ABSTRACT

Two new donor–acceptor type liquid crystalline semiconductors based on benzothiazole have been synthesized. Their structural, photophysical and electronic properties were investigated using X-ray diffraction, atomic force microscopy, cyclic voltammetry, UV–Vis, photoluminescence, and Raman spectroscopy. The liquid crystalline behaviour of the molecules was thoroughly examined by differential scanning calorimetry (DSC) and optical polarizing microscope. The DSC and thermogravimetric analysis (TGA) show that these materials posses excellent thermal stability and have decomposition temperatures in excess of 300 °C. Beyond 160 °C both molecules show a smectic A liquid crystalline phase that exists till about 240 °C. Field-effect transistors were fabricated by vacuum evaporating the semiconductor layer using standard bottom gate/top contact geometry. The devices exhibit p-channel behaviour with hole mobilities of 10^{-2} cm^2/Vs.

1. Introduction

π-Conjugated organic materials have been the subject of recent research work due to their optical, electronic properties as well as their applications in many fields such as organic light-emitting diodes (OLED) [1–3], photovoltaic cells [4–7], thin film organic field-effect transistors (OFETs) [8–13]. The organic molecules used in electronic and opto-electronic devices are generally divided into two groups: small molecules and polymers. For field-effect transistors, small organic molecules and oligomers are extensively used rather than polymeric materials. The most notable examples include pentacene [14–16], rubrene [17–20] and oligothiophene derivatives [21–24]. In the best cases, the room temperature mobility of crystalline organic semiconductors can reach the value of around 0.1–20 $cm^2 V^{-1} S^{-1}$ [25]. A majority of these organic molecules are hole conductors although ambipolar and *n*-type materials are also known [26–32]. The major challenge in device fabrication is to achieve favourable alignment of molecules between source and drain contacts enabling efficient charge transport through the semiconducting medium [33,34]. In this context, liquid crystalline materials are promising candidates as active semiconductor layers in organic electronics [35–43]. Supramolecular organization of the organic semiconductor in a thin film can be enhanced through the utilization of the liquid crystalline material [44–50]. Liquid crystalline phase can induce highly ordered, closely packed structures, leading to high mobilities within the domain boundaries [51,52]. Introduction of π-conjugated moieties into a liquid crystalline material gives many advantages in charge transport properties arising from their self-assembling nature [53–58]. They must contain a rigid, conjugated core, which is responsible for the semiconducting behaviour of the molecule. In the past few years, considerable efforts have been made to design, synthesize, and characterize such type of π-conjugated liquid crystalline materials [59–62]. In particular; smectic liquid crystalline materials because of their spontaneous alignment are good candidates for such applications. Their

self-assembling property produces multidomain films with no physical grain boundaries between the domains thus facilitating hopping of charge carriers more easily.

In our search for organic semiconductors for OFET application we focused on benzothiazole based organic molecules (Fig. 1) because of their liquid crystalline properties. We have designed and synthesized two donor–acceptor (D–A) type benzothiazole based molecules showing interesting liquid crystalline and semiconducting properties. In both molecules, the core benzothiazole ring acts as an electron acceptor unit because of the presence of sulphur and nitrogen atoms and alkyl substituted thiophene ring as a donor because of its high electron donating ability and charge carrier mobilities. These molecules show a smectic A liquid crystalline phase above the melting temperature, which results in a good alignment and packing of the molecule in the solid state. Also, the materials exhibit p-type FET behaviour with hole mobility of 10^{-2} cm^2/Vs and on/off current ratio of 1×10^3. With additional surface modification of the gate dielectric layer, it is conceivable that the transport properties of OFETs may further improve. The AFM studies of the annealed samples show a dewetting of the surface with smooth morphology.

2. Results and discussion

2.1. Synthesis and characterization

The synthetic route to compounds (a) and (b) are summarized in the Scheme 1. Benzothiazole core were synthesized according to method described in literature [63] and bithiophene derivatives were synthesized by reported procedure [64,65]. The final derivatives were synthesized by Wittig reaction and Stille cross coupling and purified by column chromatography [66,67].

2.2. Optical and electrochemical properties of the compounds

The optical and electrochemical properties of the compounds are summarized in the Table 1. The photophysical properties of these two derivatives were investigated using UV–Vis and photoluminescence spectroscopy. The absorption and emission spectra of these two compounds in solution ($CHCl_3$) and solid state are depicted in Fig. 2. Compound (a) shows two strong absorption peaks at 318 nm and 395 nm in solution and photoluminescence peak at around 504 nm (in solution) and 587 nm (in solid state). The absorption peak at 318 nm belongs to the π–π^* transition and the absorption peak at 395 nm corresponds to a charge transfer band of the donor–acceptor system [68]. Compound (b), on the other hand predominantly shows only one strong absorption peak at 390 nm in solution which belongs to the charge transfer band; the photoluminescence is observed at ~462 nm in solution and 550 nm in solid state. In case of compound (a) the donor and acceptor units are linked through a vinyl bond which inhibits a charge transfer process from the donor thiophene ring to acceptor benzothiazole ring. As a consequence both π–π^* transition and charge transfer bands are observed in the absorption spectrum. In compound

Table 1
Optical and electrochemical properties of the compounds.

Compounds	Film		Solution			CV		
	λ_{abs} (nm)	λ_{em} (nm)	λ_{abs} (nm)	λ_{em} (nm)	E_g (eV)	E_{ox}^{onset} (V)	E_{HOMO} (eV)	LUMO (eV)
a	318	587	395	504	2.6	0.35	−5.17	−2.57
b	325	550	390	462	2.8	0.37	−5.19	−2.39

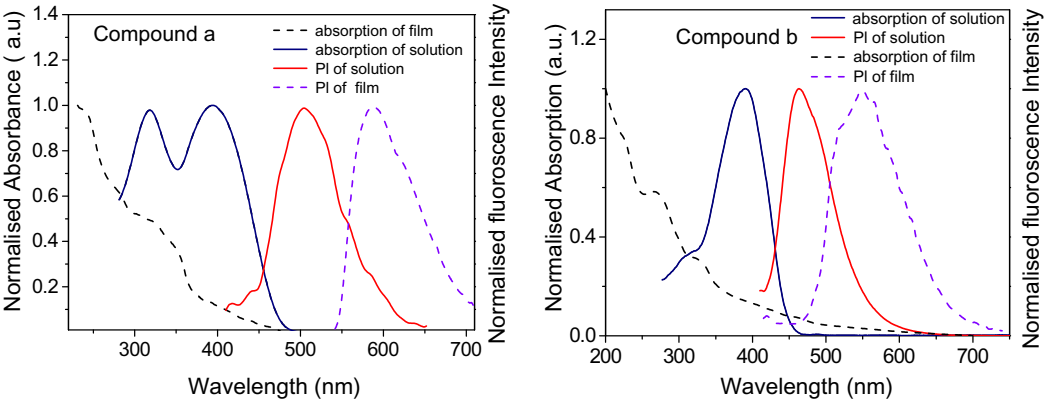

Fig. 2. UV–Vis absorption and photoluminescence spectra of compounds a and b.

(b) the donor and acceptor units are directly linked allowing a strong charge transfer process, and as a result only one peak is observed in the absorption spectrum. For both the molecules there is no sharp absorption peak in the solid state due to aggregation. The emission maxima in the solid state were observed at longer wavelengths than those in solution (80–90 nm red shift) indicating the presence of a strong interaction between the molecules (packing effect) [69] in the solid state, which is essential for good device performance. The optical band gaps, E_g, were approximated from the onset of the low energy side of the absorption spectra (λ_{onset}, solution) to the baseline. Further, the HOMO–LUMO energy levels were calculated by cyclic voltammetry measurements. The oxidation onset for the compound (a) and (b) were 0.35 and 0.37 eV, respectively, and their corresponding HOMO energy levels are −5.17 and −5.19 eV (Table 1). HOMO energy levels have been calculated by using equation HOMO = $-(E_{ox}^{onset} + 4.8)$ (eV). The LUMO levels were estimated from HOMO values and values of optical band gaps according to the equation: LUMO = HOMO + E_g^{opt} (eV). These results show that the introduction of vinyl linkage between benzothiazole and bithiophene unit inhibits donor–acceptor charge transfer and increases the effective conjugation length, thus lowering the band gap by about 0.2 eV.

2.3. Structure and morphology

To study the crystallinity of the materials, X-ray diffraction studies were performed from drop cast films that were annealed at 120 °C (Fig. 3). From the diffraction pattern it seems that both the materials are crystalline. Compound (a) exhibits distinct diffraction peaks at $2\theta = 5.7°$ and 8.3° with d-spacings of 15.2 Å and 10.5 Å corresponds to intermolecular distances. Similarly, compound (b) shows two sharp diffraction peaks at $2\theta = 6.0°$ and 8.7° with d-spacings of 14.6 Å and 10.0 Å corresponds to intermolecular distances. For both the compounds, several reflections in the wide-angle regions (between 7.6 Å and 3.6 Å), occur because of the organization within the 3D lattice and the reflections at around 3.6 Å may be due to π–π stacking of mesogens [40].

Raman scattering is particularly informative on chemical composition, segmental orientation, conformational distribution and phase identification in organic semiconductors. Fig. 4 shows the Raman spectra of as-is powder samples for both compounds. They were measured in a perfect backscattering geometry with less than 2 mW incident laser power on a 50 μm^2 area of the sample. The 1620 cm^{-1} Raman peak in compound (a) originates from the C=C stretch motion of the vinyl group [70], which is absent in compound (b). The Raman peaks in the 1600 cm^{-1} region in both compounds are from the intra-ring C–C stretch motion (ring breathing) of the phenyl group [71]. The 1564/1560 cm^{-1} peak arises from a C=C stretch motion of the phenyl ring. The Raman peaks in the 1470–1490 cm^{-1} region in both compounds are attributed to the benzothiazole unit [72]. These peaks arise from C–H bending and C–N stretch motions. The C–N stretch mode is usually an infrared active mode that may become Raman active due a lowering of the symmetry of the molecule. In compound (a) the 1487 cm^{-1} peak is seen only as a shoulder. The 1447 cm^{-1} Raman frequency in both compounds are from the C=C ring stretch motion of the thiophene unit. In thiophene-based polymers the 1447 cm^{-1} appears as an intense peak in the Raman spectrum [73]. Future Raman scattering studies from biased OFET struc-

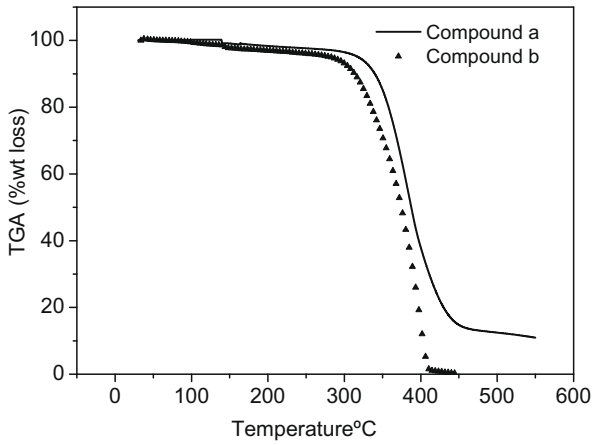

Fig. 5. TGA of compounds a and b.

tures of both compounds will yield information on the nature of electron–phonon coupling associated with charge transport mechanism in such devices.

2.4. Thermal and liquid crystalline properties

The thermal stability of the compounds (a) and (b) were investigated using thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC). Both the compounds have an excellent thermal stability, with decomposition temperatures of 320 °C (compound a) and 300 °C (compound b) as shown in Fig. 5. At temperature around 158 °C compound (a) starts melting and a liquid crystalline phase appears. This liquid crystalline phase exist up to 240 °C and a new nematic phase appears between 240 °C and 253 °C before it turns into a completely isotropic phase at around 260 °C. The existence of the nematic phase for compound (a) has been confirmed from a clear transition at 240 °C in DSC (Fig. 6). The optical polarizing images of the nematic and smectic A phase are shown in Fig. 7. Compound (b), on the other hand, starts to melt at around 177 °C and forms a smectic A phase existing up to 239 °C, beyond which it becomes a completely isotropic phase at 250 °C as shown in DSC (Fig. 6). The optical polarizing images of smectic A phase and crystalline phase were given in Fig. 7. All the phase transition temperatures including their change of enthalpy are given in the Table 2.

2.5. AFM analysis

A thin film of compound (a) was evaporated on cleaned Si wafers under vacuum evaporation (10^{-6} mbar). The thickness of the films ranged from 60 to 80 nm. Two films were utilized for the AFM studies: one as-is and the other thermally annealed. The latter was placed in an oven (under nitrogen atmosphere) and slowly heated to 120 °C and kept at this temperature for a few hours. It was then heated to 160 °C, left at this temperature for a few hours and then slowly brought back to room temperature. These temperatures were chosen to match the changes in the crystalline phase with temperature. We simultaneously recorded AFM topography and phase images. Fig. 8 shows the topography and phase images of the as-grown [(a) and (b)] and annealed sample [(c) and (d)]. The annealed samples clearly show a dewetting of the surface but with a very smooth morphology. The rms roughness of the two samples for 1 μm × 1 μm area decreased from

~3.2 nm in the as-grown sample to ~0.7 nm in the annealed sample. At this point it is not clear if the dewetting of the annealed sample may be avoided by treating the Si surface differently. We are currently exploring different

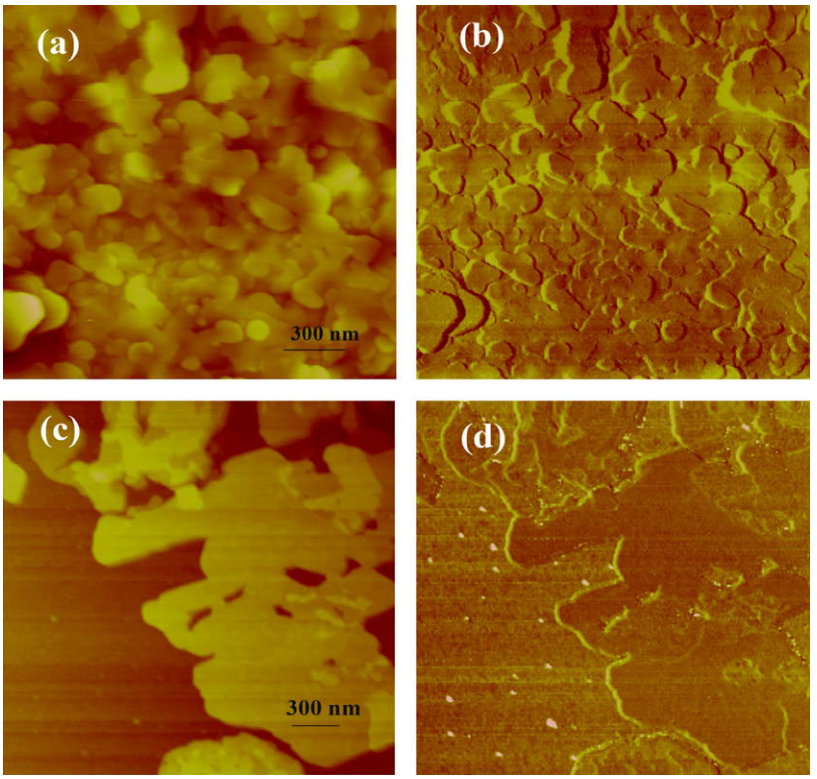

Fig. 8. AFM images of as-grown and annealed samples of compound a.

chemical treatments of Si and Si/SiO_2 interfaces for thin film growth of such liquid crystalline molecules since the small rms roughness of annealed films is extremely beneficial from the device aspect if the film coverage were better. Due to the issues with the annealed films all devices were fabricated with as-is evaporated films of compounds (a).

2.6. Field-effect transistor performance

Thin film transistors were fabricated by vacuum deposition of compound (a). The devices were fabricated using a top-contact bottom gate structure. In this work no surface modification of the Si/SiO_2 layers were done and all organic films were grown at room temperature. The devices exhibit p-channel performance. Although the output transistor characteristics from FETs fabricated with compound (b) were similar to compound (a), the former exhibited large leakage currents. It is not clear whether the leakage current in compound (b) mainly originates from the morphology of the film owing to grain boundaries and whether this can be circumvented using different gate dielectric layers. Systematic studies for improving FET characteristics using different surface modification and gate dielectrics from both compounds are in progress.

