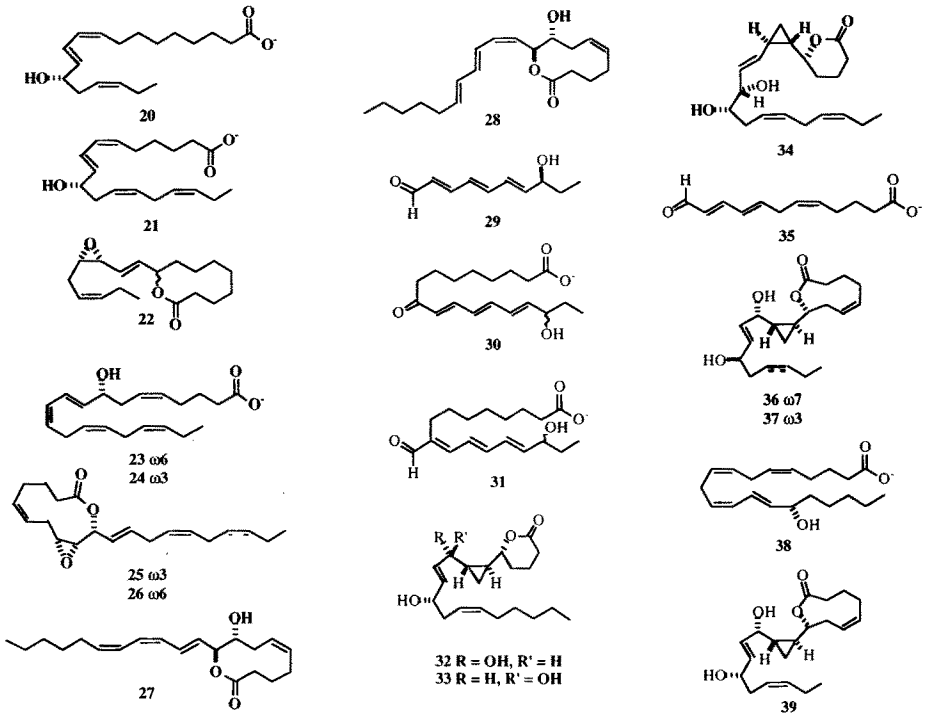


FIG. 3. Alternative radical and ionic pathways to epoxyalcohol (hepoxilins) and subsequent triol biosynthesis (trioxilins).

(potato)(41), their initial discovery from a marine organism was from the Californian red alga *Polyneura latissima* (37). The new compound, 8-[1′Z,3′Z,6′Z-dodecatrienyloxy]-5Z,7E-octadienoic acid (**12**), co-occurred with two epimeric epoxyalcohols (see above, **9** and **10**), a diol (**16**) and the simple hydroperoxide reduction product, 9*S*-HETE (**11**). Subsequently, divinyl ethers were also discovered from the brown alga *Laminaria sinclairii* (9). Collected from the Oregon coast, this kelp was rich in oxylipins and contained three new divinyl ethers (**17–19**) as well as five different monohydroxy polyunsaturated fatty acids. However, two other species of *Laminaria* were reported in the same work to contain only an assortment of the monohydroxy polyunsaturated fatty acids and none of the divinyl ethers.

The biogenesis of divinyl ethers in higher plants has been studied in considerable detail by Gallaird and Matthew (42), Crombie *et al.* (29), and Fahlstadius and Hamberg (43), and has been proposed to involve the rearrangement of an unsaturated hydroperoxide into an EAC of the type central to this review (29). Subsequently, biogenesis of divinyl ethers is envisioned to involve loss of a proton adjacent to the epoxide and electron shift from the epoxide C–C bond to quench the carbocation. In the case of *P. latissima*, this biogenetic pathway would again implicate a putative 9-LO, consistent with the origin of the co-occurring hydroxy acid and epoxyalcohols (35). In the case of *L. sinclairii*, a 15-lipoxygenase (or an ω6-lipoxygenase in the C_{18} compounds) is suggested, which in turn, is also consistent with the pattern of oxidation in the co-occurring hydroxy acids (9).

4. Carbon Chain-Cleaved Oxylipins from Various Algae

Products deriving from action of a putative "hydroperoxide lyase" have been obtained from a diversity of red, green, brown, and blue-green algae (1,2). Furthermore, in these life forms, most of the products observed are consistent with cleavage by the "homolytic-type" hydroperoxide lyase (i.e., products are formed by scission of the C–C bond between the hydroperoxide-bearing carbon and the α-methylene). In this respect, a hydroperoxide lyase was isolated and characterized from a freshwater cyanobacterium (*Oscillatoria* sp.) which converts 13*S*-hydroperoxyoctadecadienoic acid to 13-oxotrideca-9,11-dienoic acid (44). The "heterolytic-type" hydroperoxide lyase produces products arising from C–C scission between the hydroperoxide-bearing carbon and the α-olefinic carbon and is common in higher plants (17). Various mechanistic suggestions have been put forth to explain the formation of these cleavage products, some of which have implicated the intermediacy of an EAC (29). It should be noted that the terms "homolytic" and "heterolytic" represent terms to classify these two reactions and are not proven mechanistic definitions, but rather, remain proposals at the present time. Nevertheless, most microalgal and macroalgal lyase products are best rationalized as products of the "homolytic" process. It is conceivable that carbon-chain scission reactions in algae represent an alternative branch to the pathway herein proposed and emanate from the intermediate alkoxyl radical (Fig. 3); in this sense, they share a common origin with the EAC-derived metabolites.

SCHEME 2

The lone example where the "heterolytic" pathway appears to be operational in an alga is in the brown seaweed *Cymathere triplicata* (45). When this Washington kelp is exposed at low tide, an odor of cucumbers can be detected. Indeed, during extraction of this alga, our co-workers in adjacent laboratories became convinced we were making cucumber salad! In this vein, *C. triplicata* has been examined for its potential as a source of edible kelp products (46,47). Examination of the lipid constituents led us to characterize 2*E*-nonenal and 2*E*,6*Z*-nonadienal from *C. triplicata* (48), the known odorant principles from cucumber (49). In this case, the product likely results from "heterolytic" hydroperoxide lyase reaction on 12-HpETE (**41**) to give a 9-carbon aldehyde and an 11-carbon oxo-acid (Fig. 3), or the equivalent set of reactions on a 10-hydroperoxy C_{18} fatty acid, and thus, reasonably involves the intermediacy of an EAC. As should be expected, the alga was also a source of several hydroxy acids, including 12*S*-HETE (**7**), 13*S*-HOTE (**20**) (see Scheme 2—compound structures 20–39), and 10*S*-HODTA (**21**), substantiating the presence of lipoxygenase metabolism in the alga. As detailed below, this same collection of *C. triplicata* yielded a fascinating array of bicyclic ethers and tetracyclic lactones (see below).

5. Lyngbyalactone from *L. majuscula*

In addition to the above reviewed C_{18} trioxilin-type metabolite (**13**) from the cyanobacterium *L. majuscula*, a Caribbean collection of this blue-green has yielded an epoxylactone of obviously related biogenesis (Todd, J.S., and Gerwick, W.H., unpublished observations). The structure of this new metabolite, lyngbyalactone (**22**), was assembled from a standard assortment of two-dimensional (2D)-NMR and mass spectral techniques. While partial relative stereochemistry could be deduced from coupling constants, absolute stereochemistry has not yet been assigned. The structure of lyngbyalactone is consistent with a biogenesis involving a ω6-LO followed by rearrangement of the hydroperoxide to an EAC and its capture through addition of the carboxylate to C_9 (Fig. 4).

6. Sarcolactone from *Sarcodiotheca gaudichaudii*

The coldwater red alga *S. gaudichaudii* collected from the state of Washington in the United States was recognized as a source of oxylipins from observation of characteristic blue charring compounds on TLC of the crude extract (48). Subsequently, we isolated two homologous hydroxy acids, 8*R*-HETE (**23**) and 8*R*-HEPE (**24**), as well as the homolytic-type hydroperoxide lyase product from 8-HpETE, trideca-2*E*,4*E*,7*Z*,10*Z*-tetraenal (see above).

Two additional products, related to one another as deriving from ω3- and ω6-fatty acids, were obtained and characterized as epoxylactones (**25**,**26**). Their planar structures were assembled from a combination of 2D-NMR and mass spectrometry (MS) data. Stereochemistry of the epoxide and olefins followed from coupling constant analysis while the *threo* relationship of the C_9 and C_{10} substituents was demonstrated by ^{13}C NMR analysis of the 9,10-acetonide which was formed by sequentially hydrogenating sarcolactone A (**25**) to the 8,9-epoxylactone, $LiAlH_4$ treatment to form the 1,9,10-trihydroxyalkane, and acetonide formation using 2,2-dimethoxypropane and *p*-toluenesulfonic acid. An absolute stereochemistry of 8*R*,9*R*,10*R* was established for **25** by selectively opening the lactone with dilute base, methylation to the methyl ester, formation of the *p*-bromobenzoate derivative followed by circular dichroism (CD) analysis (48).

From this array of metabolites, it appears that *S. gaudichaudii* possesses an operational 8-LO, a class of lipoxygenase only previously observed in starfish (15), corals (24), and a red alga related to *S. gaudichaudii* (66). Further, as is often the case, it appears that the resulting hydroperoxide may either be reduced, subject to homolytic cleavage with subse-

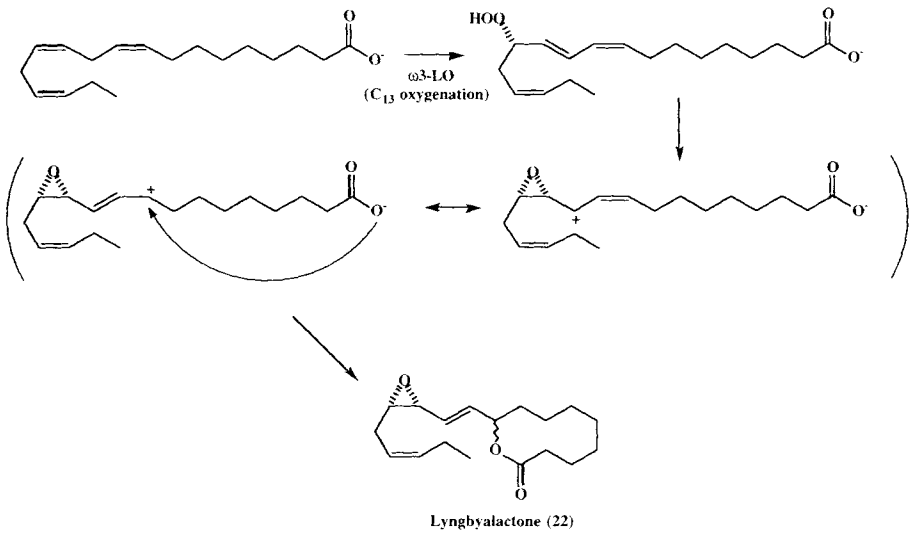

FIG. 4. Proposed biogenesis of lyngbyalactone (**22**) in the marine cyanobacterium *Lyngbya majuscula*.

quent carbon chain scission, or converted to an EAC which is trapped by the carboxylate. It is interesting to note the different fates of this proposed EAC in the two related red algae *S. gaudichaudii* and *Agardhiella subulata* (see Fig. 11 later in this paper).

7. Neodidemnilactone and Ascidiatrienolide from the Tunicate *Didemnum* spp.

The structures of three lactone-containing oxylipins from the tunicate *Didemnum moseleyi*, including neodidemnilactone (**28**), were reported and their structures confirmed by chemical synthesis (50). Neodidemnilactone is highly similar to the corrected structure of ascidiatrienolide (**27**) (51), differing only in the geometry of side-chain double bonds. Ascidiatrienolide was originally isolated from the related tunicate *D. candidum* (52). On the basis of extensive synthetic studies, the lactone ring size was modified in ascidiatrienolide from a nine-membered to ten-membered ring (51). The originally proposed structure of ascidiatrienolide was of the unusual ω7 structure class whereas the ten-membered lactone structure is more in line with established fatty acids (ω6), and predicts arachidonic acid as the ultimate precursor. Biogenetically, the presence of a 1,2 diol derivative adjacent to a conjugated triene in ascidiatrienolide (**27**) and neodidemnilactone (**28**) suggests an 8,9-epoxy-leukotriene A_4-type intermediate that is opened at C_9 by the carboxylate. This in turn could derive from an 8,9-epoxy allylic carbocation of the type proposed in this review, itself coming from 8-HpETE (Fig. 5).

8. Oxylipins from the Green Alga *Acrosiphonia coalita*

The Oregon green alga, *A. coalita*, has been a rich source of acyclic oxylipin metabolites (53). These are included in this review as they could be viewed as involving an EAC species, although, in this case a strong argument also can be made for an alkoxyl radical intermediate. An alkoxyl radical intermediate is suggested because this alga lacks lactone metabolites which logically derive from quenching of an intermediate carbocation with the carboxylate, as seen above and below for various oxylipins from other algae.

The metabolites of *A. coalita* include chain cleaved C_{10} compounds containing conjugated trienal and hydroxy functionalities (**29**) as well as the same functionality in C_{18} acids (**30**) (53). Intriguingly, this same relationship of functional groups was found in a chain-rearranged metabolite in which it is presumed that one carbon is excised from the C_{18} chain to form an aldehyde (**31**). This spectrum of metabolites is consistent with an initial metabolism of stearidonic acid by an ω10-LO (C_9 oxygenation). The hydroperoxide is then possibly subject to homolytic cleavage with ensuing carbon chain fragmentation to the α-methylene side to produce compounds such as **29**. Alternatively, rearrangement to an EAC with sequential migration of an α-epoxy proton, the carbon chain, and finally the epoxide could conceivably give the unsaturated aldehyde **31** (Fig. 6).

However, it is conceivable that all of these *A. coalita* metabolites could derive from a homolytic hydroperoxide cleavage with no ensuing formation of an EAC (17). For example, α-methylene cleavage of the alkoxyl radical could occur with subsequent carbonyl formation and a new C_8-C_{10} bond (Fig. 6). Abstraction of a hydrogen atom from what was formerly C_{10} would give a conjugated dienal or trienal, depending on the state of oxidation at the ω3 position, for at some point in the process, these metabolites become ω3-oxidized with concomitant introduction of the conjugated triene. As several of the *A. coalita* co-metabolites possessed *E,Z,E* conjugated trienes (12), which are consistent with the action

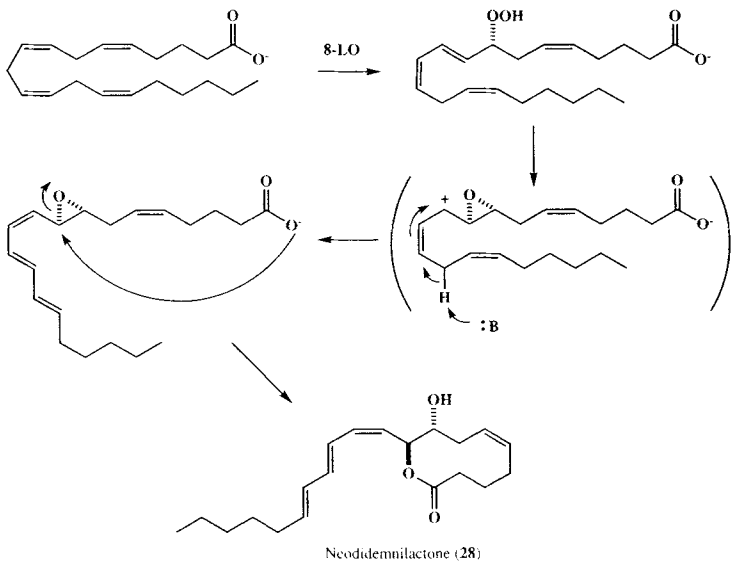

FIG. 5. Proposed biogenesis of neodidemnilactone (**28**) from the tunicate *Didemnum moseleyi*.

of an LO showing ω3 specificity, we propose this activity in the generation of metabolite **31** (Fig. 6). That radical chemistry is involved in hydroperoxide metabolism in *A. coalita* is further implicated by the isolation of four regio- and stereoisomeric epoxyalcohols which logically derive from the 9-hydroperoxide or 13-hydroperoxide. In each series, the locations of the epoxide and alcohol functionalities are consistent with rearrangement of an alkoxyl radical deriving from a homolytic O-O bond cleavage (17). However, as described above, a partially ionic mechanism to these epoxyalcohols cannot be ruled out in which an intermediate EAC is trapped with water.

CARBOCYCLIC OXYLIPINS—OXYLIPINS CONTAINING CYCLOPROPYL RINGS

1. Constanolactones from the Red Alga *Constantinea simplex*

The small mushroom-shaped Oregon alga, *C. simplex*, is a rich source of carbocyclic oxylipins of a cyclopropyl nature. The initial report of two such compounds, constanolactones A (**32**) and B (**33**) (54), has been expanded to a total of seven related products (31). The structural variation between these assorted metabolites involves ω3 and ω6 unsaturation, epimers at C_9 or C_{11}, and 1,4-diols (e.g., at C_9 and C_{12}, **32**) vs. 1,2-diols (e.g., at C_{11} and C_{12}, **34**). Planar structures and relative stereochemistry in these metabolites were determined chiefly by NMR while absolute stereochemistries were determined in most cases by either gas chromatography (GC)–MS analysis of malate fragments suitably derivatized as menthoxycarbonyl dimethyl esters or by CD analysis of benzoate esters (31).

Co-occurring with these carbocyclic oxylipins were the simple hydroxy-acids 12*S*-HETE (**7**) and 12*S*-HEPE (**8**)(54), thereby implicating a 12-LO-initiated biogenesis of the more complex carbocyclic metabolites. Their biogenesis previously has been speculated upon, and with the preponderance of lactone metabolites that this alga produces, likely involves an ionic mechanism in which an intermediate carbocation is trapped by the carboxylate. Furthermore, as all of the constanolactones are of 12*S* stereochemistry and we have shown that in constanolactone B only the 12-hydroxy group oxygen derives from molecular oxygen (55), there is good support for the 12-LO-initiated pathway. By this model (Fig. 7), hydroperoxide rearrangement to an EAC intermediate is succeeded by a potentially concerted electron shift to form the C_9-C_{10} olefin, C_6-C_8 cyclopropyl ring and δ-lactone. Speculation that this unsaturated epoxide may be the true end product of enzymatic metabolism which is then subject to nonenzymatic hydrolysis was supported by isolation of both epimers at C_9 in the 1,4-diols and both epimers at C_{11} in the 1,2 diols. Further, minor solvolysis products were isolated and characterized in which a C_9 methyl ether was presumably formed from this putative unsaturated epoxide metabolite during extraction with MeOH (31).

Accompanying these hydroxy acids and carbocyclic oxylipins was the chain cleaved "lyase" product 12-oxo-5*Z*,8*E*,10*E*-dodecatrienoic acid (**35**)(54). As this product likely results from cleavage between the hydroperoxide-bear-

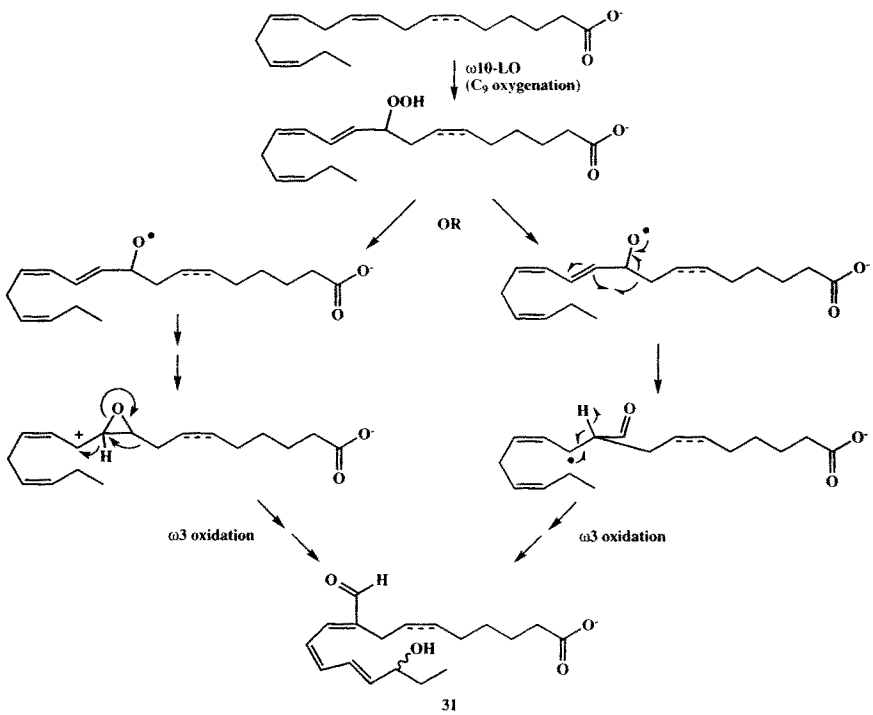

FIG. 6. Two proposals for the biogenesis of branched-chain trienal **31** from the green alga *Acrosiphonia coalita*.

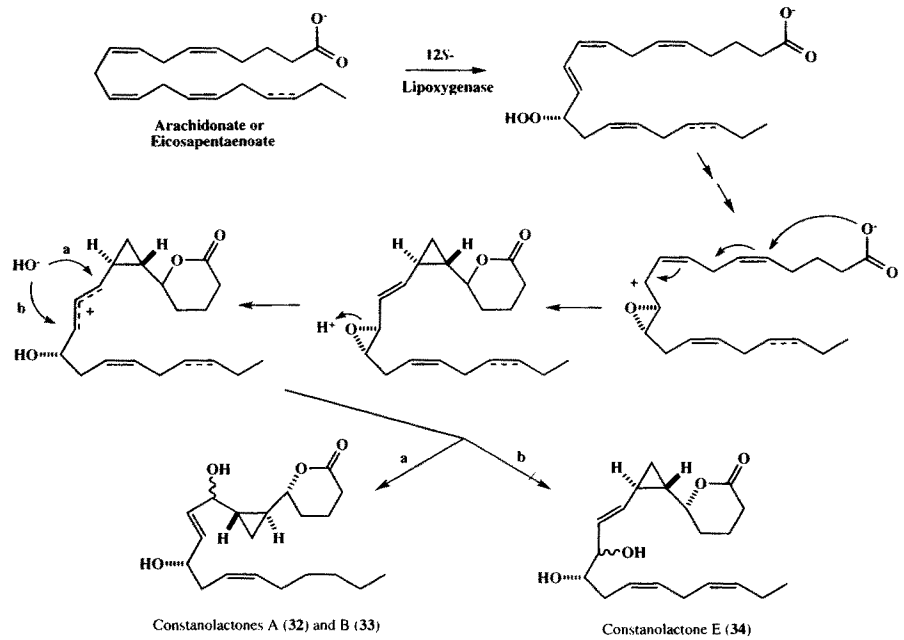

FIG. 7. Proposed biogenesis of 1,4-diol-containing constanolactones A and B (**32,33**), and 1,2-diol-containing constanolactone E (**34**).

ing carbon and α-methylene carbon (17), a radical process is implicated which would stem from a homolytic cleavage of the hydroperoxide, possibly as an early branch in the metabolism of hydroperoxides in *C. simplex* (e.g., see Fig. 3).

2. Neohalicholactones from a Sponge and a Brown Alga

Two closely related cyclopropyl ring-containing oxylipins, halicholactone (**36**) and neohalicholactone (**37**), were isolated from the Japanese sponge *Halichondria okadai* (56). Their planar structures were deduced by extensive NMR work and showed halicholactone to be a cyclopropyl lactone of the ω6 class while neohalicholatone was a comparable structure of the ω3 class. The *R* absolute stereochemistry at C_{15} was deduced for halicholactone (**36**) by comparison of the C_{14}-C_{20} fragment with an authentic standard. Subsequently, an X-ray study of neohalicholactone (**37**) provided relative stereochemistry in this series (57).

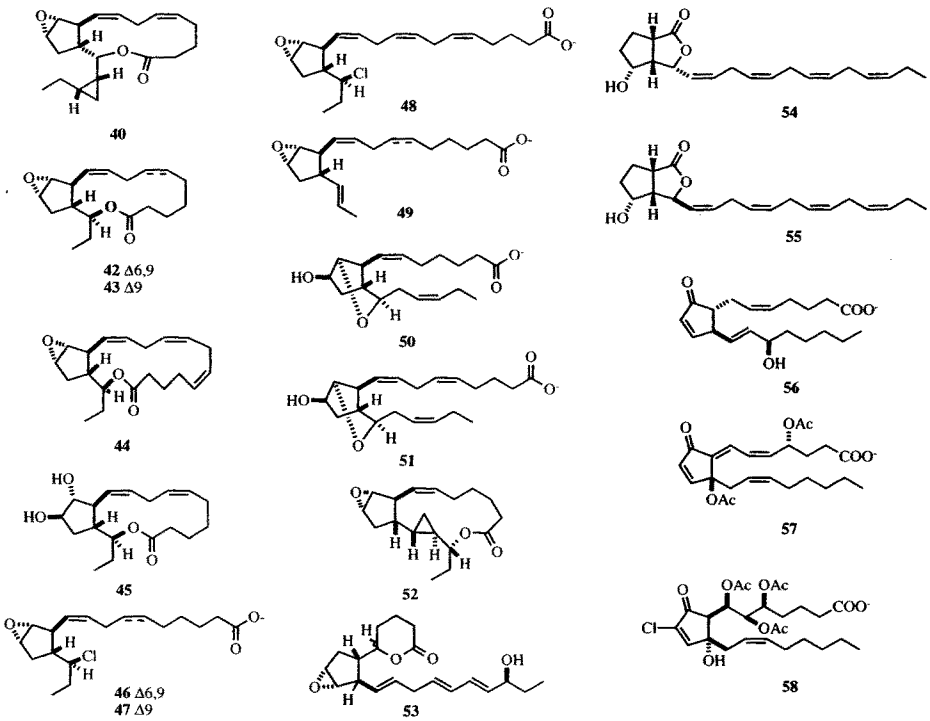
A potential complication in the structure of halicholactone and neohalicholactone was introduced by isolation and structural description of "neohalicholactone" from the Pacific brown alga *L. sinclairii* (58). From this kelp we had earlier isolated a variety of 15-lipoxygenase products, all of which had a 15*S* stereochemistry (e.g., 15*S*-HETE, **38**, see above) (9). Stereoanalysis of C_{15} in the *L. sinclairii*-derived "neohalicholactone" by conversion to the menthoxycarbonyl derivative, ozonolysis, methylation, and GC analysis showed this to be exclusively of *S* stereoconfiguration. Consideration of the proposals put forth for the biogenesis of neohalicholactone (5) led us to speculate that the C_{15}-stereochemistry would be unchanged by the biosynthetic process from the initially formed hydroperoxide.

As our isolate from *L. sinclairii* and that previously obtained from *H. okadai* had nearly identical NMR shifts and the same sign and similar magnitude of optical rotation, it was possible that the C_{15} stereochemistry as originally assigned was in error. However, clarification of this has come from synthetic studies on these metabolites (59), and indicates that the stereochemistry at C_{15} in sponge-derived neohalicholactone is correct as originally formulated (Wills, M., University of Bath, United Kingdom, personal communication). Correspondingly, it appears that the kelp-derived neohalicholactone is in fact diastereomeric to the sponge material at C_{15}. As such, it would be better referred to as "isoneohalicholactone" with its structure most accurately represented by compound **39**. Apparently, the C_{15} stereochemistry is remote enough from other stereocenters that it has minimal effect on the NMR features of the two molecules.

It is remarkable that the same functionalities and relationship of functionalities, as well as most of the relative stereochemistry, would be the same in metabolites coming from such disparate sources as red algae (**32**), brown algae (**39**), and a sponge (**36**). This finding suggests analogous biosynthetic processes at work with only the initial point of oxidation differing (*C. simplex*—12*S*-lipoxygenase; *H. okadai*—15*R*-lipoxygenase; *L. sinclairii*—15*S*-lipoxygenase).

CARBOCYCLIC OXYLIPINS—OXYLIPINS CONTAINING CYCLOPENTYL RINGS

1. Hybridalactone from the Red Alga *Laurencia hybrida*



The red alga *Laurencia hybrida* was the first marine algal source of an unusual prostaglandin analog, hybridalactone

(**40**) (see Scheme 3, compound structures 40–50) (60), and its structure elucidation and other features of its chemistry have been previously reviewed (1,5). This unusual tetracyclic metabolite possesses not only a cyclopentane ring, but also cyclopropane, epoxide, and macrolactone rings. The position of the cyclopentyl ring is unique in that it bridges C_{10} and C_{14} rather than C_8 and C_{12} as in mammalian prostanoids. These various structural features led Corey and co-workers (30) to propose a 12-lipoxygenase initiated biogenetic route to hybridalactone (Fig. 8). In this case, rearrangement of the dienyl hydroperoxide (12*S*-HpETE, **41**) to an EAC is followed by carbocyclization to an allyl carbinyl cation. Following additional cationic rearrangements, a cyclopropyl carbinyl cation intermediate could be captured through nucleophilic attack at C_{15} by the carboxylate, yielding hybridalactone. This biogenetic proposal is strengthened as it correctly predicts the relative and absolute stereochemistry of hybridalactone beginning with 12*S*-HpETE (**41**). These stereochemical features of hybridalactone had been shown through total synthesis and an X-ray crystallographic study of a heavy atom derivative. Additional studies showed other 12-LO-derived metabolites [12*S*-HEPE (**8**)(36) and 12-oxo-5*Z*,8*E*,10*E*-dodecatrienoic acid (**35**)(61)] were present in this extract, providing further support for this 12-LO-initiated route to hybridalactone. Several of the ensuing biogenetic proposals for cyclopentane-containing oxylipins in this review are conceptually based on and similar to the template (Fig. 8) originally developed for hybridalactone (**40**). Finally, it should be noted that in this case, as in several others in this review, there is evidence of a possible branch in the hybridalactone metabolic pathway which departs at the point of alkoxyl radical formation (Fig. 3) and produces 12-oxo-5*Z*,8*E*,10*E*-dodecatrienoic acid (**35**).

2. Ecklonialactones from Two Brown Algae

The Japanese kelp *Ecklonia stolonifera* morphologically resembles the well known genus *Laminaria*, and as such, is a conceivably good food source for marine molluscs, including the abalone (*Haliotis* sp.). However, it appears that this alga is protected against rampant predation by herbivores through production of defensive natural products. These include, not surprisingly, phlorotannins, a natural product class which has demonstrated antifeedant roles in many macroalgae (62). A more unusual group of defensive compounds was found in the lipid-soluble materials from *E. stolonifera*, and includes a series of tricyclic (**42-44**) (63) and bicyclic ecklonialactones (**45**) (64). The latter bicyclic compound conceptually results from epoxide hydrolysis. These structures were assembled from detailed NMR analysis and confirmed by X-ray analysis of crystalline ecklonialactone A (**42**).

Interestingly, three of the same tricyclic metabolites previously reported from *E. stolonifera* were recently isolated by our group from the related Oregon "feather boa" kelp *Egregia menziesii* (both algae are classified in the order Laminariales) (65). The absolute stereochemistry of the series was established by selective opening of the epoxide at C_{13} in this latter isolate of ecklonialactone A (**42**), formation of the corresponding *bis*(*p*-bromobenzoate), and measurement of a negative exciton chirality in its CD spectrum.

SCHEME 3

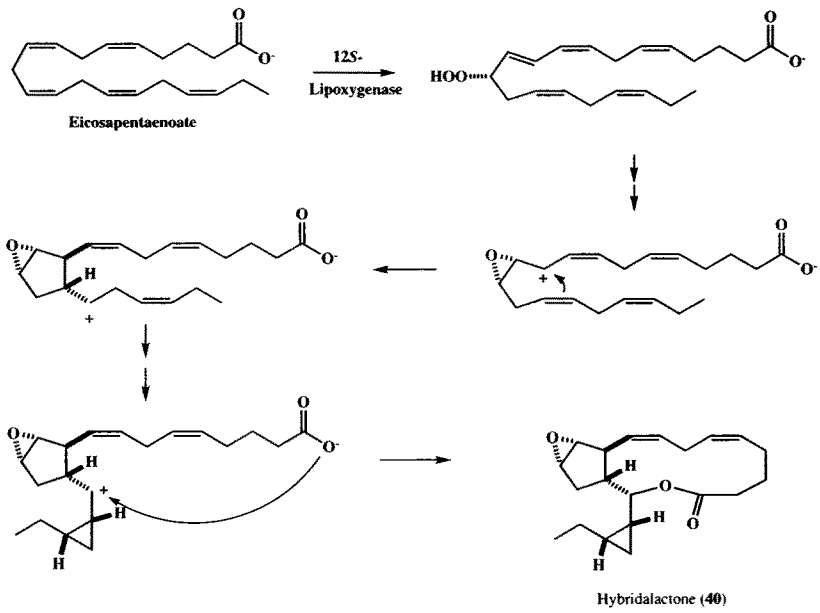


FIG. 8. Proposed biogenesis of hybridalactone (**40**) in the red alga *Laurencia hybrida* (adapted from Ref. 30).

The ecklonialactones are of obvious structural similarity to hybridalactone (see above, **40**) (30) which suggests that they may arise through an analogous series of biosynthetic events (Fig. 8). Furthermore, at comparable centers, they possess identical relative and absolute stereochemistries. The 18-carbon fatty acids stearidonic acid (18:4ω3) and α-linolenic acid (18:3ω3) are the likely precursors to ecklonialactones A (**42**) and B (**43**), respectively, while eicosapentaenoic acid (20:5ω3) is the apparent precursor to ecklonialactone E (**44**). LO oxidation of any of these precursor fatty acids at the ω6 position would yield a dienyl hydroperoxide which could rearrange to the proposed EAC (Fig. 9). In similarity to hybridalactone biogenesis, the carbocation is envisioned to induce carbocyclization, leaving a new carbocation at the ω3 position. In contrast to the remainder of the hybridalactone biogenetic pathway, this ω3 carbocation is directly captured by

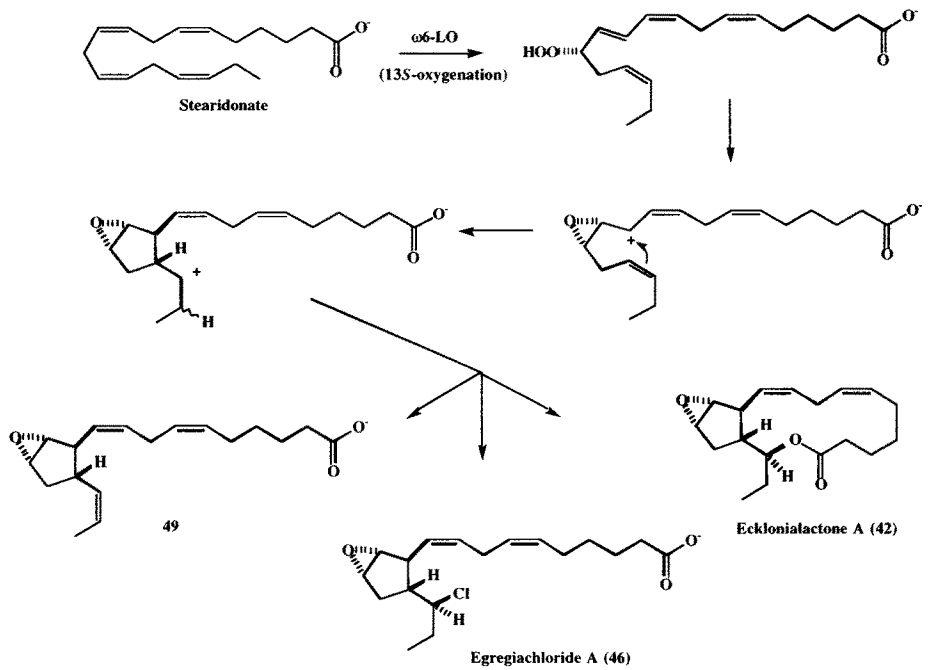

FIG. 9. Proposed biogenesis of ecklonialactone A (**42**), egregiachloride A (**46**), and egregia olefin derivative **49** in the brown algae *Ecklonia stolonifera* and *Egregia menziesii*.

the carboxylate and forms the macrolactone [14-membered ring for ecklonialactones A (**42**) and B (**43**), 16-membered ring for ecklonialactone E (**44**)]. As detailed subsequently, in *Egregia menziesii* there exist other routes for capture or quenching of this ω3 carbocation.

3. Egregiachlorides from *E. menziesii*

The Oregon brown kelp *E. menziesii* was a source of two series of carbocyclic oxylipins which conceivably derive *via* an intermediate EAC, the ecklonialactones (**42–44**, see above) (65) and the egregiachlorides (**46–48**) (32). The structures of the egregiachlorides were assembled from detailed NMR study in concert with the full data sets, and relative stereochemistry was indicated by nOe results and comparison of ^{13}C NMR spectral data with that of the ecklonialactones. Absolute stereochemistry in this series was not unequivocally established. However, on the basis of comparable rotations with the co-occurring ecklonialactones, they were proposed to be of the same enantiomeric series. A *trans*-ω2-olefin metabolite (**49**) of structure comparable to the egregiachlorides was also characterized.

Egregiachlorides A–C (**46–48**) logically derive from stearidonic acid, α-linolenic acid, and eicosapentaenoic acid, respectively. Clearly, they emanate from a similar biogenetic pathway as those producing the ecklonialactones as they possess cyclopentyl and epoxide rings at the same positions and with the same relative stereochemistries (Fig. 9). As both the C_{18} acids (**46,47**) and the C_{20} acid (**48**) are oxidized at the ω6 position, it suggests initiation of this pathway *via* a LO with ω6 specificity. The unique feature of these metabolites is the presence of a chloro functionality adjacent to the cyclopentyl ring. In the biogenesis of the ecklonialactones, this position develops positive charge which is nucleophilically captured by the carboxylate. Correspondingly, this same carbocation at the ω3 position could be captured by chloride ion to yield the egregiachlorides (Fig. 9). Alternatively, this ω3 cation could be quenched by a proton loss from the ω2 position to yield the olefin analog **49**.

4. Cymathere Ethers and Lactones from the Brown Alga *Cymathere triplicata*

As detailed above, *C. triplicata* collected from the Washington coast is rich in various hydroxy acids [12*S*-HETE (**7**), 13*S*-HOTE (**20**), and 10*S*-HODTA (**21**)] as well as odoriferous lyase products (2*E*-nonenal and 2*E*,6*Z*-nonadienal). Accompanying these simple products was a complex assortment of cyclized products, including two bicyclic ethers, cymathere ether A (**50**) and B (**51**) (45), and a new lactone, cymatherelactone A (**52**) (48). The planar structures of all three of these were assembled by careful 2D-NMR work in concert with a full spectrochemical data set. Relative stereochemistry was established by nOe measurements, coupling constants, and comparisons to model compounds. Absolute stereochemistries at the C_{10} alcohol in cymathere ether A (**50**) and the C_{16} alcohol in the lactone-opened derivative of cymatherelactone A (**52**) were established using the modified Mosher Ester method (48). Note, the absolute stereochemistry at C_{10} in this stereostructure for cymathere ether A is opposite that originally proposed (45), and leads us to present an alternative biogenetic pathway (Fig. 10) (48). Finally, absolute stere-

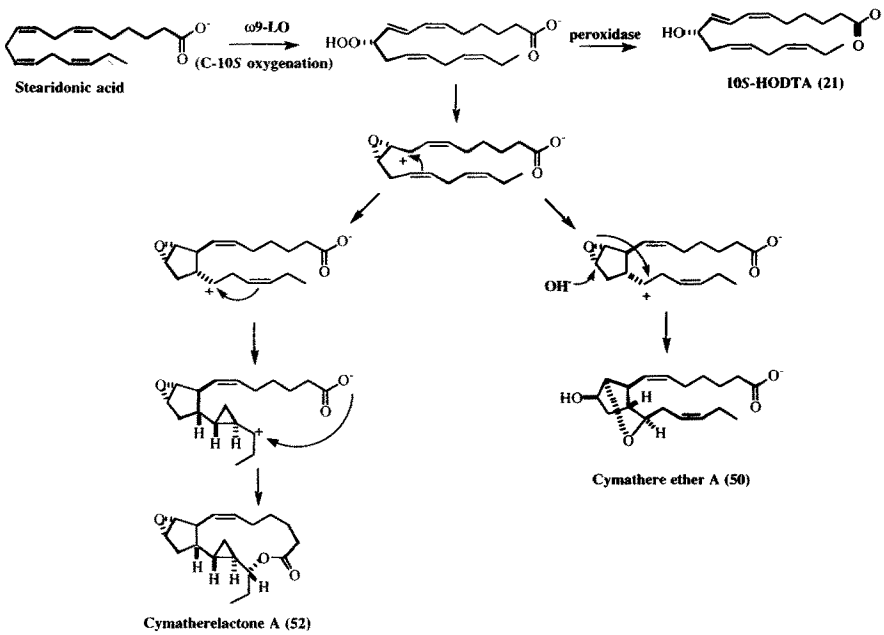

FIG. 10. Proposed biogenesis of cymathere ether A (**50**) and cymatherelactone A (**52**) in the brown alga *Cymathere triplicata*.

ochemistry at C_9 and C_{10} in the lactone metabolite **52** was separately determined by selective opening of the epoxide at C_{10} to the vicinal diol, derivatization to the corresponding *bis*(*p*-bromobenzoate), and measurement of a negative split Cotton effect (48).

The biogenetic origin of these various metabolites is likely quite similar to that proposed for the red algal metabolite hybridalactone (**40**, Fig. 8) (30). Beginning with the 18-carbon fatty acid stearidonic acid, we propose the initiating action of a ω9-lipoxygenase (C_{10} oxygenation) to 10*S*-HpODTA (Fig. 10). This is then either reduced by a peroxidase to 10*S*-HODTA (**21**) or rearranged to an epoxy allylic carbocation. This intermediate subsequently undergoes carbocyclization leaving a C_{13} carbocation. One fate for this cyclopentylcarbinyl cation is capture by the epoxide oxygen to form the C_9-C_{13} ether. This likely happens with concerted attack by water at C_{10}, yielding cymathere ether A (**50**). Another possible fate of the cyclopentylcarbinyl cation is migration of the ω3-double bond π-electrons to form the corresponding cyclopropylcarbinyl cation (Fig. 10). This apparently does not enter a "cyclopropyl-cyclobutyl-cyclopropyl manifold" as does hybridalactone (**40**) (30), but rather, is directly quenched by the carboxylate to form the tetracyclic macrolactone cymatherelactone A (**52**).

5. Agardhilactone from *Agardhiella subulata*

TLC analysis of extracts of the Atlantic red alga *A. subulata* showed the presence of blue-charring ultraviolet-active metabolites consistent with the occurrence of oxylipins. Isolation of one of these was hampered by its apparent instability as well as the co-occurrence of closely related and difficult to separate minor isomers. Nevertheless, repetitive high-performance liquid chromatography ultimately gave a greater than 95% pure sample which was amenable to structure elucidation by the combined techniques of 2D-NMR and MS (66). The new oxylipin, agardhilactone (**53**), is unique in several regards, including its highly functionalized skeleton (alcohol, diene, cyclopentyl ring, epoxide, and lactone ring). Moreover, the cyclopentyl ring is in a novel location relative to any other reported oxylipin, spanning C_6 and C_{10}. The presence and location of the epoxide, cyclopentyl, and lactone rings suggests a biogenesis for agardhilactone which hinges on the intermediacy of an EAC. In this case, initial LO oxidation is thought to occur at C_8, as in the related red alga *S. gaudichaudii*, followed by "hydroperoxide dehydrase"-type rearrangement to the 8,9-epoxide with C_{10} as an allylic carbocation (Fig. 11). Next, a flow of electrons from the 5,6-olefin to make the cyclopentyl ring and from the carboxylate to form the lactone is envisioned. Isomerization of the C_{11}-C_{12} olefin likely occurs at an early stage in the process, and then finally, a presumed 18-LO forms the diene and, following reduction, ω3 alcohol (12).

6. Bacillariolides from *Nitzschia pungens*

Marine diatoms have also been found as a source of unusual oxylipins, which in the case of *N. pungens*, may contribute to

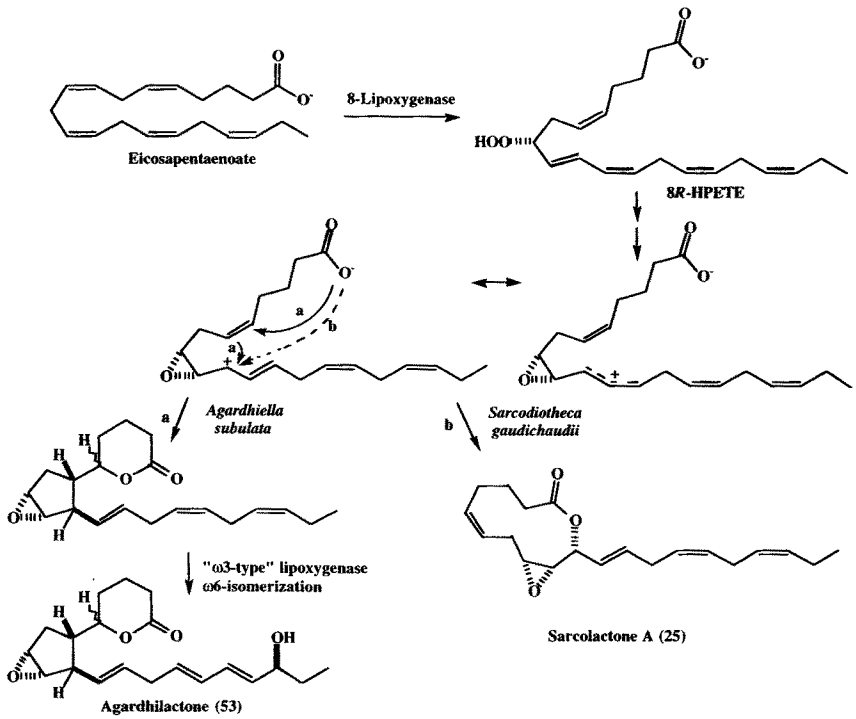

FIG. 11. Proposed biogeneses of agardhilactone (**53**) and sarcolactone A (**25**) in the related red algae *Agardhiella subulata* and *Sarcodiotheca gaudichaudii*.

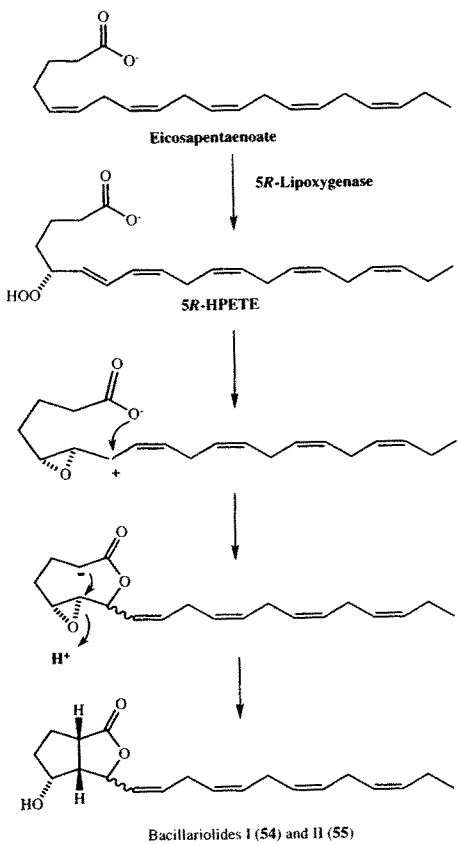

FIG. 12. Proposed biogenesis of bacillariolides I (**54**) and II (**55**) in the marine diatom *Nitzschia pungens*.

the severity of human intoxications resulting from shellfish consumed after blooms of this microalga (67,68). The structures of bacillariolides I (**54**) and II (**55**) were assembled from a normal interplay of NMR and other spectroscopic data while the absolute stereochemistry was established by X-ray crystallographic analysis of a chiral synthetic derivative (69). Biogenetically, it is conceivable that these metabolites are produced *via* a 5-lipoxygenase introduced hydroperoxide which is then converted to the corresponding epoxy allylic carbocation (Fig. 12). Following trapping of the cation by water to form the epoxyalcohol, or by the carboxylate to form an eight-membered lactone, the acidic proton at C_2 could be abstracted and the resulting anion could then attack the epoxide at C_6 to form the cyclopentyl ring and 5*S*-hydroxy group (Fig. 12). If an epoxyalcohol is an intermediate, condensation of the alcohol with the carboxylate at this point would yield the bacillariolide skeleton.

7. Clavulones, Puniglandins, and 15*R*- and 15*S*-Prostaglandins from Diverse Marine Corals

The final metabolites in this perspective are three series of related marine coral compounds: the 15*R*- and 15*S*-prostaglandins (**56**)(4,70), clavulones (**57**)(4,71), and puniglandins (**58**)(72). The 15-*epi*-prostaglandins such as 15*R*-prostaglandin A_2 (**56**), were the earliest group of prostaglandin-like materials to be discovered from marine organisms (73), and there has been tremendous subsequent interest in the mechanisms of their formation (23,24) and biological activity (4). Detailed reviews of these biosynthetic investigations have appeared previously (4,5).

While a definitive pathway from precursor polyunsaturated fatty acid to final prostaglandin A product has not been firmly established, elucidation of portions of the putative pathway has been described (Fig. 2) and involves conversion of an 8-lipoxygenase-derived polyunsaturated hydroperoxide into an allene oxide by the action of an allene oxide synthase (23,24)[hydroperoxide dehydrase (17)]. As described in the introduction to this perspective, formation of an allene oxide can be envisioned as involving an intermediate EAC which loses a proton, formally from C_9 in this case (Fig. 2). The allene oxide has a propensity to rearrange to a cyclopentenone product, which under enzymic influence, presumably occurs (but has not been shown) with stereocontrol. By either prior or subsequent oxidation at C_{15}, prostaglandins of the 15-*epi* series are produced from this LO-initiated pathway in the coral *Plexaura homomalla* (23,24). Puniglandins, such as puniglandin 1 (**58**) from the octocoral *Telesto reisii* (72), and clavulones such as clavulone I (**57**) from the soft coral *Clavularia viridis* (71), are structurally related prostanoid-like compounds with a proposed biogenesis quite similar to that suggested for the *P. homomalla* metabolites. As such, they too likely derive *via* pathways with intermediate formation of epoxy allylic carbocations (4).

CONCLUSIONS

The intermediacy of an epoxy allylic carbocation has been previously proposed in the biogenesis of a number of the above-reviewed marine oxylipins, both by ourselves as well as other workers in this field. However, as seen in this perspective on the biogenesis of a diversity of such metabolites, a more compelling case emerges for the central intermediacy and generality of an EAC. In some cases, the epoxide that is formed in this process is of *cis* configuration (e.g., **22,25, 40–44,46–49**) while in others a *trans* epoxide is produced (e.g., **3,9**). However, no discernable trend in the further metabolism or chemotaxonomy of these different epoxides is readily apparent. It is interesting to note the large number of cases in which metabolites hypothesized to emanate from a radical pathway and from a cationic pathway co-occur in the same alga. In this review, it is proposed that all of these products emanate from a single pathway, one which first involves formation of an alkoxyl radical and subsequently an epoxy allylic carbocation. From the first, a variety of chain-scission or oxygen rebound reactions occur which explain the frequent occurrence of short-chain aldehydes and epoxyalcohols in the algae. From the latter EAC intermediate, it is proposed that a variety of unusually oxidized and carbon chain-rearranged metabolites are produced.

Several interesting points arise through consideration of

the above general hypothesis. Chief among these is its highly testable nature. Evaluation of substrate analogs which carry heteroatoms or functionalities at key positions might be expected to inhibit this putative "hydroperoxide dehydrase." On the other hand, if there is as much mechanistic relatedness in these hydroperoxide rearrangements as herein speculated, this relatedness might also be mirrored in the biosynthetic enzymes and their corresponding gene sequences. Hopefully, we will see an increase in the exploration of these intriguing questions by biochemists, bioorganic chemists, and molecular biologists in the future.

ACKNOWLEDGMENTS

I thank Philip Proteau (OSU) for critically reading the manuscript and Ken Milligan for help with referencing. Research on marine oxylipin chemistry in the author's laboratory has been supported by the Oregon Sea Grant Program (R/BT-18). I thank Mats Hamberg (Karolinska Institutet, Stockholm) for helpful discussions and encouragement on the subject of this review.

Purification and Characterization of a 28 kDa Cytosolic Inhibitor of Cholesteryl Ester Hydrolases in Rat Testis

Denise S. Hines, Siowfong Wee[1], and W. McLean Grogan*

Department of Biochemistry and Molecular Biophysics, Virginia Commonwealth University, Richmond, Virginia 23298-0614

ABSTRACT: A 28 kDa inhibitory protein was purified from rat testis cytosol by sequential 40–65% ammonium sulfate precipitation, cation exchange chromatography, anion exchange chromatography, and preparative SDS–polyacrylamide gel electrophoresis. The heat-stable, trypsin-labile protein exhibited nonenzymatic, concentration-dependent inhibition of testicular and pancreatic cholesteryl ester hydrolases at all stages of purification. Copurifying at each stage was a 26.5 kDa protein which comprised 25% of the mass of the two proteins. Polyclonal antibodies raised to either or both 28 kDa and 26.5 kDa proteins by direct injection of excised electrophoretic bands cross-reacted with both proteins on western blots, immunoprecipitated both proteins, and neutralized inhibitory activity. Amino acid compositions of the individual proteins electroeluted from SDS–polyacrylamide gels were different from those of other surface-active proteins of similar molecular weights. Both proteins exhibited identical pI of 4.8 on chromatofocusing columns and two-dimensional gel electrophoresis. Although the subcellular distribution of the 28 kDa protein is unknown, its testicular cytosolic concentration, calculated from the purified protein mass, was 8×10^{-9} mols/L, which probably underestimates the actual concentration by an order of magnitude. This is greater than the minimum concentration required for *in vitro* inhibition (10^{-9} mols/L), consistent with a physiological role for this protein.

Lipids 31, 1233–1243 (1996).

Catalytic activities of surface-active enzymes are known to be influenced by the presence of other proteins associated with the substrate surface. Well-characterized, physiologically relevant examples of such interactions include the activation of pancreatic lipase by colipase (1,2); activation of lipoprotein lipase by apolipoprotein C-II (3,4); activation of lecithin/cholesterol–acyltransferase by apolipoprotein A-I (5–7), and activation of bee venom phospholipase A_2 by mellitin (8). Other proteins are known to influence activity of hydrolytic enzymes by modifying the surface of lipophilic substrates (9–11). The pathophysiological significance of such proteins is manifest in the cytolytic potential of intracellular hydrolytic enzymes, which are generally characterized by broad substrate specificities, and in the general lack of understanding of mechanisms for regulating their activity *in vivo*. It has been suggested that accessory proteins may be involved in regulation of cholesteryl ester hydrolase (CEH) in various organs (12–18). However, there has been no report of the purification or specific characterization of such a putative regulatory protein.

Several investigators in this laboratory have noted unexpectedly high recoveries of catalytic activity or loss of activity at specific stages of purification of CEH isoenzymes from rat testis (19) or liver (20). These findings were suggestive of differential loss of inhibitory or stimulatory accessory factors during the course of purification. In this report, we describe the purification and characterization of a specific testicular cytosolic protein with properties consistent with a physiological role in regulation of CEH activity.

MATERIALS AND METHODS

Chemicals and supplies. Cholesterol [1-^{14}C]oleate (59.4 mCi/mmol) and Aquasol-2 were purchased from DuPont-New England Nuclear (Wilmington, DE); heptane [high-performance liquid chromatography (HPLC) grade], from Baxter (Columbia, MD); dialysis tubing, Gelman acrodiscs (0.22 μM) and other solvents, from Fisher Scientific (Norcross, GA); Immobilon-P Transfer Membranes (PVDF), from Millipore (Bedford, MA); SDS, acrylamide, *bis*-acrylamide, TEMED, ammonium persulfate, silver stain kit, electrophoretic molecular weight markers, gelatin, blotting grade GAR-HRP and blotting grade DAB, from BioRad (Melville, NY); BCA protein assay kit, from Pierce Chemical Co. (Rockford, IL); ultrapure $(NH_4)_2SO_4$ and Coomassie R-250, from ICN (Irvine, CA); porcine pancreatic CEH, trypsin-linked agarose beads and other chemicals and reagents, from Sigma (St. Louis, MO); electrophoretic equipment, from Hoeffer (San Francisco, CA); frozen rat testes (250–350 g Sprague-Dawley rats), from Zivic-Miller Laboratories (Zelienople, PA) and Hilltop Laboratories (Scottsdale, PA); FPLC Mono S (HR 5/5 and HR 10/10) cation exchange column, FPLC Mono Q (HR 5/5) anion exchange column, FPLC

Purification of CEH. Rat testicular cytosolic CEH was prepared according to Wee and Grogan (19). Testes were homogenized in buffer (1:2 wt/vol) containing: 20 mM Tris-HCl, pH 7.5; 250 mM sucrose; 80 mM KCl; 0.05% sodium cholate; 10 mM EDTA and 0.1 mM thioglycolate. Cytosol (S104) was prepared by differential centrifugation at 2000 × *g* (30 min), 10,000 × *g* (30 min), and 104,000 × *g* (90 min); brought to 40% saturation with $(NH_4)_2SO_4$; stirred for 30 min at 4°C and centrifuged at 10,000 × *g* for 30 min. Resulting ammonium sulfate precipitate (ASP) pellets were stored at −20°C until use. ASP was redissolved in 500 µL buffer (20 mM Tris-HCl, pH 7.5; 10 mM EDTA, 0.1 mM thioglycolate, 1 mM sodium cholate), desalted over Sephadex G-25 and used as a CEH source for inhibitor assays or further purified by cation exchange chromatography.

For further purification, the desalted sample (10–30 mg) was chromatographed on a Pharmacia Mono S HR 10/10 FPLC cation exchange column (4 mL/min), eluting with 40 mL of Buffer A (20 mM Tris-HCl, pH 7.5; 0.05% sodium cholate; 0.1 mM EDTA; 0.1 mM thioglycolate); 72 mL linear gradient, 0–14% Buffer B (Buffer A + 2 M NaCl); 24 mL 14% Buffer B; 1 mL linear gradient 14–100% Buffer B; 33 mL 100% Buffer B. Fractions (8 mL) were assayed for CEH activity. Fractions 13–15 were pooled and used as a CEH source for assays. EDTA (10 mM) was added to stabilize activity. Protein was estimated by the Pierce Bicinchoninic Acid method (21).

Purification of cytosolic CEH inhibitor. Supernatant from 0–40% ASP was adjusted to 65% saturation with $(NH_4)_2SO_4$ and stirred for 30 min at 4°C. ASP (40–65%) was collected by centrifugation at 10,000 × *g* for 30 min and stored at −20°C until needed. Each ASP pellet, corresponding to ten testes, was dissolved in 1 mL 20 mM Tris-HCl (pH 7.5, 0.1 mM thioglycolate, 10 mM EDTA), desalted on a preequilibrated Sephadex G-25 column, and used for inhibitor assays or further purified.

For further purification, desalted 40–65% ASP (50–70 mg protein) was centrifuged at 10,000 × *g* for 15 min at 4°C. Supernatant was chromatographed on a Pharmacia Mono S HR 5/5 FPLC cation exchange column, eluted at 1 mL/min with 5 mL buffer C (20 mM Tris-HCl, pH 7.5, 0.1 mM EDTA and 0.1 mM thioglycolate); 3 mL linear gradient, 0–16% buffer D (buffer C + 2 M NaCl); 10 mL 16% buffer D; 3 mL linear gradient, 16–40% buffer D; 7 mL 40% buffer D, 2 mL linear gradient 40–100% buffer D; 15 mL 100% buffer D. One mL fractions were desalted and assayed for inhibitory activity. Fractions 21–24 were pooled, desalted (Centriprep-10 or Centricon-10 concentrators; Amicon Corp., Danvers, MA) and used as a source of cation exchange purified inhibitor or for further purification. For anion exchange chromatography, cation exchange purified fractions 21–24 (50–300 µg protein) were chromatographed on a Pharmacia Mono Q HR 5/5 anion exchange column (1 mL/min), eluted with 5 mL buffer C; 3 mL linear gradient, 0–16% buffer D; 10 mL 16% buffer D; 3 mL linear gradient, 16–40% buffer D; 7 mL 40% buffer D; 2 mL linear gradient, 40–100% buffer D; 15 mL buffer D. One mL fractions were collected, desalted, and assayed for inhibitory activity.

Active fractions were concentrated by TCA precipitation or Centricon-10 microconcentrator, electrophoresed on 5–20% or 9–12% SDS–polyacrylamide gradient gels (22), and silver stained to assess purity, using BioRad low molecular weight standards for calibration.

CEH activity. Rat testicular neutral cytosolic CEH activity was assayed by the modified method of Wee and Grogan (19). Each assay contained 20 mM Tris-HCl, pH 7.5, 1 mM sodium cholate, 10 mM EDTA, 0.1 mM thioglycolate, and 10–25 µg 0–40% ASP protein or 5–10 µg cation exchange purified CEH in 500 µL total volume. Tubes were preincubated 5 min at the assay temperature (32 or 37°C). Cholesterol oleate (35 µM) labeled with 2–4 × 10^4 dpm cholesterol [1-^{14}C]oleate was added in 12.5 µL acetone, and incubation was continued for 20 min, unless otherwise stated. The reaction was terminated by adding 3.25 mL methanol/chloroform/heptane (1.4:1.25:1, by vol) and 50 µL of 1 N NaOH. Product oleate was measured in the aqueous phase by liquid scintillation counting as described by Ghosh and Grogan (23).

Porcine pancreatic CEH (Sigma) was assayed as described above by the modified method of Ghosh and Grogan (20), using 1 µg CEH and 5 mM sodium taurocholate (24). Activity of all enzymes was linear with protein concentration and time of incubation.

Measurement of inhibitory activity. CEH activity was measured with and without 40–65% ASP, cation exchange purified fractions 21–24, anion exchange purified fractions 21–24, or other inhibitor sources. Inhibitor was added just prior to addition of substrate. Inhibitory activity is expressed as %inhibition = 100 × (activity without inhibitor − activity with inhibitor)/activity without inhibitor; or units (1 unit = I_{50}, amount of protein inhibiting 50% under assay conditions, evaluated from a protein concentration curve).

Electroelution. Proteins in inhibitory fractions (1.7–2 mg cation exchange purified protein or 100–150 µg anion exchange purified protein) were electrophoresed on a 9–12% SDS–polyacrylamide gradient gel. Bands corresponding to Coomassie stained 25–31 kDa markers were cut from the gel and protein electroeluted into 0.04 M Tris-Acetate, 0.002 M EDTA, pH 8.6, using a Shandon (Cheshire, England) electroeluter for 3 h at 50 mA. Electrode buffer was 0.4 M Tris-Acetate. Excess SDS was removed by extensive dialysis against 0.04 M Tris-HCl, pH 7.5. Prior to assay, sample was adjusted to pH 7.5 with dilute acetic acid. For individual bands, 28 or 26.5 kDa proteins were prestained with $CuCl_2$ (25) and destained before electroelution (26).

Phosphatase assay. Hydrolysis of *p*-nitrophenylphosphate (20 mg/mL) was measured spectrophotometrically at 410 nm (27) using assay conditions described for testicular and pancreatic CEH. The reaction was terminated by addition

of 600 µL of 0.5 M phosphate buffer, pH 7.5 and 10 mM EDTA.

Hydrophobic chromatography. Pooled cation exchange fractions 21–24 (800 µg protein) were concentrated by 65% $(NH_4)_2SO_4$ precipitation and resuspended in 1 mL 0.1 M sodium phosphate, pH 7.0, 2 M $(NH_4)_2SO_4$. The 100 µL was chromatographed on a Biogel TSK-phenyl 5PW HPLC column pre-equilibrated with the same buffer and eluted (1 mL/min) by a 60 min decreasing linear $(NH_4)_2SO_4$ gradient (2 to 0 M); followed by 20 min elution with distilled H_2O.

Production of polyclonal antibody. For primary immunization, 650 µg cation exchange purified protein (pooled and concentrated fractions 21–28) was electrophoresed on a 9–12% SDS–polyacrylamide gradient gel. The gel was stained briefly with Coomassie R-250, to visualize bands corresponding to 26.5, 27, and 28 kDa and washed to remove excess stain. Selected bands were excised, homogenized in phosphate buffered saline and Freund's complete adjuvant (1:2:2, gel–saline–adjuvant). An emulsion was generated by repeated passage between two ground-glass barreled syringes and injected intradermally at 10–15 sites on the back of a New Zealand rabbit on day 0. On days 25 and 72, booster immunizations of 300–500 µg anion exchange purified protein (fractions 21–28) were injected with Freund's incomplete adjuvant. Ten days after the third injection, serum was tested for antibodies by Western blot analysis as described below. Additional boosters were given in incomplete adjuvant 7–12 d prior to subsequent bleedings. Individual rabbits were injected with all three bands, the 28 kDa band alone, or the 26.5 kDa band alone. Preimmune serum was collected 7 d before primary immunization. IgG was prepared from immune and preimmune serums by PEG precipitation (28).

Western blot analysis. Proteins separated by SDS–PAGE (9–12% gradient) were transferred to Millipore Immobilon-PVDF membrane by semi-dry blot transfer (Integrated Separation System, Natick, MA) for 1 h at 2 mA/cm^2, according to the manufacturer's instructions. Western blot analysis was carried out as described previously (29) using 1:300 dilution of IgG (1.3 mg/mL).

Immunoprecipitation. Inhibitory proteins were immunoprecipitated from cation exchange purified inhibitor (fractions 21–28) by the modified procedure of Kessler (30,31) using antibody complexed with purified protein-A conjugated polyacrylic beads (Sigma). Beads were precoated with gelatin to decrease nonspecific binding to beads, washed to remove excess gelatin, incubated for 1 h with immune IgG or preimmune IgG, centrifuged to remove excess IgG and incubated for 1 h with inhibitor-containing fractions or buffer. Beads were then centrifuged and the supernatants collected and assayed for inhibitory activity against pancreatic CEH.

Amino acid analysis. Cation exchange purified protein (25 µg) was electrophoresed on a 9–12% SDS–polyacrylamide gradient gel, electroblotted to Millipore PVDF membrane (32), and stained with Coomassie blue R-250. Stained proteins corresponding to the two major bands (28 and 26.5 kDa) and the minor 27 kDa were excised. Quantitative amino acid analysis was carried out by Hewlett-Packard Aminoquant Methodology in the Protein Core Facility at Virginia Commonwealth University. The amino acid compositions for mature rat serum apoA-I and PLAP were translated from the reported cDNA sequences (33,34). The amino acid composition of the 28 kDa estrogen-regulated protein of Leydig cells is published (35,36,37).

Two-dimensional gel electrophoresis. Using the method of O'Farrell (38), the cation exchange purified inhibitor 200–300 µg fractions 21–24) was separated by nonequilibrium pH gradient gel electrophoresis (5.5 h at 550v) in the first dimension and 10% SDS–PAGE in the second dimension. Gels were then silver stained or transferred to PVDF membrane for Western blot analysis. Protein molecular weight and pI were compared to the migration of two-dimensional electrophoresis markers (Sigma) (pI range 7.6–3.8; MW range 17,000–89,000).

Chromatofocusing. The 200–300 µg cation exchange fractions 21–24 were chromatographed on a Pharmacia FPLC Mono P HR 5/20 column eluted (1 mL/min) with a pH 6–4 linear gradient, consisting of 3 mL 0.025 M *bis*-Tris-HCl, pH 6.3, 0.1 mM EDTA, 0.1 mM thioglycolate, followed by 39 mL 1:10 Pharmacia Polybuffer 74-HCl, pH 4.0, 0.1 mM EDTA, 0.1 mM thioglycolate. Inhibitory activity was assayed in 1 mL fractions.

Gel permeation chromatography. Cation exchange purified protein (200 µg) was chromatographed on an FPLC Superose 6 gel permeation column eluted (0.2 mL/min) with 20 mM Tris-HCl, pH 7.5, 0.1 mM thioglycolate, 10 mM EDTA, 1 mM sodium cholate, and 150 mM NaCl. Inhibitory activity was assayed in 0.5 mL fractions.

RESULTS

Testis contains a temperature-labile CEH, which is active at 32°C and inactive at 37°C, and a temperature stable enzyme, which is active at both temperatures (39,40). Both activities precipitate from rat testis cytosol in 40% ammonium sulfate (41). As seen in Figure 1 and Table 1, the 40–65% ASP inhibits both forms of testicular CEH. Although the I_{50} for inhibition of the temperature-stable component (72 µg in Fig. 1A), which persists at 37°C, is lower than that for inhibition at 32°C (580 µg in Fig. 1A), this difference may not reflect differential sensitivities of the enzymes to inhibition (see the Discussion section). The inhibition is concentration-dependent, saturable (Fig. 1A), and reversible by dilution (data not shown), suggesting a reversible binding phenomenon. The principal inhibitory activity is trypsin-labile (Fig. 2B) and retained by dialysis membrane (Fig. 2C), indicative of a protein with molecular weight >12,000. However, the inhibition is heat-stable (Fig. 2A), independent of incubation time (Fig. 3), and independent of preincubation time with CEH (data not shown), indicating a nonenzymatic mechanism. Moreover, porcine pancreatic CEH was also inhibited by this factor (Fig. 1B), suggesting a general mechanism for inhibition. Pancreatic CEH provided a more homogeneous and stable enzyme

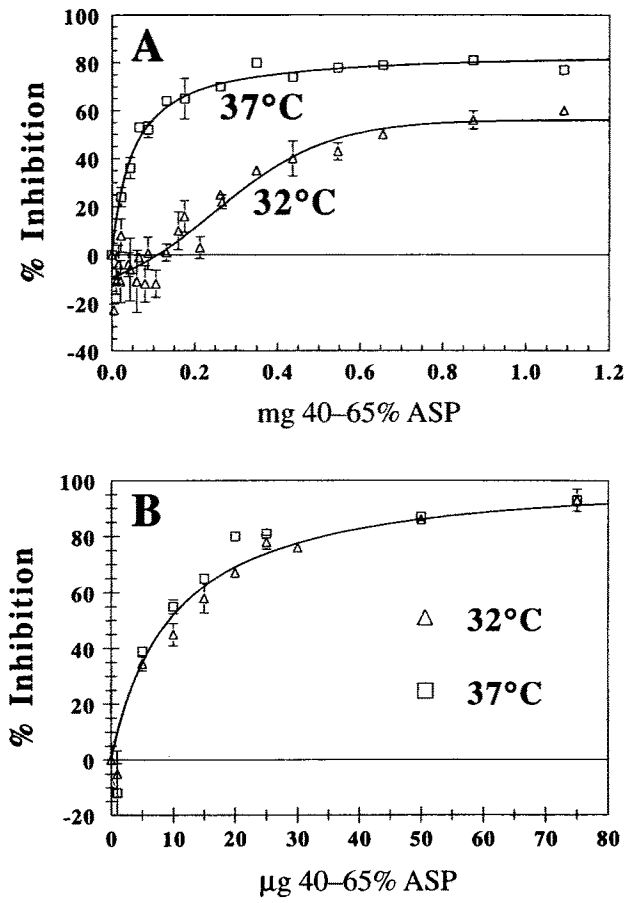

FIG. 1. Concentration-dependent inhibition of rat testicular cholesteryl ester hydrolase (CEH) (A) and pancreatic CEH (B) at 32°C (△) and 37°C (□) by the 40–65% ammonium sulfate precipitate from rat testis cytosol. Values are mean percentage inhibition of CEH control ± SEM (n = 3). Error bars not seen are contained within symbols.

model for mechanistic studies than the testicular CEH. The I_{50} for pancreatic CEH (10 µg in Fig. 1B) was somewhat lower than that for the temperature-stable testicular CEH and did not differ at 32 and 37°C, indicating that the inhibition is not intrinsically temperature-dependent.

The 40–65% ASP was further fractionated by cation exchange chromatography, yielding two major peaks of inhibitory activity in fractions 9–12 and fractions 21–28, respectively (Fig. 4A). Fractions 21–28 not only contained most of the inhibitory activity but were also much higher in specific inhibitory activity than any other fractions (Fig. 4B). As with 40–65% ASP (cf. Fig. 1A), cation exchange purified inhibitor was somewhat less effective in inhibiting testicular CEH at 32°C than at 37°C (Table 1). Although inhibition showed similar concentration dependency to that seen with 40–65% ASP (Fig. 5A), specific inhibitory activity was substantially increased (I_{50} = 10 µg in Fig. 5A; cf. 5.4 µg for 1 µg pancreatic CEH, not shown). Negative inhibition at very low inhibitor concentrations reflects activation, which persisted at every stage of purification, although it was not always apparent in the range of concentrations depicted.

Inasmuch as the testicular CEH is inhibited by phosphatase (41,42), general phosphatase activity was measured in cation exchange fractions (Fig. 4C). Coelution of the first peak of inhibitory activity with a major peak of phosphatase activity suggested that the inhibitory activity of interest was contained in the second, larger peak, which had no appreciable phosphatase activity. Thus, fractions 21–28 with 41–56% of the ASP inhibitory activity (Table 1) were used in subsequent purification steps.

Cation exchange fractions 21–28 were pooled and further fractionated by anion exchange chromatography. As seen in Figure 6, most of the inhibitory activity eluted in fractions 21–24. Although activity was assayed with the pancreatic CEH in the typical elution profile shown in Figure 6, a similar pattern was seen with testis CEH (data not shown). Moreover, specific inhibitory activities did not differ significantly between pancreatic (typically, 900 units/mg) and testicular CEH (Table 1) or between temperature-stable and temperature-labile CEH (Table 1) at this stage of purification. Inhibition by pooled anion exchange fractions (Fig. 5B) was also

[a]Inhibitory activity was measured with partially purified testicular cholesteryl ester hydrolase (CEH), as described in the Materials and Methods section. Inhibition of pancreatic CEH was similar to that of testicular CEH at each stage of purification. Total recovery is referenced to 10 testes; SDS–PAGE, SDS-polyacrylamide gel electrophoresis.

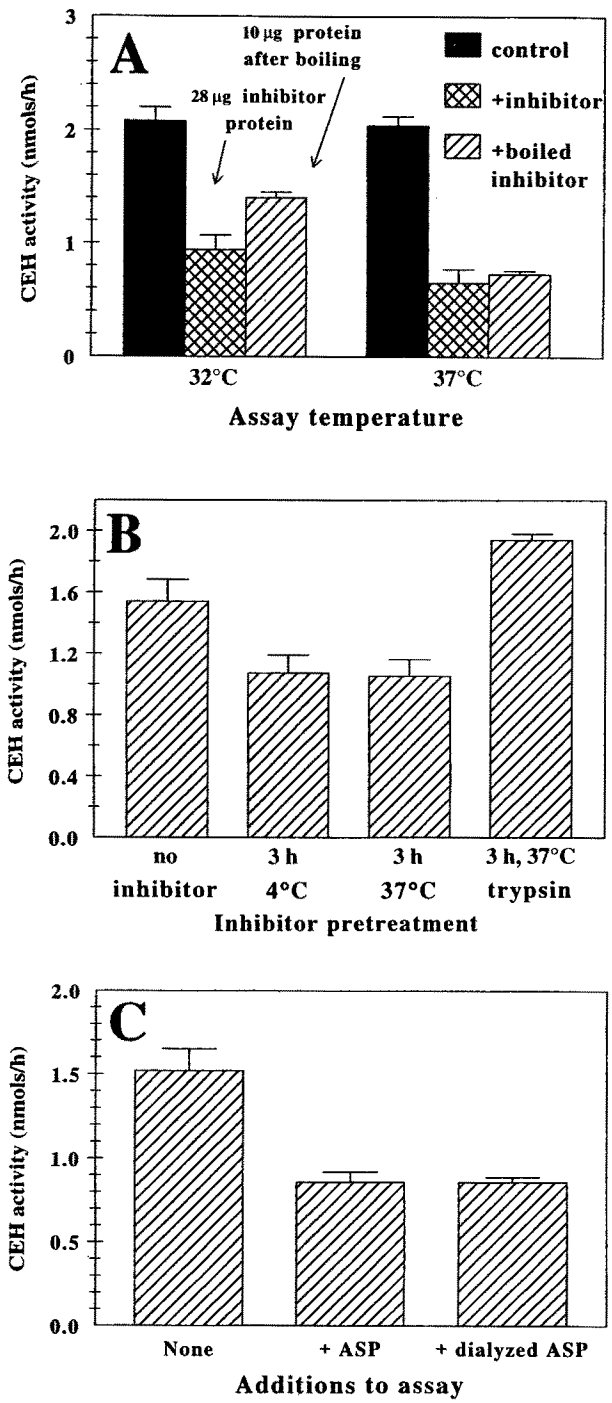

FIG. 2. Characterization of the inhibitory factor as a heat-stable protein. (A) Cation exchange purified inhibitor was boiled for 10 min and precipitated protein removed by centrifugation at 10,000 × *g* for 30 min (see Fig. 10 for recovery of protein after boiling). Rat testicular CEH was assayed at 32 or 37°C with buffer (control), with inhibitor or with equivalent supernatant from boiled inhibitor. (B) Cation exchange purified inhibitor was incubated for 3 h at 4°C or at 37°C in presence or absence of trypsin-linked agarose beads. Samples were then centrifuged at 12,000 × *g* for 5 min. Pancreatic CEH was assayed with or without 300 µL of each supernatant. (C) 40–65% ammonium sulfate precipitate (ASP) was dialyzed (M_r cutoff = 12 kDa) against 6 × 2 L assay buffer. Rat testicular CEH was assayed with or without 520 µg ASP, dialyzed or undialyzed. Values are mean percentage inhibition of CEH control ± SEM (n = 3). See Figure 1 for other abbreviation.

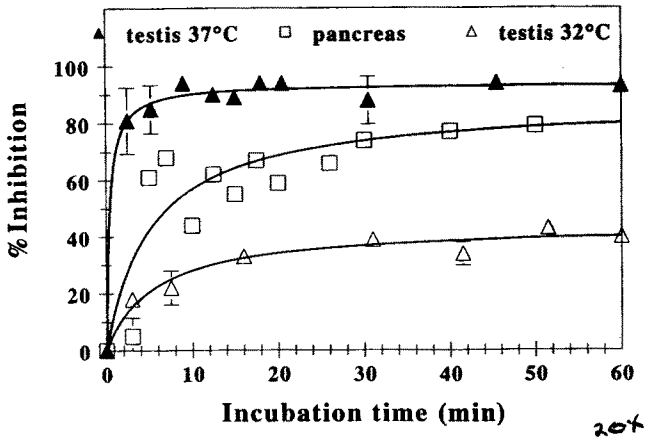

FIG. 3. Time-dependent inhibition of rat testicular CEH or pancreatic CEH by testicular cytosolic CEH inhibitor. Cation exchange purified testicular CEH or pancreatic CEH were assayed with and without cation exchange purified inhibitor (fractions 21–24) for the times indicated. Values are mean percentage inhibition of CEH control ± SEM (n = 3). Error bars not seen are contained within symbols. See Figures 1 and 2 for abbreviations.

concentration-dependent and produced a saturation curve similar to that of the 40–65% ASP and cation exchange purified fractions, whereas specific inhibitory activity was further increased (I_{50} = 3.3 µg in Fig. 5B). As in earlier stages of purification, very low inhibitor concentrations activated CEH.

Homogeneity was assessed by SDS–PAGE at each stage of purification (e.g., Figs. 7–8). However, none of the procedures resulted in a completely homogeneous protein. Moreover, purification steps beyond cation exchange gave poor recovery of total activity (see Table 1). Efforts to further purify the inhibitor by gel filtration chromatography produced a diffuse pattern of elution, indicating aggregation, even in the presence of bile salts, with no increase in specific activity (not shown). Hydrophobic interaction chromatography of ion-exchange fractions indicated that the inhibitor was hydrophobic but produced no appreciable increase in homogeneity (not shown).

Although none of the above purification procedures yielded a completely homogeneous protein, silver staining of SDS–polyacrylamide gels revealed a strong band at M_r 28 kDa in active fractions at each stage of purification (Figs. 7A and 8A). The electroeluted proteins from this band exhibited concentration-dependent inhibition of testis CEH (Fig. 5C), indicating presence of the inhibitory factor. Although the inhibition appeared to saturate at lower concentrations with the electroeluted inhibitor (by extrapolation: 40%, at 37°C; 23%, at 32°C) than with less homogenous preparations (typically 80–100%), I_{20} values were consistent with a high degree of enrichment (74 ng, 2, 8, and 20 µg, for electroelution, anion exchange, cation exchange, and ASP-purified inhibitor, respectively, assayed at 37°C). Moreover, very low concentrations of the less highly purified inhibitor also saturated at lower levels of activity (data not shown).

On narrow gradient (9–12%) SDS–PAGE, the broad 28

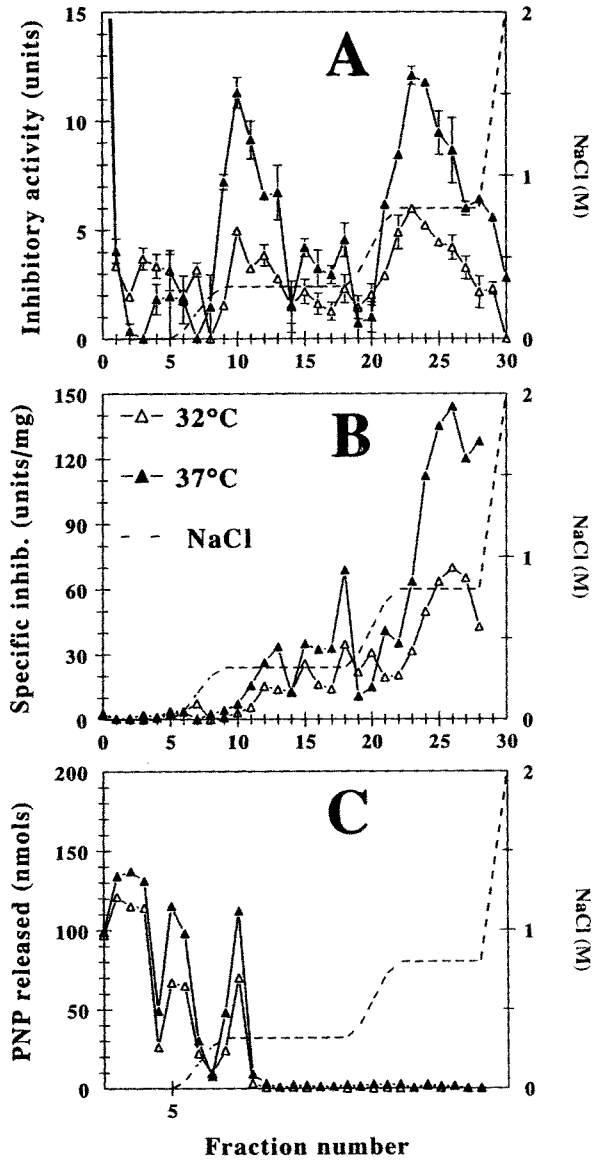

FIG. 4. Elution of CEH inhibitory and phosphatase activities from a cation exchange (FPLC Mono S) column (Pharmacia, Piscataway, NJ). Of each fraction 200 µL was assayed for inhibitory activity toward 22 µg cation exchange purified rat testicular CEH (A and B) and for pNPP hydrolytic activity (C) at 32 and 37°C. Panel A depicts units CEH inhibitory activity per fraction (purified from ten testes); panel B, specific inhibition per fraction; panel C, nmols *p*-nitrophenol (PNP) released per fraction. Values are means ± range (duplicates). Experiment was repeated with similar results. See Figure 1 for abbreviation.

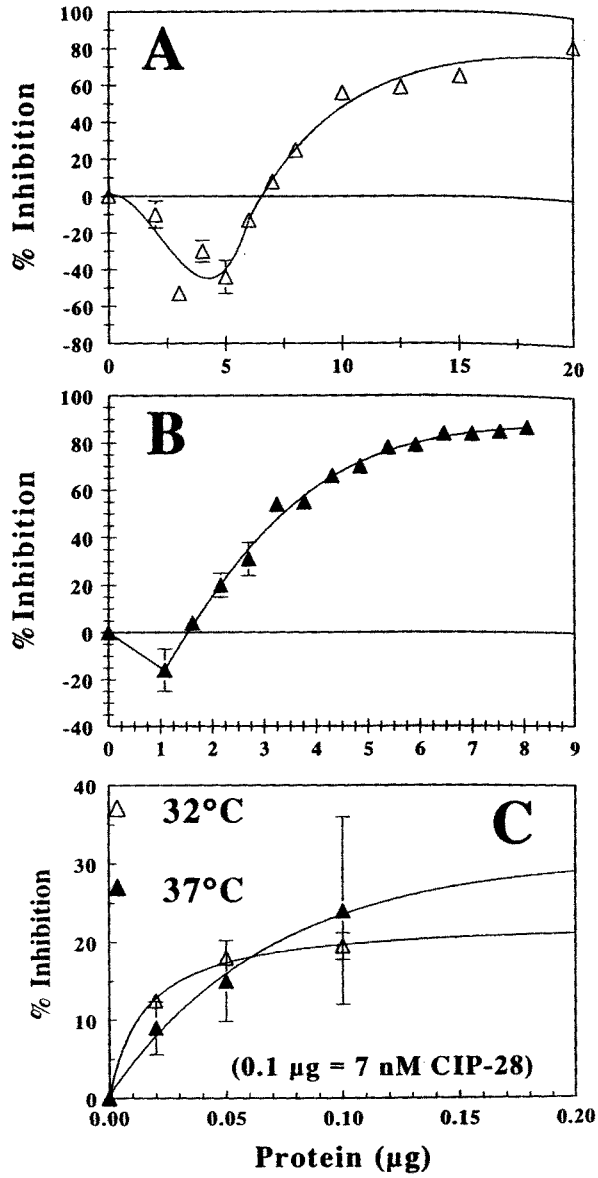

FIG. 5. Concentration-dependent inhibition of CEH by testis cytosolic inhibitor at various stages of purification. (A) Rat testicular CEH (3 µg desalted 0–40% ASP) was assayed at 32°C with cation exchange purified inhibitor (fractions 21–24); similar results were obtained at 37°C. (B) Pancreatic CEH was assayed with anion exchange purified protein (fractions 21–23); similar results were obtained with testicular CEH. (C)14.5 µg cation exchange purified rat testicular CEH was assayed at 32 and 37°C with varying amounts of electroeluted 28, 27, and 26.5 kDa proteins. Values are mean percentage inhibition of CEH control ± SEM (n = 3). Error bars not seen are contained within symbols; CIP-28, 28 kDa cytosolic inhibitor. See Figure 1 for other abbreviation.

kDa band was resolved into 28 and 26.5 kDa bands and a band at 27 kDa, which was not always visible (Figs. 8B and 9). The individual proteins could not be electroeluted in sufficient quantities to assay inhibitory activity. However, amino acid mass and composition (Table 2) were obtained for each of the three electroblotted, excised proteins of interest. The 28, 26.5, and 27 kDa proteins were present in the approximate molar ratio, 12:4:3. Consistent with their hydrophobic character, these proteins were relatively high in hydrophobic amino acids. The amino acid compositions were compared with those reported for other surface-active proteins of similar molecular weight, including Apolipoprotein A-I, phospholipase-activating protein (PLAP), and estrogen-regulated protein from Leydig cells (Table 2). Although none of the amino acid compositions were identical, Asx, Tyr, Val, Leu, Ile, Phe, Met, Pro, and Thr were equivalent in the 28 and 26.5 kDa pro-

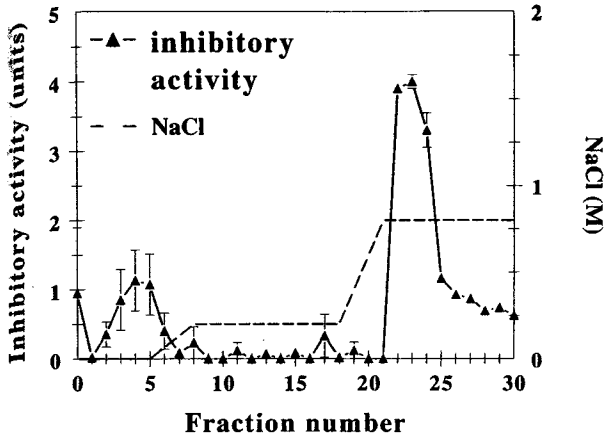

FIG. 6. Elution of cation exchange purified CEH inhibitor from an anion exchange column. Fractions 21–24 of cation exchange purified inhibitor were refractionated by anion exchange (FPLC Mono Q; Pharmacia). Of each fraction 400 μL was desalted and assayed for inhibitory activity against pancreatic CEH. Activity is reported as total units inhibitory activity per fraction (purified from 20 testes); values are mean percentage inhibition of CEH control ± SEM (n = 3). Error bars not seen are contained within symbols. See Figure 1 for other abbreviation.

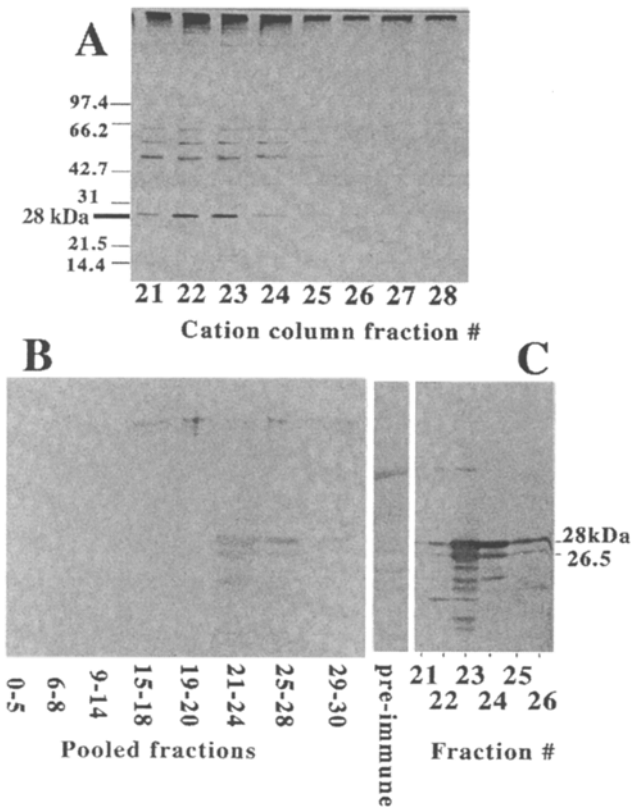

FIG. 7. Analysis of cation exchange fractions by SDS–polyacrylamide gel electrophoresis. Panel A: Silver stained 5–20% SDS–polyacrylamide gradient gel showing prominent 28 kDa band in fractions 21–28, corresponding to elution of inhibitory activity from cation exchange column. Positions of BioRad molecular weight markers are provided for comparison. Panel B: Western immunoblot of pooled cation exchange fractions, electrophoresed on 9–12% SDS–polyacrylamide gradient gel, transblotted to PVDF membrane and probed with antibody to 28 and 26.5 kDa proteins. Immunoreactive proteins at 26.5 and 28 kDa are resolved by the shallow gradient and coelute with inhibitory activity (see Fig. 4). Panel C: Western immunoblot of individual cation exchange fractions showing elution of immunoreactive 26.5 and 28 kDa proteins in fractions containing inhibitory activity (see Fig. 4). Other cross-reacting bands were also immunoreactive with preimmune sera, which did not react with 28 and 26.5 kDa proteins.

teins. Attempts to obtain primary sequences for these proteins were unsuccessful. Both proteins appeared to be *N*-terminally blocked.

Rabbit antibodies were raised by direct injection of the bands from SDS–PAGE, in combination or separately. As seen in Figure 10, strongest antibody titer was achieved with the combined proteins (lane 1), and antibodies raised to the individual 26.5 kDa (lane 2) or 28 kDa (lane 3) proteins exhibited mutual cross-immunoreactivity, further evidence that these proteins are closely related. In contrast, immunoreactivity to the 27 kDa band was not apparent with any of the antisera. The 26.5 and 28 kDa proteins were immunoreactive on western blots (Figs. 7–10 and 12) of inhibitory fractions at all stages of purification, and absent from fractions lacking activity, establishing a persistent correlation between the inhibitory activity and these proteins. Moreover, the intensity of western blot reactivity was consistent with the amount of inhibitory activity measured in various fractions (cf. Figs. 4,6 vs. Figs. 7,8).

To confirm the identity of the inhibitor, the partially purified inhibitor was precipitated with protein A-bead complexed antibodies to the 28/26.5 kDa proteins (Fig. 11). Immunoprecipitation abolished inhibitory activity in a concentration-dependent manner, whereas preimmune serum had no effect. SDS–PAGE analysis confirmed precipitation of the 26.5/28 kDa proteins with the antibody-complexed beads and removal of both proteins from the resulting supernatant (not shown).

The relationship between the 26.5 and 28 kDa proteins was further examined by two-dimensional (nonequilibrium pH gel electrophoresis/SDS–PAGE) electrophoresis. As seen in Figure 12, the pI of these proteins are identical and no additional proteins are resolved. Both proteins also eluted from an HPLC chromatofocusing column, with pI 4.8 (not shown). Consistent with this pI, the inhibitory protein was insoluble in buffers at pH 4.5–5.5 (data not shown).

Association of these proteins with the testis was confirmed by Western blotting after organ perfusion to remove blood. The 26.5/28 kDa immunoreactive proteins were undiminished in the perfused testis (data not shown).

DISCUSSION

The major CEH inhibitory activity in the 40–65% ASP of testicular cytosol is associated with unique 28 and 26.5 kDa hydrophobic proteins which have been purified to apparent homogeneity by sequential cation exchange chromatography, anion exchange chromatography, and SDS–PAGE. Homo-

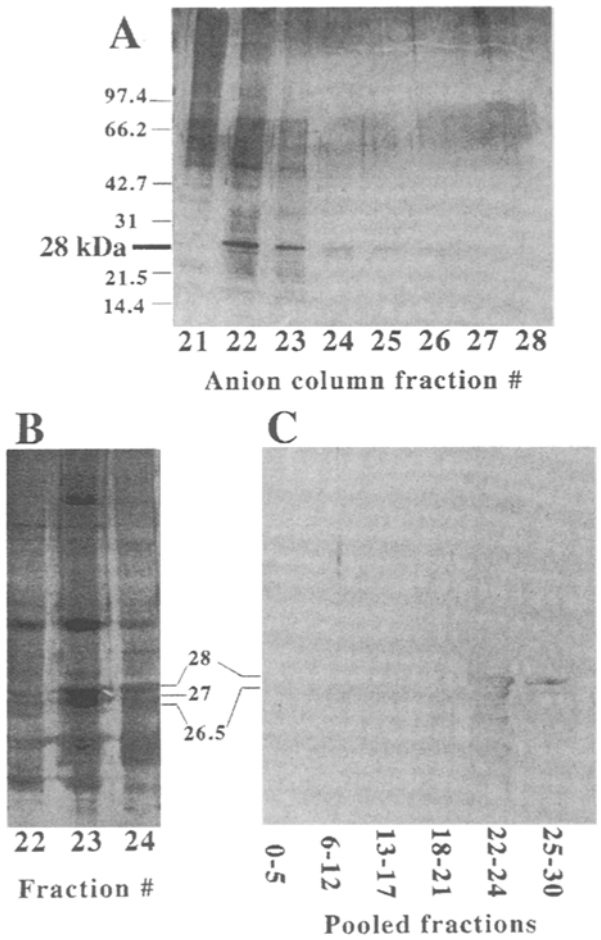

FIG. 8. Analysis of anion exchange fractions by SDS–polyacrylamide gel electrophoresis. Panel A: Silver stained 5–20% SDS–polyacrylamide gradient gel showing prominent 28 kDa band in fractions 22–28, corresponding to elution of inhibitory activity from anion exchange column. Positions of BioRad molecular weight markers are provided for comparison. Panel B: Silver-stained 9–12% SDS–polyacrylamide gradient gel showing resolution of 27 and 26.5 kDa proteins from the major 28 kDa band which co-purified with inhibitory activity (see Fig. 6). Panel C: Western immunoblot of pooled anion exchange fractions showing elution of immunoreactive 28 and 26.5 kDa in fractions 22–24 and 25–30, which contain inhibitory activity (see Fig. 6).

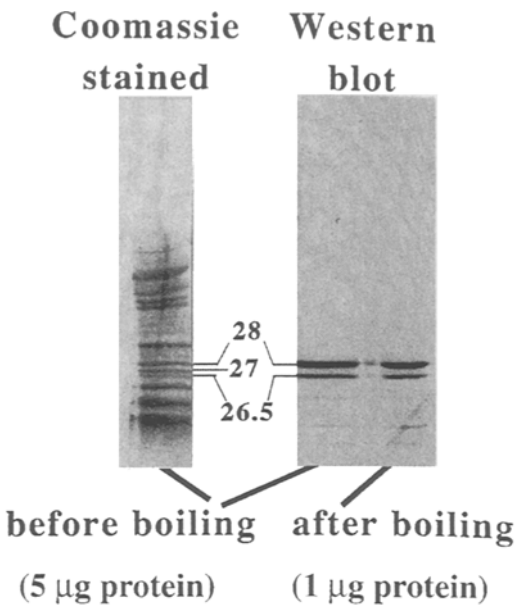

FIG. 9. SDS–polyacrylamide electrophoresis of cation exchange purified CEH inhibitor, showing bands used for immunization and electroelution of purified proteins. Cation exchange fractions 21–24 were pooled and electrophoresed on a 9–12% SDS–polyacrylamide gradient gel. Gels were stained with Coomassie blue to identify 28, 27, and 26.5 kDa bands for excision. Western blot shows immunoreactivity with antibody to 26.5/28 kDa proteins, both before and after boiling of pooled cation exchange fractions. See Figure 1 for other abbreviation.

geneity was confirmed by two-dimensional gel electrophoresis. Inasmuch as these proteins copurify with virtually all fractionation methods, share the same pI and elicit cross-reactive antibodies, they may share surface domains and both may be inhibitory. Although neither could be purified in sufficient quantity to test for individual activity, Coomassie staining, western blotting, and quantitative amino acid analysis indicate that the 28 kDa protein (CIP-28) is 3-fold higher in concentration than the 26.5 kDa protein, in inhibitory fractions at all levels of purification. Moreover, inhibitory activity is immunoprecipitated by antibodies to the 28 and 26.5 kDa proteins. Thus, it is likely that the inhibitory activity is predominantly associated with CIP-28.

Specific inhibitory activity toward testicular CEH was much lower and saturated at a lower inhibitor concentration at 32 than at 37°C, possibly reflecting lower susceptibility of the temperature-labile CEH, which contributes most of the activity at 32°C (39,40). However, this may also reflect the higher concentration of active enzymes at 32°C, whereas only the temperature-stable enzyme is active at 37°C. In support of this view, additional experiments with pancreatic CEH have shown that both the I_{50} and maximum inhibition (I_{max}) decrease as the CEH concentration increases (unpublished data). Inhibition of pancreatic CEH was not different at 32 and 37°C (Fig. 1B), ruling out an intrinsic temperature effect on inhibitory activity.

Although inhibitory activity is stable, even after boiling (Figs. 2A and 9), recoveries are unacceptably low in more highly purified preparations, apparently due to aggregation and adherence to columns, filters, and vessels. This problem was partially solved by excising individual bands from polyacrylamide gels and electroblots for immunization and amino acid analysis, respectively. Although this property prevented most studies with the pure protein in solution under conditions appropriate for CEH activity, it is consistent with a role in regulating the activity of an enzyme which acts at the hydrophilic/hydrophobic interface.

Inasmuch as CIP-28 is hydrophobic and loses its solubility as its homogeneity increases during purification, this protein is apparently stabilized in the native state by the presence of other cellular components, perhaps by association with other cytosolic proteins and with the substrate itself. This is consis-

TABLE 2
Amino Acid Compositions (mol/mol protein) of CEH Inhibitory Proteins and Other Proteins of Similar Molecular Weight

Amino acid	Rat testicular proteins			Rat serum Apo-AI (27 kDa)[a]	Estrogen-regulated protein (28 kDa)[b]	PLAP (28 kDa)[c]
	28 kDa	26.5 kDa	27 kDa			
Asx[d]	17.1	18.4	30.0	31	16.2	22
Glx[e]	18.8	24.8	34.2	40	30.7	23
Ser	27.3	19.1	13.9	8	22.6	36
His	1.9	22.0	5.0	6	6.3	11

[a]Amino acid composition translated from cDNA sequence (Ref. 33).
[b]Amino acid composition of MCF-7 Estrogen-regulated breast cancer protein (37). Monoclonal antibody to this protein recognizes a 28 kDa cytosolic estrogen-regulated rat Leydig cell protein postulated to be responsible for the early steroidogenic lesion occurring during gonadotropin desensitization (Refs. 35,36).
[c]Amino acid composition translated from cDNA sequence of phospholipase A_2-activating protein from $BC3H_1$ murine smooth muscle cells (Ref. 34).
[d]Asp + Asn residues.
[e]Glu + Gln residues; PLAP, phospholipase-activating protein. See Table 1 for other abbreviation.

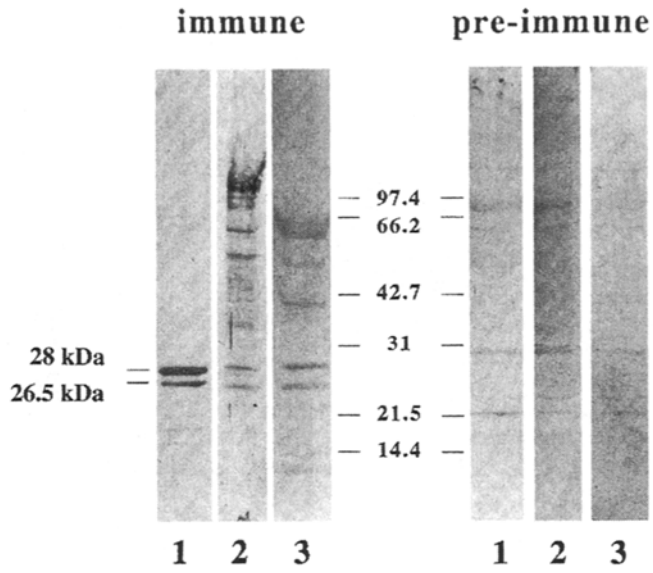

FIG. 10. Specificities of polyclonal antibodies raised to 28 kDa and 26.5 kDa proteins combined (lanes 1), the 26.5 kDa protein alone (lanes 2) or the 28 kDa protein alone (lanes 3). Each lane contains 5 μg cation exchange purified protein (fractions 21–24) electrophoresed on a 9–12% SDS–polyacrylamide gradient gel, transblotted to polyvinylidene difluoride membrane and probed with equivalent amounts of immune or pre-immune IgG. Specific 28 and 26.5 kDa immunoreactive bands are located relative to BioRad (Melville, NY) molecular weight markers.

tent with a role in regulation of CEH by reversible association with the substrate surface. Indeed, a substantial fraction of this protein is recovered from the floating fat layer after differential centrifugation (data not shown). This interaction may alter CEH activity by occluding the surface or displacing bound CEH. Although this mechanism lacks the specificity of classical competitive inhibition, it is consistent with the broad substrate specificities of hydrolytic enzymes and may play an important role in their regulation. Evidence will be presented elsewhere that this protein does in fact inhibit CEH by this mechanism.

CIP-28 can be distinguished from other reported CEH inhibitors, which are heat-labile and soluble in aqueous solution at pH 5–5.2 (13–16,43). The monomeric molecular weight of CIP-28 is much lower than those reported for the other inhibitors (typically, ≈50 kDa). Like the other inhibitors, CIP-28 is highly hydrophobic and elutes diffusely from gel permeation columns. CIP-28 shares similar properties with apolipoprotein A-I (43), including heat stability, molecular weight, and ability to inhibit CEH activity *in vitro*. However, CIP-28 and apoA-I have different amino acid compositions (Table 2), and polyclonal antibodies to CIP-28 do not recognize rat apoA-I on western blots (data not shown). CIP-28 also exhibited important differences in amino acid composition from other surface-active proteins, including PLAP (34) and estrogen-regulated protein (35,36). Thus, CIP-28 appears to be a unique protein.

The physical properties of CIP-28 which hinder recovery also make it difficult to determine the total cellular content. However, a minimum testicular content can be estimated from the amino acid analysis. Correcting for dilution factors, the lower limiting concentrations of the 28, 26.5, and 27 kDa proteins are 8.1×10^{-9}, 2.6×10^{-9}, and 2.2×10^{-9} mols/L, respectively. Although losses during purification would dictate large positive correction factors to obtain accurate values, the calculated values are comparable to minimum effective inhibitor concentrations seen in these studies (~10^{-9} M; see Fig. 5C). Moreover, the activation of CEH seen at very low concentrations (see Fig. 5), which has been reproduced with electroeluted CIP-28 (not shown), suggests that this protein may also be a positive modulator of CEH at concentrations too low to produce inhibition. Clarification of the physiological role of CIP-28 would require knowledge of localized concentrations and interactions with other cellular components. Nevertheless, it is clear that this protein is present in the testis at sufficient levels to be a potentially important regulator of CEH activity.

ACKNOWLEDGMENT

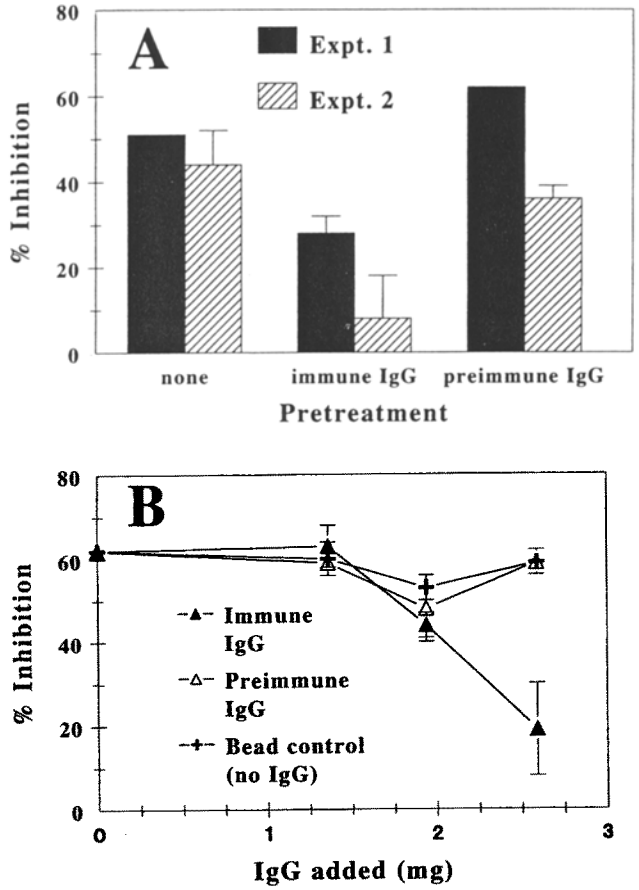

FIG. 11. Concentration-dependent immunoprecipitation of CEH inhibitory activity by immune IgG complexed with protein A conjugated polyacrylic beads. Pancreatic CEH was assayed with addition of equivalent volumes of untreated cation or anion exchange purified inhibitor; supernatant of cation or anion exchange purified inhibitor after precipitation with immune IgG; supernatant of cation or anion exchange purified inhibitor after precipitation with preimmune IgG; or supernatant of cation or anion exchange purified inhibitor after precipitation with protein A conjugated beads alone. (A) Experiment 1: complexes of 2.6 mg preimmune or immune IgG with 22 mg protein A beads were incubated with 2 μg anion exchange purified protein. Experiment 2: complexes of 3 mg preimmune or immune IgG with 25 mg protein A beads were incubated with 3 μg anion exchange purified protein. (B) Inhibitory activity in 8 μg cation exchange purified protein was precipitated by increasing amounts of IgG, as indicated. Values are mean percentage inhibition ± SEM (n = 3). Error bars not seen are contained within bars or symbols. See Figure 1 for other abbreviation.

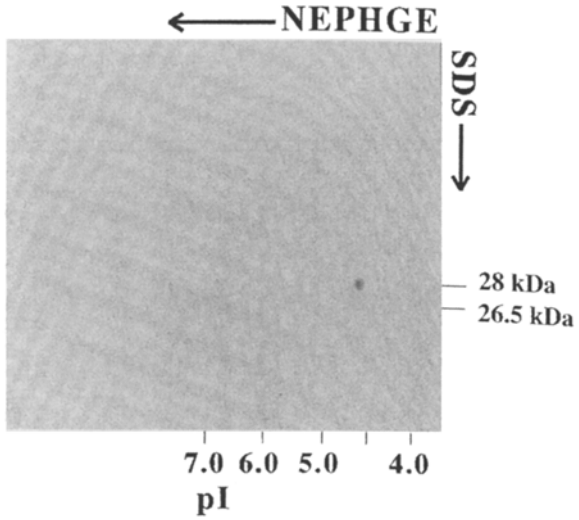

FIG. 12. Western immunoblot from two-dimensional gel electrophoresis of cation exchange purified inhibitor showing mobility of 28 and 26.5 kDa proteins. 250 μg pooled cation exchange fractions 21–28 was separated in the first dimension by nonequilibrium pH gel electrophoresis and in the second dimension on a 10% SDS–polyacrylamide gel, transblotted to polyvinylidene difluoride membrane and probed with 0.8 mg immune IgG. Molecular weight and pI were determined by comparison to two-dimensional molecular weight markers (pI 3.8–7.6; 17–89 kDa) blotted to polyvinylidene difluoride membrane and stained with Coomassie blue.

Protection by Different Agents Against Inactivation of Lipoxygenase by Hydrogen Peroxide

Manuela Pérez-Gilabert, Gerrit A. Veldink*, and Johannes F.G. Vliegenthart

Bijvoet Center for Biomolecular Research, Utrecht University, NL-3584 CH, Utrecht, The Netherlands

ABSTRACT: H_2O_2 is a potent inactivator of lipoxygenase. In this paper, the ability of different agents [mannitol, oleic, stearic and linoleic acid, *n*-butanol, and hydroperoxy octadecadienoic acid (HPOD)] to prevent the inactivation of tomato lipoxygenase by hydrogen peroxide has been studied. The involvement of $OH^{\cdot}$ in the inactivation process is suggested by the ability of mannitol to prevent the loss of activity. This radical would be produced by reaction of H_2O_2 with the Fe(II) lipoxygenase. The most effective protection was displayed by HPOD, the product of the reaction of lipoxygenase with linoleic acid. This result could be explained by the conversion of the native enzyme into the Fe(III) lipoxygenase in the presence of HPOD; the Fe(III) enzyme is not able to react with H_2O_2, and no $OH^{\cdot}$ will be produced. The protective effect obtained with oleic and stearic acid could be explained by an occupation of the active center by these inhibitors. The enzyme would not transform them, but their presence would hamper the conversion of H_2O_2 in $OH^{\cdot}$ and limit the damage in the active center.

Lipids 31, 1245–1250 (1996).

Lipoxygenases (LOX) (EC 1.13.11.12) catalyze the dioxygenation of fatty acids which contain one or more 1(*Z*), 4(*Z*)-pentadiene systems, yielding chiral (*E,Z*) conjugated hydroperoxy fatty acids (1). In mammalian tissues, LOX are involved in the initial steps of the biosynthesis of physiologically active compounds such as leukotrienes and lipoxins (2). The metabolic role of LOX in plants is still uncertain, although they have been implicated in plant senescence, in the response to pest attack as well as wounding (3,4) and in the formation of volatile flavor compounds in many plant food products (5,6).

The presence of one non-heme iron per enzyme molecule has been demonstrated in a number of LOX (7–9). From dormant soybean seeds, the enzyme is isolated as an EPR-silent Fe(II) form which is converted into the active Fe(III) form by the product hydroperoxide (10). The ability of other hydroperoxides such as H_2O_2 to convert the Fe(II)-LOX into the Fe(III) form has been studied by different groups. Some reports suggest that H_2O_2 does not activate the native enzyme (11,12), whereas other authors have demonstrated the ability of H_2O_2 to convert the soybean and reticulocyte 15-LOX from the Fe(II) into Fe(III) form (13,14). Low concentrations of H_2O_2 have been shown to stimulate the dioxygenase activity of soybean LOX (15) and 5-LOX from mammalian cells (16). H_2O_2 is also able to increase the hydroperoxidase activity of LOX, and it can replace lipid hydroperoxide in the oxidation of xenobiotics (17–19).

The irreversible inactivation of soybean LOX in the presence of H_2O_2 was reported in 1967 by Mitsuda *et al.* (20). The sensitivity of LOX to this agent is dependent on the degree of purification, the purified enzymes being more prone to inactivation by H_2O_2 than crude preparations (21). Kazeniac and Hall (22) and Jadhav *et al.* (23) reported the inhibition by H_2O_2 of the development of *cis*-3-hexenal and hexanal in blended tomatoes and in cell free tomato extracts. This data led them to suppose that LOX is involved in the sequence of reactions leading to hexanal and *cis*-3-hexenal formation from unsaturated fatty acids. Despite the fact that enzyme denaturation by H_2O_2 is not specific for LOX (17,24), the inhibitory effect of H_2O_2 has been taken as proof for the involvement of LOX in the flavor formation.

To gain further insight into the effect of hydroperoxides on LOX catalysis, we have studied the inactivation of tomato LOX by H_2O_2 and the influence of substrate, product, and inhibitors on the regulation of this process.

MATERIALS AND METHODS

Tomato LOX was purified using a modification of the method of Bonnet and Crouzet (25), (Suurmeijer, C.N.S.P., and Pérez-Gilabert, M., unpublished results). The specific activity of the enzyme was 10 enzymatic units per mg of protein. SDS-PAGE stained with Coomasie Blue showed three bands in addition to the corresponding to LOX.

Linoleic acid was purchased from Fluka (Bornem, Belgium); *n*-butanol was from Merck (Darmstadt, Germany); H_2O_2 30% wt was obtained from Aldrich (Bornem, Belgium); mannitol, stearic, and oleic acids were from Sigma (Bornem, Belgium). All other chemicals used were of analytical grade.

A H_2O_2 solution was freshly prepared every day, and its concentration was calculated using $\varepsilon_{240} = 39.4\ M^{-1}cm^{-1}$ (26).

Copyright © 1996 by AOCS Press

Oleic, stearic, and linoleic acid were dissolved in methanol. The final concentration of methanol in the reaction medium was 1% (vol/vol).

9-hydroperoxy octadecadienoic acid (HPOD) was prepared by incubation of linoleic acid with tomato LOX in 0.1 M phosphate buffer pH 6.8 at 4°C and under constant aeration. The solution was applied to a 6 mL disposable C-18 extraction column (J.T. Baker Inc., Deventer, The Netherlands) and the product eluted with methanol. High-performance liquid chromatography (HPLC) (27) showed that the main product was 9-HPOD. 13-HPOD was prepared by incubation of linoleic acid with LOX-1 from soybeans in 0.1 M sodium borate buffer pH 10 and purified using the same procedure described for 9-HPOD.

LOX activity was determined spectrophotometrically at 234 nm [ε_{234} = 25,000 $M^{-1}cm^{-1}$, (28)] in a HP8452A diode array at 25°C. The rate was calculated from the linear zone of the product accumulation curve after the lag period.

The inactivation of the enzyme by hydrogen peroxide was confirmed determining the rate of oxygen consumption at 25°C. The equipment was the Hansatech CB1 Oxygen Electrode Unit equipped with magnetic stirrer and connected to a Kratos BD 40 recorder (Hansatech Limited, Norfolk, United Kingdom).

Unless stated otherwise, the reaction medium contained 0.1 M phosphate buffer pH 6.8, 18 µM linoleic acid and 0.016 enzyme units of tomato LOX in a final volume of 1 mL, these being the optimal conditions (Suurmeijer, C.N.S.P., and Pérez-Gilabert, M., unpublished results). One enzymatic unit is defined as the amount of enzyme that gives rise to the appearance of 1 µmol of conjugated diene per minute at 25°C.

In specific experiments, the Fe (III) LOX was obtained by preincubation of the native enzyme with an 80-fold excess of 9-HPOD for 20 min. The excess of hydroperoxide was eliminated by repeated centrifugations (at least four times) of the incubation medium through a Centriprep-30 concentrator (Amicon, IJsel, The Netherlands) as described in (29). The amount of HPOD introduced in the reaction medium along with the Fe(III) LOX was calculated to be less than $5 \cdot 10^{-5}$ µmoles.

RESULTS

The effect of H_2O_2 on the LOX activity was studied following the accumulation of HPOD in the presence of 1.5 mM H_2O_2 (Fig. 1A) and the oxygen consumption (Fig. 1B). The experiment was carried out in two different ways: (a) starting the reaction by addition of enzyme or by addition of substrate (b). Compared with a control without H_2O_2 (curve c), the presence of linoleic acid in the reaction medium prevents the loss of 22% of the activity. In order to exclude that this behavior is the result of a low sensitivity of tomato LOX against the action of H_2O_2, the enzyme was incubated with H_2O_2 at concentrations ranging from 50 to 150 µM (Fig. 2). Samples of the incubation media were taken at different times, and the residual activity was measured by the addition of linoleic acid to the cuvette. In Figure 2, it is shown that when the substrate

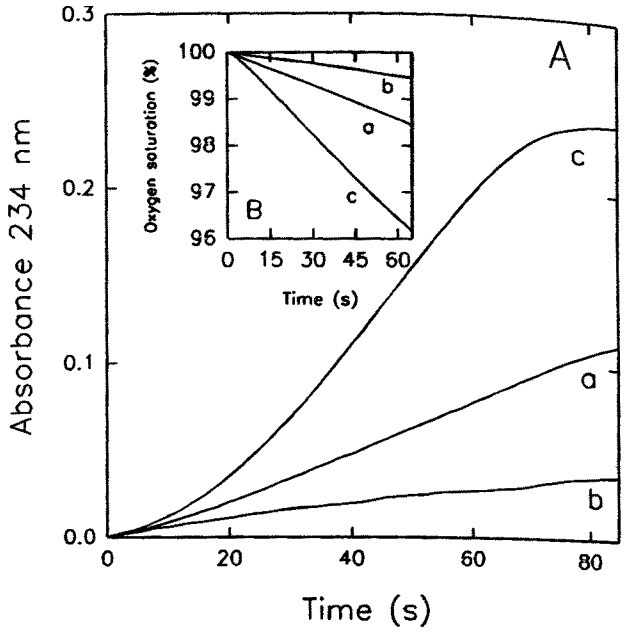

FIG. 1. (A) Progress curves for the oxidation of linoleic acid by tomato lipoxygenase in the standard reaction medium plus 1.5 mM H_2O_2 (traces a and b). The reaction started by the addition of the enzyme (a), or by the addition of the substrate (b). A control without H_2O_2 is shown in trace c. (B) The same experiment was repeated following the rate of O_2 consumption.

is not present in the incubation medium, the inactivation of LOX by H_2O_2 is dependent on the concentration of H_2O_2 and on the duration of the incubation. This inactivation is similar

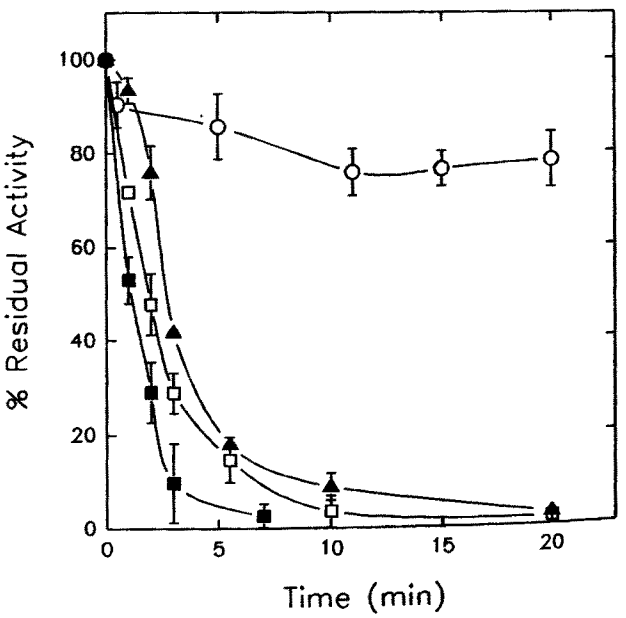

FIG. 2. Inactivation of tomato lipoxygenase by incubation with different concentrations of H_2O_2. The enzyme was incubated in the standard reaction medium containing: no H_2O_2 (○); H_2O_2 50 µM (▲); 75 µM (□), and 150 µM (■). The reaction started by the addition of linoleic acid. The mean value of three determinations ± σ_n is represented.

to that displayed by soybean LOX (20) and indicates that the sensitivity of both enzymes toward H_2O_2 is similar.

The results presented in Figures 1 and 2 suggest that the presence of linoleic acid somehow prevents the inactivation of tomato LOX by a high concentration of H_2O_2. This observation could be explained either by a direct effect of the substrate occupying the active center and thus preventing the attack of H_2O_2 on the catalytic site or by an effect of the product of the reaction.

To check if there was any relationship between the linoleic acid concentration and the percentage of the residual activity, the initial rate was measured in the presence of different concentrations of H_2O_2. The results were similar when different linoleic acid concentrations, i.e., 2.5 μM, 18 μM, or 36 μM were used (Fig. 3).

In order to find out if the product of the reaction played a role in the mechanism of protection, the enzyme was incubated with 2.5 μM 9-HPOD or 2.5 μM 13-HPOD, plus 50 μM H_2O_2 and the residual activity at different intervals of time was measured. From Figure 4, it can be concluded that the presence of either 13-HPOD (◆) or 9-HPOD (△) indeed protects the enzyme against denaturation.

This effect of HPOD can be explained by a physical protection of the active center or by a difference in the sensitivity of Fe(II)-LOX and Fe(III)-LOX to the action of H_2O_2. To distinguish between these two possibilities, the native Fe(II) LOX was preincubated for 20 min with 9-HPOD, and the excess of HPOD was removed by ultrafiltration (see the Materials and Methods section). The obtained Fe(III) enzyme was incubated with 50 μM H_2O_2, and the residual activity was measured. The results presented in Figure 4 indicate that there is no difference in activity between the experiment carried out with the enzyme preincubated with HPOD (○) or with the enzyme incubated with H_2O_2 + HPOD (◆ and △).

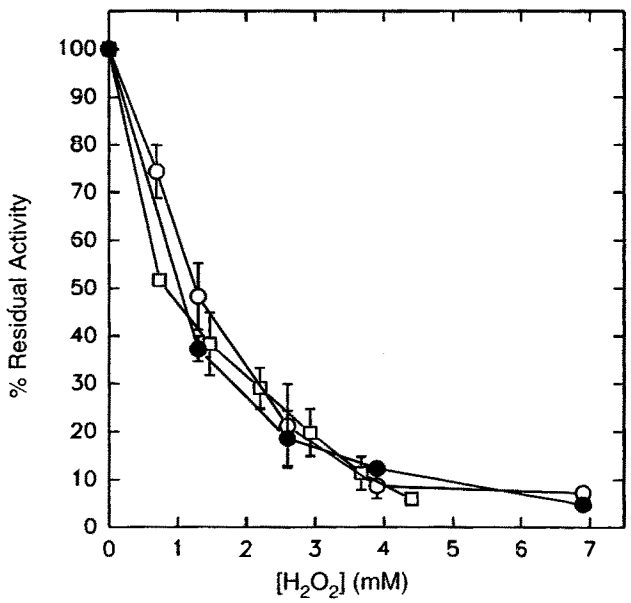

FIG. 3. Effect of the substrate on the inactivation of lipoxygenase by H_2O_2. The reaction medium contains different concentrations of H_2O_2, 0.016 enzymatic units of tomato lipoxygenase and 2.5 μM (□), 18 μM (○), or 36 μM (●) linoleic acid. The reaction started by the addition of lipoxygenase. The mean value of three determinations ± σ_n is represented.

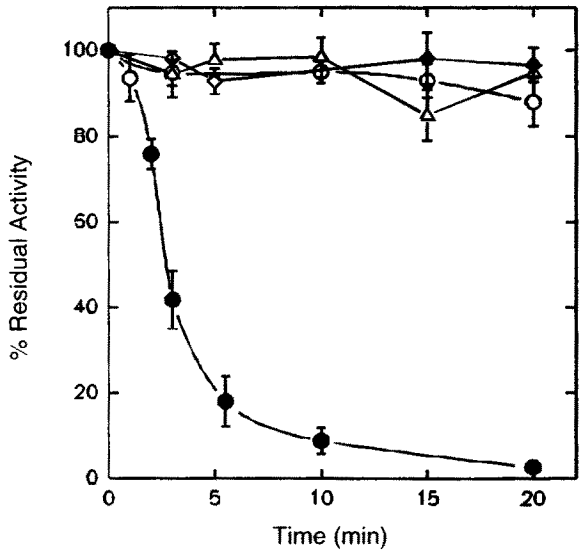

FIG. 4. Effect of HPOD on the inactivation of lipoxygenase by H_2O_2. Fe(II) (●) or Fe(III)-LOX (○) were incubated with 50 μM H_2O_2. Fe(III)-LOX was prepared as described in the Materials and Methods section. In another experiment, lipoxygenase was incubated in the presence of 50 μM H_2O_2 + 2.5 μM 13-HPOD (◆), or 2.5 μM 9-HPOD (△). In the three experiments, the reaction started by the addition of 18 μM linoleic acid. The mean value of three determinations ± σ_n is represented.

Early reports (20,30) described the differences in the protective effect displayed by certain competitive inhibitors against the inactivation of soybean LOX by H_2O_2. They observed that analogs of linoleic acid were able to protect the enzyme, whereas saturated monohydric alcohols were not effective. These differences were explained supposing that the linoleic acid analogs were able to occupy the active center, whereas the alcohols could merely attach to a hydrophobic region of the protein. In the present study, tomato LOX was incubated with H_2O_2 in the presence of different concentrations of stearic, oleic acid, or *n*-butanol (Fig. 5). It was found that oleic and stearic acids were able to prevent the inactivation when concentrations in the range of 36 μM were tested (no higher concentrations were used to avoid the turbidity of the reaction medium). However, *n*-butanol, even at a concentration of 0.2 M in the incubation medium, was ineffective in preventing the enzyme denaturation by H_2O_2 (Fig. 5). In the presence of 0.2M *n*-butanol, the residual activity is 58% with respect to a control without *n*-butanol.

It has been suggested (31) that the inactivation produced by H_2O_2 may be a consequence of reactive oxygen species such as $OH^{\cdot}$ produced by reaction with the Fe(II) in the enzyme. This radical may modify different amino acids in the active center of the enzyme such as histidine (20). The effect of mannitol, a well-known radical scavenger, (32) was also

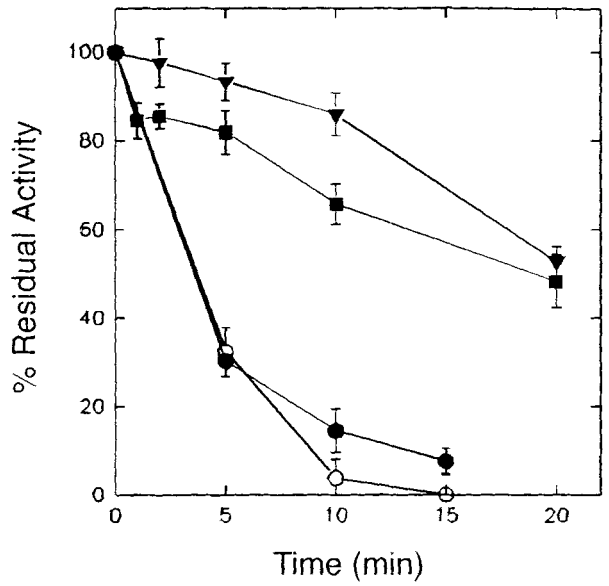

FIG. 5. Effect of different lipoxygenase inhibitors. The enzyme was incubated with 50 μM H_2O_2 plus 36 μM oleic acid (▼); 36 μM stearic acid (■); *n*-butanol 0.1M (○) or 0.2 M (●). The reaction started by the addition of 18 μM linoleic acid. The mean value of three determinations ± σ_n is represented.

tested, and it was found that only concentrations in the range of 0.2 M were able to partially prevent the inactivation (Fig. 6).

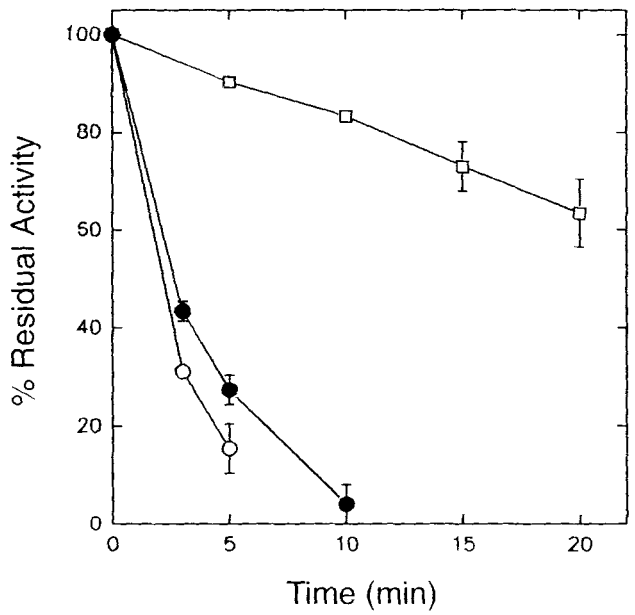

FIG. 6. Effect of mannitol. Lipoxygenase was incubated in the standard reaction medium with 50 μM H_2O_2 plus different concentrations of mannitol: 0.2 mM (○); 4 mM (●), and 0.2 M (□). The reaction started by the addition of 18 μM linoleic acid. The mean value of three determinations ± σ_n is represented.

DISCUSSION

The protective effect of different substrates on the hydroperoxidase activity of LOX against inactivation by H_2O_2 has been described recently (17–19). In the absence of a hydrogen donor, H_2O_2 causes a decrease in the rate of xenobiotic oxidation. In this paper we describe for the first time the protection of the dioxygenase activity of LOX by the substrate of the reaction.

The presence of linoleic acid in the reaction medium strongly prevents the inactivation of lipoxygenase by high concentrations of H_2O_2. In Figure 1A the progress curves for the oxidation of linoleic acid by LOX in the presence of 1.5 mM H_2O_2 are shown, thus indicating that the initial velocity depends on the order of addition of the reagents, namely first the substrate (trace a) or first the enzyme (trace b). When the reaction is started by the addition of substrate, the enzyme loses 87% of its initial activity in the time lapse between the addition of the enzyme and the addition of linoleic acid (about 10 s). However, when the reaction starts by the addition of LOX, the inactivation is 65%. The same results were obtained when the reaction was determined polarographically as the rate of O_2 consumption (Fig. 1B), thus confirming the inactivation of the enzyme.

When tomato LOX is preincubated with different concentrations of H_2O_2, a time-dependent inactivation is observed (Fig. 2). A concentration of 150 μM H_2O_2 abolishes the enzymatic activity in less than 8 min. This result indicates that the sensitivity of tomato LOX to hydrogen peroxide is similar to that reported by Mitsuda *et al.* (20) and Egmond *et al.* (31) for soybean lipoxygenase.

If the decrease in the inactivation shown in Figure 1 is a direct result of the presence of linoleic acid in the reaction medium, different responses should be expected depending on the concentration of the substrate. However, the results presented in Figure 3 show that the residual activity measured in the presence of different amounts of H_2O_2 is the same regardless of the linoleic acid concentration used (2.5, 18, or 36 μM). An alternative explanation is that the product of the reaction was the "real" responsible for the protection displayed by linoleic acid. To check this possibility, LOX was preincubated with 50 μM H_2O_2 and 2.5 μM 9-HPOD, the product of the tomato LOX reaction, or with 13-HPOD. The results presented in Figure 4 indicate that both 9- and 13-HPOD are able to avoid partially the inactivation of the enzyme. Egmond *et al.* (31) and Aoshima (33) reported a correlation between the fluorescence quenching and the inactivation of soybean LOX by H_2O_2. This quenching would be due to the conversion of Fe(II)-LOX into the Fe(III)-LOX (31):

$$\text{LOX-Fe(II)} + H_2O_2 \rightarrow \text{LOX-Fe(III)} + OH^{\cdot} + OH^{-} \quad [1]$$

The active oxygen species produced in this process would react with amino acids near or at the active site (34) inactivating the enzyme. Thus, the protection of LOX by HPOD (Fig. 4) could be explained by the conversion of the native enzyme in the Fe(III) LOX which, according to the above

scheme, is not able to react with H_2O_2. To test this hypothesis and to rule out a protection due to the attachment of the HPOD to the active center, the residual activity of Fe(III) enzyme after its incubation with 50 μM H_2O_2 was measured. In Figure 4 it is shown that while the native enzyme completely loses its activity after 20 min of incubation with H_2O_2 the Fe(III)-LOX retains its activity. This larger sensitivity of the Fe(II) toward H_2O_2 has been observed by Percival *et al.* (21) with purified human 5-LOX.

The model proposed in reaction 1 cannot explain the results obtained in this work with competitive inhibitors such as oleic and stearic acid (Fig. 5). In a recent paper, Van der Heijdt *et al.* (35) suggested the possibility that oleic acid would bind to the same site on LOX as linoleate. In this sense the protective effect obtained with oleic and stearic acid could be explained by an occupation of the active center by these inhibitors. The enzyme would not transform them, but their presence would hamper the conversion of H_2O_2 in $OH^{\cdot}$ and limit the damage in the active center. The effect of *n*-butanol, another competitive inhibitor of LOX, was also studied, but concentrations up to 0.2 M of this compound were unable to prevent the inactivation of tomato LOX by H_2O_2 (Fig. 5). This result is in accordance with the data reported for the soybean enzyme (30,36) and have been interpreted supposing that these alcohols attach to a site other than the catalytic site (30). Boyington *et al.* (37) described the existence of three hydrophobic cavities in LOX-1 from soybean; two of them connected to the iron site, while the largest cavity is not in contact with the active center. Though the three-dimensional structure of tomato LOX has not been established up until now, our results suggest the existence of similarities between tomato and soybean LOX.

The involvement of $OH^{\cdot}$ in the inactivation process suggested in reaction 1 is supported by the ability of mannitol to protect the enzyme from inactivation. In Figure 6, the results obtained by adding different amounts of mannitol to the incubation medium are shown. The high concentration of mannitol (0.2 M) needed to protect the enzyme against inactivation is explained considering that, in order to scavenge this $OH^{\cdot}$, the mannitol molecules must be present in the active center at the same time as H_2O_2, but the hydrophobicity of the active center makes the access of mannitol difficult. *In vivo*, an increase in the production of H_2O_2 has been observed after the addition of elicitors to plant cell cultures (38). This increase precedes LOX elicitation (39), suggesting that this enzyme may contribute to diminish the concentration of H_2O_2 at this metabolic stage.

The results in this paper suggest that the protective effect displayed by linoleic acid against the inactivation of tomato LOX by H_2O_2 may be the result of two different processes, one physical and the other chemical. The physical protection would be a consequence of the occupation of the active center by the substrate which would hinder the access of H_2O_2 to the catalytic site. This effect can be mimicked by those competitive inhibitors of LOX that attach to the active center. The chemical protection is produced by the HPOD synthesized by LOX or present in linoleic acid, and consists of the conversion of Fe(II)-LOX into the Fe(III) form which cannot catalyze reaction 1 and thus is insensitive to H_2O_2. Radical scavengers diminish LOX inactivation only if a high concentration is used. The lower sensitivity of crude extracts of LOX to H_2O_2 compared with purified enzyme preparations (21) could be explained by the presence in the extraction medium of "protective agents" such as substrates, competitive inhibitors, or radical scavengers that would be subsequently removed during the purification. The better understanding of the mechanism of LOX inactivation by H_2O_2, also may facilitate optimization of purification procedures.

Lipid Peroxidation in Low Density Lipoproteins from Human Plasma and Egg Yolk Promotes Accumulation of 1-Acyl Analogues of Platelet-Activating Factor-Like Lipids

Akira Tokumura*, Masaoki Toujima, Yasuko Yoshioka, and Kenji Fukuzawa

Faculty of Pharmaceutical Sciences, The University of Tokushima, Tokushima 770, Japan

ABSTRACT: Oxidative modification of low density lipoprotein (LDL) is known to be a key event for induction of atherosclerosis. However, there has been little progress in structural elucidation of oxidized lipids, especially oxidatively fragmented phospholipids retaining a glycerol backbone. In this study, we found that LDL derived from egg yolk has no platelet-activating factor (PAF) acetylhydrolase activity, and that prolonged incubation of egg yolk LDL with Cu^{2+} resulted in the formation of various PAF-like lipids: 1-acyl type phosphatidylcholines with an *sn*-2-short-chain dicarboxylate or monocarboxylate group. Only a very small amount of the PAF-like lipid having an *sn*-2-short-chain monocarboxylate group was detected by gas chromatography–mass spectrometry in Cu^{2+}-oxidized LDL from human plasma with high PAF-acetylhydrolase activity, which has been reported to hydrolyze PAF-like lipids to lysophosphatidylcholines. Preincubation of plasma LDL with diisopropyl fluorophosphate dose-dependently inhibited PAF-acetylhydrolase activity, resulting in accumulation of the PAF-like lipids when the LDL was oxidized with Cu^{2+}. As well as PAF and lysophosphatidylcholines, several PAF-like lipids were found to inhibit [^{3}H]thymidine incorporation into cultured vascular smooth muscle cells derived from rat aorta. The possible formation of PAF-like lipids by lipid peroxidation in LDL is discussed as well as its possible significance for induction of atherosclerosis.

Lipids 31, 1251–1258 (1996).

Platelet-activating factor (PAF) is a phospholipid autacoid with various potent biological activities in proinflammatory cells (1), but both its extracellular and intracellular levels are strictly controlled by enzymes for its synthesis and degradation (2). One structural feature of PAF is its glyceryl ether skeleton, which is resistant to hydrolytic enzymes and important for high affinity binding to its receptors. Another feature is a short-chain acyl group attached at the *sn*-2-position to the glycerol backbone of the PAF molecule. All natural PAF identified so far in animal tissues, body fluids, and cells have an *sn*-2-acetyl residue (3), except a PAF fraction purified from a lipid extract of the earthworm (*Pheretima* sp.), which is abundant in 1-*O*-alkyl-2-propionyl-*sn*-glycero-3-phosphocholine (GPC) (4). The earthworm was suggested to utilize more propionyl-CoA than acetyl-CoA for PAF synthesis (4). Noteworthy in this connection are the identifications of various 1-long-chain acyl analogues of PAF (acylPAF) and its analogues having an *sn*-1-long-chain acyl group and *sn*-2-short-chain dicarboxylate (DC), ω-hydroxymonocarboxylate, or monocarboxylate (MC) group other than an acetyl group, in a lipid extract from bovine brain (5–7). The possible formations of these unique phosphatidylcholines (PC) having an *sn*-2-short-chain acyl group during peroxidation of PC with an *sn*-2-polyunsaturated acyl group was extensively examined in an *in vitro* experiment with PC liposomes incubated with Fe^{2+}/EDTA in the presence of ascorbic acid (8,9). Results showed that an additional series of PC having an *sn*-2-DC semialdehyde residue were generated by lipid peroxidation as well as these three types of PAF-like lipids detected in the bovine brain lipid extract. Interestingly, the chain length of the *sn*-2-acyl group in the PAF-like lipids was dependent on the position of a double bond in the polyunsaturated fatty acyl moiety vicinal to the ester linkage in the parent PC molecule. Thus, the oxidative degradation of PC with a docosahexaenoate residue would lead to the generation of PC having both a propionate residue and a succinate residue, which were MC–PC and DC–PC, respectively, with an *sn*-2-acyl group with the shortest chain length among the authentic PC tested. A DC–PC having an azelaoyl group was previously reported to be produced by the oxidation of PC with oxyhemoglobin, and to be cytotoxic to erythrocytes (10). Oxidatively degraded PAF-like lipids were also found to be gener-

ated from membrane phospholipids in cultured vascular endothelial cells exposed to *tert*-butylhydroperoxide or cumen hydroperoxide (11).

Oxidized low density lipoprotein (LDL) is known to be a key substance for induction of atherosclerosis. LDL oxidized *in vitro* has been found to have various biological effects such as induction of chemotaxis of monocytes and promotion of transformation of macrophages to foam cells (12). Although some oxidation products of phospholipid components other than lysophosphatidylcholine (lysoPC) in LDL were suggested to be the active components for these effects, there have been only a limited number of reports on successful chemical characterization of these active lipids (13,14), because complicated reactions usually proceed in parallel during lipid peroxidation, and almost all the oxidation products are unstable. It should be mentioned, however, that Kamido *et al.* (15) have recently identified various PC with a DC semialdehyde residue in copper-oxidized LDL from human plasma by liquid chromatography–mass spectrometry.

An aim of this study was to clarify whether several types of PAF-like lipid are formed in significant amounts as secondary, but relatively stable, oxidation products of PC during incubation of LDL with Cu^{2+}. We also examined the possible cytotoxic effect of PAF-like lipids on cultures of rat aorta vascular smooth muscle cells (VSMC) as model cells at the subendothelium.

MATERIALS AND METHODS

Chemicals. [^{3}H]Thymidine (5.0 Ci/mmol) and 1-*O*-[^{3}H]-octadecyl-*sn*-glycero-3-phosphocholine (GPC, 80–180 Ci/mmol) were purchased from Amersham Japan (Tokyo, Japan). 1,2-Diheptadecanoyl-GPC, 1-heptadecanoyl-2-lyso-GPC, 1-palmitoyl-2-lyso-GPC, *Bacillus cereus* phospholipase C and fatty acid-free bovine serum albumin (BSA) were from Sigma Chemical Co. (St. Louis, MO). Hexadecyl-PAF and its lyso derivative (lysoPAF) were from Bachem Feinchemikalien AG (Bubendorf, Switzerland). *tert*-Butyldimethylchlorosilane was obtained from Sin-Etsu Chemical Co. (Tokyo, Japan). All other chemicals were purchased from Wako Pure Chemical Co. (Osaka, Japan).

PC containing an *sn*-2-short-chain acyl group such as an acetyl, butyl, caproyl, or capryloyl group were prepared by treating 1-palmitoyl-2-lyso-GPC with the corresponding short-chain acid anhydride, as described previously (16). 1-Palmitoyl-2-succinyl-GPC and 1-palmitoyl-2-glutaryl-GPC were obtained by treating 1-palmitoyl-2-lyso-GPC with succinic anhydride and glutaric anhydride, respectively, by the method described previously (6). 1-Palmitoyl-PC containing *sn*-2-azelaoyl group was prepared as described previously (6), except for the use of azelaoyl chloride instead of adipoyl chloride.

Preparation of LDL. Egg yolk-derived LDL was purchased from Q P Co. (Tokyo, Japan). Human LDL was isolated from pooled plasma anticoagulated with citrate–phosphate–dextrose solution from healthy volunteers by near vertical spin discontinuous density ultracentrifugation as described previously (17). LDL protein was determined by the method of Lowry *et al.* (18).

Fractionation of phospholipids. Lipids were extracted from LDL solution by the method of Bligh and Dyer (19). Phospholipids in the extract were fractionated into several classes by thin-layer chromatography (TLC) on a Merck Silica gel 60 plate (0.25 mm-thickness) with a developing solvent system of chloroform/methanol/water (65:35:5, by vol), and located under an ultraviolet lamp after spraying with an 1% ethanolic solution of 6-(*p*-toluidino)-2-naphthalenesulfonic acid. Regions of the silica gel containing individual phospholipids were scraped off the plate, and suspended in 4 mL of water. The phospholipids were recovered by the method of Bligh and Dyer (19), and their lipid–phosphate contents were quantified as described by Chalvarjian and Rudnicki (20).

Fatty acid analysis. PC and lysoPC from human plasma and egg yolk LDL were subjected to methanolysis by suspending the phospholipid in 0.5 mL of a 0.5% methanolic solution of hydrochloride at 100°C for 3 h with 1,2-diheptadecanoyl-GPC and 1-heptadecanoyl-GPC, respectively, as internal standards (21). The reaction mixture was diluted with 3 mL of water, and the fatty acid methyl esters were extracted twice with 3 mL of *n*-hexane. Gas–liquid chromatography (GLC) was done in a Shimadzu GC-15A gas chromatograph equipped with a DB-225 capillary column (30 m × 0.242 mm i.d., 0.25 μm thickness; J&W Scientific). Helium was used as a carrier gas, and the injection and detector temperatures were both set at 250°C. The column temperature was first 120°C for 1 min then increased to 220°C at 10°C/min.

Induction of lipid peroxidation. A solution of human LDL in 0.2 M phosphate buffer, pH 7.4 (0.5–0.6 μmol PC/mL) was preincubated at 37°C for 30 min in the presence or absence of diisopropyl fluorophosphate (DFP). A solution of commercial egg yolk-derived LDL was diluted with 0.2 M phosphate buffer to 0.5 μmol PC/mL, and then preincubated at 37°C for 30 min in the absence of DFP. Lipid peroxidation was induced by incubating the LDL with 35 μM $CuSO_4$ at 37°C for 24 h. The reaction mixture was adjusted to pH 2–3 with 1 M HCl, and the lipids were extracted by the method of Bligh and Dyer (19).

Structural analysis of PAF-like lipids. Phospholipids from oxidized LDL were separated by TLC on a Merck Silica gel 60 plate in a solvent system of chloroform/methanol/28% ammonium hydroxide (65:35:8, by vol). The plate was divided into several zones (PC zone, lysoPC zone, zone between PC and lysoPC, and zone below lysoPC), the silica gel in these zones was scraped off, and the lipids were extracted by the method of Bligh and Dyer (19) after adjusting the aqueous phase to pH 2–3, as described previously (8). Then 1 or 2 μL aliquots of the chloroform/methanol (2:1, vol/vol) solutions of phospholipid extracted from these zones were mixed with 1 μL of thioglycerol on the probe tip of insertion for fast atom bombardment–mass spectrometry (FAB–MS) of a JEOL JMS-SX102A mass spectrometer (Tokyo, Japan). The gun

high voltage, filament current, emission current, and accelerating voltage were 3 kV, 1A, 1 mA, and 10 kV, respectively.

Quantitation of MC- and DC-PC by gas chromatography-mass spectrometry (GC-MS). PAF-like lipids such as MC-PC and DC-PC were quantified by GC-MS with use of 1-palmitoyl-2-deuterated acetyl-GPC and 1-palmitoyl-2-deuterated succinyl-GPC, respectively, essentially as described previously (8). Briefly, oxidized phospholipids fractionated by TLC as described above were hydrolyzed with *Bacillus cereus* phospholipase C, and the resultant glycerides were treated with *tert*-butyldimethylchlorosilane in dimethylformamide in the presence of imidazole at 65°C for 1 h to derivatize its hydroxyl groups. For determination of DC-MC, the *tert*-butyldimethylsilyl (*t*BDMS) derivatives of glycerides were then treated with etherial diazomethane at room temperature for 10 min. The *t*BDMS derivatives of MC-PC and DC-PC were purified by TLC on a Silica gel 60 plate in a solvent system of *n*-hexane/diethyl ether (9:1, vol/vol), and analyzed in a Hitachi M-80 mass spectrometer coupled with a gas chromatograph equipped with a capillary column (J&W Scientific, DB-1, 30 m, 0.25 mm i.d., 0.25 μm-thickness). The column temperature was programmed to rise from 200 to 320°C at a rate of 10°C/min.

Measurement of PAF acetylhydrolase (PAF-AH) activity. Human plasma LDL was pretreated with various concentrations of DFP or vehicle for 30 min. To 200 μL of 0.1% BSA solution containing [^{3}H]PAF (0.02 nmol, 2.5 μCi) was added 4 mL of a solution of native egg yolk or human plasma LDL in 0.2M phosphate buffer pretreated with DFP or vehicle alone. The mixture was incubated at 37°C for various times, and then lipids were extracted by the method of Bligh and Dyer (19), and analyzed by TLC in a solvent system of chloroform/methanol/water (65:35:5, by vol). The silica gel was scraped from various zones of the TLC plate and mixed with 4 mL of Sintisol EX-H (Dojin Chemicals, Kumamoto, Japan) for measurement of the radioactivity in a liquid scintillation counter. The percentage conversions of [^{3}H]PAF to [^{3}H]lysoPAF were then calculated.

Cytotoxic effects of PAF-like lipids. The cytotoxic effects of PAF-like lipids were assessed by measuring inhibition of [^{3}H]thymidine incorporation into DNA in cultured VSMC from rat aorta stimulated with 10 ng/mL of platelet-derived growth factor, as described previously (21). PAF-like lipids were dispersed in Dulbecco's modified Eagle's medium containing 0.1% BSA, and 300 μL aliquots were added to VSMC in a 24-well plate, followed by 100-μL each of solutions of platelet-derived growth factor and [^{3}H]thymidine (0.1 μCi/well).

RESULTS

Chicken serum or plasma is reported to be devoid of PAF-AH activity (22), and therefore LDL derived from hen egg yolk is expected to lack this enzyme also, unlike that from human plasma. The PAF-AH activities of LDL from egg yolk and human plasma were assessed by measuring the conversion rate (mol%) of [^{3}H]PAF to [^{3}H]lysoPAF during incubation with 37 μM Cu^{2+} at 37°C for various times. As predicted, there was no significant degradation of [^{3}H]PAF to [^{3}H]lysoPAF during incubation of egg yolk LDL with Cu^{2+} (data not shown). Human plasma LDL was found to have high PAF-AH activity, and this activity was inhibited dose-dependently by pretreatment of the LDL with 1, 2, 5, 10 mM DFP (data not shown), in harmony with previous reports (14,23,24).

On incubation with Cu^{2+}, the lysoPC content of human plasma LDL increased markedly from 13 ± 3.8 (mean ± SE, n = 4) to 168 ± 11 nmol/mL of LDL solution, consistent with earlier reports on human LDL oxidized by Cu^{2+} (25,26), whereas, that of egg yolk LDL increased only slightly (155 ± 9% of that of native LDL, n = 3). Pretreatment of human plasma LDL with 1 and 5 mM DFP resulted in reduced generation of lysoPC during incubation with Cu^{2+} (91 ± 3.1 and 59 ± 3.0 nmol/mL of LDL solution, respectively, n = 3). These results suggest that oxidized PC including PAF-like lipids accumulate in a significant amount during the incubation with Cu^{2+} of egg yolk LDL and of human plasma LDL pretreated with DFP, since a considerable portion of the PAF-like lipid could escape the hydrolysis by PAF-AH to lysoPC. Therefore, we next tried to identify the PAF-like lipids in these Cu^{2+}-oxidized LDL by MS.

The positive ion FAB-mass spectrum of a fraction containing DC-PC in a lipid extract of oxidized egg yolk LDL separated by TLC included fragment ions characteristic of acyl analogues of PAF-like lipids: $[phosphocholine]^+$ (*m/z* 184), and $[M + H]^+$ (*m/z* 596, 610, 666, and 694 probably for 1-palmitoyl-2-succinyl-, 1-palmitoyl-2-glutaryl-, 1-palmitoyl-2-azelaoyl-, 1-stearoyl-2-azelaoyl species, respectively). The negative ion FAB-mass spectrum of the TLC fraction containing DC-PC supported the existence of 1-palmitoyl- and stearoyl-PC (Fig. 1B). The strong signals at *m/z* 255 and 283 could be assigned to palmitic and stearic anions, respectively. Furthermore, there were characteristic signals such as those of $[M - R_2CO - choline + H]^-$ (*m/z* 391 and 419 for 1-palmitoyl- and stearoyl-species, respectively), $[M - R_2CO - CH_2CH_2N(CH_3)_3 + 2H]^-$ (*m/z* 409 and 427), $[M - R_2CO - N(CH_3)_3]^-$ (*m/z* 435 and 463) and $[M - R_2CO - CH_3 + H]^-$ (*m/z* 480 and 508). Several signals were informative for the existence of DC-PC; these were $[M - H]^-$ (*m/z* 664 and 692 for 1-palmitoyl-2-azelaoyl and1-stearoyl-2-azelaoyl species). Similar negative-ion and positive-ion mass spectra were obtained by FAB-MS of DC-PC fractionated by TLC from a lipid extract of oxidized human plasma LDL pretreated with 1 mM DFP. Its negative-ion FAB-mass spectrum is shown as well as that of authentic 1-palmitoyl-2-azelaoyl-GPC in Figure 1C and A, respectively.

As shown above, FAB-MS was useful for structural elucidation of DC-PC, which are predominant PAF-like lipids in oxidized LDL from human plasma and egg yolk. Next, we used GC-MS for the quantification of not only major DC-PC but also minor PAF-like lipids. The PAF-like lipids generated from oxidized egg yolk LDL were separated by TLC into two fractions for GC-MS, as described in the Materials and Meth-

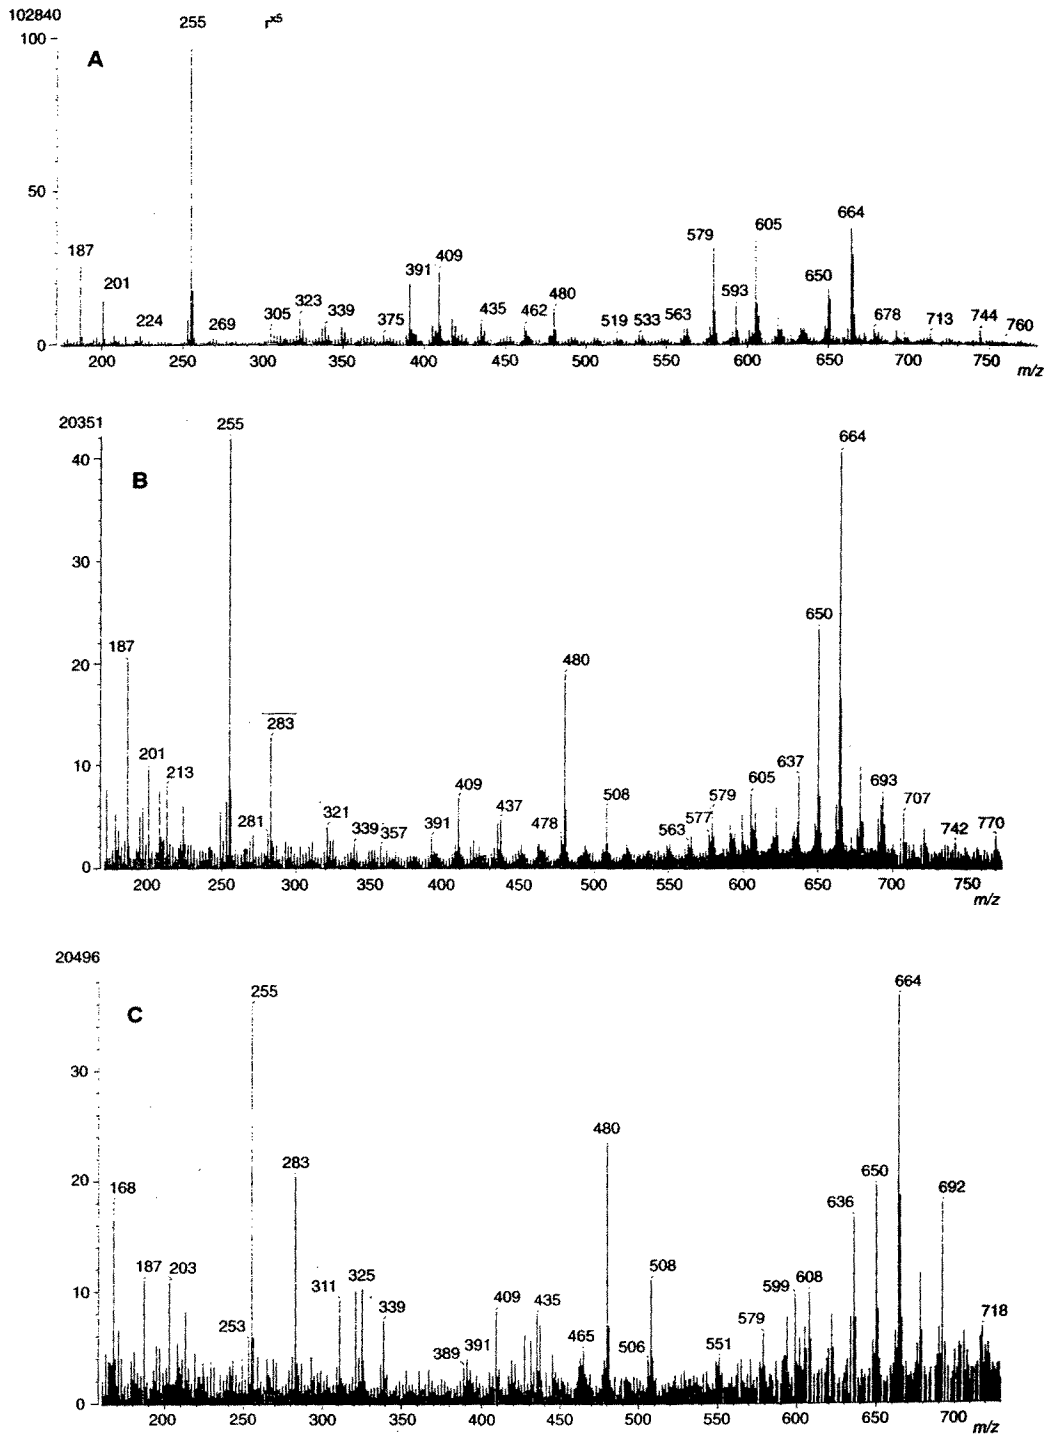

FIG. 1. Negative-ion fast atom bombardment mass spectra of authentic 1-palmitoyl-2-azelaoyl-*sn*-glycero-3-phosphocholine (A), short-chain dicarboxylate–phosphatidylcholine in Cu^{2+}-oxidized low-density lipoprotein from egg yolk (B) and human plasma pretreated with 1 mM diisopropyl fluorophosphate (C).

ods section. Results show that these two fractions consisted of eight species each of MC–PC and DC–PC, respectively. Their contents in the LDL are expressed as nmol/μmol of starting PC in Table 1. The most abundant MC–PC and DC–PC were 1-palmitoyl-2-octanoyl- and 1-palmitoyl-2-azelaoyl-species, respectively, both of which were assumed to be formed during peroxidation of 1-palmitoyl-2-linoleoyl-GPC. The total amount of DC–PC was about 100 times that of MC–PC.

No significant amount of DC–PC was detected in oxidized human plasma LDL, the fatty acid composition of PC in which was as follows: 16:0 (34.3 ± 2.5 mole%, mean ± SD,

TABLE 1
Molecular Species Composition of DC–PC and MC–PC Formed by Oxidative Fragmentation of PC in LDL[a]

[a]Values in parentheses show percentages of total amount of short-chain dicarboxylate–phosphatidylcholine (DC–PC) or short-chain monocarboxylate (MC)–PC; LDL, low density lipoprotein; DFP, diisopropyl fluorophosphate; PAF, platelet-activating factor.

$n = 3$), 18:0 (13.9 ± 0.5), 18:1 (12.1 ± 1.0), 18:2n-6 (23.7 ± 2.0), 20:3n-6 (3.9 ± 1.0), 20:4n-6 (6.9 ± 1.5), 22:6n-3 (4.0 ± 1.0), and unknown (1.3 ± 2.2). The oxidized LDL contained small amounts of MC–PC with an *sn*-2-octanoyl group, but not those having an *sn*-2-acyl group with a shorter chain than C_7 (Table 1) . This molecular species composition was different from that of MC–PC in oxidized egg yolk LDL. When the plasma LDL was treated with 1 mM DFP and then incubated with Cu^{2+}, it became rich in DC–PC rather than MC–PC, like oxidized egg yolk LDL (Table 1). The MC–PC consisted of species with an *sn*-2-propionyl, and butyryl and heptanoyl groups as well as those with an *sn*-2-octanoyl group, although the amount of the latter was the highest. The composition of molecular species of DC–PC in DFP-treated LDL from human plasma was similar to that in oxidized egg yolk LDL which contained PC having the following fatty acid composition: 16:0 (36.6 ± 1.3 mole%, mean ± SD, $n = 3$), 18:0 (10.4 ± 0.9), 18:1 (26.2 ± 0.6), 18:2n-6 (15.1 ± 1.7), 20:3n-6 (0.9 ± 0.9), 20:4n-6 (2.5 ± 0.7), and 22:6n-3 (6.0 ± 2.2).

PAF-like lipids are unique in terms of imbalance between two fatty acyl tails: a saturated long chain, and a short chain. PAF-like lipids other than MC–PC have an *sn*-2-short chain acyl residue, an end of which is modified by an oxo-, hydroxyl-, or carboxyl-group. This structural imblance should perturb the arrangement of membrane phospholipids when intercalated into the membrane at high concentration, resulting in defects in cell functions, membrane lysis, and cell death. In this study, we compared the effects of different PAF-like lipids ($10^{-6} - 10^{-4}$ M) in inhibiting [^{3}H]thymidine incorpora-

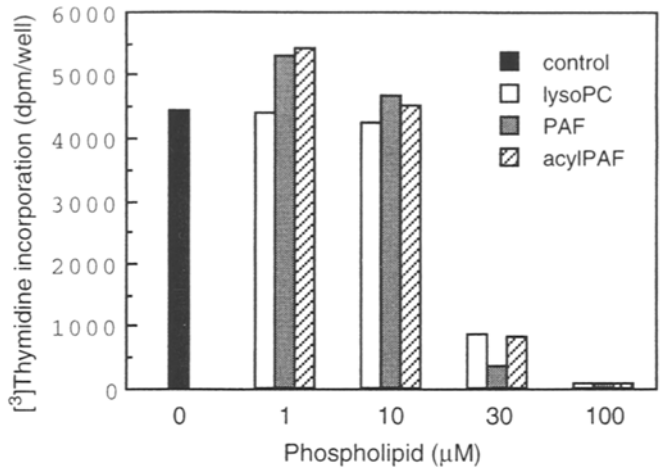

FIG. 2. Effects of different concentrations of platelet-activating factor (PAF), long-chain acyl analogue of PAF (acylPAF), and lysophosphatidylcholine (lysoPC) on [^{3}H]thymidine incorporation into DNA by vascular smooth muscle cells. Results are typical of three separate experiments performed in triplicate, and shown as mean values. Standard errors were between 4–15% of the mean values.

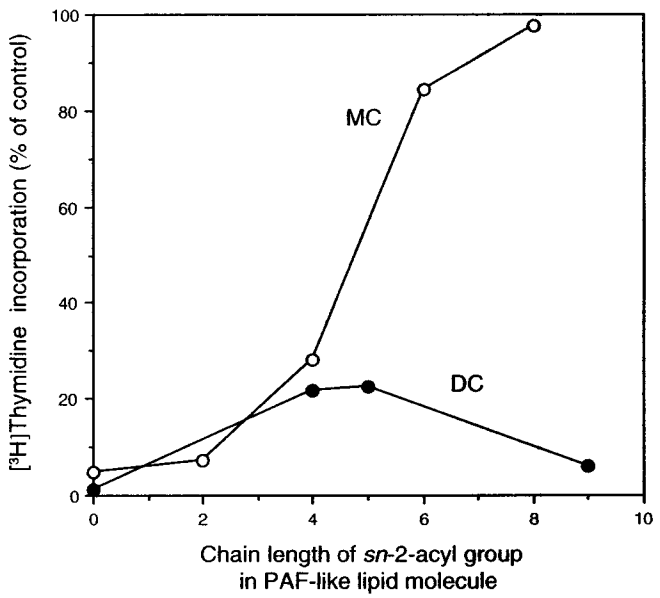

FIG. 3. Structure–activity relationships for inhibitory effects of different short-chain dicarboxylate–phosphatidylcholine (DC–PC) and short-chain monocarboxylate (MC)–PC on [^{3}H]thymidine incorporation into DNA by vascular smooth muscle cells stimulated with 10 ng/mL of platelet-derived growth factor. Results are typical of three separate experiments performed in triplicate, and mean values are expressed as percentages of the control. Standard errors were between 3–12% of the mean values. The concentrations of PAF-like lipids were all 30 μM. See Figure 2 for other abbreviations.

tion into DNA in cultured VSMC stimulated by platelet-derived growth factor. As shown in Figure 2, PAF ($C_{16:0}$) was found to be roughly equipotent to acyl-PAF ($C_{16:0}$) in inhibiting DNA synthesis in VSMC, indicating that the difference between the modes of linkage of the *sn*-1-long chain acyl group to the glycerol backbone was not a critical structural factor for the observed cytotoxic effect, unlike other biological activities expressed *via* PAF receptors such as platelet aggregation (9) and promotion of neutrophil adhesion to a gelatin matrix (27). LysoPC ($C_{16:0}$) also inhibited concentration-dependently the incorporation of thymidine into DNA stimulated by platelet-derived growth factor (Fig. 2). Next, we compared the effects of chain length (*sn*-2) in MC–PC and DC–PC (1, 3, 10, 30, and 100 μM) on their inhibitory actions, and typical results with these phospholipids at 30 μM are shown in Figure 3. With a series of MC–PC, activity decreased with increase in chain length. But, with DC–PC, the effect of an azelaoyl group (C_9) was slightly stronger than those of a succinyl (C_4) or a glutaroyl (C_5) group. These results suggest that the existence of an oxygenated functional group attached to the end of the *sn*-2-acyl group is a more important structural factor than the chain length. FR900452, a PAF receptor antagonist failed to inhibit the cytotoxic effects of DC–PC and MC–PC (data not shown). No significant potentiation by PAF, acylPAF, lysoPC, MC–PC, and DC–PC of platelet-derived growth factor-stimulated thymidine incorporation was observed at any concentrations examined.

DISCUSSION

DC–PC and MC–PC in the Cu^{2+}-oxidized egg yolk LDL were probably generated by homologous β-scission of C–C bonds of intermediate compounds having a reactive alkoxy radical that had been generated from a PC hydroperoxide (28). We suppose that DC(C_9)–PC and MC(C_8)–PC, the most abundant species in each class of PAF-like lipid generated during peroxidation of LDL from egg yolk, are formed by oxidative degradation of 1-palmitoyl-2-linoleoyl-GPC, on the basis of our previous works with synthetic PC peroxidized in Fe^{2+}/EDTA/ ascorbate system (8,9). Similarly, sets of other species of DC–PC (C_8, C_5, C_4) and MC–PC (C_7, C_4, C_3) would be derived from PC having an eicosatrienoate, arachidonate, and docosahexaenoate group, respectively. In fact, the main polyunsaturated fatty acid in LDL from the egg yolk used in this study was linoleate (61.6 mole% of the total polyunsaturated fatty acyl group in the PC), followed by docosahexaenoate (24.5%), arachidonate (10.2%), and eicosatrienoate (3.7%), whereas the percentages of total DC–PC were 68.5, 5.5, 10.8, and 15.2% for the C_9, C_4, C_5, and C_8-species. The reason why the percentages of these DC–PC were not proportional to those of potential parent PC is unclear at present.

When LDL from human plasma was incubated with Cu^{2+} under the same conditions as those for egg yolk LDL, only MC(C_8)–PC was detected in a very small amount, and a considerable amount of lysoPC was found to be accumulated, consistent with earlier reports (25,26). PAF–AH in human plasma has been shown to be bound mainly to LDL (29), and partially-purified PAF–AH has been reported to hydrolyze some PAF-like lipid having a butyryl, glutaroyl, succinyl, or oxovareloyl group (23,30). If PAF-like phospholipids are produced during peroxidation of PC in human plasma LDL, they would be degraded further to lysoPC by the high PAF–AH activity in plasma LDL (23). This possibility was supported by the following findings in the present investigation: (i) Results with [^{3}H]PAF showed reduced PAF–AH activity in DFP-treated LDL. (ii) Peroxidation by Cu^{2+} of human plasma LDL treated with DFP resulted in both the accumulation of DC–PC and MC–PC in comparable amounts to those detected in egg yolk LDL, and the lower level of lysoPC than that in the LDL oxidized in the absence of DFP. DC–PC produced in human plasma LDL seems to be a good substrate for PAF–AH, even when the chain length of the *sn*-2-acyl group is as long as 9. Consistent with previous results on the substrate specificity of PAF–AH in human plasma obtaind using synthetic substrates (23,30), PAF–AH hydrolyzed MC–PC having an acyl group with a chain length of less than 8, because MC(C_8)–PC was detected in similar amounts in oxidized LDL incubated with Cu^{2+} in the presence and absence of DFP.

In this study, we could detect only occasionally PC having a short-chain dicarboxylate semialdehyde residue as a methyloxime derivative (Tokumura, A., *et al.*, unpublished observation), whereas Kamido *et al.* (15) isolated some aldehydic PC as 2,4-dinitrophenylhydrazones from Cu^{2+}-catalyzed peroxidation of human plasma LDL. This inconsistency may be due to the difference in the derivatization procedure, since that the incubation of oxidized LDL with 2,4-dinitrophenylhydrazine could displace protein-bound aldehydes from their Schiff base complexes and convert them, together with the free aldehyde, into the dinitrophenylhydrazones (15), but that the derivatization of PC having an aldehyde moiety to methyoxime was done after its extraction by organic solvent from oxidized LDL. Interestingly, in the presence of phenylmethylsulfonylfluoride, relatively more of the PC having C_5 aldehyde group was shown to be recovered from oxidized human plasma LDL than in the absence of the PAF–AH inhibitor (15), in analogy with our results on MC–PC from the LDL preincubated with and without DFP.

In an advanced stage of atherosclerosis, monocyte-derived macrophages and VSMC migrating to the subendothelium tend to become foam cells by two mechanisms involving oxidized LDL (31). One is excess uptake of oxidatively modified LDL by these cells through a scavenger receptor. The other is the deleterious effect of oxidized LDL on these cells. LysoPC, a possible active component in oxidized LDL, was shown to potentiate [^{3}H]thymidine incorporation into VSMC from rat aorta (32,33) in a narrow range of concentrations, but at higher concentrations to inhibit DNA synthesis (21,33), as Cu^{2+}-oxidized human plasma LDL did (34,35). Thus, in this study, we examined the effects of PAF-like lipids on DNA synthesis in the VSMC, and compared them with that of lysoPC. As expected, the cytotoxic effects of MC–PC with a longer acyl

chain was weaker. In contrast, the cytotoxic effect of DC–PC was independent of the chain length of the *sn*-2-dicarboxylate group. The structure–activity relationship was similar to the apparent substrate specificity of human plasma PAF–AH against oxidatively fragmented PC formed in human plasma LDL. During the preparation of this paper, Heery *et al.* (14) reported that Cu^{2+}-induced oxidation of human plasma LDL resulted in the generation of unknown polar phospholipids that stimulate incorporation of [^{3}H]thymidine into DNA in cultured VSMC from bovine coronary artery and rat aorta, and that these mitogenic effects were inhibited by pretreatment with either a PAF receptor antagonist or PAF–AH. The discrepancy between this interesting report and our study might be due to that platelet-derived growth factor was included in our assay system, but not in that used by Heery *et al.* (14). In this study, our interest was limited to the structure-activity relationships of cytotoxic effects of DC–PC and MC–PC at relatively high concentrations, which were independent of the activation of PAF receptor.

In summary, we demonstrated that PAF-like lipids such as DC–PC and MC–PC were actually generated by peroxidation of human plasma and egg yolk LDL with Cu^{2+}, and confirmed the idea that PAF–AH contributed to the degradation of oxidatively fragmented phospholipids such as PAF-like lipids as well as the inactivation of PAF (23,24). The high ability of PAF–AH to bind to LDL from human plasma, but not to that from egg yolk, favors its clearance preventing the harmful effect of oxidized phospholipids formed in the lipoprotein.

ACKNOWLEDGMENTS

We thank Etuo Endo and Mayumi Yamakawa, Tokushima Blood Center, Japanese Red Cross Society, for providing pooled human plasma. This study was supported in part by a grant from the Sugiyama Sangyo Foundation.

ABSTRACT: Recently, we have reported that anthocyanins show strong antioxidative activity, but no attention has been paid to anthocyanins from the viewpoint of the reaction mechanism of alkylperoxyl radicals; therefore, we investigated the reaction products of antioxidative anthocyanins (cyanidin 3-*O*-β-D-glucoside). Cyanidin 3-*O*-β-D-glucoside was reacted with 2,2′-azobis(2,4-dimet hylvaleronitrile) to generate the alkylperoxyl radicals, and the reaction products were isolated by high-performance liquid chromatography. The products were identified as 4,6-dihydroxy-2-*O*-β-D-glucosyl-3-oxo-2,3-dihydrobenzofuran and protocatechuic acid. Based on reaction products, the antioxidative mechanism of cyanidin 3-*O*-β-D-glucoside may be different from that of α-tocopherol; cyanidin 3-*O*-β-D-glucoside would produce another radical scavenger, as it would break down the structure and scavenge the radicals.
Lipids 31, 1259–1263 (1996).

Excess production of active oxygen species, such as hydroxyl radicals, superoxide anion radicals, and singlet oxygen and other radicals, is thought to cause damage in cells. This damage is thought to be strongly associated with carcinogenesis, mutagenesis, aging, and atherosclerosis (1–5). Endogenous antioxidants are expected to protect the biological functions of cells (1,6–9). There is increasing interest in the protective biochemical function of natural antioxidants contained in dietary plants, which are candidates for the prevention of oxidative damage caused by oxygen-free radical species (9–12).

Because no attention had been directed to edible beans as natural sources, we previously reported screening for the antioxidative activity of edible beans (13). Among the beans tested, colored pea beans (*Phaseolus vulgaris* L.) had marked activity. These results indicated that pigments contained in the seed coat might play an important role as antioxidants. This background prompted us to investigate the pigments as antioxidants chemically. Three anthocyanin pigments, pelargonidin 3-*O*-β-D-glucoside (P3G), cyanidin 3-*O*-β-D-glucoside (C3G) and delphinidin 3-*O*-β-D-glucoside (D3G), were isolated and identified as antioxidants from red and black beans (*Phaseolus vulgaris* L.) (14–16). Among the pigments isolated, C3G had marked antioxidative activity in a linoleic acid autoxidation system at pH 7.0 (15).

Anthocyanin pigments are widely distributed in the human diet through crops, beans, fruits, and vegetables (17), suggesting that we ingest considerable amounts of anthocyanin pigments from plant-based daily diets. The pigments may play an important role as dietary antioxidants for prevention of oxidative damage caused by active oxygen radicals in living systems. Furthermore, they may be safe and can be used as drugs for some oxidative-damage-induced diseases.

Tocopherols are important antioxidants in food and biological systems, and the reaction products of tocopherols with alkylperoxyl radicals generated from azo-compounds have been isolated and identified. The antioxidative mechanism has been assumed (18–20); however, no studies have ever tried to clarify the antioxidative mechanism of anthocyanins and the reaction products with alkylperoxyl radicals.

In general, anthocyanin pigments are stable under acidic conditions, but they are unstable under neutral or alkaline conditions (21). Interestingly, C3G shows strong antioxidative activity, though at neutral pH, suggesting that flavylium cation form which is concerned with color, may not be essential for expression of the antioxidative activity of C3G.

In the present study, C3G was reacted with an alkylperoxyl radical, which was generated by the reaction of 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) and molecular oxygen, and oxidative products of C3G with AMVN were isolated and identified to clarify the antioxidative mechanism of C3G.

MATERIALS AND METHODS

Chemicals. AMVN and protocatechuic acid were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). The commercial food color material, San Red No. 5A, derived from violet corn (*Zea mays* L.) containing C3G, was obtained from San-Ei Gen F.F.I., Inc. (Osaka, Japan). All solvents were distilled in all-glass still before use.

Purification of C3G from commercial food color material. Commercial natural food color material, San Red No. 5A

(160 mL), was concentrated *in vacuo*, and the crude pigment obtained was used for fractionation in an Amberlite XAD-7 column (45 mm × 400 mm; Organo Co., Ltd., Tokyo, Japan). First, the column was eluted with 1.5 L of distilled water containing 0.1% trifluoroacetic acid (TFA) to remove citric acid and other unwanted substances, and then 1.5 L of methanol containing 0.1% TFA was eluted to obtain the pigment fraction. The eluent was concentrated *in vacuo*, and C3G was isolated from the methanol fraction (5.0 g) using preparative high-performance liquid chromatography (HPLC) with a Develosil ODS-10 column (20 mm × 250 mm; Nomura Chemical Co., Ltd., Aichi, Japan) monitored by a spectrophotometric detector (LC-10AV 530 nm; Shimadzu Works, Co., Ltd., Kyoto, Japan). Acetonitrile (20%) in water containing 0.1% TFA was used as an eluent at a flow rate of 5.0 mL/min. 230 mg of pure C3G (purity, more than 98%) was finally obtained. The structure and purity were confirmed by proton (^{1}H), and carbon (^{13}C) nuclear magnetic resonance (NMR), fast atom bombardment–mass spectra (FAB–MS), ultraviolet (UV)-visible (vis) and infrared (IR) spectra before use.

