In conclusion, we have systematically analyzed the outcoupling efficiencies of OLEDs. The green and blue phosphorescent OLEDs based on $Ir(ppy)_3$ doped CBP layer and Firpic doped mCP layer were used as examples, respectively. Emphasis was given to the effect of the thickness of the ITO layer on the OCEs. OCEs over 30–32% and 27–29% are possible for green and blue OLEDs, respectively, in contrast to the common belief of 20–22%. The high efficiencies are achievable with thinner ITO layers, 100 nm and 80 nm for green and blue PhOLED, respectively. If the ITO layer is 150 nm thick, the maximum OCE is about 22% which is consistent with previous results. Our theoretical OCEs are very much consistent with the external quantum efficiencies of recent high efficiency OLEDs. Even though our analysis was based on specific devices, the OCEs obtained in this analysis must be quite general for OLEDs since the refractive indices of organic semiconductors are not so much different from each other.

the inset of Fig. 1. Poly(3-hexylthiophene) (PAT6):6,6-phenyl-C_{61}-butyric acid methyl ester (PCBM):NaPc/FWCNT composites were obtained by mixing PAT6 and PCBM (weight ratio = 1:1) with NaPc/FWCNT in 1,2-dichlorobenzene. The photo-sensitive region was fabricated by spin-coating PAT6:PCBM:NaPc/FWCNT on indium tin oxide (ITO)-coated glass substrate followed by the deposition of Al contact layer by thermal evaporation.

A well-dispersed individual NaPc/FWCNT hybrid was observed in transmission electron microscopy (TEM, Fig. 1, Hitachi 8000). Organic molecules are densely attached on FWCNT by π–π stacking. The π–electronic interaction between NaPc and FWCNT facilitates packing NaPc fine crystallites onto the sidewall instead of columnar aggregates [11,12]. Thus, the rough organic layer prevents the formation of bundled nanotubes, which improves the solubility and processibility of FWCNT in organic solvents. A well-regulated microstructure is promisingly advantageous to electron transfer between NaPc and FWCNT.

The ultraviolet–visible–near-infrared (UV–vis–NIR) absorption spectra (SHIMADZU UV-3100FS) of (a) NaPc and (b) NaPc/FWCNT in tetrahydrofuran (THF) are shown in Fig. 2. NaPc solution exhibits a strong absorption band in UV region with a board shoulder from 600 to 900 nm centered at 705 nm stemming from Q bands of the annulation of benzene [13]. NaPc/FWCNT solution (Fig. 2b) shows a new shoulder at 1028 nm with the band edge at 1150 nm and a board band of NaPc molecules with the maximum at 701 nm. The red-shifted band in the near-infrared region is attributed to the conjugation extension and charge delocalization. The planar aromatic NaPc molecules were uncovalently adsorbed onto the sidewall of CNT with delo-

calized π-conjugated system by π–π stacking. The red-shifted absorption in the electronic energy state with NaPc molecules in close proximity to the surface of FWCNT indicates the conjugated interaction between NaPc and FWCNT.

The surface morphology of PAT6:PCBM:NaPc/FWCNT film (∼150 nm, r.m.s. = 2.0–3.0 nm) was observed by atomic force microscopy (AFM, JEOL JSPM-5200). Fig. 3 shows a continuous film of low roughness without spherical crystallites or islands of aggregate. Compared with single NaPc or PCBM, this co-deposition produces significant changes film consistent with decreased intermolecular interaction of amorphous mixed film [11]. This microstructure greatly enlarges the donor–acceptor interface within the diffusion length of the exciton generation for charge dissociation.

Fig. 4 presents optical absorption spectra of (a) PAT6:PCBM and (b) PAT6:PCBM:NaPc/FWCNT films by spin-coating. PAT6:PCBM shows a strong absorption band in high energy region. Both two peaks at 280 and 340 nm are attributed to electronic transition of PCBM, and the shoulder centered around 440 nm stems from PAT6. PAT6:PCBM:NaPc/FWCNT film exhibits a board absorption band with a maximum of 710 nm and edge at around 1100 nm. This near-infrared absorption was assigned to the conjugated extension of NaPc/FWCNT. Our previous research founded that the device of ITO/NaPc-MWCNT-P3HT/Al exhibited nearly twice higher photocurrent in the near-infrared region (700–800 nm) than that without MWCNT due to efficient charge transfer and mobility [14]. The marked increase in the photocurrent and photovoltaic performance offers a great promise to detect near-infrared light.

Near-infrared optical response of ITO/PAT6:PCBM:-NaPc/FWCNT/Al device was investigated. *I–V* curve characteristic under dark and illumination at 780 nm (power density of 295 mW/cm^2) was obtained using an electrometer of Keithley 6514 with a DC power supply of Advantest R6145. The plot in Fig. 5 shows that the photocurrent of the devices increases at any voltage upon the illumination of near-infrared light at 780 nm due to efficient exciton absorption of PAT6:PCBM:NaPc/FWCNT film. Near-infrared optical response indicates that photo-generated charges induced by the creation and dissociation of carriers can be conducted to the reverse electrode leading to the evident photocurrent. Moreover, the magnitude of increase in photocurrent is higher than that of the bias amplitude. Uniform blending NaPc/FWCNT hybrid with P3HT:PCBM enable the exciton diffusion to the interface before the recombination and the continuous paths for photo-generated charge transport to the electrode forming the photocurrent. Field dependent dissociation of carriers at the interface results in the enhancement of photocurrent at high bias magnitude [15], because more carrier are pulled out leaving space for the dissociation, which, in contrast, is hindered by charge confinement at low bias. Illumination of NaPc/FWCNT hybrid using near-infrared light results in the generation of the enhanced photocurrent. Near-infrared optical response was attributed to efficient exciton absorption and charge transfer at the interface.

In conclusion, a NaPc/FWCNT hybrid was prepared by packing NaPc crystallites onto the sidewall by π–π stacking. Individual-dispersed NaPc/FWCNT is advantageous to charge transfer. A continuous PAT6:PCBM:NaPc/FWCNT film shown in AFM enlarges donor–acceptor interface. The near-infrared band of PAT6:PCBM:NaPc/FWCNT film with the edge at 1100 nm stems from the conjugation extension by π–π stacking. Devices exhibits the photocurrent illuminated by near-infrared light at 780 nm due to the efficient exciton absorption and charge transfer at the interface. Results offer a great potential to design a highly efficient NOD using CNT-conjugated dye hybrid.

state and hence a net spin of 1/2 for $V(TCNE)_x$ [10]. Thus, the material can be described as a fully spin-polarized semiconductor. $V(TCNE)_x$ thus offers many of the advantages of the traditional organic semiconductors used in organic spintronics [11], but also include fully spin-polarized transport levels that should further aid both spin injection and transport. Hence, we propose a new hybrid organic spin valve design where $V(TCNE)_x$ is a spin-transporting *and* spin-filtering material sandwiched between two ferromagnetic (FM) metal contacts, see Fig. 1(a) and (b), in contrast to the previously proposed design where the $V(TCNE)_x$ layer functions as the soft magnet (spin detector) in Fig. 1(c) [12]. The new design makes use of the fully spin-polarized transport levels of $V(TCNE)_x$ that are expected to both enhance and preserve the injected spin polarization from the FM contacts. This spin valve could operate in a variety of modes with, e.g., a traditional soft and hard FM design or two identical FM contacts. The former situation would enable four different resistances to be obtained, see Fig. 1(b), whereas the latter would provide only the standard on/off functionality (Fig. 1(a)) but have the advantage of using only one FM metal in the fabrication process.

As spin injection and detection in a spintronic device occurs at the FM/organic/FM interfaces, the quality of those are of crucial importance. The organic film is generally fragile and depositing a metallic material on top of it often introduces substantial damage, making the contact poorly defined. The FM atoms (or clusters) might penetrate into the organic film and chemically react with the organic molecules [15]. The magnetic properties of the FM top contact is highly dependent on the roughness of the substrate [13], which is known to be rather high of an organic surface [14], and of course of the interaction with the substrate as well. Besides, the layer between the two FMs has to be thin enough so the spins do not flip before they reach the spin detector FM [3].

In this paper X-ray photoelectron spectroscopy (XPS) and near edge X-ray absorption fine structure spectroscopy (NEXAFS) results on the Ni/$V(TCNE)_x$ interface are reported in comparison with XPS results the Ni/TCNE interface model system.

2. Materials and methods

$V(TCNE)_x$ thin films (<100 Å) were prepared by a method based on physical vapor deposition, PVD [6]. The vanadium metal (purity 99.9%) was deposited using a portable Omicron® PVD source and were allowed to react with TCNE in room temperature, forming thin films on sputter-cleaned Au substrates. Thin films (~50 Å) of pristine TCNE were deposited on sputter-cleaned Au substrates at −160 °C. The base pressure in the chamber was in the high 10^{-10} mbar range and the pressure was in the low 10^{-8} mbar range during preparation of both types of films. Nickel was deposited by an Omicron® PVD source in small steps, ranging from a (sub)monolayer (~5 Å) to a multilayer (~20 Å).

The Ni/$V(TCNE)_x$ interface was studied *in situ* using XPS and NEXAFS (performed in the partial electron yield method) at beamline D1011 of the MAX-II storage ring at the synchrotron radiation facility MAX-lab in Lund, Sweden. The end-station is equipped with a SES-200 electron energy analyzer and the base pressure of the system is low 10^{-9} mbar. The energy calibration was performed such as errors of the monochromator and the analyzer were taken into consideration.

Preparation and XPS of Ni/TCNE as well as preparation and additional XPS of Ni/$V(TCNE)_x$ were performed in the

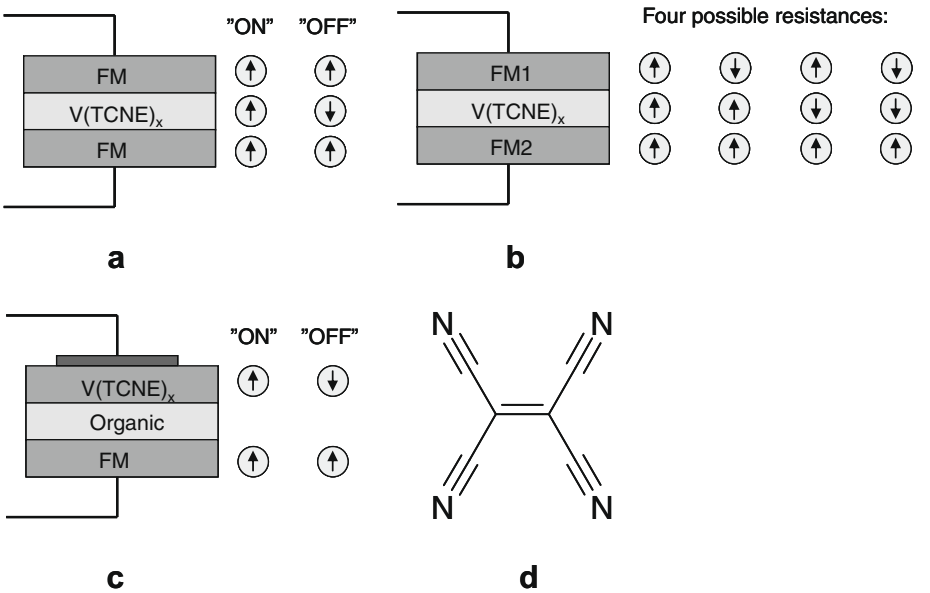

Fig. 1. Different spin valve designs and their possible resistances. (a) $V(TCNE)_x$ sandwiched between two identical FM contacts. (b) $V(TCNE)_x$ sandwiched between two different FM contacts. (c) $V(TCNE)_x$ and a FM contact sandwiching an organic semiconductor. Since $V(TCNE)_x$ is a semiconductor, a metallic contact on top of $V(TCNE)_x$ is needed. (d) The chemical structure of TCNE.

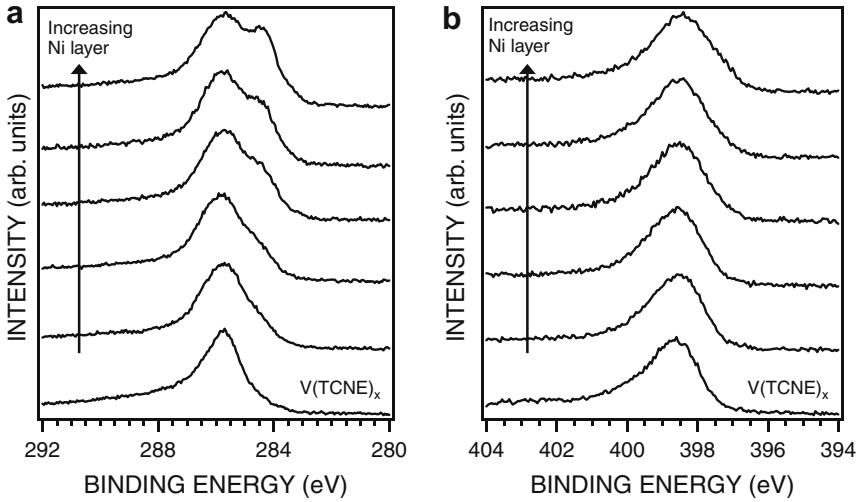

Fig. 2. Core levels upon increasing Ni deposition on $V(TCNE)_x$. The spectra are shifted with respect to pristine $V(TCNE)_x$. (a) C(1s), taken at photon energy 400 eV. (b) N(1s), taken at photon energy 720 eV.

home laboratory using a Scienta® ESCA 200 spectrometer. X-ray photoelectron spectroscopy (XPS) were performed using monochromatized Al(K_α) X-rays at $h\upsilon = 1486.6$ eV. The Ni/$V(TCNE)_x$ and Ni/TCNE interfaces were prepared under the same conditions in the home laboratory as in MAX-lab.

3. Results

3.1. Ni/$V(TCNE)_x$ interface

The features in the C(1s) spectrum (Fig. 2(a), bottom spectrum) of pristine $V(TCNE)_x$ has previously been assigned to a main peak located at 285.9 eV and a shake-up on its higher binding energy side [7]. Depending on preparation method there might also be a shoulder on the lower binding energy side (at ~284 eV) of the main peak, originating from residual by-products from the chemical reaction between the precursors [7]. For $V(TCNE)_x$ prepared by the PVD technique this shoulder is not present since only pure vanadium and TCNE are used in the film preparation [6]. However, an excess of metal upon PVD preparation gives a low binding energy feature, which was explained by metal binding to the vinyl bridge of TCNE [6,16]. Upon increasing Ni, a shoulder on the low binding energy side of C(1s) emerges. When the sample is tilted with respect to the detector, making the measurement more surface sensitive, the shoulder becomes even more pronounced (not shown here).

The N(1s) core level (Fig. 2(b), bottom spectrum) of pristine $V(TCNE)_x$ has its main feature at 398.5 eV. It origins from high to low binding energy from, a shake-up, vanadium-coordinated nitrogen and uncoordinated nitrogen, the latter responsible for the asymmetric N(1s) peak [7]. Given that the V^{2+} in $V(TCNE)_x$ is known to coordinate to six nitrogen atoms, some must remain uncoordinated since each TCNE molecule contains four nitrogen [17]. Upon increasing Ni coverage, the N(1s) spectra are modified on the lower binding energy side of the main peak. However, the changes are not as evident as for C(1s) and are seen only as a broadening of the N(1s) core level. When the sample is tilted, as described above, the broadening of the N(1s) core level becomes even more obvious. The V(2p) core level (spectra not shown here) remains unchanged upon increasing Ni.

The C K-edge of pristine $V(TCNE)_x$ (Fig. 3(a)) has its absorption onset located at 284 eV, originating from a transition to the LUMO of $V(TCNE)_x$ [9,18]. When Ni is deposited on $V(TCNE)_x$, the absorption onset decreases in intensity. The same occurs for the N K-edge (Fig. 3(b)), which has its absorption onset at 397 eV [18]. The V L-edge (not shown here) remains unchanged upon Ni deposition.

3.2. Ni/TCNE interface

The C(1s) core level of pristine TCNE is located at 287.4 eV (Fig. 4(a), bottom spectrum). The asymmetry of the C(1s) peak originates from cyano and vinyl carbon which differs with 0.4 eV only [19]. Upon increasing Ni deposition two new features appear on the lower binding energy side of C(1s). The new features are slightly more pronounced when making the measurements more surface sensitive, but their relative intensity is still significantly lower at the corresponding multilayer coverage compared to Ni/$V(TCNE)_x$, suggesting a more extended interface region for Ni/TCNE.

The N(1s) core level (Fig. 4(b)) of pristine TCNE is found at 400.1 eV. Since there is only one type of nitrogen present in TCNE, the peak is symmetric and well defined. Upon increasing the thickness of the Ni layer, a new feature on the low binding energy side appears. It mimics C(1s) in that the feature is more distinct when the measurements are performed more surface sensitive. The new features appear at the same deposition step for both C(1s) and N(1s) core levels.

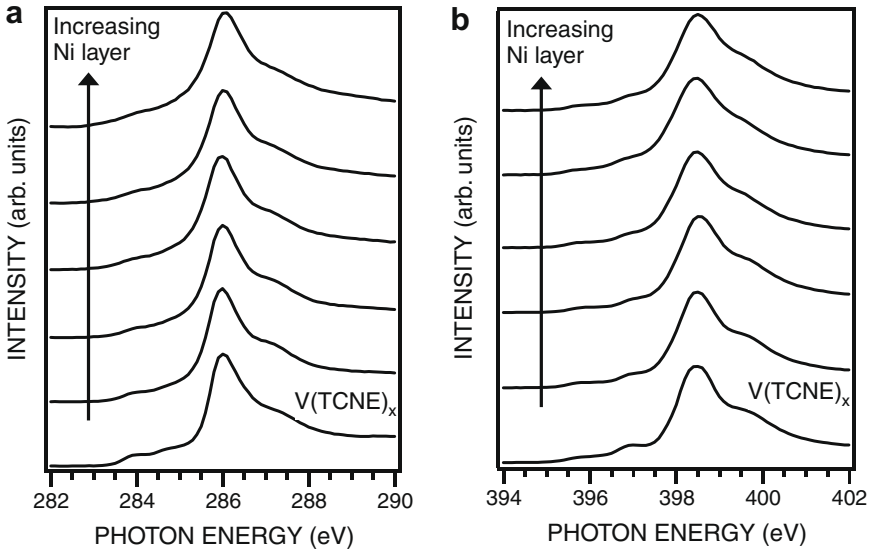

Fig. 3. NEXAFS spectra upon increasing deposition of Ni on $V(TCNE)_x$. (a) C K-edge. (b) N K-edge.

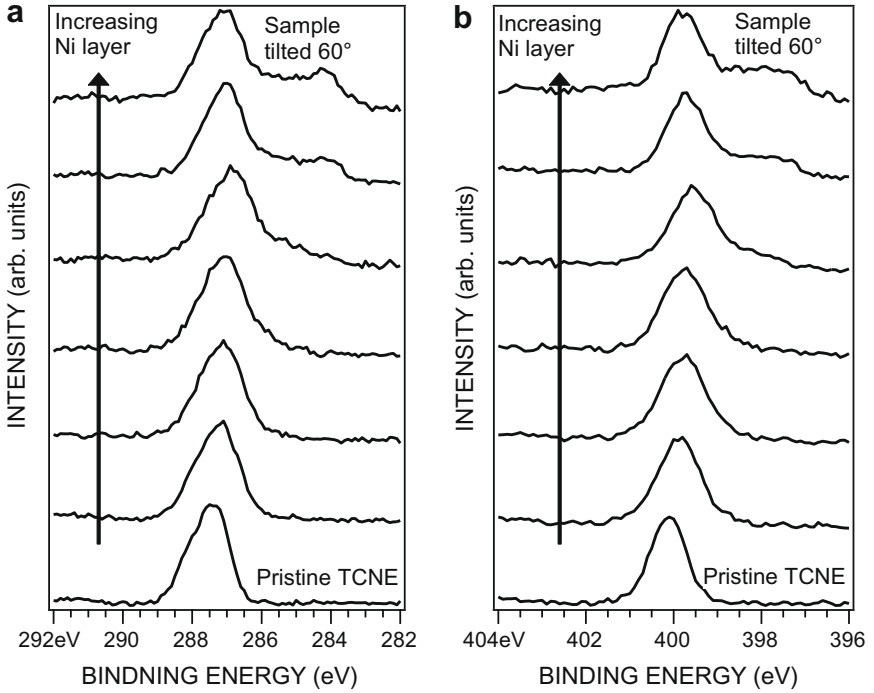

Fig. 4. Core levels upon increasing Ni deposition on pristine TCNE. The spectra are measured with respect to the Fermi level energy. (a) C(1s). (b) N(1s). The two topmost spectra of C(1s) and N(1s), respectively, are taken at the same Ni thickness, but the sample position with respect to the detector is different in order to make the measurements of the topmost of all spectra more surface sensitive.

4. Discussion

Both the XPS and NEXAFS results clearly show chemical interaction between Ni and TCNE. As the V(3d) core levels and V L-edge remain unaffected by Ni there is no vanadium-nickel interaction. Hence, the possible binding situations that can occur are cyano groups bonded to Ni, vinyl groups bonded to Ni, or a combination of both bonded to Ni. Studies of similar systems (π-conjugated organic materials with vinyl- and cyano groups forming interfaces with transition metal atoms) [20] showed that the transition metal preferentially bond to the cyano group but also that the vinyl group is an option. The Ni/TCNE system indicate an interaction where both the carbon and nitrogen atoms

simultaneously are affected by the Ni deposition and furthermore that two different new peaks appear in the C(1s) core level as the interface forms. This suggests that Ni attacks both the vinyl and the cyano groups of the TCNE molecule. The evolution of the C(1s) and N(1s) core levels upon Ni deposition for the $V(TCNE)_x$ is quite different, however. The C(1s) core level shows only one strong new peak appearing with a weak low binding energy shoulder upon Ni deposition. The N(1s) core level undergoes a broadening but does not display the new extended low-bonding energy feature of Ni/TCNE. This suggests that the Ni interaction with $V(TCNE)_x$ occurs mainly at the vinyl linkage of TCNE. The likely explanation for the difference is that most of the cyano groups of $V(TCNE)_x$ are coordinated to vanadium ions and hence not available as reaction sites. The distinct peak closest to the original C(1s) core level feature in Figs. 2(a) and 4(a) are thus assigned to vinyl carbon – nickel bonds and the weak shoulder in Fig. 2(a) (second new peak in Fig. 4(a)) are assigned to cyano group – nickel bonds, the latter producing the new low binding energy feature in the N(1s) core level spectra of Fig. 4(a). The evidence for lesser Ni diffusion into the $V(TCNE)_x$ as compared to TCNE is likely an affect of the compactness of the $V(TCNE)_x$ films obtained from PVD fabrication [6].

The Ni induced disruption of the vinyl linkage (and non-coordinated cyano groups) greatly modifies the LUMO of $V(TCNE)_x$ (as evident from the sharp decrease in intensity of the C and N K-edge absorption edges). This will increase the electron injection barrier as well as degrade the magnetic property of the interface region. Hence, a Ni/$V(TCNE)_x$ contact, and in extension probably any FM transition metal contact, is not optimal for use in a spin valve based on $V(TCNE)_x$. In conventional organic electronics, inserting a buffer layer between the top contact and the organic layer has been widely adopted in order to eliminate the risk of chemical interaction between the layers and hence improve the device performance [21,22]. This approach has recently successfully been adopted in spintronics devices, as well [23]. The results above indicate that a buffer layer between $V(TCNE)_x$ and Ni should be employed in design and fabrication of devices based on $V(TCNE)_x$.

5. Conclusions

In this paper a new hybrid organic spin valve design, i.e. FM/$V(TCNE)_x$/FM, is proposed, where the semiconducting $V(TCNE)_x$ layer delivers both spin-transporting *and* spin-filtering functionality. The electronic structure of the Ni/$V(TCNE)_x$ interface was investigated by means of XPS and NEXAFS and the results were interpreted together with XPS studies of the Ni/TCNE model system. $V(TCNE)_x$ and Ni interact chemically at the interface and both the cyano (that are not coordinated to V) and the vinyl groups participating in the reaction while vanadium remains unaffected. The interface region is fairly abrupt with no significant Ni diffusion into the $V(TCNE)_x$. The disruption of the vinyl linkage (and non-coordinated cyano groups) greatly modify the former LUMO of $V(TCNE)_x$ which will increase the electron injection barrier as well as degrade the magnetic network at the surface. These results indicate the need for a buffer layer between $V(TCNE)_x$ and Ni, and in extension most likely for any FM contact in the FM/$V(TCNE)_x$ structure.

present study, we investigate the device characteristics of OFETs with Au electrodes modified with SAMs of 1-alkanethiol molecules, and show that such OFETs exhibit anomalous hysteretic output characteristics. The hysteresis can be reasonably explained by the structural change of the SAMs, which is caused by the application of an electric field parallel to the alkyl chain of the SAM molecules. This result implies the realization of the electrical detection of electrically-stimulated SAM switching, and should provide a useful contribution toward the development of molecular switches.

2. Experimental details

About 50 nm thick Au source/drain electrodes with 5 nm thick adhesion layers of Cr were formed on a highly-doped Si substrate covered with a 400 nm thick thermal oxide layer. Prior to electrode formation, the substrate surface was treated to impart hydrophobicity by a conventional hexamethyldisilazane treatment [6]. The substrate with formed electrodes was then submerged into a 0.01 M ethanol solution of 1-alkanethiol to form SAMs on the Au electrodes. After the SAM formation, the substrate was rinsed with pure ethanol and ultrasonicated for 1 min to desorb physisorbed 1-alkanethiol molecules on the SAMs. The molecules forming the semiconductor channel of the OFET were then deposited through a metal shadow mask. Although electrical shorts in SAMs are often formed upon vapor deposition of metals onto SAMs [7], a soft molecular layer deposited onto the SAM-modified electrode can avoid such damage in this study. The constructed device (Fig. 1) had a channel length of 30 μm and a channel width of 3 mm. FET characteristics were measured at room temperature under dark, high vacuum conditions.

C_{60} and pentacene molecules were used for the semiconductor channels. Both n-type C_{60} FETs and p-type pentacene FETs exhibited similar results. Although all the experimental results presented were obtained using C_{60} FETs, the discussion is also valid for hole transport.

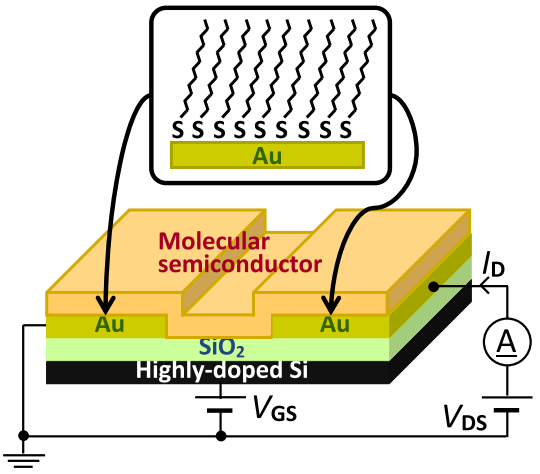

Fig. 1. Schematic diagram of the FET structure used in this study. The surfaces of the Au source/drain electrodes were modified with 1-alkanethiol SAMs. I_D, V_{DS}, and V_{GS} denote the drain current, drain voltage, and gate voltage, respectively.

3. Results

Fig. 2 shows (a) transfer (drain current, I_D, versus gate voltage, V_{GS}) and (b) output (I_D versus drain voltage, V_{DS}) characteristics of a C_{60} FET. SAMs of 1-dodecanethiol ($C_{12}H_{25}SH$; C12) molecules were formed on the Au electrodes by substrate immersion for 12 h. The voltage sweep rate used was 0.25 V/s. The transfer characteristics display a hysteresis where the I_D values for the forward sweep of V_{GS} from 0 to 120 V are higher than those for the backward sweep from 120 to 0 V. Such hysteretic behavior has been widely observed for OFETs and is interpreted as a carrier-trapping effect where carrier traps are gradually formed in the channel and trapped charges screen the gate electric field [8]. However, the output characteristics display an anomalous reversed hysteresis where the forward sweep I_D values are smaller than the backward ones, which was not observed for a C_{60} FET without SAMs on the electrode surfaces. Although this type of hysteresis can be observed in FETs with ferroelectric gate insulators that exhibit slow polarization, the present device has a conventional gate dielectric of SiO_2. Furthermore, the same type of hysteresis should also be observed in the transfer characteristics if the hysteresis is due to the ferroelectric characteristics of the gate insulator. Thus, it is concluded that the anomalous hysteresis originates from the SAM insertion into the metal–organic interface.

In order to clarify the difference between the transfer and output curves, the order of voltage application was investigated. To measure the transfer characteristics, V_{DS} is firstly set and then V_{GS} is swept, and vice versa for the output characteristics. Fig. 3 shows the time evolution of

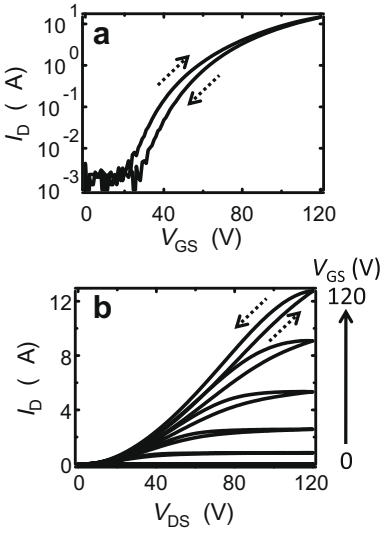

Fig. 2. (a) Transfer ($I_D - V_{GS}$) and (b) output ($I_D - V_{DS}$) characteristics of a C_{60} FET with Au source/drain electrodes modified with SAMs of 1-dodecanethiol molecules by substrate immersion in an ethanol solution of the SAM molecules for 12 h. The voltage sweep rate was 0.25 V/s. The dashed arrows indicate the voltage sweep directions.

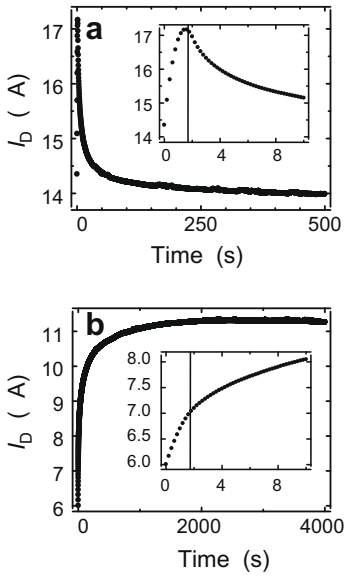

Fig. 3. Time evolution of I_D for a C_{60} FET identical to that used for Fig. 2, immediately after application of V_{DS} and V_{GS}. Data were acquired using two types of voltage-application orders to mimic the (a) transfer ($V_{DS} \rightarrow V_{GS}$) and (b) output ($V_{GS} \rightarrow V_{DS}$) characteristics. The firstly-applied voltages (V_{DS} for (a) and V_{GS} for (b)) were set to 120 V by gradually increasing at a rate of 0.1 V/s. After setting the first voltages, the second voltages (V_{GS} for (a) and V_{DS} for (b)) were set to 120 V at a rate of 10 V/s. Insets enlarge the first 10 s of the evolution. The first 1.8 s denoted by the solid lines can be considered as the response time of the measurement circuits, including the FET itself.

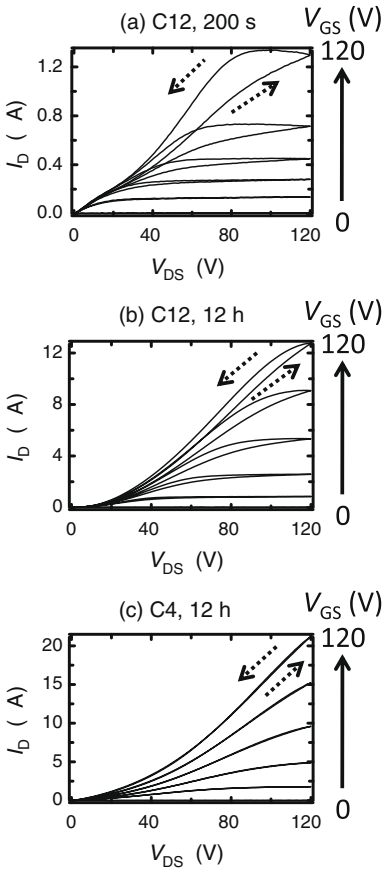

Fig. 4. Output characteristics of C_{60} FETs with Au source/drain electrodes modified with SAMs of (a and b) 1-dodecanethiol ($C_{12}H_{25}SH$; C12) and (c) 1-butanethiol (C_4H_9SH; C4) molecules by substrate immersion in an ethanol solution of the SAM molecules for (a) 200 s and (b and c) 12 h. The C_{60} FET used for (b) is identical to that used for Figs. 2 and 3. The voltage sweep rate was 0.25 V/s. The dashed arrows indicate the V_{DS} sweep directions.

I_D with two types of voltage-application order to mimic the transfer and output characteristics. Firstly-applied voltages (V_{DS} for Fig. 3(a) and V_{GS} for Fig. 3(b)) were set to 120 V by gradually increasing the absolute value at a rate of 0.1 V/s. After 1200 s to set the first voltages, the second voltages (V_{GS} for Fig. 3(a) and V_{DS} for Fig. 3(b)) were set to 120 V using a rate of 10 V/s. The time evolution curves of Fig. 3 were recorded immediately after the second-voltage applications. The first 1.8 s can be considered as a response time of the measurement circuits including the OFET itself. Fig. 3(a) mimics the transfer characteristics by application of voltages in the order of V_{DS} and V_{GS}. After the response time, I_D decreases with time, which accounts for the hysteresis observed in Fig. 2(a). On the other hand, Fig. 3(b) mimics the output characteristics by application of voltages in the order of V_{GS} and V_{DS}, and shows an increase in I_D. This is the same tendency as that observed in Fig. 2(b). These results indicate that the application of V_{DS}, which forms an electric field almost parallel to the alkyl chains of 1-alkanethiol molecules, causes the anomalous hysteresis where I_D is larger in the backward V_{DS} sweep than that in the forward sweep.

To clarify the reason for such a hysteresis, the effects of surface density and alkyl-chain length of SAM molecules were examined. Fig. 4 shows the output characteristics of three devices with different molecular species or different average surface densities of SAM molecules. The average surface density was varied by changing the substrate immersion period in an ethanol solution of SAM molecules. The self-assembly of 1-alkanethiol molecules on Au(1 1 1) surfaces is known to be almost complete within several minutes, but that on polycrystalline Au films is slower and the immersion period of 200 s employed for the device shown in Fig. 4(a) should result in an incomplete monolayer [9]. To confirm this, water contact angles were measured with Au films modified using the same conditions as those for Fig. 4. The measured values were 97° (C12, 200 s; Fig. 4(a)), 105° (C12, 12 h; Fig. 4(b)) and 100° (1-butanethiol (C_4H_9SH; C4), 12 h; Fig. 4(c)). A shorter period of SAM formation resulted in a lower water contact angle, which confirms incomplete coverage (or defective structure) of the SAM on the Au film surface. In addition, the shorter alkyl-chain length resulted in a lower angle. This result may reflect the fact that short chains cause rather defective SAMs, due to weak inter-chain interaction. All three devices display the same-type hysteresis with larger I_Ds in the backward sweeps, as shown in Fig. 4, although the hysteresis observed for the device employing C4 SAMs is too small to be clearly observed. The results show that lower density and longer chains of SAM molecules cause a larger hysteresis.

4. Discussion

The structure of 1-alkanethiol SAMs is stabilized by van der Waals interaction between the alkyl chains. The lower density of the SAM molecules corresponds to a larger separation between the alkyl chains and should lead to weaker interaction between them. The larger hysteresis observed for the device with lower-density SAMs can be interpreted as weaker inter-chain interaction, i.e., the less-stabilized SAM structure causes a larger hysteresis. Thus, the hysteresis very likely originates from a structural change of the SAMs. The most probable form of structural change is a V_{DS}-induced order–disorder transition of the SAM structure. Such switching behavior of SAMs caused by an applied electric field has been observed as a change in the wettability of a surface modified with a 16-mercapto-hexadecanoic acid SAM [10]. The electric field pulls hydrophilic terminal groups toward the substrate surface and the SAM-modified surface can become hydrophobic [11]. During the order–disorder transition, the ordered phase stabilized by the van der Waals interaction between the alkyl chains is broken, and each alkanethiol molecule no longer stands on the surface. The observed hysteresis is a current-increasing type, where I_D was higher during the backward sweep of V_{DS} than I_D during the forward sweep. There are two possible mechanisms that can link the structural change with the current increase.

Charge carrier conduction through alkanethiol SAMs is understood as a tunneling of the carriers through alkyl chains [12]. The alkyl tunneling barrier should be narrower in the disordered phase of SAMs than that of the ordered phase with standing alkanethiol molecules. The transition to a disordered phase may form a space between the SAM-modified electrode and the C_{60} active layer. The tunneling current is proportional to $\exp(-\beta d)$, where β is the decay constant and d is the width of the tunneling barrier. The reported values of β for alkyl chains and vacuum are approximately 1.2 and 2.3 $Å^{-1}$ [13], respectively. Therefore, the simple replacement of alkyl chains with vacuum should decrease the tunneling current through the interface, which is opposite to the observed hysteresis. However, if the movement of C_{60} molecules occurs simultaneously to fill the space formed by the tilting of SAM molecules, then the structural change results in a simple narrowing of the tunneling barrier and an increase in the drain current.

A possible mechanism other than tunneling-barrier narrowing is a change in the Schottky barrier height at the interface between the Au electrode and the C_{60} active layer. A recent theoretical calculation predicts that the work function change of electrodes by SAM modification $\Delta\Phi$, is proportional to $\cos\theta$, where θ is the tilt angle of the SAM molecules from the surface normal [14]. This indicates that the tilting of SAM molecules lowers the $\Delta\Phi$ value. $\Delta\Phi$ reported for clean polycrystalline Au films with 1-alkanethiol SAMs is approximately -1.2 eV, and is roughly independent of the alkyl-chain length [15]. However, in the present case, no special care was taken to clean the Au surface before the SAM formation, so that the Au surface is most likely contaminated. Electric dipoles formed at the interface between a contaminated metal and molecular layer are smaller than those for clean metal-molecular layer interfaces [16]. The $\Delta\Phi$ value of our interfaces was around -0.2 eV [17]. Therefore, considering the work function of a polycrystalline Au film (5.1 eV [18]) and the minimum energy of the conduction band derived from the lowest unoccupied molecular orbital of C_{60} molecules (4.6 eV, which is calculated from the threshold ionization energy of 6.17 eV [19] and an optical band gap of ca. 1.6 eV, assuming a crystalline thin film [20]), the electron injection barrier at the interface between the C_{60} active layer and the SAM-modified Au electrodes is expected to be around 0.3 eV. This value should be higher and I_D should decrease when tilting of the SAM molecules occurs. Therefore, it is concluded that the lowering of $\Delta\Phi$ cannot explain the observed current-increasing hysteresis.

The previous discussion suggests that the anomalous hysteresis observed in OFETs with source/drain electrodes modified with 1-alkanethiol SAMs occurs by tunneling-barrier narrowing induced by V_{DS}. However, the microscopic cause of the switching behavior is still unclear, because the application of V_{DS} can provide two types of stimuli; an electric field and an electric current. An electric field couples with the polar groups or the electric dipole of the SAM molecules, and such a coulombic force can change the structure of the SAMs. For an electric current, an electron has the ability to excite inter- and/or intra-molecular vibrations by inelastic tunneling through the alkyl chains, and the excited inter-chain vibrations can break the ordered phase SAM structure. A FET is a switching device that can turn off the electric current through it; therefore, by employing the FET structure, it is possible to apply an electric field without electric current flow (see the low-V_{GS} region of Fig. 2(a)). To measure the time evolution in Fig. 3(a), V_{DS} was firstly set to 120 V with a rate of 0.1 V/s (in total 1200 s to set V_{DS}) and then V_{GS} was set to 120 V with a rate of 10 V/s, in order to mimic the measurement of the transfer characteristics. Application of both V_{DS} and V_{GS} is necessary to turn on the device. Therefore, for this measurement, only an electric field was applied before an electric current started to flow. The decrease in I_D after the setting of V_{GS} in Fig. 3(a) indicates that the structural switching of SAMs was almost finished within 1200 s before the setting of V_{GS}. On the other hand, Fig. 3(b) shows the time evolution immediately after the application of V_{DS} and the structural change evolved at the same time. Fig. 3(b) also shows that the I_D increase was almost completed within several hundred seconds, which supports that the structural switching was almost finished within 1200 s before V_{GS} application when acquiring the data of Fig. 3(a). Therefore, the structural switching of SAMs is thought to be induced by an electric field. Naturally the I_D values in Fig. 3(a), where the switching was largely completed, are higher than those in Fig. 3(b), where the switching had just started.

Finally, it should be noted that the shapes of the hysteretic curves, in particular Fig. 4(a), show gate-voltage dependence. Generally, larger hystereses were observed with higher gate voltages. Higher V_{GS} values induce higher concentration of charge carriers in the channel, which

indicates that larger hystereses appear with larger currents. The current increase by SAM switching can be interpreted as tunneling-barrier narrowing. The tunneling current is proportional to $\exp(-\beta d)$. If the barrier width is reduced from d to $d-t$ and the tunneling current changes from I_i to I_f, then an increase in the tunneling current $I_f - I_i$, is expressed as $I_i[\exp(\beta t) - 1]$. This means that the current increment should be larger with larger currents, i.e., with higher V_{GS} values. Although the current through the device is not wholly determined by tunneling through the alkyl chains of SAMs, this can cause the gate-voltage dependence of the hysteretic behavior. However, the shape of the hysteretic curves is determined by two competing effects; in addition to the current increase by the SAM switching, current decrease by the gate bias stress should also be taken into account. The latter effect also depends on V_{GS}; higher V_{GS} values cause larger bias stresses. The sparser SAM (Fig. 4(a)) should increase the relative contribution of the former effect, due to the less-stabilized SAM structure, and thus the gate-voltage dependence of the hysteresis is clearly observed in Fig. 4(a). In the case of denser SAMs (Fig. 4(b) and (c)), the relative contribution of the former effect is less and as a consequence the gate-voltage dependence becomes less apparent.

5. Conclusions

The device properties of n-type C_{60} FETs with Au source/drain electrodes modified with 1-alkanethiol SAMs were investigated and were found to exhibit anomalous hysteretic output characteristics, where the I_D values in the forward sweep of V_{DS} from 0 to 120 V were smaller than those in the backward sweep of V_{DS} from 120 to 0 V. This is opposite to the generally observed hysteresis induced by the carrier-trapping effect [8], where the I_Ds in the forward sweep are larger than those in the backward sweep. Measurements on FETs employing different SAM densities and different alkyl-chain lengths showed that FETs with lower density and/or longer length SAM molecules display a larger hysteresis, which indicates that the hysteresis is caused by tunneling-barrier narrowing accompanied by the structural change of the SAMs, most probably an order–disorder transition of the SAM structure [11]. From time evolution measurements of I_D immediately after the application of V_{DS}/V_{GS}, an electric field parallel to the alkyl chains of the SAM molecules, V_{DS}, was found to induce switching behavior. It should be noted that p-type pentacene FETs also displayed the anomalous hysteresis, which indicates that the phenomenon occurs in both electron- and hole-transport systems.

The SAM modification of source/drain electrodes is an effective method to achieve energy level matching at the interface between electrodes and a molecular active layer, and thus gain effective charge injection from the electrodes into the molecular layer. The present study has revealed the occurrence of anomalous hysteretic behavior in OFETs with SAM-modified electrodes and has yielded important information for analysis of the operation of OFETs. Particular attention should be paid to OFETs that have source/drain electrodes modified with low-density/long-chain SAMs. Furthermore, there is a possibility that the anomalous hysteresis could cancel out the hysteresis caused by the charge-trapping effect. This could be achieved by tuning the density and length of SAM molecules on source/drain electrodes.

Exploiting the self-assembly of molecules to realize basic electronic components will pave the way for molecular-scale electronics [4]. The anomalous hysteresis found in this study is indicative of the switching of SAMs induced by electrical stimulation. Such electrically-stimulated switching of SAMs has been observed as a change in the wettability of a gold surface modified with a 16-mercapto-hexadecanoic acid SAM [10]. However, in order to realize an electric molecular switch, it is necessary to tune the electric conductance using an electrical method. Recently, the reliable conductance switching of SAMs has been achieved by the optically induced isomerization of diarylethene molecules [21]. On the other hand, the present result indicates the electrical detection of electrically-stimulated switching, which should have significant implications with respect to achieving a future molecular switch.

Generally, microscopic probing techniques such as scanning probes [22] and break junctions [23] are used to assess molecular-scale electronic junctions. However, the microscopic conductance of the junctions, i.e., single molecule conductance, typically varies by many orders of magnitude, but SAMs provide an average conductance of many molecules and may offer a more reliable assessment of the junction [24]. In addition, SAMs can amplify molecular-level conformational switching to macroscopically measurable changes by the synergistic molecular reorientation of ordered molecules [10]. Therefore, the anomalous hysteretic behavior observed in the present study can be regarded as a manifestation of molecular-level conformational switching by an electric field, which was amplified through the synergistic switching of ordered molecules forming the SAM, and was finally detected as a macroscopic change in I_D.

investigated the feasibility of air atomizing spray technology for large-area/low-cost fabrication of organic electronic and optoelectronic thin-film devices based on solution-processable polythiophene derivatives. There, a manually operated airbrush was utilized to fabricate different devices while comparing electrical and electro-optical characteristics, as well as film morphology and roughness of spray-coated devices to those of spin-coated ones with similar structure [8].

In this article we present a detailed investigation on the layer formation process during spray deposition of organic thin-films and its relation to solution properties and process parameters. By considering layer formation to be a stacking of individual droplets onto the substrate followed by partial merging between adjacent ones, we are able to correlate deposition conditions to the electrical and electro-optical characteristics of fabricated devices. Other than in previously reported research activities, we apply the technological framework developed here not only to the fabrication of organic photovoltaic devices, but also to the fabrication of organic thin-film transistors. This work clearly demonstrates the feasibility of this deposition technology for the fabrication of diverse organic electronic and optoelectronic devices independent of substrate material and geometry.

2. Materials and methods

Spray technology is used in a wide variety of applications such as surface coating, humidification, combustion and many more. Each application area requires different spray nozzles to fulfill the specified criteria and achieve the desired results. The layers deposited here were sprayed by an air atomizing nozzle. This type of nozzles provides, along with ultrasonic spray nozzles, the finest degree of atomization. It is worth mentioning that ultrasonic spray nozzles have also been successfully applied to the deposition of active layers [9] and hole-selective contacts [10] in organic photovoltaic devices. For our static test system, a commercially available automatic air atomizing spray gun (Krautzberger GmbH, Germany) was used. All ink containing parts of the spray gun are resistant to organic solvents and are therefore suitable for the desired application. Fig. 1(a) shows a schematic drawing of the test setup, indicating the vertical arrangement of nozzle and substrate. The spray gun contains an internal pneumatic control system which is activated by an electromechanical 3/2-way valve connected to a timer for precise spray time adjustment. Other spray gun settings that were varied to obtain the desired spray characteristics are material flow rate, atomizing gas (N_2) pressure and nozzle-to-sample distance. The performance of any kind of spray nozzle is strongly dependent on its size and geometry as well as on the physical properties of the liquid being atomized and the gaseous medium surrounding the droplets. For air-assisted nozzles the diameter of the orifice is the most significant dimension for atomization. Here a nozzle with 0.5 mm orifice diameter was chosen. The physical properties of the liquid being atomized have a direct effect on the flow and spray characteristics in a spray nozzle. Density, viscosity and surface tension are among the most critical fluid properties. As most liquids exhibit only minor differences in density, the significance of this property for atomization is rather low. However, higher density tends to result in a larger average droplet size. An increased viscosity tends to hinder any natural instabilities leading to fluid breakup, which results in a delayed disintegration and increased average droplet size in the spray. Surface tension plays a very important role because it represents the force resisting the formation of new surface area. Hence it affects the droplet size as well as the spray angle. Fluids with higher surface tension tend to produce sprays with an increased average droplet size and a decreased spray angle. In addition, boiling point and vapor pressure of solvents are of great significance for the drying behavior of droplets in a spray and hence the process of layer formation. The three solvents used in the work presented here are toluene, p-xylene and o-dichlorobenzene (Merck KGaA, Germany) having boiling points of 110.6 °C, 138.3 °C and 180.5 °C, respectively.

In all our experiments the atomizing gas pressure was kept below 1 bar in order to achieve a reasonable spray pattern and prevent the gas flow from pushing away the droplets already on the substrate before completely drying. Depending on the solution to be deposited, i.e. polymer and solvent type, the nozzle-to-sample distance can only be varied within a certain range. One can distinguish between three regimes: wet, intermediate and dry [3]. In the wet regime, the nozzle-to-sample distance is low resulting in the formation of a wet polymer layer on top of the substrate, hence producing inhomogeneous layers with no real thickness control. On the other hand, in the dry regime, when the nozzle-to-sample distance is high, the entire solvent is evaporated before reaching the sample and a polymer powder is formed. The intermediate regime is the one more suitable for the deposition of organic thin films. In this regime, homogeneous layers can be formed and the thickness can be precisely controlled by adjusting the spray time. It is important to mention, that the evaporation rate of the atomized liquid, and hence the different deposition regimes, is strongly dependent on the properties of the chosen solvent (e.g. boiling point and vapor pressure) as well as the droplet size achieved for a given set of process parameters.

The general device architectures for the organic photodetectors and thin-film transistors fabricated are illustrated in Fig. 1(b) and (c), respectively. For the fabrication of the organic photodetectors, ITO-electrodes with the desired structure were patterned on glass by conventional photolithography. The structured ITO-glass substrates were then cleaned by sonication in acetone and isopropanol in sequence. PEDOT:PSS aqueous dispersion (CLEVIOS™ P VP CH 8000) was deposited by spin coating at 2000 rpm for 20 s and then dried on a hot plate at 150 °C for 15 min. The active layer of the device consisted of a blend of regioregular poly(3-hexylthiophene-2,5-diyl) (P3HT) (Rieke Metals Inc.) and [6,6]-phenyl C61 butyric acid methyl ester (PCBM) (Solenne B.V.) as donor and acceptor materials, respectively. The P3HT:PCBM (1:1) blend was deposited from a solution of 0.5 wt% concentration in the different solvents. All samples were then placed

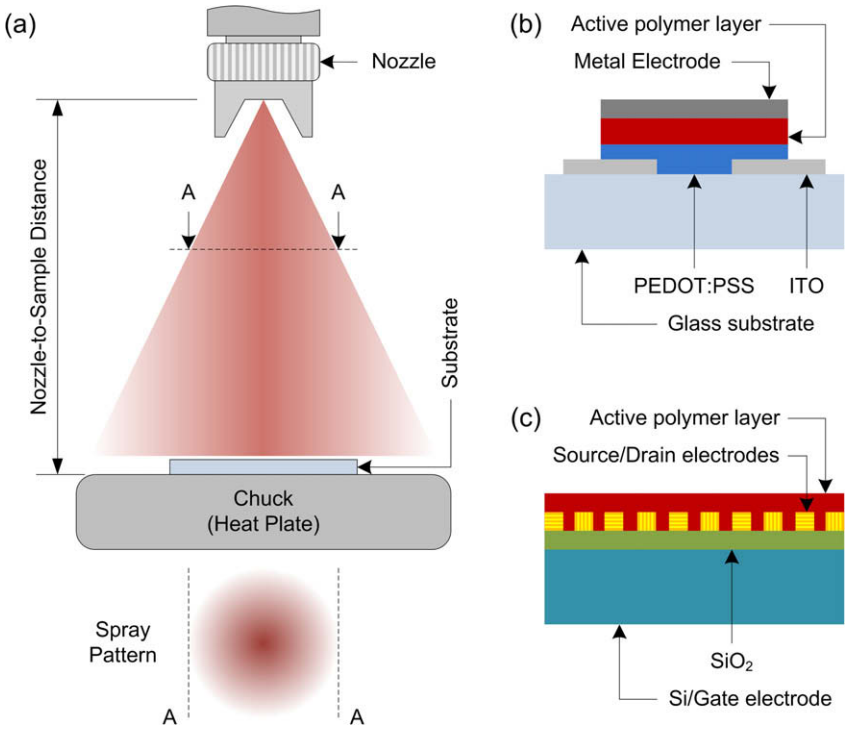

Fig. 1. (a) Illustration of the implemented experimental setup for spray deposition, showing the basic components and the resulting spray pattern while indicating the vertical arrangement of nozzle and substrate. (b) General layout of an organic photodetector showing the layer stack comprising two organic layers sandwiched between two electrodes. (c) General layout of an organic thin-film transistor showing a single organic layer deposited onto an interdigitated electrode structure. For both device types the active polymer layer was spray-coated.

again on a hot plate for annealing at 140 °C for 15 min. Finally, a LiF(1 nm)/Al(120 nm) cathode was thermally evaporated on top. The active area of each diode was defined by the ITO-electrode to be 25 mm^2. Organic thin-film transistors were fabricated on highly p-type doped Si wafers, on which a 45 nm thick SiO_2 layer was thermally grown. An interdigitated electrode structure (IDES) consisting of a 2 nm thick Ti layer (to promote Au adhesion on Si) followed by a 45 nm Au layer was evaporated on top of the SiO_2. The spacing formed between the source and drain contacts of this interdigitated structure was chosen to be 20 μm. Regioregular P3HT was used as a semiconductor for the channel of our p-type TFT and was deposited on top of the sample from a solution of 0.5 wt% concentration in xylene. Device fabrication was finalized by an annealing step at 120 °C for 10 min. Note that all organic layers were deposited in ambient conditions, only annealing steps and device encapsulation were performed in an inert gas atmosphere inside a glove box.

3. Results and discussion

Operating in the intermediate regime, the process of layer formation can be thought of as a process of successively stacking individual droplets onto the substrate at a certain rate. In the following we will discuss experimental results supporting this idea and correlating it to the performance of fabricated devices. By the correct choice of process parameters the effect of dissolving previously deposited droplets by new ones can be significantly minimized. This allows the fabrication of devices with more complicated layer stacks from the same solvent. However, if droplets arriving at the substrate are too dry, it can be assumed that a large portion of these droplets form separate domains and that charge transport across domain boundaries is impeded. For this reason, droplets arriving at the substrate surface should still be wet to an extent allowing a minimum of merging between individual droplets. Spray deposition from low boiling point solvents shows a higher sensitivity to process parameters and ambient condition variations due to a narrower intermediate regime and hence suffers from poor reproducibility. The lower evaporation rate of high boiling point solvents makes the deposition process less sensitive and easier to control over a larger parameter space. In order to ensure an optimal merging between droplets, we introduce a deposition approach in which we operate within the wet regime while heating up the substrate in order to speed up the drying of wet droplets arriving at the substrate. This approach allows the formation of dry layers with good thickness control over time, enhancing at the same time reproducibility, especially of devices deposited from low boiling point solvents (e.g. toluene). The substrate heating during deposition is a very important parameter which still has to be carefully optimized. Our investigations showed that, as a rule of thumb, the substrate temperature should be close to the boiling point of the used solvent. This turned out to be valid also for spray deposition of the conducting poly-

mer PEDOT:PSS (aqueous dispersion), which confirmed the applicability of our deposition approach to other organic conducting and semiconducting material systems in different types of solvents.

Fig. 2(a) shows a comparison of the IV-characteristics of four spray-coated organic photodetectors (OPDs) D1, D2, D3 and D4 where a dichlorobenzene based P3HT:PCBM blend was sprayed for 10, 15, 20 and 25 s, respectively. Each device was measured under dark and illuminated (halogen light source with 100 mW/cm^2) conditions. A clear decrease of the dark current density can be observed for longer spray durations, i.e. higher layer thickness, leading to an increase in the on/off-ratio of the respective OPD. Sample D4 exhibits a dark current density as low as 3.8×10^{-5} mA/cm^2 and an on/off-ratio of 8.2×10^4 at -1 V bias. This low dark current density is remarkable considering the relatively large active area of our devices compared to the ones reported by Tedde et al. [6]. Due to the increased layer thickness however, the series resistance rises from 81 Ω/cm^2 for D1 to 155 Ω/cm^2 for D4, leading to a decrease in the forward current density. Nevertheless, we are still able to achieve around one order of magnitude higher forward current densities at +2 V, with respect to devices presented by Tedde et al. [6]. This indicates an enhanced charge transport in layers prepared using our deposition approach. Due to the extremely high surface roughness, which depending on spray parameters can be above 100 nm [8], precise layer thickness measurement using profilometry or atomic force microscopy become rather meaningless. To be able to quantify the layer thickness and gain an idea about its dependence on the spray duration, optical transmission measurements on spray deposited layers were performed and the absorption spectrum of the blend material was calculated from reference measurements carried out on spin-coated layers of known thickness. An absorption coefficient of approx. 1×10^5 cm^{-1} at a wavelength of 510 nm (P3HT absorption peak), which corresponds to values found in literature [11], was then used to estimate the thickness of spray deposited layers. Note that the value obtained from this calculation represents an averaged absorption thickness over the illuminated area of about 25 mm^2, which is on a significantly larger scale than that of the individual droplets. The estimated layer thickness was then plotted versus

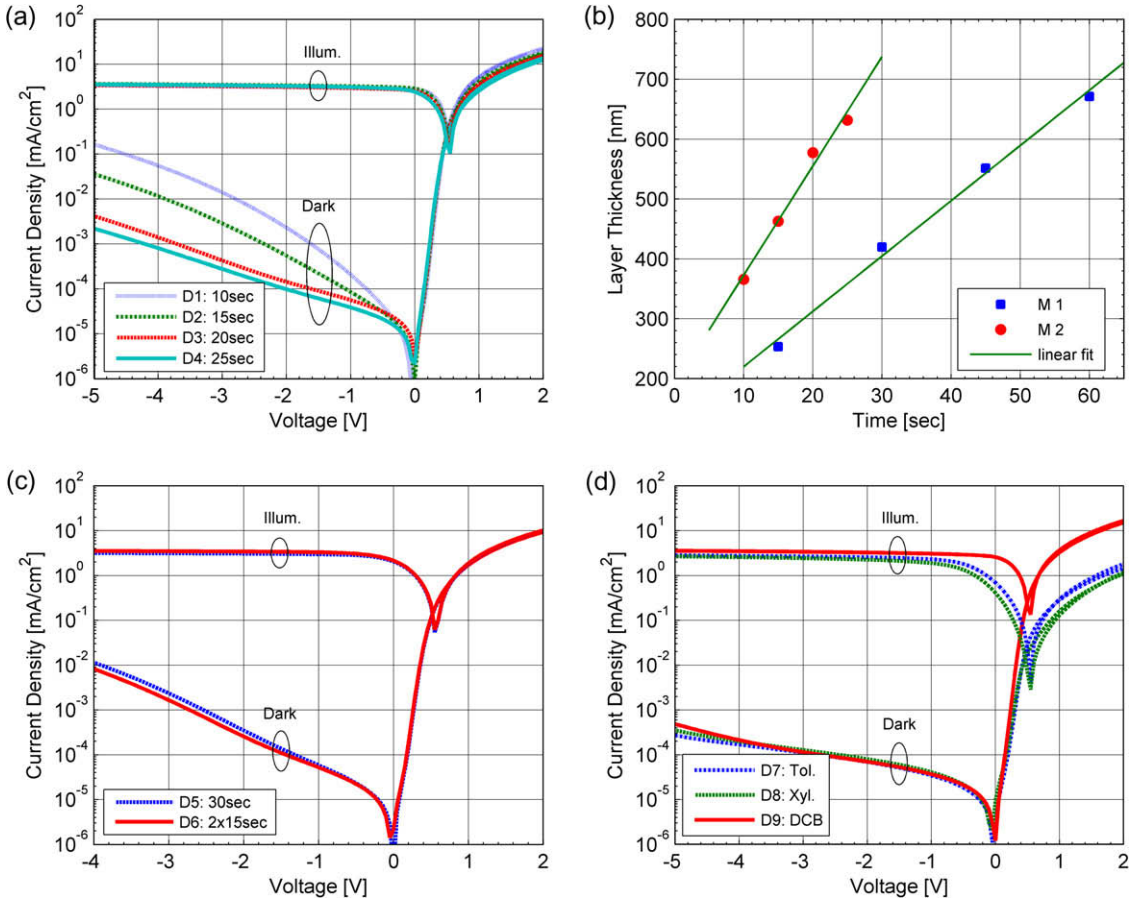

Fig. 2. (a) Comparison of the IV-characteristics of four spray-coated OPDs D1, D2, D3 and D4 with a P3HT:PCBM blend sprayed for 10, 15, 20 and 25 s, respectively. (b) An estimated layer thickness calculated from transmission measurements of spray-coated layers plotted versus spray duration. M1 and M2 indicate two different material flow rates, where M2 > M1. (c) IV-characteristics of devices fabricated by depositing the blend as a single coat of 30 s spray duration for the first device D5 and as a double coat of 15 s spray duration each for the second device D6. (d) IV-characteristics of three devices (D7, D8 and D9) representing the best device obtained from each of the three solvents, toluene, xylene and dichlorobenzene.

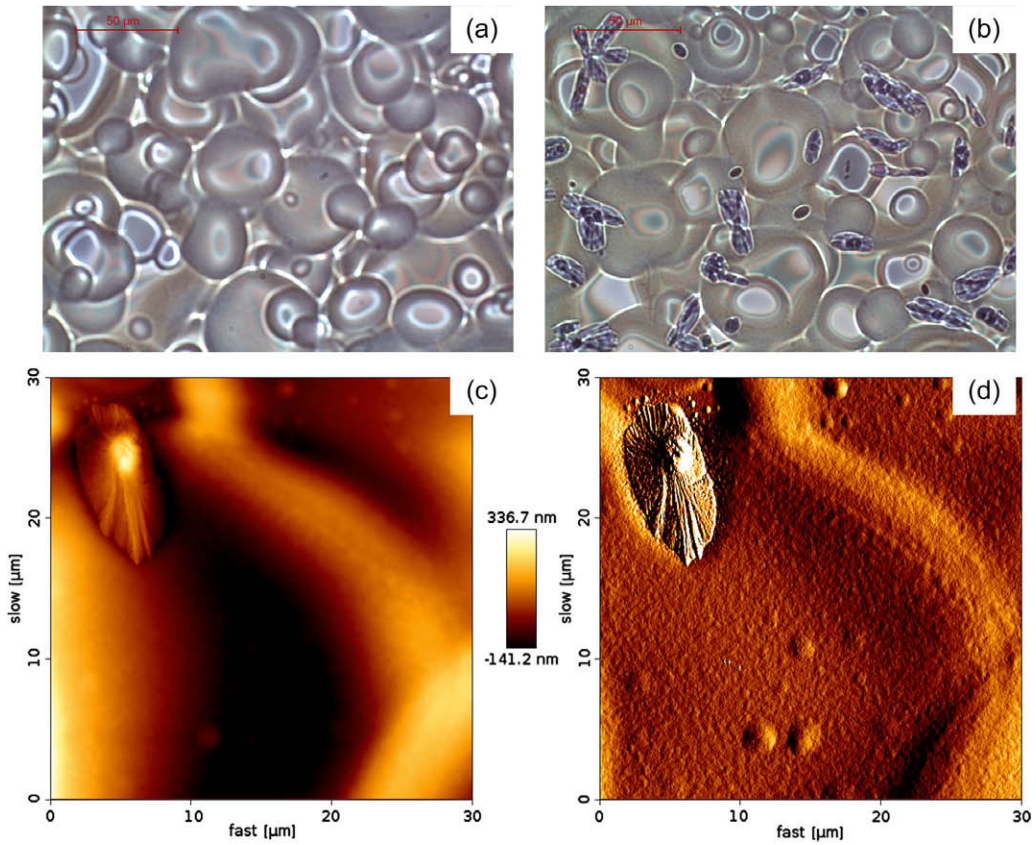

Fig. 3. (a) Microscopic image of a spray deposited blend layer. Individual droplets can be distinguished and a pinhole-free layer is built up by the successive stacking of such droplets. (b) Microscopic image of the same layer after a thermal annealing step, which reveals the formation of the typical and well-known PCBM crystalline structures. (c) AFM height image of the spray-coated P3HT:PCBM layer after annealing, visualizing the huge height differences existing. (d) An error image of the same area, clarifying the contours of the individual droplets and indicating the formation of a PCBM crystalline structure across their boundaries.

spray duration and is shown in Fig. 2(b). M1 and M2 indicate two different material flow rates, where M2 is higher than M1. The four measurement points shown for M2 in the figure correspond to the four devices shown in Fig. 2(a). By fitting a line through the measurement points it becomes clear that for the correct choice of spray parameters, the layer thickness exhibits a linear dependence on the spray duration over a wide range. In order to further verify the suggested description of the layer formation process, we examined single-coat and multiple-coat deposition. For this purpose two OPDs were fabricated, in which the P3HT:PCBM layer was deposited as a single coat of 30 s spray duration for the first device D5 and as a double coat of 15 s spray duration each for the second device D6. The IV-characteristics of both devices are plotted in Fig. 2(c), showing almost identical behavior with only small discrepancy, which lies within the usual fabrication uncertainty and can therefore be neglected, confirming results already obtained by Tedde et al. [6] and further supporting the suggested description of the layer formation process.

Single layers as well as complete OPDs presented so far were deposited from a dichlorobenzene based P3HT:PCBM solution. The reasons for preferring a high boiling point solvent were already discussed at the beginning of this section. Nevertheless, it is possible to fabricate devices with reasonable performance from other solvents, such as toluene and xylene. Due to the different behavior of each solvent when sprayed, most process parameters have to be entirely readjusted for each solvent. This makes a direct comparison between devices fabricated from different solvents rather misleading. Instead, we present the best device obtained out of each solvent, while applying only necessary changes to spray settings. For the same reason, we preferred to fix the substrate temperature used for spray deposition of the P3HT:PCBM blends to 150 °C for all three solvents discussed in this article. Fig. 2(d) shows the IV-characteristics of three devices (D7, D8 and D9) fabricated from three different solvents. All three devices exhibit low dark current densities of around 4×10^{-5} mA/cm^2 and an on/off-ratio between 4.6×10^4 and 8.4×10^4 at -1 V bias, while maintaining a dark current density as low as 4.6×10^{-4} mA/cm^2 and an on/off-ratio of 7.8×10^3 even at -5 V bias in case of D9. At low reverse bias (below -1 V) and under forward bias however, the dichlorobenzene based device shows significantly higher current density, which is up to one order of magnitude higher than for the other two devices at a bias voltage

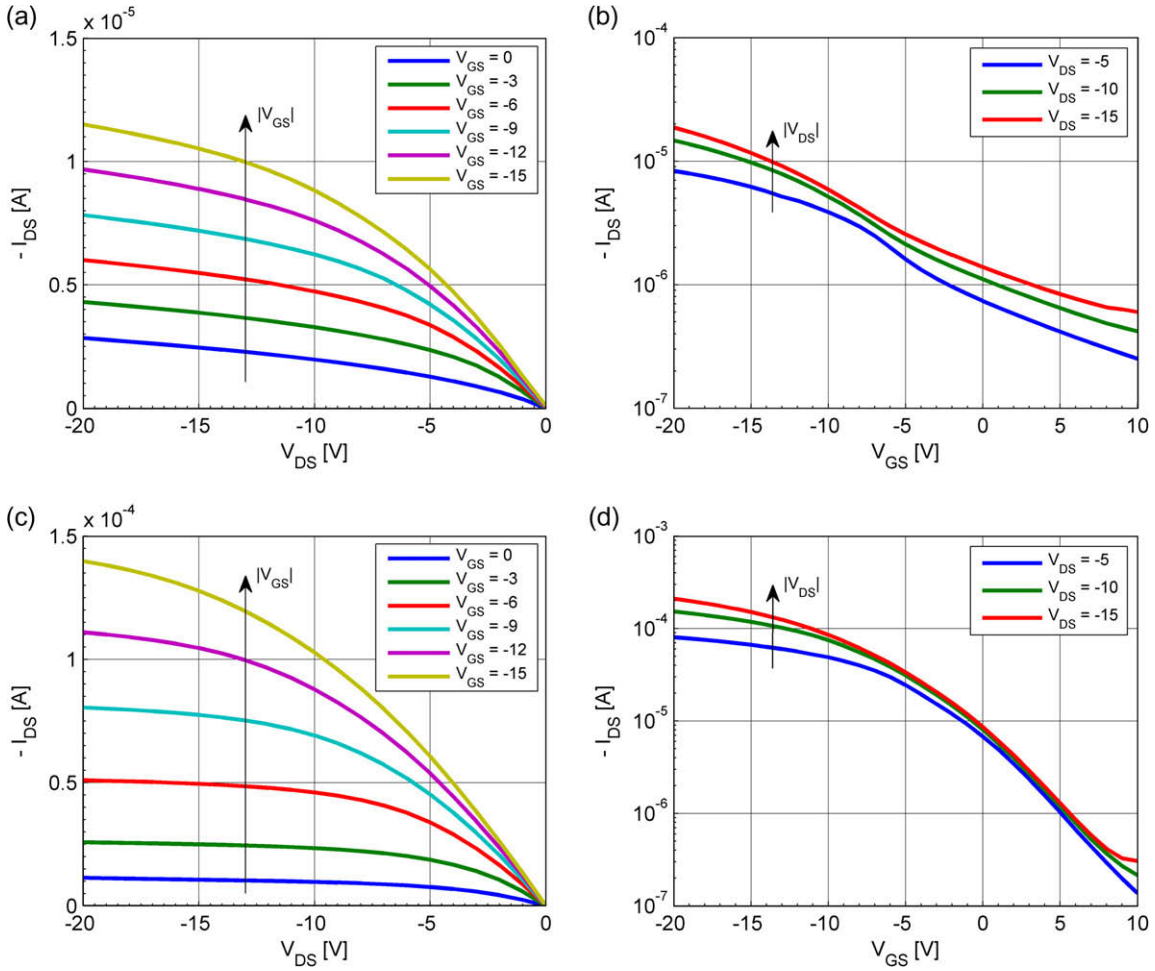

Fig. 4. (a) Output characteristics ($I_D V_{DS}$) of a device where the active polymer was deposited in the wet regime on a heated substrate forming a dry layer and (b) the corresponding transfer characteristics ($I_D V_{GS}$). (c) Output characteristics ($I_D V_{DS}$) of a device fabricated using a wet deposition approach and (d) the corresponding transfer characteristics ($I_D V_{GS}$). A field effective mobility of approx. 1.1×10^{-3} cm^2/V s can be calculated for the wet deposited device, which is about one order of magnitude higher than for the other.

above +1 V. In addition to that, the best results of devices prepared from a dichlorobenzene based solution were easier to obtain, less sensitive to variations in the process parameters and hence showed a much higher reproducibility.

Based on the linear relation of layer thickness and spray duration as well as the similarity between single-coat and multiple-coat deposition, we can confirm our view of the layer formation process proposed at the beginning of the article. This is further supported by examining microscopic images of spray deposited blend layers, as shown in Fig. 3(a). In this image individual droplets can be distinguished and a pinhole-free layer is built up by the successive stacking of such droplets. Spreading and deformation of droplets upon impact on the substrate could also be observed in other optical and atomic force microscopy images, which are not shown here. Droplets, which are originally assumed to be spherical, are deformed into more disk-like structures of increased diameter and heightened boundaries. This deformation is typical for spray deposited layers and is expected to depend on the droplet velocity at impact and solvent properties such as surface tension. Topography investigations carried out on spray deposited layers by atomic force microscopy reveal an extremely high surface roughness on a scale larger than the average droplet dimensions. Despite this high surface roughness, the results presented above demonstrate state of the art OPDs fabricated by spray deposition. On a sub-micrometer scale, a surface topography similar to spin-coated layers can be observed, which was suggested to indicate a similar nano-morphology and hence be one of the reasons for the good device performance [8]. Hoth et al. observed no significant difference in the ideality factor measured for spray-coated and doctor-bladed devices. This was explained by a rather comparable distribution of the donor and acceptor interfaces throughout the bulk of the heterojunction, again indicating a similar nano-morphology [7]. Taking a closer look on optical microscopy images of the same spray deposited layer shown in Fig. 3(a), this time however after the thermal annealing step usually performed for all devices, reveals the formation of the typical PCBM crystalline structures well known from the anneal-

ing of spin-coated P3HT:PCBM layers [12–14]. Such an image is shown in Fig. 3(b). It is interesting to notice that the crystallization of PCBM does not seem to be confined only within individual droplets, but is rather randomly distributed and can occur across the droplet boundaries as well. The existence of such crystalline structures reaching even over several droplets indicates that individual droplets in a spray-coated layer can behave to a certain extent as a continuous layer depending on the degree of merging between droplets during deposition and do not necessarily act as isolated domains. This picture is consistent with our proposed view of the layer formation process and gives another possible explanation for the competitive device performance of spray-coated OPDs. Fig. 3(c) shows an AFM height image of the spray-coated P3HT:PCBM layer after annealing measured in contact mode. There a crystalline PCBM structure can be seen while visualizing the huge height differences existing in a spray-coated layer. An error image of the same area is shown in Fig. 3(d), clarifying the contours of the individual droplets and the formation of the PCBM crystal across their boundaries.

Spray technology was also used to fabricate other classes of organic thin-film devices, such as organic light emitting diodes (OLED) based on MEH-PPV as the light emitting polymer and organic thin-film transistors (OTFT) based on P3HT as the p-type semiconducting polymer. Here we will present some of the results obtained for the OTFTs fabricated using spray deposition. First devices were prepared using exactly the same approach as for the OPDs, meaning that the polymer was deposited in the wet regime on a heated substrate forming a dry layer. The measured output characteristics ($I_D V_{DS}$) of this kind of device are shown in Fig. 4(a) along with the corresponding transfer characteristics ($I_D V_{GS}$) shown in Fig. 4b. Upon examination of these plots, one can clearly observe a transistor-like behavior with saturating drain current. The drain current of such spray-coated OTFT is about one order of magnitude lower than what is usually expected from devices of the same structure fabricated using other deposition techniques. This is also reflected in an extracted field effective mobility of approx. 1.02×10^{-4} cm^2/V s. Further, an on/off-ratio of only 5.8×10^{1} can be achieved. The lower mobility may not be surprising if the process of layer formation is taken into account, where the droplets arriving at the substrate are immediately dried. Such a fast growth of the active layer is known to have a negative effect on the mobility of OTFTs [15,16]. By operating the spray gun in the wet regime without heating the substrate, a wet layer of P3HT is formed on top of the substrate. This wet layer is then left to dry for some time, thereby introducing more time for reorganization. The inhomogeneous P3HT layer resulting from this deposition approach does not cause any additional problems. This is due to the fact that the P3HT layer thickness does not play an important role in device performance as long as it is sufficiently thick to allow the formation of a channel between source and drain contacts. By applying this deposition approach, the layer formation process becomes comparable to processes such as drop casting and dip coating, where a slow growth of the layer is achieved. Fig. 4(c) shows the output characteristics of an OTFT fabricated using the wet deposition approach. There significantly higher currents of up to 140 μA at −20 V drain bias and −15 V gate bias can be observed. The field effective mobility calculated from the transfer characteristics of such devices, plotted in Fig. 4(d), is approx. 1.1×10^{-3} cm^2/V s and an on/off-ratio of 5.8×10^{2} can be measured at −5 V drain bias.

4. Conclusion

In conclusion, we implemented a simple and low-cost spray-coating test setup using a commercially available automatic air atomizing spray gun. Using this setup we could successfully fabricate different classes of organic thin-film devices exhibiting performances comparable to ones fabricated using other deposition technologies. The technological framework developed based on the deposition approach presented here proved to enhance controllability of the process and reproducibility of the fabricated devices. For the correct choice of process parameters, the layer formation process can be thought of as a process of successively stacking individual droplets onto the substrate at a certain rate. Further, microscopy investigations indicated that individual droplets in a spray-coated layer can behave to a certain extent as a continuous layer depending on the degree of merging between droplets during deposition and do not necessarily act as isolated domains. Gaining insight into the layer formation process and correlating it to device performance represents an important step towards the realization of arbitrary shaped organic electronic devices fabricated by spray deposition.

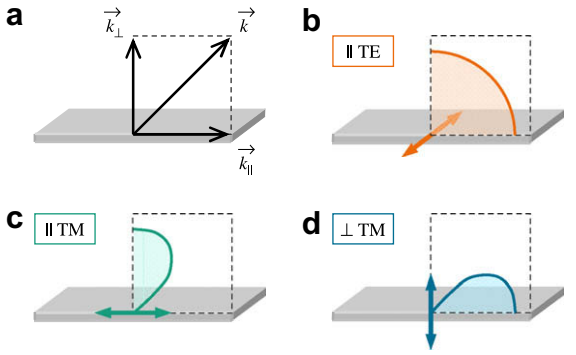

Fig. 1. (a) The wave-vector k (representing the direction of observation or measurement) and its two components in the directions parallel ($k_{||}$) and perpendicular ($k_{\perp}$) to the interfaces of the layered system are shown. The orientations of the dipole transition moments (arrows) of the three orthogonal dipoles ||TE (b), ||TM (c), and ⊥TM (d), with respect to the layered system are also illustrated. The indicated schematics of the internal radiation patterns of the dipoles correspond to those in the homogenous, infinite emissive material and are distorted in the presence of the interfaces of the layered system.

the corresponding polarization of the emitted radiation (transverse-electric "TE", transverse-magnetic "TM"); the direction of measurement or observation is represented by the wave-vector k [see Fig. 1 (a)].

Two major effects need to be pointed out when discussing the relevance of the emitter orientation in OLEDs: First, perpendicularly oriented active sites emit most power in the direction parallel to the interfaces [see Fig. 1(d)], and not in the desired perpendicular direction. Second, different interference conditions with the surrounding multilayer system apply to the fields of the three basic orthogonal dipoles. Consequently, the orientation of the emissive sites in the light-emitting material has a major impact on the device performance and overall efficiency [6,7]. Most common and optimized OLEDs stacks are designed in order to enhance the emission of parallel dipoles as this allows extracting most power to the outside medium air. This optimized stack architecture tends to trap almost all light generated by perpendicularly oriented dipoles inside the layered system or the substrate glass. As s result, the optical outcoupling efficiency for emitters with isotropic orientation is ~1/3 lower than for exclusively parallel oriented emitters. In the past, the external quantum efficiency (EQE) of devices was frequently used as a starting point to estimate internal properties of OLEDs such as the singlet-triplet generation ratio in the emissive material or the internal luminescence quantum efficiency q [6,8,9]. Because the orientation of the emissive sites strongly affects the optical outcoupling efficiency, it has to be known precisely for such estimates to be meaningful.

The orientation of the emissive sites in spontaneously emitting materials utilized in OLEDs is determined by the molecular morphology of the particular material. Considering *polymeric* materials deposited from solution by spin-coating, the polymer chains usually align in the plane of the film and the emissive sites tend to adopt this preferential orientation, as indicated by various photoluminescence (PL) and Raman studies [4,9–11]. Still, the chromophore could be attached to a polymer side-chain rather than to the backbone, which would cancel any orientation-correlation suggested from the spin-coating process. For a long time, vacuum deposited *small-molecule* materials were believed to have no preferred emitter orientation due to their rather isotropic, small molecular structure. Only recently, strong birefringence accompanied by a preferred parallel orientation of the transition dipole moments in vacuum deposited small molecular films was observed in PL investigations and attributed to the increased molecular length of the molecules [12].

In general, PL experiments suffer from the fact that the initially photo-generated excited states are not necessarily equal to those in EL operation [9]. Furthermore, the molecular orientation might depend on the exact deposition conditions and post-processing techniques [13]. Consequently, an *in situ* investigation of the orientation of the dipole transition moment in electrical operation is desirable.

In this study we propose and demonstrate a general method to determine the orientation of the emissive dipole moments in OLEDs *in situ* via optical characterization. The method is based on two main ideas. First, a special OLED stack is utilized, where the distance between the emissive sites and the metallic cathode is well adapted. Due to constructive interference, the contribution of perpendicularly oriented dipoles to the radiation pattern in air is optically enhanced. Second, these perpendicular dipoles contribute to TM polarized light emission only. Consequently, the TE polarized emission can be utilized to investigate the profile of the emission zone and the internal electroluminescence spectrum independent of the emitter orientation. Subsequently analyzing the radiation pattern with TM polarization allows quantifying the contributions form parallel and perpendicular emitters. In general, the method can be applied to all classes of emissive materials for OLEDs, including *small-molecule* and *dendrimer* materials. However, in the present study we apply it to a *polymeric* emitter material and show that the actual orientation of the emissive sites must be described by a superposition of both, parallel and perpendicular components.

2. Method

2.1. Optical modeling

The angular (θ, angle to the layered system normal) and spectral (λ, wavelength) radiation pattern of an emitter inside the OLED stack is simulated assuming a continuously oscillating dipole source [5]. The dipoles electromagnetic fields in the system are evaluated using a transfer-matrix formulation of the well known Green's function model by Chance et al. [14]. For further details on the generation of the dipole fields see Ref. [15] and references therein. In order to ensure normalization of the power emitted from the dipole in the layered system, we utilize the equivalence between the probability for spontaneous emission of a photon via a dipole transition and the radiated power of a classical dipole source in the corresponding layered system [5]. By this means, the so-called microcavity effect or rather the influence of OLED stack on the rate of emission can be regarded [3].

At this point it is worth noting that all calculations are performed with a self-developed software tool. Each layer within the OLED stack is assumed to have smooth, parallel interfaces and a certain thickness. The interaction between materials and radiation is regarded by the wavelength-dependent complex refractive index ($n + i\kappa$, with refractive index n and extinction coefficient κ). The emissive material is treated as loss-free when simulating the light generation process [5], whereas the complex refractive index is used to describe light propagation through the emissive layer and all other layers of the multilayer system utilizing a transfer-matrix method [16]. *Polymeric* as well as *small-molecule* materials are likely to exhibit birefringent optical properties [10,12], having different optical properties in the plane of the film ($n_{||}$, $\kappa_{||}$) and normal to the plane ($n_{\perp}$, $\kappa_{\perp}$). This optical birefringence and its dispersion can be fully accounted for in our simulations, based on previous approaches [4,17].

In real OLED devices the emissive material can be treated as an ensemble of incoherent radiators [18], where distributions in (a) emitter location, (b) dipole orientation, and (c) wavelength-dependent spectral intensity account for (a) the profile of the emission zone, (b) the distribution of emitter orientation, and (c) the internal EL spectrum. Finally, the emission pattern from the OLED $P(\theta,\lambda)$ can be obtained by an incoherent superposition of all single emitter contributions. By this means, $P(\theta,\lambda)$ corresponds to the experimentally accessible radiant intensity of a device.

2.2. Basic measurement approach

As illustrated in Fig. 1, any particular orientation of the emissive dipole moment can be decomposed into the three orthogonal dipoles (||TE, ||TM, ⊥TM). Parallel dipole moments contribute to both TE and TM polarized radiation, whereas perpendicular moments emit TM polarized radiation only [5,15]. Consequently, polarization dependent measurements allow the separation of the contributions from parallel and perpendicular dipoles. One basic idea for our measurement is to analyze the TE polarized radiation at first and determine the internal EL spectrum as well as the profile of the emission zone. This step is independent of the dipole orientation, since perpendicular dipole moments do not contribute to TE polarized radiation [19]. Keeping the internal EL spectrum and emission zone fixed while analyzing TM polarized radiation, the emitter orientation remains the only unknown parameter, which can be adjusted to match TM experiment and simulation.

In order to sense perpendicular dipoles in the TM polarized optical far-field of an OLED, their contributions to the radiation pattern must be sufficiently large compared to the TM polarized contributions arising from parallel dipoles. Here, we take advantage of the fact that the three orthogonal electrical dipoles interfere in different ways with the surrounding layered system. Additionally, they exhibit intrinsically distinct radiation patterns [5], which are schematically indicated in Fig. 1. Furthermore, the propagation through the surrounding layered system is polarization-dependent. As a result, the contribution of the three orthogonal dipoles to the far-field radiation pattern and to the device efficiency is significantly different.

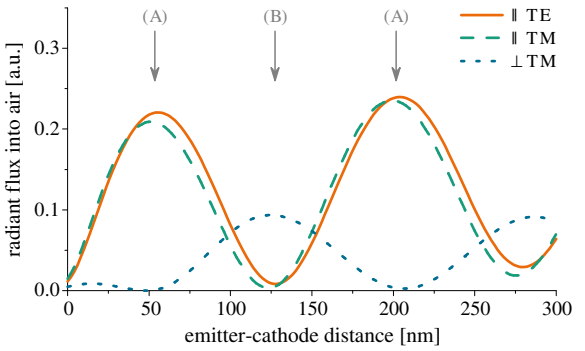

Fig. 2. As a measure for the contribution to the OLEDs far-field radiation pattern, the calculated radiant flux at λ = 500 nm is shown as a function of the emitter–cathode distance for the three single dipoles ||TE (line), ||TM (dashed), and ⊥TM (dotted) embedded in the OLED stack depicted in Fig. 3 but with 300 nm EML thickness. Evidently, parallel and perpendicular dipoles experience opposite interference conditions. In common, optimized OLEDs the emissive sites are placed around positions (A) to ensure a large optical outcoupling efficiency for parallel dipoles. However, position (B) is favorable for the detection of contributions from perpendicular transition moments in the optical far-field.

This is particularly evident in bottom emitting OLED structures where the emitter interacts with its reflected field from the metallic cathode and the interference conditions depend on the emitter-cathode distance.

As a measure of the far-field contribution, the radiant flux (i.e. emitted intensity into air integrated over all emission angles) at λ = 500 nm of the three orthogonal dipoles embedded in an OLED stack (300 nm emissive layer thickness, see Fig. 3 for details of the stack) was calculated as a function of the emitter–cathode distance (see Fig. 2). Evidently, the emission from parallel and perpendicular emitters experiences opposite interference conditions. This might be surprising at first, because one might expect that the difference in phase shift of approximately π (at moderate emission angles) upon reflection of TE and TM polarized light at the cathode results in a different interference behavior for TE and TM radiation. However, the typical character of dipole emission has to be taken into account as well, i.e. the interference behavior additionally depends on the initial phase relation of the relevant electromagnetic fields emitted by the dipoles in the *backward* direction towards the cathode and the *forward* direction towards the OLED substrate. The *forward* and *backward* emitted electric TE fields of a parallel oriented dipole (||TE) oscillate in phase initially. In case of the magnetic TM fields, there is a π phase difference for a parallel emitter (||TM), but an in-phase-behavior for perpendicularly oriented dipoles (⊥TM) [20]. Combining both effects (the phase difference due to cathode reflection and the initial phase relation of the emitted fields) results in a similar interference behavior for the TE and the TM waves of parallel dipoles (||TE, ||TM) while the interference effects of the radiation from perpendicularly oriented emitters are shifted by π (⊥TM). This π phase shift corresponds to a discrepancy in the emitter–cathode distance of a quarter wavelength $\lambda/(4n_{EM})$, where n_{EM} is the refractive index of the emissive material. Thus, at emitter–cathode distances where parallel emitters experience constructive interfer-

ence, destructive interference emerges for perpendicularly oriented emitters and vice versa. Constructive interference of parallel dipoles is expected at emitter–cathode distances of $1\cdot\lambda/(4\,n_{EM})$, $3\cdot\lambda/(4\,n_{EM})$, ..., and constructive interference of perpendicular dipoles occurs at emitter–cathode distances of $2\cdot\lambda/(4n_{EM})$, $4\cdot\lambda/(4\,n_{EM})$, ... The rigorous numerical simulation predicts slightly displaced positions of interference maxima and minima as the imperfect cathode mirror induces a non-ideal phase shift. Although the considerations above are strictly valid only for single, small emission angles θ, minor deviations occur when the radiant flux is analyzed (see Fig. 2).

In our case the optimum emitter position for an efficient OLED stack emitting preferentially into air would be around 50 nm or around 200 nm (positions (A) in Fig. 2) where parallel dipole contributions experience constructive interference. At these positions the perpendicular contributions undergo destructive interference. Consequently, the distribution of the dipole moment orientation is almost impossible to be obtained using standard, efficient OLED geometries, because virtually all light generated by perpendicularly oriented emitters is trapped inside the OLED stack. In contrast, changing the emitter–cathode distance by $\approx\lambda/(4n_{EM})$ to about 125 nm (position (B) in Fig. 2) yields a large far-field contribution from perpendicular dipole moments accompanied by weaker outcoupling of the radiation from parallel dipoles. This is the desired case for the present measurement.

It is worth noting that Fig. 2 illustrates the typical misery for light-emitting materials with isotropic emitter orientation: at the position for optimal outcoupling almost all light from perpendicular dipoles is trapped inside the OLED stack. Thus, nearly one third of the intrinsically emitted light is lost to the multilayer system.

2.3. Experimental

The calculations summarized in Fig. 2 are based on a monochromatic emitter localized at a single position within the emissive layer. However, most real OLEDs exhibit an expanded emission zone and a broad emission spectrum. Therefore, the interference contrast reduces and the intensity difference between TM radiation from parallel and perpendicular dipoles decreases in comparison to Fig. 2.

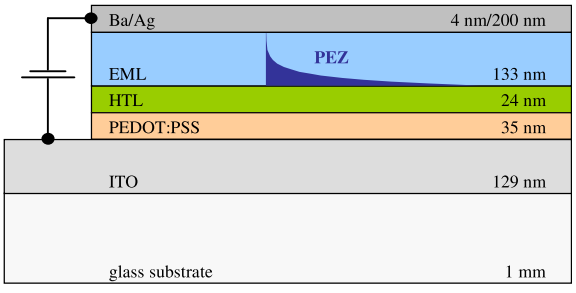

Fig. 3. The structure of the OLED utilized in this study and the exponentially decaying profile of the emission zone (PEZ) are schematically shown.

In order to still observe radiation from perpendicular dipoles in the optical far-field, the emission zone must be relatively well confined and the distance of the emissive sites to the cathode must be well adapted. In *small-molecule* OLEDs the emissive layer (EML) can be made very thin and the emitter–cathode separation can be adjusted via the thickness of an additional electron transport layer. *Polymeric* OLEDs can exhibit a confined emission zone at the anode sided interface of the EML if the emissive material is electron-dominated [2]. Accordingly, changing the EML thickness corresponds to a variation of emitter–cathode distance in this case.

We followed the latter approach in our study utilizing a *polymeric* OLED. A sketch of the OLED stack used is depicted in Fig. 3. The organic layers PEDOT:PSS (35 nm, Clevios P AI4083), hole transport layer [21] (HTL, 24 nm), and blue emitting conjugated polymer [2] (EML, 133 nm) were deposited by spin-coating on commercial glass substrates pre-coated with indium tin oxide (ITO, 129 nm). The HTL was crosslinked to immobilize the material prior to the deposition of the EML [22]. Finally, a thermally evaporated cathode of Barium (Ba, 4 nm) and Silver (Ag, 200 nm) capped the stack. For the approach described here, the EML thickness was adjusted to 133 nm in order to match the desired interference criterion around the mean wavelength of the internal EL spectrum of the emissive material.

The prerequisite for any optical simulation concerning OLEDs is the knowledge of the *passive* optical properties of the layered system, i.e. the materials complex refractive indices and layer thicknesses. The complex refractive indices of the thin film materials were determined by a dispersion-model-free approach utilizing reflection–transmission-spectroscopy of single supported films [1]. This measurement revealed that the emissive material is birefringent and that the magnitude of birefringence is wavelength-dependent. However, the material properties are well described by a uniaxial refractive index model. In the wavelength-range of interest (400 – 650 nm) the measured complex refractive indices are given in the Appendix for completeness. In order to determine the layer thicknesses, several additional reference stacks were fabricated and analyzed by profilometry as well as by reflection–transmission spectroscopy [1]. By this means we were able to measure the thickness of each layer to an accuracy of ±2 nm.

The internal luminescence quantum efficiency q of the emissive material enters the simulation when evaluating the relative emission rates for parallel and perpendicular transition moments [3]. Because the investigated material is a fluorescent polymer, the q-value represents the fluorescence quantum efficiency for a radiative transition from the excited singlet state into the ground state of the material. Note that charge carrier spin statistics, or rather the ratio of generated excited singlet and triplet states, is not included in the q-value. However, q plays a minor role for the present investigation because (a) the relative emission rates for parallel and perpendicular dipoles are not essentially different from unity for the distance of the emissive sites to the cathode of about 133 nm and (b) the materials q-value does not influence the interference

conditions of the emissive sites [19]. Nevertheless, we determined the q-value of the emitter material to be $q = 0.27 \pm 0.05$ in electrical operation [3] and take all associated effects into account in the present analysis.

In order to access the optical far-field, polarized angular radiation patterns are recorded utilizing a rotational stage and a fiber-spectrometer. The resulting experimental data have an accuracy of $\Delta\lambda < 5$ nm and $\Delta\theta < 0.5°$ as well as an intensity uncertainty below 2%.

3. Results and discussion

3.1. TE-polarization: internal EL spectrum and profile of the emission zone

Perpendicularly oriented dipoles do not contribute to TE polarized radiation. Consequently, only parallel dipole moments need to be considered when analyzing the TE emission pattern. By fitting the simulated TE polarized far-field radiation pattern to the experimental data across the whole spectral (λ = 400–650 nm) and angular (θ = 0°–90°) range, the internal EL spectrum of the emissive material and the profile of the emission zone can be deduced. For this analysis, the spectral characteristics of the far-field radiation pattern hold information about the internal EL spectrum [Fig. 4(f)], which was found to be identical to the previously determined PL spectrum [2] within the precision of the measurement. Furthermore, the angular characteristics of the emission pattern are related to the interference conditions at the position of the emissive sites and provide information about the emission zone. In a previous study, we have provided direct evidence for electron-dominated current in the emissive material and the former data indicated that the emission is exclusively generated within a about 10 nm wide sheet at the EML-HTL interface [2]. However, in the present study the emission pattern can be modeled satisfactorily only when assuming an exponentially shaped profile at the anode sided interface of the EML with an 1/e-width of (10 ± 2) nm, in agreement with Ref. [2].

Measured and modeled TE polarized emission patterns are shown in Fig. 4 (a–e) for representative constant emission angles ($\theta = 0°$, $\theta = 72°$) and emission wavelengths (λ = 450 nm, λ = 500 nm, λ = 550 nm). Perfect coincidence between experiment and simulation over the whole angular and spectral range is found, suggesting a high quality of the measurement and the theoretical model. The spectral emission in forward direction (Fig. 4(a), $\theta = 0°$) and into oblique emission angles (Fig. 4(b), $\theta = 72°$) is considerably suppressed for spectral components around 500 nm due to the desired destructive interference of parallel dipole contributions. Furthermore, as a result of the pronounced interference conditions at the position of the emissive sites, the angular radiation characteristics deviate from a Lambertian emission significantly [see Fig. 4(c–e)]. Still, the remarkably modulated behavior can be reproduced well by the simulation in the whole spectral range of emission. In fact, this pronounced angular characteristic allows for an accurate determination of the profile of the emission zone (PEZ). As an example, Fig. 5 shows the expected angular emission pattern at λ = 500 nm for a slightly narrower emission zone (Fig. 5(a), PEZ-width = 8 nm) and for a slightly broader emission zone (Fig. 5(b), PEZ-width = 12 nm). In both cases, there is a significant disagreement between simulated and experimental data, indicating a nanometer accuracy for the measurement of the emission zone. Similarly, the measured angular emission characteristics cannot be modeled accurately assuming any other emission zone which is of a different qualitative shape but still physically meaningful, e.g. a Gaussian profile centered at the HTL-LEP interface. Solely an exponential profile leads to a satisfactorily agreement between simulated and experimental data.

In result, the internal EL spectrum and the profile of the emission zone of the emissive material are disclosed. Both *active* material properties will be kept fixed for any further analysis.

3.2. TM-polarization: emitter-orientation

At this stage the only parameter remaining unknown is the distribution of the emissive sites in the emissive material, or rather the relative amount of perpendicular dipoles contributing to the radiation pattern. As pointed out above, the analysis will be most sensitive to contributions of perpendicular emitters in those spectral ranges where the parallel emitter contributions undergo destructive interference. Here, the OLEDs microcavity was designed to match this criterion at a wavelength of around 500 nm.

Fig. 6 shows the measured TM polarized emission pattern for representative constant emission angles ($\theta = 60°$, $\theta = 72°$) and emission wavelengths (λ = 450 nm, λ = 500 nm, λ = 550 nm), accompanied with the simulated emission pattern assuming contributions from *parallel dipole moments only*. In comparison to the simulations shown in Fig. 4, no assumption and no parameter has been changed; the polarization of the radiation is the only difference between Fig. 4 and Fig. 6. The emission in forward direction ($\theta = 0°$) arises from parallel dipoles only and the two polarization states TE and TM cannot be distinguished at $\theta = 0°$. Accordingly, there is perfect coincidence between measured and modeled emission in forward direction (Fig. 6(c–e) for $\theta = 0°$), similar to the TE polarization (Fig. 4). Regarding oblique emission angles on the contrary, the simulated emission spectra [Fig. 6(a and b)] and angular radiation pattern [Fig. 6 (c–e)] significantly underestimate the measured TM-emission in the wavelength range 450 nm $\leqslant \lambda \leqslant$ 550 nm. This clearly indicates missing contributions from perpendicular dipole moments in the calculation. It is worth noting, that the discrepancies are of a qualitative nature and cannot be compensated by simply scaling the datasets. Still, there are spectral regions (λ < 450 nm and λ > 550 nm) where the TM radiation characteristics can be modeled quite accurately assuming parallel dipoles only. These correspond to spectral ranges outside of the desired interference criterion, i.e. with too few perpendicular emitter contributions with respect to the emission caused by parallel active sites. This reflects the situation found in common, optimized OLEDs where the perpendicular dipole contributions are "invisible" in

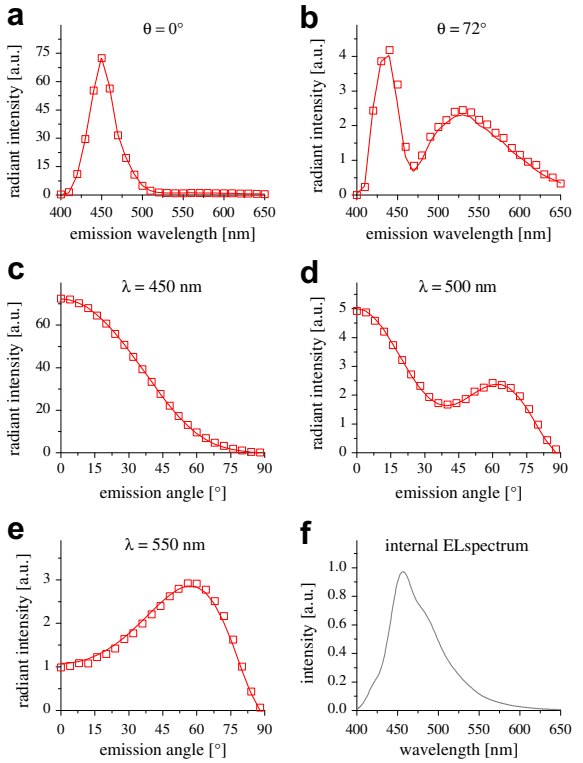

Fig. 4. The measured TE radiation pattern (squares) is shown for representative constant emission angles (a), (b) and emission wavelengths (c–e). By corresponding reverse simulations (lines), the internal EL spectrum of the emissive material (f) and the profile of the emission zone (not shown) were deduced.

the optical far-field relative to the rather intense emission from parallel dipoles.

In contrast, *including perpendicular dipole moments* into the simulation, the measured TM polarized emission pattern can be modeled accurately across the whole spectral and angular range (see Fig. 7). The simulated data in Fig. 7 correspond to a fraction of $p_{\perp} = (0.07 \pm 0.02)$ perpendicular dipoles, provided that $p_{||} = 1.00$ parallel dipoles contribute to the radiation pattern. The uncertainty of ±0.02 arises equally from the error in the width of the profile of the emission zone and the uncertainty of the refractive index measurement for the perpendicular refractive index. In other words, 93.5% parallel and 6.5% perpendicular dipole moments generate the radiation pattern of the *polymeric* emissive material. Assuming that the orientation of the emissive dipole moments follows a Gaussian distribution, this result means that the dipoles stagger around the preferred parallel direction with an 1/e-angle of about ±22°. Note that the isotropic emitter orientation commonly associated with *small-molecule* emissive materials corresponds to a fraction of 66.7% parallel and 33.3% perpendicular dipole moments.

Finally, it is worth recapitulating the parameters entering the calculation and how they were acquired: (a) the *passive* optical properties of the layered system (material refractive indices and layer thicknesses) were determined by separate spectroscopic methods [1], (b) the q-value of

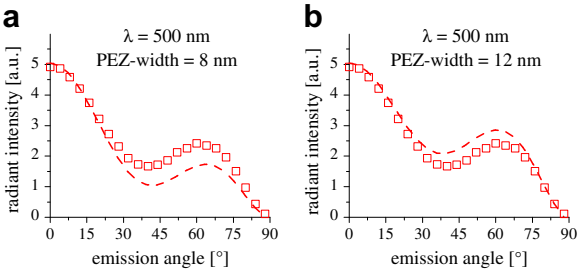

Fig. 5. Measured TE polarized angular emission characteristics at $\lambda = 500$ nm (squares) and corresponding simulations (dashed) assuming a slightly narrower (a) and slightly broader (b) emission zone. The discrepancies illustrate the high accuracy of the profile of the emission zone (PEZ) determination (see Fig. 4(d), corresponding to a PEZ-width of 10 nm).

the emissive material has been measured in a previous study [3], and (c) the *active* parameters internal EL spectrum and profile of the emission zone were known from the analysis of the TE radiation pattern and were kept fixed. The amount of perpendicular dipole moments contributing to the radiation pattern then remained the only free parameter for the reverse simulation of the TM polarized emission. We note that the resulting perfect coincidence between experimental and modeled TE and TM radiation patterns across the whole spectral and angular range can only be achieved with this dataset of *passive* and *active* properties of the layered system and the emissive material, respectively. Changing the input-parameters beyond their confidence intervals would result in significant qualitative discrepancies between measurement and simulation.

4. Conclusions

In summary, we have presented a general method for the *in situ* determination of the emitter orientation in OLEDs. We applied the method to a *polymeric* emissive material and deduced the orientation of the emissive dipole moments from measurements of the optical far-field of OLEDs in electrical operation. According to our results, the radiation pattern is generated by a fraction of 93.5 % parallel and 6.5 % perpendicular dipole moments. By this means we were able to proof the existence of perpendicular dipole moments in polymeric OLEDs. This measurement was basically enabled by an adapted OLED stack with an unusual emitter–cathode separation which increased the visibility of perpendicular dipole transition moments in the optical far-field. Commonly used, more efficient OLED device architectures prevent the determination of emitter orientation from the far-field pattern, because only parallel emitters contribute significantly to the emission into air.

In general, the presented method can be applied to all classes of OLED emissive materials. It is noteworthy that for the present study the emissive material is assumed to consist of one emissive species with an intrinsic spectrum independent of the dipole orientation. However, without loss of generality different molecular moieties can be mod-

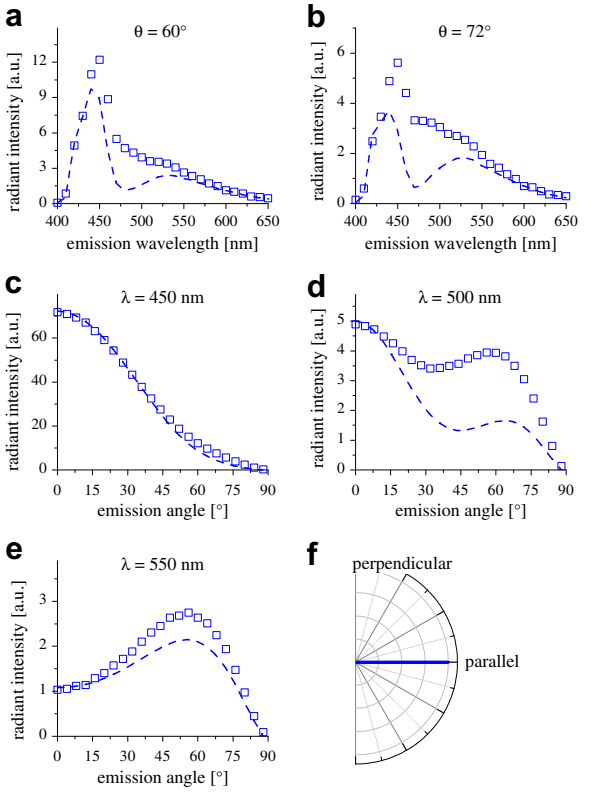

Fig. 6. The measured TM radiation pattern (squares) is shown for representative constant emission angles (a), (b) and emission wavelengths (c–e). The corresponding reverse simulations (dashed lines) are performed assuming parallel emitters only (f). The discrepancies indicate the missing contribution from perpendicular dipoles.

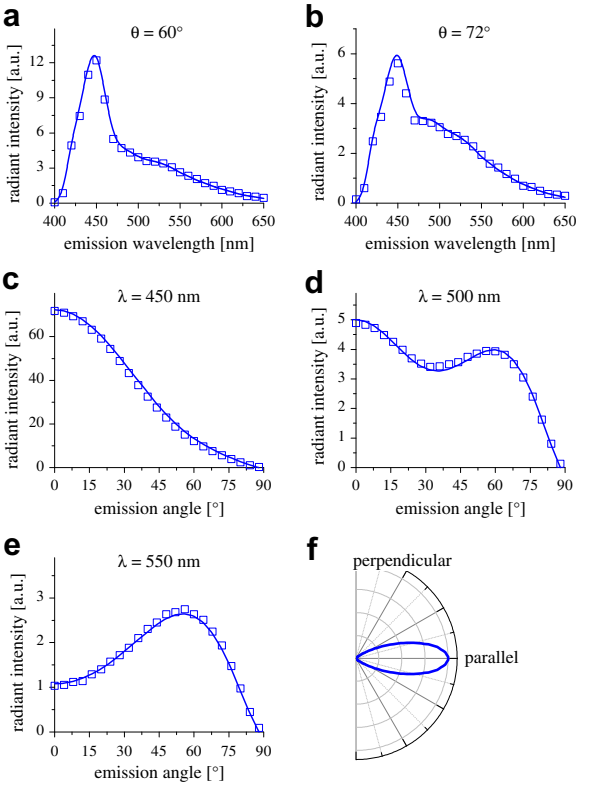

Fig. 7. The measured TM radiation pattern (squares) is shown for representative constant emission angles (a), (b) and emission wavelengths (c–e). The experimental data is identical to that in Fig. 6. The reverse simulations (lines) assume a fraction of 93.5 % parallel and 6.5 % perpendicular dipoles, corresponding to a Gaussian distribution where the dipoles stagger around the preferred parallel direction with an 1/e-angle of ±22° (f). Orientation of emissive dipoles in OLEDs: quantitative *in situ* analysis.

eled as a superposition of an appropriate number of emissive species with different emission spectra and orientation distributions. Provided the emission spectra are sufficiently distinct, the present approach can be extended to analyze all emitters individually. For this purpose additional OLED stacks featuring adapted ETL thicknesses might be required. Relevant examples worth noting here are three color white emitting polymer blends investigated previously [23,24] and polyfluorene, known to exhibit a rich phase behavior with significant impact on the emissive spectral characteristics [25].

The knowledge of the actual dipole orientation is a fundamental prerequisite to any precise quantitative simulation of the optical performance of OLEDs and to an accurate quantification of potential loss channels as well as to approaches to optimize the optical outcoupling efficiency of OLEDs. Moreover, estimates on internal emitter properties (singlet/triplet-ratio or internal luminescence quantum efficiency q) that start form external device measures (like the EQE) should be supported by precise information about the emitter orientation. Furthermore, the presented method could assist the development of new materials that exhibit a preferred parallel orientation of emissive species and thus promise higher optical outcoupling efficiencies.

Appendix A

An approximation of refractive index n and extinction coefficient κ within the wavelength interval $\lambda = 400$–650 nm is (x = wavelength/100 nm): substrate: $n = 1.5 + 0.62/x^2$, $\kappa = 0$; ITO: $n = 1.3 + 2.6/x$, $\kappa = 0.03 - 0.01x + 0.001x^2$; PEDOT:PSS: $n = 1.42 + 0.66/x$, $\kappa = 0.07 - 0.031x + 0.004x^2$; HTL: $n = 1.57 + 0.2/x + 0.04/(x - 3.8)$, $\kappa = 0$; EML: $n_{||} = 1.42 + 1.7/x + 0.015/((x - 4.16)^2 + 0.03)$, $\kappa_{||} = 0.736 \cdot \exp[-((x - 4)/0.17)^2]$, $n_{\perp} = 1.51 + 0.2/x + 0.003/((x - 4.16)^2 + 0.03)$, $\kappa_{\perp} = 0.135 \cdot \exp[-((x - 4)/0.17)^2]$. The accuracy of the method used to determine these values [1] is about $\Delta n_{||} \approx 0.01$, $\Delta k_{||} \approx 0.001$, $\Delta n_{\perp} \approx 0.05$, and $\Delta k_{\perp} \approx 0.02$. The metal cathode was described by the Silver optical properties taken from [26], neglecting the presence of the thin electron injection layer Barium. This approach has proven

to yield consistent results here, but might need to be confirmed for other cathode preparation conditions.

[19] As a result of considering the influence of the layered system on the rate of emission and the internal luminescence quantum efficiency q of the emissive material, there is a constant multiplicative factor to all TE contributions which is depending on the orientation of the emissive sites, i.e. depending on perpendicular dipoles as well. However, because this factor is constant to all TE contributions there is no influence on the TE interference conditions.

fluorene) (PFO) based devices, relying on the evolution of electromodulation spectrum with the applied dc voltage. Screening of the applied electric field was observed in the presence of a low work function (Ba) cathode, which was supposed to be due to strong electron injection and accumulation at the anode interface [3]. In this paper, we investigate poly (9,9-di-(2-ethylhexyl)-9*H*-fluorene-2,7-vinylene)) (PFV) based devices with a relatively high work function (Al) cathode by electroabsorption (EA) spectroscopy to probe the effect of PEDOT:PSS on built-in voltage, and compare the experimental results with those obtained previously on PFO. In a second part, the thermally stimulated current (TSC) technique was used to probe the trapped charge density in poly (9,9-dihexylfluorene-co-*N*,*N*-di(9,9-dihexyl-2-fluorenyl)-*N*-phenylamine) (PF-*N*-Ph) based devices. First results show that this technique is adequate to characterize electron or hole trap levels that could be created deliberately close to the anode, or the cathode, respectively.

2. Experimental overview

Devices with an active area of 10 mm^2 were fabricated by successively spin coating an ITO anode with a 40–50 nm thick layer (2000 rpm, 60 s) of PEDOT:PSS (Baytron P VP AI4083, H.C. Starck), followed by a layer of polyfluorene. ITO coated glass substrates (VisionTek Systems Ltd.) were previously cleaned in successive ultrasonic baths of distilled water, ethanol and acetone. After drying in nitrogen atmosphere, they were treated by UV ozone before use. A 100 nm thick layer of poly (9,9-di-(2-ethylhexyl)-9*H*-fluorene-2,7-vinylene)) (PFV, Sigma–Aldrich) or a 70–80 nm thick layer of poly (9,9-dihexylfluorene-co-*N*,*N*-di(9,9-dihexyl-2-fluorenyl)-*N*-phenylamine) (PF-*N*-Ph) was deposited by spin coating. Their chemical structures are shown in Fig. 1. Finally, a 100 nm aluminium cathode was evaporated under high vacuum conditions ($<10^{-4}$ Pa) and the devices were encapsulated with a glass coverlid using a UV-cured epoxy resin.

Electromodulation spectroscopy was proposed [4] to probe internal electric field in organic components due to the inadequacy of conventional techniques for thicknesses lower than 5 μm [5]. This consists in applying to the device a combined ac modulation and dc operating voltage and measuring changes in the transmission (T) of a probe beam (150 W xenon lamp, Oriel) through the active layer(s) using phase sensitive lock-in detection (SR830, Stanford Research). The light beam entered the sample through the glass substrate with a 45° angle of incidence, and was detected after double transmission and reflection on the back aluminium electrode. Provided that the origin of the electromodulation signal is Stark effect (it is then called electroabsorption), theory predicts that the fractional change in transmission $-\Delta T/T$ is proportional to the third order dc Kerr nonlinear susceptibility and the square of the electric field. One can deduce that the differential transmission is then modulated at both the 1st and 2nd harmonic frequencies in accordance with the following equations:

$$-\frac{\Delta T}{T}(1\omega) \propto \mathrm{Im}\,\chi^3(\lambda) E_{dc} E_{ac} \cos(\omega t) \quad \text{1st harmonic}$$

$$-\frac{\Delta T}{T}(2\omega) \propto \mathrm{Im}\chi^3(\lambda) E_{ac}^2 \cos(2\omega t) \quad \text{2nd harmonic}$$

Under conditions of low carrier injection, the bulk electric field E_{dc} is related to the dc component of the applied voltage V_{dc} by $E_{dc} = (V_{dc} - V_{BI})/d$, where V_{BI} is the built-in voltage and d is the thickness of the layer. V_{BI} is thus the applied voltage at which the first harmonic (1ω) EA spectrum is cancelled.

To examine the change induced by the presence of interface states, which may be the origin of electron trapping at the anode side, TSC experiments were used to determine the traps in devices [6–8]. The measurements were carried out using a cryostat whose temperature was controlled by an Oxford ITC 503 unit. A Keithley 230 programmable voltage source coupled with a Keithley 617 electrometer was used for monitoring the TSC spectra.

Two similar types of structures have been fabricated which differ by the presence of PEDOT:PSS layer. ITO/PEDOT:PSS/PFV/Al and ITO/PFV/Al structures have been investigated by EA spectroscopy. ITO/PEDOT:PSS/PF-*N*-Ph/Al and ITO/PF-*N*-Ph/Al structures have been investigated by TSC technique.

3. Results and discussion

Fig. 2 shows the first harmonic electromodulation spectrum of an ITO/PFV/Al device for different applied dc voltages ranging from −3 to 1 V. The signal is composed of two broad peaks, centred at approximately 385 and 465 nm, respectively, and with opposite signs. The increase of the

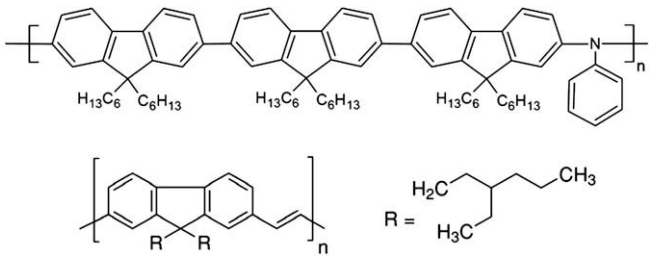

Fig. 1. Chemical structures of polyfluorene derivatives used in this study: poly (9,9-dihexylfluorene-co-*N*,*N*-di (9,9-dihexyl-2-fluorenyl)-*N*-phenylamine) and poly (9,9-di-(2-ethylhexyl)-9*H*-fluorene-2,7-vinylene), respectively.

applied dc bias does not modify the shape of the 465 nm peak, which is not clear for the 385 nm peak. The origin of the 385 nm could be a combination of Stark effect and effects that might arise from photogenerated charges [9]. We, therefore, focused on the low energy (465 nm) peak and verified the linear variation of the 1ω signal and the quadratic variation of the 2ω signal with V_{ac}, in agreement with the electroabsorption theory. As shown in the inset of Fig. 2, the extent of the electroabsorption spectrum [10] can be correlated with the PFV absorption range. Interestingly, one can measure an electroabsorption spectrum for $V_{dc} = 0$ V, which proves the existence of an internal built-in electric field.

Fig. 3 shows the first harmonic electromodulation spectrum of an ITO/PEDOT:PSS/PFV/Al device for different applied dc voltages ranging from −3 to 3 V. The signal is very similar in shape to that of Fig. 2, although a ∼8 nm wavelength shift was noticed that we could not explain.

In Fig. 4, the evolution of the low-energy peak as a function of applied dc bias was reported. A linear variation was obtained in agreement with the theoretical prediction of electroabsorption. The different slopes observed for ITO/PFV/Al and ITO/PEDOT:PSS/PFV/Al devices are due to different values of V_{ac} used for measurements. Built-in voltages deduced from Fig. 4 are 1 and 1.9 V, respectively.

The current–voltage characteristics presented in the inset of Fig. 4 show a strong reduction of the threshold voltage when using PEDOT:PSS. This voltage, above which a large double injection occurs, passes from approximately 10–15 to 3–4 V. Obviously, this result can be attributed to the anode modification. However, the 0.9 V increase of built-in voltage is inconsistent with the work function difference between ITO and PEDOT:PSS. Approximate values of 4.9 eV for ITO and 5.2 eV for PEDOT:PSS have been measured by Kelvin probe and supplied by H.C. Starck, respectively. Interestingly, the values of built-in voltages measured in the presence or not of PEDOT:PSS are very similar to those measured in PFO-based devices [3]. According to Lane et al. [11], the addition of a PEDOT:PSS layer leads to a pinning of the Fermi level of the anode to the HOMO of the active layer. Indeed, the built-in voltage was found to be nearly equal to the difference between the PFO ionization potential (5.8 eV) and the approximate value of aluminium work function (4.1 eV). Our results are in accordance with this theory, considering the ionization potential of PFV (5.73 eV) [12]. The hypothesis of the accumulation of negative charges at the PEDOT:PSS/polyfluorene interface may thus be generalized to various polyfluorene derivatives, which motivated the following investigation of trapped charges in PF-*N*-Ph based devices by an alternative method, namely the TSC technique.

Fig. 5 shows TSC characteristics measured on ITO/PEDOT:PSS/PF-*N*-Ph/Al diode with different charging voltages: $V_C = -6, -4, -2, +2, +3, +4, +5, +6$ V. The TSC spectra intensity increased with the applied voltage as observed in trap measurements of OLEDs, indicating that the trap filling depends on the bias condition [13]. A large width peak, which appears distributed in the temperature range (100–280 K), is clearly observed. Furthermore, the intensity of the peaks is lower for negative applied voltages compared to that obtained in diodes biased with positive applied voltages. All the peaks cannot be clearly distinguished because of their overlapping. However, with a reverse voltage, two peaks are observed with the following relaxation temperatures $Tm \sim 150$ K and $Tm \sim 200$ K. With a forward applied voltage higher than 3 V, two shoulders appear clearly at $Tm \sim 125$ K and $Tm \sim 250$ K in addition to these two peaks, indicating that additional trapped charges are released. The TSC peaks are denoted as A, B, C, and D.

Due to the overlapping of TSC peaks (A, B and C), TSC spectra display broad peaks and hence the position of the individual peaks and theirs trap parameters could not be clearly determined. For resolving TSC spectra, we obtained the activation energy E_T of each peak by the initial rise

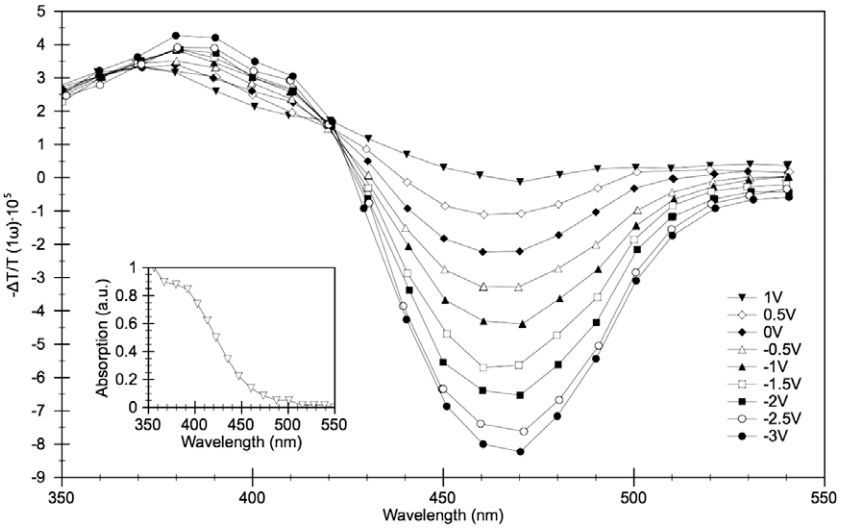

Fig. 2. 1 kHz first harmonic (1ω) electroabsorption spectra of an ITO/PFV (100 nm)/Al structure at various applied dc reverse biases. Inset: absorption spectrum of a PFV film in the visible range.

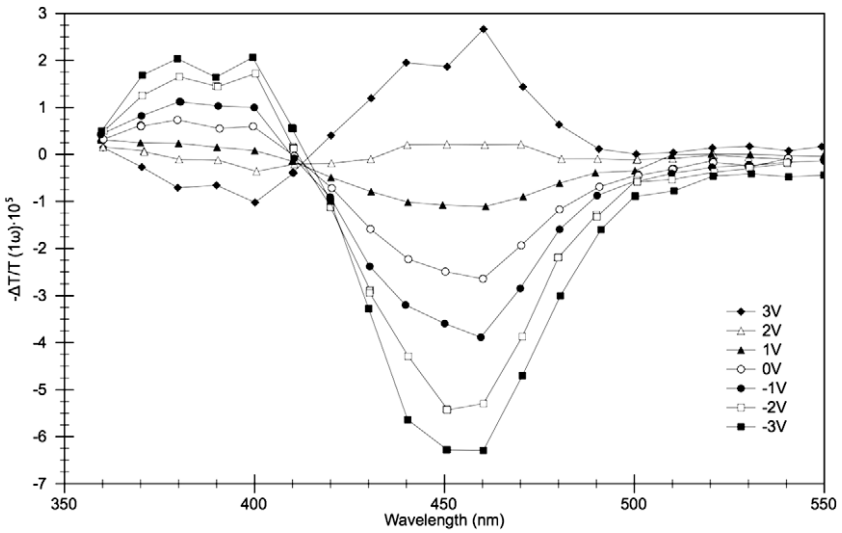

Fig. 3. First harmonic (1ω) electroabsorption spectra of an ITO/PEDOT:PSS (50 nm)/PFV (100 nm)/Al structure at various applied dc biases. 0.3 V rms modulation bias of frequency 1 kHz was used.

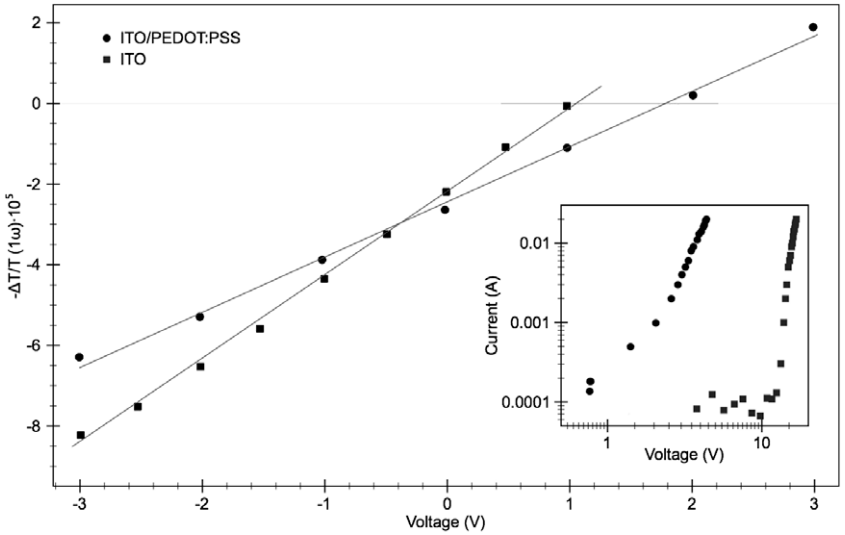

Fig. 4. Variation of the electroabsorption signal at 465 and 457 nm as a function of the applied dc bias for the ITO/PFV (100 nm)/Al and ITO/PEDOT:PSS (50 nm)/PFV (100 nm)/Al structures, respectively. Their current–voltage characteristics are presented in the inset.

method and its density by the measurement of the corresponding TSC intensity. Each individual component has been then computed from Cowell and Woods' relation [14] knowing its determined activation energy E_T and its peak position obtained by measuring the TSC spectra with different charging voltages. Next, by subtracting the computed spectrum from the experimental one, we obtained step by step, the values of activation energy of those peaks whose position could be identified by varying the applied voltage as explained previously.

In the inset of Fig. 5, the current–voltage characteristic of ITO/PEDOT:PSS/PF-*N*-Ph/Al at $T = 300$ K is reported. The diode shows a turn-on voltage of $V_{TO} \sim 4$ V. Peaks A and D depend strongly on the applied voltage, and appear when $V_C > V_{TO}$ suggesting that they are minority-like traps. Furthermore, at high temperatures (>300 K), we note the onset of an additional peak labelled E, which is visible in both directions.

Fig. 6 shows the decomposition of TSC spectra obtained with $V_C = +6$ V using the fitting curve to evaluate the activation energy and the trap density. The decomposition of TSC spectra obtained with $V_C = +6$ V is reported in the inset of Fig. 6. It is noted that the intensities of the peaks are lower in reverse direction than in forward direction. The decomposition of TSC spectrum with $V_C = -6$ V shows that the intensities of peaks A and D are smaller than that of peaks B and C suggesting that the latter is related to the injection of majority carrier, while at $V_C = +6$ V, peaks A

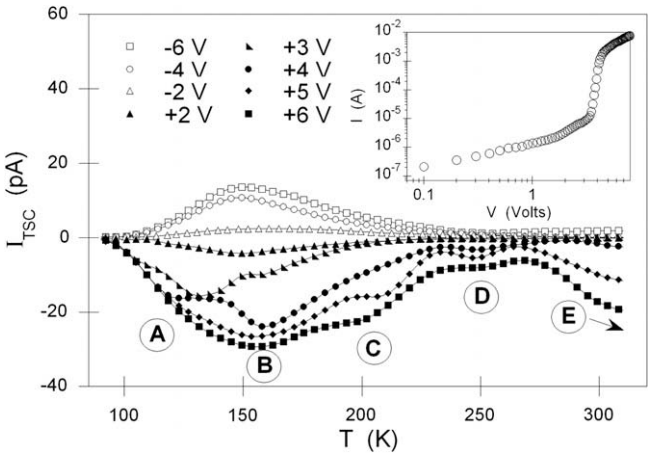

Fig. 5. TSC spectra recorded in an ITO/PEDOT/PF-*N*-Ph/Al diode using the following parameters: T_H = 300 K, β = 0.1 K/s, with different charging voltages: V_C = −6, −4, −2, +2, +3, +4, +5, +6 V. Inset is *I–V* characteristics of ITO/PEDOT/PF-*N*-Ph/Al structure measured at *T* = 300 K.

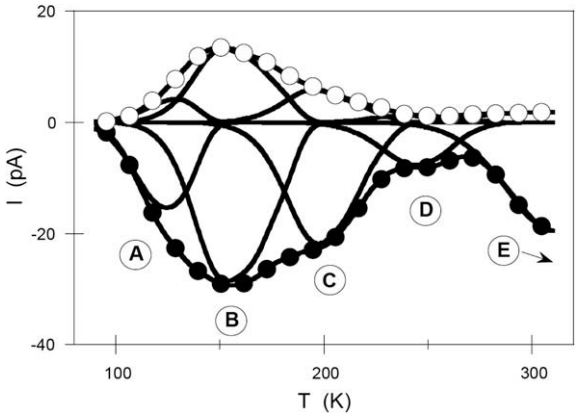

Fig. 6. Resolution of the TSC spectrum obtained with the following parameters: T_H = 300 K, β = 0.1 K/s, V_C = +6 V (●) and V_C = −6 V (○) by using the computed curves from the Cowell and Woods' relation [14] with the activation energies determined from the Arrhenius plots.

and D have stronger intensity indicating that they are related to minority carriers. As peak E is not entirely visible, we could not identify clearly its type (electron or hole traps). The trap parameters determined from the decomposition analysis are summarized in Table 1. Note the trap density of the level E represents the inferior limit because the corresponding TSC peak is not entirely visible. The density of traps has been measured at an applied voltage of +6 V.

In order to observe the influence of the hole injection layer on the defect formation, ITO/PF-*N*-Ph/Al diodes have been investigated by TSC technique. Fig. 7 shows the TSC characteristics measured on ITO/PF-*N*-Ph/Al and ITO/PEDOT:PSS/PF-*N*-Ph/Al diodes with a charging voltage of V_C = 6 V. We note that peaks A, B, E are present in both devices whereas peaks C and D are only observed in ITO/PEDOT:PSS/PF-*N*-Ph/Al diode. The inset of Fig. 7 shows the current–voltage characteristic, measured at *T* = 300 K, indicating a turn-on voltage of V_{TO} = 8.5 V. By comparing *I–V* measured in both structures of diodes, we note that the density of current is lower in ITO/PF-*N*-Ph/Al diode

Table 1
Summary of the trap parameters in ITO/PEDOT:PSS/PF-*N*-Ph/Al and ITO/ PF-*N*-Ph/Al diodes.

Peak	*T* (K)	ITO:PEDOT:PSS/PF-*N*-Ph/Al		ITO/PF-*N*-Ph/Al	
		E_T (eV)	N_T (cm^{-3})	E_T (eV)	N_T (cm^{-3})
A	124	0.13	2.4×10^{16}	0.13	1.5×10^{16}
B	153	0.22	6.1×10^{16}	0.23	3.4×10^{16}
C	198	0.33	4.4×10^{16}	–	–
D	247	0.45	1.5×10^{16}	–	–
E	>320	0.59	$>2.7 \times 10^{16}$	0.57	$>1.5 \times 10^{16}$

whereas the turn-on voltage is higher than that of ITO/PEDOT:PSS/PF-*N*-Ph/Al diode because of the absence of the PEDOT:PSS layer which favours hole injection from the anode into the active layer.

Peaks A, B, E are present in both devices. By using the decomposition technique, the trap parameters related to peaks A, B, E observed in ITO//PF-*N*-Ph/Al diode have been determined and are reported in Table 1.

Types A, B, E traps observed in both devices have similar activation energies indicating that they have a similar origin. The density of traps is measured for V_C = +6 V. We can note that the trap density measured in ITO/PF-*N*-Ph/Al diode is lower than those determined in ITO/PEDOT:PSS/PF-*N*-Ph/Al diode. As observed in *I–V* characteristics, the density of current is higher for ITO/PEDOT:PSS/PF-*N*-Ph/Al diodes due to the presence of PEDOT:PSS that favours hole injection. Consequently, more charges are injected into the active layer and hence more charges are trapped. As types C and D traps are not detected in ITO/PF-*N*-Ph/Al diodes, their formation are therefore related to the presence of the PEDOT:PSS layer, confirming the hypothesis previously formulated [3].

4. Conclusion

We have investigated the modifications of the interface formed between a PEDOT:PSS layer and the active polymer in polyfluorene derivative (PFV and PF-*N*-Ph) based diodes.

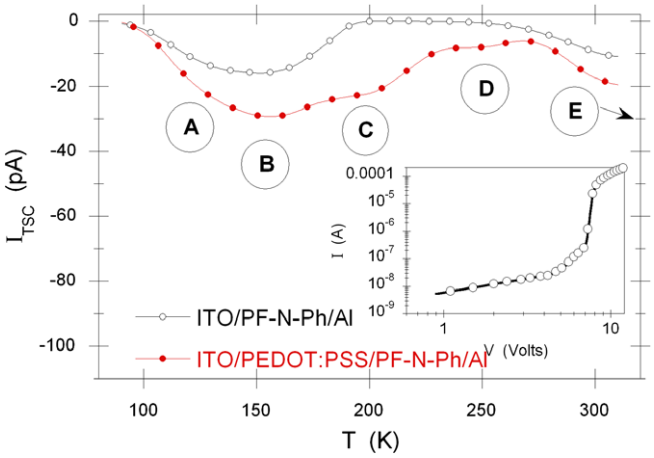

Fig. 7. TSC spectra recorded in ITO/PEDOT/PF-*N*-Ph/Al (●) and ITO/ PF-*N*-Ph/Al (○) diodes using the following parameters: T_H = 300 K, β = 0.1 K/s, with V_C = +6 V. Inset is *I*–*V* characteristics of ITO/PF-*N*-Ph/Al structure measured at *T* = 300 K.

By using two different spectroscopic techniques, which are complementary, we showed that the PEDOT:PSS/PF contact layer acts as an electron trapping surface, favouring accumulation of negative charges and thus an additional electric field at the interface. The presence of such a field modifies the electroabsorption spectrum of the diodes, as experimentally observed. Quantitative characterization of the trap centres has been performed using the TSC technique on diodes with and without a PEDOT:PSS layer, and the evidence of additional trap level creation induced by the PEDOT:PSS layer was clearly brought out. TSC is therefore proposed as a tool for deeper investigation of charge trapping at the electrodes. The data of the trap parameters could be used in future studies for modelling the charge injection from the anode of different devices, taking into account the PEDOT:PSS layer.

5-dioctyl-2,5-dihydropyrrolo [3,4-] pyrrole-1,4-dione] PCBTDPP, one of the best in this new class of low-bandgap polymers [11,12], in bulk heterojunction (BHJ) solar cells (OPV). Our preliminary measurements demonstrated a PCE of 1.6% from this class of materials [11]. Through further optimizations of the active layer thickness, donor/accepter loading ratio, and the selection of solvent, we have improved PCE from 1.6% to 3.2% when PCBTDPP is blended with $PC_{70}BM$.

Solar cells were fabricated using blends of PCBTDPP and $PC_{60}BM$ or $PC_{70}BM$ in different solvents and/or ratios and at various spin coating rates to reach desired active layer parameters. Precleaned indium tin oxide (ITO) coated glass substrates were used as anode. Poly(3,4-ethylenedioxythiophene):poly(sterenesulfonate) (PEDOT:PSS) was spin coated at 7000 rpm for 60s and baked for 1 h at 120 °C, as hole transport layer. After cooling down to room temperature, active layers with desired ratio and thickness were spin coated on top of the PEDOT:PSS layers. Finally, a lithium fluoride (LiF)/aluminium (Al) cathode was thermally evaporated through a shadow mask under high vacuum. The active area of the solar cell is 1 cm^2.

Scheme 1 presents the chemical structure of PCBTDPP and the energy level diagram of the BHJ solar cells.

The photovoltaic performances of those solar cells were tested under AM 1.5G irradiation of 100 mW cm^{-2}, which was calibrated using a KG5 filter covered silicon photovoltaic solar cell traceable to the National Renewable Energy Laboratory (NREL).

2. Experimental results

The thin film UV–Vis absorption spectra of pristine (PCBTDPP), $PC_{60}BM$ and $PC_{70}BM$ are shown in Fig. 1.

The pure PCBTDPP film exhibits two main absorption bands in the visible range, one in the wavelength range of 332–483 nm and the other in 502–760 nm, leaving an absorption minimum around 500 nm. As compared to $PC_{60}BM$, $PC_{70}BM$ has significantly higher absorption in the spectral range of 400–600 nm, complementary to the absorption minimum of PCBTDPP, making $PC_{70}BM$ a better electron donor material for use with PCBTDPP in BHJ solar cells.

Fig. 2 shows the external quantum efficiency (EQE) spectra of the solar cells composed of PCBTDPP blended with $PC_{60}BM$ and $PC_{70}BM$. The measured devices in each case were fabricated with the best weight ratio and thickness of active layer for $PC_{60}BM$ and $PC_{70}BM$, respectively. The EQE of $PC_{60}BM$-based device shows a maximum of 34% at 665 nm with a drastic decrease around 500 nm, which is consistent with the absorption data discussed in Fig. 1. On the other hand, the $PC_{70}BM$-based device demon-

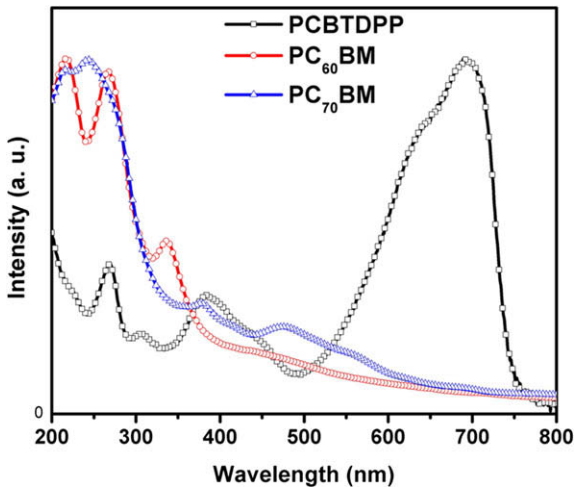

Fig. 1. UV–visible absorption spectra of PCBTDPP, $PC_{60}BM$ and $PC_{70}BM$ films.

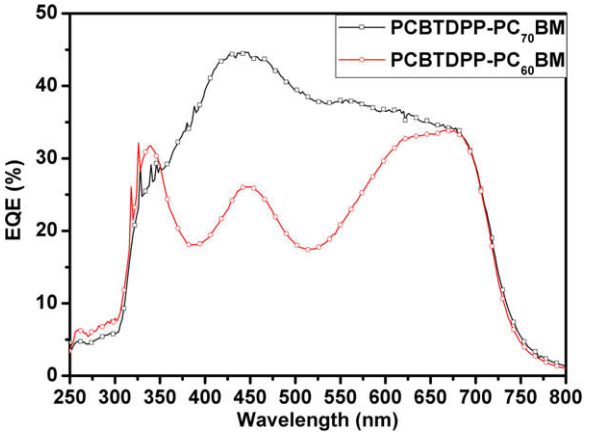

Fig. 2. EQE spectra of PCBTDPP blended with $PC_{60}BM$ (1:3) and $PC_{70}BM$ (1:3) devices.

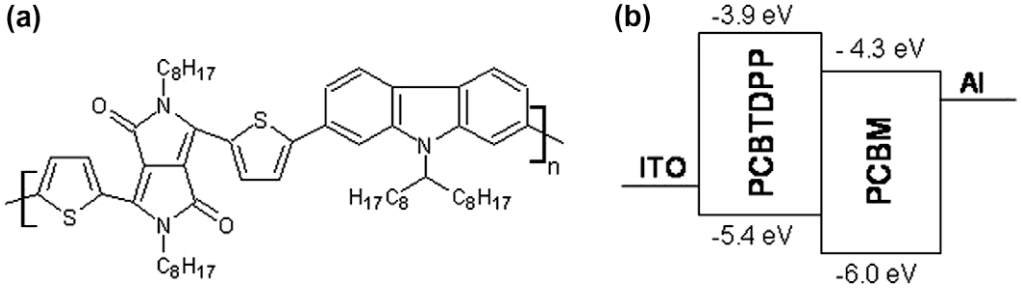

Scheme 1. (a) Chemical structure of PCBTDPP. (b) Energy band diagram of the BHJ solar cell (PCBTDPP: PCBM).

strates increased EQE across the whole visible spectral range, with a maximum of 45% at 450 nm, which indicates that the $PC_{70}BM$ is a much better acceptor than $PC_{60}BM$ for use with PCBTDPP. All the following optimizations will be done with this acceptor.

In order to optimize the ratio, thickness, and morphology of PCBTDPP:$PC_{70}BM$ bulk heterojunction films and study their effects on the device performance, solar cells using this couple with different weight ratios (1:2, 1:3, 1:4), thicknesses (from 60 to 130 nm) were fabricated with different organic solvents, and tested using standard solar cell characterization procedures.

First, we tested the effect of the PCBTDPP:$PC_{70}BM$ ratio on the device performance (Table 1). With increasing $PC_{70}BM$ ratio, the open-circuit voltage remained the same for all devices, but the short-circuit current density increased from 6.7 mA/cm^2 to 7.9 mA/cm^2 when the ratio was increased from 1:2 to 1:3. It is known that higher acceptor ratio ($PC_{60}BM$ or $PC_{70}BM$) favours the formation of a phase separated interpenetrated network with sizable domains [13], which in turn favours effective charge separation. However, the current decreased again to 6.5 mA/cm^2 when the ratio was increased up to 1:4. The impact of the donor ratio on the fill factor is also obvious. The maximum value was obtained with a ratio of 1:3. It is clear that the concentration of $PC_{70}BM$ in the blend has a strong impact on J_{sc} and the FF. For the PCBTDPP:$PC_{70}BM$ system, the best ratio is 1:3. Too high a $PC_{70}BM$ ratio will not only lead to lower J_{sc} and fill factor, but also a lower V_{oc}. Janssen et al. have already shown that saturating the active layer with $PC_{70}BM$ leads to a decrease in the J_{sc} and fill factor due to phase separation [14].

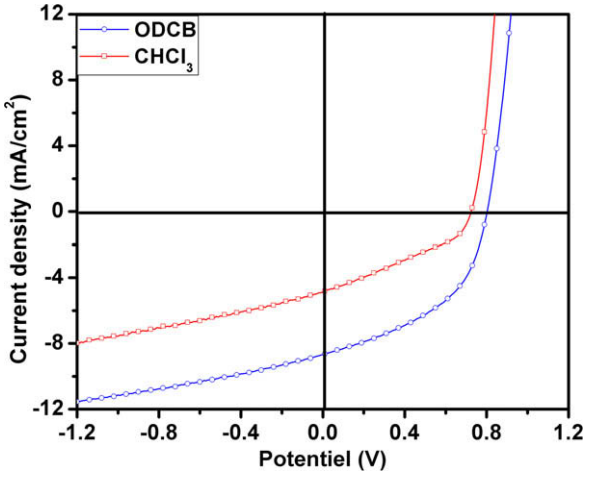

Fig. 3. *J–V* characteristics of ITO/PEDOT:PSS/PCBTDPP:3$PC_{70}BM$/LiF/Al devices with an active layer prepared by using $CHCl_3$ or ODCB as solvent. The active layers have the same thickness of 90 nm.

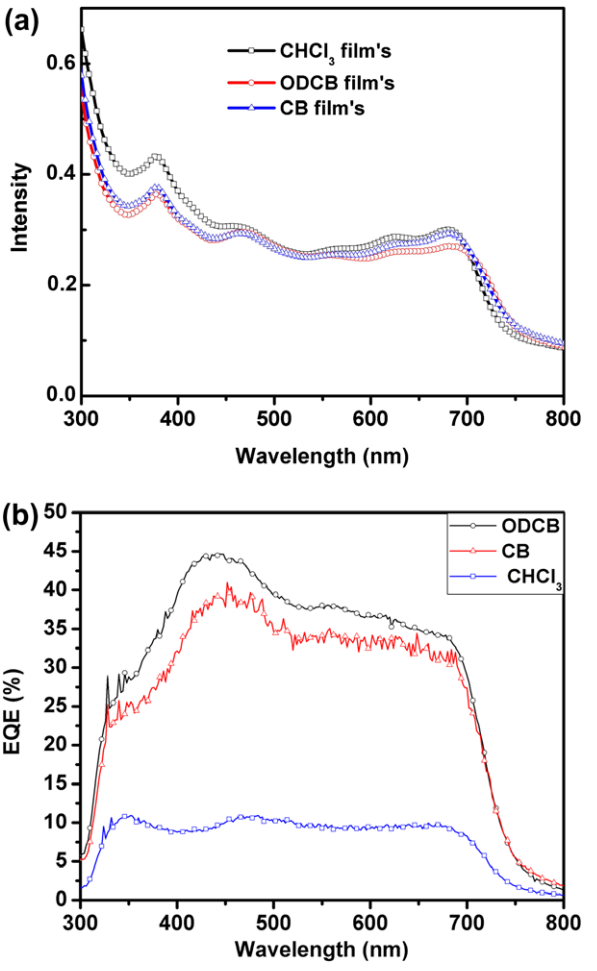

Fig. 4. (a) UV–vis absorption of PCBTDPP:$PC_{70}BM$ films prepared using different solvents; (b) External quantum efficiency (EQE) spectra of corresponding PCBTDPP:$PC_{70}BM$ solar cells.

The choice of electron donor and acceptor materials for use in BJH devices and their loading ratio is the first important step towards solar cell optimization. The choice of solvents is another important step [15]. It has a strong impact on the nano-scale morphology of the active layer, which plays an important role in the performance of solar cells [16] and OFETs [17].

In order to study the solvents effect on the morphology of the active layer and the solar cell performance, thin films of PCBTDPP:PCBM (1:3) blend were prepared using non-aromatic and aromatic solvents.

Table 2 summarizes the photocurrent densities of the solar cells in which the active layers were prepared with different solvents. Non-aromatic (chloroform ($CHCl_3$)) and aromatic (chlorobenzene (CB), and 1,2-Orthodichlorobenzene (ODCB)) solvents were used to study the solvent effect. Different active layer thicknesses were realised by using different spin rate in order to study the thickness effect on the photovoltaic performance of these devices.

The best device prepared using chloroform as solvent has a power conversion efficiency $\eta = 1.2\%$, a short-circuit current density $J_{sc} = 4.8$ mA/cm^2, an open-circuit voltage $V_{oc} = 0.72$, and a fill factor FF = 35%. The devices prepared using chlorobenzene as solvent show higher performance with $\eta = 2.5\%$, $J_{sc} = 6.8$ mA/cm^2, $V_{oc} = 0.79$ Volt, and FF = 47%. The devices prepared by using ODCB as solvent demonstrate the best performance with $\eta = 3.2\%$, $J_{sc} = 8.6$ mA/cm^2, $V_{oc} = 0.80$ V, and FF = 47%. The I–V curves of devices prepared using $CHCl_3$, and ODCB are shown in Fig. 3. Through this device optimization process, our PCBTDPP based solar cells have improved ~100% in power conversion efficiency as compared to our initial result 1.6%

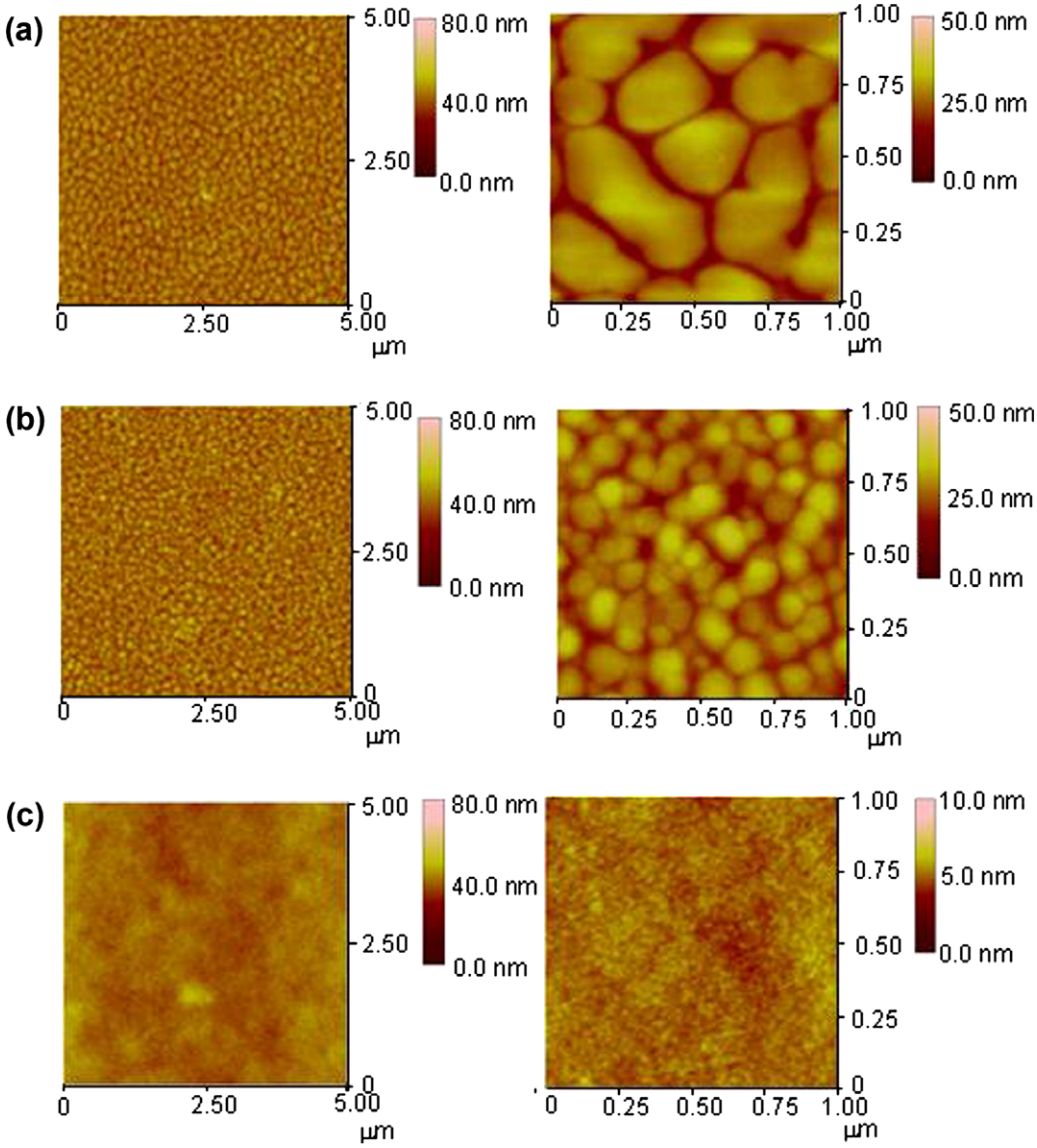

Fig. 5. 5×5 µm and 1×1 µm AFM images of PCBTDPP:3PC$_{70}$BM blend films spin-cast from different solvents: $CHCl_3$ (a), CB (b), and ODCB (c). These pictures are taken from active layers of the best devices obtained for each solvent.

[11], and ~40% as compared to the results reported recently by Zhou et al. (2.26%) using a similar polymer with different side chain [12]. This improvement can be attributed to the increased light absorption by replacing $PC_{60}BM$ with $PC_{70}BM$, as well as the optimized donor/acceptor ratio and active layer thickness.

The best values of the fill factor up to 45% were obtained when aromatic solvent (ODCB or chlorobenzene) was used, and the fill factor remains reasonably high up to an active layer thickness of 130 nm. In contrast, when chloroform was used as solvent, the average FF is less than 40%. The best values of short-circuit current were obtained at an active layer thickness of 90 nm in each case, independent of the solvent choice. The best V_{oc} values were obtained when chlorobenzene or ODCB was used as solvent. The V_{oc} decreased dramatically when chloroform was used, the same as other photovoltaic parameters, indicating that non-aromatic solvent is not preferred for making PCBTDPP based devices.

From the data shown in Table 2, we can conclude that for PCBTDPP:$PC_{70}BM$ (1:3) devices, the best film thickness is around 90 nm for maximum efficiency, and ODCB is preferred for active layer preparation.

The better performance of the devices prepared by ODCB is attributed to the optimized nano-scale morphology of the bulk heterojunction film with an average domain size around 20 nm. The most noticeable improvements in device performance are the fill factor and short-circuit current density, which are known as parameters directly dependant on the nano-scale morphology.

The external quantum efficiency (EQE) of a photovoltaic cell is given by the ratio between the number of electrons produced in the outer circuit and that of incident photons on the device. Fig. 4 compares the EQE spectra of PCBTDPP:$PC_{70}BM$ solar cells prepared with different solvents, as discussed above. The device prepared using ODCB as solvent shows the best overall EQE, which has the slowest drying rate among the three. The highest monochromatic EQE values for devices prepared using ODCB or CB are 44% and 41%, respectively. While that of the device prepared using chloroform is less than 22%. These results confirmed that even if we optimize the acceptor and donor ratio and the active layer thickness, it is also necessary to use the right solvent for the active layer preparation.

The surface morphology of PCBTDPP:$PC_{70}BM$ (1:3) active layers prepared using the three solvents was investigated by the atomic force microscopy (AFM). The tapping mode AFM images of the film prepared using chloroform (Fig. 5) show over-sized grain structures ~140 nm, indicating a large scale phase separation. The domains size is too large for efficient exciton dissociation. The surface morphology of the film spin cast from chlorobenzene is well-defined and the domain size is much smaller, ~50 nm. The situation improves even further when 1.2-dichlorobenzene is used as solvent, the film show much finer grain sizes (20–30 nm) with better organization and uniformity. This best organization observed on AFM pictures is in agreement with the solar cell performance. This indicates that the choice of solvent for active layer preparation is a crucial factor to get the optimum film morphology in order to realize the best device performance [18,19].

3. Conclusion

In this work, we have demonstrated how to control the nano-scale morphology of PCBTDPP:$PC_{70}BM$ bulk heterojunction by choosing right solvent, and donor/acceptor ratio. For this particular material, aromatic solvents deliver better device performance. AFM study connects the high device performance to better and organized phase-separated domains which provides an optimized *D–A* interface for efficient exciton dissociation and continuous electron and hole conducting channels necessary for efficient charge transport between electrodes. By replacing $PC_{60}BM$ with $PC_{70}BM$, we have significantly increased the light absorption in the spectral region where the PCBTDPP absorption is at minimum, and thus improved the short-circuit current density. With these optimization steps, we have improved the PCE from 1.6% in our previous study [11] to 3.2%.

2. Experimental

2.1. Materials and measurements

9H-fluoren-9-one, *n*-butyllithium (*n*-BuLi), triethyl borate and chlorodiphenylphosphine (Aldrich Chem. Co.) were used without further purification. 2,2′-Dibromobiphenyl (TCI Chem. Co.), hydrogen peroxide (Duksan Sci. Co.) and sodium hydrogen carbonate (Junsei Chem. Co.) was used as received. Tetrahydrofuran was distilled over sodium and calcium hydride.

The ^{1}H nuclear magnetic resonance (NMR) was recorded on a Varian 200 (200 MHz) spectrometer. The photoluminescence (PL) spectra were recorded on a fluorescence spectrophotometer (HITACHI, F-7000) and the ultraviolet–visible (UV–Vis) spectra were obtained using a UV–Vis spectrophotometer (Shimadzu, UV-2501PC). The differential scanning calorimeter (DSC) measurements were performed on a Mettler DSC 822e under nitrogen at a heating rate of 10 °C/min. The low and high resolution mass spectra were recorded using a JEOL, JMS-AX505WA spectrometer in FAB mode. The energy levels were measured with a cyclic voltametry.

2.1.1. Synthesis of 4-bromo-9,9′-spirobifluorene (**1**)

2,2′-Dibromobiphenyl (11.00 g, 35.25 mmol) was dissolved in THF (70 mL) in the 250 ml two-neck flask. The solution was cooled to −78 °C and *n*-BuLi (10 M in hexane, 4.23 mL) was added dropwise slowly. The whole solution was stirred at −78 °C for 3 h, followed by addition of a solution of 9H-fluoren-9-one (7.62 g, 42.30 mmol) in THF (40 mL) under argon atmosphere. The solution was gradually warmed to ambient temperature and quenched by saturated, aqueous $NaHCO_3$ (110 mL). The solution was extracted with dichloromethane. The combined organic layers were dried over magnesium sulfate, filtered, and evaporated under reduced pressure. The white powdery product was obtained and the crude product was placed in other two-necked flask, and dissolved in acetic acid (300 mL). Catalytic amount of aqueous HCl (30 mL) was then added and the whole solution was refluxed for 12 h. After cooling to ambient temperature, purification by column chromatography with a mixed solvent of dichloromethane and *n*-hexane as an eluent gave a white powder.

Yield 50%. T_g 66 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.68–8.65 (d, 1H), 7.86–7.82(d, 2H), 7.53–7.34 (m, 3H), 7.26–6.63 (m, 15H). ^{13}C NMR ($CDCl_3$), δ 150.9, 148.3, 147.7, 141.1, 140.3, 139.2, 132.5, 131.6, 128.4, 127.8, 127.4, 126.8, 126.4, 123.8, 123.5, 122.9, 122.2, 122.0, 119.9, 118.9, 116.0 ppm. MS (FAB) *m*/*z* 395 [(M + 1)+].

2.1.2. 9,9′-Spirobifluorene-4-yldiphenylphosphine (**2**)

The 4-bromo-9,9′-spirobifluorene (1.00 g, 2.53 mmol) was put into the THF (20 mL) solvent in the 100 ml two-neck flask. The solution was cooled to −78 °C and *n*-BuLi (10 M in hexane, 0.3 mL) was added dropwise slowly. The whole solution was stirred for additional 3 h, followed by addition of a solution of chlorodiphenylphosphine (0.67 g, 3.04 mmol) under argon atmosphere. The resulting mixture was gradually warmed to ambient temperature and quenched by methanol (7 mL). The mixture was extracted with dichloromethane. The combined organic layers were dried over magnesium sulfate, filtered, and evaporated under reduced pressure. The white powdery product was obtained to 0.25 g (19%).

2.1.3. 4-Diphenylphosphine oxide-spiro[fluorene-9,9′-fluorene] (SPPO11)

A solution of 4-diphenylphosphine oxide-9,9′-spirobifluorene (0.25 g, 0.49 mmol), dichloromethane (50 mL), and hydrogen peroxide (10 mL) were stirred overnight at room temperature. The organic layer was separated and washed with dichloromethane and water. The extract was evaporated to dryness affording a white solid, which was further purified by column chromatography to yield 0.24 g of chemically pure SPPO11.

Yield: 96%. T_m: 314 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.68–8.64 (d, 1H), 7.85–7.71(M, 6H), 7.52–7.49 (m, 6H), 7.40–7.14 (m, 4H), 7.11–6.61 (m, 8H). ^{13}C NMR ($CDCl_3$), δ 150.4, 150.2, 148.1, 147.7, 144.9, 141.2, 139.3, 133.5, 133.3, 132.9, 132.6, 132.2, 132.0, 130.9, 128.7, 128.5, 128.2, 127.8, 127.4, 126.8, 125.5, 125.4, 124.7, 123.7, 123.0, 122.2, 120.0, 118.9 ppm. MS (FAB) *m*/*z* 517 [(M + 1)+].

2.1.4. OLED fabrication and measurement

A basic device configuration of indium thin oxide (ITO)/poly-3,4-ethylenedioxythiophene:polystyrenesulfonate (PEDOT:PSS)/*N*,*N*′-di(1-naphthyl)-*N*,*N*′-diphenylbenzidine (NPB) (20 nm)/*N*,*N*′-dicarbazolyl-3,5-benzene (mCP) (10 nm)/**SPPO11**:FIrpic (30 nm, 10%)/2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP, 5 nm)/tris(8-hydroxyquinoline) aluminium (Alq_3) (20 nm)/LiF (1 nm)/Al (100 nm) was used to evaluate the SPPO11 as a host for the blue PHOLEDs. The doping concentration of the FIrpic was optimized at 10% and it was fixed in all devices. The blue PHOLED with the **SPPO11** as the electron transport layer instead of the BCP/Alq_3 was also fabricated and the simple blue PHOLED without the BCP/Alq_3 was prepared as the simple device. In addition, the blue PHOLED with the 2-diphenylphosphine oxide-9,9′-spirobifluorene (**SPPO1**) was fabricated to study the effect of the substitution position of the diphenylphosphine oxide on the device performances of the blue PHOLEDs. Device structures of the blue PHOLEDs are shown in Fig. 1. The devices were encapsulated with CaO and a glass lid after cathode deposition. Current density (*J*)–voltage (*V*)–luminance (*L*) characteristics and electroluminescence (EL) spectra of the devices were measured with Keithley 2400 source measurement unit and Minolta CS 1000A spectroradiometer.

3. Results and discussion

The synthesis of the 4-bromospirobifluorene which was an intermediate compound of the SPPO11 was difficult because the bromination of the spirobifluorene leads to the substitution at 2 position of the spirobifluorene. Therefore, few compounds with a substituent at the 4 position of the spirobifluorene were synthesized [13,14]. One way to synthesize the 4-bromospirofluorene is to use

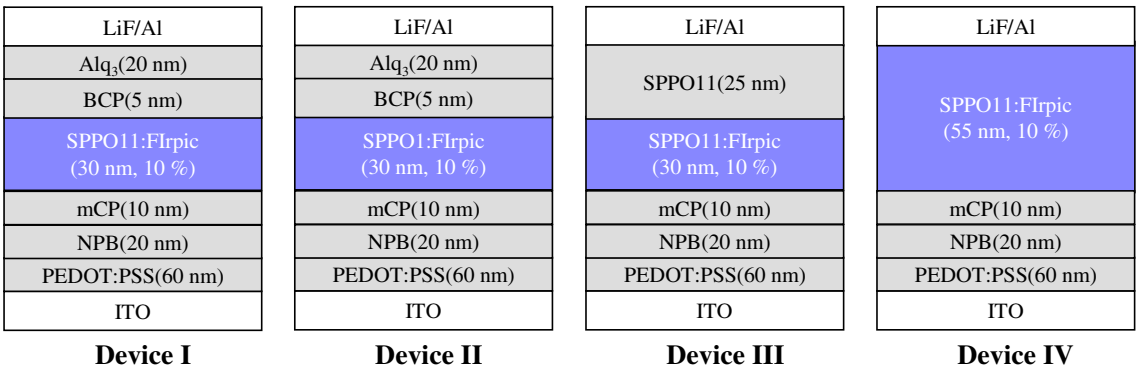

Fig. 1. Device structures of the blue PHOLEDs with the SPPO11 and SPPO1 hosts.

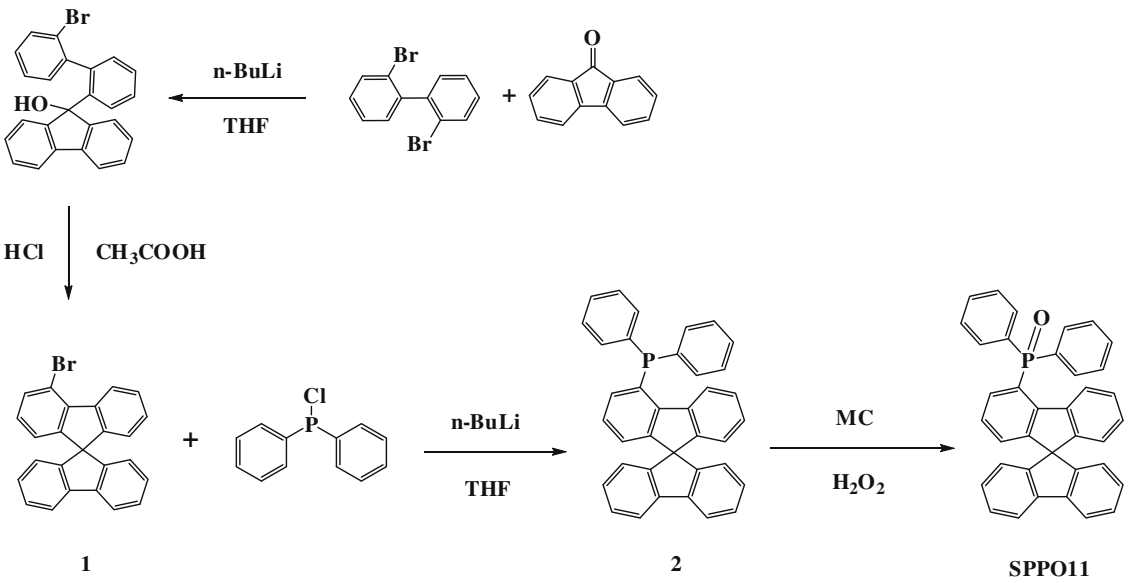

Scheme 1. Synthetic route of SPPO11.

Table 1
Physical properties of the SPPO11 and SPPO1.

2,2′-dibromobiphenyl. As shown in the Scheme 1, the 2,2′-dibromobiphenyl was reacted with *n*-BuLi followed by the reaction with fluorenone. The use of 1 equivalent of *n*-BuLi resulted in the lithiation of only one bromo unit of the two bromo substituents in the 2,2′-dibromobiphenyl. Therefore, the reaction of the mono-lithiated 2,2′-dibromobiphenyl with the fluorenone followed by dehydration lead to the synthesis of the 4-bromo-9,9′-spirobifluorene. This synthetic route is very simple to prepare the 4-bromo-9,9′-spirobifluorene. The 4-bromo-9,9′-spirobifluorene was reacted with chlorodiphenylphosphine through the lithiation and then dehydrated by hydrogen peroxide, yielding the SPPO11.

The physical properties of the SPPO11 were compared with those of the SPPO1 to investigate the effect of the diphenylphosphine oxide substitution position on the physical properties. Physical properties of the SPPO11 and SPPO1 are summarized in Table 1 and Fig. 2. The UV–Vis absorption and PL emission peaks of the SPPO11 were similar to those of the SPPO1, but the red shift of

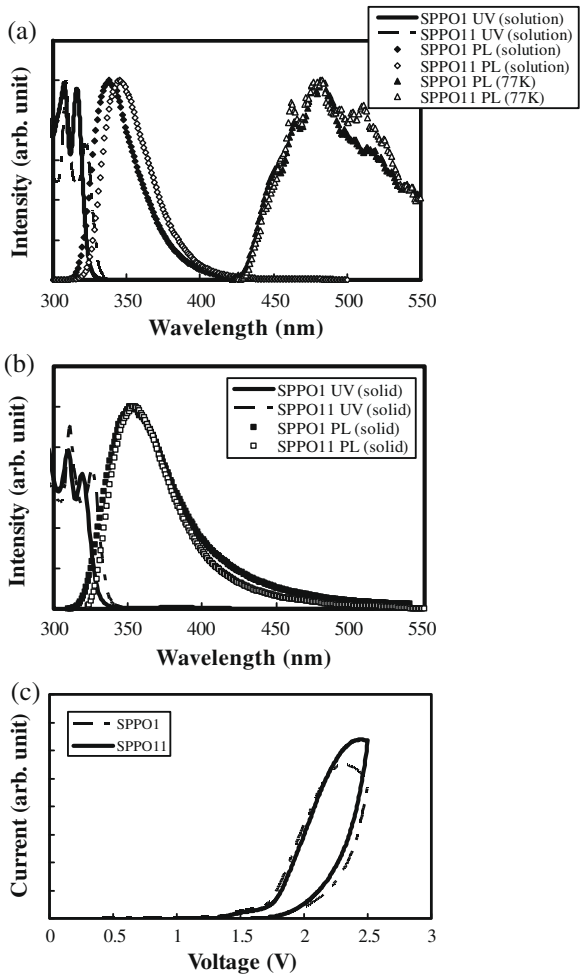

Fig. 2. UV–Vis, PL spectra and CV data of the SPPO1 and SPPO11 (a) UV–Vis and PL in solution, (b) UV–Vis and PL in solid state, (c) CV.

the UV–Vis absorption and PL emission were observed. The absorption peak around 308 nm was the same in the SPPO1 and SPPO11, but the absorption peak around 320 nm was red shifted in the SPPO11 by about 6 nm. The emission peak was also shifted to long wavelength in the SPPO11. In the solid film case, the UV absorption peak was similar to that of the solution except for the slight red shift of the absorption peak, while the emission peak was different. The emission peak of the SPPO11 was in the long wavelength range in solution, but the peak position of the emission peak in the solid film was similar. This is closely related with the geometrical structure and molecular orbital distribution of the SPPO1 and SPPO11 in Fig. 3. The molecular packing of the SPPO11 is difficult due to the steric hindrance of the diphenylphosphine oxide at 4 position of the spirobifluorene, resulting in less molecular interaction in solid state. Therefore, the peak position of the PL emission of the SPPO1 and SPPO11 was similar. In addition, the emission peak of the SPPO11 was narrower than that of the SPPO1 due to the suppressed molecular interaction in solid state.

The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) distribution of the SPPO11 and the SPPO1 were studied to understand the physical properties of the SPPO1 and SPPO11 at molecular level and they are shown in Fig. 3. Density functional theory (DFT) calculations for host materials were carried out using a suite of Gaussian 03 program to understand the observed properties of the materials at the molecular level. The nonlocal density functional of Becke's 3-parameters employing Lee–Yang–Parr functional (B3LYP) with 6-31G* basis sets was used for the calculation [15]. The HOMO was distributed over the spirobifluorene unit of the SPPO11 and SPPO1, while the LUMO was localized in the fluorene group connected to the diphenylphosphine oxide. Comparing the HOMO distribution, both the SPPO11 and SPPO1 showed uniform orbital distribution, resulting in similar HOMO level. There was only 0.02 eV HOMO level difference between the SPPO1 and the SPPO11. In the LUMO case, the LUMO of the SPPO11 was localized in the fluorene unit connected to the diphenylphosphine oxide, while the LUMO of the SPPO1 was rather dispersed. The LUMO of the SPPO1 was distributed over the diphenyl unit in the diphenylphosphine oxide as well as the fluorene unit. The diphenyl unit in the diphenylphosphine oxide is an isolated unit as the conjugation through the phosphine oxide unit cannot be extended due to the tetrahedral structure of the phosphine oxide. Therefore, the electrons in the diphenyl unit are isolated and the LUMO level is shifted upward from the vacuum level due to lack of conjugation. The phenyl group is less conjugated than the spirobifluorene group, leading to the upward LUMO level shift. This LUMO level shift results in the large bandgap in the SPPO1 compared with SPPO11. Even though there is steric hindrance in the SPPO11, the geometrical structure of the spirobifluorene core was not affected by the position of the diphenylphosphine oxide.

The different substitution position of the diphenylphosphine oxide also affects thermal properties of the SPPO1 and SPPO11 and the T_g of the SPPO11 was improved significantly by the substitution of the diphenylphosphine oxide at 4 position of the spirobifluorene. The T_g depends on the molecular rigidity of the backbone structure and the steric hindrance of the molecule. Comparing the molecular rigidity of the molecule, the SPPO11 and the SPPO1 have the same rigid spirobifluorene core structure with the diphenylphosphine oxide unit. The difference between the SPPO11 and the SPPO1 is the steric hindrance between the diphenylphosphine oxide unit and the spirobifluorene core. The rotation of the diphenylphosphine oxide in the SPPO11 is limited due to the steric hindrance of the diphenyl unit with the spirobifluorene unit as the diphenyl unit and the fluorene unit is in plane. However, the rotation of the diphenylphosphine oxide in the SPPO1 is not hindered by the spirobifluorene group as the diphenylphosphine oxide group is out of plane with the spirobifluorene group. The steric hindrance suppressed the free rotation of the diphenylphosphine oxide group, increasing the T_g of the SPPO11.

The high T_g induced by the steric hindrance improved the morphological stability of the SPPO11. Fig. 4 shows the optical microscopic pictures of the SPPO11 and SPPO1

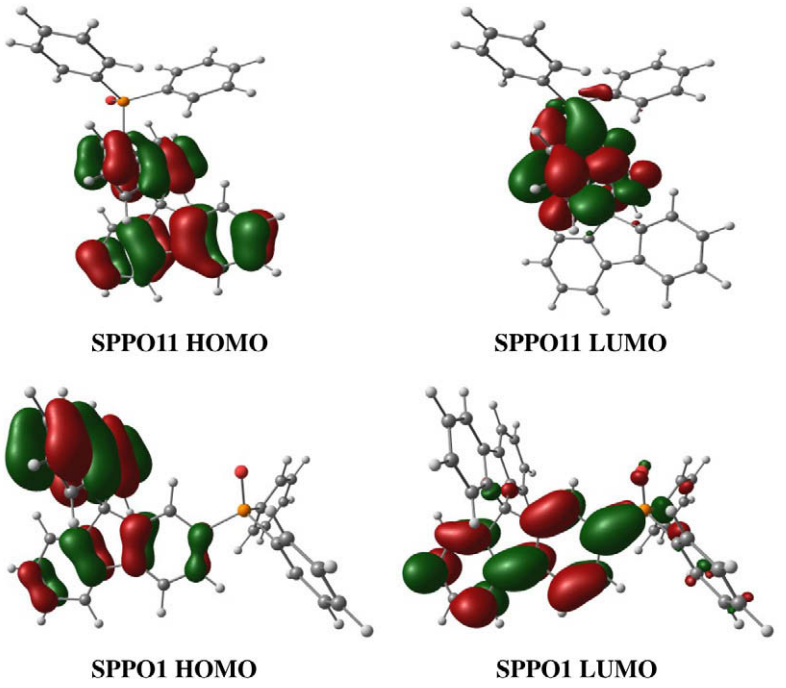

Fig. 3. Molecular simulation results of the SPPO11 and SPPO1.

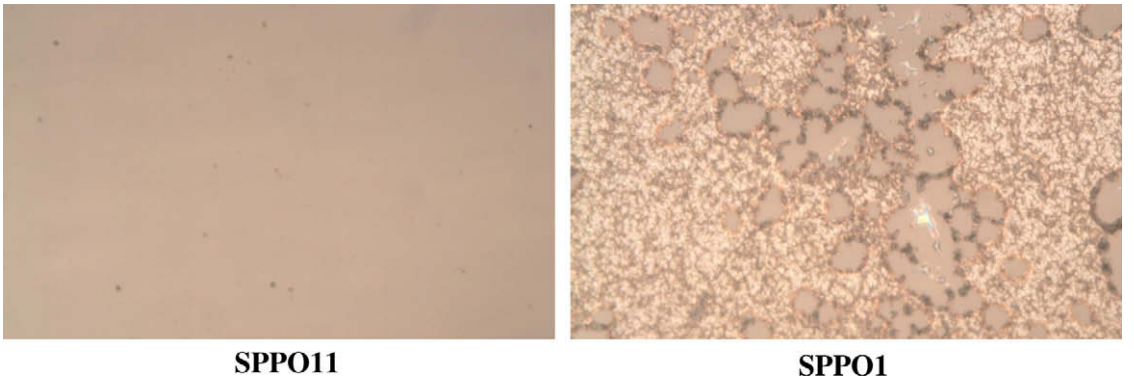

Fig. 4. Optical microscopic pictures of the SPPO11 and SPPO1 after thermal treatment at 80 °C for 10 min.

film after thermal treatment at 80 °C for 10 min on glass substrate. The crystallization of the SPPO1 was serious after thermal treatment and most of the film was crystallized. However, the SPPO11 film maintained the amorphous film morphology of the thermally deposited film even after thermal treatment. This indicates that the steric hindrance of the SPPO11 suppress the crystallization.

Electron only devices of the SPPO11 and SPPO1 were fabricated to compare the effect of substitution position on the electron injection. Fig. 5 shows the current density–voltage curves of the electron only devices of the SPPO11 and SPPO1. The device structure of the electron only devices was ITO (150 nm)/SPPO1 or SPPO11 (100 nm)/LiF (1 nm)/Al (100 nm). The electron current density of the SPPO11 was higher than that of the SPPO1,

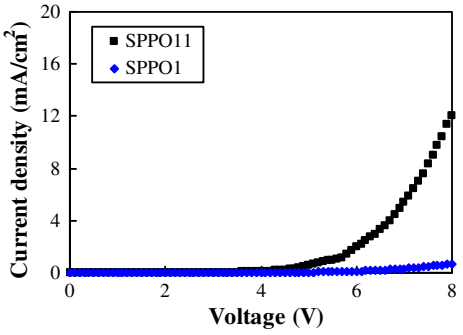

Fig. 5. Current density–voltage curves of the electron only devices of the SPPO11 and SPPO1.

indicating that the SPPO11 is better than the SPPO1 in terms of electron density. The electron density is determined by the LUMO level and electron mobility of the materials. The LUMO of the SPPO11 was 2.82 eV, while the LUMO of the SPPO1 was 2.73 eV. There was 0.09 eV energy level difference between the SPPO11 and the SPPO1. The LUMO level of the SPPO11 is better for electron injection than that of the SPPO1, leading to high electron density. In addition, the high electron mobility of the SPPO11 is also responsible for the high electron density of the SPPO11. The electron mobility of the SPPO1 was 5×10^{-4} cm^2/V s, while that of the SPPO11 was 7×10^{-4} cm^2/V s.

The triplet bandgap of the SPPO11 was 2.78 eV and it was similar to that of the SPPO1. The triplet bandgap of 2.77 eV is wide enough for energy transfer to the FIrpic dopant and the SPPO11 was evaluated as the host for the FIrpic. The device performances of the SPPO11 blue device (device I) were optimized by changing the doping concentration of the FIrpic and were compared with those of the SPPO1 (device II). The doping concentration of the FIrpic in the device I was optimized at 10%.

The *J*–*V*–*L* curves of the SPPO11 and SPPO1 blue PHOLEDs are shown in Fig. 6. The *J* and *L* of the SPPO11 device were higher than those of the SPPO1 device. The high *J* and *L* of the SPPO11 device are due to the efficient electron injection as shown in the electron only device data in Fig. 5. The electron density of the SPPO11 device was increased, resulting in the increase of the *J* and *L* of the SPPO11. The high *L* of the SPPO11 device indicates that more electron injection generates more excitons in the emitting layer.

The quantum efficiency and power efficiency of the SPPO11 and SPPO1 devices are shown in Fig. 7. The quantum efficiency of the SPPO11 device was higher than that of the SPPO1 device and a maximum quantum efficiency of 17.2% was obtained at 200 cd/m^2 compared with 15.6% of the SPPO1 device. The current efficiency was as high as 35.3 cd/A in the SPPO11 device. The high quantum efficiency of the SPPO11 device can be explained by the high electron density in the emitting layer. The hole injection from the ITO to the SPPO11 emitting layer is efficient as the multilayer structure of PEDOT:PSS/NPB/mCP was used as the hole transport layer. Therefore, holes can be effectively injected from the ITO to the SPPO11 emitting layer and more electron injection can balance the holes and electrons in the emitting layer, improving the quantum efficiency of the SPPO11 device. The high quantum efficiency and low driving voltage of the SPPO11 device also enhanced the power efficiency and a high power efficiency of 26.0 lm/W was obtained in the SPPO11 device.

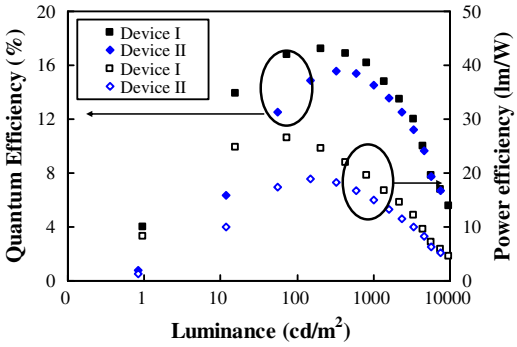

Fig. 7. Quantum efficiency and power efficiency curves of the blue PHOLEDs with SPPO11 and SPPO1 hosts.

The device performances of the SPPO11 device was further optimized by changing the device structure of the SPPO11 devices. A device with the SPPO11 as an electron transport layer instead of the BCP/Alq_3 (device III) and a device with SPPO11:FIrpic emitting layer without any electron transport layer (device IV) were fabricated. Figs. 8 and 9 shows the *J*–*V*–*L* and efficiency–*L* curves of the device I, device III and device IV. The current density and luminance were increased in the device III, while they were reduced in the device IV compared with device I. The high current density of the device III can be explained by the reduced interfacial trap at the interface. Device III had no interface between the emitting layer and the electron transport layer because the SPPO11 was used as both the host and the electron transport layer. Therefore, there was no interfacial energy barrier and interfacial traps, increasing the electron density in the emitting layer. The increased electron density in the emitting layer enhances

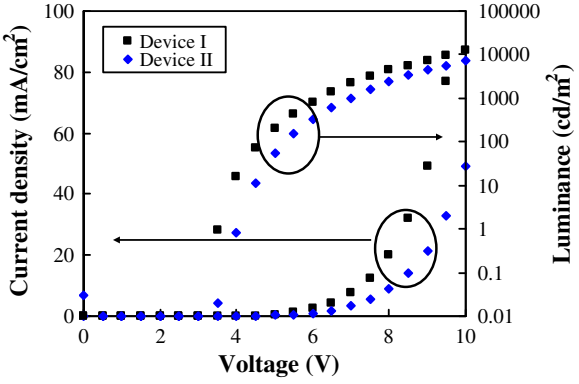

Fig. 6. Current density–voltage–luminance curves of the blue PHOLEDs with SPPO11 and SPPO1 hosts.

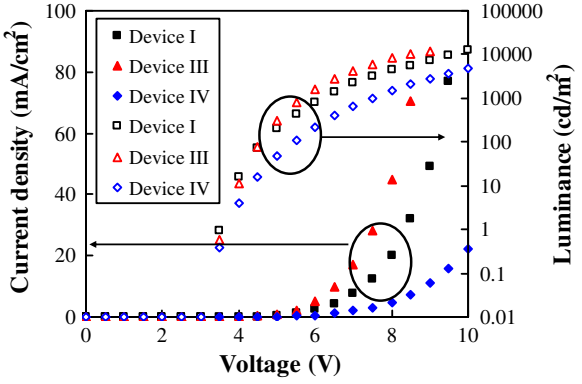

Fig. 8. Current density–voltage–luminance curves of the blue PHOLEDs with the SPPO11 as a host material according to the device structure.

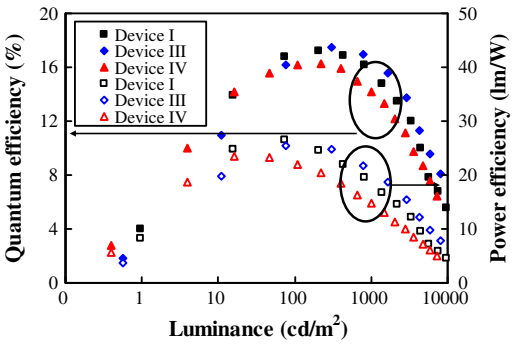

Fig. 9. Quantum efficiency and power efficiency curves of the blue PHOLEDs with the SPPO11 as a host material according to the device structure.

the quantum efficiency of the device III. A quantum efficiency of 17.5%, a current efficiency of 35.6 cd/A and a power efficiency of 24.7 lm/W were achieved at 300 cd/m^2 in the device III.

The current density was reduced in the device IV without the SPPO11 electron transport layer. The reduction of the current density is due to the electron trapping by the FIrpic dopant material. The LUMO level of the FIrpic was 3.2 eV compared with 2.82 eV of the SPPO11. The LUMO level difference between the SPPO11 and FIrpic induces electron trap by the FIrpic dopant, decreasing the current density of the device IV. The reduced electron density in the device IV has negative effect on the charge balance in the emitting layer, resulting in rather low quantum efficiency and power efficiency compared with device I.

4. Conclusions

In conclusion, the substitution of the diphenylphosphine oxide at 4 position of the spirofluorene was better than the substitution at 2 position in terms of thermal stability and electron injection. The SPPO11 could be effectively synthesized through the simple synthetic route for the synthesis of the 4-bromo-9,9′-spirobifluorene and high quantum efficiency was achieved in the device with the SPPO11 host. Therefore, the 4-bromo-9,9′-spirobifluorene can be used as an intermediate compound for the synthesis of thermally stable organic semiconductor materials for organic electronics applications.

encountered in the formation of SAMs because of lateral siloxane crosslinking. On the other hand, for polymer dielectrics it has been demonstrated that they can be used to optimize the pentacene film growth mode, control the film morphology, and understand the relationship between surface viscoelasticity of polymers and device performance [14,16,17]. However, their device performances are still lower than SAM-modified devices.

Polystyrene (PS) is a low-cost thermoplastic polymer, which is transparent and can form uniform thin films. When it is spin-coated onto the SiO_2/Si substrate, the pendant phenyl groups tend to be oriented toward the film surface normal, independent of casting solvent, molecular weight, and film thickness [18]. The benzene ring orientation on the surface can potentially be used to facilitate ordered growth of semiconductors such as pentacene and, thus, provide a more efficient transistor channel than that on the SiO_2 surface. So far, the highest achievable mobility using PS as a dielectric layer is ~0.8 cm^2/V s due to imperfectly oriented benzene rings at the PS film surface that cannot effectively control the top-layer pentacene order [17].

Previously, Fischer et al. reported that the surface of a spin-coated PS film showed a rather disordered arrangement of phenyl groups which have a 30° tilt angle from surface [18]. After annealing at 120 °C, these phenyl groups became ordered at the PS/air interface and tilted away from the surface normal in an angular range near 57° [19]. Such a surface can create a good template to orient layers of molecular semiconductors on top and facilitate charge transport near the interface of semiconductor/dielectric. This inspires us to explore the use of thermally treated PS thin film to modify the pentacene/SiO_2 interface for achieving high-performance OTFT devices.

In this article, the tilt angle of PS's phenyl groups and the surface energy of PS films are changed by thermal annealing at 80 and 120 °C. Pentacene films were deposited onto the PS films (about 10 nm thickness) with different phenyl ring tilt angles. We found that pentacene formed a highly crystalline film with larger grain sizes and better connectivity on the PS films with the flatter orientation of phenyl groups. Carrier mobility up to 4 cm^2/V s and a large on/off current ratio of $>10^7$ could be achieved from the resulting OTFTs. These are among the highest values reported for the pentacene-based OTFTs.

2. Experimental

The sum frequency generation (SFG) spectra of PS films were obtained by overlapping visible and tunable IR laser pulses (25 ps) in time and space at incidence angles of 72° and 61.5°, respectively. The visible beam with a wavelength of 532 nm was delivered by an EKSPLA Nd:YAG laser operating at 50 Hz, which was also used to pump an EKSPLA optical parametric generation/amplification and difference frequency unit based on barium borate and $AgGaS_2$ crystals to generate tunable IR laser radiation from 1000 to 4000 cm^{-1}. The spectral resolution in the C–H stretching region was 1 cm^{-1} for the visible and IR lasers. Both beams were only mildly focused and had a diameter of approximately 1 mm at the sample. The energy for each beam was 150 μJ per pulse. The SFG signal generated at the sample was then analyzed by filters and a monochromator, detected with a gated photomultiplier tube and stored in a computer. The spectra were collected with 200 shots per data point in 4 cm^{-1} increments. For a given sample, the SFG measurements were repeated at least three times and the collected spectra were averaged to produce the final spectra presented in this work. Spectra were collected using ssp and sps (sum, visible, and infrared) polarization combinations. The SFG spectra were normalized by the product of the IR and visible pump beam intensities.

OTFTs were fabricated with a top-contact configuration (Fig. 2a) according to the following procedure. A heavily doped n-type silicon wafer and 300 nm thick layer of thermally grown SiO_2 (Montco Semiconductors) were used as the gate and gate insulator, respectively. The substrates were cleaned in water, acetone and isopropyl alcohol (IPA). Then, the PS (Aldrich, molecular weight: 280,000, glass transition temperature: 100 °C) buffer layer was spin-coated onto the surface of SiO_2 and the thickness was measured to be about 10 nm by AFM. After that, the substrates were placed into a vacuum oven and baked about 30 min at different temperatures (80 and 120 °C) under vacuum. Pentacene (Aldrich without further purification) was deposited onto the substrates by high vacuum evaporation at a rate of 0.4 Å s^{-1} from a resistively heated quartz crucible at 4×10^{-7} Torr to achieve a total film thickness of 50 nm, and subsequently Au films (50 nm) as drain and source electrodes were deposited onto the organic layer through a shadow mask. For a typical device, the channel length (L) and width (W) of the OTFT were 55 and 1550 μm ($W/L = 28$), respectively, thus, creating a series of OTFTs investigated in our experiments. All devices were characterized with an Agilent 4155B semiconductor parameter analyzer under ambient conditions without any precautionary measures being taken to isolate the devices from exposing to ambient oxygen and moisture. The morphologies of organic semiconductor films were investigated using a Digital Instruments nanoprobe atomic force microscope (AFM) in contacting mode at room temperature. Tips were etched silicon tips with a typical resonant frequency of 300–350 kHz. X-ray reflectivity was measured using a Siemens D5000 XRD with Cu-Kα radiation. Advancing contact angle values of water were measured and surface energies were calculated using the Young equation [20].

3. Results and discussion

Fig. 1 displays SFG spectra of polystyrene films (untreated and thermally treated at 80 and 120 °C) taken with ssp (upper panel) and sps (lower panel) polarization combination. The fitting routine for the SFG data [21] used the following expression for the SFG intensity [22]:

$$I_{\mathrm{SFG}} \propto |\chi^{(2)}|^2 = \left| \chi^{(2)}_{\mathrm{NR}} e^{i\phi} + \sum_v \int_{-\infty}^{\infty} \frac{A_v e^{i\phi_v} e^{-[\omega_L - \omega_v/\Gamma_v]^2}}{\omega_{\mathrm{IR}} - \omega_L + i\Gamma_L} d\omega_L \right|^2 . \quad (1)$$

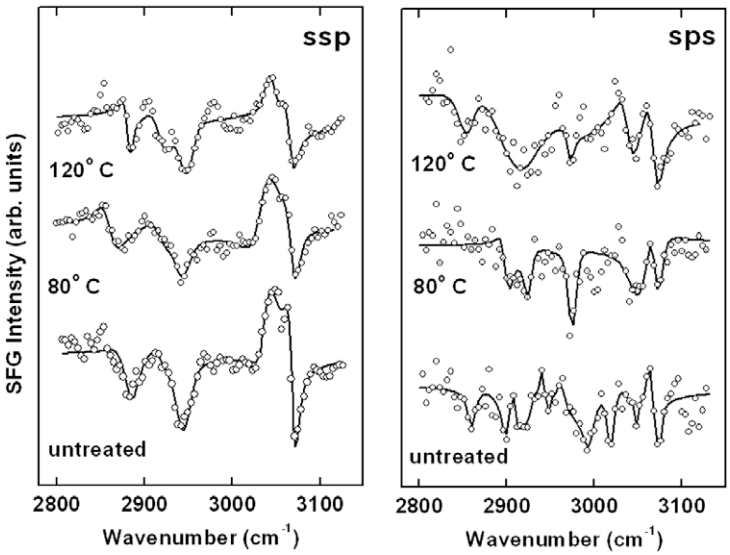

Fig. 1. SFG spectra (open circles) of polystyrene films untreated and thermally treated at 80 and 120 °C collected with ssp (upper panel) and sps (lower panel) polarization combination. Fits of Eq. (1) to the data are also shown (solid lines). The spectra were offset for clarity of presentation.

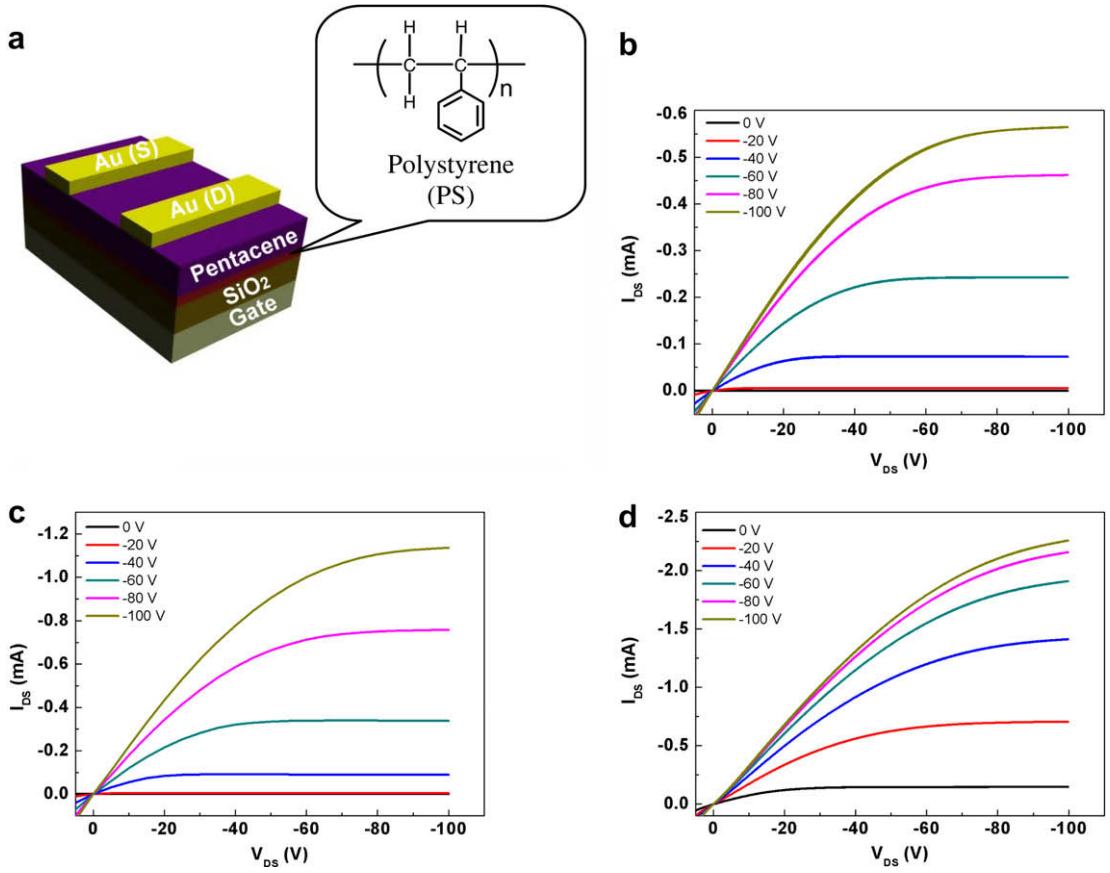

Fig. 2. Molecular structure of PS and the cross-sectional view of OTFTs (a) and output characteristics of pentacene TFTs with PS buffer layer untreated (b) and thermally treated at different temperatures: (c) 80 °C and (d) 120 °C.

Here, $\chi^{(2)}_{NR}$ is the second order non-linear susceptibility of the non-resonant background, A_v is the strength of the vth vibrational mode, ϕ denotes the phase of the respective mode, and ω_{IR} refers to the frequency of the incident IR

field. The integral is over Lorentzian lines, centered at ω_L and a width Γ_L, having a Gaussian distribution. In the fits, the Lorentzian line widths were set to 2 cm^{-1} and Γ_v was allowed to vary since the two contributions to the total line width could not be separated within the accuracy of the measurements. The ssp spectra are dominated by resonances near 3043 and 3068 cm^{-1}. The feature at 3043 cm^{-1} is assigned to ring mode υ_{7b}, while the latter mode can be unequivocally assigned to the υ_2 phenyl ring C–H stretching mode [23–25]. A shoulder near 2922 cm^{-1} is commonly associated with the asymmetric CH_2 stretching mode (d^-) of the polystyrene backbone [26–28]. The sps SFG spectra consist of weak but discernible features related to the υ_{7a} and υ_2 phenyl ring modes, as well as the d^- methylene mode. A quantitative analysis of the effect of film annealing on the orientation of the phenyl rings can be performed by evaluating the intensity ratios of selected features in the ssp and sps spectra [27]. The details of this calculation have been reported elsewhere and we will discuss the method only briefly here [29–31]. Following the procedure and notation described in Refs. [27,32], we have analyzed the intensities for the most prominent spectral feature, the υ_2 mode, in ssp and sps spectra to determine the molecular susceptibility ratio

$$\frac{\langle\beta_i\rangle_{xzx}}{\langle\beta_i\rangle_{xxz}} = \frac{A_i^{sps}F^{ssp}}{A_i^{ssp}F^{sps}}. \quad (2)$$

Here, β_i are the resonant molecular hyperpolarizabilities, A_i are the oscillator strengths according to Eq. (1), F are the Fresnel factors for given polarization combinations, and $\langle\rangle$ denotes a distribution over the tilt (Θ) angles against the surface normal and twist (ψ) angles about the molecular axis. The intensity ratio can be used to calculate molecular tilt angles for a given trial orientational distribution. We have assumed a delta function for Θ (i.e. uniform tilt angle for all phenyl rings) and an isotropic average of ψ. For the tilt angle calculation, we have to make assumptions about the molecular hyperpolarizability β_{ijk} of the υ_2 mode. Due to the C_{2v} symmetry of the υ_2 ring mode and low cross section for out-of-plane Raman polarizability we consider only β_{aac} and β_{ccc} [33]. In accord with published procedures based on density functional theory (DFT) and bond additive polarizability calculations we have assumed $\beta_{aac} = 0.86\beta_{ccc}$ (a, b, c denote the coordinates in the molecular frame with c in line with the 1′–4′ axis of the phenyl ring) and 0 for all other elements of the hyperpolarizability tensor β_{ijk} [27]. Based on these assumptions we can calculate the molecular tilt angle using:

$$\frac{(r-2)\sin^2\Theta}{r + r\cos^2\Theta + 2\sin^2\Theta} = \frac{A_i^{sps}F^{ssp}}{A_i^{ssp}F^{sps}}. \quad (3)$$

with $r = \beta_{aac}/\beta_{ccc}$. The refractive indices for air, silicon dioxide and polystyrene used to calculate the Fresnel factors were $n_{air} = 1$, $n_{SiO_2} = 1.45$ and $n_{PS} = 1.53$, respectively. The resulting intensity ratios, Fresnel factors, and hyperpolarizability ratios are summarized in Table 1 along with the resulting tilt angles. The determined tilt angles were 27°, 39° and 62° for the film untreated and thermally treated at 80 and 120 °C, respectively (the uncertainty of these values is ±5° which is a combination of the errors of the intensity ratios, the Fresnel factors and uncertainties of the value for r). The determined tilt angles clearly show the orientation of the phenyl group changes significantly due to the thermal treatment. The relative phase of the resonant and the non-resonant contributions are closely related to the molecular orientation. It has been elegantly shown for phenylsiloxanes on Si/SiO_2 that relative phases comparable to those observed here are related to phenyl groups pointing away from the surface [27]. Thus, we can conclude that the rings are oriented away from the surface with a mostly upright orientation for the film untreated, and that they assume a strongly tilted configuration after annealing. The low tilt angle value for the film without thermal treatment is in good agreement with NEXAFS studies of very thin polystyrene films. In this study, Stöhr and Samat report a tilt angle value of 30° [34]. The strongly tilted orientation observed after the 120 °C treatment has been reported by many groups. The majority of SFG studies of the orientation of annealed polystyrene report a flat orientation of the phenyl ring with respect to the surface [27,35]. Interestingly, the tilt angle value for the 80 °C-annealed film is in-between the 120 °C-annealed and unannealed surface. It is possible that the reorientation within the polystyrene film is thermodynamically restricted by the lower process temperature.

The contact angles and surface energies of the PS films untreated and thermally treated at different temperatures are listed in Table 2. The water contact angle of PS films without thermal treatment is about 102.6°, which is comparable to previous results [36]. When the thermal treatment temperature is increased, the water contact angle decreases, dropping to 95.8° for the film treated at 120 °C. The surface energy of the PS film without thermal treatment is about 36.7 mJ/m^2 while that of PS film treated at 120 °C is 48.5 mJ/m^2. Thus, as the phenyl groups of PS tilt away from the interface normal, the surface energy increases. The surface energy of pentacene was reported to be 47.4 mJ/m^2 [37]. Therefore, annealing the PS film at

SFG results for the studied polystyrene films untreated and thermally treated at 80 and 120 °C.

Film treatment temperature (°C)	A^{sps}/A^{ssp}	F^{ssp}/F^{sps}	$\langle\beta_i\rangle_{xzx}/\langle\beta_i\rangle_{xxz}$	Θ
120	0.37	0.93	0.34	62°
80	0.23	0.93	0.21	39°
Untreated	0.13	0.93	0.12	27°

Table 2
Contact angle and surface energy of PS films untreated and thermally treated at 80 and 120 °C and electrical parameters (saturation region) of the devices based on them.

Temperature (°C)	Water contact angle (°)	γ_s (mJ/m²)	μ (cm²/V s)	V_T (V)	On/off ratio
Untreated	102.6 ± 1.0	36.7	0.8	40	10^8
80	97.9 ± 0.9	44.6	2.0	26.4	10^8
120	95.8 ± 0.9	48.5	4.0	6.5	10^7–10^8

120 °C results in a flatter phenyl group orientation with respect to the surface and a surface energy that is comparable in value to that of pentacene. Matching the surface energy of the dielectric to pentacene is known to enhance device performance, especially the charge carrier mobility [37,38].

Pentacene TFTs with top-contact geometry were fabricated as shown in Fig. 2a and PS buffer layers were untreated and thermally treated at 80 and 120 °C, respectively. Devices were tested in air and in a dark environment at room temperature. The output and transfer characteristics of devices are shown in Figs. 2 and 3. All devices exhibited good p-type TFT behaviors and the current–voltage characteristics conform well to the conventional transistor model in both linear and saturated regimes. The maximum saturation current at each gate voltage increased markedly with the increased thermal treating temperature which is consistent with previous studies [39]. The mobilities of the devices in the saturated regime were extracted from the following equation:

$$I_{DS} = C_i \mu (W/2L)(V_{GS} - V_T)^2 \quad (4)$$

where I_{DS} is the drain current, C_i is the capacitance per unit area of the gate dielectric layer, and V_{GS} and V_T are the gate voltage and threshold voltage, respectively. The field-effect mobilities of the devices were calculated from the linear fit of the square root of I_{DS} versus V_{GS} in the saturated regime. V_T was determined by extrapolating the linear section of the square root of I_{DS} versus V_{GS} to $I_{DS} = 0$. Table 2 summarizes OTFT electrical parameters in both linear and saturation regions, including carrier mobilities, on/off current ratios, and threshold voltages. It can be clearly observed that the carrier mobility of the devices is dependent on the thermal treatment temperatures of the PS films. For the devices based on the PS film untreated, carrier mobility of ca. 0.8 $cm^2/V\,s$, a threshold voltage about 40 V and on/off ratio of about 10^8 in the saturation region are observed which are similar to those of previous devices [14,17]. For the device using the PS film treated at 80 °C, the carrier mobility reaches 2.0 $cm^2/V\,s$, an increase of more than 2×, and the threshold voltage is reduced down to 26.4 V. When the PS thermal treatment temperature was increased to 120 °C, the performance of the devices is enhanced with a mobility of ~4.0 $cm^2/V\,s$, a large on/off ratio about 10^7–10^8, and a low threshold voltage about 6.5 V. This is among the best results reported for pentacene-based OTFTs. Thus, higher-temperature thermal treatments of PS thin film that produces a flat orientation of phenyl groups and then a decrease in surface energy leads to better device performance (higher carrier mobility and lower threshold voltage). This could be ascribed to better matched surface energies between pentacene and phenyl groups at the surface of PS film that results in formation of a highly crystalline pentacene film with good interconnection [15,38].

To clarify the origin of the enhanced OTFT performance, it is important to investigate the difference of nucleation, film growth, morphology and crystallinity of pentacene deposited onto the different PS films. The surface roughness of the gate dielectric can significantly affect the nucleation of deposited pentacene molecules, its thin-film growth, and eventually the device performance [40]. Thus, we first investigated the surface roughness of PS films. The atomic force microscopy (AFM) images of PS films with different thermal treatments on SiO_2 showed a very similar topography with smooth surface (as shown in Fig. 4). The root-mean-square (RMS) roughness is 0.2–0.3 nm for the films untreated and treated at 80 and 120 °C. These results are consistent with the RMS of the thermally growth SiO_2 ($R_q \approx 0.4$ nm) [39]. Therefore, the difference among pentacene morphologies and device parameters can be mainly attributed to the nature of PS–pentacene interface, since the surface roughness of the PS films are almost identical. Fig. 5 shows the AFM images of pentacene films deposited onto different PS films. During the initial stages of pentacene film growth, numerous large two-dimensional islands were formed on the untreated PS film and no conglomerated island structures could be observed. As the thickness of deposited pentacene films continued to increase, the islands grew both vertically and laterally, and eventually coalesced. With the higher-temperature treated PS films, the pentacene films were inclined to lateral growth of the grain. The step height of islands was about 2.4–4.8 nm, which

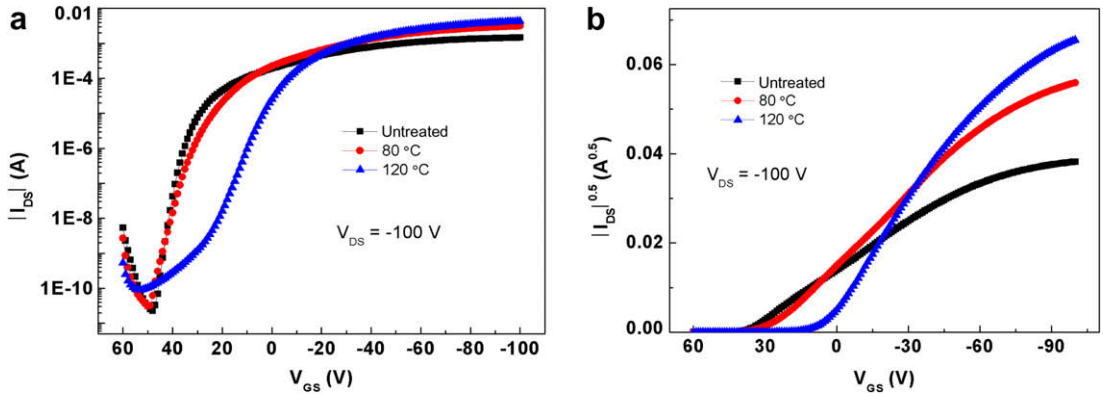

Fig. 3. $\log_{10}(|I_{DS}|)$ versus V_{GS} (a) and $|I_{DS}|^{1/2}$ versus V_{GS} (b) characteristics of pentacene TFTs with PS buffer layer untreated and thermally treated 80 and 120 °C.

corresponds to the thickness of 2–3 monolayers, considering the long axis of pentacene molecule [41]. For pentacene film deposited on PS (after thermal treatment at 80 and 120 °C), the predominant interconnection between the grains was observed at a thickness of ~2 nm. However, for the pentacene film deposited on untreated

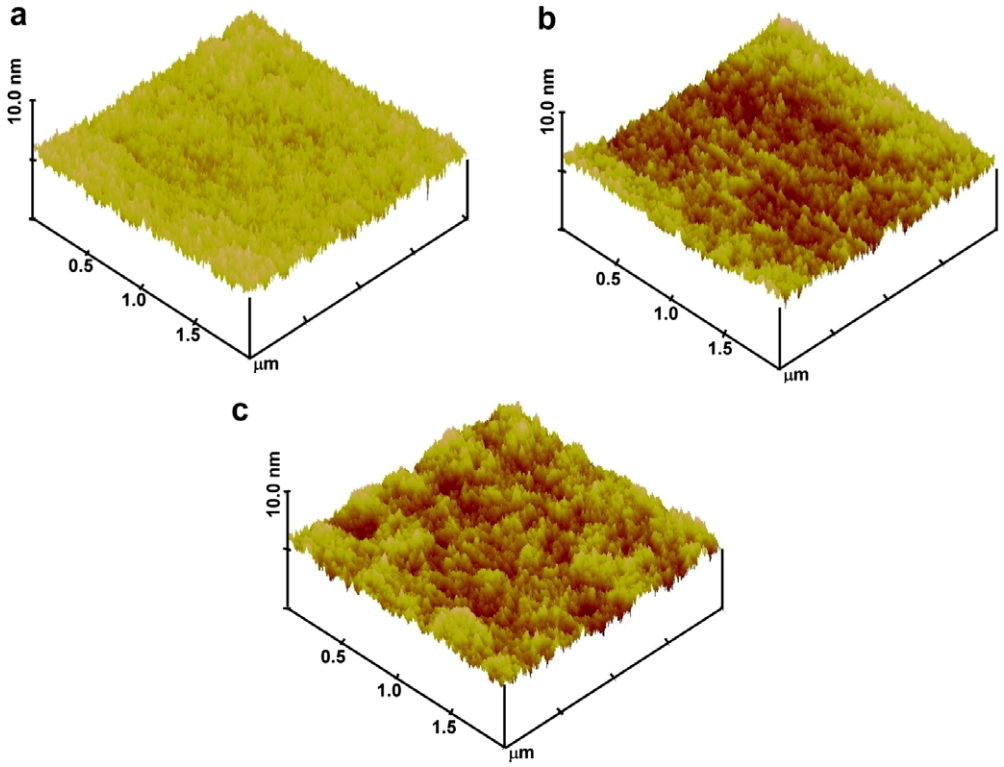

Fig. 4. AFM images of the surface of PS thin films untreated (a) and thermally treated at (b) 80 °C and (c) 120 °C. All images are 2 μm × 2 μm in size.

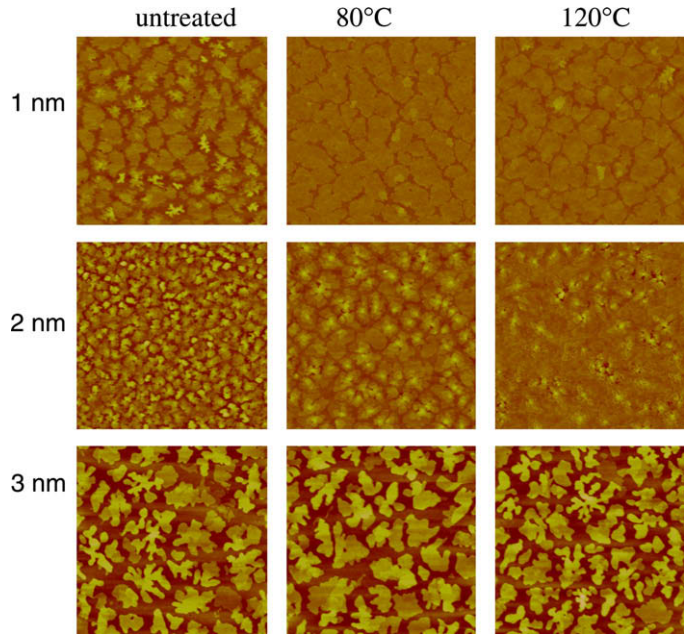

Fig. 5. AFM images at various thicknesses during the initial stages of pentacene film growth on PS films untreated and thermally treated 80 and 120 °C. All images are 5 μm × 5 μm in size.

PS, no connection between grains could be observed until the thickness of pentacene film reached 3 nm. This thickness value is lower than those reported for pentacene deposited on top of SAMs or other polymer dielectrics [15,39]. The low film thickness needed to form interconnected pentacene grains on the surface is attributed to the flat orientation of underlying phenyl groups at the surface of PS films and then the good connection between pentacene grains facilitates efficient charge transport [15]. Similar results were observed for devices made with an ordered octadecyltrichlorosilane (ODTS) SAM treated SiO_2 surface [15].

To investigate the crystalline phase and crystallinity of the deposited pentacene films, X-ray diffraction (XRD) measurements were performed. The X-ray patterns of the scans for 50 nm thick pentacene films deposited onto PS/SiO_2 are shown in Fig. 6. Only (0 0 l) reflections can be observed for all of the pentacene films, indicating that all pentacene nanocrystals in the pentacene films are oriented with their (0 0 l) phases parallel to the PS film [42,43]. For all the pentacene films, all peaks corresponding to (0 0 l) planes come from the substrate-induced thin-film phase with the same interlayer spacing of 15.4 Å, while the peaks corresponding to bulk phase with a vertical periodicity of 14.5 Å are not observed in our XRD patterns. It indicates that the pentacene molecules on PS films are apparently affected by the interaction with PS surface, because the thin-film phase is surface-induced and energetically less stable compared to the bulk phase [44]. Dimitrakopoulos et al. reported that the coexistence of thin-film and bulk phases can cause high defect densities in the pentacene films, leading to lower mobilities in devices [45]. Furthermore, the diffraction peak intensities increase with increasing annealing temperature of the PS films, indicating the crystallinity of the deposited pentacene films is increased at higher temperatures. This result showed that the flat orientation of phenyl groups on the surface of PS film tends to lead to the formation of higher crystallinity pentacene films, which in turn, facilitates better charge transport.

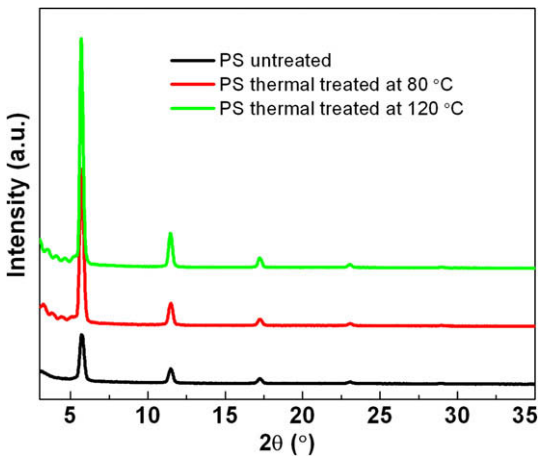

Fig. 6. XRD patterns of pentacene films on PS thin films untreated and thermally treated at 80 and 120 °C.

4. Summary

SFG results showed that the phenyl groups of polystyrene thin films untreated and thermally treated at 80 and 120 °C point away from the PS surface normal with tilt angles of 27°, 39° and 62°, respectively. The phenyl groups' flat orientation in PS films annealed at higher temperatures results in a higher surface energy of the PS films. OTFTs with an untreated and thermally treated PS buffer layer between SiO_2 and organic semiconductors were also fabricated. The device's performance is proportional to the thermal treatment temperature, viz. OTFTs based on the PS film with a flat orientation of the phenyl groups resulted in higher device performance. AFM and XRD results showed that a more highly oriented and crystalline pentacene film was grown on PS films with flatter phenyl group orientations. These pentacene films also had better interconnection between the crystalline domains. The devices with the PS films thermally treated at 120 °C exhibit the highest performance, producing a mobility of 4.0 cm^2/V s, an on/off current ratio of $\sim 10^7$–10^8, and a threshold voltage of about 6.5 V in the saturation region.

stability and higher mobility values than their organic counterparts. Oxide semiconductors also can be process at low-temperatures and are compatible with flexible substrates. Therefore, they are an attractive alternative to electron transport organic semiconductors for the realization of hybrid circuits based on complementary metal-oxide semiconductor technology. To date, there are only few reports of hybrid complementary circuits [6–8]. On flexible substrates, Oh et al. [6] recently demonstrated complementary inverters on polyethersulfone (PES) substrates using ZnO and pentacene channels with the same aspect ratio. Following this hybrid approach, these inverters showed the highest reported static gain of 100 V/V at a switching threshold voltage of 5 V with a supply voltage of 7 V. Although not provided in the paper, unbalance noise margins can be expected in such inverters. Furthermore, ZnO films are polycrystalline even when deposited at room temperature, leading to channels with grain boundaries that deteriorate the TFT stability, uniformity, and performance [9]. On the other hand, pentacene/*a*-IGZO complementary inverters only have been reported on rigid substrates [7] with gains of 56 V/V with supply voltage of 7 V but at a switching threshold voltage of 2.8 V. Unbalanced noise margins can also be expected in that case.

Here, we report on hybrid pentacene/*a*-IGZO complementary inverters composed of TFTs with different channel aspect ratios fabricated on flexible PES substrates. We propose a method to find the switching threshold voltage based on the resistance of the *p*- and *n*-channel TFTs, discuss the conditions for an optimum supply voltage, and propose a method for its estimation. With this method, we demonstrate hybrid complementary inverters that combine a high gain of 130 V/V at V_D = 25 V with a switching threshold voltage (V_M) of 12.5 V that allows high and balanced values of noise margins with values of 84% the theoretical maximum.

2. Device fabrication and electrical characterization

Hybrid inverters were fabricated with a bottom gate and top-contact source and drain electrode geometry, as shown in Fig. 1a. First, a tri-layer of Ti(7 nm)/Au(70 nm)/Ti(7 nm) was deposited using electron-beam (e-beam) at room temperature on flexible PES substrates (*i*-components) through a shadow mask. A 300 nm-thick Si_3N_4 gate dielectric layer was deposited by PECVD at 180 °C. A 30 nm-thick *a*-IGZO (Ga_2O_3:In_2O_3:ZnO = 1:1:2 mol%) active layer was then deposited by rf sputtering at a low-temperature of 90 °C using a power of 125 W, a working pressure of 6 mTorr, and an O_2/Ar (1/20) atmosphere using a shadow mask. Then, a 50 nm-thick layer of pentacene was deposited using thermal evaporation with a substrate temperature of 25 °C and an initial pressure of 2×10^{-8} Torr. Prior to thermal evaporation, pentacene was purified using gradient zone sublimation. Finally, Au(25 nm)/Al(25 nm) source/drain electrodes were deposited through a shadow mask over the pentacene and *a*-IGZO channels. Complementary inverter circuits, as shown in Fig. 1b, were constructed using *p*-channel pentacene and *n*-channel *a*-IGZO TFTs with a channel length of L = 180 μm and channel widths of W^p = 4000 μm and W^n = 400 μm, respectively. A picture of the flexible inverters is shown in Fig. 1c. The use of Au source/drain electrodes is expected to yield balanced electron and hole injection since, in both cases, the energy barrier for charge injection is ~0.6 eV [10,11]. The channel width ratio of W^n/W^p = 10, was selected to compensate for: (1) differences in electron and hole mobility; and (2) differences in the threshold voltage. The gate electrodes were patterned for both TFTs and served as the input voltage (V_{IN}) of the inverter circuit.

The current–voltage characteristics of independent *p*- and *n*-channel TFTs, fabricated on the same substrate with the same channel aspect ratio as those used in the complementary inverter, are shown in Fig. 2a–d. The transfer and

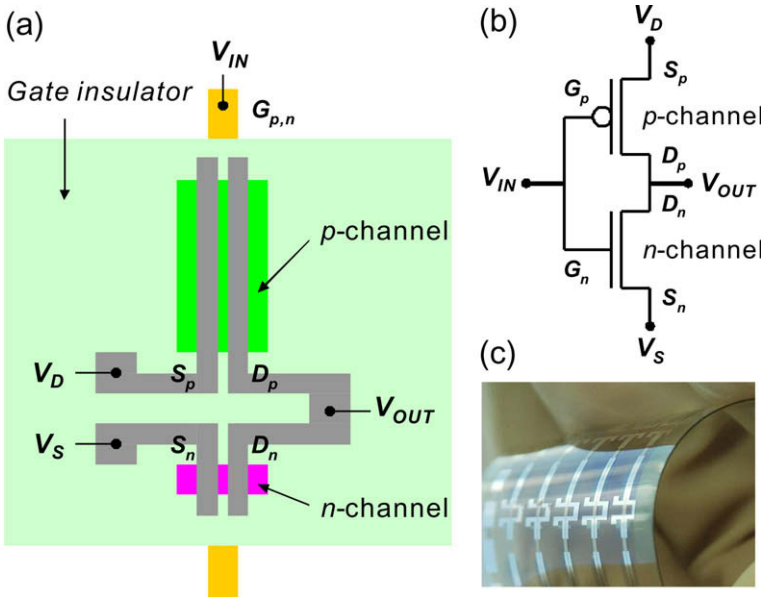

Fig. 1. (a) Schematics of the hybrid complementary inverter fabricated on a PES substrate with pentacene and *a*-IGZO as active channel layers. (b) Complementary inverter circuit diagram. (c) Photograph of complementary inverters on PES.

output characteristics of all TFTs were measured using an Agilent E5272A medium-power source/monitor unit connected to a probe station. The transfer curves and leakage currents measured for both forward and reverse gate biases are shown in Fig. 2a (*p*-channel) and Fig. 2b (*n*-channel). A saturation mobility of 0.13 cm^2/Vs and a threshold voltage of −10.3 V were obtained for pentacene TFTs. These values are comparable with the ones found in pentacene/Si_3N_4 TFTs on rigid substrates [12]. The small hysteresis in these TFTs, also found on rigid substrates, is due to a shift in the threshold voltage which is attributed to trapping at the pentacene/Si_3N_4 interface. The use of passivation layers is expected to significantly improve the hysteresis characteristics of these pentacene TFTs [2] without significantly affecting the properties of the *a*-IGZO channel. The *n*-channel *a*-IGZO TFT shows a saturation mobility of 3.8 cm^2/Vs and a threshold voltage of 13.6 V with negligible hysteresis. On rigid substrates, higher mobility values have been obtained because differences in processing conditions are expected to yield *a*-IGZO films with a slightly different stoichiometry than previously obtained. Higher mobility values are expected upon further optimization of the deposition process. The output curves shown in Fig. 2c (*p*-channel) and Fig. 2d (*n*-channel) exhibit good linearity at low drain-to-source voltage (V_{DS}) despite the relatively large energy barrier for charge injection.

3. Experimental method and analysis of complementary inverter

The static performance of an inverter is evaluated by its static gain and noise margin values. Achieving high and balanced noise margin values is necessary for reliable circuit operation in complex logic circuits such as ring oscillators. The noise margin, is limited by the steepness of the transition and by the position of the switching threshold voltage ($V_M = V_{IN} = V_{OUT}$). Highest values of noise margins are found when the ideal condition $V_M = 0.5V_D$ is met, hence when $V_M = V_{IN} = 0.5V_D = V_{OUT}$. However, the value of V_{IN} at which this transition occurs is generally not $0.5V_D$. The actual value of V_M depends on the range of V_D. A complementary inverter can be modeled by two series-connected voltage-dependent variable resistors. In general, for a given supply voltage, V_D, V_M corresponds to the input voltage that makes equal the resistance of the *n*-channel TFT ($R_{TN} = V_{DS}/I_{DS}$) and the *p*-channel TFT ($R_{TP} = -V_{DS}/-I_{DS}$). Note that R_{TN} and R_{TP} can be extracted from independent TFTs either from the output characteristics through the condition $V_{GS} = V_{DS}$ (as shown in Fig. 2c and d), or by directly measuring I_{DS} in a TFT with shorted gate and drain electrodes ($V_{GS} = V_{DS}$). Fig. 3 shows the values of R_{TN} and R_{TP}, extracted by following the first approach, for different values of $V_{GS} = V_{DS}$. Also note that the conventional analytical equation used to find V_M, derived from the MOSFET square law model, assumes that the mobility and threshold voltage remain constant during operation [13,14]. However, in organic or oxide TFTs, this analytical approach may not always hold true. An accurate calculation of V_M would require a fitting procedure to get the functional dependence of the mobility and threshold voltage as a function of V_{GS} and V_{DS}. In contrast, the proposed method does not require any fitting parameters, such as mobility or threshold voltage, and

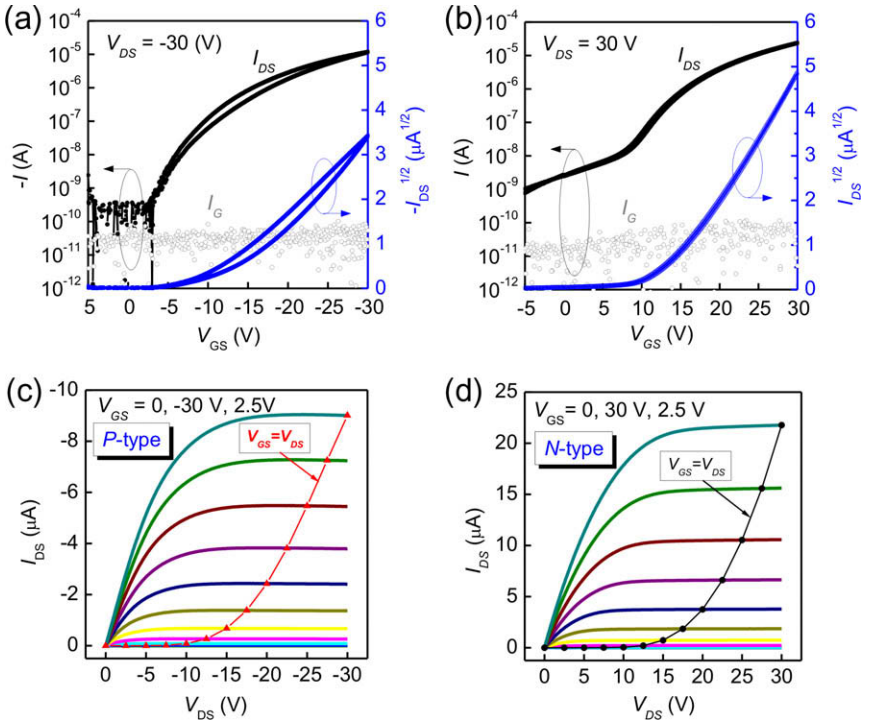

Fig. 2. Representative (a) hysteresis transfer and (c) output characteristics of pentacene TFTs with $L = 180$ μm and $W^p = 4000$ μm. Representative (b) hysteresis transfer and (d) output characteristics of *a*-IGZO TFTs with $L = 180$ μm and $W^n = 400$ μm.

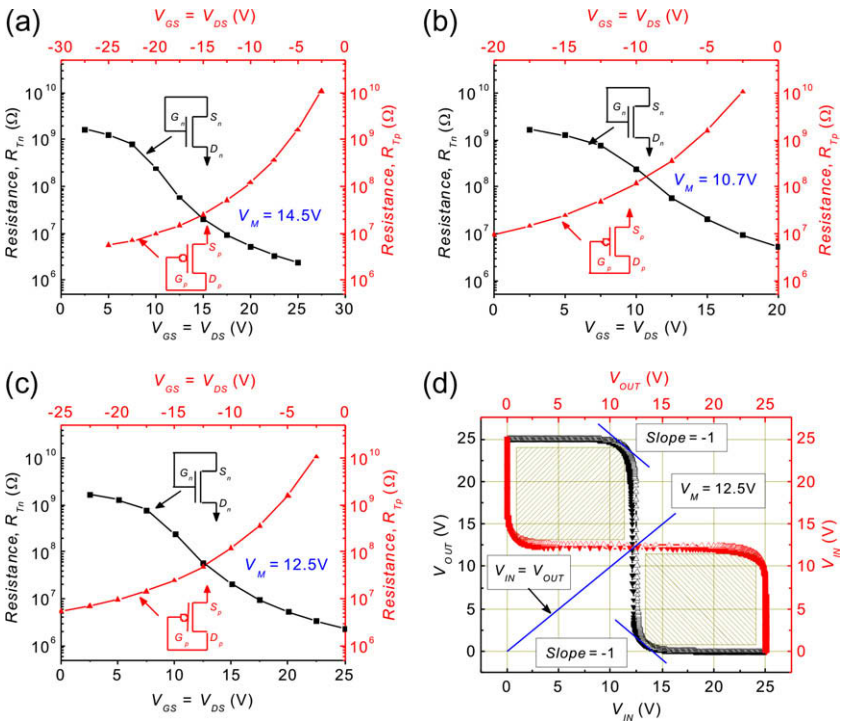

Fig. 3. Total resistance of pentacene *p*-channel and *a*-IGZO *n*-channel TFTs at $V_{GS} = V_{DS}$ by sweeping V_{GS} from (a) 0 V to ±30 V (positive for *n*-channel TFT, negative for *p*-channel TFT), (b) 0 V to ±20 V, and (c) 0 V to ±25 V (Insets show schematics of *n*- and *p*-channel TFT at $V_{GS} = V_{DS}$). (d) Bi-stable hysteresis voltage transfer characteristics at $V_D = 25$ V.

in principle requires just a pair of measurements of R_{TN} and R_{TP} as a function of $V_{GS} = V_{DS}$.

As mentioned earlier, to achieve balanced noise margins it is important to find the optimum value of V_D, such that $V_M = 0.5V_D$. To find the optimum range for V_D, a graphical solution is proposed as follows: (1) first, for a given range of $V_{DS} \in [0, \pm V_D]$ ($+V_D$ for the *n*-channel TFT and $-V_D$ for the *p*-channel TFT), the value of V_M is calculated as previously described; (2) if $V_M \neq 0.5V_D$ the range of V_{DS} needs to be adjusted. As shown in Fig. 3a, if $V_M < 0.5V_D$, then V_D needs to be decreased and the procedure start over again until $V_M = 0.5V_D$ is found. Correspondingly, as shown in Fig. 3b, if $V_M > 0.5V_D$, V_D needs to be increased and the procedure repeated until the condition $V_M = 0.5V_D$ is found. Fig. 3c shows the values of R_{TN} and R_{TP} extracted following this procedure for V_{DS} [0,±25 V], the range where $V_M = 0.5V_D = 12.5$ V. Note that testing at different V_D values is not really necessary once the output characteristics are measured for a large enough range of $V_{GS} = V_{DS}$. This is because the values of I_{DS} and consequently R_{TN} and R_{TP} can be interpolated from the output characteristics of the *n*- and *p*-channel TFTs. Therefore, the absolute value of the difference of R_{TN} and R_{TP}, $R_d = |R_{TN} - R_{TP}|$ can be estimated for arbitrary values of V_D. The value of V_M is given as the $V_{GS} = V_{DS}$ value where R_d reaches a minimum value. If $V_M \neq 0.5V_D$, the range of the V_D can be adjusted numerically until the condition $V_M = 0.5V_D$ is found as described before. Fig. 3d shows the measured bi-stable hysteresis voltage transfer characteristics at a supply voltage of $V_D = 25$ V. The cross-hatched rectangles, defined by the

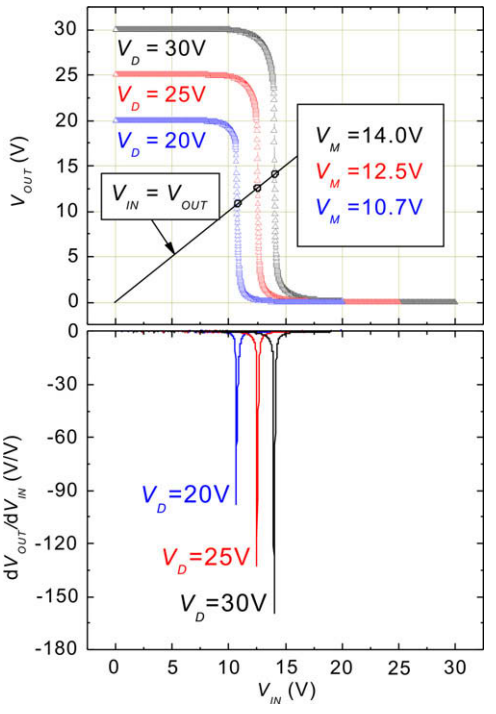

Fig. 4. Voltage transfer characteristics and static gain of the hybrid complementary inverter.

negative slope criteria [13,14], are used to determine a graphical solution of the noise margins for a given inverter characteristic. At $V_D = 25$ V, the inverters show identical noise margin low (NM_L) and noise margin high (NM_H) of 10.5 V (84% of their theoretical maximum). These values are among the highest values obtained in organic, or hybrid inverters. Fig. 4 shows the measured voltage transfer characteristics and static gain values of the inverter for $V_D = 20$, 25, and 30 V. The maximum static gain values for $V_D = 20$ and 30 V are -100 V/V at $V_M = 10.7$ V and -165 V/V at $V_M = 14.5$ V, respectively. The corresponding values of NM_H and NM_L are 7.5 and 9.4 V for $V_D = 20$ V, and 13.9 and 11.4 V for $V_D = 30$ V. As expected from a shift of V_M from its optimum value, unbalanced noise margins are obtained when $V_D \neq 25$ V. While higher gain values are obtained at larger V_D values, from a circuit operation perspective the best compromise is obtained when balanced noise margins are achieved. At the switching threshold voltage values, $R_{TP} = R_{TN}$ are 164, 54.3, and 23.5 MΩ for $V_D = 20$, 25, and 30 V, respectively. From these values we estimated a maximum dissipated power of 1.22, 5.76, and 19.1 μW for $V_D = 20$, 25 and 30 V respectively.

4. Conclusion

In summary, we demonstrated organic–inorganic hybrid complementary inverters fabricated on flexible PES substrates that use *n*- and *p*-channel TFTs with channels having different aspect ratios to achieve high static gains and balanced high noise margins. With a Si_3N_4 gate dielectrics, *p*- and *n*-channel TFTs show saturation mobility values of 0.13 and 3.8 cm^2/Vs. We also proposed a new approach to find the switching threshold voltage and the optimum value of V_D to operate a complementary inverter. Using this method, we demonstrated hybrid inverters that achieve a very high gain of 130 V/V at $V_D = 25$ V with high and balanced noise margin values of 84% of their theoretical maximum. In contrast with previous analytical methods, the proposed method does not requires fitting to any transistor model, can be implemented with a pair of measurements and should also be applicable to any complementary or complementary-like (one that uses ambipolar TFTs) inverter configuration.

those in LEC devices, which are dynamic structures that form, readjust, and dissipate in response to changes in the applied voltage [20]. Although the dynamic nature of the electrochemical doping of CPs offers many important advantages, it would for several applications be of interest to permanently stabilize a desired doping structure that is formed during the doping process. For instance, a significant time lag between the application of voltage and attainment of a stable response (e.g., current rectification and/or light emission), during which the doping structure is built *via* a redistribution of mobile ions, is an obvious drawback in applications where a fast and consistent behavior is important. Immobilization of ions is the key to the stabilization of an electrochemically induced doping structure in CPs in general and LECs in particular. More specifically, ion mobility is an obvious prerequisite during the doping process, but the subsequent stabilization of a desired doping structure requires that the mobility of the ions is eliminated.

Gao and co-workers were the first to demonstrate LEC devices with stabilized doping structures, when they utilized the temperature dependence of the ion mobility of lithium-salts in a poly(ethylene oxide) (PEO) matrix, thereby establishing the so-called "frozen-junction" concept [23,24]. They formed the p–n junction at room temperature, at which the lithium-salt ions exhibit a reasonable mobility in the PEO matrix. When the device is subsequently cooled to a low temperature with the bias maintained, the ion mobility drops to essentially zero [23,24]. A number of subsequent studies on the topic of frozen-junction operation have appeared in the scientific literature, but the concept currently suffers from an impractical sub-ambient operation temperature and/or limited long-term stability [25–30]. An alternative novel approach for doping structures with room temperature stability, conceptualized by Cheng and Lonergan, includes the employment of a bi-layer structure comprising charge-complementary ionic CPs and a subsequent solvent-induced removal of the mobile ions [31]. However, the plausibly most practical and generic route towards permanently stabilized doping structures, as introduced by Leger et al., involves a "chemical stabilization" route [32–35]. In the pioneering paper [33], it was the dopant counter-ions (being polymerizable ion-pair monomers) that were chemically modified and effectively locked in place *via* a polymerization reaction. In a later study, Yu et al. have demonstrated that it is possible to attain stabilized doping *via* chemical cross-linking of the ion-transport material (in the form of a polymerizable small molecule) [36].

In this article, we report results on an expanded study of the merits of the chemical stabilization concept. We evaluate and compare the performance of LEC devices comprising light-emitting p–n junctions built and stabilized in accordance with the approaches of Leger et al. and Yu et al., as well as by two new approaches. We find that the best performing LEC devices, from the viewpoints of light-emission, current rectification, and long-term stability, are those that utilize a combination of polymerizable ions, a polymerizable ion-transport material, and a radical-initiator compound.

2. Material and methods

2.1. Ion-pair monomer synthesis

The ion-pair monomer (i.e., the polymerizable salt) 2-(methacryloyloxy)ethyl trimethylammonium 2-acrylamido-2-methyl-1-propane sulfonate (METMA/AMPS) was synthesized in accordance with a previously published procedure [37,38]. About 0.250 g (1.47 mmol) silver nitrate and 0.060 g (1.5 mmol) sodium hydroxide were mixed together in 10 ml of water in darkness, and the resulting silver hydroxide precipitate was filtered over a frit. The recovered silver hydroxide was added to 0.20 g (0.95 mmol) AMPS-H (Aldrich), which had been dissolved in 2 ml water and treated twice with activated carbon. The mixture was stirred in an ice bath for 4 h to yield AMPS-Ag. 0.21 g (1.0 mmol) METMA-Cl (Polysciences) dissolved in 5 ml water was added drop wise to the AMPS-Ag mixture, during which precipitation of silver chloride was observed. This mixture was stirred for 3 h in an ice bath, where after the silver chloride was filtered away and the water allowed to evaporate under vacuum at room temperature. A glassy solid material was extracted using acetone, and this material was subsequently recrystallized to yield a white solid METMA/AMPS compound in a yield of 60%. ^{1}H NMR (D_2O): δ 5.60 and 6.06 (m, 5H, vinyl-H), δ 4.53 (s, 2H), δ 3.69 (s, 2H), δ 3.32 (s, 2H), δ 3.13 (s, 9H), δ 1.81 (s, 3H), δ 1.38 (s, 6H).

2.2. Materials

The CP used throughout this study was a decyloxyphenyl substituted poly(1,4-phenylene vinylene) termed superyellow (SY, Merck, Darmstadt, FRG), and it was used as received. The ion-transport materials, poly(ethylene oxide) (PEO; $M_w = 5 \times 10^6$ g/mol), poly(ethylene glycol) diacrylate (poly-PEO; $M_w = 575$ g/mol) and trimethylolpropane trimethacrylate (TMPTMA), were all purchased from Aldrich (Steinheim, FRG) and used as received. The salt lithium trifluoromethanesulfonate ($LiCF_3SO_3$; Alfa Aesar, Karlsruhe, FRG) was dried at $T = 473$ K under vacuum before use. The radical-initiator 2,2′-azobis(2-methylpropionitrile) (AIBN) was purchased from Serva (Heidelberg, FRG) and used as received. Fig. 1 presents the chemical structures of the compounds used for the fabrication of the LEC devices.

2.3. Device preparation and measurements

The solutions for the fabrication of the presented LEC devices (see Table 1) were prepared by mixing the below listed master solutions in appropriate amounts. System (A): 5 mg/ml SY in chlorobenzene (CB), 10 mg/ml PEO in CB, and 5 mg/ml METMA/AMPS in CB. System (B): 5 mg/ml SY in toluene, 10 mg/ml PEO in cyclohexanone (CH), 5 mg/ml METMA/AMPS in CH, and 10 mg/ml AIBN in CH. System (C): 5 mg/ml SY in tetrahydrofuran (THF), 10 mg/ml TMPTMA in THF, and 10 mg/ml $LiCF_3SO_3$ in THF. System (D): 5 mg/ml SY in toluene, 10 mg/ml PEO in CH, 5 mg/ml METMA/AMPS in CH, and 10 mg/ml AIBN

in CH. The solutions were stirred on a magnetic hot plate at $T = 323$ K for at least 5 h immediately before the deposition.

The indium tin oxide (ITO) coated glass substrates (1.5×1.5 cm^2, 20 Ω/square; Thin Film Devices, Anaheim, CA) were cleaned by sequential ultrasonic treatments at

room temperature in detergent (Extran MA 01, Merck), acetone, and isopropanol. The LEC devices were fabricated in a sandwich cell architecture by spin-coating solution onto an ITO-coated glass substrate for 60 s at 800 rpm (for active materials of systems (A), (B) and (D)) or 2000 rpm (for active materials of system (C)). The resulting active material film was thereafter dried at $T = 333$ K for at least 5 h. The thicknesses of the active material films, as established by atomic force microscopy, were: 200 nm (system (A)), 120 nm (system (B)), 100 nm (system (C)), and 120 nm (system (D)). Aluminium electrodes were deposited on top of the film by thermal evaporation at $p < 2 \times 10^{-4}$ Pa. All of the above device preparation procedures, except the cleaning of the substrates, were carried out in two interconnected N_2-filled glove boxes ($[O_2] < 3$ ppm, $[H_2O] < 0.5$ ppm). Device measurements were performed under

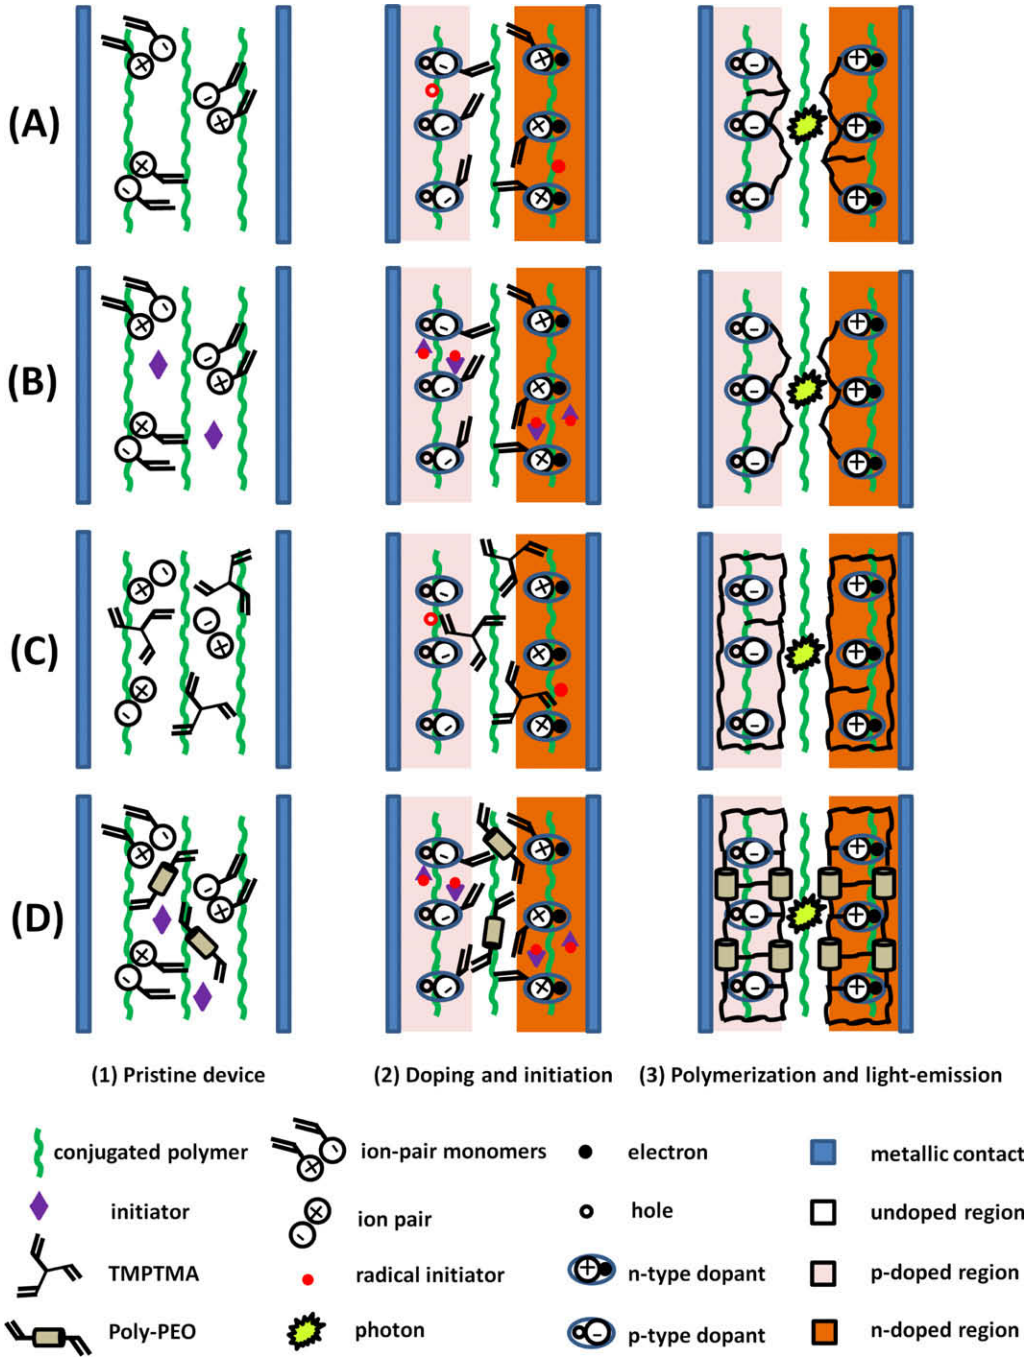

Fig. 2. Schematic illustration of the doping and chemical stabilization processes in the four types of baseline LEC systems (A–D) under study. Note that the dopant radical-initiators depicted in the second column of (A) and (C) correspond to injected holes and electrons, and are as such in reality charge-compensated by counter-ions in close proximity. For clarity, we have chosen to omit these ions from the schematic.

vacuum ($p < 10^{-3}$ Pa) in an optical-access cryostat (Advanced Research Systems). A computer-controlled source-measure unit (Keithley 2400) in combination with a calibrated photo-diode with an eye response filter (Hamamatsu, S9219–01) connected through a current-to-voltage amplifier to a HP 34401A digital multimeter were employed for the optoelectronic characterization of the devices. The scan rate for the *I–V* measurements presented in Figs. 3–6 was 0.5 V/s.

3. Results and discussion

We report results on four different types of baseline systems, for which the permanent stabilization of the doping profile was attempted in accordance with the following basic principles: (A) Chemical cross-linking of ion-pair monomers (i.e., a polymerizable salt); (B) chemical cross-linking of ion-pair monomers utilizing an added radical-initiator compound; (C) chemical cross-linking of the

ion-transport material; and (D) chemical cross-linking of ion-pair monomers and the ion-transport material utilizing an added radical-initiator compound. Fig. 2 presents a schematic of our view on how the initial doping and the subsequent stabilization of the doping should be attained.

For clarity, we have chosen to present data (and experimental detail) for only one device structure for each system group. However, it is appropriate to point out that we have tested a large number of different device structures under different biasing conditions, and that the presented data represent the "best" performing device in each system group. Moreover, in order to accommodate a straightforward comparison and evaluation of the different system groups from a stabilized doping and functional device perspective, we have chosen to focus on a number of distinct device properties, specifically the current rectification ratio (RR), the initial brightness following the pre-bias step, the retained brightness after a 12 h period of storage under open-circuit condition, and the current efficacy for light-emission. These values for the best performing device structures in each group are summarized in Table 1 above, and the performance of each device structure is discussed in detail in the following four sections.

3.1. System (A): cross-linking of ions

Leger and co-workers [33] introduced an innovative concept for the permanent stabilization of a p–n junction doping profile in LEC devices, when they replaced the conventionally used "inert" salt (typically an alkaline metal salt or an ionic liquid) with an ion-pair monomer that can be polymerized *via* radical initiation. Following a pre-bias period, such LEC devices exhibit uni-polar light-emission and a high current rectification ratio of RR > 100 at high operating voltage, which are both indicators of stabilized doping. The authors proposed that the polymerization of the ion-pair monomers could be initiated at the site of the electrochemical doping of the conjugated polymer, since the hole and electron dopants in effect are highly reactive radicals that presumably can initiate a polymerization reaction of the ion-pair monomers in accordance with the process depicted in Fig. 2A.

We have utilized METMA/AMPS as the ion-pair monomer and fabricated sandwich cells with an active material blend, comprising SY, PEO, and METMA/AMPS in a (1:0.4:0.1) mass ratio, sandwiched between an ITO anode and an Al cathode. The devices were initially "pre-biased" at $V = +10$ V at room temperature for an extended period of 1.5 h (data not shown). During the pre-bias period the current is observed to increase significantly with time in a continuous fashion, and at the end of the pre-bias period the device begins to emit light. These are well-known fingerprints of a functional LEC device, and it is accordingly clear that the employed METMA/AMPS ion-pair monomer: (i) exhibits ionic mobility in the active material, and (ii) can function as counter-ions to accommodate electrochemical doping of SY.

The data displayed in Fig. 3 (and summarized in Table 1) for the device of system (A) were recorded after the pre-bias had been removed. In agreement with the results presented by Leger et al., we found that a pre-biased device exhibited uni-polar light-emission, i.e., it only emitted light when biased with the same voltage polarity as it had been pre-biased. In contrast, conventional LECs comprising mobile ions typically exhibit bi-polar light-emission, as the doping is reversible, and the light-emitting p–n junction accordingly can form in both bias directions [20]. However, a device based on a stabilized p–n junction doping profile is also expected to exhibit a high current rectification, but as we found a large and rather erratic current at reverse voltages up to $V < -15$ V (see Fig. 3a), the current rectification ratio was very low (and also difficult to quantify). Moreover, a practical stabilized doping profile should be stabile over time under open-circuit conditions, but we found that the brightness at $V = +15$ V had dropped to 15% of its initial value after 12 h at open-circuit (see Fig. 3b). A further drawback seen with the pre-biased devices of system (A) was that the brightness was invariably very low. This was also manifested in the turn-on voltage for light-emission (defined to be the voltage at which the device emits 1 cd/m^2), which for the pre-biased device depicted in Fig. 3 was very high at $V_{\text{turn-on}} = 11$ V.

3.2. System (B): cross-linking of ions with added initiator

The poor long-term stability of the pre-biased devices of system (A) under open-circuit conditions (see Fig. 3 and Table 1) implies that a significant fraction of the

ion-pair monomers were not polymerized during the pre-bias step. Moreover, the low brightness indicates that the assumed polymerization mechanism with onset *via* dopant radical initiation might not be preferable, as this process plausibly damages the fluorescent and/or electronic-transport capacity of the conjugated polymer (here, SY). In order to rectify these problems, and to attain a higher degree of polymerization and a more stable doping profile as well as higher brightness, we chose to investigate the effects of adding AIBN as a radical-initiator to the active material blend. The expectation was that the AIBN initiator would assist in the formation of an extended and stabile cross-linked chemical network between the different ion-pair monomers without including – and potentially damaging the electroluminescent properties of – the conjugated polymer, as illustrated in Fig. 2B.

A sandwich cell, comprising an active material blend of SY, PEO, METMA/AMPS, and AIBN in a (1:0.17:0.06:0.003) mass ratio sandwiched between an ITO anode and an Al cathode, was pre-biased at $V = +10$ V for 1.5 h at $T = 360$ K. The employment of the elevated temperature was motivated by that the decomposition of AIBN into two free-radical fragments and the related rate of the subsequent radical-initiated polymerization will both increase with increasing temperature. During the pre-bias period the current and brightness were found to increase with time, in a similar fashion as for the device of system (A). The turn-on time for light-emission was, however, notably faster, which can be attributed to a significantly higher ion mobility of the METMA/AMPS ion-pair monomer in an amorphous PEO matrix (at $T = 360$ K), as compared to a semi-crystalline PEO matrix (at room temperature) [16].

The typical performance of a pre-biased device of system (B) is shown in Fig. 4 and summarized in Table 1. Following the removal of the pre-bias, it exhibited uni-polar light-emission, a relatively high current efficacy for a conjugated-polymer-based LEC of 1.1 cd/A at $V = +10$ V, and a notably increased brightness. (Note the expanded voltage range in Fig. 3.) However, although the overall performance of pre-biased devices of system (B) was improved in comparison to devices of system (A), it was still not satisfying. The latter is exemplified by the large and rather erratic current that was once again observed at reverse voltages, which precluded a meaningful establishment of a current rectification ratio. The long-term stability was furthermore not impressive, as manifested in the brightness that dropped to 2% of its initial value after 12 h storage under open-circuit conditions.

3.3. System (C): cross-linking of the ion-transport material

Yu and co-workers [36] recently demonstrated an alternative approach for the attainment of chemically stabilized doping structures in LEC devices, when they employed a polymerizable "small molecule" ion-transport material in combination with a non-polymerizable alkaline salt as the electrolyte. In the seminal study, the liquid trivinylic monomer TMPTMA was utilized as ion-transport material instead of the commonly employed PEO. The chemical structure of TMPTMA is presented in Fig. 1. Its three methacrylate groups can readily be polymerized into a rigid, covalently cross-linked network that effectively impedes diffusion of other molecules. The authors demonstrated pre-biased LEC devices with rather impressive stability and relatively high light-emission efficiency following this concept, and it was proposed, in analogy with the physical "frozen-junction" approach [13,24,39], that the stability resulted from an effective elimination (freeze-in) of the ion-transport capacity of TMPTMA when it was spatially immobilized *via* polymerization [36].

We have fabricated sandwich cells with an active material blend, comprising SY, TMPTMA and $LiCF_3SO_3$ in a (1:0.5:0.1) mass ratio, sandwiched between an ITO anode and an Al cathode. The devices were pre-biased at $V = +12$ V at room temperature for almost 4 h. At the end of the pre-bias period, the light-emission intensity and the current exhibited a drastic rapid increase to high values, in agreement with the observation for a similar system in Ref. [36], but it is notable that the elapsed time up to this point was markedly longer in our experiments. We attribute this difference to a thicker active material in the herein studied devices, which is concomitant with a lower ionic conductance and a slower turn-on time [40].

The data for a typical pre-biased device of system (C) are displayed in Fig. 5 and summarized in Table 1. The sandwich cell device showed promising uni-polar current and emission characteristics, and the current rectification ratio was rather high (RR = 700 at $V = \pm 10$ V). These data are in good qualitative agreement with those reported by Yu et al. on a similar system, but the quantitative values for the brightness and current efficacy were lower in the experiments reported here. Furthermore, the p–n junction doping profiles in system (C) are considerably more stabile over time in comparison to systems (A) and (B), as evidenced by the brightness drop by only 14% from its initial value after 12 h under open-circuit conditions.

3.4. System (D): cross-linking of ions and ion-transport material with added initiator

Inspired by the promising results for devices of system (C), we attempted to combine the approaches taken in systems (B) and (C). In other words, we simultaneously employed a polymerizable ion-pair monomer (METMA/AMPS), a polymerizable ion-transport compound (poly-PEO), and a radical-initiator compound (AIBN) in addition to the conjugated polymer (SY) as the active material. The goal was to induce a doping profile by the pre-bias, which would at the end of the pre-bias period include both the ions and the ion-transport material as integral parts of a large and interconnected immobile ionic network. We further hoped that the addition of the radical-initiator compound would facilitate an efficient and complete polymerization and eliminate the need for polymerization initiation *via* dopant radicals generated on the conjugated polymer SY, as we suspected that a dopant-initiation could lead to quenching of the electroluminescence and result in low brightness and current efficacy values. An idealized view of the operation and stabilization of such an LEC is illustrated in Fig. 2D.

Sandwich cells, with (SY:poly-PEO:METMA/AMPS:AIBN) in a (1:0.17:0.06:0.003) mass ratio as the active material positioned between an ITO anode an Al cathode,

were pre-biased at $V = +5$ V for 2 h at room temperature. The current and brightness increased in a continuous manner during the initial part of the pre-bias period, but at the end of the period they stabilized at essentially constant values, which were taken as an indicator of stabilized doping.

The data displayed in Fig. 6 and Table 1 were recorded after the pre-bias had been removed. Such pre-biased devices exhibited notably well-behaved uni-polar current and emission characteristics, as for instance quantified by an excellent current rectification of RR = 1900 at $V = \pm 10$ V. Moreover, the brightness and current efficacy for the pre-biased devices of system (D) were clearly higher than in the other investigated systems, and the stability over time was relatively impressive as the drop in brightness after 12 h under open-circuit was a mere 13%, with the major drop taking place during the first 2 h following the removal of the pre-bias. Thus, the overall performance of stabilized devices of system (D) was superior to the other investigated systems (see Table 1), although it is clear that further improvement in the long-term stability of the doping structure is clearly needed for practical applications. It should also be noted that the optoelectronic performance of these stabilized devices are not yet on par with state-of-the-art dynamic LEC devices, as demonstrated by that turn-on voltages of the order of the band-gap potential and current efficacies of the order of 3–9 cd/A have recently been reported for various manifestations of dynamic-junction LECs based on the same conjugated polymer SY [41–43].

