## S Supporting Information

**ABSTRACT:** The phase behavior of grafted d-polystyrene-*block*-poly(methyl methacrylate) diblock copolymer films is examined, with particular focus on the effect of solvent and annealing time. It was observed that the films undergo a two-step transformation from an initially disordered state, through an ordered metastable state, to the final equilibrium configuration. It was also found that altering the solvent used to wash the films, or complete removal of the solvent prior to thermal annealing using supercritical CO<sub>2</sub>, could influence the structure of the films in the metastable state, though the final equilibrium state was unaffected. To aid in the understanding to these experimental results, a series of self-consistent field theory calculations were done on a model diblock copolymer brush containing solvent. Of the different models examined, those which contained a solvent selective for the grafted polymer block most accurately matched the observed experimental behavior. We hypothesize that the structure of the films in the metastable state results from solvent enrichment of the film near the film/substrate interface in the case of films washed with solvent or faster relaxation of the nongrafted block for supercritical CO<sub>2</sub> treated (solvent free) films. The persistence of the metastable structures was attributed to the slow reorganization of the polymer chains in the absence of solvent.

## ■ INTRODUCTION

Grafted polymer films (otherwise known as polymer brushes) have garnered much attention due to their desirable physical properties relative to conventional nongrafted films (including improved mechanical robustness and prevention of dewetting), giving grafted films great potential as surface coatings.<sup>1–3</sup> Alongside this, advances in polymerization techniques, such as polymerization from surface bound initiators,<sup>4,5</sup> and functionalization chemistry, including various “click” reactions,<sup>6,7</sup> have allowed for great diversity in the types of films that can be produced.

Grafted diblock copolymer films are a particularly interesting subset of these films. It is well-known that block copolymers can undergo microphase separation to form a number of structures with periodicities on the order of tens of nanometers, and this makes them candidates for the next generation of sensors, membranes, or lithographic templates.<sup>2,8</sup>

Recently, the phase diagram of dry (i.e., solvent free) diblock copolymer brushes (DCBs) has been simulated using self-consistent field theory (SCFT).<sup>9</sup> This model determined that four phases may be formed: hexagonal, stripe, inverse hexagonal, and uniform (Figure 1).

This is fewer than observed with bulk block copolymers systems due to the fact that microphase separation in these films is effectively two-dimensional. The confinement of the polymer also introduces two additional variables into the phase space. As with bulk block copolymers, the phase behavior of DCBs is dependent on the molecular weight of the polymer ( $M_n$ ), the composition ( $f$ ), and the Flory–Huggins interaction parameter

( $\chi$ );<sup>8</sup> however, DCBs also show a dependence on both the grafting density ( $\sigma$ ) and the relative surface tensions of the two blocks ( $\Delta\gamma$ ).<sup>9</sup>

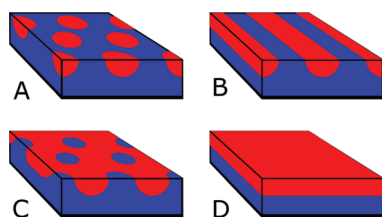

These variables are often expressed in molecular weight independent terms to allow for comparison between different polymer films, with  $\chi N$ ,  $\Lambda N$ , and  $L/aN^{1/2}$  typically being used to describe the interaction strength, surface tension, and grafting density contributions, respectively.<sup>10</sup> Here  $N$  is the degree of polymerization,  $\Lambda$  is a term proportional to  $\Delta\gamma$ ,<sup>9</sup>  $L$  is the measured film thickness, and  $a$  is the mean free end-to-end length. The film is also usually discussed in terms of an upper (nongrafted) polymer block,  $A$ , and a lower (grafted) block,  $B$ . Unlike the bulk phase diagram, the dry brush phase diagram is noticeably asymmetric; it also displays strong dependences on both  $\sigma$  and  $\Delta\gamma$ .<sup>9,10</sup>

In a recent publication we described the first attempt to compare the experimental morphology with the dry brush theoretical model.<sup>10</sup> In that study we observed all four phases, demonstrating a qualitative agreement with the model; however, we also found that there were substantial quantitative differences between the experimental and theoretical phase behavior.<sup>10</sup> It was subsequently concluded that the most probable cause of this variation was the retention of solvent in the films.

**Figure 1.** The four phases formed by microphase-separated DCBs: (A) hexagonal, (B) stripe, (C) inverse hexagonal, and (D) uniform. The nongrafted block is colored red and the grafted block blue.

In the bulk state, the effect of solvent has been examined from both a theoretical and an experimental perspective.<sup>11–14</sup> At low solvent volumes the polymer is plasticized by the solvent leading to an increase in the rate of polymer chain diffusion while concomitantly decreasing the glass transition temperature ( $T_g$ ). For block copolymers additional consideration needs to be given to the strength of interaction between the solvent and the two polymer blocks. With a neutral solvent (i.e., a good solvent for both blocks) the phase diagram is largely unchanged; however, the solvent improves the miscibility of the two polymer blocks, leading to an effective decrease of  $\chi$  with increasing solvent content.<sup>15,16</sup> In the dilution approximation,  $\chi$  decreases linearly with the volume fraction of polymer,<sup>15</sup> and such a correlation has been experimentally shown to accurately predict shifts in the order–order transitions (OOT), though it is less accurate with predicting shifts in the order–disorder transition (ODT).<sup>16,17</sup> If the solvent used shows a preference for one block over the other, then the first block will be swollen more than the second. This will cause an increase in the relative volume fraction of the preferred block and correspondingly shift the expected phase boundaries.<sup>11</sup>

In this report the effect of solvent on microphase separation in DCBs is examined using a range of solvents. The films were prepared using d-polystyrene-*block*-poly(methyl methacrylate),  $\text{dPS}_x\text{PMMA}_y\text{OH}$ , copolymers, where  $x$  and  $y$  define the approximate size of each block (in kDa) and the OH represents the terminal hydroxyl group through which the polymers are grafted to the surface. The films were subsequently treated using a number of pure and mixed solvents. Specifically, toluene, tetrahydrofuran (THF), dichloromethane (DCM), and ethyl acetate were the pure solvents used, all of which are good solvents for both polymer blocks. The mixed solvent used was a 1:1 v/v mixture of cyclohexane and acetone. Individually, each of these is nonsolvent for one of the blocks;<sup>10,18,19</sup> however, the mixture itself is a good solvent for the copolymers used. Solvent free films were also prepared through treatment with supercritical  $\text{CO}_2$  ( $\text{scCO}_2$ );  $\text{scCO}_2$  is a poor solvent for dPS and PMMA, but it is known to swell both polymers and subsequently will remove excess solvent from the film.<sup>20,21</sup> In addition, the effect of the annealing process (either thermal or solvent annealing) and annealing time on structure of the films was examined.