Fig. 9 shows the transfer characteristics for a forward and reverse sweep from an OFET using compound (a); the inset shows the output characteristics where the drain-source voltages were swept from 0 to −20 V. The highest hole mobility, calculated from the saturation regime (V_{DS} = −60 V), was estimated as 0.01 cm^2/Vs. The on/off ratio was obtained as 10^3 from I_{DS} at V_{GS} = 0 V and V_{GS} = −60 V; the threshold voltages were relatively low at

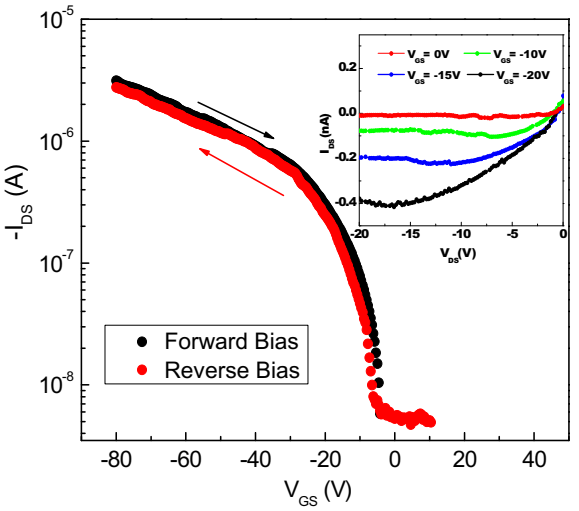

Fig. 9. The transfer characteristics for a forward and reverse sweep and output characteristics (inset) from an OFET fabricated using compound a.

~7 V. We point out that there is a lot of room for improvement for device performance. It is well established that surface modification by octyltrichlorosilane (OTS) or hexamethyldisilazane (HMDS) self-assembled monolayers can improve charge carrier mobilities and on/off ratios by more than an order of magnitude [67]. The results presented here are a proof of concept that the liquid crystalline benzothiazole compounds are excellent candidates for application in organic electronics.

3. Conclusions

Two new liquid crystalline donor–acceptor type benzothiazole derivatives have been synthesized by simple synthetic methods and characterized by optical absorption and photoluminescence spectroscopies, Raman scattering, differential scanning calorimetry, and thermogravimetric analysis. The field-effect transistor performance of one of the benzothiazole compounds shows that these materials have a great potential for future application in organic devices.

4. Experimental details

4.1. Synthesis

All chemicals were purchased from S.D. Fine Chemicals Ltd.; Mumbai, India and Spectrochem Pvt. Ltd.; Mumbai, India, except tributyltinchloride, $Pd(PPh_3)_4$ and potassium tert-butoxide which were bought from Sigma Aldrich.

^1H NMR and ^{13}C NMR spectra were recorded using Bruker 400 MHz. Chemical shifts were given in parts per million and coupling constants (J) in Hertz.

4.1.1. Synthesis of 2-(4-((E)-2-(5-(5-decylthiophen-2-yl)thiophen-2-yl)vinyl)phenyl)benzo[d] thiazole (a)

To a solution of 5-(5-decylthiophen-2-yl)thiophene-2-carbaldehyde (1) (0.617 g, 1.08 mmol) and Wittig salt (2) (0.347 g, 1.03 mmol) in dry $CHCl_3$ was added t-BuO^-K^+ (0.139 g, 1.2 mmol) in ethanol at room temperature. After allowing the mixture refluxing for 4 h, water was added and extracted with $CHCl_3$. The organic phase was dried over sodium sulphate. After removal of the solvent, the residue was purified by silica gel column chromatography with 30% chloroform and hexane as the eluent. Yield 67%.

^1H NMR (400 MHz, $CDCl_3$): δ 8.02–8.00 (m, 3H), 7.85–7.83 (d, J = 8 Hz, 1H), 7.51–7.49 (d, J = 8 Hz, 2H), 7.45–7.41 (dt, 1H), 7.34–7.30 (dt, 1H), 7.23–7.19 (d, J = 16 Hz, 1H), 6.95–6.39 (m, 3H), 6.84–6.80 (d, J = 16 Hz, 1H), 6.62–6.60 (d, J = 8 Hz, 1H), 2.75–2.71 (t, J = 8 Hz, 2H), 1.63–1.53 (m, 4H), 1.30–1.18 (m, 12H), 0.83–0.80 (t, J = 8 Hz, 3H).

^{13}C NMR (400 MHz, $CDCl_3$): δ 146.00, 140.71, 137.63, 129.53, 128.10, 127.95, 127.72, 126.40, 125.20, 124.90, 123.47, 123.44, 123.41, 121.61, 31.88, 31.58, 30.19, 29.55, 29.32, 29.06, 22.67, 14.10.

ESIMS [Found: m/z 542.1 $[M+H]^+$, Calcd. for $C_{33}H_{35}NS_3$ $[M+H]^+$: 541.19.

Anal. Calcd. for $C_{33}H_{35}NS_3$: C, 73.15; H, 6.51; N, 2.59; S, 17.75. Found C, 71.84; H, 6.19; N, 3.64; S, 16.10.

4.1.2. Synthesis of 2-(4-(5-(5-decylthiophen-2-yl)thiophen-2-yl)phenyl)benzo[d]thiazole (b)

Tributyl(5-(5-decylthiophen-2-yl)thiophen-2-yl)stannane (3) (0.515 gm, 0.86 mmol) and 2-(4-bromophenyl)benzo[d]thiazole (4) (0.250 g, 0.86 mmol) were dissolved in 25 ml of dry DMF. $Pd(PPh_3)_4$ (50 mg, 0.04 mmol) was added and the mixture was stirred for 16 h at 95 °C. After cooling to room temperature the solvent was removed in rotavapor and the yellow color solid compound was purified by column chromatography (SiO_2/chloroform:Hexane (v:v 1:1)) to give b as a yellow solid. Yield 65%.

^1H NMR (400 MHz, $CDCl_3$): δ 8.11–8.045 (m, 3H), 7.93–7.91 (d, J = 8 Hz, 1H), 7.72–7.70 (d, J = 8.3 Hz, 2H), 7.52–7.49 (dt, 1H), 7.41–7.38 (dt, 1H), 7.33–7.32 (d, J = 3.7, 1H), 7.11–7.10 (d, J = 3.7 Hz, 1H), 7.05–7.04 (d, J = 3.5 Hz, 1H), 6.71–6.70 (d, J = 3.4 Hz, 1H), 2.82–2.79 (t, J = 8 Hz., 2H), 1.71–1.66 (m, 4H), 1.36–1.19 (m, 12H), 0.89–0.86 (t, J = 6.9 Hz, 3H).

^{13}C NMR (400 MHz, $CDCl_3$): δ 146.32, 140.94, 138.79, 136.37, 134.22, 128.15, 126.45, 125.75, 125.26, 124.76, 124.00, 123.68, 123.12, 121.61, 31.90, 31.59, 30.21, 29.55, 29.34, 29.08, 22.67, 14.09.

ESIMS [Found: m/z 516.2 $[M+H]^+$, Calcd for $C_{31}H_{33}NS_3[M+H]^+$: 515.17.

Anal, Calcd. for $C_{31}H_{33}NS_3$:C, 72.19; H, 6.45; N, 2.72; S, 18.65. Found C, 72.26; H, 6.29; N, 3.33; S, 18.21.

4.2. Instrumental analysis

Thermal properties were studied under nitrogen atmosphere on Mettler DSC-1 instrument. Thermal gravimetric analysis (TGA) was conducted on Mettler Toledo TGA/SDTA 851e (temperature rate 10° C/min under N_2). The electrochemical properties of both the molecules were examined by using cyclic voltammetry (CH instrument). The electrolyte solution employed were 0.1 M Bu_4NPF_6/THF solution using platinum as working electrode and Ag/Ag+ as the reference electrode at a scan rate of 100 mVs^{-1} under Argon atmosphere.

Absorption spectra were recorded on Perkin Elmer (Lambda 35) UV–Vis Spectrometer and fluorescence emission spectra were recorded by using Perkin Elmer Spectrofluorophotometer (LS 50B) for both solution as well as solid state. Films of the two molecules were fabricated on quartz substrate from orthodichlorobenzene solution by spin casting. The absorption and fluorescence spectra of solution state were taken in chloroform (conc. 1×10^{-5} mol/L). Optical polarizing microscopic images of liquid crystalline phase were taken by Olympus- BX-51 polarizing microscope.

The AFM measurement was performed with a Nanoscope IIIa (Veeco Instruments, Inc.) operating in the tapping mode. Commercial ultra-sharp, rectangular silicon cantilevers made by Micromasch ($250 \times 35 \times 1.7$ μm^3) were used having a nominal spring constant of ~0.35 N/m and a resonance frequency of ~33 kHz.

The Raman spectra were collected using an Invia Renishaw spectrometer attached to a confocal microscope with $a \times 50$ long working distance objective and a 785 nm line

of a diode laser as the excitation wavelength. Typical laser power was a few mW on the sample.

OFET Fabrication: The devices were fabricated using a top-contact bottom gate structure with gold source and drain electrodes. A heavily p-doped silicon (1 0 0) wafer was used as the gate electrode with 200 nm bare SiO_2 layer as the gate dielectric insulator. Thin films (100 nm) of compound (a) were deposited on SiO_2 by vacuum sublimation at a rate of 0.2 Å/s under a pressure of 10^{-6} mbar. The substrate was kept at room temperature. Patterned Au layers of thickness 60 nm were deposited for the source (S)–drain (D) contacts. Typical S–D channel length (L) and width (W) for OFETs were 500 μm and 5 mm, respectively. The device characteristics were measured at room temperature with two source meters, Keithley 2400 and Keithley 236, configured together using a program written in LabView. The source–drain current and the source-gate leakage currents were measured with Keithley 236, which has a resolution of 10 fA.

Organic single crystal
Solution-grown crystals

ABSTRACT

Organic semiconducting molecules are receiving a large attention because of their potential applications, spanning from OLEDs to plastic photovoltaics to bio-chemical sensors. However, the electronic transport properties of these materials are still not fully understood, and organic single crystals (OSCs) may represent model materials for assessing the charge transport mechanisms, thanks to their high purity and molecular order. Here we show for the first time that solution-grown, millimiter-sized organic single crystals of 4-hydroxycyanobenzene (4HCB) possess a clear and reproducible three-dimensional anisotropy in their main transport parameters: (i) charge carrier mobility, (ii) distribution of the electronic density of states and (iii) deep traps energy and concentration, and we report intrinsic-like three-dimensional mobility values for these crystals. These findings demonstrate that the electronic spatial anisotropy of OSCs extends well beyond the carrier mobility, and open the way to the development of novel electronic device architectures based on the simultaneous exploitation of different electronic responses along the three spatial directions of the crystal.

1. Introduction

Organic semiconductors are considered promising materials for implementing low-cost and large-scale produced electronics [1–8]. Among the most attractive prospects in this field are the possibility of tailoring functionalities by molecular design [9] and the realization of flexible devices [10–12], distinctive and unique features that open the way to the attainment of versatile and multifunctional electronic systems. However, in order to achieve this goal, a number of issues relative to the charge transport in organic materials are yet to be clarified. In particular, a clear and well defined comprehension of the electronic behaviour of these materials (including a complete description of the fundamental electronic states of the charge carriers) has still to be gained and related to their structural properties.

In this view, organic single crystals (OSCs) offer the possibility to effectively probe the electronic behaviour of organic materials. In fact, thanks to their long-range molecular order, they limit charge carrier trapping and hopping phenomena due to grain boundaries, interfaces and structural imperfections, and provide an almost ideal work bench for the study of intrinsic electronic transport. Nonetheless, the low symmetry of organic molecules leads to anisotropically packed crystal structures, that affect their transport properties (for example, the direction of the strongest π-orbitals overlap usually coincides with the direction of the highest carrier mobility [13–19]). This asymmetry, on one hand introduces difficulties in a clear understanding of the transport behaviour of organic semiconductors, but on the other hand it offers the tool to investigate the correlation between the three-dimensional molecular stacking order of OSCs and their recently found

anisotropic electronic transport properties. In particular, in the last years different mobilities have been measured along the two dimensions (2D) in the main crystal plane for micro- or nanometer sized organic single crystals, either vapour deposited [13–19] or solution-grown [20–22].

These findings, associated to the intrinsic three-dimensional (3D) molecular asymmetry and packing anisotropy of OSCs, suggest that the anisotropic behaviour of the electronic transport could actually extend into the 3D realm. Indeed, we have recently showed that 4-hydroxycyanobenzene (4HCB) single crystals exhibit a three-dimensional anisotropic mobility, although this has been assessed using two different measurement techniques along the three crystallographic directions [23].

Another point to be considered when dealing with OSCs transport properties is that hardly avoidable differences in the crystal growth conditions and in the experimental method used to determine the mobility (usually based on a field effect transistor, FET) lead to significant discrepancies in the carrier mobility values reported for the same type of OSC (e.g. for rubrene single crystals: [7,13–17,19,24–27]). In fact, the device fabrication processes and the defects at the crystal/gate dielectric interface unpredictably affect the absolute measured mobility, as well as its reproducibility [7,15,17,26,28]. The already mentioned inherent structural anisotropy of OSCs introduces additional complexity to this issue.

Finally, besides carrier mobility other transport parameters are of fundamental importance in determining the electronic behaviour of a semiconductor: the density of states (DOS) distribution, the concentration of the electrically active electronic states and their energy level have to be known in order to develop a consistent charge transport model. This knowledge becomes even more fundamental if the mentioned parameters vary along the three different dimensions in space, especially if novel electronic device architectures have to be developed. For example, monocrystal-based, single gated devices capable of delivering source-drain responses where the gain depends on the spatial direction along which the electrodes are aligned, may be envisaged as useful tools for lowering the amount of components of a single chip. However, up to date, a full assessment of the 3D anisotropy of the carrier transport properties of OSCs is still lacking.

In this work we show that, by means of Space Charge-Limited Current (SCLC) and photocurrent spectroscopy analyses, it is possible to carry out on solution-grown, macroscopic 4-hydroxycyanobenzene (4HCB) single crystals (Fig. 1) a complete characterization of several key electronic transport parameters. In particular, we determine (i) the majority carrier mobility, (ii) the density of states (DOS) distribution of the intrinsic electronic states, (iii) their concentration and (iv) their energy levels in the band gap. We bring to evidence that all of these properties are clearly anisotropic in the crystal three dimensions, with very good reproducibility over more than 30 different crystals. Moreover, we compare the carrier mobilities found along the two main crystal axes *a* and *b* using the SCLC method with the corresponding ones determined on 4HCB crystals by means of the air–gap FET technique [22,23]. From this comparison, the remarkable agreement between the two sets of values obtained with two different and independent experimental techniques points to the likely intrinsicity of the found mobility values.

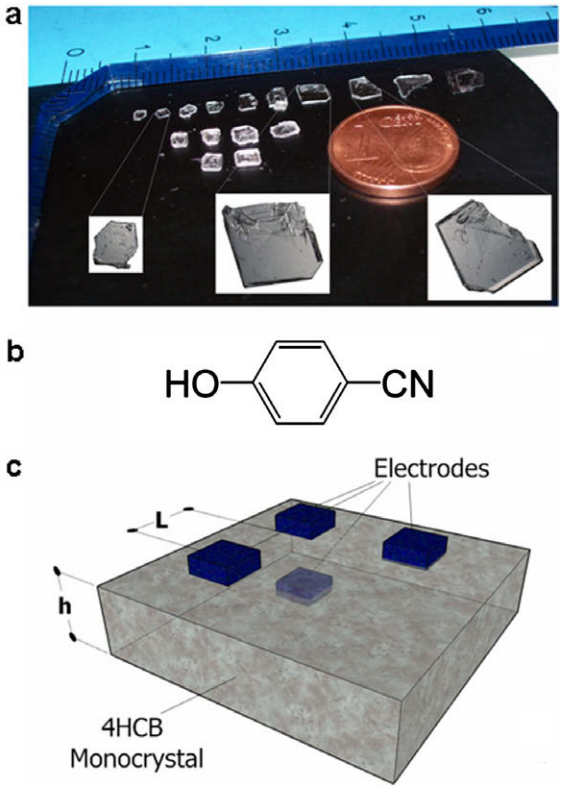

Fig. 1. (a) Examples of solution-grown 4HCB single crystals investigated in this work, (b) chemical structure of 4-hydroxycyanobenzene (4HCB) and (c) layout of the electrical contacts used for the electronic transport characterization.

2. Experimental

4HCB was purchased from FLUKA (99+%). The raw material was dissolved in pure ethylic ether (technical grade), and the solvent was allowed to slowly evaporate under a hood in standard laboratory conditions. The resulting 4HCB crystals have been washed thoroughly with warm petroleum ether. About 150 mg of so-purified 4HCB crystals were dissolved in 10 ml of ethylic ether, filtered through a 0.45 μm Teflon filter and left in a 500 ml beaker covered by a petri dish, at controlled temperature (approximately 6 °C) for about 48 h. A complete and slow evaporation of the solvent delivered beautiful and transparent crystals, left on the bottom of the beaker. Following this procedure, crystals with thickness varying from 150 μm to 600 μm may be grown. The higher the concentration of 4HCB in ether, the bigger (in size and thickness) the obtained crystals. The crystals have been gently removed from the beaker using a spatule, and used for the preparation of the devices with no further treatment. The molecular packing and orientation of the 4HCB crystals with respect to the crystal axes have been investigated by X-ray diffraction measurements, that assessed a clear

3D packing anisotropy [22]. The thickness of the crystals has been measured by optical microscopy methods.