4. Conclusions

We have systematically tested, evaluated, and compared a number of different "old" and new approaches for the attainment of a chemically stabilized doping structure in LEC devices. We found that the pioneering concept of chemically connecting the dopant counterions *via* utilization of polymerizable ion-pair monomers alone resulted in light-emitting devices with poor stability and low brightness. The addition of a radical-initiator compound to this type of active material blend improved the brightness, presumably because the emissive conjugated polymer is relieved of the role of acting as radical initiation site for polymerization; however, the stability remained poor. The alternative concept of employing a small molecule ion-transport material that can be cross-linked into large and immobile polymeric structures during the initial pre-bias operation yielded distinctly improved results in the form of a high current rectification ratio and a decent stability under open-circuit conditions. The best performance was, however, attained from a device that combined all of the above concepts, as its active material comprised polymerizable ion-pair monomers, a cross-linkable ion-transport material, and a radical-initiator in addition to the conjugated polymer. Such chemically stabilized devices exhibited a highly respectable current rectification ratio of almost 2000, a good light-emission efficiency, and a decent long-term stability under idle conditions.

Acknowledgments

The authors wish to thank Jeroen Verhage and Ryan Chadwick for valuable preliminary experiments in the synthesis of ion-pair monomers, and Andreas Sandström for assistance with the LEC characterization. The authors are grateful to Kempestiftelserna, Carl Tryggers Stiftelse, and the Swedish Research Council (Vetenskapsrådet) for financial support. a flexible OLED panel using a gravure printed light emitting polymer [8]. No formulation details or efficiency values were reported, but the device operated at 100 cd/m^2 for 1000 h. Indium-tin oxide (ITO) nanoparticles have been successfully printed on flexible substrates [9]. Tuomikoski et al. reported OLEDs with printed poly (3,4-ethylene dioxythiophene): poly (styrene sulfonate) (PEDOT:PSS) and a polyfluorene light emitting polymer on these substrates [10]. These achieved a maximum electroluminescent quantum efficiency of 0.1% and a luminance of 100 cd/m^2 at a drive bias of 5 V. Recently, OLEDs with printed PEDOT:PSS and an unidentified light emitting polymer have also been fabricated [11]. Although no efficiency values were reported, the devices achieved 100 cd/m^2 at a drive bias of 4.2 V and a maximum luminance of 5000 cd/m^2.

Despite these advances, device performance so far has been relatively poor and no luminosity (lm/W) or luminous efficiency (cd/A) values have been reported. There has also been minimal discussion on the development of ink formulations and what may be occurring during film formation and drying.

Here we report in detail the gravure contact printing of the hole injection layer and the organic emissive layer for high performance, flexible, polymer light-emitting diodes (PLEDs). We develop a wide range of PEDOT:PSS and light emitting polymer printing formulations which, when optimised, achieve highly uniform films of appropriate thickness and very low surface roughness. We explain and discuss these formulations in terms of such factors as substrate wetting and lateral Marangoni forces. Our optimised devices have an identical performance to spin-coated control devices. They also achieve maximum luminosity and luminance values in the range reported for state-of-the-art green-emitting flexible PLEDs.

2. Experimental

2.1. Materials

The PEDOT:PSS (Baytron Clevios™ AI4083) dispersion was purchased from H.C. Starck GmbH. Triton X-100 and other solvents were obtained from Sigma–Aldrich. Substrates were polyethylene terephthalate (PET) coated in sputtered ITO (R_s = 40–60 Ω/sq) OC50 films from CPFilms Inc. The ITO on PET substrates were first etched by hydrochloric (HCl) acid diluted with DI water at a ratio of 2:1 (HCl:DI water) for 80 s to form ITO stripes, defined by acid resistant tape, with a width of 0.8 mm. They were then cleaned with acetone and IPA in an ultrasonic bath and then washed with deionized (DI) water. This was followed by oxygen plasma treatment using an Emitech K 1050X plasma asher.

2.2. LED preparation and characterization

Printing was with a Labratester I from Schläfli Maschinen. Cleaned substrates were printed with PEDOT:PSS formulations using a steel cliché with an engraved pattern of 70 or 90 lines/cm of tetragonal shaped cells with a width of about 140 and 110 μm, respectively, and depth of 35–40 μm. This was at a printing speed of 35 m/min. After baking at 75 °C for 10 min in air, the LEP formulations were printed using a cliché with an engraved pattern of 40 lines/cm of tetragonal shaped cells with a width of 250 μm and depth of 60–70 μm at the same speed. The cliché surface area is about 17 cm × 23 cm. The total engraved area is about 12 cm × 12 cm. Film thicknesses were measured by profilometer-calibrated optical absorption using an ATI Unicam UV–Vis spectrophotometer. For reference devices, 55 ± 5 nm layers of PEDOT:PSS were deposited by spin-coating at 2000 rpm and then baked at 75 °C for 10 min in air. 75 ± 5 nm layers of LG1300 were deposited by spin-coating at 2500 rpm a 1.15 wt% LEP in *p*-xylene solution. Layer thicknesses were measured by a Tencor Instruments Alpha Step 200 surface profilometer (accuracy ±10%).

After deposition of LG1300, all samples were transferred to a nitrogen atmosphere glove box (<2 ppm H_2O, <0.1 ppm O_2) to anneal at 120 °C for 1 h. The cathode of 10 nm Ca followed by 100 nm Al was then thermally evaporated (vacuum pressure 4×10^{-6} mbar) with a shadow mask to define electrodes of 4.2 mm^2 (3 mm × 1.2 mm) area. JVL measurements were performed using a Keithley 2410 Source-Measure Unit and a Topcon BM-9 luminance meter. PLEDs were assumed to be Lambertian sources. No cavity effects were observed. Electroluminescent emission spectra were recorded using a Keithley 2400 SourceMeter an Ocean Optics USB 2000 charge-coupled device spectrophotometer.

Additional demonstration devices were fabricated with a larger light emission area of 0.42 cm^2 (width: 1.4 cm, height: 0.3 cm).

2.3. Contact angle measurement and morphology

Contact angle measurements and wetting envelope calculations were performed with a Krüss DSA 100. The surface energy of the substrates were calculated by measuring the contact angle of the Sessile droplet using threes reference fluids (water, diiodomethane and ethylene glycol). For the surface energy of PEDOT:PSS surface, only diiodomethane and ethylene glycol were used as water is likely to swell the polymer layer. These two fluids were found to have a negligible effect on the polymer surface after the films had been thermally annealed. The surface tension (SFT) of the different formulations were calculated by measurements using the Pendant droplet method. The SFT of the fluid was then analyzed to obtain its polar and dispersive components by measuring the contact angle of the fluid on Teflon substrate using the Sessile droplet method. Wetting envelopes of the substrates were calculated from these measured surface energy components using the Fowkes method. All SFT values are listed in Supplementary Tables S1 and S2. The tapping mode atomic force microscope (AFM) measurements were conducted using a Nano-R™ AFM from Pacific Nanotechnology. A Zeiss Axioplan Microscope with a Nikon Coolpix P5100 digital camera was used to capture micron scale surface images.

3. Results and discussions

3.1. Gravure printing process and printing of PEDOT:PSS

The gravure printing process is illustrated in Fig. 1a. Unlike spin-coating or ink-jet printing it is a contact technique. The printer configuration used in this work (i) consists of a planar cliché (printing plate) and a flexible substrate attached to a freely-rotating cylindrical drum. Upon printing the cliché moves to the left and doctor blade (used to scrape ink into the cliché ink cells (ii)) and substrate drum move to the right. The tetrahedral cells (typical width 50–200 μm) on the cliché surface form the pattern to be printed. The substrate and cliché are then pressed together (iii), the lower surface energy of the substrate relative to the cliché and the shear forces pulling the ink onto the substrate. The ink droplets deposited from the cells then coalesce (iv), form a continuous layer of thickness 5–10 μm (v), the solvents evaporate (vi) depositing a thin film of the solute (vii).

PEDOT:PSS is the standard hole injection layer material used in PLEDs, being deposited between the transparent indium-tin oxide (ITO) anode contact and the light emitting polymer (LEP) (Fig. 1b and c). It planarizes the anode surface, allows better adhesion between anode and LEP, and improves hole injection into the LEP by increasing the anode work function to 5.1–5.2 eV [12,13]. Commercial PEDOT:PSS formulations developed for spin-coating are water based with a high surface tension of 70–80 mN/m. Initial attempts to gravure print the unaltered formulations on untreated ITO gave very poor results.

This can be explained by considering the surface tension (made up of polar σ_p and dispersive σ_d components) of the unaltered PEDOT:PSS formulation (point A) and the surface-energy wetting envelope (calculated using the Fowkes method) of the untreated ITO shown in Fig. 2a. The formulation lies far outside the wetting envelope and as result dewets. To vary the surface energy, the ITO was exposed to an oxygen plasma [2,14]. Fig. 2a shows the resultant wetting envelopes for 30 and 50 W exposure for 1 min. The plasma treatment increases the oxygen content of the ITO, greatly increasing its polar component and decreasing its dispersive component. This increases the surface energy envelope towards the unaltered PEDOT:PSS formulation, but it still lies outside. Gravure printing the unaltered formulation is shown in Fig. 2b(i). The result is still very poor, the film breaking up into large non-uniform streaks in the printing direction. Although not as extreme as the untreated ITO situation, solution surface tension is still too large compared to the substrate surface energy.

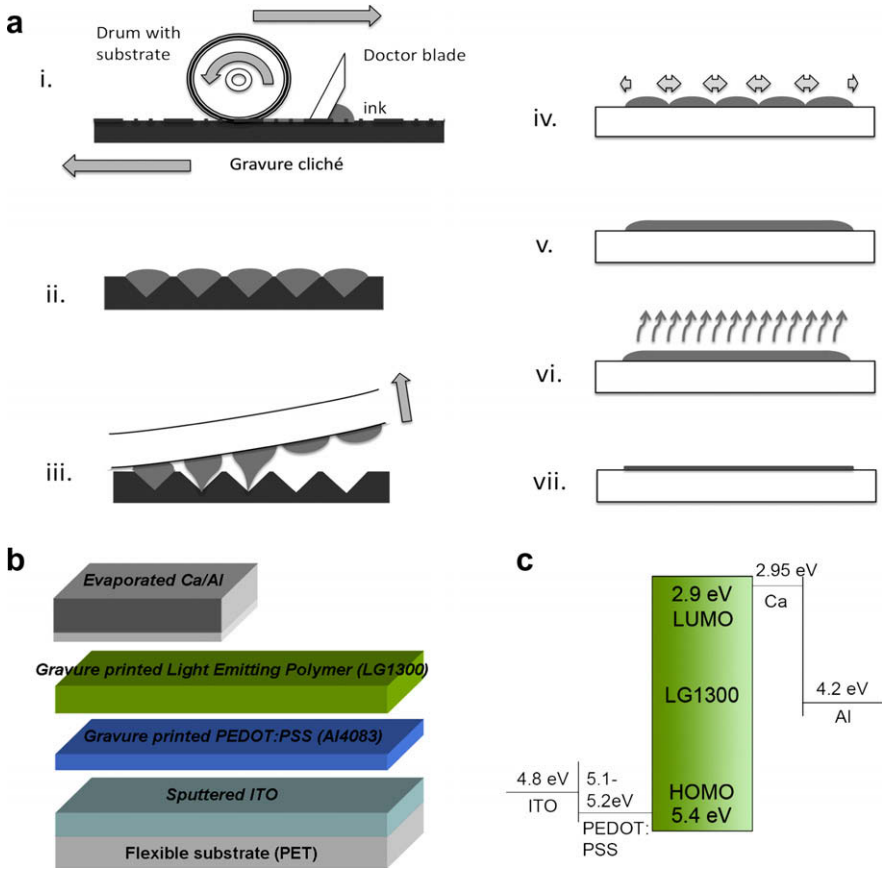

Fig. 1. (a) Gravure printing process. (b) Structure of gravure printed PLEDs. (c) Energy level diagram of the printed PLED consisting of ITO (anode), PEDOT:PSS (hole injection layer), LG1300 (LEP), Ca (cathode) and Al (capping layer).

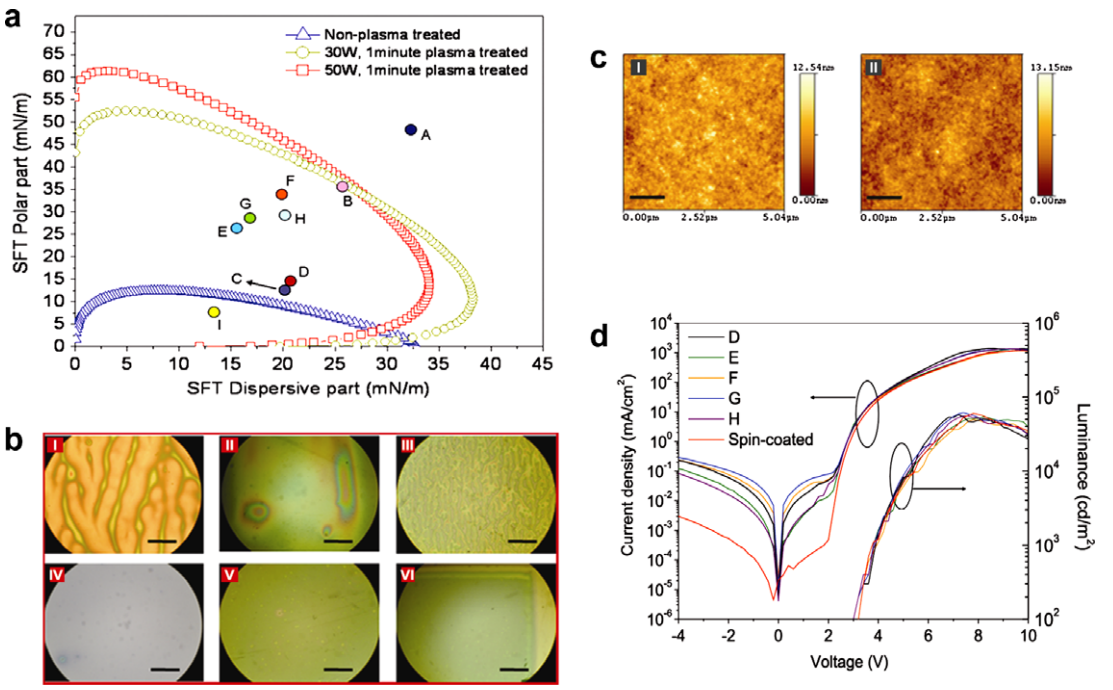

Fig. 2. (a) Wetting envelopes of oxygen plasma treated ITO on PET substrate with various surface tensions of mixtures: Pristine PEDOT:PSS (AI4083), A; This was modified (vol.%) at 5 (PEDOT:PSS): 1 (solvent) ratio with ethylene glycol, B; Triton X-100, C; IPA, D; ethanol, E; methanol, F; acetone, G; acetonitrile, H; vol.% of 10 (PEDOT:PSS): 5 (IPA): 1 (Triton X-100) ratio, I. (b) Optical microscopic images from these printed PEDOT:PSS formulations: i, A; ii, B; iii, C; iv, D; v, I; vi, edge of I; (scale bar indicates 1 mm). (c) AFM images of spin-coated (i) and gravure printed formulation D (ii) (scale bar indicates 1 μm). (d) Performance of PLEDs with spin-coated and printed PEDOT:PSS (formulations as above) and spin-coated LEP.

PLEDs have been fabricated with spin-coated films of PEDOT:PSS formulations blended with ethylene glycol [15,16]. PEDOT:PSS mixed with ethylene glycol (5:1 ratio by volume) lies just inside the wetting envelope (see Fig. 2a, point B). The printed formulation (Fig. 2b(ii)) gives poor coverage and large regions of different thickness. Ethylene glycol has a high boiling point (B_p = 197.3 °C) and will take a long time to evaporate. Mixing a water-based formulation with a higher boiling point, lower surface tension solvent is expected to oppose solution spreading due to the Marangoni effect [17] which, especially when combined with de-pinning of the contact line [18] and a slow evaporation rate [19], will pull the solute inwards during drying [20]. These effects along with the small difference between surface tension and substrate surface energy are likely to result in this unevenness.

Triton X-100 [21] is a viscous non-ionic detergent with a high boiling point ($B_p \geqslant 200$ °C). It has both hydrophilic and hydrophobic endgroups, which should allow a change in the balance between surface tension and surface energy favoring better wetting. A formulation of PEDOT:PSS mixed with Triton X-100 (5:1 by volume) lies deep within the wetting envelope (Fig. 2a, point C). The printed formulation (Fig. 2b(iii)) gives good overall coverage, but the film is non-uniform and has broken up into fine interconnected streaks aligned in the printing direction. This is again a high boiling point, low surface tension solvent, which will take a long time to dry and will have the same spreading issues as ethylene glycol.

However, surfactants can disrupt the surface tension driven Marangoni forces at very low concentrations [22]. Certainly the large scale aggregation and poor coverage found for ethylene glycol is not seen here. The fine streaks in Fig. 2b(iii) are of approximately the same width as the cliché ink cells (200 μm), indicating that it is at the moment of printing (Fig. 1a(iii)–(iv)) where this formulation has failed. We note that at the concentrations here the surfactant should form a close packed monolayer at the air–liquid interface with the hydrophobic head groups on the air side and the hydrophilic tail groups on the water side. During printing it will be torn out of the ink cells onto the substrate, which will involve considerable shear forces. This is likely to disrupt the monolayer, intermixing the surfactant with the liquid. Even if this intermixing does not occur and the monolayer is intact, it then faces the problem that what was the air–liquid interface is now the substrate–liquid interface. The droplet has been inverted. This will not only change the wetting properties at the moment of printing but may disrupt the spreading of the film if the monolayer cannot reorganize itself onto the air–liquid interface sufficiently quickly. We suggest that these type of effects may form a possible explanation as to why this printed formulation, combined with its high boiling point and low surface tension, retains some memory of the cliché ink cells.

To stay deep within the wetting envelope and also avoid high boiling point solvents, the PEDOT:PSS formulation was blended with IPA (B_p = 82.4 °C). Fig. 2b(iv) shows a gravure printed film of PEDOT:PSS mixed with IPA (5:1 ratio by volume). This formulation lies within the wetting

envelope (Fig. 2a, point D). The printed films are highly uniform and show very good coverage. Similar good printing results were obtained using PEDOT:PSS blended at a 5:1 ratio by volume with low boiling point, low surface tension solvents such as ethanol (B_p = 78.5 °C), methanol (64.6 °C), acetone (56.2 °C) and acetonitrile (81.6 °C). These all lie within the wetting envelope (Fig. 2a, points E, F, G and H, respectively). The use of a lower boiling point, lower surface tension solvent will result in Marangoni forces which favor spreading and act against aggregation during drying [17]. The faster evaporation rate, which may also result in evaporative cooling and an increase in formulation viscosity [23], will additionally act against the possibility of formulation flow and aggregation during the later stages of drying (Fig. 1a(vi)). All of these factors should contribute to the observed excellent printing results. All printed PEDOT:PSS films have a thickness of 55 ± 5 nm over an area of order 1 cm^2 (within the accuracy of the profilometer this was identical to that achieved by spincoating).

The coffee-stain effect [24], a major problem found for ink-jet printing [18,20,25], was observed for some of the above films. This can be ascribed to the capillary forces and Marangoni forces acting in the same direction, depositing solute at the film edge [25]. To avoid this, the above formulations were printed with a small amount of the surfactant. PEDOT:PSS: IPA: Triton X-100 blended at a ratio 10:5:1 volume lies very deep within the wetting envelope (Fig. 2a, point I) and gives a highly uniform printed film (Fig. 2b(v)). The edge of the gravure printed film is very well defined, the surfactant disrupting enough of the Marangoni flow and lowering the contact angle at the pinning-line to avoid non-uniform deposition. The corner of the film in Fig. 2b(v) is shown in Fig. 2b(vi). This exactly follows the cell pattern of the particular plate, consisting of a large uniform area with a thin border of width 200 μm. This demonstrates the ability to print PEDOT:PSS to this resolution.

Fig. 2c shows AFM images of spin-coated and gravure printed (5:1 by volume IPA) PEDOT:PSS films. The gravure printed film shows a slightly greater thickness variation over the 5 × 5 μm^2 area, but the overall RMS roughness of about 1.2 nm is the same for both films.

The gravure printed films were tested in PLEDs with spin-coated LEP layers. The current density–voltage–luminance (JVL) characteristics are shown in Fig. 2d. All the gravure printed PEDOT:PSS devices compared very favorably against a spin-coated PEDOT:PSS device. The highest current density and luminance values for a given bias were obtained for the IPA formulation (5:1 by volume), this having the optimum bulk and interfacial morphology.

3.2. Gravure printing of LEP layer

Having successfully printed PEDOT:PSS, we next consider printing the LEP as well. The wetting envelope of the surface of PEDOT:PSS is shown in Fig. 3a. It has a less polar but more dispersive wetting envelope compared to the 50 W oxygen plasma treated ITO. This envelope

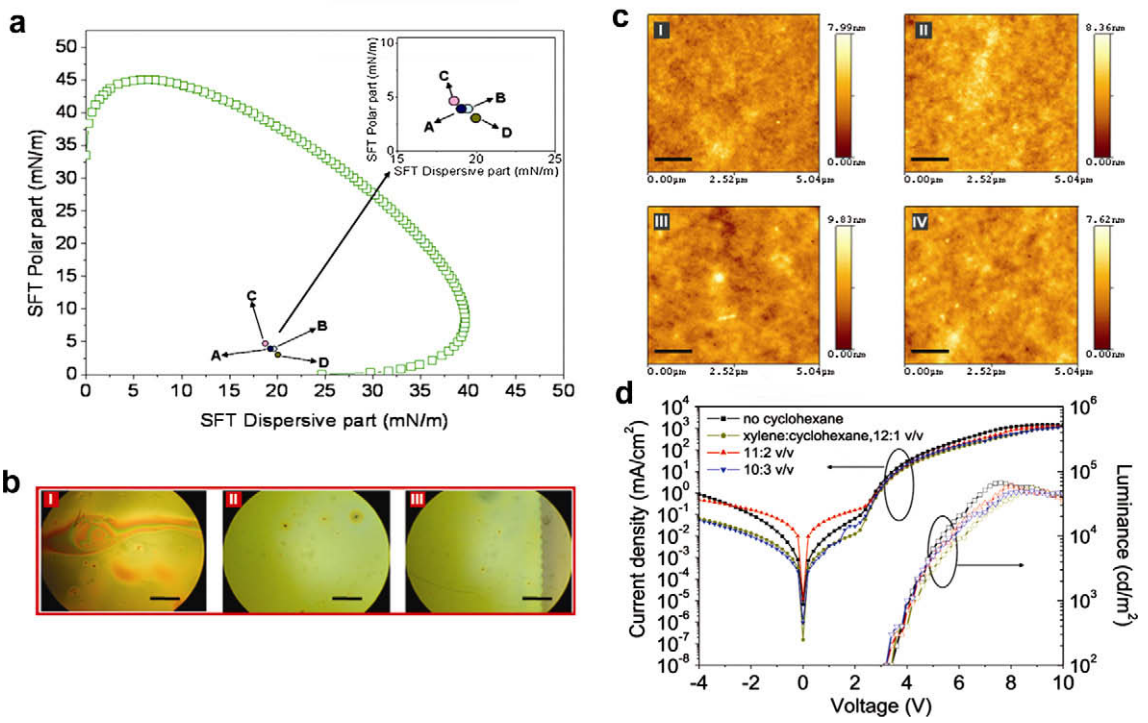

Fig. 3. (a) Wetting envelope of printed PEDOT:PSS surface with surface tensions of formulations of 0.8 wt.% LG1300 in: pure *p*-xylene, A; pure toluene, B; *p*-xylene:indan 5:1 v/v, C; *p*-xylene:cyclohexane 5:1 v/v, D. (b) Optical microscopic images of printed LG1300 formulations: i, C; ii, D; iii, edge of D; (scale bar indicates 1 mm). (c) AFM images of spin-coated (i) and printed LG1300 from pure *p*-xylene (ii) and printed LG1300 *p*-xylene:cyclohexane 12:1 v/v (iii) and 10:3 v/v (iv); (scale bar indicates 1 μm). (d) Performance of PLEDs with gravure printed LG1300 at different *p*-xylene:cyclohexane volume ratios.

encompasses a broad range of dispersive, non-polar organic solvents. The LEP used in this study was LUMATION™ Green 1300 (LG1300), a green emitting polyfluorene copolymer [26–28]. The solvents conventionally used for spin-coating LG1300 are *p*-xylene (B_P = 138.3 °C) and toluene (B_P = 110.6 °C). LG1300 formulations of *p*-xylene and toluene (0.8% by weight) lie close to each other within the PEDOT:PSS wetting envelope (Fig. 3a, points A and B). However, gravure printing of these formulations resulted in non-uniform films.

Given the results for PEDOT:PSS, solvent blends were investigated using indan (B_P = 177 °C) and cyclohexane (B_P = 80.7 °C). Fig. 3a shows the position of LG1300 formulations (0.8% by weight) of *p*-xylene blended with 5:1 ratio by volume of indan and cyclohexane (points C and D, respectively). Both lie very close to each other and the *p*-xylene and toluene points within the PEDOT:PSS wetting envelope. Fig. 3b(i) and (ii) shows gravure printed films of the blended formulations. The indan formulation produces a highly uneven, non-uniform film of poor quality. The cyclohexane formulation, however, printed with excellent homogeneity comparable to that of spin-coated films. These again follow the trend found for PEDOT:PSS: adding the lower boiling point, lower surface tension solvent (cyclohexane) produces homogeneous printing, whereas adding the higher boiling point, lower surface tension solvent (indan) produces relatively poor printing. However, compared to the successful PEDOT:PSS formulations, the difference in solvent surface energy is nearly an order of magnitude smaller so we expect a smaller Marangoni effect [20,23]. Other factors such as more rapid drying and evaporative cooling increasing the polymer solution viscosity [23] may contribute to the cyclohexane formulation being favorable.

During drying polymer solutions form surface gels at the solution–air interface [23,29]. Such surface gel formation has typically been observed to occur at higher polymer concentrations and thicker film thicknesses than used here. However, the evaporation from the surface layer of the lower boiling point, more favourable solvent component combined with the drop in temperature from evaporative cooling may be enough to drive the surface layer into this regime. If it does occur, such surface gel formation would be expected to help stabilize the drying formulation.

Evaporative cooling driven Bénard–Marangoni convection has been observed in evaporating polymer solutions of thickness >500 μm [23], but the solution thickness here of 10 μm would give a vertical Marangoni number far below the instability threshold. Vertical solution density driven Rayleigh–Bénard or Rayleigh–Taylor type instabilities [23,30,31] are also precluded by the film thickness and the continuously changing, multi-directional *g*-forces experienced in this printing method.

We also note that Fig. 3b(iii) shows the complete absence of any coffee-stain effect, consistent with a relatively low outward Marangoni flow. It means that gravure printing can achieve very well defined pixels with uniform emission over the whole device area. An additional advantage of low boiling point solvent formulations is that residual solvent removal can be done quickly at room temperature. This is vital for high-speed, R2R printing on low heat resistance, flexible plastic substrates.

Fig. 3c shows AFM images of the surface of LG1300 spin-coated from *p*-xylene (i), printed from *p*-xylene (ii) and printed from *p*-xylene blended with cyclohexane at ratios of 12:1 (iii) and 10:3 (iv) by volume. The RMS surface roughness is 0.73, 0.92, 0.88 and 0.7 nm, respectively. As the fraction of cyclohexane is increased, the gravure printed films become increasingly smooth on a sub-micron level, eventually reaching the value found for the spin-coated films. This indicates that the film uniformity and smoothness achieved with these formulations occurs on both large (>1 mm) and small scales (<1 μm).

PLEDs were gravure printed using LEP formulations with different fractions of cyclohexane (Fig. 3d). All printed LEP films had a thickness of 75 ± 5 nm over an area of order 1 cm^2 (within the accuracy of the profilometer this was identical to that achieved by spincoating). An increased fraction of cyclohexane generally decreases the current and maximum luminance values but increases device efficiency. This indicates a lower hole and/or electron current but a better charge balance and/or recombination zone position [12]. The maximum device efficiency was found to be at a ratio by volume of 10:3.

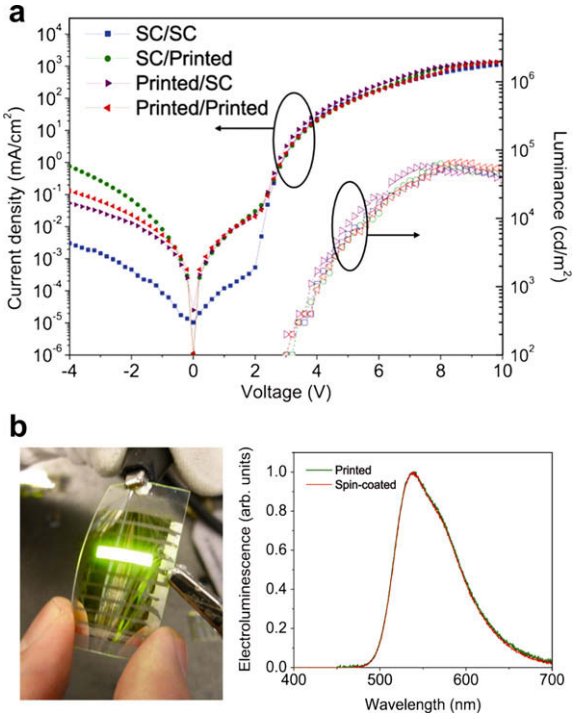

Fig. 4. (a) Performance of spin-coated and gravure printed PLEDs (PEDOT:PSS/LG1300). The formulations used for gravure printing are PEDOT:PSS (AI4083) mixed with IPA in vol.% of 5:1 (AI4083:IPA) and 0.8 wt.% of LG1300 in vol.% of 10:3 (*p*-xylene:cyclohexane). (b) Photograph of light emission from a fully printed flexible PLED (left) and electroluminescence spectrum of fully gravure printed and fully spin-coated PLEDs (right). The size of the light emission area is 0.42 cm^2 (width: 1.4 cm, height: 0.3 cm).

Table 1
Performance parameters of spin-coated and gravure printed PLEDs. The first two columns indicate the deposition methods used for the PEDOT:PSS and LG1300 layers. L_{max} is the maximum luminance achieved. η_L and η_P are the efficiency (cd/A) and luminosity (lm/W) values, respectively (reported at representative luminance of 100 and 1000 cd/m^2; the absolute maxima are also reported). The voltage values (in brackets) indicate the bias voltages applied to the devices for each measurement.

PEDOT:PSS	LG1300	L_{max} (cd/m^2)	~100 cd/m^2		~1000 cd/m^2		η_{max}	
			η_L	η_P	η_L	η_P	η_L	η_P
Spin-coating	Spin-coating	55,700 (8.6 V)	5.4 (3 V)	5.7	4.7 (4 V)	3.7	9 (7 V)	5.7 (3 V)
Spin-coating	Printing	62,800 (8 V)	5.9 (3 V)	6.2	4.9 (4 V)	3.9	8.3 (6.6 V)	6.2 (3 V)
Printing	Spin-coating	58,000 (7.4 V)	6.1 (3 V)	6.4	4.5 (3.8 V)	3.7	9.3 (6.4 V)	6.4 (3 V)
Printing	Printing	65,900 (8.6 V)	5.16 (3 V)	5.4	4.4 (4 V)	3.5	8.8 (7 V)	5.4 (3 V)

3.3. Performance comparison between gravure printed and spin-coated PLEDs

Finally, we compare PLEDs with the PEDOT:PSS and the LEP layers either spin-coated or gravure printed using the optimised formulations. Fig. 4a shows the JVL characteristics. Table 1 lists the PLED performance values. The relatively high drive bias for the maximum luminance of the PLEDs can be attributed to the poor conductivity of the ITO on PET substrates (σ = 1282 S/cm) compared to a reference ITO on glass substrates (σ = 5000–6000 S/cm). There is a higher leakage current when gravure printed layers are present, indicating increased surface roughness at the anode. However, the built-in potential just above 2 V is unchanged. When in the on state, the JV and LV characteristics of all devices are almost identical across all applied bias values. The PLED performance values in Table 1 are also similar. When both layers are spin-coated, at a display brightness of 100 cd/m^2 the devices have luminosity, efficiency and drive bias values of 5.7 lm/W, 5.4 cd/A and 3 V, respectively. When both layers are gravure printed, the values are 5.4 lm/W, 5.2 cd/A and 3 V, respectively. The maximum luminance values for fully spin-coated and gravure printed are 56,000 and 66,000 cd/m^2, respectively. The values for devices with one layer printed and one layer spin-coated cover a similar range.

State-of-the-art polyfluorene copolymer green-emitting flexible PLEDs have been fabricated on transparent barrier-layer substrates with high conductivity anodes [32]. These have achieved a maximum luminosity of 9.9 lm/W, a maximum efficiency of 10 cd/A and a maximum luminance of 20,000 cd/m^2. Our gravure printed devices achieve values of 8.8 lm/W, 5.4 cd/A and 66,000 cd/m^2, respectively. These are very comparable, even though we are using a poorer conductivity anode.

Fig. 4b also shows light emission from a device where both PEDOT:PSS and LEP layers are gravure printed. The flexible PLED has highly uniform emission over all drive voltages. The emission spectrum is also identical to the spin-coated control device.

4. Conclusions

In summary, we have shown that gravure contact printing can be used to deposit the organic layers in high performance, flexible PLEDs. We have designed multi-component formulations to print both the hole injection layer of PEDOT:PSS and the light emitting layer of a polyfluorene copolymer. The optimum formulation for PEDOT:PSS was found to consist of adding a low boiling point organic solvent to the as-purchased water-based formulation with the optional addition of a small amount of surfactant to eliminate any coffee-stain effects which can sometimes occur. The optimum formulation for the light emitting polymer was found to consist of a blend of low and high boiling point organic solvents. We suggest that the success of these formulations is due to optimising both substrate wetting, the lateral Marangoni forces and the stability of the film during drying. We were able to achieve highly uniform films with a very low surface roughness and a thickness optimised for PLED performance. Our final optimised devices have an identical performance to spin-coated control devices and achieve maximum luminosity and luminance values in the range reported for state-of-the-art, green-emitting flexible PLEDs. Recently, we have shown that Ag ink can also be gravure printed to form the gate electrode in multilayer gravure printed polymer field-effect transistors [33]. Development of low work function metal inks or other electron injection materials should allow the PLED cathode to be printed. Suitable flexible barrier-layer substrates can also be used to provide appropriate encapsulation after printing [32]. All the components necessary for the high-speed, mass production of large-area organic electronic displays and lighting are finally coming together.

Acknowledgements

The authors thank the Sumitomo Chemical Company Ltd. for providing the LUMATION™ Green 1300 (LG1300) light emitting polymer and Professor Jenny Nelson for experimental support. We also thank Dr. Monika Voigt, Dr. Jongin Hong and Justin Dane for useful discussions on printing and surface chemistry.

semiconducting properties, oligothiophene-based molecules can also self-assemble into crystalline nanoaggregates under special growth conditions [22], which could further increase their application potential in future, nanoscale optoelectronic devices.

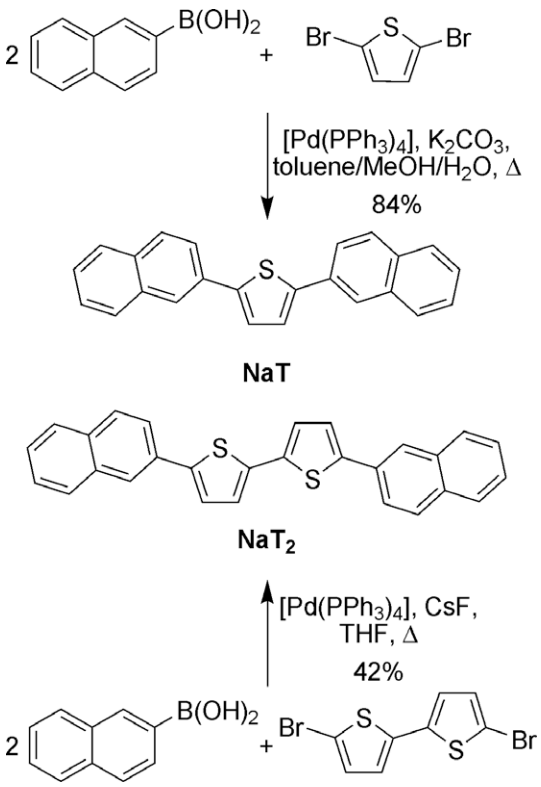
In addition to OFETs and OLEDs, the organic light-emitting field-effect transistor (OLEFET) is an excellent platform to investigate charge transport and light-emitting mechanisms of organic materials. Moreover, the combination of current modulation and light emission in OLEFETs make them interesting for display applications since the number of components could be reduced compared to the traditional design with an LED and a driver transistor. However, unipolar devices with bottom contact configuration operated by direct current (DC) voltages at the gate contact suffer from weak light emission, which in addition is restricted to the vicinity of the contact with the highest energy barrier for charge-carrier injection [3,23]. These drawbacks are mainly due to (a) the necessity to inject holes and electrons simultaneously and (b) to the different mobilities of those species. They can be overcome by a novel operating method, in which an alternating electric field is used to sequentially inject holes and electrons [24]. Here, we report on the electroluminescence properties of two novel naphthyl end-capped (bi)thiophenes (NaT and NaT_2) examined in an AC-biased OLEFET geometry. We observe electroluminescence from both compounds even when only one of the source–drain electrodes is biased relative to the gate electrode; the other electrode floating. The observation of light emission in this configuration, which basically corresponds to a metal–insulator–semiconductor diode, shows that a single injecting electrode is sufficient to produce clear electroluminescence that can be modulated by the applied gate voltage amplitude and/or frequency.

2. Experimental

2.1. Materials synthesis

Scheme 1 depicts the synthesis of the two naphthyl-end-capped (bi)thiophenes, 5,5-bis(naphthyl)-2,2′-bithiophene (NaT_2) and 2,5-bis(naphthyl)-thiophene (NaT). Actually, the synthesis of NaT_2 has been achieved before using a Stille cross-coupling approach [21], while NaT has only been part of some recent patents [25]. Recently, we were able to employ Suzuki cross-coupling protocols for the synthesis of oligophenylenes and oligothiophenephenylenes similar to NaT and NaT_2 thereby avoiding toxic organotin compounds [26]. Thus, we decided to make use of this strategy here, too.

Solvents were dried, distilled and stored under argon according to standard procedures. 2-Bromonaphthylboronic acid, 2,5-dibromothiophene, and 5,5′-dibromo-2,2′-bithiophene were purchased from commercial sources and used as received. Reactions were performed under an argon atmosphere in oven-dried glassware using standard Schlenk techniques. Thin-layer chromatography was performed on aluminum TLC plates (silica gel 60 F254) from Merck and the products were visualized under UV-light



Scheme 1. Synthesis of naphthyl end-capped thiophenes NaT and NaT_2.

(254 or 366 nm). Products were purified by sublimation under ultra-high-vacuum.

Mass spectra were recorded on a Finnigan MAT-95XL. UV/Vis spectra were measured on a Jena Analytic Specord 200 spectrometer in a 1 cm quartz cuvette. Fluorescence spectra were taken on an Aminco Bowman AB2 spectrometer in a 1 cm quartz cuvette. Elemental analyses were carried out with a Heraeus Vario EL.

2.1.1. NaT

A two-neck flask equipped with a condenser was charged with 2,5-dibromothiophene (1.5 g, 6.20 mmol), 2-naphtylboronic acid (2.24 g, 13.02 mmol), K_2CO_3 (2.57 g, 18.6 mmol) and $[Pd(PPh_3]_4$ (358 mg, 0.31 mmol, 5 mol%). A mixture of toluene, MeOH and water (60/30/3 mL) was added and the reaction mixture was refluxed for 50 h. After the mixture was allowed to cool down to room temperature the precipitate was collected and washed with toluene, CH_2Cl_2, and H_2O (2×80 mL each). The crude product was sublimed in ultra-high-vacuum (5.4×10^{-7} mbar, 296 °C (sand bath temperature)) to give 1.75 g (84%) of the desired product.

UV–vis (CH_2Cl_2): $\lambda_{max} = 282$, 352 nm; fluorescence (CH_2Cl_2): $\lambda_{max} = 399$, 420 nm; MS (EI): *m*/*z* (%): 336.1 (100) $[M]^{\cdot+}$, 168.0 (15) $[M]^{2+}$; HRMS (EI, *m*/*z*): $[M]^{\cdot+}$ calcd for $C_{24}H_{16}S$, 336.0969; found: 336.0977. Anal. calcd for $C_{24}H_{16}S{\cdot}1/5H_2O$: C, 84.77; H, 4.86; S, 9.43; found: C, 84.74; H, 4.65; S, 9.51.

2.1.2. NaT_2

A two-neck flask equipped with a condenser was charged with 5,5′-dibromothiophene (794 mg, 2.46 mmol), 2-naphtylboronic acid (888 mg, 5.05 mmol), CsF (1.12 g, 7.38 mmol), and $[Pd(PPh_3]_4$ (123 mg, 0.074 mmol, 3 mol%). THF (50 mL) was added and the reaction mixture was refluxed for 50 h. After allowing to cool to room temperature the precipitate was collected and washed with THF, CH_2Cl_2, and H_2O (2 × 50 ml each). The crude product was sublimed in ultra-high-vacuum (1.4×10^{-7} mbar, sand bath temperature 278–319 °C) to give 433 mg (42%) of the desired compound.

UV/Vis (CH_2Cl_2): λ_{max} = 303 nm; fluorescence (CH_2Cl_2): λ_{max} = 383 nm; EI–MS (*m*/*z* (%)); 418.1 (100) $[M]^{\cdot+}$, 209.0 (18) $[M]^{2+}$; HRMS (EI, *m*/*z*): $[M]^{\cdot+}$ calcd for $C_{28}H_{18}S_2$, 418.0844; found: 418.0858. Fig. 1. Schematic diagram of the electrical circuit together with a bottom contact/bottom gate OLEFET configuration.

2.2. Device fabrication and characterization

Both compounds with p-type characteristics are thermally stable solids so that they can be vapor deposited to form high quality polycrystalline films providing high charge-carrier mobility and air stability. Therefore, such organic thin films with a thickness of 52 nm are chosen as active light-emitting layers in a bottom gate/bottom contact (BG/BC) OLEFET configuration with various channel lengths (Fig. 1).

The device architecture is adapted from Yamao et al. who proposed a novel biasing method, in which an alter-

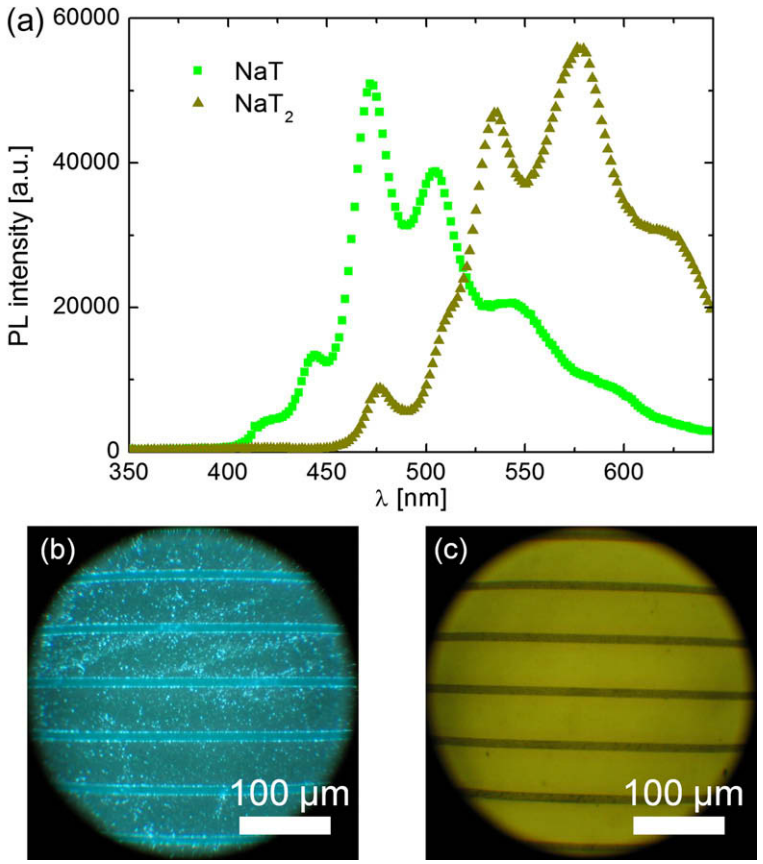

Fig. 2. (a) Photoluminescence spectra of NaT and NaT_2 thin films after excitation with a 325 nm wavelength laser. Fluorescence microscope images of (b) NaT and (c) NaT_2 thin films deposited on the FET device substrate.

nating current (AC) voltage is applied to the gate terminal of a BG/BC OLEFET with a phenylene–thiophene oligomer as the active organic layer [24]. Their study demonstrated that the AC gate voltage allows injection of holes and electrons from source and drain electrodes, respectively, leading to intense light emission within the channel region. Moreover, a noble metal (Au) can be used to inject both holes and electrons and gold is therefore also used in our study.

Highly n-doped silicon (ρ = 0.025 Ω cm) served as back gate electrode, on which 300 nm SiO_2 (C = 11.5 nF cm^{-2}) was thermally grown. An interdigitated array of titanium/gold (2 nm/30 nm) source and drain electrodes was fabricated on SiO_2 by optical lithography, metal evaporation (electron beam heating), and lift-off. The channel width W is summed up to 2.66 cm, and the channel length L varies from 2.5, 5 to 10 μm. The substrate fabrication was completed by etching out a rectangular area (defined by photolithography) in the SiO_2 film using buffered hydrofluoric acid and then depositing titanium/gold (10 nm/50 nm) as the contact pad to the back gate, which is depicted in Fig. 1. The substrates were cleaned by one minute ultrasonic agitation in acetone followed by five minutes DI-water rinse. Organic thin films with a thickness of 52 nm were then deposited onto the substrates at room temperature and under vacuum conditions (2×10^{-6} mbar) at a rate of 0.1–0.4 Å s^{-1}.

The photoluminescence spectra of both materials were collected by exciting the materials with a He–Cd laser (wavelength of 325 nm) and recording the spectra with an ARC SpectraPro-150 spectrometer in ambient air. A Nikon eclipse ME 600 epifluorescence microscope with a mercury UV lamp was used to obtain fluorescence images of the deposited organic materials. The electroluminescence experiments have been carried out under vacuum conditions ($\sim 8 \times 10^{-5}$ mbar). Source and drain were symmetrically biased relative to ground using two Delta Elektronika ES075-2 DC power supplies, while the gate electrode was biased by a Grundig FG100 function generator amplified by a Falco Systems WMA-300 voltage amplifier. A schematic diagram of the electrical circuit along with an OFET structure is illustrated in Fig. 1. Light emission was detected either with a Navitar microscope and a Lumenera Infinity1 camera or an ARC SpectraPro-150 spectrometer.

3. Results and discussion

3.1. Photoluminescence

Fig. 2(a) shows the photoluminescence characteristics of 52 nm thin films obtained upon vapor deposition of NaT and NaT_2, respectively. The spectra indicate green–blue light emission from NaT and yellow light emission from NaT_2. This is consistent with the fluorescence images shown in Fig. 2(b) and (c), respectively. Since naphthyl end-capped (oligo)thiophenes are semiconducting materials, the peaks of the spectra can be attributed to the transition from the vibrational ground state of the electronic excited state to vibrational states of the electronic ground state. The wider HOMO–LUMO gap of NaT compared with NaT_2 suggested by the spectra in Fig. 2(a) is in agreement with the HOMO–LUMO gap decreasing trend with the increasing number of thiophene rings in naphthyl end-capped oligothiophenes reported by Tian et al. [21].

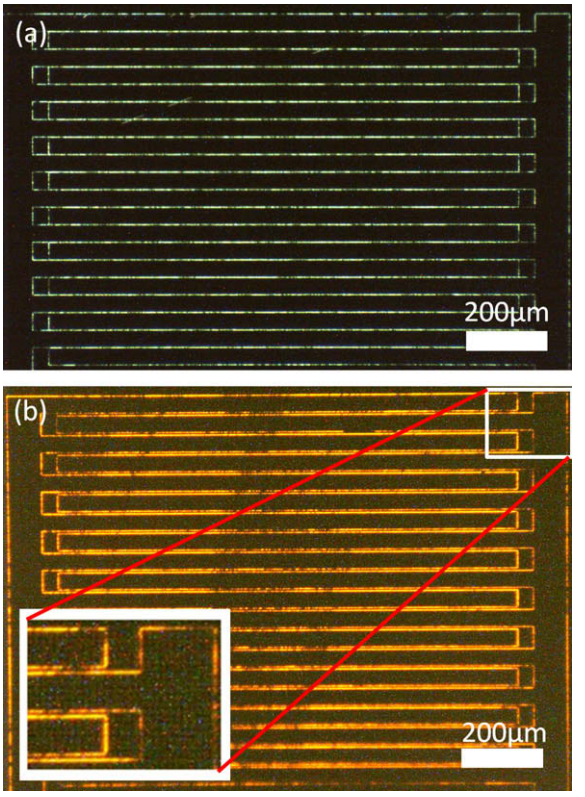

Fig. 3. Optical microscope image of electroluminescence from a 52 nm thin film of NaT (a) and a 52 nm thin film of NaT_2 (b) operated by a sinusoidal AC gate voltage.

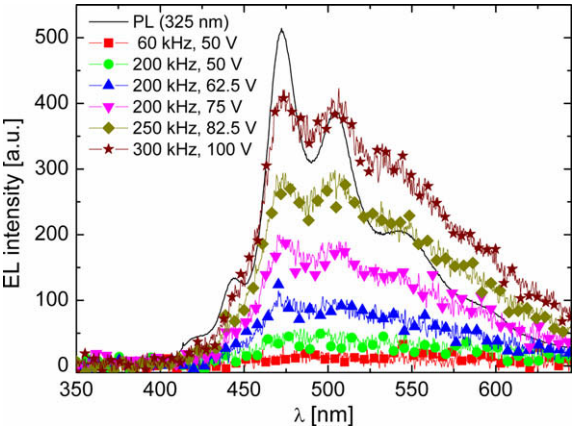

Fig. 4. Electroluminescence spectra of a 52 nm NaT thin film operated under drain and source voltages of $V_d = -V_s = 0$ V and an AC gate voltage with varying frequencies and amplitudes. The photoluminescence spectrum (scaled by a factor of 100) is also shown for comparison.

3.2. Electroluminescence

Both the green–blue electroluminescence from NaT and the yellow electroluminescence from NaT_2 can be observed in an optical microscope. Fig. 3(a) shows a NaT device with 2.5 μm channel length emitting green–blue light generated by drain and source voltages of $V_d = -V_s = 10$ V and an AC gate voltage with a frequency of $f = 200$ kHz and an amplitude of $V_g = 87.5$ V. Electroluminescence of a NaT_2 device with 10 μm channel length is presented in Fig. 3(b) ($V_d = -V_s = 15$ V, $f = 200$ kHz, and $V_g = 62.5$ V). The inset of Fig. 3(b) demonstrates that electroluminescence can be observed from both sides of the channel close to the injecting contacts, and also occurs along the periphery of an individual electrode. This is consistent with previous observations on other organic semiconductors [4]. However, light emission from opposing electrodes cannot be distinguished in devices with short channel lengths such as 2.5 and 5 μm. It is important to note that the electroluminescence from NaT_2 is more intense than that from NaT under the same experimental conditions. This is related to the smaller HOMO–LUMO gap and assumed higher carrier mobility of NaT_2 compared with NaT [21].

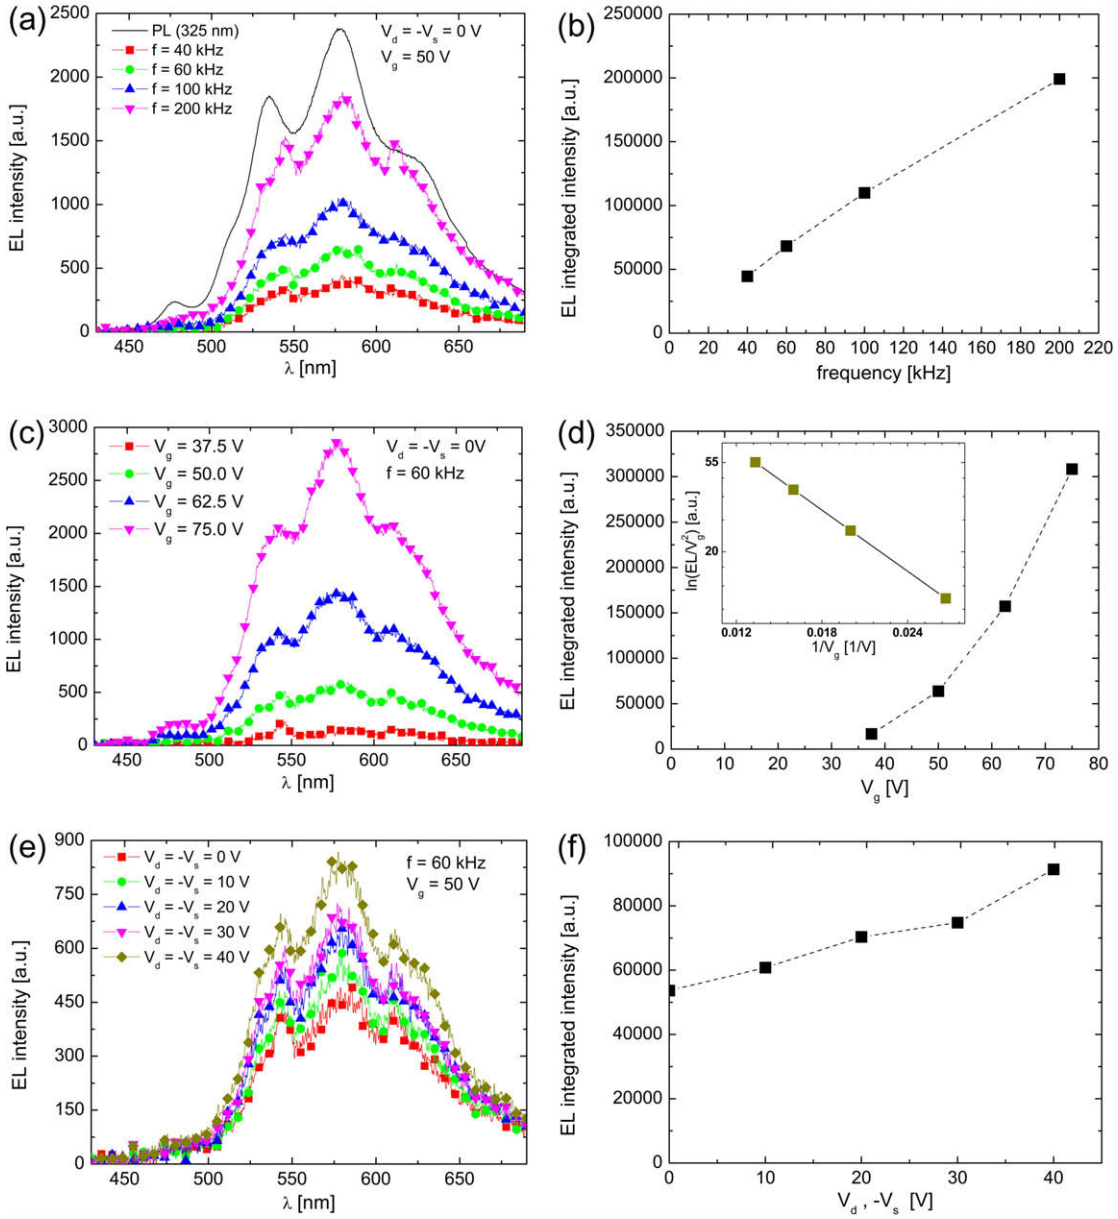

Fig. 5. Electroluminescence spectra of a 52 nm NaT_2 thin film (channel length 5 μm) with variable frequency of AC gate voltage (a), AC gate voltage amplitude (c) and drain and source voltages (e). The graphs on the right hand side show the total intensity (spectra integrated from 431 to 690 nm) as a function of frequency (b), amplitude of AC gate voltage (d), and drain and source voltages (f). The inset in (d) is a Fowler–Nordheim type plot of the intensity vs. gate voltage amplitude.

Since emission takes place from both sides of the channel and along the periphery of an individual electrode, the mechanism of electroluminescence cannot involve charge-carriers drifting across the channel to meet and recombine with their counterparts at the opposite electrode. We elaborate on this aspect in the next section.

Fig. 4 shows the electroluminescence spectra of a NaT device with 2.5 μm channel length. The source and drain voltages are maintained at zero volts for the whole series of experiments while the frequency and the amplitude of the AC gate voltage are varied. A photoluminescence spectrum is also depicted in Fig. 4 in order to compare to the electroluminescence spectra. Obviously, the intensity of the electroluminescence output increases with frequency and with voltage amplitude. The EL spectra show background noise due to their relatively low intensity, however, it is still clear that the peak positions correspond to those observed in the PL spectrum and that the same electronic transitions are therefore responsible for the light emission.

The light emission intensity from NaT_2 is significantly higher than that of NaT, leading to more well-resolved electroluminescence peaks as demonstrated in Fig. 5. Fig. 5(a) shows a clear dependence of the electroluminescence intensity on the AC gate voltage frequency. Fig. 5(c) and (e) illustrate how the EL spectrum depends on the gate voltage amplitude as well as drain and source voltages, respectively. Fig. 5(b), (d), and (f) show the relationships between the total EL intensity and the various operating parameters. The data points have been obtained by integrating the corresponding spectra in Fig. 5(a), (c), and (e), respectively, from 431 to 690 nm. The intensity increases approximately linearly with the frequency of the gate voltage (Fig. 5(b)) whereas it depends non-linearly on the gate voltage amplitude (Fig. 5(d)). The inset in Fig. 5(d) shows a Fowler–Nordheim type plot of the intensity vs. gate voltage amplitude including a fit line.

3.3. Discussion

The initial linear relationship between intensity and the AC gate voltage frequency can be interpreted as a result of more holes and electrons recombining if more AC voltage cycles are accomplished within a fixed time interval. For a further increase in frequency, a deviation from the linear dependence is expected [4,27]. This can also be inferred from Fig. 5(b), which indicates that the EL intensity tends to deviate from a straight line at 200 kHz. This deviation could be caused by the short time period for injection at high frequencies. At the highest frequencies, sample degradation made it impossible to study further the high-frequency behaviours.

To explain the observed EL output occurring both from the periphery of an individual electrode and from two different areas within the channel region, we propose a light generation mechanism composed of two sequential steps as depicted in Fig. 6. During the positive half-period of the gate voltage, electrons are injected from the gold electrode to the organic material, where they are trapped. In the second (negative) half-period, holes are injected and

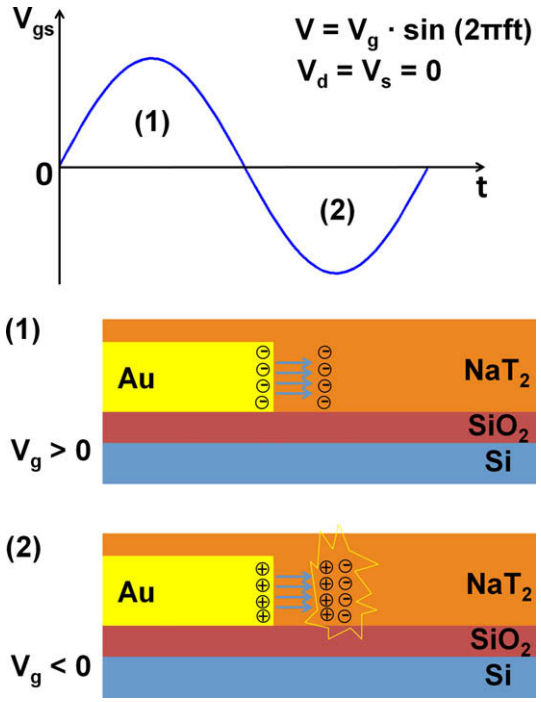

Fig. 6. Schematic diagram of the device operating mechanism. During the positive semi-period of the gate voltage (marked '1'), electrons are injected from the Au electrode into the organic semiconductor. During the subsequent negative semi-period (marked '2'), hole injection causes recombination and photon emission.

can recombine with the trapped electrons. The total intensity output then depends on either the electron or the hole injection process, whichever is less probable. One way to further elaborate on the light generation mechanism in our devices would be to study the time-resolved light output and correlate with the source–drain current as done by Yamao et al. [24].

The inset in Fig. 5(d) shows a Fowler–Nordheim (F–N) type plot using light intensity and gate voltage as parameters [27]. Strictly speaking, the F–N theory describes tunneling through a barrier into a delocalized state, which is not the case here where the charge-carriers form trapped states (polarons) in the organic semiconductor and the charge transport occurs as incoherent hopping [28]. However, the excellent fit of the measured data points to the F–N behaviour does suggest that the device current and thus the light intensity are governed by an injection barrier at the metal–organic interface.

In the data presented in Fig. 5(d), both the source and drain contact were connected to ground. If they are biased symmetrically (i.e. $V_d = -V_s$), the light intensity increases with increasing magnitude of the drain and source voltages as seen in Fig. 5(f). Adding a negative voltage to the source electrode must increase the electron injection during the first (positive) semi-period of the gate voltage compared to the injection occurring with the source electrode connected to ground. In the second (negative) half-period, the subsequent hole injection will likewise be reduced. However, in the symmetri-

cally biased configuration, the hole injection occurring from the drain contact should increase and the electron injection should decrease. Assuming that the limiting factor on the light emission is electron injection, one should therefore anticipate that the light emission occurring at the source (drain) electrode would increase (decrease). Since the data in Fig. 5(f) represent the average over a large area, it therefore suggests that the increase occurring at the source electrodes more than outweighs the intensity decrease at the drain electrodes. However, the detailed mechanism of this effect is still not clearly understood. Yamao et al. also observed an increasing light intensity with increasing magnitude of the drain and source voltages [24], however their model deals with recombination of holes and electrons injected from opposite electrodes as opposed to ours that only includes one injecting electrode, so a direct comparison is not feasible.

4. Conclusions and outlook

Two naphthyl end-capped (oligo)thiophenes are implemented in an easy-fabricated OLEFET structure utilizing an AC gate voltage to obtain intensified electroluminescence. The intensity of the electroluminescence emission is linearly proportional to the frequency of the AC gate voltage amplitude and is non-linearly dependent on the amplitude of the AC voltage. We propose that this non-linearity is caused by the carrier injection process, which, although occurring into localized states in an organic semiconductor nevertheless obeys a simple Fowler–Nordheim relationship. Further experiments are aimed at studying this effect in more detail and at integrating nanostructured organic material [22] on the device substrate to realize nanoscale OLEFETs [4]. In addition, it must be expected that tuning of the injection barrier can lead to more efficient light emission. This could for example be realized by modifying the gold electrodes via, e. g., adsorption of an organic layer prior to deposition of the organic semiconductor [29].

ting, light absorbing, and charge transporting ability in order to be able to perform multiple functions in OSCs, OLEDs, and OTFTs. Thus, it is rare to use the same organic materials as the active layer in individual devices based on different mechanisms. For these reasons, only a few dual functional or tri-functional organic materials have been reported in the literature [6,7]. For dual functional materials, rubrene [6a], triphenylamine–thiophene derivatives [6b], and triarylamine–carbazole based dendrimers [6c] have been investigated as both OLEDs emitting and OSCs donor material and tri-functional materials for the use in OSCs, OLEDs, and OTFTs using triphenylamine–oligothiophene conjugated molecules and fluorene–silole conjugated copolymers have been reported [7]. However, tri-functional materials based on triphenylamine–oligothiophene conjugated molecules showed a power conversion efficiency of 0.32% in OSCs, a poor green light emitting efficiency in OLEDs, and a field-effect mobility of 1.1×10^{-2} $cm^2 V^{-1} s^{-1}$ and on/off current ratio of 200 in OTFTs [7a]. Also, while a tri-functional material based on fluorene–silole conjugated copolymers showed a good power conversion efficiency of 2.01% in OSC devices, it showed a poor red emitting ability of external quantum efficiency of 0.17% in OLEDs, and poor field-effect mobility of 4.5×10^{-5} $cm^2 V^{-1} s^{-1}$ in OTFTs [7b]. The overall efficiency of these tri-functional materials is not high.

On the other hand, acene derivatives [8] have been extensively investigated as organic semiconductors for individual optoelectronic devices [9–11]. In particular, among the acene molecules, tetracene [12,17], pentacene [13,14,18], picene [15], anthanthrene [16], anthradithiophene [19a], and anthracene [19b], derivatives have been widely investigated as useful organic semiconductors for OSCs, OLEDs, and OTFTs [12–16,19]. However, tri-functional acene materials which can be used for emitting material in OLEDs, donor material in OSCs, and active material in OTFTs have not, to our knowledge, been reported so far in the literature.

Herein, we report that naphtho[2,3,*a*]pyrene (**NP**) (Fig. 1), a fused aromatic acene, can be utilized as an efficient multifunctional organic semiconductor material for optoelectronic devices to fabricate OSCs, OLEDs, and OTFTs devices by a vacuum deposition method. **NP** exhibited a maximum power conversion efficiency of 0.48% in OSCs which is considered a good efficiency among the acene molecules [19]. In addition, sky blue OLEDs at 3% **NP** doping exhibited a current efficiency of 4.4 cd A^{-1} and a power efficiency of 3.4 lm W^{-1} which are considered generally good EL efficiencies compared to that of sky blue acene based dopants such as chrysene [10] and anthanthrene derivatives [16a,b]. Also, 5% **NP** doping green OLEDs exhibited a power efficiency of 1.8 lm W^{-1} and a current efficiency of 3.9 cd A^{-1}. In particular, OTFTs using **NP** as an active layer exhibited a field-effect mobility (μ_{FET}) of 0.12 $cm^2 V^{-1} s^{-1}$, a threshold voltage (V_{th}) of −10.8 V, and an on/off current ratio of 6.8×10^6.

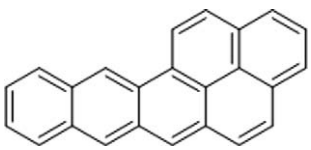

Fig. 1. Molecular structure of **NP**.

2. Experimental

2.1. Materials and instrument

The organic materials such as **NP**, C_{60}, CuPc, NPD, BPhen, and CBP were purchased from Aldrich, Lumtree, and Gracel. Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) was purchased from H.C. Stark. All the materials were purified by temperature gradient vacuum sublimation prior to use for devices. UV–Vis spectra were recorded on a Beckman DU 650 spectrophotometer. Fluorescence spectra were recorded on a Jasco FP-7500 spectrophotometer. Cyclic voltammetry (CV) was performed using a CH Instruments 660 Electrochemical Analyzer (CH Instruments, Inc., Texas). AFM experiments were performed using an asylum MFP-3D instrument in AC mode with Si_3N_4 cantilevers and XRD analyses were carried out with a Rigaku (λ = 1.5418 Å, 298 K) X-ray instrument. Decomposition temperatures (T_d) were obtained using a Q−5000−IR TGA instrument.

2.2. OSCs fabrication

A 30 nm-thickness of PEDOT:PSS was used as a hole injection layer (HIL). The thin film thickness of **NP** was prepared by an evaporation process from 10 to 100 nm. Then, a 30 nm-thickness of fullerene (C_{60}) as an acceptor was also evaporated. Next, a 8 nm-thickness layer of 4,7-diphenyl-1,10-phenanthroline (Bphen) as a exciton blocking layer (EBL) was evaporated. Finally, 100 nm-thickness of aluminum was evaporated onto the Bphen layer (Fig. S2). The current–voltage measurements of the devices were measured on a Keithley 237 instrument. The device performances were characterized under uniform illumination (AM 1.5G illumination intensity of 100 mW cm^{-2}) using a solar simulator (Newport, 91160A). The light intensity at each wavelength was calibrated using the standard Si solar cell as a reference.

2.3. OLEDs fabrication

A 10 nm-thickness of copper phthalocyanine (CuPc) was used as a hole injection layer (HIL) and a 30 nm-thickness of 4,4′-bis[*N*-(naphthyl-*N*-phenylamino)biphenyl (NPD) was used as a hole transport layer (HTL). A 30 nm-thickness of emitting layer (EML) was prepared by co-evaporating *N*,*N*′-dicarbazolyl-4,4′-biphenyl (CBP) as a host and 1, 3, 5 wt.% of **NP** as a fluorescent dopant. The fluorescent dopant concentration of **NP** was varied from 1 to 5 wt.%. Next, 30 nm-thickness layer of 4-biphenyloxolatoaluminium(III)bis(2-methyl-8-quinolinato)-4-phenylphenolate (Balq), as a hole blocking layer (HBL) and electron transporting layer (ETL) was evaporated. Then, LiF as an electron injection layer (EIL) was also evaporated. Finally, a 100 nm-thickness of aluminum was deposited on the LiF layer (Fig. S3). The emission properties were

determined using PR650 spectra scan spectracolorimeter as a source meter.

2.4. OTFTs fabrication

The transistors based on **NP** were fabricated with the top-contact geometry. We used a heavily doped Si wafer as the gate electrode and non-pretreated or octadecyltrichlorosilane (OTS)-pretreated SiO_2 layer (thickness, ca. 300 nm) as the gate dielectric. Prior to deposition, the **NP** starting material was purified by temperature gradient vacuum sublimation to improve the purity of the active layer. The **NP** films (ca. 500 Å) were then grown by vacuum sublimation, using a home-made apparatus, at a rate range of 0.4–0.8 Å s^{-1} under a working pressure of 2.0–2.5 $\times$ 10^{-6} torr. Gold source/drain electrodes were evaporated on top of the films through a shadow mask with a channel length (L) of 50 μm and a channel width (W) of 1000 μm (Fig. S6). Electrical characterization of the transistors was performed at room temperature in air by using a Keithley 4200-SCS semiconductor analyzer. The field-effect mobility (μ) was calculated in the saturation region (V_{DS} = −100 V) from the plot of the square-root of drain current vs. V_{GS} using the following equation: $I_{DS} = (W\text{-}C_i\mu(V_{GS} - V_T)^2)/2L$, where I_{DS} is the source-drain saturation current; C_i (1.1 $\times$ 10^{-8} F) is the capacitance of the SiO_2 insulator; W/L is the ratio of the width to the channel length; V_{GS} and V_T are the gate-source and threshold voltages, respectively.

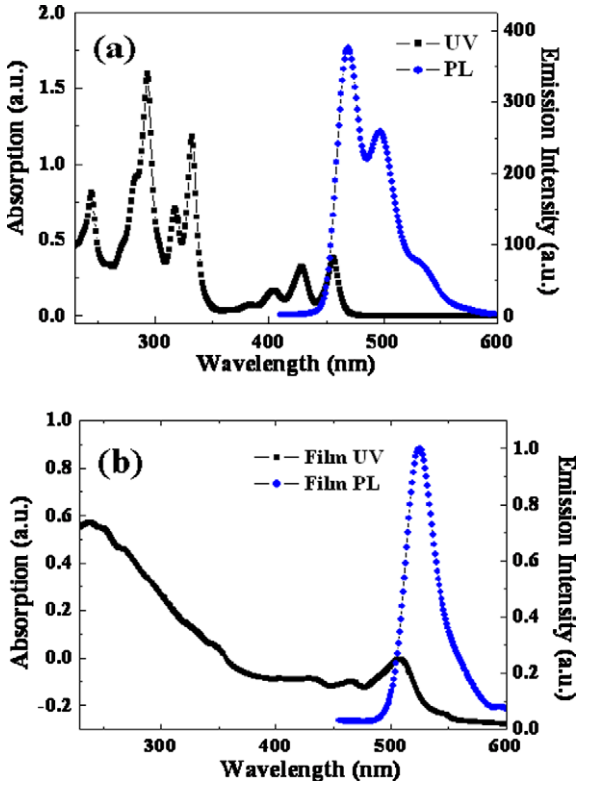

Fig. 2. UV and PL spectra of 0.02 mM **NP** in CH_2Cl_2 (a) and solid film (b).

3. Results and discussion

The UV spectra of **NP** show multiple absorption bands at 292, 332, 428, and 456 nm in CH_2Cl_2 and broad absorption bands at 269, 465, and 507 nm in solid film, respectively. The PL spectra of **NP** show sky blue emission at 468 and 497 nm in CH_2Cl_2 and green emission at 523 nm in solid film, respectively (Fig. 2). Both film UV and PL spectra of **NP** were significantly red-shifted in comparison with those in CH_2Cl_2, which is attributed to the flat structure of the **NP** molecule.

The photoluminescence quantum yield of **NP** was estimated to be 0.61 using anthracene as a standard [20]. Thermal gravimetric analysis (TGA) data reveal that **NP** has high thermal stability (T_d = 271 °C, Fig. S7).

In order to study the electrochemical properties of **NP**, we measured the cyclic voltammetry. **NP** shows a reversible oxidation process associated with stable cation radical generation. On the other hand, the reduction potential of **NP** was not observed in cyclic voltammetry. The half oxidation potential of **NP** was observed at $E_{1/2}$ = 0.50 V after ferrocene/ferrocenium correlation (Fig. S1). From these results, the HOMO energy value of **NP** (−5.30 eV) was calculated. The LUMO energy value of **NP** (−2.80 eV) was calculated from the cross-section wavelength between absorption and emission spectra (Table 1).

To investigate the efficient multifunctional properties of **NP**, we fabricated three representive types of organic electronic devices. First, we fabricated OSCs with the configuration of ITO/PEDOT:PSS (30 nm)/**NP** (x nm)/C_{60} (30 nm)/Bphen (8 nm)/Al (100 nm). The thickness of **NP** was varied from 10 to 100 nm.

Fig. 3 shows the current density vs. voltage (I–V) characteristics of heterojunction solar cells. All the OSCs show the solar cell behavior. Heterojunction solar cell using 10 nm-thick **NP** exhibited a significantly low power conversion efficiency (PCE) of 0.003% and short circuit current (I_{sc}) of 0.056 mA cm^{-2} due to the thin **NP** film, which cannot efficiently absorb the sunlight. On the other hand, an OSC device using 45 nm-thick **NP** exhibited the open circuit voltage (V_{oc}) of 0.37 V, short circuit current of 2.0 mA cm^{-2}, and power conversion efficiency of 0.35%, under simulated AM 1.5 solar irradiation at 100 mW cm^{-2}. In particular, when the thickness of **NP** was optimized at 80 nm, the OSC device exhibited a significantly increased power conversion efficiency of 0.48%, an open circuit voltage of 0.59 V, and a short circuit current of 1.9 mA cm^{-2}, under simulated AM 1.5 solar irradiation at 100 mW cm^{-2}. However, as the thickness of **NP** increased further to 100 nm, the device exhibited a significantly reduced short circuit current of 0.46 mA cm^{-2} and power conversion efficiency of 0.02% due to the thick **NP** film, in which excitons cannot be efficiently separated between hole and electron. We found that the performance of OSC devices using **NP** depends critically on the donor (**NP**) film thickness of the active layer. Typically, varying **NP** film thickness in the active layer resulted in changing the power conversion efficiency from 0.003% to 0.48%. Despite the narrow absorption range of **NP**, the maximum power conversion

efficiency (0.48%) obtained in this study is considered high among the acene derivatives in OSCs (due to the good hole mobility of **NP**). This is the first report on **NP** based OSC donor materials. Our results indicate that among the acene derivatives, **NP** can be regarded as a good donor material for heterojunction solar cells. The overall device performance data based on **NP** and C_{60} are summarized in Table 2.

Second, OLED devices were fabricated using **NP** as a dopant molecule, with the configuration of ITO/CuPc (10 nm)/NPD (30 nm)/emitting layer (EML 30 nm)/Balq (30 nm)/LiF (1 nm)/Al (100 nm). Emitting layers of 30 nm-thickness were prepared by co-evaporating CBP as

a host and *x* wt.% **NP** as a fluorescent dopant. Fig. 4 shows the photoluminescence (PL) in CH_2Cl_2 and electroluminescence (EL) spectra with different doping ratios of **NP**. The PL spectra of **NP** in CH_2Cl_2 show the sky blue emission centered at 468 and 497 nm. At 1% and 3% **NP** doping, the EL spectra show the similar sky blue emission compared to that of PL emission (Fig. 4).

The similar pattern of the PL and EL spectra of 1% and 3% **NP** doped device suggests that EL spectra should be attributed to an emission from a singlet excited state of **NP** in the emitting layer. On the other hand, the 5% **NP** doped device shows green emission centered at about 479, 514, and 550 nm (Fig. 4). This is most likely due to the formation of an excimer resulting from the aggregation of **NP** dopant molecules in the emitting layer. This could be due to the planar molecular structure of **NP**, which cannot prevent aggregation in the emitting layer. We were able to change the emission color from sky blue to green by varying the

NP doping ratio. This result indicates that the EL emission depends on the **NP** doping ratio in the emitting layer.

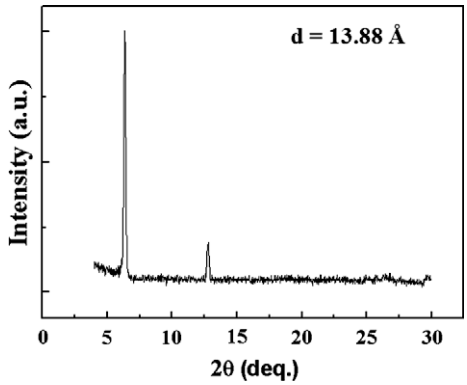

Fig. 8. X-ray diffraction (XRD) pattern of the thin films of **NP** grown on SiO_2 at RT.

Fig. 5 shows the sky blue and green emitting EL device data. The sky blue OLED device at 1% **NP** doping shows a power efficiency of 0.7 lm W^{-1} and current efficiency of 1.7 cd A^{-1}. In particular, the OLED device at 3% **NP** doping shows the maximum power efficiency of 3.4 lm W^{-1} and current efficiency of 4.4 cd A^{-1}, and a Commission Internationale de l'Eclairage (CIE) coordinates of (0.17, 0.39). At 3% **NP** doping, the maximum power efficiency and current efficiency of the EL device are considered generally good. Therefore, the efficiencies of OLEDs using **NP** are higher than those of devices using other acene materials such as chrysene [10] and anthanthrene derivatives [16a,b].

Furthermore, at 5% **NP** doping, the green OLED device shows a power efficiency of 1.8 lm W^{-1} and current efficiency of 3.9 cd A^{-1}, and a CIE coordinates of (0.31, 0.52). As a result, the EL at 5% **NP** doping showed green emission with generally good luminous power efficiency and current efficiency in OLED devices. Also, the turn-on voltage is reduced as the doping concentration of **NP** increases. It

is presumably because **NP** can be used as efficient carrier transport channel at high doping concentration of **NP** (Fig. 5b) [16c]. All EL device data are summarized in Table 3. As a result, **NP** can be used as sky blue dopant material as well as green dopant material in fluorescent OLEDs. Although the operation mechanisms of OLEDs and OSCs are different, **NP** shows good efficiencies for both OLEDs and OSCs due to the good photoluminescence quantum yield and hole mobility.

Third, the possibility of **NP** being used for charge transport channels in OTFTs was investigated by the fabrication of OTFTs using top-contact geometry (Fig. S6).

Fig. 6 shows the output and transfer characteristics of top-contact OTFTs using **NP** deposited at a substrate temperature (T_{sub}) of 75 °C on OTS-treated SiO_2. From the electrical transfer characteristics, we obtained parameters such as the field-effect mobility, on/off current ratio, and threshold voltage for the devices. The OTFTs based on **NP** showed a field-effect mobility of 0.12 $cm^2 V^{-1} s^{-1}$, threshold voltage of −10.8 V, and on/off current ratio of 6.8×10^6 under ambient conditions. The electrical properties of **NP** based OTFT devices fabricated under various conditions are summarized in Table 4. To investigate the cause of the different OTFTs performance under various conditions, we studied the film morphology of thin **NP** active layers using atomic force microscopy (AFM). Fig. 7 shows AFM images of **NP** active layers deposited on SiO_2 (left column) and OTS/SiO_2 (right column) at RT, 75 °C, and 110 °C. The connectivity of **NP** grains deposited on a SiO_2 substrate at RT has poor, low field-effect mobility. However, **NP** films deposited on an OTS/SiO_2 substrate at RT show improved film connectivity and field-effect mobility. In particular, densely packed grains on an OTS/SiO_2 substrate at 75 °C were observed and showed the best field-effect mobility among **NP** based devices under various conditions, due to improved interconnectivity in the channels of the **NP** films. Also, at 110 °C, we observed that sub-micron-sized **NP** grains deposited on SiO_2 were disconnected, and as a result, showed no electrical properties. However, the films deposited on OTS/SiO_2 were connected, and as a result, showed electrical properties.

When the morphological characteristics of thin-film **NP** were investigated by X-ray diffraction (XRD), the patterns displayed 2nd order diffraction peaks and the intense XRD peaks in low angle side indicated a highly ordered lamellar structure within **NP** with a period of 13.88 Å (Fig. 8).

4. Conclusion

We found that **NP** can be commonly used as an effective tri-functional material for three representative kinds of devices in organic electronics. In order to prove the fact, we fabricated the OSCs, OLEDs, and OTFTs using **NP** molecules as active layers. First, an optimized 80 nm-thick **NP** based OSC device exhibited a good power conversion efficiency of 0.48%. Second, an OLED device with 3% **NP** doping showed sky blue emission and a power efficiency of 3.4 lm W^{-1} and a current efficiency of 4.4 cd A^{-1}, and a CIE coordinates of (0.17, 0.39). OLEDs with 5% **NP** doping showed green emission and a power efficiency of 1.8 lm W^{-1} and a current efficiency of 3.9 cd A^{-1}. Third, OTFTs based on **NP** exhibited a field-effect mobility of 0.12 $cm^2 V^{-1} s^{-1}$, a threshold voltage of −10.8 V, and an on/off ratio of 6.8×10^6. Consequently, **NP** turned out to be a promising organic semiconductor material which can be used as an efficient blue or green light emitting material, and efficient solar cell donor, and an organic semiconductor for OTFTs. Further studies on modified **NP** based organic semiconductors for optoelectronic devices are in progress.

conductivity [8–13], roughness, mechanical strength, etc., of the vacuum deposited metal thin film. The first steps of growth of a typical and largely used noble metal like silver have been deeply investigated, showing different growth mode, like Volmer-Weber [14–17] or Stranski-Krastanov [18,19], depending on the substrate type and on the vacuum metal deposition rate.

Moreover the vacuum deposition technique can induce different growth modes, therefore thermal evaporation, RF/DC sputtering, ion-beam assisted deposition and e-beam evaporation have been investigated in the last years by numerous research teams [20–25]. The growth mode can influence the final RMS roughness of the metal thin film, as well as the other physical properties, such as the transparency or the conductivity. In particular, the growth mode associated to e-beam is very similar to that observed in thermal evaporation. In both cases the metal atoms are evaporated heating the bulk material inserted in a crucible obtaining a vapor of atoms that have a low energy and momentum. The big advantage of the e-beam deposition is that it limits the heating of the material to a small area of the bulk material avoiding problems related to the over-heating of the crucible and the possible alloying between the bulk and the crucible material. The thin films obtained with these techniques are not very dense and, in general, show a polycrystalline columnar growth. In contrast, more dense films can be obtained using sputtering or high energy deposition techniques where the ejected atoms have high energy and momentum and tend to form dense amorphous thin films. However, in these last cases small clusters of evaporated material can be projected on the thin film surface decreasing the thin film surface uniformity and increasing its roughness. Considering these aspects, the e-beam evaporation technique has been selected to obtain the thin Silver films to be used as anode in our micro-cavity OLEDs. Moreover, it has been observed by atomic force microscopy (AFM) analysis that rough surface topography of silver thin films grown with different deposition techniques is directly related with the substrate (for example, Si or SiO_2). Preliminary deposition tests of silver thin films directly on our borosilicate glass substrate highlight the high surface roughness of the thin film as well as its poor adhesion to the substrate, incompatible with the fabrication of a working OLED device. To improve this aspect, and also the adhesion properties, nucleation layers have been used on the substrates.

The aim of our investigation was to found the optimized growth condition to obtain a semi-transparent, conductive and adherent silver thin film to be used as anode of a small molecule blue emitting bottom micro-cavity OLED, based on bis-(2-methyl-8-quinolinato)-4-(phenyl-phenolato)aluminum-(III) ($BAlq_3$). By optical simulation and by resistivity and mechanical consideration [8–13], a silver thickness of 25 nm has been selected to obtain the micro-cavity spectral peak at a wavelength of 460 nm and to optimize the OLED efficiency at that wavelength. The silver anode must also present a sufficiently strong adherence on the borosilicate glass to allow the spin-coating deposition of a 40 nm hole injection poly(3,4-ethyl-enedioxythiophene)/polystyrene-sulphonate (PEDOT-PSS) layer avoiding the modification of the anode (roughness, breaks). The PEDOT-PSS layer has been used to improve hole injection by the anode. The molecular architecture of our micro-cavity OLED, implies a 60 nm thick multilayer stack (described in the Chapter 3 of this paper) beside the 40 nm PEDOT-PSS layer that leads to a very high sensitivity to short circuit induced by Ag surface spikes or roughness.

In this paper, we present the optimization of thin film deposition of a 25 nm thick silver film on cleaned borosilicate glass using different nucleation layers (Cr, Ge and a-C:H). The deposition rates of both the nucleation and silver layers can be modified by tuning the process parameters.

To measure the surface roughness of the different thin Ag films with and without PEDOT-PSS layer over large areas, of the order of 1 mm^2, a high resolution white-light interferometer based optical profiler has been used instead of an AFM that only allows the measure of very small surface ($100 \times 100\ \mu m^2$). Surface morphology investigations of the same samples have also been performed using a field emission gun scanning electron microscope (FEG-SEM).

The PEDOT-PSS layer deposition effect on the total surface roughness has been measured for all different bi-layers (Cr/Ag, a-C:H/Ag and Ge/Ag) deposited at different rates. In particular, the deposition conditions of an optimized Ag surface with a 40 nm PEDOT-PSS over-layer presents a very smooth surface and does not exhibit significant spikes (higher than 8.3 nm) over a large measured surface of 1 mm^2, have been identified.

2. Experimental

For this experiment high quality polished borosilicate glass substrates of 1 mm thick have been used. Before coating the samples with the different nucleation layers, an ultrasonic cleaning with organic solvents (acetone, iso-propanol and ethyl alcohol) and de-mineralized water in a class 10 clean-room has been performed on each substrate. All samples have then been dried with nitrogen. After cleaning, the samples have been transferred in different vacuum chambers for the deposition of the nucleation layers of 5 nm thick, the choice of this thickness being driven by adherence improvement requirements, selected during previous tests. Different high vacuum deposition techniques have been used:

- Pure chromium (99.999%) thin film of 5 nm was thermally evaporated in a VEECO evaporator at a pressure of 2×10^{-4} Pa and a deposition rate of 0.04 nm/s.
- Multi-polar microwave plasma excited at distributed electron cyclotron resonance (MMP-DECR) was used in this work for hydrogenated amorphous carbon (a-C:H) deposition. The plasma reactor is described in the literature [26]. Methane gas was injected through a mass flow controller with a rate of 7.4 sccm and the working pressure was set at 0.1 Pa. The microwave power was 400 W. In order to obtain a homogeneous 5 nm thick a-C:H thin film, the deposition time lasted 2 min.
- Pure germanium (99.999%) was deposited by electron beam-technique in a BOC EDWARDS 500 evaporator. Two different evaporation rates of 0.01 nm/s (low rate

deposition) and 0.2 nm/s (high rate deposition) have been used for the germanium thin film evaporation. During both evaporations the pressure was maintained at 5×10^{-4} Pa.

Pure silver (99.999%) was evaporated at 0.05 or 1.1 nm/s on the nucleation layers by electron-beam deposition in a BOC EDWARDS 500 evaporator. A silver film was first evaporated with a deposition rate of 0.05 nm/s on glass substrates previously coated with chromium, hydrogenated amorphous carbon and low rate deposited germanium. A second silver evaporation was realized with a deposition rate of 1.1 nm/s on samples with chromium, hydrogenated carbon and high rate deposited germanium. For all the samples the silver film thickness was 25 nm, as monitored by a calibrated quartz microbalance; during depositions the pressure was maintained at 5×10^{-4} Pa. All evaporations have been performed at ambient temperature and no post-processing have been done on the prepared samples. For each different nucleation layer, two samples were prepared. The first ones were used to analyze the Ag deposition, the second ones were coated with a 40 nm layer of PEDOT-PSS, using a spin-coating process. The PEDOT-PSS was deposited at a speed of 2500 rpm for 30 s in the clean room. After the PEDOT-PSS coating, the samples were annealed at 100 °C in air atmosphere for 5 min.

The surface morphology of the samples has then been investigated with two different techniques. Roughness measurements have been carried out with a noncontact white-light interferometer precision optical profiler WYKO NT3000, using the instrument in Phase Shifting Interferometry (PSI) mode. The PSI measurements mode allows to obtain a vertical resolution as high as 0.3 nm. A 5× objective has been used to measure a 1 mm^2 sample surface. For each sample, mean roughness (R_a), root mean square roughness (R_q) and maximum peak-to-valley height of the surface (R_t) have been determined over probed surface.

A JEOL JSM 6700 F field emission gun scanning electron microscope has also been used to image the samples surface with a resolution of 1 nm at 15 kV and 2.2 nm at 1 kV. The samples coated with PEDOT-PSS were metalized with less than 1 nm of platinum before being observed. All the samples were cleaved and the measures were carried out with a base voltage of 5 kV.

3. Results and discussion

The roughness parameters, measured with the optical profiler, of the thin Ag films (over coated or not by the 40 nm PEDOT-PSS layer) deposited on different nucleation layers are reported in Table 1, as function of the deposition rate of the Ag thin films. R_a is the most common parameter to characterize a surface but R_q provide information about roughness heterogeneity over surface. Therefore, a small difference between the R_a and R_q values indicates a low spike density and, in general, a more uniform surface. R_t represents the distance between higher peak and lower valley and provides information about spikes height, but this value represents a point and not a statistical value, opposite to the first two. Considering the most significant roughness parameters, R_a and R_q, it is evident from the table that the surface roughness depends on the nucleation layer in the following way: Cr > a-C:H > Ge, for both low and high deposition rates.

Moreover in all measured samples the micro-roughness shows a dependence from the deposition rate. In particular, independently of the nucleation layer, the Ag films deposited with a high rate present a smoother surface, as can be seen from Figs. 1 and 2, where the 3D surface profile of the low (0.05 nm/s) and high (1.1 nm/s) deposition rate Ag films on the nucleation layers are reported together with the histograms of their surface height distributions.

The silver thin film growth on different nucleation layers has been ascribed by several authors [11,28–31] to an heterogeneous nucleation process. So, the surface smoothing observed using a high rate deposition can be explained by some consideration on heterogeneous nucleation in the first phases of thin film growth. The heterogeneous nucleation is governed by the following rules:

$$\left[\frac{\partial \Delta G^*}{\partial T}\right]_R > 0 \qquad \left[\frac{\partial r^*}{\partial T}\right]_R > 0 \quad \text{and}$$

$$\left[\frac{\partial \Delta G^*}{\partial R}\right]_T < 0 \qquad \left[\frac{\partial \Delta G^*}{\partial R}\right]_T < 0$$

where ΔG^* is the volume critical free energy, r^* is the critical radius for heterogeneous nucleation, T is the temperature and R is the deposition rate. Typically higher temperatures lead to larger r^* and subsequently larger ΔG^*. Consequently the barrier for nucleation is higher at

Table 1
The roughness measured values of the Ag evaporated surfaces are presented in this table. The measurements have been performed with a WYKO NT 3000 optical profiler; the values of R_a (arithmetic average roughness), R_q (root mean square roughness) and R_t (peak to valley) are listed, expressed in nm. The thickness of the Cr, a-C:H and Ge nucleation layers has been set to 5 nm each. The values obtained both at low (0.05 nm/s) and high (1.1 nm/s) deposition rates are here compared. For both deposition rates, the surfaces have been measured without and with the over-coating of a 40 nm PEDOT-PSS layer.

Low rate (0.05 nm/s)						High rate (1.1 nm/s)					
Without PEDOT			With PEDOT			Without PEDOT			With PEDOT

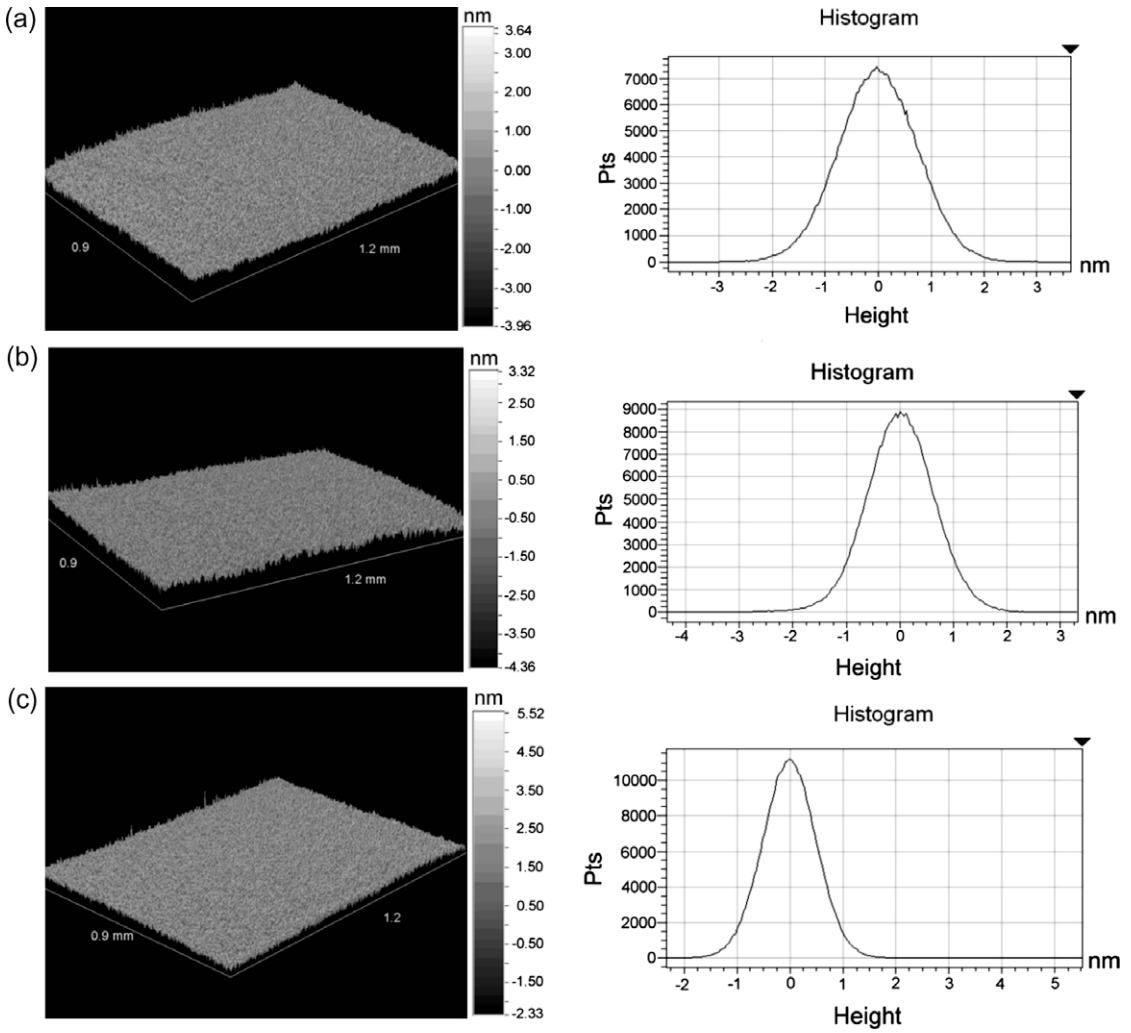

Fig. 1. 3D surface profile of the Ag low rate (0.05 nm/s) evaporated surfaces measured by WYKO NT3000 in PSI mode and histograms of the height distribution, measured in nm, over the measured surface of $1.2 \times 0.9\ mm^2$ (image size: 736×480, step size of 1.65 μm): (a) 5 nm chromium and 25 nm silver, (b) 5 nm hydrogenated amorphous carbon and 25 nm silver, and (c) 5 nm germanium and 25 nm silver.

higher temperature which leads to a decrease in N^* (larger and fewer grains). Once more, higher deposition rates lead to lower r^* and, subsequently, lower ΔG^*. Consequently the barrier for nucleation is reduced at higher evaporation rates which leads to an increase of N^* (i.e. smaller, more numerous grains).

SEM images reported in Figs. 3a and c & 4a and c show that the nucleation of Ag on Cr and a-C:H nucleation layers starts from isolated Ag clusters. The morphology of the Ag surface over Cr and a-C:H nucleation layers presents large voids and isolated islands that are denser for the samples grown at high evaporation rate confirming that high rate imply a larger number of nucleation sites and, consequently, an earlier silver coalescence with a reduced surface roughness. This is also evident considering that the differences between the R_a and R_q values, reported in Table 1, are always smaller in the case of high rate deposition. This implies a higher surface homogeneity over a large area, as measured by the optical profiler.

Silver, and in general the noble metals, has been reported [13,28–30] to grow on oxidized surfaces in 3D island mode. Cr is easily oxidized when extracted from the evaporator and then the successive growth is governed by the accumulation of Ag atoms by surface diffusion and coalescence into large three dimensional clusters (Volmer-Weber growth mode). In contrast, a-C:H layers can not be as oxidized as Cr [32]. It suggests that Ag growth on a-C:H layer is controlled by another process.

The morphology of Ag thin film grown on a Ge nucleation layer, shown in Fig. 5a and c, appears to be different from the first two. In particular, it is possible to note that even if the silver film grows from Volmer-Weber mechanisms, the grain texture is smaller and the grain density is much higher than in the previous cases. No voids can be observed between adjacent grains that form a dense columnar continuous Ag film with high grain density and a smooth surface. Also in this case the high rate deposited film has a lower roughness than the low rate one, as it can

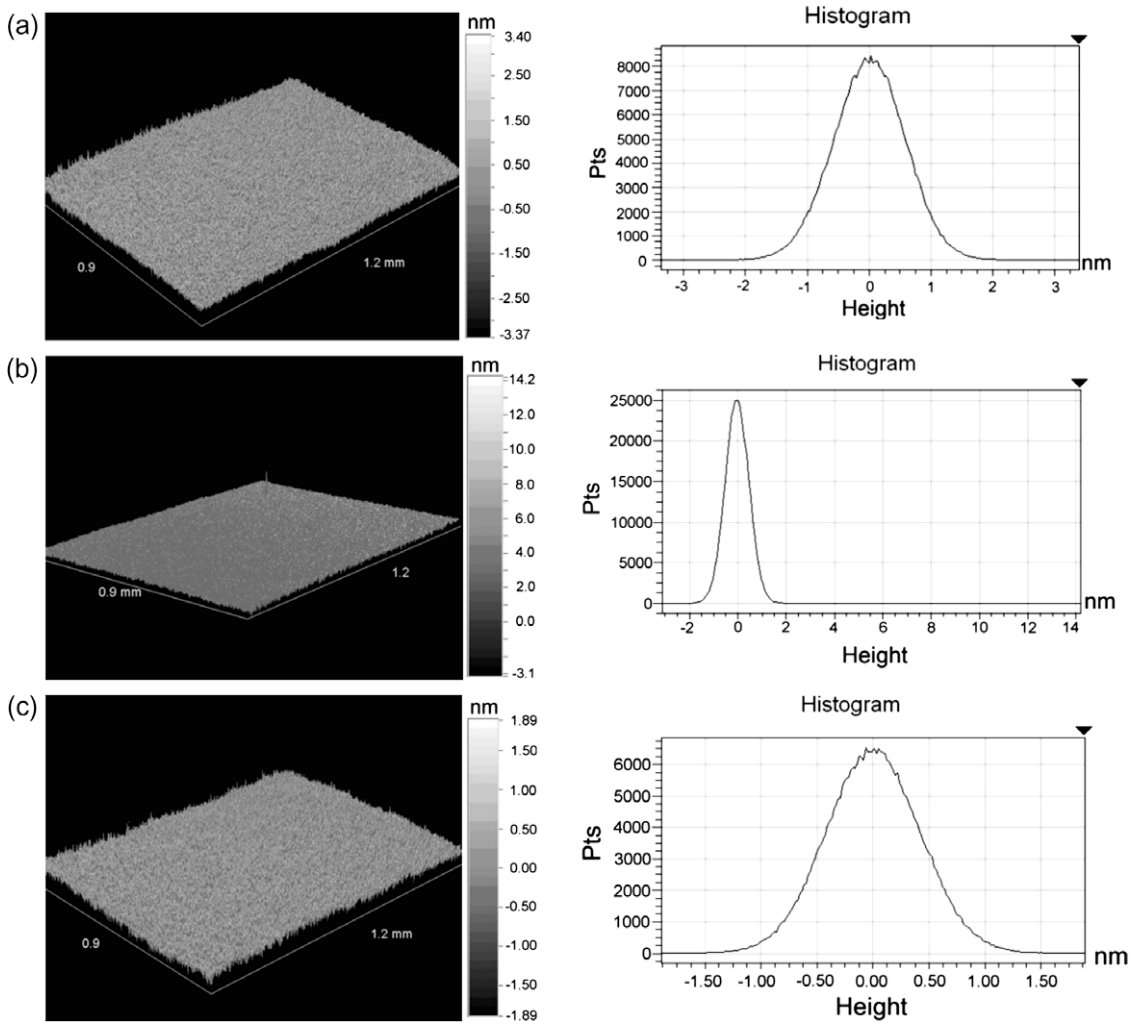

Fig. 2. 3D surface profile of the Ag high rate (1.1 nm/s) evaporated surfaces measured by WYKO NT3000 in PSI mode and histograms of the height distribution, measured in nm, over the measured surface of 1.2×0.9 mm^2 (image size: 736×480, step size of 1.65 μm): (a) 5 nm chromium and 25 nm silver, (b) 5 nm hydrogenated amorphous carbon and 25 nm silver, and (c) 5 nm germanium and 25 nm silver.

be seen from Table 1. In the low rate deposition Ge/Ag film it is possible to observe, from Fig. 5a, the growth of some tenths nanometer large Ag grains over the smooth under layer. These Ag grains induce a slight increase in surface roughness over large area.

A possible explanation to the significantly different surface morphologies observed in the Ge/Ag bi-layer is the strong affinity of Ag and Ge. It is known that, in certain Ag concentration [33,34] and at room temperature, an amorphous alloy of Ag and Ge could be formed in the very first stage of Ag evaporation on Ge. In our experimental condition this effect is possible considering that the eutectic temperature of an Ag/Ge alloy is 924 °C and that the evaporation temperature of the Ag is 958 °C at a pressure of 10^{-4} Pa. However, as reported by Randhawa et al. [35,36], the Silver largest content which could form the homogeneous amorphous phase deposited at room temperature for the Ge/Ag alloy is around 12%. With increasing the silver content, very fine Ag crystalline grains are observed, their density being dependent on the silver content and therefore on the film deposition rate. Therefore, we suppose that in our case the growth of polycrystalline silver thin film is preceded by an initial Ge/Ag alloy homogeneous amorphous layer, the thickness of which amounts only few nm. On the contrary the immiscibility of Cr/Ag in terms of characteristic of electronic structures of constituent metals is well known and a possible metastable Cr/Ag alloy is possible only after a thermal annealing, which was not performed in our case. The same holds also for the a-C:H/Ag bi-layer. In the last two cases the coalescence of the 3D Ag crystalline grains formed at the Ag/nucleation layer interface is retarded (coalescence thickness of 10 nm) as compared to the Ge/Ag case where there is a coalescence evidence at a silver film thickness of 5 nm, as confirmed by mechanical profilometer and ellipsometric measurements that will be discussed elsewhere. Also the morphology of the 40 nm thick PEDOT-PSS film deposited on the different Ag surfaces is strongly dependent on the

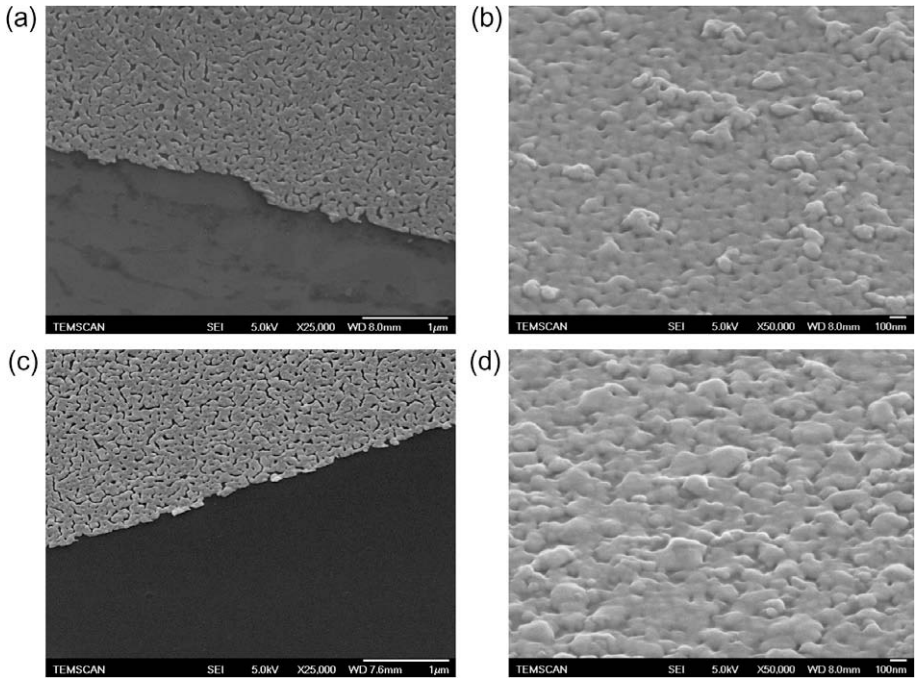

Fig. 3. FEG-SEM images of the surface morphology of the Cr/Ag evaporated bi-layer with and without a 40 nm PEDOT-PSS over-layer: (a) 5 nm Cr and 25 nm Ag evaporated at low rate (0.05 nm/s) without PEDOT-PSS, (b) 5 nm Cr and 25 nm Ag evaporated at low rate (0.05 nm/s) with PEDOT-PSS layer, (c) 5 nm Cr and 25 nm Ag evaporated at high rate (1.1 nm/s) without PEDOT-PSS layer, (d) 5 nm Cr and 25 Ag evaporated at high rate (1.1 nm/s) with PEDOT-PSS layer. ((a) and (c) Magnification 25,000× and (b) and (d) magnification 50,000×, 5 kV acceleration voltage).

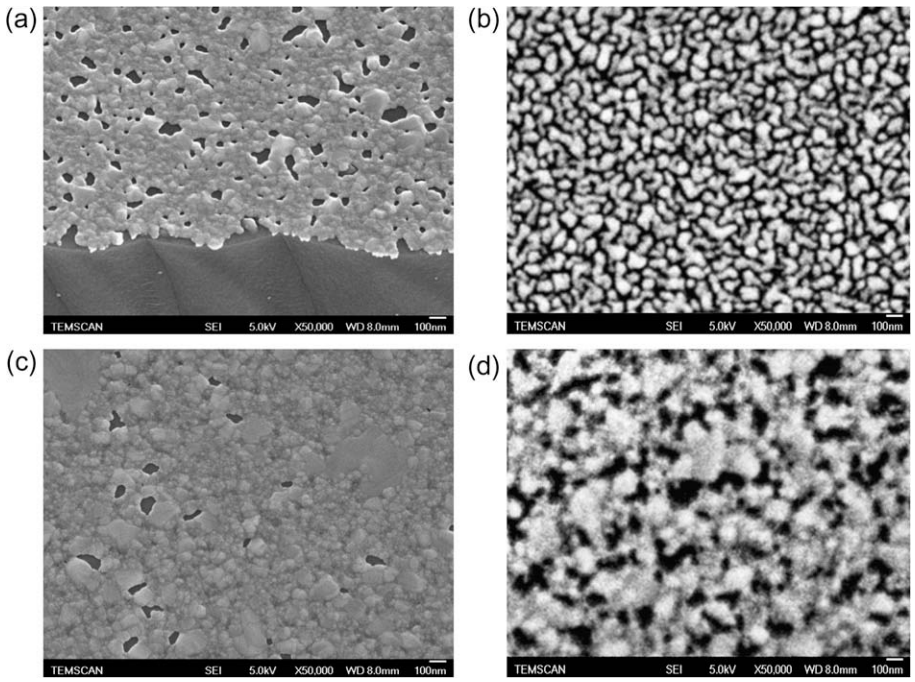

Fig. 4. FEG-SEM images of the surface morphology of the a-C:H/Ag evaporated bi-layer with and without a 40 nm PEDOT-PSS over-layer: (a) 5 nm a-C:H and 25 nm Ag evaporated at low rate (0.05 nm/s) without PEDOT-PSS, (b) 5 nm a-C:H and 25 nm Ag evaporated at low rate (0.05 nm/s) with PEDOT-PSS layer, (c) 5 nm a-C:H and 25 nm Ag evaporated at high rate (1.1 nm/s) without PEDOT-PSS layer, (d) 5 nm a-C:H and 25 Ag evaporated at high rate (1.1 nm/s) with PEDOT-PSS layer. (Magnification 50,000× and 5 kV acceleration voltage).

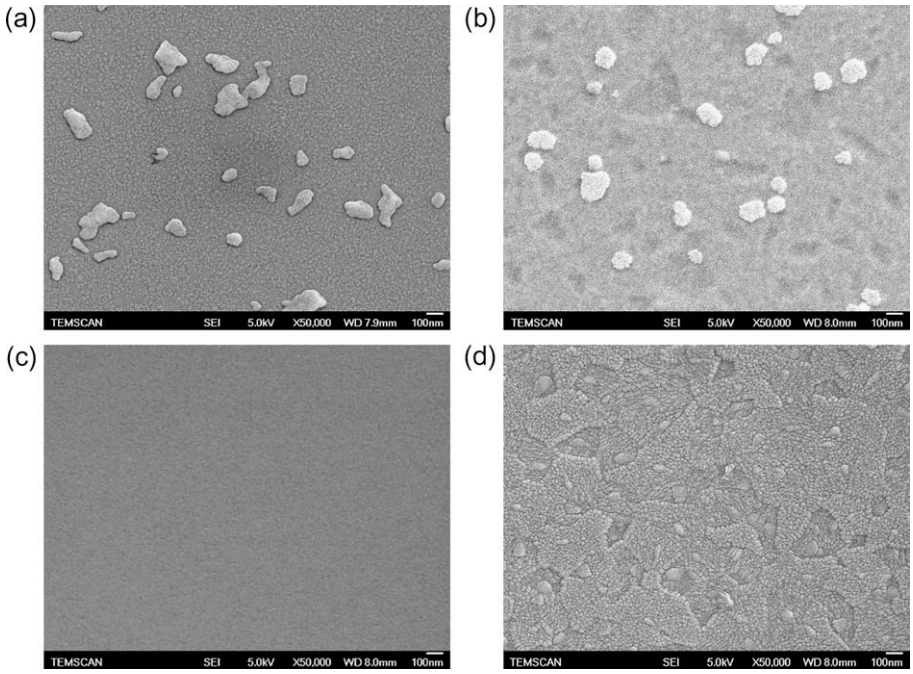

Fig. 5. FEG-SEM images of the surface morphology of the Ge/Ag evaporated bi-layer with and without a 40 nm PEDOT-PSS over-layer: (a) 5 nm Ge and 25 nm Ag evaporated at low rate (0.05 nm/s) without PEDOT-PSS, (b) 5 nm Ge and 25 nm Ag evaporated at low rate (0.05 nm/s) with PEDOT-PSS layer, (c) 5 nm Ge and 25 nm Ag evaporated at high rate (1.1 nm/s) without PEDOT-PSS layer, (d) 5 nm Ge and 25 Ag evaporated at high rate (1.1 nm/s) with PEDOT-PSS layer. (Magnification 50,000× and 5 kV acceleration voltage).

nucleation layer, as it can be seen from the SEM images reported in Figs. 3b and d, 4b and d, & 5b and d. This effect is observable also in the surface roughness values (Table 1): in contrast with what is measured for Ag on nucleation layer, the PEDOT-PSS layer roughness is more important on a-C:H/Ag than in Cr/Ag. As can be seen in Figs. 3b and d & 4b and d, on Cr/Ag and on a-C:H/Ag surfaces the voids are not completely filled by the polymer and some small PEDOT-PSS aggregates appear on the surface. In the case of Ge/Ag films, where the surface previous to the PEDOT-PSS coating is more uniform, a smooth 2D PEDOT-PSS distribution is clearly observable (Fig. 5b and d). Also in this case, it is possible to note the aggregation of smaller PEDOT-PSS grains. The higher planarity of the Ge/Ag surfaces is maintained, also with a slight worsening of the total roughness. It is evident that in all cases the PEDOT-PSS deposition is not smoothing the surfaces but it leads to a slight worsening of the micro-roughness, probably due to the centrifugal force applied during the spin-coating process. The latter may induce accumulation of polymer near the spikes of the Ag surface. This effect could depend on the different PEDOT-PSS surface wettability of the Ag surfaces grown on the different nucleation layers. So, an investigation of surface wettability and surface energy of the different bi-layers has been carried out as well. These measurements, performed with a contact angle DIGI-DROP (GBX-Instrumentation) instrument, will be discussed more extensively elsewhere, but a PEDOT-PSS wettability dependence on the nucleation layer has been found with the following result: Ge > Cr > a-C:H. Moreover, the Ag film grown on Ge nucleation layer at high rate presents the higher water and PEDOT-PSS wettability with a contact angle of 15.6° and 22.8°, respectively.

The Ag thin films, grown on different nucleation layers and coated with the 40 nm PEDOT-PSS layer, were then used as anode for a blue emitting small molecule based bottom micro-cavity OLED fabrication. The following molecular architecture has been used to produce the samples: nucleation layer [5 nm], Ag [25 nm], PEDOT-PSS [40 nm], a-NPB (*N*,*N*′-bis(naphthalene-1y1)-*N*,*N*′-bis(phenyl)benzidine) [20 nm], $BAlq_3$ (bis-(2-methyl-8-quinolinato)-4-(phenyl-phenolato)aluminum-(III)) [40 nm], LiF [0.7 nm] and Al [100 nm]. The total thickness of the organic layers is rather small, so the emitting device is prone to short circuits.

In order to fabricate the OLED samples a mask with four circles of different diameters (1, 2, 4 and 6 mm, respectively) has been used. The OLED have been fabricated by thermal evaporation from Knudsen cells under high vacuum condition ($<10^{-4}$ Pa) in the same evaporation chamber used to prepare the Ag anode (BOC EDWARDS 500). The final samples have then been encapsulated in a pure nitrogen filled glove box directly connected with the evaporation chamber.

The OLED samples prepared with the Cr/Ag and a-C:H/Ag, both at high and low rate, presented short circuits distributed all over the whole surface and it was not possible to switch them on. The use of the bi-layer Ge/Ag anode deposited at low rate allows to obtain only very unstable devices of small dimension (not more than 1 mm diameter) with a very short lifetime and prone to short circuit formation after the voltage application. But the samples

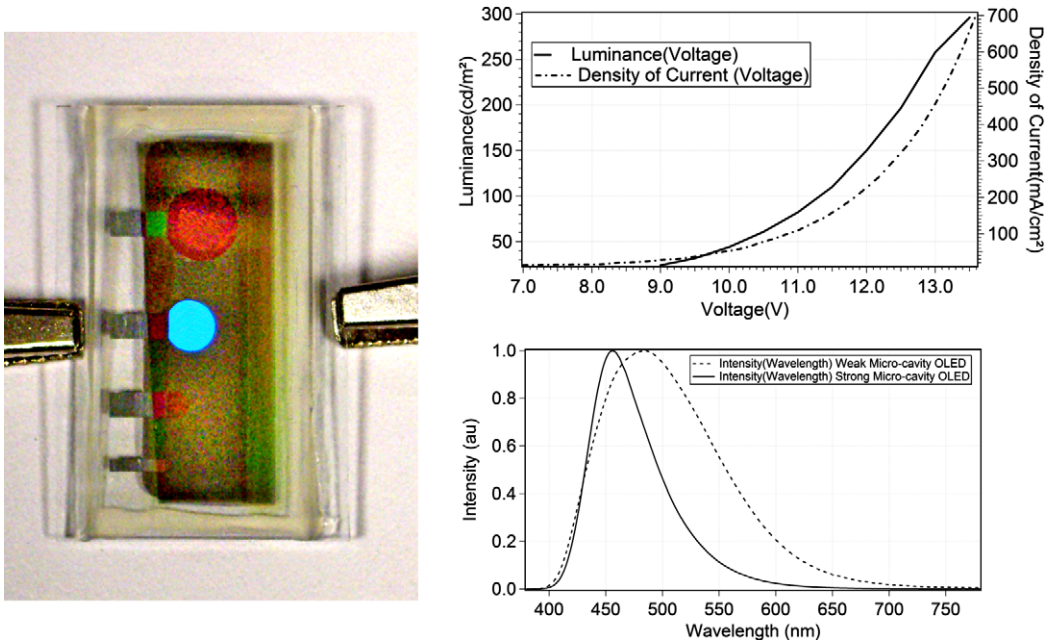

Fig. 6. Left: picture of a bottom blue emitting micro-cavity OLED fabricated over a 5 nm Ge and 25 Ag bi-layer anode evaporated at high rate (1.1 nm/s) on a borosilicate glass substrate. The lighting device is based on fluorescent $BAlq_3$ emitting layer and has a 4 mm diameter. Right: upper graph *L–V* and *J–V* curves of the imaged device, recorded with a source meter specifically developed at LAPLACE laboratory. Bottom graph: comparison of the spectral emissions of the strong micro-cavity (Ag anode – full line) and the weak micro-cavity (ITO anode – dashed line) OLED devices, measured at normal incidence with a Minolta CS-1000 spectrophotometer. For the strong micro-cavity OLED the peak wavelength is at 459 nm with a FWHM of 55 nm, for the weak micro-cavity OLED the peak wavelength is at 485 nm with a FWHM of 123 nm.

fabricated using the Ge/Ag deposited at high rate showed a very interesting behavior. No short circuits were evident in the first three devices (1, 2 and 4 mm diameter), the emitting surfaces were very uniform and the switching voltage at 1 cd/m^2 was at 8.9 V, comparable (V = 8.8 V) with that obtained using the same molecular architecture and a commercial ITO anode (thickness = 120 nm with a sheet resistance of ≈20 Ω/□). A picture of the 4 mm diameter device with the *J–V* and *L–V* curves, measured in air, is shown in Fig. 6. In the same figure, the spectral emission of the Ag based micro-cavity OLED (strong micro-cavity) and that of the device fabricated using an ITO anode (weak micro-cavity) are compared. The strong micro-cavity peak wavelength is at 459 nm and the spectrum is quite narrow (FWHM of 55 nm), confirming the simulated micro-cavity effect, while the weak micro-cavity OLED peak wavelength is at 485 nm with a FWHM of 123 nm. The luminous efficiencies (LE) of both devices are quite low, but comparable with that of literature reported devices fabricated with fluorescent emitters with similar spectral emission [37]. In particular, the weak-micro-cavity device presented a LE = 1 cd/A at a luminance of 100 cd/m^2 while the strong micro-cavity OLED exhibit a LE = 0.35 cd/A, at the same luminance. The difference in LE can be ascribed to the photopic response which is much weaker in the blue region of the spectrum. Our micro-cavity OLEDs are envisaged for a particular application, where only the normal viewing angle is important, so the luminance has been measured only at normal incidence. Several OLED samples using the Ge/Ag with high deposition rate anode have been fabricated with a good repeatability and with a long lifetime (more than 1500 h at a luminance of 100 cd/m^2).

A different method of Silver OLED anode fabrication for both top and bottom emission devices with good injection properties has been reported in literature [38,39]. However, in this latter case a modification of the Ag anode surface with a CF_x plasma treatment is required to improve the hole injection, making the fabrication process quite complicated and expensive. In our case, the very simple fabrication method and the absence of post-processing make the silver based bi-layer anode very interesting for application in bottom micro-cavity OLED devices, also for relatively large area, due to its small roughness and to the very low significant spikes density.

4. Conclusion

A systematic investigation on roughness smoothing of a thin film Ag based OLED micro-cavity anode has been performed using different nucleation layer and deposition rates. A very accurate surface morphology investigation, based on a white-light interferometry optical profiler and on a field emission gun scanning electron microscope, on vacuum deposited bi-layers have indicated that high rate (1.1 nm/s) deposition of silver films allows to obtain smoother surfaces on all the nucleation layers used in this study (Cr, a-C:H and Ge). In particular, an optimized silver anode obtained using a 5 nm Ge nucleation layer and a high Ag (1.1 nm/s) deposition rate has been successfully used to obtain a long lifetime,

large area (12.5 mm^2) and short circuit free blue emitting bottom OLED micro-cavity.

Acknowledgments

The authors would like to thanks for the valuable discussions Prof. Maya Kiskinova of Sincrotrone Trieste, Trieste (Italy). We are also grateful to Mr. Benoit Schlegel of Service Instrumentation-LAPLACE, Univ. Paul Sabatier, Toulouse (France) for the Chromium deposition and to "Lumière et Matière" group of the LAPLACE for the support in the research activities.

pioneering works [13–17] based on this formalism, which are very interesting from the theoretical as well as experimental point of view.

Several *ab initio* methods [18–21] are there which may be utilized to study electron transport properties through molecular junctions. At the same time, tight-binding model has been extended to density functional theory (DFT) for transport calculations [22]. But in case of molecular systems, the investigations based on this theory (DFT) have some quantitative discrepancies compared to the experimental predictions. Moreover, these *ab initio* theories are computationally very expensive. To avoid this we do model calculations by using a simple tight-binding framework.

In the present article we do a theoretical study of multi-terminal electron transport through a single phenalenyl molecule [23,24] attached to semi-infinite one-dimensional (1D) metallic leads. We do numerical calculations based on single particle Green's function formalism [25,26] to evaluate conductance, reflection probability and current–voltage characteristics. Quite interestingly, we show that the positions where the leads are connected to the molecule as well as the presence of other leads have eloquent effects on these transport properties. Moreover, these characteristics are also influenced significantly by the molecule-to-lead coupling strengths. These aspects can be utilized in designing nanoelectronic devices.

We organize the paper as follows. With a brief introduction (Section 1), in Section 2 we describe our model and the theoretical background. Results are analyzed in Section 3. Finally we conclude our results in Section 4.

2. Model and a view of theoretical formulation

In this section we focus our attention on the systems where a single phenalenyl molecule is attached symmetrically or asymmetrically to semi-infinite 1D metallic leads through thiol (SH bond) groups. The models are shown schematically in Fig. 1(a)–(c) where, the number of leads attached to the molecule is 2–4, respectively. To evaluate the conductance (g) and current (I) through this single molecular system we adopt the Green's function technique. For this, first we define the Green's function for the whole system as,

$$G = (E - H)^{-1} \tag{1}$$

where $E = \epsilon + i\eta$ with η arbitrarily very small number which can be set as zero in the limiting approximation. ϵ is the injecting electron energy. H is the Hamiltonian of the entire system which is of infinite dimension. So, the above equation deals with the inversion of an infinite dimensional matrix corresponding to the system consisting of a finite size molecule and semi-infinite leads. However, the full Hamiltonian can be partitioned into sub-matrices that correspond to the individual sub-systems like,

$$H = H_M + \sum_{p=1}^{N} \left(H_p + H_{pM} + H_{pM}^{\dagger} \right) \tag{2}$$

where H_M and H_p are the Hamiltonians of the molecule and lead-p, respectively. N is the number of leads to which the molecule is attached. H_{pM} represents the coupling matrix that will be non-zero only for the adjacent points in the molecular system (molecule with sulfur atoms) and the lead-p. Here all the leads are treated on an equal footing. Within the non-interacting picture, the tight-binding Hamiltonian of the molecular system can be manifested as,

$$H_M = \sum_i \epsilon_i c_i^{\dagger} c_i + \sum_{\langle ij \rangle} t \left(c_i^{\dagger} c_j + c_j^{\dagger} c_i \right) \tag{3}$$

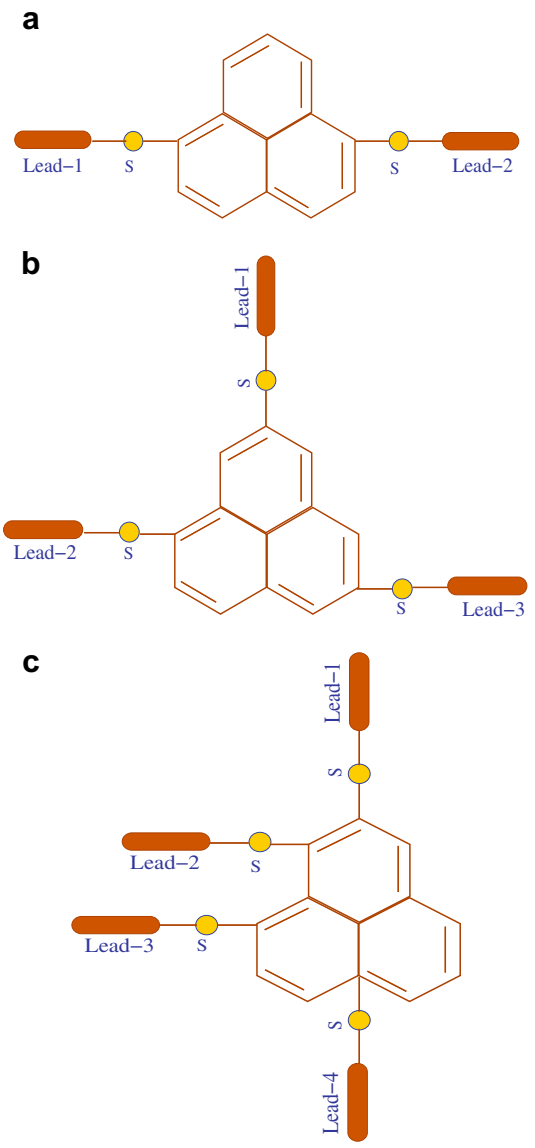

Fig. 1. Multi-terminal quantum system. A phenalenyl molecule is attached symmetrically or asymmetrically to semi-infinite 1D metallic leads through thiol (SH bond) groups in the chemisorption technique where sulfur (S) atoms reside and hydrogen (H) atoms remove. The filled yellow circles correspond to the location of S atoms. The number of leads attached to the molecule is 2, 3 and 4 as shown in (a), (b) and (c), respectively. Leads are denoted by lead-1, lead-2, lead-3 and lead-4. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

where ϵ_i is the on-site energy, t is the nearest-neighbor hopping integral and $c_i^\dagger$ (c_i) is the creation (annihilation) operator of an electron at the site i. Each lead can be described by using a similar kind of tight-binding Hamiltonian, as given in Eq. (3), characterized by two parameters ϵ_0, the on-site potential and t_0, the nearest-neighbor hopping integral.

Following the partition of the Hamiltonian, the Green's function can also be partitioned into sub-matrices and the effective Green's function for the molecular system can be indited (using Lowdin's partitioning technique [27,28]) as,

$$G_M = \left(E - H_M - \sum_{p=1}^{N} \Sigma_p\right)^{-1} \tag{4}$$

where Σ_p is the self-energy due to the coupling of the molecular system to the lead-p. It is straightforward to obtain an explicit expression for self-energy corresponding to lead-p,

$$\Sigma_p = H_{pM}^\dagger G_p H_{pM} \tag{5}$$

where $G_p = (E - H_p)^{-1}$ is the Green's function of lead-p. All the coupling informations are inscribed into this self-energy expression. Once the Green's function is established, the coupling function Γ_p can be easily obtained from the equation [29,30],

$$\Gamma_p(E) = i\left[\Sigma_p^r(E) - \Sigma_p^a(E)\right] \tag{6}$$

where the advanced self-energy Σ_p^a is the Hermitian conjugate of the retarded self-energy Σ_p^r. Thus, we can write,

$$\Gamma_p = -2\mathrm{Im}(\Sigma_p^r) \tag{7}$$

In order to evaluate the conductance for the multi-terminal quantum system, we use the Büttiker formalism [29], valid at much low temperature and bias voltage, in the form,

$$g_{pq} = \frac{2e^2}{h} T_{pq} \tag{8}$$

where T_{pq} is the transmission probability of an electron across the molecular system from the lead-p to lead-q and it is related to the reflection probability by the equation,

$$R_{pp} + \sum_{q(\neq p)} T_{qp} = 1 \tag{9}$$

which is obtained from the condition of current conservation [31]. Now, this transmission probability can be expressed in terms of the effective Green's function of the molecular system and molecule-to-lead coupling as,

$$T_{pq} = \mathrm{Tr}\left[\Gamma_p G_M^r \Gamma_q G_M^a\right] \tag{10}$$

where G_M^r and G_M^a are the retarded and advanced Green's functions of the molecular system, respectively. Γ_p and Γ_q represent the couplings of the molecule to the lead-p and lead-q, respectively. Since the coupling matrix H_{pM} is non-zero only for the adjacent points, n and m, the transmission probability becomes [32],

$$T_{pq} = 4\Delta_p(nn)\Delta_q(mm)|G_M(nm)|^2 \tag{11}$$

where $\Delta_p(nn) = \langle n|\Delta_p|n\rangle, \Delta_q(mm) = \langle m|\Delta_q|m\rangle, G_M(nm) = \langle n|G_M|m\rangle$ and Δ_p, Δ_q are the imaginary parts of Σ_p and Σ_q, respectively.

In case of two-terminal system [33], Eq. (8) becomes quite simpler like,

$$g = \frac{2e^2}{h} T \tag{12}$$

and accordingly, the reflection probability becomes $R = 1 - T$. For the two-terminal quantum system the above expression (Eq. (12)) is the so-called Landauer conductance formula.

The current I_p passing through the lead-p can be obtained from the following expression [29],

$$I_p = \frac{2e}{h} \sum_q \int_{-\infty}^{\infty} T_{pq}(E)\left[f_p(E) - f_q(E)\right] dE \tag{13}$$

where $f_{p(q)} = f(E - \mu_{p(q)})$ is the Fermi distribution function with the chemical potential $\mu_{p(q)} = E_F \pm eV_{p(q)}/2$. E_F is the equilibrium Fermi energy. Throughout this calculation, we assume that the entire voltage is dropped across the molecule-lead interfaces as this assumption introduces a minimal effect on the behavior of the I–V characteristics. In this article we set $c = h = e = 1$ for the sake of simplicity.

3. Numerical results and discussion

In order to illustrate the results, let us first mention the values of different parameters used in our numerical calculations. All the on-site energies of molecule, sulfur atom and leads are set to zero, while the nearest-neighbor hopping strengths are fixed at 3 for both the molecule (t) and leads (t_0). But the values of molecule-to-lead coupling strengths (τ_p for lead-p) are different from the value assigned for t and t_0. Based on the molecular coupling strength, we analyze our results in two distinct regimes. One is the weak-coupling regime and the other is the strong-coupling regime. In the first case, $\tau_p \ll t$ and we set $\tau_p = 0.5$. In the second case, $\tau_p \sim t$ and for this regime we fix $\tau_p = 2.5$. Here we consider that τ_p's are identical for all the leads p and set the equilibrium Fermi energy E_F at 0.

3.1. Conductance–energy characteristics

In the forthcoming sub-sections we present the characteristic properties of electron transport for two-, three- and four-terminal molecular systems where the molecules are attached to leads via thiol-linking groups (SH bond). In experiments, leads are generally designed from gold (Au) and the thiol groups are linked by using chemisorption technique [34] where hydrogen (H) atoms remove and sulfur (S) atoms survive.

3.1.1. Two-terminal conductance

In Fig. 2 we present the variation of two-terminal conductance g (red curves) and reflection probability R (green curves) with injecting electron energy E. The results in the weak molecule-to-lead coupling limit are shown in (a) and

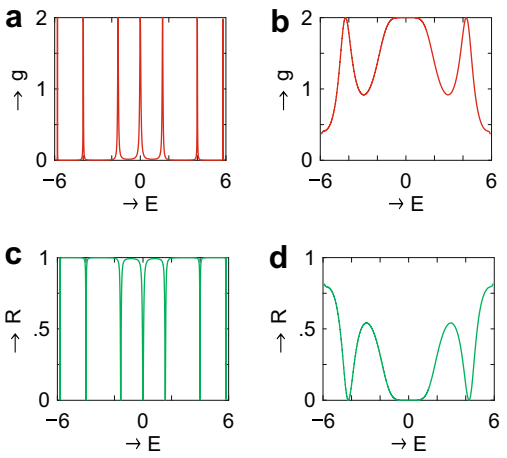

Fig. 2. Conductance g (red lines) and reflection probability R (green lines) as a function of energy E for the two-terminal molecular system. (a) and (c) Represent the results for the weak-coupling limit, while (b) and (d) correspond to the same for the strong-coupling limit. Conductance g is measured in unit of e^2/h, while the energy E is measured in unit of t. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

(c), while (b) and (d) represent the same for the strong molecule-to-lead coupling limit. In the weak-coupling regime, the presence of sharp resonant peaks indicates that electron transmission occurs at some typical energy values, while for all other energies conductance vanishes (see Fig. 2(a)). All these resonant peaks are associated with the energy eigenvalues of the molecular system, and therefore, we predict that conductance spectrum is a fingerprint of the electronic structure of the system. Most of the resonant peaks approach the value 2, the maximum value of g following the Landauer conductance formula (see Eq. (12)) and hence T goes to unity at these resonances indicating ballistic transmission through the molecular wire. But the behavior of conductance spectrum changes in case of the strong molecule-to-lead coupling limit. Width of each resonant peak becomes larger and larger as we increase gradually the molecule-to-lead coupling strength and for a large molecular coupling, we have the situation where electron transmission takes place for the entire energy range (for illustration, see Fig. 2(b)). The effect of such broadening comes from the imaginary parts of the self-energies [29]. All these phenomena emphasize that fine tuning in the energy scale is necessary as long as the coupling strength is much weak, while it is not required in case of the strong molecule-to-lead coupling limit.

This scenario is just inverted in case of reflection probability R. In the weak-coupling regime, sharp dips appear (Fig. 2(c)) for some particular energy values where conductance shows resonant peaks, as R follows the simple relation $R = 1 - T$ for the two-terminal molecular system. For all other energy values, $R = 1$ indicating no transmission of electron across the molecule. The effect of molecule-to-lead coupling is exactly similar to that for conductance spectrum. In the strong-coupling regime (see Fig. 2(d)), the reflection probability no longer reach the maximum value (1) for the entire energy range.

3.1.2. Three-terminal conductance

To illustrate the results for the three-terminal quantum system, constructed by attaching three leads to the molecule (see Fig. 1(b)), let us start by referring to Fig. 3 where the first column shows the conductance spectra g_{pq} (from lead-p to lead-q) and the second column presents the nature of reflection probability R_{pp}. Similar to the two-terminal molecular system, some sharp peaks appear in the conductance spectra. But the point is that for the three-terminal system most of the resonant peaks do not reach the value 2. From the conductance spectra it is clear that the heights are much reduced compared to the two-terminal case. This is solely due to the effect of quantum interference of the electronic waves passing through different arms of the molecular rings. In this three-terminal system, three leads are attached asymmetrically to the molecule at three different locations, which provide different path ways for electron transmission between the leads. This introduces anomalous features in the conductance spectra as illustrated in Fig. 3(a)–(c). Moreover, in this three-terminal case, nature of variations of reflection probabilities is not so simple as we get in the case of two-terminal molecular system. Here, it is not necessary that R_{pp} shows dips or peaks where g_{pq} has peaks or dips since it (R_{pp}) depends on the combined effect of T_{pq}'s obeying the expression given in Eq. (9). Another important point we like to mention here is that, one can easily find T_{qp} for any two leads q and p if T_{pq} is known since the relation $T_{pq} = T_{qp}$ holds true following the time-reversal symmetry. The effect of

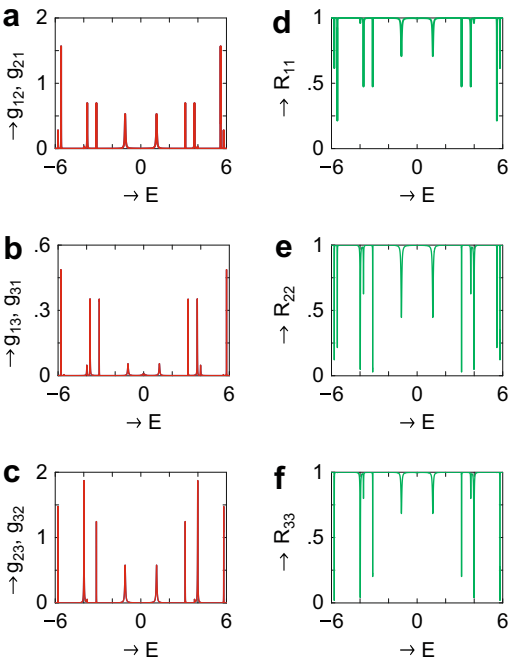

Fig. 3. Conductance g_{pq} (red curves) and reflection probability R_{pp} (green curves) as a function of energy E for the three-terminal molecular system. All the spectra are given only for the weak-coupling regime. Conductance is measured in unit of e^2/h, while the energy is measured in unit of t. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

molecule-to-lead coupling strength is identical to the case of two-terminal conductance and therefore, we do not show those results further.

3.1.3. Four-terminal conductance

The transport properties of the four-terminal molecular system are also described by investigating various conductances g_{pq} and reflection probabilities R_{pp} those are obtained from Eqs. (8) and (9), respectively. The results are plotted in Fig. 4 considering the weak molecule-to-lead coupling. In each figure g_{pq} and g_{qp} are plotted and they are superposed to each other due to their symmetry. Sharp resonant peaks of different heights for some particular energies appear in the conductance spectra similar to the two- or three-terminal conductance spectra. From the conductance spectra, the effect of quantum interference associated with the molecule-to-lead interface geometry is well understood. Also the dependence of electron transport on molecular coupling strength is exactly similar to that in Fig. 2 and accordingly, the results are not given further. Comparing the results given in Figs. 3 and 4 we observe that, the conductances for two particular leads located at the same positions of the molecule exhibit completely different features in presence of the other leads. For instance, g_{13} of the four-terminal system and g_{12} of the three-terminal system show different spectra though these two conductances are evaluated for the two leads located at the same positions of the molecule. Similarly, careful observation depicts that pathways between the lead-2 and lead-3 of the three-terminal system are exactly similar to that between lead-2 and lead-4 of the four-terminal system. In spite of this the corresponding spectra, i.e., g_{23} of Fig. 3 and g_{24} of Fig. 4 are different from each other due to the presence of the fourth lead. The effect of the leads are incorporated into the self-energies which lead to the change in conductance spectra. Thus, we can say that the presence of additional leads has a pronounced effect on the electron transport properties. In R–E spectra given in Fig. 5, we get various dips at different energies depending on the combined effect of the transmission probabilities (Eq. (9)), similar to the case of three-terminal system. All the reflection probabilities are calculated only for the limit of weak molecular coupling. Exactly similar feature, except the broadening, will be observed in the case of strong-coupling.

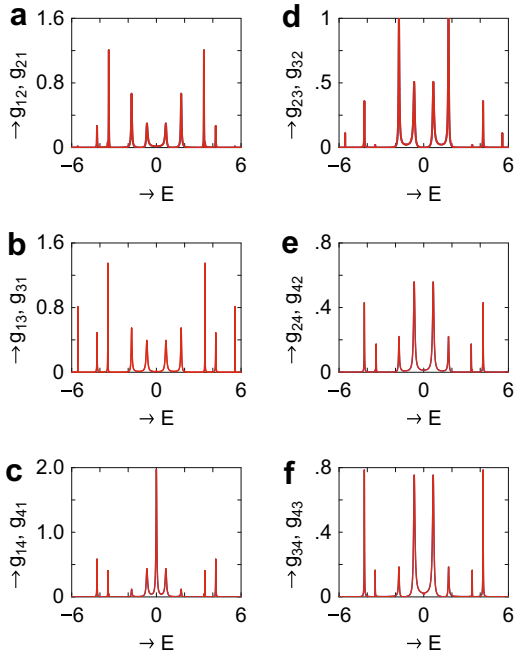

Fig. 4. Four-terminal conductance g_{pq} (in unit of e^2/h) as a function of energy E (in unit of t) in the limit of weak molecular coupling.

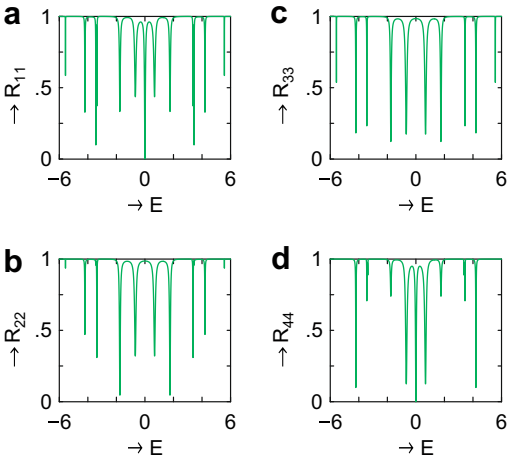

Fig. 5. Reflection probability R_{pp} as a function of energy E (in unit of t) for the four-terminal quantum system. These results correspond to the weak-coupling regime.

3.2. Current–voltage characteristics

The scenario of electron transport through molecular junction becomes much more transparent when we discuss the current–voltage (I–V) characteristics, where the current is evaluated by integrating the transmission probability T using Eq. (13). The nature of the variation of transmission probability is exactly similar to that of conductance spectra except the factor 2 as we have assumed $e = h = 1$ in the Landauer conductance formula (Eq. (12)). Here, we discuss the I–V characteristics for two-, three- and four-terminal molecular systems separately in the following sub-sections.

3.2.1. Two-terminal molecular system

As an illustration, we display the I–V characteristics for the two-terminal system in Fig. 6, where (a) and (b) correspond to the results for the weak and strong molecule-to-lead coupling limits, respectively. For this two-terminal case, current can be expressed mathematically as follows,

$$I = g(V_1 - V_2) = gV_{12} \tag{14}$$

where V_{12} is the voltage difference between the lead-1 and lead-2. In the case of two-terminal molecular system, we have attached two leads to the molecule and their chemi-

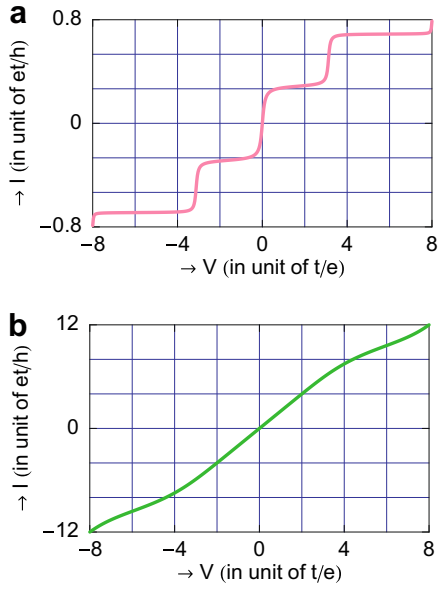

Fig. 6. Current I (in unit of et/h) as a function of applied bias voltage V (in unit of t/e) for the two-terminal molecular system. (a) Weak-coupling limit and (b) strong-coupling limit.

cal potentials are changed as the bias voltage is applied. With the increase of the voltage, the gap increases more and more and eventually crosses molecular energy levels one after another. Accordingly, current channels are opened up and jumps in the I–V curve appear. This provides staircase-like structure in the current–voltage spectrum and only for the case of weak molecular coupling these sharp steps appear. But this feature, i.e., step-like changes gradually towards continuous nature with the increase of molecule-to-lead coupling strength. In addition to that, current amplitude becomes much higher compared to the case of weak-coupling limit. By noting the area under the curve of Fig. 2(b) the reason behind this enhancement of current amplitude is clearly understood. Thus, it can be manifested that molecule-to-lead coupling strength has a significant influence on molecular transport.

3.2.2. Three-terminal molecular system

Now, we describe the current–voltage characteristics for the three-terminal system where we find the current I_p in lead-p by integrating the transmission function T_{pq} considering the effects of other terminals. To be more precise, we write the current expressions for three different leads as follows,

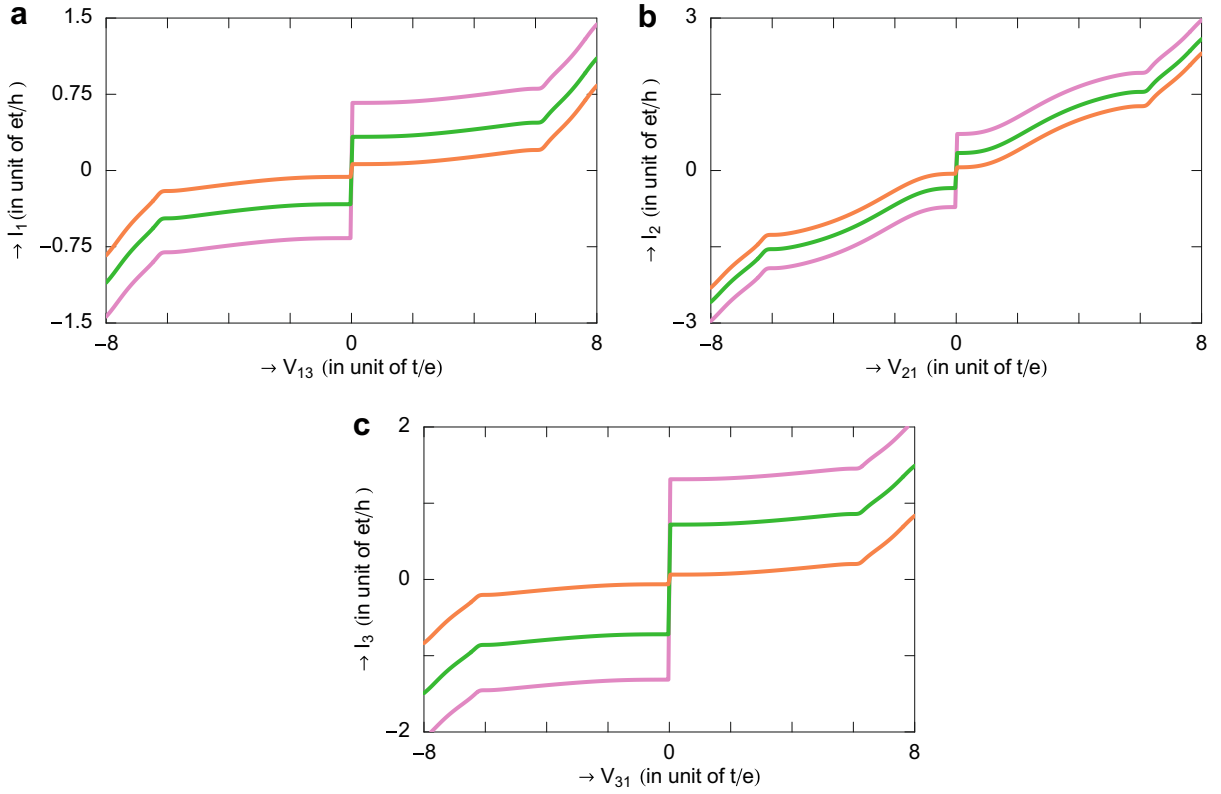

Fig. 7. I–V characteristics for the three-terminal molecular system in the limit of strong-coupling. (a) I_1 as a function of V_{13} $(= V_1 - V_3)$, keeping V_{12} $(= V_1 - V_2)$ as a constant. The orange, green and magenta colors correspond to $V_{12} = 1, 2$ and 3, respectively. (b) I_2 as a function of V_{21} $(= V_2 - V_1)$, considering V_{23} $(= V_2 - V_3)$ as a constant. The orange, green and magenta colors correspond to $V_{23} = 1, 2$ and 3, respectively. (c) I_3 as a function of V_{31} $(= V_3 - V_1)$, keeping V_{32} as a constant. The orange, green and magenta colors correspond to $V_{32} = 1, 3$ and 5, respectively. Current is measured in unit of et/h, and the bias voltage is measured in unit of t/e. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

$$I_1 = g_{12}(V_1 - V_2) + g_{13}(V_1 - V_3) = g_{12}V_{12} + g_{13}V_{13} \quad (15)$$
$$I_2 = g_{21}(V_2 - V_1) + g_{23}(V_2 - V_3) = g_{21}V_{21} + g_{23}V_{23} \quad (16)$$
$$I_3 = g_{31}(V_3 - V_1) + g_{32}(V_3 - V_2) = g_{31}V_{31} + g_{32}V_{32} \quad (17)$$

where $V_{pq} = (V_p - V_q)$ is the voltage difference between the two leads named as lead-p and lead-q.

In Fig. 7(a), we plot I_1 for the lead-1 as a function of V_{13} for different fixed values of V_{12} in the strong molecule-to-lead coupling limit. The orange, green and magenta curves represent the currents for $V_{12} = 1, 2$ and 3, respectively. It is clear from the figure that for a constant value of V_{12}, the moment we switch on the bias voltage between lead-1 and lead-3, current rises to a large value. Then, for a wide range of V_{13}, it (I_1) slowly increases with the rise of V_{13} and finally the rate of increment of the current gets enhanced when V_{13} is quite high. This behavior, i.e., the rate of increment of the current with bias voltage solely depends on the positions of resonant peaks in the g–E spectrum. For a particular value of V_{13}, I_1 increases as we increase V_{12} which is clearly visible from three different curves plotted in Fig. 7(a).

The variation of current I_2 through lead-2 as a function of V_{21} is shown in Fig. 7(b), keeping the voltage V_{23} as a constant. The currents are evaluated in the strong-coupling limit, where the orange, green and magenta lines correspond to $V_{23} = 1, 2$ and 3, respectively.

In a similar fashion in Fig. 7(c) we display I_3—V_{31} characteristics for different fixed values of V_{32} considering the case of strong-coupling limit. The orange, green and magenta curves correspond to $V_{32} = 1, 3$ and 5, respectively.

The characteristic features of the currents I_1, I_2 and I_3 passing through three different leads are quite analogous to each other. Depending on the conductance–energy spectra, we get different current amplitudes for three different leads which are clearly observed from the results presented in Fig. 7(a)–(c). All these currents are computed only for the strong-coupling limit. We can also determine the currents for the limit of weak-coupling and in that case we will get sharp step-like features as a function of bias voltage with much reduced amplitude compared to the strong-coupling case. The origin of step-like behavior in current is clearly mentioned in the case of two-terminal molecular system (Section 3.2.1).

From the above current expressions (Eqs. (15)–(17)) we see that the current in anyone lead is related to two potential functions. For instance in Eq. (15), there are two

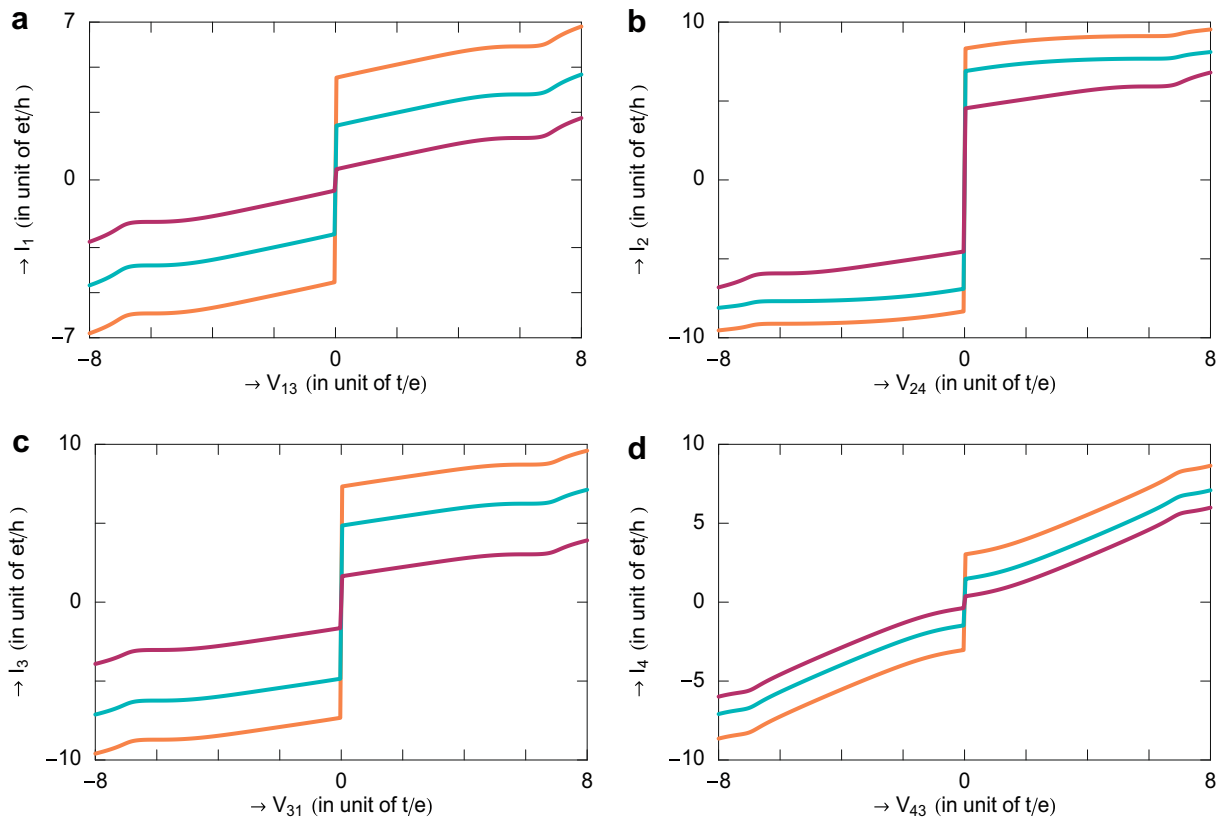

Fig. 8. I–V characteristics for the four-terminal molecular system in the strong-coupling regime. (a) I_1 as a function of V_{13}, keeping V_{12} and V_{14} as constant. The dark-red, blue and orange colors correspond to $V_{12} = V_{14} = 1, 3$ and 5, respectively. (b) I_2 as a function of V_{24} ($= V_2 - V_4$), keeping V_{21} and V_{23} as constant. The dark-red, blue and orange lines correspond to $V_{21} = V_{23} = 2, 4$ and 6, respectively. (c) I_3 as a function of V_{31} considering V_{32} and V_{34} as constant. The dark-red, blue and orange curves correspond to $V_{32} = V_{34} = 1, 3$ and 5, respectively. (d) I_4 as a function of V_{43} ($= V_4 - V_3$) keeping V_{41} and V_{42} as constant, where the dark-red, blue and orange lines correspond to $V_{41} = V_{42} = 1, 5$ and 9, respectively. Current is measured in unit of et/h, and the bias voltage is measured in unit of t/e. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

parameters like V_{12} and V_{13}. Keeping V_{12} as a constant we plot the current I_1 in terms of V_{13} (see Fig. 7(a)). At the same time, we can also draw the I_1–V_{12} characteristics, considering V_{13} as a constant. Both for these two cases, the characteristic features are quite similar. This argument is also valid for the other two current expressions (Eqs. (16) and (17)).

All the above features of current–voltage characteristics in this three-terminal molecular system clearly support the basic features of a traditional macroscopic transistor. Thus we can predict that the three-terminal molecular system may be utilized to design a nanoscale molecular transistor.

3.2.3. Four-terminal molecular system

Finally, we focus our attention on the current–voltage characteristics for the four-terminal molecular system. In this molecular system, the current expressions for the four different leads are as follows,

$$I_1 = g_{12}(V_1 - V_2) + g_{13}(V_1 - V_3) + g_{14}(V_1 - V_4) = g_{12}V_{12} + g_{13}V_{13} + g_{14}V_{14} \quad (18)$$

$$I_2 = g_{21}(V_2 - V_1) + g_{23}(V_2 - V_3) + g_{24}(V_2 - V_4) = g_{21}V_{21} + g_{23}V_{23} + g_{24}V_{24} \quad (19)$$

$$I_3 = g_{31}(V_3 - V_1) + g_{32}(V_3 - V_2) + g_{34}(V_3 - V_4) = g_{31}V_{31} + g_{32}V_{32} + g_{34}V_{34} \quad (20)$$

$$I_4 = g_{41}(V_4 - V_1) + g_{42}(V_4 - V_2) + g_{43}(V_4 - V_3) = g_{41}V_{41} + g_{42}V_{42} + g_{43}V_{43} \quad (21)$$

where V_{pq} is the voltage difference between the lead-p and lead-q.

As representative examples, in Fig. 8(a) we plot the current in lead-1 (I_1) as a function of V_{13} keeping V_{12} and V_{14} as constant. The results are computed for the strong-coupling limit, where the dark-red, blue and orange curves correspond to $V_{12} = V_{14} = 1, 3$ and 5, respectively. The variation of current I_1 as a function of V_{13} in this four-terminal molecular system is quite similar to that as presented in the case of three-terminal system (Fig. 7(a)). For a particular value of V_{13}, here also the current amplitude gets increased with the rise of V_{12} and V_{14}. But quite significantly we observe that, for a particular value of V_{13}, the current I_1 passing through the lead-1 of four-terminal system acquires much higher amplitude compared to the three-terminal system (see Figs. 7(a) and 8(a)). The reason behind this enhancement of current amplitude is explained as follows. From Eq. (18) we see that I_1 contains three additive terms where the contributions come from other leads, while in Eq. (15) there are two additive terms. The additional term appears in Eq. (18) is due to the presence of fourth terminal which is responsible for the larger current in four-terminal system compared to the three-terminal one.

In case of the current I_2 through lead-2 we show the variation with respect to V_{24}, keeping V_{21} and V_{23} fixed to a particular value as presented in Fig. 8(b). The currents are determined in the strong-coupling regime, where the dark-red, blue and orange lines correspond to $V_{21} = V_{23} = 2, 4$ and 6, respectively.

Similarly, in Fig. 8(c) we display I_3–V_{31} characteristics considering V_{32} and V_{34} as constants in the limit of strong-coupling. The dark-red, blue and orange lines represent the currents for $V_{32} = V_{34} = 1, 3$ and 5, respectively.

At the end, in Fig. 8(d) we show the variation of current I_4 passing through lead-4 as a function of V_{43} in the limit of strong molecular coupling, when V_{41} and V_{42} are kept as constants. The dark-red, blue and magenta curves correspond to the currents for $V_{41} = V_{42} = 1, 5$ and 9, respectively.

Similar to the case of three-terminal molecular system, for this four-terminal case, we can also plot the current through any lead-p in aspect of the other potential functions as given in Eqs. (18)–(21). For all these cases, the characteristic features are very much similar those are presented in Fig. 8(a)–(d), and hence, we do not re-plot the results further.

4. Closing remarks

In the present paper we have used a parametric approach to study multi-terminal electron transport through a single phenalenyl molecule. Using a simple tight-binding framework we have performed all the numerical calculations through single particle Green's function formalism. The basic features of electron transport in this molecular system are explored by investigating the multi-terminal conductance, reflection probability and current. Following a detailed description of electron transport in two-terminal quantum system, we have revealed the essential features of electron transport in the three- and four-terminal quantum systems separately.

Our clear investigation predicts that the electron transport in multi-terminal molecular system significantly depends on (a) the molecule–lead interface geometry, (b) the presence of other leads and (c) the strength of molecular coupling to the side attached leads. The unique characteristics of this phenalenyl molecule with a very small size has enhanced the importance of the present article. Our parametric study provides several significant features to reveal electron transport through any complicated multi-terminal quantum system.

In the present paper we have done all the calculations by ignoring the effects of temperature, electron–electron correlation, etc. We need further study by incorporating all these effects.

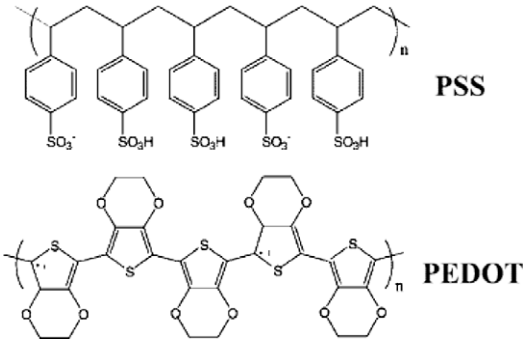

Scheme 1. Chemical structure of PEDOT:PSS.

the conductivity of PEDOT:PSS. Thus, there is still room for the further improvement of the conductivity of the PEDOT:PSS film.

Recently, we reported a new and simple method to significantly enhance the conductivity of PEDOT:PSS by treating the PEDOT:PSS film with aqueous solution of a certain salt, such as $CuCl_2$ or $InCl_3$ [27]. Conductivity enhancement by a factor of 700 was achieved. The conductivity enhancement was related to the softness parameter of the metal ion of the salt. A salt whose metal ion has a positive softness parameter can significantly enhance the conductivity of PEDOT:PSS, while a salt whose metal ion has negative softness parameter has negligible effect. Based on those results, we proposed that the mechanism for the conductivity enhancement of PEDOT:PSS by a salt treatment is related to the ion-induced charge screening between the positively charged PEDOT and negatively charged PSS chains, which results into the replacement of some PSS^- with the small anions from the salt as the counter anions of $PEDOT^+$, the loss of some PSS chains and the conformational change of the PEDOT chains. Though the role of the metal ions on the conductivity enhancement was well studied, it is unknown whether the anion of the salt affects the conductivity enhancement. In this manuscript, we report the anion effect on the salt-induced conductivity enhancement of PEDOT:PSS. The conductivity of the PEDOT:PSS film can be enhanced by a factor of more than 1000 after treated with aqueous solution of $CuBr_2$ or InI_3. In contrast, the conductivity enhancement was less significant and negligible when the PEDOT:PSS film was treated with aqueous solutions of $CuSO_4$ and $Cu(CH_3COO)_2$, respectively. This study on the anion effect helps elucidate the mechanism for the salt-induced conductivity enhancement of PEDOT:PSS.

2. Experimental

PEDOT:PSS aqueous solution (Baytron P, renamed to Clevios™ P, Item No. 1802705, Lot No. HCE07P107) was purchased from H.C. Starck. The concentration of PEDOT:PSS was 1.3% by weight, and the weight ratio of PSS to PEDOT was 2.5. All other chemicals were purchased from Sigma–Aldrich. These materials were used without further purification.

PEDOT:PSS films were prepared by spin-coating the PEDOT:PSS aqueous solution on $1.3 \times 1.3\ cm^2$ glass substrates. The substrates were pre-cleaned by detergent, de-ionized (DI) water, acetone and isopropyl alcohol in sequence. The PEDOT:PSS films were dried at 110 °C on a hot plate for 30 min. The film thickness was *ca.* 130 nm. The salt treatment was similar to that in our early report [27]. The treatment with a salt solution was performed by dropping 150 μL aqueous solution of a salt on a PEDOT:PSS film on a hot plate at 140 °C. The film dried after about 5 min. The salt-treated PEDOT:PSS films were cooled down to room temperature in air and rinsed with de-ionized water triply. Then, they were dried at 140 °C again.

The conductivities of the polymer films were measured by the van der Pauw four-point probe technique with a Keithley 2400 source/meter. The electrical contacts were made by pressing indium on the four corners of each PEDOT:PSS film on glass substrate. The UV–Vis–NIR absorption spectra of the polymer films were taken with a Varian Cary 5000 UV–Vis–NIR spectrometer. The X-ray photoelectron spectra (XPS) were taken with an Axis Ultra DLD X-ray photoelectron spectrometer equipped with an Al Ka X-ray source (1486.6 eV). The samples for FTIR were prepared by dispersing polymers in KBr pellets, and the FTIR spectra were acquired with a Varian 3100 FT-IR spectrometer. The atomic force microscopic (AFM) images of the polymer films were obtained using a Veeco NanoScope IV Multi-Mode AFM with the tapping mode. The thicknesses of the films were determined with an Alpha 500 step profiler. The temperature dependences of the resistivities of the untreated and salt-treated PEDOT:PSS films were measured using a Janis Research VPF-475 dewar with liquid nitrogen as coolant and a Conductus LTC-11 temperature controller.

3. Results and discussion

3.1. Salt-induced conductivity enhancement

The as-prepared PEDOT:PSS films exhibited a conductivity of 0.2 S cm^{-1}. They are treated with solutions of various salts. Table 1 listed the conductivities of the PEDOT:PSS films after treated with 0.1 M and 1 M aqueous

Table 1
Conductivities of PEDOT:PSS films after a treatment with 0.1 M and 1 M aqueous solution of various salts.

Salt	Softness parameter of cation[a]	Softness parameter of anion[a]	Conductivity[b] (S cm^{-1})	Conductivity[c] (S cm^{-1})
$CuSO_4$	+0.38	−0.38	5.1	33.4
$Cu(CH_3COO)_2$	+0.38	−0.22	1.1	1.2
$Cu(ClO_4)_2$	+0.38	−0.3	57.1	127.8
$CuCl_2$	+0.38	−0.09	29.0	168.7
$CuBr_2$	+0.38	+0.17	74.3	187.5
$InCl_3$	+0.48	−0.09	95.5	136.0
$InBr_3$	+0.48	+0.17	145.9	152.0
InI_3	+0.48	+0.5	177.5	191.6

[c] Treated with 1 M solution.

solutions of cupric (Cu^{2+}) and indium (In^{3+}) salts with various anions. These results indicate that the anions significantly affected the conductivity of PEDOT:PSS. The conductivity of the PEDOT:PSS film increased to 74.3 S cm^{-1} after it was treated with 0.1 M $CuBr_2$ aqueous solution, while it was only 5.1 S cm^{-1} after treated with 0.1 M $CuSO_4$ aqueous solution. In addition, the conductivity just slightly increased to 1.1 S cm^{-1} after it was treated with 0.1 M $Cu(CH_3COO)_2$ aqueous solution. The remarkable difference was observed on the conductivities of the PEDOT:PSS films treated with various 1 M Cu^{2+} aqueous solutions as well. The anion effect on the conductivity enhancement was also observed when the PEDOT:PSS films were treated with solutions of various In^{3+} salts.

The results presented in Table 1 indicate that I_3^- and Br^- salts give rise to the most significant conductivity enhancement. In fact, the conductivity of the PEDOT:PSS film was enhanced from 0.2 S cm^{-1} to 220 S cm^{-1} and 264.8 S cm^{-1} after treatments with 2 M $CuBr_2$ aqueous solution and 2 M InI_3 aqueous solution, respectively. The latter conductivity is higher than that of the as-prepared PEDOT:PSS film by a factor of more than 1300.

The conductivities of the salt-treated PEDOT:PSS films were plotted against the softness parameters of the anions of the salts (Fig. 1a). The conductivities of the PEDOT:PSS films treated with 0.1 M aqueous solutions of various sodium (Na^+) salts were presented as well. Two conclusions were obtained from Fig. 1a. The first conclusion is that the dominant factor for the salt-induced conductivity enhancement is the metal ions of the salts. No remarkable conductivity enhancement was observed for PEDOT:PSS treated with Na^+ salts, whose anions have softness parameters varied from −0.38 to 0.5, while significant conductivity enhancement was observed for that treated with solutions of Cu^{2+} and In^{3+} salts. The second conclusion is that the anion effect on the conductivity enhancement is inconsistent with the softness parameters of the anions. For example, ClO_4^- had a softness parameter lower than Cl^-, while the 0.1 M $Cu(ClO_4)_2$-treated PEDOT:PSS films exhibited a conductivity higher than the 0.1 M $CuCl_2$-treated PEDOT:PSS film. The $CuSO_4$-treated PEDOT:PSS films had a conductivity higher than the $Cu(CH_3COO)_2$-treated PEDOT:PSS films as well, though SO_4^{2-} has a softness parameter lower than CH_3COO^-. This is different from the effect of the metal ions on the conductivity enhancement of PEDOT:PSS, for which the conductivity enhancement is consistent with the softness parameters of the metal ions [27].

Presumably, the inconsistence of the conductivity enhancement with the softness parameter of the anions is because only the enthalpy change is taken into account in the softness parameter [28,29]. Thus, the softness parameters can provide only a rough estimation for the association of an ion with other species. As we proposed, the salt treatment of the PEDOT:PSS films involves three processes: the dissociation of the salt, the association of the metal ions with PSS^-, and the association of the anions with $PEDOT^+$. The reason for the consistence of the softness parameters with the effect of metal ions on the conductivity enhancement of PEDOT:PSS is that the entropy change for the association of the metal ions with PSS^- is close since

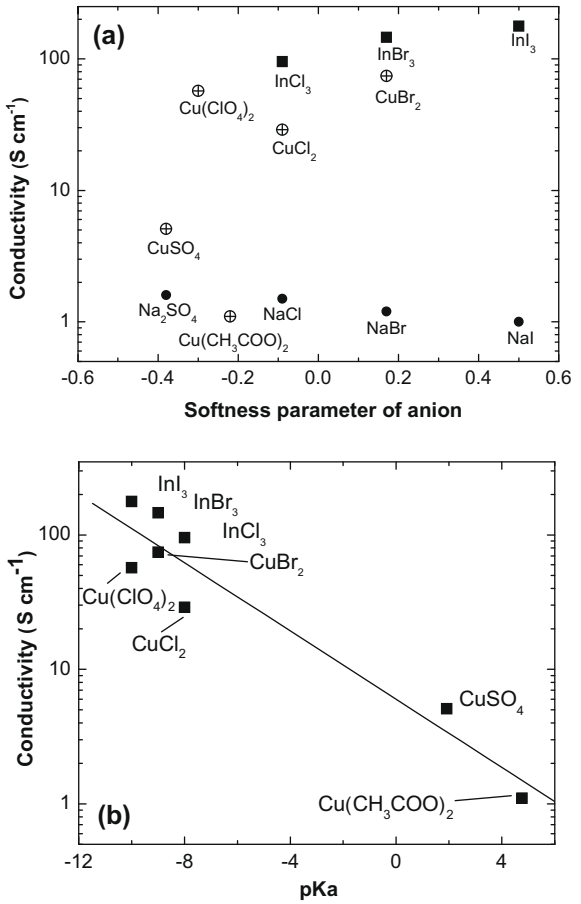

Fig. 1. Conductivities of PEDOT:PSS films treated with 0.1 M solutions of salts. (a) Conductivities versus softness parameters of anions, and (b) conductivities versus pK_a values of acids corresponding to the anions. The softness parameters are obtained from reference 28. The pK_a value for SO_4^{2-} is the pK_{a2} of sulfuric acid. The straight line in (b) is a linear fitting of the data.

all the metal ions have close sizes. This becomes different for the anion effect on the conductivity enhancement of PEDOT:PSS. The entropy changes can be quite different for different anions, particularly multi-atom anions like SO_4^{2-} and CH_3COO^-. Hence, the softness parameters are too rough to estimate the processes involving the anions. We turn to other parameters characteristic of the association of the anion with cation. The dissociation of the salts may be linearly related to the dissociation constants of the acids corresponding to the anions, since the association of metal ions with organic ligands is proportional to the association of metal ions with hydroxide [30]. The value of the acid dissociation K_a for an acid HA, which defined as

$$HA \rightarrow H^+ + A^-,\ K_a = [A^-][H^+]/[HA], \text{and } pK_a = -\log K_a,$$

can provide more accurate information for the dissociation of the anion A^- with other species. We plotted the conductivity enhancement against the pK_a values of the corresponding acids of the anions (Fig. 1b). The conductivities of the salt-treated PEDOT:PSS films are consistent with

the pK_a values of the anions. The conductivity enhancement became more significant for the anions with lower pK_a values. The logarithm of the conductivity almost linearly decreases with the increasing pK_a value. The best fitting of this linear relationship indicates

$$\log\sigma = 0.78 - 0.127pK_a.$$

The relationship between the anion effect on the conductivity enhancement of PEDOT:PSS and the acid association constants of the anions is consistent with the mechanism we proposed. The association of the metal ions with PSS^- can be roughly described in terms of the softness parameters of the metal ions, while the softness parameters of the anions cannot provide accurate information for the dissociation of the salts and association of the anions with $PEDOT^+$. The latter two processes involve the anions from the salt. The metal ions and $PEDOT^+$ compete for the anions during the treatment. A high dissociation constant for a salt, or a low association constant for the metal ions with the anions, benefits the association of the anions with $PEDOT^+$. Consequently, more significant conductivity enhancement can be obtained for the salts with anions of lower pK_a values.

The three processes during the salt treatment of PEDOT:PSS result into the weakening of the Coulombic attraction between $PEDOT^+$ and PSS^-, the replacement of the PSS^- chains with small anions from the salt as the counter anions of $PEDOT^+$, and the loss of PSS chains from the PEDOT:PSS films. Grain structure has been observed for the as-prepared PEDOT:PSS films with a PSS-rich shell and PEDOT-rich core for each grain [31–34]. The removal of some PSS chains, which are insulator, can effectively reduce the shell thickness, which will benefit the charge transport through the PEDOT:PSS film. Moreover, the $PEDOT^+$ chains will experience a conformational change during the salt treatment. All these contribute to the conductivity enhancement of the PEDOT:PSS films. The anion exchange between the salts and PEDOT:PSS is different from the anion exchange observed on conducting polymers doped with small anions, in which no conductivity change was usually observed [35,36].

3.2. PSS loss from PEDOT:PSS and presence of small ions in PEDOT:PSS

As discussed above, the anions from the salts affect the loss of PSS chains from the PEDOT:PSS film. This is evidenced by the absorption spectroscopy and XPS of the PEDOT:PSS treated with Cu^{2+} salts with various anions. Fig. 2 presents the absorption spectra of the treated and untreated PEDOT:PSS films in the UV range. The two bands with the absorption maxima at 193 nm and 225 nm are the absorption due to PSS [8]. The decreasing intensity of the two bands suggests the loss of some PSS chains from the PEDPT:PSS films after the treatment with the Cu^{2+} salts. In terms of these absorption spectra, the PSS loss increases with the treatment salts at this sequence: $CuSO_4$-treated < $CuCl_2$-treated < $CuBr_2$-treated PEDOT:PSS.

The PSS loss from the PEDOT:PSS films during the salt treatment is also confirmed by the S_{2p} XPS of the salt-treated PEDOT:PSS films (Fig. 3). The XPS bands with binding energies below and above 166 eV arise from the sulfur atoms in PEDOT and in PSS, respectively [33,37]. The intensity ratio of these XPS bands are related to the PSS loss from the PEDOT:PSS films. The PSS loss from PEDOT:PSS was observed in the XPS of the PEDOT:PSS films treated with polar solvents as well. The S_{2p} XPS intensity ratio of PEDOT to PSS increases after the salt treatment, and it increases at the sequence: untreated < $CuSO_4$-treated < $CuCl_2$-treated < $CuBr_2$-treated PEDOT:PSS. This is consistent with the absorption spectra of the salt-treated PEDOT:PSS films. These results can be interpreted in terms of the dissociation of the salts. A salt with higher dissociation gives rise to higher ion concentration, which can more effectively screen the Coulombic attraction between PEDOT and PSS chains, so that more PSS chains are removed from the PEDOT:PSS film during the salt treatment.

When salts of Cu^{2+} or In^{3+} that has positive softness parameter are used to treat the PEDOT:PSS, the metal ions can associate with PSS^- in PEDOT:PSS. This can result into the presence of the small anions from the salts into the PEDOT:PSS films. This is supported by the FTIR spectros-

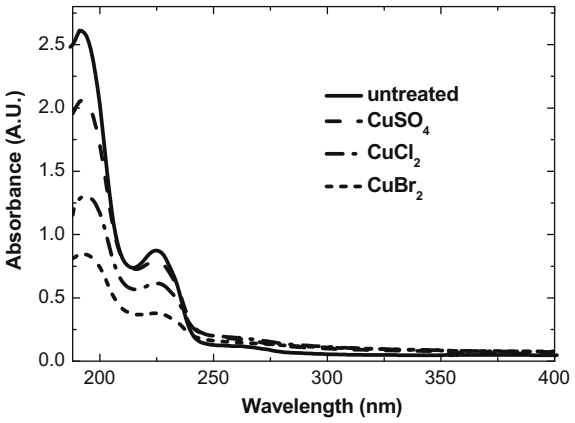

Fig. 2. UV–Visible absorption spectra of PEDOT:PSS films untreated and treated with 1 M $CuSO_4$, $CuCl_2$ and $CuBr_2$.

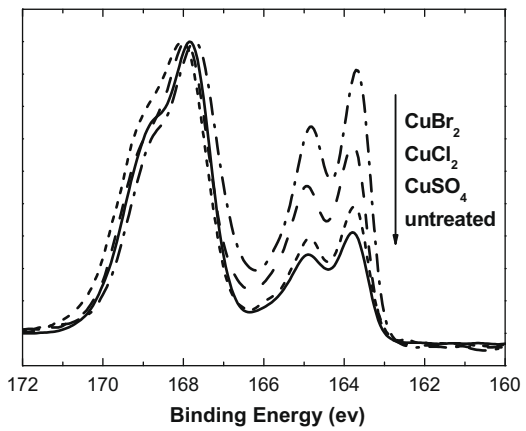

Fig. 3. S_{2p} XPS spectra of PEDOT:PSS films untreated and treated with 1 M $CuSO_4$, $CuCl_2$ and $CuBr_2$.

copy and XPS of the salt-treated PEDOT:PSS films. PEDOT:PSS films treated with salts of multi-atom anions, such as $CuSO_4$ and $Cu(ClO_4)_2$ were studied by the FTIR spectroscopy, since the multi-atom anions have IR-active vibrational bands. Fig. 4 shows the FTIR spectra of the untreated and $CuSO_4$-treated PEDOT:PSS films, $CuSO_4$ and poly(styrenesulfonic acid) (PSSH). Two vibrational bands at 661 and 603 cm^{-1} due to SO_4^{2-} were observed in the FTIR spectrum of the $CuSO_4$-treated PEDOT:PSS film. This suggests the presence of the SO_4^{2-} anions in the PEDOT:PSS films after the treatment with $CuSO_4$ solution.

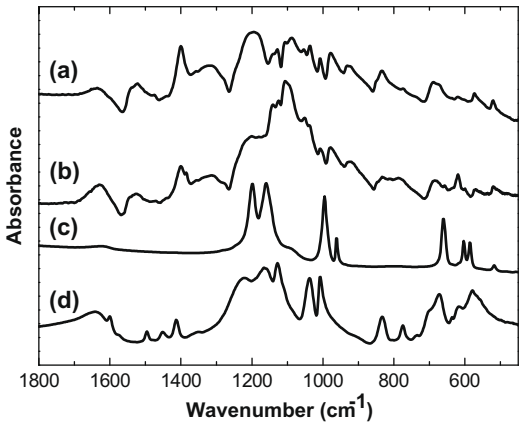

Fig. 4. FTIR spectra of (a) untreated PEDOT:PSS, (b) PEDOT:PSS treated with 0.1 M $CuSO_4$, (c) $CuSO_4$ and (d) PSSH.

The PEDOT:PSS films treated with salts of mono-atom anion, such as $CuCl_2$ and InI_3, were investigated by XPS. XPS signals of Cu^{2+}, Cl^- and In^{3+} were detected in the PEDOT:PSS films treated with these salts. This also indicates the presence of the salts in the PEDOT:PSS films after the salt treatment.

3.3. Morphology and conduction mechanism of PEDOT:PSS films

The loss of some PSS chains and the presence of salt in the PEDOT:PSS film can affect the film morphology. This is revealed by the AFM study of the salt-treated PEDOT:PSS films (Fig. 5). An as-prepared PEDOT:PSS film was quite smooth with a roughness of 1.06 nm. It became rough for the PEDOT:PSS film treated with 0.1 M $CuSO_4$ solution and quite rough for the one treated with 0.1 M $CuBr_2$ or 0.1 M InI_3 solution. The roughnesses were 1.86 nm, 2.59 nm, and 3.00 nm for the PEDOT:PSS films treated with 0.1 M $CuSO_4$, 0.1 M $CuBr_2$ and 0.1 M InI_3 solutions, respectively. The increase in the roughness is due to the increasing grain size after the salt treatment. The grain size increases at the sequence of untreated < $CuSO_4$-treated < $CuBr_2$-treated < InI_3-treated PEDOT:PSS. The increasing gain size can be attributed to the loss of some PSS chains from the PEDOT:PSS films.

The increased grain size can facilitate the charge transport across the grains. Effect of the salt treatment on the conduction mechanism was investigated by characterizing the temperature dependence of resistivities of the PEDOT:PSS films before and after the treatment with various

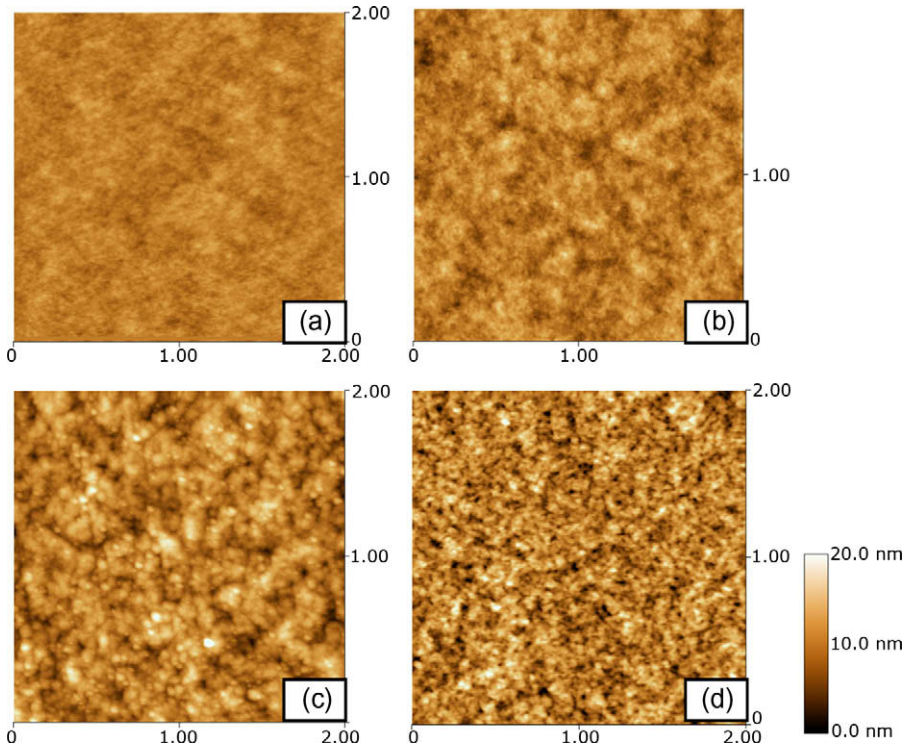

Fig. 5. AFM images of PEDOT:PSS films (a) untreated and treated with 1 M (b) $CuSO_4$, (c) $CuCl_2$ and (d) $CuBr_2$. The unit for the AFM images is μm.

salts. The resistivities of the PEDOT:PSS films treated with various solutions of 1 M Cu^{2+} salts was studied from 300 K down to 110 K (Fig. 6). The temperature dependences of the resistivities can be fitted by the one-dimensional variable range hopping (VRH) mechanism [10,38,16]

$$R(t) = R_0 \exp\left[\left(\frac{T_0}{T}\right)^{1/2}\right],$$

where $T_0 = 16/k_B N(E_F) L_{\parallel} L_{\perp}^2$ is the energy barrier between localized states with $N(E_F)$ being the density of the states at the Fermi level and $L_{\parallel}$ ($L_{\perp}$) being the localization length in the parallel (perpendicular) direction. The T_0 value remarkably changed for the PEDOT:PSS film after the salt treatment. It was 2660 K for the untreated PEDOT:PSS film, and it decreased to 974 K, 407 K and 359 K for the PEDOT:PSS films treated with 1 M $CuSO_4$, $CuCl_2$ and $CuBr_2$, respectively. The T_0 values are consistent with the conductivities of these PEDOT:PSS films at room temperature, which are 0.2, 33, 169 and 188 S cm^{-1} for the untreated, $CuSO_4$-treated, $CuCl_2$-treated and $CuBr_2$-treated PEDOT:PSS films, respectively. Therefore, the conductivity enhancement of the PEDOT:PSS film by the salt treatment can be attributed to the lowering energy barrier. The lowering energy barrier suggests that the salt treatment may increase the localization length.

3.4. Transient resistances of PEDOT:PSS during salt treatment

The anions of the salts can affect the dynamic process of the salt treatment, since they affect the dissociation of the salts and the association of the anions with $PEDOT^+$. This was studied by monitoring the resistance of the PEDOT:PSS films during the treatment with various salts (Fig. 7a). The configuration for the resistance measured is schematically shown in the inset of Fig. 7b. Indium (In) was pressed at the four corners of a PEDOT:PSS film to facilitate the electrical contact. Because the salt treatment was performed with indium at the four corners of each PEDOT:PSS film, the areas of the PEDOT:PSS film under indium were not treated by the salts, that is, the parts of the PEDOT:PSS film under indium kept the high resistance during the salt treatment. This is why the resistance decrease shown in Fig. 7a is less than in Table 1. Though the absolute transient resistances were not very meaningful, their change during the salt treatment provided important information for the dynamic process during the salt treatment.

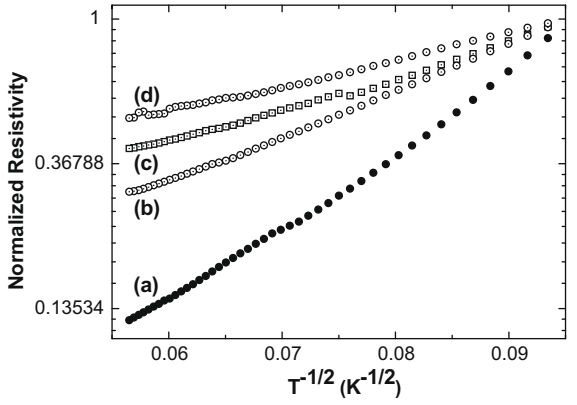

Fig. 6. Temperature dependences of the normalized resistances of PEDOT:PSS films. (a) Untreated and treated with 1 M (b) $CuSO_4$, (c) $CuCl_2$ and (d) $CuBr_2$. The resistances are normalized to that at 110 K.

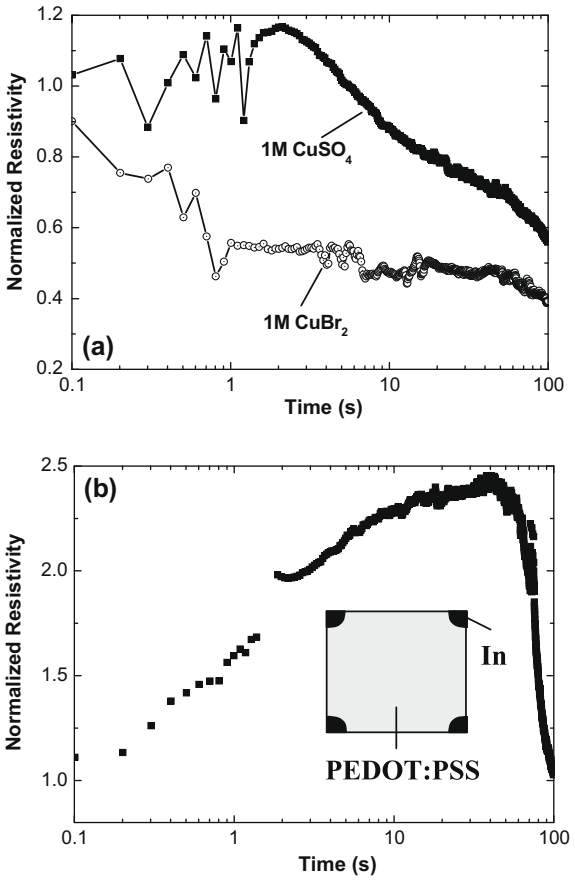

Fig. 7. Transient resistances of PEDOT:PSS films during the treatments. (a) 1 M $CuBr_2$ and 1 M $CuSO_4$ and (b) water. The resistances were normalized to the resistance of the as-prepared PEDOT:PSS film. The inset in (b) shows the configuration for the resistance measurements.

Fig. 7a presents the transient resistances of the PEDOT:PSS films during the treatment with 1 M $CuSO_4$ and 1 M $CuBr_2$ aqueous solutions. The resistance immediately decreased when the PEDOT:PSS film was treated with 1 M $CuBr_2$ solution, while it increased then gradually decreased when treated with 1 M $CuSO_4$ solution. The transient resistances are affected by two processes. One process is the swollen of the polymer chains by water, which gives rise to the decrease in the interchain charge transport and the increase in the resistance, as shown in Fig. 7b. Another process is the salt-induced resistivity decrease. The second process is the dominant process for the treatment with $CuBr_2$ aqueous solution, while the dominant process shifts from the first process to the second process for the treatment with $CuSO_4$ aqueous solution. The different transient resistances of the PEDOT:PSS films treated by the two salts can be attributed to the effect

of the anions on the dissociation of the salts and association with $PEDOT^+$.

4. Conclusions

The conductivity of the PEDOT:PSS film can be significant enhanced through a treatment with solutions of some salts. The anions of the salts can affect the salt-induced conductivity enhancement of the PEDOT:PSS film. Conductivity enhancement by a factor of more than 1000 was observed when the PEDOT:PSS film was treated with $CuBr_2$ or InI_3 aqueous solution, while the conductivity enhancement became less significant and negligible when the PEDOT:PSS film was treated with $CuSO_4$ and $Cu(CH_3COO)_2$ aqueous solutions, respectively. The anion effect on the conductivity enhancement of PEDOT:PSS is related to the competition of two processes, the dissociation of the salts and the association of the anions with $PEDOT^+$. A salt with a higher dissociation benefit the loss of more PSS chains from the PEDOT:PSS film after the salt treatment, so that it results into more significant conductivity enhancement.

continuous illumination for 100 h in pure air [17]. Therefore, its structure is expected as a promising approach from the viewpoints of durability improvement.

Chemical bath deposition (CBD) is one of the simplest methods for preparing semiconductor films as well as electrochemical deposition and sol–gel method, having an advantage such as low cost and easy technique to realize large area devices. TiO_2 or TiO_x may function as both of electron collection layer and hole blocking layer for organic solar cells [18,19]. However, to our knowledge, the CBD method for preparing titanium oxide layer has not yet been used to fabricate the PV device. In this paper, we report a readily-prepared CBD-TiO_x film working as electron collection layer of organic solar cells which exhibited PCE of 3.8% under the AM1.5G simulated sunlight.

2. Experimental

The ITO electrode was ultrasonicated in 2-propanol, and then cleaned in boiling 2-propanol, and subsequently dried in air. The CBD-TiO_x film was prepared according to the following procedure. A titanium(IV) oxysulfate ($TiOSO_4$) solution was added in a diluted hydrogen peroxide (H_2O_2) aqueous solution, and then the mixed solution was diluted just to 50 ml with ultrapure water. The concentrations of H_2O_2 and $TiOSO_4$ were adjusted to 0.03 M, respectively. This solution was transferred to a screw vial to use as the reaction bath for film deposition. The glass side of the ITO substrate was covered with an imide tape to prevent an extra deposition of TiO_x, and then the ITO substrate was immersed in the bath at 80 °C. The solution became cloudy by the application of heat, and after appropriate dipping time starting from this cloudy point, the immersed ITO substrate was pulled out from the bath. The as-deposited TiO_x film on the ITO was ultrasonicated for 10 min in water and heated on a hot plate at 150 °C for 1 h in air. Then, the chlorobenzene (CB) solution or the 2,6-dichlorotoluene: chloroform (1:1 by volume ratio, DCT:CHL) cosolvent solution containing poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl C61 butyric acid methyl ester (PCBM) of 5:4 by weight ratio was spin-coated onto the ITO/TiO_x substrate in a glove box less than 1 ppm of moisture, being subsequently heated at 120 °C for 20 min on the hot plate. Then, a PEDOT:PSS dispersion solution was spin-coated onto the P3HT:PCBM layer in an simple glove box of the relative humidity less than 35%. An Au metal as the back electrode was vacuum-deposited on the PEDOT:PSS layer. Finally, the device was heated at 150 °C for 5 min on the hot plate in air and then at 70 °C for 30 min. The effective area of the solar cell was restricted to 1.0 cm^2 by depositing the Au electrode using a shadow mask. The photocurrent–voltage (*I–V*) curves of the solar cells were measured by linear sweep voltammetry (LSV) at a scan rate of 5 V min^{-1} under an AM 1.5G simulated sunlight with 100 mW cm^{-2} intensity. The light source was from a SAN-EI Electric XES-502S solar simulator calibrated by an EKO MS-601 pyranometer equipped with a silicon diode. All the dc electric measurements were implemented using a Hokuto Denko HZ-5000 electrochemical analyzer. All measurements were carried out for non-sealed devices in an ambient atmosphere, that is, at room temperature of 15–30 °C and under relative humidity of 40–60%.

3. Results and discussion

We assumed the deposition mechanism of a TiO_x film on the ITO electrode as follows:

$$(TiO^{2+} + H_2O_2 \rightarrow Ti(O)_2^{2+} + H_2O) \quad (1)$$

$$(mTi(O)_2^{2+} + nH_2O \rightarrow [TiO_p(OH)_q]_m \cdot rH_2O + 2mH^+) \quad (2)$$

$$([TiO_p(OH)_q]_m \cdot rH_2O \rightarrow mTiO_x + sH_2O), \quad (3)$$

where the italicized characters *m*, *n*, *p*, *q*, *r*, *s*, and *x* in the above equations are unknown numbers, although the *x* value in TiO_x is less than 2. Titanyl ions are oxidized to titanium(IV) peroxide ($Ti(O)_2^{2+}$) ions by H_2O_2 (Eq. (1)) at room temperature, then a titanium(IV) oxyhydroxide ($[TiO_p(OH)_q]_m \cdot rH_2O$) is deposited on the ITO plate by hydrolysis (Eq. (2)) around 80 °C. Finally, the as-deposited $[TiO_p(OH)_q]_m \cdot rH_2O$ is converted to the amorphous-titanium(IV) oxide (TiO_x) by heat treatment at 150 °C for 1 h in air (Eq. (3)). Fig. 2 shows the photographs before and after the hydrolysis in the chemical bath containing $TiOSO_4$ and H_2O_2. As-prepared CBD solution displays red color based on the generation of $Ti(O)_2^{2+}$ ions as shown in Fig. 2a. When heated at 80 °C for about 10 min, the solution got clouded defining as 0 s of deposition initiation, see Fig. 2b. Then, an increase in white turbidity was observed by keeping at 80 °C as shown in Fig. 2c–e.

Surface AFM images of the TiO_x films are shown against the dipping time in the chemical bath at 80 °C, see Fig. 3.

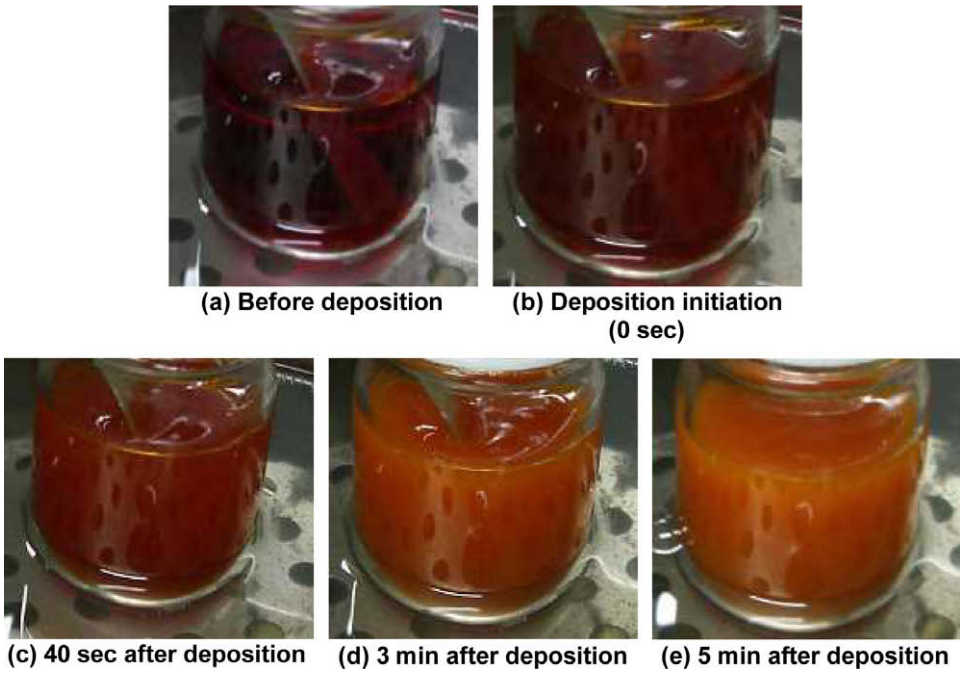

Fig. 2. Photographs before and after the hydrolysis in the chemical bath for depositing TiO_x.

The AFM images showed that the ITO substrates are gradually covered with TiO_x precursor particles. The film thickness of TiO_x film increased about linearly with the dipping time as shown in Fig. 4, but its film was considerably flat in the nano-scale, see the height scale of surface AFM images in Fig. 3.

The photo *I–V* curves of the ITO/CBD-TiO_x/PCBM:P3HT/PEDOT:PSS/Au solar cells with various thicknesses of the CBD-TiO_x layer is shown in Fig. 5, where the PCBM:P3HT (5:4 by weight ratio) blend film was prepared by spin-coating the CB solution. The cell without TiO_x layer showed the PCE of 0.82%, see dash curve in Fig. 5. Whereas the cell with TiO_x layer of 20 nm thickness exhibited a large increase in the short-circuit current (J_{sc}) and the fill factor (FF) due to rectification improvement, after all, we obtained the maximum J_{sc} of 7.22 mA cm^{-2}, the open-circuit voltage (V_{oc}) of 0.57 V, the FF of 0.57, and the PCE of 2.35%, see green solid curve in Fig. 5. This result shows that the CBD-TiO_x film acts effectively as an electron collection layer for the organic solar cell.

Fig. 6 shows the PCE change against irradiation time in air for the TiO_x cell without sealing. The PCE maintained 94% of the maximum value even after continuous light irradiation for 100 h. Further, even when the non-sealing TiO_x cell was put in relative humidity of 85% and at environmental temperature of 85 °C in the dark for 50 h, the PCE surprisingly maintained 54% of the maximum value. Very high stability was demonstrated for the non-sealing CBD-TiO_x inserted cell.

In order to improve the energy conversion efficiency of the solar cells, we have attempted to prepare an organic active layer with better morphology by thermal-annealing and controlling solvent evaporation speed after spin-coating. In a similar manner of previous report for the sol–gel TiO_x inserted solar cells [16], the PCBM:P3HT film prepared by DCT:CHL cosolvent solution showed slightly high PCE compared with that prepared by the CB solution in the CBD-TiO_x inserted solar cells, see Fig. S1. The cosolvent cell showed the J_{sc} of 8.49 mA cm^{-2}, the V_{oc} of 0.61 V, the FF of 0.62, and the PCE of 3.21%, reasonably increasing compared to the CB cell (PCE = 2.35%). The improvement of the device performance may be caused by a morphology change in the blend film suppressing the solvent evaporation rate by the DCT of higher boiling temperature. The PCE of the CBD-TiO_x inserted solar cell is by 30% higher than the PCE (2.47%) of the sol–gel TiO_x inserted solar cells under equal conditions [16]. This may be because the stabilizing agent such as acetylacetone remained in the sol–gel TiO_x film and resulted in higher film resistance. The morphology of the PCBM:P3HT film prepared by DCT:CHL exhibited much smaller nano-scale phase separation than that by CB, see Fig. S2. Therefore, the enhanced J_{sc} and FF as shown in Fig. S1 suggest that more well-connected networks were formed for each micro-separated phase of donor and acceptor in the PCBM:P3HT film prepared by DCT:CHL.

It is known that blending [6.6] diphenyl C62 bis(butyric acid methyl ester) (bis-PCBM) as an acceptor into P3HT as a donor enhances the V_{oc} of normal type solar cells compared to blending PCBM as the acceptor, because bis-PCBM has higher LUMO by ca. 100 meV than PCBM [20]. The performance of the CBD-TiO_x cell with the PCBM:P3HT or the bis-PCBM:P3HT prepared by DCT:CHL cosolvent is summarized in Table 1. The bis-PCBM cell showed the J_{sc} of 7.84 mA cm^{-2}, the V_{oc} of 0.76 V, the FF of 0.63, and the PCE of 3.81%. The photocurrent slightly decreased compared to the PCBM cell and the FF was the same. On the

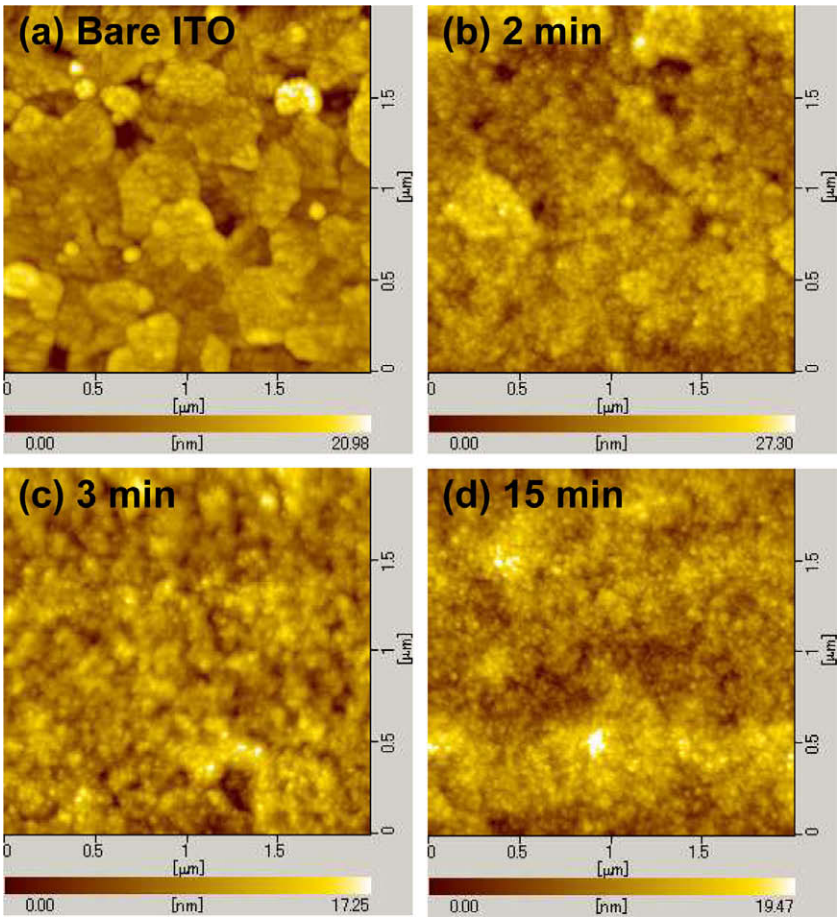

Fig. 3. Dipping time dependence of the surface AFM images of the TiO_x films prepared by CBD method. Dipping time: (a) 0 min (bare ITO), (b) 2 min, (c) 3 min, and (d) 15 min.

other hand, the V_{oc} increased by ca. 0.15 V, leading higher PCE of the bis-PCBM cell. We confirmed that the V_{oc} increment by using bis-PCBM was obtained even for the inverted-type solar cell. The slightly decreased J_{sc} of the bis-PCBM:P3HT cell may be explained by the fact that

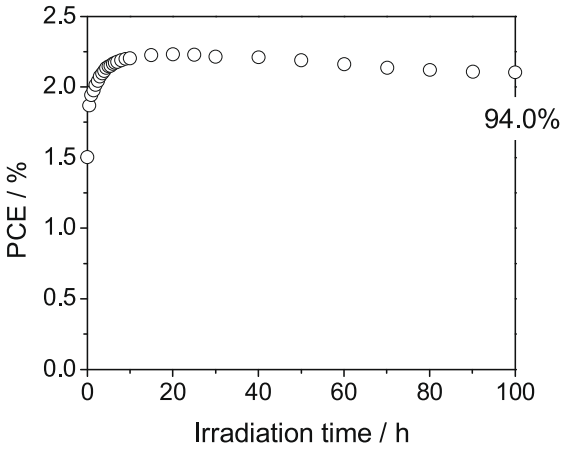

Fig. 6. Irradiation time dependence of the PCE for the non-sealed CBD-TiO_x inserted cell in air. The PCBM:P3HT blend film was prepared using the CB solution. The PCE maintained 94.0% of the maximum value (2.23%) even after continuous light irradiation for 100 h.

Table 1
Photovoltaic parameters of the PCBM:P3HT and bis-PCBM:P3HT solar cells under AM 1.5G light irradiation at 100 mW cm^{-2}.

Active layer	Solvent	J_{sc}/mA cm^{-2}	V_{oc}/V	FF	PCE/%
PCBM:P3HT	CB	7.22	0.57	0.57	2.35
PCBM:P3HT	DCT:CHL	8.49	0.61	0.62	3.21
bis-PCBM:P3HT	DCT:CHL	7.84	0.76	0.63	3.81

the electron transfer from donor P3HT to acceptor bis-PCBM became inconsiderably difficult due to the increase of the acceptor LUMO level.

4. Conclusion

In conclusion, we have proposed very convenient and useful CBD-TiO_x thin film as the electron collection layer of the inverted-type organic solar cell. In the ITO/CBD-TiO_x/bis-PCBM:P3HT/PEDOT:PSS/Au device, we obtained relatively large PCE value of 3.8%. We believe that the chemically stable CBD-TiO_x film works as a promising electron collection layer for developing polymer solar cells with high efficiency and high durability. Since the uniformed and air-stable CBD-TiO_x film can be easily prepared onto large-area ITO substrates in air, the fabrication of large-area inverted-type organic solar cell will be possible, being important to develop low-cost solar cells.

printing. The PEDOT:PSS conducting polymer was Baytron P ink from H.C. Starck. The top electrode was printed using graphite ink or Ag-filled polymer thick film (DuPont).

The device fabrication methods were graphic arts printing methods. The CuPc layer and the PEDOT:PSS layer were deposited via spray coating due to their low viscosity. The thickness of the CuPc layer was between 0.5 and 1 μm, while the thickness of the PEDOT:PSS layer was between 1 and 1.5 μm. The pitch size for each bit was 1 mm for line and space. The Ag or graphite electrodes were then patterned by screen-printing or "doctor blading" to form top electrodes and complete the devices. No barrier layer or other protecting layer was required. In addition to the printed devices, a Cu/CuPc/PEDOT:PSS/Cu laminated structure was investigated. In the laminated structure, the CuPc and PEDOT:PSS were spray coated on two separate pieces of Cu coated PET films, which were then mechanically assembled through lamination.

The electrical behaviour of the devices was characterized using *I–V* and AC impedance methods. *I–V* measurements were performed with an EG&G 263A potentiostat. For each *I–V* test, the voltage was scanned forward and reverse at a rate of 1 V/s from 0 to +5 V. Impedance spectra were obtained on a Solartron 1255 Impedance/Gain Phase Analyzer interfaced with the 263A potentiostat over a frequency range of 100 kHz to 1 Hz with a 50 mV AC voltage. All processes and tests were performed under ambient conditions.

3. Results and discussion

In order to differentiate the contribution of printing-induced interface effects from materials related effects, we have compared the DC and AC characteristics of laminated Cu/CuPc/PEDOT:PSS/Cu with a fully printed Cu/CuPc/PEDOT:PSS/Ag device. Fig. 1 depicts the *I–V* curves from a laminated and a printed crossbar cell for comparison. Both curves clearly demonstrated a bi-stable behaviour with applied voltage bias. When a voltage scan was applied, the cell current was low (10^{-5} to 10^{-7} A) at first with an exponential "diode-like" behaviour until a threshold voltage (E_{th}) was reached. At E_{th}, the current suddenly jumped a few orders of magnitude followed by linear "ohmic" behaviour (see the inset in Fig. 1 for the linear current response). After switching to the ON state, the retention of this state can be observed in the subsequent reverse voltage scan showing that the current remained high with linear *I–V* response. Such *I–V* curves are characteristics of memory devices: the ON/OFF ratios for both laminated and printed devices were greater than 10^5 when reading at 1 V.

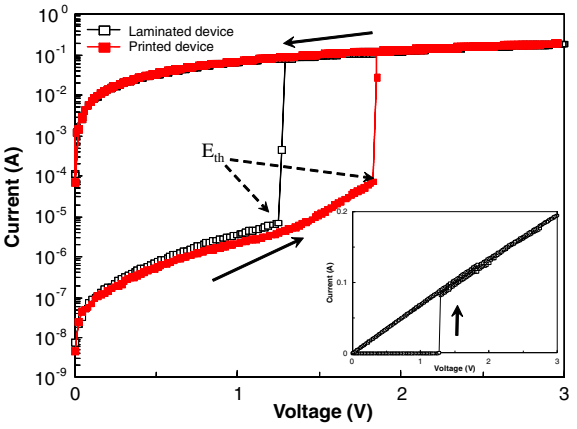

Fig. 1. *I–V* curves of printed and laminated memory device in log scale and linear scale (inset). The threshold voltages are labelled E_{th}.

However, one significant difference in the *I–V* curves for laminated and printed memory devices (Fig. 1) can be observed in the OFF state. While both displayed a similar initial current response in the OFF state, the printed device exhibited a second stage before switching to the ON state. Further analyses of the *I–V* curves for several known charge transfer mechanisms resulted in the best fit for the two stages, shown in Fig. 2. For both laminated and printed devices, it appeared that in the low voltage region Schottky charge injection from the electrode was the dominating factor. The second stage observed on the printed device fits well with Poole–Frenkel emission.

Since the printed cross-bar memory cells contain four material layers with three interfaces, we performed a layer-by-layer analysis to investigate their interfacial interactions. We measured the *I–V* curves of Cu/PEDOT:PSS, PEDOT:PSS/Ag and graphite ink (both serving as top electrodes) in direct contact, over the same voltage range as depicted in Fig. 1. The *I–V* of Cu/PEDOT:PSS, Ag/PEDOT:PSS, and C/PEDOT:PSS all showed linear current responses, suggesting ohmic contacts at these interfaces. Therefore, by elimination, we can infer that CuPc, a known hole-injecting semiconductor [7–12], is solely responsible

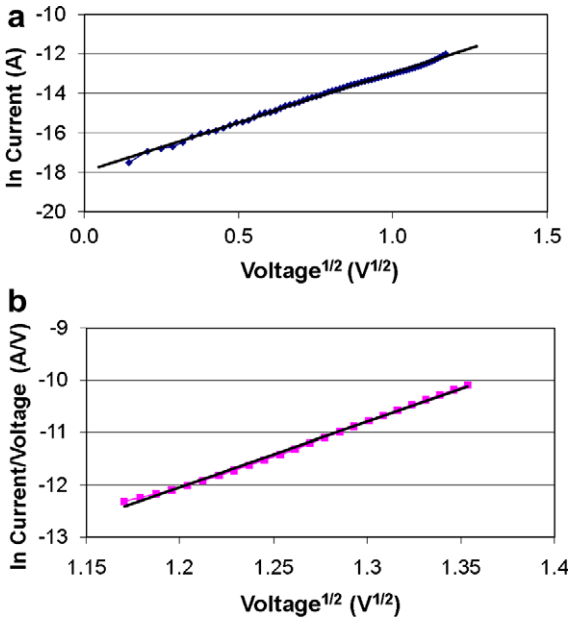

Fig. 2. Fitting of the *I–V* curve for printed Cu/CuPc/PEDOT:PSS/Ag memory in its OFF state against: (a) Schottky thermionic emission at low voltage; (b) Poole–Frenkel emission at medium voltage.

for the bi-stable behaviour observed in Fig. 1. In this case, PEDOT:PSS functioned as a hole-injection promoter as well as a conductive barrier to facilitate the printing process.

Electrochemical impedance spectroscopy (EIS) was further utilized to characterize the laminated and printed cross-bar memory cell before and after switching conditions. Fig. 3 shows the Bode plots of the laminated and printed devices in the ON and OFF states, respectively. Several interesting observations are worth noting in this figure:

1) In the ON state, impedance was under 100 Ω for both laminated and printed devices, while the phase angle was around 0°. This suggests that both devices behaved similar to pure resistors in the ON state and current was conducted through ohmic contact. This corresponds well to the *I*–*V* results in Fig. 1.
2) In the OFF state, the impedance values were in the mega-ohms range for both laminated and printed devices. The difference in the magnitude of the impedance between the ON and OFF states (Fig. 3a) was in the same order as the difference obtained from *I*–*V* measurements (Fig. 1).
3) Also in the OFF state, the phase angles of the laminated and printed devices deviated significantly from 0° (ON state), suggesting that very different current conduction mechanisms take place in the ON and OFF states.
4) Furthermore, the trend in the phase angle differed substantially between the laminated and printed devices. There was only one peak (−80°) at high frequency for the laminated device. In the case of printed device, we see a continuous distribution of phase angles from −75° at the high frequency region to around 30° at low frequencies with no clear peak distinctions.

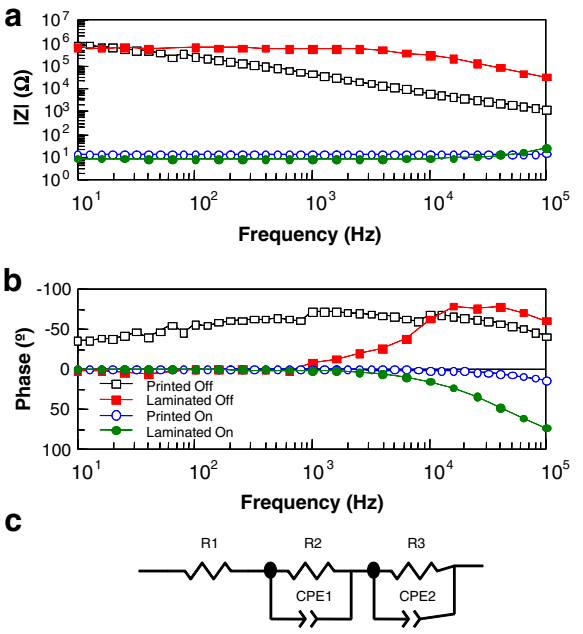

Fig. 3. Impedance spectra of a printed Cu/CuPc/PEDOT:PSS/Ag and a laminated Cu/CuPc/PEDOT:PSS/Cu memory device in OFF and ON states: (a) Bode plot for magnitude; (b) Bode plot for phase angle; (c) equivalent circuit model in OFF state.

Comparing the phase angle of both devices in the OFF state, the laminated structure had a single RC time constant. Based on our earlier work, we infer that CuPc is the sole layer responsible for the switching behaviour [6]. Considering the CuPc layer as the semiconducting layer in the laminated structure, we can see a single time constant derived from the CuPc layer in the Cu/CuPc/PEDOT:PSS/Cu structure. CuPc functioned as an insulator with capacitive Schottky-type current response (Fig. 2a) and high impedance in the OFF state until a voltage pulse switched the device to an ohmic current response and low impedance.

Judging from the phase angle, the printed device also had a near capacitive response at high frequencies which can be attributed to the capacitive behaviour of CuPc. This response was accompanied by a series of distributed elements at low frequencies. These elements and the Poole–Frenkel current conducting mechanism observed in Fig. 2b can be explained as follows: During the printing process, CuPc was sprayed down with a water based solution, and PEDOT:PSS containing water was sprayed on top of the CuPc layer, likely forming an intermediate layer containing a mixture of CuPc and PEDOT:PSS. Since PSS is a film forming polymer, we can consider this intermediate layer as a PEDOT:PSS film fused with the CuPc solid, which could be either continues or nodule-like. In such structure, one would expect to obtain a widely distributed phase angle as shown in Fig. 3b, as phase angles between 40° and 75° are an indication of a distribution of "leaking capacitors" and rough surfaces. This phenomenon is further supported by the curve fitting result in Fig. 2b for a Poole–Frenkel charge transfer. In a Poole–Frenkel mechanism, charge transfer occurs in the bulk of the materials which are filled with electrically charged defects [13,14], PEDOT and CuPc in this case. This intermediate layer does not form in the laminated structure, and therefore, in the laminated device we only see one RC due to the CuPc layer.

The impedance spectra of the printed devices fit well with a two time constant equivalent circuit (Fig. 3c). In this model, at high frequencies the spectra are dominated by a parallel RC component (also true for the laminated device), while at low frequencies a distributed (non-ideal) RC component dominates. In both cases, C is represented by the constant phase element (CPE), although the CPE at low frequencies is more like a "leaky" capacitor compared with the CPE at high frequencies. A similar equivalent circuit model was proposed for a barium/polymer/aluminum bistable system in [15], where the two RC time constants were attributed to capacitive switching followed by resistive switching. In our case, it is likely to be capacitive switching (Schottky) followed by bulk switching (Poole–Frenkel) until E_{th} is reached. When in the ON state, only the resistor is in effect. For writing and reading, having one-stage or two-stage current transmission before the ON state may not affect the overall behaviour. An alternative solvent for CuPc that is immiscible with the PEDOT:PSS solution could be used to remove the second stage if desired.

I–V and impedance measurements provided insights in terms of the current conducting mechanisms and the contributions from the manufacturing processes. Impedance spectroscopy is very sensitive to the surface and interface conditions and can provide additional information on the phase change which could not be detected by DC methods. Therefore, in the applications for cross-bar memories, one can track the variation either in resistance or phase or both, providing a much more flexible means for data storage, tracking, and management.

4. Conclusions

We have demonstrated printed Cu/CuPc/PEDOT:PSS/Ag (or C) WORM devices on a PET substrate and characterized these devices using both DC and AC techniques. The memories exhibited bi-stable behaviour with an ON/OFF ratio greater than 10^5. We examined the printing-induced material interactions in the fabricated device and observed a two-stage transition in the *I–V* curve, related to Schottky and Poole–Frenkel emission, the latter resulting from an interfacial layer formed due to the printing process. Impedance analysis proved to be an excellent tool to study this effect as it is able to deconvolute the two transmission processes.

at 25 °C under magnetic stirring for 2 h (molar ratio of $Ti(O–Bu)_4$/ACAC = 1/1). ACAC prevented $Ti(O–Bu)_4$ from forming crystalline precipitates by acting as a chelating agent prior to the sol–gel reaction [12,13]. Subsequently, 0.082 g of 0.1 N HCl and 8.454 g of DCS-SP210 were added to the solution at 25 °C and stirred for 10 h (molar ratio of $Ti(O–Bu)_4/H_2O$ (0.1 N HCl) = 1/2). The other samples (Table 1) followed the same procedure. The sol–gel reaction was heated at 80 °C for 30 min after spin-coating in the absence of UV light. The coated hybrid film was patterned through shadow mask (gab 150 μm) by exposure to 365 nm UV irradiation (200 mJ/cm^2), which induced polymerization by free radical initiation, was developed to remove uncured region by KOH developing solution (Dongjin Semichem Co., Ltd.; DCD-260CF), and was subsequently cured at 120 °C for 1 h. The hybrid film prepared in this manner was composed of cross-linked acrylic resin matrix and titania matter.

Organic thin-film transistors were fabricated on glass substrates using bottom-gate/top-contact geometry. Gold was used as the gate metal on a molybdenum buffer layer, and the sol–gel hybrid acrylic resin was used as a gate dielectric. The sol–gel mixtures were spun onto the gate metal at 2000–3000 rpm for 30 s. Hybrid films were fabricated by heating and irradiating with UV light, producing a layer of the thickness 800–1000 nm. The pentacene active layer (pentacene, Aldrich, was used without purification) was fabricated by thermal evaporation deposition, producing a layer of the thickness 80 nm, measured by a surface profiler (Alpha-Step, P-10, Tencor). The top contact OTFT devices were fabricated with variable channel width to length (W/L) and metal–insulator–metal (MIM) structures were also fabricated to analyze the electrical characteristics of organic/inorganic hybrid films on one substrate in this study.

The dielectric constant and frequency characteristics were obtained from signal capacitance measurements (impedance analyzer, SI 1260, Solartron Analytical) on the SG samples and on acryl UV resin. The current–voltage (I–V) characteristics were obtained using a Keithly 236 source-measure unit, operated by a local Igor program with GPIB communication. All the electrical characteristics of OTFTs were carried out using two Keithly 236 source-measure units, in a dark room.

3. Results and discussion

Hybrid thin films were prepared by spin-coating, UV curing, and submitting to the sol–gel reaction using the

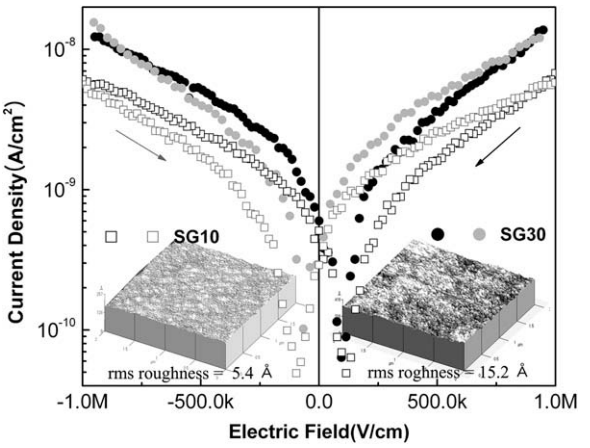

Fig. 2. Leakage current density versus electric field for hybrid dielectric films with different titania (TiO_2) content. Film thicknesses were 890 (SG10) and 995 nm (SG30). Insets show AFM images of hybrid dielectric films.

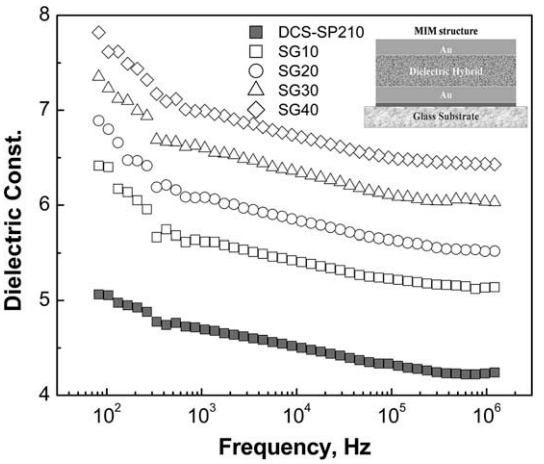

Fig. 3. Dielectric constant versus frequency characteristics with different titania (TiO_2) content. The Inset shows MIM structure employed.

procedure described in Section 2. AFM images of SG samples demonstrated that the surface morphology depended on the theoretical titania (TiO_2) content of the hybrid (Fig. 2). An increase in the theoretical titania (TiO_2) content in the mixture appeared to contribute to an increase in rms roughness. In principle, materials prepared via the sol–gel reaction due to forming crystalline phase are porous, but in this study we observed that the hybrid materials prepared via UV curing and the sol–gel reaction at nearly the same time as described previously were not porous for the reason of controlling nano crystalline phase. Hybrid films were relatively smooth, with a low rms roughness of 5.4–15.2 Å that increased with titania (TiO_2) content, and exhibited no major defects. The rms roughness of SG samples, evaluated via the *I–V* characteristics, also revealed quantitative leakage currents for the gate insulators. Fig. 2 shows typical the current density–electric field (*I–V*, exactly *J–E*) plots for a MIM structure fabricated with SG samples. Leakage current densities of at 1 MV/cm of SG samples are 5.8 nA/cm^2 (SG 10) and 12 nA/cm^2 (SG 30), respectively. Although the leakage current increased with the presence of a titania-rich phase structure in the hybrid dielectrics, SG samples acted as gate insulators in the OTFTs due to the high dielectric constant. Fig. 3 shows the dielectric constant–frequency plot for a MIM structure fabricated with cross-linked acrylic resin and SG samples. Dielectric constants increased with titania (TiO_2) content of the hybrid, but hybrid films with amorphous titania phase have the relatively low value. The dielectric constants were calculated using the equation for MIM structures:

$$C = \kappa\varepsilon_0 A/t \quad \text{(MIM structure)} \tag{1}$$

where C is the measured capacitance, ε_0 is the permittivity of free space, A is the area of the capacitor, and t is the thickness of the dielectric film. The use of high-κ materials could afford greater or comparable surface charge density at the interface with lower leakage currents even if the thicker insulators are applied. From this point of view, the possibility of dielectric constant control is one of the advantages for the hybrid dielectrics. In this study, hybrid films which have been considered both suitable capacitance and leakage currents were fabricated with a layer of the thickness 800–1000 nm.

OTFTs were fabricated using SG samples as gate insulators and pentacene as the active layer, as described in Section 2. Fig. 4(a) shows typical transfer characteristics of OTFTs, I_{ds}, $(I_{ds})^{1/2}$ versus V_g, for the device with an SG sample as the gate insulator. Transfer characteristics were determined by the saturation region, as described by the following equation:

$$I_{ds} = \frac{WC_i}{2L}\mu(V_g - V_{th})^2 = \frac{W}{2L}\frac{\kappa\varepsilon_0}{t}\mu(V_g - V_{th})^2 \quad \text{(at the saturation region)} \tag{2}$$

where C_i is the capacitance per unit area of gate insulator, V_{th} is the threshold voltage, and μ is the effective mobility. In this study, the channel width (W) and the channel length (L) of OTFTs were 2000 and 100 μm, respectively. The OTFT data and parameters calculated from (1) and (2) are summarized in Table 1. In general, the carrier mobility of OTFTs with the conventional hybrid gate insulator is deteriorated because crystalline inorganic nanoparticles blended in polymer matrix act as a charged center and a surface phonon. In addition, the blended nanoparticles increase surface roughness and –OH groups which increase the leakage current [14]. In this study, the measured carrier mobility of SG 30 was higher than that of other samples. The measured mobility was shown to be ~0.86 cm^2/V s. It was thought that the presence of the titania (TiO_2)-rich site as the amorphous phase at the interface had any effect on active sites for pentacene deposition. Furthermore, inorganic/organic hybrid in amorphous phase decreased density of –OH groups thus leakage current was reduced as shown in Fig. 4. In Fig. 4, the hysteresis behavior of SG 30 compared to SG 10 showed negligible

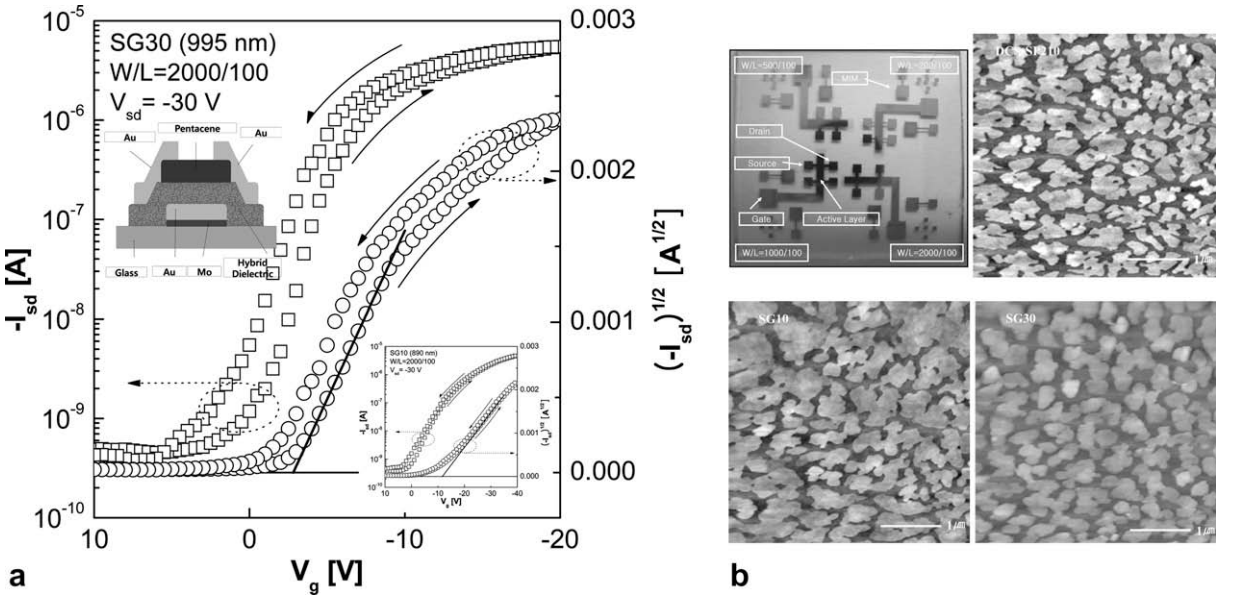

Fig. 4. (a) Transfer characteristics of OTFTs with SG30 (995 nm) and SG10 (890 nm) (the inset graph) as gate insulators. Insets show the cross sectional view of bottom-gate/top-contact OTFT employed. (b) The structure of devices fabricated in this study and atomic force microscopy images of pentacene films (5 nm) deposited on DCS-SP210, SG10, and SG30.

change, this means that the amorphous titania (TiO_2)-rich site inhibits the formation of –OH group.

Pentacene grain size of SG30 was little small, but characteristics of OTFTs were not bad. However, an excess of the titania (TiO_2)-rich sites disturbed pentacene deposition, as observed for SG 30. I_{on}/I_{off} of SG10 samples was shown to be $\sim 10^4$ larger than for other samples. I_{on}/I_{off} was not as high due to leakage current, although the output current could be enhanced by the high-κ gate insulator of the sol–gel hybrid. Threshold voltage decreased with the increase of dielectric constant according to the titania (TiO_2)-content in the sample. One result was reported by Kang et al., where V_{th} of OTFT using amorphous Gd_2O_3 as the gate insulator was smaller than crystalline SiO_2 despite the size of pentacene and the roughness of the gate insulator at the interface [15]. It was thought that amorphous titania site at the interface had any effect pentacene grain. Additional research is necessary to understand this behavior further. It was thought that in light of these results, the characteristics of OTFTs prepared with sol–gel hybrid gate insulators were sensitive to the quantity of the titania (TiO_2)-rich sites. This problem is likely to be resolved by enhancing control of the sol–gel process.

4. Conclusion

In summary, we have shown that a hybrid material formed by the appropriate combination of polymer and amorphous titania (TiO_2)-rich phase produces high capacitance relatively low-leakage gate dielectric materials. These hybrid films are easily deposited, can be patterned, are characterized by controllable dielectric constants, and are suitable for gate insulators in OTFTs. Gate insulators formed from hybrid films constitute alternatives to other candidate materials for flexible OTFTs.

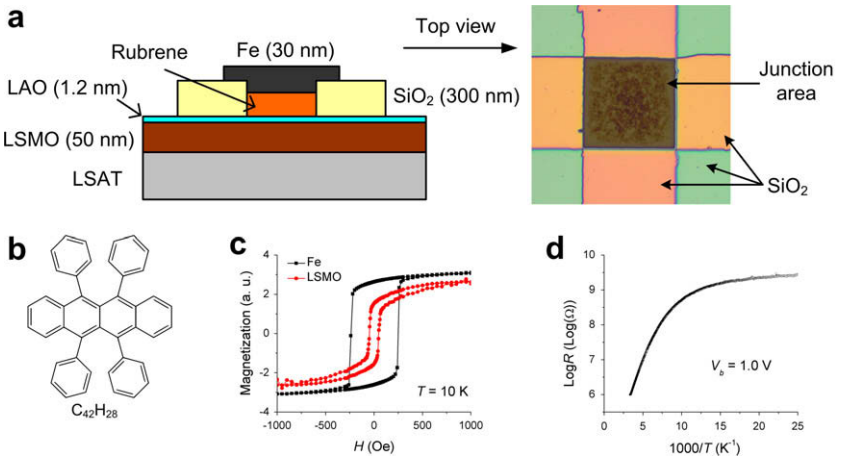

Fig. 1. (a) The schematic device structure. On the right side is the optical image of the cross-section. 50 nm rubrene is deposited in the center area of 0.2 mm by 0.2 mm surrounded by SiO_2. 30 nm Fe film will be deposited on top of rubrene layer. (b) Chemical structure of rubrene ($C_{42}H_{28}$). (c) Magnetic hysteresis loops of LSMO (50 nm) on LSAT (0 0 1) substrate and Fe (30 nm) on glass substrate. (d) Temperature dependent resistance (OFF state) of the LSMO (50 nm)/LAO/rubrene (50 nm)/Fe (30 nm) junction.

by 0.2 mm was enclosed by 300 nm SiO_2 deposited by e-beam. The sublimed rubrene (Aldrich) was used as an organic semiconductor channel and thermally deposited with controlled source temperature (~105 °C). The thickness of the rubrene layer was measured by a quartz crystal monitor and verified with a profilometer. A rigorous inspection of the surface morphology over wide range of area via AFM showed the typical RMS roughness of our thermally deposited rubrene layer was 1 ± 0.3 nm and maximum peak to peak distances were 7 ± 3 nm. On top of the rubrene layer, 30 nm of Fe was used as a second ferromagnetic layer which was deposited by e-beam evaporation. The magnetotransport measurements were performed using a Quantum Design Physical Property Measurement System (PPMS) with an external Keithley 2400 sourcemeter. Fig. 1(c) displays the magnetic hysteresis loops of a 50 nm LSMO film on LSAT (0 0 1) substrate and a 30 nm Fe film, respectively.

3. Results and discussion

The temperature dependence of the resistance of the device LSMO/LAO/rubrene (50 nm)/Fe in the initial OFF state is presented in Fig. 1(d). This temperature dependent resistance reflects the carrier injection at the metal/organic interface, which introduces the strong increase of the device resistance as the temperature is lowered. This effect of carrier injection typically saturates below 100 K [14]. Further increase of the device resistance below 100 K can be attributed to the hopping transport in the bulk of rubrene layer. This temperature dependent resistance indicates the device in the initial OFF state is controlled by carrier transport through the bulk of the organic semiconductor layer and free of pinhole channels and/or filamentary conduction channels of metallic inclusions. The current versus voltage curves were recorded in a series of bias scans at 10 K, using a two-probe configuration. Fig. 2 displays typical *I–V* curves of our device, which show the electrical bistable effect. In the first sweep, the device shows very low current in the high negative bias to low positive bias range, indicating it stays in the OFF state. However, at a threshold bias, about 4.5 V, the current increases sharply, showing the device has undergone a transition from the OFF state to the ON state. This transition can be regarded as the "write" operation in the digital memory. Furthermore, the device is able to remain in the ON state without any supplied power, which is an essential characteristic of the non-volatile memory. In the second bias sweep, started at +5 V, the current remains at the high level. The *I–V* curve is completely different from the first scan, indicating the device remains in the ON state. The device will not recover to the initial OFF state unless a high negative bias (−5 V) is applied, and this process is analogous to the "erase" operation in the digital memory. The third bias scan is identical with the fist one, and the *I–V*

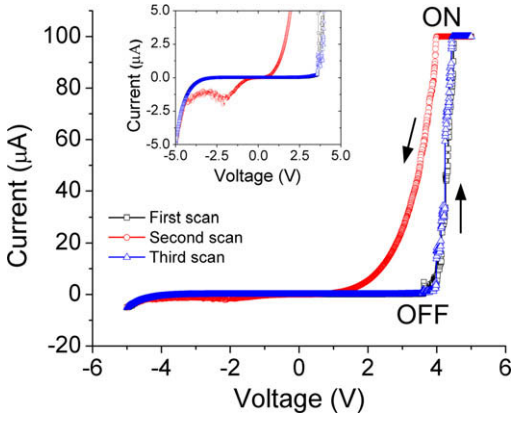

Fig. 2. *I–V* curves of the hybrid organic bistable device of structure LSMO (50 nm)/LAO/rubrene (50 nm)/Fe (30 nm) at 10 K. Initially, the device is in the OFF state. At about 4.5 V, the current increases sharply, indicating the transition of the device from the OFF to the ON state. The device is able to return to the OFF state by applying a high negative voltage. The inset shows the enlarged curves near zero bias.

curve overlaps the first sweep curve. The comparison of the *I–V* curves in the two states at different temperatures is displayed in Fig. 3. The current goes up as the temperature increases, and the two states are distinct at both low temperature and room temperature.

In addition to the electrical bistability, the magnetic field dependence of the device resistance was measured while an in-plane magnetic field was swept from +3000 Oe to −3000 Oe and then back to +3000 Oe. The spin valve magnetoresistance (MR) value is defined as: MR (%) = 100 × ($R_{AP} - R_P$)/R_P, where R_{AP} and R_P refer to the device resistance when the magnetization directions of the two ferromagnetic layers are anti-parallel and parallel, respectively. We obtained a spin valve MR value of up to 3.75% in the ON state, while no spin valve effect was observed in the OFF state. Fig. 4(c)–(e) shows the magnetoresistance curves of a 50 nm rubrene device in the ON state with a bias of 2.0, 2.5 and 3.0 V, respectively. The bias voltage dependence of the spin valve MR value is presented in Fig. 4(f), and the maximum spin valve MR 3.75% was obtained when 3.0 V was applied. We emphasize here that the spin valve effect of our device was controllable via applied bias, and it was observed only when the device was in the ON state. We did not observe this spin valve effect in room temperature, because the polarization of the LSMO decreases as the temperature increases [18]. Another difference of the magnetoresistance curves between the two states is the shape. As shown in Fig. 4(a) and (b), the high field magnetoresistance curve in the OFF state is almost flat, while the high field magnetoresistance curves in the ON state show a "wing" shape that the device resistance decreases as the external magnetic field increases. We define a high field magenetoresistance (HFMR) as HFMR (%) = 100 × ($R(0)_{max} - R(\pm 3000\ Oe)_{min}$)/$R(0)_{max}$.

Several mechanisms have been proposed to explain the electrical bistability of OBDs. Ma et al. developed a model for their three-layer OBDs involving the polarization of the metal-nanoparticle layer and charge storage at the interfaces between the nanoparticle layer and organic semiconductor [5]. Bozano et al. claimed that charge trapping and space-charge field inhibition of injection should be the reason for the resistive switching [6,7]. Cölle et al. suggested that switching was due to the oxide layer at the electrode and transport through filament [19]. Other proposed mechanisms include the bulk phenomena of the organic material [20], and the existence of localized conducting microchannels [21], etc.

Here, we propose an explanation for this combination of the electrical bistability and the bias-controlled spin valve effect. The magnetoresistance curves we obtained from the ON state show additional "wing" shape magnetoresistance. Note this shape of MR effects is similar to the reported results of Sakai et al. in a Co–C_{60} hybrid nanocomposite channel [22] and Kusai et al. in a Co–rubrene hybrid nanocomposite channel between nonmagnetic electrodes [23]. The MR effects in those previous results were attributed to the spin dependent tunneling between the Co nanoparticles through the organic molecules. Another similar MR behavior can be found in the phenomenon that was termed organic magnetoresistance (OMAR) [24–27]. In our de-

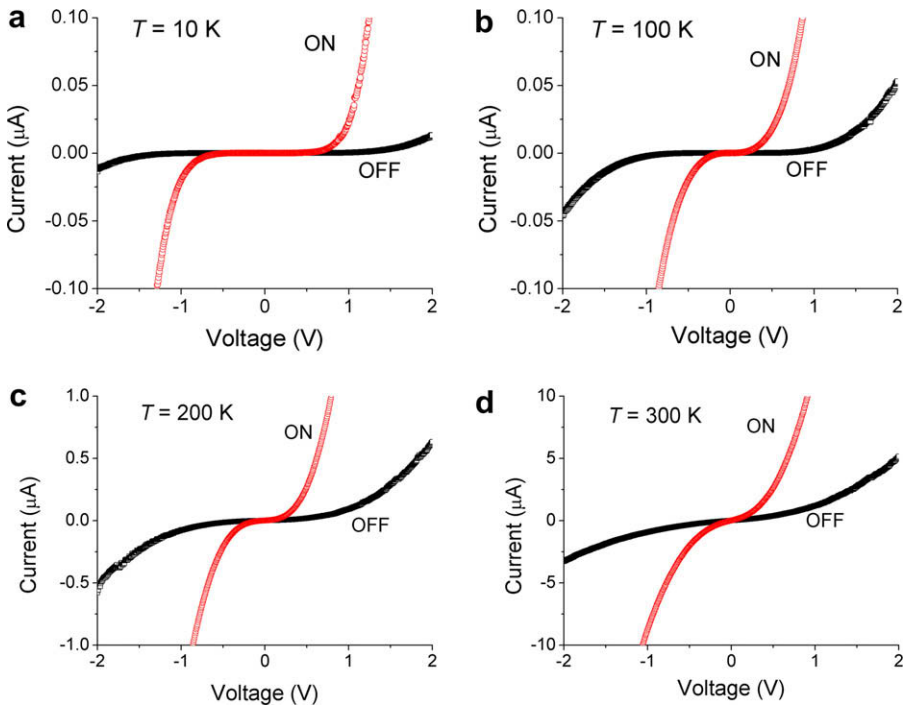

Fig. 3. Temperature dependence of the *I–V* curves. Red circles represent data points in the ON state, and black squares represent data points in the OFF state. (a) *T* = 10 K. (b) *T* = 100 K. (c) *T* = 200 K. (d) *T* = 300 K. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

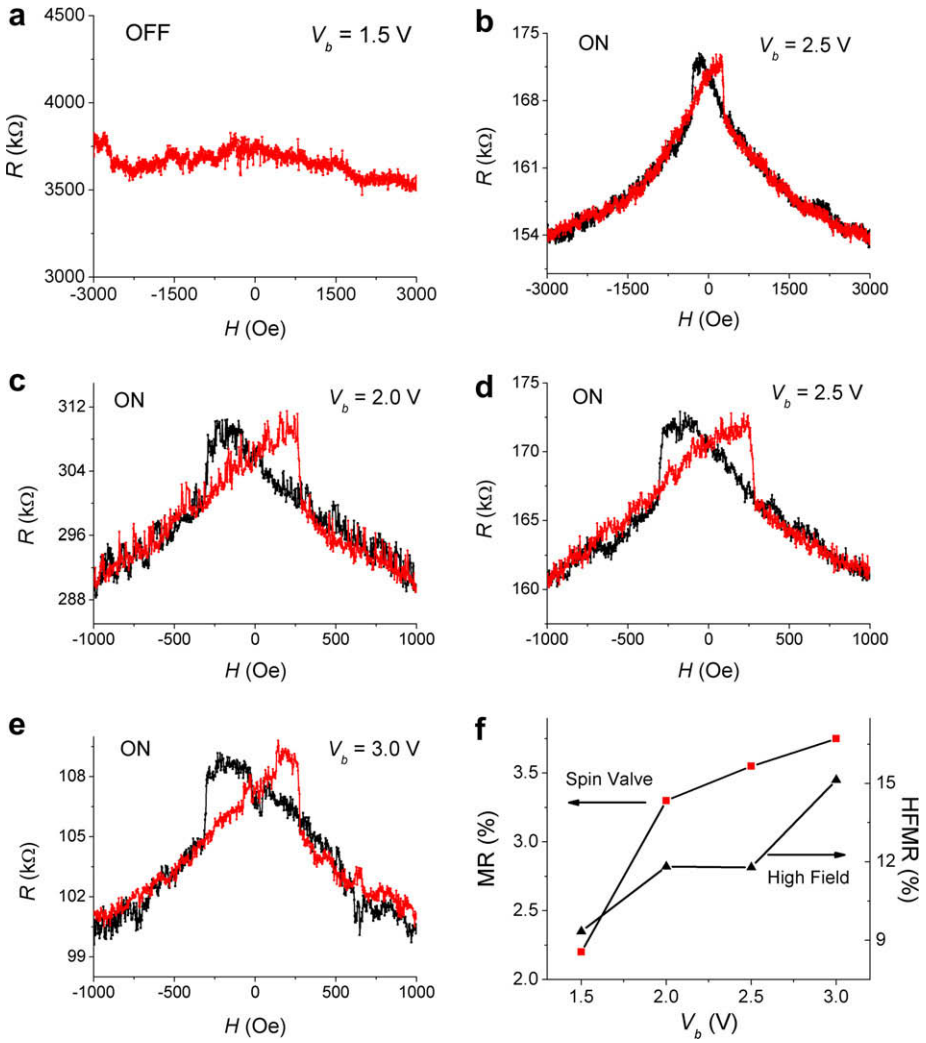

Fig. 4. Magnetoresistance curves of the 50 nm rubrene device at 10 K. (a) In the OFF state under 1.5 V (+3000 Oe to −3000 Oe). (b) In the ON state under 2.5 V (+3000 Oe to −3000 Oe). (c) In the ON state under 2.0 V bias. (d) In the ON state under 2.5 V bias. (e) In the ON state under 3.0 V bias. (f) Bias dependence of the spin valve MR value and high field MR value.

vices, this MR feature appeared only when the device was switched to "ON" states. This indicates that this additional high field MR feature in our devices is not intrinsic as the case in OMAR. We suggest that some Fe atoms migrate into the rubrene layer under high bias, forming conductive channels, although the microscopic mechanism still needs to be investigated. Starting from the OFF state in which the channels were closed, the device showed low current. At a threshold voltage, the conductive channels were turned on and the current jumped to a high level. After the power supply was removed, the channels were still open and the device remained in the ON state. Only if a high negative bias was applied, those channels were disrupted and the device recovered to the OFF state. In the ON state the conductive channels also provided efficient transport paths for the spin-polarized carriers. This high-voltage induced conduction channel introduces high field MR effects similar to the reports of Co–rubrene nanocomposite channel with nonmagnetic electrodes [23]. In addition, the ferromagnetic electrodes in our devices introduce spin valve effects at the same time.

In the OFF state, the bulk resistance of the rubrene layer dominated and it was much larger than the interface resistance. In principle, the spin valve effects rely on the spin dependent scattering at the interface. The device resistance in the OFF state was almost one order of magnitude larger than that in the ON state. Given the fact that even the maximum MR value we obtained in the ON state was relatively small—3.75%, any resistance change at the interface in the OFF state is likely overshadowed by the bulk resistance of rubrene layer. Additionally in the OFF state, the travel distance through the rubrene layer for the spin-polarized carriers could be longer than the spin-diffusion length (λ_S). The carriers would lose their spin information before they reach the other ferromagnetic electrode. Though the spins in carbon based materials are typically perceived to have

long lifetime, the transport in small molecule film heavily rely on the hopping between neighboring molecules leading to long transit time between two ferromagnetic electrodes. However, in the ON state, the presence of the conductive channels made the effective spin travel distance much shorter. The carriers could effectively maintain their initial spin states during the transport, leading to the spin valve effect.

In order to fully understand the mechanism, further detailed studies on bias and temperature dependence as well as careful study on the morphology are in progress with a variation of the device configuration and materials.

4. Conclusion

We report the integration of the electrical bistability and the bias-controlled spin valve effect in an LSMO/rubrene/Fe trilayer device. The spin valve effect can be turned on and off by applying different bias voltages. This finding is attributed to the formation of conductive channels by the migration of Fe atoms under high bias voltage. Further experimental studies are needed to fully understand the microscopic mechanism.

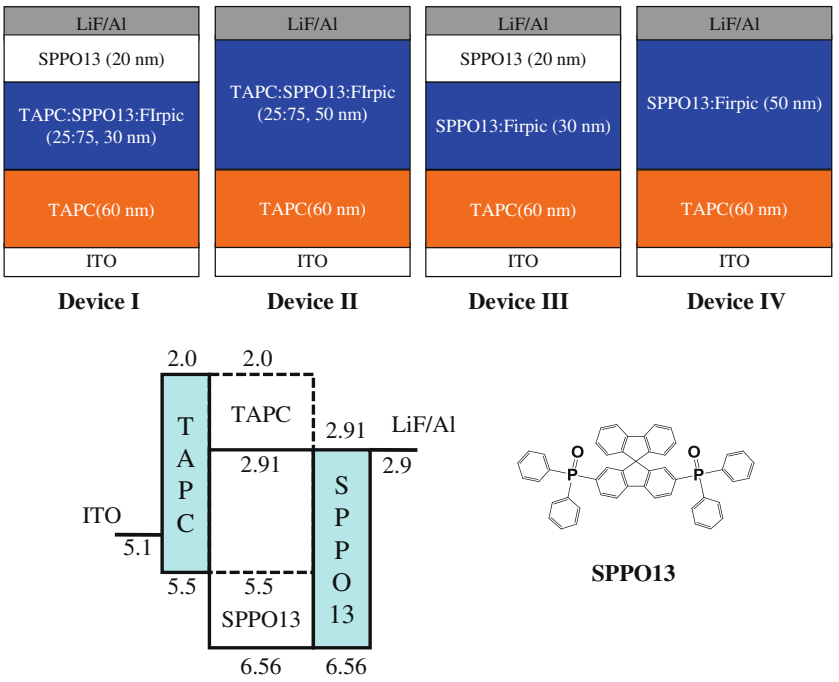

Fig. 1. Device structures of the blue devices, energy level diagram and chemical structure of the SPPO13. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

chemical structure of the SPPO13. All materials were evaporated at a vaccum pressure of 8×10^{-7} torr and all devices were encapsulated with a glass lid and a CaO getter. The device performances of the blue PHOLEDs were measured with Keithley 2400 source measurement unit and CS 1000 spectroradiometer.

3. Results and discussion

The SPPO13 has a high triplet energy of 2.73 eV and it can be used as the host material for the FIrpic blue dopant. In addition, it has the lowest unoccupied molecular orbital (LUMO) level of 2.91 eV and it is suitable as the electron transport layer of the blue PHOLEDs. Therefore, the SPPO13 was used as the host in the emitting layer and the electron transport material. The TAPC has been known to have a high triplet energy of 2.87 eV and it has the highest occupied molecular orbital (HOMO) of 5.5 eV for hole injection [4]. It has been widely used as the hole transport layer in the blue PHOLED because it can confine triplet excitons inside the emitting layer [5]. Therefore, the TAPC was used as the hole transport material and it was also combined with the SPPO13 as the host in the mixed host emitting layer [12]. The energy level diagram of the blue PHOLEDs is shown in Fig. 1.

Four blue PHOLEDs with different host materials and electron transport layer structures were fabricated. Current density–voltage and luminance–voltage curves of the blue PHOLEDs are shown in Fig. 2. The device I with the TAPC:SPPO13 mixed host showed higher current density than the device III and device IV with the SPPO13 host. The high current density of the blue PHOLEDs with the mixed host emitting layer can be explained by efficient hole injection from the TAPC hole transport layer to the emitting layer. There is an energy barrier of 1.06 eV for hole injection between the TAPC and the SPPO13. In the case of the device III and device IV, the hole injection from the TAPC to the SPPO13 emitting layer is difficult due to the HOMO level difference of 1.06 eV between the TAPC hole transport layer and the SPPO13 host. The addition of the TAPC in the SPPO13 emitting layer improves the hole injection because holes can be directly injected from the TAPC hole transport layer to the TAPC in the mixed host. Therefore, the current density of the device I was much higher than that of the device III and device IV.

Comparing the device I and device II, the device I with the SPPO13 as the electron transport layer showed higher current density than the device II without the SPPO13 electron transport layer. The TAPC:SPPO13 mixed host enhanced the hole injection, but reduced the electron injection due to electron blocking properties of the TAPC. Therefore, the current density of the device I was higher than that of the device II. However, the SPPO13 electron transport layer was not effective in the blue PHOLEDs with the SPPO13 host material. The SPPO13 has strong electron transport properties and electrons could be directly injected from the LiF/Al electrode to the SPPO13:FIrpic emitting layer. There was only 0.1 eV difference of the LUMO level between the SPPO13 and FIrpic. The small energy level difference does not induce the electron trapping by the FIrpic and the electron transport is not hindered by the FIrpic. Therefore, the device III and device IV showed similar current density and the SPPO13 electron transport layer

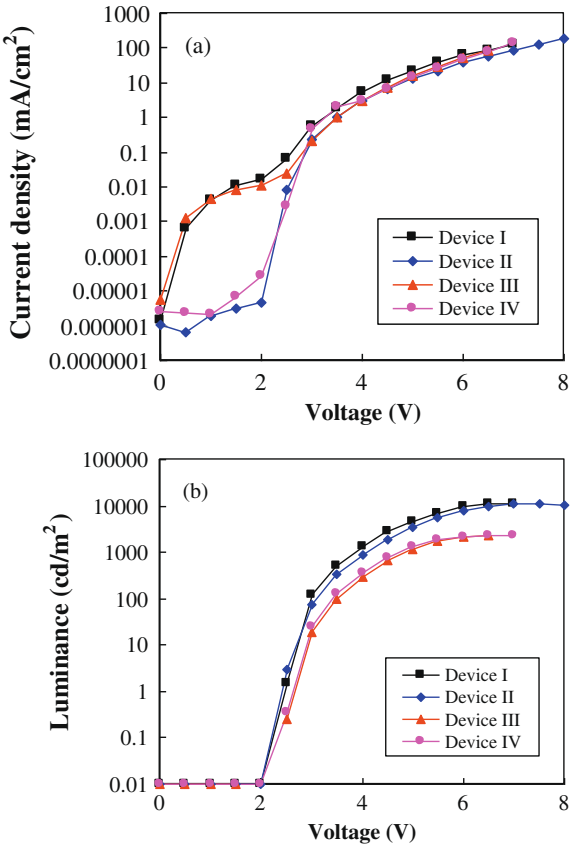

Fig. 2. Current density–voltage (a), and luminance–voltage (b) curves of the simple blue PHOLEDs. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

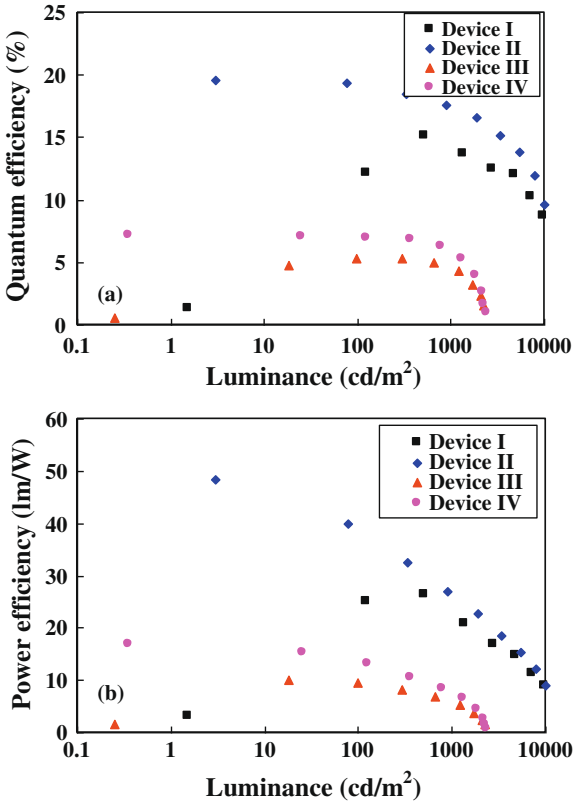

Fig. 3. Quantum efficiency–luminance (a), and power efficiency–luminance (b) curves of the simple blue PHOLEDs. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

could not greatly affect the current density. The difference of the current density below turn-on voltage (2 V) is due to the electron injection from the cathode to the electron transport layer or emitting layer. The efficient electron injection from the LiF/Al to the SPPO13 layer increased the current density at low voltage in the device I and device III, while it was difficult in the device II and device IV.