Reaction procedure. C3G was reacted with AMVN in acetonitrile/distilled water (8:2, vol, vol) at 37°C under air. The final concentrations of C3G and AMVN were 1 and 10 mM, respectively. The reaction mixture was analyzed by HPLC at intervals of 8 h to examine the time course of the reaction. HPLC analysis was carried out using a Develosil ODS-5 column (4.6 mm × 250 mm; Nomura Chemical Co., Ltd., Aichi, Japan) developed with a 30-min linear gradient of water containing 0.1% TFA to acetonitrile containing 0.1% TFA at a flow rate of 1.0 mL/min, and the peak area was calculated by monitoring UV (280 nm). The experiment was run in triplicate and expressed as the average of the area per μL of the reaction mixture.

Color stability of C3G With or Without AMVN. C3G (1mM) with 10 mM or without AMVN in acetonitrile/water (8:2, vol, vol) was incubated at 37°C under air, and the vis absorption (λmax at 530 nm) was measured at intervals of 8 h using a JASCO U-best 50 spectrophotometer (JASCO, Tokyo, Japan). The experiment was run in triplicate, and the result was expressed as the average of the measurements obtained from three independent experiments.

Isolation of reaction products. C3G (225 mg, 0.40 mmol) and AMVN (992 mg, 4.0 mmol) were dissolved in 400 mL of acetonitrile/distilled water (8:2, vol/vol), and the mixture was incubated at 37°C for 24 h in air. After that, the reaction mixture was concentrated *in vacuo*, the residue was dissolved in distilled water, and the crystals of AMVN were removed by filtration. The residue was washed in distilled water three times, and the filtrate was concentrated *in vacuo*; then preparative HPLC was carried out to isolate the reaction products using a Develosil ODS-UG-5 column (10 mm × 250 mm; Nomura Chemical Co. Ltd.) with a UV spectrophotometric detector (LC-10AV, 280 nm; Shimadzu Works, Co. Ltd., Kyoto, Japan). The products were eluted with a 20 min linear gradient ranging from 7% acetonitrile in water containing 0.1% TFA to 60% acetonitrile in water containing 0.1% TFA at a flow rate of 3.0 mL/min.

Instrumental analysis of reaction products. UV absorption spectra were recorded on a spectrophotometer with a JASCO U best-50. IR spectra was recorded on a JASCO FT/IR-8000 with KBr. FAB–MS was recorded on a JEOL JMS-DX-705L (JEOL, Tokyo, Japan) with glycerol or *p*-nitrobenzyl alcohol as the mounting matrix. Electron ionization (EI)–MS was recorded on a JEOL DX-300. ^{1}H NMR and ^{13}C NMR spectra were obtained by a Bruker ARX-400 NMR instrument (400 MHz for ^{1}H and 100 MHz for ^{13}C; Bruker Analytische Messtechnik GmbH, Rheinstetten-Forchheim, Germany) in *d*-CD_3OD containing tetramethylsilane as an internal standard for all isolated products.

RESULTS AND DISCUSSION

Color stability of C3G with or without AMVN. The color stability of C3G with or without AMVN is shown in Figure 1. C3G has the maximum absorption at 530 nm if the flavylium cation form is maintained. When AMVN was not added to the reaction mixture, the absorbance at 530 nm decreased slowly; however, 60% of C3G in the flavylium cation form was still maintained even after 48 h. On the other hand, in the presence of AMVN, the absorbance rapidly decreased, and the color was almost disappeared after 16 h. These results suggest that C3G would react with AMVN; then the flavylium cation structure would be broken by rapid scavenging of the radicals.

Time course for formation of the reaction products. Figure 2 shows the HPLC chromatogram of the reaction products derived from C3G with AMVN in 24 h. Six peaks (P1, P2, P3, P4, P5, and P6) corresponding to the reaction products of C3G appeared on the chromatograms. When C3G was incubated without AMVN in the same condition, some minor peaks were detected at 280 nm by HPLC (data not shown).

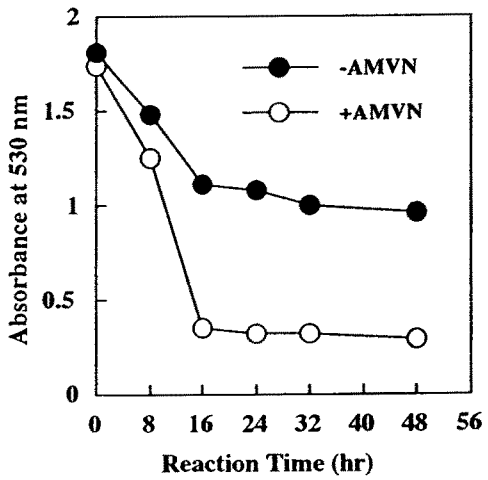

FIG. 1. Absorbance change in cyanidin 3-*O*-β-D-glucoside (C3G) at 530 nm with or without 2,2′-azobis(2,4-dimethylvaleronitrile)(AMVN). The experiment was done in triplicate, and the result was expressed as the average of three independent experiments.

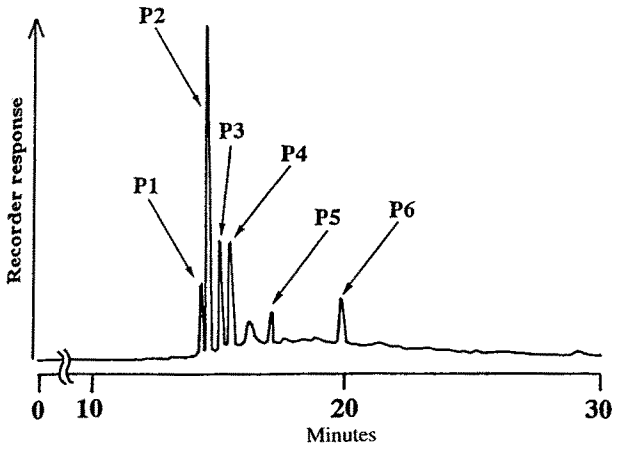

FIG. 2. High-performance liquid chromatography chromatogram of the reaction products derived from cyanidin 3-*O*-β-D-glucoside (C_3G) with 2,2′-azobis(2,4-dimethylvaleronitrile) in 24 h. Conditions: column, Develosil ODS-5 (4.6 mm × 250 mm; Nomura Chemical Co. Ltd., Aichi, Japan); eluent, linear gradient ranging from water containing 0.1% trifluoroacetic acid (TFA) to acetonitrile containing 0.1% TFA over 30 min; flow rate, 1.0 mL/min; detection, ultraviolet (280 nm); P, peak.

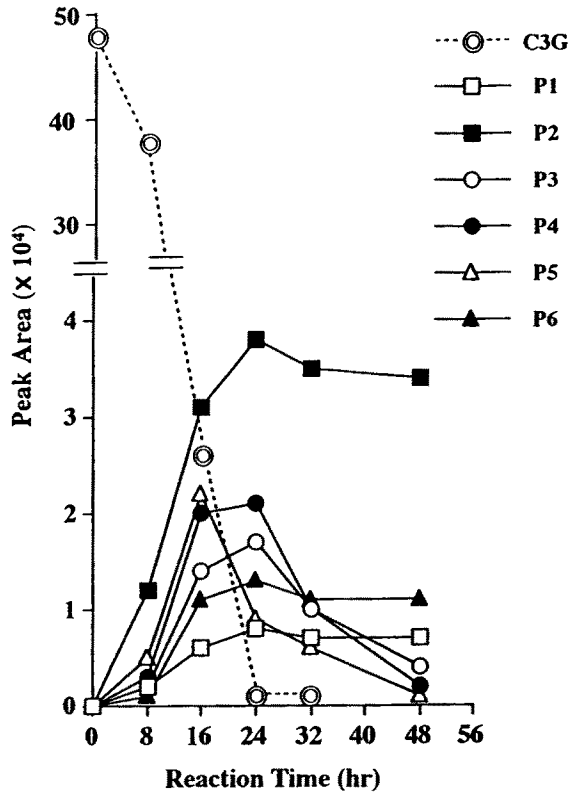

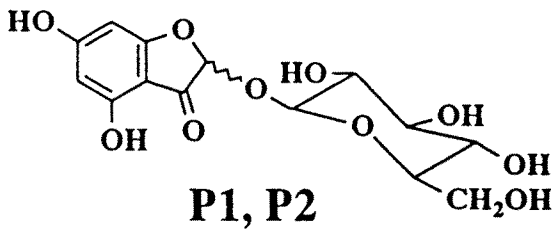

FIG. 3. Time course for the peak areas of the products by the reaction of cyanidin 3-*O*-β-D-glucoside (C3G) with 2,2′-azobis(2,4-dimethylvaleronitrile).

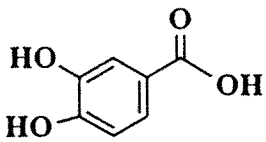
But these peaks were quite different from that of the reaction products with AMVN. Therefore, these products are not due to the autoxidation of C3G. Figure 3 shows the time course for the peak areas of the products. After 16 to 24 h, the formation of the products reached the maximum value, and they decreased beyond this time. Therefore, the reaction was stopped at 24 h, and the reaction products were isolated and identified.

Isolation and identification of the reaction products. The reaction products were purified by preparative HPLC technique, and P1 (4.6 mg), P2 (11.4 mg), P3 (5.8 mg), and P4 (12.7 mg) were isolated.



Identification of P1 and P2 (4,6-dihydroxy-2-O-β-D-glucosyl-3-oxo-2,3-dihydrobenzofuran). P1 exhibited the following properties: UV λ_{max} in methanol (nm) 291.5 (log ε = 3.94); IR υ_{max} in KBr (cm^{-1}) 3395.1, 1680.2, 1632.0, 1201.8, 1070.6, 993.5, 835.3; FAB–MS (*m/z*) 345 $[M + 1]^+$, 367 $[M + Na]^+$; ^1H NMR (in *d*-methanol) δ 5.95 (1H, *d*, *J* = 1.6, H_7), 5.91 (1H, *d*, *J* = 1.5, H_5), 5.61 (1H, *s*, H_2), 4.68 (1H, *d*, *J* = 7.6, glucosyl-1), 3.80 (1H, *d*, *J* = 12.0, glucosyl-6), 3.63 (*dd*, *J* = 5.0, 12.0, glucosyl-6), 3.38 (*m*, glucosyl-3), 3.37 (*m*, glucosyl-4, glucosyl-5), 3.28 (*m*, glucosyl-2); ^{13}C NMR (in *d*-methanol) δ 193.3 (*s*, C_3), 174.6 (*s*, C_8), 171.6 (*s*, C_6), 160.3 (*s*, C_4), 103.9 (*d*, glucosyl-1), 102.4 (*d*, C_2), 102.2 (*s*, C_9), 97.8 (*d*, C_5), 91.7 (*d*, C_7), 78.5 (*d*, glucosyl-5), 77.7 (*d*, glucosyl-3), 75.0 (*d*, glucosyl-2), 71.0 (*d*, glucosyl-4), 62.3 (*t*, glucosyl-6). P2 exhibited the following properties: UV λ_{max} in methanol (nm) 290.5 (log ε = 4.13); IR υ_{max} in KBr (cm^{-1}) 3364.3, 1701.4, 1632.0, 1194.1, 1070.6, 993.5, 829.5; FAB–MS (*m/z*) 345 $[M + 1]^+$, 367 $[M + Na]^+$; ^1H NMR (in *d*-methanol) δ 5.93 (^1H, *d*, *J* = 1.8, H_7), 5.90 (1H, *d*, *J* = 1.7, H_5), 5.77 (1H, *s*, H_2), 4.73 (1H, *d*, *J* = 7.8, glucosyl-1), 3.90 (1H, *dd*, *J* = 1.7, 12.0, glucosyl-6), 3.72 (*dd*, *J* = 5.4, 12.1, glucosyl-6), 3.37 (*m*, glucosyl-3), 3.36 (*m*, glucosyl-4, glucosyl-5), 3.28 (*m*, glucosyl-2); ^{13}C NMR (in *d*-methanol) δ 192.7 (*s*, C_3), 175.0 (*s*, C_8), 171.4 (*s*, C_6), 160.3 (*s*, C_4), 102.5 (*s*, C_9), 101.9 (*d*, glucosyl-1), 99.5 (*d*, C_2), 97.6 (*d*, C_5), 91.9 (*d*, C_7), 78.5 (*d*, glucosyl-5), 77.8 (*d*, glucosyl-3), 74.7 (*d*, glucosyl-2), 71.3 (*d*, glucosyl-4), 62.6 (*t*, glucosyl-6). Given these results and considering the two-dimensional NMR spectra, ^1H-^1H correlation spectroscopy, the ^1H-detected multiple quantum coherence spectrum, and the ^1H-detected multiple-bond heteronuclear multiple quantum coherence spectrum (data not shown), P1 and P2 were the diastereoisomers of each other and were identified as 4,6-dihydroxy-2-*O*-β-D-glucosyl-3-oxo-2,3-dihydrobenzofuran.

Identification of P4 (protocatechuic acid). P4 exhibited the following properties: UV λ_{max} in methanol (nm) 294.0 (log ε = 3.59), 259.0 (log ε = 3.84); IR υ_{max} in KBr (cm^{-1}) 3348.8, 1674.4, 1603.0, 1294.4, 1253.9, 943.3, 765.8; EI–MS (*m/z*) 154 $[M]^+$; ^1H NMR (in *d*-methanol) δ 7.44 (1H, *d*, *J* = 2.0, H_2), 7.42 (1H, *dd*, *J* = 2.0, 7.9, H_6), 6.80 (1H, *d*, *J* = 7.9, H_5); ^{13}C NMR (in *d*-methanol) δ 170.2 (*s*, C=O), 151.5 (*s*, C_4), 146.0 (*s*, C_3), 123.9 (*d*, C_6), 123.1 (*s*, C_1), 117.7 (*d*, C_2), 115.7 (*d*, C_5). From these results and the two-dimensional NMR spectral data, ^1H-^1H correlation spectroscopy, ^1H-detected multiple quantum, and ^1H-detected multiple-bond heteronuclear multiple quantum coherence spectrum (data not shown),

P1, P2

4,6-dihydroxy-2-*O*-β-D-glucosyl-3-oxo-2,3-dihydrobenzofuran

P4

protocatechuic acid

FIG. 4. Chemical structures of the oxidative products derived from cyanidin 3-*O*-β-D-glucoside (C3G; see Figure 2 for abbreviation).

P4 could be identified tentatively as protocatechuic acid. To confirm this, instrumental analysis of authentic protocatechuic acid was performed and compared with the data for P4 (data not shown). These authentic spectra were completely consistent with those of P4. Therefore, P4 was identified as protocatechuic acid. The chemical structures of these reaction products are elucidated in Figure 4.

Antioxidative mechanism of C3G. These results suggest the following mechanism for the oxidation of C3G by AMVN (Fig. 5). Water may be added to C3G, and this reaction would be reversible. C3G was reacted with AMVN, and the structure of the flavylium was broken. Group A may transfer hydrogen atoms to peroxyl radicals, oxidation then occurs, one peroxyl radical can be trapped, and the reaction products (P1 or P2) are formed and stabilized. On the other hand, group B would convert into protocatechuic acid (P4), and the radicals may be scavenged by this compound, and resulting in maintaining the antioxidative activity. Therefore, more than two radicals can be trapped by C3G.

α-Tocopherol is a chain-breaking antioxidant and reacts with peroxyl radicals to stop autoxidation of polyunsaturated fatty acids (18). α-Tocopherol transfers hydrogen atoms to peroxyl radicals, and the resulting tocopheroxyl radical rapidly reacts with the peroxyl radical to form peroxide products. Some of the tocopheroxyl radicals react with each other to form dimers and trimers.

On the other hand, C3G may have a different mechanism. The structure of C3G would be broken by peroxyl radicals,

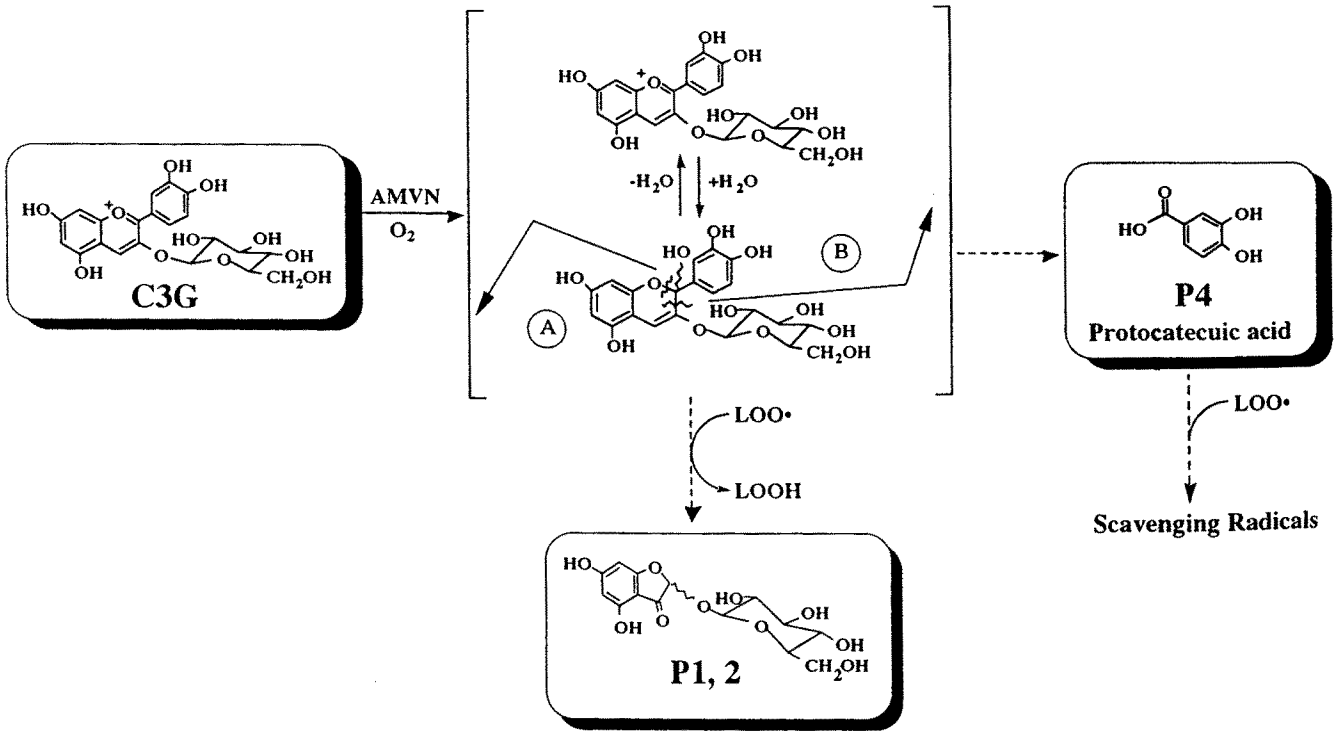


FIG. 5. Proposed mechanism for oxidation of cyanidin 3-*O*-β-D-glucoside (C3G) by AMVN. See Figures 1 and 2 for abbreviations.

the breakdown products may transfer hydrogen atoms to peroxyl radicals, and the products (P1, P2) would be formed and stabilized. During this time, protocatechuic acid, which has antioxidative activity, was also formed from C3G under the reaction conditions. Protocatechuic acid can scavenge the radicals. Namely, C3G would produce another radical scavenger, as it would break down the structure and scavenge the radicals. However, there may be another pathway to scavenge the radicals, because the other product, P3 has not been identified, and scavenging the radicals may be explained on the basis of the mechanism resulting from the reaction pathway through the formation of P3. The identification of P3 is now in progress.

Anthocyanin pigments are widely distributed in the human diet through seeds and crops such as fruits and vegetables. Red wine also has anthocyanins derived from grape skin, indicating that we ingest considerable amounts of anthocyanin pigments from a plant-based daily diet. Anthocyanin pigments are expected to play a role in reducing oxidative damage in cells. However, there is no evidence now that anthocyanins would be effective after food consumption for significantly impacting the antioxidant status of the organism by the antioxidative mechanism we proposed based on the chemical structures of the products. Therefore, it is necessary that the inhibitory effect of anthocyanin pigments against oxidative damage and the mechanism *in vivo* systems be investigated in the future. We plan to carry out a feeding experiment with the anthocyanin pigments using an *in vivo* system.

ACKNOWLEDGMENT

The authors would like to thank Dr. Takahito Ichi, San-Ei Gen F.F.I. Inc., for providing the food color material.

Increased Formation of Phosphatidylinositol-4-Phosphate in Human Platelets Stimulated with Lysophosphatidic Acid

Indu Mani, Douglas C. Gaudette, and Bruce J. Holub*

Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, Ontario, N1G 2W1, Canada

ABSTRACT: Lysophosphatidic acid (LPA, 1-acyl-*sn*-glycerol 3-phosphate), at a concentration of 1–40 μM, was found to induce the formation of [^{3}H]inositol-labelled phosphatidylinositol-4-phosphate (PIP) without significantly altering the levels of either phosphatidylinositol (PI) or phosphatidylinositol bisphosphate (PIP_2) in washed human platelets. Preincubation of platelets with the cyclooxygenase/lipoxygenase inhibitor, BW755C at 100 μM, did not alter the LPA-induced formation of PIP. Activation of platelets with the phorbol ester, phorbol 12-myristate 13-acetate (PMA), elicited a similar response (induction of PIP formation). The specific protein kinase C (PKC) inhibitor, GF109203X (10 μM), completely blocked the effect of PMA but not the LPA-induced generation of PIP. The present results indicate that LPA can induce PIP formation *via* PI-4-kinase activation, through processes which are independent of the eicosanoid/TxA_2 pathway and are not PKC-dependent.
Lipids 31, 1265–1268 (1996).

Lysophosphatidic acid (LPA, 1-acyl-*sn*-glycerol 3-phosphate) is a known agonist for blood platelet aggregation (1–3). LPA is present in human serum (2–20 μM) (4,5) but not in platelet-poor plasma (4), suggestive of its formation during blood clotting. Also, LPA is generated in washed human platelets following stimulation with thrombin (6,7). Studies by Gerrard and Robinson (8) have indicated that, in stimulated human platelets, the action of LPA largely bypasses the phospholipase C-mediated breakdown of phosphoinositides and formation of diacylglycerol and phosphatidic acid.

During the past few years, it has become apparent that platelet exposure to certain agonists including thrombin, collagen, and U46619 induces the formation of phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2) *via* the phosphorylation of phosphatidylinositol (PI) and PIP, by the actions of the PI and PIP kinases, respectively (9). These increased phosphoinositide phosphorylations appear to have important and diverse biochemical/cellular functions in mediating human platelet activation (9).

The present studies indicate that LPA markedly enhances PIP formation but not PIP_2 in washed human platelets. Also, this effect of LPA appears to occur independent of thromboxane A_2 (TxA_2)/eicosanoid formation and protein kinase C (PKC).

Abbreviations: LPA, lysophosphatidic acid; PI, phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PMA, phorbol 12-myristate 13-acetate; TLC, thin-layer chromatography; TxA_2, thromboxane A_2.

MATERIALS AND METHODS

Materials. [^{3}H] Inositol (102 Ci/mmol) was purchased from Amersham Canada Ltd. (Oakville, Ontario, Canada). Precoated thin-layer silica gel G chromatographic (TLC) plates were obtained from E. Merck (BDH Chemicals, Toronto, Ontario, Canada). Palmitoyl LPA was purchased from Avanti Polar Lipids Inc. (Alabaster, AL). BW755C was provided by Dr. R. Ippersiel of the Welcome Research Laboratories (Kirkland, Quebec, Canada). GF109203X was obtained from Calbiochem (La Jolla, CA), and phorbol 12-myristate 13-acetate (PMA) was purchased from the Sigma Chemical Co. (St. Louis, MO). All chemicals and solvents were of analytical grade. LPA was dissolved in absolute ethanol, BW755C in distilled water, and PMA and GF109203X were dissolved in dimethyl sulphoxide.

Platelet isolation and prelabelling. Blood was drawn by antecubital venepuncture from healthy volunteers who had not taken any medication for at least 10 d prior to the experiments. Washed platelet suspensions were prepared as outlined (10). Platelet phosphoinositides were prelabelled in the first wash buffer (containing 5 mM HEPES and 4 mM $MnCl_2$) by incubation with 50 μCi of [^{3}H]inositol for two hours at 37°C (10). Platelet counts were adjusted to a final concentration of 5×10^8 platelets/mL in a modified Tyrode's buffer containing 2 mM $CaCl_2$, 1 mM HEPES, and 0.35% essential fatty acid-free bovine serum albumin.

Platelet incubations. One mL aliquots of platelet suspensions were pre-incubated for 1 min in siliconized cuvettes with stirring at 900 rpm at 37°C in an aggregometer (Payton Associates, Buffalo, NY) before activation with 1–40 μM LPA or 40 nM PMA. For the experiments using the inhibitors, the platelet suspension was incubated with BW755C (100 μM) or GF109203X (10 μM) for 1 min, before addition of LPA. All reactions were stopped 2 min after stimulation with LPA or PMA by the rapid addition of 3.75 mL of chloroform/methanol/HCl (20:40:1, by vol), and the phospholipids were extracted.

Copyright © 1996 by AOCS Press

Extraction and analysis of phosphoinositides. Phospholipids including PIP and PIP_2 were extracted according to the method of Allan and Michell (11). Thin-layer separation of [^{3}H]PI, [^{3}H]PIP, and [^{3}H]PIP_2 and scintillation counting of these bands were as described in an earlier paper (10). In isolated studies, further separation of the PI-3-P and PI-4-P isomers was obtained as follows. The PIP band was scraped, eluted, and run twice on an oxalate-impregnated TLC plate using the solvent system chloroform/methanol/NH_4OH/H_2O (40:45:9:5, by vol).

Statistical analysis. The data was analyzed using a general linear model. Specific differences between treatments were analyzed by Student's *t*-tests (12).

RESULTS AND DISCUSSION

Figure 1 shows that LPA induced a time- and dose-dependent increase in the levels of [^{3}H]PIP. The effect was optimal when platelets were activated with 20 μM LPA for 2 min. There was no change in the levels of [^{3}H]PI, although [^{3}H]PIP_2 showed a slight (but not significant) decrease for up to 1 min of activation. This may indicate an early activation of phospholipase C, followed by rapid turnover of the substrate by the actions of the PI- and PIP-kinases. The present work indicates that LPA, as a platelet agonist, can induce the formation of PIP without enhancing PIP_2 accumulation, possibly *via* the enhancement of PI-kinase activity. Preincubation of platelets with the cyclooxygenase/lipoxygenase inhibitor, BW755C (100 μM), did not significantly alter the agonist-induced formation of PIP (the corresponding mean values for [^{3}H]PIP upon LPA exposure were 151.8 and 151.7% of resting values in the absence and presence of BW755C, respectively). At this concentration, BW755C has been previously shown to completely block eicosanoid production (13). Thus, this LPA-induced rise in PIP appears to occur *via* eicosanoid/TxA_2-independent mechanisms. Further analysis of the PIP band, *via* TLC separation of PI-4-P from PI-3-P, showed that most of the radioactivity was associated with the PI-4-P fraction, indicating an activation of PI-4-kinase. For subsequent routine experiments, 10 μM LPA and a 2-min incubation time were employed.

Activation of platelets with 1-oleoyl-2-acetyl-glycerol (14) and with PMA (15) have been reported to cause significant increases in the levels of PIP and, to a lesser extent, in PIP_2. Table 1 shows that activation of platelets with the phorbol ester, PMA (40 nM, 2 min), increased the generation of PIP (by 188%), without significantly affecting the levels of PIP_2. This pattern was similar to that obtained with LPA. It has been suggested that one of the roles of PKC would be the induction, by phosphorylation, of PI-kinase activity (15). Therefore, to test if the effects of LPA were mediated by PKC, platelets were preincubated with the specific PKC inhibitor GF109203X (10 μM) before activation with either LPA or PMA (16). It was observed that at this concentration GF109203X completely blocked the aggregation of platelets induced by both PMA as well as LPA (data not shown). However, it was interesting to note that, whereas GF109203X also blocked the effect of PMA in enhancing PIP formation, it had no effect on the LPA-induced generation of PIP. The latter results suggest that the LPA stimulation of PIP production *via* PI-4-kinase is PKC-independent. Further, it appears that in LPA-stimulated platelets, the formation of PI-4-P and platelet aggregation are not related events.

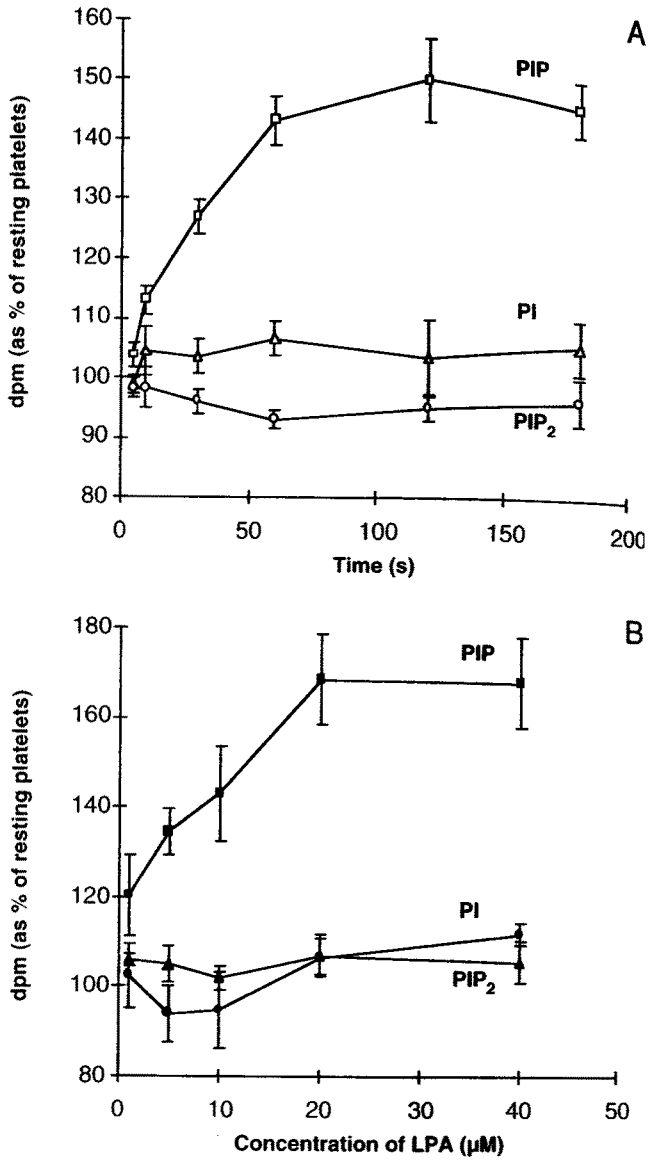

FIG. 1. Washed human platelets prelabelled with [^{3}H]inositol were incubated with (A) 10 μM LPA for different periods of time (5, 10, 30, 60, 120, and 180 s) or (B) different concentrations of LPA (1, 5, 10, 20, and 40 μM) for 1 min, before the reactions were stopped and lipids extracted as described in the Materials and Methods section. The different phosphoinositides were separated by TLC, and the areas corresponding to PI, PIP, and PIP_2 were scraped and counted in a scintillation counter. Values are reported as mean ± SEM (from three experiments performed in duplicate). The resting dpm values for PI, PIP, and PIP_2 were 12720 ± 511, 1776 ± 141, and 1377 ± 106, respectively.

TABLE 1
Effect of the Protein Kinase C Inhibitor GF109203X on PMA- or LPA-Induced Formation of [^{3}H]Inositol-Labelled Phosphoinositides[a]

Phospholipid	Radioactivity in resting platelets (dpm)	Radioactivity in stimulated platelets (as % of resting platelets) PMA (40 nM)	GF (10 μM) + PMA (40 nM)	LPA (10 μM)	GF (10 μM) + LPA (10 μM)
PIP	1892 ± 19	287.6 ± 15.2**	118.6 ± 4.7[b]	143.1 ± 4.1*	146.3 ± 1.0*
PIP_2	2653 ± 95	124.4 ± 5.7	110.1 ± 2.6	96.2 ± 1.5	112.5 ± 1.4

[a]Significantly different **($P < 0.001$) and *($P < 0.01$) from unstimulated values.
[b]Significantly different ($P < 0.001$) from corresponding values in the absence of the inhibitor. Values are reported as mean ± SEM (n = four experiments performed in triplicate). PMA, phorbol 12-myristate 13-acetate; LPA, lysophosphatidic acid; PIP, phosphatidylinositol-4-phosphate; PIP_2, phosphatidylinositol-4,5-bisphosphate.

The finding herein, that LPA activates PI-4-kinase, is of interest since it has been reported that PI-4-kinase is associated with the transformation and proliferation of hepatoma cells. Olson (17) has reported enhanced PI-kinase activity in the early stage of hepatocarcinogenesis and Rizzo and Weber (18) showed that there is a marked increase in the activity of PI-4-kinase in transplantable hepatomas and in sarcoma. Although the results shown here are in platelets, which are not proliferating cells, it is possible that LPA causes the same effect of increasing PI-4-P levels in other cells too. Thus the results of the present study lead us to speculate that the reported mitogenic properties of LPA (19,20) may stem, in part, from its ability to activate the enzyme PI-4-kinase.

At the time of preparation of this manuscript, Zhang and Rittenhouse (21) reported an activation of PI-3,4-P_2 and PI-3,4,5-P_3 formation *via* phosphoinositide 3-kinase in LPA-stimulated human platelets. However, in that study, the authors did not report upon PIP formation. We too have confirmed an LPA-induced rise in PI-3,4-P_2 (data not shown); this phosphoinositide represents approximately 8% of the total radioactivity in the total PIP_2 fraction (the remaining 92% being represented by PI-4,5-P_2).

In conclusion, the present findings indicate that LPA can markedly induce the formation of PI-4-P *via* activation of PI-4-kinase in washed human platelets. This LPA-induced formation of PI-4-P appears to occur independent of TxA_2/eicosanoid formation and PKC activation. However, the specific biochemical mechanisms regulating this formation of PI-4-P remain to be elucidated.

Differential Inhibitory Effects of Garlic-Derived Organosulfur Compounds on Cholesterol Biosynthesis in Primary Rat Hepatocyte Cultures

Rolf Gebhardt* and Halgund Beck

Physiologisch-Chemisches Institut, University of Tübingen, D-72076 Tübingen, Germany

ABSTRACT: Using primary rat hepatocyte cultures, the potency of several garlic-derived organosulfur compounds to inhibit cholesterol biosynthesis *in toto* as well as at early and late steps of this metabolic pathway was compared. Concerning early steps, allicin significantly inhibited incorporation of [^{14}C]acetate into nonsaponifiable neutral lipids already at concentrations as low as 10 μM, while diallyl disulfide and allyl mercaptan were effective above 100 μM only. Likewise, inhibition in response to the two vinyl-dithiins started at 500 μM. If [^{14}C]acetate was replaced by [^{14}C]mevalonate, inhibition due to allicin, diallyl disulfide, and allyl mercaptan disappeared suggesting that HMGCoA-reductase was the target of inhibition. In contrast, for the vinyl-dithiins a stimulation of mevalonate incorporation was found. Concerning the late step, the potency to exert accumulation of lanosterol presumably by inhibiting lanosterol 14α-demethylase decreased in the order allicin > diallyl disulfide > allyl mercaptan = 1,3-vinyl-dithiin >> 1,2-vinyl-dithiin, the effect of the latter compound being close to zero. With respect to the total inhibition of [^{14}C]acetate labeling of cholesterol, the half-maximal effective concentration-value of allicin was determined to be 17 ± 2 μM compared to 64 ± 7 μM for diallyl disulfide and to 450 ±20 μM for allyl mercaptan. Cytotoxicity as determined by the lactate dehydrogenase leakage assay was slightly higher for the two vinyl-dithiins than for diallyl disulfide and allyl mercaptan, but was apparent only at concentrations higher than 10 mM and, consequently, was irrelevant for the effects described. These results demonstrate that different garlic-derived organosulfur compounds interfere differently with cholesterol biosynthesis and, thus, may provoke multiple inhibition of this metabolic pathway in response to garlic consumption. The fact that allicin was the most effective inhibitor argues against the possibility that its degradation products, namely diallyl disulfide or allyl mercapatan, might mediate its effects, a possibility that might be true, however, in the case of the vinyl-dithiins.

Lipids 31, 1269–1276 (1996).

Garlic preparations have long been known to exert lipid-lowering effects in animals and humans (1,2). Recently, significant reduction of blood cholesterol after long-term intake of garlic powder tablets has been found for humans in double-blind placebo controlled studies (3–8). Moreover, when dosed appropriately, garlic preparations (Sapec^{R}, Kwai^{R}, Lichtwer Pharma GmbH, Berlin, Germany) were shown in a randomized double-blind study to act as efficient as the hypolipidemic drug bezafibrate in reducing total cholesterol, low density lipoprotein (LDL) cholesterol and increasing high density lipoprotein (HDL) cholesterol in a collective of patients with primary hyperlipoproteinaemia (9). Contrasting with these consistent results, little is known as yet about the mechanism(s) and the active principle(s) responsible for these effects.

Garlic preparations contain a wide variety of organosulfur compounds which are mainly derived from alliin (1,2,10). The spectrum of these sulfur-containing compounds depends considerably upon the method of drying or extraction of the original garlic bulbs, as well as upon the temperature, pH, and solvent conditions of subsequent processing. Thus, incubation in aqueous solutions of allicin, the main thiosulfinate, predominantly results in the formation of diallyl disulfide and diallyl trisulfide (11,12). In low-polarity solvents, on the other hand, mainly 1,3-vinyl-dithiin (2-vinyl-4*H*-1,3-dithiin) and 1,2-vinyl-dithiin (3-vinyl-4*H*-1,2-dithiin) are formed (11,13).

Some of these compounds have been tested in animal studies (14,15) or under *in vitro* conditions (16,17), but because of the high concentrations used it seems hazardous to draw conclusions about their physiological effectiveness. Under artificial, but nearly physiological conditions, further reactions of all these compounds may occur, particularly with cysteine (for review, see Ref. 2), thus complicating the attribution of specific effects to particular compounds. However, since allyl mercaptan is a common final product of most of these reactions, it has been suggested that this compound might play a central role in mediating the effects of garlic-derived thiosulfinates (2).

Recently, rat hepatocyte cultures have proved suitable for investigating the effects of water-soluble garlic extracts (18–21). Using this experimental system, the effects of the garlic-derived thiosulfinates allicin and ajoene on cholesterol biosynthesis could be described in detail (22). There was not

only a reduction of the incorporation of acetate into nonsaponifiable lipids by ajoene in the range of 18%, but also a shift in the pattern of sterol compounds indicating an inhibition at the level of lanosterol 14α-demethylase by both thiosulfinates (22). In the present study, we have performed comparative experiments on the effects of several other organosulfur compounds including diallyl disulfide, allyl mercaptan, and the vinyl-dithiins with those of allicin. These experiments were designed to provide information whether or not the inhibitory effect of garlic-derived thiosulfinates may be ascribed to the formation of common final metabolic products such as allyl mercaptan. It is reported that each of the compounds tested exerts a different spectrum of interactions with the biosynthetic pathway of cholesterol which only partially overlaps with that produced by allicin.

MATERIALS AND METHODS

Materials. Diallyl disulfide and allyl mercaptan were purchased from Aldrich (Steinheim, Germany). Allicin as well as the vinyl-dithiins, 1,3-vinyl-dithiin (2-vinyl-4*H*-1,3-dithiin) and 1,2-vinyl-dithiin (3-vinyl-4*H*-1,2-dithiin) were a kind gift of Prof. Dr. K.G. Wagner, (Braunschweig, Germany). The structure of these compounds is depicted in Figure 1. The purity of the inhibitors was routinely checked by high-performance liquid chromatography (HPLC). Only materials containing less than 2% impurities were used for the experiments. [U-^{14}C]Acetate, sodium-salt, [1.9 GBq/mmoles (51.3 mCi/mmoles)] and RS-[2-^{14}C]mevalonic acid, dibenzylethylendiamine salt, [2.1 GBq/mmoles (56.7 mCi/mmoles)] were obtained from Amersham/Buchler (Braunschweig, Germany). Collagenase (5,6 U/mg with Azokoll) was from Knoll AG (Ludwigshafen, Germany), and was used in batches which proved superior for the isolation of hepatocytes in our laboratory. Newborn calf serum was obtained from Vitromex (Vilshofen, Germany); Williams Medium E was from ICN Biochemicals (Meckenheim, Germany). The Extrelut^{R}20-columns were from Merck (Darmstadt, Germany). All other chemicals were from Boehringer (Mannheim, Germany), Merck, or Sigma (Daisenhofen, Germany).

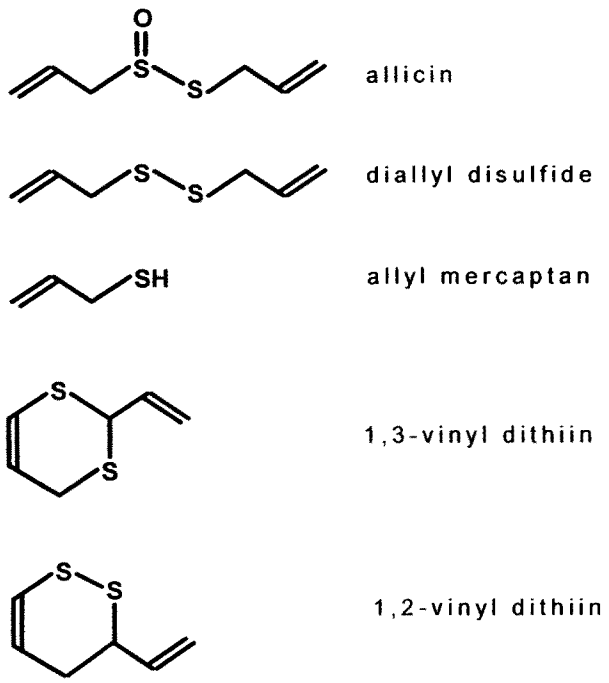

FIG. 1. Structure of garlic-derived organosulfides used in this study.

Animals. Male Sprague-Dawley rats (220–300 g) were used as hepatocyte donors. They were kept in a controlled 12-h light-and-dark cycle on a standardized diet ofAlma^{R} H 1003 (Botzenhardt, Kempten, Germany) and tap water *ad libitum*. Alma^{R} H 1003 is prepared from wheat, oilseeds, milk, and materials from sugar refinery. The macronutrient composition is as follows: 19% raw protein, 4% raw fat, 23% raw carbohydrates, 6% fibers, 7% ash, 1% calcium, 0.8% phosphorus, 0.5% sodium, 0.2% magnesium, 0.4% methionine, and 1.2% lysine. It is supplemented with 15.000 I.E. vitamin A, 500 I.E. vitamin D_3, 150 mg vitamin E, and 100 mg vitamin C per kg.

Isolation and cultivation of rat hepatocytes. Rat hepatocytes were isolated according to the two-step collagenase perfusion technique described (23). Viability of the cells averaging to 91.8 ± 3.1% was routinely checked by staining with trypan blue. The isolated hepatocytes were suspended in Williams E medium containing 10% newborn calf serum, 2 mM glutamine, penicillin (50 Units/mL), streptomycin (50 μg/mL), and 10^{-7}M dexamethasone (18,24). They were seeded in 2 mL of culture medium at a density of $1.25 \cdot 10^5$ cells/cm^2 into Petri dishes (O 60 mm) precoated with a thin film of collagen (25) and were incubated at 37°C, 90% humidity, and 7% CO_2. From 2 h on, serum-free medium was used.

Incubation of the primary cultures with purified garlic-derived organosulfur compounds. Pure diallyl disulfide, allyl mercaptan, and allicin were dissolved or diluted directly in Williams medium E to give concentrations of 1 mM or lower. Higher concentrations had to be prepared by dissolving the compounds in DMSO before Williams medium E could be added. The vinyl-dithiins were also diluted with DMSO before addition of the medium. The final concentrations of DMSO never exceeded 2%, and appropriate controls containing DMSO were run. All media were sterilized by filtration before use. Dilutions were always made with serum-free medium.

Two hours after inoculation of the hepatocyte cultures, the medium was removed and fresh medium was added containing [^{14}C]acetate [18.5 KBq/mL (0.5 μCi/mL)] and the compounds to be tested in the appropriate dilutions. After incubation at 37°C for additional 2 h, the medium was removed and the cell-layer was washed twice with saline and scraped into 2 mL H_2O distilled. The cells were homogenized by sonication (20 s, grade 3, (19,20)]. In several experiments, [^{14}C]acetate was replaced by [^{14}C]mevalonate [9 KBq/mL (0.24 μCi/mL)].

Determination of acetate incorporation into and separation of nonsaponifiable neutral lipids. The incorporation of

[^{14}C]acetate into nonsaponifiable neutral lipids was determined after saponification with 0.5 M KOH in EtOH and subsequent efficient separation on Extrelut^{R}-columns (large-pore kieselgur) as described (18,19). The neutral lipophilic nonsaponifiable substances were eluted with *n*-heptane (18,26). The precursors such as [^{14}C]acetate or [^{14}C]mevalonate are retained on the column to more than 99%. For measurements of incorporation, the eluate was collected directly in scintillation vials and measured in the scintillation counter after addition of 10 mL of Ultima Gold^{R} (Packard, Merident, CT). The yield of the elution step (93 ± 2%) and the recovery were determined as described (19).

Determination of the sterol composition of the nosaponifiable neutral lipid fraction. For determination of the newly synthesized sterol pattern, the eluate was evaporated to dryness in a vacuum concentrator (Desaga, Heidelberg, Germany), taken up in 50 µl chloroform and applied to silver-ion thin-layer chromatography (SI–TLC) plates (silica gel 60F 254; Merck) which were impregnated with silver nitrate and activated as described by Aufenanger *et al.* (26). They were developed only once using a mixture of *n*-heptane/ethyl acetate (2:1, vol/vol) on a total length of 16 cm according to Aufenanger *et al.* (26) and Pill *et al.* (27). The amount of radioactivity was determined by scraping stripes of 2 mm into vials for scintillation counting. This technique provided quite similar results as radiochromatographic scanning of the TLC plates as determined in separate validation experiments. With [^{14}C]mevalonate, a similar protocol was used. Alternatively, the sterol pattern was determined by HPLC on ODS Ultrasphere (0.46 × 25 cm) (Grom, Herrenberg, Germany) in a mobile phase of methanol/ethanol/water (86:10:4) according to Mayer *et al.* (28) with collecting fractions from the column and detection of radioactivity by scintillation counting.

Determination of cytotoxicity and other analytical procedures. Cytotoxicity of the compounds tested was determined by means of the lactate dehydrogenase (LDH) leakage assay as described (21,29). Protein was determined following the procedure of Lowry *et al.* (30).

Statistical evaluation. The EC_{50} values (half-maximal effect) were determined from the dose-response curves by use of curve-fitting programs [Fig. P and PENNZYME (31), (obtained from authors)] on a personal computer. The data were evaluated statistically using Student's *t*-test or analysis of variance. Data are given as means ± standard deviation.

RESULTS

In order to avoid any unspecific effects on the inhibition of cholesterol biosynthesis, we have directly determined the cytotoxic potential of diallyl disulfide, allyl mercaptan, and of the two vinyl-dithiins (structures see Fig. 1) in primary rat hepatocytes using the LDH leakage assay. As shown in Table 1, the two vinyl-dithiins were slightly more cytotoxic than diallyl disulfide or allyl mercaptan for rat hepatocytes. For all these compounds, however, cytotoxicity started at concentrations above 10 mM. Therefore, the exact half-maximal effective concentrations could not be determined because of the limited solubility of the compounds. Allicin, on the other hand, was more cytotoxic starting to affect the hepatocytes at 0.5 mM (22).

Incubation of primary rat hepatocyte cultures with allicin in concentrations between 0.1 and 1000 µM as early as 2 h after cultivation caused significant inhibition of the incorporation of [^{14}C]acetate into nonsaponifiable neutral lipids at concentrations above 10 µM (Fig. 2) suggesting inhibition before the formation of squalene. Diallyl disulfide and allyl mercaptan were less effective and inhibited at concentrations above 100 µM only. At 1 mM, inhibition amounted to approximately 35, 25, and 15% for allicin, diallyl disulfide, and allyl mercaptan, respectively (Fig. 2). When diallyl disulfide and allyl mercaptane were combined, their influence was close to that of twice the amount of each compound (Table 2).

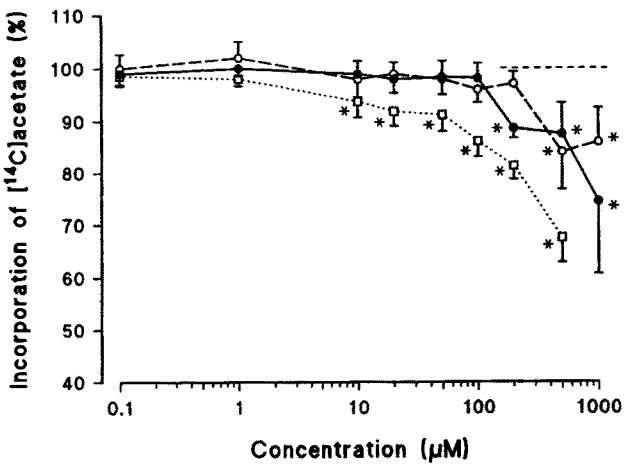

FIG. 2. Dependence of the incorporation of [^{14}C]acetate into nonsaponifiable lipids of cultured rat hepatocytes on the concentration of allicin (□···□), diallyl disulfide (●—●) and allyl mercaptan (○–○). [d]Significantly different from control: $P < 0.001$.
[e]Significantly different from control: $P < 0.01$.

There was no synergistic effect throughout the concentration range used.

As for diallyl disulfide, incubation of the hepatocytes with 1,3-vinyl-dithiin or 1,2-vinyl-dithiin also did not significantly influence [^{14}C]acetate incorporation at concentrations below 100 μM (Fig. 3). At 1 mM, a strong inhibitory effect was found which was more pronounced in the case of 1,3-vinyl-dithiin than for 1,2-vinyl-dithiin (Fig. 3).

If [^{14}C]acetate was replaced by [^{14}C]mevalonate, the inhibitory effect of allicin disappeared to a large extent (Table 2), indicating that inhibition occurs even earlier at some enzymatic step prior to the formation of mevalonate. The same was seen with diallyl disulfide and allyl mercaptan (Table 2). In contrast, 1,3-vinyl-dithiin significantly stimulated sterol synthesis from mevalonate between 1 and 10 μM (Fig. 4). 1,2-vinyl-dithiin seemed to be slightly more potent, although its effect at 0.1 μM ($P < 0.06$) was not as significant as at 10 μM ($P < 0.02$) (Fig. 4). Inhibition was either not observed (1,3-vinyl-dithiin) or occurred only at millimolar concentrations (1,2-vinyl-dithiin).

Recently, allicin and ajoene but not alliin were found to inhibit cholesterol biosynthesis not only at an early enzymatic step (HMGCoA-reductase) but also at a later step of the pathway, namely at the level of lanosterol 14α-demethylase (22). Based on structural considerations, we hypothesized that the allylsulfide moiety within these molecules might be of importance for this inhibition (Gebhardt, R., unpublished observation). Since this structural component is found in some of the organosulfur compounds studied herein, we determined whether these compounds might also inhibit this enzymatic step.

Analysis of the sterol pattern produced by the rat hepatocytes by SI–TLC (26) or HPLC consistently revealed that

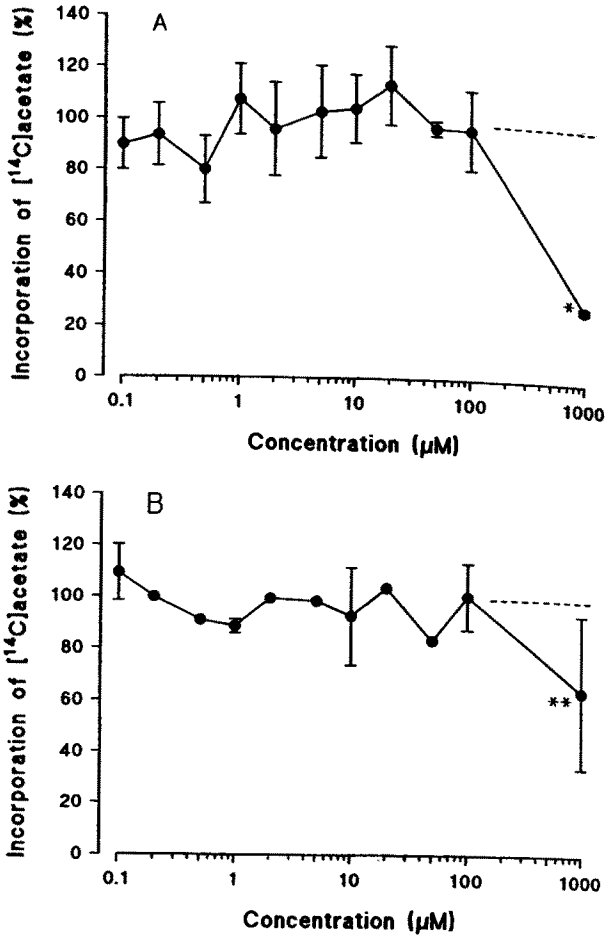

FIG. 3. Dependence of the incorporation of [^{14}C]acetate into nonsaponifiable lipids of cultured rat hepatocytes on the concentration 1,3-vinyl-dithiin (A) and of 1,2-vinyl-dithiin (B). The dashed line on the right indicates the control level. Data are expressed as percentage control and represent means ± SD of three to four independent determinations except the points without SD bars in panel B which were from one experiment only. *, Statistically different from controls, $P < 0.001$. **, Statistically different from controls, $P < 0.05$.

cholesterol was the main sterol formed from [^{14}C]acetate (Figs. 5A,B). The precursors lanosterol and 7-dehydrocholesterol amounted to 8 and 4%, respectively. As obvious from Figure 5, diallyl disulfide at concentrations above 10 μM blocked the formation of 7-dehydrocholesterol, reduced the production of cholesterol, and gave rise to corresponding amounts of lanosterol and, to a lesser extent, dihydrolanosterol. At 1 mM, almost all label derived from [^{14}C]acetate was found in lanosterol. Apart from these three compounds, other precursors contained very little label only, usually less than 8% (Fig. 5A) as confirmed independently by HPLC analysis. The results indicate that diallyl disulfide affected mainly lanosterol 14α-demethylase. Allyl mercaptan produced similar changes of the sterol pattern, but was effective only at concentrations above 200 μM (Fig. 5B).

Direct comparison of the potency of allicin, diallyl disulfide, allyl mercaptan, and the vinyl-dithiins to cause accumu-

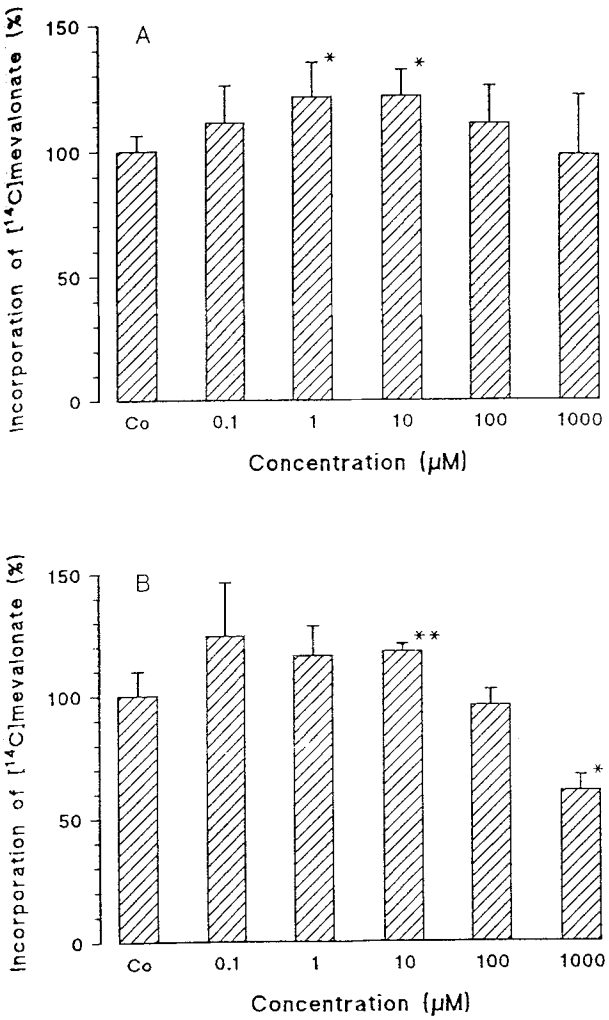

FIG. 4. Dependence of the incorporation of [^{14}C]mevalonate into non-saponifiable lipids of cultured rat hepatocytes on the concentration 1,3-vinyl-dithiin (A) and of 1,2-vinyl-dithiin (B). Data represent means ± SD of three to five independent determinations. Co, controls. *, Statistically different from controls, $P < 0.01$. **, Statistically different from controls, $P < 0.03$.

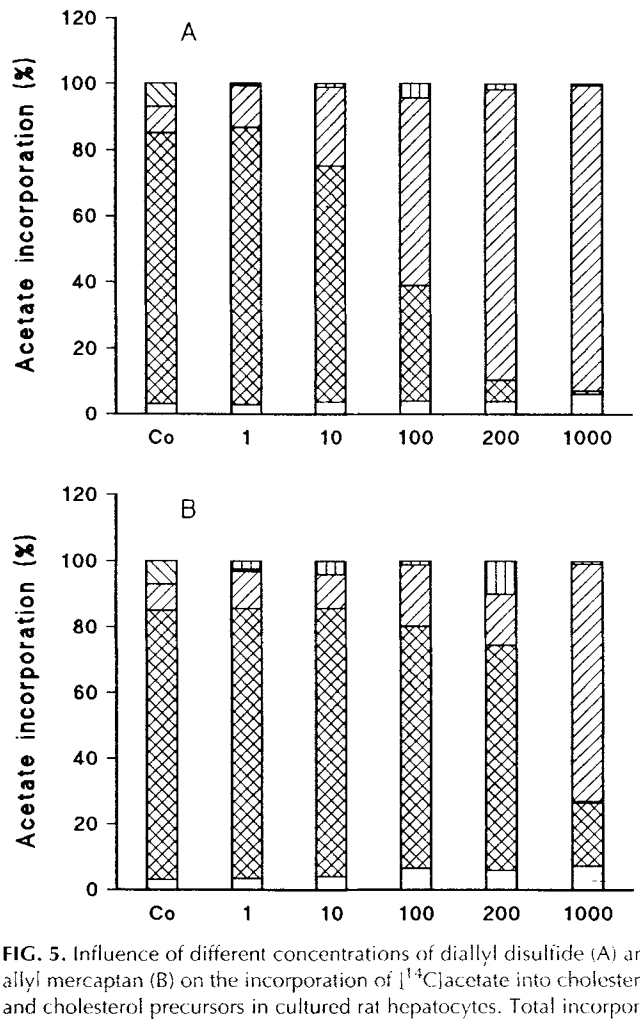

FIG. 5. Influence of different concentrations of diallyl disulfide (A) and allyl mercaptan (B) on the incorporation of [^{14}C]acetate into cholesterol and cholesterol precursors in cultured rat hepatocytes. Total incorporation was normalized to 100% for each concentration. Co, control; concentrations are given in μM. (crosshatched bar), cholesterol, (slanted-right lined bar), lanosterol, (slanted-left lined bar), 7-dehydrocholesterol, (vertical-lined bar), dihydrolanosterol, (open bar), other sterols.

lation of lanosterol at the expense of cholesterol and 7-dehydrocholesterol revealed considerable differences between these compounds (Fig. 6). Allicin was most effective with an EC_{50} value of 28 ± 4 μM (n=4) followed by diallyl disulfide with an EC_{50} value of 109 ± 14 μM (n=3). Thus, diallyl disulfide was about four times less potent than allicin. Diallyl disulfide, on the other hand, was approximately five times as potent as allyl mercaptan and 1,3-vinyl-dithiin which were almost equally effective (Fig. 6). 1,2-Vinyl-dithiin was completely ineffective and did not lead to the accumulation of lanosterol in the concentration range tested (Fig. 6).

When total incorporation of [^{14}C]acetate into cholesterol was determined, a similar sequence in the inhibitory potency of the compounds tested herein (allicin >> diallyl disulfide >> allyl mercaptan > 1,3-vinyl-dithiin and no influence of 1,2-vinyl-dithiin) was found (Fig. 7). Resulting from the different types of inhibition at early and late steps of the biosynthetic pathway demonstrated above, the quantitative effects were even more pronounced for allicin and dially disulfide than for the other compounds. Apparently, EC_{50} values amounted to 17 ± 2 μM (allicin), 64 ± 7 μM (diallyl disulfide), 450 ± 20 μM (allyl mercaptan), and > 600 μM (1,3-vinyl-dithiin) (n=4 for all compounds).

DISCUSSION

In the present study, several garlic-derived organosulfur compounds were compared for their ability to interfere with hepatocellular cholesterol biosynthesis *in toto* as well as during early and late reactions of the pathway. According to our results, the potential to inhibit incorporation of [^{14}C]acetate into cholesterol decreased in the order allicin >> diallyl disulfide >> allyl mercaptan > 1,3-vinyl dithiin, 1,2-vinyl dithiin being almost without effect. This inhibition results from different effects on early and late steps of cholesterol biosynthesis.

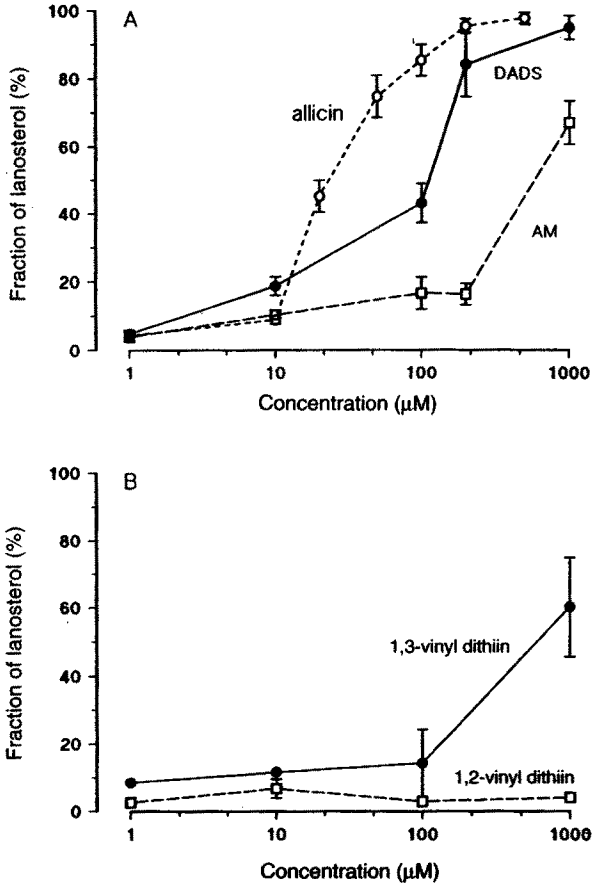

FIG. 6. Influence of different garlic-derived organosulfur compounds on the fraction of lanosterol among cholesterol and cholesterol precursors produced by cultured rat hepatocytes. (A) Concentration dependence of the influence exerted by allicin (○--○), diallyl disulfide (●—●), and allyl mercaptan (□···□). (B) Concentration dependence of the influence exerted by 1,3-vinyl-dithiin (●—●) and 1,2-vinyl-dithiin (□···□).

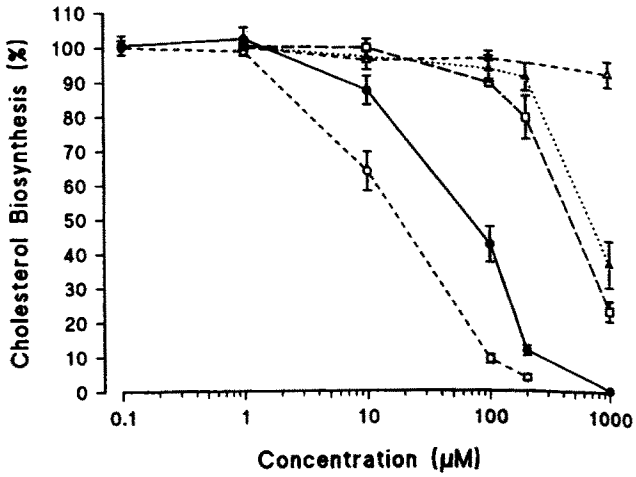

FIG. 7. Concentration dependence of the inhibition of cholesterol biosynthesis by different garlic-derived organosulfur compounds in cultured rat hepatocytes. Values are expressed as percentage of control cultures and represent means ± SD of three to four independent determinations. Allicin (○--○), diallyl disulfide (●—●), and allyl mercaptan (□···□), 1,3-vinyl-dithiin (▲···▲) and 1,2-vinyl-dithiin (△---△).

Concerning early steps of the pathway, the three compounds allicin, diallyl disulfide, and allyl mercaptan consistently inhibited the incorporation of [^{14}C]acetate into the fraction of neutral nonsaponifiable lipids which contained cholesterol, various sterol precursors, and squalene. In contrast to the results of Sendl *et al.* (17) who reported an enhanced incorporation for diallyl disulfide at 500 μM when using a liver homogenate assay system, no such enhancement was found in the intact cultured hepatocytes in the concentration range tested. When tested as early as 2 h after cultivation as done in this study, allicin was slightly more inhibitory than found recently for incubations starting after 18 h (22). Thus, the inhibitory potency of the three compounds at early steps decreased in the order allicin > diallyl disulfide = allyl mercaptan, the latter two compounds showing moderate effects only.

For allicin [this study and (22)] as well as for diallyl disulfide and allyl mercaptan, inhibition at the level of HMGCoA-reductase was apparent, because it disappeared if labeled acetate was replaced by labeled mevalonate. In the case of allicin, it has already been ruled out that the enzyme is directly inhibited in the respective concentration range (22). Whether this holds true also for diallyl disulfide and allyl mercaptan remains to be established, but there are first hints that these compounds might influence (decrease) the activity of HMG-CoA-reductase in an indirect manner through interactions with signal transduction pathways (21).

A second major result was the finding that the effects of the two vinyl-dithiins are qualitatively different from that of the other compounds tested. In contrast to all other garlic-derived organosulfur compounds tested herein and elsewhere (20,21) including allicin and ajoene (22), the vinyl-dithiins stimulated mevalonate incorporation into nonsaponifiable lipids at low concentrations between 1 and 100 μM. Only one isomer, the 1,2-vinyl-dithiin, caused inhibition at concentrations above 100 μM. At present there is no information on what enzymatic step might be stimulated in the lower concentration range. The fact that in the same concentration range incorporation of labeled acetate was not affected, i.e., remained within the variations of the controls, suggests that the vinyl-dithiins reduce the flux of acetate to mevalonate to an extent counterbalancing this stimulation. Preliminary experiments indicate that this reduction is exerted at the level of acetate uptake rather than on that of HMGCoA-reductase (Gebhardt, R., and Beck, H., unpublished observations). In this context, it is interesting to note that 1,2-vinyl-dithiin which is more lipophilic than 1,3-vinyl-dithiin (32) apparently was the more potent compound with respect to stimulation possibly due to enhanced binding to or solubilization within the plasma membrane. The two opposing effects of the vinyl-dithiins also might be responsible for the greater variations among different experiments of the data obtained with these compounds.

The third major point concerns the potential for inhibition of the cholesterol biosynthetic pathway at late steps involved in the conversion of the sterol precursors. Apparent from the

different accumulation of lanosterol, considerable differences between the organosulfur compounds tested herein also were observed for the inhibition at the level of lanosterol 14α-demethylase. As can be derived from the data presented, the inhibitory potential toward this enzymatic step decreased in the order allicin > diallyl disulfide > allyl mercaptan = 1,3-vinyl-dithiin >> 1,2-vinyl-dithiin, the latter being almost ineffective. It is obvious that inhibition at this step contributes most to the inhibition of cholesterol biosynthesis *in toto*. In addition, the accumulation of precursors due to the inhibition of lanosterol 14α-demethylase opens the possibility of an indirect inhibition of HMGCoA reductase similarly as described for other inhibitors of this enzyme (28).

Since diallyl disulfide and allyl mercaptan can occur as decomposition products of allicin in physiological buffers under certain conditions (33) or may be formed by the hepatocytes during metabolic conversion of allicin (34,35), it has been suggested that they might mediate the effects ascribed to allicin or other organosulfur compounds that might lead to their formation (2). This hypothesis can be ruled out at least partially, because of the lower sensitivity of the hepatocytes for diallyl disulfide and allyl mercaptan compared to that for allicin and the absence of any synergistic effects between diallyl disulfide and allyl mercaptan. Possibly, the common structural element of these compounds, i.e., the allylsulfide moiety, is responsible for their qualitatively similar effects. Their quantitatively different potency might be due to the adjacent structural elements similarly as has been described for the different reactivity with cysteine of the S-S bond in allicin, ajoene, and dially disulfide (2,36,37). Further studies on the structural requirements for the inhibitory action of these compounds are in progress.

Furthermore, the high concentrations of diallyl disulfide and allyl mercaptan necessary to exert any inhibition of acetate incorporation as found herein which are in the range of values published by other laboratories (16,17) render it rather doubtful that these compounds act directly by themselves, since such concentrations are unlikely to occur under physiological conditions. Thus, allicin which is at least four fold more effective might better fulfill the requirements for a definitive physiological effector, although its concentration in portal blood is not known and might be lowered by interaction with blood components (33).

On the other hand, in view of the low inhibitory potential of the vinyl-dithiins, conversion to more potent effectors may explain the findings obtained *in vivo* with oil-macerates (38). Although the vinyl-dithiins which are the predominant organosulfur compounds of oil-macerates (11,13,38,39) are relatively stable in blood (2,33), they might be sufficiently metabolized by the liver (32) to produce such effectors as diallyl disulfide or allyl mercaptan.

In conclusion, these results indicate that the influence of different garlic-derived organosulfur compounds on cholesterol biosynthesis varies considerably. Thus, it seems rather unlikely, that the observed hypocholesterolemic effect of garlic consumption may be mediated by some few (or even a single) compound(s) which are the most stable ones in the blood. Instead, one must assume that the liver may specifically sense many of the genuine or derived organosulfur compounds of garlic that are delivered to it *via* the portal vein after garlic consumption. The different stability of these compounds within the blood, however, may influence the spectrum of compounds acting on the liver and participating in the inhibition of cholesterol biosynthesis. In this respect, it is interesting that new and highly sensitive interactions with intracellular signalling pathways have been described for dially disulfide (21) or are under investigation as in the case of allicin (40, Gebhardt, R., unpublished observations).

ABSTRACT: The biosynthetic pathways of eicosapentaenoic acid (20:5n-3) in microalgae, in general, and in *Porphyridium cruentum*, in particular, are not known. Some of the putative intermediates along the suggested pathways could not be detected probably due to their low endogenous level. In order to increase the endogenous levels of the intermediates, we provided various fatty acids in the growth medium. Exogenously supplied fatty acids were indeed incorporated into algal lipids and were further metabolized along the n-6 and n-3 pathways. In the n-6 pathway, 18:2 was desaturated to 18:3n-6, elongated to 20:3n-6, and subsequently desaturated to 20:4n-6 and then to 20:5n-3. In the n-3 pathway, 18:2 was first desaturated to 18:3n-3 which was then sequentially converted, apparently by the same enzymatic sequence of the n-6 pathway to 18:4n-3, 20:4n-3, and 20:5n-3.

Lipids 31, 1277–1282 (1996).

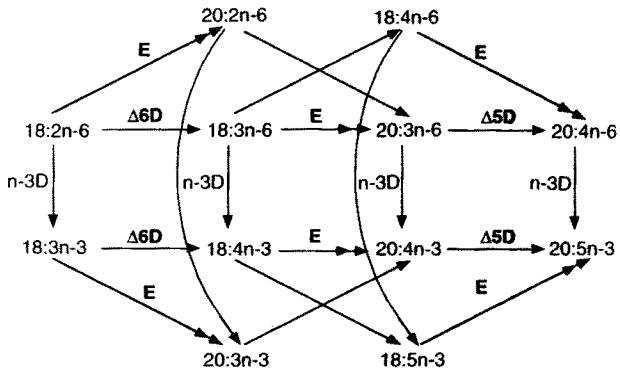

FIG. 1. Theoretically possible pathways of eicosapentaenoic acid biosynthesis in *Porphyridium cruentum*. Δ6D represents the Δ6 desaturase; E- the elongation system; Δ5D- the Δ5 desaturase; and n-3D- the n-3 desaturase.

The recent interest in the pharmacological properties of eicosapentaenoic acid (EPA) (20:5n-3) prompted the search for alternative sources for these fatty acids, such as algae (1) and fungi (2), to replace the commonly used marine fish oil. *Porphyridium cruentum* is one of the promising sources (3). In order to reach contents which will allow economical production, genetic methods must be eventually employed. This in turn requires a comprehensive understanding of the biosynthetic pathways of EPA in terms of intermediates and enzymes. The biosynthetic pathways leading to polyunsaturated fatty acids (PUFA) in leaves of higher plants were recently reviewed by Browse and Somerville (4). Except for the first double bond, desaturation involves lipid-linked fatty acids. The biosynthesis of algal PUFA is presumably similar to that of higher plants at least to the level of 18:2n-6. However, there could be 12 different theoretical pathways, at the fatty acid level, by which 18:2n-6 can be converted to 20:5n-3 (Fig. 1). One of the impediments to the elucidation of the biosynthesis of EPA is that some of the putative intermediates may be present at very low levels which makes detection difficult. Incorporation of radiolabeled precursors would give only partial results since the identification of the various molecular species of individual lipids would be extremely difficult without molecular species standards. A possible approach for increasing the endogenous content of a putative metabolite is the feeding of algal cells with exogenously supplied fatty acid intermediates (5–9). We have speculated that the incorporated fatty acid intermediates would elevate their endogenous levels and that of subsequent metabolites along the biosynthetic routes. The results of the feeding experiments indicate that most likely there are only two pathways leading to the production of EPA.

To whom correspondence should be addressed.

Abbreviations: C_n fatty acids, fatty acids with n carbon atoms; EPA, eicosapentaenoic acid (20:5n-3); GC, gas chromatography; MGDG, monogalactosyldiacylglycerol; PUFA, polyunsaturated fatty acids; X/Y, a fatty acyl group containing X carbon atoms and Y double bonds (*cis*). Pairs of numbers representing the fatty acids, when separated by a slash, designate the components in the *sn*-1 and *sn*-2 positions, respectively, of the molecular species. n-x indicates that the last double bond in a methylene-interrupted PUFA is n carbon atoms removed from the end of the chain. Δn indicates a double bond at the nth carbon atom. ΔnD indicates a desaturase that introduces a double bond at the nth carbon atom.

MATERIALS AND METHODS

Organism and culture conditions. Porphyridium cruentum strain 1380.1d was obtained from the Göettingen Algal Cul-

Copyright © 1996 by AOCS Press

ture Collection (Göettingen, Germany) and was grown on Jones' medium (11) as previously described (12) in Erlenmeyer flasks under an air–CO_2 (99:1) atmosphere at 25°C. The flasks were placed in an incubator shaker and illuminated from above at 115 μmol quanta m^{-2} s^{-1}. Cultures were grown exponentially (with proper dilution) for at least 4 d prior to the onset of the experiment and were diluted daily throughout the experiment. Solutions of fatty acids in dimethylsulfoxide were added to a final concentration of 0.17 mM. The dimethylsulfoxide concentration in the treated and control cultures didn't exceed 1%.

Extraction and fractionation of lipids. Freeze-dried samples of algal biomass were extracted by grinding with sand in chloroform/methanol/water (2:1:0.8) according to Bligh and Dyer (13). Separation into neutral lipids, galactolipids, and phospholipids fractions was performed with a silica gel cartridge (Sep-pak; Waters Division of Millipore, Milford, MA); the individual fractions were eluted successively with chloroform, acetone, and methanol, respectively. The galactolipid fraction was further separated by thin-layer chromatography on silica gel plates and developed with chloroform/acetone/methanol/acetic acid/water (100:40:20:20:10, by vol).

Separation, identification, and quantitation of molecular species of monogalactosyldiacylglycerol (MGDG) was performed by high-performance liquid chromatography on Lichrocart 250-4 (RP-18, 5 μ) cartridges (Merck, Darmstadt, Germany) by elution with 93% methanol/water at a flow rate of 2 mL min^{-1}. Peaks were detected at 205 nm, isolated, and transmethylated as described below. The fatty acid composition was elucidated by gas chromatography (GC) analysis. For quantitation of the HPLC chromatogram, we have used an evaporative light-scattering detector (ELSD-2; Varex, Burtonsville, MD). The settings of the detector were: tube temperature 130°C, nitrogen flow rate 40 mL min^{-1}.

Fatty acid analysis. Lipids were transmethylated with methanol–acetyl chloride and analyzed by GC as previously described (14). Fatty acid methyl esters were identified by comparison of their equivalent chain length (15), by cochromatography with authentic standards (Sigma Chemical Co., St. Louis, MO and *Mortierella alpina* biomass) and by GC–mass spectrometry (12). The data shown represent mean values with a range of less than 5% for major (over 10% of fatty acids) peaks and 15% for minor peaks, of four independent samples, each analyzed in duplicate.

RESULTS AND DISCUSSION

The fatty acid profile of *P. cruentum* under control conditions was composed of 18:2, 18:3n-6, 20:3n-6, 20:4n-6, and 20:5n-3 (Table 1). The appearance of fatty acids of the n-6 family point to the existence of an n-6 pathway from 18:2 to 20:4n-6 as detailed in Sequence 1. Fatty acids which could indicate the existence of the n-3 pathway that is shown in Sequence 2 were not detected except for 20:5n-3.

[a]Unidentified isomer. [b]20:3(5,11,14). [c]20:4(5,11,14,17). NL, neutral lipids; GL, galactolipids; PL, phospholipids; PUFA, polyunsaturated fatty acids.

where ΔnD indicates a desaturase that introduces a double bond at the nth carbon atom.

The failure to detect intermediates of the putative n-3 pathway could have resulted from one of two reasons (i) the n-3 pathway does not exist in this alga or (ii) the n-3 pathway does exist, but the endogenous level of the intermediates was too low for detection. However, the mere existence of certain fatty acids does not in itself prove that they are indeed intermediates in any pathway of PUFA biosynthesis. The conversion of 18:2 to 20:5 involves one elongation and three desaturation steps. Theoretically, there are at least 12 possible routes, at the fatty acid level, as shown in Figure 1. Indeed, Arao and Yamada (16) suggested that 4 pathways are operative for this conversion in *Phaeodactylum tricornutum*. A pathway in which the elongation of 18:2n-6 to 20:2n-6 precedes further desaturation was claimed to take place in *Euglena* (17).

The conversion of C_{18} to C_{20} PUFA requires one more elongation step. Since elongation occurs at the carboxyl end, the fatty acid to be elongated must first detach from the lipid where it resides. These detaching and reattaching steps which are not found in the biosynthetic pathways of C_{18} PUFA suggest that externally introduced fatty acids also could be incorporated into polar lipids. Thus, we hypothesized that a possible means to increase the endogenous levels of putative intermediates was by supplementing the growth medium with fatty acids which were assumed to participate in either pathway. We also hoped to be able to show precursor–product relationship between the putative intermediates.

Cultures of *P. cruentum* were thus fed with various C_{18} and C_{20} PUFA. After 3 d, the lipids were extracted and separated to the individual lipid classes and analyzed. All the externally introduced fatty acids were indeed incorporated into the lipids and were accumulated at proportions far exceeding those which could be observed under control conditions.

Incorporation of 18:2n-6. Growing *P. cruentum* on a medium supplemented with 18:2n-6, a branching point for the putative n-3 and n-6 pathways (Fig. 1) resulted as expected in a 2–5-fold increase in its content in all lipid fractions (Table 1). The level of subsequent intermediates of the n-6 pathway in neutral lipids and galactolipids also increased but to a much lesser extent. In the fraction of the phospholipids, the pattern was not consistent since some intermediates increased while others decreased. While putative intermediates of the n-3 family could not be detected in control cultures, they were detected in all lipid fractions following growth of the alga in the presence of 18:2n-6. The proportion of 18:3n-3 reached 0.4% in neutral and galactolipids and 0.2% in phospholipids. Furthermore, 20:4n-3 appeared in neutral and phospholipids at 0.5 and 3.8%, respectively. These data clearly indicate the ability of the algal cells to convert 18:2n-6 to 18:3n-3 by n-3 desaturase(s) and to further convert it by subsequent elongation and desaturation steps to 20:4n-3.

Incorporation of possible intermediates of the n-3 family. According to Figure 1 and the results shown in Table 1, 18:3n-3 is the immediate product of the desaturation of 18:2n-6 by n-3 (Δ15) desaturase(s), and it is the first intermediate in the n-3 pathway. In order to find out whether the appearance of other n-3 pathway intermediates after feeding with 18:2n-6 supports the n-3 pathway, we fed the alga with 18:3n-3. As can be seen from Table 2, all the fatty acids of sequence 2, as well as 20:3n-3 were detected. Thus, 18:3n-3 could be further converted to 20:4n-3 either *via* 18:4n-3, 20:3n-3, or both (Sequence 3).

$$\begin{array}{ccc} 18{:}3n\text{-}3 & \xrightarrow{\Delta 6D} & 18{:}4n\text{-}3 \\ n\text{-}3D\downarrow & & n\text{-}3D\downarrow \\ 20{:}3n\text{-}3 & \xrightarrow{\Delta 6D} & 20{:}4n\text{-}3 \end{array} \quad [3]$$

In order to determine which of the various routes in Sequence 3 is the one leading to the production of 20:4n-3 and perhaps to 20:5n-3, we provided the alga with 18:4n-3. Both the 18:4n-3 acid and its elongation product 20:4n-3 were incorporated into all lipids fractions. The latter was mainly found in neutral lipids (12.1%) and phospholipids (16.5%) (Table 2). These findings are in keeping with Sequence 2 and suggest that this pathway includes 18:4n-3 rather than 20:3n-3.

Incorporation of 20:3n-3 resulted in accumulation of this fatty acid in all lipid classes but especially in neutral lipids (Table 2). However, we could not detect even traces of 20:4(8,11,14,17) supporting our conclusion that in the postulated n-3 pathway, 18:3n-3, rather than 20:3n-3, is the precursor for 20:4n-3 (Sequence 2) and that *P. cruentum* is incapable of a Δ8 desaturation (see below). Furthermore, we have observed the appearance of 20:4(5,11,14,17) (20:4Δ5) which was identified, by comparison to authentic samples and by GC–mass spectrometry. (The significance of the appearance of nonmethylene-interrupted PUFA with respect to the specificity of the desaturases will be addressed elsewhere.)

Incorporation of possible intermediates of the n-6 family. The detection of intermediates of the n-6 pathway in control cells (Table 1) is indicative of the existence of this pathway (Sequence 1). The increase in the proportions of 20:3n-6 and 20:4n-6 following the growth of the cells in the presence of 18:3n-6 further supports this conclusion (Table 1). No fatty acids of the n-3 series (except for EPA) could be detected following growth of the alga in the presence of either 18:3n-6 or 20:3n-6 (Table 1). We thus infer that neither 18:3n-6 nor 20:3n-6 is likely substrate for an n-3 desaturation.

According to Figure 1, 20:2n-6 could be converted by a Δ8D to 20:3n-6 or by an n-3D to 20:3n-3. When provided to the cells, this fatty acid was incorporated into neutral lipids and phospholipids (Table 1). However, there was no enhancement in the level of any other fatty acid in either the n-6 or n-3 pathways while EPA actually decreased, indicating that the 20:2n-6 was not an intermediate in either pathway. Unexpectedly, we observed the appearance of 20:3(5,11,14) (20:3Δ5) and 20:4Δ5 (see above) which further supports our hypothesis that the Δ8 double bond can not be introduced to C_{20} fatty acids. Rather, a Δ6 double bond is introduced into a C_{18} fatty acid which upon elongation becomes the Δ8 double bond.

The conversion of 18:2 to EPA requires one n-3 desaturation step. Theoretically, four n-6 intermediates could be used as substrate for the n-3 desaturation, namely, 18:2n-6, 18:3n-6, 20:3n-6, and 20:4n-6 (Fig. 1). However, the data we have obtained suggest that only 18:2 (Table 1) and 20:4n-6 (see below) are desaturated to 18:3n-3 and 20:5n-3, respectively. These findings raise several questions that require further study: (i) Are both desaturations carried out by one enzyme which has broad substrate specificity or by two enzymes with specificity toward 18:2 and 20:4, respectively? (ii) If indeed two desaturases are involved and knowing that the 20:4 desaturase is apparently residing in the chloroplast, is the 18:2 desaturase located in the chloroplast or in the cytoplasm?

In similarity to the n-6 intermediates, those of the n-3 pathway, namely 18:4n-3 and 20:4n-3, were primarily concentrated in the phospholipid and the neutral lipid fractions (Table 2). This finding suggests that the Δ6 and Δ5 desaturation steps in both pathways are cytoplasmic, utilizing phospholipids as their acyl carriers. Recently, using radiolabled precursors, we have shown that the Δ6D and the Δ5D of both the n-3 and the n-6 pathways utilize phosphatidylcholine-bound fatty acids (18). Thus, we speculate that both pathways utilize the same Δ6D and the Δ5D activities.

Putative products of the Δ6 desaturase, 18:4n-3, and 18:3n-6 in the n-3 and n-6 pathways, respectively, produced seemingly unrelated phenomena. Incorporation of 18:4n-3 resulted in a surprising substantial decrease (up to 85%) in the proportion of n-6 fatty acids in every lipid class analyzed (Table 2). When either 18:3n-6 or 20:3n-6 was incorporated, we observed the appearance of 18:3n-3 which normally is not detectable (Table 1). We propose that these findings could be explained by inhibition of the Δ6 desaturation that is brought about by elevated 18:4n-3 or 18:3n-6 (Sequence 1 and 2). The decrease in the Δ6 desaturase activity caused by 18:4n-3 also would be manifested in the reduction in the level of 18:3n-6 and its metabolites in the n-6 pathway (Sequence 1), and eventually in a decrease in 20:4n-6. Similarly, inhibition of the Δ6 desaturation by 18:3n-6 led to an accumulation of 18:2 and/or 18:3n-3. The elevated level of 18:3n-3 also could result from the increased availability of 18:2 to the n-3 desaturase. In any event, the appearance of 18:3n-3 is additional indication for the existence of the first step of the n-3 pathway, namely, the conversion of 18:2 to 18:3n-3 (Sequence 2) which seems to be the rate-limiting one in the n-3 pathway.

Since one could not rule out the possibility that the pathways revealed by the feeding experiments are not operational in the absence of exogenously supplied fatty acids, we have conducted several studies using radiolabeled precursors (18). The data we have obtained supported our two-pathway hypothesis.

Molecular species of monogalactosyldiacylglycerol (MGDG). MGDG can be divided into prokaryotic and eukaryotic molecular species according to the positional distribution of fatty acid substituents. In higher plants, these molecular species are named after the different pathways from which they evolve. Thus, we attempted to determine whether the changes observed in the fatty acid profile following the incorporation of externally provided fatty acids could be attributed to all or particular molecular species.

We have shown above (Table 1) that exogenously added 18:2 increased the level of 20:4n-6 at the expense of EPA. Analysis of the molecular species of MGDG has further demonstrated a sharp increase in the proportion of

20:4n-6/20:5n-3 and 20:4n-6/16:0 and a decrease in that of 20:5n-3/20:5n-3 and 20:5n-3/16:0 (Table 3). These findings may suggest the existence of precursor–product relationship between the former and the latter in keeping with Sequences 4 and 5. Furthermore, these findings indicate that the chloroplast is the site of the n-3 desaturation of both the eukaryotic and prokaryotic species of MGDG.

$$20{:}4n\text{-}6/16{:}0 \longrightarrow 20{:}5n\text{-}3/16{:}0 \quad [4]$$

$$20{:}4n\text{-}6/20{:}4n\text{-}6 \longrightarrow 20{:}4n\text{-}6/20{:}5n\text{-}3 \longrightarrow 20{:}5n\text{-}3/20{:}5n\text{-}3 \quad [5]$$

Support to the above conclusion was recently obtained using radiolabeled precursors (16). We have found that (i) in *P. cruentum*, the diacylglycerol 20:4n-6/20:4n-6 which participates in the eukaryotic pathway is, most likely, imported from the cytoplasm, and following galactosylation, is sequentially desaturated to 20:5n-3/20:5n-3 MGDG and (ii) the prokaryotic molecular species 20:4n-6/16:0 is also desaturated to 20:5n-3/16:0.

We have also observed the appearance of the eukaryotic-like species 20:4n-6/18:2 (7.4% of MGDG) (Table 3) which was not detected in the control culture. The appearance of "eukaryotic-like" molecular species of MGDG in the prokaryotic organism, *Spirulina,* was recently reported by Pham Quoc *et al.* (10). They have shown that an externally supplied C_{18} fatty acid was incorporated into the *sn*-2 position producing C_{18}/C_{18} "eukaryotic-like" species, partially replacing the common prokaryotic species C_{18}/C_{16}. Thus, the appearance of "eukaryotic-like" species 20:4n-6/18:2 in *P. cruentum* is analogous to the C_{18}/C_{18} "eukaryotic-like" species of *Spirulina.*

Following the addition of 18:3n-3 (Table 3), we have observed the appearance of 18:3n-3/16:0 (6.8% of total molecular species) as well as a low level (0.6%) of the eukaryotic-like species 20:5/18:3n-3. It appears that externally added 18:2 and 18:3n-3 were preferentially incorporated into different positions, the *sn*-2 and *sn*-1 positions of MGDG, respectively, a phenomenon which we can not explain at the moment. In the presence of 18:4n-3, there was an almost complete elimination of all 20:4n-6-containing molecular species (Table 3), further supporting our hypothesis that 18:4n-3 inhibits Δ6 desaturation (see above). As a result of this inhibition, all C_{20}-containing molecular species were produced *via* the n-3 pathway. We have also observed a decrease from 44.2 to 32.7% in the prokaryotic 20:5/16:0 and a concurrent increase from 36.7 to 57.3% in the eukaryotic 20:5/20:5. This may indicate that 18:4n-3 and hence the n-3 pathway in which it participates is preferentially involved in the production of eukaryotic species of MGDG. Addition of 20:3n-3, which is not an intermediate in the n-3 pathway (see above), resulted in a reduction in the major eukaryotic product 20:5/20:5 (Table 3) and in the appearance of 20:5/20:4(5,11,14,17) which could result from the cytoplasmic Δ5 desaturation of 20:5/20:3n-3.

TABLE 3
Effect of Exogenously Supplied Fatty Acids to *Porphyridium cruentum* on the Molecular Species Composition of MGDG

Molecular species of MGDG	Fatty acid supplied

[a]20:4(5,11,14,17); MGDG, monogalactosyldiacylglycerol.
[b]Unidentified.

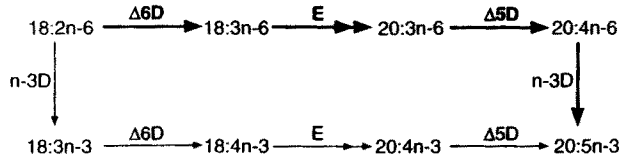

FIG. 2. Outline of the n-3 and n-6 pathways in the biosynthesis of eicosapentaenoic acid in *Porphyridium cruentum.* The dominant pathway is shown in bold. For legend see Figure 1.

Conclusions. Our data suggest that EPA in *P. cruentum* is most likely synthesized along the n-6 and n-3 pathways as presented in Figure 2.

The 18:4n-3 and 18:2 acids inhibit the Δ6 and n-3 desaturations, respectively, and could possibly be used as inhibitors for various steps in the biosynthesis of C_{20} and C_{22} PUFA.

ABSTRACT: To compare the fatty acid composition of tumor tissue from glioma patients with that of normal brain tissue, tissue samples were obtained from 13 glioma patients and from 3 nonmalignant patients. Following lipid extraction, total fatty acid composition was measured using gas–liquid chromatography. Samples were further separated into phospholipids and neutral lipids. Representative samples were then separated into phospholipid classes by thin-layer chromatography and the fatty acid composition assayed. Levels of the polyunsaturated fatty acid (PUFA) docosahexaenoic acid (DHA), were significantly reduced ($P = 0.029$) in the glioma samples compared with normal brain samples; mean values were 4.8 ± 2.9% and 9.2 ± 1.0%, respectively. This reduction in glioma DHA content was also observed in terms of phospholipids (4.6 ± 2.1% vs. 9.6 ± 0.8%, $P = 0.002$). The phosphatidylserine and phosphatidylethanolamine phospholipid classes were reduced in the glioma samples. Differences were also noted in the n-6 PUFA content between glioma and normal brain samples. The glioma content of the n-6 PUFA linoleic acid was significantly greater ($P < 0.05$) than that observed in the control samples in terms of total lipids. Thus, the fatty acid composition of human gliomas differs from that found in nonmalignant brain tissue.

Lipids 31, 1283–1288 (1996).

In 1995, there will be an estimated 17,200 new cases of central nervous system (CNS) tumors and 13,300 deaths from CNS tumors in the United States (1). The majority of these will arise from malignant gliomas of the brain (approximately 8500 new cases and 6600 deaths estimated for 1995) (2). Treatment results for malignant gliomas remain poor, especially for the most common and most aggressive glioma, glioblastoma multiforme (GBM). Despite multimodality therapy including surgery, radiation therapy, and chemotherapy, the median survival for GBM remains ≤1 yr, and long-term survival rates are dismal (3). Many different therapeutic approaches have been studied in an attempt to improve the outcome of patients with malignant gliomas, including altered forms or fractionation of radiotherapy, brachyradiotherapy, radiosensitizers, and various chemotherapeutic agents. At best, these attempts have provided modest benefit.

An alternative approach might be the use of polyunsaturated fatty acids (PUFA). Fatty acids in tissues are derived from either the diet or through biosynthesis. Saturated and monounsaturated fatty acids can be synthesized *de novo.* If sufficient amounts are not available in the diet, synthesis is increased to maintain an adequate supply. However, the n-3 and n-6 PUFA cannot be synthesized *de novo* and are derived entirely from the diet. Thus, tissue PUFA content will depend to a large extent on the diet; tissue PUFA composition will change if the diet is PUFA-deficient or PUFA-rich. The same principle applies to malignant cells, which derive all their PUFA from the host. *In vitro* data indicate that tumor cells are deficient in PUFA as compared with their normal cell counterparts (4,5). Increasing the PUFA content of tumor cells *in vitro* by incubating the cells in media supplemented with PUFA selectively potentiates tumor cell sensitivity to subsequent therapies involving oxidative stress (6); normal cells are relatively unaffected. The mechanism of this cytotoxic effect appears to be *via* enhanced free radical generation and lipid peroxidation. A reduced PUFA content also has been observed *in vivo* in tumor samples obtained from prostatic (7) and breast cancer patients (8). Moreover, increasing malignant cell PUFA content by dietary supplementation has been shown to inhibit tumor growth in nude mice implanted with human breast cancer (9) and prostatic cancer cells (10).

The purpose of the present study was to determine the fatty acid composition of human glioma tumors and compare this with the fatty acid composition of normal brain tissue. A reduction in the PUFA content of glioma cells relative to normal brain tissue could contribute to the relative resistance of gliomas to therapy. This might provide the basis for studies to determine the potential role of PUFA as adjunct agents in the radiotherapeutic treatment of gliomas.

MATERIALS AND METHODS

Patients and samples. Scientific study of resected brain tissue was approved through the institutional human use committee. Brain tissue samples were collected between February 1994 and December 1994 from 13 patients with glioma tumors and 3 control patients who were undergoing brain tissue resection for seizure disorder. Information concerning the glioma patients and the control patients are shown in Tables 1 and 2, respectively.

Tissue sample collection and lipid extraction. Fresh tissue (50 mg–1 g) was collected in the operating room and placed on ice within 10 min of resection. Any blood present was removed by washing with chilled normal saline, and the sample was then placed in a chloroform/methanol mixture ($CHCl_3$–CH_3OH; 2:1, vol/vol) and stored at −20°C until analyzed. The lipids were extracted according to the method of Folch *et al.* (11). Aliquots of lipid extract from each patient sample were separated into phospholipid and neutral lipid fractions using silicic acid column separation. Aliquots of the phospholipid fraction were separated by thin-layer chromatography into phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylserine (PS), and phosphatidylinositol (PI) fractions (12).

Fatty acid composition. Fatty acid composition was determined by gas–liquid chromatography (GLC) (12). Briefly, the fatty acid composition of each patient sample was determined in terms of the total lipid, neutral lipid, total phospholipid, and PE, PC, PS, and PI fractions. To a volume of each lipid extract, a known amount of heptadecaenoic acid methyl ester (17:0) was added as an internal standard. The fatty acids were then methylated for 50 min at 95°C with 12% BF_3 (12) and separated by GLC using a 1.9-m column packed with SP-2330 on Chromosorb Gaschrome WAW (Supelco, Bellefonte, PA). The resultant peaks were identified by comparing the retention times with those of known fatty acid methyl ester standards. Peak areas were determined by automatic integration.

Statistical analysis. Data are expressed in terms of mean ± SD. The unpaired Student's two-tailed *t*-test was used to assess the differences in mean fatty acid levels and unsaturation indices between tumor and control sample populations.

RESULTS

The fatty acid composition, in terms of total lipid extract and phospholipid fraction, for glioma samples and control brain samples are shown in Table 3. Since no significant differences were observed in terms of lipid content between tumors arising from different regions of the brain, all the glioma data were combined for comparison with control brain tissue. The percentage of fatty acids present as PUFA was essentially identical in the normal brain and glioma samples; mean values were 26.9 ± 2.2% and 27.5 ± 3.1%, respectively. However, levels of the predominant n-3 PUFA, docosahexaenoic acid (DHA) (22:6n-3), were significantly reduced in the glioma samples ($P = 0.029$); mean values were 4.8 ± 2.9% compared with 9.2 ± 1.0% in the normal brain samples. A significant reduction in glioma DHA content was also observed in terms of the total phospholipids; mean values in the glioma samples were 4.6 ± 2.1% compared with 9.6 ± 0.8% in the normal brain samples ($P = 0.002$) (Fig. 1). Measurements of the fatty acid distribution of the four phospholipid fractions PE, PS, PC, and PI revealed further evidence of a reduction in the DHA content of the glioma tissue compared with the normal brain. The DHA content of the PE and PS fractions in the glioma samples was only some 50% of that observed in the samples taken from nonmalignant brain tissue; however, these reductions were not statistically significant (Fig. 1).

Differences were also noted in the n-6 PUFA content between glioma and normal brain samples. The glioma content of the n-6 PUFA LA (18:2n-6) was found to be significantly greater ($P < 0.05$) than that observed in the control samples in terms of total lipids (Table 3). A similar pattern was observed in terms of total phospholipids, but this was not statistically significant ($P = 0.073$).

These data were used to determine the unsaturation index (UI) of the total lipid and phospholipid fractions (13). Table 4 shows the mean UI of glioma and control tissue for the total lipid, total phospholipid, and for each of the phospholipid fractions. Although none of the differences reached statistical significance, there was a consistent trend, with the glioma UI being lower than that observed in the nonmalignant control brain samples for all lipid fractions.

In four samples, three tumor and one control, tissue samples were obtained from two different areas, to determine possible differences in fatty acid content due to sample heterogeneity. In all four specimens, no significant alteration in fatty acid distribution was observed due to variation in the area of tissue sample analyzed.

[a]Each value is the mean ± SD. [b]The values do not add up to 100% because only the most prevalent fatty acids are listed. [c]$P < 0.05$. [d]$P = 0.073$. [e]ND = not detectable.

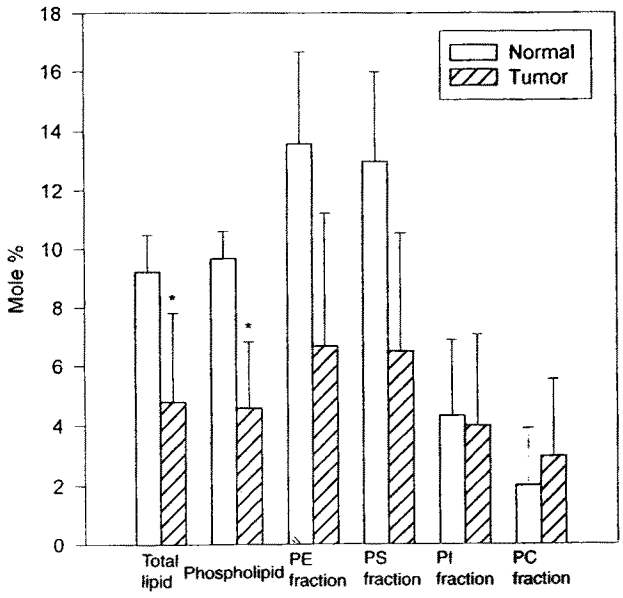

FIG. 1. Docosahexaenoic acid (DHA; 22:6n-3) levels in control and tumor brain tissue samples for the measured lipid fractions. Error bars show ± SD. PE, phosphatidylethanolamine; PS, phosphatidylserine, PI, phosphatidylinositol; PC, phosphatidylcholine. *$P < 0.03$.

TABLE 4
Unsaturation Index: Tumor vs. Control[a]

	Total lipid	Total phospholipid	PE	PS	PC	PI
Tumor	136.6 ± 13.9	135.2 ± 19.7	154.5 ± 47.4	88.9 ± 12.7	65.6 ± 33.6	90.6 ± 20.0
Control	148.8 ± 8.7	150.9 ± 4.0	198.4 ± 20.6	130.0 ± 17.4	77.5 ± 19.4	115.2 ± 15.1

[a]Unsaturation index is the average number of double bonds, on a molar basis, in the fatty acid mixture × 100. Values are mean ± SD. All differences between tumor and control with $P > 0.05$. PE = phosphatidylethanolamine, PS = phosphatidylserine, PI = phosphatidylinositol, and PC = phosphatidylcholine.

DISCUSSION

The current findings indicate that the percentage of total fatty acids present as PUFA in samples of malignant glioma tissue was essentially identical to that determined in normal brain tissue. However, there were marked differences between malignant and normal brain tissue in terms of the content of individual PUFA. A significant reduction in both total lipid and total phospholipid was noted in levels of the n-3 PUFA, DHA, in the glioma cells compared with normal brain tissue. DHA is the major n-3 PUFA in the CNS, being found in unusually high concentrations in synaptic membranes (14), the retina (15), and in particular the brain (16). The precise role that DHA plays in the CNS remains ill-defined. However, its importance is readily evident from observations indicating that dietary deprivation of n-3 PUFA is correlated with impairment of visual acuity (17) and learning ability (18). This might reflect, in part, alterations in membrane fluidity and functional properties of membrane proteins (6). In contrast, levels of the n-6 PUFA, linoleic acid (LA), were higher in the glioma tissue samples compared with control tissue. Thus, malignant human glioma tissue does appear to have an altered PUFA composition compared to nonmalignant brain tissue. These changes resulted in an apparent decrease in the UI of the glioma tissue, although the extent of this reduction did not reach acceptable levels of significance.

These data are in close agreement with previously published, even though limited, data on the fatty acid content of normal and malignant brain tissue. Stein *et al.* (19) analyzed the fatty acid composition of ten brain tumors, consisting of nine primary and one metastatic bronchogenic cancer. Due to the limited technology available at that time, only results for fatty acids up to 18 carbons in length were reported. These revealed that all glioma tissue analyzed contained increased levels of LA when compared with normal overlying cortical tissue removed from the same patient. An increase in LA content of neoplastic human tissue was also noted by White (13) from an analysis of 15 intracranial tumors, of which 7 were gliomas. White further reported decreased amounts of DHA in the PE and PC phospholipid fractions in these intracranial tumors compared with normal brain tissue. These data are consistent with the findings presented here. The mean glioma DHA content reported for the PE fraction was 6.8% compared with a value of 6.7 ± 3.7% from the current study; PC DHA content was also very similar between the two studies. Similar alterations in LA and DHA PE phospholipid fractions were observed by Sun and Leung (20). More recently, Ledwozyw and Lutnicki (21) published results for 8 gliomas and 10 meningiomas. The DHA composition for the glioma samples was again similar to the results presented here, with a mean total lipid DHA content of 5.1 ± 0.5% compared with our value of 4.8 ± 2.9% obtained in the current study.

The control tissue was obtained from three individuals who all exhibited seizure disorders. It should be noted that free fatty acid accumulation in the whole brain is a primary event following drug-induced seizures (22). Arachidonic acid appears to be the major fatty acid accumulated during these seizures, although increases in DHA have been noted experimentally (23). Thus, there exists the possibility that the values determined in the control patients in the current study might not be a true reflection of "normal" brain tissue. However, the fatty acid distribution data for the control tissue presented here are consistent with previously published data, and thus do appear to be representative of nonmalignant brain tissue (13,24,25).

The current observations of an increase in the content of LA and a decrease in 6-desaturated PUFA such as DHA further support the hypothesis that malignant cells exhibit an altered PUFA composition. Cheeseman *et al.* (4) reported a significant decrease in the PUFA content, in particular arachidonic acid (20:4n-6) and DHA, of hepatoma cells compared with normal rat hepatocytes. In contrast, the LA content of the malignant cells was elevated. These findings have been confirmed in other hepatoma cell lines (5,26). These alterations in malignant cell PUFA composition led to a reduced UI value for the malignant cells compared with that determined in the normal hepatocytes (26), an observation confirmed in the current study. A similar alteration in malignant cell PUFA content has been observed *in vivo*. Chaudry *et al.* (7) noted that malignant prostatic tissue had reduced levels of arachidonic acid (20:4n-6) and docosapentaenoic acid (22:5n-3) compared with benign prostatic tissue. This might reflect a lack of, or reduced activity of, the enzyme Δ^6 desaturase, required to desaturate LA and ALA to their respective products in malignant cells. Human cell lines exposed to oncogenic viruses, radiation, and chemical carcinogens show reduced rates of Δ^6-desaturation (27). Moreover, human lung cancer tissue transplanted into nude mice shows an absence of Δ^6-desaturase activity (28). Whatever the precise mechanism involved, it is important to note that as a consequence of this altered PUFA composition and reduction in UI values, lipid peroxidation should be significantly decreased in tumor cells

and tissues compared with the corresponding normal tissue (4). Many anticancer therapies, including irradiation, chemotherapy, hyperthermia, and photodynamic therapy, kill tumor cells by processes involving free radical generation leading to lipid peroxidation. Hence, malignant cell resistance to such therapy might be due, in part, to the altered PUFA composition, leading to a lower UI, and resultant decreased lipid peroxidation.

As noted earlier, tissue PUFA content will depend to a large extent on the diet; we are what we eat. The same principle applies to malignant cells, which derive all their PUFA from the host. Dietary studies demonstrate clearly that feeding tumor-bearing animals diets supplemented with particular fatty acids results in specific alterations in tumor cell fatty acid composition (29,30). Similarly, incubating malignant cells in culture with varying levels of different PUFA leads to specific, PUFA-dependent, changes in malignant cell PUFA content (31). The rate-limiting Δ^6 desaturase step can be bypassed by directly supplying preformed PUFA that contain 6-desaturation, such as gamma-linolenic acid (GLA, 18:3n-6). Such alterations in PUFA content and composition are associated with selective malignant cell kill; normal cells appear relatively unaffected (32). The mechanism for this cytotoxic effect appears to involve free radical generation and lipid peroxidation; it can be blocked by the addition of antioxidants (33). In addition, PUFA-enriched tumor cells exhibit increased susceptibility to subsequent treatments involving an oxidative stress, such as Adriamycin, photodynamic therapy, and iron loading (31,34).

Dietary supplementation with PUFA has been demonstrated to alter the PUFA composition of not only normal brain tissue (35,36) but also that of intracerebrally implanted tumor tissue (37). Indeed, intravenously administered fatty acids were more rapidly incorporated into the implanted tumor cells than the normal brain tissue. This ability to alter glioma cell PUFA composition might lead to an enhancement in the susceptibility of glioma cells to anticancer therapies which involve an oxidative stress, such as radiation and particular chemotherapeutic agents. These changes in PUFA composition are not tumor-specific, raising the concern that this approach might also increase the risk of normal tissue morbidity to these anticancer therapies. However, *in vitro* data suggest that normal cells are relatively unaffected by PUFA enrichment (32,38). Moreover, preliminary data from *in vivo* studies in the pig indicate that the administration of dietary PUFA for up to 16 wk after irradiation significantly reduced the severity of radiation-induced injury to the spinal cord (39).

In summary, the results of the present study indicate that the DHA content of glioma tissue is significantly reduced compared with normal brain tissue. In contrast, LA content is increased in the glioma cells. The net result of this altered PUFA content is likely to be a reduction in the susceptibility of these glioma cells to anticancer therapies which utilize free radical generation and lipid peroxidation pathways to cause tumor cell kill. We hypothesize that manipulating glioma PUFA content by dietary PUFA supplementation offers the promise of selectively increasing the susceptibility of the tumor cells to anticancer therapy. Indeed, intracerebral injections of GLA in glioma patients for 10 d (1 mg/day) after subtotal excision of the tumor, followed by radiotherapy, led to tumor regression and increased patient survival with no evidence of normal tissue toxicity (40). Thus, the addition of PUFA to the clinical armamentarium might lead to an improved therapeutic outcome for what remains an aggressive and often fatal neoplasm.

Increasing Dietary Linoleic Acid in Young Rats Increases and Then Decreases Docosahexaenoic Acid in Retina But Not in Brain

Hui-Min Su, Lisa A. Keswick, and J. Thomas Brenna*

Division of Nutritional Sciences, Cornell University, Ithaca, New York 14853

ABSTRACT: The accumulation of fatty acids in retina, brain, liver, and plasma of 30-day-old rat pups consuming various levels of linoleic acid (LA, 18:2n-6) and constant α-linolenic acid (ALA, 18:3n-3) is reported. Dams were fed graded levels of LA during gestation and lactation, and the pups were maintained on the diet of their dams until the end of the brain growth spurt at 30 d of life. Milk, and pup brain, retina, liver, and plasma were analyzed quantitatively for fatty acid profile. The percentage of docosahexaenoic acid (DHA, 22:6n-3) in retina increased from an LA-deficient dietary level, peaked at the 9:1 (LA/ALA) level, then fell for the 41:1 and 69:1 levels. In contrast, the brain DHA percentage was unaffected by dietary LA levels. Retinal unsaturated fatty acid levels paralleled liver and plasma levels. The milk fatty acid composition mirrored the diets. These data show that the retinal fatty acid composition responds sensitively to dietary fatty acid composition, similar to liver and plasma, while the brain unsaturate composition is nearly independent of dietary composition.

Lipids 31, 1289–1298 (1996).

Polyunsaturated fatty acids (PUFA) are the major components in the membrane structural lipids of neural tissues, particularly the brain and retina, which are rich in docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) (1,2). Most PUFA are deposited in brain and retina during the brain growth spurt, when brain growth exceeds that of other organs (3–5). It is during this period that the dietary demand is highest for essential brain components. Several studies indicate that nutritional deficiency during the brain growth spurt results in lasting impairment of function which is not fully corrected during subsequent periods of repletion (3,6).

The fatty acid (FA) composition of most tissues is related to dietary supply in early development (7–9), although the FA composition of the brain is remarkably constant among free-living species (10). Experimentally, it is difficult but possible to alter the brain FA content. For instance, rats fed a sunflower oil diet with 70% linoleic acid (LA, 18:2n-6) content and 0.1% α-linolenic acid (ALA, 18:3n-3) through four generations exhibited low levels of DHA, and high levels of docosapentaenoic acid (DPA, 22:5n-6) in brain cells and nervous tissues compared with those fed soy oil diet with a more balanced precursor FA concentration (55% LA and 6.7% ALA) (11). Very low dietary levels of the C_{18} parent FA during the brain growth period result in decreased levels of the long-chain PUFA (LC-PUFA), like AA or DHA, which can affect normal visual function and learning ability (12–14).

It has been known for decades that the predominant dietary C_{18} PUFA serve as precursors for desaturation and elongation to LC-PUFA, which are required as substrates for a variety of potent bioactive compounds including the prostaglandins, thromboxanes, and leukotrienes. In addition, LA and ALA are competitive substrates for desaturation and elongation (15–17), and their relative proportion in the diet affects levels of LC-PUFA found in various tissues. For instance, weanling (18) or adult rats (19) fed increasing dietary ratios of LA to ALA show higher tissue levels of DPA and lower levels of DHA. In pregnancy, higher ratios of n-3 to n-6 FA in the maternal diet result in higher concentration of n-3 FA and lower n-6 FA in pup tissues (20,21).

Although the brain and retina are similar tissues close in proximity, nutrient transport from the blood is governed by separate structures. The blood–brain barrier (BBB) helps regulate PUFA uptake and metabolism from the plasma into the brain (22,23). Some inferential information on *in vivo* FA transport across the BBB is available (24,25), although many details remain obscure, while FA transport across the blood–retina barrier (BRB) is poorly understood.

The goal of this study was to isolate the effects of dietary n-6/n-3 ratio from that of varying absolute dietary levels on brain, retina, and liver accumulation of n-3 FA in young rat pups under conditions where ALA is constant and marginally meets dietary requirements (2 g/kg diet) (12), and LA is at deficient (1.4 g/kg diet), normal (16.6 g/kg diet), or very high levels (90, 144 g/kg diet). We hypothesize that in brain, retina,

and liver the accumulation of n-3 series FA is attenuated at high dietary LA/ALA ratio even though the dietary ALA is low but sufficient to meet dietary requirements. We also report the relationship between the dietary fat compositions and n-3 and n-6 deposition in milk and pup tissue.

MATERIALS AND METHODS

Animals. Sprague-Dawley rats were purchased from Charles River Breeding Laboratories (Wilmington, MA) and were housed individually in stainless-steel mesh cages in a room where temperature and humidity were maintained at 23 ± 1°C and 60–70%, respectively, with light from 0800 to 2000. Animals had free access to tap water and food. After the rats were acclimated to the environment, five-week-old female rats were fed an ALA-deficient diet (ALAD) with adequate LA levels for 4 wk to deplete body stores of excess ALA while maintaining reproductive capacity (26,27). The gross composition of this lead-in diet and its FA composition are shown in Tables 1 and 2. Dams were divided into four groups (n = 4/group) assigned to match average body weight in each group but otherwise at random. The nine-week-old dams were switched to experimental diets and bred with chow-fed nine-week-old male rats after checking vaginal smear cell patterns. Conception was confirmed by the presence of vaginal plugs and a smear of vaginal cells to detect the presence of spermatozoa. Pups were weaned to the diet of their dam and maintained on the diets until they were sacrificed at 30 days old.

Diets. The experimental diets were modified from the AIN-76A formulation containing 20% of oil by weight, and made up commercially (Dyets, Inc., Bethlehem, PA). The diet maintained the same nutrition density as AIN-76A. Composition of diets is shown in Table 1. α-Tocopherol (0.2 g/kg; 500 IU/gm) and *t*-butylhydroquinone (TBHQ, 0.02%) were added to oils as antioxidants. The oil blend, energy components, and FA compositions of the four experimental diets are given in Table 2. Safflower oil, a source of LA, linseed oil, a source of ALA, and hydrogenated coconut oil were blended to achieve the desired FA composition. The ALA content of the oils was constant in the four diets while the LA level was varied in order to obtain LA/ALA ratios of 0.6, 9, 41, and 69. The ALA level was about 2 g/kg diet (0.4% of energy) and was sufficient to meet the dietary requirements for rats (12). The dietary LA concentration of groups 0.6, 9, 41, and 69 were 1.4, 16.6, 90, and 144 g/kg diet, respectively. The 0.6 diet is LA-deficient since the LA content is much less than the minimal LA dietary requirement in rats (28). The 9, 41, and 69 diets are referred to as the "replete" diets since they meet requirements for both LA and ALA. A fifth diet was prepared with very low levels of ALA designed as an ALAD diet. It contained sufficient LA (2.6% of energy) to satisfy the minimal requirement in rats (28).

TABLE 1
Composition of Diet Fed to the Different Experimental Groups

Ingredient	g/kg diet
Casein	235
Sucrose	271
Oil[a]	200
DL-methionine	3.5
Cornstarch	176
Cellulose	59
Vitamin E acetate (500 IU/g)	0.2
Salt mix[b]	41
Vitamin mix[c]	12
Choline bitartrate	2.4

[a]Oil was supplied from linseed, safflower, and hydrogenated coconut oil (Dyets Inc., Bethlehem, PA).

[b]Salt mix (mg/kg diet) included calcium phosphate dibasic, 20,600; sodium chloride, 3,050; potassium citrate monohydrate, 9,060; potassium sulfate, 2,140; magnesium oxide, 989; manganous carbonate, 144; ferric citrate, 247; zinc carbonate, 66; cupric carbonate, 12; potassium iodate, 0.412; sodium selenite, 0.412; chromium potassium sulfate 12 H_2O, 22.7 (AIN-76A salt mix DYETS #200000, Dyets Inc.).

[c]Vitamin mix (mg/kg diet) included Thiamin HCl, 7.08; riboflavin, 7.08; pyridoxine HCl, 8.26; niacin, 35.4; calcium pantothenate, 18.9; folic acid, 2.36; biotin, 0.24; vitamin B12, 11.8; vitamin A palminate (500,000 U/g), 9.44; vitamin D3 (400,000 U/g), 2.95; vitamin E acetate 118; and menadione sodium bisulfite, 0.944 (AIN-76A vitamin mixture, DYETS #300050; Dyets Inc.).

Sample collection. At days 10, 15, and 20 post-parturition, dams were anesthetized with ether, and milk was collected after injection of oxytocin. The 30-day-old pups were weighed, anesthetized with CO_2, and decapitated. Blood was collected into a small quantity of iced saline with EDTA as anticoagulant, and plasma separated immediately by centrifugation. The liver and brain were removed quickly, rinsed with iced saline, weighed and wrapped in foil and frozen in liquid nitrogen. Retinas were removed and placed in iced saline before being frozen. All samples were stored under N_2 and kept in a –80°C freezer until analysis.

Lipid analysis. Six pups were randomly chosen from each group for plasma, liver, and brain lipid analysis. For retinal analysis, 2 or 3 pup retinas (4–6 retinas) were pooled as one sample with a total of six samples analyzed for each group to determine the retinal FA composition. Milk and pup tissue lipids were extracted, saponified, and methylated. Briefly, total lipids were extracted from aliquots of tissue homogenate according to the method of Bligh and Dyer (29). The extracted lipids were saponified by adding 0.5N NaOH in 95% methanol solution and heating at 60°C for 10 min. Methanolic boron trifluoride (BF_3, 14%) was added, heated at 100°C for 2 min to yield FA methyl esters (FAME). FAME were removed by adding hexane and saturated NaCl. The purified FAME were taken up in hexane, with methyl heptadecanoate (Me17:0; 99+% pure; Sigma Chemicals, St. Louis, MO) added quantitatively as an internal standard. The mixture was stored under N_2 and kept in a –80°C freezer until analysis. A Carlo Erba (Milano, Italy) 5160 Mega series gas chromatograph (GC) with a J&W (Folsom, CA) DB23 fused silica capillary column (30 m, 0.32 mm i.d., 0.25 μm film) with H_2 as carrier gas was used for FAME samples. The oven was set to ramp from 60 to 255°C with three plateaus over 40 min. The individual FA peaks were identified by comparison of retention times with a standard mixture ("68A", Nu-Chek-Prep,

[a]0.6 group = the ratio of linoleic acid (LA) to α-linolenic acid (ALA) was 0.6 in the diet = LA deficient diet. EFA, essential fatty acid.
[b]9 group = the ratio of LA to ALA was 9 in the diet.
[c]41 group = the ratio of LA to ALA was 41 in the diet.
[d]69 group = the ratio of LA to ALA was 69 in the diet.
[e]ALAD = α-linolenic acid (18:3n-3, ALA) deficient diet.
[f]nd = Not detected; nc = not calculated.

Elysian, MN; "PUFA2", with added 20:3n-9, Matreya, Pleasant Gap, PA). Acceptable chromatographic separation of all FA was verified for all samples. Response factors were derived from the standard mixture and used to calculate relative concentrations. The FA compositions are expressed as weight percentage of total FA from carbon 8 to carbon 22.

Statistical methods. All data are presented as the mean ± standard deviation. Statistical differences among the four groups were determined using analysis of variance (ANOVA). When the *P*-value was significant at the 0.05 level, Tukey's *t*-test was applied pairwise to detect group differences. All statistical analyses were performed using MINITAB for Windows, version 10 (Minitab Inc., State College, PA).

RESULTS

Organ weights. Neither liver nor brain weights were significantly different among the groups, indicating that liver and brain growth in rats are not impaired by the high ratio of LA/ALA. The range of brain and liver weights was 1.40–1.43 g and 3.0–3.7 g, respectively. No gross differences in fertility were observed among dietary groups.

Milk. The FA composition of rat milk at 10, 15, and 20 d postpartum was not significantly different within dietary treatments. We therefore present only the composition of the milk at 10 d postpartum, shown in Table 3. The major n-6 and n-3 FA were LA and ALA, respectively, and were closely related to the maternal diet. The range of ALA was from 0.7 to 1.0% and was not significantly different among the groups, which was consistent with the equivalent dietary content of ALA from 0.9 to 1.1. In contrast, the LA content increased in direct proportion to their abundance in the diet, where LA was 2, 13, 32, and 50%, and the sum of n-6 series FA was 3, 16, 37, and 54% for groups 0.6, 9, 41, and 69, respectively.

Interestingly, there was no significant change in AA among the replete groups, but AA was significantly lower in the 0.6 group. Although the milk ALA concentration was independent of the LA concentration, the desaturation/elongation product of ALA, eicosapentaenoic acid (EPA, 20:5n-3) was observed only in the groups 0.6 and 9 and was below detectable limits in the others, suggesting that the higher LA levels inhibited conversion. DHA levels were significantly lower in the 69 group compared to the 0.6, 9, and 41 groups, although no statistically significant differences were found among the latter three. Taken together, the four groups show a very clear trend as mean DHA percentages drop from 0.37% to trace levels in 0.6, 9, 41, and 69 groups, respectively. This decreasing maternal DHA supply, on a relative basis, may in part be responsible for trends seen in pup tissue DHA percentages.

[g]Sum of n-6 and n-3 series of fatty acids; PUFA, polyunsaturated fatty acids.
[h]UI = unsaturation index = sum of the number of double bond · the percentage of fatty acids.
[i]n-6/n-3 = the ratio of sum of n-6 series fatty acids to sum of n-3 series fatty acids.
[j]LA/ALA = 18:2n-6/18:3n-3 = the ratio of linoleic (18:2n-6) to α-linolenic acid (18:3n-3).
[k]Triene/tetraene (T/T) = essential fatty acids deficiency index = the ratio of mead acid (20:3n-9) to arachidonic acid (20:4n-6).

Liver. Table 4 shows the FA composition of liver from 30-day old rats. The major n-6 FA were LA and AA, while DHA was the primary n-3 FA. The accumulation of PUFA in rat liver was about 52–55% and was not different among the replete groups. As shown in Figure 1, the AA percentage did not change among the replete groups, while DHA dropped in the presence of higher LA/ALA as it was observed to decrease from 15, 12, 6, to 4% among groups 0.6, 9, 41, and 69, respectively. This observation supports the hypothesis that n-6 FA compete for desaturation/elongation with n-3 FA.

The LA level, sum of n-6 or n-3 FA was unchanged between groups 40 and 70. However, a reciprocal accumulation of n-6 and n-3 FA was observed wherein the total n-6 FA increased from 9, 35, to 46% while the n-3 FA decreased from 27, 18, to 8% among groups 0.6, 9, and 41. The 0.6 group contained the greatest percentage of n-3 FA and the lowest percentage of n-6 series of FA. This observation again supports the interaction of dietary LA and ALA levels on the composition of liver FA.

The 0.6 group had significantly lower total PUFA levels than other groups, perhaps due to FA challenge by the inadequate levels of LA in diets. There was no significant difference in the unsaturation index (UI) among the four groups. The triene/tetraene (T/T) value, an essential FA deficiency index, was greater than 0.4 in the 0.6 group, indicating EFA deficiency. It is interesting to note that T/T reflected EFA deficiency under this relatively minor dietary deficiency, even though ALA was present at adequate dietary levels.

Plasma. FA composition of plasma from 30-day-old pups is shown in Table 5. LA and AA were the main n-6 plasma FA as was observed for liver, while DHA was the dominant n-3 FA. There were no significant differences in DHA level or the total amount of n-3 FA among the replete groups, although the 0.6 group showed significantly greater amounts of DHA, EPA, and total n-3 FA. A reciprocal accumulation of n-3 and n-6 FA was observed, in which the total n-3 FA decreased from 19, 6, 5, and 3%, while the n-6 FA increased from 10, 39, 60 to 69% within groups 0.6, 9, 41, and 69, respectively. The PUFA value increased from 29, 45, 64 to 71% among groups 0.6, 9, 41, and 69, respectively.

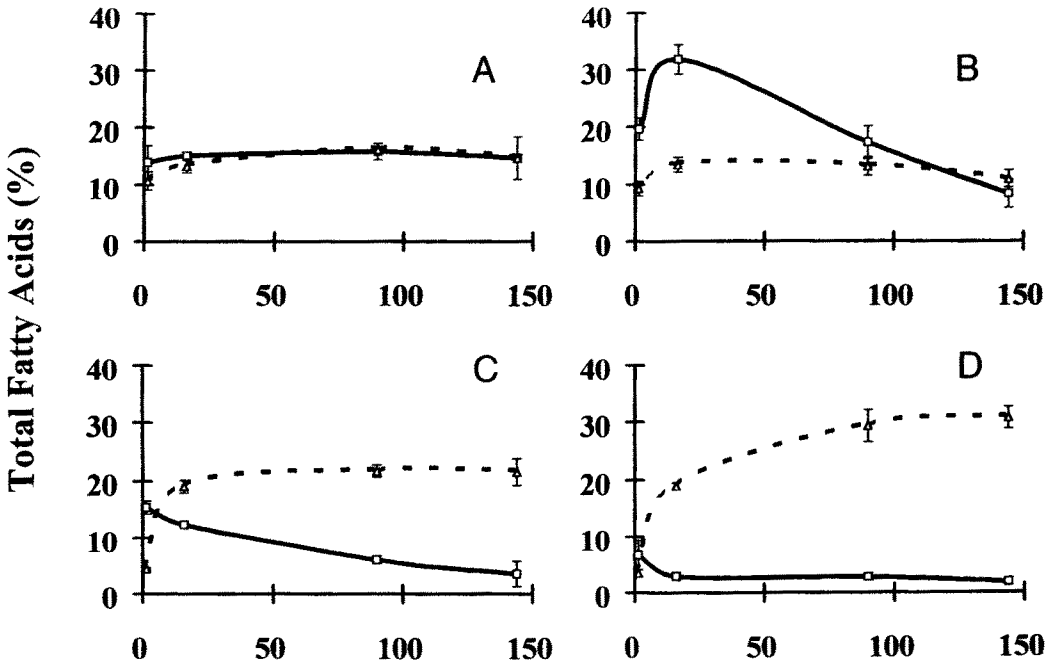

FIG. 1. Effect of increasing dietary linoleic acid (LA) concentrations with constant α-linolenic acid levels on docosahaxaenoic acid (DHA) (——) and arachidonic acid (- - - -) accretion in 30-day-old rat pups (mean ± SD) in (A) brain, (B) retina, (C) liver, and (D) plasma. The retinal DHA level responds sensitively to dietary LA as does liver and plasma, while the brain DHA level is unaffected.

[a]Values are percentage of total fatty acids and expressed as mean ± SD; trace amount less than 0.1% of total fatty acids; nd = not detected. Values with different superscript letters in the same row are significantly different ($P < 0.05$) by using the Tukey's *t*-test. See Table 3 for abbreviations.

Brain. The brain FA composition is presented in Table 6. The two major n-6 FA were AA and DPA, unlike liver and plasma where AA and LA predominate. The primary component of n-3 FA was DHA at 14–16% of total FA and was not affected by increasing dietary levels of LA as shown in Figure 1. There was no significant difference in the sum of n-3 FA. In this regard, the brain FA composition was more resistant to dietary influence than liver or plasma, as expected. The percentage of DPA, sum of n-6 FA, total PUFA, and UI were not significantly different between groups 41 and 69, but were lower in groups 0.6 and 9. No ALA was detected among the four groups. Here, the T/T value was slightly elevated in the 0.6 group, but was well below the 0.4 cutoff for EFA deficiency, suggesting that ALA masked the LA deficiency in the

brain. The AA level was significantly lower in the 0.6 group compared to the replete groups, and increased significantly from the 9 to the 41 group, while the 69 group was not significantly different from either.

Retina. Table 7 shows the FA composition of 30-day-old rat retina. In contrast to the brain, the retina n-3 FA composition responds sensitively to the dietary LA level. The percentage of n-3 FA was 34, 18, and 9% among groups 9, 41, and 69, respectively, corresponding to decreases in DHA from 32, 17, to 8% as shown in Figure 1. The major n-6 FA, AA, as well as DPA and the sum of n-6 FA, did not change in the replete groups but did drop significantly in the 0.6 group. That is, the increasing level of dietary LA did not affect the accumulation of n-6 FA in rat reina; however it decreased DHA accretion. High dietary levels of LA did not cause replacement of DHA by DPA as was observed in other studies (18,19). LA partially replaced DHA at high dietary levels, as the LA content was 1, 2, 3, and 7% among groups 0.6, 9, 41, and 69, respectively. Group 9 contained the highest amount of DHA, AA, PUFA, and UI compared with other groups and, as with the brain, the T/T value was less than 0.1 in all groups.

DISCUSSION

Bourre *et al.* (28) have investigated the effects of increasing dietary LA levels on FA accretion in retina, brain components, and other organs of 21-day-old rats, in a study similar to ours. They report constant AA levels in pup brain and retinas, while DHA dropped at high LA levels. The range of LA/ALA ratios investigated, from about 1 to 10, does not include the much higher levels attainable with common vegetable oils which are investigated here, and which showed substantial divergence between brain and retinal accumulation.

The highest dietary LA level reflecting a ratio of about 69:1 is close to the highest ratio attainable with commonly available oils while maintaining the overall calories as fat at 40%. At the other extreme of LA content, the 0.6 group was the lowest level practicably attainable while maintaining ALA at a constant, adequate level, and below requirements for LA (28). Plasma and liver of the 0.6 group (dietary LA level: 0.3% of energy) had a T/T ratio >0.4, indicating essential FA deficiency (30). The marginally adequate dietary ALA levels were apparently not sufficient to mask the T/T index at this LA intake.

As with all nutritional studies, experimental manipulation of macronutrient levels necessitates changes in absolute and relative amounts of other dietary constituents. Here, the changing LA dietary content was compensated using hydrogenated coconut oil, chosen because it contains no essential FA. Thus, the results may be influenced by the changing saturated FA levels because they are known to have an effect on, for instance, expression of the Δ9-desaturase. This study design permitted isolation of LA/ALA ratio while holding ALA constant. To the extent coconut oil FA effects can be discounted, results may therefore be ascribed to competition of LA with ALA.

Brain and retina DHA profiles differed markedly in their response to increasing dietary LA, as shown in Figure 1. High LA levels did not decrease accretion of brain DHA but had a strong effect on retinal DHA levels. In brain, there were no significant differences between DHA levels in any group, including the n-6 deficient group. Although recent

work suggests that dramatic differences in brain DHA content can be achieved with artificial rearing (31), our data is consistent with previous observations. In contrast, retinal DHA, and the sum of n-3 FA, increased from group 0.6 to group 9 and then decreased linearly in groups 41 and 69. This was the most dramatic difference in FA profiles detected in this study and indicates that the supply or metabolism of DHA differs substantially in these two presumably similar neural tissues.

Many studies show that the brain DHA concentration is resistant to dietary manipulation. Bourre *et al.* (32) pointed out that rat brain DHA was conserved even when dietary ALA is deficient for 7 mon. Arbuckle *et al.* (33) suggested that the quantity of dietary ALA rather than the dietary ratio of LA to ALA played a more important role in the accumulation of DHA in the brain. Anderson (34) demonstrated that the deposition of DHA in the brain was resistant to alterations at the early stage of brain growth spurt by feeding fish oil. Sheaff *et al.* (35) reported that conversion of DHA from ALA was not depressed by feeding high dietary LA level in young rats. Ponder *et al.* (36) showed that the DHA level in infant plasma or red blood cell was constant even in infants fed more ALA.

In contrast to brain, retina FA composition is manipulated by dietary LA/ALA level. The retina showed a maximal DHA level in group 9 and decreased significantly at higher ratios. Group 69 produced a very low retinal DHA content of 8%, which is comparable to the level found in retinal phosphatidylethanolamine of neonatal rhesus monkeys born to mothers fed n-3 deficient diets (37), but greater than the 2.5% of FA in guinea pig retinal phospholipids fed safflower oil through three generations (38). A recent study of formula-fed rat pups with LA/ALA from 0.08 to 10 maintained retinal DHA levels around 20% of total FA, suggesting that the more extreme ratios are required to produce measurable change (39). There is no data as to whether these changes are functionally significant.

In milk, ALA level was not affected by the LA level in the diets. The LA level in milk closely paralleled the level in the replete diets, at the level of about 31% according to linear regression. Since rat liver is an active desaturator, we conclude that the mammary gland takes up FA postprandially from the maternal circulation, probably as nonesterified FA after the action of lipoprotein lipase on circulating chylomicrons or chylomicron remnants. Lipoprotein lipase is active in the mammary gland and could explain the FA source (40), although it is not known if the mammary gland absorbs chylomicrons or remnants. The lower AA level found in the 0.6 group may be an indication of inadequate LA supply impairing function associated with uptake or secretion.

The n-3 FA composition of pup retina and liver was sensitive to the dietary LA level, while brain n-3 FA composition was not. Specifically, DHA accretion was much lower in pup liver and retina in the presence of high levels of dietary LA, while the brain DHA level was independent of LA levels. This result indicates that the retinal supply and/or metabolism of n-3 FA differs from that of the brain, and may more closely reflect liver secretion products. Although the retina is often regarded as a part of the brain, it is well known that the BRB and the BBB have differing permeability to a range of compounds (24,25). Differences in kinetics of essential FA retention and turnover may also explain these observations. The low DHA retina concentration in the 0.6 group is surprising and is evidence that n-6 FA are involved in retinal n-3 FA transport or metabolism.

Although LA and ALA were the dominant n-6 and n-3 FA in milk, AA and DHA were the principal FA in liver, plasma, brain, and retina at 30 d showing the pups have active enzyme systems for essential FA metabolism. For the pups, LA and AA were the primary n-6 liver and plasma FA, while the major n-6 brain and retina FA were AA and DPA, reflecting brain and retinal desaturation/elongation. Mouse brain and liver Δ-6-desaturase activity is highest during the brain growth spurt (41,42).

The dietary ratio of LA to ALA is a determining factor in the accretion of AA and DHA in fetal tissues (43) and infant erythrocytes (44), but thus far there is no clear evidence to indicate an optimal ratio for infant formula. Uauy *et al.* (8,45) proposed that the dietary ratio of total n-6 to n-3 FA should be maintained within a range of 5:1 to 15:1 during brain development. Bourre *et al.* (12) suggested the ratio range from 1 to 6 for rats. Van-Aerde *et al.* (46) emphasized that the dietary LA/ALA ratio and also the absolute level of LA and ALA should be taken into consideration and recommended that a formula range is between 5 to 15 by increasing ALA and decreasing LA content. In our study, a dietary LA/ALA ratio of 9 maintained retinal DHA at its highest levels, but we have no data indicating whether ratios closer to 1, with adequate LA, would increase retinal levels further, or indeed if the highest retinal DHA levels result in optimal function. Current practice for commercial formulas places the ratio of n-6/n-3 around 10 and preterm formulas are now available supplemented with AA and DHA. Further study is required to determine if there is an optimum ratio for human infants.

Ultrasound-Assisted Oxidative Cleavage of Acetylenic and Ethylenic Bonds in Unsaturated Fatty Esters with Potassium Permanganate

Marcel S.F. Lie Ken Jie* and Prabhavathi Kalluri

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong

ABSTRACT: The effect of ultrasound on the oxidation of unsaturated fatty esters was investigated. Unsaturated fatty esters containing acetylenic or olefinic bonds or both were oxidatively cleaved with $KMnO_4$ in aqueous acetic acid ($AcOH/H_2O$, 1:1, vol/vol for olefinic fatty esters and $AcOH/H_2O$, 9:1, vol/vol for acetylenic fatty esters) to yield the corresponding carboxylic acid moieties in quantitative yields, when the reactions were conducted under ultrasound (20 kHz, 53 W/cm^2, 8–15 min). The methyl ester derivatives of the carboxylic acid moieties formed were identified by gas–liquid chromatographic analysis. The procedure constitutes a facile method for the determination of the position of the unsaturated center (olefinic or acetylenic) in an unsaturated fatty ester substrate, especially where the unsaturated system consists of an acetylenic bond.
Lipids 31, 1299–1301 (1996).

Ultrasound has increasingly been used to accelerate diverse types of chemical reactions and has become an established technique in organic synthesis (1–5). During the last few years, a large number of papers have appeared on the use of this technique, and excellent reviews are also available (6–10). In determining the position of an unsaturated center in long-chain fatty acids, oxidative cleavage of the olefinic bond is a common method used. The standard procedure described by von Rudloff (11), which employs sodium periodate in the presence of catalytic amount of potassium permanganate, has been widely used for this purpose. However, this method is not suitable for the determination of the position of a triple bond in acetylenic fatty acids, as a complex mixture of oxidized products is normally obtained (12). Acetylenic bonds are more resistant to oxidation than ethylenic bonds and require more vigorous oxidizing conditions. Even with solutions of permanganate or dichromate, the rate of oxidation of acetylenes is generally low unless certain phase-transfer catalysts (13,14) or solid supports (15) are used. The oxidation of alcohols (16) and arylalkanes (17) by solid $KMnO_4$ under concomitant ultrasonic irradiation has been shown to result in the production of carboxylic acids in high yield. We reason that under ultrasonic irradiation of $KMnO_4$ in a suitable solvent, ethylenic and acetylenic bonds may both be readily cleaved.

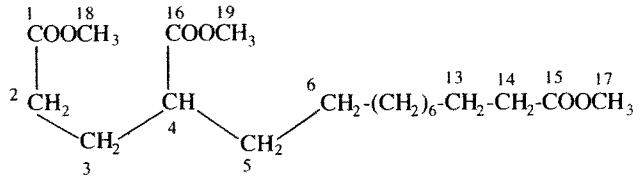
EXPERIMENTAL PROCEDURES



General procedure for the oxidative cleavage of methyl alkenoates as exemplified by the cleavage of methyl oleate (methyl 9Z-octadecenoate). A mixture of methyl oleate (0.21 g, 0.7 mmol), glacial acetic acid (10 cm^3), water (10 cm^3), and $KMnO_4$ (0.85 g, 5.38 mmol) was placed in a water-cooled jacketed glass cell. The reaction mixture was sonicated (Sonoreactor, 20 kHz, 53 W/cm^2, titanium horn; Undatim Ultrasonics, Louvain-la-Neuve, Belgium) for 8 min at 20°C. Aqueous sodium *meta*-bisulfite (10 cm^3, 5 M) was added. The reaction mixture was extracted with Et_2O (3 × 10 cm^3). The ethereal extract was washed with water (10 cm^3) and dried (Na_2SO_4). The filtrate was evaporated, and the residue was methylated by refluxing with BF_3-MeOH complex (14% w/w, 5 cm^3) in absolute MeOH (10 cm^3) for 10 min. Water (20 cm^3) was added to the reaction mixture, and the methyl ester derivatives were isolated by extraction with *n*-hexane (3 × 10 cm^3). The organic extract was washed with brine (5 cm^3) and dried (Na_2SO_4). The filtrate was evaporated under reduced pressure, and the weight of the residue was determined. Gas–liquid chromatographic analysis of the residue showed the presence of methyl nonanoate and methyl nonanedioate.

General procedure for the oxidative cleavage of methyl alkynoates as exemplified by the cleavage of methyl stearolate (methyl 9-octadecynoate). A mixture of methyl stearolate (0.21 g, 0.7 mmol), glacial acetic acid (18 cm^3), water (2 cm^3), and $KMnO_4$ (1.0 g, 6.8 mmol) was sonicated at 20°C for 15 min. Aqueous sodium *meta*-bisulfite (20 cm^3, 5 M) was added. The reaction mixture was extracted with Et_2O (3 × 10 cm^3). The ethereal extract was washed with water (10 cm^3) and dried (Na_2SO_4). The solvent was evaporated and the residue was methylated as described above. Gas Chromatographic analysis showed the presence of methyl nonanoate and methyl nonanedioate.

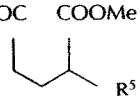
cyclopentenyl) undecanoate]. A mixture of methyl hydnocarpate (0.19 g, 0.7 mmol, isolated from *Hydnocarpus anthelminthica*) (18), glacial acetic acid (10 cm^3), water (10 cm^3), and $KMnO_4$ (0.95 g, 6 mmol) was sonicated at 20°C for 8 min. The reaction product was isolated and methylated as described above to give a triester. The structure of the triester was confirmed by nuclear magnetic resonance (NMR) spectroscopic analyses including two-dimensional ^{13}C-^1H and ^1H-^1H NMR COSY spectroscopy and high-resolution mass spectrometry (HRMS) (Scheme 1).



^1H NMR (δ_H) 1.3–1.6 (CH_2), 2.30 (*t*, J = 7.5 Hz, 14-*H*), 2.44 (*q*, J = 8.3 Hz, 3-*H*), 2.60 (quint., J = 7.9 Hz, 4-*H*), 2.72 (*t*, J = 6.4 Hz, 2-*H*), 3.66 (17-*H*, 18-*H*), 3.67 (19-*H*); ^{13}C-NMR (δ_C) 23.79 (C-5), 24.95 (C-13), 27.71 (C-3), 28.9-29.4, 34.09 (C-14), 37.02 (C-2), 44.74 (C-4), 51.43 (C-17, C-18), 51.75 (C-19), 173.33 (C-1, C-15), 174.30 (C-16); HRMS: $C_{19}H_{34}O_6$ calc. 358.9764; found 358.9777.

RESULTS AND DISCUSSION

Acidified potassium permanganate ($KMnO_4$) is normally used for the oxidative cleavage of alkenes to give the corresponding carboxylic acid moieties, while $KMnO_4$ under basic or neutral condition yields the corresponding diol derivatives (19). Considering the organic nature of the long-chain unsaturated fatty esters, aqueous acetic acid was considered the most suitable solvent system that would provide the required acidic environment in an organic phase for such reactions with $KMnO_4$ to succeed. Various mixtures of acetic acid and water were investigated to achieve the optimum condition. The results of the successful oxidative cleavage reactions of a number of ethylenic and acetylenic fatty esters with $KMnO_4$ in aqueous acetic acid under ultrasonic irradiation are presented in Table 1. A mixture of acetic acid/water (1:1, vol/vol) was used in the oxidative cleavage of the double bonds, while an acetic acid/water (9:1, vol/vol) was required for the successful cleavage of the triple bond in these unsaturated fatty esters. The same reactions conducted in pure (glacial) acetic acid were found to be incomplete even after 30 min of ultrasonic irradiation. The presence of water in the solvent system appeared therefore to be essential. Water is an extremely good conductor of ultrasonic waves and the effects of ultrasonic irradiation cause the reactants to be brought closely together through an efficient mixing or emulsification process. Reactions carried without ultrasonication were also found to be incomplete even after 12 h of stirring at ambient temperature. The need to increase the proportion of acetic acid in the solvent medium for the oxidation of acetylenic fatty esters was likely linked to the solubility of keto intermediates formed during the oxidation process. Also, the reaction time required to achieve complete oxidation of the triple bond in the acetylenic fatty esters was twice (15 min) as long as that needed for the double bond in olefinic fatty esters (8 min). These conditions reflect the higher bond strength of an acetylenic bond over that of an olefinic bond.

Oxidation of methyl oleate and methyl stearolate gave a

mixture of nonanoic acid and nonanedioic acid. These carboxylic acid moieties, as their methyl esters, were readily identified by gas–liquid chromatographic analysis. Oxidation of methyl linoleate furnished nonanedioic acid and hexanoic acid. Succinic acid, one of the oxidation products, was not isolated from the reaction mixture due to its high solubility in water. The olefinic bond in methyl hydnocarpate was readily oxidized to yield a triester on esterification. Oxidation of a synthetic conjugated diacetylenic fatty ester (methyl 9,11-octadecadiynoate) gave heptanoic acid and nonanedioic acid. Oxidation cleavage of methyl santalbate [methyl (11*E*)-octadecen-9-ynoate, isolated from *Santalbum album* seed oil] (20) also furnished heptanoic acid and nonanedioic acid, which inferred the position of the conjugated enyne system between the C-9 and C-12 carbon atoms of the alkyl chain.

When these reactions were repeated under nonultrasound condition, none of these substrates could be completely oxidized in 12 h at room temperature as a complex mixture of products was obtained. The infrared spectrum of the crude products obtained from the nonultrasonic oxidation of methyl stearolate, for example, showed the presence of keto function (1710 cm^{-1}), which was confirmed by ^{13}C-NMR analysis (signal at 210 ppm). Gas chromatographic analysis of the ester derivatives of the product mixture indicated a range of components, which reflected the partial oxidation of the substrate

From the results of these experiments (Table 1), ultrasound-assisted oxidative cleavage of acetylenic and ethylenic fatty esters with $KMnO_4$ in aqueous acetic acid provides a means of determining the position of the unsaturated centers (double or triple bond) in the alkyl chain of the fatty ester.

ABSTRACT: A simple, accurate, and fast procedure for quantitative analysis of fatty acids (FA) in simple lipid subclasses from different biological specimens is presented. Lipid extracts of isolated plasma lipoproteins (very low, low, and high density lipoproteins; VLDL, LDL, and HDL, respectively) and permanent J774 mouse macrophages were fractionated into lipid subclasses by thin-layer chromatography (TLC) on silica gel 60 plates. Bands comigrating with authentic lipid standards were scraped off under argon and subjected to direct, *in situ* transesterification with BF_3/MeOH in the presence of the TLC adsorbent. Fatty acid methyl esters were subsequently quantitated by capillary gas chromatography. A comparison of the FA content present in total lipid extracts and in lipid subclasses separated by TLC revealed recoveries ranging from 93 (J774 cell extracts) to 99.7% (LDL). The method described is applicable for the measurement of FA in individual lipid subclasses and was successfully applied to quantitatively analyze the FA composition of the phospholipid, triacylglycerol, and cholesteryl ester fraction derived from VLDL, LDL, and HDL. In J774 lipid extracts, the FA composition of the phospholipid-, monoacylglycerol-, diacylglycerol-, free fatty acid-, triacylglycerol-, and cholesteryl ester fraction was quantitated. In addition we have analyzed the time-dependent loss of the major HDL polyunsaturated fatty acids (18:2, 20:4) in the phospholipid and cholesteryl ester fraction during copper-dependent peroxidation of HDL. We have not encountered analytical problems concerning low FA recoveries from CE-rich lipid extracts as indicated by almost quantitative recoveries of FA in LDL, HDL, and J774 extracts.
Lipids 31, 1303–1310 (1996).

The determination of free and esterified fatty acids (FA) in different biological tissues and fluids has been the target of numerous investigations (1). The quantitative measurement of the total FA content is a more or less straightforward procedure, provided that some precautions of utmost importance during sample homogenization and extraction are followed (for review see Ref. 2). Usually the FA components of lipids are converted to volatile derivatives prior to gas chromatography (GC) analysis, and methyl esters are the most popular among these although other derivatization procedures are used for special purposes (3). Many conventional methods used for GC analysis of FA derivatives are multistep procedures, involving multiple extraction and evaporation steps. Since these multistep procedures are sensitive to extraction losses, different one-step derivatization techniques improving recoveries of FA have been developed. Among the more commonly reagents used for the single-step formation of fatty acid methyl esters (FAME) are BF_3/MeOH (4,5) and acetyl chloride/methanol (6–9; and citation 14 in Ref. 4). In addition, methods circumventing extraction of lipids have been described for special purposes (10).

In contrast to the procedures described above, analysis of free fatty acids (FFA) present in different biological samples or analysis of the FA composition of different lipid subclasses is more cumbersome. It has been shown that direct procedures using acetyl chloride/methanol or diazomethane as methylating agents resulted in an overestimation of plasma FFA concentrations due to co-transesterification of small amounts of esterified FA (11,12). Therefore, a separate step for isolation of the FFA fraction before subsequent FA analysis was suggested. Lipid subclasses can be fractionated by a variety of different procedures but separation on prepacked solid-phase extraction (SPE) columns or sample fractionation by thin-layer chromatography (TLC) on silica gel 60 is the most commonly used procedure (13,14). When the latter method is chosen, lipids are either eluted from the TLC adsorbent prior to transesterification of the FA constituents (2) or, alternatively, can be transesterified directly on the TLC adsorbent (4). Direct transesterification of lipids on TLC sorbents was described for lipid subclasses obtained from pig liver (15), olive oil (16), spinach (17), human (18), and mouse plasma (12). One of the commonly observed disadvantages associated with this method was insufficient transesterification efficiency of cholesteryl esters (CE) in the presence of silica gel (15), although this problem could be circumvented by elution of CE with $CHCl_3$ prior to transesterification (15) or the use of Lewis acid as transmethylating agents (19,20).

In addition, lipid/silica ratios higher than 4×10^3 were found to result in poor transesterification efficacy (17).

The aim of the present study was an investigation of the applicability of an *in situ* transmethylation procedure of free and esterified FA obtained from lipoprotein and cellular lipid subclasses adsorbed on silica gel 60. Our results demonstrate that the method described is useful for the determination of FA present in simple lipid subclasses obtained from lipoproteins and macrophages. Recoveries were almost quantitative, and we have observed no difficulties with CE-rich samples such as low density lipoprotein (LDL), high density lipoprotein (HDL), or lipid extracts obtained from lipid-laden macrophages. This is reflected by good agreement of the chemical composition of the various lipoprotein classes measured either enzymatically or calculated on the basis of the quantitative FA composition of the different lipid subclasses. The usefulness of the method is further demonstrated by good agreement of the sum of FA found in the individual lipid subclasses and the amount of FA present in the total lipid extracts.

MATERIALS AND METHODS

All organic solvents were of the highest purity available and purchased from Merck (Darmstadt, Germany). Extrelut columns were purchased from Merck. Monopalmitoyl-*rac*-glycerol, 1,2-dipalmitoyl-*sn*-glycerol, 1,3 dipalmitoyl-glycerol, tripalmitoyl-glycerol, phosphatidylcholine, cholesterol, cholesteryl-linoleate, heptadecanoic acid, butylated hydroxytoluene (BHT), and bovine serum albumin were obtained from Sigma (Deisenhofen, Germany). FAME reference mixtures (RM-3, PUFA-1, PUFA-2) were from Supelco (Vienna, Austria). J774 macrophages were obtained from ATCC (Rockville, MI). Dulbecco's modified Eagle's medium (DMEM) was purchased from Bio Whittaker (Antwerpen, Belgium), and fetal calf serum (FCS) was from Gibco (Vienna, Austria). PD-10 size exclusion columns were obtained from Pharmacia (Vienna, Austria). Enzymatic kits for phospholipid (PL), triacylglycerol (TG), CE, and cholesterol measurement were obtained from Boehringer Mannheim (Mannheim, Germany).

Lipid extraction. (i) Plasma lipoproteins. Lipoproteins of different hydrated density were isolated in a Beckman TLX-120 benchtop ultracentrifuge (Vienna, Austria) as described (21). Phosphate buffered saline (PBS, pH 7.4, 3.7 mL) were placed in the tube and underlayered with 1.7 mL of density adjusted plasma (1.24 g/mL, addition of 384 mg of solid KBr/mL plasma). The samples were spun for 2 h at 100.000 rpm (15°C). The very low density lipoprotein (VLDL), LDL, and HDL fractions were recovered by direct syringe aspiration of the lipoprotein bands and desalted by size-exclusion chromatography on PD-10 columns. PL, TG, CE, and cholesterol were quantitated with commercially available enzymatic kits according to the manufacturers' recommendations. Lipoprotein mass was quantitated on the basis of the chemical composition. Lipoprotein lipids (corresponding to 1 mg total lipoprotein) were extracted with $CHCl_3$/MeOH (2:1, Ref. 22), dried under nitrogen and redissolved in 500 µL $CHCl_3$. TLC and *in situ* transesterification were performed as described below.

(ii) Modified lipoproteins. HDL at a concentration of 1 mg total lipoprotein/mL was peroxidized in the presence of 64 µM Cu^{2+} (16 Cu^{2+} molecules/HDL particle) in O_2 saturated PBS. At the indicated time points, 1-mL samples were withdrawn to Pyrex tubes containing 1 mL of water (10 mg/mL EDTA) and 2 mL $CHCl_3$/MeOH, and lipids were extracted. Lipid extracts were concentrated on a TurboVapLV sample concentrator (Zymark, Idstein, Germany). The extracts were redissolved in 200 µL $CHCl_3$/MeOH and subjected to TLC prior to FA analysis of the lipid subclasses as described below. Acetylated LDL (acLDL) was prepared by multiple addition of 20 µL aliquots of acetic anhydride to LDL as described by Basu *et al.* (23).

(iii) Permanent J774 mouse macrophages. Adherent and confluent J774 macrophages (cultured on 75 cm^2 flasks in DMEM containing 10% FCS) were extracted twice with hexane/2-propanol (3:2, vol/vol; 5 mL, 20 min) on a plateau rotary shaker (24). Lipid extracts were dried under nitrogen and redissolved in 500 µL of $CHCl_3$. The protein content of the cellular residue was estimated according to the method of Lowry *et al.* (25). Prior to lipid analysis the cells were washed as described (24).

TLC separation of lipid extracts. To quantitate the FA composition of simple lipid subclasses, 200 or 300 µL aliquots of the lipid extracts originating from VLDL, LDL, HDL, and J774 macrophages were spotted on silica gel 60 plates under a gentle stream of argon. The plates were developed in a solvent system of hexane/diethyl ether (70:30, vol/vol) containing 1% acetic acid. The lipid bands were visualized with iodine vapor. Bands comigrating with authentic standards (≈ 10 µg/lane) were scraped off the TLC plates under an argon atmosphere in a plastic box and further processed as described below.

Preparation of FAMEs. (i) Total lipid extracts. Lipids were extracted from the various biological specimens in the presence of 100 µg heptadecanoic acid as internal standard and 500 µg BHT to prevent lipid oxidation. The organic layers were dried under a gentle stream of nitrogen and transesterified in the presence of 0.5 mL toluene and 1 mL of BF_3/MeOH (20%) at 110°C (90 min). Lipoprotein samples were freeze-dried in the presence of 100 µg internal standard (applied in $CHCl_3$ and dried under N_2) prior to transesterification of the dry residue (10). Excess BF_3 was destroyed by the addition of 2 mL of water and the FAME were extracted into 200 µL of hexane (final volume of the organic phase containing hexane and toluene was about 700 µL). Two µL were analyzed by GC as described below.

(ii) Transmethylation of individual lipid subclasses adsorbed on silica gel. The various lipid subclasses were scraped off the TLC plates and transferred to individual conical screw-capped glass tubes containing 50 µg of heptadecanoic acid and 250 µg BHT. *In situ* transesterification was performed with 0.5 mL toluene and 1 mL BF_3/MeOH in the presence of the TLC adsorbent at 110°C (90 min) without

prior extraction of the lipids. FAME were extracted into 200 μL of hexane, and 2 μL of the organic phase were analyzed by GC as described below.

Analysis of FAME by capillary GC. Separation of the FAME was performed on an HP-20M column (a nonbonded polyethyleneglycol phase; 25 m, 0.35 mm i.d.) using an HP 5890 gas chromatograph equipped with a flame-ionization detector and a split/splitless injector (Hewlett-Packard Co., Vienna, Austria). Helium was used as carrier gas, the split ratio was about 10:1. After an initial isothermal period of 5 min at 150°C, the temperature was programmed to 190°C at 4°/min and then to 215°C at 2°/min, with a hold at 215°C for 15 min. The detector temperature was 300°C; the injector was held at 300°C. Concentrations of the individual FA were calculated by peak area comparison with the internal standard. Data acquisition and calculation were performed with the Waters Millenium Software (Waters, Vienna, Austria). FA recovery was calculated from the amount of FA present in all of the simple lipid classes analyzed, and the FA concentration measured in the total lipid extract [% recovery = ($\Sigma FA_{PL,MG,DG,FFA,TG,CE}$/total FA · 100)]. In addition to these calculations, we have enzymatically measured the chemical composition of the different lipoprotein classes and compared these values with the chemical composition calculated on the basis of the FA content of the PL, TG, and CE fraction.

RESULTS AND DISCUSSION

TLC separation of lipids. Under the conditions described (hexane/diethyl ether, 70:30 containing 1% acetic acid) PL, MG, 1,2-DG, 1,3-DG, FFA, TG, and CE were clearly separated from each other. Only cholesterol and 1,2-DG comigrated in the mobile phase described above. The corresponding R_f values were: 0 (PL), 0.02 (MG), 0.15 (Cholesterol; 1,2-DG), 0.20 (1,3-DG), 0.29 (FFA), 0.61 (TG), and 0.71 (CE).

FA composition of lipoprotein lipid subclasses. The FA composition of total lipid extracts and the main lipid subclasses of autologous (i.e., lipoproteins isolated from the same plasma sample) VLDL, LDL, and HDL is shown in Tables 1–3. The majority of FA in VLDL is confined to the TG fraction, making up nearly 72% (1500 nmol/mg VLDL) of the total FA present in this particular lipoprotein (Table 1). CE and PL contained 9.6 and 18.8% (200.9 and 393.7 nmol/mg VLDL, respectively) of the remaining FA. As can be seen from Table 1, individual FA recovery ranged from 90 (22:6) to 105 (20:4) percentage. The predominant FA found in the PL fraction was 16:0. In the TG fraction 16:0 and 18:1 were the major individual FA while 18:2 was most abundant in the CE fraction. The PUFA/total FA ratio was 0.25:1 in the VLDL sample analyzed.

The FA compositions of LDL and the corresponding lipid subclasses are shown in Table 2. In accordance with the chemical composition of this lipoprotein about 55% of FA were found in the CE fraction (552.3 nmol/mg LDL corresponding to 1380 mol FA/mol LDL), while PL and TG contributed 33 and 13% of the remaining FA (343.4 and 129.1 nmol/mg LDL, respectively, corresponding to 860 and 320 mol FA/mol LDL). The recoveries for most individual FA ranged from 99 to 101%. Although all precautions were taken to avoid inadvertent oxidation of PUFA during sample workup, the recovery for 22:6 (accounting for only 0.7% of total LDL–FA) was lower (87%) compared to the other FA.

The FA content of total lipid extracts and lipid subclasses of total HDL (1.063–1.21 g/mL) was quantitated by GC. The results of these analyses are shown in Table 3. As can be seen from these data, the majority of FA was found in the PL (661 nmol/mg HDL) and CE (274.3 nmol/mg HDL) fraction. Recovery of the major FA was between 96–102%, while recoveries of 16:1, 18:1n-7, and 18:3 (contributing 0.2, 0.6, and 0.1% of total FA, respectively) were 64, 80, and 75%. PUFA (18:2, 20:4, and 22:6) constituted 34 and 63% of FA found in the PL and CE fraction, with 18:2 being the most abundant among PUFA. Overall, the total FA concentrations for VLDL, LDL, and HDL samples obtained during the present study were almost identical with our previous data (10). Furthermore, the percentage FA composition of lipoprotein lipid sub-

[a]Results shown are mean values from duplicate analyses and are given in nmol/mg total lipoprotein.

classes was similar to results published previously (14) where lipid subclasses were separated on NH_2(aminopropyl)-SPE columns.

Table 4 shows the chemical composition of the different lipoprotein samples obtained by enzymatic analysis with commercially available test kits. These data are compared with the chemical composition calculated from the amount of FA found in the corresponding lipid subclasses. The mean molecular masses used for these calculations were 800 (PL), 890 (TG), and 648 (CE), respectively. There was good agreement between measured and calculated values further supporting quantitative recovery of FA after direct transmethylation of simple lipid subclasses adsorbed on silica. For example, the HDL sample contained 25.5, 2.5, and 16.9% (w/w) PL, TG, and CE, in agreement with data reviewed (26). The corresponding calculated values were 26.4, 2.3, and 17.8%, respectively. It is noteworthy that also in the CE-rich lipoprotein samples (with exception of the LDL-PL fraction; 20 vs. 15%) there was good general agreement between enzymatic and calculated values. The difference in the calculated and enzymatically measured PL content of the LDL sample is presently not clear. It might be a reflection of the sphingomyelin content which could be accessible to enzymatic analysis but only partially accessible to BF_3/MeOH transesterification.

We have also analyzed the FA content of the various lipid subclasses in the corresponding human plasma sample (data not shown). In plasma the recoveries of individual FA were in the range of 91 (18:2) to 119 (16:1) percentage. The FFA concentration in the plasma sample was 1.06 mM, in good agreement with other reports (18,27) but higher compared to data reported by Hallaq *et al.* (0.092 mM, Ref. 11).

PUFA consumption during Cu^{2+} mediated lipid peroxidation of HDL. Recent findings have emphasized the role of HDL as the major carrier of circulating lipid hydroperoxides, acting as a sink for these potentially proatherogenic lipids (28). We have been interested in whether *in situ* transmethylation of lipid subclasses might be both a suitable and a simple analytical tool to follow PUFA consumption in the various lipid subclasses during Cu^{2+} initiated lipid peroxidation. At the time points indicated, samples were withdrawn, extracted with $CHCl_3$/MeOH, and PL, TG, and CE were separated by TLC as described in the Materials and Methods section. Silica adsorbed lipids were directly transmethylated, and

[a]Measured enzymatically and calculated on the basis of the fatty acid (FA) composition of the various lipid subclasses; VLDL, very low density lipoprotein; see Tables 1 and 2 for other abbreviations.
[b]Measured enzymatically as indicated in the Materials and Methods section.
[c]Calculation based on the FA composition of the different simple lipid subclasses of the corresponding lipoprotein.

the time-dependent loss of 18:2 and 20:4 was analyzed. PUFA consumption in the CE and PL fraction as a consequence of Cu^{2+} mediated lipid peroxidation is shown in Figure 1. Oxidation of 20:4 started almost immediately after addition of Cu^{2+} without an apparent lag phase. Oxidation of CE and PL associated 18:2 proceeded at somewhat slower rates compared to 20:4 peroxidation. There were, however, almost no differences in the (initial) oxidation rates estimated for the PL and CE fraction (3 and 2.3 nmol $mg^{-1}min^{-1}$). The observation that there is no apparent delay between surface (PL) and core (CE) PUFA oxidation is in line with results obtained during one of our earlier studies (29) where HDL peroxidation was initiated with a peroxyl-radical generating azo-compound (AAPH). In that study (29), lipid extracts were analyzed by HPLC with chemiluminescence detection, and it is noteworthy, that the (relatively) simple equipment (i.e., *in situ* transmethylation of lipids adsorbed on thin-layer adsorbents and subsequent GC analysis of FAME) used in the present study yielded comparable results.

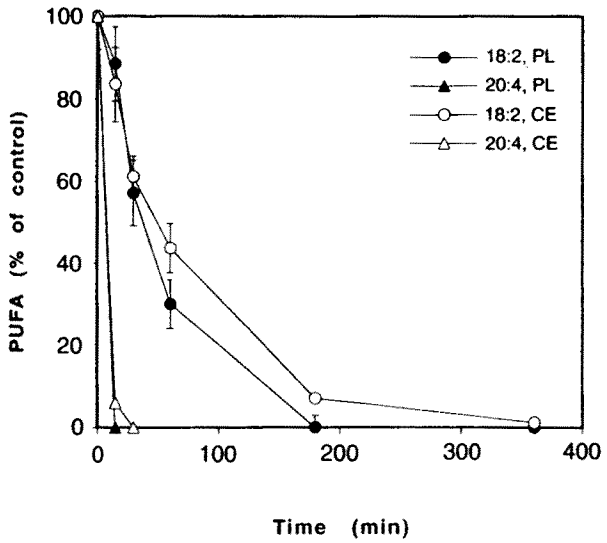

FIG. 1. Loss of high density lipoprotein (HDL)-polyunsaturated fatty acids (PUFA) during Cu^{2+}-mediated peroxidation. HDL at a concentration of 1 mg total lipoprotein/mL was peroxidized in the presence of 64 μM Cu^{2+} (16 Cu^{2+} molecules/HDL particle) in O_2 saturated phosphate buffered saline. At the indicated time points, 1 mL samples of the incubation mixture were withdrawn, extracted as described in the Materials and Methods section and subjected to thin-layer chromatography separation. Phospholipid (PL)- and cholesteryl ester (CE)-fatty acids were transesterified with BF_3/MeOH and analyzed by capillary gas chromatography. Values are given as the mean ± SD from triplicate analysis.

FA composition of J774 macrophages. Oxidation or modification of LDL by reactive lipid peroxidation products is thought to be an initiating event during atherogenesis (30), and evidence from *in vivo* studies suggest that modified LDL is present in atherosclerotic plaques (31,32). J774 macrophages are used in many laboratories to investigate mechanisms leading to the formation of lipid-laden foam cells (32,33). These studies are routinely performed using radioactively labeled lipoproteins. Here we intended to investigate if the method presented allows accurate measurements of differences in the cellular FA composition as a result of modified lipoprotein uptake.

In Table 5 the total cellular FA composition and the FA composition of individual lipid subclasses of J774 macrophages are presented. The majority of FA was found in the PL fraction (222 nmol/mg cell protein, 71% of total FA) with 16:0, 18:1, and 20:4 as the predominant FA (27, 25, and 14% of the total PL–FA, respectively). The FFA fraction in J774 macrophages was almost exclusively constituted by saturated FA, i.e., 14:0, 16:0, and 18:0, and this might reflect the steady-state concentrations of cellular FA synthesis. Calculated on a percentage basis, the FA compositions of PL, MG, DG, TG, and CE were similar. Recoveries for cellular 20:4, 20:5, and 22:6 were somewhat lower (85–92%) as compared to the other FA identified in the same samples (89–107%).

It is a well-known feature of J774 macrophages that they acquire large amounts of intracellular lipid when cultured in the presence of acLDL (33). In line with these observations, incubation of J774 cells in the presence of acLDL (20 mg/75 cm^2) led to remarkable changes in the amount and composition of cellular FA. Cultivation of J774 macrophages in the presence of acLDL increased the amount of total cellular FA from 322 to 633 nMol/mg cell protein (Table 5 vs. Table 6,

TABLE 5
Fatty Acid Composition of J774 Macrophages Cultured in the Absence of Acetylated Low Density Lipoprotein[a]

[b]Not detectable (<100 pMol).

Fig. 2) and this was also reflected by the FA composition of simple lipid subclasses. While PL– and TG–FA increased moderately by 1.4- and 3.7-fold, respectively, the FA content in the CE fraction increased almost 22-fold (7.6 and 210 nMol/mg cell protein, untreated vs. treated cells, respectively, Table 5, Table 6 and Fig. 2). The percentage FA composition of the cellular CE fraction was altered upon incubation of J774 macrophages with acLDL: While 18:0 and 18:1 contributed 15 and 16% in control cells (incubated without acLDL), these FA accounted for 32 and 26%, respectively, in cells incubated in the presence of acLDL. Concommitantly the FA concentration present in the minor lipid subclasses (MG and DG) increased 6- and 13-fold, respectively. In parallel to the increase in FA located in PL, MG, DG, TG, and CE, FFA were decreased by 66% (from 52 to 16.2 nMol/mg cell protein).

A calculation of the absolute increase in FA concentrations observed in the PL, TG, and CE fraction revealed that the increase in cellular FA closely reflected the chemical composition of an LDL particle: The overall increase of 311 nMol/mg cell protein in total cellular FA (Table 5 vs. Table 6) would correspond to an internalization of about 280 µg acLDL. According to the chemical composition of this lipoprotein, an increase by 21, 135, and 180 nMol FA/mg cell protein in the cellular PL, TG, and CE fraction would be expected. In fact we have observed that the FA content in PL, TG, and CE was increased by 39, 95, and 200 nMol/mg cell protein, respectively. These findings suggest that acLDL associated lipids are not very actively metabolized by J774 cells; however, a detailed time course is necessary to clarify this question.

Summarizing our results, we have shown that preseparation of lipid extracts obtained from different biological specimens into the corresponding lipid subclasses by TLC followed by *in situ* transmethylation of lipids adsorbed to silica is applicable to a variety of different analytical topics in the field of lipid/lipoprotein analysis. Under the conditions described, we have not encountered problems with CE-rich samples, best reflected by the high recoveries during HDL

Analysis of Triacylglycerols by Silver-Ion High-Performance Liquid Chromatography–Atmospheric Pressure Chemical Ionization Mass Spectrometry

Päivi Laakso* and Päivi Voutilainen

Department of Biochemistry and Food Chemistry, University of Turku, FIN-20014 Turku, Finland

ABSTRACT: Triacylglycerols of the seed oils rich in α- and/or γ-linolenic acid moieties were separated by silver-ion high-performance liquid chromatography (HPLC) followed by on-line atmospheric pressure chemical ionization–mass spectrometric (APCI–MS) detection. Mass spectra of most triacylglycerols exhibited abundant $[M + H]^+$ and $[M - RCO_2]^+$ ions, which defined the molecular weight and the molecular association of fatty acyl residues of a triacylglycerol, respectively. Silver ions formed weaker complexes with triacylglycerols containing γ-linolenic acid than with those containing α-linolenic acid, i.e., the elution order of molecules was $XYT_\gamma > XYT_\alpha$, $XT_\gamma T_\gamma > XT_\gamma T_\alpha > XT_\alpha T_\alpha$, and $T_\gamma T_\gamma T_\gamma > T_\gamma T_\gamma T_\alpha > T_\gamma T_\alpha T_\alpha > T_\alpha T_\alpha T_\alpha$, where T_α = α-linolenic acid, T_γ = γ-linolenic acid, and X, Y = fatty acids different from linolenic acid. Furthermore, silver-ion HPLC resulted in partial separation within equally unsaturated triacylglycerols according to differences in the combined number of acyl carbons. Regioisomeric forms of triacylglycerols were not determined from the seed oil samples, although differences were measured with reference compounds in the relative abundances of $[M - RCO_2]^+$ ions formed by a loss of a fatty acyl residue from the *sn*-2 position and the *sn*-1/3 positions. Silver-ion HPLC/APCI–MS provided valuable information for structure elucidation of seed oil triacylglycerols: 43 molecular species were identified from cloudberry seed oil, 39 from evening primrose oil, 79 from borage oil, 44 from alpine currant, and 56 from black currant seed oils. The quantitation requires to be studied further, especially in those cases where several molecular weight species of triacylglycerols eluted in a single chromatographic peak.

Lipids 31, 1311–1322 (1996).

Silver-ion chromatography is a practical technique for the separation of triacylglycerols according to differences in unsaturation (reviewed in Refs. 1–4). Previous studies have been performed by thin-layer chromatography (TLC) on silica gel plates impregnated with silver ions. More recent studies are mostly based on high-performance liquid chromatographic (HPLC) separation either on a reversed-phase column (silver ions in the mobile phase) (5) or on a silver-loaded cation-exchange column (6), or on a silver-loaded silica column (7). In general, the separation of triacylglycerols on silver-ion chromatography is based on (i) the number of double bonds in the acyl chains, (ii) the distribution of double bonds between the fatty acyl residues within a single molecule, (iii) the configuration and position of double bonds within a fatty acyl residue, and (iv) the position at which the fatty acid is esterified to the glycerol backbone.

The method introduced by Christie (8), based on separation on a silver-loaded cation-exchange column, has been most widely used and applied to the analysis of various samples, such as seed and vegetable oils (8–11), milk fat (12–14), and fish oils (15–17). The technique has not yet been used for the analysis of samples containing both α-linolenic acid (18:3n-3) and γ-linolenic acid (18:3n-6) moieties in their triacylglycerols, although resolution of ester derivatives of α- and γ-linolenic acids has been reported (18). Few studies of oils rich in γ-linolenic acid have been conducted by silver-ion chromatography, for example, evening primrose oil by silver-ion HPLC (19) and silver-ion TLC (20), and borage oil by silver-ion supercritical fluid chromatography (21). Triacylglycerols of the seeds of the plants belonging to the genus *Ribes* are relatively abundant both in γ- and α-linolenic acids. The composition of black currant seed oil has been studied, for example, by reversed-phase HPLC (22–24), high-temperature gas chromatography (GC) (24), and direct inlet chemical ionization-mass spectrometry (MS) (24,25). Recently, a separation of α- and γ-linolenic acid containing triacylglycerols with an identical number of acyl carbons and degree of unsaturation has been obtained by capillary supercritical fluid chromatography (25). However, the differentiation of co-eluting components was not possible with a flame-ionization detector (FID).

Components separated by silver-ion HPLC are most often detected with an evaporative light-scattering detector (ELSD) or with an FID, which, unfortunately, do not produce structural information on molecular compositions. Therefore, identification of the components has been done either by collection of the separated HPLC fractions and analysis of their

fatty acid compositions as methyl esters by GC, or by comparison of the retention times of unknown peaks with those of reference components. An application of an on-line combination of argentation HPLC, on a silver-loaded silica column, with MS utilizing electrospray ionization has been reported (26). Mass spectra of triacylglycerols exhibited only abundant $[M + Na]^+$ ions without information on fatty acid moieties. Information on both the molecular weights and the fatty acyl residues of triacylglycerols has been achieved by combining reversed-phase HPLC separation with atmospheric pressure chemical ionization–mass spectrometry (APCI–MS) (27,28). Mass spectra of most triacylglycerols consisted of abundant $[M + H]^+$ and $[M - RCO_2]^+$ ions.

The objectives of this study were to apply silver-ion HPLC for the separation of α- and γ-linolenic acid containing triacylglycerols in seed oils and APCI–MS for identification purposes. Chromatographic separation of triacylglycerols containing α- and γ-linolenic acid moieties is essential, because double-bond positional isomers cannot be distinguished as such by MS.

EXPERIMENTAL PROCEDURES

Materials. Oils from the seeds of black currant (*Ribes nigrum*), alpine currant (*R. alpinum*), and cloudberry (*Rubus chamaemorus*) were extracted with supercritical carbon dioxide at Flavex (Rehlingen, Germany). Evening primrose oil (*Oenothera biennis*) and borage oil (*Borago officinalis*) were commercial products purchased from a local health food shop. The oils were dissolved in *n*-hexane, after which the triacylglycerols were purified by elution through a short column of Florisil™ (Fluka Chemie AG, Buchs, Switzerland) with 10 mL *n*-hexane/diethyl ether (4:1, vol/vol). After evaporating the solvent with a stream of nitrogen, the triacylglycerols were dissolved in 1,2-dichloroethane to a concentration of ~10 mg/mL and stored under nitrogen at –20°C. All solvents used were HPLC-grade supplied by Rathburn (Walkerburn, Scotland) or Merck (Darmstadt, Germany). The triacylglycerol standards *rac*-1,2-distearoyl-3-palmitoyl-*sn*-glycerol (*rac*-18:0-18:0-16:0), 1,3-distearoyl-2-palmitoyl-*sn*-glycerol (*sn*-18:0-16:0-18:0), *rac*-1,2-dipalmitoyl-3-oleoyl-*sn*-glycerol (*rac*-16:0-16:0-18:1), 1,3-dipalmitoyl-2-oleoyl-*sn*-glycerol (*sn*-16:0-18:1-16:0), *rac*-1,2-dioleoyl-3-palmitoyl-*sn*-glycerol (*rac*-18:1-18:1-16:0), 1,3-dioleoyl-2-palmitoyl-*sn*-glycerol (*sn*-18:1-16:0-18:1), *rac*-1,2-dipalmitoyl-3-linoleoyl-*sn*-glycerol (*rac*-16:0-16:0-18:2), 1,3-distearoyl-2-linoleoyl-*sn*-glycerol (*sn*-18:0-18:2-18:0), *rac*-1,2-dioleoyl-3-γ-linolenoyl-*sn*-glycerol (*rac*-18:1-18:1-18:3n-6), 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol (*sn*-18:1-18:3n-6-18:1), 1,3-dioleoyl-2-α-linolenoyl-*sn*-glycerol (*sn*-18:1-18:3n-3-18:1), trilinoleoylglycerol (18:2-18:2-18:2), and trilinolenoylglycerol (18:3n-3-18:3n-3-18:3n-3) were purchased from Larodan (Malmö, Sweden).

GC. Fatty acid methyl esters were prepared by sodium methoxide-catalyzed transesterification of the purified triacylglycerol fractions of the seed oils (29). Separations of methyl esters on an NB-351 fused silica capillary column (25 m × 0.32 mm i.d. with 0.20 μm film; HNU-Nordion Ltd., Helsinki, Finland) were conducted with a Varian 3300 gas chromatograph (Limerick, Ireland) equipped with a split injector (split ratio 40:1) and an FID. The temperature program was from 120°C (2 min) with a rate of 3°C/min to 230°C (10 min). The injector temperature was held at 225°C and the detector at 240°C. Helium was used as a carrier gas.

