Amphetamine (AMPH) is an indirect sympathomimetic compound classified as a substrate-type releaser that distinguishes it from other stimulants that act as uptake 1 blockers, such as cocaine (COC). In mammals, AMPH elicits central stimulation, hypermotility, anorexia, analgesia and analeptic activity, mainly through the increase of extracellular brain dopamine (DA). The inversion of vesicular transporters and/or intravesicular alkalization is assumed to have a role in AMPH-induced exocytosis. However, the action mechanism of this compound has not yet been completely clarified. Recent evidence on the action of AMPHs indicates potassium channel-blocking properties in peripheral tissues. We investigated the possible involvement of a *Shaker-like* Kv1.1 channel subtype in the central effects of AMPH, using an antisense oligodeoxynucleotide (aODN) that specifically and reversibly inhibits the expression of these channels in the brain. The effect of aODN pretreatments was studied by evaluating the modification of behavioral effects induced in mice through the intracerebroventricular administration of AMPH, COC, or other compounds. The aODN in mice almost completely blocked the stimulatory effects of AMPH and other releasers but was ineffective in reducing the central activity of COC. In aODN-pretreated rats a strong reduction of the AMPH, but not of the COC-stimulated DA efflux from nucleus accumbens was observed. Our results suggest that the stimulant effects of AMPH and chemically related compounds, but not COC, require the presence of functionally active Kv1.1 channels in the brain.

Neuropsychopharmacology (2003) 28, 1096–1105, advance online publication, 9 April 2003; doi:10.1038/sj.npp.1300162

Keywords: amphetamine; cocaine; antisense oligodeoxynucleotides; Kv1.1 channels; dopamine; behavioral functions

INTRODUCTION

The sympathomimetic compound amphetamine (AMPH), which readily crosses the blood–brain barrier, induces considerable central stimulatory effects, including euphoria, insomnia, anorexia, stimulation of motility, etc (Hoffman, 2001). Neurochemical evidence indicates that, in mammals, this compound has its effects indirectly, mainly increasing the extracellular availability of dopamine (DA), in different brain regions (Samanin and Garattini, 1993). For example, dopaminergic neuronal endings located in the nucleus accumbens are important targets for the motor stimulatory effects (Kalivas *et al*, 1993), while the perifornical area seems to be the region in which AMPH and other

dopaminergic compounds selectively control food intake (Parada *et al*, 1988; Leibowitz, 1989). Together with DA, serotonin (5-HT) is known to have a central role in most behavioral functions (Parada *et al*, 1988; Inui, 2000; Frantz *et al*, 2002). Food intake is controlled by serotonergic neurons projecting from the midbrain dorsal raphe nucleus to PVN and the VM of the hypothalamus. In these areas, AMPH and, to a major extent, the more selective compound dexfenfluramine (d-FEN), act as an anorexigenic, also increasing the extracellular concentrations of 5-HT (Leibowitz, 1989; Simansky, 1996).

Indirectly acting dopaminergic and/or serotonergic compounds can be divided into two main classes relative to their mechanism of action. Some of them, such as cocaine (COC) or fluoxetine, are inhibitors of the uptake 1 mechanisms in neurons. For others, including AMPH and related phenylethylamines, the action mechanism has not yet been completely clarified. Since their effects are reduced after COC and reserpine pretreatment or chronic post-ganglionic denervation, it is generally accepted that, following the uptake into nerve endings, they displace the

neurotransmitters from the storage vesicles, by means of various mechanisms (Sulzer and Rayport, 1990; Sulzer *et al*, 1995).

The potassium channel activity, influencing the transmembrane electrochemical potential of neurons, may also affect the central release of DA, 5-HT, and other neurotransmitters (Cook and Quast, 1990; Dawson and Routledge, 1995). Outward potassium channels, opened by depolarisation, shorten the duration of the action potential (delayed rectifier) or the pattern of action potential bursts (transient or A current). Pharmacological opening of these channels displays hyperpolarizing activity, while the blockade prolongs the duration of the action potential, thus enhancing the release of neurotransmitters (Schechter, 1997). In accordance with the properties of these compounds, K_{ATP} openers, injected intracerebroventricular (i.c.v.) in mice, increase food intake, whereas K^+ channel blockers induce hypophagic effects. The role of potassium channels in behavioral function has been investigated using an antisense strategy. It was found that the repeated i.c.v. administration of an antisense oligodeoxyribonucleotide (aODN) targeting the translation start region of *Shaker-like* Kv1.1 potassium channels induces hyperphagic behaviour, together with a transient-specific reduction in the expression of this channel subtype in the mouse brain (Ghelardini *et al*, 1997).

In preliminary experiments, we used this aODN to investigate the mechanism of action of some hypophagic compounds believed to elicit their anorectic effects through a potassium channel modulation. It has been found that the aODN pretreatment decreased the hypophagic effect of certain compounds known to act as blockers of voltage-activated potassium channels and, more interesting, of AMPH, used as a reference anorectic compound in these studies (Banchelli *et al*, 2001; Pirisino *et al*, 2001). These results opened up the possibility that, in addition to its anorectic effects, the whole range of central stimulant properties of AMPH could be linked to the blocking properties of specific potassium channels.