Finally, we have extended our initial SCFT calculations that supported the solvent effect hypothesis. The results of these models are compared to the observed experimental results.

## EXPERIMENTAL SECTION

The hydroxyl-terminated diblock copolymers were purchased from PSS (Polymer Standards Service; Mainz, Germany) and used without further purification. Polished silicon wafers were purchased from Prolog

Semicon Ltd. (Ukraine). These were cleaned with a piranha solution (70%  $\text{H}_2\text{SO}_4$ , 30%  $\text{H}_2\text{O}_2$ ) at 90 °C for 1 h, washed with water and ethanol, and then dried using a stream of  $\text{N}_2$  gas. (Caution: piranha solution can react violently with organic compounds.) AR grade solvents were obtained from Fisher.

Relatively thick ( $\sim 70$  nm) films of the polymer were prepared by spin-coating 2 wt % solutions (in toluene) of the polymer at 2000 rpm onto cleaned silicon wafers. The films were annealed at 180 °C, under vacuum, for 24 h to graft the polymer chains to the surface. After cooling the wafer was cut into fragments  $\sim 1$  cm<sup>2</sup> in size. The excess (nongrafted) polymer was removed from each fragment by sonication in the desired solvent ( $2 \times 10$  min using  $\sim 5$  mL of solvent) followed by a quick rinse of each fragment with  $\sim 1$  mL of fresh solvent. The films were dried using a stream of  $\text{N}_2$  gas.

One set of toluene washed films were subsequently washed with  $\text{scCO}_2$  (35 °C and 3000 psi for 30 min) to remove the excess solvent.

Microphase separation was induced in the films by either annealing them for a second time at 180 °C under vacuum for a period of 6–192 h or by exposure to a saturated atmosphere of solvent for 24 h.

AFM images were collected with a Veeco Explorer with a 2  $\mu\text{m}$  scanner in noncontact mode. AFM tips (Veeco) with  $k = 20$ –80 N/m and  $f_0 = 130$ –320 kHz were used with a set-point ratio of 50–60%.

Ellipsometry measurements were performed at the University of Surrey, UK, on a J.A Woollam ellipsometer. The optical constants were measured using an uncoated silicon wafer, while the polymer films were modeled as a single Cauchy layer. However, due to the small thicknesses of the grafted films, the values of the Cauchy coefficients were fixed at  $a = 1.52$  and  $b = 0.001$ . When errors are reported, these represent the standard deviation across five measurements.

Gas chromatography–mass spectroscopy measurements (GCMS) were performed using a CP-PoraBond Q fused silica column (25 m  $\times$  0.25 mm; Varian) in a Trace GC Ultra GCMS (Thermo Scientific). The carrier gas (helium) flow rate was 1.2 mL/min, and the temperature was ramped from 40 to 280 °C at 15 °C/min. The samples were prepared by immersing a grafted film (previously toluene washed and dried) into a known amount of DCM for 15 min and comparing the measured total ion current from the toluene peak with previously prepared standards. THF was used as the internal reference for the system. Two sets of measurements were done: one using DCM with a known amount of toluene already present and one without. These gave similar results and all six runs were averaged to give the reported results.

Our SCFT calculations utilize the unit-cell approximation described in a recent paper by Griffiths et al.,<sup>22</sup> generalized to include solvent.<sup>15</sup>

## RESULTS

For this work two  $\text{dPS}_x\text{PMMA}_y\text{OH}$  polymers were used to prepare DCBs (Table 1). These were attached to the substrate through terminal groups on the PMMA block, leaving the smaller dPS block as the nongrafted block. A single large sample of each polymer was prepared initially before being divided into fragments prior to the removal of the excess, nongrafted, polymer; this was done to ensure the greatest homogeneity across the samples.

Ellipsometry measurements were performed on the dry films to determine the film thickness (following 6 h of thermal annealing), and from these results  $\sigma$  and  $L/aN^{1/2}$  values were calculated using known values for the monomer volume and  $a$  (Table 1).<sup>23</sup> The measured values for  $L$  reported here are similar to those previously reported for these polymers<sup>10</sup> and were found to be independent of the washing solvent used within the error of the measurement. Moreover, the calculated values of  $L/aN^{1/2}$  are suitably close to the value of 0.5 used both here and in previous SCFT models.<sup>9</sup>

To determine the volume of solvent present in the dried but unannealed films, both ellipsometry and GCMS measurements were performed on toluene washed films. The resulting calculated volume fractions of solvent in the measured films are reported in Table 2.