Silver-ion HPLC. Two different HPLC systems were used: (i) a Merck Hitachi L-6200A Intelligent pump (Hitachi, Tokyo, Japan), equipped with an SSI Model LP-21 lo-pulse unit (Scientific Systems Inc., State College, PA), combined with mass spectrometric detection, and (ii) a Shimadzu LC-9A pump (Kyoto, Japan), equipped with a Shimadzu FCV-9AL low-pressure gradient elution unit, combined with an ELSD (Cunow DDL21; Cergy-Saint-Christophe, France).

Silver-ion HPLC was performed according to the procedure introduced by Christie (6,8). A cation-exchange column containing sulfonic acid moieties (ET 250/4 Nucleosil 100-5 SA, 250 mm × 4 mm i.d., 5 μm particle size; Macherey-Nagel, Düren, Germany) was loaded with silver ions. Triacylglycerols in 1,2-dichloroethane (~5 μL) were injected onto the column and separated at ambient temperature using a ternary solvent gradient consisting of A) dichloromethane/1,2/dichloroethane (1:1, vol/vol), B) acetone, and C) acetone/acetonitrile (4:1, vol/vol). The program steps of the linear gradient were: 0 min 100% A; 10 min 50% A–50% B; 30 min 70% B–30% C; 60 min 100% C; 70 min 100% C. The flow rate was 0.8 mL/min. The column was equilibrated for 20 min at the initial conditions before each analysis.

MS. The MS determinations were conducted with a Finnigan MAT TSQ-700 instrument (San Jose, CA) equipped with an APCI source and an ICIS II data system. The MS parameters were optimized for the ionization of triacylglycerols using loop injection technique. During the HPLC–MS analyses, the vaporizer temperature was 400°C, capillary heater temperature 200°C, corona current 5 μA, sheath gas (nitrogen) pressure 50 psi, and auxiliary gas (nitrogen) flow 5 mL/min. Positively-charged ions with *m/z* values of 400–1100 were scanned with a scan time of 0.7 s. The HPLC flow of 0.8 mL/min was introduced into the APCI source without any splitting.

RESULTS

Fatty acid compositions. The samples studied were selected to represent seed oils containing (i) only α-linolenic acid, (ii) only γ-linolenic acid, and (iii) both α- and γ-linolenic acids (Table 1). Cloudberry seed oil was the example of an oil rich in α-linolenic acid (28 mol%). Evening primrose oil and borage oil were the examples of γ-linolenic acid oils. Borage oil contained 22 mol% γ-linolenic acid and evening primrose oil 10 mol%. The proportion of α-linolenic acid in these oils was negligible. The seed oils of black currant and alpine currant contained significant proportions of both linolenic acid isomers. Black currant seed oil contained 14 mol% both

[a]Average of three gas chromatographic analyses of fatty acid methyl esters.

γ-linolenic and α-linolenic acid, whereas the corresponding proportions for alpine currant oil were 9 and 18 mol%, respectively. An additional feature of the seed oils of plants belonging to the genus *Ribes* was the presence of stearidonic acid (18:4n-3). All the oils studied were abundant in oleic acid (9–19 mol%) and linoleic acid (37–72 mol%).

APCI–MS of triacylglycerols. APCI of most triacylglycerols yielded very simple mass spectra exhibiting abundant $[M + H]^+$ and $[M - RCO_2]^+$ ions, which defined the molecular weight and the molecular association of fatty acyl residues, respectively. As reported earlier by Byrdwell and Emken (27) and Neff and Byrdwell (28), the relative abundances of $[M + H]^+$ and $[M - RCO_2]^+$ ions were strongly affected by the degree of unsaturation of a triacylglycerol, e.g., saturated molecules did not produce any $[M + H]^+$ ion, whereas $[M + H]^+$ ion was the base peak in the mass spectra of more unsaturated triacylglycerols (typically the combined number of double bonds in the acyl chains is ≥4). During the optimization of the MS parameters, it was observed that the ionization efficiency of triacylglycerols decreased with increasing capillary temperature. However, the capillary temperature had to be high enough to produce a relatively low and stable signal background. Therefore, the practical capillary temperature, with the instrumentation and eluent composition used, was in the range of 170–200°C. The vaporizer temperature had to be high enough to produce good sensitivity, the optimum being around 400°C.

Silver-ion HPLC/APCI–MS of reference components. It was shown by Nikolova-Damyanova *et al.* (18) that methyl and phenacyl esters of γ-linolenic acid were less retained on a silver-loaded cation-exchange column than those of α-linolenic acid. This let us to suggest that it may also be possible to separate triacylglycerols containing α- and γ-linolenic acid moieties with the technique. Figure 1 shows the separation of 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol and 1,3-dioleoyl-2-α-linolenoyl-*sn*-glycerol by HPLC on a silver-loaded Nucleosil-5 SA column. The interaction of γ-linolenic acid containing isomer with silver ion was weaker than that of α-linolenic acid containing isomer. The components were separated to the baseline with a resolution of 2.7.

The separation of triacylglycerols on silver-ion HPLC was also affected by the regiospecific distribution of fatty acids (*sn*-2 vs. *sn*-1/3) in a triacylglycerol molecule (Fig. 2, Table 2). Isomeric triacylglycerols differing in the position of unsaturated fatty acids were partially separated, whereas sat-

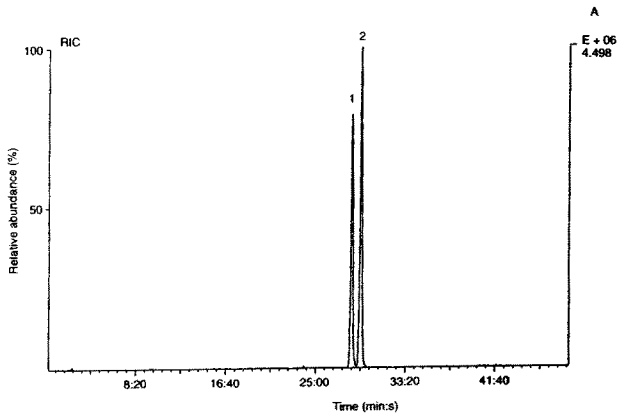

FIG. 1. Separation of 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol (peak number 1) and 1,3-dioleoyl-2-α-linolenoyl-*sn*-glycerol (peak number 2) by silver-ion high-performance liquid chromatography–atmospheric pressure chemical ionization–mass spectrometry. The analytical conditions have been described in the Experimental Procedures section. RIC, reconstructed ion chromatogram.

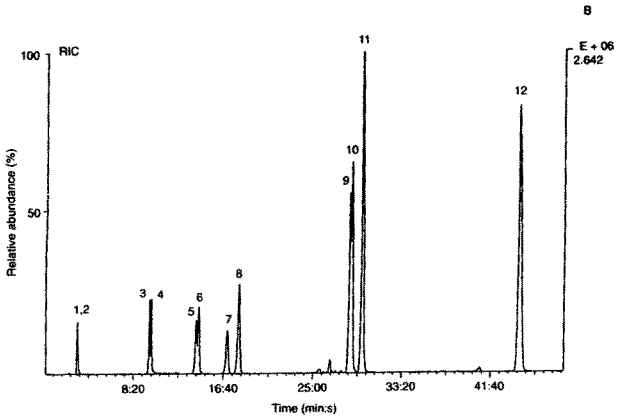

FIG. 2. Separation of triacylglycerols by silver-ion high-performance liquid chromatography according to the regiospecific distribution of fatty acids in the *sn*-2 and *sn*-1/3 positions. Components were detected by atmospheric pressure chemical ionization–mass spectrometry. Analytical conditions have been described in the Experimental Procedures section. Peak identifications: 1 = *rac*-1,2-distearoyl-3-palmitoyl-*sn*-glycerol, 2 = 1,3-distearoyl-2-palmitoyl-*sn*-glycerol, 3 = 1,3-dipalmitoyl-2-oleoyl-*sn*-glycerol, 4 = *rac*-1,2-dipalmitoyl-3-oleoyl-*sn*-glycerol, 5 = 1,3-dioleoyl-2-palmitoyl-*sn*-glycerol, 6 = *rac*-1,2-dioleoyl-3-palmitoyl-*sn*-glycerol, 7 = 1,3-distearoyl-2-linoleoyl-*sn*-glycerol, 8 = *rac*-1,2-dipalmitoyl-3-linoleoyl-*sn*-glycerol, 9 = 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol, 10 = *rac*-1,2-dioleoyl-3-γ-linolenoyl-*sn*-glycerol, 11 = trilinoleoylglycerol, 12 = trilinolenoylglycerol. See Figure 1 for abbreviation.

urated isomers were not separated at all due to the lack of interaction with silver ions. In general, the most unsaturated fatty acid moiety of a triacylglycerol esterified to the *sn*-1/3 position formed stronger interaction with silver ion than that esterified to the *sn*-2 position; for example, 1,3-dioleoyl-2-γ-linolenoyl-*sn*-glycerol eluted slightly earlier than *rac*-1,2-dioleoyl-3-γ-linolenoyl-*sn*-glycerol. With the chromatographic system used in the present study, *rac*-1,2-dioleoyl-3-palmitoyl-*sn*-glycerol had slightly stronger retention to the stationary phase than 1,3-dioleoyl-2-palmitoyl-*sn*-glycerol, thus, being an exception of the general rule. A reverse elution order of these two components or closely related ones has been achieved both by silver-ion TLC (30) and silver-ion HPLC (7,13,31). However, exceptions to the general elution order of isomeric triacylglycerols analyzed by silver-ion TLC has also been reported (30). Various eluent compositions used in separate studies may modify the stationary phase differently, thus, affecting the sample/stationary phase interaction and elution order of molecules. In addition to the regiospecific distribution of fatty acids, the separation also may be affected by differences in the chain length of the esterified fatty acyl residues, as was assumed from the good baseline separation (resolution 3.1) of 1,3-dioleoyl-2-linoleoyl-*sn*-glycerol and *rac*-1,2-dipalmitoyl-3-linoleoyl-*sn*-glycerol. Adlof (32) has recently reported the effect of chain length on the separation of triacylglycerols, diacylglycerol-monoacetates, monoacylglycerol-diacetates, and triacetin.

The regiospecific distribution of fatty acids also had an effect on the mass spectra of triacylglycerols obtained by APCI–MS (Table 2). The abundance of $[M - RCO_2]^+$ ion formed by a loss of a fatty acyl residue from the *sn*-2 position was less than that formed by a loss of a fatty acyl residue from the primary glycerol positions. As an example, the relative abundance of $[M - 16:0]^+$ ion in the APCI mass spectrum of 1,3-dioleoyl-2-palmitoyl-*sn*-glycerol was 8.5% of the abundance of the base peak, and in the mass spectrum of *rac*-1,2-dioleoyl-3-palmitoyl-*sn*-glycerol, it was 69.9%. This confirms the elution order of these regioisomeric triacylglycerols discussed above.

Silver-ion HPLC/APCI–MS of seed oils. Triacylglycerols of the seed oils studied were efficiently separated by silver-ion HPLC/APCI–MS as can be seen from the reconstructed ion chromatograms (RIC) (same as total ion chromatograms) shown in Figures 3 and 4. The analyses of triacylglycerols by silver-ion HPLC combined with ELSD produced very similar separations, differing mainly in the proportions of the separated fractions and, therefore, the ELSD chromatograms are not presented here. The identification of the eluted compo-

nents and their proportions are presented in Table 3 and 4. Almost all the molecular species listed in the tables exhibited both $[M + H]^+$ and $[M - RCO_2]^+$ ions in the mass spectra. Triacylglycerols having together two or fewer double bonds in their acyl chains formed no or only a weak molecular ion and, thus, they were identified mainly according to the ions formed by the loss of one fatty acid moiety. None of the samples analyzed contained significant amounts of saturated triacylglycerols; thus, the first eluted peak without retention to the silver-ion column was possibly due to the presence of carotenoids, especially in cloudberry seed oil. The quantitative estimates of the separated triacylglycerol fractions were based on the peak areas in the RIC (APCI–MS) and in the ELSD chromatograms without corrections according to molecular response factors. In the present study, no attempt was made to estimate the relative amounts of different molecular species eluting in a single chromatographic peak. The proportions of triacylglycerols obtained by the two detection systems were not always in accordance, which was due to variable detector response of different triacylglycerol species. In the following, the analysis of each sample by silver-ion HPLC/APCI–MS will be discussed in more detail.

(i) Cloudberry seed oil. The elution order of the triacylglycerols of cloudberry seed oil, representing an oil rich in α-linolenic acid, was $SSM > SMM > MMM > SMD > MMD > SDD > MDD > SMT_\alpha > MMT_\alpha = DDD > SDT_\alpha > MDT_\alpha >$

[a]Fatty acyl residues: S = saturated, M = monoenoic, D = dienoic, T_α = α-linolenic acid, T_γ = γ-linolenic acid, Te = tetraenoic fatty acid moiety. [b]ACN is the combined number of acyl carbons and n the combined number of double bonds in the acyl chains of a triacylglycerol. [c]The distribution of fatty acyl residues between *sn*-1, *sn*-2, and *sn*-3 positions has not been differentiated. [d]Proportions of triacylglycerols based on mass spectrometric (MS) detection. [e]Proportions of triacylglycerols based on evaporative light-scattering detection (ELSD). [f]The proportion was 23.4% of all peaks in ELSD chromatogram, %ELSD proportions presented here are calculated excluding the proportion of peak 1. [g]The triacylgycerol exhibiting the most abundant $[M + H]^+$ ion in the spectrum has been typed in bold font. [h]n.d. = Not detected or separated. [i]Tentative identification.

$DDT_\alpha \geq ST_\alpha T_\alpha > MT_\alpha T_\alpha > DT_\alpha T_\alpha > T_\alpha T_\alpha T_\alpha$, where S = saturated, M = monoenoic, and D = dienoic fatty acyl residue, and T_α = α-linolenoyl residue (Fig. 3A; Table 3). The elution order was similar to that reported earlier for linseed oil (6) with few exceptions. In the present study, one α-linolenoyl residue formed stronger interaction with silver ion than two linoleoyl residues, resulting in nearly baseline separations of *MDD* and SMT_α fractions, as well as *DDD* and SDT_α frac-

[a]Fatty acyl residues: *S* = saturated, *M* = monoenoic, *D* = dienoic, T_α = α-linolenic acid, T_γ = γ-linolenic acid, *Te* = tetraenoic fatty acid moiety.
[b]ACN is the combined number of acyl carbons and *n* the combined number of double bonds in the acyl chains of a triacylglycerol.
[c]The distribution of fatty acyl residues between *sn*-1, *sn*-2, and *sn*-3 positions has not been differentiated.
[d]Proportions of triacylglycerols based on mass spectrometric (MS) detection.
[e]Proportions of triacylgycerols based on evaporative light scattering detection (ELSD).
[f]The triacylgycerol exhibiting the most abundant $[M + H]^+$ ion in the spectrum has been typed in bold font.
[g]n.d. = Not detected or separated.

tions. Furthermore, $ST_\alpha T_\alpha$ eluted slightly after DDT_α as a shoulder peak, and MMT_α and *DDD* eluted in the same peak. In the case of linseed oil (6), *MDD* co-eluted with SMT_α, and *DDD* co-eluted with SDT_α whereas MMT_α and *DDD* were well separated. Such differences in the elution order of triacylglycerols may be caused by minor differences in the column performance or in the analytical conditions. The most abundant triacylglycerols of cloudberry seed oil, separated by silver-ion HPLC, represented *MDD*, *DDD*, MDT_α, DDT_α, and $DT_\alpha T_\alpha$ fractions. The most abundant molecular species of these fractions were 18:1/18:2/18:2, 18:2/18:2/18:2, 18:1/18:2/18:3n-3, 18:2/18:2/18:3n-3, and 18:2/18:3n-3/18:3n-3, respectively (distribution of fatty acids between *sn*-1, *sn*-2, and *sn*-3 positions is not differentiated). Overall, 43 molecular species of triacylglycerols were identified from cloudberry seed oil.

(ii) Evening primrose oil. The general elution order of the triacylglycerols of evening primrose oil (Fig. 3B; Table 3) was much the same as that for cloudberry seed oil. In addition, evening primrose contained a small *SSD* fraction which eluted between *SMM* and *MMM* fractions. Differences were observed in the retention behavior of triacylglycerols containing trienoic fatty acyl residues. The presence of γ-linolenic acid resulted in co-elution of *MDD* and SMT_γ fractions, and *DDD* with SDT_γ, where T_γ = γ-linolenoyl residue. Furthermore, the MMT_γ fraction eluted before *DDD* + SDT_γ fraction. Comparison of the retention times of the triacylglycerols of evening primrose oil with those of cloudberry seed oil showed that SMT_γ eluted before SMT_α, MMT_γ before MMT_α, SDT_γ before SDT_α, MDT_γ before MDT_α, DDT_γ before DDT_α, $MT_\gamma T_\gamma$ before $MT_\alpha T_\alpha$, $DT_\gamma T_\gamma$ before $DT_\alpha T_\alpha$, and $T_\gamma T_\gamma T_\gamma$ before $T_\alpha T_\alpha T_\alpha$. Thus, triacylglycerols containing γ-linolenoyl residues formed weaker interactions with silver ions than molecules containing α-linolenoyl residues. The general elution profile of the triacylglycerols of evening primrose oil was very similar to that reported by Christie (19). APCI–MS detection allowed achievement of information on the molecular composition of the minor constituents as well; therefore, more components were resolved and identified in the present study (39 molecular species). Identification of some minor fractions was only tentative, because a fraction yielding a similar mass spectrum was identified elsewhere in the chromatogram. Differences in the regiospecific distribution of fatty acyl residues in triacylglycerols as well as the presence of small amount of α-linolenic acid in evening primrose oil may partially explain this observation. In general, molecular species of triacylglycerols containing dienoic fatty acyl residues were typical constituents of evening primrose oil. The most abundant fractions separated by silver-ion HPLC were *SDD*, *MDD*, *DDD* + SDT_γ, and DDT_γ consisting of the most abundant triacylglycerols 16:0/18:2/18:2, 18:1/18:2/18:2, 18:2/18:2/18:2, and 18:2/18:2/18:3n-6, respectively.

(iii) Borage oil. The analysis of the triacylglycerols of borage oil by silver-ion HPLC/APCI–MS (Fig. 3C; Table 3) resulted in a more complex separation compared with evening primrose oil. The main elution order of the triacylglycerols of both γ-linolenic acid oils was similar. An additional feature of borage oil was the presence of $ST_\gamma T_\gamma$ which eluted in the same peak as DDT_γ. Both borage oil and evening primrose oil contained small amounts of triacylglycerols with tetraenoic fatty acyl residues (*Te*), such as *DDTe* and $DT_\gamma Te$. Several of the peaks in the reconstructed ion chromatogram of borage oil showed a deformed peak shape. This was actually caused by partial separation of molecular species within a single peak representing equally unsaturated molecules. In general, the molecules eluted in the descending order of molecular weight, e.g., the elution order of triacylglycerols within the *MMM* fraction (peak number 5) was 60:3 ($[M + H]^+$ ion, *m/z* 969.9) followed by 58:3 (*m/z* 941.9), 56:3 (*m/z* 913.8), and finally 54:3 (*m/z* 885.8). Moreover, the elution order of molecular species was 18:1/18:1/24:1 > 18:1/18:1/22:1 > 18:1/18:1/20:1 > 18:1/18:1/18:1. Similar separations were determined within several other peaks containing saturated and/or monoenoic fatty acid moieties, the chain length of which varied from C_{16} to C_{24} in borage oil. The same phenomenon was also observed with other oils, but to lesser extent. Thus, the separation of triacylglycerols by silver-ion

HPLC is also affected by the chain length of the fatty acyl residues. Adlof (32) has suggested recently that this kind of separation may be due to substrate interaction with the free silanol groups or with the phenylsulphonic acid groups of the stationary phase. The most abundant triacylglycerol fractions of borage oil separated by silver-ion HPLC were *MDD* + SMT_γ, *DDD* + SDT_γ, MDT_γ, and $ST_\gamma T_\gamma$ + DDT_γ. The most abundant molecular species of these fractions were 18:1/18:2/18:2, 16:0/18:2/18:3n-6, 18:1/18:2/18:3n-6, and 18:2/18:2/18:3n-6, respectively. In this study, 79 molecular species of triacylglycerols were identified from borage oil, which shows the high complexity of the sample.

(iv) Alpine currant and black currant seed oils. The RIC of the triacylglycerols of both alpine currant and black currant seed oil (Fig. 4), achieved by silver-ion HPLC/APCI–MS, were more complicated than those discussed above. The triacylglycerols of the currants were separated into 39 peaks, representing molecules from *SSM* (one double bond) to *TTeTe* (11 double bonds). The identification of the molecular species and their proportions are presented in Table 4. Altogether 44 molecular species of triacylglycerols were identified from alpine currant, and 56 from black currant seed oil. The more complex composition of black currant was mainly due to the presence of C_{20} fatty acids in the oil. The elution order of the less unsaturated triacylglycerols of the currants was similar to that achieved with α-linolenic acid and γ-linolenic acid containing oils, i.e., molecules eluted in the order of *SSM* > *SMM* > *SSD* > *MMM* > *SMD* > *MMD* > *SDD* > *MDD*. Both isomers of triacylglycerols containing either one α-linolenoyl or one γ-linolenoyl residue were separated from alpine currant and black currant seed oils. The isomer pairs of SMT_γ–SMT_α, MMT_γ–MMT_α, SDT_γ–SDT_α, MDT_γ–MDT_α, DDT_γ–DDT_α, $MT_\gamma Te$–$MT_\alpha Te$, $DT_\gamma Te$–$DT_\alpha Te$, and $T_\gamma TeTe$–$T_\alpha TeTe$ were well separated so that the molecule containing γ-isomer had a shorter retention time compared with the molecule containing α-isomer. Triacylglycerols with SDT_γ, *DDD*, and MMT_α structures eluted in the same peak which was in accordance with the results achieved with cloudberry, evening primrose, and borage oils. Molecules containing two linolenoyl residues were separated up to three isomers, which eluted in the order of $XT_\gamma T_\gamma$ followed by $XT_\gamma T_\alpha$ followed by $XT_\alpha T_\alpha$, where *X* is a fatty acyl residue different from a linolenoyl residue. The elution order of isomers was $ST_\gamma T_\gamma$ > $ST_\alpha T_\alpha$, $MT_\gamma T_\gamma$ > $MT_\gamma T_\alpha$ > $MT_\alpha T_\alpha$, $DT_\gamma T_\gamma$ > $DT_\gamma T_\alpha$ > $DT_\alpha T_\alpha$, and $T_\gamma T_\gamma Te$ > $T_\gamma T_\alpha Te$ > $T_\gamma T_\alpha Te$. Trilinolenoylglycerols were separated into four isomers which eluted in the order of $T_\gamma T_\gamma T_\gamma$ followed by $T_\gamma T_\gamma T_\alpha$, $T_\gamma T_\alpha T_\alpha$, and finally $T_\alpha T_\alpha T_\alpha$.

Triacylglycerols of both currants consisted mainly of molecules with 52 or 54 acyl carbons. In addition, triacylglycerols with 56 acyl carbons were determined in black currant seed oil, which was in accordance with the determined fatty acid composition (approximately 1 mol% C_{20} acids; Table 1) and other studies (25). The elution profiles of triacylglycerols of black currant and alpine currant seed oils achieved by silver-ion HPLC were very similar as were the molecular species compositions of the separated peaks. However, differences were determined in the relative amounts of triacylglycerol fractions (Table 4). The most abundant triacylglycerols of alpine currant eluted in the fractions representing *MDD*, SDT_γ + *DDD*, MDT_α, and DDT_α molecules. The most abundant molecular species of these fractions were 18:1/18:2/18:2, 18:2/18:2/18:2, 18:1/18:2/18:3n-3, 18:2/18:2/18:3n-3, respectively. The main fractions of black currant seed oil were *MDD*, SDT_γ + *DDD* + MMT_α, DDT_γ + $ST_\alpha T_\gamma$, and DDT_α, and the most abundant molecular species in these fractions were 18:1/18:2/18:2, 18:2/18:2/18:2, 18:2/18:2/18:3n-6, and 18:2/18:2/18:3n-3, respectively. Differences were observed in the proportions of molecules containing α- and/or γ-linolenoyl residues within equally unsaturated triacylglycerols. Alpine currant contained substantially more 18:1/18:2/18:3n-3 (MDT_α, peak number 17) compared with 18:1/18:2/18:3n-6 (MDT_γ, peak number 16), whereas the proportions of these molecular species in black currant seed oil were nearly equal. Similarly, the relative amount of 18:2/18:2/18:3n-6 + 16:0/18:3n-6/18:3n-6 (DDT_γ + $ST_\gamma T_\gamma$, peak number 19) in alpine currant was clearly less than that of 18:2/18:2/18:3n-3 (DDT_α, peak number 20), whereas the corresponding proportions were nearly the same in black currant seed oil. Such differences were expected: the ratio of the proportions of γ-linolenic acid to α-linolenic acid was ~1:1 in black currant and ~1:2 in alpine currant seed oil. Among *DTT* + *DDTe*-molecules, alpine currant contained equal proportions of 18:2/18:3n-6/18:3n-3 + 18:2/18:2/18:4 (peak number 26) and 18:2/18:3n-3/18:3n-3 (peak number 27), whereas the relative amount of 18:2/18:3n-6/18:3n-6 (peak number 25) was substantially low. The corresponding triacylglycerols of black currant seed oil were richer in γ-linolenic acid containing molecules, i.e., 8% $DT_\gamma T_\alpha$ + *DDTe*, 3% $DT_\gamma T_\gamma$ and 4% $DT_\alpha T_\alpha$ according to quantitative estimates produced by APCI–MS.

DISCUSSION

The composition and structure of oils containing γ-linolenic acid are of increasing interest due to their possible positive physiological properties, such as in the treatment of atopic eczema and diabetic neuropathy, and revealing breast pain and premenstrual syndrome (33). The physiological effects of γ-linolenic acid oils have mostly been studied with evening primrose oil and borage oil. The properties of currant seed oils have not been studied intensively, although currants contain significant amounts of γ-linolenic acid and also stearidonic acid, both of which are Δ-6-desaturation products. The medical properties of these oils are due to biochemical molecular reactions, and thus it is important to achieve information on the molecular composition of triacylglycerols. The chromatographic separation of triacylglycerols containing α- and/or γ-linolenic acid moieties is essential, because triacylglycerols containing these fatty acids cannot be distinguished as such by MS detection. In the present study, silver-ion HPLC has been shown to be an efficient method for the sepa-

ration of α- and γ-linolenic acid containing triacylglycerols in complex mixtures. Furthermore, molecular species containing stearidonic acid were determined. The on-line detection of the separated compounds by APCI–MS made it possible to achieve information both on the molecular weight and the molecular association of fatty acids of the triacylglycerol molecular species. The *m/z* values of $[M + H]^+$ ions define unambiguously the number of acyl carbons and double bonds in the molecule. The identification of relatively saturated triacylglycerols may be problematic, because they do not yield any or only a weak $[M + H]^+$ ion. Therefore, the identification of, for example, milk-fat triacylglycerols may be more difficult, and additional information, such as retention time data, will be required. The mass spectra of triacylglycerols achieved by APCI–MS are affected by the structure of the molecule, e.g., the degree of unsaturation and the regiospecific distribution of fatty acids between the *sn*-2 and *sn*-1/3 positions, as well as by the instrumental parameters of the mass spectrometer, such as capillary and vaporizer temperatures. At the present stage of the method, no attempt was made for distinction of regioisomeric triacylglycerols in complex mixtures, although differences were measured in the relative abundances of $[M - RCO_2]^+$ ions formed by a loss of a fatty acyl residue from the *sn*-2 position and the *sn*-1/3 positions of triacylglycerol reference components. The regiospecific analysis of triacylglycerols would require extensive optimization and calibration of the system. The silver-loaded cation-exchange column showed potential to separate, at least partially, unsaturated regioisomeric triacylglycerols by using a ternary solvent gradient. Similar results have been reported earlier using an isocratic eluent system consisting of acetonitrile and hexane (31). It may be possible to separate regioisomers of relatively simple triacylglycerol mixtures with an optimized silver-ion HPLC analysis as reported elsewhere (7). However, the samples of the present study, especially currants, seem to be far too complex for such separation. The quantitative estimates presented in this study were based on uncalibrated systems, i.e., no corrections to the raw data were done according to different response factors of molecular species. The quantitative analysis of triacylglycerols requires to be thoroughly studied. The presence of several molecular species within a single chromatographic peak makes it difficult to quantitate single triacylglycerols. The molecular weights of components eluting in the same peak in silver-ion HPLC may be differentiated according to their $[M + H]^+$; however, a single $[M - RCO_2]^+$ ion may be a fragment formed by a loss of one fatty acyl residue from several molecules. It may be possible to modify the elution system and ionization conditions so that triacylglycerols would yield only abundant ions consisting of the whole molecule without fragmentation. Unfortunately, in such a situation the information on molecular association of fatty acids is lost. Although quantitation may cause difficulties, the on-line detection of triacylglycerols by APCI–MS after separation by silver-ion HPLC provides valuable information for structure elucidation. Mass spectra yield information on both the molecular weight and molecular association of fatty acids of triacylglycerols. Similar data cannot be achieved by GC analysis of fatty acid methyl esters of the collected fractions separated by silver-ion HPLC.

Availability of Arachidonic Acid in Major Phospholipids of Mucosa and the Stomach Wall of Rats

Sigurdur Oli Olafsson and Sigmundur Gudbjarnason*

Science Institute, University of Iceland, IS-107 Reykjavík, Iceland

ABSTRACT: The purpose of this study was to examine the availability of arachidonic acid in phosphatdidylcholine (PC) and phosphatidylethanolamine (PE) of mucosa and the stomach wall of adult male Wistar rats fed a standard diet. There were significant differences in the fatty acid composition of PC and PE between various parts of the stomach. The mucosa had the lowest level of arachidonic acid (20:4n-6) in PC, followed by the corresponding stomach wall or glandular part, whereas the forestomach or the upper part had the highest level of 20:4n-6. The level of 20:4n-6 in PE was identical in gastric mucosa and the stomach wall of both the lower and upper parts. The levels of 18:1n-9 and 18:2n-6 were significantly higher in both PC and PE of mucosa than in the stomach wall. The levels of 16:0 and 18:0 in PC were lower in mucosa than in either forestomach or the glandular part. In mucosal PE, the levels of 18:0 and 22:6n-3 were lower than in forestomach and glandular part. The glandular part had significantly higher level of 16:0 and lower level of 20:4n-6 in PC compared to the forestomach. Conclusions: The arachidonic acid level of PC was significantly different in various parts of the rat stomach, with the lowest level in mucosa, whereas the level of 20:4n-6 in PE was identical in mucosa and stomach wall. These phospholipids had higher levels of saturated fatty acids in the stomach wall than in gastric mucosa.
Lipids 31, 1323–1325 (1996).

The rat stomach consists of three main parts, the forestomach or the upper part, and the glandular or lower part which also contains the mucosa. The upper and the lower parts of the stomach have different structures, and their roles in digestion are different since the lower part contains mucosa but not the upper part. In the forestomach above the limiting ridge, the epithelium is squamous, whereas below the limiting ridge (the body and antrum) it is glandular (1). On the luminal surface of the stomach there is a layer of surface-active phospholipids that render the mucosal surface hydrophobic and resistant to damage induced by luminal acid (2,3). Ulcerogenic substances such as aspirin cause a dissipation of this layer, leading to back-diffusion of acid and mucosal necrosis (4).

The discovery of an association between infection with *Helicobacter pylori* and peptic ulcer disease has stimulated further evaluation of mucosal defense (2). *Helicobacter pylori* release phospholipases and ammonia which have the capacity to attenuate the phospholipid-dependent hydrophobic lining of the stomach and reduce mucosal defenses. The majority of people infected with this bacterium do not, however, develop ulcers, suggesting that differences in mucosal response to infection determine whether or not an ulcer develops (5).

The susceptibility to gastric erosions or ulceration differs in different parts of the rat stomach, with the mucosa being most sensitive to damage. The purpose of this study was to compare the fatty acid composition of major phospholipids, phosphatidylcholine (PC), and phosphatidylethanolamine (PE), in different parts of the stomach. The availability of arachidonic acid was of particular interest since arachidonic acid is the precursor of prostaglandins which have been shown to have the ability to increase the resistance of gastric mucosa to damage (6).

EXPERIMENTAL PROCEDURES

Animals. Male Wistar rats were fed a standard diet (rat and mouse maintenance diet no. 1; Special Diets Services Ltd., Essex, United Kingdom). The diet contained 18.1% of 16:0, 1.6% of 18:0, 13.9% of 18:1n-9, 56.5% of 18:2n-6, and 6.5% of 18:3n-3. Other fatty acids were 0.5% or less of the total fatty acids. The fat content was 2.0% in the diet. The rats were housed in cages, 3–4 rats per cage, and maintained on 12/12 h light–dark cycle with free access to water and food. At the age of 10 mon, the rats were anesthetized with CO_2 and killed by decapitation. The rats were fasted for 18 h but had free access to water before decapitation. The stomachs were removed, opened along the greater curvature, and thoroughly washed with saline.

Lipid extraction. Gastric mucosa from three stomachs was pooled for each experiment. The lower glandular part (antrum and body) was gently scraped, and the mucosal scrapings immediately suspended in 100 mL of a mixture of chloroform/methanol (2:1, vol/vol). Each mucosal fraction was extracted in chloroform/methanol (2:1, vol/vol) for 8 h at room temperature. The solvent fraction was collected, and the precipitate was re-extracted in chloroform/methanol (1:2, vol/vol) for 8 h at room temperature. The procedure was then repeated with chloroform/methanol (1:1, vol/vol). The sol-

Abbreviations: PC, phosphatdidylcholine; PE, phosphatidylethanolamine.

Copyright © 1996 by AOCS Press

vent fractions were combined and evaporated in a rotary evaporator.

Lipid analyses. Parts from three mucosally denuded stomachs were used for each analysis. The upper part of the stomach, the forestomach, was cut from the glandular part along the limiting ridge, and each part was analyzed separately, cut into small pieces in 76 mL of methanol/chloroform/water (2:1:0.8, by vol) (7) and homogenized in a Polytron PTA 10-35 homogenizer (Kinematica, Luzern, Switzerland) for 4 × 10 s. After filtration, a biphasic system was produced by dilution with one volume of chloroform and 0.73% NaCl solution. The lower layer was withdrawn and evaporated in a rotary evaporator.

The lipid extracts from mucosa and the two mucosally denuded stomach parts were dissolved in a small volume of chloroform and separated on silicic acid columns (1.5 × 30 cm) into three major lipid fractions: neutral lipids, eluted with chloroform; glycolipids, eluted with acetone/methanol (8:2, vol/vol); and phospholipids, eluted with methanol. This report describes only the study of the major phospholipids, PC and PE.

The phospholipids contained in the methanol fraction were separated by thin-layer chromatography on prewashed and activated silica gel 60 plates (Merck, Darmstadt, Germany). The developing solvent system consisted of chloroform/ethanol/triethylamine/water (30:34:35:8, by vol). After briefly drying the plates with nitrogen, they were sprayed with 0.01% Rhodamin 6G (Sigma, St. Louis, MO) in water and inspected under ultraviolet light. The phospholipids were identified by comparison with authentic standards and PC and PE bands were then scraped from the plates. The phospholipid fatty acids were methylated with the method of Morrison and Smith (8). Fatty acid methyl esters were analyzed in a Perkin-Elmer 8410 gas chromatograph (Norwalk, CT) equipped with capillary column type DB-255 (30 m × 0.25 mm). The gas chromatograph was fitted with a Perkin-Elmer AS 8300 autosampler. The carrier gas was hydrogen at 1.5 mL/min, and the injector temperature was set at 265°C. The oven temperature was programmed at 3°C/min from 180–210°C and then 210°C steady temperature for 15 min. The detector temperature was set at 265°C (9).

The statistical tests used in the analyses of data were one-way analysis of variance. Data are expressed as mean ± SE for five preparations where mucosa from three rat stomachs were pooled per preparation.

RESULTS

The fatty acid composition of PC and PE in the mucosa and mucosally denuded glandular part and forestomach are shown in Tables 1 and 2. There were marked differences in the fatty acid composition of PC between various parts of the stomach. The mucosa had significantly lower levels of 20:4n-6, 16:0, and 18:0 but higher levels of 18:1n-9 and 18:2n-6 than the denuded gastric wall, both forestomach and the glandular part. There were also significant differences in fatty acid composition of PC between forestomach and glandular parts of the stomach, the level of 16:0 was higher in PC of the glandular part than in the forestomach whereas 20:4n-6 was lower in the glandular part (Table 1).

Others[b]	3.70 ± 1.04	4.55 ± 0.69	3.86 ± 0.64

[a]Values are the means ± SE of five preparations. Three stomachs were pooled per preparation. a, $P < 0.05$ vs. mucosa; b, $P < 0.05$ vs. glandular part.
[b]Fatty acids which are below 0.3% of total fatty acids.

The level of 20:4n-6 in PE was, on the other hand, identical in mucosa and the stomach wall. There were significant differences in the fatty acid profile of PE between various parts of the stomach (Table 2). In the mucosa, the levels of 18:1n-9 and 18:2n-6 were significantly higher and 18:0, 22:5n-3, and 22:6n-3 lower than in both the forestomach and the glandular part. The forestomach had, on the other hand, significantly lower level of 16:0 compared to both mucosa and the glandular part (Table 2).

DISCUSSION

The observations made in this study illustrate that the functionally most active part of the stomach, the gastric mucosa,

22:6n-3	1.17 ± 0.08	2.98 ± 0.20a	3.76 ± 0.14a,b
Others[c]	4.65 ± 0.85	9.01 ± 0.79	9.07 ± 0.81

[a]Values are the means ± SE of five preparations. Three stomachs were pooled per preparation. a, $P < 0.05$ vs. mucosa; b, $P < 0.05$ vs. glandular part.
[b]Derivative of fatty aldehyde.
[c]Fatty acids which are below 0.3% of total fatty acids.

had the lowest level of 20:4n-6 in PC, followed by the corresponding stomach wall or glandular part, whereas the forestomach had the highest level of 20:4n-6. The level of 20:4n-6 was thus lowest where the turnover can be expected to be greatest and reflects the availability of 20:4n-6. The level of 20:4n-6 in PE was, on the other hand, identical in gastric mucosa and the stomach wall of both the lower and upper parts.

The availability of arachidonic acid in gastric phospholipids plays an important role in production of prostaglandins and other prostanoids. The ability of gastric mucosa to resist injury induced by luminal irritants is influenced by prostaglandins. Prostaglandins and nitric oxide influence the various components of mucosal defense: they inhibit acid secretion, stimulate mucus and bicarbonate secretion, elevate mucosal blood flow, and accelerate the healing of ulcers (10). Among the prostanoids are also lipid mediators of inflammation, such as leukotrienes and thromboxane, which may contribute to the pathogenesis of gastric ulcers. *Helicobacter pylori* has been identified as a causative agent in active chronic gastritis, but these bacteria also can produce inflammatory lipid mediators such as platelet-activating factor (11).

The major phospholipids of the stomach wall contained significantly higher levels of satuated fatty acids, 16:0 and 18:0 in PC and 18:0 in PE than in the mucosa. The levels of 18:1n-9 and 18:2n-6 in PC or PE were two to four times greater in mucosa than in the stomach wall. The significance of these differences in fatty acid composition is not known. Low levels of docosahexaenoic acid were observed in PC and somewhat higher levels in PE of both mucosa and the stomech wall. Eicosapentaenoic acid was practically absent in these phospholipids.

Conclusion: The availability of arachidonic acid was markedly different in various parts of the stomach. The level of arachidonic acid was significantly different in PC of the three main parts of the stomach: the mucosa, the underlying glandular part and the forestomach, with the lowest level observed in mucosa. The level of arachidonic acid in PE was, on the other hand, identical in mucosa and the stomach wall.

INTRODUCTION

Fatty Acids and Lipids from Cell Biology to Human Disease

The supplement of this issue of *Lipids* on "Fatty Acids and Lipids from Cell Biology to Human Disease" consists of the proceedings of the 2nd Congress of the International Society for the Study of Fatty Acids and Lipids (ISSFAL). The congress took place on June 7–10, 1995, at the Natcher Conference Center at the National Institutes of Health in Bethesda, Maryland. The scientific program consisted of four plenary sessions, eight symposia, and two workshops. The program was structured to emphasize the basic mechanisms involved in the physiological, pharmacological, and pathological functions and effects of fatty acids and lipids, as well as their clinical effects on growth and development and chronic diseases. The composition of the food supply in terms of fatty acids and lipids, the importance of the appropriate ratio of n-6/n-3 fatty acids, *trans* fatty acids in human milk, and the effects of fat substitutes were also included.

The congress consisted of 77 invited papers and oral presentations selected from the submitted abstracts, and 185 posters. There were two workshops: one on "Maternal Fatty Acid Requirement During Pregnancy and Lactation," and the other on "Dietary Fatty Acids, Carnitine, Mitochondria, and Chronic Disease: The Critical Lifelong Importance of the Weaning Period." The keynote address given by Barton Childs on "The Logic of Disease" focused on individuality, and the first plenary session was on "The Role of Fatty Acids in Gene Expression." This area of research is expanding rapidly and may explain part of the mechanisms by which eicosapentaenoic acid and docosahexaenoic acid have beneficial effects in cardiovascular disease by a decrease in fatty acid synthase mRNA, and in inflammatory and autoimmune disorders (arthritis, ulcerative colitis) by decreasing IL-1β mRNA. The area of inborn errors of metabolism in fatty acid synthesis and degradation is just beginning to claim its proper place, which for so long has been dominated by genetic defects of amino acid metabolism. Major advances have taken place in our understanding of brain function due primarily to improved methods.

The information from the epidemiological studies and our increased understanding of the principal mechanisms involved indicate that it is now timely to begin intervention studies (double blind controlled clinical trials) on the role of fatty acids in the prevention and treatment of coronary heart disease, hypertension, and cancer. Intervention trials are also needed in inflammatory and autoimmune diseases and disorders, such as arthritis, ulcerative colitis, psoriasis, and others.

These proceedings were edited by Norman Salem, Artemis P. Simopoulos, Claudio Galli, and Michel Lagarde, who also served as cochairpersons of the congress, and by Howard Knapp, the editor-in-chief of *Lipids*. The papers from the four plenary sessions are followed by the papers presented at the eight symposia. The editors are grateful to the authors for their prompt submission of the papers, to the reviewers for their diligence in reviewing the manuscripts, and to Dr. Howard Knapp and the editorial office of *Lipids* for their assistance in publishing this special supplement to *Lipids* in a timely manner.

A Logic of Disease

Barton Childs*

Department of Pediatrics, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21287

I was very flattered to be asked to open these proceedings. I know too little about fatty acids and their role in homeostasis, and yet my job is to say something that unifies the program, and, if I'm lucky, something that may come to mind now and then as the meeting goes on. Ordinarily these remarks would be made by one of you, who would distill and present the essence of the field, but your program committee has decided upon an experiment. The title of the meeting is Fatty Acids and Lipids, from Cell Biology to Disease, and the experiment consists of a test of the idea that there are some general rules which, transcending fatty acids and lipids, guide us along the path from cell biology to aberration of any homeostatic system, and that allow us to think synthetically as well as analytically.

When biologists say they seek to learn how things work, they mean first, how structures fit together to form homeostatic devices that integrate to form independent, individual, open systems, and second, how nearly these open systems approximate to the goal of an adapted species. So each gene controlled unit step of homeostasis serves both an individual and an evolutionary purpose, and by virtue of "how they work" in both senses, they determine degrees of congruence of open systems with the environments within which they maintain themselves, reproduce and encounter the rigors of natural selection. That is, however reductionist the study of how things work, be they fatty acids or lipids; whatever is found must fit in with the ideas of natural selection and evolution.

Degrees of congruence implies variable adaptation to include also incongruence, or failure of one or more unit steps of homeostasis to meet demands imposed by the environment. So incongruence, some of which leads to disease, is continuous with congruence, and so its logic must also derive from natural selection and evolution.

Nothing could be more alien to the thinking of most physicians, including those educators who perceive the body as a machine that the doctor fixes when it breaks. No doubt this idea has stimulated some truly spectacular triumphs, attained because medicine has drawn so extensively upon biology to describe proximate causes and to illuminate pathogenesis, even to part a veil beyond which we seem to see a limitless progress wherein the concept of cure is prominently enshrined.

But curiously, in the face of so much success, medical educators are distressed. They wonder how students can surmount the mass of facts. They worry about the withering of the art of medicine in the face of an intervening technology, and they perceive a loss of coherence in the diversity of specialism. These are serious criticisms that imply that a medical student, overwhelmed by the volume of facts as soon forgotten as learned, will in a triumph of training over education, of information over knowledge, succumb to technology for diagnosis and to prescribed routines for treatment.

Efforts to reverse these trends seem to be directed to details rather than to an examination of the metaphor of the machine. But some have begun to recognize a conceptual alternative based on a universal language that embraces all of biology and that has the power of coherence to inform all branches of medicine. It is the language of the DNA, wherein individual ontogenies are expressed in phylogenetic terms. To be reconciled to the environment, each open system draws upon the wisdom of its own genome and its own development, both already adumbrated in the phylogenetic past. This alternative provides a synthetic outlook, offering answers to such questions as why disease exists, specifically who is at risk, and for what and when in a lifetime. And it is in answers to these questions, upon which the machine mentality is mute, that we perceive a basis for attaining a higher goal than that of cure; that of prevention.

How does this language inform a logic of disease that faces squarely the educators' concerns? And how does such a logic comprehend the inborn errors and the complex diseases that are the subject of some of our program?

We might begin by observing that every human being leads two lives. In one we are creators, repositories and transmitters of the genetic variability required to maintain the species, while in the second we use our endowment and our experiences to evolve, through development, an individuality whereby we make our place in the world. In the first we serve the species, in the second ourselves, and in both are found incongruencies that lead to disease. That is because, in serving the species, variability of both genes and culture is engendered in indifference to the welfare of particular individuals. Life at meiosis, wherein are created mutants varying from gains or losses of whole chromosomes to noncoding substitutions, is completely uncoupled from life after fertilization. And while the rules of cultures evolve in consonance with the needs of the societies they serve, they cannot suit every individual. So the incongruencies that lead to disease originate in the need for adaptive variability in both genes and culture.

This idea of incompatibility between phylogeny and cultural evolution is no part of the general lore of medicine and is wanting in the metaphor of the machine, which, in concentrating on pathogenesis and cure, allows us to forget our role as representative of the species to concentrate on that of the cultural self. But that Nature doesn't overlook human nature is demonstrated in predictions about disease that flow from its evolutionary origins, and that furnish the basis for its logic. None of these predictions is anticipated by the machine mentality.

What is predicted? First, since genes control the unit steps of homeostasis and disease results from disadaptive variations of one or more such unit steps, then all disease should be perceived as a consequence of genetic vulnerability, whether of the whole species or of individuals. Such vulnerabilities are popularly known as inborn errors, and their number is constrained only by the number of genes, and the number of disorders they characterize is a property of the manifold ways their effects can be integrated to produce signs and symptoms.

Second, given the extravagance of mutational variety generated at meiosis, there should be a gradient of selective effect maximal at conception and diminishing throughout life, and conversely, we should expect for experiences of the environment a similar gradient, measured in kind, intensity and duration, that is least at conception and increases throughout life; and these gradients should be reflected in the qualities of the diseases that characterize ontogeny and should be demonstrable in the context of the lives of a cohort of conceptuses followed from the beginning until the death of its last member.

Third, the gradient of selective effect together with the qualities of ontogeny predict that when diseases are considered in relation to each other in regard to the complexity of their origins, the time of their onsets and their threat to life and reproduction, there should emerge a pattern of continuity of these properties easily demonstrated in the fates of the cohort of conceptuses.

Fourth, the exuberance of mutational events at meiosis assures numerous mutations for every locus so that genetic heterogeneity should be assumed until shown not to exist. Heterogeneity of provocative experiences is not less to be anticipated.

Fifth, there should be an inverse relationship between selective intensity and gene frequency—and so disease. Genes high in the gradient, and their diseases—usually called "genetic," should be rare, those low in the gradient common and unassociated with disease. In between are genes that are conditional with regard to disease, contributory in some individuals, innocuous in others and often depending upon experiences of the environment.

Sixth, when differences in frequency and expression of disease by sex is not explained by sex-linkage, it may be that one sex is protected by some difference in homeostasis, in which case a greater concentration of risk factors, both genetic and experiential, is expected in affected individuals of the protected sex.

Seventh, the relative contribution to disease of genes and experiences varies reciprocally in populations, depending upon the distributions of both genes and provocative experiences. And, in conformity with the gradient of selective effect, the heritability of disease declines with age at onset.

Eighth, all of these predictions should be fulfilled within diseases no less than between.

And ninth, exceptions exist to all of these rules. Such a remark is saved from banality by observing that each human being, in being unique, is exceptional in some way. And in any case, nature the tinkerer preserves what works regardless of generalizations.

These are all in the nature of hypotheses. What evidence can be adduced to test them? First, the idea of the unit step of homeostasis, or, more familiarly, the inborn error, as a central theme in medicine, is supported in two ways: (i) the classical inborn errors continue to be described at an exponential rate (Fig. 1), and (ii) the idea that any gene is susceptible to mutation is attested by the demonstration of monogenic disease due to abnormality of so many different kinds of gene product, including growth factors, antibodies and cytokines, enzymes, receptors, signal transducers and transcription factors (1,2). In addition, numerous mutants in different constellations are shown to be associated with multifactorial disorders, genes not of overriding authority but contributing each in its unique way to the disruption of homeostasis and leading to diabetes, hypertension, coronary artery disease and so on. Acceptance of these within the rubric of the inborn error is demonstrated in the inclusion in the book *The Metabolic and Molecular Basis of Inherited Disease*, of cancer, congenital anomalies, diabetes, and gout (1). The editors, whose book is already 4600 pages, are aware that in proposing that all disease has a genetic, molecular, and metabolic basis, they have got a tiger by the tail.

Next, the gradient of selective effects is demonstrated in a U-shaped distribution of mortality rates according to age. The causes of death on the two sides of the antimode are different; prepubertal life on the left, adult life and aging on the

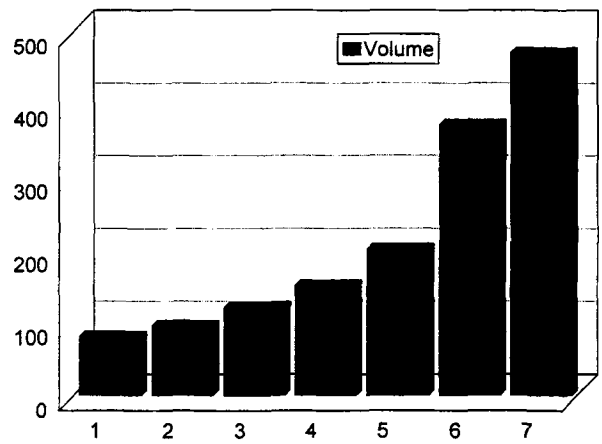

FIG. 1. Classical inborn errors are being identified at exponential rates.

right. Table 1 gives further evidence bearing on these hypotheses. In support of the gradient is the observation that the most burdensome diseases occur early in life. They are the monogenic inborn errors, disorders of high diagnostic specificity, many affected relatives, uninfluenced by social conditions, very resistant to treatment and, significantly, often preventable only by choosing not to have babies or by eliminating the affected fetus. The other column shows the reciprocal position of diseases of adult and late life; multifactorial, genetically more heterogeneous, long latency, lower diagnostic specificity, lesser burden, more responsive to social and temporal change and far more responsive to treatment and, especially, to prevention.

This comparison also brings out the overlap and continuity of disease (Fig. 2). In this hypothetical diagram, the left arm represents the mortality of intrauterine disease; a time of life of little interest to the machine mentality, but at the very core of our understanding of disease. Something like 75% of conceptuses are presumed to have been lost *in utero*. Before birth, most of our cohort is gone, much of it before implantation. That which can be recognized is due to chromosome abnormality (3), but given what we know about meiosis, there should be all sorts of defects of unit steps of homeostasis, engaged perhaps in DNA replication, in the cell cycle, cell division or the control of growth; for example an irrepressible oncogene might do a lot of damage.

So this phase of life is marked by selective purification, but since nature never reaches for perfection, there is overlap, a backwash of abnormality, mostly anomalies, that reach term. Some of these die quickly, but some do not declare themselves until later, if then. For example, an absent kidney might be noticed only in the face of infection, or trauma or not at all.

A second phase is initiated at or before birth when the fetus' efforts to assume metabolic self-control bring out all sorts of inborn errors, and while 95% of these are apparent by puberty, only 1% has onset after age 40 (4). So, while monogenic diseases characterize prepubescent life and multifactorial disorders distinguish later life, the slide shows overlap; monogenic disorders in later life and multifactorial in early life; evidence for both the gradient of selective effect and for the continuity of disease. In addition, the gradient is not exactly monotonic; there is an effect of ontogeny (4). That is, the bulk of the genetic effect is always exerted at the beginning of each developmental phase, that of the environmental effect at the end. For example, mortality at the end of intrauterine life is due to multifactorial anomalies, birth injury, infections, placental imperfection and the like, as opposed to the largely monogenic and chromosomal effects at the start. Similarly monogenic disorders distinguish early post-natal life, accidents and multifactorial disorders distinguish childhood and adolescence, and, while there is some resurgence of genetic effect in adult years, in old age the main contributor to disease is aging itself.

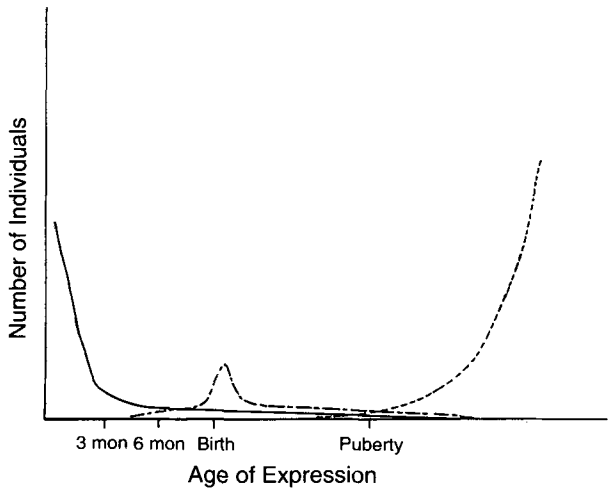

FIG. 2. Causes of mortality characteristic of three different phases of development.

TABLE 1
Differences Between Prepubertal and Postpubertal Diseases

	Prepubertal	Postpubertal
Mode of inheritance	Monogenic	Multifactorial
Age of ofset	Early	Late
Frequency	Rare	Frequent
Latency	Short	Long
Affected relatives	Numerous	Few
Diagnostic specificity	High	Low
Number of diseases	Very many	Fewer
Burden	Great	Less
Sex differences	Occasional	Frequent
Influence of migration	No	Yes
Secular change	No	Yes
Effects of SES	Some	More
Success in treatment	Some	More

The sixth hypothesis suggested that representatives of the sex with the lower incidence should require more provocation to express the disease. This prediction is demonstrated in women with premature heart attacks who, in addition to a higher mortality and strong family history, nearly always have all of the other risk factors, too (5). But once past the menopause, the risk for women is the same as that for men; there has been a decline in heritability (6).

The seventh hypothesis, that the heritability of disease decreases with age, is exemplified in greater secular effects. Prominent among these are the experiences of the Pima Indians of the United States and the Polynesians of Nauru where affluence and Western ways brought into full bloom underlying genetic propensities to type II diabetes and gout among other conditions (7). No doubt there were a few cases of diabetes and gout before Western habits, and no doubt they were strongly familial, but the Western habits played over lesser genetic vulnerabilities and the incidence of the diseases rose. These are cautionary tales. One wonders whether survivors represented in the recent decline in heart attacks among men were those with relatively less genetic variability. The rule is

that preventive measures work best in the least vulnerable, while the most vulnerable are the most resistant.

Figure 3 demonstrates the eighth hypothesis, that all characteristics are present within diseases as well as between. Gout is a disorder with onset from infancy to old age. Degree of familiarity, severity and serum urate levels all decline with age at onset and, when causes are scrutinized, we see among the very young several monogenic, severe, nearly untreatable inborn errors in which urate is over produced (8). In the middle years, classical gout, due to failure in excretion of urate, is strongly familial but generally treatable, and among the elderly are patients taking diuretics for hypertension, still familial but requiring the medication to bring on the symptoms and easily treated by the simple expedient of stopping the diuretic. Better yet, a family history of gout might be a reason not to use the diuretic in the first place. The prevalence of heterogeneity is also illustrated. Gout is a word, not a disease, and a word that loses specificity with age.

Infections and cancer are not excepted in the logic (9). Infections are a result of the actions of two genotypes, each capable of defense against the other. The human defense is massive and, in comparison, static, and vulnerability is represented in numerous inborn errors of the multi-tiered immune system, as well as in perfectly normal elements of homeostasis that become points of weakness to microorganisms whose mutational versatility defines them as such. The position of microorganisms is the reciprocal, a genetic competence to adapt rapidly to the prevailing human defense and to antibiotics, and a practical response to selection in which their "inborn errors," unlike ours, are swiftly disposed of. And cancer is associated with mutants—somatic mostly, but not always—in multiple unit steps of the homeostasis of growth (10). Both fulfill the hypotheses of the genetic gradient, continuity, heterogeneity and so on.

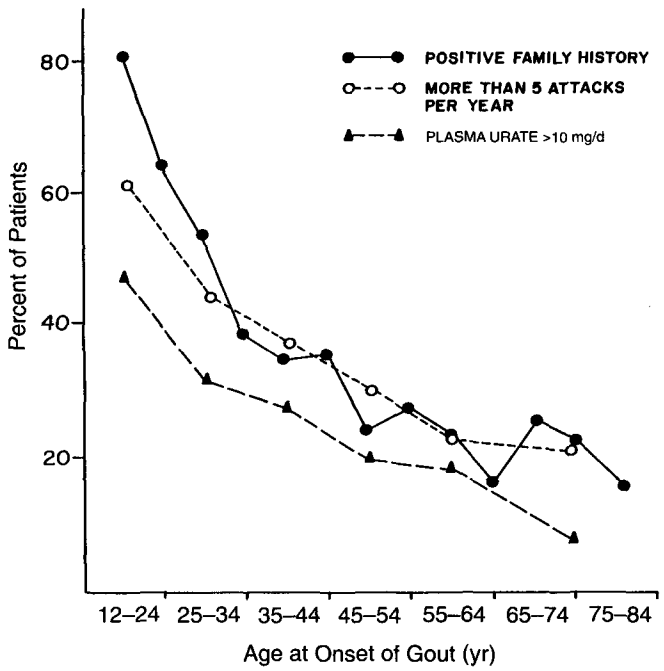

FIG. 3. The severity of gout and its rate of recurrence in families decline with age at onset.

Finally, how is this alternative superior to the metaphor of the machine, the latter having advanced our cause so efficiently? I suggest it is not superior, but inclusive; and in its emphasis on individuality and change during life, it directs our attention to prevention. If we see the body as a machine, we begin with the assumption that one way of fixing the break will do for all, although we move to more individual application when required. In contrast, the alternative begins with the assumption of individuality in both treatment and prevention; one prevention for all is likely to represent privation for the nonvulnerable and to be insufficient for the susceptible. We are told that the genome initiative will reveal everything about our genetic propensities, but until we modify our thinking to include the individuality of both genotype and ontogeny, we shall lack the insight to use the information safely and wisely.

So now the experiment is finished and the time has come when it must bear the pitiless scrutiny of judgment and interpretation. If successful, there may be some reverberations, perhaps distant, in the thinking that will characterize the meeting.

Polyunsaturated Fatty Acid Regulation of Hepatic Gene Transcription

Steven D. Clarke[a,*] and Donald B. Jump[b]

[a]Division of Nutritional Sciences, Department of Human Ecology, University of Texas–Austin, Austin, Texas 78712-1907 [b]Department of Physiology and Biochemistry, Michigan State University, East Lansing, Michigan 48824-1101

ABSTRACT: Polyunsaturated fatty acids (PUFA) of the n-6 and n-3 families inhibit transcription of a number of hepatic lipogenic and glycolytic genes, e.g. fatty acid synthase. In contrast, saturated and monounsaturated fatty acids exert no suppressive action on lipogenic gene expression. The unique PUFA regulation of gene expression extends beyond the liver to include genes such as adipocyte glucose transporter-4, lymphocyte stearoyl-CoA desaturase 2, and interleukins. Some of the transcriptional effects of PUFA appear to be mediated by eicosanoids, but PUFA suppression of lipogenic and glycolytic genes is independent of eicosanoid synthesis and appears to involve a nuclear mechanism directly modified by PUFA. With the recent cloning of a fatty acid–activated nuclear factor termed peroxisome-proliferator–activated receptor (PPAR) has come the suggestion that PPAR may be the PUFA response factor. This review, however, presents several lines of evidence that indicate that the PPAR and n-6 and n-3 PUFA regulation of lipogenic and glycolytic gene transcription involve separate and independent mechanisms. Thus PPAR appears not to be the PUFA response factor.
Lipids 31, S-7–S-11 (1996).

Several different disease states, including atherosclerosis, noninsulin-dependent diabetes (NIDDM), and certain types of cancer, have been linked to type and amount of dietary fat (1–4). Dietary fats appear to influence the onset and progression of these various diseases by exerting an effect at two levels: (i) altering fatty acid composition of membrane phospholipids (1,5,6) and (ii) regulating nuclear events that govern gene transcription (7–12). Thus the beneficial (e.g. reduced blood triglycerides) as well as detrimental (e.g. impaired glucose tolerance) effects that dietary fats exert on various diseases may involve a combination of interactive regulatory mechanisms, i.e. rapid and direct fatty acid regulation of gene transcription accompanied by long-term adaptive modulation of membrane composition leading to changes in hormone signaling. The role of membrane phospholipid fatty acid composition in hormone signaling and receptor activity has been extensively reviewed (5,6), but the notion that fatty acids rapidly and directly alter transcription of specific genes is a recent discovery. For this reason, this review focuses on the effects that dietary n-6 and n-3 fatty acids exert on gene expression.

Polyunsaturated fatty acid (PUFA) regulation of gene transcription. The unique regulatory nature of dietary polyunsaturated fats was first observed by Allmann and Gibson (13) who discovered that within 2 d of adding 2% 18:2n-6 to a high-carbohydrate, fat-free diet for mice, the rate of hepatic fatty acid biosynthesis and the activities of fatty acid synthase (FAS), malic enzyme, and glucose-6-phosphate dehydrogenase were depressed by 70%. In contrast, supplementing the carbohydrate-rich diet with palmitate or oleate had no effect on hepatic lipogenesis or activities of lipogenic enzymes. Over the past 25 years, several investigators demonstrated that dietary polyenic fatty acids of the n-6 and n-3 fatty acids suppress hepatic lipogenesis, whereas saturated and monounsaturated fatty acids have no inhibitory capabilities (7,8,10,11,14–29). This action of n-6 and n-3 fatty acids is independent of carbohydrate intake (16,25,27,28) and occurs at a level of fatty acid intake that is four- to five-fold greater than that needed to fulfill the essential fatty acid requirement for optimal growth (28).

This well-documented suppression of hepatic *de novo* fatty acid biosynthesis by dietary n-6 and n-3 PUFA reflects the unique ability of these fatty acids to reduce hepatic activities of enzymes in the fatty acid biosynthetic pathway (30). Such suppression of enzymatic activities does not represent a fatty acid–mediated impairment in enzyme catalytic efficiency (e.g., fatty acyl-CoA inhibition of acetyl-CoA carboxylase), but rather reflects a decrease in hepatic enzyme content caused by a PUFA-mediated suppression of enzyme synthesis (28). A clearer understanding of how n-6 and n-3 PUFA decrease

enzyme synthesis came in 1990 when Clarke and associates (10) demonstrated that PUFA decreased hepatic FAS mRNA levels by inhibiting the rate of gene transcription (7,8,11,12).

The transcriptional response to dietary PUFA is very rapid (10,29). For example, supplementing a high-carbohydrate, fat-free diet with 5% (w/w) menhaden oil results in a 60% suppression of transcription for the FAS, pyruvate kinase, and S_{14} genes in <3 h (29). Moreover, removal of PUFA from the diet leads to a rapid (<3 h) induction of gene transcription (10). Such a rapid response strongly suggests that PUFA directly modulate gene transcription rather than exert their influence by modifying membrane lipid fatty acid composition and altering hormone release or signaling. In support of this conclusion, we have found that hepatic insulin signaling mechanisms are not different in rats fed polyunsaturated fat (i.e., safflower oil) or saturated fat (i.e., tallow) (28). Moreover, selective control of lipogenic gene expression can be recreated with hepatocytes in monolayer culture, which eliminates from consideration modifications of hormone release (7,29).

Since the discovery that n-6 and n-3 PUFA suppress transcription of the hepatic FAS gene, several additional hepatic and nonhepatic genes were found to be transcriptionally regulated by PUFA. For example, dietary n-6 and n-3 PUFA suppress transcription of several lipogenic genes, including acetyl-CoA carboxylase (21,22), glucose-6-phosphate dehydrogenase, malic enzyme (23,25), and stearoyl-CoA desaturase 1 (33), also 20:4n-6 and 20:5n-3 are potent inhibitors of glycolytic gene expression (29). While dietary fat suppression of lipogenic and glycolytic genes is a specific response to n-6 and n-3 PUFA, both monounsaturated and PUFA appear to be able to induce genes coding for peroxisomal genes, notably acyl-CoA oxidase (34). Induction of the acyl-CoA oxidase gene, however, is greater with dietary fish oils than with dietary corn oil (Clarke, S.D., and Jump, D.B., unpublished data). It remains to be determined if this greater responsiveness to fish oil is due to the high amount of 20/22-carbon PUFA, or if it is something specific for n-3 polyenoic fatty acids. Induction of peroxisomal genes and the accompanying peroxisomal proliferation may explain the thermogenic response that results from feeding rats high-PUFA diets.

Recently, PUFA inhibition of gene transcription was found to extend to adipocytes (35) and mouse lymphoma cells (36). In preadipocytes, n-6 PUFA accelerated fat cell differentiation and induced genes of terminal fat cell differentiation such as the adipocyte fatty acid binding protein (37–40). In mature fat cells, however, 20:4n-6 suppressed expression of insulin-sensitive glucose transporter-4 while increasing expression of glucose transporter-1 (35). This effect of 20:4n-6 on adipocyte glucose transport extends to 20:5n-3 (Pekala, P.H., personal communication). Thus a logical extension of these observations is that diets high in 20:4n-6 or 20:5n-3 may lead to an impairment of insulin-dependent glucose uptake in adipose tissue and thereby exacerbate NIDDM. Clearly, PUFA exert a very unique influence of gene transcription in a number of different cell types, which may explain the numerous beneficial as well as detrimental effects attributed to various dietary fats.

Structural characteristics of a PUFA inhibitor. Unfortunately, the specific fatty acid mediator responsible for regulating gene transcription is unknown. Analyses of double-bond positioning and configuration, however, have yielded some insight into the nature of the PUFA inhibitor. First and foremost, an inhibitor fatty acid must contain two double bonds, and these must be positioned between carbons of 9–10 and 12–13 of an 18-carbon fatty acid (28). Dieneoic fatty acids (i.e., 5,13–22:2) without this positioning are ineffective as transcriptional inhibitors (28). In addition, at least one of these double bonds must be *cis*, but the other can be in the *trans* configuration (28). Such structural requirements for an inhibitory fatty acid suggested that the PUFA inhibitor may be an eicosanoid. Numerous studies with a wide array of eicosanoid inhibitors, however, have failed to prevent PUFA suppression of lipogenic gene expression (18,31,32). Interestingly, supplementing the arachidonic acid analogue, eicosatetraynoic acid (ETYA), to a diet containing corn oil or 18:2n-6 prevented PUFA suppression of lipogenic genes (15,25,32), but feeding 20:4n-6 with ETYA reinitiated PUFA suppression of fatty acid biosynthesis (32). An examination of hepatic fatty acid composition indicated that ETYA suppressed Δ6 desaturase activity. Thus, in addition to requiring double bonds at carbons 9 and 12, it appears that a double bond must also be introduced at position 6 of an 18-carbon PUFA (15,25,32). It remains unclear, if Δ5 desaturase activity is essential for the PUFA effect.

Inhibitory potency of n-9, n-6, and n-3 fatty acids. Saturated and monounsaturated fatty acids have little or no capacity to suppress expression of hepatic lipogenic and glycolytic genes (28). In fact, under some conditions, monounsaturated and saturated fatty acids have been found to enhance expression of genes encoding lipogenic enzymes (7,16). This stimulatory response may be due to a competitive action of the noninhibiting fatty acid with the suppressive PUFA metabolite.

Opinions vary with respect to the relative antilipogenic potency of n-6 and n-3 fatty acids. In general, 18:2n-6 and 18:3n-3 are equipment suppressors of FAS, glucose-6-phosphate dehydrogenase, and malic enzyme gene expression (16). Menhaden oil, however, suppresses hepatic FAS expression two to three times more effectively than does safflower oil (28). The greater potency of fish oil is observed as a two-fold greater maximal suppression of FAS activity and as a threefold lower requirement for fish oil to achieve 50% maximum inhibition (28). In addition, fish oil is a far more potent inducer of hepatic peroxisomal acyl-CoA oxidase expression than is corn oil (Clarke, S.D., Turini, M., and Jump, D.B., unpublished data). Moreover, fish oil induction of acyl-CoA oxidase extends to several nonhepatic tissues, while corn oil appears to have little impact on acyl-CoA oxidase expression in nonhepatic tissues (Turini, M., and Clarke, S.D., unpublished data). A further difference between fish oil and vegetable oil lipids is that fish oil markedly suppresses expression of hepatic pyruvate kinase, while vegetable oils rich in 18:2n-6 fatty acids appear to only minimally impair glycolytic gene expression (10, 12). These differences in gene responsivity may suggest

that transcriptional regulatory mechanisms vary among various affected genes. To partially address this question, we compared the relative potency of 20:4n-6 with comparable levels of 20:5/22:6n-3 supplied by fish oil (28). Interestingly, fatty acid synthase expression was equally reduced by 20:4n-6 or fish oil (28). Thus, the greater inhibitory effectiveness of fish oil over vegetable oils is in part due to the presence of 20/22-carbon PUFA in the fish oil. It remains to be determined, however, if pyruvate kinase and acyl-CoA oxidase are equally responsive to dietary 20:4n-6 and 20:5n-3.

The differential response of pyruvate kinase and FAS to 18:2n-6, and presumably 18:3n-3, vs. the fatty acid products of Δ6 desaturase may have significance for dietary recommendations. Dietary oils rich in 18:2n-6 may suppress hepatic lipogenesis and lower hepatic triglyceride production, but because 18:2n-6 is less effective as a suppressor of glycolytic enzyme expression, hepatic glucose metabolism may continue and lead to an increased substrate availability for ketone synthesis. Such a feature is clearly undesirable in an NIDDM subject. Conversely, fatty acid products of Δ6 desaturase appear to coordinately suppress glycolytic and lipogenic genes. In this way, hepatic glucose oxidation may be reduced, but the glucose may be repartitioned into hepatic glycogen synthesis (3). Thus both 20:4n-6 and 20:5n-3 may potentially function equally well as fuel-partitioning agents in modulating hepatic glucose metabolism and improving the NIDDM condition.

PUFA-response region and possible PUFA-responsive transcription factors. While the identity of the fatty acid effector has not been established, significant progress has been made in localizing potential *cis*-acting elements affected by dietary PUFA. Using transfection analysis, Jump and associates (11,12,41) demonstrated that polyenoic n-6 and n-3 fatty acids suppressed chloramphenicol acetyltransferase expression in cultured rat hepatocytes that were transfected with vectors containing –4315 to +19bp and –4300 to +12 b.p. of the S_{14} and pyruvate kinase genes, respectively. Additional 5′-deletion studies revealed that the PUFA-response region mapped to sequences located at –220 to –80 b.p. and –197 to –96 b.p. of the S_{14} and pyruvate kinase genes, respectively (11,12). Using linker scanner mutation analysis, the precise PUFA- response sequence was determined to be located in the LS-4 (–143 to –135 b.p.) and LS-5 (–130 to –123 b.p.) regions of the pyruvate kinase promoter (12). Interestingly, these regions are part of the site thought to mediate the insulin/carbohydrate induction of transcription for the pyruvate kinase and S_{14} genes (11,42). In light of this observation, it is interesting to speculate that PUFA may mediate its suppressive effects on lipogenic and glycolytic gene expression by interfering with the nuclear action of the insulin-signaling cascade. Such a PUFA/insulin interaction, however, may not be universal because the FAS gene also contains an insulin/carbohydrate response region in its proximal promoter (43), but PUFA do not regulate FAS gene transcription at this site (Clarke, S.D., Turini, M., Jump, D.B., and Thelen, A., unpublished data).

Because of the rapidity with which dietary PUFA suppress transcription of lipogenic and glycolytic genes, we proposed that PUFA may be a ligand for a specific nuclear transcription factor that functioned as a dominant-negative suppressor of gene transcription (28,30). Our concept of a PUFA-binding protein was strengthened by the discovery and cloning of a family of nuclear transcription factors termed peroxisome-proliferator–activated receptors (PPAR) (39,44–50). PPAR are members of the steroid-like receptor superfamily and are located in the nucleus of a number of tissues, including the liver and adipocytes (44–50). Activators of PPAR include a diverse group of compounds such as amphipathic carboxylates, herbicides, plasticizers, and most importantly fatty acids (39,44–50). Interestingly, peroxisomal-proliferating agents, such as clofibrate, reportedly suppress expression of FAS and inhibit hepatic lipogenesis (34). Moreover, the time course for induction of the peroxisomal enzyme acyl-CoA oxidase by clofibrate is comparable to that for suppression of FAS expression (34). Collectively, these data led many investigators to suggest that PPAR is the *trans*-factor responsible for mediating the fatty acid regulation of gene transcription (39,44–50). A number of recent *in vivo* and *in vitro* studies, however, fail to support the PPAR hypothesis.

First, the PUFA-response region in the proximal promoter of the pyruvate kinase and S_{14} genes binds several transcription factors, but the region does not contain a PPAR-response element nor does it bind PPAR (12,41). In fact, linker scanning mutation analysis of the PUFA-response region in the pyruvate kinase gene indicated that PUFA affected the HNF-4 site of the PUFA-response region (12). It is noteworthy that HNF-4, like PPAR, is a member of the steroid-receptor superfamily, but there is no evidence at this time indicating that fatty acids regulate HNF-4 or alter interactions with its response element. Moreover, the putative HNF-4 target site for PUFA regulation of gene transcription may not be common to all glycolytic and lipogenic genes. As an example, the FAS gene contains a carbohydrate-like response sequence in its proximal promoter and in the first intron, but functional analysis studies with fatty acid synthase gene sequences ranging from –2195 to +750 b.p. have failed to detect a PUFA-response region even though PUFA are potent inhibitors of fatty acid synthase gene transcription (Clarke, S.D., Turini, M., Jump, D.B., and Thelen, A., unpublished data). Thus it is likely that PUFA regulate gene transcription in multiple ways and/or at multiple sites in genes encoding lipogenic and glycolytic enzymes.

Secondly, the strongest evidence suggesting tha fatty acids regulate gene transcription by modulating PPAR actions is derived from transcription *trans*-activation assays (45,48). In these assays, however, saturated, monounsaturated, and polyunsaturated fatty acids all have equal potency as activators of PPAR, and all induce PPAR-mediated gene transcription (45,48). Thus PPAR-like proteins do not appear to exhibit the selectivity required to explain PUFA control of gene expression. In addition, feeding mice the potent PPAR-activator ETYA induced peroxisome proliferation, as indicated by the significant rise in hepatic acyl-CoA oxidase mRNA level, but ETYA had no effect on FAS expression (Turini, M., and Clarke, S.D., unpublished data). Similarly, linoleic and

arachidonic acids, which potently suppress FAS gene expression, had no effect on expression of acyl-CoA oxidase (Turini, M., and Clarke, S.D., unpublished data). Thus induction of peroxisomal and suppression of lipogenic and glycolytic genes appear to involve independent mechanisms.

We have known for nearly 30 yr that dietary polyenic n-6 and n-3 fatty acids potently inhibit hepatic fatty acid biosynthesis. The teleological explanation for this unique action of PUFA resides in their ability to suppress the synthesis of n-9 fatty acids. By inhibiting fatty acid biosynthesis, dietary PUFA reduce availability of substrates for stearoyl-CoA desaturase (30) and in turn reduce availability of n-9 fatty acids for incorporation into plasma membranes. In this way, essential biological processes dependent on essential fatty acids (e.g. reproduction and transdermal water loss) continue to operate normally. Therefore, if essential fatty acid intake did not regulate n-9 FAS, survival of the organism would be threatened. During the past 20 yr, we have gradually elucidated cellular and molecular mechanisms by which dietary PUFA modulate fatty acid biosynthesis and n-9 fatty acid availability. Central to this mechanism has been our ability to determine that dietary n-6 and n-3 PUFA regulate transcription of genes coding for lipogenic and glycolytic enzymes (8,11,12). Moreover, we have found that dietary fish oils are more potent inhibitors of gene expression than are dietary vegetable oils, but this is due to the fact that fish oil contains a high amount of 20- and 22-carbon polyenoic fatty acid rather than due to intrinsic potency differences between n-6 and n-3 fatty acids.

The potential mechanisms by which n-6 and n-3 PUFA govern gene transcription are numerous, and it is unlikely that any one mechanism can fully elucidate the nuclear actions of PUFA. The difficulty in providing a unifying hypothesis at this time stems from (i) the many metabolic routes taken by PUFA on entering the hepatocyte and (ii) the lack of identity of a specific PUFA-regulated *trans*-acting factor. Nevertheless, a collection of information is available which has led us to propose the mechanistic scheme outlined in Figure 1. Clearly, PUFA are not only utilized as fuel and structural components of cells, but also serve as important mediators of gene expression (30). As regulators of gene expression, PUFA (or their metabolites) are thought to affect the activity of transcription factors, which in turn target key *cis*-linked elements associated with specific genes. Whether this targeting involves DNA–protein interaction or the protein/protein interactions of PUFA-regulated factors is unclear. A better understanding of the nuclear actions of PUFA will clarify the role of these compounds in lipid metabolism and lead to a better understanding of the role of PUFA in disease processes such as NIDDM and certain forms of cancer.

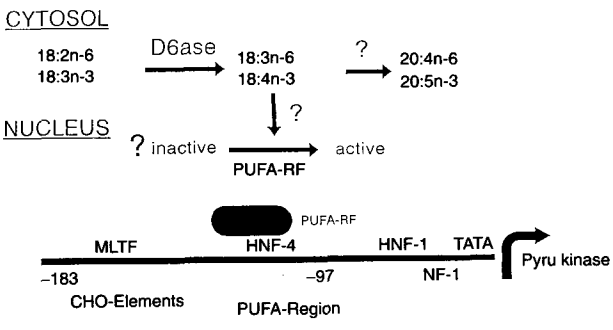

FIG. 1. Using the pyruvate kinase gene as a model, the potential mechanism by which polyunsaturated fatty acids (PUFA) may regulate hepatic gene transcription is outlined. The essence of the model is that Δ6 desaturation is essential for PUFA control of transcription and that desaturase products activate a hypothetical nuclear response factor that interacts with the HNF-4 *trans* factor to modulate transcription: D6ase = Δ6 desaturase; PUFA-RF = a hypothetical nuclear PUFA-response factor; MLTF, major late transcription factor.

Effect of Polyunsaturated Fatty Acids in Obese Mice

M. Thomas Clandinin*, Sukhinder Cheema, Dan Pehowich, and Catherine J. Field

Nutrition and Metabolism Research Group, Department of Agricultural, Food, and Nutritional Science, University of Alberta, Edmonton, Alberta, T6G 2P5, Canada

ABSTRACT: Genetically obese (ob/ob) mice display a variety of metabolic differences from lean litter mates. In the obese state, fatty acid desaturation-elongation in brown adipose tissue mitochondria is apparently altered, resulting in differences in membrane fatty acid composition. This change in membrane lipid environment appears to influence GDP binding and therefore the activity of the proton conductance pathway associated with regulation of energy expenditure in these animals. In liver, binding of insulin to the nuclear membrane is increased by feeding a high polyunsaturated/saturated (P/S) diet fat. Consumption of a high P/S diet decreased mRNA levels for fatty acid synthase, acetyl-CoA carboxylase, malic enzyme, and pyruvate kinase in obese and lean animals. Expression of mRNA for these lipogenic enzymes was higher in obese animals and suggests that obese mice may be resistant to polyunsaturated fatty acid feedback control of gene expression.
Lipids 31, S-13–S-22 (1996).

Essential fatty acids (EFA) and nonessential fatty acids that can be synthesized *de novo* from acetyl-CoA are essential for energy balance, membrane biosynthesis, and other specialized functions. The dietary balance among these components affects partitioning of how each may be utilized on a whole-body basis (1). Intake of fatty acid affects molecular mechanisms involved in nutritional regulation of fatty acid synthesis (2), coordinate control of glycolytic and lipogenic gene expression (3,4), and transcription of stearoyl-CoA desaturase-2 gene (5).

Obesity is accompanied by abnormalities in systemic carbohydrate and lipid metabolism and in insulin secretion and insulin action. Phenotypic emergence of this genetic defect begins early in life and may profoundly alter development of adipose tissue toward excessive fat storage (6–8). The problem of obesity is essentially a problem of energy balance. Excess caloric intake relative to caloric expenditure leads to the storage of extra fat at various rates, depending on the degree of imbalance (9).

Abbreviations: BAT, brown adipose tissue; EFA, essential fatty acids; FABP, fatty acid binding protein; GDP, guanosine 5′-diphosphate; NaTES, sodium N-tris (hydroxymethyl) methyl-2-aminoethane sulfonic acid; ob/ob, genetically obese; PC, phosphatidylcholine; PE, phosphatidylethanolamine; P/S, polyunsaturated/saturated.

In the genetically obese (ob/ob) mouse, brown adipose tissue (BAT) appears to act primarily as an energy buffer in the overall regulation of energy balance (10). High metabolic efficiency associated with defective BAT thermogenesis (11) results in a positive energy balance, which may manifest itself in obesity. Although there are notable exceptions (12–14), in general these mice exhibit reduced responses to norepinephrine stimulation (15,16), even in the cold (17), with the consequence that ob/ob mice maintain a lower body temperature when mildly cold-exposed (16). This defect in cold-induced nonshivering thermogenesis appears to be coupled with a reduced capacity for diet-induced thermogenesis (18–20), a phenomenon characterized by elevated thermogenesis and higher metabolic efficiency. Dietary treatment can also augment BAT thermogenesis (21–24). A high fat diet rich in EFA has been shown to partially reverse the impaired response of BAT to norepinephrine (25). Evidence showing that a high-fat cafeteria diet can normalize low sympathetic nervous activity in BAT (26) suggests (i) that the ob/ob mouse may respond more rapidly to dietary fat than to dietary carbohydrate and (ii) that enhancement of BAT thermogenesis and increased metabolic efficiency in high-fat cafeteria-fed mice is integrally linked to the hypothalamus and the mechanism by which the hypothalamus senses energy intake (10).

Using diets of defined composition, it has been shown that BAT thermogenic activity, as determined by mitochondrial guanosine 5′-diphosphate (GDP) binding, can be influenced by fatty acid composition of diets consumed (22). This implies that the amount and type of dietary fatty acids are important in the regulating of BAT thermogenesis. Moreover, it suggests that a defect in BAT thermogenesis in the ob/ob mouse may also have its origins at the level of the inner mitochondrial membrane, the site of the 32,000 kD uncoupling protein that regulates energy dissipation across the membrane. Dietary fatty acids can alter mitochondrial membrane composition (27), and thus the lipid environment of the proton conductance pathway, or its purine nucleotide binding sites. This may be of significance in that other tissues in obese mice [i.e., liver (28,29) and epididymal fat pads (29)] show marked changes in the relative proportions of linoleic acid (18:2n-6) and arachidonic acid (20:4n-6) as obesity is expressed. This suggests that the obese genotype affects membrane fatty acid composition through alterations in the desaturation-elongation of n-6 fatty acids, presumably *via* effects on Δ6- and/or Δ5-desaturase activity.

In preobese pups, increased lipogenic capacity of adipose tissue is due to preferential channeling of nutrients into fatty acids. A number of enzyme activities related to lipid storage are coordinately increased in a tissue-specific manner (30–32), predominantly in the liver. *De novo* fatty acid biosynthesis is catalysed by two enzyme systems that function sequentially: acetyl-CoA carboxylase and fatty acid synthase. At the primary site for *de novo* synthesis of long-chain fatty acids, most of the NADPH required is furnished via malic enzyme. Activities of acetyl-CoA carboxylase, fatty acid synthase, and malic enzyme are altered in the obese state (33–35). Obesity is also associated with glucose intolerance and alterations in carbohydrate metabolism (36). Among important glucose metabolic enzymes are pyruvate kinase and phosphoenolpyruvate carboxykinase, both of which are highly sensitive to the nutritional and hormonal state of the animal (37,38).

Dietary polyunsaturated fats are potent inhibitors of hepatic fatty acid synthesis and triglyceride synthesis (39–41). It appears that alterations in dietary fat influence enzyme activity by up or down regulating gene transcription. Thus, it is important to understand the role of dietary fat in regulating energy metabolism and the lipid and carbohydrate metabolic enzymes at the genetic level in obese mice. The present study addresses the question of the effect of dietary fat composition on BAT energy metabolism and expression of other enzymes involved in lipid and carbohydrate metabolism in the liver.

MATERIALS AND METHODS

Animals and diets. Six-week-old male obese mice (ob/ob) and their lean litter mates (ob/+) or (+/+) (Jackson Laboratories, Bar Harbour, Maine) were caged in pairs and provided with water and diet *ad libitum*. The animal room was maintained at 24 ± 1°C with a 12-h light/12-h dark photo period. Diets contained the following essential nutrients per kg: 270 g high-casein protein, 200 g starch, 208 g glucose, 50 g nonnutritive cellulose, 10 g vitamin mix, 50 g mineral mix, 2.8 g choline chloride, 6.3 g inositol, and 2.5 g L-methionine. The lipid component of the diet was provided by mixing hydrogenated beef tallow, safflower oil, and linseed oil. Each diet contained 20% (w/w) fat. The amount of hydrogenated beef tallow, safflower oil, and linseed oil was altered to result in either a high (P/S = 1.0) or low (P/S = 0.25) polyunsaturated/saturated (P/S) fatty acid ratio (Table 1). At six weeks of age, half of the ob/ob and normal lean mice received the high P/S diet, and the remainder were fed the low P/S diet for an additional four weeks.

Mitochondrial preparation and analysis. Mice were killed by cervical dislocation, and BAT was pooled from interscapular, subscapular, and cervical regions. Mitochondria were isolated in a buffer consisting of 0.25 M sucrose, 5 mM NaTES, pH 7.2, and 1 mM EGTA from BAT pooled from two mice (42). Whole mitochondria were used immediately for measurement of purine nucleotide binding, and an inner mitochondrial membrane-matrix fraction was isolated for determination of cytochrome oxidase activity and analysis of fatty acid composition. The inner membrane-matrix fraction was prepared after incubation with digitonin, as described by Schnaitman and Greenawalt (43) and further purified by sucrose density gradient centrifugation (44). Whole and inner mitochondrial membrane protein content was determined spectrophotometrically (45). Activity of cytochrome oxidase in the inner membrane was determined by monitoring reduction of ferrocytochrome c (46). Purine nucleotide binding was assessed in whole mitochondria by measuring the specific binding of [^{3}H]GDP. Mitochondria were incubated for 10 min at 22°C in 100 mM [^{14}C] sucrose (6 kBq/ml; New England Nuclear), 10 μM [^{3}H]GDP (Na^{2+} salt, 10 kBq/ml; New England Nuclear, Sauga, Ontario, Canada), 20 mM TES, pH 7.1, 1 mM EDTA, and 5 μM rotenone (47).

TABLE 1
Fatty Acid Composition of Diets[a]

Diet (% w/w)	High P/S	Low P/S
14:0	1.8	3.4
16:0	16.9	23.8
18:0	25.9	43.2
18:1	8.9	6.5
18:2(6)	44.2	12.9
18:3(3)	1.3	1.2
Total saturated	43.5	78.60
Total polyunsaturated	45.6	20.60
P/S ratio	1.0	0.25

[a]Diet lipid was achieved by mixing fat in the following proportions: for polyunsaturated/saturated (P/S) 1.0—hydrogenated beef tallow 42%, safflower oil 56%, linseed oil 2%, for P/S 0.25—hydrogenated beef tallow 76%, safflower oil 22%, linseed oil 2%.

Lipid analysis. Total lipids were extracted from mitochondrial membranes in chloroform/methanol 2:1 (vol/vol) containing ethoxyquin as antioxidant followed by chloroform/methanol 7:1 (vol/vol) saturated with freshly prepared 28% aqueous ammonia. Extracts were then partitioned against 0.2 M KCL, dried, and then resuspended in chloroform/methanol 19:1 (vol/vol) and stored at –80°C under N_2. Phospholipid classes were separated on HP-K high-performance silica-gel plates (Whatman, Clifton, NJ) using chloroform/methanol/2-propanol/potassium chloride (0.25%)/triethylamine (20:9:25:6:18, vol/vol) as the solvent system (48). Individual phospholipid fatty acids were methylated using 14% (w/w) boron trifluoride in methanol. Fatty acid methyl esters were then separated by gas–liquid chromatography using a fused silica BP-20 capillary column (25 m × 0.25 mm i.d.; SGE, Ringwood, Australia). Analytical conditions used separated fatty acids from 12 to 24 carbons in length (49).

Quantitation of mRNA. Total RNA was extracted from liver samples using a guandinium-isothiocyanate method (50). RNA concentration was measured spectrophotometrically (A_{260}/A_{280}). A known amount of total RNA isolated was applied to nitrocellulose paper, and relative amounts of mRNA coding for fatty acid synthase (EC 2.3.1.85), acetyl-CoA carboxylase (EC 6.4.1.2), malic enzyme (EC 1.1.1.40), pyruvate kinase (EC 2.7.1.40), and phosphoenolpyruvate carboxykinase (EC 4.1.1.32) were determined by slot-blot hybridization with specific ^{32}P-labeled cDNA probes. The probes, donated by D.W. Back (Queen's University,

TABLE 2
Body Weights of ob/ob and Normal Lean Control Mice Fed a High or Low P/S Ratio Diet

	P/S	Lean	Obese
Initial weight (g)	1.0	18.1 ± 1.3	36.0 ± 2.6
Six weeks	0.25	17.9 ± 1.2	35.3 ± 2.5
Final weight (g)	1.0	22.1 ± 1.2	53.5 ± 2.7[a]
	0.25	20.7 ± 1.6	48.9 ± 2.7

[a]Significantly different from obese mice fed the P/S 0.25 diet, P < 0.05, n = 16. Six-week-old obese and lean mice were fed experimental diets for four additional seeks. See Table 1 for abbreviations.

Kingston, Ontario, Canada), were labeled by the random primer method (Prima-A-Gene labeling system; Promega). Hybridization was carried out in a shaking water bath for 36 h at 42°C. The hybridization solution contained 40% formamide, 4*x* SSPE buffer, 10% dextran sulphate, 5*x* Denhardt's solution, 0.2% SDS, and 100 mg/mL calf thymus DNA. After hybridization, the membranes were washed in 2*x* SSC, 0.1% SDS, 0.1*x* SSC, 0.1% SDS, 0.1*x* SSC, and 0.1% SDS at 50°C for 30 min. Membranes were air-dried, and slots were cut out and counted in a scintillation counter for ^{32}P. Nonspecific binding was elevated using pBR322 plasmid.

Enzyme assays. Activity of fatty acid synthase was measured following the method of Nepokroeff *et al.* (51). A unit of enzyme activity represents the synthesis of 1 nmole of palmitic acid per min. Malic enzyme was determined using the method of Hsu and Lardy (52). The rate of NADPH formation was proportional to enzyme concentration up to a change of 0.2 optical density units per min at 340 mμ. The method of Inoue and Lowenstein (53) was followed to determine acetyl-CoA carboxylase. One unit of enzyme activity was equal to 1 μmole of malonyl-CoA formed at 37°C per min. Pyruvate kinase and phosphoenolpyruvate carboxykinase were assayed following the method of Imamura and Tanaka (54) and Petrescu et al. (55), respectively. For pyruvate kinase, 1 unit of enzyme was defined as the amount catalyzing the formation of 1 μmole of pyruvate/min. Phosphoenolpyruvate carboxykinase activity was expressed as nmoles NADH oxidized/min/mg protein.

Statistical analysis. The effect of diet treatment and physiological state on enzyme activities, GDP binding, and mRNA levels were compared by analysis of variance procedures. Values are group means ± SEM for n = 6. Treatments without a common superscript are significantly different ($P < 0.01$).

RESULTS

At the commencement of dietary treatment (age 42 d), obesity was evident in the ob/ob genotype. After four weeks of feeding (age 70 d), the body weight of the obese mice that had been fed the high P/S diet was significantly greater than the obese mice that had been fed the low P/S diet (Table 2). There was no significant effect of diet on the body weight of the lean animals. While obese animals that had been fed the high P/S diet gained more weight than those on the low P/S diet, it should be noted that total energy intake was not measured, and therefore we cannot eliminate the possibility of minor differences in fat absorption.

Cytochrome oxidase activity. The activity of cytochrome oxidase did not differ by diet or genotype (Fig. 1).

Purine nucleotide binding. The specific binding of GDP to BAT mitochondria was influenced by genotype and dietary lipid. GDP binding was significantly lower ($P < 0.01$) in ob/ob mice that had been fed high or low P/S diet, compared to normal lean controls that had been fed the same diets (Fig. 1). The ratio of GDP binding was the same between obese and lean animals that had been fed the same diet. GDP binding in both obese and lean animals fed a low P/S diet was reduced, but not significantly, compared to animals that had been fed a high P/S diet (Fig. 1). GDP binding, however, was not different between obese mice that had been fed a high P/S diet compared to normal lean mice fed a low P/S diet.

Inner mitochondrial membrane fatty acid composition Fatty acid composition of BAT inner mitochondrial membrane from the ob/ob mouse is influenced by genotype and by type of dietary fatty acids consumed. Obese animals that had been fed a low P/S diet exhibited lower membrane levels of total saturates in the phosphatidylcholine (PC) (Table 3), phosphatidylethanolamine (PE) (Table 4), and cardiolipin fractions (Table 5). For the PC and PE fractions, reduction in total saturates was due primarily to lower levels of 18:0, whereas in cardiolipin, both 16:0 and 18:0 were significantly lower (data not illustrated). Similar trends were observed in animals that had been fed the high P/S diet (i.e., a decrease in

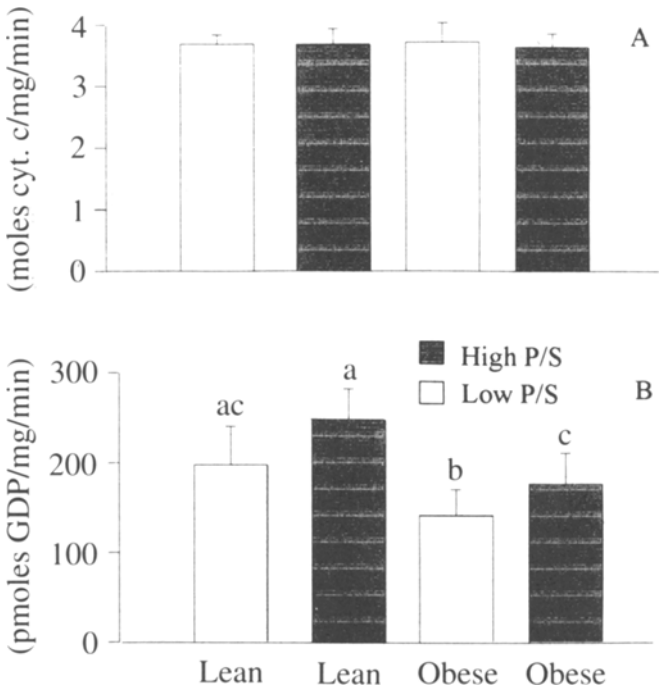

FIG. 1. Cytochrome oxidase activity (A) and GDP binding in brown adipose tissue mitochondria (B) from obese and normal lean mice fed a high or low P/S diet. Results are expressed as means ± SEM, n = 8. Bars that do not share a common superscript are significantly different ($P < 0.05$).

levels of total saturated fatty acids), with the exception that in the cardiolipin fraction total saturates were lower, but not significantly. Lower levels of 18:0 in obese animals accounted for the lower total levels of saturates.

In all three of the phospholipid fractions examined, total levels of monounsaturated fatty acids were higher in obese animals, regardless of diet fed (Tables 3–5). All the major monounsaturated fatty acids increased in obese animals: 16:1, 18:1n-9, and 18:1n-7. In the obese state, the inner mitochondrial membrane accumulated linoleic acid (18:2n-6) in PC and PE in animals that had been fed the high P/S diet. Levels of 18:2n-6 were lower in cardiolipin and in PE in animals on the low P/S diet. At the same time, levels of arachidonic acid (20:4n-6) declined in PC, but increased in PE and cardiolipin. In contrast, 20:3n-6 accumulated in all phospholipid fractions examined, with the result that the ratio of 20:3n-6/18:2n-6 (Δ6-desaturase index) increased in all three phospholipid fractions. Relatively high levels of 20:4n-6 in the PE fraction, coupled with a small increase in 20:3n-6 in the obese state, suggests an apparent inhibition of Δ5-desaturase activity. Similar decreases in the Δ5-desaturase index were observed in the PC and cardiolipin fractions. While significant accumulation of 18:2n-6 occurred in the membrane, the total level of n-6 polyunsaturated fatty acids did not increase in obese animals that had been fed either diet, compared to their lean controls.

In the same genotype, feeding a diet high in n-6 polyunsaturated fatty acids (P/S = 1.0) influenced the fatty acid composition of PC, PE, and cardiolipin relative to a saturated fatty acid diet (P/S = 0.25). For the PC fraction, total levels of saturated fatty acids were lower in lean animals that had been fed the high P/S diet, with 18:0 being reduced the most.

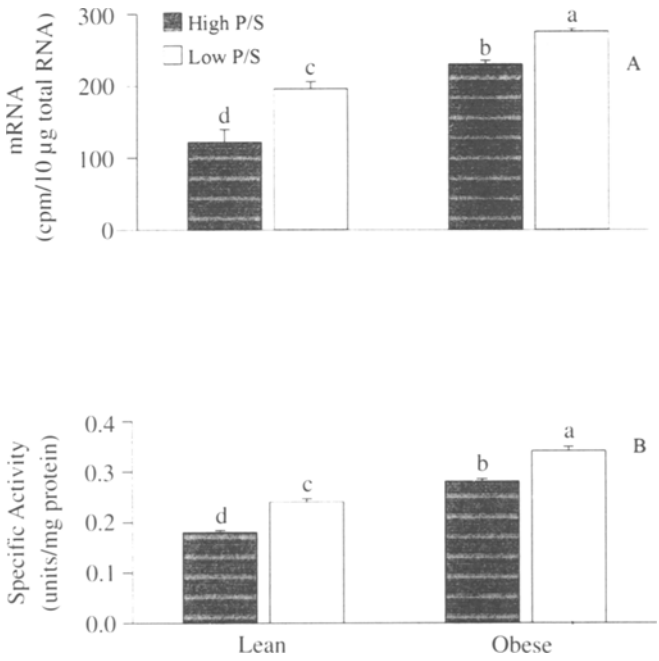

FIG. 2. Hepatic fatty acid synthase mRNA and specific activity. Values are means ± SEM, n = 6. Bars without a common superscript are significantly different ($P < 0.01$).

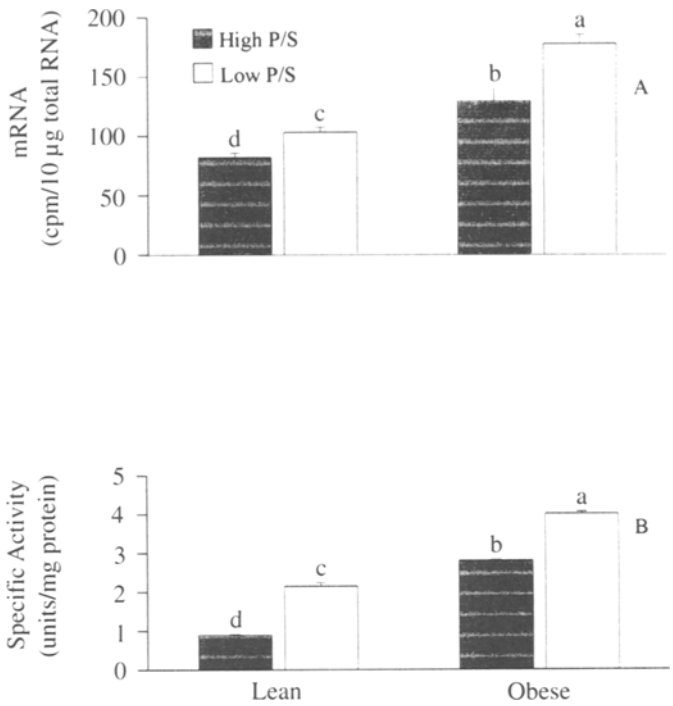

FIG. 3. Relative abundance of hepatic malic enzyme mRNA and malic enzyme specific activity. Values are means ± SEM, n = 6. Bars without a common superscript are significantly different.

Similar reductions in 18:0 in the PE and cardiolipin fractions resulted in an overall decrease in total saturation of these phospholipids. The influence of the high n-6 diet did not appear as marked in obese animals. While this trend was toward a lowering of total saturates, differences were not significant. The influence of diet was greatest on relative amounts of monounsaturated fatty acids. In all phospholipid fractions, total levels of monounsaturated fatty acids decreased in animals fed the P/S = 1.0 diet, compared to the same genotype on the P/S = 0.25 diet. With a few exceptions, notably in the PE fraction, 16:1, 18:1n-9, and 18:1n-7 were all lower in animals that had been fed the high P/S diet.

Feeding the high n-6 diet had the effect of elevating membrane levels of total n-6 fatty acids in both lean and obese animals (Tables 3–5). In all cases, 18:2n-6 accumulated in all the phospholipid fractions; there was no change in membrane levels of 20:4n-6 in PC and PE, but there was an increase of 20:4n-6 in cardiolipin. The Δ6-desaturase index was not affected by diet in the PC fraction from lean animals, the PE fraction from obese animals, or cardiolipin from both lean and obese animals, but decreased in all other animals fed the P/S = 1.0 diet. The Δ5-desaturase index was lower in PC from lean and obese animals that had been fed the high P/S diet, but higher in the cardiolipin fraction from the same animals. In the PE fraction, the Δ5-desaturase index was higher in lean animals fed the high P/S diet compared to the low P/S diet and was highest in obese animals.

Membrane levels of n-3 fatty acids were lower in all phospholipid fractions from animals that had been fed the high P/S diet resulting in significant increases in the n-6/n-3 ratio in all the phospholipid classes.

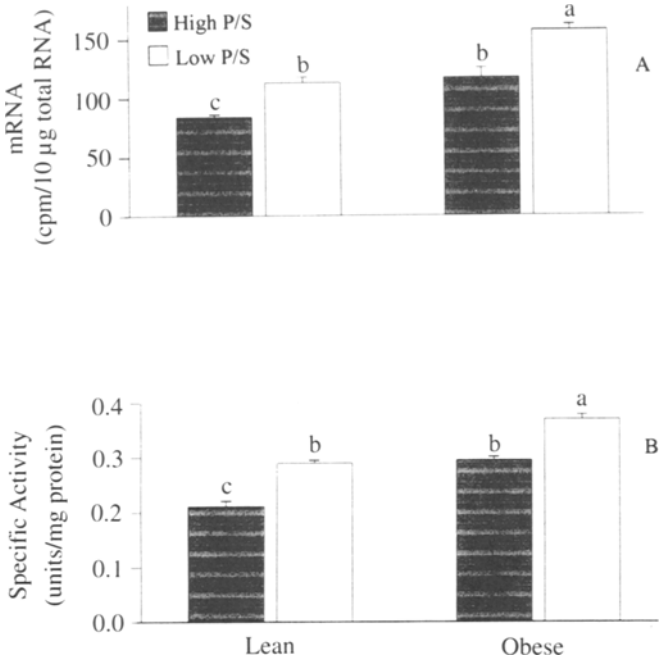

FIG. 4. Hepatic acetyl-CoA carboxylase mRNA level and specific activity. Values are means ± SEM, n = 6. Bars without a common superscript are significantly different.

Effect of diet and obesity on enzymes of lipogenesis. Combined data from six animals per group for the mRNA levels and enzyme activities of fatty acid synthase, acetyl-CoA carboxylase, and malic enzyme are illustrated (Figs. 2–4).

Hepatic fatty acid synthase and malic enzyme mRNA levels were significantly elevated in ob/ob mice, compared to lean mice (Fig. 2A and 3A). Fatty acid synthase and malic enzyme activity also showed a significant increase in ob/ob mice compared to lean mice (Figs. 2B and 3B). Dietary polyunsaturated fat (P/S = 1.0) depressed both fatty acid synthase and malic enzyme activity in both lean and obese mice. Suppression of fatty acid synthase and malic enzyme activity by dietary polyunsaturated fats is associated with a decrease in fatty acid synthase mRNA and malic enzyme mRNA abundance (Figs. 2A and 3A).

mRNA level and enzyme activity of acetyl-CoA carboxylase increased significantly in ob/ob mice, as compared to lean mice (Fig. 4A). Increase in mRNA level was concomitant with an increase in enzyme activity for acetyl-CoA carboxylase in obese mice compared to lean mice (Fig. 4B). Lower levels of dietary saturated fatty acid and high levels of dietary polyunsaturated fat seemed to depress transcription of acetyl-CoA carboxylase and enzyme activity in both lean and obese mice (Figs. 4A and 4B).

Effect of diet and obesity on carbohydrate metabolic enzymes. Hepatic pyruvate kinase mRNA level increased in ob/ob mice, compared to lean mice (Fig. 5A). Pyruvate kinase enzyme activity also increased in ob/ob mice, as compared to lean mice (Fig. 5B). Dietary fat composition had no effect on pyruvate kinase mRNA level or enzyme activity in either lean or obese mice, compared to mice that had been fed a diet high in saturated fats (Figs. 5A and 5B).

There was no change in phosphoenolpyruvate carboxykinase specific activity (mean ± SEM) and mRNA level (mean ± SEM level) in lean and obese mice (Figs. 6A and 6B) fed either the high (P/S = 1.0) or low (PS = 0.25) P/S diets.

DISCUSSION

In the present study, feeding a high P/S diet compared to a low-P/S diet increased GDP binding in both lean and obese mice, indicating that a high-fat diet appears to influence diet-induced thermogenesis in obese (ob/ob) mouse. Earlier studies suggest that the extent to which energy expenditure is enhanced may be dependent on the fatty acid composition of the diet (22). In particular, a high-fat diet rich in polyunsaturated fatty acids is more effective at stimulating thermogenic activity in BAT than is a diet rich in saturated fatty acids. The mechanism by which fatty acids regulate BAT thermogenesis is unclear but may be the consequence of direct stimulation of the proton conductance pathway or modulation of sympathetic regulation. Another possibility suggested by others (56,57) and by this study is that effective proton conductance of the inner mitochondrial membrane is determined in part by the lipid environment of the pathway. The obese state may foster a lower proton conductance pathway and consequently an impairment of thermogenesis.

In the present study, a clear pattern of alterations in fatty acid composition in the BAT inner mitochondrial membrane is also apparent. Inner mitochondrial membranes from obese animals are less saturated, but higher in monounsaturated fatty acids. The fact that the level of 18:0 is lower in obese animals with a corresponding increase in 16:1n-7 and 18:1n-9 suggests

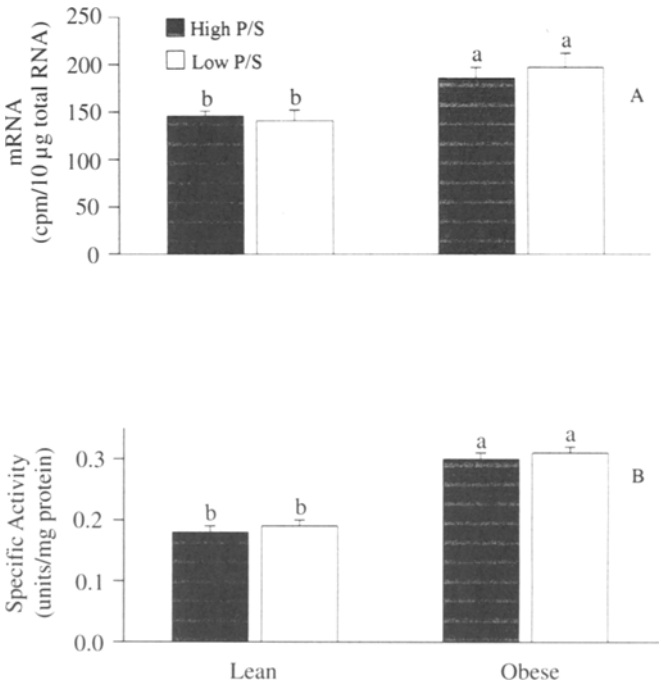

FIG. 5. Relative abundance of hepatic pyruvate kinase mRNA and specific activity of pyruvate kinase. Values are means ± SEM, n = 6. Bars without a common superscript are significantly different.

a stimulation or enhanced induction of the Δ9-desaturase pathway. Thus it would appear that the thermogenic response of BAT can be modulated by dietary lipid levels independent of the state of obesity. Similar increases in monounsaturated fatty acids have been observed in ob/ob mouse hepatic plasma membranes (58), total liver phospholipids, and epididymal fat pad triglycerides (29), and obese (fa/fa) rat serum, from the kidney and heart (59). In contrast to monounsaturated fatty acids, the majority of tissues from obese animals appeared to have reduced levels of linoleic acid (58–59). One significant exception was an increase in 18:2n-6 in total heart phospholipids in the obese Zucker rat (59). In the present study, 18:2n-6 levels were also higher in PC from obese mice, regardless of diet, and in cardiolipin from obese mice fed a high P/S diet. The observation that the Δ6-desaturase index was higher for all three phospholipid fractions in obese animals suggests that a higher proportion of 18:2n-6 is desaturated and elongated to other polyunsaturated fatty acids in the obese state. The apparent reduction in 18:2n-6 levels in PE and cardiolipin was accompanied by a reduction in membrane arachidonic acid, albeit to a lesser degree. The net result was that the ratio of 20:4/20:3 indicated that Δ5-desaturase was inhibited, thus reducing the further desaturation and elongation of 18:2n-6 to longer-chain polyunsaturates. This too appeared to be common to other tissues examined in genetically obese animals in that lower Δ5-desaturase activity has been observed in ob/ob mouse total liver phospholipids (29) and several tissues in the obese Zucker rat (59). It is worth noting that, in the other studies reported, only total lipid or total phospholipid analysis was undertaken, and differences in individual phospholipid class composition were not measured.

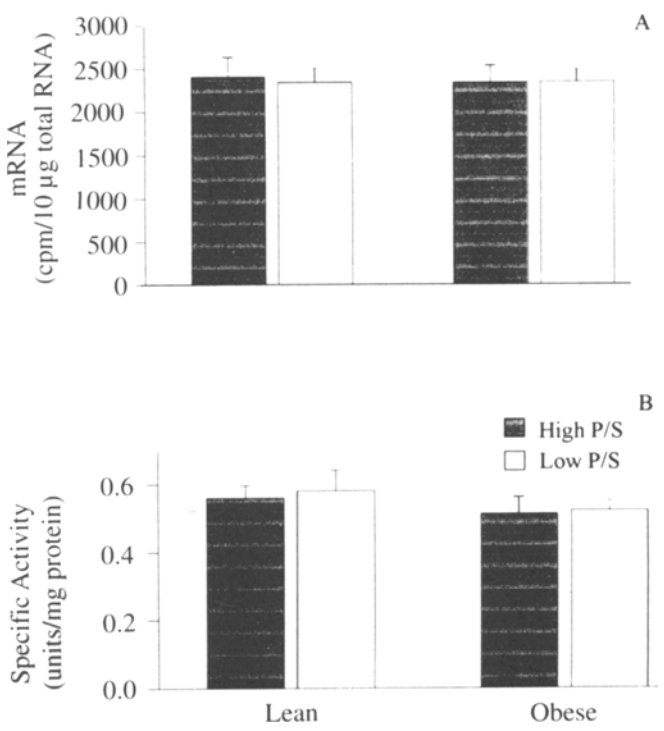

FIG. 6. Relative abundance of phosphoenolpyruvate carboxykinase mRNA and specific activity. Values are means ± SEM, n = 6.

Unlike liver phospholipids (29), metabolism of n-3 fatty acids appeared to be relatively unaffected in the BAT inner mitochondrial membrane of obese mice. Activity of cytochrome oxidase did not differ by diet or genotype, indicating that oxidative capacity of mitochondria was not altered in the ob/ob genotype, nor influenced by dietary lipid treatment under the conditions described. This is not unexpected, as all three phospholipid classes examined had low levels of total n-3 fatty acids and only trace amounts of 18:3n-3. Since 18:2n-6 and 18:3n-3 compete as substrates for Δ6-desaturase, reduction of total n-3 fatty acids in both lean and obese animals on the high-P/S diet reflects domination of the desaturation pathway by 18:2 as the result of high dietary levels. The result is that the ratio of n-6/n-3 fatty acids increased in both lean and obese animals that had been fed the high P/S diet. These observations suggest that at least by the end of a four-week feeding regimen, a diet high in polyunsaturated fatty acids may partially ameliorate the defect in activity of the proton conductance pathway in the ob/ob mouse.

Relating changes in membrane fatty acid composition to proton conductance in genetic obesity is not easily achieved.

There is some controversy as to the physiological significance of GDP binding measurements, with recent evidence suggesting that binding reflects activity rather than purported alterations in the amount of uncoupling protein (60). In cold-exposed rats, GDP-dependent changes in proton conductance appeared to be associated with functional changes in the pathway rather than the amount of uncoupling protein or masking of its active sites (61). If this is indeed the case, the present study confirms that in the obese state thermogenesis is depressed as a consequence of a decrease in activity of the proton conductance pathway. It also confirms that activity of the pathway can potentially be modified by diet fat and perhaps by fatty acid constituents of the inner mitochondrial membrane. GDP-dependent proton conductance was enhanced in rats deficient in EFA, both at thermoneutrality and when cold adapted (62). In the presence of GDP, a significant proportion of GDP-independent proton conductance can be measured in EFA-deficient rats, indicating existence of a basal conductance, that may be influenced by membrane fatty acid composition. At present, it is difficult to explain how an EFA-deficient diet, which undoubtedly depletes membrane 18:2n-6, enhances proton conductance whereas in the present study a high 18:2 diet also results in an apparent increase in proton conductance. Perhaps diet-induced changes in the phospholipid class content are also involved (63).

In summary, the present study demonstrates that metabolism of monounsaturated and n-6 polyunsaturated fatty acids are altered in the inner mitochondrial membrane of the ob/ob mouse. Apparent transitions in Δ5-desaturase activity and enhanced Δ6-desaturase activity serves to change the fatty acid profile of PC, PE, and cardiolipin in inner mitochondrial membranes of obese animals. Feeding a diet high in linoleic acid accentuates these changes. While we have not determined to what extent the impact of altered lipid environment on the proton conductance pathway contributes to the overall depression of thermogenesis in the ob/ob mouse, it is clear that activity of proton channels can be modulated by dietary fatty acids.

A defect in regulation of fatty acid synthesis was postulated in obesity many years ago (64). Since then, high-fat diets (>30% cals from fat) have been shown to inhibit lipogenesis. Dietary polyunsaturated fats are potent inhibitors of hepatic fatty acid and triglyceride synthesis. The objective of this study was to determine if the effect of dietary polyunsaturated fats on hepatic gene transcription for lipogenesis and the conversion of carbohydrate to lipid is different for the obese state when compared to the lean state. This comparison was made at a dietary fat level (40% cals from fat) where a near-maximal level of inhibition of *de novo* lipogenesis from carbohydrate would be expected. Data from this study demonstrate that higher activities of fatty acid synthase, acetyl-CoA carboxylase, malic enzyme, and pyruvate kinase in the liver of obese mice is due to stimulation of gene transcription measured at higher tissue mRNA levels. In the obese state, these results are consistent with a major role for increased *de novo* fatty acid synthesis in the pathogenesis of obesity in ob/ob mice. The close correlation between mRNA levels and specific enzyme activity suggests that regulation of fatty acid synthase, malic enzyme, acetyl-CoA carboxylase, and pyruvate kinase was at the pretranslational level, mainly at the level of gene transcription.

The findings suggesting that low dietary saturated fat and high dietary polyunsaturated fat suppressed expression of fatty acid synthase are consistent with those recently observed (65). This high dietary polyunsaturated fat ratio (P/S = 1.0) also suppressed mRNA levels and enzyme activities for malic enzyme and acetyl-CoA carboxylase in both lean and obese mice; however, mRNA level and enzyme specific activity for pyruvate kinase and phosphoenolpyruvate carboxykinase were not affected by dietary polyunsaturated fats (P/S = 1.0). Fatty acid synthase revealed maximum suppression by dietary polyunsaturated fats, compared to malic enzyme and acetyl-CoA carboxylase. Decrease in liver fatty acid synthase mRNA level was more pronounced in lean mice, as compared to obese mice, which reveals that obese mice are resistant to polyunsaturated fatty acid feedback control of gene expression.

Mechanisms by which dietary polyunsaturated fats inhibit fatty acid synthase, acetyl-CoA carboxylase, and malic enzyme gene expression has been difficult to elucidate. Induction of fatty acid synthase is explicable if polyunsaturated fatty acid or a metabolic end-product directly regulates fatty acid synthase mRNA production either by controlling transcription, RNA processing, or mRNA stability (65). Clarke and Jump (66) proposed that n-6/n-3 fatty acids, which inhibit fatty acid synthase and S14 gene transcription, are transported through the plasma membrane and subsequently bind to the cytosolic fatty acid binding protein (FABP). They further hypothesized that the FABP shuttles the 18-carbon fatty acids to the Δ6-desaturase and subsequently carries fatty acid products to the nucleus, where the cytosolic FABP is transferred to a specific nuclear FABP. This nuclear FABP binds to a specific *cis*-acting element, which operates to govern gene transcription.

Suppression of mRNA level and enzyme activities by polyunsaturated fatty acids was highly specific for lipogenic enzymes and was not observed for pyruvate kinase or phosphoenolpyruvate carboxykinase. The findings in the present study for pyruvate kinase are similar to those of Toussant *et al.* (67), who showed that activities of pyruvate kinase were altered by dietary linoleate. Taken together, results of this study demonstrate that expression of genes for fatty acid synthase, malic enzyme, acetyl-CoA carboxylase, and pyruvate kinase is higher in the liver of the ob/ob mouse, with no effect on phosphoenolpyruvate carboxykinase gene expression. The overexpression of these enzymes appears to be an early feature of the onset of obesity.

ABSTRACT: n-3 Polyunsaturated fatty acids abundant in marine lipids suppress certain inflammatory and immune reactions, and dietary marine lipid supplements have antiinflammatory effects in experimental and human autoimmune disease. Previous work by other investigators demonstrated that dietary marine lipid supplements suppressed production of cytokines from stimulated human peripheral blood mononuclear cells *ex vivo*. The present study further documents the ability of n-3 fatty acids to inhibit cytokine formation, and in part defines the mechanism of the inhibition of production of interleukin-1β (IL-1β) by dietary n-3 fatty acid. Female BALB/c mice were each fed a fat-free balanced diet to which was added either a refined fish oil (FO) preparation as a source of n-3 fatty acid, or beef tallow (BT), which consisted primarily of saturated and monoenoic fatty acids. After ingesting the experimental diets for periods ranging from 3 to 12 wk, spleen cell preparations were stimulated *ex vivo* with either lipopolysaccharide (LPS) or phorbol 12-myristate 13-acetate (PMA), and proIL-1β mRNA (IL-1β mRNA) was measured by northern analysis. Levels of IL-1β mRNA in both LPS- and PMA-stimulated cells from BT-fed mice were elevated to a greater extent than in cells from FO-fed mice, at most concentrations of LPS and PMA. Stability of LPS-stimulated mRNA levels after actinomycin D was similar for BT and FO groups, indicating that lower levels of IL-1 mRNA with FO groups was related to suppressed IL-1 gene transcription and not due to accelerated transcript degradation. Nuclear run-on transcription assays revealed a more transient expression of the IL-1β gene in LPS-stimulated spleen cells from FO-fed mice compared to cells from BT-fed mice. We conclude that dietary marine lipids reduce transient expression of the IL-1β gene in stimulated splenic monocytic cells. Preliminary results from nuclear run-on transcription assays indicate that n-3 fatty acids may not change the initial rate of gene transcription but may promote more rapid shutting down of transcription of this gene after induction than do alternative lipids.

Lipids 31, S-23–S-31 (1996).

Dietary n-6 and n-3 polyunsaturated fatty acids are essential for normal health in humans and other mammalian species. A large body of evidence from epidemiologic and experimental studies has also documented that the relative quantities of n-6 and n-3 fatty acids can alter a variety of cell functions and disease states (1–3). Dietary n-3 fatty acids are incorporated into tissue phospholipids, accompanied by replacement of n-6 fatty acids, including arachidonic acid. These changes are associated with reductions in the capacity of cells to produce eicosanoids, and it has been postulated that reduced production of prostaglandins and leukotrienes by cells enriched in n-3 fatty acids may contribute to their antiinflammatory effects. It is also clear, however, that alterations in eicosanoid formation cannot account for all the biological effects of n-3 fatty acids (4). In addition to inhibition of eicosanoid production, the presence of elevated levels of n-3 fatty acids may suppress cytokine formation. A study of human volunteers demonstrated that a dietary supplement of marine oil for 6 w significantly reduced quantities of interleukin-1α (IL-1α), IL-1β, and tumor necrosis factor-α (TNF-α) produced by lipo-polysaccharide (LPS)-stimulated peripheral blood mononuclear cells *ex vivo*, as measured by radioimmunoassay (5). An additional study of patients with rheumatoid arthritis ingesting a dietary supplement of fish oil (FO) found suppression of IL-1 production by LPS-stimulated peripheral blood mono-nuclear cells, compared to control patients ingesting an olive oil supplement (6). These reports raise the possibility that suppression of cytokine expression by n-3 fatty acids may contribute to antiinflammatory effects of these lipids.

Previous studies demonstrated that dietary marine lipids markedly reduced severity of the spontaneous autoimmune glomerulonephritis in murine lupus strains, which are models for the human disease, systemic lupus erythematosus (7–10). Subsequent controlled clinical trials documented modest but significant antiinflammatory effects of dietary marine lipid supplements in patients with rheumatoid arthritis, and one study reported beneficial effects of dietary marine lipids in patients with systemic lupus erythematosus (6,11–14). Mechanisms of these well-documented antiinflammatory effects of n-3 fatty acids are unclear. n-3 Fatty acids were shown to suppress formation of eicosanoids, including leukotriene B4 and other 5-lipoxygenase

[1]The IL-1β cDNA probe detects proIL-1β mRNA, which is referred to as IL-1β mRNA throughout the paper for convenience.

products (6,15). Cyclooxygenase products may also be inhibited by n-3 fatty acids (4), but this effect seems unlikely to account for beneficial effects of n-3 fatty acids on murine lupus, since a cyclooxygenase inhibitor did not alter the course of autoimmune disease in one of these strains (16).

Several lines of evidence indicate that cytokines play an important role in the pathogenesis of inflammatory reactions (17–19). Elevated levels of mRNA for IL-1β and TNF-α are present in kidneys of mice with autoimmune glomerulonephritis, and administration of recombinant IL-1α and TNF-α may aggravate murine autoimmune disease under certain conditions (20,21). Synovial tissues from patients with rheumatoid arthritis contain IL-1, TNF-α, and other cytokines, and these and other observations led to the conclusion that these cytokines have an important role in the pathogenesis of this disease (18,22).

To clarify mechanisms by which n-3 fatty acids suppress cytokine production, we have investigated the effects of a dietary marine lipid on the levels of IL-1β mRNA in murine spleen cells that have been stimulated to produce cytokines *ex vivo*. Results of these studies demonstrate that dietary n-3 fatty acids reduce steady-state IL-1β mRNA levels in isolated spleen cells that have been stimulated with either LPS or phorbol 12-myristate 13-acetate (PMA). Experiments with actinomycin D–treated cells as well as nuclear run-on transcription assays demonstrated that dietary n-3 fatty acids reduce IL-1β production by depressing the total amount of gene transcription. Furthermore, preliminary examination of nuclear run-on kinetics suggests a mechanism for reduced IL-1β gene transcription involving an effect targeted not at the activation of gene transcription, but alternatively at the distal regulatory repression that generates the transient transcriptional response usually observed for this gene. Consequently, n-3 fatty acids, in contrast to alternative fatty acids, could result in more efficient activation of the transcriptional clamp previously described (23).

METHODS

Diets. Experimental diets consisted of a fat-free powder (85 wt%) to which was added one of two lipid preparations (15%). The fat-free powder (ICN Nutritional Biochemicals, Cleveland, OH) provided a balanced diet consisting of casein 21%, cellulose 15.6%, sucrose 58.5%, and a balanced salt mixture and essential vitamins, including 50 mg/kg of α-tocopherol. Lipids were stabilized with 0.02% *t*-butylhydroquinone. Female BALB/c mice were fed with experimental diets beginning at age 2 mo. Diets were given *ad libitum*, except for brief restrictions occasionally to maintain mean weights of each dietary group within 5% of each other. Fatty acid composition of dietary lipids has been published elsewhere (24). Beef tallow (BT) (ICN Nutritional Biochemicals) primarily consisted of saturated (48%) and monoenoic (47%) fatty acids, with 4.7% n-6 fatty acid in the form of linoleic acid and essentially no (<1%) n-3 fatty acids. The FO preparation (Nissui 28; Nippon Suisan Kaisha, Ltd., Tokyo) contained 55% n-3 fatty acid, 3.5% n-6 fatty acid, with the remainder (40%) as saturated and monoenoic fatty acids.

Cell preparation and stimulation. Groups of mice were sacrificed by cervical dislocation after feeding with experimental diets for varying time intervals. Spleens were rapidly removed and minced, and erythrocytes were hemolyzed with NH_4Cl. Spleen cells were washed three times with RPMI 1640 (Cellgro; Mediatech Inc., Herndon, VA) and filtered through fine mesh gauze. Cell viability was over 95%, based on trypan blue dye exclusion. Spleen cells (10^8) were cultured in 5 mL RPMI 1640 medium with or without varying doses of LPS (*E. coli* 055:B5, Sigma Chemical Co., St. Louis, MO) or PMA (Sigma Chemical Co.) for 4 h or other time intervals as indicated. Analysis of a representative spleen cell preparation fluorescence-activated cell sorter utilizing monoclonal antibodies to immunoglobulin G and Thy-1 revealed 38% Ig^+ cells, 29% Thy-1^+ cells. The small percentage of monocytes could not be determined accurately by the cell sorter using an anti-Mac-1, but histologic analyses of Wright–Giemsa-stained smears revealed 3–5% monocytes, with no differences in percent monocytes between FO and BT groups in two experiments. Others have reported that percentages of lymphocytes and monocytes in murine spleen cell preparations similar to ours were not altered by dietary n-3 fatty acid (25).

Preparation of mRNA and northern blot analysis. Total cellular RNA was prepared by guanidinium thiocyanate lysis (26). Gel electrophoresis of RNA was carried out using 1% agarose gels containing 6% formaldehyde, loading the gels with 10 mg RNA/lane (27). Ethidium bromide was added to the loading buffer, and the 28S and 18S ribosomal RNA bands were located with ultraviolet light. RNA was then transferred to nitrocellulose filters (Schleicher & Schull, Keene, NH). Prehybridization, hybridization, and autoradiography were performed according to standard procedures (28). The murine IL-1β probe was a 1600-base pair fragment of the full-length cDNA (29). The β-actin probe (provided by Dr. Mary Goldring) was a 700-base pair fragment of the full-length cDNA (30). cDNA Probes were labeled with [α-^{32}P]dCTP using a random primer method (31).

Nuclear isolation and transcriptional run-on assay. For run-on transcription experiments, spleen cells were incubated with 1 ng/mL LPS for 0 to 3 h. Nuclei were isolated from spleen cells after incubation with LPS by lysis in 0.05% NP 40 (Boehringer Mannheim Biochemicals, Indianapolis, IN) as previously described (32–34). Isolated nuclei were stored at –80° in a glycerol buffer until the run-on reaction was carried out. For the run-on transcription assay, $6–8 \times 10^7$ spleen cell nuclei were incubated with 150 mCi [α-^{32}P]uridine triphosphate for 30 min at 26–28°C. The reaction was stopped by addition of 100 mg tRNA and 100 μg/mL DNase. Proteinase K was added and incubated for 30 min at 42°C. RNA was extracted with phenol-chloroform, passed through G-50 sephadex spun columns (28) (Pharmacia Biotech Inc., Piscataway, NJ), and precipitated with 5% trichloroacetic acid at 0°C. RNA was resuspended and treated with 0.2 M NaOH for 15 min at 0°C. After neutralization, the RNA was precipitated with ethanol and resuspended in the hybridization mix. Denaturation was achieved by heating at

85–90°C for 10 min. Hybridization took place on nitrocellulose filters with each dot containing 5 mg plasmid DNA (35,36). Within each experiment, the same number of counts of nascent RNA, 1–1.6 x 10^7 cpm, was added to each dot.

Fatty acid analysis of spleen cell phospholipids. Spleen cell lipids were extracted with chloroform/methanol (2:1) using a modified Folch method (35). Total phospholipids were isolated by thin-layer chromatography on silica gel G with a solvent consisting of petroleum ether/ether/acetic acid, 70:30:1 (36). The phospholipid band that remained at the origin was scraped from the plate, and phospholipid fatty acids were transmethylated using BF_3. Fatty acid methyl esters were analyzed by capillary gas chromatography as described by Ackman, with minor modifications (37).

RESULTS

Analysis of LPS- and PMA-stimulated IL-1β mRNA. Spleen cells were obtained from mice fed with either BT or FO diets

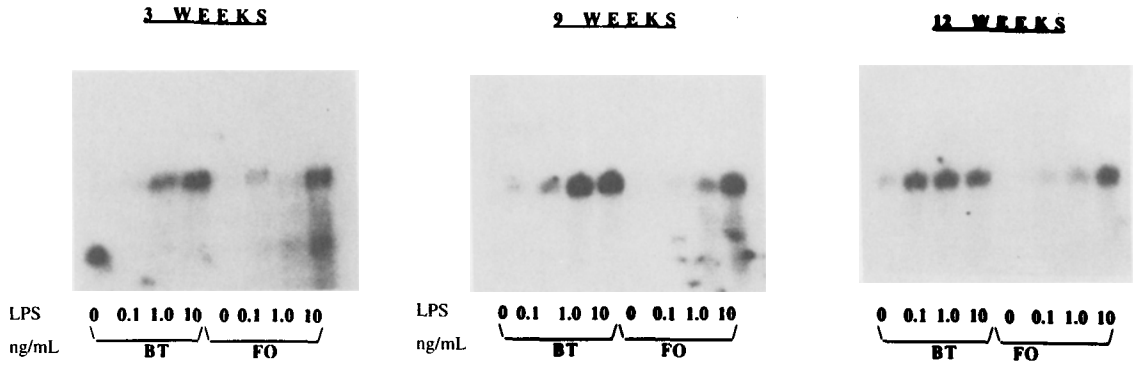

FIG. 1. Northern analysis of total RNA extracts from spleen cells isolated from mice fed for varying time intervals with diets containing either beef tallow (BT) or fish oil (FO) as their lipid components. Cells were stimulated with lipopolysaccharide (LPS) for 4 h prior to RNA extraction. RNA was transferred to nitrocellulose membranes and hybridized with a cDNA probe for murine proIL-1β. Equal quantities of RNA (10 μg) were applied to each lane. Arrows indicate the location of 18S and 28S RNA.

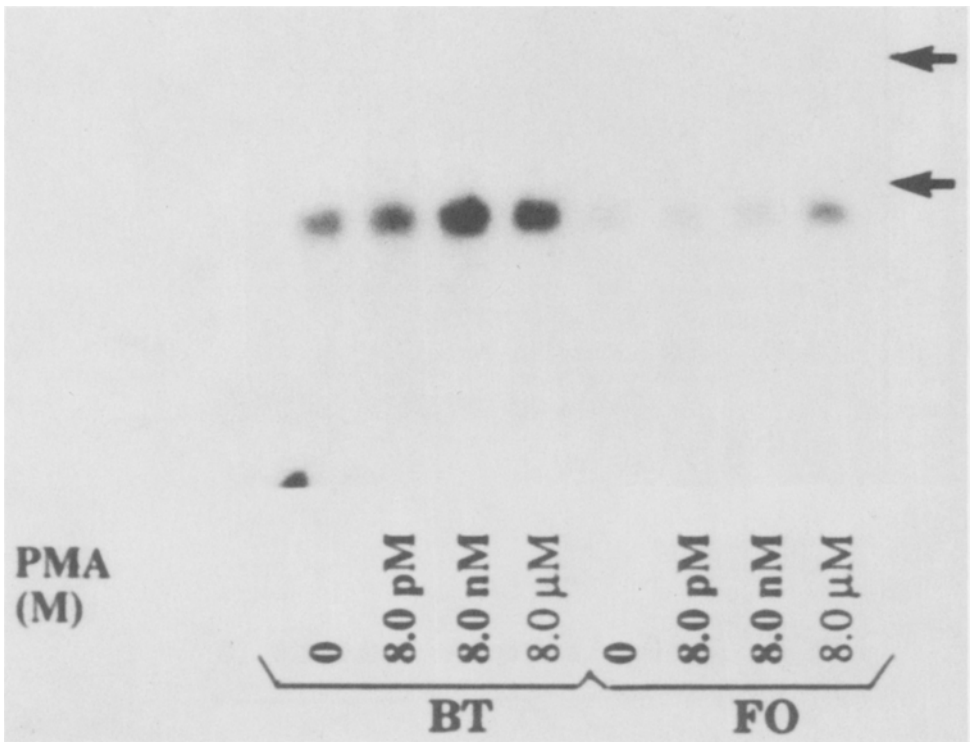

FIG. 2. Northern analysis of proIL-1β mRNA from phorbol 12-myristate 13-acetate (PMA)-stimulated murine spleen cells. Cells were obtained after administration of experimental diets for 12 wk. Abbreviations as in Figure 1.

for varying time periods and were stimulated *ex vivo* to produce IL-1β by either LPS or PMA. In the first experiment (Fig. 1), groups of mice were fed with experimental diets for either 3, 9, or 12 wk prior to stimulation of cells with LPS. In the next experiment (Figs. 2 and 3), mice were fed for 12 wk prior to stimulation of the cells with either LPS or PMA. In each experiment, the amount of LPS-inducible 1.7 kB proIL-1β mRNA derived from FO-fed mice cells was less than that of the BT controls, at most concentrations of LPS or PMA used. In the first experiment (Fig. 1), after 12 wk of feeding, a maximal intensity of the IL-1β mRNA band occurs at 0.1 ng/mL LPS with BT cells. In contrast, only faint bands occur at the lower two concentrations of LPS with FO cells, but at the highest concentration of LPS of 10 ng/mL, intensity of the band is similar to bands with stimulated cells from the BT group. These results are consistent with a lower sensitivity of FO cells than BT cells to LPS, but levels of IL-1β mRNA in most cases are similar in both groups of cells at the highest concentration of LPS.

Results in Figure 2 demonstrate that after PMA stimulation the maximum response of cells from the BT group occurs at 8 nM PMA, whereas in cells from the FO group only the highest concentration of PMA of 8 micromolar produces a signal above background level, and the response observed is less than that seen with the BT group. Aliquots of cells from this experiment were also stimulated with LPS (Fig. 3), with similar results to those seen at 12 wk in Figure 1. This membrane was also hybridized with a human β-actin probe as an internal control for cell numbers and the state of cell differen-

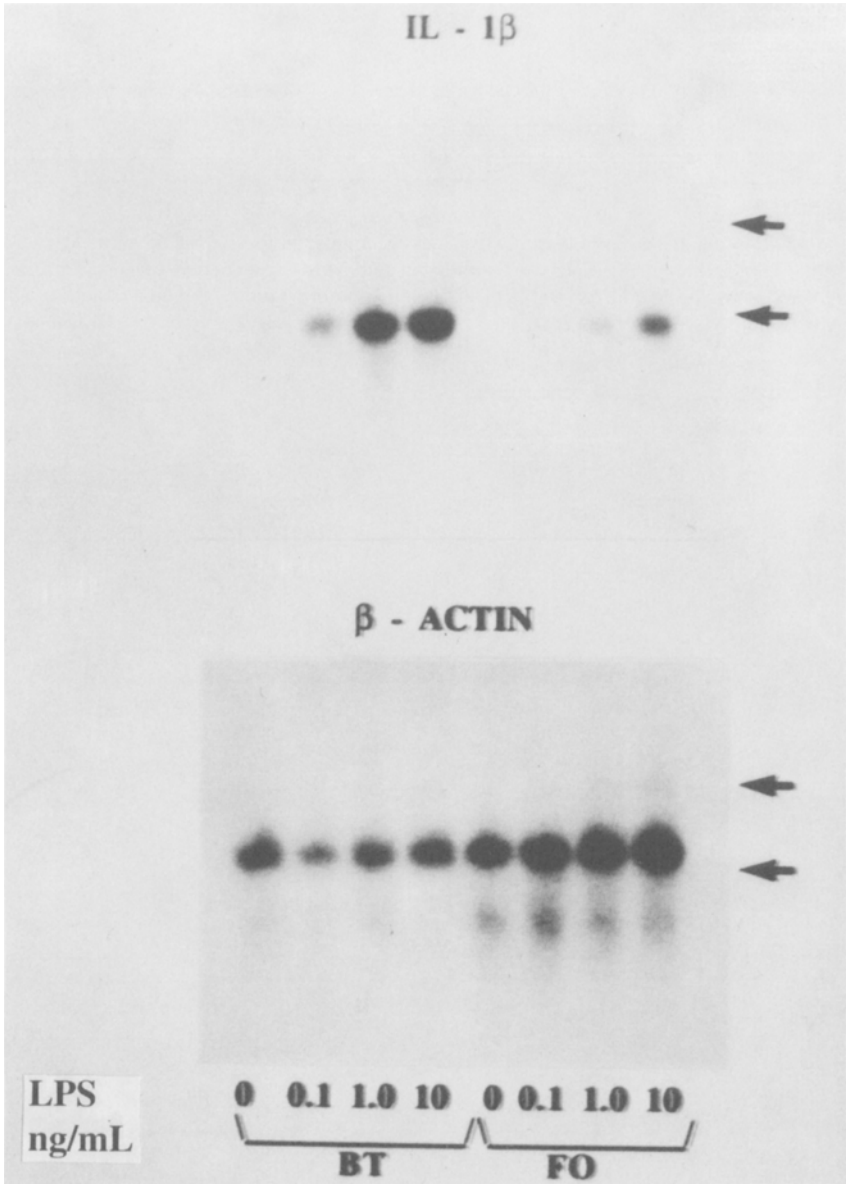

FIG. 3. Analysis of RNA extracts from LPS-stimulated murine spleen cells for proIL-1β and β-actin mRNA. Cells were aliquots of the same preparation used for PMA stimulation in Figure 2. Abbreviations as in Figures 1 and 2.

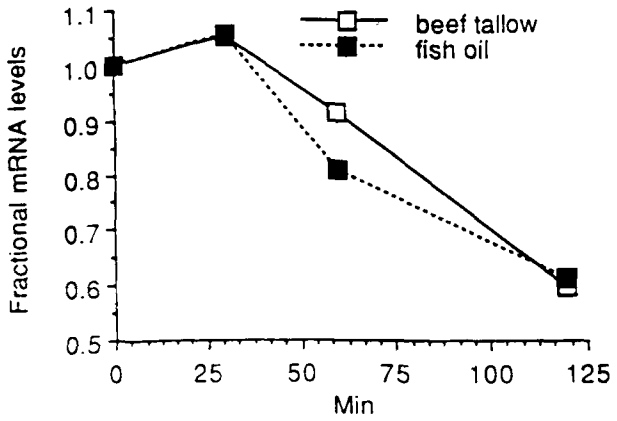

FIG. 4. Degradation rates of IL-1β mRNA from LPS-stimulated murine spleen cells. Cells were stimulated with LPS at 10 ng/mL for 5 h, after which actinomycin D was added to replicate cultures. After incubating with actinomycin D (5 mg/mL) for time periods indicated, each culture was subjected to northern analysis. Quantities of IL-1β mRNA were determined by scanning densitometry. Quantities of mRNA are expressed as the ratios of the densities at each time interval to the densities at the time of addition of actinomycin D (t = 0). Abbreviation as in Figure 1.

tiation. In contrast to results with the IL-1β probe, the β-actin band intensities with LPS stimulation are slightly more intense with the FO group than with the BT group, demonstrating the specificity of IL-1β mRNA effects.

Stability of LPS-stimulated IL-1β mRNA. Since it has been demonstrated that cytokine mRNA have relatively rapid turnover rates, we considered the possibility that reduced levels of IL-1β mRNA generated by cells from FO-treated mice could be achieved by an enhanced rate of decay of the message, compared to the BT group (39). To investigate this possibility, we determined rates of decay of IL-1 mRNA from LPS-stimulated spleen cells after exposure to actinomycin D. Cells were stimulated with 10 ng/mL LPS for 5 h, after which 5 mg/mL actinomycin D were added. Total RNA was isolated from these cells after incubation with actinomycin D for periods up to 2 h and subjected to northern analysis. Results in Figure 4 demonstrate that there is no significant difference in the rates of decay of IL-1β mRNA between the BT and the FO groups (t 1/2 = 2–3 h), indicating that the rate of transcription of the IL-1β gene in these LPS-stimulated cells is reduced in the FO group compared to the BT group.

Nuclear run-on transcription assays. Actinomycin D results suggest that transcriptional regulation is likely to be responsible for the steady-state differences between BT- and FO-fed animals' *ex vivo* cellular responses. Nuclear gene transcription was directly examined by nuclear run-on assay in which isolated nuclei are allowed to complete arrested transcription in the presence of radiolabelled ribonucleotide triphosphates, thus creating probes that can be assessed by hybridization to DNA targets fixed to nitrocellulose membranes. We demonstrated in three separate experiments reduced transcription from the IL-1β gene in LPS-stimulated spleen cells from mice fed the FO diet, compared to mice fed the BT diet. Results of two run-on experiments done in duplicate are shown in Figure 5. In both experiments, no signifi-

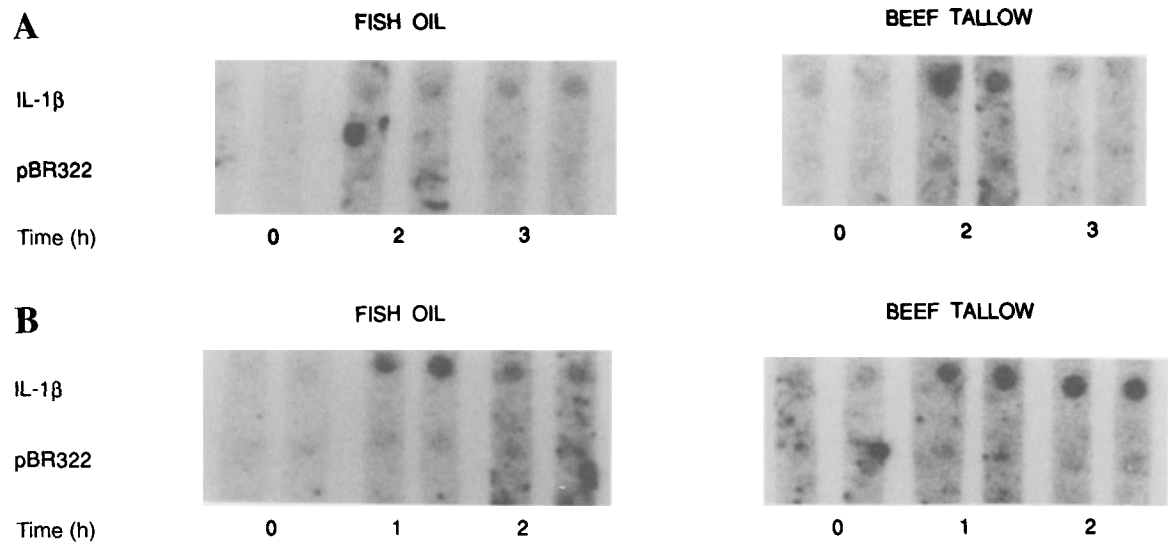

FIG. 5. Nuclear run-on transcripts after LPS stimulation. Nuclei were isolated from murine spleen cells that had been stimulated with LPS (1 ng/mL) for 0 to 3 h as indicated. Radiolabelled nascent RNA transcripts were prepared by incubating 6–8 x 10^7 nuclei with 150 mCi [a-^{32}P]uridine triphosphate. Radiolabelled RNA was isolated from the nuclei by digestion with DNase and protease K followed by phenol-chloroform extraction, G-50 sephadex spun column (Boehringer, Indianapolis, IN) purification, and trichloroacetic acid precipitation. RNA was treated with 0.2 M NaOH, and precipitated with Na acetate-ethanol. Equal counts of RNA (from 1.0 to 1.6 x 10^7 cpm per sample) were used to probe dots on nitrocellulose strips containing 5 mg denatured IL-1β cDNA, or denatured pBR322 plasmid DNA as a control: A) Spleen cells stimulated for 0, 2, and 3 h; B) Spleen cells from different mice than in experiment 1, stimulated for 0, 1, and 2 h. In both experiments, mice were fed described experimental diets for 12 wk before sacrificing to obtain spleen cells.

cant transcription was detected at 0 time, and faint signals were seen after 2 and 3 h of LPS stimulation from FO-fed mice. BT-fed mice showed more activity after 2 h of stimulation than FO-fed mice, with less activity after 3 h. No significant activity was seen with the vector control pBR322 as the target. Figure 5B reveals that there was increased transcription at 1 h of stimulation with RNA from both groups of mice, but at 2 h of stimulation, intense uptake continued with cells from BT mice, while FO cells returned to baseline. Thus, between 0 and 1 h following LPS exposure, the initial rate of IL-1β gene transcription was similar in cells from FO-fed and BT-fed mice. Beyond 1 h, however, transcription in cells from FO-fed mice shut down more rapidly than transcription from BT-fed mice. These findings indicate that dietary n-3 fatty acids reduce the levels of IL-1β mRNA by increasing the efficiency of the rapid gene shutdown associated with the transient expression usually observed for the IL-1β gene (38,50).

Fatty acid analyses of spleen cell phospholipids. Fatty acid analyses of spleen cell preparations were carried out after both 6 and 12 w feeding with each of the experimental diets. The wt% of each polyunsaturated fatty acid present in significant quantities is listed in Table 1. Administration of the FO diet was associated with large increases in the content of long-chain n-3 fatty acid in spleen cell phospholipids. Total polyunsaturated fatty acid content remained nearly constant, regardless of dietary lipid ingested or duration of experimental diets. Elevation of n-3 fatty acid content is therefore accompanied by reduction in n-6 fatty acid content, with relatively small differences in the contents of saturated and monoene fatty acids. The major n-6 fatty acid present is arachidonic acid, which is reduced in cells from the FO group to approximately one-third of the content of arachidonic acid in cells from the BT group. There are also large increases in contents of the three major n-3 fatty acids in cells from the FO group

TABLE 1
Fatty Acid Composition of Total Phospholipids Mouse Speen Cells[a]

	Six weeks[b]		Twelve weeks[b]	
Fatty acid	BT	FO	BT	FO

DISCUSSION

Results presented in this report demonstrate that dietary n-3 fatty acids inhibit sustained transcription of the IL-1β gene in stimulated spleen cells *ex vivo* by affecting the kinetics of gene expression beyond 1 h poststimulation. Others reported previously that dietary supplements of n-3 fatty acids inhibit production of IL-1 and TNF-α by LPS-stimulated human peripheral blood mononuclear cells (5,6). Studies reported here help clarify the mechanism of cytokine inhibition by n-3 fatty acids. Our experiments demonstrate that dietary n-3 fatty acids reduce steady-state levels of IL-1β mRNA in both LPS- and PMA-stimulated murine spleen mononuclear cells *ex vivo*. Reduced levels of IL-1β mRNA in stimulated spleen cells appear to arise from suppression of IL-1β gene transcription by n-3 fatty acids, based on the reduced rate of transcription beyond 1 h of *ex vivo* cell stimulation as assessed by nuclear run-on assays. Also, similar decay rates for IL-1β mRNA in cells from either FO- or BT-fed mice support the argument for a transcriptional effect. Reduced nuclear transcription does not appear to be related to a decreased induction, but rather to a more rapid shutdown of transcription following induction, as exhibited by the altered kinetics beyond 1 h of treatment. The IL-1β gene was previously shown to be transiently transcribed in various cell lines as well as in peripheral blood monocytes (38). This transient expression is due to the immediate and rapid induction that occurs in the absence of protein synthesis, followed by an almost immediate shutdown resulting from the action of a *de novo* expressed protein, which has been referred to as the transcriptional clamp (23). These data support a model in which either n-3 fatty acids induce a more vigorous expression of the clamp protein(s) or in which BT inhibits clamp expression (compared to alternative fatty acids). Therefore, the role of FO may be to support the strong expression of a protein factor that limits IL-1β gene transcription.

Neither the present nor the previous studies utilized a system containing a single cell type, raising the possibility that the FO effect could be exerting its effect by altering composition of cell preparations from which the cytokines were derived. In the studies reported here, we cannot determine which cell type is responsible for the major portion of IL-1β mRNA, although spleen monocytes are a likely source. We considered the possibility that dietary n-3 fatty acids altered composition of spleen cell preparations such that the percentage of cells containing major quantities of IL-1β mRNA after stimulation was reduced, but the following considerations make this possibility unlikely. No difference in numbers of B-cells and T-cells between BT and FO groups were observed

by fluorescence-activated cell sorter analysis, and no differences in monocytes were observed microscopically. Others also reported that percentages of lymphocytes and monocytes in similar murine spleen cell preparations were not altered significantly by changes in dietary lipids, including n-3 fatty acids (25). The PMA experiment demonstrates that the decreased responsiveness of FO cells is not specific for LPS induction, since the data in Figure 1 demonstrate that responsiveness of FO cells to PMA is less than that of BT cells by over three orders of magnitude.

The mechanism of inhibitory effects of n-3 fatty acids on production of IL-1β mRNA by activated mononuclear cells is unknown. The experimental diets achieved major modifications in the polyunsaturated fatty acid composition of spleen cells, with large reductions in n-6 fatty acids and reciprocal elevations in the contents of n-3 fatty acids, but we have not determined the relationship, if any, between changes in phospholipid fatty acid composition and suppression of IL-1β gene transcription. Our experiments demonstrate that this suppression applies to both a transmembrane and a soluble stimulant, each of which acts by complex, but different, mechanisms (39).

The following evidence indicates that induction of transcription of both IL-1 and TNF-α genes by LPS and PMA may be mediated by activation of protein kinase C. Induction of LPS responsiveness in U937 cells is associated with the stimulation of mRNA synthesis for the G protein Gi2 (40). It was suggested that PMA induces protein kinase C–mediated phosphorylation of endogenous substrates such as the transcriptional activator, AP-1, that could in turn induce transcription of the Gi2 gene. It was also reported that PMA induction of IL-1 by the human monocytic cell line THP-1 was inhibited by a selective protein kinase C inhibitor (41). Since protein kinase C utilizes both diacylglycerol and phospholipids as cofactors, it is possible that the changes in fatty acid composition of phospholipids associated with higher levels of dietary n-3 fatty acids could inhibit the activity of protein kinase C due to changes in the structures of its lipid cofactors.

Certain eicosanoids have been found to modify the production of cytokines. Inhibition of LPS-induced TNF-α mRNA production from murine peritoneal macrophages was observed with prostaglandin E_2 ($PGE_{1)}$ and PGE_2, but leukotriene B_4 (LTB_4), and LTC_4 had no effect (42). Conversely LTB_4 and LTD_4 enhanced production of IL-1 by human peripheral blood monocytes that had been stimulated by LPS and other agonists (43). Since dietary marine lipids reduce production of 5-lipoxygenase products by human leukocytes (6,15), it is possible that suppressed LT production by mononuclear cells from FO-treated mice could reduce IL-1 production, perhaps by interfering with a key early signaling requirement. Another study, however, reported that LTB_4 did not enhance LPS-stimulated IL-1 production by murine peritoneal macrophages (44), and thus LT enhancement of IL-1 synthesis may be limited to certain cell types. We have not yet examined effects of LT on IL-1 production by spleen cell preparations utilized in experiments reported here.

Dietary n-3 fatty acids also suppress formation of prostaglandins and thromboxanes, although production of prostacyclin in humans is not affected significantly (45–48). Although the E prostaglandins suppress TNF-α mRNA production, as noted above, and also suppress production of IL-1 protein (44,49), evidence indicates that inhibition of IL-1 production is at a post-transcriptional level, since IL-1β mRNA levels are unaffected in stimulated U937 cells by PGE_2 (49). In any event, the E prostaglandins inhibit cytokine production, and thus the usual reduction of PGE levels by n-3 fatty acids, if such inhibitory effects occurred in our experimental system, would have augmented cytokine mRNA levels.

This study demonstrates that dietary n-3 fatty acids suppress levels of IL-1 mRNA in murine spleen cells following activation by two different stimuli, and results with LPS-stimulated cells indicate that the mechanism involves inhibition of induction of IL-1 gene transcription by n-3 fatty acids. Molecular mechanisms for inhibition of IL-1 gene transcription by n-3 fatty acids remain to be determined. IL-1 gene expression depends on the integrity of an upstream LPS and PMA responsive enhancer and a tissue-specific promoter, and both of these regions bind positive factors important for gene expression. This raises the possibility that n-3 fatty acids may interfere with the function of factors necessary for maximal IL-1 gene induction.

ACKNOWLEDGMENTS

We are grateful to Dr. Mary Goldring for providing the β-actin probe. This work was supported by grants AR 03564, AR 43518, CA68544, and AI 27850 from the National Institutes of Health, and a grant from the Davis Family Foundation.

Polyunsaturated Fatty Acids Inhibit Hepatic Stearoyl-CoA Desaturase-1 Gene in Diabetic Mice

Katrina M. Waters and James M. Ntambi*

Departments of Biochemistry and Nutritional Sciences, The University of Wisconsin–Madison, Madison, Wisconsin

ABSTRACT: Insulin and dietary fructose independently induce stearoyl-CoA desaturase 1 (SCD1) gene expression in diabetic mouse liver. In the present study, we again used diabetic mice and supplemented a high fructose diet with polyunsaturated fatty acids (PUFA) to determine the selective repression of SCD1 gene expression by dietary PUFA, as previously shown in normal mice. We saw dramatic repression of SCD1 mRNA expression, with trilinolenin at 3% and triarachidonin at 1% supplementation. We also observed significant repression of insulin-induced SCD1 mRNA upon supplementation of the noninducing starch diet with PUFA. In conclusion, our data demonstrate that PUFA negatively regulate hepatic gene expression through an insulin-independent mechanism.

Lipids 31, S-33–S-36 (1996).

Stearoyl-CoA desaturase (SCD) is a key enzyme involved in biosynthesis of unsaturated fatty acids and regulation of this process. The enzyme catalyzes the Δ^9-*cis* desaturation of C_{16} and C_{18} fatty acyl-CoAs, leading to synthesis of palmitoleoyl- and oleoyl-CoA as major products (1). Hepatic SCD enzyme levels, like a number of lipogenic enzymes, are increased by a high-carbohydrate diet (2), and this increase in enzyme activity correlates positively with the abundance of SCD mRNA in liver (3,4). We showed that this increase in stearoyl-CoA desaturase gene 1 (SCD1) mRNA is due to enhancement in the transcriptional activity of the SCD1 gene (5). Recently, we observed that the increase in SCD1 mRNA caused by fructose and insulin can occur independently in diabetic mice, whereas the transcriptional induction requires both inducers (6). This is consistent with other lipogenic genes, such as fatty acid synthase and S14, which are known to be transcriptionally activated by insulin and fructose (7,8), leading to stimulation of lipogenesis in liver.

Polyunsaturated fatty acids (PUFA) have been shown to reduce genetic expression of many enzymes in the biosynthesis of fat, including SCD1, fatty acid synthase, acetyl-CoA carboxylase, and malic enzyme (5,9–11). A fat-free, high-carbohydrate diet supplemented with 3% triarachidonin (20:4) represses induced SCD1 mRNA by more than 95% and transcription by 75% (5). Arachidonic and eicosapentaenoic (20:5) acids have also been shown to reduce SCD1 mRNA levels in cultured primary hepatocytes by as much as 90% (12). This dramatic repression suggests that PUFA, or some PUFA metabolite, have a distinct and significant role in lipogenic gene regulation.

In this study, we examined the mechanism of PUFA repression of SCD1 mRNA in diabetic mice to determine if this repression was insulin dependent. We found that both trilinolenin (18:3) and triarachidonin significantly repress fructose-induced SCD1 mRNA in insulin-deficient mice, as shown by RNase protection analysis. Both trilinolenin and triarachidonin also repress insulin-induced SCD1 mRNA when diabetic mice are given a physiological dose of regular and lente (slow-acting) insulin. None of these manipulations affect β-actin mRNA levels, showing that this effect is specific to SCD1. Overall, our results show that PUFA repress SCD1 mRNA through an insulin-independent mechanism.

MATERIALS AND METHODS

Fructose and starch diets were made in our laboratory using appropriate sugars obtained from Fisher Scientific (Springfield, NJ) and Purina Formulab Diet 5008 (Richmond, IN). Regular (bovine) insulin was purchased from Sigma (St. Louis) and lente (porcine) insulin was from Eli Lilly Corp. (Indianapolis). cDNA for the β-actin riboprobe was purchased from Ambion, Inc. (Austin). All plasmid DNA were isolated by modification of the SDS-NaOH method (13), and nucleic-acid–modifying enzymes were purchased from Promega Biotechnology Inc. (Madison), Boehringer Mannheim (Indianapolis) and New England Biolabs (Beverly, MA). Butylated hydroxytoluene, streptozotocin, trilinolenin, and triarachidonin were all obtained from Sigma.

Animals and treatments. Male BALB/c mice, used throughout this study, were obtained from the Department of Biochemistry of the University of Wisconsin in Madison. Mice (4–6 weeks old) were made diabetic by four daily intraperitoneal

injections of streptozotocin (5 mg/100 g) in sodium citrate (pH 4.5), as described previously (6). Diabetes was confirmed by high fasting glucose levels determined by using Clinetex (Fisher Scientific) and animals were considered diabetic when blood glucose levels exceeded 250 mg/dL. Animals were maintained on a complete diet of Purina Formulab Diet 5008 throughout the entire course of streptozotocin injections. Once diabetic, mice were fasted for 12 h and then switched from the chow diet to either an 80%-fructose or 80%-starch diet for 24 h. When stated, trilinolenin and triarachidonin were supplemented at 3 and 1%, respectively, with 0.1% butylated hydroxytoluene as an antioxidant, and all diets were made fresh daily. Insulin was administered to diabetic animals at a combined dose of regular insulin (3 units/100 g) intraperitoneally and lente insulin (30 units/100 g) subcutenously. All animals were given free access to tap water. Blood glucose levels were again measured upon sacrifice for all mice to check for proper hormonal status.

Measurement of mRNA. Total hepatic RNA was isolated according to Chirgwin et al. (14), and RNase protection analysis of SCD1 and β-actin mRNA expression was performed as described previously (6). Quantification of relative mRNA was determined by laser densitometric scanning (Molecular Dynamics, Sunnyvale, CA) of autoradiograms. Integrity of the RNA used for the RNase protection analysis was verified by fractionating 30 μg total liver RNA on a 1% agarose gel containing 6.7% formaldehyde and visualizing RNA by ethidium bromide staining.

RESULTS

Effect of PUFA on fructose induction of SCD1 mRNA in diabetic mice. SCD1 is transcriptionally induced upon fasting and then refeeding a fat-free, high-carbohydrate diet. Dietary PUFA have been shown to repress transcription of SCD1 in livers of normal mice (5). We have recently shown that fructose and insulin are capable of inducing SCD1 mRNA independently; however, transcriptional induction requires both fructose and insulin. To determine whether the PUFA-mediated repression of SCD1 was insulin dependent, diabetic mice were fasted and refed an 80%-fructose diet with or without supplemented PUFA. Trilinolenin was supplemented at 3%, and triarachidonin was supplemented at 1%; SCD1 mRNA levels were analyzed by RNase protection analysis using SCD1- and β-actin complementary riboprobes (Fig. 1A). Autoradiograms were subjected to laser densitometric scanning, and results of this are shown in Fig. 1B. Trilinolenin repressed fructose-induced SCD1 mRNA levels by 90% and triarachidonin by 93%, whereas β-actin mRNA levels were not significantly changed. These results show that PUFA regulate SCD1 gene expression via an insulin-independent mechanism. This is consistent with Wilson et al. (15), who observed that dietary unsaturated fat could repress overall liver lipogenesis in severely diabetic rats, whereas saturated fat had no effect.

Effect of PUFA on insulin induction of SCD1 mRNA in diabetic mice. Figure 1 showed that PUFA regulate SCD1 in insulin-deficient mice. To determine if PUFA can repress insulin induction of SCD1 mRNA in the absence of inducing carbohydrate, diabetic mice were fasted and then refed a noninducing 80%-starch diet for 24 h. Insulin was administered for 18 h before sacrifice. Where indicated, trilinolenin and triarachidonin were supplemented to the starch diet at 3 and 1%, respectively. SCD1 and β-actin mRNA levels were measured by RNase protection and quantitated as described above.

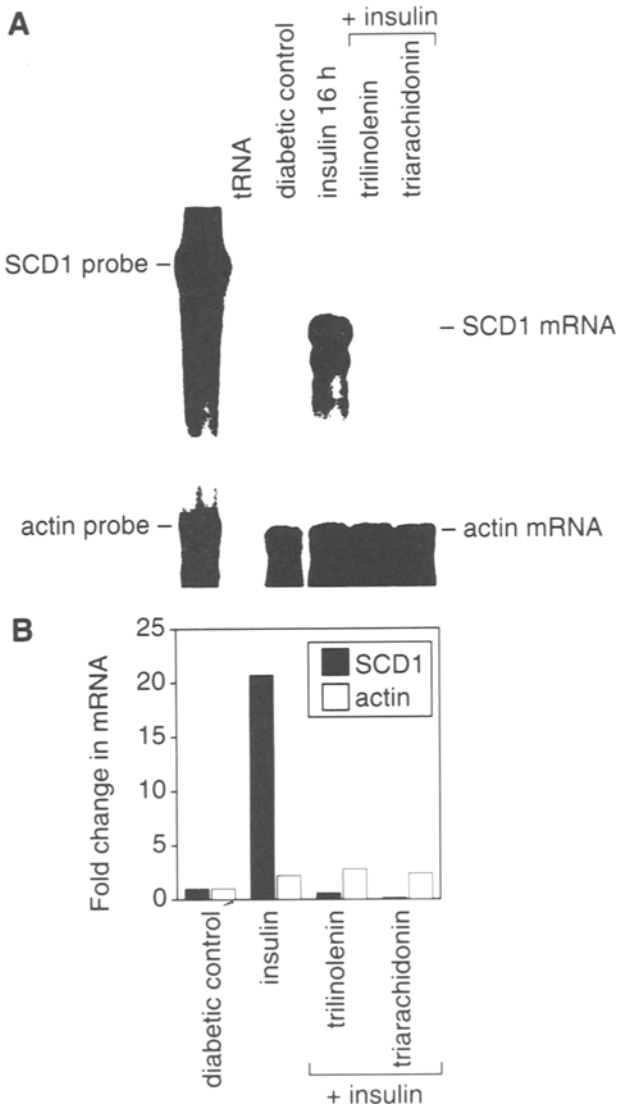

FIG. 1. Repression of fructose-induced SCD1 mRNA by trilinolenin and triarachidonin. Mice were made diabetic by 4 daily injections of streptozotocin and were considered diabetic when blood glucose levels reached > 250 mg/dL. Mice were then fasted for 12 h and switched from chow diet to 80%-fructose diet for 24 h. Where indicated, trilinolenin and triarachidonin were supplemented at 3 and 1%, respectively. Livers were harvested, and total RNA was isolated as described. (A) SCD1 and β-actin mRNA were measured by RNase protection analysis using radiolabeled complementary riboprobes and visualized by autoradiography. (B) autoradiograms in A were subjected to laser densitometry to measure relative change in mRNA, and data are normalized to control diabetic animal. Films of differing exposures were scanned, giving essentially identical results.

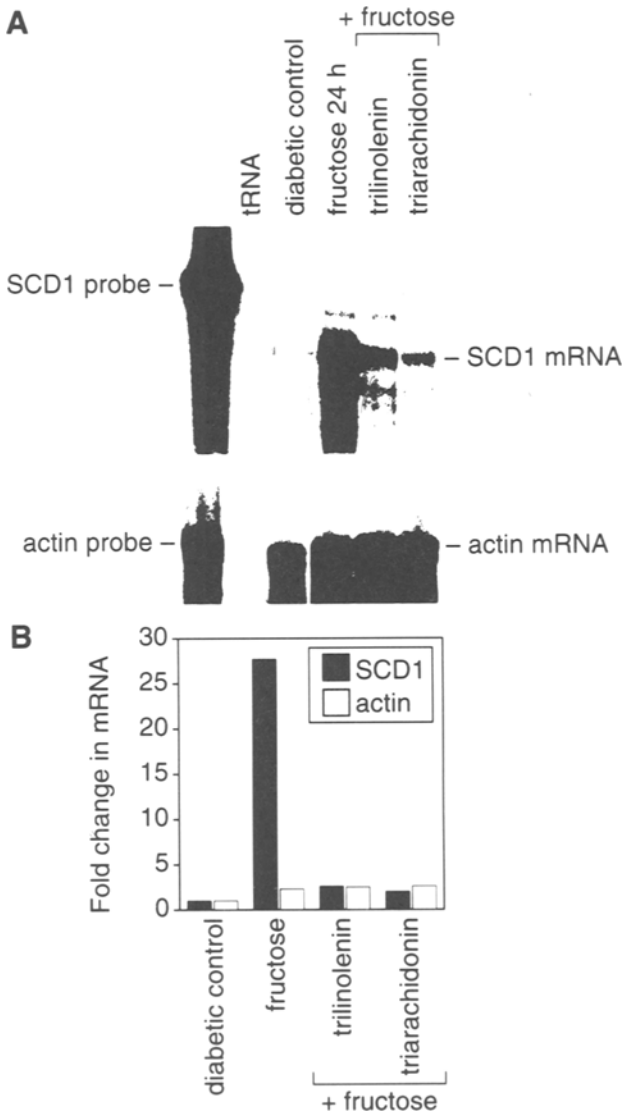

FIG. 2. Repression of insulin-induced SCD1 mRNA by trilinolenin and triarachidonin. Mice were made diabetic as described. Once diabetic, mice were fasted for 12 h and then switched from chow diet to 80%-starch diet for 24 h, with trilinolenin and triarachidonin supplemented at 3 and 1%, respectively, where stated. Insulin was given in a combined dose of 3 U/100 g regular insulin intraperitoneally and 30 U/100 g lente insulin subcutaneously. Livers were harvested, and total RNA was isolated as described. (A) SCD1 and β-actin mRNA were measured as for fructose, and autoradiograms are shown; (B) autoradiograms in A were subjected to laser densitometry, and data are normalized to control diabetic animals.

Autoradiograms and data are shown in Fig. 2. As with fructose, trilinolenin and triarachidonin repressed SCD1 mRNA levels by 97 and 99%, respectively, and again β-actin mRNA levels were not significantly altered. Control animals receiving insulin vehicle injections showed no effect on SCD1 or β-actin mRNA levels (data not shown). This study shows that PUFA repress insulin-dependent SCD1 mRNA levels in the absence of inducing carbohydrate and that these manipulations are specific to SCD1.

DISCUSSION

Stearoyl-CoA desaturase genes (SCD1 and SCD2) encode a key enzyme involved in biosynthesis of unsaturated fatty acids and in regulation of this process. Hepatic SCD1 transcription has been shown to increase by fasting and then refeeding a fat-free, high-carbohydrate diet to animals (5); it decreases upon supplementation of the fat-free diet (or media) with PUFA (5,12). In a recent study, we found that the full induction of SCD1 mRNA observed previously in the normal mouse could not be restored by either insulin or fructose alone, but instead required a combination of the two or a combination of glucose and insulin (6). In this study, we have shown that PUFA repress SCD1 mRNA in diabetic mice independently of insulin. Trilinolenin and triarachidonin suppress fructose-induced SCD1 mRNA levels by 90 and 93%, respectively, with no effect on β-actin levels. Likewise, trilinolenin and triarachidonin repress insulin-induced SCD1 mRNA levels by 97 and 99%, respectively, again with no effect on β-actin levels. We believe that PUFA are repressing SCD1 transcription, as well as posttranscriptional regulation of mRNA, since transcriptional repression of SCD1 by PUFA has been shown previously in normal animals (5).

Repression of fatty acid biosynthesis by PUFA is not universally found in all tissues. Rat adipose tissue lipogenesis is repressed by dietary long-chain fat supplementation, but to a lesser extent than in liver tissue (16), and rat lung tissue lipogenesis has been shown to be resistant to repression by dietary unsaturated fat (17). Medium-chain-length triglyceride has been shown to induce lipogenesis in liver of diabetic rats in an insulin-dependent manner (18), apparently by a distinct and separate mechanism than what we are observing with PUFA. Dietary polyunsaturated fat has also been shown to reduce triiodothyronine's induction of rat liver fatty acid synthase and malic enzymes in a dose-dependent manner (19).

For stearoyl-CoA desaturase, the picture still remains unclear. Cultured lymphocytes exhibit similar repression of SCD2 transcription by arachidonic acid as SCD1 in hepatocytes (20), whereas linoleic acid is suggested to induce SCD2 mRNA in neonatal mouse brain (21). Many studies of PUFA repression of lipogenic genes have been reproduced in primary hepatocyte culture (12,22–23), and a PUFA-responsive element has been localized for fatty acid synthase (24) and S14 (25) genes. It has been suggested that PUFA repression of lipogenic genes is mediated by peroxisome proliferator-activated receptors (12). We do not believe this to be the case, since peroxisome proliferators actually induce SCD1 mRNA in mouse liver [Miller, C.W., and Ntambi, J.M., (1995) submitted for publication], unlike the repression seen with PUFA. This suggests that SCD1 may be regulated by some mechanism unique from that of other lipogenic genes. Details of this mechanism remain unknown at the time of this report.

Another recent study showed that SCD1 mRNA is repressed by arachidonic acid in cultured H2.35 liver cells (26), and we have found that this repression can be transcriptionally reproduced using chloramphenicolacetyltransferase reporter gene constructs containing portions of the SCD1 promoter region

(Sessler, A.M., and Ntambi, J.M., unpublished data). This immortal cell culture model provides a tool for identifying SCD *cis*-acting elements without the complications of primary hepatocyte culture or transgenic animal studies. It is hoped that more precise identification of the carbohydrate/insulin-, PUFA-, and peroxisome proliferator-dependent factors that regulate SCD1 gene expression will be achieved with these H2.35 liver cells in culture.

Effects of Different Polyunsaturated Fatty Acids on Growth-Related Early Gene Expression and Cell Growth

A. Sellmayer[a,b,*], U. Danesch[a], and P.C. Weber[a]

[a]Institut für Prophylaxe und Epidemiologie der Kreislaufkrankheiten, Universität München, München, Germany, and [b]Medizinische Klinik Innenstadt, Universität München, München, Germany

ABSTRACT: Effects of polyunsaturated fatty acids on expression of early-response genes c-*fos* and Egr-1 and induction of cell growth were assessed in Swiss 3T3 fibroblasts. Stimulation with arachidonic acid increased mRNA levels of c-*fos* and Egr-1. This effect was inhibited by preincubation with cyclooxygenase inhibitors and restored by addition of prostaglandin E_2 (PGE_2), the predominant eicosanoid produced in Swiss 3T3 fibroblasts. Further signaling of PGE_2 was mediated by a protein kinase C–dependent pathway, since downregulation, or inhibition, of protein kinase C reduced increases in mRNA levels. Parallel to the stimulatory effects on mRNA levels, AA and PGE_2 also increased cell growth, as determined by uptake of [^{3}H]-thymidine. In contrast to arachidonic acid, n-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) did not increase c-*fos* and Egr-1 mRNA levels or cell growth. Furthermore, preliminary data indicate that EPA and DHA even reduce the stimulatory effect of AA, which is associated with reduced formation of PGE_2. In conclusion, our data indicate that AA increases expression of growth-related early genes c-*fos* and Egr-1 in Swiss 3T3 fibroblasts by its conversion to PGE_2 and subsequent activation of protein kinase C, whereas n-3 fatty acids do not activate this signaling cascade.
Lipids 31, S-37–S-40 (1996).

Arachidonic acid (AA) and its metabolites have recently been identified as a novel group of intracellular second messengers (1) regulating ion channels and activities of enzymes involved in signal transduction, such as GTPase-activating protein or protein kinases (1,2). In addition, AA and its metabolites have been found to modulate gene expression. Endogenous formation of cyclooxygenase or noncyclooxygenase metabolites of AA has been implicated to mediate expression of early-response genes c-*fos*, Egr-1, c-*myc*, or c-*jun* in different cell types after mitogenic stimulation (3,4) or treatment with H_2O_2 (5,6). Furthermore, stimulation with lipoxygenase or cyclooxygenase metabolites of AA also increased early gene expression (7–9), indicating that endogenously produced eicosanoids may modulate early gene expression in an autocrine or paracrine way. In addition, a more direct effect of polyunsaturated fatty acids (PUFA) on the expression of gene coding for enzymes of fatty acid metabolism has been reported. PUFA, including AA and other n-6 and n-3 fatty acids, transcriptionally repressed expression of the fatty acid synthase gene (10), the hepatic S_{14} gene (11), and the genes coding for stearoyl-CoA desaturase (12). Based on chimeric gene constructs (10,11), an AA response element has been identified but not yet sequenced.

Apart from modulation of gene expression, AA and n-3 PUFA have also been implicated to differentially influence cell growth. Most observations indicate a promitogenic activity of n-6 PUFA (4,13,14), whereas n-3 PUFA have been reported to mainly reduce pathologic growth (15–17). We studied Swiss 3T3 fibroblasts to further delineate signaling pathways involved in the regulation of early gene expression and possibly cell growth by PUFA. We characterized a novel mechanism by which AA induces c-*fos* and Egr-1 expression (18) and found evidence that n-3 PUFA differentially influence gene expression and cell growth in 3T3 fibroblasts.

EXPERIMENTAL PROCEDURES

Tissue culture. Tissue culture conditions for Swiss 3T3 fibroblasts were essentially as described (18). In particular, cells were regularly split every seven days, and all experiments were performed with confluent cultures.

Northern blot analyses. After stimulation for 30 min, RNA extraction and Northern blot analyses were performed essentially as described previously (18). For hybridization, cDNA coding for the 0.48 kb human c-*fos* fragment from exon 4, the 2.6 kb mouse Egr-1 fragment, and the 0.8 kb rat GAPDH fragment were subcloned in riboprobe vectors. RNA transcribed from these riboprobe vectors was used as probes and hybridized to the blots, as detailed elsewhere (18). The same blot was hybridized to all three probes in two steps.

Determination of thymidine incorporation. Cell growth was determined by incorporation of [^{3}H]-thymidine. Cells were serum-deprived for 24 h and stimulated by addition of PUFA, prostaglandin E_2 (PGE_2), or epidermal growth factor (EGF) for 24 h in the presence of 0.5 μCi [^{3}H]-thymidine. trichloroacetic acid (TCA)-precipitable radioactivity was quantified by liquid scintillation counting in a β-counter.

Metabolism of [^{14}C]-arachidonic acid. Eicosanoid formation was analyzed as detailed previously (18,19). Cells were stimulated with 10 μM AA [0.5 μCi (1 μM) [^{14}C]-AA plus 9 μM nonradioactive AA] for 15 min. After fluid extraction, eicosanoids were separated by reverse-phase high-performance liquid chromatography (HPLC) (19). Metabolites were identified by their characteristic retention times and by coelution of authentic standards. Eicosanoids were quantified after correction for the recoveries of the internal standard PGB_2 added prior to extraction and of total radioactivity in each sample. In addition, PGE_2 formation in cells stimulated with 10 μM AA, eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) was quantified by ELISA (Cascade Biochemicals, Reading, United Kingdom), as recommended by the manufacturer.

RESULTS

Stimulation with AA (2.5–10 μM) or with the calcium ionophore A23187 (10 μM), which activates phospholipase A_2 to release endogenous AA from phospholipids, induced accumulation of c-*fos* and Egr-1 mRNA. Preincubation with the cyclooxygenase inhibitor indomethacin (0.1–10 μM) or other cyclooxygenase inhibitors markedly reduced induction of early gene expression by AA, indicating that intrinsic cyclooxygenase activity is required to mediate the effect of AA.