All the electrical measurements reported in this paper have been done at room temperature in darkness using a Keithley Source-Meters 2400 and Electrometers 617 and 6512. Data were acquired at a slow gate voltage sweep, with different sweep rates. No significant hysteresis or time relaxation were observed. The ohmic contacts on 4HCB were fabricated using silver epoxy (Epo-Tek E415G) at a fixed distance, in order to form pairs of contact pads perpendicular to each other (Fig. 1c).

As already reported in the literature [22] the performance of the air–gap FETs fabricated with these contacts assessed the p-type conductivity of the material and the good hole injecting properties of the electrical contacts. Spectral photocurrent (PC) measurements were carried out in the planar configuration with an optical flux of 1×10^{13} photons/cm^2 at $\lambda = 450$ nm. PC spectra were recorded in air at 295 K. The low-level injection conditions ensured that no alteration in the crystal electrical response was induced by the PC measurements, as assessed by comparing many consecutively acquired PC spectra. A good reproducibility of the electrical measurements has been assessed over many tested crystals. No sign of permanent ageing or degradation of the crystals was observed, neither from the *I–V* curves nor from PC analyses.

3. Results and discussion

We have carried out current–voltage analyses using the Space Charge-Limited Current (SCLC) method [29,30] along all of the three spatial direction of 4HCB crystals. SCLC is a relatively easy-to-handle room temperature method that, if properly applied, allows to determine several relevant bulk transport parameters of OSCs, such as the carrier mobility and the concentration, the energy and density of states distribution of the dominant deep traps [31,32]. SCLC curves have a symmetric character for positive and negative biases and are characterized by a linear region (ohmic) followed by a Space Charge Limited (SCL) one and finally by the Trap-Filled-Limited (TFL) region, when a steep increase of the current occurs (Fig. 2). Such a behaviour is related to the balance between thermally generated and injected carriers, and to the occupation of the dominant deep traps in the material. At $V \geqslant V_{TFL}$ (the voltage at which the SCL/TFL transition occurs) the charge injected by the contacts fills all the traps and the transport enters the trap-free regime, with a sharp current increase. For a given distribution of states, the equations describing the SCL *J–V* characteristics can be obtained by solving simultaneously the current equation and the Poisson's equation. In order to do so, however, the following assumptions are usually introduced: (i) to consider unipolar majority carrier transport (holes in our case [22]); (ii) to neglect the density of thermal carriers with respect to injected carriers; and (iii) to assume the diffusion term in the current equation to be small with respect to the drift term.

Two different sample geometries can be used for SCLC measurements, i.e. the sandwich-like one (with electrical contacts on opposite sides of the crystal) and the planar gap-like one (with the two contacts on the same surface) [31–34]. In the sandwich geometry the transport is assumed to be one-dimensional and follows the Mott and Gurney model [35], that describes transport in bulk material:

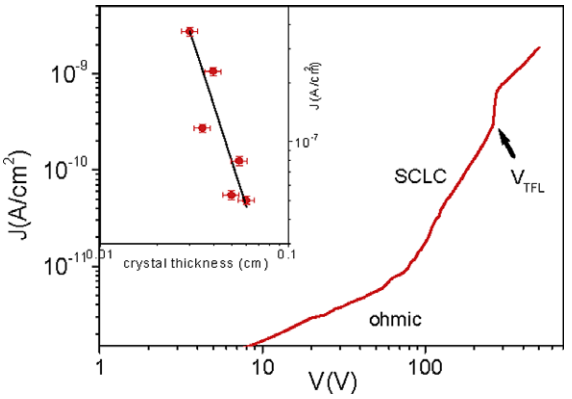

Fig. 2. Typical SCLC characteristic of a 4HCB single crystal. The ohmic, SCLC and Trap-Fill-Limited Voltage (V_{TFL}) are highlighted. The inset shows the L^{-3} dependence of the measured current as a function of the crystal thickness, assessing the occurrence of proper bulk conduction during the SCLC analyses.

$$J = \frac{9}{8}\varepsilon\mu\frac{V^2}{L^3}$$

where *J* is the current density for the applied voltage *V*, *L* is the thickness of the organic layer (electrode separation), ε is the dielectric constant of the material and μ is the carrier mobility. In the planar geometry, the transport is two-dimensional (2D) and has been modelled by Geurst [36] as:

$$J = \frac{2}{\pi}\varepsilon\mu\frac{V^2}{L^2} \quad (1)$$

where *L* is the electrodes separation (see Fig. 1c). In this case the thickness of the organic layer, *h*, becomes a key parameter for the determination of the type of transport: for $L/h > 200$ the 2D law (Eq. (2)), will dominate the carrier transport, while bulk, 1D transport (Eq. (1)) occurs if $L/h < 10$ [33]. We applied these models to our data and, since the thickness of the examined 4HCB crystals varied between 150 and 600 μm, L/h was always small enough to grant 1D transport also in the planar electrode configuration.

A typical curve measured in the sandwich geometry along axis *c* of a 350 μm thick 4HCB crystal is shown in Fig. 2, where the ohmic, SCLC and TFL regimes are highlighted. The inset of Fig. 2 reports the L^{-3} dependence of the measured current as a function of the crystal thickness, at a constant electric field of 9×10^3 V/cm, and assesses the occurrence of proper bulk conduction transport during SCLC analyses [30,32]. SCLC measurements on axes *a* and *b* were carried out in the planar electrode configuration.

The intrinsic-like carrier mobility μ_{SCLC} can be obtained from Eq. (1) calculated at $V = V_{TFL}$. We have measured SCLC curves along axes *a*, *b* and *c* over 30 different (in size and thickness) crystals, finding maximum mobility values of

1×10^{-1}, 4×10^{-2} and 2×10^{-5} cm^2/Vs, respectively (Table 1, column μ_{SCLC}–Max). The average mobility values for each axis are also reported in Table I (column μ_{SCLC}–Ave), and both the maxima and average values show clear anisotropic behaviour along the three different crystal directions.

We recently reported anisotropic mobilities in similar 4HCB crystals measured with air–gap FETs (columns μ_{FET}-Max and -Ave in Table 1) [23]. Air–gap FETs offer the advantage of reducing the influence of the interface with the gate dielectric, that usually lowers the effective mobility value [7,15,17,26,28].

A comparison between the μ_{SCLC} and the FET-measured one (μ_{FET}) brings to evidence that: (i) for each axis the SCLC-measured mobility is always higher or, in the worst case, equal to the FET-determined one. These observations point to the intrinsic nature of the mobility values determined by SCLC, to the reliability of the SCLC technique as a mobility measurement tool and to the overall good electronic quality of solution-grown 4HCB crystals; (ii) both FET and SCLC measurements deliver maximum and average values that do not differ much. The limited difference between the μ_{SCLC} and the μ_{FET} values confirms that air–gap OFETs may provide a mobility measurement tool able to minimize interface effects induced by the gate dielectric [7,26,28], one of the major cause for mobility reduction in OFETs.

Fig. 3 shows the mobility measured along each one of the three axes of the very same crystal for three different crystals, highlighting a marked and reproducible 3D anisotropic transport in each of the three. It is also noteworthy that each crystal has been repetitively measured along the three axes, providing reproducible results. The consistency of the measured values over several different crystals, which even had different dimensions, confirms that the measured mobilities may be actually considered as intrinsic to the crystal, and that the measurements did not affect their electronic properties, although all the tests were carried out in normal laboratory atmosphere and at room temperature.

Another very important transport parameter that can be obtained from the SCLC method is an estimate of the density of electrically active traps in the material, N_T, using the relation $N_T = \varepsilon V_{TFL}/(eL^2)$, where e is the electron charge, with the underlying assumption that the traps are uniformly distributed in the material. We thus calculated N_T for each crystallographic axis and the average trap density found along each crystallographic axis is reported in Table 1 (column N_T). While along axis a and axis b the concentration of traps is substantially comparable, the same parameter is one order of magnitude higher for axis c. These findings are in line with the higher mobilities found along axes a and b with respect to axis c, and confirm the inherently anisotropic nature of the electronic parameters of OSCs.

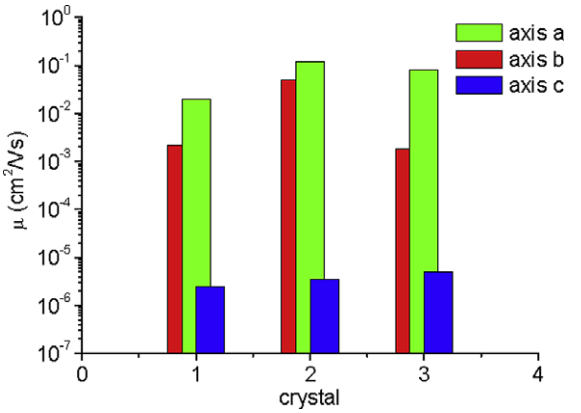

Fig. 3. Charge carrier mobility measured by SCLC along the three different spatial directions on the same crystal for three different crystals, clearly showing the anisotropy and reproducibility of the measurements.

The shape of the SCLC curve reflects the increment of the space charge with respect to the shift of the Fermi level as a function of the applied bias, and thus mirrors the energy dependence of the density of states (DOS) distribution. By analyzing the SCLC curves with a differential analysis method developed by Nespurek and Sworakowky [37,38], it is possible to extract an energy distribution of states $h(E_F)$ directly from a single current–voltage curve:

$$h(E_F) = \frac{x_1 x_2 \varepsilon V}{2eL^2 kT(m-1)} \tag{2}$$

The position of the Fermi level, E_F, can be obtained using the following equation:

$$E_F = kT \ln \frac{L}{x_1 N_v e \mu} + kT \ln \frac{J}{V} \tag{3}$$

where is $m = d(\ln J)/d(\ln V)$, $x_1 = (2m-1)/m$, $x_2 = (m-1)/m$ and N_V is the effective density of states in the highest occupied molecular orbital (here $N_V = 5 \times 10^{21}$ cm^{-3}).

We have hence analyzed the SCLC curves obtained along the 3 crystal axes according to this model, and we have obtained the three DOS distributions shown in Fig. 4. One has to keep in mind that by assuming a unipolar

Table 1
Charge carrier mobility μ_{SCLC} and trap density N_T, obtained from the SCLC analysis of J–V curves with the Mott–Gurney theory for the three crystal axes a, b and c. N_T^* is the trap density evaluated from the differential analysis of SCLC curves. μ_{FET} is the charge carrier mobility obtained from OSC FET measurements. Average values, measured over 30 crystals.

Crystal axis	μ_{FET} (cm^2/Vs)[23]		μ_{SCLC} (cm^2/Vs)		N_T (cm^{-3})	N_T^* (cm^{-3})
	Max.	Ave.	Max.	Ave.

b	9×10^{-3}	5×10^{-3}	2×10^{-2}	6×10^{-3}	1×10^{11}	4×10^{12}
c	–	–	2×10^{-5}	5×10^{-6}	5×10^{12}	2×10^{13}

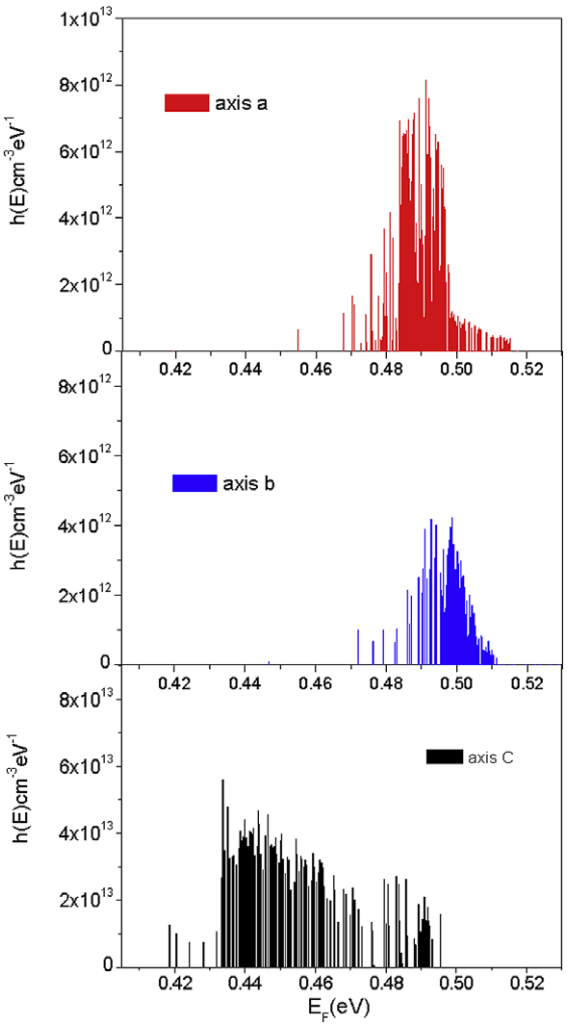

Fig. 4. The DOS distribution of the electrically active states obtained from SCLC measurements along the three spatial directions of 4HCB crystals, showing an anisotropic energy distribution and concentration of states.

majority carrier type conduction (holes in our case), the method of Nespurek and Sworakowski allows to reveal only the deep states that interact with the majority carrier band (the valence band in our case) This means that the peak energies in the $h(E_F)$ functions shown in Fig. 4 correspond to the dominant hole deep states.

In the planar axis *a* the DOS is centered at an energy of (0.49 ± 0.01) eV, along axis *b* at an energy of (0.50 ± 0.01) eV, while along axis *c* the DOS is shifted at (0.45 ± 0.02) eV (the associated error is estimated from the scattering of the data within the various investigated crystals). Trap states at comparable energies have been recently reported along one of the axes of rubrene single crystals [32,39] and in pentacene [40]. Further evidence on the presence of deep electrically active states in 4HCB crystals is provided by spectral PC analyses, that we carried out along axes *a* and *b* on the same crystal. The photoconductivity yield spectrum is reported in Fig. 5, showing the HOMO–LUMO transport edge located at 4.5 eV, followed by exciton related features at energies >4.0 eV. A large band of deeper states is clearly visible at lower energies in the spectrum, starting at 4.0 eV and peaking at approx. 0.50 eV from the HOMO–LUMO gap, a value in line with the results obtained from the above reported SCLC analyses on the DOS energy distribution. In addition, from Fig. 5 it is also evident that the number of electrons excited per incident photon is larger along axis *a* than along axis *b*, again in good agreement with the DOS distributions reported in Fig. 4, where the density of states is higher along *a* than along *b*.

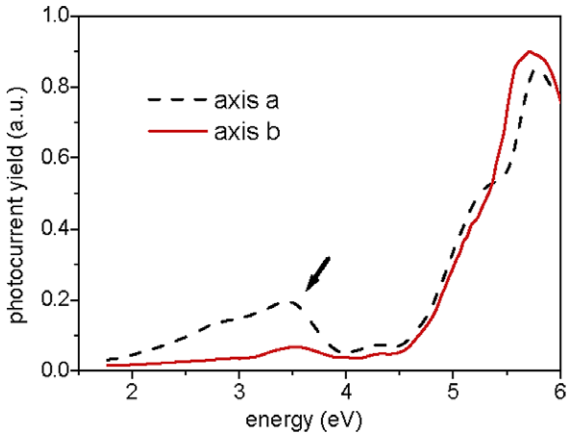

Fig. 5. Photocurrent yield as a function of the incident photon beam energy for 4HCB single crystals, along the two planar direction of the crystals, axis *a* (dotted line) and axis *b* (solid line). The arrow highlights the peak associated to the band of states located in the band-gap corresponding to the DOS distribution found by SCLC analyses.

The $h(E_F)$ distribution represents the actual density of trapped carriers $N_T(E)$ [30,32] and it is hence possible to exploit it to obtain trap density values along the three axes *a*, *b* and *c*, $N^*_{Ta,b,c}$ more accurate than the previously calculated ones. In fact, the density of traps $N_{Ta,b,c}$ extracted from the V_{TFL} method and reported in Table 1 is often underestimated, due to inhomogeneities in the trap distribution and to the occurrence of Poole–Frenkel effects at voltages close to V_{TFL}, that hinder a complete filling of all the traps [41]. The more accurate determination of the trap densities $N^*_{Ta,b,c}$, also reported in Table 1 for the three crystal axes, delivers again anisotropic values along the three crystal axes, and in line (although, as expected, higher in absolute values) with the corresponding $N_{Ta,b,c}$.