The present work was therefore designed to better evaluate the involvement of Kv1.1 channel subtypes in the central effects of AMPH using a battery of tests that are able to evaluate analeptic activity, pain perception, motor activity, food intake, and other behavioral functions. In these experiments, the activity of COC, d-FEN and other indirectly acting dopaminergic and serotonergic compounds was evaluated, for reference, in mice pretreated with specific aODN.

MATERIALS AND METHODS

Animals

Male Swiss albino mice (24–26 g) and albino rats (150–200 g) from Morini (San Polo d'Enza, Italy) were used. In all, 15 mice or five rats were housed per cage. The cages were placed in the experimental room 24 h before the test for acclimatization purposes. The animals were fed a standard laboratory diet and tap water *ad libitum*; they were kept at $23 \pm 1^\circ\text{C}$, with a 12 h light/dark cycle, and light at 7 am. All experiments were carried out in accordance with the European Community Council's Directive of

November 24, 1986 (86/609/EEC) relative to experimental animal care. All efforts were made to minimize animal suffering and to reduce the number of animals used (in any case, since otherwise indicated, at least 10 animals per group were used in each behavioral protocol).

Hot-Plate Test

The method adopted was described by O'Callaghan and Holtzman (1975). Mice were placed inside a stainless-steel container that was set thermostatically at $52.5 \pm 0.1^\circ\text{C}$, in a precision water bath from the KW Mechanical Workshop, Siena, Italy. Reaction times (s) were measured with a stopwatch before, and 15, 30, and 45 min after administration of the analgesic drugs. The end point used was the licking of the fore or hind paws. Those mice scoring less than 12 and more than 18 s in the pretest were rejected (30%). An arbitrary cutoff time of 45 s was adopted.

Hole-Board Test

The hole-board test consisted of a 40 cm square plane with 16 flush-mounted cylindrical holes (3 cm diameter) distributed 4×4 in an equidistant, grid-like manner. Mice were placed on the center of the board one by one and allowed to move about freely for a period of 10 min each. Two electric eyes crossing the plane from midpoint to midpoint of opposite sides, thus dividing the plane into four equal quadrants, automatically signalled the movement of the animal (counts/5 min) on the surface of the plane (locomotor activity). Miniature photoelectric cells in each of the 16 holes recorded (counts/5 min) exploration of the holes (exploratory activity) by the mice. In each group, 12–15 mice were tested.

Pentobarbital-Induced Sedative/Hypnotic Effects

The method was described by Adzu *et al* (2002). Mice received 5 μl i.c.v. injections of test compounds, or saline in the control group. Sodium pentobarbital (25 mg/kg) was administered i.p. to the animals 15 min after they received saline or the test compounds. The time that elapsed between the administration of pentobarbital until loss of the righting reflex was recorded as the onset of sleep, while the time from the loss of the righting reflex (in which the mouse cannot roll back when turned over) until recovery was recorded as the sleeping time.

Drug Administration by i.c.v. Route

The i.c.v. administration was performed under ether anesthesia with isotonic saline used as solvent, according to the method described by Haley and McCormick (1957). During anesthesia, the mice were grasped firmly by the loose skin behind the head. A hypodermic needle (0.4 mm external diameter) attached to a 10 μl syringe was inserted perpendicularly through the skull and no more than 2 mm into the brain of the mouse, where a 5 μl solution was then administered. The injection site was 1 mm to the right or left of the midpoint on a line drawn through to the anterior base of the ears. Injections were performed randomly into the right or left ventricle. To ascertain that solutions were

administered exactly into the cerebral ventricle, some mice were injected with 5 μ l of diluted 1:10 India ink and their brains were examined macroscopically after sectioning. The accuracy of the injection technique was evaluated, with 95% of injections being correct. Before i.c.v. administration of the compounds used, it was assessed that the pH values of the nanomolar compound solutions, ranging from 7.2 to 6.7, did not vary significantly from those of the saline (pH = 6.8 ± 0.4).

Evaluation of Food Consumption

The mice did not have access to food for 12 h, but water was available *ad libitum*. A weighed amount of food (standard laboratory pellets) was given, and the amount consumed (evaluated as the difference between the original amount and the food left in the cage, including spillage) was measured 15, 30, 45, and 60 min after i.c.v. or i.p. administration of saline or drug solutions, with an accuracy of 0.1 g. An arbitrary cutoff time of 60 min was used, and the total amount of food consumed was expressed in mg/mouse/60 min.

Antisense Oligonucleotides

24mer phosphodiester oligonucleotides (ODNs) were capped by a terminal phosphorothioate double substitution and purified by high-performance liquid chromatography (HPLC; Genosys, The Woodlands, TX, USA). The antisense oligonucleotide (aODN) (5'-CGA CAT CAC CGT CAT GAT GAA AGG-3') was designed by targeting the 5' portion of the murine Kv1.1 mRNA, residues 575–598 of the published cDNA sequence (Chandy *et al.*, 1990).