The GCMS results qualitatively demonstrate that some solvent remains in the films even after drying with a stream of N<sub>2</sub> gas, though there is disagreement between the two techniques in qualitative terms and all of the measured values have large errors associated with them. It is likely that some of the variation between the two techniques can be attributed to the underlying assumptions made when analyzing the results. For the ellipsometry it was assumed that the refractive index of the polymer film was constant and that there was no difference in the optical constants associated with the substrate (see Experimental Section). This left the film thickness as the only variable to be fitted, with the measured change in film thickness assumed to be proportional to the volume fraction of solvent in the washed film. For the GCMS measurements it was assumed that the washing procedure efficiently removed all of the target from the film, such that the measured amount of toluene in the carrier solvent could be directly compared to the toluene content of the films. Both sets of assumptions have the potential to introduce error into the final measurement. Unfortunately, improving the quality of these measurements is difficult due to the very low volumes of solvent incorporated in the films, and it is not possible to conclude which set of numbers are most accurate. Nevertheless, the above results are consistent with similar experiments carried out on nongrafted polymer films, with both Perlich et al.<sup>24</sup> and Garcia-Turiel and Jerome<sup>25</sup> observing that there is a significant amount of solvent trapped in the film—measured to be between 8 and 14% for toluene in thin polystyrene films.<sup>24</sup> Residual solvent was also observed in the films even after relatively long periods of heating, suggesting that the interaction between the polymer and solvent is strong.<sup>24</sup> These results are supported by other studies,<sup>26</sup> though a recent publication claimed no solvent was present.<sup>27</sup> It has also been reported that there is an additional strong interaction between the solvent and the substrate in certain systems (including in polymer films on silicon wafers).<sup>13,24,25</sup>

Interestingly, both the ellipsometry and GCMS data show a much larger toluene concentration in the dPS<sub>47</sub>PMMA<sub>135</sub>OH films. While the exact cause of this is unknown, or indeed how significant the difference is given the errors associated with the measurements, it is possible that this variation is due to the lower grafting density of the dPS<sub>47</sub>PMMA<sub>135</sub>OH films. A larger distance between grafting points should allow for greater

**Figure 2.** AFM phase images of dPS<sub>47</sub>PMMA<sub>135</sub>OH (left) and dPS<sub>62</sub>PMMA<sub>69</sub>OH (right) solvent annealed with toluene (first row), THF (second row), DCM (third row), and ethyl acetate (fourth row).

interpenetration of solvent, and this may, in turn, lead to higher solvent retention.

The assumption in the ellipsometry that the refractive index of the solvent and polymer is the same will clearly not be valid for a film expanded with scCO<sub>2</sub>. Therefore, to examine the effect that scCO<sub>2</sub> will have on DCBs a test was done using a thick (effectively nongrafted) dPS<sub>62</sub>PMMA<sub>69</sub>OH film. Post scCO<sub>2</sub> treatment the film was determined to have a thickness of 80.9 nm; however, following thermal annealing (for 6 h at 180 °C) it was observed that the film thickness had decreased to 73.2 nm. This result indicates that, like the grafted films washed with solvent, those treated using scCO<sub>2</sub> should undergo a volume contraction during thermal annealing.

**Solvent Annealing.** Solvent annealing has previously been used to good effect to facilitate the formation of microphase-separated structures in nongrafted diblock copolymer films,<sup>28</sup>

with microphase-separated structures being formed after relatively short annealing times.<sup>29</sup> However, the same experiment performed on the DCBs examined here was far less successful. As can be seen in Figure 2, there is only weak microphase separation in some of the films (with ethyl acetate showing the strongest segregation) following a 24 h solvent annealing period. (Note: PMMA appears as the brighter phase in the AFM phase images.<sup>30</sup> The topographic images corresponding to the phase images present below are provided in the Supporting Information.)

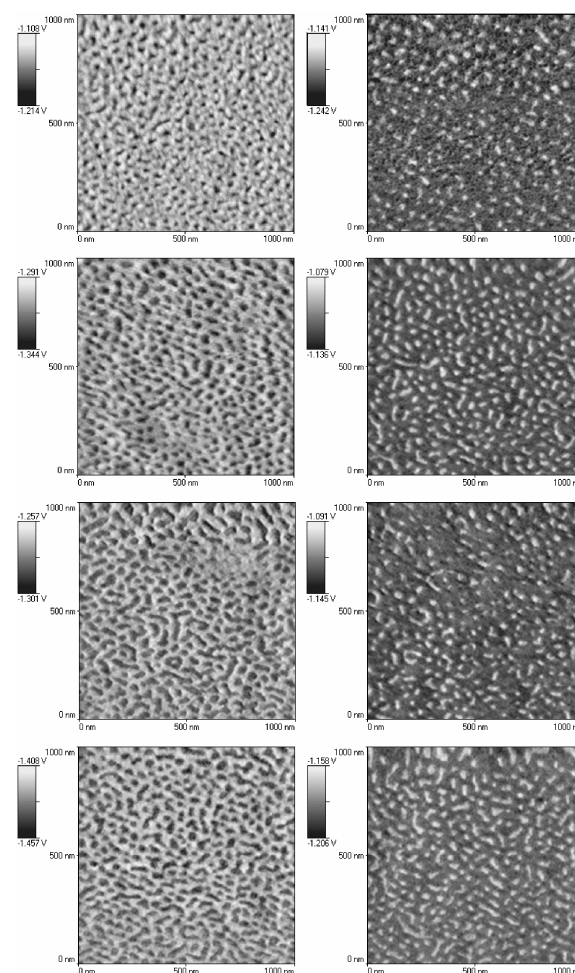

For the film displaying noticeable microphase separation the structures are relatively disordered over long length scales when compared with nongrafted films. However, similarly low ordered structures have recently been produced by both single-chain-in-mean-field<sup>31</sup> and dissipative particle dynamics simulations<sup>32</sup> of DCB films in the presence of solvents.

The most probable cause for the lack of microphase separation in these samples is the reduction in the magnitude of  $\chi$  (in line with the dilution approximation) caused by presence of the solvent. The theoretical model for dry DCBs shows that the critical  $\chi N$  value below which only the uniform phase is formed is relatively high when compared to the equivalent ODT critical point in the bulk phase diagram,<sup>9</sup> making DCBs more sensitive to dilution with solvent. This issue is discussed further in the section relating to the computer modeling results below.

From a theoretical perspective, inclusion of solvent into a DCB yields a ternary system, for which three separate interaction parameters are required: one for the polymer–polymer interaction ( $\chi_{AB}$ , equivalent to  $\chi$  for the dry brush) and two polymer–solvent interactions ( $\chi_{AS}$  and  $\chi_{BS}$ ). It is the magnitude of these latter two that determines the uptake of solvent by the respective polymer blocks.