To identify the cyclooxygenase metabolite, 3T3 cells were stimulated with [^{14}C]-AA alone, and lipid extracts were analyzed by HPLC. The predominant eicosanoid produced spontaneously was found to be PGE_2, as evidenced by its specific retention time on HPLC and cochromatography of authentic standards. In addition, using monocytic U937 cells, we previously confirmed by gas chromatography–mass spectrometry analysis that a compound eluting with the same retention time on HPLC was PGE_2 (19).

Given that PGE_2 is the main metabolite of AA in 3T3 fibroblasts, its effect on c-*fos* and Egr-1 mRNA levels was determined. PGE_2 (10 μM) alone increased accumulation of both mRNA to the same degree as did AA. Furthermore, PGE_2 reversed the inhibitory effect of indomethacin on mRNA accumulation in 3T3 cells stimulated with AA, indicating that endogenous conversion of AA to PGE_2 mediates induction of early gene expression.

PGE_2 has been found to transduce its signal by binding to at least three different receptor subtypes (EP_{1-3}; 20), which activate different second messenger systems. Binding to the EP_1 receptor stimulates phospholipase C, leading to generation of inositolphosphates and diacylglycerol, which finally result in increased cytosolic free calcium levels and activation of protein kinase C (PKC). In contrast, activation of EP_2 and EP_3 receptor subtypes either enhance (EP_2) or decrease (EP_3) adenylate cyclase activity; resulting in respective changes in cAMP levels.

To further characterize intracellular signaling pathway(s) activated by PGE_2, we determined intracellular cAMP levels and evaluated effects of PKC inhibition and of agents known to increase cAMP on the levels of c-*fos* and Egr-1 mRNA. In cells stimulated with AA or PGE_2, cAMP levels were only 1.5-fold higher, as compared to unstimulated cells, whereas treatment with forskolin (50 μM), a compound that directly activates adenylate cyclase, resulted in a 15-fold increase. Similarly, agents known to increase cAMP formation [forskolin and dibutyryl cAMP (10–100 μM)] did not increase mRNA levels in a manner comparable to AA or PGE_2, indicating that activation of adenylate cyclase is not involved in AA- or PGE_2-induced expression of c-*fos* and Egr-1. In contrast, downregulation of PKC by prolonged stimulation with phorbol myristate acetate (PMA) (800 nM) or inhibition of PKC by chelerythrine (20 μM) or calphostin C (0.5 μM) almost completely inhibited c-*fos* and Egr-1 mRNA accumulation in cells stimulated with AA or PGE_2.

Taken together, these data indicate that exogenously added or endogenously released AA induces c-*fos* and Egr-1 mRNA accumulation by its endogenous conversion to PGE_2 and subsequent activation of PKC, possibly by binding to an EP receptor subtype linked to activation of phospholipase C (Fig. 1).

Increased expression of early genes has been reported to occur as an early response to mitogenic stimulation (21,22). To further relate increases in c-*fos* and Egr-1 mRNA levels to cell growth, the effect of AA and PGE_2 on uptake of [^{3}H]-thymidine was assessed. Both AA (10 μM) and PGE_2 (1 μM) increased thymidine incorporation by 167 ± 32% and 150 ± 21%, respectively.

In contrast to AA or PGE_2, treatment with the n-3 PUFA EPA (10 μM) or DHA (10 μM) increased neither thymidine

TABLE 1
Effects of AA, EPA, or DHA on Thymidine Incorporation and PGE_2 Formation[a]

PUFA added	AA[b]	EPA[c]	DHA[d]
Thymidine uptake (% control)	167 ± 32	112 ± 20	103 ± 12
PGE_2 formation (ng/mL)	3237 ± 247	147 ± 137	70 ± 12

[a]Data are presented as mean ± SD from three independent experiments. In the control condition, cells were treated with the vehicle for polyunsaturated fatty acids (PUFA), ethanol, only. [b]AA = Arachidonic acid. [c]EPA = Eicosapentaenoic acid. [d]DHA = Docosahexaenoic acid.

incorporation nor formation of PGE_2 (Table 1). Furthermore, preliminary data indicate that EPA and DHA do not induce accumulation of c-*fos* and Egr-1 mRNA and even antagonize effects of AA on gene expression and cell growth. This is paralleled by decreased PGE_2 formation, indicating that antagonistic effects of n-3 and n-6 PUFA on early gene expression and cell growth are mediated by differential stimulation of PGE_2 formation and subsequent activation of PKC.

DISCUSSION

Among the many biochemical activities of AA and its metabolites, regulation of gene expression has recently been identified as a novel property of PUFA and eicosanoids. Apart from genes coding for enzymes of fatty acid metabolism (10,12,23), eicosanoids have been found to modulate the expression of various early-response and growth-related genes (3–6), many of them coding for transcription factors. The molecular mechanism underlying modulation of gene expression by PUFA are not yet fully characterized, however. Studying genes coding for enzymes of fatty acid metabolism, deletion analyses, and chimeric constructs suggested that AA and other n-3 and n-6 PUFA may directly interact with a fatty acid response element (10,11), although its nucleotide sequence has not yet been identified. Furthermore, n-3 and n-6 PUFA have been found to stimulate transcriptional activity of the promoter of the acyl-CoA oxidase gene, which is required for fatty acid ß-oxidation, by activation of the peroxisome proliferator activator receptor (23), a transcription factor belonging to the superfamily of nuclear receptors.

Although these observations indicate a direct transcriptional activity of PUFA, this has not been confirmed by studying early genes. Accordingly, we found that in Swiss 3T3 fibroblasts AA induces expression of c-*fos* and Egr-1 after its conversion to PGE_2 and subsequent activation of PKC. This signaling cascade has essentially been confirmed in a study by Simonson *et al.* (24), demonstrating that, in rat mesangial cells, AA and PGE_2 induce c-*fos* and c-*jun* expression through a cAMP-independent and PKC-dependent mechanism. Both studies indicate that activation of a PGE_2 receptor on the plasma membrane, possibly the EP_1 receptor subtype, is involved to further stimulate PKC and transduce the signal to the nucleus.

In conclusion, our observations and those reported by Simonson *et al.* (24) provide evidence that, in addition to a direct transcriptional effect of fatty acids, AA induces expression of early genes by an autocrine or paracrine mechanism requiring its endogenous conversion to the cyclooxygenase metabolite PGE_2, which further activates PKC-dependent intracellular signaling to increase early-gene mRNA accumulation. Consistent with this intracellular signaling cascade, antagonistic effects of n-3 fatty acids EPA and DHA on AA-induced mRNA accumulation and cell growth can at least in part be explained by their inhibitory effect on PGE_2 formation.

The Cardiac Antiarrhythmic Effects of Polyunsaturated Fatty Acid

Jing X. Kang[a] and Alexander Leaf[a,b,*]

Departments of Medicine, [a]Massachusetts General Hospital, [b]West Roxbury VA Medical Center, Harvard Medical School, Boston, Massachusetts 02129

ABSTRACT: Each year in the United States alone some 250,000 persons die within one hour of an acute myocardial infarction. These deaths are largely due to ischemia-induced ventricular arrhythmias, primarily ventricular fibrillation (VF). Thus a safe, simple means of preventing such arrhythmias has considerable public health benefit potential. We have demonstrated that the intravenous infusion of n-3 polyunsaturated fatty acids (PUFA) from fish oils will prevent ischemia-induced VF in prepared, nonanesthetized, exercising dogs, confirming earlier feeding studies in rats. We show that this protective effect is due to an action of the free acidic form of the PUFA to alter the electrophysiology of individual cardiac myocyte so that the cells are electrically more stable. The electrophysiologic effects, in turn, result from direct and specific effects of the PUFA to block the fast voltage-dependent sodium channels. The binding of the free fatty acids is directly to the protein of the sodium channels and results in prolongation of the inactivated state of these channels. Other ion channels are also affected by the PUFA. Two clinical trials with n-3 PUFA are mentioned which inadvertently support the antiarrhythmic potential of PUFA ingestion.
Lipids 31, S-41–S-44 (1996).

There has been suggestions prior to the 1980s that polyunsaturated fatty acids (PUFA) are antiarrhythmic (1,2). McLennan and Charnock (3–5) have shown this to be the case in studies in rats fed diets high in saturated fat, olive oil, sunflower seed oil or tuna fish oil. Both saturated fat and olive oil resulted in a high incidence of irreversible ventricular fibrillation (VF) when an experimental myocardial infarction was produced. The sunflower seed oil reduced the high incidence of VF, but the tuna fish oil prevented the malignant arrhythmia entirely. With Billman, we have confirmed directly the prevention of cardiac sudden death from VF in an arrhythmia-prone dog model (6). Now in 11 of 14 prepared, conscious, exercising dogs tested, the ischemia-induced VF has been prevented by an intravenous infusion of a fish oil emulsion containing primarily a mixture of eicosapentaenoic acid (C20:5n-3, EPA) and docosahexaenoic acid (C22:6n-3, DHA) just prior to the ischemic insult ($P < 0.006$). The intravenous route of administration was used after we had found that the action of these long chain polyunsaturated fatty acids occurred quickly and to demonstrate unequivocally that the protective effect is caused by these to n-3 fatty acids and not by some other constituent of the diets or fish oil.

Our laboratory has been studying the mechanism of the antiarrhythmic action of polyunsaturated fatty acids. The neonatal rat cardiac myocyte preparation has proven useful for these studies. The hearts of 1–2 d old rats are treated with trypsin and collagenase to separate individual myocytes which are cultured in appropriate media (7). By the third day the cells have grown into clumps of syncytia which beat spon-

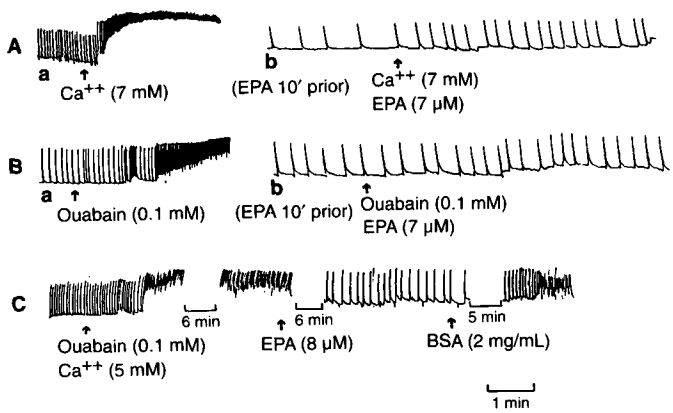

FIG. 1. Tracings show prevention and termination of arrhythmias by (EPA). Perfusion of the myocytes with a solution containing 7 mM calcium (Aa) or 0.1 mM ouabain (Bb) induced contracture and fibrillation of the myocytes. Washing the cells with medium containing 1.1 mM calcium for 5–8 min. returned the rhythm to the control beating rate. Then the cells were perfused with a medium containing 7 mM EPA. After 10 min when the beating rate had slowed, addition of the 7 mM calcium (Ab) or 0. I mM ouabain (Bb) failed to induce contracture or fibrillation in the same cells. The slow beating rate was returned to the control rate by adding delipidated bovine serum albumin (BSA), which has a high binding affinity for free fatty acids, to the perfusate (not shown). (C) After induction of contracture and fibrillation by toxic concentrations of calcium (5 mM) and ouabain (0. I mM), addition of EPA (8 μm) terminated the fibrillation and contractures and led to slow normal contractions. Subsequent addition of BSA (2 mg/mL) extracted the EPA from the myocytes, and in the continued presence of the high concentrations of calcium and ouabain, reestablished the contractures and fibrillations.

taneously and rhythmically so their beating rate and contraction amplitude can be readily recorded. A number of substances known to produce malignant ventricular arrhythmias in humans have been tested for their effects on these isolated myocytes: ouabain (100 μM) or elevated medium calcium concentration (7–8 μM) (7), β-adrenergic agent (isoproterenol, 2–4 μM) (8), lysophosphatidyl choline or acylcarnitine (2–5 μM) (9). When EPA or DHA (2–10 μM) are added to the fluid bathing the myocytes, the beating rate invariably slows within a couple of minutes (Fig. 1). Addition of the EPA or DHA prior to the arrhythmogenic agent will prevent the occurrence of the arrhythmia. But addition in the presence of the contracture and fibrillation induced by the arrhythmic agent will terminate the arrhythmia. Subsequently, the free fatty acids can be extracted from the myocytes by adding delipidated bovine serum albumin (BSA) to the medium perfusing the cells and in 2–3 min the arrhythmia recurs. Albumin has some three high affinity and four lower affinity binding sites for free fatty acids (10). Delipidated albumin can reverse the direction of the usual traffic of free fatty acids and withdraw them from the cells. If instead of the free fatty acid the triglyceride or ethyl ester of EPA or DHA is added to the medium, no prevention or termination of an arrhythmia is achieved. Only the free acid form of the fatty acids is able to prevent or to terminate an arrhythmia promptly. If the EPA or DHA had been ingested orally as the triglyceride, the usual form in which it is present in fish oil, there would have been ample time for esterases in the gut and plasma to liberate the free fatty acid which then would be available to prevent or terminate an arrhythmia.

This simple observation tells us some very important facts about the system. Firstly, only the free fatty acids are antiarrhythmic. Secondly, incorporation of the fatty acid into the phospholipids of the cell membrane or other covalent binding to membrane constituents is not required to produce their antiarrhythmic action; were such the case, the arrhythmia would not recur when the free fatty acid is recalled from the myocytes since it is only the free fatty acid that is avidly bound by the albumin.

With the invariable effect of EPA and DHA to slow the beating rate of the isolated neonatal rat cardiac myocytes without affecting the amplitude of the contractions as a simple assay for antiarrhythmic activity, we screened other fatty acids for their antiarrhythmic potential (7). We found that antiarrhythmic activity was not confined only to EPA and DHA, but included α-linolenic acid (C18:n-3, LNA), the parent compound of the n-3 class of PUFA which can be elongated in our bodies to EPA and DHA. A surprise was that the long chain n-6 PUFAs also had antiarrhythmic capabilities, including linoleic acid (C18:2n-6, LN), the parent fatty acid of the n-6 family from which arachidonic acid can be formed in our bodies. Arachidonic acid proved anomalous in its behavior, however. In one third of the experiments, it produced effects identical to that of EPA and DHA, in another third it had no effect on the beating rate, but in the remaining one third it induced violent contractures and arrhythmias. When the arachidonic acid (C20:4n-6, AA) was added to the myocytes together with inhibitors of cyclooxygenase and lipoxygenase, it invariably then also behaved like EPA and DHA in the assay system. Thus, it is the cyclooxygenase and lipoxygenase metabolites of the AA which are arrhythmogenic and the free fatty acid of AA is antiarrhythmic. Oleic acid (C18:1n-9), a monounsaturated fatty acid, and the saturated fatty acids lauric, myristic, palmitic and stearic had no antiarrhythmic properties. The fatty acids mentioned have all been tested separately for their true antiarrhythmic action in addition to the assay system.

Thus, it seems now that the structural requirement for an antiarrhythmic action is a long-chain, hydrophobic, aliphatic compound with a free carboxylic acid group at one end and two or more carbon-carbon unsaturated bonds. We have not tested rigorously the possibility of different potencies of antiarrhythmic effects among the different PUFA, but EPA and DHA are indistinguishable in their effects and seem to be somewhat more active than other PUFA. Because of the potential arrhythmic actions of eicosanoids generated from AA when n-6 PUFA of vegetable origin are ingested, the n-3 PUFA, which are present in our diets largely from fish oils, rather than the n-6 PUFA are the preferred class of fatty acids to consider for potential clinical application.

Because the EPA and DHA are capable of preventing or terminating tachyarrhythmias caused by diverse arrhythmogenic agents, it became apparent that their action is likely to be on the basic excitability/automaticity of the cardiac myocytes. Thus with Dr. Yong-Fu Xiao we undertook to perform whole cell voltage-clamp measurements to examine the electrophysiologic effects of these PUFA on the electrical cycle of the neonatal rat cardiac myocytes. The results are of considerable interest (11). With one microelectrode within the myocyte and the other in the surrounding bathing medium, the cell membrane electrical potential can be monitored. In the resting or diastolic state, the membrane potential of these cells is some −70 mV. A depolarizing electrical stimulus elicits a classic action potential when the threshold potential for opening of the fast sodium channel is reached and an action potential very similar to that observed in human endocardial ventricular myocytes is elicited. When the isolated myocyte is exposed to EPA or DHA (5–10, μM) added to the bathing medium, the resting or diastolic membrane potential becomes slightly, but significantly, hyperpolarized and the threshold potential for the gating of the sodium channel becomes more positive. The consequence of these two effects is that it now requires a 50% increase in the strength of a depolarizing electrical stimulus to elicit an action potential. Perhaps of even greater importance to the antiarrhythmic action of the PUFA is the marked 150% increase in duration of the refractory period of the myocytes in the presence of the PUFA due to a slowing of the Phase 4 depolarization. The changes in electrophysiology induced by the PUFA are just the opposite of those produced by ischemia which causes partial depolarization of the membrane potential with increased electrical excitability. These changes result from changes in conductances

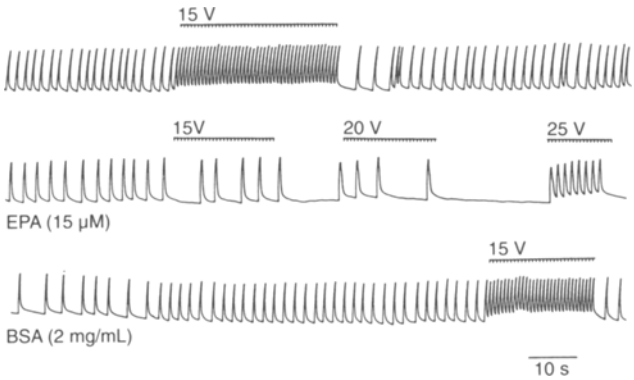

FIG. 2. Effect of EPA on the response of cultured myocytes to electrical pacing. Cells were paced as described in the text. Tracings show the response of cell contractions to the electrical stimuli (as indicated by the bars above the contraction tracing) before perfusion with EPA (top tracing), during perfusion with EPA (15 μm) (middle tracing) and after washout with BSA. In the presence of EPA, the stimuli at external field strength of 15 or 20 volts no longer elicited contraction responses from the myocytes. At a field strength of 25 volts the myocytes begin to respond, but are captured only by every other imposed stimulus. After the EPA has been withdrawn from the myocytes by the BSA, the cells again respond to stimuli at 15 volts field strength. The three tracings were made consecutively from the same cell. Abbreviations as in Figure 1.

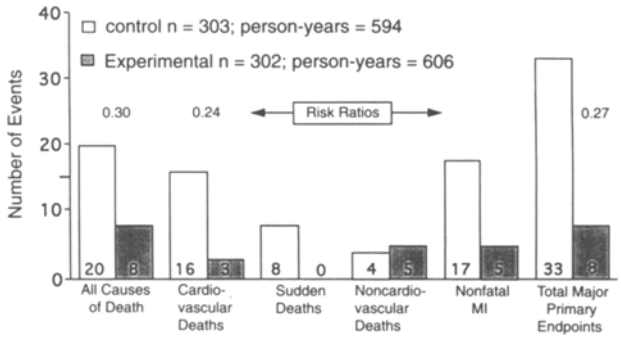

FIG. 3. A summary of the clinical trial, "Mediterranean α-Linolenic Acid-Rich Diet in Secondary Prevention of Coronary Heart Disease" (Ref. 14). 605 men who had a recent heart attack were randomized equally into a control and experimental cohort. The former were instructed to follow a prudent post-infarction diet while the latter were given more stringent dietary instructions, which included omitting red meats and dairy fat and eating more vegetables, fruits, legumes, and breads. They were allowed to use olive oil and given a soft margarine made of canola oil, which contains some 10% α-linolenic acid. Figure 3 summarizes the main results of the study. Relevant to the present topic was the suppression of sudden death among the experimental cohort (with permission of publisher and authors). End points (27 mon mean follow up).

of ion channels in the cell membranes and account for the diminished excitability of the myocytes. The fast sodium channel we have found to be partially inhibited by the PUFA (12), but the reduced duration of the action potential and the hyperpolarization of the diastolic membrane potential suggests that other channels, probably calcium or potassium channels, or even chloride channels, are also modulated by the PUFA.

The decrease in electrical excitability of the myocytes resulting from these electrophysiologic actions of the PUFA can be demonstrated directly, as shown in Figure 2. In this experiment, the myocytes were induced to contract by electrical stimuli generated by an imposed electrical field established between two platinum electrodes. When the electrical field strength was 15 volts, the myocytes increased their beating rate to match the rate of the imposed electrical stimuli. While the myocytes were exposed to EPA (15 μM) stimuli at 15 volts or even 20 volts failed to pace the contractions. At an imposed electrical field strength of 25 volts the cells began to be captured by the stimuli, but responded only to every other stimulus. When the EPA was extracted from the same myocytes by delipidated BSA, the myocytes regained their initial electrical sensitivity and contracted in response to each stimulus imposed at a field strength of 15 volts.

One can readily sense that with this increased stabilization of the membrane potentials in the presence of these fatty acids, the myocytes are less prone to respond to every aberrant depolarizing stimulus which may impinge upon them during an ischemic stress, whether it be from reentry, circus stimuli or from early or delayed after potentials. The slowing of the beating rate of the myocytes is not the cause of the antiarrhythmic properties of the PUFA. It is these electrophysiologic changes induced by the PUFA which result in both their antiarrhythmic effects and the slowing of the beating rate.

Thus far, we have not conducted clinical trials to test the antiarrhythmic effects of these PUFA in humans. There are, however, two published clinical trials, which perhaps inadvertently have examined this possibility; both were secondary prevention trials (13,14). In both studies, striking reductions in all-cause and cardiac mortality were found in the experimental groups, who were receiving the n-3 PUFA. Prevention of cardiac sudden death contributed to the favorable outcomes. Figure 3 is a summary of the more recent of these two clinical trials (14). There was some 70% reduction in all-cause mortality resulting from the reduction in cardiovascular deaths. Noteworthy to this discussion was the prevention of "sudden deaths" in the group receiving α–linolenic acid in their diets. The survival curves in both studies (not shown) demonstrated separation of the mortality for the experimental versus the control cohorts commencing very early (within only a few months) with implementation of the experimental diets. This is in contrast to the findings when cholesterol-lowering treatments were studied, in which a full two years of the regimen transpired before the survival curves separated (15)

Clearly, we have much more work ahead to determine exactly which ion channels are affected by the PUFA and to learn how the PUFA change the conductances of the ion channels. However, we feel now that with the modest understanding we have already gained and the unquestionable prevention of ischemia-induced malignant ventricular arrhythmias in our dog studies (6), which support the findings in feeding studies in experimental animals or *ex vivo* tissue studies by others (2,3–5,16), it is time that carefully designed clinical trials be undertaken to test the antiarrhythmic effects of these

PUFA in humans. Each year in the United States alone some 50 to 60% of the 500,000 deaths annually resulting from acute myocardial infarctions are due to malignant ventricular arrhythmias occurring within one hour of the acute infarction so the potential benefit from these to n-3 PUFA of fish oil may be large.

ACKNOWLEDGMENTS

This study was supported in part from an NIH, NIDDK research grant, ROI DK-38165. We are grateful to Caren Kachoris for assistance in preparing the cultured neonatal rat cardiac myocytes.

Eicosapentaenoic Acid Is Primarily Responsible for Hypotriglyceridemic Effect of Fish Oil in Humans

ABSTRACT: The aim of this study was to determine whether eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA), or both, were responsible for the triglyceride (TG)-lowering effects of fish oil. EPA (91% pure) and DHA (83% pure), a fish oil concentrate (FOC; 41% EPA and 23% DHA) and an olive oil (OO) placebo (all ethyl esters) were tested. A total of 49 normolipidemic subjects participated. Each subject was given placebo for 2–3 wk and one of the n-3 supplements for 3 wk in randomized, blinded trials. The target n-3 fatty acid (FA) intake was 3 g/day in all studies. Blood samples were drawn twice at the end of each supplementation phase and analyzed for lipids, lipoproteins, and phospholipid FA composition. In all groups, the phospholipid FA composition changed to reflect the n-3 FA given. On DHA supplementation, EPA levels increased to a small but significant extent, suggesting that some retroconversion may have occurred. EPA supplementation did not raise DHA levels, however. FOC and EPA produced significant decreases in both TG and very low density lipoprotein (VLDL) cholesterol (C) levels ($P < 0.01$) and increases in low density lipoprotein (LDL) cholesterol levels ($P < 0.05$). DHA supplementation did not affect cholesterol, triglyceride, VLDL, LDL, or high density lipoprotein (HDL) levels, but it did cause a significant increase in the HDL_2/HDL_3 cholesterol ratio. We conclude that EPA appears to be primarily responsible for TG-lowering (and LDL-C raising) effects of fish oil.
Lipids 31, S-45–S-49 (1996)

It has long been known that fish oil lowers triglyceride levels by about 25–35% (1), and it has been assumed that eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), or both were responsible. Few controlled studies in humans, however, have examined EPA and DHA supplementation separately to determine effects of each fatty acid (FA). Supplementation with purified EPA has in most studies lowered triglyceride levels, but these have not been well-controlled trials (2–9). Effects of purified DHA on human serum lipoprotein levels has not been reported. The purpose of placebo-controlled studies reported here was to compare effects of relatively pure EPA and DHA to a fish oil concentrate (FOC) containing both EPA and DHA on fasting lipids, lipoproteins, and phospholipid FA composition in healthy volunteers.

MATERIALS AND METHODS

Subjects. Healthy subjects (n = 49) were recruited from the University of Kansas Medical Center staff and student population. The subjects were normolipidemic, except that triglyceride (TG) levels were in the higher end of normal (50th–90th percentile for their age and sex). Both men and women were included in the study. Characteristics of the study groups are shown in Table 1.

Supplements. All n-3 FA supplements were given as ethyl esters and may be obtained from the Fish Oil Test Materials Program of the U.S. National Institute of Health/Department of Commerce. All supplements were provided in 1-g capsules, except for 14 of the 25 subjects in the EPA group, who were given EPA in liquid form (with the oil dispensed in single-dose, opaque, plastic vials, flushed with N_2 and stored at 4°C); the other 11 subjects received encapsulated EPA. Liquid supplementation was necessary because it was the only dosage form available at the time these subjects were studied. FOC, EPA, and DHA preparations contained the following amounts of EPA and DHA, respectively: 41% and 23%; 91% and 1.7%; and 4.3% and 83%. The OO placebo contained 67% ethyl oleate.

Protocol. Data from three separate studies are reported in this paper. In the first study, 11 subjects were assigned to take 3 grams per day (g/d) EPA, 5 g/d FOC and 5 g/d OO placebo. In the second study, 9 subjects were assigned to take 3 g/d DHA, 5 g/d FOC, and 5 g/d OO placebo. Both of these were randomized, crossover, single-blind studies with at least 2 wk of wash-out between the 3-wk supplementation phases. All supplements given were encapsulated. In the third study (conducted several months later), 29 subjects were randomly assigned to take either 3 g/d EPA in liquid form (n = 14), or 5 g/d FOC (n = 15) in addition to the OO placebo in a parallel-group design. Placebo was taken for 2 wk followed by n-3 FA supplements for 3 wk. In all, a total of 9 subjects took OO and DHA (DHA group), 25 subjects took OO and EPA (EPA group), and 35 subjects took OO and FOC (FOC group). The subjects were instructed to maintain their normal lifestyles

and background diets throughout the study. Fasting blood samples were drawn twice at the end of each supplementation period and analyzed for changes in lipid and lipoprotein levels. FA composition of the plasma phospholipid fraction was also determined.

Methods. Serum total cholesterol, TG, and high density lipoproteins (HDL) cholesterol (C) were measured enzymatically on a Cobras Mira as previously described (10). Very low density lipoprotein (VLDL) and low density lipoprotein (LDL) C levels were calculated by the Friedewald equation (11). Plasma lipids were extracted and separated by thin layer chromatography, and FA composition in the phospholipid fraction was determined by combined thin layer and gas chromatography as previously described (10).

Statistics. Data obtained from the two blood draws at the end of each supplementation phase were averaged before comparison. Data are presented as mean ± SD. Values at the end of placebo and n-3 treatment phases were compared by the paired *t* test, and a difference with $P < 0.05$ was considered to be statistically significant.

RESULTS

Compliance. Compliance was assessed by capsule count and by weighing the EPA vials before and after dosing. More than 95% of each supplement was taken; adjusting for supplement composition, mean intakes (g/d) of EPA and DHA were as follows: FOC, 2.01 and 1.12; EPA, 2.81; and DHA 2.36. Thus total n-3 FA intakes were similar in the three supplementation groups (2.4–3.1 g/d), and intakes of EPA and DHA, when given singly, were greater than those taken by the FOC group.

Plasma phospholipid FA composition. Linoleic and arachidonic acid levels decreased significantly on the FOC and EPA supplements (Table 2). FOC supplementation increased plasma phospholipid EPA by fourfold and DHA by twofold vs. placebo levels. Supplementation with purified EPA led to the same fourfold increase in EPA levels but did not change DHA levels. DHA supplementation more than doubled DHA levels and increased EPA significantly (0.3 to 0.7%).

Fasting lipids and lipoproteins. On FOC supplementation, TG and VLDL cholesterol levels were lowered by 20% ($P < 0.001$; Table 3). FOC also caused the LDL cholesterol level to increase by 10% ($P < 0.05$). Total HDL cholesterol did not change on FOC supplementation, but the HDL_2 cholesterol level increased by 27% ($P < 0.01$) while the HDL_3 cholesterol decreased by 6% ($P < 0.01$). EPA lowered TG and VLDL C by 16% and increased in LDL cholesterol levels by 6% (both $P < 0.01$). Although EPA increased total HDL C level by 6% ($P < 0.05$), there were no significant changes in HDL subfractions. DHA supplementation, on the other hand, had no TG-lowering or LDL-raising effect. The only lipoproteins affected by DHA were HDL subfractions. HDL_2 C increased by 38%, and HDL_3 C decreased by 8% (both $P < 0.05$). Total C level did not change on any supplement.

TABLE 1
Characteristics of Study Groups

Characteristics	EPA[a] group ($n = 25$)	DHA[b] group ($n = 9$)	FOC[c] group ($n = 35$)
Sex (M/F)	8/17	4/5	13/22
Age ± SD	30.1 ± 6.6	31.0 ± 11.8	28.9 ± 7.6

[f]LDL C = Low density lipoprotein cholesterol.

DISCUSSION

This is the first study to compare the effects of (relatively) pure EPA and DHA to both a placebo and to a FOC containing both FA in humans. The most well-known effect of the FOC-decreased TG levels was reproduced by supplementation with EPA, but not with DHA. Since the DHA group was relatively small (n = 9 vs. 25 in the EPA group and 35 in the FOC group) and thus underpowered, we cannot be sure that it would not have an effect in a larger group. The failure of DHA to achieve a statistically significant TG reduction, however, was caused by a small mean effect (–3%), not by a large variance. Conversely, the percent change in LDL C was identical for both EPA and DHA (+6%), but the smaller number of subjects in the latter group prevented the difference from being significant. It is possible that combined with EPA, DHA might be more effective. It should be noted that we fed 2.4 g DHA in the DHA period and less than half this amount in the FOC period; yet TG were reduced with FOC but not DHA. Thus EPA is more likely than DHA to be the hypotriglyceridemic agent in fish oils.

Although EPA has been reported in 7 studies to be hypotriglyceridemic in humans (2–8), all were "before-and-after" designs, and none included a placebo comparison. In the only study to include a placebo (9), EPA did not significantly lower TG levels. Previous human studies using purified DHA have not been reported. Childs *et al.* (12) fed EPA-rich and DHA-rich fish oils to normal volunteers in an attempt to determine how each FA affected lipid levels. They concluded that both EPA and DHA were equally hypotriglyceridemic, but that DHA also lowered LDL, while EPA did not. The difficulty with this study was the use of very high intakes of n-3 FA. For example, the DHA-rich diet (15 g DHA/d) was "contaminated" with 5 g EPA—nearly twice the amount of EPA fed here to our EPA group. Likewise, the EPA-rich diet (which provided 12 g EPA/d) contained more DHA (3.1 g/d) than our DHA group received. Thus no conclusions regarding separate effects of EPA and DHA can be drawn from this study.

Effects of EPA and DHA on lipoprotein metabolism have been studied in rats and in cultured cells. EPA has lowered circulating TG levels in rats (13,14), but only with very high doses (1–2 g/kg/d). Adjusted for body surface area, equivalent

TABLE 2
Effects of n-3 Fatty Acid (FA) supplements on Selected FA from the Plasma Phospholipid Fraction (% Total FA)[a]

	Placebo	FOC	Placebo	EPA	Placebo	DHA
Fatty acid	(n = 35)		(n = 25)		(n = 9)	
Oleic acid	10.4 ± 6.5	8.4 ± 2.2	8.6 ± 2.6	7.7 ± 2.3	9.5 ± 1.6	8.7 ± 1.1
Linoleic acid	17.1 ± 4.3	15.2 ± 4.2[b]	16.1 ± 4.9	13.4 ± 3.9[b]	19.8 ± 2.2	16.8 ± 5.7
Arachidonic acid	8.7 ± 3.8	6.7 ± 2.2[b]	7.8 ± 2.8	6.5 ± 2.4[b]	9.1 ± 1.2	8.3 ± 1.7
Eicosapentaenoic acid	0.7 ± 0.5	3.2 ± 1.3[b]	0.9 ± 0.6	4.0 ± 1.7[b]	0.3 ± 0.1	0.7 ± 0.4[b]
Docosahexaenoic acid	2.0 ± 0.6	3.3 ± 1.3[b]	1.7 ± 0.7	1.7 ± 0.6	2.3 ± 0.6	5.2 ± 0.9[b]

[a]See Table 1 for abbrevations.
[b]$P < 0.005$ vs. respective placebo.

doses in humans would be 12–24 g/d (15). We fed less than 3 g/d in this trial and found a clear hypotriglyceridemic effect. DHA was without hypotriglyceridemic effect in rats even at these high doses (13,14). Studies in cultured cells and perfused livers have shown that EPA inhibits TG synthesis/secretion in rat (16,17) and rabbit (18) hepatocytes, in $HepG_2$ cells (19,20), and in perfused rat livers (21,22). These findings are consistent with our observations in humans. DHA, however, was also reported to lower TG secretion from rat hepatocytes (23), $HepG_2$ cells (19), and perfused livers (21), and these findings contradict human and intact animal data.

In most studies in normolipidemic subjects, n-3 FA have had no significant impact on LDL C levels, but, in hypertriglyceridemic patients, LDL usually increases with fish oil feeding (1). Reasons for this increase have never been clearly determined. If fish oil inhibits hepatic TG production, then it is difficult to explain why LDL (the product of VLDL catabolism) levels are increased. If precursor (VLDL) levels are reduced, then product (LDL) levels should be, also. It has been suggested that fish oil feeding reduces the size of VLDL secreted by the liver (24), and further that these smaller VLDL particles are more readily converted into LDL (25). There is evidence, however, to suggest that n-3 FA do not increase circulating levels of small VLDL (26). Another mechanism by which n-3 FA might raise LDL levels is by stimulating the conversion of VLDL to LDL by increasing lipolytic rates *in vivo*. This seems unlikely, since fish oil treatment has repeatedly been shown to not stimulate lipoprotein lipase (LpL) activity measured in postheparin plasma both in humans (27–29) and in animals (30–32). In addition, intralipid clearance is not enhanced by pretreatment with n-3 FA (10). Conversely, n-3 FA supplementation stimulated endogenous (preheparin) LpL activity (33), although these findings await confirmation. The other possible mechanism for the LDL-raising effect of n-3 FA is slowed LDL catabolism, perhaps due to an inhibition of LDL receptor activity, as has been suggested from cell culture studies (20,34,35) but not in intact rats (36). There is no good human data regarding this question.

Both FOC and DHA significantly increased HDL_2 C while decreasing HDL_3 C levels. A similar effect has been reported with fish oil feeding in normal volunteers (37–39) and in hyperlipidemic patients (40,41). EPA alone had no such effect (3) in confirmation of our findings here. HDL_2 C levels have been inversely associated with coronary heart disease in seven of eight recent studies and with the severity of coronary disease in six of nine studies (42). Thus n-3 FA-induced increase in this HDL subfraction may contribute to the antiatherogenic potential of fish oils.

We were able to explore the question of how EPA and DHA are interconverted in adult humans. The underlying assumption has long been that EPA is elongated and desaturated directly to DHA (43). Sprecher and colleagues (43), however, have now shown in the rat that, although EPA can be converted into DHA, it takes a more circuitous route, being first converted into 24:6n-3 and then β-oxidized back to 22:6n-3. Whether this pathway exists in adult humans is not known, but since high intakes of 18:3n-3 (linolenic acid) can produce small increases in both EPA and DHA levels (44–46), it is assumed to be active. Results of our study argue against direct conversion of EPA to DHA and somewhat in favor of retroconversion of DHA to EPA. von Schacky and Weber (47) reported that 6 d of 6 g EPA/d resulted in no net increase of DHA in plasma phospholipids. They also found that DHA feeding (same dose and duration) increased EPA levels in the same lipid class. Retroconversion of DHA to EPA has also been reported by others (7). Findings of our study using many

[c]Significantly different at least $P < 0.05$.

more subjects fed smaller doses of n-3 FA for 21 d instead of 6 d support these conclusions. Another possible explanation of our findings, however, is the small amount of EPA in the DHA supplement (4%; providing 120 mg EPA/d) may have contributed to the small rise in plasma EPA levels (Table 2). Thus, from our data, no firm conclusion can be made *vis à vis* retroconversion of DHA to EPA.

In conclusion, we have obtained evidence that EPA is likely to be the hypotriglyceridemic FA in fish oils and that it is not readily converted into DHA. Furthermore, although DHA has little to no impact on serum lipid levels, it may be retroconverted to EPA in humans. Further studies are needed to clearly define individual effects of EPA and DHA on human lipid metabolism.

A New Relationship Between Total/High Density Lipoprotein Cholesterol and Polyunsaturated Fatty Acids

Edward Siguel*

Boston University Medical Center, Boston, Massachusetts,
and Nutrek, Inc. Brookline, Massachusetts 02146-0001

ABSTRACT: Dietary and plasma fatty acids have been linked to total cholesterol but not to the ratio of total/high-density lipoprotein cholesterol (TC/HDLC). To evaluate the relationship between dietary and plasma levels of polyunsaturated fatty acids (PUFA) and TC/HDLC, we analyzed cross-sectional and longitudinal data using 519 plasma samples (50% men, 50% women) from subjects participating in the Framingham Heart Study and results from a study feeding diets rich in either n-6 linoleic acid or n-3 α-linolenic acid with or without fish oil supplements (n-3 derivatives). Values of TC/HDLC are inversely related to the percent of plasma PUFA when both variables are measured at the same time in different subjects, $R = 0.82$, $P < 0.000001$. PUFA in phospholipids increase in response to increased dietary intake of different PUFA, either n-3 or n-6 or fish oils. There was a highly significant inverse relationship between TC/HDLC and the percent of PUFA in phospholipids, $R = 0.97$, $P < 0.001$. The relationship was similar regardless of the source and type of dietary fatty acids. A similar relationship existed when only the baseline points were considered. When plasma PUFA % increases, either in response to a diet high in PUFA or across different subjects, TC/HDLC ratios decline. Evaluation of plasma fatty acid profiles and increased balanced dietary intake of PUFA to bring fatty acid profiles of subjects with low PUFA plasma levels closer to the profile of a healthy reference group is an effective approach to reduce high TC/HDLC. Reductions of more than 50% in TC/HDLC appear feasible with dietary modification alone. Further research into fatty acid metabolic activity may determine the biochemical basis of common dyslipidemias.
Lipids 31, S-51–S-56 (1996).

It is well established that increased dietary polyunsaturated fatty acids (PUFA) reduce total/high density lipoprotein cholesterol (TC/HDLC) (1,2). Dietary intervention studies provided evidence that eating PUFA and fish oils reduces biochemical risk factors associated with cardiovascular disease (3). Optimization of lipoprotein levels with diet or drugs regresses coronary artery disease (4) and reduces the risk of angiographic progression (5), a risk reduction attributed primarily to a reduction in TC/HDLC (American Heart Association, 1995 Annual Meeting, unpublished communications).

It is not known whether substantial reductions in TC/HDLC, similar to those achieved with drugs, can be achieved with the essential fatty acids (EFA) linoleic acid (18:2n-6, LA), α-linolenic acid (18:3n-3, ALA) or fatty acids found in fish oil (ALA n-3 derivatives). A computer search found no published data on the relationships between plasma fatty acids and TC/HDLC levels, although many equations have been described linking dietary fatty acids to cholesterol. The problem with dietary data alone is that it is impossible or impractical to accurately track dietary fatty acids, conversion of calories to PUFA or other fats, calorie utilization, and metabolism. Thus dietary intake data are only a rough approximation of what people eat and accumulate as PUFA, even when subjects comply with experimental requirements.

Since the 1960s, Kingsbury *et al.*, among others, found fatty acid abnormalities in patients with different types of atherosclerosis (6) and myocardial infarction (7). Serum fatty acid patterns were shown to be good predictors of myocardial infarction (8), and low dietary intake of LA correlated with the predisposition to myocardial infarction (9). Moreover, among several variables, LA in serum total lipids was found to be the single most effective predictor of cardiovascular death in postinfarction middle-aged men (10). Lower levels of PUFA were found in phospholipids of subjects with sudden cardiac death (11). In addition to preventing or correcting physiological abnormalities that may arise from low plasma PUFA levels, correction of abnormally low levels of PUFA with dietary PUFA has additional clinical applications if it can be shown to reduce cardiovascular end-points (such as myocardial infarct, angina, stroke, and hypertension). Using food to reduce the TC/HDLC ratio, considered one of the best surrogate indices for heart disease risk, would have implications for health care costs. Lowering TC/HDLC with diet or drugs can prevent heart disease morbidity and mortality and regress atherosclerotic disease. Lowering TC/HDLC with drugs can cost more than $2,000 per patient per year. With

more than 50,000,000 Americans having abnormal cholesterol, treating everybody with drugs would cost more than $100 billion annually!

In a cross-sectional study of about 100 subjects, criticized as having a small sample size, Siguel and Lerman (12) found an inverse relationship between PUFA and TC/HDLC. To confirm and expand those results, we report here the analyses of 519 samples from the Framingham Heart Study. In a recent study, Mantzioris *et al.* (13) fed 30 subjects n-3 or n-6 fatty acid–rich diets. They found what appeared to be a "neutral effect on cholesterol." We analyzed both sets of data using a different model to characterize fatty acid status and found that increasing low PUFA levels with dietary PUFA drastically decrease TC/HDLC in the manner we predicted (12). These relationships have major implications for nutrition policy and medical care.

MATERIALS AND METHODS

We obtained about 3,000 leftover plasma specimens kept frozen for 3–6 years at –70°C from participants in the Framingham Cardiovascular Offspring Study Cycle 4. Fatty acids were measured using 0.100 mL plasma (14,15) , the extraction procedure described by Lepage and Roy (16), and a 100 m capillary column optimized to separate fatty acids over approximately 180 min. We identified peaks that characterize sample deterioration. There was no evidence of fatty acid degradation in the samples used. Any deterioration would most likely reduce the PUFA, introducing errors that lower the statistical significance of the models used. We selected for fatty acid analyses 519 samples randomly distributed by subject age and sex (ages 30–69, approximately 50% men and 50% women). Our objective was to have 480 samples; we oversampled, anticipating that some of the samples would have deteriorated. No evidence of deterioration was seen, and therefore all were used. To eliminate unusual subjects with rare metabolic disorders, we restricted this study to subjects with cholesterol between 90 mg/dL and 350 mg/dL and subjects with triglycerides <400 mg/dL.

Many factors, such as pipetting, evaporation, calibration, venipuncture method, fasting, and recent diet, can increase or decrease total and HDL cholesterol measurement. The ratio TC/HDLC cancels some of this variability due to sample concentration, dilution, or other factors that proportionately affect both variables. For these reasons, TC/HDLC may be a more reliable variable than total or HDL cholesterol alone. Among the fatty acid variables, PUFA (%) summarizes all the EFA and their polyunsaturate derivatives. Because PUFA concentration in mg/dL of plasma is highly correlated with lipid levels, whole plasma fatty acid concentrations is not a suitable independent variable (12). Most plasma PUFA is found in lipoproteins. Thus a reasonable biological hypothesis is that the concentration of PUFA in lipoproteins, roughly equivalent to the percentage of PUFA in plasma, is a major variable associated with TC/HDLC.

Statistical significance usually tests for difference from zero. Many variables have regression coefficients with values slightly larger than zero, which are statistically different from zero with a large sample size. To confirm that PUFA was strongly associated with TC/HDLC, we used a technique that further reduced the effects of weak relationships.

Samples were sorted by sex and ordered in accordance with the previously measured values of TC/HDLC. Rather than using the more conventional approach of dividing the sample into tertiles or quartiles (3–4 groups), we computed average values of 10 consecutive samples for a total of 52 data points (25 men, 27 women, one of the points had 9 cases). This averaging process eliminates a spurious relationship between TC/HDLC and PUFA and reduces random variability and measurement error. This approach is rarely used because many relationships in epidemiological studies are weak and would disappear. We averaged values of 10 data points to preserve strong relationships, while eliminating as much as possible of random variability and weak relationships. In general, grouping more data points eliminates more weak variables and leaves fewer points for further multivariate analysis. Groups of 10 were chosen as a reasonable compromise for future analysis. Averaging reduces effects of variables that are randomly distributed across, i.e., are independent of, TC/HDLC. If there is no relationship between TC/HDLC and PUFA plasma levels, the distribution of PUFA levels is similar for all groups of subjects. If PUFA is a poor predictor of TC/HDLC, average values of PUFA for each group would be about the same, and the R value of the equation linking PUFA to TC/HDLC would be small. This approach detects biologically significant differences rather than merely statistically significant differences found with a large sample size. The nature of the relationship is not altered by grouping the data.

Reference (normal) levels for EFA were determined in the manner usually performed with other essential nutrients. Individuals without known disease and with biochemical parameters within established normal levels (healthy subjects) were used to establish reference ranges. We diagnose EFA deficiency (EFAD) or insufficiency (EFAI) by biochemical deviation from established reference ranges in the same manner that we diagnose low vitamin or mineral levels, low HDL, or high cholesterol (18). The term EFAI was created to distinguish biochemical EFAD from EFAD previously associated with severe clinical signs.

Mantzioris *et al.* (13) randomly assigned 30 subjects to two dietary treatment groups. One group took flaxseed oil rich in ALA (n-3) for 4 wk, supplemented later by 4 wk on fish oil. The other group followed a diet rich in LA (n-6) for 4 wk, supplemented later by 4 wk on fish oil. Fatty acids in plasma phospholipids were measured at baseline, 4 wk and 8 wk, for a total of 6 measurements. Although the range of PUFA values was narrower for phospholipids than for whole plasma, consistent with the hypothesis that humans closely regulate PUFA phospholipid levels, there was a positive linear relationship between PUFA % levels in plasma and phospholipid (Siguel, E., unpublished data). We searched for relationships relating the percent or ratio of lipid variables to the percent or ratio of

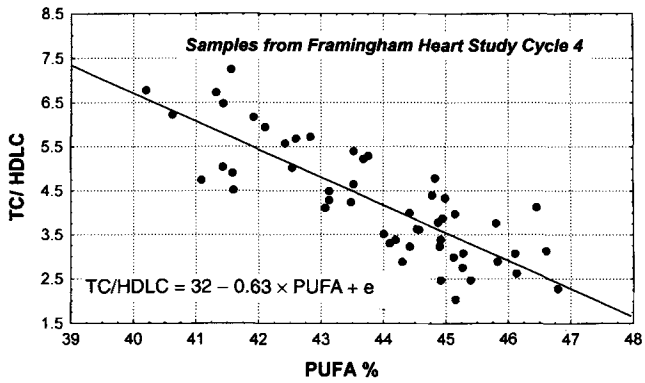

FIG. 1. Changes in total/high density lipoprotein cholesterol (TC/HDLC) vs. plasma polyunsaturated fatty acids (PUFA).

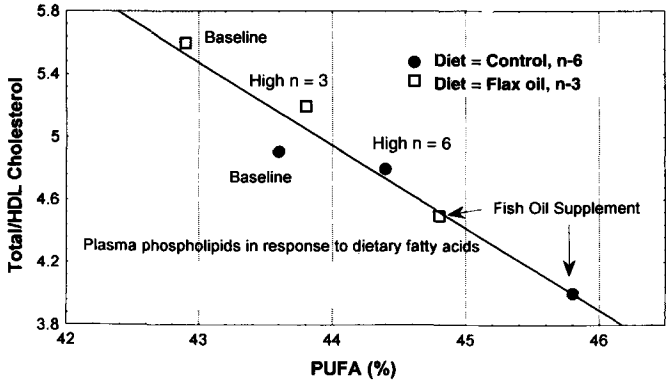

FIG. 2. Changes in total/high density lipoprotein cholesterol vs. increase in n-6 and n-3 fatty acids. See Ref. 13.

fatty acid variables, particularly the ratio of TC/HDLC as a function of PUFA (%). Statistical and graphics analyses were done using EXCEL (Microsoft Corp., v. 5.0); and STATISTICA (StatSoft, Inc., Tulsa, OK).

RESULTS

Regression analysis with all 519 points found a highly significant statistical relationship with PUFA. However, such relationship could be a statistical artifact. Linear regression using the 519 data points with TC/HDLC as the dependent and PUFA (%) as the independent variables had $R = 0.32$ ($F = 58$, $P < 0.000001$). Limiting the analysis to cholesterol values between 100 and 300 and triglycerides under 300 eliminated 16 samples, with $R = 0.27$ ($F = 39$, $P < 0.000001$). Figure 1 displays the relationship between TC/HDLC and PUFA (in percent) for the 52 groups of subjects. The relationship is highly linear, with $R = 0.82$, $P < 0.000001$. Either with the grouped or individual data, TC/HDLC declines as PUFA (%) increases.

Table 1 lists the values of TC/HDLC, PUFA, monounsaturated fatty acids (MUFA), PUFA/MUFA, and PUFA/saturated and monounsaturated fatty acids (NoPUFA) for each of the 6 data points (3 diets or 3 time periods for n-3 and n-6) in the Mantzioris *et al.* study (13). At baseline, subjects had PUFA levels below our reference values (18), suggesting that these subjects had EFAI according to our criteria (12). As expected, plasma PUFA increased when subjects ate more dietary PUFA, either in the form of n-3 or n-6 fatty acids or fish oil. Figure 2 shows the inverse relationship between plasma TC/HDLC and PUFA, correlation coefficient $R = 0.97$, $P < 0.001$.

DISCUSSION

These results show that in cross-sectional (different subjects, one time blood measurements) and longitudinal studies (same subjects on different diets for different time periods), TC/HDLC declines when PUFA increases, in a direct and highly linear inverse proportion to PUFA levels. Together, these results provide evidence that plasma PUFA levels have a significant effect on TC/HDLC and that TC/HDLC levels can be modulated by changes in dietary PUFA. A related study feeding diets low or high in fat and high in PUFA found similar relationships, with those subjects eating the low-fat diet having higher TC/HDLC and lower PUFA than subjects eating a high PUFA diet (19). Although not shown, both the percent and concentration of saturated and monounsaturated fatty acids are positively correlated with TC/HDLC in the Framingham samples. Future reports will describe relationships between individual lipids, percents and concentrations of specific fatty acids, age, sex, height, and weight.

Mantzioris *et al.* (13) reported a different model of the relationship between cholesterol and fatty acid profiles. Instead of comparing TC/HDLC, the authors compared total and HDL cholesterol. Comparing only changes in cholesterol across treatment groups, as done by the previous authors, is ineffective because individuals rarely follow the treatment diet as well as the investigators expect, and thus the expected group differences due to diet may not materialize when gauged by plasma PUFA. Differences in exercise, environmental temperature, body metabolism, and eating behavior drastically affect the net balance of PUFA in the body.

TABLE 1
Cholesterol Ratios vs. Fatty Acid Ratios

Case	Code	Weeks	TC/HDLC[a]	PUFA[b]	MUFA[c]	PUFA/MUFA	PUFA/NoPUFA[d]
Baseline	Control	0	4.91	43.6	11.8	3.69	0.77
n-6	Control	4	4.80	44.4	11.6	3.83	0.80
+ Fish oil	Control	8	4.00	45.8	10.0	4.58	0.85
Baseline	Flax	0	5.60	42.9	12.2	3.52	0.75
n-3	Flax	4	5.20	43.8	11.2	3.91	0.78
+ Fish oil	Flax	8	4.50	44.8	10.2	4.39	0.81

[a]T/HDLC = Total/high density lipoprotein cholesterol.
[b]PUFA = Polyunsaturated fatty acids.
[c]MUFA = Monounsaturated fatty acids.
[d]NoPUFA = Saturated and monounsaturated fatty acids.

Blood lipid values are difficult to predict from dietary intake because the same diet will produce different changes in body fatty acid composition in different individuals (it is impossible to have identical lifestyles, and so forth). Studies that evaluate the risk-protecting effects of different mixtures of dietary fatty acids or low-fat diets ought to analyze the plasma fatty acid composition of subjects to determine the net effects of carbohydrate and fat and their interaction with exercise, food processing (i.e., hydrogenation), oxidation, and other variables affecting net *cis* EFA intake. Dietary intake data may misrepresent what the subject actually eats. For example, n-3 intake is almost impossible to ascertain from dietary data because of the huge variability in n-3 composition of oils used with foods even when the same brand is used (due to factors such as hydrogenation and cooking) and the lack of data on foods rich in n-3 such as green peas and eggs. There are no requirements that food manufacturers maintain constant EFA composition even in their own brands; EFA composition of common foods such as eggs or chicken varies according to the feed used, which in turn depends on global market prices for corn (no n-3), soy (has n-3), and other chicken feeds.

Thus it is hazardous to explain physiological changes only on the basis of presumed dietary intake; it is essential to do plasma fatty acid analysis to obtain a better gauge of changes in body fatty acid composition. Plotting TC/HDLC vs. plasma PUFA values relates two physiological variables measured on the same sample and can be a better indicator of the effects of dietary fatty acids on plasma lipids.

What is noteworthy is that the % of plasma PUFA accounts for most of the variability in TC/HDLC, as can be seen from Figures 1 and 2. These findings support the hypotheses of Siguel and Lerman (12) and Sinclair (24) that the level of PUFA is the most important factor in atherosclerotic and coronary heart disease. As can be seen in Table 1, HDL increases and triglycerides decrease when PUFA increases, in the manner predicted by Siguel and Lerman (12), who proposed that plasma cholesterol and triglyceride levels are determined or regulated, in great part, by EFA metabolism, which is in part determined by the total amounts of each type of fatty acid in the body.

We hypothesize that low-calorie diets reduce TC/HDLC in many overweight subjects by burning saturated fatty acids preferentially over PUFA and thereby increasing the percent of total plasma PUFA. This effect is most pronounced when overweight subjects with significant adipose tissue reserves of PUFA lose weight. When normal weight individuals maintain their weight on low-calorie, low-fat diets low in EFA, however, plasma PUFA is likely to decline, and TC/HDLC may increase (19,27). Replacing fat with calories from low-fat foods may decrease plasma PUFA levels and therefore increase TC/HDLC. Consistent with this hypothesis, a study by Schaefer *et al.* (28) found that low-fat diets, without weight loss, lead to a substantial decline in HDL, and increases in triglycerides and TC/HDLC. During their study (about 3 mon), 2/29 subjects (about 6%) developed evidence of heart disease; one had an infarct.

There is overwhelming evidence that diets rich in PUFA can lower TC/HDLC. PUFA, particularly n-3 derivatives, have been proposed for the treatment of a variety of cardiovascular diseases (29). The active conversion of EFA precursors, ALA and LA, to their derivatives (14) suggests that many people obtain adequate n-3 and n-6 derivatives from ALA and LA, and that these fatty acids can produce drastic declines in TC/HDLC. Subjects with low body levels of EFA or those who need EFA derivatives could be at high risk on a low-fat or strict vegetarian diet deprived of EFA derivatives. Reduced formation of EFA derivatives has been associated with insulin-dependent diabetes, alcoholism, and aging (30). For these subjects, a low-fat diet or a vegetarian diet deprived of EFA derivatives could lead to higher TC/HDLC, higher triglycerides, and perhaps an increased incidence of heart disease. These results do not mean that all PUFA have equivalent effects on TC/HDLC. The subjects in these feeding studies had substantially elevated TC/HDLC ratios. They also had substantially lower then desirable levels of PUFA. When both n-6 and n-3 levels are low, most mixtures of n-6 and n-3 may decrease TC/HDLC. The effects of different n-6 and n-3 fatty acid mixtures are likely to be different for subjects less deficient in PUFA.

It is generally accepted that proper dietary treatment requires a mixture of n-3 and n-6 fatty acids and their derivatives because ideal health depends on an optimal ratio of n-3/n-6 fatty acids (31). Siguel and Lerman (12) recommend a treatment diet that will bring the plasma fatty acid profile of a patient closer to the profile of a healthy reference population. A trial period of ingestion of an oil high in both 18:2n-6 and 18:3n-3 (i.e., soybean oil), together with appropriate antioxidants, may be the best way to raise EFA and decrease cholesterol. After soybean oil supplementation for several months, fatty acid analysis helps to determine whether 18:3n-3 is sufficient to increase 20:5n-3 in blood and lower triglycerides, or whether fish oils are necessary to lower triglycerides. One must also recognize that the dietary balance of n-3 and n-6 can be a modulator of eicosanoid activity, platelet aggregation (3), and incorporation of PUFA in cell membranes (19).

Linear regression is a customary statistical method, and it is easy to interpret, but its value is limited to the range analyzed. Averaging TC/HDLC ratios reduces the influence of extreme points and narrows the range of PUFA %. Individuals can have plasma values of PUFA below 39% or above 48%, not shown in Figure 1. Obviously, Figure 1 does not imply that when PUFA = 60%, TC/HDLC = 0. The biological relationship between TC/HDLC and PUFA % most likely follows a curve that would plateau at TC/HDLC slightly below 2; finding a more biological relationship requires further studies.

Individual patients have a great deal of biological noise in their measurements, and they may not respond to maneuvers that seem very plausible on a population basis. While, on a statistical basis, increasing PUFA may lower TC/HDLC, on an individual basis results are less predictable. Physiological and measurement variability in cholesterol and PUFA % may exceed 30%. Thus the specific response of levels of TC/HDLC in one individual to dietary changes in PUFA may not follow

the relationship shown in this paper, particularly over a short period of time. Reasonable intake of PUFA over a period of several months is small compared with the large reserves of fatty acids in adipose tissue of most people.

Many physicians believe that drug therapy is needed because dietary changes alone are not sufficient to drastically reduce TC/HDLC. These views are supported by the American Heart Association, which asserted that diet can only lower cholesterol by up to 15%, and thus drug therapy may be necessary (32). This belief is derived from the fact that conventional treatment diets have relatively small amounts of EFA (often below 10 g/d), not enough to significantly change PUFA levels. Gronn *et al.* (19) used 36 g/d of n-6 and 6 g/d of n-3 derivatives to achieve minor reductions in TC/HDLC and total triglycerides over a 4-wk period. Substantial changes in body fat composition may take years to accomplish by dietary change. Given these factors and the random variability in lipid and fatty acid measurements, individual reductions in abnormal lipids may not reflect average statistical results, and perseverance is required for dietary changes to affect lipids.

This study shows that an inexpensive diet high in PUFA can drastically reduce TC/HDLC. Furthermore, eating PUFA to bring plasma levels closer to those of a healthy population may improve life expectancy through mechanisms other than their effect on TC/HDLC. Siscovick *et al.* (33) showed that reduced levels of n-3 PUFA in red blood cells are associated with increased risk of cardiac arrest. Patients who have low HDL and very high TC/HDLC (usually greater than 7), however, probably due to a genetic defect in making HDL rather than acquired factors (i.e., obesity or low PUFA), may not respond as expected to dietary changes in PUFA.

Treatment of cardiovascular disease through nutrition is less expensive than using drugs or surgery, and it can be equally or more effective. Diagnosis of lipid abnormalities through fatty acid analysis may lead to a new classification of dyslipidemia based on biochemical processes. Treatment of lipid abnormalities through manipulation of PUFA levels may change preventive medicine approaches and reduce health care costs. More research is needed to explore the relationship between lipids, *cis*, and *trans* fatty acids, and biochemical or genetic abnormalities associated with low HDL.

ACKNOWLEDGMENTS

This work was supported in part by Nutrek, Inc., and grant no. R01 HL39681 from the National Institutes of Health. These results were presented in part at the International Society for the Study of Fatty Acids and Lipids, Washington, DC, June 1995. The author expresses his appreciation to the Framingham Heart Study for providing access to plasma samples and lipid records.

Control of Endothelial Leukocyte Adhesion Molecules by Fatty Acids[1]

Raffaele De Caterina* and Peter Libby

Vascular Medicine and Atherosclerosis Unit, Cardiovascular Division, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachussetts

ABSTRACT: Dietary balance of long-chain fatty acids (FA) may influence human susceptibility to pathological processes which involve the interaction of leukocytes with vascular endothelium, such as atherogenesis and inflammation. Such interaction is largely mediated by the *de novo* or increased expression of endothelial leukocyte adhesion molecules on vascular endothelial cells, able to tether and stably bind leukocytes onto the vessel wall, and by the production of leukocyte chemoattractants. Endothelial cells do not normally support high levels of leukocyte adhesion. They do so, however, when exposed to a number of stimuli, such as oxidized low density lipoprotein bacterial lipopolysaccharides, and inflammatory cytokines, which induce phenotypic changes generally referred to as "endothelial activation." We compared various FA in their ability to modulate endothelial activation by cytokines. FA included linoleic, arachidonic, oleic, eicosapentaenoic and, docosahexaenoic acid (DHA) as representatives of the n-6, n-3 polyunsaturated FA and of the monounsaturated FA. The n-3 FA DHA, and, to a lesser extent, oleate, at nutritionally compatible concentrations, were able to reduce endothelial expression of Vascular Cell and Adhesion Molecule-1 (VCAM-1). In further studies, DHA dose- and time-dependently reduced also the expression of E-selectin, Intercellular Adhesion Molecule-1, interleukin (IL)-6 and IL-8, in response to IL-1, IL-4, tumor-necrosis factor, or bacterial endotoxin. The magnitude of this effect paralleled its incorporation into cellular phospholipids. Also, coordinate with reduced surface adhesion molecule expression, DHA reduced the adhesion of human monocytes and of monocytic U937 cells to cytokine-stimulated endothelial cells. These effects were accompanied by a quantitatively consistent reduction in VCAM-1 mRNA, indicating a pretranslational control of adhesion molecule gene expression. These novel properties of FA as modulators of endothelial activation may help to explain the influence of dietary FA intake on atherogenesis and inflammation.

Lipids 31, S-57–S-63 (1996).

Dietary lipid quantity and source can affect a variety of physiological responses of the human organism, thereby modulating the risk of development of diseases (1–4). In particular, dietary long-chain unsaturated fatty acids (FA), which are, quantitatively, minor lipid components in the diet, have been shown to modulate a wide number of cell responses to environmental stimuli (5–7). Among polyunsaturated fatty acids, a clear distinction of properties has emerged in these last years between the n-3 and the n-6 families. With some notable exceptions (8), epidemiological studies have suggested an inverse relationship between intake of n-3 (FA) and the incidence of cardiovascular disease (9–17), which is at least partially attributable to a reduced incidence of atherosclerosis (18). Consumption of n-3 FA diminishes atherogenesis in the nonhuman primate (19), as well as in other animal species (reviewed in Refs. 6 and 7). In addition to atherothrombotic diseases, inflammatory/immune diseases such as psoriasis, bronchial asthma, and thyrotoxicosis have been inversely associated epidemiologically with dietary intake of n-3 FA (9).

Efforts to understand the mechanism of action of n-3 FA have largely focused upon their effects on eicosanoid production. However, the hypothesis that n-3 FA act through alterations of eicosanoids cannot explain many facets of their biological activity, including the well-appreciated hypotriglyceridemic (20) and antihypertensive (21) effects. In addition, an ever growing number of other properties, potentially linked to the inhibition of atherogenesis or inflammation, appear to be also eicosanoid-independent. These include the decreased production of tissue factor (22) and cytokines (23) from monocyte–macrophages, the decrease in production of platelet-derived growth factor-like mitogens from endothelial cells (24) and monocyte–macrophages (25,26), and effects on the activation of immediate-early response genes (27). Thus, there is a general need to investigate new mechanistic explanations for anti-atherogenic and antiinflammatory effects of n-3 FA (28).

Atheroma formation and inflammation both require the adhesion of circulating leukocytes to the endothelium and their subsequent transendothelial migration (29–36). These processes depend on the endothelial expression of specific endothelial leukocyte adhesion molecules, such as Vascular Cell Adhesion Molecule-1 (VCAM-1), Intercellular Adhesion Molecule-1 (ICAM-1), and E-selectin, that recognize cognate ligands on leukocytes (37-39), and on the production of endothelial leukocyte-specific chemoattactants, such as Mono-

cyte Chemoattractant Protein-1 (40), and interleukin (IL)-8 (41)

We hypothesized that n-3 FA may modulate endothelium-dependent mechanisms in atherogenesis and inflammation, such as the expression of endothelial leukocyte adhesion molecules and the production of endothelial chemoattractants. In more general terms, we hypothesized that endothelial cell responses to cytokine-stimulation (endothelial activation) could be modulated by changes in the relative proportions of specific FA in cell lipids.

METHODS AND RESULTS

Cultured human adult saphenous vein endothelial cells (HSVEC) were grown from unused portions of saphenous veins from coronary bypass surgery, as described previously. Cells were incubated for hours to days in 96-well plates with various unsaturated FA, including oleic acid (18:1, n-9), linoleic acid (18:2, n-6), arachidonic acid (20:4, n-6), eicosapentaenoic acid (EPA; 20:5, n-3) and docosahexaenoic acid (DHA; 22:6, n-3), the most abundant unsaturated FA, esterified in cell membrane phospholipids, used as sodium salts (Nu-Chek-Prep, Elysian, MN), and dissolved in Medium 199 containing 5% (volume to volume) fetal calf serum plus Endothelial Cell Growth Factor, heparin, l-glutamine, and antibiotics [Because fatty acids were dissolved in serum-containing medium (5% volume to volume), a 1 mM concentration of fatty acids corresponds, assuming a concentration of albumin in serum of about 4 g/dl, and a molecular weight for albumin of about 60,000, to about 0.5 mmol fatty acid/g albumin, and to a molar ratio of fatty acids to albumin of about 30 (30 mol fatty acids per mol of albumin.)]. Cells were then stimulated by cytokines [IL-1, tumor necrosis factor (TNF), IL-4] or bacterial lipopolysaccharide (LPS), still in the presence of added FA or in control conditions. The expression of cell-associated surface molecules was assessed by cell-surface enzyme immunoassays. These were carried out by incubating monolayers first with saturating concentrations of specific mouse monoclonal antibodies to human VCAM-1 (Ab E1/6), E-selectin (Ab H18/7), ICAM-1 (Ab HU 5/3), Major Histocompatibility Complex-Class I (MHC-I Ab W6/32)(43), or the monoclonal antibody E1/1, recognizing a constitutive and noncytokine inducible endothelial cell antigen (44); then with biotinylated goat antimouse IgG (Vector); and finally with streptavidin-alkaline phosphatase (Zymed). Repeated washings were performed between each incubation step. The surface expression of each protein was quantified by colorimetric reading of the optical density of the wells 15–60 min after the addition of a chromogenic substrate (*para*-nitrophenylphosphate), as described (43). Preincubation of HSVEC for ≥ 24 h with DHA and, to a lesser extent, with oleic acid, but not of other FA (including, notably, EPA), significantly decreased the expression of VCAM-1 induced by IL-1α or TNF, as assayed by cell surface enzyme-immunoassay (EIA). Therefore, further experiments focused on DHA DHA inhibited cytokine-induced expression of all three adhesion molecules assayed (VCAM-1 > E-selectin > ICAM-1) in a concentration-dependent manner (half maximal inhibition at <10 μM), at all time points examined during cytokine stimulation (Table 1). DHA inhibited VCAM-1 expression with all stimuli tested, including IL-1α (1–10 ng/mL), IL-1ß (1–10 ng/mL), TNFα (1–10 μg/mL), IL-4 (50–100 ng/ml), or LPS (1–10 ng/mL, from *Escherchia coli*).

TABLE 1
Endothelial Cell Expression of VCAM-1 and E-Selectin (o.d. mU) in Response to Interleukin-1 (10 ng/mL), in the Absence and in the Presence of DHA (10 μM), as a Function of Time After Cytokine Stimulation[a]

	VCAM-1		E-Selectin	
Time (h)	Control	DHA	Control	DHA
0	4 ± 5	5 ± 5	1 ± 2	1 ± 2
2	15 ± 3	10 ± 3	396 ± 20	205 ± 15
6	302 ± 12	140 ± 10	770 ± 42	402 ± 36
22	296 ± 25	100 ± 10	435 ± 50	230 ± 15

[a]Data (mean ± SEM) are pooled from two experiments, yielding >16 replicates for each time point. VCAM-1, Vascular Cell Adhesion Molecule-1; DHA, docosahexaenoic acid.

Flow cytometric analysis of suspended HSVEC confirmed decreased cytokine-stimulated cell surface expression of VCAM-1 by DHA. HSVEC were preincubated with medium supplemented with DHA (10 μM, 48 h) or in control conditions, after which IL-1α (10 ng/mL) was added for another 24 h. The surface expression of VCAM-1 was assessed incubating HSVEC, suspended in Hank's buffered saline solution with 3 mM EDTA, with the mouse anti-human monoclonal antibody E1/6 (specific for VCAM-1) and, subsequently, with goat anti-mouse $F(ab')_2$ form IgG (H + L), labeled with fluoresceine-isothiocyanate (Caltag), at 4°C. After washings and fixation in 1% formaldehyde, cell suspension was passed through a Becton-Dickinson (Rutherford, NJ) FACScan analyzer. DHA pretreatment significantly ($P < 0.01$) decreased the median intensity of fluorescence and splayed the distribution (Fig. 1), indicating that DHA limited cytokine-induced VCAM-1 expression in a substantial population of cells.

Various control experiments examined the selectivity of DHA actions on endothelial cells. Cell number (counting), morphology, and viability (Trypan blue exclusion) were not affected by preincubation with DHA concentrations up to 25 μM for periods up to 96 h. Total and cell-associated protein synthesis was assessed in the presence or absence of DHA. To this purpose, HSVEC were cultured in 12-well plates in the presence/absence of DHA, at 10 or 25 μM for 24–96 h, and subsequently stimulated with IL-1α for periods up to 24 h. At the time of IL-1 addition, ^{3}H-leucine (New England Nuclear, Boston, MA) was also added at 0.2 μCi/10^4 cells), and total protein synthesis was then evaluated by counting radioactivity after cold trichloroacetic acid precipitation of supernates and of total cell extracts at various time points, as described previously (45). DHA did not alter total and secreted protein synthesis, measured as incorporation of radioactivity into trichloroacetic acid-precipitable material after

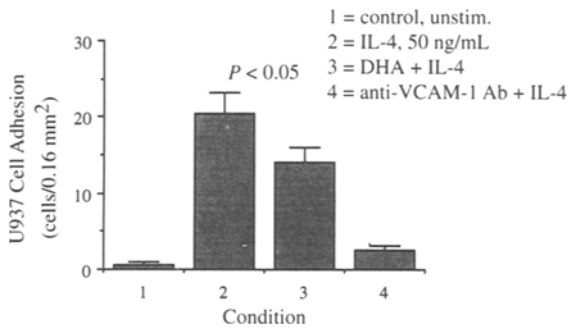

FIG. 1. Flow cytometric analysis of the effect of docosahexaenoic acid (DHA) on interleukin (IL)-1–induced Vascular Cell Adhesion Molecule-1 (VCAM-1) expression by endothelial cells. Human saphenous vein endothelial cells (HSVEC) were preincubated with medium supplemented with DHA (10 μM, 48 h) or in control conditions, after which IL-1α (10 ng/mL) was added for another 24 h. The surface expression of VCAM-1 was assessed detecting the binding of the mouse anti-human monoclonal antibody E1/6 (specific for VCAM-1). As controls, primary incubations were performed with a monoclonal antibody (E1/1) recognizing an endothelial surface antigen not induced by cytokines, or with a nonbinding antibody. The graph shows the mean ± SEM of the cell distribution of fluorescence intensity in the various conditions, as derived from original plots representing the intensity of fluorescence vs. cell number (total cells counted: 10^4 for each condition). Note the increase in fluorescence intensity after IL-1 stimulation, and its significant inhibition ($P < 0.01$, at Kolgomorov-Smirnov statistics) and spreading by DHA. Baseline fluorescence in unstimulated conditions is superimposable to that obtained with a nonbinding antibody, indicating the virtual absence of baseline expression of VCAM-1 in HSVEC; fluorescence after incubation of cells with an antibody (E1/1) directed against a constitutive endothelial antigen showed increase in mean fluorescence intensity compared to that obtained with a nonbinding antibody, and not modified by either cytokines or DHA (data not shown), indicating the presence of a noncytokine-inducible antigen on cell surface. Unstim, unstimulated.

labelling of the cells with ^{3}H-leucine. Nor did DHA alter the expression of certain other constitutive endothelial surface molecules, such as MHC-I and the antigen recognized by the monoclonal antibody E1/1 in EIA and flow-cytometry. These results indicate that the observed inhibition of cytokine-induced molecule expression by DHA was not due to a nonspecific toxic effect.

Inhibition of VCAM-1 expression by DHA depended on the time of incubation of HSVEC with DHA, requiring pretreatment and increasing for up to three days. The relationship of these kinetics with the reequilibration of polyunsaturated FA pools inside the cells was explored by parallel assessment of the FA composition of endothelial cells upon incubation with DHA. Relative amounts of DHA and of the individual chemical species of the n-3 and n-6 families were obtained by integration of peaks obtained by gas–liquid chromatographic separation of fatty acids from HSVEC monolayers, identified by comparison with retention times of FA standards. HSVEC, at passage 3–4, contained 5.7% of DHA, as percent of total FA, at baseline. Incubation of HSVEC with 10 μM DHA progressively increased total DHA incorporated in cellular lipids up to a maximum of 14.3% at 48 h, accompanied by increased total n-3 FA and a corresponding decrease of total n-6 FA. Such changes closely mimic those occurring in humans during dietary supplementation with n-3 FA, which produces a sustained enrichment of DHA in cellular phospholipids (46). The kinetics of DHA's effect on adhesion molecule expression roughly paralleled its incorporation into cellular lipids (Fig. 2).

In response to IL-1, TNF, or LPS, endothelial cells secrete IL-6 and IL-8, local mediators of the inflammatory response (41,47). DHA pretreatment also reduced HSVEC IL-6 and IL-8 secretion induced by IL-1, as measured by EIA in the supernate of HSVEC cultures, by commercially available kits (Genzyme, Boston, MA, and R&D, Minneapolis, MN) (Table 2). This is evidence that a vast number of changes in endothelial phenotype occurring during cytokine activation can be affected by specific FA.

Further experiments explored possible mechanisms by which DHA inhibits the endothelial expression of cytokine-induced molecules, using VCAM-1 expression as an index. The possibility that DHA acts by retroconversion to EPA, the direct precursor of eicosanoids of the n-3 series, seems highly unlikely. Despite some retroconversion of DHA to EPA in DHA-treated HSVEC (upon incubation with 10 μM DHA, EPA content increased from undetectable levels up to 2.1% at 72 h), exogenous EPA did not limit cytokine-induced VCAM-1 expression. In addition, treatment of HSVEC with the cycloxygenase inhibitors aspirin (100 μM) or indomethacin (5 μM), concentrations that completely suppressed IL-1–induced production of prostacyclin [assessed by EIA of its stable hydrolytic product 6-keto-PGF1α (Cayman Chemical,

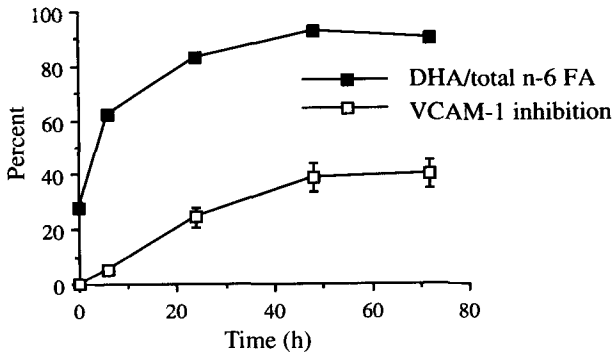

FIG. 2. The percent inhibition of IL-1α–stimulated VCAM-1 expression (open squares) as a function of DHA preincubation time, as obtained in cell-surface enzyme immunoassay experiments; each time point is the mean ± SEM from ≥3 experiments, each consisting of ≥16 comparisons between DHA-treated and control cell monolayers. The panel also shows the corresponding time course of DHA incorporation into total cell lipids (filled squares) from parallel HSVEC cultures, expressed as the percent ratio of DHA to total n-6 fatty acid (FA) in total cellular lipid, as determined by gas–liquid chromatography. There is a lag phase in the effect of DHA on VCAM-1 expression, with a minimal inhibition of VCAM-1 expression at a time (6 h), when the ratio DHA/total n-6 FA was half-maximal, after which there is a rough parallelism between incorporation and extent of VCAM-1 inhibition (reproduced with permission from the American Heart Association). Abbreviations as in Figure 1.

TABLE 2
The Effect of DHA (96-h preincubation) on the Secretion of IL-6 and IL-8 by Human Saphenous Vein Endothelial Cells[a]

	IL-6 (ng/10^6 cells)	IL-8 (ng/10^6 cells)
Control, no IL-1α	<0.2	0.5 ± 0.1
Control + IL-1α 10 ng/mL	9.0 ± 0.9	83.3 ± 3.1
DHA (10 μM) + IL-1α 10 ng/mL	6.5 ± 0.6[b]	69.3 ± 1.8[b]

[a]Values are mean ± SEM of protein concentrations assayed in duplicate in medium from ≥4 monolayers in each control unstimulated condition and ≥8 monolayers for each stimulated condition. Experimental conditions, in 12-well plates, are otherwise similar to those described for detection of cell surface antigens. Abbreviations as in Table 1.
[b]$P < 0.01$ in comparisons with corresponding control, stimulated condition (Student's *t*-test for unpaired data).

Ann Arbor, MI)] in the cell supernatants) did not alter DHA's effect (Fig. 3). Therefore, contrary to the traditional explanation for many effects of n-3 FA (48,49), DHA's actions on endothelial cells, which do not possess a 5-lipoxygenase pathway, does not appear to depend on conversion to eicosanoids. DHA also reduced levels of mRNA encoding VCAM-1 in IL-1α– or TNF-stimulated HSVEC (by 40 ± 10%, mean ± SEM, as determined by densitometry of Northern blots at 6–9 h in 4 different experiments), indicating that reduction of VCAM-1 synthesis after cytokine stimulation by DHA occurs, at least in part, at a pretranslational level (Fig. 4).

To study the functional consequences of DHA-induced reduction in the expression of adhesion molecules, we tested whether DHA treatment affected the adherence of human monocytic cells (U937 cells or flow-elutriated human monocytes) to HSVEC. U937 cells (American Type Culture Collection; NCAUR, Peoria, IL) were grown in RPMI medium 1640 containing 10% fetal calf serum and concentrated by centrifugation at 1×10^6 cells/mL. HSVEC were grown to confluency in the presence or absence of DHA (10 μM) in 6-well tissue culture plates for 96 h, after which human recombinant IL-4 (Genzyme) was added at 50 ng/mL for 24 h, in order to induce the expression of VCAM-1. For control, some monolayers were treated with a mouse anti-human monoclonal antibody (E1/6) against VCAM-1. The adhesion assay was performed by adding 1 mL of the concentrated U937 cell suspension to each monolayer under rotating conditions (63 rpm) at 21°C (50,51). After 10 min, nonadhering cells were removed by gentle washing, and monolayers fixed with 1% paraformaldehyde. The number of adherent cells was determined by counting six different fields using an ocular grid and a 20× objective (0.16 mm^2/field). Fields for counting adherent leukocytes were located at half-radius distance from the center of the monolayers. Adhesion of these leukocytes to endothelial cells under nonstatic conditions partially depends on VCAM-1 expression (50). Indeed, U-937 cell adhesion to HSVEC was practically absent without cytokine stimulation of HSVEC, and increased >30-fold after IL-4 stimulation (at 50 ng/mL) and >90-fold after IL-1 stimulation (10 ng/mL). This cytokine-stimulated adhesion was inhibited by the anti-VCAM-1 monoclonal antibody E1/6 (incubated for 1 h prior to the adhesion assay) by 40 ± 10% in the case of IL-1, and by 83 ± 12% in the case of IL-4, a more selective inducer of VCAM-1 in HSVEC, as in human umbilical vein endothelial cells (51). DHA pretreatment of HSVEC monolayers significantly inhibited IL-4–induced (Fig. 5) and IL-1–induced ad-

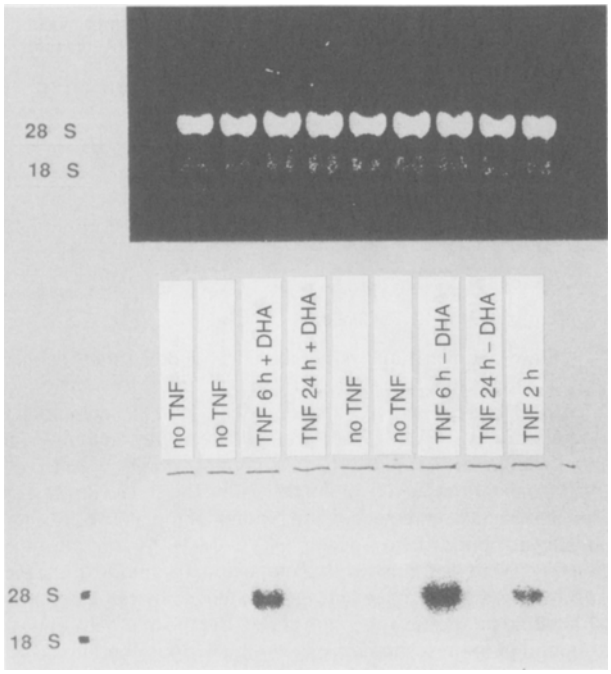

FIG. 4. Ethidium bromide staining for total RNA (upper panel), and Northern analysis of VCAM-1 mRNA (lower panel), at various time points after IL-1 stimulation, in DHA-treated HSVEC (10 μM, 48 h preincubation) and in control conditions. DHA preincubation decreases VCAM-1 mRNA (by about 50% by densitometry) during the time course of mRNA induction. Notice that the data on tumor necrosis factor (TNF) effect on VCAM-1 expression at 24 h has no match, for the design of the original experiment, in a lane with DHA + TNF for 24 h. Abbreviations as in Figure 1.

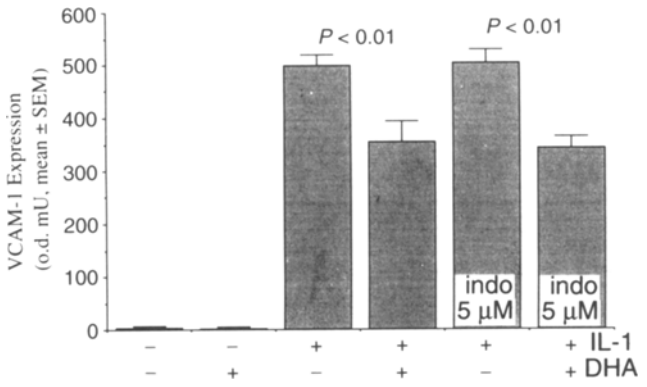

FIG 3. Indomethacin (indo, 5 μM), at a concentration able to suppress completely prostacyclin production by endothelial cells (data not shown), does not alter the effect of DHA (10 μM, 48 h preincubation) on IL-1-stimulated (24 h) VCAM-1 expression by endothelial cells. Similar results have been obtained with aspirin 100 μM. Abbreviations as in Figure 1.

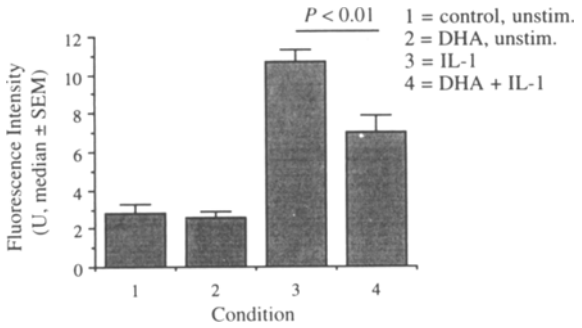

FIG. 5. The effect of DHA treatment of HSVEC on the adhesion of monocyte-like cells to HSVEC after cytokine stimulation. U937 cells adhere only to a minor extent to HSVEC not exposed to cytokines. The adhesion is dramatically increased by treatment of the monolayer with IL-4, a phenomenon which is almost entirely accounted for by the expression of VCAM-1, as it is almost completely inhibited by a treatment of the monolayer with saturating concentrations of the antibody E1/6 for 1 h prior to the assay. DHA pretreatment of the monolayer also inhibits the adhesion of U937 cells to a substantial extent, paralleling the inhibition of VCAM-1 expression as assessed by cell-surface enzyme immunoassay and flow-cytometry. IL-1–induced U937 cell adhesion was also reduced (10–40% in three different experiments, data not shown). Quantitatively similar results were obtained with flow-elutriated human monocytes. Bars show (mean ± SEM) cell counts/0.16 mm^2. Abbreviations as in Figure 1.

hesion, to a degree comparable to the inhibition of VCAM-1 surface expression, as assessed by direct assays of the protein. Similar results were obtained with flow-elutriated human monocytes (data not shown).

DISCUSSION

We show here that specific FA may alter the endothelial expression of a variety of cytokine-induced leukocyte adhesion molecules and of secretable protein products implicated in leukocyte recruitment and the local amplification of inflammation. The concentrations of FA (specifically of DHA) required for this modulation lie well within the range of those achievable during *in vivo* administration (46), suggesting that these *in vitro* findings may have a relevance in explaining dietary effects of FA. Also, the time-requirement for these effects to occur agrees with previous observations that most biological effects of changes in the n-3/n-6 FA balance are not acute, but require incorporation into cellular phospholipids (6,7). At variance from other known effects of n-3 FA (48,49), the presently described modulation appears to be totally independent of DHA metabolism to cyclooxygenase products.

We presently report a previously unsuspected difference in biological properties of DHA vs. EPA. It is unclear why DHA, but not EPA, was effective in reducing cytokine-induced VCAM-1 expression. EPA did potentiate the effect of DHA at concentrations at which EPA alone was ineffective. Also, EPA reduced IL-8 production stimulated by IL-1, although to a lesser extent than DHA. Several recent reports have recently described properties of DHA not shared by EPA (52–58), including a preferential (DHA vs. EPA) release by phospholipase A_2 from phosphatidylethanolamine, where most DHA usually accumulates (59). ^{14}C DHA radiolabelling of HSVEC, followed by thin-layer chromatographic separation of the various phospholipid classes, confirmed a preferential accumulation of DHA in phosphatidyle-thanolamine. The structure–activity relationship for these modulatory effects still require further testing, however.

DHA may regulate the protein expression of cytokine-induced molecules at different levels. Interference with cytokine-receptor binding or the initial events of signal transduction seems unlikely, as DHA limited the effects of structurally unrelated agonists (different cytokines and LPS), which bind to different receptors and use different signal transduction pathways. The reduction in VCAM-1 mRNA, consistent with data from measurement of protein expression, indicates a pretranslational level of action. As transcriptional regulation is the only type of regulation for endothelial leukocyte adhesion molecules reported so far (60), a transcriptional regulation by DHA seems likely, but has yet to be proven.

A recent report indicates that some polyunsaturated FA can be selective, redox-sensitive regulators of VCAM-1 gene expression in human vascular endothelial cells (61). In this report, linoleic and arachidonic acid could induce VCAM-1 expression in the absence of stimulating cytokines (61). Whether such induction can also be manipulated by substituting n-3 to n-6 FA also remains to be ascertained.

Dietary supplementation with n-3 FA concentrates can increase plasma DHA concentration from the low micromolar range up to more than 100 μM (46). Our results show that even much lower concentrations, as those achievable in plasma by moderate fish intake (62), can reduce cytokine-induced endothelial "activation." Our results thus provide a novel mechanism by which quantitatively minor dietary lipid components may influence cell physiology and the pathogenesis of certain inflammatory diseases, including atherosclerosis.

ACKNOWLEDGMENTS

Original work described in this paper was supported by NIH grant HL-48743 (to Peter Libby), and grants by SPA-Pharmaceuticals, Milan, Italy, and Italian National Research Council (to Dr. De Caterina). The other co-authors of the original paper (*Atheroscl. Thromb. 14*, 1829–1836) where most of the findings here reported have been first described, namely Dr. Myron I. Cybulsky and Dr. Michael A. Gimbrone Jr., Vascular Research Division, Department of Pathology, at Brigham and Women's Hospital, Boston, and Dr. Steven K. Clinton, at the Dana Farber Cancer Institute, Boston, MA, are acknowledged with gratitude. We also thank Dr. Alexander Leaf for fatty acid analyses; Dr. Charles N. Serhan for advice on thin- layer chromatography; Dr. Francis W. Luscinskas for help in adhesion experiments; and Dr. Maria Muszynski, D.V.M., for help with cell culture experiments.

Fats for the Food Industry: Implications for Cholesterol-Lowering

Paul Nestel*, Manny Noakes, and Peter Clifton

Baker Medical Research Institute, Melbourne; CSIRO Division of Human Nutrition, Adelaide, Australia

ABSTRACT: The special needs of the food industry may not always coincide with what is healthiest for consumers. People always demand optimal taste, flavor and texture; they expect shelf-stability, convenience and novelty. The edible oils and fat industry has been particularly vulnerable in this regard but has tried, often very successfully, to modify its products to take into account the customer's preferences and their health. The following review illustrates some potential strategies in the retail and commercial sectors, especially in baking, frying and food service areas. Given the large increase in the consumption of convenient, small portion meals, the fat content and composition of such meals and products will critically influence further outcomes in areas related to cardiovascular disease, cancer, obesity and diabetes.

Lipids 31, S-65–S-69 (1996).

Edible fats which are suitable for certain food service and bakery purposes need to be solid or semi-solid at room temperature. Commonly used are animal fats such as tallow or vegetable fats and blends comprising palm oil, coconut oil and partially hydrogenated soybean oil. Their public health disadvantage lies in the high content of lauric, myristic, palmitic or trans fatty acids (TFA), each of which has been shown to raise the plasma low density lipoprotein (LDL) levels in people, especially those at high risk from hypercholesterolemia.

Interesterification. Another approach is to harden liquid oils through interesterification. The rearrangement of certain fatty acids within triglyceride molecules changes the physical characteristics. One of the perceived constraints to this strategy is the possibility that the process of interesterification may increase the likelihood of that fat raising plasma LDL concentrations more than the native oil since the structure of the triglyceride may influence cholesterol metabolism.

Since unsaturated fatty acids normally occupy the middle or *sn*-2 position of a triglyceride molecule, and saturated fatty acids one of the outside (*sn*-1 or *sn*-3) positions, it is possible that an exchange of positions during interesterification will alter the influence of the fat on cholesterol metabolism. The fatty acid at the *sn*-2 position is conserved within the monoglyceride during fat absorption, whereas the outside fatty acids, absorbed as free fatty acids, are partially replaced by endogenous fatty acids in reconstituted triglycerides.

In the following experiments, we have re-examined the effects of transesterification on plasma lipids by comparing two blends of identical fatty acid composition, one of which has been randomized. The fatty acids were derived from palm kernel, palm stearin, palmolein and sunflower oils so that interesterification would lead to the enrichment of the *sn*-2 position with the saturated fatty acids, lauric, myristic and palmitic acids (Tables 1 and 2).

dominantly lauric, myristic, palmitic, oleic and linoleic acids), and (iii) an interesterified form of the high palm. Both high palm margarines led to similar LDL cholesterol levels (4.43 ± 0.94 and 4.54 ± 0.88 mmol/L, respectively) and were significantly higher than the high linoleic fat (4.02 ± 0.85 mmol/L, $P < 0.001$) (Table 3). Interesterification transferred substantial palmitic acid to the *sn*-2 position and this was reflected in plasma chylomicrons.

The study also confirms that high-palmitic fats give higher plasma cholesterol levels than those rich in linoleic acid, even when the latter contain moderate amounts of TFA. Although further studies and comparisons of different mixtures of fatty acids, especially those likely to be used for commercial purposes, are required, the available data favor the conclusion that interesterification per se does not adversely influence plasma lipid concentrations through the rearrangement of the triglycerides and provides a strategy for hardening fats which is an alternative to using TFA.

A recent report by Zock *et al.* (1) also showed that the positional distribution of palmitic acid in two contrasting margarines failed to affect plasma LDL or high density liproprotein cholesterol levels significantly.

Commercial frying oils. It is estimated that up to one third of fat energy is derived from commercially prepared foods with fried foods probably contributing a significant proportion of this. There is good evidence that this contribution is likely to rise with trends toward an increase in expenditure in snacks and takeaway foods in the last ten years.

A major use of cooking fats is in deep fat frying where it functions as heat transfer medium and contributes desirable flavor and texture to fried foods. Functionally, such oils need to be stable at the high temperature and moisture exposure,which is characteristic of commercial usage where oils are used repeatedly and frying may occur over several hours. During heating, polyunsaturated fatty acids (PUFA) polymerize, creating a viscous oil which produces a greasy product. Furthermore, as in the case of stored snack items, the stability of the fat will determine shelf-life, the more saturated the oil the more stable it is to oxidative and hydrolytic breakdown.

Major frying fats in Australia are tallow and palm oil, both of which are highly stable to oxidation and also have good palatability and mouth-feel. However, they are also highly saturated fats making them nutritionally undesirable in countries that experience high rates of coronary heart disease (CHD).

Linolenic rich oils such as canola and soybean oils are particularly susceptible to undesirable changes. Substantial hydrogenation of these oils renders them more stable, but results in levels which may negate their lipid lowering potential. Sunflower and safflower oils are also unsuitable commercial frying oils because of their high PUFA content. In contrast, oils high in monounsaturated fatty acids are relatively resistant to oxidation. Recently, a high oleic genetic variant of sunflower oil (Sunola™) has been developed which has the stability and potentially the nutritionally desirable characteristics required in a frying fat. Solid partially hydrogenated fats with moderate levels of TFA, but with adequate linoleic acid, have also been developed for baking and have been shown to have cholesterol lowering attributes (2).

We have compared the effects on plasma cholesterol levels of three types of cooking fats suitable for frying. Twenty-three hypercholesterolemic men and women participated in a double-blind, cross-over trial of palm oil, a high oleic genetic variant of sunflower oil (Sunola™) and a newly developed semisolid blend with moderate TFA (20%) but designed to have lipid lowering potential through unsaturates (55% *cis*-oleic and 9% linoleic). The test blends provided 20% energy. Palm oil resulted in the highest LDL concentration (4.18 ± 0.81 mmol/L), with Sunola (3.77 ± 0.58 mmol/L) and

TABLE 4
Mean Differences in Plasma Lipids (mmol/L ± SD) Between Test Diets

Plasma lipids	Palm-Sunola™	Palm-test	Sunola™-test
Total cholesterol	0.51 ± 0.37[a]	0.31 ± 0.32[a]	-0.21 ± 0.30[c]
LDL Cholesterol	0.42 ± 037[a]	0.28 ± 0.41[a]	-0.14 ± 0.37
Triglyceride	0.17 ± 0.39	-0.03 ± 0.39	-0.21 ± 0.40[c]
HDL cholesterol	0.04 ± 0.09[b]	0.08 ± 0.10[b]	0.04 ± 0.09[c]

[c]$P < 0.05$ Sunola™ vs. test. See Table 3 for abbreviations.

the experimental blend (3.88 ± 0.70 mmol/L) resulting in the lower levels. The difference between the latter two blends was statistically insignificant (Table 4).

The purpose of this study was to compare the effects on plasma cholesterol levels of three types of frying fats. Palm oil is widely used in commercial practice and monounsaturated oils are finding favor on health grounds. One disadvantage of the latter is its liquid state and for this reason, we tested a semi-solid formulation in which the mix of fatty acids was likely to be less cholesterol raising than palm oil.

The results show that compared to palm oil, Sunola™ oil led to significantly lower total and low-desnity lipoprotein. The test blend behaved similarly to Sunola™ in terms of LDL cholesterol lowering and this occurred despite the increase of $C_{18:1}$ *trans*. Palmitic acid is the major saturated fatty acid in the palm oil blend. An approximate 10% energy substitution of palmitic by oleic acid in our mildly hypercholesterolemic subjects resulted in a fall of 0.50 mmol/L in total cholesterol. The current weight of evidence suggests that palmitic acid is cholesterol-elevating relative to oleic acid and that this effect is particularly pronounced in populations where the majority of people have plasma total cholesterol concentrations above 5 mmol/L. Palmitic acid is the major saturated fatty acid in the Australian diet, contributing 48% of total saturated fatty acids or 7% energy. Snack foods, baked goods and confectionery currently contribute 20% of the total palmitic acid consumed. The replacement of palmitic acid, where possible in the food industry, is a desirable goal.

In the present study, *trans* intake was estimated to be less than 1% energy in the palm and Sunola™ phases primarily from dairy and beef products. During the test blend phase, *trans* intakes increased by 4.8% energy with a concomitant increase of 1.5% energy in linoleic acid. It has been suggested that it is the overall ratio of linoleic to palmitic acid in commercial oil blends that determines LDL lowering potential and that, if this is adequate, the inclusion of modest amounts of TFA will not negate this (2). It is therefore of interest that the ratios of linoleic/palmitic acid were similar in Sunola™ and the test blend at about 1:1 and that there was no significant difference in LDL cholesterol between the two oils.

In conclusion, monounsaturated oils such as Sunola™ are clearly preferable to palm oil in the food service industry, in terms of cardiovascular risk. Further, it is possible to design formulations of blends, such as the test blend used in this study, which are partially solid and suitable for commercial frying purposes but have a favorable effect on plasma LDL cholesterol levels compared with palm oil. While economically Sunola™ oil is more expensive than tallow or palm oil, its stability to continuous deep fat frying makes its overall cost reasonably competitive with current frying fats.

Biological manipulation of milk fat. Milk and butter intake has been clearly associated with higher CHD rates in different countries (3). Correlation with cardiovascular disease mortality is likely to be mediated by the effect of dairy fats on the plasma LDL cholesterol.

Dairy products (excluding butter) make a substantial contribution to saturated fat intake (25–29%) in Westernized countries. In Australia, fats from dairy foods currently comprise 25% of the total fat intake and as much as 40% of the saturated fatty acids. The hypercholesterolemic effect of dairy products has been conclusively demonstrated in numerous controlled studies. Two of the principal saturated fatty acids in butterfat, namely myristic and palmitic acids, have been identified as major dietary factors that raise LDL cholesterol.

In vivo fat-modified dairy products are an innovation involving a technology in which protected unsaturated lipids are fed to ruminants resulting in milk and tissue lipids with reduced saturated fatty acids. We examined the impact of these novel dairy fats on plasma lipids in a human dietary trial (Table 5). Thirty-three men and women participated in an eight week randomized cross-over trial comparing fat-modified and conventional dairy products. During the test periods, the fat-modified products resulted in a 0.28 mmol/L (4.3%) lowering of total cholesterol which was significant at $P < 0.001$. Most of this fall was in LDL cholesterol which fell by 0.24 mmol/L ($P < 0.001$) whereas high density lipoprotein

TABLE 6
Mean (± SD) Plasma Lipoproteins During Baseline, Control, and Fat-Modified Phases

Plasma lipids (mmol/L)	Baseline	Control	Fat-modified
Total cholesterol	5.89 ± 0.89	6.50 ± 0.98	6.22 ± 0.82[a]
LDL cholesterol	3.95 ± 0.75	4.49 ± 0.90	4.25 ± 0.71[a]
HDL cholesterol	1.19 ± 0.30	1.30 ± 0.33	1.28 ± 0.33
Triglycerides	1.67 ± 0.85	1.57 ± 0.72	1.54 ± 0.66

[a]$P < 0.001$ control vs. fat-modified. See Table 3 for abbreviations.

cholesterol and triglycerides remained essentially unchanged (Table 6).

The cows were fed supplements of a primarily monounsaturated source by using canola seed (protected from hydrogenation in the rumen) and the additional use of Vitamin E in the ration which is also transferred to the secreted milk to stabilize PUFA.

It can be concluded that modifying the fat composition of milk and related dairy products through the substitution of palmitic and myristic acids by oleic, linoleic and linolenic acids will result in a significant improvement in the plasma lipoprotein profile in humans. We observed a fall of 0.28 mmol/L (4.3%) in total plasma cholesterol by substituting the fat modified dairy products for conventional products. Cholesterol-lowering intervention trials suggest that this alone could reduce clinical coronary disease by 9% without appreciably changing eating habits.

TFA. TFA in the food supply have recently generated controversy which appears to many nutritionists to have gained undue notoriety. Scientific discussion should focus mainly on the link between TFA and coronary heart disease prevalence and risk. This is clearly the major current health issue. The least controversial issue relates to the effects of TFA on plasma lipids. While much of the data were derived from dietary interventions with partially hydrogenated fats and oils and only more recently with specified TFA, it is agreed that LDL cholesterol is raised. However, while the LDL are higher than with the corresponding unhydrogenated oils, the levels are marginally lower than occur with highly saturated fats such as butter or palm oil (4). Since this is clearly dose related, the contribution which TFA make to the total LDL raising potential of the diet will depend on the mix of foods chosen by an individual. Thus the effect of saturates in the diet will substantially exceed that of TFA, given their relative proportions in edible fat eaten by most people. One major recommendation would be supported by most objective nutritionists: to encourage the edible oil industry to introduce new technologies for hardening oils which will reduce the TFA load. However, this must not be interpreted, as has been occurring, that saturated fats as butter are preferable. The scientific evidence is clearly against that extrapolation.

Less certain are the effects of TFA on HDL cholesterol-lowering and on Lp(a) concentrations (4,5). It is likely that significant HDL lowering becomes important only at higher intakes of TFA such as are eaten only by a small minority. The problem inherent in Lp(a) measurement and the paucity of reports that Lp(a) are raised leave that issue in the uncertain basket (4).

Most controversial is the alleged link between TFA consumption and CHD. Of some concern is that in the two most influential studies, by Ascherio *et al.* (6) and Willett *et al.* (7) who ranked CHD risk by quintile of TFA intake, the lowest risk was in the mid-quintile and not in the lowest quintile. This would lead to the conclusion that eating around 3–4 g TFA daily is more protective against CHD than eating none at all.

Of further interest is that in some case-control studies (8) in which tissue TFA concentrations were the indices of TFA consumption, the link with CHD occurred with *trans* 16:1 which is derived from animal fat and not from hydrogenating vegetable oil. By contrast tissue *trans* 18:1, derived through hydrogenation, was not associated with CHD.

More recently, two reports do not confirm the American studies. In eight European countries and Israel, the TFA content of adipose tissue (a reliable index of the kind of fat eaten during the preceding year or so) was measured in case-control studies (671 men after myocardial infarction and 717 controls). There was no association between *trans* oleic acid (elaidic acid) and clinical events (9).

In a second study, from England, there was again no association between the *trans* isomers of oleic and linoleic acids and sudden cardiac death (10). Given the objective for further reductions in saturated fat intake, one would like to see TFA included in whatever reductions take place in total fat consumption.

Structured Lipids. These are families of triglycerides structured through interesterification to provide novel, designer fats not found in nature. They are generally mixtures of long, medium and short chain fatty acids, designed for specific health benefits and functional suitability for use in bakery products and confectionery, where fat substitutes may not perform well.

The health perspectives are to reduce energy content, lower plasma cholesterol and to improve body functions such as immunity. The principles have been to use poorly or less well absorbed fatty acids such as behenic or stearic acids and interesterifying them with medium chain e.g., octanoic or decanoic acids or short-chain e.g., butyric or propionic acids. Two such products, Caprenin and Salatrim, appear to have energy values of only five kal/g, but their potential to lower cholesterol levels is not established. Dairy fats have also been interesterified with medium chain fatty acids to achieve the above health benefits. Fish oil fatty acids have been interesterified with short and medium chain fatty acids to achieve better absorption of eicosapentaenoic acid while delivering more butyrate into the intestine to hopefully benefit the gut mucosa.

Factors Affecting Resistance of Low Density Lipoproteins to Oxidation

O. Ziouzenkova, S.P. Gieseg, P. Ramos, and H. Esterbauer*

Institute of Biochemistry, University of Graz, Graz, Austria

ABSTRACT: Oxidation resistance (OR) of low density lipoproteins (LDL) is frequently determined by the conjugated diene (CD) assay, in which isolated LDL is exposed to Cu^{2+} as prooxidant in the range of 1–10 μM. A brief review on major findings obtained with this assay will be given. A consistent observation is that vitamin E supplements or oleic acid–rich diets increase OR. Oxidation indices measured by the CD assay and effects of antioxidants very significantly depend on the Cu^{2+} concentration used for LDL oxidation. For medium and high Cu^{2+} concentrations, the relationship between lag time and propagation rate can be described by a simple hyperbolic saturation function, which has the same mathematical form as the Michaelis–Menten equation. At medium and high Cu^{2+} concentrations (0.5 to 5 μM), vitamin E increases lag time in a dose-dependent manner. The increase is higher for 0.5 μM Cu^{2+} as compared to 5 μM. At low Cu^{2+} concentrations (0.5 μM or less), the mechanism of LDL oxidation changes. Significant oxidation occurs in a preoxidation phase, which commences shortly after addition of Cu^{2+}. Preoxidation is not inhibited by vitamin E. It is concluded that much additional work is needed to validate the importance of oxidation indices derived from CD and similar assays.
Lipids 31, S-71–S-76 (1996).

Oxidative modification of low density lipoproteins (LDL) most likely plays an important role in the development of atherosclerosis (1,2), but many questions on factors determining oxidation resistance (OR) of LDL and how reliable indices characteristic for OR can be measured remain unanswered (3). At present, we have very limited knowledge on how and where oxidation of LDL is initiated *in vivo*, the knowledge of which would be crucial in identifying important factors for protection of LDL against oxidative modification *in vivo*. At present, it is generally believed that lipid peroxidation is the process most relevant for producing LDL with high atherogenic potential. Therefore numerous studies have aimed to evaluate the role of antioxidants and other factors for protecting LDL against lipid peroxidation. Examination of recent literature clearly shows that most laboratories working on this subject expose isolated LDL to prooxidants (e.g., copper ions, azo-initiators, ultraviolet light, cells) and measure progress and/or extent of lipid peroxidation. One such model to measure kinetic parameters that has become very popular is copper ion (Cu^{2+})–promoted oxidation in conjunction with continuous measurement of the conjugated diene absorption at 234 nm (CD assay). It should be emphasized that we have developed this CD assay primarily as a time marker (4) useful for basic kinetic studies, but we did not intend to propose the assay for routine clinical-chemical analyses of OR of LDL. It was perhaps the report by Regnström and colleagues (5) on the inverse relationship between OR of LDL (measured by lag time of Cu^{2+}-dependent oxidation) and severity of myocardial infarction that led to the assumption that the CD assay is a biologically relevant model and gives indices (e.g., lag time) of clinical importance. In the meantime, many studies were published in which this assay was used to explore the importance of antioxidants and dietary fats for OR of LDL and to evaluate relationships between OR and severity and progression of atherosclerosis in humans and animals. A selected list of studies

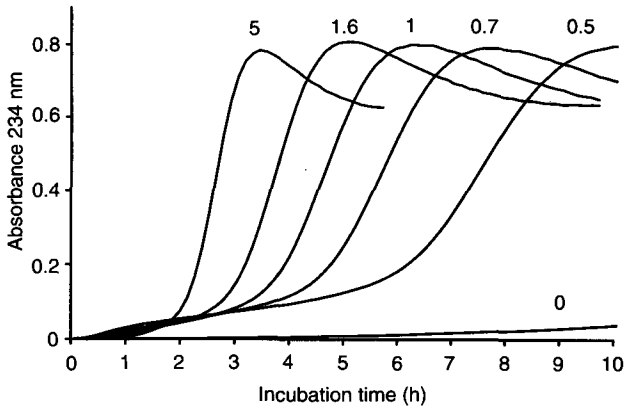

FIG. 1. Oxidation of LDL with medium to high Cu^{2+} concentrations. LDL (0.1 μM) in phosphate-buffered saline was oxidized at 30°C with the indicated concentrations (0.5 to 5.0 μM) of Cu^{2+}, and conjugated dione (CD)-curves were recorded. Also shown is CD increase without added Cu^{2+} (0).

TABLE 1
Selected Studies (1994/1995) on Oxidation Resistance of Low Density Lipoproteins (LDL) Measured by the Conjugated Diene Assay

Authors	Major finding
1994	
Stalenhoef *et al.* (6)	Patients with familiar defective apolipoprotein B had decreased *t*.[a]
Kontush *et al.* (7)	In 20 healthy subjects vitamin E content did not correlate with *t*.
Reaven *et al.* (8)	In combination with vitamin E, 18:1[b] increased the OR[c] and 18:2[d] decreased the OR of LDL subfractions.
Sasahara *et al.* (9)	In probucol-treated monkeys on cholesterol diets, the increase in *t* correlated with reduction in lesion size.
Nenseter *et al.* (10)	Cholesterol feeding reduced *t* of rabbit LDL; thiobarbituric acid reactive substances and peroxides were increased.
Fruebis *et al.* (11)	In probucol-treated rabbits (1% in diet) *t* increased from 2 to > 16 h.
Thomas *et al.* (12)	In primates with different fatty acid diets, *t* correlated with vitamin E in cases of polyunsaturated fatty acid diet, yet not with saturated and monounsaturated fatty acids.
Kleinveld *et al.* (13)	In Watanabe heritable hyperlipidemic rabbits, vitamin E treatment increased *t* and decreased *v*.[e]
Maggi *et al.* (14)	In 37 uremic patients, *t* decreased, *v* increased, and *t* correlated with vitamin E.
Tribble *et al.* (15)	OR of LDL subfractions was correlated with their ubiquinol-10 and vitamin E contents.
Tsai *et al.* (16)	Patients with poorly control insulin-dependent diabetes mellitus showed shorter *t*, but the distribution of LDL subfractions did not differ from control subjects. Uric acid and vitamin A decreased in diabetes.
Nyyssonen *et al.* (17)	Supplementation with vitamin E, β–carotene, ascorbate, and selenium increased *t* and decreased *v* of oxidation of LDL + very low density lipoproteins.
1995	
Winklhofer-Roob *et al.* (18)	LDL of cystic fibrosis patients had decreased *t*. Vitamin E and β–carotene supplementation normalized the OR; *t* correlated with vitamin E.
Jialal *et al.* (19)	Minimum dose of 400 IU/d vitamin E was needed to significantly increase the OR of LDL.
Suzukawa *et al.* (20)	Supplementation of low-dose vitamin E for 3 wk protected LDL against oxidative modification (increase in *t* and decrease in *v*) and decreased *v* in high-density lipoprotein.
Livrea *et al.* (21)	Vitamin A supplements increased *t* and decreased *v*.
Croft *et al.* (22)	In 45 healthy individuals, vitamin E was not correlated with *t*; *v* negatively correlated with 18:1 and positively with 18:2.
Gaziano *et al.* (23)	β–carotene supplementation did not increase *t*.
Mosinger (24)	*t* and CD_{max}[f] correlated with LDL cholesterol.

[a]*t* = Lag time.
[b]18:1 = Oleic acid.
[c]OR = Oxidation resistance.
[d]18:2 = Linoleic acid.
[e]*v* = Propagation rate.
fCD_{max} = Extent of oxidation.

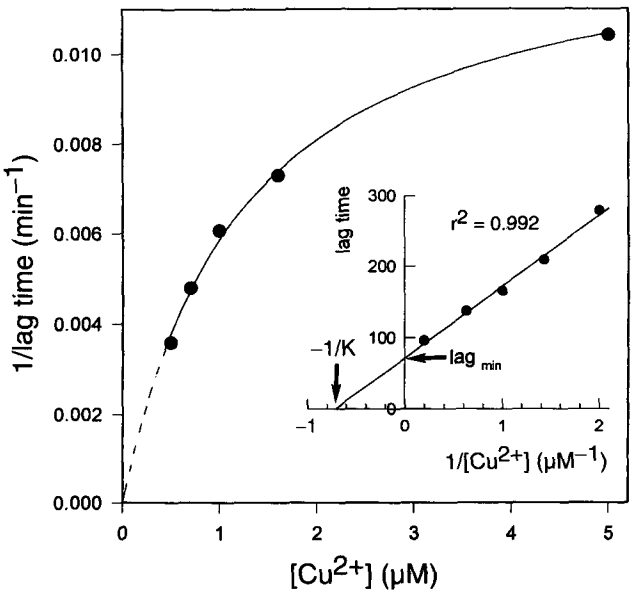

FIG. 2. Relationship between lag time and the Cu^{2+} concentration. Data derived from Figure 1. Lag time is the intercept of the tangent to the slow and fast increase of conjugated diene (4).

published recently (1994 to March 1995) can be found in Table 1.

Interpretation of such studies is usually confused by the fact that quite different assay conditions are used. In retrospect, we feel that it would have been important to emphasize that oxidation indices derived from a CD curve strongly depend on concentration of Cu^{2+}, LDL, temperature, pH value and other extrinsic factors. We have shown (25) that the temperature dependence of lag time and propagation rate can fully be described by the Arrhenius law; core melting of LDL has no or only a minor effect on OR.

In this study, we performed a systematic investigation to elucidate the effect of Cu^{2+} concentration on OR of LDL. We show for the first time that the copper concentration has not only a pronounced effect on the mechanism of LDL oxidation but also on the antioxidant action of vitamin E.

MATERIAL AND METHODS

Human LDL was prepared by ultracentrifugation using a single-step discontinuous gradient in a Beckman (Palo Alto, CA) NVT 65 rotor (26). LDL oxidation was carried out as previously described (27) with 0.1 μM LDL (equal to 0.25 mg total LDL mass/mL) in phosphate-buffered saline pH 7.4 and $CuSO_4$ as prooxidant. Cu^{2+} concentrations are given in the text. CD curves were recorded in a Beckman DU-640 spectrometer equipped with an auto-cellholder with six cuvettes and a Peltier-element temperature control. In all experiments, the temperature was 30°C (27). LDL antioxidants were determined in principle as described in (2). Loading of LDL with α-tocopherol was performed as described previously (28).

RESULTS AND DISCUSSION

Oxidation of LDL with medium and high Cu^{2+} concentrations. The original protocol for measurement of CD curves recommended 0.1 μM LDL (equal to 0.25 mg LDL mass/mL) and 1.6 μM Cu^{2+} (4). This gives lag times of about 30 to 180 min depending on the donor (2). Figure 1 clearly shows that increasing Cu^{2+} reduces lag time and increases rate of propagation, whereas lowering Cu^{2+} from 1.6 to 0.5 μM results in increase in lag time and decrease in propagation rate. The extent of oxidation, characterized by the CD_{max} value prior to onset of decomposition, is virtually independent of Cu^{2+} concentration. Figure 2 shows that for Cu^{2+} concentrations ≥ 0.5 μM the relationship between lag time and Cu^{2+} can be described by Equation 1, where lag is the lag time in minutes obtained with a certain concentration (μM) of added $[Cu^{2+}]$; lag_{min} is the minimum value for the lag time; and K is the Cu^{2+} concentration for lag = 2 lag_{min}:

$$\frac{1}{\text{lag}} = \frac{1}{\text{lag}_{min}} \cdot \frac{[Cu^{2+}]}{K + [Cu^{2+}]}$$

Figure 3 shows that propagation rate v approaches a maximum with increasing Cu^{2+} concentration. This relationship can be described by Equation 2 (25), where v is the propagation rate in ΔA_{234}/min or μM dienes/min obtained from the first derivatives of the CD curve; v_{max} is the maximum value for the propagation rate; and K′ is the Cu^{2+} concentration for $v = v_{max}/2$:

$$v = v_{max} \cdot \frac{[Cu^{2+}]}{K' + [Cu^{2+}]}$$

Note that both Equations 1 and 2 represent hyperbolic saturation functions, with the same mathematical form as the Michaelis–Menten equation. In analogy to Line-Weaver-Burk plots, strict linear relationships for the lag time or propagation rate can be obtained by plotting lag vs. the reciprocal value of $[Cu^{2+}]$(Fig. 2 inset) or by plotting $1/v$ vs. the reciprocal value of Cu^{2+} (Fig. 3 inset).

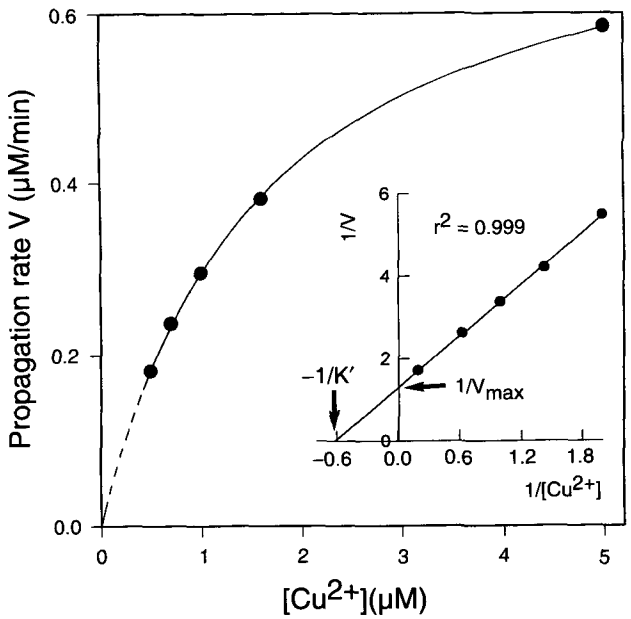

FIG. 3. Relationship between rate of propagation (v) and Cu^{2+} concentration. Data derived from Figure 1, v was determined from the first derivative of the conjugated diene curves (27).

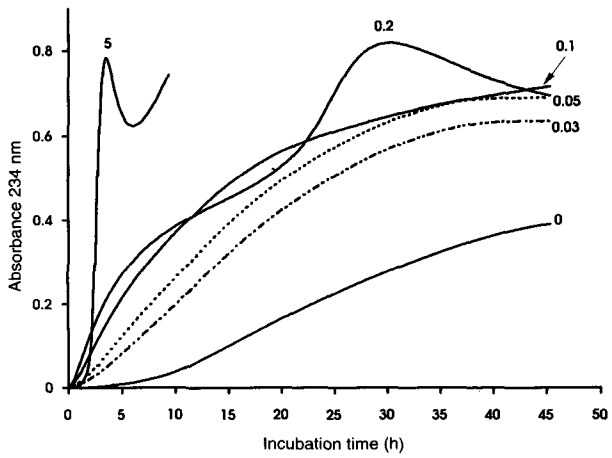

FIG. 4. Oxidation of low density lipoprotein (LDL) with low Cu^{2+} concentration. The same LDL sample as was used in Figure 1 was oxidized with 0.2, 0.1, 0.05, and 0.03 μM Cu^{2+}, and the conjugated diene increase was measured. Also shown for comparison is oxidation with 5 μM Cu^{2+} and oxidation without added Cu^{2+}.

Oxidations with low Cu^{2+} concentrations. In previous LDL oxidation studies performed and published by us (2,29) and other authors (Table 1) Cu^{2+} concentrations of 0.5 μM or higher were used. As shown in Figure 1, such concentrations are capable to fully oxidize LDL within a period of 10 h or less. The reason for using $Cu^{2+} > 0.5$ μM was simply a logistic one: such conditions allow us to oxidize LDL within several h, a reasonable time to complete experiments within a working day or during an overnight run. Moreover, CD curves measured under such conditions show the classical profile with a lag phase, propagation phase, and decomposition phase. We had no rational reason to presume that this trend to longer lag times and lower propagation rates would not continue if Cu^{2+} is further decreased. When the same LDL sample used for the experiments shown in Figure 1 was oxidized with Cu^{2+} of 0.2 μM or less, however, the shapes of the CD curves unexpectedly changed completely (Fig. 4).

In the experiment with 0.2 μM Cu^{2+}, oxidation occurred in several consecutive steps. The first steps, denoted by "preoxidations," commenced a few min after addition of Cu^{2+}, lasted about 10 h, and caused heavy oxidation of LDL with about 50% of CD_{max}. Then followed an inhibited interval with slow increase of CD and a second rapid oxidation leading to CD_{max}. The inhibited interval and the second rapid rise of CD most likely represent the classical lag phase and propagation phase characteristic for oxidation with medium or high Cu^{2+} concentrations. With Cu^{2+} concentrations of 0.1, 0.05, and 0.03 μM, CD curves exhibited the preoxidation stage and the inhibited interval, but no propagation phase. Preoxidation rate decreased with decreasing Cu^{2+} concentration (0.5 to 0.03

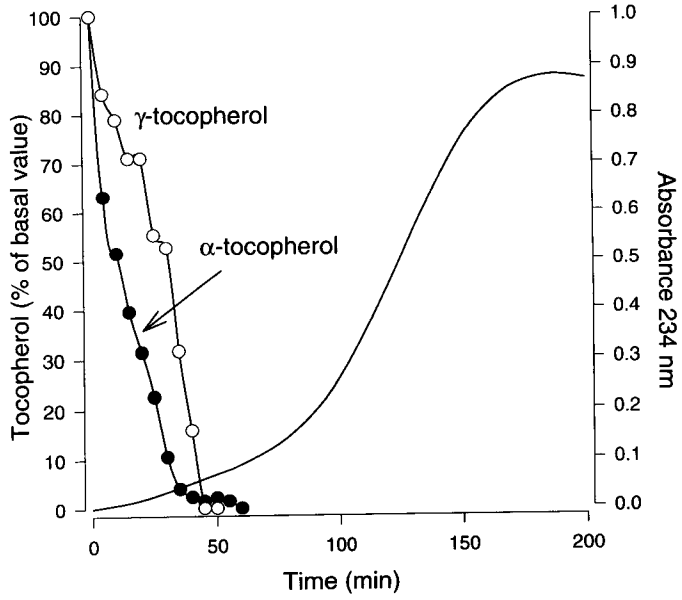

FIG. 5. Temporal relationship between loss of vitamin E and oxidation (conjugated diene-increase) of low density lipoprotein (LDL) with 1.6 μM Cu^{2+}. Initial concentrations were 0.609 μM α-tocopherol, 0.038 μM γ-tocopherol, and 0.1 μM LDL.

μM), but was in all instances higher than the rate during the lag phase in oxidations with 0.5 to 5.5 μM Cu^{2+}. Figure 4 also shows that the LDL sample without added Cu^{2+} was heavily oxidized after 45 h.

Antioxidants delay onset of propagation. It has previously been shown (2,29) that onset of propagation is preceded by the lag phase during which the LDL becomes progressively depleted of its antioxidants, with α-tocopherol as the first and β–carotene as the last to be depleted. This chronology was observed in LDL oxidations with medium and high Cu^{2+} concentrations in the range of about 1 to 10 μM. We have repeated these experiments, and results were in full agreement with our previous observations. A representative example for loss of vitamin E is shown in Figure 5. It has also been reported by us (2,29) and other authors (Table 1) that loading LDL with α-tocopherol either *in vitro* or by vitamin E supplements increases the length of the lag phase and therefore delays onset of propagation. As shown in Figure 6, the effect of α-tocopherol on lag time strongly depends on the concentration of Cu^{2+} used for oxidation. The effect is much more pronounced in oxidations with 0.5 μM Cu^{2+}, as compared to 5 μM Cu^{2+}. This may explain why some authors using high Cu^{2+} concentrations found no effect of vitamin E on lag time.

Antioxidants cannot prevent "preoxidation." Figure 7 shows an oxidation of LDL with 0.2 μM Cu^{2+}. The CD curve clearly exhibits a step wise oxidation with a preoxidation phase lasting about 10 h. During this stage, CD reached about 50% of CD_{max}, indicating that LDL becomes heavily oxidized prior to the onset of the propagation phase, which occurred at about 24 h. The average rate of diene formation during the first 10 h was 21 nM/min. We also measured the consumption of antioxidants and found that their concentration only slowly decreased during the preoxidation phase. After 10 h, a time-point when LDL was already heavily oxidized, only 38 and 12% of α- and γ-tocopherol were consumed (Fig. 7). Consumption of β–carotene and lycopene was 55 and 75%, respectively (data not shown). Average consumption rate of α-tocopherol (initial content 3.2 mol/mol LDL) was 0.2 nM/min, 100 times less than the CD production rate. From these experiments and others performed under comparable conditions, it is evident that LDL antioxidants do not prevent preoxidation promoted by low Cu^{2+} concentrations. In one experiment (data not shown), LDL was loaded *in vitro* with α-tocopherol and then subjected to oxidation with a low Cu^{2+} concentration. α-Tocopherol had no effect on the rate of CD increase during the preoxidation phase, but the length of this phase was prolonged. At present, it is not clear whether the preoxidation reflects perhaps tocopherol-mediated propagation (30) or is due to other, specific elementary reactions characteristic for low rate of initiation.

At present, we have very limited knowledge on how and where LDL oxidation is initiated *in vivo* and how quickly oxidation proceeds (1,2). This information is, however, crucial to intelligent design of assays, which give biologically relevant answers on factors determining OR of LDL *in vivo*. Many studies based on the classical CD assay (2, 29, and references in Table 1) revealed that vitamin E supplements or an oleic acid–rich diet significantly increase OR of LDL. Case-control studies and intervention trials with antioxidants (Table 1) also suggest some relationships between OR (measured by the lag time in CD assay) and progression and severity of atherosclerosis. It cannot be denied, however, that the oxidation indices and conclusions, which can be derived from CD assays, strongly depend on assay conditions (Figs. 1–4). For example, vitamin E can be ineffective

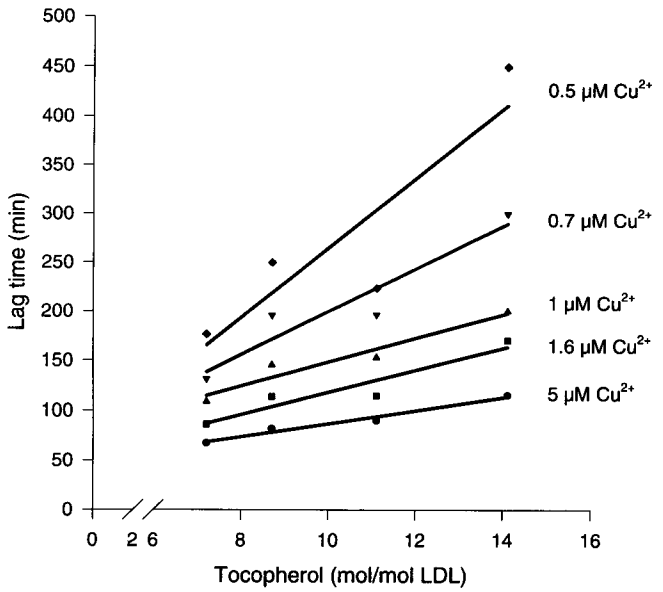

FIG. 6. Effect of α-tocopherol in the length of lag time measured with different Cu^{2+} concentrations. Low density lipoprotein (LDL) samples with different α-tocopherol contents (7.2, 8.7, 11.1, and 14.1 mol/mol LDL) were prepared and oxidized at 30°C with Cu^{2+} concentrations ranging from 0.5 to 5 μM. The graph shows that increase of lag time depends on both α-tocopherol content and Cu^{2+} concentration.

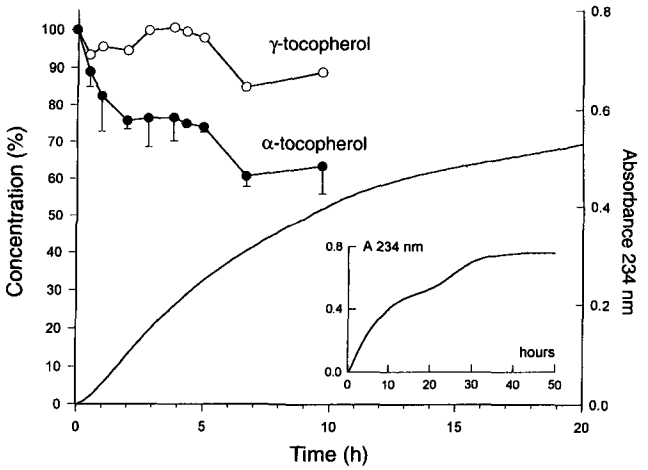

FIG. 7. Temporal relationship between loss of vitamin E and oxidation (conjugated diene increase) of low density lipoprotein (LDL) with 0.2 μM Cu^{2+}. Initial concentrations were 0.325 μM α-tocopherol, 0.016 μM γ-tocopherol, and 0.1 μM LDL.

(Fig. 7) or significantly increase lag time (Fig. 6), depending on the concentration of Cu^{2+} used as prooxidant. Much further work is needed to clarify whether oxidation indices measured *in vitro* are really suitable and important for predicting a risk.

Determinants of Antioxidant Status in Humans

Andreas M. Papas*

Eastman Chemical Company, Kingsport, Tennessee 37662-5230

ABSTRACT: Antioxidant status in humans reflects the dynamic balance between the antioxidant system and prooxidants and has been suggested as a useful tool in estimating the risk of oxidative damage. This paper reviews determinants of antioxidant status such as diet including antioxidant nutrient and nonnutrient intake, absorption and bioavailabilty, dietary components such as polyunsaturated fatty acids and transition metals, food storage and processing, chemical form, chirality and formulation of supplemental compounds and alcohol intake; environmental factors such as pollutants, ultraviolet radiation and smoking; injury and disease, medications and other medical treatments such as radiation; strenuous exercise; and physiological stage or conditions such as those in premature babies and the elderly. It is proposed that, in addition to current focus on tissues, the antioxidant status of digesta should be considered because of its effect on specific tissues and potential health implications.

Lipids 31, S-77–S-82 (1996).

Oxidation and production of free radicals are an integral part of human metabolism. Oxygen is the ultimate electron receptor in a closely linked electron flow system that produces energy in the form of ATP. Under certain conditions, the electron flow may become uncoupled, leading to production of free radicals, which are molecules with unpaired electrons and thus very reactive. Examples of free radicals include superoxide ($O^{\bullet}_2$), hydroxyl ($OH^{\bullet}$), peroxyl ($RO^{\bullet}_2$), alcoxyl ($RO^{\bullet}$), oxides of nitrogen ($NO^{\bullet}$, $NO^{\bullet}_2$), and thiyl ($RS^{\bullet}$). In addition, free radical reactions may be induced by reactive oxygen–containing species (ROS) generated in biological systems such as phagocyte activation, lipid oxidation, the arachidonate pathway, autoxidation of catecholamines, reduced flavins and hemoprotein, and iron-mediated reactions. Examples of ROS include singlet oxygen ($^1O_2$), hydrogen peroxide (H_2O_2), and hypochlorous acid (HOCl) (1–3).

Free radicals and ROS are either produced deliberately to serve important biological functions or accidentally. For example, activated phagocytes produce ROS and use them in the killing of some strains of bacteria and fungi. $O^{\bullet}_2$- plays a useful role in intercellular signaling and cell growth regulation. At high concentrations, however, free radicals and ROS react with nonradicals and can initiate adverse chain reactions such as lipid peroxidation. They also damage other important molecules, including proteins, carbohydrates, and DNA. Because of their high potential to damage vital biological systems, free radicals have been implicated as contributing factors to aging (4) and development of chronic disease, including heart disease and cancer (1–3,5).

Living organisms have developed complex antioxidant systems to control production and reduce damage from free radicals. This paper reviews briefly the antioxidant system in humans and discusses major factors determining its status.

Antioxidant system. The components of the antioxidant system may be classified on the basis of their origin as endogenous or dietary. Endogenous components include glutathione (GSH, also present in foods) and Se-glutathione peroxidase, Fe-catalase, NADPH, ubiquinol-10 (reduced coenzyme Q_{10}), Mn, Cu, Zn-superoxide dismutase, and uric acid. Metal-binding proteins include albumin (and albumin-bound thiols and billirubin), Fe- and Cu-binding proteins (transferrin, ceruloplasmin), and Fe-complex binding proteins (heptoglobin, hemopexin).

Antioxidants of dietary origin include tocopherols (vitamin E), ascorbate (vitamin C), vitamin A, carotenoids (ß-carotene, lycopene, lutein, and so forth), and Se (and other metals essential for the function of antioxidant enzymes). Many foods contain synthetic antioxidants (butylated hydroxyanisole, butylated hydroxytoluene, propyl gallate, and tertiary butylhydroquinone) as additives to inhibit lipid peroxidation (6), which, however, may have antioxidant effects in the body.

Antioxidants may also be classified on the basis of other criteria such as solubility in lipid or water, proteins (enzymatic and nonenzymatic), or small molecules, among others. The function of individual antioxidants should be viewed in the context of a system with significant interdependence and additive or synergistic effects. For example, ascorbic acid and GSH may play a role in regeneration of vitamin E.

Antioxidant status. The balance between antioxidants and prooxidants in living organisms is defined as antioxidant status. This balance is dynamic and, in the human body, is tipped slightly in favor of oxidation (1), as evidenced by ongoing damage of DNA, lipids, carbohydrates, proteins, uric acid, and so forth. The body has adapted to this slight imbalance by developing repair mechanisms including ligases, nucle-

ases, polymerases, proteinases, and phospholipases, to name a few. In addition, gradual and modest increase in oxidation induces production of endogenous antioxidants, thus providing a type of feedback-regulation mechanism (7).

Oxidative stress, a serious imbalance favoring oxidation, is said to result from excessive production of ROS and free radicals or from weakening of the antioxidant defense system (7). Severe oxidative stress can cause cell damage. Thus prevention of oxidative stress may be important for good health and prevention of disease.

Factors affecting antioxidant status. Antioxidant status is determined by factors affecting the antioxidant system and/or production of free radicals and ROS. Major factors affecting antioxidant status will be grouped as follows: diet, food, and alcohol; environment; injury and disease; physiological stage, exercise, aging, and other factors.

Diet, food, and alcohol, more than any other factors, directly affect both the antioxidant system (by supplying dietary antioxidants and cofactors of endogenous antioxidants) and production of free radicals and ROS [especially polyunsaturated fatty acid (PUFA) and alcohol]. In contrast, the major direct effect of other factors is on production of free radicals and ROS, with possible indirect effect on production of endogenous antioxidants by feedback mechanisms (7) or by reducing appetite and absorption of dietary antioxidants (for example injury and disease).

Diet, food, and alcohol: dietary antioxidants. Major components of the antioxidant system derived from the diet include tocopherols and tocotrienols (vitamin E), ascorbate (vitamin C), vitamin A, and its precursor, β-carotene. Other nutrients are essential for normal function of endogenous systems; minerals Cu, Mn, Zn, Se, Fe, and the vitamin riboflavin are important cofactors of antioxidant enzyme systems. In addition, phytochemicals, not recognized as nutrients (carotenoids such as lycopene, lutein, astaxanthin and others, bioflavonoids, phytosterols, and so forth), may play important antioxidant roles in the body (8).

Tissue levels of dietary antioxidants are affected directly by the amount and food composition of the diet (9,10) and by supplementation. GSH and uric acid may also be affected by diet. In contrast, dietary control of antioxidant enzymes and proteins is limited, except for deficiency of metal cofactors or serious malnutrition. Optimal intake of dietary antioxidants such as vitamin E is not known. Recent epidemiological studies indicated that risk of heart disease was lower in men and women taking 100 IU or more of vitamin E for more than one year (11,12). This level is several-fold higher than the recommended dietary allowance (RDA). Some current major clinical trials evaluate 300 and 400 IU/day (Hennekens C.H., and Yusuf, S., personal communications). For phytochemicals, there are no established RDA, and optimal intake is not known.

Chemical form, chirality, absorption, bioavailability, biochemical interactions between dietary antioxidants, and other factors affect antioxidant status. For example, dietary fat affects absorption of vitamin E and β-carotene (13,14). Similarly, high dietary levels of β-carotene affect absorption of lutein and possibly other carotenoids. Malabsorption may be caused by disease and drugs and will be discussed later. The d-α-tocopheryl forms (RRR) of vitamin E have higher bioavailability than the corresponding dl (all-racemic) forms (15,16). RRR-α-tocopherol is preferentially secreted in blood and incorporated into tissue in comparison to all-rac-α-tocopherol and non-α-tocopherols, namely β, γ, and δ (16).

Other dietary components. Nonantioxidant dietary components, especially those that can be oxidized or can promote oxidation, may have a major effect on antioxidant status. For example, high levels of PUFA are known to increase the requirement of vitamin E (17), which may be used to reduce formation of peroxides and other oxidation products. Other dietary components such as Cu and Fe are major promoters of free radical reactions. Reaction of Fe salts with H_2O_2, known as the Fenton reaction, yields the extremely reactive HO• (1). Phenolic phytochemicals such as isoflavonoids, which have been shown to have lipid antioxidant properties and may have beneficial health effects, can also promote damage of DNA and proteins by reducing metal ions such as Fe and oxidizing in their presence to generate H_2O_2 and $O^{\bullet}{}_2^-$ (18).

Food processing. Storage, handling, processing, and cooking of food can result in oxidative damage (5). The degree of damage and resulting oxidation products depend on a variety of factors, including temperature, exposure to light and air, amount and saturation of lipid material, presence of oxidation promoting metals, and other factors. Peroxides and prooxidants in processed foods affect antioxidant status.

Alcohol. Modest consumption of alcohol appears to cause desirable increase in high density lipoprotein (HDL) (19) and reduction in platelet aggregation (20); some alcoholic drinks, especially wine, supply phytochemicals (isoflavonoids, tannins, and so forth) having antioxidant effects including inhibition of low density lipoproteins (LDL) oxidation (18,20). Alcohol consumption, however, has been associated with increased liver damage and increased risk for chronic disease, especially some forms of cancer. It is now recognized that alcohol causes formation of acetaldehyde, which is hepatotoxic, not only by the main alcohol dehydrogenase mediated reaction, but also by an accessory microsomal pathway that generates oxygen radicals. Depressed glutathione levels, inactivation of some enzymes, detection of exhaled ethane and pentane, reduction in iron in the liver, and increased thiobarbituric acid-reactive substances (TBARS) may be the result of free radical production (2,21). It was reported recently (22) that plasma ascorbic acid, α-tocopherol, and Se were lower in men consuming even modest amounts of alcohol compared to controls, while malondialdehyde was higher, indicating an adverse effect on antioxidant status. Alcohol may also affect antioxidant status by reducing food intake and by altering metabolism of key nutrients, thereby promoting deficiencies as well as toxic interactions with food components such as β-carotene (21).

Environment. Air pollutants, tobacco smoke, and exposure to chemicals and ionizing radiation are major environmental factors initiating free radical reactions.

Air pollutants. The most damaging pollutants are nitrogen dioxide (NO_2), produced primarily from combustion in automobile engines, and ozone, produced mostly from NO_2 by photochemical reactions and from oxygen and gasoline vapors (22). NO_2 adds to double bonds and abstracts labile hydrogen atoms, initiating lipid peroxidation and production of free radical species. It also reacts directly with vitamin C and oxidizes it. Lipids from lungs of rats exposed to NO_2 had lower PUFA and indications of increased diene hydroperoxides, TBARS, and cholesterol epoxides, indicating autoxidation. Alveolar macrophages in rabbits exposed to NO_2 showed decreased resistance to viruses and reduced phagocytic activity; in rats it caused a change in arachidonic metabolism (2,23).

Ozone, although not a free radical, is a strong oxidant and may lead to free radical production by reacting with PUFA to form ozonides and by inducing autoxidation of lipids (24). It has also been suggested that the intermediate product of an ozone-olefin reaction, called the Criegee zwiterion, breaks down to hydroperoxide, which can initiate autoxidation, and aldehydes, which have been suggested to be inflammatory signals. Ozone reacts directly with vitamin E. Vitamin C also may be affected because it is believed to reduce the tocopherol radical. It has been shown that animals with low vitamin E status were easily injured by chronic ozone exposure and that vitamins E and C were protective. It was also reported that vitamin E was higher in the lungs of animals exposed to ozone, probably as defensive response (25).

Other environmental pollutants include halogenated hydrocarbons and pesticides. Although many chemicals do not spontaneously generate free radicals, their metabolism by the cytochrome P-450 enzyme system may cause free radical reactions (2).

Tobacco smoke. More than 1,000 chemical compounds are found in gas and tar fractions of tobacco smoke. NO_2, one of the major compounds in the gas phase, has been suggested to react with smoke olefins to form carbon-centered radicals. Alcoxyl radicals were also detected by spin trapping methods (26). In addition, tobacco smoke may increase free radical production indirectly by activating neutrophils. It has been suggested that nitric oxide, the precursor of NO_2, reacts with $O^{\bullet}{}_2^-$ to form peroxynitrite, which inactivates α-1-proteinase. The tar phase contains a semiquinone radical promoting formation of H_2O_2, which, along with transition metals, may inhibit the α-1-proteinase but at a slower rate. This inhibition may be related to increased production of elastase and development of emphysema (2,27). Several studies have shown that smokers have lower plasma levels of vitamins E, C, and β-carotene due to both lower intake and increased metabolic use. Even larger differences in favor of nonsmokers were reported for alveolar fluid (23,27,28). These findings and supporting epidemiological data provided impetus for evaluating the effect of supplemental antioxidants on the incidence of lung cancer. The Finnish study (a major intervention study), however, failed to show any reduction of lung cancer in heavy, long-term male smokers receiving supplemental β-carotene (25 mg/d) and/or dl-α-tocopheryl acetate (50 IU/d); actually, mortality from lung cancer was 18% higher in the β-carotene-supplemented group (29). No conclusive explanation for these unexpected results is available. It has been proposed that cancer development may have been progressing for several years, and antioxidants tested could not reverse this process. In addition, the adverse β-carotene effect may have resulted from its interaction with the high alcohol intake of a large number of participants (21).

Ionizing radiation. Sunlight and especially its ultraviolet component, initiate free radical reactions within cells, as evidenced by induction of lipid peroxidation (30) and suppression of replicative DNA synthesis due to DNA damage (31). Artificial sources of light with similar spectrum and other sources of ionizing radiation produce similar effects (32). It has been suggested that skin cancer and skin aging are associated with damage from free radical reactions. Antioxidants, and particularly dietary or topically applied vitamin E, inhibited lipid peroxidation and immunosuppresion and restored thymidine incorporation in mice suggesting that ultraviolet radiation affected the antioxidant status (33,34).

Injury and disease. Injury and disease affect the antioxidant status by reducing the supply of dietary antioxidants and by increasing production of ROS and free radicals. Tissue damage is caused by a variety of factors, including infection, trauma and burns, ultrasound, X-ray and other radiation, surgery and ischemia, reperfusion, exposure to high oxygen levels, excessive exercise, medications, toxins, and so forth. Chronic disease such as heart disease, cancer, arthritis, cataracts, diabetes, and others may also cause tissue damage and inflammation. In acute injury and infection, production of ROS, free radicals, and mediators of inflammation, is a secondary phenomenon, yet possibly very important in causing additional damage. In contrast, oxidative damage has been suggested as major causative factor for chronic disease with clinical symptoms and secondary increase in ROS and free radicals appearing much later (1,4,7).

Tissue injury causes free radical formation by releasing heme proteins and transition metals (mainly Fe), activation or increase of enzymes involved in free radical–generating reactions, increased utilization of antioxidants, and disruption of electron transport chains (1,2,35). In addition, tissue injury is associated with increased production of mediators such as prostaglandins, leucotrienes, interleukins, interferons, and tumor necrosis factors leading to inflammation. Activated macrophages are important sources of free radicals (35).

Diseases affecting the supply of dietary antioxidants. Many disease conditions and drugs depress appetite and thus affect the supply of dietary antioxidants and cofactors of endogenous antioxidants. Other diseases, such as cholestasis, fat malabsorption syndrome, short bowel syndrome, abetalipoproteinemia, and cystic fibrosis impair absorption or transport of vitamin E and other dietary antioxidants, leading to

serious deficiencies (36,37). Treatment with a water-soluble form of vitamin E improved vitamin E status in cholestatic children (37) and in a patient suffering from short bowel movement (38). Some diseases are associated with intestinal inflammation, fungi and bacterial infections, and diarrhea and thus affect absorption of nutrients. For example, lower blood levels of some vitamins and minerals in patients with acquired immunodeficiency syndrome may be be due in part to impaired absorption (39). Deficiency of key antioxidant components, such as vitamin E and Se, increases susceptibility to infection, which may be related to the antioxidant status (40,41).

Injury and disease associated with iron-catalyzed radical reactions. Some disease conditions such as sickle cell anemia, other hemoglobinopathies, iron overload disease, and cerebrospinal hemorrhage, and others causing tissue damage and hemolysis, release Fe and other transition metals, which catalyze free radical reactions, producing peroxy radicals (1,2,42,43). Similarly, premature babies and even normal-term babies have iron forms capable of catalyzing free radical reactions (44). Exposure of premature babies to high concentrations of oxygen causes retinopathy, probably due to oxidative damage.

Ischemia and reperfusion. Ischemia forces cells into anaerobic metabolism and causes uncoupling of the electron transport system, release of catecholamines, and production of xanthine oxidase. Reoxygenation results in catalysis of purines to uric acid and production of $O^{\bullet}_2$- and H_2O_2, production of other radicals from uncoupled electron transport, autoxidation of catecholamines, and activation of phagocytes. In addition, release of hemoglobin from damaged cells accelerates free radical production (45).

Chronic disease. For chronic diseases such as heart disease, cancer, and cataracts, major attention has been focused on the strong contributory role of oxidative damage from ROS and free radicals. For heart disease, a current hypothesis suggests that oxidation of LDL, probably mediated by monocytes and smooth muscle cells, and its uptake by the macrophage scavenger receptor to form foam cells, is a major contributor to atherosclerosis (46). Carcinogens and tumor promoters give rise directly to free radical reactions (47). Similarly, these reactions have been implicated in the development of arthritis, cataracts, emphysema, and other chronic diseases (1,2,4,7). The effect of chronic disease, however, on antioxidant status, is secondary and results primarily from tissue damage and activation of phagocytes (1,4).

Other diseases, medical treatments, and medications. In addition to reducing appetite, causing diarrhea, or otherwise affecting absorption and utilization of nutrients, other diseases, including infectious diseases, affect the antioxidant status by causing cell damage or by causing inflammation and increased production of phagocytes, as described above. Drugs may have direct effects on absorption, transport, and utilization of nutrients (48,49).

Radiation treatment causes lipid peroxidation and other free radical reactions similar to those produced by environmental radiation. Drugs and toxins may cause free radical reactions directly or through metabolites produced by the cytochrome P-450 detoxification system.

Physiological stage, aging, exercise, and other factors. Premature babies are susceptible to oxidative stress due to immature intestinal (poor absorption of nutrients) and lung function, hemolysis, and iron-mediated free radical production, as discussed above. At the other end of the spectrum, oxidative damage has been suggested as a contributory factor in the aging process (3). Aging has a secondary effect on antioxidant status because it is associated with higher incidence of inadequate nutrient intake, decline of organ function, weaker immunity, chronic disease, and higher intake of medications (3,48,49).

Strenuous exercise was reported to produce biochemical reactions similar to acute infection (50) and cell damage and thus it induces similar free radical reactions as evidenced by increased indices of oxidation including breath pentane (51,52).

It is believed that other factors which cause major emotional and/or physical stress, such as fear, grief, and physiological and hormonal changes, can affect the antioxidant status either by reducing appetite and/or by causing biochemical reactions in the body, which cause production of free radicals.

Evaluation of antioxidant status. Antioxidant status can be evaluated by direct measurements of components of the system, such as glutathione, tocopherol, ascorbate, and others, or, more commonly, indirectly by measuring oxidative stress (53,54). Because free radicals and ROS are extremely reactive and have a very short life, they can be measured directly only by electron spin resonance. In practice, the electron spin trap is used to measure radical spin adducts. Most other methods measure adducts, endproducts, or other compounds that are indicators of oxidative damage. These include lipid hydroperoxides, oxidized DNA, TBARS, malondialdehyde, conjugated dienes, oxidized LDL, volatile hydrocarbons, eicosanoids, H_2O_2, and others (54,55).

Due to strong preference for noninvasive methods for humans, the focus has been on indicator products present in breath (volatile hydrocarbons, H_2O_2), urine (TBARS, malondialdehyde, eicosanoids), and blood (TBARS, oxidized LDL, H_2O_2, glutathione, and others).

Antioxidant status of the digesta. Currently, antioxidant status is almost exclusively considered in the context of blood and other tissues. It may be appropriate, however, to consider the digesta as a major component. From the time of ingestion of food to excretion of fecal material, digesta undergoes major physical and chemical changes, including acidification, complex enzymatic and other reactions, emulsification of lipids with bile salts, and so forth. In addition, microflora in the gut is an integral part of digestion and may influence absorption. Microflora is affected by diet composition, disease, medication, and other factors. The many complex reactions occurring in the gut could lead to production of free radicals and ROS, which may have a direct effect in the development of digestive cancers, intestinal inflammation, and possibly

other diseases. In addition, harmful endproducts are absorbed and can cause tissue damage. Current concepts of absorption and bioavailability may not fully reflect the utility of various compounds and formulations. For example, rats fed equimolar amounts of α- or γ-tocopherol showed a significantly higher concentration of α in the blood, while most of the γ was found in the feces. γ-Tocopherol reduced plasma lipid peroxidation more than did α (56,57). Its potential for reducing peroxides and mutagens in the feces is being evaluated. In addition, γ-tocopherol was suggested as superior for detoxification of NO_2 (58). Yet γ-tocopherol is considered of little value as a form of vitamin E (51). Similarly, other compounds that are not absorbed or are absorbed and appear in urine without known biological function may have biological functions, including antioxidant function (59); this function may be, in part, in the digesta or the urinary tract.

Changing antioxidant status with nutritional supplements. Although there is substantial agreement that a significant imbalance in the antioxidant status favoring prooxidants may be harmful, benefits of altering the balance in favor of antioxidants remain controversial. Some researchers suggest that boosting the antioxidant status has no benefits and can be harmful (60,61). A prooxidant role of vitamin C has been suggested, especially in conditions of impaired iron metabolism, such as hemochromatosis or transfusion therapy (62). A prooxidant effect of vitamin E on LDL oxidation has been suggested from *in vitro* data (63) but prooxidant effect *in vivo* has not been shown. It has also been suggested as a promoter of initiated skin tumors in mice when applied topically (64). Proposed beneficial effects of supplementary antioxidants have been based on a large number of epidemiological studies that showed that high intake of fruits and vegetables (65,66) was associated with significantly lower risk for disease, especially heart disease and cancer. Furthermore, supplemental vitamin E, in excess of the RDA, has been suggested to reduce risk of heart disease (10,11). Fortunately, a large number of intervention clinical studies are now in progress and will help our understanding of the antioxidant status in health and disease.

Antioxidants, Lipoprotein Oxidation, and Arterial Function

K. Richard Bruckdorfer*

Department of Biochemistry and Molecular Biology, Royal Free Hospital School of Medicine, London, United Kingdom

ABSTRACT: Lipoproteins have an important influence on arterial tissues. High levels of low density lipoproteins (LDL) may inhibit arterial function in terms of the release of nitric oxide from the endothelium. This inhibition is enhanced by the oxidation of these lipoproteins which may occur during the development of atherosclerosis. Many of these effects are due to lipid oxidation products. The impairment of the release of nitric oxide and vasodilatation may be partially attenuated by antioxidants. LDL may also enhance the activity of blood platelets, especially when they are mildly oxidized. Oral administration of antioxidants may decrease the activation of platelets to a limited extent. Lipid peroxides may play a role in these processes. *Lipids 31*, S-83–S-85 (1996).

Oxidation of lipoproteins is considered to occur primarily in the arterial wall, although low levels of lipid peroxides are found in plasma associated with both low and high density lipoprotein (LDL and HDL, respectively) fractions (1). Plasma lipid peroxides may arise from release of slightly oxidized LDL from the subendothelial region of fatty streaks or more advanced plaques. Alternatively, they may arise from intestinal absorption of lipid peroxides in the diet. The endothelium may be exposed on the luminal side to low concentrations of these oxidation products, whereas on the abluminal surface, greater exposure to these cytotoxic molecules may occur in areas affected by atherosclerosis.

One of the principal properties of the endothelium is its ability to regulate vascular tone, mainly by release of nitric oxide (NO) in response to the pulsatile action of circulation or through receptor-mediated processes by specific agonists, some of which may be released by activated platelets. NO is biosynthesized from L-arginine by the action of NO synthase, which has several forms, mainly represented by its constitutive form in the endothelium, and which is regulated by intracellular calcium concentrations. Release of NO has two important effects: (i) relaxing arterial smooth muscle, thereby regulating arterial tone and influencing blood pressure, and (ii) inhibiting of platelet activation at the endothelial surface. Both these effects are achieved by an increase in intracellular cyclic GMP concentrations as a result of a direct interaction of NO with guanylyl cyclase.

There is now ample evidence that in atherosclerotic vessels there is a reduced ability of the artery to respond to agonists that evoke relaxations, e.g., acetylcholine and substance P. This may be observed by angiographic measurements of coronary vessel diameter in response to these agonists. This impairment of relaxation often precedes detection of occlusion of vessels using angiography. We found that at least part of this impairment may be caused by LDL (2). In organ bath studies, we showed that native LDL (nLDL) will partially and reversibly inhibit relaxation of rabbit aortic rings to acetylcholine or calcium ionophores. Subsequently, it has been shown that impairment of relaxation occurs in hypercholesterolaemia and that impairment can be reduced by cholesterol-lowering drugs, using forearm blood-flow measurements by plethysmography (this shows effects on resistance vessels) and ultrasound (large vessels) to demonstrate impairment (3,4). If LDL is oxidized with Cu^{2+}, impairment is intensified, especially after preexposure of the aortic rings to oxidized LDL (oxLDL) for short periods (5). Some samples of oxLDL produce an irreversible impairment of relaxation. Similarly, inhibition by oxLDL is observable in smaller coronary vessels, which may be classed as resistance vessels (6). In one study in atherosclerotic vessels, impairment of relaxation was found to be paradoxically associated with an increase in release of NO, possibly indicating a compensatory or protective adaptation (7). We have shown, however, that release of NO from cultured endothelial cells is decreased by oxLDL and, to a lesser extent, by nLDL when bioassayed with target fibroblasts (cyclic GMP) sensitive to NO. There is also an increase in the activity of superoxide dismutase, which should protect NO from reaction with superoxide anion and the consequent formation of peroxynitrite. Many of these actions of oxLDL can be demonstrated to varying extents, to be due to the products of lipid oxidation: lysophosphatidylcholine, hydroperoxy and hydroxy fatty acids, as well as cholesterol oxides, e.g., 7-keto cholesterol (8–11). Lysophosphatidylcholine appears to be the most potent.

These actions of lipoproteins may be decreased by antioxidants. HDL are known to have antioxidant properties and can

reverse effects of oxLDL, but have little effect on nLDL (12). By giving probucol orally to human donors and then oxidizing isolated LDL in the presence of Cu^{2+}, impairment of relaxation is reduced. Probucol and other antioxidants (except HDL), will not reverse impairment of relaxation by oxLDL in the organ bath, since oxidation has already occurred. Both probucol and ascorbate, however, will reverse inhibitory effects of nLDL using the same procedure. Animal experiments have also shown some beneficial effects of antioxidants, and it was found that dietary supplementation with α-tocopherol in cholesterol-fed rabbits reduced impairment caused by the cholesterol diet. We have shown recently that probucol not only reverses atherosclerosis seen in adult Watanabe hereditary hypercholesterolaemic rabbits, but also partly restores the severe loss of vasodilatory properties seen in the vessels of these animals (13). We are currently studying effects of antioxidants in human subjects.

Finally, lipoproteins and antioxidants are reported to have effects on blood platelets (14). In our hands, nLDL has a mildly inhibitory effect on platelets, which may be associated with binding of nLDL to fibrinogen binding site on the glycoprotein IIb/IIIa complex on the platelet plasma membrane. These effects may be demonstrated by using conventional platelet aggregometry and also by flow cytometry using fluorescent antibodies (15). LDL that have been severely oxidized in the presence of Cu^{2+} also inhibit platelets because some oxidation products such as lysophosphatidylcholine are known to inhibit platelet activation. Minimally oxidized LDL (mmLDL), however, containing lipid peroxides (40–50 nM), slightly above the range seen in normal plasma, increase sensitivity of platelets to conventional platelet agonists. Addition of 15-hydroperoxy-eicosatetraenoic acid to nLDL to achieve the same peroxide concentration as mmLDL also has the same effect. If the concentration of 15-hydroperoxy-eicosatetraenoic acid is increased tenfold over those in mmLDL, the peroxides become inhibitory.

The presence of nLDL, mmLDL, or oxLDL has only slight effects on the sensitivity of platelets to inhibition by NO, reducing their sensitivity to NO. In complete contrast, hydrogen peroxide increases the sensitivity platelets to NO by two orders of magnitude (16). Lipid peroxides do not interfere with these interactions.

The literature concerning effects of antioxidants of platelet activation is conflicting. In recent studies, we have found that there is a small, but in some cases significant, decrease in the sensitivity of platelets to agonists ADP, collagen, and arachidonic acid and an increased sensitivity to the platelet inhibitor prostaglandin E_1 following supplementation of human volunteers with tocopherol, ascorbate, and β-carotene. This work complemented earlier observations of Salonen *et al.* (17) that patients with low antioxidant status and high plasma lipid peroxide concentrations had platelets that were more sensitive to platelet agonists and more likely to release platelet secretory proteins such as β-thromboglobulin.

These studies indicate that lipid peroxides and antioxidants have opposing effects on both endothelium and platelets and may influence the course of events in atherosclerosis/thrombosis.

The Effect of Modest Vitamin E Supplementation on Lipid Peroxidation Products and Other Cardiovascular Risk Factors in Diabetic Patients

Sushil K. Jain[a], Robert McVie[a], John J Jaramillo[a], Melissa Palmer[a], Tiney Smith[a], Z.D. Meachum[b], and Rufus L. Little[b]

ABSTRACT: Among many factors, elevated lipids and lipid peroxide levels in blood are major risk factors in the development of cardiovascular disease in diabetic patients. This study has examined whether oral supplementation of vitamin E, an antioxidant, has any effect on blood lipid peroxidation products (LP) and lipid profile of diabetic patients. Thirty-five diabetics(D) were supplemented with DL-α-tocopherol (E) capsule (orally, 100 IU/d) or placebo (P) for three months in double-blind clinical trials. Plasma E was analyzed by HPLC and LP by the thiobarbituric acid-reactivity; serum lipids by auto-analyzer. Data were analyzed using paired *t*-test and Wilcoxon Signed Rank Test. Vitamin E supplementation significantly lowered LP and lipid levels in diabetic patients; there were no differences in these parameters after P supplementation. There were no differences in the duration of diabetes and ages of D between P- and E- supplemented groups. This study suggests that vitamin E supplementation significantly lowers blood LP and lipid levels in diabetic patients.
Lipids 31, S-87–S-90 (1996).

It has been proposed that some of the complications of diabetes are associated with the increased activity of reactive oxygen species and accumulation of lipid peroxidation products (1–3). The evidence for increased lipid peroxidative damage in diabetes has been reported as far back as 1979 by Sato *et al.* (4). These authors reported that the average level of lipid peroxide in plasma is higher in diabetic patients than in normal people, and that diabetic patients with angiopathy had higher lipid peroxide levels than other diabetic patients. Because atheroma contains high levels of lipid peroxide, Sato *et al.* (4) further suggested that high levels of lipid peroxide in plasma may cause an increase in lipid peroxidation levels in the intima of the blood vessel which may then initiate the formation of atherosclerosis. Subsequent studies from other laboratories have confirmed that blood of both Type-I and Type-II diabetics as well as diabetic rats has elevated levels of lipid peroxidation products (5–16). Increased levels of lipid peroxides and LP in the blood can attack the blood vessels and cause cellular injury (17). Even slight injury to the endothelial cells of the artery or oxidative modification of lipoproteins has been implicated in atherogenesis (1,17). The present study was undertaken to examine the effect of daily supplementation with a modest dose of antioxidant vitamin E (100 IU) on blood level of LP and lipids in Type-I (IDDM) diabetic patients.

MATERIALS AND METHODS

Diabetic patients who agreed to participate in this study were asked to come to the diabetic clinic after overnight fasting and before taking any insulin. They were told to bring their insulin and syringes for use after drawing the blood. All patients were provided with free breakfast at the medical center cafeteria after the blood drawing. The routine check-up of the patients was done after they had eaten their breakfast. Alternate diabetic patients visiting the clinic were assigned to oral vitamin E (100 IU) or placebo capsule daily until the next visit (after three months). There was no control on the diet of these patients. Physicians and researchers in the laboratory did not know which patients were on vitamin E or placebo in the study. Only the nurse in charge knew about the assignment of patients to vitamin E or placebo. Thirty-five diabetics were enrolled in this study. Fasting blood was collected before the start of and after the period of vitamin E or placebo supplementation from each diabetic. All diabetic patients included in this study had Type-I diabetes (insulin-dependent). African-Americans were grouped as blacks and Caucasian-Americans were grouped as whites. All biochemical analyses were done immediately after blood collection. Plasma vitamin E was measured by high-performance liquid chromatography (13). Malondialdehyde (MDA) was measured by the thiobarbituric acid reactivity (18). Serum triglycerides, total cholesterol, and high density lipoprotein- and low density lipoprotein-cholesterol were determined by auto-analyzer. Before the code opening, out of 35 diabetics enrolled, six were deleted for non-compliance for reasons such as lost bot-

tle, lost track, started taking another medicine, or patient was found to have thyroid disorder. After the analyses and code opening, there were 13 D on E and 16 D on P supplementation for which data were analyzed using paired *t*-test and Wilcoxon Signed Rank Sum test.

RESULTS

The distribution of patients in terms of age, daily insulin use, duration of diabetes, sex, race and supplementation was similar between vitamin E and placebo supplemented diabetic groups. Table 1 shows that plasma α-tocopherol level expressed as per ml or per total phospholipid was markedly higher in diabetic patients supplemented with vitamin E compared with baseline values. However, there was no effect on vitamin E level in placebo supplemented diabetic patients compared with baseline values. The lower γ-tocopherol level in vitamin E-supplemented group suggests that higher α-tocopherol levels are due to its exogenous supplementation.

Table 2 shows that MDA level was significantly lower ($P < 0.05$) in diabetic patients after supplementation with vitamin E but not in patients supplemented with placebo, compared with respective baseline levels. The effect of vitamin E on plasma LP was observed even after its normalization with total phospholipid. There was no difference in the baseline plasma MDA levels between vitamin E or placebo supplemented groups.

Table 3 shows that vitamin E supplementation significantly lowered ($P < 0.03$) the plasma triglyceride levels in contrast to placebo-supplementation when compared with the respective baseline values. However, there was no effect of vitamin E or placebo supplementation on the total, high density lipoprotein- or low density lipoprotein-cholesterol of diabetic patients. There was also no difference in the mean insulin dosage intake by patients between before the start (D_1, 0.89 + 0.1; D_2, 1.0 + 0.1) and during the study (D_1 + E, 0.86 + 0.1; D_2 + P, 0.97 + 0.1) in both the groups.

DISCUSSION

The elevated level of lipid peroxides can cause oxidative injury to blood cells, crosslinking of membrane lipids and proteins (19,20), destabilization of membrane lipid organization (21–24), accelerated cellular aging (19,20,25), prostacyclin/prostaglandin imbalance and vasoconstriction (26). The level of LP is increased in plasma and other tissues of rats with alloxan- or streptozotocin-induced diabetes and in both Type I and Type II diabetic patients (4–16). The increase in plasma lipid peroxide levels of diabetic rats disappeared when diabetic rats were supplemented with 90 IU vitamin E/kg diet for 10 wk (27) or with 500 IU vitamin E/kg diet for 4 wk (28). However, there is no study that has examined the effect of vitamin E supplementation on plasma level of LP in diabetic patients. The present study has found a significant reduction in the level of LP after vitamin E supplementation in Type-I diabetic patients. This suggests that a modest dose of vitamin E supplementation can scavenge the lipid peroxidation processes in diabetics presumably caused both by the increased oxygen radical activity due to autoxidation of glucose and/or inactivation of antioxidative enzymes by the hyperglycemia (18,29).

The increase in plasma triglyceride levels was blocked in diabetic rats after vitamin E supplementation with intramuscular injections (30) or with dietary additions (27) and in dia-

[a]Values are mean ± SE; n is the number of patients in each diabetic group. Differences in values between different superscript letters, [b,c] ($P < 0.01$) and [d,e] ($P < 0.03$) are significant.

betic patients (31) supplemented with pharmacological doses of vitamin E (900 mg/d for 3 mon). The present study using a modest dose of vitamin E supplementation also found an inhibitory effect on triglyceride accumulation but not on total-cholesterol and low density lipoprotein-cholesterol in Type I (IDDM) diabetic patients. The decrease in the triglyceride may be related to an improvement in the fasting plasma glucose level, and could also be due to an increase in the activity of lipoprotein lipase similar to that has been observed in the vitamin E supplemented diabetic rats by other investigators (27,30).

This study suggests that vitamin E supplementation significantly lowers blood lipid peroxidation products and triglyceride levels and could be beneficial in reducing risk of cardiovascular disease in diabetic patients.

Departments of [a]Medicine and [b]Pathology, The University of Texas Health Science Center, San Antonio, Texas 78284-7874

ABSTRACT: Studies from our laboratory indicate that n-3 (fish oil, FO) lipids at 10% (w/w) in a nutritionally adequate, semipurified diet, and supplemented with equal levels of antioxidants, extended the life span of lupus-prone (NZB/NZW)F_1 (B/W) female mice as compared to n-6 (corn oil, CO) lipids. The early rise of autoimmune disease in CO-fed mice was closely linked to the loss of T-cell function. Both IL-2 production and IL-2 receptor expression were reduced due to the loss of naive T-cells and a rise in memory T-cells. Proliferative response to both mitogens and superantigens (staphylococcal enterotoxins A and B) was higher in FO-fed 6.5-mon-old mice. These changes paralleled decreased PGE_2 production by splenic cells from FO-fed mice.

Analysis of mRNA expression in different organs revealed differential effects of dietary lipids. In FO-fed mice, transforming growth factor β1 (TGF β1) expression was decreased in kidneys, but splenic tissues had higher expression of TGF β mRNA. As TGF β promotes programmed cell death (PCD), we studied the effects of CO and FO on PCD rates in lymphocytes. Both propidium iodide staining and DNA fragmentation were elevated in lymphocytes of FO-fed mice when compared to CO-fed mice of similar age. Also, increased PCD correlated closely with increased Fas gene expression. Thus, in addition to various other antiinflammatory effects, dietary FO appears to increase PCD and prevent accumulation of self-reactive immune cells in lymphoid organs. Further studies are required to dissect the pro- and antiinflammatory mechanisms associated with dietary n-3 and n-6 lipids in modulating autoimmune disorders or malignancy during aging.

Lipids 31, S-91–S-96 (1996).

Fish oil (FO) supplementation has antiinflammatory effects in both humans and experimental animals and delays onset of autoimmunity, cardiovascular disease, and cancer, particularly when compared to diets relatively enriched in saturated fats of animal origin (1,2). Because of adverse effects of animal fats, consumption of vegetable oils containing both monounsaturated n-9 and polyunsaturated fatty acids (rich in 18:2n-6) is rising significantly in the United States (1–3). Though vegetable oils rich in n-6 fatty acids reduce the incidence and the severity of cardiovascular disease, these lipids (particularly hydrogenated fats) have been linked to proinflammatory effects and the rise of certain cancers, rheumatoid arthritis, and other autoimmune disorders during aging (4). Though n-6 lipids reduce serum cholesterol levels, they usually tend to elevate linoleic acid (18:2n-6) levels and arachidonic acid (20:4n-6) levels in the tissue phosphoglycerides. Corn oil (CO) is rich in linoleic acid, and its consumption increases production of free radicals and cyclooxygenase metabolites such as thromboxane A_2 and leukotriene B_4 (LTB_4). In contrast, FO contains highly polyunsaturated fatty acids, eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), which act synergistically to inhibit prostaglandin E_2 (PGE_2) production and are thus antiinflammatory (5). Because of these beneficial effects, marine oils, especially menhaden oil, are receiving increasing attention as a source of C_{20} and C_{22} carbon n-3 fatty acids.

Animals and diet. We and others have reported that reduced calories and/or low-fat diets preserve T-cell functions, decrease autoantibody production, and reduce immune complex-mediated glomerulonephritis in (NZB/NZW)F_1 (B/W) mice (6–8). B/W mice spontaneously develop a disease similar to human systemic lupus erythematosus (SLE), which has been used as an animal model to elucidate the pathogenesis of the disease (9,10). The majority of the immunological abnormalities associated with human SLE are also seen in B/W mice, including hypergammaglobulinemia (a result of generalized B-cell hyperactivity), production of autoantibodies against a wide variety of endogenous antigens, formation of immune complexes, and a variety of associated histopathological manifestations (e.g., glomerulonephritis) (9,10). Female B/W mice under normal feeding conditions die between 6–10 mon of age, while males die between 10–22 mon of age. Death usually occurs as a result of renal failure. During the past 25 years, we have utilized female B/W mice for dietary

studies because of early onset of disease and short life span, which we found responsive to dietary manipulations (11–15).

Though dietary supplementation with FO significantly extends life span and alleviates autoimmune symptoms in B/W and MRL mice with lymphoroliferative (*lpr*) gene (MRL/*lpr* mice) (11–18), molecular mechanisms associated with these beneficial effects have not been fully explored. Therefore we sought to determine effects of isocaloric CO- or FO-enriched diets fed *ad libitum* on immunological and molecular parameters associated with onset and progression of disease in B/W mice. We fed weanling B/W mice a nutritionally adequate, semipurified diet supplemented with either CO or FO (10% wt/wt) and equal levels of antioxidants (11). Both oils were supplemented with 2.5 g tocopherol (α and γ) and *tert*-butylhydroquinone (TBHQ)/kg of oil to prevent peroxidation, as recommended by the Fish Oil Test Material Program (National Institute of Alcohol Abuse and Alcoholism). Each diet therefore contained ~215 mg vitamin E/kg (vitamin E from oil and from vitamin mixture) (11).

Immunological studies. We observed that B/W mice become more susceptible to autoimmune disease when fed a CO-supplemented diet (vs. FO) and expressed significantly higher levels of serum anti-dsDNA antibody levels, a parameter known to serve as a highly prognostic marker for onset and severity of renal disease (17). When splenocytes were stimulated with optimal concentrations of mitogens and superantigens, a significantly higher proliferative response was noted in FO-fed mice (vs. CO). When spleen cells were cultured in the presence of Con A for 48 h, and interleukin-2 (IL-2) levels were determined by a bioassay utilizing cytotoxic T-lymphocyte line 2 (CTLL-2) cell line, IL-2 levels (μ/mL) were significantly lower ($P < 0.05$) in FO-fed mice (vs. CO) (17). Though the percentage of $CD4^+$ and $CD8^+$ cells in splenocytes from both CO- and FO-fed mice (FACS analysis) did not differ, a significant decrease in Ig^+ cells ($P < 0.05$) was noted in FO fed group (vs. CO) (17). Also, IL-2 receptor expression fluorescense activated cell sorting (FACS) was significantly increased in FO-fed mice (data not shown), indicating a delay in shift from naive to memory cells in a T-cell subpopulation. In fact, spleens from FO-fed mice had higher naive and lower memory T-cells (17).

We next sought to determine whether FO supplementation alters gene expression in various organs associated with onset and progression of autoimmune disease in B/W mice. We studied expression of both mRNA and protein levels for the oncogenes-c-*myc* and c-*ras*- in spleens, transforming growth factor β (TGF β) in both spleen and kidneys and antioxidant enzymes (catalase, CAT; glutathione peroxidase, GSH-Px; and superoxide dismutase, SOD) in livers (enzyme activity and mRNA) and kidneys (mRNA expression).

Densitometric analysis of total RNA from spleens by Northern analysis (to compensate for any loading differences, values are expressed in ratios ± SEM of c-*myc*, c-*ras* or TGF β to GAPDH) revealed lower expression of c-*myc* and c-*ras* mRNA in FO-fed (vs. CO) mice, while TGF β mRNA was significantly higher (Fig. 1). Furthermore, in FO-fed mice, protein products (Western blotting) of both oncogenes was significantly lower, and for TGF β it was significantly higher (17).

TGF β was initially characterized on the basis of its ability to induce a transformed phenotype in normal rat kidney fibroblasts in culture (19). TGF β are now recognized as multifunctional, regulatory factors influencing a remarkable array of physiological processes, including embryogenesis, hematopoiesis, angiogenesis, immune function, inflammation, myogenesis, osteogenesis, tissue repair, and remodeling (20). Hence, TGF β impacts virtually every organ system, and it may not be surprising that aberrant expression or regulation of these molecules has been implicated in numerous pathological conditions, including autoimmune disorders, glomerulonephritis, diabetic nephropathy, tumorigenesis, and immunosuppression associated with acquired immunodeficiency syndrome and malignancies (19–21).

TGF β not only affects a plethora of physiological processes, but also elicits diverse cellular responses and may have both inhibitory or stimulatory effects on the same cell, depending on cell type, state of differentiation, and context of other factors or signals in the cellular environment. In FO-fed mice, significantly elevated TGF β expression was observed at both mRNA and protein levels. Also, significantly lower oncogene-c-*myc* and c-*ras*- expression was noted, indicating

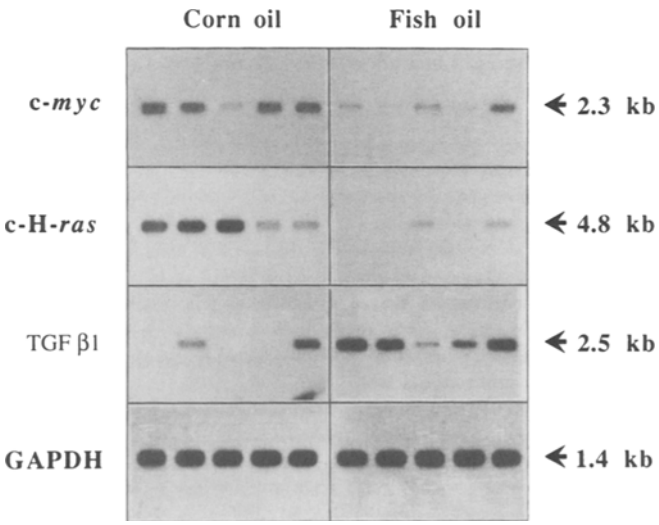

FIG. 1. Inhibition of c-*myc* and c-*ras*, and upregulation of transforming growth factor β (TGF β) mRNA expression by dietary fish oil supplementation (10% w/w) in spleens of 6.5-mon-old B/W mice (18). For Northern blot analysis, 20 μg of total RNA/lane was denatured, electrophoresed through 2.2 M formaldehyde/0.8% agarose gel, and electroblotted onto nitrocellulose. Blots were prehybridized, hybridized, washed, and autoradiographed as described (18). Autoradiographic exposure time was 36 h to 5 d. Blots were reprobed after stripping off previous labeling. GAPDH was used as an internal control and indicates equal levels of RNA loading in all lanes of the gel. Each lane represents an RNA sample from one animal.

that FO supplementation is immunosuppressive by increasing or by maintaining higher levels of the immunoregulatory molecule TGF β in splenic lymphoid cells (17). As Ig^+ cells and the serum anti-dsDNA antibody levels were significantly lower in FO-fed mice, this in turn may be due to higher levels of TGF β. Though it is a significant contribution to the field of nutrition that the source of dietary lipids can modulate TGF β expression, it has been shown previously in various *in vitro* studies that TGF β has immunosuppressive effects on immune cells, particularly on B-cell proliferation and immunoglobulin production (17).

TGF β and lupus nephritis. In contrast to its beneficial immunosuppressive properties, expression of TGF β has been reported to play a pathological role in various models of glomerulonephritis (22). Its role in either the initiation or progression of lupus nephritis is not known, however. Cellular proliferation is an important pathological element in the development of lupus nephritis. In an inflammatory process, local generation of TGF β may promote resolution of inflammation, but persistent production of TGF β, possibly in combination with cytokines, may promote accumulation of extracellular matrix (23). In CO-fed mice, a significantly higher histological score (vs. FO-fed mice, 1-fold lower, $P < 0.05$) and a higher frequency of perivascular infiltration of mononuclear cells was observed (12). Northern and Western blot analyses revealed significantly higher TGF β expression in kidneys from CO-fed mice as compared to FO-fed mice (12). Also, expression of fibronectin, one of the components of ECM, is significantly elevated in kidneys of CO-fed (vs. FO-) mice (12). Intercellular adhesion molecule-1 (ICAM-1), which is normally expressed on endothelial cells of glomeruli in kidneys and whose expression is increased by several fold in inflammatory conditions (24), was also significantly elevated in CO-fed mice (12). IL-1 and TNF α alter endothelial cell morphology and induce expression of adhesion molecules, including ICAM-1 (24). In kidneys from CO-fed mice (vs. FO) significantly lower IL-1, IL-6, and TNF α mRNA and protein levels were observed (14), indicating that higher levels of TGF β in kidneys might have modulated expression of these inflammatory cytokines. Taken together, these results indicate the dual nature of TGF β, behaving as a (beneficial) immunosuppressant in the spleen, but as a pathological agent in kidneys.