The corresponding aODN sequence for rat (5'-TGA CAT CAC CGT CAT GAT GGA TGC-3'), encoding for mRNA to the Kv1.1 channel, was the same as used in previous studies (Meiri *et al.*, 1997). To evaluate the specific antisense effects of the oligodeoxynucleotides, a fully degenerated phosphorodiester phosphorothioate-capped oligonucleotide (dODN) was used as negative control. The fully degenerated 24mer is a collection of about 3×10^{14} different molecular species (5'-NNN NNN NNN NNN NNN NNN NNN NNN-3'; where N = G, C, A, or T). Therefore, for the nanomolar–micromolar range concentrations used in the antisense experiments, the dODN was present at the site of action in a subattomolar concentration, which is totally insufficient for any antisense effect. For more details on the aODN and dODN syntheses and the RT-PCR analysis of mKv1.1 mRNA in the mouse or rat brain tissues, the reader may refer to our previous papers (Meiri *et al.*, 1997; Ghelardini *et al.*, 1997; Galeotti *et al.*, 1997a,b).

Administration of Antisense Oligonucleotides

During *in vivo* experiments to favor cell penetration and to minimize the degradation of the oligonucleotides, phosphorothioate-capped phosphodiester oligonucleotides associated with an artificial cationic lipid (DOTAP = N-(1-(2,3-dioleoyloxy)propyl)-N,N,N-trimethylammonium methyl sulfate) proved to be suitable for enhancing cellular uptake (Quattrone *et al.*, 1994). To evaluate the effect of the treatments on the behavioral parameters under investiga-

tion, some preliminary experiments were performed. Mice were randomly assigned to an antisense oligonucleotide (aODN), degenerated oligonucleotide (dODN), vector (DOTAP), saline, or naive group. A suitable amount of oligonucleotide was preincubated at 37°C for 30 min with 13 μ M DOTAP. Each group received a single i.c.v. injection (5 μ l; 3 nmol of ODN) on days 1, 4, and 7. All behavioral tests were performed 24 h after the last i.c.v. injection of aODN or dODN, when the maximal inhibition in the expression of mKv1.1 mRNA in the mouse brain tissue was detected using RT-PCR analysis (Ghelardini *et al.*, 1997; Galeotti *et al.*, 1997a,b).

Having verified that the dODN did not induce any evident modification in the basal behavioral function of mice, as compared to saline- or vector-injected animals (data not shown), dODN-treated animals were used as controls in all experiments.

Some experiments with AMPH or tetraethylammonium HCl (TEA) on food consumption were also repeated 7 days after the last ODN treatment, to evaluate the recovery of the effect of test compounds when the Kv1.1 channel expression was completely restored (Galeotti *et al.*, 1997a,b).

In Vivo Microdialysis Procedures

Rats received sodium pentobarbital (60 mg/kg, i.p.) as surgical anesthesia. An indwelling jugular catheter made of Silastic Medical Grade tubing (Dow Corning, Midland, MI) was implanted. Each rat was then placed in a stereotaxic apparatus for craniotomy. A plastic intracerebral guide cannula (CMA 12, CMA/Microdialysis, Acton, MA) was implanted above the nucleus accumbens (ML + 1.5 mm and AP + 1.6 mm from bregma, DV –6.2 mm from dura) according to Baumann *et al.* (1994). Animals were housed singly and allowed 7–10 days to recover.

Microdialysis was carried out by following a previously described method (Baumann *et al.*, 1994). In brief, a probe of 2 mm \times 0.5 mm (CMA/12, CMA/Microdialysis) was placed inside the guide cannula, and a polyethylene extension tube (PE-50) was attached to the jugular catheter. Each rat was placed in a bowl, where free movements were allowed. Ringers' solution, containing 147.0 mM NaCl, 4.0 mM KCl, and 1.8 mM CaCl₂, was pumped through the probe at 0.5 μ l/min. Beginning 2–3 h after insertion of the probe, dialysate samples were collected at 20-min intervals and immediately assayed for DA by HPLC using electrochemical detection. After DA stabilization in dialysate, three baseline samples were collected and DA concentrations were expressed as a percentage of the baseline.

The effects of local infusions of AMPH or COC were assessed in animals pretreated with aODN to Kv1.1 or dODN (controls), given according to the same dosage schedule previously described for mice. AMPH or COC were administered via reverse dialysis, in a single dose of 2 or 5 μ g, respectively, 60 min after the probe insertion. Samples were collected for 280 min after the start of the experiments. At the end of the experiments, the location of the probes in the brain was evaluated by means of histological analysis. The data included in this study refer to rats bearing probes correctly placed within the nucleus accumbens.

Analysis of DA in Dialysate Samples

Aliquots of the dialysate (5 μ l) were injected directly into a microbore HPLC column coupled to an amperometric detector. A glass carbon working electrode was set at a potential of +700 mV relative to an Ag/AgCl reference. A mobile phase consisting of 14.2 g monochloroacetic acid, 6.8 g NaOH, 350 mg sodium octyl sulfate, 80 mg disodium EDTA, 1 ml triethylamine, 6% MeOH, 6% CH₃CN per liter of water (final pH = 5) was pumped at a rate of 60 μ l/min with a constant column pressure of 2500–3000 psi. Standard curves of DA, constructed before the injection of dialysate samples, were linear over a wide range of concentrations. The lowest limit of assay sensitivity for DA was 200fg/5 μ l sample.