The luminance of the blue device is also shown in Fig. 2. The luminance followed the same tendency as the current density. The device I showed the highest luminance at the same voltage due to the high current density. The driving voltages of the device I at 100 and 1000 cd/m^2 were only 2.9 and 3.8 V, while those of the device II at 100 and 1000 cd/m^2 were 3.1 and 4.1 V even without the SPPO13 electron transport layer. The good hole injection property of the TAPC and the electron injection property of the SPPO13 significantly lowered the driving voltage of the blue PHOLEDs.

The quantum efficiency and power efficiency of the simple blue PHOLEDs are shown in Fig. 3. The device I and device II showed higher quantum efficiency than the device III and device IV. In particular, the device II exhibited the highest quantum efficiency. The maximum quantum efficiency of the device II was 19.6% and the quantum efficiencies at 100 and 1000 cd/m^2 were 19.2% and 17.5%, respectively. The high quantum efficiency of the device II can be explained the charge balance in the emitting layer. Holes are efficiently injected from the TAPC hole transport layer to the TAPC:SPPO13 mixed host emitting layer and electrons can also be injected from the LiF/Al electrode to the mixed host emitting layer. The efficient hole and electron injection improves the charge balance in the emitting layer, resulting in high quantum efficiency in the device II. The charge balance is degraded in the device I because of too high electron density in the emitting layer. The low quantum efficiency of the device III and device IV is mainly due to the poor hole injection originated from the high energy barrier for hole injection. Efficient electron injection and poor hole injection disrupt the charge balance in the emitting layer, leading to low quantum efficiency. The quantum of the device II was similar to that of other devices with three layer or four layer device structures [4,5,11]. The use of the TAPC:SPPO13 mixed emitting layer enabled the fabrication of simplified high efficiency blue PHOLEDs. The efficiency roll-off of the blue PHOLED was also affected by the device structure and the efficiency roll-off was reduced in the device with a mixed host emitting structure. This results is in agreement with the data reported in the literature [12].

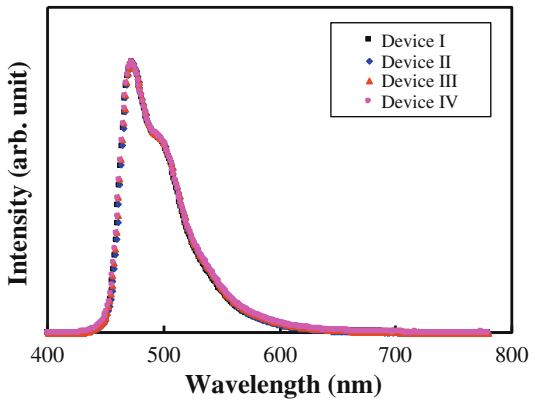

Fig. 4. Electroluminescence spectra of the simple blue PHOLED. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

The power efficiency of the blue PHOLEDs was also high in the device II. The quantum efficiency of the device II was high and the driving voltage of the device II was as low as 3.1 V at 100 cd/m^2 and 4.1 V at 1000 cd/m^2 even without any p or n doped charge transport layer. The low driving voltage and high quantum efficiency of the device II enhanced the power efficiency of the device II. The maximum power efficiency of the device II was 48.5 lm/W and the power efficiencies at 100 and 1000 cd/m^2 were 38.1 and 26.0 lm/W. The good electron injection property of the SPPO13 and hole injection property of the TAPC enabled the fabrication of the simple two layer blue PHOLED with high power efficiency. In the case of the device I, the low quantum efficiency of the device I reduced the power efficiency although the driving voltage of the device I was less than 3 V at 100 cd/m^2. The low power efficiency of the device III and device IV is due to the low quantum efficiency and high driving voltage. The power efficiency level of the device II with only TAPC charge transport layer and mixed emitting layer was comparable to that of the state of the art value reported in the literature using common device structure with two or three charge transport layers for high efficiency and low driving voltage [4,5,11].

Electroluminescence (EL) spectra of the simplified blue PHOLEDs are shown in Fig. 4. All devices showed similar emission spectra with a peak maximum at 474 nm corresponding to the FIrpic emission. The EL spectra was not affected by the device structure. The change of the emission in the blue device induces the change of the EL spectra, but the emission zone of the blue PHOLED fabricated in this work may be close to the electron transport layer side due to strong electron transport properties of the SPPO13. Therefore, there was little change of the vibrational peak in the EL spectra of the simplified blue PHOLEDs.

4. Conclusions

In summary, high power efficiency blue PHOLEDs with simple device structure made up of only two organic layers could be effectively fabricated by combining the hole transport type TAPC and electron transport type SPPO13 host materials. A high power efficiency of 48.5 lm/W and a high quantum efficiency of 19.6% were achieved in the simple blue PHOLEDs. Therefore, this approach can be useful to simplify the device structure and improve the device structure of the blue PHOLEDs.

efficiency as well as reduced efficiency roll-off at high current density.

In this work, high efficiency deep blue PHOLEDs with peak external quantum and power efficiencies of 22.9% and 41.2 lm/W were developed with a mixed host structure, which were combination of two hosts with a hole transport-type host and a electron transport-type host both doped with the FIr6. We have demonstrated the device characteristics including the charge carrier balance mechanism for both the single host and the mixed host structure devices. Moreover, we found that the mixed host structure was effective to control the charge carrier injection and transport in EML, thus obtained highly improved efficiency in deep blue PHOLEDs.

2. Experimental

Two hole transport-type host materials, *N*,*N*′-dicarbazolyl-3-3-benzene (mCP) and 4,4′,4″-tris(*N*-carbazolyl)triphenylamine (TcTa), were combined with an electron transport-type host UGH3 because they have high hole mobility as well as high triplet energy of 2.9 and 2.85 eV, respectively [14,21]. A series of organic light-emitting devices in this study were made using the configuration: indium tin oxide (ITO) (70 nm)/1,1-bis[(di-4-tolylamino)phenyl]cyclohexane (TAPC) (50 nm)/EML (30 nm)/1,3,5-tri(m-pyrid-3-yl-phenyl)benzene (Tm3PyPB) (20 nm)/Tm3PyPB:Cs (30 nm)/LiF (1 nm)/Al (120 nm). For deep blue PHOLEDs, six different mixed host devices and standard device with single UGH3 host material as reference were prepared to investigate the effect of host property on device characteristics. Hole transport-type mCP (Device A) or TcTa (Device B) composition in the mixed host device were 50%, 30%, and 10%, respectively. A deep blue light-emitting FIr6 dopant which has high triplet energy of 2.80 eV [17–20], was doped in the EML and the doping concentration of FIr6 was fixed at 10%.

To achieve efficient blue PHOLEDs, effective confinements of both the charge carriers and the triplet excitons are necessary [10,14,17]. Therefore, TAPC and Tm3PyPB with wider triplet energy level (T_1 = 2.9 and 2.78 eV, respectively, which are higher than that of FIr6 (T_1 = 2.72 eV)) and low-lying the highest occupied molecular orbital (HOMO) and high-lying the lowest unoccupied molecular orbital (LUMO) energy levels, respectively, were used as a hole-transporting layer (HTL) and as an electron transporting layer (ETL), respectively. The electron mobility of Tm3PyPB ($\sim 7.0 \times 10^{-4}$ cm^2/V s at 2.5×10^5 V/cm) [21–23] is one to two orders of magnitude lower than the hole mobility of TAPC ($\sim 1.0 \times 10^{-2}$ cm^2/V s at $\sim 10^5$ V/cm) [17]. Accordingly, n-doped ETL (4 mol% cesium doped TmPyPB) was introduced for effective electron injection and charge carrier balance within EML. The chemical structures of materials and energy level diagrams used in this study were shown in Figs. 1 and 2.

ITO was cleaned with the standard oxygen plasma treatment. The OLED grade materials were purchased and used without further purification. All organic layers were deposited in a high vacuum chamber below 5×10^{-7} torr and thin films of LiF and Al were deposited as a cathode electrode. The OLEDs were transferred directly from vacuum into an inert environment glove-box, where they were encapsulated using a UV-curable epoxy, and a glass cap with a moisture getter. The electroluminescence spectrum was measured using a Minolta CS-1000. The current–voltage (*J*–*V*) and luminescence–voltage (*L*–*V*) characteristics were measured with a current/voltage source/measure unit (Keithley 238) and a Minolta CS-100, respectively.

3. Results and discussion

The current density–voltage–luminance curves of the mCP:UGH3 mixed host devices (Device A) are shown in Fig. 3a according to the relative content of two host

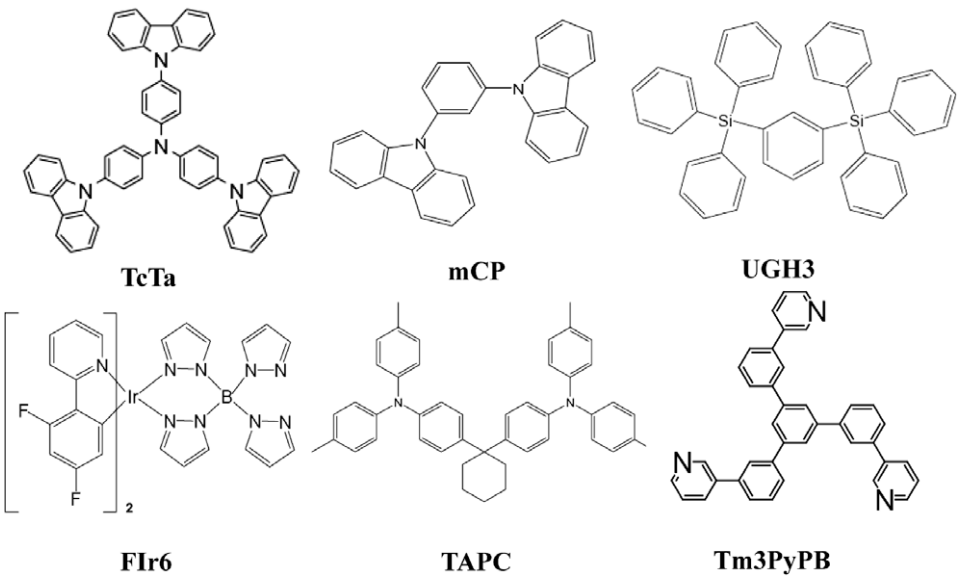

Fig. 1. Chemical structures for the materials tested in this study.

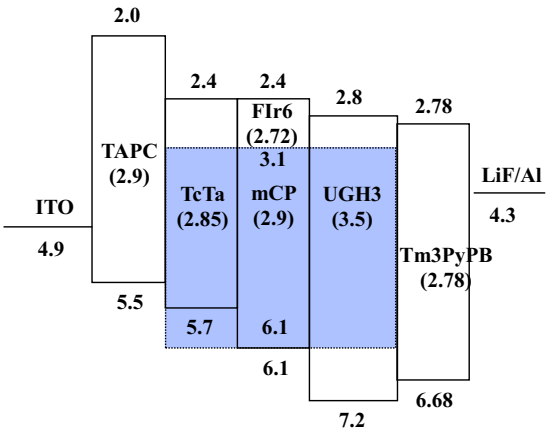

Fig. 2. Energy level diagrams for the materials tested in this study.

materials. The current density of Device A was gradually increased with increasing mCP content in the mixed host devices. Moreover, the driving voltages of Device A at a luminance of 1000 cd/m^2 reduced consequently and were 6.6, 6.3, 5.4, and 5.15 V, respectively. These increased current densities and reduced driving voltages in Device A with the addition of mCP to UGH3 can be explained by facilitated hole injection and transport from TAPC to UGH3 through mCP content. As shown in Fig. 2, the highest occupied molecular orbital (HOMO) level of the TAPC and UGH3 are 5.7 and 7.2 eV, respectively, therefore the hole injection from TAPC to UGH3 was greatly restricted due to the HOMO level difference of 1.5 eV between TAPC and UGH3. However, in case of mCP:UGH3 mixed host Device A, the HOMO level of mCP (6.1 eV) is higher-lying than that of UGH3 (7.2 eV) which led to lower energy barrier for hole injection. Moreover, mCP is also better than UGH3 in terms of hole mobility because mCP is a hole-transport-type host, while the UGH3 is slightly electron-transport-type host. Based on these carrier-transporting ability and the HOMO energy level differences between two hosts, the current density and the luminance at the same voltage in mixed host devices were highly increased.

As shown in Fig. 3b, the current density as well as luminance behavior in case of the combination of TcTa and UGH3 host (Device B) was more definite than those in case of Device A. The driving voltages difference of Device B (TcTa:UGH3 = 5:5, 4.15 V) and Device B (TcTa:UGH3 = 0:10, 6.6 V) at a luminance of 1000 cd/m^2 is 2.45 V which is almost 40% reduction. Therefore, we could also expect huge luminance efficiency improvement in mixed host structure. Both TcTa and mCP have similar LUMO levels (2.4 eV) and hole mobility, thus more dramatic current density enhancement can be understood by speculating HOMO level difference. Compared with mCP, TcTa has only 0.2 eV hole injection barrier from TAPC to TcTa, which leads to much higher current density and lower operating voltage in Device B. By gathering up above results, we found that proper introduction of hole transport-type host (mCP or TcTa) into electron transport-type host (UGH3)

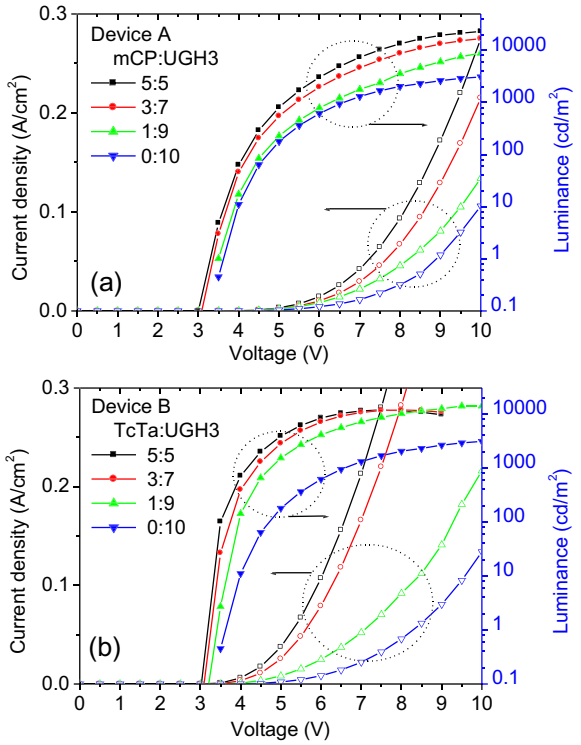

Fig. 3. Current density–voltage–luminescence (*J*–*V*–*L*) characteristics of (a) Device A and (b) Device B.

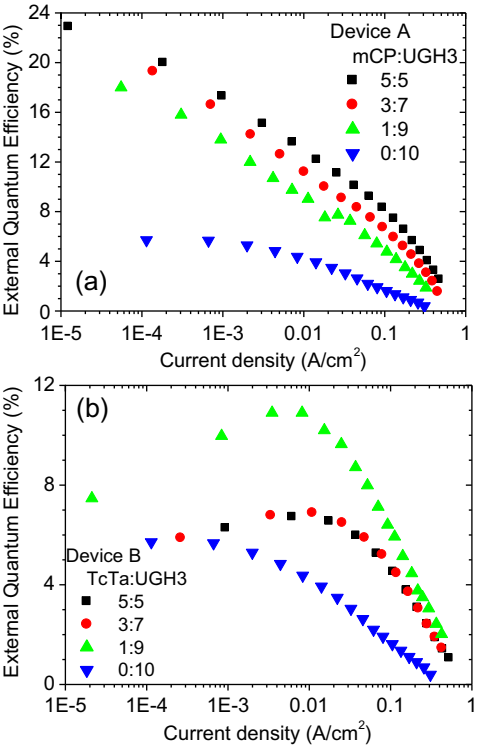

Fig. 4. External quantum efficiency versus current density characteristics of (a) Device A and (b) Device B.

can enhance charge carrier density and reduce driving voltage in the EML.

The external quantum efficiency of the deep blue PHOLEDs with mixed host structure were plotted against current density and luminance in Figs. 4 and 5. Both Device A and B with mixed host structure showed remarkably enhanced performance than UGH3 single host device. In case of Device A, the peak external quantum efficiencies (EQEs) were increased with increasing mCP content in the mixed host devices and the peak EQE of 22.9% at a luminance of 4.9 cd/m^2 were obtained in Device A (mCP:UGH3 = 5:5). This value is better than any other external quantum efficiency values for FIr6 based deep blue PHOLEDs and more than four times higher than that of UGH3 single host device (peak EQE of UGH3 sing host device is 5.71% at 11.0 cd/m^2).

The current efficiency of the deep blue PHOLEDs with mixed host structure were also highly improved as shown in Fig. 6. The peak current efficiency of mixed host Device A are 39.5, 37.7, and 36.7 cd/A, respectively, and those of mixed host Device B are 11.6, 11.8, and 18.7 cd/A, respectively, while that of single UGH3 host device is only 9.68 cd/A.

As we mentioned earlier, the light-emitting efficiency of OLEDs is determined by holes and electrons balance in the EML [20–24]. In case of UGH3 single host device, there is a quite mismatch between holes and electrons because UGH3 was known as slightly electron transport-type host material and its hole carrier mobility is quite low. Moreover, the recombination zone of UGH3 single host device is positioned at shallow region of the TAPC/EML interface due to this hole/electron imbalance which resulted in detrimental triplet quenching process such as the triplet–triplet annihilation (TTA) or triplet-polaron annihilation (TPA) in the EML [25,26]. However, an efficient hole injection through introduction of hole-transport-type host with high hole mobility and adequate HOMO level into the EML resulted in improved charge balance as well as recombination zone distribution overall EML, therefore highly enhanced light-emitting performances in deep blue PHOLEDs were obtained as shown in this study.

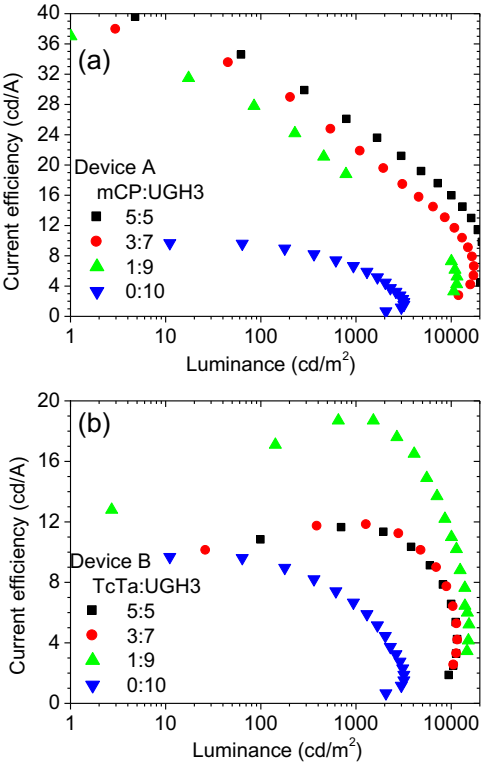

Fig. 6. Current efficiency versus current density characteristics of (a) Device A and (b) Device B.

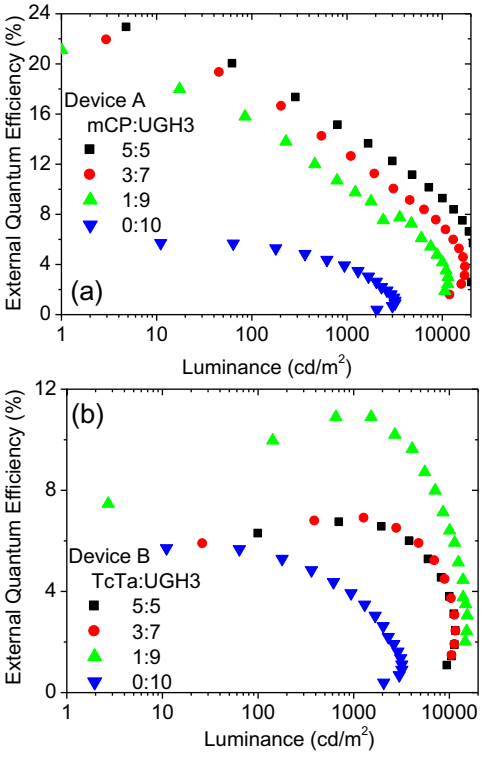

Fig. 5. External quantum efficiency versus luminance characteristics of (a) Device A and (b) Device B.

Note that the performance trends as increasing TcTa content in Device B are slightly different from those in Device A. Even though the EQEs of mixed host Device B are also increased compared to UGH3 single host, the maximum EQE is only 10.9% and obtained in the 1:9 mixed host structure not in the 5:5 mixed ratio. This phenomenon is contrary result to our previous report that the best light-emitting performances of FIrpic based blue PHOLEDs were obtained in the 5:5 mixed TcTa:UGH3 host structure [21].

To examine this discrepancy, we inspected the electroluminescent (EL) spectrum of Device A and B in detail. As shown in Fig. 7, all Device A and B exhibited a similar maximum luminescence wavelength at a driving current of 10 mA/cm^2, near 460 nm, which is originated from the triplet emission of FIr6 dopant and the second vibration peaks with a wavelength of approximately 490 nm. However, we could find some differences between Device A

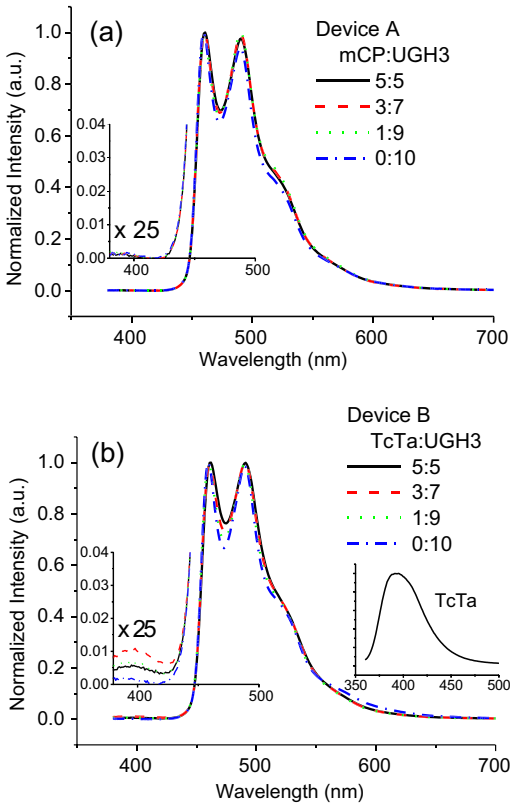

Fig. 7. Normalized electroluminescence spectra of (a) Device A and (b) Device B at a driving current of 10 mA/cm^2 (left inset: magnified EL spectra; right inset: photoluminescence (PL) emission of TcTa 30 nm-thick films on quartz plate).

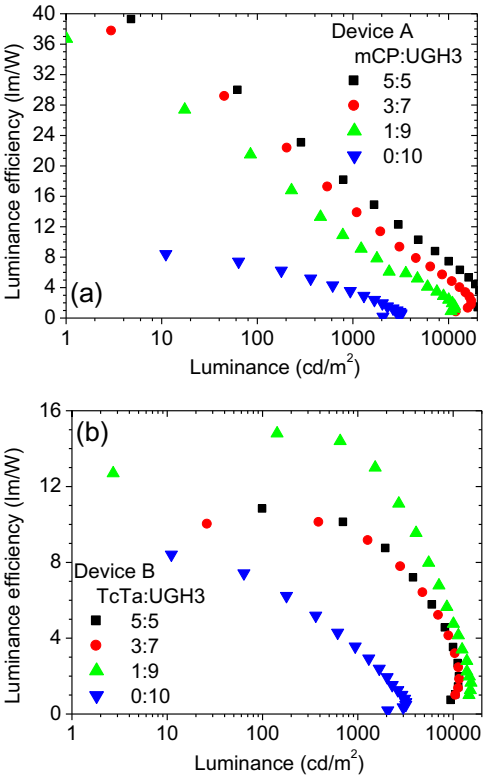

Fig. 8. Luminance efficiency versus brightness characteristics of (a) Device A and (b) Device B.

and B from the provided left inset of Fig. 7a and b, which shows the magnified EL spectra in the range of 380–500 nm. In case of the mCP:UGH3 mixed host Device A, there are little emission appeared even at the magnified EL spectra. On the other hands, new EL spectra appeared near 393 nm in case of the TcTa:UGH3 mixed host Device B. This new EL spectra could be presumed to be TcTa fluorescent emission which is shown in the right inset of Fig. 7b. The more precise cause of this new EL emission is being investigated and will be reported elsewhere.

Relatively lower light-emitting performance of TcTa:UGH3 mixed host Device B compared to mCP:UGH3 mixed host Device A could be understood by ineffective hosting property of TcTa host [27]. As shown in Fig. 2, the HOMO energy level of FIr6 (6.1 eV) is 0.4 eV lower-lying than that of TcTa (5.7), however that of mCP (6.1 eV) is identical. Therefore, this mismatching of HOMO energy level between TcTa and FIr6 would lead to inefficient deep blue electro-phosphorescent emission even though hole injection of TcTa incorporated Device B is highly improved.

The luminance efficiency of the deep blue PHOLEDs with mixed host structure were plotted against luminance in Fig. 8. Increased EQEs along with reduced driving voltages result in a significantly enhanced luminance efficiency of 39.2 lm/W with Device A (mCP:UGH3 = 5:5) without any out-coupling enhancement technique, in which is 4.6 times enhancement comparing with that of UGH3 single host device (peak luminance efficiency of UGH3 sing host device is 8.41 lm/W at 11.0 cd/m^2). The luminance efficiency of Device A (mCP:UGH3 = 5:5) slightly reduced to 27.9 and 17.2 lm/W at a luminance of 100 and 1000 cd/m^2, respectively. With considering the potential of improved out-coupling technique to achieving 2.3 times enhancement, the external luminance efficiency can be expected over 90 lm/W [3,10,28].

4. Conclusion

We have demonstrated that the performances of deep blue PHOLEDs were significantly improved by using mixed host structure and found that device characteristics depend on combination/composition of mixed host material properties. A peak external quantum and luminance efficiencies of 22.9% and 39.2 lm/W were achieved in the mCP:UGH3 mixed host device, which is mainly attributed to the charge carrier injection/transport balance as well as the recombination region distribution within EML by the optimization of mixed host properties.

emitters with simpler device structures, which might eventually replace the existing illumination sources [18,19]. Up to date, almost all phosphor excimer based WOLEDs utilized Pt complexes as dopant emitters [18–22]. In our insight, no Ir complex has been applied in this technique.

Recently, we reported highly efficient orange-red OLEDs based on a new iridium complex $(DMBA)_2Ir(acac)$ (DMBA = 5,6-dihydro-9,10-methylenedioxy-benzo[c]acridine, acac = acetylacetonate) with relatively broad excimer emission [23]. In the present work, we report the first example of WOLEDs incorporating the complex $(DMBA)_2Ir(acac)$ in combination with an efficient blue iridium complex bis(4′,6′-difluorophenylpyridinato) iridium (III) picolinate (FIrpic). Through adjusting the doping concentration, varying the thicknesses and locations of emission layers, pure white emission and high luminescent efficiencies were achieved.

2. Experimental

2.1. Materials

The complex $(DMBA)_2Ir(acac)$ was synthesized as we reported before [23]. Other materials were purchased and all compounds used were subject to temperature-gradient sublimation under high vacuum before fabrication of the devices.

Selected spectroscopic data of $(DMBA)_2Ir(acac)$: ^1H NMR ($CDCl_3$, 400 MHz) δ: 8.08 (s, 2 H), 7.71 (s, 2 H), 7.01 (s, 2 H), 6.64 (d, J = 7.2 Hz, 2 H), 6.56 (t, J = 7.2 Hz, 2 H), 6.33 (d, J = 7.6 Hz, 2 H), 6.04 (s, 2 H), 6.00 (s, 2 H), 4.90 (s, 1 H), 3.26–3.30 (m, 2 H), 3.04–3.15 (m, 6 H), 1.60 (s, 6 H). Anal. Calcd for $C_{41}H_{31}IrN_2O_6$: C, 58.63; H, 3.72; N, 3.34. Found: C, 58.48; H, 3.85; N, 3.48.

2.2. OLED fabrication and measurement

The EL devices were fabricated by vacuum deposition of the materials at 10^{-4} Pa onto a clean glass sheet that was pre-coated with a layer of indium tin oxide with a sheet resistance of 10 Ω square^{-1}. The deposition rate for the organic compounds was 0.1–0.2 nm s^{-1}. The cathode of LiF/Al was deposited by first evaporating LiF (1 nm) at a deposition rate of 0.01 nm s^{-1} and then evaporating aluminum (100 nm) at a rate of 0.1–0.2 nm s^{-1}. The cathode was then capped with silver metal (100 nm) by evaporation silver at a rate of 0.3 nm s^{-1}. Current, voltage, and light-intensity measurements were made simultaneously using a Keithley 2400 source meter and a Newport 1835-C optical meter equipped with a Newport 818-ST silicon photodiode.

3. Results and discussion

As described in our previous report [23], the complex $(DMBA)_2Ir(acac)$ had been used to fabricate highly efficient orange to red phosphorescent OLEDs with an external quantum efficiency of 17.7% and maximum brightness of 66,312 cd m^{-2}. An additional benefit of the complex $(DMBA)_2Ir(acac)$ is its relatively broad emission band with an emission peak at 620 nm and a shoulder at 572 nm covering the spectral range from yellow to saturated red. On the other hand, the well known complex FIrpic have been used widely for the fabrication of WOLEDs due to its very high photoluminescence (PL) quantum efficiency in wide gap host and high EL efficiencies [12,13]. Thus the orange-red phosphorescent iridium complex $(DMBA)_2Ir(acac)$ and the blue phosphorescent iridium complex FIrpic were selected in this work for the fabrication of WOLEDs. The molecular structures of the two Ir complexes and the related materials are shown in Fig. 1.

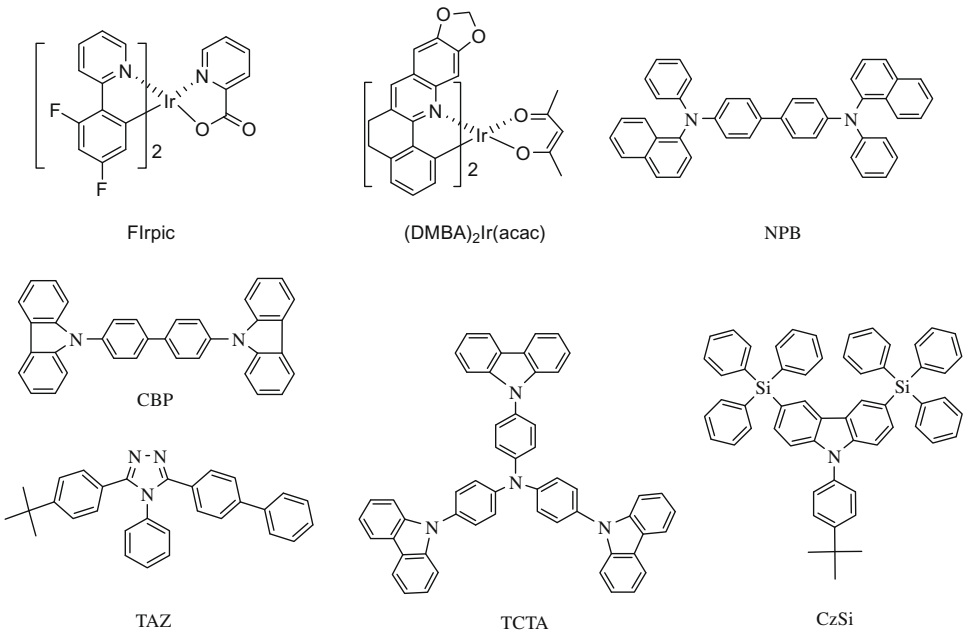

Fig. 1. Molecular structures of compounds used in EL devices.

According to our previous investigations, the highest EL efficiencies and broad emission could be achieved by doping $(DMBA)_2Ir(acac)$ into CBP (4,4′-*N*,*N*′-dicarbozole biphenyl) host at a doping concentration of 5%. So the doping concentration of $(DMBA)_2Ir(acac)$ was kept 5% for the first type of WOLEDs, while the thickness of the orange-red layer varied. Firstly, Device A was fabricated with a structure of ITO/NPB (30 nm)/TCTA (20 nm)/FIrpic:CzSi (7%, 20 nm)/$(DMBA)_2Ir(acac)$:CBP (5%, 200 nm)/TAZ (50 nm)/LiF (1 nm)/Al (100 nm), where 4,4′-bis(1-naphthylphenylamino)-biphenyl (NPB) and 4,4′,4″-tris[*N*-carbazolyl]-yriphenylamine (TCTA) were used together as the hole-transporting layers, 9-(4-*tert*-butylphenyl)-3,6-bis(trisphenylsilyl)-9H-carbazole (CzSi) and CBP as the host of the blue and orange-red emission layers, respectively, 3-(4-biphenylyl)-4-phenyl-5-(tert-butylphenyl)-1,2,4-triazole (TAZ) as the electron transporting layer, and LiF as the electron injection layer (Fig. 2). Device B was fabricated, where the thickness of the orange-red emission layer was reduced to 100 nm.

The maximum brightness of the two devices reached 24,150 cd m^{-2} and 24,012 cd m^{-2}, while the maximum external quantum efficiencies (EQE) were as high as 12.7% and 9.8%, respectively. Unfortunately, as shown in Fig. 3, both of the two devices exhibited bluish-white emission. Compared with the blue emission from FIrpic, the relative intensities of the orange-red emission from $(DMBA)_2Ir(acac)$ were weak for both of the devices. It should be noted that the relative intensity of orange-red emission of device B was greater than that of device A, although the thickness of the orange-red emission layer of device B was only half of device A. It can be presumed that it was the holes combining with electrons in the blue emission layer that gave the intense blue emission band in the EL spectra. This phenomenon also showed that increasing the thickness of the orange-red emission layer may not increase the relative intensity of the orange-red emission for this type of WOLEDs. With the hint of this preliminary result, we designed and fabricated device C, with the doping concentration of FIrpic reduced to 4% to decrease the

Table 1
Summary of the device characteristics.[a]

Devices	Brightness (V) (max, cd m^{-2})	External quantum efficiency (%)		Current efficiency (cd A^{-1})		Power efficiency (lm W^{-1})		CIE(x,y) at 10 V
		Max	1000 cd m^{-2}	Max	1000 cd m^{-2}	Max	1000 cd m^{-2}	
A	24,150 (16.5)	12.7	8.9	25.6	18.0	20.2	8.1	(0.23, 0.35)
B	24,012 (11.5)	9.8	7.5	20.9	16.1	16.4	8.4	(0.27, 0.38)
C	19,386 (14.0)	10.4	7.3	21.6	15.1	17.0	6.3	(0.41, 0.36)
D	15,648 (11.5)	9.9	8.9	23.6	21.0	14.8	11.0	(0.27, 0.38)
E	18,676 (16.5)	12.2	8.8	27.0	19.2	18.9	6.3	(0.35, 0.37)

[a] Detailed structures of the emitting layers of the devices: A: FIrpic:CzSi (7%, 20)/$(DMBA)_2Ir(acac)$:CBP (5%, 200); B: FIrpic:CzSi (11%, 20)/$(DMBA)_2Ir(acac)$:CBP (5%, 100); C: FIrpic:CzSi (4%, 10)/$(DMBA)_2Ir(acac)$:CBP (5%, 20); D: $(DMBA)_2Ir(acac)$:CBP (1%, 3)/FIrpic:CzSi (11%, 20)/$(DMBA)_2Ir(acac)$:CBP (1%, 10); E: $(DMBA)_2Ir(acac)$:CBP (5%, 3)/FIrpic:CzSi (7%, 20)/$(DMBA)_2Ir(acac)$:CBP (5%, 10).

relative intensity of the blue emission. The thicknesses of the blue and orange-red emission layers were reduced to 10 and 20 nm, respectively.

The EL spectra at different applied voltages (normalized at the emission peak of $(DMBA)_2Ir(acac)$) of device C are shown in Fig. 4. The EL showed balanced contributions from both blue emission of FIrpic and orange–red emission of $(DMBA)_2Ir(acac)$, giving a pure white emission. At the applied voltage of 12 V, the Commission International de l'Eclairage (CIE) coordinates were calculated to be (0.39, 0.36), which was very close to the ideal white point of (0.33, 0.33). A summary of the device characteristics is listed in Table 1. A maximum brightness of 19,386 cd m^{-2} at 14.0 V, an EQE of 10.4%, power efficiency (η_p) of 17.0 lm W^{-1} and current efficiency (η_c) of 21.6 cd A^{-1} at 4.0 V were achieved (Table 1). In the characterization of WOLEDs for lighting applications, the light emitted from all surfaces of the substrates can in principle be directed to the forward viewing direction by some lighting fixture. According to previous report, the total quantum and power efficiencies (η_t) are about 1.7 times of the forward viewing efficiencies [1,13,20]. As such, device C gave a peak total EQE and a total power efficiency of 17.7% and 28.9 lm W^{-1}, respectively. At the brightness of 1000 cd m^{-2}, the forward viewing EQE and current efficiency remained high at around 7.3% and 15.1 cd A^{-1}, respectively.

Color variation with increased bias/brightness was observed for device C, which is commonly seen in previous reported WOLEDs [24–27]. Blue emission grew relatively to the orange-red emission at high applied voltages, causing the CIE coordinates to shift from (0.44, 0.37) at 6 V to (0.39, 0.36) at 12 V. The transportation of holes and electrons in the EL device is related to the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of the materials used in EL devices. The LUMO energy level of $(DMBA)_2Ir(acac)$ (2.73 eV) is close to that of FIrpic (2.9 eV), while FIrpic has a much deeper HOMO energy of 5.8 eV than that of $(DMBA)_2Ir(acac)$ (5.07 eV). It can be predicted that $(DMBA)_2Ir(acac)$ may function as effective hole traps. The combinations of holes and electrons may concentrate in the orange-red emitting layer at low applied voltages in device C due to the relatively low mobility of electrons. As the applied voltages increased, the stronger electronic field enhanced the electron mobility, therefore, the blue emission was enhanced due to the shift of combination zone closer to the blue emission layer. According to previous report, the color variation issue may be mitigated by

creating another channel in the device [13]. With the help of such a strategy, the second type of WOLEDs were designed by inserting a thin layer of $(DMBA)_2Ir(acac)$ doped in CBP between the hole-transporting layer and the blue emission layer to balance the blue and orange-red emission at different voltages.

Device D was fabricated using the structure of ITO/NPB (30 nm)/TCTA (20 nm)/$(DMBA)_2Ir(acac)$:CBP (1%, 3 nm)/FIrpic:CzSi (11%, 20 nm)/$(DMBA)_2Ir(acac)$:CBP (1%, 10 nm)/TAZ (50 nm)/LiF (1 nm)/Al (100 nm). The EL spectra at different applied voltages are presented in Fig. 5. The color variation was greatly reduced, giving stable white emission. The CIE coordinates were calculated to be (0.30, 0.38) at an applied voltage of 6 V. At an applied voltage of 10 V, the CIE coordinates were calculated to be (0.27, 0.38), which were very close to that of 6 V, giving a slight CIE shift ($\Delta x = 0.03$, $\Delta y = 0.00$).

It can be predicted that the addition of a layer of $(DMBA)_2Ir(acac)$ in CBP between the hole-transporting layer and the blue emission layer could effectively trap the holes at low voltages. At the same time, the thickness was only 3 nm in device D, so the combination zone might concentrate next to the blue emission layer leading to balanced white emission at low applied voltages. In other words, the hole transportation and recombination with electrons was confined by the addition of a layer of $(DMBA)_2Ir(acac)$. While at high voltages, the combination zone might shift toward the other interface of the blue-emitting layer, but it would be restricted by the other layer of $(DMBA)_2Ir(acac)$ in CBP. Therefore, stable white emission could be obtained at different applied voltages. For device D, a maximum brightness of 15,647 cd m^{-2} at 11.5 V, a maximum EQE of 9.9%, power efficiency of 14.8 lm W^{-1} and current efficiency of 23.6 cd A^{-1} at 5.0 V were achieved

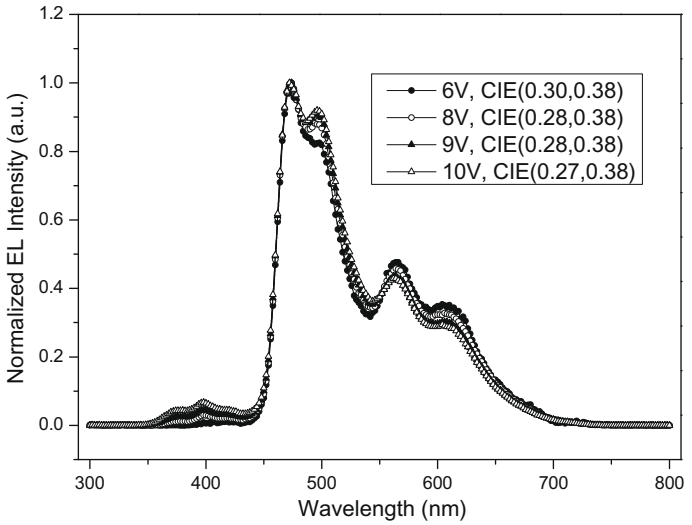

Fig. 5. EL spectra of device D at different applied voltages.

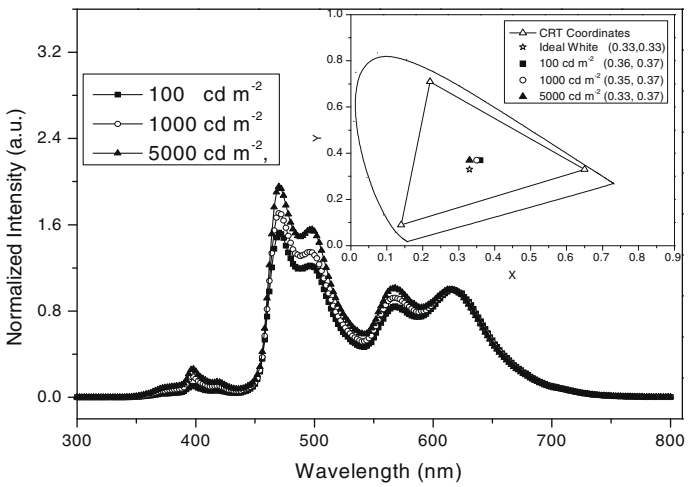

Fig. 6. EL spectra and CIE coordinates of device E at different brightnesses.

(Table 1). At a high brightness of 1000 cd m^{-2}, the forward viewing EQE and current efficiency remained quite high at 8.9% and 21.0 cd A^{-1}, respectively. The maximum brightness of device D was not as high as that of the previous three devices, but the efficiencies at high brightness (1000 cd m^{-2}) were the highest among these four devices.

Encouraged by the results of device D, we conducted further optimization of the doping concentrations of blue and orange-red emitters in order to get white emission with better color purity. In device E, the doping concentration of FIrpic was reduced to 7%, while the doping concentration of $(DMBA)_2Ir(acac)$ was increased to 5%. As shown in Fig. 6, more balanced emission with best CIE coordinates was achieved. No significant color variation at different brightnesses was observed for device E. At a practical brightness of 100 cd m^{-2}, the CIE coordinates were calculated to be (0.36, 0.37), close to (0.33, 0.37) at a high brightness of 5000 cd m^{-2}. A maximum brightness of 18,676 cd m^{-2} at 16.5 V, with a maximum EQE of 12.2%, power efficiency of 18.9 lm W^{-1} and current efficiency of 27.0 cd A^{-1} at 4.5 V was achieved (Fig. 7, Table 1), corresponding to total efficiencies of 19.7%, 45.9 cd A^{-1} and 32.1 lm W^{-1}, respectively. At a high brightness of 1000 cd m^{-2}, the forward viewing EQE and current efficiency remained quite high at 8.8% and 19.2 cd A^{-1}, respectively. Compared with the first type of devices (A, B, and C), devices D and E exhibited higher efficiencies (Fig. 8), especially at higher brightness (Table 1).

As shown in Figs. 5 and 6, the excitons were not firmly confined inside the desired emitting layers as evidenced by the blue emission centered at 400 nm in these devices. It is reported that such high-energy emission might origin from

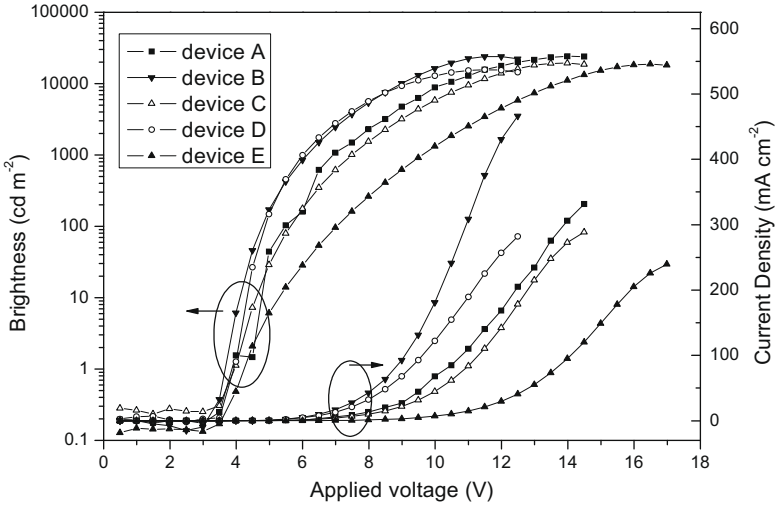

Fig. 7. Brightness–voltage–current density characteristics of the devices.

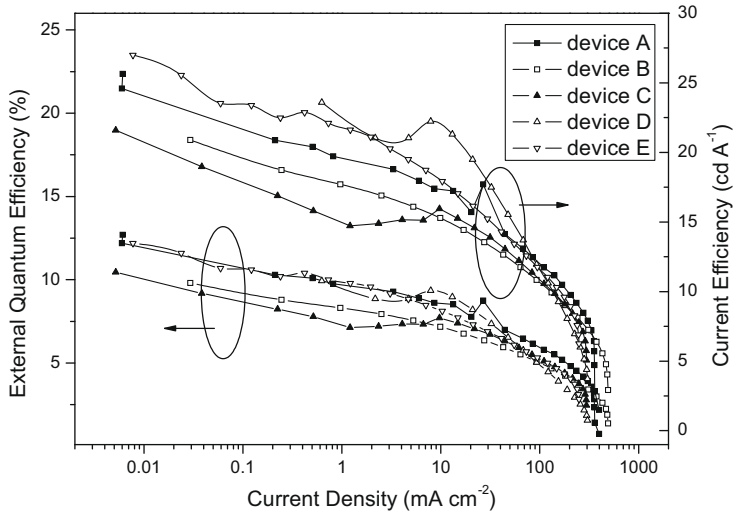

Fig. 8. External quantum efficiency–current density–current efficiency characteristics of the devices.

TCTA or/and TAZ [28]. In the red-emitting devices using $(DMBA)_2Ir(acac)$ as dopant emitter and TCTA as hole-transporting materials, no emission band at 400 nm was observed [23]. So it can be predicted that the high-energy emission comes from TAZ. In order to eliminate such an emission band, BCP was used instead of TAZ in a reference device E1 [NPB (30 nm)/TCTA (20 nm)/$(DMBA)_2Ir(acac)$: CBP (5%, 3 nm)/FIrpic:CzSi (7%, 20 nm)/$(DMBA)_2Ir(acac)$: CBP (5%, 10 nm)/BCP (10 nm)/LiF (1 nm)/Al (100 nm)]. For device E1, no emission at 400 nm was observed. A maximum brightness of 8968 cd m^{-2} and a maximum EQE of 4.3% were achieved, which were much lower than those of device E. These results indicate that the use of TAZ can improve the device efficiencies much more than BCP, although the emission at 400 nm with a relative intensity of below 0.1 was observed.

4. Conclusions

In conclusion, we report the first application of excimer emission of an iridium complex in highly efficient white OLEDs. By utilizing the iridium complex $(DMBA)_2Ir(acac)$ with broad excimer emission and an efficient blue Ir complex FIrpic, highly efficient phosphorescent WOLEDs can be obtained. The two-component phosphorescent WOLEDs exhibited pure white emission with CIE coordinates close to the ideal white emission (0.33, 0.33). By incorporating a blue-emitting layer sandwiched between two red-emitting layers and thereby forming a triple-emitting-layer device structure, WOLEDs exhibit stable white emission at different biases/brightnesses with maximum EL efficiencies of up to 12.2%, and 27.0 cd A^{-1} for the forward viewing direction, corresponding to total efficiencies of 19.7%, 45.9 cd A^{-1} and 32.1 lm W^{-1}. At a high brightness of 1000 cd m^{-2}, the EL efficiencies remained high at 8.8% and 19.2 cd A^{-1}.

nanoparticles at the organic–cathode interface and show that this results in a more efficient light emission mainly attributed to an enhanced internal quantum efficiency. We achieved an enhancement of a factor of 4.1 for a current density of 60 mA/cm^2.

2. Experimental

Nanoparticles of different materials and sizes were introduced between the emission layer and the cathode. Our devices were designed as shown in Fig. 1: a 1 mm-thick glass substrate covered with 130 nm of indium tin oxide (ITO), a layer of 20 nm of poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS), a layer of 50 nm of phenylene substituted poly(para-phenylenevinylene) (Ph-PPV; better known as Super Yellow from Merck OLED Materials GmbH) followed by nanoparticle clusters and a cathode consisting of 50 nm calcium and 250 nm aluminum. The substrates are 25 mm × 25 mm in size and feature four active areas of 5 mm × 5 mm each.

The PLED fabrication steps were as follows. The ITO-covered glass substrates were cleaned first with acetone and then with isopropanol in an ultrasonic bath for 15 min, respectively. The surface of the ITO was then exposed to an oxygen plasma as a last cleaning procedure and to make the surface hydrophilic. All following fabrication steps were conducted in a glove box under nitrogen atmosphere. The PEDOT:PSS was spin coated onto the ITO surface at a spinning speed of 2000 rpm. Afterwards, the substrates were baked in a vacuum oven at 140 °C for 30 min to eliminate the residues of water in the PEDOT:PSS layer. On top of this film the Super Yellow was applied by spinning the solution (3 mg/ml) at 1000 rpm. The modified PLEDs had an extra spin coating step before they were metalized with calcium and aluminum. Three different dispersions were prepared with SiO_2 and TiO_2 nanoparticles. The nanoparticles both were available as aqueous solutions (Ludox: 34 wt.% SiO_2 in H_2O, 20–30 nm in diameter, and a 10 wt.% suspension of TiO_2 in H_2O, 20–130 nm in diameter; purchased from Sigma–Aldrich). Due to the strong dependance of the physical parameters on the fabrication method, it is difficult to determine the exact values. Typically, the refractive indices of SiO_2- and TiO_2-thin films are in the range of 1.46–1.55 and 2.4–2.6, respectively. Since the surface of Super Yellow is hydrophobic, we mixed the aqueous solutions with diethylene glycol (DEG) to enhance adhesion of the dispersions and thus of the nanoparticles during the spin coating process. The first dispersion was a mixture of SiO_2 and DEG at a ratio of 1:1. The second and third dispersions contained SiO_2 and TiO_2 at ratios of 1:1 and 1:4, respectively, and were then mixed with DEG at a 1:1 ratio. All three dispersions were spin coated at 3000 rpm and 5000 rpm to investigate the effect of different particle concentrations on the performance of the devices. When applying the dispersion via a pipette onto the samples the wettability was not high enough to spread the dispersion over the whole device surface. The dispersion was concentrated around a circle of about 1.5 cm in diameter before starting the spin coating process. From SEM micrographs the nanoparticle concentration could be determined to 1–2 nanoparticle clusters per 4 μm^2. During operation these parts of the active areas on each substrate covered with the nanoparticles reveal an enhanced light output. An additional DEG-reference PLED with DEG but without nanoparticles was fabricated to investigate any effects originating from DEG. The PLEDs were then completed with a cathode of calcium and a cover layer of aluminum. To allow for electrical and optical characterization at normal atmospheric conditions, the samples are encapsulated using epoxy resin adhesive and a glass cover. Measurements of *J–V* curves and electroluminescence (EL) of the devices were made with a source-measure unit (Keithley SMU 238) and an integrating sphere (Gigahertz-Optik, UMBB-210) being connected via a multimode fiber to a spectrometer (Acton Research Corporation SpectraPro-300i) with an intensified charge-coupled device (Princeton Instruments PiMax:512). Angle resolved EL measurements were performed using the same source-measure unit, spectrometer and intensified charge-coupled device. In that case, the device was mounted on a goniometer and was rotated around the vertical axis, while the multimode fiber was kept fixed. For comparison angle resolved photoluminescence (PL) measurements were carried out in a similar way. A UV laser (Newport, Explorer Scientific All Solid State UV Laser, EXPL-349-120-CDRH) was coupled into a UV optical fiber, which was attached to the goniometer to maintain a constant spot size on the PLED while rotating the goniometer.

3. Results and discussion

Fig. 2 shows the current density–voltage (*J–V*) characteristics (a) and the luminous flux versus voltage (b) and current density (c). The DEG-reference shows the lowest

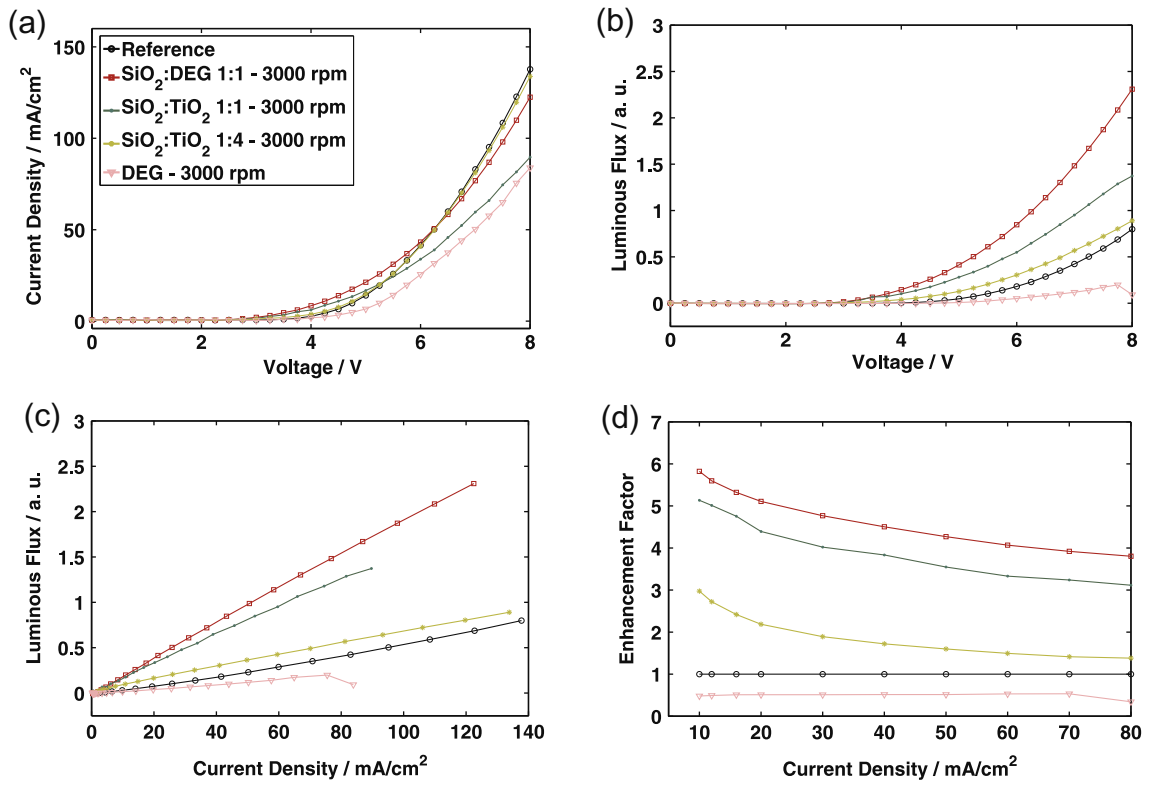

Fig. 2. Electronic and optical measurements of PLEDs with nanoparticle clusters between the emission layer and the cathode for different nanoparticle composites. The *J–V* curve (a) shows an increase in current injection for the modified devices at low current densities. The luminous flux versus the voltage (b) and the current density (c) reveal the increased performance for all devices with embedded nanoparticle clusters. The overall enhancement factor normalized to the reference PLED depending on the current density is shown in (d).

current values. Fig. 2(b) reveals that devices with SiO_2 and a low or zero TiO_2 content start to emit light with an onset voltage reduced by at least 1 V as compared to the other devices (see also Table 1). In addition, these PLEDs perform also much better at higher voltages. The same picture can be drawn from Fig. 2(c), where the light output is shown in dependence of the current density. Devices with only SiO_2 or with SiO_2 and a low TiO_2 content show the best performance with an efficiency enhancement of factor 4.1 and 3.3, respectively (at 60 mA/cm^2 current density). PLEDs with SiO_2 and a higher TiO_2 content achieved a better light output than devices with no nanoparticles at all. The DEG-reference performed very poorly. Different spin coating velocities resulted in no difference in the performance for most devices. Only for the PLEDs with the SiO_2:TiO_2 1:1 dispersion a small difference is obtained. For clarity reasons only the data for the samples spin coated at 3000 rpm is shown. The overall enhancement factor normalized to the reference device depending on the current density is shown in Fig. 2(d). We observe the highest relative enhancement for low current densities. For higher current densities space charge effects might lead to a lower enhancement factor. The angle resolved EL measurements in Fig. 3(a) were performed while supplying a constant current density of 20 mA/cm^2. The PLEDs with only SiO_2 nanoparticles had an over eight times higher light output than the reference device, independent of the spin coating velocity. With increasing TiO_2 content the performance decreased, whereas the DEG-reference again performed poorly. All devices feature a nearly Lambertian emission characteristic. Fig. 3(b) shows the angle resolved PL measurements. In contrast to all EL measurements the reference device reveals the best performance. The light output decreases with increasing TiO_2 content, while the DEG-reference offers the worst light output. Again, a Lambertian profile is observed. The variation in light output is much smaller compared to the EL measurements.

Table 1
Voltages of the different samples at a current density of 5 mA/cm^2.

Sample	Voltage at 5 mA/cm^2 (V)
Reference	4.32
SiO_2:DEG 1:1 – 3000 rpm	3.57
SiO_2:TiO_2 1:1 – 3000 rpm	3.73
SiO_2:TiO_2 1:4 – 3000 rpm	4.19
DEG – 3000 rpm	4.78

There are several aspects to be considered in order to explain the behavior of the nanoparticle-modified devices. The fact that the DEG-reference performs so poorly compared to all other devices proves that DEG as a source of any positive effect in the performance of all modified devices can be excluded. The enhancement cannot be

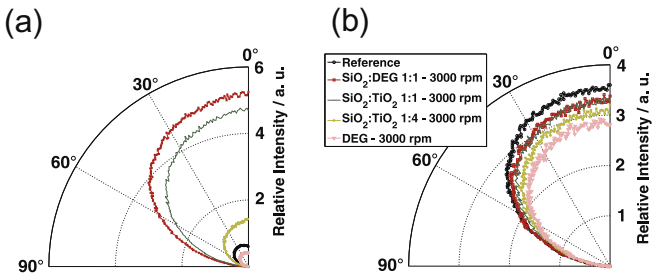

Fig. 3. Angle resolved EL and PL measurements of PLEDs with nanoparticle clusters between the emission layer and the cathode for different nanoparticle composites. EL measurements in (a) were performed at a constant current density of 20 mA/cm^2. PL measurement in (b) were conducted using a UV laser (349 nm) as excitation source.

attributed to an optical scattering effect either, since in this case the PL measurements should reveal a similar enhancement as the EL measurements while the *J–V*-characteristics should remain unchanged. This is not observed. In contrast to Bliznyuk et al. [14] the current density of the modified devices is decreased at higher voltages, which at first sight might indicate a worsened electron injection, due to a blocking effect of the nanoparticle clusters. However, this seems to be very unlikely when considering the lower turn-on voltage for the modified devices. The hole mobility in ordinary PPV is two orders of magnitude higher than the electron mobility [19], resulting in a recombination zone that is very close to the calcium cathode. In addition the barrier for hole injection is lower than the barrier for electron injection. Hence, the *J–V*-characteristics of the devices is mainly determined by the holes [20]. The nanoparticle clusters, arbitrarily distributed between the Super Yellow and the calcium layer, create a randomly nanopatterned cathode interface. This gives rise to locally enhanced fields again resulting in an higher electron injection rate, in turn leading to a better charge balance. The enhanced internal quantum efficiency entails finally an increased luminescence. This interpretation is supported by the lower turn-on voltage and the high enhancement factor at low current densities. The variation in the enhancement for different nanoparticle cluster mixtures is mainly attributed to the size of the nanoparticles itself and to the size of the clusters they form.

4. Conclusion

In conclusion, we have fabricated PLEDs with SiO_2 and TiO_2 nanoparticle clusters between the emission layer and the cathode. We have demonstrated a 300% increase in the EL efficiency of these devices. The nanoparticle clusters increase the electron injection at the nanoparticle cluster–cathode interface therefore enhancing the internal quantum efficiency. This effect is particularly beneficial for solution processed devices, since these nanoparticles are low cost and easy to handle and might be an alternative to additional polymer layers for controlling charge injection and balance.

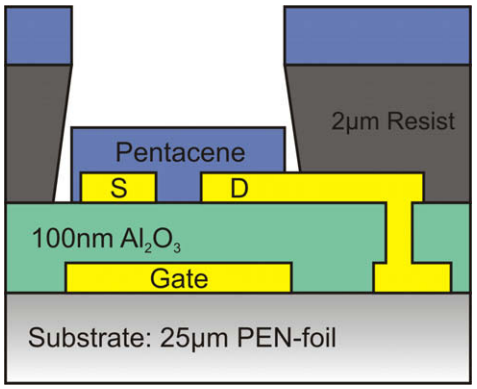

Fig. 1. Cross-section of the organic thin-film transistor process on foil having Al_2O_3, treated with a self-assembled monolayer of trichloro(phenethyl)silane, as gate dielectric.

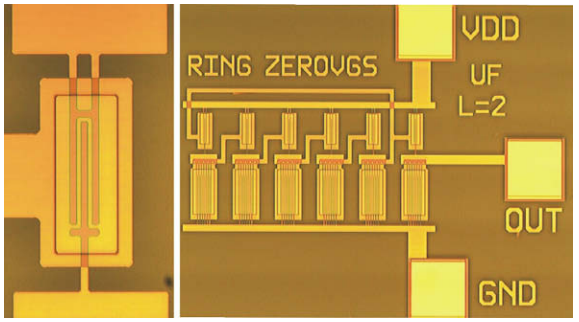

Fig. 2. Micrograph image of (left) a single transistor with channel length $L = 2$ μm and source/drain finger size of 5 μm and (right) a 5-stage ring oscillator with channel length $L = 2$ μm.

capacitance of 70 nF/cm^2, treated by a self-assembled monolayer of trichloro(phenethyl)silane. That, in turn, allows for some downscaling the transistor channel length, in our case to 2 μm, while maintaining a reasonable output resistance in saturation of Ro = 9.75 MΩ at 0 V gate-source voltage. A cross-section of this process flow is depicted in Fig. 1. Fig. 2 shows a micrograph image of a 5-stage ring oscillator realized in this technology.

This organic thin-film circuit technology allows to design with lower overlap capacitance and to downscale the transistor channel length, within the boundaries achievable by existing high-throughput tools (e.g. steppers used in backplane manufacturing). In this work, we varied the channel lengths (L) of the circuits between 20 μm and 2 μm. We also limited the gate-source and gate-drain overlap capacitances by decreasing the width of the finger-shaped source and drain contacts (that overlap the gate) from 5 μm to 2 μm. Fig. 2 shows a micrograph image of one transistor. All devices and circuits are processed on 25 μm thick polyethylene naphthalate (PEN) foil, which was, during processing, laminated on a 150 mm carrier substrate, and delaminated after completion of the process.

3. Results and discussion

Typical transfer and output curves of transistors fabricated in this technology, having $L = 5$ μm and 2 μm, are depicted in Fig. 3. The transistors are normally-on and the charge carrier (hole) mobility exceeds 0.5 cm^2/Vs for both 2 and 5 μm channel length devices. The output resistance in saturation at gate-source voltage of 0 V is 206.6 ± 8.1 MΩ for $L = 5$ μm and 9.75 ± 0.22 MΩ for $L = 2$ μm. Fig. 4 shows a typical transfer curve of a zerovgs-load

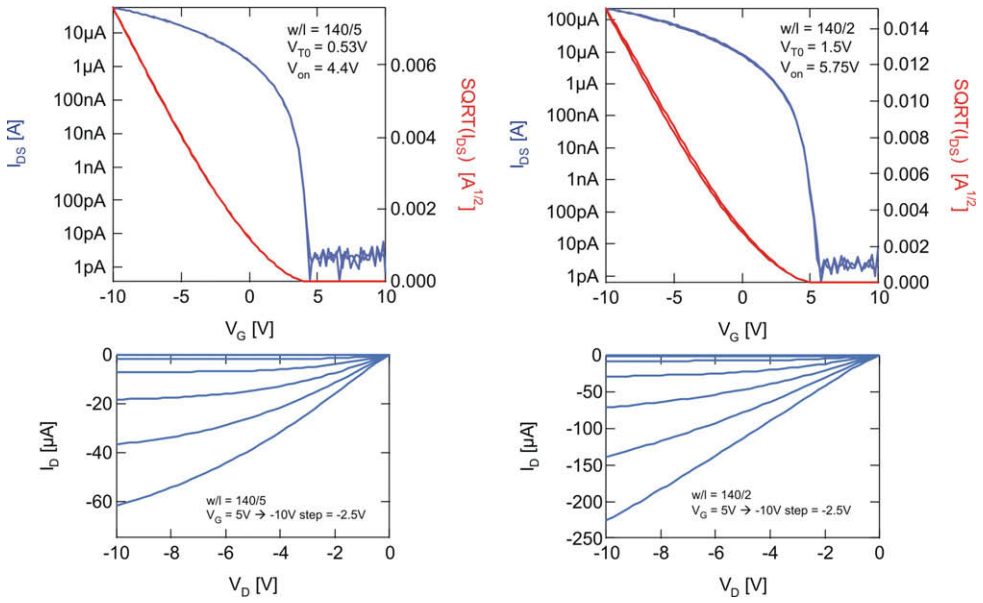

Fig. 3. Typical measured (top) transfer and (bottom) output curves of transistors with (left) $W/L = 140/5$ and (right) $W/L = 140/2$. The mobility exceeds 0.5 cm^2/Vs, off-current is below 10 pA.

inverter [3] with channel lengths of 5 μm and 2 μm, having reduced gate-drain and gate-source overlap while varying the supply voltage between 5 and 20 V. The ratio between drive and load transistor is 1:10. Both inverters show high gains and noise margins.

In Fig. 5, the extracted main parameters of an inverter (noise margin and gain) are plotted as a function of supply voltage for different inverters with varying channel length and overlap capacitance. The gain of these inverters varies from 3.8 to 34.5 for increasing channel length at a supply voltage of 20 V. This is mainly due to a lower output resistance with increasing channel lengths. The noise margin figure indicates that long channel lengths yield more robust inverters with larger noise margins at different supply voltages. As a consequence, the inverters with long channel lengths are more robust at supply voltages below 10 V, at the expense of lower speed. This effect is shown in Fig. 6, where we plot the inverter stage delay as a function of

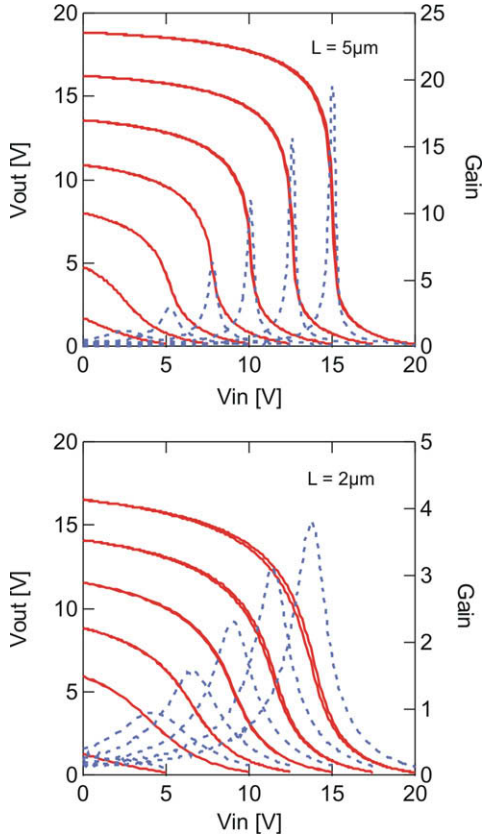

Fig. 4. Series of measured transfer curves of an inverter when varying the supply voltage between 5 and 20 V for transistors having a drive:load transistor ratio of 1:10 (zerovgs-load inverter configuration), source/drain finger sizes of 2 μm and a channel length of (top) 5 μm and (bottom) 2 μm. The solid lines represent the measured transfer curves, whereas the dashed lines represent the calculated gain.

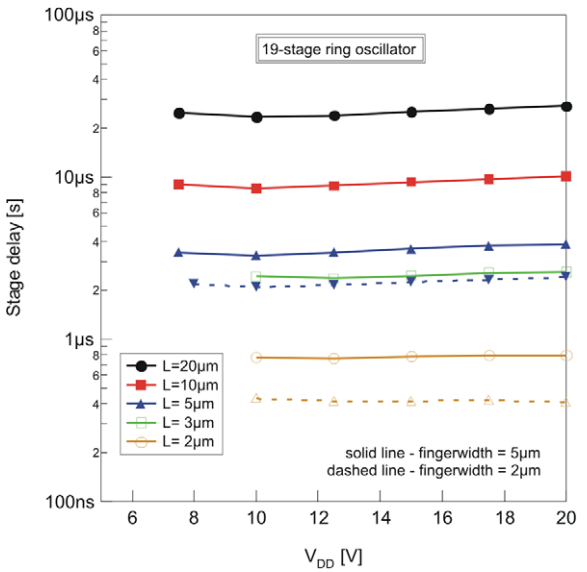

Fig. 6. Overview of stage delays versus supply voltage, measured on 19-stage ring oscillators with varying channel lengths, between 20 μm and 2 μm (color and symbol codes) and source/drain finger sizes of 5 μm (solid lines) and 2 μm (dashed lines).

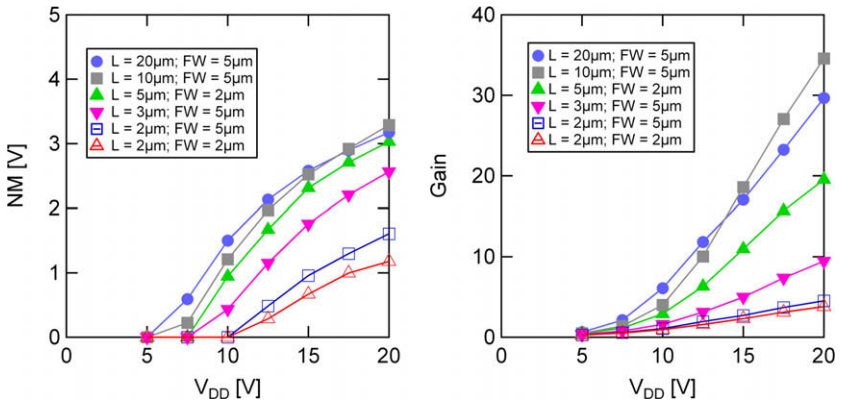

Fig. 5. Noise margin (left) and gain (right) as a function of increasing supply voltage, extracted out of the measured transfer curves of inverters having different channel lengths (20–2 μm) and different overlap capacitance (finger width FW = 5–2 μm).

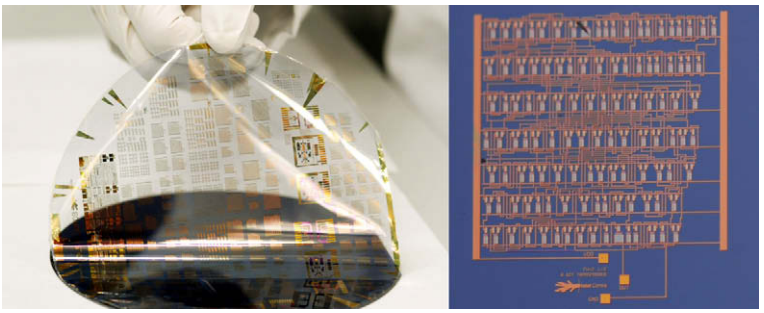

Fig. 7. Photograph of the 150 mm foil being delaminated from the carrier wafer (left) and a detailed die picture of the 8 bit RFID transponder chip on foil (right). The die size is 24.73 mm^2. The design comprises 294 transistors.

supply voltage, as extracted from 19-stage ring oscillators, for transistors with channel lengths varying from 20 μm to 2 μm and with gate-overlap of the transistor-fingers ranging from 5 μm to 2 μm. Stage delays below 1 μs, and as low as 400 ns, are shown at V_{DD} as low as 10 V. The effect of decreasing the overlap capacitance is also shown in Fig. 6 for the circuits having a channel length of 2 μm and 5 μm: shrinking the overlap from 5 μm to 2 μm improves the stage delay by a factor of 1.5–2.

We proceeded with the design and realization of 8 bit RFID transponder chips, having a channel length of 2 μm and either 5 μm or 2 μm finger widths. Fig. 7 shows the photographs of the 150 mm wafer and a zoom of the die. The corresponding schematic is depicted in the inset of Fig. 8. This figure also depicts the output signal of both types of transponders having a channel length of 2 μm. The obtained data rate is 8.69 kb/s for the channel length of 5 μm and finger width of 2 μm. A data rate of 21.68 kb/s has been obtained for a channel length of 2 μm and finger width of 5 μm. In agreement with the two-fold faster inverter stage delay for the 2 μm fingers, the data rate of this transponder is also twice as high as that of the design with 5 μm fingers. The obtained data rate of the 8 bit transponder with channel length and fingers of 2 μm is a record 50 kb/s, which is a 25-fold improvement over the latest published result [4].

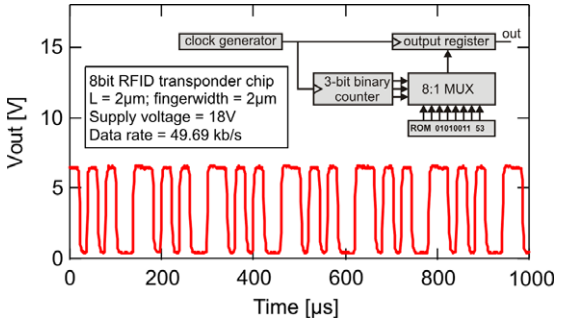

Fig. 8. Measured signal of the 8 bit RFID transponder chip having transistors with channel length of 2 μm. The width of the source-drain fingers is also 2 μm. The supply voltage for the 8 bit transponder chip was 18 V, yielding a data rate of 49.69 kb/s. The inset shows the schematic overview of the digital logic portion of the 8 bit transponder chip.

4. Conclusions and outlook

In summary, this work shows that organic RFID transponder chips with EPC-compatible data rates can be realized with organic semiconductors, mainly thanks to the combination of such semiconductors with high-k dielectrics without penalty in the charge carrier mobility. The high-k dielectrics allow high accumulation charge densities, hence drive current, and open options for shorter channel lengths, down to 2 μm, without loss of saturation in the transistor output characteristics. Specific figures for the speed that we achieved are gate delays in 19-stage ring oscillators down to 400 ns at V_{DD} = 10 V, and bit rates for 8 bit RFID transponders of 50 kb/s at V_{DD} = 18 V.

This work was performed in collaboration between IMEC and TNO in the frame of the HOLST Centre.

2. Experimental

2.1. Materials

C_4-DFQA and C_4-QA (Chart 1) were synthesized according to the reported procedure [6,10], and Alq_3 and NPB were purchased from Aldrich and purified by vacuum sublimation.

C_4-DFQA (75% yield): MS: *m/z* 460.2 $[M]^+$. Anal. Calcd for $C_{28}H_{26}F_2N_2O_2$ (460.51): C, 73.03; H, 5.69; N, 6.08. Found: C, 73.26; H, 5.67; N, 6.05. ^1H NMR ($CDCl_3$): δ 8.75 (s, 2H), 8.18–8.20 (d, 2H), 7.52 (s, 2H), 7.54 (s, 2H), 4.49–4.55 (t, 4H), 1.97–2.02 (m, 4H), 1.56–1.67 (m, 4H), 1.09–1.14 (t, 6H).

C_4-QA (91% yield): MS: *m/z* 424.0 $[M]^+$. Anal. Calcd for $C_{28}H_{28}N_2O_2$ (424.0): C, 79.22; H, 6.65; N, 6.60. Found: C, 79.01; H, 6.90; N, 6.33. ^1H NMR ($CDCl_3$): δ 8.75 (s, 2H), 8.55 (dd, J = 8.0 Hz, J = 1.0 Hz, 2H), 7.74 (td, J = 7.75 Hz, J = 1.50 Hz, 2H), 7.50 (d, J = 9.0 Hz, 2H), 7.25 (t, J = 7.5 Hz, 2H), 4.5 (t, J = 8.0 Hz, 4H), 2.0 (m, 4H), 1.67 (m, 4H), 1.12 (t, 7.5, 6H).

2.2. Instrumentation

^1H NMR spectra were recorded on Bruker AVANVE 500 MHz spectrometer with tetramethylsilane as the internal standard. Mass spectra were recorded on a GC/MS mass spectrometer. Photoluminescence spectra were recorded on a Perkin–Elmer LS 55 spectrophotometer. UV–vis spectra were recorded on a Shimadzu UV-2550 PC spectrometer. Electrochemical measurements were performed in anhydrous CH_2Cl_2 with a BAS 100 W bioanalytical electrochemical work station, using Pt working electrode, platinum wire as auxiliary electrode, and a porous glass wick Ag/Ag^+ as reference electrode, standardized against ferrocene/ferrocenium couple, scan rate 100 mV s^{-1}. Element analyses were performed on a Flash EA 1112 spectrometer. The EL spectrum, brightness, CIE coordinates and the current–luminance–voltage characteristics of the devices were measured with a rapid scan system using a Photo Research PR650 spectrophotometer and a computer-controlled, programmable, direct-current (DC) source (Keithley 2400).

2.3. OLEDs fabrication and characterizations

The devices were grown on a glass, which was precoated with indium tin oxide (ITO) having a sheet resistance equal to 20 $\Omega\,cm^{-2}$. The ITO glass was routinely cleaned by ultrasonic treatment in detergent solutions, followed by rinsed with acetone, boiled in isopropanol, rinsed in methanol, and then in de-ionized water. The glass was dried in vacuum oven between each cleaning step above. The devices were fabricated by successive vacuum deposition of organic materials onto ITO-coated glass substrate. Prior to the deposition, all the organic materials were purified by sublimation method. The deposition sources Alq_3 and the QA derivatives were set in separate quartz crucibles whose temperatures were independently controlled by coil heaters. A very thin layer of LiF could enhance electron injection from aluminum cathode. A shadow mask with 2 × 3 mm^2 openings was used to define the cathodes. EL spectra, brightness, and current–voltage characteristics were measured at room temperature under ambient atmosphere.

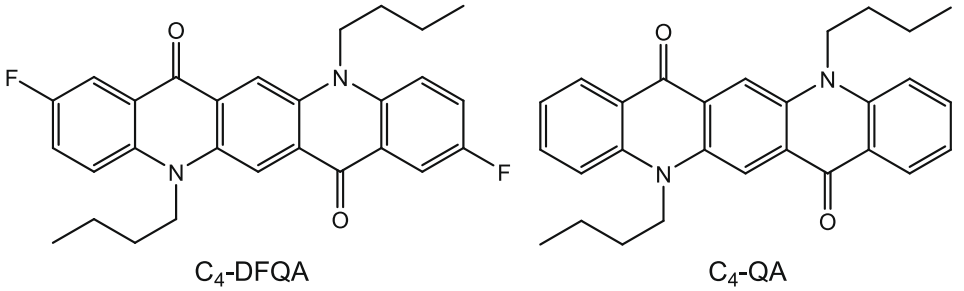
3. Results and discussion

3.1. Absorption and photoluminescent (PL) properties

The UV/vis and PL spectra of C_4-DFQA are shown in Figs. 1 and 2, and for comparison, the corresponding spectra of C_4-QA were also measured under the same conditions. Both of QA derivatives in dilute THF solution exhibited intense absorption bands at 490, 520 nm for C_4-DFQA and 500, 535 nm for C_4-QA. The comparison of the absorption spectra of QA derivatives and the PL spectrum of Alq_3 indicates a perfect overlap of them suggesting a possible energy transport from Alq_3 (as a host) to QA derivatives. Fig. 2 showed the comparison of the PL spectra of C_4-DFQA and C_4-QA in THF solution (1.0×10^{-6} M). The emission spectra profiles are approximately similar with a sharp emission peak at 535 and 520 nm, and a shoulder at around 575 and 555 nm, which demonstrate a spectral shift with molecular modification by the influence of the introduction of fluorine atom. In addition, the very high PL quantum yields in solution (97% for C_4-DFQA and 91% for C_4-QA) implied that both of them could be highly valuable fluorophores for OLEDs.

3.2. EL properties

To investigate the EL properties, two devices (I and II) were fabricated with the same configuration of [ITO/NPB (30 nm)/emitter (25 nm)/Alq_3 (35 nm)/LiF (0.5 nm)/Al] (NPB = 4,4-bis(*N*-(1-naphthyl)-*N*-phenylamino)biphenyl).



C_4-DFQA C_4-QA

Chart 1. Chemical structures of C_4-DFQA and C_4-QA.

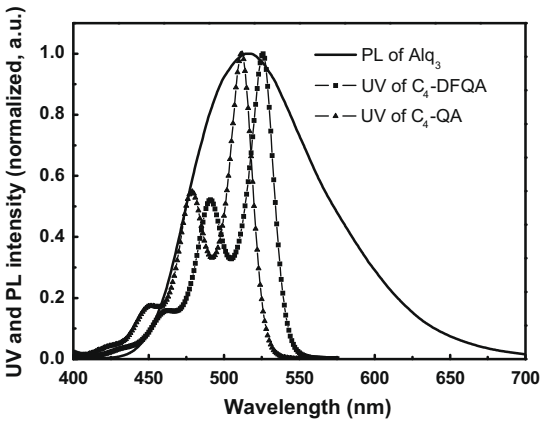


Fig. 1. UV absorption spectra of C_4-DFQA and C_4-QA and PL spectrum of Alq_3 in THF.

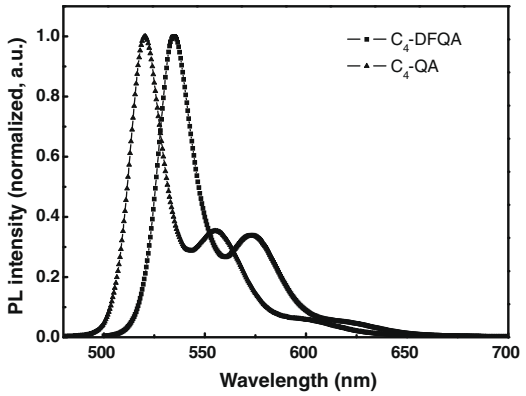

Fig. 2. PL emission spectra of C_4-DFQA and C_4-QA in THF.

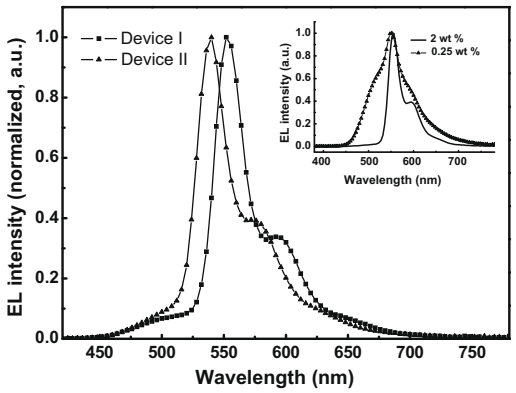

Fig. 3. EL spectra of devices I and II at the brightness of 1000 cd m^{-2}. Inset: EL spectra of the Alq_3: C_4-DFQA-based devices with the doping concentration of 2 and 0.25 wt.% at the brightness of 1000 cd m^{-2}.

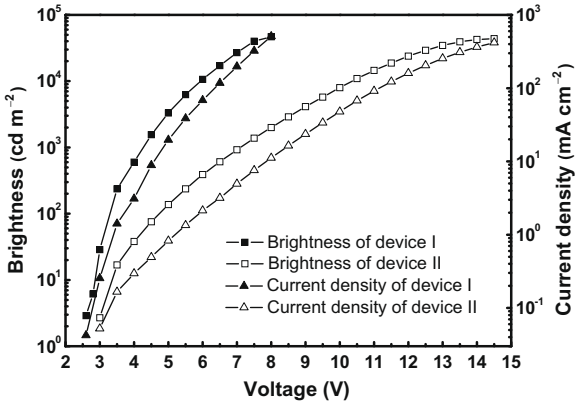

Fig. 4. Brightness vs. current density vs. voltage characteristics of devices I and II.

In the devices, the Alq_3: QA derivatives (Alq_3: C_4-DFQA for device I and Alq_3: C_4-QA for device II) doped films were employed as emitting layer with the doping concentrations of 0.5% (weight concentration). Here, NPB, and Alq_3 were served as hole-transporting and electron-transporting layers, respectively.

The EL spectra (Fig. 3) of devices I and II (at 1000 cd m^{-2}) displayed the expected emission features, and only slight emission in the wavelength of about 500 nm being observed indicating that the energy transfer from Alq_3 to C_4-DFQA and C_4-QA occurred almost completely. Both devices above exhibited bright yellowish-green emission, independent of the applied voltages in the range of 3–16 V, and the Commission Internationale de l'Eclairage (CIE) coordinates are (CIE: 0.42 and 0.56) and (CIE: 0.36 and 0.60) for device I (with C_4-DFQA) and device II (with C_4-QA), respectively.

Device I exhibited a rather low turn-on voltage (1 cd m^{-2} at 2.5 V), which is even lower than that of device II (3.0 V), and the EL intensity of device I showed rapid rise after the onset voltages (Fig. 4). At 8.0 V, devices I reached the peak radiance (46,680 cd m^{-2}), whereas devices II needed higher voltages (14.5 V) to obtain the same brightness levels (43,680 cd m^{-2}). Moreover, device I showed very low driving-voltages at the practical brightness of 100 and 1000 cd m^{-2} as low as 3.2 and 4.2 V, respectively, which are much lower than those of device II (4.7 and 7.1 V, respectively). In addition to its better brightness/driving-voltage performance, devices I also exhibited significantly higher power efficiency than that of device II in the whole brightness range (Fig. 5). For device I, a maximum power efficiency of 15.2 lm W^{-1} was obtained at the voltage of 4 V with a brightness of 598 cd m^{-2}, which is much higher than that of device II (10.7 lm W^{-1} was achieved at the voltage of 4.5 V with a brightness of 75 cd m^{-2}). It is also noteworthy that at the practical brightness of 100 and 1000 cd m^{-2}, the power efficiencies of device I remained as high as 13.6 and 13.5 lm W^{-1}, respectively, which are also higher than those of device II (10.6 and 8.2 lm W^{-1}, respectively). In view of almost same peak current efficiency (19.3 cd A^{-1} for device I at 4 V and 19.2 cd A^{-1} for device II at 6.5 V) and similar current efficiency-brightness curves of devices I and II each other, the pronounced power efficiency enhancement of the C_4-DFQA-based device could partly profit from the very low driving-voltages, which may suggest that an effective charge injection and well balanced charge carrier should

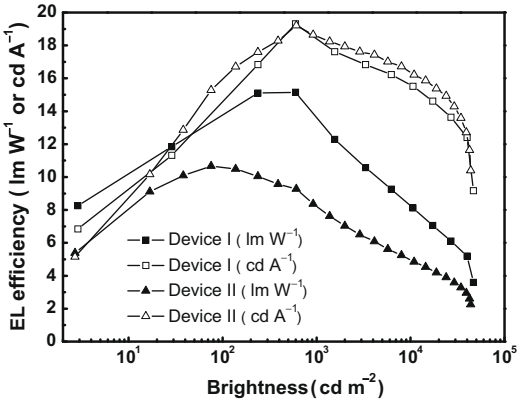

Fig. 5. Current efficiency vs. power efficiency vs. brightness characteristics of devices I and II.

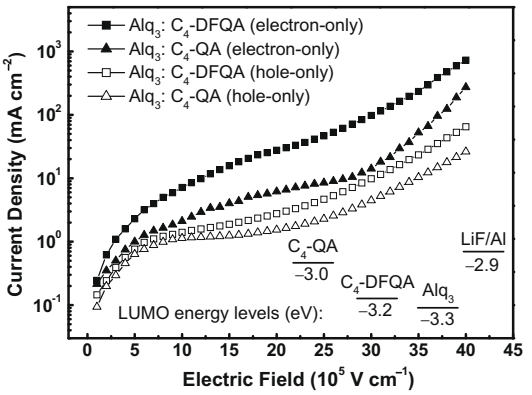

Fig. 6. Current density–electric field characteristics of Alq_3: C_4-DFQA and Alq_3: C_4-QA films in single-carrier devices. The inset shows the LUMO energy levels of the materials.

be achieved in the device I based on C_4-DFQA [8]. In addition, for comparison purpose, Alq_3: C_4-DFQA-based devices with the doping concentration of 2 and 0.25 wt.% were fabricated. The inset of Fig. 3 shows C_4-DFQA concentration dependence of spectra. At the concentration of 0.25 wt.%, one shoulder in the wavelength region of 500 nm due to Alq_3 was observed. More than this, the EL efficiency of C_4-DFQA also displayed obviously concentration-dependent property, which is similar to other QA derivatives [6]. A significant decrease in power efficiency was observed at higher (2 wt.%) and lower (0.25 wt.%) doping concentration due to significant self-quenching of C_4-DFQA and insufficient energy transfer from Alq_3 to C_4-DFQA, respectively.

To further understand both charge injection and carrier transport in the emitting layer, single-carrier devices [12–14] were fabricated using the following configurations: [Al/active molecular layer (60 nm)/Al] (electron-only device) and [ITO/active molecular layer (60 nm)/Au] (hole-only device). A low work function metal (Al) is used as the electrodes in electron-only devices, whereas a metal (Au) or a metal oxide (ITO) with a high work function is used as the electrodes in hole-only devices. For comparison purpose, Alq_3: C_4-DFQA (0.5%) and Alq_3: C_4-QA (0.5%) doped films were used as the active molecular layers for both electron-only and hole-only devices (Fig. 6). Clearly, in the hole-only devices, both current densities are comparable. However, in the electron-only devices, the current density of Alq_3: C_4-DFQA is much higher than that of Alq_3: C_4-QA. The results can be explained by the lower LUMO energy level of C_4-DFQA (−3.2 eV) than that of C_4-QA (−3.0 eV) (Fig. 6 inset) induced by introducing the strong electron-withdrawing fluorine atoms into the QA derivative, which in direct conjunction with the main emissive π-backbone [11]. More importantly, according to the Hammett substituent parameters, meta-substituting to the carbonyl groups in the phenyl ring would enhance the electron-withdrawing ability of fluorine atoms, which is a favorable factor to lower the LUMO level in the C_4-DFQA. Therefore, the electron injection barrier from Alq_3 to C_4-DFQA (0.1 eV) is obviously lower than that from Alq_3 to C_4-QA (0.3 eV), thus in the C_4-DFQA-based device, electron injection from Alq_3 to C_4-DFQA was accelerated. In addition, Fig. 7 shows the cyclic voltammograms for cathodic reductions of C_4-DFQA and C_4-QA, and both compounds exhibited one reversible redox couple. However, the half-wave reduction potential ($E_{1/2}^{red}$) of C_4-DFQA was obviously higher than that of C_4-QA, and it suggests that C_4-DFQA has stronger electron-accepting property, which could lead to its higher electron-transporting ability than C_4-QA [15].

On the other hand, since the charge mobility of NPB is generally 1–2 orders higher than in the other materials used [16–18], this improvement of electron injection and transporting in the Alq_3: C_4-DFQA layer may result in that there are more electrons counterpoise the holes injecting into the emitting layer from NPB in device I than in device II [19,20]. Consequently, it led to a stable charge carrier balance, and efficient recombination within the emitting layer of the C_4-DFQA-based device, which was consistent with the pronounced EL performance enhancement of the C_4-DFQA-based device with lower onset and driving-voltages than that of the C_4-QA based device presented in Fig. 4.

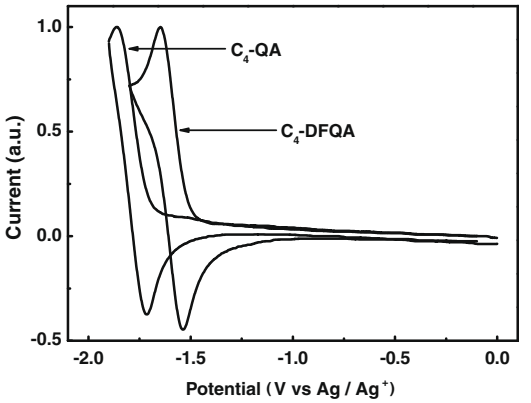

Fig. 7. Cyclic voltammograms of C_4-DFQA and C_4-QA.

4. Conclusions

In summary, we have fabricated the remarkably high-efficient fluorescent OLEDs by using a novel fluorinated QA derivative (C_4-DFQA) doped in Alq_3 as the emitting layer, which showed very low driving-voltage (the turn-on voltage is 2.5 V, the practical brightness of 100 and 1000 cd m^{-2} are realized at 3.2 and 4.2 V, respectively) and high power efficiency with the peak value of 15.2 lm W^{-1} (4 V, 598 cd m^{-2}, and 19.3 cd A^{-1}). These results represent very high EL performance based on the simple HTL–EML–ETL architecture from fluorescent organic emitters. The stability studies of device based on C_4-DFQA and further optimization of molecular structure to enhance the EL performance of QA derivatives are in progress.

iridium complex as the dopant [10]. Recently, we reported blue-green-emitting polymer OLEDs using cationic iridium complexes as dopants [11]. The devices showed a peak current efficiency of 20.2 cd A^{-1} [11]. Nevertheless, a systematic evaluation of the use of cationic iridium complexes in OLEDs has not been reported, and white OLEDs using cationic iridium complexes as emitters have not yet been explored.

In this paper, a systematic investigation on blue-green to red and white OLEDs is carried out using cationic iridium complexes as dopants and poly(*N*-vinylcarbazole) (PVK) as the host. These cationic iridium complexes have been previously developed and used in highly efficient LECs [7,12]. Due to the low sublimability of cationic iridium complexes, light-emitting layers of OLEDs have been deposited from cost-effective solution processes.

2. Experimental

2.1. Materials

The cationic iridium complexes (Scheme 1): Irdf-pyim, Ir-pzpy, Irdf-pybi, Ir-pyim, Ir-pybi, and Ir-qlbi, which are blue-green-emitting (489 nm), blue-green-emitting (475 nm), green-emitting (528 nm), yellow-green-emitting (554 nm), orange-emitting (588 nm), and red-emitting (627 nm) in CH_3CN solutions, were prepared in the laboratory and crystallized from CH_2Cl_2/hexane before use [7,12]. Poly(3,4-ethylenedioxythiophene:poly(styrene sulfonate) (PEDOT:PSS) was purchased from H.C. Starck, Inc. PVK was purchased from TCI, Inc. And 1,3-bis[5-(4-*tert*-butylphenyl)-1,3,4-oxadiazol-2-yl]benzene (OXD-7), 2-(4-biphenylyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD), 1,3,5-tris(1-phenyl-1H-benzo[d]imidazol-2-yl)benzene (TPBI), and bis(2-methyl-dibenzo[f,h]quinoxalinato-*N*,C2′)-iridium(III)(acetylacetonate) [Ir(MDQ)$_2$(acac)] were purchased from Nichem Fine Technology Co., Ltd. All materials were used as received without further purification.

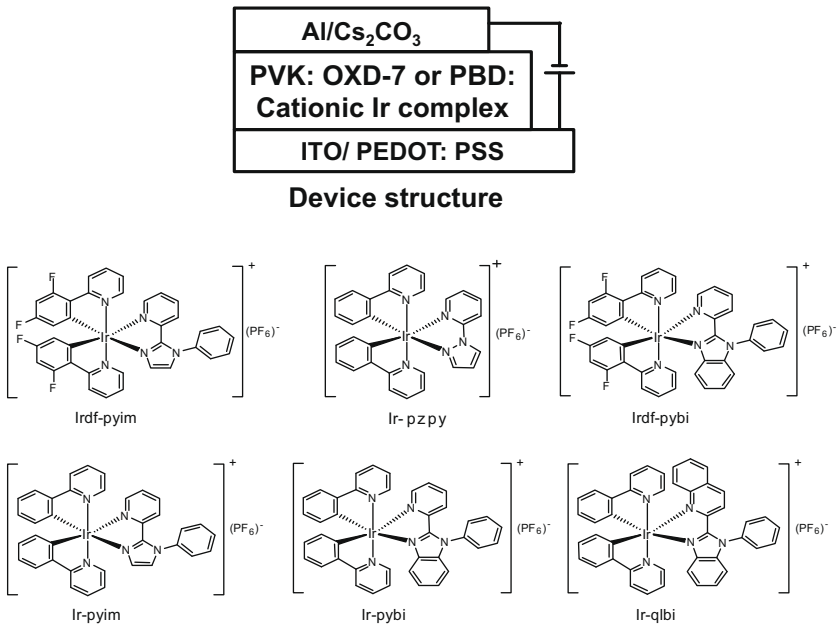
2.2. Fabrication and characterizations of OLEDs

Indium–tin-oxide (ITO) substrates with a sheet resistance of 15 Ω/□ were sufficiently cleaned by ultrasonication in detergent and deionized water and then treated with UV-zone before use. The PEDOT:PSS layer was spin-coated in air and baked at 200 °C for 10 min. The light-emitting layer was spin-coated onto the PEDOT:PSS-coated substrates from 1,2-dichloroethane solutions of PVK:OXD-7 or PBD:cationic iridium complexes in a nitrogen-filled glove box. The coated substrates were annealed at 80 °C for 30 min. The substrate was transferred to an evaporation chamber integrated with the glove box. TPBI was evaporated at a rate of 1–2 Å/s under a pressure of 4×10^{-4} Pa. The Cs_2CO_3/Al bilayer cathode was evaporated at rates of 0.2 and 10 Å/s for Cs_2CO_3 and Al, respectively, under a pressure of 1×10^{-3} Pa. The current–voltage–brightness characteristics of the devices were characterized with a Keithley 4200 semiconductor characterization system. The EL spectra were collected with a Photo Research PR705 spectrophotometer. All measurements were performed in an ambient atmosphere without encapsulations.

3. Results and discussion

3.1. Single-layer devices

Cationic iridium complexes, which emit light ranging from blue-green to red, are shown in Scheme 1. The detailed photophysical and electrochemical characteristics of the complexes have been presented in previous studies



Scheme 1. OLED device structure and the cationic iridium complexes.

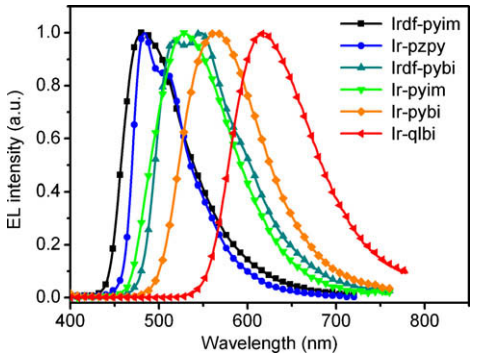


Fig. 1. EL spectra of the single-layer devices doped with different cationic iridium complexes.

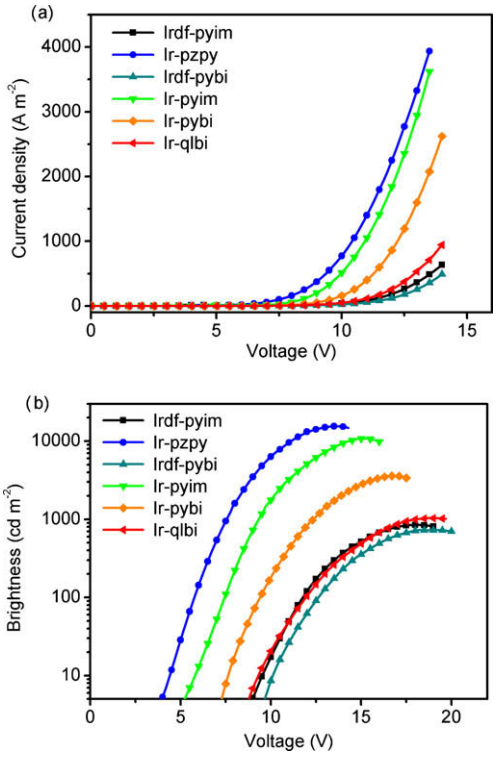

Fig. 2. Current density–voltage (a) and brightness–voltage (b) characteristics of the single-layer devices doped with different cationic iridium complexes.

[7,12]. PVK was used as a host material for the cationic iridium complexes because of its high triplet energy, excellent film-forming properties, and high hole-transport ability [13]. To facilitate electron transport in the light-emitting layers, PBD or OXD-7 was mixed into the PVK host [14–20]. The structure of the single-layer devices (Scheme 1) is ITO/PEDOT:PSS (40 nm)/PVK:30% PBD or OXD-7:10% cationic iridium complexes (80 nm)/Cs_2CO_3 (4 nm)/Al (120 nm). OXD-7 was used for the blue-green-emitting Irdf-pyim and Ir-pzpy because of its high triplet energy, while PBD was used for the other four complexes that have low-energy emissions [17]. Fig. 1 depicts the EL spectra of the devices. The devices showed blue-green to red electroluminescence, with the emission spectra covering nearly the entire visible region. The EL spectra resemble the PL spectra of the cationic iridium complexes in solutions or thin films, indicating that electroluminescence originated from the doped cationic iridium complexes [7,12].

Fig. 2 shows the current density–voltage and brightness–voltage curves of the single-layer devices. The detailed electrical characteristics are summarized in Table 1. In Fig. 2a, the current density–voltage curves shift toward the high voltage region when the doped complexes change from Ir-pyim, Ir-pybi to Ir-qlbi. The complexes Ir-pyim, Ir-pybi, and Ir-qlbi have the same cyclometalated ligands, 2-phenylpyridine (Ppy), on which the highest occupied molecular orbitals (HOMOs) of the complexes are localized. However, the complexes Ir-pyim, Ir-pybi, and Ir-qlbi have different ancillary ligands, on which the lowest unoccupied molecular orbitals (LUMOs) are localized [7,12]. As a result, the HOMO levels of Ir-pyim, Ir-pybi, and Ir-qlbi, ranging from −5.6 to −5.7 eV, are almost the same, while the LUMO levels of Ir-pyim, Ir-pybi, and Ir-qlbi are −2.8, −3.0, and −3.3 eV, respectively, which show a descending order as the conjugation length of the ancillary ligands increases [12]. The energy level diagrams of the single-layer devices are illustrated in Scheme 2. The LUMO levels of the complexes are below those of PVK (−2.2 eV) or PBD (−2.4 eV), leading to deep electron traps in the complexes [8,11,20]. The HOMO levels of the complexes (−5.6 to −5.7 eV) are relatively above that of PVK (−5.8 eV), leading to shallow hole traps in the complexes. Since the LUMO levels descend from Ir-pyim, Ir-pybi to Ir-qlbi, the strength of electron-trapping by the complexes increases, which leads to the shift of the current density–voltage curves toward the high voltage region (Fig. 2a) and the gradual increase in turn-on voltages (Table 1) when the doped complexes change from Ir-pyim, Ir-pybi to Ir-qlbi.

Due to severe electron-trapping by the complexes, recombination zones in OLEDs are expected to be located close to the cathodes, leading to exciton quenching and, thereby, inferior device performance. Nevertheless, the peak current efficiency of the single-layer, blue-green device doped with Ir-pzpy reaches 10.5 cd A^{-1}, which approaches the efficiency of counterpart devices using the conventional blue-green phosphorescent emitter, FIrpic, as the dopant [16]. Better performance of the device doped with Ir-pzpy is related to less severe electron-trapping by Ir-pzpy because the LUMO level of Ir-pzpy (−2.6 eV) is the highest among the six complexes.

At the same biasing voltages, the current density of the device doped with Irdf-pyim is lower than that of the device doped with Ir-pyim (Fig. 2a). Although Irdf-pyim and Ir-pyim have the same ancillary ligands, 2-(1-phenyl-1H-imidazol-2-yl)pyridine (Scheme 1), the LUMO level of Irdf-pyim (−2.9 eV) is lower than that of Ir-pyim (−2.8 eV) because the electron-withdrawing fluorine atoms in Irdf-pyim make the complex more electron deficient. Electrons are expectedly trapped more strongly by Irdf-pyim than by Ir-pyim. In contrast, the HOMO level of Irdf-pyim (−5.9 eV) is much lower than that of Ir-pyim (−5.6 eV) because of the fluorine atoms attached to the

Table 1
Electrical characteristics of the single-layer devices.[a]

Complex	V_{on} (V)[b]	J (A m^{-2})[c]	$\eta_{c,max}$ (cd A^{-1})[d]	B_{max} (cd m^{-2})	EL λ (nm)	CIE (x, y)
Irdf-pyim	6.9	40.4	0.6 (0.3%)	890	484	(0.21, 0.38)
Ir-pzpy	3.6	774.2	10.5 (4.1%)	15,500	482, 508	(0.19, 0.46)
Irdf-pybi	6.5	23.6	0.5 (0.2%)	730	516, 548	(0.37, 0.57)
Ir-pyim	4.0	515.7	4.1 (1.3%)	11,500	528	(0.35, 0.56)
Ir-pybi	5.1	160.1	1.2 (0.4%)	3600	566	(0.47, 0.52)
Ir-qlbi	6.1	49.0	0.4 (0.3%)	1100	618	(0.62, 0.38)

[a] The device structure is ITO/PEDOT:PSS (40 nm)/PVK:30% OXD-7 or PBD:10% complexes (80 nm)/Cs_2CO_3 (4 nm)/Al (120 nm); OXD-7 was used for Irdf-pyim and Ir-pzpy while PBD was used for the other four complexes.

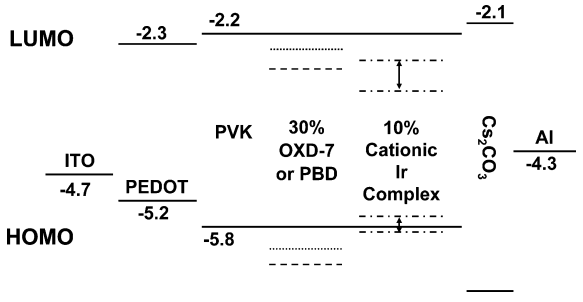

Scheme 2. Energy level (unit: eV) diagrams of the single-layer devices. The HOMO and LUMO levels of the complexes were calculated from their redox potentials [7,12] and the double arrows represent the range of energy levels of the six complexes. The HOMO and LUMO levels of OXD-7 (dashed lines) are −6.5 and −2.8 eV, respectively; those of PBD (dotted lines) are −6.3 and −2.4 eV, respectively [21].

cyclometalated ligands in Irdf-pyim [12]. During the device operation, carriers are expected to hop between the complex molecules, forming another carrier-transportation channel, because the doping concentration (10 wt.%) of the complexes in the light-emitting layers is relatively high [8,11]. For the device doped with Ir-pyim, holes can be directly injected into the HOMOs of Ir-pyim. The holes can then move along the HOMOs and eventually combine with electrons to form excitons. In the device doped with Irdf-pyim that has a stabilized HOMO, holes cannot be easily injected into the HOMOs of Irdf-pyim nor move along them because the HOMO of Irdf-pyim is below that of PVK. Largely due to strengthened electron-trapping and suppressed hole injection and transportation via the complex molecules, the device doped with Irdf-pyim shows lower current density and inferior performance (higher turn-on voltage and lower efficiency) compared with the device doped with Ir-pyim (Fig. 2a and Table 1). Similar to the cases concerning Irdf-pyim and Ir-pyim, the device doped with Irdf-pybi shows lower current density and inferior device performance compared with the device doped with Ir-pybi (Fig. 2a and Table 1).

3.2. Devices with electron-transporting/exciton-blocking layers

To improve device performances, electron-transporting/exciton-blocking TPBI layers were inserted between light-emitting layers and cathodes. The device structure is ITO/PEDOT:PSS (40 nm)/PVK:30% OXD-7 or PBD:10% cationic iridium complexes (80 nm)/TPBI (30 nm)/Cs_2CO_3 (4 nm)/Al (120 nm). The detailed electrical characteristics are summarized in Table 2. Fig. 3 shows the current density–voltage and brightness–voltage curves of the devices. Similar to the case of single-layer devices, current density–voltage curves shift toward the high voltage region when the doped complexes change from Ir-pyim, Ir-pybi to Ir-qlbi (Fig. 3a), due to gradually strengthened electron-trapping by the complexes. The device doped with Irdf-pyim shows lower current density and inferior device performance compared with the device doped with Ir-pyim. Similarly, the device doped with Irdf-pybi shows lower current density and inferior device performance compared with the device doped with Ir-pybi (Fig. 3a and Table 2).

After insertion of the TPBI layers, the device performance largely improves because of suppressed exciton quenching at the cathode interfaces [8,11]. The peak current efficiencies of the blue-green, green, yellow, and red-emitting devices reach 24.3, 25.3, 20.5, and 4.2 cd A^{-1}, which correspond to external quantum efficiencies (EQE) of 9.7%, 8.1%, 7.1%, and 3.2%, respectively. The high efficiencies indicate the great feasibility of using cationic iridium complexes as phosphorescent dopants in OLEDs. Higher device performances are believed to be achievable if the doping concentrations of the complexes and the thickness of the TPBI layers are optimized. The relatively low efficiency of the red-emitting device is largely due to the low luminescent efficiency of Ir-qlbi compared with those of other complexes [7,12].

In phosphorescent OLEDs, efficiency always exhibits a severe roll-off at high brightness mainly because of triplet–triplet annihilation [22–24]. Fig. 4 shows the dependence of the current efficiency–brightness characteristics of devices with TPBI layers. In Fig. 4, devices with cationic iridium complexes used in this study show efficiency roll-offs at high brightness, similar to phosphorescent OLEDs with neutral iridium complexes [22–24]. However, for the blue-green device doped with Ir-pzpy, the maximum efficiency (24.3 cd A^{-1}) is reached at 1020 cd m^{-2}, and at 10,100 cd m^{-2}, the efficiency remains 19.6 cd A^{-1}. For the green device doped with Ir-pyim, the maximum efficiency (25.3 cd A^{-1}) is reached at 600 cd m^{-2}, and at 6200 cd m^{-2}, the efficiency remains 20.0 cd A^{-1}. For the yellow device doped with Ir-pybi, the maximum efficiency (20.5 cd A^{-1})

Table 2
Electrical characteristics of the devices with TPBI blocking layers.[a]

Complex	V_{on} (V)[b]	J (A m^{-2})[c]	$\eta_{c,max}$ (cd A^{-1})[d]	B_{max} (cd m^{-2})	EL λ (nm)	CIE (x, y)
Irdf-pyim	5.2	19.1	6.8 (2.9%)	6100	486	(0.20, 0.40)
Ir-pzpy	4.2	258.8	24.3 (9.7%)	30,300	484, 508	(0.19, 0.47)
Irdf-pybi	6.5	2.4	11.6 (3.7%)	5800	514, 540	(0.35, 0.57)
Ir-pyim	4.4	107.6	25.3 (8.1%)	38,500	526	(0.34, 0.56)
Ir-pybi	5.5	7.8	20.5 (7.1%)	22,100	564	(0.46, 0.52)
Ir-qlbi	6.5	4.4	4.2 (3.2%)	6300	620	(0.61, 0.38)

[a] The device structure is ITO/PEDOT:PSS (40 nm)/PVK:30% OXD-7 or PBD:10% complexes (80 nm)/TPBI (30 nm)/Cs_2CO_3 (4 nm)/Al (120 nm); OXD-7 was used for Irdf-pyim and Ir-pzpy while PBD was used for the other four complexes.

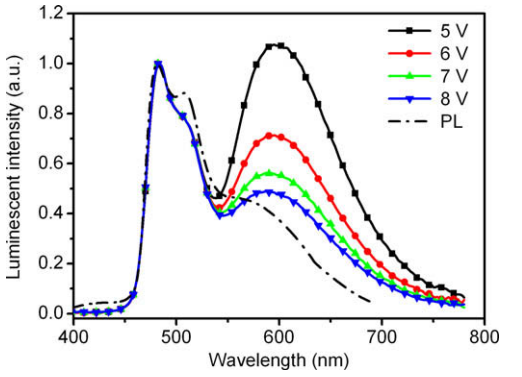

Fig. 5. EL spectra of the white device W1 biased at different voltages. The dashed line represents the PL spectrum of the light-emitting layer.

is reached at 240 cd m^{-2}, and at 2400 cd m^{-2}, the efficiency remains 16.6 cd A^{-1}. The largely retained efficiencies at high brightness suggest that the bipolar transporting host of PVK:PBD or OXD-7 helps to broaden the recombination zone and reduce the concentration of triplet excitons. Moreover, the ionic nature of the chromophores will be beneficial in reducing aggregations of dopants in the polar host and thus producing less severe triplet–triplet annihilations at high current densities.

3.3. White devices

White OLEDs were fabricated by co-doping blue-green and red-emitting complexes. In this study, Ir-pzpy was selected as the blue-green emitter because of its higher device performance compared with Irdf-pyim. The structure of the white OLED is ITO/PEDOT:PSS (40 nm)/PVK:30% OXD-7:10% Ir-pzpy:0.25% Ir-qlbi (80 nm)/TPBI (30 nm)/Cs_2CO_3 (4 nm)/Al (120 nm) (Device W1). Fig. 5 shows the EL spectra of the white-emitting device that were biased at different voltages. The relative intensity of the red to the blue component in the EL spectra is larger than that in the PL spectrum, indicating that charge-trapping by the low-gap Ir-qlbi plays an important role in the operation of the white-emitting device [19]. At low voltages,

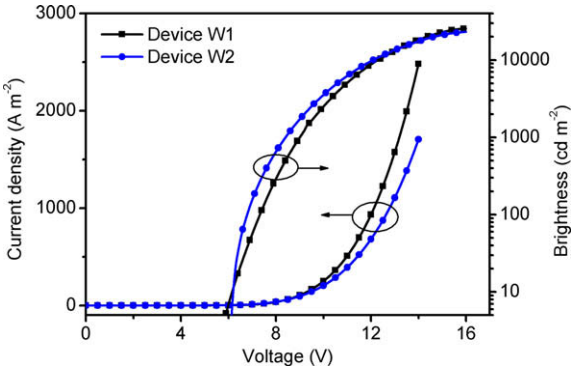

Fig. 6. Current density–brightness–voltage characteristics of the white devices.

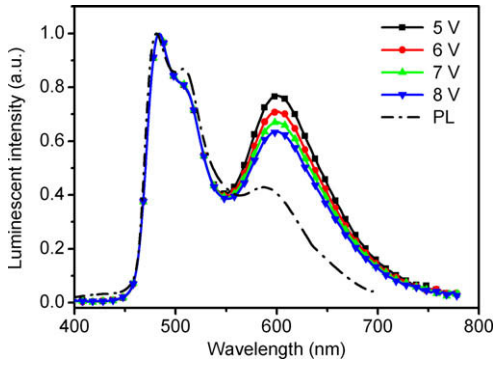

Fig. 7. EL spectra of the white device W2 biased at different voltages. The dashed line represents the PL spectrum of the light-emitting layer.

electrons are more likely injected into Ir-qlbi with a low LUMO level, trapped, and combined with holes. As a result, the relative intensity of the red to the blue emission at low voltages is higher than that at high voltages in white electroluminescence. This leads to a change of CIE coordinates from (0.43, 0.43) to (0.35, 0.44) when the biasing voltage increases from 5.0 to 8.0 V.

The current density brightness–voltage curves of the white-emitting devices are shown in Fig. 6, and the detailed electrical characteristics are summarized in Table 3. For the white-emitting device W1, the peak current efficiency reaches 16.7 cd A^{-1}, corresponding to an EQE of 7.8%, and the peak power efficiency reaches 6.8 lm W^{-1}.

Among the six cationic iridium complexes, the luminescent efficiency of Ir-qlbi (3% in CH_3CN solution) is the lowest [7,12]. To further improve the performance of the white-emitting device, the red-emitting Ir-qlbi was replaced with an efficient red-emitting neutral iridium complex $Ir(MDQ)_2(acac)$, which has a high luminescent efficiency of 48% in CH_2Cl_2 solution [25]. The device structure is ITO/PEDOT:PSS (40 nm)/PVK:30% OXD-7:10% Ir-pzpy:0.25% $Ir(MDQ)_2(acac)$ (80 nm)/TPBI (30 nm)/Cs_2CO_3 (4 nm)/Al (120 nm) (Device W2). Fig. 7 shows the EL spectra of the white-emitting device that were biased at different voltages. By comparing the EL and PL spectra in Fig. 7, the important role of charge-trapping in the operation of the white-emitting device can be observed [19]. The HOMO (−5.4 eV) and LUMO (−2.8 eV) levels of $Ir(MDQ)_2(acac)$ are within the energy gap of the PVK host, indicating that both holes and electrons will be deeply trapped by $Ir(MDQ)_2(acac)$. The CIE coordinates of the white-emitting device W2 change from (0.39, 0.43) to (0.37, 0.44) when the biasing voltages increase from 5.0 to 8.0 V.

Fig. 6 also shows the current density brightness–voltage curve of the white device W2. The detailed electrical characteristics are summarized in Table 3. Due to the high luminescent efficiency of $Ir(MDQ)_2(acac)$, the peak current efficiency of the white device W2 reaches 20.7 cd A^{-1}, corresponding to an EQE of 9.8%, and the peak power efficiency reaches 8.5 lm W^{-1}.

Similar to other phosphorescent OLEDs with unstable PVK hosts, all devices reported in this study show short lifetimes [19]. In OLEDs, the doping concentration (10 wt.%) of the cationic iridium complexes is low, and the PF_6^- anions are hindered from migrating in the dense polymer film of PVK. This is quite different from LECs, where a large quantity (>80 wt.%) of cationic iridium complexes are used in the active layer and abundant PF_6^- anions migrate easily under electrical biases [2–5]. The detailed degradation mechanism for LECs, although unclear, is believed to be associated with migration of ions and accumulation of ions at electrode interfaces [2,4]. Therefore, we believe that degradation processes in LECs are not likely to occur in OLEDs with a small quantity of cationic iridium complexes functioning only as the phosphorescent dopants. Using solution-processable and stable host materials, OLEDs doped with cationic iridium complexes can achieve longer operating lifetimes.

4. Conclusion

Using cationic iridium complexes as dopants, solution-processed OLEDs were fabricated with peak current efficiencies of 24.3, 25.3, 20.5, and 4.2 cd A^{-1} for the blue-green, green, yellow, and red electroluminescence,

Table 3
Electrical characteristics of the white devices.[a]

	Red dopant	V_{on} (V)[b]	$\eta_{c,max}$ (cd A^{-1})[c]	B_{max} (cd m^{-2})	EL λ (nm)	CIE (x, y)	
						5 V	8 V
W1	Ir-qlbi	4.2	16.7 (7.8%)	25,700	484, 594	(0.43, 0.43)	(0.35, 0.44)
W2	$Ir(MDQ)_2$ (acac)	4.0	20.7 (9.6%)	23,300	484, 600	(0.39, 0.43)	(0.37, 0.44)

[a] The device structure is ITO/PEDOT:PSS (40 nm)/PVK:30% OXD-7:10% Ir-pzpy:0.25% red dopant (80 nm)/TPBI (30 nm)/Cs_2CO_3 (4 nm)/Al (120 nm).
[b] The voltage to reach 1 cd m^{-2}.
[c] Data in parenthesis denote the external quantum efficiencies.

respectively. During device operation, electrons were trapped by the complexes, especially by complexes with low-energy emissions; that is, low LUMO levels. Complexes with cyclometalated 2-phenylpyridine ligands were found to show better device performances compared with complexes with cyclometalated 2-(2,4-difluorophenyl)pyridine ligands. White OLEDs were fabricated with a peak current efficiency of 16.7 cd A^{-1}, which was improved to 20.7 cd A^{-1} when the red-emitting ionic complex was replaced with an efficient red-emitting neutral iridium complex. Thus, cationic iridium complexes, in addition to their use in LECs, are promising phosphorescent dopants in solution-processed OLEDs. This material and technique can be used to produce highly efficient blue-green to red and white electroluminescence.

lasing threshold and cavity-size-dependence of the threshold. We believe that observed size-dependence of the lasing threshold indicates the participation of cavity QED.

2. High temperature deposition of BP1T crystals

If organic crystal films without grain boundaries and/or cracks can be formed on Si/SiO_2 substrates over large area, it is ideal situation for fabricating the laser devices. However, it takes rather long time to develop the organic crystals epitaxy technology. Therefore, it is realistic approach to clip microcavities from a part of the organic crystal film without grain boundaries and/or cracks. Actually, TPCO crystals with the size over several hundred micrometer were grown on a substrate in liquid phase [14]. We also tried to grow the one of TPCO co-oligomers, 2,5′-bis(4-biphenylyl)-thiophene (BP1T) onto Si/SiO_2 substrates by using the high temperature deposition method.

Fig. 1 shows micrographs of BP1T co-oligomer films formed on the bare thermally-oxidized silicon films on the Si substrates. The deposition rate of BP1T was fixed around 0.1 nm/s. The substrate temperatures are indicated in the figure. The pressure of the deposition chamber was on the order of 10^{-6} Pa during the deposition. With the increase of the temperature, the re-evaporation effect becomes strongly, and island like single crystals grow and overlap each other. Therefore, we can grow BP1T single crystals over several tens of micrometers by choosing the proper temperature and deposition rate. Fig. 2 shows micrographs of BP1T crystal films fabricated by annealing (left part) and by the high temperature deposition method (right part). In the case of annealing, films are annealed on a hot plate and are crystallized at 220 °C [12,13].

We have been used annealed films to form microcavities. These films had many grain boundaries and cracks, as shown in the left part of Fig. 2. On the other hand, the crystal film fabricated by the high temperature deposition method has cracks, but no grain boundary, as shown in the right part of Fig. 2. Therefore, we can form the microcavity from a BP1T single crystal when we choose a part of the crystal film without grain boundaries and cracks.

In order to obtain crystal films without grain boundaries by using the high temperature deposition method, we need a substrate with a flat and defect-less surface. Actually, single crystal like growth is obtained only on the bare thermally-oxidized silicon films or polymer films, as shown in the bottom part of Fig. 3. We used amorphous fluorocarbon polymer, cytop (CTX804.5A, ASAHI GLASS Co., Ltd., Japan; in the report, we indicate the cytop polymer as CTX), which was spin-coated on a Si/SiO_2 substrate with the thickness of 300 nm. When BP1T films were fabricated on the sputtered SiO_2 film and slightly processed thermally-oxidized silicon films, we could not obtained single crystal like films, as shown in the upper part of Fig. 3. The high temperature deposition method, described here, is only the usual thermal vapor deposition method, but we can fabricate single crystals over several tens of micrometers on the proper substrates. Usual organic films like pentacene fabricated by the thermal vapor deposition frequently have grain boundaries [15]. The reason is not clear now, but it is a very good property of BP1T and suitable for fabricating microcavities.

3. Fabrication processes of microdisk cavities in BP1T crystals

If we fabricate microcavities in the high temperature deposition films, we need to use the clip-out fabrication process [12]. In this process, Cr/Si/Cr layers were formed before resist baking. Metallic layers have much smaller thermal expansion factor than that of organic layers, so that the thin metallic layers frequently wrinkled or at worst were removed from underground organic layers. Therefore, we improved the fabrication method by using a lift-off process of metallic layers. Fig. 4 shows the improved fabrication process. Here, we first fabricated organic layers, by using the high temperature deposition method with thickness of 200–400 nm. We have used electron-beam (EB) lithography

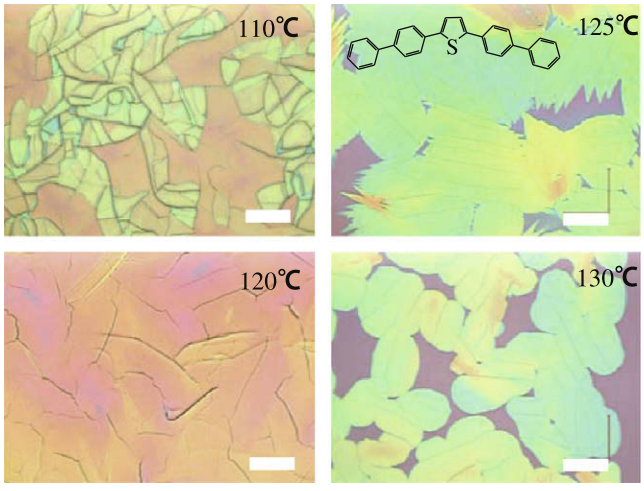

Fig. 1. Microscope images of high temperature deposition films. Substrate temperature is shown in each figure. White lines shown in the bottom right part indicate the scale of 20 μm. The molecular structure of BP1T is also indicated in the inset.

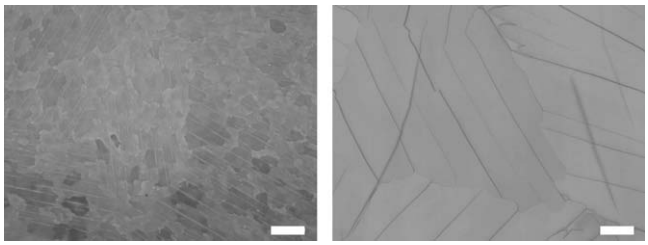

Fig. 2. The left part shows the microscope image of the annealed film and the right part shows that of the high temperature deposition film. White lines shown in the bottom right part indicate the scale of 10 μm.

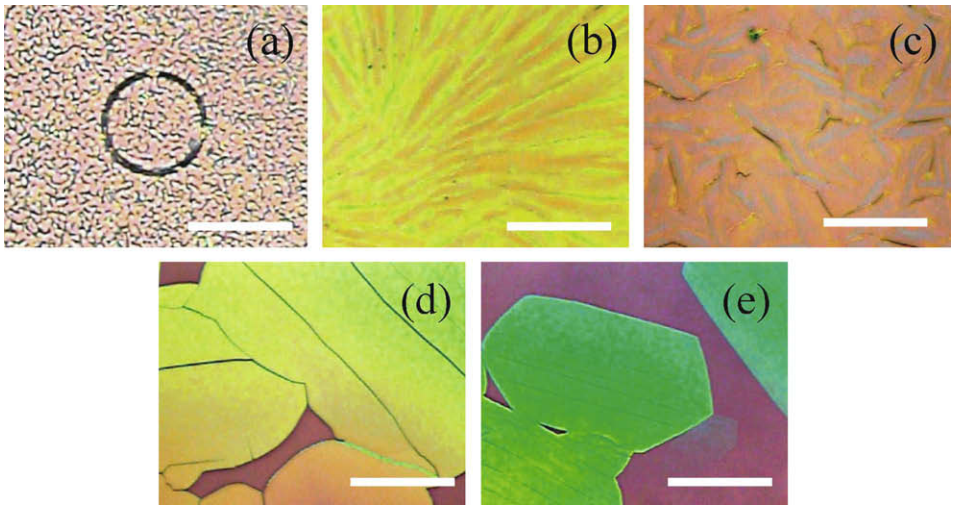

Fig. 3. Microscope images of high temperature deposition films observed on the various substrates; (a) on the sputtered SiO_2 film, (b) on the slightly ashing (by using a O_2-plasma asher, 300 W-10 Pa-300 s) surface of the thermally-oxidized silicon film, (c) on the slightly ashing (in 5% diluted HF solution-30 s) surface of the thermally-oxidized silicon film, (d) on the bare surface of the thermally-oxidized silicon film, and (e) on the bare CTX804.5A film, respectively. White lines shown in the bottom right part indicate the scale of 20 μm.

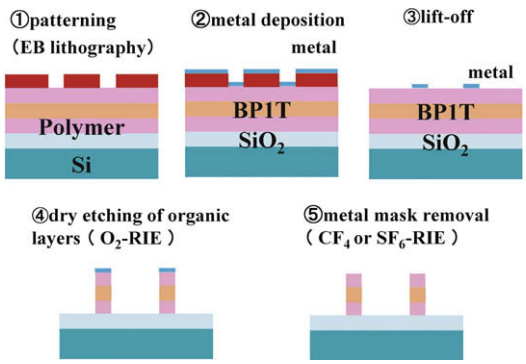

Fig. 4. Schematic drawing of fabrication processes of microcavities; ① EB lithography, ② metal deposition on the patterned substrate, ③ lift-off of the metal on the resist, ④ O_2-RIE of BP1T crystal films and buffered CTX and overcoated CTX layers, and ⑤ CF_4-RIE of the Cr-mask layer or SF_6-RIE of the Ti-mask layer, respectively.

to define microdisk patterns on the resist (OEBR-1000, Tokyo Ohka Kogyo Co., Ltd., Japan). To avoid charging of samples during EB irradiation, Espacer (Showa Denko K.K., Japan) films were formed on the resist films.

After EB lithography, a metallic mask layer was deposited by using thermal vapor deposition. Resist films and metal films onto the resist layer were removed by using the ultrasonic cleaning in acetone solution. After the lift-off process, O_2 reactive ion etching (RIE) was adopted to fabricate organic microdisk cavities. All of the RIE processes were carried out under the condition of 50 sccm-70 W-2.5 Pa by using SAMCO, RIE-200L. Two kinds of metal masks, Cr and Ti were used and removed by using CF_4 and SF_6 gases, respectively. Thickness of both Cr and Ti masks was 25 nm. RIE durations of the O_2, CF_4 and SF_6 were approximately 270, 1200 and 150 s, respectively. The O_2-RIE duration was determined to be nearly complete etching of BP1T crystals without metal masks, and CF_4 and SF_6-RIE durations were determined to remove metal masks completely.

Fig. 5 shows scanning electron micrographs (SEM) images of microdisks fabricated by using Ti masks. Slight surface roughness is observed on the side wall of cavities, but we can obtain quite complete disk shaped cavities by using the Ti-mask process. Microdisks fabricated by using Ti masks showed bright luminescence, almost same with that of unprocessed films.

On the other hand, when Cr masks were used instead of Ti masks, the top part of 1 μm disk was removed.

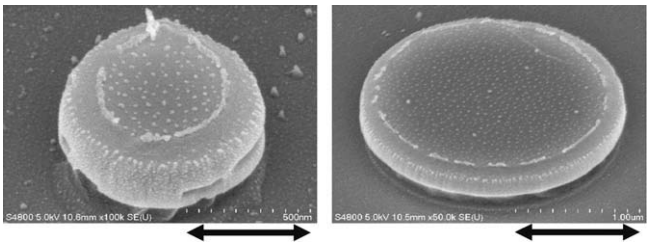

Fig. 5. SEM images of microdisks fabricated by using Ti masks. Black arrows indicate the scale of 1 μm in both images.

Luminescence yield of the microdisks were very low and disks were not lasing under the optical excitation. Therefore, microdisks fabricated by using Cr masks were probably damaged during the long CF_4-RIE duration. The short RIE duration to removing the metal masks are important to obtain good disk cavities.

Slight residuals of films and dotted structures are observed on the disks, as shown in Fig 5. They are probably remained CTX films, which have been almost removed during the SF_6-RIE process. The yield of 2 μm disks was higher than that of others. Disks with small diameter tend to remove from substrate. Disks with large diameter tend to contain cracks of organic crystals and slight residual of metal masks around the edge of disks.

4. Optical excitation experiments

We carried out experiments of pulse excitation at 397 nm with a 10–15 ps width onto BP1T microcavities. The spot size was estimated to be $33 \times 23\ \mu m^2$. We assumed uniform lateral distribution of the excitation beam. Therefore, the excitation density was estimated to be the incident light energy divided by the spot size. The transition dipole moment of each BP1T molecule is aligned to a molecule length axis and is nearly vertical to the substrate. Therefore, *p*-polarized light with the incident angle of 60° was used to excite BP1T microdisks for efficient optical pumping. Luminescence was collected by an 50× objective lens and detected by a liquid N_2 cooled charge-coupled device attached to a monochromator. All experiments were carried out at room temperature.

Fig. 6 shows the laser emission spectra of BP1T microcavities. Amplification and lasing were observed both at inhomogeneously broadened 0–1 and 0–2 vibration lines [2–4]. The lasing threshold of the 0–1 line is usually lower than that of the 0–2 line, and almost all of our samples show lasing peaks around the 0–1 vibration line, as shown at 2.63–2.70 eV. Note that almost all of the modes have doublet structures. It is well known that the high-*Q* WGM show the doublet mode structure reflecting clockwise (CW) and counterclockwise (CCW) propagation [16]. If we adopt this model as an origin of the doublet, we can obtain the estimated values of the cavity lifetime from the width of the mode, and the scattering lifetime from the mode separation of the doublet. The inverse of the lifetime was estimated to be 1.0–1.2 meV for the cavity lifetime and 1.8–4.0 meV for the scattering lifetime. The *Q* value can be estimated from the cavity lifetime as 2400. This *Q*

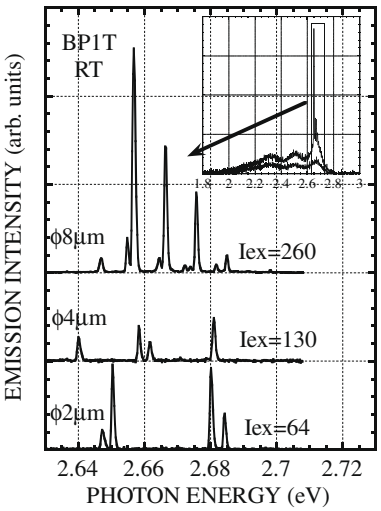

Fig. 6. Lasing spectra of BP1T microdisks. Whole luminescence spectra observed in the 8 μm disk are shown in the inset, before (I_{ex} = 51 μJ/cm^2) and after (I_{ex} = 200 μJ/cm^2) the lasing. The disk diameters and excitation densities in the unit of μJ/cm^2 are shown.

value seems to be too small to observe such large splitting of CW and CCW doublet modes [17].

Another origin of the doublet modes is higher WGM, which has multi peaks of electromagnetic field in the radial direction. Actually, in the finite differential time domain (FDTD) analysis, higher WGMs were sometimes appeared around the main WGM. However, in the 4 μm disk case, only the central mode is doublet. Some additional structures and/or deficits may be the origin of the doublet only in the central mode. Anyway, the actual origin of the doublet mode is not identified now, we ignore the doublet structures. In the 4 μm disk case, we chose the high energy-side peak of the central mode so as to be equal interval of the mode separation. In the 2 μm disk case, the mode interval between two high energy-side peaks are nearly equals to that between two low energy-side peaks, so that the mode interval is determined to be unique.

When we assume the situation mentioned above, the lasing spectra show the regular intervals, indicating the WGMs in microdisks. Mode intervals of all the microcavities are plotted in Fig. 7, as a function of the inverse of the resonator length *L*, which is assumed to be the circumference length. The energy intervals are inversely proportional to the circumference length, so that the lasing mode intervals are ascribed to WGM.

Fig. 8 shows the sum of the lasing mode intensity as a function of the excitation density. The lasing threshold values of microdisks 8, 4, and 2 μm in diameter were estimated to be 99, 57, and 32 μJ/cm^2, respectively, as indicated by arrows in Fig. 8. The threshold for the microdisk 2 μm in diameter is the smallest. The lasing threshold is almost proportional to $1/L$, as is shown in Fig. 7. In the framework of cavity QED, the lasing threshold should decrease with the increase of the cavity-mode separation, leading to the lower lasing threshold of the smaller cavity [18,19]. Such behavior was observed in III–V inorganic microdisk cavities and well described cavity-QED calculations [19]. The observed results of the cavity-size-dependence, including the lowest lasing threshold of the smallest microdisk is well coincide with the previous report.

Note that we did not provide any measurement showing QED effects directly. However, in the early work on the microdroplets showed cavity-QED effects (stimulated emission enhancement) even in the multimode cavity, microspheres with 14 μm in diameter [20]. The stimulated emission enhancement is also reported in the 40 μm cylindrical microcavities made of polymer [21]. Situations of light confinement in the microsphere, microcylinder and microdisk are different, but we believe that our observations in the 2–8 μm microdisks are ascribed to cavity-QED effects (also stimulated emission enhancement). The condition where the stimulated emission enhancement can be observed holds, because the cavity resonance width is much broader than the radiative width of BP1T [22].

The lasing threshold of the thermally annealed crystalline films was reported to be 1400 μJ/cm^2 in the bulk film part [12]. The thickness of the annealed film was fixed at 400 nm and that of films in this report is 200–400 nm. The thicker films tended to be lasing easily in this thickness range, so that the lasing threshold can be compared directly. Lasing threshold of the microdisk 2 μm in diameter is reduced to 2.3% of it. In a previous report, the threshold was 200 μJ/cm^2 in a microring cavity 8 μm in diameter [13]. Comparing the value with lasing threshold for a microdisk 8 μm in diameter in this report, 99 μJ/cm^2, we can reduce the lasing threshold by half. This reduction is achieved by the high temperature vapor deposition method. Additional reduction is considered to be due to the cavity-QED effect which accompanies reduction of number of lasing modes 8 μm to that with 2 μm [22].

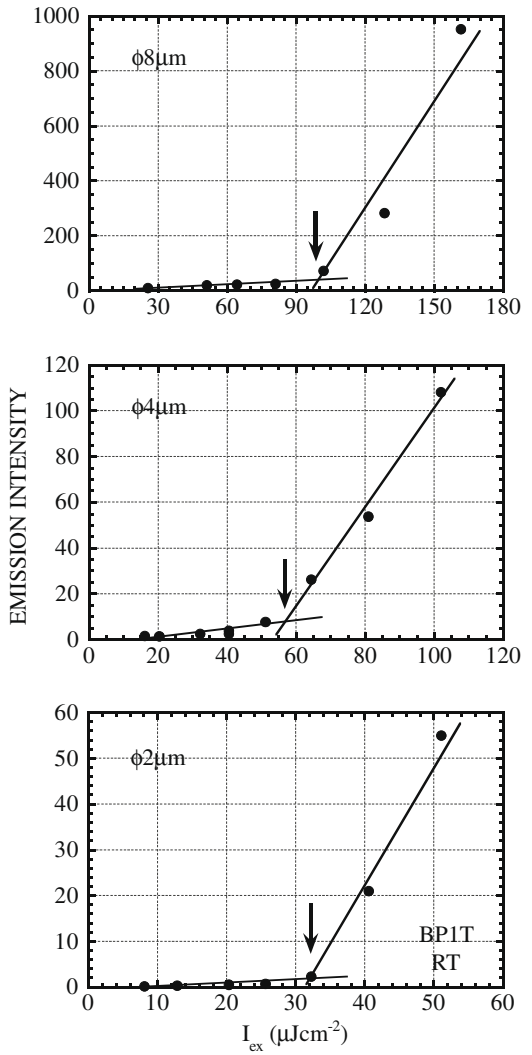

Fig. 8. Excitation density dependence of spectral peaks of the 0–1 line on the microdisks. Results on all microcavities show clear lasing threshold.

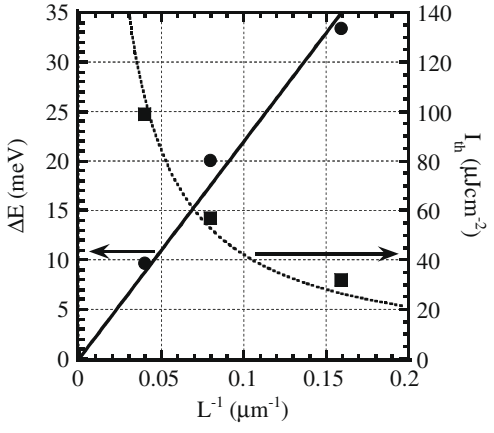

Fig. 7. Mode intervals ΔE observed on microdisks (the left axis) and lasing threshold (the right axis), respectively. Solid and dotted lines indicate liner dependence of L^{-1} and L, respectively.

We could not observe the lasing threshold of the microdisk 1 μm in diameter, because the luminescence intensity of the 1 μm disk below the lasing threshold was lower than the detection limit. When the excitation density was 30 μJ/cm^2, the luminescence spectrum of the 1 μm disk was sharp peak indicating lasing. Therefore, threshold of the 1 μm disk is found to be as low as that of the 2 μm disk. Further study will be needed to observe the threshold of smaller microdisks.

In case of inorganic semiconductor microdisks, smaller microdisks less than 1 μm in diameter were fabricated and single mode lasing was observed [23,24]. In case of organic semiconductors, micropillar cavities with the

diameter of 3 μm were fabricated [25]. From time resolved fluorescence experiments on the pillar cavities with 3–9 μm in diameter, the participation of Purcell Effect was reported. These reports clearly indicate the progress of microdisk cavities of both inorganic and organic semiconductors. However, there is no report where microdisk cavities of organic semiconductor crystals with a few μm in diameter are fabricated. To our knowledge, this is the smallest microdisk cavity made from organic crystals ever reported.

5. Transport experiments

As already mentioned, TPCO materials have good performance of the transport property as well as the optical properties. We also observe the field effect transistor (FET) properties of the BP1T film fabricated by the high temperature deposition method described above. Fig. 9 shows a micrograph of FET structures. A schematic of the FET is also shown in the inset. The deposition condition was similar with that of the microdisks fabrication. Gate dielectric layers were composed from the 500 nm thick SiO_2 layer and the 300 nm cytop layer. Gold source and drain electrodes were deposited on the BP1T crystal film by using a thin stainless mask. After the metal electrodes deposition, FETs were overcoated by cytop layer except for the contact parts.

Fig. 10 shows plots of source drain current–voltage (Isd–Vsd) FET output characteristics with the change of the gate voltage (Vg). The output curves show clear p-channel FET properties. Fig. 11 shows the plot of Isd–Vg transfer characteristics operated at Vsd = 100 V by solid circles. Field effect mobility of holes was found to be 0.034 $cm^2\ V^{-1}\ s^{-1}$ from the fitting. The fitting line is shown by the solid line in the figure. This value is two orders of magnitude smaller than that of 5,5″-bis(biphenyl-4-yl)-2,2′:5′,2″-terthiophene (BP3T) single crystals [26], but comparable to the shorter TPCO crystals such as 5,5′-bis(4-biphenylyl)-2,2′-bithiophene (BP2T) and/or 1,4-bis(5-phenylthiophene-2-yl)benzene (AC5), probably the highest value for BP1T [14,27,28]. This fact indicates the high temperature deposition method described in this report is good fabrication method for optical microcavities and also for electrical pumping devices.

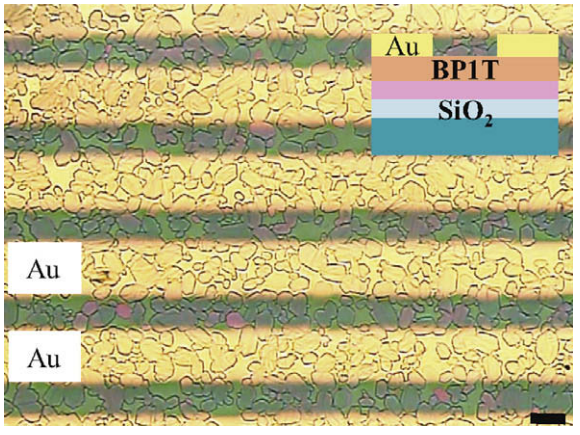

Fig. 9. Microscope images of FET devices fabricated by using high temperature deposition films. A black line shown in the bottom right part indicates the scale of 50 μm.

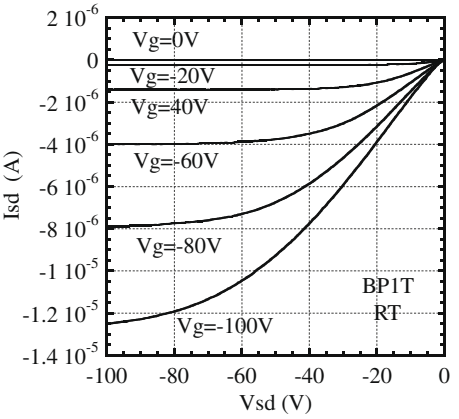

Fig. 10. Source–drain current (Isd) FET output for various gate voltage (Vg) fabricated by using high temperature deposition films.

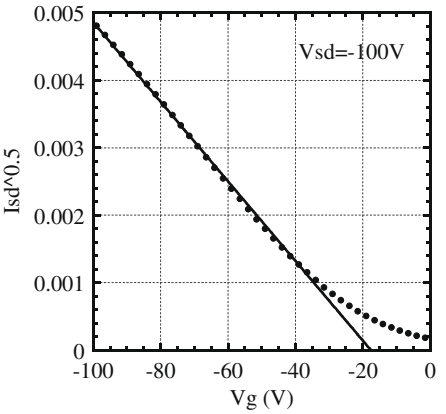

Fig. 11. Solid circles show the observed transfer curve of p-channel FET devices operated at Vsd = −100 V. The solid line shows the fitting line indicating the field effect mobility of 0.034 $cm^2\ V^{-1}\ s^{-1}$.

For the future developments of electrical pumping devices, there are many possible bottleneck processes such as electron and hole injection yields from electrodes [29], the conversion efficiency from electrons and holes to excitons [30], loss mechanisms of electrons, holes and excitons [31], and some kinds of thermal effects. Under the relatively low carrier mobility the bottleneck is considered to be the conversion efficiency from electrons and holes to excitons [30]. On the other hand, under the high mobility over 1 $cm^2\ V^{-1}\ s^{-1}$ the conversion efficiency is over 10% (assuming the same condition of Ref. [30] except for mobility), so that one of other processes may become the main bottleneck for electrical pumping. The FET devices reported here do not reach this region, but BP3T single crystal FET devices reported in Ref. [26] reach the region. Further as already pointed out by the high efficient electroluminescence work, when electrically injected electrons and holes directly form excitons such as direct gap

inorganic III–V semiconductor crystals, the intermediated states are not the bottleneck of exciton formation [32]. There are no reports of these bottleneck processes in TPCO systems, but further studies are needed to clarify the effectiveness of TPCO systems to the application for current injected devices.

6. Summary

We have fabricated BP1T microdisk laser cavities by using the high temperature deposition method and improved fabrication process. As a result, we can obtain microdisk cavities 1 μm in diameter. The cavities have no grain boundaries and cracks, so that each cavity is composed from a single crystal. The lasing spectra show the regular intervals, indicating the WGM in microdisks. The lasing threshold is almost proportional to $1/L$, as indicated by cavity QED. The smallest lasing threshold is reduced to 2% of bulk annealed films on the microdisk 2 μm in diameter. A part of the reduction comes from the improved quality of crystal films and another part of the reduction from the small disk size. The BP1T crystal films fabricated by using the high temperature deposition method also show the good performance of p-channel FET operation.

requires the development of top-absorbing devices. Furthermore, metallization in CMOS-technology is generally accomplished with a low work-function material such as aluminum, which can also be used as cathode material in organic devices. But when a low work-function material is used as bottom electrode of an hybrid detector, the layer sequence of the whole device has to be inverted [5–11].

An inverted layout is also appealing for flexible organic solar cells, since the brittle and expensive ITO conventionally used as bottom electrode can be replaced by a metal deposited with a cost-efficient roll-to-roll process [12–14]. Furthermore, as metals can be patterned with soft lithography techniques, periodic structures can be introduced to increase the optical mean free path in the device and therefore the amount of absorbed light [10,13,15–17]. In bottom-absorbing devices various metal grid electrodes with high electrical conductivity and high optical transmittance can replace conventional ITO contacts [18–20].

The challenge in inverting the layer sequence mainly concerns the spin-coating of the water-based poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) solution on top of the hydrophobic photoactive layer. The electron-blocking PEDOT:PSS layer in photodiodes is used for decreasing the dark current and for enhancing charge injection/collecting properties. To attain a sufficient wetting of PEDOT:PSS, the surface of the photoactive layer can be modified [6,11,21]. Alternatively, wetting agents can be added to the PEDOT:PSS [7,8].

We focused on an oxygen plasma process which improves the wettability of the hydrophobic photoactive layer for the following water-based PEDOT:PSS deposition. Plasma treatment is a widespread application in the plastics industry to activate polymeric surfaces for subsequent lacquer coating, but its importance for organic electronics, i.e. sequent deposition of aromatic and water-based solutions, is not yet realized. Recently, we applied this method to overcome biocompatibility problems of solution-processed organic layers, enabling growth of living cells on those modified surfaces [22]. Hsiao et al. [11] first used an oxygen plasma treatment to fabricate an inverted solar cell but without reporting about changes of wettability. In this paper, we present a solution-processed top-absorbing inverted organic photodetector using oxygen plasma treatment and discuss the impact of the plasma on material and device properties.

2. Experimental methodology

2.1. Fabrication

The fabrication of the photodetectors is performed in a glove box under nitrogen atmosphere. For the plasma treatment, the devices were transferred in air from the glove box to a plasma asher (TePla 100-E) within a minute. The layer sequence of an inverted device is shown in Fig. 1.

The bottom electrode, consisting of 100 nm aluminum, was thermally evaporated on a glass substrate in a vacuum chamber situated in the glove box. The photoactive blend material, PCBM:P3HT, was processed with a weight ratio of 1:1 and solved in toluene with a mixing ratio of blend:toluene = 2:100 (wt.), stirred overnight and spin-coated on the bottom electrode, resulting in a layer thickness of about 110 nm, on the subsequent day. P3HT was purchased from Rieke Metals Inc. and PCBM from Solenne BV. The low-pressure oxygen plasma treatment was performed with a magnetron (2.45 GHz) coupling microwaves into an oxygen gas at a pressure of about 0.2 Torr. After plasma treatment, the PEDOT:PSS formulation Clevios P VP CH 8000 by H.C. Starck was spin-coated on the active layer with a thickness of about 170 nm. Semi-transparent gold electrodes (20 nm) with an area of 7 mm^2 were thermally evaporated on top of the device using a shadow mask.

Non-inverted photodiodes without plasma treatment as references for the inverted ones were also fabricated. As

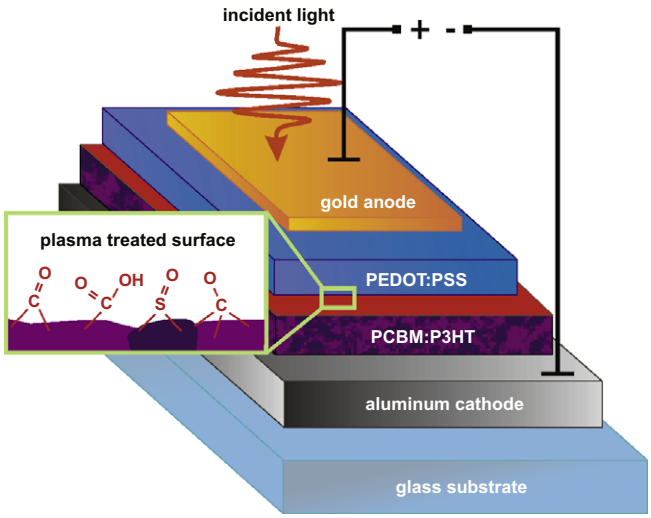

Fig. 1. Layer structure of the inverted design. The incident light is transmitted through a semi-transparent, 20 nm thick gold electrode. The enlargement illustrates the oxidation of the PCBM:P3HT blend surface due to plasma treatment.

anode material gold was replaced with indium-tin-oxide (ITO). Apart from that, processing conditions and layer thicknesses were the same as compared to the inverted devices.

Before characterization outside the nitrogen atmosphere, the devices were lateral encapsulated with a UV-hardened epoxy resin and thin glass sheets.

2.2. Characterization

Morphological characterization was performed with an atomic force microscope (AFM) JEOL 5100, operated in tapping mode. The root-mean-square (RMS) surface roughness was determined evaluating an area size of 4 μm^2.

The adhesion of PEDOT:PSS on top of a plasma-treated PCBM:P3HT blend layer has been evaluated by measuring the contact angle of a PEDOT:PSS drop on top of the blend. We used a setup consisting of a CCD-camera, a backlight and a horizontal leveled stage. A drop of the water-based PEDOT:PSS solution was deposited on a spin-coated blend layer on top of a glass substrate and a picture was taken immediately afterwards. The contact angle between drop and surface is determined assuming that the drop shape is spherical. The accuracy of the measurement is limited by the manual procedure and it is estimated to be <2°.

The blend surface was analyzed per X-ray photoelectron spectroscopy (SPECS MCD5 XPS instrument). The base pressure in the XPS analysis chamber was about 5×10^{-10} mbar. The samples were excited with X-rays with a monochromatic MgKα radiation at 1253.6 eV. The photoelectrons were detected with a hemispherical analyzer positioned normal to the sample surface. The energy resolution was about 0.3 eV. The C(1s) and S(2p) high resolution spectra were taken at a pass energy of 15 eV and with a 0.025 eV energy step.

For voltage-current characterization under illuminated conditions an halogen lamp with a calibrated power density of 100 mW/cm^2 was used. The spectral resolved external quantum efficiency was measured by lock-in-technique (Merlin Digital Lock-in Radiometry system), using a solar simulator with 300 W power and an Oriel Cornerstone 260 monochromator.

For dynamic measurements a green LED, illuminating the organic photodiode with square light pulses, was used. Pulses were generated by a waveform generator Keithley 2602. The photocurrent of the diode was amplified by a FEMTO Current Amplifier DHPCA-100 and the transient voltage measured by a 1.5 GHz digital sampling oscilloscope (LeCroy Wavepro 715zi). The response time of the whole setup (mainly determined by the LED and the current amplification) is <0.5 μs.

3. Impacts of oxygen plasma treatment

3.1. Wettability change of the PCBM:P3HT blend

We investigated the adhesion of the water-based PEDOT:PSS solution on top of spin-coated PCBM:P3HT blend layers which were exposed to an oxygen plasma.

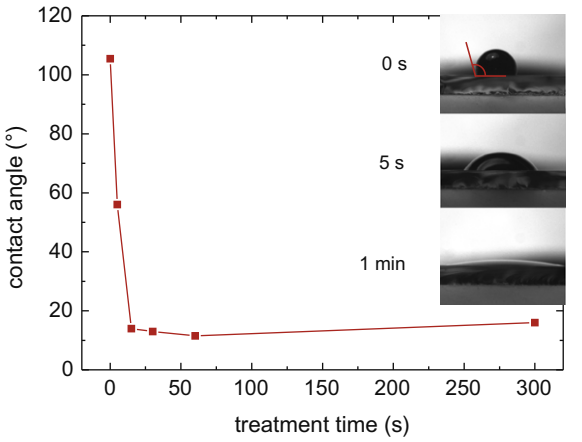

Fig. 2. Decrease of the PEDOT:PSS droplet contact angle on different long treated blend surfaces. The evaluation was performed with photographs as shown as inset.

High contact angles imply that cohesion forces inside the liquid dominate over adhesion to the solid surface. On hydrophobic surfaces the contact angles are larger than 90°, while highly hydrophilic surfaces exhibit contact angles close to zero.

The effect of oxygen plasma can be mainly controlled by varying process parameters such as treatment time and microwave power density. Fig. 2 shows the change of the contact angle of a PEDOT:PSS droplet as a function of the plasma treatment duration. The untreated blend surface has a very hydrophobic contact angle of about 106°. Even very short plasma treatment times result in a strong decrease of the contact angle which is saturating for treatments longer than 15 s. The plasma treatment leads to highly hydrophilic surfaces with contact angles <15° which are suitable for subsequent spin-coating of homogenous PEDOT:PSS layers. The best adhesion shown in Fig. 2 corresponds to a contact angle of 11° for 1 min treatment time.

3.2. Physical impact on the PCBM:P3HT blend

AFM-measurements on the blend surfaces were performed before and after the plasma treatment to find out if the quality of the surface is influenced by the process. Since metals, as the bottom electrode in the inverted device, can heat up in a plasma environment and therefore may enhance the chemical reaction with oxygen on the blend surface, the blend layers were spin-coated on glass substrates which were previously covered with an aluminum layer (100 nm). Several samples with 1 min and 5 min treatment times (with 100 W input power) were investigated. The root-mean-square roughness was determined before the exposure to the plasma and subsequently remeasured after the treatment. The untreated samples as well as the treated ones show the same root-mean-square roughness of about 1.3 ± 0.1 nm. For treatment times longer than 5 min an etching process starts at the edges of the samples while the blend distant from the edges remains unaffected. We conclude that the oxygen plasma treatment with appropriate settings of time and input power leads

primarily to a surface activation and does not act as an etching process.

Unless otherwise noted, a temporal setting of one minute is applied in device fabrication since the wettability of the PCBM:P3HT blend is best (Fig. 2) and etching effects can be excluded.

3.3. Chemical change of the PCBM:P3HT blend surface

Blend layers were investigated using X-ray photoelectron spectroscopy (XPS) in order to extract qualitative and quantitative information about the oxygen species generated on the blend layer surface (within material depths <5 nm) with subject to different long plasma treatments (100 W, 0.2 Torr).

Fig. 3 shows the S(2p) spectra. Without plasma treatment, only a signal at 164 eV is present which is related to the sulfur in the thiophene ring of P3HT. Beside the main peak, a second feature appears after plasma treatment at about 169 eV, which can be assigned to sulfur oxides. The oxidation of the thiophenes is getting more dominant with longer treatment times. After an abrupt rise to an oxide content of about 25% at 15 s, it increases to 60% at 5 min treatment as shown in the inset of Fig. 3. In spite of such high amounts of oxygen on the blend surface, the device performance is not negatively influenced, as it will be discussed later.

The C(1s) spectrum of an untreated and a 1 min long treated blend surface is shown in Fig. 4. Here the chemical change of the main components of the organic blend, the C—C and C—H bonds (P1), is represented. With plasma treatment a higher energy shoulder besides the main peak at 285.0 eV becomes apparent. According to typical chemical species found on plasma treated polymers [23,24], we can qualitatively identify three different components (P2, P3, P4) to the spectrum shoulder on the right side of the main peak (see Fig. 4). The P2 peak at 286.5 eV corresponds to C—O bonds (hydroxyl, ether), P3 at 287.5 eV to carbonyl

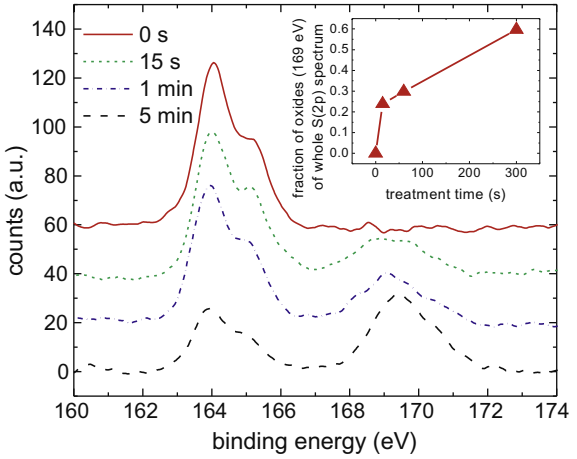

Fig. 3. Decomposition of the S(2p) peak (164 eV) of P3HT due to different long plasma treatments. The inset shows the increase of the integrated area of the sulfur oxides (around 169 eV) with respect to the integrated area of the whole spectrum. At 165 eV the $S(2p\frac{3}{2})$ signal is visible.

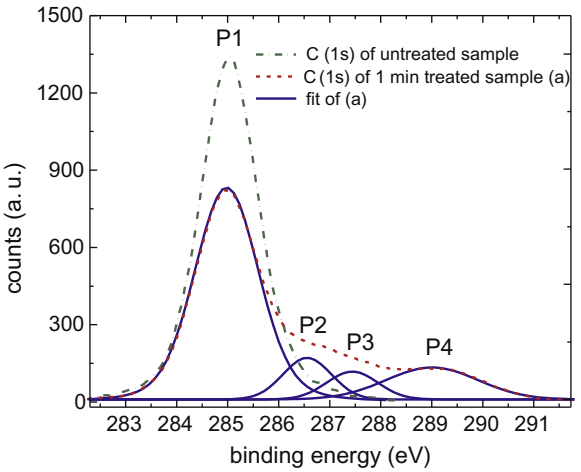

Fig. 4. Decomposition of the C(1s) peak of the PCBM:P3HT blend after a 1 min long plasma treatment. The envelope curve represents the measured spectrum of the 1 min treated sample. Using Lorentz–Gauss shapes, different peaks (P1–P4) were fitted.

(C=O) or double ether (O—C—O) bonds, and P4 at 289.0 eV is due to ester (O=O—OH) and carboxyl (O=C—O) groups. All these species are polar functional groups enhancing the hydrophility of the blend surface.

3.4. Inverted photodetector characteristics

3.4.1. IV-characteristics

IV-curves of an inverted organic photodiode together with those of a non-inverted device are shown in Fig. 5. The plasma treatment was performed with 100 W input power and applied for 1 min.

The non-inverted photodiode exhibits typical light and dark current characteristics [1]. In comparison, the inverted device shows an equally good light-on/light-off ratio for an external bias larger than −1 V indicating an efficient

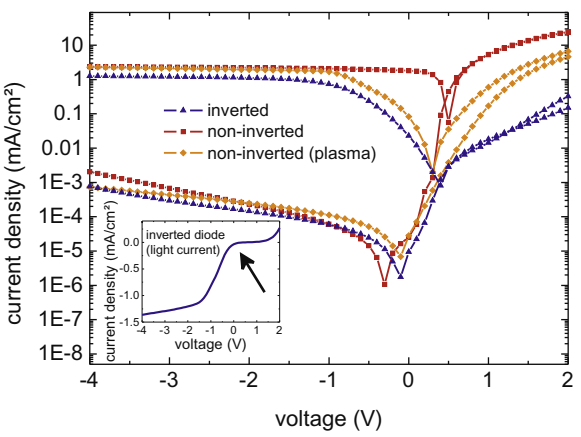

Fig. 5. Typical IV-curves of an inverted diode and a non-inverted reference diode (with an ITO-anode) with and without additional plasma treatment for dark and illuminated conditions. The applied light intensity was 100 mW/cm². The inset shows the light current of the inverted diode in a linear scale, the kink is indicated by the arrow.

current transfer through the plasma treated blend and into the high work-function gold anode. The decreased light-current for the whole reverse bias range is due to reduced light transmission through the semi-transparent gold anode. This point will be discussed further in Section 3.6.

Obvious differences to the non-inverted reference are the decreased forward current of the inverted diode (factor 100 @ +2 V) and an inflection point of the light IV-curve close to the open circuit voltage V_{oc} which is observable as a kink in the linear scale (see inset in Fig. 5).

The forward photocurrent density of an inverted diode measured up to 3 V is shown in Fig. 6. For bias voltage <0.5 V the current can be well fitted with an exponential increase $e^{qV/nkT}$ (with q = elementary charge, n = ideality factor, k = Boltzmann constant, T = temperature) according to the Shockley equation for inorganic diodes. For increasing voltage the current slope begins bending downwards (which might be related to a serial resistance) before it increases stronger again for bias larger than +2.2 V best fitted with a V^4 voltage dependence. The V^m law with $m \geqslant 2$ is valid for space charge limited current (SCLC) [25]. Without traps and without an effect of the electrical field on the mobility $m = 2$ is valid, but if traps or a field dependent mobility are involved $m > 2$ accounts. Since the plasma treatment introduces interface states by generating oxides on the blend, we assume that the current transport across this interface is dominated by trap-assisted hopping processes at sufficient large bias.

In organic electronics, a kink in the IV-curve is often observed during lifetime measurements [26,27] of solar cells and is related with oxygen diffusion into the device forming insulating interfaces, especially between the low work-function electrode and the polymer layers. The formation of the photocurrent kink can be explained by a slow charge transfer at the material interfaces [28]. Considering the decreased forward current, we can assign the kink of the IV-curve of Fig. 5 to space charge limited current due to the oxides introduced by the plasma treatment. This will be further discussed in Section 3.5 where it is shown that the slow charge transport across the plasma treated blend-PEDOT:PSS interface is due to charge accumulation which in turn reduces the internal electric field of the device. To compensate the built-in voltage, which corresponds almost to the open circuit voltage, a smaller external bias voltage has to be applied. Thus, the V_{oc} of the plasma treated device shifts to lower values (Fig. 5) compared to the reference one. Considering the application of the inverted devices as organic solar cells, this effect acts detrimental on the device performance as well as the negative curvature of the photocurrent kink in the fourth quadrant which reduces the short circuit current and the fill factor.

To find out if the impact of the plasma treatment is different strong on the constituents (PCBM, P3HT) of the blend, we fabricated a non-inverted device, as described in Section 2.1, with a blend layer exposed to an oxygen plasma (100 W, 1 min) prior to aluminum evaporation. Since the blend(PCBM)-Al interface of the non-inverted device enables electron transport and the blend(P3HT)-PEDOT:PSS interface of the inverted device enables hole transport, a different device performance would indicate a different impact of the interface states, introduced by the plasma treatment, on the carrier transport through PCBM and P3HT. While the non-inverted photodiode which was not exposed to an oxygen plasma presents no kink (Fig. 5) the plasma-treatment leads to the formation of a kink similar to that of the inverted device. A pronounced difference between the plasma-treated non-inverted (diode (a)) and inverted diodes is the increased forward current density (factor 25 @ +2 V) although both show a SCLC regime with a V^4 behavior, for diode (a) even starting at bias voltage >0.5 V. The increased current of diode (a) has to be related with an increased density of trapping states of the PCBM molecules. This is currently still under investigation.

To determine the influence of an increasing oxidation of the blend layer on the electronic performance, inverted devices were fabricated with different treatment times and different microwave powers. The on/off ratio between light and dark current was similar for different samples, but a change of the forward current density, especially of the photocurrents (Figs. 7, 8), could be observed. For either increasing treatment time or plasma power the current

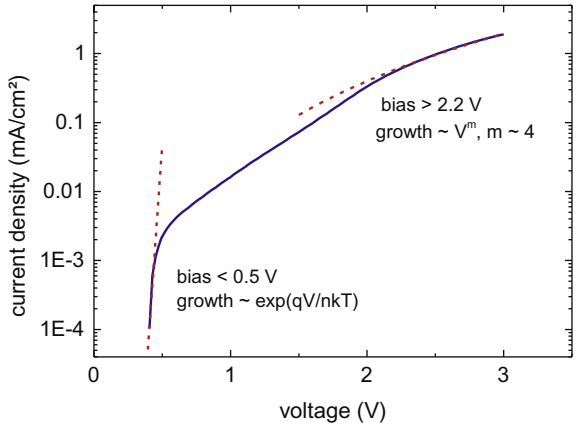

Fig. 6. Semilogarithmic plot of forward current density of an inverted device. The dashed curves represent fitted curves.

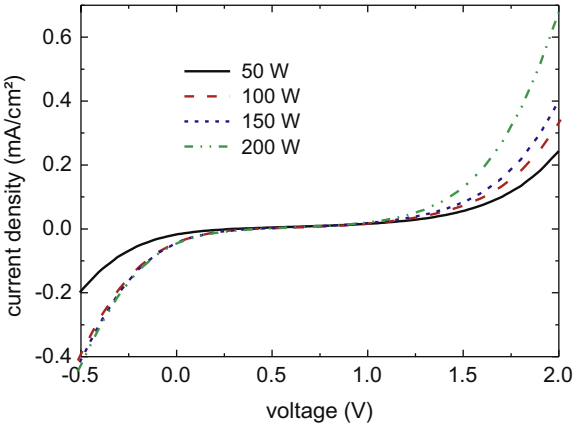

Fig. 7. IV-curves (linear scale) under illuminated conditions (100 mW/cm^2) for plasma treatment performed with different power settings.

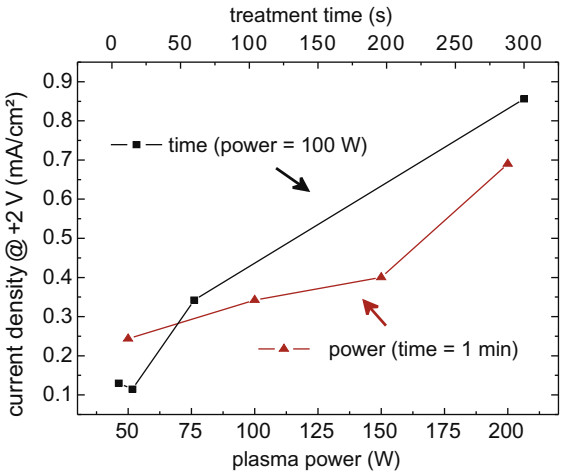

Fig. 8. Increase of the forward photocurrent density @ +2 V with increasing plasma treatment time and microwave power.

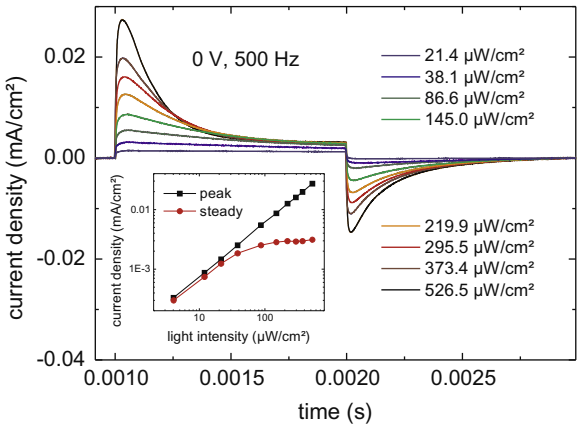

Fig. 9. Photocurrent density shape versus time of various light intensities (1 ms long square pulse) without applied bias voltage. The inset shows the increase of the photocurrent peak and the steady state value as function of the light intensity on a double-logarithmic scale.

density increases too. This is again a consequence of the current transport by trap-assisted hopping. As shown in Fig. 3, the amount of sulfur oxides increases on the blend surface with time and thus consequently also the number of hopping states. An increased oxidation is also expected with rising power. The varying input power has also an effect on the kink shown in Fig. 7. For the smallest applied power (respective times $\leqslant$15 s, not shown here) the kink is more pronounced. Since the kink has a negative impact on the quantum efficiency and the dynamic behavior (see Section 3.6, 3.5) minimum settings for plasma power and time have to be chosen for good device performance.

3.5. Dynamic behavior

The decreased photocurrent at small reverse bias voltages across the plasma treated blend surface, which is shown as kink in the IV-curve, leads to a characteristic shape of the photodiode dynamic response. In Fig. 9 the photocurrent of an inverted device after illumination with a 1 ms long square light pulse with different intensities is shown.

Illumination of the device with the pulse leads to the formation of a peak at the beginning of the light pulse response which starts to decrease within a time range of about 0.5 ms to a steady state value. A similar transient shape was observed before by Zaus et al. [29] when inserting a hole-conductor layer with low hole mobility in a non-inverted PCBM:P3HT photodetector. The effect observed in the inverted diodes can be explained by a hampered charge transport at the blend-PEDOT:PSS interface because of hole trapping at the plasma induced oxides. The consequence is a continuous increase of accumulated positive charge at the interface, associated with a reduction of the electric field inside the active layer and also of the light-current flowing [29]. This effect corresponds to the decrease of the peak value in Fig. 9. While the peak value increases linearly with increasing light intensity (see inset) as for normal organic photodiodes [1], for the steady state value a saturation effect occurs at about 50 µW/cm² indicating a decreasing internal electrical field with an increasing amount of photogenerated carriers.

For external bias voltage larger than −1 V, a value at which the kink of the IV-curves disappears, we observed a behavior typical for organic photodetectors independent of the light intensity. Within typical rise times of about 5 µs @ −1 V the photocurrent reaches a plateau, see Fig. 10. The −3 db-cut-off frequency of an inverted device measured @ −4 V is about 500 kHz (Fig. 11) which is also a typical value for organic photodetectors [30] and high enough for many imaging applications.

3.6. Quantum efficiency

To prove that the plasma treatment does not have a negative impact on the active layer we tried to compare the external quantum efficiency, defined by the ratio of generated electrons to incoming photons, of the inverted device with that of the non-inverted reference as shown

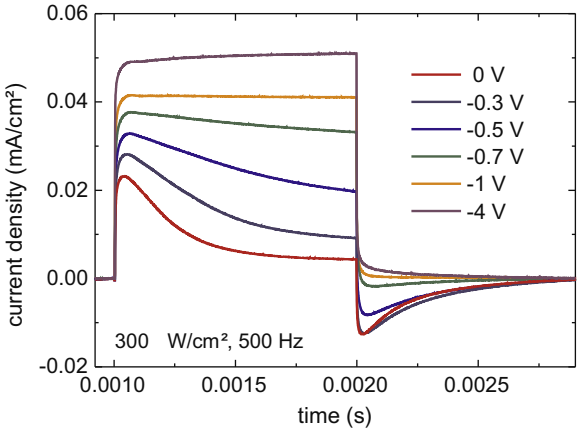

Fig. 10. Dependence of the dynamic photocurrent density shape of various bias voltages. The light intensity is 0.3 mW/cm².

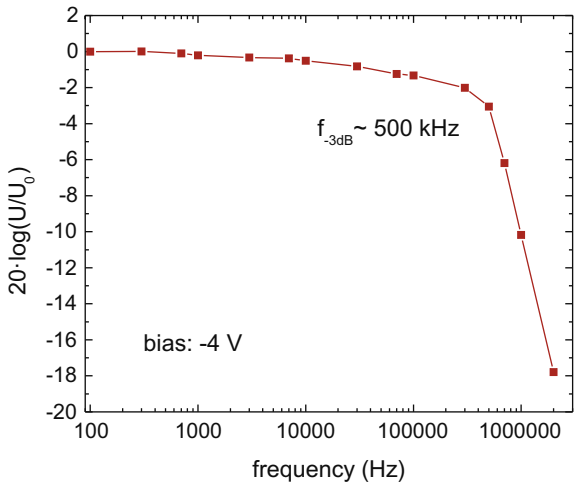

Fig. 11. Frequency response of the inverted diode for an applied voltage of −4 V.

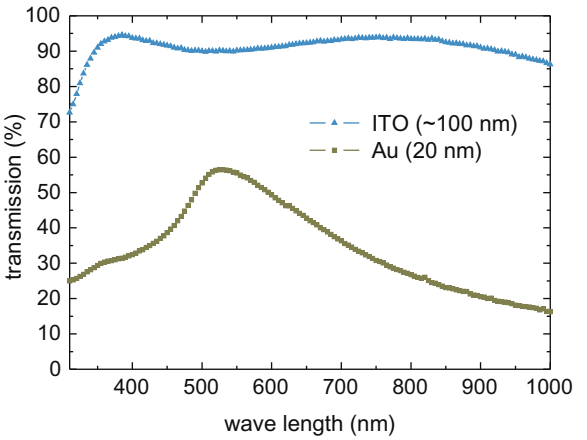

Fig. 13. Transmission of a 20 nm thick gold layer and of an about 100 nm thick ITO-anode.

in Fig. 12. Since the transparent electrodes consist of gold respectively ITO, the different transmittances of the materials have to be taken into account. In Fig. 13 the transmittance of 100 nm ITO and 20 nm gold are shown. Although the transmittance maximum of the semi-transparent gold anode corresponds to the absorption maximum of the PCBM:P3HT layer in the device, the overall transmittance is significantly reduced compared to the anode of the non-inverted device. At 500 nm, for a non-inverted device, about 80% of the incoming light is transmitted to the blend layer (through the glass substrate, the ITO-anode and a 170 nm thick PEDOT:PSS-layer). In an inverted device only about 50% of the photons @ 500 nm reach the blend layer after passing the encapsulation, the gold and the PEDOT:PSS layer. Both values are measured at a complete stack of relevant materials after substracting the absorbance of the glass substrate. The spectral resolved EQE @ −4 V for both devices is shown in Fig. 12. Comparing the EQE @ 500 nm with the amount of light reaching the active layer after transmission, 80% of the photons are converted into current for both the non-inverted and the inverted diode. Thus the reduced EQE of inverted devices can be completely explained by the loss of light due to the reduced transmission of gold. By patterning the gold we are currently trying to improve the light transmission.

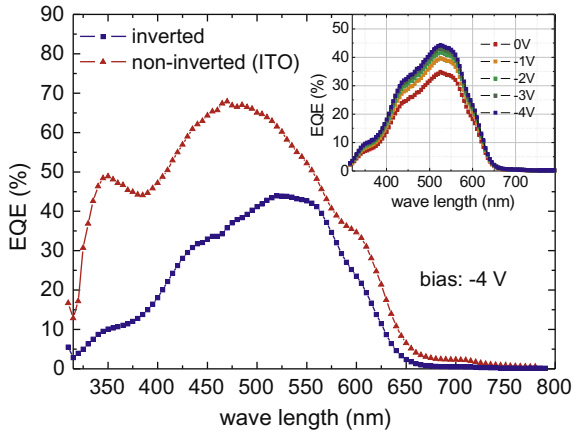

Fig. 12. External quantum efficiency (EQE) of an inverted and a non-inverted diode (gold respective ITO as transparent anode material) for an external bias voltage of −4 V. The inset shows the bias dependence of the EQE of the inverted diode.

The EQE of inverted devices increases strongly non-linear with increasing bias voltage. As can be seen in the inset of Fig. 12, from −1 V to 0 V bias the EQE decreases as much as between −4 V to −1 V. This strong decrease of the EQE for bias voltages close to 0 V can be attributed to accumulated charges at the plasma induced oxide layer and the resulting slow charge transfer which can also be seen in the kink of the IV-curves of Fig. 5 in Section 3.4.1 and discussed in Section 3.5. A saturation of the efficiency is reached for bias voltages larger than −5 V, resulting in a maximum EQE for the inverted device with a 110 nm thick photoactive layer of about 45%.

4. Conclusion

We successfully demonstrated the fabrication of an inverted organic photodiode using an oxygen plasma treatment process in order to spin-coat PEDOT:PSS on top of the photoactive blend layer. The device performance is influenced by the oxides introduced by the plasma treatment. Acting as traps, the oxides shape the IV-curves according to space charge limited current (SCLC), leading also to a kink of the photocurrent for biasing smaller than −1 V. Thus the dynamic photoresponse and the quantum efficiency are strongly influenced in this regime, but since photodetectors are usually driven at higher reverse bias, the effects do not hamper the device performance for usual operating voltages. Inverted devices fabricated with suitable plasma parameters show comparable on/off-ratios between dark and photocurrent for sufficient reverse bias as non-inverted reference diodes. Also the EQE, taking the decreased transmission of the gold anode into account, is not lowered compared with the references. Thus we conclude that the plasma treatment does not introduce severe

damages to the blend layer and these promising results allow the application of the inverted diodes as photodetectors, also in combination with inorganic electronics as CMOS-technology.

In this work, we present all-polymer ECTs, where the electrolyte is patterned within a self-supported membrane. The membranes are prepared by the roll-to-roll suitable electron beam irradiation induced grafting (EB) technique (Fig. 1) that was recently used by our group for fabricating low-voltage EDLC gated OFETs [10]. The ion conducting membranes provide a number of benefits: (1) the membrane is thick and robust, but still flexible. (2) The membrane is chemically resistant. (3) By using the EB technique we can tailor-make the membrane to be ion conducting in any desired way and pattern. (4) We may vary the base-material and/or the functional group. The latter is especially attractive for various sensor applications [4]. We use flexography, which is a roll-to-roll manufacturing technique [11], to print the PEDOT/PSS source-, drain- and gate-electrodes onto the patterned membrane. Because of an intrinsic feature of the PEDOT, we also demonstrate a write-once read many times (WORM) memory device that is based upon the printed all-polymer ECT.

2. Materials and methods

The porous poly(vinylidene difluoride) (PVDF) (Millipore GVHP00010, 125 μm of thickness, 0.22 μm of pore size), styrene (Acros), toluene (LabScan) and 1,2-dichloroethane were all of reagent grade and used as received. Irradiation was carried out through a patterned aluminum mask using an ESI Electrocurtain 175 electron accelerator (Energy Sciences Inc.) under ambient air at an acceleration voltage of 175 kV. The irradiated (20 kGy) membranes were immediately immersed in 140 ml of styrene and 60 ml of isopropanol. The monomer solution was purged with nitrogen for 30 min prior to grafting and an inert atmosphere was maintained throughout the reaction. The reaction was carried out in nitrogen atmosphere at 80 °C for 2.5 h. After the reaction the grafted membranes were extracted with chloroform and dried at 40 °C in a vacuum oven. For sulfonation the patterned membranes were immersed in 0.5 M chlorosulfonic acid in 1,2-dichloroethane at 30 °C for 24 h. The sulfonated membranes (PVDF:PSSA) were washed thoroughly with ethanol and water. The overall process is illustrated in Fig. 1.

Before printing of the PEDOT/PSS-structures, the membranes were boiled in water for 30–60 min and, thereafter, dried at room temperature. A tabletop flexographic printing unit (Flexiproof 100 from R K Print Coat Instruments Ltd.) was used to print the structures. The selected anilox-roll had a transfer-volume of 18 cm^3/m^2. A lithographically patterned OHKA-rubber plate (Espoon Painolaatta Oy) was used as the flexible printing plate. The conductive polymer dispersion was a mixture of water based PEDOT/PSS (Baytron P) and ethylene glycol. The latter was used as a conductivity enhancer. Two mixtures of the dispersion were separately used in this work. The first one was Baytron P with added ethylene glycol (60 vol%) (PEDOT content approx. 0.45 wt.%), while in the second mixture the viscosity of Baytron P was adjusted by partially removing water by evaporation. The concentrated "gelled" PEDOT/PSS dispersion had an added ethylene glycol content of 20 vol% (PEDOT content approx. 1.2 wt.%). Seven consecutive layers were printed in order to gain high pristine conductivity. Between each printing step the printed layer was dried with a hot air blower. In the measured ECTs, the distance between the gate and the transistor channel (i.e., the PEDOT/PSS-channel between the source and the drain that covers the PVDF:PSSA-pattern [5]) was varied between 200 and 600 μm. The transistor channel area was varied between 0.9 and 1.7 mm^2, while the gate area was kept at about 50 mm^2.

The ECTs were stored and characterized at room temperature and in controlled humid atmosphere. In this work all devices were tested in relative humidity (RH)-levels of RH = 40–70%. All current–voltage characteristics, except for the current–time measurement, were measured with a Keithley 2636 System SourceMeter (source/drain-probes) and a Keithley 2400 SourceMeter (gate-probe) and further connected to a computer with suitable software. The current–time measurements were done with an Agilent 4142B Parameter Analyzer connected to a computer with suitable software. The voltage step for all current–voltage measurements was 0.1 V and different delay-times were used. For the WORM-experiments the WRITE-voltage (gate-voltage) was $V_G = -25$ V and was applied for 30 s.

3. Results and discussion

A schematic figure of the flexographic printing technique is shown in Fig. 2. By using a porous membrane, the transfer of the water based PEDOT/PSS is improved, including on the ungrafted PVDF-surface. This results in a good print pattern, as shown in Fig. 2c. The ECT is a three-terminal device with the source, the drain and the gate placed laterally to each other on the PVDF:PSSA-pat-

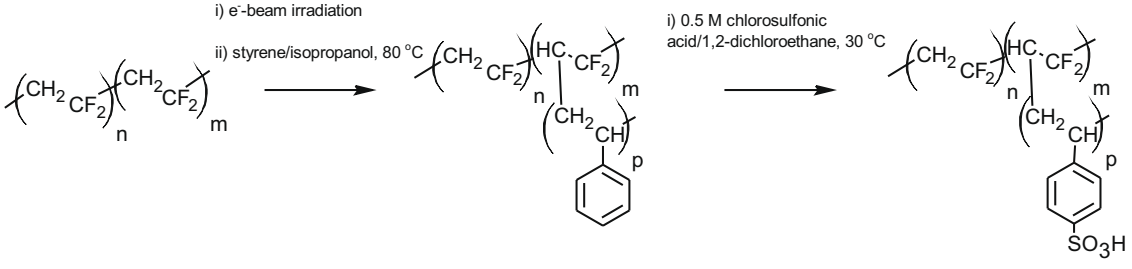

Fig. 1. The preparation procedure of the PVDF:PSSA membrane. The three major steps are (1) electron beam irradiation through a patterned mask, (2) grafting and (3) sulfonation.

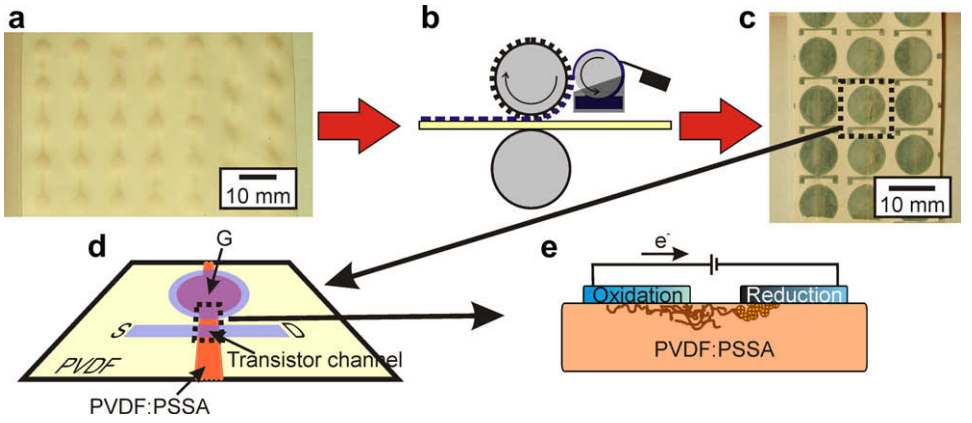

Fig. 2. (a) The patterned porous PVDF:PSSA-membrane. (b) Flexography is a roll-to-roll manufacturing technique. (c) The photograph shows a strip of printed PEDOT/PSS based ECTs. (d) A schematic figure of the PEDOT/PSS based ECT. D, S and G are the drain, the source and the gate respectively. (e) The gate and the transistor channel are connected via the PVDF:PSSA (dotted area in (d)). Thus, as schematically shown, they form an electrochemical cell.

tern (Fig. 2c and d). Thus, the electrodes can be placed on the same printing plate, which means that problems such as aligning of the electrodes may be avoided. Furthermore, the flexographic printing can, in principle, be done in one step. In practice, though, up to seven consecutive PEDOT/PSS layers were printed in order to get a high pristine conductivity. We note, however, that the number of printed layers may be reduced, since PEDOT/PSS and ethylene glycol compositions can provide conductivities of up to 500 S/cm with a dry thickness of only a few tens of nanometers [12]. The calculated dry thickness of the printed structure is 0.6–1.5 μm. The actual dry thickness may slightly vary due to an incomplete transfer of ink from the anilox roll and due to some possible penetration into the pores of the membranes. Local thickness analysis determined by atomic force microscopy on the printed PEDOT/PSS pattern is in agreement with the calculated value. Noteworthy is that the gelled PEDOT/PSS/ethylene glycol dispersion provides a sharper print pattern and, thus, a reduced risk for electronic short-cuts. Moreover, the pristine conductivity of the transistor channel is slightly higher compared to the other PEDOT/PSS dispersion (uppermost by a factor of three).

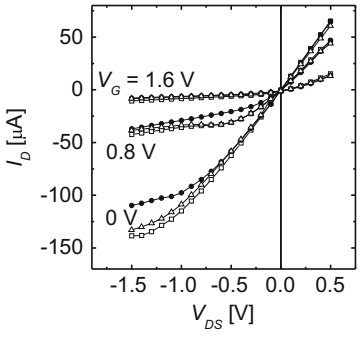

Fig. 3. Output-characteristics of an all-polymer ECT subsequently measured at delay-times 1 s (open square), 5 s (filled circle) and at 1 s again (open triangle).

Three output-characteristics for a printed ECT are shown in Fig. 3. The characteristics are subsequently measured at delay-times 1 s (open square), 5 s (filled circle) and 1 s (open triangle). The ECT was allowed to rest for 3 min between the characteristics. Since the PVDF:PSSA is hygroscopic, the ionic conductivity varies at different RH-levels [13]. The ECTs are therefore better operated in a slightly humid atmosphere. The devices were also tested after 3 months of storing in a controlled humidity and showed similar output-current levels and behavior, as compared to the pristine device. This is anticipated, since PEDOT is known to be a stable conducting polymer [14]. The modulation of the drain-current (I_D) is governed by the well-known redox-reaction for PEDOT/PSS:

$$\mathrm{PEDOT^+PSS^-} + \mathrm{M^+} + e^- \leftrightarrow \mathrm{PEDOT^0} + \mathrm{M^+PSS^-}, \quad (1)$$

where $\mathrm{M^+}$ is a proton in the case of PVDF:PSSA. By operating the ECT in the third quadrant, the transistor channel is reduced and the current is quenched. Therefore, the ECTs are "normally-on" devices and the transistor-operation is reversible in this mode. Based on the calculated thickness values for the PEDOT/PSS layer, the pristine conductivity in the transistor channel range from 5 to 15 S/cm (measured at a delay-time of 1 s, at $V_G = 0$ V and at a drain-voltage of $V_{DS} = -0.5$ V). The on/off ratios for the ECTs are usually 10^2–10^3.

If assuming that the gate, the PVDF:PSSA and the transistor channel forms an ideal electrochemical cell (Fig. 2e), and further neglecting any possible electronic leakage, then the total number of protons ($\mathrm{M^+}$) that participates in the redox-reaction can simply be estimated from:

$$Q = \int_0^{t_f} I_G dt, \quad (2)$$

where Q is the charge, I_G is the gate-current and t is the time. Indeed, the subsequent variation of the delay-time in Fig. 3 corresponds with the time-dependence of Eq. (2). A longer delay-time results in a decline in both the on- and off-currents as well as in a change in the pinch-off. Consequently, a higher number of charges participate

in reducing the transistor channel, as described by (1) and (2). There is a small mismatch between the first and the third output-characteristic (open symbols, delay-time 1 s), which could result from an incomplete re-oxidation of the transistor channel. The pinch-off at $V_G = 0$ V is caused by protons from PVDF:PSSA that attract towards the drain at higher negative V_{DS} and reduces the transistor channel [15]. Consistently, we observed that the same pinch-off disappears within the used measurement range when the transistor channel is thicker. In a thicker PEDOT/PSS layer a part of the transistor channel still remains oxidized (conducting) and, therefore, I_D maintains an ohmic behavior throughout the sweep at $V_G = 0$ V.

Several inherently conductive polymers, e.g., PEDOT, possess a finite potential window of high conductivity [16,17]. At elevated potentials and in the presence of nucleophiles (such as water) the polymer undergoes overoxidation and is, hence, susceptible for structural modifications. The charge percolation in the conjugated polymer is terminated, due to disrupted π-conjugation, and the polymer looses its high electronic conductivity [18,19]. Overoxidation of PEDOT results in a drop of conductivity by orders of magnitude [19], also shown in Fig. 4. On the other hand, an opposite high potential (i.e., a high reduction potential of the transistor channel) does not destroy the percolation path. Instead, though, the PEDOT-gate is subjected to a high oxidation potential. Nevertheless, the PEDOT/PSS based ECT can be operated in the third quadrant (Fig. 3) with a fast recovery of the high conducting state, as demonstrated by Fig. 4.

Overoxidation is acknowledged as a major challenge for conducting polymers in general and ECTs in particular. Overoxidation has, however, also been utilized, e.g., for designing isolated conductive patterns on PEDOT/PSS-sheets [20] and for pumping ions in an ECT-like set-up [21]. We use overoxidation of PEDOT to demonstrate a WORM memory functionality of the ECT. WORM-devices, that employ at least one organic layer, have earlier been motivated and successfully demonstrated by others [22–24]. In the WORM-device, the active material acts like a fuse. The transition from a high-conductivity state (“1”) to a low-conductivity state (“0”) is realized by applying a high, negative WRITE-pulse (V_G). The PEDOT is overoxidized and the conductivity is permanently destroyed by almost three orders of magnitude (Fig. 5). The “0”-state is permanent at controlled RH-levels (±3% in Fig. 5).

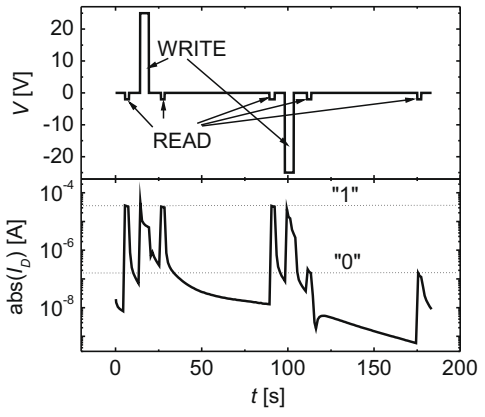

Fig. 4. By applying a positive V_G pulse (WRITE) the transistor channel is reduced. However, the electronic current recovers almost immediately. By applying a negative V_G pulse, the transistor channel is overoxidized and the electronic conductivity is permanently terminated. The WRITE-voltage is $V_G = \pm 25$ V, respectively, and applied for 5 s. The READ-voltage is $V_D = -2$ V and applied for 2 s.

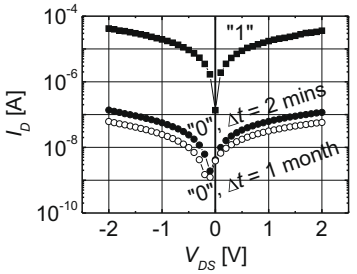

Fig. 5. A WORM-ECT characterized before and after the WRITE-pulse. Δt denotes the time-step between the WRITE-pulse and reading. The deviation in the “0”-currents are mainly due to slightly different RH-levels during the sweeps.

Basically, I_D in Fig. 5 can be expressed as $I_D = I_{SD} + I_{GD}$, where I_{SD} is the current between the source and the drain and I_{GD} between the gate and the drain respectively. $I_D \approx I_{SD}$ at “1”, that is, the electronic current in the transistor channel dominates ($I_{SD} \geqslant 100\, I_{GD}$). At “0”, on the other hand, $I_D = I_{SD} + I_{GD}$ albeit I_{GD} being the dominating term. In the “0”-state, I_D is also highly sensitive to changes in RH, which is due to the hygroscopic nature of the PVDF:PSSA. This results in a reversible increase of I_D at higher RH and vice versa. I_{SD} behaves identically at various RH, which clearly indicates that the conductivity of the PEDOT/PSS is dominated by its ionic contribution [25]. At RH = 100%, though, $I_D \approx I_{GD}$ ($I_{SD} \leqslant 0.1\, I_{GD}$). At this RH-level the increased I_D did still not reach up to the high current level at “1”. Moreover, below RH = 20% there were minimal ionic contribution from both I_{GD} and I_{SD} and the measured I_D was five to six orders of magnitude lower than at “1”. Consequently, the electronic resistance has increased by more than five orders of magnitude after overoxidizing the PEDOT, which corresponds with earlier reported values [19,20]. We note that a fairly long WRITE-pulse (30 s) was intentionally selected in order to ensure terminal reduction of I_D. The WRITE-pulse is therefore not optimized for applications. Several parameters affect the degree of overoxidation, such as the volume (area × thickness) of the transistor channel, the degree of grafting of the PVDF:PSSA (i.e., the ionic conductivity) [13], various contact effects and resistances as well as the ambient RH. Nevertheless, the demonstrated WORM-ECT provides a simple and low-cost possibility for permanent storing of information, such as for intelligent labeling.

4. Summary

Low-voltage and all-polymer ECTs have been fabricated on self-supported and patterned PVDF:PSSA membranes. The fabrication and the characterization of all devices have been carried out in air. The PVDF:PSSA is prepared by the electron beam irradiation induced grafting technique. The

transistor structure is printed with flexography using a PEDOT/PSS/ethylene glycol dispersion as the redox-active material. The ECTs are fabricated in lateral device geometry and display reversible behavior when operated in the third quadrant. However, when applying a sufficiently high negative gate bias, the transistor channel is irreversibly overoxidized. We have utilized overoxidation for demonstrating WORM memory functionality in the ECT. This work provides an example of a simple and low-cost application for all-polymer electronics.

2. Experiments

2.1. Sample preparation

The structure of fluorescent device is shown in Fig. 2a. An indium tin oxide (ITO) coated glass substrate (purchased from Aldrich) with a sheet resistivity of 8–12 Ω/square was used as the substrate. About 100 nm N′,N′-di(naphthalene-1-yl)-N,N′-dipheyl-benzidine (α-NPD) and 100 nm tris-(8-hydroxyquinolino) aluminum (Alq_3) were deposited successively as the hole transporting layer and emitting/electron transporting layer, respectively. Then a cathode was deposited consisting of a 2 nm Cs layer followed by 150 nm of Al. The ITO substrate was cleaned by ultrasonicating in ethanol and acetone. Following this, the ITO was treated in ozone for 20 min. The α-NPD and Alq_3 were purchased from Luminescence Technology Corporation. The deposition of the organic layers was performed using Knudsen-cells in a vacuum chamber with a base pressure during evaporation of $\sim 10^{-7}$ Torr. Cs was deposited with alkali metal dispenser (purchased from SAES Getters). The deposition rate of organic materials was about 0.1 nm/s. Calibrated quartz crystal microbalances were used to determine the deposition rate. The structure of phosphorescence device is shown in Fig. 2b. Doping of 5% Btp_2Ir(acac) in CBP was performed by controlling the evaporation rate by monitoring the quartz crystal microbalances.

The sample OLEDs and unipolar devices were transferred from the deposition chamber to glove box filled with dry N_2 (concentration of H_2O and oxygen was less than 100 ppm) without exposing them to air. The electrical connection to the OLED was made using 20 μm-diameter Cu wire with In contact. Then the OLED sample was sealed in a glass box using photo-hardening epoxy (Threebond 3124) together with a zeolite desiccant (Shinagawa Kasei Co., Ltd.).

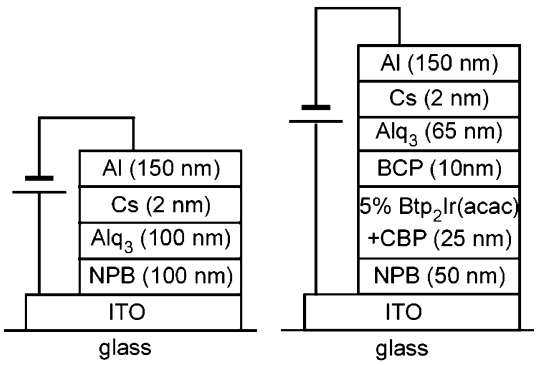

Fig. 2. Device structures (a) fluorescent device (b) phosphorescent device. The abbreviations are as follows. BCP: 2,9-dimethyl-4,7-diphenyl-phenanthroline, Btp2Ir(acac): bis(2-(2′-benzo[4,5-α]thienyl) pyridinato-N,$C^{3\prime}$) iridium (acetyl-acetonate), CBP: 4,4′-N,N′-dicarbazole-diphenyl.

2.2. Measurement

MFE was measured at 300 K in superconducting magnet using Physical Property Measurement System (PPMS; Quantum Design). The magnetic field was perpendicular to the device plane. The magnetic field was increased from 0 to 9 T and then was decreased from 9 to 0 T in order to check the temporal changes. The results are shown after confirming pure MFE is observed, unless stated otherwise. The emission intensity was measured with photon counter H7155-21 (Hamamatsu Photonics) in magnetic shielding made of thick iron plates and cylinders. The shielding of photon counter was tested by introducing light with vari-

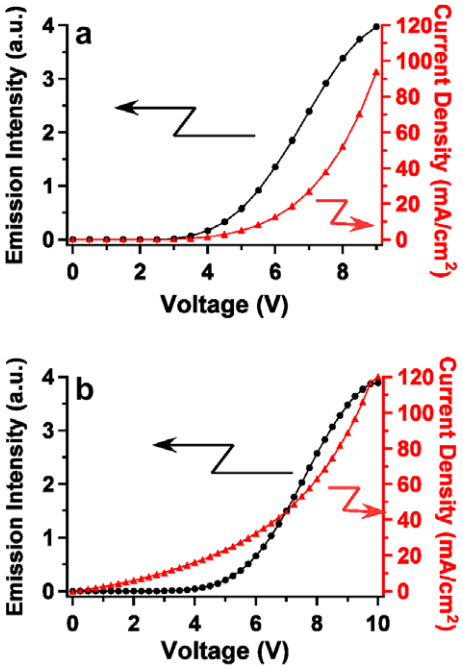

Fig. 3. Normalized emission intensity and current density as a function of the voltage without applying the magnetic field (0 T) (a) fluorescent device (b) phosphorescent device.

ous intensities by optical fiber to make sure there was no magnetic field dependence on its output. The bias was applied by the Keithley 6487 picoammeter/voltage source in constant voltage mode.

3. Results

3.1. Fluorescent OLED

First we show the characteristics of the fluorescent device without applying the magnetic field. Fig. 3 shows the emission intensity and current of the fluorescent and phosphorescent OLED as a function of voltage. It is reported that TTA in Alq_3-based fluorescent OLEDs occurs when the current density is larger than 100 mA/cm^2 [17] and some of our measurement exceeds this limit. However, since the magnetic field dependence of TTA appears only at low temperatures [13,14], we consider we can neglect contribution from TTA in the present measurement at 300 K.

The emission intensity, current, and emission efficiency of the same device under the magnetic field are shown in Fig. 4. The emission intensity and current show different magnetic field dependence on the sweep direction (0 T → 9 T → 0 T) (Fig. 4a and b). However, their ratio, i.e. emission efficiency, does not show the hysteresis as shown in Fig. 4c. It means that the hysteresis comes from the charge injection process from the electrodes to the emission layer. We found that the "hysteresis" is dependent on both of the magnetic field and the time from the start of the current flow. The time dependence is probably due to the bias stress on the device, but the magnetic field dependence might be related with MFE of the trap/detrap processes.

The emission efficiency (and also the emission intensity and the current) increase steeply as a function of B when it was less than 0.02 T as reported in the literature, and gradually decreases as B was further increased. It should be noted that the decrease in the mid–high B region is *convex* function, which cannot be explained by widely accepted behavior of hfc, Δg, and TTA mechanisms which exhibit *concave* behavior against B. We will discuss this point later.

In order to see dependence on B more clearly, we re-plotted Fig. 4c as a function of B^2. Fig. 5a clearly shows the linear decrease of the fluorescent efficiency against B^2 in the range of 0.1–6.5 T. On the other hand, by re-plotting Fig. 4c as a function of $B^{1/2}$ (Fig. 5b), it is noticed that the decrease of the emission efficiency shows $B^{1/2}$ dependence in the range of 6.5–9 T.

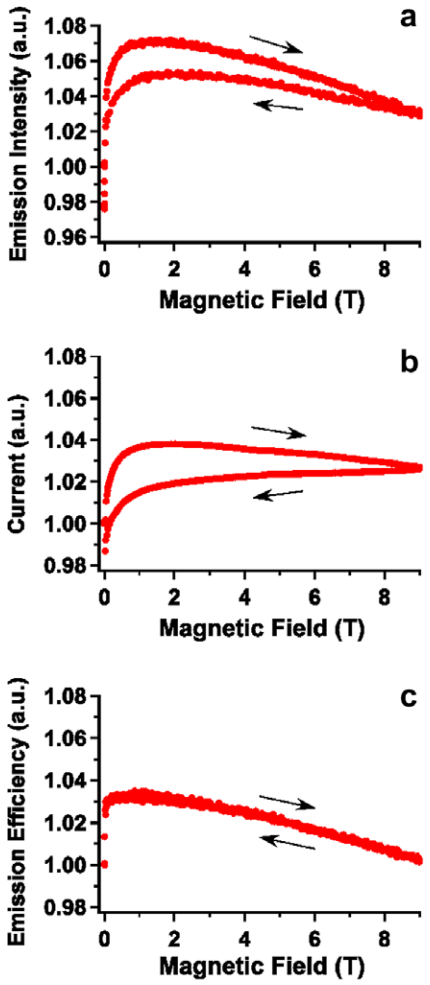

Fig. 4. Magnetic field effect of the fluorescent device (normalized at zero field). (a) Emission intensity, (b) current, (c) emission efficiency at 4 V. The arrows show the sweep direction of the magnetic field (0–9/9–0 T).

3.2. Phosphorescent OLED

Fig. 6 shows the MFE on the emission efficiency of the phosphorescent OLED. In contrast to the results of the fluorescent device, it did not show the magnetic field depen-

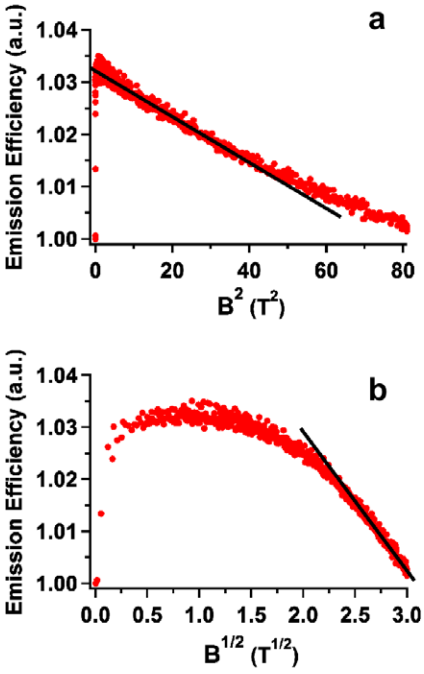

Fig. 5. Normalized emission efficiency of the fluorescent device plotted against (a) B^2 (b) $B^{1/2}$.

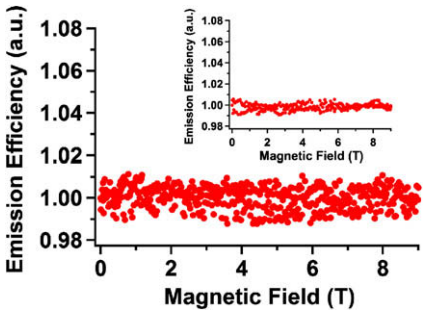

Fig. 6. Magnetic field effect of the phosphorescent device (normalized at zero field). The result at 10 V is shown in the inset.

dence. Although we changed the driving voltage (4, 6, 8, 10 V), the magnetic field dependence did not appear.

3.3. Magnetoresistance measurement of unipolar devices

In order to investigate the charge balance factor which might influence the EL efficiency, we measured the magnetoresistance of the majority and minority carriers in α-NPD and Alq_3 by making the unijunction devices with different work function electrodes (Au and Cs). All of the devices showed Ohmic *I–V* characteristics in the measured range (−10 to 10 V). The results of MFE on the current at constant voltage are shown in Fig. 6a–d. The voltages were chosen to give current in the range of 10–100 μA and the results are shown after normalization at zero field. It is easily noticed that the MFEs on the conductivity of the majority carriers (holes in α-NPD and electrons in Alq_3) are negligible, whereas linear decreases in the conductivity was observed for the minority carriers (electrons in α-NPD and holes in Alq_3). Since the *I–V* characteristics are Ohmic, it shows the mobility values of the minority carriers decrease linearly as a function of the magnetic field.

4. Discussion

We found the decrease in the fluorescent efficiency in organic EL devices proportional to B^2 in the range of 0.1–6.5 T. Such dependence has not been reported to the authors' knowledge.

The EL efficiency (η_{ext}) is given by the following:

$$\eta_{ext} = \alpha \times \Phi_{PL} \times \Phi_{exciton} \times \gamma \quad (1)$$

Here, α, Φ_{PL}, $\Phi_{exciton}$, γ are the light extra efficiency, quantum efficiency of organic material, exciton formation efficiency, and carrier balance factor, respectively.

α is related with the magnetic field via Faraday/Kerr effects with interference. The Faraday rotation of the nonmagnetic and thin organic layers is not significant even at 9 T and interference would not change as a function of magnetic field. Thus we can neglect α. The fluorescent in optically excited organic dyes in the magnetic field has been studied in detail [18], but B^2 dependence in high magnetic field was not reported in the literature. Therefore, our result cannot be explained by Φ_{PL}. Since all known mechanism of MFE on $\Phi_{exciton}$ gives concave dependence on *B* as mentioned earlier, we here tentatively rule out the contribution from $\Phi_{exciton}$ as the main mechanism of the present B^2 dependence.

The remaining factor in Eq. (1) is the charge balance factor. We examined various models to relate the MFE on the charge balance factor, and the following is the only model that can barely explain the B^2 dependence. We observed that the conductance of the minority carrier changes linearly as a function of magnetic field as shown in Fig. 6. We considered various models based on our observation (Fig. 7) that the mobility of the minority carrier (μ) depends upon the magnetic field (B) as

$$\mu = \mu_0(1 - aB) \quad (2)$$

where μ_0 and a are materials dependent constants. Since the EL intensity is determined only by the charge balance if the carrier recombination rate is proportional to the radiation [19], Eq. (2) gives the fluorescent efficiency linearly related with B^1. However, our experiments showed that the current remains almost constant as a function of the magnetic field in the mid–high *B* range. We have found that we can deduce the B^2 dependence from Eq. (2) with additional two assumptions. The assumptions are as follows: (i) the emission region is very narrow and only the recombination at this region contributes to the emission. This is reasonable because Alq_3 layer (200 nm) is much thicker than the thickness of emission region of ordinary devices [20]. The interfacial mixing and the damage caused by the electrode formation might also justify this assumption, (ii) the hole current (J_h) and electron current (J_e) are balanced in the emission region when $B = 0$. Since the mobility of the majority carrier is smaller in Alq_3 than α-

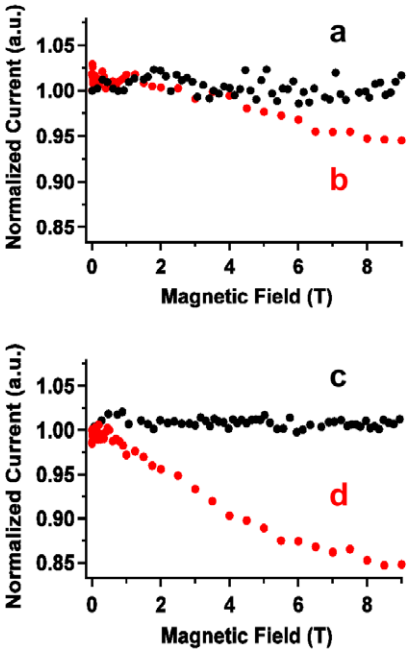

Fig. 7. Magnetic field effect of conductance of unipolar devices (normalized at zero field). (a) Au/α-NPD/Au (holes), (b) Au/Cs/α-NPD/Cs/Au (electrons), (c) Au/Cs/Alq_3/Cs/Au (electrons), and (d) Au/Alq_3/Au (holes).

NPD [21,22], it is believed that the recombination and the emission occurs in Alq_3. This assumption is also reasonable because the device characteristics (Fig. 3), in which turn-on voltage of current is almost the same as that of emission intensity, show that this device has good carrier balance.

Since the current is constant as a function of B, $J_h + J_e$ is constant. From the assumption (ii), $J_h = J_e$ at the emission region when $B = 0$. The emission region is in Alq_3 and Eq. (2) becomes

$$J_h = J_0(1 - aB),$$

where J_0 is a constant.Because $J_h + J_e$ is constant, J_e at the emission region can be written as

$$J_e = J_0(1 + aB).$$

The recombination rate is proportional to $J_h J_e$

$$J_h J_e = J_0^2(1 - aB)(1 + aB) = J_0^2(1 - a^2B^2)$$

and the decrease of the emission proportional to B^2 is explained.

Although this model is based on several assumptions which are not commonly considered so far, we could not think of better ones. We understand that the carrier transport of unipolar devices are not the same as the bipolar devices, for example, charge injection at the electrodes might be strongly involved in the minority carriers. However, our finding of linear MFE on minority carriers has not been reported and no theoretical prediction has been made to the author's knowledge. There might exist other mechanisms which also explain these results, but we hope the present result and discussions may stimulate the study of MFE on organic semiconductors and devices. Although TTA is not likely to work at room temperature and hfc will saturate at relatively low magnetic field, ΔG works at high magnetic field region and might be cooperative with other factors.

There is another mechanism which might explain the B^2 dependence, although it is not consistent with the results on the unipolar devices (Eq. (2)). It is theoretically predicted that the decrease of the conductivity proportional to B^2 is characteristics of magnetoresistance of hopping transport and that it levels off to the B^1 dependence when the magnetic field is high [21]. If it is applicable to the carriers in the emission layer of an OLED, the charge balance of the device will change in the same manner as the conductance and the emission decrease proportional to B^2 will be observed. The difficulty of this model is that we did not see such magnetoconductance in unipolar devices with n-type and p-type organic single layers.

In the range beyond 6.5 T, we observed $B^{1/2}$ dependence (Fig. 5b). In the study of the radical pair in solution, it is known that the density of singlet excitons decreases in proportion to $B^{1/2}$ by Δg mechanism [23]. The magnetoconductance of the minority carriers shown in Fig. 7 start to saturate in the range beyond 6.5 T. Although we do not know the mechanism of this saturation, it might be the reason why $B^{1/2}$ dependence due to Δg mechanism start to appear in this region.

5. Conclusion

We measured EL efficiency of fluorescent and phosphorescent OLEDs in the magnetic field up to 9 T and we found quadratic decrease as a function of the magnetic field between 0.1 and 6.5 T. We also measured magnetoconductance of unipolar devices and observed that only minority carriers show significant magnetoconductance decreasing linearly with the magnetic field (15% at 9 T in Alq_3). $B^{1/2}$ dependence in the range beyond 6.5 T can be explained by MFE on the density of singlet exciton caused by Δg mechanism.

spiro-OMeTAD on top of the TiO_2 film. Immediately after solution deposition, the solution fills the pores effectively, and the filling fraction of spiro-OMeTAD inside the pores is the same as the volumetric concentration of the solution. The wet layer on top of the film then acts as a reservoir to increase the filling fraction beyond the macroscopic solubility of spiro-OMeTAD in the solvent. As the solution evaporates, the concentration of spiro-OMeTAD in the reservoir increases, and more spiro-OMeTAD diffuses into the pores. This infiltration process stops when enough solvent has evaporated for the spiro-OMeTAD to become immobile. For thicker films, the maximum filling fraction is further limited kinetically by the quantity of spiro-OMeTAD that can infiltrate into the pores before the critical solution concentration is reached. The filling fraction of thick films may increase if the solution evaporation is slowed down. Doctor-blading allows for slower solvent evaporation than spin coating because it does not introduce rapid air flow during film deposition. The size of the reservoir on top of the dyed TiO_2 film is very important in pore filling. An under-sized reservoir leads to low filling fraction and over-sized reservoir leads to a thick spiro-OMeTAD overlayer. Both scenarios result in suboptimal charge transport. In developing a new deposition technique for HTMs in ss-DSCs, optimizing the reservoir size is required to maximize performance.

2.2. Effect of solution concentration

The first parameter we varied in optimizing the reservoir size is the spiro-OMeTAD solution concentration. We performed pore filling on TiO_2 films with two different thicknesses (2.5 and 5.0 μm) and compared the filling fraction from doctor-blading and spin coating. The parameters for doctor-blading are documented in the experimental section. The detailed procedure for measuring the filling fraction is reported elsewhere [18]. First, the overlayer thickness is measured with SEM cross-section. Then, the sample is immersed in a known volume of chlorobenzene to dissolve the spiro-OMeTAD out from the pores. The spiro-OMeTAD can be quantified by measuring the absorption in the solution phase.

Fig. 1a and b shows the filling fraction and overlayer thickness of 2.5- and 5-μm thick TiO_2 films as a function of spiro-OMeTAD solution concentration. It shows that a solution concentration below 270 mg/mL results in an under-sized reservoir (evident from the absence of overlayer) and low filling fraction. When the solution concentration was raised above 360 mg/mL, there was a spiro-OMeTAD overlayer on top of TiO_2 film. The formation of an overlayer usually indicates that the filling fraction can no longer be increased by increasing solution concentration [18]. Indeed, when the solution concentration was further

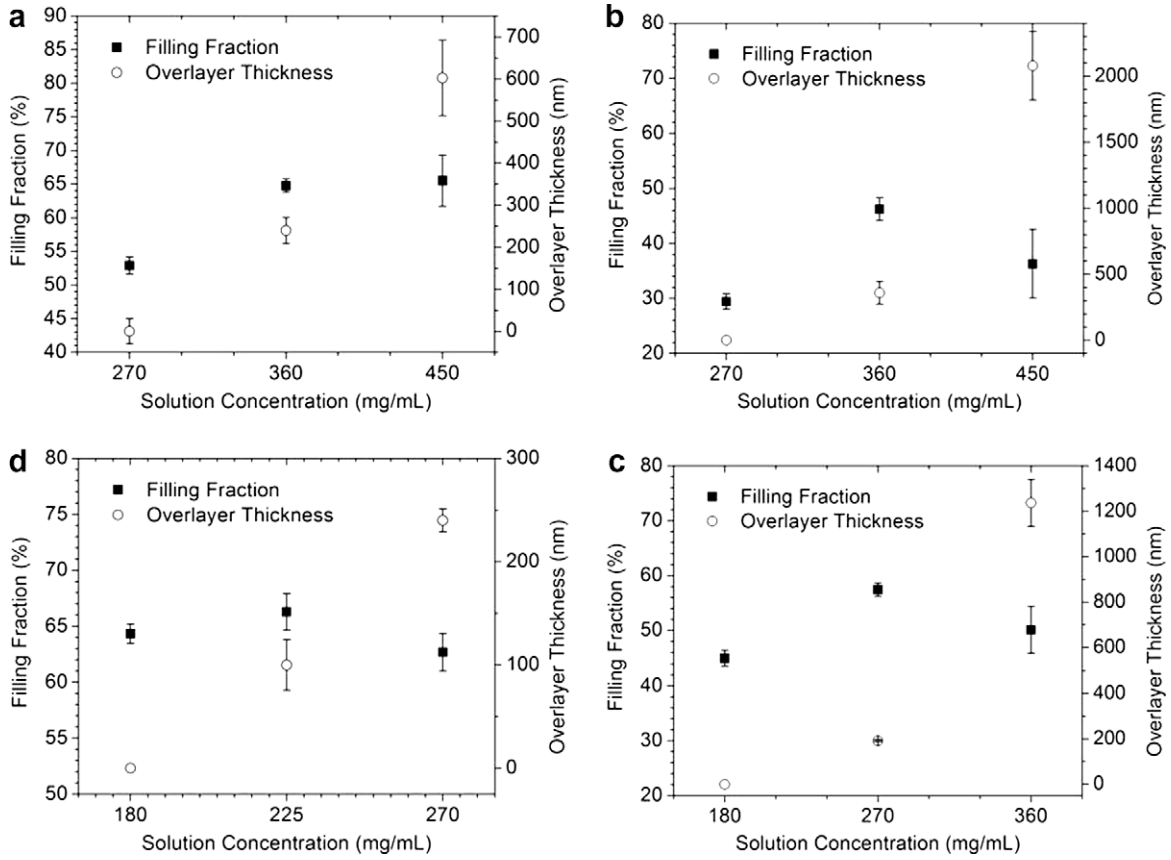

Fig. 1. Filling fractions and overlayer thicknesses of TiO_2 films with two different thicknesses and spiro-OMeTAD deposition techniques. (a) 2.5 μm, doctor-blading; (b) 5.0 μm, doctor-blading; (c) 2.5 μm, spin coating; (d) 5.0 μm, spin coating.

increased to 450 mg/mL, the filling fraction remained relatively constant and the overlayer became much thicker.

The 5-μm thick TiO_2 film infiltrated with 450 mg/mL solution appears to have lower filling fraction than other samples. The reason is as follows: in measuring the filling fraction, the spiro-OMeTAD in the pores is calculated by the total spiro-OMeTAD amount minus the amount presented in the overlayer. When the overlayer thickness becomes comparable with TiO_2 film thickness, any error in overlayer thickness measurement causes large error in the filling fraction.

For comparison purposes, the filling fractions and overlayer thicknesses of samples filled with spin coating are shown in Fig. 1c and d. For spin coating, the optimized solution concentration depends strongly on the TiO_2 film thickness. The optimized solution concentration changed from 180 mg/mL for 2.5-μm thick TiO_2 films to 270 mg/mL for 5-μm thick films. Also, for 2.5-μm thick TiO_2 films, doctor-blading at room temperature can already attain a filling fraction around 65%, which is comparable to the value obtained from spin coating. However, for 5-μm thick TiO_2 films, the filling fraction from doctor-blading at room temperature is lower than that obtained from spin coating. To increase the filling fraction, the spiro-OMeTAD solution is doctor-bladed at elevated temperature.

2.3. Effect of solution temperature

The advantages of doctor-blading at an elevated temperature are twofold: it lowers the solution viscosity and increases the solubility of spiro-OMeTAD in chlorobenzene. Both factors facilitate the infiltration of spiro-OMeTAD and consequently increase the filling fraction.

The effect of increasing the doctor-blading temperature on the filling fraction of 5-μm TiO_2 films is shown in Fig. 2. When the temperature was raised from 20 to 80 °C, the filling fraction increased from 46% to 53%, while the overlayer thicknesses remained relatively unchanged. The filling fraction of 53% at 80 °C is comparable with the value obtained from optimized spin-coating condition as shown in Fig. 1d. We note that increasing the deposition temperature only increased filling fraction for doctor-blading samples and not for spin-coating samples, possibly because spin-coating samples cool much more rapidly. It is conceivable that raising the temperature even higher may further increase filling fraction. However, when the temperature was raised to 100 °C, the rapid evaporation of chlorobenzene made the doctor-blading process hard to control and resulted in non-uniform overlayers. Therefore, we stopped the temperature study at 80 °C and used this temperature in the fabrication of the solar cell.

2.4. Solar cell performance

After deposition of spiro-OMeTAD, the silver electrodes were thermally evaporated onto the sample, and the *J–V* curves of the solar cell were measured under simulated one-sun illumination. Fig. 3 shows the current density–voltage (*J–V*) curves of devices made from doctor-blading and spin coating. The two deposition techniques give approximately equal device efficiencies, which is expected because of the equal filling fractions. Devices from doctor-blading tend to have a slightly higher fill factor and lower open-circuit voltage compared with spin coating. The nature of these differences is outside the scope of this study, but it is possible that these differences resulted from different spiro-OMeTAD overlayer thicknesses of films deposited by doctor-blading and spin coating.

The reproducibility of the device performances from doctor-blading was also tested. For each device thickness, we made at least four identical devices, and the standard deviations of the efficiencies were within 7%. Table 1 compares the average device performances of ss-DSCs made from two spiro-OMeTAD deposition techniques.

In addition to delivering equally efficient devices as spin coating, doctor-blading also uses far less material. The loss of coating solution can be as high as 95% for spin coating [20] and as low as 5% for doctor-blading [21]. The efficient usage of materials by doctor-blading is demonstrated for

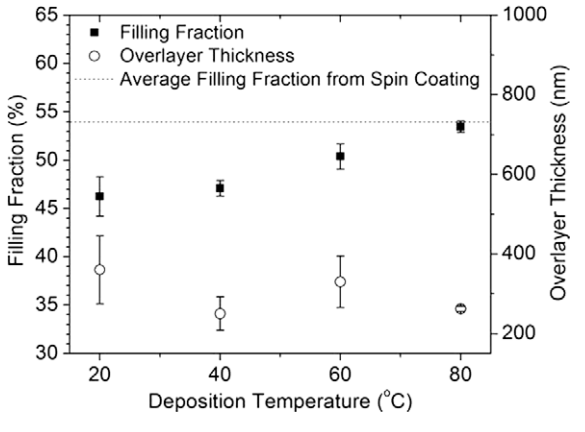

Fig. 2. Filling fractions and overlayer thicknesses of 5-μm thick TiO_2 films doctor-bladed at different temperatures with 360 mg/mL spiro-OMeTAD solution in chlorobenzene. The dotted line indicates the average filling fraction of 5-μm thick TiO_2 films from spin coating.

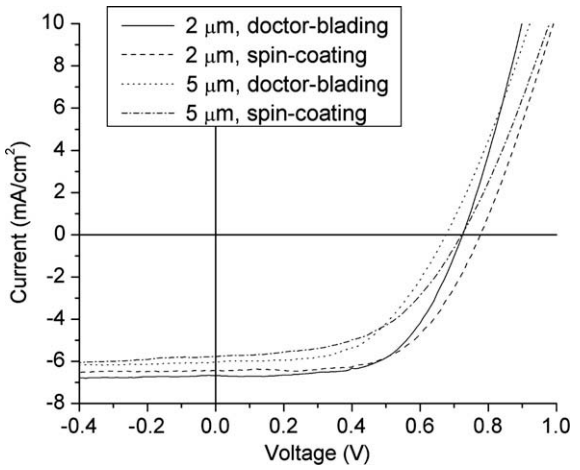

Fig. 3. Current density–voltage (*J–V*) curves of solid-state dye-sensitized solar cells made from doctor-blading and spin-coating spiro-OMeTAD. Two different device thicknesses were tested: 2 and 5 μm.

Table 1
The device performance of ss-DSCs made from spin coating and doctor-blading deposition of spiro-OMeTAD. The values shown above are averaged values and standard deviations of at least four devices made under identical conditions.

	Jsc (mA/cm^2)	Voc (V)	Efficiency (%)	Fill factor
2 μm, doctor-blading	6.86 ± 0.37	0.73 ± 0.01	3.01 ± 0.13	0.61 ± 0.03
2 μm, spin coating	6.80 ± 0.26	0.76 ± 0.03	3.02 ± 0.16	0.58 ± 0.02
5 μm, doctor-blading	5.88 ± 0.45	0.68 ± 0.01	2.13 ± 0.13	0.54 ± 0.02
5 μm, spin coating	5.77 ± 0.90	0.71 ± 0.02	2.00 ± 0.10	0.49 ± 0.04

our relatively small device areas as well. For 5-μm thick TiO_2 films (1.5 cm by 2 cm), we used 35 μL of 270 mg/mL spiro-OMeTAD solution for spin coating, and 10 μL of 360 mg/mL solution for doctor-blading; in this case, doctor-blading uses 60% less spiro-OMeTAD than spin coating. When the device area is further increased, the reduction of material usage by doctor-blading will be much more pronounced.

2.5. Directions to improve filling fraction

The optimized thickness of ss-DSCs is approximately 2 μm due to the compromise between light absorption and charge collection [19]. Devices made with TiO_2 films thicker than 4 μm are usually less than 2% [22]. In contrast, the 5-μm thick ss-DSCs reported here, made from either doctor-blading or spin-coating concentrated spiro-OMeTAD solution, achieved an average efficiency well over 2%. We propose that the improved efficiency results directly from the enhanced filling fraction. When spiro-OMeTAD is deposited on 5-μm thick TiO_2 film by conventional recipe of spin coating a 180 mg/mL solution, the filling fraction is extrapolated to be only 41% [18], much lower than the 53% filling fraction reported in our optimized recipe. This indicates that one of the possible directions of improving the performance of thick ss-DSCs is to increase the filling fraction because higher filling fraction results in better charge collection. However, the fact that 5-μm thick devices still have a lower short-circuit current and open-circuit voltage than 2-μm thick ones means there is room for improvement.

It is instructive to consider what limits the filling fraction at values substantially below unity. For 2-μm films, we found that changing the particle size from 20 to 45 nm does not increase the filling fraction. This indicates the filling fraction for 2 μm films is not limited by the constrictions inside the porous network, but by the viscosity-concentration curve of the spiro-OMeTAD solution. We propose that when the spiro-OMeTAD-chlorobenzene mixture contains 65% spiro-OMeTAD by volume, the viscosity is too high for spiro-OMeTAD to easily diffuse; this is when the infiltration stops. If this hypothesis is right, it has the following implications: (1) solution-based infiltration methods will never be able to achieve 100% filling fraction because there have to be some solvent molecules inside the HTM film to make HTM molecules mobile. Void formation occurs when the solvent molecules evaporates. (2) To get to 100% filling fraction, a solvent-free method such as melt infiltration has to be used [23,24]. Unfortunately spiro-OMeTAD has very high melting temperature (248 °C as determined by differential scanning calorimetry), which makes it impossible to be used for melt infiltration since the sensitizing dye is damaged at this temperature [25]. To get to 100% filling fraction, new HTMs that have lower glass transition temperatures and stay amorphous even when being heated above T_g must be developed [26].

Despite the aforementioned fundamental limitation of spiro-OMeTAD pore filling, the filling fraction for thick films can still be improved by optimizing the solution deposition techniques. It was mentioned previously in Section 2.1 that using doctor-blading to deposit spiro-OMeTAD solution results in a slower evaporation, which gives spiro-OMeTAD more time to infiltrate prior to the drying of solution. In our previous studies, slowing down the evaporation by decreasing the spin-coating speed appears to improve filling fraction [18]. However, in this study, the slightly slower evaporation rate from doctor-blading did not result in substantial increase of filling fraction. A more detailed study on the evaporation rate and its influence on pore filling with doctor-blading deposition will be necessary to further optimize this technique. We have tried treating the deposited spiro-OMeTAD film with solvent vapor to soften the film to enhance diffusion [27], but it led to extensive crystallization of spiro-OMeTAD that can be observed in the optical microscope, which hurts the device performance. Other possible methods to accomplish higher filling fraction include switching to a high boiling point solvents during doctor-blading or spin coating.

3. Conclusions

We have demonstrated the use of doctor-blading to deposit spiro-OMeTAD in solid-state dye-sensitized solar cells. After optimizing the solution concentration and temperature, we achieved an equal pore filling fraction with doctor-blading and spin coating for 2.5 and 5-μm thick films. The efficiencies of devices made with these two deposition techniques are comparable, and the materials utilization of spiro-OMeTAD is significantly better for doctor-blading. This demonstrates the potential for doctor-blading to be used in future commercial production of solid-state dye-sensitized solar cells.

4. Experimental

4.1. Sample preparation

FTO substrates (Hartford Glass TEC 15) were first patterned through etching with Zinc powder and HCl (12%). Then, the substrates were cleaned by sonication sequentially in 10% Extran solution, acetone and isopropanol [28]. Samples used for solar cell measurements were coated with a compact layer of TiO_2 (50 nm) by aerosol spray pyrolysis using air as carrier gas [29]. Mesoporous

TiO_2 films were then deposited from commercially-available paste (Dyesol 18NR-T) using screen-printing. These sheets were slowly heated to 500 °C and baked for 30 min in air. Samples used for solar cell measurements are treated with acidic $TiCl_4$ solution [30] by immersing the samples in 0.02 M $TiCl_4$ aqueous solution overnight at room temperature. The samples were then heated to 450 °C and subsequently cooled to 80 °C before being immersed in Z907 dye solution for 12–18 h. The dye solution comprised of 0.3 mM of Z907 (Solaronix SA) in 1:1 mixture of acetonitrile and tert-butyl alcohol. Prior to making the solution, Z907 dye has been purified by column chromatography following published procedure [31].

4.2. Spiro-OMeTAD infiltration

The formulation of spiro-OMeTAD solution has been published elsewhere [18]. For spin coating, a small quantity (30–50 μL) of the spiro-OMeTAD solution was deposited onto each TiO_2 film (1.5 cm by 2 cm) at room temperature and left for 1 min before spin coating at 2000 rpm for 45 s in air. Doctor-blading was done with a commercially-available machine (CX-4 motorized film applicator, mtv Messtechnik oHG) with blade speed of 15 mm/s. The blade height was controlled by adjusting the screws on the doctor-blade (UA 3000 universal film applicator, mtv Messtechnik oHG). The blade height was 40 μm for TiO_2 films of 2 μm thick, and 80 μm for TiO_2 films of 5-μm thick. The solution (10 μL) was first deposited using a micropipette onto an area of the FTO substrate not covered by TiO_2, then spread onto TiO_2 film with doctor-blade. For the temperature-dependence experiment, we first put the both the spiro-OMeTAD solution and the TiO_2 film on top of a hot plate that has been set to the desired temperature, and let the system equilibrate for 5 min. Then, the TiO_2 film was transferred onto the doctor-blading machine and the solution was immediately deposited. We note that because the doctor-blading machine does not contain a heating element, the true doctor-blading temperature may be slightly lower than the value reported. After spiro-OMeTAD deposition, the film was left to dry overnight in air at room temperature.

4.3. Device fabrication and photovoltaic measurements

For efficiency measurements, silver electrodes (200 nm) were thermally evaporated onto the film under vacuum below 10^{-6} torr.

Current density–voltage (J–V) measurements were carried out with a Keithley 2400 source meter and a 91160 300 W Oriel solar simulator equipped with a 6258 ozone-free Xenon arc lamp and an air mass (AM 1.5 G) filter. The lamp intensity was measured with an NREL calibrated silicon photodiode, with spectral mismatch accounted for.

sensitive to oxidizing species [16,17], even at very low concentrations [18] and insensitive to reducing gases [19]. Among all gases present in atmospheric air, only NO_2 and O_3 induce significant electrical responses [20]. Consequently, these organic materials provide to sensing devices a first level of selectivity.

We have previously demonstrated that the selective and real-time monitoring of O_3 in atmosphere can be achieved using the faster kinetics of reaction between O_3 and copper phthalocyanine (CuPc) thin films as compared to NO_2 [21]. As complementary, the selective measurement of NO_2 could be achieved by means of chemical filters removing O_3 from air sample and being chemically inert toward the target gas. Because of their high reactivity with O_3, organic dyes like indigo and its derivatives are relevant [22–24]. Indeed, the carbon–carbon double bond of indigo molecules strongly reacts with O_3 through an ozonolysis process, leading to the irreversible formation of isatin groups [25]. However, in previous published papers, the use of indigo as filter was limited to cartridges [26] or impregnated membranes placed upstream the sensing device.

This paper is focused on the development of an all-organic gas microsensor dedicated to the selective monitoring of NO_2 at low concentrations. The innovation of this work is based on the realization of indigo thin films by thermal evaporation as integrated O_3 filter onto semiconductor chemical gas sensors. As compared to filtering cartridges, the strong interests of the development of integrated filters are an easiest miniaturization of the device, a higher level of mobility and the possibility to improve filtering efficiency by working at higher temperature not requiring additional heating system.

The filtering yield of indigo powder was firstly established. After filtering film characterization by FT-IR spectroscopy, electrical responses of sensor have been determined toward oxidizing pollutants. The metrological characteristics will be discussed. The influence of indigo film thickness on electrical response was investigated too.

2. Experimental

2.1. Device

The design of the gas sensor is reported in Fig. 1. The sensitive layer is a 300 nm thin film of copper phthalocyanine, CuPc and the filtering membrane consists in a thin film of indigo with thickness in the range 10–100 nm. These two organic layers have been successively realized from commercial powder by thermal sublimations. The deposition processes have been performed by means of a commercial high vacuum thin film evaporator (VE-770, VEECO) into a specific chamber maintained into secondary vacuum (residual pressure close to 2×10^{-6} mbar). Thin film thickness and deposition rate have been measured by in situ quartz crystal microbalance maintained at room temperature and controlled by means of a commercial automatic deposition control system (ADS-220, VEECO). To obtain homogenous thin films, the deposition rate was set to 0.2 nm s^{-1}.

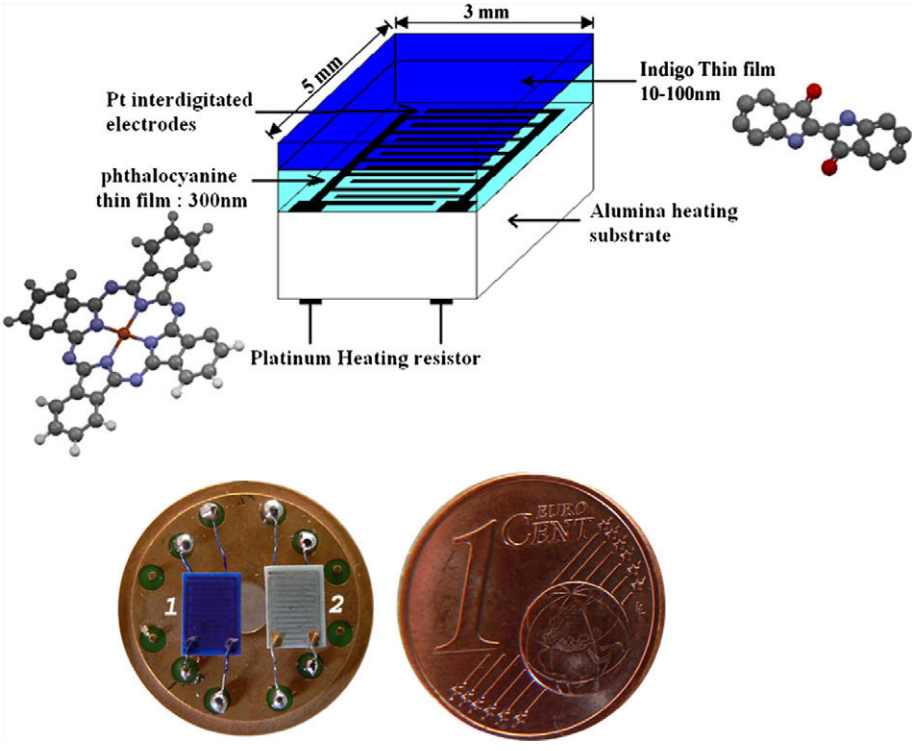

Fig. 1. Scheme of the all-organic sensor structure; (1) CuPc (300 nm)/indigo (50 nm) sensor device; (2) indigo (50 nm) thin film onto alumina substrate with screen-printed interdigitated electrodes.

This organic bi-layer system was realized onto $5 \times 3 \times 0.6\ mm^3$ alumina substrates maintained at room temperature. These substrates included screen-printed platinum interdigitated electrodes on the upper side to measure phthalocyanine electronic conductivity and Pt heating resistor with a predefined thermal coefficient = $2–3 \times 10^{-3}\ °C^{-1}$ on the lower side to control device temperature. No consecutive post-deposition annealing was realized to obtain more sensitive layers [27]. The dimensions of the interdigitated electrodes being perfectly determined (L: length = 25 mm; l_s: inter-electrode space = 0.125 mm), the CuPc electronic conductivity $\boldsymbol{\sigma}$ of thin film with thickness **e** can be determined from electrical current **I** passing through the sensor polarized under bias voltage **U** according to the following equation:

$$\boldsymbol{\sigma} = \frac{\mathbf{I} \cdot l_s}{\mathbf{U} \cdot L \cdot \mathbf{e}} \quad (2)$$

Electrical conductivity being an intrinsic parameter of materials, i.e., both independent from layer thickness, polarization conditions and electrode dimensions, sensor response will be defined as conductivity variations versus time.

2.2. FT-IR characterization

Indigo thin films were investigated and compared to powdered sample by a THERMO NICOLET 5700 FT-IR spectrometer in the range 400–4000 cm^{-1} with 4 cm^{-1} resolution. Thin films were realized by thermal evaporation under secondary vacuum on transparent silicon substrates without any subsequent thermal or gas treatment.

2.3. Gas exposures

For measurements under gas, two experimental test benches have been developed. The first was devoted to the determination of filtering yield of indigo powder towards O_3 and NO_2. Indigo powder was put into a polytetrafluorethylene (PTFE) exposition chamber between two PTFE filter membranes with low porosity (pore size = 5 μm). O_3 was delivered and monitored, respectively, by ozone generator and UV photometric commercial analyzer (ozone analyzer with internal ozone generator Thermo Electron Corporation, model 49i). NO_2 in air was delivered by commercial calibrated cylinders (MESSER France) and monitored by chemiluminescent NO_x analyzer (Thermo Electron Corporation, model 42i). Experiments in a large concentration scale were possible by dilution under pure and dried air by means of mass flow controllers. A three-way solenoid valve driven by an external timer has allowed the cyclic quantification of gas concentrations upstream and downstream the filter and consequently the determination of the filtering yield.

The second experimental bench was devoted to the determination of the sensing performances of all-organic gas sensor prototypes. A schematic representation and a complete description of this apparatus have been already reported [21]. Sensors were put in a PTFE exposure chamber, polarized under 1.5 V d.c. via interdigitated electrodes and regulated at 80 °C. At the chamber output, commercial gas analyzers have monitored in real-time O_3 and NO_x concentrations. Studied concentrations range was 20–200 ppb and all experiments have been realized under dry atmosphere (RH < 2%).

3. Results and discussion

3.1. Filtering efficiency

If the high filtering yield of indigo toward O_3 is well-established, its behaviour toward NO_2 must be determined for such application. Fig. 2 represents the filtering yield of indigo powder at room temperature versus gas concentration for NO_2 and O_3 exposures. The filtering yield $\boldsymbol{\eta}$ and its uncertainty are then defined by the following equations:

$$\boldsymbol{\eta} = (C_{\text{upstream}} - C_{\text{downstream}})/C_{\text{upstream}} \quad (3)$$

$$\Delta\boldsymbol{\eta} = \boldsymbol{\eta} \cdot \frac{C_{\text{upstream}} \cdot \Delta C_{\text{downstream}} + C_{\text{downstream}} \cdot \Delta C_{\text{upstream}}}{C_{\text{upstream}}(C_{\text{upstream}} - C_{\text{downstream}})} \quad (4)$$

with concentration uncertainties (ΔC) determined according to analyzer manufacturer data. Taking into account the determination method of yield uncertainty, this later is obtained in the worst case and obviously overestimated.

The great reactivity of indigo with O_3 molecules is confirmed by the high filtering yields in the overall investigated concentration range. Whatever the concentration, the O_3 filtering yield remains constant at 99%. Taking into consideration the value with their errors, the filtering yield of indigo is close to 100%.

For NO_2, the filtering yield is between (5 ± 5)% and (8 ± 2)%, the highest yields being determined at the highest concentrations. The highest errors are obtained at lowest concentrations and are intrinsic to the commercial analyzers. Thus, between 20 and 200 ppb, a concentration range commonly measured in urban atmosphere, indigo powder exhibits total ozone filtering with a high level of selectivity. After 100 ppm h of gas exposure, this trend remains unaltered.

3.2. IR characterization of indigo thin film

Thermal evaporation is a simple method to realize thin films. Nevertheless, it's necessary to check that no chemical decomposition occurs during the thermal process. Therefore, just after thermal evaporation, the nature of the thin films was characterized by FT-IR spectroscopy. Fig. 3 represents IR spectra of powder and of as-prepared 50- and 100-nm thick films of indigo in the 400–3500 cm^{-1} range. No major difference is noticed between spectra obtained with 50 nm of indigo and with 100 nm. So, the thickness is not influent on the chemical composition of the layer. Moreover, spectra of powder and films are closely similar. Both wavenumbers and relative intensities of the various vibration bands being similar, chemical bonding and molecular interactions are nearly similar in the powdered and layered samples. That justify that the powder and the thin films correspond to the same material. So, indigo molecules are not altered by its thermal sublimation. The most important difference between

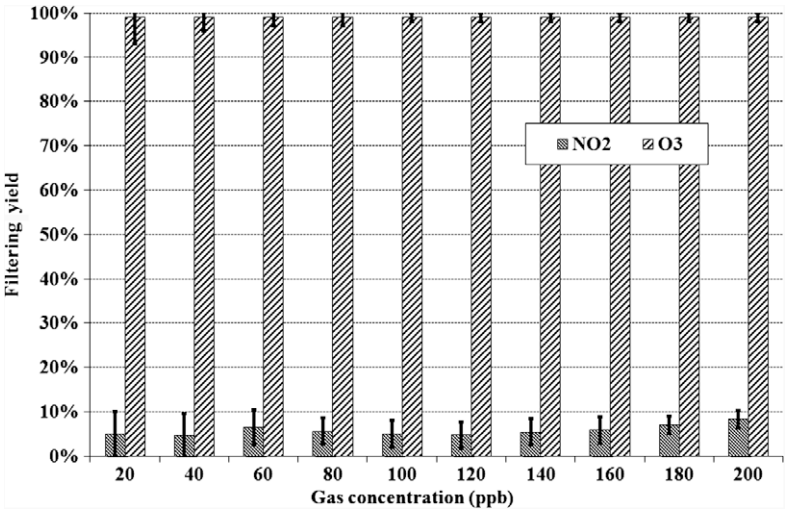

Fig. 2. Filtering power of indigo powder versus nitrogen dioxide (NO_2) and ozone (O_3) concentrations in the 20–200 ppb range, determined at room temperature.

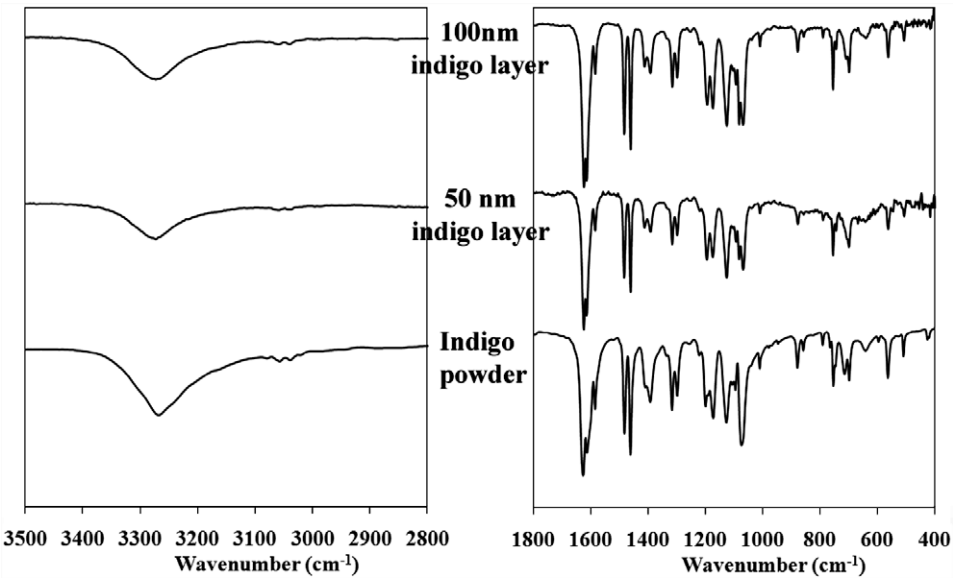

Fig. 3. FT-IR spectra of indigo powder, 50 and 100 nm as-prepared thin films on transparent Si in the 400–3500 cm^{-1} range.

powder and thin films appears on the spectra at 1060–1100 cm^{-1}. Such disparity can be attributed to carbon–oxygen bonds. This is interpreted as a weak unintentional oxidation of indigo layers by atmospheric air before FT-IR analysis. Nevertheless, this phenomenon of weak extend should be mainly localized at the surface [17].

3.3. Gas responses

To reach a NO_2 selective response, it becomes necessary to optimize the indigo layer thickness. Indeed, a too thin filtering film would induce a non-negligible sensor response to O_3 while a too thick film could prevent the diffusion of NO_2 molecules to the sensing element inducing low sensor sensitivity. Fig. 4 represents the conductivity variations versus time of 300 nm CuPc layer with and without additional upper indigo layer, exposed to 75 ppb of ozone during 2 h with consecutive return under purified air. Two thicknesses have been reported, i.e., 10 and 50 nm, and experimental results were obtained for sensors maintained at 80 °C. This figure highlights various phenomena occurring on the devices. During the initialization stage, the initial electrical conductivity of copper phthalocyanine sensitive film determined under purified air decreases with indigo thickness. The authors interpret this behaviour as a protection effect of the sensitive film by the filtering layer. Indeed, the conductivity of metallophthalocyanines is predominantly extrinsic and due to

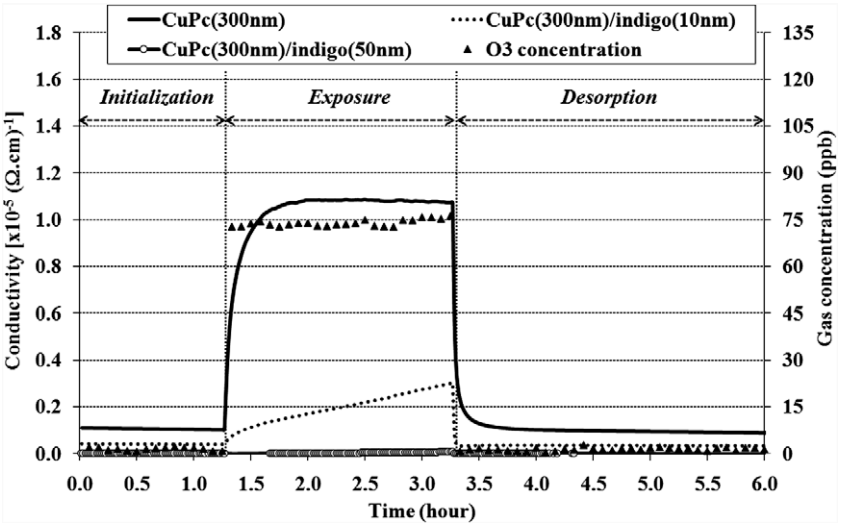

Fig. 4. Electronic conductivity versus time of CuPc (300 nm) thin film with and without upper integrated indigo filtering layer exposed to 75 ppb of ozone in purified air at 80 °C.

doping process by oxidizing species like O_2, NO_2 and O_3. In our case, because the devices were not maintained in confined atmosphere prior to tests under gas, indigo thin film prevents the non-intentional exposure of CuPc to O_3 and therefore, contributes to lower value of initial conductivity. Thicker is the filtering layer, lower is the initial conductivity.

During exposure, whereas for 10 nm indigo film sensor response is strongly reduced, no significant response toward O_3 was measured above 50 nm. This thickness is sufficient to prevent the diffusion of ozone through the filtering layer to the sensitive element and to involve all O_3 molecules in ozonolysis reaction with indigo molecular units. Moreover, during desorption step, the conductivity measured after exposure remains constant and equal to the initial value. So, the reaction products of ozonolysis, i.e., isatin groups, have no influence on the electrical conductivity of the sensitive film. As a consequence, integrated indigo thin film with thickness as high as 50 nm acts as a total O_3 filter and no sensor response is measured when this pollutant is present in air.

To demonstrate the selectivity of our all-organic device, sensor responses for the target and major interfering gases, obtained in the same working conditions, have been compared. Fig. 5 represents conductivity variations versus time of CuPc (300 nm)/indigo (50 nm) bi-layer structure maintained at 80 °C and consecutively exposed to the same NO_2 and O_3 increasing concentrations during

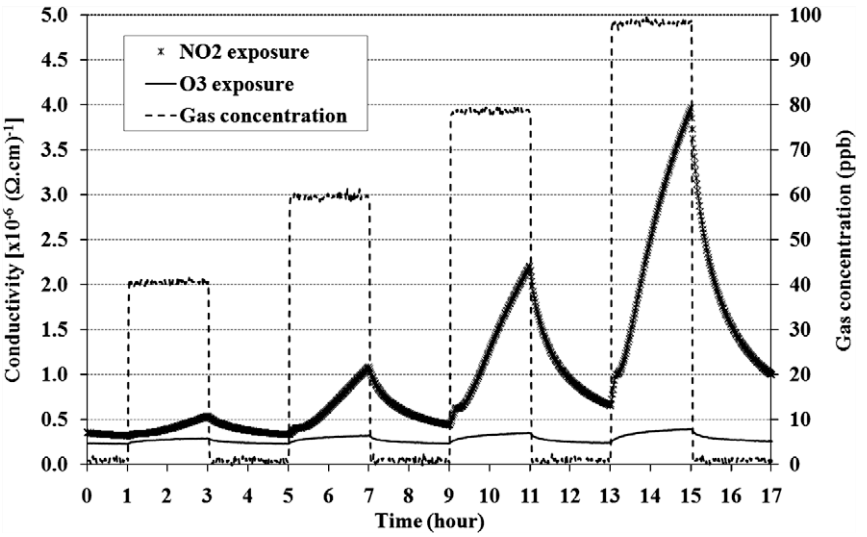

Fig. 5. Time dependence of the electronic conductivity of CuPc (300 nm)/indigo (50 nm) sensor structure exposed to the same NO_2 (⁎) and O_3 (▬) concentrations between 40 and 100 ppb at 80 °C with consecutive return under purified air.

2 h. After each exposure, sensor was maintained at the same temperature under purified air during 2 h too. During experiments, gas concentrations at the output of the exposure chamber were monitored by commercial gas analyzers and are reported on the right scale. Results illustrated by Fig. 5 emphasize the high sensitivity to low NO_2 concentrations. The electrical conductivity increases by 70% for 40 ppb as compared to initial value determined before gas submission and is multiplied by 6 for 100 ppb. Moreover, the signal/noise ratio is high. That implies a threshold of detection lower than 40 ppb and a resolution lower than 20 ppb. But the better improvement remains the selectivity toward NO_2 due to the high O_3 filtering yield of indigo. For comparison, conductivity variation due to 40 ppb of NO_2 is three times greater than this induced by the same concentration of ozone. For 100 ppb, this ratio increases to 23. Nevertheless, the shape of the conductivity versus time curves (Fig. 5) indicates low kinetics of adsorption and desorption. This results in longer response and recovery times and could be an important disadvantage for the NO_2 monitoring application in atmosphere. Such problem can be easily resolved by the implementation of a judicious methodology of measurement already experimented in previous works [28].

4. Conclusion

The efficient measurement of NO_2 in air has been successfully performed by the development of an original all-organic gas sensor. The judicious choice of CuPc as the sensitive material provide to our device a partial selectivity toward oxidizing gases because its electrical conductivity is only influenced by these species. Moreover, a low threshold of detection and a high resolution are obtained due to the high sensitivity of CuPc to NO_2 and O_3. The high level of selectivity to NO_2 is due to the relevant use of indigo and its ability to filter selectively O_3 as experimentally established in this work. Indigo thin layers with controlled thickness can be easily realized by thermal evaporation without chemical alteration as demonstrated by FT-IR analysis. As a result, CuPc-based NO_2 sensors with integrated O_3 filtering thin film exhibit selective responses at low concentrations, a threshold of detection to few ppb and a high resolution lower than 20 ppb. Real-time measurements could be easily obtained by the implementation of a judicious methodology already experimented. The very high resistivity of indigo thin films allows their integration on sensing devices avoiding short-circuits. Thus, it constitutes an universal ozone chemical filter for all types of semiconductor gas sensors and generally, for various electronic devices.

using a combination of p-type and n-type inorganic metal oxides as a middle connection unit in tandem polymer PV cells and investigating the origin of V_{OC} in tandem PV cell. Herein, we fabricate tandem polymer PV cells using a combination of TiO_x and MoO_3 as a middle connection unit to link the two subcells. It is found that inserting a thin Al layer between the TiO_x and MoO_3 layers realizes tandem PV cells and the V_{OC} of the tandem cell is summation of the two subcells. The origin of V_{OC} in tandem PV cells is discussed.