Autoimmunity and apoptosis. Within the immune network, TGF β mediates a negative feedback circuit inhibiting activation, proliferation, and effector functions. TGF ß decreases c-*myc* oncogene expression in lymphokine-stimulated T-cells and $CD4^+$ cells are affected more than are $CD8^+$ T-cells. Since TGF β modulates proliferation or function of every immune cell type, it is not surprising that its absence has devastating consequences as seen in TGF β knock-out mice (25,26). Accumulation of autoreactive B- and T-cells and severity of inflammation observed in some tissues of these mice raises the question of whether this pathology is somehow associated with aberrant cell death as a result of lower apoptosis or programmed cell death (PCD) in the immune system. Excess accumulation of cells can be due to either increased proliferation or decreased apoptotic cell death. In fact, TGF β expression has been associated with negative regulation of growth. It inhibits DNA synthesis in liver, mammary gland, and uterine endometrium (27). Enhanced expression of TGF β was found in castration-induced regression of prostate and in regressing tumors, suggesting its involvement in PCD (27). In primary cultures of uterine endometrial cells and of hepatocytes, TGF β induced cell death (28). In our dietary studies in B/W mice, spleens from FO-fed mice (vs. CO) expressed significantly higher levels of TGF β and lower levels of c-*myc*. Hence we studied the degree of apoptosis in the splenocytes from both CO- and FO-fed mice.

Reliable methods to assess apoptosis include endonuclease-mediated DNA fragmentation (ladder formation; extensive degradation of chromosomal DNA into oligomers of about 180 b.p.) and propidium iodide (PI) uptake and flow cytometric analysis of PI-stained apoptotic cells. Splenocytes from young FO-fed mice (vs. CO) did not show differences in PI staining, but old mice at 8–10 mon of age showed higher PI-positive cells (Fig. 2). Also in older mice, splenocytes exhibited higher DNA fragmentation (cultured for 18 h in the presence or absence of dexamethasone at 10^{-7} M; data not shown). Although differences in PCD appear to be small, *in vivo* physiological PCD may play a role in modulating autoimmune disease. Encouraged by these results, we have studied the effects of dietary CO and FO on expression of Fas, one of the positive modulators of apoptosis, in splenocytes.

The Fas antigen belongs to a receptor supergene family that includes TNFR, B-cell antigen CD40, NGFR, and T-cell Ag OX40 (29). Fas is broadly expressed on myeloid and lymphoid cells, on fibroblasts, liver cells, heart muscle, and in the ovarian follicle (29). The cytoplasmic domain of Fas probably interacts with signal transduction molecules such as G-proteins, kinases, and/or phospholipases since it has no apparent intrinsic enzymatic activity. Its importance is further emphasized by the fact that the Fas gene was found to be defective in mice carrying the lymphoproliferation (lpr) mutation, closely resembling human SLE (29). This defect in Fas expression leads to excessive numbers of self-reactive T-cells escaping from negative selection in the thymus, resulting in autoimmune disease. FO supplementation significantly increased or maintained higher levels of Fas gene expression in spleens from B/W mice (30). Also, Western blot analysis complemented gene expression, and significantly higher Fas protein levels were observed in the spleens of FO-fed (vs. CO-) mice (data not shown; 30). Thus, increased survival of B/W mice on FO may be due to higher apoptosis of autoreactive T-cells and elimination of self-reactive cells in the periphery. Further, higher PCD was also noted in lymphoid cells from both spleen and thymic tissues from MRL/*lpr* mice on calorie restriction (31).

Autoimmunity and antioxidant enzyme activity and gene expression. Since autoimmune diseases have multifactorial etiologies including genetic, hormonal, viral, and immunological factors, inability of the antioxidant defense system to

cope with oxidative stress has also been reported to contribute to disease progression (32,33). Unsaturated fatty acids can undergo free radical-initiated chain reactions. GSH-Px acts to protect cellular components such as unsaturated fatty acids from free radical oxidation by converting hydrogen peroxide, a potent endogenous free radical generator, to water. Though CAT plays a similar role as that of GSH-Px, GSH-Px is reported to be more important than CAT in hydroperoxide catabolism. Conversely, SOD detoxifies superoxide radicals, and all three enzymes play an important role in the host's antioxidant defense mechanism. Vitamin E, a lipophilic free radical scavenger, protects unsaturated fatty acids by terminating chain reactions involving fatty acid peroxyradicals. In-

TABLE 1
Effect of 10% (w/w) Corn Oil–Krill Oil–or Fish Oil–Based Diets on Activities of Hepatic Cytosolic Antioxidant Enzymes in B/W Mice (11)

Enzyme	Corn oil	Krill oil	Fish oil
Catalase[c]	59.1 ± 4.4[a]	529.9 ± 27.5[b]	472.0 ± 55.8[b]
GSH-Px[d]	25.5 ± 2.0[a]	98.7 ± 5.9[b]	106.0 ± 3.4[b]
SOD[e]	7.2 ± 0.3[a]	.9 ± 0.4[b]	10.2 ± 0.2[b]

[a,b]Values are mean ± SEM of 5 mice/group. Values with different superscript letters (a,b) in the same row are significantly different at $P < 0.05$ level as analyzed by Student's *t*-test with Bonferroni adjustment.
[c]Catalase activity is expressed as μmoles H_2O_2 reduced/mg protein/min.
[d]Glutathione peroxidase (GSH-Px) activity expressed as μmoles NADPH oxidized/g protein/min.
[e]Superoxide dismutase (SOD) activity is expressed in units/mg protein.

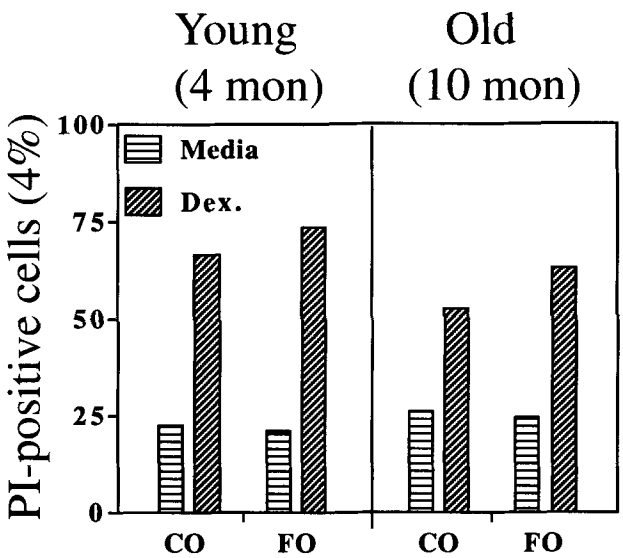

FIG. 2. Effects of dietary corn oil (CO) and fish oil (FO) (10% w/w) on programmed cell death (PCD) in splenocytes from young and old B/W mice as assessed by propidium iodide staining. PCD was lower in old mice on both diets as compared to that in young. Dexamethasone-induced PCD was higher in FO-fed mice (vs. CO) in both young and old mice. PI, propidium iodide.

adequate levels of vitamin E in the presence of low selenium uptake may also result in higher frequency of tumor development. We have demonstrated the importance of supplementing FO-containing diets with vitamin E. Both increased membrane vitamin E and decreased thiobarbituric acid-reactive substances (TBARS) generation was found by supplementing 500 IU of vitamin E with FO-containing diets (34). We have also studied the effects of dietary supplementation of CO and FO on free radical generation and the status of antioxidant defenses in livers and kidneys of B/W mice. TBARS in liver cytosolic fractions were significantly higher in CO-fed mice, indicating higher free radical generation (11). Hence we became interested in testing whether or not the degree of peroxidation in subcellular membrane lipids in autoimmune mice was due to defects in the antioxidant defense system. For this purpose, we analyzed enzyme activity for CAT, SOD, and GSH-Px in the liver cytosolic fraction, and mRNA expression for these enzymes in livers from CO- and FO-fed mice. Both enzyme activity (Table 1) and mRNA expression of these key antioxidant enzymes were significantly lower in the livers (Fig. 3) and kidneys (Fig. 4) of CO-fed mice (vs. FO) (11,12), indicating weaker antioxidant defense mechanisms in various organs in B/W mice fed a CO diet. As described earlier (11), the diets as well as the oils (CO and FO) were supplemented with equal levels of antioxidants, so that our results could not have been compromised because of differences in dietary antioxidant levels.

In summary, the use of highly refined FO with adequate antioxidant supplementation appears to delay onset of autoimmune disease when compared to n-6 (CO)-containing diets. FO also modulates PCD and enhances antioxidant enzyme mRNA levels and decreases free radical-induced tissue damage *in vivo*. Further studies at the molecular level are needed to dissect the protective mechanisms of FO.

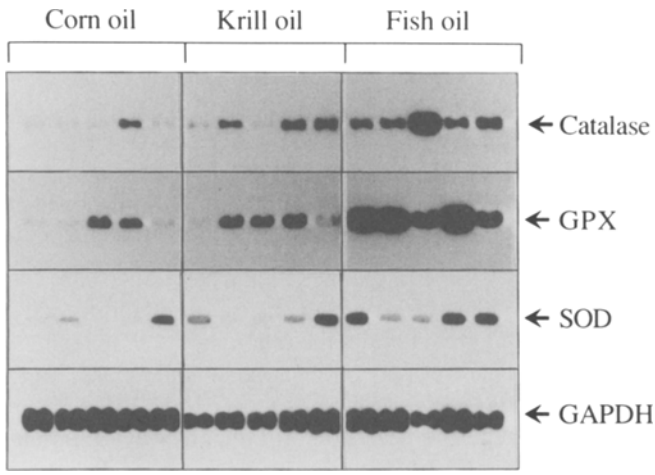

FIG. 3. Higher hepatic antioxidant enzyme gene expression (Northern blot) in 6.5-mon-old B/W mice fed a diet supplemented with CO or FO (10% w/w) (12). Autoradiographic exposure time was 8 d for the enzymes and 36 h for GAPDH. Similar to fish oil, krill oil is a source of n-3 lipids, and krill oil also increased (vs. CO) enzyme gene expression significantly. Each lane represents an RNA sample from one animal. Abbreviations as in Figure 2.

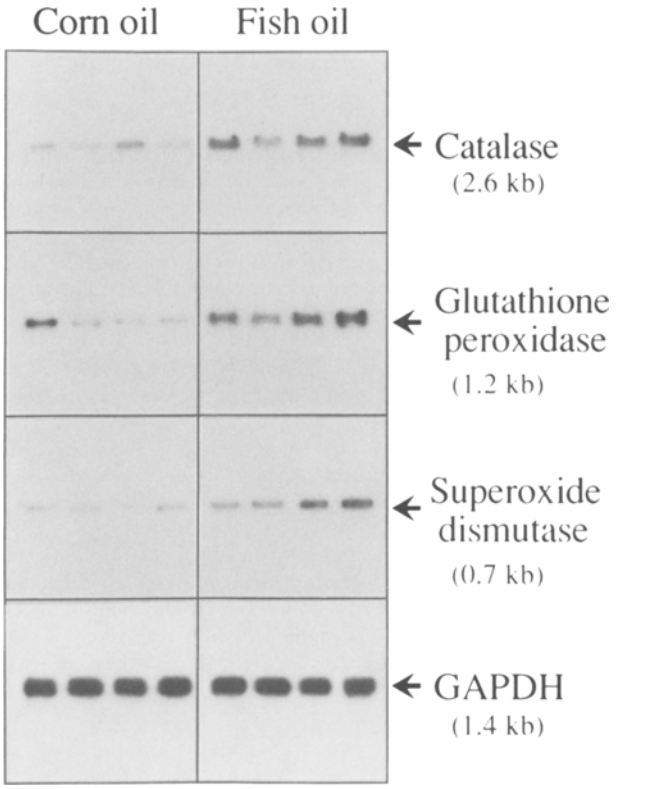

FIG. 4. Northern blot analysis of total RNA isolated from kidneys of 6.5-mon-old B/W mice fed a diet supplemented with CO or FO (10% w/w) (15). Autoradiographic exposure time was 4 d for the enzymes and 36 h for GAPDH. Each lane represents an RNA sample from one animal. Abbreviations as in Figure 2.

In Vivo Labeling of Brain Phospholipids by Long-Chain Fatty Acids: Relation to Turnover and Function

Stanley I. Rapoport

Laboratory of Neurosciences, National Institute on Aging, National Institutes of Health, Bethesda, Maryland 20892

ABSTRACT: An experimental method and model are described to quantitate kinetics of *in vivo* incorporation of fatty acids (FA) into stable brain phospholipids. When a radiolabeled long-chain FA is injected intravenously in a rat, it rapidly equilibrates with brain FA–CoA, the precursor pool for phospholipids. As different labeled FA enter different *sn* positions of specific phospholipids, a combination of labels can be used to investigate roles of different phospholipids in brain function and structure. By taking into account dilution λ of specific activity of brain FA–CoA, compared with specific activity of FA in plasma, half-lives of FA in individual brain phospholipids can be calculated. Values for λ less than 0.02 suggest marked recycling, and give half-lives two orders of magnitude smaller than literature values. A half-life of arachidonate in phosphatidylinositol of 0.66 h (turnover = 105 %h) is consistent with active participation of this FA in phospholipase A_2mediated signal transduction.

Lipids 31, S-97–S-101 (1996).

Brain functional activity and structural integrity are related to half-lives of acyl groups within phospholipids (1,2). Until recently, these terms were estimated by injecting radiolabeled precursors intracerebrally and killing animals at different times thereafter to determine phospholipid radioactivity (3–5). Unfortunately, intracerebral injection damages brain tissue and provides half-lives that ignore recycling and/or *de novo* synthesis.

To overcome these limitations, we developed an *in vivo* method and model to quantify incorporation into and half-lives of fatty acids (FA) in brain phospholipids (6). An albumin-bound radiolabeled unacylated long-chain FA is injected intravenously (i.v.). Labeled and unlabeled FA in plasma are monitored until the animal is killed at 20 min and the brain is prepared for chemical analysis or quantitative autoradiography. Different FA tracers pulse label specific *sn* positions in different brain phospholipids.

MODEL AND RESULTS

In our model, we identify two experimentally-accessible brain compartments (Fig. 1): (i) an "unstable" final precursor FA (acyl)– CoA pool whose specific activity equilibrates rapidly with plasma specific activity, on the time-scale of an experiment; and (ii) a "stable" phospholipid/neutral lipid compartment in which FA turnover is slow compared with the time scale of an experiment. Fast kinetics of FA–CoA are consistent with evidence that its specific activity equilibrates with plasma unacylated FA specific activity within 1 min after tracer injection and that 90% of brain radioactivity at 1 min after injection is within stable lipids after passing through FA–CoA (see below) (6–8). Furthermore, tracer incorporation into stable brain lipids is independent of regional cerebral blood flow (rCBF), indicating that the model can be used for explicit imaging of incorporation (9). Flow independence reflects almost total (>99.99%) steady-state binding of plasma unacylated FA to plasma protein, a fast off-rate for its release from protein, its high permeability at blood-brain barrier, and rapid equilibration between unacylated FA in plasma and brain Fa–CoA (10–13). This can be seen as follows:

The extraction fraction E of a FA from blood by brain is defined as follows:

$$E = 1 - e^{-\alpha\tau}\,1 = 1 - e^{-aV/rCBF} \qquad [1]$$

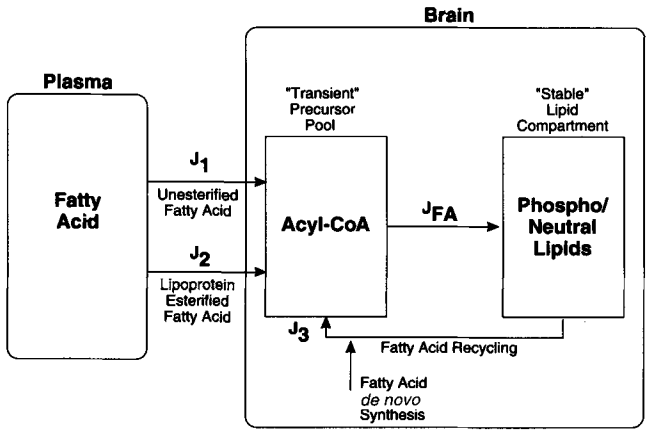

FIG. 1. Diagram for uptake of a fatty acid (FA) from plasma into brain FA (acyl)–CoA pool, and hence into stable phospholipids and neutral lipids. J_1, flux of unesterified FA from plasma into FA–CoA; J_2, flux of esterified FA on plasma lipoproteins into FA–CoA; J_3, flux from *de novo* synthesis and recycling from stable lipids into FA–CoA; J_{FA}, net flux of FA from FA–CoA to stable lipids. At steady state, $J_{FA} = J_1 + J_2 + J_3$

Abbreviations: FA, fatty acid; i.v., intravenous; NBM, nucleus basalis of Meynert; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; rCBF, regional cerebral blood flow

Copyright © 1996 by AOCS Press

where α is a rate constant (s^{-1}), τ is transit time of blood in brain (1 s in the rat), V is brain blood volume (cm^3 per g brain) and rCBF is in units of $cm^3.s^{-1}$ per g brain. Mean transit time $\tau = V/rCBF$ and as $E \approx 0.05$ (see above), Equation 1

$$E = \alpha\tau = \alpha V/rCBF \quad [2]$$

Brain uptake U ($\mu mol.s^{-1}$ per g brain) equals Ec_{bl}rCBF:

$$U = \alpha V c_{bl} \quad [3]$$

where c_{bl} (μmol per ml) is the arterial-end FA blood concentration. As capillary volume is independent of rCBF (14), uptake U also is flow-independent.

Brain Fa–CoA equilibrates rapidly with unacylated FA in plasma. Indeed, one min after a step elevation in plasma specific activity of [^{3}H]arachidonate (Fig. 2) or of [9,10-^{3}H]palmitate, specific activities of the respective unacylated FA and Fa–CoA pools in brain have reached steady states (7,8). Such rapid equilibration allows increased neuronal demand for incorporation of FA into phospholipids to be easily met by the large reservoir of unacylated FA in blood. As U is independent of rCBF, J_{FA} and J_l also will be flow-independent (6). Furthermore, incorporation of the FA into stable lipids from the Fa–CoA pool is so fast that 90% of brain radioactivity is acylated by 1 min after a radiolabeled-FA infusion (Fig. 3).

The net rate of incorporation of FA from Fa–CoA into brain phospholipid i (Fig. 1) is as follows (6):

$$J_{FA,i} = k^*_i c_{pl}/\lambda \quad [4]$$

where c_{pl} is cold plasma unacylated FA concentration and k^*_i ($cm^3.s^{-1}$ per g brain) is the incorporation coefficient of unacylated FA from plasma to phospholipid i. k^*_i equals brain radioactivity $c^*_{br,i}$ (T) in phospholipid i at time T of sampling, divided by the integral of plasma FA radioactivity from the beginning of infusion to time T (6):

$$k^*_i = c^*_{br,i} \div \int_0^T c^*_{pl}\,dt \quad [5]$$

λ is the extent to which Fa–CoA radioactivity due to labeled unacylated FA in plasma is diluted by unlabeled FA derived from acylated plasma sources and from brain recycling/*de novo* synthesis. At a steady state, λ is the ratio of specific activity of Fa–CoA in brain to specific activity of unacylated FA in plasma:

$$\lambda = \frac{J_1}{J_1 + J_2 + J_3} = \frac{J_1}{J_{FA}} \quad [6]$$

As $J_2 << J_1$ in adult rats (Purdon *et al.*, submitted for publication), a low value for λ would be caused by recycling and/or *de novo* synthesis.

At the steady state, turnover (%h) $F_{FA,i}$ of a FA in phospholipid i equals:

$$F_{FA,i} = \frac{J_{FA,i}}{c_{br,i}} = \frac{k^*_i c_{pl}}{\lambda c_{br,i}} \quad [7]$$

and thus, half-life (h) of FA in i equals:

$$t_{1/2,i} = 0.693/F_{FA,i} \quad [8]$$

Following an i.v. injection of a radiolabeled FA, maximum brain labeling occurs by 10 min and is mainly of lipids (>87%), particularly phospholipids (Tables 1,2). [9,10-^{3}H]palmitate labels mainly phosphatidylcholine (PC) in its *sn*-1 position, [1-^{14}C]arachidonate labels mainly phosphatidylinositol (PI) and PC in their *sn*-2 positions, and

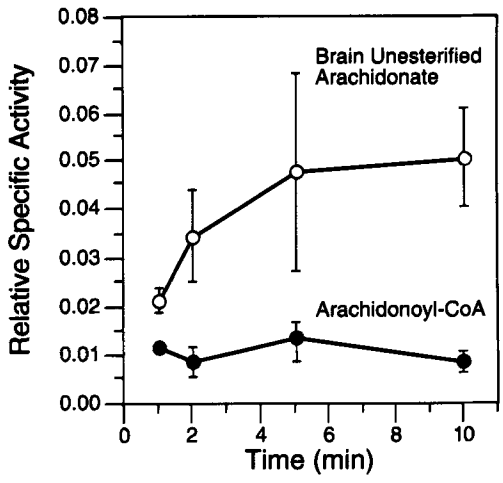

FIG. 2. Specific activity of arachidonate in brain unacylated arachidonate and arachidonoyl-CoA related to specific activity of unacylated arachidonate in arterial plasma of pentobarbital-anesthetized rats, following step elevation in plasma [^{3}H]arachidonate. Each point represents mean ± SEM for 3–4 animals, except for arachidonoyl-CoA at 1 min, when n = 1. From Washizaki *et al.* (7).

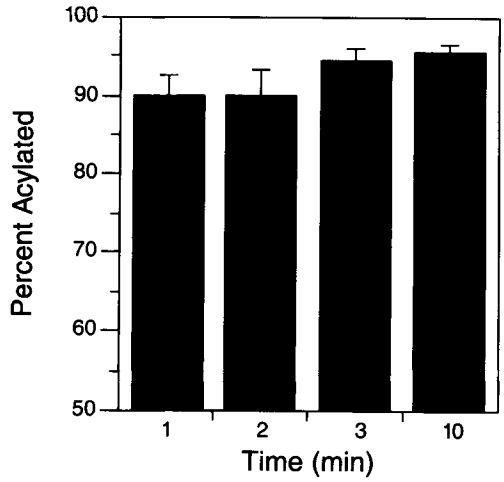

FIG. 3. Percent acylated [3H]arachidonate in brain of anesthetized rat, at various times after establishing a steady state plasma specific activity by i.v. infusion. Each bar represents mean + SD for 3-4 animals. From Washizaki *et al.*(7).

TABLE 1
Distribution of Radioactivity Within Brain Lipid Fractions in Awake Rats, 15 Min After a 5-min I.V. Infusion of Each of Three Labeled Fatty Acids[a]

Fraction	Fatty acid tracer (percent total brain radioactivity) [9,10-^{3}H]Palmitate	[1-^{14}C]Arachidonate	[1-^{14}C]Docosahexaenoate
Lipid fraction	89.2 ± 1.11	89.4 ± 0.49	87.1 ± 0.95
Phospholipids	51.7 ± 0.64	72.9 ± 0.80	64.7 ± 0.94
Sphingomyelin	1.21 ± 0.18	ND	ND
Phosphatidylcholine	31.7 ± 1.09	27.4 ± 0.22	17.2 ± 0.79
Phosphatidylserine	0.92 ± 0.20	2.09 ± 0.23	2.59 ± 0.30
Phosphatidylinositol	7.34 ± 0.20	35.6 ± 0.41	6.92 ± 0.68
Phosphatidylethanolamine	10.5 ± 0.94	7.14 ± 0.22	37.6 ± 0.82

[a]Values are mean ± SEM for 3–7 rats. From Nariai *et al.* (18) and Noronha *et al.* (15).

[1^{14}C]docosahexaenoate labels mainly phosphatidylethanolamine (PE) and PC in their *sn*-2 positions [Noronha, 190 #1501; Nariai, 1991 #1497]. Thus, combined use of the three FA tracers can provide estimates of *in vivo* half-lives and turnovers of specific acyl groups within specific brain phospholipids.

Half-lives of arachidonate and of palmitate within different brain phospholipids have been determined with Equations 7 and 8, using experimental values of λ (Table 3) (7,8). $t_{1/2,i}$ was shortest in PI of all the phospholipids for each of the FA, consistent with participation by PI in numerous activation processes (1,2). Furthermore, arachidonate had shorter half-lives within each phospholipid class than did palmitate, reflecting its involvement in phospholipase A_2-mediated signal transduction. The calculated $t_{1/2,i}$ of arachidonate in PC was 1.7 h (turnover = 41 %/h) compared with 9–14 d obtained with intracerebral injection and with 10–13 h in brain microsomes (4). Arachidonate-containing molecular species of PC and PI have been identified with half-lives <12 h (5), whereas our $t_{1/2,i}$ for arachidonate in PI was only 0.66 h (turnover = 105). Our calculated half-lives for palmitate ranged from 2.3 h (turnover = 30 %/h) to 13.3 h (turnover = 5.2%/h), much shorter than the published estimates of 3–23 d that ignored dilution (3).

A number of drugs can activate phospholipase A_2 via membrane-bound GTP-binding proteins, releasing arachidonate and other unsaturated acyl groups from *sn*-2 positions of phospholipids and thereby producing lysophospholipids (Fig. 4) (1). By prelabeling the Fa–CoA pool prior to drug administration by i.v. labeled arachidonate, for example, increased incorporation of label from the Fa–CoA pool into resultant lysophospholipids can be quantified and localized using autoradiography at sites of phospholipase A_2 activation. Thus, the muscarinic M_1 agonist arecoline in awake rats increased incorporation of injected [1-^{14}C]arachidonate into *sn*-2 positions of PI and PC, and of [1-^{14}C]docosahexaenoate into PE and PC, thereby increasing overall brain k* for each tracer (15) (Table 4). The effect on [1-^{14}C]arachidonate was blocked by atropine, and occurred in 83% of brain regions with M_1 receptors. In contrast, arecoline had no significant effect on incorporation of [9,10-^{3}H]palmitate, consistent with lack of involvement of *sn*-1 acyl groups on PC in cholinergic signal transduction.

Upregulation of phospholipase A_2-mediated signal transduction involving the M_1 receptor has been demonstrated using the FA method. The nucleus basalis of Meynert (NBM) provides cholinergic input to the ipsilateral neocortex and is pathological in humans with Alzheimer disease (16). Two weeks after a unilateral ablation of the NBM in rats, resting glucose metabolism and resting incorporation of [1-^{14}C]arachidonate have been reported to be bilaterally symmetrical (17,18), whereas arecoline administration increased incorporation of [1-^{14}C]arachidonate into the cortex on the lesioned side (Fig. 5) (18). In unstimulated rats, however, incorporation of [9,10-^{3}H]palmitate was increased into the ipsilateral cortex, consistent with evidence for membrane remodeling involving PC (De Micheli, E., unpublished data).

In this regard, incorporation of labeled palmitate into brain has been shown to be altered with a chronic lesion of the NBM (see above), Wallerian degeneration, chronic sensory

TABLE 2
Distribution of Radiolabeled Fatty Acids Within *sn*-1 and *sn*-2 Positions of Brain Phospholipids That Receive Most of the Label, 15 Min After I.V. Injection in Awake Rats[a]

Fatty acid tracers	Phospholipid	Percent distribution of radiolabel *sn*-1 position	*sn*-2 position
[9,10-^{3}H]Palmitate	PC	82.5 ± 1.9	17.5 ± 1.9
	PE	90.7 ± 0.5	9.3 ± 0.5
[1-^{14}C]Arachidonate	PC	7.8 ± 1.9	92.2 ± 1.9
	PI	0.0 ± 0.0	100 ± 0
[1-^{14}C]Docosahexaenoate	PC	22.9 ± 5.2	77.1 ± 5.2
	PE	0 ± 0	100 ± 0

[a]Values are mean ± SEM for 3–7 rats. From Nariai *et al.* (18).

TABLE 3
Half-Lives of Fatty Acids Within Individual Phospholipids of the Rat Cerebral Cortex[a]

Fatty acid	Phospholipid class PC	PS	PI	PE
	$t_{1/2,i}$, h			
Palmitate (16:0)	11.5	13.3	2.33	12.0
Arachidonate (20:4)	1.7	8.3	0.66	23.8

[a]Data calculated as described [Robinson, 1992 #1608] using λ = 0.011 for arachidonate, 0.0161 for palmitate (7,8). See Table 2 for abbreviations.

TABLE 4
Unidirectional Whole-Brain Incorporation Coefficients for Fatty Acid Tracers, Measured 15 Min Following 5-Min I.V. Infusion of Radiolabel and Intraperitoneal Administration of 15 mg.kg^{-1} Arecoline in Awake Rats

	Unidirectional Incorporation Coefficient, k*, cm^3.s^{-1} per g brain × 10^{-4}		
Fatty acid tracer	Control	Arecoline (15 mg/kg)	Change (%)
[9,10-^{3}H]Palmitate	0.88 ± 0.06	0.94 ± 0.04	+11
[1-^{14}C]Docosahexaenoate	3.08 ± 0.14	4.48 ± 0.26[a]	+48
[1-^{14}C]Arachidonate	3.13 ± 0.18	4.42 ± 0.27[a]	+41
[1-^{14}C]Arachidonate ± 4 mg/kg atropine[b]	3.30 ± 0.15	2.54 ± 0.31	−24

Mean ± SEM for 3–9 animals.
[a]Differs significantly from control mean, $P < 0.05$
[b]Atropine was given prior to arecoline infusion in one set of experiments, whereas methylatropine was administered routinely to prevent peripheral effects of arecoline. From DeGeorge *et al.* (15).

deprivation, recovery from transient ischemia and brain development, but not during acute changes in functional activity (15,18–24). These observations, and the fact that PC is the major phospholipid in cell membranes (25,26), suggest that labeled palmitate, which is incorporated into the *sn*-1 position of PC, can be used to examine neuroplasticity involving membrane remodeling or cell growth. [1-^{14}C]arachidonate and [1-^{14}C]docosahexaenoate appear to be more useful markers for acute changes in functional activity, and for chronic changes in phospholipase A_2-mediated signal transduction (see above) (15,24). In the future, [^{11}C]positron-emitting isotopes of long-chain FA might be used with positron emission tomography to examine human brain phospholipid metabolism *in vivo* in health and disease (27).

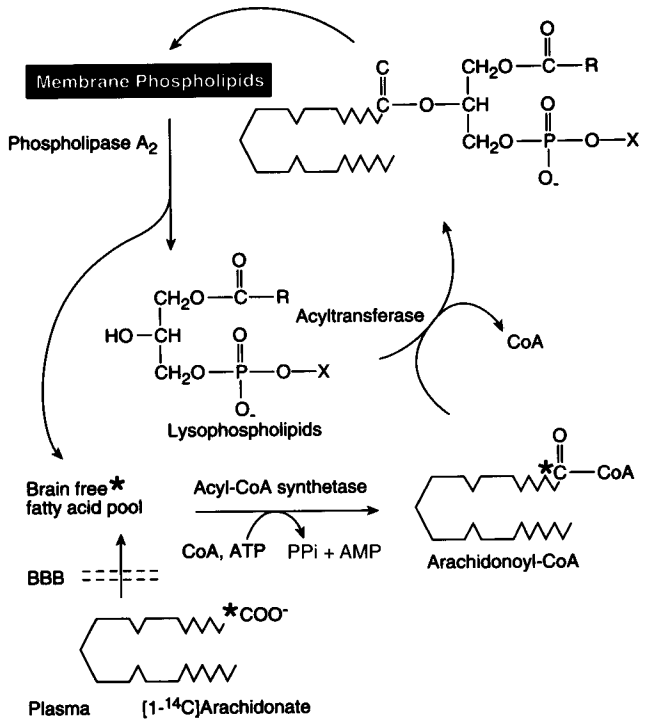

FIG. 4. Cycling of arachidonate following activation of phospholipase A_2. Unlabeled arachidonate that is released from a phospholipid (upper right) is reacylated into the brain acyl-CoA pool. The latter has been prelabeled by labeled unacylated [1-^{14}C]arachidonate in blood plasma, and provides labeled tracer for transacylation into resultant lysophospholipids.

Essential Fatty Acid Uptake and Metabolism in the Developing Rodent Brain

Robert J. Pawlosky, Glenn Ward, and Norman Salem, Jr.*

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcoholism and Alcohol Abuse, Division of Intramural Clinical and Biological Research, Rockville, Maryland

ABSTRACT: Studies were carried out to determine whether the brain takes up and metabolizes essential fatty acids during early postnatal development in rodents. Rats and mice were dosed with deuterium-labeled linoleic and linolenic acids either by intraperitoneal injection or by gavage. Animals were killed at different times thereafter, and organs were removed. Brains, livers, and blood were analyzed by gas chromatography–negative-ion-mass spectrometry for labeled fatty acids. To determine whether fatty acids were present in the brain apart from cerebral blood, a subset of animals was exsanguinated by perfusion with buffered saline, and the brain was then fractionated into subcellular components. Results demonstrated that the brain took up both labeled essential fatty acids within 8 h from the time of dosing. There was on average a greater uptake of linolenic acid into the cerebellum than into the cerebral cortex during the first 8 d of life in rats. The amount of linoleic acid taken into either region was similar, however. Docosahexaenoic acid intermediates, 20:5n-3 and 22:5n-3, were also found labeled in the brain. Time-course labeling experiments indicated that these intermediates may be converted to 22:6n-3 within the brain. A rise of labeled 22:6n-3 in the brain at 24 h appeared to be due to uptake of this fatty acid from the blood. The amount of labeled 22:6n-3 in the brain continued to increase beyond 24 h, and this did not appear to be correlated with its blood concentration. These results suggest that, during development in the rodent, different regions within the brain may vary in their capacity to synthesize 22:6n-3, and this may be correlated with regional growth rates.
Lipids 31, S-103–S-107 (1996).

In mammals, there is rapid brain growth during prenatal and early postnatal periods of development, and accumulation of long-chain polyunsaturated fatty acids is important for overall neural tissue formation. In the rat, for example, growth of the cerebellum occurs almost entirely during the first 15 d after birth, whereas much of the cerebral cortex is formed before birth (1). In humans, the brain-growth period occurs from approximately the third trimester of pregnancy to about 18 months after birth (2). Over the past two decades, a number of published reports have suggested that the brain itself may be an alternative site of polyunsaturated fatty acid biosynthesis during development (2–12). One recent report in felines demonstrated that the brain rather than the liver produces neural 22:6n-3 from 22:5n-3 (13). Other investigators have suggested that the brain controls liver synthesis of docosahexaenoic acid and signals the liver to increase 22:6n-3 production when appropriate (14). In either case, experimental evidence is needed to clarify the brain's role in supplying neural long-chain polyunsaturated fatty acids during development to support either of these hypotheses.

The first report of the use of deuterium-labeled fatty acids to study fat metabolism was published in 1935 (15). It has only been through current advancements in modern chromatography techniques coupled with the application of the high sensitivity and specificity of mass spectrometry, however, that has led to the establishment of routine tools for trace analysis *in vivo* (16).

A study was carried out in rodents to determine whether the brain takes up and metabolizes 18-carbon essential fatty acids during the early postnatal period. Animals were dosed with deuterium-labeled fatty acids, and tissues were analyzed by gas chromatography–mass spectrometry for labeled metabolites. Regional accumulation of 18:2n-6 and 18:3n-3 was determined by dissecting the cerebellum away from the frontal cortex and analyzing the compartments separately. To accurately locate labeled fatty acids in the brain, 3 animals were perfused with a buffered saline solution to remove the blood. A comparison was made between liver, blood, and brain levels of d_5-22:6n-3 throughout 7 d following an oral dose of d_5-18:3n-3 ethyl ester.

EXPERIMENTAL PROCEDURES

All animal procedures were carried out in accordance with the National Institutes of Health (NIH) animal care and welfare guidelines, and the protocol was approved by the National Institute on Alcoholism and Alcohol Abuse (NIAAA) Animal Care and Use Committee. Mothers were maintained on a standard rodent diet, NIH-31, containing 22 energy-percent (en%) fat for the duration of these studies, and young animals suckled from their mothers. Maternal diet contained fatty acids in the following percentages:16:0 (3.4 en%), 16:1n-7 (0.5 en%), 18:0 (1.5 en%), 18:1n-9 (4.8 en%), 18:1n-7 (0.5 en%), 18:2n-6 (7.4 en%), 18:3n-3 (0.88 en%), 20:4n-6

(0.04%), 20:5n-3 (0.70 en%), and 22:6n-3 (0.55 en%). Deuterium-labeled fatty acid ethyl esters, d_5-18,18,18,17,17-18:2n-6 and d_5-18,18,18,17,17-18:3n-3, were obtained from Cambridge Isotope Laboratories (Woburn, MA).

Uptake of d_5-18:3n-3 and d_5-18:2n-6 in rat brain. Separate groups of rats on days 2, 3, 4, 5, 6, 7, and 8 of life were dosed with 1 mg of both d_5-18:2n-6 and d_5-18:3n-3 ethyl esters by gavage. Animals were killed by cervical dislocation 48 h after dosing, blood was taken, brains were removed, and the cerebellum and cortex were dissected out.

To determine if d_5-18:3n-3 was taken up into the brain as distinct from cerebral circulation, a group of three 2-day-old rats were dosed with 1 mg d_5-18:3n-3 ethyl ester, and 8 h later they were anaesthetized by placing them over wet ice. Chest cavities were opened, and animals were perfused with a buffered saline solution using a 33-gauge needle and syringe to puncture the right ventricles of the hearts. Brains were then removed and homogenized in phosphate buffered saline using a hand-held ground-glass homogenizing vessel. Homogenates were centrifuged at 12,000 × *g* for 20 min, producing the P1 pellet (whole cells and capillaries). The supernatant was then centrifuged at 100,000 × *g* for 1 h to obtain a microsomal pellet (P2).

Uptake of d_5-18:3n-3 and accumulation of d_5-22:6n-3 in mouse brain. Eighteen three-day-old C57BL/J6 mice were given an injection of 50 μg d_5-18:3n-3 directly into the intraperitoneal cavity using a 33-gauge needle. Animals were killed at 2, 4, 24, 48, 72, and 96 h after injection, the brain and liver were dissected out, and homogenized, and lipids were extracted.

Lipid extraction and pentafluorobenzyl (PFB) ester formation. Samples of homogenized brains (in some cases, cerebellum and cortex) and 100-mg pieces of liver were homogenized in water, and lipids were extracted using the Bligh and Dyer total lipid extraction procedure (17). Deuterium-labeled fatty acids were hydrolyzed and then derivatized to their pentafluorobenzl (PFB) esters using PFB bromide containing diisopropylethylamine in acetonitrile (1:10:1,000, by vol), as previously described (16).

Capillary gas chromatography–mass spectrometry analyses. Deuterium-labeled fatty acids were analyzed in the selected ion mode by gas chromatography–mass spectrometry on a Hewlett-Packard 5989 GC–MS (Palo Alto, CA), as previously described (18). Deuterium-labeled products were quantified using relative response factors for the individual analyses and an internal standard, 23:0, added in the nonesterified fatty acid form.

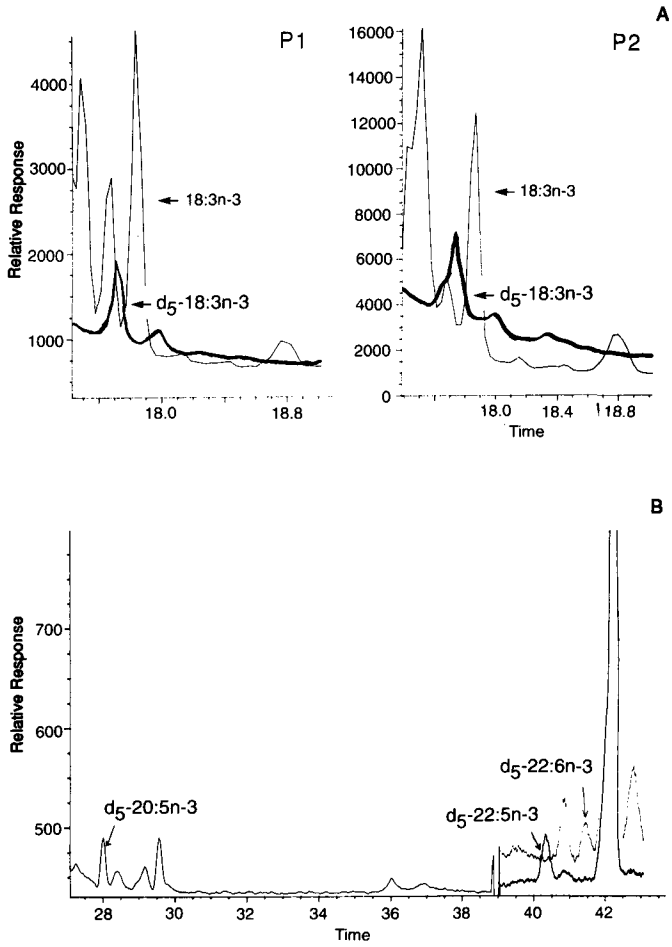

FIG. 1. A. Gas chromatography–mass spectrometry-selected ion chromatograms (SIM) for the ions *m/z* 277 and 282 of the fatty acyl pentafluorobenzyl (PFB) derivatives obtained from whole rat brain extracts. Animals were given a single oral dose of 1 mg d_5-18:3n-3 ethyl ester. The panel designated as P1 is the SIM tracing of the derivatized pellet obtained from low speed (12,000 × *g*) centrifugation of whole brain homogenate. The panel designated as P2 is the SIM chromatograph of the pelleted material resulting from the supernatant that was centrifuged at high speed (100,000 × *g*). The ion at *m/z* 277 represents the PFB ester of 18:3n-3, and the ion at *m/z* 282 represents d_5-18:3n-3. B). SIM chromatographs of the PFB derivatives of fatty acids extracted from whole rat brain homogenates. Chromatographs show the isotopically labeled fatty acids, 20:5n-3 at *m/z* 306, 22:5n-3, at *m/z* 334, and 22:6n-3 at *m/z* 332, 8 h after dosing animals with 1 mg d_5-18:3n-3 ethyl ester.

RESULTS

In the perfused whole rat brain, d_5-18:3n-3 was detected as early as 8 h after dosing (Fig. 1A). There was a 30% enrichment of the labeled 18:3n-3 in the microsomal fraction P2, as compared to a 16% enrichment in whole cells and capillaries, P1. This indicated that the isotope was associated with neural cells as well as being present in capillaries. The n-3 fatty acids, d_5-20:5n-3 and d_5-22:5n-3, were also detected in the rat brain (Fig. 1B). These results confirm other reports demonstrating that 18-carbon essential fatty acids are taken up into the neonatal brain, where they may be converted to long-chain polyunsaturated fatty acids (2–12).

In another experiment in which mice were dosed with d_5-18:3n-3 by intraperitoneal injection, labeled 18:3n-3 was observed in both brain and liver. In the liver after 24 h, the amount of d_5-18:3n-3 had decreased about eightfold from the maximum amount observed at 2 h. At the same time, the level of d_5-18:3n-3 had increased in the brain (Fig. 2). This contrasts with results reported by Scott and Bazan (14) where

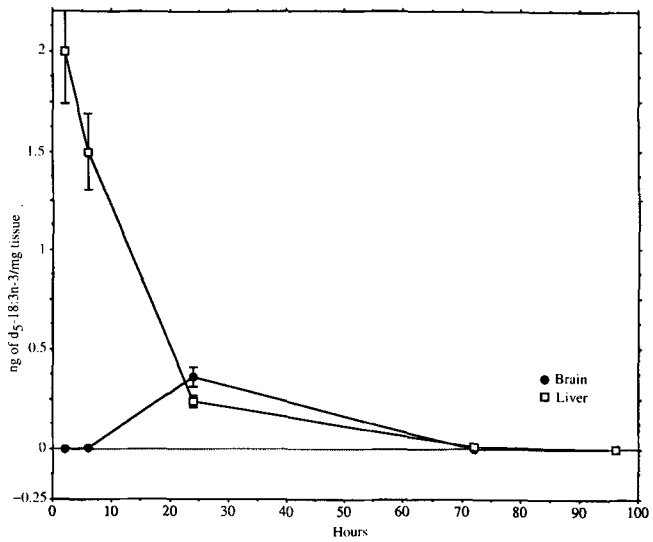

FIG. 2. Plots of the time course of d_5-18:3n-3 concentration in the livers and brains of 3-day-old mice (n = 3 for each time-point) given an intraperitoneal injection of 50 µg of d_5-18:3n-3. Livers and brains were sampled at 2, 6, 24, 72, and 96 h following the injection.

they failed to observe any uptake of labeled 18:3n-3 in the mouse brain following an injection of labeled 18:3n-3. The reason for these incongruous observations is unclear, but it may be related to differences in experimental methodology. The isotope labeling pattern of the fatty acids was determined in the earlier work using high-pressure liquid chromatography with radioactive detection. It is possible that this system did not have sufficient resolving power to separate the closely

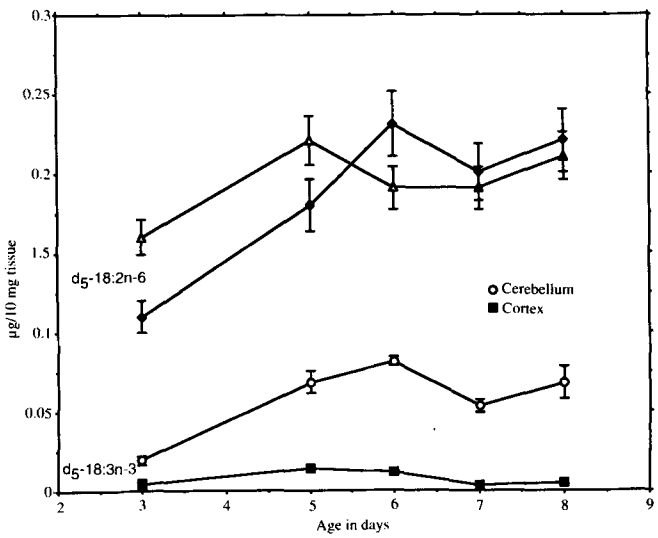

FIG. 3. Uptake of d_5-18:2n-6 and d_5-18:3n-3 into cerebellums and forebrains of neonatal rats (n = 3 for each time-point) after a 1-mg oral dose of the labeled fatty acids. Animals were killed 48 h after being given a dose of the isotope. The age indicates the time at which the sample was taken.

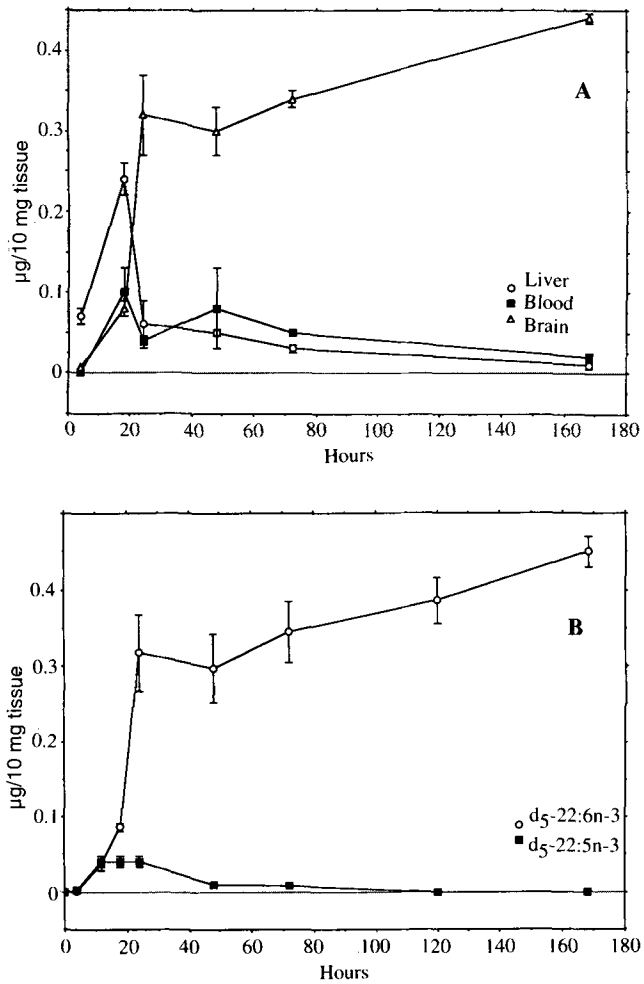

FIG. 4. A). The time course of d_5-22:6n-3 accumulation in the livers, blood, and brains of 3-day-old rats (n = 3 for each time-point) given a single oral dose of 1 mg d_5-18:3n-3 ethyl ester. B). The time course of d_5-22:6n-3 and d_5-22:5n-3 in the brains of 3-day-old rats (n = 3 for each time-point) that had been given a dose of 1 mg d_5-18:3n-3 ethyl ester.

eluting labeled 18:3:n-3 from 22:6n-3 (14). Also, there may be dietary differences in essential fatty acid intake between the two experiments.

In rats there was a much greater uptake of d_5-18:3n-3 into the cerebellum than into the cerebral cortex throughout the first 8 d of life (Fig. 3). There were similar amounts of d_5-18:2n-6 observed in both brain regions, however. This indicates that the developing cerebellum may have a greater requirement for n-3 fatty acids than does the cortex, and it suggests the possibility that different regions of the brain may vary in the level of docosahexaenoic acid synthesis. Alternatively, the higher level of d_5-18:3n-3 in the cerebellum may indicate that there is a lower conversion rate to d_5-22:6n-3 within that region.

In the rat brain it appeared that the primary accumulation of labeled docosahexaenoic acid resulted from liver production of 22:6n-3, which was subsequently taken up from the

blood (Fig. 4A). Isotope enrichment of 22:6n-3 reached a maximum in the liver and blood 18 h following the d_5-18:3n-3 dose; at 24 h there was a sharp increase in the amount of d_5-22:6n-3 in the brain. This concurs with the results reported by Scott and Bazan in mice (14). In the present study, however, isotopic enrichment of 22:6n-3 in the brain continued to increase after 24 h, while blood levels of d_5-22:6n-3 had fallen. At 168 h, there was a 25% greater enrichment of the 22:6n-3 in the brain than that at 24 h. One possible explanation for this increased enrichment is that other n-3 fatty acids are being converted to d_5-22:6n-3 within the brain. Previous studies have provided evidence for the brain conversion of n-3 fatty acids to 22:6n-3 (3–12). For example, appreciable amounts of labeled 20:5n-3 and 22:5n-3 were detected in brains of mice several hours after animals received a dose of labeled 18:3n-3 (14). These may have originated from the neural metabolism of labeled 18:3n-3. Furthermore, both labeled 20:5n-3 and 22:5n-3 decreased in the brain between 2 and 72 h. Moreover, when radiolabeled 18:3n-3 is injected into the brain, 22:6n-3 rapidly becomes labeled (4,5,12). In the present study, d_5-22:5n-3 decreased in the brain, while d_5-22:6n-3 increased (Fig. 4B).

DISCUSSION

Both neonatal mice and rats were found to take up labeled 18-carbon fatty acids into the brain. There was about a 15% lower amount of d_5-18:3n-3 in the perfused brain compared to nonperfused tissue, demonstrating that fatty acid was found in both the brain parenchyma and in cerebral arteries. Moreover, d_5-18:3n-3 was found in the P2 subcellular fraction of the brain. These results differ from an earlier report in mice (14) but confirm other reports in rats and other species (2–12). The diet used by Scott and Bazan (14) differed from the one used in this study, and this may partially account for these different observations.

In the rat during the first 8 d of life, the d_5-18:3n-3 was more highly enriched in the cerebellum than in the cerebral cortex. In contrast, the concentration of d_5-18:2n-6 was about the same in both compartments. This is significant in that, in the rat, development of the cerebellum, including the elaboration of dendrites and subsequent synapses, is occurring at a much greater velocity during this period than is the cortex (1). Therefore, increased accumulation of n-3 fatty acids may be a nutrient requirement for formation of these structures. Another possible explanation of this data is that there may be a lower conversion rate of 18:3n-3 to 22:6n-3 within the cerebellum, and this brings about a buildup of the precursor. This hypothesis, however, does not take into account that the cerebellum is growing at a rapid rate and presumably requires fatty acids for elaborating new membranes.

These findings also indicate that a portion of the labeled 22:6n-3 intermediates, such as d_5-20:5n-3 and d_5-22:5n-3 were metabolized to 22:6n-3 within the brain. It is significant that 18:3n-3 conversion to 22:6n-3 is occurring in both the liver and brain in neonatal animals when the maternal diet contains long-chain polyunsaturated fatty acids, since it is uncertain whether in young animals their synthesis is regulated by the inclusion of long-chain polyunsaturated fatty acids in the diet (18,19).

The present study supports the view that, in rodents during postnatal development, the liver contributes a major supply of 22:6n-3 to the brain for neural development. This study, however, also supports suggestions from previous work indicating that the developing rat brain has the capability to synthesize long-chain polyunsaturated fatty acids and that this may be an additional source of 22:6n-3 required during development (2–12). The findings suggest that, based on selected uptake of 18:3n-3, there may also be different regional requirements for and capabilities to biosynthesize 22:6n-3 in the brain. Based on these findings, the quantitative significance of brain biosynthesis of 22:6n-3 may be significant and suggest that more detailed studies of essential fatty acid metabolism and brain development are needed to fully understand the nature of this function in the brain.

ABSTRACT: The exchange of docosahexaenoic acid (22:6n-3) within lipid pools in rat and human has been followed as a function of time after the ingestion of triglycerides (TG) containing 22:6n-3 labeled with ^{13}C (^{13}C 22:6n-3). The ^{13}C abundance in the fatty acid was measured by gas-chromatography-combustion isotope ratio mass spectrometry which allowed the detection of 0.001 atom ^{13}C percent ^{12}C. The ^{13}C 22:6n-3 appearance was rapid in the TG of very low density lipoprotein plus chylomicron fraction, in which the maximal labeling was observed at 3 and 2 h after ingestion in rat and human, respectively. Concomitant with the TG utilization of this fraction by lipoprotein lipase from tissues, unesterified ^{13}C 22:6n-3 appeared in the plasma albumin. ^{13}C 22:6n-3 bound to albumin was mostly present in unesterified form before 12 h post-ingestion while after that period, lysophosphatidylcholine (lysoPC) bound to albumin carried higher ^{13}C 22:6n-3 concentrations. These lyso-PC were mostly from hepatic origin and might represent a potential source of 22:6n-3 redistribution to tissues. The ^{13}C 22:6n-3 uptake into rat brain PC and phosphatidylethanolamine was still increasing when the concentration of plasma unesterified ^{13}C 22:6n-3 had already dropped to a minimal plateau value and during the period of maximal plasma circulation of ^{13}C 22:6n-3-lysoPC bound to albumin. In contrast, the uptake of ^{13}C 22:6n-3 into blood platelet PC occurred during the phase of important circulation of ^{13}C-22:6n-3 bound to albumin, suggesting the *in vivo* efficiency of the Lands pathway for this fatty acid. It is concluded that ^{13}C 22:6n-3 esterified in TG is rapidly absorbed and redistributed within plasma lipoproteins and that its redistribution within the two lipid species bound to albumin might influence its uptake by platelets and rat brain.

Lipids 32, S-109–S-115 (1996).

The n-3 family of polyunsaturated fatty acids has received much interest because of evidence that these compounds are antiatherogenic (1) and may also be essential nutrients (2). Among these fatty acids, docosahexaenoic acid (22:6n-3) is present in high concentrations in phospholipids (PL) of neurospecialized membranes from brain (3) and retina (4) and its depletion from these tissues leads to functional impairments in animals (5) and babies (6,7). The antiatherogenic properties of n-3 fatty acids result from their combined effects on blood lipids (8) and from their incorporation into cellular lipids where they interfere with the arachidonic acid cascade (1). It has been shown that the *in vitro* incorporation of 22:6n-3 into platelets decreased their aggregation and the binding of a thromboxane analogue to its receptor (9,10). The forms of transport of this fatty acid in plasma lipids for efficient distribution to blood cells and target tissues such as brain have been poorly reported.

In the present study, we have followed the 22:6n-3 exchange within lipid compartments, based on isotopic substitution, to establish precursor-product relationships in lipid synthesis. The metabolic fate of 22:6n-3 has been traced *in vivo* in rat and human using 22:6n-3 labeled by the stable isotope ^{13}C and a detection by gas chromatography-combustion isotopic ratio mass spectrometry (GCC-IRMS). Triglycerides containing ^{13}C 22:6n-3 (^{13}C 22:6-TG) were ingested by rats or human subjects and the appearance of the ^{13}C fatty acid was followed as a function of time in plasma lipoprotein, platelet and rat brain lipids.

It was shown that ^{13}C 22:6-TG was rapidly absorbed and redistributed within plasma lipoproteins and the albumin fraction and that the ^{13}C 22:6n-3 incorporation in lipid species bound to albumin influenced its uptake by platelets and rat brain.

METHODS

Synthesis of triglycerides containing [^{13}C]docosahexaenoic acid. These TG were produced by growing a microalgae strain in a defined medium containing 0.9 g/L (batch 1) or 3 g/L (batch 2) of D-[1-^{13}C] glucose (Eurisotop, Saint Aubin, France). In batch 1, ^{13}C 22:6n-3 represented 36 mol% of total TG fatty acids and had a ^{13}C abundance of 2.04 atom %. In batch 2, ^{13}C 22:6n-3 represented 46 mol% of total TG fatty acids and had a ^{13}C abundance of 7.72 atom %. Sixty % of the ^{13}C 22:6n-3 was located at the *sn*-2 position of the TG.

Rat experiment. Male Sprague-Dawley rats (300 g) were fed a standard lab chow diet (Souriffarat, Genthon,

Cheyssieu, France). The tracer TG were taken to dryness under nitrogen and immediately dispersed into 600 µL of skim milk for rat intubation. After fasting the animals overnight, they received 3 mg of ^{13}C 22:6-TG from batch 1 or 2, by intragastric intubation and were further left free access to a solution of water containing 2% glucose, 0.5% NaCl and 0.01% KCl (wt/vol) until sacrifice. At various times after feeding, animals were anaesthetized by peritoneal injection of pentobarbital and 10 mL of blood were taken via aortic puncture in chilled plastic syringes containing acid-citrate-dextrose as anticoagulant (0.8% citric acid, 2% citrate, 2.45% dextrose, pH 4.5).

Human experiment. Overnight fasted healthy subjects absorbed the tracer TG (280 mg of batch 2) mixed in a yogurt and had breakfast immediately after this. At various periods of time after ingestion, blood was taken by venopuncture into chilled plastic syringes containing acid-citrate-dextrose. Blood sample was also collected just before the tracer ingestion to measure the basal ^{13}C abundance in lipid pools.

Preparation of biological samples. All experimental steps were performed at 4°C. Blood samples were immediately centrifuged at 100 g for 15 min, to obtain platelet-rich plasma (PRP). PRP was centrifuged at 1000 g for 10 min and the supernatant was treated for lipoprotein preparation. The resulting platelet pellet was rinsed twice and gently resuspended into a Tyrode/Hepes buffer, containing 1 mM EDTA, pH 6.4 (11). This cell suspension was immediately centrifuged at 1000 g for 10 min, rediluted into Tyrode/Hepes buffer, without EDTA pH 7.35, and frozen at −20°C. Lipoproteins were separated into very low density lipoproteins (VLDL) plus chylomicrons (VLDL/Chyl), low density lipoproteins (LDL), high density lipoproteins (HDL) and a nonlipoprotein fraction containing albumin by ultracentrifugation at 600,000 g in a fixed angle rotor (Kontron, TFT 80.49) for 2 h at 4°C, using NaCl/KBr density gradient (11).

Fractionation and quantification of lipids. Total lipids were extracted from plasma, platelets, and lipoprotein preparations according to Bligh and Dyer (12). The extraction of brain lipids was performed according to Folch (13). Lipid classes were prepared by spotting the lipid extract on silica gel 60 plates and eluting the total PL, free fatty acids, TG and sterol esters (SE) with hexane/diethyl ether/acetic acid (80:20:1, by vol), as a mobile phase. Lipids from lipoproteins and the albumin fraction were separated into lysophosphatidylcholine (lysoPC), phosphatidylcholine (PC) and phosphatidylethanolamine (PE) on thin-layer chromatography plates with chloroform/methanol/H_2O (65:25:4, by vol), as the mobile phase. Platelet, red blood cell, and brain PL classes were purified by TLC migration with chloroform/methanol/14% aqueous methylamine (60:20:5, by vol) as a mobile phase, after predeveloping the plate with chloroform/methanol (80:8, vol/vol). Lipid classes were scraped off the plate and treated with 5% H_2SO_4 in methanol for 90 min for fatty acid methyl ester preparation. Lipid classes were quantified by adding internal standards in the extraction mixture. Triheptadecanoylglycerol, 1,2-diheptanoyl-glycero-3-phosphocholine and -phosphoethanolamine, heptadecanoyl-lysoPC and heptadecanoic acid (17:0) (Sigma Chemical, St. Louis, MO) were added when appropriate and the absolute amount of fatty acid methyl esters were determined by gas chromatography (GC) analyses, relative to the known amount of added 17:0. Fatty acid methyl esters were analyzed and quantified by GC, using an SP 2380 capillary column (30 m × 0.32 mm; Supelco, Bellefonte, PA). Prior to their GCC-IRMS analysis, fatty acid methyl esters were purified by HPLC using a 5 µm Superspher 100 C18 column (Merck, Darmstadt, Germany) and an isocratic elution with acetonitrile/H_2O. They were detected by UV absorbance at 210 nm, collected and the different fractions were rapidly taken to dryness under nitrogen.

GCC-IRMS analyses. Samples were injected into an HP 5890 gas chromatograph equipped with a Ross injector and a Supelco capillary column (SP-2380, 0.25 mm × 30 m). A heart-cut valve directed the helium flow either to the flame ionization detector or to a quartz tube filled up with CuO, heated at 800°C, where CO_2 was generated from fatty acids by catalytic combustion. The effluent was then driven into a water trap before its ionization by electron impact in the source of the isotope ratio mass spectrometer (SIRA 12; VG Isogas, Middlewich, United Kingdom). The different isotopomers were collected onto three different collectors at *m/z* 44, 45, and 46. Before and after the CO_2 peaks generated from the fatty acids, a CO_2 sample reference of known enrichment calibrated against the international standard (Pee Dee Belemnite: PDB) was automatically injected into the mass spectrometer (11).

Expression of results. $^{13}C/^{12}C$ of samples and reference were used to calculate the δ per 1000 value ($\delta^{13}C‰$) with the following equation:

$$\delta^{13}C‰ = \frac{(^{13}C/^{12}C \text{ sample} - {}^{13}C/^{12}C \text{ reference}}{{}^{13}C/^{12}C \text{ reference})} \times 10^3 \quad [1]$$

where the reference is the international PDB standard, which is CO_2 obtained from the carbonate shell of a cretaceous mollusk. As this international standard is rich in ^{13}C, the natural ^{13}C abundance of samples are negative $\delta^{13}C‰$ values. Results were also expressed as ^{13}C atom percentage (atom %). The atom % excess could be calculated by subtracting the basal ^{13}C abundance from the ^{13}C abundance in samples. The ^{13}C 22:6n-3 appearance in biological samples was also expressed as the absolute amount of ^{13}C 22:6n-3 in the lipid pools at various time points by determination of ^{13}C 22:6n-3 dilution in the pools with a standard curve and by multiplying this value by the endogenous 22:6n-3 concentration, measured by GC.

RESULTS

Rat experiment. The ^{13}C 22:6n-3 appearance in VLDL/Chyl-TG was followed as a function of time after the ingestion of the ^{13}C 22:6-TG labeled at 2.04 atom % (Fig. 1). The labeling in this fraction increased from basal $\delta^{13}C‰$ values to

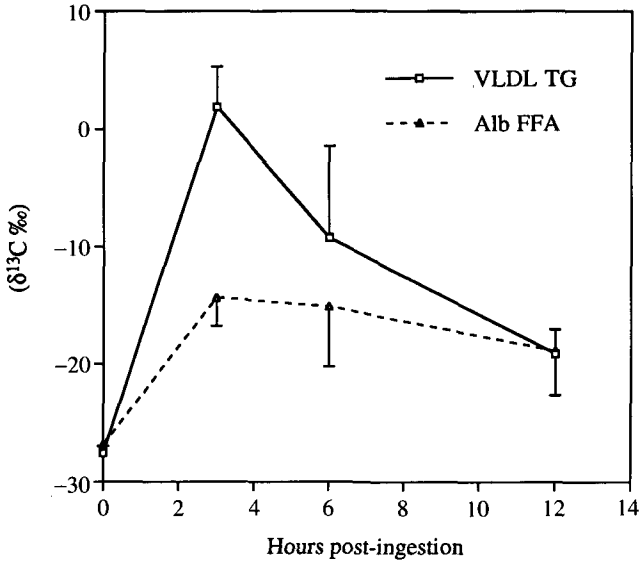

FIG. 1. The appearance of ^{13}C 22:6n-3 in very low density lipoprotein/chylomicron-triglycerides (VLDL-TG) and in unesterified fatty acids bound to albumin (Alb FFA), as a function of time after the ingestion of ^{13}C 22:6n-3-triglycerides. Rats were given a 3 mg intragastric dose of ^{13}C 22:6n-3-triglycerides labeled at 2.04 atom %. Lipoprotein and albumin fractions were prepared by ultracentrifugation at 600,000 g for 2 h and the lipid classes were purified by thin-layer chromatography. Each point represents the mean ± SEM of 3–4 rats.

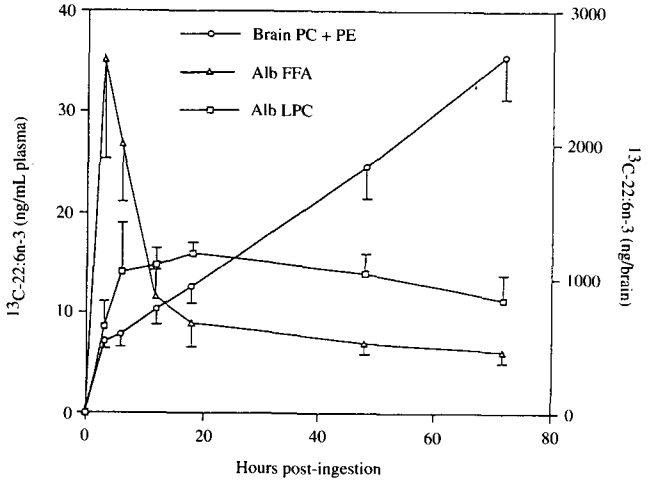

FIG. 2. The time course of ^{13}C 22:6n-3 concentrations in rat plasma unesterified fatty acids bound to albumin (Alb FFA), in plasma lysophosphatidylcholine bound to albumin (Alb LPC) and in brain phosphatidylcholine plus phosphatidylethanolamine (Brain PC + PE), after the ingestion of the ^{13}C 22:6n-3-triglycerides labeled at 7.72 atom %. The ^{13}C 22:6n-3 amount in each lipid class was calculated from the δ^{13}C‰ values and from the 22:6n-3 endogenous concentrations. Each point represents the mean ± SEM of 3–5 rats.

+1.87 ‰, 3 h after ingestion and was already maximal at this time point to further decline until 12 h. The ^{13}C abundance in 22:6n-3, from unesterified fatty acids bound to albumin, paralleled the evolution observed in VLDL/Chyl-TG with a maximal appearance of −14.39‰ at 3 h and further declined. In rats having absorbed the ^{13}C 22:6-TG labeled at 7.72 atom %, the ^{13}C 22:6n-3 appearance was followed in the plasma albumin. Two lipid species carrying significant amounts of endogenous 22:6n-3 were identified in this fraction. The unesterified fatty acids and lysoPC contained 1.35 ± 0.34 μg/mL and 1.55 ± 0.38 μg/mL of endogenous 22:6n-3, respectively (mean ± SD). The time course of ^{13}C 22:6n-3 appearance was different in the two lipid species. A maximal δ^{13}C‰ value of +189‰ was observed in unesterified fatty acids 3 h after ingestion followed by a decline of the labeling until 12–18 h and a plateau from these time points to 72 h post-ingestion (not shown). In contrast, the labeling of lysoPC was more progressive until 6 h and plateaued from 6 to 72 h to a δ^{13}C‰ value which was around 4-fold higher in lysoPC than in unesterified fatty acids (not shown). The ^{13}C 22:6n-3 appearance in these two lipid species was also expressed as the absolute amount of ^{13}C 22:6n-3 at various time points (Fig. 2). While the ^{13}C 22:6n-3 concentration was higher in unesterified fatty acids than in lysoPC at 3 h, it reached comparable levels at 12 h and plateaued until 72 h post-ingestion where it was twice higher in lysoPC than in unesterified fatty acids. The ^{13}C 22:6n-3 appearance into brain PL was followed as a function of time after the tracer ingestion. The magnitude of isotopic variations was moderate in PC and PE, due to the huge dilution of the tracer in the endogenous brain 22:6n-3. The sum of ^{13}C 22:6n-3 incorporation in PC and PE was reported in Figure 2. It increased progressively over all the periods studied and did not plateau after 12 h during the phase of minimal plasma circulation of ^{13}C 22:6n-3 bound to albumin.

Human experiment. The ^{13}C 22:6n-3 appearance in TG from VLDL/Chyl, HDL and LDL in a healthy human subject was followed as a function of time after the ingestion of 280 mg of the tracer TG labeled at 7.72 atom % (Fig. 3A). The δ^{13}C‰ value was maximal in VLDL/Chyl-TG at 2 h which was the earliest time point investigated, dropped until 24 h and then plateaued throughout the end-period. A concomitant maximum of labeling at 3 h was observed in LDL-TG with a lower δ^{13}C‰ value than in VLDL/Chyl-TG (+1100 ‰ vs. +3500 ‰, respectively). The labeling increased in HDL-TG until 6 h where it reached +1400 ‰ and declined to a plateau value similar to the two other TG fractions (+110 to +120 ‰ at 72 h). The labeling in VLDL/Chyl-PL was higher than in HDL- and LDL-PC, until 24 h, where it reached comparable plateau values. The labeling was the highest in PE from LDL and HDL, but it decreased after 24 h in both fractions (Fig. 3 B,C). A comparison of the ^{13}C 22:6n-3 appearance in HDL-PC and lysoPC bound to albumin in three subjects having absorbed the tracer labeled at 7.72 atom % is reported in Figure 4. The labeling was always higher in lysoPC than in HDL-PC, refuting a precursor-product relationship from HDL-PC to lysoPC by the action of lecithin cholesterol acyl transferase (LCAT) in plasma. The ingestion of the tracer induced a sharp and rapid rise in platelet PC, followed roughly by a plateau

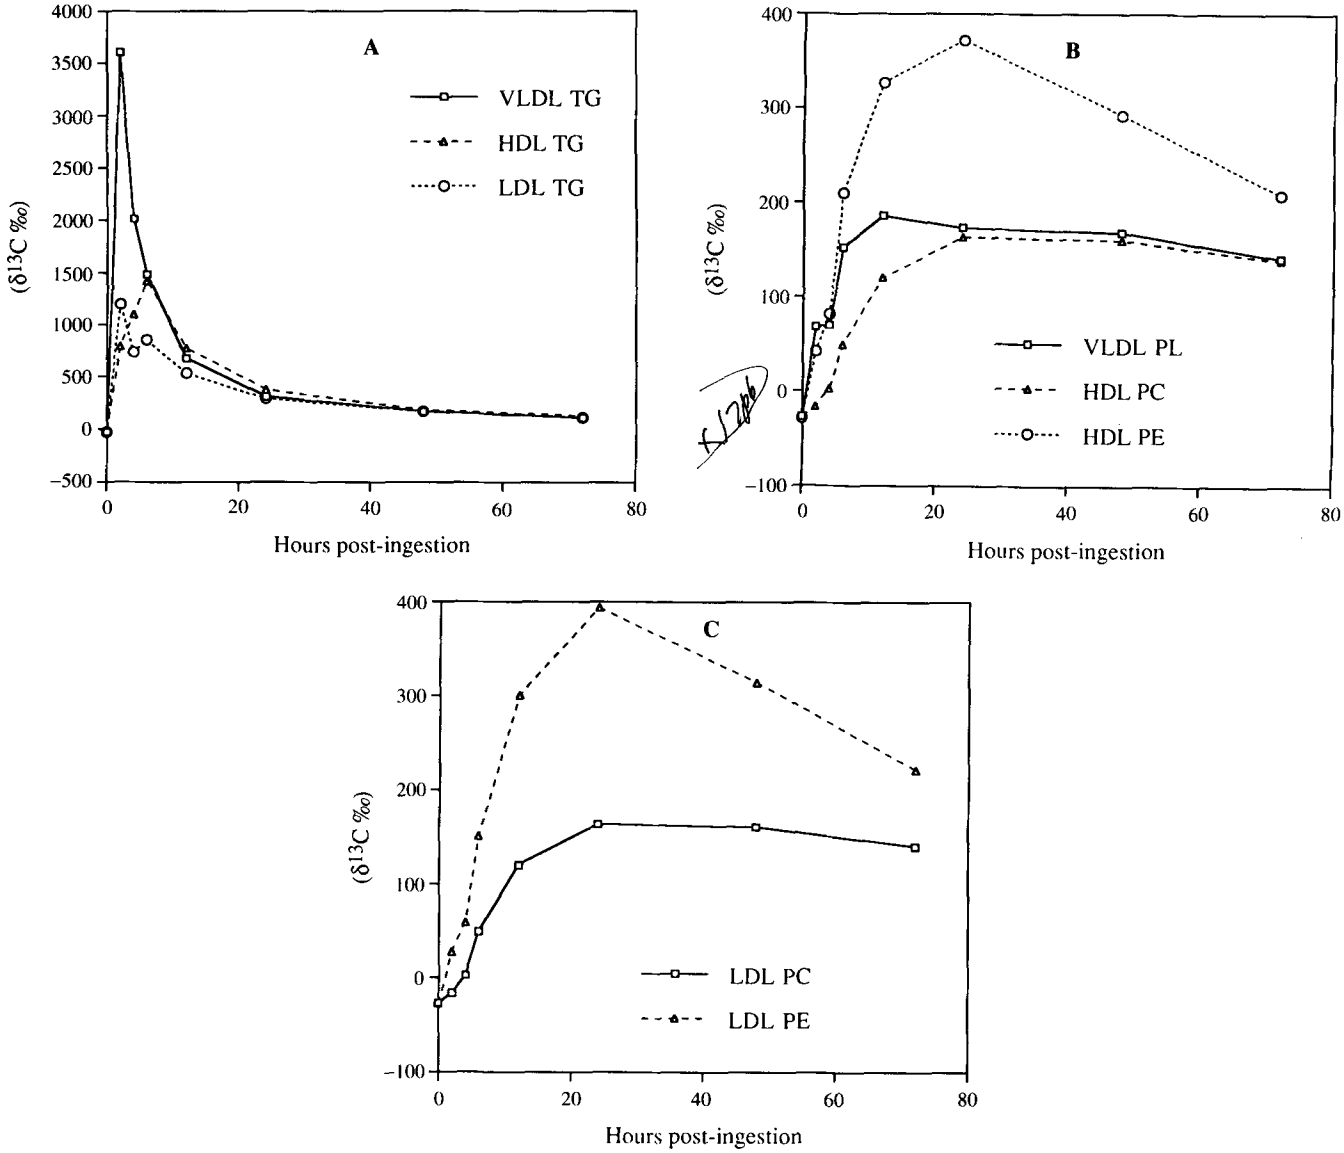

FIG. 3. Time course for the appearance of ^{13}C 22:6n-3 in lipoproteins from a human subject after a single ingestion of the ^{13}C 22:6n-3-triglycerides labeled at 7.72 atom %. (A) in triglycerides from VLDL plus chylomicrons (VLDL-TG), from high density lipoprotein (HDL) (HDL-TG) and from low density lipoprotein (LDL) (LDL-TG). (B) in phospholipids from VLDL (VLDL-PL), in PC and PE from HDL (HDL-PC, HDL-PE). (C) in PC and PE from LDL (LDL-PC, LDL-PE). Abbreviations as in Figures 1 and 2.

over the 12–48 h period (Fig. 5). The comparison with the kinetics of ^{13}C 22:6n-3 bound to albumin shows that ^{13}C 22:6n-3 accumulated into platelet PC during the phase of maximal circulation in plasma of the ^{13}C 22:6n-3 bound to albumin. Finally, since the tracer TG ingested had no detectable ^{13}C 22:5n-3 and ^{13}C 20:5n-3, the retroconversion of ^{13}C 22:6n-3 in rat and human was calculated by summing the amounts of ^{13}C 22:5n-3 and ^{13}C 20:5n-3 measured in plasma PL, TG, and SE 3 h after the ingestion of the tracer (batch 2) (Table 1). The retroconversion of ^{13}C 22:6n-3 appeared to be 8-fold higher in rat than in human.

DISCUSSION

Utilization of stable isotopes for biomedical research has been stimulated by the concern in using radiotracers in humans and by the recent development of sensitive techniques for quantitative detection of stable isotopes (14). Results of the present study show the potential of GCC-IRMS to trace ^{13}C 22:6n-3 in lipid compartments *in vivo*, even after a dose of ^{13}C fatty acid, only double of the natural abundance. Precision of the measurements is dependent on accurate determinations of the baseline due to natural ^{13}C enrichment. The baseline ^{13}C content in 22:6n-3 from four control rat lipid classes was 1.0830 ± 0.0005 atom %. This ensures precise determinations of very low ^{13}C abundance after tracer intake, as observed in tissues presenting poor uptake and/or high labeling dilution. For example, an uptake of 0.00086 ± 0.00018 atom % excess could be detected in rat brain PE 3 h after ingestion of the tracer labeled at 7.72 atom %. Moreover, the $^{13}C/^{12}C$ ratio, the equivalent of specific activity of radioisotopes, is direct isotopic

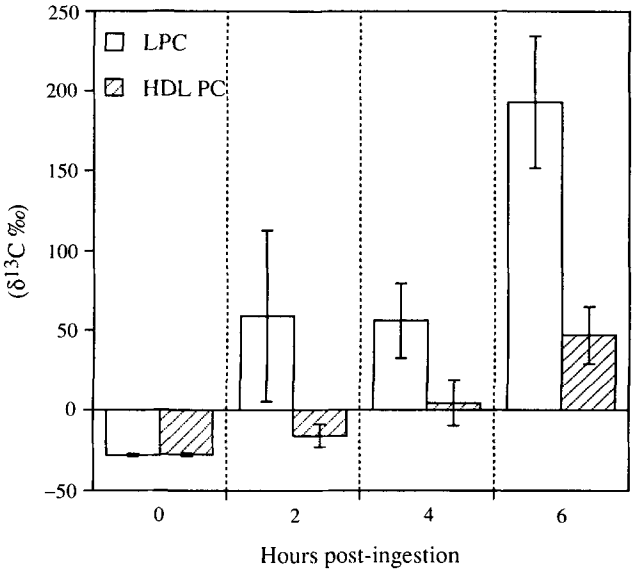

FIG. 4. The ^{13}C 22:6n-3 appearance in lysophosphatidylcholine bound to albumin (LPC) and in phosphatidylcholine from HDL (HDL-PC) in human subjects having absorbed the ^{13}C 22:6n-3-triglycerides labeled at 7.72 atom %. Results are the mean ± SD from three subjects. Abbreviations as in Figure 3.

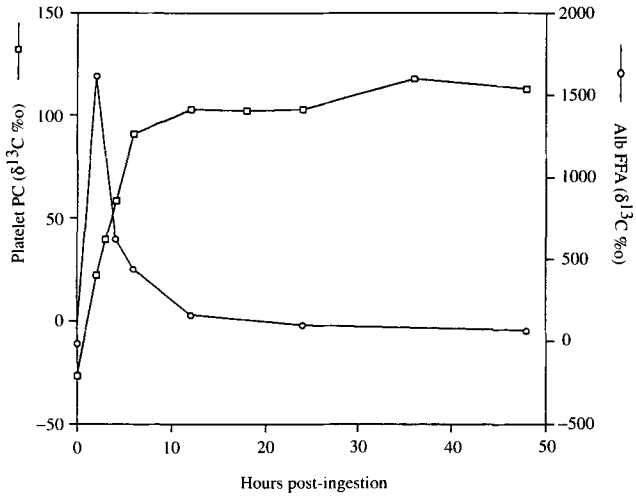

FIG. 5. A comparison of the ^{13}C 22:6n-3 appearance in platelet phosphatidylcholine (Platelet PC) and in plasma unesterified fatty acids bound to albumin (Alb FFA) in a human subject after a single ingestion of the ^{13}C 22:6n-3-triglycerides labeled at 7.72 atom %.

spectrometer data, independent of recovery and laboratory treatments.

^{13}C 22:6n-3 esterified in the tracer TG was rapidly absorbed in view of the maximal appearance of ^{13}C 22:6n-3 in VLDL/Chyl-TG at 2 and 3 h which were the earliest time points of kinetics, in human and rat, respectively. Concomitant with the utilization of the VLDL/Chyl-TG by lipoprotein lipase from tissues using this fatty acid for their own lipid synthesis, unesterified ^{13}C 22:6n-3 appeared in the plasma albumin fraction. Albumin is the known carrier of unesterified fatty acids in plasma mammals (15). Confirming a previous study in rat, where ^{14}C 22:6n-3 was given as free fatty acid by gavage (16), the present work shows that albumin also carries 22:6n-3 in rat and human after ingestion of the fatty acid esterified in TG, which is its natural form of absorption. The quantification of the ^{13}C 22:6n-3 bound to albumin, done in rats having absorbed the tracer labeled at 7.72 atom %, shows that before 12 h post-ingestion, ^{13}C 22:6n-3 was mostly present in unesterified form, but by 12 h, lyso-PC transported higher concentration of ^{13}C 22:6n-3. It has been shown that albumin stimulates the release of lyso-PC from isolated perfused rat liver and cultured hepatocytes (17). These hepatic lysoPC are mostly unsaturated which is different from the saturated lysoPC synthesized by LCAT in plasma. A physiological function of the lysoPC release from the liver seems to be the supply of extrahepatic tissues with choline and unsaturated fatty acids (18). The present study shows a quantitatively important synthesis of ^{13}C 22:6n-3-lysoPC *in vivo*, which could be a potential source of 22:6n-3 redistribution to tissues. It is generally admitted that the brain, which appears to contain little lipoprotein lipase, does not absorb TG readily, but that the classical route for its fatty acid supply would be the fatty acids bound to albumin (19). However, Anderson *et al.* (20) has recently reported that the developing rat brain can incorporate chylomicron fatty acids; other possible forms of supply, such as lyso-PC, have also been suggested (18,21). Our time course shows that the brain ^{13}C 22:6n-3 uptake into PC and PE was not maximal at 12 h when the labeling in plasma VLDL/Chyl-TG and unesterified fatty acids had already dropped to a minimal plateau value. The uptake linearly increased until three days after ingestion, suggesting other supply forms, such as ^{13}C-22:6n-3-lyso-PC, the concentration of which plateauing after 6 h. These observations are supported by recent work reporting that ^{3}H-22:6n-3 brain uptake was higher in young rats injected with ^{3}H-22:6n-3-lyso-PC than with unesterified 3H-22:6n-3 (22).

In humans, the rapid ^{13}C 22:6n-3 incorporation into VLDL/Chyl-TG was accompanied by the concomitant appearance of ^{13}C 22:6n-3 in LDL-TG, with a maximal δ^{13}C‰ value at 2 h. The maximal δ^{13}C‰ values of VLDL/Chyl-TG

TABLE 1
The Retroconversion of ^{13}C 22:6n-3 in Rat and Human[a]

	Rat (ng/mL plasma)		Human (ng/mL plasma)	
^{13}C 22:6n-3	1002 ± 192		1190 ± 651	
^{13}C 22:5n-3	17.1 ± 4.4	(1.7%)	6.92 ± 3.18	(0.58%)
^{13}C 20:5n-3	69.6 ± 15.2	(6.9%)	4.69 ± 4.98	(0.39%)
		(8.6%)		(0.97%)

[a]The retroconversion of ^{13}C 22:6n-3 was calculated by summing the amounts of ^{13}C 22:5n-3 and ^{13}C 20:5n-3 measured in plasma phospholipids, triglycerides, and sterol esters, 3 h after the ingestion of the tracer. Numbers in brackets represent the percentage of ^{13}C 22:6n-3 metabolized in ^{13}C 22:5n-3 or ^{13}C 20:5n-3. Results are the mean ± SEM of 3–4 rats and the means ± SD of three human subjects.

and LDL-TG was compatible with the precursor-product relationship between these fractions and shows the rapid synthesis of LDL from VLDL by degradation of TG and some PL (23). The maximal $\delta^{13}C‰$ value in HDL-TG was observed at 6 h, indicating that HDL progressively took up TG, probably by combined mechanisms of cholesteryl ester transfer protein activity and lipolysis of TG-rich lipoproteins (24). The ^{13}C 22:6n-3 appearance at the beginning of the time course was more rapid in VLDL/Chyl-PL than in PL from HDL or LDL, in accordance with their known secreted origin from liver and intestine (23). The ^{13}C 22:6n-3 appearance was higher in HDL- and LDL-PE than in the corresponding PC and this might result from a preferential affinity of hepatic ethanolaminephosphotransferase for 1-saturated,2-docosahexaenoyl precursors (25). The decrease of ^{13}C 22:6n-3 appearance observed in HDL- and LDL-PE, at around 18 h might be explained by the hepatic N-methylation of PE which is preferential for 22:6n-3-PE (26) or by the activity of hepatic lipase using PE as a specific substrate (27).^{13}C-22:6n-3-lysoPC bound to albumin was also synthesized, as observed in rat, quickly after ingestion and the $\delta^{13}C‰$ values were always higher than in the corresponding HDL-PC. This excludes a possible origin of ^{13}C 22:6n-3-lysoPC as product of plasma LCAT activity on the saturated fatty acids of HDL-PC and shows that ^{13}C 22:6n-3-lysoPC is mostly synthesized from a highly enriched precursor. The origin of ^{13}C 22:6n-3-lysoPC as liver secretory product is well in accordance with the previous observation that lysoPC produced by perfusion of rat livers is predominantly unsaturated (17).

The appearance of ^{13}C 22:6n-3 in platelet PC was rapid and reached the maximal plateau $\delta^{13}C‰$ values at around 6 h after the tracer ingestion during the phase of maximal plasma circulation of unesterified ^{13}C 22:6n-3 bound to albumin. It is known that blood platelets exchange *in vitro* their PL fatty acids with medium fatty acids bound to albumin by a acylation/deacylation pathway, the Lands pathway, although the importance of this metabolism has not been proved *in vivo* (28). The present observation shows that platelets continuously exchange their PC fatty acids with plasma fatty acids during their circulating life span and proves that 22:6n-3 is a substrate for the Lands pathway *in vivo*.

Finally, the quantification of ^{13}C 22:5n-3 and ^{13}C 20:5n-3 formed by retroconversion at 3 h, time point of maximal appearance of these fatty acids, showed that the tracer circulated mostly as ^{13}C 22:6n-3, although the retroconversion was higher in rat than in human. Whether the latter difference was due to species specificity or resulted from the endogenous amounts of 22:6n-3 in plasma lipids, which is higher in rat than in human, remains to be determined.

Synthesis of Fat in Response to Alterations in Diet: Insights from New Stable Isotope Methodologies

Marc K. Hellerstein*

ABSTRACT: Synthesis of fatty acids, or *de novo* lipogenesis (DNL), is an intensively researched metabolic pathway whose functional significance and metabolic role have nevertheless remained uncertain. Methodologic problems that limited previous investigations of DNL *in vivo* and recent methodologic advances that address these problems are discussed here. In particular, deuterated water incorporation and mass isotopomer distribution analysis techniques are described. Recent experimental results in humans based on these techniques are reviewed, emphasizing dietary and hormonal factors that modulate DNL and quantitative significance of DNL under various conditions, including carbohydrate overfeeding. The somewhat surprising finding that DNL appears not to be a quantitatively major pathway even under conditions of surplus carbohydrate energy intake, at least in normal adults on typical Western diets, is discussed in depth. Nutritional and metabolic implications of these results are also noted, and some speculations on possible functional roles of DNL in normal physiology and disease states are presented in this context. In summary, methodologic advances have added to our understanding of DNL and its regulation, but many questions concerning quantitation and function remain unanswered.

Lipids 31, S-117–S-125 (1996).

The enzymatic machinery for endogenous synthesis of fatty acids (FA) from acetate subunits is present in microbes, plants, and animals. Many biochemists have devoted their careers to studying genes and proteins involved in this pathway, also termed *de novo* lipogenesis (DNL). Nevertheless, a central functional question has remained unanswered: How much DNL actually occurs in organisms that can also ingest exogenous fats? A widely held concept is that DNL serves as a disposal route for surplus nonfat calories, especially carbohydrates (CHO) and ethanol, into the storage pool of body fat. This model of DNL as an overflow valve within the cellular or organismal energy economy has been difficult to evaluate because reliable techniques for measuring true rates and metabolic sources of DNL in living organisms until recently had not been available. Over the past three or four years, however, two methods have been developed that allow direct and accurate measurement of DNL in humans: mass isotopomer distribution analysis (MIDA) and deuterated water incorporation. A somewhat surprising experimental result has emerged, based on these methods—namely, that DNL is not a quantitatively important pathway under most circumstances in humans. These findings make the functions of DNL less certain, but potentially more interesting.

Here I review recent advances related to measurement and physiologic roles of DNL. First, I discuss the central methodologic problem that had to be resolved for measurement of DNL with isotopes (labeling of the intracellular true precursor pool) and how MIDA and ^2H_2O incorporation resolved this problem. Then I describe recent investigations using MIDA to measure DNL in humans under a variety of conditions, and I conclude with a discussion of the possible functions of DNL.

Overview of DNL as a pathway. Several features of DNL must be noted when considering the synthesis of FA as an integrated pathway rather than as a series of component enzymes. The first point is the thermogenic cost. Conversion of CHO to FA prior to oxidation dissipates an estimated 28% of the energy available to the organism if the carbohydrates were oxidized directly (1). This high thermogenic cost has variously been considered a reason for the organism to avoid DNL (energy wasteful) or a useful mechanism of thermogenesis (e.g., in brown fat, or to prevent weight gain during CHO overfeeding). The second point is that true DNL implies synthesis from 2-carbon units and should be distinguished from elongation of preformed FA. Though both DNL and elongation involve addition of activated acetate units in the form of malonyl-CoA, the former process produces nonessential FA, by definition, while the latter interacts with essential FA as well. The third aspect to consider is the current enzymologic model of the regulation of DNL. The malonyl-CoA/acetyl-CoA carboxylase (ACC) regulation model of DNL (2–7) is one of the most powerful and unifying of contemporary meta-

bolic hypotheses. The model is that malonyl-CoA concentrations integrate FA oxidation and synthesis (2,3) and prevent concurrent activity of these opposing pathways. Furthermore, malonyl-CoA concentrations are in turn sensitive to CHO-derived metabolites in the cell (oxaloacetate, pyruvate, citrate) and to the activity of the hormonally controlled enzyme ACC (4–7). In this biochemical context, the fourth point is the presumed function of DNL in the cellular and organismal energy economy. Based on its obvious function in plants and single-cell organisms as a route for storage as lipids of excess non-lipid-derived energy, the same function for DNL has been presumed for omnivorous mammals such as humans. Enzymology and molecular genetics of regulation have supported this view in that factors relating to CHO availability (substrates and hormones) regulate activity and synthesis of the enzymes of DNL (8–10). As we see later in the paper, however, quantitative investigations have not supported this as the usual physiologic function of DNL, at least in adults with typical Western diets. Finally, tissue sites of DNL should be noted. Species differences exist regarding relative importance of liver vs. adipose tissue as the major site of DNL. In rodents, adipose DNL may be at least as important as hepatic DNL (11), whereas for humans the general consensus is that liver is the predominant site (12,13). This formulation may not always be correct for humans, however. In addition, other specialized tissues may also perform DNL under certain circumstances, e.g., lactating mammary gland (14).

Measurement of DNL: historical problems. It may seem peculiar that some of the questions just mentioned remain unanswered. Why don't we know more definitively the quantitative importance of DNL, or the tissue site of DNL in humans, or the relation between molecular genetic and physiologic events? The main reason for persistent uncertainty in this field is methodologic: Reliable techniques for measuring true rates and metabolic sources of DNL in living organisms, including humans, had not been available until recently. It is therefore worth discussing in some detail methods used for measuring DNL.

Indirect calorimetry. Indirect calorimetry, or measurement of gas exchange, has been used for many years as an index of DNL (1,15). When nonprotein respiratory quotient (RQ) is >1.0, net DNL is believed to be occurring in the organism or tissue being studied, since the RQ of DNL is well above 1.0, whereas the RQ of CHO, protein, and FA oxidation are 1.0, ~0.83, and 0.70, respectively (1,16). The problems are that this is a nonmechanistic "black-box" measurement based on many assumptions (16) and, more importantly, that it only can measure net DNL rather than the true unidirectional synthesis of FA. If fat is being both oxidized and synthesized from CHO in the organism concurrently, the net RQ becomes 1.0, and indirect calorimetry reports only that CHO oxidation is occurring. Thus, indirect calorimetry cannot exclude DNL/FA oxidation substrate cycles, which may be important in metabolic regulation (17), and indirect calorimetry cannot quantify true flux rates through DNL. Nevertheless, indirect calorimetric measurements have generally indicated that *net* DNL is unusual in humans, even when fed surplus CHO energy in a single meal or for several days (18–22). Unfortunately, these results could not definitively establish rates of DNL.

Isotopic methods. Dynamic biochemical processes, such as DNL, are most appropriately measured by use of isotopes. Administration of labeled precursors allows newly synthesized molecules to be identified over an experimentally defined time period and permits the relationships among regulatory factors, specific metabolic precursors, and chemical fluxes to be quantified. Measurement of any metabolic process that involves polymerization biosynthesis (combination of repeating monomeric subunits into a polymer) has a fundamental requirement, however (23,24). It is necessary not only to measure how much of the labeled substrate is converted to the polymer of interest, but also to measure the degree of labeling of the true intracellular precursor (the monomeric pool from which the polymer is synthesized). For DNL, the biosynthetic precursor is cytosolic acetyl-CoA (Fig. 1A). How to gain access to the labeling (specific activity or enrichment) of the lipogenic acetyl-CoA pool has presented a long-standing problem for measurement of DNL. The acetyl-CoA pool is particularly complex, in that there are numerous potential metabolic sources of acetyl-CoA whose input varies in a regulated manner according to metabolic conditions. Moreover, cellular acetyl-CoA pools used for different metabolic pathways are compartmentalized and inhomogeneous. For example, acetyl-CoA for hepatic ketogenesis exhibits different labeling than acetyl-CoA for tricarboxylic acid cycle, lipogenesis, and cholesterogenesis in liver (25). It is therefore not possible to infer how much of a labeled substrate has actually entered the lipogenic acetyl-CoA pool relative to unlabeled substrates, or to use surrogate measures of acetyl-CoA (e.g., ketone bodies) to represent the true precursor pool for DNL (26).

The older literature attempting to measure lipid synthesis from ^{14}C-labeled acetate in fact represents an excellent example of the general methodologic principle concerning the importance of measuring precursor pool-specific activity. Several early investigators concluded that insulin plus glucose inhibits cholesterogenesis by hepatocytes, based on lower incorporation of ^{14}C-acetate into cholesterol. It is now clear that these conclusions were entirely wrong because dilution of acetyl-CoA by unlabeled glucose (from activation of glycolysis and pyruvate dehydrogenase activity by insulin) was not accounted for. Cholesterogenesis was in fact stimulated, although total label incorporation was reduced, as would have been apparent if the precursor specific activity had been measured.

An experimental solution to the problem of the lipogenic precursor pool: labeled water incorporation. Awareness of the precursor pool problem 30 years ago led to the development of the $^{3}H_2O$ incorporation technique for measuring DNL and cholesterogenesis (27). This approach solves the problem of the precursor pool by bypassing it. Instead of labeling lipids with a traditional labeled metabolite, a labeled cofactor (H_2O that exchanges with NADPH) is used. Because water mixes freely across almost all biological membranes,

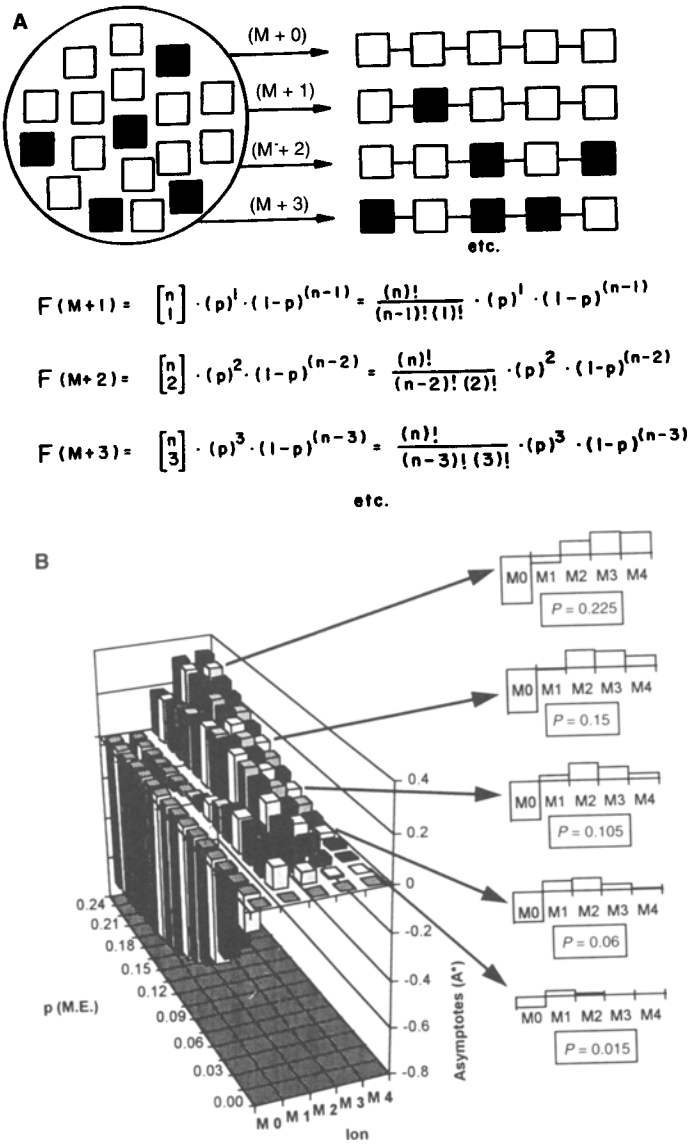

FIG. 1. A) Model of the relationship between isotope enrichment of the monomeric subunits in a precursor pool and the abundance of mass isotopomer species in its polymeric biosynthetic product. Frequency (f) of each isotopomeric species containing *x* labeled subunits [■] out of a total of *n* subunits is calculated from the probability (*p*) that each precursor subunit is labeled, according to the binomial-expansion (shown) (35). B) Three-dimensional histogram showing the effect of varying acetyl-CoA precursor pool enrichment (*p*) on the pattern of mass isotopomer enrichments in a polymer composed repeating acetate submits, in this example, cholesterol. The excess fractional abundances of M_0- to M_4-cholesterol isotopomers from [2-^{13}C]-acetate label are shown. Each cross-sectional slice shown represents the isotopomer pattern characteristic of a particular value of *p*. By analysis of the isotopomer pattern, it is therefore possible to infer the value of *P* (34).

isotopic compartmentalization is considered unlikely, and the specific activity of any body water pool can be used to represent the specific activity of water at the site of synthesis. More recently, ^2H_2O incorporation was pioneered by Jones *et al.* (28–31) for measuring lipid synthesis in humans. Although long considered the gold standard for lipid synthesis, labeled water-incorporation methods are based on a number of assumptions and nonmeasured parameters that may compromise interpretability of results, particularly in human subjects.

Hydrogen is in fact incorporated into lipids both from NADPH and H_2O itself. It is therefore necessary to choose a hydrogen:carbon (H:C) ratio for a newly synthesized lipid molecule that reflects the proportion of H atoms in NADPH that are in equilibrium with cellular water. Unfortunately, the proportion of NADPH hydrogen atoms that derive from water is variable, according to the metabolic sources of NADPH in the cell at a particular time—pentose phosphate pathway, malic enzyme, and so forth. (31). Administration of ethanol, for example, changes the H:C ratio (32). Techniques for estimating the H:C ratio experimentally have also been problematic. Early techniques used the ^{14}C-specific activity of cellular ketone bodies to represent true ^{14}C-acetyl–CoA specific activity (33) and to calculate H:C incorporation ratios. It is now clear that this approach is flawed, since cellular acetyl-CoA pools are highly compartmentalized and differentially labeled (25) and since ketone bodies are synthesized in mitochondria; thus these do not even reflect the cytosolic acetyl-CoA pool in theory. Despite these concerns, a constant standard value for the H:C ratio based on these early *in vitro* studies has typically been used for studies in whole animals and humans (28–30). A recent study using a more rigorous technique for directly measuring the H:C ratio in cholesterol (34), for example found that the ratio was quite variable, ranging from 20 to 30, in contrast to the constant value of 22 typically assumed by researchers. A significant overestimation of cholesterol synthesis would occur if a value of 22 is used for H:C in cholesterol when the true number is 27 or 30. The same considerations apply for DNL as for cholesterol synthesis.

Nevertheless, ^2H_2O incorporation has provided one technique for measuring DNL in humans that makes an attempt to define the true precursor isotope enrichment. Using this approach, Jones *et al.* (28–31) have investigated effects of diet composition and temporal patterns on FA synthesis.

Another experimental solution to the precursor pool problem: mass isotopomer distribution analysis (MIDA). A more recent solution has been developed for measuring polymerization biosynthesis and the true precursor pool, based on the principle of combinatorial probabilities (34–37). Mass isotopomer distribution analysis (MIDA) uses nonradioactive (stable) isotopes with quantitative mass spectrometry. The basic principle of MIDA is that the isotope distribution or labeling pattern of a polymer synthesized from an isotopically perturbed monomeric precursor pool conforms to the binomial (or multinomial) expansion (Fig. 1). The proportion of unlabeled, single-labeled, double-labeled (and so forth) molecular species of a polymer is a function of the probability that each precursor subunit was isotopically labeled (*p*) and the fraction of newly synthesized polymers present (dilution of newly synthesized polymers by preexisting natural abundance molecules). Calculations are somewhat more complex

than analyzing a simple binomial distribution, because carbon in nature contains ^{13}C at an abundance of approximately 1.09% (34); one must therefore calculate the difference between natural and isotopically perturbed distributions (34,36). It can be shown mathematically (34,36), however, that the internal relationship between mass isotopomers (e.g., the ratio between single-labeled and double-labeled molecules) is uniquely determined by p, the true precursor enrichment, independent of dilution of the polymer by unlabeled molecules (Fig. 1B). One can therefore calculate p from the isotope pattern in the polymer. Alternatively, a matrix correction for natural abundance contribution to the labeling pattern (40) or nonlinear best-fit regression equations (41) can be used to calculate p. Once p is known, it is a simple matter to calculate fractional synthesis (f), according to the standard precursor/product relationship (34,36). MIDA and analogous combinatorial probability methods have been used for measuring endogenous synthesis of FA (35–38,42,44), cholesterol (38,45), gluconeogenesis (39), glyconeogenesis (39,46), protein synthesis (47,48) and bile acid synthesis (49) [Kuipers, F., Bandsma, R., Neese, R., and Hellerstein, M.K. (1995) unpublished observation].

MIDA provides a number of advantageous theoretical and practical features for measuring DNL. First, there can be no disputation as to whether the correct acetyl-CoA pool was isolated for the particular lipid product of interest, since calculation is based on the lipid molecule itself. Acetate units in a molecule itself obviously reflect the acetyl-CoA pool from which the molecule was synthesized. Second, metabolic contribution to the lipogenic acetyl-CoA pool from various substrates (glucose, acetate, ethanol, and so forth) can be measured (38,44). Also, precursor pools for synthesis of different lipids can be compared, to determine, for example, whether cholesterol and FA derive from the same precursor pool (38) and thus might compete for substrate, whether *de novo* and chain-elongated FA share a common acetyl-CoA pool (35), or whether the metabolic source of different lipids varies according to physiologic conditions [Kuipers, F., Bandsma, R., Neese, R., and Hellerstein, M.K. (1995) unpublished observation]. Higher-order polymers can also be studied by MIDA; triglycerides can in principle be analyzed as polymers of palmitoyl-CoA, for example, of glycogen as a polymer or glucose subunits. Finally, from the analytic perspective, MIDA requires only a single biochemical isolation and measurement step, performed on the polymer of interest itself. The need for isolating putative biochemical precursors (cellular acetyl-CoA, triosephosphate, and so forth) is obviated. For secreted polymers, MIDA is therefore completely noninvasive (no tissue sample is required); for retained polymers, it is still simpler and less laborious than biochemical isolation of a precursor molecule.

In summary, there now exist two techniques for measuring DNL in humans: MIDA and deuterated water incorporation. This represents significant progress, since only a few years ago no rigorous methods were available. Both techniques use stable isotopes with mass spectrometry, thereby avoiding exposure to radioactivity. MIDA possesses certain advantages over water-incorporation techniques, particularly the ability to characterize metabolic behavior of the intracellular precursor pool (sources, fates, turnover, compartments, and so forth) and freedom from reliance on unmeasured correction factors (the H:C ratio assumed for water-incorporation calculations).

DNL in humans on standard Western diets. Based on these methodologic advances, hepatic DNL has been measured in humans under a variety of experimental conditions. We (35) first measured hepatic DNL in normal men (nonobese, nondiabetic, not overfed, on their standard *ad libitum* diets). The fraction of circulating very low density lipoprotein (VLDL)-palmitate and stearate derived from DNL after a 16-h infusion of [1-^{13}C]-acetate was 1–2% fasted and <5% after 8 h of feeding, whether with a food meal, intravenous glucose (at 7–10 mg/kg/min), or an oral liquid formula (at 7–10 mg CHO/kg/min). Total hepatic DNL was therefore <1 g palmitate per day, a trivial contribution in comparison to typical dietary fat intake (100 g/day or more). Jones and Schoeller (28) have presented a similar estimate of DNL (<2 g/day) using ^2H_2O incorporation. These results support previous conclusions from indirect calorimetry (18–22) and comparison of adipose tissue to diet FA composition (49) that DNL is not an active pathway under usual conditions on a modern (high-fat) diet.

We then measured DNL in young women and obese men (38). Although a significant menstrual cycle variation was observed in women, with three-fold higher values of fractional DNL in the follicular phase compared to the luteal phase, the calculated fat burden imposed by DNL per year was small (a couple of pounds) in comparison to the dietary fat burden (about 100 pounds a year). It is therefore unlikely that DNL explains body-composition differences between men and women. DNL was also slightly elevated in obese, hyperinsulinemic men (38), but again could not account for body-composition differences.

Effects of dietary CHO manipulations. Are there any dietary circumstances where DNL is substantially increased? Schwarz *et al.* (50,51) have measured the effects of oral fructose on DNL. When given at equicaloric doses as glucose (7 mg/kg/lean tissue/min for 6 h), fructose caused an almost twenty-fold increase in fractional DNL above fasting values, whereas glucose had almost no effect. Close to 30% of circulating triacylglycerol (TG)-palmitate came from DNL after this rather moderate dose of fructose. Even so, only a small proportion of the fructose load was converted to fat (less than 5%). Hudgins *et al.* (52,53) (Rockefeller University) have studied DNL in normal subjects placed on very-low-fat/high-CHO eucaloric liquid formula diets (10% fat, 70% CHO) for 25 days under metabolic ward conditions. Fractional DNL measured by MIDA increased to about 20% (fasted) and 30% (fed). A nonisotopic approach (dilution of VLDL-TG 18:2 relative to dietary and adipose FA 18:2, which were matched in the study) confirmed a substantial contribution from DNL to FA in VLDL-TG. Absolute hepatic DNL calculated by MIDA was nevertheless rather modest (e.g., less than 5 or 10 g fat synthesized per day) on these eucaloric, very low fat diets.

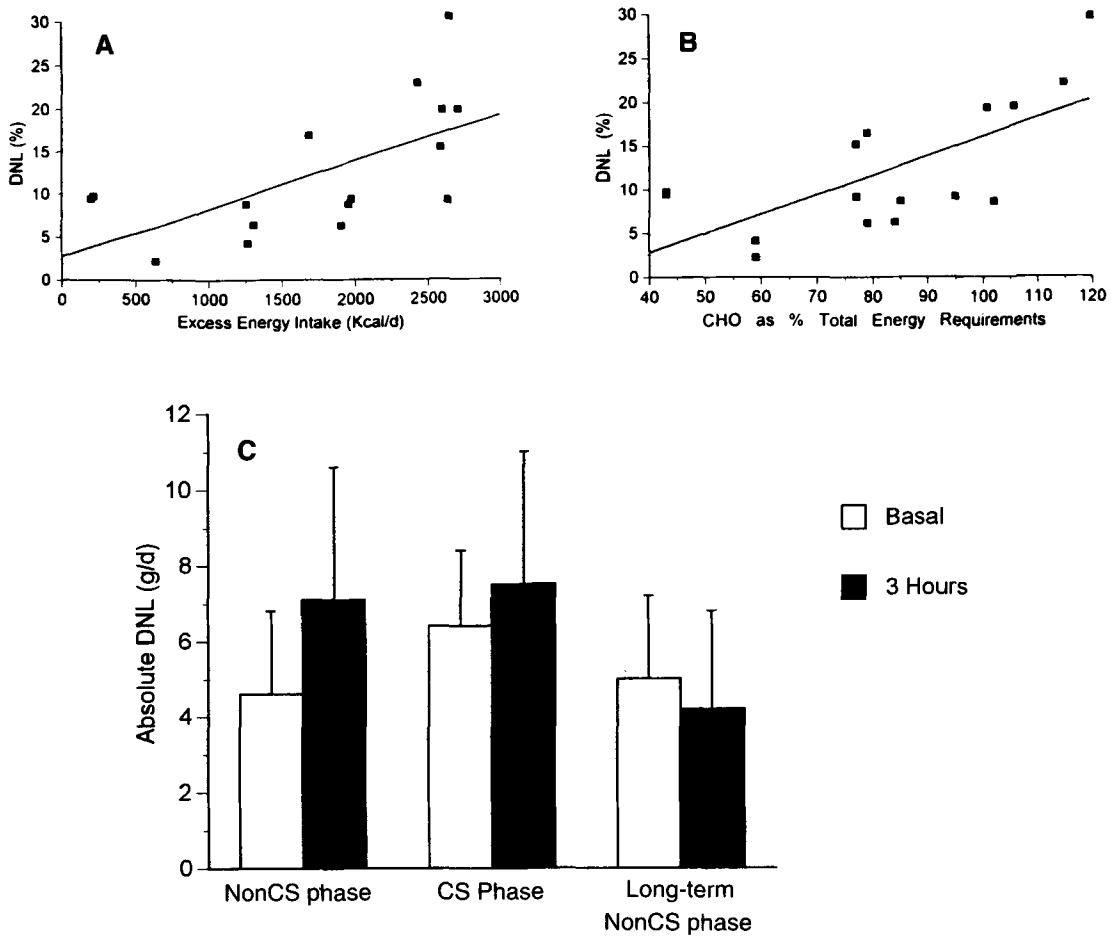

FIG. 2. Effect of *ad libitum* overfeeding on *de novo* lipogenesis (DNL) in humans, and interaction with cessation of cigarette smoking (CS): A) relationship between excess energy intake (kcal/day above estimated daily requirements) and fractional DNL ($r^2 = 0.39$, $P < 0.01$); B) relationship between percent of daily energy requirements provided by carbohydrates (CHO) and fractional DNL ($r^2 = 0.47$, $P < 0.01$); C) absolute DNL during CS and non-CS phases. Basal refers to fasting value. 3 hours refers to value after 3 h of CS of nonsmoking.

Effects of overfeeding. It can legitimately be argued that these conditions do not represent a true test of DNL if the pathway functions as a disposal route for *surplus* CHO energy. It might be necessary to overfeed CHO—that is, provide surplus energy in the form of CHO to the whole body—to induce DNL. It should be noted that previous indirect calorimetric data have generally failed to show much net DNL in overfed humans, at least on a mixed diet, unless ingested at enormous excess (20–22). Our first data in this area came out of a study in which we were asking whether the weight gain after cessation of cigarette smoking (CS) could be due in part to increased DNL. To address this question, Hellerstein *et al.* (43,55) studied smokers under metabolic ward conditions during a week of CS, then a week of no CS, and repeated measurement following four more weeks of abstention from CS. We evaluated two dietary conditions—one in which a constant metabolic diet was given (43) and one in which *ad libitum* intake was allowed (54). DNL was not increased by cessation of CS per se. Several subjects on *ad libitum* diets overate to a remarkable extent, however (54). Some subjects consumed 5,500–6,000 kcal/day, with 3,000–4,000 kcal from CHO. Fractional DNL was substantially increased in the *ad libitum* diet group, and a strong positive correlation was observed between calculated surplus energy intake or CHO energy intake and fractional DNL (Figs. 2A and 2B), implying that a dose–response relationship exists. When absolute DNL was calculated, however, <10 g/day of FA (palmitate and stearate) was synthesized even in subjects with the highest DNL rates (Fig. 2C). Synthesis of new fat was therefore quantitatively minor compared to ingestion of dietary fat (>100 g/day) in these individuals (54).

We have since followed up on these observations by administering defined diets containing up to 50% excess or deficit of energy as CHO or fat for 5-day periods (55). Fractional DNL was found to be a remarkably sensitive index of recent CHO energy intake—increasing more than ten-fold on

surplus CHO and becoming unmeasurably low on CHO-deficient diets, while exhibiting a linear dose–response relationship to CHO intake. DNL did not increase above baseline values on 50% excess *fat* calories. CHO intake over the preceding 5 days could in fact be diagnosed with near 100% sensitivity and specificity by DNL, which therefore represented an objective biomarker of recent CHO energy intake. Nevertheless, absolute hepatic DNL accounted for <5 g of fat synthesized, even on 50% surplus-CHO diets (55).

Several obvious questions are raised by these findings. First, where do excess CHO calories go, if not into DNL? Second, are surplus CHO calories therefore "free"—i.e., do they not contribute to body-fat stores? And third, what may be the function of DNL, if storage of surplus CHO energy as fat is not a quantitatively important process? The answers to the first two questions are clear from our substrate oxidation measurements (43,55) and those of previous investigators (20–22). Addition of CHO in excess to a mixed diet results in preferential oxidation of dietary CHO and sparing of dietary fat from being oxidized. Thus, surplus CHO may not itself be converted to fat, but it nevertheless will result in increased body-fat stores by preventing dietary fat from being oxidized. The answer to the second question is therefore no, CHO calories are not free. Nonprotein RQ rises to close to 1.0 on surplus CHO intake even after an overnight fast (22,55), indicating nearly complete (>90%) suppression of fat oxidation.

The distinction between excess CHO being converted to fat vs. sparing oxidation of fat is not just a technicality, however, despite the shared consequence of either process on body-fat stores. Attempts to understand or prevent adverse effects of overfeeding depend on establishing the precise metabolic fate and consequences of surplus energy intake. For example, some health-food entrepreneurs have proposed use of an inhibitor of DNL, (-)hydroxycitrate, for treatment of obesity. If this is intended to reduce storage of fat by reducing its synthesis from CHO, our results make it clear that the strategy will not be quantitatively effective. Also, we observed that short-term changes in CHO intake and energy balance exerted striking effects on fasting hepatic glucose production (HGP) in normal humans (55) and patients with non-insulin-dependent diabetes mellitus (NIDDM) (56). Increased HGP accounted for most of the increased CHO oxidation that occurred in the fasted state in subjects who had been overfed CHO for 5 days. Increased fasting HGP therefore serves a metabolic function in the context of a system where surplus CHO energy ingested during the day is not immediately converted to fat for later oxidation at night (i.e., a cyclic system with RQ >1.0 and <1.0 during the day and night, respectively), but instead is stored as liver glycogen, which provides fuel for oxidation at night (a noncyclic system with a steady RQ close to 1.0 during both day and night). Since increased HGP is a major contributing factor to insulin resistance and NIDDM (57), the inability of humans to use the DNL pathway as a disposal route for excess CHO in mixed diets may be an important factor in the etiology of NIDDM.

Studies of overfeeding on mixed diets cannot establish what would happen to DNL if a true surplus of CHO energy were present in the absence of dietary fat—i.e., if a very-low-fat surplus-CHO diet were administered for long enough to saturate the maximal whole body glycogen storage capacity. This experiment has yet to be done under controlled conditions, as will be explained later.

What are the functions of DNL? If DNL does not generally act as a sink for disposal of overflow CHO energy, what then are its functions? There are several possible answers to this question.

(1) DNL has no physiologic functions, but is a vestigial pathway in humans. This seems unlikely a priori, in view of the complex machinery for DNL and the regulation that clearly occurs *in vivo* as well as *in vitro*.

(2) DNL is important *in utero* for embryonic development, but becomes unimportant postnatally when exogenous FA can be ingested and absorbed (i.e., it is a vestigial pathway developmentally). This is an interesting possibility that has some support. The apparently limited ability of FA to cross the placenta combined with enormous lipid demands of the developing fetus (especially for myelination in the central nervous system and deposition of subcutaneous fat during the third trimester of pregnancy) suggest that DNL may be very active *in utero*. One model is that after delivery, ingestion of a high-fat diet (in breast milk) suppresses DNL. This has not been established in humans, however.

Two recent observations provide some indirect evidence on this hypothesis. The first is from a mouse knock-out model (58). Knockout of the gene for apolipoprotein B results in lethality *in utero*. It may be speculated that inability to transport lipid synthesized in the fetal liver to the central nervous system is responsible. The second observation is clinical (Chwals, W., personal communication). Premature infants who are stressed can exhibit remarkably high RQ values (1.10–1.20) when treated with intravenous nutrition, consistent with massive *net* DNL. Perhaps this reflects persistence of the prenatal pattern, in the face of relative energy excess. Both these speculations must be tested experimentally, however.

(3) DNL is important on very-low-fat diets but is unimportant on the unnaturally high-fat modern diet (i.e., is a vestigial pathway culturally). As noted above, DNL is at least qualitatively increased on eucaloric very-low-fat diets in normal adults (52,53). It will be of interest to establish whether large short-term adaptations in DNL do occur in response to day-to-day variations in energy balance in subjects on a very-low-fat diet. If so, DNL may function in the energy balance economy but only if modulation of dietary fat oxidation is not available as a first metabolic option.

(4) DNL is in fact important for storage of surplus CHO energy, but the proper experiment has yet to be carried out. Effects of true CHO energy surplus (CHO in excess of total energy expenditure, for long enough to saturate glycogen stores and in the presence of a low-fat diet) on DNL have not

yet been determined. The simple expedient of replacing fat with CHO in the fuel mixture or expanding whole body glycogen stores would no longer be an option for disposal of surplus CHO energy in this setting. Another possibility to consider is that until now the wrong tissue has been evaluated. Perhaps adipose tissue can become a significant site of DNL under certain circumstances, in which case adipose biopsies for measurement of DNL would be required. Some indirect evidence has been presented that, at least during intravenous feeding of sick patients, adipose DNL may become active [Wolfe, R.R. (1994) personal communication].

(5) DNL serves regulatory roles, perhaps as a signal of CHO availability in tissues. Malonyl-CoA concentrations and perhaps DNL influence fuel selection (FA oxidation vs. reesterification) in liver and muscle (2–4) and secretion of insulin in the pancreatic ß-cell (59). The sensitive qualitative response of DNL to CHO energy balance (55) may therefore influence fat balances not through the input of new FA but by controlling FA oxidation.

(6) DNL is necessary for synthesis of special pools of lipids. The metabolic source of the myristate used for acylation of proteins (60), for example, is not known. Is there a dietary myristate requirement, or is this FA synthesized *de novo*? This will be interesting to establish and is amenable to experimental study using the techniques previously described.

(7) DNL becomes important in specialized tissues or under special conditions. The lactating mammary gland appears to have a very active DNL pathway, at least in animal models (14). The metabolic source of lipids in breast milk of humans has not yet been established, however. Brown fat also may have extremely active DNL, which may be one mechanism of adaptive thermogenesis in this organ (Danforth, E., personal communication). Ob/Ob mice exhibit up to fifty-fold increased DNL (61), although contribution to their increased body-fat stores is not clear.

Does DNL have a role in disease? There are several disease conditions to which DNL might contribute. Some speculations are as follows: (i) hypertriglyceridemia (especially CHO-induced) (64–66), (ii) wasting syndromes [e.g., acquired immune deficiency syndrome (AIDS)] and partitioning of nutrients (42,69–73), (iii) alcoholic liver disease (fatty liver) (68), (iv) membrane FA composition (e.g., insulin resistance) (75). Hypertriglyceridemia, especially in response to high-CHO diets (62–64) may be influenced by DNL either directly (through addition of FA to VLDL-TG) or indirectly (through inhibition of tissue FA oxidation and stimulation of hepatic reesterification). Alcoholic liver disease is preceded by fatty infiltration of the liver, which could be at least in part, a consequence of ethanol-stimulated DNL or secondary inhibition of tissue FA oxidation (65,66). Body-composition abnormalities characteristic of patients with wasting in AIDS— preservation of body fat relative to lean body mass (67) and repletion of body fat rather than lean body mass during refeeding (68–70)—may be influenced by DNL. We reported (42) that DNL is paradoxically elevated in patients with weight loss due to AIDS. Moreover, the presence of increased DNL predicted poor lean-tissue response to nutrient supplementation (71), consistent with either a causal role for DNL in altered nutrient partitioning or a role for DNL as a marker of underlying cytokine abnormalities (72). Finally, altered membrane FA composition has been associated with a number of clinical conditions, including insulin resistance (73). If DNL alters qualitative FA composition in susceptible individuals, it could contribute to disease without being an important pathway quantitatively in the whole body.

In conclusion, before a process can be discussed, it must be amenable to measurement. This is now possible for DNL by two methods: MIDA and deuterated water incorporation. Based on these direct isotopic measurement techniques, a somewhat surprising model has emerged of how the human body handles excess CHO energy. DNL does not seem to be a highly traveled pathway, at least in normal adults on typical Western diets. A more detailed understanding of the quantitative contribution from DNL and testing of other potential functions of DNL are required. These remaining areas of uncertainty should now be accessible to experimental analysis, however, based on the recent methodologic advances.

ACKNOWLEDGEMENTS

I acknowledge key contributions of some of my collaborators on the studies discussed here, particularly Drs. Richard Neese, Jean-Marc Schwarz, and Cedric Shackleton. The work also could not have been done without the laboratory contributions of Dennis Faix, Ken Wu, and Scott Turner and the careful work of the nurses at San Francisco General Hospital General Clinical Research Center (GCRC). These studies have been partially supported by grants from the National Institutes of Health (NIH) (DK40995), Tobacco-Related Diseases Research Program of the State of California (1RT475), University of California at Berkeley (Biomedical Research Support Grant and College of Natural Resources), American Diabetes Association (Clinical Research Grant), University of California Universitywide Task Force on AIDS (R87-SF091 and R89-SF170), Nora Eccles Treadwell Foundation, and Division of Research Resources of the NIH (GCRC grant RR-00083).

In Vivo ^{13}C Nuclear Magnetic Resonance: Applications and Current Limitations for Noninvasive Assessment of Fatty Acid Status

Stephen C. Cunnane,* Sergei S. Likhodii, and Gerard Moine[1]

Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Canada M5S 1A8

ABSTRACT: As a noninvasive method, *in vivo* ^{13}C nuclear magnetic resonance has potentially important applications in understanding the metabolism of long chain fatty acids in organs of living humans. At present, this methodology is most advanced for research on glucose utilization. However, the main ^{13}C signals visible *in vivo* are from fatty acids in adipose tissue and the olefinic signals can be used to noninvasively estimate adipose tissue content and relative dietary intake of polyunsaturates and monounsaturates. The low natural abundance of ^{13}C improves the utility of this isotope for fatty acid tracer studies. Due to excessive signal broadening, uniform ^{13}C-labelling seems to have limited application in *in vivo* fatty acid studies. Tracer fatty acids with ^{13}C enrichment at a specific carbon position, i.e., [3-^{13}C]γ-linolenate, appear to be the most useful for *in vivo* tracer studies. Development of methods permitting resolution of ^{13}C enrichment in structural lipids of lean tissues will be an important breakthrough which may make human tracer studies feasible and worthwhile.
Lipids 31, S-127–S-130 (1996).

Our aim here is to review the background to *in vivo* ^{13}C nuclear magnetic resonance (NMR) spectroscopy and to describe current efforts to apply this methodology to noninvasive measurement of fatty acid status and metabolism. The purpose of this approach to determining fatty acid metabolism is to address the need for noninvasive methodology applicable to studying organ composition and metabolism, especially in infants. The technical challenges to obtaining meaningful data are significant but the recent availability of isotopically-labelled tracer fatty acids developed specifically for *in vivo* NMR studies has helped make these studies more feasible.

Using naturally abundant ^{13}C, *in vivo* ^{13}C NMR experiments have been done in experimental animals and humans for 15 yr (1–4). This methodology has recently shown very useful application in noninvasively monitoring the metabolism of glucose in both human brain (5) and skeletal muscle (6). Relatively large doses of ^{13}C-glucose are required for these human studies and, as in other clinical investigations, blood samples are taken for routine assays, i.e., glucose and insulin measurements in this case. Otherwise, these experiments are noninvasive and provide information on the time course and route of metabolism of glucose in individual organs. Aside from the importance of the metabolic questions they address, these experiments demonstrate a clear application of *in vivo* ^{13}C NMR in noninvasive studies of glucose metabolism in humans of all ages. The goal in *in vivo* NMR studies of fatty acid metabolism is to have a similar degree of success as has been achieved in the work on glucose metabolism but the impediments are different and perhaps more daunting.

Principles of in vivo *^{13}C NMR. In vivo* ^{13}C NMR methods are well-established in animal and human models and have been in use for at least a decade to monitor glucose metabolism (1–7). For research in humans, a horizontal bore magnet is required and most of these magnets have a clear internal bore of about 1 m. The subject lies prone and the whole body is inserted into the magnet on a sliding bed. Smaller magnets with an internal bore of 15–40 cm have also been used to acquire spectra from the limbs of human subjects (8). For animal models, vertical bore magnets with a field strength of up to 9–10 Tesla are available and have the advantage of much better signal-to-noise than can be achieved at lower field strengths.

Aside from magnetic field strength and surface coil design, three important considerations affect the quality of *in vivo* NMR data: the sensitivity of NMR to detect a particular nucleus and the abundance and mobility of the molecule in question. NMR sensitivity is an inherent feature of the nucleus itself and, for the main nuclei of biological interest, sensitivity is significantly higher for protons and ^{31}P than for ^{13}C. Protons and ^{31}P are both essentially 100% abundant but the NMR-sensitive isotope of carbon (^{13}C) is only about 1.1% abundant. Hence, detection of ^{13}C is considerably more difficult than detection of protons or ^{31}P. The "mobility" of a

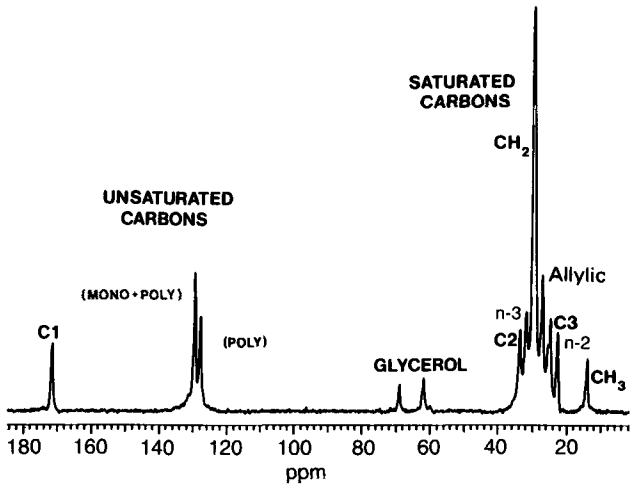

FIG. 1. *In vivo* ^{13}C nuclear magnetic resonance spectrum obtained at 4.7 T. The spectrum is of epididymal adipose tissue in a living rat. The main signal clusters are identified. Reprinted from Reference 9, with permission.

molecule, i.e., its ability to undergo tumbling motion, also determines how easy it is to detect and resolve different molecules by NMR. Molecules in biological matrices are less mobile than those in solution so, even under optimal conditions, *in vivo* NMR always has considerably lower resolution of the available information than can be achieved with samples in solution. Small molecules are more mobile than large molecules so free amino acids are easier to detect *in vivo* than proteins. Fatty acids are mainly deposited in tissues as phospholipids or as triglycerides. Triglycerides are mostly present as liquid droplets and exhibit more mobility than phospholipids which are mostly constrained by the structure of biological membranes. Hence, fatty acids in the free form (unesterified) or esterified into triglycerides are easier to detect *in vivo* than those present in phospholipids.

In vivo *^{13}C NMR of fatty acids.* The main ^{13}C NMR signals visible in *in vivo* spectra are from fatty acids in subcutaneous fat (Fig. 1). ^{13}C NMR signals from fatty acids cluster in five main regions: (i) the carboxyls around 175 ppm, (ii) the olefinic carbons around 130 ppm, (iii) signals for glycerol at 62 and 69 ppm, (iv) the aliphatic carbons between 20 and 35 ppm and (v) the terminal methyl carbons at 14 ppm (Fig. 1). In adipose tissue, there is little detectable influence of different dietary fatty acids on carboxyl, glycerol, aliphatic, or terminal methyl carbon resonances, but the olefinic region is sensitive to differences in fatty acid unsaturation (9,10). *In vivo*, the olefinic region consists of a pair of peaks centered at about 130 to 128 ppm. These two peaks overlap considerably, but it is generally possible to detect the break between them which is necessary to derive information about the degree of fatty acid unsaturation in the adipose tissue.

In theory, all unsaturated fatty acids contribute to these two peaks but in practice, adipose tissue is rich in oleate (18:1n-9) and linoleate and the total of the other unsaturated fatty acids rarely accounts for more than 5–8% of adipose tissue fatty acids (11). The "outer" olefinic carbons of linoleate (C_9,C_{13}) give rise to most of the signal at 128 ppm while the "inner" olefinic carbons of linoleate (C_{10},C_{12}) plus the two unsaturated carbons of oleate (C_9,C_{10}) both contribute to the signal at 130 ppm. On the assumption that these two peaks are due only to the four unsaturated carbons in linoleate and the two unsaturated carbons in monounsaturates represented by oleate, linoleate would contribute equally to both peaks and, therefore, subtraction of the integrated peak area at 128 ppm from that at 130 ppm gives the relative area for monounsaturates by difference. Hence, an estimate of the ratio of polyunsaturated fatty acids (PUFA) to monounsaturates in adipose tissue can be determined noninvasively (9).

In practice, the only significant exception to the assumption that the olefinic region of *in vivo* spectra of adipose tissue arises from linoleate and monounsaturates comes from the two main PUFA in fish—eicosapentaenoate (20:5n-3) and docosahexaenoate (22:6n-3). These two fatty acids are highly unsaturated and, if present in adipose tissue at > 2–3%, contribute significantly to the "inner" olefinic signals at 128 ppm (9). However, these two fatty acids are not normally consumed in high enough amounts to accumulate significantly in human adipose tissue (11) so, under usual dietary conditions, they would generally have a minor influence on the ratio of PUFA to monounsaturates.

The responsiveness of the olefinic region in *in vivo* ^{13}C NMR spectra to dietary fat (9) and the knowledge that human adipose tissue composition is directly related to fatty acid intake (12) and not to fatty acid synthesis (13) has stimulated interest in determining PUFA intake based on the relative peak areas at 128 and 130 ppm. Cystic fibrosis (8) and vegetarianism (14) have both been shown to significantly alter the PUFA/monounsaturate peak ratio in ^{13}C NMR spectra of subcutaneous adipose tissue obtained noninvasively. In each case, comparisons were made with the fatty acid composition of adipose tissue determined by gas chromatography so the level of confidence in the *in vivo* NMR is good. These are important steps towards applying ^{13}C NMR in subjects from which it is becoming ethically less acceptable to sample blood or adipose tissue, i.e., babies.

Fatty acids in lean tissues are mostly in relatively immobile phospholipids and, therefore, organs such as liver generate much less overall signal than the adipose tissue which comes between the liver and the surface coil. Isolation of samples of lean tissues clearly shows that most abdominal tissues or organs normally have little or no NMR-visible fatty acids signals (9). In principle, this could work out to be an advantage for studies of fatty acid metabolism because if the intensity of the adipose tissue signal could be reduced or eliminated, a low natural abundance ^{13}C NMR signal in the underlying organ of interest would allow one to more easily detect the presence of a tracer fatty acid.

At present, it is not possible to resolve more information from *in vivo* ^{13}C NMR spectra obtained in human subjects than total PUFA and their ratio to monounsaturates and saturates in subcutaneous adipose tissue. Even though there appears to be a good correlation between data derived from

NMR spectra and measurements of fatty acids in needle biopsies of adipose tissue by gas ghromatography, the *in vivo* NMR approach provides relatively crude information. Very few centers have access to NMR spectrometer equipped for *in vivo* ^{13}C studies in humans and, in the infant population in which this method theoretically and ethically has the most application, reduction of data quality due to proton coupling and movement of the patient reduces its usefulness. If it is ethically acceptable to obtain a blood sample for diagnostic purposes in appropriate cases, it should also be acceptable to obtain a needle biopsy of 5–20 mg of fat which can then be analysed by gas chromatography to yield far more useful and detailed information than a crude ratio of the three main groups of fatty acids (11).

Tracing fatty acid metabolism. Using ^{13}C as a tracer isotope takes advantage of the wide signal dispersion in carbon spectra and the numerous different bond environments (carboxyl, olefinic, aliphatic, allylic, doubly allylic) in different fatty acids and lipids thereby potentially providing extensive detail about the "molecular" location of ^{13}C enrichment. This has been clearly demonstrated in *in vitro* NMR studies of ^{13}C-PUFA metabolism (1,2,15) but *in vivo* studies are less advanced. In our experience, the quality of ^{13}C enrichment data obtained *in vivo* is dependent on the type of ^{13}C tracer used.

If the tracer is uniformly (U) labelled, ^{13}C mass/dose could be as much as 18–20 times that of a tracer labelled with ^{13}C at a specific carbon. This may enhance overall detection or permit lower doses to be used. Unlike labelling at a single carbon (typically C-1), this also means that the metabolism of the entire molecule can be traced rather than assuming one tracer carbon, i.e., C-1, represents the metabolism of the entire molecule. ^{13}C-^{13}C coupling is not a significant problem if only one carbon (or two adjacent carbon sites) is enriched, but with U-^{13}C labelling this is a problem *in vivo* because the resulting multiplets overlap sufficiently so that the molecular location of the ^{13}C is harder to determine accurately. This is especially true in lean tissues such as brain in which the fatty acid signals are poorly resolved to start with due to their motion being constrained within membranes. Furthermore, in the case of using an orally-dosed ^{13}C PUFA precursor in suckling rats, the ^{13}C is widely dispersed in brain lipid components such as arachidonate, cholesterol, palmitate (16:0) and oleate (18:1n-9) (2). This generalized incorporation of ^{13}C into brain lipids is readily detected *in vivo* by the improved signal/noise from the presence of the additional ^{13}C in brain lipids (2). However, the ^{13}C labelling of specific carbons of brain cholesterol is not visible *in vivo* even though it is well-resolved by *in vitro* NMR techniques (15) and is quantitatively significant (2). Thus, in our limited experience, it is not yet possible to use *in vivo* NMR to determine the specific lipid or fatty acid location of a U-^{13}C fatty acid tracer in a lean tissue without subsequent lipid extraction and further analysis *in vitro*.

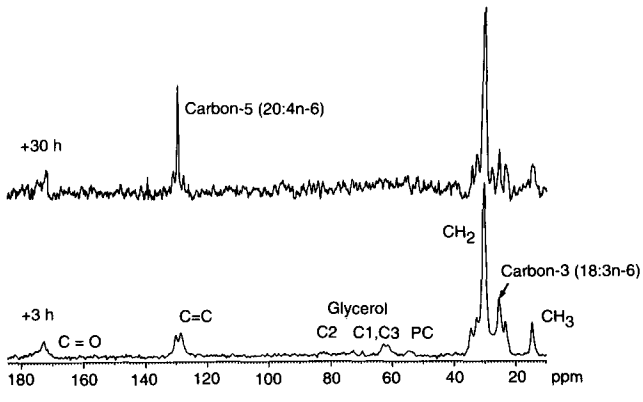

FIG. 2. *In vivo* ^{13}C nuclear magnetic resonance spectra of the abdominal region of living rat pups (10 d old) acquired at 7.4 T in a vertical bore magnet. Control spectra are comparable to those shown in Figure 1. The C-3 region (24.7 ppm) is seen to increase in these spectra obtained 3–30 h after dosing with [3-^{13}C]γ-linolenate. At 3 h post-dosing, no change is visible in the olefinic region where C-5 of arachidonate is located. By 30 h, a significant amount of the γ-linolenate has been metabolized to arachidonate and the ^{13}C-enriched carbon (originally C-3) has become an olefinic carbon and causes the resulting increase in the signal at 128.9 ppm.

Locating the ^{13}C at a specific carbon in the fatty acid tracer greatly improves the chance of seeing the actual molecular site of labelling *in vivo*. If the ^{13}C-enriched carbon is at a CH_2 position which is then desaturated to an olefinic carbon during the fatty acid's metabolism, the extent of that metabolism is, in principle, detectable *in vivo*. For example, using *in vivo* ^{13}C NMR, [3-^{13}C]γ-linolenate (18:3n-6) is visible in the stomach and liver of the suckling rat (Fig. 2). Since the ^{13}C moves from C-3 to C-5 (an olefinic carbon) when the γ-linolenate gets metabolized to arachidonate, the resulting shift in resonance is considerable and is visible *in vivo*. Thus, it is possible to use ^{13}C-labelled fatty acids which are labelled at appropriate and specific carbons to noninvasively trace metabolism of the precursor PUFA and its conversion to the main longer chain metabolite, i.e., arachidonate. It is still not yet clear whether only fatty acids present in freely mobile lipids, i.e., free fatty acids or triglycerides, are visible *in vivo*, but these types of experiments should facilitate answering this important question.

Conclusion. The goal of detecting tracer fatty acids or their products in organ lipids of living human subjects by *in vivo* ^{13}C NMR is worthwhile because it represents one of the few approaches by which we can learn how dietary PUFA are utilized in humans and therefore how best to develop therapeutic strategies for their effective application in chronic human disease. Theoretically, this methodology would be particularly useful for understanding the utilization of dietary PUFA in infants because the development of the brain occurs largely in the first two years of life and many infants are still exclusively fed formula milks the composition of which may not be ideal for optimal cognitive and behavioural development. However, at present, the objective of tracing fatty acid metabolism in living human subjects remains elusive. Tracer fatty acids with high ^{13}C-enrichment at a carbon which undergoes desaturation have provided the first clear indication that this methodology is feasible (Fig. 2). This has only been achieved

at high magnetic field strength and in suckling rat pups receiving a relatively large dose of tracer. If new methods can be developed which reduce the background signal from adipose tissue or facilitate extraction of signals in more rigid lipids (phospholipids, cholesterol), the goal of experimentally monitoring fatty acid metabolism in living humans may hopefully be attained.

ABSTRACT: The fractional conversion rates of plasma phospholipid α-linolenic acid (18:3n-3) and linoleic acid (18:2n-6) to docosahexaenoic acid (22:6n-3) and arachidonic acid (20:4n-6), respectively, and the fractional rates of incorporation of 22:6n-3 and 20:4n-6 into plasma phospholipids were determined in 27 healthy 3-wk-old term infants who had received formulas with ~16% of fat as 18:2n-6 and 0.4% (n = 6), 1.0% (n = 11), or 3.2% (n = 10) as 18:3n-3 from birth. The infants were given a single dose of both [U-^{13}C]18:2n-6 and [U-^{13}C]18:3n-3 with a feeding, and blood samples were collected 8, 12, and 24 h afterward for determination of the isotopic enrichments of the [M + 18] isotopomers of plasma phospholipid fatty acids by negative chemical ionization gas chromatography/mass spectrometry. A simple precursor/product compartmental model was used to estimate fractional rates of conversion and incorporation. All infants converted 18:3n-3 to 22:6n-3 and 18:2n-6 to 20:4n-6. Although the fractional rate of conversion of 18:3n-3 to 22:6n-3 did not differ among groups, the fractional rate of incorporation of 22:6n-3 into the plasma phospholipid fraction was greater in infants who received 3.2% vs. 0.4% or 1.0% 18:3n-3 (4.1 ± 2.2 vs. 1.6 ± 1.5 or 2.0 ± 1.0% of the plasma phospholipid 22:6n-3 pool daily). The fractional rate of conversion of 18:2n-6 to 20:4n-6 was less in infants who received the 3.2% 18:3n-3 intake (0.4 ± 0.3% of the plasma phospholipid 18:2n-6 pool daily vs. 1.1 ± 0.7% and 0.8 ± 0.5% in those who received 0.4 and 1.0% 18:3n-3, respectively). The fractional rate of incorporation of 20:4n-6 into plasma phospholipid also was less in the 3.2% vs. the 0.4 and 1.0% 18:3n-3 groups (2.7 ± 1.4% vs. 5.9 ± 2.6 and 4.4 ± 1.7%, respectively, of the plasma phospholipid 20:4n-6 pool daily).
Lipids 31, S-131–S-135 (1996).

The consistent finding of higher docosahexaenoic acid (22:6n-3) and arachidonic acid (20:4n-6) levels in plasma and tissue lipid fractions of infants fed either human milk, which contains these fatty acids, or formulas supplemented with these fatty acids vs. formulas containing only their precursors is frequently interpreted as evidence that infants either cannot convert the precursor essential fatty acids [α-linolenic (18:3n-3) and linoleic acid (18:2n-6)], respectively, to 22:6n-3 and 20:4n-6 or have limited capacities to do so. Recent studies have shown that both term and preterm infants can convert precursors to products (1,2), but whether conversion is adequate to meet the considerable needs of 22:6n-3 and 20:4n-6 by developing tissues remains unknown. Further, while a high intake of either 18:3n-3 or 18:2n-6 relative to the other is known to inhibit desaturation and elongation of the other (3,4), little quantitative information about this issue is available. Recently, we studied effects of 18:3n-3 intake, or the intake ratio of 18:2n-6/18:3n-3, on plasma and erythrocyte fatty acid patterns, growth and visual development of term (5) and preterm infants (6). In a subset of these infants, we also attempted to quantitate fractional rates of conversion of 18:3n-3 to 22:6n-3 and 18:2n-6 to 20:4n-6 as well as fractional rates of incorporation of 22:6n-3 and 20:4n-6 into the plasma phospholipid fraction. Calculated fractional rates of conversion and incorporation of this subset of 3-wk-old term infants who had received 18:2n-6 intakes of 16% of total fat and 18:3n-3 intakes of 0.4, 1, or 3.2% of total fat from birth are reported here.

MATERIALS AND METHODS

Subjects. Twenty-seven term neonates participating in the previously mentioned study (5) and assigned at birth to receive a formula with ~16% of fat as 18:2n-6 and 0.4% (group A, n = 6), 1.0% (group B, n = 11), or 3.2% as 18:3n-3 (group C, n = 10) were selected randomly at the time of initial enrollment to participate in the studies reported here. The three groups were comparable with respect to gestational age, birth weight, head circumference, gender, and ethnic background, as well as age and weight at the time of study. Except for 18:3n-3 content, nutrient contents of the formulas were identical and similar to those of Enfamil® (Mead-Johnson Nutritionals, Evansville, IN), i.e., 9% of energy as protein, 41% as lactose, and 50% as fat. The study was approved by the Institutional Review Boards of Baylor College of Medicine (Houston, TX) and Harris County Hospital District (Houston, TX). Written, informed parental consent was obtained for all infants enrolled.

At 3 wk of age, each infant was given from 25–40 mg/kg of [U-^{13}C]18:2n-6 and 20–25 mg/kg of [U-^{13}C]18:3n-3

methyl esters (95–99% chemical purity, 99% isotopic purity; Martek Biosciences Corp., Columbia, MD). Labeled fatty acids were added to a small aliquot of formula, the mixture was sonicated for 60 min, and the sonicated mixture with labeled fatty acids intact (based on periodic assessments) was fed to the infant immediately by nipple. To minimize loss of labeled fatty acids, additional aliquots of formula were added to the sonication vessel before being fed to the infant.

Blood samples were collected in EDTA tubes 8, 12, and 24 h after administration of the labeled fatty acids; plasma and erythrocytes were separated immediately and stored at −70°C until processed further. Plasma phospholipids were separated as described by Hamilton and Comai (7), and fatty acids of this fraction were derivatized to pentafluorobenzyl esters (8) using 1 mL of 0.1M tetrabutylammonium phosphate as buffer and 400 μL of 0.13 M α-bromo-2,3,4,5,6-pentafluorotoluene in methylene chloride as reagent (80°C for 1 h).

Enrichment of the [M + 18] isotopomers of the pentaflurobenzyl esters was determined by negative chemical ionization gas chromatography/mass spectrometry (Hewlett-Packard 5989 mass spectrometer equipped with a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA), using selected ion monitoring. Samples were eluted on capillary columns, and chromatographic peaks were identified both by comparison of retention times to those of fatty acid standards (Sigma Chemical Co., St. Louis, MO) and by mass determination. Isotopic enrichments (precision, 1–5%) were expressed as tracer/tracee ratios.

A simple precursor/product compartmental model was used to quantitate fractional rates of conversion of plasma phospholipid 18:3n-3 and 18:2n-6, respectively, to 22:6n-3 and 20:4n-6 and fractional rates of incorporation of 22:6n-3 and 20:4n-6 into the plasma phospholipid fraction. Parameters of the compartmental model were computed with the Simulation Analysis and Modeling program (SAAM; University of Washington, Seattle, WA).

In this model (Fig. 1), compartments M_1 and M_2 represent relative concentrations of precursor and product fatty acids in the plasma phospholipid fraction as determined by conventional gas chromatography (9). The decline in precursor enrichment (Fig. 2) secondary to some combination of exchange, oxidation, and/or storage is expressed by the rate constant $k_{0,1}$; that secondary to conversion of the precursor to the longer-chain, more unsaturated product(s) is expressed by the rate constant $k_{2,1}$. Thus, the fractional rate of conversion of the precursor can be calculated as: $k_{2,1}/(k_{0,1} + k_{2,1}) \times 100$. Since the phospholipid content of neither the precursor nor product changes appreciably over the period of study, it is assumed that the fractional rate of incorporation of the product into the plasma phospholipid fraction is equal to its fractional catabolic rate, expressed by the rate constant $k_{0,2}$. The fractional rate of incorporation, of course, is related to the fractional rate of synthesis of the product. All rate constants can be derived from the exponential curves of the decline in precursor enrichment and the increase in product enrichment observed in each infant over the 24-h period of study (Fig. 2). Because behavior of tracer is assumed to be the same as for tracee, the rate constants calculated from changes in enrichment of the labeled precursors and products are assumed to be the same for the total precursor and product pools.

Statistically significant differences among groups ($P < 0.05$) in fractional rates of conversion of precursor to product and incorporation of product into the plasma phospholipid fraction were detected by analysis of variance followed, if indi-

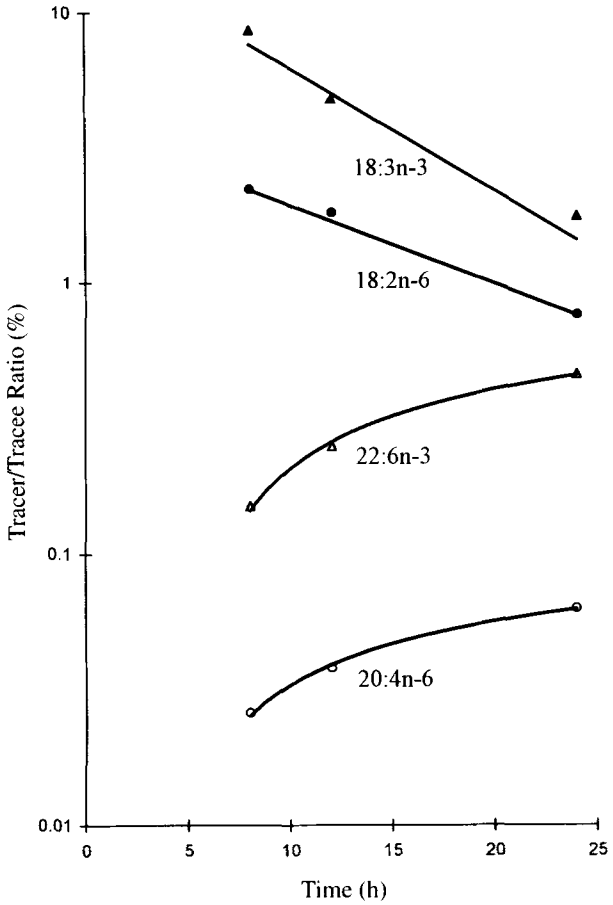

FIG. 2. Tracer/tracee ratios (specific activity) of precursors (18:3n-3 and 18:2n-6) and products (22:6n-3 and 20:4n-6) in plasma phospholipids of a representative three-week-old infant 8, 12, and 24 h after administration of [U-^{13}C]18:2n-6 and [U-^{13}C]18:3n-3 methyl esters (note semilogarithmic scale).

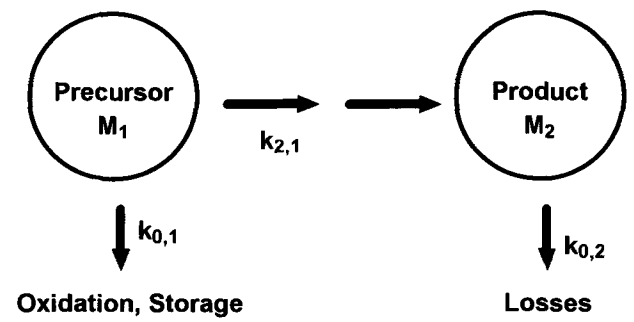

FIG. 1. Precursor/product compartmental model. M_1 and M_2 represent the plasma phospholipid precursor and product pools, respectively. Fractional catabolic rate of the precursor = $k_{0,1} + k_{2,1}$; fractional catabolic rate of the product = fractional rate of incorporation of the product = $k_{0,2}$; fractional conversion rate of the precursor = $k_{2,1}/(k_{0,1} + k_{2,1}) \times 100$.

cated, by a multiple comparison procedure (Fisher's Least Significant Difference).

RESULTS

Figure 2 shows the decline in enrichment of [M + 18] isotopomers of precursors, 18:3n-3 and 18:2n-6, and the increase in enrichment of [M + 18] isotopomers of 22:6n-3 and 20:4n-6 observed in a representative infant. Enrichments of [M + 18] isotopomers of n-3 fatty acids observed in the plasma phospholipid fraction of all infants 8, 12, and 24 h after administration of the labeled precursor are shown in Table 1. Those of the n-6 fatty acids at the same times are shown in Table 2. From these data, it is clear that all infants converted 18:3n-3 to 22:6n-3 and 18:2n-6 to 20:4n-6; however, there was considerable variability within as well as among groups. This variability is not surprising; the precursor enrichment is a function of the dose of precursor administered, the rate and extent of its absorption, as well as the rate and extent of its metabolism and incorporation into the plasma phospholipid fraction, all of which, in turn, affect enrichment of the products. Thus, to quantitate rates of conversion and incorporation, it is necessary to consider, simultaneously, enrichments of both precursors and products, including rates of change in enrichments of each.

[a]n.d. = Not detected.

Mean rate constants and fractional rates of conversion and incorporation of the three groups, as calculated from the model using the data summarized in Tables 1 and 2, are shown in Table 3. Overall, the data from all infants fit the model with a residual error of 10% or less. The mean fractional rate of conversion of 18:3n-3 to 22:6n-3 did not differ significantly among groups. However, since the 18:3n-3 content of the plasma phospholipids (M_1) of group C was 3.7-fold larger than that of group A and 3.3-fold larger than that of group B, the fractional rate of incorporation of 22:6n-3 into the plasma phospholipid fraction was significantly higher in group C vs. groups A and B.

The mean fractional rate of conversion of 18:2n-6 to 20:4n-6 was lowest in group C, which received the highest 18:3n-3 intake. The mean fractional rate of incorporation of 20:4n-6 into the plasma phospholipid fraction also was lowest in group C.

DISCUSSION

The data reported above confirm that 3-wk-old term infants can convert 18:3n-3 and 18:2n-6, respectively, to 22:6n-3 and 20:4n-6. They also provide quantitative estimates of the effect of the dietary intake of 18:3n-3 on fractional rates of conversion of 18:3n-3 to 22:6n-3 and 18:2n-6 to 20:4n-6, as well as the fractional rates of incorporation of 22:6n-3 and 20:4n-6

into the plasma phospholipid fraction. Dietary 18:3n-3 intake did not result in a statistically significant difference in fractional rates of conversion of 18:3n-3 to 22:6n-3. Because the 18:3n-3 content of the plasma phospholipid fraction was highest in the group that received the 3.2% 18:3n-3 intake, however, this group's fractional rate of incorporation of 22:6n-3 into the plasma phospholipid fraction was 2.5-fold greater than that of the group that received only 0.4% of total fat as 18:3n-3. In contrast, the highest vs. the lowest 18:3n-3 intake resulted in a 64% lower fractional rate of conversion of 18:2n-6 to 20:4n-6 and a more than 50% lower fractional rate of incorporation of 20:4n-6 into the plasma phospholipid fraction.

The validity of these conclusions, of course, depends on the validity of the model used to calculate fractional rates of conversion of precursor fatty acids and incorporation of the products into the plasma phospholipid fraction. In addition to the assumptions of steady state and equivalence of labeled and unlabeled pools, the model assumes that mass flow from precursor to product is unidirectional. While none of these assumptions is entirely valid, all are reasonable. More problematic with respect to the physiological relevance of the model are the assumptions that the only source of precursor converted to product is the precursor content of the plasma phospholipid fraction and that the only source of product incorporated into the plasma phospholipid fraction is that converted from the precursor content of this fraction. In addition, since it must be assumed that the plasma phospholipid fraction is part of a central, rapidly miscible pool, it also is assumed that the fatty acid composition of the plasma fraction is representative of all fractions of the central pool. Despite the number of assumptions inherent in the model, all apply equally to each dietary group. Thus, any differences among groups in calculated fractional rates of conversion of precursors to products and/or incorporation of products into the plasma phospholipid fraction are likely to reflect relative differences in fractional rates of conversion and incorporation incident to 18:3n-3 intake.

While the data reported apply strictly to only the plasma phospholipid fraction, it is likely that they are applicable to other fractions as well. For example, in rats, a modest increase in 18:3n-3 intake resulted in a lower 20:4n-6 content in all plasma and tissue lipid fractions (10). Further, in young human adult volunteers, a high intake of 18:2n-6 suppressed incorporation of long-chain polyunsaturated n-3 fatty acids into all plasma lipid fractions (11). Thus, it is very likely that the higher rate of incorporation of 22:6n-3 and the lower rate of incorporation of 20:4n-6 into plasma phospholipids observed in infants who received the highest dietary 18:3n-3 intake occurs also in the plasma triglyceride and cholesterol ester fractions. Interestingly, the mean fractional rate of incorporation of 20:4n-6 into the plasma phospholipid fraction observed in the group of infants who received the lowest 18:3n-3 intake (i.e., 5.9 ± 2.1% SD of the plasma phospholipid 20:4n-6 pool daily) is very similar to "the fractional rate of synthesis" of serum total lipid 20:4n-6 reported by Demmelmair *et al.* (1) in younger infants fed a low 18:3n-3 formula, i.e., 6.2 ± 1.0% SEM of the 20:4n-6 content of the serum total lipid fraction daily.

Unfortunately, neither the data reported here nor elsewhere are sufficient to calculate, or estimate, the amounts of long-chain polyunsaturated fatty acids synthesized daily. With respect to the data reported here, this is largely because there are no data concerning the magnitude of the pool of precursor and product fatty acids of any lipid fraction. This lack of information with respect to the plasma pool size can be remedied, but doing so will not clarify the relationship between plasma and tissue pools. Conversely, it is clear from the data reported here that a dietary 18:3n-3 intake of 3.2 vs. 0.4% of total fat results in a roughly 2.5-fold greater rate of incorporation of 22:6n-3 into the plasma phospholipid fraction and, concurrently, depresses both the rate of conversion of 18:2n-6 to 20:4n-6 and the rate of incorporation of 20:4n-6 into the plasma phospholipid fraction by about the same percentage. These are the first reported data concerning relative rates of conversion of 18:3n-3 and 18:2n-6 to 22:6n-3 and 20:4n-6, respectively, and the relative rates of incorporation of 22:6n-3 and 20:4n-6 into any lipid fraction. Whether these relative rates apply to fractions other than the plasma phospholipid fraction remains to be determined.

Enzyme Replacement and Gene Therapy for Gaucher's Disease

Roscoe O. Brady* **and Norman W. Barton**

National Institute of Neurological Disorders and Stroke, Bethesda, Maryland 20892

ABSTRACT: The lipid storage disorders have long been considered primary candidates for enzyme replacement therapy. This goal has been achieved with a remarkable degree of success in Gaucher's disease. Among the accomplishments that were important to obtain clinical benefit were the development of a large-scale procedure to purify human placental glucocerebrosidase and a method to target this enzyme to lipid-storing macrophages through glycoform modification. In addition, the effectiveness of recombinantly produced macrophage-targeted glucorerebrosidase has recently been demonstrated. Because macrophages originate from stem cells in the bone marrow, ex vivo transduction of these cells with retroviral vectors containing the cDNA for human glucocerebrosidase is being explored for the genetic therapy of Gaucher's disease.
Lipids 31, S-137–S-139 (1996).

Gaucher's disease is the most prevalent of the human lipid-storage disorders. It is caused by excessive accumulation of the sphingoglycolipid glucocerebroside (Fig. 1) in organs and tissues throughout the bodies of patients with this condition. The spleen and liver become greatly enlarged, pulmonary function decreases, and extensive deterioration of the skeleton frequently occurs. Patients are anemic and often have dangerously low platelets, predisposing them to hemorrhages. This disorder is caused by a deficiency of the enzyme glucocerebrosidase, which catalyzes hydrolytic cleavage of glucose from glucocerebroside (1). The product of the reaction, ceramide (*N*-fatty acyl sphingosine), is either reutilized for biosynthesis of larger sphingolipid homologues, such as sphingomyelin (ceramide-phosphocholine), or is further catabolized to sphingosine and free fatty acid. The latter reaction is catalyzed by the enyzme ceramidase. Because the activity of this enzyme in mammalian tissues is much less than that of glucocerebrosidase, it is presumed that reutilization of the ceramide is the preponderant pathway. Most of the glucocerebroside that accumulates in the spleen, liver, and bone marrow is believed to arise from the turnover of membrane components of red and white blood cells. The major neutral lipid in erythrocyte stroma is globoside (Fig. 2). Senescent red blood cells are removed from circulation primarily by macrophages in the spleen and liver. The stromal components are sequentially biodegraded by exoglycosidases. It is believed, however, that most of the glucocerebroside in these organs arises from the turnover of leukocytes (2), where lactosylceramide (Fig. 3) is the major sphingolipid component. In rare Gaucher patients with the infantile (type 2) phenotype with extensive brain involvement, glucocerebroside that accumulates in neurons is believed to be derived from gangliosides that turn over with great rapidity in the neonatal period of life.

Enzyme replacement. Soon after the enzymatic defect in Gaucher's disease was demonstrated, both enzyme and gene (DNA) therapy were proposed for treatment of patients with this disorder (3). To explore the feasibility of enyzme therapy, human placental tissue was used as a source of glucocerebrosidase to minimize the sensitization of patients to an exogenous protein. After a long period of endeavor, a small amount of glucocerebrosidase was isolated that was of sufficient enough purity so that it would not be harmful if injected into patients with Gaucher's disease (4). We discovered that intravenous administration of placental glucocerebrosidase caused a significant reduction in the amount of glucocerebroside that had accumulated in the liver and lowered the concentration of this lipid in the blood from a three- to fourfold elevation to the normal range (5). Of particular note was the fact that the rate of reaccumulation of glucocerebroside, at least in the blood, was quite slow (6). We were not able to scaleup the original enzyme purification method to extend this investigation to more patients. We therefore spent a considerable amount of time developing another isolation procedure based on the high degree of hydrophobicity of glucocerebrosidase (7). An inconsistent reduction of hepatic glucocerebroside, however, was obtained when this preparation was administered to patients.

Most of our data indicates that intravenous infusion of exogenous glucocerebrosidase could reduce accumulated glucocerebroside. We believe that the lack of consistency seen with glucocerebrosidase purified by the hydrophobic chromatography procedure was due to lack of uniform delivery of this enzyme to macrophages where the lipid is stored. This inconsistency was eventually overcome in the following fashion. It was learned that lysosomal enzymes are glycoproteins (8) and that the major portion of glucocerebrosidase resides in these organelles (9). Macrophages were found to have a lectin on their surface that avidly interacts with mannose-terminal glycoconjugates (10). We analyzed the carbohydrate composition of glucocerebrosidase and found four oligosaccharide chains. Three of these exhibited a complex carbohydrate pattern terminating for the most part with *N*-acetylneuraminic acid (11). Mannose was present, but it was internal to molecules of *N*-acetylneuraminic acid, galactose, and *N*-acetylglucosamine (Fig. 4). Several procedures were carried out to enrich the mannose content of glucocerebrosidase (12). The most effective method was the sequential enzymatic cleavage of the three external monosaccharides with exoglycosidases to produce mannose-terminal enzyme. This preparation was much more effectively targeted to macrophages than native glucocerebrosidase (13).

We then began a series of investigations in patients with the macrophage-targeted glucocerebrosidase. We obtained convincing evidence of clinical benefit in a child with Gaucher's disease (14). We then performed a dose-response investigation to determine the quantity of enzyme that caused consistent reduction of stored glucocerebroside in patients (13). Based on the findings in this study, we elected to administer 60 U of macrophage-targeted glucocerebrosidase per kg of body weight every 2 weeks to patients with Gaucher's disease. Twelve patients participated in this clinical efficacy trial. All showed dramatic improvement in their clinical manifestations of Gaucher's disease (Fig. 5) (15). Their hemoglobin levels and platelet counts increased, the size of their enlarged spleens and livers greatly diminished, and impaired pulmonary function and skeletal abnormalities improved. On the basis of these findings, enzyme replacement therapy for patients with Gaucher's disease using macrophage-targeted human placental glucocerebrosidase was approved by the U.S. Food and Drug Administration on April 5, 1991. More than 1,500 patients throughout the world are now benefiting from this treatment.

Glucocerebrosidase was subsequently produced recombinantly in Chinese hamster ovary cells. This enzyme is also targeted to macrophages by the same exoglycosidase procedure described previously. Recombinant glucocerebrosidase is as effective as the placental enzyme for treatment of patients with Gaucher's disease (16). It is expected that this product will eventually completely supplant the use of placental enzyme.

Gene therapy. Because glucocerebroside-storing macrophages arise from stem cells in bone marrow, patients with Gaucher's disease are particularly attractive candidates for gene therapy. Retroviral vectors are commonly used to intro-

duce desired genes into dividing stem and progenitor cells. We therefore developed a construct containing the cDNA for human glucocerebrosidase (Fig. 6). We have shown that transduction of progenitor cells obtained from bone marrow of patients with Gaucher's disease restores glucocerebrosidase activity to a normal level in these cells (17). Long-term expression of human glucocerebrosidase has been documented in mouse macrophages (18). Recently, long-term expression of human glucocerebrosidase has also been demonstrated in nonhuman primates (19). These findings provide a firm basis for gene therapy for patients with Gaucher's disease. National Institutes of Health (NIH) Recombinant DNA Advisory Committee and the U.S. Food and Drug Administration have approved a phase-1 study of retroviral-mediated transfer of human glucocerebrosidase cDNA into hematopoietic stem cells of patients with Gaucher's disease. Both bone marrow and peripheral blood will be used as sources of stem cells. This investigation is expected to be begin promptly. It is anticipated that gene therapy will eventually be the treatment of choice for a number of lipid-storage diseases since, if effective, it will provide a permanent cure for patients with these disorders.

Very Long-Chain Fatty Acids in Diagnosis, Pathogenesis, and Therapy of Peroxisomal Disorders

Hugo W. Moser* and Ann B. Moser

Kennedy Krieger Institute and Departments of Neurology and Pediatrics at Johns Hopkins University, Baltimore, Maryland 21205

ABSTRACT: Abnormally high levels of very long-chain fatty acids (VLCFA) are a feature in nine of the fifteen peroxisomal disorders that have been identified so far. Saturated VLCFA accumulate in X-linked adrenoleukodystrophy, appear to disrupt membrane structure, and may play a role in the pathogenesis of a brain inflammatory response. Dietary therapy initiated when patients are still asymptomatic may be of clinical benefit.
Lipids 31, S-141–S-145 (1996).

Fifteen peroxisomal disorders have now been identified and are listed in Table 1. They are subdivided into two major groups, namely disorders of peroxisome assembly, in which the organelle fails to form normally and multiple peroxisomal functions are defective, and a second category in which defects involve a single peroxisomal protein and structure of the organelle is intact. Peroxisomal proteins are synthesized in free polyribosomes most commonly in their mature form, enter the cytoplasm, and are targeted to the organelle by mechanisms that are beginning to be clarified (1). Complementation analysis (2) indicates that there are at least 11 distinct genetic defects that can disturb these import mechanisms, and mutations have been defined in two of these (2). Ten of these complementation groups are associated with phenotypes that range from the Zellweger syndrome, the most severe form in which psychomotor development is virtually absent and usually leads to death during the first year, to the somewhat milder neonatal adrenoleukodystrophy (NALD) and infantile Refsum disease (IRD), in which the clinical manifestations resemble the Zellweger syndrome, but are somewhat milder, and some patients have reached adulthood. Most patients with the phenotype of rhizomelic chondrodysplasia punctata (RCDP) belong to a single and separate complementation group. X-Linked adrenoleukodystrophy (X-ALD) is the most common peroxisomal disorder. This gene defect involves a peroxisomal membrane protein that appears to be a member of the ATP-binding cassette transporter superfamily (3). Clinical manifestations associated with isolated deficiencies of acyl-CoA oxidase (AOX), bifunctional enzyme (BIF), or thiolase are indistinguishable from those of the Zellweger-NALD-IRD complex (2).

Levels of very long-chain fatty acids (VLCFA) in plasma are increased in the Zellweger syndrome, NALD, IRD, X-ALD, AOX, BIF, and peroxisomal thiolase deficiency, and our laboratory has diagnosed more than 3,000 patients with these disorders. The various disorders can be distinguished by combined appraisal of clinical features, biochemical patterns, and complementation analysis (2). The various disorders have somewhat different patterns of VLCFA excess (Table 2). Additional tests of peroxisomal function are often required for precise diagnosis. VLCFA levels are not increased in RCDP.

There is evidence that VLCFA play a pathogenetic role in several peroxisomal disorders. Pathological manifestations of X-ALD involve mainly the adrenal cortex and the nervous system. While adrenal dysfunction is the result of accumulation of cholesterol esterified with VLCFA, pathogenesis of the nervous system pathology is more complex. Two types of nervous system pathology occur (4). The first type involves part of the axon most distant from the cell body and is associated with a loss of myelin in tracts associated with these axons. It presents clinically as slowly progressive spasticity of the lower

Table 1
Peroxisomal Disorders

Assembly deficiencies	Single peroxisomal enzyme deficiencies
Zellweger syndrome	X-linked adrenoleukodystrophy
NALD[a]	Acyl-CoA oxidase deficiency
Infantile Refsum	Bifunctional enzyme deficiency
Hyperpipecolic acid	Peroxisomal thiolase deficiency
Rhizomelic chondrodysplasia punctata	DHAP[b] alkyl transferase deficiency
	Alkyl DHAP synthase deficiency
	Glutaric aciduria type III
	Classical Refsum disease
	Hyperoxaluria type 1
	Acatalasemia

[a]NALD = Neonatal adrenoleukodystrophy.
[b]DHAP = dihydroxyacetone phosphate.

extremities in the young adult, progresses slowly over decades, and is referred to as adrenomyeloneuropathy (AMN). In the second type, there is rapidly progressive demyelination, which affects mainly parieto-occipital lobes of the brain and spares the axons at least initially. There is intensive perivascular infiltration by T-cells, B-cells, and macrophages and prominent immunoreactivity for cytokines such as tumor necrosis factor in astrocytes and macrophages (4). This type of pathology occurs mainly in young boys and progresses rapidly, often leading to an apparently vegetative state within two years (5). These two highly variant phenotypes often occur within the same family. Segregation analysis suggests action of an autosomal modifier gene (5), which is thought to act by modulating intensity of the brain inflammatory response. Tumor necrosis factor α bioactivity is increased in serum of boys with the rapidly progressive form of X-ALD, but not in patients with AMN (6).

Excess of saturated VLCFA in membranes of X-ALD patients increases microviscosity of red cell membranes (7) and impairs capacity of cultured adrenal cells to respond to adrenocorticotrophic hormone (8). Physical properties of saturated VLCFA, such as hexacosanoic acid (C26:0), differ profoundly from palmitic and stearic acids. Albumin binds only one mole of C26:0, and rate of transfer of C26:0 from model membranes to albumin is 3 to 4 orders slower than that of palmitic acid. Calorimetric studies indicate that excess C26:0 disrupts membrane structure (9). Gradually increasing accumulation of saturated VLCFA may thus cause axonopathy in AMN. Powers *et al.* (4) postulate that in boys with brain inflammatory response, VLCFA excess leads to an additional and different pathological response, namely initiation of a cytokine-mediated inflammatory cascade.

Recent studies in our laboratory suggest that markedly increased levels of VLCFA also play a role in pathogenesis of neurological deficits in the Zellweger syndrome and disorders of peroxisome assembly. Zellweger syndrome patients have a severe and characteristic defect of neuronal migration (10), which is the major cause of the profound mental retardation and intractable seizures associated with these disorders. Because of the multiplicity of biochemical defects that exist in the Zellweger syndrome, it is difficult to pinpoint which of these are the cause of this neuropathological deficit. We have shown recently that a similar neuronal migrational defect existed in a patient with an isolated defect of the peroxisomal BIF (11). Correlational analysis suggests that these neuronal migrational defects occur in patients with plasma levels of C26:0 in excess of 3 μ/ml and suggest that the excess of VLCFA alone plays a role in pathogenesis of the neuronal migration defect (11). An entirely different additional neuropathogenetic mechanism is indicated by the studies of Martinez *et al.* (12), who demonstrated that patients with disorders of peroxisome assembly have severe deficiencies of docosahexaenoic acid. We have confirmed their findings in the study of plasma of 55 patients with various disorders of peroxisome assembly (Table 2).

Studies to determine whether reduction of VLCFA levels is of clinical benefit to patients with peroxisomal disorders are in progress. In patients with X-ALD, administration of a 4:1 mixture of glyceryl trioleate and glyceryl trierucate oil, also referred to as Lorenzo's Oil, combined with a reduced dietary fat intake, normalizes levels of saturated VLCFA in plasma within 4 wk (13). The oil is thought to act by reducing endogenous synthesis of saturated VLCFA by the microsomal elongating system. Administration of the oil also increased the plasma levels of docosahexaenoic acid (DHA) (Table 2). Clinical results have been disappointing in patients who already had neurological symptoms at the time therapy was begun (14). This lack of success in symptomatic patients may be due to the difficulty of reversing neurological damage that has already occurred, as has been the experience with phenylketonuria and congenital hypothyroidism.

Another possible explanation is the recent demonstration that, while considerable amounts of erucic acid were present in the postmortem liver and adipose tissues of patients who had been treated with the oils, levels of this substance in the brain were the same as in untreated patients (15). Administration of the oil thus may not have reduced the endogenous synthesis of saturated VLCFA in brain. Results have been more encouraging in 52 boys with X-ALD in whom dietary therapy was begun while they were still free of symptoms and who have continued on this therapy for a mean of 56 mon. Ten percent of these boys have become disabled (16) as compared to our estimate that this would have occurred in 30–40% of untreated patients. While these results are preliminary, because of the need for longer follow-up and statistical concerns, they are sufficiently encouraging to warrant continuation of the trial, and an international study protocol was initiated at the 1994 meeting of the Society for the Study of Inborn Errors of Metabolism. Diet must be monitored, since it causes a moderate reduction of platelet count in 40% of patients (17), which appears to be correlated with levels of erucic acid in platelets (18). Platelet count increases again when erucic acid intake is eliminated or reduced. Dietary therapy may cause a reduction of levels of DHA in plasma and red blood cells (Table 2), which can usually be restored by supplementation with essential fatty acids. We have also conducted studies of oral administration of DHA in five patients with disorders of peroxisome assembly. Biochemical results of this therapy confirm those presented by Martinez *et al.* (12).

Losses of Arachidonic Acid in Rat Liver After Alcohol Inhalation

Norman Salem, Jr.*, Michelle Reyzer, and John Karanian

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, Rockville, Maryland 20852

ABSTRACT: This paper presents an animal model of alcoholism in which rats were exposed to alcohol by inhalation and were fed a diet that simulated the poor diet of some alcoholics. It is hypothesized that some of the pathophysiological effects of alcohol are related to its effects on essential fatty acid metabolism and composition of vital organs. A diet that contains no 20- and 22-carbon essential fatty acids and has low levels of 18-carbon essential fatty acids was used as a dietary challenge. Addition of a second metabolic challenge, i.e., alcohol, led to loss of tissue polyunsaturates, particularly liver arachidonate. A method of cycling alcohol inhalation for 12 h/d was also presented, which was also shown to lower liver arachidonic acid content.

Lipids 31, S-153–S-156 (1996).

Alcoholism is a devastating illness of modern civilization that causes great misery, disease, and economic loss. It also is associated with homicide, assault, and suicide and affects 20–40 % of those hospitalized in urban settings (1). It is believed to affect nearly 14 million Americans. Confounding the direct toxic effects of alcohol on various organ systems is the poor diet that many alcoholics are believed to consume (2). It has been noted in recent reviews that alcohol exposure leads to the losses of essential fatty acids (EFA) in various tissues (3,4). It is hypothesized that losses of EFA may underlie some of the pathologic changes associated with alcoholism, particularly in the liver and brain. These losses may be the result of the direct and indirect effects of alcohol within the organism and a reduction in EFA intake due to poor dietary habits and food selection. In one recent publication, Pawlosky and Salem (5) demonstrated a loss in liver, plasma, and brain long-chain polyunsaturates in cats exposed to moderate levels of alcohol for 6 mo when they were fed a diet low in EFA (5).

A rodent model that employs a diet low in EFA together with alcohol exposure might be of great utility for the study of the potentiating effects of diet limitation of these nutrients on the course of alcoholic pathology. Changes in brain composition, in particular, have been somewhat variable in animal models of alcoholism (4), and a key uncontrolled variable may be the dietary EFA composition. This paper describes an attempt to develop such a rodent model.

[a]Data are expressed as the mean of the weight percent of each fatty acid ± SEM in the brain total lipid extract for n = 6 animals per group. Abbreviations are as in Table 2.
[b]Results were analyzed using unpaired, two-tail *t*-test. *P* values are indicated where less than 0.05.

random manner into two groups: half received 1 wk of continuous ethanol inhalation, and the other half were placed in inhalation chambers to which no alcohol was introduced. The design and implementation of the alcohol inhalation chambers was previously described in detail (6). Blood alcohol concentrations were determined after tail vein bleeding and the use of a colorimetric assay kit (Sigma Chemicals, St. Louis, MO). The rats were sacrificed at the end of the dietary treatments by cervical dislocation. All animal procedures were approved by the National Institute on Alcohol Abuse and Alcoholism Animal Care and Use Committee.

Fatty acid analysis. The rats were decapitated and organs removed for fatty acid analysis. The brain and approximately

1 g liver were removed and homogenized. Blood was removed and separated into red blood cells, platelets, and plasma by centrifugation. Lipids were extracted from all tissues using the method of Bligh and Dyer (7), with the exception that red blood cell lipids were extracted using the method of Reed *et al.* (8). A portion of the total lipid extracts from each tissue was transmethylated using 14% wt/vol BF_3-methanol at 100°C for 120 min to which hexane was added [25% vol/vol hexane, modified from Morrison and Smith (9)]. The fatty acid methyl esters were injected into a Hewlett Packard 5880A gas chromatograph (Palo Alto, CA) in the split mode with a DB-FFAP (J&W, LaPalma, CA) capillary column (0.25 mm i.d. x 30 m), a flame-ionization detector, and hydrogen as carrier gas at a linear velocity of 55 cm/sec. Injector and detector temperatures were set to 240°C, and the oven temperature program was as follows: 130°C to 175°C at 4°C/min, 175°C to 210°C at 1°C/min, 210°C to 240°C at 30°C/min, with a final hold of 30 min. The fatty acid methyl esters were identified by comparison of retention times to standard mixtures (Nu-Chek-Prep, Elysian, MN).