Reagents and Drugs

The oligonucleotides used for the antisense strategy were from Genosys (The Woodlands, USA). DOTAP was from Boehringer-Mannheim (Mannheim, Germany). AMPH sulfate, tyramine hydrochloride (TYR), tetraethylammonium HCl, charybdotoxin (CTX), and gliquidone (GLI) were purchased from the Sigma Chemical Company (St Louis, MO, USA). COC HCl was supplied by USL 10D (Policlinico

di Careggi), Florence; phentermine hydrochloride (PHE) was generously provided by Professor F Mari, Department of Forensic Medicine, Florence; d-fenfluramine (d-FEN) was obtained from S.A.L.A.R.S. (Milan). Chromatographic reagents, buffer salts, and other chemicals used in the microdialysis experiments were obtained from the Sigma Chemical Company (St Louis, MO, USA). The drugs used for the behavioral experiments were dissolved in isotonic (NaCl 0.9%) saline. Drug concentrations were prepared in such a way that the necessary dose could be administered by i.c.v. injection in a volume of 5 μ l/mouse. Antisense and degenerated oligonucleotides were dissolved in the vector (DOTAP) at least 30 min before injection.

Statistical Analysis

All experimental results are given as the mean \pm SEM. An analysis of variance (ANOVA) was used to verify the significance between two means of the behavioral results, and was followed by Fisher's protected least significant difference procedure for *post hoc* comparison. The results of dose-response experiments of Figure 1 in the dODN and aODN pretreated animals, at each dose of AMPH, were analyzed performing pairwise comparisons with unpaired *t*-tests followed by Bonferroni corrections for multiple

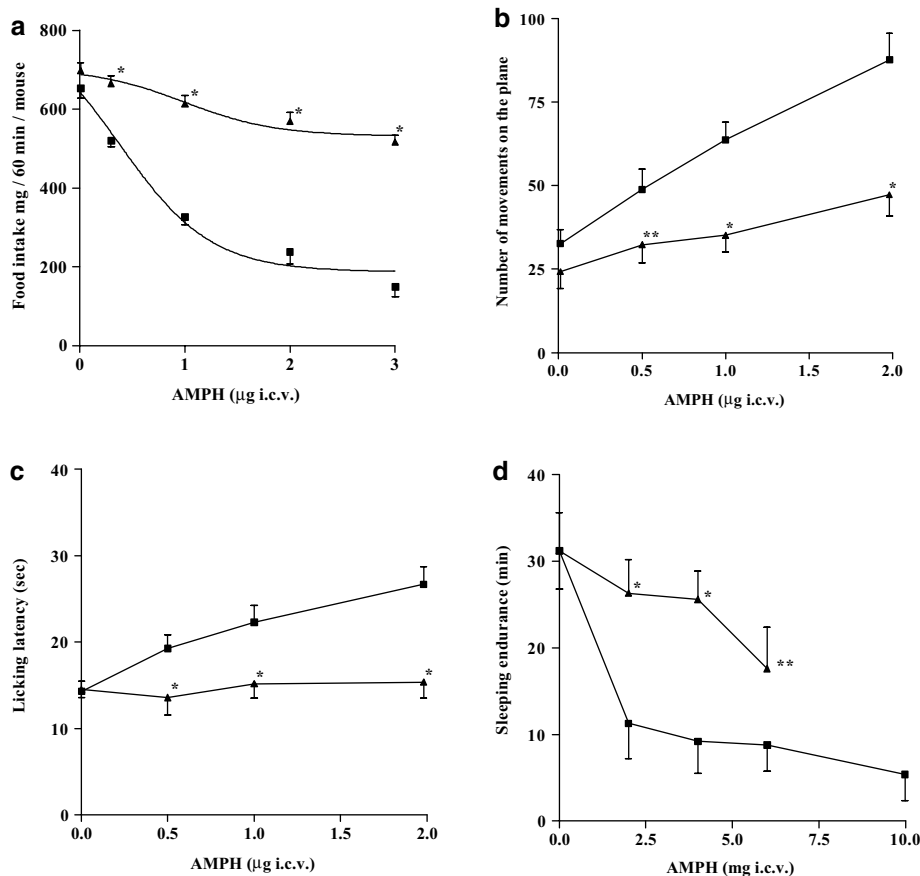

Figure 1 Effect of the pretreatment with aODN (\blacktriangle) or dODN (\blacksquare) to Kvl1.1 channels (3 nmol per single i.c.v. injection at days 1, 4, and 7) on the behavioral effects of increasing doses of i.c.v. AMPH. (a) AMPH-induced reduction of food intake in 24 h fasted mice, 60 min after food readministration; (b) AMPH-stimulated motor activity, measured in hole board apparatus, 15 min after drug administration; (c) AMPH-increased licking latency in mouse hot-plate test, 15 min after drug administration; (d) AMPH-induced reduction of pentobarbital hypnosis in mice. * $P < 0.01$ in comparison with dODN-pretreated mice taken as controls. ** $P < 0.05$ in comparison with dODN-pretreated mice taken as controls. Each point represents the mean \pm SEM of at least 10 mice.

comparisons. *P*-values of less than 0.05 were considered significant. Data were analyzed using the stat view software for Macintosh (1992). For the microdialysis experiments, the first three samples collected before any experiment were considered as baseline samples; subsequent DA concentrations were expressed as a percentage of the mean of this baseline. For these studies, according to Baumann *et al* (1994), ANOVA evaluations were performed on the AMPH-stimulated percent DA release in aODN-pretreated rats and were then compared with the effects observed in dODN-pretreated animals used as controls.

