ELECTROLYTIC OXIDATION OF THIOCYANATE AND SELENOCYANATE SALTS  
AND THE PHOTOELECTROCHEMICAL EFFECT.

Abstract. New photosensitive materials can be obtained by electrochemical oxidation of thiocyanate and selenocyanate salts. Using (K,Na)SCN eutectic melt, the formation of an electrodic deposit, with photoelectrochemical properties, has already been reported by us. To improve the photoelectrochemical characteristics of the deposit, further investigations were carried out in the following systems: selenocyanate ammoniate, KSCN-Acetamide eutectic mixture and KSCN ethylene carbonate solution. Attempts to obtain a massive deposit in the ammoniate solution were unsuccessful due to ammonia oxidation. Measurements performed on the other KSCN systems show that temperature is a parameter of remarkable importance. In fact, lowering the temperature one obtains a decrease on formation of parathiocyanogen on behalf of the polytrithiocyanogen, the species that gives rise to the photoeffect.

Anodic deposits obtained from electrolytic oxidation of both  $\text{SCN}^-$  in (K,Na)SCN eutectic melt, and  $\text{SeCN}^-$  in ammoniate solution of  $\text{KSeCN}$ , show photoelectrochemical properties<sup>1-4</sup>.

In molten thiocyanate salts, it was observed that a remarkable increase in the photoeffect occurred with decreasing temperature and this was ascribed to increase in formation of  $[(\text{SCN})_3]_x$ , i.e. the

semiconductor material, with respect to  $(\text{SCN})_x$ , i.e. the insulating material. Accordingly, new experiments were performed in acetamide and ethylene carbonate solvents, in which both low temperature conditions and high salt concentrations are allowed. Conductivity measurements made on deposits obtained from electrolytic oxidation of  $\text{SCN}^-$  in these solvents, show linear dependencies of  $\ln R$  on  $1/T$ , as expected for a semiconductor material (Fig. 1). A gap energy of

about 0.13 eV can be computed from the slope of the line. Note that deposits previously obtained from molten salts showed an opposite dependence on temperature<sup>1</sup>. This behaviour suggests that formation of semiconductor-like species  $[(\text{SCN})_3]_x$  should predominate in the electrolytic oxidation of  $\text{SCN}^-$  under the present experimental conditions. Photopotentials of about 300–400 mV and photocurrents of about 10  $\mu\text{A}$ , were obtained with materials prepared in such a way.

In selenocyanate ammoniate solution<sup>2,4</sup>, the formation of both anodic deposit, possibly  $(\text{SeCN})_x$  matrix with trapped  $(\text{SeCN})_3^-$ , and

a soluble specie,  $(\text{SeCN})_3^-$ , was observed at current densities below  $0.3 \text{ mA/cm}^2$ . At higher current densities only deposit formation was observed. However, massive growth of deposit could never be observed due to ammonia oxidation. Nevertheless the thin layer of deposit obtained exhibits photoeffect<sup>2</sup>(Fig. 2). Cathodic stripping of the deposit was studied in the dark and under irradiation with visible light (Fig. 3). A positive shift of peak potential can be observed in the latter condition. This effect of light was observed also if the covered electrode was exposed to light before potential scanning. Therefore the effect cannot be ascribed to deposit thinning with light. Moreover the potential shift is actually higher than that directly observed, owing to the negative photopotential arising under light irradiation. By contrary, the reduction peak of the  $(\text{SeCN})_3^-$  species in solution (when produced from low current density electrolyses) is not light sensitive. Experiment of Fig. 3 shows further evidence for the increasing conductivity of deposit under irradiation.