The magnitude of  $\chi_{AS}$  and  $\chi_{BS}$  can be approximated using the solubility parameter for materials involved; we have used the values given by Hansen (Table 3).<sup>33</sup>

Larger values of  $\chi_{AS}$  and  $\chi_{BS}$  indicate that the two components are less miscible. From the above values it would therefore be expected that, of the pure solvents, toluene and THF should swell the films least and, by application of the dilution approximation, be most likely to produce microphase-separated films. This is evidently not the situation observed in the above AFM images, and so direct comparison of the interaction parameters for different systems is not useful. Nevertheless, as is demonstrated later, the relative selectivity of the solvents does seem to correlate with the experimental results.

**Figure 3.** AFM phase images of dPS<sub>47</sub>PMMA<sub>135</sub>OH (left) and dPS<sub>62</sub>PMMA<sub>69</sub>OH (right) thermally annealed at 180 °C for 6 h after washing with toluene (first row), THF (second row), DCM (third row), and ethyl acetate (fourth row).

Possible reasons for the lack of direct comparability between the calculated solubility parameters include the application of bulk solubility parameter to thin films, use of generic values for the polymers (which were nondeuterated homopolymers), inaccuracies when  $\chi$  is relatively high,<sup>33</sup> and the reduced degrees of freedom of the polymer in grafted films.

For films washed with solvent then quickly dried, the AFM images did not show any nonuniform phase structures, regardless of the solvent used (results not shown). This drying process is equivalent to the rapid drying experienced during spin-coating, a process that frequently produces microphase-separated structures.<sup>34</sup> The absence of similar structures in these films points to additional constraints acting on the film.

In line with the dilution approximation, dissolving of the copolymer in solvent, be it free in solution or as an immersed grafted film, will prevent microphase separation. Upon rapid drying of the solvent, microphase-separated structures will only be observed if the rate of polymer diffusion is commensurate with or faster than the rate of solvent loss. On the basis of the solvent annealing results, microphase separation would only be expected in the ethyl acetate and DCM washed films; however, even with these films no structure is observed. It is apparent therefore that reorganization of the polymer chains in the grafted films is

**Table 4. Circularity and Periodicity Values for the 6 h Annealed Films**

	dPS <sub>47</sub> PMMA <sub>135</sub> OH		dPS <sub>62</sub> PMMA <sub>69</sub> OH	
	Circ	period (nm <sup>-1</sup> )	Circ	period (nm <sup>-1</sup> )

relatively slow when compared with nongrafted films, leaving the grafted films in a kinetically trapped disordered state. (Note: for grafted films, there is no theoretical difference between the uniform state (Figure 1) and a nonequilibrium or disordered state due to the inherent alignment of the polymer chains away from the surface.)

**Thermal Annealing. Short Annealing Periods.** As was previously observed,<sup>10</sup> annealing for a short period of time at high temperatures and low pressures results in strong microphase separation within these films (Figure 3). Ordering was observed in as little as 3 h, which is slightly slower than the speed of microphase separation observed with nongrafted films.<sup>35</sup> For all of the films treated with neat solvents, those prepared from dPS<sub>47</sub>PMMA<sub>135</sub>OH show hexagonal-type ordering, while those prepared from dPS<sub>62</sub>PMMA<sub>69</sub>OH show inverse hexagonal-type ordering.

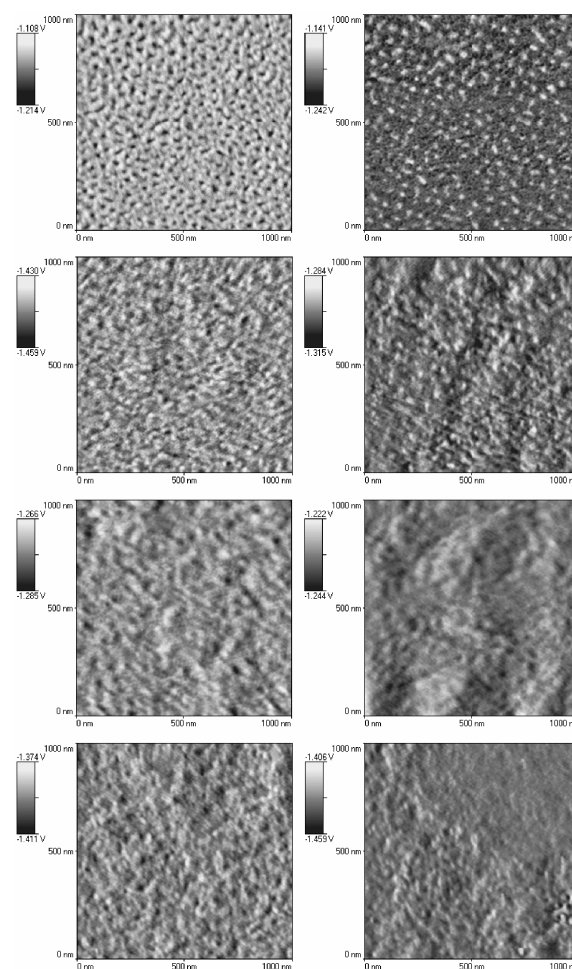

However, within these assignments there is a noticeable solvent effect on the shape of the dPS and PMMA domains. The magnitude of the shape anisotropy was determined by calculating the circularity, Circ, of the minor domains in the AFM images, where  $\text{Circ} = 4\pi[\text{area}/\text{circumference}]$ , with the area and circumference being determined using image analysis. At the same time the periodicity of the films was determined using fast Fourier transform analysis (Table 4).

Of the neat solvents, the ethyl acetate treated films had the greatest anisotropy for both dPS<sub>47</sub>PMMA<sub>135</sub>OH and dPS<sub>62</sub>PMMA<sub>69</sub>OH, while THF treated films had the least anisotropy. Notably, although the solvent content of the annealed films was not examined here, it is reasonable to assume, based on the work of Perlich et al.,<sup>24</sup> that annealing the films at 180 °C for 6 h would be sufficient to remove the vast majority of the solvent.