RESULTS

Single-Dose Treatments

The central behavioral effects of some compounds endowed with different mechanisms are reported in Table 1. The effect of these compounds in animals pretreated with aODN to Kv1.1 was compared with that observed in mice pretreated with dODN. As detailed in the 'Materials and methods' section, the mice were treated with a single i.c.v. injection of aODN, dODN, or vehicle at days 1, 4, and 7. Each animal received 3.0 nmol of aODN dissolved in 5 μ l of vehicle, a dosage previously verified as significantly reducing channel expression in the brain of mice (Galeotti *et al*, 1997a, b). The results shown in Table 1 and in Figure 1 indicate that the pretreatment with aODN, as well as with dODN, was unable to modify significantly motor behavior, licking latency, endurance of barbiturate-induced sleeping or food intake in animals, as compared to the controls (saline-treated) groups.

The potassium channel blockers TEA, GLI, CTX were administered with a single i.c.v. injection, in doses ranging from 1 to 5 μ g/5 μ l of vehicle, a dosage regimen previously verified as being effective in inducing anorectic effects (Banchelli *et al*, 2001; Pirisino *et al*, 2001). It was found that, at the dose used, these compounds were without effect in modifying all the behavioral functions of mice with the exclusion of food intake. In mice that had fasted for 12 h they significantly reduced food consumption, as observed

after 60 min from the administration of compound. As shown in Table 1, the aODN (but not the dODN) almost completely suppressed the anorectic effect of 5 μ g of TEA, while it was completely ineffective in antagonizing the similar anorectic effect of 5 μ g GLI or 1 μ g CTX.

Conversely, AMPH and the other chemically related phenylethylamines TYR or PHE modified all the behavioral responses of the mice. In accordance with the known pharmacological effects of AMPHs, a significant analgesic effect, a reduction in barbiturate-induced sleeping and in food intake or hypermotility was observed when 2 μ g of AMPH or 3 μ g of TYR or PHE was administered i.c.v. to the mice.

A similar pattern of central pharmacological activity was observed for COC. However, in contrast to the results obtained with AMPH, the aODN pretreatment was completely ineffective in antagonizing the central response induced by COC. A lack of effect of aODN pretreatments was also observed for the anorectic effects of d-FEN.

AMPH Dose-Response Curves

These experiments were performed in order to better evaluate the role of Kv1.1 expression in the behavioral effects of an increasing AMPH dosage regimen. We had previously verified that the ODNs or vehicle pretreatments (3.0 nmol/5 μ l/mouse i.c.v.) did not modify the behavioral parameters under investigation as compared to the effect of saline in naive mice (data not shown; see for reference Galeotti *et al*, 1997a, b). Therefore, we compared the dose-response curves for AMPH in aODN groups with those in dODN-pretreated animals.

In Figure 1a, the reduction in food consumption induced by AMPH in 24 h fasted mice is reported. AMPH ranged from 0.5 to 3.0 μ g/mouse i.c.v. and food consumption measured 60 min after food readministration and drug injection. A clearcut dose relation was found for the hypophagic effect of AMPH, with an approximate ED₅₀ of 2.3 μ g/mouse. According to what was observed in single-dose treatments, the aODN considerably reduced the anorectic effect of AMPH. In the control animals, the

^aSignificant change (*P* < 0.01) of the behavioral parameters considered in comparison with those of the respective control mice (saline injected). Each value represents the mean \pm SEM of at least 10 animals.

*Significant (*P* < 0.01) in comparison with the anorectic effect of the compound in dODN pretreated animals. NT, not tested.

highest dose of AMPH (3 μ g) reduced the food consumption by about 77% while, in the aODN group the same effect was not statistically significant (about 25%), as compared to the response obtained with the lower dose (0.5 μ g) of AMPH. The effect of aODN pretreatment was also evaluated for motor stimulatory activity and for the analgesic effect elicited by increasing the doses of AMPH. The results shown in Figure 1b and c indicate that AMPH induced its effects at a range of doses similar to those used in food intake experiments. In agreement with what was observed for the hypophagic effect of AMPH, the latter behavioral parameters were almost totally abolished by aODN.

Lastly, the ability of aODN to reduce the effect of AMPH was verified in animals in which the inhibition of pentobarbital-induced sleeping was assessed in the presence of increasing doses of AMPH. Again, the aODN pretreatment consistently reduced the effect of AMPH (Figure 1d), with the exclusion of doses exceeding 5 μ g/mouse, which induced aspecific central toxicity in the animals, as revealed by an evident subcomatose state.