2. Experimental details

Fig. 1 shows the designed device structure of the tandem polymer PV cell and the chemical structures of active materials used in this study. The blends of poly(3-hexylthiophene) (P3HT)/[6,6]-phenyl C61-butyric acid methyl ester (PCBM) and of poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b′]dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBT)/[6,6]-phenyl C71-butyric acid methyl ester ($PC_{70}BM$) are used as the active layers in subcells, respectively. PCPDTBT is a kind of low-band-gap conjugated polymer, and its lowest unoccupied molecular orbital (LUMO) and highest occupied molecular orbital (HOMO) levels are −3.6 and −5.3 eV respectively [20]. The dominant absorption of PCPDTBT is located at the region of 600–900 nm. The absorption of P3HT:PCBM (1:0.8 in weight ratio) and PCPDTBT:$PC_{70}BM$ (1:3 in weight ratio) blends are shown in Fig. 2. The absorption of P3HT:PCBM blend film dominates at the range of 500–650 nm, which is complementary to the absorption of PCPDTBT:$PC_{70}BM$ blend film. The indium tin oxide (ITO)-coated glass with a sheet resistance of 10 Ω/square was used as the substrate. A 40-nm-thick PEDOT:PSS (Baytron P AI 4083) layer was spin-coated onto the ITO glass substrate to serve as an anode buffer layer. The sample was then baked at 120 °C for 30 min in an oven. A P3HT:PCBM blend layer (1:0.8 in weight ratio, 100 nm) was spin-coated on PEDOT:PSS layer from chlorobenzene solution in glove box to serve as an active layer in bottom subcell. An electron-transporting layer of TiO_x (9 nm) was deposited on top of the P3HT:PCBM layer by means of sol–gel chemistry from ethanol solution of tetrabutyl titanate ($Ti[OC_4H_9]_4$) precursor. The film is subjected to hydrolysis to form a TiO_x layer (the ratio of Ti to O is 1:1.74). The sample was then annealed at

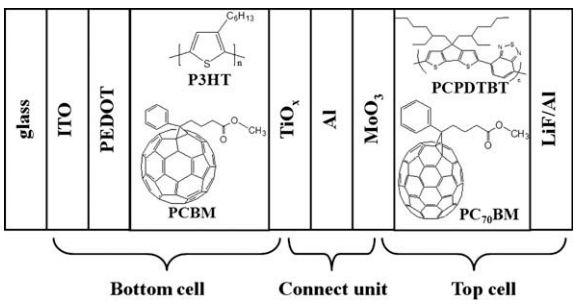

Fig. 1. The tandem PV cell architecture and the active materials used in this study.

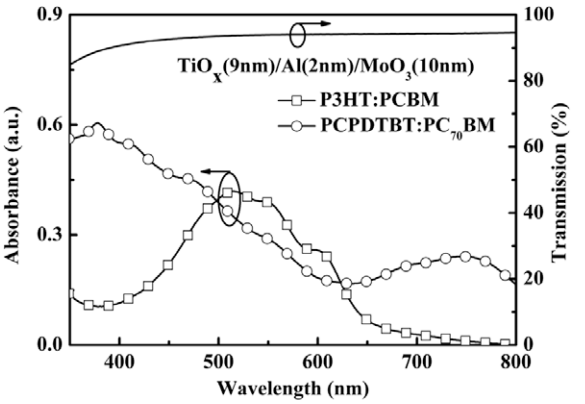

Fig. 2. Transmittance of the middle connection unit with a structure of TiO_x (9 nm)/Al (2 nm)/MoO_3 (10 nm), and absorbance of the P3HT:PCBM (1:0.8, 100 nm) and PCPDTBT:$PC_{70}BM$ (1:3, 100 nm) blend film.

150 °C for 10 min in glove box. The Al (2 nm)/MoO_3 (10 nm) layers were thermally deposited onto the TiO_x layer *in vacuo* at a pressure of about 4×10^{-4} Pa. A PCPDTBT:$PC_{70}BM$ blend (1:3 in weight ratio) layer was spin-coated on the MoO_3 layer from chlorobenzene solution to serve as an active layer in the top subcell. Finally, the LiF (1 nm)/Al (100 nm) electrode was thermally deposited. The devices were annealed at 160 °C for 5 min inside glove box and encapsulated for measurement. The active area of the PV cells was about 0.12 cm^2.

Current density–voltage (*J–V*) characteristics of the PV cells were measured using a computer-controlled Keithley 236 source meter in the dark and under AM1.5G illumination from a calibrated solar simulator with an irradiation intensity of 100 mW/cm^2. Ultraviolet photoelectron spectroscopy (UPS) was carried out using Thermo ESCALAB 250 surface analysis system equipped with a He-discharge lamp providing He–I photons of 21.22 eV. The absorption and transmission measurement was performed using Shimadzu UV-3600 spectrophotometer.

3. Results and discussion

In order to investigate influence of the middle connection unit on the PV performance of tandem polymer PV cell, the tandem cells with P3HT:PCBM blend as the active layers in subcells are fabricated. For tandem polymer PV cells with two subcells being linked in series, the middle connection unit should act as a recombination site for electrons and holes photo-generated in bottom and top subcells. The PV performance of the tandem polymer PV cells with TiO_x/MoO_3 as a middle connection unit is summarized in Table 1. The TiO_x layer in the middle connection unit serves as an electron-collecting layer in bottom cell since its LUMO level is −4.4 eV, providing an Ohmic contact with the LUMO of PCBM (−4.3 eV) for electrons generated in the bottom subcell. The MoO_3 with a HOMO level of −5.4 eV serves as a hole-collecting layer in top subcell. However, the tandem PV cell with TiO_x (18 nm)/MoO_3 (10 nm) as a middle connection unit merely shows a V_{OC} of 0.51 eV, close to its single active layer PV cells. It indi-

Table 1
PV performance of the tandem polymer PV cells based on P3HT:PCBM blend with different middle connection units.

TiO_x/Al/MoO_3 (nm)	V_{OC} (V)	J_{SC} (mA/cm^2)	FF	PCE (%)	R_S (Ω cm^2)
18/0/10	0.51	2.66	0.29	0.40	671
18/2/12	1.04	2.17	0.23	0.52	52
18/2/10	1.02	2.69	0.23	0.63	55
18/2/8	0.84	1.97	0.30	0.49	189
9/2/10	1.03	3.74	0.39	1.50	30
6/2/10	0.86	0.78	0.39	0.26	610

cates that the tandem architecture is not well realized and there exists large V_{OC} loss. While the tandem PV cell with a structure of TiO_x (18 nm)/Al (2 nm)/MoO_3 (10 nm) as the middle connection unit demonstrates well tandem effect as shown in Table 1, which shows a V_{OC} of 1.02 V, much higher than that of the tandem cell with TiO_x (18 nm)/MoO_3 (10 nm) as the middle connection unit. The series resistance (R_S) of the tandem PV cells is decreased from 671 to 55 Ω cm^2 by inserting a thin layer of Al (2 nm) between the TiO_x and MoO_3 layers. It may be attributed that the thin Al layer acts as an efficient recombination site for holes and electrons generated in the two subcells. The tandem PV structure is well established with TiO_x/Al/MoO_3 as the middle connection unit since V_{OC} of the tandem PV cell is double of V_{OC}s in P3HT:PCBM blend PV cells [21]. The thicknesses of TiO_x and MoO_3 layers in the middle connection unit are optimized for achieving best PV performance and the results are also summarized in Table 1. The tandem PV cell with optimized TiO_x (9 nm)/Al (2 nm)/MoO_3 (10 nm) as the middle connection unit shows a V_{OC} of 1.03 V, a short-circuit current (J_{SC}) of 3.74 mA/cm^2, and a fill factor (FF) of 0.39. The values give an overall PCE of 1.5%. The tandem PV cell with TiO_x (9 nm)/Al (2 nm)/MoO_3 (10 nm) structure shows a smallest R_S of 30 Ω cm^2 among these PV cells. Further increasing the thicknesses of TiO_x or MoO_3 would increase R_S of PV cells. However, decreasing their thicknesses also increases R_S of the tandem PV cell, together with decreased V_{OC} and J_{SC}. This may be attributed to that the spin-coated 6-nm-thick TiO_x layer after hydrolysis is not a continuous film, which may result in the active layer of the bottom cell is in contact with the MoO_3 layer or the active layer of the top cell is directly in contact with the TiO_x layer. Hence, the function of the TiO_x/Al/MoO_3 structure is weakened and the formed reverse current would reduce the PV performance of the tandem PV cell. Transmittance of the TiO_x (9 nm)/Al (2 nm)/MoO_3 (10 nm) structure is shown in Fig. 2. It can be seen that the TiO_x (9 nm)/Al (2 nm)/MoO_3 (10 nm) structure shows a transmittance higher than 95% in the range of 400–800 nm due to wide band-gap of TiO_x and MoO_3. The high transmittance of the middle connection unit may favor the incident light passing through it and being absorbed efficiently by the top subcell.

As demonstrated above, the V_{OC} of the tandem PV cells is dramatically increased by replacing the TiO_x/Al/MoO_3 structure for the TiO_x/MoO_3 structure. It is speculated that the energy level alignment at TiO_x/MoO_3 interface may play an important role in determining the final V_{OC} of the tandem PV cell. In order to explore the underlying physical mechanism, UPS measurements were conducted for the TiO_x, TiO_x/MoO_3 and TiO_x/Al/MoO_3 films that were deposited on silicon substrate to determine the electronic structures at the TiO_x/MoO_3 and TiO_x/Al/MoO_3 interfaces. Since the TiO_x layer is prepared via spin-coating and it is difficult to measure *in situ* the electronic structure at the TiO_x/MoO_3 and TiO_x/Al/MoO_3 interfaces via sequential deposition of each layer, individual samples of the TiO_x, TiO_x/MoO_3 and TiO_x/Al/MoO_3 films are prepared and measured under same condition for comparison. The proposed energy level diagrams at the TiO_x/MoO_3 and TiO_x/Al/MoO_3 interfaces are shown in Fig. 3. The values of HOMO for TiO_x and MoO_3, the work function (E_F) for Al, and the vacuum level for each material were extracted from the UPS spectra. The values of LUMO for TiO_x and MoO_3 were determined from UPS spectra together with their absorption spectra. Compared to the vacuum level of TiO_x layer, the vacuum levels of MoO_3 in the TiO_x/MoO_3 and TiO_x/Al/MoO_3 structure shift upwards 0.34 and 0.84 eV, respectively. The vacuum level shift results in the offset changes between the LUMO of TiO_x and HOMO of MoO_3. As shown in Fig. 3(a), there is an offset of 0.66 eV between the LUMO of TiO_x and HOMO of MoO_3 for the TiO_x/MoO_3 structure. Such a large offset would result in a large V_{OC} loss during charge recombination for the tandem polymer PV cells. When a thin layer of Al is inserted between the TiO_x and MoO_3 layers, the electronic levels at the TiO_x/MoO_3 interface are realigned due to negative charge transfer from Al to MoO_3 as shown in Fig. 2(b), and the offset between the LUMO of TiO_x and HOMO of MoO_3 is reduced to 0.16 eV. The small offset between the LUMO of TiO_x and HOMO of MoO_3 reduces energy loss when the photo-generated electrons and holes in the subcells recombine in the middle connection unit, and hence the V_{OC} of the resulted tandem polymer PV cells is enhanced.

The tandem polymer PV cells with the blends of P3HT:PCBM and PCPDTBT:PC_{70}BM as the active layer in the two subcells are fabricated by using the TiO_x (9 nm)/Al (2 nm)/MoO_3 (10 nm) structure as a middle connection unit. The complementary absorption of the P3HT:PCBM

and PCPDTBT:PC_{70}BM blends covers the whole visible region. The single active layer PV cells with structures of ITO/PEDOT (40 nm)/P3HT:PCBM (100 nm)/TiO_x (9 nm)/Al (100 nm) and ITO/MoO_3 (10 nm)/PCPDTBT:PC_{70}BM (100 nm)/LiF (1 nm)/Al (100 nm) were also fabricated for comparison studies. The illuminated *J–V* characteristics of the tandem PV cell and the two single active layer PV cells under 100 mW/cm^2 AM 1.5G illumination are shown in Fig. 4, and their PV parameters are summarized in Table 2. It can be seen that the V_{OC} of the tandem PV cell is 1.12 V, which is nearly the sum of the V_{OC}s of the two subcells (0.56 and 0.60 V), indicating that the TiO_x (9 nm)/Al (2 nm)/MoO_3 (10 nm) structure is a kind of good candidate for the middle connection unit in tandem polymer PV cells. The J_{SC} of the tandem PV cell is about 5.51 mA/cm^2, lower than each single PV cell based on different active layers. This may be attributed to that the partial overlapped absorption of the P3HT:PCBM and PCPDTBT:PC_{70}BM films at the visible region and the optical field redistribution in the tandem structure when the two cells are stacked. The overall PCE of the tandem PV cell is 2.92%, higher than those of the single active layer PV cells (2.37% and 1.97%). The PCE of the tandem PV cell is expected to be further enhanced if the morphology of the P3HT:PCBM and PCPDTBT:PC_{70}BM blends is well optimized and the photocurrent of the two subcells is well matched.

4. Conclusion

In summary, we developed a kind of highly transparent middle connection unit for tandem polymer PV cells, which consists of an electron-transporting TiO_x, a thin Al layer and a hole-transporting MoO_3 layer. The open-circuit voltage origin of the resulted tandem PV cells is demonstrated. It is found that the thin Al layer inserted between the TiO_x and MoO_3 layers not only provides an efficient recombination site for electrons and holes photogenerated in the two subcells, but also realigns the electronic energy levels at the TiO_x/MoO_3 interface to increase the open-circuit voltage of the tandem PV cell.

future application as the active semiconductor in circuits fabricated on flexible substrates. It is not surprising therefore that increasing interest has been shown in films composed of blends of small molecules in a host polymer matrix. Of particular interest are blends in which the small molecule undergoes phase-segregation after deposition, yielding a stratified layer of the semiconductor at the surfaces of the binder. Madec et al. [8,9] have shown that such behaviour occurs in blends of TIPS-pentacene in semicrystalline, side-chain aromatic insulating binders such as isotactic polystyrene (iPS) and isotactic poly(α-vinyl naphthalene) (iPVN). Significantly, TFTs fabricated from such blends retained high saturation hole mobility down to 10 wt.% of the active material [8,9]. In the case of TMTES, we believe that the naphthalene pendant core of iPVN enhances π–π stacking. Furthermore, the tacticity of the binder has an influence on phase segregation in favour of stratification, thus enriching the active interface with the organic semiconductor species [8]. An atactic binder on the other hand, due to strong interaction between the components rather than weaker Van der Waals interaction associated with iPVN, results ultimately in an amorphous glass that does not exhibit transistor action.

While the primary focus of the investigation reported here was to establish the performance of organic TFTs formed from a blend of TMTES-pentacene in the binder iPVN over a wide temperature range, the study provided evidence for the robustness of devices formed from such blends when subjected to thermal stress, which could prove beneficial for integration in the R2R process.

2. Experimental

The synthesis of TMTES-pentacene has been fully described elsewhere [7]. A blend composed of 50 wt.% of TMTES-pentacene in iPVN was made by mixing equal volumes of freshly prepared stock solutions (1% w/w in tetralin) of TMTES-pentacene and iPVN. TFTs were fabricated as discrete, bottom-gate, top contact transistors on silicon dioxide thermally grown on heavily doped, silicon wafers (see inset of Fig. 4). The oxide was 300 nm thick and after cleaning for 15 min each in de-ionised water, methanol and acetone was immersed in a 10 mM solution of octadecyl trichlorosilane in anhydrous toluene for 20 min at 60 °C. After drying the substrates on a hot-plate for 2 h in air at 120 °C, aliquots of the pure TMTES-pentacene or the blend were drop-cast onto the pre-treated oxide, and dried at room temperature under normal atmosphere. Then the substrates were left under vacuum overnight to remove any entrapped solvent. Film quality for the blend-based devices was good with no sign of de-wetting from the surface. Gold source and drain electrodes, 50 nm thick, were thermally evaporated at a pressure of 10^{-6} mbar through a shadow mask defining 9 transistors per substrate each with a channel 60 μm long and 2 mm wide.

Device characteristics were measured several days after fabrication, initially in air in the dark, using a Keithley Model 4200 Semiconductor Characterisation System. Subsequently, the devices were placed in an Oxford Instruments Cryostat and their characteristics measured over the temperature range 353 K to 153 K under a vacuum of $\sim 10^{-5}$ mbar. Voltages V_G and V_D were applied to the gate and drain electrodes, respectively with the source grounded. Device current, I_D, was measured at the drain. Output characteristics were obtained first, followed by the transfer characteristics. Except for a few cases, the voltage sweeps were started from zero.

Atomic force microscope (AFM) images were obtained using a XE100 AFM (PSIA Inc, Seoul, Korea) in the non-contact mode at a scan rate of 0.3 Hz. The silicon cantilever had a nominal spring constant of 40 N/m, a resonant frequency of 325 kHz and an aluminium coating on the back to increase signal feedback. Topography and phase images were recorded simultaneously.

3. Results and discussion

Typical output characteristics of pure TMTES-pentacene and iPVN–TMTES-pentacene transistors, measured at room temperature in air, are given by the continuous curves in Fig. 1a and b, respectively. Both device types exhibit behaviour consistent with the standard equations for TFTs in the linear and saturation regimes, namely,

$$I_D = \frac{W}{L}\mu C_{OX}\left[(V_G - V_T)V_D - \frac{1}{2}V_D^2\right] \quad (1)$$

and

$$I_{Dsat} = \frac{W}{2L}\mu_{sat} C_{OX}(V_G - V_T)^2 \quad (2)$$

respectively, where W and L are the width and length of the channel region, μ and μ_{sat} the mobilities in the linear and saturation regimes, respectively, C_{OX} the oxide capacitance per unit area, and V_T the threshold voltage. The performance of the pure material was clearly superior to that of the blend, showing a saturation mobility, μ_{sat}, $\sim$0.3 $cm^2/V\,s$ for (V_G = 30 V) compared with $\sim$0.07 $cm^2/V\,s$ in the blend for the same applied voltage. This is not surprising given the structural differences in the deposited films highlighted by the AFM phase images in Fig. 2. Here are shown films of (a) the pure TMTES-pentacene and (b) the iPVN–TMTES-pentacene blend prepared utilising the same drop-casting technique used for TFT fabrication. The pure material crystallised into flat, interconnected platelets while the blend phase-separated into TMTES-pentacene-rich regions characterised by a feathery morphology separated by narrow, electrically more insulating iPVN-rich regions. Although device currents were generally lower in the blend, the presence of iPVN did confer some compensating benefits. For example, it improved the temperature stability of devices (demonstrated below) and increased the apparent ON–OFF ratio of devices. Lateral conduction through the unpatterned, more conductive pure TMTES-pentacene film led to high gate leakage through regions of gate oxide remote from the TFT under test. As a result, OFF currents were several orders of magnitude greater than for an iPVN–TMTES-pentacene TFT measured under the same conditions.

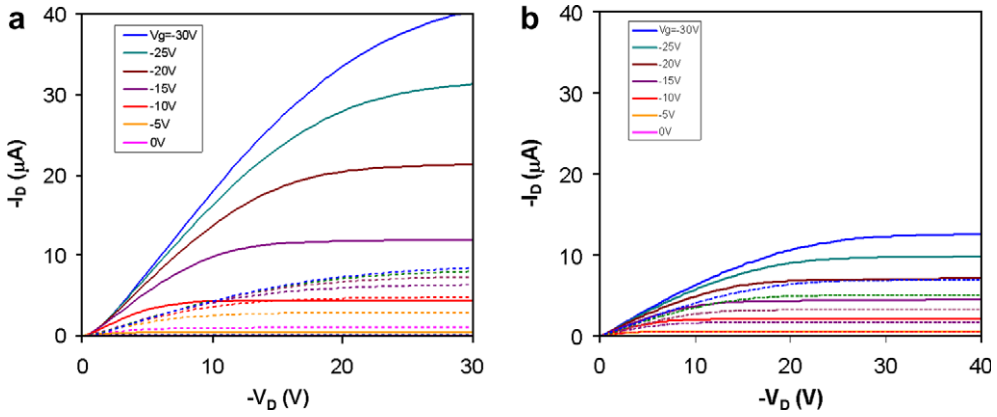

Fig. 1. Output characteristics of a TFT fabricated from (a) pure TMTES-pentacene and (b) TMTES-pentacene: iPVN blend, measured at 293 K in air (continuous curves) and in vacuum (dashed curves).

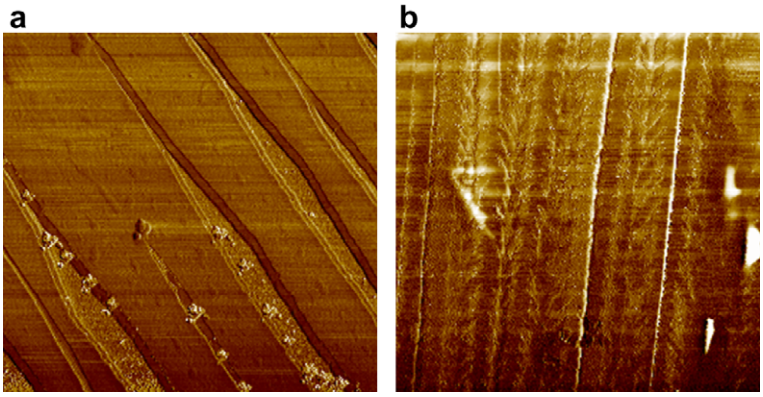

Fig. 2. AFM phase images of (a) a pure TMTES-pentacene and (b) iPVN–TMTES-pentacene films prepared following the same drop-casting and spreading procedures used for fabricating OFETs. The feathery regions in the blend are TMTES-pentacene-rich regions separated by narrow, bright iPVN-rich regions. The images are both 20 μm × 20 μm.

Interestingly, after several hours under vacuum, I_D decreased for both device types although the effect was greater for the pure semiconductor. Consequently, there was little difference in the output characteristics of the two device types measured under vacuum (Fig. 1 dashed curves), with $\mu_{sat} \sim 0.06$ cm^2/V s for pure TMTES-pentacene and $\sim$0.04 cm^2/V s in the blend. It seems, therefore, that exposure to atmosphere is important for achieving the highest performance in TMTES-pentacene devices. That both device types perform better in air than in vacuum points to oxygen doping of the semiconductor as reported for other organic semi-conductors [10]. The blend appears to be less sensitive, presumably owing to the encapsulation of the TMTES-pentacene by the iPVN.

A set of measurements was then taken starting at 353 K and ranging down to 153 K before warming the devices slowly to room temperature overnight for further characterisation (Fig. 3). A significant difference in behaviour was then observed. The iPVN–TMTES-pentacene device recovered its previous performance, albeit with a small shift in threshold voltage. The pure TMTES-pentacene device suffered permanent degradation (dashed curves in Fig. 3c) with μ_{sat} now reduced by more than an order of magnitude to $\sim$0.003 cm^2/V s. Indeed several such devices failed completely, particularly at low temperatures. In this context, differential scanning calorimetry measurements in the range from room temperature down to −100 °C proved interesting. Samples of pure TMTES showed a reversible phase transition near −80 °C which was absent in the blend. Anthony and co-workers [11] in their study of the phase change in TIPS pentacene at $\sim$124 °C observed that even though the change of polymorph was reversible upon thermal cycling, crystals still showed signs of thermal stress as evidenced by the presence of long fracture lines along the slip axis of the crystal. When these macro defects are present the mobility of the devices can drop by several orders of magnitude because of disrupted charge flow. We suggest that iPVN has a protective effect by preventing the low temperature phase change and the associated physical modification in the TMTES.

Owing to the unreliability of pure TMTES-pentacene devices, the remainder of this study focused only on TFTs fabricated from the blend. These devices retained excellent device characteristics with good saturation over a wide

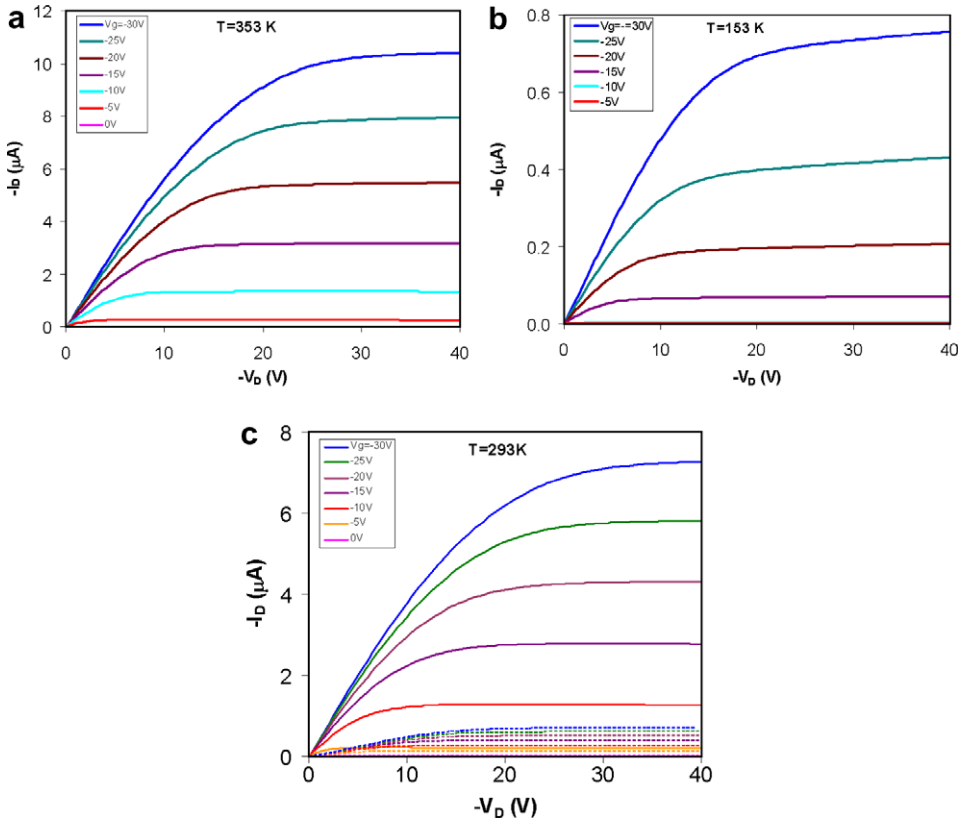

Fig. 3. Output characteristics of TFTs fabricated from the iPVN–TMTES-pentacene blend and pure TMTES-pentacene, measured at (a) 353 K, (b) 153 K and then back at (c) 293 K after warming up of the measurement cell. For comparison in (c) are also shown (dashed curves) the characteristics of one of the few pure TMTES-pentacene devices that survived temperature cycling.

temperature range and, as demonstrated in Fig. 3, room temperature performance was recovered following the temperature cycle.

Transfer characteristics obtained at several different temperatures for the blend are plotted in semi-logarithmic form in Fig. 4. In all cases, the threshold for the onset of channel conductance is clearly visible. Taking the current flow at threshold to be the OFF current and the maximum current observed to be the ON current, the ON–OFF ratio is seen to decrease from just under $\sim 10^6$ at 353 K to $\sim 10^4$ at 153 K.

The iPVN appears to confer a beneficial thermo-mechanical property on films formed from the resulting blend which enables the TFTs to withstand cooling from 353 K to 153 K with little loss of performance upon returning back to room temperature. However, the presence of the insulating iPVN component of the blend leads to a general decrease in the effective mobility which may be attributed partly to the reduced TMTES-pentacene concentration at the oxide/blend interface and partly due to the presence of a parasitic resistance associated with the source and drain contacts.

The presence of contact resistances in organic TFTs has been widely reported [12–18] and methods described for extracting resistance values from device currents using, for example, the transfer line method (TLM) and also by combining device currents with measurement of the contact potential drop using Scanning Kelvin Probe Microscopy (SKPM) [19].

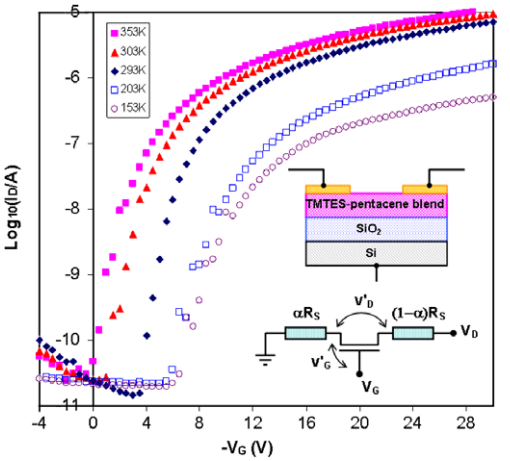

Fig. 4. Transfer characteristics of a TFT fabricated using the iPVN–TMTES-pentacene blend measured at different temperatures in the order 293 K, 353 K, 303 K, 203 K and 153 K. The inset shows a diagram of the device cross-section and a circuit description with parasitic resistances αR_S and $(1-\alpha)R_S$ associated with the source and drain contacts, respectively.

In the present bottom gate, top contact devices the semiconductor layer is relatively thick ($\sim$100 nm) as a

result of the drop-casting technique used in the fabrication. Consequently, the parasitic resistances of the bulk semiconductor layer between the source/drain contacts and the respective ends of the induced channel could be significant and will add to any resistance associated with the contacts themselves. In Fig. 4 we represent such resistances by αR_S and $(1-\alpha)\,R_S$ in series with the source and drain, respectively with $0 \leqslant \alpha \leqslant 1$. The gate and drain voltages sensed by the channel now differ from the applied voltages in which case Eq. (1) for the linear regime becomes

$$I_D = \frac{W}{L}\mu C_{OX}\left[(V'_G - V_T)V'_D - \frac{1}{2}V'^2_D\right] \tag{3}$$

where $V'_G = (V_G - \alpha I_D R_S)$ and $V_D' = (V_D - I_D R_S)$. For very low device currents, when both $I_D R_S$ and V_D are very much smaller than $(V_G - V_T)$ then Eq. (3) reduces to the form used by Horowitz et al. [14] i.e.

$$I_D = \frac{W}{L}\mu C_{OX}(V_G - V_T)(V_D - I_D R_S). \tag{4}$$

The total series resistance, R_S, may then be calculated from the channel conductance, $g_d = \partial I_D/\partial V_D$, measured at low voltages: in the present case for $0 \leqslant V_D \leqslant 0.5$ V. Since the dependence of μ on V_G is not known *a priori*, following Horowitz et al. [14], we first assume the empirical form

$$\mu = a(V_G - V_T)^b \tag{5}$$

where a and b are arbitrary constants. Substituting for μ in Eq. (4) then yields

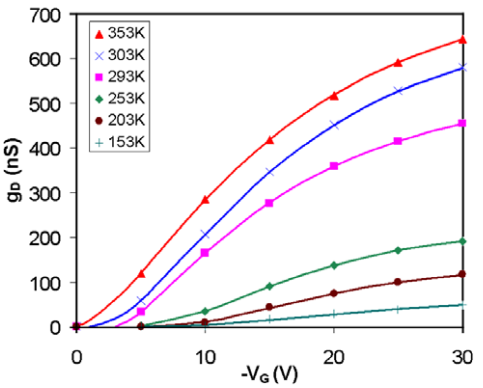

Fig. 5. Channel conductance extracted from the linear regime of the output characteristics ($0 \leqslant V_D \leqslant 0.5$ V) plotted as a function of the gate voltage, V_G. The marked points are from experiment, while the curves show the fits based on Eq. (6). The measurements were carried out in the sequence 293 K, 353 K, 303 K, 253 K, 203 K and 153 K.

$$g_D = \frac{Ka(V_G - V_T)^{1+b}}{1 + KR_S a(V_G - V_T)^{1+b}} \tag{6}$$

where $K = (W/L)C_{OX}$. In principle, a 4-parameter, least squares fit can now be performed to experimental g_D vs. V_G data to obtain values for a, b, R_S and V_T.

However, given the limited data available for each curve (Fig. 5), V_T was assumed to be the turn-on voltage observed in the transfer characteristics [12]. This is justified since V_T can be estimated to a reasonable degree of precision from this data and, in all but one case, was consistent with the onset of conduction in the output characteristics.

The fits obtained following this procedure (full curves in Fig. 5) are excellent when using the V_T and R_S values listed in Table 1. Values for a and b are not included since they have little significance. As explained by Horowitz et al. [14] they are simply dummy variables used to provide a crude, initial approximation to the voltage dependence of μ.

The width-normalised value of R_S at room temperature are at the upper end of the range (2–200 kΩ cm) reported by Gundlach et al. [13] for top-contact pentacene TFTs. Interestingly, the results show a gradual progression of V_T from positive to increasingly negative values as the temperature decreases, suggesting a gradually increasing positive trapped charge at the insulator-semiconductor interface or in the insulator itself, as observed for pentacene TFTs [20]. Over the same temperature range, R_S increased from 234 kΩ cm to 2.64 MΩ cm.

For the second run at 293 K, i.e. the measurements made after warming up the device from 153 K, the approach described above was not possible. Seemingly, the thermal cycle made the device prone to voltage stressing; the turn-on voltage shifted from ~0 V in the output characteristics to ~3.5 V in the subsequently measured transfer characteristics. Such behaviour is indicative either of deeply trapped electrons at the interface [21] or polarisation within the insulator. When fitting the curve for this case, therefore, V_T was constrained to a value in the range ±1 V and gave a good fit with $V_T = +0.7$ V i.e. similar to the value estimated from the output plots. It is worth noting that after the thermal cycle, R_S measured at room temperature had increased from 1.6 MΩ to 2.1 MΩ. This suggests that the morphological changes we believe to be responsible for the failure of the pure TMTES devices also occur in the iPVN-TMTES devices but are limited in the blend by the beneficial action of the binder.

The resistances, R_S, listed in Table 1 are plotted in Arrhenius format in Fig. 6 and are seen to lie moderately well on a straight line corresponding to an activation

Table 1
Values of V_T and R_S giving the best fit to the conductance plots in Fig. 5. For comparison with the literature, R_S is also quoted as the channel-width-normalised value. Values for the parameters a and b are not listed since these were dummy variables used to give an initial approximation to the voltage dependence of V_G [14]. For comparison, the corresponding values extracted from the initial measurements made in air for the same device were $V_T = 0$ V and $R_S = 1.13$ MΩ.

	353 K	303 K	293 K	252 K	203 K	153 K	292 K (2)

Normalised R_S (MΩ cm)	0.234	0.260	0.320	0.820	1.26	2.64	0.420

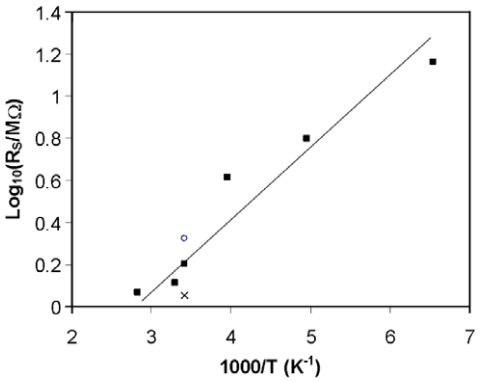

Fig. 6. Arrhenius plot of the series resistance R_S extracted by fitting Eq. (6) to the conductance data in Fig. 5. The 3 data points shown for 293 K correspond to the initial measurements in air (×) and in vacuum (■), and the subsequent measurement under vacuum after the low temperature measurements (○).

energy of ~0.07 eV, giving confidence that the adopted approach is reasonable. Interestingly, the highest occupied molecular orbital (HOMO) of TMTES-pentacene has been estimated to lie at −5.19 eV below the vacuum level [7]. A gold electrode with workfunction ~5.1 eV would, therefore, create a barrier of ~0.09 eV for hole injection into the semiconductor – a similar value to the activation energy estimated above, which suggests that R_S may be associated with the source contact.

The values of R_S and V_T estimated above may now be combined in an attempt to determine the true dependence of μ on V_G. In the presence of parasitic series resistances, pinch-off i.e. the onset of saturation occurs when

$$V'_D = V'_G - V_T \tag{7}$$

i.e. when

$$V_D = (V_G - V_T) + (1-\alpha) I_{Dsat} R_S \tag{8}$$

It is readily shown that, so long as the device is in saturation ($I_D = I_{Dsat}$), the true mobility may be determined from the transfer characteristic using the equation

$$\mu = \frac{2L}{WC_{OX}} \cdot \frac{I_{Dsat}}{(V_G - V_T)^2 - 2\alpha R_S I_{Dsat}(V_G - V_T) + \alpha^2 R_S^2 I_{Dsat}^2}. \tag{9}$$

Since the parameter α is not known, we consider three possible cases that set bounds on the true mobility. Examples of the gate-voltage dependence of the effective mobility, calculated from the Eq. (2) (solid diamonds) are compared in Fig. 7 to the results calculated from Eq. (9). (i) $\alpha = 0$: In this case, R_S is associated entirely with the drain

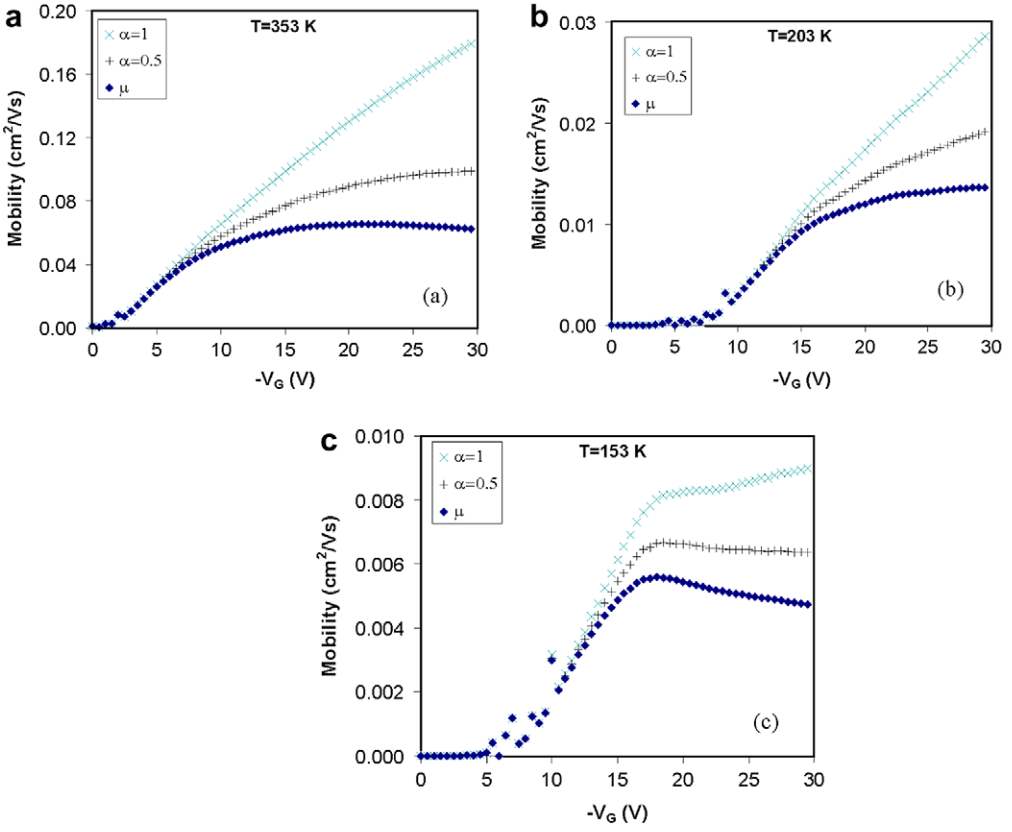

Fig. 7. Effective mobility (filled diamonds) at (a) 353 K, (b) 203 K and (c) 153 K calculated directly from the transfer data using Eq. (2). Also shown are the corrected mobilities calculated using Eq. (9) and assuming the presence of a series resistance associated entirely with the source ($\alpha = 1$) and divided equally between source and drain ($\alpha = 0.5$).

contact so that Eq. (9) reduces to that for an ideal device and the effective mobility (filled diamonds in Fig. 7) will be the true mobility. We may discount this case because (a) μ is unlikely to decrease at higher values of V_G and (b) there will inevitably be limits on the ability of the source to supply carriers to the channel.

(ii) $\alpha = 1$: Now R_S is associated entirely with the source electrode so that applying Eq. (9) to the transfer data in Fig. 4 now produces the almost linear dependence on V_G reported by others for organic TFTs [14,20]. That the activation energy deduced for R_S is close to that expected for the hole injection barrier from gold into TMTES-pentacene supports the notion that R_S could be associated mainly with the source. However, the monotonic increase with V_G appears to break down at 153 K pointing to limitations of the model at this low temperature. Further work will be necessary to check this point.

(iii) $\alpha = 0.5$: In this scenario, R_S is shared equally between source and drain contacts. This is a feasible proposition given the thickness of the semiconductor lying between the contacts and the extremities of the channel. Application of Eq. (9) to the transfer data now produces plots intermediate between the other two but which tend to saturation.

Supplementary Scanning Kelvin Probe Microscopy showed a linear change in potential between the electrodes, even with the device in saturation. Furthermore, no discontinuity in potential, a characteristic feature associated with a contact resistance, was observed at the electrode edges. We believe, therefore, that contact resistance at the electrodes is small and that the measured potential was that developed by the parasitic source-drain leakage current which masked the underlying potentials associated solely with the accumulation channel. Measurements conducted on a series of devices with different channel lengths, the so-called transmission line (TLM) method, were similarly inconclusive owing to significant scatter in the data obtained from devices with different channel lengths. We believe that such variability arose from randomness in the phase separation of the blend and that the series resistance in the device is most likely to be associated with the bulk material interposed between the contacts and the channel i.e. the case corresponding to $\alpha = 0.5$. A reduction in the semiconductor film thickness coupled with better control of phase separation should then lead to significant improvement in device performance.

4. Conclusions

A detailed study has been undertaken into the electrical behaviour of TMTES-pentacene and iPVN–TMTES-pentacene bottom gate top contact TFTs over the temperature range 153–353 K.

Uncorrected estimates of the saturation mobility in the iPVN–TMTES-pentacene devices displayed the commonly observed gate voltage-dependence i.e. increase to a maximum followed by a slight decrease in response to increasing gate voltage [14,22]. In keeping with other reports, we associate such behaviour with the presence of parasitic series resistance, R_S, in the device. Not surprisingly, R_S extracted from conductance measurements in the linear regime, is related to an activated process with activation energy ~0.07 eV which we conclude is associated with bulk semiconductor material lying between the source/drain electrodes and the accumulation channel.

When corrected for series resistance effects, the true mobility in the blend-based devices is likely to be a continually increasing function of V_G, depending on the extent to which the source resistance dominates device behaviour. Significantly increased mobilities should be achievable at room temperature by reducing the series resistance e.g. by reducing the thickness of the semiconductor layer.

It has also been shown that atmospheric oxygen improves device performance presumably through a slight reduction in bulk series resistance by its doping effect on the semiconductor. Furthermore, incorporating TMTES-pentacene in a binder appears to confer the advantage of reducing lateral transport, an important property for reducing cross-talk between devices in printed circuits.

Finally, devices based on the iPVN–TMTES-pentacene blend show good transistor behaviour over the whole temperature range from 353 K down to 153 K. In contrast, the pure TMTES-pentacene devices were unreliable, frequently failed and showed diode-like characteristics at the lowest temperature. Furthermore, devices formed from the blend were more robust, recovering their initial room temperature behaviour after the thermal cycle, albeit at the cost of changes in turn-on voltage and parasitic series resistance. We believe that this is the first reported observation of the thermo-mechanical stabilisation of semi-crystalline organic semiconductor behaviour through blending with an insulating polymer. From a materials science perspective, such a finding offers the opportunity for rapid transfer of this technology to the R2R process since it allows more flexibility in the temperature range permitted in subsequent processing steps.

hole transporter [5]. Among them, the dye is essential in DSSC since it is the origin of the photocurrent generation. In most cases, Ru-based organometallic compounds such as N719 (red dye) [6] and N749 (green dye) [7] as well as other black dyes have been used as sensitizers for the DSSCs with PCE of more than 11%. However, due to the high price of $RuCl_3$ and the difficulties of synthesizing Ru (II)–polypyridine complexes, metal-free organic dyes have recently attracted a lot of attention because of higher molar extinction coefficient [8–17] and impressive efficiencies in the range 8–9.7% have been achieved. Moreover, the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) energy levels can be rather easily tuned by controlling their molecular structures, which leads to various colors. Certain metal-free photosensitizers have been very recently synthesized and used for DSSCs [18].

Overall power conversion efficiency (PCE) of a DSSC is basically decided by the short circuit current density (J_{sc}), open circuit voltage (V_{oc}) and fill factor (FF). There are reports about a number of organic dyes giving very high J_{sc} but the overall PCE of the cell was mainly attributed to small observed V_{oc} [19,20]. V_{oc} plays an important role in controlling the PCE and is basically decided by the difference in the conduction band level of TiO_2 and potential of I_3^-/I^- redox couple in DSSCs. In an interesting report O'Regan and Grätzel [21] advocated the role of electron recombination in governing the V_{oc} based on their transient photovoltage and photocurrent measurements in the DSSCs.

A series of low band gap small molecules and polymers bearing 4-nitro-α-cyanostilbene moieties were synthesized in our laboratory and used for bulk heterojunction solar cells [22] and DSSCs [23] very recently. In continuation of this research line, herein we successfully synthesized two simple photosensitizers **D1** and **D2** based on 4-nitro-α-cyanostilbene which contain carboxy or hydroxy anchoring group, respectively. These dyes were synthesized from a one-step reaction in high yields utilizing widely available and inexpensive starting materials. A literature survey revealed that dye **D1** has not been previously synthesized. Dye **D2** has been synthesized by condensing equimolar quantities of 4-nitrobenzylcyanide with 4-hydroxybenzaldehyde [24]. A photoresponsive effect has been observed with polyamide/cyanostilbene systems [25]. Upon comparing the present dyes **D1** and **D2** to those of reference 23 the following differences are observed. (i) The dyes **D1** and **D2** are very simple, while the previous dyes are complex. **D1** and **D2** are among the simplest photosensitizers which have been reported in the literature. (ii) The most remarkable difference is that **D1** and **D2** are prepared from one step reaction only, while the previous from multiple step reactions. (iii) **D1** and **D2** are unsymmetrical molecules while the previous are symmetrical. The dyes **D1** and **D2** were characterized in DSSCs using quasi-solid-state polymer electrolyte, FTO/TiO_2 photoanode and Pt/FTO counter electrode. The DSSC based on **D1** showed higher PCE than that for **D2**, which is attributed to the higher dye loading and electron lifetime for the **D1** based cell.

2. Experimental

2.1. Reagents and solvents

4-Nitrobenzyl cyanide was synthesized from the nitration of benzyl cyanide with concentrated nitric and sulfuric acid [26]. 4-Carboxybenzaldehyde and 4-hydroxybenzaldehyde were recrystallized from ethanol and water, respectively. Tetrahydrofuran (THF) was dried by distillation over CaH_2. All other reagents and solvents were commercially purchased and were used as supplied.

2.2. Synthesis of dyes

2.2.1. 4-Nitro-4′-carboxy-α-cyanostilbene (*D1*)

A flask was charged with a solution of 4-carboxybenzaldehyde (0.5102 g, 3.33 mmol) and 4-nitrobenzyl cyanide (0.5400 g, 3.33 mmol) in ethanol (30 mL). Sodium hydroxide (0.60 g, 15.00 mmol) dissolved in ethanol (10 mL) was added portionwise to the stirred solution. The mixture was stirred for 1 h at room temperature under N_2 and then it was concentrated under reduced pressure to remove ethanol. Water was added to the concentrate and then dilute hydrochloric acid was added to this solution to precipitate **D1** as a dark-green solid. It was filtered and washed thoroughly with water (0.70 g, 72%).

FT-IR (KBr, cm^{-1}): 3408 (O–H deformation of carboxyl); 2170 (cyano); 1684 (carboxylic C=O); 1592 (aromatic); 1534, 1384 (nitro).

^1H NMR ($CDCl_3$, ppm): 12.09 (broad, 1H, carboxyl); 8.19–8.12 (m, 4H, aromatic ortho to nitro and carboxyl); 7.70 (s, 1H, olefinic); 7.51–7.45 (m, 4H, aromatic meta to nitro and carboxyl).

Anal. Calc. for $C_{16}H_{10}N_2O_4$: C, 65.31; H, 3.43; N, 9.52. Found: C, 64.94; H, 3.40; N, 9.58%.

2.2.2. 4-Nitro-4′-hydroxy-α-cyanostilbene (*D2*)

This dye was similarly prepared in 60% yield from the reaction of 4-hydroxybenzaldehyde with 4-nitrobenzyl cyanide (mol ratio 1:1) in ethanol in the presence of sodium hydroxide. The reaction mixture was stirred for 1 h at room temperature under N_2 and then it was concentrated under reduced pressure to remove ethanol. Water was added to the concentrate and **D2** precipitated as a dark-green solid.

FT-IR (KBr, cm^{-1}): 3422 (O–H stretching of hydroxyl); 2168 (cyano); 1592 (aromatic); 1530, 1342 (nitro).

^1H NMR ($CDCl_3$, ppm): 8.18 (m, 2H, aromatic ortho to nitro); 7.71 (s, 1H, olefinic); 7.48 (m, 2H, aromatic meta to nitro); 7.24 (m, 2H, aromatic meta to hydroxyl); 6.84 (m, 2H, aromatic ortho to hydroxyl); 5.34 (s, 1H, hydroxyl).

Anal. Calc. for $C_{15}H_{10}N_2O_3$: C, 67.67; H, 3.79; N, 10.52. Found: C, 67.26; H, 3.85; N, 10.63%.

2.3. Fabrication of dye-sensitized TiO_2 electrode and DSSC assembly

TiO_2 paste was prepared by mixing 1 g of TiO_2 powder (P25, Degussa), 0.2 mL of acetic acid, 1 mL of water. Then 60 mL of ethanol was slowly added while sonicating the

mixture for 3 h. Finally, Triton X-100 was added and a well dispersed colloidal paste was obtained (TiO_2). The whole procedure is slow under vigorous stirring. The mixture was stirred vigorously for 2–4 h at room temperature and then stirred for 4 h at 80 °C to form a transparent colloidal paste. The TiO_2 paste was deposited on the F-doped tin oxide (FTO) coated glass substrates by the doctor blade technique. The TiO_2 coated FTO films were sintered at 450 °C for 30 min. Before immersing into the dye solution, these films were soaked in a 0.2 M aqueous $TiCl_4$ solution overnight in a closed chamber. After being washed with deionized water and fully rinsed with ethanol, the films were heated again at 450 °C for 30 min, followed by cooling to 60 °C.

The nitrogen doped TiO_2 paste was synthesized via sol gel method using urea as nitrogen source. A solution of urea was prepared by dissolving an appropriate amount of urea in 90 mL of deionised water and it was added to the paste of TiO_2 under vigorous stirring at 80 °C. The deposition of the nitrogen doped TiO_2 film is the same as described earlier. The crystallite size of nitrogen doped TiO_2 was determined using X-ray diffraction analysis with Cu Kα as radiant source and wavelength ($\lambda = 0.1541$ nm). The crystallite size D was calculated by the Sherrer equation.

The dyes were dissolved in THF solution (0.5 mM) and the TiO_2 electrode was immersed in the dye solution for 10 h and after sensitization the dye electrode was washed.

For the composite electrolytes preparation, 0.0383 g of TiO_2 powder (P25, Degussa) was dried for about 24 h at 250 °C. After drying a quasi-solid-state polymer electrolyte containing 0.0383 g of P25 TiO_2 powder, 0.1 g of LiI, 0.019 g of I_2, 0.264 g of PEO, and 44 μL of 4-*tert*-butylpyridine in 1:1 acetone/propylene carbonate was prepared. The mixture was continuously stirred at 80 °C in water bath for about 4–5 h. The polymer electrolyte was spread on the sensitized TiO_2 film by spin coating to form a hole-conducting layer. The counter electrode was platinized by spin coating H_2PtCl_6 solution (2 mg in 1 mL isopropanol) onto the FTO coated glass substrate and then heated at 450 °C for 30 min in air. The dye-sensitized photoelectrode containing the quasi-solid-state polymer electrolyte and the counter electrode were clamped together and separated by 20 μm spacer.

2.4. Characterization methods

IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrometer with KBr pellets. ^{1}H NMR (400 MHz) spectra were obtained using a Brucker spectrometer. Chemical shifts (δ values) are given in parts per million with tetramethylsilane as an internal standard. UV–vis spectra were recorded on a Beckman DU-640 spectrometer with spectrograde THF. Elemental analyses were carried out with a Carlo Erba model EA1108 analyzer.

The electrochemical properties of both dyes were studied by using cyclic voltammetry (CV) (HCH instrument). The dyes were coated on platinum disk and immersed in 0.1 M Bu_4NPF_6 acetonitrile solution. CV was recorded using Platinum disk as working electrode and Ag/Ag^+ as the reference electrode at a scan rate of 20 mV s^{-1}.

The current–voltage (*J–V*) characteristics of the devices in dark and under illumination were measured by semiconductor parameter analyzer (Keithley 4200-SCS). A xenon light source (Oriel, USA) was used to give an irradiance of 100 mW/cm^2 (the equivalent of one sun at AM 1.5) at the surface of the device. The photoaction spectrum of the devices was measured using a monochromator (Spex 500 M, USA) and the resulted photocurrent was measured with Keithley electrometer (model 6514), which is interfaced to the computer by LABVIEW software. The electrochemical impedance spectra (EIS) measurements were carried out by applying bias of the open circuit voltage (V_{oc}) and recorded over a frequency range of 1 mHz to 10^5 Hz with ac amplitude of 10 mV. The above measurements were recorded with an electrochemical impedance analyzer equipped with FRA.

3. Results and discussion

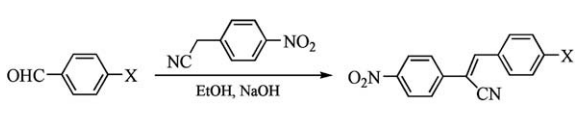
3.1. Synthesis and characterization

Dyes **D1** and **D2** were conveniently synthesized by the one-step reaction outlined in Scheme 1. In particular, 4-carboxybenzaldehyde or 4-hydroxybenzaldehyde reacted with an equivalent amount of 4-nitrobenzyl cyanide in ethanol in the presence of sodium hydroxide to afford **D1** and **D2**, respectively. **D1** was obtained as sodium salt and the acidification of the latter by hydrochloric acid yielded the free dye. *tert*-Butoxide could be used instead of sodium hydroxide for the condensation reaction. Both compounds were obtained as dark-green solids which were soluble in common organic solvents like THF, chloroform and dichloromethane. Moreover, they were soluble in ethanol due to the presence of the carboxy or hydroxy group. Even though these dyes are small molecules, films of them could be obtained from their solutions by spin-casting.

Structural characterization of dyes was accomplished by FT-IR and ^{1}H NMR spectroscopy. Since these dyes are differentiated only from their anchoring groups, their spectra were similar. They showed common absorption bands around 1530, 1380 (NO_2), 2170 (cyano) and 1592 cm^{-1} (aromatic). Besides, **D1** displayed absorptions at 3408 and 1684 cm^{-1} (carboxyl), while **D2** at 3422 cm^{-1} (hydroxyl). The ^{1}H NMR spectra showed common peaks approximately at 8.18 (aromatic ortho to nitro) and 7.70 ppm (olefinic). Finally, **D1** and **D2** displayed characteristics signals at 12.09 and 5.34 ppm assigned to the carboxyl and hydroxyl, respectively.

3.2. Photophysical properties

The photophysical properties of the dyes were investigated in both dilute (10^{-5} M) THF solution and thin film.



Scheme 1. Synthesis of dyes **D1** and **D2**.

Fig. 1 depicts the UV–vis absorption spectra of the dyes which have been normalized with respect the long-wavelength absorption. The photophysical characteristics of the dyes are summarized in Table 1.

Generally, the absorption curves of the dyes were broad and covered a wide range of the spectrum from 300 to ~750 nm. This attractive feature was attributed to the 4-nitro-α-cyanostilbene segment as it has been well established in our previous publications [22,23]. The long-wavelength absorption maximum ($\lambda_{a,max}$) was located at 617–655 nm. The thin film absorption curves of the dyes absolutely coincided above 550 nm and exhibited absorption onset at 761 nm corresponding to an optical band gap (E_g^{opt}) of 1.63 eV. This value of E_g^{opt} conforms to those of other related materials which contain 4-nitro-α-cyanostilbene moieties [22,23].

The UV–vis spectra of the sensitizers absorbed on TiO_2 film are shown in Fig. 2. The absorption spectrum of the blank TiO_2 film was subtracted from the curve. It can be seen in this figure that the absorption spectra were broadened, when anchored at the TiO_2 surface, as compared to pure dye spectra. Such broadening has been observed in other organic sensitizers on TiO_2 electrodes [27]. Strong interaction between the adsorbed dye molecules and oxide molecules in the TiO_2 surface leads to aggregate formation and consequently broadening the absorption spectrum. This might be correlated with the dye–TiO_2 and dye–dye interactions. The broadened absorption of dyes loaded on the TiO_2 film is advantageous for light harvesting of the solar spectrum. The concentration of the **D2** dye adsorbed on the film is lower than that of **D1**. This is attributable to impaired surface packing due to OH anchoring group of **D2**.The energetic alignment of the HOMO and LUMO energy levels is crucial for an efficient operation of the sensitizer in a DSSC. To ensure efficient electron injection from the excited dye into the conduction band of the TiO_2 films, the LUMO level must be higher in energy than the TiO_2 conduction band edge. The HOMO level of the sensitizer must be lower in energy than the redox potential of the I^-/I_3^- redox couple for efficient regeneration of the sensitizer cation after photoinduced electron injection into the TiO_2 film. The electrochemical behaviour of the sensitizers was investigated by CV [28] and the data are listed in Table 1. The HOMO and LUMO levels of both sensitizers are suitable for DSSCs. The difference between the LUMO of dye and the conduction band of TiO_2 should be higher than 0.2 eV for efficient electron injection. The LUMO energy levels (**D1**: −3.5 eV and **D2**: −3.7 eV) are sufficiently higher than the conduction band of TiO_2 (−4.0 eV). Hence, an efficient electron transfer from the excited dye to the TiO_2 is

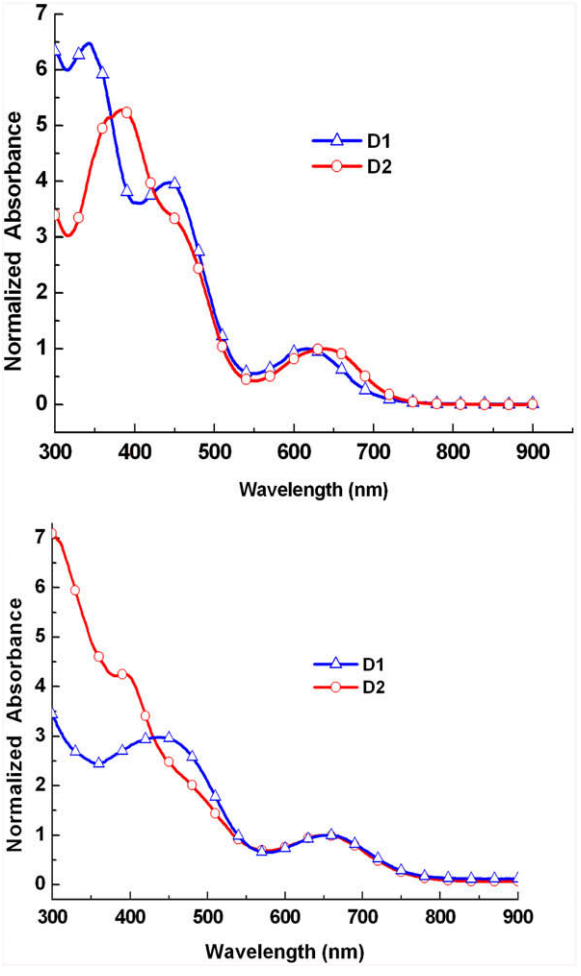


Fig. 1. Normalized absorption spectra of dyes in THF solution (top) and thin film (bottom).

Table 1
Optical and electrochemical properties of **D1** and **D2**.

Dye	D1	D2
$\lambda_{a,max}$[a] in solution (nm)	617	639
$\lambda_{a,max}$[a] in thin film (nm)	652	655
Thin film absorption onset (nm)	761	761
E_g^{opt}[b] (eV)	1.63	1.63
HOMO (eV)	−5.2	−5.4
LUMO (eV)	−3.5	−3.7
E_g^{el}[c] (eV)	1.7	1.7

[a] $\lambda_{a,max}$: the long-wavelength absorption maxima from the UV–vis spectra in THF solution or in thin film.
[b] E_g^{opt}: optical band gap determined from the absorption onset in thin film.
[c] E_g^{el}: electrochemical band gap determined from cyclic voltammetry.

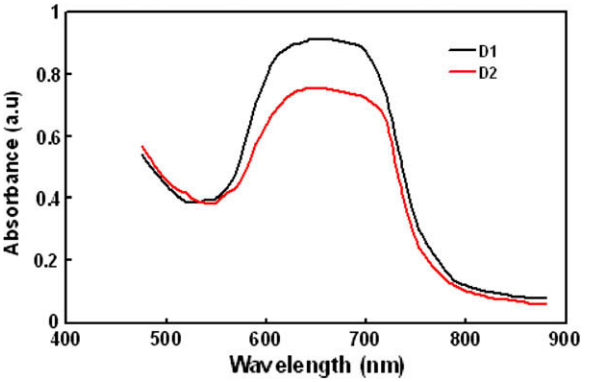

Fig. 2. UV–vis absorption spectra of the dyes adsorbed on TiO_2 films.

ensured. The HOMO energy levels of the dyes (**D1**: −5.2 eV and **D2**: −5.4 eV) are lower than the standard potential of the I^-/I_3^- redox couple (−4.83 eV vs. vacuum) [29]. Thus sufficient driving force for the regeneration of the oxidized sensitizer is available in DSSCs using these materials.

3.3. Photovoltaic performance

Fig. 3 shows the incident photon to current efficiency (IPCE) spectra for the DSSCs based on **D1** and **D2**. The IPCE data of **D1** sensitizer exhibit efficiency higher than 55% in the range 550–750 nm with a maximum value about 70% at 650 nm. On the other hand, the IPCE value for the DSSC based on **D2** dye is lower than that for **D1** in the same wavelength region. The IPCE for a DSSC can be expressed as

$$\mathrm{IPCE}(\lambda) = \mathrm{LHE}(\lambda)\phi_{\mathrm{inj}}\eta_{\mathrm{c}}$$

where LHE(λ) is the light harvesting efficiency of the photoelectrode, ϕ_{inj} is the charge injection efficiency from the excited state of dye into conduction band of the nano-crystalline semiconductor, and η_{c} is the collection efficiency of the injected electron by the electrode. The parameter LHE(λ) is related to the dye loading on the surface of the TiO_2 photoanode. We have estimated the amount of dye loading for both devices and found that it is slightly higher for **D1** than **D2**. In particular, the amount of the adsorbed dyes (dye loading) on the TiO_2 films were estimated by desorbing the dyes with basic solution, and the surface concentrations were determined to be 3.21×10^{-8} and 3.14×10^{-8} mol cm^{-2} for **D1** and **D2**, respectively. Therefore, the LHE(λ) does not much affect the IPCE. The improvement in the IPCE for DSSCs based on the **D1** may be mainly due to the other parameters, such as ϕ_{inj} and η_{c}. The parameter ϕ_{inj} depends on the energy difference between the LUMO of the dye and conduction band of TiO_2. This energy difference is higher for the DSSCs based on **D1** than **D2**. Therefore, the electron injection efficiency is higher for solar cells based on **D1** than **D2** leading to improved IPCE. The loss in the IPCE is probably caused by the reduced charge collection efficiency. The slightly lower dye loading favors the increased charge recombination between free electrons in the TiO_2 conduction band and oxidized species (tri-iodide) in the electrolyte at the uncovered TiO_2 surface.

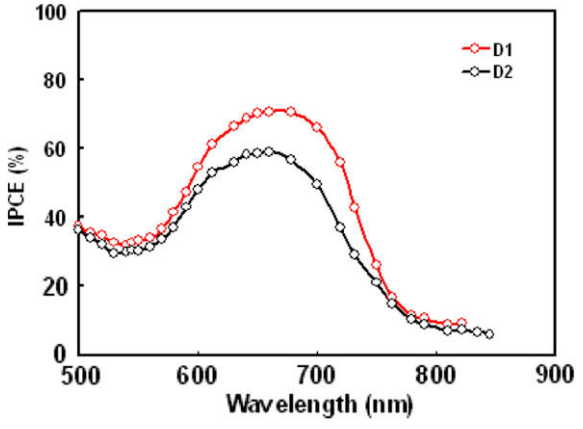

Fig. 3. The IPCE spectra of DSSCs fabricated with **D1** and **D2**.

The *J–V* characteristics of the DSSCs based on **D1** and **D2** are shown in Fig. 4. The photovoltaic parameters i.e. short circuit photocurrent (J_{sc}), open circuit voltage (V_{oc}), fill factor (FF) and power conversion efficiency (η) are summarized in Table 2. Depending on different anchoring groups, these dyes show different PCE in spite of the same band gap. The lower J_{sc} for DSSC based on **D2** is consistent with the lower IPCE, because the adsorbed amount of **D2** on the surface of TiO_2 is lower than **D1**. The lower value of V_{oc} can be explained by the increased charge recombination with the redox species which are present in the electrolyte.In DSSCs, the charge separation occurs in the adsorbed dyes by the injection of excited electrons into the conduction band of TiO_2 and reduction of the resulting dye cations by I^- in the electrolyte. Then, at short circuit conditions, the electrons and I_3^- diffuse towards the photoanode and Pt counter electrodes, respectively. Consequently, the charge collection efficiency is related to electron diffusion coefficient (D) and electron lifetime (τ) in TiO_2. The electron lifetime is defined as the average time spent in the TiO_2 electrode. If the electron diffusion length, which is $(D\tau)^{0.5}$, is shorter than the thickness of the TiO_2 electrode, the electrons in TiO_2 are recombined with the dye cations and/or I_3^- during the diffusion. The high IPCE of the present DSSCs indicates that the recombination at short circuit conditions is negligible. At open circuit conditions, the injected electrons in TiO_2 are accumulated until the charge injection rate is balanced with the recombination rate. The recombination rate depends upon the electron lifetime in the TiO_2 electrode. The electron lifetime of the electron also depends on the reorganization energy of dye used in the DSSC [30].

The electrochemical impedance spectra of the DSSCs based on **D1** and **D2** were measured to investigate the kinetic process about the back reaction. The electrochemical

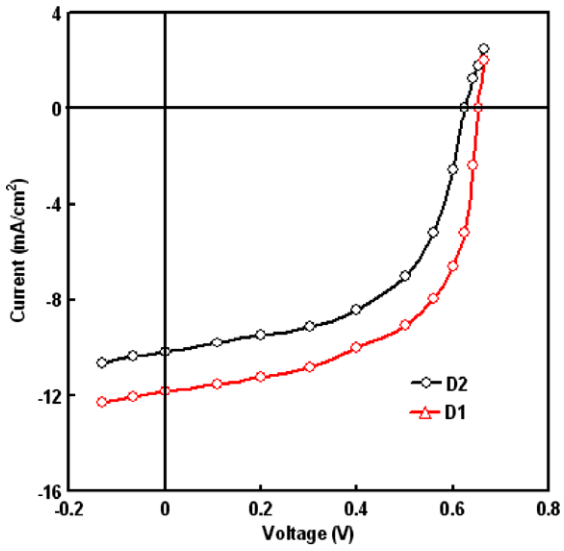

Fig. 4. *J–V* characteristics under illumination of DSSCs based on **D1** and **D2** dye.

Table 2
Photovoltaic performance of the quasi solid state DSSCs for the two dyes on different measured conditions.

Dye	Short-circuit current (J_{sc}) (mA/cm^2)	Open circuit voltage (V_{oc}) (V)	Fill factor (FF)	Power conversion efficiency (η) (%)
D1[a]	11.8	0.65	0.63	4.80
D2[a]	10.2	0.61	0.56	3.50
D1[b]	11.9	0.69	0.66	5.42
D2[b]	10.4	0.65	0.60	4.00

[b] With nitrogen doped TiO_2 photoanode.

impedance spectra of the DSSCs based on **D1** and **D2** in the form of Bode plots in dark at forward bias of 0.65 V are presented in Fig. 5. The peak at intermediate frequencies (~100–1 Hz) is mainly attributed to the charge transfer at the TiO_2/electrolyte interface [31]. The electron lifetime (τ) can be calculated by the reciprocal of peak frequency (f_p) [31]

$$\tau = 1/\omega_p = 1/2\pi f_p$$

The electron lifetime for the DSSC based on **D1** is 25 ms which is about 1.6 times longer than the DSSC based on **D2** with electron lifetime of 15 ms. The open circuit voltage decay analysis also shows that DSSC based on **D1** has a longer electron lifetime than that of DSSC with **D2**. The longer electron lifetime of the DSSC with **D1** contributes to its superior photovoltaic performance.

We measured photovoltage decay of the devices at various white light intensities in order to study the charge recombination rates between electrons in TiO_2 conduction band and tri-iodide ions in the electrolyte [32]. The recombination rates are plotted in Fig. 6 versus the open circuit voltage of the DSSC, adjusted by varying the white light intensities. The V_{oc} in the cell is given by the difference between the redox level of the electrolyte and the quasi Fermi level of TiO_2. It can be determined by the concentration of free charge carriers. This plot allows us to compare the recombination rate at equal charge density concentration in the TiO_2 films. The recombination rate is known to increase exponentially with increasing light intensity due to a filling of intra-band trap states in the TiO_2. This allows a faster de-trapping of electrons to the conduction band

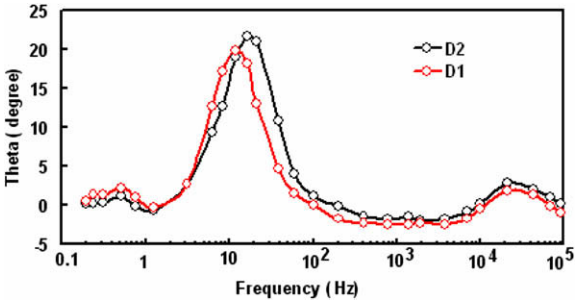

Fig. 5. The electrochemical impedance spectra of the DSSCs based on **D1** and **D2** in the form of Bode plots in dark at forward bias of 0.65 V.

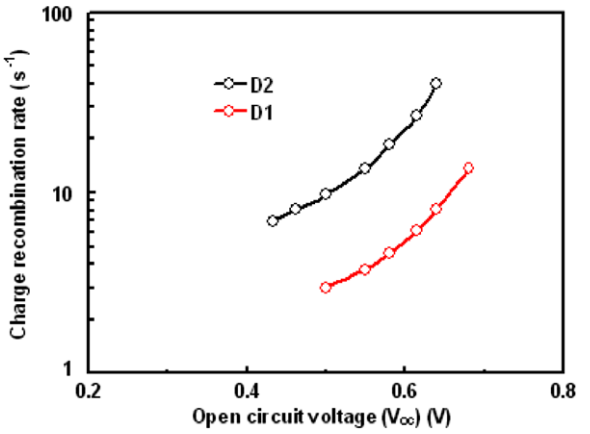

Fig. 6. Comparison of charge recombination rate in DSSCs based on the **D1** and **D2**.

and subsequent recombination with tri-iodide [33]. The recombination rate for DSSC based on **D2** is about two times higher than that for DSSC with **D1**, which can be attributed to an increased current (dark current) due to the recombination of electrons in conduction band of TiO_2 with the tri-iodide ions in the electrolyte. The higher recombination rate also leads to a decrease in the free charge carriers in the conduction band of TiO_2, which induces a downward shift of conduction band of TiO_2 towards the iodide /tri-iodide potential. Both the higher recombination rate and the downward shifted conduction band in the DSSC based on **D2** explain the lower V_{oc} measured in the *J–V* characteristics. Additionally, the higher charge recombination rate reduces the charge collection efficiency and consequently the J_{sc} and PCE.

It has been reported that the addition of nanoparticles such as TiO_2 and SiO_2 in the electrolyte can increase the ionic conductivity [34]. In these nanocomposite electrolytes, the anion species are aligned around the nanoparticles, facilitating the electron exchange reaction [33]. It is noted that the TiO_2 nanoparticles with particle size of 5–10 nm are selected because they are sufficiently smaller that the pore diameter of the typical nanoporous TiO_2 layer (15–25 nm). In our case the ionic conductivity of electrolyte with and without TiO_2 nanoparticle is 0.11 and 0.18 mS cm^{-1}, respectively. For comparison, we have also measured the *J–V* characteristics of the DSSC of **D1** dye based on the quasi solid state electrolyte without TiO_2 nanoparticles, under illumination intensity of 100 mW/cm^2 and found that the J_{sc} and V_{oc} are about 9.6 mA/cm^2 and 0.72 V, respectively. This is attributed to the lower concentration of free tri-iodide ions near the dye attached to TiO_2 surface, because the surfaces of the nanoparticles can immobilize the ions. This also results in slightly smaller V_{oc} owing to the high electron concentration at TiO_2 surface of electrolyte. The charge transport in electrolyte medium may be effectively facilitated by adding nanoparticles to the polymer electrolyte. The enhancement in the solar cell performance upon the introduction of the TiO_2 nanoparticles in the polymer electrolyte is due to the improved ion conductivity.

3.4. Effect of nitrogen doped TiO_2 photoanode

One crucial component in DSSCs is that the nanostructure TiO_2 electrode has some oxygen deficiency in the crystal structure [35]. The oxygen deficiency could create electron–hole pairs. The oxidizing holes can react with dye or be scavenged by iodide ions [36]. These processes result in shortening the electron life time. Consequently doping with nitrogen into the TiO_2 crystal structure can improve the oxygen deficiency and decrease the back reaction. Asahi et al. reported at 2001 that photocatalytic activity can be achieved by nitrogen doping. Considerable research on nitrogen doping in TiO_2 film has been extensively conducted [37]. Recently, doping of nitrogen into TiO_2 for the improvement of DSSCs performance has been reported [38]. We have attempted to improve the photovoltaic performance of the DSSCs using nitrogen doped TiO_2 photoelectrode.

The nitrogen doped TiO_2 materials prepared by modified sol gel method using urea as nitrogen carrier display a yellow color and are characterized by X-ray diffraction (XRD) analysis. XRD spectrum of the nitrogen doped TiO_2 powder shows anatase phase. The average crystallite size calculated from the broadening of the (1 0 1) XRD peak of the anatase phase was 20.3 and 17.5 nm for doped and undoped TiO_2, respectively. We have observed a little shift in the (1 0 1) peak position for nitrogen doped TiO_2 which is consistent with the work reported earlier [39].

Fig. 7a shows the *J–V* characteristics of the DSSCs based on the nitrogen doped photoelectrode using **D1** and **D2**. The photovoltaic performance of the DSSCs is shown in Table 2. It is apparent from this table that V_{oc} and FF shift to higher values with the nitrogen doped TiO_2 electrode, whereas J_{sc} remains almost unchanged. The increase of V_{oc} in the presence of nitrogen compared with that in the absence of nitrogen may be explained by the change in the quasi Fermi level (E_f) of TiO_2 photoelectrode. Using Fermi level pinning, these two parameters are described by the relationship [40]:

$$V_{oc} = |E_f - E_{red}|$$

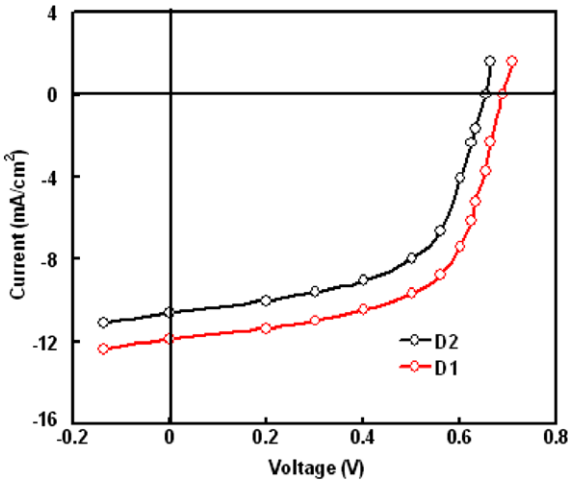

Fig. 7a. *J–V* characteristics under illumination of DSSCs based on **D1** and **D2** dye using nitrogen doped TiO_2 photoelectrode.

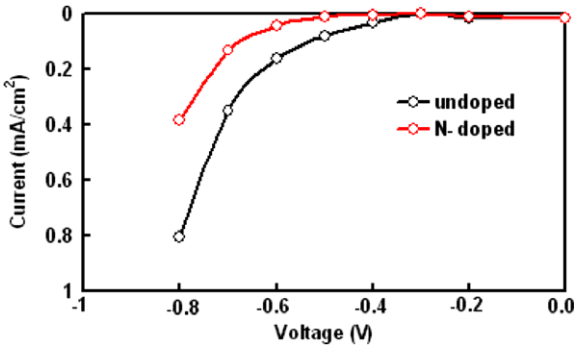

Fig. 7b. Dark *J–V* characteristics under illumination of DSSCs based on **D1** and **D2** using nitrogen doped and undoped TiO_2 photoelectrode.

where E_{red} is the standard reduction potential of redox couple, assuming that the E_{red} does not vary with the addition of nitrogen. Therefore, the increase in V_{oc} of the DSSCs with the addition of nitrogen in the TiO_2 photoelectrode, may be attributed to the retarding of the dark current, as shown in Fig. 7b, or to the decrease of the charge recombination. The addition of nitrogen in the TiO_2 can suppress the production of the dark current. By comparing the dark current of DSSCs based on nitrogen doped TiO_2 and bare TiO_2 photoanode, it is observed that the nitrogen doped DSSC exhibit smaller dark current. This indicates that the nitrogen doping could successfully retard the charge recombination at the TiO_2/dye/electrolyte interface. Thus, the nitrogen doped TiO_2 introduced formation of O–Ti–N structure which can suppress the reduction of I_3^- on the TiO_2 electrode. The onset voltage in the dark current for DSSC also shifts to higher voltage with nitrogen doped TiO_2 electrode as compared to undoped TiO_2 electrode. This means that E_{fb} of TiO_2 shifts towards the vacuum level with doping, leading to higher value of V_{oc}.

In the Bode plots of electrochemical impedance spectral data, it can be seen that adding nitrogen into TiO_2 shifts the middle frequency peak to lower frequency, as shown in Fig. 8. This corresponds to an increase in the electron lifetime and suppressing the back transfer of photoexcited electron from nitrogen doped TiO_2 nanoparticles to the electrolyte at TiO_2/dye/electrolyte interface. This confirms that the nitrogen doping into TiO_2 photoanode can improve the performance of the DSSC.

4. Conclusions

Two new photosensitizers **D1** and **D2** based on 4-nitro-α-cyanostilbene with carboxy or hydroxyl anchoring group were synthesized in high yields from a one-step reaction only. The long-wavelength absorption maximum was located at 617–655 nm with thin film absorption onset at 761 nm which corresponds to an optical band gap of 1.63 eV. Quasi solid state dye-sensitized solar cells were fabricated using polymer gel electrolyte and dyes **D1** and **D2**. In DSSC based on **D1**, IPCE about 70% at the absorption maxima was observed with overall PCE of 4.8%. The lower PCE in the case of **D2** is ascribed to the reduction in the photocurrent due to less dye loading on the TiO_2 surface, since **D2** has the OH anchoring group. The lower PCE of the DSSC based on the **D2** has also been ascribed in terms of increased recombination rate and lower electron lifetime. It was found that the PCE of the DSSCs has been enhanced when a nitrogen doped TiO_2 photoanode is used. The increase in PCE is attributed to the retardation of charge recombination and the introduction of nitrogen, which replaced the oxygen deficiency in the titania crystal lattice. The enhanced electron lifetime for doped TiO_2 DSSCs could be attributed to the formation of O–Ti–N in the TiO_2 electrode to retard the recombination reaction at the TiO_2/electrolyte interface, as compared to DSSC based on undoped TiO_2 electrode. Additionally, the E_{fb} of TiO_2 is also affected slightly by the presence of nitrogen which is responsible for the improvement in V_{oc} and PCE.

Despite these unique advantages, however, the vast majority of organic phototransistors demonstrated to date operate at high voltages that typically exceed |20| V [9–12]. This represents a major technology bottleneck since most targeted device applications – e.g. portable and battery-powered optical sensors etc. – require significantly lower voltages (i.e. <|10| V). Therefore, successful implementation of the phototransistor technology in future generations of optical sensors would not only require the development of high performance device architectures but also the demonstration of low operating voltage organic phototransistors.

Here we demonstrate the first low-voltage and low-power ambipolar organic transistors based on self-assembled monolayer (SAM) gate dielectrics and suitably designed p/n-heterostructure semiconducting layers. The incorporation of SAM gate dielectrics has proven effective at reducing the dielectric thickness and thereby reducing the operating voltage of organic field-effect transistors to <3 V [15–18]. Interestingly, these low-voltage ambipolar transistors are found to respond to visible light. For instance, by illuminating the device with blue light, the source–drain current can be modulated by a few orders of magnitude. This effect is attributed to electron transfer from the donor material – i.e. the pentacene layer in this case – to the acceptor material, namely [6,6]-phenyl-C_{61}-butyric acid methyl ester [$PC_{61}BM$], occurring at the pentacene/$PC_{61}BM$ interface (see Fig. 1a). Simultaneous measurement of incident light intensity and photoinduced channel current allows the response speed and external quantum efficiency (EQE) of these phototransistors to be estimated. By integrating two phototransistors we are also able to demonstrate low-voltage complementary-like inverters with high signal gain and interesting light-sensing properties.

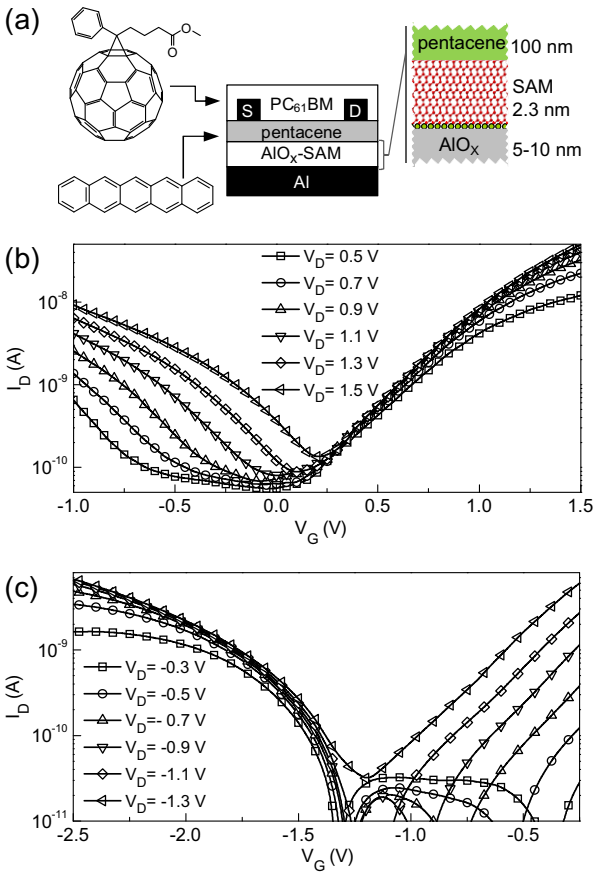

Fig. 1. (a) Molecular structures of $PC_{61}BM$ and pentacene and a schematic representation of the bottom-gate, middle-contact p–n heterostructure transistor used in this study. (b) Transfer characteristics of the low-voltage heterostructure ambipolar OFET (L = 50 μm, W = 1 mm) measured in the dark with positive V_D. (c) Transfer characteristics of the same OFET measured in the dark with negative V_D.

2. Experimental

Aluminium gate electrodes were thermally deposited onto glass substrates under high vacuum. The surfaces of the gate electrodes were oxidized in oxygen plasma leading to the formation of native alumina a few nanometres thick [16]. A 1.7 mg/ml solution of octadecylphosphonic acid (ODPA) in isopropanol was drop-cast onto the electrodes followed by rinsing with pure isopropanol. The substrates were then thermally annealed for 20 h at 140 °C under ambient-pressure in N_2. Following this a pentacene layer (100 nm) was deposited by thermal sublimation under high vacuum (10^{-9} bar) at a rate of 1 Å s^{-1}. Gold source (S) and drain (D) electrodes (45 nm) were then thermally deposited onto the pentacene layer. Finally, a 20 mg/ml solution of $PC_{61}BM$ in chlorobenzene was spin-cast onto the devices at 1000 rpm for 60 s. Commercially available 99.9% pure sublimed grade pentacene and 99.5% pure $PC_{61}BM$ were used in this study. A schematic of the device architecture and the molecular structures of the materials used are shown in Fig. 1a. Electrical characterisation was carried out in N_2 at atmospheric pressure using a Keithley 4200 semiconductor parameter analyser. An indium gallium nitride (InGaN) light emitting diode (LED) with a peak emission at 469 nm (blue light) was used for optical illumination.

3. Results and discussion

Fig. 1b shows the ambipolar transfer characteristics of a low-voltage OFET with a channel length (L) and width (W) of 50 μm and 1 mm, respectively, measured in the dark with drain voltages between V_D = 0.5 V and V_D = 1.5 V. Fig. 1c shows the ambipolar transfer characteristics of the same low-voltage OFET measured in the dark with drain voltages between V_D = −0.3 V and V_D = −1.3 V. The transistor can be considered to consist of a separate bottom-gate, top-contact pentacene p-channel (formed at the SAM/pentacene interface) and a bottom-gate, bottom-contact $PC_{61}BM$ n-channel (formed at the pentacene/$PC_{61}BM$ interface). Depending on the applied voltage at the gate and drain electrodes, charge injection will take place into the different semiconducting channels. The ODPA SAM dielectric implemented in this device has been thoroughly characterised in our previous work [17,18]. Geometrical capacitances in the range of 600–800 nF cm^{-2} [17] and

leakage current densities of metal–insulator–metal structures on the order of 10^{-9} A cm^{-2} [18] were observed.

The specific device structure of Fig. 1a can be referred to as bottom-gate, middle-contact (BG-MC). Middle-contact heterostructure OFETs based on pentacene and C_{60} have previously been shown to exhibit good ambipolar transistor behaviour [19]. Using standard OFET models [1], the electron and hole mobilities were calculated from the transfer characteristics to be $\mu_e = 0.2$ cm^2/Vs and $\mu_h = 7 \times 10^{-4}$ cm^2/Vs, respectively. The asymmetry of the two channels is attributed to a disruption of the pentacene layer morphology upon deposition of the $PC_{61}BM$ solution. Prior to deposition of the $PC_{61}BM$ layer, the hole mobility was measured to be $\mu_h \sim 10^{-1}$ cm^2/Vs (data not shown), possibly suggesting that the $PC_{61}BM$ solution affects the integrity of the pentacene film slightly. This is incidentally believed to also lead to a very smooth pentacene/$PC_{61}BM$ interface, facilitating good electron transport. The threshold voltages calculated from plots of $I_D^{1/2}$ versus V_G in the saturation regime (not shown) were found to be 0.7 V and −1.4 V for the n- and p-channels, respectively. Using impedance measurements performed on the OFETs, the geometrical capacitances of the gate dielectrics for the $PC_{61}BM$ and pentacene channels were calculated yielding ~70 nF cm^{-2} and ~800 nF cm^{-2}, respectively. These measurements were carried out at a frequency of 400 Hz. Above 200 Hz the dependence of the measured capacitance on signal frequency was found to be negligible (data not shown).

To examine the suitability of these low-voltage ambipolar OFETs as light-sensors, we have studied their operating characteristics under illumination. When illuminated with blue light (λ_{peak} = 469 nm) the drain current (I_D) of the transistors was found to increase (Fig. 2a). The n-channel threshold voltage (V_T) also changed by −0.2 V under illumination at 3.2 mW cm^{-2} whilst the p-channel V_T remained constant. The threshold voltage shift is attributed to changes in the density of trapped charges at the interface between the two semiconductors [20], whilst the increase in off-current is attributed to the creation and dissociation of photo-generated excitons near the $PC_{61}BM$/pentacene interface, a process similar to that observed in pentacene/fullerene heterojunction solar cells [21]. These two effects have previously been referred to as photoconductive and photovoltaic effects, respectively [9]. The inset in Fig. 2a shows the energy levels of the two semiconductor materials and the suitability of this energetic interface for effective charge transfer from the lowest unoccupied molecular orbital (LUMO) level of pentacene to the LUMO of $PC_{61}BM$. The fact that the p-channel threshold voltage remains unchanged under illumination suggests the majority of dissociated charges do not reach the rather distant pentacene:SAM interface – approximately 100 nm away, i.e. the thickness of the pentacene layer – where hole transport across the channel is taking place. By analysing the evolution of either V_T or I_D, under p-channel operation as a function of illumination intensity, one could in principle calculate the density of photo-generated charges, i.e. the number of electrons transferred from pentacene to $PC_{61}BM$. Although these measurements are beyond the scope of this work, they clearly demonstrate the potential of bi-layer phototransistors for use not only as photosensors but also as a test-bed for fundamental studies.

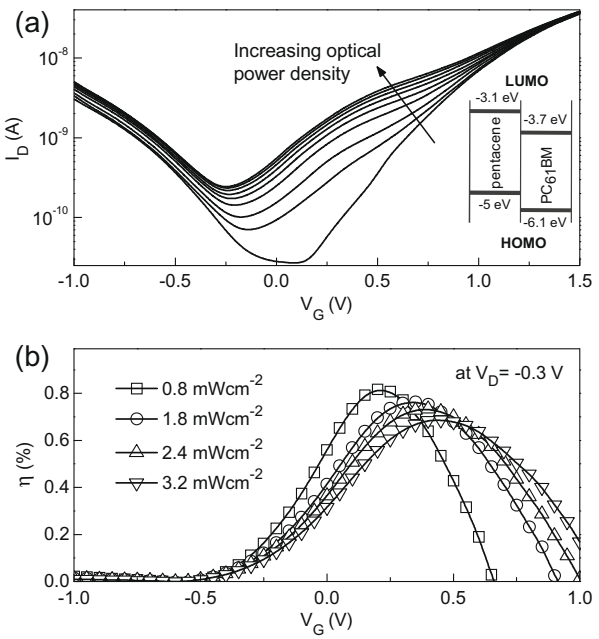

Fig. 2. (a) Transfer characteristics of heterostructure ambipolar OFET (L = 50 μm, W = 1 mm) measured at V_D = −1 V, under blue light illumination (using a λ_{peak} = 469 nm LED) with incident optical power densities between 0 and 3.2 mW cm^{-2}. Inset: simplified energy diagram of the pentacene/$PC_{61}BM$ interface. (b) External quantum efficiency of the same OFET, measured at V_D = −0.3 V, as a function of V_G for different incident optical power densities.

From Fig. 2a it can clearly be seen that the magnitude of photo-generated current in the off-state is modulated by the power density of incident light. By defining the external quantum efficiency (EQE) η, as the ratio of the number of photo-generated carriers that contribute to the drain current to the number of photons incident on the transistor channel area, the EQE of the phototransistors can be defined as:

$$\eta = \frac{(I_{light} - I_{dark})hc}{ePA\lambda_{peak}}$$

Here I_{light} and I_{dark} are the transistor drain currents under illumination and in the dark, respectively, h is the Plank constant, c is the speed of light in *vacuo*, e is the magnitude of the fundamental unit of charge, P is the incident optical power density, A is the area of the transistor channel and λ_{peak} is the peak wavelength of the incident light. For these measurements the LED source is approximated to be monochromatic.

A plot of η versus V_G for a range of optical power densities is shown in Fig. 2b.The observed reduction in the peak EQE with increasing optical power density is most likely attributed in the saturation of photo-generated carriers. Further details on this mechanism can be found elsewhere [22]. The peak EQE of these phototransistors was found to be approximately 0.8%. From Fig. 2b it can also be seen that the transistor photoresponsivity can be tuned by the V_G potential. By biasing the transistor at V_G = 0.5 V and V_D = 1 V and pulsing the LED, the dynamic response of the

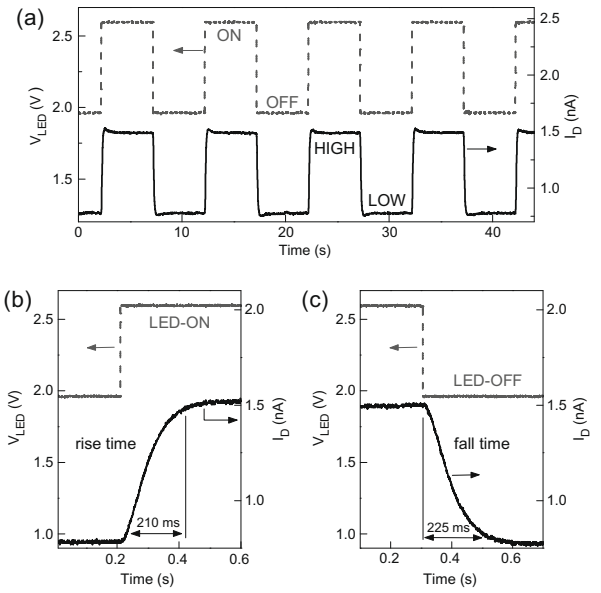

Fig. 3. (a) Evolution of channel current in an OFET (L = 50 μm, W = 1 mm), measured at V_D = 1 V and V_G = 0.5 V, as a function of time under pulsed light (λ_{peak} = 469 nm) illumination. The upper (dashed) trace shows the voltage applied to the LED (V_{LED}) while the lower (solid) trace shows the evolution of the channel current versus time. (b) Switch-on and (c) switch-off optical response of OFET as a function of time.

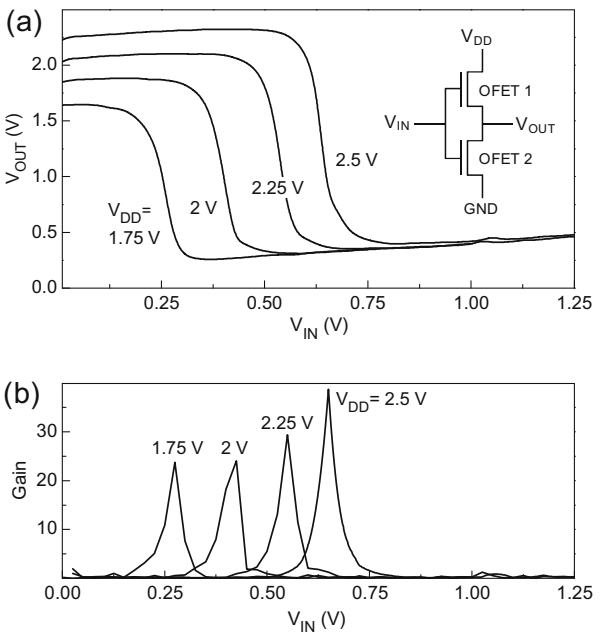

Fig. 4. (a) Transfer characteristics (V_{OUT} versus V_{IN}) of a low-voltage complementary-like inverter consisting of two SAM-based heterostructure OFETs measured at different supply voltages (V_{DD}). Inset: circuit diagram of complementary-like inverter. (b) Small-signal gain versus V_{IN} at different V_{DD}.

phototransistor was also measured (Fig. 3). The switch-on and switch-off times for this device were approximated from the dynamic measurements shown in Fig 3b and c, respectively, yielding values in the range 210–225 ms. The relatively low switching speed is attributed to the large overlap between the source/drain and gate electrodes and the large channel length, resulting in: (i) high RC constants and (ii) long carrier transit times. Significant improvement is anticipated through device design optimisation such as development of phototransistors with aligned gate electrodes and shorter channel lengths. The response time, whilst long for most photodetector applications, is significantly shorter than observed lifetimes of trapped charges (minutes to days) [20]. This supports our interpretation that the changes in I_D observed in the off-state are mainly due to photo-generated charges and not changes in trap-state occupation densities. Hence, there is a clear benefit in using a heterojunction ambipolar phototransistor as opposed to a unipolar phototransistors for optical sensing [9].

By using two low-voltage ambipolar transistors with similar channel dimensions we have also been able to fabricate low-voltage complementary-like voltage inverters. The inverter circuit employed together with a representative set of operating characteristics are shown in Fig. 4a. The gain characteristics as a function of V_{IN}, at different supply voltages, are also shown in Fig. 4b. The circuit exhibits sharp voltage swings indicating good inverter operation. The peak small-signal gain for this particular circuit is on the order of 35 and is obtained at maximum supply voltage. The signal gain together with the asymmetry of the trip point could in principal be further improved by circuit design optimisation but is beyond the scope of this work.

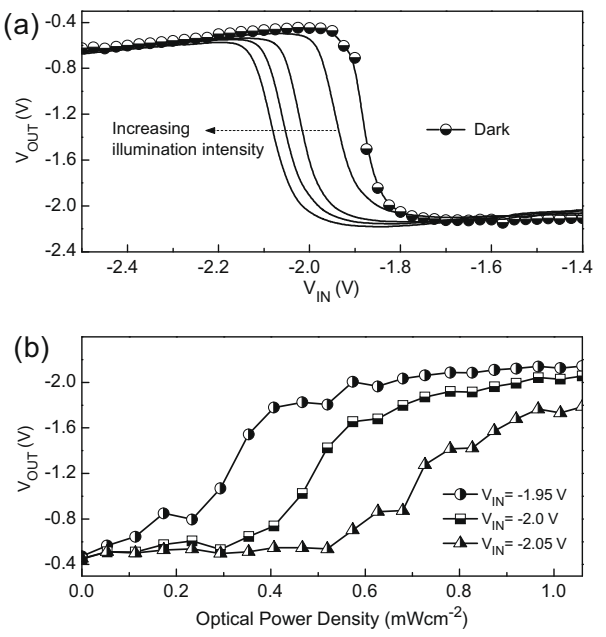

Fig. 5. (a) Transfer characteristics of a low-voltage inverter measured in the dark and under blue light (λ_{peak} = 469 nm) illumination with incident optical power densities between 0–1.2 mW cm^{-2}. (b) Effect of incident optical power density on V_{OUT} measured at a fixed V_{DD} (−2.5 V) and different V_{IN} biases.

One very interesting property of these low-voltage complementary-like circuits is the strong dependence of their operating characteristics on incident light. This effect is demonstrated in Fig. 5a where the transfer characteristics measured in dark are plotted together with those measured under blue light illumination with different intensities. This effect is believed to be due to changes in the n-channel threshold voltage under illumination. By biasing the inverter at an appropriate V_{DD} and V_{IN}, the device can hence be used as an optical switch, switching from a low $|V_{OUT}|$ to a high $|V_{OUT}|$ once light above a threshold power density is detected. The threshold optical power density can be tuned through a choice of V_{DD} and V_{IN}, as shown in Fig. 5b.

4. Conclusions

Low-voltage ambipolar organic field-effect transistors have been fabricated from bi-layer semiconductor structures and self-assembled monolayer gate dielectrics. Under optical illumination the source–drain current was found to increase, allowing the devices to be used as low-voltage phototransistors. The peak external quantum efficiency of the devices was found to be approximately 0.8%, while the response time was in the range 210–225 ms. Using two transistors with similar dimensions, low-voltage complementary-like inverters were demonstrated. The operating characteristics of these circuits were shown to be light-intensity dependent, allowing the inverters to be used as optical sensors with tuneable responsivity. This work is a significant step towards the fabrication of low-power phototransistor-based imaging arrays.

elusive due to the complexity of designing such material: broadband absorption covering the whole visible spectrum (400–800 nm) in the neutral state, extra requirement of distinct and low oxidation potentials for electropolymerization, simultaneous depletion of absorption bands upon doping and so forth. Indeed, to date, only one example of black PEC has emerged from Reynolds' laboratory [30] by using chemical co-polymerization of an increasingly substituted donor–acceptor (D–A) system [31]. Therefore, it is a challenging task to access electrochemically to a neutral state black polymer in view of optoelectronic devices, displays (road signs, clocks and shop displays), windows shades along with many flexible and portable art and design applications [32,33]. Furthermore, black polymers would also be highly valuable for solar cell applications [34].

Recently, our endeavors directed to the design and synthesis of novel organic π-conjugated polymers [29,35] prompted us to investigate the fate of two D–A systems, **1** and **2**. We found that D–A systems **1** and **2** were able to produce saturated blue and green colors after electropolymerization (**P1** and **P2**), respectively (Fig. 1) [36]. Since the oxidation potential values of both monomers are very close to each other (1.01 V for **1** and 0.98 V for **2** vs. Ag/AgCl), oxidation of **1** and **2** in the same medium can form random copolymers due to competing reactions between them during the electrolysis.

Since the sum of the electronic absorption spectra of **P1** and **P2** covered the whole range of visible spectrum (400–800 nm) (see Fig. 1), it was envisaged that electrochemical co-polymerization via repetitive cycling or constant potential electrolysis of **1** and **2** with a certain monomer feed-ratio might provide an entry into neutral state black polymers. In this paper, we wish to report the electrochemical polymerization of a discreet combination of two D–A systems which provided a soluble neutral state black polymeric electrochromic (**P(1-co-2)**). To the best of our knowledge, (**P(1-co-2)**) is the first electropolymerized polymer absorbing virtually the whole visible spectrum (400–800 nm) in the neutral state with a low bandgap (1.45 eV). Furthermore, it exhibits excellent operational and/or environmental stability.

2. Results and discussion

2.1. Electropolymerization

Initially, the redox behavior of a mixture of **1** and **2** was investigated by cyclic voltammetry (CV). Although both monomers were highly soluble in dichloromethane (DCM), the cyclic voltammograms of **1**, **2** and their mixture were recorded in a mixture of DCM and acetonitrile (ACN, as a non-solvent) in order to hinder the solubility of the polymer film, which was formed on the electrode surface, by cosolvent effects. The cyclic voltammogram of a mixture of **1** and **2** with 1:4 monomer feed ratio in 0.1 M tetrabutylammonium hexafluorophosphate (TBAH)/DCM–ACN (3/2, v/v) exhibits two consecutive oxidation peaks at 0.93 V and 1.01 V indicating that the electrochemical co-polymerization of **1** and **2** was feasible. Upon successive scans a new reversible redox couple was also noted, which indicates the formation of corresponding copolymer (**P(1-co-2)**) film on the electrode surface (Fig. 2).

The as-prepared polymer film had black color in the neutral state and it was soluble in common organic solvents (DCM, $CHCl_3$, etc.) and slightly soluble in toluene and diethylether, which clearly suggested that it could easily be processed over surfaces via spin coating, spraying and printing techniques (Fig. 3).

However, it was noteworthy that the peak current versus scan rate curve of the copolymer during p-type doping was linear which brought convincing evidence that the redox process is not diffusion-limited. Interestingly, it was also found that the polymer film has shown almost the same charge/discharge behavior between the scan rates of 50 mV/s and 200 mV/s. The data suggests that the charge transport takes place rapidly through the coated polymer film and the electroactive sites remain unaltered

(a) Cyclic voltammogram during the repeated scan electropolymerization of a mixture of **1** and **2** with 1:4 monomer feed ratio to give **P(1-co-2)** in 0.1 M TBAH/DCM–ACN (3/2, v/v) at a scan rate of 100 mV/s, Pt disk working electrode, and (b) scan rate dependence of the **P(1-co-2)** film in 0.1 M TBAH/ACN at different scan rates (mV/s); (a) 50; (b) 75; (c) 100; (d) 125; (e) 150; (f) 175; and (g) 200.

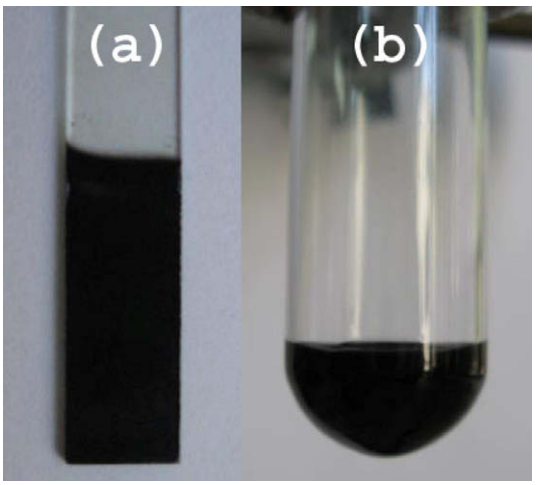

Fig. 3. **P(1-co-2)** film on ITO glass slide and **P(1-co-2)** in DCM.

independent of the externally induced potential. This intriguing feature paves the way for utilizing **P(1-co-2)** as p-type material in supercapacitors and/or transistors [37].

The long-term stability upon switching and/or cycling plays a key role on the electrochromic performance of the devices and smart windows. Therefore, the electrochemical stability of **P(1-co-2)** was tested by cycling the polymer film between its neutral and oxidized states at a scan rate of 200 mV/s. As shown in Fig. 4, no appreciable change in the electrochemical response of **P(1-co-2)** was observed and 90% of the electroactivity was still kept even after four thousands of cycles. Note that the stability tests were carried out under air atmosphere and the system was not sealed (sealing would further increase the long-term stability of the material upon switching and/or cycling). It can be safely concluded that **P(1-co-2)** exhibits both operational stability and environmental robustness under ambient conditions.

2.2. Spectroelectrochemistry

The changes in the optical absorption spectrum of **P(1-co-2)** film coated on ITO glass slide were recorded in situ to elucidate the electro-optical properties. In the neutral state, **P(1-co-2)** exhibited a broad absorption band with three shoulders at 422 nm, 522 nm and 660 nm extending virtually over the full visible spectrum (Fig. 5). When compared to the absorption bands of **P1** (580 nm) and **P2** (342 nm, 712 nm) in Fig. 1, the spectrum of the product confirms the formation of a copolymer since the absorption bands of the claimed copolymer do not exactly match the corresponding homopolymers. **P(1-co-2)** had a lower band gap of 1.45 eV, which was calculated from the commencement of the low energy end of the π–π^* transition at 660 nm, than chemically obtained black random copolymer of Reynolds and coworkers [30] (E_g = 1.64 eV). The intensities of the π–π^* transition bands decreased simultaneously upon p-type doping, which unambigiously indicated the presence of a homogeneous polymer film rather than bilayer. Furthermore, a new absorption band beyond 900 nm started to intensify due to the formation of charge carriers during doping process (Fig. 5). These absorbance variations occurred around an isosbestic point which appeared at 796 nm (1.56 eV), suggesting that only two phases coexisted. Upon further oxidation, the polaron band reached a maxima while the π–π^* transition band diminished completely.

Finally, these changes in the electronic absorption spectra of **P(1-co-2)** film upon doping nicely reflected by a color change from black (L = 14.3, a = 0.29, b = 0.35) in the neutral state to transmissive grey (L = 39.2, a = 0.29, b = 0.33) in the oxidized state (Fig. 5). The percentage transmittance change ($\Delta\%T$) between the redox states was found to be 15.3% for 522 nm. The optical stability is an important feature for such materials to be amenable for use in electrochromic and optical devices. It was noted that the copolymer film did not loose its electroactive property completely when switched between its neutral and oxidized states. For example, the copolymer film re-

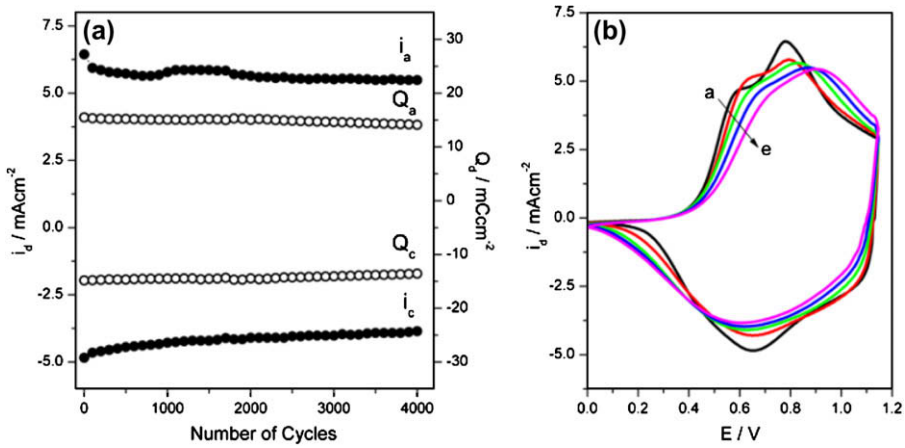

Fig. 4. (a) Relationship of anodic (i_a), cathodic (i_c) peak currents and the charge (Q_a)/discharge (Q_c) variations of **P(1-co-2)** as a function of number of cycles and (b) cyclic voltammetry stability of **P(1-co-2)** film at a scan rates of 200 mV/s between 0.0 V and 1.1 V in 0.1 M TBAH/ACN. Number of cycle: (a) 1; (b) 1000; (c) 2000; (d) 3000; and (e) 4000.

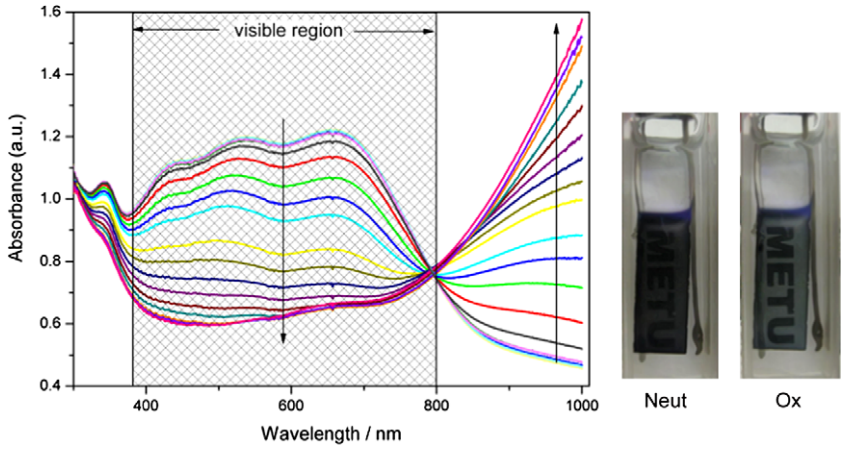

Fig. 5. Electronic absorption spectra of the **P(1-co-2)** film coated on ITO electrode at various applied potentials between 0.0 V and +1.2 V in 0.1 TBAH/ACN, and the colors of the **P(1-co-2)** in different redox states.

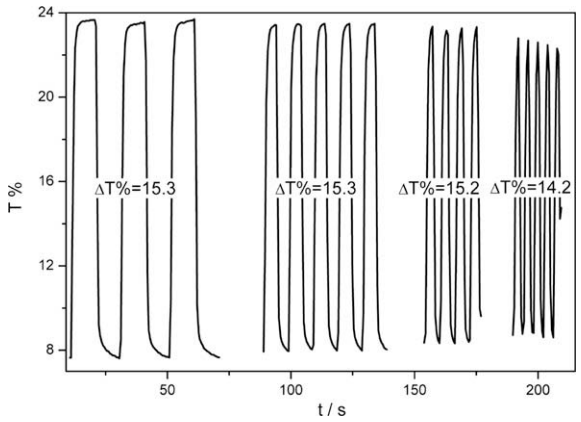

Fig. 6. Chronoabsorptometry experiment at 522 nm for **P(1-co-2)** film on ITO electrode in 0.1 M TBAH/ACN while the polymer was switched between −0.1 V and 1.0 V (vs. Ag wire) with a switching time of 10 s, 5 s, 3 s and 2 s.

tains 72.3% of its electroactivity for the first 2000 cycles. Switching time between the redox states or different colors is also a crucial parameter to realize the versatility of the electrochrome. Hence, the transmittance changes (optical contrast) was recorded via square-wave potential methods between 0.0 V and 1.2 V with switching times of 10 s, 5 s, 3 s and 2 s. As shown in Fig. 6, **P(1-co-2)** film preserved its electro-optical properties with no appreciable changes and the polymer film gave response in a very short time. For example, only 1.1% optical contrast change was observed when the switching time was decreased to 2 s. These features show the versatility of the polymer film for the construction of high performance displays and electrochromic devices.

3. Conclusion

In conclusion, a new soluble neutral state black PEC, (**P(1-co-2)**), which was obtained by electrochemical means

was disclosed. To the best of our knowledge, this is the first example of electropolymerized materials absorbing nearly the whole visible spectrum (400–800 nm) in the neutral state. Furthermore, (**P(1-co-2)**) has a low bandgap (1.45 eV) and it exhibits excellent operational and environmental stability. Considering the fact that low bandgap black polymers hold promise for both solar cells and electronic ink-based applications, we hope that **P(1-co-2)** would give us ample opportunity for innovative technological applications. Work along these lines is currently underway in our laboratories.

4. Experimental

4.1. Materials and methods

All chemicals were purchased from Aldrich Chemical and used as received unless otherwise noted. 0.1 M tetrabutylammonium hexafluorophosphate (TBAH) dissolved in dichloromethane (DCM) and acetonitrile (ACN) was used as electrolyte solution. A platinum disk (0.02 cm^2) and a platinum wire were used as working and counter electrodes, respectively, as well as a Ag/AgCl in 1.0 M NaCl reference electrode or a silver wire as a pseudo-reference electrode (calibrated externally using 5 mM solution of ferrocene/ferrocenium couple). Repetitive cycling or constant potential electrolysis was used to obtain the polymer films. Electro-optical properties were investigated by using an indium tin oxide (ITO, Delta Tech. 8–12 Ω, 0.7 cm × 5 cm) electrode as well as a platinum wire as counter electrode and a Ag wire as a pseudo-reference electrode. In order to equilibrate the redox behavior of the polymer film and to obtain repeated results, the coated polymer films were switched between their neutral and oxidized states several times before electroanalytical and optical studies. Electroanalytical measurements were performed using a Gamry PCI4/300 potentiostat–galvanostat. The electro-optical spectra were monitored on a Hewlett–Packard 8453A diode array spectrometer. FT-IR spectra were recorded on Nicolet 510 FT-IR with attenuated total reflectance. Photographs of the polymer films were taken by using a Canon (PowerShot A75) digital camera. The details of synthesis, characterization and properties for **1**, **2**, **P1** and **P2** will be reported elsewhere. 4,7-Dibromobenzo[c][1,2,5]selenadiazole [38] was prepared according to literature procedures.

4.1.1. Representative procedure for the synthesis of *1* and *2*

To an argon degassed solution of tributyl(3,3-didecyl-3,4-dihydro-2H-thieno[3,4-b][1,4]dioxepin-8-yl)stannane (243 mg, 0.334 mmol) and 4,7-dibromo-2-decyl-2H-benzo[d][1,2,3]triazole or 4,7-dibromobenzo[c][1,2,5]selenadiazole (0.134 mmol) in dry toluene (15 ml) was added $Pd(PPh_3)_2Cl_2$ (18.8 mg, 0.0268 mmol) and the mixture was heated under reflux overnight. After cooling to room temperature, the solvent was removed under reduced pressure. The crude mixture was chromatographed on silica gel by eluting with methanol:chloroform (4:1, v/v) to give **1** or **2**.

4.1.2. 2-Decyl-4,7-bis(3,3-didecyl-3,4-dihydro-2H-thieno[3,4-b][1,4]dioxepin-6-yl)-2H-benzo[d][1,2,3]triazole (*1*)

40% yield; ^{1}H NMR (400 MHz, $CDCl_3$, δ): 7.94 (s, 2H), 6.49 (s, 2H), 4.69 (t, J = 7.2 Hz, 2H), 3.95 (s, 4H), 3.86 (s, 4H), 2.09 (t, J = 7.2 Hz, 2H), 1.43–1.37 (m, 8H), 1.31–1.22 (m, 62H), 0.85–0.82 (m, 12H); ^{13}C NMR (100 MHz,$CDCl_3$, δ): 150.3, 147.5, 142.4, 124.7, 122.0, 118.3, 105.1, 78.05, 77.97, 44.1, 44.0, 32.3, 30.8, 30.2, 29.8, 29.6, 29.5, 29.3, 23.2, 23.1, 14.3; FT-IR (ATR, cm^{-1}): 2917, 2851, 1516, 1480, 1451, 1407, 1378, 1255, 1164, 1029, 833, 797, 727, 647, 611. density dependence of the hole mobility into account. Neglecting the charge–carrier density dependent effect would lead to an overestimation of p_0 by an order of magnitude for the 1:600 doping ratio. Further understanding of the charge transport in doped conjugated polymers is required to advance the performance of polymeric optoelectronic devices. In this study we investigate the field (E) and temperature (T) dependence of the charge transport of p-type doped MEH-PPV. We demonstrate that in order to describe the hole transport at low temperatures and high electric fields a field-assisted ionization of the F4-TCNQ dopants has to be taken into account.

Upon addition of p-type doping free holes are introduced into the organic semiconductor. At low voltages these free holes, or background density p_0, will largely outnumber the charges that are injected from the contacts. As a result an Ohmic-like current will flow, given by

$$J_\Omega(V,T) = qp_0(T)\mu_p(T,p_0(T),E)\frac{V}{d} \tag{1}$$

with q the magnitude of electron charge, p_0 the free hole density, μ_p the hole mobility, d the thickness of the polymer layer, and $E = V/d$. At higher voltages space–charge due to holes injected from the contacts will start building up and a transition to the space–charge limited current (SCLC) will occur. From Eq. (1) it is already obvious that the analysis of the temperature dependence of the J–V characteristics is not straightforward: the amount of free holes p_0 might be temperature-dependent due to a thermally activated ionization process of the dopant. Furthermore, the mobility will not only depend on temperature due to the hopping of holes in a disorder broadened Gaussian DOS, but also on the free hole density p_0 (that in itself also might be temperature-dependent) due to the filling of states in the tail of the Gaussian DOS [19,20]. All these possible temperature-dependent contributions from the density and mobility have to be disentangled in order to understand the charge transport. To measure the T-dependence of the transport in conducting polymers upon doping, MEH-PPV hole-only devices were made by sandwiching the matrix in between two metal contacts. As a bottom electrode indium–tin-oxide (ITO) covered with PEDOT:PSS was used, and a Pd top electrode of 20 nm was thermally evaporated on top of the MEH-PPV layer under a chamber pressure of 8×10^{-7} mbar and then capped with 100 nm of Au. The MEH-PPV was dissolved in toluene, whereas for F4-TCNQ tetrahydrofuran (THF) was used as the solvent. Further details of the processing are given in Ref. [18]. A Keithley 2400 SourceMeter and a Solartron SI 1260 Impedance/Gain-Phase analyzer were used for the I–V and C–V measurements, respectively. All electrical measurements were performed in a nitrogen-purged glove box and the temperature was controlled by a cyrosystem with liquid nitrogen.

As a first step we investigate the temperature- and density dependence of the hole mobility in MEH-PPV by measuring the SCLC in *undoped* MEH-PPV. Fig. 1(a) shows the current density versus voltage (J–V) characteristics of a PEDOT:PSS/ undoped MEH-PPV /Pd/Au hole-only device at various temperatures. The J–V characteristics are numerically modeled by using a recently developed transport model, that takes into account both the field E and density p dependence of the hole mobility μ_p [19]. The mobility is given by

$$\mu_p(T,p,E) \approx \mu_p(T,p)f(T,E), \tag{2}$$

with

$$\mu_p(T,p) = \mu_0(T)\exp\left[\frac{1}{2}\hat{\sigma}^2 - \hat{\sigma})(2pa^3)^\delta\right], \tag{3}$$

$$\mu_0(T) = \mu_0 c_1 \exp(-c_2\hat{\sigma}^2), \tag{4}$$

$$\delta = 2\frac{In(\hat{\sigma}^2 - \hat{\sigma}) - In(In4)}{\hat{\sigma}^2}, \tag{5}$$

$$\mu_0 = \frac{a^2\upsilon_0 e}{\sigma}, \tag{6}$$

and

$$f(T,E) = \exp\left\{0.44(\hat{\sigma}^{3/2} - 0.22)\left[\sqrt{1 + 0.8\left(\frac{Eea}{\sigma}\right)^2} - 1\right]\right\} \tag{7}$$

where, $\hat{\sigma} \equiv \sigma/K_bT$ with σ the width of the Gaussian DOS, and a is the lattice constant. The lines in Fig. 1(a) are the numerically calculated J–V characteristics using a μ_{p0} of 6.4×10^3 m^2/Vs, an a_{p0} of 1.55 nm, and a σ_{p0} of 0.143 eV. These parameters are similar to the ones reported for another PPV derivative with a similar mobility [19], and the temperature dependence of the J–V characteristics is well described, both at low and high voltages. The activation energy of the mobility Δ_{mobility} at low fields and densities, defined as $\mu_p\ (T,\ 0) = \mu_0\ \exp(-\Delta_{\text{mobility}}/kT)$, typically amounts to 0.42 eV.

With $\mu_p(T,p,E)$ known we can analyze the J–V characteristics of the p-type doped MEH-PPV. Fig. 1(b) shows the J–V characteristics of p-type doped MEH-PPV with a molar doping ratio of 1:150. The linear part of the J–V characteristic (Eq. (1)) is governed by the product of the hole density p_0 and the hole mobility μ_p. With $\mu_p(T,p,E)$ known (Eqs. (2)–(7)) we can determine them individually, leading to $p_0 = 2.2 \times 10^{23}$ m^{-3} and $\mu_p = 1.2 \times 10^{-9}$ m^2/V s at room temperature. The enhanced mobility upon doping is a direct result from the filling of the tail states of the Gaussian DOS by holes. The resulting rise of the Fermi-level decreases the energy step required for hopping towards the transport states, which enhances the mobility.

Under the assumption that the temperature dependence $p_0(T)$ is very small and can be neglected the full temperature- and voltage dependence of the transport in the doped MEH-PPV can be numerically calculated. The calculations using $\mu_p(T,p,E)$ in combination with a constant p_0 of 2.2×10^{23} m^{-3} are shown in Fig. 1b by the solid lines. However, we observe that the model calculations become inconsistent with the experiments at high electric fields (E) and low T (<270 K). At low voltages the experimental hole currents exhibit a weaker temperature dependence as expected from the model. Furthermore, at high voltages the experimental J–V curves show a stronger dependence

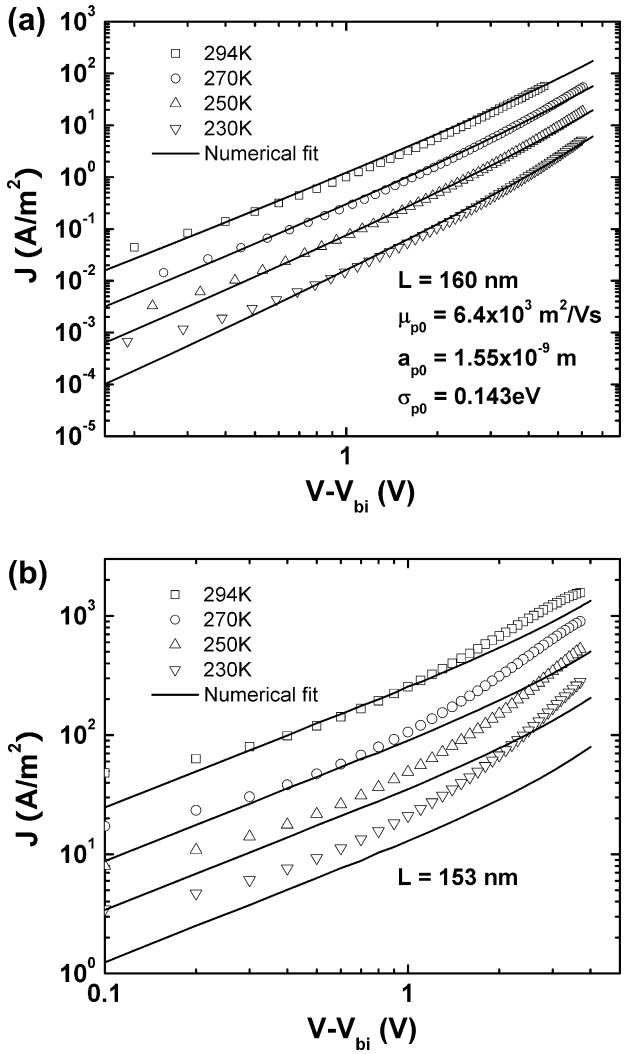

Fig. 1. Current density versus voltage characteristics of (a) an undoped and (b) a doped MEH-PPV hole-only device with a molar doping ratio of 1:150. Shown by the solid lines are the numerically calculated currents using a constant free hole density (p_0).

on voltage. As a result the inclusion of only a constant background density p_0 in the existing charge transport model characterized by $\mu_p(T,p,E)$ is not sufficient to explain the *J–V* characteristics of *p*-type doped MEH-PPV.

One could argue that the mobility as measured in the undoped sample is not only changed by the density p_0, but also by the presence of the F4-TCNQ$^-$ counter ions. The hole transport in undoped conjugated polymers is dominated by energetic and positional disorder [21,22]. Upon doping the energetic disorder and corresponding width of the Gaussian density of states (DOS) is expected to increase due to potential fluctuations caused by the Coulomb field of randomly distributed dopant ions [23,24]. Such a modification of the DOS upon doping would lead to a reduction of the mobility as well as to an increased temperature dependence of the mobility. This enhanced temperature dependence would even further increase the discrepancy between calculations and experiments at low fields. Furthermore, in a previous study [18] we verified by *C–V* measurements that the p_0 as extracted from the *J–V* measurements, thereby making use of the intrinsic density dependence of the mobility as obtained in the undoped sample, is indeed correct. If the mobility would have been strongly modified upon doping other than due to the increase of the carrier density our extracted densities from the *J–V* measurements would deviate from the densities as obtained from the *C–V* measurements. Theoretically, the modification of the Gaussian DOS upon doping is also expected to set in at higher densities, typically when $N_A^- > 10^{23}$ m^{-3} [24,25]. As a result in our experimental regime with the amount of ionized acceptors N_A^- low in the $\sim 10^{23}$ m^{-3} no significant change of the mobility is expected other than due to the increased free carrier concentration.

By comparing the amount of doping with the free hole density we find that only ~1% of the F4-TCNQ molecules in the MEH-PPV are ionized. A possible explanation for this low doping efficiency may be phase separation between the

host and the dopant, in which case only dopant molecule at the interface between the two phases will ionize. Our modeling results shown in Fig. 1(b) demonstrate that the field- and temperature dependence of the doped sample can not be described assuming a constant p_0. We postulate that the strong increase of the J–V characteristics at high voltages and the reduced temperature dependence is a result of a *field-assisted* release of holes from the dopants. We therefore introduce a field-dependent p_0 with a Poole–Frenkel like dependence on the applied electric field,

$$p_0(E) = p_0 \exp(\gamma\sqrt{E}) \tag{8}$$

where, p_0 is now the zero-field free hole density, and γ the field-enhancement factor. In Fig. 2 the J–V characteristics are shown at various temperatures for doped MEH-PPV hole-only devices with varying molar doping ratios of 1:600, 1:350, 1:250 and 1:150. The corresponding free hole density p_0 is ranging from 5×10^{22} to $2.0 \times 10^{23}\ m^{-3}$, respectively. Since for every molar doping ratio a new solution is made the thickness after spin coating is slightly varying. The lines are the numerical simulations by combining the mobility from Eqs. (2)–(7) and the field-enhanced free carrier density given by Eq. (8). We assume that p_0 is temperature independent. Taking the field-assisted ionization of the dopants into account a good description of the J–V characteristics can be made, as shown by the solid lines in Fig. 2. The variation of γ with temperature and doping concentration is shown in Fig. 3a. We find that similar to the prefactor that is responsible for the field-dependent mobility in disordered materials [26], γ follows the empirical relation

$$\gamma = B\left(\frac{1}{k_B T} - \frac{1}{k_B T_0}\right) \tag{9}$$

with $T_0 = 400$ K and the prefactor B ranging from 1.3×10^{-5} to 6.4×10^{-6} eV(m/V)$^{1/2}$ for the range of $p_0 = 5 \times 10^{22}\ m^{-3}$ to $p_0 = 2 \times 10^{23}\ m^{-3}$, respectively. These values for B are considerably smaller than the values reported for the field-dependent mobilities [26]. The increase of p_0 as a function of the electric field is plotted in Fig. 3(b) to illustrate the impact of the electric field on the background hole density from doping. We find that a p_0 of $\sim 10^{22}\ m^{-3}$ is enlarged by $\sim$5 times at high E and 2–3 times for a p_0 of $\sim 10^{23}\ m^{-3}$. In the field-enhanced charge transport the factor γ is usually related to a hopping distance [27]. For higher doping concentrations it is expected that the average distance that holes will have to hop from a dopant molecule to a site of the matrix will decrease. This would result

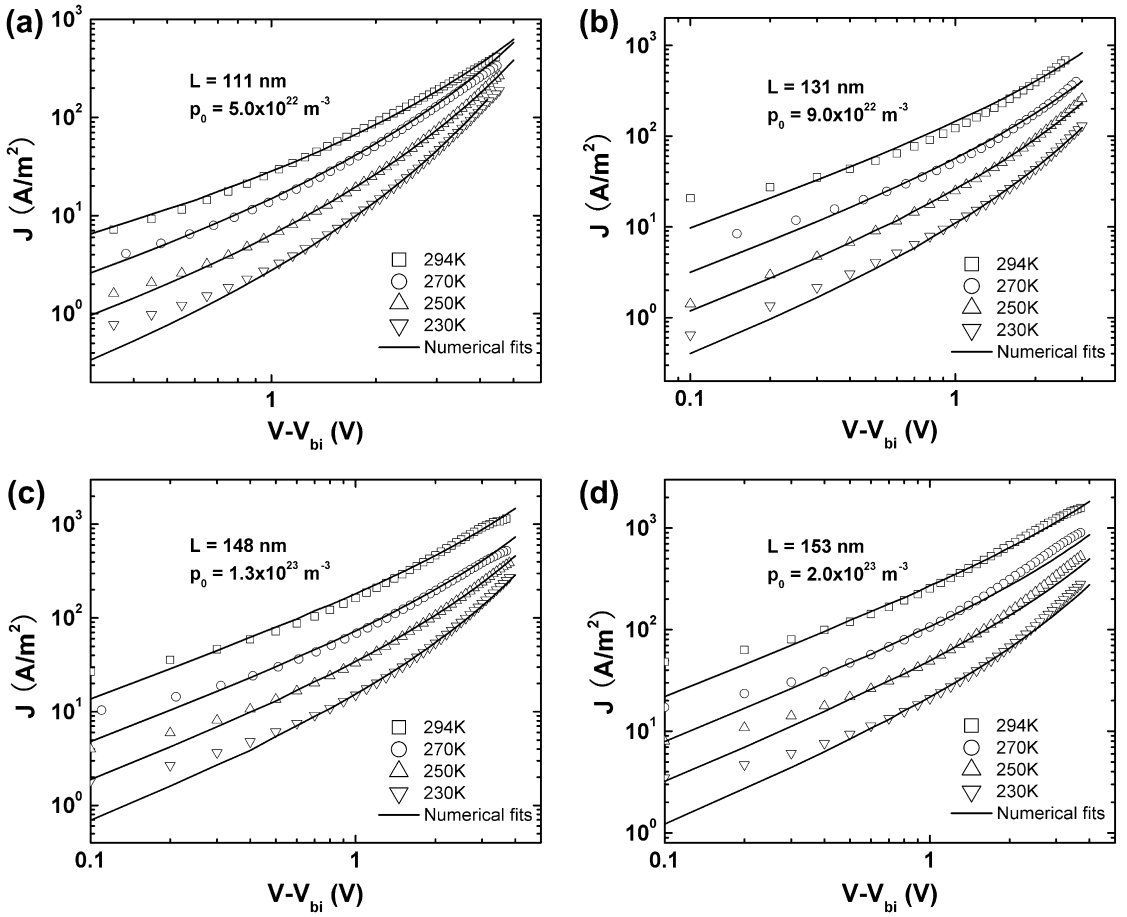

Fig. 2. Current density versus voltage characteristics of MEH-PPV hole-only devices with various doping concentrations. Also represented (solid lines) are the calculated current densities taking a field-dependent background hole density into account.

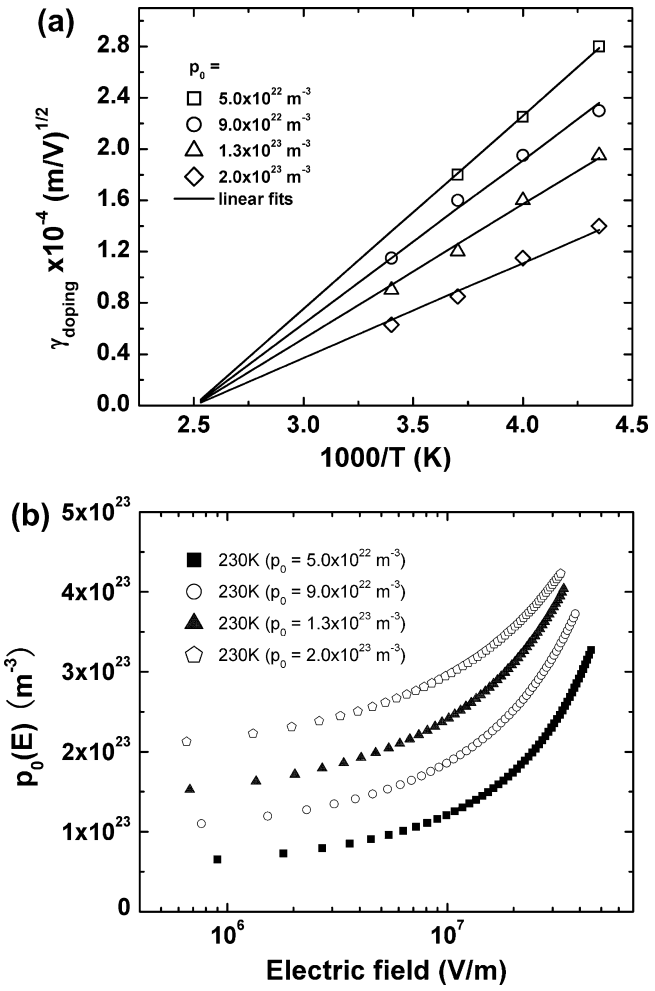

Fig. 3. (a) Field-enhancement factor γ versus temperature for different doping concentrations. (b) Free hole density calculated as a function of electric field at T = 230 K.

in a weakening of the field-enhanced ionization factor, but at present a microscopic theory or explanation is still lacking.

As a last step we investigate the temperature dependence of the low-field background density p_0 using impedance spectroscopy. For this we fabricate Ag/MEH-PPV Schottky diodes with an Ohmic PEDOT:PSS back contact. The molar doping ratio amounts to 1:500. Fig. 4(a) shows the capacitance of the depletion region versus voltage at room temperature. The capacitance at zero-voltage slightly reduces upon cooling down, indicating that the density of free holes is slightly reduced at low temperatures. A reduced density will lead to an enlargement of the depletion region with a resulting smaller capacitance. The capacitance of the depletion region C is given by

$$\frac{1}{C^2} = \frac{2\left(V - V_{bi} - \frac{kT}{q}\right)}{q\varepsilon_s p_0}, \tag{10}$$

with V_{bi} the built-in voltage and ε_s the permittivity of the semiconductor. As a result, from the slopes of the lines in Fig. 4(a) p_0 can be determined at various temperatures. The temperature dependence of p_0 is plotted in Fig. 4(b). At a doping level of 3.4×10^{22} m^{-3} we obtain that the activation energy for the ionization of free holes from the F4-TCNQ acceptor in MEH-PPV only amounts to 46 meV. This means that in the entire temperature interval of 230–300 K the p_0 only changes by a factor 1.5. For higher doping levels the change of p_0 with temperature is within experimental error. The observed activation energy of p_0 is so small that its weak temperature dependence does not affect the modeling results shown in Fig. 2b. Therefore, the C–V measurements confirm that a temperature independent p_0 is a valid assumption in the modeling.

It might seem counterintuitive that the strongest γ occurs at the lowest doping densities, whereas in a previous study [18] we showed that at low background densities the room temperature J–V characteristics could be reasonably well described by a constant background density p_0. At low voltages the J–V characteristics of doped semiconductors exhibit an Ohmic behavior, as given by Eq. (1). At a certain voltage V_t the charges injected from the contact overwhelm the charges from the doping and the current becomes space–charge limited. This transition voltage V_t

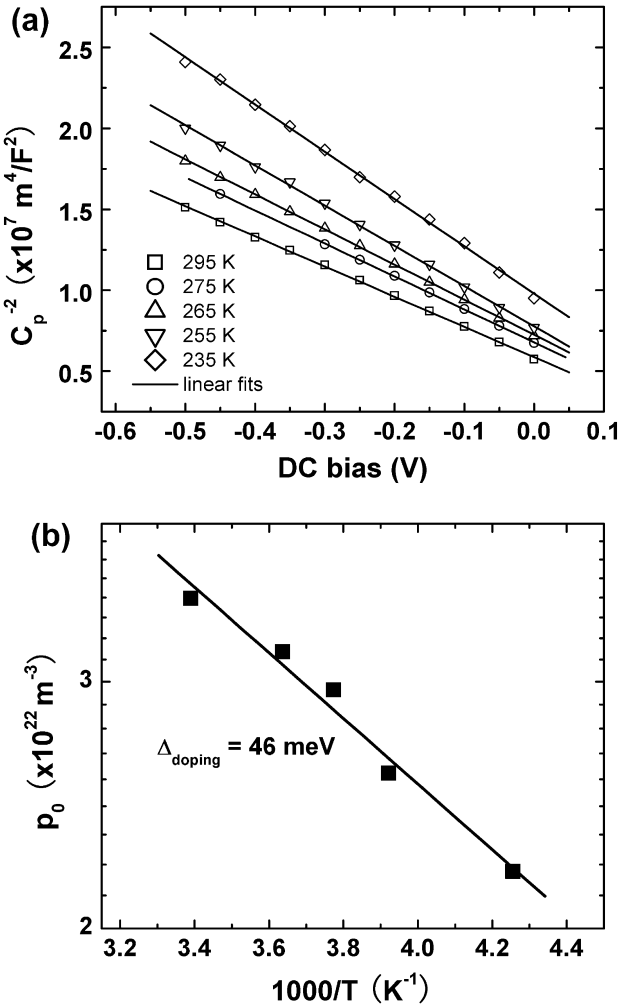

Fig. 4. (a) Depletion capacitance as a function of negative bias for a MEH-PPV Schottky diode at various temperatures. (b) Extracted background hole density as a function of temperature. The activation energy amounts to $\Delta_{doping} = 46$ meV for $p_0 = 3.4 \times 10^{22}$ m^{-3}.

depends on the amount of doping; for low doping densities V_t is also low, meaning that the Ohmic regime is only observable in a small voltage range. The enhancement of p_0 at higher voltages ($>V_t$) and fields is then not really visible in the J–V characteristic. For high doping densities the resulting Ohmic behavior due to the large p_0 dominates the J–V characteristics over a much larger voltage range, and then the increase of p_0 with field, together with the enhancement of the mobility by the increased p_0, make this effect strongly visible.

In conclusion, the transport in MEH-PPV doped with F4-TCNQ can be explained by taking into account a field-assisted ionization of the dopant, leading to a field-dependent background carrier density. The ionization of the dopants becomes more pronounced at low temperatures and high electric field.

we compared the performances of PPE pentacene TFTs with and without SAM layer using pentafluorobenzenthiol (PFBT) on Au. The SAM can enhance the hole injection to p-type semiconductor [12].

An inverter circuit composed of two enhancement mode PPE pentacene TFTs, was demonstrated in this work. The channel widths of driver and load transistors of a inverter were 500 μm and 100 μm, respectively, with channel length of 6 μm.

A PPE pentacene was synthesized according to the method described in the literature [13]. PPE pentacene has photo-oxidation stability through delocalized π-electrons from the pentacene at C_6, C_{13} positions. Fig. 1(a) shows the chemical structures of PPE pentacene and PFBT. A PPE pentacene is soluble in various solvents such as toluene, chlorobenzene and 1,2-dichlorobenzene. The PPE pentacene solution was prepared by dissolving it in 1,2-dichlorobenzene (10 mg/mL) and filtered through 0.45 μm poly(tetrafluoroethylene) membrane filter.

The PPE pentacene TFT reported here has an inverted coplanar structure. The 100 nm thick AlNd layer was deposited by sputtering and then patterned for use as gate electrodes. Poly(4-vinylphenol) (PVP) layer was used for organic gate dielectric that was coated by spin-casting onto the patterned gate electrodes. Organic gate dielectric precursor was prepared from a solution of PVP and poly(melamine-co-formaldehyde) as a cross-linking agent, in propylene glycol mono-methyl ether acetate (PGMEA). This gate dielectric was cured at 180 °C in a vacuum oven [14]. The Cr/Au (5 nm/50 nm) source/drain electrode deposited by sputtering was made on the cross-linked PVP. To have selective coating on the TFT region, a bank of 450 nm thick poly(vinylalcohol) (PVA) layer was formed by photolithography.

Then, O_2 plasma was treated on the gate dielectric to make it clean. And the substrate was immersed in PFBT (10 mL in ethanol) solution for 2 h and rinsed using ethanol several times for SAM treated Au surface. The electrode modification was performed in a dry nitrogen glove box to avoid the influence of air. Finally, PPE pentacene was coated by spin-casting at 2000 rpm for 10 s and then the TFT was annealed at 80 °C for 30 min in N_2 environment to eliminate the solvent residue. The ratio of channel width to length for the OTFT studied in this work was 200 μm/6 μm.

Fig. 1(b) shows the selective growth process on the TFT region. The PVA bank acts an organic semiconductor (OS) solution reservoir and the wettability of OS on the PVP gate dielectric affects the selective growth. Upon spin-coating using PPE pentacene solution, the OS solution covers whole region of substrate at first and then de-wetting process starts in a few minutes from the PVA surface and it is accelerated by the difference in thickness between PVA and PVP layer which has better wettability compared to PVA surface. As a result, OS solution gathered inside of a PVA bank. PPE pentacene grain grows during the solvent evaporation so that OS island pattern inside of banks could be achieved. The film thickness depends on the amount of OS solvent inside of a bank. To improve the performance of the PPE pentacene TFT, Au surface was modified with PFBT to increase its work function, which decreases the injection barrier between Au and PPE pentacene [15].

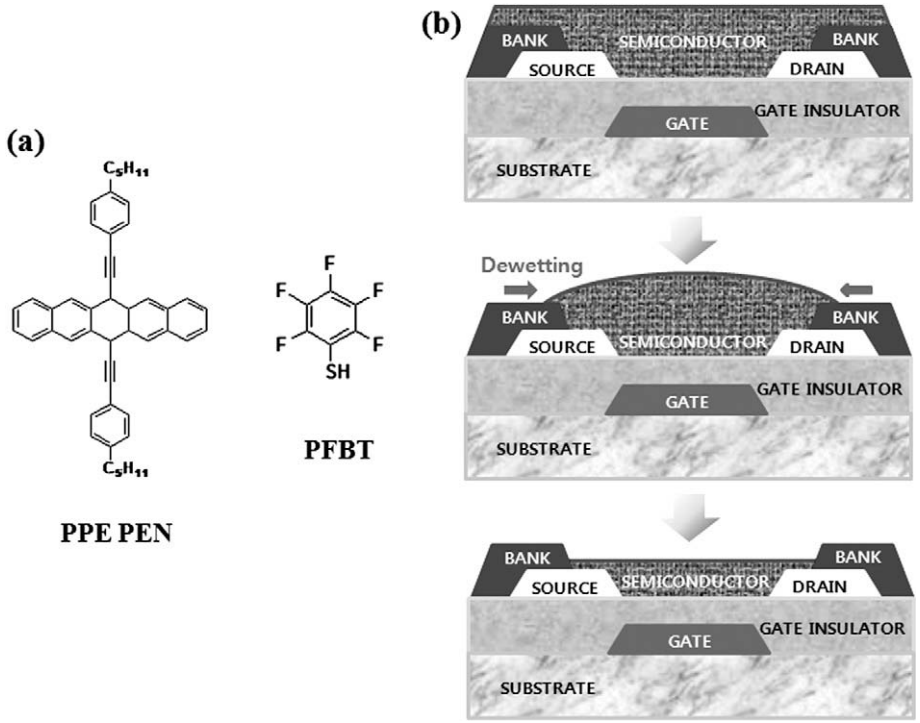

Fig. 1. Chemical structures of PPE pentacene and PFBT (a) and selective coating process of PPE pentacene on the channel region (b).

Fig. 2 shows the polarized optical microscope image of the TFTs with and without PFBT treatment on Au (a) and the transfer characteristics of the OTFTs (b). The semiconductor solution gathered together, resulting in selective crystallization of the PPE pentacene inside of banks. Regardless of PFBT treatment, the selective coating of PPE pentacene could be possible. The device having PFBT layer on the Au exhibited higher on-current compared to that of the OTFT with bare Au.

Fig. 2(c) shows the output characteristics of PPE PEN TFT with PFBT modified Au. A HOMO energy level of PPE pentacene is ~5.28 eV and the work function of bare Au is 5.1 eV, so there is a 0.18 eV injection barrier between PPE pentacene and Au. However, after modification of Au with PFBT, the work function of Au increases to 5.3 eV so that injection barrier decreases and thus TFT performance is improved.

The drain current I_D in the saturation region was achieved from

$$I_D = \frac{C_{PVP}\mu_{FE}W}{2L}(V_G - V_T)^2, \quad (1)$$

where, C_{PVP} is the capacitance of a cross-linked PVP gate insulator, μ_{FE} is the field-effect mobility, W/L is the ratio of channel width to channel length, and V_T is the threshold voltage. The thickness of the cross-linked PVP used as the gate dielectric was 550 nm and its permittivity was 3.6 [14].

The PPE pentacene OTFT with bare Au electrode exhibited the field-effect mobility (μ_{FE}) of 0.005 $cm^2/V\,s$ in the saturation region, an on/off current ratio (I_{on}/I_{off}) of 10^6, a V_T of 4.0 V and a gate voltage swing (S) of 1.2 V/dec. On the other hand, the PPE pentacene TFT with PFBT modified Au exhibited the μ_{FE} of 0.02 $cm^2/V\,s$ in the saturation region, an I_{on}/I_{off} of 10^7, and V_T of −0.4 V and S of 0.8 V/dec.

Fig. 3 shows the polarized microscope optical images of array pattern before (a) and after (b) selective coating. There is clearly selective coating on the TFT region, not on the pixel region. This demonstrates the growth of organic semiconductor only on the TFT region, not on the ITO pixel region for display and sensor applications.

Fig. 4(a) shows the polarized microscope optical image of inverter circuit by selective coating process and voltage transfer characteristics (b) and signal gain of the inverter (c). The inverter composes of two enhancement mode p-channel transistors, the channel widths of driver and load transistors are 500 μm and 100 μm, respectively with channel length of 6 μm.

In order to make organic inverter using p-type transistors, depletion and enhancement mode characteristics are needed for zero drive inverter which has some advantages such as wider swing range, higher gain, lower power dissipation compared to that of diode-connected inverter [15,16]. Although we used two enhancement mode p-channel transistors for inverter, good transfer characteristics with a signal gain ($\partial V_{OUT}/\partial V_{IN}$) of >1.5 were achieved.

In conclusion, we have developed the selective coating process using spin-casting of PPE pentacene solution inside of banks. PFBT modification on Au electrode improves the TFT performance. A bottom contact TFT with the PPE pentacene, using self-organize process, exhibited the μ_{FE} of 0.02 $cm^2/V\,s$, I_{on}/I_{off} of 10^7 and S of 0.8 V/dec. An inverter

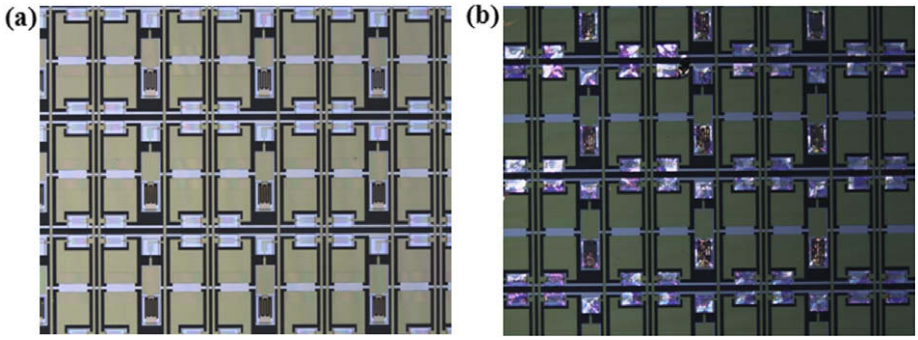

Fig. 3. Optical images of array pattern before (a) and after (b) selective coating.

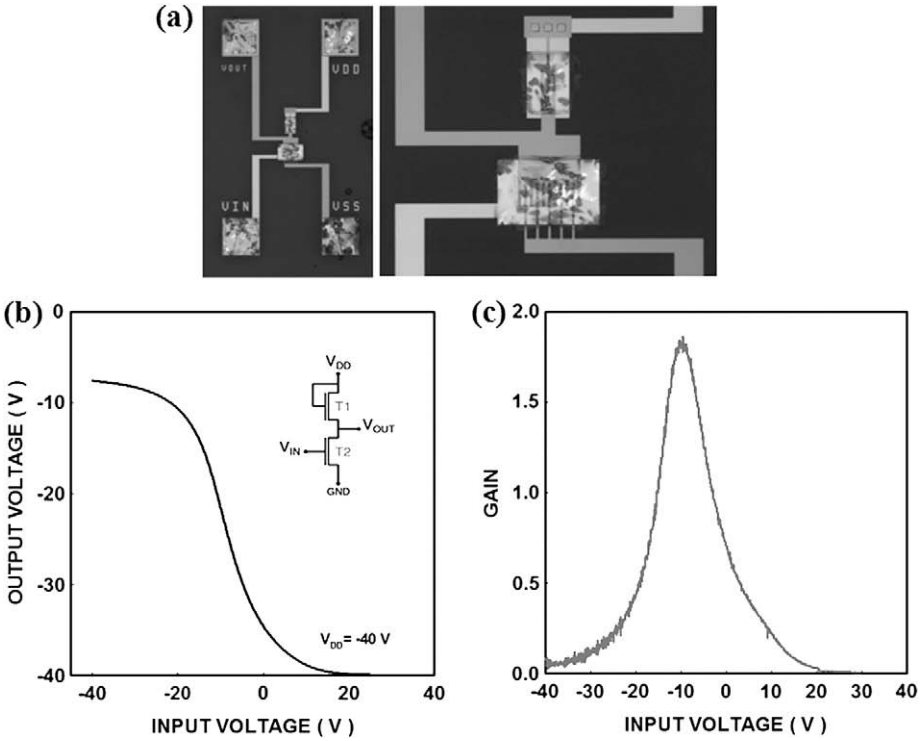

Fig. 4. Polarized optical microscope image of an inverter by selective coating (a), output voltage characteristics of an inverter as a function of input voltage (b) and signal gain of an inverter (V_{DD} = −40 V) (c).

circuit made of PPE pentacene TFTs was demonstrated using the selective coating. This result indicates that self-organized process can be applied to make low-cost flexible organic electronics.

processing. The CIE coordinates of the white light are improved from (0.45, 0.46) to (0.39, 0.39). Most importantly, the hole and electron fluxes are balanced after solvent processing, which favors improving the luminous efficiency. A light-emitting efficiency of 12 cd/A is achieved, about 50% increase compared to the as-spincoated device.

2. Experimental methods

The white light polymer material used in this study is poly(9,9-di-*n*-octylfluorene)-co-4,7-bis(4-(N-phenyl-N-(4-methylphenyl)amino)pheny-2,1,3-benzothiadiazole) (PF-BT05) and its chemical structure is shown in Fig. 1. PF-BT05 is a white emissive polymer by controlling the content of benzothiadiazole (0.05 mol%) for realizing incomplete energy transfer from fluorescent PFO backbone to orange fluorescent benzothiadiazole moieties. The white PLEDs have a structure of indium tin oxide (ITO)/60 nm poly(ethylenedioxythiophene):poly(styrene sulfonic acid) (PEDOT:PSS)/130 nm PF-BT05/10 nm Ca/Al (100 nm). The PEDOT:PSS was first spincoated onto the ITO-coated glass substrate from water solution and then annealed at 110 °C in air for 30 min. The PF-BT05 white emissive layer was deposited on the PEDOT:PSS layer via spincoating from toluene solution and exposed to toluene vapor for 24 h at room temperature and then annealed for 30 min at 20 °C in a vacuum oven. The solvent processing procedure: PF-BT05 films spincoated on ITO glass substrates were hung above the toluene liquid in the airtight container at room temperature for 12, 24 h to obtain different contents of crystalline phase. The Ca/Al cathode was thermally evaporated under vacuum at a base pressure of 3×10^{-4} Pa. The EL characteristics of the WPLEDs were measured using Keithley 2400 source meter and PR650 Spectroscan photometer. All the measurements were carried out at room temperature under ambient conditions.

3. Results and discussion

Fig. 2 shows the absorption and photoluminescence (PL) spectra of PF-BT05 thin films without and with solvent processing for 12, 24 h. The absorption of PF-BT05 films is similar to that of pure PFO because of the low contents of benzothiadiazole moieties in PF-BT05. The main absorption peak of the as-spincoated and solvent processing PF-BT05 films is located at about 380 nm, which is attributed to the π–π^* absorption of PFO backbone. However, the absorption spectra of PF-BT05 film shows an additional peak at 432 nm after being exposed to toluene vapor for

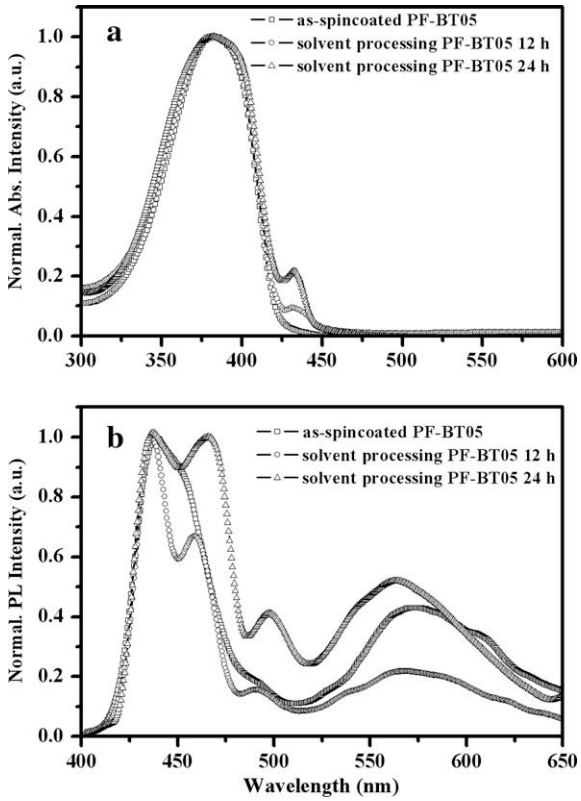

Fig. 2. UV–visible absorption (a) and PL spectra (b) of the as-spincoated and solvent processing PF-BT05 films.

12, 24 h and the intensity of the peak at 432 nm increases with increasing the treatment time, which indicates that the content of crystalline PFO increases with the increasing the treatment time. Considering the results, we note that the presence of small contents of crystalline PFO phase that has an extended conjugation length in amorphous PFO matrix leads to the formation of the additional absorption peak [18]. This is in accordance with the previously reported by Lu et al. [19]. The corresponding PL spectra of the PF-BT05 film exposed to toluene vapor exhibits a crystalline PFO phase emission shape with the three characteristic peaks at 439, 467, 496 nm, as shown in Fig. 2(b) [19].

Moreover, the EL intensity of blue emission increases compared to that of the orange emission from benzothiadiazole moieties after solvent processing, as shown in Fig. 3(a). Although a white emission consisting of blue and orange component is observed for the device based

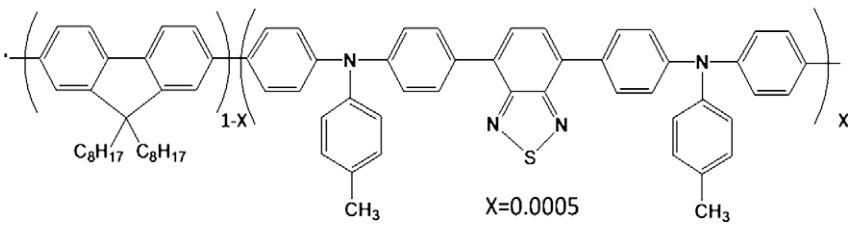

Fig. 1. The chemical structure of single white emissive polymer PF-BT05.

on as-spincoated PF-BT05 film, the CIE coordinates of (0.45, 0.46) are not pure white emission because of the weak blue emission from the PFO backbone. However, the EL spectra of the device is greatly enhanced while exposing the PF-BT05 film to toluene vapor for 24 h at 20 °C and the CIE coordinates are improved to (0.39, 0.39). This indicates that there exits efficient energy transfer from amorphous PFO to the crystalline phase of PFO and the presented crystalline phase acts as efficient blue dopants [19]. Thus, the crystalline phase of PFO and the benzothiadiazole moieties serve as blue and orange fluorescent dopants in the amorphous PFO matrix, respectively, and the white emission of PF-BT05 is enhanced. Fig. 3(b) shows EL spectra of the device based on the solvent processing PF-BT05 film under driving voltages of 8, 10, 12 V, respectively and no obvious variation in the EL spectra or the CIE coordinates was observed as the bias was varied, which indicates that the recombination zone is confined in the emissive layer.

We also carried out the experiment of Grazing-incident X-ray diffraction for the as-spincoated and solvent processing PF-BT05 films, as shown in Fig. 4. The as-spincoated PF-BT05 film is almost amorphous phase while the solvent processing PF-BT05 film shows three diffraction peaks at 7.15°, 14.65°, and 20.3°, corresponding to (2 0 0), (1 4 0), and (2 5 0) + (5 3 0) reflections of crystalline PFO backbone, respectively [16,18].

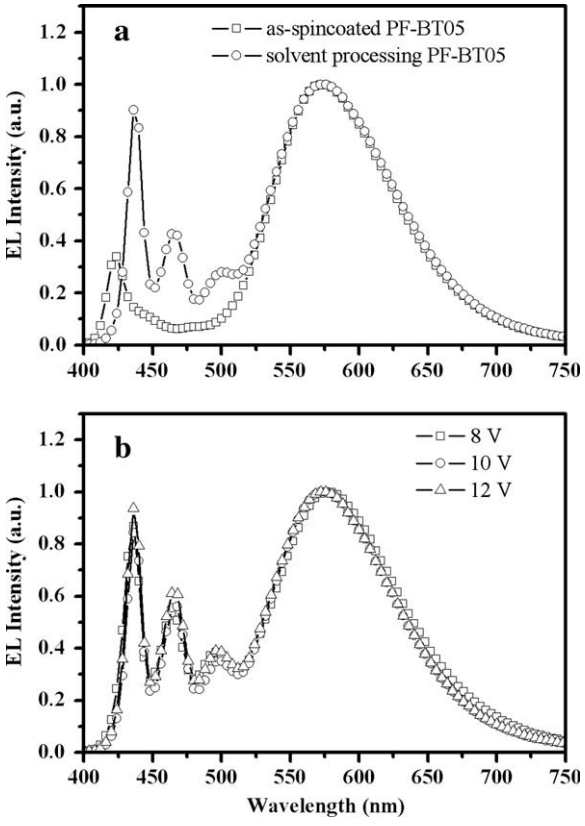

Fig. 3. EL spectra (a) of the WPLEDs based on the as-spincoated or solvent processing PF-BT05 films and EL spectra (b) of the WPLED based on the solvent processing PF-BT05 film under different voltages.

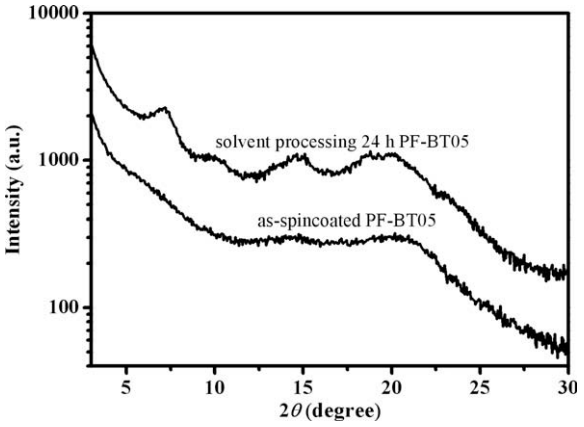

Fig. 4. Grazing-incident X-ray diffraction for the as-spincoated and solvent processing PF-BT05 films.

Fig. 5 plots the EL characteristics of the WPLEDs with and without solvent processing. For as-spincoated device, maximum brightness and current efficiency are 24,840 cd/m^2, and 8.2 cd/A, respectively. For solvent processing device, the corresponding results are 37,820 cd/m^2, and 12.1 cd/A, respectively. The performance of the latter device is better than that of as-spincoated device. It is noted that the current of the solvent processing device decreases compared to that of the as-spincoated device.

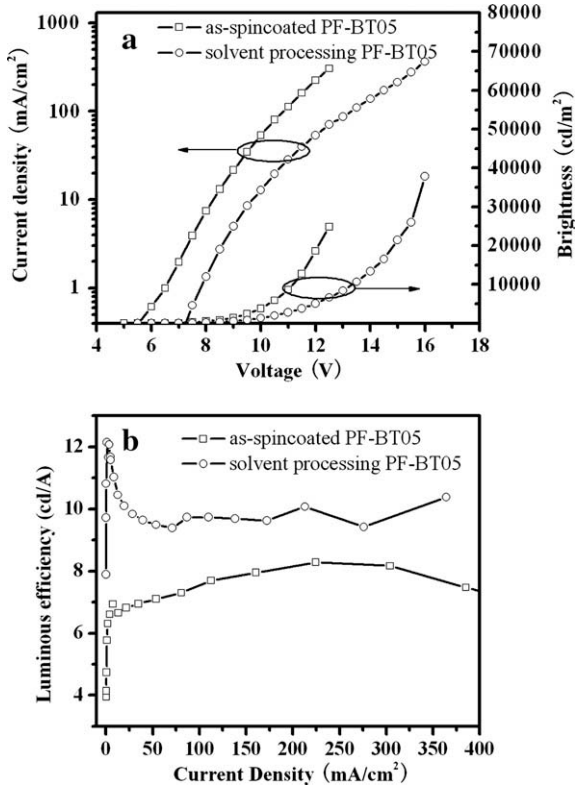

Fig. 5. The V–J–B characteristics (a) and luminous efficiencies (b) of the WPLEDs based on the as-spincoated or solvent processing PF-BT05 films.

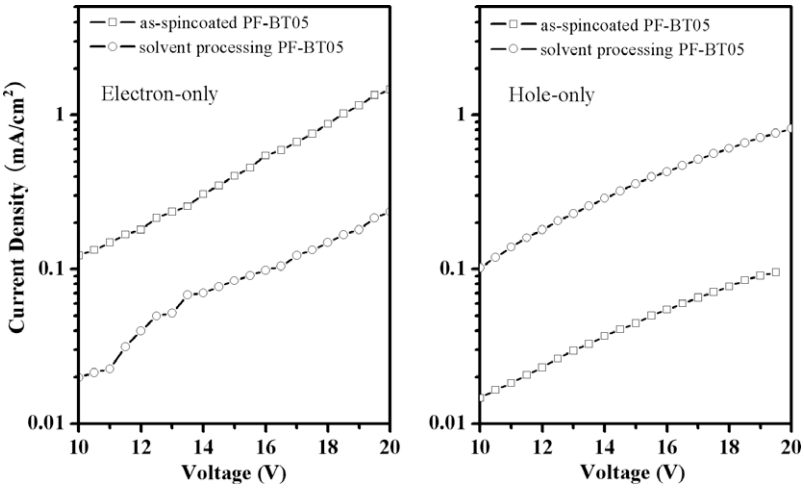

Fig. 6. V–J characteristics of the electron-only and hole-only devices based on the as-spincoated or solvent processing PF-BT05 films.

The physics behind the high performance due to the presence of crystalline PFO is described below. Single-carrier devices of electrons and holes reveal that the hole flux increases and the electron flux decreases with the solvent processing, as shown in Fig. 6. Hole-only and electron-only devices have structures of ITO/PEDOT:PSS (60 nm)/PF-BT05 (200 nm)/MoO_3 (5 nm)/Al (80 nm) and Al (80 nm)/PF-BT05 (200 nm)/Ca (10 nm)/Al (80 nm), respectively. It is found that the ratio of electron flux to hole flux decreases from 7.8 to 1.2 at a voltage of 12 V and from 9.9 to 1.5 at a voltage 16 V after solvent processing, indicating that the hole and electron fluxes are well balanced. The enhanced hole transport after solvent processing may be attributed to more compact stack of PFO backbone and longer conjugated length of crystalline PFO chains [20], while the decreased electron current is due to the presence of crystalline phase of PFO acting as electron traps [19]. The balanced hole and electron fluxes in PF-BT05 film after solvent processing enhance the luminous efficiency of the device.

The above findings show that the overall performance of the device based on the solvent processing PF-BT05 film was improved. On the other hand, the use of thermal annealing could also enhance the EL intensity and luminous efficiency of WPLEDs, which was presented in our earlier publication [21].

4. Conclusions

In summary, both luminous efficiency and color purity of the WPLED based on single white emissive polymer PF-BT05 are enhanced in virtue of solvent processing. Solvent processing not only induces presence of crystalline phase of PFO backbone that acts as blue dopants for enhancing color purity, but also favors balancing the hole and electron transport to improve the light-emitting efficiency, about 50% increase compared to the as-spincoated device. It may provide a new way to improve the device performance of PFO-based WPLEDs.

Sato et al. have shown that VCC can be expressed as a space integration of the vibronic coupling density (VCD) η, which gives a local picture of vibronic coupling in a molecule [14–18]. VCD is the product of the electron-density difference $\Delta\rho$ and the derivative of the nuclear–electronic potential v. $\Delta\rho$ is the electron-density difference between the ionic and neutral states. The magnitude of η depends on the degree of overlap between $\Delta\rho$ and v. A molecule with small overlap has small VCCs and is expected to be good for charge-transporting material. We have calculated the VCDs of N,N′-bis(3-methylphenyl)-N,N′-diphenyl-[1,1′-biphenyl]-4,4′-diamine (TPD) cation and reported that localization of $\Delta\rho$ on N atoms makes η small, which results in small VCCs for the cation [19]. The good transport property of TPD originates from the small VCCs. The importance of N atom in a mechanism of hole-transporting process has been discussed elsewhere [20,21]. The VCD analysis further suggests that conformational change in tolyl and phenyl groups as well as central biphenyl unit contributes to the reorganization energy [21]. This result is consistent with that obtained by Wang and co-workers using a different method [22].

Various carbazole derivatives having good thermal stability have been synthesized and used as hole-transporting materials [23–25]. Carbazole N atom is expected to localize $\Delta\rho$, reduce VCCs, and enhance the hole mobility. In this study, we calculate VCDs for biphenyl, fluorene, and carbazole (Fig. 1) cations and investigate the reason for the VCC ordering by analyzing VCDs. Because methylene- and imino-bridging of biphenyl yields fluorene and carbazole, respectively, we investigate the effect of the methylene and imino on the VCDs and VCCs.

2. Theory

The Hamiltonian of a molecule is expressed as

$$\mathscr{H}(\mathbf{r},\mathbf{R}) = \mathscr{H}_{\mathrm{e}}(\mathbf{r},\mathbf{R}) + \mathscr{T}_{\mathrm{n}}(\mathbf{R}), \tag{1}$$

where $\mathscr{H}_{\mathrm{e}}(\mathbf{r},\mathbf{R})$ is an electronic Hamiltonian, $\mathscr{T}_{\mathrm{n}}(\mathbf{R})$ is the nuclear kinetic energy, and $\mathbf{r}$ and $\mathbf{R}$ denote sets of electronic and nuclear coordinates, respectively. Herzberg–Teller expansion of the electronic Hamiltonian yields

$$\mathscr{H}_{\mathrm{e}}(\mathbf{r},\mathbf{R}) = \mathscr{H}_{\mathrm{e}}(\mathbf{r},\mathbf{R_0}) + \sum_i \left(\frac{\partial \mathscr{H}_{\mathrm{e}}(\mathbf{r},\mathbf{R})}{\partial Q_i}\right)_{\mathbf{R_0}} Q_i + \cdots, \tag{2}$$

where $\{Q_i\}$ is a set of mass-weighted normal coordinates for the ith vibrational mode and $\mathbf{R_0}$ is the nuclear configuration of the equilibrium geometry in the neutral state. The VCC for the ith mode is defined by

$$V_i = \left\langle \Psi^+(\mathbf{r},\mathbf{R_0}) \middle| \left(\frac{\partial \mathscr{H}_{\mathrm{e}}(\mathbf{r},\mathbf{R})}{\partial Q_i}\right)_{\mathbf{R_0}} \middle| \Psi^+(\mathbf{r},\mathbf{R_0}) \right\rangle, \tag{3}$$

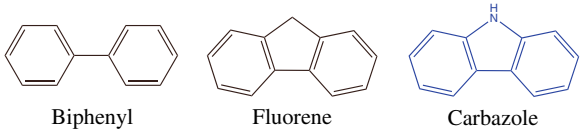

Fig. 1. Structural formulas for biphenyl, fluorene, and carbazole.

where $\Psi^+(\mathbf{r},\mathbf{R_0})$ is the electronic wave function of the cation state at the equilibrium geometry in the neutral state. Eq. (3) can be written as

$$V_i = \sum_A \frac{1}{\sqrt{M_A}} \mathbf{e}_A^{(i)} \cdot \left\langle \Psi^+(\mathbf{r},\mathbf{R_0}) \middle| \left(\frac{\partial \mathscr{H}_{\mathrm{e}}(\mathbf{r},\mathbf{R})}{\partial \mathbf{R}}\right)_{\mathbf{R_0}} \middle| \Psi^+(\mathbf{r},\mathbf{R_0}) \right\rangle = \sum_A V_{i,A}, \tag{4}$$

where M_A is the mass of nucleus A. $\mathbf{e}_A^{(i)}$ is the mass-weighted 3D component of atom A of the ith vibrational mode $\mathbf{e}^{(i)}$, and denotes the relative magnitude of displacement of nucleus A. The direction of $\mathbf{e}^{(i)}$ is defined such that V_i becomes negative; that is, structural deformation toward $\mathbf{e}^{(i)}$ lowers the energy of the cationic state. $V_{i,A}$ is called the atomic vibronic coupling constant (AVCC) of the Ath atom and represents the contribution from the Ath atom to VCC V_i.

When the Hellmann–Feynman theorem [26] holds, V_i can be expressed in terms of the electron-density difference $\Delta\rho$ and the derivative of the nuclear–electronic potential v_i [14–18]:

$$V_i = \int \Delta\rho(\mathbf{x}) \times v_i(\mathbf{x}) d\mathbf{x}, \tag{5}$$

where

$$\Delta\rho(\mathbf{x}) = \rho^+(\mathbf{x}) - \rho(\mathbf{x}), \tag{6}$$

$$v_i(\mathbf{x}) = \sum_A v_{i,A}(\mathbf{x}) = \sum_A -\frac{Z_A}{\sqrt{M_A}} \mathbf{e}_A^{(i)} \cdot \frac{\mathbf{x}-\mathbf{R}_A}{|\mathbf{x}-\mathbf{R}_A|^3}, \tag{7}$$

where Z_A is atomic number, $\rho^+(\mathbf{x})$ and $\rho(\mathbf{x})$ are electron densities for the cationic and neutral states, respectively, and $\mathbf{x}$ denotes a position in 3D space. The product $\Delta\rho(\mathbf{x}) \times v_i(\mathbf{x})$ is called the VCD [14–18] and is denoted by $\eta_i(\mathbf{x})$,

$$\eta_i(\mathbf{x}) = \Delta\rho(\mathbf{x}) \times v_i(\mathbf{x}), \tag{8}$$

which gives a local picture of the vibronic couplings in the molecule.

Atomic vibronic coupling density (AVCD) $\eta_{i,A}$ is defined by

$$\eta_{i,A}(\mathbf{x}) = \Delta\rho(\mathbf{x}) \times v_{i,A}(\mathbf{x}) = \Delta\rho(\mathbf{x}) \times \left(-\frac{Z_A}{\sqrt{M_A}} \mathbf{e}_A^{(i)} \cdot \frac{\mathbf{x}-\mathbf{R}_A}{|\mathbf{x}-\mathbf{R}_A|^3}\right). \tag{9}$$

AVCD represents the contribution from the Ath atom to η_i. Space integration gives the AVCC $V_{i,A}$:

$$V_{i,A} = \int \eta_{i,A}(\mathbf{x}) d\mathbf{x}. \tag{10}$$

The sum of the AVCDs is equal to the VCD η_i,

$$\eta_i(\mathbf{x}) = \sum_A \eta_{i,A}(\mathbf{x}). \tag{11}$$

3. Method of calculation

We used the 6-31G basis set with their first derivatives [27] (denoted as 6-31G+der) so as to satisfy the Hellmann–

Feynman theorem [26], and confirmed that the theorem was satisfied for all systems. We optimized the structures of neutral biphenyl, fluorene, and carbazole at the B3LYP/6-31G+der level of theory. We assumed D_2 symmetry for biphenyl and C_{2v} symmetry for fluorene and carbazole, and confirmed by vibrational analysis that they are stationary minima. A scaling factor of 0.963 [28] was used for B3LYP/6-31G+der theoretical frequencies. We calculated electronic structures of the cationic states at the UB3LYP/6-31G+der level using the optimized geometries of the neutral states. All the DFT calculations were done using Gaussian 03 software [29]. Current and power loss calculations were performed based on Datta [13]. Neighboring molecules are considered as electrodes with the Fermi levels which are set to the HOMO levels shown in Fig. 3. We employed the electronic coupling $\tau = 0.5$ eV and temperature $T = 298$ K.

4. Results and discussion

4.1. Equilibrium geometries

Fig. 2 shows B3LYP/6-31G+der optimized geometries for neutral biphenyl, fluorene, and carbazole with an atomic numbering scheme. Biphenyl has a twisted structure (Fig. 2a). Deviation from planarity is due to steric repulsion between H1–H1′ atoms and H5–H5′ atoms. In a planar structure, the calculated distance between H1 and H1′ atoms is 1.949 Å; in the twisted conformation, the estimated distance is 2.403 Å. The calculated torsion angle between the two benzene rings of biphenyl is 40.3°, being small compared with experimental values of 44.4° [30] and $45 \pm 10°$ [31] determined by gas-phase electron diffraction. In solutions, the estimated twisted angles are 19–26° [32]; in a solid crystalline form at room temperature, the two benzene rings are coplanar [33–36]. These facts suggest that intermolecular interaction overcomes steric repulsion between H atoms. Our calculated geometrical parameters are listed in Table 1, along with experimental results obtained by X-ray analysis for crystalline biphenyl at 110K [37]. Although calculated and experimental results are not in agreement, especially for the dihedral angle between the two benzene rings, nonplanarity does not affect VCC ordering for the biphenyl cation, as discussed in Section 4.2.

The carbon skeleton of fluorene is calculated to be coplanar (Fig. 2b). Whether it is coplanar or bent has been controversial in experiments. By X-ray analysis of crystalline fluorene, Brown et al. [38] and Belsky et al. [39] determined that it is coplanar, while Gerkin et al. determined that it is bent[40]. Although lack of planarity can arise from intermolecular interaction between the H6 atom of one molecule and the C1 and C1′ atoms of a neighboring molecule, our calculation does not consider such interactions. Our calculated geometrical parameters, listed in Table 1, are in good agreement with experimental results [40]. The molecular structure of carbazole resembles that of fluorene, with the methylene group replaced by an imino group. In their solid crystalline forms, intermolecular interactions cause both fluorene and carbazole to be

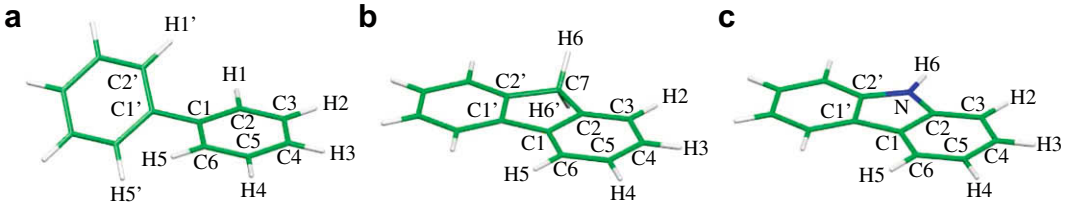

Fig. 2. Geometries optimized at the B3LYP/6-31G+der level of theory with the atomic numbering scheme for various neutral moieties: (a) biphenyl; (b) fluorene; and (c) carbazole.

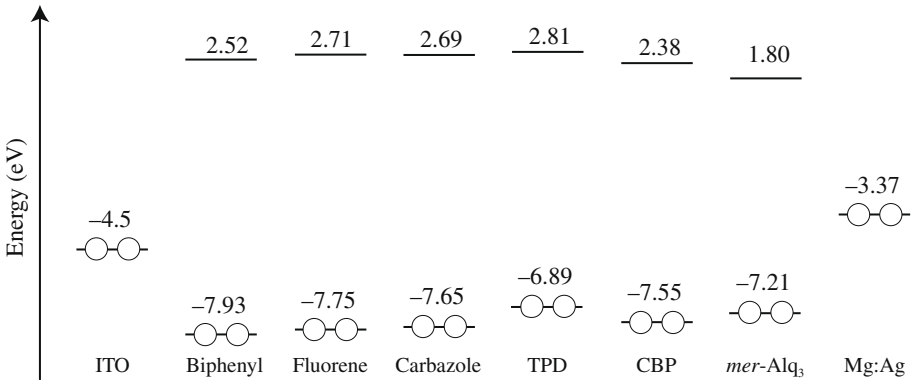

Fig. 3. HOMO/LUMO energy-level diagrams for neutral biphenyl, fluorene, carbazole, TPD, CBP, and *mer*-Alq_3 calculated at the RHF/6-31G+der level of theory. Experimental work functions with opposite signs of an ITO thin film [44] and Mg:Ag alloy [45] are also shown as the Fermi energies of ITO and Mg:Ag electrode surfaces.

Table 1
Geometrical parameters of optimized structures of neutral biphenyl, fluorene, and carbazole calculated at the B3LYP/6-31G+der level. Numbers in parentheses are experimental values [37,40,41]. Bond lengths are in Å; bond angles and dihedral angles are in degrees.

slightly bent [41,42], whereas the optimized geometry of carbazole is planar (Fig. 2c). Differences in the geometrical parameters of carbazole and fluorene are observed in five-membered rings; the C2–N bond is much shorter than the C2–C7 bond because of π delocalization in the pyrrole ring. Our calculated bond lengths and angles, listed in Table 1, are in satisfactory agreement with experimental results [41].

Fig. 3 shows orbital energy levels of HOMOs and lowest unoccupied molecular orbitals (LUMOs) for biphenyl, fluorene, and carbazole together with those for TPD, CBP, and meridional tris(8-quinolinolato)aluminum (*mer*-Alq_3). TPD and CBP are widely used as hole-transporting materials, and Alq_3 as an emitting material and electron-transporting material [1]. HOMOs and LUMOs were calculated at the RHF/6-31G+der level using General Atomic and

Molecular Electronic Structure System (GAMESS) general *ab initio* quantum chemistry package program [43]. Experimental work functions with opposite signs to those for ITO thin film [44] and Mg:Ag alloy [45] are also shown in the figure as Fermi energies of ITO and Mg:Ag electrode surfaces. ITO and Mg:Ag electrodes are widely used as anodes and cathodes, respectively, in multilayer OLEDs. Carbazole has a higher HOMO energy level than do biphenyl and fluorene, suggesting that it exhibits higher hole-injection efficiency.

4.2. Vibronic coupling density analysis

Fig. 4 shows calculated VCCs for biphenyl, fluorene, and carbazole cations. VCCs are smaller for carbazole than for the others. The trend in VCC ordering for fluorene is similar to that for biphenyl. For both biphenyl and fluorene, the largest VCC corresponds to a C–C stretching mode (1589.13 and 1594.25 cm^{-1}, respectively). The experimental frequencies are 1610 [46] and 1612 [47] cm^{-1}, respectively, which are in satisfactory agreement with our theoretical results; for carbazole, the largest two VCCs correspond to a C–C stretching mode (1608.91 cm^{-1}) and a N–H stretching mode (3529.22 cm^{-1}). The calculated frequencies are in agreement with the experimental frequencies of 1625 and 3421 cm^{-1} [48]. These various C–C stretching modes are clearly different; the associated VCCs are -4.192×10^{-4} au for biphenyl, -3.440×10^{-4} au for fluorene, and -2.390×10^{-4} au for carbazole. In spite of their similarities in molecular structure, the largest VCC for carbazole is small compared with those for biphenyl and fluorene, suggesting that carbazole is the superior transporting material. The reorganization energy for biphenyl is calculated to be 0.387 eV, which is close to the value calculated using the different basis set (0.36 eV) [49].

Fig. 5a1–c1 shows the (largest VCC) C–C stretching modes for biphenyl, fluorene, and carbazole cations. Note that these modes involve inter-ring C–C (C1–C1′) stretching and intra-ring C–C (C2–C3 and C5–C6) stretching vibrations. For biphenyl and fluorene, the mode directions correspond to a quinoid deformation, which converts the molecular geometry from benzenoid to quinoid. The C1–C1′, C2–C3, and C5–C6 bonds shorten, while the C1–C2, C3–C4, C4–C5, and C6–C1 bonds lengthen. Since we have defined the mode directions such that their VCCs become negative, quinoid deformations stabilize the cationic states. For carbazole, the vibration phase is the opposite: the C1–C1′, C2–C3, and C5–C6 bonds lengthen, while the C1–C2, C3–C4, C4–C5, and C6–C1 bonds shorten. Quinoid deformation does not occur, and the optimized structure of carbazole cation is not quinoid-like. The AVCCs of the three C–C stretching modes in the figure are listed in Table 2. Values for the C1 and C3 atoms are much smaller for carbazole than for biphenyl and fluorene. A value for the carbazole C5 atom is much smaller for the biphenyl C5 atom. Values for the carbazole C4 and C6 atoms are comparable to those for the fluorene C4 and biphenyl C6 atoms. Contributions to the VCCs from H and C7 (N) atoms are small. Hence, the smaller VCC of the carbazole C–C stretching mode is due to the C1, C3, and C5 atoms. We can understand the reason for this result by considering VCD distributions.

Fig. 5a2–c2 shows derivatives of nuclear–electronic potential v for C–C stretching modes with the same isosurface value. The distribution of v_i reflects the vibrational mode; v_i around atom A is distributed along a component of vibrational vector $\mathbf{e}_A^{(i)}$, and is large around an atom for which $|\mathbf{e}_A^{(i)}|$ is large (Eq. 7). $|\mathbf{e}_A^{(i)}|$ is the relative magnitude of displacement of nucleus A toward a negative (blue) region around it. For in-plane modes, v_i has a large negative value at which interatomic distance is small. Values of $|\mathbf{e}_A^{(i)}|$ for the three C–C stretching modes in Fig. 5a1–c1 are listed in Table 3. For biphenyl and fluorene, v_i distributions of the C–C stretching modes are similar because the associated $|\mathbf{e}_A^{(i)}|$ values are close. Large negative v_i values (blue regions in Fig. 5a2 and b2) are observed for the C1–C1′, C2–C3, and C5–C6 bonds (that is, the bond lengths are shorter), and large positive values are observed for the C1–C2, C3–C4, C4–C5, and C6–C1 bonds. For carbazole, the phase of v_i is opposite to that for biphenyl and fluorene, but the magnitudes of $\mathbf{e}_A^{(i)}$ is comparable to that for fluorene. Thus, the $|v_i|$ distribution for carbazole is almost identical to that for fluorene, suggesting that differences in VCC magnitude among the three molecules is due to the differences in the distribution patterns of the electron-density difference $\Delta\rho$.

Fig. 5a3–c3 shows electron-density difference $\Delta\rho$. For biphenyl, $\Delta\rho$ is large across the C1–C2 and C6–C1 bonds and C4 atom (Fig. 5a3). For fluorene, $\Delta\rho$ is similarly distributed (Fig. 5b3) and, on the C1–C2 and C6–C1 bonds, greatly overlaps with v_i. $\Delta\rho$ is small on fluorene's methylene group. In contrast, for carbazole, $\Delta\rho$ distribution changes as a result of imino-group substitution. $\Delta\rho$ is large on the N atom; it is also large on the benzene ring C3 and C5 atoms (where, for biphenyl and fluorene, it is small) and relatively small on the benzene ring C1 and C2 atoms. For carbazole, $\Delta\rho$ is limited around the N, C3, and C5 atoms, whereas for biphenyl and fluorene, it extends over the C1–C2 and C6–C1 bonds. This difference affects the degree of overlap between $\Delta\rho$ and v_i.

Fig. 5a4–c4 shows vibronic coupling densities η_i. For biphenyl and fluorene, since v_i and $\Delta\rho$ overlap significantly on the C1–C2 and C6–C1 bonds, the AVCDs of the C1, C2, and C6 atoms are large. The sums of the AVCCs of the C1, C1′, C2, C2′, C6 and C6′ atoms are -2.864×10^{-4} au for biphenyl and -2.580×10^{-4} au for fluorene, corresponding to 68.3% and 75.0% of their respective VCCs. This result suggests that vibronic coupling in biphenyl and fluorene occurs mainly on the C1–C2 and C6–C1 bonds, where η_i is large. However, around the C4

atom, although $\Delta\rho$ is large, since v_i is small, η_i is small, which explains why the associated AVCCs are small. For fluorene, since the methylene group's $\Delta\rho$ and v_i are small, its η_i is also small.

Fig. 6 shows HOMO electron densities for neutral biphenyl, fluorene, and carbazole. The HOMO electron densities have a π-orbital character. By comparing Fig. 6a–c with Fig. 5a3–c3, we find that regions where $\Delta\rho$ is negative also have a π-orbital character, with similar distribution patterns, suggesting that electron difference comes mainly from the HOMOs. In addition, regions where $\Delta\rho$ is positive have a σ-orbital character, due to relaxation of the occupied molecular orbitals other than the HOMOs. The positive $\Delta\rho$ reduces Coulomb repulsion from the negative $\Delta\rho$ of the π-orbitals.

Figs. 7 and 8 show the AVCDs and reduced AVCDs (RAVCDs), respectively, of the C and N atoms for the C–C stretching mode for carbazole. The AVCD $\eta_{i,A}$ contains contributions for which the space integrals vanish because of symmetries of basis functions and $v_{i,A}$. The RAVCD $\bar{\eta}_{i,A}$ is calculated by subtracting such contributions from the AVCD $\eta_{i,A}$ [50]. Hence, the space integrals of the AVCDs and RAVCDs give the corresponding AVCCs:

$$\int \eta_{i,A}(\mathbf{x})d\mathbf{x} = \int \bar{\eta}_{i,A}(\mathbf{x})d\mathbf{x} = V_{i,A}. \tag{12}$$

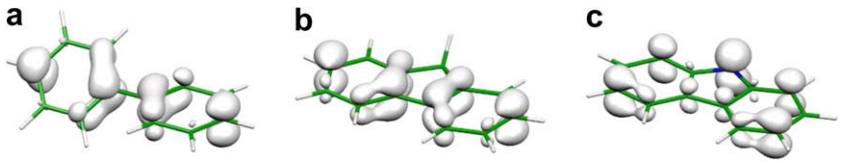

Fig. 6. HOMO electron-density distributions for various neutral moieties at an isosurface value of 0.04 au: (a) biphenyl; (b) fluorene; and (c) carbazole.

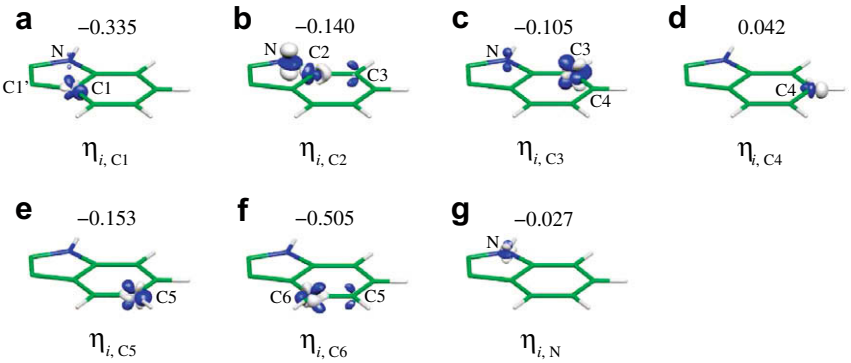

Fig. 7. Atomic vibronic coupling densities $\eta_{i,A}$ of the C and N atoms for the C–C stretching mode of carbazole at an isosurface value of 2.0×10^{-5} au. Blue shows where values are negative; white shows where values are positive. The number above each figure is the corresponding atomic vibronic coupling constant. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

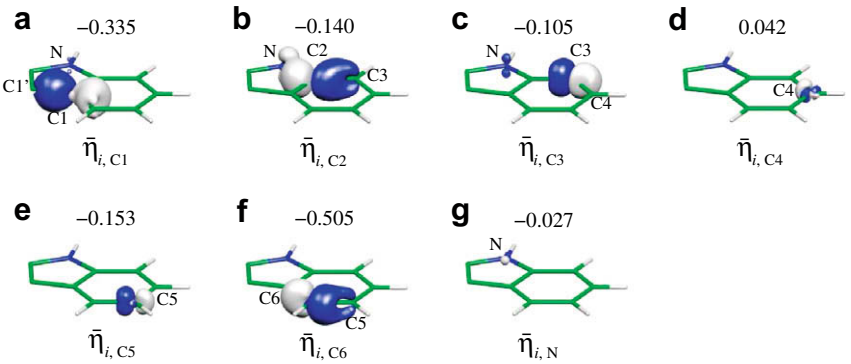

Fig. 8. Reduced atomic vibronic coupling densities $\bar{\eta}_{i,A}$ of the C and N atoms for the C–C stretching mode of carbazole at an isosurface value of 2.0×10^{-5} au. Blue shows where values are negative; white shows where values are positive. The number above each figure is the corresponding atomic vibronic coupling constant. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The distribution pattern for $\bar{\eta}_{i,A}$ is simpler than that for $\eta_{i,A}$. For carbazole, the C1 and C6 atoms contribute significantly to the VCCs (Table 2). On the C1 atom, although $\Delta\rho$ is relatively small, since v_i is large, the AVCD $\eta_{i,C1}$ gives a large positive or negative value around the C1 atom (Fig. 7a). The region where values are negative is larger than the region where they are positive. This feature is also observed for $\bar{\eta}_{i,C1}$ (Fig. 8a). On the C1 atom, the region where $\bar{\eta}_{i,C1}$ is negative is large, so the AVCC is large and negative (-0.335×10^{-4} au). Similarly, on the C6 atom above and below the benzene ring, overlap between v_i and $\Delta\rho$ gives a negative distribution, so the C6 atom has a large negative AVCC (-0.505×10^{-4} au), whose contribution is clearly seen for $\bar{\eta}_{i,C6}$ (Fig. 8f).

On the C5 atom, since $\Delta\rho$ is large, $\bar{\eta}_{i,\,C5}$ is also large (Fig. 8e). The region where values are negative is larger than the region where they are positive, so the AVCC is negative (-0.153×10^{-4} au). However, since the difference between the negative and positive regions is small, the AVCC is smaller for the C5 atom than for the C1 and C6 atoms.

The AVCC of the C3 atom (-0.105×10^{-4} au) is close to that of the C5 atom. This is because the distribution pattern for $\eta_{i,C3}$ (Fig. 7c) is similar to that for $\eta_{i,C5}$ (Fig. 7e). $\eta_{i,C3}$ and $\bar{\eta}_{i,C3}$ are negative for the N atom because the C3 atom is located nearby. The region where values are negative is slightly larger than the region where they are positive, which explains why the C3 atom has a small negative AVCC (Fig. 8c).

$\Delta\rho$ has a small positive value on the C4-H3 bond. Hence, around the C4 atom, $\eta_{i,C4}$ and $\bar{\eta}_{i,\,C4}$ are small (Figs. 7d and 8d). Because the positive region of $\eta_{i,C4}$ is larger than the negative region, the C4 atom has a small positive AVCC(0.042×10^{-4} au).

For the C2 atom, both negative and positive $\bar{\eta}_{i,\,C2}$ (Fig. 8b) regions are largely distributed on the C2–N and C2–C3 bonds. The small AVCC for the C2 atom results from cancellation of these positive and negative regions on the C2–N and C2–C3 bonds.

By comparing $\eta_{i,C2}$ (Fig. 7b) with η_i (Fig. 5c4), we find that for the N atom, the η_i distribution comes from $\eta_{i,C2}$ and not $\eta_{i,N}$ (Fig. 7g). The latter is considerably small because v_i is negligibly small. The small overlap between $\Delta\rho$ and v_i is responsible for the small AVCC of the N atom. v_i for the N–H stretching mode (Fig. 4c) is distributed on the N–H6 bond and can overlap with $\Delta\rho$ around the N atom. However, since the overlap region is limited on the N–H6 bond, the VCC of the N–H stretching mode is not large (1.894×10^{-4} au). Thus, imino-bridging changes the $\Delta\rho$ distribution pattern and weakens vibronic coupling in the benzene rings.

We calculated current through a single fluorene and carbazole molecule employing the NEGF theory including inelastic scattering [13]. Here, we consider a suppression effect originating from the intramolecular vibronic coupling on the current. Actually, in the bulk systems, intermolecular vibronic coupling can be a dominant factor governing the suppression effect. However, the small intramolecular vibronic coupling is a necessary condition for design of transporting materials and first, we should consider the suppression effect due to the intramolecular vibronic coupling.

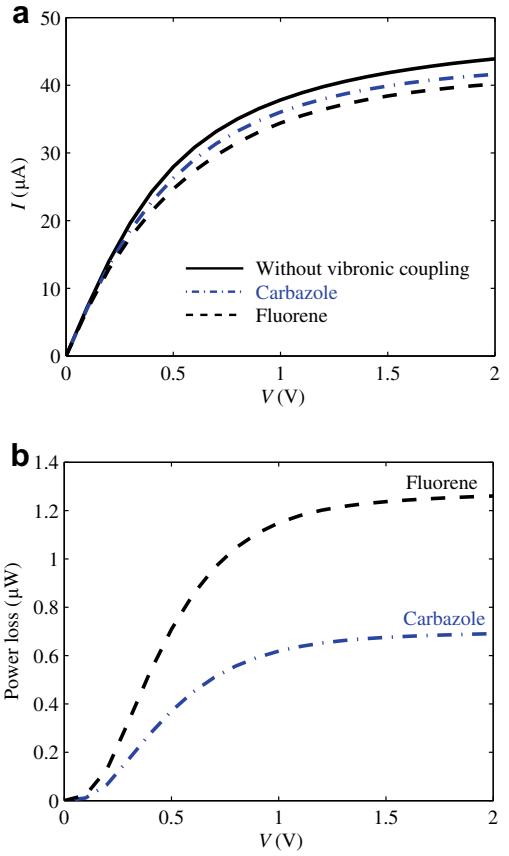

Fig. 9. (a) Current–voltage characteristics and (b) power loss.

Fig. 9a shows I–V characteristics. The solid line shows the I–V characteristics in the absence of vibronic coupling; the dot-dashed and dashed lines show the I–V characteristics for carbazole and fluorene, respectively, in the presence of the vibronic coupling. Fig. 9a shows that the vibronic coupling reduces the current and the suppression effect is larger for fluorene (having the large VCCs) than for carbazole (having the small VCCs). Fig. 9b shows power loss due to the vibronic coupling. Note that, without vibronic coupling, the power loss dose not occur. At $V = 2$ V, the power loss in carbazole is about half that in fluorene. Fig. 9 suggests that a molecule with small VCCs is good charge-transporting and low power-loss material. The carbazole N atom can weaken the vibronic coupling and enhance hole-transporting property.

Fig. 10a1–c1 shows Hartree–Fock (HF) VCCs for biphenyl, fluorene, and carbazole cations. Geometry optimization and vibrational analysis for neutral biphenyl, fluorene, and carbazole were done at the RHF/6-31G+der level of theory. Cationic states of the molecules were calculated at the UHF/6-31G+der level of theory. A scaling factor of 0.8929 [51] was used for RHF/6-31G+der theoretical frequencies. All the HF calculations were done using GAMESS package program. The trend in VCC ordering in

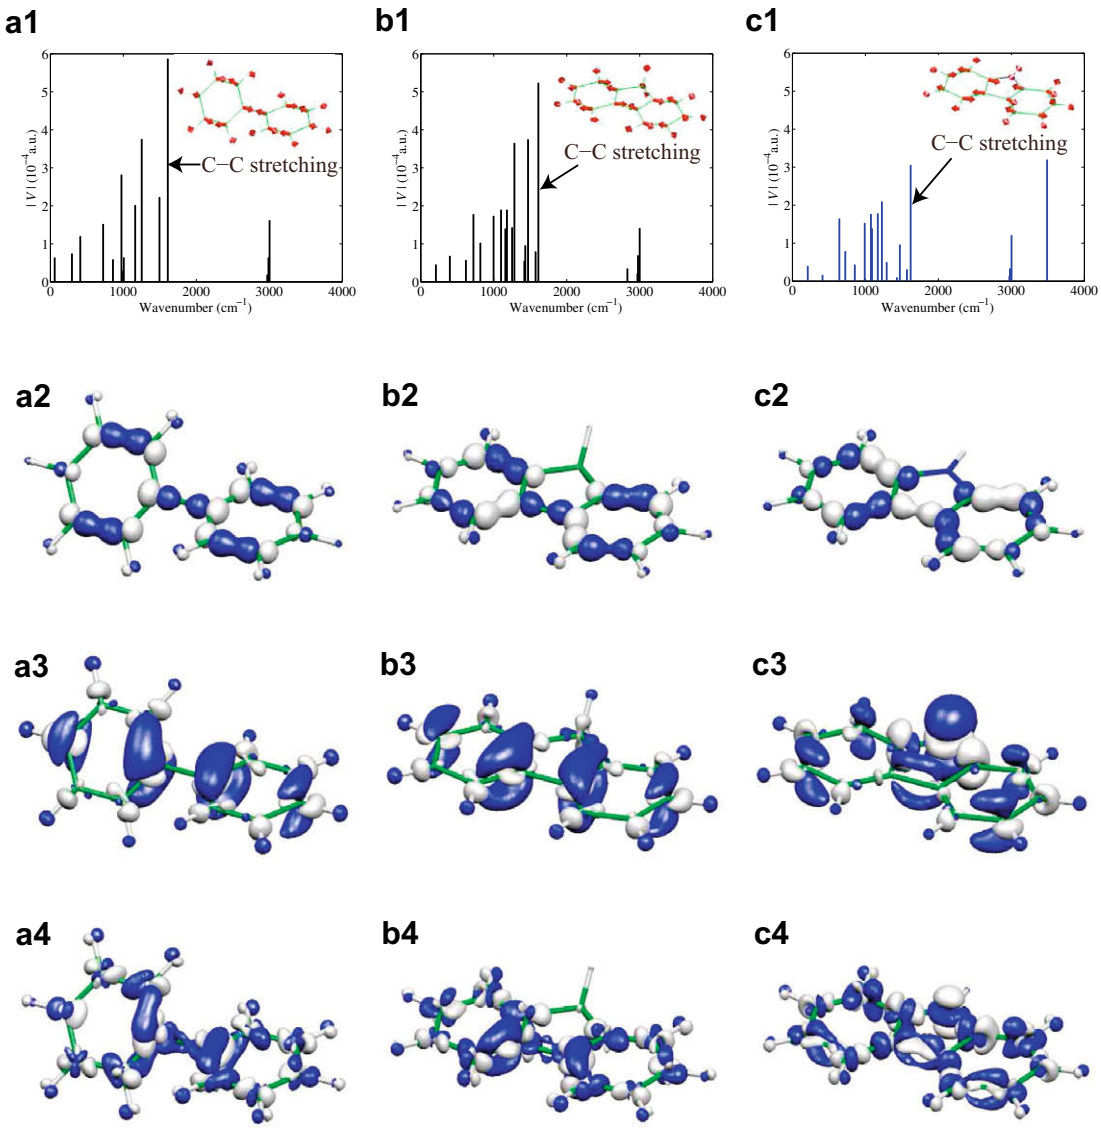

Fig. 10. Absolute values of vibronic coupling constants $|V|$ for various cations calculated at the UHF/6-31G+der level of theory: (a1) biphenyl; (b1) fluorene; and (c1) carbazole. (a2)–(c2) Nuclear–electronic potential derivatives of the modes shown in (a1)–(c1) at an isosurface value of 0.01 au. (a3)–(c3) Electron-density differences due to ionization at an isosurface value of 0.04 au. (a4)–(c4) Vibronic coupling densities at an isosurface value of 2.0×10^{-5} au. Blue shows where values are negative; white shows where values are positive. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 10a1–c1 is similar to that in Fig. 4a–c; for biphenyl and fluorene, the largest VCC corresponds to a C–C stretching mode (1608.87 and 1610.88 cm^{-1}, respectively); for carbazole, the largest two VCCs correspond to a C–C stretching mode (1620.01 cm^{-1}) and a N–H stretching mode (3490.04 cm^{-1}). The C–C stretching modes having the large VCCs are shown in Fig. 10a1–c1. Comparing Fig. 10a1–c1 with Fig. 4a–c, the VCCs calculated at the UHF/6-31G+der level are large compared with those calculated at the UB3LYP/6-31G+der level. We can understand the reason for the difference in VCC size using the VCD analysis.

Fig. 10a2–c2 shows ν_i for the modes shown in Fig. 10a1–c1. Comparing Fig. 10a2–c2 with Fig. 5a2–c2, ν_i calculated using the HF method is as large as that calculated using the B3LYP method, suggesting that electron correlation does not influence ν_i distribution significantly.

Fig. 10a3–c3 shows $\Delta\rho$ for biphenyl, fluorene, and carbazole. The isosurface value in Fig. 10a3–c3 is the same in Fig. 5a3–c3. $\Delta\rho$ calculated using the HF method has a large value. This is because without electron correlation, electron delocalization is underestimated. $\Delta\rho$ across the C1–C2 and C6–C1 bonds is larger in Fig. 10a3 than in Fig. 5a3; $\Delta\rho$ across the C1–C2 and C6–C1 bonds is larger

in Fig. 10b3 than in Fig. 5b3; $\Delta\rho$ on the N atom is larger in Fig. 10c3 than in Fig. 5c3.

Fig. 10a4–c4 shows η_i calculated at the UHF/6-31G+der level of theory. Large $\Delta\rho$ leads to large η_i and consequently large VCCs. Since $\Delta\rho$ is less delocalized for carbazole than for biphenyl and fluorene, electron correlation effects on $\Delta\rho$ is smaller. Hence, for carbazole, the differences between η_i calculated using the UB3LYP and UHF methods are small compared with those for biphenyl and fluorene. For biphenyl and fluorene, the HF method significantly overestimates the VCCs because $\Delta\rho$ is highly delocalized. The AVCC of the C1 atom of biphenyl and fluorene calculated using the HF method are -1.263×10^{-4} and -1.346×10^{-4} au, respectively, which are more than twice those calculated using the B3LYP method (-0.582×10^{-4} and -0.628×10^{-4} au, respectively). The VCCs are closely related to the reorganization energy. Large/Small VCCs give a large/small reorganization energy. The overestimation of the reorganization energy with the HF method has been reported by Sancho-García et al. [52] For vibronic coupling calculations, the UHF/6-31G+der level of theory gives qualitatively good results, and sometimes quantitative results.

5. Conclusions

We calculated the VCDs of biphenyl, fluorene, and carbazole cations. VCD analysis reveals that strong localization of the electron-density difference on the N atom leads to the small VCCs of carbazole. In general, localized electron-density differences on an atom decreases the vibronic coupling and enhance hole mobility. Replacing the biphenyl or fluorenyl moieties in the molecule with the carbazolyl moiety can weaken vibronic coupling in the molecule and improve hole mobility. This guiding principle opens a new way for molecular design of carrier-transporting materials based on VCD analysis. Though the HF method gives qualitatively good results, it sometimes yields overestimated VCC. This is because the electron-density difference calculated by the HF method is highly delocalized over the bonds, compared with the DFT method. Therefore, for carbazole, the HF method yield quantitatively good result, since the electron-density difference in carbazole does not largely delocalized over the bonds.

materials as active layers in several different devices. Therefore, only a few bi-functional or tri-functional organic materials have been developed thus far [11,2b,12]. To the best of our knowledge, triarylamine derivatives have not been used as multifunctional materials such as light-emitting and hole-transporting materials in OLEDs, donor materials in OSCs, and organic semiconductors in OTFTs.

Here, we report the first example of a multifunctional material that can be used as a deep blue emitting and hole-transporting material in OLEDs, a donor material in OSCs, and an active material in OTFTs. In particular, an OLED device derived from 4,4′,4″-tris(4-naphthalen-1-yl-phenyl)amine (**1-TNPA**) emitted blue light similar to the National Television Standard Committee (NTSC) standard blue and exhibited good electroluminescence (EL) efficiency compared to known blue fluorescent dopants [13–15]. Furthermore, in the case of **1-TNPA**, more efficient hole transport, compared to 4,4′-bis[*N*-(naphthyl-*N*-phenyl amino)]biphenyl (NPD), was observed [5,6,16]. Further, **1-TNPA** can be used as a donor in OSCs and as an organic semiconductor in OTFTs.

2. Experimental section

2.1. Materials and instruments

Organic compounds such as C_{60}, CuPc, NPD, BCP, Alq_3, and ADN were purchased from Aldrich, Lumtree, and Gracel Display. Absorption (UV) spectra were recorded on a Beckman DU 650 spectrophotometer. PL spectra were recorded on a Jasco FP-7500 spectrophotometer. CV spectra were obtained using a CH Instruments 660 electrochemical analyzer. AFM experiments were performed using an Asylum MFP-3D instrument in AC mode and XRD analyses were carried out using a Rigaku (λ = 1.5418 Å; 298 K) X-ray instrument. Decomposition temperatures (T_d) and glass transition temperatures (T_g) were obtained using Q-5000-IR thermal gravimetric analysis (TGA) and DSC-Q-1000 differential scanning calorimetry (DSC), respectively. These TGA and DSC analyses were performed at 5 °C min^{-1} under a N_2 atmosphere.

2.2. Synthesis

4,4′,4″-Tris(4-naphthalen-1-yl-phenyl)amine (**1-TNPA**): a mixture of tris(4-bromophenyl)amine (2.00 g, 4.14 mmol), 1-naphthaleneboronic acid (2.50 g, 14.5 mmol), potassium carbonate (2 M, 20 mL), and tetrakis(triphenylphosphine) palladium (238 mg, 0.206 mmol) in THF/H_2O was heated at 80 °C for 24 h. After cooling to room temperature, all the volatiles were evaporated in vacuum and the reaction mixture was extracted with dichloromethane. The organic phase was washed with H_2O and dried over $MgSO_4$. The solvent was evaporated to give the product, which was purified by silica gel column chromatography using a mixture of ethyl acetate and hexane as the eluent (1:20) and then recrystallized from dichloromethane and hexane to give a solid product (yield: 680 mg, 34%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 8.17 (d, 9 Hz, 3H), 8.01 (d, 6 Hz, 3H), 7.94 (d, 18 Hz, 3H), 7.61 (d, 9 Hz, 6H), 7.58 (d, 6 Hz, 6H), 7.54 (d, 6 Hz, 6H), 7.51 (d, 12 Hz, 6H). ^{13}C NMR (125 MHz, $CDCl_3$): δ (ppm) 147.0, 140.0, 135.4, 134.1, 131.8, 131.2, 128.5, 127.6, 127.1, 126.2, 126.1, 125.9, 125.6, 124.2. Mass: Calcd. for $C_{48}H_{33}N$ $[M]^+$ 623.2613, HR-Mass: 623.2613.

2.3. Cyclic voltammetry

The electrochemical properties of **1-TNPA** were studied using cyclic voltammetry (CV) in CH_2Cl_2 solutions (1.00 mM) with 0.1 M tetra-*n*-butylammoniumhexafluorophosphate ($TBAPF_6$) as the supporting electrolyte. A glassy carbon electrode was employed as the working electrode and referenced to an Ag reference electrode. All potential values were calibrated against the ferrocene/ferrocenium (Fc/Fc^+) redox couple.

2.4. Blue OLED device fabrication

A 10-nm-thick layer of copper phthalocyanine (CuPc) was used as a hole injection layer (HIL), and a 60-nm-thick layer of NPD was used as a hole-transporting layer (HTL). A 50-nm-thick emitting layer (EML) was prepared by using 9,10-di(2-naphthyl)anthracene (ADN) as a host and 5–12 wt% **1-TNPA** as a fluorescent blue dopant. The fluorescent dopant concentration of **1-TNPA** was varied from 5 wt% to 12 wt%. Next, a 20-nm-thick tris(8-hydroxyquinolinato)aluminum (Alq_3) layer, which served as an electron transporting layer (ETL), was evaporated. Then, a LiF layer, which served as an electron injection layer (EIL), was also evaporated. Finally, a 100-nm-thick Al layer was deposited onto the LiF layer (Fig. S1). The emission properties were determined using a PR-650 spectrascan spectracolorimeter as a source meter.

2.5. Green OLED device fabrication

A 70-nm-thick NPD layer and a 70-nm-thick **1-TNPA** layer were used as a reference HTL and as a new HTL, respectively. Next, a 60-nm-thick Alq_3 layer was evaporated as an electron transporting layer and a green emitting layer. Then, LiF as an electron injection layer was also evaporated. Finally, a 100-nm-thick Al layer was deposited onto the LiF layer (Fig. S2).

2.6. OSC device fabrication

A 30-nm-thick poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS) layer was used as a hole injection layer (HIL). Various **1-TNPA** layers with thicknesses from 10 nm to 20 nm were prepared by evaporation. Then, a 40-nm-thick fullerene (C_{60}) layer, which served as an acceptor, was also evaporated. Next, a 5-nm-thick 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) layer, which served as an exciton blocking layer (EBL), was evaporated. Finally, a 100-nm-thick Al layer was evaporated onto the BCP layer (Fig. S3). The current–voltage measurements for the devices were performed on a Keithley 237 instrument. The device performances were characterized under uniform illumination (AM 1.5G illumination intensity of 100 mW cm^{-2}) using a solar simulator

(Newport, 91160A). The light intensity at each wavelength was calibrated using the standard Si solar cell as a reference.

2.7. OTFT device fabrication

We used a heavily doped Si wafer as a gate electrode and a SiO_2 or an octadecyltrichlorosilane (OTS)-pretreated SiO_2 layer (thickness: ca. 300 nm) as the gate dielectric. The **1-TNPA** films (thickness: ca. 500 Å) were grown by vacuum sublimation at rates of 0.4–0.8 Å s^{-1} under a working pressure of 2.0–2.5 $\times$ 10^{-6} torr using an apparatus devised in our laboratory. Au source/drain electrodes with a channel length (L) of 50 μm and a channel width (W) of 1000 μm were evaporated on top of the films through a shadow mask. The electrical characterization of the transistors was performed in air at room temperature using a Keithley 4200-SCS semiconductor analyzer. The field-effect mobility (μ) was calculated in the saturation region (V_{DS} = −100 V) from a plot of the square-root of drain current *vs.* V_{GS} by using the following equation: $I_{DS} = (WC_i\mu(V_{GS} - V_T)^2)/2L$, where I_{DS} is the source–drain saturation current; C_i (1.1 $\times$ 10^{-8} F) is the capacitance of the SiO_2 insulator; W/L is the ratio of the channel width to the channel length; and V_{GS} and V_T are the gate–source and threshold voltages, respectively.

3. Results and discussion

3.1. Synthesis and photophysical properties

Scheme 1 shows the synthesis of **1-TNPA** examined in this study. A mixture of tris(4-bromophenyl)amine, 1-naphthaleneboronic acid, potassium carbonate, and tetrakis(triphenylphosphine)palladium was refluxed in a N_2 atmosphere in tetrahydrofuran/water solution to afford **1-TNPA** in 34% yield. The photophysical properties of **1-TNPA** are shown in Fig. 1. The absorption spectrum of **1-TNPA** in dichloromethane shows intense bands at 279 nm and 340 nm. The photoluminescence (PL) spectrum of **1-TNPA** in dichloromethane shows a deep blue emission at 436 nm. The full width at half maximum (FWHM) of **1-TNPA** in dichloromethane solution is 63 nm. The PL quantum yield of **1-TNPA** in ethanol solution was estimated to be 0.22 using anthracene as a standard [17].

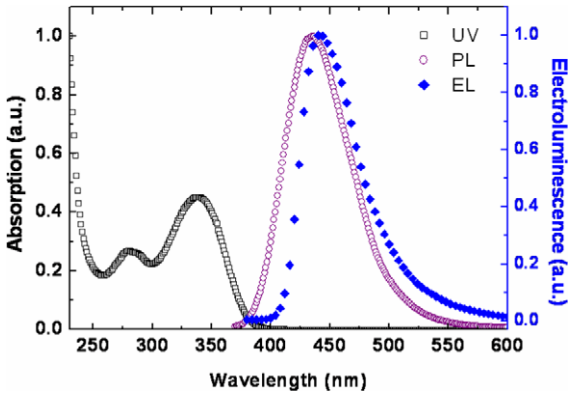

Fig. 1. UV and PL spectra of **1-TNPA** (0.02 mM) in dichloromethane and EL spectra of 3% **1-TNPA**-doped device.

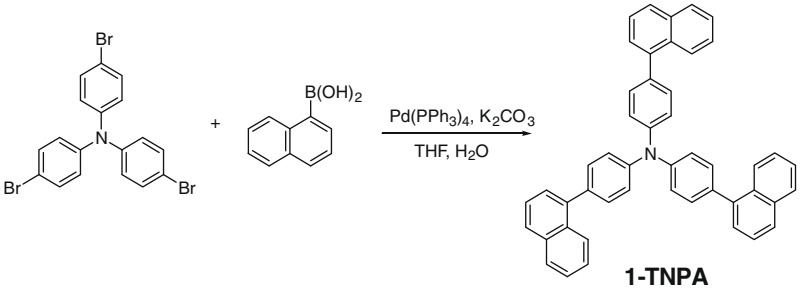
3.2. Thermal and electrochemical properties

The thermal stability of **1-TNPA** was investigated by TGA and DSC. **1-TNPA** shows a thermal stability of T_d = 470 °C, as revealed by the TGA thermogram (Fig. S10), which suggests that **1-TNPA** is stable during the vacuum thermal sublimation process used in organic semiconductor fabrication. When the sample of **1-TNPA** was heated, an endothermic peak was observed at around 176 °C. However, no crystallization and glass transition were observed in the DSC analysis. When the heated sample of **1-TNPA** was cooled to room temperature, it formed an amorphous glass. When the glass sample of **1-TNPA** was heated again, glass transition took place at around 109 °C (Fig. S11). DSC experiments revealed that **1-TNPA** has the property of an amorphous glass with a glass transition temperature (T_g) of 109 °C and therefore no crystallinity.

Fig. 2 shows the cyclic voltammogram of **1-TNPA** in dichloromethane. **1-TNPA** undergoes a reversible oxidation process associated with stable cation radical generation. The half oxidation potentials ($E_{1/2,ox}$) of **1-TNPA**, NPD, and ferrocene were observed to be 0.76 V, 0.59 V, and 0.31 V, respectively (Figs. 2 and S12). Therefore, the highest occupied molecular orbital (HOMO) energy values of **1-TNPA** and NPD were calculated to be $E_{HOMO} = -[(1.4 \pm 0.1) \times (0.45) - (4.6 \pm 0.08)\,eV] = -5.23$ and $E_{HOMO} = -[(1.4 \pm 0.1) \times (0.28) - (4.6 \pm 0.08)\,eV] = -5.00$ eV, respectively [18]. However, the half reduction potential was not determined from CV measurements. The lowest



Scheme 1. Synthesis of **1-TNPA**.

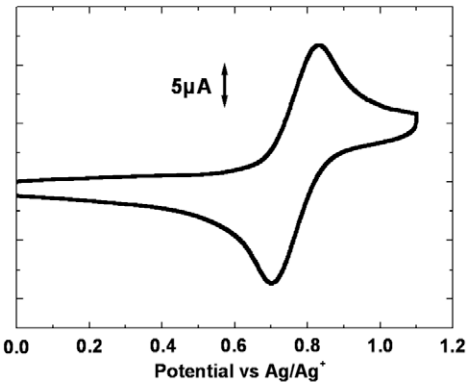


Fig. 2. Cyclic voltammogram of 1.00 mM **1-TNPA** in dichloromethane.

unoccupied molecular orbital (LUMO) energy value of **1-TNPA** (−3.27 eV) was determined from the cross-sectional wavelength between the absorption and emission spectra.

3.3. Blue emitting material in OLEDs

To investigate the versatility of **1-TNPA** as an organic semiconductor, we fabricated four types of organic electronic devices using **1-TNPA**: blue and green emitting OLEDs, an OSC, and an OTFT. To investigate the blue emitting property of **1-TNPA**, we fabricated blue fluorescent OLEDs with the configuration of ITO/CuPc (10 nm)/NPD (60 nm)/emitting layer (50 nm)/Alq_3 (20 nm)/LiF (1 nm)/Al (100 nm). Emitting layers were prepared by co-evaporating ADN as a host and *x* wt% **1-TNPA** as a fluorescent dopant.

Fig. S5 shows the PL in dichloromethane and EL spectra for different doping ratios of **1-TNPA**. All the EL spectra show a deep blue emission. These results indicate that hole–electron recombination takes place at the **1-TNPA** layer. The FWHM of the EL spectrum for 3% **1-TNPA** doping is 61 nm. Since the FWHMs of PL and EL spectra are similar, we attribute the blue EL to the intrinsic emission of **1-TNPA** with no emission interference from Alq_3 [13b]. In particular, the 3% **1-TNPA**-doped EL device showed a pure blue emission with Commission Internationale de l'Eclairage (CIE) coordinates of (0.15, 0.12) at a current density of 6.3 mA cm^{-2}, which is similar to the NTSC standard blue CIE coordinates (0.15, 0.09). Similarly, for a device with 5−8% **1-TNPA** doping, the EL spectra also show the deep blue emission. Since the EL spectra of **1-TNPA** devices with different doping levels have similar patterns, it is suggested that the EL spectra should be attributed to emission from an excited state of **1-TNPA** in the emitting layer. On the other hand, the EL device showed blue emission centered at around 460 nm (Fig. S5) for 10−12% **1-TNPA** doping. As the doping ratio of **1-TNPA** was increased from 3% to 12%, the λ_{max} of the EL spectra was slightly red-shifted because of the aggregation of **1-TNPA** dopant molecules in the emitting layer. This could be due to the molecular structure of **1-TNPA**, which cannot prevent the aggregation in the emitting layer.

Fig. 3 shows plots of the current density (mA cm^{-2}) *vs.* current efficiency (cd A^{-1}) and current density (mA cm^{-2}) *vs.* external quantum efficiency (%) characteristics of ITO/CuPc (10 nm)/NPD (60 nm)/EML (ADN + **1-TNPA** = 50 nm)/Alq_3 (20 nm)/LiF (1 nm)/Al (100 nm) devices. The EL performances depend on the doping ratio of **1-TNPA** in the emitting layer. The optimized 3% **1-TNPA**-doped device had a maximum current efficiency of 3.1 cd A^{-1} and an external quantum efficiency of 3.0% at a current density of 3.4 mA cm^{-2}. At this doping ratio, maximum EL efficiency and a blue emission similar to NTSC blue were observed. We attribute the improved EL performance to the greater charge balance and better exciton confinement within the emission layer. A comparison of the EL device, involving the use of **1-TNPA** as a fluorescent dopant, with the known NTSC standard deep blue fluorescent dopant materials reveals that the current efficiency of 3.1 cd A^{-1} and the external quantum efficiency of 3.0% are generally satisfactory [13–15]. The 8% **1-TNPA**-doped EL device had a slightly reduced current efficiency of 2.5 cd A^{-1} and an external quantum efficiency of 2.3% at a current density of 4.3 mA cm^{-2}. The 12% **1-TNPA**-doped EL device had a current efficiency of 2.1 cd A^{-1} and an external quantum efficiency of 1.7% at 4.7 mA cm^{-2}. When the doping ratio of **1-TNPA** changed from 3% to 12%, the current efficiency and external quantum efficiency slightly decreased from 3.1 cd A^{-1} to 2.1 cd A^{-1} and from 3% to 1.7%, respectively. The relatively reduced EL efficiency can be attributed to a

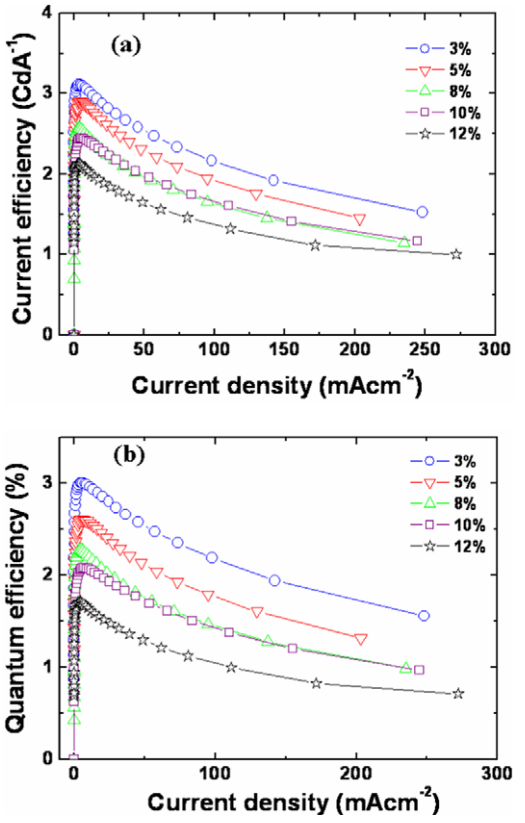

Fig. 3. A blue emitting EL device with configuration ITO/CuPc (10 nm)/NPD (60 nm)/EML (ADN:**1-TNPA** = 50 nm)/Alq_3 (20 nm)/LiF (1 nm)/Al (100 nm). less balanced hole and electron recombination at the emitting layer caused by the aggregation of **1-TNPA** dopant molecules. The entire EL device data are summarized in Table 1; the data indicate that **1-TNPA** can be used as an efficient deep blue emitting material.

3.4. Hole-transporting material in green emitting OLEDs

Recently, NPD has been widely used as a standard hole-transporting material in OLEDs [5,6,16]. In this study, in order to compare the hole-transporting properties of **1-TNPA** with those of NPD, we fabricated two types of fluorescent OLEDs with the configuration of ITO/**1-TNPA** or NPD (70 nm)/Alq_3 (60 nm)/LiF (1 nm)/Al (100 nm). Figs. 4(a) and S8 show the EL spectra and CIE coordinates of the NPD- and **1-TNPA**-based OLED devices. The EL spectra of both the **1-TNPA**- and NPD-based devices showed identical green emissions centered at 528 nm, and the CIE coordinates of both **1-TNPA**- and NPD-based devices were almost equal. The similar EL spectra and CIE coordinates of NPD- and **1-TNPA**-based devices suggest that the EL spectra and CIE coordinates should be attributed to an emission from an excited state of Alq_3 in the emitting layer. This indicates that **1-TNPA** can also be used as a hole-transporting material in green emitting OLEDs.

Fig. 4(b) shows that the maximum current efficiency of the **1-TNPA**-based device is 4.4 cd A^{-1}, which is 45% higher than that of the NPD-based reference device (3.0 cd A^{-1} at 25 mA cm^{-2}). Fig. S7(e) shows that the maximum power efficiency of the **1-TNPA**-based device is 2.0 lm W^{-1}, which is 33% higher than that of the NPD-based reference device (1.5 lm W^{-1} at 25 mA cm^{-2}, Table 2). The enhancement of both current efficiency and power efficiency when using **1-TNPA** as the hole-transporting material can be attributed to a more balanced recombination of holes and electrons at the emitting layer because of the formation of a hole blocking barrier which results from the low HOMO energy level of **1-TNPA**. This finding is supported by the current density *vs.* voltage data (Fig. S7(g)); at all voltages, the **1-TNPA**-based device shows a lower current density than the NPD-based reference device [5a]. Also, the turn-on voltage of the **1-TNPA**-based device (2.6 V) was slightly lower than that of the NPD-based reference device (2.8 V) because of a more balanced hole and electron recombination in the emitting layer. The **1-TNPA** device needs a higher voltage than the

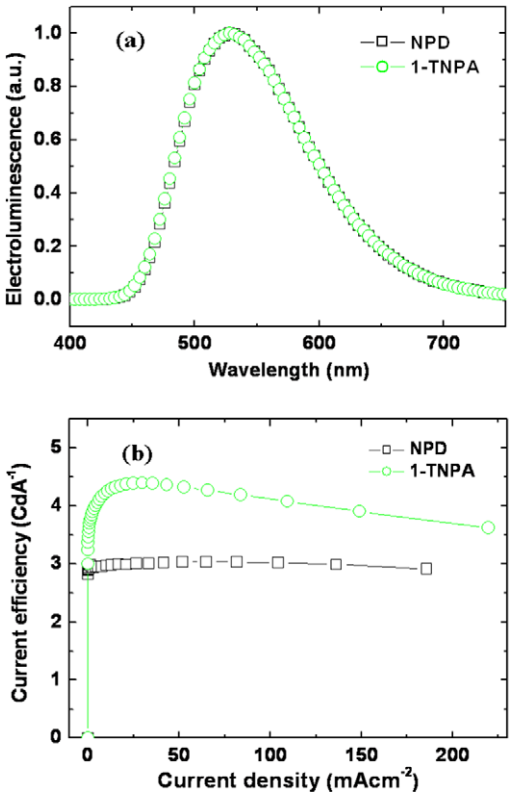

Fig. 4. A green emitting EL device with configuration ITO/NPD or **1-TNPA** (70 nm)/Alq_3 (60 nm)/LiF (1 nm)/Al (100 nm). (a) EL spectra and (b) current density (mA cm^{-2}) *vs.* current efficiency (cd A^{-1}) characteristics.

NPD-based reference device for these two devices to have the same current density or luminance. It is because the HOMO (−5.23 eV) energy level of **1-TNPA** is lower than that of NPD (−5.00 eV) and results in a higher hole blocking barrier which consequently retards the hole-transporting in the **1-TNPA**-based device. Therefore, **1-TNPA** can be used in green emitting OLEDs as a better hole-transporting material when compared to NPD.

3.5. Donor material in OSCs

To investigate the photovoltaic effect of **1-TNPA**, we fabricated OSCs with the configuration of ITO/PEDOT:PSS (30 nm)/**1-TNPA** (*x* nm)/C_{60} (40 nm)/BCP (5 nm)/Al (100 nm).

Fig. 5 shows the current–voltage characteristics of **1-TNPA**- and C_{60}-based heterojunction solar cells under AM 1.5 simulated solar illumination (intensity: 100 mW cm^{-2}). All the devices show photovoltaic behavior. In general, increasing the active-layer thickness increases the absorption ability; however, the absorption will be limited by the slow charge transport and separation in the active layer of the heterojunction device. Thus, it is important to optimize the active-layer thickness to improve the power conversion efficiency of the heterojunction devices. The 10-nm **1-TNPA**-based device had a short circuit current (I_{sc}) of 1.02 mA cm^{-2}, an open circuit voltage (V_{oc}) of 0.72 V, and a fill factor (FF) of 28%; from these data, the power conversion efficiency (PCE) was determined to be 0.21%, and this was attributed to the thin **1-TNPA** film. In the case of the thin **1-TNPA** active layer (10 nm), the absorption of the sunlight is reduced. The optimized **1-TNPA**-based device (film thickness: 15 nm) had an increased short circuit current of 1.35 mA cm^{-2} and an open-circuit voltage of 0.87 V; the FF was 38%. From these data, an increased maximum power conversion efficiency of 0.45% was calculated. By contrast, the device with a 20-nm **1-TNPA** active layer had a slightly reduced short circuit current of 1.3 mA cm^{-2}, an open-circuit voltage of 0.70 V, and an FF of 39%; from these data, a slightly reduced power conversion efficiency of 0.36%, which is attributed to the thicker thin film, was calculated. In the case of the thick **1-TNPA** active layer, effective charge transport and separation were affected, and they were limited by the low charge carrier mobility and diffusion length. In this study, the optimal thickness of the **1-TNPA** layer (15 nm) results in a maximum power conversion efficiency of 0.45%. Therefore, the change in the thickness of the **1-TNPA** film in the active layer changed the power conversion efficiency from 0.21% to 0.45%. Overall, the power conversion efficiency of **1-TNPA**-based OSCs was not high compared with other small-molecule-based OSCs because of the short absorption range (250–370 nm) and poor crystalline property of **1-TNPA**. Nevertheless, to the best of our knowledge, there are no reports of organic electronic materials that act as blue emitting materials as well as hole-transporting materials in OLEDs and donor materials in

OSCs. The data on the overall performance of **1-TNPA**- and C_{60}-based devices are summarized in Table 3.

3.6. Active material in OTFTs

To investigate the field-effect mobility of **1-TNPA**, we fabricated an OTFT involving the use of **1-TNPA** as an active material with top-contact geometry (Fig. S4). Fig. 6 shows the output and transfer characteristics of top-contact OTFTs involving the use of **1-TNPA** deposited on OTS/SiO_2 at a substrate temperature (T_{sub}) of 75 °C. From the electrical transfer characteristics, we obtained device parameters such as the field-effect mobility, on/off current ratio, and threshold voltage. The **1-TNPA**-based OTFT device showed a field-effect mobility (μ) of $1.5 \times 10^{-5}\ cm^2\ V^{-2}\ s^{-1}$, a threshold voltage ($V_{th}$) of −27.6 V, and an on/off current ratio (I_{on}/I_{off}) of 1.0×10^3 at 75 °C. The moderate field-effect mobilities of the OTFT devices derived from **1-TNPA** and triphenylamine derivatives [7b] can be attributed to the fact that it is difficult to maintain these derivatives perpendicular to the substrate. **1-TNPA**-based OTFTs exhibited similar field-effect mobilities of $1.5 \times 10^{-5}\ cm^2\ V^{-2}\ s^{-1}$, which were moderate compared to those of other triphenylamine derivatives [7b]. The morphological characteristics of **1-TNPA** were investigated by X-ray diffraction (XRD) and atomic force microscope (AFM). The thin-film XRD patterns indicated a poorly ordered structure of **1-TNPA** on the substrate (Fig. S9). Fig. 7 shows AFM images of **1-TNPA** active layers deposited on SiO_2 (left column) and OTS/SiO_2 (right column) at RT and 75 °C. The connectivity of **1-TNPA** grains deposited on a SiO_2 and OTS/SiO_2 substrate at RT and 75 °C is poor, which leads to low field-effect mobility. The data on the **1-TNPA**-based OTFT device for various conditions are summarized in Table 4.

4. Conclusion

We have developed the first multifunctional organic material (**1-TNPA**), which can be used as a deep blue emitting and hole-transporting material in OLEDs, as a donor material in OSCs, and as an active material in OTFTs. In particular, in the case of **1-TNPA**-based devices, efficient, deep blue emission similar to the NTSC standard blue was observed. **1-TNPA** can be used as a hole-transporting material which is more efficient and thermally stable than NPD. **1-TNPA** can be also used as a donor in OSCs and as an organic semiconductor in OTFTs.

material content in discrete field-effect transistors (FETs) can indeed be reduced by addition of a suitable second component. In fact, when using *semicrystalline:semicrystalline* macromolecular binaries, most prominently of P3HT and high-density polyethylene (HDPE), this concept lead to ultra-low threshold systems, in which only a few weight percent of the semiconducting species was required for providing a percolating network. A percolation threshold of as little as 3 wt.% was indeed demonstrated in these systems, which yielded devices with an electronic performance equal to devices comprising neat P3HT. Moreover, blending resulted in additional benefits, including mechanical toughness and improved air stability [9].

However, the crystalline nature of the two components in P3HT:HDPE binaries reduced the flexibility in selecting certain processing parameters, most importantly with regard to the solution deposition temperature, as the crystallization sequence needed to be strictly controlled in order to realize a low-percolation threshold structure [9]. In fact, it was shown that the semiconductor had to solidify prior to the electronically inactive material. In the case of P3HT:HDPE blends, this implied that deposition from solution had to be performed above the crystallization temperature T_c of the added insulator; i.e. at temperatures > 115 °C (depending on molecular weight, chain linearity, etc., of the HDPE utilized). Yet, a process requiring such elevated deposition temperatures can be technologically impractical and may increase production cost beyond the scope of the envisioned market for most plastic electronics products as, among other things, thermally robust substrates such as polyethylene naphthalate (PEN) would be required rather than the much cheaper polyethylene terephthalate (PET). Furthermore, control of film uniformity and the printing procedure in general could be problematical at application temperatures above 120 °C, especially when employing fabrication methods such as flexure/gravure technologies [15] or ink-jet processing [16].

One way to decrease the processing temperature of such crystalline:crystalline semiconductor:insulator blends would be to use an inactive component that has a lower melting temperature [17]. This option may, however, compromise the temperature range that final products can be utilized in, limiting their application to relative low-temperature environments only. We, therefore, set out to find a semicrystalline bulk polymer permitting the realization of low-percolation blends via low-temperature processes without, however, sacrificing the temperature window that the final device can be used in. As a consequence, we attempted to find a low-cost commodity polymer with (i) a better solubility than P3HT in a given solvent with $T_c^{\text{insulator}} < T_c^{\text{P3HT}}$ when processing the blend from solution and (ii) a high melting temperature (T_m > 150 °C) to allow for an application temperature (i.e. the maximum temperature the final product can be used at) of >80 °C.

We selected poly(vinylidene fluoride) (PVDF) as the inactive second component as this relatively low-cost, semicrystalline polymer is readily available, soluble in a variety of commercially available solvents and melts at 165 °C [18]. Additional functionalities may also be introduced in blends with PVDF, due to the different crystalline

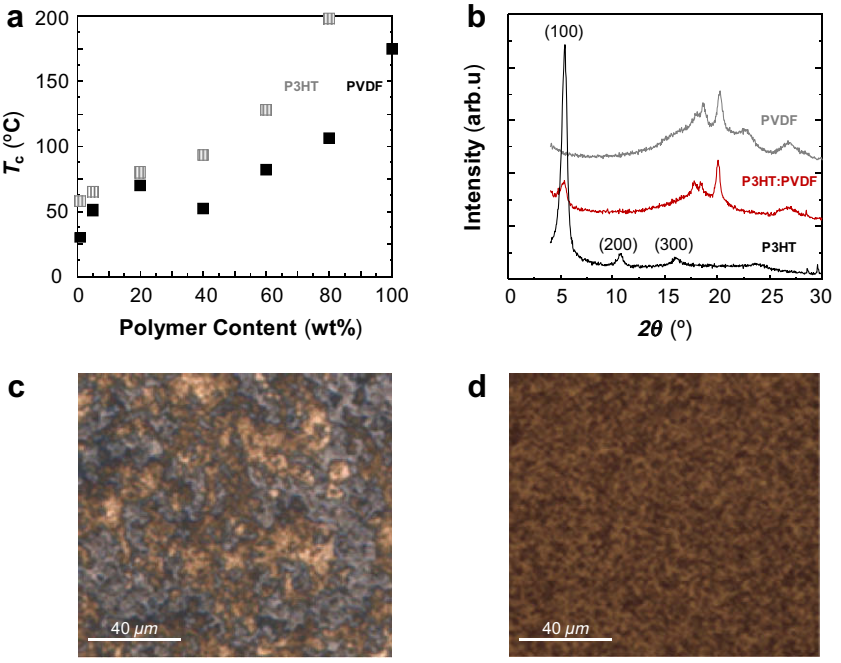

Fig. 1. (a) Superimposed phase diagram showing the crystallization temperature of P3HT (open symbols) and PVDF (black symbols) in cyclohexanone as measured in the respective binary system in differential scanning calorimetry. P3HT crystallizes prior to PVDF at all concentrations. (b) Wide-angle X-ray 2θ-diffractograms of cast P3HT:PVDF blend structures. Data of reference films of the neat components are also shown for comparison. (c, d) Polarized optical micrographs of blend films formed by spin-coating a formulation comprising 4 wt.% P3HT from (c) xylene, and (d) a xylene:cyclohexanone mixture.

phases that this polymer can form, some of which feature ferroelectric properties [18].

For realizing low-percolation blends, we were required to find a solvent for the P3HT:PVDF blends systems that favours PVDF dissolution over P3HT. One such solvent is cyclohexanone, in which, conveniently, P3HT was found based on differential scanning calorimetry data to solidify prior to PVDF at all temperatures and compositions (cf. Fig. 1a). This solution phase behavior in principal should allow for the casting or printing of the active layer and subsequent solvent extraction within a relatively broad processing window, provided that the deposition temperature is kept above T_c^{P3HT}. However, unfortunately, the relatively large difference between the solidification temperatures of the two components resulted in rather inhomogeneous thin-film architectures when cast from cyclohexanone, with large domains of 10–20 μm-size being visible (cf. optical micrograph presented in Fig. 1c); and as a consequence, variable, often very poor transistor device performances were obtained.

Clearly, use of just one solvent does not afford itself to gain sufficient control over the final microstructure of P3HT:PVDF blends. This limitation can, however, be readily overcome by the use of solvent mixtures. For instance, when adding xylene to the P3HT:PVDF:cyclohexanone solutions, which is known to be a good solvent for P3HT even at room temperature, the difference between the two polymers' solidification temperatures could be significantly reduced; i.e. the solubility of P3HT was slightly increased (and thus T_c^{P3HT} was lowered), whilst the solubility of PVDF was not significantly affected by the addition of xylene (i.e. T_c^{PVDF} essentially remained unaltered). Therefore, introduction of xylene lead to a minor increase in solidification rate of PVDF, whilst the one of P3HT was decreased. Thereby a solvent mixture of a cyclohexanone:xylene ratio of 3:1 (by weight) seemed to provide the best compromise between solubility and solidification rate of the two components, allowing blends to be spin-coated at substrate temperatures as low as 40 °C. Indeed, homogenous thin-film architectures were obtained with such solvent mixtures (Fig. 1d), with domains of the size of 5 μm and less being visible in optical microscopy, which we attribute to the fact that P3HT and PVDF solidified at very similar temperatures (P3HT prior to PVDF) and rates. However, we like to note that due to the *semi*crystalline nature of both P3HT and PVDF the full extent of the phase separation is difficult to estimate, especially within their amorphous regions. Some information was, nonetheless, obtained from wide-angle X-ray scattering (WAXS), in which reflections characteristic for both P3HT as well as the common, paraelectric α-phase of PVDF [18] was found (Fig. 1b).

Encouraged by the fact that homogenous films could be produced directly from solution using deposition temperatures as low as 40 °C, we fabricated field-effect transistor devices by spin-coating PVDF-rich blends from such 3:1 cyclohexnanone:xylene solutions (kept at 80 °C) onto pre-patterned (lift-off) transistor structures with a 230 nm-thick, thermally grown silicon dioxide as gate dielectric. The latter had been treated with octyltricholorosilane (OTS). Several semiconductor:insulator ratios were investigated.

The transistor performance was found to be almost independent of composition of the P3HT:PVDF blends used in the formulation. Devices of good transistor performance were reliably obtained at a P3HT content of as little as 4 wt.%. Only at less than 3 wt.% P3HT the device uniformity started to be adversely affected, resulting in a lower yield of working FETs (<20%) compared to the high reproducibility in device fabrication we obtained at higher P3HT contents (Fig. 2a). The FETs featured very low gate leakage currents and high field-effect mobilities of up to 0.04 cm^2/Vs, which is comparable to neat P3HT devices. Some minor hysteresis between forward and backwards scans and relatively large turn-on voltages were observed (Fig. 2). These characteristics are, however, not uncommon features for P3HT devices. In fact, such properties are more

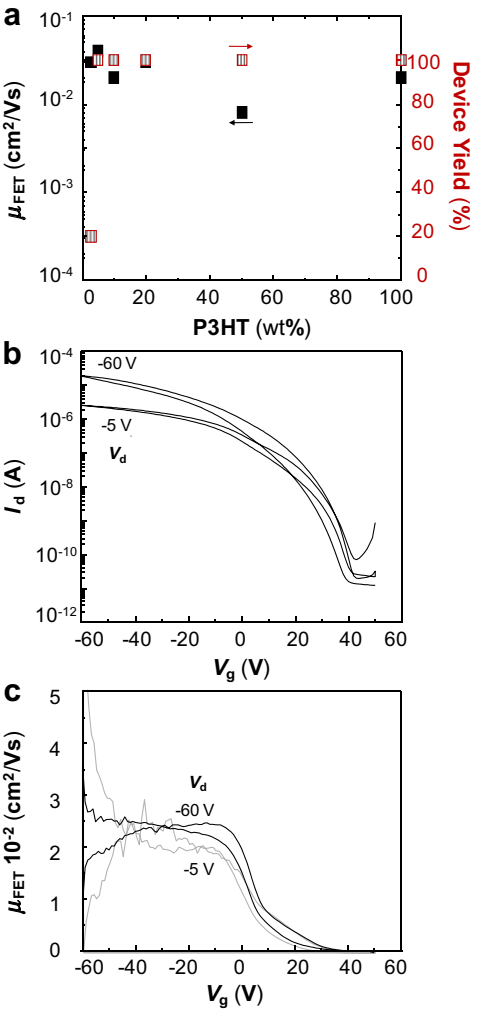

Fig. 2. (a) Field-effect mobility (black symbols) and device fabrication yield (open symbols) of P3HT:PVDF blends, plotted as function of P3HT content. The mobility was unaffected by the addition of the insulating PVDF, and the yield of working devices was only drastically reduced at a P3HT content of less than 3 wt.%. (b, c) FET device performance of a typical FET fabricated from a P3HT:PVDF binary comprising 4 wt.% semiconductor: (b) transfer characteristic and (c) corresponding field-effect mobilities.

likely to be related to the OTS layer quality and the SiO_2 dielectric that was used [19]. For instance, reference devices made from neat P3HT showed very similar transfer plots to the blend devices. Furthermore relatively large variations were found between devices fabricated on the same substrate type, but with different OTS treatments.

In order to illustrate that our P3HT:PVDF formulations are transferable to roll-to-roll processing and have the potential to be used on flexible substrates, we fabricated transistors using an organic gate dielectric. For this purpose, devices were fabricated by depositing the organic insulator D206 (supplied by Merck) onto the gate via spin-coating. To provide a passive, orthogonal surface, the dielectric was then crosslinked by UV irradiation before gold source-drain electrodes were deposited. In the final fabrication step, the semiconducting blend formulation (4.4% wt.% P3HT; 95.6 wt.% PVDF) was spin-coated in inert atmosphere on top of these multilayer architectures.

The resultant devices were measured in inert conditions (to minimize affects from ambient air). Good device performance was achieved with high charge-carrier mobilities (Fig. 3a and b), however, unfortunately, high OFF-currents were observed. This is, though, not uncommon for P3HT devices, especially when they were exposed to, e.g., oxygen from ambient conditions [20,21]. We therefore attributed these undesirable device characteristics not to the presence of the PVDF in the active layer, but rather to doping of the P3HT component. Indeed, the D206 dielectric layer (deposited in ambient conditions) may be susceptible to absorption of O_2 originating in such doped P3HT structures at the active layer/dielectric interface [*NB:* Note that we attempted to increase the ON–OFF current ratio by annealing blend transistors in vacuum at elevated temperatures in the range of 80–100 °C, however, no improvement was, unfortunately, observed in field-effect transistor characterization after this treatment].

We continued exploring P3HT:PVDF formulations comprising 4 wt.% P3HT and more, and scrutinized if these formulations can be deposited in a scaleable manner. For this purpose devices were flexographically [22] printed in air onto bottom-gate devices comprising of the organic Merck D206 gate dielectric, emulating printing speeds of up to 90 m/min. Good device performance was obtained also for such printed FETs, however, as already observed for the spin-coated devices, relatively large OFF-currents were again recorded due to the strong tendency of P3HT for doping. In addition, a rather pronounced hysteresis was observed in these printed devices, which we attribute to the fact that printing of the P3HT:PVDF blend was conducted in air, in contrast to the above described spin-coated FETs, in which the active layer was deposited in an inert atmosphere and thus featured essentially identical forward and backwards scans. Nonetheless, our results illustrate that roll-to-roll techniques for the manufacture of low-cost organic electronics products can be used for the fabrication of organic FETs.

In summary, we have addressed one key bottleneck of crystalline:crystalline semiconductor:insulator blends,

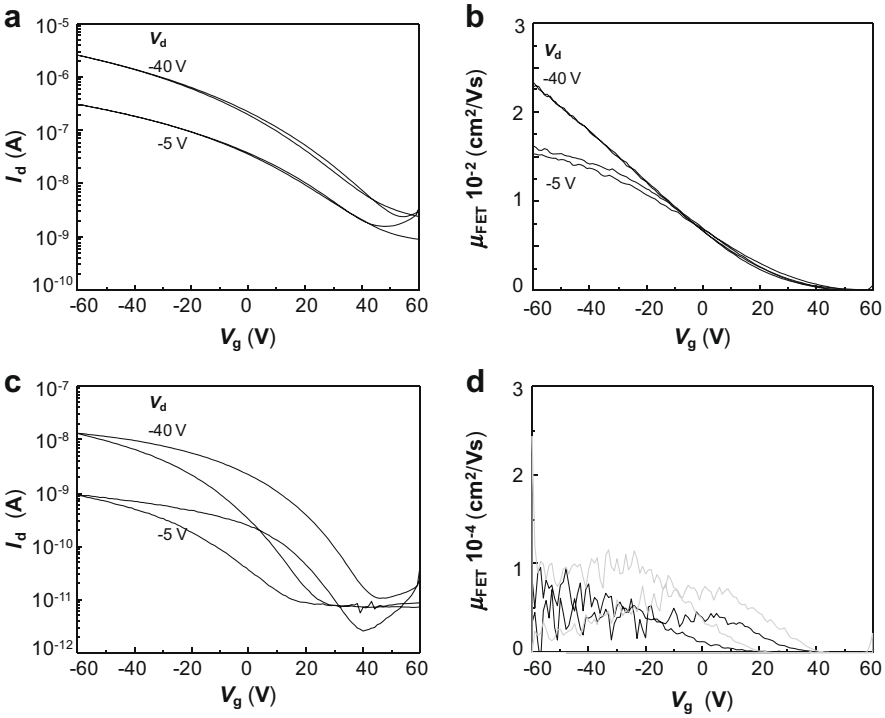

Fig. 3. (a, b) Typical FET performance of a P3HT:PVDF blend device (4 wt.% P3HT content) spin-coated in inert atmosphere, comprising the Merck organic dielectric D206, fabricated onto a flexible PEN substrate: (a) transfer characteristics and (b) corresponding FET charge-carrier mobility. (c, d) Device performance of a FET structure (with the an D206 gate dielectric) manufactured *in air* by flexo-printing using a 4 wt.% P3HT formulation.

such as P3HT:HDPE binaries, i.e. that fact that they require relatively high deposition temperatures, thus, are not compatible with certain flexible substrates and/or deposition methodologies, such as ink-jet printing, gravure printing and the like. We demonstrated here that systems based on P3HT:PVDF seem to provide interesting alternatives as they allow deposition from solution at temperatures well below 50 °C permitting fabrication of organic field-effect structures using flexographic processes. Obviously, our formulations may be adjusted for use in even less demanding methodologies, for instance, gravure techniques, which do not need an intermediate rubber transfer as patterning is achieved by a structured analox. In addition, further work is ongoing to substitute P3HT with a more environmentally stable semiconductor, such as poly(2,5-bis(3-alkylthiophene)thieno(2,3-*b*)thiophenes) [23]. This may assist in avoiding the high OFF-currents due to the doping of the semiconductor. Moreover, materials could be investigated which have been demonstrated to have higher charge-carrier mobilities than P3HT [24,25].

the UV-PDs has been focused on inorganic counterparts with wide-band gap semiconductor such as GaN (150 mA/W) [10] and SiC (150 mA/W) [11], but these inorganic partners require complicated fabrication technique with high expenses. Since organic UV-PDs have the strongpoint of simple fabrication process, recently organic UV-PDs based on blend of N,N-diphenyl-N,N-bis(3-methylphenyl)-(1,1-biphenyl)-4,4-diamine (TPD) and tris(8-hydroxy-quinoline) aluminum (Alq) was reported, but its UV responsivity is distinctively lower than the inorganic partners [12].

It is recognized that the dissociation of photo-generated exciton must occur at DA interface that needs the D and A species to have low ionization potential (IP) and high electron affinity (EA), respectively, to have as large carrier motilities as possible for both materials. 1,3,5-Tris(3-methylphenyl-phenylamino) triphenyamine (m-MTDATA) presents high hole mobility of 3×10^{-5} cm^2/V s [13] and a low IP of 5.1 eV [14], moreover, it was used as D-material in UV sensitive PV devices [15–17]. Our group has fabricated m-MTDATA/tris(8-hydroxy-quinoline) gallium (Gaq) based UV PD diode by using m-MTDATA as the donor and Gaq as the acceptor [18], but its photo-response spectrum evidently covers visible waveband, i.e., it is not visible-blind, which was attributed to its stronger absorption at visible region of 400–450 nm [18]. Therefore, a new A-material with weaker light absorption at visible spectral region must be selected. Zhang et al. have observed that the absorption peak of the metal-8-hydroxy-quinoline (Mq) complexes is dependent on the metal ion radii, that is, larger ion radii based Mq complex must lead to blue-shift of the absorption peak due to the stronger polarization [19]. We have noted that trivalent Gd (Gd^{3+}) with larger ion radii of 0.11 nm should exhibit weaker absorption at visible spectral region in comparison with Gaq complex due to smaller ion radii of Ga^{3+} (0.047 nm). In addition, Gdq should have larger electron-transporting (ET) property because erbium-q complex (Erq) has higher ET and electrical properties. Moreover, Erq also belongs to one of RE elements and has almost identical ion radii; hence Gdq also seems to exhibit larger ET ability [20,21]. Basing on the argument, it is expected that the PD diode with m-MTDATA/Gdq blend could offer high photo-response and it could be sensitive to the pure UV waveband.

In this letter, we will demonstrate PD diodes using Gdq as the A-material. For comparison, photo-sensitivities of other REq-PD diodes (RE = Y, La, Lu or Eu) were also studied. For the reason that the trivalent RE ions (RE^{3+}) in REq complexes behave inert electric configuration and do not contribute to light radiation from the RE^{3+} ions at UV excitation except for Eu^{3+} ion that emits red luminescence under UV illumination or electrical excitation. It is observed that 1:1 ratio m-MTDATA:Gdq-PD (Gdq-PD) diode exhibits a maximum photo-responsivity of 230 mA/W with VB among the REq-PDs at −7.5 V bias. We have noted that the responsivity considerably related to the exciplex formation of D:A blends and the optical properties of the REq complexes.

2. Experimental

All the REq complexes were synthesized according to methods reported in Refs. [20,21] and function as the A-materials in the PD diode system. Their blend films were thermally deposited on the quartz substrates in a vacuum chamber at the pressure of 5×10^{-4} Pa for the absorption and photoluminescence (PL) measurements. The PD diodes were fabricated on cleaned indium tin oxide (ITO) coated glass substrates with a sheet resistance of 25 Ω/sq in vacuum chamber. The organic layers were deposited at a rate of 2 Å/s; the evaporating rate of LiF and Al cathode were controlled to be 0.5 and 10 nm/s with the thickness of 1 and 200 nm, respectively. All the vacuum chambers were controlled at pressure of 5×10^{-4} Pa; the deposition rates and thickness of the layers were monitored using oscillating quartz monitors. Absorptions and PL spectra of the neat D- and A-material films and their blend films were determined with a Shimadzu UV-3101 PC spectrophotometer and a Hitachi F-4500, respectively. The PD diodes with structures of ITO/m-MTDATA:REq (1:1, 60 nm)/LiF (1 nm)/Al were fabricated, but the m-MTDATA-to-Gdq ratio for Gdq-PD diodes was 1:3, 1:1 and 3:1, respectively. Photocurrent spectral responses of all the PD diodes were measured under illumination of a 40 μW/cm^2 Xe lamp. Current–voltage (I–V) characteristics of the devices were recorded in dark and under illumination of 365 nm UV light with different intensities through the ITO side. The excited state lifetime of the exciplex emission of (m-MTDATA:Gdq) 1:1 blend film was measured by an F-900 Fluorescence and Phosphorescence lifetime spectrophotometer. All the measurements were carried out at room temperature under ambient condition. Besides, the operational lifetime of the UV PD is about 440 min under a constant illumination of 365 nm UV light with an intensity of a 8 μW/cm^2 Xe lamp and an illumination of a fluorescent lamp with an illumination power of 20 mW/cm^2 for observing its durability.

3. Results and discussion

The absorption spectra of the blend films of m-MTDATA:REq and the neat films of m-MTDATA and Gdq are indicated in Fig. 1(a), respectively. For comparison, the inset indicates relative absorption spectra of 1:1 blend film of m-MTDATA:REq, here RE are Y, La, Gd, Lu and Eu, respectively. We have noted that blue-shifting absorption peak of the Gdq film occurs comparing to Gaq [18], which describes that the photocurrent response of Gdq-PD diode could focus on the pure UV spectrum region. This is attributed to markedly lower absorption intensity of Gdq complex at 400–475 nm comparing with that of Gaq [18]. From the inset it can be seen that the figure of the absorption band of m-MTDATA:Gdq blend film is semblable with the other REq but the absorption intensity of m-MTDATA:Gdq and m-MTDATA:Euq blend films are maximum and minimum, respectively, which will be discussed later. Fig. 1(b) describes the photocurrent spectral responses of REq-PD diodes with 1:1 ratio of m-MTDATA:REq at zero bias, note that the photocurrent response locates almost at 300–400 nm UV spectrum region and Gdq-PD diode offers a maximum photocurrent density.