4. Conclusions

In conclusion, we have grown from solution high quality, millimiter-sized organic single crystals of 4HCB that allowed us to carry out a complete 3D characterization of their electrical transport properties. By means of SCLC measurements we evidenced a clear 3D anisotropy for several main electronic transport parameters of the crystals, namely (i) the charge carrier mobility, (ii) the DOS distribution of the electrically active deep states, (iii) the concentration and (iv) the energy of dominant carrier traps. We reproducibly determined these parameters along the three different crystal axes over a large number of samples,

using a differential analysis of SCLC curves and photocurrent spectroscopy to investigate the energy states in the *a*–*b* plane, and we showed examples of anisotropic mobilities measured in all the three dimensions of the same single 4HCB monocrystal. Moreover, the comparison between the mobility values obtained by SCLC analyses and by air–gap OFET measurements demonstrate a remarkable agreement, confirming that air–gap OFET measurements consistently reduce the effects of interface states on the mobility. Finally, the permanence of anisotropic 3D mobility even after repeated *I*–*V* measurements demonstrates the fair robustness of the 4HCB solution-grown crystals under room temperature and atmosphere conditions.

These results indicate that solution-grown, macroscopic and easily obtainable 4HCB organic single crystals may be considered as model compounds for a deeper understanding of the anisotropic transport behaviour of organic semiconductors. As an outlook, the here demonstrated 3D electronic anisotropy of OSCs opens the way towards the realization of novel electronic devices, based on the exploitation and control of transport parameters that differ in the three spatial directions, for fully functional 3D device architectures.

ABSTRACT

We have shown that triazine compounds of 2-biphenyl-4-yl-4,6-bis-(4′-pyridin-2-yl-biphenyl-4-yl)-[1,3,5]triazine (DPT) and 2,4-bis-biphenyl-4-yl-6-(4′-pyridin-2-yl-biphenyl-4-yl)-[1,3,5]triazine (MPT) work as excellent electron-transport layers (ETLs) of organic light-emitting diodes (OLEDs). By replacing a typical ELT of tris(8-hydroxyquinoline) aluminum (Alq_3) with the DPT ETL and the MPT ETL, driving voltages and power conversion efficiencies of OLEDs operated at a current density of 50 mA cm^{-2} are improved from 7.7 ± 0.2 V and 1.41 ± 0.10 lm W^{-1} (Alq_3) to 6.0 ± 0.1 V and 1.62 ± 0.09 lm W^{-1} (DPT) and 5.2 ± 0.1 V and 1.88 ± 0.18 lm W^{-1} (MPT), respectively. Half lifetimes of the OLEDs operated at the same current are also enhanced from 3200 h (Alq_3) to 4200 h (MPT) by using the MPT ETL. The reduction in driving voltage is found to arise from more efficient electron injection at interfaces of DPT/cathode (a barrier height of ≈0.61 eV) and MPT/cathode (a barrier height of ≈0.51 eV) than at an interface of Alq_3/cathode (a barrier height of ≈0.73 eV) as well as better electron mobilities of DPT (8.7×10^{-5} cm^2 V^{-1} s^{-1} at an electric field of 5.0×10^5 V cm^{-1}) and MPT (1.4×10^{-4} cm^2 V^{-1} s^{-1} at the same field) than that of Alq_3 (4.1×10^{-6} cm^2 V^{-1} s^{-1} at the same field [Naka et al., Synth. Met. 111–112 (2000) 331.]). A high-mobility electron-transport material of 4,7-diphenyl-1,10-phenanthroline (BPhen) is also used as an ETL for comparison of OLED characteristics.

1. Introduction

Although organic light-emitting diodes (OLEDs) have been significantly developed over the last decade [1,2], driving voltages, power conversion efficiencies, and operational stability of OLEDs must be further improved for practical applications, such as flat panel displays. In general, organic materials used for OLEDs are basically insulators having carrier mobilities lower than 10^{-3} cm^2 V^{-1} s^{-1} [3–6]. Also, carrier injection barrier heights of several hundred meV are present at heterojunction interfaces of electrode/organic and organic/organic in OLEDs [7,8]. Therefore, high electric fields are required to overcome the low mobilities and the barrier heights, degrading the OLED performances. In particular, electron mobilities are known to be much lower than hole mobilities in most organic materials [3–6]. If a high-mobility electron-transport material (ETM) can be developed, it will be possible to further improve the OLED performances.

Various ETMs have been reported and used to date, such as oxadiazoles [9], triazoles [10], phenanthrolines [11], and triazines [12]. Klenkler et al. recently demonstrated that replacing tris(8-hydroxyquinoline) aluminum

doi:10.1016/j.orgel.2009.09.016

(Alq_3) with a triazine compound of 4,4′-bis-[2-(4,6-diphenyl-1,3,5-triazinyl)]-1,1′-biphenyl (BTB) as an electron-transport layer (ETL) can reduce driving voltages of OLEDs from 6.86 V to 4.51 V at a current density of 25 mA cm^{-2} [13]. Thus, we focus our attention on triazines among the ETMs due to their characteristics of wide energy gaps and high electron-transport [13,14]. From results of synthesizing and testing a wide variety of triazine derivatives, 2-biphenyl-4-yl-4,6-bis-(4′-pyridin-2-yl-biphenyl-4-yl)-[1,3,5]triazine (DPT) and 2,4-bis-biphenyl-4-yl-6-(4′-pyridin-2-yl-biphenyl-4-yl)-[1,3,5]triazine (MPT) are found to work as excellent ETLs of OLEDs. The chemical structures of DPT and MPT are shown in Fig. 1. Results of time-of-flight (TOF) measurements reveal that vacuum-deposited films of these triazines have very good electron mobilities of 8.7×10^{-5} cm^2 V^{-1} s^{-1} (DPT) and 1.4×10^{-4} cm^2 V^{-1} s^{-1} (MPT) at an electric field of 5.0×10^5 V cm^{-1}, which are one-to-two orders of magnitude higher than that of Alq_3 (4.1×10^{-6} cm^2 V^{-1} s^{-1} at the same field [4,6]), but are slightly lower than that of an ETL material, 4,7-diphenyl-1,10-phenanthroline (BPhen) (5.8×10^{-4} cm^2 V^{-1} s^{-1} at the same field [6]). Moreover, higher LUMO (lowest unoccupied molecular orbital) energy levels of DPT (-2.97 ± 0.02 eV) and MPT (-3.07 ± 0.02 eV) lead to efficient electron injection from a cathode when compared with Alq_3 (-2.85 ± 0.02 eV) and BPhen (-2.83 ± 0.02 eV). In other words, the electron mobilities and the electron injection barrier heights can be modified by changing the number of pyridine substitutes in a triazine framework.

In this study, we have shown that driving voltages of OLEDs operated at a current density of 50 mA cm^{-2} are reduced from 7.7 ± 0.2 V (Alq_3) to 7.0 ± 0.2 V (BPhen), 6.0 ± 0.1 V (DPT), and 5.2 ± 0.1 V (MPT) by replacing the typical Alq_3 ETL with the ETLs of BPhen, DPT, and MPT due to the enhanced electron injection and/or transport. Power conversion efficiencies at 50 mA cm^{-2} are also improved from 1.41 ± 0.10 lm W^{-1} (Alq_3) to 1.55 ± 0.07 lm W^{-1} (BPhen), 1.62 ± 0.09 lm W^{-1} (DPT), and 1.88 ± 0.18 lm W^{-1} (MPT) due to the voltage reduction mentioned above. Among OLEDs investigated in this study, an OLED with the MPT ETL has the longest half lifetime of 4200 h under operation at 50 mA cm^{-2}. For better understanding of the improved OLED performances, details of optical, electrical, and thermal characteristics of DPT and MPT are investigated.

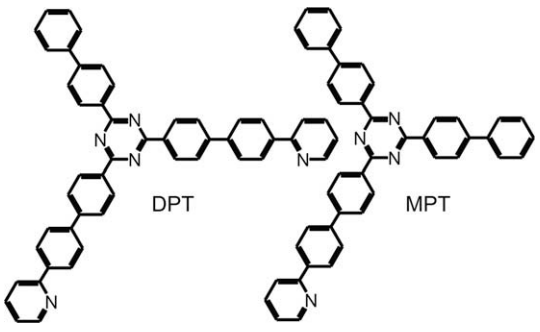

Fig. 1. Chemical structures of molecules of DPT and MPT.

2. Experimental

The devices (A)–(F), whose structures are shown in Fig. 2a, were fabricated using a vacuum deposition condition as previously reported in Ref. [15]. The ITO, the α-NPD, and the LiF stand for indium tin oxide as a hole-injecting anode layer, *N*,*N*′-diphenyl-*N*,*N*′-bis(1-naphthyl)-1,1′-biphenyl-4,4′-diamine as a hole-transport layer (HTL) [16], and lithium fluoride as an electron injection layer (EIL) [17], respectively. Since use of a very thin hole-injection layer (HIL) of molybdenum oxide (MoO_3) can improve both driving voltages, power conversion efficiencies, and operational stability of OLEDs [15,18,19], a 0.75 nm MoO_3 HIL was introduced between the ITO and the α-NPD for all devices. The completed devices were encapsulated together with an oxygen and moisture absorbing desiccant sheet using a glass cap and an ultraviolet curing epoxy resin inside a nitrogen-filled glove box. The driving voltages, the current densities, the external quantum efficiencies, the luminance, and the power conversion efficiencies of the devices were measured using conditions as previously reported in Ref. [15]. The changes in voltage and luminance with operational time were measured under dc driving of (A)–(F) at 50 mA cm^{-2} at room temperature to estimate the voltage increase rates and the half lifetimes, at which the luminance drops to one-half of the initial luminance.

To investigate the electron injection and transport characteristics of Alq_3, BPhen, DPT, and MPT, the electron-only devices (I)–(VIII), whose structures are shown in Fig. 2b, were fabricated using a similar condition as previously reported in Ref. [15]. To prevent hole-injection from the ITO anode, 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) having a high ionization potential energy level of −6.25 eV was inserted as a hole-blocking layer (HBL) between the ITO and the ETL in (I)–(VIII). In fact, all electron-only devices exhibited no electroluminescence (EL) during their current density–voltage measurements.

3. Results and discussion

3.1. Optical, electrical, and thermal characteristics of DPT and MPT

The UV–vis absorption spectra and the fluorescence (FL) spectra of 50 nm films of DPT and MPT on quartz substrates are shown in Fig. 3. The films of DPT and MPT have the almost similar optical characteristics. The absorption peak wavelengths of DPT and MPT are 332 nm and 325 nm, respectively. The FL spectra of the films are nearly mirror images of the absorption spectra. The FL peak wavelengths of DPT and MPT are 431 nm and 424 nm, respectively [20]. Moreover, the ionization potential energy levels of DPT and MPT are measured to be -6.06 ± 0.02 eV and -6.25 ± 0.02 eV, respectively, using an AC-2 photoelectron yield spectrometer (Riken Keiki). The electron affinity energy levels of DPT and MPT are roughly estimated to be -2.97 ± 0.02 eV and -3.07 ± 0.02 eV, respectively, by subtracting the absorption onset energies [≈3.09 eV (400 nm) for the DPT film and

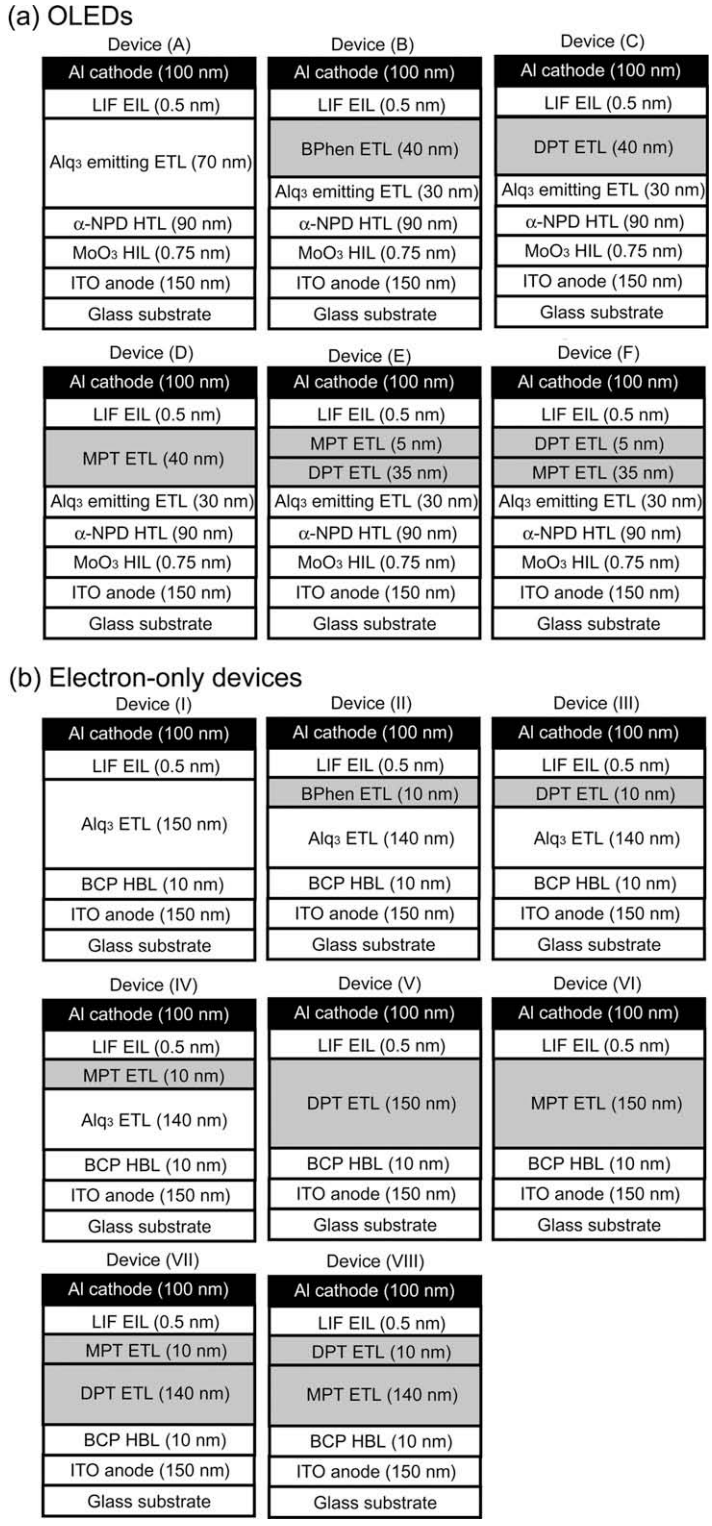

Fig. 2. Schematic structures of (a) OLEDs (A)–(F) and (b) electron-only devices (I)–(VIII).

≈3.18 eV (389 nm) for the MPT film] from the ionization potential energy levels.

The energy-level diagrams of the OLEDs and the electron-only devices estimated using the above-mentioned technique are depicted in Fig. 4a and b, respectively. The smaller-energy-gap layer of Alq_3 (≈2.86 eV) is sandwiched between the wider-energy-gap layers of α-NPD (≈3.05 eV), BPhen (≈3.38 eV), DPT (≈3.09 eV), and MPT (≈3.18 eV),

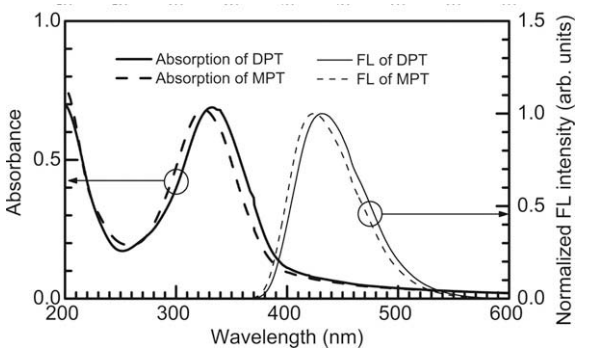

Fig. 3. UV–vis absorption spectra and FL spectra of vacuum-deposited films of DPT and MPT on quartz substrates. FL spectra were measured using excitation light wavelengths at absorption maxima.