Time Dependence of the aODN Effects

The aODN injection (3 nmol i.c.v. per mouse) prevented the hypophagic response of TEA, AMPH, and other compounds, as shown in Table 1. This antagonistic effect was detected 24 h after the end of the aODN pretreatment. In contrast 7 days after the last aODN injection, the effect of the oligonucleotide disappeared and the same animals were once again sensitive to the anorectic effect of TEA or AMPH (Figure 2).

Microdialysis Experiments

The results obtained with the local infusion of 2 μ g of AMPH or 5 μ g of COC in freely moving rats are shown in

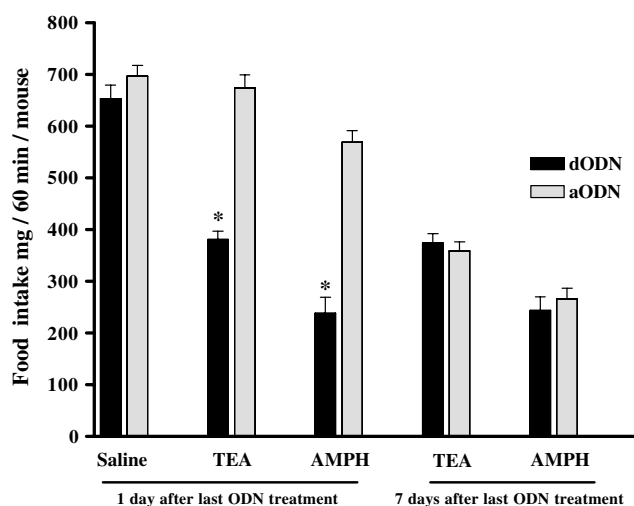

Figure 2 Recovery of the anorectic response of i.c.v.-administered TEA (5 μ g) or AMPH (2 μ g) in aODN or dODN (controls) pretreated mice. At 7 days after the last aODN injection, the inhibitory effect of the aODN was completely lost. * $P < 0.01$ in comparison with dODN-pretreated mice taken as controls. Each point represents the mean \pm SEM of at least 10 mice.

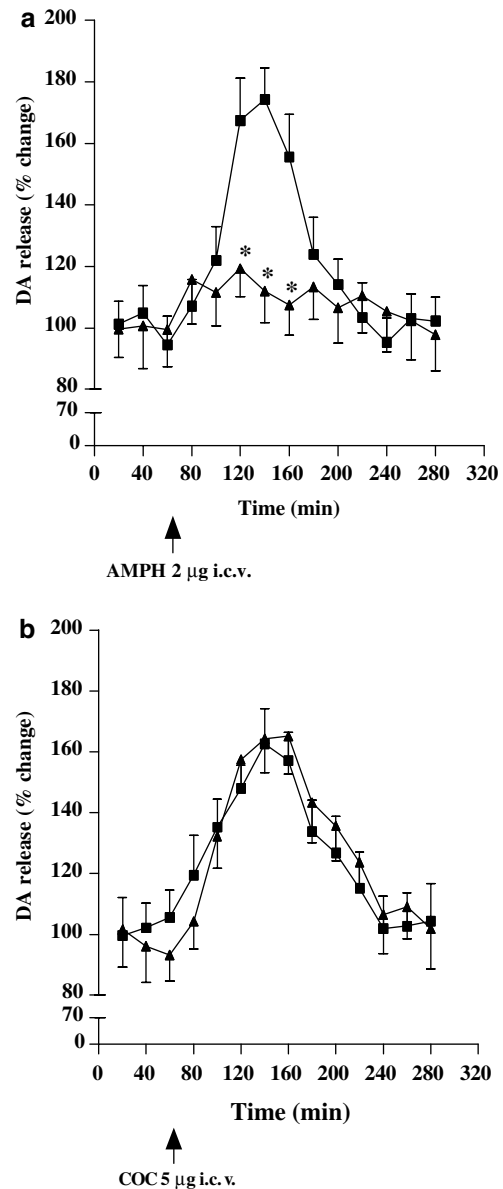

Figure 3 The effect of aODN or dODN (controls) to Kv1.1 channels (3 nmol per single i.c.v. injection at days 1, 4, and 7) on (a) 2 μ g i.c.v. AMPH-induced or (b) 5 μ g i.c.v. COC-induced DA release from nucleus accumbens in freely moving rat. * $P < 0.01$ in comparison with dODN-pretreated mice taken as controls. Each point represents the mean \pm SEM of five rats.

Figure 3a,b. As described in the Materials and methods section, the percentage change in the DA efflux refers to the release from the nucleus accumbens. At 120–160 min after AMPH infusion, the maximum increase in DA release (50–70% over the basal values) was observed in control, dODN-pretreated, rats. Similar results were obtained in animals that received local infusion of COC. The most relevant difference in these experiments was that the AMPH-induced increase of DA release was almost completely prevented by the aODN pretreatment, while the same effect induced by COC remained unmodified in aODN-pretreated rats.