The anisotropy trends observed with these films is somewhat unusual in that for the dPS<sub>47</sub>PMMA<sub>135</sub>OH films it is the circularity of the dPS domains being measured, while in the dPS<sub>62</sub>PMMA<sub>69</sub>OH films it is the PMMA domains. For the systems treated with ethyl acetate (and to a lesser extent with DCM) the observed elongation of the domains indicates that these films are almost in the stripe phase. That both of the ethyl acetate treated films are showing this indicates that the stripe phase has an expanded footprint in the phase space due to the presence of the solvent.

It should also be noted that the phases formed here are slightly different to the predicted dry brush phases (Figure 1), as the corresponding topographic images for the above phase images indicate that the dPS domains are higher than the PMMA domains (Supporting Information Figures III and IV).

Correlations between the height and phase shift in tapping mode AFM have been observed before, and in part, the observed

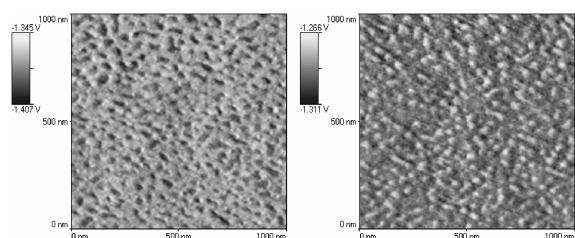

**Figure 4.** AFM phase images of dPS<sub>47</sub>PMMA<sub>135</sub>OH (left) and dPS<sub>62</sub>PMMA<sub>69</sub>OH (right) washed with toluene and then thermally annealed at 180 °C for 6 h (first row), 24 h (second row), 96 h (third row), and 192 h (fourth row).

height variation can be attributed to stiffness variation across the surface.<sup>36</sup> However, Wang et al. (who examined nongrafted block copolymer films) have shown that the topographic variation is generally real.<sup>37</sup>

**Long Annealing Periods.** The microphase-separated structures observed after a 6 h annealing period showed good long-term stability at room temperature, with the structures being unchanged more than 4 months after the 6 h annealing process. However, further annealing at high temperatures and low pressures led to a gradual but dramatic loss of structure in all the films examined here (Figure 4). It is clear, therefore, that the microphase-separated structures shown in Figure 3 are not equilibrium dry DCB structures. The formation of metastable structures upon drying of the film has previously been noted in nongrafted films,<sup>35</sup> but the structure change observed here in moving from this metastable state to the final equilibrium state are much more pronounced.

Given the lack of observed microphase separation visible in the AFM images after 192 h of annealing, it can be concluded that both of the polymers are tending toward a uniform type structure. Some of the dPS<sub>47</sub>PMMA<sub>135</sub>OH films exhibit a slightly mottled appearance, but the low contrast of these structures points to a near homogeneous film being present. The characteristic size of these

**Figure 5.** AFM phase images of films treated with  $\text{scCO}_2$  and annealed: (left)  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$ , annealed for 24 h, and (right)  $\text{dPS}_{62}\text{PMMA}_{69}\text{OH}$ , annealed for 6 h.

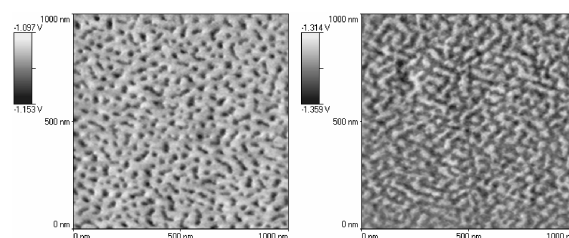

features is also much greater than the radius of gyration of the polymer, and so they cannot correspond to microphase separation. Degradation of the polymer was also eliminated as a cause of the loss of structure (results not shown).

On the basis of the theoretical model for the dry brush (at  $\Delta N = 0$ ), it would be expected that the  $\text{dPS}_{62}\text{PMMA}_{69}\text{OH}$  films would form the uniform phase, while  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$  would form the stripe phase. That  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$  instead forms the uniform phase can only be explained by the surface tension difference between the two polymers. Previously published SCFT models observed that a  $\Delta N$  value of  $-0.15$  produced a significant change in the phase diagram.<sup>9</sup> As this  $\Delta N$  value is equivalent to a  $\Delta\gamma$  of  $\sim 0.12$  mN/m, it was subsequently hypothesized that for most real systems the magnitude of  $\Delta N$  would dominate the phase behavior.<sup>10</sup> This would indeed appear to be the case here, as the surface tension difference between the two polymers used here, at 1.0 mN/m ( $\gamma_{\text{PS}} = 40.2$  mN/m and  $\gamma_{\text{PMMA}} = 41.2$  mN/m),<sup>38</sup> is as small as can be reasonably produced.

Relative to the 6 h annealed films, the films annealed for 192 h present smooth surfaces, indicating a minimization of the surface energy and supporting the conclusion that these films are at or near equilibrium.

**Treatment with Supercritical  $\text{CO}_2$ .** Returning to the metastable stable ordered structures, an attempt was made to produce a solvent-free film by soaking toluene washed films in  $\text{scCO}_2$ . The success of this solvent removal process could not be confirmed directly in the grafted films due to the restrictions on the ellipsometry modeling; however, the ellipsometry data on thick nongrafted films (see above) demonstrates that  $\text{scCO}_2$  swells the polymers while at the same time is capable of dissolving small molecules.<sup>21</sup> We assume therefore that the majority of the residual solvent was removed from the films after treatment with  $\text{scCO}_2$ <sup>39</sup> and that the film thickness increases following the treatment process, with void spaces in the film providing the additional volume.<sup>40</sup> The  $\text{scCO}_2$  treatment process itself did not induce microphase separation and the treated, but unannealed films presented a disordered/uniform structure (results not shown).