Fig. 2(a) depicts I–V characteristics of the five REq diodes at reverse biases under illumination of 365 nm UV

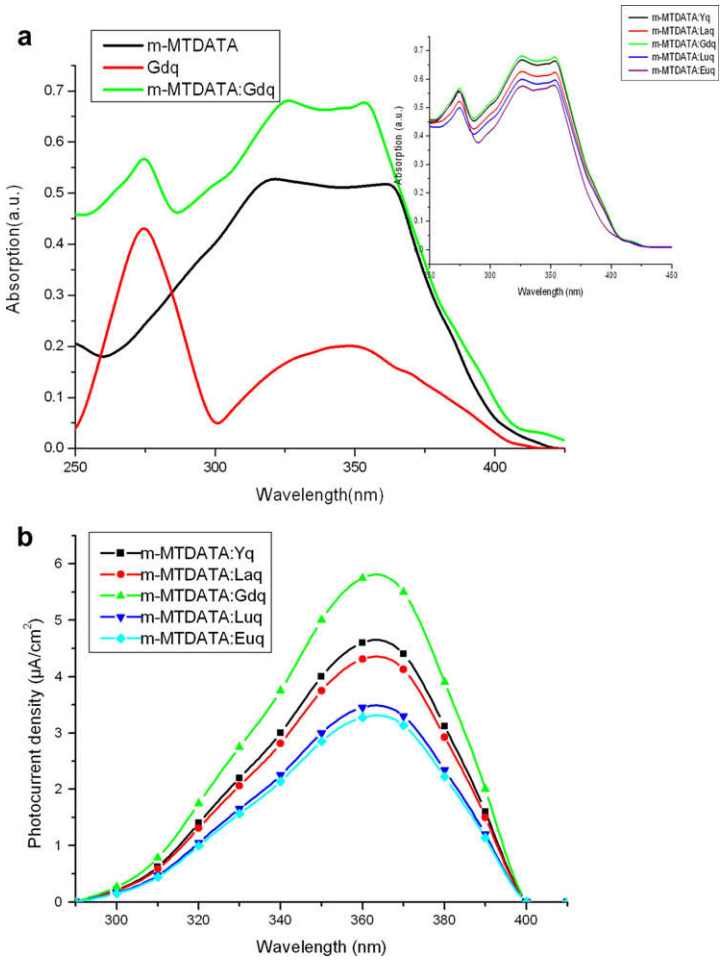

Fig. 1. (a) The absorption spectra of the blend films of m-MTDATA:Gdq and neat films of m-MTDATA and Gdq, the inset: relative absorption spectra of 1:1 blend films of m-MTDATA:REq (RE is Y, La, Gd, Lu and Eu). (b) The photocurrent spectral response of PD diode with m-MTDATA:REq blend with 1:1 ratio at zero bias.

light with a 1.2 mW/cm^2 and *I–V* characteristic of the Gdq-PD at dark, respectively, as well the inset indicates the photo-responses of the five REq-PD diodes as a function of UV light intensity at −7.5 V. It can be seen that current density of the REq-PD diodes significantly increases with the reverse voltage. The dark currents of the Gdq and other REq-PD devices are extremely low, the photocurrent-to darkcurrent ratio is about 260. Fig. 2(b) depicts the photo-responses of Gdq-PD device at −2, −6 and −7.5 V as a function of UV light intensity. It can observe that Gdq-PD diode exhibits a maximum photocurrent density of 276 μA/cm^2 and a peak photo-response of 230 mA/W among the five PD diodes. From Fig. 2(b) we obtained that the photo-sensitivities of Gdq-PD diodes are 64, 169, and 230 mA/W at −2, −6 and −7.5 V under illumination of 365 nm UV light, respectively. We can see that Gdq-PD presents a peak photosensitivity at any irradiation intensity comparing with other REq-PD diodes. Moreover, the photocurrent response of the PD device at a given voltage is almost unchanged with the increase in irradiation intensity from 0.4 to 7.0 mW/cm^2. This suggests that there is no obvious buildup of space charge, which can cause derivation from linear dependence of irradiation. Therefore, achievement of so high photosensitivity for Gdq-PD diode could be explained as below. It is noticed that the photocurrent densities of a PD diode at zero bias is actually short circuit current density (*Isc*) of a PV diode [1,22]. From Fig. 2(a) we also obtained that the photocurrent densities of Gdq, Laq, Yq, Luq and Euq-PD diodes at zero bias are 52.3, 33.1, 32.7, 27.8 and 25.7 μA/cm^2, respectively, and Gdq-PD diode offers a maximum high photocurrent response. That is, if a PV diode could offer higher *Isc*, a higher PD response could be obtained for the same structure PV diode because the PV and photodetection performances of the organic devices are likely to approach at zero bias [1,22]. Note that the five REq-PD diodes have the same structure so the fact that the PV performance increases with the increase in *Isc* would also lead to the same increasing trend of their PD photo-responses at reserve biases.

Fig. 3(a) and (b) depicts the PL spectra of above five blends, neat m-MTDATA and the neat REq films, respec-

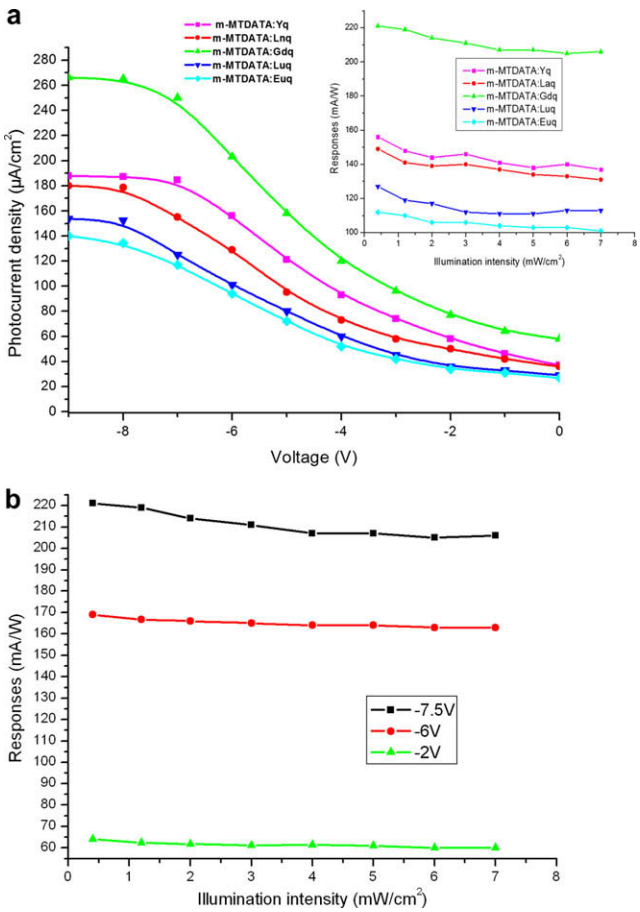

Fig. 2. (a) *I–V* characteristics of PD devices with various REq complexes at changing reverse bias under illumination of a 365 nm UV light with an intensity of 1.2 mW/cm^2. Inset: the photo-responses of the five REq-PD diodes at −7.5 V. (b) The photo-responses of the Gdq-PD device at −2, −6 and −7.5 V, respectively.

tively, as well (c) indicates PL spectra of 3:1, 1:1 and 1:3 blend films of m-MTDATA:Gdq under excitation of an 365 nm UV light, respectively. Comparing Fig. 3(a) and (b) we can seen that the PL spectral peaks are longer for the five blend films than for the five neat REq films, which were ascribed to overlapping of the D:A interfacial exciplex emission bands with the bulk PL. We also observe that PL intensities of the either blend or neat films of Gdq and Euq are, respectively, weakest and strongest among the five REq systems, which are corresponding to their photosensitivity (see Fig. 2(a) and the inset). From Fig. 3(c) we also see that the 1:1 ratio film behaves most low PL intensity among the PL spectra of 3:1, 1:1 and 1:3 blend films of m-MTDATA:Gdq, While both PL spectra of 3:1 and 1:3 blend films composed of not only the intermolecular exciplex emission, but also of the m-MTDATA and Gdq-bulks, the PL emissions of the two blends provide highly stronger than the 1:1 blend film. We note that 1:1 m-MTDATA:Gdq blend based PD diode offers the highest PD response over other two PD diodes based on 3:1 (162.8 μA/cm^2) and 1:3 (193.7 μA/cm^2) blend ratio of m-MTDATA:Gdq. So we can conclude that the photosensitivity is related closely to PL emission of the blend, i.e., the stronger the PL intensity the blend and/or bulk films are, the photosensitivity is the lower.

The findings can also be understood as follows. The geminate electron–hole pairs could be resulted from the intermolecular interface in the m-MTDATA:REq blend film under UV illumination, and thus there would be competition processes between the dissociation and collapse of the geminate carrier pairs [23,24]. We observed that the relative intensity of the exciplex emission of 1:1 ratio m-MTDATA:Gdq blend is the lowest among the three ratio based Gdq diode, and no bulk emissions were almost determined comparing with other REq-PD diodes, as shown in Fig. 3(a) and (b) although neat Gdq film also provides PL (Fig. 3(b)). For m-MTDATA:Euq blend film, both PL emissions of Eu^{3+} center and 8-hydroxyquinoline ligand of the complex occurred, leading to the lowest PD response due to the competition of the PL emission coming from exciplex, Euq and Eu^{3+} centers with the exciton dissociation. Thus the dissociation of the geminate carrier pairs should be less so that Euq-PD diode offers the lowest photocurrent response. The responses of Yq, Laq and Luq-PD diodes are lower than that of Gdq-PD diode due to their stronger bulk PL emissions as well. The competition be-

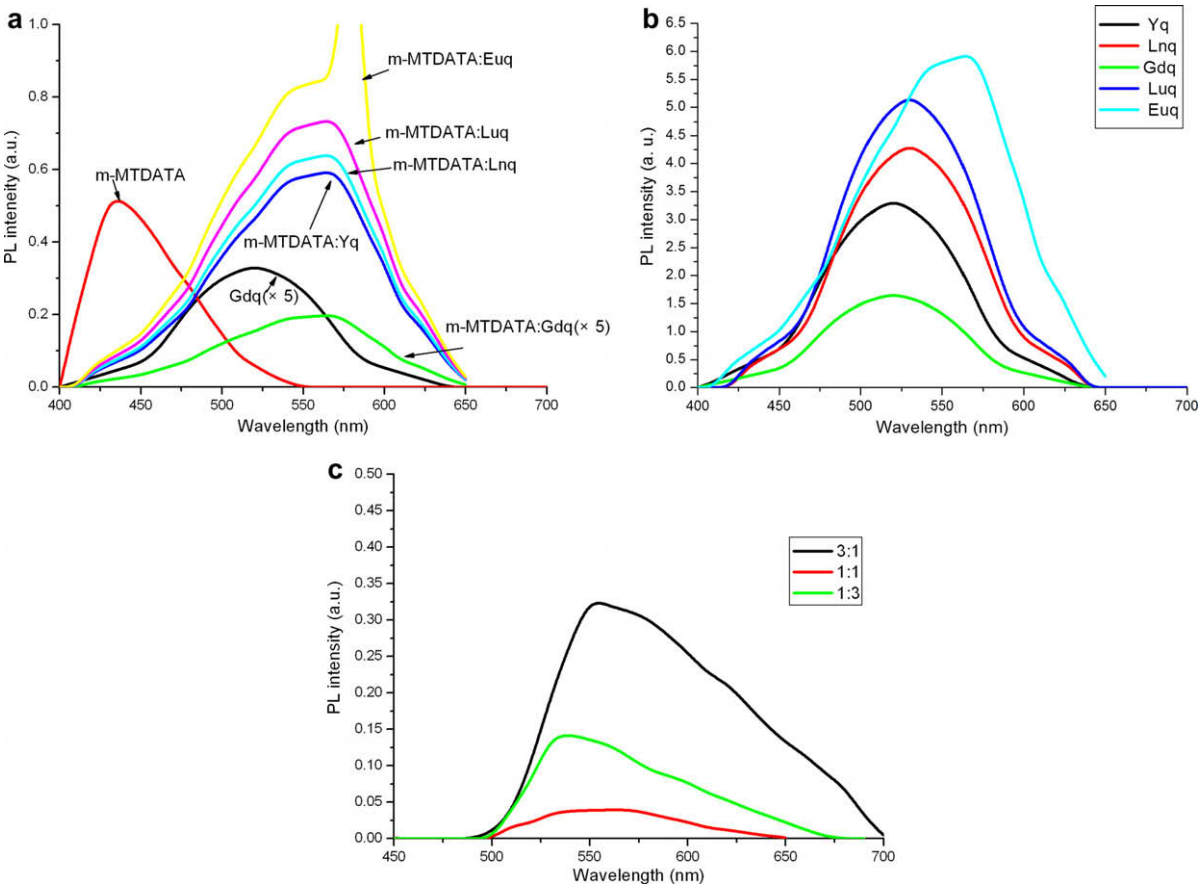

Fig. 3. (a) The PL spectra of above five blends and neat m-MTDATA and Gdq films, (b) the PL spectra of above five RE complexes at excitation by 365 nm UV light and (c) the PL spectra of 3:1, 1:1 and 1:3 blend films of m-MTDATA:Gdq under excitation 365 nm, respectively.

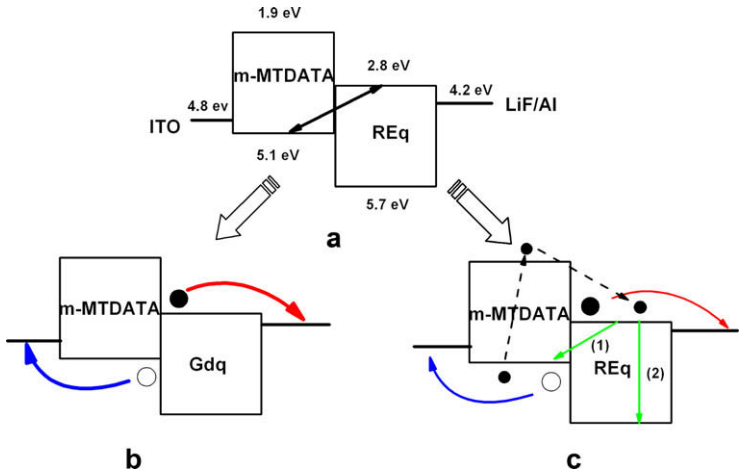

Fig. 4. (a) The geminate charge pair formation at the intermolecular interface of m-MTDATA/REq, (b) the dominant PV (PD) process of m-MTDATA/REq devices at very weak emissions of bulk and/or exciplex, and (c) weaken PV work at intensive emissions of exciplex (1) and/or bulk (2). Double direction arrow: Generated electron–hole pair; ● and ○: electron and hole that are resulted from exciton decomposing at the interface. Red and blue arrows denote the electron and hole transports into the respective electrodes, respectively. Dash arrow: electron transfer processes from HOMO of m-MTDATA to LUMO of REq, green arrow (1) and (2) represent emissions from exciplex and/or bulk of another REq-PD diodes except for Gdq at zero bias. The lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO) levels of REq were cited from Ref. [24] and the LUMO and HOMO of m-MTDATA cited from Ref. [25]. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

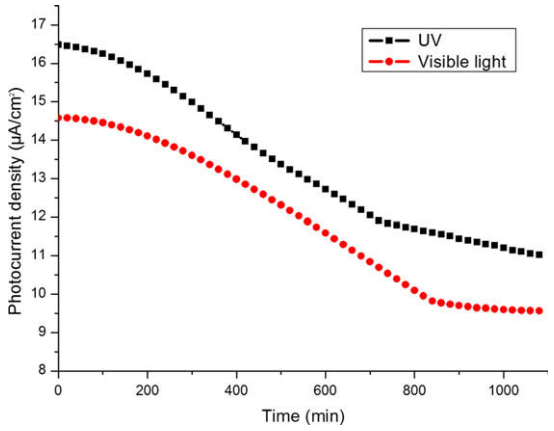

Fig. 5. The dependence of the photosensitivity on the illumination time by 365 nm UV light illumination with a 8 μW/cm^2 Xe lamp and an illumination of a fluorescent lamp with a power of 20 mW/cm^2.

tween dissociation and collapse of the geminate carrier pairs is depicted in Fig. 4. Fig. 4(a) depicts the schematic level diagram of the geminate charge pair formation. It also describes the dominant dissociation process of the geminate carrier pairs forwards into free electrons and holes (Fig. 4(b)) as well as provides the dominant exciplex and/or bulk emission processes which produced from collapse of the geminate carrier pairs (Fig. 4(c)). But the fact that the difference in photocurrent responses among Yq, Laq and Luq-PD diodes is not clearly understood now.

The reason that the photosensitivity is markedly high for Gdq-PD diode than for other REq-PD diodes may be also attributed to the paramagnetic property of Gd^{3+} ion and a very long exited state lifetime (1.3 μs) of PL emission of the exciplex between m-MTDATA:Gdq blend film is different from that of exciplex fluorescence [23], while it is more like to triplet, i.e., phosphorescence exciplex [25], and the more details are under studying. It is well known that organic materials generally are not so much stable under UV illumination, thus we measured the dependence of the photosensitivity on the illumination time by 365 nm UV light illumination and fluorescent lamp, respectively, as described in Fig. 5. We note that the degradation of the photo sensitivity not so much serious, which will be further studied.

4. Conclusion

In conclusion, visible-blind UV photo-detectors (PDs) were fabricated by using series of complexes of RE (RE = Y, La, Gd, Lu or Eu) with 8-hydroxyquinoline (REq) as the A component and m-MTDATA as the D components, respectively. It is discovered that Euq diode offers a maximum bulk PL emission that leads to a small photo-response. The fact is that the peak photosensitivity of Gdq-PD among the REq-PD diodes is attributed to its dominant exciton dissociation process resulted from extreme weak exciplex and bulk emissions and the strongest UV absorption. On the other hand, the realization of visible-blind UV Gdq-PD diode should be resulted from the blue-shift of the absorption band. These findings inspired us to realize that Gdq is an intriguing complex because of its excellent PD performance, and it can be expected that Gdq complex may also be used to design other organic electronic device with high performance. Beside it is believed that the photo-degradation of the Gdq-PD diode is not so much severe the working lifetime of the PD diode will be considerably improved if the PD device will be enveloped to obstruct from atmosphere.

developed a range of orthogonal solvents for the non-damaging patterning of organic materials [12], whilst some of the present authors have reported a simplified lithographic method, known as interlayer lithography, in which the resist layer is placed between the substrate and the material to be patterned [11]. Both methods allow for the fabrication of high quality electronic devices utilizing conventional photolithographic equipment, indicating that photolithography has considerable potential as a versatile patterning method for plastic electronics.

In previous work, we used interlayer lithography in combination with an intermediate conductivity formulation of PEDOT:PSS (Clevios P) to fabricate efficient organic light-emitting diodes and photodetectors with feature sizes at the millimetre scale [11]. In this paper, using a recently released high conductivity formulation of PEDOT:PSS (Clevios PH500), we extend the interlayer technique to organic field-effect transistors (OFETs) with source–drain electrode spacings in the micron range.

2. Results and discussion

Fig. 1 shows a schematic illustration of the interlayer method as applied here. First, a conventional negative photoresist (SU 8-2) is spin-coated on the substrate (Fig. 1a). Second, the resist is exposed through a mask by a UV source, initiating a cross-linking reaction that renders the exposed regions insoluble (Fig. 1b). Third, the target material (PEDOT:PSS) is spin-coated on top of the resist (Fig. 1c). Finally, the coated substrate is immersed in a developer, which dissolves the unexposed resist and simultaneously removes the target material above, leaving a patterned layer of PEDOT:PSS on top of an identically patterned layer

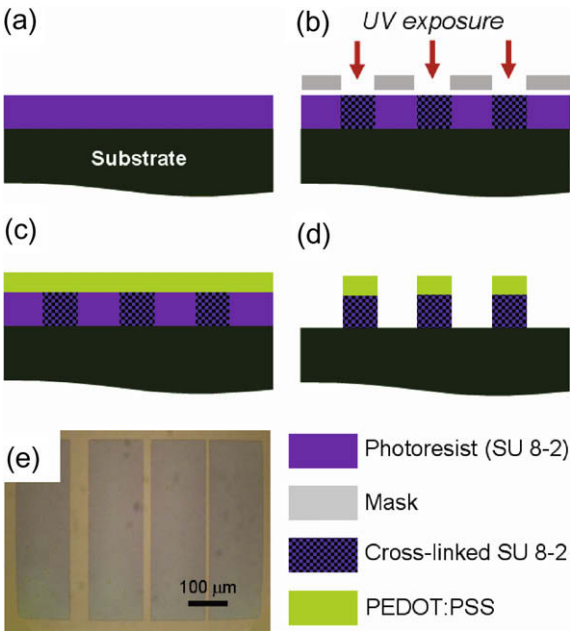

Fig. 1. (a–d) Schematic of the interlayer patterning method. (e) Micrograph of patterned PEDOT:PSS (150 μm width and 500 μm length) stripes on glass with inter-stripe spacings of 50, 20, and 10 μm from left to right.

of the cross-linked resist (Fig. 1d). In conventional photolithography the cross-linked resist is physically or chemically stripped away after patterning. In the interlayer approach, by contrast, it is retained between the target material and the substrate, meaning fewer (less damaging) process steps are required to complete the patterning procedure. The interlayer lithography process can also be configured in other ways – e.g. one can use a positive resist or carry out the exposure step after deposition of the target material [11].

SU 8-2 was selected as the resist material due to its high transparency and its good thermal, chemical and mechanical properties [24]. To minimize the obtrusiveness of the interlayer on the subsequent device architecture, the as-received SU 8-2 precursor was diluted with an SU 8 thinner prior to use, thereby reducing the thickness of the final film from ~1.4 μm to 230 ± 20 nm under standard spin-coating conditions (see Section 4). The combined height of the patterned [SU 8-2]/PEDOT:PSS bilayer was 350 ± 20 nm, implying a PEDOT:PSS thickness of ~120 nm for the chosen spin conditions. Fig. 1e shows an optical micrograph of four adjacent 500 × 150 μm rectangles of PEDOT:PSS, separated by distances of 50, 20, and 10 μm from left to right. The procedure can easily replicate features on the near micron-scale, yielding highly transparent patterned films of PEDOT:PSS with transmission $T > 90\%$ at 550 nm. The spacings shown do not reflect the ultimate feature sizes achievable with the interlayer method and in recent work we have achieved electrode separations down to 4 μm (see Fig. S1), close to the ~1 μm resolution limit of the equipment employed. Under specific circumstances, it is even possible to pattern at sub-micron length scales (700 nm) [25].

The patterning procedure was found to cause a ~15% drop in conductivity compared to unpatterned Clevios PH500 on glass (see Fig. S2), but the patterned films still exhibited conductivities >360 S/cm – a value that is higher than has been recently reported by others for the same PH500 formulation [8,26–28] and which is significantly above the baseline value of 300 S/cm specified by the supplier H.C. Starck GmbH.

To evaluate the utility of the interlayer method, arrays of closely spaced source and drain electrodes were patterned in PEDOT:PSS using glass and polyethylene terephthalate (PET) substrates (Fig. 2a and b). The electrodes were prepared with different channel lengths (L) in the range of 20–100 μm and channel widths (W) of 500, 1000 and 2000 μm. The enlarged image in Fig. 2c shows typical source and drain electrodes with $L = 20$ μm and $W = 1000$ μm.

Top-gate/bottom-contact p-type OFETs were fabricated using either 2,8-difluoro-5,11-bis(triethylsilylethynyl)-anthradithiophene (diF-TESADT) or a blend of diF-TESADT and poly(tri-arylamine) (PTAA) [29] as the semiconductor, CYTOP as the dielectric and Al as the gate electrode (Fig. 2d). Both pristine and blended forms of diF-TESADT have been used effectively in OFETs, the latter exhibiting superior stability at the expense of lower mobility. Ambipolar transistors were fabricated in the same way, except a spin-coated layer of [6,6]-phenyl-C_{61}-butyric acid methyl-ester (PCBM) [30] was used as the semiconductor.

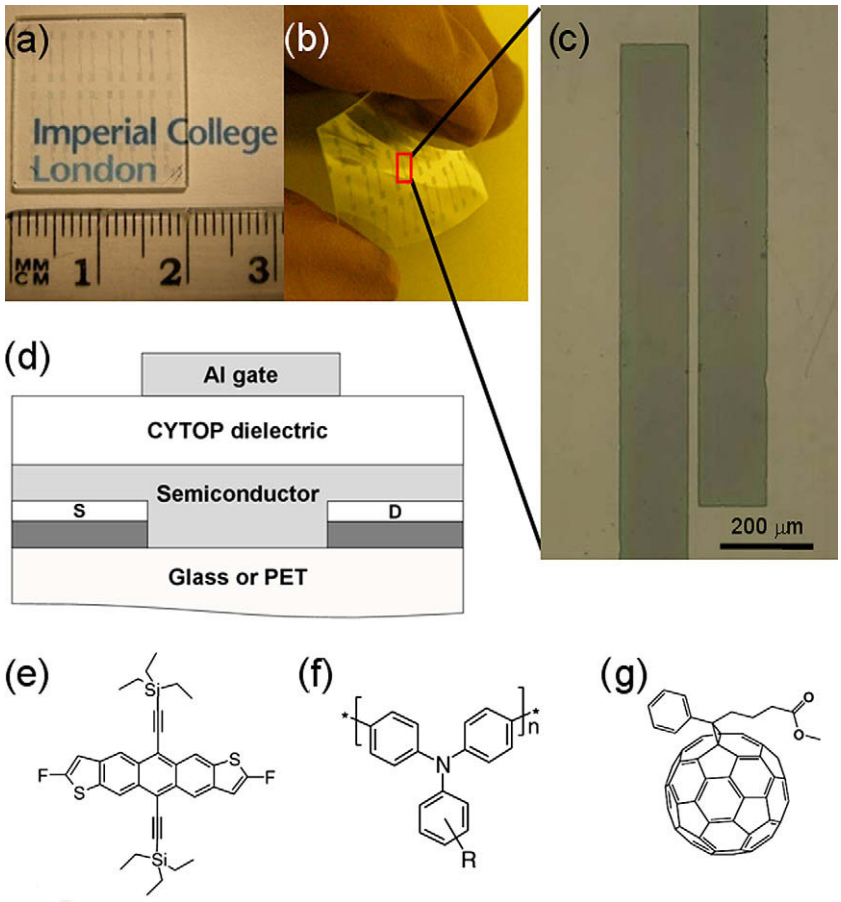

Fig. 2. (a and b) PEDOT:PSS array patterns fabricated on glass and PET, respectively. (c) Individual PEDOT:PSS source and drain electrodes patterned with 20 μm spacing on PET. (d) A schematic diagram of the *top-gate/bottom-contact* OFET configuration. (e–g) Chemical structures of diF-TESADT, PTAA, and PCBM, respectively.

Using the interlayer method with a metal shadow mask to control exposure of the photoresist, we were able to fabricate functioning transistors with channel lengths down to 20 μm. Excessively short values of L resulted in heavily injection limited device characteristics, and the best results were obtained using source–drain separations of 60, 30 and 50 μm for the diF-TESADT, diF-TESADT/PTAA and PCBM devices, respectively.

Fig. 3a and b shows transfer and output characteristics of a typical pristine diF-TESADT transistor with $L = 60$ μm. The device had an on/off ratio of $\sim 10^4$ and a hole mobility of 1 $cm^2/V\,s$, determined from plots of $I_D^{1/2}$ versus V_G in the saturation regime using the gradual channel approximation [31]:

$$I_{D,Sat} = \frac{WC_i}{2L}\mu(V_G - V_T)^2 \quad (1)$$

where W and L are the width and length of the transistor channel, C_i is the geometrical capacitance of the gate dielectric, V_G is the gate voltage, V_T is the threshold voltage, and I_D is the measured drain current. Fig. 3c and d shows the transfer and output characteristics of a typical diF-TESADT/PTAA transistor with $L = 30$ μm. The device had a moderate on/off ratio of $\sim 10^3$ and a lower mobility of 0.25 $cm^2/V\,s$. For both devices, I_D was observed to increase non-linearly with drain voltage (V_D) in the low V_D regime (Fig. 3b and d), which is attributable to a combination of contact resistance effects arising from the ~0.35 eV barrier[1] to hole injection at the PEDOT:PSS/diF-TESADT interface and possible access resistance effects associated with the transport of charge from the contact to the conducting channel [14].

The mobilities reported here compare favourably with values obtained from diF-TESADT based OFETs utilizing untreated gold electrodes (0.1–1 $cm^2/V\,s$). In the case of diF-TESADT/PTAA OFETs, improvements in hole mobility up to 2.4 $cm^2/V\,s$ have been reported when the source and drain electrodes are treated with a self-assembling monolayer of pentafluorobenzenethiol due to enhanced film crystallinity and an increase in the effective work function of gold [32,33]. Since no treatment of the PEDOT:PSS layer was carried out here, it is likely that similar enhancements in OFET mobility could be achieved through

[1] Note: the Fermi level of the PEDOT:PSS electrode is ~5.0 eV [7,8] while the highest occupied molecular orbital of diF-TESADT is ~5.35 eV [29].

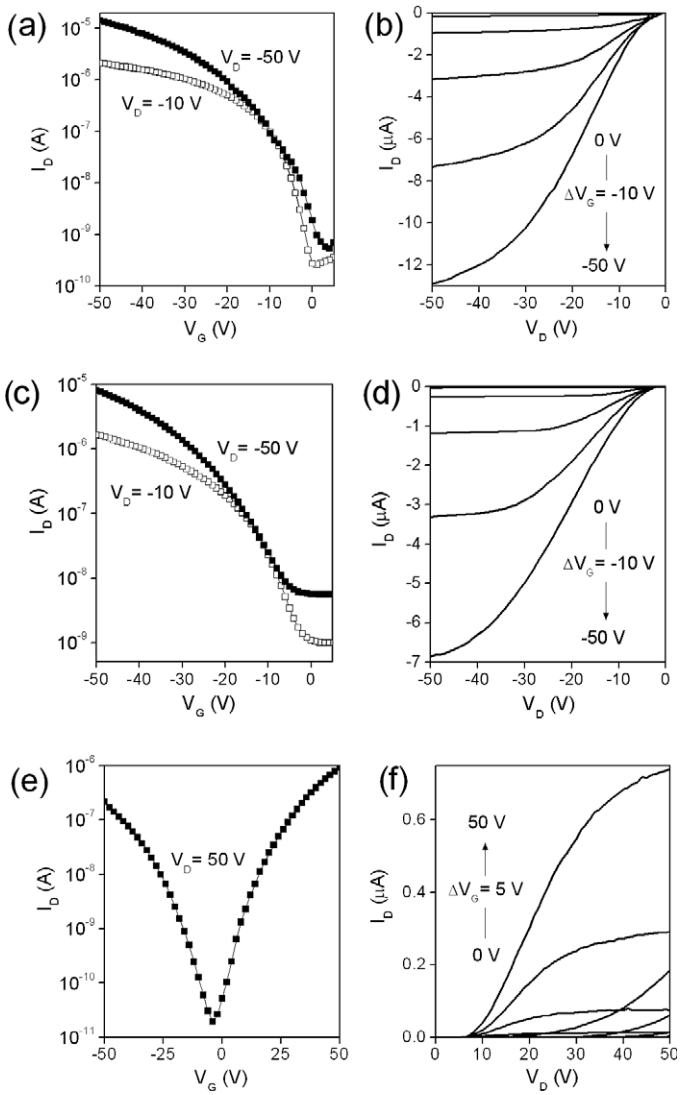

Fig. 3. Transfer and output curves for typical transistors with PEDOT:PSS source and drain electrodes patterned on glass by interlayer lithography, using: (a and b) pristine diF-TESADT (L = 60 μm, W = 1 mm, and C_i = 2 nF/cm^2), (c and d) diF-TESADT/PTAA blend (L = 30 μm, W = 1 mm, and C_i = 2 nF/cm^2), and (e and f) ambipolar PCBM (L = 50 μm, W = 1 mm, and C_i = 2 nF/cm^2).

appropriate surface modification (there are several reports of improved carrier injection from surface-modified PEDOT electrodes, e.g. treatment with octadecyltrichlorosilane has been shown to aid hole injection in OLED devices [34], while treatment with tetrakis-(dimethylamino)ethylene was reported to assist electron injection by inducing a ~0.5 eV reduction in the effective work function [35]).

To determine whether the interlayer method could be applied to the fabrication of transistors on flexible substrates, a diF-TESADT/PTAA based device with L = 30 μm was fabricated on PET as previously described. The hole mobility was lower than the equivalent device on glass at ~0.015 cm^2/V s (see Fig. S3), which we attribute to the poor surface adhesion of the organic layer to PET and changes in crystallization arising from the different surface energy of the PET substrate. This agrees with previous reports where it has been found that carefully controlled treatment with oxygen plasma (which was not employed here) is needed to achieve high mobilities [33]. (Note, treatment by oxygen plasma has previously been reported also to have a beneficial effect on the surface properties of PEDOT:PSS, leading to improved hole injection and transport when applied to OLEDs and OPVs [36]).

Fig. 3e and f show typical transfer and output characteristics for a PCBM transistor on glass with L = 50 μm. The frontier orbital energies of PCBM are 6.1 and 3.7 eV, resulting in energy barriers to hole and electron injection of 1.1 and 1.3 eV, respectively. The transistors accordingly exhibit ambipolar characteristics and can operate in both hole ($V_G << 0$ V) and electron ($V_G >> 0$ V) accumulation modes (Fig. 3e). On/off ratios of >10^4 were observed in both modes with the hole mobility (0.005 cm^2/V s) being an order of

magnitude lower than the electron mobility (0.05 $cm^2/V\,s$) in agreement with previous reports [30]. To our knowledge, this is the first demonstration of ambipolar charge transport in PCBM based transistors employing PEDOT:PSS source/drain electrodes. The performance parameters of the p-type and ambipolar OFETs are summarized in Table 1.

To verify whether the interlayer method could be applied to simple electronic circuits, we fabricated complementary voltage inverters comprising a diF-TESADT/PTAA p-type transistor and a PCBM n-type transistor (inset of Fig. 4) on separate substrates connected by metal wires. The lower hole mobility obtained with diF-TESADT/PTAA is beneficial here as it results in a better match to the low electron mobilities obtained with PCBM. The transfer characteristics of the inverter measured in a quasi-static mode at various supply voltages (V_{DD}) are shown in Fig. 4. The inverter executed the expected logic function with a maximum signal gain ($|dV_{OUT}/dV_{IN}|$) of ~16 at V_{DD} = |70| V and a noise margin equal to half the maximum theoretical value (i.e. $NM_{max} = V_{DD}/2$), similar to previously reported solution-processed complementary inverters [37]. The slight hysteresis in the operating characteristics of the inverter is a direct consequence of the hysteresis in the transfer curves of the PCBM transistor.

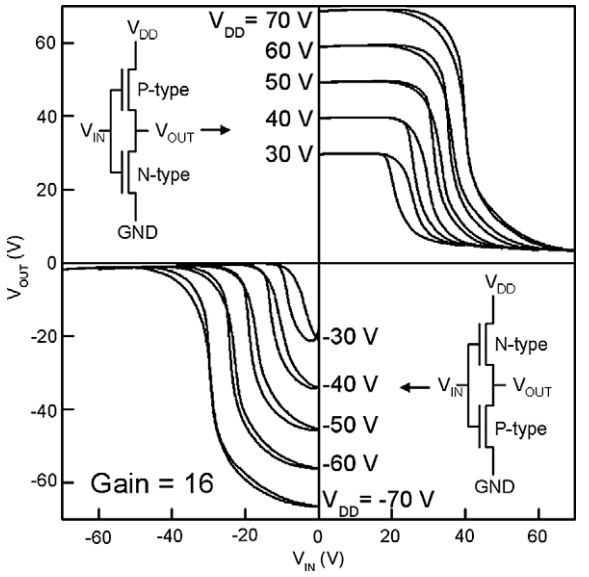

Fig. 4. Transfer characteristics of a complementary voltage inverter consisting of a p-type transistor with diF-TESADT/PTAA and an n-type transistor with PCBM, both fabricated using interlayer lithography (L = 50 μm and W = 1 mm). Inset: circuit diagram of complementary inverter.

3. Conclusions

We have used interlayer lithography to pattern high conductivity PEDOT:PSS electrodes for OFET applications, with conductivities >360 S/cm and pattern gaps $\geqslant$4 μm. Despite the 350 nm thickness of the [SU 8-2]/PEDOT:PSS electrodes, the resultant transistors exhibited similar performance characteristics to conventional Au-based transistors, whilst offering high transparency in the visible spectrum (>90% at 550 nm), sufficient for many screen- and window-integrated applications. Hole transporting OFETs based on diF-TESADT and diF-TESADT/PTAA exhibited high mobilities of up to 1 and 0.25 $cm^2/V\,s$, respectively, while ambipolar OFETs based on PCBM exhibited electron and hole mobilities of 0.05 and 0.005 $cm^2/V\,s$, respectively. Complementary voltage inverters based on diF-TESADT/PTAA and PCBM OFETs fabricated by the interlayer technique exhibited excellent operating characteristics with wide noise margin and high signal gain. Hence, it is evident that interlayer lithography offers a viable route to cost efficient, solution-processed, and flexible organic electronics. Finally, we note that although we have focused here on top-gate/bottom-contact OFETs with PEDOT:PSS source and drain electrodes, the interlayer method can also be applied to metals, including Ag and Al, and to other device configurations such as bottom-gate transistors as will be described in a future manuscript.

Table 1
Summary of device characteristics obtained for p-type and ambipolar transistors using PEDOT:PSS source–drain electrodes patterned on different substrates.

	p-Type diF-TESADT Glass	diF-TESADT/PTAA Glass	diF-TESADT/PTAA PET	Ambipolar PCBM Glass
μ_h ($cm^2/V\,s$)	~1	0.1–0.25	0.015	0.005
μ_e ($cm^2/V\,s$)	–	–	–	0.05
I_{on}/I_{off}	$\sim10^4$	$\sim10^3$	$\sim10^2$	$>10^4$

4. Experimental

SU 8-2 photoresist was diluted with SU 8 thinner in a 1:3 weight ratio and spin-coated onto clean glass or PET at 5000 rpm for 40 s. The resist was soft-baked on a hot plate at 65 °C for 1 min and at 95 °C for 1 min, before being exposed to 250 mJ cm^{-2} of 365 nm radiation using a Karl Suss MJB 3 mask aligner. After exposure, the resist was baked on a hot plate at 65 °C for 1 min and at 95 °C for 2 min. Clevios PH500 (H.C. Starck GmbH) doped with 5% dimethylsulphoxide was spin-coated onto the SU 8-2 at 1000 rpm for 20 s, and then annealed at 120 °C for 10 min (PET) or 130 °C for 10 min (glass). The unexposed SU 8-2, together with the overlying PEDOT:PSS, was removed by sonicating the sample in the developer (propylene glycol monomethyl ether acetate) for 3–5 min, leaving behind a patterned layer of PEDOT:PSS on top of an identically patterned resist layer. The conductivity of the PEDOT:PSS films was measured using the standard four-point probe technique. *Top-gate/bottom-contact* OFETs were fabricated on glass and PET using patterned PEDOT:PSS as the source and drain electrodes, prepared as above. For the p-type transistors, either a pristine film of 2,8-difluoro-5,11-bis(triethylsilylethynyl)-anthradithiophene (diF-TESADT) in toluene (15 mg/ml) or a 2:1 by weight composite film of diF-TESADT and poly(triaryl-amine) (PTAA) in anhydrous tetralin (40 mg/ml) was used as the organic semiconductor, and spin-coated onto the PEDOT:PSS layer at 1500 rpm before baking at 95 °C for 5 min in nitrogen.

Ambipolar OFETs were fabricated using methanofullerene [6,6]-phenyl-C_{61}-butyric acid methyl-ester (PCBM) in chlorobenzene (10 mg/ml) as the semiconductor, which was deposited by spin-coating at 1000 rpm in nitrogen. In both cases a dielectric layer of CYTOP was spin-coated on top of the semiconductor layer at 1700 rpm and dried at 95 °C for 15 min in nitrogen. Finally, a top-gate aluminum electrode was deposited by thermal evaporation under high vacuum (10^{-6} mbar) through a shadow mask. Electrical characterization of the samples was performed in air (diF-TESADT) or in an inert nitrogen atmosphere using a Keithley SCS 4200 parameter analyzer. To fabricate the inverters, separate n- and p-type transistors were connected via metal wires as shown in the inset to Fig. 4.

polymer-ZnO QDs and the graphene layer. Current–voltage (*I–V*) measurements on the UV photodetectors under an illumination of a 365-nm-UV light at 300 K were performed to characterize device performance. The carrier transport mechanisms at work in the UV photodetectors are described on the basis of the *I–V* results.

The hybrid poly-*N*-vinylcarbazole (PVK)–ZnO QD composites, the graphene layer, and the PEDOT:PSS layer used in this study were prepared on indium–tin–oxide (ITO)-coated glass substrates by using spin-coating and attachment methods. The ITO-coated glass substrates were alternately cleaned ultrasonically in acetone and methanol at 27 °C for 10 min and were rinsed in de-ionized water. The chemically-cleaned ITO-coated glass substrates were then dried by using N_2 gas with a purity of 99.9999%. The PEDOT:PSS (Sigma–Aldrich) was spin coated on the pre-cleaned ITO glass substrates and then annealed at 150 °C for 10 min. ZnO QDs were synthesized by modifying a simple method with the use of a dimethylformamide (DMF) reduction. Solutions were formed by dissolving zinc acetate dehydrate [$Zn(CH_3COO)_2{\cdot}H_2O$] (1 wt%) in DMF in the proper proportion, after which the zinc-acetate-dehydrate/DMF solution was stirred for 10 min at room temperature. The mixture was then heated to 105 °C at a heating rate of 2 °C/min and was maintained at the that temperature for 5 h, resulting in the formation of colloidal ZnO QDs. After the ZnO QDs had been synthesized at 105 °C for 5 h, they were cooled to room temperature. The colloidal ZnO QDs were mixed with the PVK. Subsequently, the ZnO QDs and PVK dispersed in the DMF solution were deposited onto a PEDOT:PSS film by using a spin-coating method at 2000 rpm for 25 s, and the solvents existing on the samples were removed by putting the samples onto a hotplate at 90 °C for 30 min.

The graphene films were synthesized by modifying the SiO_2-coated Si substrates. The SiO_2-coated Si substrates for growing the graphene films were cleaned ultrasonically by using acetone and ethanol, and then rinsed in de-ionized water. After a chemically-cleaned SiO_2-coated Si substrate had been dried by using N_2 gas with a purity of 99.9999%, a Ni thin film with a thickness of 200 nm was grown on the SiO_2-coated Si substrate by using thermal evaporation. Graphene films were synthesized by using a chemical vapor deposition (CVD) method. A 200-nm polycrystalline Ni film was deposited onto a pre-cleaned SiO_2-coated Si substrate by using a thermal evaporator. Subsequently, the Ni thin film on the SiO_2-coated Si substrate was annealed at 1000 °C for 20 min. The graphene layer was formed with gas mixtures of CH_4, Ar, and H_2. After the graphene films had been grown by using the CVD reaction, the substrates were immersed in a HF solution to remove the SiO_2 layer, were etched in a TFG solution to remove the Ni film, and were then rinsed with de-ionized water. Because graphene floats on water due to the hydrophobic nature of graphene, the formed graphene layer was attached to the hybrid PVK–ZnO QD composites layer. Finally, an Al top electrode with a thickness of 150 nm was thermally deposited through a metal mask at a system pressure of 1×10^{-6} Torr. A schematic diagram of the UV photodetectors fabricated in this work is shown in Fig. 1.

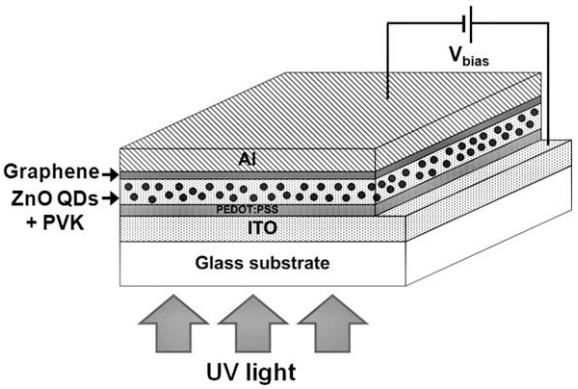

Fig. 1. Schematic diagram of the structure of the UV photodetector studied in this work.

I–V measurements were performed by using a HP 4140B *I–V* meter at room temperature. The TEM measurements were performed in a JEM 2100F transmission electron microscope operating at 200 kV.

Fig. 2 shows a cross-sectional SEM image of the UV photodetectors consisting of hybrid PVK–ZnO QD composites incorporating graphene and PEDOT:PSS layers. The top layer is graphene, and the thicknesses of the PEDOT:PSS layer and of the hybrid ZnO QDs + PVK layer were both about 80 nm.

Fig. 3(a) shows a plane-view TEM image of the hybrid ZnO QDs + PVK layer. The ZnO QDs are randomly distributed in the PVK matrix. A particle-like structure with a diameter of 110 nm was formed in the PVK layer, as shown in Fig. 3(a). The ZnO QDs, indicated by arrows, were attached to the surface of the particle-like PVK, and graphene sheets with a thickness of about 2 nm were formed on the PVK layer, as shown in Fig. 3(b).

Fig. 4 shows an absorbance spectrum for the hybrid ZnO QD and PVK/PEDOT:PSS layers grown on the ITO substrate. The optical absorbance spectrum of the ITO-coated glass substrate is chosen as a reference background. The absorbance of the ITO-coated glass substrate has been subtracted from the spectrum to remove the effects of the substrate. The dominant absorbance peak at 360 nm is attributed to the hybrid ZnO QDs and PVK layer. The broad absorbance peak around 550 nm is related to the PEDOT:PSS layer [21].

Fig. 5 shows the *I–V* curves for the UV photodetectors under illumination with a 365-nm UV light at a power of 6 W and in the dark. When the UV light was used to irradiate the fabricated photodetectors, the difference between the dark current and the photocurrent increased linearly at lower bias voltages and then increased exponential at higher bias voltages, as shown in Fig. 5(a). The plots shown in Fig. 5(b) indicate that the photocurrent of the UV photodetector devices with a graphene under illumination with 365-nm light at 0.4 V was 7.15×10^{-3} A and that the dark current at 0.4 V was 7.98×10^{-11} A. The ratio of the photocurrent to the dark current was about 10^8.

Fig. 6 shows the *I–V* characteristics for the UV photodetectors with and without a graphene layer. The

photocurrents of the UV photodetectors at 0.4 V with and without a graphene layer were 7.15×10^{-3} and 3.36×10^{-5} A, respectively. ZnO QDs under illumination with UV light generated electron–hole pairs. Because the holes move through the PEDOT:PSS layer, the holes located at the ground state of ZnO QDs are transferred to the ITO electrode. A PVK hole transport layer is utilized to reduce the energy barrier between the ZnO QDs and the PEDOT:PSS layer. The introduction of the PVK layer facilitates the transport of the separated holes, resulting in an enhancement of the photodetectors performance [8]. The graphene layer with a high electrical conductivity provides an efficient pathway for the conduction-band electrons to move to the Al electrode. The attachment of the graphene layer to the hybrid ZnO QDs and the PVK layer might facilitate the transport of separated electrons, thus enhancing the photoresponse of the photodetectors, as shown in Fig. 6. Furthermore, the large area of the graphene layer allows large-area photodetectors to be fabricated. When the photodetectors were left in the ambient air conditions during 1 month, the same photocurrents of the UV photodetectors were obtained. No significant degradation of the photodetectors under illumination of the UV light after several hours of continuous

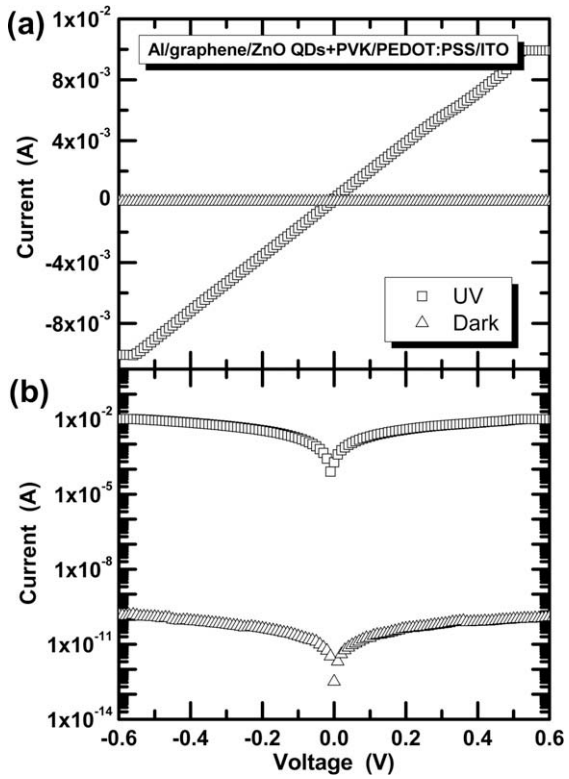

Fig. 5. (a) Currents as functions of the applied voltage for the UV photodetector in the dark (rectangles) and under illumination by a 365-nm UV light at a power of 6 W (triangles). (b) Plot of log currents of Fig. 4(a) as functions of the voltage.

stress was observed, indicative of the photoresponse stability of the photodetectors.

Fig. 7 shows a schematic diagram of the energy bands corresponding to the carrier transport mechanisms of the holes and electrons during UV illumination for the device. When a 365-nm UV light illuminates the photodetectors through the ITO electrode, the photons penetrate into the hybrid ZnO QDs and PVK layer, resulting in the creation of the excitons. When the photogenerated excitons diffuse into both the PEDOT:PSS and the graphene layers, while the electrons move to the Al electrode through the graphene layer, the holes transfer to the ITO layer through the PVK and the PEDOT:PSS layers. Therefore, the electrons and holes are accumulated at the ITO and the Al layers, respectively, resulting in the generation of the photocurrent of the UV photodetectors.

In summary, UV photodetectors were fabricated utilizing hybrid ZnO QDs and PVK layer incorporating graphene and PEDOT:PSS layers. TEM images showed that the ZnO QDs were distributed on the surface of the PVK layer and that the graphene layers were deposited on the PVK layer containing the ZnO QDs. The graphene layer served as an electron transport layer. The UV photodetectors under illumination with 365-nm light at 0.4 V showed a ratio of the photocurrent to the dark current of approximately 10^8. The photocurrent of the UV photodetectors containing the graphene layer was much higher than that of the detectors

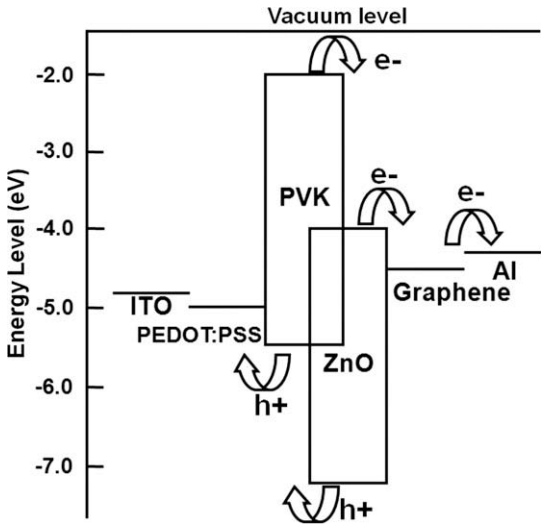

Fig. 7. Schematic diagram of the energy bands corresponding to the carrier transport mechanisms of the holes and electrons during UV illumination for the device.

without the graphene layer. These results indicate that a hybrid ZnO QDs–PVK layer incorporating graphene and PEDOT:PSS layers hold promise for potential applications in next-generation large-area UV photodetectors.

2. Experimental

Among the various techniques to grow 1D ZnO nanostructures, the cost-effective electrodeposition method was used in this work for the preparation of large area of nanorods because of the low-temperature processing, arbitrary substrate shapes, and precise control of the size of nanorods. ZnO nanorods were electrodeposited in 0.005 M $Zn(NO_3)_2$ and 0.005 M hexamethylenetramine aqueous solutions. Devices were fabricated on cleaned indium tin oxide (ITO) coated glass substrates with a sheet resistance of 25 Ω/□. All depositions were carried out in a configured glass cell at 90 °C, in which an ITO substrate, a platinum plate, and a Ag/AgCl electrode in saturated KCl served as the working electrode, the counter electrode and the reference electrode, respectively. All electrodepositions were done at a potential of −0.9 V vs. the reference electrode. The durations of the deposition were 20 min. PVK (10 mg/ml) was spin-coated onto ZnO nanorods at 800 r/min. Then films were baked in a vacuum oven for 30 min at 100 °C. A thin layer of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) was spin-coated on the PVK film at 2000 r/min. After this step the films were baked in a vacuum oven for 1 h at 120 °C. Finally, Au was evaporated onto the device as the top electrode. The field emission scanning electron microscopy (FESEM) measurements were performed on the Hitachi FESEM S-4800. The optical transmission spectra and the absorption spectra were recorded using a Shimadzu UV-3101PC spectrophotometer. The photoluminescence (PL) measurement was carried out in a JY-630 micro-Raman spectrometer employing the 325 nm line of a He–Cd laser as the excitation source. The photoresponse of the ZnO nanorods/PVK hybrid photodetector was studied using a 150 W Xe lamp, a monochromator, a chopper (EG&G 192), and a lock-in amplifier (EG&G 124A). Current–voltage (*I*–*V*) characteristics of the devices were measured using a Keithley 2400 source meter connected with a GPIB controller to a computer under dark or illumination at 365 nm. PL decay time was measured using an Edinburgh FL 920 Spectrometer, in which the exciting wavelength was 325 nm by using a hydrogen lamp and the PL emission wavelength was probed at 380 nm. All the measurements were carried out at room temperature under ambient conditions.

3. Results and discussion

Fig. 1(a) shows the typical FESEM image of ZnO nanorods almost aligned vertically on the ITO substrate. The diameter and the length of the nanorods are in the ranges of 20–40 and 800–1000 nm, respectively. Fig. 1(b) shows the PL spectra of the ZnO nanorods excited by the 325 nm line of a He–Cd laser. In the PL spectrum, a strong and sharp UV near-band-emission is observed with a peak centered at 378 nm, which is explained by the recombination of free excitons [13,14]. Meanwhile, a weak deep level green emission is found. The origin of the deep level emission in ZnO is not yet clearly understood but is generally

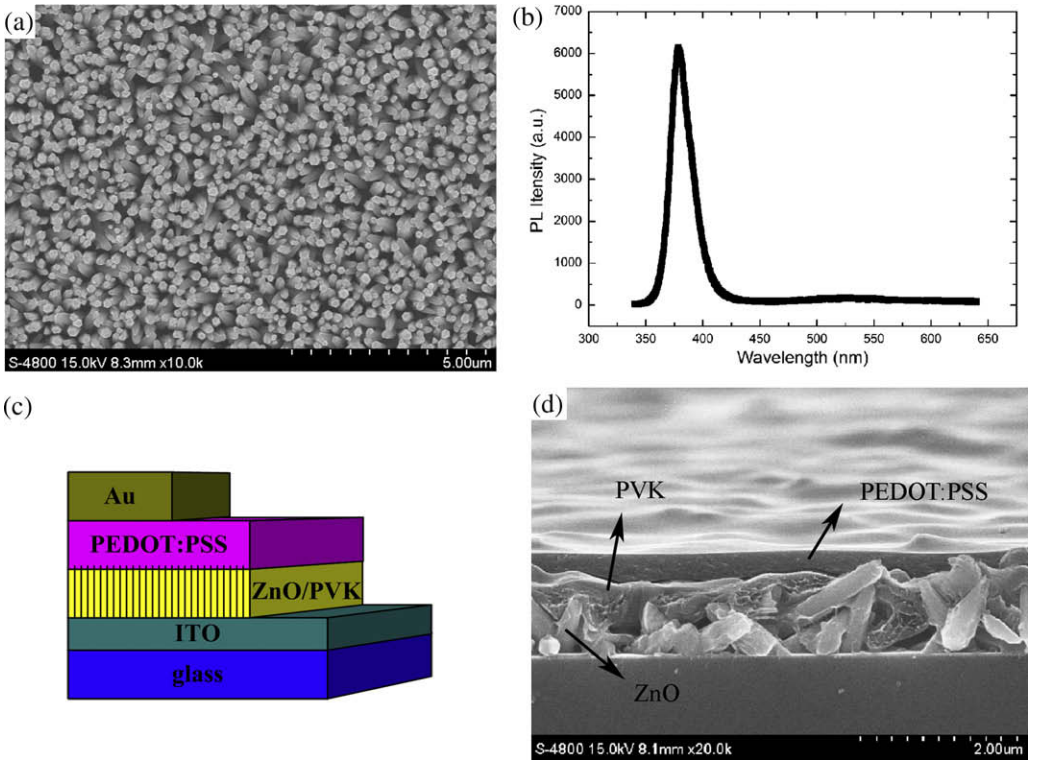

Fig. 1. (a) The FESEM image of ZnO nanorods. The scale bar is 5 μm. (b) The PL spectra of the ZnO nanorods. (c) The schematic diagram of the ZnO/PVK hybrid device. (d) The cross-section field emission SEM images of ZnO nanorods after covered with PVK and PEDOT:PSS by spin-coating. The scale bar is 2 μm.

attributed to structural defects, single ionized vacancies, and impurities [15]. The excellent optical properties of ZnO nanorods, deduced from the strong and sharp excitonic emission and the low deep level emission, indicate that the ZnO nanorods are of high optical quality, making them more suitable for fabricating UV-PDs. Fig. 1(c) shows the schematic diagram of the ZnO/PVK hybrid device. From the cross-section FESEM image shown in Fig. 1(d), different layers could be observed clearly. ZnO nanorods are completely covered with PVK and PEDOT:PSS. And the Au electrode does not directly connected with nanorods, which ensures a junction could be formed between ZnO nanorods and PVK.

The *I–V* characteristics of the ZnO/PVK heterojunction device measured in the dark is shown in Fig. 2. The current density of the device increases gradually with the bias voltage, and a typical *p–n* junction behavior with the clearly rectifying *I–V* characteristics was found, indicating the formation of a *p–n* junction interfaces between the PVK and ZnO nanorods. The *I–V* characteristics of the PD under illumination of a 1.2 mW/cm^2 365 nm UV lamp was also shown in Fig. 2. A maximum current density of 132 μA/cm^2 is obtained at −5 V bias, corresponding to a response of 110 mA/W.

Fig. 3(a) shows the absorption spectra of ZnO nanorods and PVK and the transmission spectrum of the ITO glass. It could be observed that the transmission of ITO glass is as high as 80%, when the wavelength is longer than 350 nm. And there is a sharp absorption edge for the wavelength shorter than 350 nm. For PVK a strong absorption band presents between 320 and 350 nm, and there is no absorption for the light wavelength longer than 360 nm. The absorption spectrum of ZnO nanorods shows a typical semiconductor property. A sharp absorption edge located at 380 nm could be clearly detected. Fig. 3(b) shows the photoresponse spectra of the device illuminated from both the ITO glass and Au electrode sides. As shown in the figure, the photoresponse of the PD illuminated from ITO glass presents a peak at 364 nm with a weak shoulder at around 335 nm. It is interesting to found that the photoresponse is a narrow band with a full width at half maximum (FWHM) of only 26 nm, indicating a high spectrum selectivity property of the PD. At the same time a very sharp cutting-off at about 400 nm is observed in the photoresponse spectrum. The ultraviolet–visible rejection ratio (R364/R400 nm) for the devices is as high as 10^3. While the PD illuminated from Au electrode the photoresponse shows the same shape (shown in the insert of Fig. 3), but a little broader in the short-wavelength region than the one illuminated from ITO glass side. And the intensity of the photoresponse peak is lowered one order of magnitude because of the high reflection for the Au electrode.

Due to the absorption peak of PVK is predominantly located in the range of 320–350 nm, the photoresponse of the PD at 335 nm could be deduced originated from PVK. Based on the absorption and transmission spectra shown in the Fig. 3(a), there are no absorptions for PVK and ITO for the light wavelength longer than 360 nm. Only ZnO has the absorption edge of 380 nm, which is in agreement with other reports [11,16]. Thus, the photoresponse peak located at 364 nm could be attributed to the absorption of the ZnO nanorods. When illuminated from the ITO side the light would meet ZnO at first and most UV light could be absorbed by ZnO nanorods, which induces the photoresponse for the wavelength smaller than 400 nm. A part of UV light with the wavelength shorter than 360 nm could reach the PVK layer to form another photoresponse peak

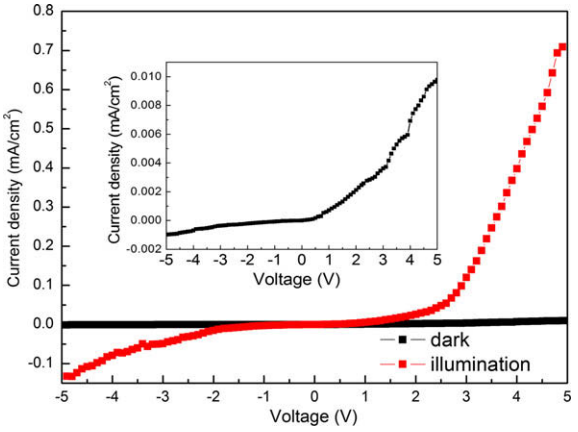

Fig. 2. The current–voltage characteristics of the ZnO/PVK heterojunction diode measured in the dark and under illumination at 365 nm, respectively. The inset shows the current–voltage characteristics of the ZnO/PVK heterojunction diode individually measured in the dark.

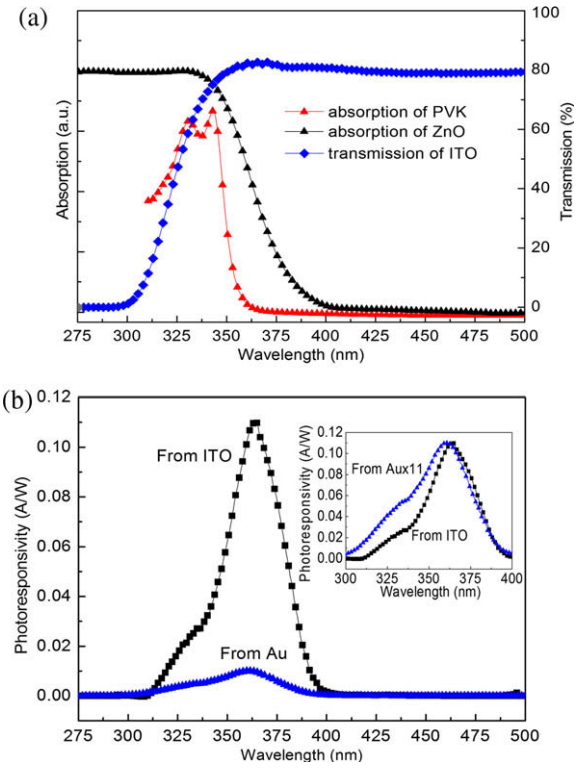

Fig. 3. (a) The absorption spectra of ZnO nanorods and PVK and the transmission spectrum of the ITO glass. (b) The photoresponse spectra of the device illuminated from both the ITO glass and Au electrode. The inset shows the shape comparison of the photoresponse spectra of the device illuminated from the ITO glass and Au electrode.

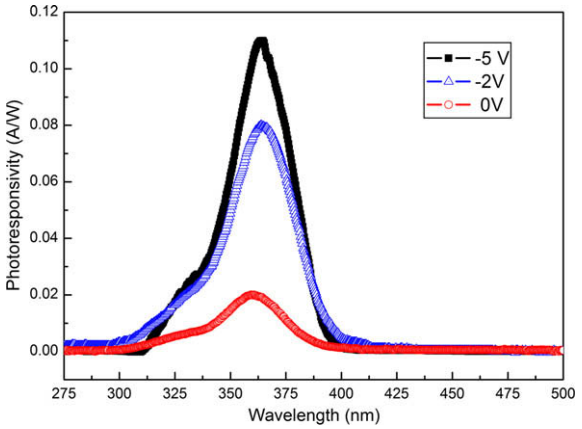

Fig. 4. The photoresponse spectra of the device illuminated from the ITO glass at different biases.

at 335 nm. But when illustrated from the Au side, the light would meet the PVK layer at first, which induced the intensity ratio of the photoresponse peaks located at 335 and 364 nm became increased a little. And in both cases, the ITO glass and the PVK layer serve as filters when the wavelength of the incident light shorter than 350 nm, which induced the weak photoresponse for the device in the short-wavelength region. Fig. 4 shows the photoresponse spectra of the device at different biases, in which the position of the photoresponse band keeps almost unchanged. This result conforms the active region of PDs is ZnO nanorods.

To further understand the charge transfer processes in the ZnO/PVK hybrid system, the PL spectra of the ZnO nanorods, PVK pristine film, and the ZnO nanorods/PVK hybrid film and the PL decay spectra of the PVK pristine film, and the ZnO nanorods/PVK hybrid film were investigated, as shown in Fig. 5. The PL spectra of ZnO nanorods and PVK pristine film showed emission peaks located at 380 and 410 nm, respectively. The PL intensity of the ZnO nanorods/PVK hybrid film is dramatically reduced compared with both the ZnO nanorods and the PVK pristine film, which indicates an efficient charge transfer process from ZnO to PVK and PVK to ZnO. (In order to make the PL spectra comparable, all the condition, such as the sample position, the wide of slid, the power of incident light, et al., were kept the same.)

The transient PL decay measurements were carried out for the PVK pristine film, and the ZnO nanorods/PVK hybrid film. The decay curves were shown in Fig. 5(b). The exciting light was illuminated from the PVK side for the ZnO/PVK hybrid sample. Although from the PL spectra shown in Fig. 5(a), both ZnO and PVK have the PL emission at 380 nm, the signals of the PL decay time measurement were mainly from the PVK layer. By fitting these curves, decay times can be obtained, PVK shows an exponential decay with a decay time of 27.95 ± 0.92 ns. In the ZnO nanorods/PVK hybrid film, a shorter decay time of 21.74 ± 0.76 ns ascribe to PVK were obtained. The shortened lifetimes indicate a new deactivation pathway for the excited state. The ZnO emission decay reflects the charge recombination via radiative and nonradiative processes. With constructing the ZnO/PVK hybrid system an additional pathway is introduced through the electronic coupling in the interface of ZnO and PVK.

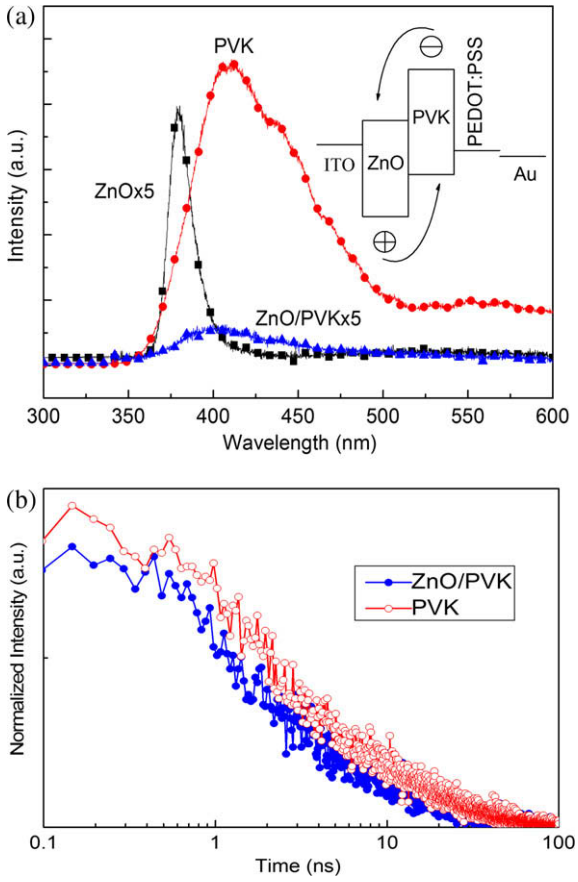

Fig. 5. (a) The PL spectra of ZnO nanorods, PVK layer and ZnO/PVK. The inset shows the corresponding energy levels for the materials used in the hybrid device. (b) The decay curve of PVK and ZnO/PVK hybrid film. The exciting wavelength was chosen at 325 nm, and the PL emission wavelength was probed at 380 nm.

The inset of Fig. 5(a) shows the charge carriers generation processes in the UV-PDs. Under the illumination of UV lamp, photogenerated electron–hole pairs are produced in both ZnO nanorods and PVK. The holes in ZnO nanorods will migrate from the valance band to the highest occupied molecular orbital (HOMO) of PVK due to the higher HOMO of PVK (5.8 eV) than the valance band of ZnO (7.2 eV), while the electrons in PVK will migrate from the LUMO to the conduction band of ZnO due to the lower conduction band of ZnO (4.0 eV) than the LUMO of PVK (2.3 eV) [17]. Then the holes and electrons in the PVK HOMO and ZnO conduction band will transport to the Au and ITO electrodes, respectively. The energy level matching between ZnO and PVK facilitates the fast interfacial charge transfer and increases the separation efficiency of electron–hole pairs and the carrier generation efficiency. Such an interfacial charge transfer between ZnO nanorods and PVK reduces the probability of the recombination of electron and hole. Due to the above charge transfer and separation processes the PL intensity is decreased and the photoresponse is promoted.

4. Conclusions

In summary, high spectrum selectivity visible-blind UV-PD based on ZnO nanorods was demonstrated. The photo-response showed a narrow band centered at 364 nm with a FWHM of only 26 nm. This finding has potential values for further study of high spectrum selectivity and low-cost PD since the complete processes are compatible for large area and flexible substrate fabrications.

on μCP-OTS is less ordered and exhibits a lower crystallinity compared with P3HT deposited on conventional LPD-OTS. In spite of the lower degree of crystallinity, P3HT FETs fabricated on μCP-OTS exhibit a high field-effect mobility that is comparable to the mobility for LPD-OTS. Furthermore, P3HT FETs on μCP-OTS exhibit even better subthreshold characteristics.

2. Experimental section

A highly doped Si wafer with a 300-nm surface layer of thermally grown SiO_2 was used as a substrate. The substrate was immersed in hot, concentrated H_2SO_4 for 30 min and then repeatedly washed with deionized water, acetone, and hexane in an ultrasonic bath, followed by UV/O_3 cleaning. For the μCP, a poly(dimethylsiloxane) (PDMS) sheet was used as a stamp. The PDMS stamp was immersed in a solution of 50 mM OTS in hexane for 1 h. After removing it from the solution, the PDMS stamp was dried for 10 min and put in contact with the SiO_2 substrate surface for 2 h to fabricate the OTS SAM. The OTS-modified substrate was then rinsed with hexane and ultrasonically cleaned in ethanol for 1 min to remove any excess layers. Finally, the substrate was dried at 100 °C for 5 min. For the LPD, the cleaned Si/SiO_2 substrate was directly immersed in a solution of 10 mM OTS in anhydrous toluene for 7 days, and then rinsed with toluene and ultrasonically cleaned in ethanol for 1 min. Other treatments were the same as those for the μCP-SAMs. All SAM depositions were performed under an N_2 atmosphere with a humidity of approximately 3%. The formation of SAMs on the substrate was confirmed by ellipsometry and water-contact angle measurements. Plexcore OS 1100 P3HT (regioregularity > 95%, average molecular weight = 25,000–35,000, Plextronics, Inc.) was used. P3HT thin films were fabricated onto the OTS-treated substrates by spin coating from 1 wt.% solution in toluene under ambient conditions. The thicknesses of P3HT films were approximately 100 nm on both μCP and LPD SAMs. GIXD measurements were performed at the beam line BL46XU of the SPring-8 synchrotron at the energy of 10 keV. Rocking curves were measured in the secular setup looking at the (1 0 0) peak by Cu Kα X-rays (~8.0 keV) with a rotating target energy of 15 kW.

For FET measurements, gold source and drain electrodes were evaporated onto the P3HT films through a shadow mask. The channel length and width were 50 μm and 1.5 mm, respectively. The FET characteristics of the fabricated devices were measured in ambient conditions after annealing at 150 °C under vacuum for 1 h.

3. Results and discussion

We carefully deposited the SAMs under controlled water conditions to obtain good SAMs with smoother surfaces [15]. Table 1 shows the characteristics of OTS SAMs prepared by the μCP and LPD methods on SiO_2 surfaces. Ellipsometry measurements indicate that both OTS SAMs are slightly thicker than reported values of about 28 Å [16,17]. However, the thicknesses are constant for prolonged deposition of OTS, indicating the formation of well-defined monolayers. Both OTS-treated surfaces have a high water-contact angle and a small root mean square (R_{MS}) roughness, which are comparable to published values [16,17]. No clear differences between both SAMs were observed by these measurements.

Table 1
Ellipsometric thickness, water-contact angle, and RMS roughness of OTS SAMs prepared by μCP and LPD methods.

	Thickness (Å)	Contact angle (°)	R_{MS} (Å)
μCP	30.8	108	4.7
LPD	29.3	108	5.7

Fig. 1(a) and (b) shows the typical transfer characteristics of P3HT FETs on OTS SAMs fabricated by the μCP and LPD methods, respectively. Both devices exhibit good FET characteristics with on/off ratios of over 10^3, but the device with μCP-OTS exhibits a lower subthreshold swing than that with LPD-OTS. The electrical performance of P3HT FETs is summarized in Table 2. We characterized more than 40 devices for each OTS SAM. The field-effect mobilities of the devices on each OTS SAM are almost the same, and are typical of P3HT with similar molecular weight [9,10]. However, the device on μCP-OTS has a smaller negative threshold voltage V_{th} compared with LPD-OTS. Similar negative V_{th} has generally been observed in P3HT FETs with OTS-treated substrates [5,9]. The smaller V_{th} in the device on μCP-OTS indicates a lower density of charge traps at the P3HT/SiO_2 interface [18], which leads to good subthreshold characteristics, as shown in Fig. 1(a).

Fig. 2(a) and (b) shows the out-of-plane and in-plane GIXD patterns of P3HT films spin-coated onto LPD-OTS and μCP-OTS SAMs, respectively. For the P3HT film on LPD-OTS, three orders of intense peaks are observed in the out-of-plane pattern, and the in-plane diffraction displays a distinct (0 1 0) peak. The (h 0 0) and (0 k 0) diffraction peaks of P3HT films are attributed respectively to a lamellar structure caused by interdigitating alkyl side chains and π-stacked polymer backbones that result from the self-organization of P3HT molecules [5].

The results for the P3HT film on LPD-OTS indicate that highly ordered lamellae are preferentially oriented parallel to the substrate (edge-on orientation). Such self-orientation behavior on SAM-treated substrates is consistent with previous reports [5,9,10] and provides efficient π-stacking of P3HT molecules along the substrate surface and enhanced field-effect mobility. In contrast, P3HT orientation on the μCP-OTS is quite different. The out-of-plane diffraction of the P3HT film on the μCP-OTS shows relatively intense (1 0 0), (2 0 0), and (3 0 0) peaks and, in addition, exhibits a clear (0 1 0) peak. For in-plane diffraction, the (0 1 0) peak disappears. This result indicates that μCP-OTS induces face-on orientation of P3HT molecules and decreases π–π stacking along the in-plane direction.

The rocking-curve measurement also reveals the decrease in edge-on oriented structure for P3HT film on the μCP-OTS surface (Fig. 3). The intensity of the (1 0 0) lamella peak for P3HT film on μCP-OTS is weaker than that for P3HT film on LPD-OTS. However, the peak width for P3HT film on μCP-OTS is almost the same as that for

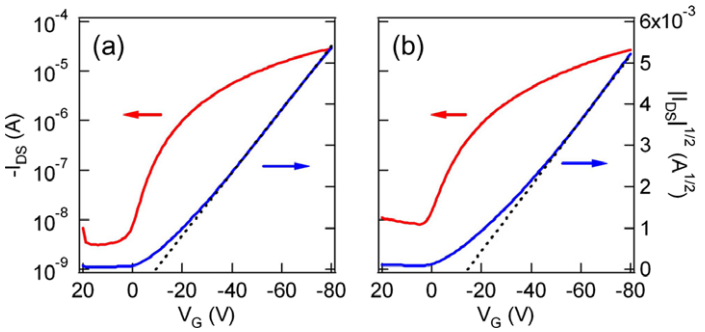

Fig. 1. Transfer characteristics measured in P3HT FETs on (a) μCP-OTS and (b) LPD-OTS SiO_2 dielectrics at a drain voltage of −80 V.

Table 2
Electrical performances of P3HT FETs deposited on OTS SAMs fabricated with the μCP and LPD methods.

	Field-effect mobility (cm^2/Vs)	V_{th} (V)
μCP-OTS	$(3.0 \pm 1.1) \times 10^{-2}$	-4.7 ± 3.4
LPD-OTS	$(3.1 \pm 0.4) \times 10^{-2}$	-12.6 ± 3.5

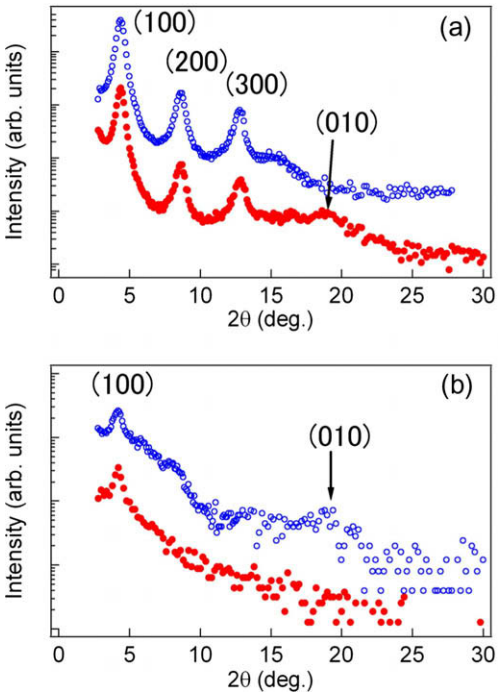

Fig. 2. (a) Out-of-plane and (b) in-plane GIXD profiles for P3HT films on LPD-OTS (upper line) and on μCP-OTS (lower line) SiO_2 dielectrics.

P3HT film on LPD-OTS, indicating that the edge-on structure in P3HT films on μCP-OTS is also less disordered. The results displayed in Figs. 2 and 3 indicate that P3HT film on μCP-OTS exhibits lower crystallinity than P3HT film on LPD-OTS and that P3HT film on μCP-OTS contains crystalline grains oriented face-on as well as edge-on.

It has been widely accepted that the low crystallinity and face-on orientation of P3HT molecules prevent efficient charge transport in the π-stacking direction and significantly decrease field-effect mobility [5,9]. However, our results indicate otherwise. P3HT FETs on μCP-OTS exhibit high mobility comparable to the device on LPD-OTS and exhibit better subthreshold characteristics. The improved subthreshold characteristics observed in the device on μCP-OTS clearly indicate a decrease in the density charge traps, suggesting that the disordered region between crystalline regions strongly affects charge transport in P3HT films with OTS-treated substrates. The influence of grain boundaries has been extensively studied in polycrystalline thin films such as pentacene, and the field-effect mobility in these systems is significantly limited by charge trapping in grain boundaries [19,20].

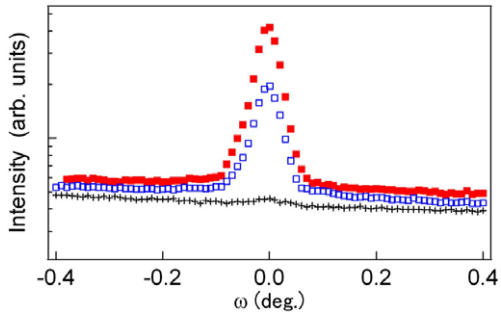

Fig. 3. Rocking curve on the (1 0 0) peaks of P3HT films on LPD-OTS (solid squares), μCP-OTS (open squares), and untreated SiO_2 dielectrics (crosses).

Conversely, the influence of grain boundaries on mobility has been less studied for polycrystalline polymer semiconductors. However, the influence of grain boundaries on charge-carrier transport (similar to that observed in pentacene) has been reported for poly(2,5-bis(3-alkylthiophene-2-yl)thieno[3,2-*b*]thiophene) (pBTTT) [21,22]. The lower subthreshold swing observed in P3HT FETs on μCP-OTS is attributed to charge trapping in a lower density of energetically distributed trapping centers at the grain boundaries [23]. P3HT on μCP-OTS exhibits a lower crystallinity and is less edge-on oriented than P3HT on LPD-OTS, but the field-effect mobility of P3HT FETs on μCP-OTS is almost the same as that of P3HT FETs on LPD-OTS. The results obtained here suggest that the

charge-carrier transport in highly ordered P3HT films is significantly limited by carrier trapping at the grain boundaries, similar to polycrystalline pentacene. In the highly ordered P3HT films on LPD-OTS, the formation of well-ordered P3HT grains can induce a higher degree of disorder at the grain boundaries to relax the strains caused by the adjacent grains with different orientations. The disorder at the grain boundaries causes frequent carrier trapping and hence reduces field-effect mobility. By contrast, the degree of disorder at the grain boundaries is expected to be lower in the less ordered P3HT film on μCP-OTS, which is evident from the improved subthreshold characteristics in P3HT FET on μCP-OTS. Less frequent carrier trapping in case of the lower degree of disorder improves the field-effect mobility in the less ordered P3HT film on μCP-OTS. As a result, the field-effect mobility in the less ordered P3HT film on μCP-OTS is comparable to that in the highly ordered P3HT film on LPD-OTS.

4. Conclusions

We have demonstrated the high performance of P3HT FETs on μCP-OTS. The electrical characteristics are comparable to those of P3HT FETs on LPD-OTS. Surface treatment of the SiO_2 dielectrics with OTS SAMs prepared by the μCP method influences the molecular orientation in the P3HT films, which is quite different from the orientation obtained with the conventional LPD method. The P3HT molecules on μCP-OTS exhibit a lower crystallinity and are less edge-on oriented than those on LPD-OTS, but both P3HT films exhibit almost the same field-effect mobility. The comparable field-effect mobility in P3HT thin films on μCP-OTS originates in the lower density of trapping centers located at the grain boundaries.

vacuum-free PSCs [8–10]. The high transmittance of PH500 film also makes it a good electrode for semi-transparent solar cells [11–14]. However, the wettability of the solution on the present layer is a crucial problem in all-solution-processed fabrication of PSCs. For example, the surface of the active layer poly(3-hexylthiophene) (P3HT):[6,6]-phenyl C61-butyric acid methyl ester (PCBM) is really hydrophobic, so that the deposition of the aqueous PEDOT:PSS solution on the surface of P3HT:PCBM by spin-coating becomes difficult. Many methods have been developed recently to solve this problem, including the modification of the wettability of PEDOT:PSS by doping surfactants, such as Zonyl [2], D-sorbital [15] or isopropanol [16]. However, it is known that doping surfactants could possibly decrease the conductivity and the work function of PEDOT:PSS at the same time [2,8,15,16]. Hau et al. reported that they got a PEDOT:PSS (Baytron 4083) film on P3HT:PCBM by spin-coating where the PEDOT:PSS (Baytron 4083) was diluted with isopropyl alcohol and n-butyl alcohol. However, the process needs repetitious thermal treatments, and thus becomes complicated and time-consuming [9,17]. The plasma treatment on P3HT:PCBM was also proposed to make its surface more hydrophilic [7], but this could damage the surface of P3HT:PCBM film. Several novel techniques were also developed to deposit the aqueous PEDOT:PSS onto hydrophobic surface of the active layer of PSCs such as spray-coating process [10], However, the thick films formed from spray-coating lead to non-transparent electrodes and high vacuum process must be used to remove the excess moisture.

In this work, we fabricated semi-transparent inverted PSCs by all-spin-coating vacuum-free process. ITO modified by ZnO NPs was used as cathode and PAH-D [18] was introduced as an interfacial layer on the surface of P3HT:PCBM. The aqueous PAH-D microgels can be directly spin-coated onto the hydrophobic active layer without any pre-treatment or post-treatment. At the same time, the PAH-D interfacial layer can effectively transfer the surface of P3HT:PCBM from hydrophobic to hydrophilic as well as increase the adhesion and bonding strength between the active layer and the PH500 anode. The photovoltaic performance of the semi-transparent PSCs under top and bottom illumination was investigated and the highest PCE of about 1.86% was achieved under simulated AM 1.5 illumination (100 mW/cm^2) from bottom side with a reflective white paper on the back side. The semi-transparency of Cell A have the potential for use as the subcell of tandem solar cells and power-generating tinted thin-film coatings on windows and other architectural surfaces [11,15]. The all-spin-coating vacuum-free processing provides a possibility for the high-throughput all-solution-processed fabrication of PSCs by roll-to-roll processing [9].

We fabricated two types of PSCs in current work. For all-spin-coating processed PSC (Cell A), patterned ITO (20 Ω) was cleaned by sequential ultrasonic treatment in detergent deionized water, acetone, and isopropyl alcohol for 10 min, respectively, then treated by O_2 plasma for 5 min. A thin layer of ZnO NPs (~50 nm), synthesized using the method described by Beek et al. [19], was spin-coated onto ITO-coated glass. Afterward, a chlorobenzene (CB) solution of P3HT:PCBM (Lumin Tech Inc.) (50 mg/ml) with a weight ratio of 1:0.8 was spin-coated onto the ZnO NPs modified layer to achieve a thickness of 250 nm. Then the film was annealing at 150 °C for 15 min in glove box [4]. Subsequently the aqueous PAH-D (1 mg/ml), synthesized according to the literature [18], was dipped on the surface of the P3HT:PCBM film and spin-coating at 3000 rpm for 30 s. At last a PH500 layer of about 200 nm was spin-coated on the PAH-D film (~10 nm). The active area of Cell A was defined by the overlapped area of PH500 and ITO. For conventional PSC (Cell B), PEDOT:PSS (Baytron P VP A1 4083) was spin-coated onto cleaned patterned ITO glass to form a film of 40 nm and dried at 120 °C for 10 min. Later, a P3HT:PCBM film (~250 nm) was spin-coated onto the top of PEDOT/PSS (Baytron P VP A1 4083) layer and treated by the same methods as Cell A. At last, a patterned LiF (0.6 nm)/Al (100 nm) electrode was deposited by thermal evaporation in vacuum through a shadow mask. Both of Cell A and Cell B have an identical active area of 10 mm^2 which was defined by the overlapped area between the anode and cathode. The current density–voltage (J–V) characteristics were recorded using Keithley 2400 Source Meter in the dark and under simulated AM 1.5 illumination (100 mW/cm^2) by Solar Simulators (SCIENCETECH SS-0.5 K). The transmittance data were measured by UV–Vis–NIR Spectrophotometer (Shimadzu UV 3600). Film thicknesses were measured by Veeco DEKTAK 150 surface profilometer. Atomic force microscopy (AFM) images and root mean square (RMS) roughness were measured by atomic force microscopy (S II Nanonavi probe station 300hv). All fabrication and characterizations were performed in an ambient environment.

The device structure of Cell A is ITO/ZnO NPs/P3HT:PCBM/PAH-D/PH500, which is shown in Fig. 1a. The structure of Cell B is ITO/PEDOT:PSS/P3HT:PCBM/LiF/Al. In the inverted Cell A, ZnO NPs was used as a hole blocking and electron collecting layer which can be more easily processed into thin layer via spin-coating at room temperature compared to the high temperature sol–gel processed ZnO layer [20]. The AFM image of ZnO NPs film on ITO is shown in Fig. 1b. The RMS roughness of ITO coated by ZnO NPs is 2.02 nm which is slightly rougher than that of ITO (1.78 nm).

To investigate the function of the PAH-D layer, the contact angles of P3HT:PCBM surfaces before and after deposing PAH-D were measured by dipping a drop of water on the surface. As shown in Fig. 2a, the contact angles are

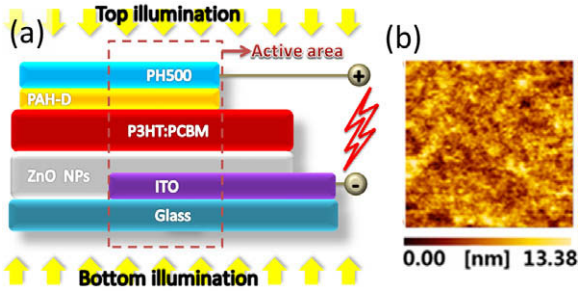

Fig. 1. (a) The schematic structure of Cell A. (b) AFM image of ZnO NPs film, the scan size was 2 × 2 μm^2.

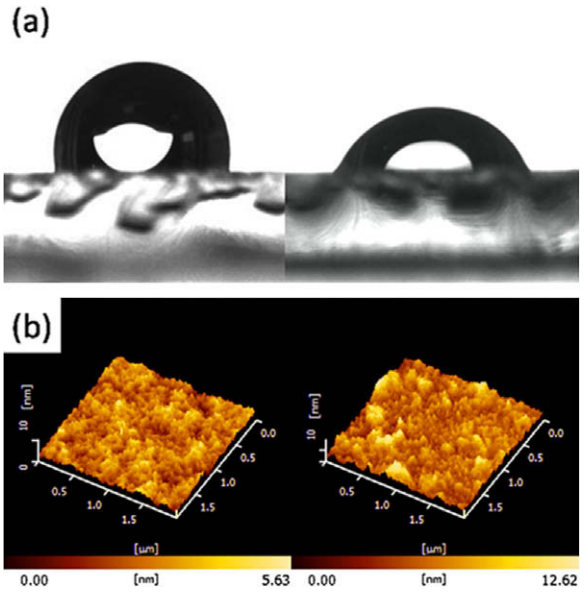

Fig. 2. (a) Pictures of a drop of water on the surface of P3HT:PCBM and P3HT:PCBM/PAH-D. (b) AFM images of the surfaces of P3HT:PCBM and P3HT:PCBM/PAH-D, the scan size was $2 \times 2\ \mu m^2$ and the increment of Z range was 10 nm.

about 101 ± 2° and 62 ± 3° for the surfaces of P3HT:PCBM without and with PAH-D, which means the surface is changed from hydrophobic to hydrophilic after depositing a PAH-D layer. Fig. 2b shows the AFM images of the surface morphologies of P3HT:PCBM without and with PAH-D. The RMS roughness of P3HT:PCBM with PAH-D is 1.99 nm which is slightly rougher than that of P3HT:PCBM without PAH-D (0.86 nm). The deposition of PAH-D on P3HT:PCBM is mainly based on the hydrophobic/hydrophobic interaction between the hydrophobic surface of P3HT:PCBM and the hydrophobic backbone of PAH and dextran in PAH-D microgel where the van der Waals interactions and other multiple weak interactions might contribute to the deposition of PAH-D at the same time [18,21]. The PAH-D microgel is positively charged in aqueous solution due to the amine groups. Therefore, during the spin-coating process of PH500 which contains polyanion PSS, there will be electrostatic interaction between the PSS and PAH-D. This interaction enhances the adhesion and bonding strength between the top PH500 electrode and PAH-D interfacial layer as well as improves the wettability of PH500 on the active layer [18].

The transmittance curves of ITO substrate, PH500 (200 nm) and Cell A with a structure of Glass/ITO/ZnO NPs (50 nm)/P3HT:PCBM (250 nm)/PAH-D (10 nm)/PH500 (200 nm) were shown in Fig. 3. Both of the electrodes ITO and PH500 have a high transmittance over the visible spectral range. While in the spectral region of 400–650 nm, where the main absorption of P3HT:PCBM locates, the transmittance of the ITO-coated glass substrates is 81–87%, about 10% higher than that of PH500 (200 nm) (70–80%). For Cell A, in the spectral region between 300 and 350 nm, the transmittance of Cell A is less than 10% due to the low transmittance of ITO-coated glass substrate. In

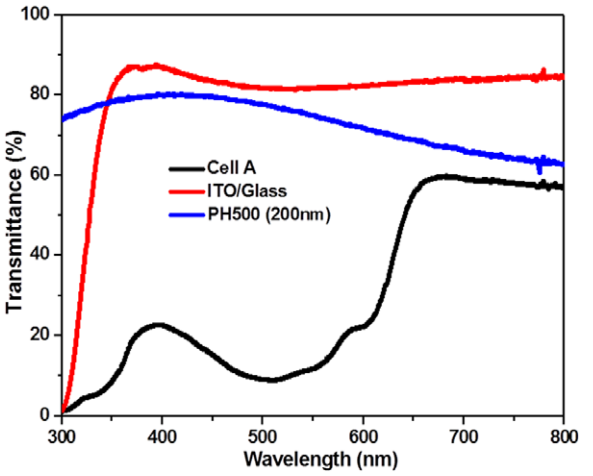

Fig. 3. Transmission spectra of ITO-coated glass substrate (20 Ω), PH500 (200 nm) and Cell A with a structure of Glass/ITO/ZnO NPs (50 nm)/P3HT:PCBM (250 nm)/PAH-D (10 nm)/PH500 (200 nm).

the region between 350 and 600 nm, where the P3HT:PCBM active layer has efficient absorption, the transmittance is mainly in the range of 10–20%. And the transmittance increased from 20% to 60% in the region between 600 and 650 nm. Transmittance of around 60% is found in the region from 650 to 800 nm.

Table 1 presents the overall photovoltaic performance of Cell A and Cell B, while Fig. 4 shows the J–V characteristics of Cell A and Cell B under 100 mW/cm^2 AM 1.5 simulated solar light and in dark. Cell A shows a V_{oc} of 0.58 V, a J_{sc} of 5.18 mA/cm^2, an FF of 42.8% and a PCE of 1.29% under top illumination from PH500 side. The J_{sc}, FF and PCE are 6.10 mA/cm^2, 46.7% and 1.68% when illuminated through glass/ITO side. The increase of PCE of Cell A under bottom illumination is mainly due to the higher J_{sc} caused by the higher transparency of ITO than that of PH500 (200 nm). Because both PH500 anode and ITO cathode are transparent, the J_{sc} of Cell A is sensitive to the light reflection which could be enhanced effectively by simply adding a reflective Al foil or white paper on the back side of the solar cells [8]. As shown in Fig. 4, when a reflector of Al foil or white paper is added on the back side of Cell A and light illuminated from ITO side, the J_{sc} is enhanced from 6.10 to 6.68 mA/cm^2 because of the reflection of the unabsorbed light back into the active layer and the PCE is enhanced from 1.68% to 1.86%.

In order to confirm the performance of Cell A, we measured 30 cells under simulated AM 1.5 illumination

Table 1
Photovoltaic performance of Cell A and Cell B.

Device	Illumination	V_{oc} (V)	J_{sc} (mA/cm^2)	FF (%)	PCE (%)
Cell A	Bottom	0.59	6.10	46.7	1.68
Cell A	Top	0.58	5.18	42.8	1.29
Cell A (paper)	Bottom	0.59	6.68	47.3	1.86
Cell B	Bottom	0.59	7.16	62.1	2.62

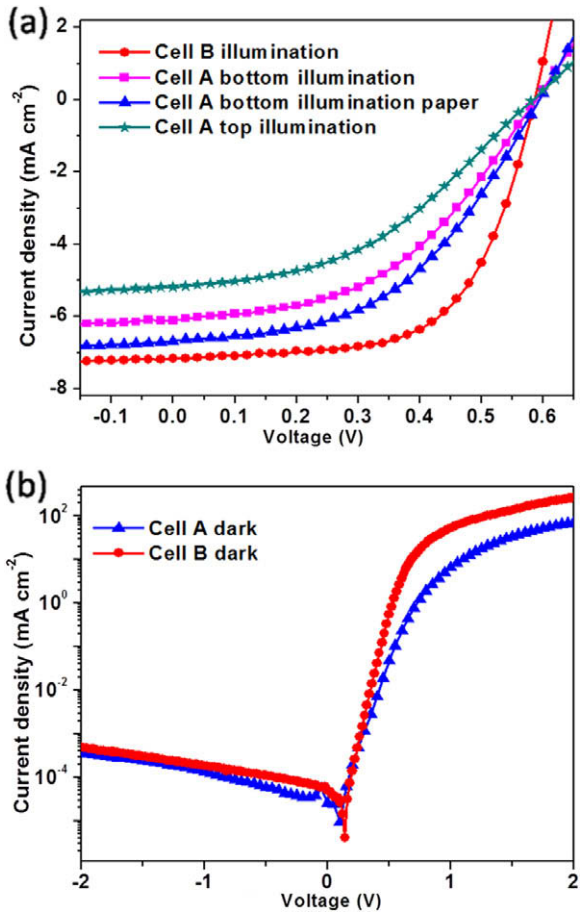

Fig. 4. (a) *J–V* characteristics of Cell B (circle) and Cell A under bottom illumination (square), bottom illumination with a white paper backside (triangle) and top illumination (star) by simulated AM 1.5 solar light (100 mW/cm^2). (b) *J–V* characteristics of Cell A (triangle) and Cell B (circle) in dark.

(100 mW/cm^2) (with a white paper on the back side). According to the statistical results, the J_{sc}, V_{oc}, FF and PCE are mainly in the range of 7.14 ± 0.75 mA/cm^2, 0.58 ± 0.02 V, 45 ± 3% and 1.85 ± 0.15%, respectively.

Cell B exhibited a V_{oc} of 0.59 V, a J_{sc} of 7.16 mA/cm^2, an FF of 62.1% and a PCE of 2.62%. Comparing the performances of Cell A and Cell B, they have the same V_{oc} of about 0.59 V which indicates the introduction of PAH-D layer has little influence on the V_{oc}. The J_{sc} of Cell A (6.68 mA/cm^2) which illuminated from bottom side with a reflector is 6.7% lower than Cell B (7.16 mA/cm^2). The lower J_{sc} is due to the transparency electrode which cannot reflect the unabsorbed light back into the active layer for further efficient absorbance. The FF of Cell A (47.3%) was about 24% lower than Cell B (62.1%) under bottom illumination with a reflective layer. The decrease in FF is mainly due to the higher sheet resistance of the PH500 electrode than the Al electrode [2,9]. We fitted the series resistance of Cell A and Cell B through the forward portion of dark current to be 14.1 and 6.1 Ω cm^2. The higher resistance of Cell A leads to a reduced FF. The lower J_{sc} and FF limited the PCE of Cell A which is about 70 percent that of Cell B.

In conclusion, semi-transparent inverted PSCs were fabricated by all-spin-coating vacuum-free process. A PAH-D layer was introduced to modify the surface wettability of P3HT:PCBM film for depositing the aqueous-solution-processed PH500 anode as well as enhancing the adhesion and bonding strength between the active layer (P3HT:PCBM) and conducting polymer electrode (PH500). The photovoltaic performance of the semi-transparent PSCs under top and bottom illumination was investigated and the highest PCE of about 1.86% was achieved under simulated AM 1.5 illumination (100 mW/cm^2) from bottom side with a reflective layer on the back side which is about 70% that of conventional PSCs. The semi-transparency of Cell A have the potential for use as the subcell of tandem solar cells and power-generating tinted thin-film coatings on windows and other architectural surfaces. The all-spin-coating vacuum-free processing provides a viability of high-throughput all-solution-processed fabrication of PSCs by roll-to-roll processing.

a-Si:H thin-film transistors from the transfer electrical characteristics of these devices measured at different temperatures [10]. The method is based on the analysis of the thermal activation energy of the channel conductance. In particular, the activation energy reduces when increasing the gate voltage as the Fermi level moves towards the band edge. The rate at which the Fermi level shifts when increasing the gate voltage is influenced by the density of localised states in the gap. Then, assuming that charge density within the channel is dominated by trapped carriers, the DOS can be related to the derivative of the activation energy with respect to gate bias. Lang et al. followed the same method to calculate the DOS of single-crystal pentacene field-effect transistors [11]. Research on single-crystal organic semiconductors is interesting because it contributes to establish limits to the device performance based on intrinsic transport properties [12]. Single-crystal devices are also helpful to detect electronic levels in the gap related to contaminants unintentionally incorporated during the growth of the crystal or due to ambient operation [13]. However, real applications are still based on thin-film devices with much higher densities of localised states. Hence, the study of the DOS in OTFTs will give a more accurate description of the trap-limited transport in this kind of devices. In a previous work, our group reported the DOS in the gap of PTCDI-C_{13} active layers used in *n*-channel OTFTs [14]. In this work, we have characterized pentacene OTFTs to study the variation in the DOS of the active layer after a thermal annealing in vacuum. These results are compared to those reported in the literature by different methods for single-crystal and thin-film pentacene devices.

2. Experimental – Fabrication and characterization

The OTFTs studied in this work were fabricated using the inverted-staggered (top contact) structure shown schematically in the inset of Fig. 1. The substrate consisted in a thermally oxidized silicon wafer that provided the gate dielectric (SiO_2) of thickness (t_{ox}) 150 nm. Pentacene was used as purchased from Aldrich Chemical (99.9% purity) and neither self-assembled monolayers were used to improve the device performance. The pentacene active layer (50 nm) was deposited in a vacuum system with base pressure below 10^{-6} mbar that is only used to evaporate organic molecules. The sublimation temperature for pentacene was regulated near to 160 °C to maintain a stable deposition rate around 0.5 Å/s. After pentacene deposition, the samples were exposed to air for a few minutes while they were transferred to a different vacuum chamber used to evaporate the metallic contacts. The drain and source gold electrodes were obtained using a shadow mask that defines a channel length (L) and width (W) of 50 and 600 μm, respectively. The fabricated OTFTs were electrically characterized in dark and under vacuum conditions (10^{-1} mbar) to reduce oxidation effects during the electrical characterization process. The electrical characteristics were measured using an Agilent 4156C parameter analyzer. The device temperature was varied from 300 to 390 K by means of a MMR Technologies controller (model K-20).

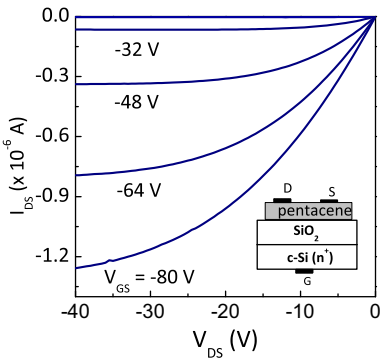

Fig. 1. Output characteristic of one of the fabricated pentacene OTFTs. The inset shows the inverted-staggered (top contact) structure of the studied devices.

The electrical characteristics of organic devices can be strongly influenced by the history of the sample (bias stress, thermal treatments) and by measuring conditions. Factors such as temperature and ambient exposure can lead to significant differences in the measured characteristics, especially concerning subthreshold and leakage currents [15]. Therefore, strict control was taken in order to obtain confident electrical measurements for the OTFTs under study. First, initial tests were performed at room temperature in order to check the correct functioning of the fabricated devices. Afterwards, the samples were heated to 110 °C and annealed for 1 h in vacuum to eliminate any rest of moisture. During the initial temperature rise, the OTFTs were electrically characterized between 30 and 90 °C in 10 °C steps by measuring the output, transfer and saturation characteristics. In order to ensure thermal stabilization, the samples were kept around 20 min at each temperature before doing electrical measurements. Besides, several voltage sweeps were done to check the reproducibility of the electrical characteristics before taking definitive data. These measurements were repeated while the samples slowly cooled down to room temperature. Finally, a second temperature rise and its corresponding electrical characterization were done to observe the effect of the previous annealing on the device performance. Either for temperature rise or fall, each set of complete measurements lasted for approximately 2 h including stabilization times.

3. Results and discussion

Fig. 1 shows the output characteristic of one of the fabricated pentacene OTFTs. The expected electrical characteristics for *p*-channel field-effect transistors were obtained. The field-effect mobility was calculated from a linear fit to the saturation characteristic (not shown) obtaining a relatively high value of 0.41 cm^2/Vs. In a previous work we observed dendritic microstructures for similar pentacene samples, which is a typical feature of device quality films. In particular, X-ray diffraction spectra and atomic force microscopy images revealed a polycrystalline structure with domains of diameter in the range of 100–200 nm [16].

The transfer characteristics were measured at different temperatures during heating and cooling cycles (see

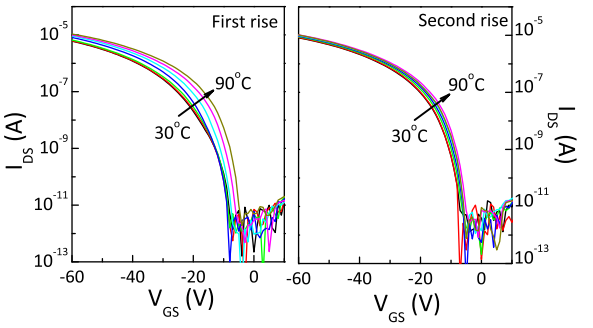

Fig. 2. Transfer characteristics of the pentacene OTFTs measured at different temperatures (from 30 to 90 °C) in vacuum while cooling down the device after an annealing (left) and in a final temperature rise (right). The V_{DS} voltage was −10 V for all these measurements.

Fig. 2) following the procedure described in the previous section. The main differences with temperature were observed for weak accumulation in the above threshold regime. As it can be clearly observed in Fig. 2, the transfer curves spread more during the first temperature rise (left) than in the second one. These differences would indicate that thermal treatments have induced a variation in the DOS of the pentacene active layer. In order to better understand this effect, the drain current has been plotted as a function of the reciprocal temperature (Arrhenius plot) for different gate voltages (inset of Fig. 3). Since the transfer characteristics were measured at a fixed V_{DS} voltage, the drain current is proportional to the conductivity σ of the accumulation channel:

$$I_D = V_{DS} t \frac{W}{L} \sigma \tag{1}$$

where t is the thickness of the channel (typically a few nanometers) [3]. The inset of Fig. 3 evidences that σ presents a thermally activated behaviour $\sigma = \sigma_0 \exp(-E_a/kT)$ with E_a decreasing with the gate voltage in the whole measured range. The activation energy E_a in the MTR model is

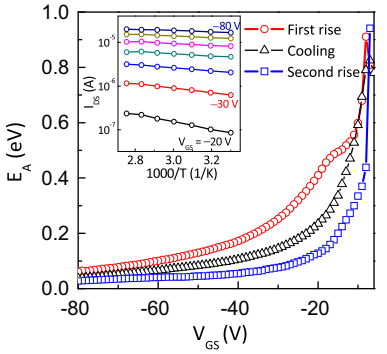

Fig. 3. Activation energy of the channel conductivity as a function of V_{GS} for the transfer characteristics measured during an initial temperature rise, while cooling down the device after a thermal annealing (110 °C for 1 h) and in a last temperature rise. The inset shows the Arrhenius plot of the drain current for different gate voltages corresponding to the first temperature rise cycle shown in Fig. 2. The lines are exponential fits to calculate the activation energy of the channel conductivity.

interpreted as the energy barrier for thermal release of trapped carriers, which can be considered the distance from the Fermi level position to the transport band edge (in this case the valence band). The dependence of E_a with the gate voltage is shown in Fig. 3 for the three measured cycles: during the first temperature rise, while cooling down the samples and in a final temperature rise. The overall behaviour of the activation energy with the gate voltage is similar in all cases. The E_a value is relatively high (0.6 eV) for low gate voltages (just above threshold), but it steadily decreases with V_{GS} until it saturates in a value below 50 meV (strong accumulation). However, the rate at which E_a varies with the gate voltage is clearly different for each curve. A fast variation of E_a with V_{GS} indicates that the Fermi level easily shifts towards the band edge. This behaviour would indicate a low density of localised states that have to be filled by trapped carriers. On the contrary, a high DOS in the gap would result in slower variations of E_a with V_{GS}. Actually, the DOS can be estimated from the derivative of E_a with respect to V_{GS} [10,11]:

$$N(E) = \frac{C_i}{q} \frac{1}{t \frac{dE_a}{dV_{GS}}} \tag{2}$$

where E is the energy measured from the valence band edge, C_i the capacity of the insulator per unit area and q the elementary charge. Eq. (2) has been applied to the data shown in Fig. 3 in order to calculate the DOS in the region from the valence band edge to approximately the middle of the gap (see Fig. 4). A channel thickness (t) of 5 nm has been considered for the calculation according to previous works [3,11]. In all three cases the DOS exponentially increases up to 10^{19} cm^{-3} close to the valence band edge ($E < 0.2$ eV). In analogy to inorganic amorphous semiconductors, this exponential region of the DOS can be assumed as a band tail of localised states induced by structural disorder [3]:

$$N_t(E) = N_0 \exp\left(-\frac{E - E_v}{kT_0}\right) \tag{3}$$

where the slope of the exponential distribution kT_0 is an indirect measure of disorder. A clear difference observed

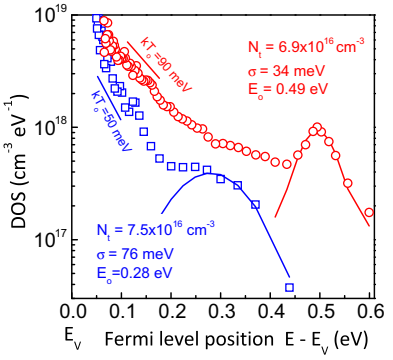

Fig. 4. Density-of-states in the gap of pentacene calculated from the derivative of the activation energy of the channel conductivity in the heating and cooling cycles shown in Fig. 3. The slopes of the exponential band tails (Eq. (3)) and Gaussian fits (Eq. (4)) to the resolved deep level distributions are also indicated.

in Fig. 4 is the broader band tail (kT_0 = 90 meV) for the first temperature rise compared to the second one (kT_0 = 50 meV). Such thinning of the band tail seems to indicate that the thermal annealing done between both measurements has effectively reduced some structural disorder in the pentacene layer. Moreover, the field-effect mobility calculated from the saturation characteristic increased from an initial value of 0.41–0.55 cm^2/Vs. The curve for the cooling cycle is probably affected by thermal quenching effects because release times from deep localised states can be relatively long. Therefore, electrical measurements taken during the cooling cycle were rather likely obtained out of thermal equilibrium and will not be discussed.

Apart from band tails attributed to the intrinsic disorder of pentacene molecules, other features most probably due to extrinsic contaminants can be resolved in Fig. 4. The initial DOS shows a deep level in the gap that can be fitted considering a Gaussian distribution of states:

$$N(E) = \frac{N_d}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(E-E_0)^2}{2\sigma^2}\right) \quad (4)$$

where N_d is the total density-of-states related to this defect, E_0 its position in the band gap and σ the standard deviation of the distribution. According to the fit shown in Fig. 4 the defect density is 6.9×10^{16} cm^{-3} and it is located at E_v + 0.49 eV with a standard deviation of 34 meV. This level could not be detected in the final temperature rise for the annealed device. In a previous work [17], charge DLTS measurements on pentacene Schottky diodes also evidenced a deep level after bias stress. As in the present case, a thermal annealing in vacuum was able to heal the defect and prevent its regeneration. Such similar metastable behaviour suggests that both defect levels could be related to a same contaminant. Goldmann et al. [18] have also proposed a deep level in pentacene to interpret the electrical characteristics of single-crystal field-effect transistors after bias stress. They related this defect to water molecules adsorbed to the SiO_2 dielectric, since it could not be detected when a self-assembled monolayer was used to provide a hydrophobic surface. Pernstich et al. [19] determined that a discrete trap at E_v + 0.43 eV was necessary to fit the experimental data reported by Goldmann. Considering experimental uncertainties and that these results were obtained for single-crystal devices, the metastable defect that we observe in Fig. 4 could also correspond to adsorbed water molecules. Then, one might expect that a thermal annealing at 110 °C for 1 h in vacuum would be enough to remove most water content in the OTFT.

On the other hand, a Gaussian distribution of localised states centered at E_v + 0.28 eV can be resolved in the second temperature rise. According to the fit shown in Fig. 4 the density-of-states related to this level is 7.5×10^{16} cm^{-3} with a broader energy distribution of standard deviation 76 meV. Surely, this last distribution was already present in the first rise but hidden by the much wider band tail. Recently, Knipp and Northrup [20] comprehensively studied the electrical characteristics of pentacene OTFTs exposed to oxygen under different bias conditions. They concluded that a Gaussian distribution of acceptor states at E_v + 0.29 eV should be included to fit experimental data. These states were attributed to the dissociation of oxygen and its bonding to carbon atoms of adjacent pentacene molecules. The persistence of this level after a thermal annealing would be in accordance with a strong chemical bond of the contaminant. Actually, a number of studies can be found in the literature reporting levels around E_v + 0.3 eV in pentacene. These works include the electrical characterization of single-crystal pentacene devices [11,21], capacitance DLTS measurements on OTFTs [22] and even theoretical first-principles pseudopotential density functional calculations [23].

4. Conclusions

This study contributes to a more complete understanding of trap-limited transport in OTFTs. The activation energy of the channel conductance as a function of the gate voltage collects valuable information about the DOS in the active layer. Particularly, the DOS from approximately mid gap to the band edge can be calculated in the accumulation channel close to the interface with the dielectric. This approach can be a good complement to more elaborated characterization techniques as DLTS. The method can be applied to thin-film transistors based on any other organic semiconductor offering valuable information about the density of localised states in the gap, either due to structural disorder or related to extrinsic contaminants. In this work, we have studied the effect of a thermal annealing (110 °C for 1 h) in the DOS of pentacene thin-films under vacuum conditions. A deep level in as deposited pentacene was completely healed by the thermal annealing. Desorption of water molecules is a plausible explanation of this metastability. We also observed a reduction in the width of the band tail, which could be interpreted as an enhanced ordering of pentacene molecules due to the annealing process. This effect could be also promoted by the desorption of water molecules that would be disarranging the pentacene structure. Finally, a persistent broad band of localised states around 0.3 eV has been attributed to oxygen atoms strongly bond to pentacene molecules.

zone, whereas has reduced quenching effects in the green emission region.

2. Experimental

The OLEDs consisted of organic multilayers sandwiched between indium tin oxide (ITO) and Al electrodes. The pre-patterned ITO glass substrates (sheet resistance ~15 Ω/□) were sequentially cleaned in acetone, ethanol, and de-ionized water, and then exposed to oxygen plasma for 5 min. The organic films were deposited by high-vacuum thermal evaporation at rates of about 0.1 nm/s. The structure consisted of a 45 nm *N*,*N*′-di(naphth-2-yl)-*N*,*N*′-diphenylbenzidine (NPB) hole transporting layer (HTL), an $Ir(ppy)_3$ EML sandwiched between two 20 nm 4,4′-*N*,*N*′-dicarbazole-biphenyl (CBP) layers, a 15 nm 2,9-dimethyl-4,7-diphenyl-phenanthroline (BCP) hole blocking layer (HBL), and a 15 nm tris-(8-hydroxyquinoline) aluminum (Alq_3) electron transporting layer. Finally, a 0.5 nm LiF and 120 nm Al cathode were deposited on the organic film through a shadow mask. A set of samples was prepared, which differed only in the thickness of the neat $Ir(ppy)_3$ layer from 1 to 26 nm. For comparison, green OLEDs doped with 7 wt.% $Ir(ppy)_3$ as well as OLEDs with a 3 nm neat $Ir(ppy)_3$ EML and a 15 nm 4,4′,4″,-tris(*N*-carbazolyl) triphenylamine (TCTA) EBL were also fabricated. All the devices have an emitting area of 3 mm × 3 mm. The energy level diagram of the OLED structure is schematically shown in Fig. 1. The OLEDs were encapsulated with glass lids in N_2 and characterized at room temperature. The electrical characteristics were measured using an Agilent 4156C semiconductor analyzer. The emission spectra were recorded as a function of injection current in the range of 10^{-5}–10^{-1} A/cm^2 using a silicon photodiode-array fiber-optic spectrometer. To calculate EQE, the OLEDs were placed directly onto the surface of a calibrated silicon photodetector and all emitted photons from the glass side were captured.

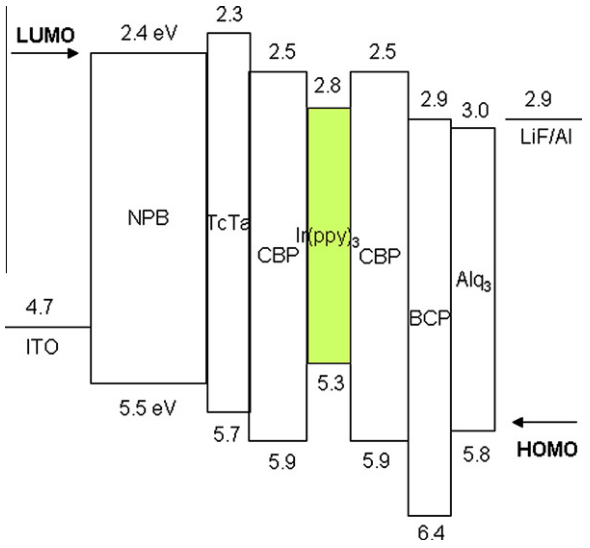

Fig. 1. Energy level diagram of OLEDs with a neat $Ir(ppy)_3$ EML.

3. Results and discussion

Fig. 2 compares the EL spectra of the OLEDs having 4 nm $Ir(ppy)_3$ with and without a TCTA EBL at increasing injection currents. The OLED with TCTA has a recombination zone limited to the $Ir(ppy)_3$ layer, emitting green light with a main peak at 523 nm and a shoulder at ~546 nm. The spectrum exhibits a red shift of ~9 nm with respect to the emission of OLEDs doped with 7 wt.% $Ir(ppy)_3$ as well as an increased tail band at red wavelengths. These are characteristic features of an aggregate state of $Ir(ppy)_3$ molecules [4,7]. At low injection currents (<50 μA), the OLED without TCTA has similar green EL spectra. However, above 50 μA, a broad band emerges at the high-energy side

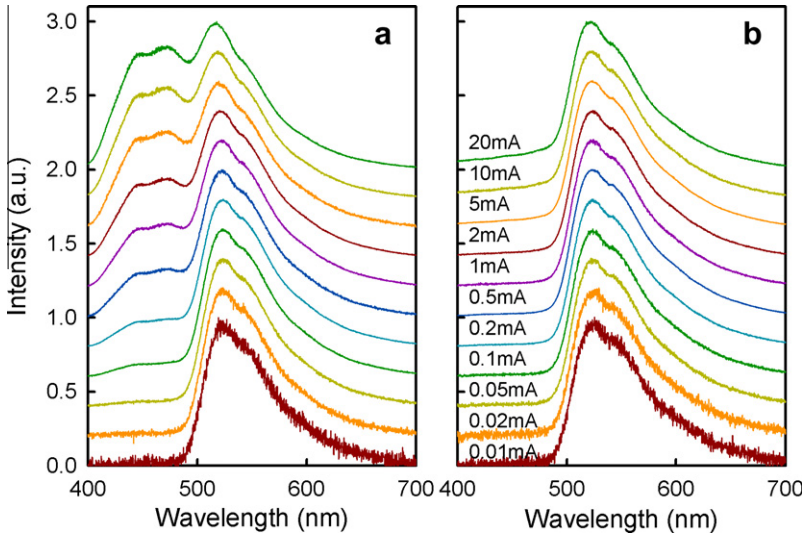

Fig. 2. Normalized EL spectra of OLEDs with and without a TCTA EBL at increasing injection currents. Both OLEDs have a 4 nm neat $Ir(ppy)_3$ EML.

of the main peak, which is attributed to blue fluorescent emission from NPB. The blue band increases rapidly with increasing current, and its intensity is comparable with that of the green emission at 20 mA. It is evident that at elevated injection levels, a significant amount of electrons can surmount the barrier at the NPB/CBP interface and recombine with injected holes in the NPB HTL. In other words, the exciton formation and recombination zone is partially shifted and broadened as the current is increased.

The light output power–current–voltage (*L–I–V*) characteristics of the two OLEDs are displayed in Fig. 3a. As seen, the TCTA EBL causes an additional 1.2 V voltage drop at 20 mA. Interestingly, the OLED without TCTA is roughly twice as bright as its counterpart with TCTA over the tested current range. The current-dependent EQE of the OLEDs is shown in Fig. 3b. At low currents, both OLEDs emit green light and have comparable efficiencies. The EQE of the OLED with TCTA decreases steadily as the current is increased due to increasing quenching effects such as TTA and triplet-polaron quenching (TPQ) [5]. In contrast, the EQE of the OLED without TCTA starts to increase at 50 μA, which marks the onset of electron leakage from the EML to HTL and shift of the recombination zone. It reaches the maximum value at 0.2 mA and then drops significantly at higher currents due to current-induced quenching. It is thus clear that the zone shift caused by electron overflow doubles the chance for excitons to recombine radiatively. The overall emission of both OLEDs is remarkably reduced, as compared to OLEDs doped with $Ir(ppy)_3$, due to strong concentration quenching in neat $Ir(ppy)_3$. The EQE of the OLED with TCTA is found to be one order of magnitude lower than that of OLEDs doped with 7 wt.% $Ir(ppy)_3$ at 10 mA/cm^2.

In order to gain further insight of the underlying luminescence mechanism, we decompose the spectra of the OLED without TCTA into two components: green and blue. An example is shown in Fig. 4. The blue band, which is the subtraction of the scaled spectrum of the OLED with TCTA at 10 mA from the overall spectrum, matches well with the EL of a device which has a simple structure of ITO/NPB/BCP/Al (also shown in Fig. 4). The latter is believed to be dominated by the fluorescence from NPB. The intensity ratio of the green peak and the overall emission is plotted as a function of current in Fig. 5. As seen, the ratio is equal to 1 at low currents and starts to drop at 50 μA. At 20 mA, the green peak accounts for only 53% of the overall emission. Fig. 5 also shows the intensity ratios of green emission of the OLEDs with and without TCTA. The ratios are close to unity at low currents (<0.02 mA), where the current-induced quenching is minimal, as well as high currents (>5 mA), when both OLEDs suffer severely from TTA and TPQ. In the intermediate injection regime, stronger quenching effects can be expected in the OLED with TCTA due to carrier confinement by the electron and hole blockers. Indeed, the green intensity of the OLED without TCTA is considerably higher at moderate currents (by 48% at 0.2 mA), suggesting reduced quenching in the EML as a result of electron overflow. We have found that the efficiencies of the OLEDs with and without TCTA at 20 mA are 12% and 23%, respectively, assuming a unity efficiency for OLEDs with 7 wt.% $Ir(ppy)_3$ randomly doped in CBP. Therefore, in the former, 88% excitons suffer nonradiative decay in the $Ir(ppy)_3$ layer due to quenching. However, we estimate that less than 45% of excitons are quenched in the latter, considering that NPB singlet emission account for 47% of the overall emission as well as only 25% of the excitons (singlets) in NPB can be harvested due to spin statistics.

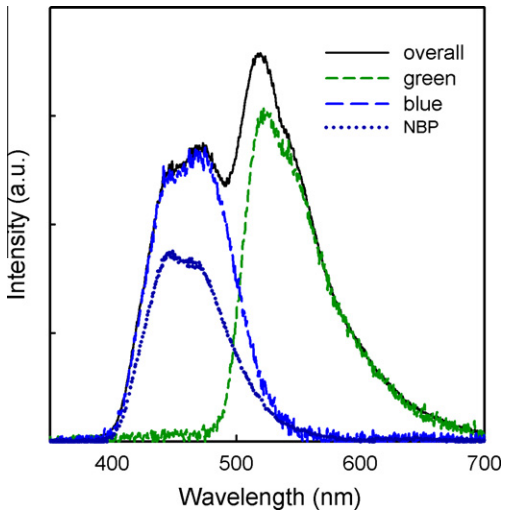

Fig. 4. EL spectrum of $Ir(ppy)_3$-OLEDs without a TCTA EBL at 10 mA, decomposed into blue and green emission components. The fluorescence of NPB is also shown for comparison.

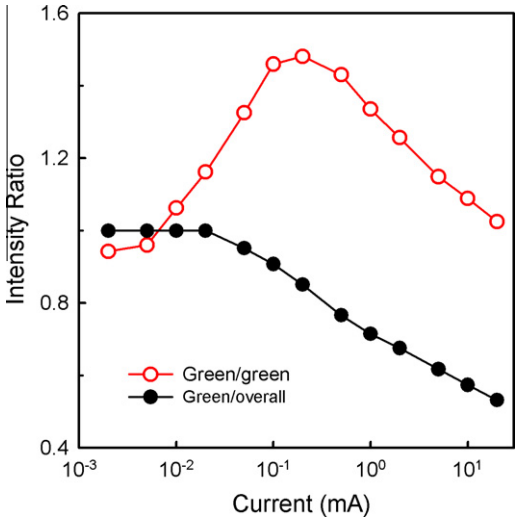

Fig. 5. Intensity ratio of green emission and overall EL of an OLED without a TCTA EBL, along with the intensity ratio of green emission from OLEDs with and without an EBL, as a function of injection current.

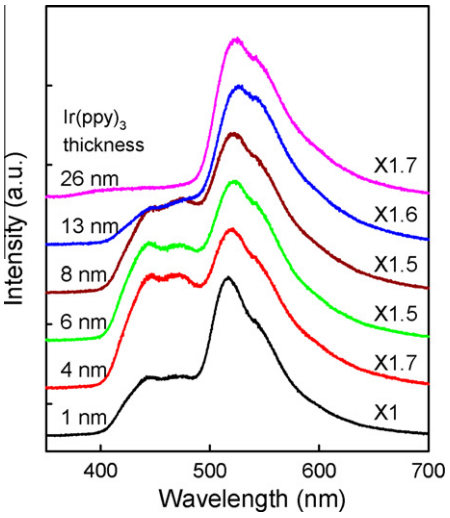

Fig. 7. Normalized EL spectra of OLEDs with a neat $Ir(ppy)_3$ EML of 1–26 nm measured at 10 mA.

To investigate the possible impact of quenching on the distribution of injected carriers and their recombination zone, we characterized OLEDs with the $Ir(ppy)_3$ EML thickness varying from 1 to 26 nm. It was found that the forward voltage increases gradually with increasing $Ir(ppy)_3$ thickness (Fig. 6), suggesting that a small extra bias must be applied to maintain the current transport across the neat $Ir(ppy)_3$ layer. The normalized EL spectra of these OLEDs at 10 mA are depicted in Fig. 7. The OLED with 1 nm $Ir(ppy)_3$ has the highest light output. This is because the EML is less than one monolayer thick, so the $Ir(ppy)_3$ likely forms a partial layer with a relatively small degree of aggregation and concentration quenching. Significant blue emission is seen for OLEDs with $Ir(ppy)_3$ up to 13 nm. With increasing thickness, its relative intensity increases, peaks at 4 nm, and then decreases. Despite a lower overall emission power, the OLED with 4 nm $Ir(ppy)_3$ has an integrated blue intensity ~16% higher than that of the OLED with 1 nm $Ir(ppy)_3$. This unusual behavior suggests that the bands in the 4 nm EML are more easily filled up due to stronger concentration quenching. It appears that, like phosphorescence itself, quenching of phosphorescence in $Ir(ppy)_3$ is also a slow process which increases the dwell time of electrons in the EML, allowing electrons to escape. In other words, electron overflow and the shift of the recombination zone are enhanced by quenching in the $Ir(ppy)_3$ EML.

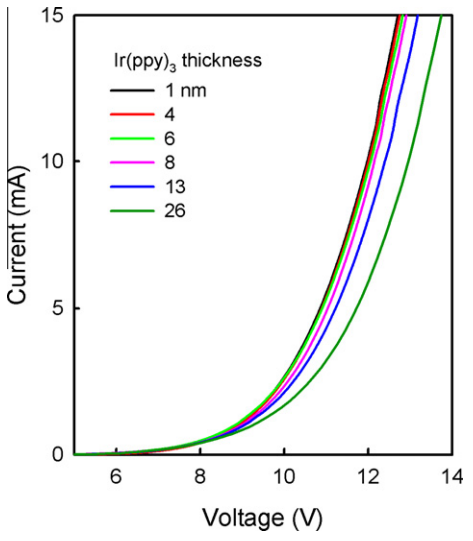

Fig. 6. Forward *I–V* characteristics of OLEDs with a neat $Ir(ppy)_3$ EML of 1–26 nm.

As the $Ir(ppy)_3$ layer grows thicker, the blue emission decreases because the EML functions as a more effective carrier blocking layer due to its low mobilities [12]. As seen, an $Ir(ppy)_3$ layer of 26 nm is able to prevent electrons from overinjection and limit the recombination zone in the $Ir(ppy)_3$ layer. However, the green light emission does not increase with increasing $Ir(ppy)_3$ thickness as expected from the suppressed blue emission. As seen in Fig. 8a, which shows the green emission intensity of the OLEDs at three different currents, plotted as a function of the $Ir(ppy)_3$ thickness. The OLEDs with $Ir(ppy)_3$ >6 nm have nearly constant output power of green light. This may suggest that the effective green emission zone is limited to ~6 nm wide. Since no singlet emission from CBP was observed, singlet and triplet excitons formed on the CBP molecules close to the interface are quickly transferred to $Ir(ppy)_3$ molecules through Förster and Dexter energy transfer, respectively [11]. The latter is a short-range process, whereas the former features long-range energy transfer with the transfer rate k_{Fnr} proportional to $(R_0/R)^6$, where R_0 is the Förster radius and R is the CBP–$Ir(ppy)_3$ spacing. The majority of the excitons are therefore generated on $Ir(ppy)_3$ molecules located near the CBP/$Ir(ppy)_3$ interfaces [13]. The Förster radius between CBP and $Ir(ppy)_3$ has been found to ~3 nm [8]. Assuming that excitons form at both interfaces, the effective $Ir(ppy)_3$ emission zone width should be on the order of 6 nm, which is consistent with

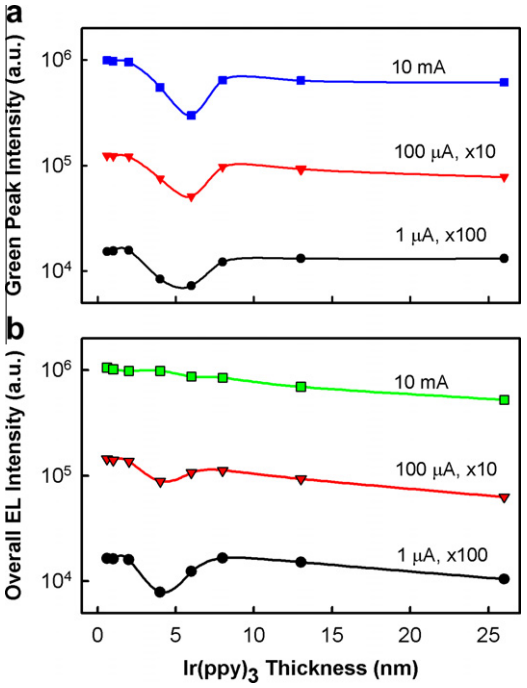

Fig. 8. (a) Green light intensity of OLEDs with a neat $Ir(ppy)_3$ EML of 1–26 nm measured at 1 μA, 100 μA and 10 mA. (b) Overall emission power of the OLEDs as a function of the $Ir(ppy)_3$ thickness at various current densities.

above finding. For OLEDs with thin $Ir(ppy)_3$, both the green light and overall emission (see Fig. 8b) decrease initially and reach the minimum value at 4 nm. In another study, we found that the EL intensity of OLEDs with neat $Ir(ppy)_3$ sandwiched between EBL and HBL also reached the minimum at 4 nm, which marked the saturation of the tail band emission centered at 580 nm as well. Both are indicative of the maximum concentration quenching in the $Ir(ppy)_3$ EML [4]. The correlation between the maximum quenching in the 4 nm EML and the strongest blue emission from the HTL (as seen in Fig. 7) supports our conclusion that electron overflow and zone shifting are enhanced by the quenching effects in the EML. The slight decrease in the overall emission power above 6 nm can be attributed to stronger photon reabsorption and carrier trapping by thicker films.

The fact that the minimum light emission occurs at 4 nm may suggest that the concentration quenching in $Ir(ppy)_3$ mainly arises from a long-range energy transfer from excited molecules to unexcited molecules with a Förster radius $R_0 \approx 4$ nm [4]. One possible mechanism is that dipole–dipole interactions and energy exchange between excited molecules and adjacent unexcited molecules readily occur and repeat for multiple times [3]. The resonant energy transfer may facilitate deactivation processes which account for the loss of most excited state energy to thermal vibrations in neat $Ir(ppy)_3$. Such a quenching process would be even slower than phosphorescence, supporting our earlier hypothesis. When $Ir(ppy)_3$ grows thicker than R_0, the distant molecules will have a minimal quenching impact on the excitons generated mainly near

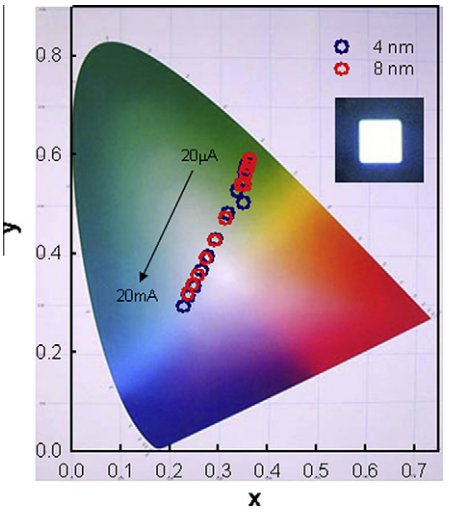

Fig. 9. CIE coordinates of OLEDs with 4 and 8 nm $Ir(ppy)_3$ at various currents. The inset shows a photograph of the OLED with 4 nm $Ir(ppy)_3$ recorded at 5 mA.

the CBP/$Ir(ppy)_3$ interfaces, but still contribute to EL emission if they are still located in the effective green emission zone. Our results also suggest that TTA and TPQ may play a minor role in concentration quenching processes. As the $Ir(ppy)_3$ grows thicker, excitons spread out and are further separated, the rates of TTA and TPQ at the same injection current are expected to decrease. However, this is different from the trend we observed above. This conclusion is also supported by the finding that the quenching magnitude exhibits a very weak dependence on the injection current.

The OLEDs with an $Ir(ppy)_3$ EML of 4–10 nm take advantage of the increased band tail emission at red wavelengths from aggregate $Ir(ppy)_3$ molecules and emit white light. Fig. 9 illustrates the *Commission internationale de l'Eclairage* (CIE) diagram with CIE coordinates of the OLEDs with 4 and 8 nm $Ir(ppy)_3$ at various currents. The coordinates are strongly dependent on current. From 50 μA to 20 mA, the emission color shifts from greenish white to bluish white. At 1 mA, the CIE coordinates of the OLED with 4 nm $Ir(ppy)_3$ are (0.28 and 0.39), corresponding to a cold white light. The efficiency is 6.5 cd/A, which is comparable with the performance of typical white florescent OLEDs [1,14]. A photograph of such a white OLED is shown in the inset. It is known that the color stability of state-of-the-art phosphorescent white OLEDs is limited by the short lifetimes of phosphorescent blue emitters [1]. Based on the results obtained herein, we may envision an alternative cost-effective white OLED concept which combines a stable fluorescent blue emitter and an efficient phosphorescent yellow–green emitter, given that the brightness of different colors can be balanced through good spatial control of the recombination zone.

4. Conclusion

In summary, we studied the influence of concentration quenching on the carrier dynamics in OLEDs with a neat $Ir(ppy)_3$ EML. It has been found that electron overflow from

the EML at elevated currents was enhanced by the quenching effects, leading to a broadened recombination zone and blue emission from the NPB HTL. Combining the blue florescence of NPB and less-quenched yellowish green phosphorescence of $Ir(ppy)_3$, the OLEDs emitted white light with an overall efficiency twice as high as compared to similar OLEDs with an additional TCTA EBL. These findings suggest that concentration quenching in $Ir(ppy)_3$ is probably a slow process involving multistep dipole–dipole energy exchange interactions, allowing for carrier escape from the EML.

excellent film-forming properties upon solution process. Highly efficient white emission (22.3 cd A^{-1}, 11.6%) was obtained from a single emitting layer formed after spin-coating a solution of blue- and red-phosphor co-doped tBu-OXDTFA [10]. However, in these reports, an additional hole-blocking/electron-transporting layer which was made by thermal vapor deposition was introduced into the device structure in order to achieve high efficiency, thus leading to increased fabrication complexity.

In this paper, we demonstrate high performance, single emitting layer small-molecule WOLEDs via solution process. A home-made host material with good solubility in common organic solvents, excellent film-forming ability and high triplet energy (2.88 eV), namely 9,9-bis[4-(3,6-di-tert-butylcarbazol-9-yl)phenyl]fluorene (TBCPF) [19,20], was used as the host material in this study. 1, 3-Bis[(4-tert-butylphenyl)-1,3,4-oxadiazolyl]phenylene (OXD-7) was included in the host to facilitate electron transport [21]. Two or three phosphorescent iridium complexes were doped into the host matrix to enable white light emission. An optimized single active layer device having a pure-white emission shows a maximum luminance efficiency of 20.8 cd A^{-1} (7.2 lm W^{-1}), and a maximum luminance of 26,600 cd m^{-2}. While by adding a hole-blocking/electron-transporting layer, a maximum luminance efficiency of 29.6 cd A^{-1} (15.6 lm W^{-1}), and a maximum luminance of 22,300 cd m^{-2} were obtained. The origin of the efficient white emission and energy transfer in this white-emitting system are also discussed by using photophysical measurements and transient techniques.

2. Experimental

For the device fabrication, a sufficiently cleaned indium-tin-oxide (ITO)-coated glass substrate was treated with O_2-plasma. An approximate 40 nm of poly(ethylendioxythiophene):poly(styrene sulfonic acid) (PEDOT:PSS) was first spun-cast onto the substrate as the hole-injecting layer. The substrates were then taken into a nitrogen glove-box, where phosphorescent dyes doped TBCPF:OXD-7 layer was spin coated onto PEDOT:PSS layer from chlorobenzene solution, and annealed at 100 °C for 30 min, yielding a smooth film with a thickness of approximate 100 nm. For instance, a root mean square (RMS) surface roughness value is 0.86 nm and peak-valley (P-V) value is 7.34 nm (an area of 5 × 5 μm^2) for the triply-phosphorescence-doped light-emitting layer. We used bis(2-(4,6-difluorophenyl)-pyridinato-*N*,$C^{2'}$) picolinate (FIrpic) for blue dye, iridium tris(2-(4-tolyl)pyridinato-*N*,$C^{2'}$) ($Ir(mppy)_3$) for green dye, and iridium bis(1-phenylisoquinoline) (acetylacetonate) ($Ir(piq)_2acac$) for red dye. The substrate was then transferred into an evaporation chamber, where the 2,2′,2″-(1,3,5-phenylene)-tris(1-phenyl-1H-benzimidazole) (TPBI, if needed) was evaporated at an evaporation rate of 1–2 Å/s under a pressure of 8×10^{-4} Pa. The Cs_2CO_3/Al bilayer cathode of the device was formed by the thermal evaporation of Cs_2CO_3 and Al under a pressure of around 1×10^{-3} Pa. The diode area is 9 mm^2.

TBCPF was synthesized in our laboratory [19]. The device architectures and the molecular structures used for fabrication of the devices are shown in Fig. 1.

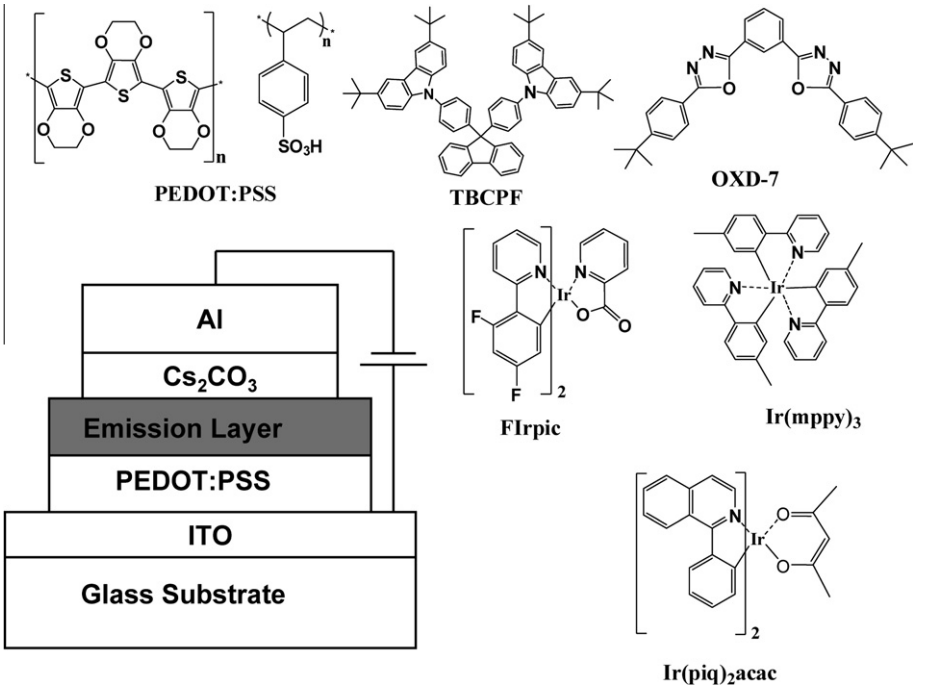

Fig. 1. The device architecture used in this study and the molecular structures of the used materials.

Thin films for photophysical characterization were formed onto quartz substrates by spin-coating chlorobenzene solutions. Absorption spectra were recorded with a UV–vis spectrophotometer (Agilent 8453) and PL spectra were recorded with a fluorospectrophotometer (Jobin Yvon, FluoroMax-3). The transient PL measurements were carried out using steady state and time-resolved fluorescence/phosphorescence spectrometer (FLSP920, Edinburgh Instruments Ltd.). Nanosecond Flashlamp nF900, which operates with a hydrogen gas fill to provide sub-nanosecond optical pulses in 110–850 nm depending on optics and gas fill at repetition rates to 100 kHz, was used as the photoexcitation source. The thickness and surface morphology of the films were measured by using an Atomic Force Microscopy (AFM, Seiko, SPA-400). The *J–L–V* characteristics were performed with a Keithley 4200 semiconductor characterization system. The EL spectra and the CIE coordinators were collected on a spectrophotometer (Photo Research PR705). All the measurements were carried out in air at room temperature without further encapsulation.

3. Results and discussion

3.1. Solution-processed small-molecule WOLEDs characterization

The composition and performance of the all phosphorescent WOLEDs are summarized in Table 1. The blue phosphor FIrpic concentration was maintained at 10 wt.% of the total blend while the weight ratio of TBCPF:OXD-7 was fixed at 2:1. White emission could be realized through carefully adjusting the concentrations of the green and red dyes so as to balance the contributions from different emitters.

For the doubly-doped devices with FIrpic and red dye $Ir(piq)_2acac$, according to the weight ratio of FIrpic:$Ir(piq)_2acac$, devices are designated as Device I (50:1), II (40:1), III (30:1), and IV (20:1). Fig. 2a shows the electroluminescence (EL) spectra at 9.0 V of these devices. Two major peaks at 476 nm, from FIrpic, and 622 nm, from $Ir(piq)_2acac$, and a small shoulder peak at 500 nm, from FIrpic, are observed. There is a monotonous increase in the red emission as the doping concentration of $Ir(piq)_2acac$ relative to that of FIrpic increases from 1:50 to 1:20. As shown in Table 1, the CIE coordinates of devices at 9.0 V fluctuate from (0.332, 0.392) to (0.453, 0.355). Of which, the EL colors of Devices I (0.332, 0.392), II (0.342, 0.366) are close to the ideal CIE coordinates of pure white color.

For the triply-doped structure with different weight ratios of FIrpic:$Ir(mppy)_3$:$Ir(piq)_2(acac)$ (50:1:1, 40:1:1, 30:1:1, 20:1:1, 30:0.5:1, 20:0.5:1), the performances of the corresponding Devices V–X are also summarized in Table 1, the EL spectra of the devices are shown in Fig. 2b. The light emissions are all dominated by the contribution from green emitter $Ir(mppy)_3$ despite its low concentration. The CIE coordinates of all devices, together with the pure white light CIE coordinates of (0.333, 0.333), are shown in Fig. 2c for comparison. Significantly, the emission color remains stable upon the variation of the applied voltage. For instance, Fig. 2d shows the EL spectra and the CIE coordinates of Device II at varied current density. When the current density changes from 15 A m^{-2} to 1650 A m^{-2}, the CIE coordinates of Device II change from (0.352, 0.366) to (0.368, 0.371), all around the white light equi-energy point (0.333, 0.333). From the EL spectra, it can be observed that the relative intensity of the blue component of the emission increases initially with the applied voltage, and then the red emission starts to increase slightly at high applied voltage. We attribute the high color stability of these devices, which is important for illumination, to the simple structure with a single emission layer and the minimized shift of excitons in the recombination zone [22,23].

Current density-luminance-voltage (*J–L–V*) characteristics and luminous efficiency-power efficiency-current density characteristics of Devices I–IV are presented in Fig. 3. Device II is closest to pure-white emission color and is characterized by a maximum forward viewing luminous efficiency of 16.0 cd A^{-1} at 70 A m^{-2} and 8.3 V. Furthermore, the maximum power efficiency of Device II is 5.9 lm W^{-1} at 28 A m^{-2} and 7.4 V. Device II reaches a maximum luminance of 27,200 cd m^{-2} at 15.8 V and 4490 A m^{-2}.

The triply-doped devices with the green emitter $Ir(mppy)_3$ in the emission layer have higher efficiencies than those of doubly-doped devices. This can be explained by the fact that $Ir(mppy)_3$ is a very efficient green emitter. Besides, the photonic response of human eyes to green light is much stronger than those to blue and red lights. Device VII with the CIE coordinates of (0.347, 0.442) at 9.0 V has the best performance with the corresponding efficiencies of 20.8 cd A^{-1} at 65 A m^{-2} and 8.8 V, and 7.2 lm W^{-1} at 34 A m^{-2} and 7.7 V, respectively. Device VII reaches a maximum luminance of 26,600 cd m^{-2} at 14.2 V and 2237 A m^{-2} (Table 1). The high performance could be attributed to the excellent film-forming ability and the high triplet energy of TBCPF as well as charge balance in the emitting layer. It is worth pointing out that these single-active-layer WOLEDs achieved high efficiencies comparable to previously reported solution-processed WOLEDs with an additional thermally deposited hole-blocking/electron-transporting layer [7,10].

To further improve the device performance, a 20-nm-thick hole-blocking/electron-transporting TPBI layer was inserted between the 80-nm-thick light-emitting layer and the cathode with the active layer kept at 100 nm. As shown in Table 1, after the insertion of the TPBI layer, in spite of slightly degraded white color purity, a substantially enhanced luminance efficiency of 29.6 cd A^{-1} with the external quantum efficiency of 15.6% at 22 A m^{-2} and 6.8 V, and 15.6 lm W^{-1} at 6.3 A m^{-2} and 5.3 V, respectively (Device XI). The enhanced performance of double-layer Device XI with a thin TPBI layer are mainly due to the thin TPBI layer as a hole-blocking/electron-transporting layer, and confining the exciton in the emitting layer.

In addition, color quality must be considered if the devices are used for illuminance. As shown in Table 1, the triply-doped Devices V–XI all have appropriate color

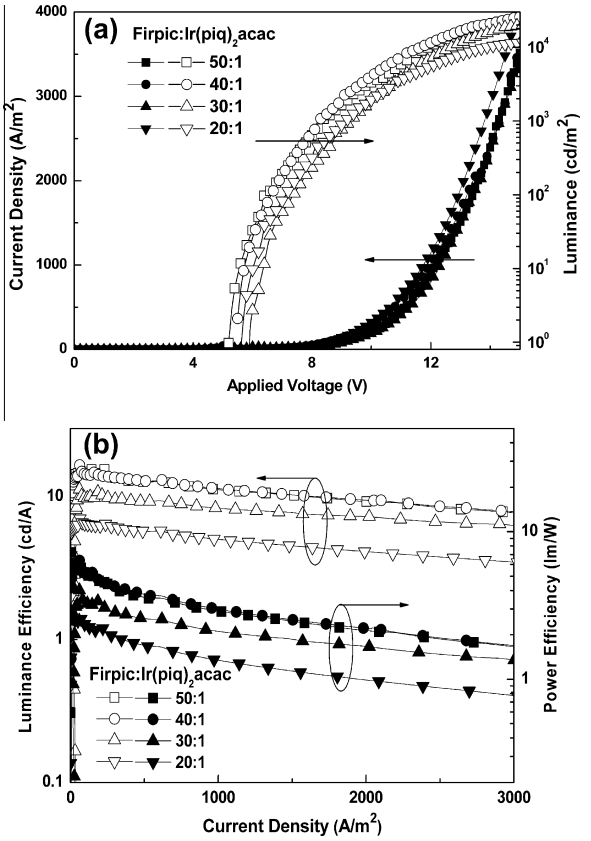

Fig. 3. Current density–luminance–voltage (*J–L–V*) characteristics (a) and luminous efficiency-power efficiency-current density (b) characteristics of the doubly-devices with different ratio of FIrpic to $Ir(piq)_2acac$.

temperature (CT) within 3600–5500 K and relative higher Color Rendering Index (CRI > 70). It is worth noting that single-layer Device VII has a CT value of ~5160 K (which is close to the CT of standard daylight 5500 K) and a relatively higher CRI value of 75.

3.2. Energy transfer mechanism in the single emission layer

Since TBCPF and OXD-7 in the host matrix both have relatively high triplet energy levels, when charge carriers are injected into the single emission layer, two independent processes which are related to the emission of the dopants may occur: energy transfer from the host to the phosphorescent guests via Förster or Dexter process, and charge trapping at the narrow band gap dyes. To understand the energy transfer mechanism in the single white emission layer, photoluminescence (PL) and transient PL decay analyses were employed.

Fig. 4 shows the PL spectrum of TBCPF:OXD-7 in chlorobenzene, absorption spectra of FIrpic, $Ir(mppy)_3$ and $Ir(piq)_2acac$ in chlorobenzene. All complexes exhibit an intense ligand $^1\pi$–π^* absorption band centered around 280–350 nm with a weak absorption band extending from 350 nm to the visible region, which is originated from the metal–ligand charge-transfer (MLCT). The PL spectrum of TBCPF:OXD-7 overlaps well with the MLCT absorption

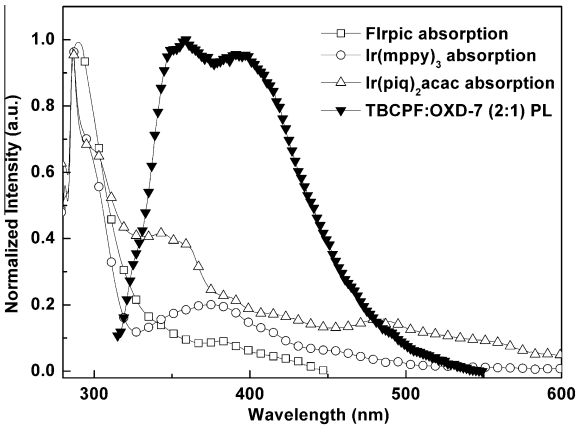

Fig. 4. The PL spectrum of TBCPF:OXD-7 film spun cast from chlorobenzene solution, absorption spectra of FIrpic, $Ir(mppy)_3$ and $Ir(piq)_2acac$ in chlorobenzene solution.

bands of FIrpic and $Ir(mppy)_3$, implying an efficient Förster energy transfer from host to FIrpic and $Ir(mppy)_3$. However, the MLCT absorption of $Ir(piq)_2acac$ is centered around 420–480 nm, which has almost no overlap with the emission spectrum of TBCPF:OXD-7, indicating the Förster energy transfer unlikely occur from the host to $Ir(piq)_2acac$. Moreover, comparing the PL spectra (Fig. 5) from the emission layers with the EL spectra (Fig. 2) of the corresponding devices, the relative intensities of the narrow band gap green and red dyes in EL spectra are both higher than those in PL spectra of films with the same concentration. It indicates that both energy transfer from host matrix to $Ir(mppy)_3$ and charge trapping in $Ir(mppy)_3$ may occur, just as the case of FIrpic in the same host matrix [20]. Charge trapping is regarded to be the dominant process for the formation of $Ir(piq)_2acac$ excitons because of inefficient Förster energy transfer between host and $Ir(piq)_2acac$. In addition, the fact that the host emission peaked at 380 nm was observed in PL but not in EL also supports the presence of charge trapping process in the dye-doped systems.

Fig. 6 gives room temperature time-resolved transient PL decays of the doubly-doped films. For the doubly-doped

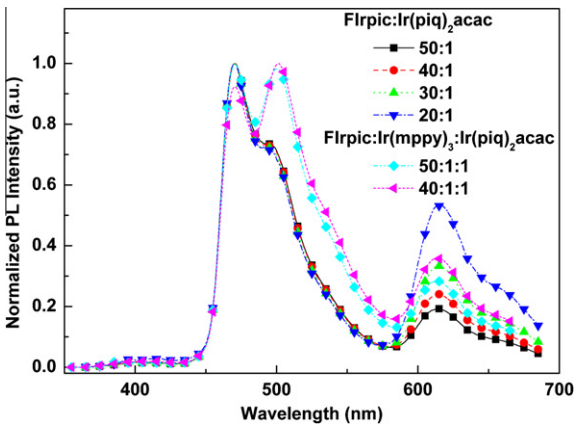

Fig. 5. PL spectra of the films with various ratios of dyes.

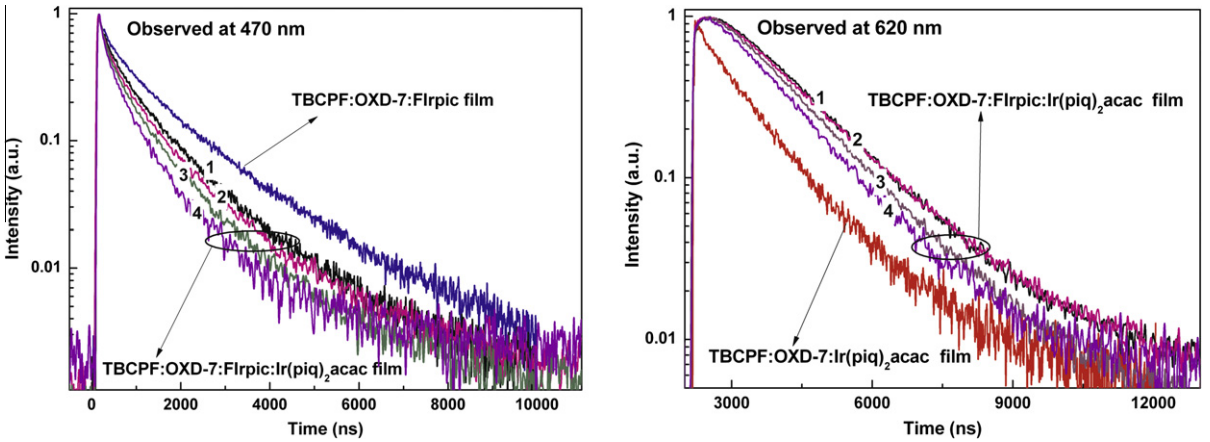

Fig. 6. Room temperature time-resolved transient PL decays for the doubly-doped films with various weight ratios. FIrpic: observed at 470 nm; $Ir(piq)_2acac$: observed at 620 nm. The weight ratios of FIrpic:$Ir(piq)_2acac$ are 50:1(1), 40:1(2), 30:1(3) and 20:1(4), respectively.

system (Fig. 6), the response of FIrpic in the film doped with FIrpic:$Ir(piq)_2acac$ is obviously shorter than that of the only FIrpic-doped film. Moreover, it becomes shorter with the relative weight ratio of $Ir(piq)_2acac$ increases. While the decay of $Ir(piq)_2acac$ in the film doped with FIrpic:$Ir(piq)_2acac$ is much slower than that of the only $Ir(piq)_2acac$-doped film. It means that energy transfer from the triplet of FIrpic to that of $Ir(piq)_2acac$ via Dexter energy transfer process occurs in the co-doped system. By comparing transient PL decays of the films with or without $Ir(mppy)_3$ (Fig. 7), it is noted that the decay of FIrpic in the triply-doped film is faster than that in the doubly-doped film, indicating the presence of Dexter energy transfer process from the triplet of FIrpic to that of $Ir(mppy)_3$. However, the response of $Ir(mppy)_3$ in the triply-doped film is shorter than that of the only $Ir(mppy)_3$-doped film, implying Dexter energy transfer also arises from $Ir(mppy)_3$ to $Ir(piq)_2acac$. Additionally, the decay of $Ir(piq)_2acac$ in the triply-doped film is faster than that in doubly-doped film, because the total Dexter energy transfer to $Ir(piq)_2acac$ decreases in the presence of $Ir(mppy)_3$. The efficient white emission could be attributed to the high triplet energy level of TBCPF and the full utilization of both singlet and triplet excitons.

4. Conclusions

In summary, highly efficient solution-processed single layer white-emitting OLEDs based on small molecules have been realized. For the devices with all-phosphorescent dopants, a maximum luminance efficiency of 20.8 cd A^{-1} and a maximum luminance of 26,600 cd m^{-2} were achieved. After a thin TPBI layer was inserted between the light-emitting layer and the cathode, the maximum efficiency of white emission was further improved to 29.6 cd A^{-1} (15.6 lm W^{-1}). The CIE coordinates of all white-emitting devices, which are all within or close to the white emission region, shift slightly with the variation of the bias voltage. The study on the origin of the white emission demonstrated that energy transfer from the host to the dyes via Förster or Dexter process, the energy transfer from the wide-gap dyes to the narrow-gap dyes via Dexter process, and charge trapping at the phosphorescent dyes all exist in the dye-doped systems. The simplicity of the device structure and the fabrication method, together with the high efficiencies observed, suggests that these white-emitting single layer WOLEDs fabricated by wet process based on small molecules are a promising candidate for low cost and high performance WOLEDs.

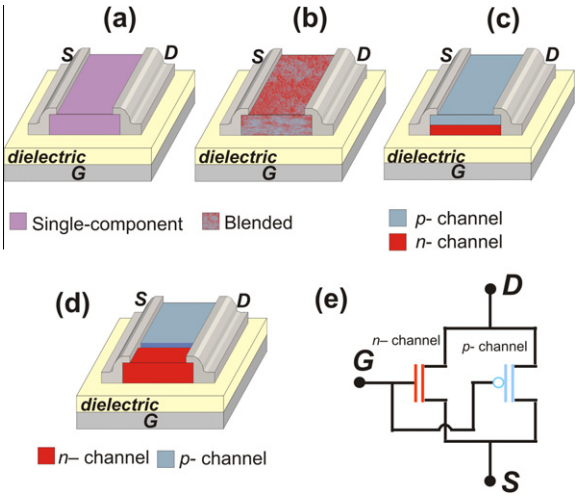

Fig. 1. (a) Ambipolar TFTs geometries: (a) single-component; (b) blended; (c) vertical bilayer; (d) co-planar. (e) Equivalent circuit of an ambipolar TFT with geometry (d) or in the limit of infinite recombination.

In previous ATFT geometries, with a shared channel aspect ratio, this requirement led to the stringent condition of finding a material or material combination with matched electron and hole mobilities. This condition constitutes a major barrier for the realization of ATFTs with balanced operation, particularly when following a hybrid organic–inorganic material approach.

Transparent transition metal-oxide semiconductors, such as ZnO and amorphous-IGZO (a-IGZO), are attractive because they can be processed at low temperatures on flexible substrates and have better electron mobility values and ambient shelf stability than their organic counterparts [9,10]. Amorphous-IGZO is a particularly attractive alternative to *n*-channel organic materials because despite its amorphous morphology, the isotropic nature of the metal *s* orbitals constituting the bottom of its conduction band leads to high electron mobility (10 cm^2/Vs) [9]. Oxide semiconductor-based ATFTs so far rely on the use of hybrid organic–inorganic structures with semiconductor channels vertically distributed (Fig. 1c) because *p*-channel oxide semiconductors that match the electrical performance and low processing temperatures of their *n*-channel counterparts are proving difficult to realize [11]. Such hybrid ATFTs, using pentacene and various metal-oxide semiconductors with vertically distributed channels, have recently been demonstrated [12,13]. However, they either show balanced mobilities during *n*- and *p*- mode operation, $\mu_{n\text{-}op}$, $\mu_{p\text{-}op}$ respectively, with low values in the range of 10^{-2} cm^2/Vs [12,13], or when higher mobility values have been reported ($\mu_{n\text{-}op}$ = 13.6 cm^2/Vs and $\mu_{p\text{-}op}$ = 0.16 cm^2/Vs), the difference in material properties has led to unbalanced ATFT operation [14]. Note that we refer to *p*- and *n*-mode operation to emphasize the fact that this refers to the way an ATFT is biased and not to transport characteristics of its channels.

In this work, we introduce co-planar channel geometry for the realization of ATFTs. Fig. 1d illustrates this geometry, wherein *n*- and *p*-channels, with different aspect ratio, are distributed horizontally without overlapping with each other. In the limit of an infinite recombination rate in the channel, ATFTs operate equivalently to *n*- and *p*-channel TFTs connected in parallel [15]. Fig. 1e shows the equivalent circuit in such a limit. The proposed ATFTs physically realize this geometry. Furthermore, in this geometry, the differences in electron (μ_e) and hole (μ_h) mobility, and threshold voltages are compensated by resizing the aspect ratio of the *n*- and *p*-channels. The absence of a *pn*-heterojunction removes potential problems associated with charge recombination, trapping, and control of the semiconductor morphology at this interface. We show that in this configuration, the number of regimes of operation of an ATFT are increasing from six [15] to eleven, and lead to ATFTs that achieve a high performance because the onset of operation for ambipolar behavior can be controlled. While a similar geometry has been reported in the past [16], a key difference of our approach is that channel resizing allows the implementation of ATFTs with a variety of materials regardless of their relative mobility. This removes a key barrier for the realization of high performance ATFTs since the high charge mobility and optimized performance of unipolar TFTs can be preserved. We demonstrate that the proposed approach leads to hybrid organic–inorganic ATFTs with a performance similar to that of unipolar TFTs, preserving high charge mobility and threshold voltages. Furthermore, despite the large difference in mobility between materials, these ATFTs achieve balanced *n*- and *p*-type operation.

2. Device fabrication and electrical characterization

We fabricated thin-film transistors with a bottom gate top electrode geometry on heavily *n*-doped silicon substrates (*n* + -Si) with a Ti/Au (20/200 nm) layer, deposited with a Kurt J. Lesker electron-beam (AXXIS e-beam) deposition system on the backside, to act as the gate electrode. A 200 nm-thick Al_2O_3 (Al_2O_3, ε_r = 9) layer grown by atomic layer deposition (ALD) (Savannah100, Cambridge Nanotech Inc.) served as the gate dielectric. The Al_2O_3 films were deposited at 110 °C using alternating exposures of tri-methyl-aluminum ($Al(CH_3)_3$) and H_2O vapor at a deposition rate of approximately 0.1 nm per cycle. Each deposition cycle (one monolayer) lasted 24 s, yielding a total deposition time of around 13 h for 2000 cycles [17]. Measurements of the capacitance of metal–insulator-metal (MIM) structures with geometry Au/Al_2O_3/Si/Ti/Au and with areas ranging from 1 to 5 mm^2 yielded a capacitance density of 40 nF/cm^2.

Non-overlapping pentacene (hole transport) and amorphous-InGaZnO (*a*-IGZO) (electron transport) channels horizontally distributed with different aspect ratios were fabricated on top of the Al_2O_3 gate dielectric as shown in the insets of Fig. 3. We deposited a 30 nm-thick *n*-channel *a*-IGZO (Ga_2O_3:In_2O_3:ZnO = 1:1:2 mol%) active layer by rf-sputtering through a shadow mask at room temperature using a power of 125 W, at a working pressure of 5 mTorr, in an O_2/Ar (1/10) atmosphere, and we annealed the devices at 275 °C for 25 min in air. Then, we deposited 50 nm of pentacene as a *p*-channel active layer using thermal evaporation at a deposition rate of 0.3 Å/s, with a

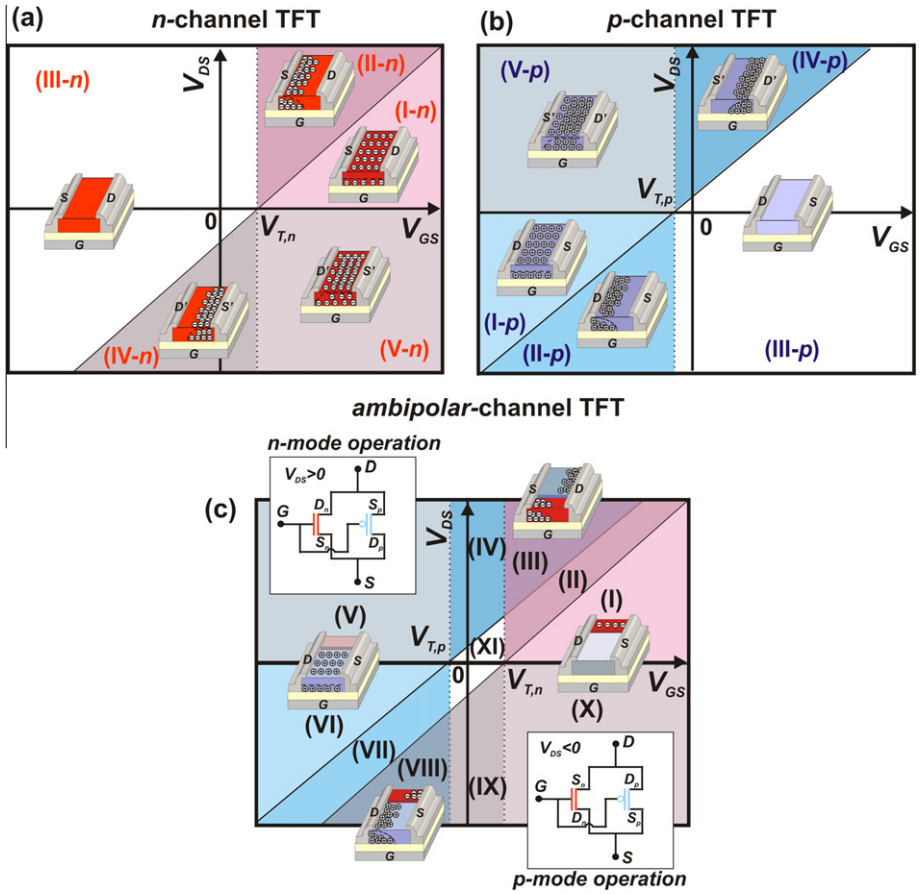

Fig. 2. Charge distributions and energy diagrams under five different regimes found during *n*-channel (a) and *p*-channel (b) operation of TFTs, respectively. (c) Equivalent circuit, 11 different operation regimes, and schematics of charge distributions found during ambipolar TFT operations.

substrate temperature of 25 °C, and at an initial pressure of 2×10^{-8} Torr. Prior to thermal evaporation, we purified pentacene using gradient zone sublimation. The horizontal channels had a channel length of $L = 180$ μm and channel widths of $W^p = 4000$ μm and $W^n = 400$ μm for the *p*- and *n*-channel, respectively. We fabricated independent unipolar pentacene and *a*-IGZO TFTs with the same geometry as reference. The channel width ratio of $W^n/W^p = 10$, was selected to compensate for: 1) differences in μ_e and μ_h; and 2) differences in the threshold voltage observed in unipolar devices.

Finally, we deposited a 50 nm-thick Au film through a metal shadow mask to define the top source/drain electrodes. Gold was used because it provides a similar charge injection energy barrier of $\sim$ 0.6 eV for the injection of holes into pentacene and electrons into *a*-IGZO [18,19]. In ATFTs with a co-planar geometry, further optimization of the injection characteristics can easily be achieved by selecting suitable metals for the source and drain electrodes of each channel. The samples were transferred in a vacuum-tight vessel, to avoid air exposure, into a nitrogen glove box (O_2, $H_2O < 0.1$ ppm) for electrical testing. The output characteristics (drain current I_{DS} vs. drain-source voltage V_{DS} at multiple constant gate-source voltages V_{GS}) and transfer characteristics (I_{DS} vs. V_{GS} at fixed V_{DS}) of the TFTs were measured using an Agilent E5272A medium-power source/monitor unit connected to a probe station.

3. Operation of ambipolar thin-film transistors

Holes, electrons or both can dominate the current flowing through an ATFT depending on the electrical bias across the channel. In the literature, six different regimes have been identified in the operation of an ATFTs by assuming a single threshold voltage for *n*- and *p*-type operation [15]. However, assuming a single V_T is in general not a good approximation for two unipolar TFTs operating in parallel.

In the most general case, the threshold voltage of the *n*-channel ($V_{T,n}$) and *p*-channel ($V_{T,p}$) can be expected to be different. The implications of such a change are better understood by reviewing the operation of unipolar TFTs. Fig. 2a shows the five regimes of operation of an unipolar *n*-channel TFT. For positive V_{DS} values the current varies linearly with V_{DS} if $0 < V_{DS} < V_{GS} - V_{T,n}$ (regime I-*n*), and saturates if $0 < V_{GS} - V_{T,n} < V_{DS}$ (regime II-*n*). These regions are divided by the pinch-off condition defined as $V_{DS} = V_{GS} - V_T$ and represented by the diagonal line in Fig. 2a. If $V_{GS} - V_T < 0$ (regime III-*n*), the TFT is off because the barrier for

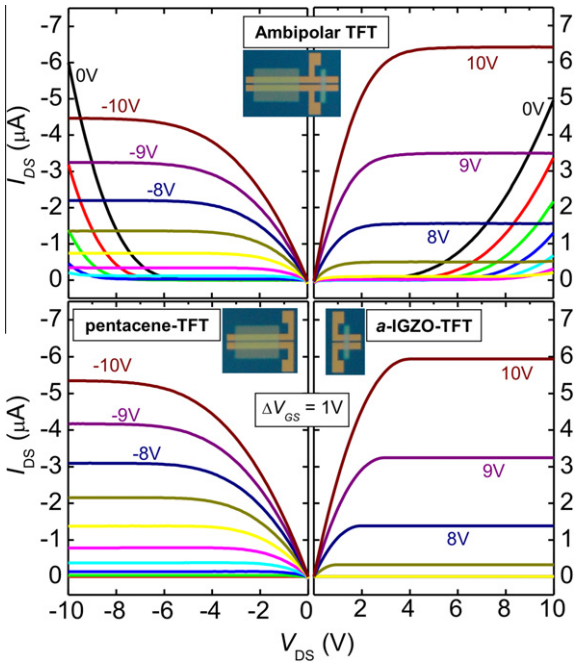

Fig. 3. Comparison of output characteristics of ambipolar TFTs during *p*-mode and *n*-mode operation with corresponding unipolar *p*-channel (pentacene) TFT and *n*-channel (*a*-IGZO) TFT output characteristics. Insets show pictures of the devices.

electron injection from either electrode increases as $V_{GS} - V_T$ becomes increasingly negative. If now we apply a negative V_{DS}, the driving force for electron injection at the drain is larger than at the source electrode. Under this condition, electron currents can flow from the drain to the source. Since the terms drain and source are relative to the direction of current flow, the roles of source and drain are reversed. Therefore, an *n*-channel TFT biased at $V_{DS} < 0$ is being referred to as operating in reverse mode. In reverse mode operation, $S = D'$, and $D = S'$, where the primes denote the effective role played by that electrode. Considering that the source electrode remains grounded, $V_S = 0$ V, the main consequence of this change is that a change in $V_{DS} = V_D - V_S = V_D = V_{S'}$ leads to a simultaneous change of $V_{GS'}$ and $V_{D'S'}$. This implies that for an *n*-channel TFT that follows the square-law model, the current–voltage equations in reverse mode are given by:

$$I(V_{DS} < V_{GS} - V_{Tn} < 0) \propto -(V_{GS'} - V_{Tn})^2 = -(V_{GD} - V_{Tn})^2, \quad (1)$$

$$I(V_{DS} < 0 < V_{GS} - V_{Tn}) \propto -(V_{GS'} - V_{Tn})V_{D'S'} + V_{D'S'}^2 = (V_{GD} - V_{Tn})V_{DS} + V_{DS}^2. \quad (2)$$

These equations describe the current–voltage characteristics of regimes IV-*n* and V-*n*, respectively. If $V_{GS} - V_{T,n} < V_{DS} < 0$, the TFTs remains off (regime III-*n*) due to the large barrier for electron injection at the drain and source electrodes. Fig. 2b shows the analogous five regimes of operation for a *p*-channel TFT.

In the most general case, the current–voltage characteristics of an ATFT arise from the linear superposition of the five operating regimes of its unipolar channels due to its parallel circuit configuration. Fig. 2c shows the eleven operating regimes that result from such a superposition. The key difference provided in this configuration with respect to the previous descriptions of ambipolar TFT behavior, is that two additional regimes exist, regime II (intersection of II-*n* and III-*p*) and VII (intersection of II-*p* and III-*n*), where unipolar currents can reach saturation in one channel without experiencing significant "leakage" currents from the other channel. By displacing the onset of ambipolar operation, regime III (intersection of II-*n* and IV-*p*) and VII (intersection of II-*p* and IV-*n*), a co-planar channel geometry leads to the possibility of controlling the "leakage" currents in ATFTs if the threshold voltages are tailored independently. Note that if $V_{T,n} = V_{T,p}$, the six regimes of operation for an ATFT commonly described in the literature are recovered.

4. Co-planar channel ATFTs

Fig. 3 shows the output characteristics of hybrid ATFTs and of unipolar pentacene and *a*-IGZO TFTs. The relatively high gate-dielectric capacitance density allows all TFTs to reach saturation at low V_{DS}. The drain-source currents (I_{DS}) measured in ATFTs yield values similar to those measured in unipolar TFTs. In contrast with unipolar TFTs, for $V_{GS} < V_{T,n(p)}$ and at large V_{DS}, I_{DS} increases due to "opposite" carrier electron ($-3\text{ V} < V_{GS} < 0$) and hole currents ($0 < V_{GS} < 5$ V) that arise in reverse mode operation. As previously mentioned, the appearance of these "leakage" currents is directly related with the values of the threshold voltages for the *n*- and *p*-channels $V_{T,n(p)}$. As V_{GS} is increased above threshold, I_{DS} monotonically increases due to unipolar operation (regimes I and VI) until it reaches saturation (regimes II and VII) when $|V_{GS} - V_{T,n(p)}| < |V_{DS}|$. Due to channel resizing, the on-currents for the *p*- and *n*-mode operation are well-balanced. Furthermore, since in the saturation regimes II and VII, only one channel remains active in the ATFT, the current–voltage characteristics are nearly identical to those of unipolar TFTs, with no "opposite" carrier contributions even at large $|V_{DS}|$ values.

Fig. 4a shows the overlapping hysteresis transfer characteristics for ATFTs at different values of V_{DS} below saturation. At $|V_{DS}| = 0.5$ V, the transfer characteristics of ATFTs are due to single carrier charge transport in the operating regimes I and II for *n*-mode operation, VI and VII for *p*-mode operation and the regime XI where both channels remain off. This allows the on–off current ratio (I_{on-off}) to approach 10^5 at $|V_{DS}| = 0.5$ V as shown in Fig. 4a. In these regimes the field-effect mobility (μ_{FE}) can be determined through the transconductance, g_m, using the following equation:

$$g_m = (\partial I_{DS}/\partial V_{GS})|_{V_{DS}=\text{small}} = (\mu_{FE}\,\varepsilon_0\,\varepsilon_r\,WV_{DS})/(Ld) \quad (3)$$

where W is the channel width, L is the channel length, ε_0 is the free-space permittivity, ε_r is the dielectric constant of the gate insulator, and d is the thickness of the gate insulator. Fig. 4b shows a direct comparison of the field-effect

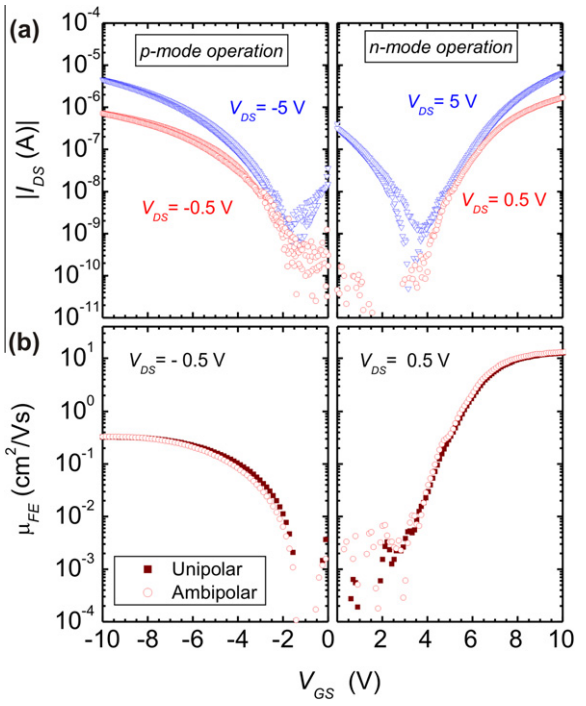

Fig. 4. (a) Hysteresis transfer characteristics at low V_{DS} measured in ambipolar TFT during *p*-mode and *n*-mode operation. (b) Comparison of the field-effect mobility measured in an ambipolar TFT during *p*-mode and *n*-mode operation with that measured on *p*-channel (pentacene) TFT and *n*-channel (*a*-IGZO) TFT in the linear regime.

mobility values (μ_{FE}) in ATFTs and unipolar TFTs. Unlike previous approaches, the values of μ_{FE} found in ATFTs equal those in their unipolar counterparts with values approaching $\mu_{p\text{-}op} = \mu_h = 0.3$ cm^2/Vs and $\mu_{n\text{-}op} = \mu_e = 10.5$ cm^2/Vs. Within the resolution of our setup, all parameters between ATFTs and unipolar TFTs are identical in this regime. Close to saturation, at 5 V, I_{on-off} approaches 10^4 despite the increase of the off-currents due to ambipolar operation in regimes III and VIII. Fig. 5 shows that at larger values of $|V_{DS}|$, the I_{on-off} in ATFTs is further reduced due to "opposite carrier" contributions in the ambipolar regimes. This is a typical signature of ATFTs and is expected even if, as in this case, the individual channels of the ATFT show a performance similar to that of unipolar TFTs. However, Fig. 5 also shows that for large enough values of V_{GS}, the values of I_{DS} in these ATFTs rapidly converge to the values found in unipolar TFTs. Since around pinch-off ($|V_{DS}| = |V_{GS} - V_{T,n(p)}|$) the ATFT is expected to operate like a unipolar TFT, the source-to-drain current for both unipolar and ambipolar TFTs can be approximated by:

$$I_{DS} = \frac{\mu \varepsilon_0 \varepsilon_r W}{2Ld}(V_{GS} - V_{T,n(p)})^2, \quad (4)$$

where μ is the effective saturation mobility, and $V_{T,n(p)}$ is the effective threshold voltage. A summary of the parameters extracted through a fitting procedure using Eq. (4) is found in Table 1. Although in the linear regime the output and transfer characteristics of these ATFTs show nearly identical performance with respect to unipolar TFTs, in saturation, I_{on-off} values are reduced due to ambipolar operation. However, the effective mobility, threshold voltages and values of I_{DS} are similar to the ones measured in unipolar TFTs.

5. Conclusion

In conclusion, we proposed a co-planar channel geometry for the realization of high performance ambipolar TFTs. Using non-overlapping horizontal channels of pentacene and *a*-IGZO we demonstrated hybrid organic–inorganic ambipolar TFTs with channels that show electrical

properties comparable to those found in unipolar TFTs with the same channel aspect ratios. By retaining key parameters of the electrical performance of unipolar TFTs, this geometry can easily be implemented with other material platforms, and may be particularly useful for printable materials. From a materials perspective, this work shows that future breakthroughs in performance of unipolar *n*-channel and *p*-channel semiconductors could directly transposed into ambipolar transistors and circuits. We expect that this geometry will provide new strategies for the realization of high performance ambipolar TFTs and novel ambipolar microelectronic circuits.

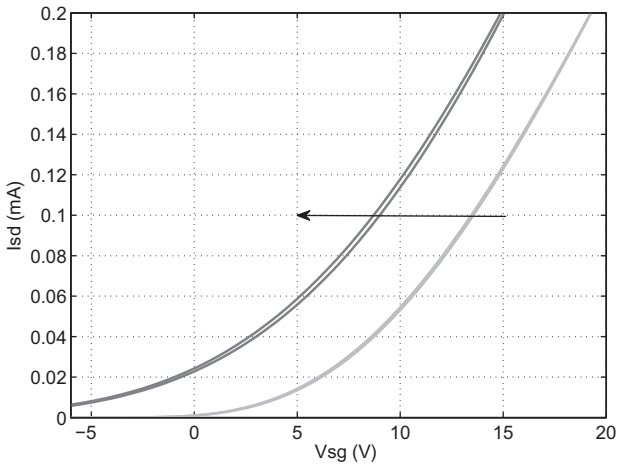

Fig. 1. Effect of bias stress on the transfer curve. The stress conditions are $V_{SG} = V_{SD} = 15$ V, for 24 h under ambient conditions, i.e., with exposure to O_2, H_2O, light and temperature fluctuations. The effect is mainly a V_t shift.

design strategy for technologies with p-OTFTs only is presented.

The second most important technological issue for analog circuit design is the shift of the mean threshold voltage (V_t) value. This V_t shift can have different causes. Run-to-run variations at production-time can result in a shift of the mean V_t value. Moreover, bias stress as well as trapping caused by water and oxygen occur at run-time and cause V_t shift over time. Bias stress in organic semiconductors follows from carrier trap states at the dielectric–semiconductor interface or in the dielectric that compensate for the applied electric field [10,11]. Bias stress can be exacerbated by the presence of water and oxygen molecules at the semiconductor, as well as by light [12–14]. The effect of oxygen is explained by chemical reaction with the pentacene molecule, according to Refs. [15,16]. Other Refs. [17,18] explain the behavior by diffusion of O_2 in the pentacene. Bias stress at negative V_{SG} (with the pentacene transistor in the off-state or mild electron accumulation) is faster and more degrading than bias stress at positive V_{SG} (transistor in on-state with hole accumulation) [11]. As can be seen in Fig. 1, our measurements confirm that V_t shifts over several volts when the transistor is biased in the O_2- and H_2O-containing ambient environment, where also light and temperature changes are present. From this figure it can be concluded that V_t shift is a very important and hardly predictable effect to deal with when designing analog circuits.

A third technological effect that needs to be considered for circuit design is mobility (μ) variation. A certain variation of mobility is present on wafer as well as from run-to-run. Moreover, mobility degradation occurs when transistors are biased or exposed to ambient environment, containing O_2 and H_2O, for long time [19]. Mobility variation influences the current through a transistor. In a main amplifier and assuming that all transistors undergo the same mobility change, this effect results in a bandwidth variation only. As the current through each transistor varies linearly with the mobility, the DC behavior of the circuit is not affected. Mobility variation becomes an issue when transistors are biased in the linear region as resistors, i.e. as a resistor in an RC integrator. Then the exact value of R is important for the RC product. In general, μ variation is to first instance of less importance for basic analog design than V_t shift.

A fourth important drawback of the technology is the mismatch between V_t of different transistors, resulting from on-wafer variations. Despite certain variability over

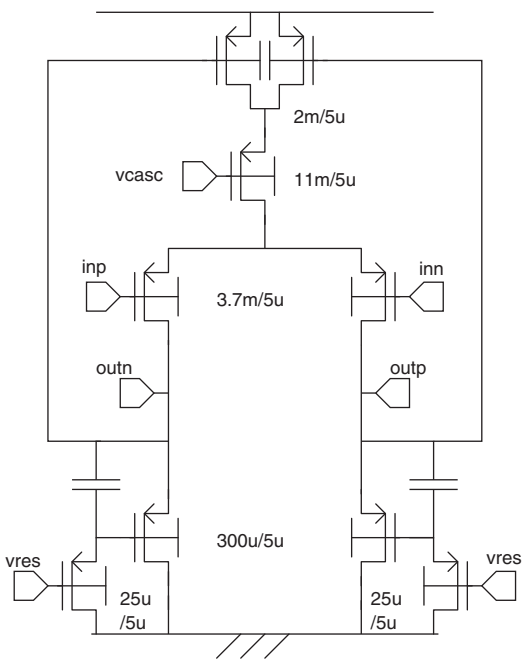

Fig. 2. Proposed schematic of the single-stage differential amplifier with p-type load, bootstrapped gain enhancement, CMFB, cascoding and backgate steering.

the full wafer, adjacent transistors show a satisfying likeliness [1]. Therefore special attention is required for the placement and lay-outing of transistors. Furthermore it is also very important to reduce mismatch sensitivity during the circuit design.

The applied pentacene-based technology [1,2] with three metal layers provides p-type organic bottom-gate thin-film transistors (p-OTFT) with typical length of 5 μm and metal–organic insulator–metal capacitors. The substrate for this technology is a plastic foil.

3. Design strategy and simulation

The presented design strategy is adapted to the limitations of the technology, starting with the unavailability of n-OTFTs. Therefore solutions must be found for replacing n-type load transistors. Moreover, as discussed above, V_t shift over time as well as μ shift and mismatch have to be considered in the design strategy. This work focuses on the design of a single-stage differential amplifier and improves a basic differential pair with four techniques, applying bootstrapped gain enhancement, linear common-mode feedback, backgate steering and cascoding. Fig. 2 gives the schematic of the presented single-stage amplifier.

As no n-OTFTs are available, p-OTFTs are applied as load transistors. Two straightforward options are shown in Fig. 3a and b. The gate of the load p-OTFT can be connected to the drain, resulting in a diode load with the load transistor biased in saturation region, or to the source, hence be biased in cut-off region. The diode-connected load scores better for higher BW and is less sensitive to V_t shift over time whereas the cut-off load implies higher input–output gain but is sensitive to leakage current variations. A bootstrapped gain enhancement technique, shown in Fig. 3c, adds a high-pass filter with very low 3 dB frequency from source to gate. This technique combines the advantages,

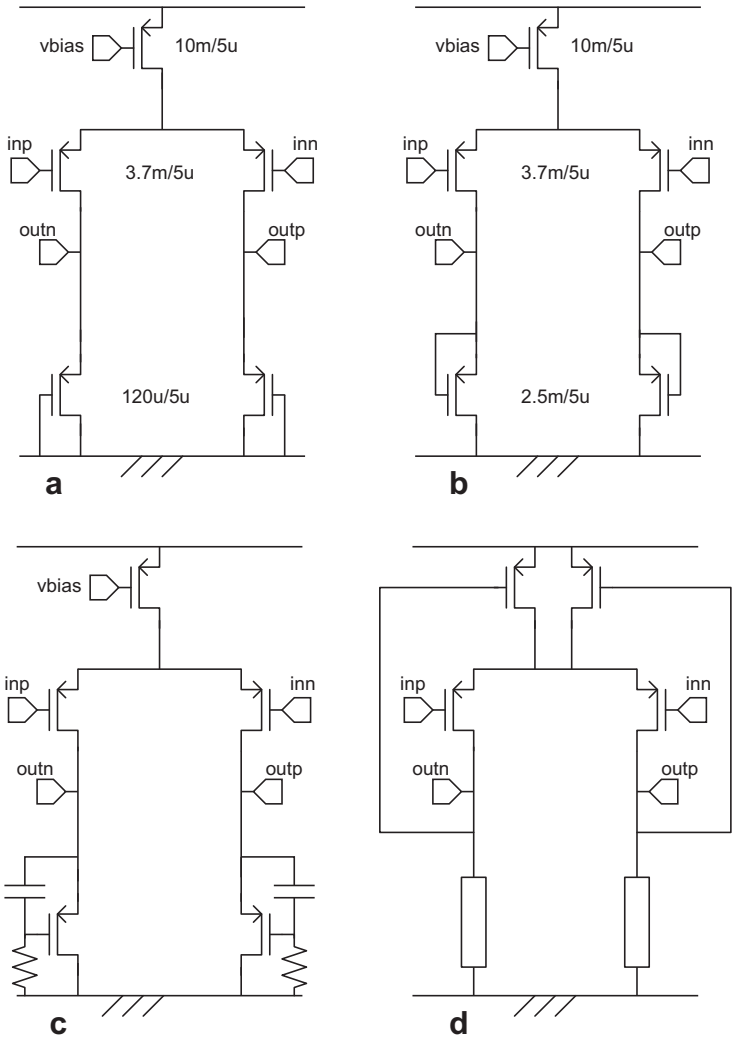

Fig. 3. Differential pairs with (a) a diode-configuration load, with device dimensions as in simulation, (b) a cut-off configuration load, with device dimensions as in simulation, (c) bootstrapped gain enhancement and (d) linear common-mode feedback.

low V_t-sensitivity and high gain, in one load topology. Compared to diode loads the gain is now increased, due to bootstrapping of the transimpedance. Compared to cut-off loads, the sensitivity to V_t and leakage current is reduced due to higher overdrive biasing. However, V_t mismatch still causes current difference in the branches, degrading offset, CMRR, and gain. Also, higher gain of 'bootstrapped' loads compared to diode loads causes worse offset and linearity from input pair V_t mismatch. Nevertheless this topology is an expedient trade-off between the diode and cut-off loads. The price paid for this trade-off is the low-frequent pole of the high-pass filter. By pushing it to very low frequencies, its influence is neutralized. In this work the high-pass filter is implemented with a metal–insulator–metal capacitor and a transistor in (deep) cut-off region with the gate off-chip tunable as the resistor.

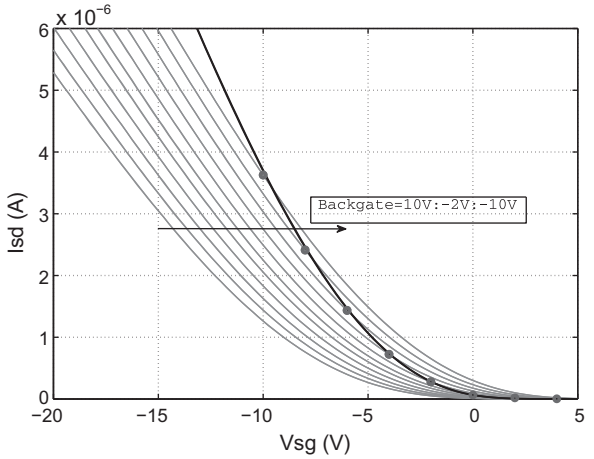

Fig. 4. Measured V_G–I_D-curves for a varying voltage applied to the backgate of the transistor. The black curve shows the measured behavior when gate and backgate are connected.

Therefore a 3 dB-point lower than 50 mHz is obtained by tuning this cut-off resistor.

The input differential pair is biased with small $V_{SG} - V_t$. To reduce their mismatch sensitivity a linear common-mode feedback (CMFB) circuit is applied. This circuit technique is shown in Fig. 3d. It applies a feedback loop and therefore overcomes common-mode input signals and stabilizes the DC output voltage. V_t shift in the presented differential amplifier influences mostly the differential pair. V_t shift over time can thus be modeled as a common-mode input effect. Therefore this technique reduces again V_t-sensitivity of the circuit. Measurements show that the CMRR for the presented topology is 12 dB.

The cascode transistor influences the CMFB loop gain slightly positively. Its effect is limited since the lowest resistance at the virtual ground node is seen through the sources of the differential input pair.

In our technology, the transistors can be designed to have two gates, i.e., the thin-film semiconductor is located between two dielectrics, and metal layers can be defined on each side to operate as gates [20]. The bottom-gate is the nominal gate. The top-gate is a backgate. We can use steering of the backgate to our advantage, to shift the threshold voltage of the transistor V_G–I_D transfer characteristics of the nominal gate. V_t shifts almost linearly by 350 mV/V applied to the backgate, as can be seen in Fig. 4. When this backgate is now connected to the gate of the transistor, the V_G–I_D behavior becomes steeper and therefore results in a higher g_m. An additional advantage of the backgate, physically located on top of the pentacene thin-film, is that it acts as encapsulation that shields the semiconductor from air, providing better air-stability of V_t and μ.

Simulations are performed to compare the behavior of the topology, proposed in this work, against the initial topologies in Fig. 3a and b, for two separate cases: The effect of an overall V_t shift for all the transistors and the effect of V_t mismatch in one load transistor. The

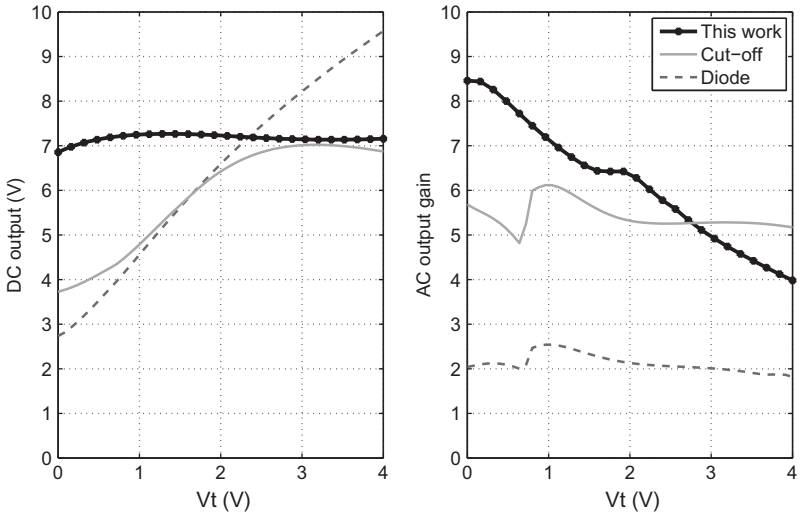

Fig. 5. Simulated effect of an equal V_t shift in all transistors for the cut-off load topology, diode load topology and for the topology described in this work. The DC common-mode output voltage (left) and the AC differential-mode output gain (right).

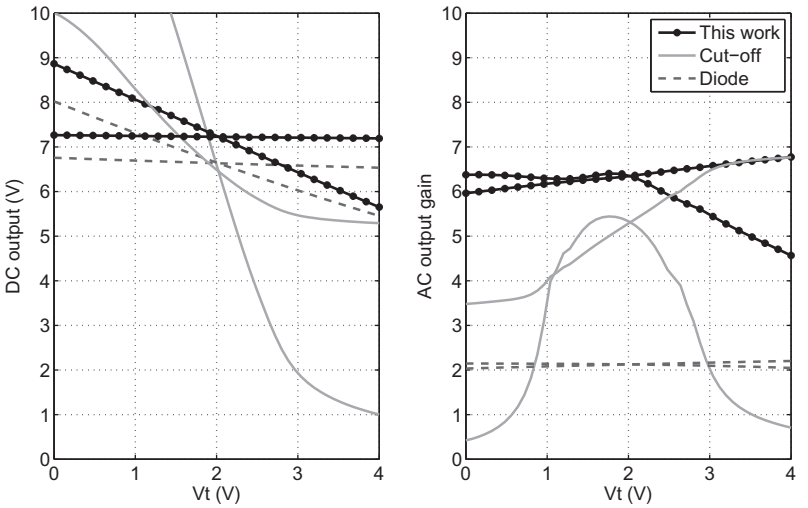

Fig. 6. Simulated effect of a V_t shift of one load transistor for the cut-off load topology, diode load topology and for the topology described in this work. The DC output node voltages (two per topology) (left) and the differential-mode output node AC gains (right).

simulations are carried out for a 15 V supply voltage and with the transistor sizes given in the figures. All three topologies were simulated with the backgate steering technique. Fig. 5 shows the effect of an overall V_t shift for all transistors. The figure shows that the DC output of the diode-connected load is very sensitive to this type of variations. This is due to the unbalanced effects of V_t on the input pair (low $V_{GS} - V_t$) and on the load transistors (high $V_{GS} - V_t$). The cut-off load topology is flat in a small region but becomes, for the same reason, equally sensitive as the diode load when V_t goes below 2 V. For large shifts of V_t the presented topology performs the best due to the bootstrapping technique and CMFB. The AC plot on the right panel shows that the AC behavior of the presented topology is higher but varies the most. This is explained by the varying current when CMFB loop resettles the output voltage. Fig. 6 shows the effect on the (differential) output node voltages of mismatch on the load transistors. The cut-off load is very sensitive to V_t mismatch, both in DC and AC behavior, since the currents in the branches are very sensitive to V_t mismatch. Therefore different currents will flow in the branches and cut-off load is therefore unwanted. Both other topologies perform well, as their currents are less sensitive to V_t mismatch, yet the CMFB topology reaches much higher gain. Globally, we prefer the CMFB topology, as we favor a circuit with a known and reliable DC behavior with as much as possible gain.

4. Measurement results

The measurement results of the single-stage amplifier are presented in Fig. 7. It shows the AC behavior of the pristine single-stage amplifier and after 4 months shelving and then DC biasing it for 10 days at a 15 V supply voltage, both in ambient environment. We can distinguish two different effects on the AC gain curve. The band pass gain decreases as a result of the V_t shift that was discussed above. This decrease amounts only to 4 dB, which is quite moderate.

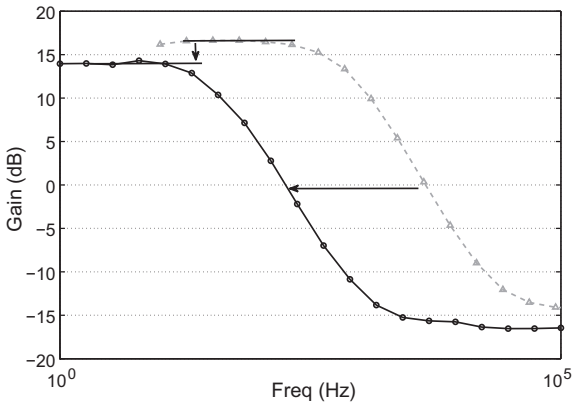

Fig. 7. Gain curve for pristine amplifier (gray) and after 4 months shelved in air followed by continuous biasing for 10 days at 15 V supply voltage in ambient (black). The gain and the bandwidth decrease as a result of V_t shift and μ degradation. By applying analog techniques the gain decrease is limited to only 4 dB.

Furthermore, the bandwidth is reduced owing to the mobility degradation while being shelved and biased in the presence of O_2 and H_2O mentioned in Section 2. Finally, as a measure for the distortion the IP3 interception point in this differential amplifier after degradation is measured to be 18 dB V.

5. Conclusion

We discuss the challenges for analog design in pentacene technology and present a strategy for V_t-insensitive design. The strategy was applied to a single-stage differential amplifier. It applies CMFB, bootstrapped gain enhancement, cascoding and backgate steering and reduces the V_t-sensitivity of the circuit. The circuit performs with 18 dB gain. After 4 months of storing and 10 days of

stressing at a 15 V supply voltage, both in ambient environment, the DC output does not change significantly and AC gain degrades only by 4 dB. We conclude that such robust design of analog circuits will enable the design of organic AD converters that are applicable for organic smart-sensor systems.

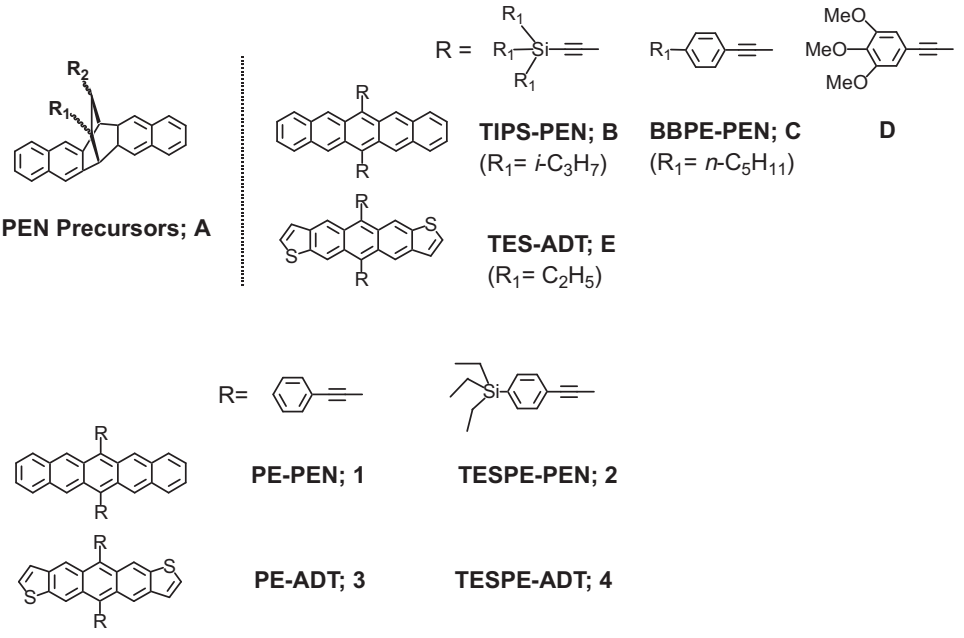
cessable p-channel triethylsilylethynyl **ADT** derivative (**TES–ADT; E**) with a mobility as high as 1.0 $cm^2/V\,s$ was reported by Jackson and co-workers [9]. Meanwhile, trimethoxyphenylethynyl-substituted **PEN** and **ADT** (**D**) derivatives have also been reported with relatively low carrier mobility from solution-processed films [10]. All of these studies demonstrated that ethynyl/phenyl substituents on the **PEN**/**ADT** cores significantly influence the solid state electrical performance [11]. Presumably, more conjugated phenyl groups connected to the ethynyl group might be expected to further enhance self-assembly of the aromatic moieties into closely π-stacked arrays, therefore improving intermolecular orbital overlap and the resulting device performance. To prove this postulation, four solution-processable **PEN** and **ADT** derivatives (**1**–**4**) bearing phenylethynyl and triethylsilylphenylethynyl substituents were synthesized, characterized, and incorporated in OTFTs. From the single-crystal X-ray diffractions and film morphologies of these four compounds, it has been clearly seen that both substituents did strongly affect the intermolecular stacking of these new derivatives. With the bulky triethylsilyl (TES) moiety appended to the phenylethynyl group, the molecular packings of compounds **2** and **4** via X-ray analysis were peculiarly engaged in 2-D "slipped-crossed" stacking to accommodate the bulky TES groups, which were very different from those of compounds **1** and **3**, and therefore, substantially directed their electronic performance fabricated via drop-casting (*vide infra*).

2. Experimental section

2.1. Materials and methods

All chemicals and solvents used in this work were of reagent grade and were obtained from Aldrich, Arco, or TCI Chemical Co. Reaction solvents (toluene, benzene, ether, and THF) were distilled under nitrogen from sodium/benzophenone ketyl, and halogenated solvents were distilled from CaH_2. ^1H and ^{13}C NMR spectra were recorded on a Bruker 500 or a Bruker DRX-200 instrument. Differential scanning calorimetry (DSC) was carried out on a Mettler DSC 822 instrument at a scan rate of 10 K/min. Thermogravimetric analysis (TGA) was performed on a Perkin–Elmer TGA-7 thermal analysis system using dry nitrogen as a carrier gas at a flow rate of 40 mL/min. The optical absorption and fluorescence spectra were obtained using JASCO V-530 and Hitachi F-4500 spectrometers, respectively, and all spectra were measured in a specified solvent at room temperature. The IR spectra were obtained using a JASCO FT/IR-4100 spectrometer. Differential pulse voltammetry experiments were performed using a CH Instruments/CHI621C Electrochemical Analyzer. All measurements were carried out at the temperatures indicated with a conventional three-electrode configuration consisting of a platinum disk working electrode, an auxiliary platinum wire electrode, and a non-aqueous Ag reference electrode. The supporting electrolyte was 0.1 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$) in a specified dry solvent. All potentials reported were referenced to an Fc^+/Fc internal



standard (at +0.6 V). Elemental analyses were performed on a Heraeus CHN-O-Rapid elemental analyzer. Mass spectrometric data were obtained with a JMS-700 HRMS instrument. Prime grade silicon wafers (p^+-Si) with ~300 nm (±5%) of thermally grown oxide (from Montco Silicon) were used as device substrates.

2.2. Synthesis

2.2.1. Synthesis of 6,13-bis(phenylethynyl)pentacene (*PE-PEN*; *1*)

The procedure was reported in the literature [12]. ^{1}H NMR (200 MHz, $CDCl_3$): δ 9.32(s, 4H), 8.08(dd, J = 6 Hz, 3 Hz, 4H), 7.93(dd, J = 8 Hz, 1 Hz, 4H), 7.55–7.41(m, 10H). Deep blue crystals suitable for X-ray diffraction were crystallized by slow diffusion of hexane into a xylene solution of compound **1**. The molecular structure of **1** was confirmed by X-ray diffraction and is shown in Fig. 4 below (cif file of 1 is in SI).

2.2.2. Synthesis of 4-triethylsilylphenyl acetylene (*5*) [13]

As shown in Scheme 1, under nitrogen, 35.6 mL of 2.5 M *n*-BuLi (in hexane, 0.089 mol) was slowly added to a 100 mL dry ether solution of 1,4-dibromobenzene (20 g, 0.085 mol) at −50 to −30 °C, and the mixture was then stirred at 0 °C for 1 h. Next, 15.1 mL of chlorotriethylsilane (0.085 mol) was slowly added to the above mixture and stirring was continued for 8 h. Water was then added to the reaction mixture, and the organic layer was collected. After solvent evaporation, the desired oily 1-bromo-4-triethylsilylbenzene was purified by distillation at 110 °C/0.02 Torr giving 21.7 g of product (94% yield). ^{1}H NMR ($CDCl_3$): δ 7.47(d, J = 8 Hz, 2H), 7.33(d, J = 8 Hz, 2H), 0.96(t, J = 8 Hz, 9H), 0.78(q, J = 8 Hz, 6H).

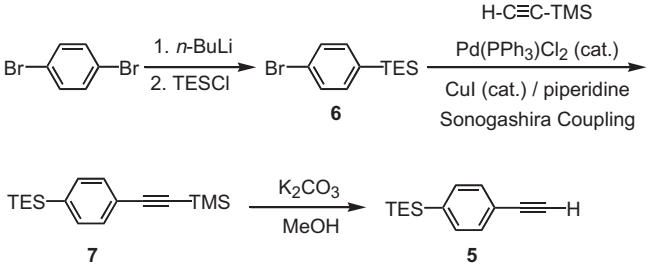
Under nitrogen, a mixture of dry 1-bromo-4-triethylsilylbenzene (2.0 g, 7.4 mmol), $Pd(PPh_3)_2Cl_2$ (0.103 g, 0.15 mmol), CuI (56 mg, 0.3 mmol), and 15 mL of dry piperidine was stirred at 0 °C for 10 min, and then trimethylsilylacetylene (1.58 mL, 11 mmol) was added to the mixture. The mixture was then stirred at 80 °C for 18 h. After cooling to room temperature, the solvent was removed under vacuum, and a methanol (20 mL) solution of K_2CO_3 (3.07 g, 22.2 mmol) was added to the mixture and stirring was continued at room temperature for 2 h. The methanol was then removed under vacuum, and the organic product was extracted with hexane and then filtered through a Celite flash column. The concentrated crude product was finally purified via chromatography (silica gel; hexane as the eluent) giving 1.36 g of desired oily product (85% yield). ^{1}H NMR($CDCl_3$): δ 7.46–7.45(m, 4H), 3.09(s, 1H, C–H), 0.95(t, J = 8 Hz, 9H), 0.79(q, J = 8 Hz, 6H).

2.2.3. Synthesis of 6,13-(4-triethylsilylphenylethynyl)-pentacene (*TESPE–PEN*; *2*)

Under nitrogen, 2.5 mL of 2.5 M *n*-BuLi (in hexane, 6.25 mmol) was slowly added to a 20 mL THF solution of 4-triethylsilylphenylacetylene (1.24 g, 5.7 mmol) at 0 °C, and the mixture was stirred at 60 °C for 3 h. The resulting black-brown lithium phenyl acetylide solution was then transferred to a dry THF (50 mL) solution of pentacen-6,13-dione (0.3 g, 1.0 mmol) at 0 °C, and the mixture was refluxed for 12 h. After cooling to room temperature, 5 mL of water was added into the reaction mixture and a deoxygenated $SnCl_2$ (3 g, 15.7 mmol)/HCl (5 mL, 10%) solution was added to the reaction and stirring was continued at room temperature for 3 h. Water was added to the reaction mixture and the organic layer was collected and purified by chromatography (silica gel; hexanes as the eluent) and recrystallization from hexane, giving 39 mg of blue solid (5.6% yield). ^{1}H NMR (200 MHz, $CDCl_3$): δ 9.29(s, 4H), 8.04(m, 4H), 7.87(d, J = 8 Hz, 4H), 7.65(d, J = 8 Hz, 4H), 7.41(m, 4H), 0.91(t, J = 8.0 Hz, 18H), 0.85(q, J = 8.0 Hz, 12H). Deep green crystals suitable for X-ray diffraction were crystallized by slow evaporation of an ether solution of compound **2**. The molecular structure of **2** was confirmed by X-ray diffraction and is shown in Fig. 6 below (cif file of 2 is in SI).

2.2.4. Synthesis of 5,11-bis(phenylethynyl)anthradithiophene (*PE-ADT*; *3*)

Under nitrogen, 7.6 mL of 2.5 M *n*-BuLi (in hexane, 0.019 mol) was slowly added to a 20 mL dioxane solution of phenylacetylene (1.95 g, 0.019 mol) at 0 °C, and the mixture was stirred at room temperature for 1 h. The resulting black-brown solution was transferred to a dry dioxane solution (30 mL) of anthradithiophene-5,11-dione [4a] (0.306 g, 0.96 mmol) at 0 °C, and then the mixture was refluxed for 4 h. After cooling to room temperature, 0.5 M NH_4Cl solution (50 mL, 0.25 mol) was added to the reaction mixture, and the organic layer was collected. Hexane was then added to the collected solution to precipitate green-brown 5,11-dihydroxy-5,11-bis(phenylethynyl) anthradithiophene (0.28 g, 54% yield). ^{1}H NMR (200 MHz, $CDCl_3$):



Scheme 1. Synthesis of 4-triethylsilylphenyl acetylene 5.

δ 8.79(s, 2H), 8.73(s, 2H), 7.76–7.72(m, 4H), 7.56(d, J = 5 Hz, 2H), 7.47–7.35(m, 8H), 4.33(t, J = 5 Hz, 2H, OH).

Under nitrogen, a deoxygenated acetic acid (7.5 mL, 50%) solution of $SnCl_2$ (8.4 g, 0.044 mol) was added to the above dioxane solution (45 mL) of 5,11-dihydroxyl-5,11-bis(phenylethynyl)anthradithiophene (0.28 g, 0.53 mmol), and the mixture was stirred at room temperature for 2 h. Next, water was added to the resulting pink-red solution and the resulting purple precipitate was collected by filtration and washed with ether and hexane. The product was further purified via recrystallization from *p*-xylene giving 0.12 g of the product (46% yield). ^{1}H NMR (200 MHz, $CDCl_3$): δ 9.23(s, 2H), 9.17(s, 2H), 7.87–7.84(m, 4H), 7.57–7.47(m, 10H). MS (FAB) (*m*/z) calcd. for $C_{34}H_{18}S_2$: 490 (M^+), Found: 490. Purple-red crystals suitable for X-ray diffraction were crystallized by slow diffusion of hexane into a xylene solution of compound **3**. The molecular structure of **3** was confirmed by X-ray diffraction and is shown in Fig. 5 below (cif file of 3 is in SI).

2.2.5. Synthesis of 5,11-Bis(4-triethylsiliylphenylethynyl)-anthradithiophene (*TESPE–ADT*; *4*)

Under nitrogen, 2.0 mL of 2.0 M isopropyl magnesium chloride (4.0 mmol) in THF was slowly added to a 20 mL THF solution of 4-triethylsilylphenylacetylene (0.86 g, 3.95 mmol) at 0 °C, and the mixture was stirred at 60 °C for 2 h. The resulting black-brown solution was then transferred to a dry THF solution (50 mL) of an anthradithiophene-5,11-dione (200 mg, 0.624 mmol) at room temperature, and then the mixture was refluxed at 60 °C overnight. After cooling to room temperature, 1.5 mL of water and a deoxygenated $SnCl_2$ (3.0 g, 15.7 mmol)/HCl (5 mL, 10%) solution was added to the reaction mixture, and stirring was continued at 60 °C for 3 h. Water was next added to the reaction mixture, and the organic layer was collected and purified by chromatography (silica gel; hexane as the eluent) and recrystallization from ether, giving 160 mg of purple-red precipitate (36% yield). ^{1}H NMR (300 MHz, $CDCl_3$): δ 9.22(s, 2H), 9.16(s, 2H), 7.83(d, J = 7.5 Hz, 4H), 7.63(d, J = 7.5 Hz, 4H), 7.56(d, J = 6 Hz, 2H), 7.48(d, J = 6 Hz, 2H), 1.02(t, J = 7.5 Hz, 18H), 0.88(t, J = 7.5 Hz, 12H). Purple-red crystals suitable for X-ray diffraction were crystallized by slow evaporation of an ether solution of compound **4**. The molecular structure of **4** was confirmed by X-ray diffraction and is shown in Fig. 7 below (cif file of 4 is in SI).

2.3. X-ray crystal structure determinations of compounds *1–4*

The selected crystals were mounted on a glass fiber. Data collection on compounds **1**–**3** and **4** were carried out on a BRUKER SMART APEX CCD and a NONIUS Kappa CCD diffractometer, respectively, with Mo radiation (λ = 0.71073 Å) at 150(2) K. After data collection, the frames were integrated and absorption corrections were applied. The initial crystal structure was solved by a direct method, the structure solution was expanded through successive least-squares cycles, and the final solution was determined. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms attached to the carbons were fixed at calculated positions and were refined using a riding mode. Crystal data, data collection, and refinement parameters are summarized in Table 1.

Table 1

2.4. Semiconductor film deposition and characterization

All p^+-Si/SiO_2 substrates were cleaned via sonication in absolute ethanol for 3 min and then by oxygen plasma treatment for 5 min (20 W, 0.5 Torr). For an SiO_2 coating layer, –$SiMe_3$ groups were introduced using hexamethyldisilazane (HMDS) and were deposited by placing the clean SiO_2 substrates in a N_2-filled chamber saturated with HMDS vapor for 48–72 h. For vacuum deposition, semiconducting materials were thermally deposited at $\sim 6 \times 10^{-6}$ Torr (~500 Å, 0.2–0.3 Å/s) at 20 or 50 °C. For drop-casting, a 0.1–0.2 wt.% solution (in toluene, tetrachloromethane, chlorobenzene, or dichlorobenzene) of each compound was placed on a clean substrate (1 cm × 1 cm) on a hot plate at a preset temperature. The temperature setting was ~50 °C lower than the boiling point of the corresponding solvent. The substrates were kept under a saturated vapor of solvent (the same solvent used to dissolve the compound) until the solvent evaporated completely. Films were then annealed in a vacuum oven to remove the residual solvent. Thin films of the organic semiconductors were analyzed by optical microscopy and wide angle $\theta - 2\theta$ X-ray diffraction (XRD) (Rigaku ATXG) using monochromated Cu Kα radiation. For TFT device fabrication, top-contact electrodes (~70 nm) were deposited by evaporating gold ($\sim 1 \times 10^{-6}$ Torr) through a shadow mask with a channel length (L) of 100 μm and a channel width (W) of 500–5000 μm.

2.5. Electrical Measurements

All OTFT measurements were carried out in ambient conditions using a Keithly 6430 subfemtoammeter and a Keithly 2400 source meter, operated by a local Labview program and GPIB communication. The mobilities (μ) were calculated in the saturation regime using the relationship [14]: $\mu_{sat} = (2I_{DS}L)/[WC_i(V_G - V_T)^2]$, where I_{DS} is the source–drain saturation current, C_i is the gate dielectric capacitance (per area), V_G is the gate voltage, and V_T is the threshold voltage. The latter can be estimated as the x intercept of the linear section of the plot of V_G vs. $(I_{DS})^{1/2}$.

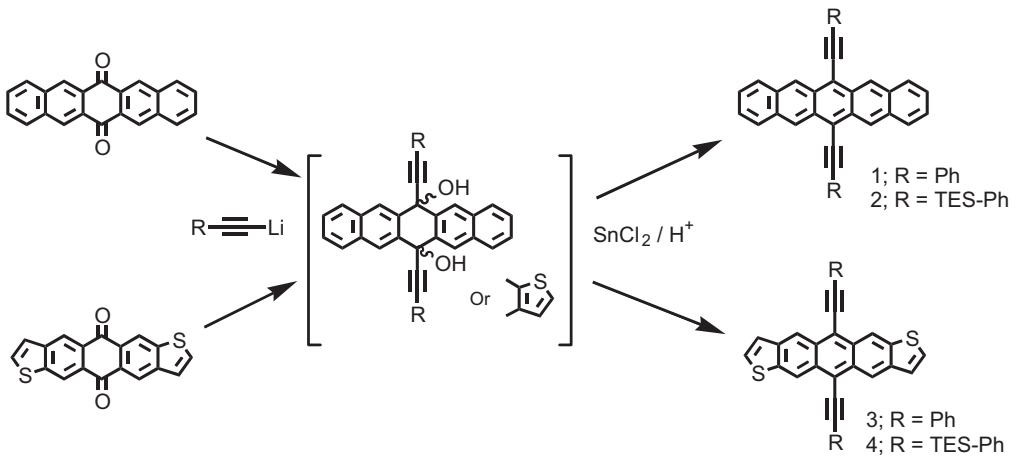
3. Results and discussion

3.1. Synthesis

The synthesis of four soluble **PEN**- (**1** and **2**) and **ADT**- (**3** and **4**) based compounds was achieved according to Scheme 2 following known synthetic approaches for other soluble **PEN** or **ADT** derivatives [9]. Starting from pentacene or ADT quinone, phenylethynyl-substituted **1** and **2** as well as triethylsilylphenylethynyl-substituted **3** and **4** were obtained via phenylethynyl anion alkylation and $SnCl_2$/HCl reduction, with overall yields of 50%, 6%, 46%, and 36%, respectively. Compared to **PEN** or **ADT**, compounds **1**–**4** exhibited significantly enhanced solubility in common organic solvents. Noteworthy is that triethylsilylphenylethynyl (**TESPE**-) substituted compounds **2** and **4** were very soluble in common organic solvents such as hexanes, ether, and benzene.

3.2. Thermal and optical properties

As summarized in Table 2, **ADT** derivatives exhibited greater thermal stability than do the analogous **PEN** derivatives. Thus, compounds **3** and **4** exhibited higher thermal decomposition temperatures (339 and 168 °C, respectively) than compounds **1** and **2** (255 and 86 °C, respectively). Note that **ADT** derivative **3**, the most thermally stable compound prepared in this study, did not exhibit a melting endotherm up to 339 °C in differential scanning calorimetry (DSC) measurements and exhibited weight loss only on heating above 320 °C, as demonstrated by thermogravimetric analysis. Compared to the phenylethynyl groups, triethylsilylphenylethyl substituents significantly decreased the thermal stability of the corresponding arenes. In particular, pentacene derivative **2** decomposed at 86 °C, which might explain the low synthetic yield of the corresponding compound. **Pen** and **ADT** derivatives with the present core substituents exhibited significantly red-shifted optical absorption spectra. Pentacene derivatives **1** and **2** in C_6H_5Cl exhibited λ_{max} values of ~664 nm (vs. ~579 nm for pentacene), while ADT



Scheme 2. Synthesis of soluble **PEN** and **ADT** derivatives **1**–**4**.

Table 2
Thermal, optical absorption/emission, and electrochemical data for compounds **1–4**.

Comp.	Decomp. T_d (°C)	TGA (°C; 5%)	Optical[b] λ_{max} (nm)	Reductive potential (V)[c]	Oxidative potential (V)[c]	ΔE_{gap} (eV)	
						(UV)[b]	(DPV)[c]
1	255	423	662	−0.924	0.876	1.76	1.80
2	86	382	666	−0.864	0.836	1.73	1.70
PEN	373[a]	297	579	−1.27	0.820	2.07	2.09

4	168	239	576	−1.14	0.956	2.05	2.10
ADT	450[a]	306	490	−1.63	0.940	2.47	2.57

[a] Melting temperature.
[b] In C_6H_5Cl.
[c] In *o*-$C_6H_4Cl_2$ at 100 °C (Fc/Fc^+ as an internal standard at +0.6 V).

derivatives **3** and **4** exhibited λ_{max} values of ~574 nm (vs. ~490 nm for ADT; Fig. 1), demonstrating extended π-electron delocalization from the molecular core to the phenylethenyl substituents. Calculated from the onset of the optical absorption, pentacene derivatives **1** and **2** exhibited smaller HOMO−LUMO energy gaps than do ADTs **3** and **4**, which was consistent with the energy gap values derived electrochemically (*vide infra*).

The photooxidative stability of derivatives **1–4** was investigated by monitoring the absorbance decay at λ_{max} in aerated C_6H_5Cl solutions while exposing to white light (fluorescent lamp) at room temperature (Fig. 2) [15].

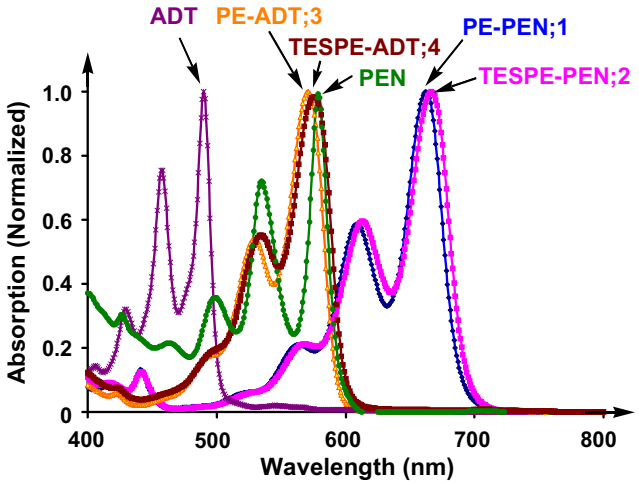

Fig. 1. Optical absorption spectra of compounds **1–4** in C_6H_5Cl solution.

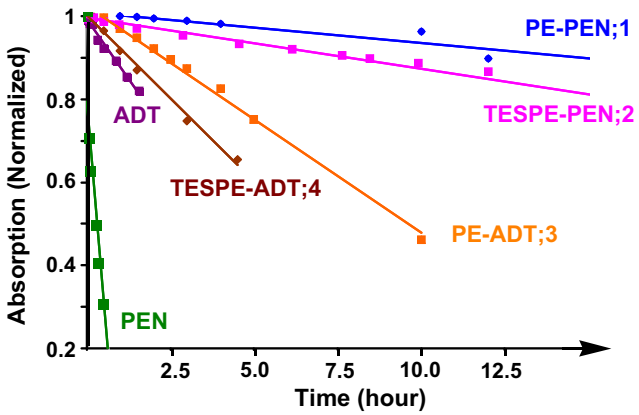

Fig. 2. Photostability of compounds **1–4** in a C_6H_5Cl solution, as monitored by optical spectroscopy under white light at room temperature.

Decomposition was observed for all compounds under these conditions over 24 h. Nevertheless, the core-substituted compounds in this study exhibited longer half-lives than non-substituted **PEN** and **ADT**, demonstrating enhanced stability via core substitution, as observed for other pentacene derivatives [16]. The phenylethynyl-substituted compounds (**1** and **3**) exhibited enhanced photostability compared to triethylsilylphenylethynyl-substituted derivative **2** and **4**. Note that under ambient conditions (O_2 and H_2O present) without white light, no decomposition was observed for these soluble **ADT**s and **PEN**s, demonstrating their potential as solution-processable organic semiconductors.

3.3. Electrochemical characterization

Differential pulse voltammograms (DPVs; using ferrocene/ferrocenium as internal standard at +0.6 V) of compounds **1–4** were recorded in dichlorobenzene at 100 °C [17], and the resulting oxidation and reduction potentials are summarized in Table 2 [18]. For the **PEN** series, the DPV spectra of compounds **1** and **2** exhibited oxidative peaks at +0.84 V and +0.88 V as well as reductive peaks at −0.86 V and −0.92 V, respectively (using ferrocene/ferrocenium as the internal standard at +0.6 V); both oxidative and reductive peaks were shifted to more positive values than those of **PEN** (+0.82 V and −1.27 V, respectively). Similar shifts of both oxidative and reductive peaks were observed for the **ADT** series. The HOMO levels of the ADT derivatives were therefore slightly lower than those of the pentacene derivatives (Fig. 3; assuming ferrocene/ferrocenium oxidation at 4.8 eV). In contrast, the LUMO levels of these soluble compounds were significantly lower in both series compared to unsubstituted **PEN** and **ADT**, which can be attributed to more extensive π-electron delocalization [19]. Overall, the electrochemically-derived HOMO−LUMO energy gaps were ranked in the order of **1** ≈ **2** < **PEN** ≈ **3** ≈ **4** < **ADT** (Fig. 3), in agreement with the values obtained from optical spectroscopy (Table 2).

3.4. Single-crystal structure analysis

The diffraction-derived crystal structures of compounds **1–4** are shown in Figs. 4–7, respectively, and the corresponding data are summarized in Table 1. The molecular packings of phenylethynyl-substituted compounds **1** and **3** were similar to that reported for **BBPE–PEN** [3g]. As shown in Figs. 4–7, the phenyl moieties attached to the ethynyl group were not coplanar with the central **PEN** or **ADT** cores, but had torsional angles of 11.8° and 22.5° (**1**; Fig. 4D), 10.1° (**3**; Fig. 5D), 16.6° (**2**; Fig. 6D), and 18.1° and 28.2° (**4**; Fig. 7D), respectively [20]. The molecular pac-

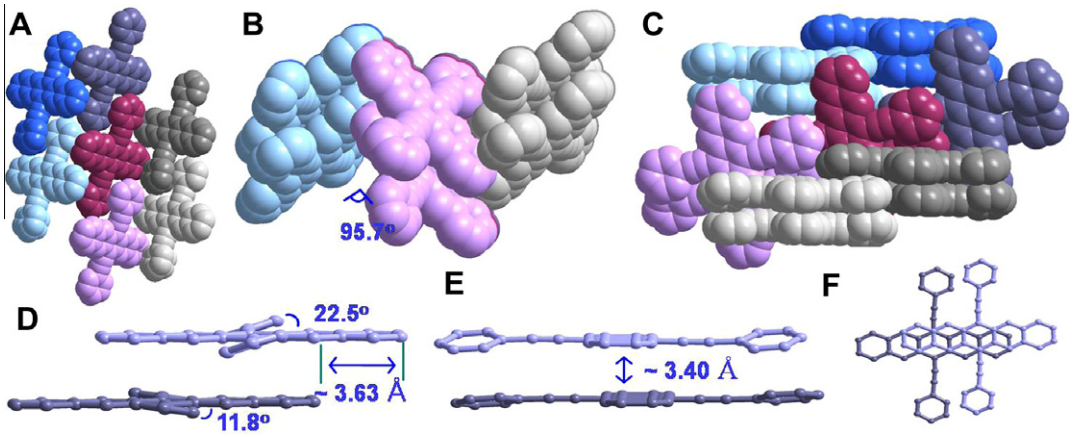

Fig. 4. Crystal structure of compound **1**. (A) Top view (space filling model). (B) Front view. Each of the π-stacks interweave with each another in a herringbone packing at an angle of 95.7°. (C) Side view. (D) Front view. The core interlayer spacing (~3.40 Å) and C_6H_5 groups have torsional angles of about 11.8° and 22.5° with respect to the **PEN** plane. (E) Side view. (F) Top view. The **PEN** cores form 2-D slipped stacks.

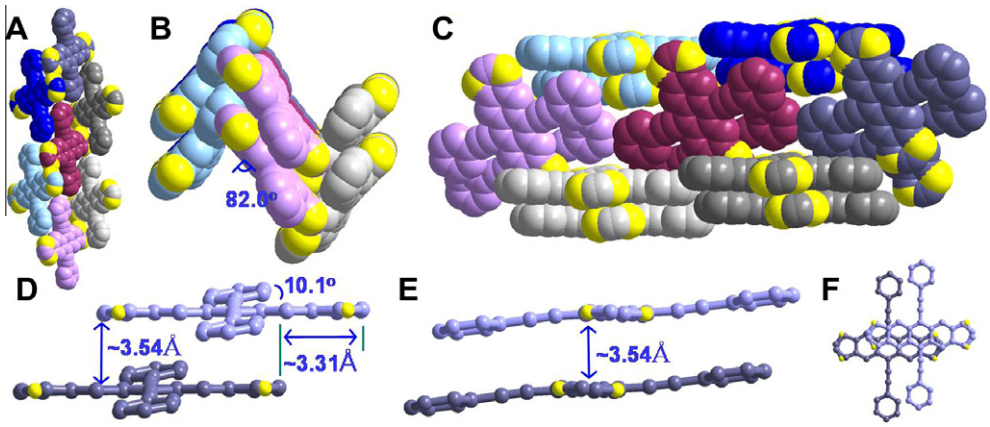

Fig. 5. Crystal structure of compound **3**. (A) Top view (space filling model). (B) Front view. Each of the **ADT** π-stacks interweave with each another in a herringbone motif at an angle of 82°. (C) Side view. (D) Front view. The core interlayer spacing (~3.54 Å) and C_6H_5 groups have torsional angles of about 10.1° with respect to the **ADT** plane. (E) Side view. (F) Top view. The **ADT** cores form 2-D slipped stacks.

kings of **1** and **3** were similar, exhibiting a herringbone-type packing with tilt angles of 95.7° and 82.0° (Figs. 4B and 5B), respectively [20]. In each packing column, the **PEN** or **ADT** cores formed 2-D slipped stacks and adopted a nearly face-to-face packing motif (Figs. 4 and 5), with an interplanar angle of ~0° and interplanar distances of

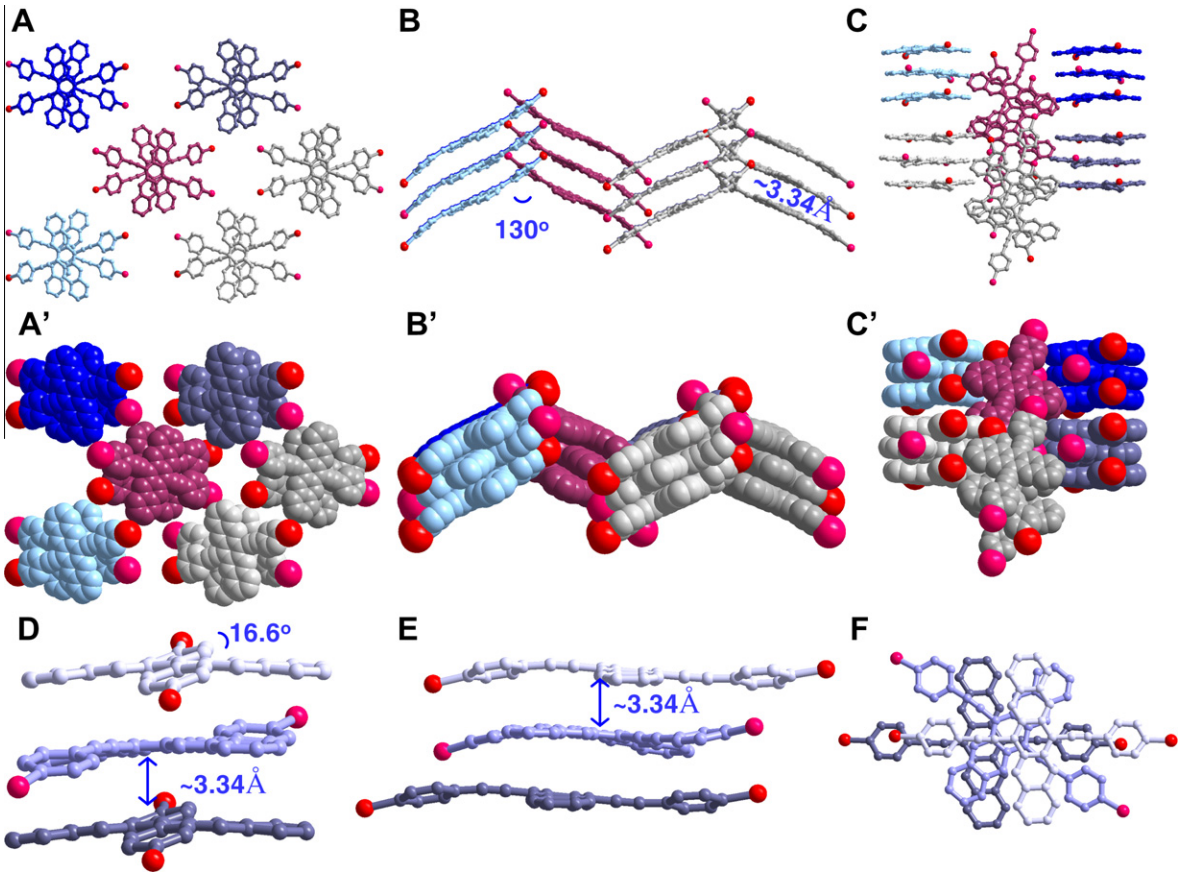

Fig. 6. Crystal structure of compound **2**. (A) Top view. The **PEN** cores form 2-D "slipped-crossed" stacks. (B) Front view. Each of the **PEN** π-stacks interweave with one another in a herringbone motif at an angle of 130°. (C) Side view. (D) Front view. The core interlayer separation (~3.34 Å) and the C_6H_5 groups have torsional angles of ~16.6° with respect to the **PEN** plane. (E) Side view. (F) Top view. The "slipped-crossed" π-stacks of **PEN**s (A′, B′, and C′ are space filling models of A, B, and C, respectively).

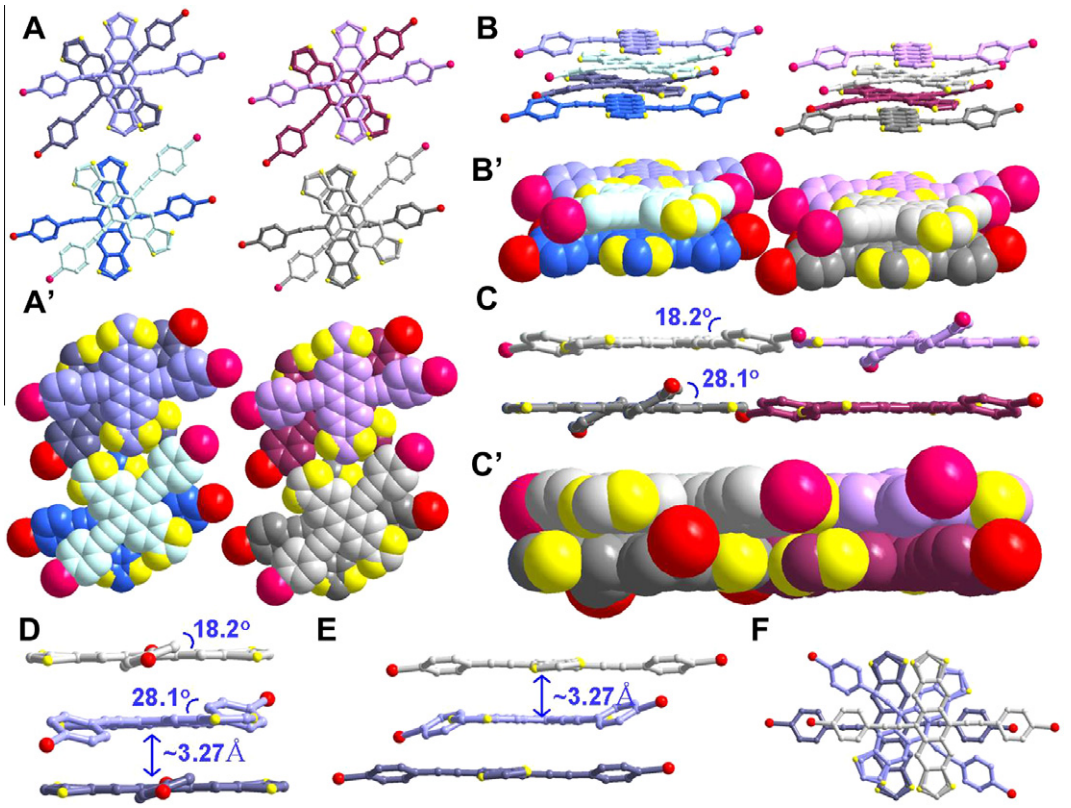

Fig. 7. Crystal structure packing of compound **4**. (A) Top view. The **ADT** cores form 2-D "slipped-crossed" stacks. (B) Front view. Each of the **ADT** π-stacks interweave with each another. (C) Side view. (D) Front view. The core interlayer separation (~3.27 Å) and C_6H_5 groups have torsional angles of ~18° and 28° with respect to the **ADT** core. (E) Side view. (F) Top view. The "slipped-crossed" π-stacks of **ADT**s (A′, B′, and C′ are space filling models of A, B, and C, respectively).

~3.40 Å and ~3.54 Å (Figs. 4D and 5D), respectively [20]. Note that the **PEN** or **ADT** cores were not perfectly aligned with each other but were slipped ~3.63 Å (**1**) and ~3.31 Å (**3**) along the long axis as well as half a unit cell length along the short axis (Figs. 4E and 5F), revealing a close-packed layered structure with intimate π–π overlap.

With the bulky triethylsilyl (TES) moiety appended to the phenylethynyl group, the molecular packings of compounds **2** and **4** were very different from compounds **1** and **3,** as shown in Figs. 6 and 7, respectively. The substitutions of relatively bulky TESPE groups into peripositions of polyacenes did disrupt the herringbone structure of the main Pen and ADT core [21]. Compounds **2** and **4** engaged in 2-D "slipped-crossed" stacking to accommodate the bulky TES groups. For compound **2**, each of the **PEN** π-stacks interweaved with one another in a herringbone motif at an angle of 130° (Fig. 6B), while this interweaving angle is nearly 180° for compound **4** (Fig. 7B and C). The **PEN** or **ADT** cores stacked with interplanar separations of ~3.34 Å and ~3.27 Å (Figs. 6E and 7E), respectively. Note that this bulky TES substituent induced significant deviations from planarity in the **PEN** core of compound **2**, in contrast to the other three compounds of this study (Fig. 6D and E). For compound **4**, the interplanar distance is very comparable to those in TES–ADT (3.25 Å) [3a]. The shortest interplanar distance and planarity (with core interweaving angle of ~180°) of compound **4** may explain the highest electronic performance among all compounds employed in this study (*vide infra*; [22]).

3.5. Thin-film transistor characterization

Top-contact/bottom-gate OTFTs were fabricated by drop-casting [23] films of compounds **1**–**4** onto bare and HMDS-treated p^+-Si/SiO_2 substrates (compound **3** was also fabricated via vacuum deposition on both substrates) [24], followed by Au deposition through a shadow mask to define the source and drain electrodes. OTFT characterization

Table 3
Charge carrier mobility (μ, $cm^2/V\,s$)[a], current on/off ratio (I_{on}:I_{off}), and threshold voltage (V_T, V) data for OTFTs fabricated with compounds **1**–**4** on bare Si/SiO_2 substrates.

Compound	Solvent	μ	I_{on}:I_{off}	V_T
1	C_6H_5Cl	0.001	10^4	−1.0
2	C_6H_5Cl	0.0004	10^4	−7.3
3	C_6H_5Cl	0.005	10^4	−10.0
3[b]		0.015	10^{3-4}	−1.2
4	Toluene	0.013	10^4	−15.0

[a] Calculated in the saturation regime.
[b] This device was fabricated on an HMDS-treated SiO_2 substrate by vacuum deposition.

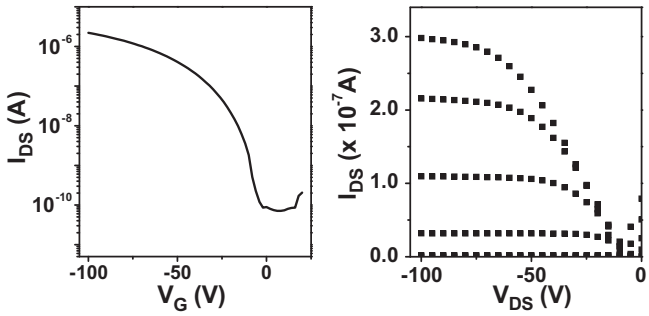

Fig. 8. Transfer and output characteristics of a representative OTFT fabricated with compound **4**. The films were drop-cast from toluene.

was performed in ambient conditions, and the corresponding device characteristics are summarized in Table 3 and Fig. 8 [25].

The devices fabricated with compounds **1**–**4** all exhibited TFT activity as p-channel semiconductors. In general, enhanced performance was observed: (a) in the **ADT** families versus the **PEN**s, and (b) when chlorobenzene was used as the drop-casting solvent. All the compounds employed in this study were sufficiently soluble in common solvents (e.g., toluene, chlorobenzene, and dichlorobenzene) at room temperature. As a preliminary fabrication of the device via solution-process, we prepared for thin films of each compound via drop-casting from the solution. For **PEN** derivatives, the highest carrier mobility values of 0.001 and 0.0004 cm^2/V s were observed for films of compounds **1** and **2,** respectively, drop-cast from chlorobenzene. The corresponding I_{on}:I_{off} and V_T values were 10^4 and −1 to −7 V for these **PEN**-based materials. In contrast, **ADT**-based devices fabricated by drop-casting exhibited relatively high mobilities of 0.005 cm^2/V s for compound **3** (from chlorobenzene), and 0.013 cm^2/V s for compound **4** (from toluene). Similarly to the **PEN** series, I_{on}:I_{off} and V_T values of 10^4 and −10 to −15 V were observed for the **ADT** derivatives. All of the devices were characterized after two months of storing under nitrogen (without being exposed to light) and did not show any degradation in performance (both mobility and current on/off ratios).

3.6. Thin-film microstructure

Film crystallinity and morphology are frequently strongly correlated with OTFT performance. Film morphologies and microstructures for the present new class of materials were studied by optical microscopy and X-ray diffraction for drop-cast thin films. Optical microscopic examination of the drop-cast films revealed pronounced differences in morphology between the **PEN** and **ADT** derivatives (Fig. 9). Polycrystalline platelet-like features were observed for the **ADT**-based films, while relatively fewer crystalline features were observed for drop-cast films of the **PEN** derivatives, which is in accord with the performance of the corresponding TFTs (*vide supra*).

With crystal structure in hand, we could simulate the XRD powder pattern and assign the reflections observed in the film XRD data (Fig. 10). Comparing these data can be useful to analyze the molecular ordering of the compounds. Fig. 10 shows a graphical comparison of experimental and simulated data, with a $\theta - 2\theta$ scan for a drop-casted film of

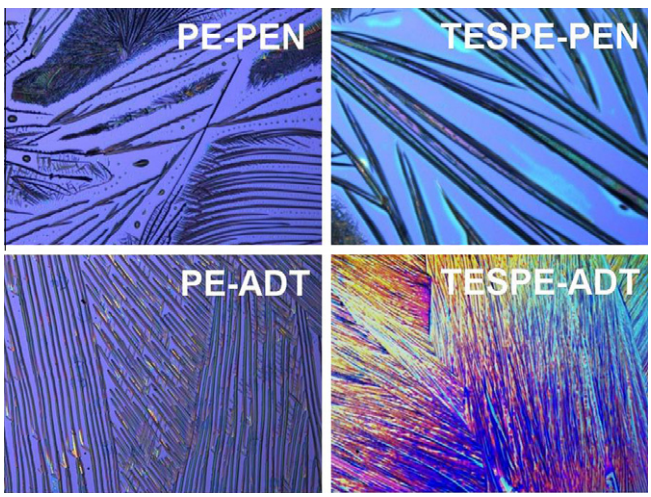

Fig. 9. Optical micrographs of drop-cast films of compounds **1**–**4**. All images were taken at 50× magnification.

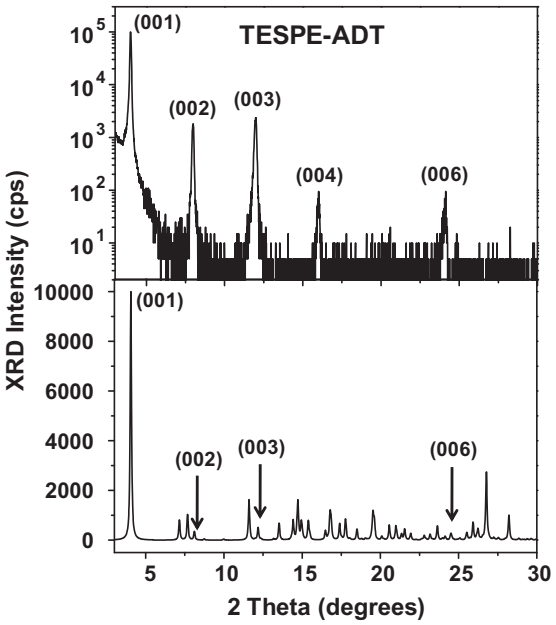

Fig. 10. Comparison of the $\theta - 2\theta$ XRD scans of drop-cast films of **TESPE–ADT** on bare Si/SiO_2 substrates (top) with the simulated powder pattern (bottom).

compound **4** on bare Si/SiO_2 substrate, and a powder pattern generated from the single-crystal data. As shown, (0 0 1) reflection family from (0 0 1) to (0 0 6) was pronounced, indicating predominant ordering of the molecules in c direction. For other compounds, the (0 1 1) reflections for compound **1** and (1 2 0) reflections for compound **2** could be assigned, indicating no predominant ordering in the direction of the unit cell axis for both compounds (Fig. S5). For compound **3**, powder pattern did not show (1 0 0) reflections which were present in the film XRD [26].

Overall, the thin film XRD microstructural analysis showed features in agreement with the optical microscopic analysis. Fig. 11 shows representative $\theta/2\theta$ out-of-plane XRD scans for drop-cast films on bare Si/SiO_2 substrates. As shown, the **ADT** derivatives exhibited more highly textured films having large peak intensities with multiple Bragg reflections. Notably, compound **4** exhibited the highest film texturing with multiple Bragg reflections up to (0 0 6), indicating high film crystallinity and in agreement with the TFT performance (*vide supra*). The estimated *d*-spacing value from the (1 0 0) reflection for compound **4** was 22.2 Å (which corresponds to the length of the *c* axis of the unit cell in the crystal structure), indicating a crystalline polymorph where the majority of the molecules have edge-on orientation on the substrate surface and with the π–π stacking direction parallel to the substrate, thereby facilitating in-plane charge transport from source to drain. The diffraction patterns of compounds **1** and **3** showing relatively low carrier mobilities (0.001–0.005 $cm^2/V\,s$) exhibited multiple Bragg reflections (up to three peaks) but with modest peak intensities, and with the latter material evidencing two different phases or growth orientations. Estimated *d*-spacings for these compounds were in the narrow range of 11.6–12.0 Å, probably

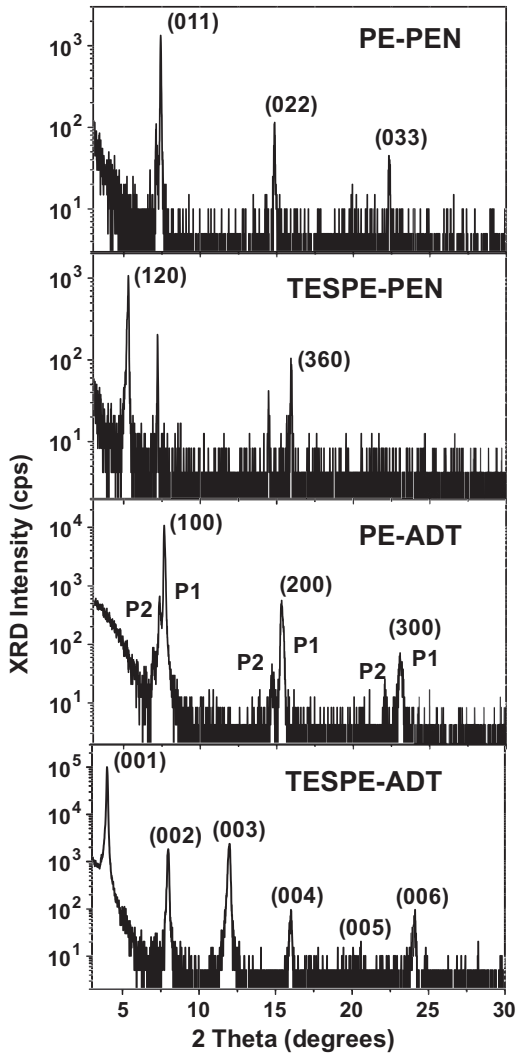

Fig. 11. Representative $\theta - 2\theta$ XRD scans (in logarithmic scale) of drop-cast films of the indicated materials on bare Si/SiO_2 substrates (P1 and P2 indicate two different phases). Peaks are assigned in comparison with the powder pattern generated from the single crystal structures.

indicating similar molecular organization in the films. Compound **2**, with the lowest OTFT performance, exhibited two Bragg reflections having modest peak intensities.

4. Conclusions

In summary, four solution-processable pentacene (**PEN**) and anthradithiophene (**ADT**) derivatives have been synthesized and found to exhibit OTFT p-channel transport. The phenylethynyl substituents were found to be effective in increasing the solubility and environmental stability of the corresponding semiconductors. From the preliminary fabrication of the device via drop-casting, compared to the **PEN** derivatives, the **ADT**-based compounds exhibited higher device performance with respectable carrier mobilities of 0.005–0.013 $cm^2/V\,s$. The magnitudes of the mobilities were strongly correlated with the film

morphology and microstructure. These results provide new information about the structural characteristics of **PEN** and **ADT**-based semiconductors and the attractions of using these cores and substitutents for designing more solution-processable OTFT materials. A further complete and detailed device fabrication via other solution-processing methods is underway [22].

[22] Improved TFT performance for compound 4 was achieved by device fabrication via spin-coating.
[23] Standard deviations for 5 devices are typically <20%.
[24] All the compounds were fabricated via vacuum deposition on bare Si/SiO_2 and HMDS-treated substrates at various temperatures. But only one compound (compound 3) exhibited good device performance. The other compounds are inactive or exhibit very low performance (mobility $<10^{-6}$ cm^2/V s).
[25] All the available data for all compounds are in the Supporting Information (Tables S1–S2 and Figs. S1–S4).
[26] Except compound **4**, the X-ray diffraction pattern of the semiconductor films did not match the simulated powder pattern. This is likely due to polymorph formation (which is clearly shown in compound **3**).

The transferred bilayer active layer pure poly(3-hexylthiophene)/pure [6,6]-phenyl C61-butyric acidmethyl ester (pure P3HT/pure PCBM) should have discrete composition profile at the P3HT/PCBM interface. This study demonstrates, that a bilayer of P3HT and PCBM prepared by means of a stamping transfer method has an unexpected film composition that is, similar to the composition gradient of BHJ film generated from a P3HT/PCBM blended solution. In this study, we also discuss how a intermixing of P3HT/PCBM bilayer is occurred and affects the performance of the device.

2. Experimental details

First, a ITO glass was cleaned by chloroform, acetone and isopropanol to remove residual organic materials on the ITO surface which was then treated by oxygen plasma for 10 min in order to enhancing hydrophilic property. A sample of poly(3,4-ethylene dioxythiophene: poly(styrene sulfonate) (PEDOT:PSS, Baytron P), which is conducting polymer of hole transporting material was diluted to methanol and spin-coated to a thickness of approximately 35 nm. Using a digital-controlled hotplate, we pre-baked the devices in PEDOT:PSS at 200 °C for 5 min to evaporate the water contents. The stamping-transferred bilayer device, which composed of P3HT (approximately 150 nm) and PCBM (approximately 85 nm) from chlorobenzene, was well coated on the UV-PC film (as shown in inset of Fig. 1 and Fig. S1). Each P3HT and PCBM layer was then individually transferred from the UV-PC film to the PEDOT:PSS-coated ITO substrate, which was heated on a hotplate at 90 °C. The UV-PC film with the P3HT or PCBM layer was attached to the heated substrate and rubbed with cotton swabs with uniform force of 18.8 kg/cm^2 until the P3HT or PCBM layer coated on the PC film totally adhered to the heated substrate. When the stamping transfer process was conducted with simple physical force at a suitable temperature, the coated layer from the UV-PC film was perfectly transferred to the PEDOT:PSS-coated ITO with a reproducibility. A TiO_x interlayer with a thickness of approximately 3 nm was inserted between the bilayer and the Al cathode to enhance the device performance [3]. Subsequently, an Al metal electrode with a thickness of 150 nm was thermally deposited under a pressure of 1.7×10^{-6} Torr. To improve the interfacial contact between the active layer and the Al cathode, we used a thermal annealing process that involved the use of a digitally controlled hotplate at 150 °C for 30 min in a glove box. The active area of the printed bilayer with the thermally deposited Al electrode was correctly confirmed in the range of 3–6 mm^2 with a video microscope (SV-35). The *J–V* curves were measured at an illumination rating of AM 1.5 by using a Keithley 2400 source measure unit. A 1000 W xenon lamp of Oriel 91193 which is intensity was calibrated using a silicon reference cell (Fraunhofer ISE, Certificate No. C-ISE269) served as the light source to the devices. The surface morphology and the roughness of the transferred bilayer were analyzed with an atomic

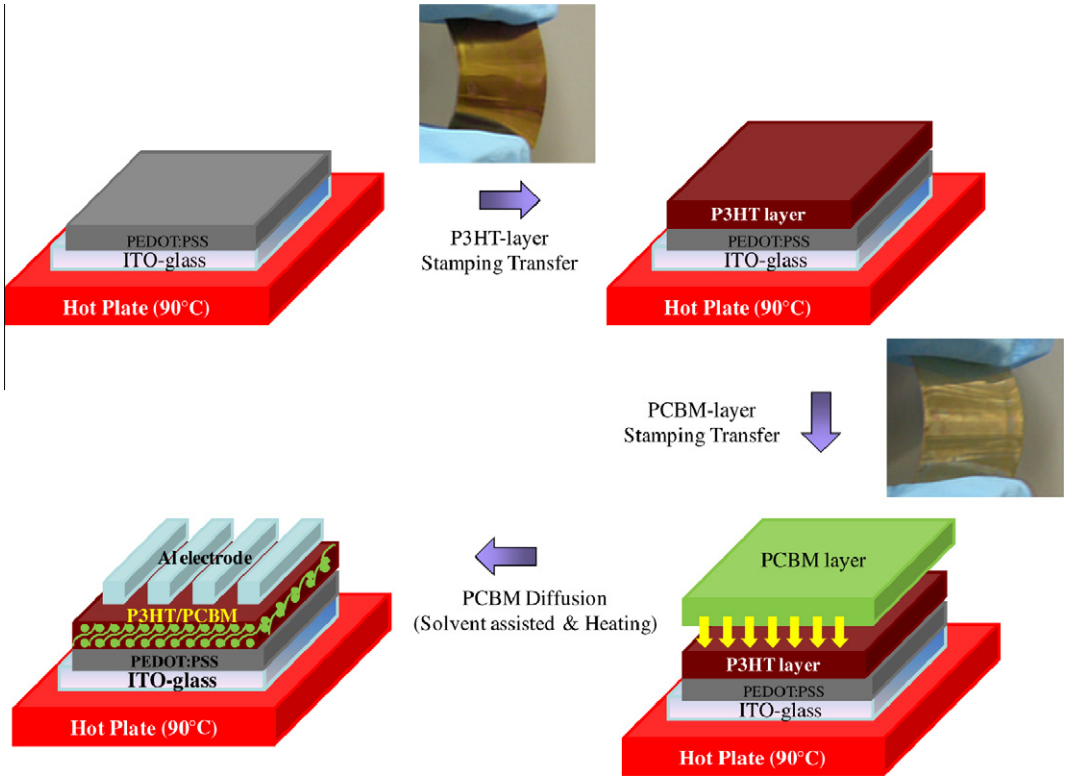

Fig. 1. Schematic diagram of the proposed device structure produced by using a stamping transfer technique of the P3HT/PCBM bilayer with a UV-curable resin-coated polycarbonate film.

force microscope (Veeco, USA; noncontact tapping mode, D3100).