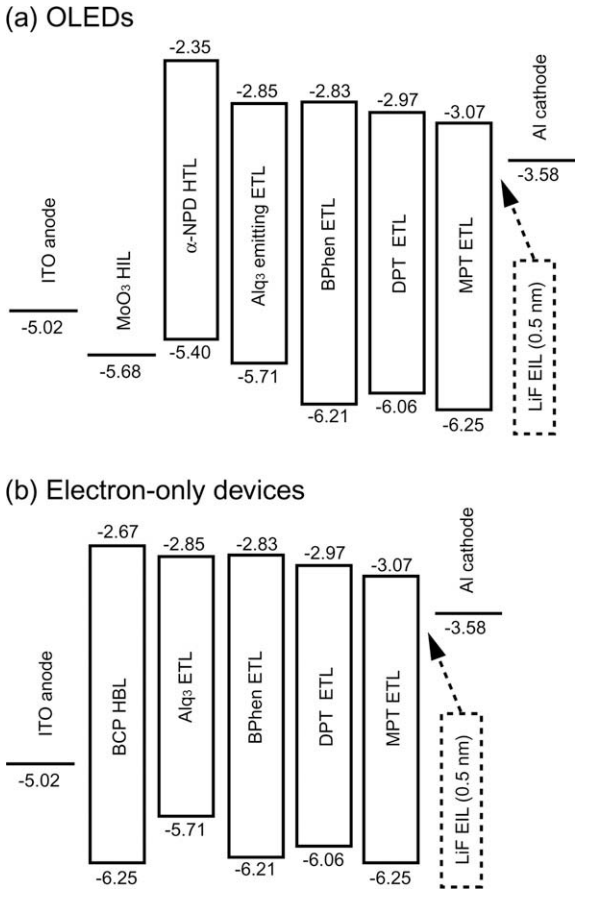

Fig. 4. Energy-level diagrams of (a) OLEDs (A)–(F) and (b) electron-only devices (I)–(VIII).

indicating that Alq_3 excitons are well confined in the Alq_3 layer. Moreover, the electron injection barrier heights at the interfaces of Alq_3/Al, BPhen/Al, DPT/Al, and MPT/Al are calculated to be ≈0.73 eV, ≈0.75 eV, ≈0.61 eV, and ≈0.51 eV, respectively, from the differences between the electron affinity energy levels of the ETLs and the work function energy level of the Al cathode (Fig. 4a). Comparing these barrier heights, more efficient electron-injection is expected to occur at the interfaces of DPT/Al and MPT/Al than at the interfaces of BPhen/Al and Alq_3/Al. It is noted that these barrier heights may be overestimated since a LiF EIL has been used between an ETL and an Al cathode layer to enhance electron injection from Al [17]. However, we suppose that the qualitative comparison of the electron-injection characteristics is possible using the above-mentioned barrier heights.

In addition to the smaller electron injection barrier heights, the films of DPT and MPT have very good electron transport abilities. The electron mobilities of the films are analyzed using structures of glass substrate/ITO (110 nm)/DPT (870 nm) or MPT (1550 nm)/Al (100 nm) with a TOF measurement condition as previously reported in Ref. [5]. The electron transients of DPT and MPT have less clear plateaus (Fig. 5a). The electron transit time (t_{TR}) of DPT and MPT is estimated from a change in slope in the double logarithmic plots as shown in Fig. 5b. The electron mobilities (μ) of the films under a wide range of electric fields are determined from the relationship [4–6] $\mu = L^2/(t_{TR}V)$ (1), where L is the cathode–anode spacing and V is the voltage. The μ of these films is found to be field dependent (Fig. 5c). Here, the field-dependent mobility [4–6] can be expressed as $\mu = \mu_0 \exp(\beta E^{0.5})$ (2), where μ_0 is the zero field mobility, β is the field dependence parameter, and E is the electric field. Fitting the μ-$E^{0.5}$ plots with Eq. (2) yields $\mu_0 = 3.6 \times 10^{-6}$ cm^2 V^{-1} s^{-1} and $\beta = 4.5 \times 10^{-3}$ cm$^{0.5}$ V$^{-0.5}$ (DPT) and $\mu_0 = 5.8 \times 10^{-6}$ cm^2 V^{-1} s^{-1}

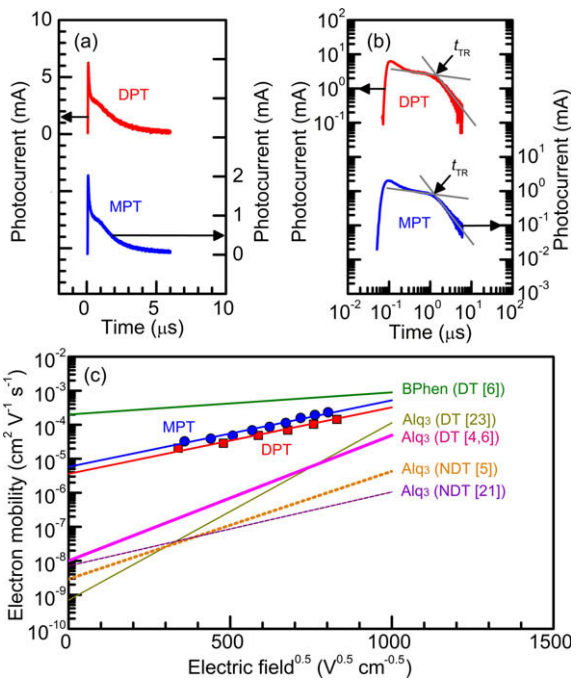

Fig. 5. (a) Double linear plots and (b) double logarithmic plots of TOF electron transients from DPT and MPT at electric field of 5.8×10^5 V cm^{-1} and (c) electric field dependence of TOF electron mobilities of DPT and MPT, which is compared with that of previously reported TOF electron mobilities estimated from dispersive transport (DT) and non-dispersive transport (NDT) of Alq_3 [4–6,21,23] and DT of BPhen [6].

and $\beta = 4.5 \times 10^{-3}$ cm$^{0.5}$ V$^{-0.5}$ (MPT) (Fig. 5c). It has been shown that electron transients of Alq_3 films are changed from a non-dispersive shape to a dispersive shape by exposing the films to oxygen and water atmosphere [5,21,22]. The μ obtained from non-dispersive transport (NDT) and dispersive transport (DT) of Alq_3 [4–6,21,23] and BPhen [6] is plotted together with that of DPT and MPT in Fig. 5c. The reported μ of Alq_3 is slightly dependent upon research groups. As can be seen in Fig. 5c, the measured μ of DPT and MPT is found to be the intermediate values between those of Alq_3 (for example, $\mu_0 = 1.0 \times 10^{-8}$ cm^2 V^{-1} s^{-1} and $\beta = 8.5 \times 10^{-3}$ cm$^{0.5}$ V$^{-0.5}$ [4,6]) and BPhen ($\mu_0 = 2.0 \times 10^{-4}$ cm^2 V^{-1} s^{-1} and $\beta = 1.5 \times 10^{-3}$ cm$^{0.5}$ V$^{-0.5}$ [6]) and is, however, comparable to those of triazine compounds previously reported [13,24,25].

The thermal characteristics of DPT and MPT are investigated using differential scanning calorimetry (DSC 200, SEIKO). The measured glass transition temperatures of DPT and MPT are 136 °C and 108 °C, respectively, and the measured melting temperatures of DPT and MPT are 340 °C and 279 °C, respectively. The observed high glass transition temperatures are expected to provide high thermal stability for the OLEDs operated at elevated temperature.

3.2. Injection and transport of electrons in OLEDs and electron-only devices

We investigate that how the use of the ETLs of Alq_3, BPhen, DPT, and MPT affects the driving voltages of the OLEDs. The current density–voltage characteristics of (A)–(D) are shown in Fig. 6a. The driving voltages of (A)–(D) operated at a current density of 50 mA cm^{-2} are summarized in Table 1. Replacing the Alq_3 ETL with the BPhen ETL reduces the driving voltages from 7.7 ± 0.2 V (A) to 7.0 ± 0.2 V (B) at 50 mA cm^{-2}. Since the electron injection barrier heights at the interfaces of Alq_3/Al (≈0.73 eV) and BPhen/Al (≈0.75 eV) are almost similar, the voltage reduction is attributable to the highest electron mobility observed in the BPhen ETL (Fig. 5c). On the other hand, the driving voltages at 50 mA cm^{-2} are reduced from 7.7 ± 0.2 V (A) to 6.0 ± 0.1 V (C) and 5.2 ± 0.1 V (D) by replacing the Alq_3 ETL with the DPT ETL and the MPT ETL due to the decrease in electron injection barrier height from ≈0.73 eV (Alq_3/Al) to ≈0.61 eV (DPT/Al) and ≈0.51 eV (MPT/Al) as well as the increase in electron mobility by one-to-two orders of magnitude (see Fig. 5c). Although the electron mobility of the BPhen ETL is higher than those of the DPT ETL and the MPT ETL, the driving voltage of (B) with the BPhen ETL (7.0 ± 0.2 V) becomes higher than those of (C) with the DPT ETL (6.0 ± 0.1 V) and (D) with the MPT ETL (5.2 ± 0.1 V), indicating that the decrease in electron injection barrier height is more advantageous than the increase in electron mobility to reducing the voltages. To double-check the change in the driving voltages of (A)–(D), the electron-only devices (I)–(IV), the structures of which are shown in Fig. 2b, were fabricated and tested. The current density–voltage characteristics of the electron-only devices (I)–(IV) (Fig. 6b) are found to be changed in the manner similar to those of the OLEDs (A)–(D) (Fig. 6a).

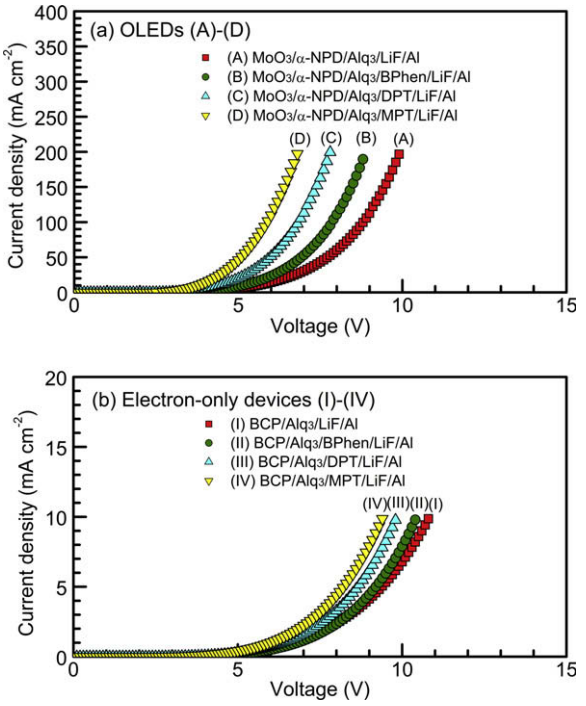

Fig. 6. (a) Current density–voltage characteristics of (a) OLEDs (A)–(D) and (b) electron-only devices (I)–(IV).

As discussed in the previous Section 3.1., the difference in the electron injection barrier height between the interfaces of DPT/cathode and MPT/cathode is only ≈0.1 eV. Also, the ratio of the mobility of the MPT ETL to the mobility of the DPT ETL is as small as ≈1.6. Therefore, we investigate that either electron injection or electron transport plays an important role in improving the driving voltage of (D) relative to (C). To do this, the current density–voltage characteristics of the OLEDs (C)–(F) and the electron-only devices (V)–(VIII) are compared (Fig. 7a and b). The structures of (C)–(F) and (V)–(VIII) are also shown in Fig. 2a and b, respectively. Using a 5 nm MPT ETL between the DPT ETL and the LiF EIL leads to a reduction in the driving voltage from 6.0 ± 0.1 V (C) to 5.4 ± 0.1 V (E). On the other hand, the driving voltages increase from 5.2 ± 0.1 V (D) to 5.8 ± 0.1 V (F) by inserting a 5 nm DPT ETL between the MPT ETL and the LiF EIL. The similar change in voltage is observed in the electron-only devices (V)–(VIII). In general, while transport-limited currents (such as space-charge-limited currents) are changed proportional to carrier mobilities [26], injection-limited currents (such as tunneling injection currents and thermionic emission currents) exponentially increase with decreasing barrier heights [7,27,28]. From these, we infer that the decrease in electron injection barrier height by ≈0.1 eV predominantly reduces the driving voltages of the OLEDs than the increase in electron mobility by ≈1.6 times, which is in good agreement with the results discussed previously using the BPhen ETL.

In all devices, we observed green EL from electrically excited Alq_3 molecules. The shapes and the peak tops

Table 1
Driving voltages, luminance, external quantum efficiencies, power conversion efficiencies, half lifetimes, and voltage increase rates of (A)–(F) operated at 50 mA cm^{-2}.

Device	Driving voltage (V)	Luminance (cd m^{-2})	External quantum efficiency (%)	Power conversion efficiency lm W^{-1}	Half lifetime (h)	Voltage increase rate (V h^{-1})
(A) Alq_3	7.7 ± 0.2	1622 ± 129	0.98 ± 0.02	1.41 ± 0.10	3200	4.1×10^{-4}
(B) BPhen	7.0 ± 0.2	1599 ± 94	0.99 ± 0.03	1.55 ± 0.07	400	8.0×10^{-3}
(C) DPT	6.0 ± 0.1	1540 ± 98	0.99 ± 0.01	1.62 ± 0.09	2800	1.4×10^{-4}
(D) MPT	5.2 ± 0.1	1557 ± 133	0.97 ± 0.02	1.88 ± 0.18	4200	1.0×10^{-4}
(E) DPT/MPT	5.4 ± 0.1	1547 ± 102	0.97 ± 0.01	1.83 ± 0.11	3700	1.2×10^{-4}
(F) MPT/DPT	5.8 ± 0.1	1512 ± 130	0.99 ± 0.01	1.68 ± 0.15	2900	1.7×10^{-4}

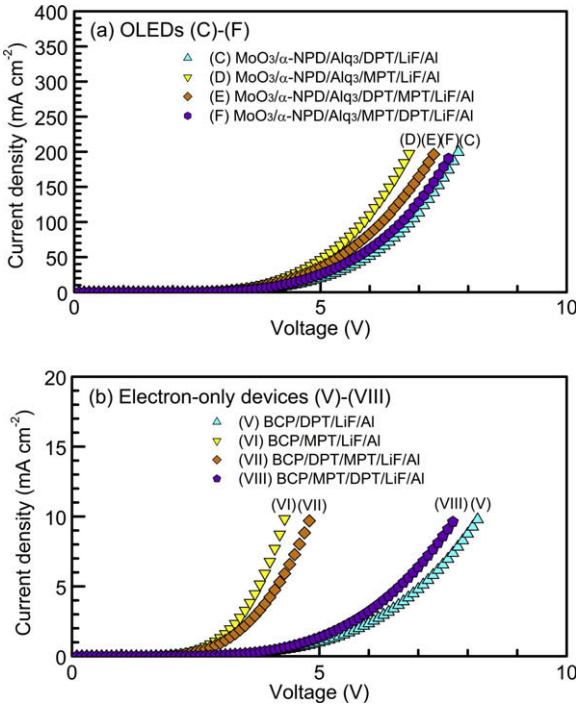

Fig. 7. (a) Current density–voltage characteristics of (a) OLEDs (C)–(F) and (b) electron-only devices (V)–(VIII).

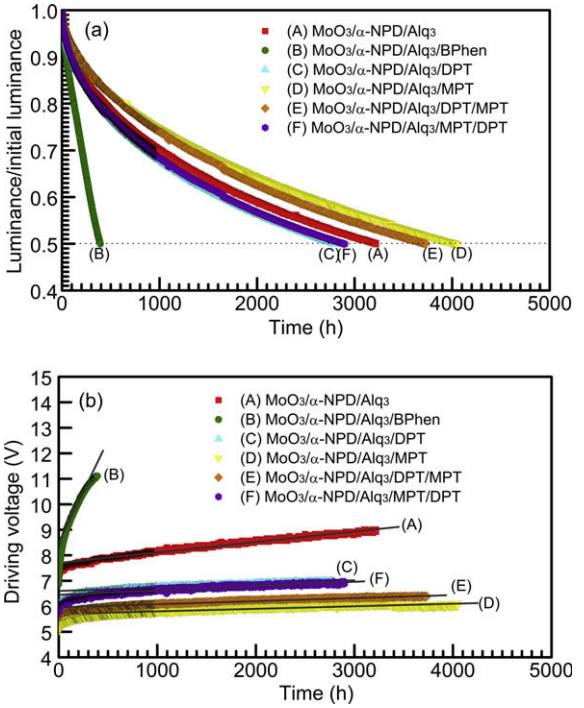

Fig. 8. (a) Luminance/initial luminance-time characteristics and (b) driving voltage–time characteristics of OLEDs (A)–(F) operated at 50 mA cm^{-2}.

(528–530 nm) of the EL spectra are consistent with those previously reported [16,29,30] and they are independent of current densities. A carrier recombination efficiency of electrons and holes in a carrier recombination zone is known to affect current density–voltage characteristics [26]. However, the external quantum efficiencies of (A)–(F) at 50 mA cm^{-2} are almost similar (≈1%) (Table 1), indicating that a change in carrier recombination efficiency causes a negligible effect on the driving voltages of the OLEDs. On the other hand, the power conversion efficiencies at 50 mA cm^{-2} are improved from 1.41 ± 0.10 lm W^{-1} (A) to 1.88 ± 0.18 lm W^{-1} (D) due to the voltage reduction discussed above (Table 1).