DISCUSSION

The primary aim of this study was to evaluate the effect of an antisense strategy in relation to the Kv1.1 potassium channel subtype on the central effects of AMPH in mice. To this end, the effect of AMPH on food intake, motor behavior, pain threshold, and barbiturate-induced sleeping time was compared to the effect of TEA, ChTX, and GLI, which are known to block different types of potassium channels (Cook and Quast, 1990; Edwards and Weston, 1993).

Molecular cloning has confirmed the presence of various species of at least four subfamilies of voltage-gated potassium channel genes in the brain (Tempel *et al*, 1988; Stuhmer *et al*, 1989; Swanson *et al*, 1990). The Kv1.1 subtype, a voltage-dependent, *Shaker-like* potassium channel that is widely distributed in the central nervous system (Wang *et al*, 1994) is able to modulate transmembrane potential and neuronal functions (Hopkins and Tempel, 1992; Bosma *et al*, 1993; Wang *et al*, 1994).

We investigated the potassium channel modulating effect of AMPH, TEA, ChTX, GLI, and other reference compounds by assuming that a reduced expression of the Kv1.1 channel subtype should depress those behavioral functions that are presumably linked to this target. As a general feature, aODNs are short synthetic DNA segments complementary to sequences of an mRNA target. By forming DNA/mRNA heteroduplexes, aODNs can transiently inactivate single genes, specifically preventing translation and/or stimulating mRNA cleavage by RNase, and thus downregulating the synthesis of the encoded protein (Kashihara *et al*, 1998). The administration schedule of aODN anti-Kv1.1 (a single i.c.v. injection on days 1, 4, and 7 before the administration of compounds) was chosen for this study on the basis of previous results obtained in quantitative RT-PCR analysis. These results had shown that this treatment significantly reduced (by more than 60%) the expression of these channels in the mouse brain (Galeotti *et al*, 1997a, b).

AMPH, TYR, PHE, d-FEN, and COC were tested, in single-dose experiments, in ODN pretreated animals. The results obtained in terms of food intake and other behavioral tests indicate that a suppression of Kv1.1 channel expression in the mouse brain considerably reduced the central effects of those stimulants that are chemically related to the phenylethylamine skeleton with the exception of d-FEN.

The behavioral effects of AMPH, TYR, PHE, d-FEN, and COC were not completely correlated with the effects obtained with TEA, GLI, or ChTX. At the doses used, these latter compounds reduced food intake without changing the barbiturate-induced sleeping endurance or motor and explorative behavior. Owing to their depolarizing properties, TEA, GLI, or ChTX can increase the central release of different neurotransmitters, including acetylcholine, nor-epinephrine, DA, and 5-HT (Drukarch *et al*, 1989; Hu and Fredholm, 1991; Boireau *et al*, 1991; Schechter, 1997). Considering that, similar to food intake, the other behavioral parameters used in our tests are also regulated by neurons that release different transmitters, including 5HT and DA, into discrete brain areas, the results obtained with these blockers should be regarded as contradictory. To explain these observations, it must be considered that, as

previously assessed (Galeotti *et al*, 1999), higher doses of these compounds induce strong motor activity and seizures in mice, which impairs other behavioral evaluations. These results showed that the food consumption is more sensitive than other central functions to the low doses of the potassium channel blockers used in this work.

On the other hand, since a more extensive analysis of the central stimulatory effects of TEA, ChTX, or GLI would surpass the aim of the present work, the dosage regimen of these compounds—which are capable of modifying behavioral parameters different from food intake—was not investigated further.

In our experiments, only the anorectic effect of TEA was significantly reduced by the aODN pretreatment, while the same activity induced by ChTX or GLI was unaffected. These results clearly demonstrate that a strong reduction in the Kv1.1 channel expression in the mouse brain abolishes the effect of a compound (TEA) which, notwithstanding its nonselective channel blocking properties, presumably acts on this channel subtype as an anorexigenic. Conversely, the failure of the aODN to reduce the central activity of ChTX or GLI indicates that, at least at the doses used, the anorectic effect of these latter compounds seemingly does not involve a modulation of Kv1.1 channels: Ca^{2+} -activated, a different type of voltage-activated or K_{ATP} channels are presumably the target for ChTX or GLI effects, respectively.

Dose-response experiments also showed that, differently from TEA, it was not possible to separate the anorectic doses of AMPH from those that elicited analgesic, analeptic, or motor stimulatory effects. This feature made it difficult to better evaluate the specific role of AMPH, particularly in analgesia and food consumption experiments, which can be indirectly affected by changes in arousal and motor behavior. Several studies provide support for this point. It has in fact been suggested that AMPH-induced reduction of sleeping time, anorexia, hyperlocomotion, or analgesia are distinct behavioral effects of this compound (Samanin and Garattini, 1993; Altier and Stewart, 1998; Inui, 2000). In any case, the observation that aODN suppresses all the behavioral effects of AMPH in an apparently noncompetitive manner indicates that the central activity of this compound is closely dependent on the number of functionally active Kv1.1 channels actually expressed in the brain. As shown in Figure 2, the complete recovery of the central anorectic effects of AMPH and TEA 7 days after the last i.c.v. injection of aODN further supports these conclusions. These data indicate that the knockdown of Kv1.1 channels produced by the aODN pretreatment is reversible. Furthermore, they indicate that, 7 days after the end of the last aODN treatment, there is a complete recovery of the channel functionality, suggesting a lack of toxicity and neural damage after this aODN treatment.