3. Results and discussion

As shown in Fig. 1, for the device fabrication of P3HT/PCBM bilayer we used stamping transfer technique. The preparation involved a method of making UV-curable resin-coated polycarbonate (UV-PC) film as reported in our previous results [12]. A silicon wafer was cleaned by organic solvent, and treated by Trichloro-(1H, 1H, 2H, 2H – perfluorooctyl) silane (FOTS) to reduce the surface energy of the wafer, then the self-assembled monolayers (SAMs) were generated in the film to get the imprinting property [23]. The UV-curable resin was uniformly dropped between the flexible PC film and silicon wafer and flattened with a roller to well adhesion. The PC film was cured by UV for 3 min at the wavelength of 365 nm and wafer was detached. The size of UV-PC film is dependent on the area of used silicon wafer therefore it is easy to maximize the film areas.

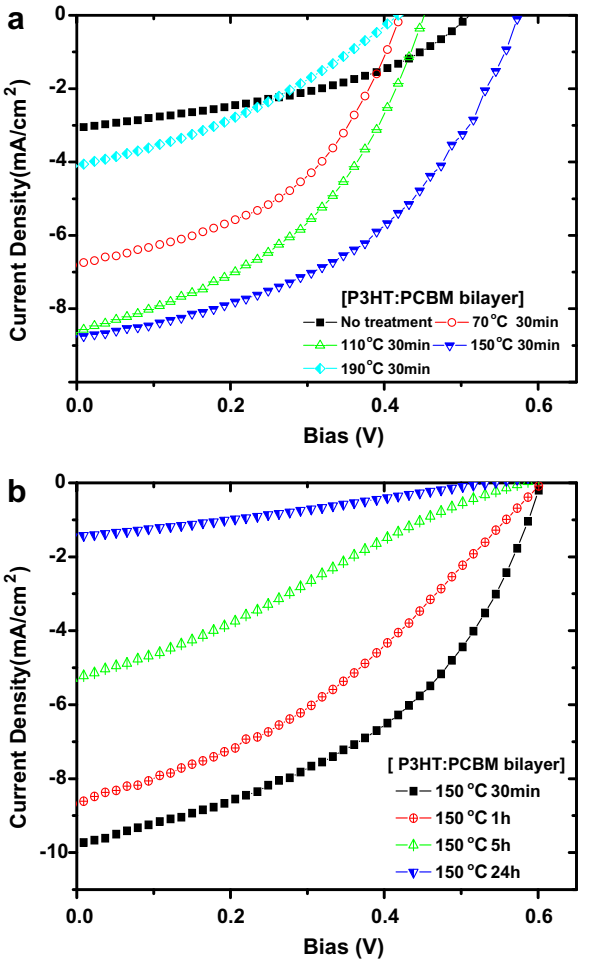

Fig. 2. (a) photocurrent–potential (*J–V*) curves of the stamping-transferred P3HT/PCBM bilayer devices in relation to various kinds of annealing temperatures; (b) *J–V* curves of P3HT/PCBM transferred bilayer devices that use a TiO_x interlayer as an effective electron transporting layer in relation to the annealing time.

Fig. 2a illustrates the photocurrent–potential (*J–V*) curves of the stamping-transferred P3HT/PCBM bilayer devices in relation to various kinds of annealing temperatures. For a device without the thermal annealing process, the power conversion efficiency (PCE) shows only 0.64% with the rms (root mean square surface roughness) value of 13 nm from AFM images of Fig. 3a and b. This result can be explained by low photocurrent density value due to decreased charge carrier mobility of no annealing [24]. However, when the annealing temperature is increased from 70 °C to 150 °C over the glass temperature of P3HT, all the device values, namely V_{oc}, J_{sc}, FF, and η (%), are enhanced because the closed packing structures of the reorganized P3HT polymer chain provide an efficient exciton dissociation [25]. Additionally, thermal annealing process plays an important role to produce an effective nanoscale interpenetrating network with crystalline order for P3HT/PCBM components in the bilayer structure [26]. This result confirms that the PCE value is increased from 0.64% to 2.34% in stamping-transferred bilayer devices after the devices annealed at an optimum temperature with the rms value of 8 nm from AFM images of Fig. 3c and d. Generally, p-type and n-type double-layer solar cells have low conversion efficiency. However, the devices prepared by means of the transfer stamping method with pure P3HT and pure PCBM have high level of efficiencies without destroy of previous printed bottom layer, as shown in Fig. 2. Moreover, Fig. 2b shows *J–V* curves of P3HT/PCBM transferred bilayer devices that use a TiO_x interlayer as an effective electron transporting layer in relation to the annealing time. Annealing of the device at 150 °C for 30 min enhances the PCE (%) to 2.63% with the increased photocurrent density value of 9.76 mA/cm^2. Also, the stamping-transferred bilayer device with a TiO_x interlayer showed improved fill factor value of 0.45 [27,28]. However, the efficiency of the device rapidly decreases if the device is heated continually for 24 h.

Fig. 4 shows the SEM images of P3HT/PCBM bilayer with post-annealing of 150 °C for 30 min or with post-annealing after continuous heating of 100 °C for 24 h. From these results, it can be demonstrated that the morphologies of bilayer active film were closely related to the annealing condition. This outcome suggests that prolonged annealing induces thermal degradation as well as the possibility of negative changes in the active layer at the inner region of the P3HT/PCBM interface with unwanted morphological changes, thus resulted in deterioration of the active polymer in the device due to the irregular aggregated domains as shown in the SEM images of Fig. 4b. Therefore, the rms values of the bilayer with P3HT/PCBM active film were gradually changed depending on annealing time from Fig. 3.

Fig. 5 shows the peak-to-peak Auger signal of the P3HT/PCBM bilayer as a function of the depth (nm) from the top to bottom layer. The sulfur element was only detected in the P3HT composition; therefore the degree of interpenetration in the P3HT/PCBM layer can be confirmed by Auger electron spectroscopy depending on the distribution and concentration gradient of the sulfur contents. Interestingly,

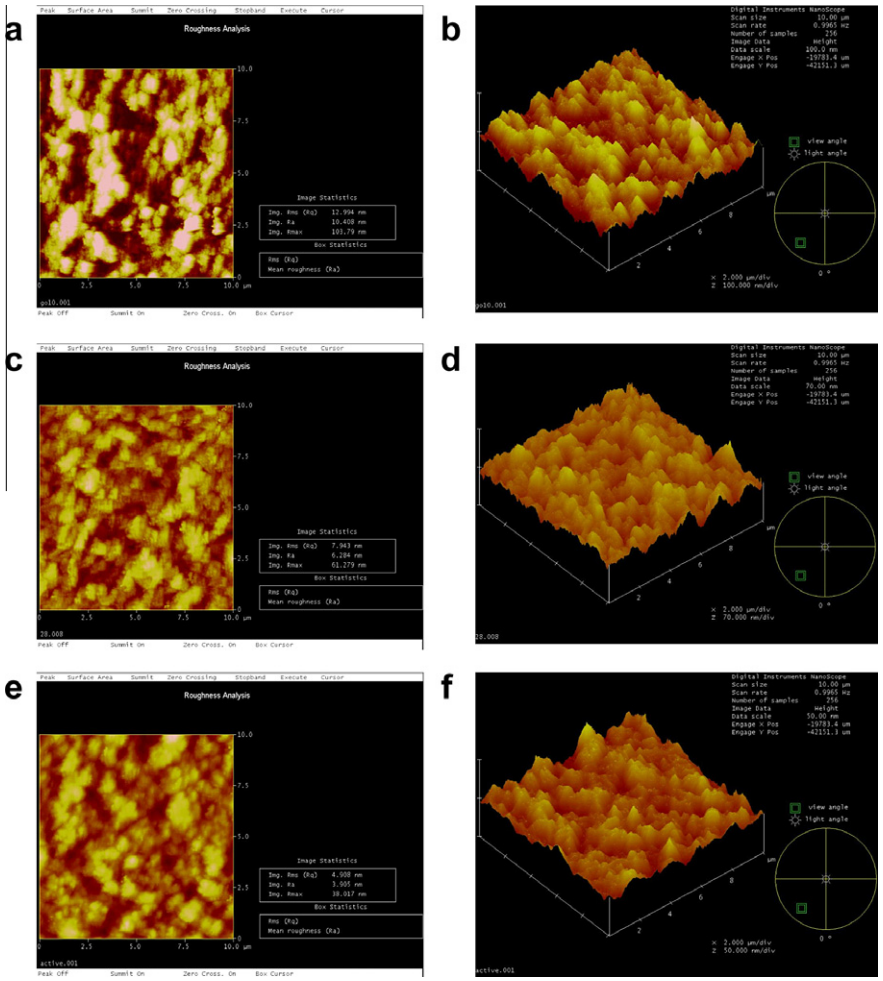

Fig. 3. AFM 2D or 3D images of stamping-transferred P3HT/PCBM bilayer depending on annealing time; (a and b) no annealing, (c and d) annealing with 150 °C for 30 min, and (e and f) annealing with 150 °C for 24 h.

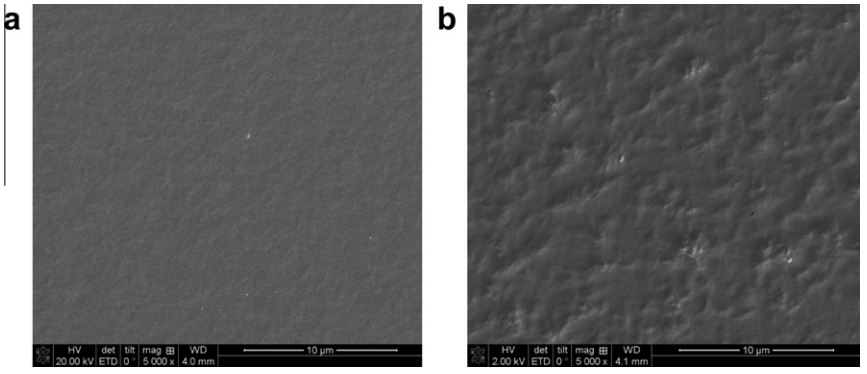

Fig. 4. SEM images of stamping-transferred P3HT/PCBM (a) bilayer with post-annealing of 150 °C for 30 min (b) bilayer with post-annealing and continuous heating of 100 °C for 24 h.

the transferred bilayer film (100% P3HT/100% PCBM) with an annealing time of 30 min does not show a sharp increase in the sulfur signal throughout the entire active region of the P3HT/PCBM bilayer. In our previous paper, a sharply increased gradient slope at the interface between the P3HT-rich region and the PCBM-rich region during the stamping process were observed, as shown in Fig. S2. As a results, when the Auger spectroscopy of the P3HT/PCBM bilayer is compared with that of the P3HT/PCBM BHJ film as shown in Fig. 5, the concentration profile of the bilayer looks like that of the BHJ film, suggesting the solid–solid intermixing behavior during the stamping

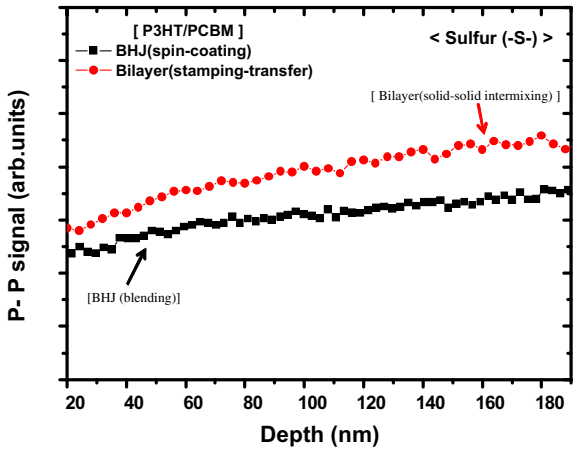

Fig. 5. Depth profile of P3HT/PCBM BHJ or bilayer with stamping transfer technique after the post-annealing of 150 °C for 30 min (Auger electron spectroscope).

transfer process. It seems that the residual chlorobenzene solvent in PCBM films on the UV-PC film after the spin-coating process can help swelling of P3HT bottom layer during rubbing process with cotton swabs (fully dried PCBM film do not have such a smooth profile). Then PCBM molecules might be able to penetrate into the P3HT molecules in the bottom layer because of the small molecular size of PCBM. However, when P3HT/PCBM blended film was transferred on the bottom layer by stamping method, this solid–solid intermixing behavior was not observed because of the large molecular size of P3HT. Polymeric P3HT molecules might induce steric-hindrance for the PCBM molecules to migrate into the P3HT bottom layer.

4. Conclusions

In conclusion, solid–solid intermixing was firstly observed in a stamping-transferred P3HT/PCBM bilayer film, firstly. Owing to the residual solvent, the stamping-transferred P3HT/PCBM bilayer film have BHJ like concentration profile; it does so by means of solid–solid intermixing. This unique discovery can be applied in preparing concentration-graded BHJ film from controlling solid–solid intermixing behavior for more in-depth understanding of the correlation between cell performances and P3HT/PCBM bilayer concentration profile.

and explicit hypothesis and approximations, based on specific organic materials physics.

Charge transport efficiency in organic semiconductors has been constantly improved during the past two decades, probably due to improved material elaboration and better control of the device process. The transport efficiency is commonly quantified through the carrier mobility, characteristic of an average carrier speed versus electric field, whatever the transport physics at the molecular scale. Best reported values at room temperature are in the order of 1–10 $cm^2 V^{-1} s^{-1}$ [12].

The second most limiting factor of OFET performances is the poor injection efficiency from source to drain electrodes through the transistor channel [11,13]. This behavior is closely linked to the device process and should find solutions in near future using appropriate electrode material and surface treatment [14]. However, this nonlinear injection problem must be accurately described and taken into account in an OFET model, as it strongly influences the extraction of important parameters such as mobility or threshold voltage.

This work focuses on the influence of nonlinear injection on the device performances. A self-consistent model is developed and described in detail, implementing the nonlinear injection at the source contact in an original manner, with explicit assumptions whenever needed in order to allow deeper discussion of the organic physics involved.

In Section 2, highlighting the differences between the conventional silicon metal-oxide-semiconductor field effect transistor (MOSFET) model and its organic counterpart, we describe the transistor structure and the model basics, including leakage resistance, ohmic drain and source series resistances, and a mobility dependence on the local gate voltage. In Section 3, the method for implementing nonlinear injection at the source contact is described, allowing a self-consistent calculation of the drain/source current/voltage characteristics. In Section 4 the impact of nonlinear injection is illustrated through simulations with typical OFET parameters, and comparison with experimental data is given. Following, impact of nonlinear injection on mobility and threshold voltage is described in-depth. Finally, a study of the internal injecting field allows to predict instabilities and even breakdown in organic FETs.

2. OFET model: basics

2.1. OFET assumptions and structure

The OFET schematic structure considered in this paper is a bottom-contact structure as depicted in Fig. 1.

The organic semiconductor (OSC) is considered intrinsic, with no doping and no traps, and with a uniform spatial concentration of sites N_0, available to carriers accumulated by the gate bias and injected by the source contact. Any generation, either optical or thermal for example, is neglected in the semiconductor material. Consequently, carriers are always brought from source and/or drain electrodes [15,16]. The isolating material is assumed to be ideal, with no leakage current, no charge and no traps. Source and drain electrodes always behave ohmic (i.e. linear).

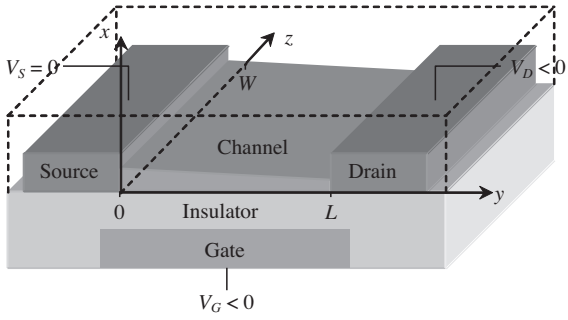

Fig. 1. Schematic drawing of a bottom-contact OFET structure, where the conductive channel is in linear regime.

In an ideal situation, the OSC can transport either electrons or holes, as demonstrated in several publications [17,18], and the transistors should be ambipolar. This happens if both types of charges are injected in the channel and are mobile. In the usual case, only one carrier type contributes to the OFET drain/source current characteristic (I_{DS}). This can be understood considering that either only one carrier type can be injected, due to a high electrode/channel energy barrier [18], or that one carrier type is not mobile, for example if it is trapped at the insulator/OSC interface as stated in [17]. Most published OFET current-voltage characteristics are dominated by only one carrier type, and the devices are usually called p-type transistor or n-type transistors if the carriers are respectively holes or electrons.

In this work, single carrier OFETs are considered, in particular p-type OFETs, as they are widely studied. However, the model can be easily transposed to n-type OFET with minor sign changes.

The OFET structure considered in this paper takes the ohmic source and drain series resistances R_S and R_D into account. Also, an intrinsic conductivity in the OSC bulk (independent of the gate bias) is modeled by an ohmic resistance R_B set between the source and drain electrodes, as depicted in Fig. 2. This conductivity may result from residual doping of the OSC (see for example [19]), and is responsible for poor saturation of the drain current characteristic.

When carrier injection from the source electrode into the transistor channel is linear (i.e. ohmic behavior), the channel is formed near the source contact edge and the intrinsic source potential is $V_{Si0} = V(y = 0)$ (Fig. 2). Thus for a given bias point (U_{DS},U_{GS}), the intrinsic voltage drops U_{GSi0} and U_{DSi0} are given by:

$$U_{GSi0} = V_G - V_{Si0} = U_{GS} - R_S I_{DSi}, \quad (1)$$

$$U_{DSi0} = V_{Di} - V_{Si0} = U_{DS} - (R_S + R_D) I_{DSi}, \quad (2)$$

where I_{DSi} is the intrinsic drain current. Note that we will use the following notations: V stands for potentials, whereas U is used for voltage drops. The external drain to source current I_{DS} is expressed by:

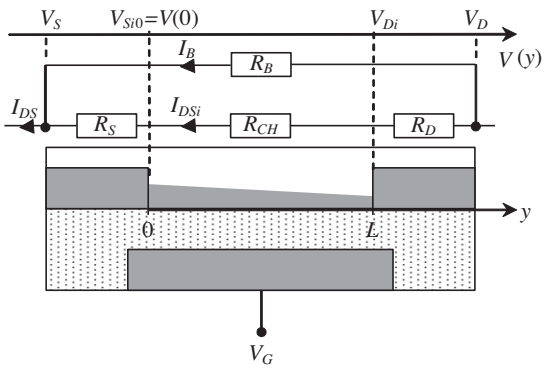

Fig. 2. OFET schematic and associated electrical model, with intrinsic and extrinsic potentials, parasitic resistances, and leakage currents.

$$I_{DS} = I_{DSi} + I_B, \tag{3}$$

where $I_B = U_{DS}/R_B$ is the leakage current due to R_B (Fig. 2).

In practical transistor characterization, the source potential is usually grounded and is the reference potential (Fig. 1). We will now focus on the computation of the intrinsic drain current $I_{DSi}(U_{DSi},U_{GSi})$ in presence of injection phenomena, as equation (Eq. 3) easily allows to determine the extrinsic drain current I_{DS}.

2.2. Source/drain intrinsic current model

The model basics are derived from the silicon MOS transistor model [20]. Within the gradual channel approximation, given the intrinsic drain current follows:

$$I_{DSi}dy = -W\mu(y)C_i[V_G - V(y) - U_T]dV(y) \tag{4}$$

where U_T is the threshold voltage, $C_i = \varepsilon_i/d_i$ is the insulator capacitance per unit area, and ε_i and d_i are respectively the insulator permittivity and thickness. Considering a mobility dependence on the local gate bias $\mu(y) = \beta[-(V_G - V(y) - U_T)]^\gamma$ (see [13,21,22]), where β and γ are fitting parameters, integration of (Eq. 4) gives the intrinsic drain current in the linear (Eq. 5) and saturated (Eq. 6) regime:

$$I_{DSi} = \frac{W}{L(\gamma+2)}\beta C_i[(U_{DSi0} - U_{GSi0} + U_T)^{\gamma+2} - (U_T - U_{GSi0})^{\gamma+2}] \tag{5}$$

$$I_{DSi} = I_{DSi\,sat} = -\frac{W}{L(\gamma+2)}\beta C_i(U_T - U_{GSi0})^{\gamma+2} \tag{6}$$

2.3. Potential and longitudinal electric field along the channel

The potential profile $V(y)$ and the longitudinal electric field $E_y(y)$ are required to implement nonlinear injection at the source contact, since injection phenomena are highly sensitive to the electric field. For a given intrinsic current I_{DSi}, integrating (Eq. 4) from (y) to the intrinsic drain $(y = L)$ gives the voltage drop in the channel referenced to the extrinsic source $U_{yS}(y) = V(y) - V_S$:

$$U_{yS}(y) = U_{GS} - U_T + \left[(U_{DSi} - U_{GSi} + U_T)^{\gamma+2} - \frac{I_{DSi}(\gamma+2)(L-y)}{WC_i\beta}\right]^{\frac{1}{\gamma+2}} \tag{7}$$

The electric field along the channel is obtained by derivating $U_{yS}(y)$:

$$E_y(y) = \frac{-I_{DSi}}{WC_i\beta}\left[(U_{DSi} - U_{GSi} + U_T)^{\gamma+2} - \frac{I_{DSi}(\gamma+2)(L-y)}{WC_i\beta}\right]^{-\left(\frac{\gamma+1}{\gamma+2}\right)} \tag{8}$$

3. OFET model with nonlinear injection

Nonlinear injection at the conductor/OSC interface may occur due to combined effects: the barrier height Φ_B at the conductor/OSC interface, the tunneling distance for injected carriers [23], the concentration of accessible sites in the OSC (N_0) [24], the carrier mobility, or the presence of molecular dipoles [25]. These injection phenomena limit the drain current and are partially controlled by the temperature in organic devices. The effects of nonlinear injection at the source and drain electrodes have been quantitatively measured by different near-field techniques: the near-field microwave microprobe (NFMM) [26] or the scanning-probe potentiometry using the atomic force microscopy principles, called Kelvin Probe Force Microscopy (KPFM) [27]. The KPFM measurements provide the electrostatic potential profile along the channel of a biased OFET [21,27–31]. Fig. 4 in Bürgi et al. [28] shows an example of such a potential profile, where most of the potential drop occurs at the injecting electrode (the source), as stated in [28,29]. In the following, as a first approximation, we will only consider the potential drop near the source, U_{inj}, neglecting the potential drop near the drain contact as in [28,31] and [32].

3.1. Nonlinear injection model and OFET specific assumptions

Nonlinear injection has been widely studied in OLEDs [33] and several models have been proposed to explain the current/voltage characteristic: thermoionic and/or tunnel injection [34], Space Charge Limited Current [35], injection in amorphous systems [22,24,25,36,37]. They all aim at a current density expression (J_{inj}) as a function of the electric field (E_{inj}) at the injecting interface. The corresponding injecting current I_{inj} can be expressed as:

$$I_{inj} = S_{inj} \times J_{inj}(E_{inj}), \tag{9}$$

where S_{inj} is the injecting surface.

The injection model used in this paper was proposed by Campbell Scott [24,37]. It describes carrier injection from a conductive electrode into an amorphous OSC, and has been successfully compared to experimentally results [38]. As stated in [24], the injecting current density can be expressed by:

$$J_{inj}(E_{inj}) = -4\Psi^2(f)N_0e\mu(0)E_{inj}\exp(f^{1/2})\exp\left(-\frac{e\Phi_B}{kT}\right) \tag{10}$$

where $f = e^3E_{inj}/4\pi\varepsilon_S k^2T^2$, k is the Boltzmann constant and $\psi(f) = f^{-1} + f^{-1/2} - f^{-1}(1 + 2f^{1/2})^{1/2}$.

Note that when the carrier mobility depends on the local gate voltage, the expression of $\mu(y)$ (Section 2.B) is used and the mobility in (Eq. 10) is evaluated at $y = 0$.

In OLED, the injecting surface S_{inj} simply corresponds to the surface of the injecting electrode, and E_{inj} can be approximated by the ratio of the applied bias to the electrode separation. This relation suggests that the electric field lines are perpendicular to the injecting electrode and that the region between the electrodes is fully depleted. Implementing the injection model becomes straightforward, allowing comparison of the simulated $I_{inj}(E_{inj})$ with the $I-V$ measurements.

In OFETs, the situation is different. First, the depleted area doesn't extend on the entire channel length but on a distance called Y_{inj} from the intrinsic source ($y = 0$). The associated voltage drop U_{inj} is defined by $U_{inj} = V(Y_{inj}) - V(0) = V_{Si} - V_{Si0}$ where V_{Si} is the new intrinsic source potential in presence of nonlinear injection (Fig. 3). Also, the longitudinal injecting electric field is no more uniform over the entire injecting surface, located at the source contact edge. The intrinsic drain current I_{DSi} being equal to I_{inj}, and considering the transistor geometry, (Eq. 9) rewrites for bottom contact OFET as:

$$I_{DSi} = W\int_0^{X_m} J_{inj}(E_{inj}(x))dx \tag{11}$$

where X_m is the thickness of the source electrode (Fig. 3).

Some approximations are necessary to evaluate (Eq. 11). The total injecting thickness X_m is divided in two intervals: $[0;X_C]$ and $[X_C;X_m]$ where X_C is the channel thickness at $y = 0$ (i.e. the thickness of the conductive part of the OSC where most of the accumulated charges are located). The injection region near the source contact edge is divided in two regions I and II (Fig. 3) with corresponding longitudinal electric fields E_{inj_I} and E_{inj_II} evaluated at $y = 0$. The drain current is then:

$$I_{DSi} = WX_C J_{inj}(E_{inj_I}) + W(X_m - X_C)J_{inj}(E_{inj_II}) \tag{12}$$

Finally, taking nonlinear injection into account, the computation of the intrinsic drain current $I_{DSi}(U_{DSi},U_{GSi})$ requires the evaluation of six variables (J_{inj}, E_{inj_I}, E_{inj_II}, U_{inj}, Y_{inj} and X_C) from six independent equations. The following paragraph describes our approach to obtain these equations and the method to solve them in a self-consistent approach.

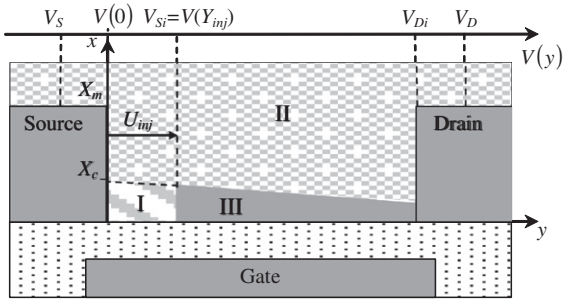

Fig. 3. Schematic bottom contact OFET channel cross-section figuring three regions used in the nonlinear injection model. Region I: depleted zone where the gradual channel approximation fails. Region II: intrinsic OSC. Region III: accumulated charge forming the channel in which the gradual channel approximation is valid.

3.2. Method to implement injection self-consistently

OFETs $I_{DS}(U_{DS},U_{GS})$ characteristics have already been simulated with nonlinear injection, in Refs. [32,39,40] and [41]. However, all of these implementations show limitations. In [39] if the injecting current model does not require the knowledge of S_{inj} and Y_{inj}, two fitting parameters are used instead. In Ref. [40], two head to tail diodes are used to account for $I-V$ nonlinearities. If suitable for circuit design, this approach does not help to understand the device physics. Finally, in Ref. [32] and [41], the depleted length Y_{inj} is a parameter adjusted at each bias to fit experimental results.

The present approach computes simultaneously the I_{DS} drain current and all internal injecting variables in a self-consistent way, without the help of any fitting parameter, in particular without any dependence of internal parameters on gate or drain bias (threshold voltage, concentration of accessible sites...). The hypothesis and approximations used in our approach are described in the following.

1. Channel thickness at the source contact
   Considering a uniform carrier distribution over the available site concentration N_0 (see discussion in section D), the accumulated charge density per unit channel area at the source contact $Q_S(y = 0) = C_i(U_{GSi0} - U_T)$ is equal to eN_0X_C, giving:
   $$X_C = -\frac{C_i}{eN_0}(U_{GSi0} - U_T) \tag{13}$$
2. Poisson's equation in the injecting region
   The abrupt change in the potential slope near the source contact, experimentally observed [28], results from a strong longitudinal electric field gradient: the usual gradual channel approximation may fail near the source electrode. Consequently, according to the 2D Poisson equation, the longitudinal electric field gradient will induce a modification of the channel charge density, compared to the usual accumulated charge due to the gate bias when no nonlinear injection occurs: a depleted region is created at the source contact edge, due to the presence of a high injecting electric field and its gradient.
   Fig. 3 shows a schematic drawing of the source/drain area, divided into three regions. Region I is the depleted zone in front of the channel where the accumulated charge is pushed away by the injecting electric field. Region II and III are respectively the intrinsic OSC and the channel where the usual gradual channel approximation is still valid. To allow an analytic resolution, abrupt transitions have been considered between the different regions.
   In presence of nonlinear injection, the 2D Poisson's equation in depleted region I becomes:
   $$\frac{\partial E_{x_I}(x,y)}{\partial x} + \frac{\partial E_{y_I}(x,y)}{\partial y} = 0 \tag{14}$$
   The main assumption at this step is that the gradient of the transverse electric field $\frac{\partial E_{x_I}(x,y)}{\partial x}$ due to the applied gate bias is not modified compared to the usual gradual channel approximation: i.e. there should be an accumulated

charges ρ_{ch} due to the still present gate bias, but these charges are pushed away from the contact edge by the high longitudinal field. The longitudinal field gradient in region I is then given by:

$$\frac{\partial E_{y_I}(y)}{\partial y} = -\frac{\rho_{ch}(y)}{\varepsilon_S} \tag{15}$$

3. Electric field at the injecting contact and potential drop due to nonlinear injection
Integrating (Eq. 15) using the uniform charge density eN_0 gives the expression of the injecting longitudinal electric field in region I:

$$E_{y_I}(y) = \frac{eN_0}{\varepsilon_S}(Y_{inj} - y) + E_y(Y_{inj}) \tag{16}$$

where $E_y(Y_{inj})$ is the electric field at the depleted zone edge given by (Eq. 8). The injecting electric field $E_{y_I}(0)$ at the source contact edge in region I is given by:

$$E_{y_I}(0) = E_{inj} = \frac{eN_0}{\varepsilon_S} Y_{inj} + E_y(Y_{inj}) \tag{17}$$

This longitudinal field at the electrode edge E_{inj} determines the current density in the case of nonlinear injection (Eq. 10). The potential profile in region I can be obtained integrating (Eq. 16):

$$V_{y_I}(y) = \frac{eN_0}{2\varepsilon_S} y^2 - \left(\frac{eN_0}{\varepsilon_S} Y_{inj} + E_y(Y_{inj})\right) y \tag{18}$$

Finally, the potential drop due to nonlinear injection $U_{inj} = V_{y_I}(y = Y_{inj}) - V_{y_I}(y = 0)$, according to (Eq. 18), is expressed as:

$$U_{inj} = -Y_{inj}\left(\frac{eN_0}{2\varepsilon_S} Y_{inj} + E_y(Y_{inj})\right) \tag{19}$$

The injecting electric field E_{inj_II} at the source contact in region II is obtained from (Eq. 8) at $y = 0$:

$$E_{inj_II} = \frac{-I_{DSi}}{WC_i\beta}\left[(U_{DSi} - U_{GSi} + U_T)^{\gamma+2} - \frac{I_{DSi}(\gamma+2)L}{WC_i\beta}\right]^{-\left(\frac{\gamma+1}{\gamma+2}\right)} \tag{20}$$

4. Intrinsic drain current expressions including nonlinear injection
In presence of nonlinear injection, the intrinsic gate and drain voltages are respectively given by:

$$U_{GSi} = U_{GSi0} - U_{inj} = U_{GS} - R_S I_{DSi} - U_{inj} \tag{21}$$

$$U_{DSi} = U_{DSi0} - U_{inj} = U_{DS} - (R_S + R_D) I_{DSi} - U_{inj} \tag{22}$$

These equations show that nonlinear injection will be observed on the transistor characteristics only if the voltage drop U_{inj} is significant compared to the applied biases U_{GS} and U_{DS}.
The channel being formed from $y = Y_{inj}$ to $y = L$, integration of (Eq. 4) along the channel gives the drain current in linear regime (Eq. 23) and in saturated regime (Eq. 24):

$$I_{DSi} = \frac{W}{(L - Y_{inj})(\gamma+2)}\beta C_i[(U_{DSi} - U_{GSi} + U_T)^{\gamma+2} - (U_T - U_{GSi})^{\gamma+2}] \tag{23}$$

$$I_{DSi} = I_{DSi\,sat} = -\frac{W}{(L - Y_{inj})(\gamma+2)}\beta C_i (U_T - U_{GSi})^{\gamma+2} \tag{24}$$

Note that equations Eqs. 12,23,24 are implicit and use the previous expressions of E_{inj_I}, E_{inj_II}, U_{inj}, Y_{inj} and X_C.

5. Algorithm
At a given bias point (U_{DS},U_{GS}), the drain current I_{DS} must be computed using an iterative process. The calculation requires a set of parameters: the temperature (T), some technological parameters (W, L, and γ, U_T, ε_S, C_i, R_S, R_D, R_B, N_0 and X_m), and parameters linked to the injection model (in our case the barrier height Φ_B Eq. 10). From a given drain current at step n, the next step current is evaluated using successively Eqs. (13), (20), (12), (17), (19), (21)–(23) or Eq. 24, and finally Eq. 3. A Newton–Raphson convergence method [42] is used to minimize the relative error on the drain current.

4. Results and discussion

4.1. characteristics and internal injection variables

In this section, the model outputs are illustrated. All simulations are performed at room temperature for $W/L = 50$, a 100 nm insulator thickness, and a threshold voltage of −5 V (Table 1). To emphasize nonlinear injection effects, and unless otherwise stated, the mobility will be considered constant for all simulations ($\beta \equiv \mu = 10^{-2}$ cm^2 V^{-1}s^{-1} and $\gamma = 0$ in the expression of the mobility given in paragraph II.B). Other parameters are specified for each simulation: resistances R_S, R_D, and R_B, barrier height Φ_B and concentration of accessible sites N_0.

Typical values have been chosen for both the concentration of accessible sites, ($N_0 = 5 \times 10^{18}$ cm^{-3}, lower than the molecular concentration [43,44]), and for the barrier height ($\Phi_B = 0.55$ eV [32,45,46]). These values are representative of a number of organic semiconductor materials. For example, a barrier height in the range 0.2–0.6 eV is often observed between Au or Cr and organic semiconductor such as P3HT or pentacene [32,45,46], and even higher barriers can be expected from ionization energy and electron affinity measurements [47]. Φ_B and N_0 will be varied in section C to account for various situations. Fig. 4 compares the simulated OFET $I - V$ characteristics with or without ($\Phi_B = 0$) nonlinear injection phenomena. As expected, in the case of nonlinear injection, a diode like characteristic is observed at low drain bias (as often reported [29,31,32,48–51]), as well as a decrease of the drain current for all regimes.

Table 1
OFET parameters used for all simulations.

$W = 1000$ μm	$L = 20$ μm	$\mu = 10^{-2}$ cm^2 V^{-1} s^{-1} $T = 300$ K	$C_i = 3.45 \times 10^{-4}$ Fm^{-2} $\varepsilon_S = 2.65 \times 10^{-11}$ Fm^{-1}	$U_T = -5$ V	$X_m = 300$ nm

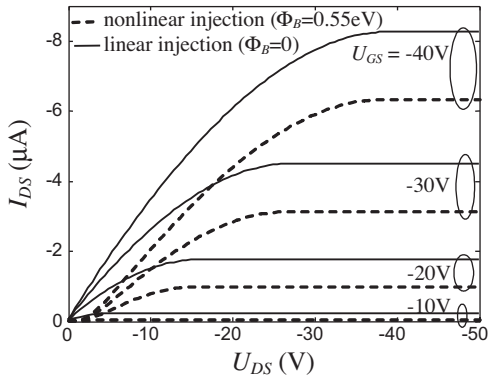

Fig. 4. Simulated $I_{DS}(U_{DS})$ at different U_{GS} with or without nonlinear injection ($R_S = R_D = 500k\Omega$, $R_B = \infty$ and $N_0 = 5 \times 10^{18}$ cm^{-3}).

The internal nonlinear injection parameters, E_{inj} and U_{inj}, calculated self consistently and corresponding to the simulation given Fig. 4, have been plotted in Fig. 5. Both E_{inj} and U_{inj} follow the $I_{DS}(U_{DS},U_{GS})$ characteristic shape: they increase with the drain bias, saturate with the drain current and increase with the gate bias. The injecting electric field (0–5 MV cm^{-1}) is found within the range usually measured in OLEDs [23,25]. The injecting potential drop (0–3 V) is also in agreement with KPFM measurements [28].

The depleted length Y_{inj} and the channel thickness X_C (Eq. 13) are reported in Table 2 for each gate bias, in saturation. The depleted length, never exceeding 20nm in this case, is always very small compared to the channel length ($L = 20$ μm for this simulation). This is a major difference with injection models developed in OLEDs. An experimental verification using the KPFM technique will be challenging since the spatial resolution is about 50nm [27], however improving in high vacuum conditions.

4.2. Comparison with experimental results

$I_{DS}(U_{DS},U_{GS})$ characteristics from Hamadani and Natelson [32] and from our measurements with strong nonlinear behavior have been fitted using the OFET model.

Table 2
Simulated depleted length and channel thickness in saturation for nonlinear injection. The gate bias conditions are those of Fig. 4. ($R_S = R_D = 500$ kΩ, $R_B = \infty$, $\Phi_B = 0.55$ eV and $N_0 = 5 \times 10^{18}$ cm^{-3}).

U_{GS} (V)	−10	−20	−30	−40
Y_{inj} (nm)	12.9	15.9	17.1	17.8
X_C (nm)	2.1	6.3	10.1	13.7

First, experimental data from Ref. [32] were used. These measurements were performed on P3HT bottom-contact organic transistor on degenerated P$^+$ silicon substrate used as gate. The insulator was a thermal SiO_2, with evaporated Chrome electrodes. The Cr/P3HT barrier height is about 0.4–0.5 eV [28,52], inducing nonlinear effects on the $I_{DS}(U_{DS},U_{GS})$ characteristics. The technological parameters given in Ref. [32] are listed in Table 3. The $I_{DS}(U_{DS},U_{GS})$ measurements at low drain bias and the corresponding simulations are depicted in Fig. 6. The fitting parameter values used for these simulations are given in Table 4.

A good agreement is observed all over the characteristics, with a unique parameter set, constant for all bias points. The mobility value is that of usual P3HT devices. The barrier height is in the order of the theoretical value, considering a reasonable concentration of accessible sites, which allows reproducing the shape of the current curves. The series resistances were found negligible compared to the minimum channel resistance (about 3MΩ). In addition, the potential drop at the source contact was found in the range [0; −4V], and the injecting electric field does not exceed 5 MV cm^{-1}, below the breakdown limit (see paragraph yD). Finally, the depletion length varies from 3nm to 15nm (not accessible to present KPFM resolution), and the channel thickness lies within [4; 13nm], corresponding to a few monolayers.

In order to validate the model up to saturation, P3HT bottom-contact OFET were fabricated, on degenerated P$^+$ silicon substrate used as gate. The gate insulator is 116nm of thermal SiO_2. Ti (10nm) / Au (300nm) circular source and drain electrodes are patterned by lithography. The P3HT was drop casted from a chloroform solution, and measured under vacuum conditions. The Au/P3HT barrier height is about 0.5 eV [28], inducing nonlinear effects

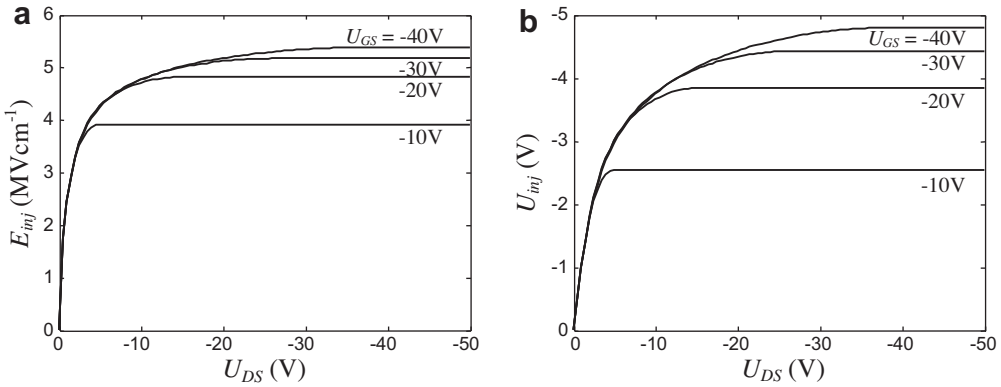

Fig. 5. Simulated injecting electric field (a) and injecting potential drop (b). The bias conditions are those of Fig. 4. ($R_S = R_D = 500$ kΩ, $R_B = \infty$, $\Phi_B = 0.55$ eV and $N_0 = 5 \times 10^{18}$ cm^{-3}).

Table 3
Physical OFET parameters used in Hamadani and Natelson [32].

$W = 200\ \mu m$	$L = 25\ \mu m$	$C_i = 1.73 \times 10^{-4}\ F m^{-2}$	$\varepsilon_S = 2.65 \times 10^{-11}\ F m^{-1}$	$X_m = 30\ nm$	$T = 300\ K$

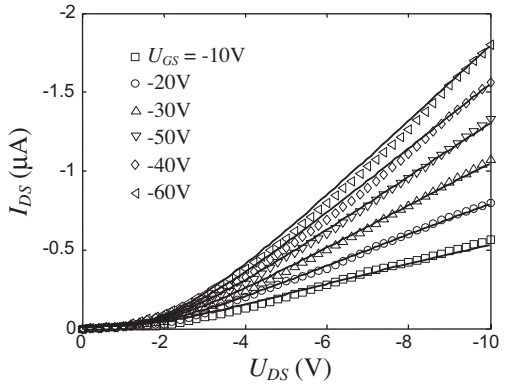

Fig. 6. $I_{DS}(U_{DS})$ characteristics in linear regime (symbols: measurements [32]/full lines: simulations).

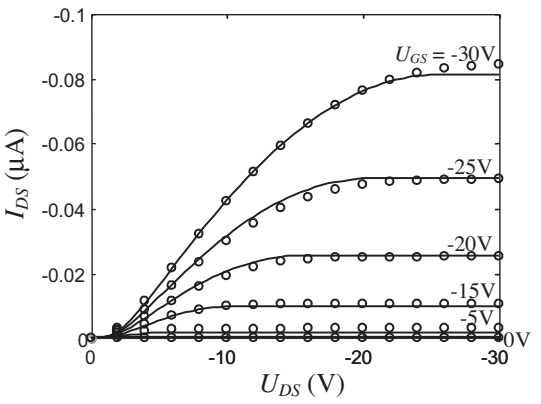

Fig. 7. Measured and fitted non-linear $I_{DS}(U_{DS})$ characteristic, in both linear and saturated regimes (open symbols: measurement/full lines: simulation).

on the $I_{DS}(U_{DS},U_{GS})$ characteristics. The technological parameters of the device are given in Table 5. The transistor $I_{DS}(U_{DS},U_{GS})$ characteristic in both linear and saturated regimes, and the corresponding simulations, are depicted in Fig. 7. The resulting parameter values are listed in Table 6.

Again, agreement is observed all over the characteristic, both in linear and saturated regimes, with a unique parameter set for all bias points. The series resistances were found negligible and set to zero, with no bulk leakage. The barrier height is in the order of the theoretical value. The mobility is found constant, close to $10^{-3}\ cm^2\ V^{-1}s^{-1}$. In addition, the potential drop at the source contact was found in the range [0; −4V], and the injecting electric field is lower than 5 MV cm^{-1}. Finally, the depletion length varies from 5nm to 17nm, and the channel thickness lies within [2; 10nm], corresponding to a few monolayers.

These comparisons demonstrate the model ability to simulate non-linear OFET characteristic in a self-consistent approach, with a single and constant parameter set. In the latter case, only four parameters were used to fit the entire characteristic with good agreement: μ, U_T, Φ_B and N_0. Note that the apparent mobilities found with the usual method (see section C.1 bellow) differ from those used to fit the measurements. This extraction error is illustrated in the next paragraph.

4.3. Mobility and threshold voltage extraction

1. Usual extraction procedure
   The usual mobility and threshold voltage extraction procedure uses the $\sqrt{I_{DS}}$ versus U_{GS} plot in saturation regime [20], based on the first order equation $I_{DS} = \frac{W\mu C_i}{2L}(U_{GS} - U_T)^2$ (see Fig. 8). From this equation in the ideal case, the plot is linear with. In practical case, the abscise intercept is the apparent threshold voltage $U_{T_{app}}$, and the apparent mobility is obtained from the slope following $\mu_{app} = \frac{2L}{WC_i}\frac{\partial\sqrt{I_{DS}}}{\partial U_{GS}}$.
   However, the presence of parasitic effects (series resistances and nonlinear injection in particular) will strongly affect this plot, as will be illustrated below. The extracted threshold voltage and mobility behavior with gate bias for example may be misleading, and the extracted apparent mobility μ_{app} and threshold voltage $U_{T_{app}}$ may be far from their intrinsic values.
   Fig. 8 highlights this issue: a plot of $\sqrt{I_{DS}}$ versus U_{GS} is shown, calculated (i) without any uneven contact contribution, (ii) with series resistances, or (iii) with series resistances and injection barrier. Compared to the ideal situation (i), the plot is no more linear and the slope of the characteristic decreases with either series resis-

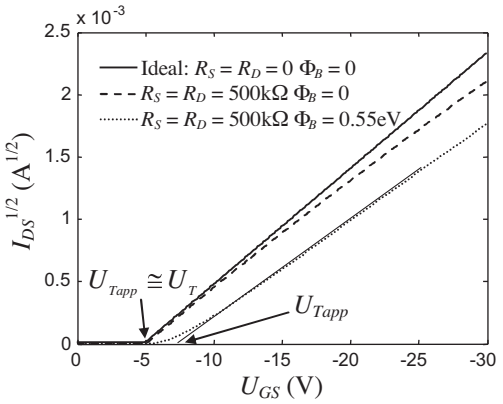

Fig. 8. Usual $\sqrt{I_{DS}}$ versus U_{GS} plot in saturation regime ($U_{DS} = -50$ V), used for the mobility and threshold voltage extraction ($U_T = -5$ V, and $N_0 = 5 \times 10^{18}$ cm^{-3}).

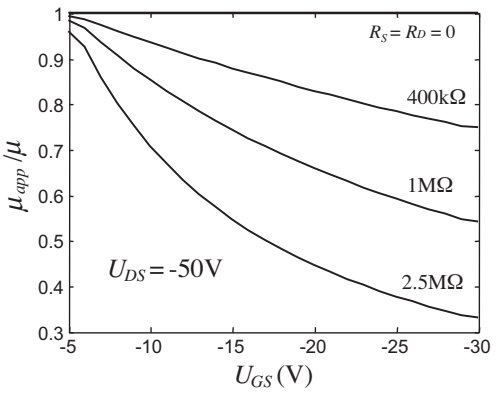

Fig. 9. Extracted apparent mobility on bulk mobility ratio versus gate bias for different series resistances.

tances or injection barrier. The extracted mobility μ_{app} is reduced, and may even show an apparent dependence on the gate voltage. Also, the apparent threshold voltage $U_{T_{app}}$ is clearly over estimated in presence of an injection barrier whereas it is not modified ($U_{T_{app}} \cong U_T$) when only ohmic series resistances are considered. A quantitative analysis of the extracted values is given below.

2. Series resistances and effective mobility
The detrimental influence of the series resistances on the effective mobility is well known [20,51]: the mobility decreases with the gate bias in presence of series resistances, as illustrated in Fig. 9, where the ratio of the extracted apparent mobility μ_{app} to the bulk mobility μ (the model parameter) is plotted against gate bias. The series resistance values (here $R_S = R_D$) are swept from 0Ω up to the channel resistance calculated at $U_{GS} = -30$ V and $U_{DS} = -2$ V. The extracted apparent mobility decreases to a third of its bulk value when the series resistances equal the channel resistance. Series resistances should be estimated prior to the mobility extraction for a better understanding of the transistor physics. For example, the Transfer Line Method (TLM) may be used [40,51,53–55].
3. Nonlinear injection effects on extracted mobility
Figs. 10 and 11 illustrate the influence of an injection barrier on the extracted apparent mobility in saturation regime ($U_{DS} = -50$ V), varying the injection model parameters Φ_B and N_0. Both figures show a decrease of the apparent mobility when the injection efficiency decreases (i.e. when Φ_B increases or when N_0 decreases). An increase of the apparent mobility with gate bias is also observed. Figs. 10b and 11b show the corresponding evolution of μ_{app}/μ in saturated regime ($U_{GS} = -30$ V and $U_{DS} = -50$ V) respectively versus the barrier height Φ_B or versus the concentration of accessible sites N_0. These results show that the knowledge of the injecting parameters is mandatory for an accurate extraction of the mobility.
It is now obvious that the apparent mobility is highly sensitive to uneven source/channel contacts. The apparent mobility decreases with gate bias when series resistances are high (Fig. 9), whereas when nonlinear injection occurs, it increases with gate bias (Figs. 10a and 11a). Unfortunately, these two parasitic source/channel phenomena (and possibly others) are likely to be simultaneously present in organic transistors, leading to various dependences of the apparent mobility on gate bias [43,51,54–58]. By combining series resistances and nonlinear injection effects, exotic behaviors can be simulated for $\mu_{app}(U_{GS})$ (linear increase or decrease, with or without saturation...) for a given intrinsic mobility. Despite that the mobility dependence on gate bias is supported by serious arguments [22,56,59,60], the above discussion demonstrates that such analysis from experimental results should be undertaken very carefully, particularly when both series resistances and nonlinear injection are present on the device. Although some correction procedures are possible for series resistances alone [56,57], an analytical correction is no more possible when both effects are present.
4. Nonlinear injection effects on extracted threshold voltage
In the literature, high threshold voltages are often reported when OFETs present nonlinearities (see for example Fig. 6 in Ref [54]). In this section, we will establish that nonlinear injection shifts the extracted apparent threshold voltage $U_{T_{app}}$ from the intrinsic value U_T, when using the usual extraction method. Such plots have been simulated in Fig. 12a for various injection efficiencies, through different barrier heights. These simulations show an increase of the apparent threshold voltage when increasing barrier heights.

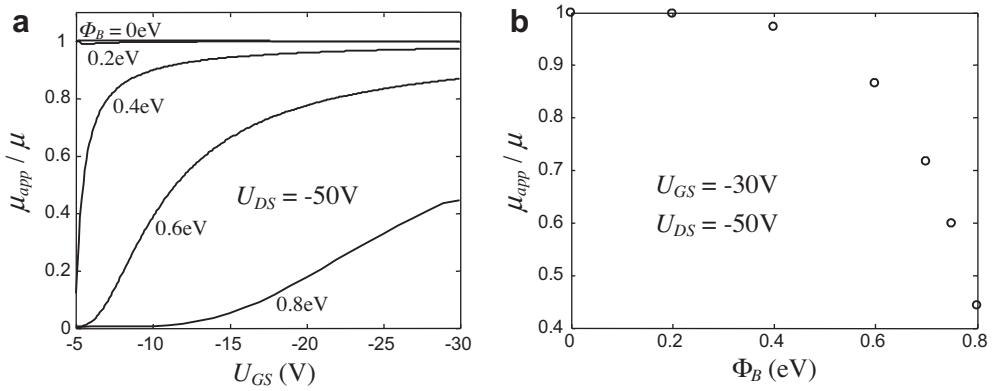

Fig. 10. (a) Extracted apparent mobility versus gate bias for different barrier height values ($R_S = R_D = 0$, $R_B = \infty$ and $N_0 = 5 \times 10^{18}$ cm^{-3}). (b) Corresponding μ_{app}/μ ratio versus Φ_B for an operating point in saturation.

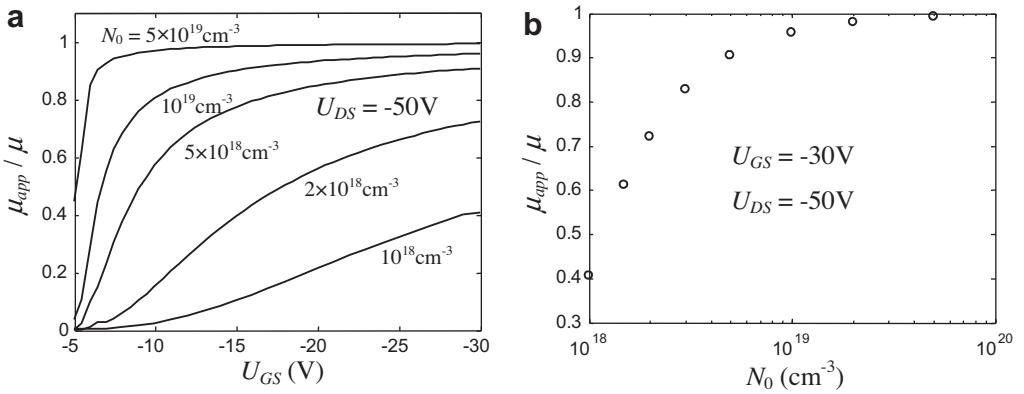

Fig. 11. (a) Extracted apparent mobility versus gate bias for different concentration of accessible sites ($R_S = R_D = 0$, $R_B = \infty$ and $\Phi_B = 0.55$ eV). (b) Corresponding μ_{eff}/μ ratio versus N_0 for an operating point in saturation.

When extracted at very high gate bias, we found that the threshold voltage shift equals the injection voltage drop U_{inj}, as shown Fig. 12b (full line). This can be understood considering that $U_{GS} = U_{GSi} + U_{inj}$ (Eq. (21) for $R_S = 0$). At threshold, $U_{GS} = U_{T_{app}}$ and $U_{GSi} = U_T$ which gives $U_{T_{app}} = U_T + U_{inj}$. However, for real devices, the measurements are usually performed at limited gate bias to prevent gate breakdown, which lowers the extracted threshold values, between the intrinsic value U_T and the maximum shifted value $U_T + U_{inj}$.

To illustrate these trends, simulations have been performed at three operating points in saturation regime ($U_{GS} = U_{DS} = -20, -50, -100$ V) and for various barrier heights. For a given operating point, $U_{T_{app}}$ varies linearly with U_{inj} for the different barrier heights (the different symbols on dashed lines). The asymptote $U_{T_{app}} = U_T + U_{inj}$ (full line in Fig. 12b) is reached when the bias point is taken extremely high, where the $\sqrt{I_{DS}} = f(U_{GS})$ characteristic becomes linear whatever the barrier height.

As for the apparent mobility, it is now clear that the apparent threshold voltage is highly sensitive to any injection barrier at the source/channel contact. The usual extraction method will fail in presence of both contact resistances and nonlinear injection. The simulations have shown that the extracted values can be far from the threshold voltage U_T. Even if nonlinear injection is not the only reason for high extracted threshold voltages, it must be taken into account to interpret experimental results. In this respect, studies of threshold voltage under different physical conditions (temperature change, voltages stress...) must be undertaken with care each time nonlinear effects are suspected on the device. The log(I_{DS}) versus U_{GS} plot should be preferred to study the gate behavior near threshold since in this case, the extraction is much less sensitive to parasitic effects: it is performed at lower current, where the injecting voltage drop is negligible.

Mobility and the threshold voltage are both highly process-dependent, and are first order parameters to evaluate an OFET technology. The previous section emphasized the difficulties encountered to obtain these parameters accurately from measured current characteristics. Injection barriers may ruin usual correction procedures. The self-consistent OFET model developed here is a useful tool for OFET technology evaluation, providing better understanding of nonlinear injection effects, and even allowing intrinsic parameter extraction. Due to the numerous

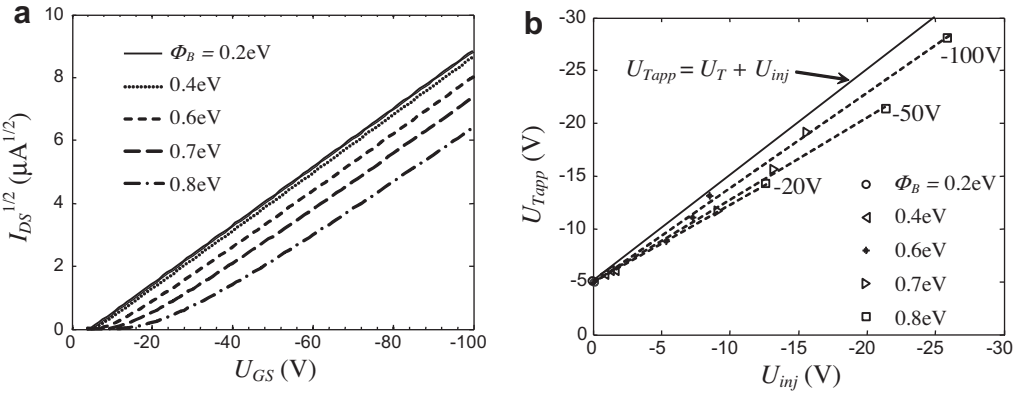

Fig. 12. (a) $\sqrt{I_{DS}}$ versus U_{GS} characteristics in saturation regime ($U_{DS} = -100$ V) for various barrier heights. (b) Corresponding apparent threshold voltage $U_{T_{app}}$ as a function of the calculated injection voltage drop U_{inj}. Extractions are performed at three operating points: $U_{GS} = U_{DS} = -20, -50, -100$ V(dotted lines), and at extremely high gate bias (full line). ($U_T = -5$ V, $R_S = R_D = 0$, $R_B = \infty$ and $N_0 = 5 \times 10^{18}$ cm^{-3}).

physical effects at work in an OFET, various characterization tools should also be used to improve the overall OFET understanding. In particular, Φ_B and N_0 contribution to current-voltage nonlinear characteristics appear to be strongly correlated, and complementary experiments should be used to clarify their respective contribution.

4.4. Prediction of instabilities and breakdown in OFET

OFET electrical characteristics sometimes present unexpected behaviors like noise, instabilities, or even breakdown. This could be due to high internal electric fields in the device. The critical electric field (at breakdown) depends on the nature of the organic materials, but may also be highly sensitive to the technological process. This limit can be estimated to 5–6 MV cm^{-1} [32]. The following study focuses on the electric field intensity at the source electrode (where the electric field is maximum) in presence of nonlinear injection. Note that the injection model used in this work was not developed to describe carrier injection under very high electric fields, where other contributions to the current density could take place. The present work intends to highlight possible high fields in the transistor channel rather than to describe the breakdown physics itself.

As it could be anticipated, simulation shows that low injection efficiency causes high injecting fields. Nonlinear injection can also produce a diode like behavior at low drain biases, as already mentioned (Fig. 4). However, in some cases, the effect of an injection barrier is not directly visible on the measured characteristics, as shown in the inset of Fig. 13, and it is then sometimes difficult to associate the observed instabilities with a poor contact. This section discusses these issues.

The inset in Fig. 13 shows an example of simulated $I_{DS}(U_{DS},U_{GS})$ characteristics where nonlinear injection effects are hardly visible. This occurs when both the barrier height and the concentration of accessible sites are high. The corresponding injecting electric fields at the source are plotted in Fig. 13. For a large range of operating points,

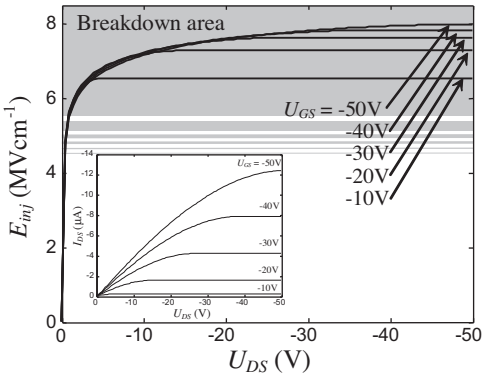

Fig. 13. Injecting electric field versus U_{DS} corresponding to the simulated $I_{DS}(U_{DS},U_{GS})$ characteristics in presence of (invisible) nonlinear injection (inset) ($R_S = R_D = 500$ kΩ, $R_B = \infty$ and $\Phi_B = 0.65$ eV and $N_0 = 5 \times 10^{19}$ cm^{-3}).

the electric field exceeds the 5–6 MV cm^{-1} breakdown limit. Moreover, the breakdown field is reached at very low drain bias, just above a few volts. In such situations, unexpected breakdown can occur even at low drain bias.

Fig. 14a and b shows the electric field behavior versus the barrier height for different concentrations of accessible sites, respectively in linear regime ($U_{GS} = -50$ V and $U_{DS} = -5$ V) and in saturation regime ($U_{GS} = -30$ V and $U_{DS} = -50$ V). The electric field values are found to increase with increasing Φ_B: the higher the barrier height, the higher the electric field required to inject charges from the source contact into the channel. In linear regime (Fig. 14a), a barrier height higher than 0.6 eV causes the electric field to exceed the breakdown limit over a wide range of available site concentrations, except for low N_0 values (<5 × 10^{18} cm^{-3}). This trend is even more pronounced in saturated regime (Fig. 14b). The injecting field values are also found to increase with increasing N_0, which goes against the intuitive idea that a high concentration of available sites should promote the injection efficiency, as in OLEDs. However it can be easily understood. For a given gate bias, the conductive channel thickness X_C varies as $1/N_0$ (Eq. 13). A high concentration of available sites

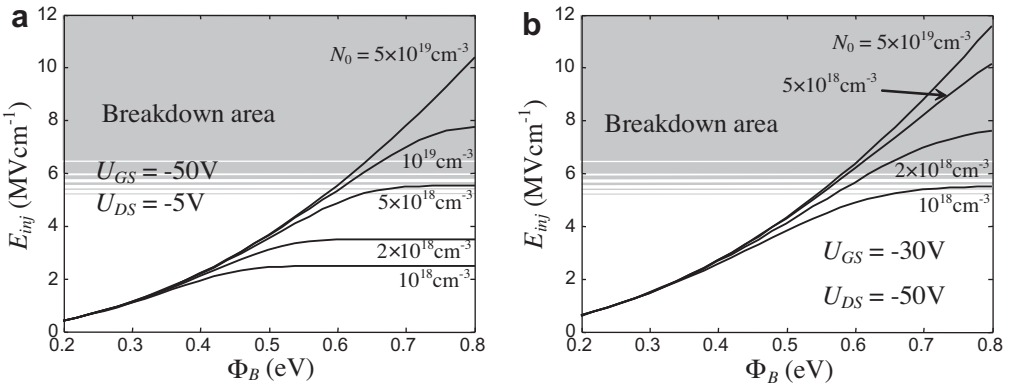

Fig. 14. Simulated injecting electric field versus barrier height for different concentrations of accessible sites (a) in linear regime and (b) in saturated regime ($R_S = R_D$ = 500 kΩ and $R_B = \infty$). The breakdown is estimated to 5–6 MV cm^{-1}.

reduces the channel thickness, which in turn reduces the injecting surface. A higher injecting field is then necessary to achieve a given drain current.

Nonlinear injection is found to cause very high electric fields at the source contact, in particular when a high concentration of accessible sites is available. It is believed that these high fields are responsible for instabilities, noise, and even breakdown in organic FETs suffering from poor contacts.

Also, importantly, simulations show that a nonlinear diode-like characteristic is only observed for low concentrations of accessible sites. At high concentrations, results indicate that injection effects should not be observed on the current characteristic (see Fig. 13). However, many nonlinear characteristics are observed in the literature (and in the labs), suggesting that the concentration of available sites is much lower than the molecular concentration, and that the injecting surface extends far from the insulator interface. This is the main reason why the spatial concentration of accumulated carriers was considered constant in this work, rather than governed by a Boltzmann or Fermi Dirac statistic over a given density of states. Indeed, simulations have been performed using a conventional 3D DOS and the Boltzmann approximation, with an effective density of states N_V taken close to the molecular concentration. Main results were: (i) the resulting carrier concentration is located very close to the insulator/OSC interface, approaching the molecular concentration at high gate bias, (ii) the channel thickness is limited to a few monolayers and the injecting surface is reduced consequently (iii) the resulting $I_{DS}(U_{DS},U_{GS})$ characteristic never exhibits a nonlinear diode-like behavior, even for high barrier heights. This does not agree with widely reported experimental results. Consequently, the only strategy would have been to reduce the effective density of states to very small values, which does not make much sense. In order to provide a clear and simple view of the problem, highlighting the issue of the low density of accumulated carriers and its large extension far from the interface, it was preferred to use a simple low density repartition, uniform in space, even though when the origins of this low density will be clarified, a statistical energetic approach will be required for precise quantitative modeling.

5. Summary and perspectives

OFET performances are mainly limited by the transport efficiency in the channel and by the quality of the source and drain ohmic contacts, often suffering from high series resistances and nonlinear injection. These parasitic effects often occur simultaneously in OFETs. To study the influence of uneven contacts, we developed a one-dimensional self-consistent bottom-contact OFET electrical model.

The model is based on the usual silicon MOS field-effect transistor model, and the different assumptions relative to the organic based FET have been detailed and discussed. To take some of the organic FET specific parasitic effects into account, the model includes source and drain series resistances, a bulk leakage resistance, and nonlinear injection effects at the source electrode, that constitute the main and most original contribution of this paper. The calculation of the drain current uses a specific current density versus injecting electric field model developed for OLED, adapted to the bottom-contact organic transistor. All of the physical variables associated to the nonlinear injection (injecting electric field, potential drop near the source, corresponding depleted length) are calculated at the same time, in a self-consistent approach. This has the advantage of avoiding the use of any fitting parameters (bias dependent or arbitrary fixed) in place of internal variables. An overall coherence is obtained, and the calculated internal variables can be used to analyze and understand some of the OFET misbehaviors.

The model capabilities were first illustrated through various current/voltage and internal variables simulation results with a set of typical parameters. In presence of an injection barrier, the nonlinear diode-like behavior of the drain current at low drain bias has been evidenced, as well as an overall decrease of the drain current characteristic. All internal injecting variables were found to be coherent with measurements, as demonstrated for different P3HT based OFETs. The self-consistent model proved to be an efficient characterization tool, providing intrinsic internal

parameters such as mobility and threshold voltage, as well as internal potential profiles and electric fields.

The model was used to illustrate the influence of the parasitic effects on the extracted mobility and threshold voltage. The square root of the drain current versus gate voltage curve in saturation regime is commonly used to extract an effective mobility and an effective threshold voltage. Whereas all simulations have been performed with a unique mobility and threshold voltage, we have shown that the combined effects of series resistances and nonlinear injection could lead to various types of extracted apparent mobility variation with gate bias. We have also shown that the shift of the extracted threshold voltage in presence of nonlinear effects can reach the injecting voltage drop at the source contact. This section shows that the apparent mobility behavior with gate bias obtained from such measurements should be considered with precautions since it is most of the time unreliable. The self-consistent OFET model is believed to improve the extraction results since the main source/channel contact parasitic effects are taken into account.

A study of possible instabilities and breakdown due to nonlinear injection in OFETs was undertaken, based on the calculation of the internal injecting electric field. For a source/channel barrier higher than 0.5–0.6 eV, a 5–6 MV cm^{-1} breakdown limit is reached over a wide range of concentrations of accessible sites, above $3–5 \times 10^{18}$ cm^{-3}. At high concentrations, breakdown conditions can appear even at low drain bias, with hardly visible effect on the transistor current/voltage characteristics. Finally, from an experimental point of view, this study suggests that very high electric fields, responsible for instabilities, electric stress, or even breakdown, can be present in devices suffering from contact injection barrier. Improvements of the source and drain contacts appear as a key priority.

The self-consistent OFET model developed in this paper is a powerful tool for electrical characterization. Its capabilities have been demonstrated through simulations and comparison with experimental data, providing a coherent set of internal parameters. It should help to improve and to gain confidence in the knowledge of organic field effect transistor physics.

the use of SiO_2/Si substrates coated with hydrophobic polymer drastically reduced the hysteresis (increasing $|V_G|$ is called the forward measurement mode, and decreasing $|V_G|$ the reverse measurement mode). Furthermore, we have quantitatively analyzed the suppression of drain current in a plot of $|I_D|^{1/2}$ vs. $|V_G|$ for high $|V_G|$ by the introduction of a mobility reduction factor θ.

2. Experimental

The structure of the picene thin film FET is shown in Fig. 1a. The surface of the 400 nm thick SiO_2 gate dielectric was coated with either Cytop™ or polystyrene after cleaning the SiO_2 surface as described elsewhere [6]. M-type Cytop™ was purchased from Asahi Glass Co., and polystyrene from Aldrich Co. Coating solutions were 8.6 wt% Cytop™ in CT-solv 180 (Asahi Glass Co.), and 1.8 wt% polystyrene in toluene. The Cytop™ films were formed by spin coating at 500 rpm for 5 s and 4000 rpm for 40 s; polystyrene films were formed by spin-coating at 1000 rpm for 5 s and 4000 rpm for 40 s. Picene films 17 and 20 nm thick were deposited on the Cytop™ and polystyrene-coated SiO_2/Si substrates, respectively. Source/drain Au electrodes 40 nm thick were formed on the picene thin films. Channel length L and channel width W were 30 μm and 2.9 mm, respectively, for the picene FET with a Cytop™-coated SiO_2 gate dielectric, while L and W were 30 μm and 2.2 mm, respectively, for the picene FET with a polystyrene-coated SiO_2 gate dielectric. O_2 gas with 0.014 ppm of water was used to measure the effect of O_2 exposure on the picene FETs. The O_2 gas was introduced into the measurement cell to investigate the FET characteristics and the amount of O_2 was precisely regulated by monitoring the vacuum gauge. Experimental details (O_2 concentration, exposure time, pumping time, etc.) of O_2 gas exposure and pumping are described in the text.

3. Results and discussion

Fig. 1b shows the transfer curve for the picene thin film FET with a hexamethyldisilazane (HMDS)-coated SiO_2/Si gate dielectric (picene/HMDS/SiO_2 FET), measured after dynamic pumping at 10^{-6} Torr for 1 h. The transfer curves show a large hysteresis between forward and reverse measurements, as reported previously [7,8]. The μ values were determined to be 0.019 and 0.13 $cm^2\,V^{-1}\,s^{-1}$, respectively, from the forward and reverse transfer curves, consistent with earlier reports [7,8]. Fig. 1b includes a photo of water on the HMDS-coated SiO_2/Si surface, with a contact angle of 84°. Fig. 1c shows the transfer curves for the picene/Cytop™/SiO_2 FET, measured after dynamic pumping at 10^{-6} Torr for 1 h. The hysteresis is drastically reduced. Fig. 1c includes a photo of water on a Cytop™-coated SiO_2/Si surface, with a contact angle of 90°, suggesting a more hydrophobic surface. The μ values determined from the forward and reverse transfer curves were 0.051 and 0.17 $cm^2\,V^{-1}\,s^{-1}$, respectively. These μ values show that the operational speed of a picene FET is not reduced by the use of a Cytop™-coated SiO_2/Si gate dielectric.

Fig. 1d shows the transfer curves for a picene/polystyrene/SiO_2 FET, measured after dynamic pumping at 10^{-6} Torr for 1 h; the μ values were determined to be 0.08 and 0.16 $cm^2\,V^{-1}\,s^{-1}$ from the forward and reverse transfer curves, respectively. The transfer curves show less

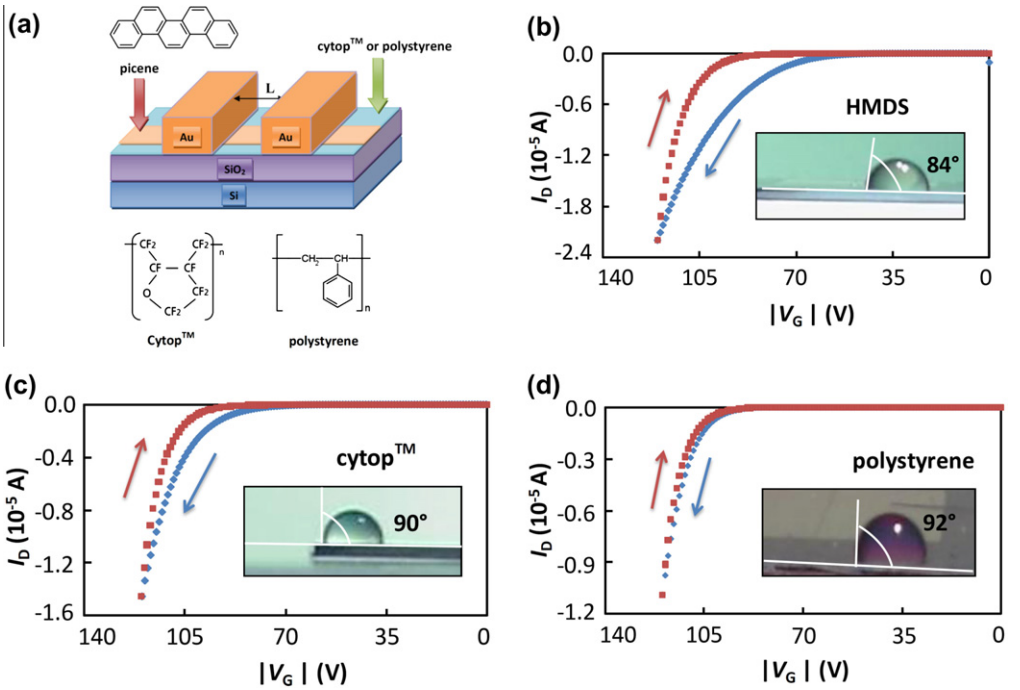

Fig. 1. (a) Structure of the picene thin film FET. Molecular structures of picene, Cytop™ and polystyrene are shown. Transfer curves for (b) picene/HMDS/SiO_2, (c) picene/Cytop™/SiO_2 and (d) picene/polystyrene/SiO_2 FETs. Inset photos show water on the surfaces.

hysteresis than those for the picene/Cytop™/SiO_2 FET. Fig. 1d includes a photo of water on a polystyrene-coated SiO_2/Si substrate. The contact angle of 92° was almost the same as that of water on Cytop™ (Fig. 1c). As seen from Fig. 1b and d, the pronounced hysteresis found in the transfer curves of the picene/HMDS/SiO_2 FET substantially disappeared in the picene/polystyrene/SiO_2 FET. This result strongly supports the hypothesis that water is responsible for the hysteresis in the transfer curves. Here it should be noted that despite displaying the same water contact angle, the picene/polystyrene/SiO_2 FET hysteresis is much smaller than that of the picene/Cytop™/SiO_2 FET. In order to identify the origin of the lower hysteresis with the polystyrene-coated SiO_2/Si substrate, we examined the surfaces of Cytop™ and polystyrene-coated SiO_2/Si substrates with atomic force microscopy (AFM) (not shown). The surface roughness of Cytop™-coated SiO_2/Si is much larger than that of polystyrene-coated SiO_2/Si. Actually, the root mean square roughness, R_{rms}, of the Cytop™-coated SiO_2/Si surface was 1.5 nm, which is larger by a factor of 5 than the 0.34 nm roughness of the polystyrene-coated SiO_2/Si surface. This large roughness difference may explain the hysteresis difference between the FETs, *i.e.*, the H_2O molecules involved in the nanoscale concavity in the Cytop™-coated SiO_2/Si surface may produce the bias-stressed hysteresis in transfer curves, and the contact angle should not be affected by H_2O molecules in the nanoscale concavity, because contact angle is a macroscopic phenomenon.

Fig. 2a shows the O_2-exposure response of $|I_D|$ ($|I_D|^{max}$) for picene/Cytop™/SiO_2 FET, measured at $V_G = -120$ V and $V_{DS} = -120$ V. The period of O_2 exposure and dynamic pumping was set at 24 h in the investigation of O_2 exposure effects on the picene FETs. The $|I_D|^{max}$ value increased within a few minutes of O_2 exposure, and after 5 h $|I_D|^{max}$ had increased to 70% of its value after a 24 h exposure for a wide range of O_2 concentrations from 0.1 to 8 Torr. After 24 h of O_2 exposure, $|I_D|^{max}$ increased to a value 1.4 times higher than that measured just before O_2 exposure. When the O_2 gas exposure was greater than 100 Torr, after 24 h $|I_D|^{max}$ increased to a value 1.8 times higher than that measured just before O_2 exposure (not shown).

As can be seen from Fig. 2a, $|I_D|^{max}$ decreases rapidly with dynamic pumping at 10^{-6} Torr, reaching the minimum value within 5 h. We previously observed an increase in $|I_D|^{max}$ for the picene/HMDS/SiO_2 FET with increasing O_2 exposure from 16 to 500 Torr, which could be directly related to the increase in μ caused by shallow trap reduction [8]. Our scenario for the O_2 gas sensing effect of a picene thin film FET is that the shallow traps which consist of positively charged defects and impurities are screened by polarized O_2, $O_2^{\delta-}$ when the picene FET is exposed to O_2, so the effective trap abundance decreases, thus increasing μ and the absolute value of the switch-on drain current [8]. On the other hand, when the O_2 gas contained in the picene thin film is dynamically exhausted, the effective trap abundance increases owing to the removal of $O_2^{\delta-}$ around trap centers, thus decreasing μ and the absolute switch-on drain current [8].

In this study, we reduced the O_2 concentration down to 0.01 Torr and investigated the $|I_D|^{max}$ response to O_2 exposure. In practice, the difference, $\Delta|I_D|^{max}$, between the minimum and the maximum $|I_D|^{max}$ values slowly decreases down to that at 0.01 Torr of O_2, as is shown in Fig. 2b (0.01 Torr of O_2 corresponds to ~10 ppm of O_2). The ratio of $\Delta|I_D|^{max}$ at specified O_2 concentrations to that at 7.5 Torr of O_2 is shown together with the estimated standard deviation (error bar) in the inset of Fig. 2b. Here, the plot shows the average value of three picene FET devices, and the clear dependence of O_2 sensing properties on the O_2 concentration is apparent. Actually, even in 10^{-2} Torr of O_2, a non-vanishing $\Delta|I_D|^{max}$ is observed. Thus, the reproducibility of O_2 sensing properties is confirmed in a picene thin film FET.

The minimum value of $|I_D|^{max}$ (Fig. 2a) corresponds to the $|I_D|^{max}$ at 10^{-6} Torr. The minimum value (baseline shown by dashed line in Fig. 2a) decreases monotonically

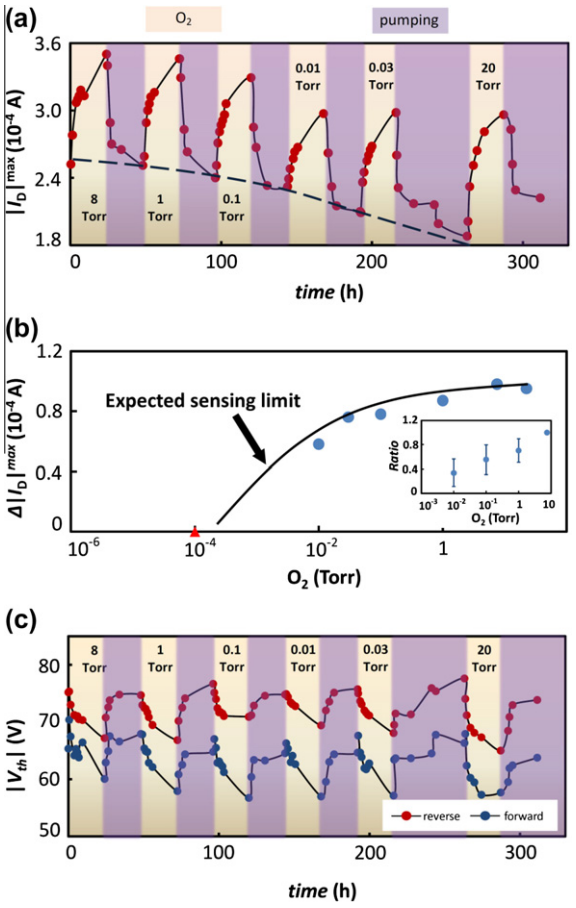

Fig. 2. (a) Plots of $|I_D|^{max}$ vs. O_2-exposure/exhaust time and (b) $\Delta|I_D|^{max}$ vs. O_2 concentration in the picene/Cytop™/SiO_2 FET. The dashed line in (a) refers to the baseline, *i.e.*, the minimum $|I_D|^{max}$ values after dynamic pumping at 10^{-6} Torr. In (b), the expected sensing curve is drawn as a function of O_2 concentration, and the expected minimum sensing limit is shown in the graph. Inset in (b), the average value at certain times of the ratio of $\Delta|I_D|^{max}$ to that at 7.5 Torr (estimated with three picene thin film FETs). (c) Plots of $|V_{TH}|$ vs. O_2-exposure/exhaust time in the picene/Cytop™/SiO_2 FET. In (c) the red and blue circles refer to the $|V_{TH}|$ determined from the reverse and forward transfer curves, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

with repeated pumping, suggesting that repeated O_2-exposure causes no accumulation of O_2 at interface between the Cytop™-coated SiO_2 and the picene layer.

The $\Delta|I_D|^{max}$ at 0.01 Torr of O_2 went down to 80% of the $\Delta|I_D|^{max}$ at 0.1 Torr of O_2, as can be seen from Fig. 2a and b, suggesting that even an O_2 exposure of less than 0.01 Torr can cause a significant increase in $|I_D|^{max}$. As we obtained no FET response to an O_2 exposure of 10^{-4} Torr in the preliminary experiment on the O_2-exposure effect on a picene FET, the $\Delta|I_D|^{max}$ vs. O_2 concentration curve can be represented as in Fig. 2b. This curve refers to the expected detection curve of this picene field-effect sensor for O_2 gas. When the picene/Cytop™/SiO_2 FET was exposed to 0.03 Torr of O_2 after a 0.01 Torr O_2 exposure and subsequent dynamic pumping, the $\Delta|I_D|^{max}$ recovered to the value expected for 0.03 Torr on the detection curve drawn in Fig. 2b. The picene thin film FET can detect a level as low as 0.001 Torr (~1 ppm) of O_2, as indicated by the curve (Fig. 2b); the preliminary experiment on the O_2-sensing properties of a picene thin film FET confirms a non-vanishing $\Delta|I_D|^{max}$ after exposure to 1 ppm of O_2. These results clearly indicate the potential usefulness of a picene thin film FET as an O_2-gas sensor.

The response of the μ value of the picene/Cytop™/SiO_2 FET to O_2 exposure is clear, and in particular the μ value determined from the forward transfer curve shows a large response to O_2 exposure (not shown). O_2 exposure enhanced the μ values determined from both the forward and reverse transfer curves, and the response was exactly consistent with that of $|I_D|^{max}$ (Fig. 2a), supporting our previous model in which the increase in $|I_D|^{max}$ due to O_2 exposure originates substantially from the response of μ as produced by the shallow trap reduction [8]. As can be seen from Fig. 2c, exposing the picene/Cytop™/SiO_2 FET to O_2 lowered $|V_{TH}|$, and removing the O_2 enhanced $|V_{TH}|$. These results clearly show that the O_2 exposure influences the traps formed in the band gap, because the variation of $|V_{TH}|$ is closely associated with the quantities of shallow and middle traps. Thus we can conclude from these investigations that the trap reduction caused by O_2 exposure produces the observed increase in $|I_D|^{max}$ and μ, as well as the decrease in $|V_{TH}|$.

Plots of $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ for the picene/Cytop™/SiO_2 and picene/polystyrene/SiO_2 FETs stored for 0, 6 and 24 h under an O_2 atmosphere are shown in Fig. 3a and b. Before O_2 exposure these FETs were dynamically pumped for 24 h under 10^{-6} Torr, and then exposed to 8 and 10 Torr of O_2 gas. The V_{DS} was −120 V, *i.e.*, a saturation regime. Here, it should be noted that the $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plots of the picene/Cytop™/SiO_2 FET (Fig. 3a) and the picene/polystyrene/SiO_2 FET (Fig. 3b) stored for 6 and 24 h under an O_2 atmosphere deviate from the expected straight line and the plots are suppressed in the high $|V_G|$ region, showing that the μ values are not constant but decrease with an increase in $|V_G|$. The $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plots show more suppression of the drain current with extended O_2 exposure. This suppression of drain current in the $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plot in the high $|V_G|$ region can be attributed to the reduction of mobility caused by the scattering of carriers.

Since the carriers are often pushed against the gate dielectric in a vertical electric field, the spatially averaged

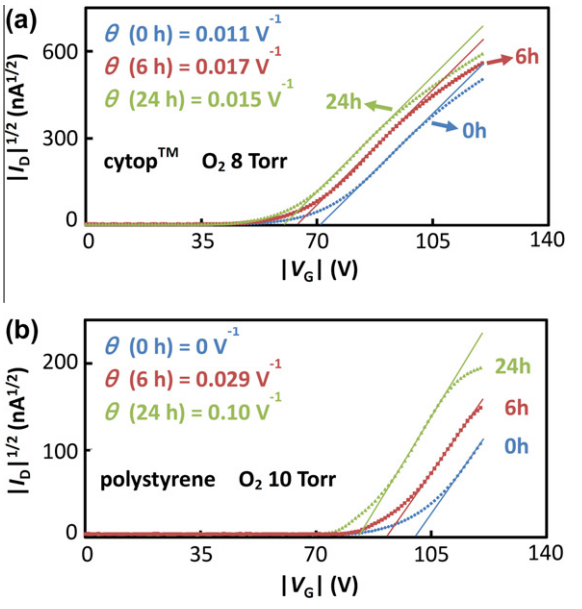

Fig. 3. (a) $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plots for the picene/Cytop™/SiO_2 FET and (b) the picene/polystyrene/SiO_2 FET. The O_2 exposure time is given in the graphs. Straight lines indicate the lines without the suppression effect expected from the general MOS formula in the saturation regime. The θ values estimated are given in the graphs.

surface mobility, μ_{eff}, estimated under the applied V_G, known as the gate-dependent effective surface mobility, is reduced in comparison with the surface mobility, μ_0, in the absence of V_G. The relation between μ_{eff} and μ_0 is expressed by [9],

$$\mu_{eff} = \frac{\mu_0}{1 + \theta(|V_G| - |V_{TH}|)} \quad (1)$$

As seen from Eq. (1), μ_0 is affected by two variables, θ and effective gate voltage $|V_G| - |V_{TH}|$. Therefore, μ_0 can be reduced by increasing $|V_G| - |V_{TH}|$ if θ does not vanish. As the $|V_{TH}|$ of the picene FET is reduced under O_2-exposure, the decrease in μ at high $|V_G|$ (Fig. 3a and b) may be explained by the increase in $|V_G| - |V_{TH}|$. In order to investigate whether θ remains constant with O_2-exposure, the θ values for the picene/Cytop™/SiO_2 and picene/polystyrene/SiO_2 FETs were estimated at $V_G = -120$ V; μ_{eff} $(= \frac{L}{WC_0(|V_G|-|V_{TH}|)} \frac{d|I_D|}{d|V_G|})$ was estimated from the numerical derivative, $\frac{d|I_D|}{d|V_G|}$, of the $|I_D|$ vs. $|V_G|$ curve at 120 V, while μ_0 was estimated from the $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plots in the linear region with the general MOS FET formula [10], *i.e.*, μ_0 refers to the general μ in the saturation regime. The θ value estimated from each plot is described in Fig. 3a and b. These results show an enhancement of θ with an increase in O_2 exposure time. Actually, the θ value saturates in picene/Cytop™/SiO_2 FET for O_2 exposures longer than 6 h, although it increases monotonously in picene/polystyrene/SiO_2 FET with an increase in O_2 exposure time. Furthermore, θ was vanishing in the $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plot (0 h) measured just after the O_2-exposure of picene/polystyrene/SiO_2 FET (Fig. 3b), while a non-zero θ value (0.011 V^{-1}) is obtained even immediately after O_2 exposure of the picene/Cytop™/SiO_2

FET (Fig. 3a). These may directly reflect the difference in the surface roughness/morphology between Cytop™-coated and polystyrene-coated SiO_2 surfaces. As a consequence, the suppression in $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plots observed in the high $|V_G|$ region is produced both by an increase in θ and a reduction in $|V_{TH}|$. Although it is difficult to precisely identify the physical origin of θ, this value is closely associated with the scattering effects that prevent carrier migration from source to drain electrodes. As is described above, the θ value may be enhanced by an increase in surface roughness as well as the existence of scattering centers. This means that θ may provide a new measure to evaluate surface morphology.

4. Conclusion

We have fabricated a selective and efficient O_2 gas sensing system using picene thin film FETs. The large hysteresis in the transfer curves that was observed in an earlier picene thin film FET [7,8] was substantially eliminated by the use of SiO_2 coated with strongly hydrophobic polymers. A picene thin film FET will sense O_2 usefully at concentrations as low as 1 ppm. Furthermore, we found a suppression of drain current in $|I_D|^{\frac{1}{2}}$ vs. $|V_G|$ plots in the high $|V_G|$ region and analyzed it quantitatively by introducing a mobility reduction factor. The suppression effect increases with increasing O_2 exposure time, and the mobility reduction factor is enhanced, indicating the enhancement of hole scattering by O_2 adsorption on the surface, which is the opposite effect to the enhancement of $|I_D|$ produced by the shallow trap reduction.

increased V_{oc}. In this study, we show how boron subphthalocyanine chloride (SubPc, Fig. 1a) is a suitable donor material for use in conjunction with $F_{16}CuPc$ and bilayer OPV cells are demonstrated with significantly improved PCE values of 0.56%.

2. Experimental details

The OPV cells were fabricated on commercially available indium-tin-oxide (ITO) coated glass substrates (Psiotec, 100 nm thick ITO, $R_s < 15\ \Omega\ sq^{-1}$) after initial solvent cleaning. The substrates were then exposed to an atmosphere of UV/ozone to remove any remaining carbon residues. The materials used in the cells were molybdenum oxide (MoO_x, Aldrich, 99.99%), SubPc (Aldrich), $F_{16}CuPc$ (Aldrich) and bathocuproine (BCP, Aldrich). The organic materials were purified twice by thermal gradient sublimation prior to deposition. All layers were grown by vacuum deposition in an organic molecular beam deposition system (Kurt J. Lesker Spectros) with a base pressure of about 5×10^{-8} mbar and the deposition rates were monitored using a series of quartz–crystal microbalances, where $\sim$0.4 Å s^{-1} was used for MoO_x, $F_{16}CuPc$ and BCP, while $\sim$1.5 Å s^{-1} was used for SubPc. Al cathodes were deposited *in situ* by evaporation through a shadow mask to a thickness of 100 nm, giving an active area of 0.16 cm^2.

Current–voltage (J–V) curves for the cells were measured with a Keithley 2400 sourcemeter in air under AM1.5 solar illumination at $\sim$100 mW cm^{-2} using a Newport Oriel solar simulator, where the intensity was calibrated using a monocrystalline silicon solar cell (PV Measurements, Inc.). Electronic absorption spectra were recorded using a Perkin–Elmer Lambda 2 spectrometer. External quantum efficiency (EQE) measurements were obtained using the Newport Solar Simulator and a PTI Monochromator. The monochromatic light intensity was calibrated with a Si photodiode (Thorlabs) and chopped at 500 Hz. Signal detection was performed with a current–voltage amplifier (Laser Component UK Ltd., DHPCA-100) and a lock-in amplifier (Stanford Research SR 830 DSP).

3. Results and discussion

Three basic SubPc/$F_{16}CuPc$ OPV cells were fabricated: (A) ITO/SubPc(14 nm)/$F_{16}CuPc$(35 nm)/Al; (B) ITO/SubPc(14 nm)/$F_{16}CuPc$(35 nm)/BCP(8 nm)/Al; and (C) ITO/MoO_x(5 nm)/SubPc(14 nm)/$F_{16}CuPc$(35 nm)/BCP(8 nm)/Al. Given the known low exciton diffusion length of SubPc films, the thickness of the donor layer in each cell was fixed at 14 nm [16,17]. The optimum thickness of the $F_{16}CuPc$ layer for the cells was determined to be 35 nm. The experimental results for the different cells are summarised in Table 1. Cell A demonstrates a very low PCE of 0.02%, with the V_{oc}, short-circuit current density (J_{sc}) and fill factor (FF) being 0.22 V, 0.46 mA cm^{-2} and 0.21, respectively. After inserting the BCP and MoO_x layers all cell parameters increase very significantly. BCP is a wide-band-gap organic material and plays an important role in the SubPc/$F_{16}CuPc$ cell. Firstly, it can act as an exciton-blocking barrier and stops excitons diffusing towards the Al electrode [18]. It also acts as a diffusion barrier for the top Al contact, helping to eliminate the creation of Al-induced charge-transfer states in the $F_{16}CuPc$ layer [18]. Perhaps most importantly, BCP also behaves as a buffer layer and prevents direct contact between the $F_{16}CuPc$ and Al, which otherwise can lead to a low conductivity phase region comprising three-dimensional $(F_{16}CuPc)_3Al$ species [19]. Hence in cell B, in which a BCP layer is incorporated into the cell, J_{sc} increases from 0.46–1.90 mA cm^{-2}, and the FF increases accordingly from 0.21 to 0.31. The MoO_x acts as a more efficient hole-extracting layer than the bare ITO substrate. The ITO Fermi level can be pinned to the valance band of the MoO_x interlayer [20], where the latter is closely aligned with the HOMO of the SubPc donor, as shown in Fig. 1b. Inclusion in cell C results in an improvement of the V_{oc} from 0.2 to 0.4 V. Additionally, the insertion of the MoO_x layer also minimises variations in cell performance by decoupling the photoactive layer from the electrically inhomogeneous ITO electrode [20]. The combined effect of adding the BCP and MoO_x layers leads to a dramatic increase in PCE from 0.02% to 0.56%, with V_{oc} = 0.40 V, J_{sc} = 2.54 mA cm^{-2} and the FF = 0.55. Corresponding J–V curves of the three cells

Table 1
Key cell performance parameters obtained under 1 sun illumination from SubPc/$F_{16}CuPc$ OPV cells fabricated on ITO: (A) ITO/SubPc(14 nm)/$F_{16}CuPc$(35 nm)/Al; (B) ITO/SubPc(14 nm)/$F_{16}CuPc$(35 nm)/BCP(8 nm)/Al; (C) ITO/MoO_x(5 nm)/SubPc(14 nm)/$F_{16}CuPc$(35 nm)/BCP(8 nm)/Al.

Cells	V_{oc}/V	J_{sc}/mA cm^{-2}	FF	PCE/%
A	0.22	0.46	0.21	0.02
B	0.21	1.90	0.31	0.13
C	0.40	2.54	0.55	0.56

recorded under 1 sun illumination are shown in Fig. 2. In these cells, although the energy gap between the Al cathode and the F_{16}CuPc LUMO is large (0.70 eV), Fermi level pinning can occur and spontaneous charge transfer between the Al and the LUMO of the F_{16}CuPc becomes possible [21].

Electronic absorption spectra of single layer F_{16}CuPc and SubPc thin films as well as a F_{16}CuPc/SubPc bilayer film are shown in Fig. 3. The EQE obtained for cell C is also shown. For F_{16}CuPc, absorption occurs between 550 and 850 nm with three peaks at about 640, 704 and 788 nm. For SubPc, absorption occurs between 450 and 650 nm with two main peaks at about 540 and 588 nm. The bilayer structure therefore demonstrates good absorption in the visible range of the spectrum from 450 to 850 nm, although the absorption intensity of the F_{16}CuPc layer is only about half that of the SubPc layer. Consequently, the EQE of the corresponding OPV cell suggests that the major contribution to the photocurrent in the wavelength range 450–650 nm comes from the SubPc donor layer, while the F_{16}CuPc acceptor layer provides a small contribution from 550 to 850 nm where the EQE is about 5%.

Fig. 4 shows the device parameters obtained for cell C as a function of the thickness of the F_{16}CuPc acceptor layer (in the range 15–45 nm). The V_{oc} and FF change marginally with typical values of 0.40 V and 0.55, respectively. By contrast, the J_{sc} changes considerably increasing from about 1.7 mA cm^{-2} at 15 nm to the peak value of 2.54 mA cm^{-2} at 35 nm which results in the optimised PCE of 0.56%. The exciton diffusion length in phthalocyanine materials such as CuPc is reported to be about 10 nm [22,23]. Consequently, in the case of F_{16}CuPc, it is almost certainly less than the 35 nm layer thickness required for optimisation of the OPV cells. This optimum thickness represents a balance between optical interference effects and the built-in electron field strength within the device [24,25].

The stability of cell C was measured under constant illumination for 60 min under ambient conditions. Fig. 5 shows the percentage degradation of each key device parameter from the value at 0–60 min. The percentage degradation of the V_{oc}, J_{sc}, and FF are about 2.5%, 5%, and 4%, respectively, resulting in an approximately 10% degradation in the overall PCE. This stability is much better than that typically observed for equivalent bilayer heterojunction cells

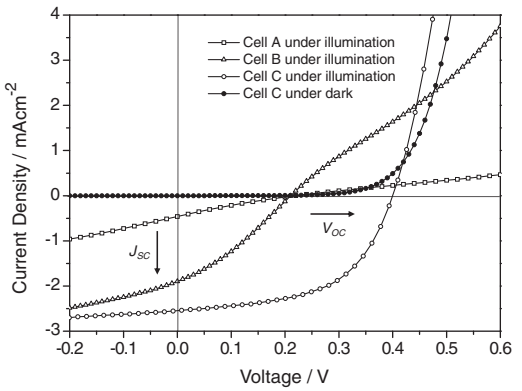

Fig. 2. *J–V* curves recorded under 1 sun illumination for cell A: ITO/SubPc(14 nm)/F_{16}CuPc(35 nm)/Al; cell B: ITO/SubPc(14 nm)/F_{16}CuPc-(35 nm)/BCP(8 nm)/Al; and cell C: ITO/MO_x(5 nm)/SubPc(14 nm)/F_{16}CuPc-(35 nm)/BCP(8 nm)/Al. The corresponding *J–V* curve for cell C recorded in the dark is also shown.

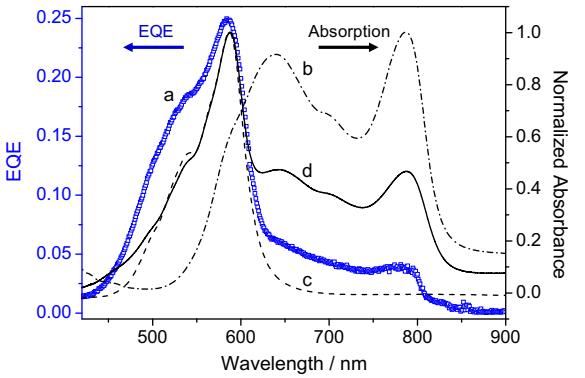

Fig. 3. (a) EQE of the device with the structure ITO/MoO_x(5 nm)/SubPc(14 nm)/F_{16}CuPc(35 nm)/BCP(8 nm)/Al. (b)–(d) are the normalized electronic absorption spectra of a F_{16}CuPc single layer (35 nm), a SubPc single layer (14 nm) and a SubPc (14 nm)/F_{16}CuPc (35 nm) double layer.

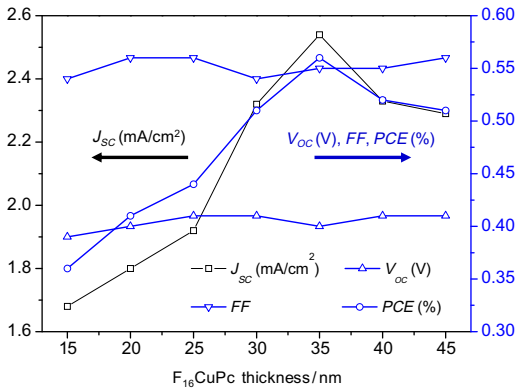

Fig. 4. Effect of F_{16}CuPc thickness on the V_{oc}, J_{sc}, FF and PCE for the cell structure ITO/MoO_x(5 nm)/SubPc(14 nm)/F_{16}CuPc(15–45 nm)/BCP-(8 nm)/Al.

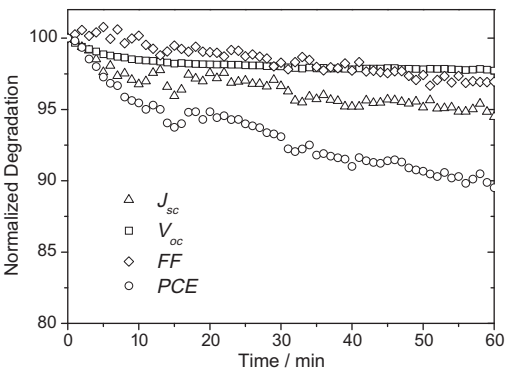

Fig. 5. Normalised degradation of the V_{oc}, J_{sc}, FF and PCE values obtained for cell C under constant illumination for 60 min under ambient conditions.

fabricated with the more commonly used C_{60} acceptor for nominally identical conditions (ca. 50% degradation) [26]. This improvement results from the improved stability of the acceptor materials as well as the use of the MoO_x interlayer which blocks adverse interfacial effects at the ITO/SubPc interface.

4. Conclusion

In summary, we have shown that F_{16}CuPc can be used as an electron accepting layer in bilayer heterojunction OPV cells using a SubPc donor. The F_{16}CuPc/SubPc heterojunction cells show good performance and stability, with a PCE of 0.56% obtained for optimum layer thickness and only 10% degradation in cell performance after constant illumination for 60 min under ambient conditions. The EQE demonstrates that the photocurrent comes from excitons created in both the SubPc and F_{16}CuPc layers although the latter shows a small contribution. The results suggest that F_{16}CuPc has the potential to be a promising electron acceptor material in small molecule OPV cells.

dihydroxide). Thus, a layered-structure of the nanocomposite PEI/TiO_x gate dielectric layer is easily prepared using conventional LBL deposition techniques, as PEI in water has a positive electric charge and TALH has a negative charge in water.

2. Experiment

Fig. 1a–c show schematic illustrations of the SWCNT–TFT structure and the LBL self-assembly process utilized for preparing the PEI/TALH gate dielectric layer. The octahedral coordination structure of TALH is shown in Fig. 1d. The experimental process involved alternating adsorption of 0.1 wt.% PEI and 5 wt.% TALH via a dipping method, onto the oppositely charged substrate, followed by rinsing with deionized (DI) water and drying. More specifically, cleaned Si-wafer substrates were first exposed to a 0.1 wt.% PEI solution for 15 min and then thoroughly rinsed with excess DI water for 5 min. Subsequently, the PEI coated substrates were dipped into a 5 wt.% TALH solution for 15 min, washed with DI water, and then dried with N_2 gas. The above deposition procedure was repeated 15 times to obtain the multi-layered structure $(PEI/TALH)_{15}$. The resulting substrate was then heated to 95 °C for 24 h in order to convert the precursor into a TiO_x nanostructure [11]. The specific details of the LBL deposition and annealing conditions to form the PEI/TALH composite have been reported previously. Unlike the water-sensitive alkoxide precursor, the deposited TiO_x precursor TALH on PEI is slowly converted into a TiO_x nanostructure, then into a densely structured titania-polymer network by heating at 95 °C [11–13].

The thickness and nanostructure of $(PEI/TALH)_{15}$ nanocomposite films was characterized via high-resolution transmission electron microscopy (HRTEM), as shown in Fig. 2. The film used for analysis consisted of three layers with a $(PEI/TALH)_{15}/SiO_x/Si$ structure (Si is the substrate and SiO_x is a naturally oxidized layer formed during cleaning of the Si). The presence of a thin SiO_x inter-layer would significantly reduce the total gate capacitance due to its low-k properties. The thickness of the $(PEI\text{-}TiO_x)_{15}$ nanocomposite film, as measured by HRTEM imaging, was about 70 nm, and the average deposition thickness was calculated to be 4.7 nm/bilayer. Notably, the latter value is similar to that previously reported by Gentle, 4.9 ± 0.5 nm/bilayer [11].

The surface morphology of the gate dielectric layer produced by the LBL deposition process was characterized using atomic force microscopy (AFM), as shown in Fig. 3a. We found that the surface roughness of the titania nanocomposite films $(PEI\text{-}TiO_x)_{15}$ was R_q = 5.07 nm (R_a = 3.66) and suggest that incomplete cleaning and the bulky structure of TALH may contribute to the creation of such a rough surface. In the application of SWCNT–TFTs, the dielectric surface roughness would not be a significant factor in the device performance, as well-crystallized SWCNT strands are randomly deposited on the dielectric surface and make a network structure of active layers. On the other hand, active layers of most other organic/inorganic semiconducting materials are disturbed by a rough dielectric surface, because they are crystallized on the surface of the gate dielectric layer after deposition [14–16].

The SWCNT coating solution was produced by the dispersion of thermally and chemically purified SWCNTs (ASP-100F, Hanwha Nanotech) in 1-methyl-2-pyrrolidone

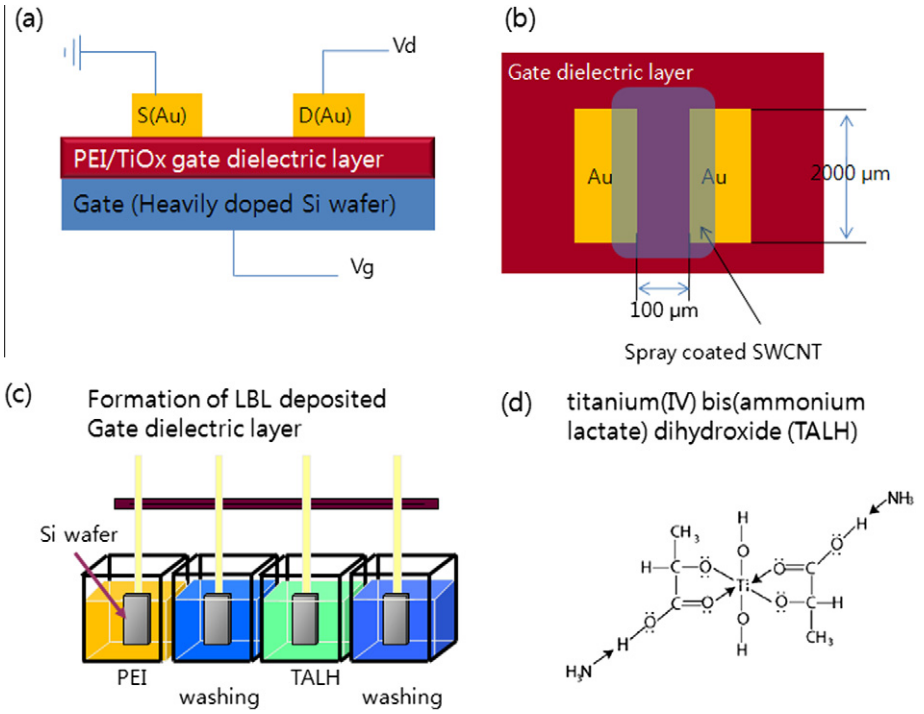

Fig. 1. (a–b) Schematic illustrations of SWCNT–TFT structure (c) preparation of a PEI/TiO_x nanocomposite gate dielectric layer through layer-by-layer deposition methods, and (d) the octahedral structure of the titanium oxide precursor, TALH.

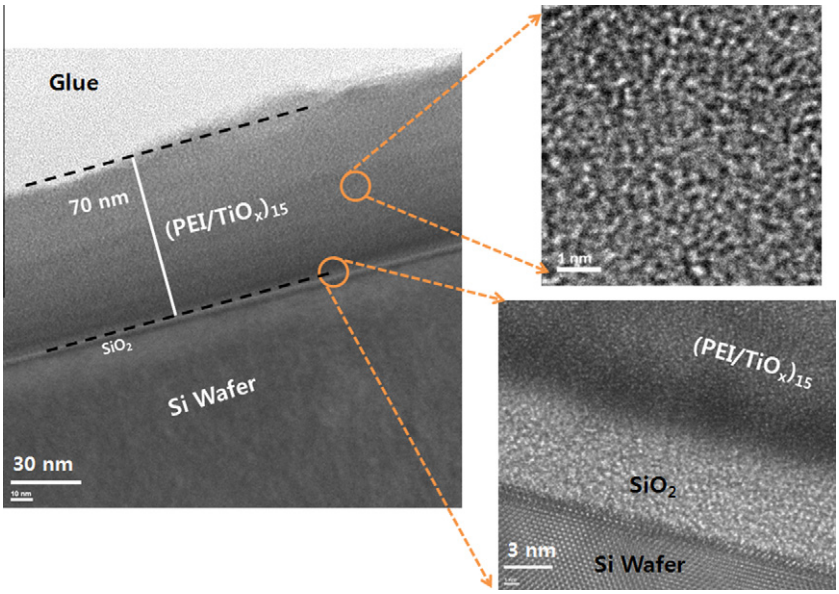

Fig. 2. High resolution TEM images of the PEI/TALH nanocomposite gate dielectric layer. A cross-section of the gate dielectric layer shows that the $(PEI/TiO_x)_{15}$ gate dielectric layer has a thickness of about 70 nm and a calculated average deposition thickness of 4.7 nm/bilayer.

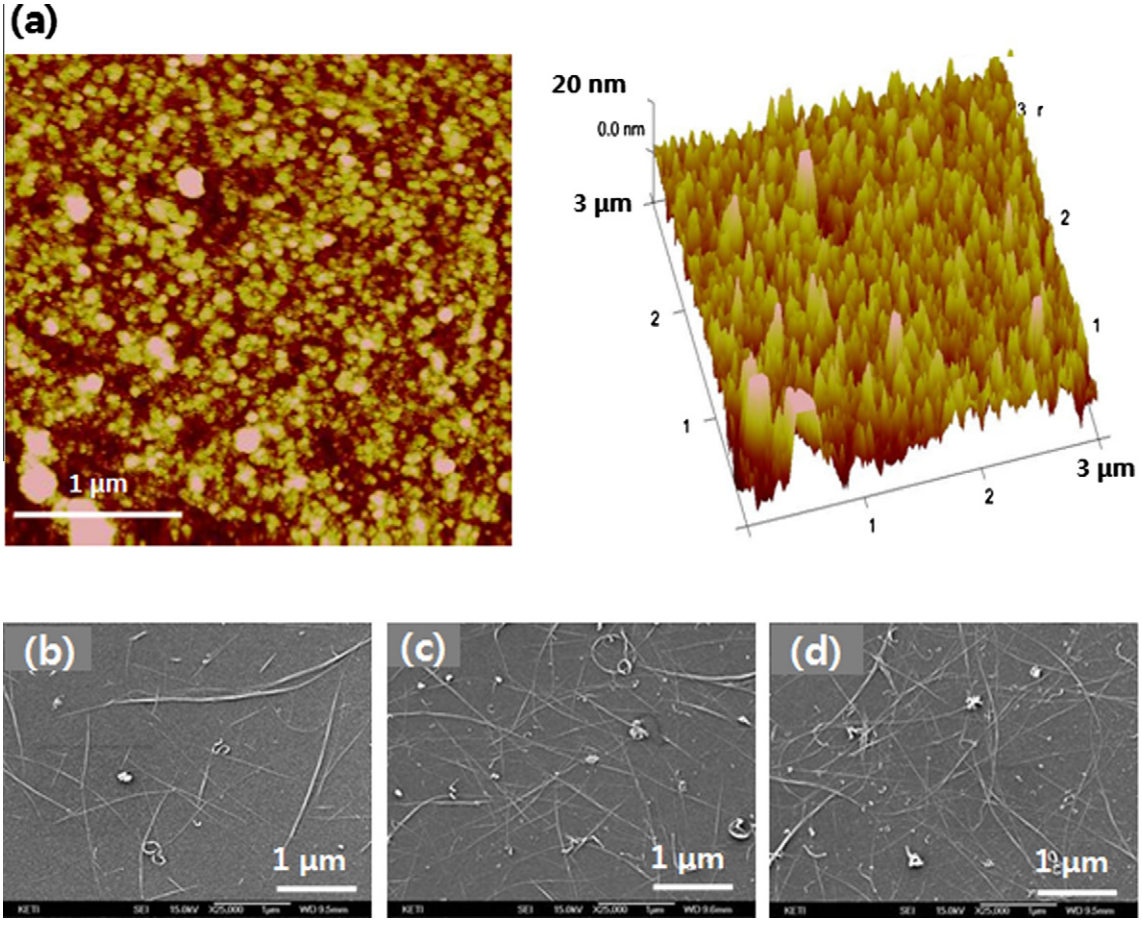

Fig. 3. (a) AFM images of the surface morphology of the PEI/TALH deposited gate dielectric layer. The surface roughness of the nanocomposite films formed by LBL assembly was found to be R_q = 5.07 nm (R_a = 3.66). (b–d) The morphology of the sprayed SWCNTs on the gate dielectrics, for spray times of 60, 120, and 150 s, respectively.

(NMP; Sigma–Aldrich). SWCNTs (ASP-100F) synthesized by the arc-discharge method are usually 15 μm in length and 1.2 ± 0.2 nm in diameter. The SWCNT concentration used was 0.01 mg/ml, and the polystyrene was added to prevent SWCNT aggregation in the dispersion. In previous experiments, we found that the amount of polystyrene used significantly affected the current density of the TFT channel. With increasing polymer binder content, the on/off ratio increased while the mobility declined due to improved insulation characteristics. According to previous results, an SWCNT/polymer mass ratio of 1/45 was suitable for spray-coating methods; hence we prepared our SWCNT solutions following the same methodology.

3. Result and discussion

The capacitance of the gate dielectric, determined through measurements in which the PEI/TALH dielectric layer was sandwiched between Au dots and heavily-doped Si substrates, was found to be 118 nF/cm^2 when measured at 100 kHz. The calculated dielectric constant from the measured capacitance and dielectric thickness is 13.3, which is much lower than literature values for amorphous titanium oxide (40–50) [17]. This discrepancy is likely due to the PEI inter-layer and SiO_2 layer in the dielectric composite, and presence of residual precursor decreasing the capacitance.

The SWCNT–TFT active layers were deposited by spray coating method and directly patterned using a metal shadow mask. Fig. 3b–d show FE-SEM images of the SWCNT networks in the channel after spray coating for 60, 120, and 150 s, respectively. As the spray coating time increased, SWCNTs within the channel became layered and more numerous, thus increasing the number of electric current paths in the channel. In our coating system, spray coating for over 150 s deposits an excessive amount of SWCNTs on the active layer, thereby generating a conductive film and decreasing the on/off ratio. In our system, a spray time of 120 s was suitable for active layer deposition.

The transfer and output characteristics of the fabricated top-contact geometry of SWCNT–TFT are shown in Fig. 4a and b, respectively. The transfer curves show that our PEI/TiO_x layered dielectric-based devices could be operated at gate voltages below −2 V and that they exhibit good linear/saturation behavior in their output characteristics. The field-effect mobility measured in the linear regime was as high as 6.7 cm^2/V s (V_D = −0.1 V), and the threshold voltage was −0.88 V. The sub-threshold swing was as low as 260 mV/decade, and the on/off current ratio was 500. Without any separation process of SWCNTs, both metallic and semiconducting SWCNTs were present in the active

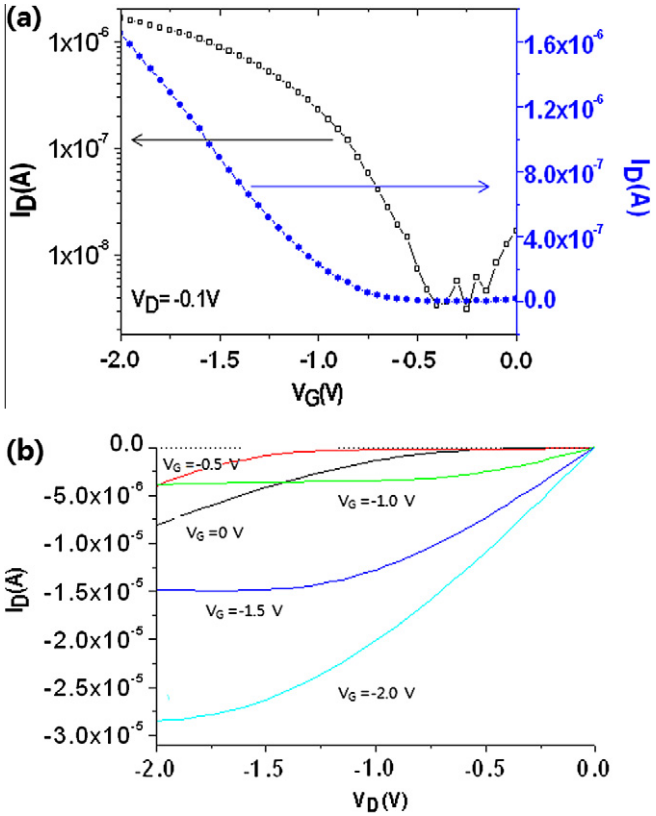

Fig. 4. Electric characteristics of the SWCNT–TFT. (a) The transfer curve of the TFT, measured at V_D = −0.1 V. The leakage current is less than 0.01 μA and the on/off ratio is about 500. (b) The output curve, exhibiting good linear/saturation behavior. The leakage current shown at low V_D originated from the high-k material with a narrow band gap.

layer, resulting in a relatively low on/off ratio compared to other semiconducting materials. However, the high mobility (>6.7 $cm^2/V\,s$) and low operating voltage (<2 V) of the TFTs reported here make them well suited to switch device applications that do not require a high on/off ratio, such as RF-IF tags.

Our TFT shows outstanding operational characteristics with drain current (I_D) saturation in the elevated drain voltage (V_D) region and good linear behavior near $V_D = 0$. It is likely that this high dielectric capacitance produces charge carriers at a low operation voltage, thereby reducing the effective driving force for leakage. However, at gate voltage (V_G) = −0 V, or −0.5 V, a relatively large leakage current is shown in the output curve in the region of elevated V_d. This likely arises due to the electric field through the gate dielectric layer being maximized under these conditions, thus inducing leakage current through the high-*k* dielectric material with a narrow band gap.

4. Conclusion

We have developed a simple and promising LBL self-assembly method for a high-*k* titania nanocomposite gate dielectric layer, and fabricated a TFT with an SWCNT active layer. The high capacitance of the dielectric layer results in a high mobility at a low operating voltage and a relatively low leakage current without separation of the metallic and semiconducting SWCNTs. We envisage that this simple solution deposition process will find applications in the fabrication of switch devices for low-end market products.

in a blue-emitting polyfluorene-triaryamine (PF-TAA) based copolymer [13,14] and in the archetypical small-molecule material α-NPD [15], which is frequently used in OLEDs. Both studies revealed that equally good descriptions of the steady-state current density *versus* voltage ($J(V)$) curves could be obtained from both models, but that a distinction could be made on the basis of the effective hopping site densities obtained. For PF-TAA only the GDM led to a hopping site density close the actual molecular site density, whereas for the same reason the CDM was found to be most appropriate for α-NPD. Using the alternative model led for both cases to a discrepancy of almost one order of magnitude or more in the site density.

The question now arises whether it would also be possible to describe the $J(V)$ curves of single-carrier devices based on *electron* transporting materials using the GDM or the CDM, and whether it would again be possible to make a distinction between both models on the basis of the site density obtained. Making such a comparison is expected to be more difficult than for hole-transporting materials, as in polymers [16–18] as well as in small-molecule materials [19,20] the electron mobility is often affected by trap states. So far, no comparison was given of analyzes of the electron mobility in disordered organic semiconductors using the GDM and the CDM, including the possible effect of the presence of trap states and including the effects of the charge carrier density dependence of the mobility.

In this paper, we investigate whether such an extensive analysis can be given for the electron transport in sandwich-type devices based on the small-molecule material bis(2-methyl-8-quinolinolato)(4-phenylphenolato)aluminum (BAlq). This material is used in OLEDs as a (sky-blue) emitting layer [21–23], as a host material in dye-doped emitting layers [22,24], as a hole-blocking layer [21,25–28], and as a "barrier-softening" interfacial layer in between the electron transporting and emissive layers [29]. As a hole-blocking material it is known to allow for high lifetimes, up to 160,000 hours at a luminance level of 100 cd/m^2 [25]. BAlq is photochemically stable [30], and has a glass transition temperature of 92 °C [31]. The structure of BAlq (see Fig. 1(a)) is similar to that of the frequently used material tris(8-quinolinolato)aluminum (Alq_3). We study devices operating in the space-charge-limited current regime, so that the current density is to a large extent determined by the bulk transport rather than by the injection process. The temperature and layer-thickness dependence of the $J(V)$ curves is found to be well described by assuming that the DOS is a superposition of a Gaussian "host" DOS and an exponential "trap" DOS. A similar shape of the DOS was found recently to provide a good description of the electron transport in poly-phenylene-vinylene (PPV) derivatives [17] and in a polyfluorene-based copolymer [32]. Good descriptions can be obtained within the GDM as well as the CDM. However, as for α-NPD, the analysis within the CDM provides a hopping site density which is by far closest to the experimental value, which provides a strong indication that also for BAlq the site energies are spatially correlated.

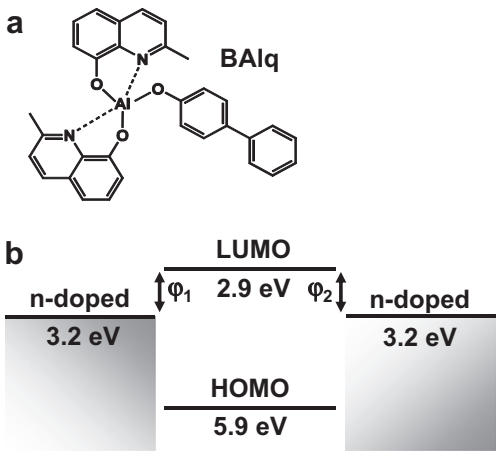

Fig. 1. Chemical structure of the BAlq molecule (a) and schematic energy diagram of the device structures used in this study, indicating the electron injection barriers at the anode (ϕ_1) and at the cathode (ϕ_2), and the HOMO and LUMO energies of BAlq (b).

2. Device structure and experimental results

For investigating the electron mobility in BAlq, devices with the following layer structure were fabricated:

Glass|**ITO**|**NDL**|**BAlq**|**NDL**|**Al**,

with NDL a ~50 nm n-doped small-molecule layer. After a UV/ozone treatment of the indium tin oxide (ITO, ~100 nm) patterned glass substrates, NDL and BAlq layers were evaporated in a high-vacuum system, with a substrate temperature of ~295 K, followed by evaporation of an aluminum cathode layer. The devices were encapsulated with a glass lid enclosing a desiccant getter to prevent water and oxygen contamination. Four series of four nominally identical devices with an active area of 20 mm^2 were fabricated on a single substrate. Combining the total thicknesses of the NDL|BAlq|NDL stacks, obtained from Transmission Electron Microscopy (TEM), with the relative thicknesses of the separate layers as deduced from Ion-Beam Etching X-ray Photoelectron Spectroscopy (IBE-XPS) measurements, the BAlq layer thicknesses of the four series were determined to be 70, 106, 158 and 258 nm, with an uncertainty of ~7%. The separate organic layers were not easily resolved from TEM. The aluminum and oxygen in the BAlq layers yielded good contrast using IBE-XPS.

The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energies of BAlq are located at ~5.9 eV and ~2.9 eV below the vacuum level, respectively [25]. Fig. 1(b) gives a schematic energy diagram of the device structure, indicating the energy-level alignment at the interface between BAlq and the NDLs. The NDL used is molecularly doped using an organic material with a high-lying HOMO level, as described for various host–guest combinations by Waltzer et al. [33]. The NDL is known to give rise to good electron injection into BAlq, judged from the observation of efficient light emission from multilayer OLEDs using BAlq together with the NDL

at the electron injecting side. From low-frequency capacitance–voltage ($C(V)$) measurements a symmetrical peak in the capacitance is observed at $V = 0$ V with a height ~8% larger than the geometrical capacitance, C_{geom}, measured at high frequencies. We view this as an indication that the built-in voltage (V_{bi}) is close to 0 V, as expected from the use of the symmetric NDL sandwich structure. Furthermore, the relatively small peak height (which would be $\sim 1.29 \times C_{geom}$ in the absence of an injection barrier and disorder [34]) indicates that the electron injection barrier at the interface between the NDL and BAlq is expected not to be larger than a few tenths of an eV. From the analysis presented below we find $\phi = 0.3$ eV for both interfaces, leading to an effective Fermi energy of the NDLs of 3.2 eV. The relative permittivity (ε_r) of BAlq obtained from the analysis of C_{geom} at frequencies in the range 10^2–10^5 Hz is 3.8 ± 1.0. For a variation of ε_r within these uncertainty margins there is no significant change in the quality of the description provided by the models for the experimental data, nor in the optimal parameters found, except for a change in the mobility values obtained. A change of ε_r from 3.8 to 2.8 (4.8) was found to lead to an increase (decrease) of the mobility values obtained of less than 25%.

The BAlq volume density, taken equal to the density of Al atoms in a series of BAlq thin films deposited on silicon substrates as obtained from Inductively Coupled Plasma Atomic Emission Spectrometry (ICP-AES) measurements, is $(1.5 \pm 0.1) \times 10^{27}$ molecules per m^3. It is essentially identical to the volume density in the crystalline bulk material, 1.507×10^{27} m^{-3} [35].

Fig. 2 shows measured $J(V)$ curves for the four thicknesses at room temperature, both on a linear voltage and current density scale (inset), and on a log–log scale (main panel). A maximum electrical power density $\sim 1 \times 10^3$ W/m^2 was allowed, in order to prevent substantial heating of the devices. The curves are highly symmetric around $V = 0$ V, consistent with the complementary evidence from the $C(V)$ measurements that $V_{bi} \cong 0$ V. The observation of a $J(V)$ curve with a slope of 2 on log–log scale (dotted line) would indicate space-charge-limited current

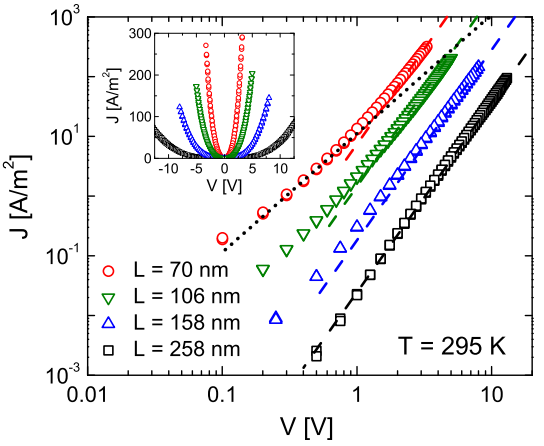

Fig. 2. Experimental $J(V)$ curves for four thicknesses of the BAlq layer, at 295 K. The dotted line has a slope of 2. The dashed lines are fits to the data at high voltages with a slope of 3.2. The inset shows the same data on a linear scale.

with a constant mobility. However, the experimental curves are much steeper, in particular above 1 V. The dashed lines are linear fits to the data at high voltages, and have a slope of ~3.2. Within a drift-only transport model, the observation of a linear log(J)–log(V) curve with a slope much larger than 2 is an indication of trap-limited charge transport in an exponential trap density of states [20,36,37,16,38].

3. Analysis of $J(V)$ curves

The temperature-dependent $J(V)$ curves for the four thicknesses of the BAlq layer are shown in Fig. 3 (symbols). They are analyzed using a drift-diffusion device model as presented in Ref. [39], assuming carrier density and electric field dependent mobility functions as described by the GDM and the CDM, and including the possible presence of injection barriers (see Ref. [15]) and of an additional exponential trap DOS. The total DOS is for energies $E < 0$ described as

$$\rho(E) = \frac{N_t}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{E^2}{2\sigma^2}\right) + \frac{N_{trap}}{k_B T_0} \exp\left(\frac{E}{k_B T_0}\right), \qquad (1)$$

with σ and N_t the width and the density of hopping sites for the Gaussian DOS, k_B the Boltzmann constant and T_0 and N_{trap} the parameters determining the characteristic depth and density of trap sites (if defined as the integral of the exponential trap DOS up to the top of the Gaussian DOS), respectively. The DOS is shown schematically in Fig. 4. For $E > 0$ the exponential contribution is assumed to vanish. The experiments are only sensitive to those trap states which are actually occupied, in the tail of the DOS. Therefore, the precise energy at which the formal (rather artificial) cutoff of the exponential trap DOS is taken, in this work at $E = 0$, is of no significance to the current density as long as it is sufficiently high. Furthermore, the actual total density of trap states can therefore be much smaller than N_{trap}, which is only meant to provide (in combination with the Gaussian "host" DOS) the most proper description of DOS in the tail region. We also note that in the model no distinction is made concerning the physical nature of the states forming the "host" and the "guest" DOS. The local occupancies of host and trap sites at any position in the device are calculated by assuming local thermal equilibrium, i.e. assuming thermally induced detrapping as described within the multiple-trap-and-release model. The current density is calculated using the local free carrier densities and the mobility and diffusion coefficient enhancements corresponding to these densities, whereas the field across the device is calculated by solving Poisson's equation using the total carrier density distribution.

The optimal parameter set for each mobility model is obtained as follows. For a given $\{N_t, \sigma, N_{trap}, T_0\}$ combination, we determine the fitting error between the experimental and calculated $J(V)$ curves for each individual layer thickness and temperature. For each calculated curve, the (temperature dependent) mobility in the zero electric field and carrier density limit, $\mu_0(T)$, is treated as a free parameter. It only shifts the log(J)–V curves vertically. The built-in voltage, $V_{bi} \equiv (\phi_1 - \phi_2)/e$, with e the elementary charge, is set to 0 V. For each $\{N_t, \sigma, N_{trap}, T_0\}$ combination

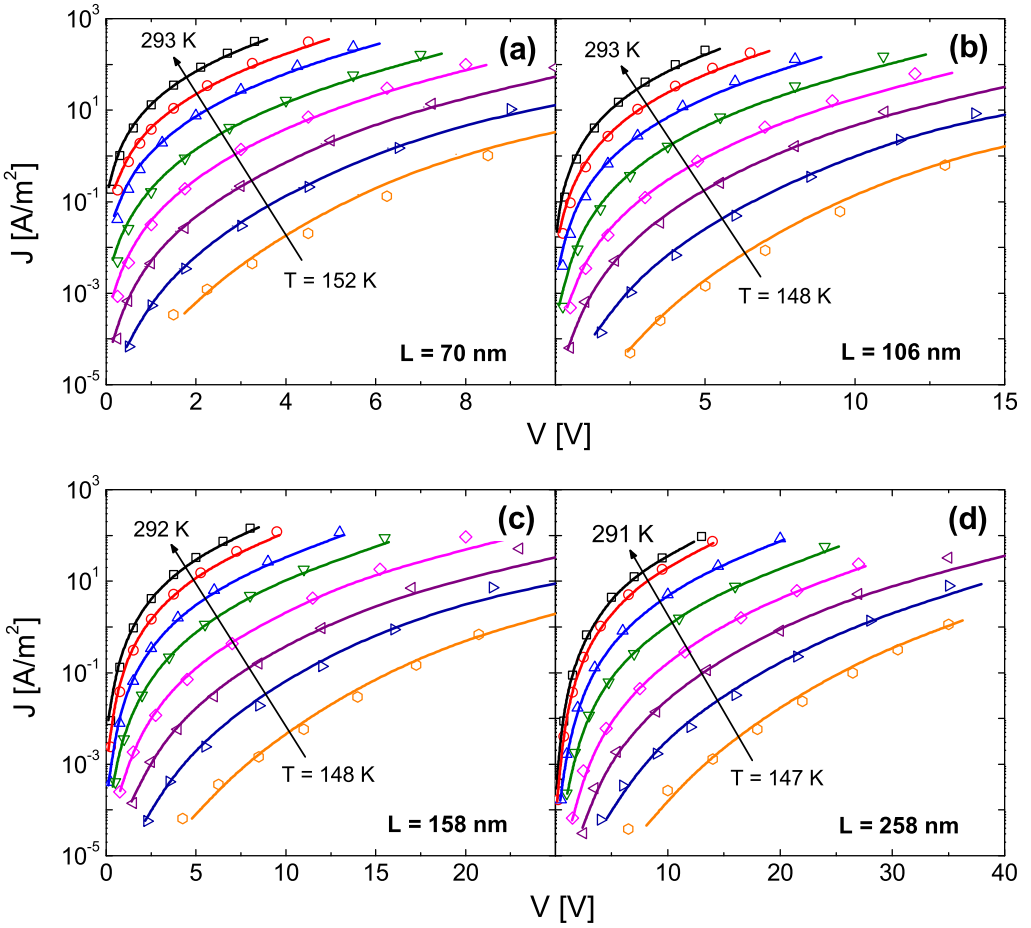

Fig. 3. Measured (symbols) and calculated (solid curves) $J(V)$ for devices with a BAlq layer thickness of 70 nm (a), 106 nm (b), 158 nm (c), and 258 nm (d), as a function of temperature. The temperature was varied in steps of ~20 K. The calculations were performed using a drift-diffusion device model assuming correlated Gaussian disorder (CDM) and a superimposed exponential density of trap states, using the parameters given in Table 1.

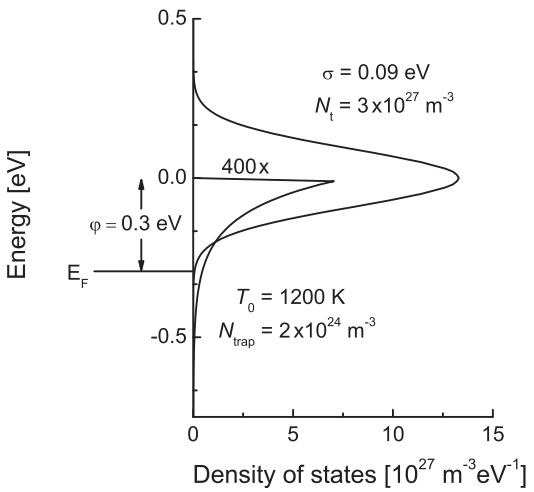

Fig. 4. Schematic of the energy-level alignment in the devices studied, indicating the Gaussian DOS and the exponential trap DOS (enhanced by a factor 400), and the injection barrier at the electrodes. The parameter values indicated are the result of this study, and have been obtained using the CDM.

the total error is calculated as a sum of mean square errors of the fits for all thicknesses and temperatures. By minimizing this total error, we obtain the optimal parameter set. The procedure is repeated for several values of the injection barriers with the constraint $\phi = \phi_1 = \phi_2$, leading to $\phi = 0.3 \pm 0.1$ eV. This value is within the range expected from the $C(V)$ measurements.

The best simultaneous description of all thickness-dependent and temperature-dependent $J(V)$ data using the GDM and using the CDM were obtained for the set of parameters given in Table 1. The parameters μ_0^* and C mentioned in the table describe the temperature dependence of μ_0 and are discussed below. Fig. 3 shows the results for the CDM (solid curves). The results for the GDM led to an equally good fit. For both models, a description of the full set of $J(V)$ curves without traps led to very high error values and to unphysically high thickness and temperature dependent values of V_{bi}. To our point of view, the assumption that the material is free of traps can therefore be discarded. We consider the parameter values obtained from the analysis using the GDM including traps as physically realistic, except for the site density, which is ~7 times *smaller* than the volume density of BAlq

Table 1
Overview of the GDM and CDM parameter values that optimally describe the experimental $J(V)$ curves.

Parameter	GDM	CDM
N_t (10^{27} m^{-3})	0.20 ± 0.04	3 ± 1
σ (eV)	0.08 ± 0.01	0.09 ± 0.01
N_{trap} (10^{24} m^{-3})	1.0 ± 0.5	2.0 ±Ł0.5
T_0 (K)	1200 ± 100	1200 ± 100
μ_0^* (10^{-8} m^2/(V s))	4 ± 1	1.7 ± 0.5
C	0.59 ± 0.16	0.46 ± 0.11
$\phi_{1,2}$ (eV)	0.3 ± 0.1	0.3 ± 0.1
ε_r	3.8 ± 1.0	3.8 ± 1.0

molecules. For the CDM, which leads to otherwise similar parameter values, the site density is ~2 times *larger* than the density of molecules. We view this much better correspondence as an indication that for BAlq the LUMO site energies are spatially correlated. The finding that N_t is a factor ~2 larger than the molecular density could be rationalized by assuming that each BAlq molecule contributes two LUMO states, localized on the two identical ligands. This picture is supported by the results of electronic structure calculations [26]. Both ligands may be viewed as a hopping site for electrons if the electronic coupling between these two ligands is small, so that these states are almost degenerate. A similar situation was encountered in Ref. [15] for the case of α-NPD.

Within the GDM and the CDM, the temperature dependence of μ_0 is given by $\mu_0(T) = \mu_0^* \exp\{-C[\sigma/(k_B T)]^2\}$ [8,5]. Fig. 5 shows that both $\log(\mu_{0,CDM}(T))$ and $\log(\mu_{0,\ GDM}(T))$ vary linearly with $1/T^2$, in a manner which is essentially the same for the four BAlq layer thicknesses. Both results are thus consistent with the assumption of hopping in a Gaussian DOS. The uncertainty attributed to the C-values is almost completely due to the uncertainty in the σ-values, which in part determine the slope of the fit lines. The C-values depend weakly on the decay length α^{-1} of the wavefunctions in between which the hopping takes place, at least for the case of the GDM [5,40], and increase slightly with a decreasing decay length. It is assumed that α^{-1} is typically equal to a tenth of the intersite distance [3]. Within the GDM the C-value is then expected ~0.42 (see Ref. [4]), and for the CDM Monte Carlo modeling [7] and 3D-ME modeling [8] have then yielded $C \sim 0.36$ and $C \sim 0.29$, respectively. The values obtained from the fits, $C = 0.59 \pm 0.16$ and 0.46 ± 0.11 for the GDM and the CDM, respectively, are both relatively high but (given the error margins) not inconsistent with the typical values mentioned above. The (at present preliminary) indication that the C-values are relatively large would indicate that the wavefunction decay length in BAlq is relatively small. A small value of the wavefunction decay length would be expected to lead to a small value of μ_0^*, the mobility in the zero-density, zero-field and high temperature limit. Indeed, μ_0^* is a factor of ~30 smaller than for α-NPD, for which the site density is essentially the same as for BAlq (if evaluated within the CDM) but for which the experimental value of $C = 0.34 \pm 0.07$ [15] is more close to the typical values of C mentioned above.

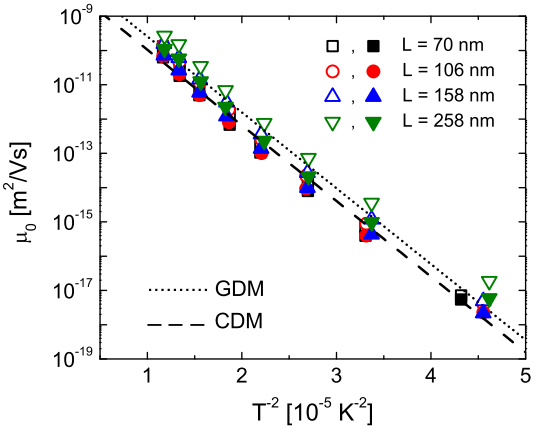

Fig. 5. Temperature dependence of the mobility in the zero field and carrier density limit for the CDM (closed symbols) and the GDM (open symbols). The results are shown for a thickness of the BAlq layer of 70 nm (squares), 106 nm (circles), 158 nm (triangles pointing up), and 258 nm (triangles pointing down). The dashed (CDM) and dotted (GDM) lines are linear fits to all data.

4. Conclusions

In conclusion, we have shown that a consistent description of the layer-thickness and temperature dependence of the current density in BAlq-based devices may be obtained by assuming a DOS that is a superposition of a Gaussian DOS and an exponential trap DOS. Accurate descriptions can be obtained assuming random disorder (Gaussian Disorder Model) as well as correlated disorder (Correlated Disorder Model), in the latter case making use of a recent description of the field and charge carrier density dependence of the mobility in systems with correlated Gaussian disorder resulting from charge–dipole interactions [8]. Based on a comparison of the hopping site densities with the experimental molecular site density, we argue that in BAlq the LUMO site energies are spatially correlated. We emphasize that, although the specific form of the CDM used in this work is based on the assumption of dipolar disorder, any microscopic model giving rise to a similar distance dependence of the energy correlation function [8] would give rise to a similar mobility function. Our findings thus support the point of view that upon modeling the electron transport in small-molecule OLEDs, the roles of energetic disorder, spatial correlation and the presence of trap states cannot be disregarded.

Acknowledgements

The authors would like to thank A.C.A. Jonkers for carrying out the ICP-AES measurements, and M.A. Verheijen and R.G.R. Weemaes for carrying out the TEM measurements. This research has received funding from the Dutch nanotechnology program NanoNed (contribution S.L.M.v.M.), and from the European Community's Program No. FP7-213708 (AEVIOM, contribution R.C.).

PEDOT:PSS can serve as both an HTL and as an EBL in normal and inverted device architectures due to its band structure, which has a lower electron affinity (or higher lowest unoccupied molecular orbital (LUMO)) than P3HT, providing an energy barrier for electron transfer to the anode. The band offset of the HTL in a BHJ is critical to establish the device polarity [7]. However, PEDOT:PSS has been shown to degrade or limit device performance in multiple ways. Although the reported energy levels for PEDOT:PSS and P3HT vary dependent upon material preparation and measurement technique, the LUMO of PEDOT:PSS is essentially fixed at about 0.6 eV above the LUMO of P3HT [9], which may be insufficient as an electron barrier. The aqueous PEDOT:PSS suspension is also highly acidic, with a measured pH of 1.2 [10]. This prohibits use of PEDOT:PSS as an HTL on a number of high performance and low cost transparent conductors that are easily etched in acidic solutions. In addition, due to the hygroscopic nature of PEDOT:PSS films, water may be absorbed resulting in proton release and corrosion of the ITO anode subsequently allowing indium diffusion throughout the device [11]. This, combined with the possible release of water from PEDOT:PSS into the active layer or the cathode can substantially degrade devices [12], lowering lifetimes and overall performance. These limitations have led to investigations of other materials to effectively replace PEDOT:PSS as the HTL in OPV devices [7,13].

An ideal candidate to replace PEDOT:PSS as the HTL would be a wide band-gap ($E_g > 3$ eV) *p*-type material transparent to most of the solar spectrum. It should minimize TCO/donor contact resistance and the dark current by providing a large energy barrier to electron transfer while maximizing charge transfer between the TCO and the highest occupied molecular orbital (HOMO) of the donor material. We note that HTL performance also depends upon conductivity but varies with the junction type and loss mechanisms. Intrinsic stability and chemical compatibility with the active layer and the ITO or other ZnO-based TCO materials are also necessary for long device lifetimes [7].

As shown in the band diagram below, a p-type metal oxide, such as NiO, has a wide band-gap and valence band energy close to the HOMO of P3HT. The high conduction band energy of NiO inhibits electron recombination with the anode while the valence band allows for efficient conduction of holes to the anode. Favorable vacuum energy level alignment and material stability indicate that NiO has many of the required characteristics of an efficient HTL material in OPV devices.

Recently, NiO deposited via pulsed laser deposition (PLD) has been shown to work well as a HTL for polymer solar cells, with devices exhibiting improved open-circuit voltage (V_{OC}), short-circuit current density (J_{SC}), and fill factor (*FF*) relative to a PEDOT:PSS control [7,14]. The NiO was shown to be chemically stable and inert in relation to ITO and P3HT:PCBM [7]. We have previously demonstrated that the work function of the NiO film can be tailored by controlling the oxygen partial pressure during the deposition [14]. Additionally, we have also been able to induce large increases in the NiO work function by O_2-plasma treatment of the NiO prior to deposition of the active layer [14].

However, the NiO layers in these studies were deposited via PLD, which is neither scalable nor a cost effective deposition method. Previous efforts to deposit NiO from solution have been attempted but require very high annealing temperatures to make NiO [15]. In this article we explore using solution deposited NiO (sNiO) followed by a lower temperature anneal as an HTL to improve device efficiency and stability while maintaining low-cost methods of production.

In this work, we demonstrate that sNiO films from a nickel metal organic ink precursor achieve similar OPV device performance to results seen with NiO films from PLD. The device structure, ITO/NiO/P3HT:PCBM/Ca/Al, is shown schematically in Fig. 1. Our results show sNiO thin-films to be an effective replacement for PEDOT:PSS in OPV devices. We achieve a tunable φ_w in the sNiO films by post-processing with an O_2-plasma of varied power and time. The change in φ_w with plasma treatment is found to be greater in magnitude and have a faster decay time than PLD based materials [14]. While the plasma treatment is necessary for proper device function, the φ_w of the sNiO layer was shown to be higher than necessary to match to the HOMO of P3HT without negatively affecting the device performance. To elucidate the nature of the change in the φ_w and determine if it results from a change in effective band-gap or enhanced electric field at the interface resulting from changes in the local carrier concentration we employ a simple 1-D Poisson solver to model the NiO/Active Layer interface.

The precursor solution used to synthesize the sNiO films was based on a patented nickel ink developed in our lab for the deposition of Ni using direct write solution processing contacts via ink-jet or continuous flow printing, resulting in material with conductivities rivaling that produced by vacuum deposition [16]. The ink is a complex in which the Ni coordinates to two diamine groups, $[Ni(en)_2](HCO_2)_2$; en = $H_2N(CH_2)_2NH_2$, and is suspended in the solvent. At increased temperatures the solvent and the metal organic decomposes leaving behind a high quality metal contact [16]. The complex was hydrated by mixing 50% by volume DI water and had a final Ni ink concentration of 0.34 M as measured by ICP.

All films were deposited onto commercially patterned ITO (~10 Ω/sq, thin-film devices) substrates after 5 min of ultrasonic cleaning in acetone followed by isopropyl alcohol. Substrates were plasma-cleaned immediately prior to HTL deposition in 0.8 Torr of O_2 at 155 W. The sNiO films were synthesized by spin-coating the diluted nickel ink at 4000 rpm for 60 s followed by annealing on a hot plate in air at 250 °C for 1 h, resulting in approximately 10 nm thick films. Film thickness was determined using a Dektak 8 Profilometer after masking a section of the substrate with Kapton tape prior to the spinning process.

sNiO films were characterized to examine their structural, optical, and electrical properties. The grain-size and surface morphology were also examined via an Asylum Research MFP-3D AFM. Reflectance and transmittance spectra were collected for the sNiO and PEDOT:PSS films on ITO over the UV, visible, and Near-Infrared (NIR) regions using a Shimadzu UV-3600 UV–Vis–NIR Spectrophotometer. Surface potential measurements were conducted using

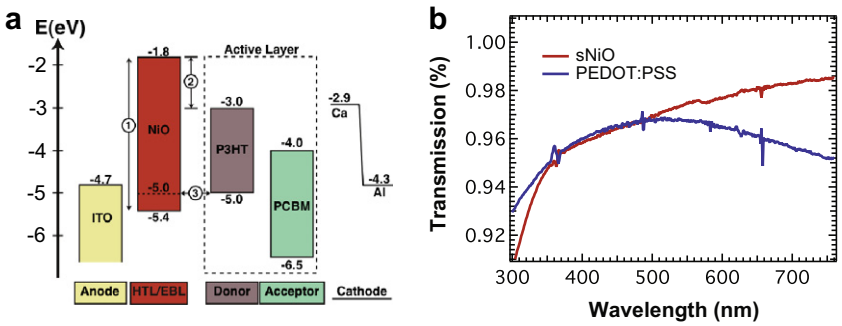

Fig. 1. (a) Energy diagram of the NiO BHJ cells fabricated in this work. NiO provides favorable HTL properties: (1) a wide band-gap for transparency, (2) sufficient electron blocking energy and (3) Fermi-level lineup with the HOMO of the donor for hole collection. (b) Graph of transmission versus wavelength for sNiO and PEDOT:PSS on quartz substrates.

an Electrostatic Voltmeter (Monroe Electronics ISOPROBE 244A) in an inert atmosphere of N_2. The work function (φ_w) of a material is often assumed to approximate the Fermi energy but may include effects from both surface dipoles and changes in carrier concentration via doping or changes in defect densities. All φ_w measurements were taken relative to the Inconel™ stainless steel reference, which was measured to have a φ_w of −4.33 eV as determined from ultraviolet photoelectron spectroscopy (UPS). To examine the effect of surface treatments and processing procedures on the φ_w of NiO films, they were plasma treated using an RF O_2-plasma at various powers and treatment times with no bias applied to the substrate.

PEDOT:PSS films were used as the control HTL, two coats of PEDOT:PSS (Baytron P VP AI 4083 filtered to 0.45 μm using a nylon filter) were spin cast at 6000 rpm for 50 s followed by a 1 h anneal at 130 °C in air. For the O_2-plasma treated sNiO films the active layer was immediately spun on in an inert atmosphere. A solution of 1:1 P3HT:PCBM (used as received from Rieke Metals and Nano-C, respectively) in 1,2-dichlorobenzene (50 mg/mL total) was stirred at 60 °C and 600 rpm for several hours prior to deposition at room temperature. The active layer was spun at 600 rpm for one minute then allowed to slow dry in a covered petri dish for approximately 1 h [4]. After drying, the active layer was annealed at 110 °C for 10 min in N_2. Top electrodes were then deposited with 20 nm of Ca followed by 100 nm of Al via thermal evaporation through a shadow mask to form six 0.11 cm^2 devices or one 1.0 cm^2 device on each substrate at a pressure of less than 7×10^{-8} Torr [7].

Devices were characterized using a solar simulator housed in an inert atmosphere. Contact was made to both the ITO and Al electrodes, from which voltage was sourced and the resulting current was measured. The short-circuit current (J_{SC}) was calculated based on measured device areas of 0.11 cm^2 or 1.0 cm^2. Shunt resistance and series resistance (R_s) were calculated at 0 V and 0 mA/cm^2, respectively. External quantum efficiency (EQE) was measured without white light biasing the device on a system calibrated with a Si photo-diode illuminated with a Xe 300 W lamp chopped to create an excitation signal detected by lock-in amplification. Integrated EQE spectra were used to verify J_{SC} values.

The sNiO films were characterized by AFM to evaluate the surface morphology and roughness. The root-mean square surface roughness of the films synthesized from the hydrated ink was 2.47 nm as determined by AFM, which is similar to roughness values typically obtained for commercially available ITO [17,18].

The optical transmittance and reflectance over the UV and visible spectrum of the sNiO films are comparable to PEDOT:PSS. The transmittance of the two films shown in Fig. 1 indicates that PEDOT:PSS is more transparent in the UV and at lower wavelengths, while sNiO is more transparent approaching the NIR wavelengths. The reflectance, however, indicates that PEDOT:PSS is slightly less reflective over most of the UV and visible compared to the sNiO film. Overall, the transmitted light that reaches the active layer is similar for both HTLs.

To better determine the dependence of φ_w with plasma treatment, the φ_w of sNiO films was measured in N_2immediately after O_2-plasma treatment at 155 W. The O_2-plasma treatment power and exposure time were varied for sNiO films revealing significant differences in the measured φ_w. The main reactive components of the plasma, O^- and O^{2+} were assumed to drive oxidation of the Ni films. The results, shown in Fig. 2, demonstrate that sNiO films respond to plasma treatment by increasing the φ_w. The sNiO films display a saturation behavior at longer treatment times (~5 min), after which the φ_w no longer increased with further plasma treatment.

We stored all solar cells in a dark inert environment and retested solar cells with sNiO and PEDOT:PSS over two weeks after fabrication. All OPV devices showed similar V_{OC} degradation. This is due to the sensitive Ca electrode dominating the degradation of the devices. Thus the in device HTL stability is at a minimum comparable to PEDOT:PSS.

In order to investigate the effect of the plasma treatment on sNiO, a time dependent φ_w study was conducted by measuring the φ_w every 20 s over a time-span of 2 h in an inert atmosphere. It was observed that the φ_w of films degraded quickly as shown in Fig. 2. This would indicate a change in the surface chemistry of the plasma treated sNiO. Because of the magnitude of the transient behavior in the φ_w, the experimental technique used to evaluate φ_w, and the lack of measurable conductivity in the sNiO, this effect may be associated with a change in either the

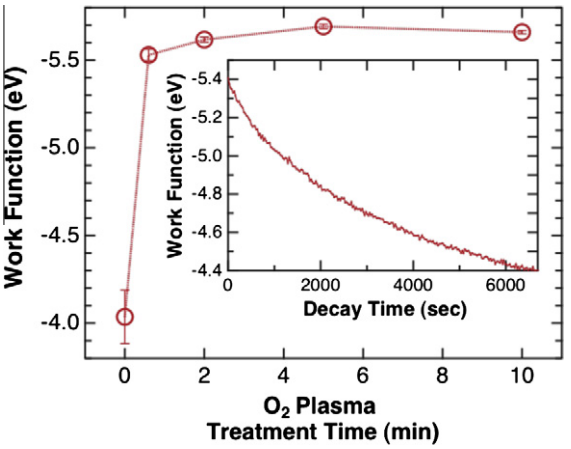

Fig. 2. φ_w response of sNiO films synthesized from Ni ink to O_2-plasma treatment time at 155 W at 0.8 Torr O_2. Inset: φ_w transient of sNiO films after O_2-plasma treatment as measured in N_2.

density of oxygen vacancies or the oxidation state of the Ni in the sNiO [19]. Further studies are underway to evaluate the exact affect of the O_2-plasma treatment on the sNiO films.

In order to compare the performance of solution deposited sNiO in OPV devices, BHJ solar cells were fabricated and tested under simulated one-sun conditions. The best sNiO-based devices were those O_2-plasma treated so that the observed φ_w immediately before deposition of the active layer was in the range of −5.0 eV up to −5.6 eV. The optimized sNiO devices, resulted in PCE that are equivalent to PEDOT:PSS control devices. These devices utilized a sNiO HTL that had a φ_w of −5.6 eV before deposition of the active layer. Table 1 summarizes the results obtained via current–voltage characteristics of the solar cells with a spectral mismatch of 1.0.

The thickness of the sNiO films also has important effects. Thicker films produced devices with lower V_{OC}, lower J_{SC} and higher R_s. Thinner films failed to produce uniform devices on a substrate causing inconsistent performance, perhaps due to incomplete surface coverage. In addition, previous studies have shown that 10 nm was the optimal thickness in PLD deposited NiO films with an active layer thickness of about 220 nm [7]. This optimal thickness of the active layer blend, however, could be different for devices with sNiO as opposed to PEDOT:PSS, though this was not considered in this study.

With the optimal sNiO devices, higher *FF*, slightly lower J_{SC} and similar V_{OC} were obtained, in relation to the PEDOT:PSS control device. This leads to similar PCE of 3.6% for both sNiO and PEDOT:PSS HTLs. Reported series and shunt resistances were calculated by taking the inverse slopes at V_{OC} and J_{SC}, respectively. The series resistance is lower in the sNiO devices as compared to PEDOT:PSS. The lateral conductivity of the sNiO cannot be measured using our 4-point probe setup, unlike PEDOT:PSS, indicating that the bulk conductivity of the sNiO is lower than that of PEDOT:PSS. Therefore, the decrease in series resistance in the OPV devices is likely due to reduced contact resistance at the ITO/sNiO and sNiO/active layer interfaces. Fig. 3 displays the current–voltage characteristics of PEDOT:PSS and sNiO-based devices. Device yield was above 90%, similar for all tested HTLs.

An unexpected aspect of the device performance was the sNiO films with much deeper observed φ_w than the assumed optimal −5.0 eV worked best. It should be noted that the plasma treatment of these films is the key to producing the best-functioning devices with non-treated films exhibiting poor *FF* and low V_{OC}. It is possible that it is simply cleaning off any organic contaminants or remaining solvent at the surface, revealing the higher φ_w sNiO beneath. Or it may be that the surface oxidation state is shifted during O_2-plasma treatment either reducing a tunneling barrier or pinning the P3HT HOMO level closer to the NiO valence band. However, higher than expected φ_w indicates that there may be charging of the surface from the plasma, and it is subsequently degrading quickly over time. It is most likely that there is surface oxidation, which would change the φ_w and the doping of the p-type NiO thin-film, modestly increasing conductivity while facilitating good ohmic contact, hole collection, and electron blocking characteristics. We can also not yet rule out other mechanisms, which may result in effective charge transport at this interface such as Fermi-level pinning. However, these types of interfacial mechanisms demand that more importance be placed on the electric field, and therefore surface doping in the sNiO layer than the measured φ_w of the layer. Before recombination can occur, a high electric field would accelerate the already dissociated charge

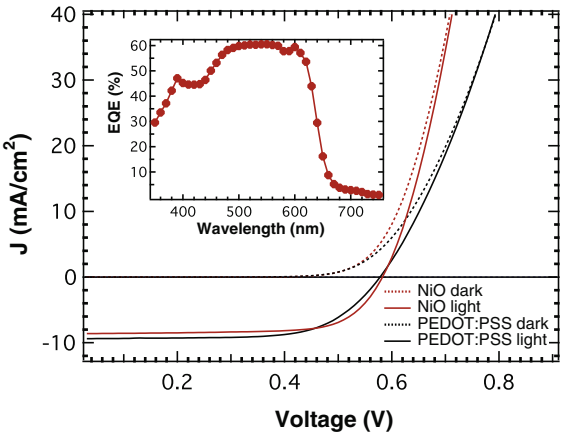

Fig. 3. Current–voltage characteristics of the best OPV devices based on sNiO and PEDOT:PSS HTLs. Inset: IPCE of sNiO device.

Table 1
Solution NiO and PEDOT:PSS control device summaries.

HTL	V_{OC} (mV)	J_{SC} (mA/cm^2)	*FF*	PCE (%)	R_{shunt} (Ω cm^2)	R_{series} (Ω cm^2)
sNiO	583 ± 5	−8.6 ± 0.1	0.71 ± 0.004	3.6 ± 0.1	1600 ± 400	6.0 ± 0.2
PEDOT:PSS	578 ± 3	−9.4 ± 0.3	0.66 ± 0.02	3.6 ± 0.1	2200 ± 300	8.1 ± 0.2

carrier toward the proper electrode. Higher electric fields would therefore correspond to enhanced current collection. This hypothesis is consistent with a simple 1-D Poisson model that was compiled in an earlier study to evaluate both the electric field and band-bending due to such doping effects at the interface [14]. This simple model does show very high fields across the NiO for the case of a reasonable enhancement of the carrier concentration at the NiO surface and will be the subject of future studies.

The results of this study indicate that solution processed NiO may be used in lieu of PLD NiO thin-films in standard BHJ OPV devices. Furthermore, sNiO is an effective replacement for PEDOT:PSS as an HTL. Results showed similar efficiency for solar cells with sNiO compared to PEDOT:PSS controls. Both the precursor ink formulation and the processing conditions were optimized to produce 10 nm sNiO HTL films that enabled both electron blocking and hole collection indicative of high quality selective contacts essential for BHJ devices. Further studies will evaluate the effect of the sNiO films on the device lifetime and the specific mechanisms present enabling high performance.

large amount of organic materials and devices. We demonstrate inverted solar cells with precursor ZnO electron transport layers for three well-studied polymer:fullerene systems, i.e. based on poly(3-hexylthiophene) (P3HT), poly[9,9-didecanefluorene-*alt*-(bis-thienylene) benzothiadiazole] (PF10TBT) and poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-*b*;3,4-*b*′]dithiophene)-*alt*-4,7-(2,1,3-benzothiadiazole)] (PCPDTBT). As an acceptor the standard [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM) has been used. All three blends can provide power conversion efficiencies in excess of 4% in combination with a fullerene acceptor [23–25]. Our inverted solar cell structures using precursor ZnO exhibit a performance that is identical to conventional bottom-anode–top-cathode geometry solar cells.

2. Experimental

Zinc oxide layers were prepared by dissolving 20 mg/mL of $Zn(acac)_2$ hydrate (obtained from Sigma–Aldrich) in absolute ethanol under ambient conditions, stirring for several hours at 50 °C and subsequently filtering with a 0.2 μm pore size PTFE filter. ITO covered glass substrates were cleaned with soap and deionised water, followed by ultrasonic treatment in acetone and 2-isopropanol. Afterwards they were dried in an oven at 140 °C for 10 min in ambient conditions, followed by UV-ozone treatment for 20 min. $Zn(acac)_2$ was spin cast in air at 1000 rpm, while both solution and substrates were held at 50 °C. Hydrolysis of the precursor was carried out in air during 30 s on a hotplate at 120 °C. This generally resulted in a 20 nm thick layer of ZnO. ZnO typically requires UV illumination to transform from an intrinsic semiconductor into an n-type material by desorption of O_2^- radicals from the surface [26,27]. After illumination with a Steuernagel SolarConstant 1200 metal halide lamp, a reduction of the work function from 4.2 to 3.7 eV was measured with a Kelvin probe calibrated to a gold reference. This is in line with the assumption of injection of electrons into the conduction band by UV illumination and a corresponding raise of the Fermi level. P3HT:PCBM (1:0.8 by weight, 15 mg/mL of polymer) was dissolved in chloroform. PCPDTBT:PCBM (1:2.5 by weight, 7 mg/mL of polymer) was dissolved in a chlorobenzene solution containing 1.5 wt.% 1,8-octanedithiol, which was added to increase the photovoltaic performance of the resulting devices as described in literature [23,28]. PF10TBT:PCBM (1:4 by weight, 3 mg/mL of polymer) was dissolved in pristine chlorobenzene. ITO substrates were cleaned as described before. PEDOT:PSS (Clevios P VP AI 4083) was spin cast in air to yield a 50 nm layer on the substrate. Spin casting of the P3HT:PCBM and PCPDTBT:PCBM blends was done in a nitrogen atmosphere, while PF10TBT:PCBM was spin cast in air. Thermal evaporation was performed at a pressure of 10^{-6} mbar for all materials (LiF, Al and MoO_3). MoO_3 powder was obtained from Sigma–Aldrich and was used as received. The evaporation rate was held constant at 0.05 nm/s to produce a smooth film of 10 nm and 1 nm for MoO_3 and LiF, respectively. Finished cells were illuminated through illumination masks with a Steuernagel SolarConstant 1200 metal halide lamp, calibrated to 1 sun intensity and corrected for spectral mismatch with the AM1.5G spectrum using a Si reference cell. The calculated mismatch factors for P3HT:PCBM, PF10TBT:PCBM and PCPDTBT:PCBM in this setup amounted to 1.40, 1.40 and 1.03, respectively [29]. Electrical characterization was done with a Keithley 2400 SourceMeter.

3. Results and discussion

The optical absorbance of a 20 nm layer of ZnO was measured with respect to a glass reference with a Perkin-Elmer Lambda 900 spectrophotometer and is shown in Fig. 1. Note the excellent optical transparency in the visible range of wavelengths of the precursor made ZnO film. The optical absorbance of the precursor layer before conversion is shown for reference. The inset provides a determination of the optical band gap of the ZnO films through extrapolation of the linear regime in the quadratic absorption to 3.53 eV. Furthermore, the structure of $Zn(acac)_2$ is shown for clarity. Fig. 2 shows the structure of the completed cells, along with the materials used for the active layers. The current density–voltage characteristics of the P3HT:PCBM, PF10TBT:PCBM and the PCPDTBT:PCBM cells under illumination are shown in Fig. 3. All photoactive layers were approximately 80 nm thick. Table 1 shows the performance parameters for all solar cells presented in this study. We observe that the performance parameters and thus the cell efficiencies are very close for cells with the conventional and inverted geometry. The reported efficiencies are in good agreement with previously published values for optimized PF10TBT:PCBM cells [24]. The efficiency of the PCPDTBT:PCBM cells has been increased in comparison to a previous publication, which is due to decreased recombination by addition of 1,8-octanedithiol in these devices [28,30]. Furthermore, optical absorption simulations based on the transfer matrix formalism have been performed on the two structures for the PF10TBT:PCBM blend [31–34]. The optical constants needed for this simulation

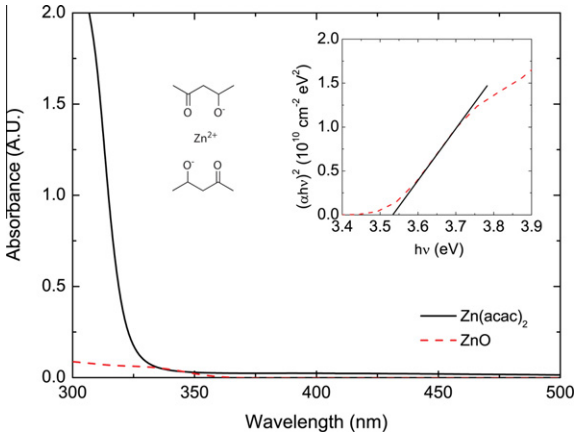

Fig. 1. Optical absorbance of a 20 nm layer of ZnO. The absorbance of the $Zn(acac)_2$ precursor layer is shown for reference. The inset shows the determination of the optical band gap for the ZnO layer. The chemical structure of $Zn(acac)_2$ is shown for clarity.

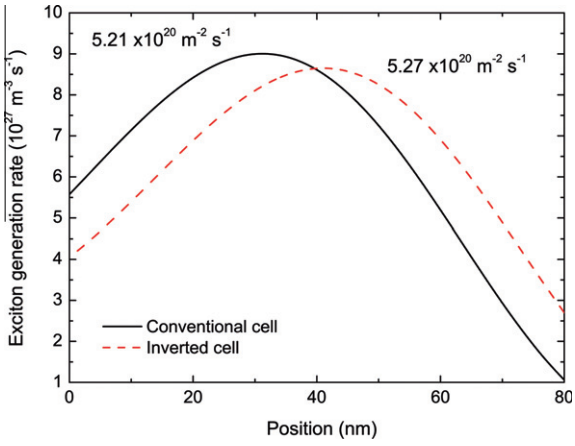

Fig. 4. Simulated exciton generation rates in conventional and inverted geometry cells. The origin is defined as the substrate side of the device. The integrated generation rates are shown for the two geometries.

Table 1
Photovoltaic properties of conventional and inverted PF10TBT:PCBM, P3HT:PCBM and PCPDTBT:PCBM solar cells under 1 sun white light illumination.

Photoactive layer	Type	J_{sc} (A m^{-2})	V_{oc} (V)	FF (%)	MPP (mW cm^{-2})
PF10TBT:PCBM	Conventional	67.3	0.96	61	4.0
	Inverted	66.1	0.95	59	3.7
P3HT:PCBM	Conventional	87.6	0.57	66	3.2
	Inverted	91.5	0.59	60	3.2
PCPDTBT:PCBM	Conventional	91.8	0.61	50	2.8
	Inverted	91.4	0.58	50	2.6

were obtained with variable angle spectroscopic ellipsometry [24,35]. The layer thicknesses of the ZnO and MoO_3 layers for this simulation have been defined as 20 and 10 nm, respectively. This was done to mimic the actual devices as closely as possible, and as such these thicknesses are not necessarily optimized for the optical field. As can be seen in Fig. 4, the calculated integrated exciton generation rates for both the conventional and inverted cells are equal to within 1% for the two structures. This validates the experimentally observed equal short-circuit currents under the assumption of equal internal quantum efficiencies. In this figure the origin is defined as the point in the photoactive layer where the light first enters the device,

i.e. the substrate side. For the conventional device the light is directly reflected at the aluminium top electrode, whereas for the inverted device the 10 nm of MoO_3 acts as an optical spacer, thereby changing the shape of the absorption envelope.

4. Conclusions

In summary, we have shown the electrical operation of inverted solar cells with an ITO/ZnO cathode, fabricated through the low temperature decomposition of $Zn(acac)_2$. The performance of these cells is shown to be equivalent to cells made in the conventional bottom-anode–top-cathode geometry. The simplicity of fabrication of these inverted solar cells without loss of performance will stimulate a further systematic investigation on their enhanced stability.

the moment, according to Starck's Clevios company, the product TM PH 510 has conductivity of 300 S cm^{-1}. For organic LED applications the electrical conductivity must be as high as possible and independent of moisture. However, the electrical conductivity of PEDOT:PSS layers depends on the level of humidity. From 20% RH up to 57% RH the conductivity increases to the value higher than 13% and from 57% RH to 90% RH it decreases to 70% of the original value (see Fig. 1). With the number of recurrent cycles the change is a little bit smaller but still exists.

The aim of the present work was to prepare a polymer on the basis of PEDOT with conductivity independent of humidity (further mentioned as PEDOT:PTSA) and to characterize its surface properties with photoemission spectroscopies and SEM, as well as to investigate the interface properties with nickel phthalocyanine (NiPc) thin films. Increasing research efforts were devoted to metal phthalocyanines [(MePcs) M-C32H16N8] which are planar molecules formed by stable π-conjugated macrocycles coordinating a central metal atom. Due to their unique optical and electronic properties, the high temperature chemical and photochemical stabilities, the low-cost of preparation processes and their tendency to self-assemble on metal surfaces forming ordering aggregates, make MePcs suitable to easily control the properties at the organic/metal or/and inorganic interfaces and therefore they are considered to be promising materials for many electronic applications such as gas sensors, field-effect transistors, and solar cells [10,11]. In this study, we compare the electronic structure of the NiPc/PEDOT:PTSA interface investigated by core level X-ray and valence band ultra-violet photoemission spectroscopies (XPS and UPS, respectively), with the energy level alignment for NiPc thin films on other technically relevant substrates such as PEDOT:PSS, ITO and Au which have been studied previously [12–14]. PEDOT:PSS has quite similar chemical structure to PEDOT:PTSA, ITO has similar work function to PEDOT:PTSA and, Au is a metal electrode which forms ohmic contacts and can be used as reference for the determination of the position of the energy levels in respect to the Fermi level. All interfaces are formed and investigated in ultra high vacuum (UHV) to eliminate all possibilities of ambient contamination.

2. Experimental

PEDOT:PTSA (the chemical structure is given in Fig. 2a) was prepared by the polymerization of the 3,4-(ethylenedioxy)thiophene (EDOT) monomer in the presence of a

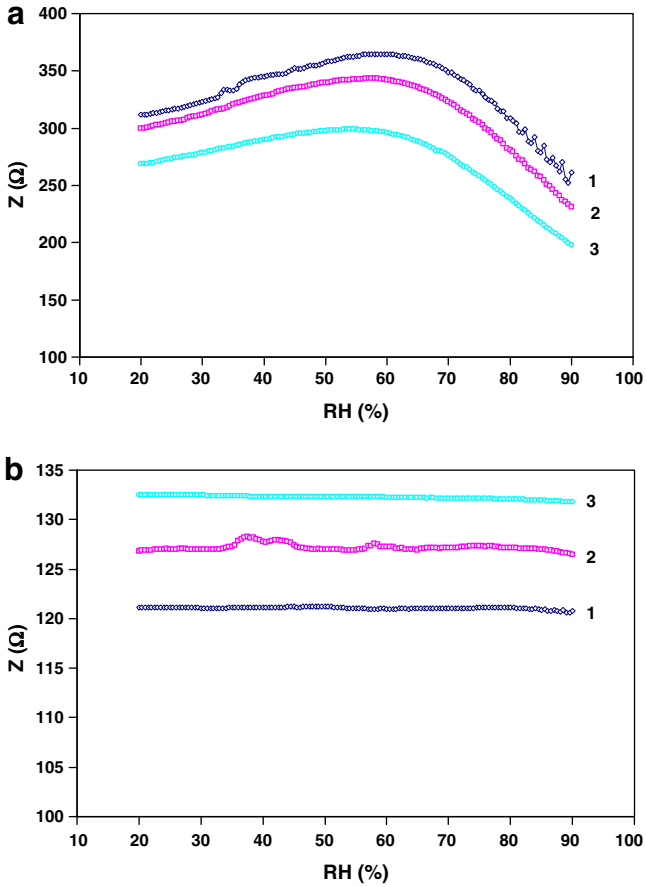

Fig. 1. Humidity dependences of the impedance at different temperatures for: (a) PEDOT:PSS, (b) PEDOT:PTSA (before ethanol washing). Curve 1 – 20 °C, curve 2 – 30 °C, and curve 3 – 50 °C.

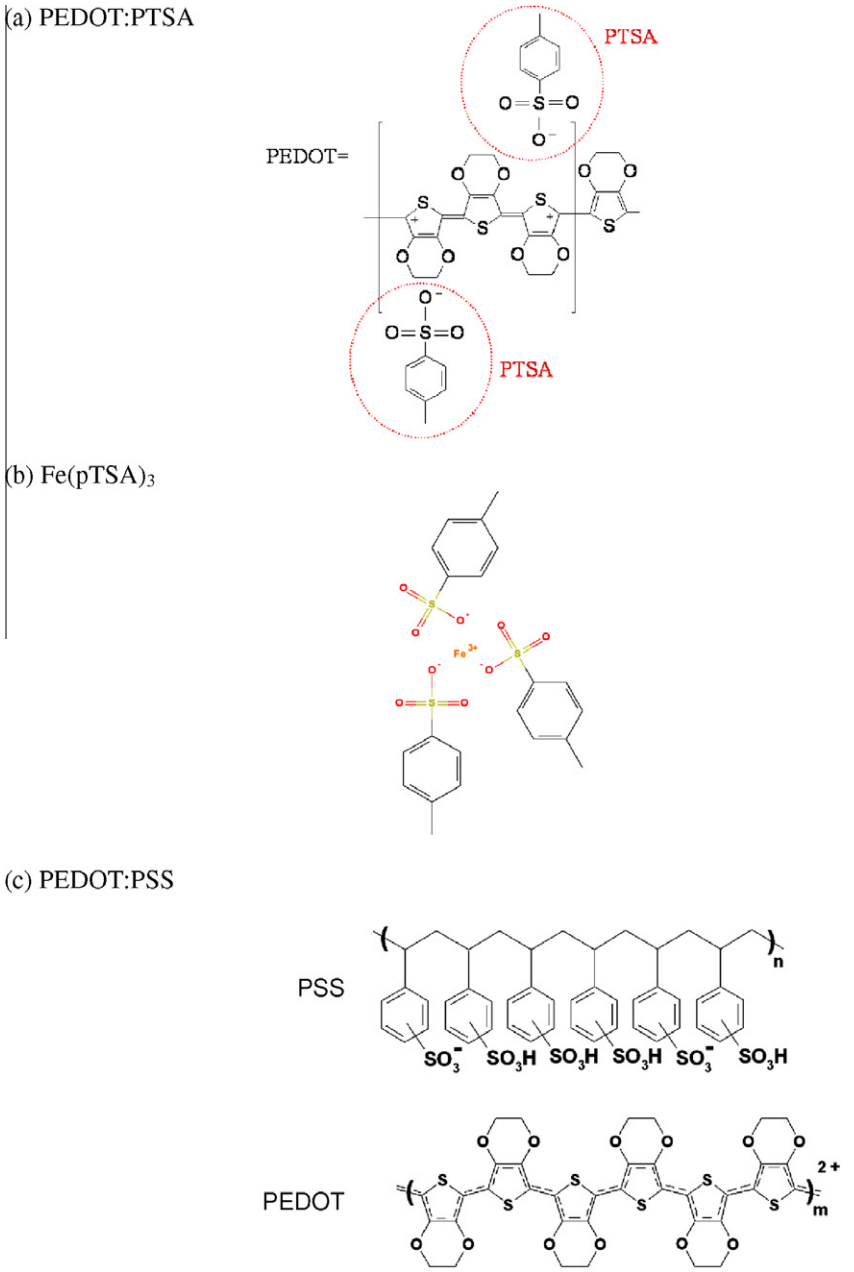

Fig. 2. Chemical structure of (a) PEDOT:PTSA, (b) iron(III) toluensulfonate $Fe(pTSA)_3$ and (c) PEDOT:PSS.

stoichiometric or less than stoichiometric amount of the catalyst, iron(III) toluensulfonate $Fe(pTSA)_3$ (see Fig. 2b), which is an organic acid ligand combined with iron III and butan-1-ol. When the components are mixed in solution, a small portion of the monomer tends to polymerize even at room temperature. The polymerization solution may also contain a dopant. However, iron(III)toluenesulfonate supplies both the dopant (anion toluenesulfonate) and the oxidative polymerization catalyst (iron(III) cation). In particular, the PEDOT:PTSA films were prepared by dipping in the polymerization solution consisting of the mixture of solutions: iron(III) toluensulfonate (10 parts, Clevios™ CB) in butan-1-ol, *N*-methylpyrrolidone (0.1 part, Sigma–Aldrich) and ethyl alcohol (12 parts), 1 part of EDOT (Clevios™ M) in isopropyl alcohol and butyl alcohol (all parts are by weight). All chemicals of reagent grade were used without purification. PEDOT:PSS films were prepared by dipping in an aqueous dispersion (Clevios™ P – chemical structure displayed in Fig. 2c). The PEDOT:PTSA thin films were prepared by spin coating (2100 rpm) on the surface of a fluorinated tin oxide (FTO) coated-glass. After the deposition, the PEDOT:PTSA samples were kept 24 h on air to finish the polymerization and finally, the samples were washed in ethanol.

The surface of the samples was studied right after their introduction in UHV, after thermal treatment at 110 °C for 1 h and after in situ mild argon sputtering for 5 min (4×10^{-6} mbar of argon pressure, accelerating voltage of 0.2 keV and incidence angle of 45°), by XPS (non-monochromatic Al Kα) and UPS (HeI excitation line). The measurements were performed in a multi-chamber ultra high vacuum system described previously [12]. The characterization of the surface was followed by thermal evaporation of commercial NiPc powder (Alfa Aesar) in a step-wise manner from a home-made Knudsen cell kept at 425 °C in a vacuum of about 5×10^{-8} mbar. The temperature of the substrate (PEDOT:PTSA) was 20 °C and the total thickness of the NiPc film was about 7.0 nm. After every deposition step the analysis of the surface was carried out with XPS (Al Kα, analyser pass energy of 97 eV) and UPS (HeI). The calibration of the spectrometer is described elsewhere [12]. The work function was measured biasing the specimen at −12.30 V to separate sample and analyser high binding energy cut-offs.

Humidity dependence of impedance was measured by Hewlet–Packard AC Bridge (type HP4274A). Thin films were deposited by spin coating on the system of interdigital gold electrodes, gap 20 μm.

3. Results and discussion

3.1. PEDOT:PTSA

3.1.1. Surface characterization

Fig. 3 shows the SEM pattern of the film prepared by dipping in pre-polymerized solution consisting of the monomer and oxidizer (catalyst) in the ratio of 2:1 and then washed in ethanol. The film was quite homogeneous while its thickness was about three times lower than before the washing process. Note, that PEDOT:PSS films forms very homogeneous films with much smaller grains in comparison with PEDOT:PTSA.

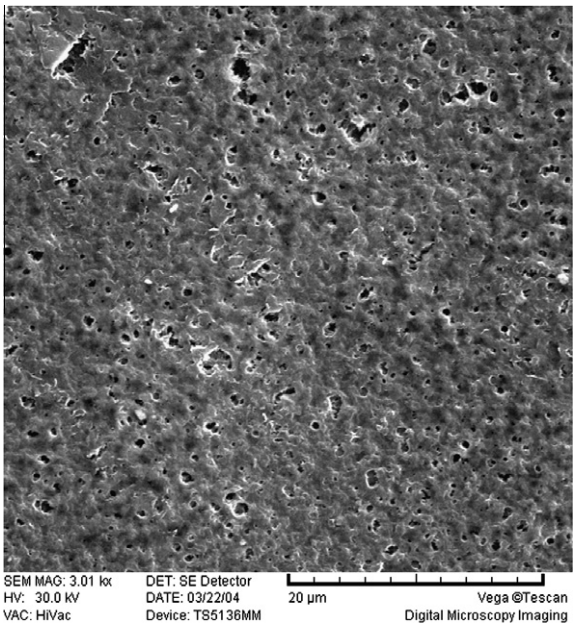

Fig. 3. PEDOT film prepared by the polymerization of EDOT in the presence of less than the stoichiometric amount of the oxidative polymerization catalyst (PTSA), after the ethanol washing.

Analysis of the XPS (Al Kα) plots shows that the overview spectra of the PEDOT:PTSA surface is dominated by the expected elements (C, O and S) in agreement with the chemical structure of the polymer. The S2p band consists of two components with binding energies 164.2 ± 0.1 and 167.7 ± 0.1 eV. The peak at lower binding energy is due to the sulphur atoms linked to carbon in the chemical structure of PEDOT, while the peak at higher binding energy is attributed to the sulphur atoms in PTSA (Fig. 4a). Both contributions are splitted in two spin orbit doublets at the binding energies 164.0 ± 0.1 and 165.3 ± 0.1 eV for PEDOT and 167.4 ± 0.1 and 168.6 ± 0.1 eV for PTSA, respectively, with the ratio of $2p_{3/2}$ to $2p_{1/2}$ peaks equal to 2:1 [15,16]. During the annealing and argon sputtering procedures no significant change in the position of the overall S2p peak was observed (not shown). However, the PEDOT-to-PTSA ratio calculated from the areas under the S2p core level spectra seems to change from 1:0.4 for the as received surface to 1:0.25 upon annealing, without any further change after sputtering (1:0.24). It should be noted here that the nominal ratio of PEDOT-to-PTSA is 1:0.5 (1:1.2 by weight). From the spectrum it is also possible to estimate the thickness of the surface PTSA component [15]. The thickness equivalent of PTSA amount at the surface is 3.80 nm for the as-loaded polymer and 3.30 nm for the annealed one revealing a partial removal of the blend from the surface during the annealing procedure. During the sputtering no significant (thickness) reduction was observed.

The binding energy of the XPS O1s peak from the as-loaded PEDOT:PTSA surface is 533.00 ± 0.05 eV and can be splitted into three components according to the different chemical bonds of the oxygen atoms (Fig. 4b). The component at 533.4 eV of binding energy is attributed to the C–O–C bonds from PEDOT [15], the component at 533.0 eV is due to –OH groups and the component at 531.9 eV can be attributed to O═S bonds in PTSA. Upon heat treatment and sputtering procedure the contribution of PTSA to the overall O1s signal significantly decreases, confirming the possible partly removal of PTSA.

The XPS C1s peak was found at 285.20 ± 0.05 eV and can be analysed in two components attributed to C–C bonds (285.2 eV) and to C–O and C–S bonds (286.7 eV) (Fig. 4c). In the case of C1s peak it is not possible to distinguish the contributions of PEDOT and PTSA to the overall signal. Upon annealing and sputtering no significant change in the shape and energetic position of C1s peak was observed.

The valence band structure of the as-loaded PEDOT:PTSA surface as obtained by UPS is shown in Fig. 5. The $HOMO_{cut\text{-}off}$ was determined at about 2.5 eV, while two broad peaks in the energy range of 6–7 eV and 9–10 eV are clearly visible. The work function was found equal to $e\Phi = 4.2 \pm 0.1$ eV for the as-loaded surface, similar to that measured for a sputtered clean ITO surface [17]. After

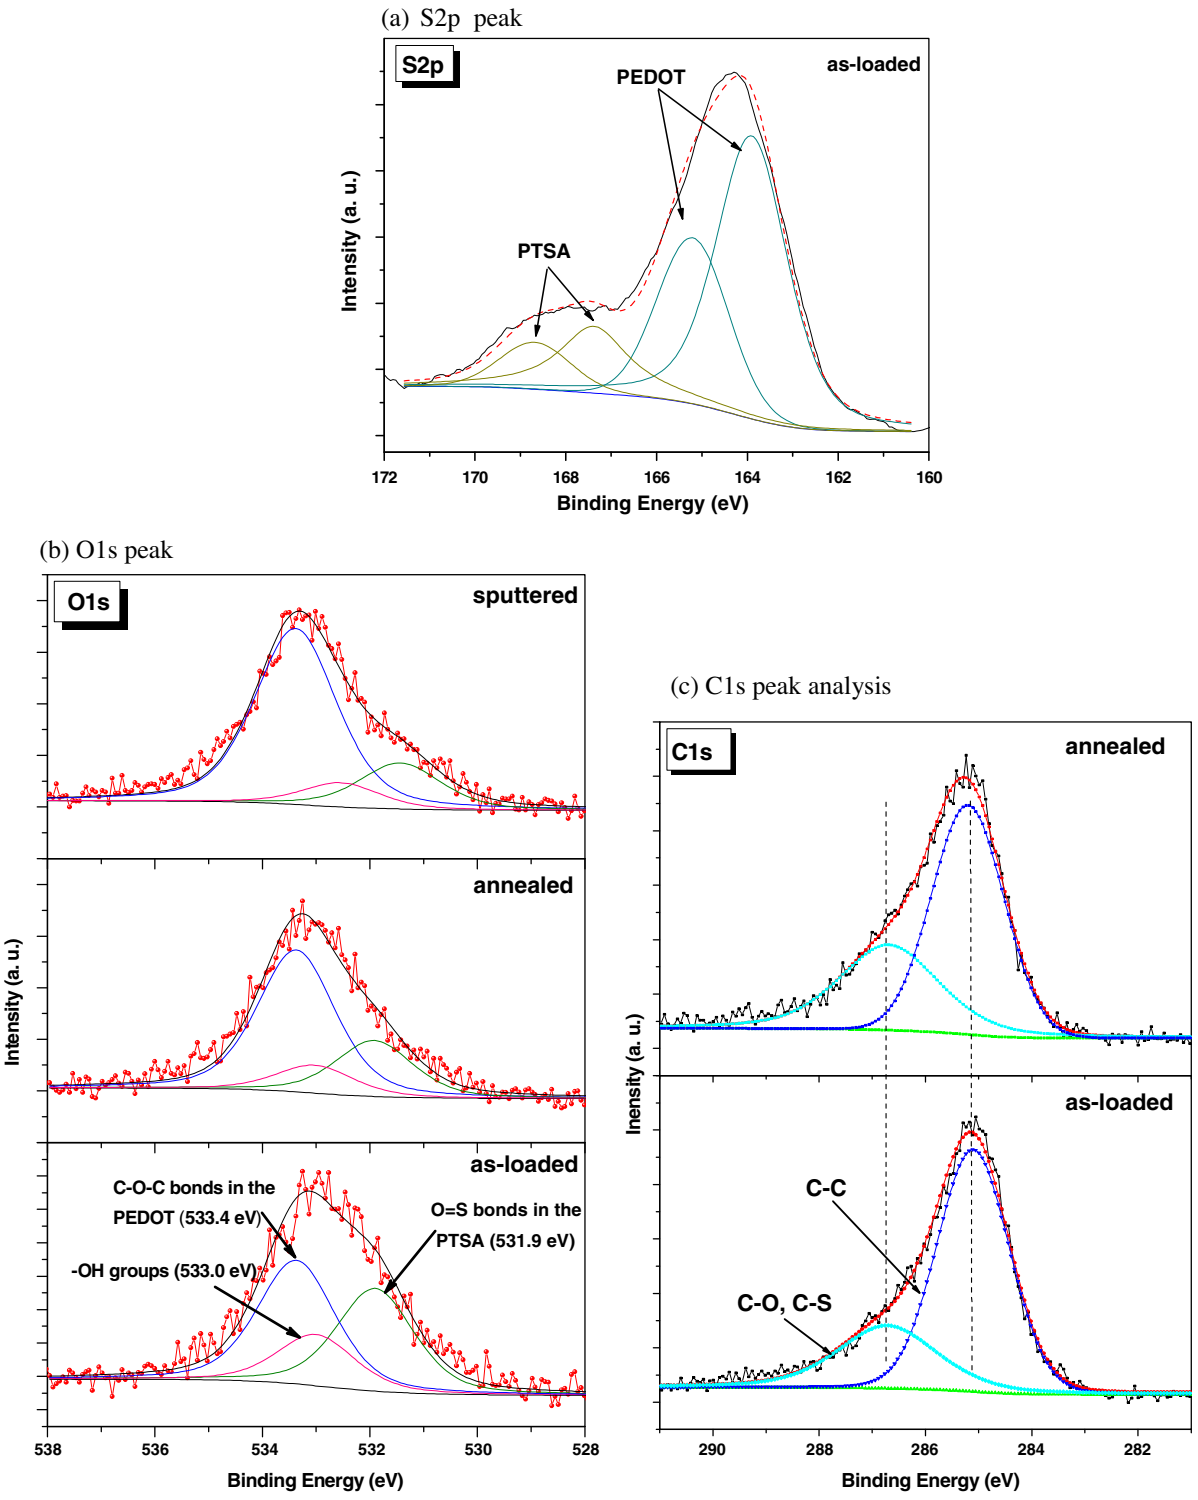

Fig. 4. Analysis of the XPS (Al Kα) data for the (a) S2p (smoothed) for the as-loaded PEDOT:PTSA surface, (b) O1s peak for the as-loaded, thermal treated and sputtered surface, and the (c) C1s peak for the as-loaded and annealed surface.

sputtering the work function decreases to 3.9 ± 0.1 eV, while we observe a slight increase of the density of states close to the Fermi level, indicating a more conductive surface.

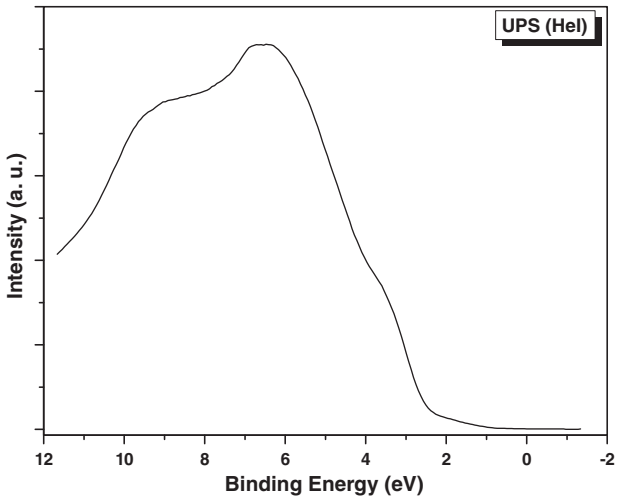

Fig. 5. Valence band structure for the as-loaded PEDOT:PTSA surface.

3.1.2. Dependence of impedance on humidity

As already mentioned in the introduction, PEDOT layers can be used for the construction of gas sensors. The accurate determination of the gas concentration assumes that the measured signal is independent on humidity of an environs or it is compensated by electrical element which uses the data from a humidity sensor. The first way is more simple, but it requires a sensing element which is not humidity dependent. The PEDOT:PTSA polymer seems to fulfill this condition. In Fig. 1 the humidity dependences for PEDOT:PSS (Fig. 1a) and PEDOT:PTSA (Fig. 1b) films for different temperatures are displayed. The humidity independency of PEDOT:PTSA film is clearly seen therefore, the result suggests that PEDOT:PTSA is suitable material for sensing applications. However, two facts must be mentioned: (i) the impedance of PEDOT:PSS is higher and for the used electrode configuration, it is nearly independent on the film thickness in comparison to PEDOT:PTSA. For the later, the impedance is lower and further decreases with the increasing of the film thickness. (ii) From the temperature dependences of the humidity derives that the PEDOT:PSS films behave as semiconductors whereas those of PEDOT:PTSA behaves as metals (electrical conductivity decreases with increasing temperature).

3.2. NiPc/PEDOT:PTSA interface

The characterization of the PEDOT:PTSA surface was followed by successive depositions of NiPc thin films on the as-loaded surface of the polymeric surface (substrate in the following). The binding energy of the XPS peaks related to the substrate does not change upon the deposition procedure, indicating the absence of chemical reaction with the NiPc molecules. The N1s peak will be used to obtain useful information for the formed interface, as the C1s peak is not suitable for the analysis due to the contribution from the carbon of the substrate. Fig. 6, exhibits the change of the energetic position of the XPS N1s peak with increasing NiPc film thickness. There is no band bending at the organic NiPc energy levels, while at the thick film the N1s peak reaches a plateau at about 399.30 ± 0.05 eV, in agreement with the recently investigated inert interfaces (NiPc/Au, NiPc/Ag and NiPc/ITO) [13,14]. The main contribution to the N1s peak is due to the two chemically non-equivalent N-atoms of the organic molecule, separated by about 0.3 eV and a weaker shake-up feature at higher binding energy (not shown). For better comparison, the change of the energetic position of the XPS N1s peak at the NiPc/ITO, NiPc/PEDOT:PSS and NiPc/Au interfaces are also given in the same figure (Fig. 6). Similar to the NiPc/PEDOT:PTSA interface, at the NiPc/ITO interface the final position of the N1s peak is also found at 399.30 ± 0.05 eV. There is a slight upward shift of the binding energy at low coverage, while for thicker films the energetic position of the N1s core level peak remains almost stable indicating the absence of band bending at the NiPc energy levels [14]. At the NiPc/PEDOT:PSS interface, the N1s peak remains almost stable up to ~3.0 nm of organic film thickness indicating a Fermi level pinning in the gap of NiPc, while for thicker films it exhibits an upward shift of ~0.3 eV and reaches the final position at 399.00 ± 0.05 eV of binding energy [12]. In the case of the metallic substrate, the final state effects and the pillow effect contribute strongly to the shifts of the core levels up to 1.0 nm of organic film thickness, while for thicker films the organic energy levels bend, leading to the alignment of the NiPc and Au foil Fermi levels [13]. The XPS Ni2$p_{3/2}$ peak exhibits similar behavior to the N1s peak and it is centered at 855.90 ± 0.05 eV of binding energy for a 5.0 nm thick film.

The question now arises whether or not the UPS characteristics of the substrate are affected by the presence of the organic molecules. The UP spectra gradually changes upon the deposition process, as shown in the left part of Fig. 7. The valence band of NiPc is fully developed at ~2.0 nm of film thickness and is composed of four peaks in agreement with previous spectroscopic studies [13]. The highest occupied molecular orbital (HOMO) cut-off position is located at 0.80 ± 0.05 eV for a 2.0 nm thick NiPc film and remains constant upon further depositions (right part of Fig. 7). The expected position for the bulk is near the midgap as

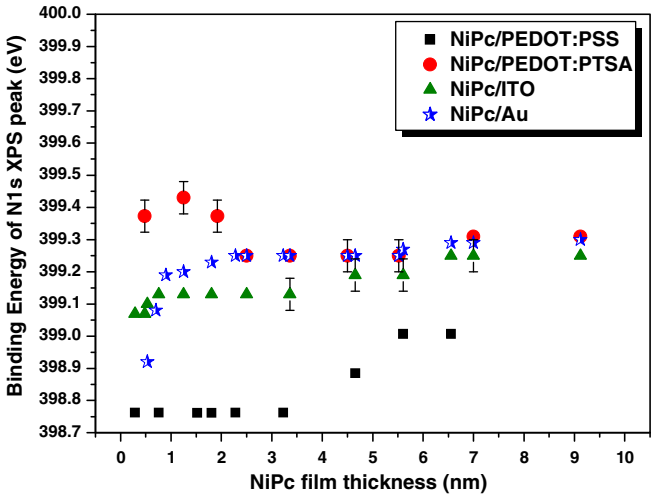

Fig. 6. Binding energy shift of the XPS N1s peak during the formation of the NiPc/ PEDOT:PTSA interface. For comparison, the corresponding shifts of the N1s peak for the NiPc/PEDOT:PSS, NiPc/ITO and NiPc/Au interfaces are also shown.

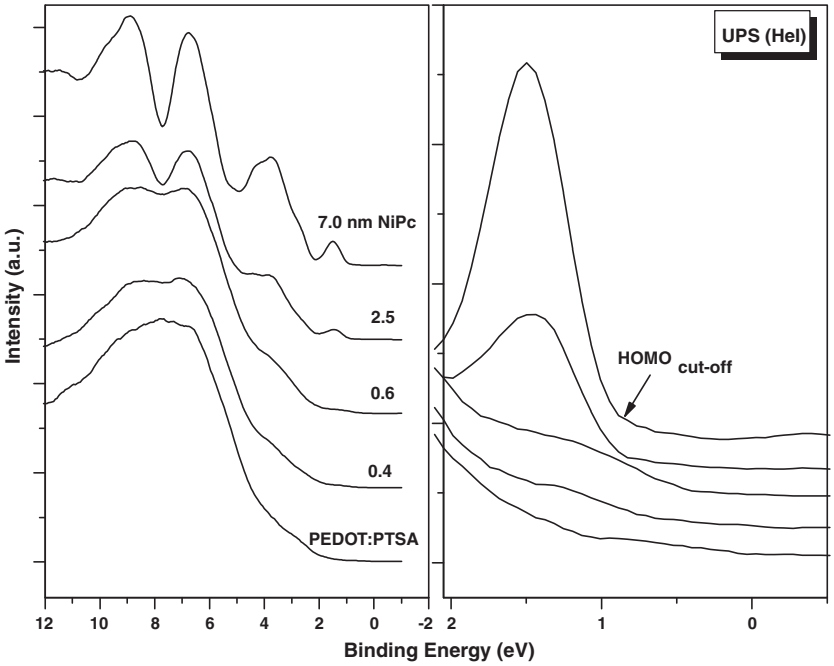

Fig. 7. Evolution of the UPS spectra (HeI) for the NiPc/PEDOT:PTSA interface with increasing NiPc film thickness. On the right part, the low binding energy region is shown magnified (3×) for the determination of the $HOMO_{cut\text{-}off}$ position.

for the NiPc/metals interfaces [13], which is not the case in the present study, revealing that NiPc is more p-doped as at the NiPc/PEDOT:PTSA interface. This behavior will be discussed later on in the context of the chemical type of each substrate.

Upon the successive depositions of NiPc films on the as-loaded polymeric substrate, the cut-off in the spectrum which defines the vacuum level, is shifted to higher binding energy. Thus, the work function of the surface is shifted towards lower binding energies. This is displayed in Fig. 8, where the change of the vacuum level position as a function of the NiPc thickness is shown. At the first steps of deposition and for coverage up to ~1.5 nm, the vacuum level is shifted towards lower energies. For thicker NiPc films it reaches a plateau at about 3.9 ± 0.1 eV, which corresponds to the work function of the NiPc considering Fermi level alignment between the two materials in contact. This value is in agreement with the reported value for the NiPc overlayer in the case of the NiPc/metal interface [13]. For comparison, the vacuum level shift at the

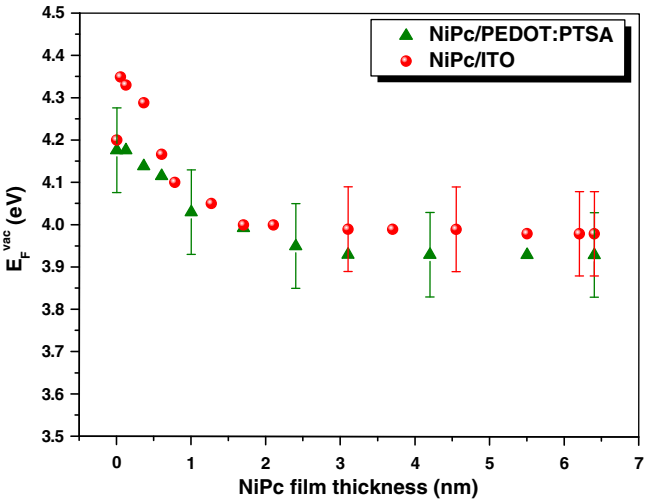

Fig. 8. Vacuum level shifts (E_F^{vac}) as a function of the organic (NiPc) film thickness deposited on the as-loaded PEDOT:PTSA surface and on sputter-cleaned ITO.

NiPc/ITO interface is also shown at the same figure, as the two substrates, ITO and PEDOT:PTSA, have similar work function values.

During the deposition of NiPc on the PEDOT:PTSA and on ITO surface the drop of the vacuum level can be understood on the basis of an interface dipole formed between the substrate and the organic layer as no chemical interaction is observed. The total decrease of the work function at NiPc/PEDOT:PTSA and NiPc/ITO interfaces is 0.3 eV and 0.2 eV, respectively, resulting in an interfacial dipole layer of the same magnitude. In both interfaces, in the absence of a strong chemical interaction, the equilibration of the chemical potentials across the full layer stack leads to the formation of an outward pointing electric dipole at the interface. As a result the lowering of the vacuum level is observed which influences the energy level alignment. The difference between the Fermi level and the $HOMO_{cut\text{-}off}$ position represents the hole injection barrier (Φ_{bh}) at the interface which was found to be 0.8 ± 0.1 eV, similar to that found in the case of the NiPc/metals interfaces, lower than the corresponding barrier at the NiPc/ITO interface (1.0 eV) and significantly higher than the Φ_{bh} in the case of NiPc/PEDOT:PSS interface (0.5 eV). The $HOMO_{cut\text{-}off}$ energy is related to the ionization potential (E_{ion}) of the NiPc overlayer according to the equation

$$HOMO_{cut\text{-}off} = E_{ion} - e\Phi_{(NiPc)}$$

where $e\Phi_{(NiPc)}$ is the work function of phthalocyanine. The barrier for the injection of electrons Φ_{be} can be expressed as

$$\Phi_{be} = \Phi_{bh} - E_g$$

where the energy gap E_g (the energy difference between HOMO and LUMO) is taken from electronic structure calculations and it is equal to E_g = 2.4 eV for the NiPc layer [18]. Fig. 9 summarizes the energy level line-up at the NiPc/PEDOT:PTSA interface as derived by the photoemission results. In Table 1 the properties of the interfaces between

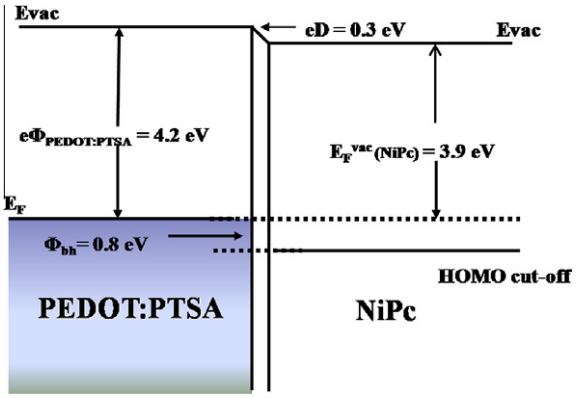

Fig. 9. Schematic energy level diagram for the NiPc/PEDOT:PTSA interface.

NiPc and other substrates (Au, ITO and PEDOT:PSS) are displayed for comparison. According to this table, NiPc forms abrupt interfaces with Au, ITO, PEDOT:PSS and PEDOT:PTSA. In all cases, the direction of the dipole points outwards, with '+' away from the surface. The large interface dipole observed at the NiPc/Au interface is related to the significant electron density at the metal surface, which is rearranged by the presence of the organic NiPc molecules. In the case of metals, when an atom or molecule is deposited on a metallic surface, Coulomb repulsions between the atom and the surface metal electrons locally suppresses the tail of the metal electron cloud that spills into vacuum. This phenomenon leads to the reduction of the metal work function and it is known as "pillow effect" [19,20]. In contrary, in the case of ITO and PEDOT:PTSA, the absence of surface electron tail in addition with the low density of states of the NiPc molecules leads to the formation of small interface dipoles. However, although both substrates have similar work functions, in the case of PEDOT:PTSA the hole injection process is more efficient. The Φ_{bh} at the NiPc/PEDOT:PTSA interface is similar to that found in the case

Table 1
The properties of the interfaces between NiPc and Au, ITO, PEDOT:PTSA and PEDOT:PSS substrates. eD represents the interface dipole, $e\Phi$ is the work function, E_F is the Fermi level position, Φ_{bh} is the hole injection barrier and V_b is the band bending at the organic NiPc energy levels.

	$eD \pm 0.10$ (eV)	$HOMO_{cut\text{-}off} \pm 0.05$ (eV)	$e\Phi_{sub} \pm 0.10$ (eV)	E_F^{vac} (NiPc) ± 0.10 (eV)	$\Phi_{bh} \pm 0.10$ (eV)	$V_b \pm 0.05$ (eV)
Au	1.05	1.00	5.2	4.0	0.85	0.15
ITO	0.20	1.00	4.2	4.0	1.00	–
PEDOT:PTSA	0.30	0.80	4.2	3.9	0.80	–
PEDOT:PSS	0.70	0.50	4.9	3.9	0.50	0.30

of NiPc/Au, revealing the possibility of this material to be used in the development of electronic devices with increased efficiency. Furthermore, it is also possible to prepare PEDOT:PTSA films on flexible substrates and fabricate devices which would attribute mechanical flexibility. Comparing now PEDOT:PTSA with PEDOT:PSS, we would expect similar results, as both substrates have about the same chemical structure. However, this is not the case, as in the NiPc/PEDOT:PSS interface the pinning of the Fermi level in the gap of the NiPc in addition with the presence of band bending at the NiPc energy levels, results in a more efficient electron transfer from the substrate to the organic NiPc film than in the case of the PEDOT:PTSA substrate.

4. Summary

The surface electronic structure of a new synthesized polymer film (PEDOT:PTSA) with higher conductivity than PEDOT:PSS was characterized upon annealing and sputtering procedures. PEDOT:PTSA acts as an ordinary conducting substrate for which the initial work function is lowered upon adsorbing the NiPc molecules. AC electrical conductivity is independent of humidity in the range of 20–90% RH which makes the PEDOT:PTSA polymer suitable for sensor applications. From the temperature dependence of the conductivity one can expect metallic behavior. This is also confirmed by the photoemission results where the properties of the NiPc/PEDOT:PTSA interface resemble those of the NiPc/metals.

most recent observation of the effect of Madelung potential on work function [16] indicates the complicated interface electronic configuration of the PEDT:PSS system with both electronic and ionic conducting components.

In the context of the complex electric and electronic behaviors introduced above, this work reports some new phenomena associated with the charge conduction of PEDT:PSS films. We present the negative differential resistance (NDR) observed for a metal/PEDT:PSS/metal sandwich configuration. The NDR peaks exhibit different manifestations as a function of the films thickness and the PEDT:PSS/electrode interface. We propose that hole injection and resonance tunneling, hole trapping and extraction, and ionic motion are responsible for the NDR behaviors and remnant voltage observed in this work. Our results emphasize the effect of film/electrode interface and film thickness on the formation of distinctive *IV* characteristics, and is useful for a complete understanding on the charge conduction mechanism of PEDT:PSS.

2. Results and discussion

PEDT:PSS aqueous solution (Baytron 4083, H.C. Stark GmbH, Germany) was drop-cast onto an Al foil substrate to form thin films (see Supporting Information SI-i for experimental). The typical thickness of the films is ~100 nm and ~1.0 μm, respectively. Fig. 1(a) exhibits the optical photos of the 100-nm-thick and 1.0-μm-thick films respectively collected using the CCD camera of our atomic force microscope (AFM) [17,18] system. Under identical photo-taking conditions, the thicker film exhibits a darker contrast relative to the Al substrate. The specific value of the thickness was obtained by using AFM to measure the Al-PEDT:PSS cross section height (i.e., the boundary of the bright and dark regions in Fig. 1(a)). Fig. 1(b) shows a typical AFM morphology image of the 1.0-μm-thick film, and Fig. 1(c) is the representative current map of the same film collected using conductive AFM (cAFM) [19]. Due to the conducting property of PEDT:PSS, many microscopic conductive sites are observed on the current map. Fig. 1(d) displays the optical absorption spectrum of the 1.0-μm-thick film, and the spectrum is in agreement with the oxidation state or doping level (0.3 hole/ring) of the Baytron 4083 PEDT:PSS used in this work [1,2,20]. Similar AFM morphology and current images, and absorption spectrum were also observed for 100-nm-thick films (data not shown).

Fig. 2(a) shows the typical *JE* (current density~field) curves collected for the 100-nm-thick PEDT:PSS film in the ITO/PEDT:PSS/Al sandwich configuration (see SI-ii for experimental). The *JE* curves were obtained by scanning the ITO electrode voltage from −10 to 10 V at different rate of 0.2, 1.0 and 4.0 V/s, respectively. It can be seen that, instead of the most common monotonous *JE* dependence, the *JE* curves are characterized by large current peaks in both negative and positive voltage regions. Such current peaks are referred to as negative differential resistance (NDR) in the literature, and are often reported for self-assembled monolayers, organic films, and polymer/nanoparticles (NPs) composites [21–25]. In self-assembled monolayers, the NDR behavior arises from the redox centers of the molecules [21], while it is induced by NPs-based trap states in the case of polymer/NPs composites [22,23]. To the best of our knowledge, Fig. 2(a) represents the first observation of NDR for a 100-nm-thick PEDT:PSS film. In Fig. 2(b), we show the energy diagram of the ITO/PEDT:PSS/Al device and propose an interface-states-facilitated hole resonant tunneling mechanism for the observed NDR characteristic. Since PEDT:PSS is a well-known hole-transporting polymer, charge conduction in the sandwich device should be dominated by hole injection from the electrode to PEDT:PSS and subsequent hole hopping/tunneling

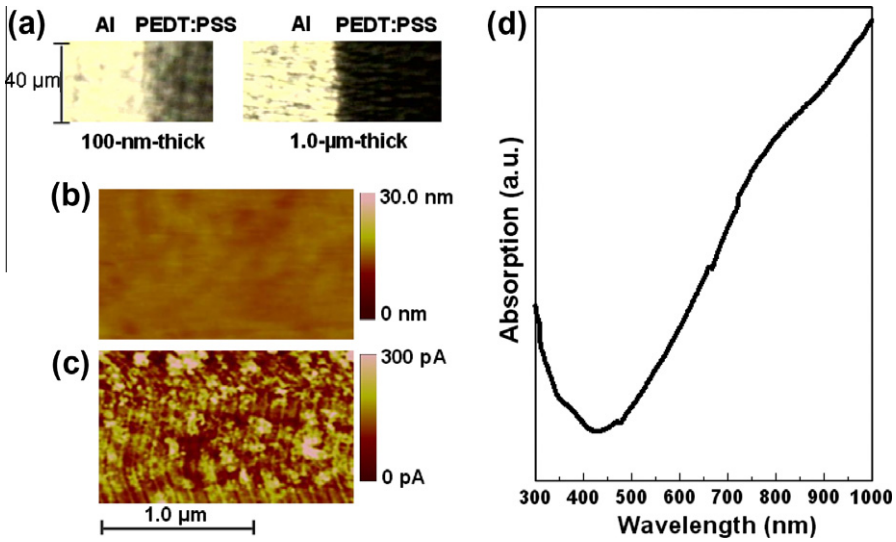

Fig. 1. (a) Optical micrographs showing the formation of the 100-nm-thick and 1.0-μm-thick PEDT:PSS films drop-cast on Al foil substrate, respectively. AFM morphology image (b) and cAFM current map (c) of the 1.0-μm-thick PEDT:PSS film, respectively. A tip bias of −2 V was used for current mapping. (d) Optical absorption spectrum of a 1.0-μm-thick PEDT:PSS film drop-cast on a transparent glass slide.

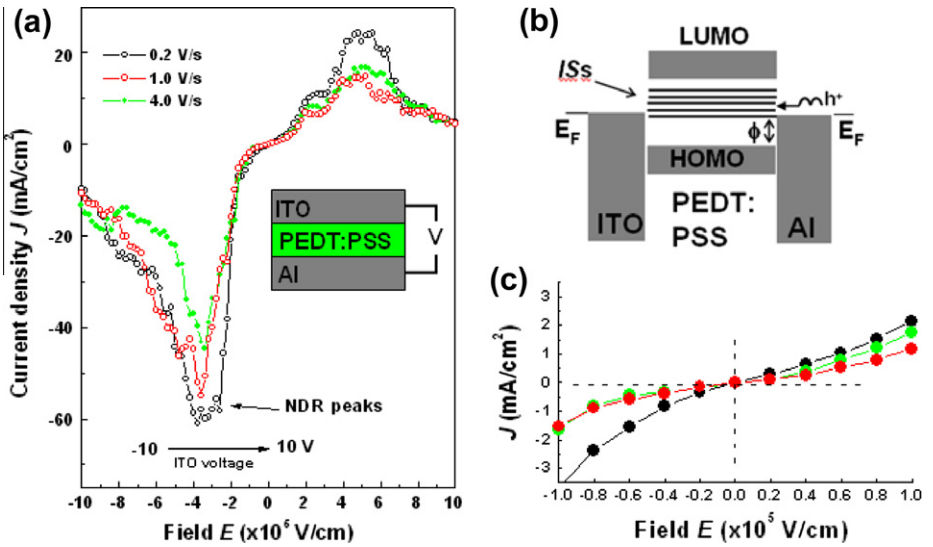

Fig. 2. Typical *JE* curves observed for the ITO/100 nm PEDT:PSS/Al sandwich device (see the inset). The *JE* curves were collected by scanning the ITO electrode voltage from −10 to 10 V at different rate of 0.2, 1.0 and 4.0 V/s, respectively. (b) Proposed NDR mechanism involving interface states (*ISs*) formation at the metal/PEDT:PSS interfaces and subsequent hole resonant tunneling through the *ISs*. (c) Fine features of the same *JE* curves in (a) near the zero-field region showing no remnant field, that is, the *JE* curves all pass through the origin of the coordinates.

throughout the film. Without interface states (*ISs*) formation at the Al/PEDT:PSS contact, there is an energy barrier ϕ for hole injection from the Fermi level E_F of Al to the HOMO (highest occupied molecular orbital) of PEDT:PSS. This often leads to nonlinear monotonous *JE* dependence as a function of the reduction of ϕ by electrode voltage. However, the NDR peaks observed in Fig. 2(a) indicate that charge conduction in the present case is not governed by the energy barrier ϕ. Therefore we propose there are *ISs* formed at the PEDT:PSS/electrode interfaces (see Fig. 2(b)), and these *ISs* provide the resonant states for holes to tunnel through the PEDT:PSS film. In Fig. 2(a), in the $-10 \rightarrow 0$ V voltage range, holes are injected from Al to PEDT:PSS, and the resonant tunneling is peaked at -3.4 V (or -3.4×10^5 V/cm). In the $0 \rightarrow 10$ V range, holes are injected from ITO, and the resonant tunneling peak appears at ~5.0 V (or 5.0×10^5 V/cm). The different NDR peak locations reflect the different E_F alignment of ITO and Al respectively relative to the *ISs*. In addition, the NDR peak intensity in the negative voltage region is systematically higher than that in the positive voltage region. Again, this is an outcome of the different density of *ISs* formed at the two metal/PEDT:PSS interfaces. The correlation of NDR to interface states will be further discussed in Fig. 4 which shows the quenching of NDR by using photoexcitation to saturate the *ISs*. The *JE* curves in Fig. 2(a) are reversible: in our experiments, when the ITO electrode voltage was scanned forward from −10 to 10 V (trace) and backward from 10 to −10 V (retrace) in one go, NDR peaks similar to those in Fig. 2(a) were observed in both the trace and retrace *JE* curves (see Fig. S1 in SI-iii). We also fabricated Au/100-nm thick PEDT:PSS/Au symmetrical devices for *JE* curve measurements. In this case, NDR peaks almost symmetrically located in the negative and positive voltage regions were observed (see Fig. S2 in SI-iv). In addition, we also compared the *JE* curves obtained at 25 and 100 °C respectively (see Fig. S2), and essentially no difference was observed in the NDR behavior between the two temperatures.

All the above results indicate that charge conduction in the 100-nm-thick PEDT:PSS films is electronic in nature. Firstly, the NDR peak intensity and position observed in Fig. 2(a) do not show a systematic dependence on the voltage scan rate *r*. In our experiments, the voltage scan was conducted at different rate of $r = 0.2$–4.0 V/s, and similar NDR peaks were observed regardless of *r*. The alteration (<20%) of the NDR peak intensity observed in Fig. 2(a) for $r = 0.2$, 1.0 and 4.0 V/s, respectively, is within our experimental error caused by sample-to-sample and measurement-to-measurement variations. Based on the resistivity (500–5000 Ωcm) of the PEDT:PSS polymer used in this work, hole resonant tunneling is a fast process in the sub-μs time scale, [26] so the change of scan rate in the ms-s scale should not affect the tunneling process. This is why no rate-dependence is observed for the NDR peaks shown in Fig. 2(a). Secondly, the fine features (see Fig. 2(c)) of the same *JE* curves shown in Fig. 2(a) near the zero-field (or zero-voltage) region clearly show that all the *JE* curves pass through the origin of the coordinates. This observation rules out the formation of remnant field/voltage during the *JE* curve measurements. If ionic process is involved, it will cause a large remnant field E_r (or remnant voltage V_r) and a strong rate-dependence as demonstrated below in Fig. 3 for 1.0-μm-thick PEDT:PSS films.

Fig. 3(a) displays the typical *JE* curves obtained for the 1.0-μm-thick PEDT:PSS film sandwiched between ITO and Al electrodes. Although the *JE* curves were collected under identical conditions used in Fig. 2(a), they are distinctly different from those displayed in Fig. 2(a). It can be seen in Fig. 3(a) that the *JE* curves are highly asymmetric: the current in the negative voltage region is monotonous, and is two orders higher than that in the positive

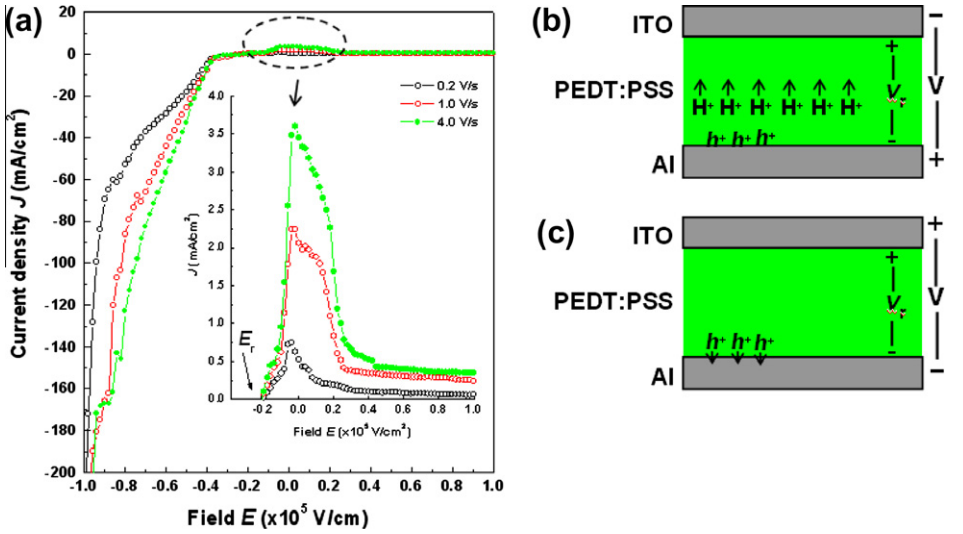

Fig. 3. Typical *JE* curves of the ITO/1.0 μm PEDT:PSS/Al device collected by scanning the ITO electrode voltage from −10 to 10 V at different rate of 0.2, 1.0 and 4.0 V/s, respectively. The inset displays the fine features of the *JE*s in the −2 to 10 V region. (b) Hole injection and trapping, H^+ ionic motion and remnant voltage V_r formation in the −10 → 0 V ITO electrode voltage scan. (c) Hole extraction by the Al electrode in the 0 → 10 V ITO electrode voltage scan.

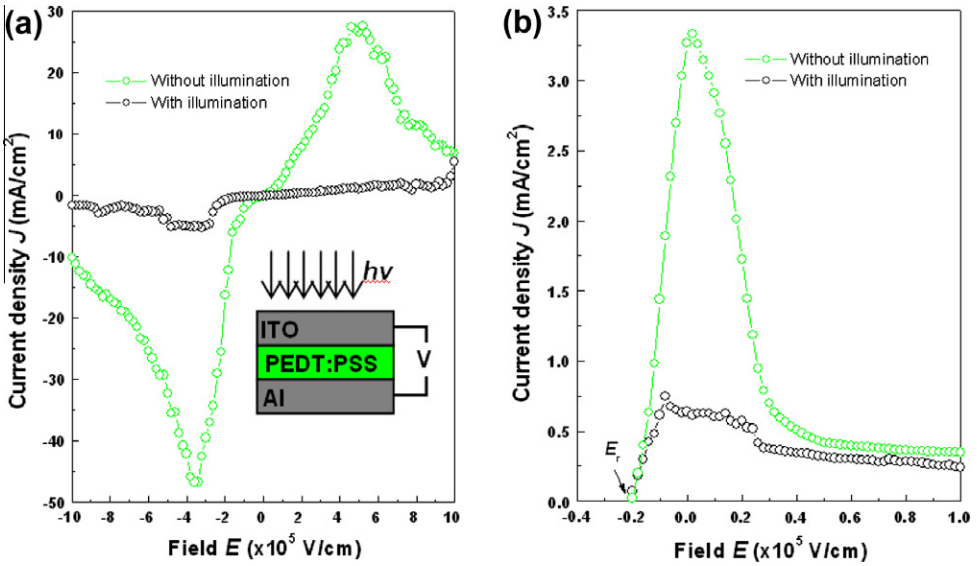

Fig. 4. *JE* curves of the ITO/PEDT:PSS/Al device collected with and without 405 nm light illumination, respectively. The *JE* curves were obtained by scanning the ITO voltage from −10 to 10 V at a rate of 4.0 V/s. The thickness of the PEDT:PSS film is (a) 100 nm and (b) 1.0 μm, respectively.

voltage region. The fine features in the inset of Fig. 3(a) reveal the formation of NDR peaks only in the positive voltage region. Moreover, the NDR peak height and peak area increase monotonously with the increase of voltage scan rate, and a large remnant field of $E_r = 0.2 \times 10^5$ V/cm (or remnant voltage of $V_r = 2.0$ V) is observed for all the *JE* curves in the inset of Fig. 3(a). This observation is in sharp contrast to the nearly symmetrical, rate-independent, and E_r-free *JE* curves observed in Fig. 2(a) for the 100-nm-thick PEDT:PSS films. We suggest that not only electronic but also ionic processes are involved in charge conduction in Fig. 3(a). As proposed in Fig. 3(b), in the −10 → 0 V ITO voltage scan, holes are injected from Al to PEDT:PSS, but due to the large thickness (~1.0 μm) of the film, they are not able to tunnel through the film. So the injected holes are trapped at the interface, thus leading to the absence of NDR peaks in the voltage scan. At the same time, H^+ ionic motion is switched on in the thicker PEDT:PSS film (see Fig. 3(b)), and the cationic motion contributes large ionic current to the total current. This is why the current density is very large (e.g., −200 mA/cm² at $E = -1.0 \times 10^5$ V/cm) in the −10 → 0 V voltage scan shown in Fig. 3(a). In PEDT:PSS, only the small H^+ is highly mobile, while the large polyanion PSS^- chain is essentially immobile. This causes a dipole-like remnant field $E_r = 0.2 \times 10^5$ V/cm or remnant voltage $V_r = 2.0$ V (see the inset of Fig. 3(a)) whose polarity is

opposite to that of the electrode voltage V (see Fig. 3(b)). Similar ionic motion in solid-state PEDT:PSS films has also been observed in previous works,[8,9] and in those early cases, the ionic motion were observed to cause hysterestic *JE* characteristics.

When the ITO voltage enters the $0 \rightarrow 10$ V positive region, the electrode voltage V is in the same polarity as V_r. Both V and V_r facilitate the extraction of trapped holes by the Al electrode (see Fig. 3(c)). It is the extraction of trapped holes at the PEDT:PSS/Al interface that leads to the NDR peaks observed in the inset of Fig. 3(b). Due to the large V_r of 2.0 V, the NDR peak is located near $V = 0$ V, and the NDR behavior dominates the *JE* characteristic in the entire $0 \rightarrow 10$ V voltage region as displayed in the inset of Fig. 3(a). It is clear that in the negative voltage region, charge conduction is governed by hole injection/trapping and cationic motion, while it is characterized by hole extraction and ionic relaxation in the positive voltage region. This is the origin for the drastically different current level and *JE* characteristic between negative and positive voltage regions observed in Fig. 3(a). Compared to hole hopping, ionic motion in polymer is in general a slow process, [27] and recent scanning Kelvin probe measurements [26] revealed that the time constant for ion motion in PEDT:PSS films is in the order of second. Since the *JE* curves in Fig. 3(a) have a strong ionic component, the *JE* dependence should be sensitive to the voltage scan rate used in this work. This is reflected by the monotonous increase of the NDR peak intensity and peak area when the scan rate r is increased from 0.2 to 4.0 V/s shown in the inset of Fig. 3(a).

It is instructive to discuss why the current density J of the 1.0-μm-thick film (Fig. 3a) at a lower field of -1.0×10^5 V/cm is ~20 times that of the 100-nm-thick film at a higher field of -10×10^5 V/cm (Fig. 2a). Intuitively, one would expect a larger current density for a higher field. However, it should be noted that this expectation is mainly valid for steady-state charge transport in which the injected charges are immediately conducted and collected without being trapped in the conducting medium. Typical examples include space-charge limited transport and thermionic emission limited transport, in both of which, the current density increases as a monotonous function of increasing field [28]. In the case of Fig. 2a, however, the *JE* curves are dominated by dynamic and non-steady charge transport due to the formation of interface states (*IS*s) in the HOMO–LUMO gap. Here, the *IS*s can trap the injected holes, and the trapped charges are conductable only under certain resonant fields or voltages. The observation that the current density at -4.0×10^5 V/cm is 5 times that at -10×10^5 V/cm (Fig. 2a) is an indication that a higher field does not necessarily yield a larger current density when *IS*s-induced transient switching behavior is at work in carrier conduction. In Fig. 3a, the *JE* curves also contain the element of transient conduction as signified by the NDR peaks, and are further complicated by the involvement of H^+ ionic transport. Therefore, in the case of non-steady transport and charge trapping/releasing, the *JE* characteristic can significantly deviate from that predicated by rules based on steady-state transport. So it is possible that, under identical voltage, the 1.0-μm-thick film has a higher current density than that of the 100-nm-thick film. Moreover, the current of the 1.0-μm-thick film comprises significant amount of ionic component as evidenced by the -0.2×10^5 V/cm remnant field caused by ionic motion, while the one of the 100-nm-thick film only contains electronic current without the ionic component. This provides another source for the higher current density of the 1.0-μm-thick film shown in Fig. 3a.

It is important to clarify why H^+ ionic motion is present in the thick film, while it is absent in the thin film. In the case of the thick film shown in Fig. 3b, holes are injected from the Al electrode and are then trapped at the Al/film interface because they cannot tunnel throughout the large thickness of the film. The trapping of holes would raise the positive potential of the film in contact with the Al electrode. We believe that the hole-induced positive potential generates the driving force for the motion of positive H^+ ions to the other side of the film. In the thin film shown in Fig. 2, however, holes can conduct through the thin film by resonant tunneling during the voltage scan. So the hole-trapping-induced positive potential present in the thick film is absent in the thin film. Therefore, H^+ motion is not activated in the thin film due to the lack of the positive potential associated with the trapped holes.

It is observed that the NDR behavior is sensitive to photoexcitation, while the ionic motion is inert to it. As demonstrated in Fig. 4(a), without photon illumination, the *JE* curve collected for the 100-nm-thick PEDT:PSS film is characterized by NDR peaks in negative and positive voltage regions. When 405 nm photons was used to illuminate the PEDT:PSS film (see the inset of Fig. 4(a)), the NDR peaks were observed to disappear from the *JE* curves. In the case of 1.0-μm-thick films, the NDR peak is also significant quenched by photon illumination as shown in Fig. 4(b). We propose that the quenching of NDR in Fig. 4(a) is due to photoexcitation in PEDT:PSS, such that the *IS*s shown in Fig. 2(b) are occupied by excitons, and are therefore not available for hole injection and subsequent resonant tunneling. The energy of the 405 nm photon is $h\nu = 3.1$ eV, which is high enough to create excitons in PEDT:PSS whose band gap is $E_g = 1.5$ eV [1–3]. Similarly in Fig. 4(b), photon illumination saturates the *IS*s for hole injection and extraction, again causing the quenching of the NDR peak. The above observation provides a support to the interface states-facilitated resonant tunneling model proposed in Fig. 2(b), because such states are located in the band gap, and are usually very sensitive to photoexcitations. Note that in Fig. 4(b), light illumination does not affect the remnant field E_r: both of the *JE* curves exhibit the same E_r of 0.2×10^5 V/cm regardless of photon illumination. Therefore, it is clear that photoexcitation quenches the NDR behavior by saturating the interface states, while it does not affect the ionic motion which is a bulk property and is independent of interface electronic configurations.

The above thickness-dependent *JE* behavior is a common phenomenon generally observed for the metal/PEDT:PSS/metal sandwich configurations. In our experiments, we used other metals including Ag, Au, and graphite as electrodes for *IV* measurements, and obtained results

qualitatively similar to those shown in Figs. 2–4. In a control experiment, when one metal electrode is replaced by Si semiconductor (lightly B-doped, 0.1–0.3 S/cm) to form the metal/PEDT:PSS/Si device configuration, the NDR behavior disappears, and the *JE* curve follow the common monotonous dependence. Fig. 5(a) displays the typical *JE* curves collected for an ITO/100 nm PEDT:PSS/Si device. It can be seen that the *JE* curve exhibits rectification behavior that is characteristic of p-n junction formation in the device. When the device was illuminated by 405 nm light, photocurrent is generated especially in the negative ITO voltage region. Similar results were also obtained for 1.0-μm-thick PEDT:PSS films, and the *JE* curves obtained in this case showed no rate-dependence. The observation in Fig. 5(a) is in sharp contrast to that of Figs. 2–4, and indicates that the manifestation of the NDR peak is only associated with PEDT:PSS/metal interfaces. In Fig. 5(b–c), we compare the difference between PEDT:PSS/metal and PEDT:PSS/semiconductor (Si) interfaces. Since both PEDT:PSS and Si have band gaps, their interface is governed by the formation of a depletion layer with a height V_d and a width W_d. For such a p-n junction configuration, charge conduction is usually dominated by thermionic emission [28] over the depletion layer, and the corresponding *JE* curve is rectifying as shown in Fig. 5(a). In addition, the built-in voltage V_d is essential for the transfer for photoexcited carriers from PEDT:PSS to Si, thus leading to the formation of photocurrent under conditions of light illumination (see Fig. 5(a)). In the case of PEDT:PSS/metal interfaces, there is no depletion layer and thus no V_d to help draw photocarriers across the junction, therefore no photocurrent is observed in Fig. 4. Consequently, the photoexcited carriers stay in the interface states of PEDT:PSS, thus causing the quenching of NDR observed in Fig. 4. In Fig. 5(c), the continuous band structure of metal makes the metal → PEDT:PSS charge injection the dominant transport mechanism in the metal/PEDT:PSS/metal device. So the difference in electron and hole injection dynamics, and the presence of interface states which accommodate the injected charges, often work jointly to cause novel *JE* characteristics. Indeed, numerous previous results on the electric peculiarity of PEDT:PSS were also observed in metal/PEDT:PSS/metal device configurations [4,10,11,16]. For example, current peaks were observed for an ITO/40 nm PEDT:PSS/Au sandwich device, and the origin was attributed to the sequential oxidation and reduction (doping and de-doping) of PEDT in the voltage scan [4]. In other works, the faster electron injection rate relative to that of hole injection in a Au/PEDT:PSS/Au device leads to the formation of insulating states, which provides a basis for the operation of erasable read-only memory devices [10,11]. The novel observation of the Madelung potential effect [16] is the latest example of the complex electronic properties of the PEDT:PSS/metal interfaces. In our case, we interpret the NDR behaviors observed in Figs. 2–4 as a consequence of hole injection and resonance tunneling through interface states, and this phenomenon is again mainly associated with the PEDT:PSS/metal charge-injection interface.

It is instructive to discuss the drastic difference in *JE* characteristics between the 100-nm-thick (see Fig. 2) and 1.0-μm-thick (see Fig. 3) PEDT:PSS films. Here, hole resonant tunneling and NDR behavior dominate the charge conduction in the 100-nm-thick film, while ionic motion, remnant voltage formation, and hole extraction are the key features of the *JE* curves observed for the 1.0-μm-thick film. One tentative mechanism for the thickness dependence is related to the phase segregation of PEDT and PSS layers in PEDT:PSS films. There are reports [12–15] showing that hole-conducting PEDT

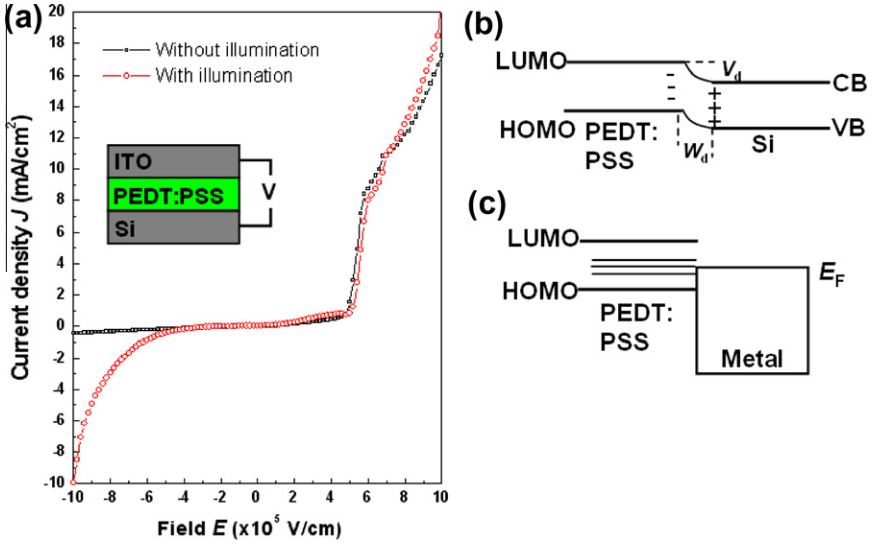

Fig. 5. (a) *JE* curves of an ITO/PEDT:PSS/Si device collected with and without 405 nm light illumination, respectively. The thickness of the PEDT:PSS films is ~100 nm, and the voltage scan rate is 1.0 V/s. Comparison of the different electronic configuration between the PEDT:PSS/Si (b) and PEDT:PSS/metal (c) interfaces.

segments are separated by hole-insulting PSS segments in a layer-by-layer fashion in the PEDT:PSS film. So hole hopping in the vertical direction is hindered by the alternative conducting/insulating layer arrangement, while it is not affected in the lateral direction because the in-plane hole transport can proceed through any of the conducting PEDT layers. On the basis of this, we propose that in the 100-nm-thick film, the degree of phase segregation is low, or the number of segregated layers is small, such that hole transport in the vertical direction is not affected. Therefore, when holes are injected into the interface resonant states, they can tunnel throughout the thickness of the film, thus leading to the observation of NDR peaks shown in Fig. 2(a). When the film thickness increases to 1.0 μm, the phase segregation would also increase, causing the formation of more alternating PEDT and PSS layers in the film. Consequently, holes cannot tunnel throughout the film due to the blockage by the insulting layers. Instead, the injected holes are trapped at the PEDT:PSS/metal interface, and are then extracted from the interface only when the polarity of the electrode voltage changes. At the same time, H^+ cationic motion is not influenced by such phase segregation because ions can move in both PEDT and PSS phases with a high mobility.[8,9] So in the 1.0-μm-thick film, when hole transport is blocked, hole are then trapped at the interface, and the trapping generates a positive potential. This positive potential in turn provides a driving force to facilitate H^+ ionic motion as discussed in Fig. 3b. Therefore, the thickness dependence is associated with the switching from hole-dominated conduction to cation-dominated conduction when the thickness of the PEDT:PSS film is increased.

In conclusion, we have presented some new charge conduction mechanisms based on hole resonant tunneling and ionic motion in PEDT:PSS films. Negative differential resistance peaks, asymmetrical ionic current, and remnant voltage are observed for PEDT:PSS films with different thickness. These distinct *JE* characteristics are an outcome of hole injection/tunneling, hole blockage by phase segregation, and cationic motion and relaxation. Our results highlight the decisive role of PEDT:PSS/metal interface and film thickness in the determination of charge transport mode, and is helpful in clarifying the diverse *JE* characteristics reported in the literature.

$$k(E) = \beta_L \frac{3}{4\pi a^3} e^{-\frac{\Delta E}{kT}} \left(1 + b + \frac{b^2}{3} + \frac{b^3}{18} + \cdots\right) \quad (2)$$

where; $\beta_L = e(\mu_h + \mu_e)/\varepsilon_0\varepsilon$ is the Langevin recombination coefficient, μ_h, μ_e are hole and electron mobilities, respectively, ε is the dielectric constant, ΔE is the coulumbic binding energy of the geminate e–h pair, a is the initial e–h pair separation, $b = \frac{e^3 E}{8\pi\varepsilon_0\varepsilon(kT)^2}$.

Consequently, the photocurrent can be written as:

$$J_{ph}(E) = eG(E)L \quad (3)$$

where $G(E) = G_{\max}P(E)$ is the generation rate of free carriers.

2. Experiment

Sexithiophene photovoltaic cells used here are of the sandwich type in which an organic material is deposited between two metallic contacts with different work functions. Samples were made by evaporating a 150 nm thick -6T onto ITO coated glass followed by vacuum deposition of the top semi-transparent aluminum contact which determines the dimensions and the shape of our pixels (Fig. 1). *I–V* characterization of sandwich cells both in the dark and under illumination were performed using a HP 4140 pico-Amperemeter/DC voltage source. Samples were illuminated by a halogen–tungsten lamp.

In transient measurements we used a N_2 laser pulse of short duration (0.4 ns) at 337 nm delivering an energy of 10 μJ which corresponds to 2×10^{13} incident photons per incident pulse. The sample was illuminated through the Al side as shown in Fig. 1. The photocurrent was measured with a Tektronik TDS 620 Fast Oscilloscope.

3. Results and discussion

3.1. I–V characterization

Electric characterization of ITO/6T/Al samples showed a diode-like behavior with an on/off ratio of 10^3. Current versus voltage bias results in an asymmetric curve as shown in Fig. 2.

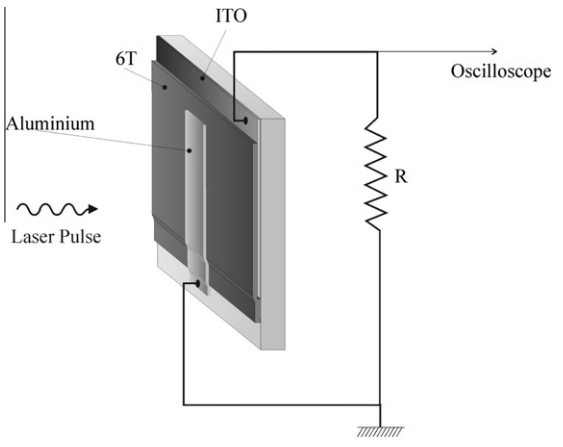

Fig. 1. Experimental setup for transient measurements.

This behavior is usually accounted for either by a classical Schottky-type contact between organic layer and the top aluminum electrode or by a Metal–Insulator–Metal (MIM) structure with the metal electrodes are of different work functions. The latter type is the most probable in organic materials because both low thickness (typically few hundreds of nanometers) and carrier density (in the range of 10^{-17} cm^{-3}) contribute to the so-called rigid band diagram which best describes the optoelectronic properties of sandwich-type organic diodes. In this approximation we assume that the intrinsic electric field is uniform over the organic active layer and its magnitude is proportional to work function difference of the two electrodes. Photovoltaic behavior of ITO/6T/Al is perceptible by comparison of both *I–V* curves in dark and under white light illumination. In the first case short circuit current is nearly 10^3 times lower than in the latter case. However in the region between 0 and V_{OC} the curve is far from the ideal case as can be seen in Fig. 2. Originally this behavior used to be accounted for by strong contact resistance which is known to be responsible for poor photovoltaic conversion efficiency, but this does not account for the inversed curvature of the *I–V* characteristic in the region 0–V_{OC}. To account for this behavior we plotted the effective photocurrent versus effective potential lying in the layer.

The effective electric field in the bulk results from the algebraic sum of the built-in field E_{bi} and the applied field E_a, hence the effective potential lying in the bulk is the difference between the applied voltage (V) and the built-in potential (V_{bi}). Fig. 3 shows effective photocurrent density ($J_{ph} = J_d - J_l$) obtained by subtracting the dark current (J_d) from recorded current under illumination (J_l) versus effective potential. In the case of pristine crystalline materials, which is our case, we assume that initial separation of the e–h pair a is constant, in contrast with polymers where one should consider a spatial distribution of separation distances [9].

Experimental data is fitted according to Eq. (3) for an initial electron–hole pair separation $a = 0.5$ nm and $\beta_L = 1.35 \times 10^{-5}$ cm^3 s^{-1} assuming an average mobility of 1.5×10^{-6} cm^2 V^{-1} s^{-1} and a dielectric constant $\varepsilon = 2$.

In sexithiophene the distance between two nearest neighbor molecules is 0.5 nm which is equal to the initial e–h pair separation. This would suggest that the CT exciton which is the precursor of the free carriers [7], lies between two neighboring molecules.

3.2. Transient measurements

Time-resolved response of ITO/6T/Al cell is shown in Fig. 4. The inset shows that photocurrent can not be fitted by a simple exponential decay, which indicates that the photocurrent is neither a trap controlled process nor a phonon-assisted one as is the case in Schottky-type porous silicon cells [10]. In turn this would suggest a different kinetic flow of free carriers.

Fig. 5 shows the absorption spectrum of the 150 nm thick film deposited on quartz. The absorption coefficient

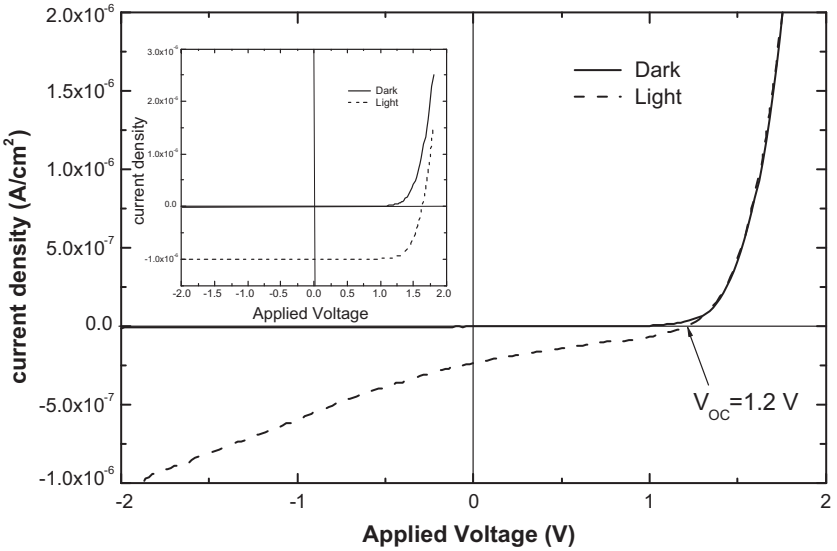

Fig. 2. Current versus applied voltage of ITO/6T/Al in dark and under illumination. The inset shows an ideal case according to which photocurrent is field independent.

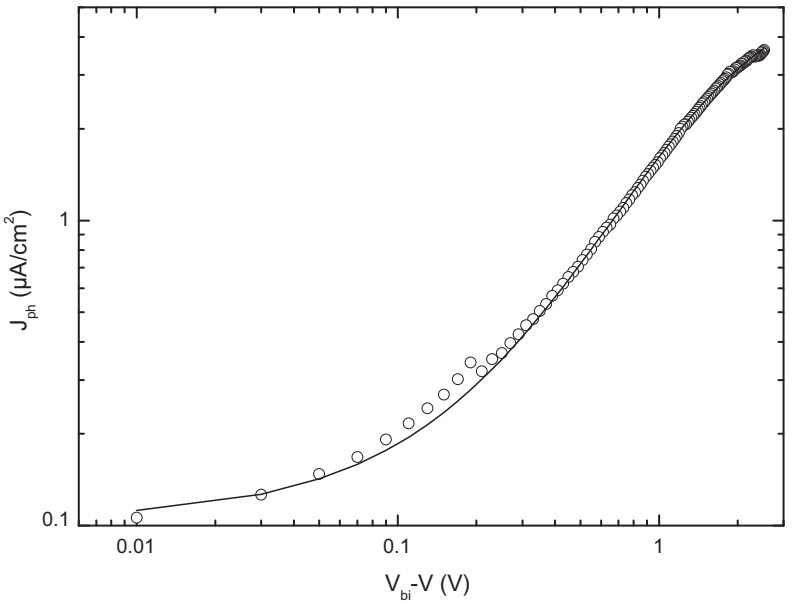

Fig. 3. Effective photocurrent versus effective potential. Experimental data (○) is well fitted (–) according to Eq. (3).

corresponding to the laser excitation wavelength is 10,421 cm^{-1}. Consequently, the penetration depth being assumed to the distance at which the incident light intensity is divided by e is about 900 nm which is by far greater than the thickness of the sample. Therefore one can assume to a very good approximation that the exciting laser pulse is absorbed within the whole sample thickness. This would suggest that photogenerated charge carriers arise from the bulk.

Transient photoconductivity in 6T single crystals revealed a bimolecular recombination process [11,12] which is described by the following equation.

$$\frac{\partial n_{ph}}{\partial t} = G - \beta n_{ph}^2 - \frac{n_{ph}}{\tau} \quad (4)$$

where β is the bimolecular recombination rate and τ is the charge carrier's lifetime. Comparing the scale over which we observe photocurrent decay (tens of microseconds) to pulse width (0.4 ns) one can reasonably make the assumption that carrier flow starts after the generation process is over. Consequently within this approximation we may consider $G = 0$ in Eq. (4)

$$\frac{\partial n_{ph}}{\partial t} = -\beta n_{ph}^2 - \frac{n_{ph}}{\tau} \quad (5)$$

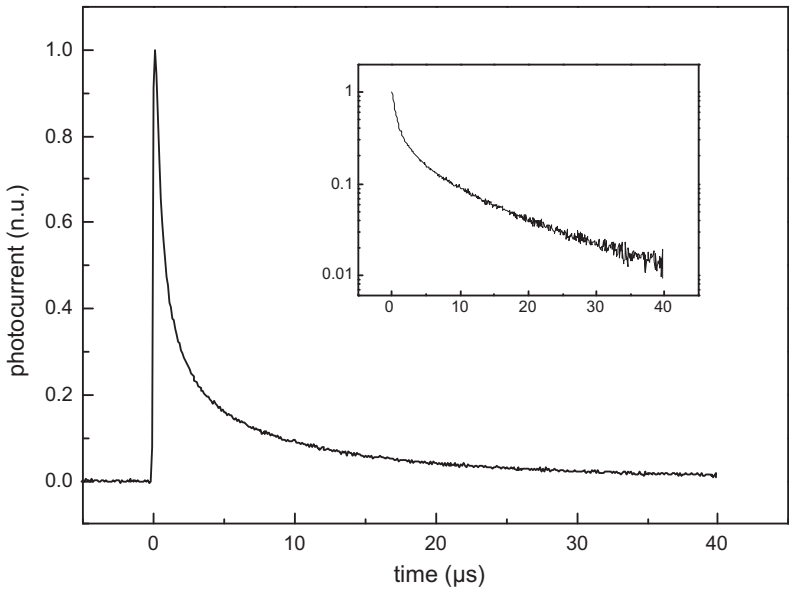

Fig. 4. Transient response of ITO/6T/Al cell illuminated by a 0.4 ns–370 nm laser pulse. The inset shows *y*-log scale of photocurrent decay.

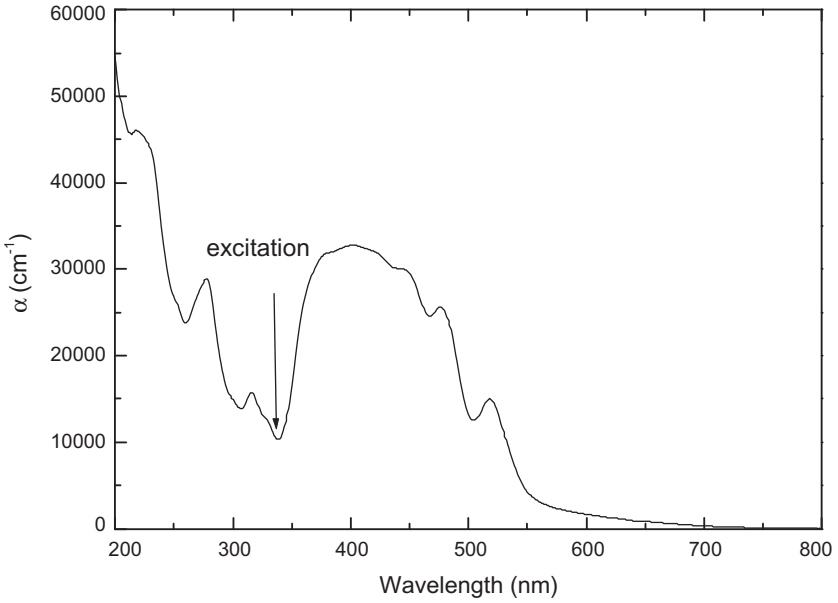

Fig. 5. Absorption spectrum of 6T(150 nm) deposited on quartz. The arow shows the excitation wavelength.

Eq. (5) is a Bernoulli-type differential equation the solution of which can be written as follows:

$$n_{\mathrm{ph}}(\mathrm{t}) = \frac{1}{\mathrm{A}\ \exp(\frac{\mathrm{t}}{\tau}) - B} \tag{6}$$

where: $A = \frac{1}{n_0} + \beta\tau$ and $B = -\beta\tau$, n_0 is the carrier density generated at $t = 0$. The transient photocurrent is directly proportional to carrier density $n(t)$ and may be fitted by this equation assuming that intrinsic electric field and mobility do not vary in time. Assuming that the built-in electric field E_{bi} is constant during carriers transit, transient photocurrent and photogenerated carrier density can be related by the following equation:

$$j_{ph}(t) = n_{ph}(t)\, e\, \mu_T\, E_{bi} \tag{7}$$

And rearranging gives:

$$n_{ph}(t) = \frac{j_{ph}(t)}{e\, \mu_T\, E_{bi}} \tag{8}$$

Fig. 6 shows a *y*-log-scale fit of transient photocurrent with a carrier lifetime $\tau = 30$ μs and a bimolecular rate constant β of 8.7×10^{-7} cm^3 s^{-1}. Assuming mobility of carriers

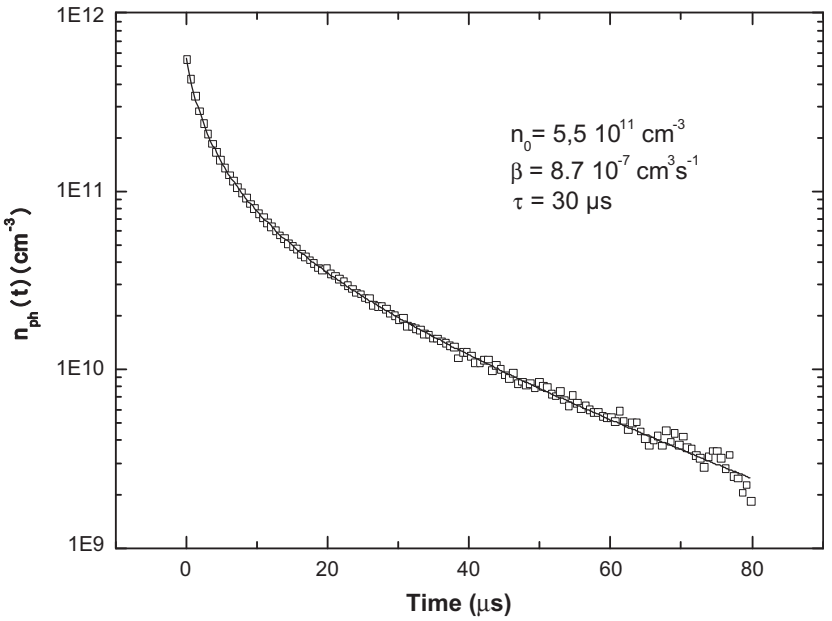

Fig. 6. *y*-Log scale fit of the density of photogenerated carriers decay using Eq. (6). The bimolecular model fits perfectly experimental results.

in polycrystalline sexithiophene thin films of 1.5×10^{-6} $cm^2\,V^{-1}\,s^{-1}$ [13] and static dielectric constant of 2 one can estimate the Langevin recombination coefficient $\beta_L = 1.35 \times 10^{-5}\ cm^3\,s^{-1}$.

According to Pivrikas et al. [14] the necessary condition to achieve conversion efficiency worthy of a solar cell is the inequality: $\mu\frac{\beta_L}{\beta} > 5 \times 10^{-3}\ cm^2\,V^{-1}\,s^{-1}$ where μ is the mobility of free carriers. In our case this condition is not fulfilled since: $\mu\frac{\beta_L}{\beta} \approx 2.25 \times 10^{-9} \ll 5 \times 10^{-3}\ cm^2\,V^{-1}\,s^{-1}$

The charge carrier transit time t_{tr} is related to the mobility by the following equation

$$t_{tr} = \frac{d}{\mu E}$$

The built-in electric field is related to the sample thickness by $E = \frac{\Delta\varphi}{d}$ where $\Delta\varphi = \varphi_{Al} - \varphi_{ITO} \approx 0.6$ eV φ_{Al} and φ_{ITO} being respectively the Aluminum and ITO work functions; $d = 1.5 \times 10^{-5}$ cm is the sample thickness and $\mu = 1.5 \times 10^{-6}\ cm^2\,V^{-1}\,s^{-1}$ is the charge carrier mobility, that is:

$$t_{tr} = \frac{d^2}{\mu\Delta\varphi} \approx 2.5 \times 10^{-4}\ s.$$

It turns out that only a small fraction of photogenerated carriers that can reach the electrodes contribute to the photocurrent so those carriers should not be located far from the electrodes than a distance d_0 which is deduced by equating the transit time t_{tr} to the lifetime τ that is

$$d_0 = \sqrt{\mu\tau\Delta\varphi} = 5\ nm.$$

4. Conclusions

The unsatisfactory performance of organic photovoltaic cells can be accounted for by two main factors. The first is attributed to the nature of photogenerated excitons that is the strong biding energy which prevents an efficient creation of free carriers in the bulk. This behavior is interpreted in terms of Braun–Onsager theory according to which the dissociation of geminate photocreated tightly bound pairs occurs with a quasi-vanishing probability. In the case of polycrystalline sexithiophene thin films the initial separation of geminate pairs is in the order of the nearest neighbor separation distance which is about 0.5 nm. The second is due to the conjunction between the low mobility of free carriers in organic materials and their short lifetime. Indeed the free photogenerated carriers in the bulk i.e. far from electrodes do not have enough time to reach the contacts and contribute to photocurrent.

synthesized in 1996 have remained unchanged over time [12,13]. PDPV, whose chemical structure is reported in Fig. 1, consists of a poly(para-biphenylene vinylene) chain where the hydrogen atoms on the vinylene double-bond are substituted with phenyl rings. This chemical modification has been shown to increase the photostability of this polymer, slowing down the photo-oxidative degradation processes [14]. Other interesting chemical and photophysical properties result from the replacement of the vinylene hydrogens by phenyls, such as solubility in a range of common organic solvents, relatively high solid-state PL quantum efficiency (~60%) due to increased conformational entropy in the solid state that reduces π–π interactions and consequent detrimental aggregation [15,16]. Importantly, a large Stokes' shift (~1.14 eV) between the absorption and the emission band is observed in this compound, due to conformational relaxation in the excited state of the substituted vinylene unit allowed in this glassy polymer [15,17]. This particular feature has been recently applied for the production of white-emitting LEDs based on non-resonant polymer blends [18].