3.3. Operational stability of OLEDs

The luminance/initial luminance-time (L/L_0–t) characteristics and the driving voltage–time (V–t) characteristics of (A)–(F) are shown in Figs. 8a and b, respectively. The half lifetimes of the OLEDs are determined to be 3200 h (A), 400 h (B), 2800 h (C), 4200 h (D), 3700 h (E), and 2900 h (F) (Table 1) from Fig. 8a [31]. Moreover, the straight-line approximation of the V–t curves (the solid lines in Fig. 8b) gives the voltage increase rates: 4.1×10^{-4} V h^{-1} (A), 8.0×10^{-3} V h^{-1} (B), 1.4×10^{-4} V h^{-1} (C), 1.0×10^{-4} V h^{-1} (D), 1.2×10^{-4} V h^{-1} (E), and 1.7×10^{-4} V h^{-1} (F) (Table 1). The longest half lifetime of 4200 h and the lowest voltage increase rate of 1.0×10^{-4} V h^{-1} obtained in (D) are excellent values when compared with previously reported OLEDs based on α-NPD and Alq_3 [15,16].

Replacing the Alq_3 ETL with the MPT ETL increases the half lifetimes from 3200 h (A) to 4200 h (D). Although the half lifetime of (C) with the DPT ETL (2800 h) is shorter than that of (A) with the Alq_3 ETL (3200 h), inserting the 5 nm MPT ETL between the DPT ETL and the LiF EIL (the DPT/MPT/LiF unit) enhances the lifetimes from 2800 h (C)

to 3700 h (E). On the other hand, the lifetimes are degraded from 4200 h (D) to 2900 h (F) by using the MPT/DPT/LiF unit. In the case of the BPhen ETL, the device (B) has the shortest lifetime of 400 h among the devices. From these results, inserting the MPT layer between the ETL and the LiF EIL is found to be more important for the operational stability of the OLEDs than using the layers of Alq_3, BPhen, and DPT. Since various degradation models of Alq_3-based OLEDs have been proposed [32], the proposed degradation models cannot fully explain the lifetime results obtained in this work. Detailed degradation mechanisms of the OLEDs are now under investigation.

4. Conclusions

We have shown that triazine films of DPT and MPT have very good electron mobilities of 8.7×10^{-5} cm^2 V^{-1} s^{-1} (DPT) and 1.4×10^{-4} cm^2 V^{-1} s^{-1} (MPT) at an electric field of 5.0×10^5 V cm^{-1}, which are much higher than that of Alq_3 (4.1×10^{-6} cm^2 V^{-1} s^{-1} at the same field [4,6]), but are slightly lower than that of BPhen (5.8×10^{-4} cm^2 V^{-1} s^{-1} at the same field [6]). Moreover, the triazine films have higher LUMO energy levels of -2.97 ± 0.02 eV (DPT) and -3.07 ± 0.02 eV (MPT) than the films of Alq_3 (-2.85 ± 0.02 eV) and BPhen (-2.83 ± 0.02) have, resulting in that electron injection at interfaces of DPT/cathode and MPT/cathode is more facile than that at interfaces of Alq_3/cathode and BPhen/cathode. By comparing performances of OLEDs having the ETLs of Alq_3, BPhen, DPT, and MPT, a decrease in electron injection barrier height at the ETL/cathode interfaces is found to predominantly reduce driving voltages of the OLEDs than an increase in electron mobility of the ETLs. Thus, the OLED having the MPT ETL has the lowest driving voltage of 5.2 ± 0.1 V, the highest power conversion efficiency of 1.88 ± 0.18 lm W^{-1}, and the longest half lifetime of 4200 h at a current density of 50 mA cm^{-2} among the OLEDs investigated in this study. These results indicate that MPT with the high electron mobility and the high LUMO energy level is a promising candidate for use as an ETL for fabricating high-performance OLEDs.

ABSTRACT

We report solution-processed hybrid LEDs, emitting infrared light with enhanced efficiency, based on PbSe nanocrystal (NC) lumophores embedded a conjugated polymer forming the nanocomposite active layer. The effect of device geometry and the NC-polymer blend composition on device performance is studied in detail. Increasing the PbSe NC concentration leads to a substantial decrease in device current, and an increase in efficiency and turn-on voltage. Analysis of the device data indicates that the PbSe NCs act as carrier traps and radiative recombination centers. With optimized concentration of NC emitters and active layer thickness, the devices exhibit an external electroluminescence quantum efficiency of 0.83% at a peak emission wavelength of 1280 nm.

1. Introduction

Colloidal semiconductor nanocrystals (NCs), by virtue of the large tunability in their bandgap, high luminance efficiency, narrow spectral emission and high photo-stability, are an attractive choice as lumophores as well as sensitizers in next-generation optoelectronic devices such as light-emitting diodes (LEDs) [1–3], photodetectors [4,5] and solar cells [6–8]. Their compatibility with facile low-temperature solution-processing opens up the possibility of fabricating organic/inorganic hybrid devices at low-cost with device performance similar to their inorganic counter-parts. For electroluminescent device applications, combining the advantages of the rapidly developing organic LED (OLED) technology with the attractive properties of semiconductor NCs has led to advances in these hybrid LEDs: the external quantum efficiency (EQE) has improved by over two orders of magnitude, and highly saturated color emission across the visible spectrum has been achieved. Several hybrid light emitters employing visible-range NCs and organic semiconductors have been demonstrated with maximum EQEs up to 2% [9,10]. On the other hand, little work has been done to explore such devices emitting at infrared (IR) wavelengths, although large area near-IR emitters and absorbers can lend themselves to a number of applications including chemical spectroscopy, night vision and biomedical sensing. Additionally, electroluminescent sources with activity in the 1.3–1.55 μm window can specifically find applications in optical communications. Owing to the paucity of molecular and polymeric organic semiconductors with efficient tunable emission beyond 1 μm wavelength, the use of semiconductor NCs emitting in the near-IR offers a particularly attractive alternative. However, only a few infrared electroluminescent hybrid devices been reported to date and they have shown low external quantum efficiencies [2,11,12].

Early work on hybrid LEDs primarily focused on wide-gap semiconductor NCs emitting at visible wavelengths. The first published work on hybrid LEDs incorporating colloidally grown semiconductor NCs by Colvin and co-workers [1] demonstrated low device efficiency, limited by inefficient charge injection and poor charge transport. A fundamentally different device architecture of hybrid LEDs by Coe et al. [3], seeking to isolate the functionalities of charge transport and exciton recombination, utilized a

monolayer of NCs as the emitter in a multilayer structure similar to heterostructure OLEDs. This approach resulted in significant improvement in device efficiency. Subsequent enhancement in luminous power efficiency was achieved by Jen and co-workers by optimizing charge injection through the use of thermally polymerized hole transport layer (HTL) [13] and by thermal annealing of the emission layer [10]. In IR emitting hybrid devices, the highest external electroluminescence quantum efficiency (ELQE) achieved was ca. 0.5% using core–shell InAs/ZnSe NCs as lumophores [2]. However, in solution processable LEDs with PbSe or PbS NCs as the IR emitters, external EQEs have been limited to only ~0.001% and 0.27%, respectively [11,12]. Given the high photoluminescence quantum yield of these IV–VI semiconductor NCs [14] in solution, a proper choice of active layer composition and design of device architectures should lead to higher IR emission efficiency.

In this study, we demonstrate solution-processed hybrid infrared LEDs with enhanced efficiency using PbSe NCs as lumophores dispersed in a conjugated polymer to form a nanocomposite electro-active layer. Among the IV–VI semiconductors, PbSe NCs constitute an interesting system because of the ease of realizing quantum modulated optical properties in the infrared range. Due to the large Bohr exciton radius in PbSe, about 46 nm, quantum confinement effects begin to appear at relatively large particle dimensions and wavelength tunability can easily be achieved. Additionally, highly reproducible colloidal synthesis yields PbSe NCs with narrow size distribution and well-defined band-edge excitonic transitions tunable between 0.9 and 2.0 eV. To fabricate infrared emitting hybrid LEDs, PbSe NCs were homogeneously dispersed in a conjugated polymer matrix to form the nano-composite used for the electro-active layer. The effect of device geometry and polymer blend composition on device performance was studied in detail. We found that both the operating voltage and the NIR emission quantum efficiency increase with increasing concentration of NCs in the polymer matrix. The increase in operating voltage and EQE suggests that the NCs act as traps for both electrons and holes resulting in an increase in radiative recombination at the NC sites. The concentration of NC emitters and the thickness of the active layer were optimized, yielding devices with an external ELQE of 0.83% which is significantly higher than the efficiencies reported previously [11,12].

2. Experimental

2.1. Nanocrystal synthesis and processing

We tailored the synthesis of NCs by making appropriate variations to existing literature methods [15] to obtain highly monodispersed, discretely luminescent and easily solution processable NCs over a wide range of synthetically accessible sizes. In a typical reaction, PbO (4 mmol) and oleic acid (11 mmol) were added to 1-octadecene (35 ml). The reaction mixture was stirred under heat and argon flow for 45 min. When the temperature reaches 155 °C, 12 mmol of 1 M TOP-Se (selenium dissolved in trioctylphosphine) and 0.11 ml of DPP (diphenyl phosphine) were rapidly injected. The resulting NCs are withdrawn in two aliquots (typically after 30 s and 60 s) and quenched with cold toluene (~15 ml). Subsequently the NCs are precipitated and extracted by adding acetone and ethanol followed by centrifugation.

Following previously established procedures, those that lead to narrow NC size distribution and remove excess unreacted organics and reaction byproducts, a rigorous three-step post synthesis washing of NCs was adopted without compromising the colloidal stability. After an initial precipitation with acetone and ethanol, the precipitate is dissolved in toluene and kept in a freezer for 10 min to initiate the precipitation of salts. The sample is then centrifuged and the NC containing supernatant is removed. Ethanol is added to the supernatant and a second precipitation is carried out. The resulting precipitate is again dissolved in toluene and a final precipitation with a mixture of acetone and ethanol is carried out. Finally, the NCs are dried under argon, and dissolved in chlorobenzene for device fabrication or tetrachloroethylene for optical characterization.

2.2. Device fabrication

To fabricate the light-emitting devices studied herein, a 40 nm layer of poly(3,4-ethylenedioxythiophene) doped with poly(styrenesulfonic acid) (PEDOT:PSS) was spin coated on pre-cleaned indium tin oxide (ITO) coated substrates and baked in air at 180 °C for 20 min. PEDOT:PSS serves as a hole injection layer and also planarizes the ITO surface to prevent any unwarranted shorts. Monodispersed NCs and poly[2-methoxy-5-(2′-ethyl-hexyloxy)-1,4-phenylene vinylene] (MEH-PPV) were blended in chlorobenzene in various proportions to yield different active-layer compositions. This solution was then spin casted as the active-layer on the PEDOT:PSS coated substrates and baked under N_2 at 60 °C for 15 min. Subsequently, an 8 nm layer of the electron transporting and hole-blocking material bathocuproine (BCP) was deposited by thermal evaporation in a chamber pressure below 2×10^{-6} Torr. Finally, a composite metal cathode of LiF/Al was evaporated through a shadow mask.

2.3. Nanocrystal and device characterization

The absorption spectra of colloidal NCs in tetrachloroethylene were collected using a Varian Cary 500 UV–vis-near-IR spectrophotometer. A SPEX 270M spectrometer was used for acquisition of the emission spectra. Transmission electron microscopy (TEM) images were obtained using a JEOL model JEM-200CX microscope at an acceleration voltage of 200 kV.

The current–voltage-emission measurements were performed on the devices in the ambient on a test fixture using a Keithley 2400 source meter interfaced in conjunction with a Thorlabs InGaAs photodiode (model # FGA21-CAL) with NIST traceable calibration. A longpass filter with short-wavelength cutoff at 830 nm was used to eliminate any visible emission from the polymer matrix. Electroluminescence quantum efficiency in the infrared was determined by measuring emission intensity in the forward

direction and converting it to total external emission. EL spectra were recorded using an Ocean Optics near-IR spectrometer (model NIR256-2.1) with an InGaAs detector array.

3. Results and discussion

3.1. Nanocrystal characterization

Fig. 1a shows typical near-IR absorption and photoluminescence (PL) spectra for ~4 nm diameter PbSe NCs and Fig. 1b shows the size-tunable IR absorption for the NCs with diameters ranging from 3 nm to 7 nm. The TEM micrograph image shown in the inset of Fig. 1a showing the uniformity of the d-spacing of the planes of the highly regular 2-dimensional hcp lattice confirms the characteristic narrow size distribution [evident also from the full width at half maximum (FWHM) of the PL spectrum ~130 nm] of the PbSe NCs obtained without any post-synthetic size selective processing. Based on the tunable absorption spectra (shown in Fig. 1b) spanning a wide range of infrared wavelengths (1000–1900 nm), we expect this device platform to yield solution-processed IR emitters.

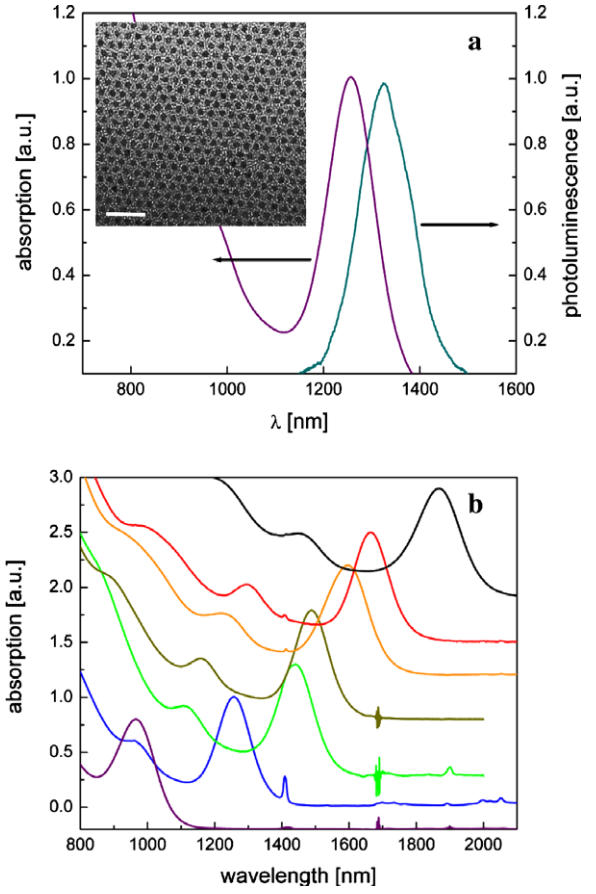

Fig. 1. (a) Typical absorption (peak at 1260 nm) and photoluminescence (peak at 1320 nm) spectra of 4 nm sized PbSe NCs. The inset shows a transmission electron micrograph image of the same particles; scale bar 20 nm. (b) Size-tunable absorption spectra of PbSe NCs (diameter ~2.5–6.5 nm) in the infrared.

3.2. Hybrid polymer/nanocrystal LEDs

Hybrid LEDs with semiconductor NCs dispersed in a conjugated polymer have previously been reported. However, the reported efficiencies were usually quite low due to the unfavorable alignment of the conduction/valence band edges of the wide-gap NCs with the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energies of the conjugated polymer and inefficient energy/charge transfer from the polymers to the NCs. For narrow gap semiconductors such as PbSe, both the conduction and valence band edges of the NCs are in close proximity of the LUMO–HOMO gap of many conjugated polymers, and it is expected that energy/charge transfer from the host polymer to the PbSe NCs should be more efficient. In this work, MEH-PPV was used as the polymer matrix. Fig. 2 shows the device architecture employed and the energy levels of the PbSe NC based LEDs. The HOMO–LUMO energies of the polymer [16] and BCP [17] are obtained from the literature. The valence and conduction band levels of the NCs employed here (~4 nm diameter) are estimated using optical absorption data and reported bulk energy levels [18] and considering quantum size effects [19]. MEH-PPV has been widely used for polymer LEDs and its HOMO energy matches the valence band edge of these NCs. At the same time, the conduction band edge of the NCs is well within the bandgap of MEH-PPV and efficient electron transfer from the polymer to the PbSe NCs is expected. It should be noted that organometallically synthesized PbSe NCs are capped with a layer of oleate ligands to prevent aggregation and to passivate their surfaces. Due to the insulating nature of the organic ligands, the presence of a large amount of capping groups can result in inefficient charge transfer [20]. Thus, to achieve efficient EL from these lumophores, high purity NCs free of excess organics are important. To realize this end, the NCs were subject to a rigorous three-step post-synthesis washing (see experimental section) to eliminate excess organics and reaction byproducts without compromising the colloidal stability.