It is well known that AMPH, or COC, elicits its locomotory stimulatory effect mainly by increasing the extracellular concentration of DA in the mesolimbic system: the nucleus accumbens is an important target for these effects (Kalivas *et al*, 1993; Giros *et al*, 1996; Bardo, 1998). Other evidence also indicates that 5-HT and glutamate transmission contribute to the central activity of these stimulants (Chiamulera *et al*, 2001; Simansky, 1996).

AMPH and COC also have analgesic properties, which probably involve a stimulation of D_2 inhibitory presynaptic

receptors (Schuelke *et al*, 1996; Altier and Stewart, 1998). The observation that AMPH, like morphine, can increase extracellular DA in the nucleus accumbens, the ventral tegmental area and the amygdala brain areas known to be involved in antinociception, is consistent with this view (Morgan and Franklin, 1990; Schuelke *et al*, 1996).

Potassium channels modulate the drug-induced antinociception. For example, K_{ATP} openers potentiate morphine or tricyclic antidepressant-induced analgesia in mice, while blockers which are devoid of analgesic properties do not seem to modify significantly morphine antinociception (Ocana and Baeyens, 1993; Ocana *et al*, 1996; Galeotti *et al*, 2001). These observations are in good agreement with the absence of analgesic effects of TEA, ChTX, and GLI as observed in the present work. On the contrary, AMPH, TYR, PHE, and COC all elicited antinociceptive effects in the hot-plate test, significantly increasing the licking latency in mice. The most relevant difference between these compounds was that the aODN pretreatment abolished the analgesic effect of AMPH-like derivatives, but not that of COC. The lack of effect of aODN pretreatment was also verified for all the behavioral tests using COC that were performed on mice.

Notwithstanding the fact that AMPH and COC both display indirect dopaminergic/serotonergic properties, it is well known that these compounds act with different mechanisms in increasing the extracellular concentration of neuromediators. COC is known to be a neuronal uptake 1 blocker, whereas AMPH, PHE, and TYR are classified as substrate-type releasers (Sonders *et al*, 1997; Waymient *et al*, 1998). To explain this difference, it has been postulated that the latter amines increase exocytosis by promoting a reverse transport from synaptic vesicles to cytosol (Sulzer and Rayport, 1990; Sulzer *et al*, 1995). It has also been suggested that AMPH and other substrate-type releasers induce exocytosis by elevating the intragranular pH, thus disrupting the association of catecholamines with Ca^{2+} , ATP, and vesicular proteins (Mundorf *et al*, 1999).

Recently, some electrophysiological results have focused on the possibility that AMPH may directly block the transient outward K^+ current responsible for the action potential repolarization in cardiac myocytes (Casis *et al*, 2000). Other investigations point to the delayed rectifier K^+ channels blocking properties in order to explain the anorectic effect of d-FEN, a releasing agent that is structurally related to AMPH (Hu *et al*, 1998). Owing to these properties, AMPH and d-FEN are suspected of facilitating the appearance of cardiovascular or pulmonary toxicity in abusers.

The present results are reasonably in agreement with the possibility that AMPH also acts as a blocker of voltage-operated potassium channels in central compartments, in turn inducing depolarization, Ca^{2+} elevation, and neuronal exocytosis. The observation that aODN pretreatment substantially reduces the AMPH-induced DA efflux in rat microdialysis experiments, while also impairing the central activity of TYR and PHE (both substrate-type releasers that share the phenylethylamine skeleton with AMPH), reinforces the view that *Shaker-like* Kv1.1 subtypes are primarily involved in these effects. Conversely, the failure of the aODN to reduce the anorectic effect of d-FEN could be explained with the observation that this preferential

serotonergic agent (Baumann *et al*, 2000) may block channel subtypes different from Kv1.1 (such as Kv1.5 or Kv2.1), as proposed for the activity of this compound in rat taste cells (Hu *et al*, 1998).

Finally, the lack of an effect of aODN in counteracting the stimulant activity of COC could be attributed to the ability of this compound to increase, at least at the dosage used in these experiments, the extracellular DA by means of an action mechanism different from that of AMPH. This view seems to be in agreement with the results of microdialysis experiments, showing that aODN pretreatments completely prevent DA efflux induced in rats by 2 μ g i.c.v. AMPH, but not by 5 μ g i.c.v. COC (Figure 3a, b). These results are also consistent with the observation that K_{ATP} openers attenuate the central effects of AMPH, but not those of COC (Rosenzweig-Lipson *et al*, 1997), and further suggest that the exocytotic process stimulated in neurons by indirectly acting, dopaminergic substrate-type releasers could be triggered early by a reduction in *Shaker-like* Kv1.1 potassium channel conductance.