In the following, we report the optical properties of solid films and LEDs incorporating an active layer of PDPV, fabricated with a similar batch of PDPV to the one that was used in similar studies published immediately following the synthesis in 1996 [12]. The synthesis of PVPD was reported in 1983 [19]. Subsequently it was shown that this sample has a 50:50 distribution of *cis* and *trans* vinylenes and can be regarded as a polymeric derivative of tetraphenylethene, it has a disordered structure and the phenyl units are twisted with respect to the planes of the vinylenes [15]. The use of this sample allows a direct comparison of the photophysical and EL properties of PDPV. We present CW and time-resolved PL along with EL and current–voltage–luminance (IVL) response of LEDs whose characteristics are comparable to those reported for a similar batch of PDPV 13 years ago.

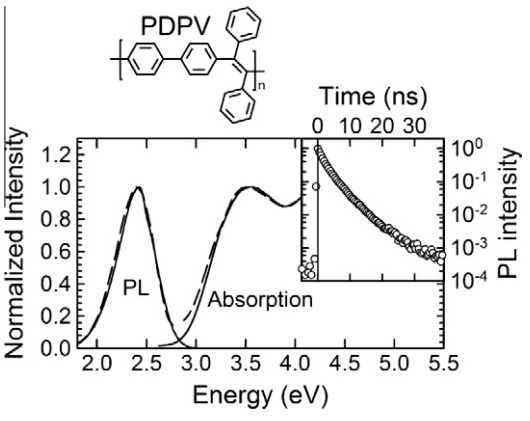

Fig. 1. Top: Chemical structure of poly(4,4'-diphenylene diphenylvinylene); Bottom panel: optical absorption and PL spectrum of a spin cast film of PDPV on fused silica (solid line). The absorption and PL spectra for solid films of a similar batch of PDPV from Cacialli et al. are reported as dashed lines [12]; Inset: PL decay profile at 2.39 eV for a spin cast film of PDPV excited at 3.30 eV.

2. Experimental details

The synthesis of the materials is described in Ref. [19]. The material was stored in powder form, in the dark (inside a glass transparent vial which was in turn kept inside a cardboard container that prevented light from reaching the material), in air, and at room temperature. Optical absorption spectra were obtained using an Agilent 8453 spectrophotometer. CW and time-resolved PL measurements were carried out using a ps-pulsed diode laser (pulse duration = 40 ps, 371 nm) as excitation source and detecting the PL with a photomultiplier coupled to a monochromator and a time-correlated single-photon counting unit (time resolution ~150 ps). The PL efficiency of solid films was measured in a N_2-saturated integrating sphere using the same excitation source. LEDs were fabricated by cleaning ITO covered soda-lime glass in acetone, isopropanol and sequentially in O_2-plasma [20,21], followed by spin coating of the hole-injecting layer poly(3,4-ethylenedioxythiophene):poly(styrenesulfonic acid) (PEDOT:PSS) and PDPV. The cathode consisted of 50 nm Ca capped with 150 nm of Al. A Keithley 2400 sourcemeter was used to apply the voltage and measure the current, while a calibrated Si photodiode, coupled to a Keithley 2000 multimeter through a preamplifier, measured the light output. The electroluminescence (EL) spectra were obtained by an Andor Shamrock spectrograph coupled with an Andor Newton CCD unit cooled to −50 °C.

3. Results and discussion

In Fig. 1, we present the optical absorption and PL spectrum for solid films of PDPV on spectrosil (solid curves). The characteristic Stokes' shift of about 1.15 eV can be observed between the first absorption band (3.44 eV) and the PL spectrum (centred at 2.39 eV). Our data coincide with the results reported in 1996 (dashed lines) [12]. In both cases, the PL spectrum is featureless and shows a full width at half-maximum of about 0.5 eV due to structural disorder in solid PDPV films [13]. The shape of the room temperature PL spectrum does not show vibronic structure, and appears to be essentially featureless, suggesting that decay is not mono-molecular in nature. In fact, we find that the PL decay (excited at 3.30 eV, and collected at 2.39 eV) of PDPV films follows a multi-exponential kinetics, with an effective lifetime of 2.2 ns (as defined from the time at which the PL intensity decays by a factor $1/e$) [22]. The PL efficiency is measured to be 60 ± 6% [23], which is in essential agreement, or even slightly better than previously reported [12].

Fig. 2a shows the current–voltage–luminance (IVL) characteristics of PEDOT:PSS/PDPV/Ca LEDs. Luminous turn-on (defined at 0.01 cd/m^2) occurs at 5.1 V (although the characteristics only deviate from zero at ~6 V on a linear-scale plot) and a luminance above 800 cd/m^2 is achieved at 10 V. This is a significant improvement compared to the operating voltage of 30 V or so that was required to obtain a similar luminance for the multilayer devices reported in 1996 [12]. We relate this increase in light output to improved LED design, in particular to better

hole-injection by the PEDOT:PSS hole-injection layer, and to the absence of an intermediate polyvinylcarbazole (PVK) film, as already noted in reference [24].

The inset of Fig. 2a shows the EL spectrum of our LEDs and that of the ITO/PPV/PVK/PDPV/Ca LED from Ref. [12]. We find that the shape of the EL does not change over the range of voltage investigated, i.e. 5–15 V. In addition, there is again a lack of vibronic structure that is entirely analogous to what observed for the PL. A similar shape is observed for the low energy portion of the emission between the two spectra, with only a very minor blue shift, which we consider is due to differences in the device architecture and the expected influence of interference effects. Note, in fact, that the present structures do not include the PPV and PVK layers (and related refractive indices mismatch), as in the "1996 LEDs". This has implications for both the partial reflections and subsequent constructive/destructive interference of the light generated within the active layer, as well as for the location of the recombination region as a function of the distance from the electrodes, and again on the particular nature of the ensuing interference effects [25].

The more significant difference in the blue tail of the spectra in the "1996 LEDs" is due to re-absorption of the emitted photons by the PPV hole-injection layer in those devices [12].

The external quantum efficiency (EQE) as a function of the current density is reported in Fig. 2b for our devices.

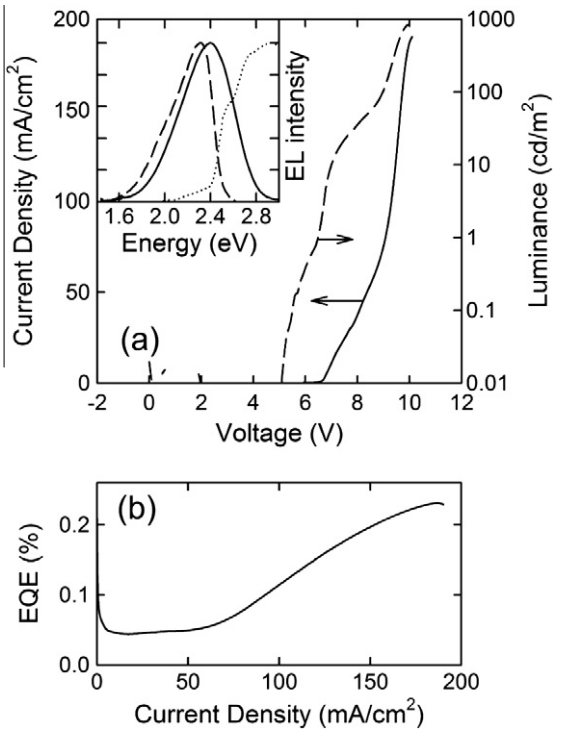

Fig. 2. (a) Current density (solid line) and luminance (dashed line) as a function of voltage for a PEDOT:PSS/PDPV/Ca LED. Inset: EL spectrum for the same device (solid line), and the extracted EL spectrum for the ITO/PPV/PVK/PDPV/Ca LED (dashed line) reported by Cacialli et al. [12]; (b) External quantum efficiency (EQE) as a function of current density corresponding to the electrical response in (a).

A maximum EQE of 0.23% is obtained for the PEDOT:PSS/PDPV/Ca. This agrees remarkably well with the maximum internal quantum efficiency (IQE) of 1.2% reported in 1996 [12], which had been calculated according to the formula IQE = $2 \times n^2 \times$ EQE, with $n = 1.5$ [26–28].

4. Conclusions

In summary, we have shown that the optical and electroluminescence properties of a polyphenylene vinylene derivative (PDPV) are stable over a period of time of at least one decade. As a result, we are able to produce LEDs with similar efficiencies to those reported soon after the synthesis of the polymer, but with higher light output and lowered turn-on voltage due to improved LED design. We conclude that lack of saturated aliphatic C–H bonds adjacent to either an aromatic ring or an ether oxygen, that are notoriously susceptible to oxidation, in addition to storage in dark, to avoid both photo-doping and photo-oxidation effects [29], offer effective protection against degradation.

[23] This value of PL efficiency is higher than previously reported (45 ± 5%). However, the discrepancy is only 4%, once the error bars are considered, and is well within the scatter that is generally observed between different batches of the same material. This may depend, for example on a different cis–trans ratio (not precisely controlled in this material), which has a significant influence, as demonstrated for a similar, although different material [15]. We also note that the results are not entirely comparable since a different laser source was used here.

improving the power conversion efficiency for small laboratory cells [19–21] through optimization of materials and the protocol used for preparation.

Titanium dioxide has been extensively employed as photoresponse material [22]. Particularly, TiO_2 in the form of nanotube is expected to have some improved properties for photoresponse applications compared with colloidal or other forms of titania [23,24]. Titania nanotubes (TiO_2NTs) have been extensively investigated due to their distinguishing feature of one-dimension nanostructure nature for applications in the areas of photocatalysis and solar cells [25]. Some efforts have been paid to modify TiO_2 nanotubes or explore new TiO_2 nanotubes-based systems [26–29]. One of the promising approaches is based on the association of TiO_2 nanotubes with other semiconductors. These nanocomposites can provide strong coupling effects, which are distinctive from the primary nanomaterials [30]. The obtained materials with heterostructure exhibit improved physical and chemical properties over their single-component counterparts [31].

There were many literature about solar cells based on hybrid of polymers and inorganic [32–37]. However, there is little report about nanocomposites based on polythiophene and TiO_2 nanotubes.

In this paper, amorphous titania nanotubes with diameters between 20 and 30 nm were successfully synthesized by hydrothermal method. Poly(3-octylthiophene) and titania nanotubes were combined to form a new organic/inorganic material by situ-chemical method. Chemical interaction in the material was found by X-ray photoelectron spectroscopy, infrared spectrum and X-ray diffraction. Results from UV–vis spectra, fluorescence spectra and cyclic voltammetry curves indicate that P3OT/TiO_2NTs nanocomposite is a new kind of p-n type promising material with excellent performance in photoelectric applications. Solar cell was sensitized by P3OT/TiO_2NTs. A solar-to-electric energy conversion efficiency of 0.593% was attained with the system.

2. Experiments details

2.1. Synthesis of poly(3-octylthiophene)/titania nanotubes composite

2.1.1. Preparation of titania nanotubes by hydrothermal method

TiO_2 nanotubes were prepared by hydrothermal method. 6 g TiO_2 as precursor was added to 10 M NaOH, stirring vigorously at ambient temperature for 24 h. The suspension liquid was further transferred into the stainless steel reactor with Teflon substrate. The reactor was placed in the oven at 120 °C. After maintaining for 72 h, the solution was filtered by centrifugation and washed to neutral. The alcogel was added to 0.1 M hydrochloric acid, stirring vigorously at ambient temperature for 5 h. The solution was filtered by centrifugation and washed to neutral. The water in the sol was replaced by absolute ethanol. The alcogel obtained was transferred into a crucible and dried at room temperature. The powders of TiO_2 nanotubes were finally prepared.

2.1.2. Synthesis of poly(3-octylthiophene)

The conducting poly(3-octylthiophene) was synthesized with Fe(III) as catalyst according to Ref. [38].

2.1.3. Synthesis of poly(3-octylthiophene)/titania nanotubes composite

8 ml chloroform, 0.2 g 3-octylthiophene, 0.2 g TiO_2NTs prepared above were added into 100 ml flask, ultrasonic dispersing for about 15 min. Some amount of $FeCl_3$ was dissolved in chloroform, and then gradually dropped into the system. After above dropping, the system reacted stirring with the protection of high-purity nitrogen for 3 h at 0 °C. Product was slowly added into methanol followed by a settlement and filtration. Then they were washed by methanol in a soxhlet extraction for 20 h. P3OT/TiO_2NTs nanocomposite powder was finally prepared by vacuum drying at room temperature.

Dissolve 0.01 g P3OT/TiO_2NTs in 2 ml isopropyl alcohol, drop the liquid obtained above evenly on a clean quartz glass and ITO conductive glass. Then red-brown P3OT/TiO_2NTs nanocomposite films were prepared by vacuum drying method.

2.1.4. Solar cell sensitized by P3OT/TiO_2NTs

The solar cell was prepared according to Ref. [39]. Dissolve 0.01 g TiO_2NTs in 2 ml ethanol, drop the liquid obtained above evenly on a clean FTO substrate, meanwhile suffered spinning by a uniform plastic machine at the rate of 3000 r/min for 20 s. After drying at room temperature, the anode was sensitized by P3OT P3OT/Precursor and P3OT/TiO_2NTs isopropyl alcohol solution, respectively. H_2PtCl_6 was evenly dropped on another FTO substrate, calcining at 380 °C for 30 min to prepare Pt electrode, which packaged with the sensitized anode. And then inject electrolyte and seal. The sensitized solar cells were finally prepared.

2.2. Measurements

Transmission electron microscope (TEM) and scanning electron microscope (SEM) measurements were performed on a HITACHI-800. X-ray diffraction (XRD) measurements were performed using a Shimadzu HR6000X (Cu target X tube, voltage 40.0 kV, current 30.0 mA). Infrared spectra (IR) were recorded by a prestige-21IR spectrophotometer with KBr pellet. X-ray photoelectron spectroscopy (XPS) analyses were conducted by ESCALAB 250, testing the electronic binding energy of the samples. UV–vis spectra were measured using Hitachi U-3010 spectrophotometer. The Fluorescence spectra were measured by Hitachi F-7000 spectroluorophotometer at room temperature. Cyclic voltammetry measurements were carried out with the Potentiostiostat/Galvanostat (EG&G PAR Model 283). The counter electrode was platinum and the reference electrode was non-aqueous Ag/Ag^+. The CV curves were record in acetonitrile with 0.1 M $LiClO_4$ at a scan rate of 50 mV/s. Before using, the solution was insufflated with N_2 for 30 min. Current–voltage (I–V) measurements were taken in air at room temperature (298 K) using a Keithley 236 high current source power meter under white-light illumination from a 500 W xenon lamp. The light intensity was

about 100 mW/cm^2 on the sample surfaces measured by a photodetector. To measure the decay, the short-circuit current (J_{SC}) and open-circuit voltage (V_{OC}) as a function of the illumination time were recorded.

3. Results and discussion

3.1. TEM and SEM measurements of TiO_2NTs

Fig. 1(a) and (b) demonstrated TEM and SEM results of TiO_2NTs separately. The capillary tubes can be seen from the Fig. 1(a) clearly. It proved that both open ends titania nanotubes with internal diameters between 25 and 30 nm and tube wall thickness of 5–8 nm were successfully synthesized. The straight tubes with complete morphology and external diameter 30–40 nm can be seen from the Fig. 1(b) clearly. In addition, the titania nanotubes have excellent crystal form and a high conversion rate. Layered structure can be seen clearly from the end of the nanotubes by zooming in multiples of electron microscopy. The results suggested that the synthesis of titania nanotubes was controlled by "curl" reaction mechanism [40], that is, the precursor curl for multi-walled nanotubes under high-temperature and alkaline hydrothermal conditions.

3.2. XRD Characterization of TiO_2NTs

The XRD patterns for the precursor TiO_2 and TiO_2NTs are shown in Fig. 2. In XRD patterns of precursor TiO_2 particles, the peaks at 25.40°, 37.92°, 48.12°, 53.96°, 55.16°, 62.72°, 68.80°, 70.36° and 75.08° are assigned to the (101), (004), (200), (105), (106), (213), (116), (107) and (215) lattice planes, which are attributed to the signals of the anatase phase. It can be calculated that the average TiO_2 particle is 41 nm by Scherrer formula. After concentrated alkali treatment, the lower diffraction peak intensities of product indicated that the crystallinity decreased. X-ray diffraction patterns of TiO_2NTs have also changed. There are no obvious diffraction peaks of TiO_2 except for Ti-based diffraction peaks (24.32° and 48.44°). This indicated that the TiO_2NTs are amorphous TiO_2. The strong diffraction peak in the 9.6° (<10°) is characteristic peaks of pore structure. (200) lattice plane indicated that the layer spacing of TiO_2NTs is 4.19 nm. TiO_2NTs are multi-layer tube, each single-layer equivalent to the "one-TiO_2 molecular layer" thickness, a lattice structure of the three-dimensional extension cannot form between layers, so TiO_2NTs are amorphous. In the hydrothermal process and under the high-temperature, high pressure and alkalic condition, TiO_2 particles were peeled off into thin slices along the (010) crystal face. TiO_2 particles of the smaller size are greatly influenced by environmental. The original surface of anatase crystal structure subject to relatively large extent of the damage. The ordered state between crystal particles suffer from damage, the amorphous structure of TiO_2NTs is formed.

3.3. IR results of TiO_2NTs

The IR spectra for the precursor TiO_2 and TiO_2NTs are shown in Fig. 3. The peak at about 3410 cm^{-1} belongs to the stretching vibration of –OH groups in water, which is physically adsorbed on the surface of TiO_2. The bending vibration occurs at 1636 cm^{-1}. The weak peak at about 1500 cm^{-1}corresponds to Ti–OH characteristic absorption. In the IR spectra for the precursor TiO_2, there is the characteristic absorption band of Ti–O–Ti in the 440–780 cm^{-1} region [41]. It is wide and flat. But for TiO_2NTs, the vibration band at about 666.2 cm^{-1} becomes acromion and the vibration band at about 496.5 cm^{-1} becomes sharp visibly. This implies that the Ti–O vibrational frequencies become smaller after the formation of tube and Ti–O bond length changes in a certain extent. In addition, the fine structure disappears and the band becomes broad after the formation of tube. This is due to quantum size effect and surface effect of nano-particles. This shows that the shape size of TiO_2NTs is smaller.

3.4. XPS Characterization of TiO_2NTs

Fig. 4a–e is the high-resolution XPS of the precursor TiO_2 and TiO_2NTs.

In the TiO_2NTs sample (Fig. 4a), the XPS shows Ti, C and O. The impurities, Na and Cl were not evident in the sample. The electronic binding energy of the Ti2p in the

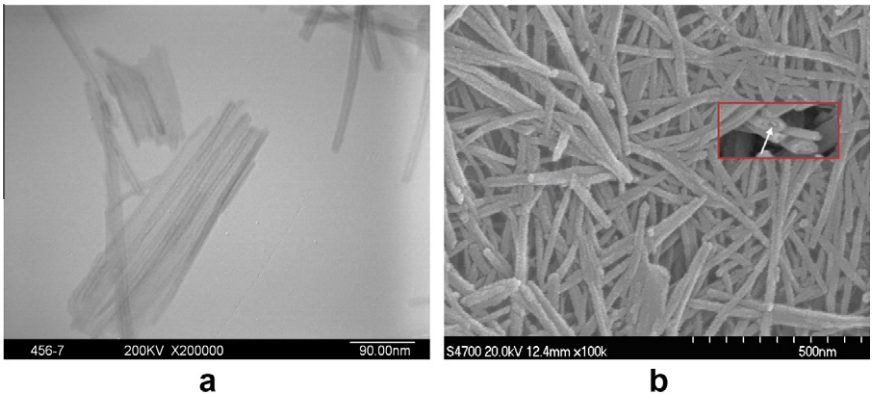

Fig. 1. (a) TEM patterns of TiO_2NTs. (b) SEM patterns of TiO_2NTs.

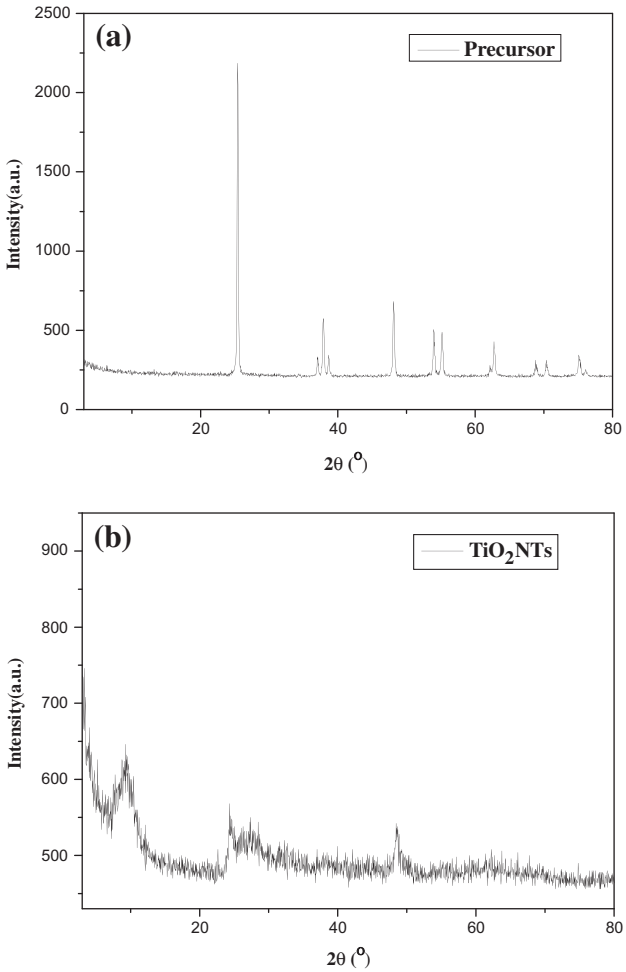

Fig. 2. XRD patterns of Precursor and TiO_2NTs.

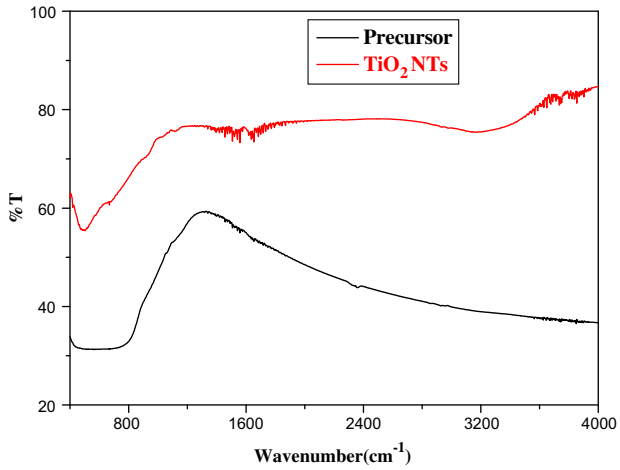

Fig. 3. FT-IR spectra of Precursor and TiO_2NTs.

precursor TiO_2 is consistent with the data found in Ref. [42]. It is seen that Ti in TiO_2 is mainly tetravalent in Ti–O. Fig. 4b shows the narrow scans for Ti2p peaks located at 464.45 eV (Ti $2p_{1/2}$) and 458.71 eV (Ti $2p_{3/2}$) of the TiO_2NTs. Compared to precursor TiO_2, a low binding energy-shift has taken place. This indicates that the

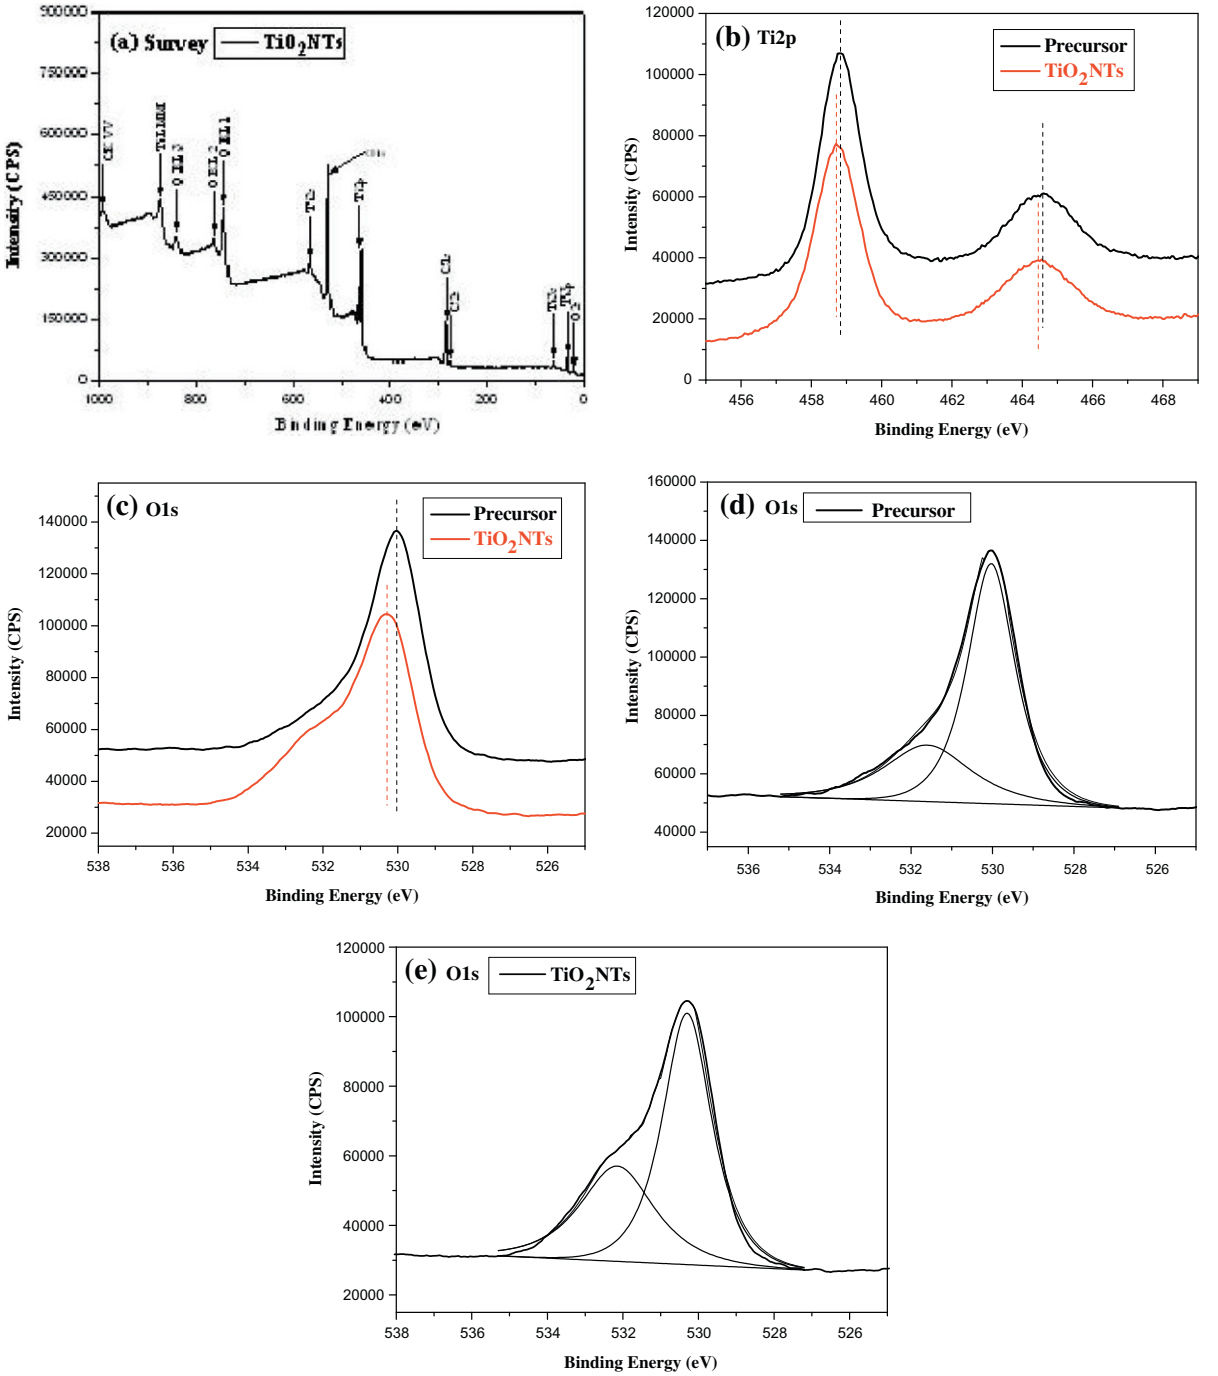

Fig. 4. XPS spectra of Precursor and TiO_2NTs.

chemical environment around Ti atom changes after formation of the tube. The electronic binding energy of the O1s in the precursor TiO_2 is consistent with the data found in Ref. [42]. It is seen that O in TiO_2 is mainly negative bivalent in Ti–O. Fig. 4c shows the narrow scans for O1s peaks located at 530.30 eV of the TiO_2NTs. Compared to precursor TiO_2, a high binding energy-shift has taken place. This indicates that the chemical environment around O atom changes after formation of the tube.

Two oxygen peaks at 531.60 eV and 530.03 eV were found in the spectra of precursor TiO_2 after curve fitting (see Fig. 4d). The former is attributed to anatase Ti–O of common vertex O, and the latter is attributed to anatase Ti–O of common side O.

Two oxygen peaks at 532.17 eV and 530.30 eV were found in the spectra of TiO_2NTs after curve fitting (see Fig. 4e). The former is attributed to anatase aberrance Ti–O of common vertex O, and the latter is attributed to anatase aberrance Ti–O of common side O. The precursor curls for multi-walled nanotubes under hydrothermal conditions, resulting in the original Ti–O bond distortion and rigider. Therefore, the vibrational frequencies become smaller. The results are basically the same with the IR measurements.

3.5. SEM measurements of P3OT and P3OT/TiO_2NTs

The P3OT and P3OT/TiO_2NTs samples were studied by SEM. The results are summarized in Fig. 5. In Fig. 5, the morphology of (Fig. 5a) P3OT is compared at a magnification of 5000× and the morphology of (Fig. 5b) P3OT/TiO_2NTs is compared at a magnification of 100,000×. As it is clearly visible, the layered structure of the P3OT is well distinguishable from the P3OT/TiO_2NTs where surface inhomogeneity is much more expressed. In Fig. 5b, it can be seen clearly that a majority of TiO_2NTs were linked and coated by the P3OT film compared with scanning electron microscope of TiO_2NTs in Fig. 1b. Due to the extreme thinness of the P3OT shell (approximately 1–2 nm), it is not possible to make it visible in the SEM micrograph. The incomplete covering of the nanotubes could be explained by the fact, that these nanotubes were always agglomerated. Some nanotubes were shielded and could not be covered with P3OT. For the following investigations this small amount of uncovered or partially covered nanotubes had no significant influence on the results.

3.6. XRD characterization of P3OT/TiO_2NTs

The XRD patterns for the P3OT, TiO_2NTs and P3OT/TiO_2NTs nanocomposite are shown in Fig. 6. For the P3OT, the broad peak at 15–28° indicates the presence of an amorphous phase, while the peaks at 5.52°, 5.52°, 9.56°, 13.96° and 24.76° reflect the crystalline structure. The peak at 24.76° is attributed to the interchain distance between the π-stacking oxidized chains. The Bragg equation gives 1.31 nm for this value. Peaks at 5.52°, 9.56° and 13.96° are consistent with the layered structure of POT, which has a dominant first-order reflection at 5.52°. The angle indicates that the lamellar interlayer spacing is

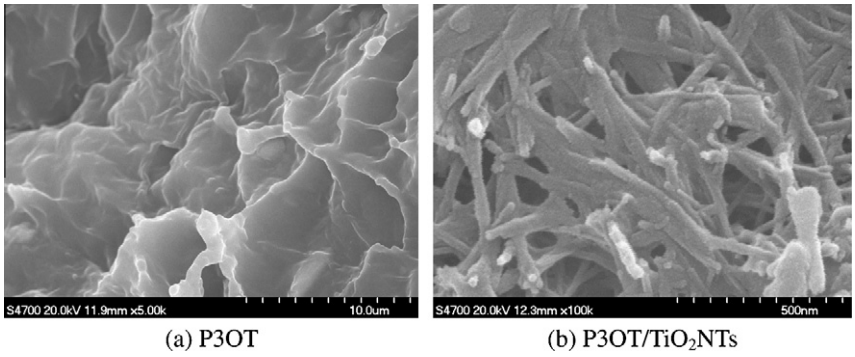

Fig. 5. SEM patterns of P3OT and P3OT/TiO_2NTs nanocomposite.

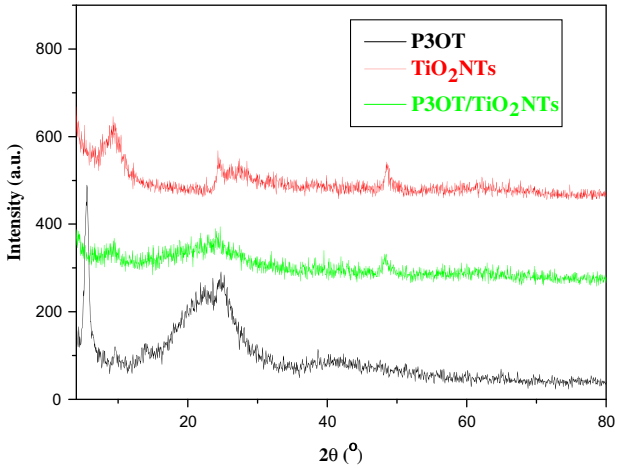

Fig. 6. XRD patterns of P3OT, TiO_2NTs and P3OT/TiO_2NTs nanocomposite.

1.60 nm [43]. The diffraction peak of polythiophene is quite narrow, showing a high degree of crystallization, plane structure and high regularity and orderly manner.

The XRD patterns of TiO_2NTs were discussed in Section 3.2 in detail.

For the P3OT/TiO_2NTs composite, the XRD data mainly show strong peaks of TiO_2NTs. The characteristic P3OT broad peak cannot be seen easily on the XRD patterns of P3OT/TiO_2NTs composite. The XRD patterns of the nanocomposite have higher background intensity, lower diffraction peak intensities, smaller interplaner spacing and reduced sharpness of the peak profiles than TiO_2NTs, which confirm the chemical interaction between P3OT and TiO_2NTs.

3.7. XPS Characterization of P3OT/TiO_2NTs

Fig. 7a–f is the high-resolution XPS spectra of P3OT, TiO_2NTs and P3OT/TiO_2NTs.

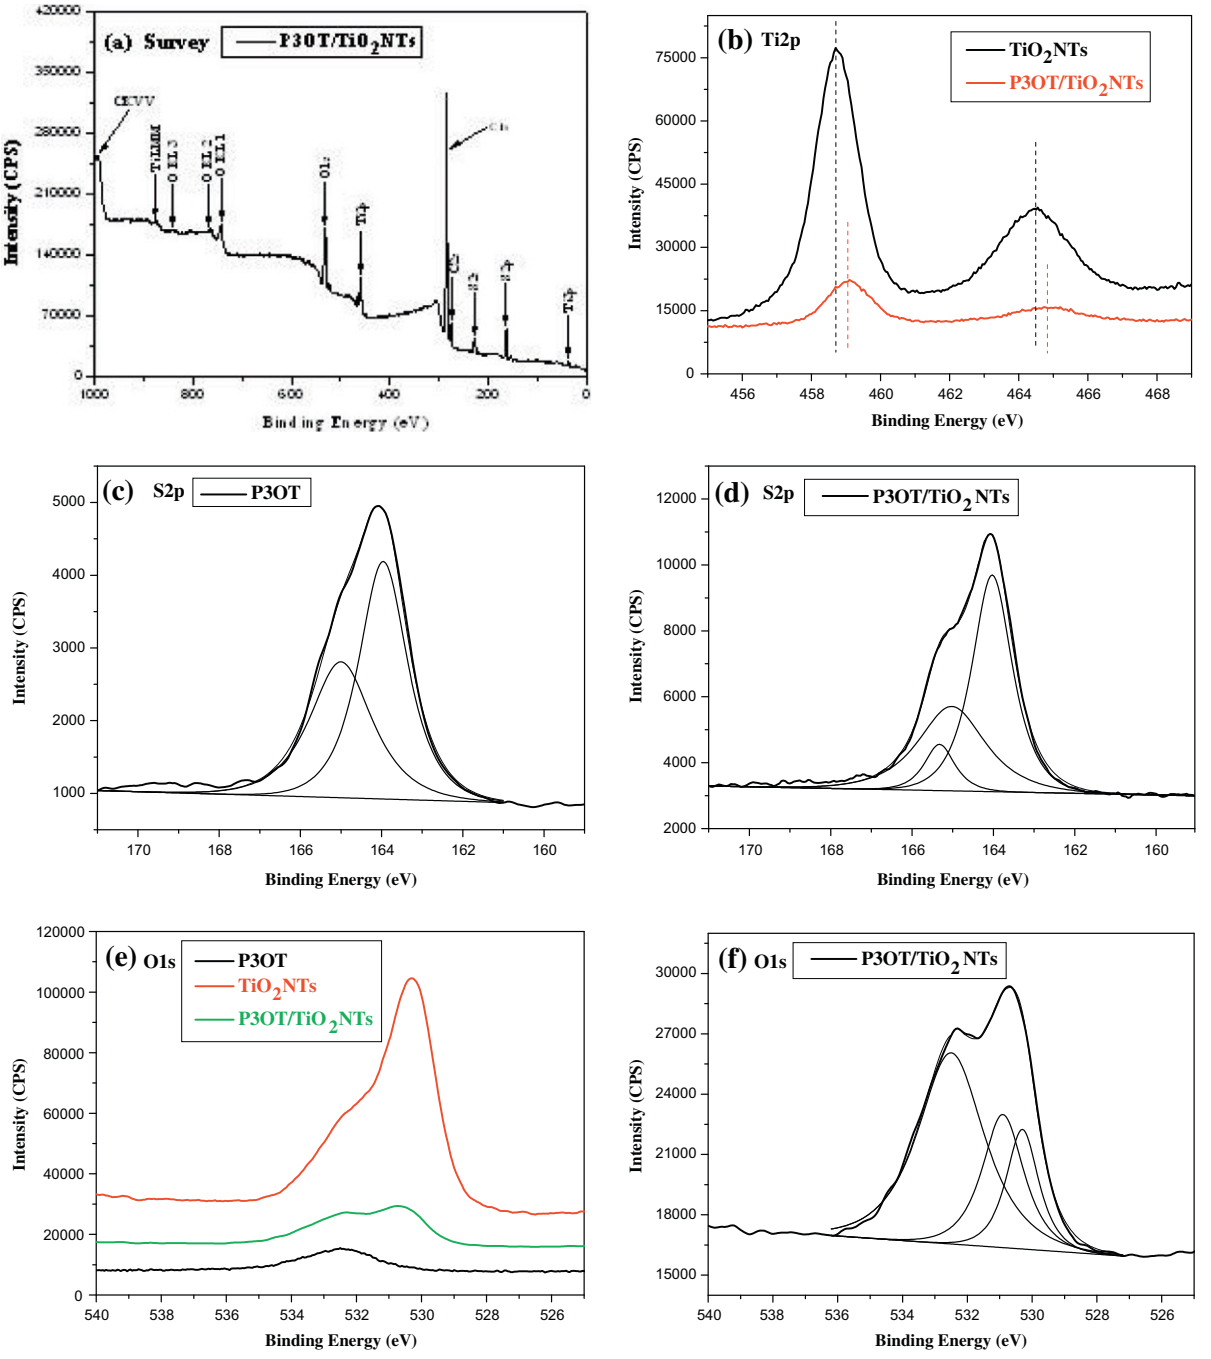

Fig. 7. XPS spectra of P3OT, TiO_2NTs and POT/TiO_2NTs nanocomposite.

In the P3OT/TiO_2NTs sample (Fig. 7a), the XPS shows Ti, O, C and S. The oxidation medium, $FeCl_3$, and the reduced form, $FeCl_2$, were not evident in the composite.

The electronic binding energy of the Ti 2p in TiO_2NTs was discussed in Section 3.4 in details. Fig. 7b shows the narrow scans for Ti2p peaks located at 464.82 eV ($Ti2p_{1/2}$) and 459.06 eV ($Ti2p_{3/2}$) of the P3OT/TiO_2NTs. Compared to TiO_2NTs, high binding energy-shift took place obviously. This indicates that the Ti atom interacted with some other atoms except O after composite reaction.

In Fig. 7c, two sulfur peaks (S2p3/2) were found, one with the binding energy 164 eV for neutral thiophene units in the polymer chain and the other with the binding energy 165 eV for oxidized thiophene units, enlarged binding energy scale between 160 and 170 eV [44,45]. In Fig. 7d, there are there sulfur peaks 164,165 and 165.3 eV in the XPS spectra of P3OT/TiO_2NTs. The peak at 165.3 eV indicates that the S atom interacted with some other atoms except C after composite reaction. In the investigated examples, there are 8.80% of the peak area at 165.3 eV in P3OT/TiO_2NTs, 35.65% of the peak area at 165 eV in P3OT/TiO_2NTs and 34.12% of the peak area in P3OT. This indicates that the S atoms lose their valence electron due to the interaction with some other atom than C on formation of the composite.

Two oxygen peaks at 532.5 eV and 530.3 eV were found in the spectra of P3OT/TiO_2NTs (see Fig. 7e and f). The former is attributed to P3OT, and the latter to TiO_2NTs. A strong peak at 530.9 eV is obtained after curve fitting. The result indicates that O atom will interact with atom(s) other than C and Ti after reaction. It is inferred that there are two chemical interactions in the complex, one between the π-stacking chains of P3OT and the O on the surface of TiO_2NTs and the other between the S of P3OT and the Ti at the surface of TiO_2NTs.

3.8. IR results of P3OT/TiO_2NTs

Fig 8 shows the FT-IR spectra of P3OT, TiO_2NTs and P3OT/TiO_2NTs nanocomposite. Peaks from both TiO_2NTs and P3OT are observed in the spectra of the nanocomposite, but the band originating from P3OT shifts to a lower wave number. For the nanocomposite, a broad band at about 3360 cm^{-1} indicates the presence of –OH groups on the surface of the complex. There is a low-intensity peak at about 2953 cm^{-1}, which may be attributed to the thiophene ring C_β–H stretching vibration. Peaks at 2920 cm^{-1} and 2842 cm^{-1} belong to the C–H of CH_2 or CH_3 symmetric and asymmetric stretching modes. The asymmetric and symmetric deformation vibrations occur at 1311 cm^{-1} and 1453 cm^{-1}. The peak at about 1640 cm^{-1} corresponds to thiophene ring C–S stretching vibration and the peak at about 1505 cm^{-1} corresponds to thiophene ring C = C stretching vibration. The 1135 cm^{-1} band corresponds to the C_α–C_α single resonance absorption. These are the characteristic peaks of P3OT [46]. In addition, there is the characteristic absorption band of Ti–O–Ti at about 470 cm^{-1} in TiO_2NTs, which was discussed in Section 3.3 in detail. It is noteworthy that this broad peak becomes sharper and narrower as the introduction of TiO_2NTs, which correspond to the chemical interaction between P3OT and TiO_2NTs.

3.9. UV–vis spectra of P3OT/TiO_2NTs nanocomposite film

The UV–Vis spectra of P3OT solid film, TiO_2NTs and P3OT/TiO_2NTs nanocomposite films are presented in Fig. 9. It shows the characteristic spectrum of TiO_2NTs ranges from 220 to 360 nm, which is its fundamental absorption of Ti–O bond in TiO_2NTs. The UV–Vis spectrum of P3OT indicates a λ_{max} at 489 nm and corresponds to a π–π* transition, and displays a weak absorption near TiO_2NTs. From the spectrum of P3OT/TiO_2NTs nanocomposite film, it can be seen that there were two absorption bands with maximum wavelength of 271 and 518 nm in ultraviolet region and visible light region, respectively. The band from 220 to 300 nm is assigned to the characteristic absorption of TiO_2NTs and the P3OT adsorption band in the UV light region. The other band is attributed to the electron transition from the valence bond to the antibonding polaron state (π–π* type) of P3OT [47,48]. Compared with the spectrums of TiO_2NTs and P3OT, the P3OT/

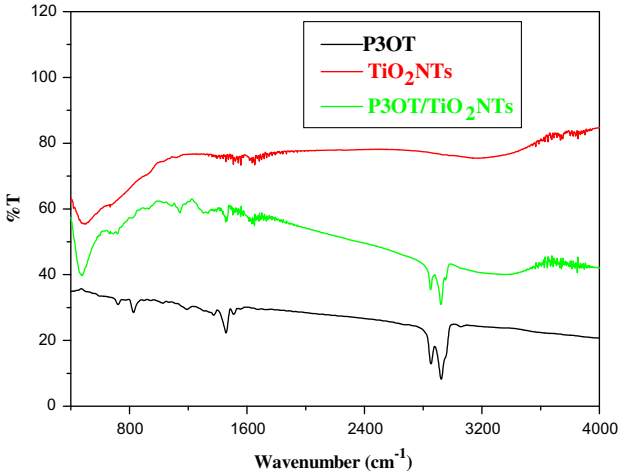

Fig. 8. FT-IR spectra of P3OT, TiO_2NTs and P3OT/TiO_2NTs nanocomposite.

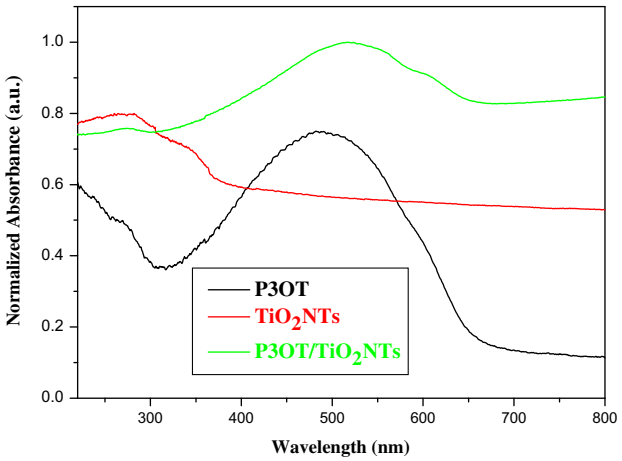

Fig. 9. UV–Vis absorption spectra of P3OT, TiO_2NTs and P3OT/TiO_2NTs nanocomposite.

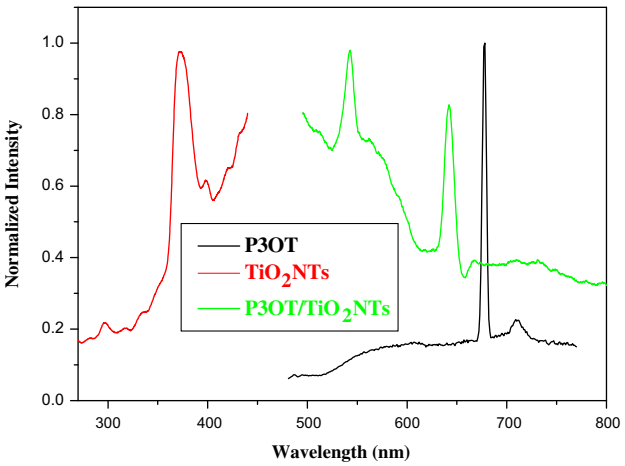

Fig. 10. Luminescence emission spectra of P3OT, TiO_2NTs and P3OT/TiO_2NTs nanocomposite.

TiO_2NTs nanocomposite film absorbs much more UV–Vis light, obviously. The red-shift in visible region and much more absorption of visible light may result from the chemical interaction between P3OT and TiO_2NTs in the composite, which refer in the discussion of XRD, XPS and IR above.

3.10. Fluorescence spectra of P3OT/TiO_2NTs nanocomposite film

The emission spectra of P3OT solid film, TiO_2NTs and P3OT/TiO_2NTs nanocomposite films are shown in Fig. 10. The emission peak of P3OT ranges from 650 to 750 nm with the maximum emission in 677 nm. The emission peaks of TiO_2NTs mainly range from 300 to 400 nm with the maximum emission in 373 nm. The blue-shift appears compared with TiO_2 film [49], which results from quantum size effect of nanotube. The luminescence spectrum of the P3OT/TiO2NTs nanocomposite film is totally different; for example, there are two main emission peaks in visible light region with λ_{em} of 542 nm and 642 nm, respectively. This represents a novel optical property for a new chemical interaction between P3OT and TiO_2NTs. The similar discussion was present in Ref. [39]. The experiment results prove that the P3OT/TiO_2NTs is a new material.

3.11. Cyclic voltammetry

From the CV curves in Fig. 11, the samples' potential can be gained [7]. The frontier orbital and energy gap of P3OT, TiO_2NTs and P3OT/TiO_2NTs nanocomposite are listed in Table 1. The values are in accordance with the literature for P3OT [50] and TiO_2NTs [51]. From the CV curves of P3OT, it is found that its oxidation area (where the potential is higher than zero) is larger than the reduction area (where the potential is lower than zero), and the initial oxidation potential is fairly low compared to TiO_2NTs. The initial oxidation potentials of the P3OT/TiO_2NTs nanocomposite film are lower than each of the components, while the initial reduction potentials of the P3OT/TiO_2NTs nanocomposite film are higher than each of the components. The energy gap of P3OT/TiO_2NTs nanocomposite is only 0.672 eV. The results indicated that P3OT/TiO_2NTs

Φ_{ox} and Φ_{red} potentials (vs 0.01 Ag^+/Ag in CH_3CN) determined by cyclic voltammetry. Calculated according to $Eg = \Phi_{ox} - \Phi_{red}$. *E*HOMO and *E*LUMO from *E*HOMO = $-(\Phi_{ox} + 4.44)$ eV, and *E*LUMO = $-(\Phi_{red} + 4.44)$ eV [52,53].

composite is a new promising p–n type composite material.

3.12. Performance parameters of dye-Sensitized Solar Cells

The photovoltaic performance of the device is shown in Fig 12 and all the parameters of P3OT and P3OT/TiO_2NTs sensitized solar cell are listed in Table 2. Under standard global AM 1.5 G (100 mW/cm^2) solar condition, the P3OT sensitized solar cell gave a short-circuit current (J_{SC}) of 0.350 mA, open-circuit voltage (V_{OC}) of 0.350 V, effective area (Sea) of 0.482 cm^2 and fill factor (FF) of 0.338, corresponding to an overall conversion efficiency (η) of 0.086%; the P3OT/Precursor sensitized solar cell gave a short-circuit current (J_{SC}) of 0.406 mA, open-circuit voltage (V_{OC}) of 0.510 V, effective area (Sea) of 0.375 cm^2 and fill factor (FF) of 0.688, corresponding to an overall conversion efficiency (η) of 0.380%. the P3OT/TiO_2NTs sensitized solar cell gave a short-circuit current (J_{SC}) of 0.543 mA, open-circuit voltage (Voc) of 0.566 V, effective area (Sea) of 0.250 cm^2 and fill factor (FF) of 0.483, corresponding to an overall conversion efficiency (η) of 0.593%. The overall conversion efficiency enhancement of P3OT/TiO_2NTs can be related to the chemistry interaction between P3OT and TiO_2NTs in the composite, which refer to the XPS discussion. In the UV–vis spectra, the P3OT/TiO_2NTs nanocomposite film ab-

Table 2
Performance parameters of dye-sensitized solar cells.

Dye	J_{SC}(mA)	V_{OC}(V)	P_{max}(mW)	FF	Sea(cm^2)	η (%)
P3OT	0.350	0.350	0.0414	0.338	0.482	0.086
P3OT/Precursor	0.406	0.510	0.1425	0.688	0.375	0.380
P3OT/TiO_2NTs	0.543	0.566	0.1483	0.483	0.250	0.593

FF = $P_{max}/(J_{SC} * Voc)$. $\eta(\%) = P_{max} * 100\%/(P * Sea)$. AM 1.5: P = 100 mW/$cm^2$.

sorbs much more visible light, so the incident photon-to-current conversion efficiency was high.

4. Conclusion

Amorphous titania nanotubes with diameters between 20 and 30 nm were successfully synthesized by hydrothermal method using anatase TiO_2 as the precursor and 10 M NaOH as the mine to the agent. A conducting polymer composite, poly(3-octylthiophene)/titania nanotubes (P3OT/TiO_2NTs) was synthesized by chemical method. Transmission electron microscope (TEM) and scanning electron microscope (SEM) depict the morphology of the samples, defining that TiO_2NTs were successfully coated by poly(3-octylthiophene) molecules. X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and infrared spectroscopy (IR) showed the chemical interaction of poly(3-octylthiophene) and titania nanotubes in the composite. Cyclic voltammetry (CV) curves showed that the forbidden band gap of the P3OT/TiO2NTs composite is 0.672 eV, realizing the complementary advantages of n and p semiconductor. Ultraviolet–visible spectra (UV–vis) and fluorescence spectra (PL) show that its optical performance is far superior to poly(3-octylthiophene) and titania nanotubes separately. Solar cell was sensitized by P3OT/TiO_2NTs. A solar-to-electric energy conversion efficiency of 0.593% was attained with the system. The results show that P3OT/TiO_2NTs nanocomposite is a promising material with excellent performance in photoelectric applications.

doping by potassium. The molecular structure of FePc ($C_{32}H_{16}N_8Fe$) is schematically shown in Fig. 1.

It has a planar structure with D_{4h} point symmetry. The molecule consists of the central Fe atom surrounded by four nitrogen atoms (pyrrole, N_1); four other nitrogen atoms – (bridging aza, N_2); 32 carbon atoms – the pyrrole (C_1) and the benzenes (C_{BZ}: C_2, C_3 and C_4). Our measurements were performed by photoemission spectroscopy (PES) and near-edge X-ray absorption fine structure (NEXAFS) using synchrotron radiation, and the experimental results are completed by DFT calculations.

2. Experimental details

The PES experiments were performed using the soft-X-ray synchrotron light emitted by the high-energy resolution I511 beamline at MAX-Lab (Lund, Sweden). The beam line is designed for surface science experiments and is equipped with a SCIENTA electron analyzer for PES.

The NEXAFS measurements were done using the soft-X-ray light provided by the Russian-German high-energy resolution dipole beam line (RGBL) at the Berliner Speicherring für Synchrotronstrahlung (BESSY, Berlin, Germany). This line delivers moderate-intensity radiation with a continuous distribution over a wide photon energy range and therefore is well suited for the NEXAFS measurements of organic materials which are relatively fragile and potentially could be damaged under intense irradiation. In a previous investigation [11] it was shown that the FePc films are very resistant for 3–4 h to typical X-ray fluxes at a bending magnet beamline. Nevertheless, during the measurements we regularly changed the spot position of the radiation beam on the sample surface to avoid possible damage of the organic film. The spectra were recorded in total electron yield mode and normalized to the incident photon flux. The resolution for the NEXAFS measurements is determined exclusively by the performance of the beam line and varied from 80 meV to 90 meV FWHM when going from the C 1*s* (~283 eV) to the N 1*s* (~400 eV) thresholds, and was approximately 100 meV for the Fe absorption thresholds. The acquired spectra were energy calibrated using the C $1s \rightarrow \pi^*$ and N $1s \rightarrow \pi^*$ photoionization spectra of CO_2 and N_2 gases. In NEXAFS experiments the photon incidence angle was selected to be 35° relative to the normal to the sample surface. We have chosen this angle to explore simultaneously both: the $1s \rightarrow \pi^*$ and $1s \rightarrow \sigma^*$ transitions. The pressure in the experimental systems during data acquisition was always better than 5×10^{-10} Torr. All measurements were carried out at room temperature.

As the substrate for FePc film formation, we used the (001) surface of a gold single crystal. The surface was prepared by repeated sputtering and annealing cycles after which a 5×20 surface reconstruction was observed using low energy electron diffraction, while no remaining contamination was detected in core level photoemission spectra. The FePc film was deposited from a Knudsen-type evaporator in sample preparation chambers (base pressure of 2.5×10^{-10} Torr) directly linked to the analyzer chambers. The deposition rate, monitored by a quartz microbalance, was 1–2 Å/min. The core level photoemission spectra indicated clean FePc films without detectable traces of contamination including oxygen. The FePc films used for our studies were about 70 Å thick, which is large enough to minimize signals from the gold substrate in the photoemission spectra, and small enough to avoid charging effects.

Pure potassium was evaporated onto the FePc film at rates ranging from 1 to 50 Å/min from a properly outgassed SAES alkali-metal dispenser, without detectable pressure enhance during deposition. This resulted in a uniform distribution of the potassium in the organic film as proved upon varying the emission angle of the photoelectrons. The K concentration in the FePc films was evaluated from a comparison of the relative intensities of the K 2*p* and C 1*s* core-level signals. The sensitivity factors of the core-levels for the respective photon energies were taken from the tabulated cross-sections, and we also took into account the throughput of the analyzer [12]. After each FePc or potassium deposition step, the PE measurements in the normal emission geometry were carried out with photon energies of 110 eV for the valence band (VB), 400 eV for K 2*p* and C 1*s*, 500 eV for N 1*s* core levels (CL). The overall energy resolution [full width at half maximum (FWHM)] also accounting for the thermal broadening was 130 meV for photon energies of 110 eV (valence band), 240 meV for photon energies of 400–500 eV. The E_F position in the spectra was determined after each move of the monochromator by measuring the Fermi edge and/or the Au $4f_{7/2}$ electron emission from a gold foil cleaned by ion bombardment in electrical contact with the FePc film.

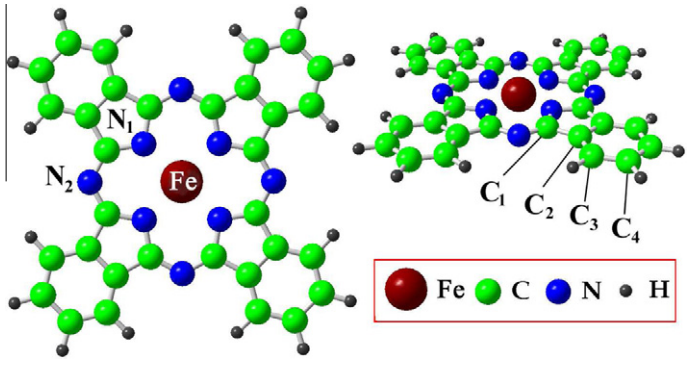

Fig. 1. Schematic demonstration of the molecular structure of the FePc molecule, where the central iron atom is surrounded by four nitrogen atoms.

The core-level C 1*s* and N 1*s* PE spectra were decomposed by a least-squares-fitting procedure in order to differentiate contributions from C and N atoms in different chemical environments. The fit was performed with Lorentzian line shapes convoluted with a Gaussian function to take into account the finite experimental resolution. Other experimental details can be found elsewhere [13,14].

3. Results and discussion

Fig. 2(a–b) shows the C 1*s* and N 1*s* core levels recorded from a FePc film as a function of potassium doping. X indicates the amount of potassium atoms per FePc molecule. The top spectra in both Figs. (for $X = 0$) represent the photoelectron emission from core levels of pristine FePc just after of organic film formation. The decomposition of the C 1*s* spectrum of pristine FePc is presented in Fig. 2(c) ($X = 0$). It appears to be very similar to decompositions, performed earlier for pristine CuPc [14–17] and CoPc [18] films just confirming previous conclusions that the C 1*s* core level is comprised of two main components: B which corresponds to the aromatic carbon of the benzene rings of Metal–Pc (C_2, C_3, and C_4) and P shifted by 1.4 eV toward higher binding energy and attributed to the carbon C_1 linked to nitrogen atoms N_1 and N_2 (pyrrole carbon). The energy shift between C 1*s* (B) and C 1*s* (P) is due to a transfer of valence charge from pyrrole carbon to the more electronegative nitrogen in the –N–C=N– bonds. The shoulder SB and the feature SP are the satellites of the B and P components, respectively [13,15,16,19–22]. The fact that we have managed to perform C 1*s* decomposition using the same parameters as in Refs. [14,17,18], could mean that the replacement of the central atom leaves the organic ligand rather unchanged.

The N 1*s* core-level spectrum of pristine FePc is shown in the Fig. 2(b). The spectrum consists of the strong peak centered at 398.62 eV and weaker peaks at 400.4 eV and 402.5 eV. Taking into account the fact that we have the same resolution as in Refs. [14,17,18] and taking the similar fitting parameters, which were used for CuPc [14,17] and CoPc [18], we have managed to decomposed the peak of 398.62 eV by two components: C centered at 398.38 eV and P centered at 398.86 eV (Fig. 2(d), $X = 0$).

The energy difference between the peaks corresponds to 0.36 eV. Component **C** at lower BE can be assigned to the four nitrogen atoms connected to the central Fe atom (N_1 in Fig. 1), while the P component can be assigned as originating from the four nitrogen atoms linked to the pyr-

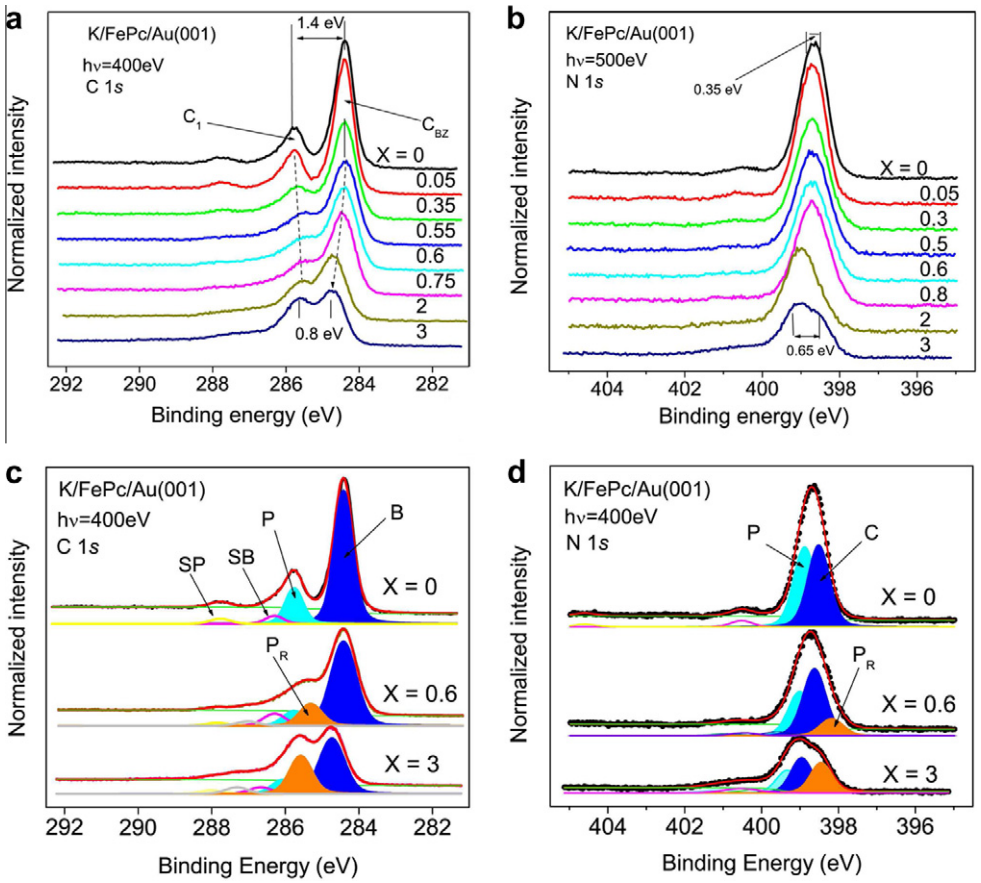

Fig. 2. C 1*s* core level (a) and N 1*s* core level (b) measured using photoemission spectroscopy of FePc thin film at RT as a function of *X* which characterize the amount of potassium atoms per FePc molecule. olle carbons. Probably unlike to the case of CuPc, where both nitrogen sites N_1 and N_2 are characterized by the same or a very similar binding energy (BE) and the main N 1*s* peak was fitted by only one component [14,17], the central Fe atom differently interacts with these N_1 nitrogen atoms which is associated with a stronger charge transfer. The latter provokes the N_1 chemical shift to lower BE by 0.36 eV. A similar shift of about 0.3 eV for FePc [23] was found from DFT calculations. Our discussion above is consistent with metal–Pc binding energy calculations [24], while the calculated BE were found to be 9.81 eV for FePc and 6.96 eV for CuPc.

With potassium doping the K 2*p* spin-orbit doublet is observed at binding energies of 294 eV and 296.7 eV and increases in intensity with increasing potassium content (Fig. 3). The energy positions of the doublet indicates that the outer *s* electrons of potassium are transferred to the FePc molecules upon intercalation [5,25]. The shape of the K 2*p* doublet basically does not change with doping till a concentration of about four potassium atoms per FePc molecule which is an indication of the existence mostly of only one inequivalent potassium site in this doping range. At a higher potassium concentration ($X = 7.5$) considered in the present investigation the spectrum shows one more feature shifted by about 2.4 eV to lower BE relative to K $2p_{3/2}$ component of main doublet. From such K 2*p* core level behavior we can conclude that at doping range $0 < X \leqslant 4$ most probably potassium ions occupy one type of equivalent positions in FePc molecule. As we will see below the first type of sites, corresponding to higher BE, is located near the asa-bridging nitrogens N_2 of the FePc molecules (see Fig. 4(b)) and is fully saturated at potassium concentration $X \simeq 4$, while another site type, corresponding to lower BE is located probable near the benzene carbons and is occupied by K ions at concentration $X \geqslant 4$. This behavior of the K 2*p* core-levels with potassium doping would parallel the effects of Rb intercalation into C_{60}, where it was concluded, that three clear features in Rb 3*d* core-level result from overlapping contributions from

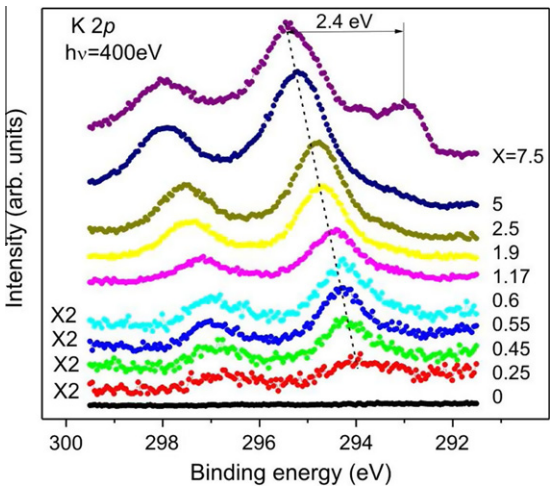

Fig. 3. K 2*p* core level measured using photoemission spectroscopy as a function of K intercalation of FePc thin film at RT.

Rb ions in tetrahedral and octahedral sites [25]. In general starting from the first deposition up to $X \simeq 7$ the total K 2*p* core-level shift of about 1 eV to higher BE was observed.

Fig. 2(a) also depicts the evolution of the C 1*s* spectra with increasing potassium doping. Upon initial potassium intercalation till about $X = 0.2$–0.3 there is a small the spectral shape change. With increasing potassium doping both C 1*s* core-level features (C_1 and C_{BZ}) show broadening, but C_1 spreads much more drastically and is shifted to lower BE. And finally C_1 becomes separated from C_{BZ} component by 0.8 eV, which is contrasted by the 1.4 eV distance in pristine FePc (see above). Note, that this feature is attributed to the carbon atoms linked to nitrogens N_1 and N_2 (pyrrole carbon). On the other hand, the line shape of the C_{BZ} feature, which corresponds to the aromatic carbon of the benzene rings C_2–C_4 almost does not change. The decomposition of the C 1*s* core level at selected potassium concentrations which is presented in Fig. 2(c) shows the appearance and growth of a new C 1*s* component P_R presented in Fig. 2(c), which is at energies in between those (C 1*s* (P) and C 1*s* (B)) related to undoped FePc, while intensity of P component reduces essentially. Such a behavior indicates, that the potassium atoms impact the pyrolle carbon atoms which results in splitting P (pyrolle component of C 1*s* CL spectrum) to two ones: (i) P (pyrolle) which originates from pyrolle C_1 atoms not influenced yet by potassium and (ii) P_R component, which originates from the same pyrolle C_1 atoms, but with different chemical environment. This component is shifted to lower BE and growths in intensity with potassium addition.

This conclusion is corroborated by the evolution of the N 1*s* core-level peak centered at 398.62 eV upon doping as shown in Fig. 2(b). With increasing potassium intercalation the spectrum shows an increase of peak width. In order to obtain a deeper insight into the chemical interaction between potassium and FePc film, we have performed a numerical peak decomposition, the results of which for selected potassium intercalations are shown in Fig. 2(d). The width of each component was taken from the N 1*s* core-level spectrum of pristine FePc (top spectrum in Fig. 2(d)) and was kept unchanged at all potassium doping. From Fig. 2(d) it is evident that components P and C which were found above as a result of decomposition of peak centered at 398.62 eV for undoped FePc show a shift to higher binding energy with doping and as a result of K addition the component P_R appears at lower binding energy, which leads to the overall N 1*s* peak broadening observed. With increasing doping one sees a rapid attenuation of left component P of the N 1*s* core level, which was attributed to the N_2 atoms linked to pyrrole carbon atoms and simultaneously a growth of component P_R which leads to an asymmetric line-shape. Thus, our data demonstrate a scenario, where upon potassium doping the K atoms ($X \leqslant 3$) occupy one type of equivalent positions in FePc molecule, namely – close to asa-bridging nitrogens N_2 as schematically drawn in Fig. 4. This decreases the relative amplitude of this P component and gives rise to the new reactive one P_R, appearing at lower binding energy as a consequence of strong charge transfer from K to N. Thus we conclude that K stronger impacts the asa nitrogen and pyrrole carbon atoms (N_2 and C_1 in Fig. 1). Moreover, there is a nega-

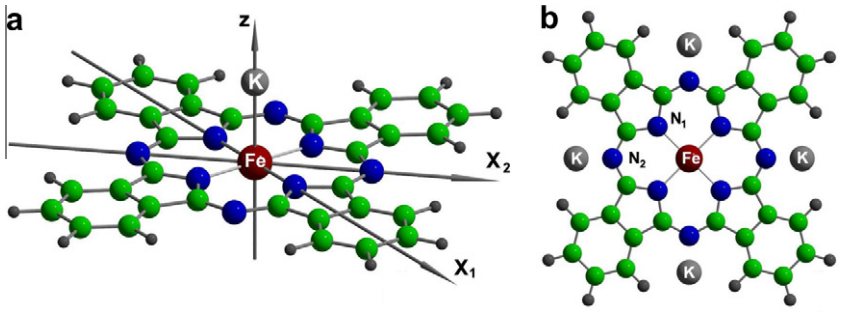

Fig. 4. (a) Schematic presentation of FePc molecule, potassium atom above of iron atom and two high symmetry axes X_1 and X_2 along which the K atom was moved being 2.0 Å above the molecular plane. (b) Schematic diagram of the possible positions of the K atoms or ions intercalated in FePc molecule for the doping concentration of four ions for one FePc molecule.

tive charge transfers to the Pc molecule. The latter is evident because one observes a strong total shift of PE spectra to higher BE, which indicates a Fermi level shift to the lowest unoccupied molecular orbital (LUMO)of FePc. Furthermore, at higher doping levels (in our measurements – at X = 7.5), different lattice sites have to be occupied. Indeed, it was shown earlier, that probably after saturation of sites closed to asa-bridging nitrogens corresponding to four potassium atoms per one FePc molecule, K atoms occupy sites close to the aromatic carbon of the benzene rings and interacts to some degree with them.

We present here also a single molecule density functional theory (DFT) study, which allows us to determine the most favorable sites, which potassium ions occupy close to FePc molecules. The calculations were performed using the linear combination of atomic orbital (LCAO) formalism based on density functional theory and realized in the CRYSTAL code [26]. We use the three parametric Becke + Lee–Yang–Parr (B3LYP) exchange-correlation functional [27] which correct self-interaction error inherent in local density and generalized gradient approximations. The electron subsystem was described by the all electron basis sets in Gaussian form, namely, we use 6-311+G** basis set for C, N and H atoms [28] and TZVP [29] basis for Fe and K. The structure of the FePc molecule was optimized. We found that the FePc molecule has a planar structure and a total magnetic moment of 2 μ_B in the ground state. The next excited magnetic configuration is a quintet ($\mu_{total} = 4\ \mu_B$) with planar atomic structure. The excited magnetic state is only 0.62 eV higher in energy then the ground state.

Taking into account our previous conclusion, that potassium strongly reacts with the asa nitrogen atoms and pyrrole carbon, we move K across the FePc molecule along two high symmetry axes X_1 and X_2 as is shown in Fig. 4(a). For detailed investigations, we assume that the potassium atom can be neutral and ionized (K^1+) and the FePc molecule can be in two magnetic states.

The results of our calculations are shown in Fig. 5. The curve with square symbols in two Fig. 5(a and b) corresponds to binding energy calculations between a FePc molecule in the excited magnetic state and neutral K. The circles show the binding energy data between a FePc molecule in the ground state and neutral potassium. Here, we have to note that we present the energetically preferable configuration where the magnetic moment of the molecule and the neutral K atom are antiparallel for both magnetic states of FePc. Thus, the curves with squares correspond to the FePc + K system with a total magnetic moment of 3 μ_B and the circles are related to the system with the total magnetic moment of 1 μ_B. The triangles describe the interaction between ionized K^+ and FePc molecule in the ground state (total magnetic moment is 2 μ_B).

For the X_1 direction (Fig. 5(a)) the interaction energy between K atom or ion and the FePc molecule is positive for any distance up to 7.5 Å, which means a repulsion between potassium and molecule. The displacement of the K atom along X_2 axis shows that the potassium atom and ion can create a stable bond with FePc molecule in both magnetic states. In this case, the potassium is situated close to the asa-bridging nitrogen N_2. The energetically preferable configuration corresponds to the system with the smallest total magnetic moment $\mu(\mathrm{FePc} + \mathrm{K}^0) = 1\ \mu_B$. We also found the charge transfer from originally neutral K atom in amount of $1e^-$ to FePc molecule. Now, taking into account that the binding energy between FePc molecule and ionized K^{1+} atom is quite large (see Fig. 5(b)) we can assume that only ionized K atoms can migrate into the FePc slab. The further relaxation of the FePc molecule with the K atom or ion shows that the potassium is still situating close to N_2 atom but out of the molecular plane. Therefore, for the comparison of the theoretical and experimental spectra one needs to analyze the interaction of the potassium with two or more FePc molecules. Finally, our theoretical data confirm conclusions above, that K atoms (ions) intercalated into FePc film occupy one type of equivalent positions in FePc molecule along X_2 axis, namely – close to of asa-bridging nitrogens N_2 as schematically shown in Fig. 4(b).

We now discuss the experimental valence-band photoemission spectra shown in Fig. 6(a and b). Here we should remark that the molecular planes of FePc deposited onto the Au(001) substrate lie parallel to substrate surface and the FePc layer is highly ordered with a square unit cell of approximately $14.2 \times 14.2\ \text{Å}^2$ aligned along the (110) and $(1\bar{1}0)$ axes of the gold surface [11]. Therefore we have recorded the VB spectra from the FePc film as a function of potassium doping at two different experimental geometries: with the **E** vector of the incoming photons near normal to the surface (P-p, Fig. 6(a)) and almost parallel to the

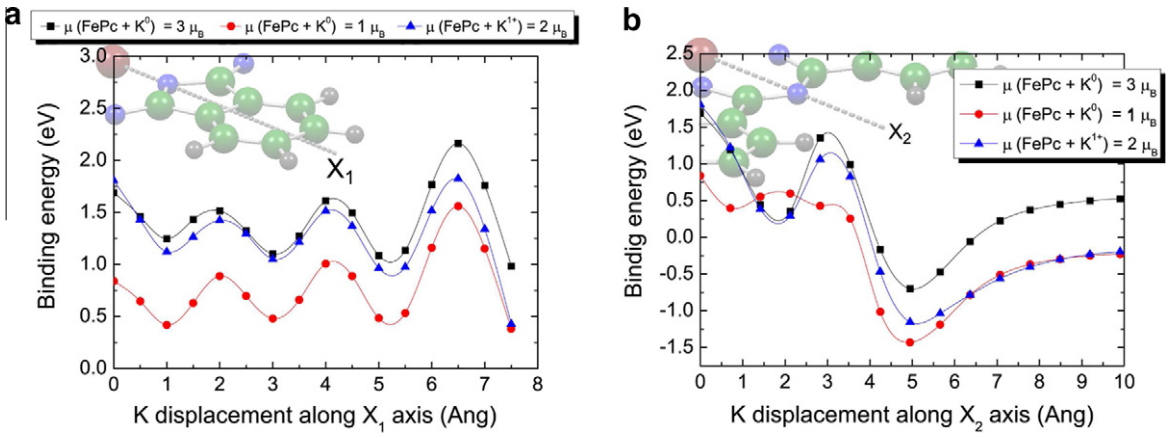

Fig. 5. The binding energy between FePc molecule in different magnetic states and potassium atom and ion as a function of K displacement along X_1 (a) and X_2 (b) axes. The details of the figure see in the text.

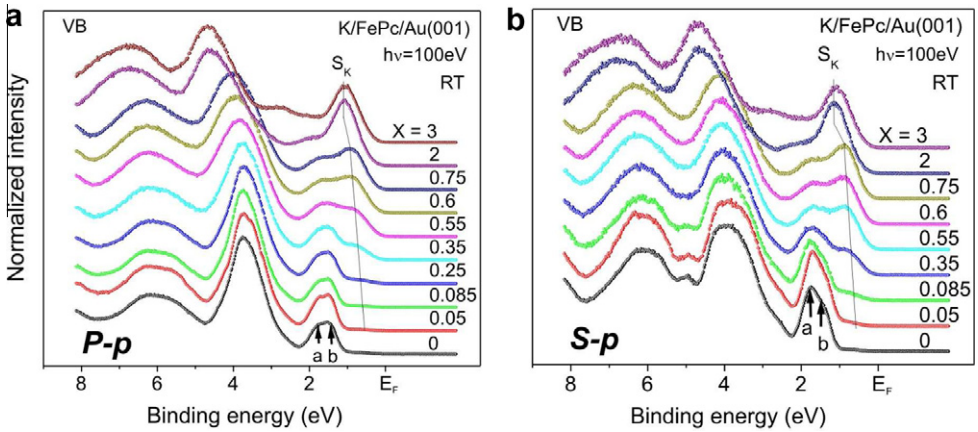

Fig. 6. VB spectra recorded from a FePc film as a function of potassium doping. (a) For the polarization vector **E** perpendicular (P-p) to the sample surface and (b) parallel (S-p) to the one.

surface (S-p, Fig. 6(b)), while the emission direction was always parallel to the **E** vector. The lowest spectra in both Fig. 6(a and b) represent the VB photoelectron emission from pristine FePc just after organic film formation. A comparison of the spectra recorded from the Au(001) substrate just before FePc film deposition (not shown here) to the spectra from the pristine organic film shows that no valence-band features of the gold substrate are visible in the VB spectra of the pristine FePc film thus confirming that the organic film spectra are representative of FePc. The polarization dependence of VB spectra can help to identify different features of the spectra [23,30]. Our calculations indicate, that the top of the VB of pristine FePc with a spectral weight maximum located around 1.7 eV below E_F has two, (a and b) components, where the first one originates from Fe 3*d* electrons, while second one is mostly due to emission from carbon of benzene rings [31]. Some earlier investigation also point out that the highest occupied molecular orbital for FePc has strong metal 3*d* character [24,32]. The onset of the FePc valence band is found at about 1.25 eV below E_F. The valence-band onset for the pristine FePc film indicates that the initial E_F position is located near the middle of the transport gap which has been reported to be 2.6 eV [33]. The midgap position of the E_F is consistent with the intrinsic nature of the FePc films as prepared in this study.

As a result of K deposition one new peak appears in the VB spectra at about 0.7 eV below E_F which is marked "S_K" (see Fig. 6). The spectral weight of this feature rises with increasing doping and can be assigned to the electron emission from the past LUMO of FePc which now becomes filled as a result of the transferred electrons from potassium, or to emission from Fe 3d states that become occupied upon charge transfer. The appearance of such a doping-induced feature in the energy gap of the organic semiconductor corresponds to what has been found for another doped organic semiconductors [10,17,34,35]. In addition, as a result of potassium doping we have found a shift of the spectra to higher binding energy, which corresponds to the E_F motion towards the conduction-band minimum.

Few years ago by means of electron-transport measurement techniques and scanning tunneling spectroscopy

(STS) the insulator-metal transitions have been observed for alkali-metal-doped Pc's and perylene tetracarboxylic dianhydride (PTCDA) [3,4]. Taking into account the fact that the PES is a direct method to prove metallicity, we recorded a series of photoemission spectra from the FePc films in the vicinity of E_F as a function of potassium doping. We did not detect any corroboration for emission from E_F in the whole doping range studied here. Therefore, we conclude that none of the K_x FePc films studied here was metallic. This is in agreement to previous PE studies [13,17], performed for K_x CuPc systems. The possible reasons for the discrepancy of the PE results and those from transport and STS measurements remains unclear (see also discussion in Ref. [17]). Finally we would like to draw attention to the fact, that upon potassium doping the polarization dependence of the photoemission data is lost. This might be due to the fact that potassium addition induces disorder or the formation of small grains of a doped phase.

In order to obtain deeper insight into the FePc electronic structure evolution upon potassium doping, we have also performed NEXAFS N 1*s* and C 1*s* measurements, which are discussed in the following.

Figs. 7 and 8 show the NEXAFS spectra of FePc at the N 1*s* and C 1*s* absorption edges as a function of K doping. The lowest absorption spectra ($X = 0$) are recorded from a pristine FePc film. The rather sharp features A, B, and C in Figs. 7 and 8 can be attributed to N 1*s* → π^* and C 1*s* → π^* excitations [36–40]. Moreover, we can suggest in analogy with [39] that the A, B, and C empty states revealed in the N 1*s* absorption spectra (Fig. 7) and the A, B, and C empty states probed in the C 1*s* absorption spectra [see Fig. 8] correspond to essentially the same π^* states, which have finite probability located at the pyrrole carbon and the nitrogen atoms linked to each other. This does not exclude contributions from excitations into C–C – π^* orbitals to these peaks.

Note that the N 1*s* core level consists of two components originating from both N_1 and N_2 nitrogen atoms (see Fig. 1) and the two core level binding energies differ by about 0.38 eV (see Fig. 2(d), top spectrum). Therefore the feature A in the N 1*s* absorption edge represents transitions from 1*s* core levels of both N_1 and N_2 nitrogen

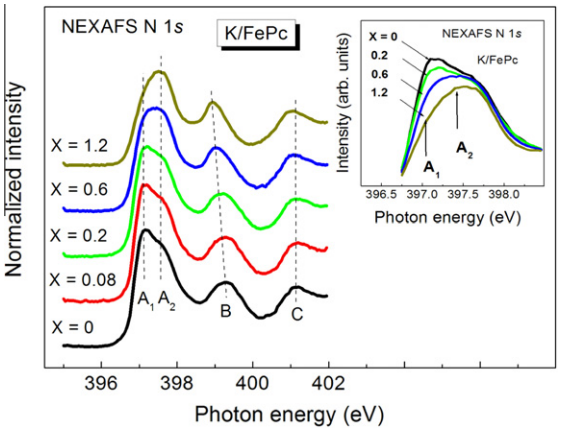

Fig. 7. NEXAFS spectra of FePc taken at the N 1*s* absorption edge as a function of potassium atoms concentration (X) per FePc molecule. The spectra were recorded at room temperature.

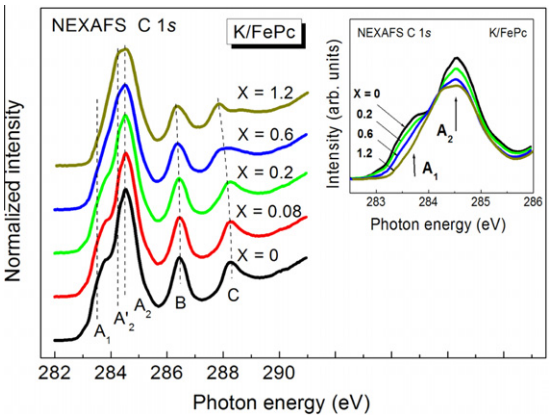

Fig. 8. NEXAFS spectra of FePc taken at the C 1*s* absorption edge as a function of potassium atoms concentration (X) per FePc molecule. The spectra were recorded at room temperature.

atoms into energetically low lying π^* states and consists also of two components: A_1 and A_2 separated by 0.38 eV, while A_1 and A_2 represent transition from N 1*s* core levels of N_1 and N_2 sites correspondently.

Now we will talk about the evolution of the NEXAFS absorption spectra at the N 1s absorption edge with potassium doping. The profile of feature *A* changes upon doping mostly by an decrease of spectral weight at the low energy side (feature A_1 in Fig. 7). This is especially evident by a direct comparison of the N 1*s* absorption spectra with different K doping in inset of Fig. 7. The intensity of the A_1 feature in Figure substantially reduces upon doping. This is a direct result of the filling of LUMO by charge transfer from the potassium ions. The intensity reduction as seen in Figs. 7 and 8 is in good correlation with the doping level. The spectral features B and C at higher photon energies show a shift to lower energies as a function of doping (see Fig. 6(a)), which parallels the situation in potassium-doped C_{60} (Ref. [41]) and can be associated with the relaxation of the molecular structure and bond lengths of the FePc molecules upon adding charge to the LUMO, which is of antibonding π^* character.

The evolution of the C 1*s* NEXAFS spectrum for FePc films as a function of potassium doping is presented in Fig. 8. With increasing potassium quantity the intensity of spectral feature A_1, which can be attributed to transitions from C 1*s* core levels of the benzene carbon atoms (C_2, C_3, C_4) into the LUMO, decreases. This behavior becomes more evident in inset of Fig. 8, where the C 1*s* absorption spectra for selected potassium content are superimposed. We can conclude that the density of states of the LUMO decreases with K doping as a consequence of filling this molecular orbital. Assuming that the LUMO wave function has a finite probability at both carbon and nitrogen sites in FePc, it is obvious that the filling of this molecular orbital becomes observable at both the N 1*s* and C 1*s* absorption edges. The second finding in the C 1*s* NEXAFS spectra is emergence and development of a new peak at the lower photon energy of about 0.3 eV relative to the A_2 absorption peak as a result of increasing K concentration (see Fig. 8, A_2). This observation becomes more

clear in inset of Fig. 8. We can attribute this appearance to a chemical shift to lower BE of the C 1*s* level of a number of pyrrole carbon atoms C_1 (see Fig. 1) due to the existence of potassium ions close to the FePc molecules, which leads to a downshift of the absorption edge. Indeed, the fit analysis of the C 1*s* core level photoemission data for selected doping levels proves the appearance and growth of a new C 1*s* component shown in Fig. 2(c), which is at energies in between those (C 1*s* (P) and C 1*s* (B)) related to undoped FePc. This explanation is in full agreement with the chemical shift observed for the pyrrole nitrogen atoms as a function of doping (see Fig. 2(d) and the discussion above). Besides, the absorption peaks B and C at higher photon energies as presented in Fig. 8 move to lower energies with increasing potassium content, similar to what is seen for the nitrogen absorption data.

4. Summary

This contribution presents the photoemission and photoabsorption studies of K doped FePc using synchrotron radiation. Our findings indicate that with potassium doping the density of states in the energy region of the LUMO is reduced. In addition, the spectral alteration as established for both C 1s and N 1s absorption edges can be explained in consideration of the charge transfer and the related changes (chemical shifts) of the corresponding core levels. Moreover, our observations indicate the filling of the LUMO of FePc with electrons that stem from potassium, and it is established that the potassium ions are located closely to pyrolle nitrogen atoms of the FePc molecule.

molecular orbital (LUMO) levels were obtained in thin films made from the solution-processible quinoidal oligothiophene [QQT(CN)4] by laser irradiation treatment using a near infrared scanning laser system. The excitation wavelength was carefully chosen to match the absorption band of this material in thin film in order to be able to heat locally the devices in micro-sized regions delimited by the laser spot size. The majority carrier type conversion was attributed to the effects of a thermal treatment on QQT(CN)4 film morphology, resulting in dramatic changes in both charge injection processes and charge carrier hopping distances [23,27]. The proposed new patterning method was then used to realize complementary organic inverters, NAND and NOR logic circuits in QQT(CN)4 thin films spin-coated on top of a polyimide gate dielectric [23].

In this manuscript, we report a comparative experimental study of the electrical performance of solution-processed organic inverters based on the combination of ambipolar as-prepared and n-type top-contact QQT(CN)4 OFETs patterned by direct laser writing. These logic circuits were fabricated using SiO_2 and polyimide as gate insulating materials. The results show the effects of the laser irradiation on the characteristics of the inverters including a significant increase of the gain and a notable improvement of the on-state. We also found that the insertion of a thin polyimide film between the QQT(CN)4 and the SiO_2 layers could reduce selectively the electron field-effect mobility and improve the off-state of the inverters. Spatial and selective control of the ambipolar characteristics in QQT(CN)4 thin films by combining the direct laser writing technique and the patterning of the polyimide film enables the fabrication of purely CMOS organic inverters based on a solution-processed organic thin film made from a single organic semiconductor. The high performance of these devices, together with their good stability in air and their ease of fabrication via solution-processing methods show the high potential of QQT(CN)4 and quinoidal oligothiophenes for future organic electronic applications.

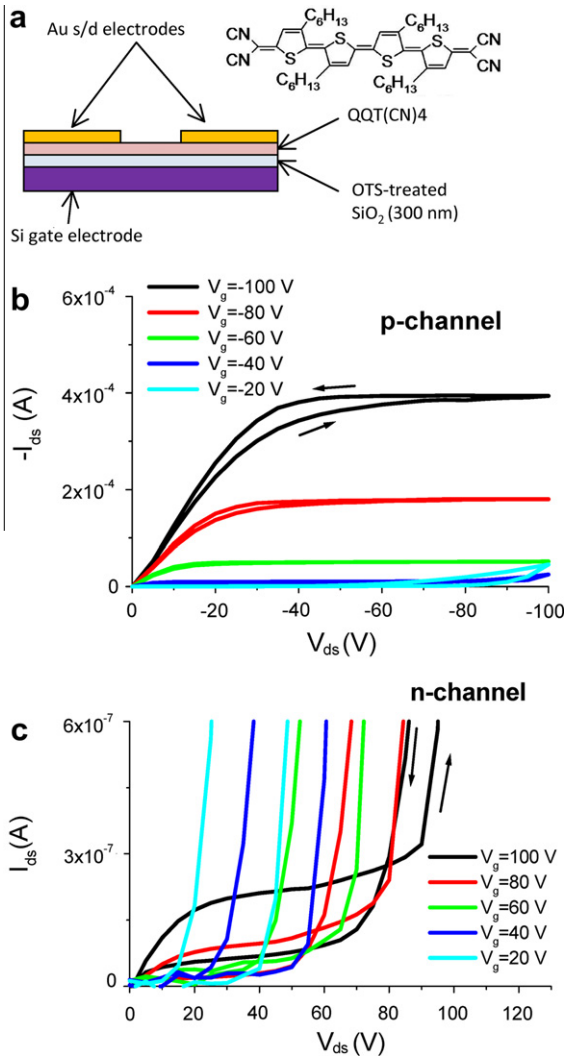

Fig. 1. (a) Schematic representation of an ambipolar Au top-contact QQT(CN)4 OFET with an OTS-treated 300 nm thick SiO_2 dielectric layer. Output characteristics of this device in (b) hole enhancement and (c) electron enhancement modes. The QQT(CN)4 thin film was used as-prepared and had a thickness of about 90 nm. Channel length and width are 45 μm and 4 mm, respectively.

2. Experimental

QQT(CN)4 was synthesized according to an improved procedure that has been described in the literature [28]. Its chemical structure is shown in Fig. 1a. OFETs and complementary inverters were fabricated on top of heavily doped n-type silicon wafer substrates with thermally grown SiO_2 layers. Three different gate dielectrics were used in this work: (i) an octadecyltrichlorosilane (OTS)-treated 300 nm thick SiO_2 layer, (ii) a 1 μm thick polyimide film and (iii) a 300 nm thick SiO_2 layer onto which a 150 nm thick polyimide film was formed by spin-coating. The OTS treatment of the precleaned SiO_2 surface was achieved by a soak in 5 mM solution in hexane for nearly 10 h. The samples were then rinsed in hexane solution and heated at 120 °C for 2 min. The 1 μm thick polyimide films were spin-coated from a solution of precursor (Kyocera CT4112) in *N*-methyl-2-pyrrolidinone onto 25 nm thick Al gate electrodes thermally evaporated through a shadow mask on the substrates (silicon wafers with 1 μm thick SiO_2 layer). To form 150 nm thick polyimide films, the solution of polyimide precursor was diluted appropriately prior to the deposition by spin-coating. QQT(CN)4 thin films were then spin-coated onto the dielectric layers from a 10 mg/ml chloroform solution at 3000 rpm. Top contact Cr drain/source electrodes were thermally evaporated on top of the devices (ii). The two other types of OFETs [(i) and (iii)] used gold as top-contact metal electrodes. Channel length (L) and channel width (W) were 45 μm and 4 mm. Laser-conversion of the QQT(CN)4 films by direct laser writing was performed before the evaporation of the source/drain electrodes using the laser patterning system and the experimental conditions previously described [23]. The laser irradiation of the samples at a wavelength of 1060 nm and a power of 6.7 W was carried out in air. The laser spot size illuminating the organic thin

films corresponding to the full-width at half maximum was measured by a beam profiler to be around 300 μm. The distance between two consecutive lines during the sample scanning was chosen to be half of the spot size. The speed of the laser irradiation scanning was 0.1 mm/s for the OFETs using the 1 μm thick polyimide film and 0.04 mm/s for the two other device structures. The electrical measurements were performed in ambient atmosphere using a couple of picoammeter/voltage source units (Keithley, model 6487) and a source meter unit (Keithley, model 2400).

3. Results and discussion

The ambipolar nature of charge transport in QQT(CN)4 OFETs using OTS-treated SiO_2 as gate dielectric and Au top contact source/drain electrodes (schematic device structure shown in Fig. 1a) can be seen in the output characteristics displayed in Fig. 1b and c. At both high positive and negative bias V_g and low source–drain voltage V_d, saturation of the drain current I_d is clearly observed, indicating that the device operates in electron and hole accumulation modes, respectively. On the other hand, at low V_g and high V_d, the device shows diode-like curves with a rapid increase of I_d with V_d, this effect being much more pronounced in the n-channel. Such a behavior is typical for ambipolar OFETs and is due to the presence of both charge carriers in the channel. In contrast, the output characteristics measured in the device based on laser-converted QQT(CN)4 thin film (Fig. 2) indicate that this device works well in the electron accumulation mode with saturation of I_d observed at positive V_g. These results are in good consistency with previous reports displaying the output and transfer characteristics of similar OFETs based on ambipolar as-prepared and n-type thermally-converted QQT(CN)4 thin films using either OTS-treated SiO_2 or polyimide as gate dielectric [23,27]. The leakage current in these devices was typically much lower than 5×10^{-7} A/cm^2 at 2 MV/cm. While electron field-effect mobility extracted from the transfer characteristics in the saturation regime is not significantly affected by laser irradiation and is about 0.004 cm^2/V s, hole field-effect mobility is measured to be around 0.07 cm^2/V s in as-prepared QQT(CN)4 film and can be decreased by the direct laser writing technique. It is important to note that the laser irradiation conditions chosen in this work (wavelength of 1060 nm, power of 6.7 W, spot size of 300 μm and scanning speeds lower than 0.1 mm/s) are sufficiently strong to completely suppress hole conduction in the devices without causing any degradation of the samples [23].

As displayed in Fig. 3a, two identical ambipolar p-type dominant as-prepared QQT(CN)4 OFETs were fabricated on the same OTS-treated 300 nm thick SiO_2 gate dielectric layer. These transistors were connected to form an inverter circuit. Fig. 3b shows the transfer characteristics of the inverter for various supply voltages (V_{DD}) ranging from 20 to 50 V. The complementary-like logic circuit operates reliably within this range of V_{DD}, as revealed by the switching behavior at an input voltage (V_{IN}) lower than V_{DD}. As shown in Fig. 3c, the highest gain for this inverter is about

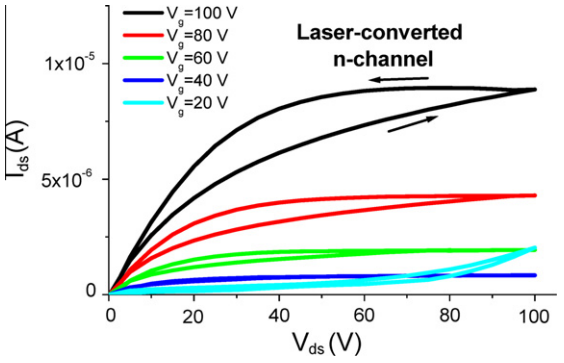

Fig. 2. Output characteristics of the laser-converted n-type Au top-contact QQT(CN4) OFET with an OTS-treated 300 nm thick SiO_2 dielectric layer in electron enhancement mode. Laser-irradiation of the sample was carried out using a fiber laser emitting at 1060 nm with a power of 6.7 W. The scanning speed was 0.04 mm/s and the spot size was measured to be around 300 μm. Channel length and width are 45 μm and 4 mm, respectively.

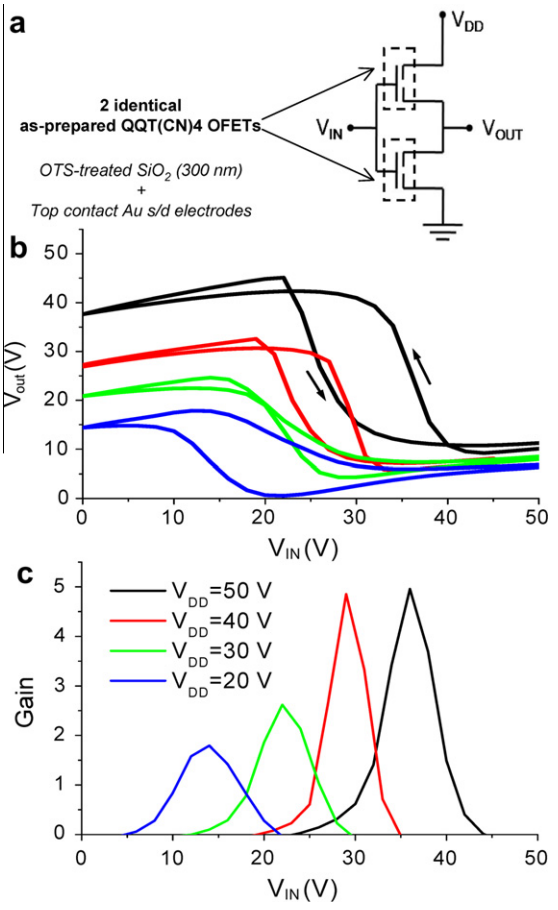

Fig. 3. (a) Schematic of the complementary inverter employing two identical ambipolar as-prepared QQT(CN)4 OFETs with an OTS-treated 300 nm thick SiO_2 gate dielectric layer and Au source drain electrodes. (b) Transfer characteristics and (c) gain of the inverter. The supply voltage (V_{DD}) was varied from 20 to 50 V.

5 for V_{DD} = 50 V and decreases up to 1.8 for V_{DD} = 20 V. These moderate values are on the same order of magnitude as those typically reported in organic inverters based on two identical ambipolar OFETs [29,30]. Because the two as-prepared QQT(CN)4 OFETs can never be completely switched off during the inverter operation, the output voltage (V_{OUT}) does not reach V_{DD} and zero, at small and large V_{IN}, respectively. The output voltage swing that we define as the difference between the minimum and maximum values of V_{OUT} is found to be 33 V for V_{DD} = 50 V. As a specific feature of ambipolar inverters [8], one must note that this circuit presents similar switching characteristics in the first and third quadrant (V_{IN} < 0 and V_{OUT} < 0) of the V_{IN} versus V_{OUT} plot (data not shown). It is also essential to mention that these inverters operate well and are stable in ambient conditions.

Similar measurements were performed in an organic inverter based on two identical ambipolar as-prepared QQT(CN)4 OFETs using 1 μm polyimide layer as gate dielectric and Cr as source/drain metal electrodes. The schematic structure of these OFETs and a picture of the inverter are shown in Fig. 4a. The transfer characteristics and the gain measured in this inverter for several V_{DD} ranging from 20 to 50 V are reported in Fig. 4b and c. We found that, for V_{DD} = 50 V, the highest gain and the output voltage swing of this circuit are about 6.1 and 35 V, respectively. These results show that the ambipolar as-prepared QQT(CN)4 inverters fabricated on OTS-treated SiO_2 and polyimide present very similar performance. The large hysteresis observed in the transfer characteristics of these logic circuits might be a real problem for practical applications and further studies are still needed to identify the causes of this effect.

As displayed in Fig. 5a, ambipolar as-prepared and laser-converted n-type QQT(CN)4 OFETs were then fabri-

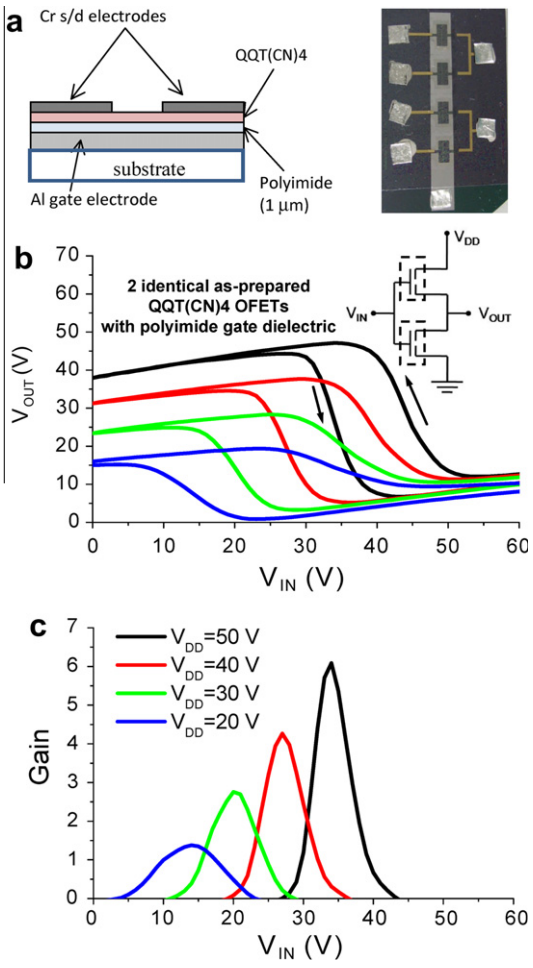

Fig. 4. (a) Schematic structure of an inverter employing two identical ambipolar as-prepared QQT(CN)4 OFETs with a 1 μm thick polyimide gate dielectric layer and Cr source drain electrodes. A top view picture of two inverter circuits fabricated on a same substrate is also shown. (b) Transfer characteristics and (c) gain of the inverter V_{DD} was varied from 20 to 50 V.

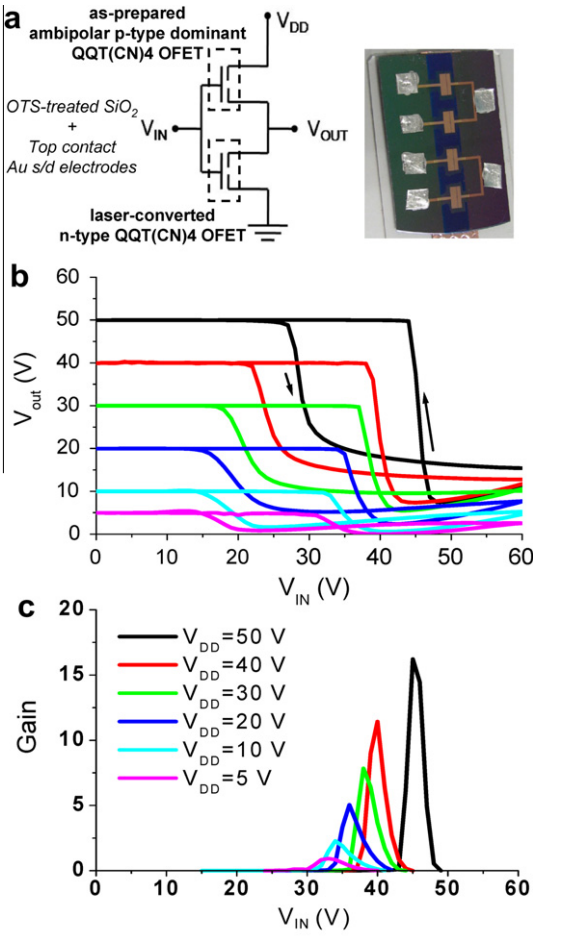

Fig. 5. (a) Schematic structure of a complementary inverter employing one ambipolar as-prepared and one laser-converted n-type QQT(CN)4 OFETs. Both transistors used an OTS-treated 300 nm thick SiO_2 gate dielectric layer and Au source drain electrodes. Laser-conversion was achieved by direct laser writing using a fiber laser emitting at 1060 nm with a power of 6.7 W. The scanning speed was 0.04 mm/s and the spot size was 300 μm. A top view picture of two inverters based on such a structure and prepared on a same substrate is also shown. (b) Transfer characteristics and (c) gain of the complementary inverter with V_{DD} varying from 5 to 50 V.

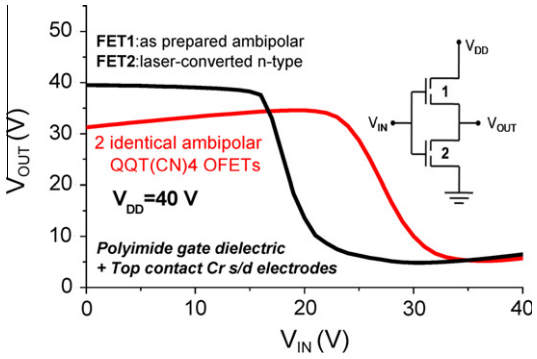

Fig. 6. (a) Transfer characteristics of the inverters employing (a) two identical ambipolar as-prepared QQT(CN)4 OFETs (red line) and (b) one ambipolar as-prepared and one laser-converted n-type QQT(CN)4 OFETs (black line). Both logic circuits used 1 μm thick polyimide film as gate dielectric layer and Cr source drain electrodes. V_{DD} was equal to 40 V. Laser-conversion was performed by direct laser writing using a fiber laser emitting at 1060 nm with a power of 6.7 W. The scanning speed was 0.1 mm/s and the spot size was 300 μm. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

cated on a single silicon substrate with OTS-treated 300 nm thick SiO_2 gate dielectric layer and were connected together to form an inverter stage. Fig. 5b shows the transfer characteristics of this logic circuit for V_{DD} ranging from 5 to 50 V. At small V_{IN} values, the ambipolar as-prepared QQT(CN)4 OFET which shows high hole field-effect mobility is on while the laser-converted OFET is off. As a result, the output voltage V_{OUT} is equal to V_{DD}. As V_{IN} is increased, the n-channel OFET is turned on and switching of V_{OUT} to low values occurs. However, because the ambipolar as-prepared QQT(CN)4 OFET is not turned off at high V_{IN} values, both devices are on and V_{OUT} cannot reach zero in the off-state of the inverter. For V_{DD} = 50 V, the output voltage swing characterizing the inversion of this circuit dramatically depends on the sweeping direction of V_{IN} and is measured to be either 42.6 V or 34.6 V. As shown in Fig. 5c, highest gain extracted from the transfer characteristics of the inverter is found to be as high as 16.2 at V_{DD} = 50 V and is still equal to nearly 1 at V_{DD} = 5 V. Overall, these results show that the laser-conversion of one QQT(CN)4 OFET from ambipolar to n-type by the direct laser writing technique can significantly improve the on-state of the inverter

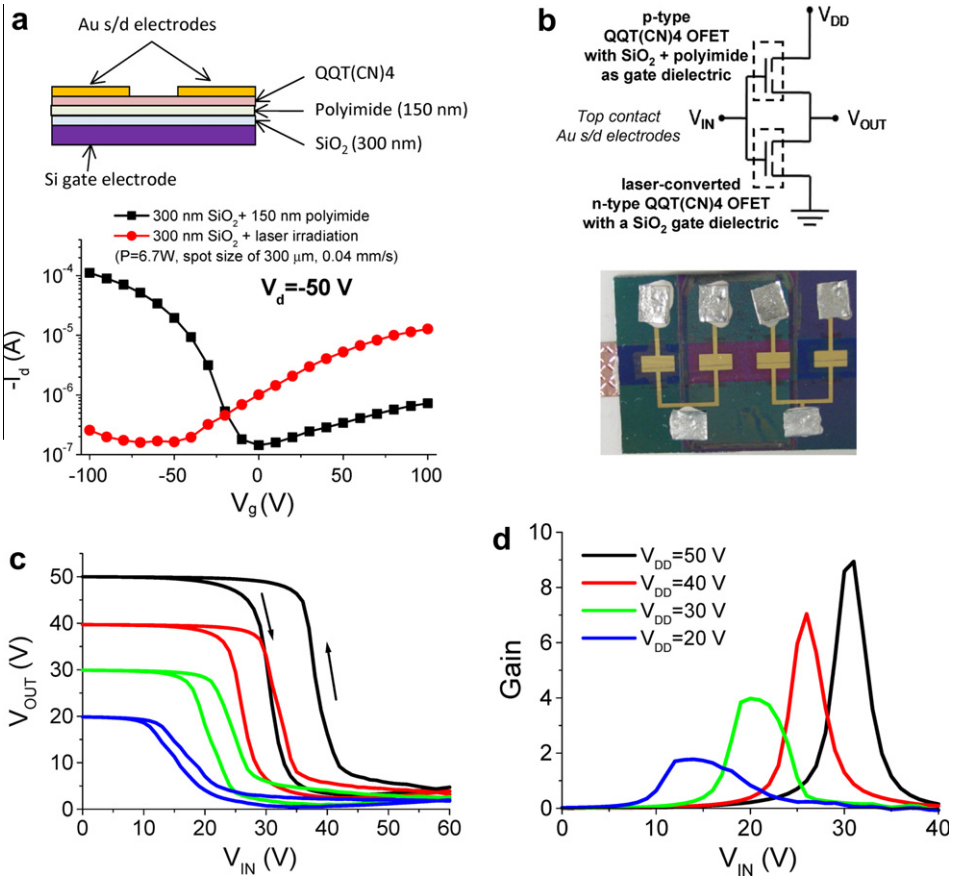

Fig. 7. (a) Transfer characteristics of p-type and n-type QQT(CN)4 OFETs at $V_d = -50$ V. The n-type device was obtained by direct laser writing and used an OTS-treated 300 nm thick SiO_2 gate dielectric layer. The structure of the p-type device is displayed. This OFET was based on an as-prepared QQT(CN)4 thin film and used a 150 nm thick polyimide layer spin-coated on top of a 300 nm thick SiO_2 layer as gate dielectric. Both transistors used top-contact Au source/drain electrodes with channel length of 45 μm and width of 4 mm. (b) Schematic representation of a purely CMOS inverter based on a single QQT(CN)4 thin film. The picture shows two inverters fabricated on the same substrate. (c) Transfer characteristics of the CMOS inverter with V_{DD} ranging from 20 to 50 V. (d) Corresponding gain measured at different V_{DD}.

and its gain. However, this approach does not lead to any improvement in the off-state and does not reduce the large hysteresis observed in ambipolar QQT(CN)4 inverters.

Fig. 6 compares, for V_{DD} = 40 V, the transfer characteristics of an ambipolar inverter and an inverter based on the combination of one ambipolar as-prepared and one photoconverted n-type QQT(CN)4 OFETs. Both logic circuits were fabricated onto a single 1 μm thick polyimide gate dielectric layer. The inversion properties of these logic circuits present similar trends as those obtained in the inverters using OTS-treated SiO_2 as gate dielectric, with the on-state improved by direct laser writing. For V_{DD} = 40 V, the output voltage swing of the photoirradiated logic circuit is measured to be around 35.2 V and is higher than the value of 29.4 V found in the ambipolar inverter. In addition, the highest gain at V_{DD} = 40 V is increased from 4.3 to 7.3 by our direct laser writing technique. Note that this behavior has been previously reported in similar QQT(CN)4 inverters fabricated onto flexible plastic substrates and patterned by thermal lithography [23].

Fig. 7a shows the schematic structure and the transfer characteristics of an ambipolar as-prepared QQT(CN)4 OFET using a 150 nm thick polyimide film on top of a 300 nm thick SiO_2 layer as gate dielectric. The device was fabricated in a top-contact configuration with gold electrodes and was characterized at $V_d = -50$ V. The result clearly shows ambipolar operation and allows us to estimate in the saturation regime hole and electron field-effect mobilities of 0.05 $cm^2/V\,s$ and 7×10^{-5} $cm^2/V\,s$, respectively. Whereas hole field-effect mobility is not notably affected by the introduction of this thin polyimide gate dielectric layer, electron transport is strongly reduced with a decrease of about one order of magnitude in mobility. This finding suggests a simple way to improve the off-state of the QQT(CN)4 inverters, the electron current in the OFET using the thin polyimide film being significantly lower than that observed in the laser-converted n-type OFET with an OTS-treated 300 nm thick SiO_2 gate dielectric. The new inverter structure is schematically represented in Fig. 7b and necessitates the patterning of the 150 nm thick polyimide film onto the substrate which can be done via the simple use of protecting tapes. Fig. 7c shows the transfer characteristics of this inverter for various supply voltages V_{DD} ranging from 20 to 50 V. This logic circuit almost shows an ideal CMOS response with V_{OUT} approaching V_{DD} and zero at low and high V_{IN}, respectively. For V_{DD} = 50 V, the output voltage swing of the CMOS inverter is equal to 46.9 V and the highest gain value is about 8.9 (Fig. 7d). It is also important to mention the notable reduction of the hysteresis in these transfer curves. Overall, these results demonstrate the possibility to fabricate a purely CMOS QQT(CN)4 inverter with enhanced performance by combining the direct laser writing technique and the patterning of a thin polyimide film onto the SiO_2 gate dielectric layer. The gain of this inverter is lower than that measured in the laser-converted QQT(CN)4 logic circuit using OTS-treated SiO_2 as gate dielectric. However, this lower gain issue is largely compensated by both the smaller hysteresis and the strong improvement of the off-state which should lead to a significant reduction of the power consumption.

4. Conclusion

In summary, we have fabricated and characterized in details the electrical properties of a series of solution-processed organic inverters based on single QQT(CN)4 thin films. Laser patterning from ambipolar to n-type QQT(CN)4 OFETs by the direct laser writing technique leads to a clear improvement of the performance in organic inverters using either OTS-treated SiO_2 or polyimide as gate dielectric layer. The laser-structured logic circuits show improved on-state at low input voltage and enhanced gain. However, they also display large hysteresis and non zero output voltage values in the off-state. To overcome these issues, we found that the introduction of a thin polyimide film spin-coated on top of a SiO_2 gate dielectric layer enables to selectively decrease the electron field-effect mobility. One laser-converted n-type OFET prepared onto OTS-treated SiO_2 and one p-type OFET fabricated onto a SiO_2/polyimide gate dielectric were successfully combined to realize a purely CMOS inverter based on a single solution-processed QQT(CN)4 thin film. This inverter presents enhanced on- and off-states as well as reduced hysteresis and gain as high as 8.9. Such a good performance qualifies this device structure as a promising candidate for applications in organic CMOS technology.

interface [7]. For example, Kobayashi et al. have described the modification and control of the electrical performance in *p*-type pentacene thin film transistors by varying the head groups of the SAM molecules, and have characterized the impact of different dipole moments of the SAM molecules at the interface [8]. Full control on the threshold voltage (V_{TH}) and the impact of the thin film morphology of the organic semiconductor has been demonstrated by using an extended series of self-assembled molecules with different functional groups (chain and head groups) [9].

Apart from the changes in properties that have been observed by using different combinations of surfaces and anchor groups (e.g., thiols, carboxylic acids, silanes, and phosphonic acids), homologous series of molecules with the same anchor group and chemically comparable molecular structure in the chain and head groups (e.g., *n*-alkanes) behave differently depending on their chain length. Although a temperature-independent exponential decrease of the tunneling current with increasing molecular chain length of *n*-alkanes is expected, several groups have observed anomalous behavior with increasing molecule length. It has been proposed that irregularities or defects in the SAM composition (loops or collapsed sites) lead to a decreased tunneling distance between the electrodes [10–12]. However, even SAMs that have been shown to form highly reliable systems, show remarkably reproducible changes in device characteristics that cannot be explained by defects, formed during SAM deposition, but rather must be due to morphological changes caused by characteristic intermolecular interactions. Recently, it was shown that the properties of organic field-effect transistors vary when the chain length of self-assembled *n*-alkyl phosphonic acids is modified. The charge carrier mobility and the morphology of a subsequent pentacene layer are affected [13–15]. Approximately, monotonic scaling is expected with increasing chain length. However, the leakage current (current density through the monolayer) saturates at long chain lengths using different *n*-alkyl phosphonic acids in molecular scale hybrid dielectrics. This effect is inconsistent with current theoretical pictures of electron tunneling through saturated *n*-alkanes. Intermolecular interactions are thus clearly of great importance for the assembly process and are instrumental in determining the SAM characteristics. A deeper understanding of these correlations is necessary in order to be able to construct molecular scale electronics rationally and to design suitable component molecules.

We now report a combined experimental and computational study of the morphology of SAMs based on *n*-alkyl phosphonic acids. The insulating nature of the SAMs, in particular those with longer chain lengths, on insulating Al_2O_3, means that direct access at atomic scale resolution (e.g., scanning tunneling microscopy – STM) is not possible. Other techniques require extremely flat surfaces (small angle X-ray scattering – SAX) and/or provide average data on thin films, lacking in local or 3D-resolution important for understanding the intermolecular effects of assembly (XPS, AFM). However, as the conduction mechanism in self-assembled monolayers of saturated alkyl chains has been clearly identified as non-resonant tunneling, electrical data can give information about the structural properties and the nature of the molecular ordering [16–19]. We report divergence of the dependence of the electrical properties of SAM-based capacitors and pentacene transistors from that expected on the basis of extrapolations of the chain length. These observations are consistent with a change in the self-assembled monolayer morphology from an amorphous state for short alkyl chains (C_6) to a quasi-crystalline state for alkyl chains from C_{10} to C_{18}. The data from electrical measurements of the thin film devices were interpreted using the Simmons model to account for the observed properties of these layers in terms of their structural organization [19]. We have also used molecular dynamics (MD) simulations as tool to provide deeper insight into the nature of the intermolecular interactions and to identify the most probable molecular assembly of the different monolayers. The proposed change in SAM morphology is consistent with the measurements of the current densities and supported by vibrational sum frequency generation (VSFG) spectroscopy results.

2. Experimental details

2.1. Device fabrication

For the fabrication of the organic/inorganic dielectrics, heavily *p*-doped silicon wafers act as substrate and serve as bottom (gate-) electrode. The inorganic part of the hybrid dielectric is grown via atomic layer deposition, yielding uniform aluminum oxide films of 2 nm thickness. The deposition was realized in a commercial Cambridge Inc. ALD reactor at 250 °C with a constant deposition rate of 1 Å per cycle. The layer thickness and composition was validated by ellipsometry and XPS measurements. The RMS roughness of the almost stoichiometric Al_2O_3 layer (relative precursor concentration <5%) was determined by AFM (contact mode) to be in the range of 0.2 nm for 1 μm^2 (Veeco Digital Instruments Dimension 3100). The organic part of the dielectric is generated by a self-assembling monolayer of *n*-alkyl phosphonic acids from solution, according to literature [2,14]. The thickness of the self-assembled monolayer correlates to the length of the stretched molecule which was calculated with ChemBioOffice 2008 (tilt angles were not considered). The capacitor stacks, containing hybrid dielectric were completed by 50 nm gold evaporated through a stencil mask (deposition rate: 0.1 nm s^{-1}), yielding single devices with an electrode area of 150 × 150 μm^2. In the case of organic transistors, preliminary to the deposition of the gold source/drain contacts, defining a channel length of 20 μm and a channel width of 150 μm, 30 nm pentacene was thermally evaporated (rate of 0.01 nm) through another stencil mask.

2.2. Electrical characterization

The electrical characterization of the capacitors and transistors was performed in ambient conditions by manually probing single devices (yield of ~90%). The transistors and the capacitor stack were contacted from the back via the low noise chuck of the probe station. To guarantee the intactness of the SAM, the top electrode was probed accurately by special probe tips for small targets

(Micromanipulator Probe Tips 7F10). Capacitance measurements with a LCZ meter (HP4277) are proceeded in the voltage range between −2 V and 2 V (double sweep, in steps of 100 mV) at a frequency of 100 kHz. Reference measurements to obtain the dielectric constant of the Al_2O_3 were performed previously (Supplementary data). Each measurement was repeated on at least five devices, yielding identical results. Electrical data of capacitor and transistor devices were recorded with a semiconductor parameter analyzer (Agilent 4156C). A minimum of 20 capacitors of each species, 10 in positive (0 to +2 V) and 10 in negative (0 to −2 V) bias polarity were investigated in single sweep mode, in steps of 40 mV. The thermal stability of the tunneling current through the hybrid dielectric was preliminary verified over a temperature range of ~80 K. The conduction mechanism in the observed voltage range was identified as direct tunneling, which is generally accepted for SAMs of saturated alkyl chains [16,17]. Transfer characteristics of at least 10 pentacene transistors for each SAM are recorded for source–gate voltage V_{GS} between 0 and −2 V in double sweep mode at a source–drain voltage of $V_{DS} = -1$ V. For each TFT the charge carrier mobility was calculated in the saturation regime using the standard formalism for field-effect transistors: $\mu = 2 \times L/(W \times C_{diel}) \times (\delta\sqrt{I_D}/\delta V_{GS})^2$, where C_{diel} is the measured dielectric capacitance, I_D is the drain current, and V_{GS} is the gate-source voltage [14,20]. Benefiting from the smooth substrate the deviations are negligible.

2.3. Simulation

All molecular dynamics simulations were carried out, using the program NAMD [21]. For the initial setup and for parts of the analysis the programs *antechamber*, *leap*, and *ptraj* from the Amber package were used [22]. The parameters are based on the general Amber force field (GAFF) [23]. The Al_2O_3 surface represents a regular 1 0 0 surface with 850 atoms in total (52 × 38 nm) and was build with Materials Studio [24]. The surface atoms were constrained in their position during the simulations. For each simulation 80 phosphonic acids were placed on the surface. The phosphonic acids were treated singly deprotonated (most reasonable approach, due to DFT calculations) and the atomic AM1-VESPA point charges were derived from semiempirical calculations with VAMP 10.0 [25,26]. Each system was minimized, equilibrated, and simulated in vacuo with periodic boundary conditions. The electrostatics were treated with particle-mesh Ewald (PME) long range electrostatics and a 10 Å cutoff for non-bonded interactions [27]. The width of the non-bonded skin was 2.0 Å. Langevin molecular dynamics with a target temperature of 350 K were performed. The complete simulation time for each system was 10 ns with an integration time step of 1 fs.

3. Results and discussion

The morphology and device characteristics of SAMs of *n*-alkyl phosphonic acids (C_6-, C_{10}-, C_{14}- and C_{18}-PA) were investigated on 2 nm thick atomic layer deposited (ALD) Al_2O_3 deposited on *p*-doped single crystalline silicon as back electrode. This stack was chosen to achieve full control of the Al_2O_3 thickness and to provide a smooth surface to ensure that the self-assembly is not significantly affected by surface roughness (typical ALD-Al_2O_3 surface roughness RMS of a 1 μm² is 0.2 nm). In Fig. 1a the drain

currents (I_D) and gate currents (I_G) of the pentacene transistor devices with different SAMs are presented. As the electrical characteristics (I_D/I_G, ON/OFF ratio, and V_{TH} – Table 1) scale with the chain length as expected for C_6-PA, C_{10}-PA and C_{14}-PA, the devices with C_{18}-PA behave very similarly to those with C_{14}-PA. The most remarkable feature is the resemblance in the progress of I_G, despite the fact that the C_{18}-PA is approximately 0.5 nm longer than the C_{14}-PA. This anomaly is even more pronounced in capacitor devices (Si/ALD-Al_2O_3/SAM/Au – Fig. 1b) and is consistent with results found for integrated devices (Al/Al_2O_3/SAM/Au) with the same molecules [14]. While the values of capacitance (measured and calculated) fit the theoretical monolayer thickness well, the current densities (J) do not follow the theoretical exponential decrease (for a constant SAM morphology) with molecule length for longer chains (Fig. 1c). Although the capacitance as an average area depending parameter is only sensitive to the mean thickness in an alternating electrical field, the current density (J) is very sensitive to weakest point in the layer. The results of MD simulations of the corresponding SAMs on Al_2O_3 surfaces are shown in Fig. 1d. The MD simulations were performed for a time scale of 10 ns, which should be long enough to provide insight into the molecular structure of the SAMs. The calculated SAM morphology changes with increasing chain length from an amorphous state for C_6-PA to a more ordered state for C_{10}-PA to highly ordered (crystalline) domains separated by gaps for C_{14}-PA and C_{18}-PA.

Considering that these morphologies, and in particular the gaps, can be penetrated by the subsequently evaporated layer (e.g., Au in a capacitor device), a reduced distance between the bottom (Si) and top electrode (Au) is expected. Schematic sketches of the corresponding device cross sections are shown in Fig. 2a. Using these assumptions, the experimental results of the capacitor devices were correlated to the Simmons model for tunneling through a thin isolating film to calculate the effective monolayer thickness [28]. No gaps are expected for amorphous SAMs with short chains (C_6-PA). The distance between the electrodes is shorter at a gap in the SAM for longer chains (C_{18}-PA) because the thermally deposited gold can penetrate into the gap to reduce the effective thickness of the layer. This increases the tunneling current through the monolayer significantly [19,28]. The Simmons model for direct tunneling through large area molecular junctions was used to fit the experimental data. The tunneling current density J is given by:

$$J = J_0\left(\phi \cdot \exp\left(-A\sqrt{\phi}\right) - (\phi + eV) \cdot \exp\left(-A\sqrt{\phi + eV}\right)\right) \quad (1)$$

where

$$J_0 = \frac{e}{2\pi h(\beta d)^2} \quad (2)$$

and

$$A = \frac{4\pi\beta d\sqrt{2m_e^*}}{h} \quad (3)$$

with h being the Planck constant, e the electron charge, β a correction parameter (0.96) and V the applied voltage (intermediate voltage range $V < \Phi/e$). According to literature a fixed effective electron mass of $m_e^* = 0.28$ me, common for saturated n-alkanes and an arbitrary mean barrier height of 5.1 eV, only one fit parameter remains for modeling the experimental tunneling current, the width d of the potential barrier [19,29]. Fig. 2b, shows the fitting results for the chosen parameters and varying barrier widths. The total length of the tunneling path between the two electrodes correlates to the different SAM thickness. The experimental values for J are described well in the intermediate voltage range (-0.3 to -1 V) by the parameter set used. Details are provided in Table S1 of the Supplementary data. While the effective monolayer thickness of 0.9 nm for C_6-PA and 1.2 nm for C_{10}-PA agree well with the calculated molecule length, there is a clear mismatch with respect to the real layer thickness for C_{14}-PA and C_{18}-PA. For extended molecular lengths of approximately 1.9 nm for C_{14}-PA and 2.4 nm for C_{18}-PA, the fitted barrier width corresponds to an effective monolayer thickness of only 1.3 nm for C_{14}-PA and 1.4 nm for C_{18}-PA.

These reduced thicknesses can be attributed to the formation of leakage paths such as gaps in the monolayers and result in the observed increase of current density. Fig. 2c shows a quantitative evaluation of the MD data. By imposing an XYZ matrix grid of 2 Å, the cell occupancy and accessibility from the top can be obtained as functions of the surface distance and topography. Exemplarily, the data for C_6-PA and C_{18}-PA demonstrate the length-dependent trend to form gaps and crystalline domains. Longer molecules are more likely to organize into crystalline domains than shorter ones because of the increased van der Waals interactions between the longer chains, that also cause the semi crystalline behavior of polyethylene (PE), which consists of the same building blocks than our SAM chains [30]. Further investigations of the SAMs by VSFG lead to the same conclusion. By comparing the intensity ratio of the CH_3 and CH_2 symmetric stretch modes in the sum frequency spectra, the ordering of a SAM can be qualitatively determined. This ratio is a measure of molecular order since conformational disorder decreases the CH_3 symmetric stretch intensity and increases the CH_2 intensity because they lose their locally centrosymmetric structure [31,32]. Our measurements reveal a clear tendency to a more ordered morphology for longer molecules indicated by an increasing CH_3 to CH_2 intensity ratio (Supporting information).

We propose that the self-assembling of molecules with shorter alkyl chain is dominated by the footprint of the phosphonic acid and yields electrically dense and amorphous monolayers. Molecules with longer alkyl chains organize into highly ordered quasi-crystalline domains separated by gaps, due to competition between the space requirements of the phosphonic acid and the van der Waals interactions of the alkyl chain [15]. Fig. 3 shows snapshots from the MD simulations that illustrate the change in morphology for increased chain lengths.

The surface distance for each of the four phosphonic acid molecules investigated is plotted against the occupancy. The first few nanometers of each monolayer are closely packed (occupancy of one) and impenetrable for arriving atoms and molecules of the subsequent layer. As the distance to the surface increases the occupancy value drops to zero at the stretched length of the molecule. For densely packed monolayers this decrease occurs abruptly, as shown for C_6-PA at a surface distance of about 1 nm. For longer molecules (C_{10}-PA to C_{18}-PA) a more gradual decrease is observed, indicating a closer stacking of the molecules to form crystalline domains and free space. This gradual decrease is most pronounced for C_{18}-PA and reflects the anomalistic feature of long chain SAMs. As the occupancy can be expressed as the geometrical dimension of the gaps at a certain distance to the surface, a critical value can be defined where gold atoms or semiconductor molecules are able to penetrate into the surface and consequently reduce the tunneling distance for the charge carriers. Setting the critical surface occupancy to an arbitrary value of about 0.90, the corresponding layer thickness can be determined from the plot. The monolayer thicknesses thus obtained (C_6-PA = 0.85 nm, C_{10}-PA = 1.13 nm,

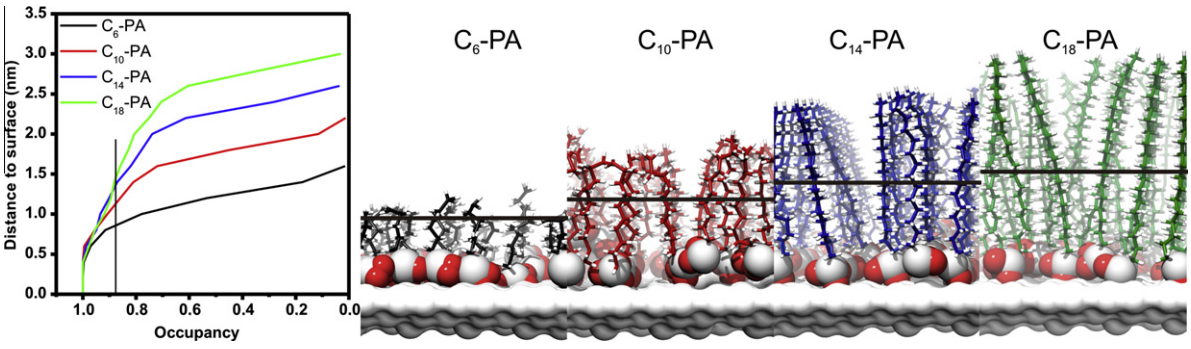

Fig. 3. Distance to surface versus occupancy plot correlated to snapshots of the MD calculations for n-alkyl phosphonic acids. The black lines indicate an occupancy of about 90% and the corresponding effective monolayer thickness.

C_{14}-PA = 1.39 nm, and C_{18}-PA = 1.46 nm) agree well with the calculated effective monolayer thickness obtained by the Simmons model described above.

However, the influence of the top layer of the devices on the ordering of the molecules and the effective monolayer thickness is not yet clear. In fact, both device setups, transistors and capacitors, show the observed feature, independent of the subsequent layer. As the MD simulations do not include the top conductor layer, it is conceivable that the penetrating molecules and atoms may expand the gaps or even cause additional gaps to form, thus increasing the number of short tunneling pathways. The presence of gaps and crystalline domains can have a strong impact on the morphology (grain size) of the subsequent pentacene layer, as observed by Hill [13]. An increased number of nucleation centers (edges of the crystalline domains) translate directly to smaller grain sizes in pentacene layers on C_{18}-SAMs (Supplementary data – Fig. S2), which affects the transistor parameters as observed [33]. As the reported feature is attributed to the different space requirements of anchor groups and alkyl chains, in other systems like thiols or silanes, similar effects are not observed so far. However, a possible way to benefit from the stability of the phosphonic acids and to overcome the structural mismatch is to synthesize molecules containing head groups or substituents that may compensate the different space requirements [1].

4. Conclusion

In conclusion, we have investigated the molecular ordering of self-assembled monolayers, both experimentally and using simulations. Combining the Simmons model with the results of the molecular dynamics simulations allows us to reproduce the observed anomalistic dependence of the electronic properties on the molecular chain length in SAMs based on *n*-alkyl phosphonic acids. The combination of the two approaches results in a reduced effective monolayer thickness compared to those expected for extended chains. This trend is more pronounced for longer alkyl chains as the molecular interaction of the carbon backbone facilitates the formation of highly ordered domains with gaps between them. Simultaneously, a change in SAM morphology from amorphous to quasi-crystalline from shorter to longer alkyl chains was observed by VSFG measurements. In general, our study shows that even small changes in the chain length can change the molecular interactions and monolayer assembly significantly. This is of enormous importance in molecular scale electronics as the device parameters are actively tunable by the molecular design (anchor group, chain, or possible "active" head group).

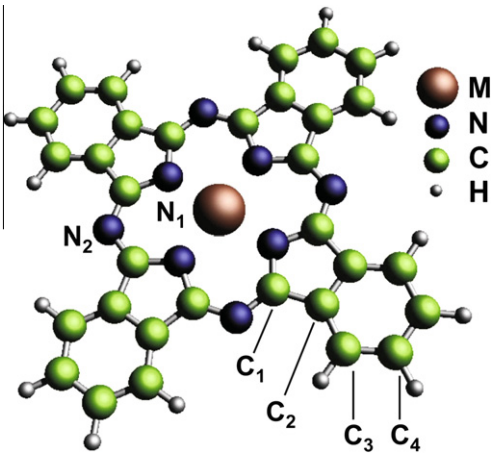

Fig. 1. Schematic illustration of the chemical structure of a transition metal phthalocyanine molecule. With M the central transition metal ion is denoted, which is surrounded by four pyrrole nitrogen (N1) and four bridging aza nitrogen (N2) atoms. The 24 carbon atoms in the outer benzene rings are labeled with C-2, C-3, and C-4, respectively. With the label C-1 the 8 pyrrole carbon atoms are denoted.

TMPc's remained unknown, which is contrasted by the profound importance of the electronic properties for the physical behavior of these materials.

Transition metal phthalocyanines as carbon-based molecules are build by a well defined and very stable π-conjugated macrocycle ring (abbreviated Pc for the phthalocyanato ion $C_{32}H_{16}N_8^{2-}$). The structure of a TMPc is shown in Fig. 1. They are characterized by the presence of a transition metal (M) ion (e.g. Mn, Fe, Co, Ni, Cu or Zn) in the formal oxidation state 2+ in their central cavity, which is surrounded by four pyrrole nitrogen (N_1), four bridging aza nitrogen (N_2), eight pyrrole carbon (C_1) as well as 24 benzene ring carbon (C_2, C_3, and C_4) atoms. Thereby, the Pc ring acts as ligand to the central transition metal ion, and the Pc^{2-} ligand forms a neutral complex with the divalent transition metal ions, whereas the bonding between the ligand and the central transition metal ion is also significantly covalent [29]. TMPc's have a planar structure with a D_{4h} point symmetry, which has been well established by experiments and calculations [30,31]. The crystal structure of the TMPc's is practically identical [32], and thin semiconducting films of TMPc's can be grown of equivalent quality independent of the transition metal [33–36]. Under the consideration that the molecules are placed in the *xy*-plane, the five metal 3*d* orbitals transform as a_{1g} (d_{z^2}), b_{1g} ($d_{x^2-y^2}$), e_g (d_π, i.e., d_{xz} and d_{yz}), and b_{2g} (d_{xy}). Thereby, the energetic order of the orbitals depends on the strength and the type of the distortion, and on hybridization effects of the metal 3*d* orbitals with the ligand orbitals. An *a-priori* determination of the energetic orbital order is not easily possible, but has to be verified by experimental investigations. For many transition metal phthalocyanines there is no complete microscopic understanding of the electronic and spin ground state. In particular, there are contradicting predictions and experiments in regard of the orbital ground state of the transition metal center [37–44].

In this contribution, we investigate experimentally the impact of the transition metal center on the electronic properties of TMPc's using electron energy-loss (EELS) and photoemission (PES) spectroscopy. By our combined spectroscopic approach we demonstrate that for the d^{10}–d^8 case (ZnPc, CuPc, and NiPc) low energy electronic properties are exclusively determined by the ligand π states. For CoPc, FePc, and MnPc the metal 3*d* states however have increased impact as they come very close in energy to the lowest unoccupied ligand orbital.

2. Experimental details

For our investigations using electron energy-loss spectroscopy (EELS) in transmission we have prepared TMPc films with a thickness of about 100 nm by thermal evaporation of the organic material onto single crystalline KBr substrates. The KBr crystals were kept at room temperature during the deposition process. Subsequently, the TMPc films were floated off in distilled water and mounted onto standard electron microscopy grids. By using this procedure we could prepare free-standing films for the EELS investigations. Prior to the EELS measurements the films were characterized in-situ using electron diffraction. This revealed that the films were essentially polycrystalline.

The electron energy-loss spectroscopy measurements in transmission were carried out at room temperature using a 170 keV spectrometer described elsewhere [45], and we note that at this high primary beam energy only singlet excitations are possible. The energy and momentum resolution were chosen to be 85 meV and 0.03 $Å^{-1}$, respectively. We have measured the loss function $\Im(-1/\epsilon(\vec{q},\omega))$ ($\epsilon(\vec{q},\omega)$ is the dielectric function) for a small momentum transfer $\vec{q}$, parallel to the film surface [45]. Further details of the sample preparation procedure and the experimental technique can be found in previous publications [45,46].

The X-ray (XPS) and ultra-violet (UPS) photoelectron spectroscopy experiments have been carried out using a commercial PHI 5600 spectrometer, which is equipped with two light sources. A monochromatized Al K_α source provides photons with an energy of 1486.6 eV for XPS. Photons with an energy of 21.21 eV from a He discharge lamp can be used to perform valence band measurements. All ultra-violet photoemission spectroscopy measurements were done by applying a sample bias of −5 V to obtain the correct, sample determined, secondary electron cutoff. The recorded spectra were corrected for the contributions of He satellite radiation. The total energy resolution of the spectrometer was determined by analyzing the width of the Au Fermi edge to be about 350 meV (XPS) and 100 meV (UPS), respectively. The binding energy (BE) scale was aligned by measuring the Fermi edge (0 eV) and the Au4$f_{7/2}$ emission feature (84.0 eV) of a polycrystalline gold substrate. Applying several cycles of Ar^+ sputtering (3 keV, 10^{-8} mbar), the polycrystalline gold foils were cleaned. Additionally, we have checked the surface composition of the sputter cleaned substrates by using X-ray photoelectron spectroscopy and did not monitor any sign of contaminations.

In a preparation chamber (base pressure 3×10^{-10} mbar), which is directly attached to the spectrometer system, TMPc films with a film thickness of about 50–60 Å have been prepared by in situ thermal evaporation with a typical evaporation rate between 1 Å/min. and 2.5 Å/min. on the gold substrates. Subsequently, the films were transferred to the analyzer chamber (base pressure 1×10^{-10} mbar) without breaking the vacuum and characterized taking a full range XPS spectrum. The number of impurities in the films was very small and below the detection limit of XPS due to the ultra-high vacuum conditions during the preparation process of the organic films. To estimate the thickness of the individual TMPc films we have monitored the attenuation of the intensity of the Au4$f_{7/2}$ substrate peak due to the organic film. Considering the procedure of Seah and Dench [47] we have calculated the mean free path of the electrons in the TMPc films to be about 2.54 nm for the kinetic energy of 1402.6 eV of the Au4$f_{7/2}$ signal from the substrate and a density of 1.62 g/cm^3 for the transition metal phthalocyanines [48,49]. We point out that this procedure to determine the thickness of the organic layers is only correct for a layer-by-layer growth. If the organic films does not grow uniformly this methods underestimates the film thickness, which is not important for our results discussed below.

3. Results and discussion

3.1. Electron energy-loss spectroscopy

As mentioned above TMPc's exhibit remarkable optical properties with an intense absorption in the visible energy region due to the conjugated π-system of the molecules. In the past decades the interpretation of this behavior has been the subject of a large number of theoretical studies [1,32,50–57]. The excitation spectra in the visible are characterized by two major excitation features. First, the Q-band located at about 2 eV is generally interpreted in terms of $\pi - \pi^*$ transitions between bonding and antibonding molecular orbitals [54]. In the UV region at higher energies the Q-band is followed by the so-called Soret (B)-band arising also from $\pi - \pi^*$ transitions.

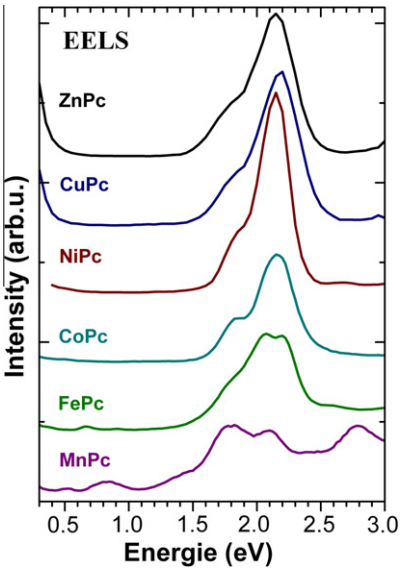

Fig. 2. Electronic excitation spectrum for TMPc films as measured using electron energy-loss spectroscopy at a momentum transfer q of 0.1 Å^{-1} representing the optical limit.

Fig. 2 displays the electronic excitation spectra of TMPc's as measured by electron energy-loss spectroscopy at a momentum transfer q of 0.1 Å^{-1} up to 3 eV. At such a small momentum transfer the data obtained by EELS can be directly compared with the optical once, since the momentum transfer q of 0.1 Å^{-1} represents the optical limit [45]. Inspection of Fig. 2 allows the identification of a number of excitation maxima and shoulders for the different TMPc's summarized in Table 1. We note that all excitation features >0.6 eV are also observed for the TMPc's disolved in dimethylsulfoxide (DMSO) as well as α-chlornapthalene (data not shown). This is also well documented in the literature [58]. On going from solution, i.e., individual molecules, to thin films a drastic broadening of the excitations occurs, also in correspondence to previous studies [59,60]. In the past this broadening has been discussed in terms of a Davydov splitting and/or the consequence of intermolecular interaction that give rise to charge transfer excitations [61,62]. The first, prominent excitation feature is clearly visible for all TMPc's at about 1.7–2 eV and is due to excitations from the ligand a_{1u} orbital into the ligand e_g orbital.

Only for FePc and MnPc there are further excitations visible at energies below the Q-band region. In detail, the excitation spectrum of FePc is characterized by low energy excitations at 0.65, 0.9, and 1.1 eV, while in the case of MnPc we observe low energy features at about 0.5, 0.75–0.9, and 1.34–1.4 eV. We emphasize that especially the excitations below 1 eV are scarcely addressed in the literature so far despite the fact that they are most likely related to the interaction between the central ion and the phthalocyanine macrocycle, and thus can give valuable insight into the orbital ground state of the central metal ion [50,63]. Various theoretical works addressed the ground state and the orbital ordering in FePc [64,41,39,37] and MnPc [65,25,53,37], respectively. We emphasize that there is no agreement between published calculations, instead three different types of ordering have been proposed for FePc [64,41,39,37] and MnPc [65,25,53,37]. In the vicinity of the chemical potential, the relevant orbitals are the ligand orbitals with a_{1u} and e_g symmetry, but also the metal 3d orbitals with e_g ($d_{xz,yz}$), a_{1g} ($d_{z^2-r^2}$), b_{2g}($d_{xz,yz}$) symmetry become very close in energy [1,38,66]. The presence of low energy excitations for FePc and MnPc clearly depicts partially filled metal 3d states slightly above the ligand (a_{1u}) orbital [50,63]. In such a case, excitations from the ligand a_{1u} state into these metal 3d states would appear at low energies as observed in Fig. 2. Moreover, in consideration of selection rules for such excitations, the only metal 3d states that can give rise to visible electronic excitation in the optical limit are those with e_g symmetry.[1] Thus, from

[1] Considering the direct products of the irreducible representations of the highest occupied ligand orbital (a_{1u}) and the metal 3d levels (b_{1g}, b_{2g}, a_{1g}, e_g) in point group D_{4h}, only $a_{1u} \times e_g = e_u$ is optically allowed.

Table 1
Absorption energies of transition metal phthalocyanines measured by electron energy-loss spectroscopy (all values given in eV).

MnPc	2.07	1.7–1.8	1.35–1.4	0.75–0.9	0.5
FePc	2.0	1.8	1.1	0.9	0.65
CoPc	2.2	1.8			
NiPc	2.15	1.7–1.9			
CuPc	2.18	1.7–1.9			
ZnPc	2.15	1.7–1.9			

our EELS studies we can already conclude the presence of only partially filled metal e_g states somewhat above the ligand a_{1u} orbital. Since these 3d states with e_g symmetry hybridize with the (lowest unoccupied) ligand e_g states, other properties of the phthalocyanine molecules must also be affected by the close vicinity of further (partially) empty states to the chemical potential.

3.2. Photoemission spectroscopy

Fig. 3 displays the measured C1s core level photoemission spectra of the transition metal phthalocyanines for a film thickness of 50–60 Å. These data slightly differ in the binding energy of the C1s emission features of the different TMPc's, which we attribute to slightly different positions of the chemical potentials in the films. The decomposition of the spectra confirms previously reported conclusions [67–72] that the C1s excitation consists of two different main features (labeled C–C and C–N in Fig. 3b) accompanied by two satellite features (labeled S_{C-C} and S_{C-N}) at higher binding energies (BE). Previously, the two main features C–C and C–N have been attributed to photoelectrons from the 24 carbon atoms in the outer benzene rings (see labels C-2, C-3, and C-4 in Fig. 1) and to the 8 pyrrole carbon atoms (label C-1 in Fig. 1), respectively. In addition, each component is accompanied by an additional less intense satellite contribution (S_{C-C} and S_{C-N}) at higher BEs. These are due to shake-up structures ($\pi \rightarrow \pi^*$ satellites) related to final state screening [67–72]. Note that the S_{C-C} satellite overlaps with the C–N main feature, i.e., a detailed analysis can only be achieved by a fit as presented in Fig. 3b. Prior to the fitting procedure, a Shirley background was subtracted from the experimental data. The results from this fitting procedure give a relative intensity ratio of the emission from the two sets of carbon atoms of about 3, which is exactly what is expected.

While the overall shape of the spectra as shown in Fig. 3a hardly changes between the different TMPc's, the fit analysis reveals that the relative binding energies of the two main components do change, which is depicted in Fig. 3c. While this energy difference is virtually constant going from ZnPc to CoPc, it substantially decreases for FePc

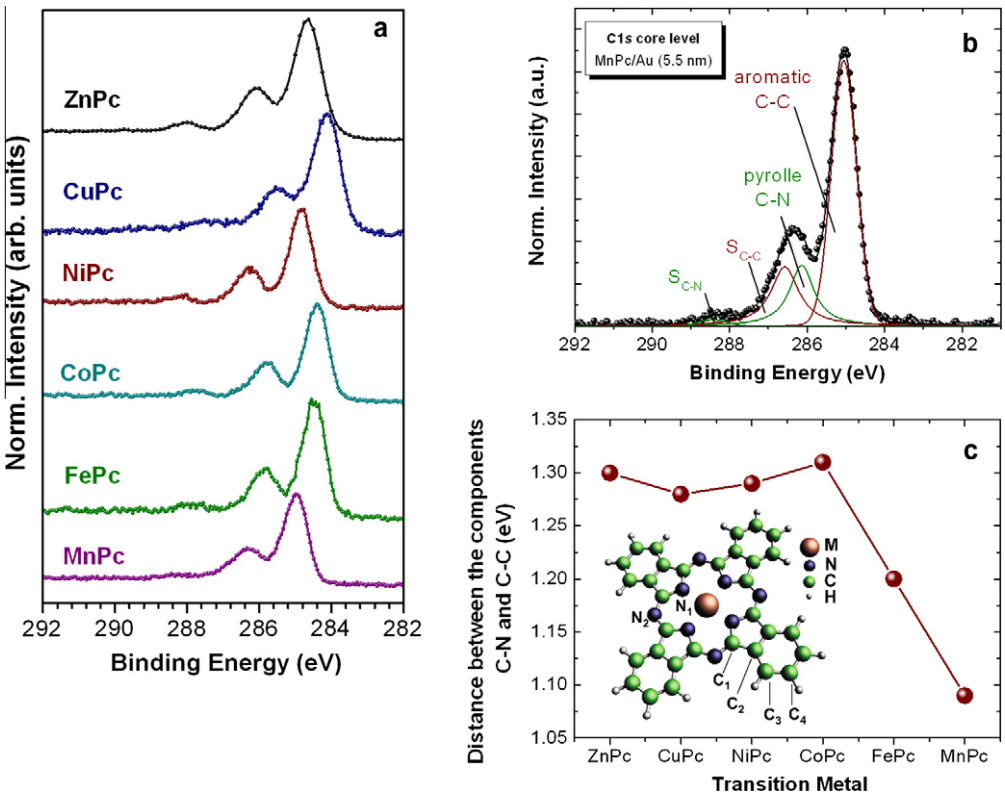

Fig. 3. C1s XPS excitation spectra as a function of the transition metal center ion (CuPc, NiPc, CoPc, FePc, and MnPc).The film thickness of the TMPc films was about 50–60 Å (a). In (b) the C1s core level spectrum for MnPc is shown. One can distinguish the aromatic carbon (C–C) and its satellite (S_{C-C}). and the carbon atoms which are linked to nitrogen atoms (C–N) and its satellite (S_{C-N}). (c) Depicts the change of the binding energy of the C–C as well as C–N components of the C1s excitation feature for the different transition metal phthalocyanines films with a thickness of 50–60 Å. As reference point we have used the values for ZnPc. The inset in Fig. 3c depicts the molecular structure of TMPc's as also depicted in Fig. 1.

and MnPc. This signals that the two sets of carbon atoms become less inequivalent for the latter two molecules. In connection to the EELS data discussed in the previous section, we ascribe this change to the increasing mixing of the metal and ligand wave functions, in particular to the hybridization of the metal 3*d* and ligand e_g states. This hybridization causes an internal charge transfer with the ligand e_g state now being slightly occupied. In view of the distribution of the ligand e_g wave function over the molecule, which has a stronger pyrrole character [42,73], it is no surprise that the additional charge on the ligand due to hybridization of the metal and ligand e_g states also affects the C1*s* core level data differently. Thus, the behavior of the binding energies as expressed in Fig. 3c confirms our picture that for FePc and MnPc the metal e_g states are energetically close to the ligand states with the same symmetry and that these two then significantly mix.

Finally, we present the valence band spectra of the transition metal phthalocyanines in Fig. 4. In general, the data in Fig. 4 confirm what has been published previously for some of the materials [74–77]. All spectra show a structure around 1.5 eV which is due to the emission from the highest occupied a_{1u} ligand state. At higher energies, further features from deeper lying orbitals are seen. Close inspection of the series as shown in Fig. 4 reveals additional information. There is a valence band feature, highlighted by the arrow, which is moving towards the chemical potential on going from top to bottom. We assign this feature to an electronic state that has significant metal 3*d* character. This first assignment is in agreement with the expectation that going down the transition metal series, the metal 3*d* levels move upwards in energy, mainly due to the smaller effective nuclear charge [38]. The consideration of photoemission cross sections can give more information on this state. At the photon energy of 21.21 eV as used in this study, the probability for emission from a carbon or nitrogen 2*p* orbital, which form the π system of the ligand, is larger than that from a transition metal 3*d* state [35,74,78,79]. This has already been demonstrated previously by other photoemission studies [80]. Therefore, the photoemission feature moving to lower binding energy in Fig. 4 most likely represents an electronic state that has a mixed wave function, which consists of metal 3*d* and ligand states. Then, this state becomes visible owing to the ligand contribution, while its energy shift reflects the energy variation of the metal 3*d* states relative to those of the ligand. Thus, the photoemission data exactly reflect what has been concluded above, i.e., the close vicinity of 3*d* and ligand states in particular for FePc and MnPc. Moreover, the most likely candidate of a metal 3*d* level that can hybridize with ligand orbitals close to the chemical potential is that with e_g symmetry, also in good correspondence to the discussion above.

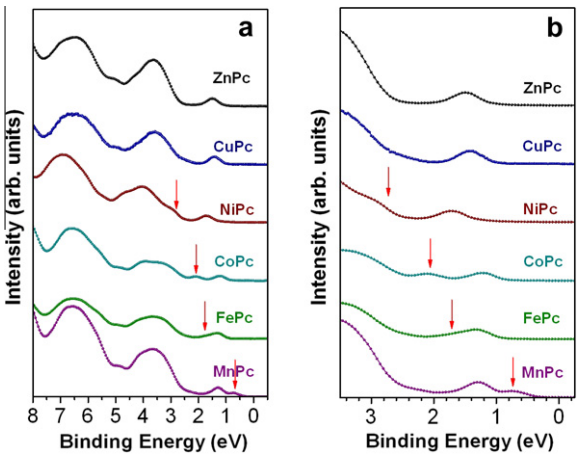

Fig. 4. The comparison of the valance band photoemission spectra of CuPc, NiPc, CoPc, FePc, and MnPc taken with a photon energy of 21.21 eV up to 8 eV is depicted in (a). On the right hand side in (b) for a better distinction of the differences in the spectra the valence band spectra are shown up to 3.5 eV. The film thickness of the TMPc films was about 50–60 Å.

Finally, we note that recent photoemission studies of CoPc with photon energies larger than 21.21 eV revealed the presence of an additional valence band feature at smaller binding energies than the ligand a_{1u} state [79]. This additional state has also been observed in scanning tunneling spectroscopy studies [81], and it has been attributed to the Co 3*d* a_{1g} orbital, which does not mix with the ligand π system. This demonstrates that further studies of other TMPc's are necessary in order to unravel all relevant electronic states near the chemical potential and their consequences, and to achieve a complete microscopic picture of the electronic degrees of freedom.

4. Summary

To summarize, our systematic spectroscopic study of transition metal phthalocyanines using electron energy-loss and photoemission spectroscopy has shown that the electronic states near the chemical potential become substantially influenced by metal 3*d* states in the case of FePc and MnPc. This has direct consequences on physical properties such as electronic excitation spectra or ionization potentials. CoPc represents an intermediate case where metal 3*d* states already are present but with lesser impact, and the low energy electronic behavior of NiPc, CuPc and ZnPc is determined by ligand orbitals only.

UV laser. It was found that the highly absorbed wavelength produces a good film and poorly absorbed will result in a powdery film. It was also found that, even though molecular weight is reduced there is no change in chemical composition of the molecules during ablation [13]. Satoru Nishio et al. studied the structural difference in the polyacrylonitrile (PAN) films with various laser wavelengths. Films of PAN were deposited for wavelengths 308 nm (XeCl), 248 nm (KrF) and 193 nm (ArF). It was found that the original structure of PAN is retained for the films deposited by ablation at 308 nm and deformation and elimination of nitrile groups occur for the films prepared by ablation at 248 nm and 193 nm, respectively. Furthermore, power dependent structural change at 248 nm was found [14]. Recently a new method of ablation has been developed called matrix assisted pulsed laser ablation (MAPLE) [15]. Sellinger et al. produced PMMA films with up to 2 wt.% carbon nanotube (CNT) in MAPLE technique using KrF laser [9]. Vrnata et al. deposited thin layers polypyrole (PPy) by MAPLE technology. Deposition was carried out by KrF excimer laser with PPy in water and dimethylsulfoxide matrix [10]. In this paper, we will discuss about fabrication of device quality films from polypyrrole-multiwalled carbon nanotube (PPy–MWCNT) nanocomposites with high loadings by pulsed laser ablation. Nanotube loadings up to 80 wt.% were used to evaluate appropriateness of employing laser ablation technique for fabrication of device quality films of nanocomposites.

2. Experimental section

2.1. Materials

MWCNT's (diameter 10–20 nm, length 10–50 μm) produced by catalytic vapor decomposition technique and with a purity of >95% were purchased from Iljin Nanotech Co. Ltd., South Korea. Pyrrole monomer (99% purity, Aldrich) was distilled under reduced pressure and stored at low temperature prior to use. Benzoyl peroxide (BPO), sodium dodecyl-sulfate (SDS), nitric acid (60% purity), hydrochloric acid (37% purity) and all other organic solvents used in this study were of analytical grade and used without further purification.

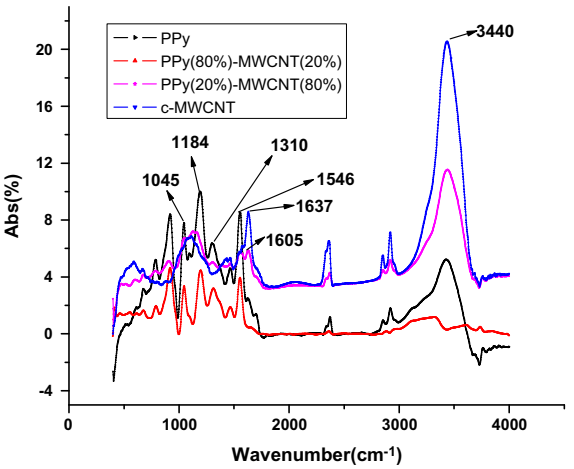

Fig. 1. FTIR of PPy, PPy–MWCNT nanocomposites and c-MWCNT.

2.2. Equipment details

Deposition of PPy and PPy–MWCNT nanocomposites were carried out by Q-switched Nydonium-doped Yttrium Aluminium Garnet (Nd-YAG) laser source (Quanta ray INDI-Newport Corporation). Operating wavelength used during deposition was 1064 nm. Analysis of nanocomposites and deposited films were carried out by X-ray photoelectron spectroscopy (XPS, ThermoFisher Scientifitic Multilab 2000), Fourier transform infrared spectroscopy (FTIR) was used to characterize the integrity of chemical composition of the polymer and nanocomposites before and after ablation. FTIR spectra were recorded on a JASCO FTIR-300E spectrometer in the wave number range of 4000–400 cm^{-1} with a resolution of 4 cm^{-1}. Samples were dispersed in KBr powder and compressed into pellets for analysis. Thickness and RMS roughness of the films were measured by optical profilometer (WYKO NT1100), X-ray powder diffraction patterns were recorded on a Panalytical Debye–Scherrer powder diffraction camera to study the bulk and film crystallinity. Scanning electron microscopy (SEM-Sirion field emission) and transmission electron microscopy (TEM-Tecnai F-30) were used for morphological studies, electrical conductivity was measured by Keithley 2182A (nanovoltmeter), 6221 (current source).

2.3. Oxidation of MWCNT's

In the oxidation process, 0.5 g of untreated MWCNT's were suspended in 10 ml of concentrated nitric acid and refluxed for 30 min in an ultrasonic bath. Subsequently, oxidation was carried out in a two necked, round-bottomed flask, equipped with a reflux condenser, mechanical stirrer and thermometer, which was mounted in a preheated oil bath. Reaction was carried out at 100 °C for 1 h. Obtained carboxy functionalized MWCNT's (c-MWCNT) were filtered using a 0.1 μm Teflon filter paper, washed with copious amount of de-ionized water until the pH value was about 7 and dried at 80 °C for 24 h [16].

2.4. Synthesis of PPy/c-MWCNT nanocomposites

Nanocomposites of PPy/c-MWCNT's were synthesized by inverted emulsion polymerization technique [17,18]. Emulsion was formed using SDS (0.2 M) in 1 M HCl solution with vigorous stirring. Various weight percentages of c-MWCNT's (20, 40, and 80 wt.%) were then dispersed in an emulsion under sonication for 1 h. For convenience, following nomenclature has been adopted in this paper: P-1 for 100% PPy, P-2 for 80% PPy and 20% MWCNT, P-3 for 60% PPy and 40% MWCNT, P-4 for 20% PPy and 80% MWCNT. Precooled solution of pyrrole monomer (0.25 M) was added to the above dispersion with constant stirring. Finally, BPO solution (0.25 M) in chloroform was added drop wise over a period of 30 min with constant stirring to initiate the polymerization. Pyrrole adsorbed on the surface of c-MWCNT's (core layer) was polymerized to form outer shell of the nanotubes. Within 30 min of the addition of BPO suspension turned black, indicating formation of polypyrrole. Reaction was continued for 5 h at room temperature. Polymerization was quenched by pouring the reaction mixture into acetone where, PPy/c-MWCNT composites precipitated out and excess BPO was dissolved in acetone. Precipitated product was then filtered and washed with copious amount of de-ionized water to remove unreacted monomer and excess SDS. Finally resulting mixture was washed with acetone and was dried under vacuum at 60 °C for 24 h.

Most of the electroactive polymers are difficult to dissolve, even if it is dissolved, presence of residual solvent in the film affects the device performance [19,20]. Furthermore, addition of nanoparticles to the polymer matrix would decrease the processability. Hence alternate methods of fabricating device quality films were evaluated. Laser ablation is an interesting technique where polymer films can be fabricated.

Pellets of nanocomposite were fabricated and used as target material for laser ablation. Pellets with 15 mm diameter and 3 mm thickness were fabricated using a desk top press, with applied pressure of 10 ton. Care was taken to keep the pellet thickness above 3 mm to safeguard the integrity of the target during ablation. Films were deposited for laser energy of 100 mJ and 50 mJ. Target and substrate are rotated at a constant speed of 60 rpm to achieve uniform ablation. Films of nanocomposites on all three different substrates i.e. silicon, glass and ITO were deposited in a single deposition to minimize batch to batch process variations that might occur. For convenience, samples were named according to deposition time, for example films of P1 is labeled as P1–2, P1–5 and P1–10 deposited for 2 min, 5 min and 10 min, respectively (Table 1).

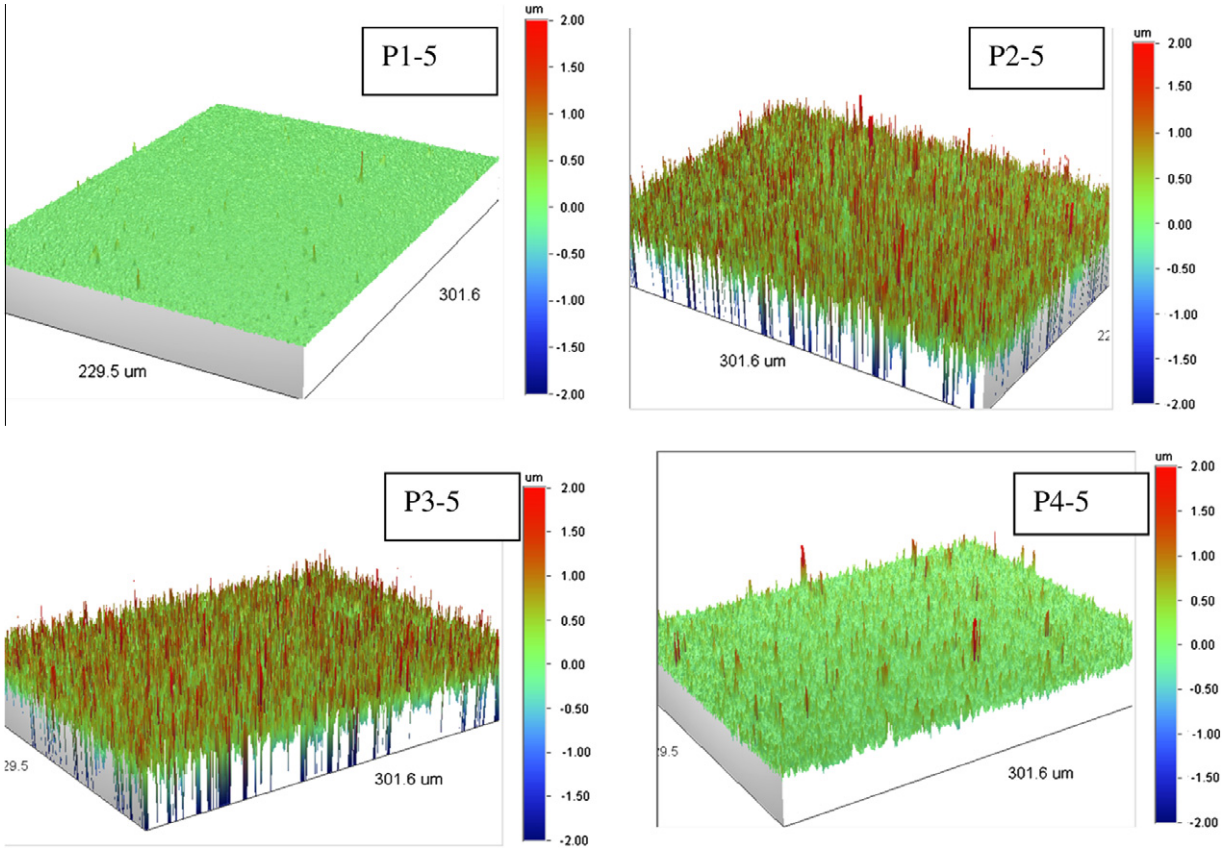

Fig. 3. Optical Profilometer of P1–5, P2–5, P3–5 and P4–5.

3. Result and discussion

FTIR spectra of chemically modified MWCNT's, PPy and PPy-coated MWCNT's are shown in Fig. 1. Characteristic bands due to newly formed polar functional groups were observed in the FTIR spectra of the MWCNT's after acid treatment in HNO_3. IR bands at 3440, 1637, and 1182 cm^{-1} were consistent with the OH stretching, C = O stretching and C–C–O stretching in modified MWCNT's, respectively [21]. In case of PPy, characteristic fundamental ring vibration appeared at 1546 cm^{-1}, and C–H in-plane vibration and C–N stretching vibration appeared at 1310 and 1045 cm^{-1}, and at 1184 cm^{-1}, respectively [22]. PPy–MWCNT's nanocomposites showed characteristics peaks for both PPy and MWCNT's. From the spectra it is evident that there is a shift in C–O peak from 1637 cm^{-1} in neat PPy to 1605 cm^{-1} in the case of PPy–MWCNT nanocomposites. Presence of carboxylic groups on the nanotube surface will increase the interaction between NH groups of the PPy and COOH groups of chemically modified MWCNT's. This indicates that PPy has modified the MWCNT surface.

Furthermore, according to Tian and Zerbi, the intensity ratios of the 1560 and 1480 cm^{-1} bands (I_{1560}/I_{1480}) is inversely proportional to the extent of delocalization [23]. Thus, polymer molecules with high concentrations of defect sites (short conjugation lengths) showed high values of I_{1560}/I_{1480}, whereas, polymer molecules with low concentrations of defect sites (long conjugation lengths) showed low values of I_{1560}/I_{1480}. It was observed that the I_{1560}/I_{1480} increases with increasing MWCNT content (i.e., with decreasing thickness of the PPy layer). This indicates that the layer of PPy that is deposited directly on the surfaces of MWCNT's has a shorter conjugation length than subsequently deposited layers, probably due to the π–π interaction between MWCNT's and pyrrole monomers. With increase in MWCNT concentration, the defect on PPy increases because nanotubes act as dopant and also due to the fact that network structure of

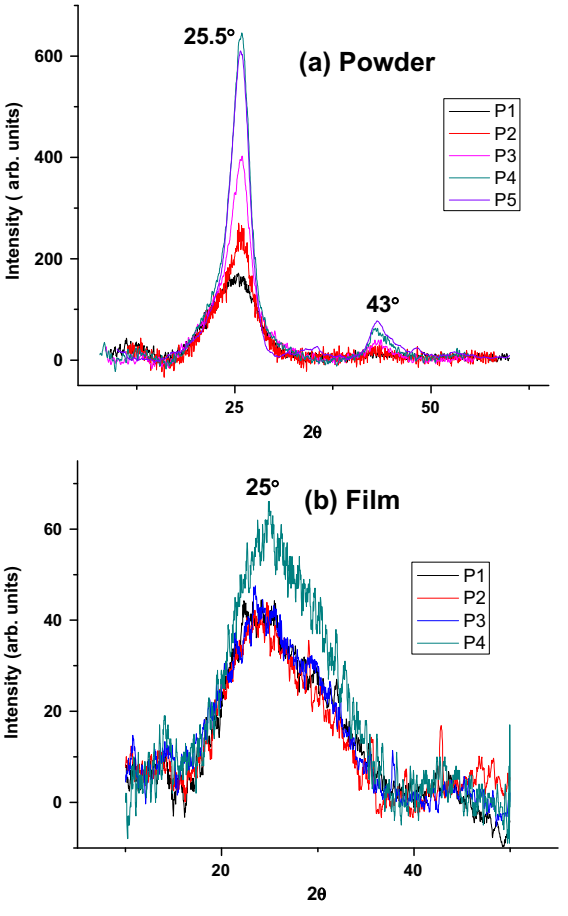

Fig. 4. XRD of PPy-MWCNT nanocomposite (a) powders, (b) films.

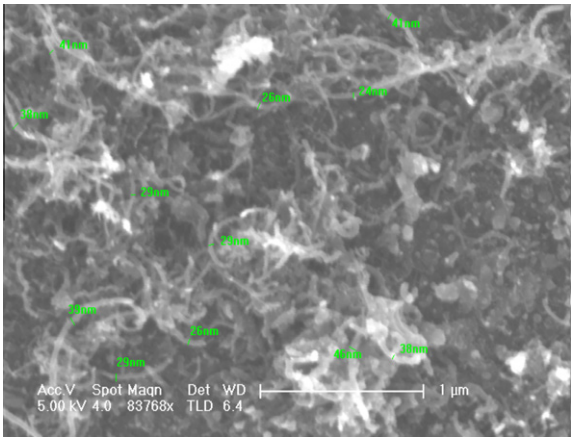

Fig. 5. Scanning electron microscopy image of P4-film.

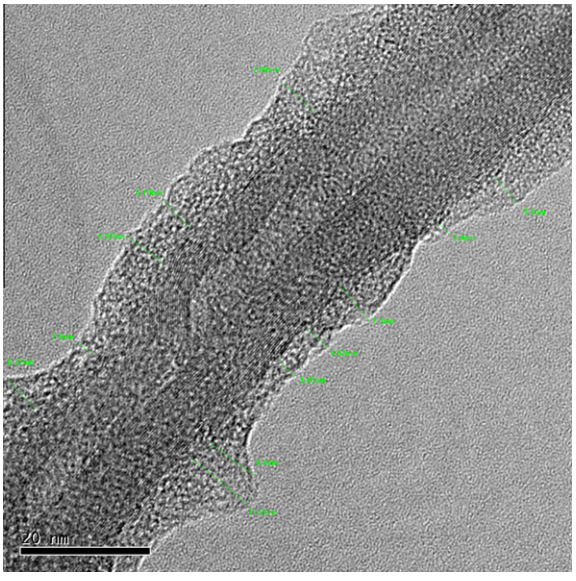

Fig. 6. Transmission electron microscopic image of P2.

MWCNT's. On the other hand, with decrease in PPy thickness some parts of MWCNT will not interact fully with PPy molecules. This results in shorter conjugation length of PPy [24].

XPS was employed to determine chemical composition of nanocomposite before and after ablation and results are tabulated in Table 2. XPS spectrum of the target material P2 is as shown in the Fig. 2. C1s peak was observed at 284.7 eV. Gaussian fitting resolves this into two peaks at 284.8 eV and 287.4 eV indicating the presence of C–C bonding and C–N, C–H bonding, respectively. N1s peak was observed at 400 eV. Gaussian fitting resolves this into two peaks at 400 eV and 402 eV indicating the presence of N–H bonding and N–C bonding, respectively. O1s peaks are observed in the spectra at 532.2 eV was believed to be due to adsorbed oxygen, on exposure to environment. Absence of peaks at 390 eV and 406 eV indicate that there is no bonding with C or N, which indicates that the films are not oxidized [25–27]. XPS of ablated film is shown in Fig. 2. C1s peak was observed at 285 eV. Gaussian fitting resolves this into two peaks at 285 eV and 287.1 eV indicating the presence of C–C bonding and C–N, C–H bonding, respectively. N1s peak was observed at 400 eV. Gaussian fitting resolves this into two peaks at 399.7 eV and 404.4 eV indicating the presence of N–H bonding and N–C bonding, respectively. O1s peaks are observed at 532.5 eV. These results are in good agreement with that of the target material. These results indicate nanocomposite does not get degraded during ablation process. XPS studies for P1 (Fig. 7 supporting information) film which is pure PPy also shows a good agreement with bulk indicating even though PLD process may change the molecular weight it does not change the chemical composition of polymer [13].

Surface roughness is very important parameter in polymer thin film devices. Higher the roughness, chances of electrically shorting the electrodes due to pin holes increases. Hence low roughness is desirable. Surface roughness and thickness of the films were measured by 3D optical surface profilometer (Fig. 3 and Table 1). It was observed that surface roughness increases initially with addition of MWCNT's however on further addition, surface roughness decreases. P1 films were found to be

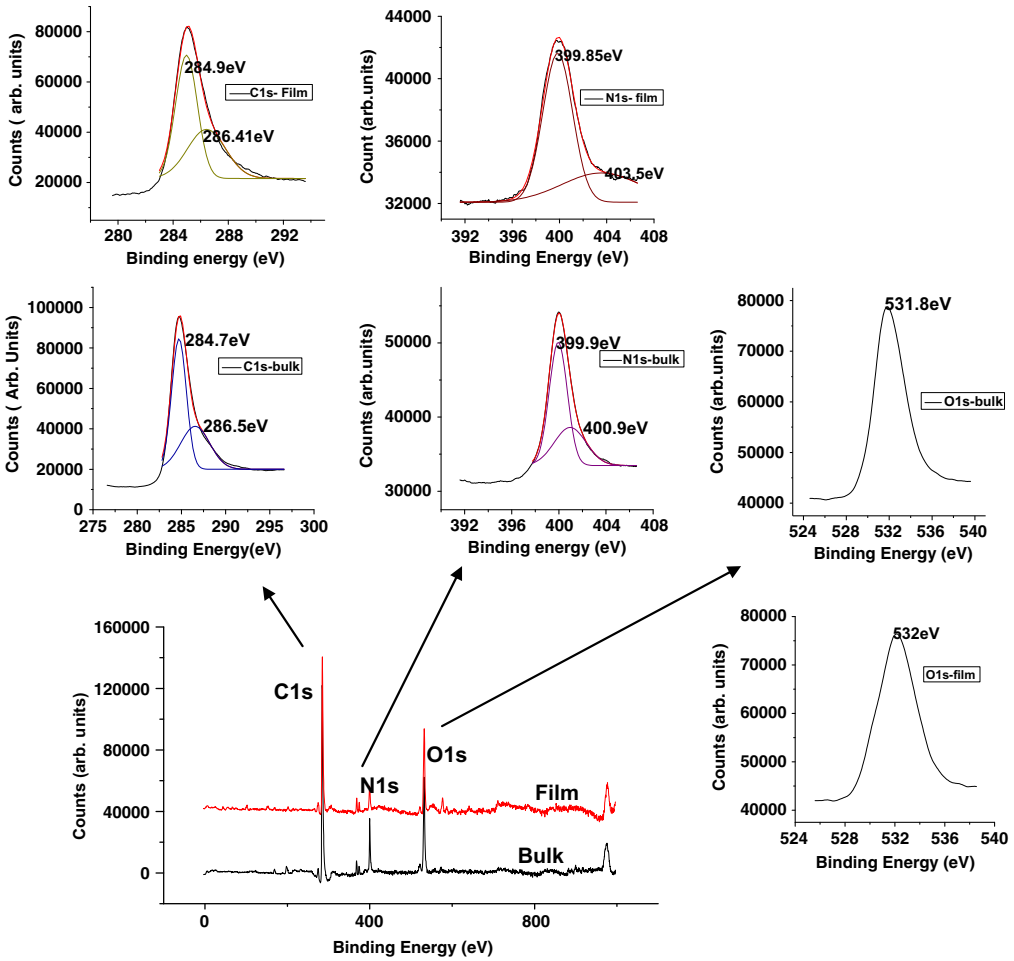

Fig. 7. (a) X-ray photoelectron spectra of P1. (b) X-ray photoelectron spectra of P3. (c) X-ray photoelectron spectra of P4.

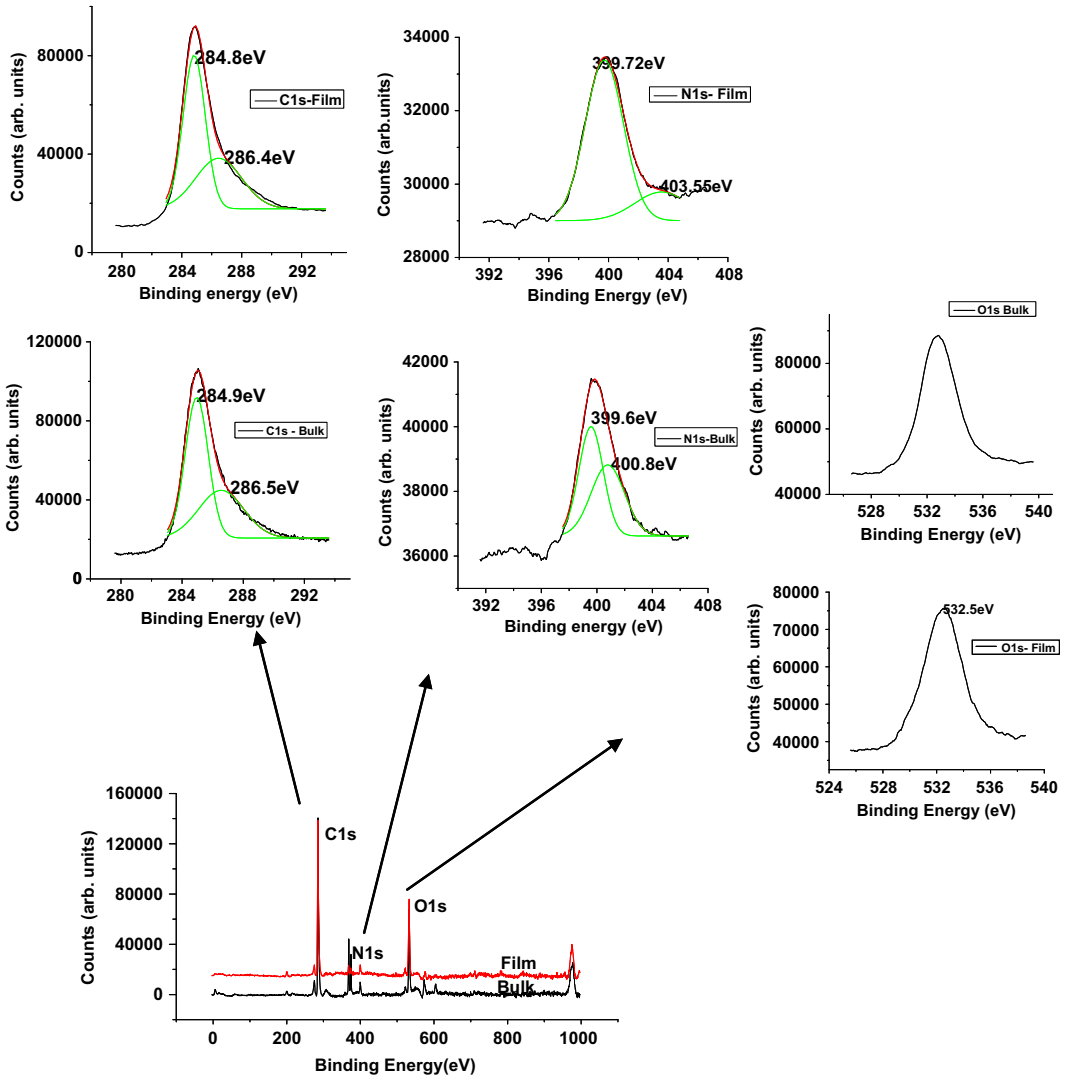

Fig. 7 (*continued*)

smoother than P2, P3 and P4 because it is not a mixture, but single homogeneous material system. On the contrary, P4, mixture of different materials viz, nanotubes and polymer, was found to be smoother than P2 and P3. Because at such high loadings, major component in the composite will be nanotubes and polymer would get filled in intricacy of MWCNT's mat structure upon film fabrication. Consequently, roughness decreases by filling up of crests and troughs formed by the nanotube matrix. In case of P2 and P3 MWCNT mat will have bigger voids because of lesser nanotube wt.% than P4. Hence, films of P2 and P3 show higher values of roughness indicating insufficient filling of voids in the matrix by the polymer. Hence intermixing of PPy-MWCNT at such loadings will result in rough surface. Films deposited for 100 mJ were rougher (RMS 320 nm) than the films deposited for 50 mJ (RMS 152 nm) moreover at 100 mJ deposition rate is too high to control the thickness. Hence, all the films fabricated in this study are at 50 mJ.

XRD analysis of pure PPy and nanocomposite powders are as shown in Fig. 4a. A broad peak at 25.5° was observed for pure PP, indicating amorphous nature of PPy. In case of nanocomposite powders, in addition to peak at 25.5° another peak at 43°, which is attributed to (1 0 0) reflection from MWCNT, was observed [28]. It was also observed that as MWCNT loading increases in nanocomposite, intensity of the peak at 43° increases and peaks become sharper. Since XRD of MWCNT show peaks at same 2θ values, increase in intensity can be attributed to increase of MWCNT loading in nanocomposites. XRD patterns of the films also show that the films are amorphous (Fig. 4b).

Distribution of MWCNT in the matrix is analyzed by scanning electron microscopy of both film and the powder (Fig. 5). Film morphology of P1 which is pure PPy, is smooth with a RMS roughness of 22 nm. Film images of P2, P3and P4 which are MWCNT loaded in various wt.% shows presence of MWCNT's and also images, which has MWCNT wt.% of 20, 40 and 80, respectively, shows that

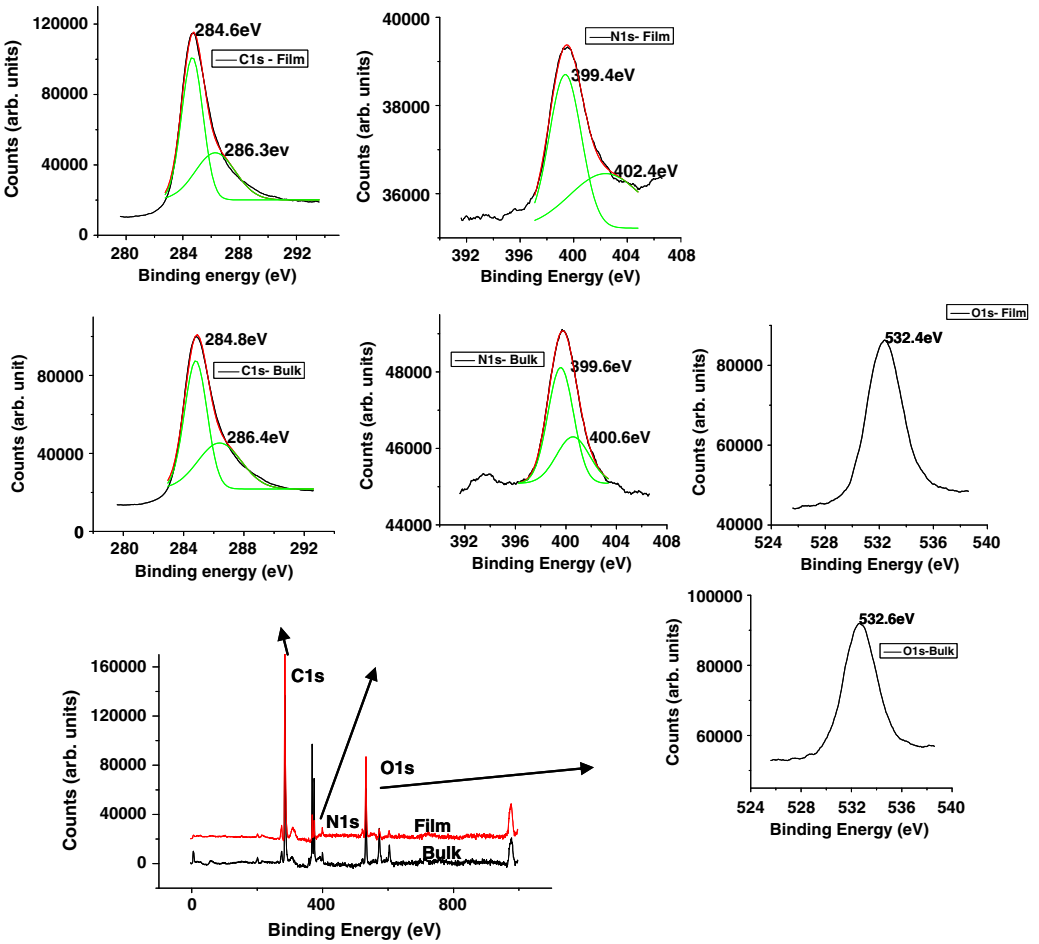

Fig. 7 (*continued*)

along with polymer MWCNT's are also ablated. Moreover, MWCNT's are distributed through out the matrix. Diameter of the MWCNT's for both film and the bulk were measured and indicated on the images. For both bulk and film, diameter of MWCNT coated with PPy varies from 24 nm to 66 nm. This indicates that polymer layer wrapped on nanotube remains intact during ablation. Many drop like features were observed in the nanocomposite films, which are attributed to the pure PPy molecular cluster (Fig. 8 supporting information).

High resolution TEM image of the MWCNT in nanocomposite (Fig. 6) shows presence of PPy coating on MWCNT wall. It was observed that polymer layer thickness is not uniform throughout the film. In this particular example we found it varies from 2 to 8 nm. This supports FTIR analysis that reason for short conjugation length as the nonuniform thickness of PPy on MWCNT walls. Polymer layer thickness was measured for all the three nanocomposites using TEM and thickness values are indicated on Fig. 9 (supporting information). Even though coating is not uniform it was observed that polymer layer thickness does not vary much from bulk to film indicating during ablation nanocomposite remains intact further supporting the evidence of the integrity of the polymer coating that was observed in SEM analysis. Measured polymer thickness of P2, P3 and P4 varies from 3–15 nm, 5–12 nm and 2–3 nm, respectively. Polymer layer thickness decreases with decrease in PPy wt.% as indicated by SEM analysis. It is evident from TEM micrographs that MWCNT web is held together by the polymer matrix indicating better intermixing of PPy and MWCNT (Fig. 9 supporting information). Even though PPy coating on MWCNT is not uniform low magnification TEM image of both bulk and film shows polymer wrapping on MWCNT's.

Conductivity of both bulk and films were measured and compared using four point probe setup. Conductivity of both bulk and films are shown in Table 1. Ablation targets were used for bulk conductivity measurement. It was observed that conductivity increases by addition of (20 wt.%) MWCNT from 0.11 S/cm to 231 S/cm. Electrical percolation threshold for carbon nanotubes in a polymer matrix are about 5–8% [29]. Increase in MWCNT loading here does not further enhance the conductivity indicating percolation threshold has already been reached. Furthermore these results also indicate that

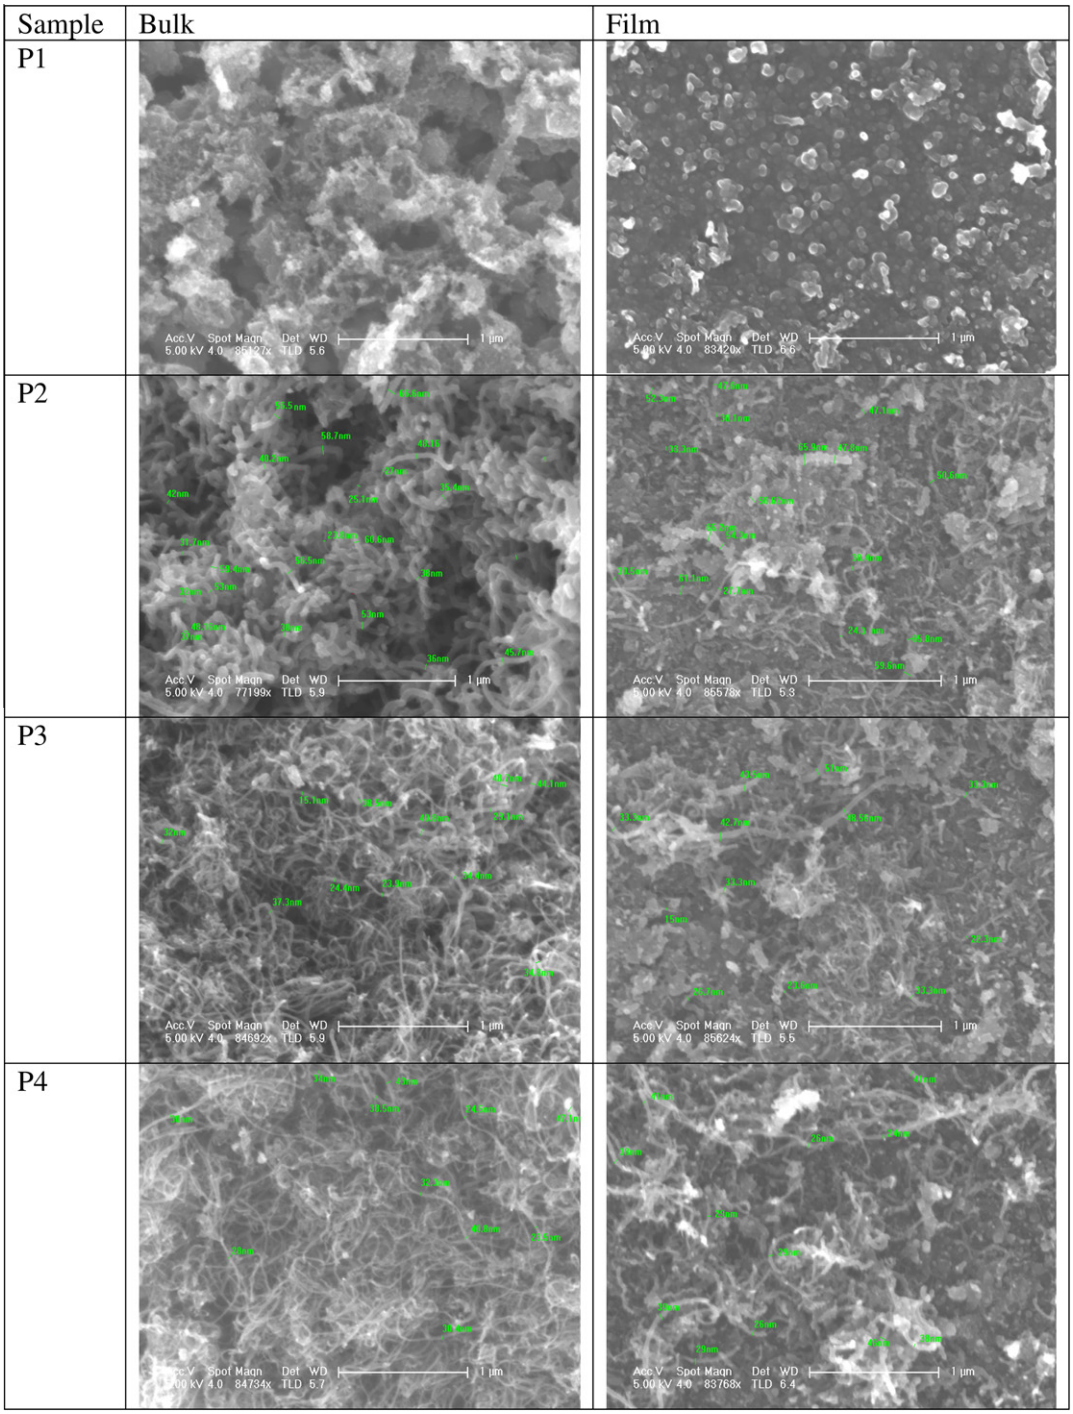

Fig. 8. Scanning electron microscopy images of P1, P2, P3 and P4.

conductivity measurements on a bulk material in pellet form is not appropriate method as conductivity varies with packing density of the pellet, pressure applied by the four point probe etc. Even slight variation of these parameters will change the conductivity values. Hence conductivity measurements of a polymer material in a thin film are appropriate compared to bulk measurements. Increase in conductivity with increase in MWCNT loading was observed in films. It was also observed that in films, conductivity decreases with increase in film thickness for all compositions except in the case of P1–2 made from neat PPy. This is because P1–2 is not continuous film (at 50 nm thickness) as indicated by SEM (Fig. 10 supporting information). Optical profilometer

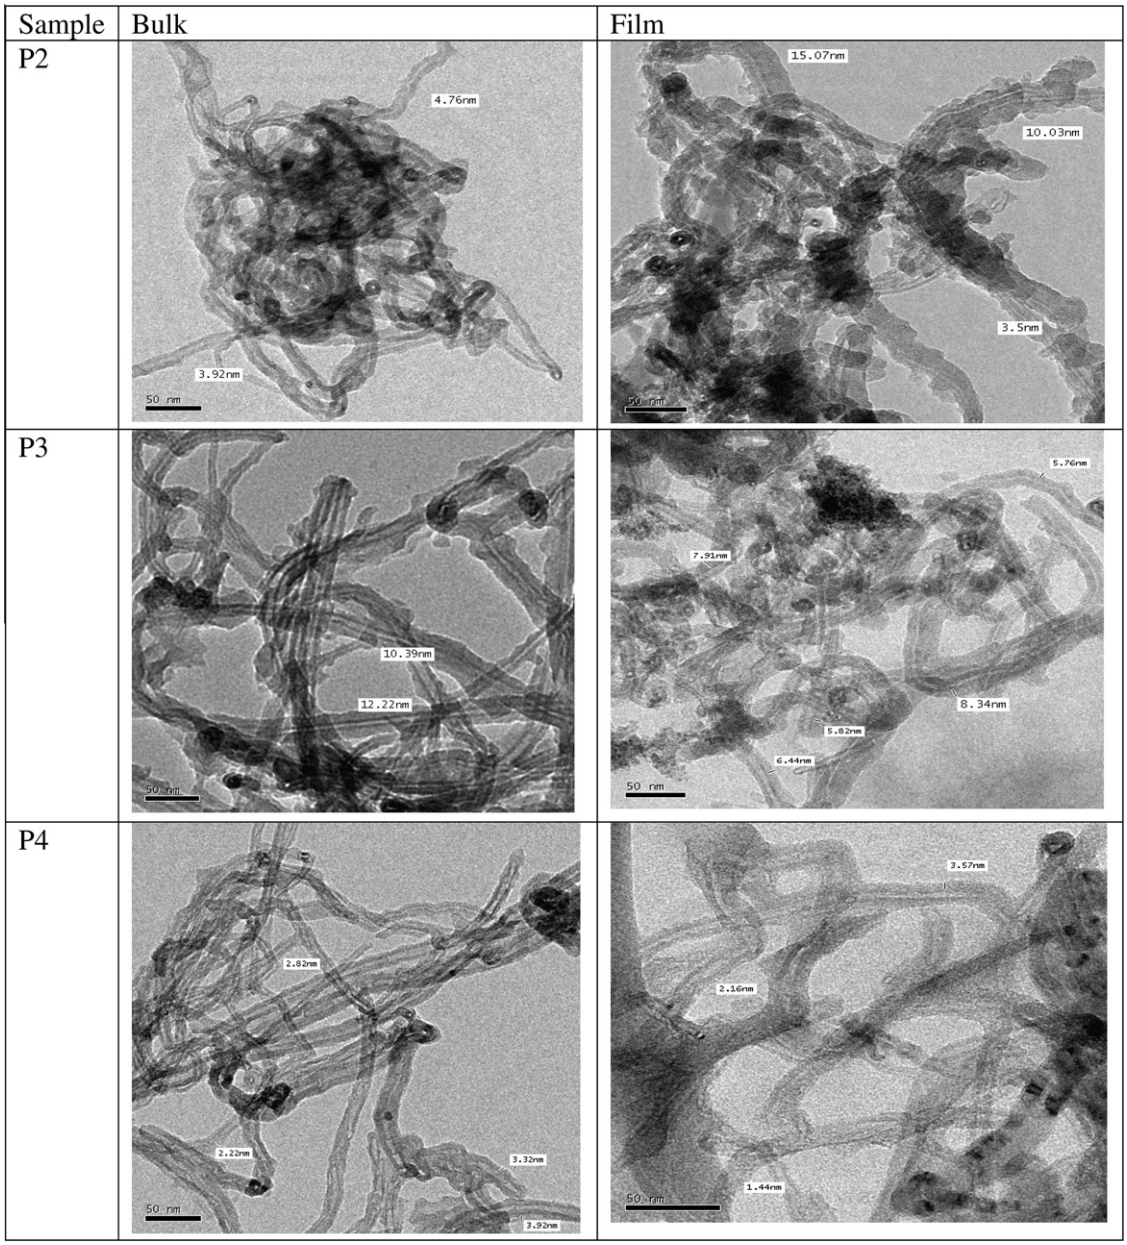

Fig. 9. Transmission electron microscopic image of nanocomposites.

indicates that the film roughness increases with increase in film thickness (Table 1). Furthermore, with increase in film thickness, impurities, structural defect density will increase, hence conductivity decreases with increasing film thickness [30]. Comparison of film conductivity with film thickness indicates that maximum conductivity was observed about 0.2 μm.

4. Conclusions

Device quality films of highly loaded nanocomposites were fabricated by pulsed laser deposition. Comparative study of X-ray photoelectron spectroscopy (XPS) of bulk and film show that polymer does not degrade during ablation. Both SEM and TEM micrographs indicate that the MWCNT's are distributed in the ablated films. Further more, MWCNT diameter does not change from bulk to film indicating that the polymer layer wrapped on MWCNT remains intact during ablation. Conductivity of both bulk and film were measured using collinear four point probe setup. It was found that conductivity of films increases with addition of MWCNT and decrease with increasing thickness. Comparative study of thickness with conductivity indicates that maximum conductivity was observed around 0.2 μm. Even for very high loading (80 wt.%) device

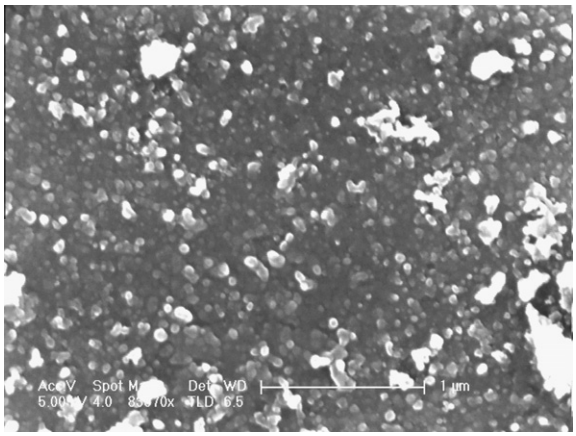

Fig. 10. SEM image of P1–2.

quality films were able to fabricate using PLD technique, indicating laser ablation is an appropriate technique for fabrication of device quality films for organic electronic applications.

determined by at least two different emitting materials, high color stability can theoretically be accomplished as long as the exciton competition among the emitting sites is delicately managed [7,11–16]. For instance, a dichromatic or trichromatic OLED with a stack of different emitting layers (EML) generally suffers from lower color stability due to the variations in exciton distribution at different driving voltages [17–19]. In this case, a spacer inserted in between the different EMLs can greatly alleviate color variation by stabilizing the exciton distribution [7,9,14,20]. Instead of using spacers, adopting phosphorescent sensitization as the main emission mechanism or fabricating independent emitting units in a pixel open up another possibility for stabilizing the color emission [14,21]. In this paper, we investigated the dependence of the color stability of green–blue OLED on the thickness of the EML and measured the carrier mobilities of *N,N′*-dicarbazolyl-3, 5-benzene (mCP) and 4,7-diphenyl-1,10-phenanthroline (BPhen). On account of the stronger electric field dependence of the carrier mobility of mCP than that of BPhen, and the larger voltage drop across the blue-EML (B-EML) than across the green-EML (G-EML) within the devices, the higher sensitivity of the EL spectrum to the applied driving voltage in the device with a thinner EML was attributed to the sharply increasing electric field. For an optimal device, the CIE coordinates were slightly shifted from (0.256, 0.465) to (0.259, 0.467) with increased luminance from 48.7 to 12,700 cd/m^2. Based on the backbone of this green–blue OLED, a highly efficient WOLED with maximum efficiencies of 26.4 cd/A and 19.8 lm/W was fabricated. It also exhibited high color stability, that is, the CIE coordinates shifted from (0.310, 0.441) to (0.318, 0.446) in the practical luminance range from 1050 to 9120 cd/m^2.

2. Experiments

Indium-tin-oxide (ITO) glass with sheet resistance of 30 Ohm/sqr and thickness of 100 nm was used as the substrate. The active region size of a test pixel was 2×2 mm^2 and the fabrication process consisted of pre-cleaning of the ITO, thermal deposition of the materials, and finally encapsulation with a glass cap [22]. The pre-cleaning process of the ITO-coated glass adhered to a standard solvent cleaning procedure, followed by an oxygen plasma treatment. The thermal deposition was performed in a high vacuum chamber ($\sim 3 \times 10^{-6}$ torr) for growing the organic and cathode materials. Finally, the as-fabricated device was hermetically sealed in a nitrogen glove box with water and oxygen at less than 0.1 ppm [23].

A hole-transporting *N,N′*-diphenyl-*N,N′*-bis(1-napthyl)-1,1′-biphenyl-4,4′-diamine (NPB) was used as the hole-transporting layer (HTL) on the ITO side and an electron-transporting BPhen the electron-transporting layer (ETL) on the complex LiF/Al side. An EML in between the HTL and ETL was created by a combination of two phosphorescent dopants of green-emitting tris(phenylpyridine)iridium (Ir(ppy)$_3$) and blue-emitting [(4,6-difluorophenyl)-pyridinato-N,C$^{2'}$]picolinate (FIrpic) and one host of mCP. For implementing a white OLED, tris(2-phenyl-1-quinoline)iridium(III), Ir(phq)$_3$ was used as a red emitting phosphorescent dopant [24]. For future discussion of the OLED, the main structure was ITO/NPB (50 nm)/EML/BPhen (30 nm)/LiF (1.2 nm)/Al (120 nm). The various EML structures under investigation will be mentioned in the corresponding discussion sections. The electrical and optical performances of the OLED were measured by a test system comprising of a Keithley 2400 source-meter and a Minolta CS-1000 spectrometer.

For the time-of-flight (TOF) measurements, the test material was deposited at a constant rate of 0.3 nm/s on the ITO substrate to form a nearly 1.5 μm thick film, which was subsequently covered by 15 nm of Al, which functioned as an electrode. The actual thickness of the organic layer was measured by a surface profiler (Dektak 150; Veeco). The frequency-doubled output of a 5-ns pulsed dye laser at 295 nm was chosen to match the peak optical absorption of the organic layer and aimed at the samples from the semitransparent Al electrode to generate carriers. The transient photocurrent created by the drift of the photoexcited carriers was monitored by a 1 GHz digital oscilloscope (LC574 AM, LeCroy). The carrier mobility μ was determined by $\mu = D/t_T E$, where D is the thickness of the organic layer, t_T is the transit time, and E is the applied electric field [25].

3. Results and discussion

3.1. Electrical properties of dichromatic (B + G) OLEDs with different B-EML thicknesses

In a blue–green dichromatic OLED, excitons would naturally be formed in or diffuse toward the G-EML due to its lower exciton energy. This EML structure often exhibited higher green emission at lower carrier injection conditions due to the abovementioned nature of the excitons, but lower green emission at higher carrier injection conditions due to the saturation of the emitting sites in the G-EML or the shift of the carrier recombination zone toward the B-EML [14]. These carrier injection related phenomena resulted in color variations at different injection conditions. As such, it was necessary to introduce a spacer to separate the two EMLs and thus improve the color stability (by resolving the color variation). The function of the spacer was to deter diffusion of the higher energy excitons in the B-EML to the G-EML [7,14]. In accordance with the necessity of a spacer for high color stability, our OLED under investigation had an EML configuration of 9%Ir(ppy)$_3$:mCP (G-EML)/mCP (spacer)/9%FIrpic:mCP (B-EML). The thicknesses of the G-EML and spacer were fixed at 30 and 4.5 nm, respectively, and that of B-EML was left as a variable. The constant G-EML thickness was decided based on efficiency optimization considerations while the constant spacer thickness was chosen to play a pivotal role in the confinement of the exciton formation zone. These two constant parameters thereby narrowed down the possible causes of color stability within the scope we will discuss later on.

Fig. 1 illustrates the device configuration and highest occupied molecular orbital (HOMO) and lowest

unoccupied molecular orbital (LUMO) of the organic materials, along with the corresponding thicknesses of the different components. The variable *X*, i.e. B-EML thickness, was set to be 18, 15, and 9 nm for Devices A, B and C, respectively. The performances of Devices A, B, C were summarized in Table 1. As shown in Fig. 2, Device A exhibited the highest driving voltage of 11.6 V at 100 mA/cm^2. As *X* was further decreased from 15 nm (Device B) to 9 nm (Device C), the driving voltage at 100 mA/cm^2 decreased from 11.3 to 10.3 V. It was observed that a 9 nm reduction in the B-EML thickness led to a reduction in driving voltage of 1.3 V.

To study the carrier transport characteristics, TOF measurements were performed to obtain the carrier mobilities of NPB, mCP, and BPhen. As shown in Fig. 3, the highest hole mobility of NPB directly indicated that the EML and ETL, either individually or in conjunction, accounted for most of the voltage drop. Since the primary drawback of TOF measurements is that they only provide information on the carrier transport properties, we sought the missing information on carrier injection properties through investigating the electrical characteristics of the OLED. For the purpose of understanding the integrated effects of carrier injection and transport in a guest:host film, devices with single G-EML, B-EML, and pure mCP EML as listed in Table 2 were examined. As shown in Fig. 4, Device S1 with a 9%FIrpic:mCP layer (B-EML) exhibited a higher driving voltage than Device S2 with a 9%Ir(ppy)$_3$:mCP (G-EML) and Device S3 with a pure mCP layer, respectively. Comparing S2 and S3, one can see that doping Ir(ppy)$_3$ into mCP reduced the driving voltage, because the Ir(ppy)$_3$ facilitated hole injection from the HTL into the EML and its hole-transport characteristics contributed to the carrier transport [26]. Therefore, as compared to the case of the B-EML, the vastly superior carrier transport properties of NPB, G-EML, mCP and BPhen therefore led to the reasonable conjecture that the a relatively large voltage drop occurred across the B-EML, as suggested by the electrical properties of Devices A, B and C.

We next considered the mCP spacer/B-EML interface, where electrons were blocked by an energy barrier established by the large LUMO difference between the FIrpic

Table 1
EML structures of Devices A, B, C, and their corresponding current efficiencies (cd/A), driving voltages, and CIE coordinates.

Device	EML (nm)						
	G-EML	Spacer	B-EML	[a]cd/A	[b]Driving voltage (V)	CIE coordinate	
A			18	22.1	11.6	[c](0.256, 0.465)	[d](0.259, 0.467)

and mCP, and accumulated on the FIrpic molecules due to their relatively lower LUMO than that of the mCP molecules. At the B-EML/BPhen interface, even though the electron injection barrier created by the LUMO of the mCP host and BPhen reduced the possibility of electron injection from the BPhen to mCP, the LUMO matching between the FIrpic and BPhen allowed a portion of the electrons to be injected into the B-EML through this interface. Based on the discussion above, the electron injection and transport mechanism in the device structure shown in Fig. 1 are likely to be as illustrated in Fig. 5.

The hole-transport mechanism in an identical device to that in Fig. 1 could also be understood by examining Device S2. The lower driving voltage of Device S2 than that of Device S3 with pure mCP accounted for a better hole carrier injection and transport due to the existence of Ir(ppy)$_3$. At the NPB/G-EML interface, the similar HOMO of Ir(ppy)$_3$ to NPB provided an additional injection channel. Within the G-EML, both the similar HOMO between the Ir(ppy)$_3$ and mCP and the outstanding hole-transport properties

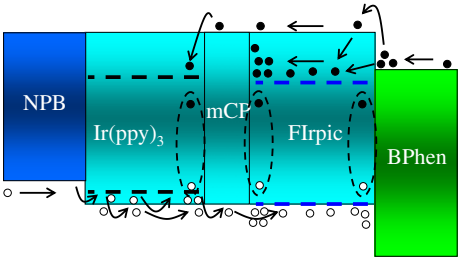

Fig. 5. Illustration of carrier injection and transport behavior in the device with structure as shown in Fig. 1. (closed circle: electron; open circle: hole). A pair of electron and hole indicates an exciton.

of Ir(ppy)$_3$ were likely to play a significant role in the transport of most of the holes through the dopants and host channels or in between [26]. At the G-EML/mCP spacer interface, the holes could easily traverse the spacer over to the B-EML due to the small HOMO difference between the Ir(ppy)$_3$ and mCP. So far, the overall picture of the carrier transport mechanism was obtained entirely as illustrated in Fig. 5, where the main recombination zone was straightforwardly found to lie within the B-EML. From the analysis of blue (FIrpic) and green (Ir(ppy)$_3$) composition in the EL spectrum of Device A, we could also recognize the location of main recombination zone. Fig. 7(a) shows that the EL spectrum of Device A comprised of 61.6% FIrpic emission along with 38.4%Ir(ppy)$_3$ emission. Furthermore, due to the lower quantum efficiency of the FIrpic [27] and the existence of exciton diffusion from the B-EML to G-EML, we could deduce that most of excitons (>61.6%) were formed in the B-EML, thus verifying the location of the main recombination zone within B-EML.

3.2. Exciton dynamics and emission properties of B + G OLED with different B-EML thicknesses

In addition to the driving voltage, different B-EML thicknesses also resulted in significant variations in the efficiency and EL spectrum. Fig. 6 shows a sharper current efficiency and external quantum efficiency (EQE) roll-off for Device C, which was mainly attributed to triplet–triplet annihilation (TTA) [28]. At low injection current densities less than 0.1 mA/cm^2, the current efficiencies of Devices A and C were similar. In this case, the TTA was not significant due to the low exciton concentration for both devices. However, as the injection current density rose to a higher level, the current efficiency of Device C dropped more

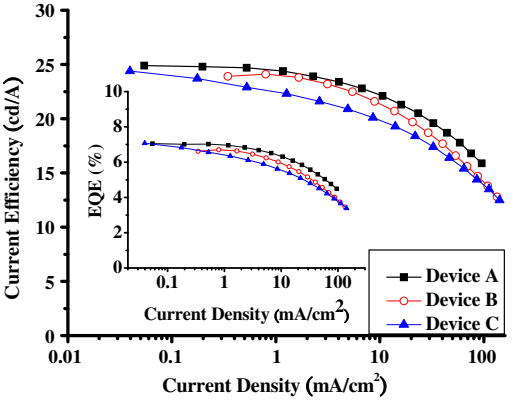

Fig. 6. Current efficiencies (cd/A) and EQE (Inset) of Devices A, B, C under different current densities.

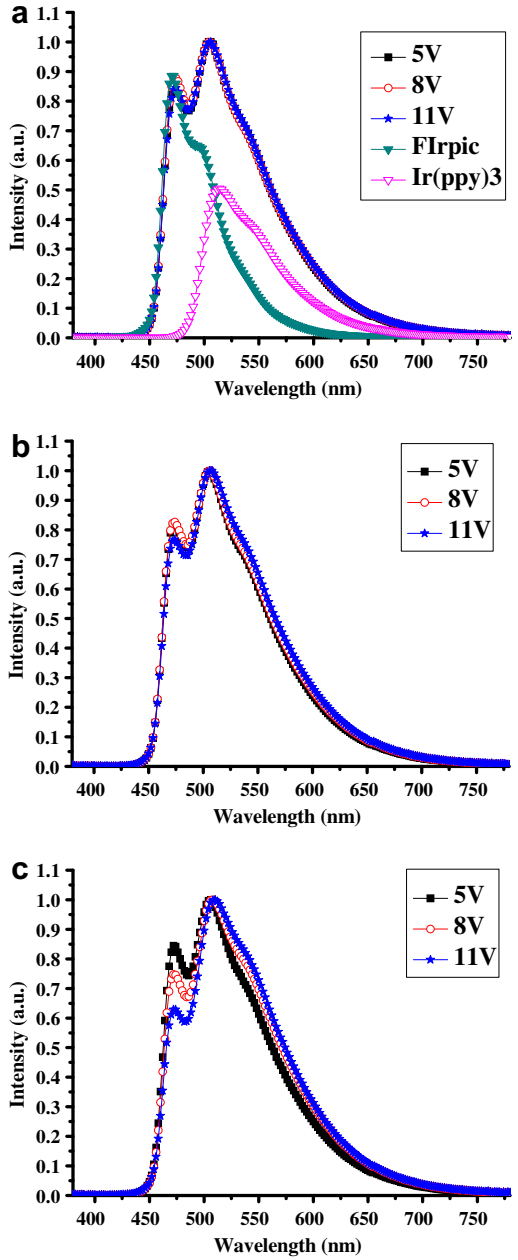

Fig. 7. Normalized EL spectra of Devices A (a), B (b), and C (c) at 5, 8, 11 V. The EL spectra consisted of FIrpic emission with peak at 470 nm and $Ir(ppy)_3$ emission with peak at 520 nm shown in (a). The fitting procedure for decomposition was: (1) transforming EL spectra from energy to photon number distribution; (2) normalizing their respective total number based on an assumption of the same EQE values in blue and green OLED; (3) finding a combination of 61.6% normalized FIrpic and 38.4% normalized $Ir(ppy)_3$ contributed to the EL spectrum of Device A.

sharply than that of Device A since the more rapid growth of the exciton concentration for the thinner B-EML resulted in more significant TTA.

As can be seen in Fig. 7, Device A (with a thicker B-EML) exhibited a constant EL spectrum, while Device C (with a thinner B-EML) exhibited notable variations in the EL spectrum as the applied voltage was increased. Naturally, the performance of Device B lied somewhere between those of Devices A and C due to its intermediate B-EML thickness. In Table 1, the CIE coordinate variation for Device A was (0.003, 0.002) from 5 to 11 V, while that for Device C was (0.028, 0.034). In other words, Device C possessed poorer color stability. Since both Devices A and C experienced TTA as the applied voltage was increased, the disparity between their color stability must be attributed to their different sensitivities to the electric field during carrier injection and transport. As discussed previously, a relatively large voltage drop occurred across the B-EML, indicating sharp changes in the electrical field on both boundaries of the B-EML. The variations in the electric field resulted in a voltage across the spacer/B-EML and B-EML/ETL interfaces. Therefore, under the same external applied voltage, the thinner B-EML in Device C would be subject to a larger electric field and a larger voltage drop would occur across the two boundaries, thereby lowering the effective injection barrier height [29]. Therefore, more electrons were accumulated on these two interfaces, with a higher possibility for injection as the driving voltage became higher.The carrier mobilities for both the mCP and BPhen were electric field dependent, as indicated by our TOF measurements as shown in Fig. 3. The parameters for the Poole–Frankel mobility of $\mu = \mu_0 \exp(\beta\sqrt{E})$ were extracted from our experimental results, and listed in Table 3. The parameter $_0$ represents the zero-field carrier mobility, β describes the electric field dependence of the mobility, and E is the applied electrical field [29–31]. As can be seen in Table 3, the β value of the electron mobility of mCP was 0.00426, which implied the highest sensitivity to the electric field. Therefore, the increase in electron mobility with the electric field could enable the electron to penetrate deeper from the B-EML/ETL interface and accumulate at the spacer/B-EML interface. Coupled with the increasing penetration probability at the spacer/B-EML interface due to the barrier lowering, the number of electrons leaking out of the B-EML to G-EML would increase, thereby intensifying the green emission with increasing driving voltage, as observed in Device C. In contrast, Device A did not encounter a significant increase in the electric field and barrier lowering due to the thicker B-EML, and therefore exhibited high color stability. At a low driving voltage (5 V), Devices A, B, C exhibited similar EL spectra. This indicated that the recombination zone distribution was similar for these three devices since no electron leakage out of the B-EML occurred at a low electric field.

The poor color stability of Device C, due to the extension of the recombination zone, was further exacerbated by TTA. In Device C, as the voltage increased, the green

Table 3
Carrier mobility μ (h for hole; e for electron), zero-field mobility μ_0 and Poole–Frankel slope β of mCP and BPhen.

Mobility μ(cm^2/V^{-s})	μ_0 (cm^2/V^{-s})	β ($(V/cm)^{-1/2}$)
mCP(h)	1.20E-04	0.00254
mCP(e)	4.00E-05	0.00426
BPhen(h)	7.34E-06	0.00174
BPhen(e)	2.90E-04	0.00056

emission grew due to the increase in excitons in the G-EML. On the other hand, the blue emission decreased due to the severe TTA in the B-EML. As a result, the percentage of blue emission was reduced, as observed in Fig. 7(c). On the contrary, Device A, which experienced the same difficulties with TTA as Device C, exhibited no deterioration in its color stability. This disparity offered a glimpse into the energy transfer paths in Device A. It pointed to the fact that excitons in the G-EML were derived mainly from the B-EML. In this case, the percentages of blue and green emission in EL spectrum would not be changed since the increase in applied voltage could only affect the exciton number in the B-EML, and not the exciton diffusion and energy transfer from the B-EML to G-EML.

Based on the knowledge of the model shown in Fig. 5 and location of the main recombination zone, we could deduce the energy transfer paths and exciton diffusion in Device A. As shown in Fig. 8, most excitons were formed in the FIrpic and mCP molecules. Subsequently, the FIrpic excitons were radiatively released to their ground states without energy being transferred to the $Ir(ppy)_3$ molecules since this energy transfer was prohibited by spin conservation. On the other hand, the mCP excitons were allowed to impart their energies to excite the FIrpic molecules or diffuse out to the $Ir(ppy)_3$ in the G-EML to generate green emission. The energy transfer paths would not be altered at different current densities since the energy transfer was independent of the number of charge carriers. For the case of Device A in which the recombination zone was entirely located within the B-EML, the color stability would not be deteriorated by TTA since the green excitons came from the energy transfer from excitons in the B-EML. The TTA only diminished the source of excitons, but was unable to alter the green and blue composition in the EL spectrum and thus the CIE coordinate. Device A exhibited high color stability with a nearly fixed CIE coordinate around (0.25, 0.46) from 5 V ((0.256, 0.465), 48.7 cd/m^2) to 11 V ((0.259, 0.467), 12,700 cd/m^2). In contrast, in Device C, the extension of the recombination zone into the G-EML due to the electron leakage out of the B-EML led to a gradually increasing percentage of green emission in the EL spectrum as the applied voltage was increased. In conjunction with a gradually decreasing percentage of blue emission due to more significant TTA in the B-EML with the increasing injection current, Device C equivalently experienced a great reduction in the blue emission in the EL spectrum and exhibited a rather low color stability, with the CIE coordinates shifting from (0.261, 0.466) at 5 V (121 cd/m^2) to (0.289, 0.500) at 11 V (17,700 cd/m^2).

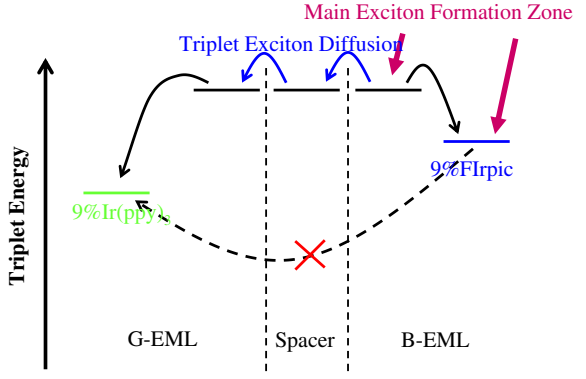

Fig. 8. Energy transfer paths in the EML of G-EML/spacer/B-EML. The dashed line indicates a prohibited energy transfer path.

3.3. White OLED with high color stability and high efficiency

Based on the EML structure of the G-EML (30 nm)/spacer (4.5 nm)/B-EML (18 nm), we further fabricated a WOLED, labeled as Device D, by doping 0.5%$Ir(phq)_3$ into the G-EML. Due to the rather low $Ir(phq)_3$ concentration, the J–V characteristics of Device D were almost the same as those of the corresponding Device A. In the inset of Fig 9(a), Device D inherited high color stability of Device A, on which it was based. Although the direct exciton formation on red dopants was inevitable, much lower red dopant concentration than green one would reduce the possibility of catching excitons by $Ir(phq)_3$ prior to $Ir(ppy)_3$

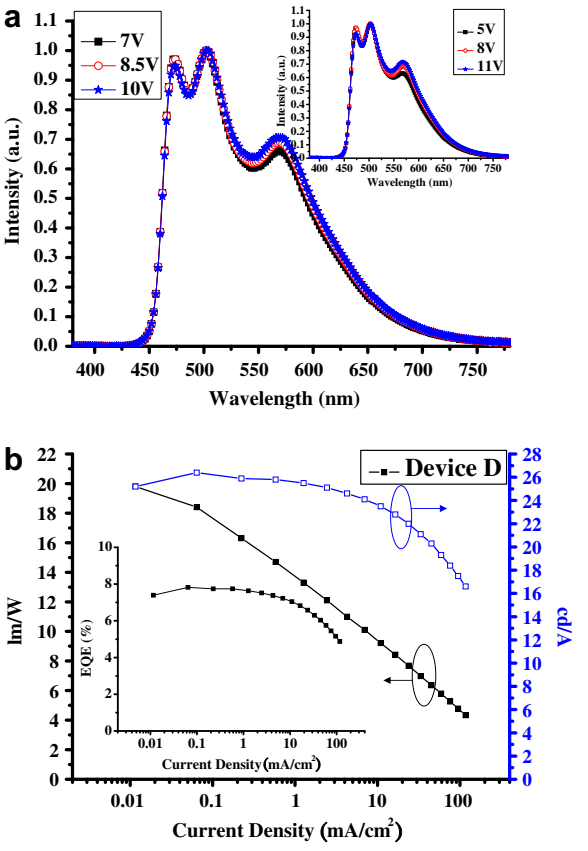

Fig. 9. (a) EL spectra of Device D at 7 V (1050 cd/m^2), 8.5 V (3740 cd/m^2), and 10 V (9120 cd/m^2). The emission with a peak around 570 nm was contributed by $Ir(phq)_3$. Inset: EL spectra of Device D at 5, 8, and 11 V. (b) Current and power efficiency of Device D with respect to current density. Device D exhibited maximum efficiencies of 26.4 cd/A and 19.8 lm/W. Inset: EQE of Device D at different current density.

[15,16], and therefore red excitons would be mainly generated by green excitons via energy transfer. The energy transfer from green to red dopants was almost independent of carrier and exciton concentration since carrier and exciton concentration was absent in the process of Förster or Dexter energy transfer [32].

As can be seen from Fig. 9(a), over the practical luminance range from 1050 (7 V) to 9120 cd/m^2 (10 V), the EL spectra were almost identical, and, thus, the CIE coordinates of Device D varied slightly from (0.310, 0.441) to (0.318, 0.446). Inset of Fig. 9(a) showed the EL spectrum of Device D when voltage changed from 5 to 11 V for a better comparison with blue–green devices (A, B, and C in Fig. 7). In addition to the outstanding color performance, Device D attained a maximum current and power efficiency, and EQE of 26.4 cd/A, 19.8 lm/W, and 7.82%, respectively, as shown in Fig. 9(b). A WOLED with high efficiency and stable color emission can be also obtained by using a thin EML (e.g. 15 nm) and suitable HTL/ETL design for confining carriers in a narrow recombination zone [16]. However, in such a device, efficiency decreased sharply with increasing current density due to serious triplet–triplet annihilation [33]. In this regard, for lower luminance applications (e.g. displays), one could design a thinner EML as proposed in Ref. [16]. For higher luminance application such as lighting, a thicker EML as revealed in this study could be needed instead.

4. Conclusion

Due to the relatively larger voltage drop across a thinner B-EML, stronger electric field dependence of the electron mobility of mCP, and energy barrier lowering at the B-EML/ETL and spacer/B-EML interfaces, it was suggested that the recombination zone extended into the G-EML for devices with a thinner B-EML as the applied voltage was increased. The extension of the recombination zone in conjunction with more significant TTA in the thinner B-EML resulted in a rather low color stability. Therefore, in addition to using a spacer to stabilize the color variation with the applied voltage, the thicknesses of individual EML should also be taken into consideration. In accordance with these two points, a blue–green OLED possessed an ultrahigh color stability, that is, its CIE coordinates were almost pinned across a wide luminance range from 48.7 to 12,700 cd/m^2. A WOLED utilizing the high color stability green–blue EML as the backbone inherited the latter's high color stability, with a nearly fixed CIE coordinate across the practical luminance range from 1050 to 9120 cd/m^2, and attained maximum efficiency of 26.4 cd/A and 19.8 lm/W.

limitation of the fabrication process. ALD-grown Al_2O_3 dielectric has several desired characteristics such as a high breakdown field (>1 V/nm), a high dielectric constant (7.8 as measured in metal/oxide/metal structure), and a low roughness (<1 nm). However, since the surface of Al_2O_3 is hydrophilic and attracts water, it is difficult to fabricate OTFTs in ambient conditions since the presence of water molecules often cause hole trapping in organic semiconductors. In order to eliminate this factor we used the well-known hydrophobic self-assembled monolayer (SAM) (1H,1H,2H,2H-perfluorooctyl) trichlorosilane (FOTS) [16] to modify the Al_2O_3 surface and make it hydrophobic. The modification of oxide gate dielectrics with hydrophobic surface modifiers is known to increase the mobility of OTFTs (see for instance [9]). The removal of residual water on the surface of the dielectric is often invoked as the origin of this increase. In our case, however, we show that it is a combination of hydrophobicity of the surface with the partial doping of the polythiophene semiconductor that drastically improves transport in the channel and leads to improved OFTF performance at comparatively low operation voltages.

2. Experimental

Heavily-doped silicon wafers were used as gate electrodes. The Al_2O_3 gate dielectric (50 nm) was deposited using a FlexAL® Atomic Layer Deposition Tool (Oxford Instruments) at 300 °C, after the native SiO_2 oxide was wet etched in buffered hydrofluoric acid. Subsequently, a 3-mercaptopropyltrimethoxysilane (MPTMS) self-assembled monolayer [17] was deposited in molecular vapor deposition tool MVD100 (Applied Microstructures, Inc.) to improve gold adhesion. Source and Drain electrodes were formed by depositing 50 nm of gold and were patterned using standard photolithography. The substrate was then cleaned in organic solvents and exposed to O_2 RF plasma (150 W) for 10 min. The FOTS layer was formed using the MVD100 tool. A 2 mg/ml solution of P3HT (Mn 25 000–35 000 Plexcore® OS 1100) in chloroform was prepared. It was spin-coated onto the substrate at 4000 rpm to give a 20 nm thick film. Electrical characterization was performed in air using a probe station equipped with two Keithley source-measure units. Structural analysis was performed using Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) at the D1 station of the Cornell High Energy Synchrotron Source (CHESS). A wide bandpass (1.5%) double-bounce multilayer monochromator defined a 10.0 keV photon beam. Samples were studied under various incident angles ranging from above the critical angle of the organic thin film to slightly above the critical angle of the underlying oxide. Scattering intensities were recorded using a 2-D area detector (MedOptics).

4. Results and discussion

Typical output characteristics from the transistors are shown in Fig. 1. The $I_{DS} - V_{DS}$ curves show linear behavior in low V_{DS} regime indicating good electrical contact between the gold electrodes and the P3HT. The field-effect hole mobility was calculated in the saturation region using [18]:

$$I_{sd,sat} = \frac{W}{2L}\mu_{sat}C_i(V_g - V_{Th})^2,$$

where W (L) is the channel width (length), C_i is the capacitance per unit area of the gate dielectric and V_{th} the threshold voltage. Good device-to-device uniformity was observed with typical mobilities ranging between 0.1 and 0.2 $cm^2 V^{-1} s^{-1}$ and with no apparent dependence on L (from 2 to 100 μm) and/or W/L ratio.

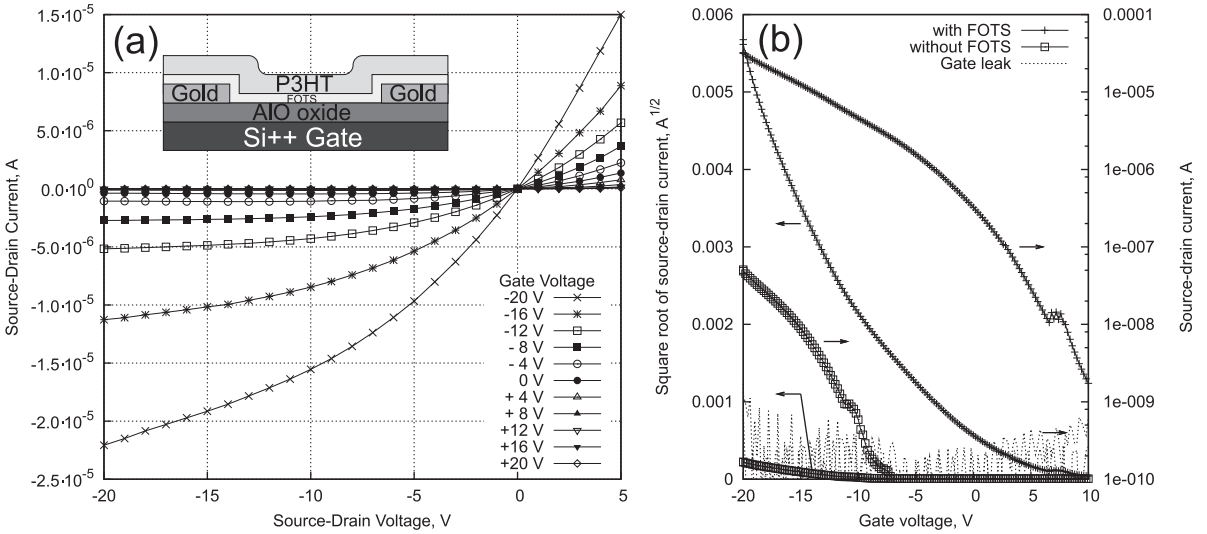

Fig. 1. (a) Output characteristic of a P3HT OTFT fabricated at ambient conditions. The channel length is 100 μm and the width is 1000 μm. Inset: schematic drawing of device structure. (b) Transfer characteristics, measured at source-drain bias of −20 V. Transfer characteristics of an OTFT without FOTS treatment also shown for comparison. The field-effect hole mobility (at $V_G = -15$ V) is 0.29 cm^2/vs. and the on/off ratio is 1.8×10^4.

Table 1
Summary of the electrical properties of P3HT OTFTs with modified Al_2O_3 surface dielectrics.

SAM treatment	Best mobility ($cm^2 V^{-1} s^{-1}$)	On/off	V_{on} (V)	References
Bare Al_2O_3	4.1×10^{-4}	$7{\cdot}10^4$	-3.6	[19]
Bare Al_2O_3	1×10^{-3}	$1{\cdot}10^3$	-10	This study
OTS	9.2×10^{-2}	54	5.6	[19]
FOTS	2.9×10^{-1}	$1.8{\cdot}10^4$	10	This study

In order to understand the influence of FOTS we fabricated a set of reference devices with a bare Al_2O_3 surface. Typical device parameters are summarized in Table 1. It is clear that the FOTS treatment significantly improves field-effect mobility and also causes a significant shift of the turn-on voltage V_{on}. The latter was determined from the transfer characteristics as the V_G that corresponds to I_{DS} = 1 nA. Data from literature on bare and *n*-octadecyltrichlorosilane (OTS)-functionalized Al_2O_3 [19] (Table 1) show a similar trend: Namely the SAM improves mobility and changes V_{on} from negative to positive values. The FOTS treatment, however, is shown to yield the highest field-effect mobility and also the largest turn-on voltage V_{on}. In addition, it causes the drain current that flows through the P3HT film at $V_G = 0$ to increase by more than three orders of magnitude (Fig. 1b).

The significant shift of V_{on} observed between the devices utilizing bare and FOTS-functionalized Al_2O_3 and the increase in the channel conductance at $V_G = 0$ constitute strong indications of doping of the P3HT from FOTS. This effect has been observed in different organic semiconductors [20,21] and was attributed to electrostatic doping due to the high dipole moment of the FOTS molecule. Another proposed mechanism of doping involves ground-state charge transfer at the interface between the organic semiconductor and FOTS [22,23]. A similar shift of V_{on} was also observed when P3HT transistors were exposed to ambient conditions presumably due to doping by oxygen [24]. Since our fabrication and testing were done in air we cannot exclude this effect, yet based on our bare Al_2O_3 device data we believe that this effect is much less pronounced than the doping caused by the FOTS. Moderate doping of polymer semiconductors is known to improve OTFT performance, an effect attributed to the formation of mobile carriers which reduce the resistance at the metal/organic interface and in the channel [25,26]. However, excessive doping leads to low on/off ratios which makes the OTFTs practically insensitive to external electrical field modulation. In contrast, the FOTS treatment of Al_2O_3 described here provides a good tradeoff between improving mobility and maintaining a high on/off ratio.

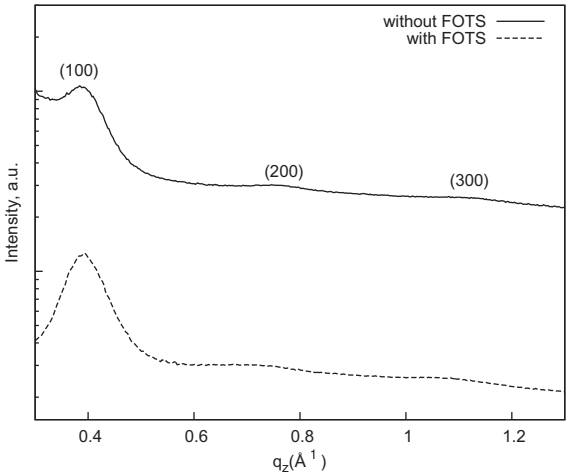

Fig. 3. Scattering intensity along the q_z from P3HT films on bare and on FOTS-functionalized Al_2O_3. The lamellar spacing was found to be 16.0 Å in both films.

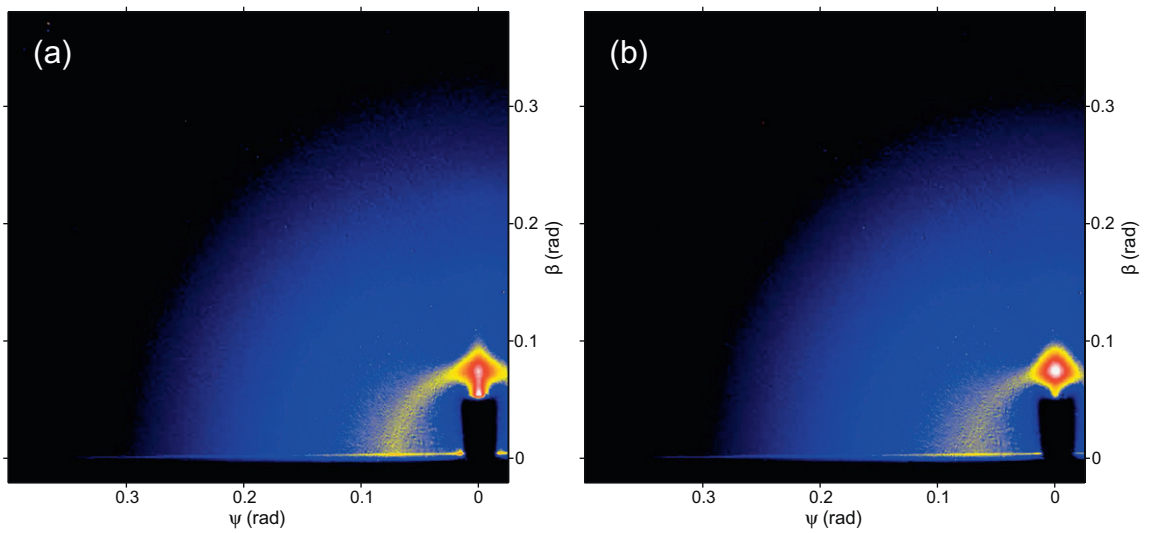

Fig. 2. 2-D GIWAXS patterns from P3HT films on bare (a), and on FOTS-functionalized Al_2O_3 (b).

2-D GIWAXS patterns from P3HT films deposited on bare and FOTS-functionalized Al_2O_3 are shown in Fig. 2, while the extracted scattering intensities along the q_z direction are shown in Fig. 3. The GIWAXS patterns are consistent with previously reported diffraction patterns [27] of P3HT with lamella forming parallel to the substrate. The lamellar spacing is 16.0 Å regardless of FOTS treatment of the dielectric. Additionally there is no difference in grain size, as is evident from the FWHM of the (1 0 0) diffraction peaks, or from the π–π stacking distance which is found to be 3.80 Å in both cases. The mosaicity of the film on FOTS shows a marginally more defect-free planar arrangement as compared to the film on bare oxide. Since bare oxide is hydrophilic and FOTS-treated oxide is fluorinated, both surfaces have oleophobic behavior, which allows P3HT film to self-organize with little or no effect of the substrate on its structure. The lack of a significant structural difference of P3HT on bare and on FOTS-treated oxide supports the conclusion that doping at the FOTS/P3HT interface is responsible for improvement of the transport properties of the film.

5. Conclusion

We showed that high-mobility polymer OTFTs can be fabricated at ambient conditions and with a process that does not require annealing of the polymer. Treatment of the Al_2O_3 gate dielectric with a FOTS self-assembled monolayer makes it possible to reach a field-effect hole mobility of 0.29 $cm^2\ V^{-1}s^{-1}$. Synchrotron X-ray scattering reveals no major influence of FOTS on film structure (as compared to bare oxide), which implies that the enhancement of device performance is caused by an interaction at the FOTS/P3HT interface rather than a structural modification of the P3HT film itself.

was measured in an integrating sphere (the total η_p measured in an integrating sphere roughly equals to the forward viewing η_p multiplied by 1.7) [12].

Another common approach for making WOLEDs involves the mixing of blue and yellow (B/Y) emissions. The main advantages of such devices are their much simpler structures and more stable colors. However, unlike fluorescent materials, the development for yellow phosphorescent materials still lags behind the materials emitting with monochromatic primary colors RGB. For example, maximal η_p for each monochromatic device has been demonstrated to be 42.7 lm/W for red (iridium(III) bis-(2-phenylquinolyl-N,$C^{2'}$)acetylacetonate, PQIr), 68.3 lm/W for green (tris-(phenylpyridine)iridium, Ir(ppy)$_3$), and 22.5 lm/W for blue (iridium(III) bis-(4′,6′-difluorophenylpyridinato)tetrakis(1-pyrazolyl)borate, FIr6) [8], respectively. On the contrary, there are only few yellow phosphorescent materials reported for achieving WOLEDs, in which the maximal η_p for monochromatic device is only 12 lm/W (bis(2-(9,9-diethyl-9H-fluoren-2-yl)-1-phenyl-1H-benzoimidazol-N,C^3) iridium(acetylacetonate), (fbi)$_2$-Ir(acac)) [9,13], whereas the chemical structures and device performance [10,11,14,15] have not been fully disclosed in other yellow-emitting OLEDs. In order to achieve white light with better color balance, the relatively low η_p for yellow phosphorescent materials unavoidably sacrifices the excessive blue emission, resulting in poor efficiency for WOLEDs. Recently, the highly efficient (η_p = 29 lm/W) yellow OLED based on yellow phosphor dopant p-PF-py has been reported by Tsuzuki et al. [16]. Nevertheless, it is desirable to develop more high performance yellow emitters and explore their applications for white OLED.

In this work, we report phosphorescent WOLEDs using a commercially available blue, iridium-bis-(4,6,-difluorophenyl-pyridinato-N,C^2)-picolinate (FIrpic) and a self-designed and synthesized yellow bis[2-(2-naphthyl)-pyridine] (acetylacetonate) iridium(III) (Ir(npy)$_2$acac) phosphors. Without using light out-coupling or p–i–n confinement structure, the WOLEDs attain a maximal forward viewing η_p of 29.2 lm/W, and a balanced white light with CIE coordinates of (0.32, 0.45).

2. Experimental

All glass substrates were coated with patterned anode indium tin oxide (sheet resistance 30 Ω/square), cleaned with Decon 90, rinsed in de-ionized water, dried in an oven, and finally treated in an ultraviolet–ozone cleaner prior to film deposition. The organic materials used have acronyms as follows: NPB: N, N′-diphenyl-1,1′-biphenyl-4,4′-diamine; mCP: N,N′-dicarbazolyl-3,5-benzene; UGH2: *p*-bis-(triphenylsilyly)benzene; and BAlq: aluminum(III) bis(2-methyl-8-quinolinato)4-phenylphenolate. WOLEDs with a structure of ITO/NPB (40 nm)/*x*%Ir(npy)$_2$acac:mCP (10 nm)/8%FIrpic:UGH2 (20 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm) were fabricated by thermal evaporation in high vacuum chamber (base pressure $\sim 10^{-6}$ Torr). The devices have a cascade-type energy band structure with a NPB hole-transporting layer, yellow- and blue-emitting hosts of mCP and UGH2, respectively, followed by a BAlq electron-transporting layer, and a LiF/Al cathode. Ir(npy)$_2$acac and FIrpic are respectively used as yellow and blue phosphorescent dopant emitters. All films were sequentially deposited at a rate of 0.1–0.2 nm/s without vacuum break. A shadow mask was used to define the cathode and to make four 0.1 cm^2 devices on each substrate. Current density–voltage–luminance (J–V–L) characteristics and electroluminescence (EL) spectra were measured simultaneously with a programmable Keithley model 237 power source and a Photoresearch PR650 spectrometer. All measurements were carried out without using light out-coupling enhancement or integrating sphere. Energies of highest occupied molecular orbital (HOMO) values of the materials were measured by using ultraviolet photoelectron spectroscopy, while energies of lowest unoccupied molecular orbital (LUMO) values were estimated by subtracting optical band gaps from the HOMO energies.

3. Results and discussion

The inset of Fig. 1 depicts the molecular structure of the iridium complex Ir(npy)$_2$acac. Identity of Ir(npy)$_2$acac was confirmed by ^{1}H-nuclear magnetic resonance, elemental analysis and mass spectrometry. Details of the molecular design and synthetic route for Ir(npy)$_2$acac will be published elsewhere. Fig. 1 shows absorption and PL spectra of Ir(npy)$_2$acac in a dilute dichloromethane solution. The EL spectra obtained from the monochromatic devices with structures of ITO/NPB (40 nm)/6%Ir(npy)$_2$acac:mCP (30 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm) for yellow and ITO/NPB (40 nm)/mCP (10 nm)/8%FIrpic:UGH2 (20 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm) for blue, denoted as Ir(npy)$_2$acac and FIrpic, respectively, are also shown in Fig. 1. It can be seen that the PL and EL peak positions of Ir(npy)$_2$acac show negligible difference (about 1 nm), while FIrpic has an EL peak at 472 nm with a shoulder at 494 nm. In addition, both FIrpic and Ir(npy)$_2$acac devices demonstrate similar maximal forward viewing η_p of 25.6 and 21.8 lm/W (device characteristics for Ir(npy)$_2$acac are shown in Fig. 2), respectively. It is worth noting that Ir(npy)$_2$acac exhibits a slightly broader emission spectrum (with a full width at half maximum (FWHM) of 87 nm) than those of (fbi)$_2$Ir(acac) (FWHM = 70 nm) [9,13] and (R-C^N^N)PtCl (FWHM = 80 nm) [10,14]. This would be beneficial for obtaining a better white color. Fig. 3 gives a schematic energy level diagram for the WOLEDs. It can be observed that the WOLED has a cascade-type energy band structure (stepped progression of HOMO or LUMO levels) for both the holes from the anode and the electrons from the cathode to the EML. This would clearly favor efficient carriers transport to the emission regions.

Fig. 4 shows normalized EL spectra of the WOLEDs with different concentrations (*x*%) of Ir(npy)$_2$acac viewed in the normal direction at a luminance of 100 cd/m^2. The EL of the WOLEDs is basically the sum of the emissions of FIrpic and Ir(npy)$_2$acac. With increasing Ir(npy)$_2$acac concentration, the relative intensity of the yellow emission (551 nm) increases and the CIE coordinates of WOLEDs shift from

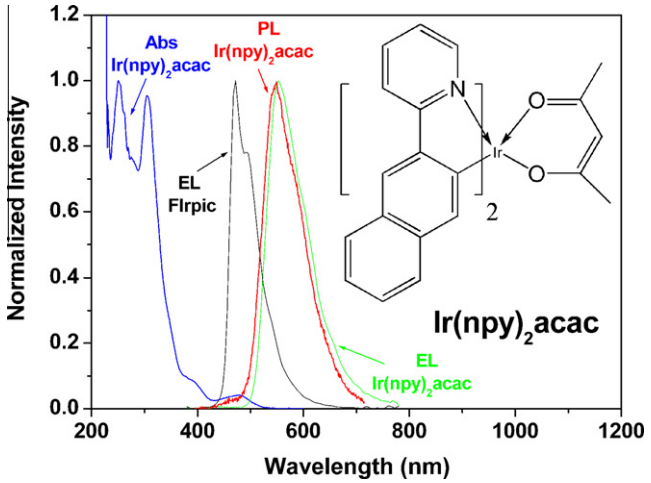

Fig. 1. Absorption and PL spectra of $Ir(npy)_2acac$ in a dilute dichloromethane solution. EL spectra from the yellow-emitting device: ITO/NPB (40 nm)/6%$Ir(npy)_2acac$:mCP (30 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm) and the blue-emitting device: ITO/NPB (40 nm)/mCP (10 nm)/8%FIrpic:UGH2 (20 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm) are also shown. Inset shows the molecular structure of $Ir(npy)_2acac$.

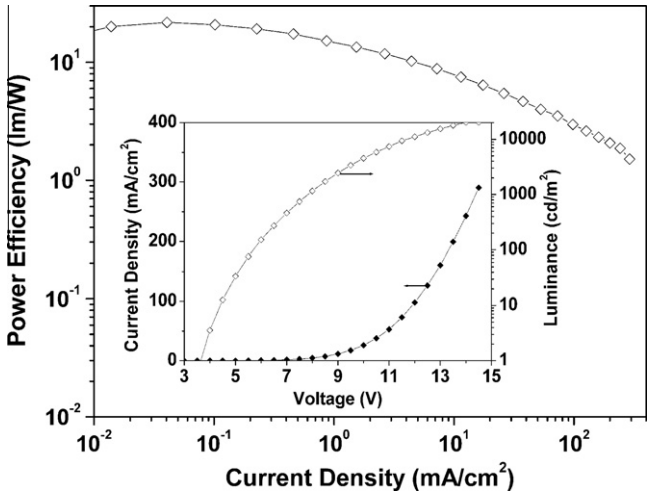

Fig. 2. Power efficiency as a function of current density of the yellow OLED. Inset shows J–V–L characteristics of the yellow OLED. Yellow OLED: ITO/NPB (40 nm)/6%$Ir(npy)_2acac$:mCP (30 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm).

(0.24, 0.39) to (0.44, 0.53). This phenomenon may be attributed to the increase in hole trapping sites formed by $Ir(npy)_2acac$ inside mCP, which is typically observed in the other yellow iridium phosphors [9]. With an optimum $Ir(npy)_2acac$ dopant concentration of 1%, the device shows balanced white emission with CIE coordinates of (0.32, 0.45). The inset of Fig. 4 shows a photograph of the WOLED with 1% $Ir(npy)_2acac$ operated at 9 V. Table 1 summarizes key operation parameters of the WOLEDs including external quantum efficiencies (η_{EQE}), η_P, and current efficiencies (η_C) etc. Upon increasing the concentration of $Ir(npy)_2acac$, η_C increases from 34.7 to 39.6 lm/W and then falls off to 36.8 lm/W. Similar trend can be observed for η_P. However, η_{EQE} shows a monotonic decrease with increasing dopant concentration. It is mainly due to the fact that η_{EQE} is independent of emission wavelength whereas η_C is sensitive to the photopic response, $g(\lambda)$, of human eye (the dotted line as shown in Fig. 4) [17]. In particular, η_{EQE} and η_C can be described by the following equation:

$$\eta_{EQE} = \frac{C\eta_c \int \lambda I(\lambda) d\lambda}{\int I(\lambda) g(\lambda) d\lambda} \quad (1)$$

where λ is the wavelength, $I(\lambda)$ is the EL intensity measured, $g(\lambda)$ is the photopic response of human eye at a particular wavelength, and C is a constant that depends on the Plank's constant, the velocity of light, and the electronic charge. Eq. (1) reveals that η_{EQE} is directly proportional to η_C and inversely proportional to $\int I(\lambda)g(\lambda)d\lambda$. In other words, the η_{EQE} increases with increasing η_C or decreasing $g(\lambda)$. $g(\lambda)$ is described by a spectral shape with a peak value

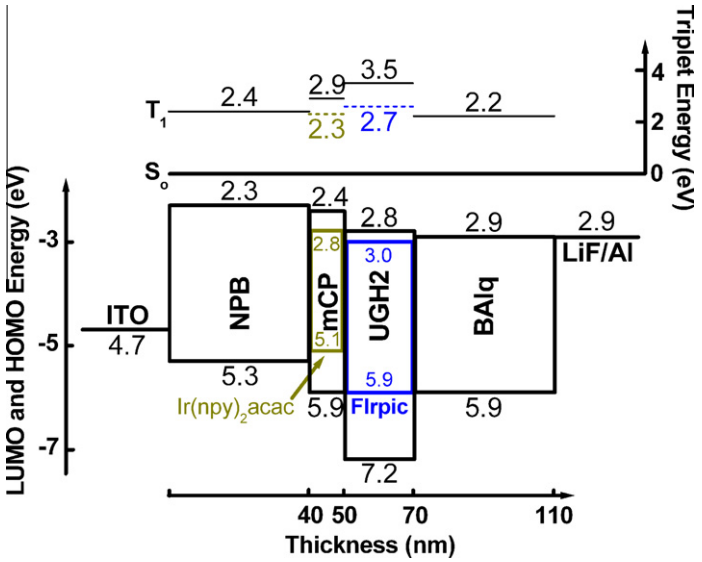

Fig. 3. A schematic energy level diagram of the WOLED.

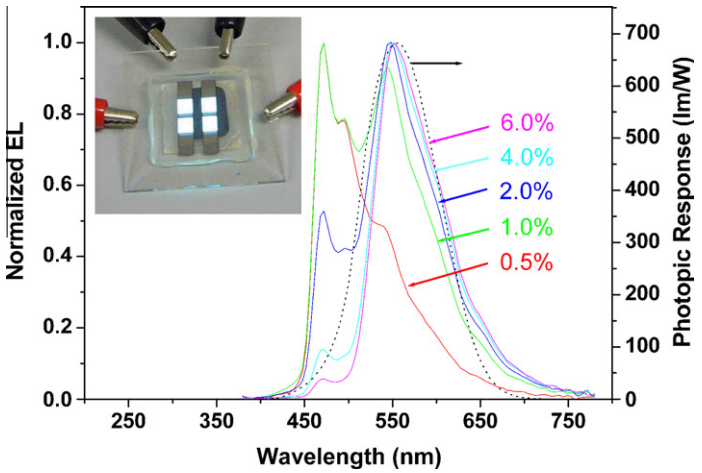

Fig. 4. Normalized EL spectra of various WOLEDs with different concentrations of $Ir(npy)_2acac$ viewed in the normal direction at a luminance of 100 cd/m^2. Inset shows a photograph of the WOLED with the optimal concentration of 1% $Ir(npy)_2acac$ at 9 V.

of 683 lm/W at λ = 555 nm and falls off rapidly towards either the red or blue. Taking the eye's spectral sensitivity into account, the η_{EQE} of yellow-emitting OLED is usually smaller than those of red- or blue-emitting devices when all devices have the same η_C, and it is also the reason why η_{EQE} decreases when the concentration of yellow

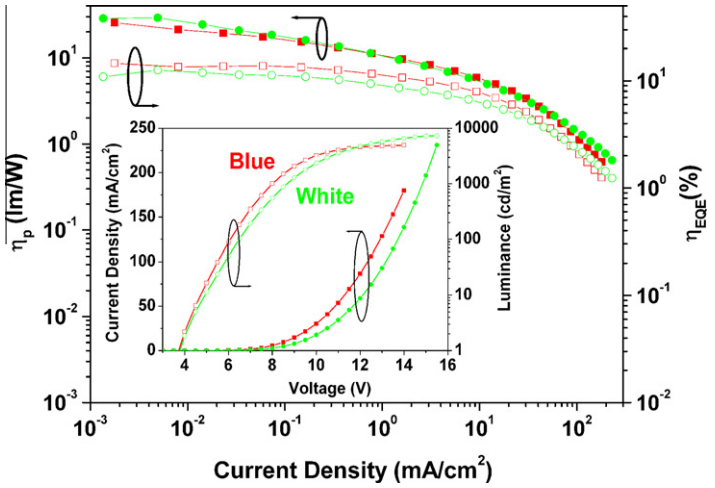

Fig. 5. Power and external quantum efficiencies as a function of current densities of the blue and the white OLEDs. Inset shows J–V–L characteristics of the blue and the white OLEDs. Blue OLED: ITO/NPB (40 nm)/mCP (10 nm)/8%FIrpic:UGH2 (20 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm). White OLED: ITO/NPB (40 nm)/1%Ir(npy)$_2$acac:mCP (10 nm)/8%FIrpic:UGH2 (20 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm).

Ir(npy)$_2$acac increases as the η_C increases. It is one of the reasons responsible for the intrinsically higher η_{EQE} of three emitters RGB WOLEDs as compared to B/Y emission WOLEDs.