Statistical analysis. Data are expressed as the mean value (n = 6) plus or minus the standard error of the mean. A student's *t*-test (unpaired, two-tailed) was applied for data analysis between the alcohol and control groups. A $P < 0.05$ was considered significant.

RESULTS

Animals were fed a diet that included only the low levels of EFA present in 1 wt% corn oil plus those in olive oil (9 wt%) for 4 wk. These animals consumed an adequate, but rather low, level of linoleic acid (18:2n-6) on the order of 1.3 en%. A much lower supply of n-3 fatty acids in the form of linolenate (18:3n-3) was present, as it comprises only about 1 and 0.5% of corn and olive oil fatty acids, respectively. One group of these was then exposed to continuous alcohol inhalation during the last week, resulting in a group mean blood alcohol concentration of 180 mg% as measured in tail blood samples. Alterations in the fatty acyl composition of the liver, platelet, erythrocyte, and brain total lipid extracts were then assessed.

Alterations in the acyl composition of the liver was the most pronounced of the tissues and cell types analyzed (Table 2). There was a highly significant loss of arachidonic acid (20:4n-6) and docosapentaenoic acid (22:5n-6) in the liver with compensatory increases in nonessential fatty acids, especially 16:1n-7. There was a loss of 26% of the docosahexaenoic acid (22:6n-3) after alcohol exposure, but this did not reach statistical significance. In the erythrocyte, there were significant increases in 20:3n-6 and 22:6n-3, indicative of alterations in fatty acid metabolism (Table 3). In the platelet, losses in 20:4n-6 and 22:6n-3 did not reach significance; however, there were the characteristic increases in nonessential fatty acids such as 18:1 (Table 4). As is characteristic of the brain, there were few alterations of acyl composition after this brief alcohol exposure, with only the slight losses of 22:5n-6 and 16:0 reaching significance (Table 5). In several cases (liver, erythrocyte, and brain), there were significant losses in the saturates 16:0 or 18:0.

To further refine this model to be a more physiologically relevant one to human alcoholism, alcohol exposure was limited to 12 h/d. In this experiment, it was observed that the decrease in the 20:4n-6 level was approximately the same (Table 6) as during continuous exposure. After 24 h of alcohol withdrawal, there was some recovery in the 20:4n-6 level (Table 6).

DISCUSSION

It is striking that a 44% loss of liver 20:4n-6 could be achieved with only a 7 d exposure to alcohol. This fatty acid has many known functions, and so such a drastic reduction in its level would be expected to have negative consequences. This loss was mainly localized to cholesterol esters and phosphatidylcholines, and little or no losses were found in triglycerides or phosphatidylethanolamines. The magnitude of this loss induced by alcohol may have been due, in part, to the reductions in dietary EFA. There was no preformed 20:4n-6 available in the diet, and the level of its precursor, 18:2n-6, was also relatively low. It is hypothesized that this dietary state mimics that of many alcoholics and that the lack of dietary oversupply creates a permissive state in which alcohol can produce greater depletions of organ long-chain polyunsaturates and organ damage.

There were few changes in EFA in blood cells or the brain after 7 d of alcohol exposure, although human alcoholics

[c]Experimental groups were compared to controls by an unpaired two-tailed *t*-test. Significant differences are noted with $P < 0.05$.

often exhibit such alterations (3,4). This may be attributed principally to the relatively short period of alcohol exposure in this experiment. For example, domestic cats subjected to a single daily dose of alcohol for 6 mo exhibited drastic losses in most plasma and liver EFA, while nonessential fatty acids in the liver increased markedly (5). It was also important that this study showed a significant loss of brain and retinal 22:6n-3, despite the resistance of this fatty acid to nutritional challenge (10–12). It thus appears that a more sustained alcohol exposure in rats will be necessary.

This study also employed a diet where the EFA were supplied by 1 wt% corn oil, and so was relatively low in these nutrients. It should be noted that these diets will by themselves lead to lower tissue levels of tissue long-chain (C_{20} and C_{22}) polyunsaturated fatty acids. This effect, however, is reflected in the dietary control values, and it is clear that alcohol exposure led to a further, greater diminution of these fatty acids.

Improvement in the rodent model of human alcoholism was also achieved with the use of cycling alcohol exposure limited to 12 h/d. This allowed the mucous membranes of the animals to recover and provided for more normal activity and eating behavior. Future experiments will further define EFA levels in the diet as modulatory variables for ethanol-related pathological effects with more prolonged exposure periods.

Arachidonic Acid to Eicosapentaenoic Acid Ratio in Blood Correlates Positively with Clinical Symptoms of Depression

Peter B. Adams[a], Sheryl Lawson[a], Andrew Sanigorski[b], and Andrew J. Sinclair[c,*]

[a]Central Region Mental Health Service, Rockhampton Base Hospital and The Centre for Mental Health Research, Central Queensland University, Rockhampton, Queensland, 4700, Australia, [b]Deakin Institute of Human Nutrition, Deakin University, Geelong, Victoria, 3217, Australia, and [c]Department of Food Science, Royal Melbourne Institute of Technology, Melbourne, Victoria, 3001, Australia

ABSTRACT: In this study of 20 moderately to severely depressed patients, diagnosed using current research diagnostic criteria and excluding known bipolar affective disorder and reactive depression, we investigated relationships between severity of depression and levels and ratios of n-3 and n-6 long-chain polyunsaturated fatty acids (PUFA) in plasma and erythrocyte phospholipids (PL). Severity of depression was measured using the 21-item Hamilton depression rating scale (HRS) and a second linear rating scale (LRS) of severity of depressive symptoms that omitted anxiety symptoms. There was a significant correlation between the ratio of erythrocyte PL arachidonic acid (AA) to eicosapentaenoic acid (EPA) and severity of depression as rated by the HRS ($P < 0.05$) and the LRS for depression ($P < 0.01$). There was also a significant negative correlation between erythrocyte EPA and the LRS ($P < 0.05$). The AA/EPA ratio in plasma PL and the ratio of erythrocyte long-chain (C_{20} and C_{22} carbon) n-6 to long-chain n-3 PUFA were also significantly correlated with the LRS ($P < 0.05$). These findings do not appear to be simply explained by differences in dietary intake of EPA. We cannot determine whether the high ratios of AA/EPA in both plasma and erythrocyte PL are the result of depression or whether tissue PUFA change predate the depressive symptoms. We suggest, however, that our findings provide a basis for studying the effect of the nutritional supplementation of depressed subjects, aimed at reducing the AA/EPA ratio in tissues and severity of depression.
Lipids 31, S-157–S-161 (1996).

Major depression is occurring at a younger age and at a higher incidence than it had been prior to 1913 (1,2). In epidemiological studies reviewed by Klerman (1), these findings, primarily for Westernized societies, were not explained by changing diagnostic criteria, changing attitudes of health professionals and societies, reporting bias, differential mortality, or institutional or other artifacts.

Of the many changes in Western society, the changes in diet corresponding to population increase in the industrial period of 1850–1995 is considered to have contributed to development of a range of medical conditions, especially cardiovascular disease and inflammatory disorders (3,4). The increase in total fats, saturated fats, and linoleic acid (LA)-rich vegetable oils during this time has been associated with a large increase in n-6/n-3 PUFA in the diet (4,5). The n-6/n-3 PUFA ratio is estimated to have risen from about 1:1 to greater than 10:1 as fats from fish, wild game, and leaves were replaced by increasing consumption of LA-rich oils from seeds. This dietary imbalance of n-6/n-3 PUFA leads to a high proportion of arachidonic acid (AA) and little eicosapentaenoic acid (EPA) in the cell membranes of most tissues, resulting in an overproduction of eicosanoids derived from n-6 PUFA such as prostacyclin, thromboxane, leukotrienes (3), and inflammatory mediators (cytokines and interleukins) (6).

Epidemiological evidence from the Multiple Risk Factor Intervention Trial of 12,866 middle-aged men in the United States revealed that there were significant inverse associations between dietary n-3 PUFA [α-linolenic acid (ALA) and long-chain n-3 PUFA] and mortality from coronary heart disease, all cardiovascular mortality, and all-cause mortality (7). In addition, there were negative associations between the ratio of n-3/n-6 PUFA (ALA/LA and total n-3/n-6 PUFA) and cancer mortality.

Smith (8) and Hibbeln and Salem (9) have hypothesized that the sharp rises in depression and other neurological disorders in this century have been fueled by increased consumption of LA-rich vegetable oils. Consistent with this hypothesis are the substantially elevated levels of prostaglandin E_2 and thromboxane B_2 (both derived from AA, a metabolite of LA) reported in patients with both unipolar and bipolar depression (10).

In this study, we investigated relationships between severity of depression and levels and ratios of n-3 and n-6 long-chain PUFA in plasma and erythrocyte PL of 20 moderately to severely depressed patients, diagnosed using research diagnostic criteria (11).

MATERIALS AND METHODS

Patients were selected from those consecutively referred for routine psychiatric treatment who were either inpatients or outpatients of the participating psychiatrists (P.A. and S.L.). Criteria for participating in the study was a diagnosis of unipolar depression according to the criteria in DSM IV (11), with no past or present diagnosis of bipolar affective disorder. There were no age or sex exclusion criteria, and in one case a second psychiatric diagnosis (anorexia nervosa) was present (Table 1). At initial assessment, all but three patients were drug-free: patient 9 was taking 50 mg doxepin, patient 13 had just commenced dothiepin 150 mg at night, and patient 11 was taking low-dose digoxin and frusemide for cardiac failure. Protocol used for this study complied with the Helsinki Declaration of 1975 as revised in 1983.

Severity of depression was measured at commencement of the study and again after treatment using the 21-item Hamilton depression rating scale (HRS) (12), which defines mild (<17), moderate (17–34), and severe depressions (>34). This was assessed by direct interview by one of the two treating psychiatrists. The HRS includes both depressive and anxiety subscales, and for this reason a clinical rating of depression, omitting anxiety symptoms, was made using a predefined simple linear estimation of severity of depressive symptoms. This rating was from 0–10 and was based on averaging the clinical impression of the two participating psychiatrists after discussion of each case. Symptoms used were severity of mood disturbance, loss of appetite, weight loss, sleep disturbance, and suicidality. A score of 1–4 was rated as mild depression, 5–7 was moderate depression, and 8–10 was severe depression. The raters were both experienced clinical psychiatrists who previously standardized their ratings for depression over a 10-yr period.

[b]LRS range from 0–10; LRS = linear rating scale.
[c]These patients were diagnosed as suffering from anorexia nervosa.

At presentation, all patients completed an assessment of dietary intake of lipids over the previous three months, based on a food frequency questionnaire from Deakin University (Geelong, Australia) (13) and a diary of all food eaten the subsequent week to check for major changes over that period. The itemized assessment included frequency of intake of butter, margarine, milk products, vegetable oils, meat including liver and kidney, fresh and canned fish, eggs, nuts, olives, avocados, cakes, cookies, pastry products, and other snack foods. Intakes of AA and EPA were calculated from data from the food frequency questionnaire and use of a locally constructed database of the long-chain PUFA content of foods (14).

At the beginning of the study, prior to any change in medication, a 10-mL blood sample (in an EDTA tube) was taken from each patient after an overnight fast. The plasma was separated by centrifugation and stored at −20°C until analyzed. Erythrocytes were washed three times in 0.9% saline and then extracted in 10 mL of chloroform-methanol (1:1, containing 10 mg/L butylated hydroxytoluene) and stored at −20°C. Blood samples were coded and analyzed blind by the lipid analyst. Plasma and erythrocyte lipids were extracted in chloroform/methanol by standard procedures (15), PL were separated from total lipids by thin layer chromatography, and PL fatty acids were formed by saponification in KOH followed by methylation using boron trifluoride in methanol (15). Fatty acid methyl esters were separated by capillary gas–liquid chromatography, as previously described (15).

Standard, routine treatment for depression was prescribed by the two participating psychiatrists, according to clinical indications. In most cases, treatment was with tricyclic antidepressants with clinical review within two to five days, followed by weekly or biweekly reviews.

Results are expressed as means ± SD, and correlations were calculated using the Pearson correlation coefficient (r). A P value of <0.05 was considered significant. All statistical analyses were performed on Minitab Version 8 (Minitab, Inc., State College, PA).

RESULTS

Clinical findings. The age of the 20 patients ranged from 19 to 79 years. The HRS measurements for depression indicated one patient with severe depression (HRS score 36), and one with mild depression (HRS score 14.5), and the remainder were moderately depressed (HRS scores from 17–34). The linear rating scale (LRS) indicated more cases of severe depression than did the HRS, due to the previously described differences between the two scales. According to the LRS, 13 patients were classified as moderately depressed and 7 as severely depressed (Table 1).

Dietary findings Ten patients reported consuming 4–5 meat meals per week, 0–2 fish meals per week, 0.5–4

eggs/week, use of margarine/vegetable oils, and infrequent consumption of nuts. One patient had a similar diet, but consumed 12 eggs per week. Five patients reported a high meat intake (>7 meals per week); 0–1 fish meals per week; 2–10 eggs/week; butter, margarine, or vegetable oil use, and infrequent consumption of nuts. Of this group, three reported a frequent consumption of snack foods. Of the remaining four subjects, patients 2 and 6 were severely anorexic with a low intake of all nutrients; patient 9 was strictly vegetarian (no fish or eggs) and patient 16 reported a fish intake of between 3–4 meals per week, less than 4 meat meals per week, 5 eggs per week, use of vegetable oils, and consumption of nuts several times per week. No patients reported major changes in the major dietary contributors of n-6 and n-3 PUFA in the 3 months prior to presentation with depression.

Biochemical findings. Plasma PUFA values for the patients (Table 2) fell within the range we previously reported for 65 female and 43 male healthy normal Australian subjects (17).

As shown in Table 3, there were significant negative correlations between erythrocyte EPA levels and the LRS for depression ($r = -0.546$, $P < 0.05$) and plasma PL docosapentaenoic acid n-3 and the LRS for depression ($r = -0.539$, $P < 0.05$) (Table 3). There were significant positive correlations between the ratio of AA/EPA in the erythrocyte PL and plasma PL with the LRS ($r = +0.729$, $P < 0.01$, and +0.527, $P < 0.05$, respectively). The AA/EPA ratio in the erythrocyte PL was also correlated with the HRS ($r = +0.472$, $P < 0.05$) (Fig. 1). The erythrocyte long-chain PUFA n-6/long-chain PUFA n-3 ratio was also significantly correlated with the LRS ($r = +0.455$, $P < 0.05$).

Clinical findings. All patients showed significant improvement in depressive symptoms over 1 to 3 months and returned to normal living and occupational activities with HRS scores of less than 10 and LRS scores of less than 4. An exception was one frail elderly man (patient 5), admitted to the hospital with severe malnutrition, who died of myocardial infarction after making a modest improvement in mood with a low dose of the antidepressant medication, mianserin.

DISCUSSION

Depression in Westernized countries is becoming increasingly common (1,2). Multifactorial hypotheses have been offered to account for depression, and diet is not thought to play a direct initial role. In some cases of depression, severe appetite loss, decreased food intake, and weight loss may occur, and these may contribute to changes in levels and/or proportions of dietary PUFA. These clinical features were found in most but not every patient in the study. Because n-6 PUFA are ubiquitous in the food supply and n-3 PUFA are relatively restricted (canola oil, fish, and other marine products), it is conceivable that appetite loss may be associated with selection of foods that are relatively low in n-3 PUFA. This was not a particular feature of this group, however,. Interpretation of the possible influences of nutrition on depression is confounded by the difficulty of determining whether depression antedates or predates dietary change.

The present group of subjects had plasma PUFA values within normal range for a larger group of healthy normal Australian subjects (17). The ratio of AA/EPA in the subjects' plasma PL and erythrocyte PL, however, correlated strongly with both the LRS and HRS. The ratio of the long-chain PUFA n-6/long-chain PUFA n-3 ratio in the erythrocyte PL was also correlated with severity of depression. The two parent PUFA in each family, LA and ALA, are in competition with each other for conversion to the long-chain 20- and 22-carbon PUFA. Diets that contain an increased level of n-6

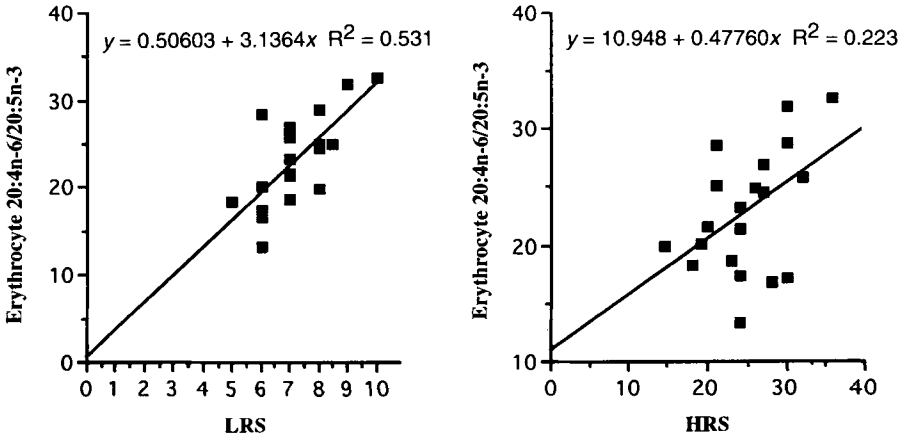

FIG. 1. The relationship between the erythrocyte 20:4n-6/20:5n-3 values and two ratings of depression (LRS = linear rating scale, $r = +0.729$, $P < 0.01$; HRS = Hamilton rating scale, $r = +0.472$, $P < 0.05$).

PUFA relative to n-3 PUFA lead to elevated levels of AA and low levels of EPA in plasma and erythrocyte lipids (18).

The concentration of PUFA in plasma PL has been used as a guide to the dietary intake of PUFA (18,19), although erythrocyte PUFA patterns have been more commonly used to indicate long-term dietary intake (20). Our findings do not appear to be simply explained by differences in intake of n-6 and n-3 PUFA between subjects, since intake of EPA, estimated from the food frequency questionnaire data, did not reveal any significant correlations with plasma or erythrocyte AA/EPA ratios ($r = 0.39$, $P > 0.05$ and $r = 0.10$, $P > 0.05$, respectively). Futhermore, patient 9 (vegetarian diet), patient 16 (high fish intake), and patient 2 (severe anorexia) had similar ratings for depression, despite major differences in diet and estimated EPA intakes (10, 380, and 50 mg per day, respectively).

Moderate to severe depression is often associated with sleep disturbance, markedly decreased food intake, and loss of weight (11). Since PUFA are essential fatty acids, changes in appetite could possibly lead to a reduced intake of both n-6 and n-3 PUFA or to an unbalanced intake of one PUFA type relative to the other. The Australian diet, like other Westernized diets, is rich in LA and relatively poor in ALA (21). LA is found in highest concentration in vegetable oils, and thus in PUFA-rich margarine, but it is also in a wide range of other foods (21). Lean meat, organ meats, and eggs contain LA and also small quantities of AA, which is readily incorporated into cell membranes (15). Normally, a low level of long-chain n-3 PUFA is the result of a low dietary intake of either the parent n-3 PUFA (ALA) from sources such as canola oil, soybean oil, and walnuts (21,22), or of the long-chain n-3 PUFA (EPA is found in highest concentration in fish and other marine foods such as shellfish, mollusks and the like, and fish oil). In this study, estimated intake of EPA from fish did not correlate significantly with plasma and erythrocyte levels of EPA ($r = 0.37$ and 0.35, respectively, $P > 0.05$), suggesting that diet was not the major influence on EPA levels in the subjects in this study.

We cannot determine whether the high ratios of AA/EPA in both plasma and erythrocyte PL are the result of depression or whether tissue PUFA changes predate the depressive symptoms. The association between the state of depression and erythrocyte and plasma PUFA levels may be a cause, an effect, or a reflection of other changes occurring during depression.

Results of this study contrast with reports from the United Kingdom by Ellis and Sanders (23) and Fehily *et al.* (24), who showed increases in EPA and DHA (long-chain n-3 PUFA) in plasma and erythrocyte PL in patients with severe depression. The patients in the present study were selected by research diagnostic criteria (11) and were a more homogeneous group than the two groups studied by Ellis and Sanders (23) and Fehily *et al.* (24), whose patients included those with known bipolar affective disorder and reactive or mild depression.

We have demonstrated a relationship between severity of depression and the plasma and erythrocyte AA/EPA ratio. More data is required before a link between dietary change, increased rates of depression and blood n-6/n-3 PUFA levels is established in a causative manner. We suggest that our findings provide a basis for studying the effect of nutritional supplementation of depressed subjects aimed at reducing the AA/EPA ratio in tissues and the severity of depression.

Fatty Acids and Schizophrenia

J.D.E. Laugharne*, J.E. Mellor, and M. Peet

University Department of Psychiatry, Northern General Hospital, Herries Road, Sheffield, S5 7AU, United Kingdom

ABSTRACT: In a controlled study of red cell membrane fatty acids in patients with schizophrenia, substantial depletions of fatty acids from both the n-6 and n-3 series were demonstrated. Arachidonic acid and docosahexaenoic acid were particularly depleted. In a separate study, dietary analysis revealed no deficiency of fatty acid intake in this patient group, but greater intake of n-3 fatty acids was associated with less severe symptomatology. Dietary supplementation for six weeks with 10 g per day of concentrated fish oil (MaxEPA) led to significant improvement in schizophrenic symptoms. This clinical improvement was related to the increased level of n-3 fatty acids in red cell membranes. These findings form part of a growing body of research data suggestive of an abnormality in cell membrane fatty acid composition in schizophrenia. The preliminary evidence for clinically effective dietary manipulation to correct such an abnormality opens up novel and exciting therapeutic possibilities.
Lipids 31, S-163–S-165 (1996).

Schizophrenia is a serious mental disorder, the aetiology of which remains unknown. From the clinical perspective, signs and symptoms are many and varied and are often classified into "positive" and "negative" symptoms. Positive symptoms refer to the delusions, hallucinations, thought alienation, and thought disorder which typically occur early on in the course of the illness and which respond well to treatment with neuroleptic drugs. The negative symptoms include emotional blunting, social withdrawal, poverty of speech and activity and cognitive deficits. These tend to occur later in the course of the illness and respond poorly to neuroleptic treatment.

The aetiology of the condition remains uncertain. The theory that it results from increased dopaminergic activity in mesolimbic and mesocortical neuronal pathways has persisted for many years. However, more recently, research interest has focused on other neurotransmitter systems including glutamatergic and serotoninergic. There is evidence for a genetic component in the aetiology and, more recently, researchers have found accumulating indirect evidence to suggest that for a subgroup, at least, the disorder is neurodevelopmental in origin (1).

Abbreviations: AA, Arachidonic acid; DHA, docosahexaenoic acid; TBARS, thiobarbituric acid reactive substances.

There is a small growing body of evidence indicating that phospholipid metabolism may be disturbed in schizophrenia. Interest has particularly begun to focus on abnormalities in the cell membrane fatty acid composition and the possible effects of such abnormalities on neuronal functioning.

Plasma fatty acids in schizophrenia. Over the last 20 y, various research workers have investigated levels of essential fatty acids in the plasma of schizophrenic patients. One early study demonstrated a raised level of α-linolenic acid (2), and work on schizophrenic patients from England, Scotland, and Ireland found consistently low levels of plasma linoleic acid and arachidonic acid (3). This latter group also demonstrated an increase in total n-3 fatty acids in plasma. Low levels of plasma linoleic acid were also found in a cohort of schizophrenic patients in Japan (4).

The most consistent reported finding is therefore the reduction of plasma linoleic acid. Similar results were found in twins, with twins concordant for schizophrenia showing greater abnormalities than those who were discordant (5).

Red Cell Membrane Fatty Acids in Schizophrenia. Our group in Sheffield has conducted a study of the fatty acid composition of red cell membranes from 23 drug treated schizophrenic patients and demonstrated substantial depletions of fatty acids from both the n-6 and n-3 series when compared to a healthy control group (Table 1). Arachidonic acid (AA) and docosahexaenoic acid (DHA) were particularly depleted. In addition, significant negative correlations between the depleted n-6 fatty acids and plasma levels of thiobarbituric acid reactive substances (TBARS), a marker of lipid peroxidation, suggested that the depletion was due to increased breakdown of the fatty acids rather than impaired incorporation of the fatty acids into membranes. Both AA and DHA concentrations appeared to be distributed bimodally. However, because measurements of symptomatology were not undertaken during this study, it was not possible to comment on any association between abnormal membrane fatty acids and symptomatology (6). In a similar study conducted in Scotland, symptoms were assessed using established rating scales. Patients with predominantly positive symptoms did not differ significantly from the control group whereas those with predominantly negative features of schizophrenia had significantly reduced levels of essential fatty acids, in partic-

ular AA and DHA. The authors suggest from their data that there is a sub-population of schizophrenic patients with significantly reduced AA and DHA in red cell membranes but not in plasma and that these patients are highly likely to have predominantly negative symptoms (7).

These deficits in DHA and AA are of special interest as these fatty acids are particularly concentrated in brain tissue. There is evidence from primate work to suggest that red cell fatty acid concentrations may reflect those of neuronal tissue (8).

Evidence for increased lipid peroxidation. The work to date investigating plasma and red cell membrane fatty acids in schizophrenia raises intriguing questions regarding the possible role of abnormal fatty acid metabolism in the chemical pathology of schizophrenia. There is, in addition, an accumulating body of data indicating increased oxidative stress in this patient group.

Two studies have demonstrated increased lipid peroxidation in schizophrenia by their findings of increased pentane levels in expired air (9,10). This is consistent with our finding of a significant negative correlation between depleted n-6 fatty acids and plasma levels of TBARS which implies increased phospholipid breakdown rather than decreased incorporation of fatty acids into the red cell membrane (7). It is interesting in the light of these results to note that increased activity of the phospholipid metabolizing enzyme phospholipase A_2 has been demonstrated in a group of schizophrenic patients and that this activity has been shown to be reduced following neuroleptic treatment (11,12). Other workers have indicated that neuroleptic drugs can reduce the breakdown of phospholipids by inhibiting phospholipase A_2 (13). Consistent with this notion of enhanced lipid peroxidation in schizophrenia is the finding in a recent controlled study of increased plasma TBARS in 20 drug-naive patients during their first psychotic episodes (14). Increased TBARS was associated with lower red cell levels of the antioxidant enzyme glutathione peroxidase and a greater severity of negative symptoms at the onset of psychosis. The possibility of peroxodative damage of neuronal tissue leading to ventricular enlargement in schizophrenia is suggested by a reported correlation between depletion of glutathione peroxidase and increased ventricle-brain ratio (15). The finding of cerebral ventricular enlargement in some schizophrenics has previously been associated with negative symptoms (16).

Neuroimaging studies. Using magnetic resonance spectroscopy, decreased levels of phosphomonoesters and increased phosphodiesters have been demonstrated in the prefrontal cortex of drug naive schizophrenic patients (17). This is suggestive of decreased synthesis and/or increased breakdown of membrane phospholipids in schizophrenic patients. These findings have been confirmed by other workers (18) and there is also some evidence that this index of increased phospholipid breakdown correlates with severity of schizophrenic symptoms (19). This body of neuro-imaging data adds more credence to the hypothesis that there is an abnormality of membrane phospholipid fatty acid composition in patients with schizophrenia.

Supplementation studies. The importance of dietary factors in schizophrenia has not been paid a great deal of attention. In this respect it is of particular interest that outcome figures from the World Health Organization Schizophrenia Study have been shown to correlate with national dietary characteristics (20). Countries in which the national diet included relatively more essential fatty acids had a better national outcome of schizophrenia than those countries in which relatively more animal fat was consumed. In addition there is evidence that the fatty acid composition of neuronal membranes can be modified by dietary fatty acid intake (21,22). Attempts have been made to treat schizophrenia with n-6 essential fatty acids including γ-linolenic acid (23). These trials produced modest and variable improvements from the clinical perspective.

Until very recently, effects of n-3 fatty acid supplementation on schizophrenic symptoms have not been investigated. Our group in Sheffield therefore studied the effects of dietary supplementation with 10 g per day of concentrated fish oil (MaxEPA) over a six week period in a cohort of 20 schizophrenic patients (24). Supplementation resulted in significant increases of red cell membrane levels of eicosapentanoic acid as well as other n-3 fatty acids. There was a concomitant reduction in membrane n-6 fatty acids. Both positive and negative symptoms improved though only negative symptoms reached statistical significance. The improvement in clinical symptoms was related to the increased level of n-3 fatty acids in red cell membranes. In the course of this study, a detailed dietary analysis of fatty acid intake was carried out prior to the supplementation. None of the patients were deficient in fatty acid intake, but it was demonstrated that a greater intake of n-3 fatty acids and particularly eicosapentanoic acid was associated with less severe schizophrenic symptoms as well as less tardive dyskinesia (a movement disorder associated with prolonged neuroleptic drug treatment). In terms of any relationships between the red cell fatty acid levels prior to supplementation and schizophrenic symptomatology, both the total symptom score and severity of abnormal involuntary movements (tardive dyskinesia) showed significant positive correlations with n-6 fatty acids in the red cell membranes.

Conclusion. The findings presented in this paper from our own group and other workers represents a growing body of research data pointing towards an abnormality of phospholipid fatty acid metabolism in schizophrenia. Such an abnormality may be of aetiological significance. This possibility is not

incompatible with current receptor based theories as fatty acids are known to interact with the relevant receptors including those for dopamine and glutamate. Activation of dopamine D2 receptors enhances calcium dependent AA release *in vitro*, and this is reversed by haloperidol, a neuroleptic drug (25). AA has multiple effects on neuronal signal transduction, including acting as a second messenger in glutamatergic neurotransmission (26). It has also been demonstrated that membrane fatty acid composition is capable of modulating receptor function and neurotransmitter release including that of dopamine (27). We have previously hypothesised that several of the biological abnormalities reported in schizophrenic patients can be related to abnormal metabolism of AA (28).

The possibility that such an abnormality may be amenable to dietary manipulation opens up interesting therapeutic possibilities. The clinical improvements with the initial open study of n-3 fatty acid supplementation reported here are encouraging. Larger placebo controlled trials are required to clarify the efficacy of such an approach.

ABSTRACT: The basis for n-3 fatty acid essentiality in humans includes not only biochemical evidence but functional measures associated with n-3 deficiency in human and nonhuman primates. Functional development of the retina and the occipital cortex are affected by α-linolenic acid deficiency and by a lack of docosahexaenoic acid (DHA) in preterm infant formulas and, as reported more recently, in term diets. Functional effects of n-3 supply on sleep–wake cycles and heart rate rhythms support the need for dietary n-3 fatty acids during early development. Our results indicate that n-3 long-chain polyunsaturated fatty acids should be considered provisionally essential for infant nutrition. DHA may also be required by individuals with inherited metabolic defects in elongation and desaturation activity, such as patients with peroxisomal disorders and some forms of retinitis pigmentosa.

Lipids 31, S-167–S-176 (1996).

Dietary essential fatty acids (EFA) have been considered part of the lipid supply necessary for energy, growth, cellular metabolism, and muscle activity. The fact that some EFA serve as indispensable dietary precursors for eicosanoid (prostaglandins, prostacyclins, thromboxanes, leukotrienes) and docosanoid formation has given greater significance to their study. During the past decade, increasing attention has focused on the role of n-3 and n-6 EFA in normal fetal and neonatal development (1–7).

Basis for nutritional essentiality. The concept that specific components of fat may be necessary for the proper growth and development of animals and possibly humans was introduced in the 1930s (8). Yet, EFA were considered of marginal importance until the 1960s, when signs of clinical deficiency became apparent in infants fed skim milk–based formula and in those given lipid-free parental nutrition (9–12). During the past decade, it has become generally accepted that n-6 as well as n-3 fatty acids (FA) play a key role in perinatal nutrition, especially for the developing central nervous system (CNS).

Clinical EFA deficiency is associated with a set of specific findings (7,9–12). This syndrome has been related mostly to combined n-3 and n-6 deficits and includes poor growth; skin lesions; decreased skin pigmentation; loss of muscle tone; degenerative changes in kidney, lung, and liver; increased metabolic rate; impaired water balance; increased fragility and permeability of cell membranes; and increased susceptibility to infection (7,9–12).

Clinical manifestations disappear after administration of diets that provide 2% or more of the total calories as linoleic acid (LA, 18:2n-6) (9–14). More subtle clinical symptoms appear in n-3 EFA deficiency. They include skin changes unresponsive to LA supplementation, abnormal visual function, and peripheral neuropathy (15). Nervous system manifestations are likely caused by an insufficient supply of the metabolic derivative of α-linolenic acid (LNA, 18:3n-3), namely docosahexaenoic acid (DHA, 22:6n-3).

Structural role of EFA in the developing nervous system. Fetus and placenta are fully dependent on maternal EFA supply for growth and development. The mother's diet before pregnancy plays an important role in determining maternal EFA status, since these essential nutrients are stored in adipose tissue and can be mobilized over time through lipolysis. Major EFA deposition in the human fetus occurs during the third trimester; phospholipids in placental vessels and uterine vasculature are dependent on EFA supplied by the mother for eicosanoid formation. Maternal preconceptional nutrition determines, in part, which specific fats accumulate in the conceptus and placental tissues (6,16,17).

The dry weight of the human brain is predominantly lipid; 22% of the cerebral cortex and 24% of white matter consist of phospholipids. Studies of several animal species and recent evidence from humans established that brain phospholipid arachidonic acid (AA, 20:4n-6) and DHA decrease, while n-9 and n-7 mono- and polyunsaturated FA increase when LA and LNA or only n-3 FA are deficient in the diet (18–20). Typically, n-3 FA-deficient cells have decreased DHA and increased levels of the end products of n-3 and n-6 metabolism, DHA and docosapentaenoic acid (DPA, 22:5n-6), respectively. Within subcellular organelles, synaptosomes and mitochondria seem to be more sensitive to a low dietary n-3 supply (19–21).

High concentrations of long-chain derivatives of EFA in the cerebral cortex and retina suggests their participation in neural and visual function. The n-3 end product, DHA, reaches levels of up to 50% of total FA in the phospholipids of these tissues (22–24). A specific association of either DHA or AA with neural tissue function has not been fully defined. In the human, Clandinin and colleagues (24) showed significant increases in AA and DHA contents of brain tissue during the last trimester of gestation. More recently, Martinez (25) provided complementary data on retinal and brain accretion of long-chain polyunsaturated fatty acids (LCPUFA), using modern methodology.

The potential for dietary EFA deficiency has become a significant issue for the nutrition of preterm-born infants, since they do not receive the third-trimester intrauterine supply of DHA and AA. Even full-term infants are at risk of DHA deficiency since most formulas are devoid of this critical EFA. Recent postmortem investigations in term infants suggest a dependency on diet in the FA composition of brain cortex. Infants who are breast fed have higher DHA and lower DPA (n-6) and AA in their cortex phospholipids relative to infants receiving cow milk-based formulas (26, 27). DHA content increases with advancing age in breast-fed infants and is proportional to the duration of human-milk feeding, while AA content remains stable. Furthermore, the dietary ratio of n-6 to n-3 FA appears relevant, as the lowest DHA and highest DPA (n-6) contents in brain cortex phospholipids were observed in preterm infants fed formulas with a high LA to LNA ratio (27).

Biochemical and functional effects of EFA in the developing nervous system. Studies in nonhuman primates characterized biochemical and functional effects of dietary n-3 deficiency. Animal models were developed using purified LA as the only dietary fat or using safflower or sunflower oil in which the n-6/n-3 FA ratio (approximately 250:1) was very high (28–31). High n-6/n-3 FA ratios are found in powdered infant formulas currently in use in some parts of the world (32, 33). If these diets are fed from conception and/or during early life, significant declines in DHA levels and elevations of DPA (n-6) contents of brain, retina, and other tissues occur in animals. Similar data was obtained from plasma and red blood cell (RBC) lipids in preterm infants fed corn oil-based formulas that have a high LA/LNA ratio (34).

Use of RBC lipids as a potential index of EFA status in retinal membranes is based on correlations between FA profiles in RBC and neural/retinal tissue from rats and nonhuman primates and in human infants (27, 35, 36).

Effects of n-3 deficiency, specifically DHA, were demonstrated on retinal photoreceptor function and maturation of cortical visual function in nonhuman primates and in preterm infants. Improved cognitive function measured by psychometric tests

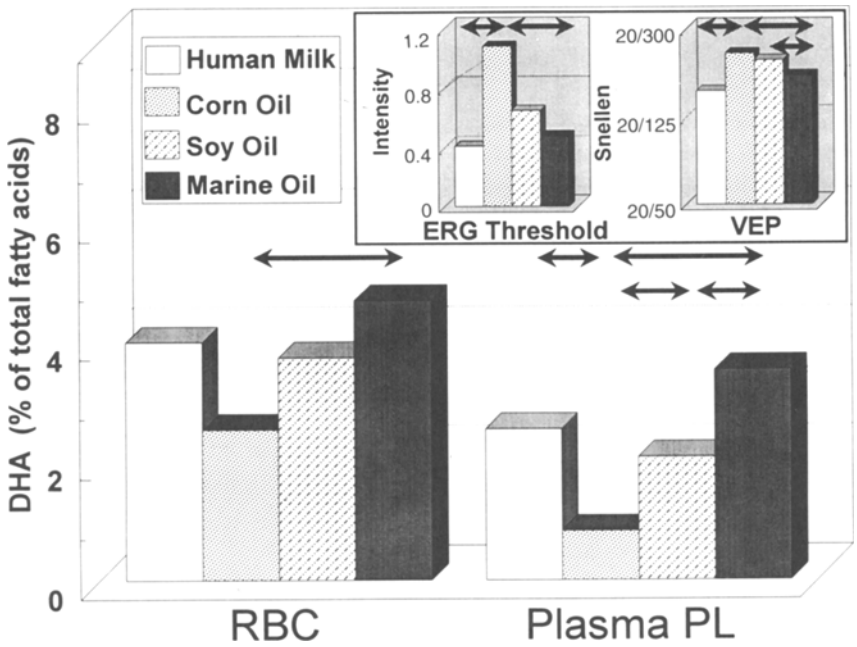

FIG. 1. Docosahexaenoic acid (DHA) in total red blood cell (RBC) lipids and plasma phospholipids (PL) of preterm infants on study diets at 36 wk postconception. Arrows indicate significant differences ($P < 0.05$) between diet groups using Newman–Keuls multiple comparison analysis: inset; rod electroretinogram (ERG) thresholds (intensity units = log scotopic troland seconds) and visual evoked potential (VEP) visual acuity (Snellen equivalents) in study infants at 36 wk.

were also shown in DHA-supplemented infants at 12 mon of age.

Infants fed fat-free parental diets provide nutritional models to study the effect of EFA deficiency on the developing brain. Initially, total parental nutrition (TPN) did not include lipids in its formulation. This allowed Fagioli *et al.* (37) to characterize effects of long-term dietary EFA deficiency on sleep organization. Studies in children who were maintained on fat-free TPN for 2 to 6 mon had consistently reduced durations of slow-wave sleep compared with children who received TPN plus essential lipids. The main difference was a lower cumulative amount of slow-wave sleep time from the second hour of night-sleep onward. These results suggest that early lipid nutrition may modulate sleep regulation and may have implications for whole-body energy expenditure during sleep, since slow-wave sleep is associated with a lower metabolic rate than are other stages of sleep (38). Interestingly, no significant difference was found in either total sleep time or intrasleep waking in the EFA-deficient group. Alterations in sleep–wake cycle development may become evident only if the methods used include evaluations that are more subtle than total sleep or waking time measures. The possibility that fat-free TPN affected structural brain lipids is suggested from these results (26, 27, 37).

Studies in preterm infants fed controlled EFA intake. Our studies (conducted in Dallas, Texas, and continued as a collaborative work in both Dallas and Santiago, Chile) have served to document the essentiality of n-3 FA in humans. Initial studies were performed in very-low-birth-weight infants, since they are particularly vulnerable to deficiency, given the virtual absence of adipose tissue stores at birth. This deficiency may be attributable to a possible immaturity of FA elongation/desaturation pathways and inadequate LNA and DHA intakes provided by formula. We and others conducted studies to evaluate the effect of n-3 in very low birth weight infants, examining effects of LNA or LNA plus DHA supplementation on plasma and tissue lipid composition, retinal electrophysiologic function, maturation of the visual cortex, and other measures of infant growth and development (39–45).

Before the 1990s, low levels of LNA were present in most infant formulas; virtually all infant formulas in developed countries are currently supplemented with LNA, and several manufacturers in Europe and Japan have added DHA or DHA plus AA to preterm formula (32, 33, 46). EFA composition of human milk (HM) and study formulas used in our studies were published previously (34). Briefly, corn oil-based formula corresponded to commercial, powdered premature formula, contained 24% LA, was extremely low in LNA (0.5%), and had no LCPUFA; soy oil-based formula was equivalent to present ready-to-feed premature formula used in the United States; and the third study formula was also soy oil-based (1.4% LNA) but was enriched with marine oil to give an n-3 LCPUFA content closer to that found in HM. At the time we started our study, n-3 LCPUFA could only be obtained from marine oil. We chose to include sufficient marine oil to mimic DHA content of HM, since we were uncertain as to how effectively preterm infants could convert eicosapentenoic acid (EPA, 20:5n-3) to DHA. The full nutritional content of the preterm milk formula and details of laboratory methods have been published (34, 39).

Composition of RBC lipids for all diet groups were similar on entry into the study (34). At the 36- and 57-wk postconception

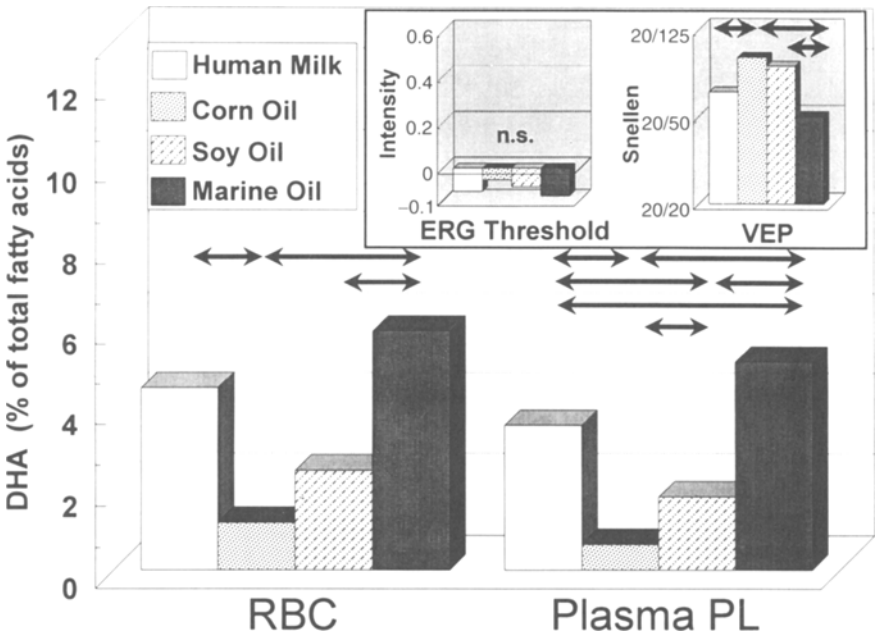

FIG. 2. Docosahexaenoic acid (DHA) in total red blood cell (RBC) lipids and plasma phospholipids (PL) of preterm infants on study diets at 57 wk postconception. Arrows indicate significant differences ($P < 0.05$) between diet groups using Newman–Keuls multiple comparison analysis: inset; rod electroretinogram (ERG) thresholds (intensity units = log scotopic troland seconds) and visual evoked potential (VEP) visual acuity (Snellen equivalents) in study infants at 57 wk.

follow-up, marked differences in DHA contents were evident in RBC lipids of all diet groups. Infants fed the n-3 FA-deficient corn oil-formula had significant reductions in DHA as compared to other formula groups. The marine oil group presented DHA concentrations elevated above all other groups. DPA (n-6) relative content found at 36 and 57 wk in RBC lipids was inversely related to DHA content. DPA (n-6) was significantly elevated in the corn oil group, in comparison to the HM and soy/marine groups. By 57 wk, differences in content of the endproducts of n-3 and n-6 FA metabolism [i.e., DHA and DPA (n-6), respectively] were greatly accentuated, compared to 36-wk values. The soy oil group had intermediate DHA and DPA (n-6) values relative to the corn and soy/marine oil groups but differed significantly from the DHA-supplemented infants (34). Figures 1 and 2 summarize changes in DHA content of RBC and plasma phospholipids observed at 36 and 57 wk postconception, respectively.

Methods for assessment of visual function have been described elsewhere, and detailed results of our studies have been recently published (39–41, 47–51). Electroretinographic responses demonstrated significantly higher threshold values from rod photoreceptors in the n-3–deficient group (corn oil-fed) at the 36-wk follow-up relative to groups receiving n-3 FA (26, 28), indicating that the sensitivity and maturity of rod photoreceptors in n-3–deficient infants were reduced significantly compared to infants fed soy/marine formula or HM. A group of 35-wk gestational age infants had their visual maturity tested a few days (3–5 d) after birth and served as a normal standard for comparison. This group of infants receiving transplacentally acquired EFA were nearly identical in all rod electroretinogram (ERG) functional indices to the equivalent conceptional age HM-fed or marine oil–fed premature infants. The soy oil-fed group had higher threshold values than did the soy/marine oil-fed group. Cone photoreceptor function was not significantly affected by diet, although trends were similar to results obtained from rods. At the 57-wk follow-up, corn oil-fed infants consistently had longer implicit times in light-adapted oscillatory potentials. The soy oil-fed infants had some response peaks differ significantly from the HM-fed infants, while the soy/marine and HM groups were similar in oscillatory potential responses. Oscillatory potentials are generated in the inner retina, mature later than distal retinal responses and most likely reflect ganglion cell–amacrine cell interactions (40).

The soy/marine oil- and the HM-fed groups had lower values of log MAR (minimal angle of resolution) (i.e., better acuity) relative to infants fed formula devoid of DHA at the 57-wk follow-up using either visual evoked potentials (VEP) or forced-choice preferential looking response methods. A log MAR value of 0 corresponds to 20/20 Snellen equivalents, while a value of 1 corresponds to 20/200. A significant negative correlation was found between RBC DHA levels and log MAR values; that is, when erythrocyte DHA levels were high, log MAR values were correspondingly low (i.e., better visual acuities). HM- and soy/marine oil–fed infants had the highest DHA/DPA (n-6) ratio in RBC and also had the best visual acuity, i.e., lowest log MAR values. The group that received soy oil as a source of n-3 had poorer VEP acuity at the 57-wk follow-up relative to the soy/marine oil-fed group, indicating that, despite ample LNA, visual function was less mature than in the DHA-supplemented infants. A group of healthy full-term, breast-fed infants matched by conceptional age was used as a control. HM- and soy/marine oil-fed groups were virtually identical to the control group, while corn and soy groups had poorer visual acuities (41, 48). Insets of Figures 1 and 2 summarize changes in ERG threshold and in VEP acuity observed in the four diet groups at 36 and 57 wk postconception, respectively. Visual acuity at 4 mon in full-term HM-fed infants was significantly better than in formula-fed infants and was virtually identical to the HM- and marine oil-fed premature groups.

Reversibility of changes in visual function observed in preterm infants cannot be fully answered from our data since the study was terminated at 57 wk postconception. Most of the ERG alterations at 36 wk normalized with time, based on the 57-wk results, except for the ganglion cell–dependent, oscillatory potentials.

Other functional effects are being evaluated in our present studies in premature infants fed HM or one of three formulas (control, lacking LCPUFA; supplemented with AA and DHA; or supplemented solely with DHA). These measures include organization of sleep–wake cycles during early development, changes in heart rate patterns during sleep states, and spontaneous activity detected by piezoelectric accelerometers during various sleep states and the wakeful period. At the time of this report, the study remains masked; thus results comparing LCPUFA-supplemented groups vs. the unsupplemented group have not been made, but comparisons between formula- and breast-fed groups are revealing.

Since intrauterine life is characterized by the virtual absence of wake periods (52) and since postnatal infants spend most of their time sleeping, study of sleep–wake cycles is an important component in evaluation of CNS development. Specific developmental patterns in infants have been described, and long-term effects of changes in sleep–wake cycles have been documented.

Sleep–wake cycle has been well characterized as a function of age during the first months of life (53–56). It is defined by a combination of physiological recordings, electroencephalogram, electrooculogram, electromyogram, cardiorespiratory pattern, and motor activity. Several striking and precise changes, with specific timing for each, occur during this period, reflecting CNS maturation and adaptation to the extrauterine environment. Typically, the full-term newborn has significantly less indeterminate sleep, with well-differentiated active sleep (AS) and quiet sleep (QS), than do preterm infants whose indeterminate sleep may represent up to 30% of total sleep time. The architecture of the sleep–wake cycle in infants differs markedly from that of older age groups. Day–night differences in sleep–wake cycles, with an increase in the ability to remain asleep during the night and remain awake during the day for progressively longer periods, begin to arise, reflecting emergence of distinctive adult sleeping traits. These trends are relevant developmental indices of brain activity and CNS functional integrity. Information on the developmental pattern for these changes is limited by the scant data available

between 6 and 24 mon of age and by the short duration (<12 h) of recording periods in most published studies.

Following the initial observations of Fagioli *et al.* (37) on the effect of EFA deficiency on sleep–wake organization, we have included polygraphic evaluation of sleep organization during early development. Our initial findings (Uauy, R., and Peirano, P., unpublished observations) confirm previous reports (57) of less AS observed in HM-fed infants; in addition, these infants showed longer duration of QS episodes, indicating a more mature pattern of CNS development. In addition, within the randomized formula groups, we find differences in AS and QS duration and in the percentage of sleep cycles within the sleep episode.

Changes during development in spontaneous heart rate variability (HRV) patterns have been associated with sympathetic and parasympathetic interactions and utilized as an index for normal brain maturation. In healthy neonates, the variability of the high-frequency component is higher in QS than in AS, while the low-frequency component is higher in AS. During development, there is a progressive increase in HRV both during AS and QS, with specific trends for each type of HRV. There is a progressive dominance of the sympathetic tone in AS, also called rapid eye movement (REM) sleep, and a predominance of the parasympathetic vagal tone in QS or non-REM sleep. Our preliminary findings (Uauy, R., and Peirano, P., unpublished observations) support published reports of a higher HRV during AS and QS in HM-fed infants, indicating a more mature pattern of CNS development (58, 59). The effect is observed in all frequency components but is more marked in the high-frequency component, suggesting a higher parasympathetic vagal tone in the HM-fed group. Within the randomized formula groups, we find differences in HRV. These differences are not observed during wake periods.

Measurement of spontaneous motor activity using piezoelectric transducers permits continuous recording of movements during sleep and wakefulness. Observations in healthy infants demonstrate a progressive decrease in motor activity with advancing age in both AS and QS (60). We have preliminary evidence (Uauy, R., and Peirano, P., unpublished observations) indicating that HM-fed infants tend to have more spontaneous activity during sleep and that the duration of movements is longer, particularly during the early wake period.

Studies in term infants fed EFA-controlled diets. We conducted a 3-yr follow-up of healthy, full-term infants to test if HM feeding, which contains significant amounts of DHA, had an effect on the development of visual function (42). The cohorts were breast fed from birth to at least 4 mon or fed for 12 mon formula containing ample LA and 0.5% of total fat as LNA. The breast-fed group was weaned to an oleic acid (18:1)-predominant formula and received egg yolk through 12 mon of age. The breast-fed group maintained higher plasma and RBC membrane phospholipid DHA concentrations throughout the first year of life. At 3 yr of age, stereo acuity, as measured by operant preferential looking techniques, was more mature in breast-fed infants relative to the formula-fed group: 92% of the breast-fed group had mature operant preferential looking stereo acuity, whereas 35% of infants in the formula-fed group met the maturity criteria. Visual recognition in the breast-fed group was also better: while only 61% of the formula-fed infants had perfect scores, 93% of the breast-fed group had perfect scores (42).

These and other data produced by Makrides *et al.* (61) are suggestive of a DHA effect on visual maturation in term infants. Definitive proof, however, must await the final results of randomized, blind, controlled clinical trials of DHA and DHA + AA supplementation in term infants. In addition, the possibility of optimizing LNA to DHA conversion by providing sufficient LNA (>0.7% of total energy) and a lower LA to LNA ratio in formula (<10:1) may also provide for sufficient DHA for normal visual function. Initial results of Ponder *et al.* (62) indicate that this alternate strategy may be simpler and less expensive than addition of n-3 LCPUFA.

A recent study by Innis *et al.* (63) concluded that the need for DHA supplementation should not be based on the alleged improved visual acuity of breast-fed infants, since, despite differences in DHA blood contents, their study revealed no differences in preferential looking acuity between breast-fed and unsupplemented formula-fed infants. The formula used in this study contained 2.1% of total fat as LNA but no LCPUFA. However, this study used a Teller acuity card protocol for acuity assessment, a method which is less sensitive than electrophysiologic techniques to subtle visual deficits.

Other controlled studies without special reference to EFA. The first studies proposing that human breast milk feeding might exert a beneficial effect on infant psychomotor development were published during the 1920s. Since then, several studies reported small but significant advantages in developmental indices for breast-fed infants. Although no study categorically demonstrated the cause for this effect, most authors suggested that nutritional factors in human milk may account for this. Over the past decade, a renewed interest in this question has arisen, and several authors suggested that EFA may play a role in the improved developmental scores during infancy and preschool years observed in HM-fed infants. These studies were reviewed recently, but most are retrospective in nature (64).

In the Rodgers study (65), one of the few long-term follow-up studies of mental development comparing breast-fed vs. formula-fed children, where family, social, and economic variables were controlled, it was found that early breast feeding was associated with better picture intelligence at 8 yr of age and better scores in mathematics, nonverbal ability, and sentence completion at 15 yr of age. The study cohorts were selected from all births occurring during one week in 1946 in Great Britain. Based on confirmed records of early diet, 1, 133 individuals were considered entirely bottle fed, and 1, 291 individuals were never bottle fed. Functional benefits were proportional to the duration of breast feeding and remained statistically significant after controlling for social, cultural, and demographic variables by multivariate analysis. These observations could not be extrapolated to current formula-fed infants because, during the observation period, children were fed unmodified, diluted cow milk with the sole addition of sugar. Protein may have been excessive, and EFA

may have been inadequate. In a recent study by Rogan *et al.* (66), 855 newborns receiving modern formula were enrolled from 1978–1982 and followed through school age. Cognitive development was assessed with appropriate methodology and confirmed the results of the earlier British study. Breast-fed infants had significantly higher scores in the Bayley scale of mental development at 2 yr, and in the McCarthy scale at 3 and 4 yr. In addition, slightly higher English grades on report cards were found in the breast-fed group after adjusting for relevant confounding variables. A recent publication from a study in Spain confirms the benefits in mental development and the lack of an effect on motor abilities (67).

A possible long-term effect of early HM feeding on brain development is also suggested by results from a controlled trial of preterm infants indicating that HM feeding by nasogastric tube for 28 d was associated with a +8.3 point intelligence quotient difference at 8 yr of age relative to a formula-fed group after controlling for socioeconomic and other maternal variables (68). These controlled observations in preterm infants indicated that HM feeding may, in fact, offer unique advantages for brain development. More recently, a study of 526 full-term infants born in Groningen, The Netherlands, between 1975 and 1979 who were followed for 9 yr demonstrated a significantly lower occurrence of neurological dysfunction in the 135 breast-fed infants (breast fed for more than 3 wk) after adjusting for obstetric, perinatal, neonatal neurological, and social differences (69).

Differences in the early functional organization of the CNS between breast- and bottle-fed infants have also been reported. Nocturnal sleep–wake state organization at 4 mo of age show that breast-fed infants spend a higher percentage of time in QS and a lower percentage of time in AS as compared to formula-fed infants (57). Furthermore, heart rate values were lower in all sleep–wake states in breast-fed infants (70). Even though total energy expenditure during AS and QS did not differ between feeding groups, the different organization of sleep states throughout the night might account for differences in energy expenditure between feeding groups (57).

There are indications that breast-fed neonates even at the age of 2 d postpartum are better organized, physiologically, than are bottle-fed neonates (58,59). They exhibit a more organized HRV pattern and a slower heart rate in both AS and QS. They also present higher incidence of low-frequency, slower heart rate, greater HRV, and elevated vagal tone, indicating more mature HRV patterns. Conversely, breast-fed neonates were also reported to be behaviorally more irritable, more difficult to test, and less able to be consoled once crying (59).

Evidence from patients with inborn errors of metabolism. There is yet no conclusive proof for an inherited metabolic defect of DHA and or AA synthesis causing altered brain or retinal function. There is increasing evidence, however, that peroxisomal diseases may be associated with defective formation of C_{22} LCPUFA. Recently, Bennett *et al.* (71) reported fascinating but uncontrolled observations on the improve-

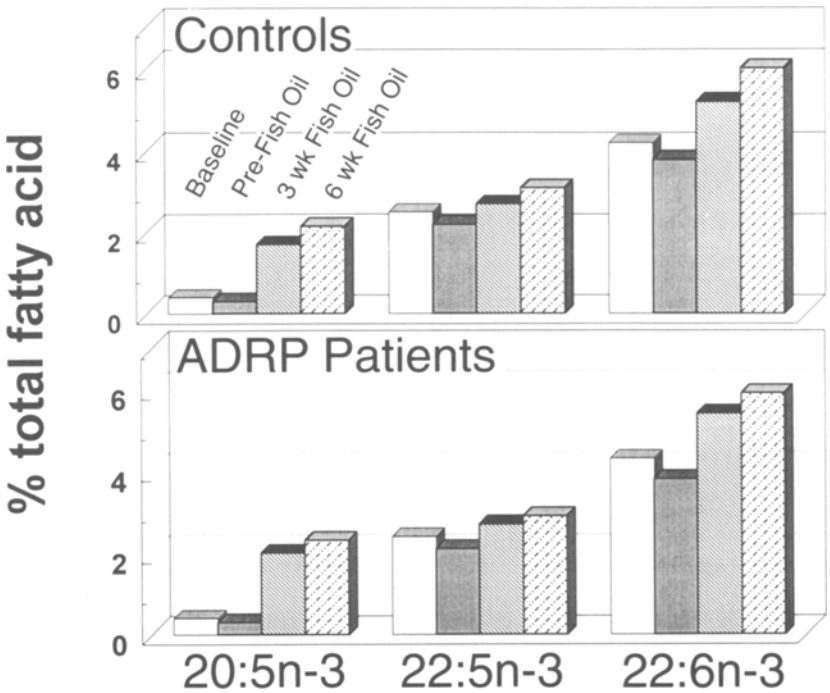

FIG. 3. Uptake of n-3 LCPUFA into red blood cell (RBC) lipids following fish oil supplementation. Levels of 20:5n-3 (EPA), 22:5n-3 (DPA), and 22:6n-3 (DHA) are reported as percent total RBC fatty acids for control and autosomal dominant retinitis pigmentosa (ADRP) subjects. Samples were obtained at baseline, after 6 wk on a controlled low-n-3 diet (pre–fish oil) and after continuing for 3 and 6 wk on the controlled diet plus daily supplementation of 3 g of a standard fish oil concentrate.

ment in neurological, retinal, and cortical electrophysiologic responses and in developmental tests in Batten's disease patients after n-3 supplementation. We studied lipid abnormalities in patients with retinitis pigmentosa (RP) and have evidence suggesting that some autosomal dominant RP (ADRP) and X-linked RP (XLRP) patients may have defective formation or incorporation of LCPUFA into membranes (72–74).

Zellweger disease. Martinez (75) provided data from several patients, indicating that, in peroxisomal disorders, brain DHA content is extremely low, plasma and RBC DHA levels are below normal, and biochemical response of these patients to fish oil supplementation is only partial. Sprecher (76) indicated that the peroxisomal β oxidation step necessary for C_{22} PUFA biosynthesis is restricted in Zellweger disease patients, since they cannot convert 24:6n-3 to 22:6n-3. Preliminary results on a limited number of patients indicate that supplementation with pure DHA is capable of preventing and also of reverting abnormal motor and mental functions associated with these conditions (77). Concomitant evidence from fibroblast studies of these patients provides supportive evidence as to the relative importance of peroxisomal β oxidation in determining biochemical and functional consequences of this disease (77).

Batten's disease. Recently, Bennett *et al.* (71) described alterations in LCPUFA metabolism in juvenile Neuronal Ceroid-lipofucsinosis, also known as Batten's disease. These patients present seizures, altered psychomotor development, retinal degeneration of rods and cones leading to blindness, motor disturbances progressing to spastic tetraplegia, and death during the first decades of life. The disease has a variable rate of progression, but in all cases it leads to mental retardation and severe motor impairment. RBC n-3 LCPUFA were found to be lower in patients with the disease relative to controls, and a significant rise was noted in these FA after marine oil supplementation (71,78). Follow-up of 6 patients after 5 to 7 yr of variable supplementation regimens demonstrated a possible amelioration in the rate of progression compared to what was predictable based on the natural history of the disease (71). Given the uncontrolled nature of these observations and the variable natural course of progression in this condition, caution should be exercised in interpreting these findings. A controlled multicenter trial is needed to clarify the clinical response to LCPUFA supplementation in these patients.

Retinitis pigmentosa. We and others have observed abnormalities in DHA metabolism in patients with RP (72–74, 79–83). RP and associated retinal degenerations are characterized by progressive night blindness and visual field constriction resulting from photoreceptor degeneration. Tissue levels of DHA and other LCPUFA may be involved in the pathophysiology of RP. There is an accumulating body of evidence that selective reductions in the plasma lipid levels of DHA may be associated with various forms of hereditary retinal degeneration (79–83). However, there were lower 18:4n-3 and higher 22:6n-3 levels in the plasma lipids of ADRP patients.

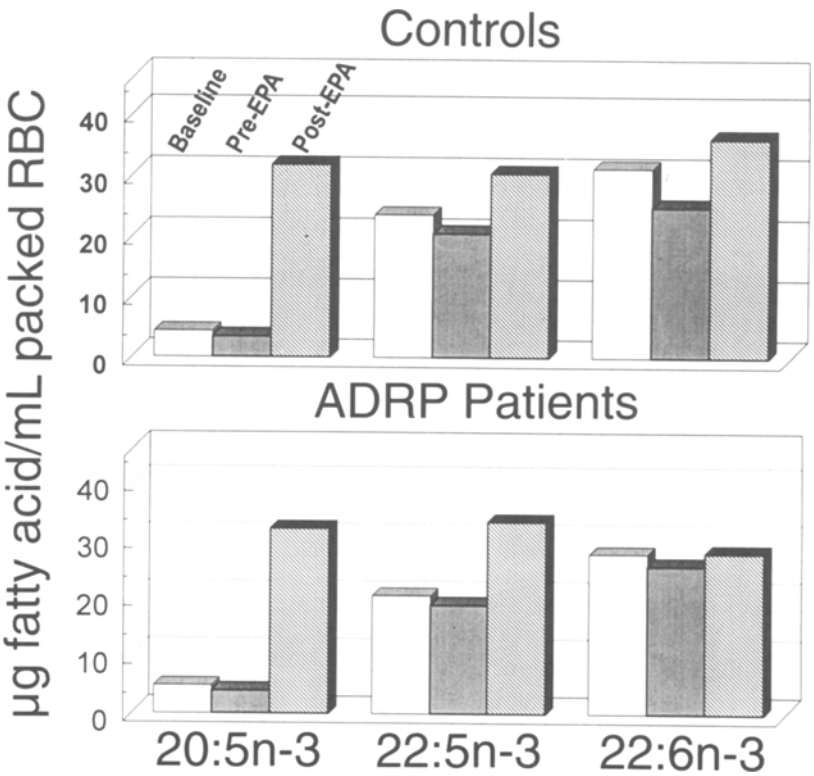

FIG. 4. Incorporation of EPA and metabolites into red blood cell (RBC) lipids following nearly pure 3 g per day EPA supplementation. Levels of 20:5n-3 (EPA), 22:5n-3 (DPA), and 22:6n-3 (DHA) are reported as μg per mL of packed RBC for control and ADRP subjects. Samples were obtained at baseline (base), after 6 wk on a controlled, low-n-3 diet (pre-EPA) and after 3 wk of the controlled diet plus daily supplementation of 3 g of EPA ethylester (post-EPA).

Segregation of patients into subgroups based on genetic inheritance type revealed that the greatest deviation from normal in plasma DHA levels was found in X-linked patients, whereas those with autosomal dominant inheritance were not significantly different from controls (84). Furthermore, specific families affected with ADRP demonstrate FA abnormalities, while other ADRP families have near normal FA profiles (80). Our results extend these findings by showing relatively similar levels of DHA in RBC among members within a family with ADRP. In ADRP, deficits in DHA levels have most frequently been identified in plasma lipids, which are rapidly modified by dietary fat intake. Abnormal lipid metabolism may result in a subnormal availability of DHA for distribution to peripheral target tissues. A limited supply of DHA for photoreceptor disc membrane structure may contribute to abnormal retinal function.

We have assessed the FA status in plasma and RBC of 50 subjects with ADRP as compared to that of 20 normal-sighted controls (72). In plasma lipids, patients with ADRP had significantly lower levels of total saturates than did the controls; derivatives of the n-6 series were significantly higher in patients with ADRP, in contrast to the lack of significant differences in n-3 FA between patients and controls. There were lower 18:4n-3 and higher 22:6n-3 in the plasma lipids of ADRP patients, however. Furthermore, a higher unsaturation index was found in the plasma lipids of patients with ADRP. In contrast to plasma, the RBC lipid FA profile of patients with ADRP compared to controls had significantly higher levels of monounsaturates and 18-carbon EFA of both the n-6 and n-3 series. Levels of n-6 LCPUFA levels were reduced in patients, particularly AA and 22:4n-6, which were markedly reduced. Overall, total n-3 LCPUFA were significantly lower than in controls. Consistent with this, the unsaturation index in RBC of patients with ADRP was reduced significantly. Full-field ERG were obtained from all patients under 50 yr of age to evaluate retinal function. Patients with lower RBC DHA levels (<3% of total FA) had significantly lower rod/cone amplitude ratios than did patients with higher RBC DHA levels (>4%) (72). Although FA changes found in ADRP patients were of moderate magnitude (<25%) compared to controls, these changes may have a significant impact on visual function if persistent over many years. This may be of particular importance for a patient who has visual function already compromised by a gene mutation.

Based on these observations, we undertook supplementation trials in a small group of patients with ADRP under controlled dietary conditions. The first trial assessed the capacity to absorb and incorporate n-3 LCPUFA as provided by a standardized fish oil concentrate. Results of this study revealed that patients did as well as controls in incorporating n-3 LCPUFA into RBC membranes, as shown in Figure 3. The second trial addressed the conversion of EPA to DHA, after oral administration of nearly pure EPA ethyl ester for 3 wk. Results of this study, as shown in Figure 4, demonstrated similar incorporation of 20:5n-3 and conversion to 22:5n-3 RBC for ADRP and control subjects after EPA supplementation. DHA in ADRP patients remained unchanged while controls exhibited a 27% higher incorporation into RBC after EPA was administered (73). These results suggest the presence of a metabolic defect in the final elongation/desaturation or β oxidation steps necessary for DHA formation from EPA.

We propose that low plasma and RBC DHA levels attributable to impaired transport or metabolism of LCPUFA may coexist with certain gene mutations and contribute to the severity of visual impairment in those with ADRP.

Our studies provide clear evidence that dietary n-3 FA deficiency affects eye and brain functions of preterm infants as measured by ERG, cortical VEP, and behavioral testing of visual acuity. Preterm infants require DHA in their diet because they are unable to form them in sufficient quantity from LNA provided by soy oil–based formula products. Dietary n-3 and n-6 FA intake resulted in discernible differences in the FA composition of plasma and RBC membrane lipids. Changes in membrane chemical structure are likely responsible for the observed functional effects. Definitive recommendations for term infants await results of randomized trials of DHA supplementation.

Preliminary evidence indicates that peroxisomal disorders, autosomal dominant and X-linked forms of RP, and possibly Batten's disease are associated with altered n-3 metabolism and may represent defects in DHA biosynthesis or incorporation into membranes. Clinical trials supplementing with pure DHA are required to evaluate this possibility further.

Our results indicate that n-3 FA are required for optimal nervous system development and for maturation of the retina in human infants and thus they should be considered essential nutrients. DHA is required by preterm infants and possibly by individuals with genetic defects in LCPUFA metabolism, such as those with peroxisomal disorders and some forms of RP.

Effect of Dietary Docosahexaenoic Acid on Brain Composition and Neural Function in Term Infants

Robert A. Gibson*, Mark A. Neumann, and Maria Makrides

Department of Paediatrics and Child Health, Flinders Medical Centre, Adelaide SA 5042, Australia

ABSTRACT: There is a need to determine whether there is a dietary requirement for docosahexaenoic acid (DHA, 22:6n-3) by term infants to achieve their full developmental potential. Studies of brain fatty acid composition demonstrated that infants who were breast fed had greater levels of cerebral cortex DHA than did infants who were formula fed, suggesting that DHA in the cerebrum is dependent on a supply in the diet. Some physiological studies reported that electrophysiological and behavioral assessments of visual function were improved in breast-fed infants relative to those fed formula and that this was related to the length of breast feeding. While some randomized studies of DHA supplementation of infant formula to term infants demonstrated that the visual function of formula-fed infants could be improved to breast-fed levels by adding DHA to formula, others failed to demonstrate an effect. Variations in dietary treatments and methods of assessment make comparison of the studies difficult. Further work is necessary to rigorously establish if there are long-term benefits of dietary DHA to the term infant.
Lipids 31, 1–XXX (1996).

Breast milk is the perfect food for the growing infant, with all nutrients in an ideal balance (1–5). Despite recommendations from health professionals and learned committees (6,7), only about 75% of Australian mothers are discharged from birth centers breastfeeding their infants. Difficulties in maintaining lactation in the home results in a rapid decline in breast-feeding rates, so that, by six months, less than 30% of those who start out doing so successfully maintain lactation (8).

Infant formula is the only recommended alternative to breast milk. Since breast milk is a living tissue containing, in addition to basic nutrients, a range of cells, and important immunoglobulins, it is not possible to exactly duplicate breast milk and provide it in an easily stored form (dry powder) that can be reconstituted at will. Approximations have been made by manufacturers that reflect the reality of stability, bioavailability, and cost. Examples of approximations made by manufacturers include proteins, mineral iron, and fats. The composition of constituent amino acids of skim-milk protein varies significantly from human milk, necessitating cow milk proteins being added at a higher level (≈1.5%) than the level found in human milk (≈1%). Iron is present in very low levels in human milk (≈1 mg/L) but is extremely well absorbed (>50%). The only forms of iron that are stable in dry-powder form tend to be poorly absorbed (<10%), necessitating iron being added at many times (>10 mg/L) the level found in human milk. Fats of human milk reflect those found in human plasma and provide a complex mixture of fatty acids, including the essential 18-carbon polyunsaturates and many long-chain (20- and 22-carbon) polyunsaturated fatty acids (LCPUFA) that are proving to have important biological activity. In contrast, infant formulas contain chiefly vegetable oils containing only 18-carbon essential fatty acids, α-linolenic acid (ALA, 18:3n-3) and linoleic acid (LA, 18:2n-6).

Despite compromises made by manufacturers, infant formulas provide the growing infant with a basic level of nutrition that results in growth rates that are as good as or better than those observed in breast-fed infants. It has only been since neurophysiological end-points have been used that the possibility of deficiencies/limitations in the fat supply of formula-fed infants has been raised. In the past, dietary fat was considered mainly a source of energy required by the baby to support rapid growth. It is now realized that the quality and composition of fat supplied to the infant has important effects on developing organs, especially the brain. Of particular interest are the results of research on the roles of two LCPUFA, docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6).

Studies comparing formula- and breast-feeding indicated that formula-fed infants had less DHA and less AA in their erythrocytes relative to breast-fed infants. This was shown to be due in part to an imbalance in the ratio of ALA and LA. However, studies that tried to increase the availability of ALA to formula-fed infants demonstrated that it was not possible to match erythrocyte DHA levels to those of breast-fed infants (2,9). These results suggest that adding LCPUFA directly to infant formula may be necessary to match fatty acid profiles of breast-fed infants.

The relationship between brain fatty acids and diet in human infancy has also been studied. Breast-fed infants (receiving

DHA and AA) have a greater proportion of DHA in their brain cortex relative to those fed formula, largely an effect of length of feeding (10). In contrast, there are no differences in levels of brain AA between breast- and formula-fed infants. This suggests that either AA is aggressively conserved in brain tissue or that the amount of AA produced from the precursor (LA) in formula is sufficient to meet the AA requirements of the rapidly growing brain.

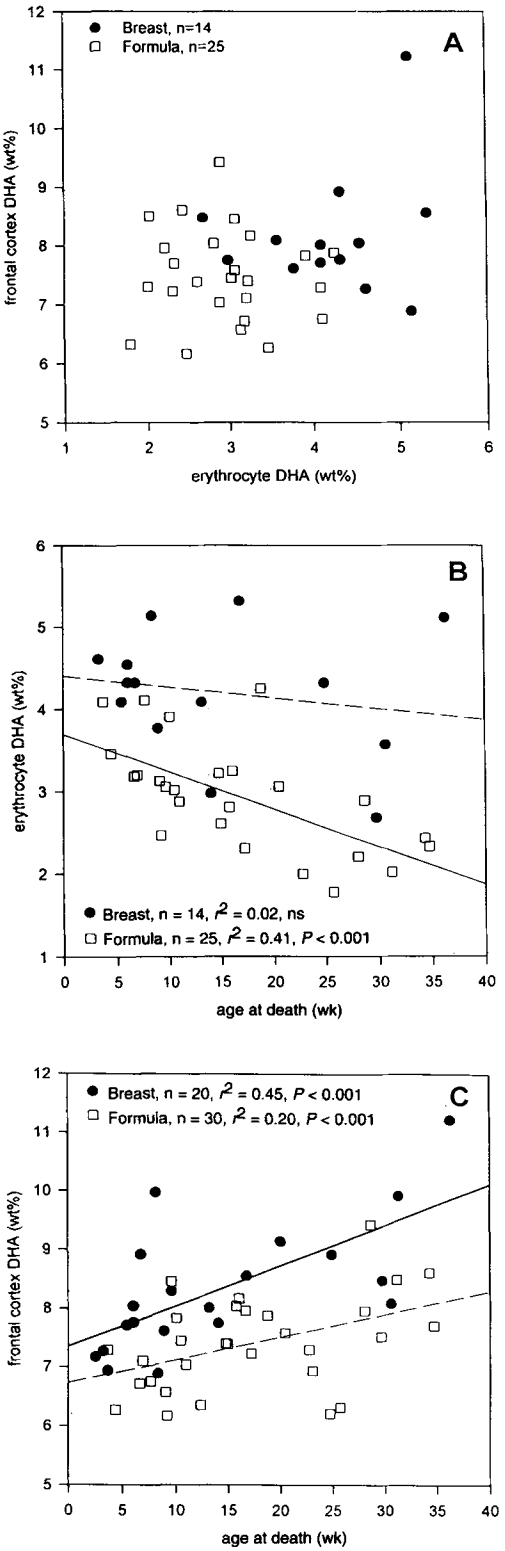

FIG. 1. A: Frontal cortex docosahexaenoic acid (DHA) as a function of erythrocyte DHA in term infants dying suddenly; B: relationship between erythrocyte DHA and age at death for breast- and formula-fed infants; C: relationship between frontal cortex DHA and age at death in breast- and formula-fed infants.

Clinical studies that associate dietary DHA with neural performance often use erythrocyte DHA as an inferred marker of brain DHA (11–13). Our results (Fig. 1) illustrate the fact that there is no simple association between cerebral DHA and erythrocyte DHA, and this may in part be explained by the different relationships among cerebral DHA, erythrocyte DHA, and age at death for breast- and formula-fed infants. For example, the proportion of cortex DHA increases with age at a greater rate for breast-fed than for formula-fed infants, while erythrocyte DHA decreases with age for formula-fed but not for breast-fed infants (Fig. 1). Despite these complicated associations, 44% of the variability in cerebral DHA could be predicted by knowing only the age at death and the level of erythrocyte DHA (10). Because both cerebral and erythrocyte DHA were influenced by diet, erythrocyte DHA may only be a valid marker of cerebral DHA if a single age is considered and if diet prior to sampling has been constant.

We examined the visually evoked potentials (VEP) of healthy term infants fed either breast milk or formula. Formula-fed infants had low erythrocyte DHA levels and reduced visual acuity, while breast-fed infants had high DHA levels and better acuity (14). We recently investigated whether differences between breast- and formula-fed term infants could be corrected by the addition of fish oil (a source of DHA) to infant formula (15). In a study involving over 70 term infants, VEP acuity in breast-fed and fish-oil-supplemented formula infants was better than in standard formula-fed infants at both 16 and 30 wk of age. Erythrocyte DHA in breast-fed and fish-oil-supplemented infants was maintained near birth levels for the entire 30-wk study period, but was reduced in infants receiving standard formula. Furthermore, VEP acuity was better in infants fed the supplemented formula or breast milk. These results are supported by clinical studies in preterm babies (12,13,16).

Most importantly, our data establish that VEP acuity is related to the length of breastfeeding. Infants breast fed for less than 16 wk had erythrocyte DHA levels intermediate between those fed breast milk continuously and those fed formula from birth when measured at 16 wk of age (Fig. 2). Furthermore, when infants were measured at 30 wk of age, only those who had received DHA for at least 16 wk had VEP acuity scores comparable to those breast fed for the entire 30 wk (Fig. 3). VEP acuity scores of those breast fed for less than 16 wk were not different than those formula fed from birth (Fig. 3). Taken together, the data indicate a need for a continuous supply of LCPUFA from breast milk for at least the first four months of life.

Growth of all infants was similar (15). AA in fish-oil-supplemented infants was reduced below levels of those fed standard formula, and this was probably exacerbated by the high levels of other fatty acids [such as eicosapentaenoic acid

(EPA), 20:5n-3] found in fish oil. This may be of some concern, as studies involving preterm infants suggest that AA is important to some aspects of growth and development (17,18).

Our results suggest that DHA levels and one visual aspect of neural performance of formula-fed infants can be normalized to breast-fed levels following supplementation with fish oil. Suppression of erythrocyte AA levels associated with the use of high-EPA fish oil as the n-3 LCPUFA supplement, however, is undesirable. Thus there is a need for a blend of fatty acids in a similar balance to breast milk, which can be safely added to formulas.

Although our results show an effect of diet on the development of the visual pathway in a group of South Australian term infants (15), other studies have not demonstrated comparable results. For example, a recent study reported by Auestad and co-workers (19) failed to demonstrate any relationship between dietary n-3 LCPUFA and visual acuity measured by sweep VEP and Teller acuity cards. These data support the study of Innis *et al.* (20), who showed that breast- and formula-fed infants have similar preferential-looking acuity development during the first three months of life. Interestingly, Carlson *et al.* (21), using formulas similar to those of Auestad *et al.* (19), demonstrated a beneficial effect of DHA on Teller acuity at two months postnatal age but not at later ages. This highlights the complexity of this area of endeavor. Uniform standards are required in study design, dietary treatments, and assessments if we are to determine whether real effects of dietary LCPUFA exist.

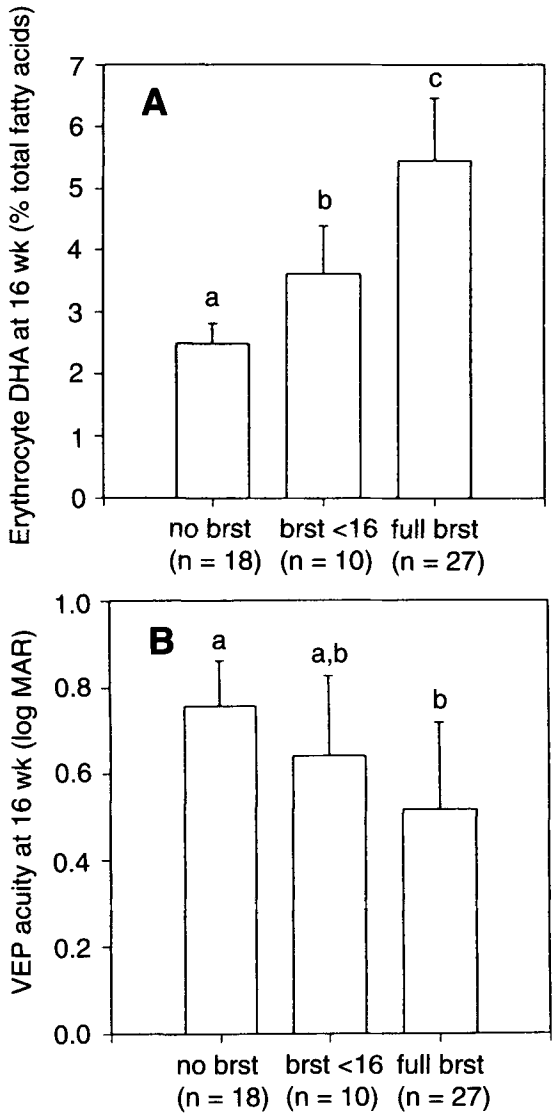

FIG. 2. Effect of breastfeeding duration on erythrocyte A: DHA ± SD and B: visually evoked potential acuity ± SD at 16 wk of age. For erythrocyte DHA, values without a common superscript a significantly different at $P < 0.0001$. VEP acuity is expressed as logMAR (log of the minimum angle of resolution), and values without common superscripts indicate significant differences at $P < 0.0005$. Abbreviation as in Figure 1.

Dietary treatments have varied widely between studies (12,13,15,16,19,21). Study formulas proposed to improve physiological outcome have contained variable DHA levels, in the presence or absence of other fatty acids, such as EPA, AA, and γ-linolenic acid (18:3n-6). The molecular type of the lipid source and the background fat blend, regarding the levels of LA and ALA, have also differed. All may affect the LCPUFA status of the infant.

Furthermore, many of these studies (12,13,16) either had no breast-fed reference groups or had breast-fed groups that received some formula. For example, Uauy *et al.* (22) complemented their human-milk reference group with increasing amounts of the fish-oil test formula, so that these infants received 50% of their energy from the test formula at four months postterm. In addition, differences exist in the DHA status of breast-fed infants (23,24), as breast milk DHA varies according to the diet of the mother.

Many of the studies have based their physiological assessments on various aspects of visual function. The electroretinogram is the specific electrical response of the retina to light and provides an assessment of the functional state of the retinal layers. Birch and coworkers (16) demonstrated an effect of n-3 LCPUFA in preterm infants at 36 wk post-conceptional age (PCA) but not at 57 wk PCA. These results concur with the findings that the retinal DHA accretion is complete by 40 wk gestation (25) and that there are no differences in retinal DHA between breast- and formula-fed infants postterm (10).

Other visual assessments, such as visual acuity, are more difficult to interpret than the results of the electroretinogram. There are both electrophysiological and behavioral ways to measure visual acuity, and acuity values obtained from such tests may be measuring different phenomena. For example, the VEP is the visually evoked response of the electroencephalogram recorded at the occipital lobe and is evoked by a moving pattern. There are several methods of VEP recording, and these largely depend on the nature of the pattern stimulator. Different patterns and different reversal rates elicit different brain responses. Studies that demonstrated differences in VEP acuity with n-3 LCPUFA status extrapolated acuity threshold from either transient or steady-state checkerboard patterns (12,15). Auestad *et al.* (19), who showed no effect of VEP acuity development with diet, assessed VEP acuity using the sweep technique with bar gratings.

Behavioral measures of acuity can be rapid and easy to use but are also subject to procedural differences. Most studies that attempted to find a relationship with n-3 LCPUFA and function used some measure of behavioral acuity. Birch *et al.* (12), using the more formal forced choice preferential looking methodology, demonstrated differences between dietary group 57 weeks PCA. Similarly, Carlson *et al.* (13,21), using a rapid acuity card technique (Teller), also demonstrated differences between treatment groups of both preterm and term infants. In contrast, other studies in term infants have failed to confirm these results using Teller acuity cards (19).

It is probably important to consider factors other than dietary DHA that may affect the DHA status of the infant including gestational age, parity, and maternal diet. The number of infants involved in the trial affect the power of the studies. For example, interpretation of preterm studies is made difficult, as there have only supposedly ever been 10 breast-fed preterm infants (22). It is difficult to extrapolate studies on visual function to developmental milestones. Developmental assessments such as Bayley's scales are strongly influenced by socioeconomic class, maternal education, and amount of stimulation the child receives in the home; these must all be controlled before the effect of any dietary treatment can be tested. Overcoming the confounding influences will require well-controlled studies involving large numbers.

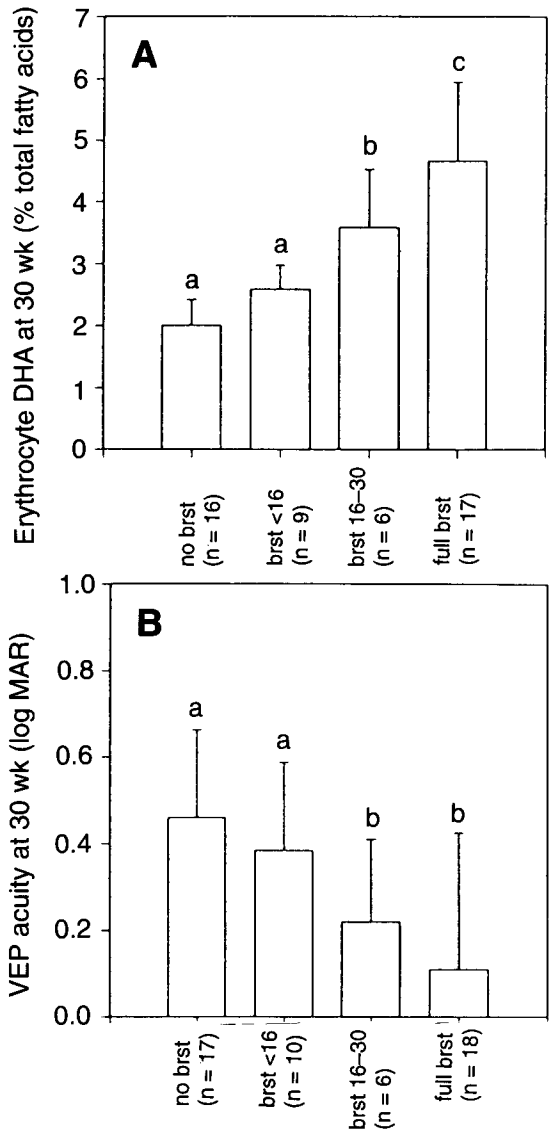

FIG. 3. Effect of breastfeeding duration on erythrocyte A: DHA ± SD and B: VEP acuity ± SD at 30 wk of age. For erythrocyte DHA, values without a common superscript are significantly different at $P < 0.0001$. VEP acuity is expressed as logMAR (log of the minimum angle of resolution), and values without common superscripts indicate significant differences at $P < 0.001$. Abbreviations as in Figures 1 and 2.

There are some tantalizing clues that suggest that early nutrition is related to long-term outcome. Barker *et al.* (26,27) reported that nutritional stress before the baby is born can be a determinant in adult cardiovascular disease, and the work of Lucas *et al.* (28) suggests that breast-milk consumption by preterm infants for the first four weeks of life is related to improvements in intelligence quotient at 7–8 y of age. In the absence of additional information, it may be circumspect to assume that a supply of LCPUFA is important, since LCPUFA accumulate in the brain when provided and are present in breast milk.

Formula manufacturers have released formulas containing LCPUFA, generally in the form of a phospholipid fraction isolated from egg yolk. They are apparently stable to oxidation in powder form but increase levels of phosphorus and choline (from the phospholipid) in the formula. Experimental batches of formulas with fish oils as sources of LCPUFA proved to be unstable in dry-powder form; however, the AA and DHA of breast-milk fats are in the form of triglycerides. Addition of LCPUFA to preterm formulas has been recommended by authorities in Europe (7) and Canada (6). The question to be addressed is whether there is a sufficient body of evidence supporting inclusion of LCPUFA in the diets of infants.

Increased Docosahexaenoic Acid Levels in Human Newborn Infants by Administration of Sardines and Fish Oil During Pregnancy

William E. Connor*, Richard Lowensohn, and Lauren Hatcher

The Division of Endocrinology, Diabetes and Clinical Nutrition, Department of Medicine and the Department of Obstetrics and Gynecology, Oregon Health Sciences University, Portland, Oregon 97201

ABSTRACT: In rhesus monkeys, maternal n-3 fatty acid deficiency during pregnancy produces infant monkeys deficient in n-3 fatty acids at birth. These results stimulated current experiments to find out if n-3 fatty acids from fish in the diets of pregnant women would influence the concentration of docosahexaenoic acid (DHA, 22:6 n-3) in the newborn human infant.

Fifteen healthy pregnant women were enrolled to receive a 9-wk dietary supplementation of n-3 fatty acids from the 26th to the 35th wk of pregnancy. Sixteen pregnant women were not supplemented and served as controls. n-3 Fatty acid supplementation consisted of sardines and additional fish oil, which provided a total of 2.6 g of n-3 fatty acids per day (d) for the 9-wk period of supplementation. This included 1.01 g DHA.

The end point of this study was the blood concentrations of DHA in the newborn infant. DHA in maternal red blood cells increased from 4.69% of total fatty acids to 7.15% at the end of the supplement period and at the time of delivery decreased (as expected) to 5.97% of total fatty acids. Maternal plasma showed a similar change from 2.12 to 3.51% of total fatty acids and then decreased to 2.35%. Levels of DHA in plasma and red blood cells of unsupplemented mothers did not change during the same time period.

Levels of DHA in blood of newborn infants differed greatly in infants born from n-3–supplemented mothers compared with control infants. In red blood cells, DHA was 7.92% of total fatty acids compared with 5.86% (control infants). Plasma values showed a similar difference: 5.05% vs. 3.47% (controls). In n-3–supplemented infants, DHA concentrations were 35.2% higher than in control infants in red blood cells and 45.5% higher in plasma.

These data indicate the importance of maternal dietary n-3 fatty acids and, in particular, maternal dietary DHA in promoting higher concentrations of DHA in the blood of the newborn infant.
Lipids 31, S-183–S-187 (1996).

The growth of the brain occurs in two phases: prenatal and postnatal. During intrauterine life, the fetal brain accumulates long-chain polyunsaturated fatty acids, docosahexaeonoic (DHA, 22:6 n-3) and arachidonic acid, which are vital components of phospholipid membranes of the newborn infant (1). These fatty acids are transported from maternal circulation across the placenta into fetal venous blood (2), from which they subsequently cross the blood–brain barrier into the central nervous system (3). The quantity of DHA that maternal circulation must supply to the fetus is considerable. The fetal brain acquires approximately 21 g/wk during the last trimester of pregnancy (4). Even more DHA, however, is stored in the white adipose tissue, 326 mg/wk.

In monkeys fed a diet deficient in n-3 fatty acids, the amount of DHA found in the maternal circulation is much lower than normal. Thus, newborn monkeys born from deficient mothers have low contents of DHA in blood and tissues, including brain and retina (5). When the n-3–deficient diet was continued after birth, infant monkeys developed impaired vision and abnormal electroretinograms (6). Premature human infants also have impaired visual function when fed standard infant formulas (7,8). Vision in these premature human infants improved considerably when fish oil,

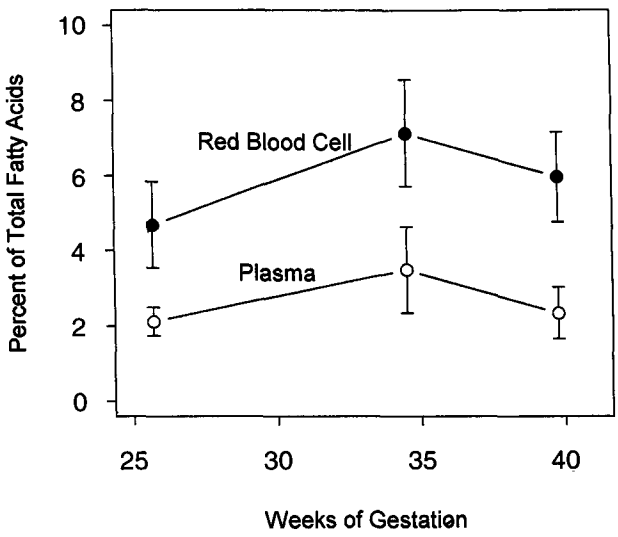

FIG. 1. Plasma and red blood cell docosahexaenoic acid (DHA) in supplemented mothers (× ± SD) at study entry (before supplementation), at end of supplementation (34 wk gestation), and at

supplying DHA and other n-3 fatty acids, was incorporated in their formulas (8). The data in premature human infants are of interest in the context of the present study because at birth blood and tissues of premature infants represent earlier timepoints in the life of the full-term infant during intrauterine growth and development.

This evidence that newborn infant monkeys are n-3 fatty acid–deficient when the maternal diet is deficient stimulated development of an experiment in pregnant women to ascertain if increasing the amount of DHA in maternal diet and then in maternal circulation would influence blood levels of DHA in the newborn infant. Our hypothesis was: would higher dietary intakes of DHA in pregnant women increase the DHA content in their newborn infants? This fatty acid is of special interest because of its importance in the development of the brain and retina.

METHODS

Volunteers. Thirty-one healthy pregnant women and their newborn offspring participated in this study. All women participating in the study signed consent forms approved by the Committee on Human Research of Oregon Health Sciences University (OHSU, Portland, OR).

Supplemented group. Healthy pregnant women attending the Obstetrical Clinic of the University Hospital (Portland, OR) were invited to participate in a study that involved increasing their consumption of n-3 fatty acids in the form of sardines and fish oil. Women were recruited at approximately 24 wk gestation but were accepted into the study until 30 wk gestation. Fifteen women consented to the study, were supplemented, and successfully completed the study.

Unsupplemented (control) group. Healthy pregnant women were recruited to participate as control subjects with no supplementation. Control volunteers were seen in a separate clinic area from supplemented women.

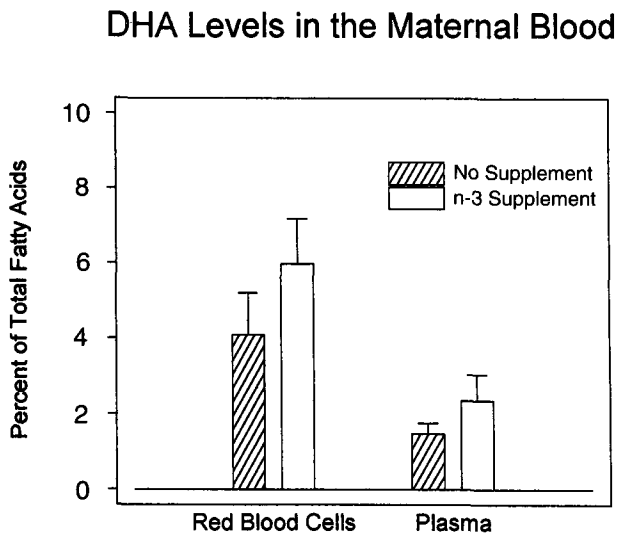

FIG. 2. Red blood cell and plasme docosahexaenoic acid (DHA) levels in supplemented and unsupplemented mothers at delivery. Red blood cell DHA was significantly different at $P < 0.0042$. Plasma DHA was significantly different at $P < 0.0042$.

TABLE 1
Fatty Acid Composition of n-3 Fatty Acid Supplements

	Percent of total fatty acids	
Supplement	Sardines	Fish oil
EPA[a]	7.5	17.9
DHA[b]	7.1	12.0
Total n-3	19.2	36.0
Total n-6	24.7	3.3
Monounsaturated	40.0	29.2
Saturated	13.6	30.4

[a]EPA = Eicosapentaenoic acid.
[b]DHA = Docosahexaenoic acid.

Supplementation. The supplementation period began at entry (24 to 30 wk gestation) and continued until 34 wk gestation at which time supplementation was discontinued. The goal of supplementation was to achieve at least 3 g/d total n-3 intake or about 1.1 g DHA. The women enrolled in the supplement group were asked to consume a combination of sardines and fish oil: $\frac{1}{2}$ can of sardines per d plus 7 fish oil capsules (1 g each) or 1 can of sardines per d plus 3 fish oil capsules. Sardines were supplied to the women in $3\frac{3}{4}$-oz tins. Those who did not tolerate sardines were asked to take 10 fish oil capsules per d in a divided dose. Women were encouraged to eat the recommended amount of sardines and supplement but were not dropped from the study if they were unable to comply fully. They were asked to report only what they did consume. Women recorded their intake of supplements and sardines on provided intake forms. These were returned at each visit. Based on the total quantity of each type of sardines eaten and number of fish oil capsules consumed, a total intake for the supplement period was calculated. Fish oil was provided by Hall Laboratories, Inc. (Portland, OR). Sardines were provided by the North Atlantic Sardine Council (Seattle, WA). Fatty acid composition of these products is listed in Table 1.

Diet assessments. The habitual dietary n-3 fatty acid intake of the pregnant women was assessed by a detailed food frequency questionnaire that identified 30 commonly eaten fish and seafood items and asked the women to identify the amounts of each item eaten in the past month.

Sample analysis. Blood samples were collected from all mothers at entry, monthly after entry, and at delivery. A sample of the infant's blood was obtained from residual blood in the umbilical cord. Samples collected at delivery were refrigerated and taken to the laboratory for analysis within 24 h. Plasma was separated immediately after centrifugation. The erythrocyte pellet was washed three times with saline. Fatty acids of lipid extracts of plasma and erythrocytes were liberated by incubation with 6% ethanolic KOH and then extracted with hexane. After methylation, fatty acids in extracts were quantitated by capillary gas–liquid chromatography as described previously (2). An internal standard of heptadecanoic acid was added to both erythrocyte and plasma extracts. Peaks were identified by computerized comparison with standards, which were run daily. Plasma and erythrocyte fatty acid concentrations are given in percent of total fatty acids.

Statistical analysis. Gestation in weeks was calculated for each study visit. Individual fatty acids for plasma and erythro-

cytes were averaged for entry, end of supplementation (34 wk gestation), and delivery. In one mother who had triplets, fatty acids of the three cord blood samples were averaged and considered as one analysis. Fatty acids for mothers in the supplemented and control groups were compared by *t* test at each time-point. Infants' fatty acids at delivery were also compared by *t* test. The Bonferonni correction for multiple *t* test comparisons was made: *P* value for fatty acid comparisons of mothers were multiplied by 42 (14 fatty acids each compared 3 times) and infants' *P* values were multiplied by 14 (14 fatty acids compared once). The level of significance was $P < 0.05$ for corrected *P* values.

RESULTS

Amounts of n-3 fatty acids consumed by both control and supplemented pregnant women. Consumption of DHA and eicosapentaenoic acid (EPA) in the usual diet of both groups of pregnant women was small and comparable in both groups: 2.5 ± 1.5 g/mo in supplemented mothers and 2.82 ± 2.2 g/mo in control mothers. Food sources of these fatty acids were largely from fish and chicken. Supplemented mothers, however, ingested 147 ± 59 g n-3 fatty acids from sardines and fish oil over the entire period. The range was 45 to 219 g. The daily amount of n-3 fatty acids was 2.6 g (range 0.95–3.1 g) and included 20:5, 22:5, 22:6n-3 fatty acids. Of the total 147 g ingested, the fatty acid breakdown between DHA and EPA was as follows: 59.4 g and 75.7 g, respectively.

Consumption of sardines depended on tolerance of the women. They were given new recipes that incorporated sardines. It was emphasized that sardines, besides being rich in n-3 fatty acids, contained ample amounts of protein and calcium. Sardine consumption was from 0–1 can per d. Fish oil capsules (1 g each) taken from 3–10 g per d depended on the quantity of sardines consumed, with more fish oil given to women who took no or very small quantities of sardines. Enrichment of n-3 fatty acids in the diet from sardines and fish oil was roughly 30-fold compared to the usual ingestion. Duration of the supplement averaged 56 d with a range of 30–81 d. No supplement of sardines or fish oil was prescribed after the 34th wk of pregnancy.

All supplemented mothers and control mothers had normal deliveries. Supplemented mothers were advised to reduce other fats in the diet because of the extra consumption of fat from fish oil and sardines.

Enrichment of DHA in plasmas and red blood cells of supplemented pregnant women. The focus of this study was on DHA, since it is the key fatty acid of the n-3 series most prominent in the brain and retina. In supplemented mothers, plasma DHA was 2.1% of total fatty acids at baseline and 3.51% at the end of supplementation some 56 d later (Fig. 1). At the time of birth, plasma values were still elevated about 11% over baseline, with DHA totaling 2.35% of total fatty acids. DHA of maternal red blood cells paralleled plasma DHA, with levels of 4.69% of total fatty acids at baseline, 7.15% at the end of supplementation, and 5.97% at the time of delivery. DHA of plasma and red blood cells of control mothers did not change from baseline to delivery. At delivery, their plasma DHA was 1.47% of total fatty acids, and red blood cell DHA was 4.08%. Thus supplemented mothers, despite taking no extra n-3 fatty acids for the last six weeks of pregnancy, still had blood levels (plasma and red blood cells) very much higher than control mothers (Fig. 2 and Table 2).

Increased DHA concentrations in blood of newborn infants from supplemented mothers. There were distinct differences in DHA concentrations in blood of infants from supplemented mothers vs. infants from control, unsupplemented mothers (Fig. 3). These differences appeared in both plasma and red blood cells. DHA content of plasma was 5.05% of

[b]*P* values adjusted to correct for multiple comparisons.

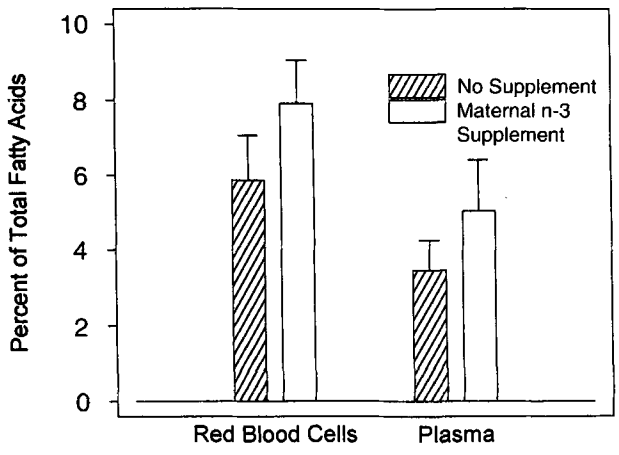

FIG. 3. Red blood cell and plasma docosahexaenoic acid (DHA) levels at delivery in newborn infants from n-3–supplemented and –unsupplemented mothers. Red blood cell DHA significantly different at $P < 0.001$. Plasma DHA was significantly different at $P < 0.011$.

total fatty acids in infants from supplemented mothers *vs.* 3.47% in infants from control mothers. "Supplemented" infants had plasma DHA levels some 45.5% higher than controls. Red blood cells of the newborn "supplemented" infants likewise showed similar increases of DHA: to 7.92% of total fatty acids vs. 5.86% of fatty acids in control infants, or 35.2% greater. These plasma and red blood cell DHA differences were highly significant.

Comparison of the mother at delivery who had taken the least amount of n-3 fatty acids with the mother who consumed the highest amount. The least amount of n-3 fatty acids consumed in a supplemented mother was only 45 g over 47 d, or an average of 0.95 g/d (Table 3). This mother can be contrasted with the mother who took the most amount of n-3 fatty acids, 219 g over a 70-day period. Her daily amount, 3.1 g, was three times greater than levels in the mother taking the least amount. Plasma DHA was 1.52% of total fatty acids (least consumption) compared to 2.39% (most). Similar comparisons for red blood cells were 5.20% (least) vs. 6.18% (most). Newborn infants from these mothers had greatly different plasma values. Plasma values were 7.59% (most) vs. 3.3% (least), more than two times the levels in infants from the "least" mothers. Newborn red blood cells showed a similar divergence: 9.91% (most) vs. 6.56% (least). In general, then, the amount of DHA in infants' plasma and red blood cells paralleled roughly the amount present in maternal blood and was related to the amount of n-3 fatty acids ingested in fish oil or sardines.

DISCUSSION

n-3 Fatty acids containing considerable quantities of DHA increased the DHA levels in both plasma and red blood cells of mothers supplemented with sardines and fish oil from midpregnancy to the 34th wk. DHA and other n-3 fatty acids were transferred across the placenta into the fetus so that at the time of birth newborn blood levels of DHA were 35% higher than levels in newborn control infants. Placental transport of DHA has been demonstrated by studies of blood taken from the umbilical cord at the time of delivery (2). There was a considerable venous–arterial difference in levels of DHA and other n-3 fatty acids. These differences were particularly noted in the red blood cells, thus raising the question about red blood cell as a prominent carrier of DHA in fetal blood.

This study was safe for both mothers and infants. Supplemented pregnant women had normal births and delivered normal full-term infants. Length of pregnancy was not affected by this kind of supplementation. The study proved the practicality of increasing levels of DHA in blood of pregnant women and then also in blood of newborn infants through dietary supplementation. Higher quantities of DHA in infants' blood would suggest higher levels also in their tissues. This greater quantity of DHA was available during the period of maximal brain and retinal development (the latter half of pregnancy). This is particularly important, since it has been shown that premature infants born during the last trimester of pregnancy have low levels of DHA in the blood and have impairment of visual development (7,8). Addition of fish oil containing DHA to formulas for premature infants increased blood DHA and improved vision (7,8). It is reasonable to hypothesize that, had the mothers of these premature infants received n-3 fatty acid supplementation during pregnancy, then their infants might well have been better off in terms of retinal and brain development at the time of their premature births.

There are several other potential benefits of n-3 fatty aid supplementation from sardines and fish oil. These are prevention of premature labor and preeclampsia. From observations in the Faroe Islands, where considerable quantities of marine oil are consumed, it has been suggested that n-3 fatty acids from marine oil might prolong gestation through inhibition of prostaglandin synthesis (10,11). This would be of value to women with habitual premature labor. Prematurity in the Faroe Islands was certainly less than in Denmark. There were more stillbirths in the Faroe Islands than in Denmark, however. Whether supplemental n-3 fatty acids would prevent premature births remains open to question. Our study, however, which was not designed to affect the onset of labor, demonstrated that supplementation with n-3 fatty acids was perfectly safe from midpregnancy to the 34th wk. There are also some indications that the incidence of preeclampsia can be reduced by fish oil consumption during pregnancy (13).

ACKNOWLEDGMENTS

This study was supported by the General Clinical Research Centers, Division of Research Resources, National Institute of Health (RR00334) The North Atlantic Sardine Council, and the Oregon Health Sciences University Foundation.

Polyunsaturation in Cell Membranes and Lipid Bilayers and Its Effects on Membrane Proteins

Simon J. Slater, MaryBeth Kelly, Mark D. Yeager, J. Larkin, Cojen Ho, and Christopher D. Stubbs*

Department of Pathology and Cell Biology, Thomas Jefferson University, Philadelphia, Pennsylvania 19107

ABSTRACT: The effect of variation of the degree of *cis*-unsaturation on cell membrane protein functioning was investigated using a model lipid bilayer system and protein kinase C (PKC). This protein is a key element of signal transduction. Furthermore it is representative of a class of extrinsic membrane proteins that show lipid dependent interactions with cell membranes. To test for dependence of activity on the phospholipid unsaturation, experiments were devised using a vesicle assay system consisting of phosphatidylcholine (PC) and phosphatidylserine (PS) in which the unsaturation was systematically varied. Highly purified PKCα and ε were obtained using the baculovirus-insect cell expression system. It was shown that increased PC unsaturation elevated the activity of PKCα. By contrast, increasing the unsaturation of PS *decreased* the activity of PKCα, and to a lesser extent PKCε. This result immediately rules out any single lipid bilayer physical parameter, such as lipid order, underlying the effect. It is proposed that while PC unsaturation effects are explainable on the basis of a contribution to membrane surface curvature stress, the effects of PS unsaturation may be due to specific protein-lipid interactions. Overall, the results indicate that altered phospholipid unsaturation in cell membranes that occurs in certain disease states such as chronic alcoholism, or by dietary manipulations, are likely to have profound effects on signal transduction pathways involving PKC and similar proteins. *Lipids 31,* S-189–S-192 (1996).

Over the past decade there has been intense study of the effects of altered membrane unsaturation on cell structure and function. Although much is now known about the effects of unsaturation on cell membrane physical properties [recently reviewed (1)], the manner in which membrane proteins are influenced by varying degrees of polyunsaturation is still not clear. Recently, the focus has shifted to examination of the effect of unsaturation at discrete regions of the membrane. For example, effects that are localized at the protein-lipid interface, or other regions of defined depth in the bilayer or in laterally separated regions of the membrane (see for e.g. Refs 2–4). The effects of increased unsaturation in a lipid bilayer include decreased lipid acyl chain order (5) and increased hydration in the head group and interchain regions (2,4,6–9). It has been proposed (4,8) that altered hydration may have marked effects on membrane protein functioning, possibly due to the formation of hydrogen bonds between the interchain water and protein amino acid side chains facing into the hydrophobic interior of the membrane.

Many of the key proteins involved in signal transduction including, for example, phospholipase A_2, phospholipase Cγ, G-proteins, raf-kinase, synaptotagmin and protein kinase C, are extrinsic membrane proteins. Some of these translocate from the cytoplasm to the cell membrane as part of early signaling processes that initiate a cascade of events that lead to

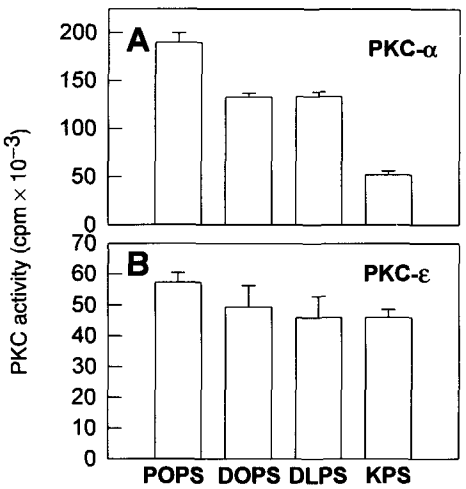

FIG. 1. Effect of phosphatidylserine (PS)-unsaturation on protein kinase C (PKC) activity. Relative activities of (a) PKCα and (b) PKCε for different PS-molecular species. The phosphorylation of MBP_{4-14} (PKCα) or PKCε-peptide using [^{32}P]ATP determined using 150 μM lipid vesicles comprised of PS/phosphatidylcholine (1:4, molar) for palmitoyl-oleoyl-PS (POPS), dioleoyl-PS (DOPS), dilinolcoyl-phosphatidylcholine (DLPS) and krill-PS (K-PS) using 0.5 μM 4B-12-O-tetradecanoyl. Experimental details are as described in the Procedures section.

events such as cell proliferation, differentiation, etc. It is becoming apparent that this interaction with the membrane is not only lipid dependent but that it depends on the membrane lipid composition. PS is believed to be a prominent mediator of the interaction of these types of proteins with the cell membrane. However, while PS interacts directly with the protein, as we have shown recently (10), other cell membrane lipids, including PC and PE, may influence this process indirectly due to effects on membrane lipid bilayer structure. The compositional aspect that seems to be important here is the degree of unsaturation of the phospholipid. The role of the *type* of unsaturation (i.e., n-3 or n-6) or distribution of double bonds along the chain remain unknown. Recent studies from this laboratory have focused the effect of varied unsaturation on the activity of PKC as an important example from the above list of proteins. Studies published so far by this laboratory and others indicate that both PC (10,11) and PS (11–13) unsaturation influence PKC activity.

The first study that investigated PS unsaturation and PKC activity, with n-3 rich trout liver as compared to bovine brain PS (13), concluded that PKC activity was decreased when PS-unsaturation increased. In another study, the opposite was concluded, that increasing the PS unsaturation (mixed species from brain) increased *maximal* PKC activity. It was shown that the effect was not due to the amount of bilayer bound PKC nor due to lateral phase separation. Also electron micrographs of the vesicles (see also (14)) showed vesicle integrity was maintained. More recently, mixed PKC species from rat brain was investigated using a multilamellar vesicle system in which PS and PC unsaturation was varied (11). Increased unsaturation led to elevated PKC activity and, in this case, PS unsaturation was also found to increase activity. However, in that study the PS unsaturation did not extend to greater than one double bond/PS. Fully (di)-saturated-PS supported only low levels of activity and was obtainable only in the presence of *unsaturated* PC. Thus, if *both* PS and PC were saturated, no activity was obtained. Overall, a roughly linear correlation between the percentage of unsaturated phospholipid and PKC activity was indicated. Interestingly, membrane fluidity did not appear to play a part since cholesterol, which greatly reduces fluidity, had little effect on PKC activity and it was reasoned that the physical parameter of importance was "head group spacing". All of these studies were complicated by the use of non-optimal vesicles systems, mixed PKC isoform preparations and the aggregatory substrate histone. Therefore, at present there is no general agreement on the effects of PS-unsaturation on PKC activity.

Recently, we found that increased PC unsaturation results in a potentiation of PKC activity in defined vesicle systems (SUV or LUV). It was further proposed that the parameter, instead of solely a function of head group spacing, was also connected with the energetics of head group interactions that *include* the tendency of some lipids, notably PE along with high unsaturation, to form non-bilayer phases, and quantified as "curvature stress" (see for e.g. Refs 15–17). Thus, when PE and highly unsaturated lipids are constrained to form a bilayer, the system gains potential "curvature" energy which may be utilized to favor the interaction of the bilayer with proteins such as PKC, a process that tends to relieve the stress energy. Studies from this laboratory (10) showed that increasing PC unsaturation increased activity. When PE was included, activity at low PC unsaturation was elevated but that at high unsaturation reduced. This was rationalized from further experiments in which PE was varied in dioleoyl-PC bilayers where it was found that the activity increased to a maximum but then declined. It was concluded that PKC activity is therefore a *biphasic* function of the effect of increasing PE and unsaturation, which is to increase head group spacing and curvature stress. Again, this study used a mixed isoform preparation although the assay system was non-aggregatory. A model in which head group spacing or a related parameter is the major factor dictating PKC activity is compatible with monolayer studies (18,19) which showed PKC activity depends on the surface pressure. In the latter, a biphasic profile of activity as a function of surface pressure was found that would be compatible with our results using bilayer systems.

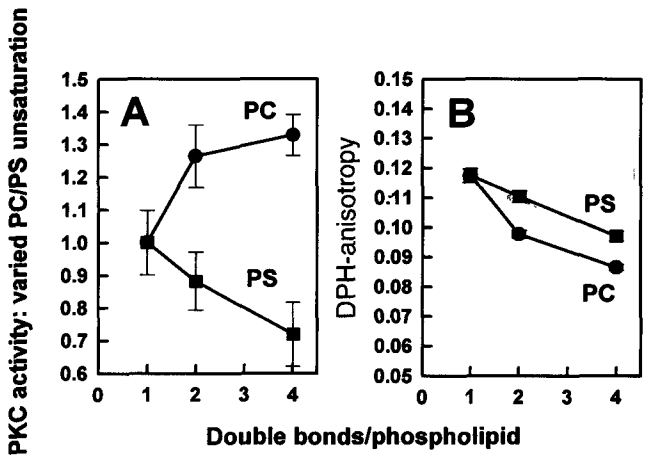

FIG. 2. Phosholipid unsaturation effects on PKC activity not explainable on the basis of lipid order. A: PKCα activity as a function of the double bonds/molecule of phosphatidylcholine (PC) or PS in PC/PS (4:1, molar) vesicles (details as described in Fig. 1). B: The fluorescence anistotropy (using DPH: 1,6-diphenyl-1,3,5-hexatriene), reflecting the lipid order, as a function of PS/PC unsaturation. Experimental details are as described in the Experimental Procedures section. Abbreviations as in Figure 1.

Considering that PS is required for PKC activation, and the fact that its fatty acid composition is highly susceptible to dietary manipulation, the finding of contradictory reports on the effects of PS unsaturation on PKC reveal the need for further study. It may be conjectured that the effects of increasing PS unsaturation might either follow that found with PC or may involve more specific protein-lipid interactions. To test this, we examined the effects of PS with varying levels of unsaturation on highly purified recombinant-PKCα isoform using a stable and non-aggregatory PKC assay system. The results indicate that increasing PS unsaturation decreases PKC activity, a finding that is opposite to the effects of PC unsaturation.

EXPERIMENTAL PROCEDURES

Materials. Myelin basic protein (MBP_{4-14}) was from LC Services (Woburn, MA). The PKCε pseudosubstrate peptide was custom synthesized by Biosynthesis, Inc. (Lewisville, TX). Lipids (from Avanti Polar Lipids, Inc., Alabaster, AL) included POPC, POPS, brain-PS (major fatty acids as mole %, 16:0 1.4; 18:0 42.2; 18:1 26.9; 18:2 4.2; 20:4 2.9; 22:6 9.7) and krill-PS (major fatty acids, 16:0 25.6, 18:0 1.3, 18:1 3.7, 18:2 1.3, 20:4 0.9, 20:5 37.9, 22:6 18.3). TPA was from Sigma (St Louis, MO). Adenosine 5' triphosphate (ATP) was from Boehringer Mannheim (Indianapolis, IN) and [γ^{32}P]ATP was from New England Nuclear (Boston, MA). All other chemicals were of analytical grade and were obtained from Fisher Scientific (Malvern, PA). DPH was from Molecular Probes (Eugene, OR).

PKC expression and purification. Recombinant PKCα (bovine) was prepared using the baculovirus-insect cell expression system as previously described (20,21). PKCε was prepared by subcloning the cDNA, obtained from a rat brain cDNA library, into a baculovirus expression vector (Yeager, M.D., Taddeo, F.J., Slater, S.J., and Stubbs, C.D., to be published). The infection of Sf9 insect cells and purification of the PKC was according to established procedures (20,21).

Preparation of vesicles. Lipids in chloroform (750 μM), in the presence of DPH (when required for lipid order measurements; DPH:phospholipid, 1:400, molar) were placed in a test tube and the solvent removed under a stream of nitrogen. The mixture was vortexed in 50 mM Tris/HCl buffer, pH 7.4 to form multilamellar lipid vesicles. Large unilamellar vesicles (LUV) were made by the extrusion technique, using an Avestin Liposofast Extruder (MM Developments, Ottawa, Canada) as previously described (22). Vesicles of a similar composition have been previously shown to be stable under the PKC-assay conditions used here (14)..

PKC activity. Activity was determined from the initial rate of incorporation of ^{32}P from [γ^{32}P]ATP (New England Nuclear) into a peptide substrate, according to a previously detailed method (10) modified from an earlier method (23). For PKCα, a peptide corresponding to the phosphorylation site of MBP_{4-14} (50 μM) was used. For PKCε activity (calcium-independent), the assay mixture contained 0.1 mM EGTA and an e-peptide in place of the MBP_{4-14}, that was based on the pseudosubstrate sequence of PKCε (24,25), a single alanine residue was replaced by a serine.

Fluorescence measurements. The steady state anisotropy of DPH was determined using an SLM 48000 fluorimeter in the T-format as previously described (2).

RESULTS AND DISCUSSION

The effect of increasing PS unsaturation in PC/PS unilamellar vesicles (4:1, molar) on recombinant-PKCα is shown in Figure 1A. It was found that increasing the level of unsaturation decreased the activity of PKC in this system. This contrasts with the results of our previous study where increasing PC unsaturation was shown to increase the activity of PKC. The PKC used in that study was a rat brain PKCα,β,γ (Ca^{2+}-dependent) mixture. However, here, the same effect was demonstrable with the recombinant-PKCα enzyme (Fig. 2A). The krill-PS, commercially obtained, is extremely rich in 20:5 and 22:6n-3 (see Methods) and gave a much reduced activity compared to the other PS species.

A major determinant of the PS and Ca^{2+} requirement in PKC is contained within the C2-domain of the enzyme. This region contains the main Ca^{2+} binding site and is found in PKCα,β,γ but not in PKCε,δ (Ca^{2+}-independent) or PKCζ (Ca^{2+} and DAG independent), although all isoenzymes retain a PS requirement. The involvement of the C2-domain in the PS unsaturation dependence was tested with a recombinant-PKCε preparation. The results again show a general trend for increased unsaturation decreasing the activity of the PKC. However, it should be noted that sensitivity to unsaturation was diminished considerably, suggesting that the C2-domain of PKC is indeed important in conferring sensitivity to PS unsaturation.

In a previous study that examined the effect of increased PC unsaturation on PKC activity, it was concluded that lipid order, assessed from fluorescence anisotropy measurements of the fluorophore, DPH, was not the major parameter sensed by the PKC. The results in Figure 2 compare the effects of increased PC and PS unsaturation on both PKC activity and on lipid order assessed from DPH anisotropy measurements. The finding of opposite effects indicate that lipid order is unlikely to explain both effects, further indicating that PKC activity is governed by head group interactions rather than those of the acyl chain region.

To further examine the question of what factor might be involved in the effects of PS unsaturation on PKC, a plot of the PS-double bond index and percentage of saturation, as a function of PKC activity, are shown in Figure 3. It can be seen

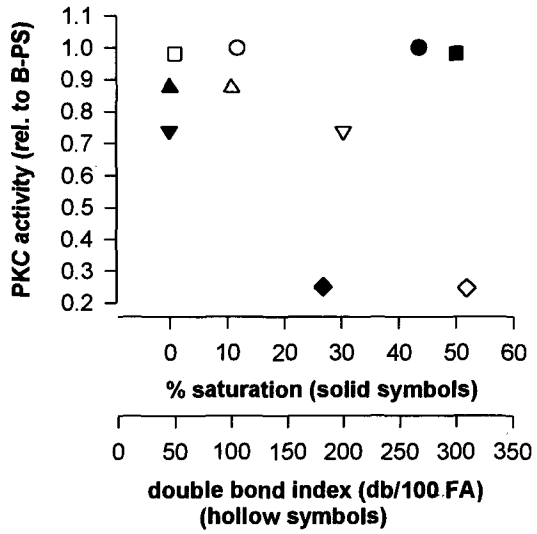

FIG. 3. PKCα activity is not simply related to the % saturation or double bond index. PKCα activity for PS/PC vesicles in which the PS was varied as a function of the % of saturated fatty acids/100 fatty acids or as a function of the number of double bonds/100 fatty acids. Brain-PS (B-PS), ●, ○, POPS, ■, □; DOPS, ▲, △; DLPS, ▼, ▽; K-PS, ◆, ◇. Abbreviations as in Figure 1.

that neither of these parameters was simply related to the effect of PS-unsaturation.

CONCLUSION

Representative PKC isoenzymes of the a and e types were shown to vary in activity as a function of PS unsaturation, activity decreasing with increased unsaturation, opposite to the effect of varied PC unsaturation. The Ca^{2+}-dependent isoform, PKCα, was found to be more sensitive than the Ca^{2+}-independent form, PKCε. It is concluded that the parameters normally used to assess unsaturation cannot explain the effect of varied PS-unsaturation. Therefore, it would appear that, by contrast to the situation with PC (10), PS molecular species interact in a specific manner with PKC. Fluorescence spectroscopic approaches are currently being investigated to elucidate the details of the PS-PKC interaction.

A Role for Phospholipid Polyunsaturation in Modulating Membrane Protein Function

Burton J. Litman* and Drake C. Mitchell

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcoholism and Alcohol Abuse, National Institutes of Health, Rockville, Maryland

ABSTRACT: Visual transduction is one of the best characterized G protein—coupled signalling systems. In addition, about 50% of the disk membrane phospholipid acyl chains are 22:6n-3, making this system ideal for determining the role of polyunsaturation in modulating membrane-signalling systems. The extent of formation of metarhodopsin II (MII), the G protein—activating photointermediate of rhodopsin, was studied in phospholipid vesicles composed of a variety of phosphatidylcholines, differing in their acyl chain composition at the *sn*-2 position. The amount of MII formed increased progressively with the level of acyl chain unsaturation at the *sn*-2 position. The effect of added cholesterol was to reduce the amount of MII formed. The acyl chain packing free volume of the rhodopsin containing lipid vesicles was characterized by a fractional volume parameter f_v derived from measurements of the time-resolved fluorescence anisotropy decay of the hydrophobic membrane probe 1,6-diphenyl-1,3,5-hexatriene. The relationship among *sn*-2 acyl chain unsaturation, cholesterol content, and MII formation is explained on the basis of variation in f_v with bilayer lipid composition and a novel model for the packing of phospholipids containing polyenoic acyl chains, such as 22:6n-3.
Lipids 31, S-193–S-197 (1996).

The fact that organisms exist under conditions of essentially constant temperature and pressure requires that cellular membrane properties, which modulate protein function, must be regulated by membrane composition. Analysis of phospholipid molecular species demonstrates a relatively high degree of heterogeneity within a phospholipid class, which is generally associated with a more diverse acyl chain composition at the *sn*-2 position (1). Neuronal and retinal tissue show the highest content of polyunsaturated acyl chains (2). About 50% of retinal rod outer-segment disk membrane phospholipid acyl chains are 22:6n-3 (1). It is especially interesting that in the disk membrane, the major phospholipid classes, such as phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylserine (PS), contain high levels of 22:6n-3 acyl chains, whereas minor phospholipids, such as phosphatidylinositol (PI) and phosphatidic acid (PA) contain predominantly 20:4n-6 phospholipids (1). Major phospholipids would be expected to play a structural role, while minor phospholipids might have a more direct functional role, suggesting that 22:6n-3 acyl chains play an important structural role in membranes. The importance of the n-3 polyunsaturated acyl chains is demonstrated by the abnormalities in visual (3) and learning skills (2) associated with a deficiency in n-3 fatty acids and docosahexaenoic acid, 22:6n-3 in particular.

In our studies we have employed the visual transduction pathway as a model system in which to study the effect of phospholipid acyl chain composition on signalling systems (4). The visual pigment, rhodopsin, serves as a prototypical G protein–coupled receptor in this pathway (5). Photoactivation of rhodopsin is analogous to agonist activation of liganded receptors. The visual transduction pathway is well suited for studies to investigate a structural role of polyunsaturated fatty acids for the following reasons: (i) changes in visual response in 22:6n-3–deficient animals are reflected in both abnormal electroretinograms and visual evoked potentials (3); (ii) all three major phospholipid classes in the retinal rod outer segment disk membrane, where rhodopsin is located, contain high levels of 22:6n-3 acyl chains (1); and (iii) the visual transduction system is a G protein–coupled receptor system (5); hence, observations made on this system will be applicable to other G protein–coupled systems.

In this paper, we describe studies in which the extent of formation of metarhodopsin II (MII), the form of photoactivated rhodopsin that activates the rod outer segment G protein, transducin, is correlated with a phospholipid acyl chain–dependent membrane physical property (4), the membrane acyl chain packing free volume. This property is defined as the difference between the measured molecular volume determined from density measurements and the molecular volume determined for the sum of the volume of atoms making up the molecule. Due to disorder and defects in the acyl chain packing, this property will always be positive. A parameter, the fractional volume f_v which is derived from the

time-resolved anisotropy behavior of the hydrophobic membrane probe 1,6-diphenyl-1,3,5-hexatriene (DPH), is used to characterize the relative acyl chain packing free volume of a variety of compositionally defined lipid bilayers (6). Results of these studies are interpreted in terms of a novel phospholipid acyl chain packing model, which directly addresses the structural role of 22:6n-3 acyl chains in membranes.

EXPERIMENTAL PROCEDURES

Sample preparation. Phospholipids were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL) and used without further purification. Butylatedhydroxyltoluene at a level of 1 molecule per 500 phospholipid molecules was added to stock solutions to prevent lipid peroxidation, and all procedures were carried out under argon. Rhodopsin was purified from frozen bovine retinas (Lawson, Inc., Lincoln, NE) *via* Concanavalin A (Pharmacia, Piscataway, NJ) affinity chromatography, and large unilamellar vesicles consisting of lyophilized lipid and purified rhodopsin in a molar ratio of 100:1 (75:1 for di-22:6 PC), respectively, were prepared using a dilution-reconstitution method (7). Total phospholipid content of vesicles was determined by phosphate analysis following the method of Bartlett (8). Samples for rhodopsin photochemical studies were prepared by diluting a vesicle stock solution with the appropriate temperature-compensated buffer (10 mM piperazine-*N,N'-bis*(a-ethanesulfamic acid, 60mM KCl, 30mM NaCl, 2mM MgCl2, 50μM diethylenetriaminepentaacetic acid) to a rhodopsin concentration of 0.25–0.30 mg/mL. Samples for DPH fluorescence studies were prepared by diluting stock solutions to 0.5 mM phospholipid, and DPH was added to level of 1 DPH per 250 lipid molecules.

Equilibrium absorbance measurements. Spectra were acquired with a Hewlett-Packard (Palo Alto, CA) 8452A diode array spectrophotometer (0.2 second measurement yielded < 0.3% bleach by measuring beam). Deconvoluted difference spectra of MI–MII equilibrium mixtures were derived from a series of 4 absorption spectra consisting of (i) unbleached sample; (ii) sample after a controlled exposure to light, which photolyzed 20–25% of the rhodopsin; (iii) sample used to obtain spectrum 2, after addition of hydroxylamine; and (iv) sample used to obtain spectrum 3, after light exposure to photolyze all of the rhodopsin in sample (9). Difference spectra consisting of the contributions from an equilibrium mixture of MI and MII, at 3 s postflash, were constructed by first deriving the spectral band corresponding to the unbleached rhodopsin. Individual MI and MII spectra were deconvoluted from the spectrum of their equilibrium mixture by using nonlinear least squares to fit the sum of two asymmetric Gaussian bands associated MI and MII, to the equilibrium spectral profile (Fig. 1). The equilibrium constant for the MI to MII conversion is given by K_{eq} = [MII]/[MI].

DPH fluorescence depolarization measurements. Fluorescence lifetime and dynamic depolarization measurements were performed at 37, 30, 20, and 10°C. Differential polarization measurements were corrected for all instrumental factors. Rotational depolarization properties were characterized with a model based on the bimodal distribution model for DPH in a lipid bilayer of Ameloot et al. (10). This model characterizes DPH equilibrium orientational properties in terms of a bimodal orientational distribution function, $f(\theta)$ (6). Overall equilibrium ordering experienced by DPH was quantified by the fractional volume parameter f_v which characterizes the volume available for probe reorientational motion relative to that available in an unhindered, isotropic environment, where $f_v = (1/2f(\theta)_{max})\int f(\theta)\sin\theta d\theta$.

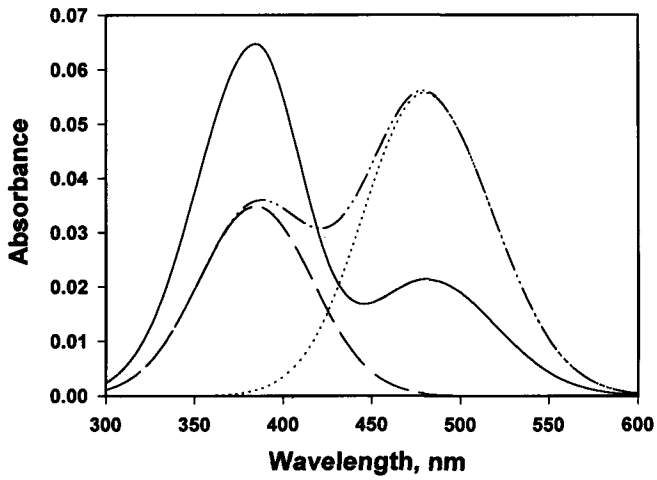

FIG. 1. Examples of the deconvolution of MI and MII spectral contributions. Metarhodopsin I (MI) (••••••), metarhodopsin II (MII) (— —), and combined MI + MII (—— ••• —— •••) spectral contributions for an MI ↔ MII equilibrium mixture in di-14:0 PC. The combined MI + MII (——) spectral contributions for rhodopsin in 16:0,22:6n-3 phosphatidylcholine (PC) are shown for comparison. Both samples were at 37°C. The deconvoluted spectral contribution were obtained using the procedure described in the Experimental Procedures section.

RESULTS

The phospholipid acyl chain dependence of the MI–MII equilibrium is demonstrated in Figure 1, where the deconvoluted spectral contributions of MI and MII for rhodopsin in 16:0,22:6n-3 PC and di-14:0 PC bilayer vesicles are shown. MI and MII have spectral peaks at 478 nm and 380 nm, respectively. Clearly, higher levels of MII formation are observed in the 22:6n-3 containing phospholipid. Data like those shown in Figure 1 allow the determination of the equilibrium constant K_{eq} for the MI–MII conversion. A comparison of K_{eq} for rhodopsin in a variety of compositionally defined phospholipid vesicles is shown in Figure 2. K_{eq} is seen to increase with higher levels of acyl chain unsaturation. The presence of a 22:6n-3 *sn*-2 chain in a mixed-chain phospholipid results in about a six-fold increase in K_{eq} relative to the saturated di-14:0 PC. Relative to both the 22:6n-3 and 20:4n-6 mixed-chain PC, the introduction of a second polyunsaturated chain results in about a two-fold increase in K_{eq}, emphasizing the importance of these chains in promoting MII formation.

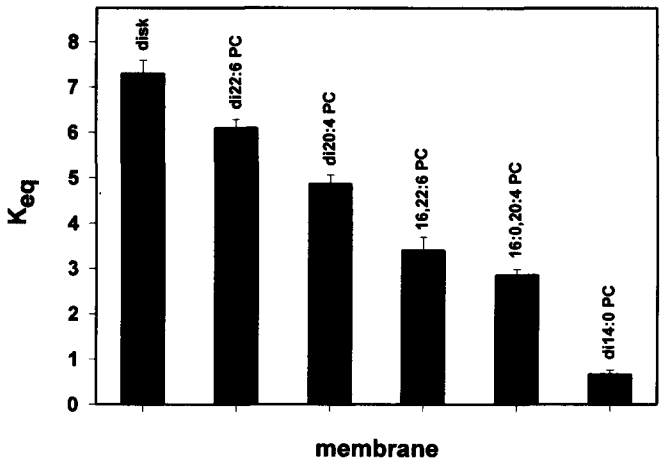

FIG. 2. The compositional dependence of the MI ↔ MII equilibrium constant K_{eq}, determined for rhodopsin in a variety of membranes at 37°C. Abbreviations as in Figure 1.

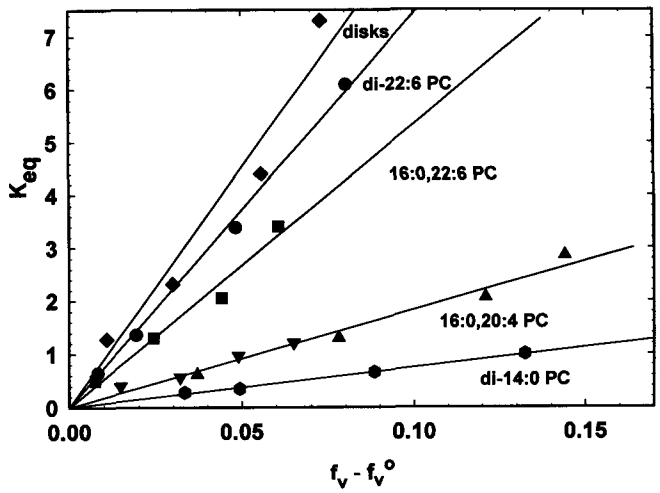

FIG. 3. Correlation between the MI ↔ MII equilibrium constant K_{eq} and the normalized fractional volume f_v—f_v^0, for rhodopsin in disks (◆), di-22:6n-3 PC (●), 16:0,22:6n-3 PC (■), 16:0,20:4n-6 PC (▲), 16:0,20:4n-6 PC containing 30 mole% cholesterol (▲), and di-14:0 PC (×✱✱). The parameter f_v^0 is the fv intercept value of the K_{eq} vs. f_v correlation line. Subtraction of f_v^0 shifts all of the correlation lines to a common origin, making a comparison of the variation in slopes of the correlation lines more direct. Samples contained a ratio of phospholipid to rhodopsin of 100:1, except for di-22:6n-3, which had a 75:1 ratio. Abbreviations as in Figure 1.

In parallel studies of the time-resolved fluorescence anisotropy of DPH, f_v was measured for the same-rhodopsin–containing vesicles. K_{eq}, for several phospholipid compositions and temperatures, is plotted vs. f_v in Figure 3. Here we see that there is a linear correlation between K_{eq} and f_v for each phospholipid and that the slope of the correlation line increases with higher levels of polyunsaturation. This result demonstrates that, at a given value of f_v, increased MII formation occurs in the more unsaturated phospholipids. The effect of having a dipolyunsaturated phospholipid is always to increase K_{eq} substantially above that measured for the mixed-chain phospholipid containing the same acyl chain in only the *sn*-2 position.

Cholesterol is an important component of biological membranes and was shown to decrease acyl chain packing free volume (11). When 30% cholesterol is incorporated into 16:0,20:4n-6 PC bilayers, both K_{eq} and f_v decrease. The resulting correlation points, however, lie on the initial correlation line determined for the cholesterol-free 16:0,20:4n-6 PC vesicles Figure 3. Similar results have been observed for egg PC containing 0, 15, and 30 mole % cholesterol (12).

DISCUSSION

In our studies, we have used the extent of photoactivation of the visual pigment, rhodopsin, as a measure of the ability of a membrane with a defined lipid composition to support optimal protein function. Data presented here demonstrate three important points relative to modulation of rhodopsin photoactivation by phospholipid acyl chain composition. These are: (i) the level of MII formed, i.e., larger values of K_{eq}, increases with the level of unsaturation, a trend that correlates with a concomitant increase in acyl chain packing free volume of the bilayer; (ii) in mixed-chain phospholipids, behavior of the system is correlated with the level of acyl chain unsaturation at the *sn*-2 position; and (iii) although cholesterol reduces both K_{eq} and the acyl chain packing free volume, the K_{eq}–f_v correlation behavior of the system is still determined by the acyl chain at the *sn*-2 position.

A phospholipid acyl chain packing model, which provides an explanation of our results, is shown in Figure 4. Substantial evidence exists to demonstrate that saturated-saturated chain interactions are stronger than unsaturated-unsaturated chain interactions (13,14), suggesting that, in mixed-chain phospholipids like 16:0,22:6n-3 PC, there will be a strong tendency for the phospholipids to pack in a fashion that maximizes *sn*-1 chain interactions. Figure 4A shows a transverse view of the disk membrane, demonstrating the tendency for the *sn*-1 chains to interact with one another. A top view of a cross section through the bilayer midplane is also shown in Figure 4B. *sn*-1 Chain interactions can be maximized by cluster formation in the plane of the membrane, where the interior of the cluster in made up of saturated *sn*-1 chains, and the exterior is composed of *sn*-2 chains. This type of cluster formation is depicted in Figure 4B. Raman vibrational spectroscopic measurements on mixed-chain PC support the existence of these types of structures (15). Conversion of MI to MII is associated with a 100-cc/mole volume change (16,17), indicating that MII has a larger volume than MI. Under such conditions, lateral compressibility of the membrane and the associated acyl chain packing free volume, are expected to play a critical role in determining activation energy for the MI–MII conversion. In the proposed phospholipid packing model, *sn*-2 chains form the interface between domains and hence determine the lateral packing properties of the system. This is consistent with our finding that the slope of the correlation line varies with the substitution at the *sn*-2 position. In addition, evidence in the literature suggests that cholesterol interacts preferentially with saturated acyl chains (13,18) and should therefore interact with *sn*-1 chains. Thus cholesterol could partition into the interior of the clusters and change the lifetime and/or the size of

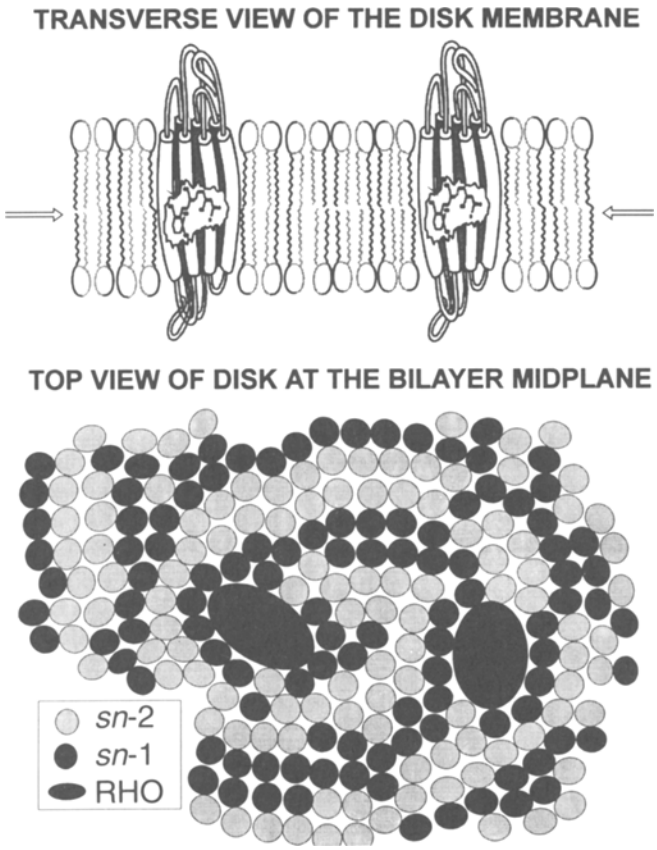

FIG. 4. The microdomain model for acyl chain-packing in a polyunsaturated, mixed-chain phospholipid bilayer containing rhodopsin. (A) Transverse view of the disk membrane showing the phospholipid *sn*-1 (black) and the *sn*-2 (gray) chain packing. (B) Top view of the disk membrane at the bilayer midplane, in which the PC molecules are depicted by pairs of circles representing the *sn*-1 chain (black) and *sn*-2 chain (gray). Rhodopsin is shown surrounded by a rapidly exchanging boundary layer of phospholipid molecules. *sn*-1 Chains are oriented toward the tightly packed interior of the domain, while *sn*-2 chains are oriented toward the domain boundary and are therefore thought to determine the lateral compressibility properties of the bilayer. As the level of unsaturation of the *sn*-2 chain increases, the interactions at the microdomain interfaces will become less cohesive, and the membrane acyl chain—packing free volume will increase, as will the lateral compressibility of the membrane. In the liquid crystalline phase, domains will have a characteristic lifetime and size, which can be influenced by the partitioning of lipid-soluble molecules, such as cholesterol, into the bilayer. Therefore, cholesterol can reduce the free volume by ordering the saturated *sn*-1 chains at the interior of the microdomain, leaving domain-domain interactions unchanged. Abbreviations as in Figure 1.

the clusters, thereby reducing the free volume. The domain interfaces, however, would still be formed by *sn*-2 chains and the lateral packing properties would still be determined by the *sn*-2 chain properties. This is consistent with our finding that, although cholesterol reduces both K_{eq} and f_v in rhodopsin containing 16:0,20:4n-6 PC (5) and egg PC vesicles (13), correlation data points for the cholesterol-containing bilayers fall on the correlation line determined for the cholesterol-free phospholipid vesicles. Our model predicts that in mixed acyl chain phospholipid bilayers, dipolyunsaturated phospholipid molecules, such as di-22:6n-3 PC, will pack between the domains, so as to maintain maximal saturated *sn*-1 chain interactions.

The studies presented here suggest that there are at least two levels whereby lipid composition can regulate membrane properties, which modulate the function of certain classes of liganded receptors. These are primary regulation by phospholipid acyl chain composition and secondary regulation by cholesterol content , the latter being dependent on the presence of a saturated acyl chain. Highly unsaturated phospholipids, such as 16:0,22:6 PC provide the membrane with unique structural properties in the form of microclusters or lateral packing domains. In addition, these phospholipids impart increased acyl chain packing free volume to the bilayer, which promotes formation of MII, the active receptor form of rhodopsin. While the level of MII formation in di-22:6n-3 PC and 16:0,22:6n-3 PC are among the highest observed in the pure phospholipid vesicle systems, the highest values of K_{eq} are observed in the disk membrane, which is a complex mixture of varied head groups and acyl chains. Further studies will be required to assess relative effects of different phospholipid classes and mixed molecular species on properties of bilayers associated with modulation of membrane protein function.

Our findings that bilayers containing lower levels of acyl chain unsaturation have reduced levels of MII formation suggest that the diminished amplitude in the α-wave of the electroretinogram observed whole in animals, which are deficient in phospholipids containing 22:6n-3 (2,3), is associated with decreased levels of photoactivated rhodopsin. Visual transduction is a prototypical G protein–coupled signalling system, where rhodopsin serves as the receptor. Therefore conclusions drawn from the present studies, relative to the enhanced formation of the active receptor conformation in 22:6n-3–containing phospholipids, should be applicable to other G protein–coupled systems, as well as receptor systems where the agonist binding site is within the bilayer and composed of several transmembrane spans.

Nuclear Magnetic Resonance Investigation of Hydrocarbon Chain Packing in Bilayers of Polyunsaturated Phospholipids

L.L. Holte, F. Separovic, and K. Gawrisch*

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: ^{2}H nuclear magnetic resonance (NMR) on chain-deuterated phospholipids has been used to study the influence of the degree of unsaturation on lipid chain packing and on area per molecule at the lipid water interface. Order and motions of deuterated stearic acid in position sn-1 of phosphatidylcholines (PC) containing 18:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:4n-6, 20:5n-3, or 22:6n-3 in position sn-2 were investigated in pure PC and in mixtures of PC in a phosphatidylethanolamine (PE) matrix. Results reveal that lipid packing in bilayers is mainly controlled by packing requirements at the lipid water interface. Increasing degrees of unsaturation lower chain order and increase area per PC molecule, whereas inclusion of PE in model membranes has the opposite effect. Chain order and motions in highly unsaturated lipid membranes are less sensitive to changes in temperature. Temperature sensitivity decreases further upon incorporation of PC into a PE matrix. Unsaturation induces chain disordering, which may be interpreted as an increase in area per molecule of lipids toward the center of the bilayer. This may result in a lower packing density of unsaturated lipids at the lipid water interface. We hypothesize that these differences in lipid packing and dynamics may influence activity of membrane proteins.

Lipids 31, S-199–S-203 (1996).

Activity of membrane-associated proteins such as rhodopsin (1–3), protein kinase C (4), calcium ATPase (5,6), apocytochrome C (7), and cytochrome b_5 (8), is sensitive to head group structure and unsaturation of hydrocarbon chains of lipid bilayers. Cells carefully control head group composition and chain unsaturation to maintain optimal conditions for cell function (9). Part of the observed correlations between lipid composition and membrane function are likely due to the biophysical properties of lipid membranes.

Attempts to link protein function to structure and dynamics of lipid bilayers have a long history. The fluid mosaic model of biological membranes highlighted the importance of a liquid crystalline lipid environment for membrane proteins (10). Unsaturation provides the appropriate fluidity for membrane proteins. The existence of a boundary layer of lipid around proteins had been suggested, with a preference for some lipid classes. In their mattress model of lipid bilayers, Mouritsen and Bloom (11) focused on the energy of a mismatch in hydrophobic thicknesses of lipid bilayers and membrane-spanning proteins. A departure from matching, e.g., as a result of differences in membrane composition, resulted in a mechanical strain in the membrane. Gruner, *et al.* (12,13) proposed that differences in spontaneous curvature of membranes result in lipid-packing stress in bilayers. Spontaneous curvature of membranes has been shown to depend on unsaturation and head group structure. Head groups and unsaturation also influence area per molecule at the lipid water interface and lateral compressibility of membranes (14). Dratz and Holte (15) introduced the molecular spring model to explain specific requirements of rod outer segment disk membranes for docosahexaenoic acid. They proposed that this sixfold unsaturated fatty acid can contract and expand with a minimal input of energy, allowing the lipid bilayer to thicken upon formation of metarhodopsin II. Using ^{2}H nuclear magnetic resonance (NMR) measurements, Holte (16) showed that lipid bilayers containing docosahexaenoic acid increased in thickness by 0.6 Å when rhodopsin formed metarhodopsin II. Straume and Litman (17) measured a fractional volume available for reorientation of fluorescence probes in membranes and demonstrated a correlation between free volume and metarhodopsin II formation. Despite many efforts, the mechanism by which lipids control protein function are not yet known. Experimental data describing bilayer structure with better resolution are warranted.

The primary tools for obtaining information about dimensions of lipid bilayers are X-ray and neutron diffraction methods (18–24). Unfortunately, the biologically relevant liquid crystalline phase of lipid water dispersions is characterized by a low degree of long-range order, which results in significant uncertainty in determination of parameters like membrane thickness and area per lipid molecule. A typical value for the resolution of membrane thickness measurements is ±1 Å, which translates into a resolution of ±2 Å^2 for area per molecule. A change in area per molecule of this order translates into an energy per lipid of about $7.5 \cdot 10^{-3}$ kT (4.5 cal/mol) (25). If we consider that every protein interacts with

100 lipid molecules in a domain or cluster, then this experimental uncertainty translates into 0.75 kT per molecule of protein (450 cal/mol). This energy must be compared with energies that shift membrane protein transitions, e.g., metarhodopsin I–metarhodopsin II equilibrium, which are of the order of 0.1 kT (60 cal/mol) (26). The crude comparison indicates that the current precision of diffraction methods may be insufficient to resolve small changes in membrane structure that are relevant for lipid protein interaction.

^{2}H NMR on deuterated lipids yields an order parameter profile of lipid hydrocarbon chains (27), which has been shown to be very sensitive to changes in thickness and area per molecule (28). While diffraction methods operate on a timescale of 10^{-11} s and shorter, measurement of deuterium order parameters has an intrinsic timescale of 10^{-5} s. Over this period of time, all lipid molecules sample every chain conformational state available in a typical bilayer, resulting in well-resolved NMR signals that are sensitive to very small changes of lipid order. The spectral resolution translates into a sensitivity for changes of bilayer thickness of ±0.2 Å and changes in area per molecule of ±0.4 Å^2. This corresponds to an energy change per lipid on the order of $3 \cdot 10^{-4}$ kT (0.18 cal/mol) or an energy of 0.03 kT (18 cal/mol) per protein molecule in a domain or cluster of 100 lipids, which is well within the range of physiologically relevant energy shifts. Thus, NMR has a sensitivity better suited for observing small changes in membrane structure that are relevant for membrane proteins, although interpretation of NMR data in terms of geometrical parameters of a bilayer is less straightforward than interpretation of diffraction data. We have used order parameter profiles of saturated *sn*-1 chains to characterize the thickness and cross-sectional area of lipid bilayers formed from lipids with 1–6 double bonds in the sn-2 position. The influence of the smaller PE head group has been studied as well. Results are combined here to describe the influence of unsaturation and head group on lipid packing.

MATERIALS AND METHODS

Unsaturated lipids were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL) and, when necessary, purified by preparative reverse-phase high-performance liquid chromatography at ambient temperature with a column packed with Adsorbosphere C18 HS 7U (Alltech Assoc., Inc., Deerfield, IL). Analytical grade methanol was used as a mobile phase. The antioxidant butylated hydroxytoluene was added at a ratio of lipid to butylated hydroxytoluene of 250:1 (mol/mol). Lipid mixtures were prepared in organic solvents. About 5 mg deuterated PC and 20 mg PE were used per sample. Solvents were removed under a stream of argon and in vacuum. Lipids were hydrated with 50 wt% deuterium-depleted water and sealed in argon-filled glass ampoules. Spectra were acquired on a Bruker MSL 300 spectrometer (Billerica, MA) with a quadrupolar echo sequence (29) using a delay time of 30 μs between pulses and a pulse repetition rate of 0.5 s. Typically, 8,196 scans were accumulated using a dwell time of 1 μs. Smoothed order parameter profiles were calculated following the method of Lafleur *et al.* (30).

RESULTS AND DISCUSSION

Introduction of the first double bond into an 18-carbon chain of PC has been shown to reduce the phase transition temperature between gel and liquid crystalline lamellar phases by more than 50°C. Among the unsaturated PC, the transition temperature of (18:0)(18:2n-6) PC was lowest (31,32). In Figure 1, typical ^{2}H NMR spectra for phospholipid water dispersions and calculated order parameter profiles are given. For pure PC and for PC in dioleoylphosphatidylethanolamine (DOPE), chain order decreases with an increasing degree of unsaturation. Changes are largest between mono- and diunsaturated lipids. Differences between lipids with 3–6 double bonds at 30°C are smaller than the experimental error. Reduction of chain order corresponds to a decrease in hydrophobic thickness of lipid bilayers of approximately 0.7 Å. In combination with the increased volume of highly unsaturated chains vs. monounsaturated chains (22 carbon atoms vs. 18), this translates into an increase in area per molecule for polyunsaturated vs. monounsaturated PC of about 5 Å^2. PC in a DOPE matrix at a molar ratio of 1:5 have significantly larger quadrupolar splittings and thus greater order of their *sn*-1 hydrocarbon chains than do bilayers of pure PC (see Figs. 1 and 2). The DOPE matrix induced the largest ordering effect on

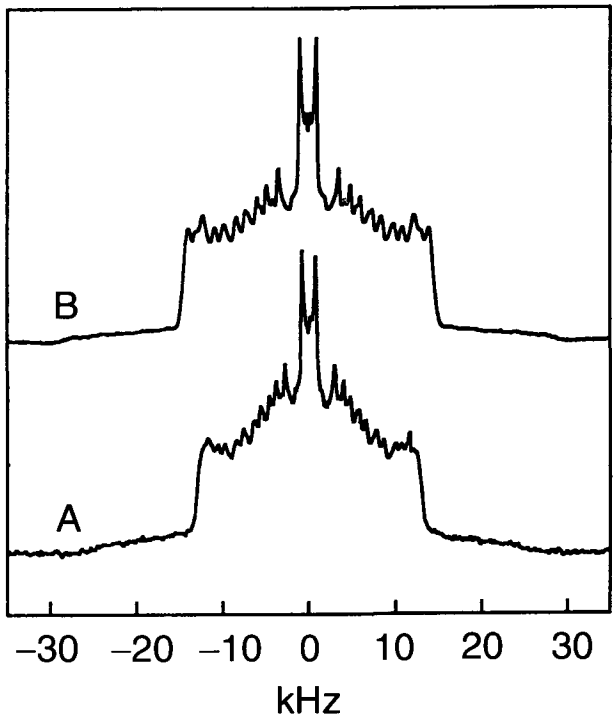

FIG. 1. ^{2}H NMR spectra for (18:0_{d35})(22:6n-3)PC at 30°C. (A) phosphatidylcholine (PC) dispersion; (B) PC incorporated into a matrix of dioleoylphosphatidylethanolamine (DOPE) (molar phosphatidylethanolamine/PC ratio = 5:1).

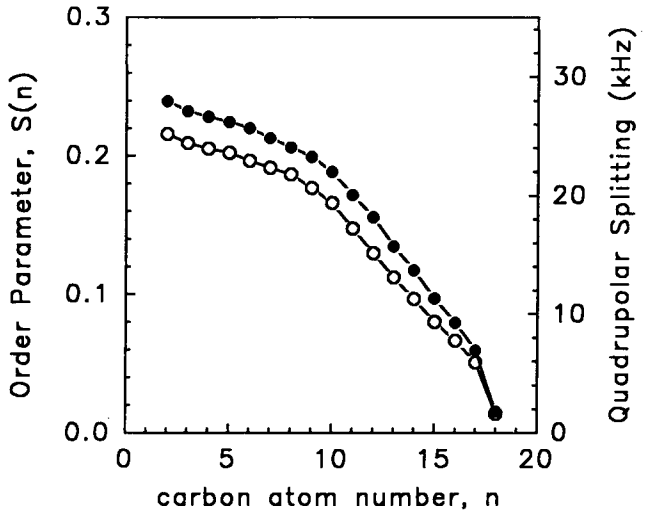

FIG. 2. Order parameter profiles of perdeuterated stearic acid calculated from spectra in Figure 1: ○ (18:0_{d35})(22:6n-3)PC; ● (18:0_{d35})(22:6n-3)PC in matrix of DOPE. The smaller PE head group compresses hydrocarbon chains of PC molecules laterally resulting in a significant increase of chain order (see Fig. 1 for abbreviations).

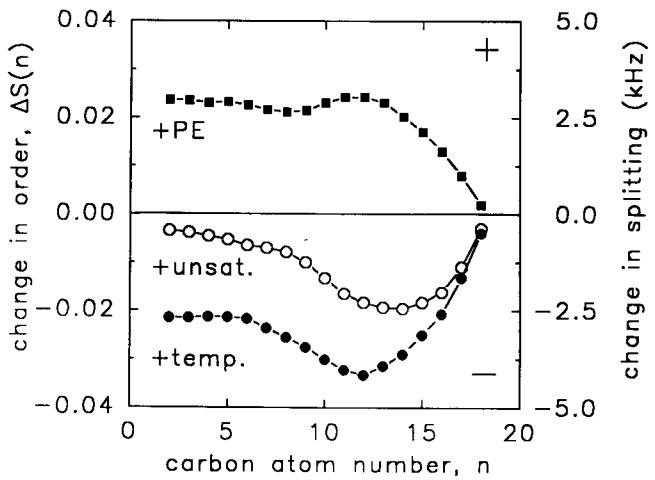

FIG. 3. Difference order parameter profiles, ΔS(n) , of perdeuterated stearic acid as a function of unsaturation, temperature, and head group composition: ○ ΔS(n) between (18:0_{d35})(22:6n-3) PC and (18:0_{d35})(18:1n-9) PC at 37°C; ● ΔS(n) of (18:0_{d35})(18:1n-9) PC between 27°C and 47°C; ■ ΔS(n) between (18:0_{d35})(22:6n-3) PC in a matrix of DOPE and pure (18:0_{d35})(22:6n-3)PC at 30°C (see Fig. 1 legend for abbreviations).

fully saturated distearoylphosphatidylcholine, while unsaturated PC appear to have significantly less lateral compressibility. Difference in order translates into an increase of hydrocarbon thickness of PE/PC vs. PC bilayers of about 1 Å, equivalent to a decrease in area per molecule of the order of 2 $Å^2$. Similar changes have been observed for chain-perdeuterated dimyristoylophosphatidylcholine (DHPC-d_{54}) incorporated into a DOPE matrix (33).

The magnitude of decrease in order along the lipid hydrocarbon chain as a result of double bonds in position *sn*-2 is largest approximately two-thirds of the way down the chain (Fig. 3). This suggests an inhomogeneous increase in area per molecule that is greatest toward the center of the bilayer (32). Such a change may indicate a wedge-shaped conformation for the acyl chain, which results in a looser packing of polyunsaturated lipids at the lipid water interface. It may explain the deeper penetration of solvent molecules into membranes containing unsaturated lipids.

The lipid hydrocarbon chain order decreases with increasing temperature (Fig. 3). Decreased chain order translates into thinner membranes and a larger cross-sectional area per molecule. Change in order as a function of temperature can be approximated by a quadratic function with a dominating linear term. Linear temperature coefficients for polyunsaturated lipids are nearly two times smaller than those of monounsaturated lipids. Incorporation of the PC into a DOPE matrix results in a reduction of the temperature coefficient of saturated and monounsaturated PC by a factor of 0.7. Both the introduction of double bonds and the presence of PE in the lipid matrix reduce the sensitivity of chain order to temperature.

The effect of unsaturation on chain order is often compared with the effect of temperature changes. Both double bonds and higher temperatures result in a decrease of chain order (Fig. 3). Comparison of order parameter profiles, however, reveals that increasing temperature lowers chain order along the entire hydrocarbon chain, while unsaturation lowers chain order mostly in the center of the bilayer. This illustrates that biophysical properties of polyunsaturated membranes are *not* equivalent to properties of less unsaturated membranes investigated at a higher temperature.

Area per lipid molecule is maintained between rather narrow limits to minimize contact between water and hydrophobic regions of the lipid (34). Free energy of the lipid water interface is the major factor that determines packing of lipids in bilayers. Bulkier PC head groups and multiple double bonds in the *sn*-2 chain of the lipids result in an increase in area at the lipid water interface. While unsaturation changes the interface through repulsive forces in the hydrophobic core, area increase induced by head group methylation is the result of changes in polar interaction and hydration. Although both interactions increase area per lipid molecule, their influence on the spontaneous radius of curvature of membranes is of opposite sign: unsaturation and the smaller PE head group favor formation of inverse hexagonal or cubic phases with highly curved monolayers, while the bulkier PC head group stabilizes the lamellar phase (35). This underscores the existence of a tight link between the hydrophobic core and the head group region for lipid packing.

How may we relate bilayer properties due to acyl chain unsaturation and head group size to lipid-protein interactions? (i) We hypothesize that the efficiency of other molecules to penetrate a bilayer is related to the loosening of lipid packing at the interface as a result of unsaturation and head group methylation. This may explain why membrane binding of some proteins depends on unsaturation and the PE/PC ratio. (ii) Unsaturation and head group size change the propensity

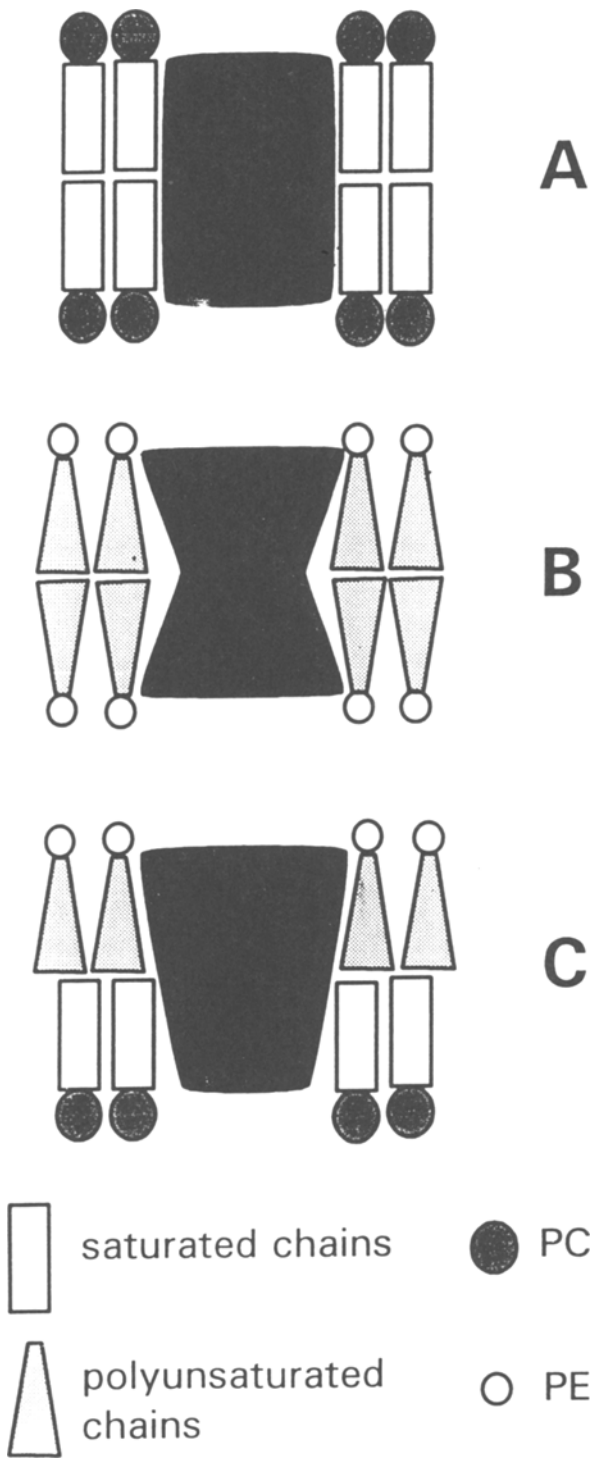

FIG. 4. Schematic representation of molecular packing of a transmembrane protein in bilayers composed of lipids with different head group size and degree of unsaturation. Lipid molecules with small head groups and polyunsaturated hydrocarbon chains accommodate protein transitions into states in which transmembrane helices are tilted (B and C). Membranes with an asymmetric distribution of lipids between monolayers may even accommodate protein structures in which the hinge region of tilt is located outside the bilayer center (C).

of lipid monolayers for curvature and therefore have an influence on membrane curvature stress in a lamellar arrangement. Changes in the arrangement of transmembrane helices during structural transitions of proteins may be favored by lipids that prefer a particular curvature (Fig. 4). This may apply to structural transitions of membrane-bound rhodopsin. Liebman *et al.* (36) suggested that the meta I–meta II transition results in an increase in splay of the 7 transmembrane helices. Tilted helices will create curvature stress in the lipid bilayer around the protein. Depending on the location of the hinge region of protein tilt, this curvature stress may differ between the monolayers. In at least one monolayer, lipids that prefer a smaller area per molecule at the lipid water interface would support the transition. This may explain why polyunsaturated lipids with the smaller PE head group favor formation of the meta II state of rhodopsin (37). (iii) Introduction of polyunsaturated fatty acids and of PE head groups into membranes reduces thermal area expansivity coefficients of membranes. The smaller PE head group reduces area per molecule at the lipid water interface and compresses hydrocarbon chains. Our results demonstrate that saturated PC are more compressed by the DOPE matrix than polyunsaturated PC, suggesting that the elastic area compressibility modulus of polyunsaturated phospholipids is higher. The meta I–meta II transition of rhodopsin has been linked to lateral expansion of rhodopsin, which may be sensitive to differences in membrane compressibility. (iv) There is evidence that proteins may interact specifically with phospholipids (38).

The data provide several mechanisms by which membrane protein function can be modulated by lipids. The small changes in membrane structure related to altered protein activity can be detected by extremely sensitive techniques only, and ^2H NMR spectroscopy is ideally suited for this requirement.

Marked Enrichment of the Alkenylacyl Subclass of Plasma Ethanolamine Glycerophospholipid with Eicosapentaenoic Acid in Human Subjects Consuming a Fish Oil Concentrate

Tim Wilkinson, Harold M. Aukema, Lisa M. Thomas, and Bruce J. Holub*

Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, Ontario, N1G 2W1Canada

ABSTRACT: Alteration in human platelet fatty acid levels with the consumption of fish oils containing eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) have been well documented, but changes in the fatty acid composition of plasma plasmalogenic phospholipid under similar circumstances have not been delineated. In the present study, subjects consumed the fish oil concentrate (MaxEPA) for 6 wk followed immediately by a 6-wk recovery period with no fish oil ingestion. Plasma total choline glycerophospholipid (GPC) and ethanolamine glycerophospholipid (GPE) subclasses isolated from blood samples obtained at 0, 3, 6, 9 and 12 wk of the experimental period were analyzed for fatty acid composition via thin-layer and gas-liquid chromatographic techniques. Consumption of fish oil for 3 or 6 wk significantly elevated the content of n-3 fatty acids while concomitantly decreasing n-6 fatty acid levels in plasma total GPC and in diacyl and alkenylacyl (plasmalogen) GPE. Alkenylacyl GPE exhibited the greatest alteration of both n-3 and n-6 fatty acid levels. Following 6 wk of supplementation with fish oil, EPA rose by 24.6 mol% in alkenylacyl GPE compared to increases of 6.7 and 7.1 mol% in diacyl GPE and total GPC, respectively. The increase in EPA (from 5.0 to 29.6 mol%) in plasma alkenylacyl GPE represents amongst the highest enrichment of EPA in any lipid yet reported in human subjects. DHA also rose by 8.0, 4.8, and 3.1 mol% in alkenylacyl GPE, diacyl GPE, and total GPC, respectively. Alkenylacyl GPE exhibited the greatest mol% decline (by 18.7 mol%) in arachidonic acid (AA, 20:4n-6) following 6 wk of fish oil supplementation. The corresponding decreases of AA in diacyl GPE and total GPC were 8.7 and 1.8 mol%, respectively. Following the 6 wk recovery period, n-3 and n-6 fatty acid levels had returned to pre-supplementation values. The marked enrichment of alkenylacyl GPE in n-3 fatty acids, especially EPA, may be of significance with respect to a unique role for this plasma phospholipid subclass in attenuating certain lipoprotein-mediated cardiovascular effects as observed with fish/fish oil consumption.

Abbreviations: AA, arachidonic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; GPC, choline glycerophospholipid; GPE, ethanolamine glycerolphospholipid; LA, linoleic acid; TLC, thin-layer chromatography.

Consumption of fish or fish oils containing n-3 fatty acids appears to offer protective effects against cardiovascular disease. Decreased arterial thrombosis may relate in part to the reduced platelet reactivity observed in fish/fish oil consumers (1,2). Accumulation of n-3 fatty acids, particularly eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), in platelet phospholipids following fish/fish oil ingestion has been extensively documented (1,2). In particular, the alkenylacyl (plasmalogen) subclass of ethanolamine glycerophospholipid (GPE) represents one of the major forms of arachidonic acid (AA) containing phospholipid in platelets (3) and, with fish oil feeding, exhibits the greatest alteration in fatty acid composition among human platelet phospholipids (4,5). Total plasma phospholipid n-3 fatty acid levels have also been shown to reflect fish consumption (6,7). We have previously shown that upon supplementation with flax or canola oils containing α-linolenic acid, plasma EPA levels are most significantly altered in the alkenylacyl GPE subclass (8), indicating that this subclass is a sensitive indicator of n-3 fatty acid intake. The enrichment of n-3 polyunsaturated fatty acids in choline glycerophospholipid (GPC) and the subclasses of plasma GPE upon human consumption of fish or fish oil containing high levels of EPA and DHA, however, has not been investigated.

GPC (predominantly diacyl species) is the major phospholipid fraction present in human total plasma or serum at approximately 70% of the total, while GPE comprises about 3% of the total plasma/serum phospholipids (9–11). Similar phospholipid compositions have been reported for the individual lipoproteins in plasma (12). GPC and GPE in human plasma/serum can be fractionated into diacyl and ether-containing subclasses with the alkenylacyl GPE subclass representing about 60–70% of total GPE (9–11). Myher *et al.* (9) have reported on the fatty acid composition of the individual subclasses of plasma phospholipids, including alkenylacyl GPE. However, the effect of fish/fish oil supplementation on the fatty acid compositions of these subclasses in human plasma have not been investigated. The purpose of the present study was to analyze the alterations in fatty acid compositions

[a]Subjects (n = 5) consumed MaxEPA for a 6-wk period followed by a 6-wk recovery period. At week 0 and after 3, 6, 9, and 12 wk, plasma choline glycerophospholipid (GPC) was analyzed for fatty acid composition. Results are given in mol% as mean ± SEM. Values across each row having different superscripts are significantly different from each other ($P < 0.05$).

of the alkenylacyl and diacyl subclasses of GPE in human plasma, as well as GPC, following the consumption of a fish oil concentrate, including the reversal of these changes following a recovery period in which no fish oil was consumed.

SUBJECTS AND METHODS

Subjects. The experimental protocol was approved by the Human Subjects Committee of the University of Guelph. Five healthy male subjects with a mean age of 26.4 years and a mean weight of 72.7 kg provided informed written consent. The subjects consumed 20 capsules of MaxEPA (Seven Seas Health Care Ltd., Marfleet, United Kingdom), a fish oil concentrate, for 6 wk at regular meal times. This provided for an intake of 3.6 g EPA and 2.4 g DHA per day. The supplementary period was followed by a recovery period of 6 wk in which no MaxEPA was consumed. During the entire experimental period and for 2 wk prior to the start, subjects were asked to refrain from consuming any seafood.

Plasma lipid isolation. At week 0, and after 3, 6, 9, and 12 wk of the experimental period, blood samples were drawn from an antecubital vein into siliconized Vacutainer tubes (Becton-Dickinson, Rutherford, NJ) containing 1/6 volume of an acid-citrate-dextrose anticoagulant (13). The blood was centrifuged at 190 x g for 15 min at room temperature to obtain the platelet-rich plasma. This was removed and centrifuged at 2000 x g for 15 min at room temperature to obtain platelet-poor plasma. Plasma lipids were extracted from 1 mL aliquots of platelet-poor plasma by the method of Folch *et al.* (14).

Separation of plasma phospholipids by thin-layer chromatography (TLC). The plasma lipid extract was applied to Merck silica gel 60 plates (BDH Chemicals Canada Ltd., Toronto, Ontario, Canada) and separated into individual phospholipid classes using a modification of the Mitchell *et al.* (15) two-dimensional TLC system as we have previously described (5). After development in the first dimension, an area of the thin-layer plate containing total GPE was exposed to concentrated HCl fumes for 10 min at a distance of 5 cm. This procedure cleaved the 1-position aldehyde group of alkenylacyl GPE producing lyso GPE acylated in the 2-position (5), which was then separated from diacyl GPE in the second dimension. After separation by TLC, the phospholipids were visualized under ultraviolet by spraying the plate with 2′-7′-dichlorofluorescein (Sigma Chemical Co., St. Louis, MO) in methanol and water (1:1, vol/vol) and exposing to ammonia vapor.

The area of the plate referred to as GPC contains the diacyl, alkenylacyl, and alkylacyl classes, which have been shown to represent 93, 3.6, and 3.4% respectively, of the total GPC in plasma (9). The lyso GPE fraction of the plate contains fatty acid acylated in the 2- position which was obtained from the acid hydrolysis of alkenylacyl GPE. Alkenylacyl GPE represents approximately 60–70% of total GPE in plasma (9–11). The area referred to as 'diacyl GPE' contains mostly diacyl GPE plus some minor amount of alkylacyl GPE. These latter two GPE classes have been documented to account for about 20–40 (9–11) and 8% (9), respectively, of total plasma GPE.

Fatty acid analysis. The GPC, diacyl GPE, and lyso GPE (from alkenylacyl GPE hydrolysis) fractions of the TLC plate were transmethylated in the presence of the internal standard, monopentadecanoin (Nu-Chek-Prep Inc., Elysian, MN), for 2 h at 80°C. The derived fatty acid methyl esters were extracted with petroleum ether, dried under nitrogen, redissolved in hexane and analyzed on a Hewlett-Packard 5890 gas-liquid chromatograph containing a DB-225 megabore column (Chromatographic Specialties Inc., Brockville, Ontario, Canada). Fatty acids were identified by comparison of peak retention times with those of known standards (Nu-Chek-Prep). Correction for any background contamination was achieved by subtracting values obtained from blank regions of the TLC plates.

Statistical analysis. Results were analyzed using a block design, with individual subjects as the blocks. Significant differences in fatty acid levels were determined by analysis of variance followed by Tukey's Studentized range test (17).

RESULTS

Tables 1, 2, and 3 show fatty acid compositions of plasma total GPC, diacyl GPE and alkenylacyl GPE, respectively, during the 6 wk of the supplementary period followed by a 6 wk recovery period. The week 0 (initial) fatty acid composi-

[a]Subjects (n = 5) consumed MaxEPA for a 6-wk period followed by a 6-wk recovery period. At week 0 and after 3, 6, 9, and 12 wk, plasma diacyl ethanolamine glycerophospholipid (GPE) was analyzed for fatty acid composition. Results are given in mol% as mean ± SEM. Values across each row having different superscripts are significantly different from each other ($P < 0.05$).

tions of all three plasma phospholipid classes were similar to previously published data (9–11). Supplementation with the fish oil concentrate, MaxEPA, caused an enrichment of plasma GPC, diacyl GPE, and alkenylacyl GPE in n-3 fatty acids, particularly EPA and DHA. EPA rose to 7.9, 7.8, and 29.6 mol% of fatty acids in total GPC, diacyl GPE, and alkenylacyl GPE, respectively, by the end of the supplementation period, while the corresponding values for DHA were 5.9, 15.8, and 27.6 mol%, respectively. The total increase in n-3 fatty acids in each phospholipid after 6 wk of fish oil supplementation was mostly accounted for by an increase in EPA (57–74% of total increase) followed by DHA (24–41% of total increase). This was also reflected in the molar ratio of EPA/DHA which increased in each of the plasma phospholipids from week 0 to week 6 and then returned to week 0 levels following the recovery period.

Concomitant with the increase in n-3 fatty acids in plasma phospholipids with 6 wk of fish oil supplementation was a decrease in n-6 fatty acid levels. Comparison of week 6 and week 0 values reveals that the individual phospholipid total mol% changes in n-3 and n-6 fatty acids were approximately equal. In plasma total GPC, linoleic acid (LA, 18:2n-6) accounted for the majority (65%) of the total decline in n-6 fatty acids with AA, 20:4n-6 responsible for just over 15% of the decrease (Table 1). In contrast, AA represented about 65% and LA about 28% of the fall in total n-6 fatty acids in both GPE classes studied (Tables 2 and 3). During the recovery period (weeks 6 to 12), fatty acid mol% values decreased (n-3 fatty acids) or increased (n-6 fatty acids) so that they were not significantly different from the pre-supplementation values (week 0) by the end of the recovery period.

At entry (week 0) n-3 fatty acid mol% values were greatest in alkenylacyl GPE compared to both diacyl GPE and total GPC. Alkenylacyl GPE was especially enriched in DHA at 19.6 mol% compared to 11.0 and 2.8 mol% in diacyl GPE and total GPC, respectively. EPA comprised 5.0, 1.1, and 0.1 mol% of fatty acids in alkenylacyl GPE, diacyl GPE, and GPC, respectively, at week 0. Similar differences for EPA and DHA in plasma alkenylacyl GPE relative to diacyl GPE and total GPC of unsupplemented subjects was observed by Myher *et al.* (9). The greatest mol% rise in n-3 fatty acids over the 6 wk supplementary period also occurred in alkenylacyl GPE. Total n-3 fatty acids increased by 33.1 mol% in alkenylacyl GPE, while in diacyl GPE and GPC the increases were 11.3 and 11.0 mol%, respectively. The 33.1 mol% increase in total n-3 fatty acids in alkenylacyl GPE was accounted for by a rise in EPA (from 5.0 to 29.6 mol%), DHA (from 19.6 to 27.6 mol%) and docosapentaenoic acid (22:5 n-3, from 4.7 to 5.2 mol%).