Upon thermal annealing, the  $\text{scCO}_2$  treated  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$  and  $\text{dPS}_{62}\text{PMMA}_{69}\text{OH}$  films formed the hexagonal and inverse hexagonal structures, respectively (Figure 5), as was observed with the films washed with neat solvents. However, it is clear that the  $\text{scCO}_2$  treatment has a pronounced effect on the polymer diffusion kinetics. Although strong microphase separation is observed in the  $\text{dPS}_{62}\text{PMMA}_{69}\text{OH}$  film after a 6 h annealing period, a much longer period of time (24 h) was needed for the  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$  film (Supporting Information Figures VII and VIII). The periodicities of the films are also slightly larger than those observed in the solvent washed films (Table 4). Nevertheless, as with the solvent treated

**Figure 6.** AFM phase images of cyclohexane/acetone washed films annealed for 6 h (left)  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$  and (right)  $\text{dPS}_{62}\text{PMMA}_{69}\text{OH}$ .

films, long annealing times again directed the films to form the uniform phase (Supporting Information).

The formation of metastable microphase-separated structures in the  $\text{scCO}_2$  treated films shows that these structures are not inherently dependent on the presence of a liquid solvent, though the nature of the solvent does have an impact on the structure of the film. The slow formation of the metastable structure in the  $\text{scCO}_2$  treated films also shows that for at least part of the annealing process enough solvent is retained in the solvent washed films to allow for faster chain diffusion. Indeed, that a metastable state forms within as little as 3 h with the solvent washed films suggests that much of the reorganization occurs early in the annealing process.

**Mixed Solvent.** In a final experiment a number of films were washed with a 1:1 v/v mixture of cyclohexane and acetone. Like most of the neat liquid systems no significant microphase separation was observed after solvent annealing (results not shown); however, significant differences were observed with the thermally annealed films (Figure 6).

For the  $\text{dPS}_{62}\text{PMMA}_{69}\text{OH}$  sample, the film formed the stripe phase, with the majority of the PMMA domains having lengths much greater than their widths. Subsequently, this film has the lowest average circularity of all of the samples examined, while at the same time having a decreased periodicity (Table 4). For the  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$  film the effect of the mixed solvent is not so dramatic; nevertheless, the periodicity of this sample is largest of all the  $\text{dPS}_{47}\text{PMMA}_{135}\text{OH}$  films examined here.

Given that cyclohexane is a nonsolvent for PMMA and acetone a nonsolvent for dPS, it is likely that the two solvents, when adsorbed into the film, will be partitioned between the two blocks, with the extent of partitioning will be limited by the entropic penalty associated with separating the two miscible solvents. The absence of microphase separation in the solvent annealed films suggests that the mixed solvent decreases  $\chi$ , in accordance with the dilution approximation, in the same manner as the neat solvents, and thus the use of two solvents does not decrease the miscibility of the two blocks.

The formation of the stripe phase in one film and the moderate anisotropy of the domains in the other (Table 4) indicates that there has also been an expansion of the footprint of the stripe phase in this system. The mixed solvent washed films therefore share some similarities with the ethyl acetate and DCM washed films, though here the interactions will be more complex due to the presence of two solvents.

**SCFT Modeling.** A range of SCFT calculations were performed on simulated DCBs at  $L = 0.5a\text{N}^{1/2}$  and  $\chi_{AB}N = 50$ , with the magnitudes of  $\chi_{AS}N$  and  $\chi_{BS}N$  being varied according to the values listed in Table 5. Changing  $\chi_{AS}N$  and  $\chi_{BS}N$  varies the “quality” of the solvent, with larger values corresponding to a

poorer solvent for that particular polymer block. A selection of the calculated phase diagrams is also shown in Figure 7 and the determined phase boundaries listed in Table 5. These phase diagrams show the free energies of the different phases as a function of  $f_A$  (the fraction of the nongrafted block), with the thermodynamically favored phase being the one with the lowest free energy at a given composition.

These models are the theoretical analogue of a diblock copolymer film immersed in solvent. Such a system was not directly examined in these experiments; however, as is demonstrated below, the models have proved useful in explaining the behavior observed in the various films examined here. The key to this comparability is the use of different  $\chi_{AS}$  and  $\chi_{BS}$  values in the simulations. Increasing the magnitude of these parameters leads to a reduction in the amount of solvent incorporated into the film (Figure 8), which mimics both a film that is in equilibrium with a solvent vapor (as opposed to the liquid solvent) and a film that has lost an amount of solvent through evaporation. At the extreme of very high  $\chi_{AS}$  and  $\chi_{BS}$  values, no solvent will be incorporated into the film, which is effectively equivalent to the case of a dry film in contact with air.