The electro-optical characteristics of an LED with a polymer/NC blend containing 1% NCs by weight are shown in Fig. 3a. The device turns on at around 3 V which is significantly lower than the previous devices with PbSe NCs in a multilayered device architecture [11]. The peak external quantum efficiency (EQE) of this hybrid LED device is ~0.1%. Fig. 3b displays the EL spectra of different devices incorporating NCs of varying sizes. The EL spectrum for each device resembles the PL spectrum of the corresponding NC solution and demonstrates the tunability of the hybrid LEDs emitting at 1290 nm, 1350 nm, and 1440 nm. The spectral FWHM of the devices shown in Fig. 3b is less than 0.14 eV, demonstrating the narrow IR emission spectra from the NCs.

3.3. Effect of nanocrystal concentration

To better understand the device characteristics, the EL properties of the hybrid LEDs were studied as a function of NC concentration. Four different concentrations of PbSe NCs in MEH-PPV films were explored for device fabrica-

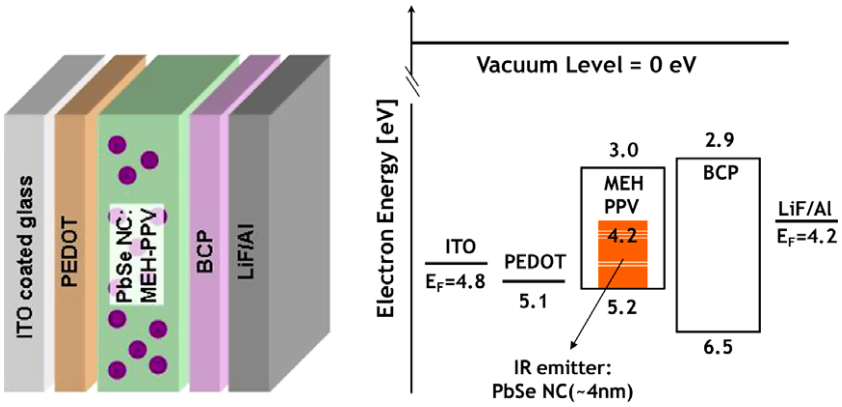

Fig. 2. Device structure and energy levels of constituent materials of the hybrid LED consisting of NC-polymer composite active layer.

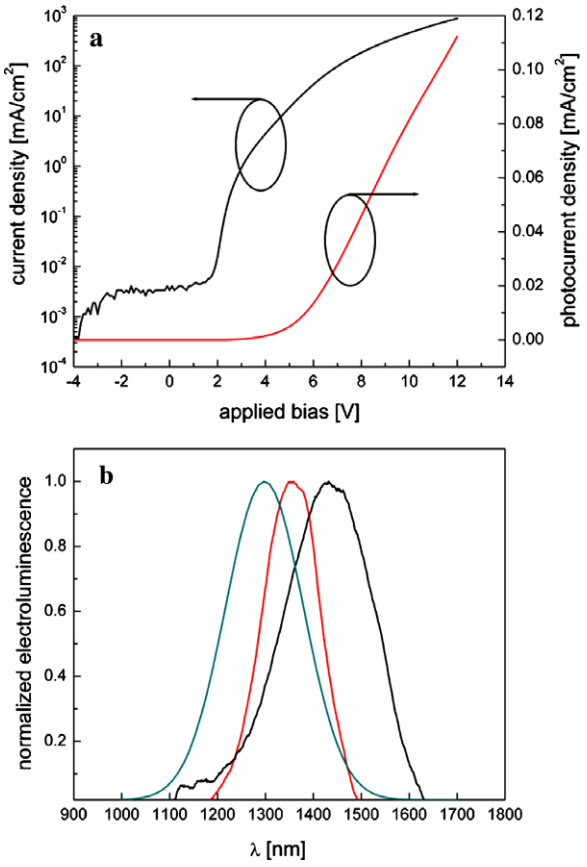

Fig. 3. (a) Hybrid infrared LED performance characteristics (current–voltage-photocurrent) of a device containing 1 wt.% PbSe NCs. (b) Normalized infrared electroluminescence spectra of different NC based hybrid LEDs tuned through choice of NC size (diameter ~3–4.5 nm).

tion: 1%, 3%, 6%, and 9% of NCs by weight. Fig. 4a shows the current density–voltage (J–V) curves for the hybrid LEDs with different compositions. The current–density decreases monotonically with increasing amount of NCs in the polymer layer at all operating voltages. To compare device performances, data from a device with a neat MEH-PPV emitting layer of the same thickness as the NC-dispersed devices are also included in the same figure. The dependence of IR light emission intensity on applied bias is illustrated in Fig. 4b. It is observed that the IR light emission intensity increases as the amount of NCs is increased from 1 wt.% to 3 wt.%, but reduces with further increase in NC content. The device with a neat MEH-PPV layer exhibits orange emission with an EQE of ~1%. Addition of the NCs increases the luminescence from the NCs at the expense of MEH-PPV emission. In fact, for the devices containing 9 wt.% NCs, the EQE from MEH-PPV emission is reduced by 90% of its value, to about ~0.1%. Additionally the turn-on voltage for the devices also increases as the amount of NCs in the film is increased.

The NIR EQE of the hybrid LEDs with varying amount of NCs as a function of device current density is displayed in Fig. 4c. At low current densities, the EQE increases from the device containing 1 wt.% NCs to the one having 3 wt.% NCs, but reduces for devices with higher amount of NCs. However, at current densities larger than 10 mA/cm^2, the device containing 6 wt.% NCs exhibits the highest external IR EQE with a peak value of 0.65%. Interestingly, the efficiencies of all hybrid LEDs remain reasonably flat over a wide range of device current densities and across the entire voltage range, without showing any significant roll-off, which indicates there is good charge balance in the devices.

The EL EQE of the hybrid LEDs depends strongly on the efficiency of excitation transfer to the NC emitters. It has been suggested that both neutral-excitation energy transfer (Förster mechanism) due to dipole–dipole interactions and direct injection of carriers are possible routes of NC excitation in hybrid LEDs [2,12]. Both these mechanisms depend strongly on the distance separating the donor and acceptor involved. As shown in the J–V plots in Fig. 4a, increasing the amount of NCs in our hybrid LEDs reduces the device currents significantly, especially at low operating voltages. For example, at 5 V the current density in the device containing 9 wt.% NCs is two orders lower than that in the neat MEH-PPV device. The decrease in current indicates that the PbSe NC sites in the polymer matrix act as charge trapping centers. The conduction band edge of PbSe NCs (~4.27 eV) is well within the en-

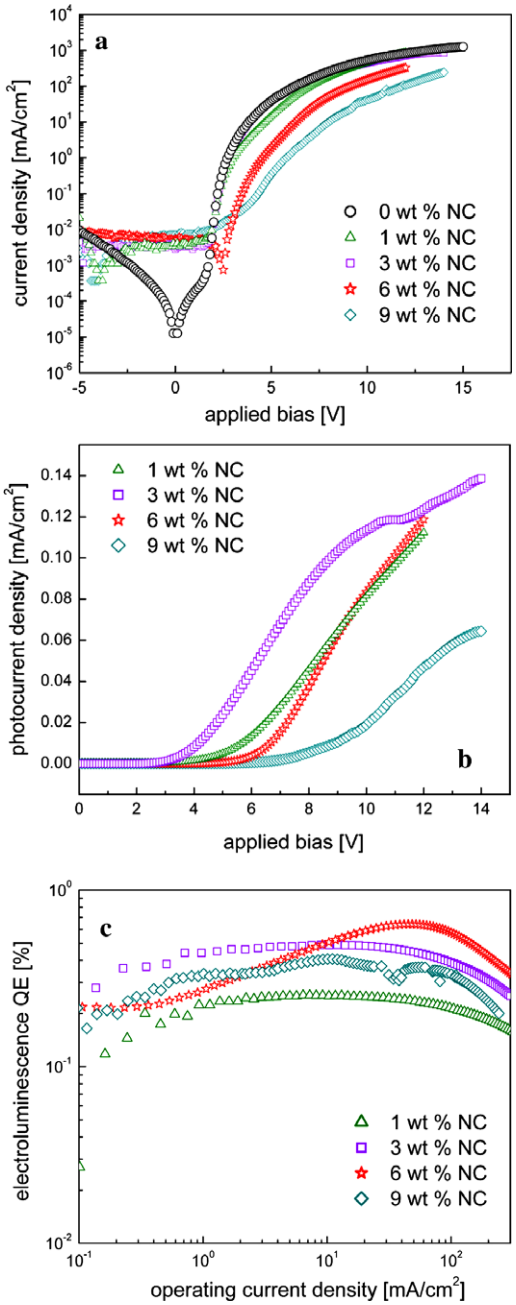

Fig. 4. Electro-optical characteristics of hybrid LEDs incorporating different amounts of NCs. (a) Current density–voltage curves. For comparison, data from an identical control device without the NCs is also plotted. (b) Infrared light emission intensity as a function of applied bias. (c) External quantum efficiencies as a function of operating current density.

ergy gap of MEH-PPV (with a LUMO level 3.0 eV) [16,21] and it favors the transfer of electrons from the polymer to the NCs, resulting in strong electron trapping in the NCs. At the same time, given that the small difference in HOMO energies of MEH-PPV (5.2 eV) [16,21] and the PbSe NCs (~5.27 eV) [22] and the fact that MEH-PPV is a hole transporting polymer, the presence of NC traps should not have a strong effect in hole transport. Therefore the addition of NCs would further increase the hole dominance. The BCP layer acts as a hole blocker and its presence enhances the recombination of blocked holes with trapped electrons in the NCs, resulting in increase in EL efficiency. It should be noted that the carrier trapping proposed here is different from carrier trapping due to chemical or structural defects. Carrier trapping due to defects leads to increase in voltage and decrease in EL efficiency. On the other hand, carrier trapping due to lumophores leads to enhancement in EL. In fact, carrier trapping leading to EL has also been observed in dye-dispersed polymer OLEDs where the drive voltage also increases with the dye doping concentration [23,24]. The increase in the turn-on voltage with higher NC content is also consistent with the presence of NC charge traps [25]. Thus, direct carrier injection into the NC emitters due to charge trapping plays an important role in determining the recombination efficiency in these hybrid LEDs. Increased carrier trapping leads to more efficient exciton formation on the NC emitting sites, resulting in higher luminescence efficiency. This is also evidenced by the significant suppression of MEH-PPV emission from the polymer host with increasing NC content in the composite. The presence of a long chain organic capping ligand can raise concern regarding the efficiency of charge transfer. However, the conformation of single chain ligands on a high curvature NC surface leaves significant portions of the surface accessible for electronic contact by the surrounding matrix [26]. It has already been demonstrated, that even the relatively long capping ligands do not impede excitation transfer to a great extent [27,28]. It should also be noted that aggregation of NCs should not be an issue here because the difference in photoluminescence and electroluminescence spectra is insignificant.

3.4. Effect of electro-active layer thickness

If the NCs act as carrier traps, increase in layer thickness increases the electron and hole trapping probability. While NC-doped MEH-PPV is hole dominant, increasing the layer thickness probably improves the charge balance due to enhanced spreading of carriers over a larger distance. As a result, we expect that the EL efficiency increases with increasing thickness of the electro-active layer. To investigate further the mechanism of trapping and EL emission, the effect of the electro-active layer thickness on the performance of the hybrid LEDs containing 6 wt.% NCs was studied. Fig. 5 shows the peak EQE of these devices as a function of nanocomposite emission layer thickness. The EQE increases with device thickness, and peaks at a value of 0.83% in a hybrid LED having a 210 nm thick active layer. Devices with active layers thicker than 210 nm showed a marked reduction in current density and EL emission efficiency. It should be noted that the peak efficiency shifts to higher current density as the device thickness increases, indicating that charge balance is improved at higher current density with thicker layer. It is also evident from the *J–V* data that an increase in active layer thickness leads to reduced current density. As the charge carriers travel through greater distances across the devices with in-

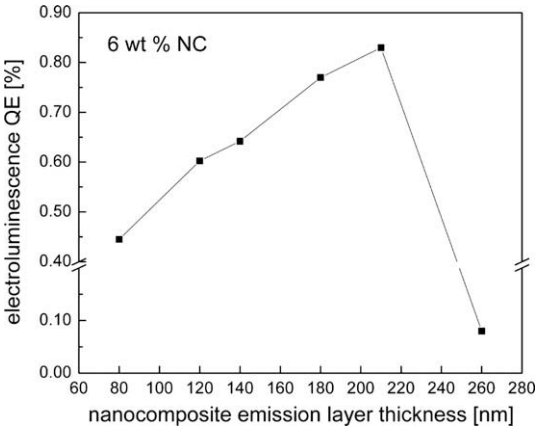

Fig. 5. External infrared electroluminescence QE as a function of active nanocomposite layer thickness for the hybrid LEDs containing 6 wt.% NCs.

creased thickness, their probability of being trapped by the PbSe NCs increases. This increased trapping efficiency results in reduced device current and enhanced EL efficiency. It should be noted that ITO has strong absorption in the NIR wavelength range being studied here. For example, the optical transmission of the ITO substrates used for device fabrication is 55% to 65% in the wavelength range between 1000 nm and 1500 nm. Taking into account the ITO absorption, the maximum EQE of our hybrid LEDs should be ~1.2% if the ITO electrode is replaced with a non-infrared-absorbing electrode. Assuming that this device has a light extraction efficiency similar to OLEDs (20%), the overall internal quantum efficiency should be ~6%, which is significantly higher than the results reported previously [11,12].

4. Conclusions

In conclusion, we demonstrated hybrid solution-processed, IR LEDs based on PbSe NC emitters. We investigated and optimized devices based on a nanocomposite blend architecture and achieved a maximum external quantum efficiency of 0.83% at a peak emission wavelength of 1280 nm. This constitutes a significant improvement over previous reports of NC based IR LEDs, but there are several approaches in device engineering and materials optimization that can lead to further enhancement in performance. For example, optimized core–shell NC structures can prevent delocalization of carriers injected into the NC while allowing for efficient energy exchange with the surrounding matrix, leading to higher internal radiative efficiency.

Length-scale effect

ABSTRACT

Conducting polymers are prevalently used in organic and flexible electronics and energy conversion devices. While their thermo-physical properties are well characterized for different processing and doping conditions, very little is known about the effect of length-scale, especially their thermal conductivity and thermal contact resistance of their interfaces with substrates. In this paper we develop an analytical model to capture the heat transfer in ultra-thin polyaniline thin films and their interfaces with other substrate materials. The model is demonstrated on 20–1000 nm thick 50% camphor-sulphonic acid doped polyaniline films patterned on silicon substrate using photolithography and reactive ion etching. The four-probe based technique allows simultaneous electrical and thermal characterization. Experimental results show a 500% and 200% increase in the in-plane thermal conductivity and electrical conductivity, respectively as the film thickness is increased from 20 nm to 1000 nm. These findings suggest up to 300% improvement in thermoelectric performance for 20 nm thick films when compared to the bulk. Such strong length-scale effects are observed to decay rapidly after 100 nm film thickness and can be attributed to the enhanced phonon scattering at the surface and interface boundaries at length-scales comparable to phonon mean free paths.

1. Introduction

Conducting polymer thin films are prevalently used in state of the art organic/flexible micro-electronic [1,2] and optoelectronic [3,4] systems, solid state energy conversion devices [5–7] and novel composites [8,9]. In particular, polyaniline (PANI, also known as the organic metal) stands out among conducting polymers because of its facile synthesis and tailorable conductivity arising from its unique doping/de-doping chemistry based on acid/base reactions and more importantly, metallic transport property [10,11]. It is a popular organic electronics material with applications including electrodes for rechargeable batteries, sensors, super-capacitors, electro-chromic displays [12]. Accordingly, the issues of electrical conductivity and compatibility with micro-electronic processing have received the most attention. The literature shows that the electrical conductivity is strongly dependent on the preparation conditions, doping chemistry and temperature [8,11–19]. Thermal transport properties, on the other hand, are comparatively less studied with only few reports on the thermal conductivity of microscale PANI films [5,20]. In fact, thermal conductivity of polyaniline is found to remain unchanged at the micro and meso scales [21], which leads researchers to focus on enhancing the electrical conductivity for better electrode or thermoelectric conversion performances.