Similar to the n-3 fatty acids, alkenylacyl GPE had the highest AA mol% at week 0 (39.4 mol% versus 17.3 and 7.9 mol% in diacyl GPE and GPC, respectively), and displayed the largest mol% decline in AA with fish oil supplementation (decline of 18.7 mol% vs. 8.7 and 1.8 mol% in diacyl GPE and GPC, respectively). In terms of percentage changes in fatty acids between week 0 and week 6, alkenylacyl GPE and diacyl GPE had similar increases in EPA and DHA and a similar decline in AA. EPA and DHA rose by 6–7-fold and 1.4-fold, respectively, and AA was approximately halved in both subclasses of GPE examined.

DISCUSSION

In this study, we report on the enrichment of human plasma phospholipids (including alkenylacyl GPE) with n-3 fatty acids following supplementation with a fish oil concentrate. Increases of n-3 fatty acids in platelet phospholipids (particularly alkenylacyl GPE) have been reported following the ingestion of fish oil (5). In this study, the level of EPA approached or surpassed the level of AA in all three plasma phospholipids studied following fish oil supplementation. This contrasts with platelet data where AA levels were far greater than EPA in each individual phospholipid despite the consumption of identical amounts of the same fish oil concentrate (5). In plasma, we found a very high enrichment of n-3 fatty acids in the alkenylacyl GPE subclass. This pronounced enrichment of EPA (to 29.6 mol%) in plasma alkenylacyl GPE is, to our knowledge, the highest enrichment of EPA in any lipid yet reported in human subjects upon supplementation with fish oil. Alkenylacyl GPE displayed the greatest alteration in n-3 and n-6 fatty acids (especially EPA and AA, respectively) following the 6 wk of supplementation with MaxEPA.

Whether this high incorporation of EPA into plasma alkenylacyl GPE contributes to the enrichment of n-3 fatty acids into platelet phospholipids has yet to be determined, as

TABLE 3
Fatty Acid Composition in the 2-Position of Plasma Alkenylacyl GPE[a]

22:5n-3	4.7 ± 0.5	5.6 ± 0.5	5.2 ± 0.3	5.3 ± 0.2	4.8 ± 0.5
22:6n-3	19.6 ± 3.1[a]	29.6 ± 2.2[b]	27.6 ± 0.9[b,c]	23.0 ± 1.5[a,c]	19.5 ± 0.9[a]

*Subjects (n = 5) consumed MaxEPA for a 6-wk period followed by a 6-wk recovery period. At week 0 and after 3, 6, 9, and 12 wk, plasma alkenylacyl GPE was analyzed for fatty acid composition. Results are given in mol% as mean ± SEM. Values across each row having different superscripts are significantly different from each other ($P < 0.05$). Abbreviation as in Table 2.

this fraction represents a minor amount of the total EPA and DHA mass in plasma. Plasma/serum total GPE comprises only about 3% of the total plasma/serum phospholipids with the alkenylacyl class representing approximatley 60–70% of the total GPE (9–11). In contrast, GPC is the major phospholipid in plasma/serum (about 70% of total plasma/serum phospholipids) (9–11) and is therefore an abundant reservoir of EPA and DHA. The high incorporation of EPA and DHA into alkenylacyl GPE compared to diacyl GPE in plasma may be due to either a preferential synthesis/release of EPA/DHA-containing alkenylacyl versus diacyl GPE in/from liver and/or a slower clearance of n-3 containing alkenylacyl GPE from the circulation. Knapp *et al.* (18) have reported upon the selective incorporation of n-3 fatty acids in the inner membrane leaflet of alkenylacyl GPE of human erythrocytes upon supplementation with fish oil.

Although the hepatic concentration of alkenylacyl GPE is very low, the liver contains very active enzymes for the synthesis of this GPE class (19). Relative to hepatic concentrations of diacyl GPE, plasma alkenylacyl GPE levels are much greater (9–11), suggesting that the presence of active synthesizing enzymes for alkenylacyl GPE in liver may be coupled to efficient secretion of this phospholipid into plasma (19). Alkenylacyl GPE may also be cleared much more slowly from blood than the diacyl species, since a plasma phospholipase A_1 activity appears to be involved in clearing plasma phospholipids from the circulation (20,21). This enzyme cleaves the *sn*-1 position fatty acids from phospholipids, but does not act on the alkenyl group of GPE plasmalogen.

The relatively high level of alkenylacyl GPE in plasma relative to the diacyl species (9–11) leads to speculation on a potential function of GPE plasmalogen in plasma. One possible function may relate to an antioxidant role. The vinyl ether linkage of plasmalogens may protect cell membranes from oxidative damage by functioning as scavengers of reactive oxygen species (22,23). The presence of alkenylacyl GPE in plasma lipoproteins may serve to guard lipoproteins against oxidation. This may have implications in the development of atherosclerosis since oxidized, but not native, low density lipoprotein is rapidly taken up by macrophages. The lipid-laden foam cells characteristic of atherosclerosis are derived, at least in part, from macrophages (24). Interestingly, total plasma GPE was suggested to be an indicator in the prediction of atherosclerosis since elevated plasma GPE, more so than any other plasma lipid, was found to correlate with atherosclerotic complications (25). Distinction between diacyl versus alkenyl GPE and the constituent 2-positioned fatty acyl chains (n-6 vs. n-3) would be of interest in this regard.

In summary, we report herein on the enrichment of plasma plasmalogenic phospholipid with n-3 fatty acids following the human consumption of a fish oil concentrate. In particular, the marked enrichment of plasma alkenylacyl GPE with EPA, and the accompanying loss of AA, is of considerable interest. The potential importance of alkenylacyl GPE in plasma and the incorporation of n-3 fatty acids into this lipid has yet to be determined with respect to lipoprotein-mediated cardiovascular effects and modification thereof upon fish/fish oil consumption.

ABSTRACT: We have demonstrated that more than 20 platelet proteins can be acylated with fatty acids via thioester linkages. These include the glycoprotein IX beta chain of glycoprotein Ib, components of the von Willebrand factor receptor on the platelet surface, P-selectin, and α subunits of G_z, G_q, and G_i. Our studies have shown that platelet proteins can be posttranslationally acylated in thioester linkages not only with palmitate but with myristate and also with the eicosanoid precursor fatty acids arachidonate and eicosapentaenoate. Thioesterification of platelet proteins with fatty acids other than palmitate may have significant functional consequences for reversible binding of proteins to membranes.
Lipids 31, S-217–S-221 (1996).

Acylation of proteins by fatty acids plays an important role in the interaction of proteins with hydrophobic membrane domains (1–5). Fatty acids can become covalently bound directly to proteins through amide linkages at *N*-terminal glycine residues and through thioester linkages to internal cysteines (1–3). Fatty acids can be indirectly yet covalently linked to proteins as part of the glycosyl-phosphatidylinositol (GPI) membrane anchor. In this complex molecule, fatty acids are part of the phosphatidylinositol moiety, and protein is linked to the carbohydrate-rich head group (4,5).

When fatty acids are incorporated into cells, the majority of them are esterified into phospholipids and triglycerides. A small amount, usually less than 2%, becomes acylated to protein (6–9). Acylation of proteins through an amide linkage occurs cotranslationally, and the fatty acid moiety does not turn over independent of the protein. The enzyme responsible for this type of modification, *N*-myristoyl transferase, has been purified, and gene coding for the protein has been cloned (10–12). This enzyme has been found to exhibit relatively rigid substrate specificity toward myristoyl-CoA as a fatty acid donor and the *N*-terminal glycine as fatty acid acceptor. A number of proteins of eukaryotic cells have been demonstrated to have amide-linked fatty acids. These include the insulin receptor α and β subunits (13), various G-protein α subunits (14–17), and the immunoglobulin heavy chain (18). Fatty acid acylation of proteins through thioester linkages occurs posttranslationally, and the fatty acid moiety attached to the protein turns over independent of the protein. Eukaryotic proteins with thioester-linked fatty acids include selected G-protein α subunits (14–17), the transferrin receptor (19), the sodium channel α subunit (20), rhodopsin (21), and ankyrin (22). As noted in this report, fatty acid acylation through thioester linkages has a much more relaxed fatty acid specificity than does fatty acid acylation through amide bonds (7,9). In the synthesis of GPI membrane-anchored proteins, addition of GPI to the protein occurs very early after synthesis of the protein. A preassembled GPI anchor is linked to the protein within the endoplasmic reticulum to produce a fully synthesized GPI-linked protein, which then makes its way to the outer leaflet of the plasma membrane. A number of cell surface proteins are bound to a GPI membrane anchor. These include alkaline phosphatase (23), decay accelerating factor (24), and the variant surface glycoprotein of trypanosomes (25).

Many studies have demonstrated significant functional consequences when a fatty acid is unable to covalently bind to protein when it is normally directed to do so. As three examples, p21Ras, a GDP/GTP–binding protein, can acquire the ability to transform cells if activated by mutations that favor the active GTP-bound form of the protein. Nonpalmitoylated mutants of activated p21Ras do not stably interact with membranes, remain predominantly cytosolic, and are unable to transform cells (26). G-protein α subunits associate with the cytoplasmic face of the plasma membrane where interactions with β-γ subunits, receptors, and effectors occur. Amino-terminal deletion mutants of α_q with removal of cysteines 9 and 10 cannot bind palmitate, are predominantly cytosolic, and are unable to activate phosphatidylinositol (PI)-specific phospholipase C (27). Finally, cysteine[341] in the carboxyl-terminal tail of the β_2 adrenergic receptor has been shown to be palmitoylated. Mutation of cysteine[341] to glycine results in a nonpalmitoylated form of this receptor and a markedly reduced ability to mediate isoproteronol stimulation of adenylylcyclase (28).

This report summarizes our studies identifying platelet proteins covalently modified by thioester-linked fatty acids and demonstrating relaxed specificity for fatty acids in

thioester linkage to proteins. Myristate, arachidonate, and eicosapentaenoate (EPA) were all found to become covalently bound to platelet proteins by thioester linkages.

EXPERIMENTAL PROCEDURES

Preparation of [^{3}H]palmitate-labeled platelet suspensions and periodate/sodium boro[^{3}H]hydride-labeled platelet suspensions, isolation of platelet glycoprotein Ib-IX complexes by immunoadsorption, preparation of platelet membrane fractions, lipid extraction of platelet proteins, release of fatty acids covalently bound to proteins and their identification by high-performance liquid chromatography (HPLC), and SDS–polyacrylamide gel electrophoresis (PAGE) and fluorography of polyacrylamide gels were all performed as previously described (6–9). Methods for preparation of [^{3}H]myristate-, [^{3}H]arachidonate-, and [^{3}H]eicosapentaenoate-labeled platelet suspensions have also been described in previous reports (7,9).

RESULTS

The platelet is an ideal system in which to study thioester linkage of fatty acids to proteins. Unlike the formation of covalent bonds between fatty acids and proteins through amide linkages or within GPI anchors, thioesterification of proteins with fatty acids is not dependent on protein synthesis. Since there is little if any protein synthesis in circulating platelets, protein acylation by fatty acids in platelets almost exclusively involves thioesterification. The first series of experiments demonstrates that

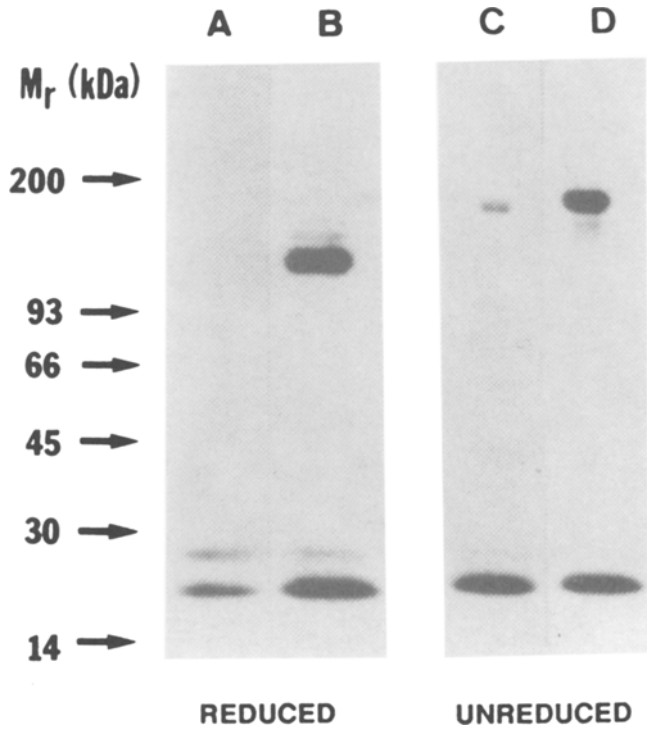

FIG. 2. Fluorogram of SZ.1-immunoprecipitated proteins from [^{3}H]palmitate-labeled platelets (lanes A and C) and from periodate/[^{3}H]$NaBH_4$-labeled platelets (lanes B and D). Platelets were isolated, labeled, and lysed, and immunoprecipitates were prepared as described in the Experimental Procedures section. Immunoprecipitated platelet proteins were solubilized in either reducing (lanes A and B) or nonreducing (lanes C and D) sample buffer and subjected to SDS–polyacrylamide gel electrophoresis on a 5–20% gradient gel followed by fluorography. Reprinted from *Journal of Biological Chemistry 264,* p. 9718, 1989.

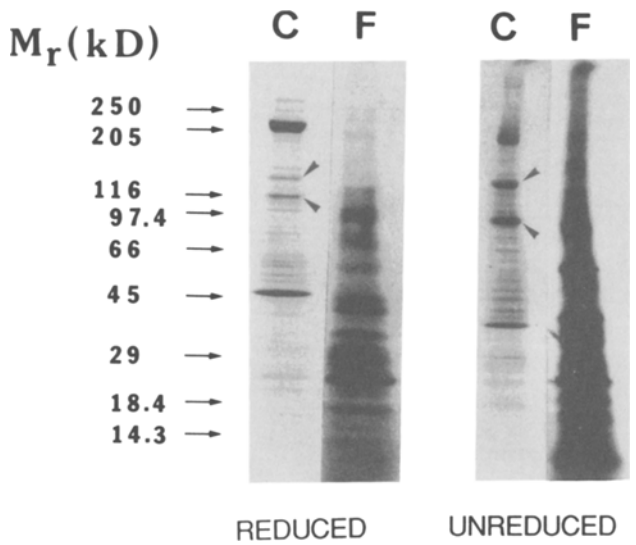

FIG.1. Recovery of [^{3}H]palmitoylated proteins in the membrane fractions of [^{3}H]palmitate-labeled platelets. The membrane fraction was isolated using a 1.0–3.5 mol/L continuous sorbitol gradient and solubilized in sample buffer with (reduced) or without (unreduced) β-mercaptoethanol and subjected to SDS–polyacrylamide gel electrophoresis. Gels were stained with Coomassie blue (C), and the radiolabeled polypeptides were visualized by fluorography (F). In each lane, 11 μg protein was applied to the gel. Glycoproteins IIb and IIIa are noted by arrowheads. Reprinted from *Blood 74,* p. 1345, 1989.

multiple platelet proteins can be esterified with radiolabeled palmitate through thioester linkages (6). Platelets were isolated by gel filtration or centrifugation and radiolabeled with 300 μCi/mL ^{3}H-palmitate for 45 min. Platelets were then delipidated extensively with multiple organic solvents. In some experiments, platelet proteins were evaluated by SDS–PAGE with protein stain or fluorography, and in other experiments platelets were processed for selective cleavage of fatty acids from proteins and HPLC of liberated fatty acids for fatty acid identification. In these experiments, approximately 1–2% of the palmitate incorporated into cells became covalently bound to protein. As shown in Figure 1, in lanes marked C for Coomassie stain, several major and many minor platelet membrane proteins are visible. Lanes marked F for fluorography in Figure 1 indicate proteins that became palmitoylated. It should be noted that there is no correspondence between the pattern of prominent proteins in the Coomassie-stained lanes and that of the intensely labeled proteins in the fluorography lanes. Extensive removal of noncovalently bound lipids by extraction with a series of solvents produced no changes in the fluorographic pattern. This indicates that fatty acids were not bound to proteins by nonspecific trapping. Following labeling with [^{3}H]palmitate,

platelet proteins were treated with alkaline methanol, which selectively releases fatty acids in ester linkage but does not release fatty acids in amide linkage. Methyl palmitate was recovered almost exclusively, indicating that the radioactivity in the SDS gels represented fatty acids, and not nonfatty acid metabolites. In support of this finding, hydroxylamine at neutral pH, which liberates thioester-linked fatty acids but not amide- or 0-ester–bound fatty acids, released radiolabeled palmitate from proteins to which it was bound.

In other studies we demonstrated that platelet glycoproteins Ib and IX, components of the platelet von Willebrand factor receptor, are palmitoylated. Platelets were isolated and then radiolabeled with [^{3}H]palmitate or sodium periodate/sodium boro [^{3}H]hydride. The platelets were lysed, and immunoprecipitation of the glycoprotein Ib-IX complex was performed using the SZ.1 monoclonal antibody (8). SDS–PAGE and fluorography were then performed to determine if the glycoprotein Ib α or β chain or glycoprotein IX was acylated with fatty acid. In Figure 2, in lanes A and C, proteins labeled with palmitate are visible. In lanes B and D, glycoproteins Ib and IX labeled with sodium periodate/sodium borohydride are shown as standards. SDS gel electrophoresis and fluorography of immunoprecipitates from [^{3}H]palmitate-labeled platelets revealed two radiolabeled bands under reducing conditions at 24 kDa and 19 kDa and 2 bands under nonreducing conditions at 170 kDa and 19 kDa. As demonstrated by comparison to the immunoprecipitates from sodium periodate/sodium boro[^{3}H]hydride-labeled platelets, [^{3}H]palmitate-labeled bands under reducing conditions correspond to glycoproteins Ib β and IX. [^{3}H]Palmitate-labeled bands under nonreducing conditions correspond to glycoprotein IX and intact glycoprotein Ib. In separate experiments, the immunoprecipitate was delipidated, and the remaining covalently bound fatty acid residues were selectively cleaved from the protein and analyzed by HPLC to identify thioester-linked fatty acids. Alkaline methanolysis followed by HPLC demonstrated that the radioactivity associated with the glycoprotein Ib-IX complex from the [^{3}H]palmitate-labeled platelets was covalently bound [^{3}H]palmitate in ester linkage to protein. Release of [^{3}H]palmitate covalently bound to glycoproteins Ib β and IX by neutral hydroxylamine further indicated that the protein and fatty acid were linked by way of a thioester bond. In other studies, we demonstrated that the platelet protein P-selectin (29) can be acylated with palmitate and stearate through thioester linkages. We also showed that palmitate and arachidonate can become bound in thioester linkage to α subunits of G_z, G_q, and G_i (30).

In more recent studies, we demonstrated that myristate can become covalently bound to platelet proteins *via* thioester linkages (7). This finding was unexpected, since myristate is known to be the predominant amide-linked fatty acid. We found that myristate was releasable with alkaline methanol from platelet proteins prelabeled with [^{3}H]myristate, which, as noted earlier, releases ester-linked but not amide-linked fatty acids. In these experiments, we also found that palmitate competed with myristate for protein binding, that myristate and palmitate bound to the same platelet proteins, and that myristate was released from protein by neutral hydroxylamine. As shown in Figure 3, the bands in the lanes marked

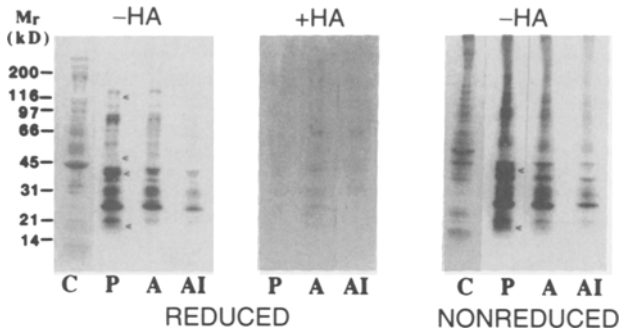

FIG. 4. [^{3}H]arachidonoylated and [^{3}H]palmitoylated proteins in platelets. Washed platelets were labeled with [^{3}H]fatty acid. Platelet proteins were then precipitated, extracted, and dissolved in sample buffer. Reduced and nonreduced samples (40 μg protein/well) were analyzed by SDS–polyacrylamide gel electrophoresis (PAGE), after which the radiolabeled proteins were detected by fluorography. SDS–PAGE of reduced samples was performed in duplicate on two parallel gels, and one of the fixed gels was subjected to neutral hydroxylamine (+HA) treatment. Lanes C, Coomassie-stained gels of platelet proteins; lanes P, [^{3}H]palmitate-labeled platelets; lanes A, platelets incubated with [^{3}H]arachidonate; lanes AI, [^{3}H]arachidonate-labeled platelets incubated with baicalein and indomethacin to inhibit cyclooxygenase and lipoxygenase. Horizontal lines on the left side of first gel represent migration distance of M_r marker proteins. Arrowheads on the P lane identify bands that can be detected only on the fluorogram of ^{3}H-palmitoylated proteins. Reprinted from *Journal of Biological Chemistry 268,* p. 18246, 1993.

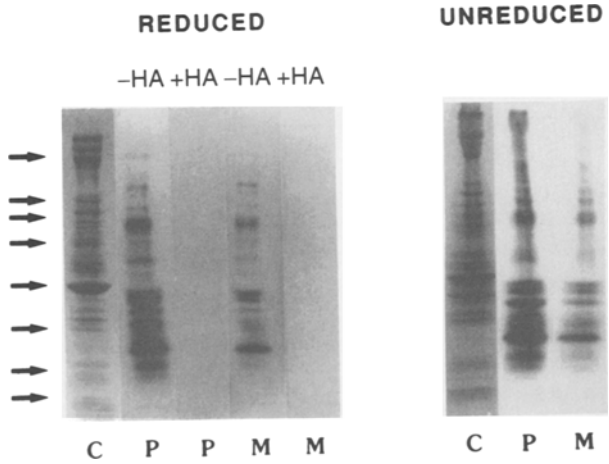

FIG. 3. [^{3}H]myristoylated and [^{3}H]palmitoylated proteins in platelets. Platelets were washed and labeled with [^{3}H]fatty acid; platelet proteins were precipitated and extracted with acetone, then analyzed with SDS–polyacrylamide gel electrophoresis and fluorography as described in the Experimental Procedures section. C, Coomassie blue staining; M and P, fluorogram of proteins from [^{3}H]myristate- (4-week exposure) and [^{3}H]palmitate- (4-day exposure) labeled platelets, respectively; –HA and +HA, gels incubated in the absence or presence of 1 M neutral hydroxylamine. To each well, 63 μg platelet protein was applied. Arrows represent migration distance of standard proteins of the following molecular mass, from top to bottom: 200, 116, 97.4, 66.2, 45, 31, 21.5, and 14.4 kDa. Reprinted from *Journal of Biological Chemistry 268,* p. 8255, 1993.

P for [^{3}H]palmitate label and M for [^{3}H]myristate label are essentially identical, indicating that myristate and palmitate bind to the same platelet proteins. As noted by the lanes marked +HA for hydroxylamine treatment, myristate has a sensitivity equivalent to palmitate for release from proteins.

We subsequently tested whether arachidonate and eicosapentaenoate can become covalently bound to proteins *via* thioester linkages (9). In these experiments, radiolabeled arachidonate or EPA was added to platelets, followed by SDS–PAGE and fluorography. In some experiments, cyclooxygenase and lipoxygenase inhibitors were added to assess the possibility that the arachidonate and EPA were first being converted to oxygenated metabolites and then becoming covalently bound to proteins. As shown in Figure 4, arachidonate and palmitate bound to most of the same proteins. There were a few proteins, noted by the arrows, that were palmitoylated and apparently not arachidonoylated. We were also able to demonstrate that arachidonate was released from protein by neutral hydroxylamine. The lanes marked +HA in Figure 4, which are markedly overexposed to permit visualization of the faint bands present, illustrate that neutral hydroxylamine was able to release the arachidonate covalently bound to proteins. Protein-bound arachidonate was slightly less sensitive to neutral hydroxylamine for release than was protein-bound palmitate. Figure 4 also shows that, in the presence of cyclooxygenase and lipoxygenase inhibitors (in lanes marked AI), there was essentially no difference in fatty acid binding to protein, although the lanes representing samples with inhibitors were somewhat less intense than those without inhibitors. The basis for this difference remains unexplained. This result indicates that the fatty acids, and not their oxygenated metabolites, bound to proteins. In other studies, we demonstrated that arachidonate and EPA were released from platelet proteins by alkaline methanol, further supporting the conclusion that these fatty acids, like myristate and palmitate, can become bound to proteins through thioester linkages. In Figure 5, it can be seen that arachidonate and EPA bind to the same platelet proteins. The more intense labeling of platelet proteins by arachidonate may reflect the slightly higher concentration of radiolabeled arachidonate (4 μM) relative to EPA (2.6 μM) used in these experiments.

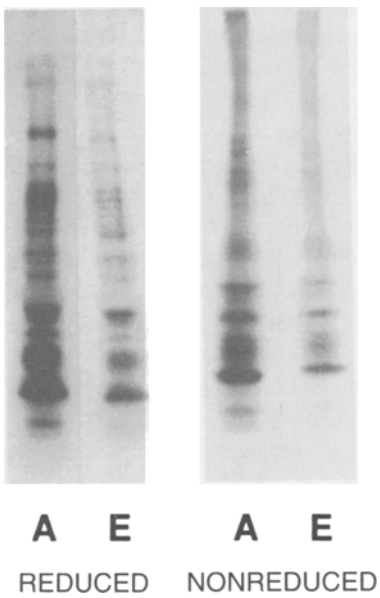

FIG. 5. Fluorograms of platelet proteins labeled with [^{3}H]arachidonate and [^{3}H]EPA. Reduced and unreduced protein samples (50 μg protein/well) of platelets labeled with [^{3}H]arachidonate (A) and [^{3}H]eicosapentaenoic acid (E) were analyzed by SDS–polyacrylamide gel electrophoresis and fluorography. Reprinted from *Journal of Biological Chemistry 268,* p. 18247, 1993. Abbreviations as in Figure 4.

DISCUSSION

Our studies indicate that many platelet proteins are thioesterified with fatty acids, including glycoprotein Ib β (8), glycoprotein IX (8), P-selectin (29), and α subunits of G_z, G_q, and G_i (30). In addition, we demonstrated that the fatty acid capable of binding to proteins in thioester linkage is not only palmitate. Myristate (7); the eicosanoid precursor fatty acids, arachidonate and eicosapentaenoate (9); and, from our studies with P-selectin (29), stearate can all become protein-bound in a thioester linkage. Posttranslational binding of myristate, palmitate, arachidonate, and EPA to platelet proteins apparently involves identical mechanisms, as these fatty acids become bound to the same set of substrate proteins. The binding of myristate or stearate instead of palmitate to proteins *via* thioester linkages may have significant consequences for membrane binding. Unlike palmitoylated proteins, proteins that are covalently bound to myristate can be found in the cytoplasm (31). Myristate is two carbons shorter than palmitate and therefore somewhat less efficient in promoting membrane binding than is palmitate. Stearate is two carbons longer than palmitate and may be more efficient than palmitate in promoting membrane binding. We speculate that there are significant functional consequences to protein myristoylation or stearoylation at internal cysteines rather than palmitoylation. On a structural basis, thioesterification with arachidonate or EPA may have even greater functional consequences for membrane binding. Myristate, palmitate, and stearate are all saturated fatty acids that have no bends in the fatty acid molecule. Arachidonate with 4 double bonds and EPA with 5 are highly twisted fatty acid molecules. Studies comparing the relative affinity for membranes of arachidonoylated proteins vs. proteins bound to saturated fatty acids have not yet been performed. Our studies with G-proteins show that several G-protein α subunits can be thioesterified with arachidonate as well as with palmitate (30).

There is another significant issue related to arachidonoylation of proteins. Upon cell activation, significant amounts of arachidonate are liberated from phospholipids by phospholipase action, and a large amount of free arachidonate is present in the cytoplasm of the cell for a brief time (32). This arachidonate is potentially available for thioesterification of proteins *via* displacement of saturated fatty acids or binding to

sites on the protein where saturated fatty acids are not present. Modification of proteins with arachidonate in the cell activation process may be an important component of protein regulation in transmission of intracellular signals. Determination of the actual amounts of palmitate, myristate, stearate, arachidonate, and EPA that are bound to platelet proteins by thioester linkages *in vivo* will be established by studies in which the thioester-linked fatty acids in the native state are specifically removed and analyzed quantitatively without the use of radiolabeled fatty acids. These studies are currently in progress in our laboratory.

Membrane-Associated and Cytoplasmic Fatty Acid-Binding Proteins

F.A. Van Nieuwenhoven, G.J. Van der Vusse, and J.F.C. Glatz*

Department of Physiology, Cardiovascular Research Institute Maastricht (CARIM), University of Limburg, Maastricht, The Netherlands

ABSTRACT: A number of cellular fatty acid-binding proteins are being implicated in the uptake and intracellular transport of long-chain fatty acids by parenchymal cells. Having been a topic of research for more than 20 years, cytoplasmic fatty acid-binding proteins now are assigned various pivotal functions in intracellular fatty acid transport and metabolism. More recently several membrane-associated fatty acid-binding proteins have been identified and these proteins are thought to function in the transmembrane transport of fatty acids. In this review, a short summary is provided of the latest developments in this research area.

Lipids 31, S-223–S-227 (1996).

Long-chain fatty acids (FA) are important compounds serving as substrates for energy-production and formation of phospholipids (1). Moreover, they can participate in signal transduction pathways (2–4). Adipose tissue takes up large amounts of FA from blood plasma for storage as intracellular triacylglycerols. In contrast, oxidative skeletal muscles and especially the heart take up FA as fuel for contractile processes. Since FA are poorly soluble in water the rapid metabolism of these FA would probably not be possible without special binding proteins, which dramatically increase the solubility of these compounds in aqueous environments. In blood and interstitium, FA are mainly bound to albumin, keeping the unbound FA concentrations extremely low (<10 nM) (5). Intracellularly, FA are most likely bound to specific cytoplasmic fatty acid-binding proteins (FABP) (6–10). More recently, membrane-associated proteins have been hypothesized to function in the cellular uptake of FA. These membrane and cytoplasmic proteins will be discussed in more detail below.

Membrane-associated FABP. The mechanism of transmembrane transport of FA into parenchymal cells has been a matter of debate for several years. Some investigators favor a mechanism in which FA cross the membrane by simple diffusion (11,12). Others found saturable uptake of FA in several cell-types, a process that could be inhibited by FA analogues, indicating that membrane-associated proteins are involved (13). Subsequently, by using various techniques, a number of such membrane proteins have been identified (Table 1). The first membrane protein described to be involved in the uptake of FA is a 40 kDa protein present in the plasma membrane of rat liver cells (14). This protein, $FABP_{PM}$, was subsequently also found in intestine (15), and heart (16). The protein seems closely related, if not identical, to mitochondrial aspartate aminotransferase (17). $FABP_{PM}$ is not an integral membrane protein but has been shown to possess affinity for membranes (17).

In 1987, Fujii *et al.* (18,19) described another membrane protein with high affinity for FA, which was designated fatty acid receptor (FAR). This protein of about 60 kDa was found to be present in kidney and heart. The third membrane protein putatively involved in FA uptake, identified in adipocytes by Harmon and co-workers (20) and recently cloned by Abumrad *et al.* (21), is an 88 kDa protein called fatty acid translocase (FAT). FAT from rat was found to be highly homologous (85%) to the human leucocyte differentiation antigen CD36, a receptor protein present among others on monocytes and platelets, and thought to be involved in adhesion phenomena and intracellular signalling (for review on CD36 see ref. 22). Comparison of rat FAT (21) and the recently cloned mouse CD36 (23) revealed an amino acid identity of 93%, which strongly suggests that these proteins are species homologues. Recent investigations showed that CD36 is an integral membrane protein with one transmembrane region (24).

In adipocytes, Trigatti *et al.* (25) found another membrane protein implicated in the transmembrane transport of FA. This 22 kDa protein was identified by photoaffinity labelling with a FA analogue. The final membrane protein hypothesized to augment cellular FA uptake that has been found up till now, is called fatty acid transport protein (FATP) (26). A functional approach using expression cloning was followed to identify this 63 kDa protein in adipocytes. FATP was shown to be an integral membrane protein present in the plasma membrane of several tissues, and has been predicted to have several membrane spanning domains (26).

The precise functions of the FA-binding membrane-associated proteins in the transport of FA across cellular membranes are still unclear. Some of the possible mechanisms by which membrane proteins could be involved in this process

TABLE 1
Membrane-Associated Fatty Acid-Binding Proteins (FABP)

Protein	Molecular mass (kDa)	Major occurrence	Reference
Membrane FABP	22	Adipose tissue	25
$FABP_{PM}$	40	Liver, heart, adipose tissue, intestine	15,16
FA receptor	56–60	Heart, kidney	18,19
FA transport protein	63	Adipose tissue, heart, skeletal muscle	26
FA translocase	88	Adipose tissue, heart, skeletal muscle	20,21

are shown in Figure 1. These proteins might function as a translocator, but it is also possible that they represent acceptors for FA released from albumin and that FA subsequently cross the plasma membrane by diffusion through the phospholipid bilayer. Albumin binding proteins have been described which could play a role in this mechanism (27). Furthermore, there might be a direct interaction between a membrane-associated FA-binding protein and (extracellular) albumin and/or (intracellular) FABP. Such interactions would ensure a controlled uptake mechanism in which FA remain protein-bound. Further characterization of the FA-binding membrane proteins will provide a better understanding of the complex transmembrane transport mechanisms of FA.

Intracellular FABP. Cytoplasmic FABP belong to a single gene family of intracellular lipid binding proteins of 14–15 kDa, capable of binding hydrophobic ligands with high affinity (28). The mammalian cytoplasmic lipid-binding proteins are listed in Table 2. Since the discovery of FABP in 1972 by Ockner and co-workers (29), nine different FABP, including the recently discovered testicular 15 kDa protein (T-LBP) (30,31), have been identified (Table 2). All lipid binding proteins are composed of two α-helices and 10 anti-parallel β-strands, organized in two β-sheets, thereby forming a clam shell-like structure (8). The lipid ligand is bound inside the molecule by interaction with specific amino acid residues within the binding pocket of the lipid binding protein (8). A recent investigation by Richieri *et al.* (32) suggests that the FABP have a higher affinity for the binding of FA than found in previous studies (7,9,10) with the dissociation constants (Kd) ranging from 2 to 1000 nM, depending on type of FABP and FA (32). A striking feature of the FABP is their relative abundance in tissues with active FA metabolism.

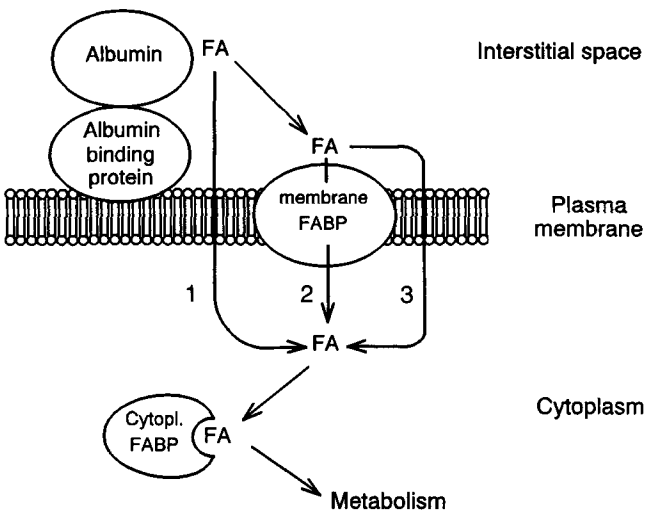

FIG. 1. Schematic presentation of the mechanism of cellular fatty acid uptake and the possible role of membrane-associated fatty acid-binding proteins in this process. Transmembrane transport could take place without the involvement of membrane proteins (1), or with a membrane protein acting as a true translocator (2), or as an acceptor for fatty acids thus, creating a steeper transmembrane gradient (3). FA, long-chain fatty acid; membrane FABP, any membrane-associated fatty acid-binding protein (see Table 1); cytopl. FABP, any cytoplasmic FABP (see Table 2).

A number of biological roles have been ascribed to the FABP: (i) Facilitation of the transport of FA to their intracellular sites of utilization. Indirect evidence was provided in studies showing a correlation between FA-utilization and FABP-content (33,34) and by showing that *in vivo* FA are bound to FABP (35,36). Furthermore, *in vitro* studies showed an increase in FA transport from isolated mitochondria to artificial phospholipid vesicles in the presence of H-, or L-FABP (37). Theoretical studies also support a role for FABP in FA-transport in cardiomyocytes (38). More direct evidence was found by transfection studies in which cells transfected with H-, L-, or A-FABP showed increased FA-uptake rates (39-41). Finally, a recent report showed that a single amino acid substitution (Ala54 -> Thr54) in human I-FABP, as occurs in some Pima Indians, causes a two-fold greater affinity for FA. This was associated with increased fat oxidation rates and with insulin resistance, also suggesting a role for I-FABP in cellular FA-transport (42). (ii) Prevention of local high FA concentrations and thereby protecting the cell against detrimental effects of FA, for instance in the ischemic heart (43). (iii) By modulating hydrophobic ligand metabolism, FABP can influence important cellular events like mitogenesis (44) and FA-mediated signal transduction pathways (3,7). Recently, a small fraction of H-FABP in rat heart and mammary gland was found to be phosphorylated upon stimulation with insulin, and it was suggested that H-FABP might play a role in signal transduction downstream from the insulin receptor (45,46). (iv) Inhibition of growth and induction of differentiation of cultured mammary epithelial cells has been reported as an extracellular function of mammary derived growth in-

TABLE 2
Mammalian Cytoplasmic Lipid-Binding Proteins[a]

Protein	Current designation	Other designations	Ligand	Major occurrence
Heart FABP	H-FABP	MDGI	FA	Heart, skeletal muscle, smooth muscle, brain, kidney, mammary gland
Liver FABP	L-FABP	Z-protein	FA, heme, bilirubin, prostaglandins	Liver, small intestine, kidney
Intestinal FABP	I-FABP		FA	Small intestine
Adipocyte lipid-binding protein	A-LBP	A-FABP, aP2	FA, retinoic acid	Adipose tissue
Epidermal FABP	E-FABP		FA	Epidermis
Brain FABP	B-FABP		FA	Nervous system
Myelin FABP	M-FABP	Myelin-P2	FA, retinoids	Nervous system
Ileal lipid-binding protein	I-LBP	I-BABP, gastrotropin	FA, bile acids	Small intestine (ileum)
Testicular lipid-binding protein	T-LBP	PERF15	ND	Testis
Cellular retinoic acid-binding protein	cRABP		Retinoic acid	Testis, nervous system, kidney, skin
Cellular retinoic acid-binding protein II	cRABPII		Retinoic acid	Skin, adrenals
Cellular retinol-binding protein	cRBP		Retinol	Widespread expression
Cellular retinol-binding protein II	cRBPII		Retinol	Intestine

[a]Data are compiled from References 3, 8, 30, 31, and 56. ND, not determined; FA, long-chain fatty acids, other abbreviation as in Table 1.

hibitor, which is identical to H-FABP (9). (v) Induction of myocyte hypertrophy through binding with a high affinity receptor is another extracellular function recently ascribed to H-FABP (47).

Regulation of expression of FABP. The expression of A-FABP and also of FAT and FATP is upregulated during differentiation from preadipocytes to adipocytes (21,26,48), and is paralleled or preceded by an increased uptake of FA (48). Recently, it was shown that FA themselves can induce the expression of A-FABP in rat preadipocytes (49).

In cardiac cells, H-FABP expression increases markedly during the first few days after birth and in the weaning period (50,51). During this period, the FA oxidation capacity is also increased (52). Recently, it was shown that FAT is co-expressed with H-FABP in rat muscles and that FAT expression followed a similar upregulation in heart during development, indicating related biological functions (53).

Diabetes is a disease in which several organs, like the heart, rely more on FA oxidation as their major energy source. In streptozotocin-induced diabetic animals, a decrease of A-FABP expression (54) and an increase in H-FABP expression (55) have been shown. These results indicate that insulin deficiency can influence FABP expression levels. Preliminary results from our laboratory show that FAT is also upregulated in rat muscles in streptozotocin-induced diabetic rats (Fig. 2). These results suggest that altered FA-handling of cells can influence FABP and FAT expression.

Concluding remarks. In the last 20 years, a number of cellular proteins with affinity for FA have been identified. Among these are nine different types of intracellular 15 kDa FABP which most likely function in facilitating the *trans*-cytoplasmic transport of FA. In the last few years, more interest in the transmembrane transport of FA has resulted in the discovery of membrane proteins that might be involved in this process. Now that the genes of most of these proteins have been cloned, molecular biological techniques can be applied to manipulate the cellular content and binding activity of

FIG. 2. Northern blot analysis of total RNA from liver, heart, soleus, and extensor digitorum longus (EDL) muscle from control and streptozotocin-induced diabetic rats using fatty acid translocase cDNA as probe.

these proteins. This might provide a better understanding of their role in the complex mechanisms by which FA are taken up and distributed in the cell.

Specificity of Polyunsaturated Fatty Acid Release from Rat Brain Synaptosomes

Hee-Yong Kim*, Lisa Edsall, and Yee-Chung Ma

Section of Mass Spectrometry, Laboratory of Membrane Biochemistry and Biophysics, National Institute of Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland

ABSTRACT: Release of specific polyunsaturated fatty acids from cell membranes may have a significant implication in biological function, considering the involvement of various fatty acids in cell signal transduction. In the present study, release of polyunsaturated fatty acids from rat brain synaptosomes by endogenous synaptosomal lipase activity was examined in comparison to that by cobra venom phospholipase A_2 (Naja naja naja). Cobra venom phospholipase A_2 (Naja naja naja) preferentially hydrolyzed docosahexaenoic acid (22:6n-3) from both synaptosomes and lipid mixtures containing similar classes of lipids commonly found in the brain. Arachidonic acid (20:4n-6) and oleic acid (18:1n-9) were also hydrolyzed; however, monoene species was hydrolyzed slower than were polyenoic species in synaptosomes. Phosphatidylethanolamine was the most preferred phospholipid class for release of 22:6n-3 fatty acid from both lipid mixtures and synaptosomes.

In contrast to hydrolysis by cobra venom phospholipase A_2, endogenous synaptosomal lipase activity preferentially hydrolyzed 20:4n-6 from rat brain synaptosomes, despite the high abundance of 22:6n-3 in synaptosomal membranes. Preferential release of 20:4n-6 was observed over a wide range of pH values and calcium concentrations. Synaptosomal 22:6 species appeared to be resistant to hydrolysis even after stimulation with various agents such as phorbolmyristate, suggesting that physiological importance of 22:6n-3 in neuronal membranes may not be as the release fatty acid.
Lipids 31, S-229–S-233 (1996).

Phospholipase A_2 (PLA_2) hydrolyzes the *sn*-2 fatty acyl chain from phospholipids producing free fatty acids and lysophospholipids (1,2). Hydrolysis of polyunsaturated fatty acids from their reservoir phospholipids occurs primarily by the PLA_2 reaction, since most of the polyunsaturated fatty acids are esterified at the *sn*-2 position of the phospholipids. Released polyunsaturated fatty acids can be metabolized to many potent biological mediators such as prostaglandins and leukotrienes (3). Lysophospholipids resulting from the PLA_2 reaction are strong surfactants and can modify physical and chemical characteristics of cell membranes significantly. Therefore, activation of PLA_2 can bring about many pathophysiological consequences, especially in cells where polyunsaturates are highly concentrated.

In neuronal membranes, docosahexaenoic acid (22:6n-3) is the most abundant polyunsaturated fatty acid esterified in phospholipids (4,5). Although 22:6n-3 is thought to be essential for proper neuronal and retinal functions (4,5), mechanisms involved in its essentiality are not clearly understood. It is possible, however, that selective release of 22:6n-3 may play an important role in cell signaling, as has been suggested for arachidonic acid (20:4n-6) selectively hydrolyzed by cytosolic PLA_2 (6,7). To test this possibility, we examined specificity in the release of polyunsaturated fatty acids from brain synaptosomes where 22:6n-3 is especially enriched, using a well-characterized cobra venom PLA_2 (Naja naja naja). The observed substrate specificity was compared with results obtained from lipid mixtures containing various classes of lipids commonly found in the brain. Specificity of release of 20:4n-6 and 22:6n-3 by endogenous synaptosomal lipase activity was characterized subsequently.

MATERIALS AND METHODS

All phospholipid standards were either purchased from or custom-synthesized by Avanti Polar Co. (Alabaster, AL). All inhibitors and stimulators used in this study were purchased from Sigma Chemical Co. (St. Louis, MO).

Preparation of lipid mixture. Lipid mixtures were prepared according to Bayburt et al. (8), with slight modifications. To minimize alterations in characteristics of lipid mixtures, 85% of the lipid composition was kept constant and only 15% of the

lipids was altered with phosphatidylcholine (PtdCho), phosphatidylethyanolamine (PtdEtn), or phosphatidylserine/phosphatidic acid (PtdSer/PtdOH) species. Total 15 μmoles of lipids [PtdCho, 20%; PtdEtn, 25%; cholesterol, 40%; phospholipid mixture containing equimoles of 1-stearoyl-2-docosahexanoyl- (18:0 22:6-), 1-stearoyl-2-arachidonoyl- (18:0 20:4-), and 1-stearoyl-2-oleoyl- (18:0 18:1-) glycerophosphocholine (Gro*P*Cho), glycerophosphoethanolamine (Gro*P*Etn), or glycerophosphoserine/glycerophosphoric acid (Gro*P*Ser/Gro*P*OH) 15%] were sonicated in 1 mL deionized water for 15 s under nitrogen. This composition was based on the reported composition of PtdCho, PtdEtn, and cholesterol in rat brain corresponding to 20, 23.6, and 39.3%, respectively (9). The suspension was frozen on dry ice and then sonicated in water for 30 min before dilution. Each incubation mixture contained 1.5 μmoles total lipids in 1 mL PLA_2 buffer (25 mM *tris*-HCl, 0.1 mM KCl, and 10 mM $CaCl_2$, pH 8.0). Alternatively, lipid mixtures were prepared by sonicating dried mixed lipids in the PLA_2 buffer for 30 min.

Preparation of synaptosomes. Synaptosomes were prepared according to Cotman (10). Synaptosomes were washed to remove Ficoll reagent by resuspending in excess phosphate-buffered saline buffer (pH 7.4) and centrifuging at 9,000 × g for 10 min at 4°C. The washed synaptosomes were reconstituted in chilled PLA_2 buffer devoid of $CaCl_2$ to a concentration of 0.167 mg protein/mL solution. Synaptosomes were incubated for 0–60 min at 37°C in the presence of $CaCl_2$ (final concentration of 10^{-7}–10^{-3} M) and 5 mg/mL fatty acid free-bovine serum albumin. Each incubation mixture contained 0.75 mL (0.125 mg protein) synaptosome suspension.

Incubation and lipid analysis. Lipid mixtures or synaptosomes were incubated with or without 0.1 unit cobra venom PLA_2 (Naja naja naja, 1,800 unit/mg protein, Sigma, Chemical Co.) at 37.5°C for 0–60 min. Appropriate inhibitors and stimulators were coincubated with synaptosomes. The reaction was terminated by acidification to pH 3.0 with formic acid, and the incubation mixture was extracted according to Bligh and Dyer (11) in the presence of 23:0 as an internal standard. An aliquot was transmethylated for gas chromatographic determination of the individual fatty acid content in the total lipid extract. Separation of various lipid classes was achieved using aminopropyl solid phase extraction columns (Varian, Harbor City, CA), as described previously (12). Separated lipids were transmethylated with BF_3-methanol (14% wt/vol, Alltech, Deerfield, IL) for 2 h at 100°C under nitrogen, according to Morrison and Smith (13), and subjected to gas chromatographic analysis, as described previously (12). Alternatively, extracts of the incubation mixture were subjected to thermospray liquid chromatography–mass spectrometry analysis, as has been described (14).

RESULTS

Studies using lipid mixtures. When lipid mixtures were incubated with 0.1 unit cobra venom PLA_2, a steady but nonlinear increase of free fatty acids was observed (Fig. 1). After the extent of hydrolysis exceeded 10% of the substrate, only a slight progress in hydrolysis was observed, as in the case with the lipid mixture containing the PtdEtn mixture (Fig. 1B). Cleavage of 22:6n3 fatty acid, however, was consistently the highest for each phospholipid class at any incubation time-point examined. Lipid mixtures obtained by both methods described in the experimental section generated qualitatively similar results, except that lipid mixtures generated by suspending lipid mixtures directly in the PLA_2 buffer by sonication yielded hydrolysis products at a slightly higher level. Hydrolysis of 20:4n-6 and oleic acid (18:1n-9) was comparable, although a slight preference of 20:4n-6 over 18:1n-9 was observed for lipid mixtures containing PtdEtn mixtures. Among phospholipid classes examined, PtdEtn was hydrolyzed most quickly, while PtdCho hydrolysis was least favored.

Hydrolysis of rat brain synaptosomes by cobra venom PLA_2. Figure 2 shows the time course of PLA_2 hydrolysis of 18:1, 20:4, and 22:6 containing phospholipids in synaptosomes. As was the case with the lipid mixtures, 22:6n-3 was the fatty acid found at the highest level in the incubation mixture at any incubation time-point. Cleavage of 20:4n-6 and 18:1n-9 species were consistently lower than for 22:6n-3 species. Synaptosomes contain 12–13% of 20:4n-6 and 19–20% of 22:6n-3 in total lipids. Although the fatty acyl content of 18:1n-9 and 20:4n-6 in synaptosomes was comparable, PLA_2 appeared to hydrolyze 20:4n-6 more favorably than 18:1n-9. When the extent of hydrolysis was expressed as the percentage of the cleaved fatty acid against the level of the individual fatty acid present in the total lipids (Fig. 2B), qualitatively similar results were obtained, indicating that the high level of cleaved 22:6n-3 is not just due to the high abundance of the substrate in synaptosomes.

To find the origin of the cleaved fatty acids, PLA_2 hydrolysis was examined at the molecular species level, using thermospray liquid chromatography–mass spectrometry (15,16). The diacylglycerol fragments of the major phospholipid molecular species were monitored selectively, as shown in Fig. 3, since they were the most abundant peak in the thermospray spectra and contained the molecular species information (15,16). For free fatty acids, $(M + NH_4)^+$ ions were selectively monitored. Since diacylglycerol fragments were common for all glycerophospholipid classes containing a given fatty acyl composition, monitoring these ions in conjunction with on-line high-performance liquid chromatography (HPLC) separation facilitated analysis of molecular species in complex mixtures. Although the intensity of these ions did not directly represent the absolute level of the respective species (14,17), comparison of chromatographic peak areas of individual molecular species before and after PLA_2 hydrolysis allowed us to monitor hydrolysis at the molecular species level. After 1 min incubation, 22:6n-3 and 20:4n-6 appeared in the chromatogram with the former at a higher level. Decrease of these species was observed from 18:0 22:6-Gro*P*Etn, 18:0 20:4-Gro*P*Ino, and 18:0 20:4-Gro*P*Etn, indicating that 22:6n-3 and 20:4n-6 were hydrolyzed initially from these species. Hydrolysis of 18:0 22:6-Gro*P*Ser was also indicated but at a lower level in comparison to 18:0 22:6-Gro*P*Etn. Further incubation decreased

18:0 22:6 and 18:0 20:4 species of all classes, as well as 18:0 18:1 and 16:0 18:1-Gro*P*Cho significantly. Decrease of 16:0 20:4-Gro*P*Cho was also observed, but to a much lesser extent. In fact, 16:0 20:4-Gro*P*Cho became the dominating 20:4 containing species after 30 min of incubation (data not shown). It also appeared that 18:0 18:1-Gro*P*Cho was more favorably hydrolyzed than was 16:0 18:1-Gro*P*Cho. Analysis of individual lipid classes by gas chromatography after separation by solid phase extraction (12) indicated similar results.

Hydrolysis of rat brain synaptosomes by endogenous lipase activity. Endogenous lipase activity was also observed

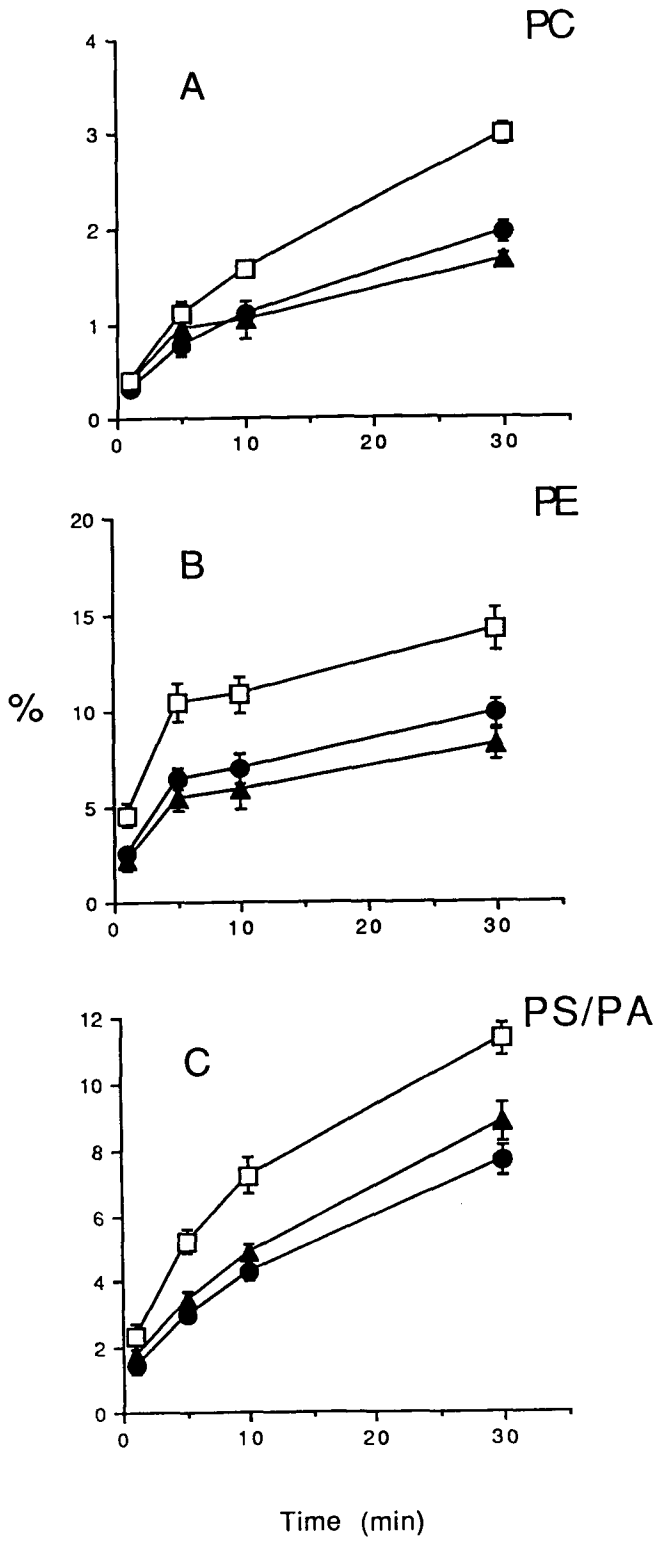

FIG. 1. Hydrolysis of PtdCho (A), PtdEtn (B), and PtdSer/PtdOH (C) containing 18:0 18:1, 18:0 20:4, and 18:0 22:6 species by cobra venom PLA_2. The average of three determinations is presented with standard error. Differences in hydrolysis of 22:6n-3 (○) and 20:4n-6 (●) at all data points were statistically significant at the $P < 0.01$ level; 18:1n-9 (▲).

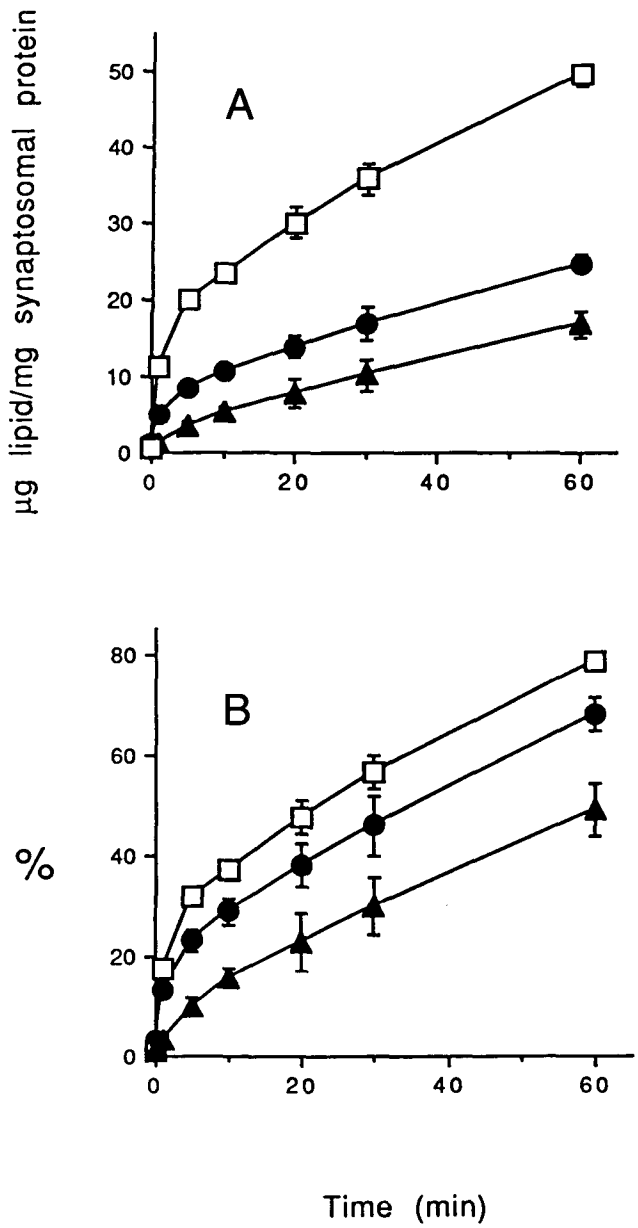

FIG. 2. Release of free fatty acids from rat brain synaptosomes by cobra venom PLA_2. Data points are presented as the absolute μg of released free fatty acid per mg synaptosomal protein (A) as well as the percentage against the total content of the corresponding fatty acid present in the incubated synaptosomes (B). The average of three determinations is presented with standard error. Differences in hydrolysis of 22:6n-3 and 20:4n-6 at all data points were statistically significant at the levels of $P < 0.001$ (all points in A), $P < 0.02$ (1, 5, 10, and 60 min points in B) and $P < 0.05$ (20 and 30 min points in B); ▲, 18:1n-9; ●, 20:4n-6, □, 22:6n-3.

in rat brain synaptosomes. Release of fatty acids by endogenous lipase activity from synaptosomes containing 0.125 mg protein was less than 10% of the hydrolysis observed with 0.1 unit cobra venom PLA_2 at any incubation time-point examined (Fig. 4). In contrast to the latter case, 20:4n-6 was found consistently at a higher level in comparison to 22:6n-3, despite the higher abundance of 22:6n-3 in synaptosomes. This hydrolysis pattern showing preferential release of 20:4n-6 was maintained in a wide range of pH values (5–9.5) and calcium concentrations (0.1 μM–100 mM), although maximum hydrolysis was achieved with 10 mM $CaCl_2$ at pH 9.

Cytosolic phospholipase inhibitors (18) partially inhibited the production of both 20:4n-6 and 22:6n-3. After 30 min of incubation, production of 20:4n-6 and 22:6n-3 fatty acids was slightly but significantly inhibited by 100 μM N-acetylneuraminic acid (NANA), 150 μM GM_3 ganglioside, and 100 μM N-glycolylneuraminic acid (NGN). Incubation with an extracellular PLA_2 inhibitor 4-bromophenacylbromide (0.5 μM) or a diacylglycerol (DG) lipase inhibitor protamin sulfate (0.5 μM) did not alter the extent of hydrolysis significantly, suggesting the possibility that a cytosolic PLA_2 may be involved in the hydrolysis process.

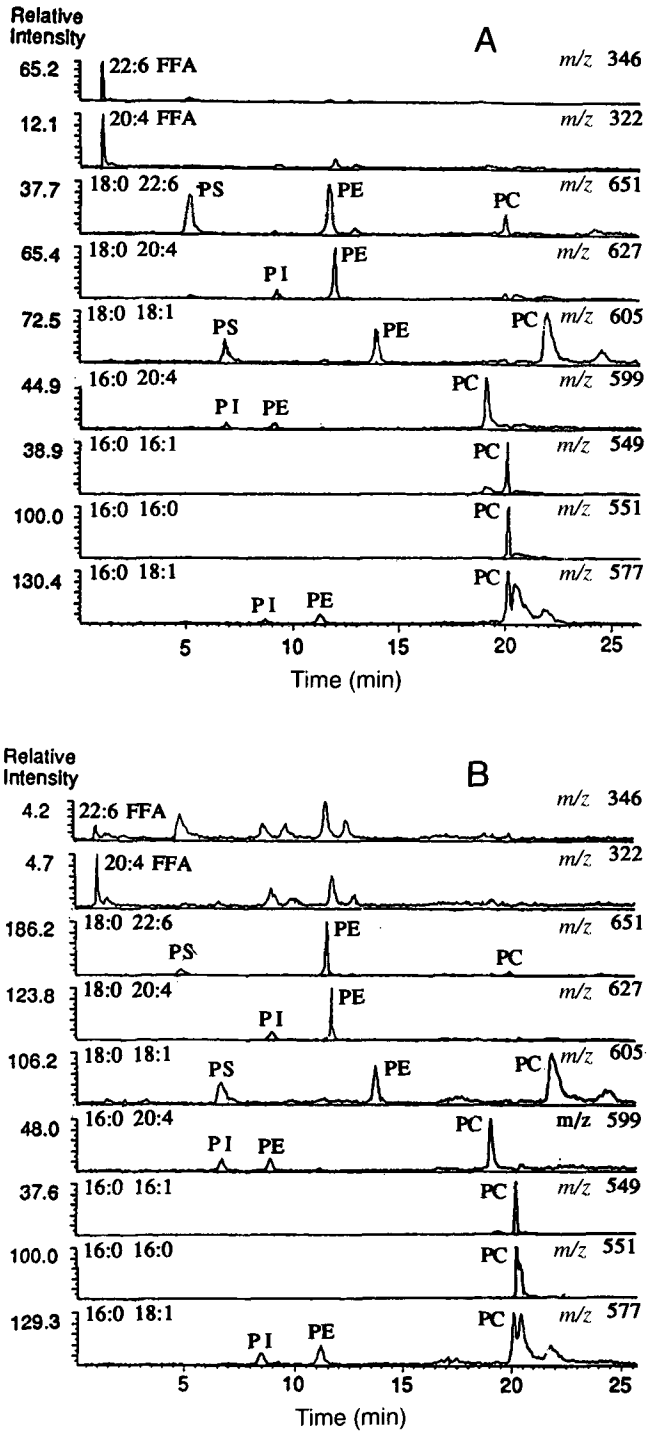

FIG. 3. Phospholipid molecular species analysis of rat brain synaptosomes before and after incubation with cobra venom PLA_2 for 1 min. Each molecular species was monitored by its diglyceride ion fragments, and relative intensity was calculated based on the area count of di-16:0-Gro*P*Cho species present in the synaptosomes. For free fatty acids, $(M + NH_4)^+$ ions were selectively monitored. Incubation time: A, 0 min; B, 1 min.

DISCUSSION

In this study, the substrate specificity of the cobra venom PLA_2 reaction was examined using lipid mixtures and rat brain synaptosomes. Results were compared with specificity observed for the synaptosomal fatty acid release by endogenous lipase activity. As indicated in data obtained with mixed lipids, cobra venom PLA_2 clearly showed substrate selectivity favoring 22:6n-3 for all PtdCho, PtdEtn, and PtdSer/PtdOH classes. Only 15 mol% of the mixed phospholipids (5 mol% each of 18:1n-9, 20:4n-6, and 22:6n-3 species) was introduced into the background lipids containing 40 mol% cholesterol, 25 mol% 16:0 16:1-GroPEtn, and 20 mol% di-palmitoyl-(di-16:0-) GroPCho. Therefore, the selectivity shown in this study did not appear to result from the different organiza-

tion of substrates at the lipid/water interface when substrates were presented to the enzyme (19). For lipid mixture and synaptosomes, hydrolysis rates were not linear, but gradually decreased after initial hydrolysis. This phenomenon may be explained by inactivation of PLA_2 during hydrolysis (20). Alternatively, product inhibition described for 85 kDa PLA_2 enzymes (21) may be considered. Due to the better affinity of the enzyme for lipid mixtures containing reaction products, free fatty acids, and lysophospholipids, the enzyme may become trapped and unavailable to other substrate vesicles. Our data obtained using mixed lipids or synaptosomes agreed that 22:6n-3 containing PtdEtn species were the best substrates, suggesting that the preferential release of 22:6n-3 is not just due to either the abundance of this species in synaptosomal PtdEtn or different efficiency in product inhibition or enzyme inactivation.

Preferential hydrolysis of 22:6n-3 by Naja naja naja PLA_2 observed in our work is similar to the findings from rat serum PLA_2 using PtdEtn liposomes obtained from rat brain synaptosomes (22). Selective hydrolysis of 22:6n-3 from rat brain synaptic membrane and myelin has been also observed from a group-II snake venom PLA_2 *Vipera russelli* (23). Since this selectivity disappeared when liposomes prepared with the lipid extract of either synaptic membranes or myelin were used as substrate (23), the authors attributed the observed selectivity to nonlipid components in membranes. Under our experimental conditions, however, the hydrolysis profile by Naja naja naja PLA_2 was similar for both lipid mixtures and synaptosomes in that 22:6n-3 containing PtdEtn species was the preferred substrate.

From our study it is clear that 22:6n-3 is selectively hydrolyzed from membranes of neuronal cells by Naja naja naja PLA_2. The selective loss of this species may cause impaired neuronal functions, as was suggested in the situation of n-3 deficiency (4,5). On the contrary, 22:6n-3 species are relatively resistant to endogenous lipase activity. While it is still not clear what the exact role of 22:6n-3 in neuronal membranes is, it is possible that the physiological importance may lie in its role as a membrane component rather than as a released free fatty acid.

Natural and Accelerated Docosahexaenoic Acid Accumulation in the Prenatal Rat Brain

Pnina Green and Ephraim Yavin*

Department of Neurobiology, The Weizmann Institute of Science, 76100 Rehovot, Israel

ABSTRACT: The quantity and distribution of docosahexaenoic acid (DHA) in major brain phospholipids (PL) was examined in the fetal rat brain before birth, using thin-layer and capillary column gas chromatography. A rapid increment of DHA content of about 187 μg/g brain/day was observed between 17 to 20 days gestation, as opposed to 39.3 ± 2.9 μg/g brain/day prior to that. Single intraamniotic injections of 5 μL ethyl-docosahexaenoate (Et-DHA) (12 μM, 4.25 mg) administered to 17-day-old fetuses were used to examine the uptake of DHA into brain PL. Three days following injection, the amount of n-3 polyunsaturated fatty acids increased by 28% compared to ethyl-oleate (Et-Ole) injected fetuses. Compared to the n-6 fatty acid family, the relative amount of DHA increased in the phosphatidylserine (PS), phosphatidylethanolamine and phosphatidylcholine (PC) lipids by 15 ($P = 0.02$), 13 and 14%, respectively. A major increase in the pool size of phosphatidylinositol and PS (110 and 50.3%, respectively), and a decrease in PC (8.2%) were observed 3 d after Et-DHA as compared to Et-Ole administration. The data suggest that a single intraamniotic administration of Et-DHA can modulate membrane PL content and alter PUFA composition.

Lipids 31, S-235–S-238 (1996).

Intrauterine life constitutes a vulnerable period in brain development, since the fetus is totally dependent upon the maternal supply of nutrients for its growth (1). The developing brain utilizes large amounts of long chain polyunsaturated fatty acids (PUFA), docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (AA, 20:4n-6) for the biosynthesis of rapidly expanding neuronal plasma membranes. Adequate dietary supply of PUFA on their precursors, linolenic and linoleic acids, is needed since these fatty acids cannot be synthesized *de novo* by mammals. Even though the rat brain growth spurt is considered a postnatal event (2,3), essential fatty acid (FA) deprivation during gestation leads to marked developmental deficits later in life (4) suggesting that significant PUFA changes occur also during pregnancy. However, data regarding these intrauterine changes in rat brain lipid FA are almost nonexistent.

DHA is found highly concentrated in brain tissue (5), but its specific role is still being investigated. To elucidate some of its functions, manipulation of brain DHA content, particularly DHA deprivation, mainly in postnatal animals, has been attempted (6). In some instances in which the fetal brain was examined, DHA content modification was done through the maternal feeding (7,8). These observations prompted us to examine alternative routes for direct fetal brain DHA modification, specifically enrichment, without the participation of the maternal metabolism. This work establishes the feasibility of the intraamniotic administration of ethyl-docosahexaenoate (Et-DHA) to accelerate the incorporation of DHA into the acyl chain groups of fetal brain phospholipids (PL). In addition, marked changes in the polar head-group composition of PL are documented.

MATERIALS AND METHODS

Pregnant Wistar (250–300 g body weight) rats were fed *ad libitum* chow containing 5 g lipid/200 g with the following fatty acid composition: 13% 16:0, 4% 18:0, 24% 18:1, 52% 18:2n-6 and 5% 18:3n-3. At days 17 and 20 of gestation (denoted E17 and E20), dams were anesthetized by intramuscular injection of 50 mg ketamine (Parke Davis, MI) and 7 mg xylizine HCl (Bayer, Leverkusen, Germany) per kg body weight (0.2 mL/300 g body weight of a 1:1 mixture of 2% xylizine HCl/Rompun and 0.1 g/mL Ketamine). After a midline abdominal incision, the uterine horns were exposed and kept moist throughout surgery with phosphate buffered saline (PBS, pH 7.4). For base line determination of brain lipids FA composition at either fetal age, the fetal brains were immediately removed upon midline incision of the abdomen and the uteri, and placed in liquid nitrogen. In the enrichment studies, E17 fetuses were injected intraamniotically through the uterine wall and amniotic sac with either 5 μL (12 μmols) Et-DHA (from Fish Oil Test Materials, NIAAA, NIH, Bethesda, MD) or an identical amount of ethyl-oleate (Et-Ole, Sigma, St. Louis, MO), both without any carrier. The uteri were returned to the abdomen, and 72 h later the fetuses were delivered by caesarean section. The fetal brains were immediately placed in liquid nitrogen upon removal.

After weighing, the brains were homogenized in 2 mL hexane/isopropanol (3:2, vol/vol) containing 5 mg% butylated hydroxytoluene, using a Branson tip sonifier, according to Hajra and Radin (9). The organic layer containing the lipid extract was separated from the residual tissue by low speed centrifugation.

The major PL, phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI) and phosphatidylserine (PS) were separated on thin-layer chromatography (TLC) by a mixture of chloroform/methanol/methylamine (40%) (130:70:30, by vol) (10). All the solvents were of HPLC grade.

Lipid spots resolved on TLC were visualized under ultraviolet light after spraying with 0.2% dichlorofluorescein in ethanol. Individual spots were identified and scraped into glass tubes and 1 mL of 14% BF_3 in methanol and 0.5 mL benzene were added. The tubes were capped under N_2 and heated at 100°C for 1 h. The methyl esters (FAME) were extracted into hexane after acidification of the mixture with 3 drops of 3N HCl and kept under N_2 at −20°C until analyzed. FAME separation was performed on a 3400 Varian GC using fused silica capillary columns [either SP-2330, 30 m × 0.25 mm inner diameter, 0.20 m film thickness (Supelco, Inc., Bellefonte, PA), or BPX70, 50 m × 0.22 mm inner diameter, 0.25 m film thickness (SGE, Melbourne, Australia)]. Column temperature was kept initially at 70°C for 1 min, then raised to 150°C at a rate of 20°C/min, further raised to 230°C at a rate of 3°C/min and after 14 min at this temperature, raised finally to 260°C at a rate of 20°C/min. Peak areas were integrated and plotted with the aid of the Varian Star Integrator computer package. FAME were identified by comparison of retention times with those of authentic standards (Nu-Chek-Prep, Elysian, MN; and Sigma Chemical, MO). Heneicosanoic acid (21:0, vol/vol) was used as internal standard for quantitation.

Lipid phosphorus was determined according to Bartlett (11).

Data were analyzed using the general linear model provided by the Statistical Analysis System (SAS) for ANOVA, nested design (12).

RESULTS

Maternal-dependent DHA accretion in the fetal brain. Total brain FA concentration increased 1.7-fold between E17 to E20 gestational age. The changes in the two essential FA family members, n-3 and n-6, however, did not proceed in parallel (Table 1). Whereas the relative concentration of the n-6 PUFA slightly decreased, that of the n-3 PUFA, consisting almost exclusively of DHA, increased substantially. Thus, the daily increment of DHA between E17 and E20 was on the average 187 μg/g brain/day. In contrast, the daily increment of DHA accretion up to E17 was on the average 39.3 ± 2.9 μg/g brain/day. This selective accumulation of DHA between E17 and E20 is reflected in the 1.5-fold increase in the DHA/total n-6 PUFA ratio (total n-6 PUFA is the sum of 20:4, 22:4 and 22:5) (Table 1).

Fatty Acids of the Developing Fetal Rat Brain[a]

Parameters	E17	E20	*P*
Total FA (μg/mg wet wt)	8.80 ± 0.56	14.90 ± 0.54	0.0001
Total n-6 PUFA (wt%)	22.36 ± 0.40	19.78 ± 0.32	0.02
Total n-3 PUFA (wt%)	7.08 ± 0.36	9.86 ± 0.35	0.0001
DHA (wt%)	6.43 ± 0.36	8.55 ± 0.39	0.0001
DHA/total n-6 LC-PUFA	0.31 ± 0.02	0.46 ± 0.01	0.03

[a]Mean ± SE, n = 6 for E17, each sample of three brains, n = 8 for E20, each sample of two brains. total n-6 polyunsaturated fatty acids (PUFA) include 18:2, 20:3, 20:4, 22:4, and 22:5; total n-3 PUFA include 18:3, 22:5 and 22:6; total n-6 long-chain (LC)-PUFA include 20:4, 22:4, and 22:5. DHA, docosahexaenoic acid.

The increase in DHA, relative to total n-6 PUFA, was noted in all major brain PL studied. As illustrated in Figure 1, there was a 1.4–1.7-fold increase in the DHA/total n-6 PUFA ratio between E17 and E20, highly significant in the PS and PE lipid fractions.

Fetal brain DHA accretion in the Et-DHA supplemented fetuses. To investigate the effect of Et-DHA supplements on the normal acquisition of DHA in the fetal brain, selected fetuses were injected on day 17 of pregnancy as detailed under methods. This mode of injection did not cause any premature deliveries. After three days following injection into the amniotic sac, all fetuses survived, suggesting that the route and amounts of Et-DHA or Et-Ole injected were not toxic.

Analysis of several FA parameters in the fetal brain at E20 is summarized in Table 2. There were no significant differences in the total brain FA concentration between the Et-DHA and Et-Ole injected fetuses. The total brain n-3 PUFA and DHA proportions increased by 28.3 and 20.7%, respectively, after Et-DHA as compared to Et-Ole administration (P = 0.009 and 0.024, respectively). There was a 47% increase of the DHA/total n-6 PUFA ratio following Et-DHA as compared to Et-Ole administration (P = 0.01). The changes of this ratio in the individual PL are depicted in Figure 2. Moderate increases of 14, 15 (P = 0.02), and 13% were observed in PC,

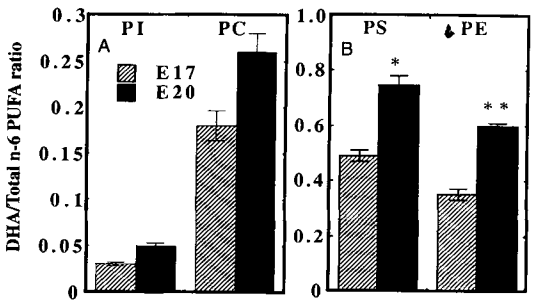

FIG. 1. Developmental changes in fetal rat brain phospholipid (PL) docosahexaenoic acid (DHA) and n-6 polyunsaturated fatty acid (PUFA). The ratios of brain PL DHA to the sum of the long-chain n-6 PUFA (20:4, 22:4, and 22:5) in the 17-d (E17, hatched bars) and 20-d (E20, dark bars) gestational age fetuses are shown. Values are mean ± SE of 4–8 samples, each E17 sample consisting of three brains and each E20 sample of two brains. *P = 0.005; **P = 0.0001.

TABLE 2
Effects of Intraamniotic Ethyl-Docosahexaenoate (Et-DHA) Administration[a]

Parameters	Et-Ole	Et-DHA	*P*
Total FA (μg/mg wet wt)	13.84 ± 0.63	13.40 ± 0.41	NS
Total n-6 PUFA (wt%)	21.85 ± 0.56	20.57 ± 0.22	NS
Total n-3 PUFA (wt%)	8.61 ± 0.22	11.05 ± 0.34	0.009
DHA (wt%)	8.55 ± 0.30	10.32 ± 0.30	0.02
DHA/total n-6 LC-PUFA	0.41 ± 0.003	0.53 ± 0.02	0.01

[a]Mean ± SE, n = 6 for ethyl-oleate (Et-Ole), n = 14 for Et-DHA, each sample of two brains. See footnotes to Table 1 for abbreviations and other information.

PS, and PE, respectively, following Et-DHA administration. A slight reduction of 7% was noticed in PI.

Since the FA changes observed in the total brain extracts were not matched by the changes in the individual PL fractions, an alternative explanation related to the pool size of the brain PL was considered. As illustrated in Figure 3, three days after Et-DHA administration, a significant increase of more than twofold in PI content ($P = 0.0009$) was observed. Similarly, PS increased by more than 50% ($P = 0.03$) and PC decreased by 8.2% ($P = 0.03$). The change in PE was not significant. Under these conditions, total brain lipid phosphorus (Pi) of Et-DHA and Et-Ole injected fetuses was similar (0.88 ± 0.03 μg/mg, and 0.83 ± 0.03 μg/mg, respectively).

DISCUSSION

After cessation of neuronal cell proliferation, the last several days before birth in the rat are characterized by an active growth and acquisition of new plasma membranes as well as the formation of stable connections between neuronal cells. The strikingly accelerated rate of DHA accretion during the last three days of pregnancy documented in this study is presumably maintained by the maternal diet. We suggest that a "growth spurt" for DHA accumulation exists, which is analogous to the traditional concept of the "brain growth spurt" coined by Dobbing (2), but significantly antedates it. This prenatal period, during which the fetus is entirely dependent on the maternal diet, is very vulnerable to nutritional insults

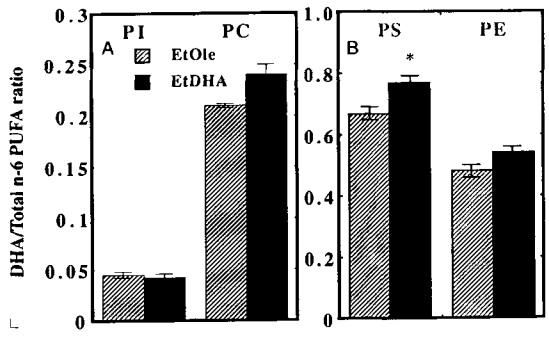

FIG. 2. Effects of ethyl-docosahexaenoate (Et-DHA) administration on the fetal rat brain PL DHA and n-6 PUFA. Symbols and abbreviations as in Figure 1, except that each sample consisted of two fetal brains. *P = 0.02. Et-Ole, ethyl-oleate.

in general and to deficiencies in the DHA supply in particular, leading to possible pathological consequences in the neonate (2,4).

The major aim of this work has been to assess the effectiveness of the intraamniotic route to accelerate the incorporation of DHA into fetal brain PL. Although the intraamniotic injection is an invasive approach, the ability to rapidly enhance DHA esterification during intrauterine life may hold potential clinical value whenever an indication for DHA deficiency exists, such as possible prematurity (13).

Our approach of direct administration of pure DHA (as its ethyl-ester) turned out to be advantageous over previous dietary approaches using oil mixture supplements (8,14–18). Most of these diets contain various combinations of DHA and eicosapentaenoic acid (EPA, 20:5n-3), which cause a decrease in n-6 PUFA after prolonged administration. This undesirable consequence of DHA enrichment (19,20) has been attributed mainly to the presence of EPA in the fish-oil supplement (21). Pure Et-DHA administration by the intraamniotic route, on the other hand, did not impair the levels of AA and was associated with only a slight, nonsignificant decrease in all the n-6 PUFA, in spite of a 21% increase in the brain DHA concentration. The ethyl ester formulation has repeatedly been used for DHA and other FA administration and is effectively absorbed and incorporated into tissues (22–25). Delivery of PUFA by the intraamniotic route has been done, to our knowledge, for the first time in the present study.

Another point of interest is the elevation of PI and PS amounts as a result of Et-DHA administration. While information pertaining to the intrauterine brain DHA accretion in the rat is scant (26), data on the FA composition in individual PL and the changes during this period are not available. Under natural, maternal feeding conditions, we show most pronounced changes in DHA composition in the PS and PE lipids. Since PE is quantitatively more abundant than PS, more of the brain DHA is esterified in the former. However, even though PS is a relatively minor PL quantitatively, it may be functionally very important (27). It is conceivable that failure to attain the proper FA composition, especially DHA in PS, may be the crucial factor in the functional deficits resulting from dietary alterations (27).

Concomitant with the accelerated DHA accumulation, we clearly demonstrate an increase in the PS content in brain tissue, most likely as a result of base exchange activity. Since serine base exchange is the only accepted pathway for PS synthesis in mammals (28,29), it would appear that Et-DHA administration enhanced the activity of this enzyme. The increase in fetal brain PI content following Et-DHA administration is presumably accomplished by enhanced synthesis via phosphatidic acid precursor, a hypothesis which needs to be examined.

In summary, we have demonstrated that a single intraamniotic administration of ethyl-docosahexaenoate to 17-day fetal rats caused both DHA-enrichment of fetal brain lipids and substantial changes in their polar-head composition 72 h later. These data suggest that at least part of the actions of this essential FA is through modulation of membrane PL content. This method of rapid modulation of DHA in fetal tissues should be instrumental in furthering our understanding of the role(s) of DHA in cell function.

n-3 Polyunsaturated Fatty Acids and Human Cytokine Synthesis

Stefan Endres

Medizinische Klinik, Klinikum Innenstadt der Ludwig-Maximilians-Universität München, Munich, Germany

ABSTRACT: The cytokines interleukin-1 and tumor necrosis factor-α are potent peptide mediators of the immune response. They exert potent cellular effects at nanomolar concentrations with target tissues ranging from the vascular endothelium, to the central nervous system and immunocompetent cells. The synthesis of these two cytokines can be suppressed pharmacologically by steroids and other immunosuppressive agents such as cyclosporin A. In previous studies we have found that such an inhibition of inflammatory cytokine synthesis can also be achieved by increasing the content of n-3 polyunsaturated fatty acids in leukocyte membranes.
Lipids 31, S-239–S-242 (1996).

The cytokines interleukin-1 and tumor necrosis factor (TNF-α) contribute to the pathogenesis of inflammatory diseases and, potentially, atherogenesis. This lends importance to our original observation that oral supplementation of omega-3 or n-3 fatty acids to diets of healthy volunteers suppresses the capacity of mononuclear cells (MNC) to synthesize interleukin-1 and TNF-α. In recent years, this finding has been extended in several directions: (i) the suppression of cytokine synthesis by n-3 fatty acids can also be observed in patients with an inflammatory disease, i.e., rheumatoid arthritis, (ii) the suppression of cytokine synthesis can also be achieved by an alteration of the diet without using lipid supplements, and (iii) suppression of cytokine synthesis is probably achieved on the level of transcription, as evidenced by decreased levels of mRNA. The mechanism by which n-3 fatty acids exert suppression of cytokine synthesis remains unknown. The effect may, however, contribute to the beneficial effects of n-3 fatty acids observed in models of chronic inflammatory disease.

The cytokines interleukin-1 and tumor necrosis factor. Cytokines are secreted proteins with central paracrine functions in inflammation and proliferation. They comprise the families of interleukins, TNF-α, interferons, and the hematopoietic growth factors. Among this large group of proteins, a subgroup initially identified as products of monocytes have a similar profile of biological activities. This group comprises: the two forms of interleukin-1, interleukin-1α, and interleukin-1β, TNF-α and, to a certain extent, interleukin-6. Among the many biological activities shared by these cytokines, their actions on endothelial cells appear to be of particular importance in the pathogenesis of atherosclerosis. Of these, interleukin-1 potentiates procoagulant acitivity, and increases production of plasminogen activator inhibitor and endothelin, as well as the formation of eicosanoids. Furthermore, it increases leukocyte adhesion by inducing the expression of adhesion molecules, and it promotes endothelial protein permeability.

Aside from their pyrogenic effects, interleukin-1 and TNF-α influence a wide array of biological functions (Fig. 1) (1). Many of the biological functions of interleukin-1 are shared by TNF-α (2).

The study of the interleukin-1 system has gained additional momentum by the discovery of the interleukin-1-receptor antagonist. This protein was identified as an endogenous inhibitor of interleukin-1 action. It shares sequence homologies with interleukin-1α and interleukin-1β and binds to the same receptor as these two proteins, but has no intrinsic activity. Aside from its enormous biological significance, the interleukin-1-receptor antagonist has proved an excellent experimental tool in demonstrating the necessary role of interleukin-1 in certain disease processes (3). Mitigating disease in animal models by adminis-

FIG. 2. Influence of n-3 fatty acids on production of interleukin-1β stimulated with endotoxin (10 ng/mL). Nine healthy volunteers added 18 g of fish oil concentrate (MaxEPA®) per day to their normal diet. *In vitro* production of interleukin-1β was determined by incubating peripheral blood mononuclear cells for 24 h with different stimuli. At the end of the incubation, the cells were lysed by freeze-thawing to obtain the total, that is, cell-associated plus secreted cytokine. Interleukin-1β was measured by specific radioimmunoassay. The columns represent the mean values for nine volunteers. Bars indicate standard error of the mean. *Indicates significant difference from the baseline (before n-3 diet) at $P < 0.05$.

tration of exogenous interleukin-1-receptor antagonist proves participation of interleukin-1 as a necessary intermediate. This approach has been used in several disease models.

The potent and diverse biological functions of cytokines such as interleukin-1 and TNF-α place particular importance on the mechanisms of their regulation and the question of targeted modulation. The synthesis of cytokines is tightly controlled by a host of extracellular factors, plasma membrane constituents and cytosolic and nuclear factors. An example of differential regulation is the pharmacological elevation of intracellular cAMP. This intervention markedly suppresses synthesis of TNF-α without affecting the synthesis of interleukin-1 (4).

Modulating the synthesis of interleukin-1 and tumor necrosis factor by n-3 polyunsaturated fatty acids. Pharmacologic agents known to reduce the synthesis of interleukin-1 and TNF-α synthesis are corticosteroids and cyclosporine A. Since interleukin-1 and TNF-α are principal mediators of inflammation, reduced production of these cytokines may contribute to the amelioration of inflammatory symptoms in patients taking n-3 fatty acid supplementation. Therefore, we have investigated the effects of n-3 fatty acids on the synthesis of the cytokines interleukin-1 and TNF-α (5).

Figure 2 illustrates the production of interleukin-1β during the course of the study. Our findings demonstrate that n-3 fatty acid supplementation reduced the ability of MNC to produce interleukin-1β upon stimulation with endotoxin. The effect was most pronounced 10 wk after stopping the supplementation and suggests prolonged incorporation of n-3 fatty acids into a pool of circulating MNC. The capacity of the MNC from these donors to synthesize interleukin-1β returned to the presupplement level 20 wk after ending supplementation. Similar results were observed for interleukin-1α and TNF-α.

The findings form a pathophysiologic rationale for therapeutic trials with n-3 fatty acids in certain diseases, e.g. rheumatoid arthritism, with documented involvement of inflammatory cytokines, such as interleukin-1 and TNF-α. Furthermore, a suppression of the magnitude we observed can only be achieved pharmacologically by administration of glucocorticoids or cyclosporine A, which have well-known adverse side effects, particularly during long-term administration.

In an animal transplant model, n-3 fatty acids even enhanced cyclosporine A-induced immunosuppression (6). In 1993, the intriguing results of a one year intervention trial with dietary fish oil in 66 patients after renal transplantation were reported (7). In this randomized, double-blind study, the daily administration of 6 g of fish oil (containing 3 g of n-3 fatty acids) had a beneficial effect on renal hemodynamics and on blood pressure in renal transplant recipients treated with cyclosporine. Furthermore, the fish-oil group had significantly fewer rejection episodes than the control group and there was a trend to increased graft survival. If these positive results are confirmed in a larger patient group, they may alter the treatment of choice for primary prevention of transplant rejection.

Other studies on the modulation of cytokine synthesis by n-3 fatty acids. Suppression of interleukin-1 and TNF-α synthesis by n-3 fatty acids has been found in other studies *in vivo* in humans (8–12). The study design and results are compared in Table 1. Of particular interest is the most recent study by the group of Meydani who, for the first time, studied the effect of n-3 fatty acids in dietary intervention (rather than as encapsulated lipid supplement) on cytokine synthesis. After a 24-wk diet that provided 1.2 g n-3 fatty acids per day, lipopolysaccharide-induced synthesis of interleukin-1β was decreased by 40%.

Recently, studies in animal models have been reported that dietary n-3 fatty acids did not inhibit, but markedly enhanced lipopolysaccharide-stimulated production of either TNF-α (13), or both interleukin-1α and TNF-α (14). In Table 2, the results of animal studies *in vivo* on the influence of n-3 fatty acids on cytokine synthesis are summarized. Interestingly, the three studies in which enhancement of cytokine synthesis was found were all performed using peritoneal macrophages from mice. In contrast, in the study by Billiar *et al.* (15) the interleukin-1 and TNF-α synthesis of Kupffer cells from rats was suppressed to an extent similar to that observed in humans. Whether this discrepancy within animal models represents a difference in the cell population studied or a difference in the species is not clear at present (16).

The mechanisms by which n-3 fatty acids affect cytokine synthesis remain unclear. However, studies demonstrating reduced levels of mRNA for platelet-derived growth factor (17) and for interleukin-1β (18) point to regulation at a pretranslational level. The decrease of interleukin-1β synthesis together

with decreased formation of interleukin-2 also translates into reduction of a functional parameter of lymphocyte activation, i.e., phytohemagglutinin-induced proliferation (19).

Conclusions. The results of this and other studies demonstrate that oral supplementation with n-3 fatty acids can markedly suppress the synthesis of interleukin-1 and, to a smaller extent, TNF-α by human MNC. Given the potent effects of these cytokines in the pathogenesis of atherogenesis and inflammation, these results argue for cytokine suppression as a mechanism contributing to the protective role of n-3 fatty acids in atherosclerosis and certain inflammatory diseases. Given the potentiating effects of both cytokines on target tissues, this finding may be even more important for effects *in vivo*. Future research in this field will focus on three questions: (i) What is the intracellular mechanism for the inhibition of cytokine synthesis? As mentioned above, reduction of cytokine mRNA points to an effect of n-3 fatty acids at the level of transcription or increased degradation; (ii) What is the precise constituent of n-3 fatty acid containing fish oil concentrates that mediates the effect? All studies on n-3 fatty acids and cytokine synthesis have used concentrated fish oil preparations. It will be of particular interest to find out whether a particular fatty acid, such as eicosapentaenoic or docosahexaenoic acid, is responsible for the effect; (iii) What is the reason for the *increase* in cytokine synthesis after feeding n-3 fatty acids that has been observed in some animal models? Some evidence points to a species or cell population difference because increase in cytokine synthesis was always observed in mouse peritoneal macrophages. One may speculate that either the preparation of the peritoneal macrophages or the immunological compartment renders the cells activated to a certain extent.

As to therapeutic recommendations it is important to stress that studying the effect of n-3 fatty acids on cytokine synthesis does not allow us to draw conclusions on clinical end points. These conclusions remain to be drawn from controlled intervention studies in patient groups that are complete or are currently in progress. However, when searching for the mechanism of clinically demonstrated beneficial effects, the cytokine system is a highly attractive area of mediating mechanisms.

Effects of Modulation of Inflammatory and Immune Parameters in Patients with Rheumatic and Inflammatory Disease Receiving Dietary Supplementation of n-3 and n-6 Fatty Acids

Joel M. Kremer

Division of Rheumatology, Albany Medical College, Albany, New York 12208

ABSTRACT: To describe the rationale and status of n-3 and n-6 fatty acid dietary supplementation in patients with inflammatory disease. The most recent literature is reviewed with a focus on rheumatoid arthritis (RA) as most investigations have described the use of n-3 supplements in this disease entity. Investigations from Europe, the United States, and Australia have described consistent improvement in tender joint scores with many investigators also observing improvements in morning stiffness. A meta analysis has confirmed the predictable improvement in tender joints. Recent studies also suggest that some patients with RA are able to discontinue nonsteroidal antiinflammatory drugs (NSAIDs) while receiving n-3 fatty acids. A large number of peer reviewed publications from around the world have established the utility of dietary supplementation with n-3 fatty acids in reducing tender joint counts and morning stiffness in patients with RA. Some patients are also able to discontinue NSAIDs while on these supplements.
Lipids 31, S-243–S-247 (1996).

Due to the mammalian inability to interconvert n-3 and n-6 fatty acids, the composition of phospholipids in cellular membranes is determined by nutritional intake (1). The fatty acids found in the membrane bilayer are substrates for the production of prostaglandin and leukotriene species essential for many biological activities including modulation of the inflammatory and immune response. It is becoming widely recognized that reproducible metabolic alterations in these pathways can be engineered by consistent modifications in dietary fatty acid content. These fatty acid induced changes have been documented in animal (2), and normal humans trials (3) and large epidemiological studies of populations consuming relatively homogeneous diets (4).

Investigations have examined the effects of dietary fatty acid supplementation in a variety of autoimmune diseases. As most of these studies have occurred in patients with rheumatoid arthritis, we will focus primarily on this disease, while briefly reviewing the results in other inflammatory disease processes. We will review the reported effects of both n-3 and n-6 fatty acids.

n-6 Fatty acids. γ-Linolenic acid (GLA) (18:3, n-6) is found in seeds from the evening primrose and borage plants. It may be converted by an elongase enzyme to dihomogammalinolenic acid (DGLA) (20:3, n-6). DGLA is oxidized by cyclooxygenase to prostaglandin E_1 (PGE_1), a monoenoic prostaglandin which has altered biologic activities from the dienoic prostaglandin PGE_2. For example, PGE_1 can inhibit platelet aggregation in humans and rats *in vivo* and *in vitro*, whereas PGE_2 cannot (5). PGE_1 dietary supplementation can suppress inflammation and joint tissue injury in several animal models of inflammation (6) and can inhibit neutrophil function. GLA dietary supplementation can suppress acute and chronic inflammation in several experimental animal models.

The subcutaneous air pouch model of inflammation was used to assess response to monosodium urate crystals or Freund's adjuvant in Sprague-Dawley rats consuming diets enriched with either safflower oil as a source of linoleic acid or borage seed oil as a source of GLA (7). Animals consuming GLA had a marked reduction of neutrophil exudate and lysosomal enzyme activity compared with those fed sunflower oil. PGE_2 and leukotreine B_4 (LTB_4) concentrations were significantly diminished in pouch exudates in the GLA fed rats. The fatty acid profiles in the serum and inflammatory cells form animals consuming primrose oil exhibited significant increases in GLA and DGLA.

When DGLA is added to human synovial cells grown in tissue culture interleukin-1B (IL-1B) stimulated growth is suppressed fivefold compared with cells grown in medium supplemented with arachidonic acid (8). Cells incubated with DGLA exhibited a 14-fold increase in PGE_1, and a 70% decrease in PGE_2 compared with cells in control medium. The increase in PGE_1 concentrations was associated with significantly enhanced levels of cAMP which the authors suggested was responsible for the antiproliferative effects. The inhibiting effect could be blocked by indomethacin, lending further

Abbreviations: DGLA, dihomogammalinolenic acid; EPA, eicosapentaenoic acid; GLA, γ-linolenic acid; IL-1B, interleukin-1B; LTB_4, B_5, leukotreine B_4, B_5; NSAID, nonsteroidal antiinflammatory drug; PAF, platelet activating factor; PGE_1, E_2, E_3, prostaglandin E_1, E_2, E_3; RA, rheumatoid arthritis; TNF, tumor necrosis factor.

support to PGE_1 mediation of growth suppression.

Human studies. An open study of only 20 patients with rheumatoid arthritis treated with GLA in combination with various vitamins showed no significant changes of any clinical or laboratory parameters over a period of 12 wk (9). An investigation comparing evening primrose oil, as a source of GLA, to olive oil in 20 patients with rheumatoid arthritis over a period of 13 weeks failed to show any significant difference between groups (10).

In a well designed study, investigators treated patients with rheumatoid arthritis with 1.4 g of GLA daily over period of 24 wk (11). They observed a clinically important reduction in both the tender and swollen joint counts of 36 and 28%, respectively, while the placebo group showed no improvement in these parameters. It had previously been demonstrated that GLA can inhibit IL-2 production by peripheral blood mononuclear cells *in vitro* (12) and may reduce the expansion of activation markers on T lymphocytes (13). The mechanism of the improvements observed was not studied (11).

n-3 Fatty acids. Eicosapentaenoic acid (EPA) can be metabolized through both the cyclooxygenase and 5-lipoxygenase metabolic pathways to form end-products with altered biological activity. The beneficial effects of these alterations on the cardiovascular system will be discussed elsewhere. EPA is metabolized to PGE_3, a compound with less inflammatory activity than PGE_2 (14). PGE_2 stimulates osteoclast activity resulting in bone resorption, a process of significance in rheumatoid arthritis. The dienoic prostaglandins also increase vascular permeability in a synergistic effect with serotonin and bradykinin (14). The E-series prostaglandins are not localized to specific tissues as is the case with thromboxane and prostacyclin which are limited to platelets and vascular endothelium respectively. Therefore, the effect of altering PGE content in any specific site will vary depending upon the tissue where the synthesis takes place (15).

The effects of n-3 fatty acids in altering eicosanoid metabolism are of great importance in immune and inflammatory disease. They can inhibit the synthesis of arachidonic acid from its linoleic acid substrate (16) possibly through competition for the 2-position occupied by arachidonate in membrane phospholipids. EPA will also directly compete with arachidonic acid as the substrate for cyclooxygenase and inhibit its metabolism into eicosanoids (17). n-3 Fatty acid ingestion thus results in the production of compounds with altered biological activity as well as a decrease in the usual amounts of biologically active arachidonate derivatives.

Ingestion of EPA is associated with the production of leukotrienes with 5 double bonds such as LTB_5 which has greatly attenuated proinflammatory activities (18). LTB_5 is usually undetectable in humans consuming a Western diet. Simultaneous with the production of small amounts of LTB_5 from stimulated neutrophils of normal subjects consuming fish oil, there are large decreases in the production of neutrophil LTB_4 (19). Neutrophil chemotaxis was significantly suppressed in these subjects after six weeks of fish oil ingestion and returned to normal after the supplements were discontinued.

Other investigators have found evidence of a selective inhibition of the epoxide hydrolase enzyme in neutrophils from normals (18) and rheumatoid arthritis patients (20) consuming fish oil because of unaltered quantities of 5-hydroxyeicosatetraenoic acid and 5-hydroxyeicosapentaenoic relative to the corresponding arachidonic acid product generated before dietary supplementation.

Chemotactic activity of neutrophils from rheumatoid arthritis patients who had ingested fish oil was found to be enhanced compared to the pretreatment state (20). This is seemingly paradoxical in view of the suppression of neutrophil chemotaxis after fish oil ingestion in normals (19). The improved chemotaxis in rheumatoid arthritis patients represents a partial correction of a reduced chemotactic activity of peripheral blood neutrophils of subjects with this disease. Platelet activating factor-acether (PAF-acether) generation of stimulated monocytes is significantly diminished (19) after fish oil ingestion, suggesting a n-3 fatty acid induced inhibitory effect of phospholipase A2 activity on substrate alkyl phospholipids which would affect PAF generation. This is of considerable interest in the context of inflammation in that PAF can stimulate tumor necrosis factor (TNF) as well as other cytokines in endothelial tissue (21) and is 1,000 times more potent than histamine in inducing changes in vascular permeability (22). Evidence suggests that PAF can also modulate T cell and monocyte function (23).

n-3 Fatty acid ingestion is associated with significant changes in the fatty acid profiles of cellular lipids. Neutrophil arachidonic acid content is reduced by 33% and EPA content is enhanced twenty-fold compared to presupplement values obtained in rheumatoid arthritis patients ingesting fish oil (20). n-3 Fatty acid ingestion is thus associated with reproducible changes in the biochemical composition of cell membranes of neutrophils and monocytes and striking alterations in the production of the metabolic end products of a myriad of inflammatory and immunologically active compounds which may influence the course of rheumatic disease.

Animal studies. Dietary modifications containing n-3 fatty acids reduce the severity of diffuse proliferative glomerulonephritis in several autoimmune strains of mice including the NZBxNZWF1, BxSB/Mpj and MRL/lpr strains (24,25). Dietary n-3 fatty acids reduce the severity of glomerulonephritis even when they are withheld until after the renal disease has begun to evolve (24). Not all observed effects of fish oil have been beneficial in the laboratory: an increased incidence of arthritis was observed in rats immunized with type II collagen who consumed a fish oil-enriched diet compared with animals ingesting beef tallow although the severity of the arthritis was the same in each group (25). An increased incidence of necrotizing vasculitis was noted in renal arteries of MRL/lpr mice with systemic lupus erythematosus-like disease, even while their glomerulonephritis was alleviated on a fish oil diet (24). Studies indicate that a mixture of n-3 fatty acids containing both EPA and docosahexaenoic acid may be more effective than either of these n-3 fatty acids by themselves (26).

Human studies. The effects of dietary fish oil supplements in patients with rheumatoid arthritis have been studied in several investigations (27–39). Studies on mostly Caucasians of Northern European background have been reported from the United States (27–31), Australia (32) and Europe (33–39). It is unlikely that background dietary habits were uniform in these populations with a highly varied geographic distribution. Some populations were known to consume a higher content of fish in their diet (36) than others (40). An improvement in the number of tender joints on physical examination is most often observed (28,30–35) with some authors reporting improvement in Ritchie Articular Index (35,38), and morning stiffness (30,32,35). Omega-3 fatty acid supplements have been studied in comparison with a variety of dietary interventions including inert paraffin wax (27), corn oil (31,35), olive oil (28–30), and a specially prepared mixture of fatty acids designed to reproduce the local dietary intake (36,38). The benefits in the number of tender joints and morning stiffness have been confirmed in a recent meta-analysis (41).

It is accurate to portray the overall clinical response to fish oil supplements reported in these investigations as modest (42,43). It is clear, however, that dietary fatty acids produce reproducible alterations in eicosanoid metabolism which should aid in the amelioration of inflammation (28,29,32,44, 45,46). In addition, fish oil supplements have been associated with a decreased production of interleukin-1B in normals (47) and patients with rheumatoid arthritis (28,30). It is the unique ability of dietary fatty acids to alter cell membrane fatty acid constituents (42) which has given rise to interest in the potential of these dietary substances to influence an array of immune parameters.

In a recently completed investigation (31), we were interested in expanding our observations of the effects of fish oil in patients with rheumatoid arthritis to determine if patients consuming high dose supplements would be better able to discontinue their non-steroidal anti-inflammatory drug compared with a control population given corn oil. Sixty-six patients entered a prospective double-blind investigation. Patients were randomized to receive fish oil ingested 130 mg/kg/d of n-3 fatty acid (ethyl ester concentrate prepared by the National Marine Fisheries Association for the National Institute of Health), while control patients consumed corn oil capsules. All patients were given the nonsteroidal anti-inflammatory drug diclofenac throughout the study and this was replaced with a placebo diclofenac, while patients continued their fatty acid supplements. Clinical evaluations were performed for several months after discontinuing the diclofenac and also after stopping the fish oil and corn oil supplements. A variety of cytokines were measured throughout the study including interleukin-1, 2, 6 and 8 and TNF-α.

Our results again showed that fish oil dietary supplementation results in significant improvement in tender joints and other clinical parameters of disease from baseline (31). However, none of the improvements in the patients receiving fish oil achieved significance at the time of the maximum duration of diclofenac therapy at 18 or 22 wk when compared with patients on corn oil. Patients receiving corn oil also exhibited many improvements during this time interval which did not achieve statistical significance. In addition, the magnitude of the improvement from baseline that we observed in patients on high dose fish oil was indistinguishable from that previously reported when patients consumed total doses of n-3 fatty acids of from 3–6 g/d (28,30). We cannot therefore recommend further investigations with the doses we employed which resulted in the ingestion of 9 g of daily n-3 supplements in a 70 kg individual.

Improvements from baseline in patients with rheumatoid arthritis consuming fish oil often do not achieve statistical significance vs. other dietary fatty acid interventions. This may be because the biological effects are not powerful enough or alternatively due to either a placebo effect or real biological effects induced by the so-called placebo fatty acids. We have previously wrestled with the issue of an ideal control fatty acid to compare with fish oil (30) and chose corn oil in our most recent investigation (31) after using olive oil (28,30). It is possible that any mono or polyunsaturated fatty acid has significant potential immune effects. We believe that the issue of the ideal placebo dietary intervention to compare with fish oil in the study of autoimmune inflammatory disease has not yet been settled.

We examined the clinical status of patients after discontinuing diclofenac while receiving fish oil and corn oil in several ways (31). We examined patient clinical status of diclofenac after the maximal duration of fish oil exposure (weeks 26 or 30) and compared this with their baseline status while receiving diclofenac. The improvement in tender joints was significant in the patients remaining on fish oil at this time when compared with both baseline status and with patients on corn oil during the same period. We again observed a significant decrease in IL-1, confirming our previous observations (28,30), but did not find significant decreases in IL-2, 6, 8 or TNF-α.

Others have reported upon whether fish oil dietary supplements can affect nonsteroidal antiinflammatory drug (NSAID) requirements in patients with rheumatoid arthritis (35,37,48). Skoldskam *et al.* used an open patient directed NSAID reduction and found that patients consuming fish oil were able to significantly reduce their NSAID dose compared with a control group. Belch *et al.* used an open, physician-directed NSAID reduction while subjects consumed only 240 mg EPA along with 450 mg of GLA and found that after one year subjects were able to significantly reduce these medications (37). Kjeldson-Kragh *et al.* (35) substituted placebo Naproxen for real drug in a stepwise manner. Because of the study design, evaluators in this investigation knew that there was a 67% likelihood that patients had discontinued Naproxen. Nevertheless, they reported that patients on fish oil tolerated stopping NSAID better than controls. Finally, Lau *et al.* (48) recently reported that patients on fish oil were able to significantly reduce their NSAID requirements compared with a control group. We believe that our recent data (31) support the previous observations that selected individu-

als with rheumatoid arthritis may discontinue NSAID therapy while consuming n-3 supplements.

Other inflammatory conditions. Subsequent to the reports of benefits of fish oil supplementation in patients with rheumatoid arthritis, n-3 supplements have been employed with some reported benefit in patients with inflammatory bowel disease (49) and most recently in IgA nephropathy (50). It is apparent that many other inflammatory conditions could hypothetically benefit from the n-3 induced changes in eicosanoid metabolism and decreased production of IL-1 previously described. It is likely that we will see many more studies examining the effects of n-3 supplements in inflammatory disease in future years.

The Significance of Polyunsaturated Fatty Acids in Cutaneous Biology

Vincent A. Ziboh*

Department of Dermatology, University of California, Davis, Calisornia

ABSTRACT: The skin epidermis displays a highly active metabolism of polyunsaturated fatty acids (PUFA). Dietary deficiency of linoleic acid (LA) and 18-carbon (n-6) PUFA results in characteristic scaly skin disorder and excessive epidermal water loss. Arachidonic acid, a 20-carbon (n-6) PUFA is metabolized via the cyclooxygenase pathway into predominantly prostaglandin E_2 (PGE_2) $PGF_{2\alpha}$, and PGD_2 and via the lipoxygenase pathway into predominantly 15-hydroxyeicosatetraenoic acid (15-HETE). The prostaglandins modulate normal skin physiological processes at low concentrations and inflammatory reactions at high concentrations. Similarly, the very active epidermal 15-lipoxygenase transforms dihomogammalinolenic acid (DGLA) into 15-hydroxy eicosatrienoic acid (15-HETrE), eicosapentaenoic acid (EPA) into 15-hydroxyeicosapentaenoic acid (15-HEPE) and docosahexaenoic acid (DHA) into 17-hydroxydocosahexaenoic acid (17-HDoHE), respectively. These monohydroxy acids exhibit anti-inflammatory properties. In contrast, the 18-carbon (n-6) PUFA is transformed into 13-hydroxy-9,11-octadecadienoic acid (13-HODE), which exerts antiproliferative properties in the tissue. Thus the supplementation of diets with appropriate purified vegetable oils and/or fish oil may generate local cutaneous anti-inflammatory metabolites which could serve as a less toxic *in vivo* monotherapy or as adjuncts to standard therapeutic regimens for the management of skin inflammaory disorders.
Lipids 31, S-249–S-253 (1996).

The nutritional significance of certain polyunsaturated fatty acids (PUFAs) was heightened when Burr and Burr (1,2) reported that rats maintained on a fat-free diet over a long period developed abnormalities characterized by growth retardation, severe scaly dermatosis of the dorsal and pedal skin, caudal necrosis and extensive water loss through the skin. Prominent in this deficiency syndrome is a defective barrier to water loss (3). Because these deficiency symptoms, notably the cutaneous symptoms, could be reversed by certain dietary PUFAs, they were designated *essential fatty acids* (EFAs).

Dietary sources. The 18-carbon n-6 and n-3 PUFAs are synthesized on land by many plants and therefore are obtained from vegetable oils. However, the longer chain members of each family are either biosynthesized *in vivo* after dietary ingestion of the shorter 18-carbon precursors or they are obtained directly from animal or marine sources. For example, the longer chain n-3 PUFAs, eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), are found in fish and marine oils and therefore can be ingested directly from these sources. The important longer chain n-6 PUFA, arachidonic acid (AA, 20:4n-6), is found in liver, brain, and muscle, which are rich dietary sources of arachidonic acid.

Significance of 18-carbon polyunsaturated acids in the epidermis: (i) *The role of linoleic acid (18:2n-6) in epidermal water barrier systems.* A specific and essential function of the 18-carbon linoleic acid (18:2n-6) is its involvement in the maintenance of the epidermal water barrier (4) which is one of the epidermal abnormalities of cutaneous EFA deficiency. This significant effect of linoleic acid (LA) was reported early in a series of studies by Prottey and co-workers who demonstrated that increased transepidermal water loss occurred in EFA-deficient animals (5). Information derived from these findings supported the special role of LA in restoring the defect of epidermal water barrier which has been induced by EFA-deficiency. In later reports, the physical structure of the epidermal water barrier was described to be sheets of stacked lipid bilayers or lamellae which fill the intercellular spaces of the uppermost layer of the epidermis (stratum corneum). These lipid bilayers contain large amounts of sphingolipids (6) of which the linoleate-rich species have been characterized as acylglucosylceramide, acylceramide and a unique acylacid (7,8).

(ii) The role of linoleic acid in hyperproliferative processes. The suggestion that the linoleyl moiety of the barrier acylsphingolipids is further metabolized by a lipoxygenase-like reaction to form first a hydroxyacylceramide and then a polyoxyacylceramide prior to modulating the barrier systems (9) stimulated great interest in developing a mechanism for

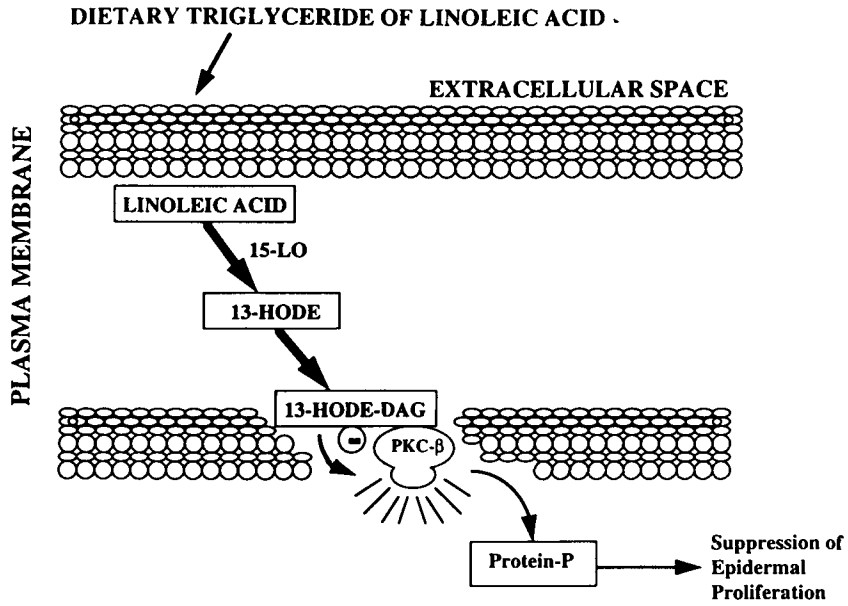

FIG. 1. Speculative scenario of dietary linolenic acid modulation of epidermal hyperproliferation via down-regulation of protein kinase C (PKC)-β. 13-HODE, 13-hydroxy-9, 11-octadecadienoic acid; 13-HODE–DAG, 13-HODE containing diacylglycerol.

linoleic acid action. The above finding prompted these investigators to propose that restoration of the defective epidermal water barrier system depended upon the formation of these oxygenated species. The view is consistent with the presence of a very active 15-lipoxygenase activity in the epidermis which converts LA (18:2n-6) into predominantly a 13-hydroxy-9, 11-octadecadienoic acid (13-HODE) (10). It seems very likely that this oxygenated metabolite is the suggested active molecular form of LA in the epidermal water barrier study.

(iii) Functional role of 13-hydroxyoctadecadienoic in the epidermis. The incubation of LA with 15-lipoxygenase prepared from human epidermis yields a major metabolite, 13-hydroxy-9, 11-octadecadienoic acid (13-HODE) (10). Interestingly, our first speculation of a possible functional role of 13-HODE arose from our observation that epidermal levels of 13-HODE were suppressed after the induction of epidermal hyperproliferation. The topical application of 13-HODE to a guinea pig model of epidermal hyperproliferation resulted in the reversal of the hyperproliferation to a normal state (11). To delineate a possible mechanism for the effect of topical 13-HODE, we demonstrated that topical 13-HODE was incorporated first into the inositol phospholipids followed by a phospholipase C-catalyzed release into 13-HODE-containing diacylglycerol (13HODE-DAG) (12). This novel 13-HODE-substituted-DAG was markedly depleted in the hyperproliferative skin in EFA deficiency, paralleling the increased activities of epidermal protein kinase C-α (PKC-α) and PKC-β. Replenishment of the hyperproliferative epidermis with topical 13-HODE resulted in the accumulation of tissue 13HODE-DAG, the selective suppression of PKC-β activity (13) and the reversal of the epidermal hyperproliferation to normal.

To establish the *in vivo* relevance of these observations, guinea pigs were made essential fatty acid deficient (EFAD). Tissue levels of putative 13HODE-DAG, PKC-isozymes and tissue hyperproliferation were determined during the development and reversal of EFAD. Findings from these experiments revealed that cutaneous 13-HODE and novel 13HODE-DAG were markedly lower in EFAD animals than in LA-enriched safflower oil-fed control animals. These reductions paralleled both the elevated EFAD-induced epidermal hyperproliferation, and the elevated expressions and activities of PKC-α and β-isozymes as determined by Western Blot. Refeeding the animals with LA/γ-linolenic (GLA) enriched safflower oil for two weeks replenished the *in vivo* tissue level of 13HODE-DAG that paralleled both the selective down regulation of PKC-β expression and activity and the reversal of hyperproliferation. These results suggest that an elevated level of epidermal 13-HODE plays a role in modulating cutaneous hyperproliferation *in vivo* via the generation of 13HODE-DAG and the selective suppression of PKC-β isozyme. A speculative scenario of the possible modulating effects of dietary LA/13-HODE on epidermal inflammatory/proliferative processes is illustrated in Figure 1.

The role of 20-carbon polyunsaturated fatty acids in the epidermis—Metabolism and functional roles: Cyclooxygenase pathway. The 20-carbon AA is the second prominent PUFA in the skin. Its functional role depends largely on the generation of biologically potent oxidative metabolites. Arachidonic accid represents approximately 6–10% of the total fatty acids in the epidermal phospholipids of guinea pigs (14). Similarly, human epidermal phospholipids contain approximately 9% AA (15). Specific epidermal enzymes metabolize AA into a variety of oxygenated metabolites, which in turn exert a variety of functions on the skin. One

major function is that AA metabolites regulate proliferative and/or differentiating processes in the epidermis. The epidermal AA when released undergoes oxidative transformations by either the cyclooxgenase to generate mainly prostaglandins E_2 (PGE_2), $PGF_{2\alpha}$, and PGD_2, or lipoxygenases which in this tissue generate mainly hydroxy fatty acids.

Functionally, the prostaglandins play a central and complex role in inflammation and therefore are pertinent to the pathogenesis and treatment of cutaneous inflammatory diseases. For example, in early reports, repeated injections of PGE_2 were reported to cause a persistent swelling of the rodent paw which interfered with ambulation. Similarly, repeated injections of PGE_1/PGE_2 into human skin resulted in cutaneous inflammatory reactions characterized by erythema, edema, and tenderness. The beneficial effects derived from administration of nonsteroidal anti-inflammatory drugs under these conditions did implicate some of these prostanoids in the cutaneous inflammatory processes.

(ii) Lipoxygenase pathway. The lipoxygenase pathway is very active in the epidermis. While the epidermal tissue or the epidermal cells (keratinocytes) lack the 5-lipoxygenase and thus cannot transform precursor arachidonic acid directly into leukotriene B_4 (LTB_4), it does, however, possess an active LTA_4 hydrolase and can transform polymorphonuclear cell (PMN)-derived leukotriene A_4 (LTA_4) into LTB_4. Thus, conversion of LTA_4 into LTB_4, can be catalyzed by epidermal LTA_4-hydrolase (16,17). The above possibility may explain the elevated LTB_4 in PMN-infiltrated cutaneous psoriatic plaque, thus, contributing to the immense skin proliferation in this desease.

The epidermal lipoxygenase enzymes also catalyze the generation of hydroxy fatty acids from a variety of polyunsaturated fatty acids. Oxygenation of arachidonic acid by epidermal 12-lipoxygenase yields 12-hydroxyeicosatetraenoic acid (12-HETE). Advances in chiral phase chromatography now reveal that 12-HETE which originally was reported to accumulate in the lesion of psoriatic patients is primarily the 12(R) epimer and not the 12(S) epimer that is the typical 12-lipoxygenase product formed by platelets.

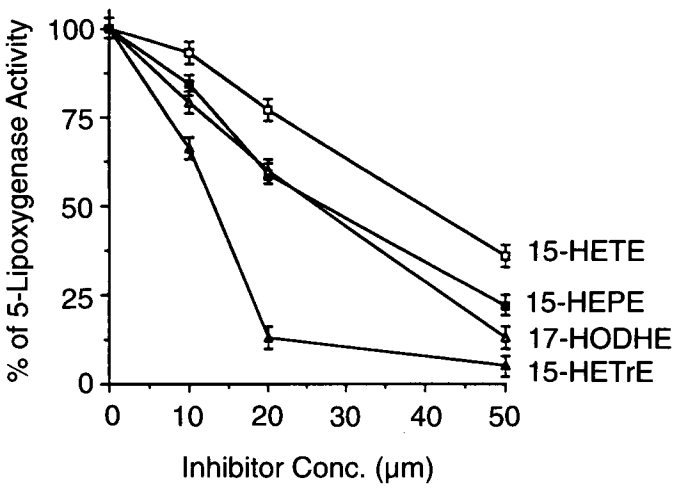

FIG. 2. Comparative effects of monohydroxy fatty acids derived from arachidonic acid, □; eicosapentaenoic acid, ■; docosahexaenoic acid, △; and dihomogammalinolenic acid, ▲.

The 15-lipoxygenase enzyme is very active in the epidermis. Metabolic products of a variety of PUFAs are generated via this pathway that exert potent biological effects in this tissue. For example, 15-HETE, a product derived from AA, has been demonstrated in human epidermis, in cultured murine and human epidermal cells (keratinocytes), in isolated human neonatal foreskin and in guinea pig epidermis. This monohydroxy fatty acid was detected in biologically active concentrations in human patients with psoriatic lesions (18). Functionally, 15-HETE was reported to inhibit 5-lipoxygenase activity and generation of LTB_4 in neutrophils and basophils *in vitro* (19). These *in vitro* effects suggest, at least in part, the anti-inflammatory potential of 15-HETE. Consistent with this anti-inflammatory potential, 15-HETE was reported to improve the symptoms of psoriasis vulgaris after intralesional injections (20).

Oxygenation of other polyunsaturated fatty acids via *15-lipoxygenase pathway*: *(i) The incubation of GLA with epidermal preparation results in its rapid elongation into dihomogammalinolenic acid (DGLA).* Similarly, dietary supplementation of guinea pig or human diet with GLA-enriched oils results in marked elevation of DGLA in the tissue. The guinea pig and human epidermis, contain a very active elongase that catalyzes the conversion of precursor GLA into DGLA (21). The DGLA, on the one hand, is metabolized by epidermal cyclooxygenase into prostaglandin of the 1-series (PGE_1), on the other hand, it is metabolized by epidermal 15-lipoxygenase into 15-hydroxyeicosatrienoic acid (15-HETrE) (22) which is a potent inhibitor of LTB_4 generation *in vitro*. When guinea pig diet was supplemented with GLA-enriched oil, 15-HETrE was generated *in vivo* in the epidermis (23). Similarly, when the human diet was supplemented with GLA-containing capsules, a significant amount of DGLA was found in the PMN phospholipids. The elevation of DGLA paralleled the decreased capacity of isolated PMNs to biosynthesize LTB_4 (24).

(ii) Metabolism of EPA (20:5n-3) and DHA (22:6n-3). The *in vitro* incubations of EPA and DHA with epidermis results in the formation of two 15-lipoxygenase products: 15-hydroxyeicosapentaenoic acid (15-HEPE) and 17-hydroxydocosahexaenoic acid (17-HODHE) respectively (25). When guinea pig diet was supplemented with EPA/DHA-enriched fish oil, marked elevation of 15-HEPE and 17-HODHE were generated in the epidermis (26).

Taken together, the 15-lipoxygenase catalyzed monohydroxy fatty acids generated from the variety of 20-carbon PUFAs are potent inhibitors of LTB_4 generation from polymorphonuclear cells. Comparative inhibitory effects of these monohydroxy fatty acids are illustrated in Figure 2. The data reveal dose-dependent *in vitro* effects of the monohydroxy acids derived from AA, EPA, DHA, and DGLA on LTB_4 generation by rat basophilic leukemic-1 (RBL-1) cells. 15-HETrE notably derived from DGLA is the most potent at 20 μM.

Modulation of epidermal eicosanoid generation: (i) Pharmacological effects. Pharmacological inhibitors of

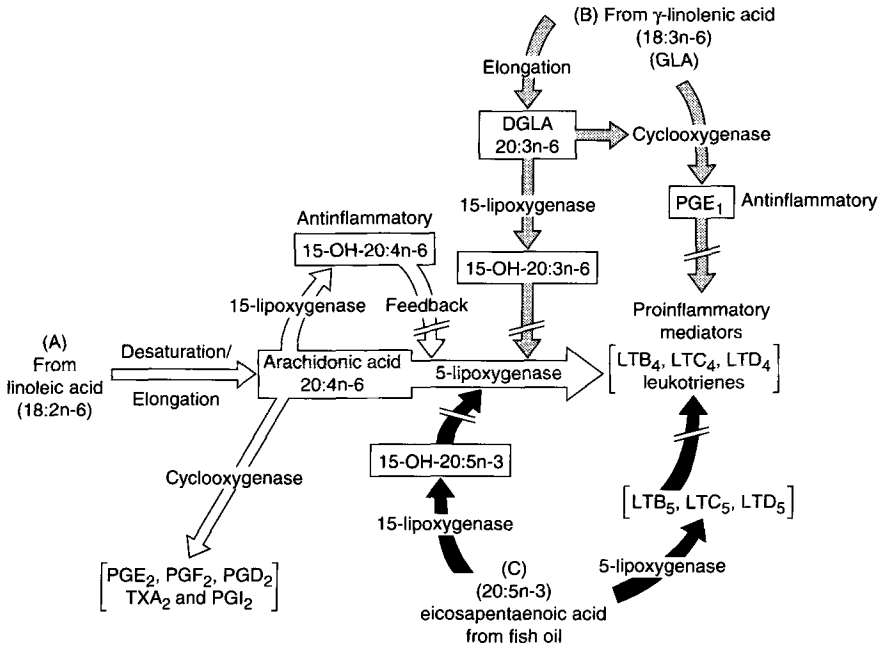

FIG. 3. A speculative scenario of the possible modulatory effects of the constituent fatty acids and metabolites from vegetable and fish oils on the generation of proinflammatory leukotrienes from arachidonic acid.

proinflammatory prostaglandins and leukotriene synthesis, as well as the antagonists of other endogenously biosynthesized inflammatory mediators, have become important front line agents or adjuncts in the treatment of a variety of inflammatory conditions. However, their uses have been limited in cutaneous inflammatory disorders. A number of 5-lipoxygenase inhibitors and antagonists selective for specific leukotrienes have been synthesized, but their efficacy for the management of inflammatory/proliferative skin disorders remains to be fully demonstrated.

(ii) Dietary effects of PUFA. Since the precursor of the variety of eicosanoids are derived from dietary PUFA, it is reasonable to expect that the *in vivo* synthesis of the mediators can be modulated by manipulation of the diets. Thus the supplementation of diets of psoriatic patients with EPA/DHA-enriched fish oil resulted in the alleviation of skin inflammatory/proliferative processes (27–29). The results of these dietary studies are compatible with the view that diets enriched with EPA and DHA exert profound effects on endogenous epidermal phospholipid fatty acid composition, on the endogenous release of AA and the biosynthesis of the inflammatory eicosanoids. For instance, the supplementation of guinea pig diet results in an epidermal increase of DGLA, which in turn parallels the increase in the levels of epidermal 15-HETrE (a 15-lipoxygenase metabolite of DGLA) (18).

A speculative scenario of the possible modulatory effects of the constituent fatty acids and metabolites from vegetable and fish oils on the generation of proinflammatory leukotrienes from AA is shown in Figure 3. The [A] pathway illustrates the metabolic transformations of dietary LA which results in the tissue generation of 15-HETE and proinflammatory leukotrienes by PMNs. The [B] pathway represents the epidermal transformation of dietary GLA (e.g. from primrose oil and/or borage oil) into DGLA and the tissue generation of 15-HETrE (via 15-lipoxygenase pathway) and PGE_1 (via the cyclooxygenase pathway). The [C] pathway represents the metabolic transformations of dietary EPA into 15-HEPE and LTB_5 from EPA. It is, therefore, reasonable to speculate that metabolites from both the [B] and [C] pathways could inhibit the *in vivo* generation of local tissue proinflammatory leukotrienes from AA. These possibilities suggest that the dietary intake of highly purified vegetable or fish oils, containing appropriate constituent PUFAs from these oils, may offer an alternative or adjunct therapeutic modality for alleviating cutaneous inflammatory disorders.

ABSTRACT: The β-adrenergic system *in cardiac* muscle cells is influenced by the n-3 polyunsaturated fatty acid (PUFA) content in cell membranes. This study deals with the specific effect of docosahexaenoic acid (DHA) as compared to other n-3 PUFA, without modification of the arachidonic acid content. Increasing the DHA content in the phospholipids of isolated cardiomyocytes did not provoke electrical or contraction modifications, except for a slightly lower plateau phase (–2 mV). Conversely, the β-adrenergic function was affected at several levels: (i) the receptor affinity for dihydroalprenolol tended to decrease (Kd) without alteration of the number of β-binding sites (β_{max}); (ii) the isoproterenol-induced (10^{-7} M and 10^{-6} M) cAMP production was significantly decreased (–20%); and (iii) the positive chronotropic response to β-adrenergic stimulation (isoproterenol, 10^{-7} M) was significantly enhanced (+80%). In order to further investigate the relationship between the decreased cAMP and the increased chronotropic response, the cells were treated with dibutyryl-cAMP, a permeant analogue of cAMP, which elicited a significantly higher chronotropic response in DHA-enriched cells than in EPA-enriched cells (+50%). The increase in DHA content in cardiac cell membranes phospholipids may thus affect the β-adrenergic system through an increase of cAMP efficiency. Although the membrane phosphatidylinositols were largely involved in the PUFA alterations, none of the parameters related to α-*adrenergic* system (chronotropic response, receptor density, affinity for prasozin, and inositide phosphate production) were influenced by the membrane DHA content.
Lipids 31, S-205–S-210 (1996).

The beneficial effects of fish oil consumption in reducing the incidence of heart disease have been attributed to their high content in long-chain n-3 polyunsaturated fatty acids (PUFA), mainly eicosapentaenoic acid (20:5n-3; EPA) and docosahexaenoic acid (22:6n-3; DHA) (1–3). Most of these beneficial effects were attributed to EPA, through its various vascular and serum consequences, including platelet aggregation, vasodilatation, and circulating lipids (4,5). Recently, the protective effect of fish oils was suggested to rely on mechanisms other than those related to their vascular influences (6). Recent studies have shown that a fish oil diet may increase the contractility of the left ventricle and improve myocardial relaxation (7). But little information is available on the direct effects of the long-chain n-3 PUFA on the cardiac function at the muscle cell level. The age-dependent changes in calcium channel density and affinity were reported to be altered by fish oil diets (8). Conversely, the influence of n-3 fatty acid supplementation of myocardial cells on the activity of Ca^{++} pump (9) and Na^{+} pump (10) is controversial. In addition, the incorporation of EPA into the membrane phospholipids (PL) of cultured cardiac myocytes appeared to protect the cells from the toxic effect of ouabain by lowering the Ca^{++} overload (11). In a previous paper, we reported that the modification of the phospholipid n-6/n-3 fatty acid ratio had no influence on the basal electrical and mechanical activities in isolated ventricular myocyte (12). Moreover, there is increasing evidence that the function of adrenergic receptors in the heart is influenced by changes in membrane PL composition (13). However, there are few studies on the specific effect of n-3 PUFA on reactivity to autonomic neurotransmitters. Some data were obtained in clinical studies, suggesting a relationship between dietary-induced lipid modifications and the cardiovascular response to noradrenaline (14). Similarly, the influence of fish oil diets on noradrenaline sensitivity, through alterations in the receptor affinity and density (15–18), adenylate cyclase (19), and/or cyclic nucleotide phosphodiesterase (20) have been reported. From the various studies published to date, it is difficult to conclude whether the effects of fish oil diets on the heart are due to a decrease in membranes n-6 PUFA or to a specific effect of the increase in DHA. The functional alterations specifically induced by the membrane enrichment in DHA remain largely unknown, although fish oil diets result in a large increase of DHA in heart membranes with little or no variation in EPA (21). Therefore, the present study deals with the consequences on ventricular myocytes of increasing membrane content in DHA without decreasing the arachidonic acid content.

MATERIALS AND METHODS

Cell culture. Rat ventricular myocyte cultures were prepared as previously described (22). The cells were grown in a standard culture medium [Ham's F10 (Seromed Biochrom, Berlin, Germany) medium supplemented with 10% fetal calf serum and 10% human serum] in a humidified atmosphere at 37°C containing 5% CO_2. After 24 h, the cells were incubated for four days in the same medium supplemented as serum albumin-bound fatty acids with either 20:5n-3 (EPA) or 22:6n-3 (DHA), which led to two populations (EPA and DHA cells) from the same cell pool (23).

Fatty acid analysis. The lipids were extracted according to Folch *et al.* (24). PL were separated from nonphosphorus lipids on silica gel cartridges (25). The lipids were transmethylated with using BF_3–methanol and the fatty acid methyl esters were analyzed by gas chromatography.

Physiological parameters. The experiments were carried out in custom made Puck's F salt solution under a paraffin oil layer (26). The intracellular voltage measurements were done using conventional microelectrodes. The cell contractions were monitored using a custom-made motion detector (27). The adrenergic stimulation was carried out as described elsewhere (27). The drugs used were: l-isoproterenol HCl (Iso; Sigma, St. Louis, MO), dibutyryl adenosine 3′,5′-cyclic monophosphate (dBcAMP), and phenylephrine (Phe; Sigma).

Messenger production. The β-adrenergic receptors were stimulated for 3 min by Iso in the presence of 3-isobutyl-1-methylxanthine (10^{-3} M). The reaction was stopped by heat shock and the intracellular cAMP content was determined by radio immunoassay (Amersham, Slough, United Kingdom). The α-adrenergic receptors were stimulated by addition of Phe, after radio labelling of phosphatidylinositol with [^{3}H]-inositol. The phosphoinositide breakdown was expressed by the accumulation of [^{3}H]-inositol-1-phosphate (Ins1P) in the presence of lithium (28,29). The method of Lowry *et al.* (30) was used for protein content measurements.

Receptor binding. The number of receptor binding sites and their affinity were measured on a whole cell homogenate obtained from a pool of 50 dishes per group. The β- and α-adrenergic receptor density was determined using [^{3}H]-dihydroalprenolol (0.15–3.0 nM) and [^{3}H]-prazosin (32–640 pM) (DuPont, NEN, Wilmington, DE), respectively. The β- and α-adrenergic receptor binding was assessed by measuring the amount of bound ligand displaced by alprenolol d-tartrate (1 μM) and phentolamine (10 μM), respectively.

Statistics. The results are presented as mean ± SEM. The data were submitted to analysis of variance (31). The differences were considered significant for $P < 0.05$.

RESULTS

Fatty acid composition. The fatty acid composition of the PL of EPA- and DHA-treated cells is shown in Figure 1. The total amounts of saturated fatty acids, monounsaturated fatty acids, and PUFA were similar in the two groups. The membrane PL of the DHA cell group were characterized by a large incorporation of DHA (approximately 15%) with little incorporation (less than 4%) of EPA and its elongation product, docosapentaenoic acid (22:5n-3). In contrast, the PL fraction of the EPA cell group contained large amounts of both EPA and docosapentaenoic acid (approximately 10% each) and only 1.5% of DHA. All these differences in n-3 PUFA contents were significant ($P < 0.001$). Conversely, the two cell groups displayed a similar content in arachidonic acid, as the n-6 PUFA composition was not significantly altered.

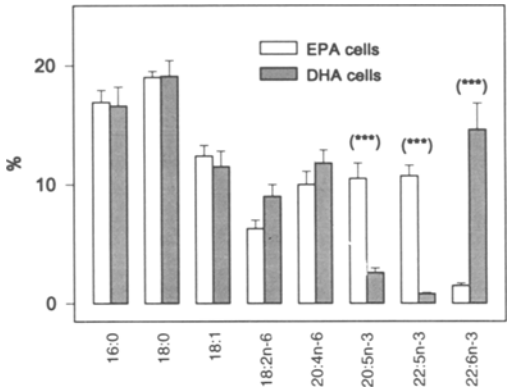

FIG. 1. Fatty acid composition of the phospholipid fraction of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) cells (as % of total phospholipid fatty acid). (***), $P < 0.001$.

Physiological properties. The amplitude of the action potential in the EPA-treated cells was slightly but significantly higher than in the DHA cells (Table 1). Conversely, no significant difference could be observed in the maximal diastolic potentials. This difference in action potential amplitude could be mainly attributed to a significantly less positive plateau potential level (–2.1 mV) in the DHA cells (see OS in Table 1). In contrast, all the time- and rate-parameters of the action potential (Table 1) were independent of the membrane DHA level. Similarly, the contraction parameters, such as duration at 80% relaxation (CD80), contraction duration at 20% relaxation (CD20), shortening time ($+C_{max}$) and relaxation time ($-C_{max}$) were not significantly different in the two cell groups.

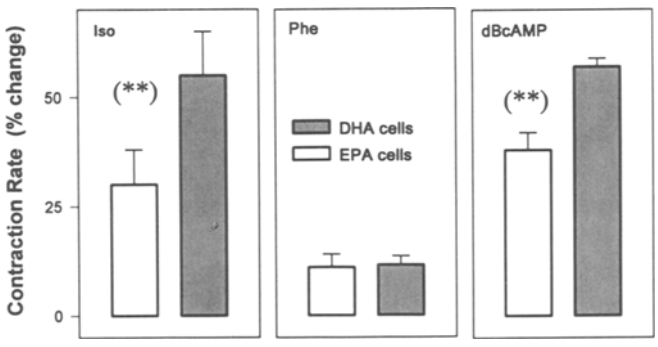

FIG. 2. Chronotropic influence of isoproterenol (Iso, 10^{-7} M), phenylephrine (Phe, 3×10^{-6} M), and dibutyryl AMP (dBcAMP, 10^{-3} M) in EPA and DHA cells. (**), $P < 0.01$; abbreviations as in Figure 1.

TABLE 1
Action Potentials (A) and Rate and Contraction Parameters (B) from Cultured Rat Cardiac Myocytes Eicosapentaenoic Acid (EPA) and Docosahexaenoic Acid (DHA) Cells[a]

A	MDP (–mV)	OS (mV)	APA (mV)	APD80 (ms)	V_{max} (V/s)
DHA cells	79 ± 1.2	15 ± 0.6 —[b]	95 ± 1.2 —[b]	139 ± 7.1	67 ± 10.0
EPA cells	81 ± 0.9	17 ± 0.9	98 ± 1.3	135 ± 3.9	73 ± 11.3
B	F (m^{-1})	CD20 (ms)	CD80 (ms)	$+C_{max}$ (ms)	$-C_{max}$ (ms)
DHA cells	269 ± 17.4	64 ± 4.7	156 ± 9.1	42 ± 1.8	51 ± 2.6
EPA cells	257 ± 15.3	69 ± 3.5	167 ± 6.8	45 ± 1.4	54 ± 2.2

[a]Values are the mean ± SEM (n = 10). Abbreviations: MDP, maximal diastolic potential; OS, overshoot; APA, action potential amplitude; APD80, action potential durations at 80% repolarization; V_{max}, maximal rate of initial depolarization of the action potential; F, spontaneous rate; CD20, CD80, contraction duration at 20 and 80% relaxation, respectively; +Cmax, –Cmax, shortening and relaxation time (measured between 20 and 80% full contraction amplitude), respectively.
[b]$P < 0.05$.

α-Adrenergic function. Both DHA and EPA cells reacted to phenylephrine addition (3×10^{-6} M), which provoked an increase in spontaneous beating frequency (Fig. 2). These chronotropic responses were of a small magnitude and represented a 10% increase in rate. The positive chronotropic effect was similar in DHA- and EPA-treated cells (the average rate elevation was 17 and 16 beats/min, respectively). The phenylephrine-induced contraction shortening in DHA cells was not significantly different from that observed in EPA cells. The density of α1 receptor binding sites expressed by β_{max} were quite similar in DHA- and EPA-treated cells (36 ± 2.6 and 37 ± 3.9 fmoles, respectively). Similarly, the affinity of these sites for [^{3}H]-prazosin expressed as Kd was not significantly different in DHA and EPA cells (140 ± 21 and 115 ± 12 pM, respectively). In the two groups of cardiomyocytes, exposure to phenylephrine (3×10^{-6} M, 10^{-4} M) caused a highly significant, dose-dependent increase in [^{3}H]-inositol phosphates (Fig. 3). However, at each phenylephrine concentration considered, the [^{3}H]-inositol phosphate production was not significantly different in DHA and EPA cells.

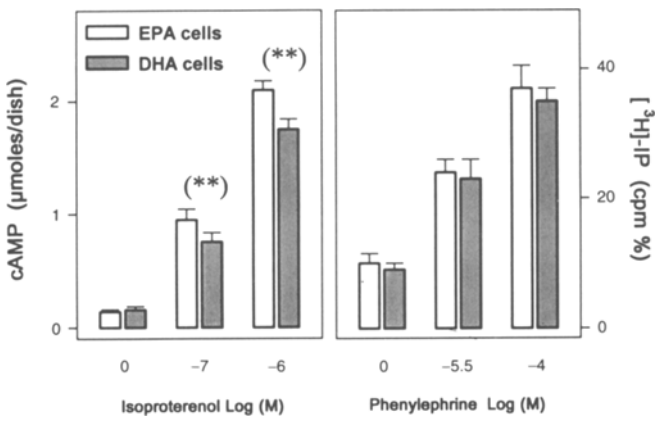

FIG. 3. Production of second messengers in EPA and DHA cells elicited by α- and β-adrenergic agonists (Phe and Iso, respectively). cAMP is expressed as µmole per dish and [^{3}H]-inositide phosphates as % of phosphatidylinositol radioactivity. (**), $P < 0.01$; abbreviations as in Figures 1 and 2; [^{3}H]-IP, [^{3}H]-inositide phosphates.

β-Adrenergic function. In the two groups, the addition of isoproterenol (10^{-6} M) caused an increase in spontaneous frequency of beatings, much more pronounced than that elicited by phenylephrine. However, the chronotropic response was significantly higher in DHA cells relative to EPA cells (Fig. 2). Additionally, isoproterenol induced a shortening of the contraction duration (data not shown), and DHA and EPA cells seemed to differ in this respect, as the isoproterenol-induced contraction shortening was significantly more pronounced in the DHA-rich cardiomyocytes. However, because contraction duration is a rate-dependent parameter, the observed difference resulted from the effect of DHA on the rate. The density of β-adrenergic receptor binding sites, as evaluated by β_{max} determination, was similar in DHA and EPA cells (42 ± 4.5 and 40 ± 3.5 fmoles, respectively). Conversely, the affinity of the β-adrenergic receptors for dihydroalprenolol tended to be lowered by DHA enrichment, as the Kd was higher in DHA- as compared to EPA-treated cells (400 ± 15 and 330 ± 28 pM, respectively). The production of cAMP in EPA and DHA cells is presented in Figure 3. In the absence of external β-adrenergic stimulation, the intracellular content in cAMP was similar in the two groups: 155 ± 16.0 nmoles/dish in DHA cells vs. 140 ± 10.8 nmoles/dish in EPA cells. The amounts of cAMP produced were strongly enhanced by isoproterenol stimulation in both groups, but the rise in cAMP induced by isoproterenol was significantly lower in DHA cells than in EPA cells (Fig. 3).

DISCUSSION

The results presented here indicate that increasing the DHA content resulted in a depressed plateau potential level, which is governed by the calcium ion channels. A relationship between EPA supplementation and calcium homeostasis has been suggested (11), but comparison with DHA was not considered. Increasing the n-3 PUFA content in PL was also reported to alter calcium transport in isolated cardiac myocyte

(9), but the study involved a change in n-6/n-3 ratio and an increase in both EPA and DHA. In a previous work, we showed that a modification of the n-6/n-3 ratio elicited by C_{18} precursors did not influence the action potential. All these results contribute to the hypothesis that some calcium channels may be influenced by changes in the fatty acid composition of the membrane, provided that these changes concern the DHA level. Similarly, the nature of the long-chain n-3 PUFA (EPA vs. DHA) in the ventricular myocyte PL do influence other membrane functions, such as the phospholipase A_2 activity (23), but not the spontaneous rate expressed by cardiomyocytes in culture, in spite of the fact that external calcium at least partly controls the beating rate of the cultured rat heart cells (32). This study confirms that membrane PUFA have no chronotropic influence in isolated cardiomyocytes (12). This is consistent with the observation that chronic EPA administration has no significant effect on heart rate in SHR and WKY rats (33). Additionally, increasing the DHA content without major alteration of the n-6/n-3 ratio did not affect the resting diastolic potential, the upstroke velocity, and the depolarization configuration. According to Karmazyn *et al.* (9), increasing both EPA and DHA and decreasing n-6 PUFA had no effect on the resting potential of rat cardiac myocytes, but delayed the final repolarization phase. The contraction duration and the shortening and relengthening times in ventricular myocytes were not affected by the DHA content, nor were they affected by the n-6/n-3 PUFA ratio (12). According Hallaq *et al.* (11), the amplitude of cell contraction is not altered by EPA incorporation, and the contraction was reported to be independent from DHA content in cardiac myocyte (34). Although myocardial contractility seems to be sensitive to an increase in n-6 PUFA (35), marked changes in the PUFA profile of heart cell membranes do not appear to affect myocardial performances (36–38). Recently, Finkel *et al.* (39) reported that EPA caused negative inotropic response in isolated papillary muscle, but the extent of fatty acid alteration was not characterized.

In a previous paper, we reported that increasing the n-3 PUFA in membrane PL enhanced the chronotropic response to isoproterenol (27). The present study provided the additional data that this chronotropic response was strengthened when EPA and DPA were replaced by DHA in the PL, although the n-6 vs. n-3 ratio was the same. Therefore, the individual PUFA may exert different effects on the myocardial β-adrenergic system. The results of this study suggest that the amount of DHA incorporated in cardiac membranes following fish oil (or n-3 PUFA) diets should be considered as a major factor, and not only the total n-3 incorporation. The DHA vs. EPA + DPA balance did not change the β-receptor binding site number (β_{max}), whereas a higher DHA level in the PL tended to induce a slight decrease in the affinity for dihydroalprenolol. Similar alterations were already reported in the heart from fish oil-fed rats (15). The balance between DHA and arachidonic acid in the membrane PL may modulate the age-dependent changes in the number and the affinity of β1-receptors (8). However, the increase in DHA decreased the isoproterenol-stimulated accumulation of cAMP. Numerous papers suggested the sensitivity of cardiac adenylate cyclase to membrane lipid environment, but often led to discrepancies (13,40). Laustiola *et al.* (41) reported that fish oil fed rats displayed a low isoproterenol-stimulated cAMP accumulation. Conversely, an enhanced catecholamine-stimulated adenylate cyclase activity has been observed in fish oil-fed pigs and rats (33,40). Again, the adenylate cyclase activity and its coupling to β-receptors may depend on the actual DHA amount in the PL as much as on the n-6 vs. n-3 balance. To further explore the apparent opposite effects of DHA on β-chronotropy and cAMP production, we studied the specific responses to dBcAMP, a permanent cAMP analogue. dBcAMP induced a significantly higher rise in rate in DHA-rich cells. The specific influence of membrane DHA content on the β-adrenergic chronotropy appears to result partly from an enhanced functional efficiency of cAMP. Membrane DHA could influence the regulation of membrane-bound components linked to automaticity, but also to the intracellular steps of the signal transduction system, such as protein kinases and/or phosphodiesterase (40). However, an influence of DHA on phosphodiesterase activity seems doubtful, as the dibutyryl derivative of cAMP used in this study is known to be phosphodiesterase-resistant. The present study provided the additional data that the DHA level in the cardiomyocyte PL did not influence their positive chronotropic response to phenylephrine, nor the rate of inositol phosphate formation, nor the density and affinity of α1-binding sites. n-3 PUFA were reported to reduce the α-adrenoceptor mediated contractile response in the isolated heart and artery (18,42). Recently, the modifications in membrane PL achieved by hormonal treatment was also shown to affect the α1-adrenergic receptor affinity, but this effect could not be related to specific fatty acid membrane changes. Accordingly, Meij *et al.* (43) reported that PUFA composition of membrane PL has no effect on the total amount of α1-stimulated inositol phosphates produced in rat heart cell cultures. However, Lamers *et al.* (44) showed that a treatment of ventricular myocytes with either linoleic acid or EPA reduced the rate of inositol phosphate production. In this study, the n-3 PUFA composition in the phosphatidylinositol fraction was markedly altered, but not the arachidonic acid content (data not shown). This suggests that the affinity of phospholipase C for the phosphatidylinositol (and, additionally, the composition of the diacylglycerol messenger) do not depend on the n-3 composition, provided that the arachidonic acid content is not altered.

In conclusion, this work provided evidence for a differential effect of the two major fish oil PUFA. Increasing the DHA content in cardiomyocyte membranes did not modify the function of the α-adrenergic system, in spite of the known involvement of PL in the α-adrenergic mechanism. Conversely, a high DHA content in the PL depressed the β-adrenergic induced cAMP production, but improved the functional efficiency of cAMP, which resulted in an enhanced chronotropic response to a β-agonist.

Quantification of Distinct Molecular Species of Platelet Activating Factor in Ulcerative Colitis

Erik Thyssen, John Turk*, Alan Bohrer, and William F. Stenson*

Department of Medicine, Washington University School of Medicine, St. Louis, Missouri 63110

ABSTRACT: The aim of this study was to characterize the synthesis and metabolism of platelet activing factor (PAF, 1-O-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) by colonic mucosa from patients with ulcerative colitis and healthy individuals. Tissue was obtained by endoscopic biopsy and by scraping the mucosa from surgical resections. Tissue was assayed for the various molecular species of PAF and its biologically inactive metabolite lyso-PAF using gas chromatography/mass spectrometry. Mucosa from surgical resections for ulcerative colitis contained C16:0 PAF (mean = 156 ng/g of mucosa), but not C18:0 PAF. PAF was not identified in mucosa from normal surgical resections or in endoscopic biopsies from either patients with ulcerative colitis or normal individuals. Both C16:0 lyso-PAF and C18:0 lyso-PAF were found in mucosa from normal and ulcerative colitis surgical resections and in endoscopic biopsies from ulcerative colitis and normal tissue. Levels of lyso-PAF were similar in ulcerative colitis and normal mucosa. Incubation of mucosa from areas of active inflammation in ulcerative colitis with the calcium ionophore A23187 increased the levels of C16:0 PAF by 2–3 fold and also increased the levels of C16:0 lyso-PAF. Addition of ^{3}H-PAF to endoscopic biopsies from either normal individuals or patients with ulcerative colitis resulted in hydrolysis to ^{3}H-lyso-PAF. The data on colonic mucosal levels of PAF are consistent with the results of earlier studies measuring PAF in patients with ulcerative colitis by bioassay. This study examines the synthesis and metabolism of specific molecular species of PAF in ulcerative colitis for the first time.
Lipids 31, S-255–S-259 (1996).

Platelet activating factor (PAF, 1-O-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a potent mediator of inflammation that causes neutrophil activation, increased vascular permeability, and vasodilation in addition to platelet activation (1). Increased levels of PAF have been found in inflamed mucosa from patients with ulcerative colitis and Crohn's disease and in the stools of patients with Crohn's disease and pouchitis after colectomy for ulcerative colitis (2–6). PAF is also thought to play an important role in the pathogenesis of necrotizing entercolitis (7). Inflammatory cells, particularly mast cells and tissue macrophages, and gastrointestinal epithelial cells have been identified as cellular sources for PAF (8). Drugs used in the treatment of inflammatory bowel disease (including corticosteroids and 5-ASA compounds) inhibit the production of PAF, raising the possibility that PAF may play an important pathogenic role in inflammatory bowel disease (2,9). In previous studies in inflammatory bowel disease, PAF has been measured by bioassay using platelet aggregation in an aggregometer (2–6). Although platelet aggregation is a highly sensitive assay for PAF, its interpretation is confounded by the interference of other products in biological samples that might enhance (ADP, certain prostanoids) or diminish (adenosine, endogenous inhibitors) platelet aggregation (10). Moreover, there are several molecular species of PAF that have biologic activity, and the platelet aggregation assay does not allow the separation of the contribution of the various molecular species.

In this study, a stable isotope dilution gas chromatographic-mass spectrometric assay (11) was applied to characterize the levels of the various molecular species of PAF and its biologically inactive metabolite, lyso-PAF, in normal human colonic mucosa and in histologically inflamed mucosa from patients with ulcerative colitis.

METHODS

Tissue collection. Endoscopic biopsies were obtained during routine colonoscopies. Three to ten endoscopic biopsies were obtained from endoscopically inflamed colons from patients with active ulcerative colitis and from endoscopically normal areas from healthy individuals undergoing screening colonoscopy. Each endoscopic biopsy weighed approximately 10 mg. Endoscopic biopsies include epithelial cells and some lamina propria inflammatory cells. Endoscopic biopsies were obtained from inflamed colonic mucosa in 11 patients with active ulcerative colitis (6 men and 5 women, mean age 41 years with a range of 22–78 years) and 8 healthy individuals (4 men and 4 women, mean age 56 years with a range of 33–85 years). Material from surgical resections was collected from the operating room. Surgical resections came from patients undergoing total colectomies for active ulcerative

colitis resistant to medical therapy (3 men and 1 woman, mean age 34 years with a range of 21–48 years). Normal colonic tissue was obtained from the uninvolved areas of surgical resections for colon cancer (2 men and 1 woman, mean age 66 with a range of 60–72 years). The surgical resections were washed and mucosa was obtained by scraping the surgical resections with a glass slide. This method yields a preparation that includes the epithelium, the lamina propria, the muscularis mucosal and the submucosa down to the level of the muscularis propria.

PAF quantitation. The samples were placed in PBS (1 mL) and an internal standard d_3C16:0 PAF (10 ng) was added. The samples were extracted for total lipids by the method of Bligh and Dyer. For quantitation of any lyso-PAF in the samples, the lipid extract was treated with propionylchloride to convert lyso-PAF to propinoyl PAF (11). The extract was concentrated to dryness under N_2 and derivatized with 100 µL propionic acid and 50 µL propionyl chloride for 45 min at 60°C. This material was dried (N_2) and reconstituted in 1 mL chloroform. PAF molecular species were purified on silicic acid extraction columns (Sep-Pak; Fischer Scientific, Fairlawn, NJ). Columns were conditioned with 5 mL ethyl acetate and 5 mL methanol using negative pressure to draw the solvent through the columns. The samples were applied to the columns and then washed with 5 mL of 1% acetic acid in chloroform and then with 5 mL of chloroform/methanol, 1:1, vol/vol. PAF was then eluted from the columns with 5 mL chloroform/methanol/water, 1:2:0.8, by vol. Chloroform and water (1.3 mL) were added to the column eluate to effect phase separation and the chloroform phase was collected and concentrated to dryness. This purified material was converted to the analogous diglyceride by digestion with phospholipase C (from *B. cereus;* Sigma, St. Louis, MO) (25 units phospholipase C in 250 µL 0.2 M sodium borate buffer, pH 8.0 with 2 mM Ca^{2+}). One mL of diethyl ether was added, and the samples were tightly capped and incubated in a shaking 37°C water bath for 90 min. The ether layer was subsequently removed, dried, and the resulting diglyceride was converted to the pentafluorobenzoyl (PFB) derivative with 10 µL pentafluorobenzoyl chloride (Sigma) in 50 µL of 4% pyridine in toluene at 80°C for 90 min. After concentrating to dryness, the PAF-PFB derivative was purified by thin-layer chromatography (TLC) on silica gel-G plates (Analtech, Newark, DE). Plates were developed first in hexane, allowed to dry, and then developed in hexane/ethyl acetate, 9:1, vol/vol. The derivatives of PAF and lyso-PAF were eluted from the silicic acid with hexane:ethyl acetate, 9:1, vol/vol. Migration positions were determined with authentic PAF-PFB standards run on outer lanes of the TLC plate. The hexane/ethyl acetate solutions containing the recovered PAF and lyso-PAF derivatives were back extracted twice with water and concentrated to dryness. Samples were then reconstituted to 20 µL heptane and analyzed by capillary column gas chromatography-negative ion chemical ionization mass spectrometry.

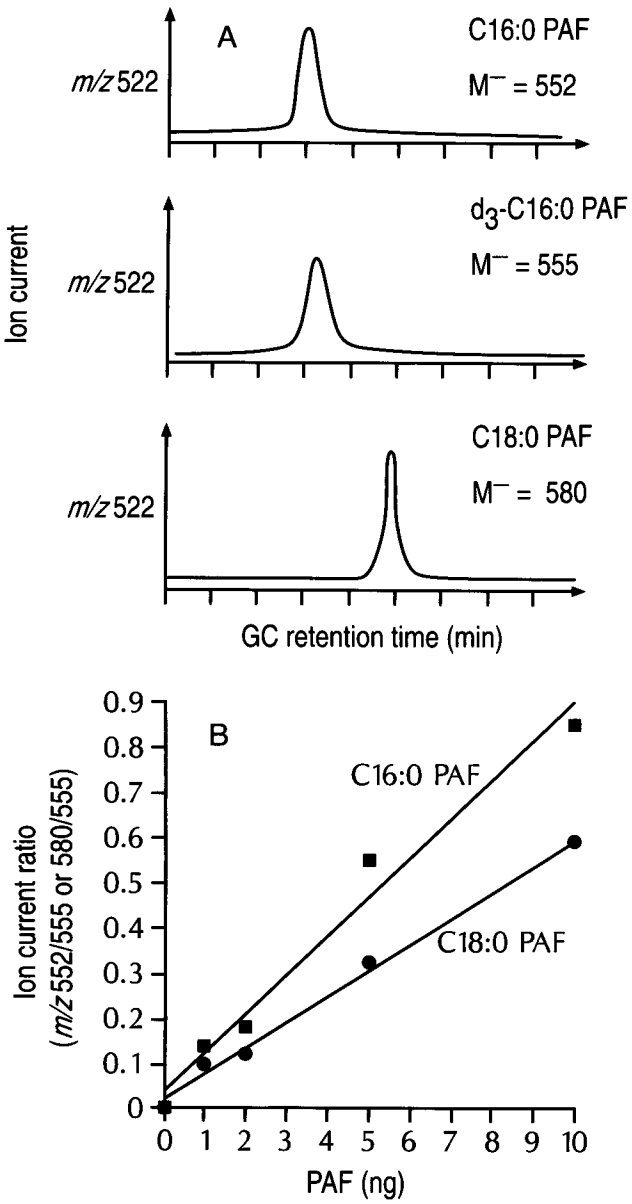

FIG. 1. Gas chromatography (GC)-mass spectrometry analysis of platelet activating factor (PAF) derivatives. The left panel shows the ion currents products by the derivatized diglycerides of C16:0 PAF, the d_3-C 16:0 PAF internal standard, and C18:0 PAF. The right panel shows typical standard curves demonstrating the correlation of authentic PAF vs. a fixed amount of the internal standard expressed as the ratio of their respective ion currents: *m/z* 552/555 for C16:0 PAF, and *m/z* 580/555 for C18:0 PAF.

Gas chromatography-mass spectrometry. Gas chromatography (GC) was performed on a Hewlett Packard 5890 gas chromatograph with a fused silica capillary column 8m Hewlett Packard Ultraperformance (methysilicone, 0.17 micron film thickness, 0.32 mm i.d.) interfaced with a Hewlett Packard model 5988 quadrapole mass spectrometer (11). Injections were made in the splitless mode with helium as the carrier gas (total flow 10 mL/min, head pressure 4 psi). The GC oven temperature was programmed from 85 to 300°C at 40°C per min beginning 0.8 min after injection. Temperatures of the GC interface and injector were maintained at 285°C. Mass spectrometry was performed in the negative ion chemical ionization mode with methane as the reactant gas (source pressure 1.5 torr). Selective ion monitoring of the following ions was performed *m/z*: 552 (C16:0-

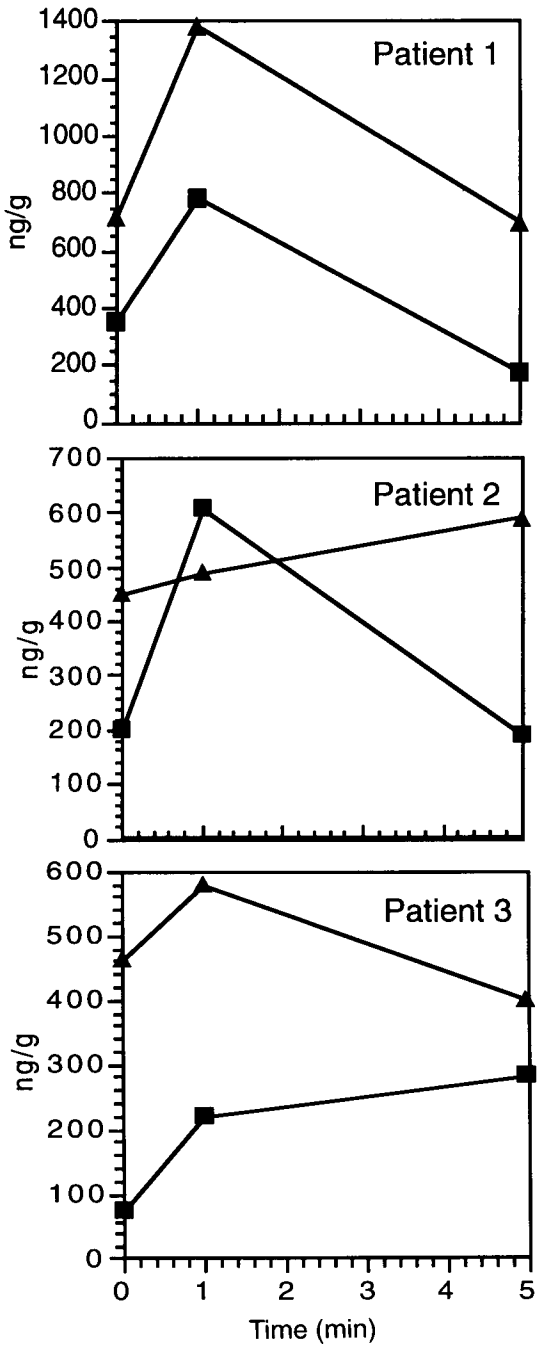

FIG. 2. Production of C16:0 PAF and C16:0 lyso-PAF by mucosa scraped from ulcerative colitis surgical resections (30 mg) incubated with A23187 (1 μM) for 0, 1, and 5 min. The tissue and media were extracted together and molecular species of PAF and lyso-PAF were measured by gas chromatography-mass spectrometry. Each panel represents a separate patient. Abbreviation as in Figure 1.

PAF); 566 (2-propionyl derivative of lyso-C16:0-PAF derivative); 580 (C18:0-PAF); 578 (C18:1-PAF); and 555 ($^2H_3$-labeled C16:0-PAF internal standard). Standard curves for PAF-PFB and lyso-PAF-PFB-propionyl derivatives were performed with each assay by combining various concentrations of the appropriate PAF or lyso-PAF standards with 10 ng of d_3C16:0 PAF internal standard. Each standard was subjected to the same isolation, purification, and derivatization procedures described above for the samples obtained from the allograft tissue. Representative gas chromatography-mass spectrometric tracings and a standard curve obtained from one experiment are shown in Figure 1.

Incubation with A23187. Samples of scraped colonic mucosa (20–40 mg), or colonoscopic biopsies (20–40 mg) were incubated with A21387 (1 μM) at 37° in phosphate-buffered saline (PBS) for various times. The tissue samples and media were extracted together by the method of Bligh and Dyer and processed for PAF and lyso-PAF quantitation as described above.

Degradation of ^{3}H-PAF. Three endoscopically obtained mucosal biopsies from either normal subjects or patients with ulcerative colitis were placed in Dulbecco's modified Eagle's medium with 1-O-^{3}H-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (8.3 nM) and incubated for various periods at 37°C. The tissue and media were extracted by the method of Bligh and Dyer, and the lipids were separated by TLC on silica gel-G. The solvent system used was chloroform/methanol/acidic acid/water (50:25:8:4, by vol). Each lipid class was identified on the basis of comigration with standards and the corresponding areas were scraped and radioactivity assessed in a Beckman scintillation counter.

RESULTS

A stable isotope dilution gas chromatographic-mass spectrometric assay was used to measure the levels of various molecular species of PAF and lyso-PAF in histologically normal human colonic mucosa and in histologically inflamed mucosa from patients with ulcerative colitis. Detectable amounts of C16:0 PAF (156 ± 141 ng/g) were found in mucosa scraped from four of four surgical resections for active ulcerative colitis (Table 1). No detectable levels of C16:0 PAF were found in ulcerative colitis endoscopic biopsies or in mucosa scraped from histologically normal endoscopic biopsies. No detectable C18:0 PAF was found in any of the surgical resections or endoscopic biopsies from either ulcerative colitis patients or normals. The lower limit of sensitivity of the gas chromatography-mass spectrometry assay for C16:0 PAF or C18:0 PAF is 1 ng (Fig. 1); with 30 mg tissue samples the lower limit of sensitivity is 33 ng/g of mucosa. Detectable levels of C16:0-lyso-PAF and C18:0 lyso-PAF were found in all of the surgical resections and all of the endoscopic biopsies. There were no significant differences in the levels in the two molecular species of lyso-PAF between samples taken

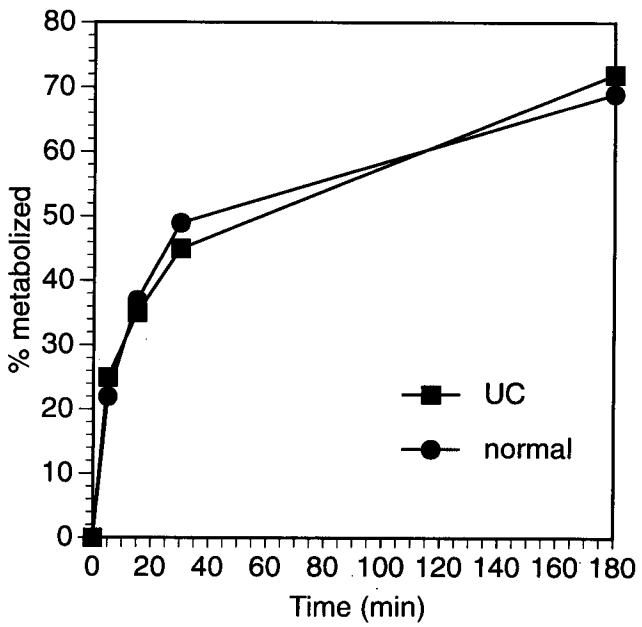

FIG. 3. Metabolism of ^{3}H-C16:0 PAF by mucosal biopsies from normals or patients with ulcerative colitis. Three endoscopically obtained mucosal biopsies from patients with ulcerative colitis were placed in Dulbeco's modified Eagle medium with 1-O-^{3}H-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (8.3 nM) and incubated for various times at 37°C. The tissue and media were extracted by the method of Bligh and Dyer and the lipids were separated by thin-layer chromatography. The data are presented as the percent of added ^{3}H-PAF metabolized at each time point. Abbreviation as in Figure 1.

from ulcerative colitis and normal individuals. There were also no significant differences in lyso-PAF levels between endoscopic biopsies and surgical resections. In contrast to PAF, where only the C16:0 molecular species was found, the C16:0 and C18:0 molecular species of lyso-PAF were present in roughly equivalent amounts.

To test the ability of colonic mucosa to synthesize PAF, surgical resections and endoscopic biopsies were incubated with the calcium ionophore A23187. The production of PAF and lyso-PAF species was measured after incubations with A23187 for 1 and 5 min. After incubation with A23187, C18:0 PAF was not detected in any sample. After incubation with A23187, C16:0 PAF production was observed only in those samples which had contained measurable basal amounts of C16:0 PAF prior to the addition of A23187. Incubation of mucosa from three of the four ulcerative colitis surgical resections with A23187 resulted in synthesis of C16:0 PAF (Fig. 2). PAF synthesis in the fourth specimen was not studied. Two of the three samples demonstrated 2–3 fold increases in PAF levels after 1 min incubation in the A23187 with a decline at 5 min. In the third sample, there was a 2-fold increase in PAF levels at 1 min and a 3-fold increase at 5 min. In each case, the increase in 16:0 PAF was accompanied by an increase in 16:0 lyso-PAF. This is consistent with degradation of PAF by acetylhydrolase.

The typical pathway for PAF degradation is hydrolysis of the acetyl group to yield acetate and lyso-PAF. Finding that lyso-PAF levels were consistently higher than PAF levels in both normal mucosal and inflammatory bowel disease mucosa raised the possibility that PAF is rapidly degraded in the human intestinal mucosa. An experiment was performed to determine whether PAF is degraded in human colonic mucosa and to assess whether there is a difference in the rate of PAF degradation between normal and ulcerative colitis mucosa. ^{3}H-PAF was incubated with colonoscopic biopsies from normal and ulcerative colitis tissue. After various times, the incubations were terminated. Lipids were then extracted from the tissues and the media together, and the radiolabelled metabolites analyzed by thin-layer chromatography. PAF was metabolized to lyso-PAF, which was further metabolized to phosphorylcholine and alkylglycerols. The rate of PAF metabolism by endoscopic biopsies from histologically normal tissue and ulcerative colitis tissue was equivalent. In both systems, 50% of the added ^{3}H-PAF was metabolized within 30 min. (Fig. 3).

DISCUSSION

In this study, we detected C16:0 PAF in inflamed colonic mucosa from patients with active ulcerative colitis, but not from histologically normal tissue. C18:0 PAF was not detected in either ulcerative colitis tissue or histologically normal colonic tissue. Both C16:0 lyso-PAF and C18:0 lyso-PAF were found in biopsies and mucosal scrapings from normal and ulcerative colitis colonic mucosa. There were no significant differences in lyso-PAF content of normal and diseased mucosa.

In earlier studies, in which PAF activity was measured by platelet aggregation, detectable quantities of PAF were found in biopsies from patients with ulcerative colitis but not in biopsies from normal individuals (2). In our study in which PAF molecular species were measured by gas chromatography-mass spectrometry, detectable levels of C16:0 PAF were found in mucosal scrapings from surgical resections for ulcerative colitis but not in ulcerative colitis biopsies. There are several factors which may contribute to these apparent differences. Probably the most important is that the gas chromatography-mass spectrometry assay, although more quantitative and specific, is less sensitive than platelet aggregation bioassay. Using 30 mg tissue samples, the lower limit of sensitivity of the gas chromatography-mass spectrometry assay is 33 ng of PAF per gram of mucosa. In platelet aggregation assays, aggregation occurs in response to as little as 5 picograms of synthetic PAF. Using the platelet aggregation assay PAF levels as low as 1 ng/g were measured in ulcerative colitis endoscopic biopsies (2). The differences between measurements of PAF levels in ulcerative colitis endoscopic biopsies in the study described here and earlier studies can therefore be explained by differences in the sensitivity of the assays. The ability of the gas chromatography-mass spectrometry method to detect C16:0 PAF in mucosal scrapings from ulcerative colitis surgical resections but not from endoscopic biopsies may reflect the higher levels of PAF in the surgical resections due to the higher level of disease activity in patients undergoing surgical resections for ulcerative colitis.

The two major biologically active molecular species of PAF are the C16:0 and C18:0 species. Relatively few studies have measured the distinct molecular species in biological samples. Where they have been measured, the C16:0 PAF has been quantitatively more significant than C18:0 PAF (12,13). For example, in transplanted dog kidneys undergoing rejection, 16:0 PAF was present in the cortex at levels 80-fold greater than C18:0 PAF and in the medulla at levels 20-fold greater (12). Our findings of high levels of 16:0 PAF and undetectably low levels of 18:0 PAF are consistent with these earlier observations. The C16:0 PAF levels in ulcerative colitis mucosal scrapings measured in this study by gas chromatography-mass spectrometry are somewhat higher than PAF levels reported previously in endoscopic biopsies from ulcerative colitis mucosa reported previously using platelet aggregation. This difference may reflect the greater level of disease activity in patients undergoing surgical resections. Although this study did not address the cellular source of the C16:0 PAF in ulcerative colitis mucosa, the results of an earlier study suggest that both inflammatory cells and epithelial cells may contribute (8).

This is the first study to measure lyso-PAF by chemical methods in inflammatory bowel disease and the first to investigate the molecular species of lyso-PAF. Earlier studies had measured lyso-PAF by converting lyso-PAF to PAF by treatment with acetic anhydride and then measuring PAF activity by platelet aggregation (4). Measurement of lyso-PAF by gas chromatography-mass spectrometry is more direct, more quantitative, and allows the separation of distinct molecular species. The finding that lyso-PAF was similar in ulcerative colitis tissue and normal tissue was not surprising. Lyso-PAF is generated by processes in addition to the hydrolysis of PAF. Lyso-PAF is produced from PAF by the action of acetylhydrolase. It can also be produced from plasmanycholine by the action of phospholipase A_2. Lyso-PAF levels are also regulated by the rate of reacylation to form plasmanylcholine and by the rates of degradation by phospholipases C and D to form diglycerides and lysoplasmanic acid. Although PAF levels are higher in ulcerative colitis colonic mucosa than normal colonic mucosa there is no evidence that the other determinants of lyso-PAF levels are different in ulcerative colitis and normal colon.

Increased PAF production in ulcerative colitis fits with enhanced production of other mediators. The first step in the synthesis of PAF through the remodeling pathway is the hydrolysis of 1-alkyl-2-acyl-*sn*-glycero-3-phosphcholine by phospholipase A_2. In addition to releasing lyso-PAF, this reaction also releases arachidonic acid, the substrate for the synthesis of prostaglandin E_2 and leukotriene B_4, both of which are present at increased levels in ulcerative colitis (14).

In summary, in this study a stable isotope dilution gas chromatographic-mass spectrometric technique was used to measure molecular species of PAF and lyso-PAF in histologically normal colonic mucosa and in inflamed mucosa from patients with ulcerative colitis. The inflamed mucosa contained detectable amounts of C16:0 PAF but not C18:0 PAF. Normal mucosa did not contain detectable amounts of either molecular species of PAF. Significant amounts of C16:0 lyso-PAF and C18:0 lyso-PAF were found in all samples with no significant difference between the levels in the normal mucosa and ulcerative colitis mucosa.

ABSTRACT: Skeletal muscle plays a major role in insulin-stimulated glucose disposal. This paper reviews the range of evidence in humans and experimental animals demonstrating close associations between insulin action and two major aspects of muscle morphology: fatty acid composition of the major structural lipid (phospholipid) in muscle cell membranes and relative proportions of major muscle fiber types. Work *in vitro* and *in vivo* in both rats and humans has shown that incorporation of more unsaturated fatty acids into muscle membrane phospholipid is associated with improved insulin action. As the corollary, a higher proportion of saturated fats is linked to impairment of insulin action (insulin resistance). Studies *in vitro* suggest a causal relationship. Among polyunsaturated fatty acids (PUFA) there is some, but not conclusive, evidence that ω-3 (n-3) PUFA may play a particular role in improving insulin action; certainly a high n-6/n-3 ratio appears deleterious. In relation to fiber type, the more highly oxidative, insulin-sensitive type 1 and type 2a fibers have a higher percentage of unsaturated fatty acids, particularly n-3, in their membrane phospholipid, compared to the insulin-resistant, glycolytic, type 2b fibers. These variables, however, can be separated and may act in synergy to modulate insulin action. It remains to establish whether lifestyle (e.g., dietary fatty acid profile and physical activity), genetic predisposition, or a combination are the prime determinants of muscle morphology (particularly membrane lipid profile) and hence insulin action.
Lipids 31, S-261–S-265 (1996).

Skeletal muscle is the major site of insulin-stimulated glucose disposal. Insulin resistance, relative failure of insulin action, and associated hyperinsulinemia are strongly linked to the development of a cluster of prevalent diseases, including noninsulin-dependent diabetes mellitus (NIDDM), obesity, hyperlipidemias, hypertension, and heart disease (1–3). While skeletal muscle insulin resistance has clearly been demonstrated in both human and experimental animal models of obesity and diabetes, the mechanisms are still poorly understood. Work from our laboratory, and others, has focused on interrelationships between fatty acid composition of muscle membrane structural lipids (phospholipids), levels of muscle storage triglyceride, muscle fiber composition, and insulin resistance. This short review is basically limited to studies in skeletal muscle and concentrates on work from our laboratory.

Muscle phospholipid composition and insulin action. A number of lines of evidence led to the current work. First, it was known from the pioneering work of Felber and colleagues (4) that diets high in fat led to increased accumulation of storage triglyceride in skeletal muscle. According to the glucose–fatty acid cycle of Randle and coworkers (5,6) and inhibitory effects of lipids on glucose storage (7), this lipid accumulation was a plausible factor in impairment of muscle glucose metabolism. The second important set of observations were noted when the euglycemic clamp for measurement of insulin action was adapted for use in rats (8,9), and the technique was further extended to use of the labeled 2-deoxyglucose method for assessing insulin action in individual tissues (10,11). Using these techniques, it was possible to demonstrate directly that high-fat feeding induced insulin resistance in individual skeletal muscles (12,13). Further, by combining ^{3}H-labeled 2-deoxyglucose and ^{14}C-labeled glucose bolus injection during the euglycemic clamp, it was possible to show that fat-feeding induced insulin resistance in both the storage and oxidation/glycolysis components of muscle glucose metabolism.