Fig. 5 shows η_p, η_{EQE} and J–V–L characteristics of the white and the blue OLEDs. The turn-on (defined as the voltage required to obtain $L = 1$ cd/m^2) and operating voltages at 10 mA/cm^2 for white OLED are respectively 3.8 and 9.3 V, which are slightly larger than those (3.7 and 8.6 V) of the blue OLED. The higher driving voltage of the WOLED may be due to the charge trapping effect of the Ir(npy)$_2$acac dopants. At a luminance of 1000 cd/m^2 (a typical brightness required for lighting source purpose), the CIE coordinates and the η_p are (0.27, 0.33) and 6.5 lm/W for the white OLED and (0.16, 0.33) and 7.0 lm/W for the blue OLED, respectively. In addition, it can be seen that the maximal forward viewing η_p, η_C, and η_{EQE} are 29.2 lm/W (roughly equivalent to a total η_p of 50 lm/W) [12], 37.2 cd/A, and 12.6% for the WOLEDs and 25.6 lm/W, 28.5 cd/A, and 14.6% for the blue OLEDs, respectively. The differences in η_C and η_{EQE} of the two devices suggest that the yellow Ir(npy)$_2$acac dopant has negative effect on the η_{EQE} while the η_C is increased by 30%. Significantly, the forward viewing efficiencies of the present WOLEDs are among the highest values reported for B/Y emission WOLEDs without optical out-coupling [1,8,11] or a p–i–n confinement structure [1].

4. Conclusion

In conclusion, we report phosphorescent WOLEDs based on the combination of our self-designed and synthesized yellow Ir(npy)$_2$acac phosphor and the commercial blue FIrpic. Such WOLEDs show a maximal forward viewing η_p of 29.2 lm/W and balanced white light with CIE coordinates of (0.32, 0.45) with superior efficiencies.

element in the development of inkjet-printing-based solar cells. In an earlier report, we have demonstrated the use of ZnO as a buffer layer for the inkjet-printing of a silver cathode in a polymer solar cell [9]. We have also reported on the performance of bulk heterojunction polymer solar cells fabricated with an inkjet-printed poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) layer. The morphology and electrical properties of the inkjet-printed PEDOT:PSS layer, as well as the overall device performance, were dramatically affected by the ink formulations containing additives, such as glycerol and a surfactant [10].

Employing a spin-coated P3HT:PCBM active layer, several research groups have reported on the formation of a phase separated morphology with crystalline P3HT and PCBM domains inside the active layer of bulk-heterojunction solar cells. Such a morphology has been achieved by use of an appropriate solvent with a specific boiling point for precise control over the evaporation rate [11,3,12], reducing the drying speed of the spin-coated films [13–15], melting of the bilayers [16], thermal annealing of the fabricated films with or without an applied external voltage [17–19], and using chemical additives [20–22]. Few efforts have been made to fabricate inkjet-printed bulk-heterojunction solar cells. Brabec et al. recently reported the solar cell devices fabricated by inkjet-printing P3HT:PCBM inks formulated with various solvent mixtures on doctor-bladed PEDOT:PSS layer [23–25]. Aernouts et al. also reported the device performance of P3HT:PCBM active layer with high boiling point (b.p.) solvent mixtures for reducing coffee-ring effect [26]. However, to the best of our knowledge, no researchers have reported on efficient polymer solar cells fabricated by inkjet-printing both the PEDOT:PSS layer and the P3HT:PCBM active layer.

In this work, we report on highly efficient and cost-effective inkjet-printed PSCs based on P3HT and PCBM inks containing various additives. All solution-processed solar cell layers—a hole transporting layer of PEDOT:PSS and a photoactive layer based on P3HT and PCBM with various additives—were inkjet-printed. The conditions of the inkjet-printed PEDOT:PSS layers were optimized based on the results of our previous study [10]. Changes in the morphology, optoelectronic properties, and overall device performance that resulted from the addition of various high b.p. additives, such as 1,8 octanedithiol (ODT), o-dichlorobenzence (ODCB), and 1-chloronaphthalene (Cl-naph), to chlorobenzene (CB) solvents were investigated.

Regioregular poly(3-hexylthiophene) (P3HT) as an electron donor and [6,6]-phenyl-C61 butyric acid methylester (PCBM) as an electron acceptor were purchased from Rieke metals and Nano-C, respectively. Poly(3,4-ethylenedioxythiophene):poly-(styrene sulfonic acid) (PEDOT:PSS) was purchased from Bayer (Baytron P AI 4083). Several high b.p. additives, such as ODT, ODCB, and Cl-naph, were obtained from Sigma-Aldrich and used as-received. In the present study, the configuration of the polymer solar cell devices was indium tin oxide (ITO)/PEDOT:PSS/active layer of P3HT:PCBM/LiF-Al. Patterned ITO glass was cleaned with chloroform, acetone, and isopropyl alcohol using an ultrasonication method. The ITO was then subject to an O2-plasma treatment. To PEDOT:PSS inks for inkjet-printing, PEDOT:PSS was mixed with additives of glycerol (0.431) and ethylene glycol butyl ether (EGBE, 0.014). Details regarding the optimization of the additive concentrations to obtain the best PEDOT:PSS layer can be found in our previous report [10]. After a solvent cleaning, the PEDOT:PSS inks were deposited on the ITO substrates using an inkjet-printing (UJ2100, Unijet, Korea) technique. The films were then dried for 20 min at 140 °C.

To optimize the parameters for the inkjet-printing of an active layer, blends (inks) of P3HT:PCBM (1:0.7, 2 wt%) in CB with different high b.p. additives of ODT, ODCB, and Cl-naph were prepared (details are given in Table 1). These inks were printed on top of the PEDOT:PSS layers by the same printer used for the PEDOT:PSS deposition. Temperatures of inkjet-printer head and substrate were kept as 26C. The printed films were then dried for 1 h at room temperature in a nitrogen atmosphere. By varying the ink concentrations and the printing speed, the optimum thickness of the P3HT:PCBM layers was found to be 150 nm. Thermal evaporation was used to deposit a LiF layer (0.5 nm thickness) on the active layer. To complete the device, an Al layer (150 nm thickness) was evaporated on top of the LiF layer. All evaporations were performed under vacuum (10-6 torr). Each completed device was encapsulated so as to measure the solar cell performance.

The current density–voltage (J–V) characteristics of the solar cell devices in the dark and under white light illumination were measured with an AM 1.5G solar simulator (300 W, Newport, USA) calibrated to 100 mW/cm2 with a standard PV reference cell (a 2 × 2 cm monocrystalline silicon solar cell, calibrated at NREL, Colorado, USA) using a Keithley 2400 source-measure unit. The open circuit voltage (Voc), short circuit current density (Jsc), fill factor (FF), and power conversion efficiency (PCE) were calculated from the J-V curves. The incident photon to collected electron efficiency (IPCE) of the devices was measured with a commercial photomodulation spectroscopic setup that included a xenon lamp (Oriel), iris diaphragms, and an AM 1.5 filter. In order to avoid an underestimation of the area of the devices due to cross-conduction through

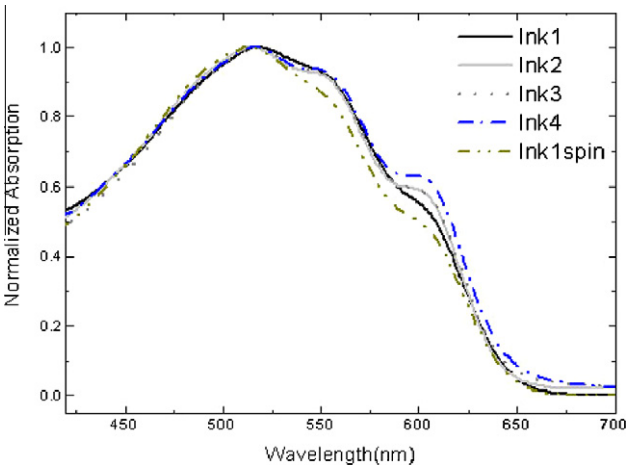

Fig. 1. UV–Vis absorption spectra of the inkjet-printed active layers fabricated from different inks.

the highly conducting PEDOT:PSS used in this study, a black mask fitted to the active area (3×3 mm) of the devices was employed [27–29]. The surface morphology and absorption spectra of the inkjet-printed active layers were analyzed using atomic force microscopy (AFM, Nanoscope IV, Multimode) and UV–Vis spectroscopy (JASCO, V-670), respectively. The crystallinity of the P3HT was examined with X-ray diffractometry (XRD, Rigaku, with a Cu Kα source). All characterizations were performed at room temperature.

Shown in Fig. 1 are the optical absorption spectra as a function of wavelength for the inkjet-printed active layers containing different additives; the reference film was fabricated by spin-coating. The film spin-coated with ink1, formulated with CB and no additives, exhibits an absorption spectrum with a maximum centered at 509 nm with two indistinct shoulders at 544 and 595 nm. For the inkjet-printed films from ink2 contained 5 vol% ODT, ink3 contained 5 vol% ODCB, and ink4 contained 5 vol% Cl-naph, a red shift with relatively wide absorption in the longer wavelength region was clearly observed; maxima were located at 513 nm, and two pronounced vibronic peaks emerged at 552 and 602 nm [30,31]. As the film thickness is identical for all four films, the observed red shift is evidence of improved π–π^* transition absorption due to the increased conjugation length of polymer chains. The increased conjugation length of the polymer chains was caused by a reduction in the density of conformational defects. The addition of a moderate amount of high b.p. additives to the CB allows for the slow evaporation of the solvent and hence, leads to enhanced P3HT crystallinity. The improvement in the crystallinity is generally observed in the case of post-annealed P3HT-based polymer solar cells [4,19]. As such, the inkjet-printing method with modified inks containing high b.p. additives can act as a substitute for crucial post-annealing treatments. When compared to spin-coated devices, inkjet-printed solar cells fabricated with inks containing additives have improved crystallinity and better light harvesting properties over a wider spectral region. Consequently, the inkjet-printed solar cells are expected to exhibit improved photovoltaic performance.

The XRD results for the inkjet-printed active layer films fabricated with different inks are shown in Fig. 2. The peak intensity at $2\theta \approx 5.3$, which corresponds to the interchain spacing associated with the interdigitated alkyl chain in P3HT [4,32], was more enhanced in the films fabricated with high b.p. additives (inks 2–4). The maximum peak intensity was observed in the film fabricated with ink4, which contained the Cl-naph additive. These results are in agreement with the trends observed for the vibronic peak in the UV absorption spectra shown in Fig. 1. In addition, when high b.p. additives are added to the inks (inks 2–4), the 2θ angle of (100) of films is moved to higher angle: 5.24 for ink 1, 5.30 for ink 2 and 3, and 5.42 for ink 4. According to the Bragg's equation ($n\lambda = 2d \sin\theta$, where n, λ, d, and θ denote the order of diffraction, wavelength of an X-ray beam, interlayer spacing, and Bragg peak position, respectively) [33,34], a interlayer spacing of films fabricated with high b.p. additives (inks 2–4) is less than that of film prepared from pure P3HT:PCBM ink (ink1). It indicates that modification of inks with high b.p. additives induces closer P3HT chains, resulting in the lower resistance to the hopping of charge carriers.

Morphology is one of the key factors that affect the performance of bulk-heterojunction solar cells. To investigate the effects of additives and inkjet-printing on the morphology, the surface of the active layer films was imaged using an atomic force microscope (AFM). Shown in Fig. 3 are the AFM images of the inkjet-printed active layers fabricated with different inks; the reference cell fabricated from spin-coating is shown for comparison. From the AFM images ($100 \times 100\mu$m), it is clear that the morphology is greatly influenced by the addition of different high b.p. additives to the CB solvent. The film prepared with ink1 (CB with no additives) possesses an rms roughness of 64 nm, which is very high when compared to the films fabricated from inks 2–4. Such a high rms roughness may be due to the high evaporation rate of the CB. If the rate of evaporation of the solvent is high, then there may not be

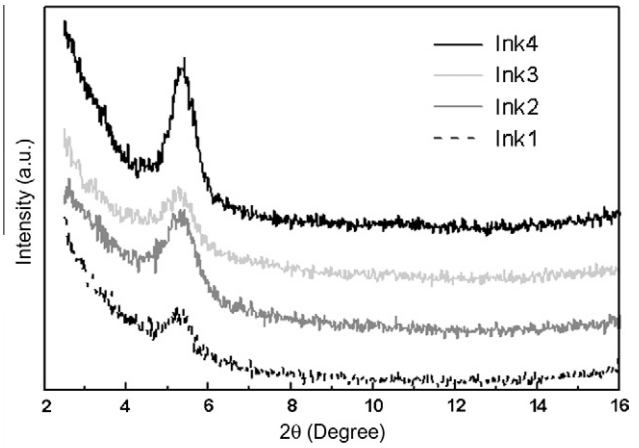

Fig. 2. XRD spectra of the inkjet-printed active layers fabricated from different inks.

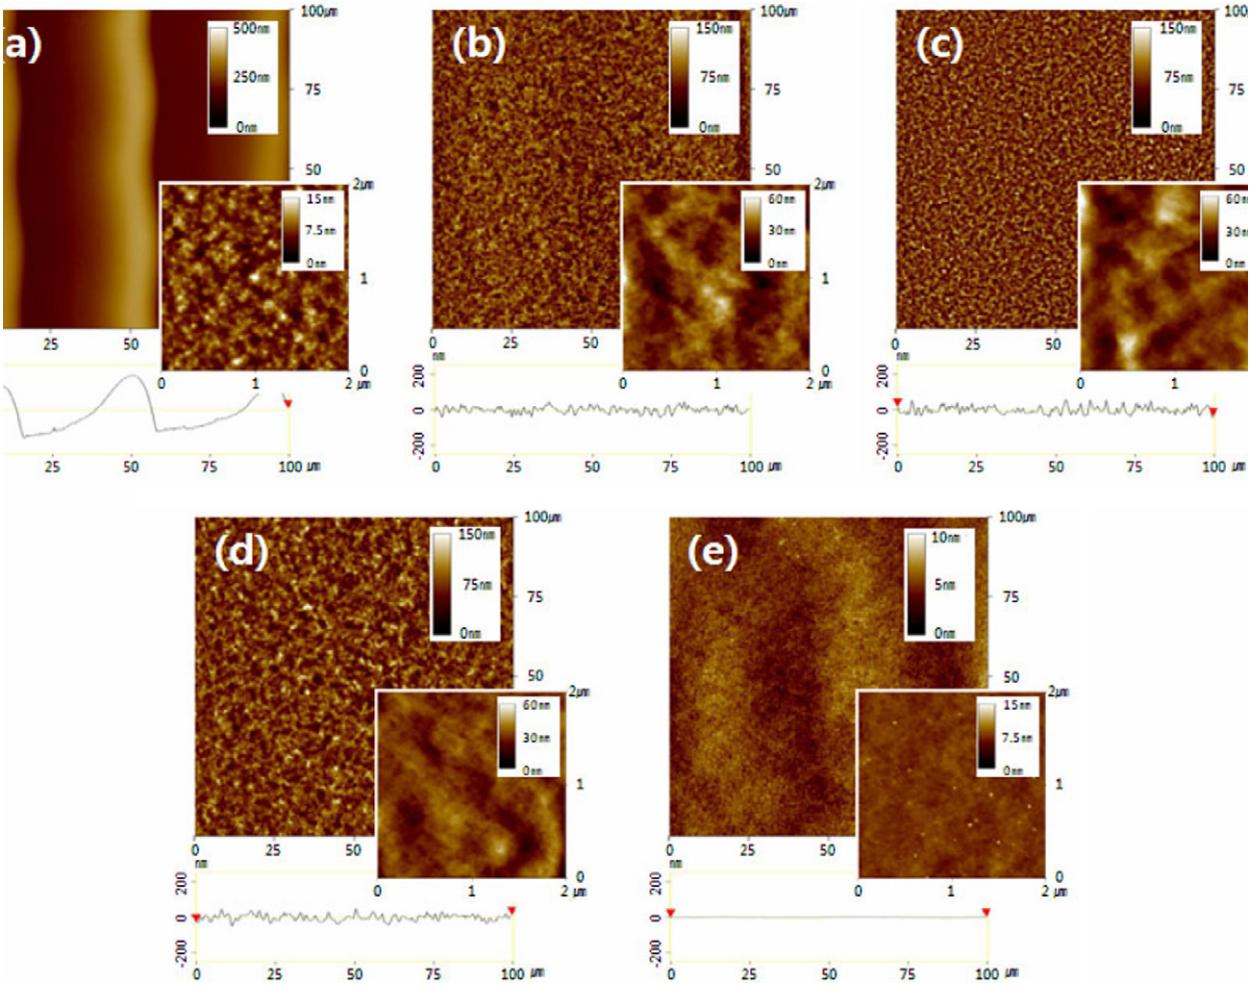

Fig. 3. AFM images of the P3HT:PCBM active layers fabricated from different inks: inkjet-printed (a) ink1 (b) ink2 (c) ink 3 (d) ink 4 and (e) spin-coated ink1.

sufficient time for self organization of the blended P3HT polymer molecules. This would result in a coating with a rough and uneven surface. On the other hand, the films from ink2, ink3, and ink4 possess moderate rms roughnesses on the order of 17.7, 20.9, and 17.9 nm, respectively. As stated above, ink2, ink3, and ink4 contain high b.p.

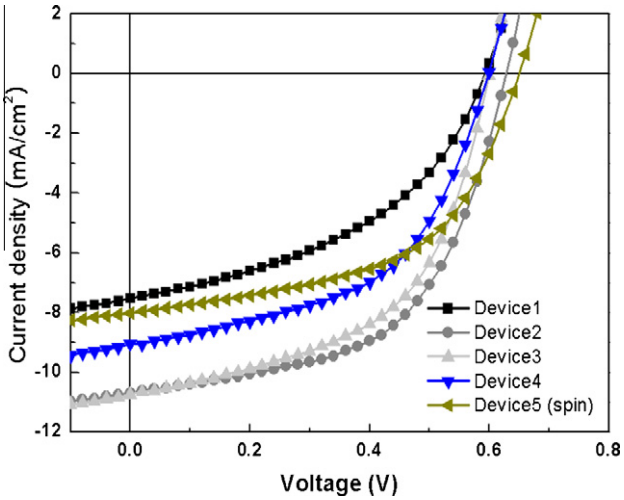

Fig. 4. J–V characteristics of the solar cell devices with P3HT:PCBM active layers fabricated from different inks.

additives of 5 vol% ODT, 5 vol% ODCB, and 5 vol% Cl-naph, respectively. The observed decrease in the rms roughness values can be attributed to the low evaporation rates of the high b.p. additives. These high b.p. additives allow for a controlled evaporation and sufficient time for self organization to occur. The additives may also provide enhanced wettability of the P3HT:PCBM inks on the PEDOT:PSS layer, leading to an active layer with a uniform film morphology and reducing the coffee-ring effect [35]. In general, it can be concluded that the addition of high b.p. additives offers control over the morphology of the P3HT and PCBM domains in the inkjet-printed active layer. The reference device (ink1) fabricated by spin-coating possessed a very low rms roughness of 1 nm, which may be due to the high spinning rate used in this study. However, when compared to the inkjet-printed films, the film spin-coated from ink1 exhibited a homogeneous morphology with no significant phase separation. The AFM images in the inset of Fig. 3 ($2 \times 2\mu m$ scan size) more clearly reveal that the films inkjet-printed from inks 2–4 show more distinct nanoscale phase separation than in the spin-coated film. The increased phase separation is a result of polymer self organization and leads to an increase in device efficiency. However, it should be noted that the film inkjet-printed from ink4 exhibits an undesirably large degree of phase separation between the P3HT and PCBM (the average size of the domains is greater than 100 nm), which may result in the restriction of charge transport.

To directly evaluate the effect of high b.p. additives on the overall device performance, the J–V characteristics of all the solar cells were measured under illumination with a solar simulator. Shown in Fig. 4 are the J–V plots for all devices; the calculated values of the solar cell parameters are summarized in Table 2. As clearly evident in Fig. 4, the device fabricated with ink1 (device 1) without any additives exhibits very poor performance with a PCE ~1.9% resulting relatively lower Voc, Jsc and FF than other devices. The observed low device performance may be due to poor P3HT crystallinity, relatively weak absorption in the longer wavelength region and undesirable film morphology (see Figs. 1–3) that serve to restrict the transport of the photo-generated charges towards the electrodes. In contrast, the device fabricated with ink2 (device 2) exhibited the best performance with a PCE of ~3.7% and an FF that increased up to ~56%. Such a result was believed to arise from a higher level of P3HT crystallinity and distinct nanoscaled phase separation morphology. These factors, in turn, led to a lower serial resistance and defect-free contact with the metal cathode. The device prepared with ink3 (device 3) had a Jsc of ~10.7 mA/cm2, which was similar to the Jsc from device 2. However, a slight reduction in the Voc to ~0.6 V was observed in device3, which led to a decrease in the PCE to ~3.4%. The device prepared with ink4 (device 4) yielded a PCE of 2.83% and lower Jsc and Voc values than those found for devices 2–3. This may due to a low photo current, which is in turn attributed to limitations in the charge transport and collection by the large phase separated morphology (see the AFM images in Fig. 3). The exact reasons of lower Voc are not clearly reported yet even though several efforts have been made to fabricate inkjet-printed bulk-heterojunction solar cells with active layer of P3HT:PCBM [24,25]. In organic solar cells, the Voc is generally governed by the energy difference between the highest occupied molecular orbital (HOMO) of the donor and the lowest unoccupied molecular orbital (LUMO) of acceptor [36]. An increase in the conjugation length due to strong chain interactions improves the crystallinity with long wavelength absorption. Such a scenario leads to an improved Jsc, but may cause a reduction in the Voc in the devices 1–4 fabricated by

Table 2
Summary of the solar cell device performance for the different P3HT:PCBM active layers containing different additives.

Devices with inks	V_{oc} (V)	J_{sc} (mA/cm^2)	FF (%)	PCE (%)
Device 1 (ink 1)	0.593	7.53	44.25	1.97
Device 2 (ink 2)	0.628	10.68	55.27	3.71
Device 3 (ink 3)	0.600	10.73	53.28	3.43
Device 4 (ink 4)	0.599	9.49	52.23	2.83
Device 5 (ink 1, spin)	0.650	8.02	53.58	2.79

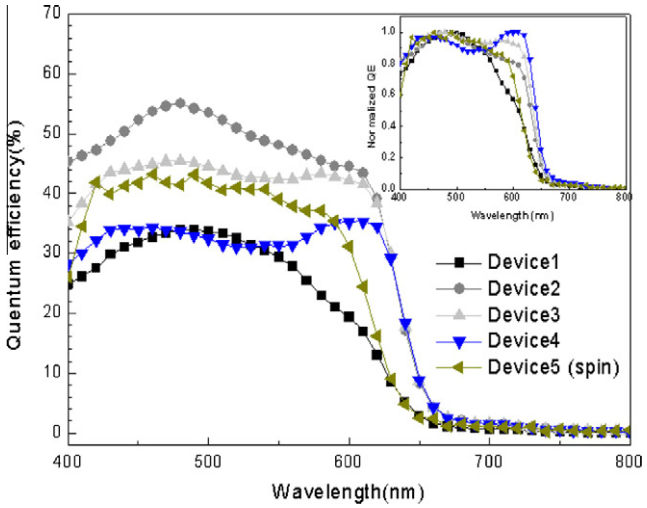

Fig. 5. The IPCE spectra of solar cell devices with P3HT:PCBM active layers fabricated from different inks.

inkjet-printing, especially in device 4 showing a high crystallinity (see Fig. 2). Device5, fabricated by spin-coating with ink1, exhibited a PCE of 2.79%, which was lower than that found in the inkjet-printed devices (devices 2–4) even though it shows a higher Voc and comparable FF than inkjet-printed devices (devices 2–4). Such a low PCE may due to poor P3HT crystallinity and weak absorption in the longer wavelength region, resulting a lower Jsc, for the active layer fabricated by the spin-coating method (see Figs. 1 and 2).

Shown in Fig. 5 are the plots of the IPCE measured for all of the devices. The dependence of the IPCE on the post-production treatment has been reported by several groups; IPCE values of up to 70–80% have been achieved [19,37–40]. Devices 2–4, which were inkjet-printed from inks 2–4 with additives, showed significant IPCE improvement in the longer wavelength region, when compared to device 1 (no additives) and device 5 (spin-coated from ink1) (see the inset of Fig. 5). While device 5 possessed a low rms roughness, it exhibited a low IPCE of 50%, when compared to devices 2–3 due to its low optical absorption in the longer wavelength region. A maximum IPCE of up to 55% was measured with device 2. Device 1, fabricated from ink1, containing no high b.p. additive, exhibited the lowest IPCE of about 30%. This may due to its low crystallinity and relatively weak absorption in the longer wavelength region. Device 4, made with ink4, exhibited a relatively low IPCE value even though it displayed good absorption at longer wavelengths. Such a scenario may be due to the limited charge transport that is related to the large degree of phase separation. The attained IPCE results are in good agreement with the trends observed in the optical absorption spectra and the device performance data shown in Figs. 1 and 4. The profound improvement in the IPCE with the addition of different additives is believed to increase both the optical absorption and the charge transport, as well as reduce recombination losses due to improvements in crystallinity and surface morphology. Therefore, it can be concluded that inkjet-printing provides a two-fold improvement in the overall solar cell performance, i.e. efficient light harvesting by improved P3HT crystallinity and enhanced charge transport and offering a better surface morphology for the top metal contact.

Bulk heterojunction polymer solar cells have been prepared with an inkjet-printed active layer of P3HT:PCBM and a PEDOT:PSS layer. For an optimum ink formulation, different high b.p. additives, such as ODT, ODCB, and Cl-naph were added to CB. The addition of high b.p. additives has greatly influenced the morphology, the optical and electrical properties, and the solar cell performance of the devices. The devices fabricated from inks formulated with high b.p. additives have exhibited improved device performance, when compared to the devices prepared without additives. Such behavior was due to optimum film morphology, improved light absorption properties, and reduced recombination losses due to an improved crystallinity and charge transport. The inkjet-printed device with an active layer of P3HT:PCBM containing the high b.p. additive ODT and a modified PEDOT:PSS layer has demonstrated the best solar cell performance with a PCE of ~3.7% and an IPCE of ~55%.

characteristics measurement of a transistor. In order to handle this problem, Petit et al. utilized pulsed gate voltage instead of constant bias to minimize the bias stress effects in OTFTs [8]. Although, this measurement method enables device characterization, which is free of hysteresis effects, it cannot be used to investigate the hysteresis itself. Therefore, in reports focusing on hysteresis characteristics, standard sweep measurements, where the bias voltages (e.g., gate voltage) are not pulsed but swept, are primarily utilized.

In this report we show the impact of electrical measurement parameters on hysteresis in standard *I–V* characteristics of OTFT. We first introduce the hole trap related hysteresis mechanism and describe how the measurement parameters can influence the hysteresis in transfer and output characteristics. In the experimental section, we explain the fabrication and characterization of our devices and show the results of the measurements performed on these devices. The results of the simulations, performed with the device simulator ATLAS, are given in Section 4, which give an insight to the trapping/detrapping process in the active layer of a pentacene TFT at different bias conditions.

2. Theory

Electronic trap states in the active layer of pentacene-based OTFTs cause a hysteresis in the *I–V* characteristics by affecting the number of available charge carriers. As explained in detail in Ref. [4], during a gate bias sweep, at negative gate biases, positive charge carriers (holes) in the accumulation layer of the pentacene film are trapped. This reduces the number of effective charge carriers and thus the drain-source current I_{DS}. When the negative gate bias is removed, the trapped carriers are slowly released and the number of available charge carriers increases. Due to this bias dependent trapping/detrapping dynamics all device characteristics including transfer and output characteristics exhibit hysteresis. The mechanism of this phenomenon is discussed in the following two subsections.

2.1. Hysteresis in transfer characteristics

In order to explain the hysteresis in the transfer characteristics of a p-type OTFT, the transient behavior of I_{DS} at different gate-source biases and the resulting *I–V* characteristics are illustrated in Fig. 1. In this example, the drain-source voltage (V_{DS}) is assumed to be set to a certain negative value and kept constant through the entire measurement, while the gate-source voltage (V_{GS}) is swept from 0 V to a negative voltage (OFF-to-ON) and then back to 0 V (ON-to-OFF). For the sake of simplicity, only one intermediate V_{GS} step is considered for each sweep direction (Fig. 1(a)). It can be seen in Fig. 1(b) that during OFF-to-ON sweep, in both steps at $t = t_1$ and $t = t_2$, I_{DS} increases stepwise as the gate voltage V_{GS} becomes more negative, but then decreases again as the number of available charge carriers decreases in time due to trapping ($t_1 < t < t_2$ and $t_2 < t < t_3$). On the contrary, during ON-to-OFF sweep, I_{DS} decreases stepwise as V_{GS} becomes less negative ($t = t_3$), but then increases transiently as the

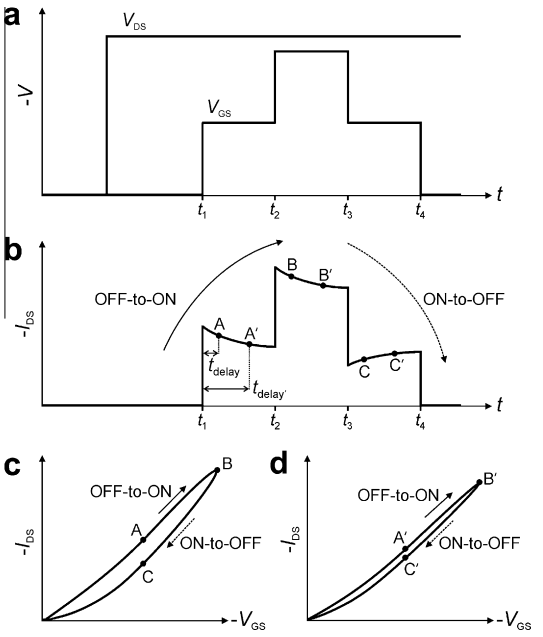

Fig. 1. Illustration of the transient response of the channel current I_{DS} during the transfer characteristics measurement of an OTFT. (a) Successive steps of drain and gate biases. (b) Transient response of I_{DS}. (c) Transfer characteristics measured with shorter delay time t_{delay}. (d) Transfer characteristics measured with longer delay time $t_{delay'}$. Hysteresis width decreases with increasing delay time.

detrapping increases the number of available charge carriers ($t_3 < t < t_4$). Due to the long time constants of the trapping/detrapping process, I_{DS} does not reach a steady state even a long time after a change in V_{GS}.

In *I–V* characteristics measurements, it is a good practice to introduce a time delay, which ensures that the DUT settles after stepping the bias. Since the time constants of hysteresis dynamics exceed the duration of a typical electrical measurement, the delay time plays a crucial role on the resulting *I–V* characteristics. To illustrate this, two different sets of measurement points with different delay times, i.e., t_{delay} and $t_{delay'}$, are depicted in Fig. 1(b), which are marked with letters A, B, C and A′, B′, C′, respectively. The resulting *I–V* characteristic from the first set of measurement points (A, B, C) with the shorter delay time t_{delay} is given in Fig. 1(c), which indicates different I_{DS} values at points A and C, although the bias voltages (V_{DS}, V_{GS}) are exactly the same at these measurement points. This leads to the hysteresis in the transfer characteristics with higher currents during OFF-to-ON sweep. If the second set of measurement points (A′, B′, C′) with the longer delay time $t_{delay'}$ is used, a different *I–V* characteristic is obtained due to the transient characteristics of I_{DS} (Fig. 1(d)). A hysteresis with the same rotational direction is still present in the characteristics; however, the width of the hysteresis becomes smaller with increasing delay time.

2.2. Hysteresis in output characteristics

The electric field in the channel of an OTFT is responsible for the accumulation of charge carriers in the active

layer and, thus, for the trapping/detrapping process. If the source electrode is grounded and kept at this potential, the electric field in the channel is determined primarily by the gate bias. The drain bias has a contribution to the field, particularly in the vicinity of the drain electrode. Regarding the electric field in this region, an increase in drain bias has the same effect, i.e., a decrease in electric field strength, as a decreasing gate bias and vice versa. This means, in case of a constant negative gate bias, a change in drain bias toward more negative voltages reduces the electric field strength near the drain electrode and trapped charges in this region are released resulting in an increase in I_{DS} [4]. If the negative drain bias is removed, the electric field strength increases, charge carriers are trapped and I_{DS} decreases. Hence, analogous to the case in transfer characteristics, a hysteresis exists in output characteristics, which will be explained using the illustration in Fig. 2. In this example, V_{GS} is assumed to be set to a certain negative value and kept constant throughout the measurement, while V_{DS} is swept from 0 V to a negative voltage and then back to 0 V to extract the output characteristics. First, we investigate the case when the hold time t_{hold}, which is the time between setting V_{GS} to a constant value and the first step of V_{DS} sweep (see Fig. 2(a)), is long such that gate bias related effects can be neglected and only the change in V_{DS} influences the current I_{DS}. Under this assumption, the transient behavior of I_{DS}, which is depicted with a solid line on the right hand side of Fig. 2(b), can be explained as follows. As V_{DS} is swept to negative voltages, in both steps, I_{DS} increases stepwise as V_{DS} becomes more negative and it increases further as the number of available charge carriers increases in time due to detrapping at the drain end of the channel. In contrary, during the other sweep direction, I_{DS} decreases stepwise as V_{DS} becomes less negative and it decreases further as the trapping reduces the number of available charge carriers. The output characteristics, extracted from the measurement points marked with letters A, B, C in Fig. 2(b), show a clear hysteresis behavior (Fig. 2(d)). At this point, it should be noted that the rotational direction of hysteresis in the output characteristics is the opposite of the case for the transfer characteristics given in Fig. 1.

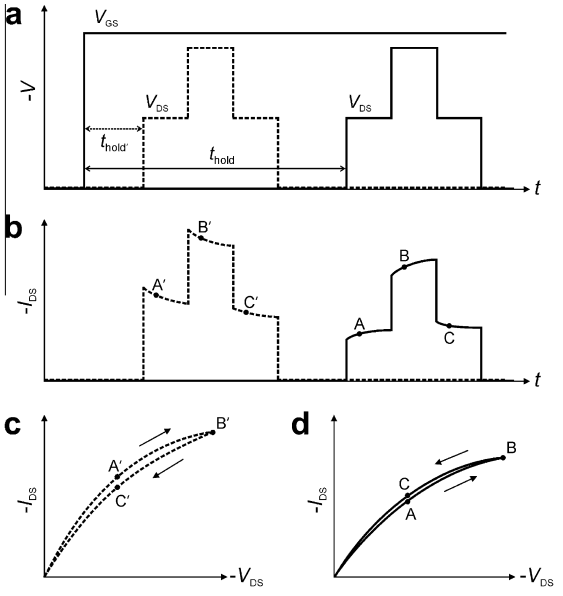

Fig. 2. Illustration of the transient response of the channel current I_{DS} during output characteristics measurement of an OTFT for two different hold times t_{hold} and $t_{hold'}$. (a) Time sequences of gate and drain biases. Wave form of V_{DS} for t_{hold} is shown with solid line and for $t_{hold'}$ with dashed line. (b) Transient responses of I_{DS}. Solid line for t_{hold}, dashed line for $t_{hold'}$. (c) Output characteristics extracted from measurement points A′, B′, C′. (d) Output characteristics extracted from measurement points A, B, C. The rotational direction of the hysteresis switches depending on the hold time.

The above explanation of hysteresis in output characteristics is only valid in case of a long hold time (t_{hold}). If the same V_{DS} sweep is applied with a shorter hold time ($t_{hold'}$), as depicted with dashes in Fig. 2(a), the effects of the V_{GS} step at the beginning of the measurement overlap with those of the consequent V_{DS} sweep. The transient effects of drain and gate bias sweeps are contradictory. Yet, regarding the effect on the strength of the electric field in the channel, hence, the trapping dynamics, gate bias predominates since it affects the field strength in the whole channel area while the drain has an influence limited to its vicinity. Consequently, in case of a short hold time ($t_{hold'}$), the transient characteristics of I_{DS} – shown with dashes on the left hand side of Fig. 2(b) – are similar to the case for the transfer characteristics given in Fig. 1(b). Consistently, the rotational direction of hysteresis in the output characteristics extracted from the measurement points A′, B′, C′ is opposite to that of the characteristics extracted from the points A, B, C (Fig. 2(c, d)).

3. Experimental

Our transistors are built in bottom gate configuration on heavily arsenic-doped Si wafer (resistivity $\leqslant 0.005\ \Omega$ cm) which serves as the gate electrode (Fig. 3). 300 nm thick, thermally grown SiO_2 forms the gate dielectric. Drain/source electrodes are deposited on the polished side of the wafer (roughness $\leqslant 2$ nm) from Cr (5 nm) and Au (40 nm) through electron beam evaporation, where Cr acts as an adhesion layer. Prior to semiconductor film deposition, the wafer is wet cleaned with acetone, isopropanol and deionized water in ultrasonic bath. Pentacene is purchased from Sigma–Aldrich and a 50 nm layer is thermally evaporated as-is at 1 Å/s through another shadow

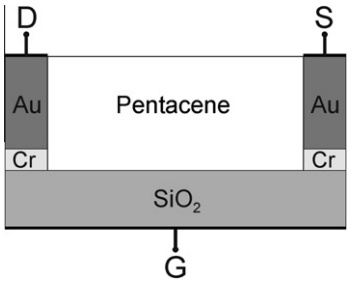

Fig. 3. Schematic cross section of a pentacene OTFT.

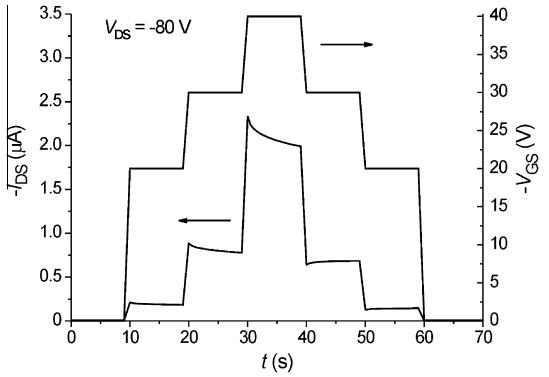

Fig. 4. Measured I_{DS} characteristics of an OTFT in response to a V_{GS} sweep.

mask. Electrical characterization is performed under dry N_2 atmosphere with $O_2 < 0.1$ ppm with an Agilent 4156C semiconductor parameter analyzer.

The transient response of I_{DS} is shown in Fig. 4 at various gate biases. At each V_{GS} step the bias is kept constant for 9 s and switched to next step with 10 V/s sweep rate. V_{DS} is set to −80 V at $t = 0$ and kept constant through the entire measurement. As explained in the previous section, in case of a constant V_{DS}, I_{DS} increases or decreases transiently depending on the change in V_{GS}. A change in V_{GS} toward more negative voltages causes a transient decrease in I_{DS} due to the decreasing number of free charge carriers through trapping. As V_{GS} is swept to less negative voltages, the charge carriers are released from the traps and I_{DS} shows a transient increase. The result is in accordance with the theory which is explained in the previous section and depicted in Fig. 1.

In order to figure out the impact of the hold time (t_{hold}) on device characteristics, output characteristics measured with different t_{hold} are also investigated. For the sake of simplicity, the output characteristic is measured at a single gate bias, i.e., $V_{GS} = -80$ V. V_{DS} is swept from 0 to −80 V and then back to 0 V with 5 V/s sweep rate. A delay time of 1 s is introduced to achieve stable measurements. An initialization step, which is suggested in Ref. [4], is utilized between subsequent measurements. Yet, the measurements are repeated with different sequences to verify that the results are free of long term degradation.

The output characteristic measured with $t_{hold} = 30$ s exhibits a hysteresis with higher currents during the backward sweep (Fig. 5(a)). This is the case where the effects of the V_{GS} change at the beginning of the measurement can be neglected since t_{hold} is long enough to ensure that V_{GS} dependent effects settle during t_{hold}. However, with decreasing t_{hold}, the rotational direction of hysteresis in the output characteristic tends to change such that the forward and backward characteristics intersect (Fig. 5(b)). This is due to the fact that the gate and drain bias related hysteresis effects are contradictory and gate bias dependent hysteresis appears in the output characteristic as t_{hold} becomes shorter. The shorter the hold time, the more dominant is the gate bias dependent hysteresis and the intersection point in the characteristic moves toward more negative V_{DS} values (Fig. 5(c)). Thus, it is possible to have contradicting rotational directions of hysteresis in the output characteristics. This result is in accordance with the theory which is depicted in Fig. 2 in the previous section. It can also be seen in Fig. 5 that the maximum value of I_{DS} decays with increasing t_{hold}.

4. Simulation

In order to get a deeper insight into the physical behavior of OTFTs during the above mentioned measurements, we performed numerical simulations with the two-dimensional device simulator ATLAS (Silvaco). The simulations are based on the solution of drift–diffusion equations coupled with the Poisson equation [9]. The device structure shown in Fig. 3 with a channel length of 25 μm has been used for simulations. The 5 nm chromium layer, which has barely effect on the electrical behavior but which is necessary as an adhesive medium for the gold electrodes in the fabricated devices, has also been considered in the simulations. For the pentacene layer, typical values have been chosen for the band gap (2.0 eV), the electron affinity (3.0 eV) and the relative permittivity (4.0). The effective density of states has been set equal to the density of molecules, i.e., 1×10^{21} cm^{-3} in accordance with Refs. [10,11]. The pentacene is assumed to be nominally undoped.

The hole mobility of 5×10^{-3} $cm^2V^{-1}s^{-1}$ has been extracted from OFF-to-ON transfer characteristic of the fabricated devices for the voltage range relevant for the simulations. A Poole–Frenkel mobility model has been

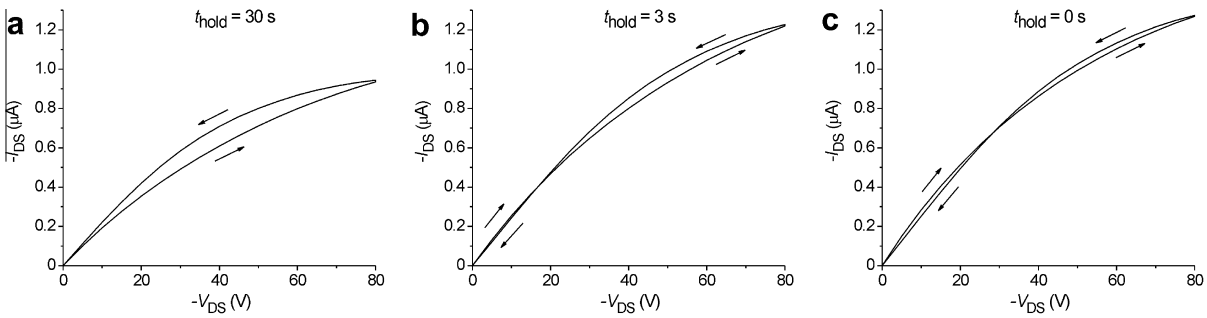

Fig. 5. Output characteristics from an OTFT measured with different hold times (t_{hold}). Gate bias dependent effects dominate in measurements with shorter hold times causing a change in the rotational direction of the hysteresis.

utilized in order to account for the electric field dependence of the charge carrier mobility. The hole Poole–Frenkel factor, β_p, has been calculated from the permittivity of pentacene [9]. Donor-type bulk traps are assumed to concentrate at a discrete energy level of 0.1 eV above the HOMO band of pentacene. A trap density of 2×10^{19} cm^{-3} is calculated from the energetic distribution of bulk traps in accordance with the literature [12]. Trap lifetimes of 5 s and 140 s have been extracted from the transient behavior of the fabricated transistors according to Ref. [6].

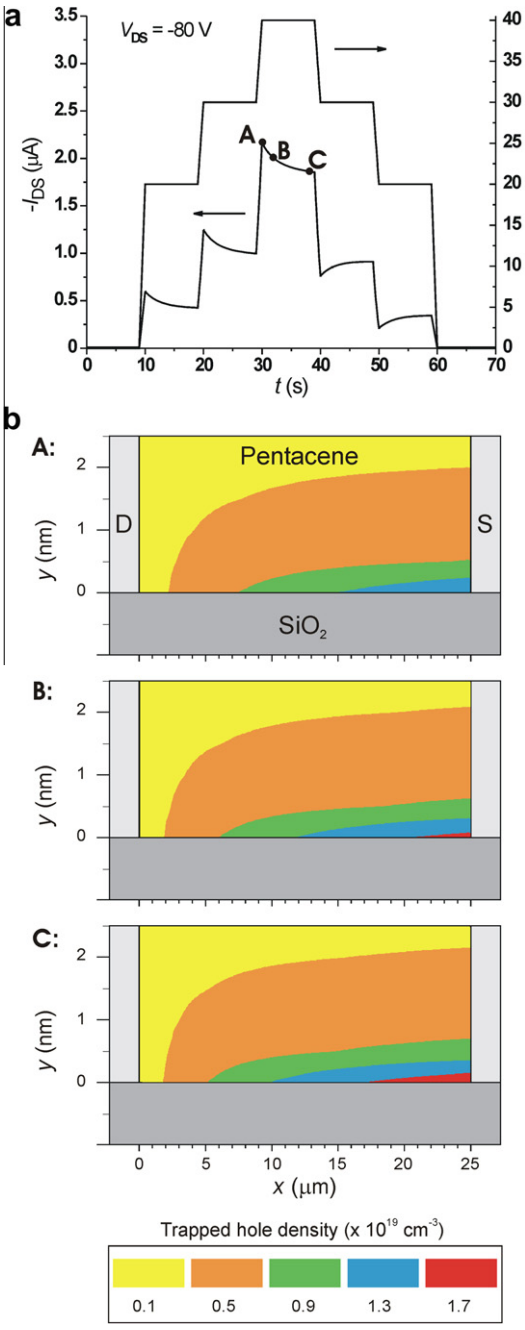

Fig. 6. Simulations performed with ATLAS. (a) Simulation of the transient response of I_{DS} of a pentacene OFET at different gate biases. (b) The density of trapped charge carriers (holes) in the channel at time points t = 30 s (A), t = 32 s (B), and t = 38 s (C). The increase in the number of trapped holes in the channel is in accordance with the transient decay in I_{DS} for 30 s < t < 38 s shown in (a).

Since the traps in the active layer of a pentacene FET are primarily responsible for the hysteresis in the device characteristics, we have performed simulations to investigate the transient response of the transistor following a change in gate bias. For this purpose, we have simulated the measurement which is given in Fig. 4, where the transient response of I_{DS} has been investigated. Parameters such as bias voltage, voltage sweep rate, and duration of the measurement are set exactly the same as in the measurement. The simulation result given in Fig. 6(a) is in good accordance with the measurement. In order to clarify the physical background of the transient change in I_{DS} during the measurement, we have investigated the change in the trapped hole density in the active layer of the transistor. For this purpose, three consecutive time points are chosen in a time span in which the bias is kept constant. These are marked with letters A, B, C, which refer to t = 30 s, t = 32 s, t = 38 s, respectively (Fig. 6(a)). At these time points, the simulated trapped hole densities are shown on the cross section of a pentacene transistor in Fig. 6(b). In order to make the change at higher concentrations more remarkable, only the first couple of nanometers of the pentacene layer are shown and a linear scale is chosen between 1×10^{18} and 1.7×10^{19} cm^{-3} for the trapped charge carrier density. As the simulation advances, an increase in the trapped charge carrier density in the channel is observed (Fig. 6(b)). This increase in the number of trapped charge carriers reduces the number of effective charge carriers in the accumulation layer causing the transient decrease in I_{DS} for 30 s < t < 38 s in Fig. 6(a). These results prove that the measurements shown in the previous section can be explained by the theory presented in this study.

5. Conclusion

The slow trapping/detrapping of bulk traps plays an important role in the transient behavior of organic semiconductor-based thin-film transistors (OTFTs) causing a hysteresis in the I–V characteristics. In this report we have presented a theory which explains how the electrical measurement parameters affect the measured hysteresis in pentacene thin-film transistors. The theory is verified through experiments and simulations where we have demonstrated that solely by changing the hold time and/or the delay time in the measurements, it is possible to change the width and even the rotational direction of the hysteresis. Therefore, it is crucial to consider the measurement parameters thoroughly prior to any comparison or conclusion on the hysteresis behavior of different OTFT samples. Yet, in many reports in literature these parameters are not given completely, which makes the reproduction of measurements and the comparison between particular results impossible. Therefore, the authors propose that it shall be a routine to comment on the electrical measurement parameters such as hold time, delay time, voltage sweep rate in all reports on OTFTs since the

influence of electrical measurement parameters on the measured device characteristics is intense.

[12] The energetic distribution of bulk traps can be described by the general form of the density of states given by $N(E) = N_0 \exp(-|E-E_0|/E_S)$ [13,14]. For the sake of simplicity, we assumed the trap distribution to be concentrated at a discrete energy level of 0.1 eV above the HOMO band of pentacene, i.e. $E_0 = 0.1$ eV. Then the volume density of traps at this energy level can be calculated by integrating the above-mentioned energetic distribution function over the band gap of pentacene. Consequently, a trap density of 2×10^{19} cm^{-3} is calculated by using the typical values from the literature, i.e. the maximum of distribution function $N_0 = 10^{20}$ cm^{-3} eV^{-1}, the characteristic width of the distribution $E_s = 0.1$ eV [13].

of light response and current modulation of the ink-jet printed low-molecular ordered TIPS-pentacene transistors, a suspended top-contact (STC) structure was employed [14].

2. Experimental

The ink-jet printed STC–TIPS-pentacene phototransistors were fabricated by the following sequence. On Corning 1737 glass substrates, 100-nm-thick indium–tin-oxide (ITO) gate electrode was deposited by sputtering and then patterned. On the top of the gate electrode, an organic gate insulator, poly-4-vinylphenol (PVP) was spin-coated and thermally cured. The PVP solution was prepared with 10 wt.% of PVP powder mixed with 5 wt.% of poly (melamine-co-formaldehyde) methylated as a cross-linking agent in propylene glycol monomethyl ether acetate. The curing temperature and time were 200 °C and 30 min, respectively. For source/drain electrode, a STC electrode structure has been built. The STC electrode structure was fabricated with 50 nm-thick Cr and 50 nm-thick Au bi-layers. With over-etching of the Cr adhesion layer, suspended Au source/drain electrodes can be formed, resulting in somewhat similar to Au top-contact structure on TIPS-pentacene films. The channel width and length of were 125 μm and 10 μm, respectively. The organic semiconductor ink, TIPS-pentacene was prepared from 1 wt.% anisole solution. The deposition of TIPS-pentacene was then performed using a piezoelectric ink-jet printing system (UniJet UJ2100) on the STC electrodes. The piezoelectric ink-jet nozzle had a diameter of 50 μm (orifice size of 50 μm). The frequency of the jetting was 150 Hz and the diameter of the ink drop was approximately 30–50 μm.

The electrical measurements were performed using a Keithley 4200-SCS in a dark and air ambient at room temperature. The steady-state white light response characteristics were carried out using a halogen lamp as a light source. For UV irradiation tests, low-pressure mercury lamp (Hamamatsu Photonics, L937-02) was used as a light source. All the light sources were placed on the top of the sample. The X-ray diffraction patterns of TIPS-pentacene films were obtained by using X-ray diffractometer (Philips, X'pert MPD, λ = 1.5406 Å).

3. Results and discussion

The STC-structured device has suspended source/drain electrode over the gate insulator. There is a very narrow gap in between (typically 50 nm), and TIPS-pentacene solution fills this gap forming a channel layer. Therefore, the device is more likely to behave as a top-contact device (Fig. 1). Typical transfer characteristics of the ink-jet printed STC–TIPS-pentacene and conventional bottom-contact TIPS-pentacene phototransistors measured in the dark are shown in Fig. 2. As shown in this figure, the STC–TIPS-pentacene phototransistors typically show much improved mobility, on-current, subthreshold slope, and reduced off-current, possibly resulting from contact improvement [14]. Such a low off-current and subthreshold slope may enable the high photosensitivity and high dynamic range of the phototransistor. For the application of the STC–TIPS-pentacene transistors as photosensitive

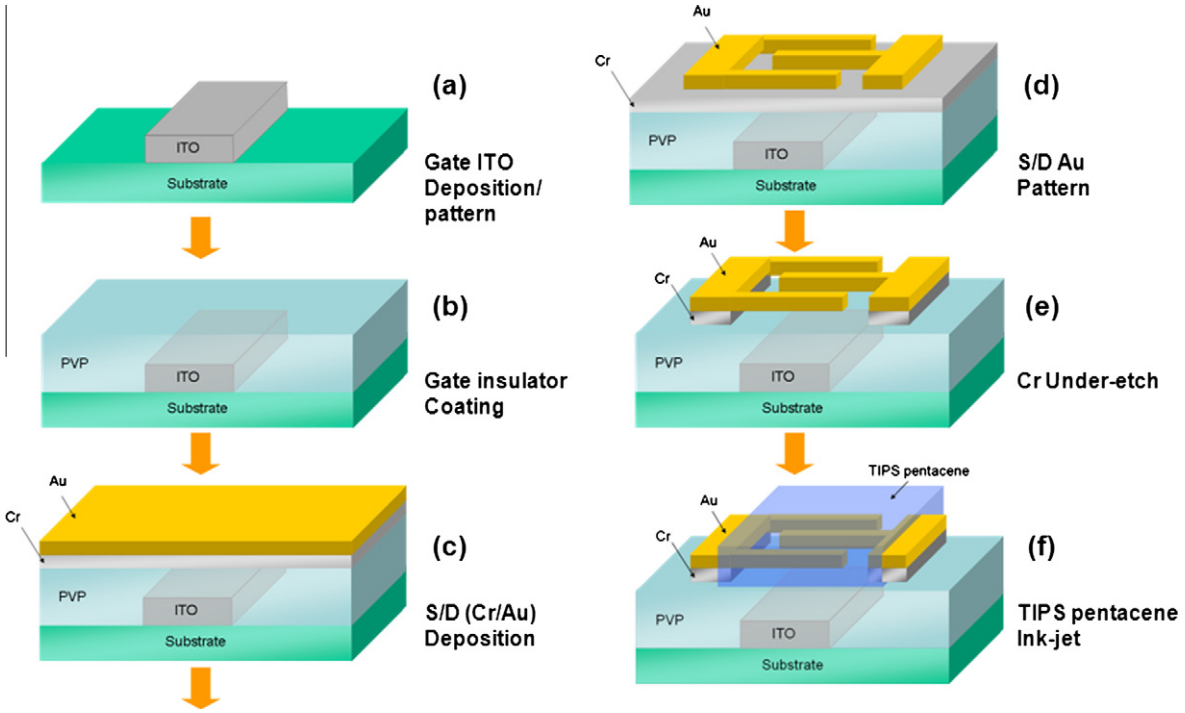

Fig. 1. Fabrication procedure of ink-jet printed TIPS-pentacene phototransistor with suspended top-contact (STC) structure.

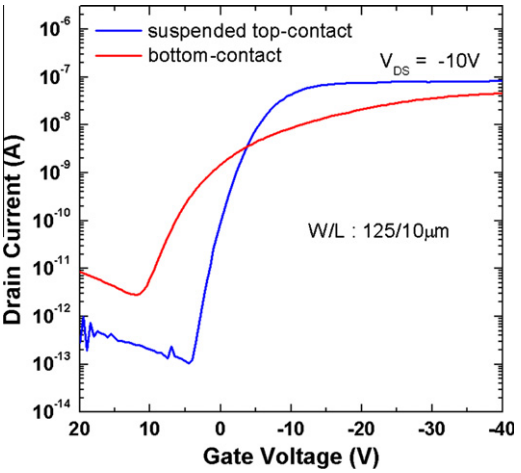

Fig. 2. The comparison of transfer characteristics of ink-jet printed conventional and STC–TIPS-pentacene phototransistor measured under dark. The channel width and length of the phototransistor were 125 μm and 10 μm, respectively.

devices, we characterized the devices in the linear regime. The linear field-effect mobility was 0.02 cm^2/V-s and the on/off ratio was 10^6–10^7. The threshold voltage (V_{th}) and subthreshold slope were determined as −4 V and 2.5 V/decade, respectively. The STC–TIPS-pentacene phototransistor showed extremely low off-current level (10^{-14}–10^{-15} A) at a low source-to-drain bias (V_{ds} = −1 V) (Fig. 3).

The gate bias dependent current modulation (I_{light}/I_{dark}) and dynamic range (20 log (I_{light}/I_{dark})) of a phototransistor are shown in Fig. 4. The illuminated light power density was controlled as 9, 11 and 13 mW/cm^2. When the light is illuminated on the phototransistor, the drain current of the phototransistor is increased due to the photogenerated excitons and localized heating by absorption and rapid thermalization of light [15]. With the light illumination the drain current (I_{light}) increased up to 10^{-8} A in the off-state showing a current modulation of 10^6–10^7. In strong accumulation regime (V_{gs} < −10 V), the current modulation is nearly unity since the number of the photogenerated charge carriers is comparable to the number of carriers accumulated by the field-effect. On the other hand, as the gate bias moves toward positive, the current modulation increases and reaches a maximum point. Further increase of the gate bias towards positive direction decreases the current modulation due to increased I_{dark}.

In a-Si:H TFTs, the dependence of photocurrent (I_{ph}; $I_{ph} = I_{light} - I_{dark}$) on illumination flux and gate bias can be explained by using the photofield effect model [16]. According to this model, the photocurrent shows a power law dependency on the illumination flux, as in Eq. (1),

$$I_{ph} \propto F^{\gamma(V_{gs})} \quad (1)$$

where, F is the illumination flux and γ is power law exponent which is a gate bias dependent factor and describes the dependency of photocurrent on light intensity. When a gate bias is applied, conduction and valence bands are bent and electrons or holes are accumulated near the insulator/semiconductor interface depending on the polarity of

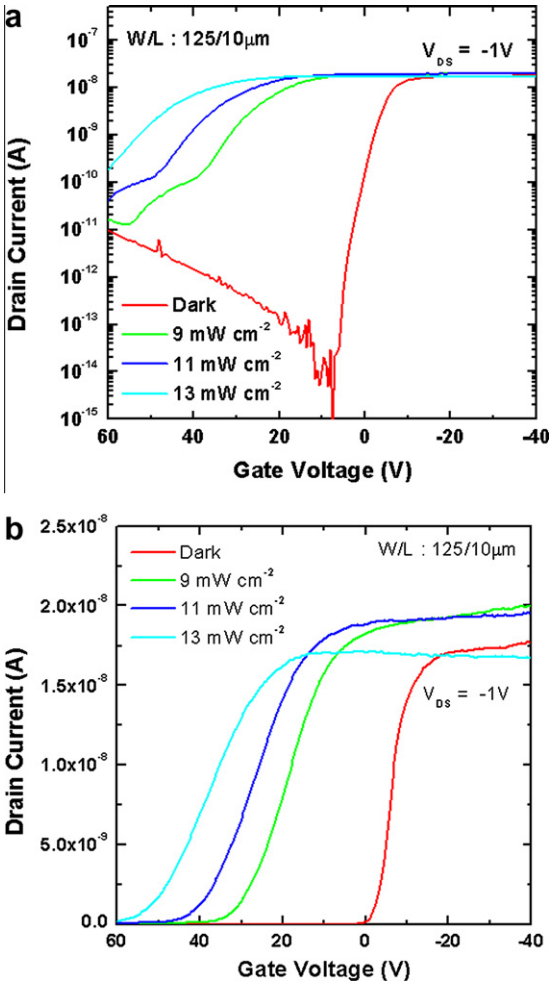

Fig. 3. The transfer characteristics of TIPS-pentacene phototransistors with a steady-state light illumination (at V_{ds} = −1 V). The light power density was varied as 9, 11 and 13 mW/cm^2; (a) in logarithm scale, and (b) in linear scale of the drain current.

the gate bias. However, when light is illuminated on the semiconductor, a redistribution of space charge in localized donor- and acceptor-like states takes place and band bending is relaxed [16]. Also, under illumination the semiconductor is at a non-equilibrium steady-state and quasi-Fermi levels (QFLs) for trapped electrons and holes are created [17]. The QFLs are separated from the equilibrium Fermi level (Fermi level under dark condition) by the factor ΔE_f, which depends on the intensity of the illumination. That is, ΔE_f increases as the illumination intensity increases and for a very high illumination level the QFLs can reach their respective band edges [17]. In the case of a-Si:H TFTs, the γ exponent gradually decreases as the gate bias is swept from negative to positive. Similar behavior of gate bias dependent γ is observed in the case of STC–TIPS-pentacene phototransistors, although the polarity of the gate bias is opposite. However, these models may not be directly applicable to organic semiconductor based TFTs since the charge transport mechanism is different and also the conventional band theory may be not appropriate to

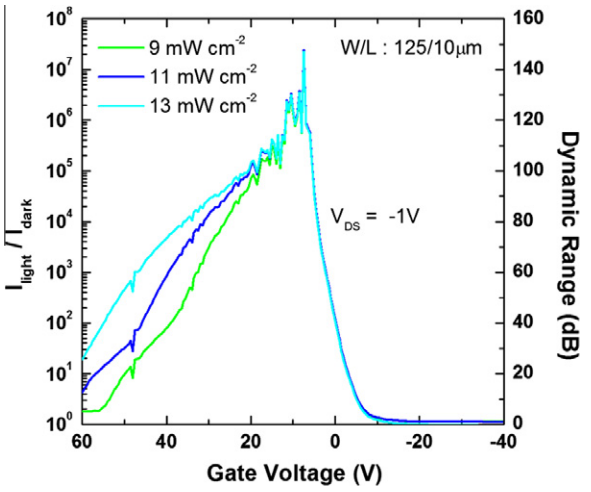

Fig. 4. The dependence of current modulation (I_{light}/I_{dark}) and dynamic range on the illuminated light power density and the gate bias. The dynamic range was calculated from the following equation. (*dynamic range* = 20 log (I_{light}/I_{dark})).

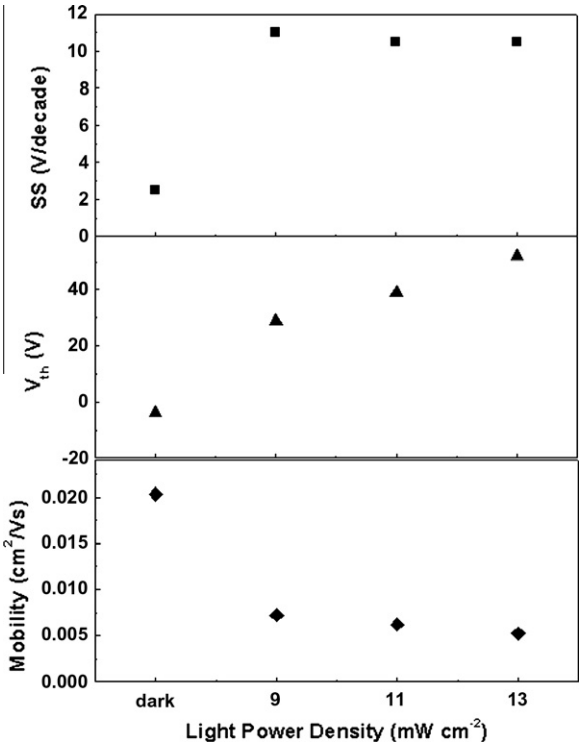

Fig. 5. The variation of field-effect mobility, threshold voltage and subthreshold slope of STC–TIPS-pentacene phototransistor as a function of incident light power density.

explain the conducting behavior of organic semiconductors.

In Fig. 5, the field-effect mobility, V_{th} and subthreshold slope of the phototransistors are shown, as a function of illuminated light power density. The field-effect mobility decreases from 0.021 cm^2/V-s to ~0.005 cm^2/V-s when the device was illuminated and the V_{th} shifts to positive as the power density increases. Also, the subthreshold slope degrades from 2.5 V/decade to ~11 V/decade. It is likely that the dependency of V_{th} on light power density is due to increasing photogenerated excitons and dissociated charged carriers. When the light is illuminated, the photogenerated carriers are formed in the bulk region of the STC–TIPS-pentacene and increase the off-current of the phototransistor resulting in the V_{th} shift. Concerning the continuous decrease of mobility, we notice from Fig. 3b that the on-state drain current decreases as the illuminated light power density increases. Especially at a light power density of 13 mW/cm^2, the drain current is even lower than that measured under dark conditions. From this observation, it is clearly understood that the white-light illumination may be one of the reasons for decreased drain current and mobility. Previously it has been reported that UV irradiation of vacuum deposited pentacene TFTs destroys the crystalline structure of pentacene film by dissociation of pentacene molecules [18]. Since most of the light sources emit at least partly into the UV spectrum, the TIPS-pentacene active layer may be damaged by irradiation by the white-light source.

To clarify the effect of UV irradiation on the electrical and physical characteristics of STC–TIPS-pentacene phototransistor, UV light was irradiated on the device and the results are shown in Fig. 6a. The intensity of irradiated UV light at a distance of 2 cm was ~12.5 mW/cm^2. During the UV exposure, photogenerated excitons are formed as in the case of light illumination and increase the drain current in the off-state. However, dissimilar to white-light illumination, the on-current level is reduced by 2–3 orders of magnitude compared to a fresh device and no gate field modulation is observed. After turning off the UV source the gate field modulation is again observed. However, the on-current level is much lower than for the fresh sample.

As suggested in the literature [18], the TIPS-pentacene film can be damaged seriously by the UV exposure losing its molecular structure, its unique crystal packing structure and its ordering. Fig. 6b shows the X-ray diffraction patterns of spin-coated TIPS-pentacene films before and after UV irradiation. Single crystal TIPS-pentacene has a triclinic structure with unit cell parameters a = 7.5650 Å, b = 7.7500 Å, c = 16.835 Å, α = 89.15°, β = 92.713° and γ = 83.63° [19]. Therefore, the peaks observed at 5.4° correspond to intermolecular spacing of 16.8 Å indicating preferential orientation of the (0 0 1)-axis normal to the surface. While the as-coated TIPS-pentacene film has a polycrystalline structure, the UV-irradiated film typically exhibits amorphous features with no diffraction peaks, which may show that the intense UV irradiation disrupts the molecular order in the film, likely by decomposition of the TIPS-pentacene molecules. Since the carrier mobility in organic semiconductors is closely related to the molecular ordering of the semiconductors [20], the degradation of field-effect mobility and reduced drain current are possibly due to the decomposition of TIPS-pentacene molecules caused by UV irradiation. These results suggest that in order to employ TIPS-pentacene phototransistors as photo-sensing elements, a proper UV-protective

passivation layer should be integrated into the phototransistor to enhance their reliability.

4. Conclusion

We demonstrated highly light-responsive organic phototransistors employing STC electrode structure and ink-jet printed TIPS-pentacene as a photo-sensing active layer. Under a steady-state illumination, the STC–TIPS-pentacene phototransistor showed high current modulation and dynamic range which suggests that the organic phototransistors based on ink-jet printed TIPS-pentacene can be a new promising candidate for the low-cost and high-performance photosensors for digital imaging applications.

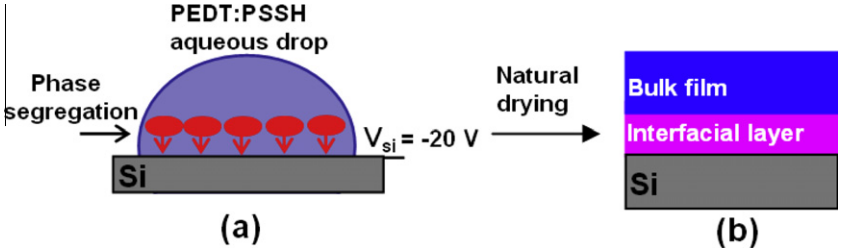
Here, we report a bias-assisted natural-drying method in film drop-casting for the formation of organic interfaces with unusual photocurrent NDR behaviors. We use PEDT:PSSH (poly(3,4-ethelynedioxythiophene:poly(styrene sulfonic acid)) as a model organic. PEDT:PSSH is a typical p-type conducting polymer blend widely used as a hole-injection layer in organic photovoltaics [6–12]. It is a phase-segregated blend due to the different water-solubility of the PEDT and PSSH phases [18–21]. As illustrated in Scheme 1, an aqueous drop of PEDT:PSSH blend is cast onto a p-type Si substrate, and the drop is then left in the ambient to dry naturally (~3 h) for the formation of the PEDT:PSSH bulk film. In a preceding work [22], we have reported that such slow natural-drying allows for phase segregation and self-organization of the blend, such that a water-insoluble interfacial layer is formed between the bulk film and substrate after the drying of the drop (Scheme 1b). In this work, we further apply a negative bias to the Si substrate simultaneously during the natural-drying of the drop. It is observed that the substrate bias can significantly modify the electronic configuration of the resultant interfacial layer, and consequently, an organic hetero-junction is formed between the bulk film and interfacial layer. The embedded hetero-junction not only enhances the $e_p - h_p$ pair separation, but also enables the storage and extraction of photocarriers. Therefore, photocurrent with strong NDR behavior is achieved for an organic optoelectronic device.

The experimental details for film preparation and photocurrent measurements are provided in Supporting information (SI). Fig. 1a displays a typical photo of the PEDT:PSSH bulk film (~1.0 μm thick) drop-cast on Si using a substrate bias (SB) of −20 V (SI-i). The bulk film is then dissolved by water rinsing to expose the interfacial layer, and when examined by the naked eyes, no feature could be observed in the interfacial area in Fig. 1b. However, our AFM [23] (atomic force microscope, SI-ii) measurements revealed the formation of nanosegregants in the interfacial area. As shown in Fig. 1c, the bare Si surface is very flat with a RMS roughness of <0.15 nm, while the interfacial area is composed of nanosegregants with an average height of ~2.5 nm (Fig. 1d). The nanosegregants are water-insoluble and superhydrophilic, similar to those prepared without SB in our preceding work [22]. Fig. 1e compares the S2p core-level spectra collected using PES [24] (photoelectron spectroscopy, SI-ii) for the bulk film and interfacial layer, respectively. The S2p spectrum of the bulk film consists of two peaks at 163.5 and 167.8 eV, which correspond to the PEDT and PSSH phases, respectively [18,20,21]. The S2p spectrum of the interfacial layer also consists of the PEDT and PSSH phases, but the peak intensity is relatively weak, and the peaks are shifted towards higher binding energy by ~1.6 eV. We attribute the shift to the charging of the interfacial layer, as similar shifts were also systematically observed for other core levels such as C1s and O1s. The above AFM and PES results are almost identical to those of the interfacial layer prepared earlier [22] without SB. Indeed, the AFM images and PES spectra of interfacial layers prepared using SB = −5, −10, and −15 V, respectively, are all similar to that shown in Fig. 1c–e. This indicates that SB does not affect the morphology and chemical composition of the interfacial layer. However, the secondary electron (SE) emission results in Fig. 1f–h reveal the effect of SB on the electronic structure of the interfacial layer. Fig. 1f displays the SE peak of the bulk film. A work function of W_F = 5.1 eV is obtained, and it is in good agreement with that reported for p-type PEDT:PSSH films [25]. The SE emission of the bulk film does not depend on the SB, because films cast using different SBs all exhibit the same SE spectrum as that shown in Fig. 1f. Fig. 1g compares the SE peaks of interfacial layers formed under SB = 0, −10, −15, and −20 V, respectively. It can be seen these interfacial layers show a lower W_F of 4.5 eV. Since charging has been observed in Fig. 1e for the interfacial layer, and the charging can result in a lower W_F by shifting the SE peak to low kinetic energy, so the value of W_F = 4.5 eV cannot be unambiguously used for the interfacial layers. However, the shape and width of the SE peaks are usually not affected by sample charging, and a clear dependence of peak width on SB can be identified in Fig. 1g. For example, the FWHM (full width at half maximum) of the sample formed without bias is only 0.5 eV, while the FWHM increases significantly when the SB is increased. The FWHM is measured to be 0.8, 1.3, and 1.8 eV for interfacial layers cast with a bias of −10, −15, and −20 V, respectively (Fig. 1g). Since SEs are located at the conduction band edge, the width of the SE peak often reflects the energy dispersion of the unoccupied states: the narrower the peak, the more discrete the electronic states; the wider the peak, the more dispersive the energy levels [24]. The increase of FWHM from 0.5 to 1.8 eV indicates that the SB can induce significant amount of electronic states in the interfacial layer. As discussed below in Figs. 2 and 3, these bias-induced empty states provide the necessary host states for the accommodation of photocarriers, and are thus responsible for the photocurrent NDR reported in this work. The dependence of FWHM on SB is



Scheme 1. (a) A PEDT:PSSH aqueous drop is cast onto a Si substrate to which a negative bias of V_{Si} = −20 V is applied. (b) Interfacial layer formation between the Si substrate and PEDT:PSSH bulk film after the natural-drying of the aqueous drop.

not monotonous: when a larger bias of −40 V is used, the FWHM of the SE peak is reduced to 0.9 eV, and the low energy cut-off is shifted to 4.1 eV (Fig. 1h).

Fig. 2a compares the photocurrent I_{ph} and dark-current I_d collected for an ITO/PEDT:PSSH/Si sample device (see the inset of Fig. 2a) by scanning the Si electrode voltage from −25 to 25 V at a scan rate of 1.0 V/s (see SI-iii and Ref. [26] for experimental). The PEDT:PSSH film in the sample device was drop-cast with a SB of −20 V, and therefore there are bias-induced host states in the interfacial layer. It can be seen the I_d is rectifying, with a much higher current in the positive voltage region. In Fig. 2a, the photocurrent is also observed in the positive voltage region, and the I_{ph} exhibits a pronounced peak, in sharp contrast to the monotonous I_d. The current peak is the so-called NDR peak previously observed only for intrinsic or dark-current [13–17]. This NDR characteristic is better viewed by subtracting I_d from I_{ph} to obtain the net photocurrent $(I_{ph} - I_d)$. As displayed in Fig. 2b, the $(I_{ph} - I_d)$ difference current is dominated by the sharp NDR peak with a peak-to-valley ratio (PVR) of ~700. Fig. 2c displays the I_{ph} and I_d collected for a control device in which the PEDT:PSSH film was drop-cast without SB. It is seen from I_d that the control device is not as rectifying as the sample device. In addition, photocurrent is observed in both the positive and negative voltage region, and most importantly, the I_{ph} does not show any NDR behavior. Since there is no bias-induced host states (Fig. 1g) in the interfacial layer of the control device, the I_{ph} NDR observed in Fig. 2a and b can be attributed to the dispersive host states induced by the SB during film drop-casting. Fig. 2d displays the I_{ph} of the sample device in Fig. 2a using different voltage scan rate of 0.17–4.0 V/s, respectively. The corresponding $(I_{ph} - I_d)$ net current in the positive voltage region is plotted in Fig. 2e. It is seen that the NDR peak shifts to higher voltage positions with increasing scan rate.

In Fig. 3, we propose a mechanism, involving the separation, storage and extraction of photocarriers, to explain the NDR behavior observed in Fig. 2. As shown in Fig. 1e, the interfacial layer causes charging in PES measurements, and is therefore more insulating compared to the bulk film. So there is a hetero-junction formed between the insulating interfacial layer and conducting bulk film. Since the bulk film is a typical p-type semiconductor, and the interfacial layer is "de-doped" as judged by its insulating nature, the hetero-junction can thus be treated as an organic p–n junction for the convenience of discussion (Fig. 3a). It is known in photovoltaics that the build-in field E_{in} of the p–n junction can attract photoelectrons from the p-side to the n-side, thus achieving the separation of

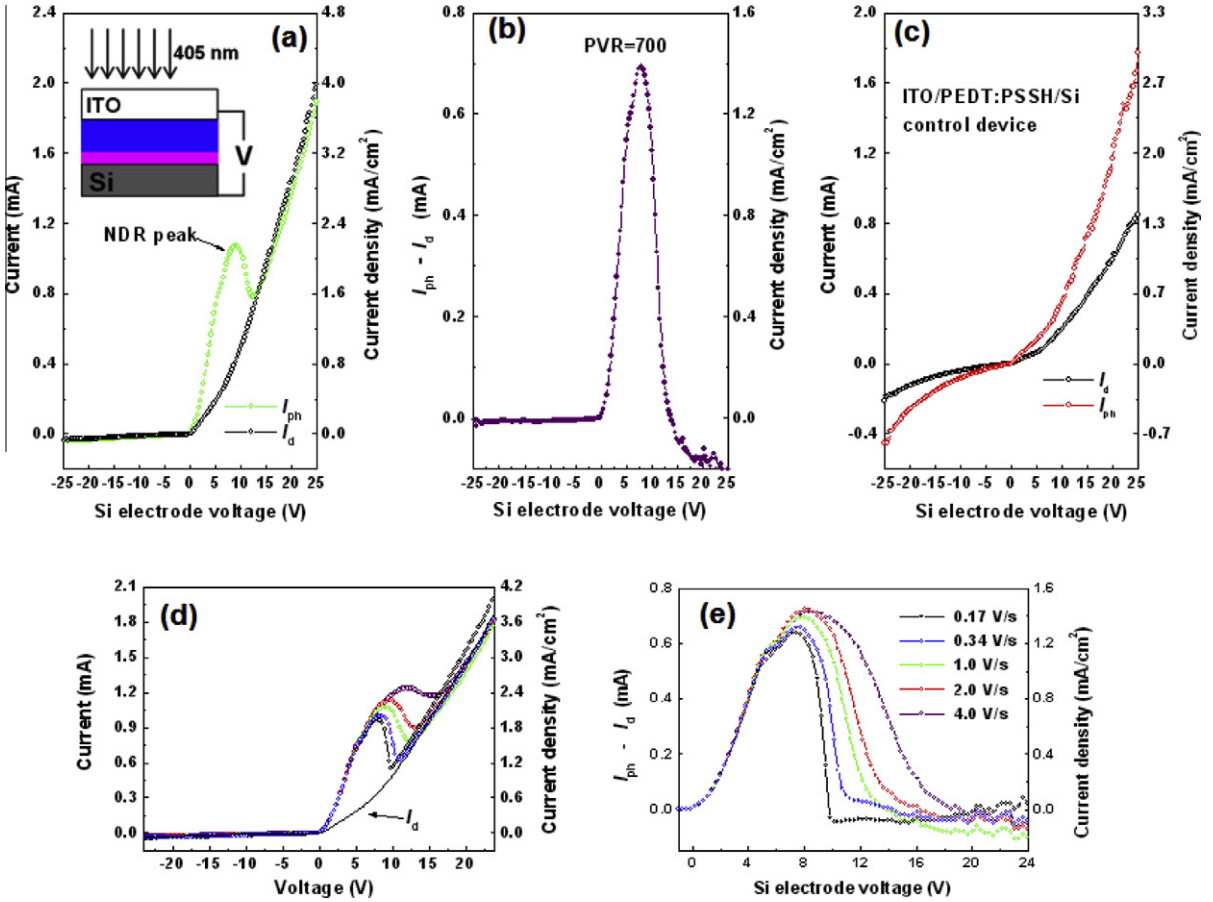

Fig. 2. (a) I_{ph} and I_d of the sample device shown in the inset. (b) The corresponding ($I_{ph} - I_d$) difference current of (a). (c) I_{ph} and I_d of the control device. (d) I_{ph} of the sample device in (a) collected using different voltage scan rates. (e) The corresponding ($I_{ph} - I_d$) difference current of (d).

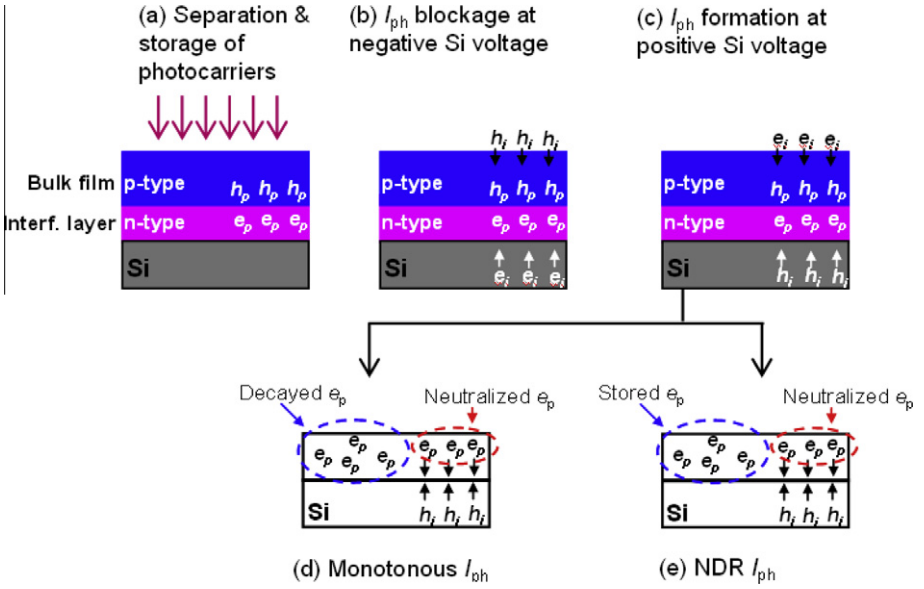

Fig. 3. Proposed I_{ph} NDR mechanism: (a) $e_p - h_p$ pair separation by the p–n junction; (b) blockage of photocurrent at negative Si electrode voltage; (c) neutralization of photocarriers at positive Si electrode voltage; (d) formation of monotonous photocurrent due to the fast decay of excess photocarriers; (e) formation of NDR due to the storage of unneutralized photocarriers.

$e_p - h_p$ pairs [5]. When the sample device is photo-illuminated, $e_p - h_p$ pairs are generated in the top bulk film. Due to the E_{in} of the p–n junction, the e_p is attracted to the n-type interfacial layer, while the h_p is kept in the p-type bulk film (Fig. 3a). Moreover, the bias-induced dispersive empty states at the junction can act as host states to accommodate and store the photoelectrons. When the Si electrode voltage is negative, intrinsic electrons e_i are injected from Si to the interfacial layer, while intrinsic holes h_i are injected from the top ITO electrode to the bulk film (Fig. 3b). Due to the Coulomb repulsion between e_i and e_p (h_i and h_p), photocurrent conduction is hindered. This is why no I_{ph} is observed in the negative voltage region in Fig. 2a. When the voltage is positive, h_i and e_i are injected into the interfacial layer and bulk film, respectively (Fig. 3c). The neutralization of h_i with e_p (and e_i with h_p) contributes additional current, thus leading to the large photocurrent in the positive voltage region in Fig. 2a. Note that in Fig. 2a the I_{ph} does not increase as a monotonous function of voltage, but instead shows a NDR peak. This unusual characteristic reflects the photocarrier-storage function of the host states. Under our experimental condition of steady photo-illumination, there is a fixed number of mobile photocarriers due to the dynamic balance between the generation and decay of photocarriers. At a low voltage, only a limited number of h_i are injected from Si (Fig. 3d), and they neutralize with the same number of e_p. The excess e_p are decayed due to their short lifetime, and thus have no contribution to I_{ph}. When the voltage is increased, more h_i are injected, and more e_p are neutralized. So the I_{ph} increases stepwise as a function of the injection voltage, as observed for the control device in Fig. 2c. In the case of the sample device with host electronic states, the excess e_p are stored in the host states, and they have a long lifetime (Fig. 3d). At a low voltage, they are not immediately neutralized because there is not enough h_i injected from Si. But these excess e_p remain mobile, and can be neutralized by h_i injected later at a higher voltage. When the voltage is increased sufficiently high, all the stored e_p are neutralized, and accordingly, the I_{ph} exhibits a peak. From this point onwards, the high external voltage overcomes the E_{in} of the organic p–n junction, such that the junction ceases its function of $e_p - h_p$ pair separation, and therefore no photocurrent can be further generated. This is why in Fig. 2a the I_{ph} drops to the level of I_d after the NDR peak. We also observed an open circuit voltage of 312 mV, and a short circuit current (flowing from ITO to Si) of 11.0 μA for the sample device. The direction of the voltage and current confirms the polarity of the embedded p–n junction proposed in Fig. 3. In Fig. 2a, the NDR is observed only for I_{ph}, but not for I_d. This is because the I_d is governed by the thermoionic emission of intrinsic carriers with a monotonous dependence on the electrode voltage. While for I_{ph}, it is based on the organic p–n junction and host states for photocarrier separation and storage.

It is possible to derive the density of the host states using the results shown in Fig. 2d and e. In Fig. 2e, when the scan rate is slow, sufficient time is allowed at each voltage step for the extraction of stored photocarriers, so more photocarriers are extracted, and the extraction completes at a lower voltage. A fast scan rate, on the other hand, leads to incomplete photocarrier collection, and consequently the NDR peak appearances at a higher voltage. At a slow rate of 0.17 V/s, the NDR peak completes in a duration of $t \approx 60$ s (Fig. 2e), and the corresponding number of extracted photocarriers is estimated to be 1.4×10^{14} by integrating the $(I_{ph} - I_d) \sim t$ plot (data not shown). This represents the maximum number of extractable photocarriers, because the NDR peak obtained using even slower rates (e.g., $\leqslant$0.02 V/s) is almost identical to that observed using 0.17 V/s rate. In the case of fast scan rate of 4.0 V/s, the completion of the NDR peak only takes 5 s, and the number of extracted photocarriers is 1.1×10^{13}, which is only 1/10 of that extracted at 0.17 V/s scan rate. The maximum number of 1.4×10^{14} photocarriers corresponds to an effective density of $7.0 \times 10^{14}\,\mathrm{cm}^{-2}$ estimated for the bias-induced host states. The formation of NDR is dependent on the polarity and magnitude of the SB during drop-casting, and can only be achieved under suitable biases which facilitate the formation of host electronic states (Fig. 4). Fig. 4 displays the evolution of I_{ph} collected for PEDT:PSSH films prepared using different substrate biases. Here, an identical bias duration of 3 h was kept while biases different in magnitude and polarity were used, respectively, to cast the PEDT:PSSH films. When the bias is zero (Fig. 4a), the I_{ph} is monotonous, and no NDR peak is observable. At a bias of −10 V (see Fig. 4b), the I_{ph} exhibits a turning point T which divides the I_{ph} into a high-slope region (0–3.3 V) and a low-slope region (3.3–15 V), but no clear NDR peak is formed. When the bias is increased to −15 V (see Fig. 4c), the NDR peak is weak but identifiable, and the NDR peak is fully developed when the bias is further increased to −20 V (see Fig. 4d). The above observation arises from the bias-induced host states discussed in Fig. 1g: when the bias is zero, the interfacial host states necessary for NDR are not formed, so the I_{ph} is monotonous. Increasing the substrate bias leads to the formation of more host states, and thus the photocurrent NDR develops accordingly. However, if the bias is too high (e.g., −40 V, see Fig. 4e), the NDR would disappear, and the I_{ph} becomes monotonous again. This observation coincides with the SE peak in Fig. 1h which shows a decrease in the dispersion of the empty states at a substrate bias of −40 V. For comparison, positive substrate biases in the range of 0–40 V were also used for film casting, but no NDR was observed for films thus prepared. Therefore, the NDR is dependent on the polarity and magnitude of the substrate bias, and can only be achieved under suitable biases which facilitate the formation of host electronic states. The NDR behavior is very stable and reproducible as demonstrated in SI-iv, and is a permanent feature inherent to the interfacial layer formed by the bias-assisted natural-drying of films. In this method, the PEDT:PSSH drop is allowed to dry naturally, such that the phase segregation and reorganization can proceed under electrostatic and thermodynamic equilibrium conditions. Such a process facilitates the formation of interfaces with the most stable configuration, as sufficient relaxation time is available during the interface formation. While in the conventional fast spin-coating method, the organic is almost "quenched" from its solution configuration onto the substrate without a chance of rearrangement. Indeed, some recent works

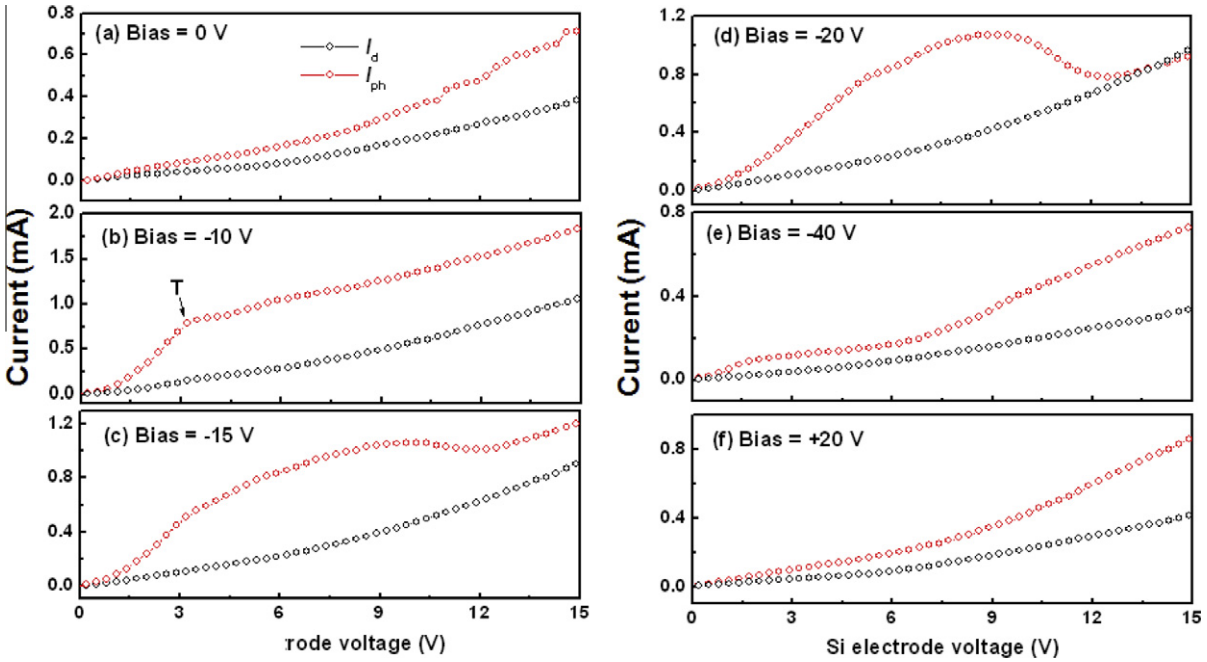

Fig. 4. Evolution of I_{ph} collected for PEDT:PSSH films drop-cast with a substrate bias of 0, −10, −15, −20, −40, and +20 V, respectively. An identical bias duration of 3 h was used for the drop-casting of the above samples. The I_{ph} and I_d were obtained by scanning the Si electrode voltage from −25 to 25 V with at a rate of 1.0 V/s. Only the 0–15 V region with the NDR peak is shown.

have pointed out that slow-drying is advantageous over fast-drying in facilitating the desired phase segregation and self-organization of photovoltaic organic blends [9,10].

In conclusion, we have demonstrated a bias-assisted natural-drying method for the formation of embedded organic hetero-junction and host electronic states. This wet method is simple, economical, and extendable to other organic systems. The hetero-junction and host states allow for the separation and storage of photocarriers, and thus photocurrent with NDR characteristic is achieved. The mechanism of the NDR and its dependence on the drop-casting substrate bias is discussed. Both the method for organic interface formation and the resulting photocurrent NDR behavior could open up new applications in organic optoelectronics.

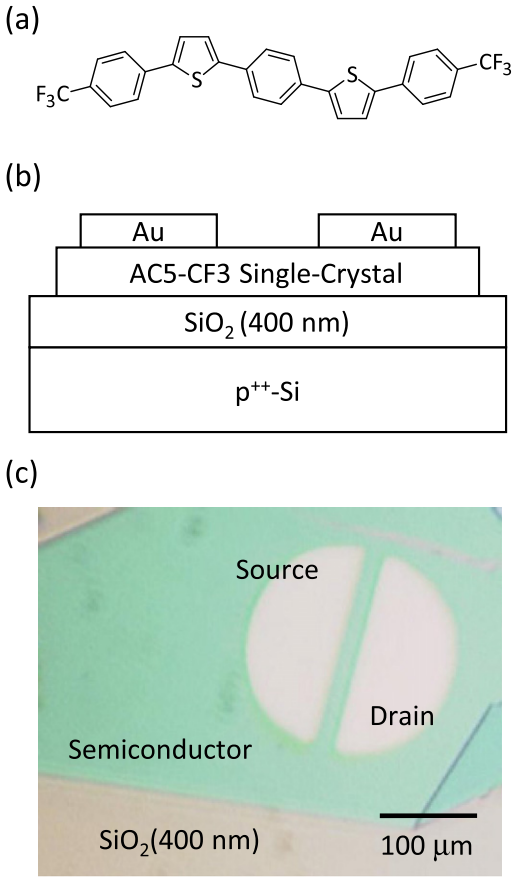

Fig. 1. (a) Chemical structure of AC5-CF3, (b) schematic cross-sectional structure and (c) example top-view photograph of FET with an AC5-CF3 single-crystal.

[22], and synthesized AC5-CF3 as shown in the Fig. 1a based on a report by Katz et al. [23]. In that article, the authors reported that a material similar to AC5-CF3 but without a CF_3 group worked as a p-type FET material with a field-effect hole mobility of 0.04 $cm^2\,V^{-1}\,s^{-1}$ at best. Here, we demonstrate that AC5-CF3 could be a potential candidate for organic n-type semiconductors that have high electron mobility. Note that Hotta et al. recently reported the synthesis of the same material [24], formation of its crystal [25], the crystal structure and its field-effect transistors (FETs) [26]. However, Hotta et al. reported that AC-CF3 single-crystal FETs showed n-type behavior and that the electron mobility of the FETs ranged from 1.6 to 3.9×10^{-2} $cm^2\,V^{-1}\,s^{-1}$. Here, we report the performance of optimally fabricated AC5-CF3 TFTs and single-crystal FETs, and demonstrate that AC-CF3 will be able to be utilised as an n-type organic transistor material with high mobility.

2. Material and methods

2.1. Material synthesis and characterisation

AC5-CF3 was synthesized by the Stille coupling reaction of 4-trifluoromethyl benzene with the corresponding stannyl reagent in the presence of Pd_2(*trans*, *trans*-dibenzylidene acetone)$_3$ and (*tert*-butyl)$_3$P in dimethylformamide with microwave heating. The synthetic root was slightly different as per a report by Katagiri et al. [24]. We confirmed its structure by matrix-assisted laser desorption/ionization (MALDI) time-of-flight (TOF) mass spectroscopy (Perspective Biosystems, Voyager-DE PRO) and ^{1}H NMR (Bruker AVANCE 400)). We used the material after sublimating it in a pure argon gas flow, and prepared AC5-CF3 single-crystals from its vapour in a chamber filled with nitrogen adding 10 vol.% hydrogen. Details of this method have been described elsewhere [27].

The ionization potential (I_p) of AC5-CF3 was determined by photoelectron emission yield spectroscopy with Riken–Keiki AC-2 at an irradiation light power of 10 nW cm^{-2}. The sample films of the organic materials were prepared by vacuum evaporation in the same conditions as can be used to fabricate TFTs on glass substrates whose surface was covered with indium thin oxide to prevent charging. We determined the lowest unoccupied molecular orbital (LUMO) level of AC5-CF3 from the difference between I_p and the band gap that was estimated from the absorption edge of 100-nm-thick AC5-CF3 thin film deposited on a quartz substrate.

X-ray diffraction (XRD) patterns were measured with a Rigaku Rotaflex using Cu Kα radiation at $\theta/2\theta$ geometry. The sample films, all with thicknesses 100 nm, were evaporated onto silicon wafers with SiO_2 in the same conditions as can be used for TFT fabrication. The X-ray was generated from a 150-mA electron beam accelerated at 40 kV. The crystal structure of AC5-CF3 was analyzed with a Bruker-AXS APEX II. We prepared the crystal for analysis from the vapour phase.

2.2. Device fabrications and measurements

AC5-CF3 FETs with a single-crystal of AC5-CF3 were fabricated as follows. A crystal was placed on a silicon wafer that had a 400-nm-thick thermally grown silicon dioxide layer as a gate insulator. Without treating the surface of the gate insulator, we simply washed the substrates with 2-propanol. After placing the crystal, we deposited gold electrodes on the source and drain electrodes on the crystal through a shadow mask. Channel length and width of the transistors were 25 and 200 μm, respectively.

We also prepared thin-film transistors using AC5-CF3 by depositing AC5-CF3 on a silicon wafer with a 200-nm-thick SiO_2 layer through thermal evaporation. We kept temperature of the substrates at a temperature in a range from room temperature to 120 °C during the deposition. The thickness of AC5-CF3 thin film was 60 nm. Finally, we prepared source and drain electrodes on the thin film by thermal evaporation of gold. Channels of the thin-film transistors were made with another shadow mask. We varied the channel length of the thin-film transistors from 30 to 100 μm, and kept the width of all the TFTs constant at 2000 μm. An Agilent semiconductor parameter analyzer (B1500A) or a pair of two Keithley source meters (2410) recorded characteristics of the transistors in a probe station (Measure Jig, MJ-10) under vacuum at room temperature.

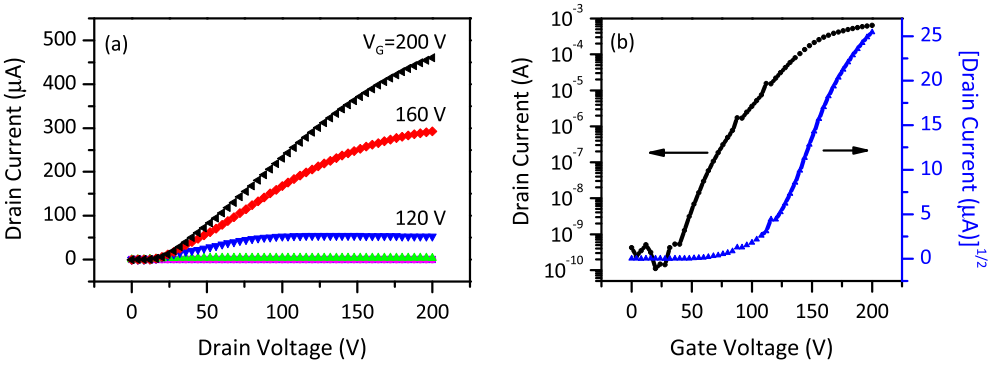

Fig. 2. (a) $I_D - V_D$ and (b) $I_D - V_G$ characteristics of AC5-CF3 single-crystal FET. We measured the $I_D - V_G$ curves at V_D of 200 V.

3. Results and discussion

Fig. 1c shows a photograph of AC5-CF3 single-crystal FET prepared by fixing a single-crystal of AC5-CF3 on silicon wafer, which has a thermally grown 400-nm-thick silicon dioxide layer, as a gate insulator. Fig. 1b shows the schematic cross-sectional structure of the FET; the configuration of the electrodes is the so-called top contact and bottom gate configuration. The crystal seems to uniformly contact the insulator as there were no obvious voids or defects in the area of the crystal seen in the photograph, and hence, the FET device should work well.

Fig. 2a shows drain current versus drain voltage ($I_D - V_D$) characteristics of AC5-CF3 single-crystal FET at several different gate voltages (V_G). As clearly shown in the figure, the device works as an n-type FET, and this means that AC5-CF3 single-crystal is an n-type semiconducting material in which electrons behave as charge carriers. The drain current at a low V_D region (below 20 V) was limited, and thus we could not observe the linear behavior. The current limitation at the low V_D region probably resulted from the configuration of the source and drain electrodes for the device. In short, similar current limitations are frequently observed in the case of the so-called top contact FETs in general, and/or the LUMO level of AC5-CF3 at 3.1 eV [28] results in a slightly large electron injection barrier from the gold source electrode to the semiconductor. However, the $I_D - V_D$ characteristics exhibited well-defined saturation behavior. Fig. 2b shows $I_D - V_G$ and the square root of $I_D - V_G$ characteristic of the FET at a drain voltage of 200 V. We obtained the field-effect mobility (μ_{FE}) of an electron in AC5-CF3 single-crystal FET from saturated drain currents ($I_{D,sat}$) based on Fig. 2b using the following equation [29]:

$$I_{D,sat} = W/2LC_i\mu_{FE}(V_G - V_T)^2 \quad (1)$$

where W and L are width and length of the channel, respectively, and C_i and V_T are specific capacitance of the gate dielectric and the threshold voltage, respectively. The obtained mobility was as high as 3.1 $cm^2\,V^{-1}\,s^{-1}$. The field-effect mobility of electrons of 3.1 $cm^2\,V^{-1}\,s^{-1}$ is higher compared to other highly mobile electrons in organic semiconductors that have been already reported [17,18,30]. This means that AC5-CF3 should be a potential candidate for n-type organic transistors. Note that the high operation voltage of 200 V probably is a result of the rather thick (400 nm) SiO_2 layer as gate insulator.

Fig. 3a shows XRD pattern of the FET with mobility of 3.1 $cm^2\,V^{-1}\,s^{-1}$. We can observe several peaks whose width is very narrow; the full width at half maximum (FWHM) of a peak at 2θ of 10.76° is only 0.09°. All the peaks result from a reflection by the *c*-axis; they are first-order and other higher-order diffractions as assigned in the figure. This indicates that the crystal is of high quality and on the substrate in which the normal direction corresponds with the direction of the *c*-axis. As shown in Fig. 4, the molecular interactions due to π-electrons appear to be stronger in the *ab* plane than in other planes, and consequently, charge carriers move smoothly in the *ab* plane. The high quality of the crystal also enhances the carrier transport in the crystal. As a result, the FET device showed a high electron mobility, which was larger than twice of a mobility in a very recent report on AC5-CF3 single-crystal FETs [31].

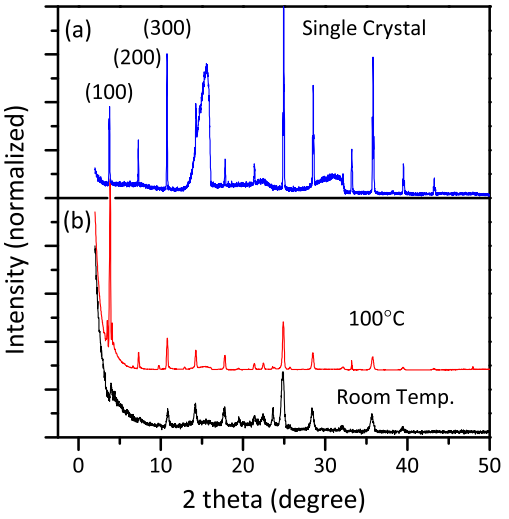

Fig. 3. (a) X-ray diffraction pattern of AC5-CF3 single-crystal that was used for the FET with electron mobility of 3.1 $cm^2\,V^{-1}\,s^{-1}$. (b) X-ray diffraction patterns of AC5-CF3 thin films deposited at different substrate temperatures.

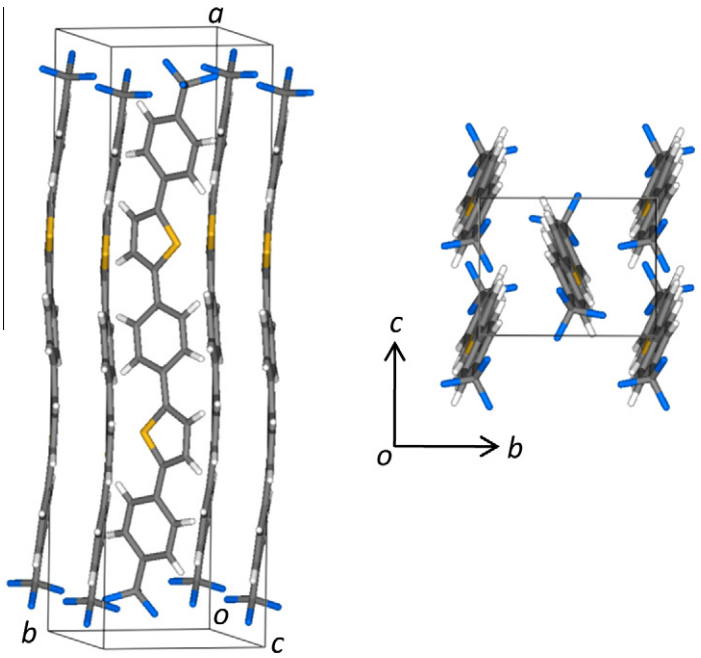

Fig. 4. Crystal structure of AC5-CF3. Images on the left and right are side and top-views, respectively. Crystal structure is as follows: crystal system: monoclinic; space group: $P2_1/c$; number of molecules in cell = 2; cell parameters: $a = 25.070(9)$ Å, $b = 7.354(3)$ Å, $c = 5.742(2)$ Å, $\alpha = \gamma = 90°$ and $\beta = 94.327(5)°$. CCDC 780290 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

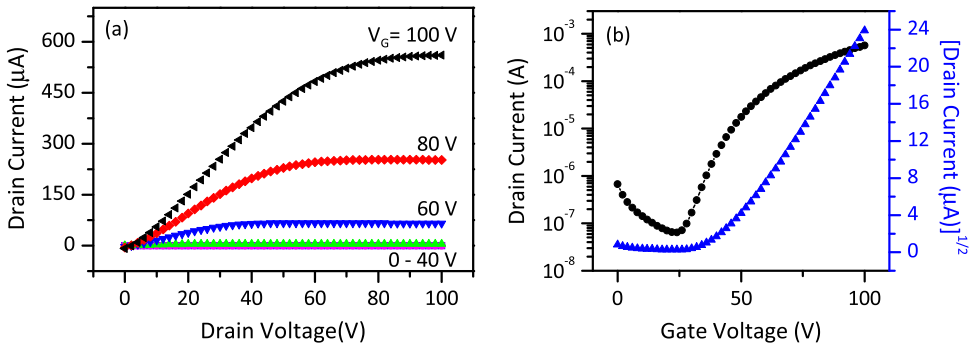

Fig. 5. (a) $I_D - V_D$ and (b) $I_D - V_G$ characteristics of AC5-CF3 thin-film transistor whose channel length is 50 μm, where AC5-CF3 thin film was deposited at a substrate temperature of 100 °C.

We demonstrated above that AC5-CF3 is a potential candidate for high mobility n-type organic semiconductors for transistors from the results of the AC5-CF3 single-crystal FET. However, mobility in thin-film states not a single-crystalline state should be more important from the viewpoint of practical use because organic transistors have received a lot of interests in the field of large-area and/or flexible electronic devices. Consequently, we describe the characteristics of thin-film transistors based on AC5-CF3 in the following paragraphs. Fig. 5a shows an example curve set of the output characteristic of AC5-CF3 thin-film transistor, where we deposited AC5-CF3 on the substrate at a temperature of 100 °C. Here, we employed Si wafers with a thin (200 nm) SiO_2 layer to reduce the operation voltage. The figure clearly shows that the device worked as an n-type TFT. Fig. 5b shows the transfer curve of TFT and also shows the square root of I_D versus V_G plot at a drain voltage of 100 V. We determined the field-effect mobility of the device from the slope of the root I_D versus V_G curve using Eq. (1); the mobility was 0.60 $cm^2\ V^{-1}\ s^{-1}$. We fabricated six TFTs under the same condition, and the average mobility was $0.55 \pm 0.05\ cm^2\ V^{-1}\ s^{-1}$. While this mobility is obviously lower than that of the FET based on a single-crystal, the mobility is sufficiently large, as large as n-type organic TFT materials [15,17].

Fig. 6 shows field-effect electron mobility, threshold voltages and sub-threshold slopes (SS) of TFTs with AC5-CF3 thin films deposited at different substrate tempera-

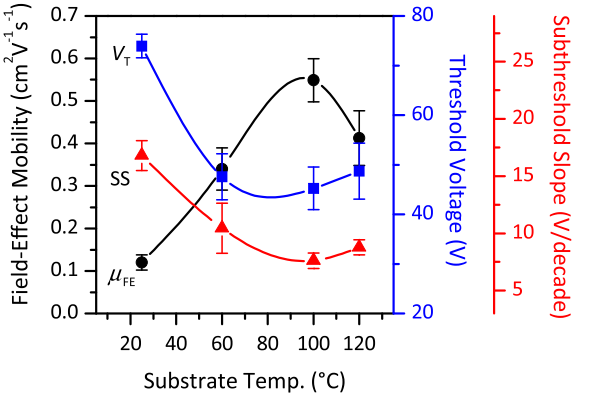

Fig. 6. Field-effect electron mobility (●), threshold voltage (■) and subthreshold slope (▲) of AC5-CF3 thin-film transistors (channel length of 50 μm) as a function of substrate temperature during the deposition of AC5-CF3.

tures. The figure clearly indicates certain tendencies: mobility increased and threshold voltage and SS decreased with increasing substrate temperature, while all the parameters became worse at a temperature of 120 °C. Fig. 7 shows the set of surface morphologies of AC-CF3 thin films prepared at different substrate temperatures. The morphological change shown in the figure is sufficiently consistent with the temperature dependences of mobility and threshold voltage. In short, the grain sizes of AC5-CF3 thin films became large with increasing substrate temperature. We believe that increasing the grain sizes directly and beneficially influences mobility. As shown in Fig. 7c, however, some deep valleys that seemed to segment adjacent grains were observed. Although we are unsure about the appearance of the valleys on the film, we speculate that the valleys appear because of a difference in the coefficients of thermal expansion (CTE) of AC5-CF3 thin films and silicon wafers because CTEs of organic materials are generally much larger than Si whose linear CTE is only $4 \times 10^{-6}\,K^{-1}$. The valleys probably interfered with electron transport of inter-grains, resulting in reduced mobility at 120 °C. Note that clear step-terrace structures appeared on all the images and the height of the steps corresponded to the length of the *a*-axis of the unit cell of AC5-CF3.

Furthermore, the threshold voltage decreased from the improved quality of AC5-CF3 thin film induced by temperature-controlled deposition. Enlarging grains at higher temperature depositions may be accompanied by qualitative improvement of thin films such as fewer defects that work as charge carrier traps. XRD patterns from AC5-CF3 thin films prepared at different temperatures shown in Fig. 3 support the qualitative improvement of the thin films. In short, the change of threshold voltage shown in Fig. 6 can be consistent with this improvement. Fig. 8 shows the channel length dependence of the field-effect mobility of AC5-CF3 TFTs prepared at different deposition temperatures. In case of the room temperature deposition of AC5-CF3, the field-effect mobility of TFTs slightly decreased with increasing channel lengths. In contrast, the mobility showed no dependence on the channel length in the case of 100 °C deposition of AC5-CF3. According to the atomic force microscope (AFM) observation shown in Fig. 7, the size of the grains is much smaller than the channel length of 30 μm even in the case of 100 °C deposition of AC5-CF3. Consequently, the independence of the mobility from the channel length observed in the case of the 100 °C deposition indicates that the deposition at higher temperature probably improves the quality of not only

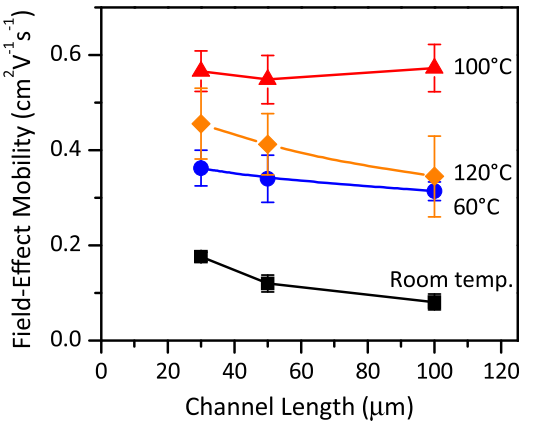

Fig. 8. Channel length dependence of field-effect mobility of AC5-CF3 thin-film transistors prepared at different substrate temperatures for AC5-CF3 depositions.

grains but also boundaries of grains. We can see from the AFM image shown in Fig. 7b that the grains with the size of about 1–3 μm tightly pack. However, the mobility of the TFTs with 120 °C depositions also decreased with increasing channel length. This phenomenon occurs because of the presence of the valleys observed in the film (see Fig. 7a).

4. Summary

We demonstrated the performance of optimally fabricated AC5-CF3 TFTs and its single-crystal FET. AC5-CF3 single-crystal FET showed field-effect mobility as high as 3.1 $cm^2 V^{-1} s^{-1}$. This value implies that AC5-CF3 must be a useful n-type organic semiconducting material. We also prepared AC5-CF3 TFTs, and the performance of the TFTs depended on the substrate temperatures during AC5-CF3 deposition. We obtained the highest performance from the viewpoint of mobility, threshold voltage and subthreshold slope when AC5-CF3 thin films were deposited at the substrate temperature of 100 °C. This was because a higher substrate temperature for the deposition enlarged the size of grains of AC-CF3 and improved the characteristics of grain boundaries. However, the 120 °C deposition induced deep valleys such as cracks and worsening mobility. AC5-CF3 TFTs prepared at 100 °C depositions showed no channel length dependence of the field-effect mobility. This is a very useful property for practical applications.

application of flexible low-cost, large-area solid-state lighting. However, to the best of our knowledge, there have been no published demonstrations of a high-efficiency blue phosphorescent OLED (the most challenging component for white OLED lighting applications) using an alternative anode material on a flexible substrate.

In this letter, we report the use of a scalable coating technique to deposit high-quality Ga-doped ZnO (GZO) films on flexible substrates at near room temperature. While we recognize that gallium is also a scarce, relatively expensive material, the total amount of gallium used in the GZO films is very small (5 at.%), whereas ITO contains >90 at.% indium. Hence, these GZO anodes may be a cost effective replacement for ITO. Using these GZO/PET substrates, we demonstrate blue phosphorescent OLEDs with high quantum and power efficiencies at a practical brightness level suitable for general lighting.

Radio frequency (RF) magnetron sputtering of GZO films was performed on glass and flexible PET substrates simultaneously in a 0.9 m box vacuum chamber having a base pressure of 4×10^{-7} Torr. A 15 cm diameter sputtering target containing 97.5% ZnO/2.5% Ga_2O_3 (at.%) with 99.99% purity (Cerac Inc., Milwaukee, WI) was used as the source. Substrates were mounted on one of three 30.5 cm diameter stainless steel pallets suspended from the chamber ceiling which allows double planetary rotation to improve coating uniformity. The plane of rotation of the substrate holders was 16.5 cm above the sputtering cathode. Prior to coating, the substrates were cleaned *in situ* with an ion beam generated by a source mounted on the chamber floor. Sputtering parameters including gas pressure and gas composition were evaluated for the production of high quality GZO films. 4% hydrogen in Ar sputtering gas at a pressure of 1 to 3 mTorr was found to be optimal for this system in this geometry. With the application of the double planetary rotation during deposition, the average variation of film thickness over the 30.5 cm pallet area was ~4%. The glass transition temperature of PET (150 °C) limits the maximum processing temperature for PET substrates [3]. During deposition, no supplementary heating was applied to the substrates and their temperature was up to 60 °C due to the energetic sputtering conditions. No damage was observed on PET substrates after deposition. Selected samples of GZO/PET films were annealed after deposition to investigate its effect on GZO film roughness, conductivity, and transparency as compared to the as-deposited films. Specifically (Table 1), annealing was performed at 110 °C under two different conditions: (a) 10 h in an air ambient at reduced pressure (253 Torr) and (b) 150 min in the atmosphere of 4% H_2/Ar (4% H_2/Ar flux at 25 standard cm^3/minute (sccm) to maintain the system pressure at 1.3 mTorr on top of the high vacuum background of 4×10^{-7} Torr). After these annealing processes no damage was noticeable on PET substrates. As seen in Table 1, annealing improves the conductivity of the GZO film on PET mainly by enhancement of mobility. However, this improvement did not lead to an observable difference between the performances of OLEDs built on the annealed GZO/PET and those built on the as-deposited GZO/PET.

GZO and ITO substrates not subject to UV ozone treatment were characterized using a series of methods. The commercial ITO/glass substrates were purchased from Colorado Concept Coatings LLC, having a 1400 Å thickness and nominal sheet resistance of 15 Ω/□ for the ITO layer. The morphology of the as-deposited GZO films on PET substrates was characterized by atomic force microscope (See supporting information in the supplemental), with a statistical grain height of 7.4 nm and a Z_{max} of 18.5 nm, comparable to commercial ITO on glass (grain height of 4.5 nm and a Z_{max} of 13.8 nm). The electrical properties of these materials without UV ozone treatment were determined using conductive atomic force microscope (c-AFM), Hall measurement and four-point probe measurements. The overall scale of c-AFM images in Fig. 1 shows that the as-deposited GZO film on PET conducts less current under the same bias (500 mV) compared to the commercial ITO on glass used as a control sample. This is explained by the difference in texture seen in Fig. 1, which suggests that compared to the control sample, the GZO film on PET has more uniformly distributed conductive domains, but those domains are much smaller in size. Carrier mobilities were measured with Hall measurement at room temperature using the Van der Pauw technique on a commercial Hall system from MMR Technologies. The thickness of the films was measured separately with a step profilometer (Tencor Instruments, Alpha Step 200 model). It was found that the carrier mobilities in the GZO films were one order of magnitude lower than that in commercial ITOs (see Table 1). The higher grain boundary density in the GZO films, and thus lower mobility due to increased disorder at grain boundaries, translates into higher resis-

Table 1
Comparison of commercial ITO/glass to GZO films fabricated on glass and flexible PET substrates with different post-deposition processing environments. The annealing temperature was 110 °C for both annealing environments. Key OLED performance metrics are also reported at a current density of 1 mA/cm^2 for OLEDs built on these anode materials.

Fabrication condition	Resistivity (ohm cm)	Carrier concentration (cm^{-3})	Mobility (cm^2/Vs)	Thickness (Å)	Optical transmittance at 475 nm	OLED operating voltage (V)	EQE (%)	η_p (lm W^{-1})	CIE coordinates
ITO/glass	1.42×10^{-4}	5.47×10^{21}	8.05	1400	89.2%	4.35 ± 0.03	16.7 ± 0.5	32.1 ± 0.9	(0.15, 0.38)
GZO/glass (as deposited)	1.66×10^{-3}	3.62×10^{21}	1.04	1550	88.0%	4.05 ± 0.02	15.2 ± 0.1	31.6 ± 0.3	(0.14, 0.39)
GZO/PET (as deposited)	3.03×10^{-3}	5.88×10^{21}	0.351	1550	85.2%	4.21 ± 0.02	16.6 ± 0.2	33.1 ± 0.3	(0.14, 0.38)
GZO/PET (annealed in 4% H_2/Ar)	2.20×10^{-3}	5.59×10^{21}	0.508	1550	86.5%	4.06 ± 0.02	16.3 ± 0.3	33.7 ± 0.4	(0.13, 0.35)
GZO/PET (annealed in low vacuum)	2.19×10^{-3}	5.73×10^{21}	0.498	1550	86.3%	3.99 ± 0.01	16.0 ± 0.6	33.7 ± 1.2	(0.14, 0.37)

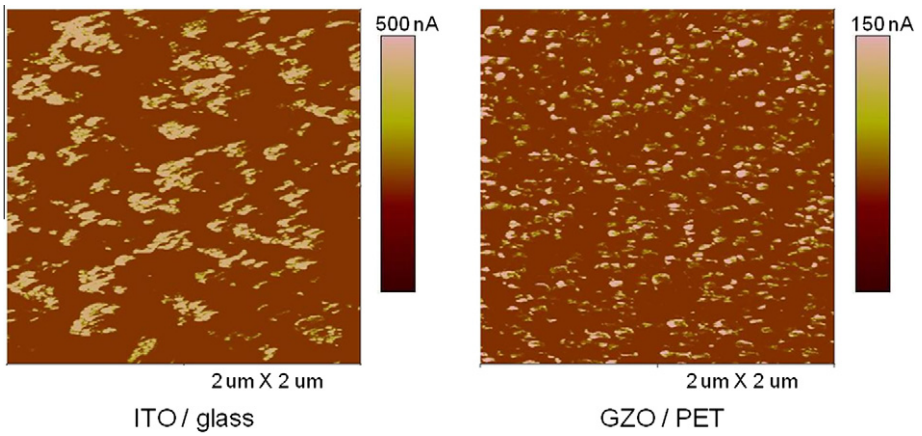

Fig. 1. Conductive AFM (c-AFM) images of films of ITO on glass (left) and GZO on PET (right), where the ITO/glass was obtained commercially and the GZO film was sputtered onto PET in 4% H_2/Ar at low temperature without annealing. Images were taken under a DC bias of 500 mV. No UV ozone treatment was performed prior to the c-AFM experiment.

tivity. This was confirmed by four-point probe measurements showing an order of magnitude higher resistivity for the GZO films than that of the ITO deposited on glass (Table 1).

The optical properties of the GZO films on PET were examined using UV–vis-NIR spectrometry and compared to the corresponding properties of ITO and GZO on glass. As seen in Fig. 2, the GZO films deposited on PET and glass, including the samples annealed under different conditions, all exhibited transmittance spectra close to that of the commercial ITO on glass. The transmittance curves for GZO on PET mainly reflect the optical properties of the deposited GZO film as is evident when comparing the GZO/PET transmittance spectra to the GZO/glass transmittance spectrum. However, the transmittance curves of all the GZO films on PET featured small oscillations as a function of wavelength showing larger periods of oscillation at longer wavelengths. This behavior can be attributed to the hard coating on the other side (opposite to the side with GZO film) of the GZO/PET substrates (PET with hard coating on one side were purchased from Tekra Inc.) which caused a noticeable interference effect. A detailed discussion of this phenomenon can be found in the supplemental information.

We utilized GZO films deposited on both glass and PET substrates to fabricate phosphorescent blue OLEDs with the device architecture: TCO/350 Å TAPC/150 Å HM-A1:5% FIrpic/500 Å PO15/10 Å LiF/1000 Å Al. Here the 1,1-bis [(di-4-tolylamino)phenyl]cyclohexane (TAPC) serves as the hole-transport layer (HTL) [12]. The emissive layer

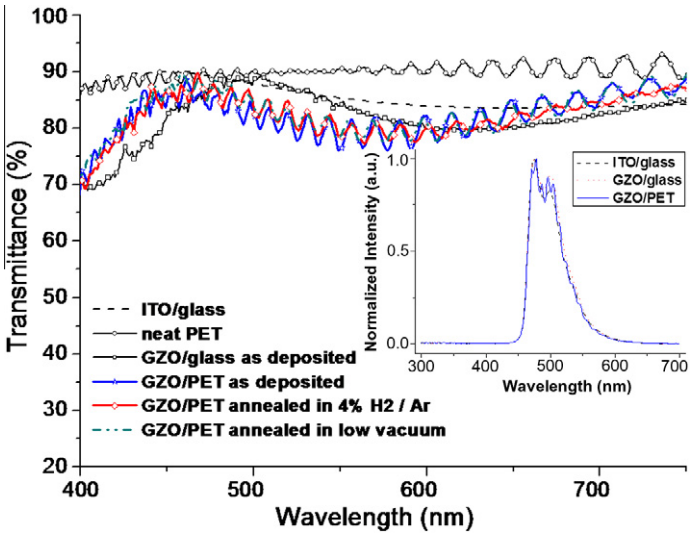

Fig. 2. Optical transmittance spectra for commercial ITO/glass, neat PET, GZO/glass, GZO/PET as deposited, GZO/PET annealed under 4%H_2/Ar, and GZO/PET annealed under low vacuum (253 Torr). The inset – electroluminescent spectra for OLEDs with the structure of TCO anode/350 Å TAPC/150 Å HM-A1:5% FIrpic/500 Å PO15/10 Å LiF/1000 Å Al. The oscillations in the spectra of GZO/PET films are due to an interference effect involving the PET substrate (see the supplementary information).

(EML) is composed of the host material 4-(diphenylphosphoryl)-N,N-diphenylaniline (HM-A1) [13] doped with phosphorescent emitter iridium (III) bis[(4,6-difluorophenyl)-pyridinato-$N,C^{2'}$]picolinate (FIrpic). The hole-blocking/electron-transporting layer (ETL) is 2, 8-bis(diphenylphosphoryl)dibenzothiophene (PO15) [14]. A thin lithium fluoride (LiF) layer facilitates electron injection from the aluminum (Al) cathode. GZO/PET substrates were cleaned in three steps: in a dilute Tergitol solution, deionized water, and 2-propanol with sonication. As controls, TCO films (GZO and ITO) on glass substrates were cleaned by sonication in a sequential series of solvents: a dilute Tergitol solution, deionized water, trichloroethylene, acetone, and 2-propanol. These substrates were then dried with flowing nitrogen. As a final step before device fabrication, all the glass and PET substrates were treated with UV ozone (UVO-Cleaner, Jelight Company, Inc.) at 15 mW/cm^2 for 15 min. Organic layers were sequentially deposited onto the substrates by thermal sublimation from tantalum boats in a high vacuum chamber with base pressure below 3×10^{-7} Torr. LiF/Al cathodes were defined by thermal deposition through a shadow mask with 1 mm diameter circular openings. Quartz crystal oscillators were used to monitor the thicknesses of the films, which were calibrated *ex situ* using ellipsometry or profilometry.

Key OLED performance metrics at a current density of 1 mA/cm^2 are summarized in Table 1. All the OLEDs employing a GZO anode, whether on a rigid or flexible substrate, manifested performance comparable to OLEDs produced using an ITO anode. OLEDs built on PET substrates exhibit a low operating voltage ($\sim$4 V), high external quantum efficiency (EQE) (16%), and high power efficiency (η_p) (33 lm/W). Fig. 3a is a typical plot of EQE and η_p as a function of luminance. It can be seen throughout the practical brightness range for general lighting (1000–4000 cd/m^2) that the OLEDs fabricated using GZO anode on PET performed nearly the same as the OLEDs fabricated using commercial ITO anode on glass. The voltage dependence of current density and luminescence of these devices are shown in Fig. 3b. The OLED devices built on GZO/PET and GZO/glass show charge transport behavior similar to ITO/glass devices, clearly demonstrating a transition from the intrinsic bulk transport regime (at low voltages, free charges are thermally generated in organic layers) to the trap filling transport regime (at high voltages, free charges injected from electrodes are filling traps in organic layers) [15]. Ohmic type *J–V* curve is observed in the intrinsic bulk transport regime for all three types of devices, indicating that none of the three TCO anodes is limiting charge transport by hole injection. GZO/glass devices exhibit a higher leakage current at low voltages as opposed to GZO/PET and ITO/glass devices, which is possibly attributable to a greater asperity on the surface of GZO/glass substrates. All three types of devices show similar turn-on voltage around 3 V. This low turn-on voltage contributes to the achieved high power efficiency as shown in Table 1. It is noteworthy that in yielding high-performance devices, the GZO/PET anode material fully processed at near room temperature performs as well as those films with post-deposition annealing (Table 1), thus indicating that the annealing step may be eliminated. This would allow a reduction in processing cost and time, and accommodate the low temperature requirements for certain devices such as top-emitting OLEDs. Additionally, as shown in the inset of Fig. 2, the electroluminescence (EL) spectra for all of the devices produced on various substrates appear very similar. Small oscillations can be observed in the EL spectra for OLEDs fabricated on GZO/PET substrates due to the interference effect previously mentioned. Consistently with the comparable EL spectra, similar Commission internationale de l'éclairage (CIE) coordinates were obtained (shown in Table 1) from operating OLEDs on the various TCO substrates. All these facts demonstrate that GZO/PET is a potential substitute for ITO/glass.

Based on the transmittance curves (Fig. 2), we calculated the average refractive index (n) and extinction coefficient (k) over visible spectrum for the materials used in this work: n(ITO) = 1.683, k(ITO) = 0.033; n(GZO) = 1.834, k(GZO) = 0.064. Since the refractive index of GZO is higher than ITO, more light will be trapped in the GZO layer of the OLED device and thus potentially reduce outcoupling efficiency so that the GZO/glass devices exhibit a slightly lower EQE than ITO/glass devices (Table 1). We also note that in spite of similar transmittance around the FIrpic emission peaks, GZO/PET substrates give slightly higher EQE than GZO/glass substrates for the same OLED device stack. We attribute this increase of EQE to the enhanced light outcoupling through a combination of two factors. First, more light escapes the GZO layer into the PET due to its higher refractive index (1.58) compared to glass (1.50) [16]. Second, due to total internal reflection above the critical angle at the air-substrate interface, only a fraction of the light can escape the substrate [17] and get collected by the photo detector. Given the certain experimental setting of finite distance from a sample's bottom to the surface of photo detector, the smaller thickness of the PET substrate (0.19 mm) compared to the glass substrate (1 mm) translates into shorter distance from light emission to the photodetector and thereby allows for less loss in the light collection. A detailed optical model is needed to quantitatively analyze the outcoupling factors in comparing devices built on GZO/PET and GZO/glass substrates. Together, these two effects are responsible for the slightly higher EQE of OLEDs based on GZO/PET versus GZO/glass. Interestingly, the higher resistivity of the GZO versus ITO and the as-deposited versus annealed GZO as the anode does not affect the OLED performance for these small pixel devices (diameter = 1 mm, 7.854×10^{-3} cm^2). For the OLEDs tested in this work, the lateral conductance (GZO film sheet resistance $\sim$100 $\Omega/\square$) across the anode is far higher than that of vertical transport through the device stack which thereby dominates the overall conductance of an OLED. The same organic layers deposited on different TCO anode materials (GZO or ITO) exhibited similar charge transport behavior (as seen from *J–V* characteristics in Fig. 3b) and operating voltage (shown in Table 1), indicating that hole injection from different TCO anodes into the same HTL is not a limiting factor for charge transport in these devices. We attribute the similar injection properties for the different TCO anodes (GZO or ITO) to the modification of anode surface work function through UV ozone treatment [18]. When the pixel size is small, the higher

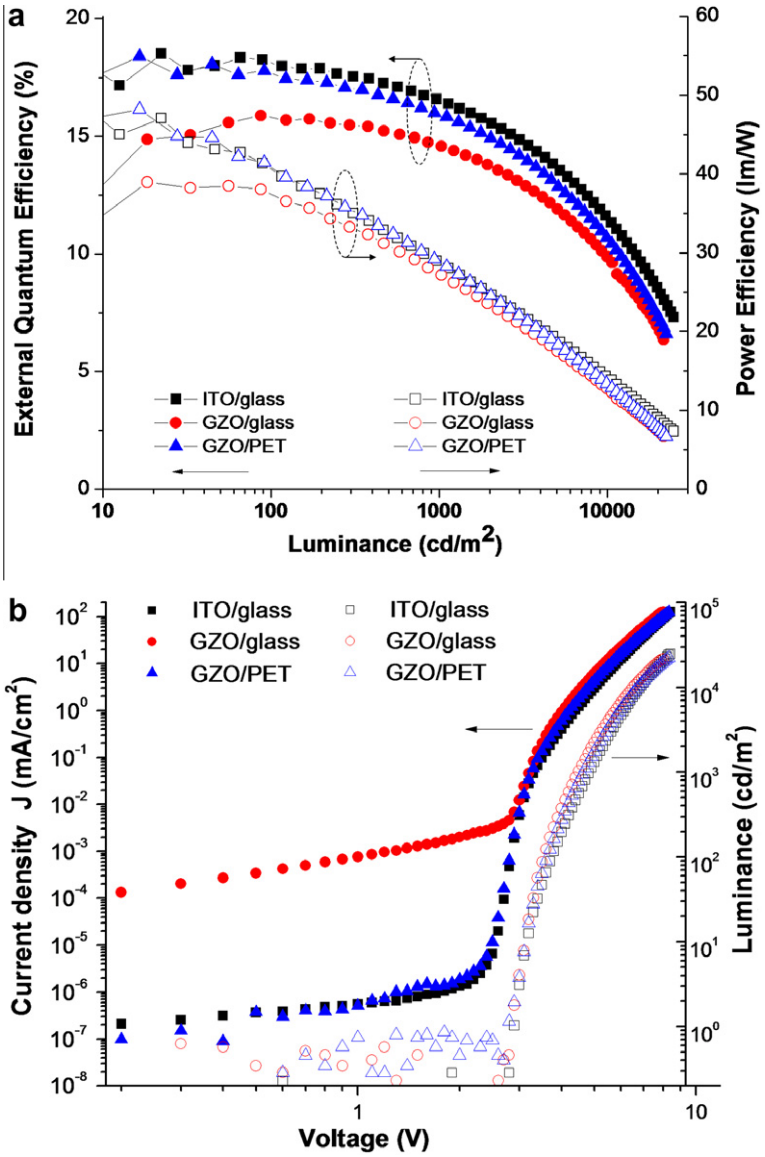

Fig. 3. (a) The luminescence dependence of EQE and power efficiency and (b) the voltage dependence of current density and luminescence for OLEDs with the structure: TCO anode/350 Å TAPC/150 Å HM-A1:5% FIrpic/500 Å PO15/10 Å LiF/1000 Å Al. Here ITO/glass was commercially purchased and GZO/glass and GZO/PET were as deposited with no post annealing. All the TCO anode substrates were treated with UV ozone before organic deposition.

resistivity of the GZO films will not significantly influence device performance. For applications where larger pixel sizes are involved (>1 cm^2) such as lighting panels for solid-state lighting purposes, the resistivity of the GZO films needs to be decreased by at least an order of magnitude to be at levels near that of commercial ITO in order to operate the large-area devices at low and uniform voltages and avoid Joule heating. As is seen in Table 1, the annealing process for GZO/PET substrates served to decrease the resistivity of the GZO films by 28%. Unfortunately, this is still an order of magnitude higher than the resistivity of commercial ITOs. Hence different strategies need to be applied such as inserting a thin, nearly transparent silver layer into the GZO film [19] or placing metal grids on the GZO surface to help distribute electrical current better [20].

In summary, indium-free GZO films have been uniformly deposited on flexible substrates over a large area using a low temperature sputtering process. Highly efficient phosphorescent blue OLED devices were built on the GZO films, which functioned as the anode. The performance of these devices compared favorably with that of the same device stack built on rigid (glass) substrates using a commercial ITO anode. This result demonstrates that indium-free TCOs on flexible substrates can serve as a low-cost and flexible substitute for OLED device manufacturing. Another interesting application of sputtered TCO films is the top contact electrode in a top-emitting, inverted OLED.

Based on our results, the as-deposited GZO, even without a post-deposition anneal, should be able to function as a top electrode in a top emitting inverted OLED for small area pixels. The greater challenge in using the GZO deposition process to form a top electrode in this device architecture would be to modify the process in order to reduce and/or eliminate damage to the underlying organic layer during the GZO deposition [21].

leading to back transfer [15–17]. As a result we have decided to follow the approach of using a non-conjugated polymer backbone [10,11,13,18–22]. However, non-conjugated homopolymers with small iridium(III) complexes can have poor solubility. For example, a homopolymer comprised of a norbornenyl derived backbone and *fac*-tris(2-phenylpyridyl)iridium(III) side chains attached to every unit was reported to be insoluble [23] and more recently a polystyrene backboned homopolymer with bis(2-phenylpyridyl)iridium(III) acetylacetonate complex side chains had only limited solubility in solvents normally used for processing [11].

Phosphorescent polymers also have difficulties with concentration quenching due to the proximity of the iridium(III) complex cores, particularly in the solid-state [11]. While most others have used co-polymers to reduce the effect of intra- and inter-polymer chromophore interactions [15,17–22,24,25], here we explore an alternative approach of a polymer composed of dendrimer side chains with the aims of controlling interactions between chromophores, enhancing the viscosity of dendrimers towards a level suitable for ink-jet printing and ensuring solubility. We have also compared the polymer to model monomers in order to determine the effects of polymerisation on the interactions between chromophores.

2. Synthesis

Poly(dendrimer) **7** has several important design features: first, it is a homopolymer; second, the core emissive unit is a heteroleptic iridium(III) complex comprising two 2-phenylpyridyl ligands and a pyridyltriazolyl co-ligand with the former responsible for the green emission; third, first generation biphenyl-based dendrons with 2-ethylhexyloxy surface groups are attached to each of the 2-phenylpyridyl ligands to control the inter-chromophore interactions and provide solubility; finally, the norbornenyl derived polymer backbone was chosen as it can be easily formed by Ring Opening Metathesis Polymerisation. The pyridyltriazolyl co-ligand was chosen as the attachment point to the polymer backbone, as it can be added to the iridium(III) without scrambling of the other ligands. The synthetic strategy for forming the poly(dendrimer) **7** is shown in Scheme 1. In principle, aldehyde **1** could be used to cleave the tetra[2-(5-{3,5-bis[4-(2-ethylhexyloxy)phenyl]phenyl}phenyl)pyridyl]diiridium(III) dichloride **4** [26] to form a complex that with subsequent reduction and ester formation with *exo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid [27] could lead to monomer **5**. However, this route requires an increased number of steps using the advanced dimer intermediate **4**, and hence the alternative route illustrated in Scheme 1 was used. The ^{1}H NMR spectra of the very polar pyridyltriazolyl and its derivatives often showed a minor component in addition to the desired compound. However, the elemental analyses were within the accepted limits, and it may be that the other components were regioisomers. Nevertheless, we have reported the yields for the early transformations as approximate. Aldehyde **1** was formed in ≈68% yield by metalation of 2-(5-trifluoromethyl-2-H-1,2,4-triazol-yl)-5-bromopyridine with *t*-butyllithium followed by reaction with *N*,*N*-dimethylformamide and subsequent hydrolysis with dilute hydrochloric acid. Reduction of the aldehyde **1** to alcohol **2** utilised lithium aluminium hydride, and **2** was isolated in ≈92% yield. Alcohol **2** was then coupled with the pre-formed acid chloride of *exo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid to give ester **3** in ≈85% yield. We chose pure *exo*-norbornene isomers for the polymerisation as they have been shown to exhibit significantly higher rates of propagation under milder conditions, with higher conversions and more control than the 80:20 *endo*/*exo* isomeric mixtures that can be formed during the Diels–Alder reaction to prepare the norbornene [28]. The higher rate of propagation is primarily due to reduced steric interactions between the growing polymer chains and the incoming monomer [29]. As expected, the cleaving of dimer **4** proceeded smoothly at room temperature, and the monomer **5** was formed in ≈43% yield. In previous work on polymers bearing small molecule iridium(III) complexes on a poly(styrene) backbone it was found that the presence of double bonds caused quenching of the luminescence. Therefore, we hydrogenated the double bond of the norbornenyl unit with hydrogen and a palladium on carbon catalyst to give compound **6** in quantitative yield as a model compound to study the effect of the double bond on the luminescent properties. Finally, polymer **7** was formed in 72% yield from monomer **5** using Grubbs III catalyst [30].

Infrared spectroscopy showed that the ester functionality of ligand **3** survived the subsequent synthetic steps with **5**, **6**, and **7** all having carbonyl stretches at 1735 cm^{-1}. The polymer was found to be thermally stable, with thermogravimetric analysis showing just a 5% weight loss at 410 °C. Differential scanning calorimetry showed that there were no thermal transitions between −20 °C and 250 °C. Gel permeation chromatography (GPC) against poly(styrene) narrow standards showed that polymer **7** had an $\overline{M}_w$ and $\overline{M}_n$ of 5.5×10^4 and 2.2×10^4, respectively, and hence a polydispersity of 2.2. Living polymerisations normally give a polydispersity close to unity, and the higher value for polymer **7** may be due to the large size of the monomer that needs to be added to the chain end where steric factors may play a much more important role in chain growth. It was possible to analyse the molecular weight of the polymer using MALDI-TOF mass spectrometry, which showed that the polymer had a peak molecular weight of 171 kDa. It is interesting to note that the GPC analysis underestimates the true molecular weight of the polymer and this arises from a different conformation of the poly(dendrimer) in solution when compared with the poly(styrene) standards.

3. Photophysical properties

Fig. 1a shows the absorption spectra of the materials. The absorption peak at less than 350 nm is attributed to π–π^* transitions in the 2-phenylpyridyl, the pyridyltriazolyl ligands, and the biphenyl chromophores in the dendrons. The weaker absorptions from 350 to 460 nm are normally reported as being due to the metal-to-ligand

Scheme 1. charge-transfer states of the iridium(III) complex. The spectra do not change on polymerisation or when the materials are spin cast into thin films indicating that strong aggregation phenomena are not occurring in either case.

Fig. 1b shows the photoluminescence spectra of the materials. All three materials have strong green luminescence in solution, with a peak at 497 nm and a shoulder at 525 nm. The similarities in the solution spectra show that, to a first approximation, the emissive properties of the iridium(III) complexes are not significantly affected either by the presence of a double bond in the norbornenyl unit in monomer **5** or by being incorporated into a polymer. Monomers **5** and **6** gave very similar solution photoluminescence quantum yields (PLQYs) of 53% and 56%. The

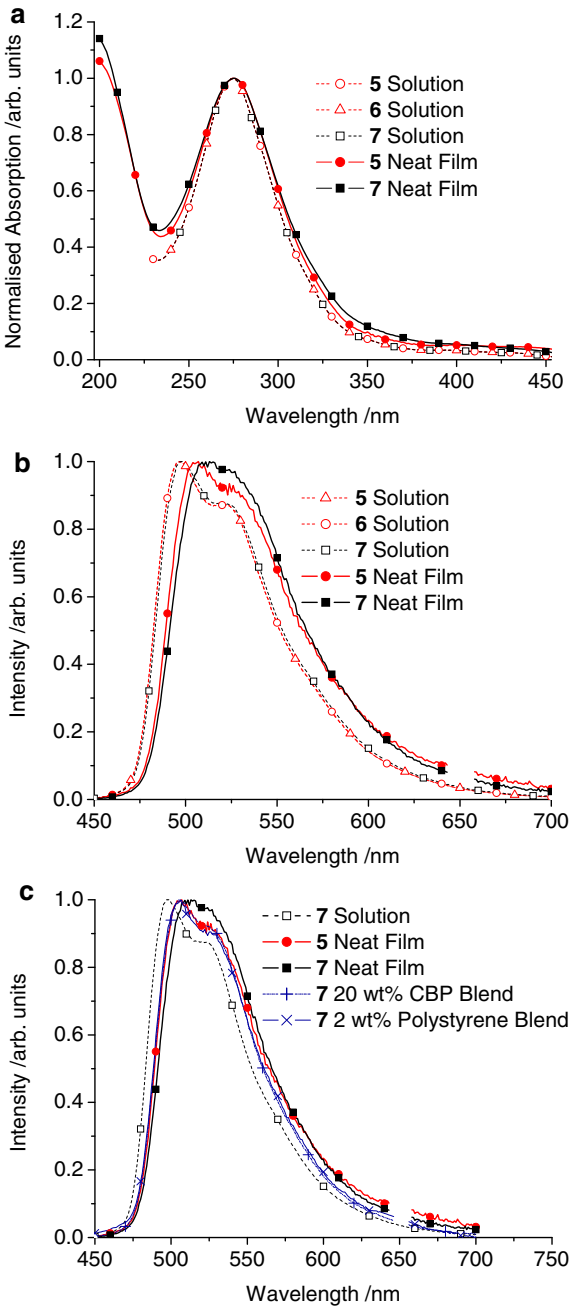

Fig. 1. Normalised spectra showing (a) the absorption of monomers **5** and **6** and polymer **7** in dilute dichloromethane solutions and monomer **5** and polymer **7** in thin films, (b) emission spectra of monomers **5** and **6** and polymer **7** in dilute degassed dichloromethane solutions and monomer **5** and polymer **7** in thin films, and (c) a comparison of the emission spectra of polymer **7** in dilute degassed dichloromethane solution, monomer **5** and polymer **7** in neat thin films, and blended films consisting of 20 wt.% of polymer **7** in a CBP host and 2 wt.% of polymer **7** in a polystyrene host.

transient luminescence lifetimes shown in Fig. 2 were also comparable at 3.07 and 3.03 μs. This indicates that the structure of the ester-linked group on the pyridyltriazolyl ligand does not significantly affect the photophysics in solution.

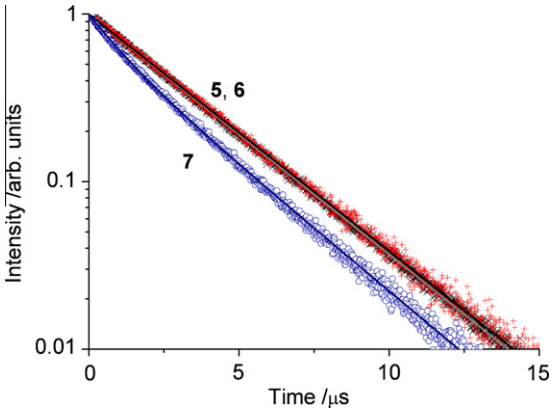

Fig. 2. Time resolved luminescence data for dilute solutions of monomers **5** (red vertical crosses) and **6** (black diagonal crosses) and polymer **7** (blue circles) in degassed dichloromethane. Fits are shown as solid lines. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Polymer **7** had a solution PLQY of 37%. The transient luminescence was best fitted by a bi-exponential decay with lifetimes (pre-exponential factors) of 1.08 μs (0.30) and 2.90 μs (0.70). The 2.9 μs component is similar to the lifetime of the monomers. However, the reduced PLQY and the shorter 1.08 μs component compared to the monomer indicate that even in the dilute solution there is some quenching of the luminescence by intra-polymer chromophore interactions due to the proximity of the iridium(III) complexes along the polymer backbone. These results compare favourably to the luminescent efficiencies reported for other norbornenyl polymers with small molecule iridium(III) complex side chains which only had a 2% PLQY in solution and a *fac*-tris(2-phenylpyridyl)iridium(III) copolymer (the homopolymer was completely insoluble) which had a PLQY of 24% [23].

The effects of inter-chromophore interactions become more pronounced in neat films of monomer **5** and poly(dendrimer) **7**. The emission peaks in Fig. 1b were both red-shifted by 10–15 nm in the film relative to the solution measurements, and the PLQY was reduced to 13% and 15%, respectively. The red-shift in the emission of the poly(dendrimer) in the solid-state is more significant than in the monomer, suggesting that it is more susceptible to aggregation effects. Nevertheless, these results are far superior to neat films of homopolymers containing small molecule iridium(III) complex side chains without dendrons [11] where the PLQY was reduced to less than 1% in the solid-state. This confirms that the addition of dendrons is an effective strategy for controlling intermolecular chromophore interactions and producing neat films with good phosphorescence [31–33].

In order to reduce intermolecular interactions and improve charge transport, 20 wt.% of poly(dendrimer) **7** was blended with the commonly-used charge transport host 4,4′-bis(*N*-carbazolyl)-2,2′-biphenyl (CBP) for the production of OLEDs. The PLQY of these blended films improved significantly to 52% and a typical photoluminescence spectrum of the blended film is shown in Fig. 1c. The

photoluminescence spectrum of the CBP blend is blue-shifted compared to the neat film, and closely resembles that of the film of neat monomer **5**. These results both suggest that inter-chromophore interactions were successfully reduced by the blend.

By contrast monomer **5** only gave a CBP blended film PLQY of 29%. This is attributed to the fact that the monomer only has dendrons attached to two ligands to protect it from aggregating and it lacks the polymer's backbone which controls the orientation of the neighbouring units. Both these effects may allow more interaction of the chromophores than in the polymer blend.

Fig. 3 shows a comparison of the phosphorescence lifetime of **7** in solution, in a 20 wt.% of **7** in a CBP blend film, 2 wt.% of **7** in a polystyrene blend film and in neat films. In all the films the phosphorescent decay is faster than in solution. It is interesting that the CBP blend film has a faster decay of 0.81 μs (0.39) and 2.02 μs (0.61) components than the solution despite the blend having a higher PLQY. The increased PLQY of the blend combined with an increased proportion of the decay in the fast component and a decrease in the lifetime of both components strongly implies an increase in the radiative rate in the CBP blended film compared to the solution.

In order to understand more fully this effect, PL lifetime studies of neat films and poly(styrene) blends with 2 wt.% of poly(dendrimer) **7** were conducted. These results are also shown in Fig. 3. The neat films gave a relatively fast three-component decay of 0.35 μs (0.26), 1.04 μs (0.72), and 2.9 μs (0.02), which indicates that there are strong chromophore–chromophore interactions quenching emission. This corresponds well to the lower PLQY of 15% for the neat film. The poly(styrene) blended films gave a slower two-component decay of 0.74 μs (0.73) and 2.16 μs (0.27), with a PLQY of 13%. From Fig. 3 it can be seen that the luminescence decay of the poly(styrene) film is slower than that of the neat film, and despite this the PLQY appears comparable. In addition, the PLQY of the 2 wt.% blend in polystyrene is much less than the 20 wt.% blend with CBP.

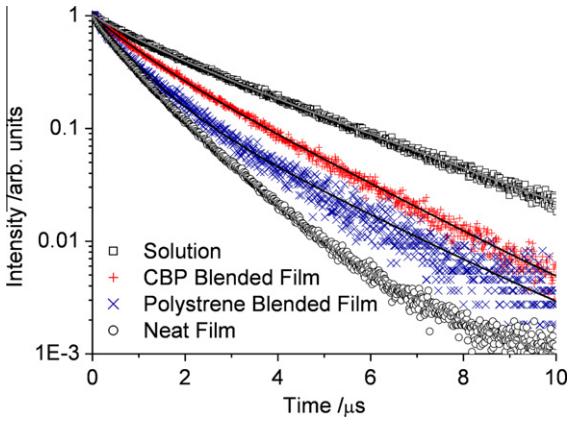

Fig. 3. Time resolved luminescence data and fits for polymer **7** in degassed dichloromethane solution and films in vacuum. The films are composed of neat polymer, 20 wt.% of the polymer dispersed in CBP and 2 wt.% of the polymer in polystyrene. Fits are shown as solid lines.

The low PLQY in the polystyrene could indicate that **7** is not well dispersed in the film however the luminescence decay in the poly(styrene) film is slower than that of the neat film. This suggests the chromophores in the poly(styrene) film do not share the same environment as in the neat film implying that phase separation alone cannot explain the low PLQY. These results, together with the apparent increase in the radiative rate of the polymer going from solution phase to the CBP blend, suggest that the emissive properties of the iridium polymer in film are dependent on other components in the blend and may be a function of differences in the chains' conformation or phase separation in the blends. These observations are consistent with the report on norbornenyl homopolymers with small molecule iridium(III) complex side chains where mixing the polymer with solutions of a 'non-polar' copolymer would lead to turbidity or even complete precipitation from solution [23].

4. Viscosity and electrical properties

The viscosity of the polymer at different concentrations in chlorobenzene was measured. Chlorobenzene was found to have a viscosity of 0.75 mPa s, and a 5 mg/ml solution of polymer **7** had a viscosity of 0.83 mPa s, which increased to 1.1 mPa s at a concentration of 25 mg/ml. This viscosity is 36% higher than simple first generation dendrimers at

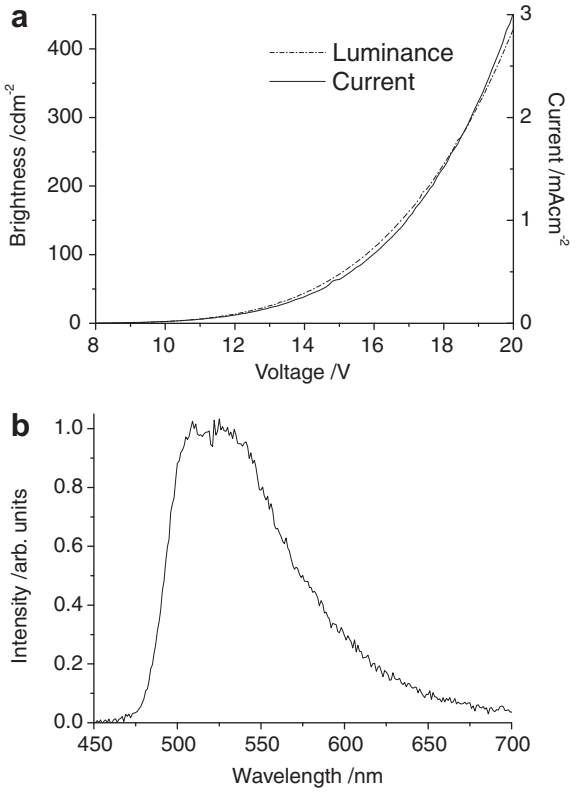

Fig. 4. Characteristics of bi-layer OLEDs using 20 wt.% polymer **7** blended into a CBP host as the emissive layer. The figures show (a) luminance and current curves and (b) the electroluminescence at 15 V.

the same concentration and is approaching the viscosity required for ink-jet printing.

The most promising blend of 20 wt.% poly(dendrimer) **7** in CBP was studied as the emissive layer in an OLED device. The devices used an aluminium/LiF cathode and a 2,2′,2″-(1,3,5-benzenetriyl)tris-[1-phenyl-1*H*-benzimidazole] (TPBI) electron transporting layer on top of the blended emissive layer on a transparent ITO anode. The devices achieved an external quantum efficiency of 5.1% and luminous efficiency of 16.4 cd/A at a brightness of 100 cd/m^2 at 15.8 V. By contrast similar devices made with blends of monomer **5** only achieved 1% EQE. The current and luminance characteristics for the polydendrimer are shown in Fig. 4a. The CIE co-ordinates of the electroluminescence were measured to be $X = 0.32$, $Y = 0.60$ at a driving voltage of 15 V. The electroluminescence spectrum is shown in Fig. 4b. A high drive voltage and the modest quantum efficiency suggest that charge transport and balance in the blend need further improvement.

5. Conclusion

The phosphorescent poly(dendrimer) reported here had excellent solubility and successfully achieved our aim of enhancing the viscosity of solutions towards the level required for ink-jet printing. The poly(dendrimer) was also moderately successful in achieving our aim of controlling chromophore–chromophore interactions in the neat film, achieving much better results than previous non-dendronised polymers. This, together with the relatively high PLQY in the film blended with CBP and the demonstration of an OLED, suggests that poly(dendrimer)s are a promising approach to ink-jet printable materials for phosphorescent LEDs.

6. Experimental methods

Commercial reagents were used as received unless otherwise noted. Use of inert atmosphere, dry glassware, and dry solvents is assumed where appropriate; the inert atmosphere used was nitrogen unless otherwise stated. Solvents were dried by passage through activated alumina in a Grubbs' column unless otherwise noted. Use of Schlenk line techniques implies the use of an argon atmosphere; dichloromethane and ethylvinyl ether were distilled from calcium hydride and deoxygenated before use. ^{1}H NMR spectra were recorded using a Bruker AV500 spectrometer, in deuterated chloroform or dichloromethane solution. For the ^{1}H NMR spectra 7.27 p.p.m. and 5.32 p.p.m. were used as the residual peaks for deuterated chloroform and dichloromethane, respectively. Abbreviations used in the assignment of the spectra are: G1-bpH = first generation branching phenyl H, spH = surface phenyl H, LH = ligand H, and NbH = norbornenyl, norbornyl or polymer backbone H. Coupling constants are quoted to the nearest 0.5 Hz. Peaks corresponding to the main component are reported. Gel permeation chromatography was carried out using PLgel Mixed-A columns (600 mm + 300 mm lengths, 7.5 mm diameter) from Polymer Laboratories calibrated with poly(styrene) narrow standards (Mp = 580–3.2 × 10^6) in tetrahydrofuran. The tetrahydrofuran was deoxygenated with helium and pumped at a rate of 1 cm^3/min at 30.0 °C. Microanalyses were carried out at London Metropolitan University, UK. UV–visible absorption spectra were recorded as solutions in HPLC grade dichloromethane or as films with a Perkin–Elmer UV–vis Lambda 25 spectrometer or a Varian Cary 300 spectrophotometer and absorption maxima are reported. Infrared spectra were recorded on a Bruker Tensor 27 FT-IR spectrometer. Thermogravimetric analysis (TGA) was carried out on a Perkin–Elmer STA6000 and differential scanning calorimetry was performed using a Perkin–Elmer Diamond DSC by ANFF-Q (the Australian National Fabrication Facility – Queensland Node, University of Queensland, QLD, Australia). Mass spectra were recorded on an Applied Biosystems Voyager DE-STR MALDI-TOF instrument, using 2-[(2*E*)-3-(4-*tert*-butylphenyl)-2-methylprop-2-enylidene]malononitrile (DCTB) matrix in positive reflection or linear mode, at the EPSRC National Mass Spectrometry Service Centre (NMSSC), Swansea, UK.

Solution samples were dissolved in dichloromethane and freeze–thaw degassed. Solution photoluminescence quantum yields were measured following the method described in [34]. Samples were excited at 360 nm. Their fluorescence was compared to a quinine sulphate in 0.05 M sulphuric acid standard, taken to have a solution quantum yield of 0.55. The optical densities of the standard and sample were similar and small (∼0.1). The accuracy of these measurements is estimated to be ±10% of the stated value.

All film samples were spin coated on fused silica substrates from dichloromethane solutions. Film photoluminescence was measured in an integrating sphere under nitrogen purge using the method described in [35]. The samples were excited by the 325 nm line of a He–Cd laser with a power of 0.1–0.2 mW.

All photoluminescence spectra were recorded in a JY Horiba Fluoromax 2 fluorimeter. Solution samples were excited at 360 nm and all film samples were excited at 325 nm.

The time-resolved luminescence measurements were performed using the time-correlated single photon counting technique making use of a cooled Hamamatsu R3809U-64 microchannel plate detector. The detection monochromator was centred at 520 nm wavelength. The samples were excited by a pulsed 393 nm Picoquant GaN laser diode. The system had a measured instrument response function with a FWHM of 200 ps. Solution samples were freeze–thaw degassed and film samples were measured in vacuum.

OLEDs were prepared on ITO substrates that had been etched with 37% hydrochloric acid and zinc powder. The ITO was then cleaned by sonication in acetone and *iso*-propyl alcohol followed by oxygen plasma ashing. The organic layer was spin cast from a dichloromethane solution containing a blend of the phosphorescent material with 80% 4,4′-*N*,*N*′-dicarbazolyl-biphenyl (CBP) by weight. The solution concentration was 10 mg/ml and spin coating at 2000 rpm resulted in ∼100 nm films. The samples were then placed in an evaporator operating at a pressure of 2 × 10^{-6} mb. A 60 nm electron transport and hole-blocking

layer of 2,2′,2″-(1,3,5-benzenetriyl)tris-[1-phenyl-1*H*-benzimidazole] (TPBI), a 0.7 nm layer of LiF and ~100 nm aluminium cathode were then sequentially deposited by thermal evaporation. A shadow mask was used to give a final active area of 6 mm^2.

The electroluminescence spectrum was recorded using a cooled Andor DV420-BV CCD spectrometer. The current and voltage characteristics were recorded using a Keithley source-measure unit and the light emission was measured using a calibrated photodiode assuming lambertian emission.

6.1. 2-(3-Trifluoromethyl-1H-1,2,4-triazol-5-yl)-5-formylpyridine **1**

t-Butyl lithium (1.7 M in hexane, 3.93 mL, 6.69 mmol) was added to a solution of 2-(5-trifluoromethyl-2-*H*-1,2,4-triazolyl)-5-bromopyridine [9] (490 mg, 1.67 mmol) in tetrahydrofuran (20 mL) at −78 °C. After 1 h *N*,*N*-dimethylformamide (565 μL, 7.36 mmol) was added and the solution was allowed to warm to room temperature over 16 h. The solution was cooled to 0 °C and aqueous hydrochloric acid (1 M, 8 mL) added. The solution was then neutralised with saturated aqueous sodium hydrogen carbonate before being extracted with dichloromethane (100 mL, 2 × 50 mL). The combined organic extracts were dried over magnesium sulfate and filtered, and the solvents were removed. The residue was purified by column chromatography over silica using diethyl ether:ethyl acetate mixture (9:1) as eluent to give **1** as a white solid (274 mg, ≈68%). (Found: C, 44.6; H, 1.9; N, 23.1. $C_9H_5F_6N_4O$ requires C, 44.6; H, 2.1; N, 23.1%); λ_{max} (DCM)/nm 215, 248; ν_{max} (KBr)/cm^{-1} 1687 (C═O); δ_H (500 MHz; $CDCl_3$) 7.65 (1H, dd, J = 7.5, J = 4.5, LH), 8.47 (1H, dd, J = 7.5, J = 1.5, LH), 8.90 (1H, dd, J = 4.7, J = 1.6, LH), 11.39 (1H, s, HCO) and 12.70 (1H, br. s, NH); δ_F (470 MHz; $CDCl_3$) −65.4; *m*/*z* (ESI) 241.0340 ($M-H^+$, 100%). $C_9H_3F_3N_4O$ requires 241.0343.

6.2. 2-(3-Trifluoromethyl-1H-1,2,4-triazol-5-yl)-5-hydroxymethylpyridine **2**

A solution of **1** (215 mg, 0.890 mmol) in diethyl ether (5 mL) was added to a stirred suspension of lithium aluminium hydride (135 mg, 3.56 mmol) in diethyl ether (5 mL) at 0 °C. The reaction mixture was allowed to warm to room temperature over 40 min. It was then cooled to 0 °C and quenched by careful addition of water (30 mL). The pH was adjusted to 5 with aqueous hydrochloric acid (3 M), and the resultant solution was extracted with diethyl ether (3 × 50 mL). The combined organic extracts were dried over magnesium sulfate and filtered, and the solvents were removed to give **2** as an off-white solid (201 mg, ≈92%). (Found: C, 44.4; H, 3.05; N, 22.85. $C_9H_5F_6N_4O$ requires C, 44.3; H, 2.9; N, 22.95%); λ_{max} (DCM)/nm 242, 280; ν_{max} (KBr)/cm^{-1} 3250 (OH); δ_H (500 MHz; CD_2Cl_2) 1.62 (1H, br. s, OH), 4.91 (2H, s, CH_2O), 7.59 (1H, dd, J = 7.5, 4.5, LH), 7.90 (1H, dd, J = 7.5, 1.5, LH), 8.63 (1H, dd, J = 4.5, 1.5, LH) and 12.53 (1H, br. s, NH); δ_F (377 MHz; CD_2Cl_2) −65.7; *m*/*z* (ESI) 267.0466 ($M+Na^+$, 100%). $C_9H_7F_3N_4NaO$ requires 267.0464.

6.3. [2-({3-Trifluoromethyl}-1H-1,2,4-triazol-5-yl)-5-hydroxymethylpyridine]-exo-bicyclo[2.2.1]hept-5-ene-2-carboxylate **3**

Oxalyl chloride (286 μL, 3.28 mmol) and *N*,*N*-dimethylformamide (one drop, cat.) were added to a solution of *exo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid (226 mg, 1.64 mmol) in dichloromethane (2 mL) at 0 °C. After 2.5 h the volatiles were removed *in vacuo* and the resultant crude acid chloride was dissolved in pyridine (250 μL, 3.09 mmol) and dichloromethane (250 μL) at 0 °C. A solution of **2** (100 mg, 0.410 mmol) in pyridine (250 μL, 30.9 mmol) and dichloromethane (250 μL) was added and the reaction mixture was allowed to warm to room temperature over 16 h. The mixture was diluted with diethyl ether (20 mL) and water (20 mL) and then neutralised with aqueous hydrochloric acid (3 M, ≈1 mL). The layers were separated and then the organic phase was washed with water (3 × 20 mL) and brine (50 mL), dried over magnesium sulfate and filtered, and the solvents were removed. The residue was purified by chromatography over silica using ethyl acetate:diethyl ether mixtures (0:1 to 1:9) as eluent to give **3** as a light brown oil (127 mg, ≈85%). (Found: C, 56.1; H, 4.1; N, 15.3. $C_{17}H_{15}F_3N_4O_2$ requires C, 56.0; H, 4.15; N, 15.4%); λ_{max} (DCM)/nm 242, 280; ν_{max} (KBr)/cm^{-1} 1742 (C═O); δ_H (500 MHz; CD_2Cl_2) 1.36–1.44 (2H, m, NbH), 1.53 (1H, dd, J = 8.5, J = 1.5, NbH), 1.93–1.98 (1H, m, NbH), 2.27–2.35 (1H, m, NbH), 2.93 (1H, br. s, NbH), 3.09 (1H, bd, J = 9.5, NbH), 5.76 (1H, m, CH_2O), 6.11–6.18 (2H, m, NbH), 7.54 (1H, dd, J = 8, 4.5, LH), 8.01 (1H, dd, J = 8, 1.5, LH), 8.63 (1H, dd, J = 4.5, 1.5, LH) and 12.31 (1H, s, NH); δ_F (377 MHz; CD_2Cl_2) −65.6; *m*/*z* (ESI) 387.1034 ($M+Na^+$, 100%). $C_{17}H_{15}F_3N_4NaO_2$ requires 387.1039.

6.4. [Bis(2-{5-[3,5-bis(4-{2-ethylhexyloxy}phenyl)-phenyl]phenyl}pyridyl)-(2-{[3-trifluoromethyl]-1H-1,2,4-triazol-5-yl}-5-hydroxymethylpyridyl-exo-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid ester)]iridium(III) **5**

Tetra[2-(5-{3,5-bis[4-(2-ethylhexyloxy)phenyl]phenyl}phenyl)pyridyl]diiridium(III) dichloride **4** [22] (100 mg, 33.2 μmol) and **3** (42.2 mg, 116 μmol) were dissolved in dichloromethane (5 mL) and stirred for 18 h in the dark. The solvents were removed, and the residue was purified by column chromatography over Sephadex™ LH-20 with methanol:dichloromethane 1:3 as eluent and then iterative preparative thin layer chromatography over silica using dichloromethane as eluent to give **5** as a green luminescent solid (51.9 mg, ≈43%). (Found: C, 70.2; H, 6.5; N, 4.5. $C_{107}H_{118}F_3IrN_6O_6$ requires C, 70.1; H, 6.5; N, 4.6%); ν_{max} (KBr)/cm^{-1} 1735 (C═O); δ_H (500 MHz; CD_2Cl_2) 0.91–0.97 (24H, m, CH_3), 1.34–1.58 (35H, m, CH_2, NbH), 1.72–1.79 (4H, m, CH), 1.97–2.01 (1H, m, Nb), 2.37–2.40 (1H, m, NbH), 2.95 (1H, br. s, NbH), 3.12 (1H, br. s, NbH), 3.91 (8H, m, OCH_2), 6.00 (2H, m, CH_2O), 6.13–6.19 (2H, m, NbH), 6.50 (1H, d, J = 8, LH), 6.54 (1H, d, J = 8 LH), 6.98–7.03 (9H, m, spH and LH), 7.06 (1H, dd, J = 7, J = 7, LH), 7.22–7.27 (2H, m, LH), 7.32 (1H, dd, J = 8, J = 2, LH), 7.60 (1H, d, J = 5.5, LH), 7.62–7.66 (8H, m, spH), 7.67 (1H, dd, J = 1.5, J = 1.5, G1-bpH), 7.71 (1H, dd, J = 1.5, J = 1.5, G1-

bpH), 7.74 (4H, d, J = 1.5, G1-bpH), 7.76–7.79 (3H, m, LH), 7.95–7.97 (2H, m, LH), 8.03–8.06 (3H, m, LH) and 8.09 (1H, d, J = 8.5, LH); δ_F (377 MHz; CD_2Cl_2) −63.6; m/z (MALDI-TOF) 1830.9 (39%), 1831.9 (55%), 1832.9 (100%), 1833.9 (95%), 1834.9 (54%), 1835.9 (20%) and 1836.9 (8%) ($M^{+\cdot}$). $C_{107}H_{118}F_3IrN_6O_6$ requires 1830.9 (42%), 1831.9 (50%), 1832.9 (100%), 1833.9 (96%), 1834.9 (54%), 1835.9 (21%) and 1836.9 (6%).

6.5. [Bis(2-{5-[3,5-bis(4-{2-ethylhexyloxy}phenyl)-phenyl]phenyl}pyridyl)-(2-{[3-trifluoromethyl]-1H-1,2,4-triazol-5-yl}-5-hydroxymethylpyridyl-exo-bicyclo[2.2.1]heptane-2-carboxylic acid ester)]iridium(III) **6**

Palladium on carbon (10%, 1 mg) was added to a solution of **5** (10 mg, 5.5 μmol) in ethyl acetate (1.0 mL). The reaction mixture was deoxygenated with three pump/fill (argon) cycles, and placed under an atmosphere of hydrogen with three pump/fill (hydrogen) cycles before being stirred for 3.5 h. The suspension was then filtered through Celite® and the solvents were removed to give **6** as a green luminescent yellow solid (10.6 mg, 100%). (Found: C, 69.9; H, 6.5; N, 4.4. $C_{107}H_{120}F_3IrN_6O_6$ requires C, 70.0; H, 6.6; N, 4.6%); ν_{max} (KBr)/cm^{-1} 1735 (C=O); δ_H (500 MHz; CD_2Cl_2) 0.90–0.97 (24H, m, CH_3), 1.18–1.60 (39H, m, CH_2, NbH), 1.72–1.79 (4H, m, CH), 1.86–1.92 (1H, m, NbH), 2.35 (1H, br. m, NbH), 2.47–2.50 (1H, m, NbH), 2.57 (1H, br. m, NbH), 3.91 (8H, m, OCH_2), 5.96 (2H, m, CH_2O), 6.50 (1H, d, J = 8, LH), 6.54 (1H, d, J = 7.5 LH), 6.98–7.02 (9H, m, spH and LH), 7.06 (1H, m, LH), 7.22–7.26 (2H, m, LH), 7.31 (1H, dd, J = 8, J = 2, LH), 7.60 (1H, br. d, J = 5.5, LH), 7.62–7.66 (8H, m, spH), 7.69 (1H, dd, J = 1.5, J = 1.5, G1-bpH), 7.70 (1H, dd, J = 1.5, J = 1.5, G1-bpH), 7.73 (4H, d, J = 1.5, G1-bpH), 7.75–7.80 (3H, m, LH), 7.93–7.96 (2H, m, LH), 8.03–8.06 (3H, m, LH) and 8.09 (1H, d, J = 8, LH); δ_F (377 MHz; CD_2Cl_2) −63.6; m/z (MALDI-TOF) 1832.8 (52%), 1833.8 (55%), 1834.8 (100%), 1835.8 (98%), 1836.8 (53%), 1837.8 (25%) and 1838 (5%) ($M^{+\cdot}$). $C_{107}H_{120}F_3IrN_6O_6$ requires 1832.9 (42%), 1833.9 (50%), 1834.9 (100%), 1835.9 (96%), 1836.9 (54%), 1837.9 (21%) and 1838.9 (6%).

6.6. Poly[(bis{2-[5-(3,5-bis{4-[2-ethylhexyloxy]phenyl}phenyl) phenyl]pyridyl}-(2-{3-trifluoromethyl-1H-1,2,4-triazol-5-yl}-5-hydroxymethylpyridyl]iridium(III))-1,4-vinylcyclopentane-2-carboxylic acid ester] **7**

Using standard Schlenk techniques, a solution of Grubbs (III) catalyst [26] in dichloromethane (1.0 mg/ml, 800 μL, 0.90 μmol) was added to a vigorously stirred solution of **6** (81 mg, 44 μmol) in dichloromethane (3.2 mL). Ethyl vinyl ether (three drops, excess) was added after 16 h. After a further 5 min the solvents were removed. The resultant crude material was then purified by iterative column chromatography over Sephadex™ LH-20 (four iterations) with methanol:dichloromethane 1:3 as eluent to remove remaining initiator and monomer, giving **7** as a green luminescent solid (58.5 mg, 72%). ν_{max} (KBr)/cm^{-1} 1735 (C=O); δ_H (400 MHz; CD_2Cl_2) 0.80–1.00 (24H, br. m, CH_3), 1.20–1.80 (35H, br. m, CH_2, CH, NbH), 1.82–2.32 (1H, br. m, NbH), 2.56–2.77 (1H, br. m, NbH), 2.91–3.47 (1H, br. m, NbH), 3.68–3.95 (8H, br. m, OCH_2), 5.10–5.46 (2H, br. m, alkene-H), 5.72–6.20 (2H, br. m, CH_2O), 6.37–6.54 (2H, br. s, LH), 6.72–7.29 (13H, br. m, spH and LH), 7.03–7.77 (18H, br. d, G1-bpH, spH, LH) and 7.79–8.07 (6H, br. s, LH); δ_F (377 MHz; CD_2Cl_2) −63.4; m/z (MALDI-TOF; DCTB) M_p = 171 kDa; GPC $\overline{M}_w = 5.5 \times 10^4$, $\overline{M}_n = 2.5 \times 10^4$, PDI = 2.2.

zinc oxide has been successfully used in hybrid solar cells [3] and bilayers of the thermally evaporated pentacene on ZnO have been investigated [4], the advantages of ZnO-polymer hybrids for ambipolar field effect transistors have not been explored yet.

In this work we used sol–gel processed ZnO nanoparticles with various Al doping levels, as the n-type semiconductor, and regioregular poly(3-hexylthiophene) (P3HT), as the p-type component, to fabricate field effect transistors (FETs) with gold source and drain contacts on a SiO_2 dielectric. Our previous work [5] evinced, *interalia*, that doping has a strong effect on the structural and electrical properties of sol–gel processed sintered ZnO:Al. The electron mobility is slightly decreasing due to structural, morphological, and ionic defects.

For the fabrication of the hybrid system presented in this paper, it was necessary to omit the sintering step for the Al doped ZnO in order to allow intrusion of P3HT into the ZnO-matrix. We show that by doping the zinc oxide nanoparticles as well as by morphological changes in the blend it is possible to adjust a balanced electron and hole mobility in the hybrid material, which is indispensable for a good performance of an ambipolar transistor. The presented data will be discussed in terms of the charge transport mechanisms in field effect transistors together with their morphology of the thin films which was monitored via X-ray reflectivity (XRR) measurements.

2. Experimental

2.1. Materials and synthesis

The synthesis of Al doped ZnO was performed according to the route introduced by Xue et al. [6]. 2-methoxyethanole (MTE), monoethanolamine (MEA), zincacetate dihydrate (ZAD) and aluminiumnitrate nonahydrate (ANN) were purchased from Sigma–Aldrich. The stabilizer MEA (2.1 ml) were dissolved in 100 ml of the solvent MTE to lead to a 0.35 M solution. The starting material ZAD (35 mmol) was added. Depending on the designated doping level ANN was admixed to the solution to achieve up to 10 at.% Al doping. The solution was stirred for 2 h. at 60 °C and subsequently aged for at least one day.

Regioregular poly(3-hexylthiophene) (P3HT) was purchased from Rieke Metals and used without further purification. P3HT was dissolved in chlorobenzene at 0.1 wt%.

2.2. Sample preparation and measurement

The field effect transistor structures were prepared on Sb-doped silicon wafers purchased at Si–Mat. The highly *n*-doped Si(001) with a nominal resistivity of about 0.02 Ωm serves as the gate electrode. The top layer of the wafer consists of 200 nm thermally grown SiO_2 which forms the dielectric. Photolithography was used to get well defined source–drain structures. Ti (1 nm) as an adhesion layer and subsequently 19 nm thick Au contacts were thermally evaporated on top of the dielectric. After cleaning the substrate with acetone and isopropanol, the ZnO solution with various Al doping level was spin coated for one minute at 3000 rpm. Thereafter, the substrate was heated to 300 °C in an oven in ambient atmosphere for 100 min in order to remove MEA. Then the samples were transferred to a glovebox where the P3HT solution was spin coated. Finally, the samples were slowly dried for 15 h. The electronic reproducibility of FETs was confirmed for several samples. The relative error was smaller than 5% and 10%, for the bare ZnO:Al and ZnO:Al/P3HT-transistors, respectively. The estimates for the conductivity and the charge carrier density show relative errors of about 20%.

The current–voltage measurements were carried-out using an Agilent Parameter Analyzer 4155C. The room temperature measurements were performed in nitrogen atmosphere before and after the infiltration of P3HT. In either transistor measurement we chose channel lengths of 160 μm, so that the channel resistance dominates the contact resistance and, hence, minimizes the influence of the contact on the measured transport parameters [7].

The X-ray reflectivity measurements were carried-out using a Diffractometer General Electrics 3003 T–T in Bragg–Brentano geometry. The X-ray measurement provides a non-destructive way of probing the layer thickness, interface roughness and the electron density of single and multi layers. For XRR, the sample is being illuminated with Cu Kα radiation at the characteristic wavelength of $\lambda = 1.5406$ Å. Typically, the reflected intensity is being plotted vs. the wave vector transfer q_z perpendicular to the surface. q_z and θ are related via $q_z = 4\pi/\lambda \sin\theta$. From $\theta = 0^\circ$ up to a critical angle θ_c, total reflection dominates, as radiation can penetrate the layer only evanescently. By the relation $\theta \sim \sqrt{\rho}$, θ_c is a measure for the electron density ρ and hence, a measure for the effective material density. The intermixing of the two phases can be determined from the attenuation of the corresponding Kiessig fringes.

3. Results

3.1. Field effect transistor measurements

The hybrid FETs were built upon a device structure using a SiO_2 dielectric and Au source and drain bottom contacts in two steps, first spin coating and heating the inorganic component, subsequently deposition of the organic component. This approach resulted in Ohmic–like contacts for electron and hole injection. The electrical parameters of the devices were investigated before and after the deposition of P3HT.

In a field effect transistor charge carriers are accumulated via a source–gate voltage V_g where the hole or electron accumulation are determined by the sign of V_g, corrected for the threshold voltage V_{th}. This provides a way to selectively determine the electron and hole mobility at various carrier densities from the transfer characteristics in the linear and saturation regime, μ_{lin} and μ_{sat}, respectively, via

$$\mu_{lin} = \frac{L}{wC_iV_d}\frac{\partial I_d}{\partial V_g} \quad \text{and} \quad \mu_{sat} = \frac{2L}{wC_i}\left(\frac{\partial\sqrt{I_d}}{\partial V_g}\right)^2, \tag{1}$$

where L and w are the channel length and width, C_i is the dielectric capacitance per unit area, I_d is the current between source and drain and V_d is the source–drain field.

An output characteristic of a transistor with unsintered 2 at.% Al doped ZnO as an active layer is shown in Fig. 1. The gate and the drain voltage, respectively, have been switched between 0 and 70 V. The output characteristic exhibits Ohmic behaviour in the linear regime, indicating efficient injection from the gold contact into the conduction band of ZnO:Al and saturation at high drain voltages. The pinch-off voltage increases quadratically with the applied gate voltage. The threshold voltage V_{th} (see Fig. 2) has been extracted from the transfer characteristic in the saturation regime. V_{th} is a measure for trapped charges in the material and at the ZnO:Al/dielectric interface and also for free charge carriers intrinsically present in the channel. It has to be noted that additional charge carriers introduced via Al doping will compensate these electron traps. The threshold voltage of ZnO:Al transistors varies between 5.5 V for the 0.8 at.% Al doped transistor and 25 V for the 5 at.% doping (see Fig. 2a).

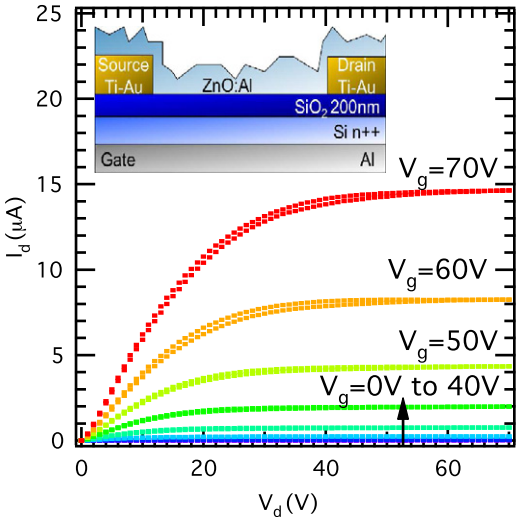

Fig. 1. ZnO:Al (2 at.%) output characteristic. Transistor details: Au bottom contacts $L = 160$ μm, $w = 62.4$ mm, SiO_2 thickness $d = 200$ nm. The inset shows a schematic drawing of the device.

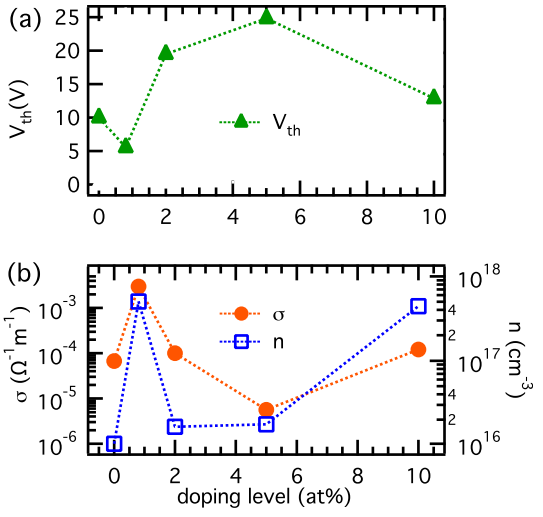

Fig. 2. Bare ZnO:Al: (a) Threshold voltage for electron transport in the saturation regime. (b) Estimated conductivity and free charge carrier density. As indicated, there is a defined correlation between V_{th} and n.

In order to investigate the electrical properties of ZnO:Al, we estimated the conductivity σ in ZnO:Al from the linear regime (low V_d) at $V_g = 0$ V using $I_d = jwd_{Au} = \sigma V_d / L \cdot wd_{Au}$, where d_{Au} is the thickness of the gold contact, $w \cdot d_{Au}$ is the area of the injecting contact (see Fig. 2b). We observe a maximum in the estimated effective conductivity of $3 \cdot 10^{-3} \Omega^{-1}$ m^{-1} for the 0.8 at.% Al doped ZnO layer, as expected for ZnO:Al [5]: Doping presumably leads to higher charge carrier densities but also leads to additional scattering centers. With $\sigma = \mu ne$, where μ is the mobility at low gate and drain voltages and e is the elementary charge, we are able to provide a rough estimate of the charge carrier density n. The charge carrier density varies

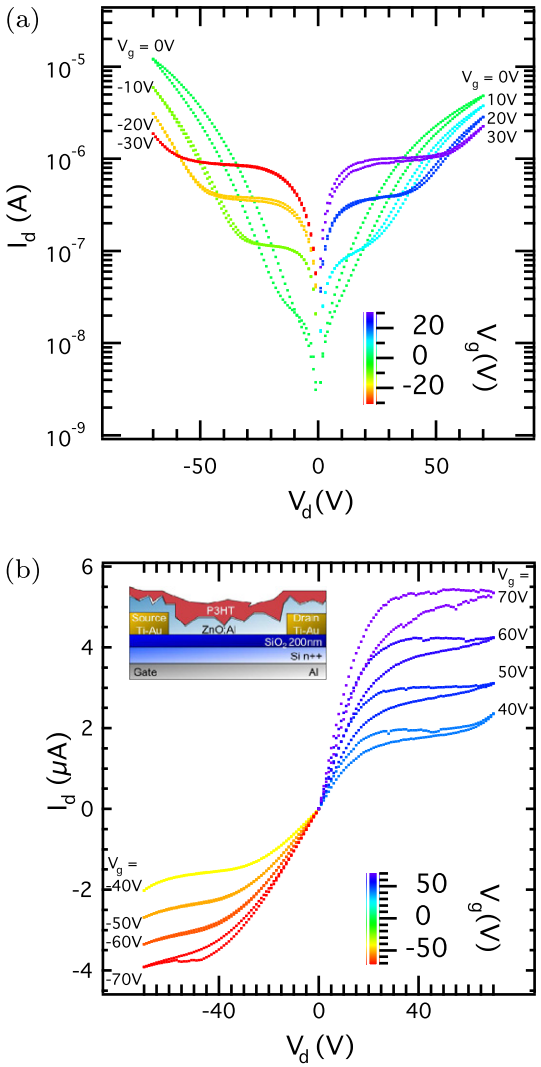

Fig. 3. ZnO:Al (2 at.%)/P3HT-transistor: output characteristic; V_g is indicated by the color scale and by the legend. Shown is the same device as in Fig 1 but with additional P3HT hole transport layer: (a) from $V_g = -30$ to 30 V, (b) from $V_g = -70$ to -40 V and from 40 to 70 V. The inset shows a schematic drawing of the device.

between $1 \cdot 10^{16}$ cm^{-3} in the nominally undoped case and $5 \cdot 10^{17}$ cm^{-3} for the 0.8 at.% Al doped layer. Additionally, we observe a relatively high charge carrier density for the highest doping level of 10 at.%. The threshold voltage V_{th} reflects the density of free charge carriers, i.e. the high n value for 0.8 at.% Al doping corresponds to a low V_{th} of 5.5 V.

3.1.1. Hybrid ZnO:Al/P3HT-transistor

After the characterization of the field effect transistors with bare ZnO:Al at several doping levels, the electronic behaviour of transistors with ZnO:Al/P3HT layers were analyzed. An output characteristic of the 2 at.% Al doped ZnO/P3HT-transistor is shown in Fig. 3. At high V_d and low V_g both, electrons and holes can be injected into the channel and form a pn-junction which leads to a diode-like behaviour. Applying high negative (positive) V_g and low V_d depletes the electrons (holes) from the channel and the device behaves as an unipolar hole (electron) accumulating transistor. Furthermore, the unipolar regime in both, hole and electron accumulation regions, shows Ohmic behaviour at low V_d. It has to be noted that we reached this Ohmic behaviour using gold for electron and hole injection and no additional modification of the dielectric was applied, making the device architecture straightforward and simple to prepare. Comparing the output characteristic of the bare ZnO:Al (2 at.%) FET (see Fig. 1) to the device, where P3HT had been coated, we observe only a slight decrease in the maximum drain current. Also, in the electron accumulation regime, an enhanced hystereses can be observed, which indicates additional trap states. We note that with Au contacts no hole accumulation could be observed in bare ZnO:Al.

The transfer characteristics of the P3HT/ZnO:Al transistors at various doping level in saturation at $|V_d| = 40$ V are shown in Fig. 4a–e. The undoped system exhibits unipolar behaviour for electrons. Similar values for the current at high positive V_g can be observed at negative V_d and low gate voltages although hole accumulation occurs only below $V_g = -50$ V. We attribute the high current at $V_g = 0$ V and $V_d = -40$ V to an enhanced efficiency of electron *and* hole injection upon applying a negative bias. The

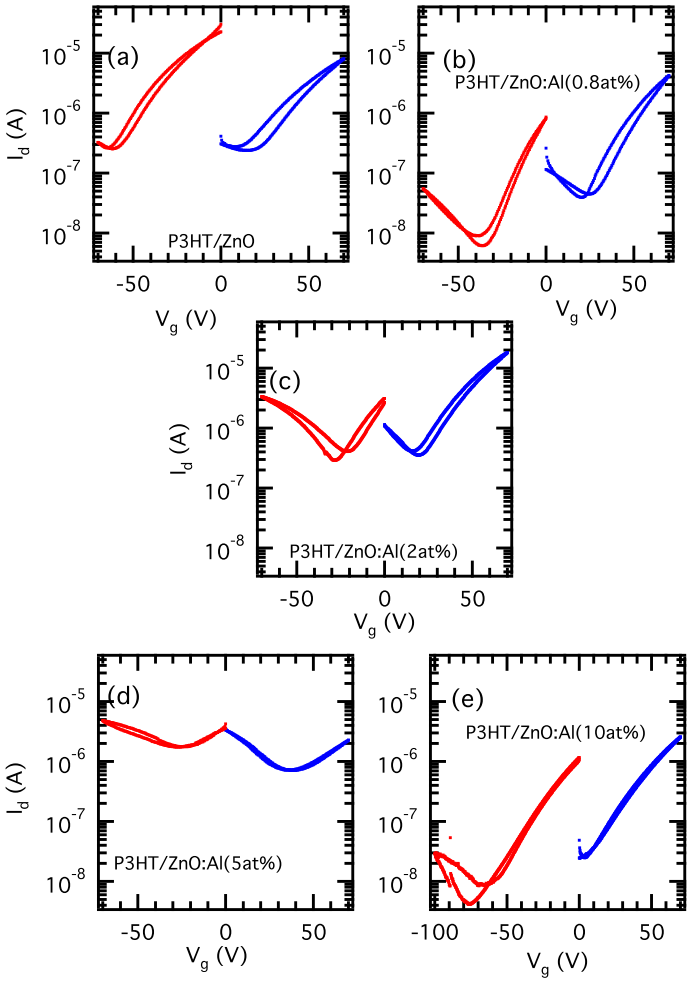

Fig. 4. ZnO:Al/P3HT-transistor: (a)–(e) transfer characteristics in saturation regime at $|V_d| = 40$ V for hole (red line) and electron (blue line) accumulation. Forward and backward direction show little charging effects. V_g ranges from −70 to +70 V, except for the 10 at% system (e). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

difference between the drain current at $V_g = 0$ V at positive and negative V_d is directly correlated to the difference in the hole and electron mobility, which will be discussed in the following. Almost symmetric behaviour can be observed for the 2 at.% doped system. The transfer characteristics of the 5 at.% doped ZnO/P3HT has the drawback of a small on/off ratio. For 10 at.% doping, the onset of hole accumulation occurs at negative voltages higher than $|V_g| = 70$ V.

Fig. 5a shows the threshold voltage V_{th} *vs.* doping level for electrons ($V_{th,n}$, closed symbols) and holes ($V_{th,p}$, open symbols) for the saturation regime. Whereas V_{th} for the electron operating mode increases from around 0 V in the undoped case to 17.5 V and stays nearly constant for higher doping levels, we observe large fluctuations of values for the threshold voltage of holes between +23.6 and −50.9 V.

The electron mobility, μ_e, at $|V_g - V_{th}| = 40$ V and $|V_d| = 40$ V is shown in Fig. 5b. μ_e decreases over one order of magnitude from $3.2 \cdot 10^{-3}$ cm^2 V^{-1} s^{-1} for the undoped system to $6.5 \cdot 10^{-5}$ cm^2 V^{-1} s^{-1} at an Al concentration of 10 at.%. This behaviour is attributed to additional defects of structural, ionic and/or electronic origin introduced via doping [5]. Obviously, the infiltration of P3HT does not significantly affect the electron mobility, μ_e in the hybrid system decreases from $2 \cdot 10^{-3}$ cm^2 V^{-1} s^{-1} to $2 \cdot 10^{-4}$ cm^2 V^{-1} s^{-1}.

The hole mobility (see Fig. 5b) in the hybrid system, without Al doping and at a doping level of 0.8 at.%, is about two orders of magnitude lower than the hole mobility observed in bare P3HT transistors (not shown). Al (2 at.%) doping of ZnO induces an increase of the hole mobility of more than one order of magnitude to $5 \cdot 10^{-4}$ cm^2 V^{-1} s^{-1}.

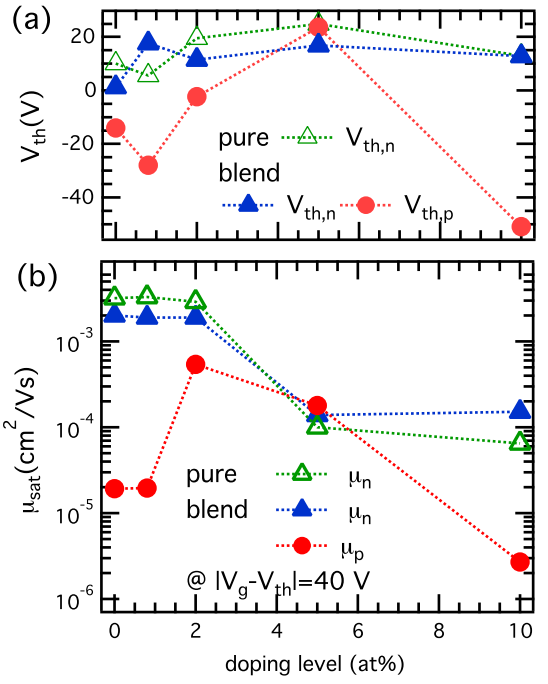

Fig. 5. ZnO:Al/P3HT-transistor: (a) threshold voltage $V_{th,n}$ for electrons and $V_{th,p}$ for holes at various doping levels. $V_{th,n}$ for bare ZnO:Al has been included for comparability, same as in Fig. 2. (b) Saturation mobility derived from the transfer characteristics; green triangles: electron mobility in bare ZnO:Al as reference, blue full triangles and red circles: electron and hole mobility in ZnO:Al/P3HT, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

In the case of hole accumulation, ZnO:Al can be assumed to be an additional dielectric. The accumulated charge per unit area Q depends on the thickness of the dielectric

$$Q = \epsilon\epsilon_0/d \cdot (V_g - V_{th}), \tag{2}$$

where ϵ and ϵ_0 are the relative and absolute permittivity of the dielectric and d is the thickness of the dielectric. Note that the calculated hole mobilities refer to a 200 nm SiO_2 dielectric solely. The assumption of a constant capacitance was verified experimentally. Capacitance measurements on Si n^{++}/SiO_2(200 nm)/ZnO:Al/Au, i.e. treating SiO_2 and ZnO:Al as two series capacitors did not reveal significant changes with respect to the bare SiO_2 dielectric. This result is plausible since the smallest capacitance, here that of SiO_2, determines the total serial capacitance.

Evidently, the undoped and the 0.8 at.% Al doped ZnO/P3HT hybrid transistors do not exhibit balanced electron and hole mobilities. μ_e and μ_p differ by two orders of magnitude. In the case of 2 at.% Al doping we observe a hole mobility of $5 \cdot 10^{-4}$ cm^2 V^{-1} s^{-1} and the value differs by only a factor of five from μ_e at the same doping level. For a doping levels of 5 at.% we indeed obtain balanced mobilities and aside from that, a decrease of the electron mobility. The highest Al doping level of 10 at.% leads to a strong decrease in μ_p and a large difference between μ_p and μ_e.

3.2. Interface morphology

The dependence of the P3HT hole mobility on the Al doping level of ZnO cannot be understood merely from the data of the electrical measurements. The relation between μ_p and doping level could have several reasons:

(i) the crystallinity of P3HT,
(ii) the interface condition of ZnO and the related ability to infiltrate P3HT,
(iii) the dielectric properties at the interface
(iv) defects or charged traps at the organic/inorganic interfaces generated by doping.

Obviously, in any of the four cases the interface morphology is of essential relevance for the density of free holes in the FET channel.

3.2.1. X-ray reflectivity

The intermixing of both semiconductor phases at the interface can be quantified via X-ray reflectivity measurements: XRR is sensitive to the electron density of the materials which differs by one order of magnitude for P3HT and undoped/Al doped ZnO. XRR has the unique advantage over, e.g. AFM, that buried interfaces can be probed on the complete sample.

The XRR measurements of ZnO/P3HT for different Al doping levels are shown in Fig. 6. The XRR measurements were carried-out on SiO_2 and additionally on sapphire

substrates. The qualitative intensity behaviour was highly reproducible. All data are from one series on SiO_2.

Four of the five hybrid structures clearly indicate Kiessig fringes. The most pronounced fringes can be detected for the 5 and 10 at.% Al doped compounds: one can distinguish between two different oscillations hinting at the two layers, P3HT and nc-ZnO:Al, respectively, and a surprisingly small roughness at their interface. The spectra of the undoped and 0.8 at.% Al doped samples comprise fringes, as well. The spectrum of the 2 at.% Al doped ZnO/P3HT does not show pronounced interference features indicating a high level of interpenetration of the organic and the inorganic component accompanied by a high effective interface roughness.

To obtain quantitative information about the thickness of P3HT and ZnO and about the interface roughness it is essential to perform simulations and fitting of the experimental data. This allows a direct determination of the interface roughness related to the infiltration of P3HT. The theoretical reflectivity was calculated by an optical matrix method, with a refinement procedure minimizing the difference between the calculated and the measured XRR curve: the program MOTOFIT [8] based on the Paratt formalism[9]. The optimization of the parameters was done by minimizing the chi square in logarithmic form. Here, χ^2 values around 5% could be obtained The real part of the scattering length density (SLD) which is directly related to the mass density and the atomic number ranges between $30.0 \cdot 10^{-5}$ and $35.5 \cdot 10^{-5}$ Å^{-2} for ZnO and between $3.0 \cdot 10^{-5}$ and $9.3 \cdot 10^{-5}$ Å^{-2} for P3HT. The layer thickness of ZnO:Al ranges between 12 and 23 nm, for P3HT between 19 and 26 nm. The extracted data including the electron density, derived from $\rho = \mathrm{SLD}/r_e$, with r_e the classical electron radius, are shown in Table 1.

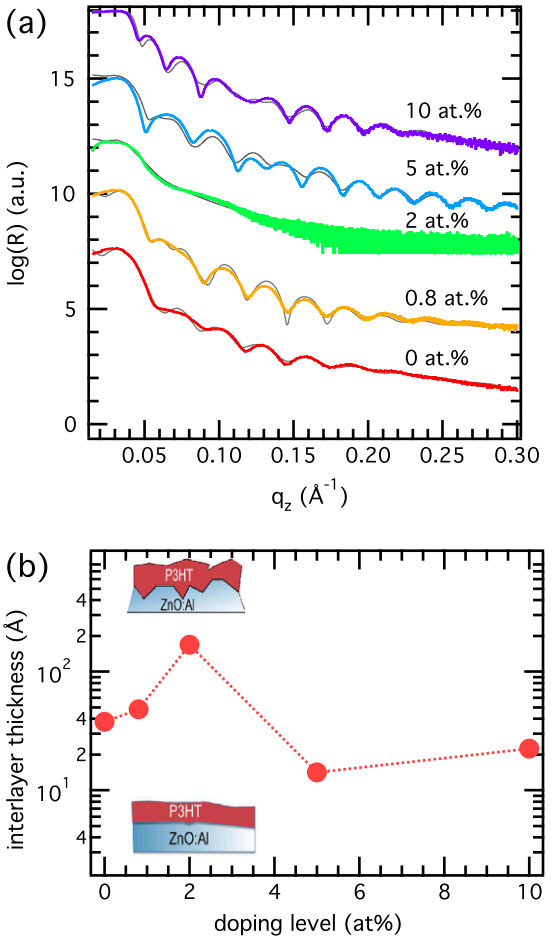

Fig. 6. (a) X-ray reflectivity curve of nc-ZnO:Al/P3HT at various Al doping levels as indicated by the legend. Grey lines are corresponding to fits based on the Paratt formalism. The profiles have been offset for clarity. (b) ZnO:Al/P3HT effective layer thickness of intermixing as derived from XRR spectra. A schematical drawing of intermixing is provided by the insets: upper drawing, high level of intermixing; lower drawing, low level of intermixing.

Table 1
Electron density ρ, thickness d and *rms* roughness r of the ZnO:Al layer resulting from fits of the XRR spectra shown in Fig. 6.

	0 (at.%)	0.8 (at.%)	2 (at.%)	5 (at.%)	10 (at.%)
$\rho_{\mathrm{ZnO:Al}}$ (e$^-$ Å^{-3})	1.1	1.1	1.3	1.1	1.2
ρ_{P3HT} (e$^-$ Å^{-3})	0.1	0.2	0.1	0.2	0.3
$\rho_{\mathrm{interlayer}}$ (e$^-$ Å^{-3})	0.1	0.4	0.2	0.9	1.0
$d_{\mathrm{ZnO:Al}}$ (nm)	15	16	12	17	23
d_{P3HT} (nm)	20	19	23	26	25
$d_{\mathrm{interlayer}}$ (nm)	4	5	19	1	2
$r_{\mathrm{ZnO:Al}}$ (nm)	2	1	1	0	1

The fits based on the Paratt formalism are shown in Fig 6a. In order to obtain appropriate fits, it was necessary to assume intermixing of the P3HT and the ZnO:Al phases. A thin intermixing layer between 1 and 5 nm is estimated for 0, 0.8, 5 and 10 at.% Al doping and a very high value of 18.6 nm for 2 at.% as shown in Fig. 6b.

4. Discussion

Al doping of ZnO results in modifications of the electron transport, which will be discussed first. Remarkably it also influences the hole mobility of the subsequently applied P3HT. The reasons for the latter will be discussed in the second part of this section.

The mobility of the inorganic ZnO decreases over an order of magnitude with increasing Al doping and it remains nearly unaffected by the infiltration of P3HT. Unlike in the sintered system [5], we observe two mobility plateaus (see Fig. 5). The mobility stays at a nearly constant level at $2\text{–}3 \cdot 10^{-3}$ cm^2 V^{-1} s^{-1} for the undoped, the 0.8 and the 2 at.% Al doped ZnO. Also no significant change could be observed for 5–10 at.% Al doping. We attribute this effect mainly to scattering of electrons: we assume, the transport in unsintered ZnO:Al is preferentially limited by charge carrier scattering effects due to the low level of crystallinity in the material, additional defects due to doping do not have a drastic effect on the mobility. It is worth mentioning, that the investigated layers are X-ray amorphous. The values for σ and the corresponding charge carrier density n of around 10^{-4} Ω^{-1} m^{-1} and 10^{17} cm^{-3} are rather low for ZnO:Al due to the omitted sintering step and, therefore, the low level of crystallinity. Also, errors due to the contact resistance can not be neglected. However, we expect this

effect to be small due to the long channel length, i.e. the transport within the semiconductor limits the current between source and drain.

The hole mobility was found to depend on the Al doping level of ZnO. The origin of this behaviour will be discussed in the following:

(i) We assume the hole transport to occur solely in P3HT, e.g. we modify the surface conditions of the undoped and doped zinc oxide layer and observe the influence on the morphology of the polymer. The hole mobility, again, is influenced by the morphology of P3HT, i.e. determined by the order of π–π-stacking and also by the orientation to the substrate because of the anisotropy of charge transport [10], and by the nanostructure of infiltration. Absorption spectra (not shown, refer to appendix) revealed interchain absorption and a similar vibronic structure and therefor a similar degree of short range order of the polymer chains on top of the variously Al doped ZnO. We note that optical absorption is a bulk sensitive technique, while the FET mobility is an interface property. However, in case of very thin layers and of layers with crystalline fraction induced by the underlying surface, the optical absorption spectra yields to (indirect) information on the interface topography.

(ii) The porosity of ZnO determines the ability to infiltrate P3HT. The hole mobility sensitively depends on the roughness of the Al doped ZnO layer. XRR spectra exhibit a strong interconnection of the organic/inorganic interface layer and the doping level. The sample with 2 at.% Al doping shows a high level of intermixing, i.e. a value of around 18.6 nm (see Fig. 6) and also the highest hole mobility (see Fig. 5) in the set of doping levels. The effective thickness of the dielectric alone can not explain the origin of the hole mobility dependence on the doping level of ZnO. Nevertheless, the highest roughness value coincides with the highest hole mobility value.

(iii) The polarizability of the dielectric, i.e. ZnO:Al in the case of hole accumulation, influences the mobility of holes accumulated at the organic/inorganic interface. Fröhlich polarons, reported for organic single crystals with different dielectrics by Hulea et al. [11], where the mobility depends on the value of the dielectric constant of the oxide, cannot describe μ_p vs. doping level, due to the necessity of a largely varying dielectric constant with doping level. A $\mu \sim 1/\epsilon$ behaviour was found. A change in ϵ of almost two orders of magnitude would be mandatory in our case, e.g. from 8 to 0.08. In the case of ZnO, we can estimate a change in ϵ from $\sim$8 to $\sim$11 [12], if Al_2O_3 is present in a high percentage at the interface at high Al doping levels. Hence, Fröhlich polarons can be excluded from having a significant influence on the dependence of the hole mobility on the Al doping level. On the other hand, the mobility in disordered organic FETs was found to be diminished due to the systematic broadening of the Gaussian density of states with dipolar disorder at the semiconductor/dielectric interface due to the value of ϵ [13]. This scenario can also be excluded from having a drastic influence.

(iv) Defects or charged traps at the organic/inorganic interfaces generated by doping can positively or negatively influence the accumulated density of free holes. In order to reach ambipolar behaviour, a balanced intrinsic carrier density of both types of charge carriers is mandatory [4]. If, e.g. the density of free electrons outbalances that of the holes, a higher negative gate voltage is needed in order achieve hole accumulation. The threshold voltage for electron transport in bare ZnO:Al transistors has been investigated (Fig. 2a). It ranges between 15.5 and 33.4 V for the undoped and the 0.8 at.% Al doped ZnO and for the 5 at.% doped system, respectively, and reflects the doping dependence of n. The threshold voltage for holes (Fig. 5), which qualitatively indicates the density of trap states, nearly parallels the hole mobility. The trap scenario is affirmed by the fact that a low threshold voltage for electrons results in a high V_{th} for holes after application of P3HT. The free electron density n reaches a maximum in the 0.8 at.% and also in the 10 at.% Al doped samples. In both cases we observe low hole mobilities, namely $2.0 \cdot 10^{-5}$ cm^2 Vs^{-1} and $2.7 \cdot 10^{-6}$ cm^2 Vs^{-1}. A lower mobility value for the highest doping level is attributed to additional traps. The lowest charge carrier density was estimated to be $1.0 \cdot 10^{16}$ cm^{-3} and was observed for undoped ZnO, although 2 at.% Al doping with $1.6 \cdot 10^{16}$ cm^{-3} and 5 at.% with $1.8 \cdot 10^{16}$ cm^{-3} do not show a significant difference. If only the free electron density was responsible for the hole mobility dependence on the doping level of ZnO, the highest hole mobility should be observed in three cases: the undoped, the 2 and 5 at.% Al doped system. This is clearly not the case.

Here, an interplay of different parameters, mainly the P3HT/ZnO:Al intermixing (ii) and the free electron density in ZnO:Al (iv), causes the maximum hole mobility at 2 at.% Al doping. Interestingly, a minimum in σ, i.e., minimum in $\mu \cdot n$ can be found for the 5 at.% Al doped sample, where we indeed observe balanced electron and hole mobilities after application of P3HT. Nevertheless, the highest hole mobility was observed for 2 at.% Al doping. The Debye screening length in ZnO:Al at 0, 2, and 5 at .% Al doping, i.e. at the moderate electron densities of about 10^{16} cm^{-3}, amounts to $\sim$20 nm. This extends over the ZnO:Al thickness and hence, the free electrons will be depleted to the P3HT/ZnO:Al interface. In the case of the 2 at.% Al doped sample, where we observe the highest degree of intermixing, we expect local field enhancement at the P3HT/oxide interface and therefore better injection and accumulation of holes.

5. Conclusion

We were able to demonstrate ambipolar charge transport in a hybrid organic/inorganic transistor consisting of the polymer P3HT and the sol–gel synthesized undoped

and Al doped ZnO. We observe the influence of doping of ZnO on its electron mobility and also on the hole mobility in P3HT. The maximum for the conductivity in unsintered ZnO has been reached for 0.8 at.% Al doping and also various Al doping levels strongly affect the density of free electrons. The electron mobility decreases with increasing doping level and stays nearly unaffected by the infiltration of the organic component. Remarkably, the hole mobility has been found to be dependent on the Al doping level of ZnO. The hole mobility reaches its maximum at the doping level of 2 at.%. By discussing several possibilities, we attribute this effect to an enhanced intermixing of ZnO:Al and P3HT, derived via X-ray reflectivity data, which is necessary for the infiltration of P3HT and to the charge carrier density variation with Al contents. To summarize, the intrinsically free electrons and the morphology, i.e. intermixing, can be controlled via Al doping of ZnO and, hence, a balanced electron and hole mobility can be adjusted in P3HT/ZnO:Al hybrids. This is the fundamental precondition for the implementation of hybrid field effect transistors in organic electronics.

Additionally to the data presented in Figs. 2 and 4 we present here the data in the linear regime for clarity. See Figs. A.7 and A.8.

Appendix B. Absorption

The absorption spectra of the material system on sapphire were recorded using a PerkinElmer Lambda950. We investigated absorption spectra in order to monitor the interchain orientation relative to the next neighbors of the infiltrated P3HT and to clarify the effect of doping on the absorption edge of ZnO:Al. The absorption spectra are shown in Fig. B.9. We observe absorption by ZnO in the UV region at wavelength lower than 380 nm, in good agreement with literature [14]. Using $(\alpha h\nu)^2 = A(h\nu - E_g)$ [15], where A is a function of the refractive index of the material, the reduced mass and the speed of light in vacuum, h is the Plancks constant, ν is the frequency of the radiation and E_g is the energy band gap. From a plot of $(\alpha h\nu)^2$ versus the photon energy an optical band gap was obtained by applying a linear fit and an extrapolation of E_g to $(\alpha h\nu)^2 = 0\ \mathrm{eVm}^{-1}$. The undoped material exhibits an optical band gap of 3.26 eV (ca. 381 nm) and a shift of 100 meV to higher energies for the highest Al doping level was observed.

The polymer P3HT absorbs in the visible between ~1.9 and ~3 eV. It has been reported that enhanced ordering of

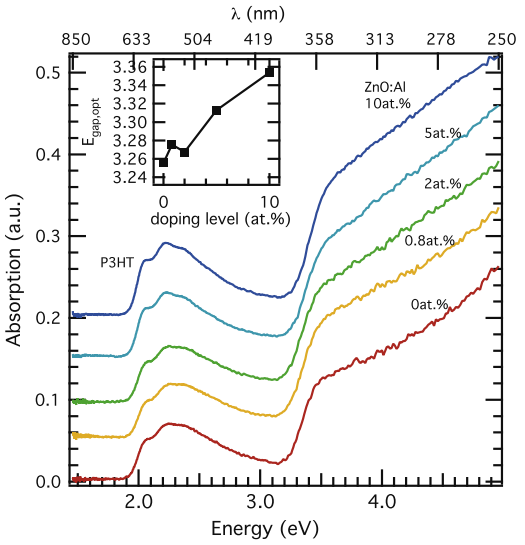

Fig. B.9. nc-ZnO:Al/P3HT absorption.

this polymer gives rise to an increased absorption at ~2.09 eV [16,17]. The absorption spectra in Fig. B.9 indicate high ordering of P3HT for all doping levels.

are bilayers of metal–metal oxide, organic–metal oxide, or organic–organic heterojunctions [1–17]. Among them, WO_3 has drawn much attention in the intermediate connectors because of its high work function (>6.0 eV) and optical transparency [19,20]. For example, tandem structures with a WO_3-based intermediate connector have been used to achieve high-efficiency OLEDs, [21,22] or organic photovoltaic cells [23]. Another advantage for using WO_3 in an intermediate connector is its operational stability compared to the p-type doped organic HTL, because the latter might cause a significant increase in the driving voltage during long-time operation [6].

Despite the extensive use of WO_3 in intermediate connectors of tandem OLEDs, its working mechanism for charge carrier generation and injection process is not yet clearly understood at the film interface level. In particular, the elucidation of the interfacial electronic structures of WO_3-based intermediate connectors is highly desirable and advantageous for interface engineering and optimization of tandem organic devices. In this work, we study the electronic structures and energy level alignment of WO_3-based intermediate connectors, consisting of an n-type organic layer, a WO_3 interlayer, and an organic HTL, by using ultraviolet and X-ray photoemission spectroscopies (UPS and XPS). Here, the n-type layer is formed by using Mg (10 vol.%) doped tris-(8-hydroxyquinoline) aluminum (Mg:Alq_3), and *N*,*N*′-bis(1-naphthyl)-*N*,*N*′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB) is used as the HTL of the adjacent EL unit. Furthermore, we investigate the impacts of the constituent materials on the functional effectiveness of a WO_3-based intermediate connector with the aim of providing insight on the design of effective connectors in tandem organic devices. For comparison, four systems, including (1) NPB/WO_3/Mg:Alq_3, (2) NPB/WO_3/Alq_3, (3) NPB/Mg:Alq_3, and (4) NPB/Alq_3, were studied.

2. Experimental

Experiments were carried out in a Kratos AXIS Ultra^{DLD} ultrahigh vacuum (UHV) surface analysis system, consisting of a multiport carousel chamber, a deposition chamber, and an analysis chamber. Base pressures in the three chambers are better than 5×10^{-10}, 5×10^{-10}, and 3×10^{-10} Torr, respectively. All organic materials were carefully sublimed twice and entirely out-gassed to ensure material purity and the study of intrinsic behavior. Film thickness was monitored by a quartz crystal microbalance. Prior to film deposition, ITO (30 Ω/□)-coated glass substrates were subjected to a routine cleaning process and *ex situ* treated by UV-ozone exposure. WO_3 and organic materials, including Alq_3 and NPB, were *in situ* evaporated in steps onto the ITO substrate from resistively heated tantalum boats in the deposition chamber at a rate of 1–2 Å/s. Samples were transferred to the analysis chamber without breaking vacuum for UPS and XPS measurements after each deposition step. UPS measurement was carried out with an unfiltered He I (21.2 eV) gas discharge lamp to characterize the valence states and the vacuum level (VL). There was no sign of sample charging in all measurements, even when the thickness of organic films reached several hundreds of Angstroms. A monochromatic aluminum Kα source (1486.6 eV) was used in the XPS measurements to study the interfacial chemical reactions and the development of possible molecular level bending across the interface. For the collection of secondary electrons, samples were negatively biased at 4 V. All measurements were performed at room temperature. The photoelectrons were collected by a hemispherical analyzer with a total instrumental energy resolution of 0.1 eV for the UPS measurements and 0.5 eV for the XPS measurements. In all the UPS and XPS spectra, the Fermi level (E_F) is referred as the zero binding energy (BE).

3. Results and discussion

3.1. Comparison of electronic structures

To understand the working mechanism of the WO_3-based intermediate connectors, electronic structure evolutions at the aforementioned four heterostructure systems were measured with UPS. Fig. 1a shows HeI UPS spectra of the WO_3/Mg:Alq_3 interface with increasing WO_3 overlayer thicknesses. The bottom spectrum was recorded from a 100 Å thick Mg:Alq_3 layer deposited on ITO substrate. Consistent with the reports in the literature [24], Alq_3 radical anion is formed upon reaction with Mg, leading to the appearance of a gap state (E_{gs}) in the forbidden energy gap as marked in Fig. 1a. The edge of the highest occupied molecular orbital (HOMO) of Mg:Alq_3 (denoted as E_H) is estimated by linear extrapolation at low BE side of the HOMO peak maximum, which locates at 3.0 eV below E_F.

As shown in Fig. 1a, deposition of the WO_3 overlayer at increasing thickness results in a progressive shift of the characteristic emission features of Mg:Alq_3 and WO_3 towards the lower BE region. This is accompanied by a 3.3 eV rising of VL. The top spectrum corresponds to the photoemission from a 50 Å thick WO_3 layer, from which the valence band edge is estimated to be at 3.3 eV below E_F. Taking into account the transport gap of 3.3 eV, the conduction band edge of the WO_3 layer seems to be pinned at the Fermi level, consistent with the previous report that WO_3 is an n-type semiconductor material [25]. In addition, it is noted that a new state can be observed in the forbidden band gap upon a 10 Å thick WO_3 deposition. It has been demonstrated that the imperfect stoichiometry of WO_3 can induce a state below Fermi level, originating from W 5*d* band [26]. As a result, the formation of the new state as observed in UPS spectra may be attributed to partial reduction of W^{6+} cation as discussed later by XPS measurement.

For comparison, Fig. 1b shows the HeI UPS spectra of the WO_3/Alq_3 interface as a function of the overlayer thickness. Spectral evolution at the WO_3/Alq_3 interface is consistent with its chemically inert nature, showing no additional spectral structures upon WO_3 deposition on Alq_3, and is different from the case of WO_3 on Mg:Alq_3 as shown in Fig. 1a.

The HeI UPS spectra of NPB deposited onto WO_3 layer on Mg:Alq_3/ITO substrate are shown in Fig. 2, where NPB

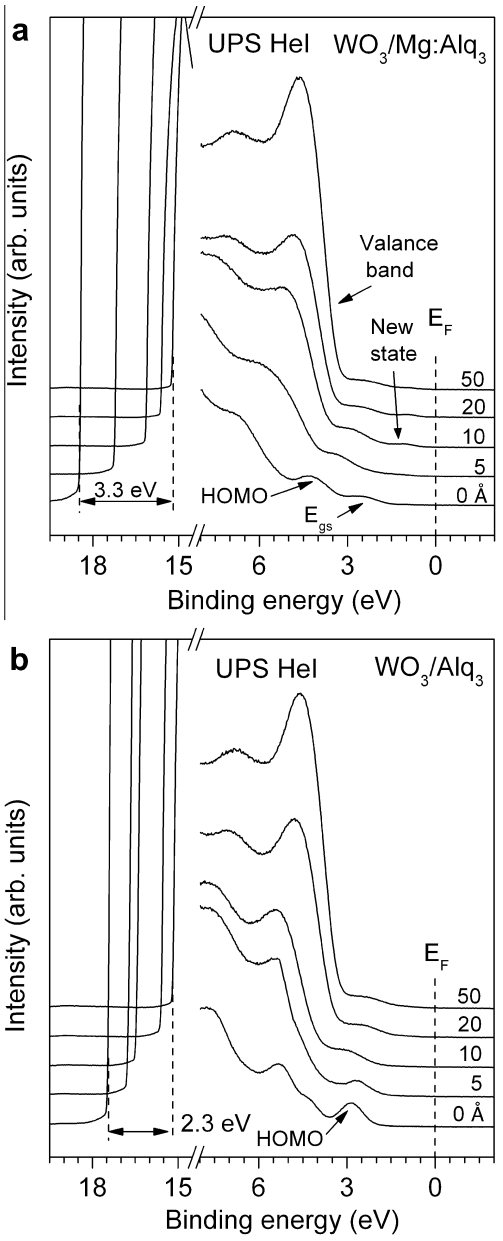

Fig. 1. HeI UPS spectra of (a) WO_3/Mg:Alq_3 and (b) WO_3/Alq_3 interfaces on ITO substrates for increasing thicknesses of the deposited layer.

thickness ranges from sub-monolayer (~2 Å) to 120 Å. The bottom spectrum is the same as that of 50 Å thick WO_3 layer in Fig. 1a. The evolution of the NPB/WO_3 interface as observed here is identical to those previously reported organic/transition metal–oxide interfaces [20,27–29]. Upon deposition of NPB, the frontier molecular orbitals of NPB gradually shift towards higher BE side, accompanied by a VL downward shift of 1.6 eV. Additionally, there is no observable feature in the organic energy gap region at the NPB/WO_3 interface, suggesting the absence of chemical interaction at the interface. Moreover, the UPS spectra evolution of NPB/WO_3 interface on Alq_3/ITO substrate (not

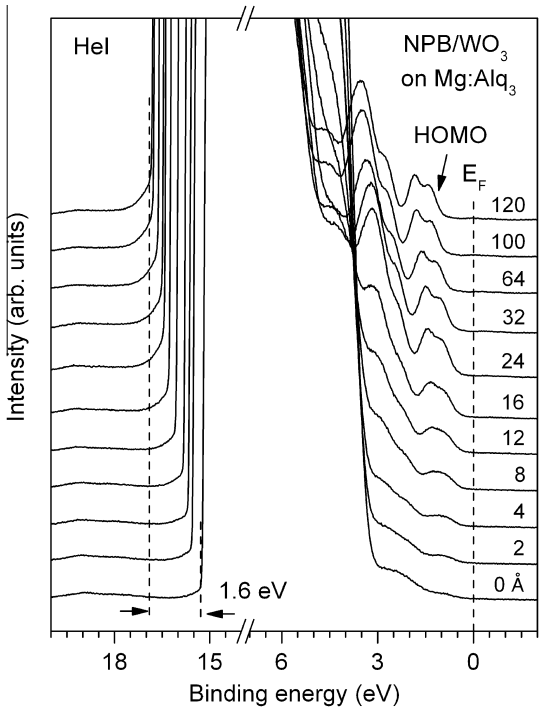

Fig. 2. HeI UPS spectra as a function of incremental NPB deposition on the WO_3/Mg:Alq_3 substrate.

shown here) is almost identical to that on Mg:Alq_3/ITO, implying the independence of its electronic structures on the underlying substrate.

In addition, UPS spectra of the NPB/Mg:Alq_3 and the NPB/Alq_3 interfaces on ITO substrate (not shown here) demonstrated that except for the intensity attenuation of the features of the Alq_3 underlayer, all the molecular level positions remain constant with a negligible vacuum level shift at the interface, indicating the absence of interface dipole and band bending in either layer.

3.2. Chemical structures and XPS spectra

To accurately separate the contributions of interface dipole and energy level bending to the interfacial energy level alignment and to determine the origin of the new state formation in the forbidden gap at the WO_3/Mg:Alq_3 interface, XPS measurements were also taken after each deposition step. Evolution of selected W 4*f* core level spectra for the NPB/WO_3/Mg:Alq_3 and NPB/WO_3/Alq_3 systems are shown in Fig. 3a and b, respectively. It is obvious that the W 4*f* spectra of a 50 Å thick WO_3 overlayer on Mg:Alq_3 and Alq_3 are virtually identical, showing sharp doublet peaks at 35.7 (W $4f_{7/2}$) and 37.9 (W $4f_{5/2}$) eV, respectively. In accordance with previous reports [26], these peak positions can be assigned to the chemical state of W^{6+}. As evident in Fig. 3a, however, an additional feature at the low BE side can be observed in W 4*f* spectra at low WO_3 coverage (i.e., <20 Å) on Mg:Alq_3, which obviously differ from those of WO_3 deposited on Alq_3. The W 4*f* spectra of a 10 Å thick WO_3 overlayer can be nicely least-square fitted by means

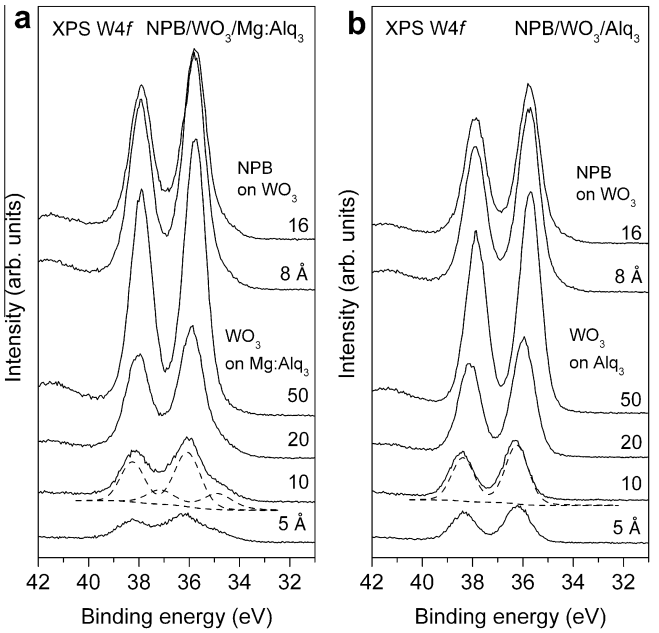

Fig. 3. XPS W 4*f* core level spectra obtained upon formation of (a) NPB/WO_3/Mg:Alq_3 and (b) NPB/WO_3/Alq_3 interfaces. The results of the least-square peak fitting of a 10 Å thick WO_3 on Mg:Alq_3 and Alq_3 substrates are represented by dashed lines.

of two main doublets to analyze the contributions of the individual components. The fitting was performed, within the experimental error, by keeping constant the energy intervals (2.2 eV) and relative intensity ratios (4:3) between W $4f_{7/2}$ and W $4f_{5/2}$ signals at the level obtained from the 50 Å thick WO_3 overlayer. Absolute energy position and width of individual sub-spectra were free fitting variables. The spectra were simulated with a fixed mixture of Lorentzian and Gaussian line shapes, and the Shirley integral background was applied to remove contributions of the inelastically scattered electrons. Consequently, the energy positions for W $4f_{7/2}$ are located at 36.1 and 34.9 eV, respectively for WO_3 overlayer on Mg:Alq_3, while W $4f_{7/2}$ is located at 36.2 (thin solid line) for WO_3 on Alq_3. The new feature (thin dashed line in Fig. 3a) in the 10 Å thick WO_3 overlayer has a chemical shift of about 1.2 eV relative to the bulk one of WO_3 (thin solid line in Fig. 3a), indicating the reduced W atoms in WO_{3-x}. This can be attributed to the reduction of W^{6+} cations by charge transfer from Mg, consistent with the appearance of a new state in the forbidden band gap as shown in Fig. 1a. These results were further confirmed by directly depositing Mg onto WO_3 layer (not shown here). Upon NPB deposition on WO_3 films, the W 4*f* doublet peak shows only changes in peak height with neither additional component nor peak broadening (Fig. 3a and b). These further confirm the absence of chemical reaction between NPB and WO_3 as observed in the UPS measurements.

3.3. Energy shifts and energy level alignment

Relative energy shifts of the valence band features and core levels extracted from UPS and XPS measurements

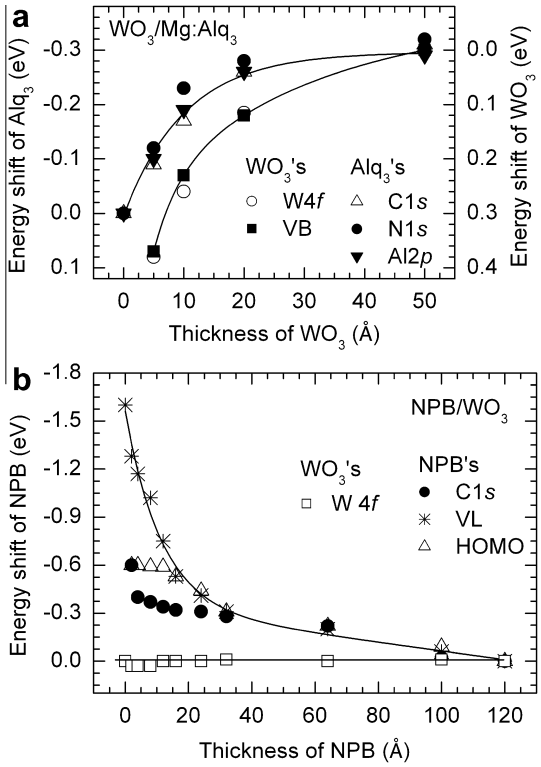

Fig. 4. Energy level shifts for HOMO, VL, and core levels of (a) WO_3 and Alq_3 in WO_3/Mg:Alq_3 and (b) NPB in NPB/WO_3 on Mg:Alq_3 substrate deduced from UPS and XPS measurements. The zero of the energy scale refers to the bulk value. The solid lines mark the energy shift.

for the NPB/WO_3/Mg:Alq_3 interface are shown in Fig. 4. It can be seen that all the core levels follow the trends of the valence band at the WO_3/Mg:Alq_3 interface. The spectral features of WO_3 at the interface show a similar upward shift of ~0.4 eV with increasing WO_3 coverage; whereas those of Alq_3 display a ~0.3 eV rigid upward shift toward the interface as shown in Fig. 4a. These results rule out the contribution from charging in Alq_3 and accurately reflect the energy level bending in organic materials at the interface. Similar phenomena can be found at the NPB/WO_3 interface, where the spectral features of NPB show a rigid downward shift with increasing NPB thickness while those of WO_3 remain almost negligible change (Fig. 4b). By comparing the amplitudes of energy shift of the core levels and the valence band features obtained by XPS and UPS measurements, respectively, the contributions of interface dipole and energy level bending to the abrupt VL shift at the two interfaces can be accurately separated [30].

Based on the UPS and XPS measurements, energy level diagrams are depicted in Fig. 5 for NPB/WO_3/Mg:Alq_3, NPB/WO_3/Alq_3, NPB/Mg:Alq_3, and NPB/Alq_3 systems on ITO substrate, respectively. Here, the E_H for organic and WO_3 layers in the intermediate connectors is extracted from the UPS spectra. Charge-transport gaps are used for more accurate estimation of the lowest unoccupied molecular orbital (LUMO) or conduction band position, E_L, for organic and WO_3 layers, which were determined by combined UPS and inverse photoemission spectroscopy (IPES) measurements (3.7 eV for Alq_3, 4.0 eV for NPB, and 3.3 eV for WO_3, respectively) [25,31]. Also, the Mg:Alq_3 films are assumed to have the same energy gap as the pristine Alq_3 films. Fermi levels are aligned across the interface in a thermodynamic equilibrium state.

It can be seen from Fig. 5a and c that upon Mg doping, LUMO of Alq_3 is closer to the Fermi level. This shows that Mg functions as an n-type dopant in Alq_3. Meanwhile, energy level bending appears at the interfaces of WO_3/Mg:Alq_3, WO_3/Alq_3, and NPB/WO_3 as shown in Fig. 5a and b. Interface dipole formation can be distinguished by subtracting the contribution of energy level bending from the VL shift for these interfaces. The interface dipoles, Δ, formed between WO_3 and organic layer suggest that WO_3 draws charges from the neighboring organic layers.

It has been demonstrated that tandem OLEDs with NPB/WO_3/Mg:Alq_3 as the intermediate connector offer good electrical behavior and luminance output, while devices without the WO_3 interlayer in the intermediate connector require high driving voltage [6]. According to the energy level diagram as depicted in Fig. 5a, the functional effectiveness of the NPB/WO_3/Mg:Alq_3 intermediate connector and thus the enhanced performance in the corresponding tandem OLED can be understood. For the NPB/WO_3/Mg:Alq_3 system, Mg:Alq_3 and WO_3 layers exhibit the n-type semiconductor property, while the NPB film is a p-type layer. As a result, upon the operation of a tandem OLED, the NPB/WO_3/Mg:Alq_3 system is actually a p/n/n junction under the reverse-bias condition. Under an applied bias, electrons can be effectively transferred from the HOMO level of NPB to the conduction band of WO_3 due to the small energy level offset. Moreover, the WO_3 interlayer between Mg:Alq_3 and NPB provides a better energy level matching in the intermediate connector. Accordingly, electrons can easily inject into the LUMO of Mg:Alq_3 due to small injection barrier at the WO_3/Mg:Alq_3 interface. In addition, Mg:Alq_3 can help to block the holes flowing from the ITO side directly into the second EL unit

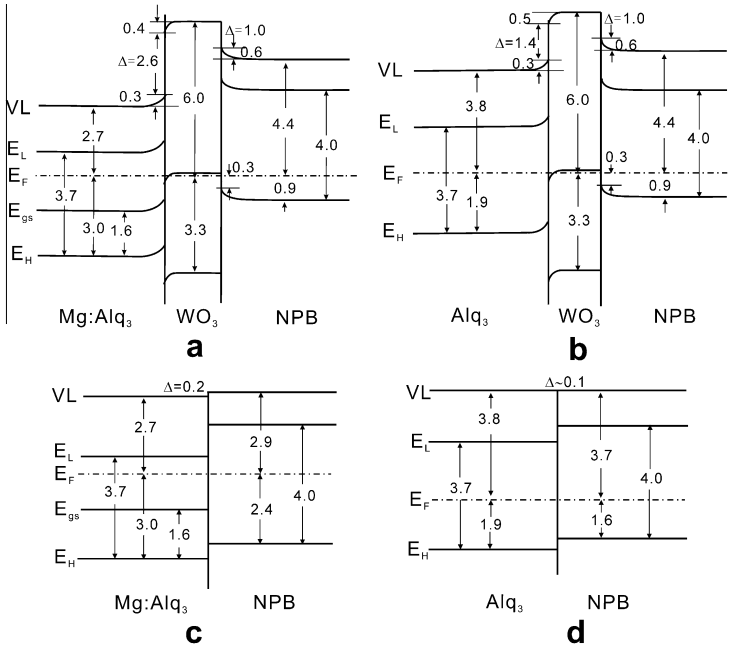

Fig. 5. Schematic energy level diagrams of (a) NPB/WO_3/Mg:Alq_3, (b) NPB/WO_3/Alq_3, (c) NPB/Mg:Alq_3, and (d) NPB/Alq_3 interfaces on ITO substrate, respectively. All the values shown are in the units of eV. The energetic positions of VL, E_F, E_{gs}, and E_H are obtained from UPS, and E_L is derived from charge-transport gaps plus E_H.

and hence reduce the leakage hole-current. As a result, such an intermediate connector facilitates efficient carrier injection from the intermediate connector into the appropriate carrier-transporting layers [6].

In the case of NPB/WO_3/Alq_3 system, the corresponding energy level diagram in Fig. 5b shows that the incorporation of a doped n-type organic layer in the intermediate connectors is critical for tandem OLEDs to function efficiently with enhanced EL efficiency. The energy offset at the NPB/WO_3 interface is identical to that of the NPB/WO_3/Mg:Alq_3 system, indicating the similar efficiency of the charge generation process. However, due to the energy level mismatch at the WO_3/Alq_3 interface, the electrons generated in WO_3 layer cannot effectively inject into Alq_3 layer, leading to the elimination of the emission in the first EL unit [17]. This is the reason why a tandem device with a NPB/WO_3/Alq_3 intermediate connector performs the *I–V* characteristics similar to that with a NPB/WO_3/Mg:Alq_3 connector, but a much lower current efficiency [6].

In contrast, the absence of WO_3 interlayer results in typical flat vacuum level alignment with neither interface dipole nor energy level bending at the NPB/Mg:Alq_3 and NPB/Alq_3 interfaces (as shown in Fig. 5c and d). The energy offset at NPB/Mg:Alq_3 (or NPB/Alq_3) interface is as large as 3.1 (or 3.4) eV. It indicates that charge transport channel between NPB's HOMO and Mg:Alq_3's (or Alq_3's) LUMO is blocked unless a higher driving voltage is applied. This is the reason why tandem devices without WO_3 interlayer exhibited poor electrical properties with current density two order of magnitude lower than that with WO_3 [6]. These findings suggest that an accurate picture of the energy level alignment at the interfaces is essential for the understanding and optimization of intermediate connectors, and the significance of a WO_3 interlayer on the intermediate connector is associated with favorable energy level matching between adjacent EL units via reducing the energy offset to a minimum.

4. Conclusions

In summary, we have obtained a comprehensive picture of electronic structures of WO_3-based intermediate connectors used in tandem OLEDs via photoemission spectroscopy. We showed that energy level offset between adjacent EL units induced by an intermediate connector is an important factor for efficient operation of tandem OLEDs. The significance of the WO_3 interlayer lies in its capability in pronouncedly modifying the energy level alignment, leading to interface dipole and energy level bending, which favor carrier injections into suitable molecular energy levels of the adjacent EL units. These results provide insight on the working mechanisms of the Mg:Alq_3/WO_3 intermediate connector and are useful references for designing new high-performance intermediate connectors in tandem organic electronic devices.

for fabricating practical large-scale devices. We are interested in BTBT moieties that contain large number of heteroatomic groups and superior molecular order. Molecules with high formula weights have been designed to realize liquid crystalline behavior at moderately high temperatures.

In this paper, we present two LC semiconducting molecules bearing thienylethenyl [1] BTBT with two different alkyl end groups. We investigated the optical, thermal, electrochemical, and photophysical properties of the new conjugated molecules. We used these solution-processable LC molecules to fabricate OTFTs and investigate their device performance. The two molecules incorporating a BTBT moiety not only offer high carrier mobility of the order of 10^{-2} $cm^2/(Vs)$ but also a high current on/off ratio, which we attributed to the annealing effect due to liquid crystalline behavior.

2. Experiment

2.1. Synthesis

All commercially available starting materials and solvents were purchased from Aldrich, TCI, and Acros Co. Compounds **1**, **2**, and **3** were synthesized following the method in the literature and a slightly modified method. [18–21]

2.1.1. 2,7-Bis((E)-2-(5-hexylthiophen-2-yl)vinyl)[1]benzothieno[3,2-b]benzothiophene (**4**)

100 mL of oven-dried, magnetically stirred RBF was charged with a solution of **1** (0.7 g, 1.29 mmol) and 5-hexylthiophene-2-carbaldehyde, with **2** (0.63 g, 3.24 mmol) in 20 mL of freshly distilled tetrahydrofuran (THF). The reaction was allowed to stand for 0.5 h, and then, potassium *tert*-butoxide (0.36 g, 3.24 mmol) was added to it. After the reaction was complete, the solution was poured into ethanol to collect the precipitates. The product was obtained after column chromatography using toluene as an eluent. Yield: 84%, 0.68 g of yellow powder. ^{1}H NMR (300 MHz, CDCl3): δ (ppm) 7.95 (s, 2H), 7.83 (d, J = 8.2 Hz, 2H), 7.58 (d, J = 8.5 Hz, 2H), 7.30 (d, J = 3.8 Hz, 2H), 6.93 (d, J = 3.8 Hz, 2H), 6.88 (d, J = 3.6 Hz, 2H), 6.71 (d, J = 3.6 Hz, 2H), 2.83 (t, 4H), 1.71∼1.55 (m, 4H), 1.44∼1.28 (m, 12H), 0.92 (t, 6H).

Anal. calcd. for $C_{38}H_{40}S_4$: C, 73.03; H, 6.45; S, 20.52. Found: C, 73.02; H, 6.43; S, 20.55.

2.1.2. 2,7-Bis((E)-2-(5-octylthiophen-2-yl)vinyl)[1]benzothieno[3,2-b]benzothiophene (**5**)

The preparation method was identical to that for **4**. Instead of 5-hexylthiophene-2-carbaldehyde, 5-octylthiophene-2-carbaldehyde was employed. After completing the reaction, the solution was poured into methanol to collect the precipitates. The product was obtained after column chromatography using toluene as an eluent. Yield: 74%, 0.65 g of yellow powder. ^{1}H NMR (300 MHz, CDCl3): δ (ppm) 7.95 (s, 2H), 7.83 (d, J = 8.2 Hz, 2H), 7.59 (d, J = 8.5 Hz, 2H), 7.31 (d, J = 3.8 Hz, 2H), 6.93 (d, J = 3.8 Hz, 2H), 6.88 (d, J = 3.6 Hz, 2H), 6.71 (d, J = 3.6 Hz, 2H), 2.83 (t, 4H), 1.71∼1.54 (m, 4H), 1.33∼1.28 (m, 20H), 0.90 (t, 6H).

Anal. calcd. for $C_{42}H_{48}S_4$: C, 74.06; H, 7.10; S, 18.83. Found: C, 74.04; H, 7.09; S, 18.78.

2.2. Instrumental analysis

^{1}H NMR spectra were recorded on a Varian Mercury NMR 400-Hz spectrometer using deuterated chloroform (Cambridge Isotope Laboratories, Inc.). Elemental analyses were performed using an EA1112 elemental analyzer (Thermo Electron Corp.). The optimized molecular geometry was calculated employing the density functional theory (DFT) using Spartan'06.

Thermal properties were studied under a nitrogen atmosphere by differential scanning calorimetry (DSC) using a Mettler DSC 821e instrument. Thermogravimetric analysis (TGA) was conducted on a Mettler TGA50 (temperature rate of 10 °C/min under N_2). Phase transition behaviors of the liquid crystals were observed in micrographic optical textures under a polarized light microscope (Olympus BH-2) with a hot stage (Mettler Toledo 90/F82HT hot stage).

The redox properties of the two molecules were examined by using cyclic voltammetry (Model: EA161 eDAQ). The electrolyte solution employed was 0.10 M tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) in freshly dried methylenechloride (MC). Ag/AgCl and Pt wire (diameter: 0.5 mm) electrodes were utilized as reference and counter electrodes, respectively. The scan rate was 50 mV/s.

X-ray diffraction (XRD) experiment was performed at varying temperatures using the synchrotron radiation (wavelength: ∼1.54 Å) of the 3C2 beam line at the Pohang Synchrotron Laboratory, Pohang, Korea. Grazing incidence XRD (GI-XRD) measurements were performed at the 10C1 beamline (wavelength: ∼1.54 Å) at the same laboratory. The measurements were obtained using scanning intervals of 2θ between 2.5° and 32°. The film samples were fabricated by drop-casting on a silicon wafer followed by drying at 70 °C under vacuum (solvent: chloroform, conc. of the solution: 10 mg/mL).

Atomic force microscopy (Digital Instruments Multimode equipped with a Nanoscope IIIa controller) operating in tapping mode with a silicon cantilever was used to characterize the surface morphologies of the samples. The film samples were fabricated by spin coating (1500 rpm) on a silicon wafer followed by drying at 70 °C under vacuum (solvent: chloroform, conc. of the solution: 10 mg/mL).

2.3. UV–Vis absorption and photoluminescence (PL) spectroscopy

Absorption spectra of samples in a solution state (chloroform, conc.: 1×10^{-6} mol/L) were obtained using a UV–VIS spectrometer (HP 8453, photodiode array type) in the wavelength range of 190–1100 nm. PL spectra of the solutions at room temperature were acquired using a Hitachi F-7000 FL spectrophotometer.

2.4. OTFT fabrication

To characterize the TFT performance, a bottom-gate top-contact device geometry was employed. Spin-coated

films (thickness: ~40–50 nm) of **4** and **5** were prepared on the heavily n-doped Si/SiO_2 substrate with monochlorobenzene as a solvent. Surface modification was carried out with octyltrichlorosilane (OTS) to produce a hydrophobic dielectric surface for more edge-on over-coated molecules. Source and drain electrodes were then thermally evaporated (100 nm) through a shadow mask with a channel width and length of 1500 and 150 μm, respectively. All field effect mobilities were extracted in the saturation regime using the relationship $\mu_{sat} = (2I_{DS}L)/(WC(V_g - V_{th})^2)$, where I_{DS} is the saturation drain current, C is the capacitance of the oxide dielectric, V_g is the gate bias, and V_{th} is the threshold voltage. The device performance was evaluated in air using a high-voltage Keithley 237 sourcemeter under ambient conditions.

3. Results and discussion

3.1. Synthesis

We report here the facile and high-yield synthesis of the new p-type BTBT-based semiconducting molecules. Scheme 1 illustrates the synthetic route for preparing the two molecules **4** and **5**. The Horner–Emmons reaction with potassium *tert*-butoxide proved beneficial as it had a high reaction yield and did not produce a catalytic residue after purification of the molecules. Two alkyl chains were added at the ends of both thienyl groups to serve as solubilizing groups and crystallization promoting moieties.

The resulting material was then purified by silica-gel column chromatography or by reprecipitation into ethanol. The identity and purity of the synthetic materials were confirmed by ^1H NMR and elemental analysis. They were found to process superior self-film forming properties and high solubility in various organic solvents such as chloroform, xylene, MC, chlorobenzene, and THF. In particular, more than 5 mg of both materials can be dissolved in 1 mL chloroform at room temperature.

3.2. UV–Vis absorption spectroscopy

The absorption spectra of the molecules in chloroform (conc.: 1×10^{-5} mol/L) are illustrated in Fig. 1. Identical absorption maxima for **4** and **5** in solution states are located at 403 (425) nm. The absorption bands of the spectrum resolved the $\pi-\pi^*$ transitions originating from the planar conjugated molecular structure. The length of alkyl chain did not affect the conjugative effect, although two thienylethenyl groups were tethered into rigid BTBT moiety. The optical band gap energies of the two molecules were determined to be around 2.75 eV. In addition, the identical PL spectra of the two molecules were observed to be mirror images of the absorption spectra and results from the same species when excited.

3.3. Thermal characterization of liquid crystalline molecules

The thermal properties of the two materials were investigated by means of thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and hot-stage polarized optical microscopy (POM).

The TGA of these molecules at a heating rate of 10 °C/min under nitrogen indicated that they have good thermal stability. Compared to the onset decomposition temperature of linear α,ω-dihexylsexithiophene (DH6T), which is at around 309 °C, these molecules have high onset decomposition temperatures (~425–433 °C) (see Table 1).

The DSC thermograms of **4** and **5** displayed phase transition behaviors (see Fig. 2). Both molecules exhibit liquid crystalline behaviors owing to the presence of a rigid BTBT central unit in combination with the heteroaromatic moieties and aliphatic parts of the molecules.

As shown in Fig. 2A, small enthalpy changes of mesophase with some extent of molecular thermal movement were observed at around 37 °C and 90 °C during the second heating cycle. Molecule **4** starts melting at 230 °C, and a liquid crystalline (LC) phase clearly appears at 260 °C. The undefined smectic LC phase exists up to 367 °C and transforms into a completely isotropic phase at around 373 °C (see Fig. 2A).

Molecule **5**, which contains longer alkyl chain tails, starts melting at 247 °C during the second heating cycle and forms a smectic phase that exists up to 356 °C. At around 360 °C, this phase becomes completely isotropic, as shown in Fig. 2B. Some transition peaks with relatively small enthalpy changes appeared during a heating cycle,

which indicates the occurrence of either solid–solid transitions with some thermal motion or ordered-to-disordered crystalline transitions. When the sample is cooled, these peaks almost disappeared owing to the stabilization of the molecules.

In order to study the crystallinity of the molecules more precisely, X-ray diffraction (XRD) studies were performed on drop-cast films at varying temperatures using synchrotron radiation of a 3C2 beamline. The two molecules were confirmed to be highly crystalline, as evidenced by sharp diffraction peaks with high intensity at 25 °C.Figs. 3 and 4 show the XRD profiles of the two molecules at two different temperatures. A high temperature of 260 °C was selected between the T_1 (T_3) and T_2 (T_4) temperatures obtained in the DSC thermograms. The frozen phase of molecule **4** at 25 °C displays distinct diffraction peaks at $2\theta = 4.42°$ and 6.66° with *d*-spacings of 20.0 Å and 13.3 Å, which correspond to the intermolecular spacings of two different types of crystalline molecules (see Fig. 3). We assumed that the length of molecule **4** in a fully extended conformation (calculated by Spartan'06, DFT mode) is approximately 36.2 Å and suggested that at 13.3 °C, the

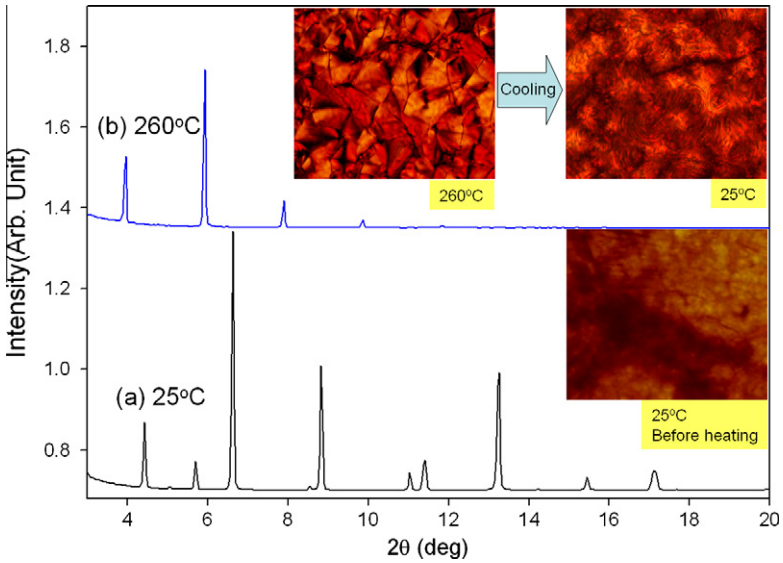

Fig. 3. X-ray diffraction patterns of molecule **4** for comparing the liquid crystalline phase recorded at 260 °C with the crystalline phase obtained at 25 °C before heating. The POM images of the phases at 25 °C and 260 °C during heating and the image obtained by cooling from 260 to 25 °C are also shown.

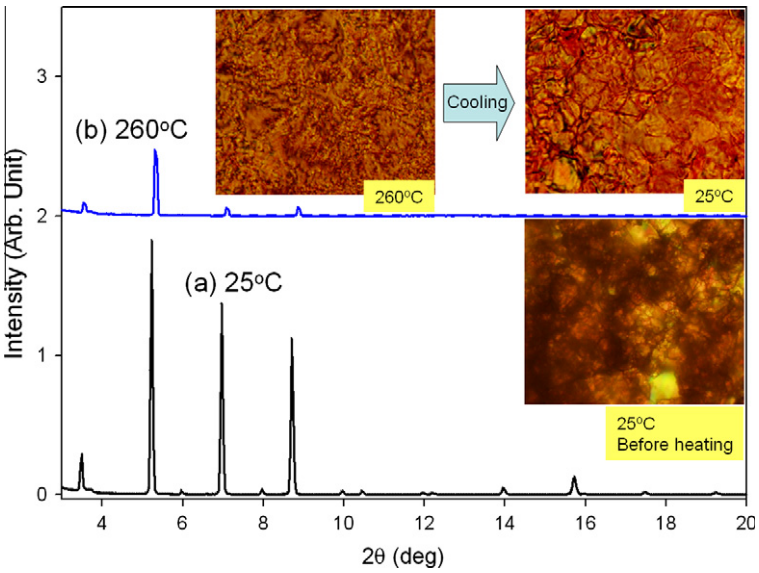

Fig. 4. X-ray diffraction patterns of molecule **5** for comparing the liquid crystalline phase recorded at 260 °C with the crystalline phase obtained at 25 °C before heating. The POM images of the phases at 25 °C and 260 °C during heating and the image obtained by cooling from 260 to 25 °C are also shown.

molecules are probably arranged vertically to the substrate with an inclination of 44.1°, owing to the interdigitation of hexyl chains. The wide angle diffraction of these molecules shows several diffraction patterns that are mostly multiple orders of the same *d*-spacing, which indicates the presence of a long-range positional order that is typical of a crystalline structure. The small angle X-ray profile at 260 °C showed layer spacings of 22.5 Å ($2\theta = 3.93°$) and 15.0 Å ($2\theta = 5.9°$); these spacings are larger than those at 25 °C, owing to the transition from the liquid crystalline state to the glassy crystal state. Concomitantly, at 260 °C, the small multiple diffraction peaks completely disappeared and the overall degree of crystallinity decreased. In order to investigate the LC properties of the molecules, POM analysis was conducted; this analysis showed a clear phase change of molecule **4** (Insets of Fig. 3). At 25 °C, an unidentified crystalline texture of the frozen glassy state was observed as a relatively dark image. When molecule **4** was further heated above 260 °C, a clear fan-like texture image of smectic C phases was observed. This texture was almost retained when the molecule was cooled to 25 °C, although some defect lines were observed in the mosaic image; this image is indicative of the crystal smectic phases.

However, the diffractogram of molecule **5** shows more than two different types of crystalline phases at 25 °C

(see Fig. 4). Although DSC thermograms showed clear phase transition peaks with a reasonable value of enthalpy change, the optical microscope did not show clear LC textures. When the sample temperature was increased up to 260 °C, a diffraction peak with the highest intensity appeared at 5.3° (*d*-spacing = 16.6 Å). When the sample temperature was increased, the intensity and position of the diffraction peak varied owing to the decrease in crystallinity. Although any specific textures were not clearly observed in the optical micrographs of molecule **5,** liquid crystallinity was verified by repeated observation. One promising property of this molecule is that the texture of the glassy solid state is quite similar to the LC texture at 260 °C as it retains the LC orderness.

3.4. Electrochemical analysis

Electrochemical characterization of the two molecules as solutions evidenced that their oxidation is reversible, which is a necessary condition for a TFT active material. The values of the ionization potential matched well with the work-function of a gold electrode. Cyclic voltammograms were recorded on a film sample, and the potentials were obtained relative to an internal ferrocene reference (Fc/Fc^+). These CV scans in the range of −2.0 V to +2.0 V (vs. Ag/Ag^+) showed quasi-reversible oxidation peaks. Unfortunately, the reduction behaviors were irreversible; therefore, we were unable to accurately estimate their HOMO and LUMO energies. To determine the LUMO levels, we combined the oxidation potential in CV with the optical energy bandgap (E_g^{opt}) resulting from the absorption edge in the absorption spectrum. Voltammograms of 4 and 5 in the film state showed that their lowest common oxidative waves are at +1.1 V. As shown in Table 1, molecules **4** and **5** have identical HOMO levels of −5.5 eV, indicating no effect of the length of alkyl chain on the electronic properties. In addition, the annealed films of **4** and **5** have identical LUMO energy levels of −2.74. The relatively higher HOMO levels may endow the material with better environmental stability.

3.5. GI-XRD

To determine the chain orientation and crystallinity of thin films for the two molecules, synchrotron grazing incidence X-ray diffraction (GI-XRD) measurements were carried out on the drop-cast films. By using a fixed grazing incidence angle (0.18°) that was above the critical angle for total internal reflection from the thin films but below the critical angle of the insulator surface, the scattering from the substrate was reduced relative to the scattering from the films [22–27].

Significantly, two different chain orientations, such as edge-on orientation of the nanocrystalline molecular domains with respect to the insulator substrates, when treated with SAMs were clearly observed in annealed films. They were evident from the different intensity distributions of the (1 0 0) reflections due to the lamellar layer structure (*d*-spacing: 29.17 Å for **4** and 32.38 Å for **5**) and the (0 1 0) reflections due to π−π interchain stacking (4.65 Å for **5**; for **4**, the diffraction peak could not be resolved clearly) through out-of-plane and in-plane geometric modes.

The highly packed crystalline molecules on the substrate may help induce carrier transport with good connection behavior. More specifically, the out-of-plane XRD pattern of as-spun **4** films on the Si/SiO_2 substrate shows seventh-order (1 0 0) reflections at 3.19°, 6.38°, 9.57°, 12.75°, 15.95°, 19.15°, and 22.40°, indicating that the film has a highly crystalline order along the out-of-plane direction. (see Fig. 5) After thermal annealing, other periodic diffraction peaks (1' 0 0) at a slightly lower angles were observed, indicating an elongated spacing between the molecules. The (1' 0 0) diffractions peaks may be due to the distortion and rearrangement of the molecules. As shown in Fig. 6, out-of plane diffraction modes were also observed; after annealing, the diffraction peak at 19.1° was observed to correlate to the distance between molecular planes. A clear diffraction was observed in the in-plane XRD measurement, also indicating high crystalline order. Analysis of the diffractograms shown in Figs. 5 and 6 leads us to conclude that both molecules are oriented perpendicular to the substrate in an edge-on manner.

3.6. Atomic force microscope (AFM) images of films

The GI-XRD measurements revealed the type of nanocrystalline structural order that prevails throughout the molecular films, while AFM observations provided images of the top surface. The morphologies of the thin films for

4 and **5** on OTS-treated Si/SiO_2 were visualized with AFM before and after thermal annealing. We prepared solutions of the two molecules and then performed spin coating to cover the dielectric surface with each solution. After completely drying the thin films, we took two micrographs before and after thermal annealing at the temperature of the liquid crystalline region, as shown in Figs. 7 and 8. In the topographic images of molecule **4**, the initial unannealed film is microcrystalline and exhibits localized large-size aggregations in a random manner. However, after thermal annealing at 180 °C for 30 min, the films reorganize into large crystalline terraces with layers lying parallel to the OTS-treated SiO_2 surface; the step height was found to be 2.6–2.7 nm, which is consistent with the length of the molecule excluding the hexyl chain on one side and the interlayer distance extracted from XRD data (Figs. 5 and 6). The terrace and step-wise structure is typical of representative organic single crystals such as rubrene and pentacene. The excellent flatness and well-defined molecular steps indicate that highly oriented crystalline films are grown on the dielectric surface. Fig. 8 shows the same phenomenon. After annealing the sample, although the domain size became larger, the step lines were nearly straight and parallel to each other in a localized crystalline domain. The average width of the molecularly flat terraces was about 3.0–3.1 nm, which is almost consistent with the molecular dimension shown in the inset. Before annealing the image of molecule **5** showed relatively smaller continuous polycrystalline grains with better network interconnection between them. However, the difference of surface topography between **4** and **5** was not so significant in this study.

3.7. Properties of OTFT made of molecules *4* and *5*

Bottom-gate top-contact OTFT devices were fabricated using gold source and drain electrodes that were thermally

evaporated using the conventional method. P-doped polycrystalline silicon was used as the gate electrode, with the OTS-treated SiO_2 surface layer used as the gate dielectric insulator. A 300-nm thin film of the semiconductor was

deposited by spin coating a 0.5 wt.% solution of the molecules in monochlorobenzene. After spin coating the solution on the insulator surface, the gold was deposited via thermal evaporation. To achieve optimal device performance, the OTFT devices made of **4** and **5** were each further annealed at 180 °C for 30 min.