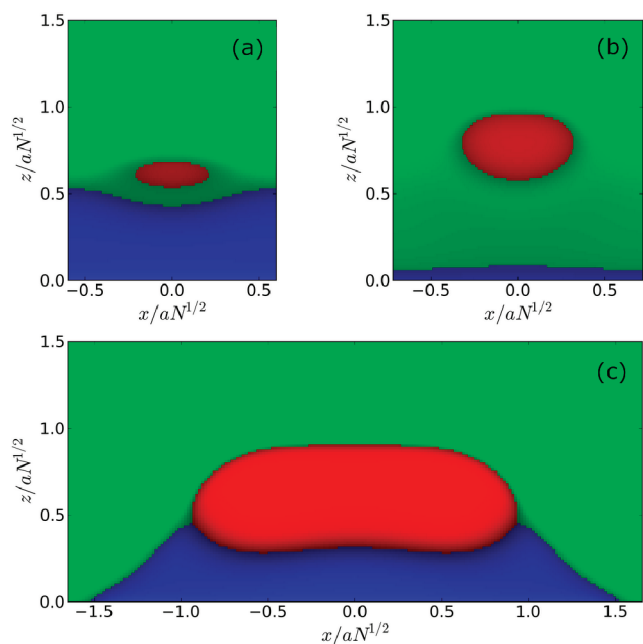

Relative to the dry brush system, the addition of a neutral solvent does not significantly alter the footprint of the nonuniform phase region. However, as is evident in Figure 8, at low  $\chi_{AS}N$  and  $\chi_{BS}N$  values the simulation predicts that there will be significant penetration of solvent into the film, with the highest solvent content in the interfacial region between the two block copolymers. When the solvent is made selective for the grafted block the footprint of the nonuniform phase region expands significantly. As Figure 8 shows, this is accompanied by a significant alteration in the topology of the film surface. For the neutral solvent case (model 4), there is only a slight corrugation of the surface, while for the selective solvent case (models 1 and 2), the corrugation is predicted to increase as  $\chi_{AS}N$  and  $\chi_{BS}N$  increase. Such corrugation was not observed in the dry brush simulations, which produced a flat surface,<sup>9</sup> but is consistent with the results reported here. The use of a solvent that is selective for the nongrafted block eliminates all of the nonuniform phases from the phase diagram (not shown). (Note: the expansion of the stripe phase predicted by model 2 is slightly different than the initial phase diagram we reported previously using the same parameters,<sup>10</sup> but this can be attributed to the greater accuracy of the models reported here.)

**Figure 7.** Free-energy plots for the model 1, 2, 3, and 4 systems;  $F$  is the free energy,  $n$  is the number of polymer chains in the simulation,  $k_B$  is Boltzmann's constant, and  $T$  is the temperature. The phases are colored: uniform (red), hexagonal (green), stripe (yellow), and inverse hexagonal (blue).

In addition to these changes with solvent selectivity, there is also notable variation in the free energy profiles with increasing  $\chi_{AS}N$  and  $\chi_{BS}N$ . For all of the simulations with low  $\chi_{AS}N$  and  $\chi_{BS}N$  values (models 1, 4, and 5), the free energy difference between the various phases is very small. Relative to thermal fluctuations this difference is negligible, and subsequently, it is expected that distinct, well-defined microphase separated structures will not form in such systems. As both  $\chi_{AS}N$  and  $\chi_{BS}N$  increase, the free energy difference between the uniform phase and the nonuniform phases increases. This is most significant for the systems where the solvent is selective for the grafted block (models 2 and 3). Some variation is also observed between the individual nonuniform phases, but generally the phase boundaries between these phases are not that sharp.

Despite the overlapping of the free energies of the different phases in the low  $\chi_{AS}N$  and  $\chi_{BS}N$  phase diagrams, these simulations have proved useful in rationalizing the behavior of the various

**Figure 8.** Transverse cross sections of the stripe phase for (a) the model 4 system ( $f_A = 0.22$ ), (b) the model 1 system ( $f_A = 0.33$ ), and (c) the model 2 system ( $f_A = 0.58$ ). Colors: red = the nongrafted block (A), blue = the grafted block (B), and green = the solvent. Areas with deeper coloration correspond to zones of mixing between the solvent and the polymer blocks, with the dominant component indicated by the hue of the color. Here  $x$  and  $z$  are the Cartesian axes that run horizontally and vertically normal to the long-axis of a stripe phase feature.

films. Indeed, as is discussed further below, the models with the lowest  $\chi_{AS}N$  and  $\chi_{BS}N$  values most accurately model the solvent washed films. Furthermore, the microphase-separated structures formed after solvent annealing and the structures present in the metastable state of the thermally annealed films (generally hexagonal for the dPS<sub>47</sub>PMMA<sub>135</sub>OH films ( $f_{PS} = 0.24$ ) and inverse hexagonal for the dPS<sub>62</sub>PMMA<sub>69</sub>OH ( $f_{PS} = 0.45$ ) films) display features characteristic of both models 1 and 2.

## DISCUSSION

The experimental systems most directly comparable with the SCFT simulations are the films that were washed with solvent and quickly dried (but not annealed). Specifically, the washed films may be compared with the results presented in models 1, 4, and 5 as these models have  $\chi_{AS}$  and  $\chi_{BS}$  values that are closest to the solubility parameters calculated for the solvents used here (Table 3;  $\chi N$  values of 70 and 100 give  $\chi$  of  $\sim 0.05$  and  $\sim 0.07$ , respectively). All of the solvent washed films generated the uniform phase, which is consistent with the small difference between the free energies of the uniform phase and the various nonuniform phases predicted by the simulations. This contrasts with nongrafted films, which frequently produce microphase separated structures when cast by spin-coating (a process equivalent to the rapid drying of grafted films).<sup>34</sup>

When the concentration of solvent incorporated into the films is decreased, as is the case with the solvent annealed films, microphase separation (albeit weak) to form nonuniform phases is observed. This is both in line with the dilution approximation and equivalent to increasing the magnitude of  $\chi_{AS}N$  and  $\chi_{BS}N$ . The presence of some microphase separation in these films

clearly indicates that there must be a meaningful difference in the free energies of the different phases (as is shown by model 2), but the poorly defined phase boundaries observed in the AFM images (Figure 2) point to significant incorporation of solvent into the region between the two polymer phases (Figure 8). For the ethyl acetate washed system the phase behavior is most accurately described by model 1. The other solvents show varying degrees of microphase separation, suggesting greater solvent content and/or selectivity for the nongrafted block, though, as is noted below, the latter is unlikely to be a significant factor.

For the thermally annealed films the film structure is dependent on the duration of the heating period. It is clear that the films undergo a two-step microphase separation process from an initially disordered state, through an ordered metastable state (displaying nonuniform structures), to a final equilibrium state. As noted above, the structure of the films prior to annealing is consistent with the results produced by the models with low  $\chi_{AS}N$  and  $\chi_{BS}N$  values, while in the metastable state the phase behavior is consistent with a model that is both selective for the grafted block and has higher  $\chi_{AS}N$  and  $\chi_{BS}N$  values.