The third line of evidence came from work (14) showing hypotriglyceridemic properties of n-3 fatty acids. The question became, if high-fat diets lead to muscle insulin resistance via the accumulation of storage lipid, would inclusion of lipid-lowering n-3 fatty acids in the high-fat diet be beneficial? Indeed that was the observation. When n-3 fatty acids were substituted into a high-fat diet, insulin resistance in skeletal muscle was prevented (15). Importantly, both the storage and oxidation/glycolysis components of glucose metabolism were ameliorated by inclusion of the n-3. The observation that both components of glucose metabolism in muscle were impaired by some high-fat diets, and both ameliorated by n-3 fatty acids, was suggestive of either multiple metabolic defects or a single defect at an early, common point in the glucose metabolic pathway, perhaps at the membrane level.

This seminal observation of the profound dependency of high-fat diet–induced insulin resistance *in vivo* on the fatty acid profile of the diet was consistent with number of *in vitro* studies. These investigations have provided evidence that changes in the composition of fatty acids within membrane phospholipids strongly influence insulin action, altering both insulin binding and action. In general, the more saturated the fatty acids in membrane phospholipid, the more deleterious the effect (16,17). Further, the highly unsaturated n-3 fatty acids may be particularly beneficial (18,19). Our recent studies using L6 myocytes have extended these observations to a muscle-derived cell line (Pan and Storlien, unpublished).

Follow-up work was aimed at extending both *in vivo* and *in vitro* work in terms of elucidating mechanisms relating muscle membrane lipid profile and insulin action. An extensive study was carried out in rodents comparing a number of high-fat diets pair-fed and differing only in the fatty acid profile of the fat components (20). Results demonstrated marked intergroup differences in insulin-stimulated glucose metabolism when assessed using the euglycemic clamp. Some high-fat–fed groups progressed to major insulin resistance, and others did not, with effects particularly pronounced in skeletal muscle. As we had originally proposed, a variable closely associated with muscle insulin resistance was accumulation of storage lipid, consistent with the accepted glucose/lipid interactions. Further, since earlier results had suggested that the metabolic defect induced by some forms of high-fat feeding was at the membrane level, it was reasoned that changing the dietary fatty acid profile might also change the fatty acid profile of membrane structural lipid, and that, in turn, may influence insulin action. Indeed, improved insulin action was clearly associated with an increased percentage of longer carbon chain, more highly unsaturated fatty acids in the muscle membrane phospholipid.

The association between membrane lipid profile and insulin action in experimental animals prompted studies in humans. The first work assessed skeletal muscle phospholipid fatty acid composition in normoglycemic volunteers undergoing coronary bypass operations and from whom rectus abdominous muscle biopsies were obtained. Results were consistent with those observed in rodents. Fasting insulin level, used as an index of insulin resistance in this normoglycemic population, was inversely correlated with the percentage of long-chain polyunsaturated fatty acids (PUFA) and with the unsaturation index (UI: the number of double bonds per fatty acyl moiety $\times$ 100) in the muscle membrane phospholipid. That is, the more unsaturated the membrane lipid, the more insulin-sensitive the individual (21). A follow-up study in young, healthy subjects used the hyperinsulinemic/euglycemic clamp to assess insulin action directly, and percutaneous biopsies of the vastus lateralis were obtained. The same relationships were found in this normal group between muscle membrane phospholipid profile and insulin action (21).

Two other studies in humans, using very different study populations, further explored these relationships. Both studies used the euglycemic clamp to assess insulin action directly and analyzed vastus lateralis muscle obtained by percutaneous biopsy. Vessby and colleagues studied an older, male Swedish population (22). Relationships were again found between insulin action and muscle phospholipid fatty acid composition. Differences between Australian and Swedish results did occur, however. In the Swedish study, the highest correlation occurred with saturated fatty acids (particularly palmitic). That is, the higher the proportion of saturated fatty acids in the muscle membrane phospholipid, the more insulin-resistant the individual. In contrast to the Borkman *et al.* study (21), relationships with the highly unsaturated fatty acids were not significant.

The third study in this series of work was carried out in the diabetes- and obesity-prone Pima Indians (23). Again, results congruent with the two previous studies were found: the more unsaturated the phospholipids, the better the insulin action. Here both individual saturated and polyunsaturated fatty acids were significantly linked to insulin action.

An interesting aspect of this last study was that it confirmed and extended observations in the original study of strong relationships between insulin action and measures of activity of the Δ5-desaturase enzyme. It is clearly true that the UI of the average Western diet is much less (UI $\approx$ 80; Australian Dietary Survey, National Health and Medical Research Council, 1991) than the UI of skeletal muscle phospholipid (which averages approximately 170 in our studies). With the exception of certain marine oils, the major dietary fatty acids must all be substantially elongated and desaturated to be transformed into the fatty acids that our results have shown to be associated with insulin sensitivity. Elongase and desaturase enzymes are crucial rate-limiting elements in this transformation. Activity of these enzymes can be determined by product/precursor ratios (for example, the ratio of 20:4n-6 to 20:3n-6 gives an index of activity of the Δ5-desaturase enzyme). While not an optimal method for measuring enzyme activity, our results in humans, both in an Australian, largely Caucasian sample (21) and in Pima Indians (23), have shown remarkably strong relationships between reduced Δ5-desaturase activity (20:4n-6/20:3n-6) and insulin resistance.

The other aspect of the Δ5-desaturase enzyme is that it is common to both the n-6 and n-3 fatty acid families; as such, there is competition between n-6 and n-3 fatty acids as substrates for desaturation. Certainly it is true that n-3 fatty acids are elongated and desaturated to a greater extent (to 22-carbon 5 and 6 double-bond fatty acids) than is true for the n-6 pathway where arachidonic acid (20:4) is the normal endpoint. This may be significant at a time in human history when we have been undergoing the first major experiment of a high level of dietary intake of n-6 fatty acids. This has been an outcome, driven by the cardiovascular literature, of the move to increase polyunsaturated fat intake and reduce saturated fat intake. Polyunsaturated seed oils available over the last 30 years have been largely n-6 in makeup. We have analyzed both our Australian and Pima Indian data in terms of the relationship between the n-6/n-3 ratio, insulin action (as indexed by fasting insulin in these normoglycemic subjects),

and obesity. Figure 1 shows the results. Clearly, the higher the n-6/n-3 ratio, the worse the insulin action and the higher the relative weight level. Interestingly, Pima Indians have a much lower level (<40%) of n-3 fatty acids than the Australian, largely Caucasian, samples. In turn, Swedish subjects of Vessby had an n-3 percentage in skeletal muscle phospholipid that was much higher again than even the Australian group and over 3 times that of the Pimas. These observations presumably reflect at least in part dietary intake of n-3 fatty acids. There is also, however, very likely to be a genetic predisposition to incorporation, elongation, and desaturation of specific fatty acids. In dietary analysis of a limited number of subjects in the Borkman *et al.* (21) study, relative amounts of, for example n-3 fatty acids, did not relate at all to apparent dietary intake. It will be interesting to determine if low levels of n-3 fatty acids in Pima Indian muscle membranes relate at all to low dietary intake or reflect a genetic predisposition. It is interesting in this regard that an intestinal fatty acid binding protein (FABP) loci on chromosome 4q has been significantly linked with insulin resistance in this population (24). It is therefore possible that the "thrifty gene" (25,26) may include control, binding, and uptake of specific fatty acids and their insertion into membranes.

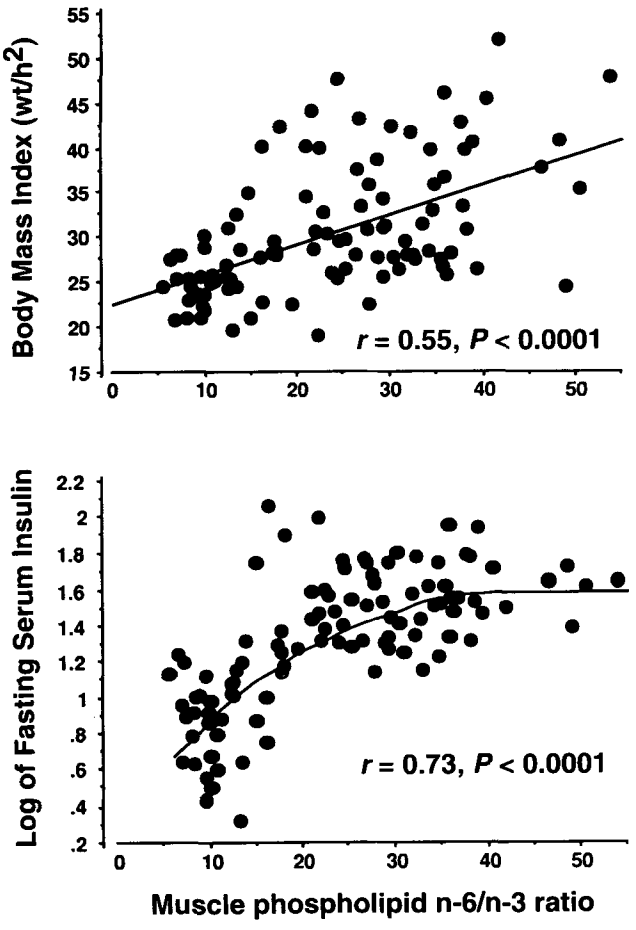

FIG. 1. Relationship between the n-6/n-3 ratio and relative adiposity (body mass index—top) and the n-6/n-3 ratio and insulin resistance (indexed by a high fasting serum insulin—bottom). The ratio of n-6/n-3 fatty acids was measured in phospholipids of muscle obtained by percutaneous biopsy of the vastus lateralis. Subjects mostly Caucasian Australians and Pima Indians (Storlien, L.H., Pan, D.A., and Lillioja, S., unpublished observations).

Relationships between muscle phospholipid fatty acid profile and insulin action have been established in adult rats and humans; however, the relative contributions of lifestyle and genetic predisposition are still unclear. In an effort to shed light on this issue, we have begun studies in human infants. Muscle biopsies are being obtained during surgery on infants who are not acutely unwell and who are near normal height and weight (operations range from talipes correction to minor gastric and cardiac repair). Initial results emphasize the major effect of diet. Breast-fed infants have a muscle membrane lipid profile much like insulin-sensitive adults. Formula-fed infants, in contrast, present a profile characteristic of insulin resistance (27). Insufficient evidence has yet been collected to assess the genetic predisposition to a certain lipid profile independent of the powerful dietary effect.

Relationship between membrane lipids and storage lipids. As noted earlier, the inhibitory effects of lipids on glucose metabolism have clearly been described (5–7). A significant feature of this glucose/lipid interaction appears to be the failure of insulin to suppress lipolysis of intramuscular storage triglyceride (28). We originally arrived at the relationship between dietary fat and insulin action via this issue. As noted earlier, a study with a large range of dietary fat profiles showed a good, inverse relationship between intramuscular triglyceride levels and insulin action in that muscle (20). In humans (29) we have now been able to show that intramuscular triglyceride levels are also closely related to whole-body insulin action independent of total adiposity. In this context it is interesting that we have recently demonstrated relationships between muscle membrane lipid composition and muscle storage lipid: the more saturated the membrane lipids, the greater the accumulation of storage lipid (30). This result is consistent with the observations of Leyton *et al.* (31), showing that more saturated fats are poorly oxidized for energy in comparison to PUFA and hence more likely to be stored (and incorporated into membranes). In addition, it is significant that, for a given carbon backbone number, n-3 fatty acids were markedly more likely to be quickly oxidized for energy than the equivalent n-6 fatty acid, which is more likely to be stored (see, for example, the 18-carbon n-6 and n-3 fatty acids).

Muscle fiber type, membrane lipids and insulin action. Finally, there are a number of aspects of muscle morphology that undoubtedly influence insulin action. One receiving current attention is the relative proportions of types 1, 2a, and 2b fibers. It has been known for some time that different fiber types exhibit enormously different sensitivity in relation to insulin's ability to promote glucose uptake (32). Type 1 (slow-twitch oxidative) and type 2a (fast-twitch oxidative/glycolytic) fibers are much more insulin-sensitive than type 2b (fast-twitch glycolytic) fibers (32). It has also been shown in humans that insulin resistance is associated with a relative in-

crease in percentage of type 2b fibers (33,34), a relative decrease in type 1 fibers (35), and indices of oxidative capacity (34,36).

To determine the relationship between muscle fiber type and membrane lipid composition, we have recently accumulated data in our laboratory on rats fed the same diet where the phospholipid fatty composition was determined on hindlimb muscles that were predominantly type 1 (soleus), type 2a (red quadriceps), or type 2b (white quadriceps). It was clear that the percentage of PUFA in membrane phospholipid was significantly higher in muscles that were predominantly of type 1 or type 2a fiber, as compared to muscles predominantly of type 2b fiber (37). Interestingly, voluntary wheel-running was able to markedly increase the percentage of type 2a fibers while lowering the percentage of type 2b fibers without significantly changing phospholipid fatty acid profile. Data such as these provide a corresponding link between muscle fatty acid composition and fiber type, which may be important in insulin action. These data support earlier suggestions (38,39), however, that factors such as diet and exercise might work synergistically via variables such as membrane lipids and fiber type to influence insulin action.

Skeletal muscle plays a major role in insulin-stimulated glucose disposal. There is now a range of evidence in humans and experimental animals demonstrating strong relationships between the fatty acid composition of structural membrane lipids and insulin action. *In vivo* work is correlative, but *in vitro* studies suggest that a causal relationship exists. There are a number of ways that a more saturated membrane lipid profile might be obtained. It may reflect dietary fatty acid profile; it may relate to a genetic alteration in the binding and subsequent incorporation of certain fatty acids (e.g., a defect in certain FABP); it may reflect a genetic defect in one or more of the enzymes of fatty acid elongation and desaturation that are necessary to turn the major dietary fatty acids into the longer-chain, more highly unsaturated fatty acids in membrane linked to good insulin action. Equally, there are a number of ways in which a more saturated membrane lipid profile might impair insulin action: these include altered insulin receptor binding and affinity as suggested by earlier work; altered ability to translocate and insert glucose transporters, and altered intrinsic activity of those glucose transporters. Hydrolysis of phospholipids in membranes will yield diacylglycerols with differing fatty acid groups, and these might interact, in their second messenger role, quite specifically with a particular protein kinase C variant for example. Work is currently under way in both *in vivo* and *in vitro* model systems to attempt to extend the evidence for the causality of the relationship between membrane lipid profile and insulin action and also to understand mechanisms involved.

Role of Lipids in Development of Noninsulin-Dependent Diabetes Mellitus: Lessons Learned from Pima Indians

National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Clinical Diabetes and Nutrition Section, Phoenix, Arizona 85016

ABSTRACT: We studied the role of lipids in the pathogenesis of noninsulin-dependent diabetes mellitus (NIDDM) in Pima Indians. High plasma levels of nonesterified fatty acid (NEFA) predicted development of NIDDM, but this effect cannot entirely be explained by the glucose–fatty acid cycle. Dyslipidemia, although often associated with diabetes, did not seem to predict NIDDM and might rather be associated with, or the consequence of insulin resistance. In some individuals, a single amino acid substitution in the intestinal fatty acid binding protein could result in increased rates of intestinal absorption of dietary NEFA and thereby contribute to increased lipid-oxidation rates and insulin resistance.

Lipids 31, S-267–S-270 (1996).

Prospective studies conducted over the past 13 years in Pima Indians have shown that obesity (especially central adiposity), insulin resistance, and impaired insulin secretion are major risk factors for the development of noninsulin-dependent diabetes mellitus (NIDDM) (1). More than 30 years ago, Randle *et al.* (2) documented that elevated nonesterified fatty acid (NEFA) concentrations result in increased fat oxidation and decreased glucose uptake and utilization in muscle. An increased production rate of NEFA from adipose tissue could therefore be responsible for insulin resistance. Insulin resistance and NIDDM are often associated with an altered lipoprotein profile, i.e., increased very low density lipoproteins (VLDL), decreased high density lipoproteins (HDL), and altered composition of low density lipoproteins (LDL) (3–6). Surprisingly, despite the abundance of information on the competition between lipid and carbohydrate metabolism at the cellular level (7–12), no prospective study has been designed to investigate the cause-and-effect relationship between high plasma NEFA concentrations and/or dyslipidemia and NIDDM. Ongoing longitudinal studies of the development of NIDDM among Pima Indians allowed us to test whether large fat cells and high rates of *in vitro* fat-cell lipolysis are associated with high plasma fasting NEFA concentrations and whether these three factors are predictive of NIDDM. We also investigated the interaction between lipoproteins and insulin resistance in development of NIDDM. Finally, we present genetic evidence that a recently identified polymorphism in a lipid binding protein gene contributes to altered lipid metabolism and predicts insulin resistance.

Predictive role of NEFA on development of NIDDM (13). We analyzed data from annual examinations of 190 nondiabetic Pima Indians. After a mean follow-up of 4.0 ± 2.4 years (mean ± SD), 47 subjects developed NIDDM. Risk factors for NIDDM were estimated by proportional hazard analysis and risk ratios (RR) with 95% confidence intervals (95% CI) calculated at the 90th and 10th percentiles of predictor variables (Table 1). Large fat cells were predictive of NIDDM (RR = 2.4; 95% CI = 12–24.8) independent of age, sex, percent body fat, and body-fat distribution. A high fasting plasma NEFA concentration was also a risk factor for NIDDM (RR = 2.3; 95% CI = 1.1–4.7) independent of sex, percent body fat, body-fat distribution, and insulin-mediated glucose uptake (Fig. 1) but not independent of insulin secretion. Basal lipid oxidation did not predict NIDDM. The relationship between fat-cell size and NIDDM is not surprising, since the volume of adipocytes is strongly related to obesity, a major risk factor for development of NIDDM (1). It is likely that larger fat cells have higher rates of lipolysis, leading to increased plasma NEFA concentrations. This hypothesis is supported

TABLE 1
Nonesterified Fatty Acids and Development of Noninsulin-Dependent Diabetes Mellitus[a]

Factors from which NEFA effect is independent	Risk ratio	95% Confidence interval
Age, sex, percent body fat, waist/thigh[b]	2.2	1.1–4.2
Sex, percent body fat, M[c]	2.1	1.1–4.2
Sex, percent body fat, M, fat cell size	2.0	0.9–4.1
Sex, percent body fat, M, acute insulin response	2.0	0.7–5.3

[a]Risk ratios and 95% confidence intervals are presented when comparing the 90th (485 μM) and 10th (248 μM) percentiles of plasma nonesterified fatty acid (NEFA) concentrations.
[b]Waist/thigh is an index of body-fat distribution.
[c]M = Insulin-mediated glucose uptake.

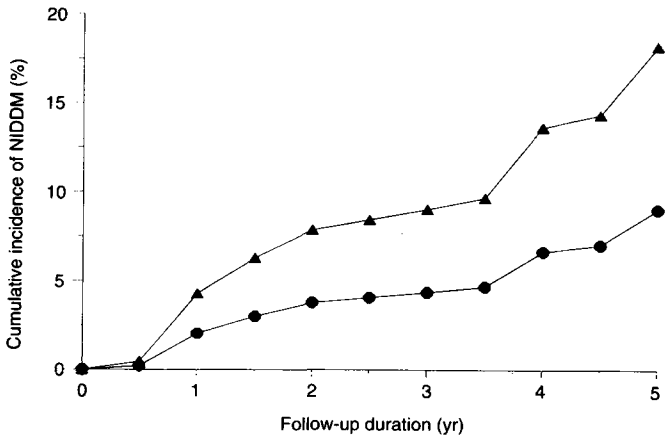

FIG. 1. Cumulative incidence (in percent) of developing noninsulin-dependent diabetes mellitus (NIDDM) for subjects at the 90th (485 μM) (▲) and 10th (248 μM) (●) percentiles of nonesterified fatty acid (NEFA) distribution. The predictive effect of NEFA is adjusted for differences in sex, percent body fat, and insulin-mediated glucose uptake (adapted from Ref. 13).

by our previous data showing that the size of the fat depot, rather than the basal rate of lipolysis *per se*, determines NEFA availability (14). In the present study, such a mechanism was also suggested by the positive correlation among average fat-cell size, basal lipolysis, and fasting plasma NEFA concentration.

The inhibitory role of NEFA on glucose disposal was proposed by Randle *et al.* more than 30 years ago (2). Subsequent clinical studies have detailed the physiological role of NEFA in regulating glucose as well as glycogen metabolism in peripheral tissues (12,15,16). The glucose–fatty acid cycle, however, cannot entirely explain the effect of NEFA on development of NIDDM since, in our study, (i) fasting plasma NEFA concentrations predicted NIDDM independently of insulin-mediated glucose uptake; (ii) basal lipid oxidation was not a significant predictor of NIDDM; and (iii) the predictive value of fasting NEFA concentrations on the development of NIDDM disappeared after adjusting for acute insulin secretion (Table 1). The last finding suggests that NEFA may increase the risk of NIDDM by inhibiting insulin secretion. This hypothesis is now supported by *in vitro* as well as *in vivo* data (17–19).

Circulating NEFA levels can affect liver metabolism. NEFA inhibit insulin receptor binding and tyrosine kinase activity in isolated hepatocytes (20) and provide energy for gluconeogenesis, thus increasing hepatic glucose output (21,22). Recently, Rebrin *et al.* (23) have suggested that insulin suppresses hepatic glucose output not directly, as generally believed, but via its regulatory action on plasma NEFA concentrations.

Predictive role of lipoproteins on development of NIDDM (24). The cross-sectional association between plasma lipoprotein abnormalities (high plasma VLDL, small dense LDL particles, and low HDL concentrations) and insulin resistance/diabetes has been well documented (3–6). Cross-sectional studies, however, cannot dissociate between cause and effect. The RR associated with each lipoprotein for the development of NIDDM is reported in Table 2. After adjustment for insulin-mediated glucose uptake, high LDL and low HDL plasma concentrations were no longer predictive of development of NIDDM. None of the lipoproteins were predictive of a worsening in insulin-mediated glucose uptake. Along with several other lines of evidence (25–28), the present study provides longitudinal data to support the idea that dyslipidemia is not causative of diabetes but, on the contrary, insulin resistance might be a possible determinant of the changes in lipoprotein profile in NIDDM.

Intestinal fatty acid binding protein and lipid metabolism. We have previously reported genetic linkage between measures of insulin action in Pima Indians and a region on chromosome 4q, which includes the intestinal fatty acid binding protein locus (*FABP2*) (29). The *FABP2* locus encodes the human intestinal fatty acid binding protein (IFABP), which binds dietary long-chain fatty acids and is expressed solely in the enterocytes of the proximal small intestine. We identified a polymorphism at codon 54 of this gene that results in an alanine-encoding allele (frequency 0.71) and a threonine-encoding allele (frequency 0.29). We have shown that the threonine-containing protein (Thr54-IFABP) has a twofold greater affinity for long-chain fatty acids than the alanine-containing protein (Ala54-IFABP) (30). In addition, cultured intestine-like cells expressing Thr54-IFABP transport long-chain fatty

TABLE 2
Unadjusted Risk Ratios and 95% Confidence Intervals for Fasting Plasma Lipoproteins and Development of Noninsulin-Dependent Diabetes Mellitus

	10th Percentile (mg/dL)	90th Percentile (mg/dL)	Risk ratio	95% Confidence interval
VLDL cholesterol[a]	7.0	23.0	1.2	0.7–2.1
LDL cholesterol[b]	79.0	141.0	0.7	0.3–1.6
HDL[c] cholesterol[d]	28.0	48.0	2.6	1.1–5.9

[b]LDL = Low density lipoproteins.
[c]HDL = High density lipoproteins.
[d]For HDL, the 10th vs. the 90th percentile of fasting plasma concentrations were compared; for all others, the 90th vs. the 10th percentile were compared.

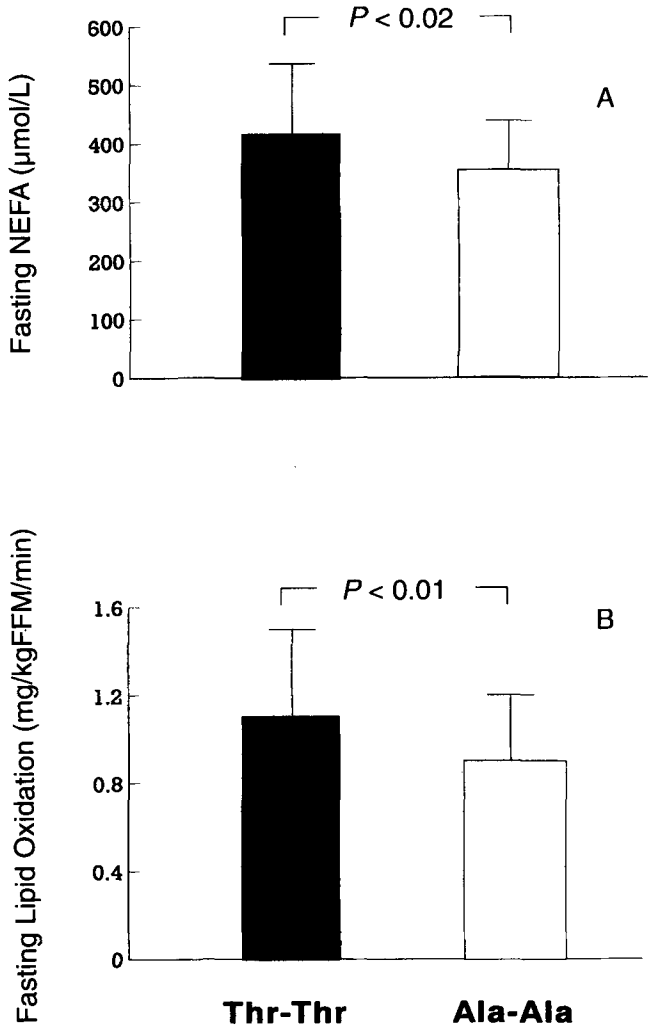

FIG. 2. A) Fasting plasma nonesterified fatty acid (NEFA) concentrations and B) lipid oxidation rates in 89 Pimas homozygous for the Thr54-intestinal fatty acid binding protein (IFABP) allele (Thr-Thr) compared to 21 Pimas homozygous for the Ala54-IFABP allele (Ala-Ala).

acid from the apical to basolateral membranes more rapidly than do cells expressing Ala54-IFABP (31). Consistent with these findings, Pimas homozygous for Thr54-IFABP had significantly higher plasma fasting NEFA concentrations and fasting lipid oxidation rates, as compared to Pimas homozygous for Ala54-IFABP (Fig. 2). Furthermore, Pimas homozygous or heterozygous for the threonine-encoding allele showed higher mean fasting insulin concentrations, higher insulin responses to oral glucose and a mixed meal, and lower insulin-stimulated glucose uptake when compared to subjects homozygous for the alanine-encoding allele (30). We are currently directly testing the hypothesis that individuals expressing Thr54-IFABP have an increased rate of transport of NEFA across the intestine compared to individuals expressing Ala54-IFABP. This may explain the association of Thr54-IFABP genotype with increased lipid oxidation rates and insulin resistance.

The role of lipids in the pathogenesis of NIDDM has been studied for more than 30 years, ever since Randle's first report of a glucose–fatty acids cycle, i.e., a competition among substrates for the oxidative pathways at the cellular level. Longitudinal studies conducted over the past 13 years in Pima Indians have shown that high plasma NEFA levels predict development of NIDDM. The effect of NEFA on NIDDM, however, cannot entirely be explained by the Randle cycle, since this effect is still present after adjusting for insulin-mediated glucose uptake. We have also shown that dyslipidemia, often associated with diabetes, does not seem to have a causative role in the development of the disease. In contrast, our analysis indicates that abnormalities in the lipoprotein profile are either associated with or a consequence of insulin resistance. Finally, we have provided evidence that a single amino acid substitution in the IFABP could result in increased rates of intestinal absorption of dietary NEFA and thereby contribute to increased lipid oxidation rates and insulin resistance.

Arachidonic Acid Maldistribution in Obesity

Stephen D. Phinney*

Division of Clinical Nutrition and Metabolism, Department of Internal Medicine, University of California, Davis, California 95616

ABSTRACT: Arachidonic acid is an important regulator of cellular function via its effects on the physical properties of membranes, in its free form, or as a substrate for eicosanoids. Dietary studies indicate that its production is regulated, but the mechanisms of this regulation and factors influencing arachidonate distribution from the site of production remain to be determined. In particular, whether there is a nonoxidative fate for arachidonate once it has been released from phospholipid has yet to be determined. Variations in the arachidonate content of serum, liver, and muscle lipid fractions have been correlated with alterations in lipogenesis and insulin action, implying a role for arachidonate in fuel partitioning. Evidence for this mechanism acting systemically has been found in genetic models of obesity in rodents and also in humans. This review proposes that variation in the distribution of arachidonate between phospholipid and cholesteryl ester fractions participates in the abnormal fuel partitioning associated with some forms of genetic obesity.

Lipids 31, S-271–S-274 (1996).

Both genetic and environmental factors play roles in the etiology of human obesity. To the extent that it is a factor in an individual, genetic variability only predisposes a person to weight gain, rather than determining the disease with certainty. Overfeeding and underfeeding studies of identical twins indicate that genetic variability is determined, in part, by varying propensities for lipid storage as opposed to its oxidation (1,2), but the biochemical mechanisms for this variability in fuel partitioning remain unknown. This paper presents the case for interindividual variability in the distribution of arachidonate (20:4n-6) between phospholipids (PL) and cholesteryl esters (CE) as an indicator of, if not an etiologic factor for, interindividual variability in fuel disposition and obesity.

In initial studies to determine if essential fatty acid (EFA) deficiency could result from extreme restrictions in fat intake during hypocaloric dieting, it was noted that obese humans had lower levels of 20:4n-6 in serum PL compared to nonobese normals (3,4). With initiation of dieting, the arachidonate in PL of obese patients quickly rose to normal and remained increased during rapid weight loss, but it rapidly declined when weight loss stopped. Thus the paucity of PL 20:4n-6 initially observed during obesity did not resolve following major weight loss (4). That this reduction in the proportion of 20:4n-6 in PL might be physiologically linked to obesity is suggested by our prior observation that a reduction in hepatocyte PL arachidonate is associated with accelerated lipogenesis and triglyceride (TG) secretion (5). Based on the observation that increased provision of fat does not increase its oxidation (6), we hypothesized that increased disposal of carbohydrate to fat would favor adipocyte lipid storage (4). Subsequently, Borkman *et al.* (7) reported that reduced 20:4n-6 in human muscle PL is associated with increased insulin resistance. Assuming that reduction in PL arachidonate in obesity is systemic (i.e., reduced muscle PL 20:4n-6 accompanies its paucity in liver), this would serve to reduce peripheral glucose disposal and concurrently enhance hepatic glucose use for lipogenesis as a secondary disposal pathway.

Using precursor/product ratios in muscle PL as an indirect measure of enzyme activity, Borkman *et al.* proposed that reduced muscle PL 20:4n-6 was due to impaired action of the Δ5-desaturase enzyme (7). Specifically, they observed that an increased proportion of 20:3n-6 and reduced 20:4n-6 was associated with insulin resistance, and from this they inferred a causal relationship between reduced action of the intervening enzyme (Δ5-desaturase) and insulin action (Fig. 1). Because arachidonic acid is predominantly produced in the liver, however, the level of its precursor in muscle is probably not the best indicator of substrate availability. Thus liver lipid fractions would be more desirable in determining precursor/product ratios, so an animal model of obesity and insulin resistance is desirable.

Two recent reports noted reduced liver PL 20:4n-6 in the obese Zucker rat (8,9), making this a good animal model to assess the relationships among fatty acids, lipogenesis, and obesity. Both reports (8,9) hypothesized impaired production of 20:4n-6 due to reduced desaturase activity, again based on precursor/product relationships in liver PL. To test the hypothesis that Δ6-desaturase is the etiologic factor causing reduced PL 20:4n-6 in this animal model, we fed lean (FaFa) and obese (fafa) weanling male Zucker rats 70 μL γ-linolenic acid (18:3n-6) by gastric gavage and compared weight gain, food intake, and percent carcass fat to analogous groups given an equal volume of soy oil by gavage (10). Following 60 days of *ad libitum* food intake, the soy oil gavage had no effect on food intake or body composition of either the lean or obese animal groups compared to chow-fed, nongavage controls. Likewise, food intake, weight gain, and per-

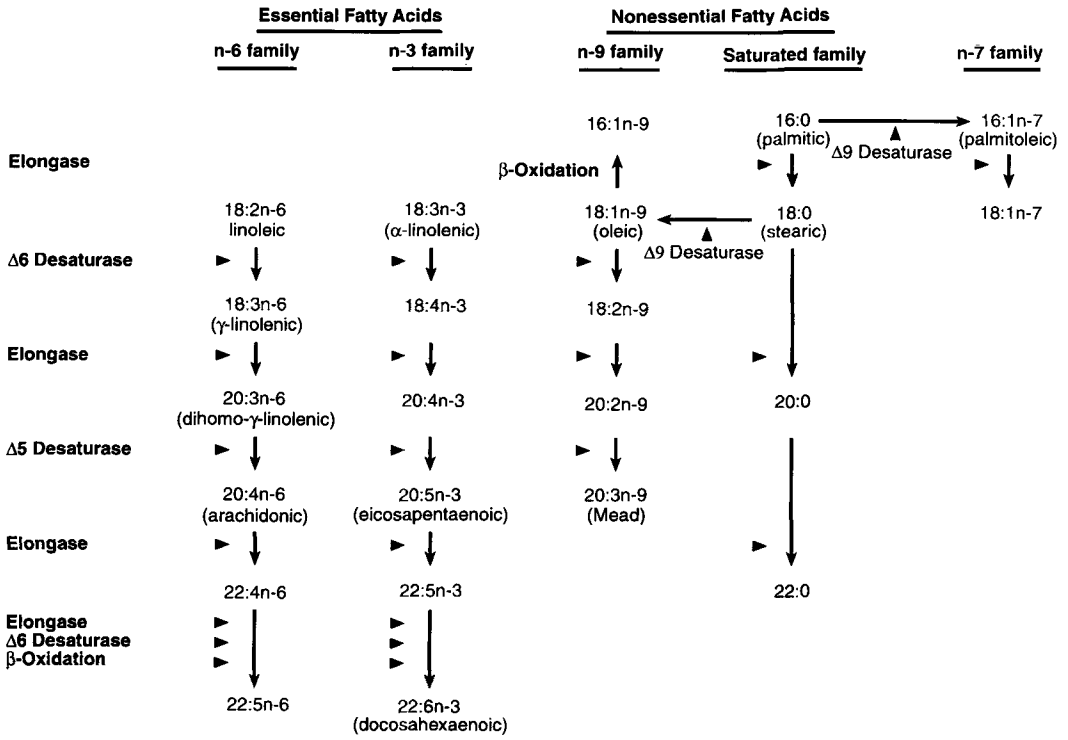

FIG. 1. Pathways involved in the endogenous modification (anabolism) of dietary fatty acids. Of particular note is the common use of the Δ6- and Δ5-desaturases in the production of the essential and nonessential highly unsaturated products 20:4n-6, 20:5n-3, and 20:3n-9.

cent carcass fat of lean animals gavaged with 18:3n-6 were no different than soy-gavaged controls. The group of obese animals gavaged with 18:3n-6, however, had markedly reduced food intake and weight gain and marginally reduced percent body fat compared to soy-gavaged obese controls. Liver PL 20:4n-6 in obese animals gavaged with 18:3n-6 was increased to normal levels by this procedure, implying that impaired Δ6-desaturase in this genotype had been overcome by the 18:3n-6 gavage. Following analysis of additional lipid fractions, however, it was noted that liver CE 20:4n-6 was dramatically increased in the soy-gavaged obese animals as compared to leans, and this excess proportion of 20:4n-6 was also seen in serum CE of both obese animal groups. An additional observation was that of marked elevation in proportions of 20:5n-3 and Mead acid (20:3n-9) in liver and serum PL and CE fractions in obese controls, with the proportions of both being reduced with 18:3n-6 administration.

Our observation of increased 20:4n-6 in liver CE of obese animals makes it unlikely that there is impaired desaturase activity (either Δ6 or Δ5) in the obese Zucker rat. While we did observe elevated proportions of both 18:3n-6 and 20:3n-6 in liver and serum PL and CE fractions in obese animals as compared to leans, an alternate explanation for their increased levels is that 20:4n-6 is being removed from PL at an accelerated rate, accumulating in the CE fraction. If PL 20:4n-6 is the feedback pool that regulates substrate entry into the fatty acid anabolic pathway (Δ6-desaturase, elongase, Δ5-desaturase), then pathway flux would be accelerated to compensate with increased 20:4n-6 production, leading to increases in its two metabolic intermediates. This would also result in enhanced production of 20:5n-3 from 18:3n-3, and 20:3n-9 from 18:1n-9. With the provision of 18:3n-6, however, the Δ6-desaturase step would be bypassed, more 20:4n-6 would be produced, and secondary product output by the anabolic pathway would be reduced. These conditions, all observed in our experiment reported in (10), are summarized here in Table 1.

Taken in total, these observations strongly support the concept of a metabolic shift (i.e., a maldistribution) of 20:4n-6 from PL to CE in the obese Zucker rat. Key to this understanding are proportionate elevations in serum and liver CE 20:4n-6 in the obese genotype, as well as increases in secondary products of the fatty acid anabolic pathway in liver and serum PL and CE fractions. That 18:3n-6 given to the obese animal nonetheless reduced food intake, weight gain, and percent body fat, while the identical dose had no effect on the lean genotype, strongly indicates an etiologic role for altered 20:4n-6 homeostasis in this animal model of genetic obesity.

The Zucker rat is a popular animal model used in the study of genetic obesity, in part because its single gene defect results in dramatic phenotypic characteristics between lean and

TABLE 1
Summary of 18:3n-6 Feeding Experiment in Obese Zucker Rats (10)

Condition	Expected result
Increased[a] 20:4n-6 loss from PL[b] to CE[c]	Reduced[a] PL 20:4n-6 Increased CE 20:4n-6 Increased fatty acid anabolic activity (i.e., increased 18:3n-6, 20:3n-6, 20:3n-9, 20:5n-3)
Increased lipogenesis due to reduced PL 20:4n-6	Increased lipogenic products (i.e., 16:0, 16:1) Decreased essential precursors (18:2n-6, 18:3n-3)
Feeding 18:3n-6 to obese genotype	Increased liver 20:4n-6 in PL Reduced secondary products (20:3n-9, 20:5n-3) Reduced lipogenesis and body fat

[a]Increased and reduced are relative to lean control animals fed soy oil.
[b]PL = phospholipids.
[c]CE = cholesterol esters.

obese animals. It differs markedly from the human disease, however, in that the latter is thought to result from variations in multiple genes. To assess potential for a distributional abnormality in 20:4n-6 in a multigenic animal model of obesity, we determined liver lipid fraction fatty acid composition from BSB mice ranging in percent body fat from 1 to 48% (11). In this animal model of obesity, unlike our finding in the Zucker rat, there was no correlation between liver PL 20:4n-6 and percent carcass fat. There was a strong positive relationship, however, between CE 20:4n-6 and carcass fat, consistent with our hypothesis of diversion of arachidonate out of the PL pool. In addition, liver PL Mead acid and 20:5n-3 were also increased in the animals with the greater percent carcass fat, supporting the concept that there is increased production of 20:4n-6 in obesity via an activated fatty acid anabolic pathway, with parallel increases in secondary products such as 20:5n-3 and Mead acid. Thus 20:4n-6 also appears to be maldistributed into the CE fraction in this animal model, but the varying degrees of reduced 20:4n-6 in PL between BSB mice and Zucker rats suggest genotype or species differences. The physiological importance of these observations in the BSB mouse is reinforced by the observation that liver CE 20:4n-6 is correlated with fasting plasma insulin (12), implying that the shift of 20:4n-6 from PL into CE is involved with impaired insulin action in the periphery.

Although increased proportions of Mead acid and reduced linoleic acid are seen in multiple lipid fractions of obese rats and mice (10,11), this should not be taken as a sign of EFA deficiency. Mead acid appears to be increased due to overall increased fatty acid anabolic pathway flux [also seen in human vegetarians (3)]. Reduced 18:2n-6 is secondary to the dilutional effects of lipogenic products such as 16:0, 16:1, and 18:0 entering the hepatic TG pool.

Another consistent finding across species is elevated 20:3n-6 with obesity. This is consistent with the observations of others (13) and viewed in isolation could be interpreted as due to reduced Δ5-desaturase activity in obesity. Pending cloning of the Δ5-desaturase gene such that we can directly quantitate its expression, this issue cannot be definitely resolved. The increased proportion of Mead acid and 20:5n-3, however, as well as the consistent observation of excess 20:4n-6 in CE fractions, strongly supports the alternative view that maldistribution rather than impaired production is extant. In this context, reliance on precursor/product ratios derived for one fatty acid family in a single PL pool should be interpreted with caution.

Based on the described animal experiments, the most consistent changes in fatty acid distribution in obesity are accumulation of 20:4n-6 in liver CE and increases in 20:5n-3 and 20:3n-9 in all PL pools. In humans with variable intakes of 18:3n-3 and in animal models fed oil low in 18:3n-3 (such as corn, olive, or safflower), however, a secondary increase in 20:5n-3 is unlikely. In addition, it appears that serum levels of 20:4n-6 in PL and CE are very sensitive to energy balance, rising with energy restriction and possibly declining with overfeeding. This variability makes serum fatty acids a less-than-consistent biomarker of obesity when energy intake is not effectively controlled.

Another important concern with our hypothesis of altered arachidonic acid distribution in genetic obesity is that it is observed across species involving a variety of separate genetic loci. In view of the central role played by arachidonic acid in regulation of cellular and organ function, however, it is likely that many genetic loci will participate in the regulation of its production and distribution. If these factors in turn influence a variety of parameters of carbohydrate and lipid fuel partitioning (e.g., lipogenesis and insulin resistance), the result could be an elegant pattern of varied energy efficiencies within a species in which multiple genes are involved. Indeed, the alterations in fuel partitioning induced by growth hormone may be due in part to alterations in the production and distribution of arachidonate (14).

In summary, these observations suggest that dynamics of 20:4n-6 production and distribution are important in regulation of lipogenesis, insulin action, and obesity in animal models and in humans. While direct measurements of 20:4n-6 flux have not been made, increased levels of secondary products such as 20:5n-3 and Mead acid can be used to infer activity of the fatty acid anabolic pathway. This, in combination with elevated proportions of 20:4n-6 in CE, supports the concept that desaturase activities are not significantly impaired in obesity. Molecular mechanisms resulting in distributional abnormalities of arachidonic acid in genetic obesity remain to be elucidated.

Gender Differences in Insulin-Induced Free Fatty Acid Suppression: Studies in an African American Population

Anne E. Sumner*, Harvey Kushner, Christina A. Lakota, Bonita Falkner, and Julian B. Marsh

The Medical College of Pennsylvania and Hahnemann University, Philadelphia, Pennsylvania

ABSTRACT: This study of African Americans (AA) was designed to investigate gender differences in insulin-induced free fatty acid (FFA) suppression. Sixty AA (34 women, mean age 34 ± 7.6 years, and 26 men, mean age 30 ± 2.9 years) participated. All subjects had an oral glucose tolerance test (OGTT). Nineteen women and 18 men also underwent a euglycemic hyperinsulinemic clamp (IC) study. Plasma insulin and FFA concentrations were obtained during both tests at 0, 60, and 120 min. While there was no gender difference in body mass index ($P = 0.21$), women had greater percent body fat ($P < 0.001$) calculated by the Siri formula. There was no gender difference in fasting FFA levels, but during the OGTT, women compared to men had significantly greater FFA suppression. Both nonobese and obese women suppressed FFA concentration by 88%, and nonobese and obese men suppressed FFA concentration by 80 and 66%, respectively. This gender difference in FFA suppression was significant ($P = 0.001$) and independent of obesity and insulin concentration. During the IC studies, there were no gender or obesity differences in FFA suppression, with women and men suppressing FFA levels by 87–89% ($P = 0.7$). Fasting insulin concentrations were higher in obese vs. nonobese ($P = 0.03$), but fasting FFA concentrations were not different ($P = 0.15$). For nonobese and obese females, fasting FFA levels were 0.55 ± 0.24 and 0.44 ± 0.26 mEq/L, respectively, and for nonobese and obese males, 0.45 ± 0.2 and 0.35 ± 0.18 mEq/L, respectively. In women, development of obesity may be enhanced by greater sensitivity to insulin-induced FFA suppression as measured during an OGTT. To detect gender differences in FFA metabolism, the OGTT is superior to the IC. The lack of elevation in fasting FFA levels in obese AA women and men has not been reported in other racial groups and may indicate a greater adipocyte sensitivity to insulin in AA.

Lipids 31, S-275–S-278 (1996).

African American (AA) women have a higher prevalence of obesity than do AA men (1). After the age of 25, 34% of AA women are obese, compared to 18% of AA men, and after the age of 45, 61% of AA women are obese, compared to 41% of AA men (1). Obesity in AA women is independent of socioeconomic status (1).

To better understand the metabolic basis for the development and maintenance of this excess obesity in AA women, adipocyte sensitivity to insulin could be studied (2). As free fatty acid (FFA) release by adipose tissue is a major determinant of FFA levels (3,4), *in vivo* adipocyte sensitivity to insulin can be assessed by obtaining FFA concentrations during an oral glucose tolerance test (OGTT) (5) or a hyperinsulinemic clamp (IC) (3,4). It is unknown whether an OGTT or an IC has greater sensitivity in studying gender differences in FFA metabolism.

This study was designed to determine if there are gender differences in insulin-induced FFA suppression in AA.

MATERIALS AND METHODS

Sixty clinically well, nondiabetic AA (34 premenopausal women, mean age 34 ± 7.6 and 26 men, mean age 30 ± 2.9, age range 21–37) participated. Obesity was defined as a body mass index (BMI) ≥ 28 (kg/m^2). Anthropometric measures were performed (arm circumference, skinfold thicknesses). From anthropometric measures, using the Siri equation, percent body fat and total body fat were calculated (6). Each subject had a 75 g OGTT. Thirty-seven of the participants (19 women and 18 men) also underwent a 2-h euglycemic IC, performed according to previously described methods (7). During both the OGTT and IC, plasma FFA and insulin concentrations were determined at 0, 60, and 120 min. Plasma FFA levels were determined by the enzymatic colorimetric method (Wako NEFA C test, Osaka). Plasma insulin concentrations were determined with a solid-phase radioimmunoassay (Coat-A-Count, Diagnostic Products Corporation, Los Angeles). The protocol of the study was approved by the Institutional Review Board of the Medical College of Pennsylvania. Statistical differences between obesity groups and gender were determined using a two-way analysis of variance (ANOVA) with a test for interactive effects. All values are expressed as mean ± SD unless otherwise indicated.

RESULTS

The mean age of the women was 4 years higher than that of the men, but all the women were premenopausal and menstruated regularly. BMI was similar in women and men (30.2 ±

6.9 vs. 27.6 ± 5.6 kg/m^2, respectively, $P = 0.12$) but women had significantly greater body fat in kilograms (30.4 ± 10.2 vs. 20.8 ± 8.5, $P = 0.001$) and percent body fat (36.1 ± 5.9 vs. 22.8 ± 6.6, $P = 0.001$). In Table 1 anthropometrics are provided by gender within each obesity group, that is, BMI ≤ 28 or ≥ 28. By BMI and arm circumference, women and men were the same size, but by skinfold thicknesses, % body fat, and total body fat in kilograms, women were significantly more obese.

Women and men had similar fasting insulin and FFA concentrations (Fig. 1). During the OGTT, at 120 min women had greater percent suppression of FFA ($P = 0.001$) (Fig. 2A). This gender difference was independent of obesity and insulin concentrations. During the IC, there was no gender difference in percent suppression of FFA (Fig. 2B). The area under the insulin curve was similar during the OGTT and IC. This means that gender differences seen during the OGTT vs. the IC cannot be attributed to differences in insulin concentrations between these two types of tests.

When obese subjects were compared to the nonobese, the obese had higher fasting insulin concentrations ($P = 0.03$) (Fig. 1A). Obese subjects were also noted to have lower fasting FFA concentrations than the nonobese, with this difference approaching significance ($P = 0.08$) (Fig. 1B).

DISCUSSION

Examination of the effect of insulin on serum FFA levels may help determine the metabolic basis for the high prevalence of female obesity in AA. Insulin affects FFA concentration in three ways: first, by inhibiting lipolysis; second, by promoting reesterification, and third, by decreasing FFA oxidation. Of these three factors, the major effect of insulin appears to be to regulate a balance between lipolysis and reesterification (3,4,8).

We found that, despite similar BMI in women and men, women had significantly greater body fat content (Table 1). During the OGTT, women suppressed FFA concentration significantly more than did men ($P = 0.001$). This gender difference was independent of obesity and insulin concentration. Therefore, if women and men have similar insulin concentrations but women suppress more, then women appear more

FIG. 1. A) Fasting insulin concentrations during the oral glucose tolerance test (OGTT). The number of women and men in each group is provided in Table 1. Data are presented as means ± SE, with data analyzed by two-way analysis of variance. Fasting insulin concentration was significant by obesity group ($P = 0.03$) but not by gender ($P = 0.13$). B) Fasting free fatty acids (FFA) concentrations during the OGTT. Data are presented and analyzed as described for A). Fasting FFA concentration by obesity group approached significance at $P = 0.08$. Gender difference was not significant ($P = 0.15$).

FIG. 2. A) Percent suppression of FFA during the OGTT. The number of women and men in each group is provided in Table 1. Data are presented as means ± SE. Data was analyzed by two-way analysis of variance (ANOVA). Gender difference in percent suppression of FFA was significant ($P = 0.001$). B) Percent suppression of FFA during the hyperinsulemic clamp (IC). Data are presented and analyzed as described for Figure 1A. The number of subjects in each group for the IC is as follows: nonobese women (10) and men (8) and obese women (9) and men (10). By two-way ANOVA, gender difference in percent suppression of FFA was not significant ($P = 0.7$). Abbreviations as in Figure 1.

sensitive to insulin-induced FFA suppression than men. Because insulin is a profoundly lipogenic hormone, this increased sensitivity to insulin in women could promote development and maintenance of obesity.

In contrast to the gender difference seen in FFA suppression during the OGTT, there was no gender difference with the IC ($P = 0.7$) (Fig. 2B). As men achieve maximum suppression during the IC, men do not appear to have a defect in insulin responsiveness (9). For men during the IC, exposure to a primed continuous intravenous infusion of exogenous insulin appears to overcome resistance to insulin secreted endogenously during the OGTT. Therefore, to study gender differences in FFA metabolism, the OGTT may be superior to the IC.

AA women are more obese than are AA men (1). There is a suggestion in our findings, however, that both AA men and women are more sensitive to insulin-induced FFA suppression than are other racial groups. If true, this insulin sensitivity to FFA suppression could promote obesity in AA men as well as in AA women. Racial differences in body size were found in the NHANES II (National Health and Nutrition Examination Survey II) data, which showed that, between the ages of 35 and 55, AA men are heavier than Caucasian men (1). Further, after the age of 12, female obesity is twice as common in AA as compared to Caucasians (1). In London, McKeigue *et al.* (5) performed 75 g OGTT with FFA concentrations determined at 0 and 120 min in 632 Europeans and South Asians. They found significant gender differences, but no racial differences. In their study, women suppressed FFA levels by 69%, and men by 55% ($P < 0.001$). AA women in our study suppressed FFA by 88%, and men suppressed 69–80%, depending on their obesity group (Fig. 2A). While FFA concentrations in our two studies were measured by different techniques, and the London study combined both the obese and nonobese, the degree of difference in FFA suppression in our two studies suggests there may be true population differences.

We found that obese AA had lower fasting FFA concentrations than did the nonobese (Fig. 1B). This difference approached significance at a P value of 0.08 and was present despite a significantly higher fasting insulin concentration in the obese ($P = 0.03$) (Fig. 1A). Studies that compared fasting FFA concentrations of obese and nonobese subjects reported higher FFA in the obese (2,10–15). These reports resulted from studies conducted on small samples of subjects ranging from 12 to 31. Our study population was considerably larger, composed of subjects within a narrow age range, and was clinically well.

Because we did not perform kinetic studies, we cannot determine the metabolic basis for the lower fasting FFA concentrations in obese AA subjects. In kinetic studies (4,8), it appears that differences in FFA levels between individuals are secondary predominantly to differences in rates of reesterification. Differences in rates of adipocyte antilipolysis are not as likely to be factors because antilipolysis in both the obese as well as the nonobese has been shown to be exquisitely insulin-sensitive (2,8,10). If differences in FFA regulation are based on differences in reesterification, then our obese subjects would have enhanced rates of reesterification. This is in contrast to obese subjects studied by Nestel *et al.* (8) with higher fasting FFA and decreased rates of reesterification. We know of no *in vivo* FFA kinetic studies in AA, but there is substantial evidence to suggest that FFA metabolism may be different in AA than in Caucasians. First, in autopsy studies in New Orleans where epidemiologic evidence suggests that the dietary fatty acid intake was similar in AA and Caucasians, fatty acid composition of their adipose tissue was different (16). Second, in *in vitro* studies of adipose tissue obtained by biopsy from those of Africans living in Canada and Caucasian Canadians, significant racial differences in sensitivity to epinephrine induced lipolysis were demonstrated (17). Yet *in vitro* studies are inadequate predictors of *in vivo* FFA metabolism precisely because *in vitro* studies cannot measure rates of reesterification (18). Therefore, to determine metabolic mechanisms for the lower FFA concentrations in obese AA *in vivo* turnover studies must be performed.

In conclusion, greater suppression of FFA during the OGTT in women compared to men suggests a greater adipose tissue sensitivity to insulin, which could promote development and maintenance of female obesity. To determine gender differences in insulin suppression of plasma FFA concentrations, the OGTT may be superior to the IC. As obese AA did not have elevated fasting plasma FFA concentrations, as reported in other populations (2,10–15), AA may have a greater adipocyte sensitivity to insulin.

Trans, n-3, and n-6 Fatty Acids in Canadian Human Milk

W.M.N. Ratnayake[a,*] and Z.-Y. Chen[b]

[a]Nutrition Research Division, Food Directorate, Health Protection Branch, Health Canada, Ottawa, Ontario, K1A 0L2 Canada, and
[b]Department of Biochemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

ABSTRACT: The presence of *trans* fatty acids in human milk may be a concern because of their possible adverse nutritional and physiological effects on the recipient infant. The mother's diet is the source of human milk *trans* fatty acids, and since these fatty acids are prevalent in many common foods of the Canadian diet, the *trans* fatty acid content and the fatty acid composition of Canadian human milk were measured by gas–liquid chromatography coupled with silver nitrate–thin layer chromatography. In samples obtained from 198 lactating mothers across Canada, the average percentage of total *trans* (sum of *t*18:1, *t*18:2, and *t*18:3) was 7.2% of breast milk fatty acids with a range of 0.1–17.2%. Analysis of *t*18:1 isomer distribution indicated that partially hydrogenated vegetable oils are the major source of these *trans* fatty acids in human milk, whereas contribution from dairy products appeared to be relatively minor. Linoleic and α-linolenic acid levels were inversely related to the total *trans* fatty acids, indicating that the elevation of *trans* fatty acids in Canadian human milk is at the expense of n-3 and n-6 essential fatty acids. Levels of arachidonic and docosahexaenoic acids did not correlate with their parent fatty acids, indicating that it might be difficult to elevate the levels of n-6 and n-3 C_{20-22} polyunsaturated fatty acids in breast milk by increasing levels of linoleic and α-linolenic acids in the mother's diet.
Lipids 31, S-279–S-282 (1996).

It is well established that *trans* and other unusual isomers of oleic and linoleic acids (1–4) that originate primarily from partially hydrogenated vegetable oil (PHVO) are transferred to human milk through maternal diets and subsequently passed on to infants (5). Several clinical studies have indicated that *trans* fatty acids (TFA) may exert some negative biological effects on the recipient infants (6–8). Particularly, TFA seem to impair the desaturation and elongation of linoleic and α-linolenic acids to their C_{20} and C_{22} polyunsaturated fatty acid (LCP) metabolites and early growth of human infants (5–8). n-6 and n-3 LCP metabolites are essential membrane components, and adequate supply of them may be required for synthesis and maturation of the central nervous system during late fetal and early postnatal growth (9).

Large amounts of PHVO are being used in Canada. For example, in 1993, Canada deodorized 807,000 tons of edible oil (mainly canola, followed by soybean), of which approximately 58% was hydrogenated for use in the manufacture of margarine (156,000 tons) and other shortenings (313,000 tons) (10). Shortenings are used in a variety of applications, including deep-fat frying in restaurants and in common bakery foods (breads, cakes, cookies, crackers, pastries, and so forth). This widespread use of PHVO in adult diets prompted us to determine the *trans* and other fatty acids in Canadian human milk. Detailed reports of this study have been published elsewhere (11,12).

MATERIALS AND METHODS

Samples of mature milk (3–4 wk after parturition) were collected from 198 lactating women across Canada. Donors were requested to express about 3–4 mL of their milk manually during each feeding starting from the very first feeding to the last feeding of the day. The collection from each donor thus represented her daily milk sample. Fat from a 5-g milk sample was extracted with $CHCl_3$-MeOH (2:1) and methylated with BF_3-MeOH. Fatty acid composition was determined by capillary (gas–liquid) GLC (SP-2560 flexible fused silica capillary column, 100 m × 0.25 mm i.d.; Supelco, Inc., Bellefonte, PA) after separating the *t*18:1 and *c*18:1 groups by $AgNO_3$-TLC (11). Positional and geometrical isomers of oleic and linoleic acids were identified as described previously (2).

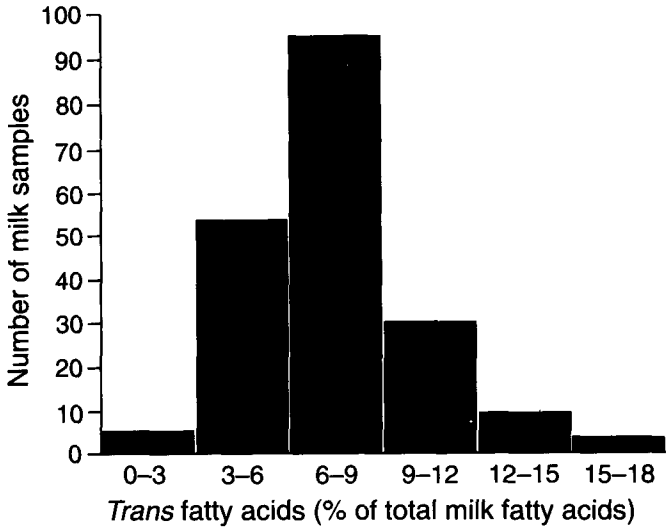

FIG. 1. Frequency distribution for *trans* fatty acid in Canadian human milk.

RESULTS

There was a wide variation (Fig. 1) in TFA content among the 198 samples, ranging from 0.1 to 17.2% of the total milk fatty acids, with a mean of 7.2% (Table 1). The most frequent occurrence (48% of the samples) was in the range of 6–9% TFA, while 22% contained more than 9% TFA. Only 6 samples contained very low levels (<3%) of TFA. As expected, the major TFA group was isomers of *t*18:1, which accounted for 5.9% of the total fatty acids. *Trans* isomers of linoleic acid were the other important group, amounting to 0.9% with 9*c*,13*t*-18:2 being the most prevalent, followed by 9*c*,12*t*-18:2, and 9*t*,12*c*-18:2.

The average *t*18:1 isomer profile of the milk samples was remarkably similar to those of partially hydrogenated canola oil (PHCO) and partially hydrogenated oil soybean (PHSO) basestocks, but it was different from that of cow milk fat (Fig. 2). Basestocks analyzed here are representative of what is available on the Canadian market.

There was no correlation among the levels of linoleic acid, α-linolenic, arachidonic, docosahexaenoic, and n-6 and n-3 long-chain polyunsaturated fatty acid (LCP) groups. Linoleic ($r = -0.29$, $P < 0.0001$) and α-linolenic ($r = -0.25$, $P < 0.001$) acids, however, were inversely correlated to *t*18:1. In addition, *t*18:1 positively correlated with stearic acid ($P < 0.01$), but no correlation was found with oleic acid.

DISCUSSION

A disturbing feature of Canadian human milk in this study is the elevated TFA level averaging 7.2% of total fatty acids, which is about 1.5- to 3.6-fold higher than values reported for many other populations (5, 13–15). These considerable differences presumably reflect a more marked prevalence of TFA in the Canadian diet. Similar high levels of TFA were also reported for Canadian human milk samples in 1976 (16), which may indicate that the TFA level in the Canadian diet has not changed over the last 18 years.

The close similarity of the *t*18:1 isomer distribution to that of PHVO shows that the major source of TFA and other isomeric fatty acids in Canadian human milk is PHVO, whereas the contribution from dairy products is minor. The 9*c*,13*t*-18:2, 9*c*,12*t*-18:2 and 9*t*,12*c*-18:2 isomers detected here are also the main linoleic acid isomers in PHVO (2), margarine (3), and bakery products (4). The very similar distribution of *t*18:1 and *t*18:2 isomers between human milk and PHVO suggests that dietary isomeric fatty acids are incorporated into human milk with no or very little alteration of their relative proportions or structures.

It is generally believed that dietary isomers of linoleic acid are not desaturated and chain-elongated to C_{20} metabolites in either humans or experimental animals consuming an adequate intake of linoleic acid (17). We have shown, however, that, in rats given PHCO with adequate levels of essential fatty acids, the above-mentioned three major *t*18:2 isomers were desaturated and elongated to their corresponding C_{20} trans polyunsaturated fatty acids (18). These metabolites, however, were not detected in human milk, perhaps because the level of linoleic acid of the mothers' diet was sufficient to prevent further metabolism of the *trans* isomers. Nevertheless, the possibility of formation of the unusual C_{20} *trans* metabolites in infants receiving human milk, particular-

ly those containing elevated levels of 18:2 isomers and lower levels of linoleic acid, should not be ruled out.

In addition to the isomeric fatty acids of PHVO origin, Canadian milk showed the presence of two other minor unusual C_{20} LCP 8*c*,14*c*-20:2 (0.19%) and 5*c*,8*c*,14*c*20:3 (<0.005%). These are not known to be present in dietary fats, but are most likely endogenously synthesized from dietary 12*c*-18:1 by alternative desaturation and elongation, as was observed in rats fed PHVO (18). In human milk analyzed here, 12*c*-18:1 accounted for 0.74% of the total fatty acids. The presence of the two C_{20} metabolites of 12*c*-18:1 in human milk suggests that humans are also capable of metabolizing isomeric fatty acids of PHVO origin.

The present study demonstrated an inverse correlation of TFA with linoleic and α-linolenic acids. We have also observed a similar correlation between TFA and linoleic acid in subcutaneous adipose tissue of Canadians (19). Further, in human milk there was no correlation of TFA with oleic acid, but there was a positive correlation with stearic acid. These relations reflect the prevalence of PHVO in the Canadian diet, because, during hydrogenation, TFA and to a lesser extent stearic acid are formed with concomitant reduction in linoleic and α-linolenic acids with practically very little change in the level of oleic acid (1). Thus it could be suggested that lower intakes of essential fatty acids by Canadians are invariably associated with high intakes of TFA.

Levels of linoleic (10.5%) and α-linolenic (1.2%) acids in Canadian milk were comparable to those reported in studies of mature human milk from women following *ad libitum* diets in different regions of the world, but their n-6 (20:4n-6, 22:4n-6, and 22:4n-6) and n-3 (20:5n-3, 22:5n-3 and 22:6n-3) LCP metabolites were lower (20). The lack of correlation between the two parent n-6 and n-3 essential fatty acids and their main metabolites, 20:4n-6 and 22:6n-3, was noted by others (15,21). These findings may indicate that low LCP levels in human milk in Canada cannot be restored by increasing dietary levels of linoleic and α-linolenic acids.

In summary, our findings suggest that breast milk in Canada generally has a high level of TFA and a low level of LCP. In view of the possible inhibitory effects of TFA on essential fatty acid metabolism (6–9) and the importance of LCP for the developing brain and retina (9), the combination of high levels of TFA and low levels of LCP in milk is a cause for concern, and its possible physiological consequences on infants should be investigated.

Characteristics of Fats in Japanese Diets and Current Recommendations

Michihiro Sugano

Laboratory of Food Science, Kyushu University School of Agriculture, Fukuoka 812-81 Japan

ABSTRACT: Although there is no firm evidence to support the "ideal" or even "appropriate" healthy level of dietary fat, the habitual fat consumption pattern in Japan seems to be a criterion for the recommended allowance both in the quantitative and qualitative points of view as judged from the life expectancy and the incidence of degenerative diseases. The new recommended dietary allowance of Japan, fifth revision effective for five years starting in 1995, adopted dietary fat levels of 20–25 energy percent, the ratio of saturated, monounsaturated, and polyunsaturated fatty acids at 1:1.5:1 and the ratio of n-6/n-3 at 4. The recommended fat level is similar to that previously consumed in Japan, and is even lower than that in diets used to treat hyperlipidemia in Western countries, current recommendations in those countries being 30 energy percent fat. Convincing data for the beneficial effects of n-3 polyunsaturated fatty acids on human health, in particular for healthy people, have been presented in only a few reports. However, the recommended n-6/n-3 ratio of 4 seems reasonable compared with the ratio of around 10 in other developed countries. In this context, it is more important to fully understand the nutritional and physiological roles of fat in healthy people rather than in those with chronic disease. At present, the low-fat dietary pattern in Japan appears to be a healthy way of eating.

Lipids 31, S-283–S-286 (1966).

The people of Japan are now the world's most long-lived. Life expectancy has risen at an unexpected rate in the past two or three decades. The average expected life span of babies born in 1993 is now 82.5 yr for women and 76.3 yr for men. Altered patterns of dietary intake appear to be a crucial factor in this increase. Of dietary components, changes in the dietary patterns of fats seem to be most influential, although these changes in dietary habit have changed the pattern of disease to one similar to that seen in developed Western countries. Currently, the three major causes of death in Japan are cancer, heart disease, and cerebrovascular disease (in that order), which contribute approximately 70% of the total death (1). Nevertheless, the incidence of these diseases is considerably lower as compared with that of other developed countries. It may not be ideal, but the feeding habits, including fat consumption, in Japan seem to be a healthy way of eating, at least for this population. Fat nutrition and physiology should be taken into consideration from both the qualitative and quantitative standpoints.

Quantitative standpoints. Of the changes in Japanese diet, the most significant has been a marked increase in daily fat intake from 21 g in 1955 to 58 g per capita (approximately 25 energy %) in 1992 (Fig. 1) (2). This change accompanied the decrease in carbohydrate intake from 425 to 289 g per day per capita in the same period. In these changes the relative increase in the amount of animal fats is more marked than that of vegetable oils. The increase in the intake of animal fat parallels that of animal protein. The current dietary fat level is still far lower than that in Western countries, but the proportion of vegetable oil is higher than in those countries. The current ratio of animal-to-vegetable fat in Japan is approximately 1:1. The drastic increase in fat intake in Japan has now reached a plateau. The increase in the incidence, but not total numbers, of death from so called "adult diseases" is also diminishing.

There is no definite agreement regarding the "desirable" level of dietary fat. Although 30 energy percent is recommended in most Western countries, it appears to be more makeshift than theoretically-derived. Similarly, it is not clear if the dietary level of 25 energy percent is adequate, as the pattern of disease in Japan is now becoming Westernized. Apparently, average Japanese fat consumption is thought to be acceptable, as it is just above the upper limit of recommendation. However, it is also true that there is a considerable bias in fat intake, and more than 35% of people are consuming much more fat (above 120%) and approximately 15% are consuming much less fat (below 80%) than the median value of the recommendation, 22.5%, indicating that only half of the Japanese people are achieving the recommendation. It is not clear presently which level, either 20 or 25 energy percent, is optional.

It is not easy to control the fat intake in developed countries, presumably due to its palatability. It seems, however, crucial to define the recommended daily allowance (RDA) of dietary fat much more clearly, i.e., either 20 or 25 percent of energy rather than using that as the range, as animal experiments have shown detectable physiological differences between both extremes (3). The Ministry of Health and Welfare of Japan addressed this point, and asked nutrition specialists to define a more precise recommendation. The 25 energy per-

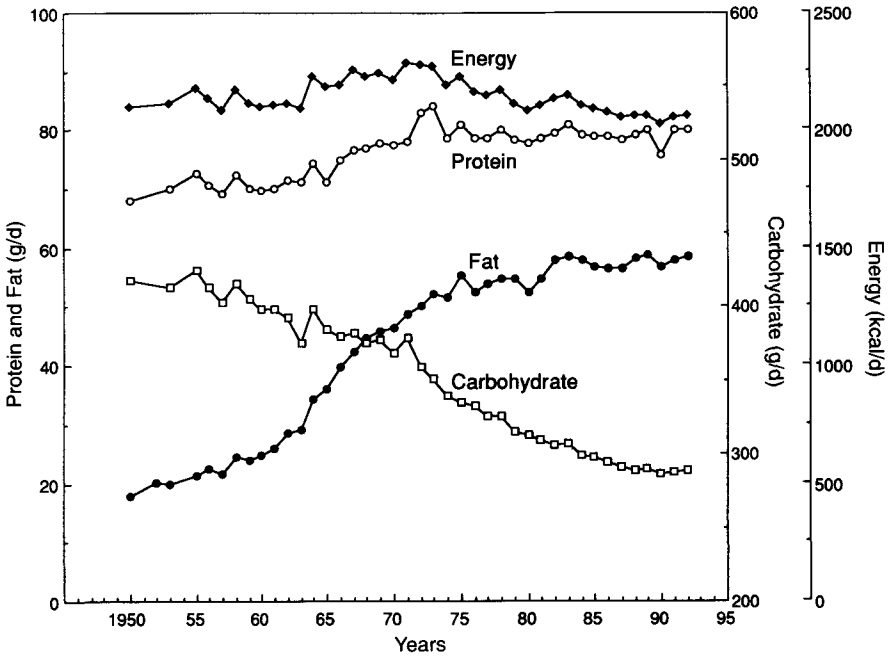

FIG. 1. Changes in nutritient intake in Japan (Ref. 2).

cent should now be regarded as the upper limit for Japan on the basis of the frequency of an increase in degenerative diseases similar to those in Western countries. The new RDA for dietary fat is summarized as follows. Quantity, 20–25 energy percent; quality: fatty acid ratio, saturated, monounsaturated and polyunsaturated fatty acids (S/M/P) = 1:1.5:1; polyunsaturated fatty acids (PUFA), n-6/n-3 = 4; and cholesterol, < 300 mg/d.

Qualitative standpoints. In the new RDA for dietary fat, the main points followed the preceding issues, but the new one simultaneously presented a preferable balance of PUFA as the n-6/n-3 ratio in addition to some revision to the balance of S/M/P.

The recommended ratio of S/M/P is 1:1.5:1. A higher value for monounsaturated fatty acids, exclusively oleic acid, was mainly based on its stability against oxidation and its abundance in regular meals in addition to avoiding the theoretical risk from increased intake of saturated fatty acids and PUFA (5).

In Japan the n-6/n-3 ratio currently recommended is 4. This value was empirically derived from the current fat intake rather than having a theoretical basis. We are consuming dietary fat at the ratio of 4:5:1 from animals, vegetables, and fish, respectively, and the n-6/n-3 ratio has apparently remained at a constant level for the past two decades (approximately 4), as shown in Figure 2 (2,6). The Japanese are consuming relatively large amounts of n-3 PUFA from fish and vegetable oils, approximately 4 g per day per capita in relation to around 15 g of n-6 PUFA. There is a decreasing trend of fish consumption in Japan, in particular in the younger generations, and the n6/n-3 ratio of their diets is apparently higher than the average value, in some cases it is above 6. However, because of the decline in ocean fishing grounds, farmed fish are now becoming more popular and available. Farmed fish in Japan have been reported to have a higher n-3 fatty acid content than do wild fish (7). Such fish are in general fatty and less expensive as well, thus unconsciously supplying a greater amount of n-3 PUFA for a lesser amount of fish.

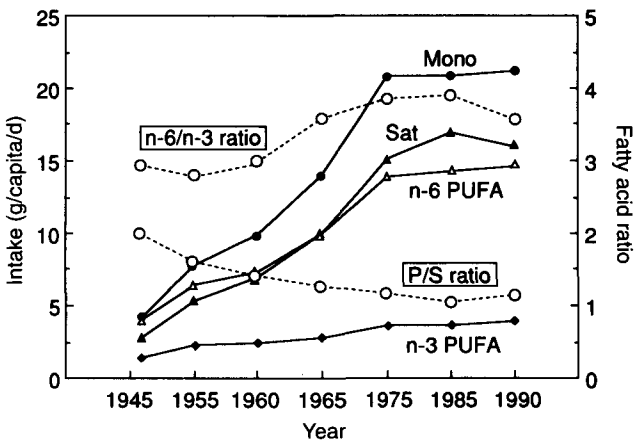

FIG. 2. Changes in the balance of fatty acid intake in Japan (Refs. 2 and 9). Ratio of linolenic acid and α-linolenic acid to their metabolites are 16:1 is 17:1, respectively. Sat, saturated; Mono, monounsaturated; PUFA, polyunsaturated fatty acids.

In addition to the high habitual fish intake in Japan, our fat source also seems to be partly responsible for a relatively high intake of n-3 PUFA. The edible fats are contributing approximately 25% of total fat intake, and two vegetable oils, rape-

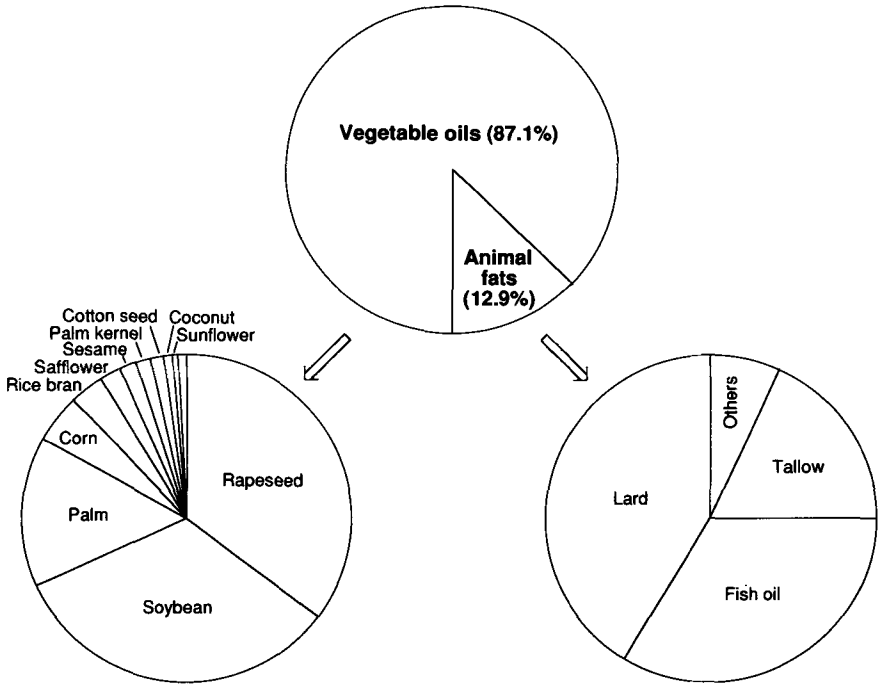

FIG. 3. Current status of the sources of dietary fats in Japan in 1993 (Ref. 8).

seed oil and soybean oil, which are exclusively α-linolenic acid-containing edible oils, account for more than 60% of total vegetable oils consumed, thus contributing a reasonable amount of n-3 PUFA (Fig. 3)(8).

The RDA considered that the n-6/n-3 ratio of 4 is acceptable for health, or at least there is no firm reason to reject this value. Some countries are now recommending a specific n-6/n-3 ratio in their RDA (9). However, at present no human data are available to indicate the optimal balance of these two series of PUFA, although a large number of animal studies are providing evidence indicating a range of beneficial physiological effects of n-3 PUFA in relation to n-6 PUFA (10,11). The proposed recommendation in most countries is between 4–10. In Western countries, where the current balance is estimated to be around 10, it would be impractical and difficult to lower the ratio to around 4.

It is also interesting that the consumption of *trans* fatty acids in Japan is very low and seldom exceeds 2 g per day per capita compared with aroung 10 g in Western countries. This was mainly attributable to the wide use of palm oil as a commercial cooking vehicle instead of the partially hydrogenated fats. In Western countries, partially hydrogenated vegetable oil is, in most cases, the exclusive source of the cooking oil in processed foods, causing a higher level of *trans* fatty acid intake. Recent human studies suggest that *trans* fat at a relatively high dietary level, in contrast to palm oil (12), worsens plasma lipoprotein profiles more than saturated fatty acids (13).

The second most important change influencing the composition of dietary fat in Japan is in the increased consumption of animal protein. Total protein intake has not changed much during the past thirty to forty years, but the proportion of animal protein has increased from 30% to more than 50%. This change also contributed to the net increase in animal fat intake. In consequence, blood cholesterol levels in Japan have gradually increased, although the dietary cholesterol intake is lower on average than in Western countries. However, because many adults have a cholesterol phobia, the new RDA stresses limited intake, less than 300 mg of cholesterol daily, only for those who are prone to respond to dietary cholesterol with increases in their plasma cholesterol.

It may be concluded that more evidence is needed that supports the physiological functions of different types and amounts of dietary fats in "healthy people." Unfortunately, the current information mainly stems from their effects on those who are patients with chronic diseases, such as atherosclerosis. Although RDA for dietary fat in Japan seems at least to meet our health needs, we have many problems relating to our food supply. These problems are internal as well as external, and must be addressed in the interests of national public health. Further work is needed to see whether similar recommendations would also be optimal for other populations with a different cultural and genetic background.

Fats in Indian Diets and Their Nutritional and Health Implications

Ghafoorunissa*

National Institute of Nutrition, Jamai Osmania, India

ABSTRACT: To arrive at fat requirements for Indians, the contribution of invisible fat should be determined. Total lipids were extracted from common Indian foods, and their fatty acid compositions were determined. This data and information on intake of various foods were used to estimate the contents of "invisible" fat and fatty acids in Indian diets. Taking into account World Health Organization (WHO) guidelines and the invisible-fat intake of Indians, recommendations were made for lower and upper limits of visible fats. In the rural poor, the "visible"-fat intakes are much lower than estimated minimum requirements. Therefore, to meet the energy needs of low-income groups, particularly young children, visible-fat intakes must be increased to recommended levels. The urban high-income group, however, should reduce dietary fat. Data on intake of various fatty acids in total diet shows that even the recommended lower limit of oil can meet linoleic acid requirements. Intake of α-linolenic acid is low, however. Increase in dietary n-3 polyunsaturated fatty acid (PUFA) produces hypolipidemic, anti-inflammatory, and antithrombotic effects. Effects of n-3 PUFA on blood lipids, platelet fatty acid composition, and platelet aggregation were therefore investigated in Indian subjects consuming cereal-based diets. Supplementation of fish oils (long-chain n-3 PUFA) as well as the use of rapeseed oil (α-linolenic acid) produced beneficial effects. Since the requirements of α-linolenic acid and/or long-chain n-3 PUFA are related to linoleic acid intake, use of more than one oil (correct choice) is recommended for providing a balanced intake of various fatty acids. Analysis of Indian food showed that some foods are good sources of α-linolenic acid. Regular consumption of these foods can also improve the quality of fat in Indian diets. Nonvegetarians, however, have the choice of eating fish to accomplish this.

Lipids 31, S-287–S-291 (1996).

In populations of developed countries, high fat consumption contributes to excess energy intake, and this is considered to be a risk factor for obesity and cardiovascular disease (1). The major nutrition related problem in India, however, is chronic energy deficiency associated with low fat intake (2). As the country is experiencing economic development, the urban affluent and middle-income groups are increasing in number, and there is a correspondingly steep escalation in the prevalence of obesity, diabetes, and cardiovascular disease in this section of the population (3). Since fat intake in India is income dependent and highly skewed (4,5), we focused our attention on the contribution of fat to nutritional status. This article encapsulates our work on contents of "invisible" fat and component fatty acids in Indian foods, offers insights into existing fat intake by Indians, and gives guidelines for ensuring correct quantity and quality of dietary fat for prevention of chronic energy deficiency on the one end and obesity and cardiovascular disease at the other end of the socioeconomic spectrum.

Dietary sources of fat are of two kinds: one is the "invisible" fat (i.e., fat present as an integral part of a food item) existing in different components of the habitual Indian diet, and the other is visible, or added, fat.

Invisible fat. Invisible fat in diet is derived from both animal and plant foods. Fat extracted by ether represents "free" lipids (6,7). Figures obtained with ether extraction show that plant foods have very little fat (8), and therefore it is not accounted for in terms of contributing to total fat intake. Since ether does not extract bound and structural lipids, it underestimates fat content in plant foods (6–8). To determine total invisible-fat content and its component fatty acids in Indian foods, food material was subjected to acid hydrolysis; total lipids (free + bound + structural) were extracted with a chloroform/methanol (2:1, vol/vol) mixture, converted to fatty acid methyl esters, and analyzed by gas chromatography against an internal standard (9,10). These data are summarized in Table 1. Although cereal and millet contain only 1–3% invisible fat, their status as bulk items in Indian diets contribute significantly to total fat intake. In cereal and millet, linoleic acid (LA) (18:2n-6) is the major fatty acid. On average, pulses and legumes provide more α-linolenic acid (ALNA) (18:3n-3) than do cereal and millet. Black gram, rajmah, and cowpea are rich sources of ALNA (LA/ALNA < 1.8). Commonly consumed condiments and spices contain significant amounts of fat. Both fenugreek and mustard seeds are rich sources of ALNA (LA/ALNA < 1.8). Analysis of fresh

vegetables showed that, on average, green leafy vegetables provide seven times more ALNA than other vegetables (LA/ALNA < 1.8) (10).

Visible fat. Several factors determine fat intake in the Indian population. First, fat intake is income dependent, and there are regional preferences in both the quantity and type of fat consumed (4,5,11). Vegetable oil is the major type of visible fat (national average 80%); vanaspati and ghee are other sources (12). Although there are several kinds of vegetable oil in India, groundnut and mustard/rapeseed oils make up 60% of the total production of oil (13).

As mentioned, there are regional preferences in the choice of oils. Groundnut oil is preferred in western and southern states. Sesame oil is preferred in south India, but in Kerala coconut oil is popular. Northern and eastern states use mustard oil. In north Karnataka and south Maharashtra, safflower oil is preferred. In recent years sunflower and rice bran oils have been introduced. Although imported palm oil has been used over the last decade, because of palm cultivation launched in India, indigenous palm oil is soon likely to be an important edible oil (13). The cost and advertisements claiming cholesterol-lowering potential of oil seem to influence the traditional and regional choice of oils, however. Vanaspati consumption is more common in northern states (12). Purchased ghee, as well as that made at home from milk, contributes to its high consumption in the urban affluent and middle-income groups (14). Relative proportions of fatty acids are known to vary in amounts of different visible fats.

Fat intake in different income groups. Dietary data from national surveys of the rural poor (an estimated 80% of the population) show that the average daily intake of cereal and millet is about 500 g, while visible-fat (oil) intake is below 10 g per person (2,4). Using data on invisible fat and fatty acids in Indian food (9,10) and information on dietary intake of the rural population (4), it has been found that cereal and millet alone furnish about 70% of the total invisible fat in the diet (9). Pulses, milk, fresh coconut, whole oilseed, and spices constitute the rest. The daily intake of cereal, millet, pulses, and

milk on an average provide about 16 g (7 en%) (en% = energy percent) fat, 5 g (2 en%) LA, and 0.6 g (0.2 en%) ALNA (9). Thus invisible fat from cereal and pulses alone furnishes two-thirds of the LA requirement (15). Two-thirds of fat present in cereal and millet are in the bound and structural forms (9). Studies in rats, however, have demonstrated that bound and structural fats in rice are biologically available (15). Diets of urban high-income groups are low in cereal (200–300 g/person/day) but contain more legumes, pulses, vegetables, and milk (also eggs and animal foods, in the case of nonvegetarians) (2,5). Therefore invisible-fat contribution to the diet is about 30 g (12 en%) (8). Average daily visible-fat intake in different segments of the urban population is about 13 g in slum-dwellers, 23 g in industrial laborers and low-income groups, 35 g in middle-income groups, and 46 g in high-income groups, but it is much higher in the top, affluent group (5,16).

Recommendation for visible fat in Indians. For adults, the World Health Organization (WHO) (17) proposed that the average intake for total fat should be between 15 and 30 en%. Taking into account the total invisible fat in diets of the rural population (9), the lower limit of visible fat (oil) in Indian diets is estimated to be about 20 g/person/day (9). Since chronic energy deficiency is a major nutritional problem in low-income groups, increasing fat/oil intake can help meet their energy needs.

Considering the amount of invisible fat in the urban high-income group, a daily intake of about 50 g/person (18 en%) would be the upper limit of visible fat (e.g., oil, ghee, vanaspati, and butter) (9). Because of the prevalance of obesity and coronary heart disease (CHD) in the urban population (3), their fat intake should be reduced.

In fulfilling the energy needs of young children through cereal/pulse diets, too much bulk would be a problem. To overcome this, it has been suggested that their diets should contain a minimum of 25 en% fat. This works out to be a daily intake of about 25 g (15 en%) per child (9). Widespread dietary energy deficiency in young children of low-income groups has been attributed to inadequate intake of diet (18). Re-examination of dietary energy intake and corresponding fat intake by preschool children belonging to different socioeconomic groups in both rural and urban areas, however, showed that increased energy intake is closely associated with increase in visible-fat intake (19). The data also show that, at visible-fat intakes corresponding to 15 en%, adequacy of energy intake is reached (20). These observations reinforce the importance of increasing energy density in diets of young children.

Quality of total fat with any visible fat. Several recommendations regarding quality of fat (21) have emphasized that the polyunsaturated fatty acid/saturated fatty acid (PUFA/SFA) ratio should be between 0.8 and 1.0. WHO (18) proposed that the range for SFA be between 0 and 10 en% and that for PUFA it should be between 3 and 7 en%. Currently, in view of the varied roles of individual SFA and PUFA, the PUFA/SFA ratio is considered obsolete, and lower and upper limits of the safe range of intake of various unsaturated fatty acids have been suggested. A balance in the intake of LA and ALNA is essential for maintaining a balance in the formation of eicosanoids of "2" and "3" series, respectively. It is therefore recommended that the dietary LA/ALNA ratio should be kept between 5 and 10. Dietary LA/ALNA ratios above 50 lead to tissue depletion of decosahexaenoic acid (DHA) and are therefore regarded as indicative of ALNA deficiency.

Quantity and quality of both invisible and visible fats determine the intake of various fatty acids in the total diet. In diets of the rural poor, invisible fat furnishes about 5 g SFA, 4 g monounsaturated fatty acid (MUFA), and 0.3 g ALNA, and the ratios of PUFA/SFA and LA/ALNA are about 1 and 13, respectively. Assuming that 20 g of any one fat/oil (suggested lower limit) is the source of visible fat, the probable fatty acid intake in the total diet was calculated (Table 2). It was found that, with any one oil, although minimum LA requirements may be met, ALNA intakes are only adequate when mustard/rapeseed or soybean oil are used. Therefore, with oils other than these, the LA/ALNA ratios are very high.

In the urban high-income group, invisible fat furnishes about 13 g SFA, 6 g MUFA, 4 g LA, and 0.6 g ALNA, and the ratios of PUFA/SFA and LA/ALNA are 0.3 and 6.0 respectively. Taking this into account, probable fatty acid intake in the total diet of this socioeconomic group is calculated with 50 g (suggested upper limit) of any fat/oil (Table 3). It was found that use of any one oil furnishes SFA about or above the upper limits of the safe range. Use of oil like safflower, sunflower, sesame, and soybean furnish high levels of LA. ALNA levels are in the desirable range only when mustard/rapeseed, soybean, or rice bran oils are used. Mustard/rapeseed oils provide about 17 en% MUFA, 13 en% of which are long chain (LC) MUFA (20:1 and 22:1). Use of safflower, sunflower, sesame, or groundnut oil as a single source of visible fat provides very high ratios of LA/ALNA. It therefore appears that, in both low and high socioeconomic groups, as long as the LA requirements are fully met (with all oils except coconut), there is a

need to increase the intake of ALNA and/or LC n-3 PUFA. In the low socioeconomic group, there is scope to increase SFA intake. It is suggested that an increase in milk intake would not only raise SFA levels but would also provide several other nutritional benefits.

PUFA nutritional status from phospholipid fatty acid composition. Dietary unsaturated fatty acids cause changes in the fatty acid composition of membrane phospholipids and in the subsequent eicosanoid spectrum (21). Enrichment of membranes with LC n-3 PUFA [eicosapentaenoic acid (EPA) and DHA] produces antithrombotic and anti-inflammatory effects (21). An inverse relationship has been reported between death rates from CHD and the ratio of arachidonic/eicosapentaenoic acids (AA/EPA) in plasma and platelet phospholipids. In populations with high death rates due to CHD (United States and Europe), the AA/EPA ratio in platelet phospholipids is about 50, whereas in the Japanese and Eskimo populations, which are less susceptible to CHD, this ratio is about 12 and 1.2, respectively (22). The fatty acid composition of platelet phospholipids was determined in apparently normal men (n = 70) belonging to an urban high-income group (Ghafoorunissa, unpublished). Wide variation was observed in the levels of EPA (1.2 ± 0.14) and AA (20 ± 0.6). EPA was not detected in 25 subjects. Mean ratio of AA/EPA was 56 ± 12 (n = 45). In about one-third of the subjects studied the mean ratio was 153 ± 24.

Effects of oils rich in n-3 PUFA on blood lipids and platelet fatty acid composition. The n-3 PUFA have hypolipidemic, anti-thrombotic and anti-inflammatory effects (21). Therefore, for prevention of several chronic degenerative diseases including CHD, increase in the intake of LC n-3 PUFA (fish and fish oil) and/or ALNA (plant foods) are recommended. From the previous discussion, it is clear that the quality of fat in Indian diets can be improved by increasing n-3 PUFA intake. Studies were therefore conducted (23) in men consuming cereal-pulse–based diets providing about 26 en% fat to determine the efficacy of using ALNA in comparison to LC n-3 PUFA for producing hypolipidemic and antithrombotic effects. Keeping LA levels constant, n-3 PUFA levels were altered by supplementing 0.2 or 0.5 en% LC n-3 PUFA (MaxEPA). To increase dietary ALNA, the visible-fat source was changed from groundnut oil (ALNA negligible) to zero erucic acid rapeseed oil (ZEAR) (ALNA 9%). The ratios of n-6/n-3 PUFA, initially 31, were reduced to 12 and 8, respectively, with LC n-3 PUFA, and to 4 with ZEAR. Results showed a decrease in total cholesterol with both levels of LC n-3 PUFA, but triglycerides were reduced with only the higher dose. Dietary increase in LC n-3 PUFA as well as in ALNA increased levels of LC n-3 PUFA in both plasma and platelet phospholipids and reduced collagen-induced platelet aggregation. The magnitude of changes were less marked with ALNA, as compared to LC n-3 PUFA, however. These observations indicate that it may be possible to favorably modify platelet functions by reducing the dietary LA/ALNA ratio. Other researchers have reported similar changes (24,25).

Mustard oil produced in India has high levels of LC MUFA (20:1 and 22:1). Extensive research has documented that LC MUFA present in mustard and rapeseed oils produce undesirable effects in experimental animals (26). Therefore, Sweden and Canada grow low–erucic-acid varieties. It has been shown that human hearts obtained during accident autopsies in Calcutta (where mustard oil is used as a major source of visible fat) have high levels of erucic acid (27).

Guidelines to ensure quality of fat. The studies discussed herein have demonstrated beneficial effects of increasing dietary n-3 PUFA (ALNA or LC n-3 PUFA) at a fixed intake of LA. Since requirements of n-3 PUFA increase with an increase in n-6 PUFA intake, it is important to moderate LA (and LC n-6 PUFA) and to increase ALNA and/or LC n-3 PUFA intake. To ensure this in the existing dietary patterns of Indians, it is advisable to (i) use oil with moderate levels of LA such as groundnut, rice bran, or sesame; (ii) when oil with high LA (safflower, sunflower, cottonseed, and soybean) is used, it can be utilized in conjunction with those that contain low LA (e.g., palm oil); (iii) use of an oil of choice along with mustard oil in approximately equal proportions will not only increase ALNA but will also keep the LC MUFA intake from mustard oil low; (iv) it is interesting to note that the combination of soybean oil with palm oil in equal proportions can also ensure quality of fat in Indian diets; (v) in addition to the constituent fatty acids, minor components present in fat/oil contribute to their nutritional and health effects. Some of these are powerful natural antioxidants (28). Use of more than one source of oil gives the added advantage of providing a greater variety of these minor components in the diet; (vi) regular consumption of ALNA-rich foods (Table 1) can contribute to increased dietary ALNA. Use of green leafy vegetables every day will not only increase ALNA intake but will also provide several other nutritional benefits (8,18); (vii) to improve the quality of fat, nonvegetarians should eat fish. Analysis of commonly consumed fish (29) indicate that fish with high fat (>5 g/100 g), medium fat (1–5 g/100 g), and low fat

Impact of Fat Substitutes on Fat Intake

Gregory D. Miller* and Susan M. Groziak

National Dairy Council, Rosemont, Illinois 60018-5616

ABSTRACT: Dietary fat is the number one nutrition concern of Americans. In response to rising consumer demand for reduced-fat foods, the food industry has developed a multitude of nonfat, lowfat, and reduced-fat versions of regular food products. To generate reduced-fat or fat-free products that have the same organoleptic characteristics of the regular fat version, food manufacturers frequently employ fat substitutes in the formulation of these foods. Fat substitutes are made from either carbohydrate, protein, or fat, or a combination of these components. Researchers have questioned the impact of fat substitutes on both fat and caloric intake. The majority of research studies in which fat substitutes were either covertly or overtly substituted for dietary fat indicate that in short-term, carefully-controlled conditions, fat substitutes can decrease both dietary fat intake and percentage of calorie intake from fat. However, individuals compensate for the caloric deficit created by the fat substitutes by increasing their consumption of other macronutrients, primarily carbohydrate. The long-term effect of fat substitutes on the fat intake of free-living individuals and weight control are unknown. People tend to eat more of a food when they know that food is reduced in fat. Fat substitutes should not be considered a substitute for sound nutrition education and a healthy lifestyle which includes regular exercise.
Lipids 31, S-293–S-296 (1996).

Today's Americans are fat-phobic. Dietary fat is the number-one nutrition concern of Americans (1). Nearly three-quarters of adults have changed their diets to decrease their fat intake (2). Three out of every four adults report that they consume reduced-fat foods and beverages (3). And just over one-half (54%) of U.S. adults choose reduced-fat versions of snack foods over the full-fat versions (4). In response to rising consumer demand for reduced-fat foods, the food industry has developed a multitude of nonfat, lowfat, and reduced-fat versions of regular food products. Today, roughly 14% of all new foods introduced into the marketplace are either reduced fat, reduced cholesterol, or reduced calorie (5).

New food products containing fat substitutes include hot dogs, bologna, oven-roasted chicken breast, smoked turkey breast, cheese, baked goods, frozen dessert, mayonnaise, salad dressing, sour cream, and potato chips (6). To generate reduced-fat or fat-free products that have the same organoleptic characteristics of the regular-fat versions, food manufacturers frequently employ fat substitutes in the formulation of these foods.

Dietary fat substitutes have existed for over a decade (7), and over the past ten years, more than 100 fat substitutes have been formulated (8). Fat substitutes are made from carbohydrate, protein, fat, or a combination of these components. Carbohydrate fat substitutes include gums such as xanthan gum; algins from kelp; modified food starches such as Stellar and STA-SLIM 143 (A.E. Staley Mfg. Co., Decatur, IL); dextrins; polydextrose; maltodextrins such as Matrin MO40, N-Oil, and Paselli SA_2 (Avebe America, Princeton, NJ); mixtures of dextrins and fiber such as Nutrifat®; fiber-based products such as inulin and oatrim (Rhone-Poulenc, Inc., Princeton, NJ); cellulose-based products such as Avicel (FMC Corp., Philadelphia, PA); and pectin-based products such as Slendid (Hercules Food Gums, Wilmington, DE) (9,10). Carbohydrate-based fat substitutes absorb water and imitate the thickness and creaminess of fat. These products are used in baked products, pudding, salad dressing, yogurt, milk, cheese products, processed meat products, spreads, dips, frosting, soup, and frozen dessert. Carbohydrate-based fat substitutes typically provide between 1 and 4 calories per g and are limited by the fact that they are often not well suited to baking, cannot be used in frying, and may reduce shelf life due to a high associated water content (21).

Protein-based fat substitutes include Simplesse® (Simplesse Co., Deerfield, IL) and Trailblazer (Kraft General Foods, Glenview, IL) (22–24). Simplesse® is made through the application of a patented heating and blending process (called microparticulation) to milk or egg-white protein. Trailblazer is created from a mixture of egg white, whey protein, and xantham gum. These fat substitutes are used in cheese, ice cream, yogurt, mayonnaise, dressing, spreads, cake, muffins, pastries, frosting, and frozen cheesecake. Like carbohydrate-based fat substitutes, protein-based fat substitutes provide between 1 and 4 calories per g and are limited by the fact that they are not well suited to baking and cannot be used in frying (21).

Fat-based fat substitutes include sucrose polyester [better known as olestra (Procter & Gamble Co., Cincinnati, OH)],

salatrim (Pfizer, Inc., New York), sorbestrin, caprenin (Procter & Gamble, Cincinnati, OH), appetize (Omegasource Corp., Burnsville, MN), and lita®. Salatrim, sorbestrin (Pfizer, Inc., New York), and caprenin provide between 5 and 9 calories per g, whereas olestra is a nondigestible compound (25–28). Fat-based fat substitutes may be used to replace fat in products such as cheese, peanut butter, potato chips, candy, spreads, oil, and ice cream.

The ease with which a fat substitute is introduced into the marketplace depends on its method of formulation. New molecules such as olestra must first be cleared with the Food and Drug Administration (FDA) as a food additive before they are used in food products. Procter and Gamble has been seeking FDA approval of the use of olestra in snack foods for over eight years. In support of this product, Procter and Gamble conducted 100 animal studies and 25 clinical trials on olestra, accumulated over 100,000 pages of research data, and spent over $200 million (26,29–31). The FDA has currently granted Procter and Gamble an extension for its patent, which expires in 1996.

If the development of a fat substitute involves applying a new process to an existing molecule (such as utilizing microparticulation to generate Simplesse), the FDA may require manufacturers to submit a petition to affirm that the fat substitute is generally regarded as safe (GRAS) (25). If, instead, the formulation of a fat substitute involves applying existing technologies to familiar molecules (such as the manufacture of maltodextrin), the fat substitute will be more readily incorporated into the marketplace (18,32).

The optimal fat substitute should feel, taste, and act like real fat when cooked or fried and contain little or no calories. Unfortunately, success in meeting all of these criteria has been limited (8,33). Most fat substitutes simulate the texture but not the taste or melting properties of real fat (26). Most aromatic chemicals that influence flavor are soluble in fat. Consequently, carbohydrate- and protein-based fat substitutes are limited by the fact that they cannot carry these compounds (26,34).

Taste is probably the most pleasing characteristic of dietary fat. Taste is generally the number-one reason why people select foods. People find it difficult to reduce their fat intake primarily because fat greatly enhances the flavor of foods (35). Reduction in the taste quality of the diet is the reason most frequently cited for consumers' inability to adhere to a reduced-fat diet (36). Even if fat substitutes can be formulated to taste just like real fat, however, the scientific community has questioned whether fat substitues will provide a significant health benefit to consumers. Researchers have raised concerns that (i) unlike dietary fat, fat substitutes do not provide essential fatty acids and fat soluble vitamins; (ii) if poorly absorbed, fat substitutes may absorb nutrients and drugs such as oral contraceptives, preventing their absorption; and (iii) fat substitutes may adversely alter the function of the gastrointestinal tract (25,26).

Additionally, researchers have questioned the impact of fat substitutes on both fat and caloric intakes. According to one estimate, dietary fat intake could be reduced by up to 10 g per day if fat-free alternatives were substituted for regular-fat cream cheese, cottage cheese, cheesecake, sour cream, salad dressing, frozen desserts, and sweet baked goods (37,38). Considering the reduction in calories that would also assumably occur when fat-free alternatives are substituted for traditional fat-containing foods, researchers estimated that use of these fat-free products would reduce the percent of total calorie intake from fat from 36 to 31%. Similarly, it has been estimated that use of Simplesse in all potential applications could reduce total fat intake from 36 to 30% of all calories (39).

The majority of controlled studies conducted on either lean or obese subjects indicate that fat substitutes can decrease dietary fat intake (35,40–44). These studies reduced intake by replacing the fat in muffins, biscuits, potato chips, cookies, frozen desserts, or shakes. One study conducted in obese adults replaced 60 g fat in a shake with olestra (41). This study reduced the daily percent of calorie intake from fat from a control level of 43 to 29% (41). A more recent study conducted in lean men replaced either 20 or 36 g fat in breakfast biscuits with olestra (35). The control diet provided 42% of total calories from fat. Replacing 20 g fat with olestra reduced the daily percent of calorie intake from fat to 39%. Replacing 36 g fat in biscuits with olestra further reduced the daily percent of calorie intake from fat to 35% (35). A 1993 study conducted in children replaced 25 g fat in a frozen dessert with Simplesse (43). This study achieved only a 1% reduction in calorie intake from fat (i.e., reducing daily fat intake from 37 to 36% of calories). Consequently, under very controlled research conditions, replacing dietary fat with fat substitutes can decrease caloric fat intake by as much as 14%. Keep in mind, however, that these studies determine the fat content of the control as well as the test diets. The length of these studies ranged from 8 to 40 days. Therefore long-term effects of fat substitutes on dietary fat intake are unknown.

In a free-living situation, fat substitutes may not produce dramatic decreases in fat intake. Using a computer modeling system, researchers have determined that several different dietary strategies are needed to realistically reduce fat intake (45,46). No single strategy can be expected to reduce fat intake to the goal of 30% of calories. Furthermore fat-reduction strategies that work best for specific people are highly individualistic (46). Consumers should be given a choice of many different fat-reduction strategies and allowed flexibility to choose strategies that best meet their needs (46). In addition, most studies conducted with fat substitutes report that individuals compensate for the caloric deficit created by use of the fat substitute by increasing their intake of carbohydrate and protein (35,42,43). This energy compensation is both unconscious (as demonstrated by studies that covertly replace dietary fat with fat substitutes (35,42,43) and conscious, as demonstrated by studies where the subjects are told they are consuming a reduced-fat food (47). People tend to eat more of a food when they know that the food is reduced in fat (47–50). Consequently, foods containing fat substitutes may help consumers reduce their dietary fat intake but not necessarily their

caloric intake, because individuals may compensate by consuming more food.

Dietary fat intake in the United States has been falling since the 1960s (51). At present, Americans consume approximately 34% of their calories from fat (62). In contrast, calorie intake and the rate of weight gain and obesity has been increasing (53,54). Today, one in three Americans is overweight (1). The current prevalence of overweight people in the United States, despite years of weight-reduction efforts, is hardly encouraging (5). Almost no data exist on the effect of fat substitutes on weight loss (6). To lose weight, it is equally important that consumers decrease their calorie intakes and increase their activity levels (57,58). Unfortunately, today, only about 7% of Americans are concerned about calories, whereas 60% are concerned about fat (1).

Will fat substitutes improve the nutrient intake of Americans by alleviating consumers' ill-founded "guilt" over consuming nutrient-dense foods from the five food groups that also happen to contain fat? Or will fat substitutes drive consumers to eat a class of foods that are low in fat but also equally low in nutrients (21)? Currently available research does not allow us to make speculations at this point.

Health professionals are also divided over the possible effect of fat substitutes on taste preference. Whereas some speculate that good-tasting foods containing fat replacements may promote a gradual acquisition of a preference for lower-fat foods (31), others propose that foods containing fat substitutes may support a taste preference for high-fat foods (59). Research indicates that people in general, and overweight people specifically, prefer the taste of high-fat foods (60). Scientists have also raised questions about the inability of low-fat foods to provide long-term satiety, compared to high-fat products (61). Some researchers hypothesize that the influence of dietary fat on satiety impacts both the perception of palatability and food preference (21). Consequently, will fat substitutes heighten a taste preference for high-fat foods that will only be satisfied by the consumption of products high in real fat?

As health professionals, we must teach consumers that macronutrient substitution in foods is not a substitute for a healthy lifestyle, which includes consuming a nutritious diet, maintaining an appropriate weight, and exercising on a regular basis (5). Foods that contain fat substitutes can be a part of a healthy lifestyle but should not be promoted as a "magic bullet" to dietary fat reduction, weight loss, or good nutrition. Instructing people to maintain a healthy lifestyle, which includes eating more foods from the five food groups, consuming fewer desserts and sweets, and exercising on a regular basis may sound like less savvy advice than offering consumers fat-free potato chips and candy bars. In the long run, however, sound nutrition advice based on principles of the five food groups, variety, and moderation, together with encouragement of an active and healthy lifestyle, will achieve greater success in optimizing the nutritional status of Americans than any proposed magic bullet.

Production of Eicosapentaenoic Acid from Marine Bacteria

Kazunaga Yazawa

Sagami Chemical Research Center, Sagamihara, Kanagawa, Japan

ABSTRACT: A marine bacterium, judged as a new species close to *Shewanella putrefaciens*, was isolated from the intestinal contents of the Pacific mackerel. The isolated strain SCRC-2378 produced eicosapentaenoic acid (EPA) as the sole polyunsaturated fatty acid, which amounted to 24–40% of the total fatty acid in the cell, which corresponded to 2% of dry cell weight. Under the optimal growth conditions (pH 7.0, 20°C, and grown aerobically for 12–18 h), the yield of SCRC-2738 reached 15 g of dry cells/L or 2×10^{10} viable cells/mL. EPA existed as phospholipid and was found in the *sn*-2 position of phosphatidylethanolamine and phosphatidylglycerol. The 38 kbp (1,000 base pairs) genome DNA fragment was cloned from SCRC-2738 and expressed in *Escherichia coli*, which resulted in the production of EPA. The nucleotide sequence of the 38 kbp DNA fragment was determined. The DNA fragment contains eight open reading frames, and three of them possess homology with enzymes involved in fatty acid synthesis. Thus, it may be possible that these EPA biosynthesis genes are applied for EPA production in yeasts or higher plants, and offer a new method for EPA synthesis as new foods containing EPA.
Lipids 31, S-297–S-300 (1996).

Eicosapentaenoic acid (EPA) is an important component in the cell membranes of animals, and its pharmacological functions are well known (1). The principal bioactivities associated with EPA are summarized in Table 1. The pharmacological functions of EPA have generally been explained from the viewpoint of an antagonistic action against arachidonic acid (2–7), especially in the case of coronary vascular disease.

The origin of EPA has been explained by a series in the marine food chain as follows: microalgae → phytoplankton → zooplankton → small fish → larger fish and marine animals. It is generally accepted that the phytoplankton are the primary producers of EPA. However, it was thought EPA may also be produced by some of the symbiotic microorganisms which are present in the intestines of blue-back fish rich in EPA, in addition to being produced by the food chain series described previously. Thus, our search for EPA-producing bacteria started, and we succeeded in finding bacteria which produced EPA. We first cloned the EPA biosynthesis gene cluster from the EPA-producing bacteria, and its analysis is in progress.

Abbreviations: EPA, eicosapentaenoic acid; GLC, gas–liquid chromatography; kbp, 1,000 base pairs; ORF, open reading frame; PE, phosphatidylethanolamine; pEPA, the plasmid isolated from strain No. 95 of SCRC-2738; PG, phosphatidylglycerol.

TABLE 1
Distribution of Fatty Acids in Phospholipids in SCRC-2738

	Fatty acid composition (mol%)			
	Phosphatidylethanolamine		Phosphatidylglycerol	
Fatty acids	*sn*-1 (α)	*sn*-2 (β)	*sn*-1 (α)	*sn*-2 (β)
14:0	3.2	0.8	1.1	0.4
i-15:0[a]	11.5	7.2	4.5	2.1
15:0	0.5	0.3	3.4	0.4
16:0	12.1	0.6	10.7	1.6

20:5	0.1	11.8	1.0	24.7

[a]*iso*-Type fatty acid.
[b]Isomers in position of double bond.

METHODS

The intestinal contents of the marine animals were diluted with sterilized seawater and the diluted contents were cultured in dozens of agar media for the selection of bacterial colonies. Various conventional media supplemented with artificial seawater (Jamarin Laboratory, Osaka, Japan) were used (8,9). Colonies formed on various agar media were cultivated singly in the liquid media to test for the presence of EPA in the cellular lipid. Each EPA-positive strain was tested immediately for bacteriological purity. The promising strains were then subjected to tests involving about 60 items for classification and identification and, after testing, were subcultured and stored.

The lipids of bacterial cells were extracted by the Folch method (chloroform/methanol, 2:1, vol/vol). The total lipid extract was then saponified and the free fatty acids obtained were methylated with CH_2N_2 and analyzed by gas–liquid chromatography (GLC) equipped with a capillary column.

Chromosomal DNA was isolated from strain SCRC-2738, an EPA-producing bacteria. The DNA was partially digested with Sau3AI and fractionated by size on 0.3% agarose gel (Sigma, St. Louis, MO). The fragments longer than 20 kbp (kbp = 1,000 base pairs) were recovered by electroelution and then ligated with BamHI-digested and dephosphorylated cosmid pWE15. The ligated DNA were packaged into the phage heads and transfected into *Escherichia coli* AG1. The trans-

formants were selected for expression of ampicillin resistance and cultivated singly in the liquid media to test for the presence of EPA in the cellular lipid.

The plasmid was isolated from an EPA-producing clone and its insert DNA fragment was subcloned for sequencing. The nucleotide sequence was determined by the dideoxy chain termination procedure.

RESULTS

About 50,000 bacterial strains were isolated from the intestines of various marine fish and other marine animals. Each of those strains was cultured as a single clone and was assessed for EPA levels by GLC analysis. EPA-producing bacteria were isolated with relatively high frequency from the blue-black fish containing high levels of EPA in their oils.

There were also several new species of marine bacteria which were phylogenetically similar to *Shewanella putrefaciens*. Among them, the intestinal strain SCRC-2738, isolated from a horse mackerel (9), had the highest EPA productivity. An electronmicrograph of SCRC-2738 (Fig. 1) indicates its size and presence of multiple flagella.

The fatty acid composition of the bacterium was simple and characteristic (10)—EPA was the only polyunsaturated fatty acid detected in significant quantities. In addition to EPA, several monoenoic acids and saturated fatty acids of the C_{13}–C_{18} range were detected. The percentage of EPA to the total fatty acids ranged from 25–40%, depending on the conditions of cultivation. In the fatty acid composition of SCRC-2738, almost none of the polyunsaturated fatty acids, varying from $C_{18:2}$ to $C_{20:4}$, were detected. This fact could be due to a high level of activity of the series of biosynthetic enzymes producing EPA.

We concluded that 90–95% of the EPA was in the form of phospholipids, and the free fatty acid fraction accounted for the remaining 5–10%. Furthermore, EPA was distributed almost equally between phosphatidylethanolamine (PE) and phosphatidylglycerol (PG). The PE and PG were studied further to determine the positional specificity of the EPA within the molecules. The PE and PG fractionated by thin-layer chromatography were isolated and mixed with snake venom phospholipase. It was found that the EPA in both PE and PG was specifically bound by an ester bond to the *sn*-2 position (Table 1).

The SCRC-2738 was cultivated in a medium (half-strength, artificial seawater containing 1–3% peptone and

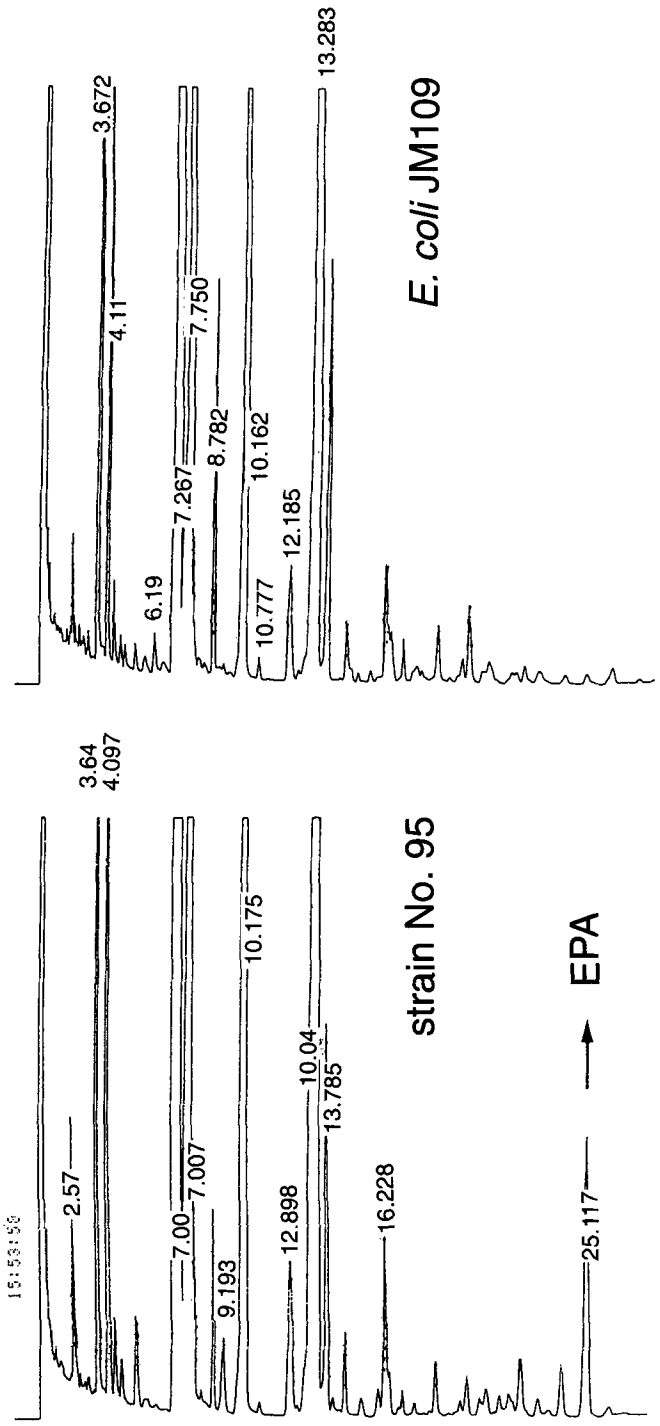

FIG. 1. Transmission electron micrograph of SCRC-2738 with negative staining.

FIG. 2. Gas–liquid chromatography of fatty acid methyl esters from the cells of strain No. 95 and *Escherichia coli* JM109. EPA, eicosapen-

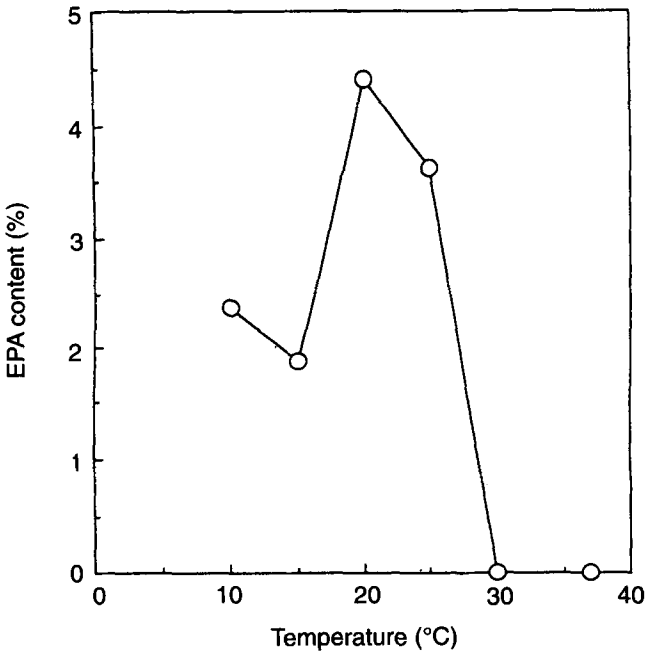

FIG. 3. Effect of growth temperature on EPA content in total fatty acids of strain No. 95. Abbreviation as in Figure 2.

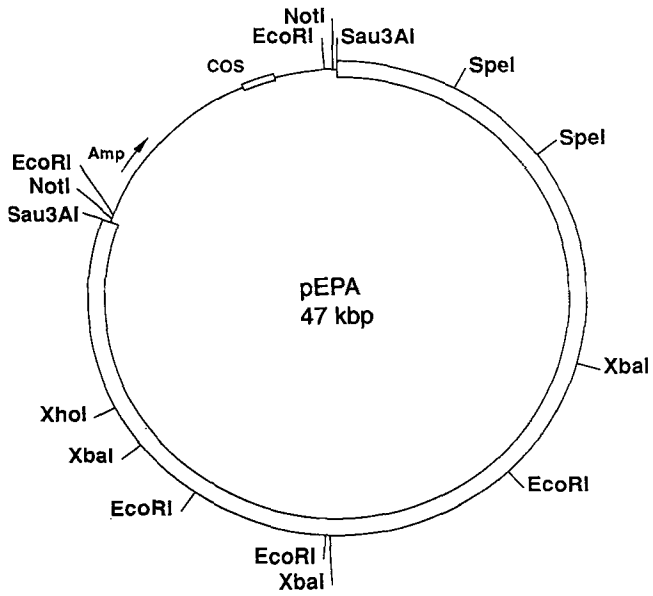

FIG. 4. Restriction map of plasmid pEPA. Abbreviation as in Figure 2.

0.5–1% yeast extract, pH 7.0) at 10 to 15°C with plenty of aeration. Under these conditions, 200–400 mg EPA was produced per liter of culture in 8 to 12 h (11). Furthermore, good EPA productivity was obtained when corn steep liquor or marine industrial waste liquid was used as a carbon source, thereby considerably reducing the overall fermentation costs. In this case, lactic acid was used to prevent the production of NH_3 and the increase of pH during cultivation. It may be possible to further reduce the cost of production by using a fed-batch culture, a high-density culture, and/or gene technology.

A genome DNA library of the SCRC-2738 was constructed and screened by EPA production. In a total of 390 analyzed clones, only strain No. 95 showed EPA productivity (Fig. 2). This means that strain No. 95 has the complete plasmid containing EPA biosynthesis genes.

It is known that growth temperature affects cellular EPA contents in SCRC-2378. As the cultivation temperature increased above 25°C, the productivity of EPA decreased, and no EPA production was observed at 30°C or higher temperature. The study of recombinant strain No. 95 indicated similar results (Fig. 3).

The plasmid was isolated from strain No. 95 and was designated pEPA; pEPA contains a 38 kbp genome DNA fragment from SCRC-2738 in the BamHI site of 8.8 kbp cosmid pWE15 (Fig. 4). The 38 kbp DNA fragment was subcloned and its nucleotide sequence was determined. In this fragment, eight open reading frames (ORF) larger than 1.0 kbp existed. To determine the ORF responsible for EPA synthesis, several deletion mutants of pEPA were constructed. pEPA-d1, which lacks XhoI-AscI fragment containing ORF1, indicates EPA

FIG. 6. Application of EPA biosynthesis genes for EPA production in yeast or plant. Abbreviation as in Figure 2.

productivity. However, pEPA-d2 (lacking ORF2), pEPA-d5,6 (lacking ORF5 and ORF6), pEPA-d7 (lacking ORF7), and pEPA-d8 (lacking ORF8) lost EPA productivity (Fig. 5). These results suggest that these ORF, except for ORF1, are involved in EPA synthesis. The deletion studies of other ORF are in progress.

A homology search of amino acid sequences deduced from the nucleotide sequences of the ORF with proteins in our database was done. ORF3, ORF4, and ORF6 showed a similarity with several enzymes involved in fatty acid synthesis (Table 2). This finding suggests that these ORF are involved in fatty acid *de novo* synthesis or in carbon chain elongation. Therefore, it is suggested that the ORF coding desaturase genes exist in the remaining ORF. The function of these ORF may be revealed by further studies. It may be possible that these EPA biosynthesis genes are applied for EPA production in yeast or plant, and offer a new method for polyunsaturated fatty acid synthesis (Fig. 6).

Eicosapentaenoic Acid Suppressed the Proliferation of Vascular Smooth Muscle Cells Through Modulation of Various Steps of Growth Signals

T. Terano*, T. Shiina, and Y. Tamura

The 2nd Department of Internal Medicine, Chiba University School of Medicine, Chiba 260, Japan

ABSTRACT: Among fatty acids, only n-3 polyunsaturated fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) inhibited the proliferation of vascular smooth muscle cells. DHA was less effective than EPA. To clarify the anti-proliferative effect of n-3 polyunsaturated fatty acid, we have explored the effect of EPA on the signal transduction pathway of platelet derived growth factor (PDGF). EPA inhibited PDGF binding on its receptor and activation of protein kinase C. EPA also suppressed c-fos mRNA expression, one of immediate early genes, through partly inhibiting c-fos transcription. These data revealed that EPA could inhibit vascular smooth muscle cell proliferation through modulating various steps of the signal transduction by PDGF.

Lipids 31, S-301–S-304 (1996).

Eicosapentaenoic acid (EPA) exerts its anti-thrombotic and atherogenic effect through the modulation of various cell functions related to atherosclerosis (1–3). We previously reported that only n-3 polyunsaturated fatty acids (PUFA) among fatty acids dose dependently inhibited the proliferation of rat cultured vascular smooth muscle cell (VSMC). Of these, EPA was most potent (4). We proposed that the change of membrane characteristics by EPA incorporation might modulate the signal transduction of growth factors. Here, we report how EPA modulates the signal transduction of growth factors, mainly platelet derived growth factor (PDGF). Growth signal of PDGF are transferred to nucleus through the activation of mitogen activated protein kinase (MAP-K) and protein kinase C (PKC). Special emphasis was placed on the effect of EPA on the signal transduction in the nucleus. Expression of immediate early growth gene, c-fos, and transcription of c-fos gene were studied.

MATERIALS AND METHODS

Materials. Fatty acid emulsions of EPA, docosahexaenoic acid (DHA), oleic acid, and linoleic acid were prepared as follows: 1,2,3 trieicosapentaenoil glycerol (98% pure, EPA–TG), synthesized by chemical condensation of glycerol and pure free EPA, was emulsified with phosphatidylcholine (PC), glycerol, tocopherol, and water according to the method of Geyer *et al.* (5). The emulsion contained 20.6% of EPA–TG, 2.3% of glycerol, 1.2% of yolk egg PC and 0.004% of tocopherol.

VSMC preparation. Rat cultured VSMC were prepared by ex-plant method as previously reported (6). VSMC were cultured by Dulbecco modified eagle medium (DMEM) with 10% fetal calf serum (FCS). Cells of passage fifth to tenth were used.

Proliferation of VSMC measured by ^{3}H-thymidine uptake. DNA synthesis was measured by incorporation of ^{3}H-thymidine (Thymidine, [Methyl-^{3}H]-(2.59–3.33 Tbq/mmol)) into VSMC. VSMC were cultured with growth medium for 60 h, and further incubated with FCS (-) DMEM containing various fatty acids-TG (40–160 μM) for 24 h and then stimulated with PDGF (PDGF-BB homodimer, human recombinant, 10–25 ng/mL; R&D Systems, Inc., Abingdon, Oxford, United Kingdom) for 24 h, and ^{3}H-thymidine uptake was measured for last 4 h. Radioactivity in TCA insoluble fraction was measured.

Fatty acid composition of total phospholipid of VSMC. VSMC were incubated with growth medium for 60 h, and further incubated with EPA–TG (40–160 μM) for 24 h (EPA-rich VSMC). Fatty acid composition of total phospholipid of the VSMC was measured by gas–liquid chromatography as previously reported (7).

PDGF binding on its receptor of VSMC. EPA-rich VSMC were incubated with various amounts of PDGF in the presence of 1 uCi of ^{125}I-PDGF (human recombinant PDGF-BB homodimer, >37 Tbq/mmol; Amersham International Co., Ltd., Amersham, Buckinghamshire, United Kingdom) for 3 h at 4°. Maximal binding site and Kd were obtained by Scatchard analysis.

Northern blot analysis for c-fos mRNA. EPA-rich VSMC were stimulated with PDGF (10–25 ng/mL) for 15–60 min. Then total RNA was isolated by AGPC (acid guanidium-thiocyanate-phenolchloroform), electrophoresed and transferred to nylon filter. Hybridization was carried out with ^{32}P-labeled probe (1.0-Kb rat c-fos cDNA fragment). Spots were quantified by Bio-image analyzer (Fuji Film Co., Ltd., Tokyo, Japan).

C-kinase activity. Particulate (membrane) and cytosolic (soluble) fractions were obtained after stimulating EPA-rich VSMC with PDGF (10 ng/mL) or 12-*O*-tetradecanoyl phorbol-13-acetate (TPA) (10^{-8}–10^{-7}M) for 15 sec to 30 min as follows: cells were scraped, sonicated, and centrifuged at

100,000 *g* for 60 min. PKC activity and protein amount of both fractions were determined with a PKC assay kit (Amersham) and western blotting using MC5 monoclonal antibody for PKC (Amersham), respectively.

Nuclear run-on assay. Nuclei from EPA rich VSMC treated with PDGF (10 ng/mL) or TPA (10^{-7} M) were prepared. Run-on transcription was carried out at 30°C for 30 min. Reaction was terminated and ^{32}P-labeled nuclear RNA was purified. The cDNA for c-fos, β-actin and plasmid vector (pSPT18) were denatured and applied to a nylon filter (Hibond-C) (10 μg per slot). Membranes were hybridized with ^{32}P-labeled nuclear RNA transcript for 48 h at 65°C. The blots were quantified by Bio-image analyzer. All experiments were performed at least twice and provided constant results.

RESULTS

EPA treatment dose dependently increased the content of EPA and docosapentaenoic acid without altering the arachidonic acid and DHA in total phospholipid of VSMC. EPA/arachidonic acid increased up to 6-fold (0.11; before treatment, 0.67; EPA 160 μM for 24 h) by EPA treatment as shown in Table 1.

DNA synthesis was enhanced up to 10–20 fold by the stimulation with optimal amount of PDGF (10–25 ng/mL). By the pretreatment of EPA–TG, DNA synthesis by PDGF was dose dependently suppressed. DHA–TG also showed a similar effect, but was less than that of EPA. Oleic acid and linoleic acid TG showed no effect on DNA synthesis as shown in Figure 1.

Nonspecific binding of ^{125}I- PDGF was less than 5% of total binding. Saturation analysis plots of the specific binding of ^{125}I-labeled PDGF revealed that EPA-TG pretreatment suppressed the binding of PDGF on its receptor of VSMC in a dose dependent manner. Scatchard analysis for PDGF receptor revealed a linear regression fit and one binding site. The Kd value was 286 fmol and maximum binding site (MXB) was 22.1 fmol/5 × 10^4 cells. EPA pretreatment suppressed the number of MXB in a dose-dependent manner (EPA 40 μM and 80 μM pretreatment; 17.4 and 14.6 fmol/5 × 10^4, respectively), but did not affect the Kd value. DHA showed a similar effect on MXB but oleic acid and linoleic acid showed no effect.

Activation of PKC was measured by evaluating the translocation of calcium-lipid dependent kinase activity or PKC protein amount from cytosol to particulate fraction in VSMC. Figure 2 shows the PKC activities recovered in the cytosol and particulate fractions of both control and EPA treated VSMC after stimulation with 10^{-7} M TPA. In basal conditions, PKC activity in both cytosol and particulate fractions did not differ between two groups of VSMC. Thirty seconds after stimulation with TPA, cytosol associated activity decreased rapidly and particulate associated activity increased without changing total PKC activity in both groups of VSMC. Particulate associated activity of EPA treated cells was less than that of control cells up to 30 min after stimulation by TPA. The similar difference was observed by measuring PKC protein amount in cytosol and particulate fractions after TPA stimulation in two groups of cells by western blotting. The translocation of PKC by PDGF was also suppressed in EPA treated cells.

TABLE 1
The Effect of Trieicosapentaenoic Glycerol Treatment on the Change of Fatty Acid Composition of Total Phospholipid of Vascular Smooth Muscle Cells[a]

	0 (μM)	40 (μM)	80 (μM)	160 (μM)

[a]The values shown are the mean (SE) of three cultures from one experiment. *$P < 0.05$, **$P < 0.01$, significantly different from zero dose values.

FIG. 1. Effect of various fatty acid triglycerols at the concentration of 0, 40, 80, and 160 μM on platelet derived growth factor (10 ng /mL) stimulated proliferation of vascular smooth muscle cells. n = 3–8, mean ± SE, **$P < 0.01$; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

The expression of c-fos mRNA maximally increased 30 min after PDGF or TPA stimulation. EPA treatment did not change the time course of c-fos mRNA expression. EPA treatment suppressed the expression of c-fos mRNA by PDGF in a dose dependent manner as shown in Figure 3. C-fos mRNA expression by TPA (10^{-7} M) was also significantly suppressed in EPA treated cells.

We next attempted to determine whether inhibitory effects of EPA on c-fos mRNA expression might result from changes in c-fos mRNA transcription or in the stability of c-fos mRNA. Nuclear run-on experiments were performed to establish whether this effect of EPA occurred at the transcriptional level. C-fos was not constitutively transcribed under serum starved conditions in VSMC. The transcription of β-actin, which served as a control of a constitutively expressed gene, was increased by serum or TPA stimulation. Almost no background hybridization of the transcripts with the vector

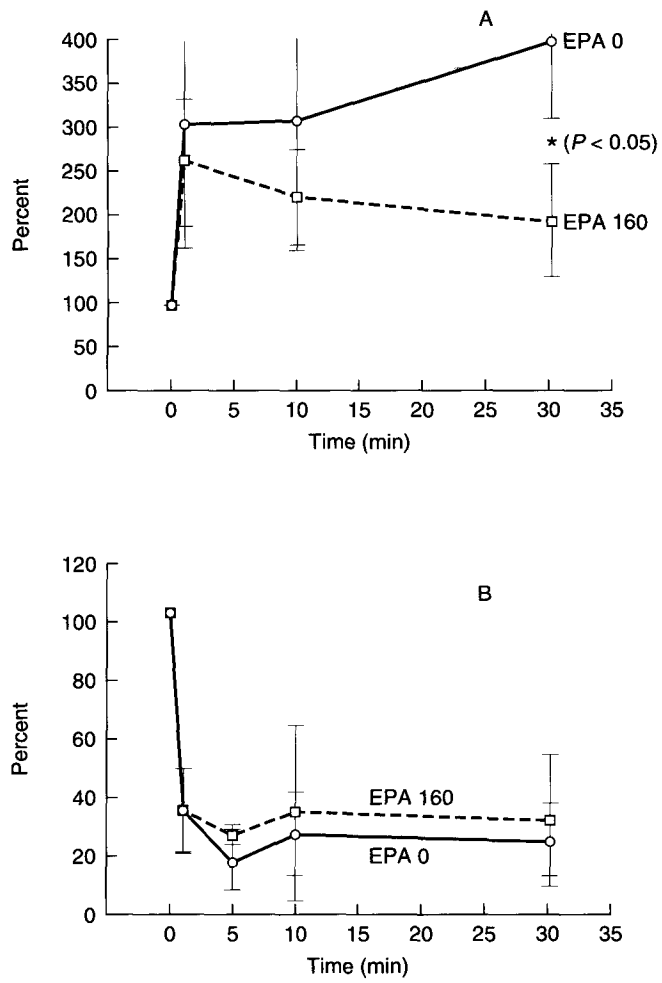

FIG. 2. Effect of 12-*O*-tetradecanoyl phorbol-13-acetate (10^{-7} μM) induced translocation of protein kinase C in vascular smooth muscle cell. n = 4, mean ± SD, *$P < 0.05$. See Figure 1 for abbreviation.

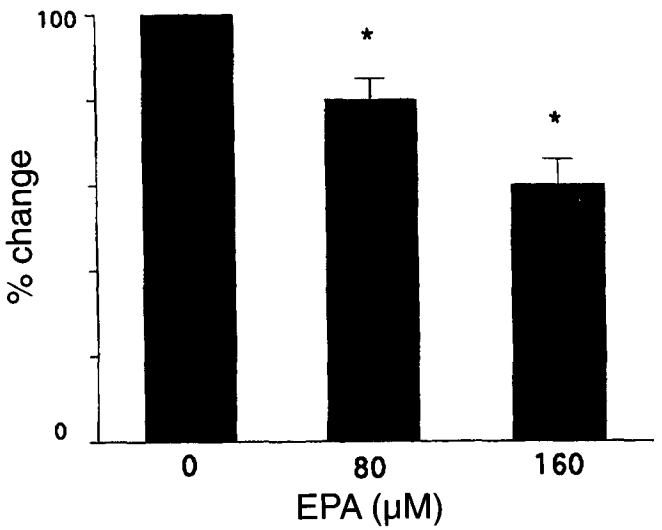

FIG. 3. Effect of eicosapentaenoic acid on platelet derived growth factor stimulated (10 ng/mL) expression of c-fos mRNA. n = 3, mean ± SE, *$P < 0.05$. See Figure 1 for abbreviation.

was detectable. 160 μM of EPA pretreatment inhibited the serum induced transcription of c-fos in VSMC.

DISCUSSION

Among PUFA, only n-3 PUFA inhibited the proliferation of VSMC. DHA was less effective than EPA and therefore we used EPA rich cells to clarify the mechanisms of PUFA to suppress VSMC proliferation (4). EPA and DHA suppressed the proliferation of VSMC possibly through the inhibition of binding of growth factors such as PDGF on its receptor. This might be derived from the change of membrane fluidity through the increase in PUFA such as EPA and DHA. PDGF binding on its receptor induces the activation of PDGF receptor through the autophosphorylation of receptor. This receptor phosphorylation leads to the activation of receptor linked several molecules, and this resulted in the activation of PKC and MAP-K. This finally induced the expression of early growth related genes including c-fos. C-fos mRNA expression is required for mitogen stimulated cell growth. EPA suppressed not only PDGF, but TPA stimulated c-fos mRNA expression in growth arrested cells in a dose dependent manner. This suggested that EPA could also act on the event after binding of growth factor on its surface receptor. In fact, EPA also directly suppressed the activation and/or translocation of PKC. PUFA are reported to regulate the expression of several genes involved in lipid metabolism and possibly regulate the PUFA response element within the proximal promotor region of some genes (8,9). EPA suppressed c-fos gene expression and transcription as demonstrated by northern blotting and nuclear run-on assay.

We first reported that the expression and transcription of growth related genes were inhibited by EPA. The effect of EPA on the promotor region of c-fos should be further clarified. EPA inhibited the proliferation of VSMC through the modulation of various steps of signal transduction by growth factor. These effects of EPA might partly explain the anti-atherosclerotic effects of EPA.

The Structure-Activity Relationship of Lipoxygenase Products of Long-Chain Polyunsaturated Fatty Acids: Effects on Human Platelet Aggregation

John W. Karanian, Hee-Yong Kim, and Norman Salem, Jr.*

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcoholism and Alcohol Abuse, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: The effect of hydroperoxy and hydroxy derivatives of various fatty acids on human platelet aggregation was determined to delineate potencies and structure-activity function. In this regard, the 22-carbon n-3 fatty acids are the most potent inhibitors in comparison to the n-6 lipoxygenase derivatives. Submicromolar levels of the docosapentaenoic (22:5) and especially docosahexaenoic (22:6) n-3 hydroperoxy and hydroxy derivatives specifically antagonize the platelet aggregating effect to arachidonic acid (AA, 20:4n-6) but not that of ADP or collagen. Chain length (22-C > 20-C), double-bond position (n-3 > n-6), and double-bond number (6 > 5 > 4) influence the degree of inhibition of AA-induced aggregation of human platelets. Moreover, significant differences in potency were associated with specific structural aspects of 22:6n-3 lipoxygenase derivatives of 22:6n-3 as follows: functional group (OOH > OH) and positional isomer (14-OOH, 14-OH, 20-OOH > 11-OOH, 17-OOH > 10-OOH > 11-OH, 8-OOH, 7-OOH > 4-OOH).

Lipids 31, S-305–S-308 (1996).

It is well known that polyunsaturated fatty acids can be oxygenated by lipoxygenases to form hydroperoxy fatty acids, the first products of the lipoxygenase reaction, and subsequently hydroxy fatty acids. Mammalian platelets are high in lipoxygenase activity and capable of enzymatically producing a number of hydroxylated products of n-6 and n-3 fatty acids. For example, docosapentaenoic acid (22:5n-3) (1) and docosahexaenoic acid (22:6n-3) (2) are metabolized to 11- and 14-hydroxy positional isomers by 12-lipoxygenase. In addition, human platelets produce a 17-OH-22:6n-3 from 15-lipoxygenase, which is also present in the platelet (3). It has been proposed that the hydroxylated metabolites may be physiologically active in platelet-vascular smooth muscle and other cell interactions (4–6). A report by Sinzinger *et al.* (7) on the occurrence of myocardial infarct in young patients with platelet 12-lipoxygenase deficiency suggests involvement of hydroxylated derivatives in the regulation of platelet function. These metabolites may interfere with thromboxane A_2/prostaglandin H_2 (TXA_2/PGH_2) receptors (8) and alter endogenous production of eicosanoids (9), thereby directly resulting in changes in cell function. Nutritional modification of the precursor fatty acid pool with n-3 or n-6 dietary supplementation or ethanol exposure alters the eicosanoid-docosanoid profile, which may result in altered cell function (10,11).

Hydroxylated fatty acids were enzymatically produced in platelets from 22:5n-6, 22:5n-3, 22:5n-5 and 22:6n-3, and hydroperoxidized 22:6n-3 fatty acids were prepared *in vitro* to perform a structure-activity study. Biological effects of hydroperoxidized and hydroxylated lipoxygenase products of n-3 and n-6 unsaturated fatty acids were characterized in human platelets.

MATERIALS AND METHODS

12-hydroperoxy-eicosatetraenoic (12-OOH-20:4n-6), 12-hydroxy-eicosatetraenoic (12-OH-20:4n-6), and 12-hydroxy-eicosapentaenoic acid (12-OH-20:5n-3) were purchased from Cayman Chemical (Ann Arbor, MI). 12-hydroperoxy-eicosapentaenoic acid (12-OOH-20:5n-3) was obtained from Calbiochem (La Jolla, CA).

Preparation of hydroperoxy 22:6n-3 derivatives. Autoxidation was performed using the procedure reported by Kim and Salem (12). Approximately 20 mg of 22:6n-3 (NuChek Prep, Elysian, MN) was dissolved in 1 mL of tetrahydrofuran in a 50-mL silanized glass, round-bottom flask. The solution was rotated under a stream of nitrogen to form a thin film of fatty acid. The flask was sealed and rotated overnight at room temperature after purging with 99.9% pure oxygen. Two more days of incubation at 5°C was required to yield a substantial conversion of hydroperoxy compounds. The contents were transferred to a silanized test tube using dichloromethane, dried under nitrogen, and redissolved in 1 mL cold methanol. An aliquot was diluted tenfold with methanol, and 20 µL was injected into a thermospray liquid chromatography/mass spectrometry (LC/MS) system for structural analysis. The total yield of hydroperoxy 22:6n-3 compounds, calculated using an extinction coefficient of 30,000 (13), was approximately 12.5%.

Preparation of soybean lipoxygenase 17-OOH- and 17-OH-22:6n-3 products. As previously reported (12), 2 mg of 22:6n-3 were dissolved in 20 μL ethanol. With vigorous vortexing, 4 mL 0.2 M borate buffer (pH 9) and then 500 μL enzyme solution (2×10^4 units/mL) were added. The mixture was incubated on ice for 30 min, then acidified with formic acid and extracted twice with dichloromethane. After being dried with a stream of nitrogen, the contents were redissolved in 1 mL methanol. An aliquot was diluted tenfold with methanol, and 20 μL was injected into a thermospray LC/MS system. The yield calculated from the ultraviolet absorbance of the products at 235 nm indicated that approximately 75% of the 22:6n-3 had been converted to the 17-OOH- and 17-OH-22:6n-3 derivatives.

Synthesis and analysis of hydroxylated 22-carbon fatty acids. Washed human platelets were prepared in a *tris*-EDTA buffer and incubated for 20 min at 37°C with 200 μM 22:5n-6, 22:5n-5, 22:5n-3, and 22:6n-3, as previously reported (14). Metabolites were then extracted twice with equal volumes of dichloromethane. Positional isomers were separated, purified and quantified using an HP-1090 high-performance liquid chromatograph (HPLC) equipped with a diode array ultraviolet detector (235 nm). A 4.6 × 25-cm Axxiom ODS column (5 μm; Thompson Instruments, Alexandria, VA) was used with a flow rate of 0.8 mL/min and a solvent system composed of 100 mM ammonium acetate and methanol. In some cases hydroxy fatty acids of interest were collected and methylated using diazomethane to analyze their structures (3).

Platelet aggregation. Human whole blood was obtained and diluted 5:1 in 3.8% citrate. Platelet aggregation to 20:4n-6 (0.25 mM) was evaluated using a Chronolog (Havertown, PA) whole blood impedance aggregometer. Whole blood samples (940 μL) were preincubated for 5 min with 50 μL of the vehicle (ethanol solution) or 50 μL of the various OOH- and OH-derivatives prior to the addition of 20:4n-6 (10 μL). The final concentration of ethanol in the platelet bath (<30 μM) did not alter platelet reactivity to 20:4n-6 at this concentration. Changes in aggregation were expressed as changes in the slope of aggregation (ohms/cm/min). In some cases, aggregating responses to ADP (2 μM; Sigma Chemical Co., St. Louis) and collagen (4 μg/mL; Sigma Chemical Co) were measured to test for specificity.

Statistics. All results were evaluated using analysis of variance and Student's *t*-test for unpaired samples. A P value of $P < 0.05$ was considered statistically significant.

RESULTS

Human platelets were preincubated with either indomethacin (0.5 mM) or 0.25 μM of the various OOH-22:6n-3, OH-22:6n-3, and OH-22:5n-3 isomers as well as other hydroxy fatty acids to determine their effect on arachidonic acid (AA)-induced (0.25 mM) platelet aggregation. The control-aggregating response to AA (20:4n-6, 0.25 mM) was generated following preincubation of the whole blood sample (950 μL) with 50 μL of the vehicle for 5 min. All other responses were referenced to this and are expressed as the change in slope. A typical control-aggregating curve is depicted in Figure 1A. Preincubation with indomethacin (0.5 mM) for 5 min blocked the aggregating response to 20:4n-6 via its blockade of the cyclooxygenase-generated mediator of aggregation, TXA_2 (Table 1). All hydroperoxy and hydroxy fatty acids tested reduced the slope of aggregation for AA. The most potent derivatives were the longer-chain (22-carbon) highly unsaturated (6 double bond) n-3 fatty acids, and the least potent were the shorter-chain (20-carbon) least-unsaturated n-3 and n-6 fatty acids (Table 1). Representative aggregating curves to 20:4n-6 are shown in Figure 1 in the absence and presence of the hydroperoxy fatty acids (A) and hydroxy fatty acids (B) tested.

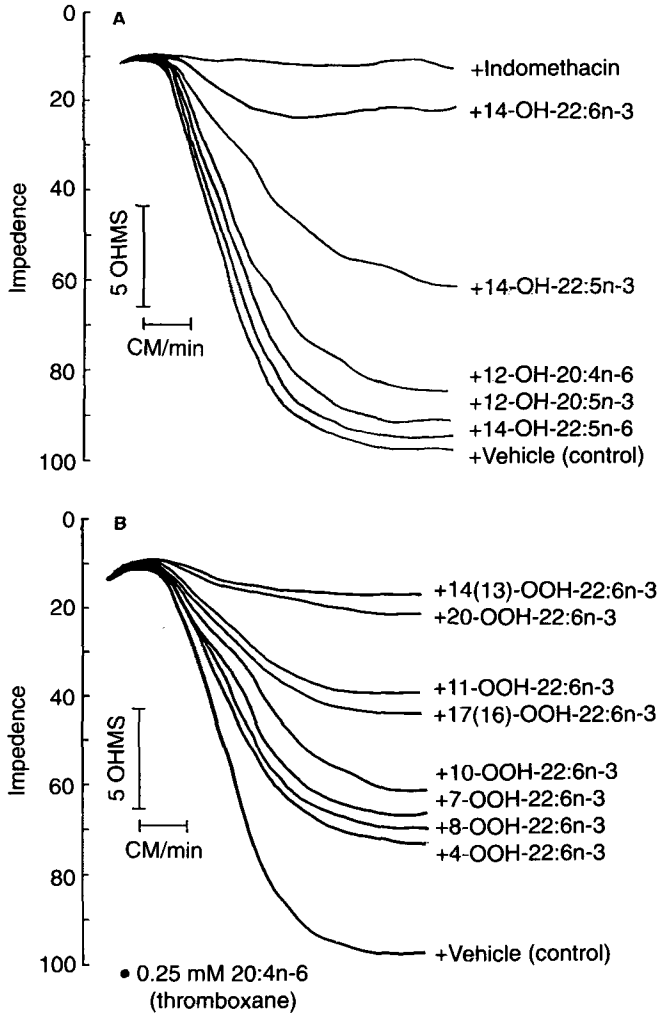

FIG. 1. A) Representative curves for arachidonic acid (20:4n-6)-induced (0.25 mM) human platelet aggregation in the presence of indomethacin (0.5 mM) and various hydroxy fatty acids (250 nM), in comparison to the control-aggregating response (vehicle-treated). B) Representative curves for arachidonic acid-induced (0.25 mM) human platelet aggregation in the presence of various hydroperoxy fatty acids (250 nM), in comparison to the control-aggregating response.

[a]Significance at $P < 0.01$.
[b]Significance at $P < 0.05$.

ADP- and collagen-induced platelet aggregation were not altered in the presence of the hydroperoxy or hydroxy 22:6n-3 fatty acids tested (12-OH-20:4n-6, 12-OH-20:5n-3, 14-OH-22:6n-3, and 14-OOH-22:6n-3).

DISCUSSION

Mammalian platelets contain an active lipoxygenase and are capable of enzymatically producing a number of n-6 and n-3 hydroxy fatty acids. Submicromolar levels of n-3 hydroperoxy and hydroxy fatty acids specifically antagonize platelet-aggregating effects of an AA metabolite, TXA_2. These are the first studies, to our knowledge, that identify a biological effect for these n-3 hydroperoxidized derivatives. With regard to structural features, the longer-chain 22-carbon metabolites of n-3 parent fatty acids with the greatest degree of unsaturation were the most potent inhibitors (i.e., 22:6n-3). These derivatives were at least one order of magnitude more potent in the platelet preparation compared to a recent report from our laboratory of similar inhibitory effects in vascular smooth muscle preparations (15). Albrand *et al.* (16) have demonstrated that the most stable conformation of the 22:6n-3 hydroxy derivatives are the coiled ones. Moreover, the most potent TXA_2 antagonist, the 14-hydroxy derivative of docosahexaenoic acid, exhibited stable conformations quite similar to those of TXA_2. Thus, specific conformations, in addition to the hydroperoxy and hydroxy functions and/or the presence of a conjugated diene, may be required for these derivatives to effectively interact with the TXA_2 receptor. Also, since the 14-OH derivative is more active than the 11-OH- and 17-OH 22 carbon n-3 positional isomers in both the present and previous studies (15,17), the position of this moiety appears crucial. Differences in potency were associated with specific structural aspects of the 22:6n-3 derivatives: the functional group (OOH > OH) and the position of oxygenation (14-OOH, 14-OH, 20-OOH > 11-OOH, 17-OOH > 10-OOH > 11-OH, 8-OOH, 7-OOH > 4-OOH) were modulating factors. These results argue for a relatively specific anti-TXA_2 activity of these lipoxygenase products.

Similarly, OH-22:6n-3 has been shown to block the TXA_2-induced decreases in cerebral blood flow and increases in mean arterial blood pressure measured *in vivo* in the rat (Karanian, *et al.*, unpublished data). Reported functional changes in platelet-aggregation in the present study may be attributed directly to antagonism at the platelet or vascular smooth muscle cell TXA_2/PGH_2 receptor. *In vitro*, OH-20:4n-6 has been shown to weakly inhibit $TXA_2/PGH2$-induced platelet-aggregation by interference at the receptor level (8). Moreover, 22-carbon n-3 parent fatty acids have been shown to inhibit both platelet-aggregation and TXA_2 binding (18,19). We have recently observed a dose-dependent inhibition of TXA_2 binding in platelets incubated with 14-OH-22:6n-3 with an IC_{50} of 0.9 μM (20). Analysis of binding parameters indicates that these derivatives induce a marked decrease in the affinity of the receptor for TXA_2 with a mild change in the number of receptor sites. Although less efficacious, inhibition of TXA_2 binding correlates strongly with inhibition of TXA_2-induced platelet-aggregation and is directly related to the concentration of hydroxy fatty acid (21). In the present study, we report that 0.25 μM 14-OH-22:6n-3 produced a 68% inhibition of AA-induced platelet-aggregation, whereas 0.9 μM produced a 50% inhibition of platelet TXA_2 binding. Changes in platelet TXA_2/PGH_2 receptor characteristics may only, in part, explain inhibitory effects of these derivatives.

Human platelets enriched with 22:6n-3 after a fish oil supplement produce small quantities of OH-22:6n-3 upon stimulation with thrombin (22). A more recent report from our laboratory, however, has demonstrated that the marked increase in the total lipid content of 22:6n-3 in rat platelets after an n-3–rich diet (23) correlated with a fourfold increase in OH-22:6n-3 production, to a level of approximately 340 picomoles (0.34 μM) per mL platelet suspension after stimulation with a calcium ionophore, A23187 (24). These recent data, taken together with the present findings, suggest that 22:6n-3 lipoxygenase derivatives may reach physiologically significant levels (>0.25 μM) with regard to platelet-vascular smooth muscle cell interactions involving TXA_2. Considering their relatively high potency as TXA_2 antagonists, they may contribute in part to the previously reported inhibitory effect of docosahexaenoic acid on AA or TXA_2-induced vascular contraction (25) and platelet-aggregation (18,26). Changes in cellular function, such as platelet-aggregation and smooth muscle contraction, may be regulated by the collective action of various lipoxygenase products of a number of polyunsaturated fatty acids.

22-Carbon hydroperoxidized lipoxygenase products may be physiologically active in platelet-vascular smooth muscle and other cell interactions. These metabolites may interfere with eicosanoid receptors (15) and alter the endogenous pro-

duction of eicosanoids (9), thereby directly resulting in changes in cell function. Although continued study of more potent hydroperoxidized analogues and their metabolism is necessary, these endogenously produced hydroperoxy/hydroxy derivatives may be involved in cardiovascular homeostasis and in certain pathophysiological states. Our understanding of the structure-activity relationships of these fatty acids may be of use in designing more efficacious TXA_2 antagonists. In this regard, these metabolites and related chemical forms may be of therapeutic value.

ABSTRACT: Major risk factors for coronary heart disease were assessed in two populations of Tanzania, one on a fish diet (FD) living along the coast of Lake Nyasa, and the other, mainly on a vegetarian diet (VD), living in a farming area. Lower blood pressure values were found in the FD subjects (n = 618) vs. VD (n = 618) (systolic blood pressure, SBP, 120 ± 15 vs. 135 ± 20, $P < 0.01$; diastolic blood pressure, DBP, 70 ± 9 vs. 78 ± 11, $P < 0.01$, respectively). In an FD subgroup (n = 61), total cholesterol (TC) (122 vs. 136 mg/dL, $P < 0.01$); triglycerides (TG) (82 vs. 105 mg/dL, $P < 0.01$); and lipoprotein (a) [Lp(a)] (19.9 ± 18.4 vs. 32.3 ± 22.4, $P < 0.001$) were lower than in a VD subgroup (n = 55). Serum fatty acids (FA) in the FD subgroup were as follows: eicosapentaenoic acid (EPA) (20:5) 2.48 vs. 0.72%, docosahexaenoic acid (DHA) (22:6) 5.93 vs. 1.49%, vs. the VD, respectively. Arachidonic acid (AA) (20:4n-6) also was higher in the FD vs. the VD group (9.85 vs. 8.30%, $P < 0.05$), whereas 18:2n-6 was about double (23.97 and 14.85%) in VD vs. FD. The peculiar serum FA pattern in FD reflected the FA of dietary fish. In fact, in four main species of lake fish, DHA was 8–19%, higher than EPA (1.8–4.2%), in contrast with the situation in cold-water fish, and AA was 5.8–8%, higher than in cold-water fish. The data, obtained in populations strictly on natural, unprocessed, low-fat diets, show that a diet based on freshwater fish results in lower BP, serum TC, TG, and Lp(a), and suggests that serum AA is not reduced when the major dietary n-3 is DHA rather than EPA.

Lipids 31, S-309–S-312 (1996).

Comparative studies in populations living on different diets have provided information on correlations between dietary fat and incidence of coronary heart disease (CHD). Consumption of manufactured foods in economically advanced countries, however, minimizes dietary differences, and comparisons among populations are limited by confounding (e.g. genetic) factors. Studies in genetically homogeneous populations that are living on differing diets are therefore quite useful. The World Health Organization (WHO) is involved in studies aimed at assessing the comparative incidence of CHD risk factors in populations living in areas with distinctly different dietary patterns. A study was thus set up by WHO and coordinated by the Institute of Clinical Medicine, University of Padua, (Italy), aimed at evaluating blood pressure (BP) and serum lipids in populations on different diets, in the Lugarawa district of Tanzania. The study was centered on two areas, one (Lupingu) on the shores of Lake Nyasa, and the other (Madilu), a distance of about 90 mi from the lake. Processed foods are not available, and the diet strictly reflects local food sources. The population living in the coastal area eats mainly fish (fish diet, FD); whereas, in the rural area, grains, potatoes, and vegetables are the main components of the diet (vegetarian diet, VD). Relationships between serum fatty acid (FA), reflecting the composition of dietary fat, and BP and serum total cholesterol (TC), triglyceride (TG), and lipoprotein(a) [Lp(a)] levels were investigated. In addition, correlations between metabolically related FA in serum lipids in the two populations were evaluated and the FA compositions of the four major edible species of lake fish were analyzed. This paper is mainly focused on serum FA profiles and on relationships among individual FA of the n-6 and n-3 series in the two population groups. The major observations are that levels of BP, TC, TG, and Lp(a) were significantly lower in the fish-eating population. n-3 FA, especially 22:6 (docosahexaenoic acid, DHA), was higher in plasma lipids of subjects on the fish diet, as expected, but in this group, levels of 20:4n-6 (arachidonic acid, AA) were also higher than in people living inland.

MATERIALS AND METHODS

BP and Lp(a) measurements were made on large population groups (over 600 subjects) in each area, whereas determinations of serum TC, TG, and serum FA profiles were carried out on a smaller, representative population, due to difficulties in analysis of a larger number of samples. The study was

based on collaboration with the rural hospital in Lugarawa, Tanzania, which participates in the medical programs of the International College for Health Cooperation (CUAMM).

Subjects. A total of 654 (368 men and 286 women) in Madilu (on a VD) and of 622 (370 men and 252 women) subjects in Lupingu (on a FD) were recruited.

Dietary assessment. Dietary survey was carried out through questionnaires collected from 25 families in each village. Dietary constituents were calculated using standard food tables (1). For collecting data, since the questionnaire adopted in the World Health Organization (WHO) MONICA study (2) could not provide reliable data on individual diets, except for salt supplementation, an accurate assessment of food consumption and composition was obtained in each family. In this manner, an indirect estimate of individual diet was obtained. Calculated daily average intakes for the VD were as follows: total calories, 1,357–2,860 kcal: 41% from maize (~250 g), 17% from rice (~100 g), 15% from beans (~100 g), 6% from potatoes (~100 g) and bananas (~140 g), and ~13% from low-alcohol beverages (1 L). Calculated daily average intakes for the FD were as follows: 1,553–2,838 total calories: 23% from fish (~500 g), 38% from tapioca (a starch obtained from the root of the cassava) (~250 g), ~7% from beans (~50 g), 6% from rice (~40 g), and 9% from low-alcohol beverages (~0.75 L). Salt intakes were 4.4 ± 1.5 g/d in FD vs. 4.0 ± 1.4 in VD, respectively.

Statistical analysis. Comparisons between groups were made by Student's *t*-test analysis. Correlations were evaluated using Pearson's coefficient.

Measurements. All subjects were subjected to BP measurements and blood drawing. Frozen serum samples were shipped to Italy; Lp(a) was measured in all samples, whereas 61 (26 men and 35 women) FD and 55 (24 men and 31 women) VD randomized samples were analyzed for lipid levels and FA profiles. FA analysis also was carried out on samples of typical lake fish. TC and TG were measured by standard techniques, and Lp(a) concentrations were determined by immunoassay (3). FA of serum lipids and of fish from Lake Nyasa were analyzed by capillary gas chromatography. Serum FA of 16 Italian subjects, 9 males and 6 females, aged 25–42, as reference samples, representative of a population on a Western diet, were also analyzed.

RESULTS

Serum TC, TG, Lp(a), and BP were significantly lower in the FD than in the VD (Table 1). Major differences, some unexpected, between the two groups were observed in major serum n-6 and n-3 polyunsaturated fatty acids (PUFA), reported in Table 2, together with levels in Italian subjects taken as reference values. Levels of 18:2n-6 were higher and those of n-3 FA lower in VD than in FD. In FD, despite elevation of n-3 FA, AA was, surprisingly, even higher than in VD, and, among the n-3, DHA was considerably elevated over the level of EPA. In the Italians, levels of 18:2 n-6 and of 20:4 n-6, were the highest and the lowest respectively, of the three groups, whereas n-3 FA levels were comparable to those in the VD group. The ratio of n-3 to n-6 FA in the FD group was about four- and eightfold that in VD and in Italians, respectively. The combined elevation of both AA and, among n-3, especially DHA, in the FD group, prompted us to analyze the FA in samples from various fish species from the lake, typically eaten by the FD group. These values (Table 3) were compared with those reported for a tropical fish and for North Atlantic mackerel. The fish species have a different total lipid content, but all contain appreciable AA and DHA concentrations higher than those of EPA. These profiles resemble those in the Equatorial Indian halibut and other tropical species (4), and are different from those of cold-water fish (5). Calculated intakes of AA in the FD group are in the range of 0.4–0.8 g/d. Although we do not yet have detailed data on fat intake, it appears that serum FA in the FD group reflected the composition of fish FA, i.e., levels of both AA and DHA were relatively high. Correlation analysis reveals that, in the n-6 sequence, serum levels of 20:3 and 18:2 (Δ6 desaturation + elongation) were correlated in both groups (Table 4), but AA was correlated with 18:2 and 20:3 (Δ5 desaturation) only in VD. In the n-3 sequence, there was a significant correlation between EPA and 18:3 in VD, but not between DHA and 18:3, or between DHA and EPA. In FD, however, there was only a correlation between DHA and EPA.

DISCUSSION

This study shows that, in genetically homogeneous population groups living on distinctly different diets, the incidence

of major CHD risk factors is different. Various components in the diets, which need to be defined and quantified, may be responsible for this; one major difference concerns consumption of fish, and this is reflected in the serum FA profiles. FA profiles of the four lake-fish species resemble those of tropical fish (3,4) and are quite different from those of nontropical fish (5). High levels of both AA and of n-3 FA, especially DHA, in serum of FD, therefore, clearly reflected the composition of fish FA. Relatively low levels of EPA in fish may partly explain why AA levels in serum of the FD group were not reduced, since EPA competes with AA more effectively than DHA for esterification into lipids. Some as yet unspecified characteristics of the diet, such as a rather low fat intake, may also be important in affecting serum PUFA profiles. For instance, levels of both AA and n-3 FA in the VD group, on a diet providing low intakes of preformed long-chain PUFA, were comparable to those in the Italian subjects, on a typically omnivorous diet. This suggests efficient biosynthesis from the 18-carbon precursors in VD, as supported also by the good product-precursor correlations in serum FA. An additional observation is that, despite high levels of AA in serum, n-3 FA still exerted beneficial effects, e.g., on BP, suggesting that these were not mediated by interference with AA utilization and with the eicosanoid system. The lower serum TG levels, and to some extent, the lower BP values in the FD group, were predictable, although differences in BP between FD and VD subjects were greater than expected from data in clinical studies (7). Additional and undisclosed dietary factors may contribute to amplify effects of the fish diet, but differences in salt intake were excluded. Finally, levels of Lp(a), an independent risk factor for CHD (6), were significantly lower in FD. Lp(a) levels are determined mainly genetically, although dietary factors appear to elevate, [e.g., *trans* (9) and saturated FA (8)], or reduce, [n-3 FA (11,12)], this variable. Unsuspected genetic factors may, however, explain different Lp(a) values in the two groups. In conclusion, the Lugarawa study shows marked differences in the incidence of major CHD risk factors in two population groups living on distinctly differing simple and unprocessed foods. In addition, consumption of fish with elevated levels of both AA and n-3 FA still results in beneficial influences on various physiological variables.

n-3 Fatty Acids Decrease Colonic Epithelial Cell Proliferation in High-Risk Bowel Mucosa

ABSTRACT: The n-3 fatty acids (C20:5, eicosapentaenoic acid; C22:6, docosahexaenoic acid) may be important in the development, growth, and metastasis of colon cancer, a leading cause of death in North America. Patients who have had a bowel neoplasm have a high risk of developing a second neoplasm, and this risk is associated with a high percentage of cells correspond to the S phase of bromodeoxyuridine (BrdUrd) labeling in mucosal epithelial cells. To determine the effect of n-3 fatty acid supplementation on DNA synthesis of rectal mucosa, patients with stage 1 or stage 2 colon carcinoma or adenomatous polyps were randomized to consume either 9 g/d n-3 fatty acid capsules or 9 g/d placebo capsules. Plasma phospholipid fatty acid analysis and proctoscopic mucosal biopsies were performed at baseline, 3, and 6 mon. Colonic crypts were isolated from the mucosa, disassociated with enzymes, and incubated with BrdUrd, and %S phase was measured by flow cytometry. The plasma phospholipid n-6/n-3 ratio was determined by gas chromatography. Supplement compliance was assessed by plasma phospholipid n-6/n-3 ratio. Mean capsule consumption in these two group was 82%. Prior to supplementation, there were no significant differences in the %S phase and the plasma n-6/n-3 ratio between these groups. Patients whose colonic epithelial cells indicated hyperproliferation at baseline showed a strongly positive correlation to the %S phase of BrdUrd uptake and the n-6/n-3 ratio. There was no significant change after n-3 treatment in patients with low baseline. Those in the placebo group showed no significant difference in n-6/n-3 ratio, although there was an increase in the %S phase of BrdUrd uptake at 6 mon. The n-3 group did not have significant side effects, and polyps were not found after completing 12 mon of n-3 fatty acid supplementation. This study suggests that n-3 fatty acid may be a useful chemopreventive agent in some patients as reflected in a plasma biomarker of colon tumor growth and metastasis. A low plasma phospholipid n-6/n-3 fatty acid ratio may serve as a nutritional marker that is associated with colonic epithelial cell hyperproliferation in the n-3–supplemented group as compared with the placebo group.Characteristics of mucosal proliferation at baseline may be a crucial factor for the effect of n-3 fatty acid supplementation.

Abbreviations: BrdUrd, bromodeoxyuridine; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FITC, fluorescein isothiocyanate; LI, labeling index.

An estimated 133,500 cases of colorectal cancer were diagnosed in the United States in 1996 (1). Colorectal cancer is the second leading cause of cancer mortality and will result in over 54,900 deaths in the United States. Epidemiological and laboratory animal studies appeared that linked high fat consumption with colorectal cancer (2). The low colon cancer rate among Alaskan and Greenland Eskimos has been associated with high consumption of fish (3,4). Animal studies indicated that the primary effect of fat is exerted on the promotion stage of carcinogenesis, with the n-6 fatty acid having been recognized as a major promoter (5–7), whereas fish oil containing the n-3 fatty acids eicosapentaenoic acid (EPA; C20:5n-3) and docosahexaenoic acid (DHA; C22:6n-3) are found to reduce tumor incidence, growth, and metastasis (8–11). The proposed pathophysiological mechanisms of fish oil protective effects include influences on the mucosal prostaglandin synthesis, reducing ornithine decarboxylase and tyrosine protein kinase activities, which has been shown to exert a proliferative effect on the colonic mucosa (12,13).

Colorectal adenomatous polyps with abnormal cell–kinetics characteristics has been suggested to be putative precursor lesions to carcinoma (14). Bruce *et al.* (15) and Lippmann *et al.* (16) showed that hyperproliferation of colonic epithelium is an appropriate intermediate end-point for chemopreventive intervention.

By the support of prior evidence, we conducted this clinical trial by use of objective flow cytometric assay. The aim of our study was to investigate the tolerance and effect of long-term n-3 fatty acid supplementation on DNA synthesis in high risk bowel mucosa and the efficacy of the plasma phospholipid n-6/n-3 ratio as a nutritional marker on the prevention of colonic tumor development and metastasis.

EXPERIMENTAL PROCEDURES

Patients with resected Dukes's A or B adenocarcinoma of the colon or rectum or severely dysplastic adenomatous polyps were recruited. All patients were eligible only after complete excision of their cancers as well as of any associated polyps. Twenty-seven patients were (2:1) randomly assigned to double-blind treatment groups: 17 for the n-3 fatty acid group and 10 for the placebo group. The n-3 capsules were composed of IND #041821 (NAOO, Charleston, SC), an n-3 ethyl ester

Copyright © 1996 by AOCS Press

concentrate prepared from vacuum-deodorized menhaden oil using transesterification, urea adduction, and short-path distillation. The concentrate contained approximately 80% n-3 fatty acid ethyl esters (44% EPA, 24% DHA, 10–12% other n-3 fatty acid ethyl esters). The placebo ethyl ester (NAOO) was prepared from corn oil. The preparation contained approximately 50% linoleic ethyl ester, 10% C_{16}, 15% other C_{18} fatty acid ethyl esters. Both capsules contained 0.2 mg/g 1,5-di-*tert*-butyl-1,4-benzohydroquinone as antioxidant, 2 mg/g tocopherols, and 2.0 mg/g cholesterol. Cholesterol was added to the placebo capsules to match the n-3 capsules. Patients were required to consume 9 capsules per day, 1 g per capsule.

Cell proliferation study: BrdUrd incorporation. Mucosal tissue obtained by proctoscopic mucosal biopsy was incubated for 20 min in 1.5 mM EDTA and 1.3 mM dithiothreitol in calcium-free, phosphate-buffered saline to separate crypt cells. After the suspension was precipitated on ice, crypt cells were prepared for enzymatic digestion. The cell suspension was filtered through a 0.22 μm sterile membrane. Single-cell suspensions were incubated at 37°C in RPMI (pH 7.2–7.4) containing 5% fetal calf serum, 20 μM fluorodeoxyuridine, and 30 μM BrdUrd for 1 h. After BrdUrd labeling, the cells were fixed in ice-cold 70% ethanol. Ethanol-fixed cells were added to 2 N HCl with 0.2% pepsin to denature the DNA for detection of BrdUrd by the fluorescein isothiocyanate (FITC)-conjugated monoclonal antibody. After incubation for 40 min in the dark, the cells were centrifuged and neutralized with 0.1 M sodium tetraborate (pH 8.5). Cells were washed and incubated with 20 μl of FITC-conjugated anti-BrdUrd antibody (Becton Dickinson, San Jose, CA) for 45 min in the dark. Nuclei labeled with BrdUrd-anti-BrdUrd-FITC were then washed and resuspended in 0.01 mg propidium iodide. After 15 min of staining, cells were ready for analysis by flow cytometry.

Flow cytometry. Cytometric analysis was performed on a fluorescence activated cell sorter (FACS) (Becton Dickinson, Mountainview, CA). Cells were excited with a 15 mW laser at 488 nm. Red fluorescence was collected through a 585-nm bandpass filter and recorded as the total amount of DNA. Green fluorescence of the BrdUrd-labeled cells was collected through a 530-nm bandpass filter and recorded as the amount of incorporated BrdUrd. Data were collected in a 64 x 64 channel distribution showing the total DNA (red) against the logarithmic amount of incorporated BrdUrd (green).

Fatty-acid analysis. Plasma phospholipid fatty acid was extracted by use of a 2:1 mixture of chloroform/methanol. Hepatadecanoic acid (Nu-Chek-Prep, Elysian, MN) was added as an internal standard prior to extraction. The chloroform layer was dried, and thin-layer chromatography with LK5D silica gel plates (Whatman Chemical Separations, Inc., Clifton, NJ) was applied to separate various lipid fractions. The solvent system used to develop the plates was a mixture of petroleum ether/diethylether/glacial acetic acid (80:20:1). Phospholipid fractions were scraped and placed into teflon-lined, screw-cap glass tubes and hydrolyzed and methylated under nitrogen in a steam bath for 45 min by 14% boron/trifluoride in methanol (Alltech Associates, Deerfield, IL).

Gas–liquid chromatography. Fatty acid methyl esters were separated and quantified by use of a Hewlett Packard (Palo Alto, CA) 5890 Series II gas chromatograph equipped with a 30-M fused silica capillary column (0.32 mm I.D., 0.20 μm film thickness, Supelco, Bellefonte, PA) and a flame ionization detector. Helium was used as the carrier gas with a flow rate of 5 mL/min. The split ratio used was 14.3:1 with injector and detector temperatures at 240°C. Oven temperature was programmed to start at 70°C, then rise to 130°C at a rate of 10°C/min; then to 150°C at a rate of 2°C/min; then reach 195°C at a rate of 3°C/min. Peaks were identified by comparison to authentic standards (Nu-Chek-Prep) by a Hewlett Packard 7673 controller. Quantitation was based on the relative responses of the internal standard and fatty acid methyl esters in the sample as compared with the responses of standards. Results were expressed in absolute concentrations (μmol/L plasma) as well as a relative percent of the total fats analyzed.

RESULTS

Fatty acid analysis of the plasma phospholipid showed that EPA and DHA contents increased over 6 mon in the n-3–supplemented group, whereas levels of linoleic acid and arachidonic acid decreased (Figs. 1 and 2). The mean of the plasma n-6/n-3 ratio in the n-3 group decreased over 6 mo. Unlike the n-3 group, the placebo group showed no significant changes in the concentration and relative percent of EPA, DHA, linoleic acid, arachidonic acid, and the n-6/n-3 ratio (Figs. 3 and 4).

The BrdUrd labeling index (LI) of colonic mucosa in the n-3 group showed a strongly positive correlation to the plasma phospholipid n-6/n-3 ratio. It is interesting that there was a wide range of BrdUrd labeling index among subjects before starting this trial. From the pattern of mucosal proliferation at baseline, it can be classified into two phenotype categories: high percent of BrdUrd-labeled cells in the S phase relative to the total number of cells examined (>10%S phase of BrdUrd LI, n = 7) and low proliferation (<10%S phase of

BrdUrd LI, n = 10). It is important to note that the responses of decreasing BrdUrd LI to n-3 fatty acid supplementation mostly resulted from reductions of patients whose baseline patterns showed abnormal or hyperproliferation (Fig. 5). All

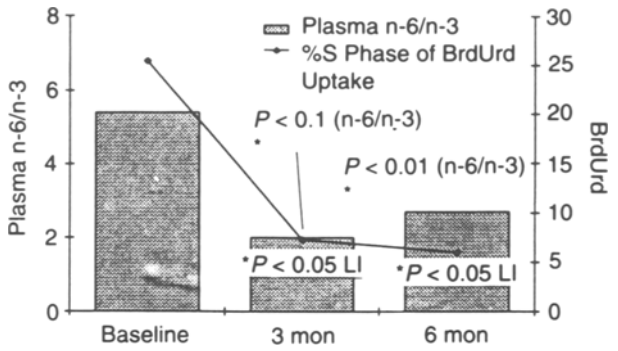

FIG. 5. Bromodeoxyuridine (BrdUrd) uptake in n-3 group.

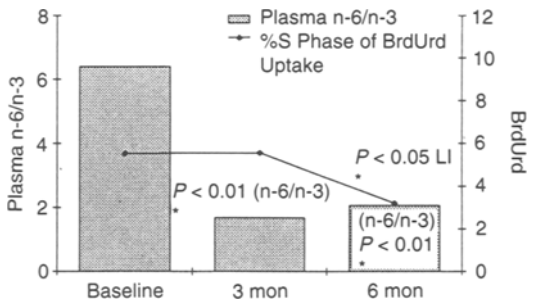

FIG. 6. Patients with high baseline proliferation on n-3 fatty acid supplement; *P* values were analyzed by Student's *t*-test. Abbreviation as in Figure 5.

hyperproliferative patients were found to have significantly decreased BrdUrd LI after 3 mon of n-3 treatment. In contrast, there was no dramatic change over time in those with low baseline LI in n-3. Subjects with high baseline LI decreased the mean proliferation rate of epitheial cells from 25.5 to 7.3 at 3 mo, along with the decline of the plasma n-6/n-3 ratio from 5.4 to 2.0. (Fig. 6). In contrast, other subjects with low baseline tended to maintain the proliferation rate, even the plasma n-6/n-3 ratio significantly decreased from 6.4 to 1.7 at 3 mon (Fig. 7). In the placebo group, the %S phase of BrdUrd uptake was increased from less than 6 to 9% at 3 mon, and to over 10% at 6 mon (Fig. 7). Despite the additional 4.5 g per d of linoleic acid consumption, the plasma n-6/n-3 ratio in the placebo group showed no significant difference. In addition, prior to supplementation, there were no significant differences in the plasma phospholipid n-6/n-3 ratio between these groups.

The fish oil supplement was well tolerated by study participants. There were no side effects, and no additional polyps were found in 12/12 patients who completed 12 mon of n-3 supplementation. Plasma fatty acid levels and capsule counts (82%) indicated good overall compliance. None of the patients experienced significant body weight gain or loss or any other physiological changes. Responses of the fatty acid profile and mucosal proliferation rate to n-3 was noticed as soon as three months after treatment started.

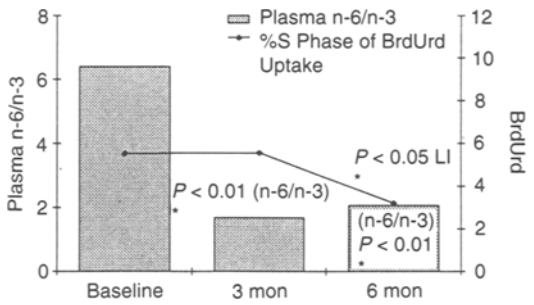

FIG. 7. Patients with low baseline proliferation on n-3 fatty acid supplement; *P* values were analyzed by Student's *t*-test. Abbreviation as in Figure 5.

DISCUSSION

In our study, the plasma phospholipid n-6/n-3 ratio successfully predicted responses of mucosal LI to fish oil supplementation. Increased incorporation of 22:6n-3 (DHA) and 20:5n-3 (EPA) and decreased incorporation of 20:4n-6 (AA) are reliable indices of n-3 supplement ingestion. Previous studies also showed that high fish oil intake altered the plasma fatty acid profile and incorporation of n-3 fatty acids into colonic mucosal cells (17). The plasma fatty acid profile has been shown to parallel the tissue status (18). Due to limitation of obtaining rectal biopsy specimens, we developed this plasma phospholipid n-6/n-3 ratio as a nutritional compliance marker. This new finding can be beneficial for the future design of fish oil chemoprevention trials.

Patients in the n-3 group experienced significant reductions in the BrdUrd LI. The effect of n-3 fatty acids was found exert only in patients with hyperproliferative patterns in this study. It seems that patients who had abnormal patterns of colonic cell proliferation benefited more from fish oil supplementation. Occurrence of adenomatous polyps in those patients who have normal baseline patterns may be not related to different types of fat intake. It has been suggested that more than one genetic pathway leads to the development of adenocarcinoma of the colon and rectum (19). It is possible that the effect of fatty acids on lowering abnormal proliferation is only capable in hyperproliferation. Anti *et al.* (18) previously reported a similar discrepancy among subjects' proliferation patterns at baseline. Our data shows that the LI of hyperproliferation could reach more than 30% BrdUrd LI, although previous data indicated that the highest percentage of LI was only in the low 20s by use of [^{3}H]thymidine autoradiography. Unlike Italian diets based on olive oil, which is low in linoleic acid, however, North American diets consume much more n-6 polyunsaturated fatty acid, which consists of more than 50% safflower, sunflower, soybean, corn, and cottonseed oils (19, 20). In our study, there was approximately 15 g/d of linoleic acid (18:2n-6) in the average diet of 30% fat content in both groups. Because of the competition between n-3 and n-6 for eicosanoid formation in the phospholipid of cell membranes, it is possible that chemoprevention studies conducted in North America need a longer period of treatment and a higher supplemental dose of n-3 fatty acids (21).

In conclusion, these cases suggest that n-3 fatty acids may be useful chemopreventive agents, as reflected in a plasma biomarker of colon proliferation tumor growth and metastasis. A decrease in the plasma phospholipid n-6/n-3 ratio can serve as a nutritional marker associated with colonic epithelial cell proliferation in the n-3–supplemented group compared with the placebo group. More studies must be undertaken, however, to test whether n-3 fatty acids are effective in inhibiting mucosa neoplastic proliferation in various genetic pathways.