The generation of the observed metastable state phase structures in the films washed with ethyl acetate, THF, and DCM is in agreement with the calculated selectivity of these solvents (Table 3). However, the same correlation with the toluene washed films runs contrary to the selectivity of the solvent and indicates that additional parameters need to be considered. Specifically, the interaction of the solvent with the substrate and the distribution of solvent in the film as a result of evaporation. In studying nongrafted PS-*block*-PMMA films, Perlich et al. observed an interaction between the solvent (toluene) and substrate (a silicon wafer), which lead to the formation of an enriched layer of solvent, 4 nm thick, at the film/substrate interface.<sup>24</sup> For the films examined here an equivalent layer would effectively swell the grafted phase relative to the nongrafted block due to the inherent asymmetry of the film. Such an interaction was not explicitly included in the simulations reported here, but the net effect of this interaction is similar to the use of a solvent that is selective for the grafted block. It is also well-known that evaporation of solvent from a film leads to a solvent gradient normal to the surface of the film as evaporation occurs only from the exposed surface of the film.<sup>24</sup> Thus, even solvents that are selective for the nongrafted block may display an apparent selectivity for the grafted block.

In considering the similarities between the experimental and theoretical results, it is apparent that the observed behavior can only be rationalized if the amount of solvent in the films in the metastable state is markedly less than that found in the films immersed in solvent or solvent annealed. Although this would seem self-evident, given the conditions to which the films are exposed during thermal annealing, we believe that this drives the formation of the different states. As has been shown in the literature,<sup>24</sup> and supported by the results published here, cast polymer films contain a significant portion of solvent that is subsequently driven off during thermal annealing. It is also well-known that increased solvent content dramatically increases the polymer diffusion rate.

We propose therefore that prior to annealing the films are both in the uniform state (formed during washing with liquid solvent and preserved, in a kinetically trapped state, upon drying) and have a relatively high solvent content. Upon heating, the increased kinetic energy of the system leads to a fast reorganization of the

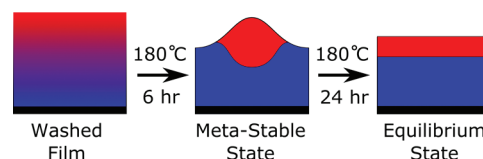

polymer chains into a pseudoequilibrium state that is defined by the fraction of solvent present. In this state, the metastable state, the residual solvent appears selective for the grafted block due to the combined effects of the evaporation gradient and the enrichment of the film with solvent at the film/substrate interface. If heating is stopped at this point, the structure becomes frozen in due to the low polymer diffusion rate with low solvent contents and at low temperatures. However, additional heating will eventually drive off all of the residual solvent, and the thermodynamic equilibrium of these films is then defined by the dry brush model. As noted earlier, the structure of the films in the dried brush state is dominated by the surface tension difference between the two polymer blocks. Consequently, both dPS<sub>47</sub>PMMA<sub>135</sub>OH and dPS<sub>62</sub>PMMA<sub>69</sub>OH are predicted to form the uniform phase.

The formation of metastable structures is not, however, reliant on the presence of a liquid solvent. When the films were treated with scCO<sub>2</sub>, a microphase-separated metastable state was still observed. For these films, the only change that occurs during thermal annealing is a collapse of the void spaces introduced into the film by the scCO<sub>2</sub> treatment. This volume change is equivalent to the volume change experienced by the solvent washed films as the solvent evaporates, and the presence of such a change goes some way to explaining the formation of the metastable state in these films. But the formation of phase-separated structures in these films can only be rationalized by considering how the polymer chains rearrange in a dry film.

In the melt state, the motion of long, linear polymer chains is restricted by entanglements, and subsequently, diffusion of the chains occurs via reptation. For large polymers, chain diffusion is generally slow, with the diffusion rate being dependent on the temperature and inversely dependent on the square of the molecular weight. With grafted films, the situation is further complicated by the attachment of one end of the polymer chain to an immovable surface. This reduces the degrees of freedom available to the polymer chain and inhibits reptation. For grafted films it is therefore expected that the diffusion rate of the free end of the polymer chain will be higher than diffusion rate of the bound end of the polymer chain—leading to an asymmetry in the rate of reorganization.

For films treated with scCO<sub>2</sub> this effect will manifest itself primarily as a faster collapse of the film at the air/film interface. With homopolymer brushes such an asymmetric collapse would not be particularly significant, however, with DCBs the effect is coincidental with the inherent asymmetry of the film—the reorganization of the film will therefore be faster for the nongrafted block, leading to faster collapse of that block and the apparent increase in the volume fraction of the grafted block. As with the solvent washed films, this relative expansion of the grafted block may effectively be modeled as the incorporation of a selective solvent into the film. A schematic of the proposed evolution of the various films is presented in Figure 9.

In summary, it is proposed that the apparent asymmetry observed in the solvent washed films is due to enhanced swelling of the lower block caused by a strong solvent–substrate interaction and gradient in solvent concentration resulting from evaporation. With the scCO<sub>2</sub> treated films the asymmetry arises from faster reorganization of the free end of the polymer. However, it should be noted that both mechanisms may operate simultaneously. It is known that scCO<sub>2</sub> interact attractively with silicon wafers and thus may cause additional expansion of the grafted block,<sup>40</sup> while it is also conceivable that void spaces may

**Figure 9.** Schematic of the structure evolution in grafted diblock films during thermal annealing.

be formed in the film washed with solvent. The latter case would arise if the rate of polymer diffusion decreased to such a point where it was no longer possible for the polymer chains to immediately compensate for solvent lost by evaporation. This will happen at some point during the evolution of the metastable state under annealing, but it will be difficult to conclude at what point one will become more dominant than the other.

## CONCLUSIONS

In this work we have examined the behavior of a number of dPS<sub>x</sub>PMMA<sub>y</sub>OH DCBs and observed dependencies on both the annealing time and nature of the solvent used to wash the films. Through the use of SCFT models we have been able to propose a mechanism that rationalizes the observed behavior in terms of contraction of the films during the annealing process; with the formation of the metastable state being most accurately described by the model for a DCB containing a solvent that is selective for the lower block. This mechanism is not specific to the system examined here and should be applicable to other DCBs.

The behavior of the films following solvent annealing was also examined and it was observed that the films did not exhibit strong microphase separation, which is in agreement with both the SCFT models and the dilution approximation.