While synthesis and doping chemistry are the two most investigated routes towards advanced conducting polymeric materials, the motivation for this paper comes from the relatively unexplored opportunities due to the

'length-scale effects' on electrical and thermal transport. The first rationale behind our approach is that as materials dimensions approach the mean free path of electrons and phonons, strong length-scale effects are expected to manifest in novel thermo-physical properties [22–24]. The second rationale is that the ever-continuing trend in miniaturization results in unfamiliar problems that can be only dealt with fundamental understanding in the length-scale effects. For example, only ten years ago, thermal management of electronics was an emerging issue, which now is regarded to be a major problem. As switching speed and circuit density increase, thermal transport will become increasingly critical in determining the operating temperature for organic electronics [22]. This is because the heat dissipation density increases non-linearly (L^{-1}) with the characteristic length-scale (L) [25]. Unfortunately, there are only a few studies in the literature that investigate length-scale effects on electrical properties at the 10–100 nm range [26,27]. On the other hand, existing thermal conductivity studies on conducting polymers only involve relatively thicker films [20,28], where the effects of geometric (film thickness) and microstructural (disordered or partially disordered structures inside films) confinement are virtually non-existent. It is important to note that there is not a single study in the literature on the thermal contact resistance of the conducting polymer based interfaces, even though such interfaces are ubiquitous in organic electronics.

While the four-probe electrical characterization technique has been universally applicable across length-scales, thermal characterization of nanoscale materials is particularly challenging. To enable simultaneous electrical and thermal characterization, we adopt the 3ω technique, which also uses four electrodes to heat up the specimen and extract the thermal conductivity by sensing the temperature changes. Here, an alternating current $I(\omega)$ is passed through the specimen, generating thermal waves that diffuse along the specimen thickness direction and modulating the resistance at 2ω frequency. The resulting voltage drop across the specimen, $V = I(\omega)R$, contains the third harmonics, 3ω, which is proportional to the temperature rise of the heater and can be used to calculate the thermal properties of the specimen [29,30]. For conducting materials, the specimen is required to be freestanding [28,31], which not only makes it impossible to measure the thermal contact resistance at the substrate interfaces but also makes specimen fabrication challenging especially for soft polymeric materials with nanometer scale thickness.

In the next section, we develop an analytical model that modifies the conventional 3ω technique to relax the freestanding specimen restriction and thus allows simultaneous characterization of electrical and thermal conductivity as well as thermal contact resistance at the interface with the substrate. The four-probe electrical conductivity measurements are very straightforward and will not be discussed in detail. We then present the experimental details and analyze the results to draw conclusions on the length-scale effects on the electrical and thermal transport in nanoscale polyaniline thin films.

2. Analytical model for thermal transport in thin films

The essence of the model developed in this study is to relax the restriction that the specimen must be released from the substrate by explicitly accounting for the heat loss to the substrate in one-dimensional heat conduction equation. Fig. 1a shows cross-sectional view of the specimen with four electrodes. The two outer probes (1 and 4) are used to supply AC electric current, and the two inner probes (2 and 3) are used to measure the voltage across the specimen. The applied sinusoidal current source ($I = I_0 \sin \omega t$) leads to Joule heating which is equal to $I^2(R_0 + \delta R)$, where δR is the resistance fluctuation of the specimen and is proportional to the temperature oscillation. A scanning electron micrograph of the top view of the setup is shown in Fig. 1b.

The heat generation and one-dimensional heat conduction through the specimen are given by [31],

$$\rho C_p \frac{\partial \theta(x,t)}{\partial t} = \kappa \frac{\partial^2 \theta(x,t)}{\partial x^2} + \frac{I_0^2 \sin^2 \omega t}{LS}(R_0 + R'\theta(x,t)) \tag{1}$$

where L and S are the length between the voltage contacts and the cross-section area of the specimen, respectively. ρ, C_p and κ are the density, specific heat and thermal conductivity. R_0 is the initial electrical resistance of the specimen at initial temperature T_0. R' is the resistance derivative of temperature $R' = \left(\frac{dR}{dT}\right)_{T_0}$ at T_0. $\theta(x,t) = T(x,t) - T_0$ is the temperature change, t is the time, x is the coordinate along the length and also the heat flow direction. In order to relax the constraint of suspended specimen, we consider balancing the heat loss across the contact to the underlying substrate $\theta(x,t)A/\sum R_t$ in the one-dimensional heat conduction equation by the introduction of underlying thermal resistance $\sum R_t$ (in the unit of m^2K/W), where A is the contact area between the specimen and substrate. The total underlying thermal resistance $\sum R_t$ is the sum of the interfacial contact resistance and the substrate conduction resistance, i.e. $\sum R_t = R_{t,\mathrm{cont}} + R_{t,\mathrm{cond}}$. Thermal resistance from the substrate can be approximated from $R_{t,\mathrm{cond}} = \frac{\lambda_s}{\kappa_s}$, where $\lambda_s = \sqrt{\alpha_s/2\omega}$ is the thermal penetration depth in the substrate, α_s is the thermal diffusivity and κ_s is the thermal conductivity of the substrate. By subtracting the thermal resistance of the substrate from the total resistance $\sum R_t$, the value of the interfacial thermal resistance can be found.

The introduction of underlying thermal resistance $\sum R_t$ turns one-dimensional heat conduction equation to be,

$$\rho C_p \frac{\partial \theta(x,t)}{\partial t} = \kappa \frac{\partial^2 \theta(x,t)}{\partial x^2} + \frac{I_0^2 \sin^2 \omega t}{LS}(R_0 + R'\theta(x,t)) - \frac{\theta(x,t)A}{LS\sum R_t} \tag{2}$$

By setting $\alpha = \kappa/\rho C_p$, $b = I_0^2 R_0/LS\rho C_p$, $c = I_0^2 R'/LS\rho C_p$, $d = A/LS\sum R_t \rho C_p$, the equation can be rewritten as

$$\frac{\partial \theta(x,t)}{\partial t} - \alpha \frac{\partial^2 \theta(x,t)}{\partial x^2} - (c \sin^2 \omega t - d)\theta(x,t) = b \sin^2 \omega t \tag{3}$$

with the following initial and boundary conditions

$$\theta(0,t) = 0, \quad \theta(L,t) = 0, \quad \theta(x,-\infty) = 0 \tag{4}$$

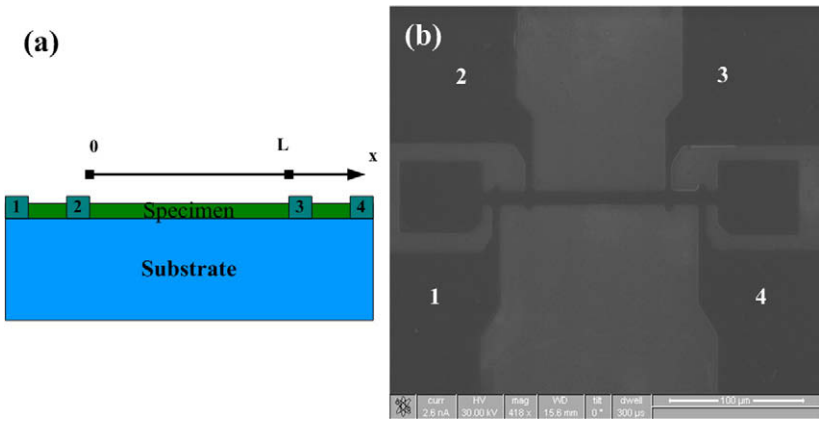

Fig. 1. (a) Cross-sectional view of the four-probe configuration (b) scanning electron microscope image of the geometry of the specimen (viewed from the top). The darker region is PANI thin film and lighter region is thermally grown silicon oxide. Scale bar is 100 μm.

The impulse theorem is employed to solve the Eq. (3)

$$\theta(x,t)=\int_{-\infty}^{t} z(x,t;\tau)\,d\tau \tag{5}$$

where $z(x,t;\tau)$ satisfies

$$\frac{\partial z}{\partial t}-\alpha\frac{\partial^2 z}{\partial x^2}-(c\sin^2\omega t-d)z=0 \tag{6}$$

with the initial and boundary conditions,

$$z(0,t)=0,\quad z(L,t)=0,\quad z(x,\tau^+)=b\sin^2\omega\tau \tag{7}$$

Fourier series can be used to expand $z(x,t;\tau)$,

$$z(x,t;\tau)=\sum_{n=1}^{\infty}U_n(t;\tau)\sin\frac{n\pi x}{L} \tag{8}$$

Substitute Eq. (8) into Eq. (6),

$$\sum_n\left[\frac{dU_n}{dt}+\left(\alpha\frac{n^2\pi^2}{L^2}-c\sin^2\omega t+d\right)U_n\right]\sin\frac{n\pi x}{L}=0 \tag{9}$$

We now set $\lambda=\alpha\frac{n^2\pi^2}{L^2}+d$.

When $c\ll\lambda$, $c\sin^2\omega t$ can be neglected, that is

$$\frac{I_0^2R'L\sum R_t}{n^2\pi^2\kappa\sum R_tS+LA}\ll 1 \tag{10}$$

Non-trivial solution of Eq. (9) is

$$\frac{dU_n}{dt}+\left(\alpha\frac{n^2\pi^2}{L^2}-c\sin^2\omega t+d\right)U_n=0 \tag{11}$$

If condition (10) can be satisfied, the solution of Eq. (11) is

$$U_n(t;\tau)=C_ne^{-\left(\alpha\frac{n^2\pi^2}{L^2}+d\right)(t-\tau)} \tag{12}$$

From initial condition in (7) and Fourier expansion in (8), we know

$$z(x,t;\tau)=\sum_n\frac{2b}{n\pi}[1-(-1)^n]\sin^2\omega\tau e^{-(\alpha\frac{n^2\pi^2}{L^2}+d)(t-\tau)}\times\sin\frac{n\pi x}{L} \tag{13}$$

We now apply the impulse theorem again to find $\theta(x,t)$,

$$\theta(x,t)=\int_{-\infty}^{t}z(x,t;\tau)\,d\tau=\sum_{n=1}^{\infty}\left\{\frac{b}{n\pi}[1-(-1)^n]\sin\frac{n\pi x}{L}\frac{1}{\lambda}\left[1-\frac{\sin(2\omega t+\phi_n)}{\sqrt{1+\cot^2\phi_n}}\right]\right\} \tag{14}$$

where $\tan\phi_n=\frac{\lambda}{2\omega}$.

For $n=1$, the temperature difference becomes,

$$\theta(x,t)=\frac{2b}{\pi}\sin\frac{\pi x}{L}\frac{1}{\lambda}\left[1-\frac{\sin(2\omega t+\phi)}{\sqrt{1+\cot^2\phi}}\right] \tag{15}$$

and the resistance variation can be obtained as

$$\delta R=\frac{R'}{L}\int_0^L\theta(x,t)\,dx=\frac{4bR'}{\pi^2\lambda}\left[1-\frac{\sin(2\omega t+\phi)}{\sqrt{1+\cot^2\phi}}\right] \tag{16}$$

The voltage of the specimen as the product of the total resistance $R+\delta R$ and the current $I_0\sin\omega t$ contains a 3ω component $V_{3\omega}(t)$. The root-mean-square value of 3ω voltage is

$$V_{3\omega}=\frac{\sqrt{2}I_0R'b}{\pi^2\lambda}\frac{1}{\sqrt{1+(2\omega/\lambda)^2}} \tag{17}$$

If $2\omega\ll\lambda$, the root-mean-square value of 3ω voltage becomes

$$V_{3\omega}\approx\frac{\sqrt{2}I_0^3R_0R'L}{\pi^4\kappa S+\frac{\pi^2LA}{\sum R_t}} \tag{18}$$

The average temperature change of the specimen can be calculated from Eq. (14)

$$\bar{\theta}\approx\frac{4I_0^2R_0L}{\pi^4\kappa S+\frac{\pi^2LA}{\sum R_t}} \tag{19}$$

By extracting the linear relationship between $V_{3\omega}$ and I_0^3 from the measurement, and combining Eqs. (18) and (19) and the heat balance Eq. (20),

$$\frac{I_0^2}{2LS}(R_0 + R'\overline{\theta}) = \frac{\overline{\theta}A}{LS\sum R_t} + \rho C_p \overline{\theta}\lambda \quad (20)$$

κ and $\sum R_t$ can be simultaneously determined, where λ^{-1} is the thermalization time,

$$\lambda = \frac{\kappa\pi^2}{L^2\rho C_p} + \frac{A}{LS\sum R_t \rho C_p}$$

3. Experimental details

The PANI specimens for this study were prepared using chemical oxidation based polymerization. CSA and PANI in the emeraldine base form are mixed in a 0.5 M ratio of CSA to phenyl-N repeat unit using a mortar and pestle and then added to the m-cresol while stirring. The solution is magnetically stirred for 48 h with an initial heating at 60 °C for 90 min to make the solution homogenous before ultrasonication for 6 h. The solution is filtered using syringe filters of 450 nm and 200 nm before casting the film. The film is obtained by spin coating the homogeneous solution onto thermally grown silicon oxide substrate and subsequently drying for 24 h and annealing for 4 h. In the experimental setup shown in Fig. 1, the PANI thin film serves as both the specimen heater and temperature sensor. To minimize the contact resistance between the electrical pads and the contact probes, a thin layer of aluminum is deposited on top of PANI thin film. A two-step lithographic process is employed to pattern the specimen and then overlay aluminum in the form of four pads by photolithography. In the second-step, PANI thin film is patterned using front-side alignment photolithography to achieve the 110-μm long, 10-μm wide filament-like specimens. Details of the fabrication processes and calibration are given in [32]. The thickness of the PANI specimens was varied from 20 to 1000 nm and measured using an atomic force microscope. Conductive epoxy is applied to connect the four pads to small diameter alloy wires that are used for electrical connections to minimize the conduction loss.

The specimen is mounted in a vacuum chamber and the temperature is maintained at 300 K. Radiation losses are minimized by shielding and convection losses are reduced by operating in a vacuum of 0.3 torr. A Keithley 6221 is used to supply constant amplitude current source to the two outer pads. The third harmonic voltages across the two inner pads are picked up by a lock-in amplifier (Stanford Research Systems SR 830). The third harmonic voltages are measured from 1 to 30 Hz. The time constant which determines the bandwidth of low pass filter is set to be 30–300 s. To satisfy Eq. (10), the input current I_0 is limited to 0.05 μA or below to increase the measurement accuracy and keep the specimen undamaged by the heat generated due to the high resistance of the specimen. The phase of the lock-in at each frequency is zeroed to improve the phase accuracy for small amplitude current and all line filters are turned off to keep them from interfering with the 3ω signals. Finally, the thermal conductivity of the specimen is evaluated by measuring the third harmonic dependence of the current.

4. Experimental results and discussion

The frequency range of AC current from 1 to 30 Hz is used to fulfill the frequency limit: $2\omega \ll \lambda$, i.e., $2\omega \ll \frac{\kappa\pi^2}{\rho C_p L^2} + \frac{A}{\rho C_p LS\sum R_t}$. In order to measure the thermal conductivity using the above method, the low frequency limit should be established by obtaining the frequency dependence of the root-mean-square (rms) value of the third harmonic voltage $V_{3\omega}$. Fig. 2a shows the frequency dependence of $V_{3\omega}$ in measuring the thermal conductivity of 20-nm thick PANI films. As shown in Fig. 2a, the voltage measured at the third harmonic decreases as the frequency is increased. By fitting the curve shown in Fig. 2a to Eq. (17), the value of λ was found to be on the order of 100 s^{-1}. Meanwhile, C_P was also extracted. For frequencies below 5 Hz, we can consider $2\omega \ll \lambda$. The low frequency limit is established by setting the frequency at 3 or 4 Hz for all the thicknesses. Hence the thermal conductivity can be derived from Eq. (18) by the current dependence of voltage $V_{3\omega}$. Fig. 2b shows the applied current dependence of voltage $V_{3\omega}$ of 20-nm thick PANI films at 4 Hz. The amplitude of the current varies from 0.005 to 0.05 μA. The signal follows well the predicted third power law as shown in Eq. (18). Relationship between $\sum R_t$ and k is extracted according to Eq. (18) and Fig. 2b. By the combination of Eqs. (18), (19) and (20), the in-plane thermal conductivity of the 20-nm thick PANI thin film is calculated to be 0.0406 W/m K, and the underlying total thermal resistance is 0.806 K m^2/W by subtracting the thermal resistance of the substrate from the total resistance $\sum R_t$. The high interfacial thermal resistance could be attributed to many factors, including surface characteristics of the interfacial region and adhesion of PANI with the substrate.

Fig. 2c and d presents the measured rms value of 3ω voltages in the frequency range 1–30 Hz and the linear relationship between $V_{3\omega}$ and I_0^3 of 110-nm thick PANI films, respectively. For other thicknesses, it has also been found that the applied current dependence of voltage $V_{3\omega}$ of PANI films follows the predicted third power law as shown in Eq. (18). By substituting the interfacial thermal resistance of 0.806 K m^2/W and the linear relationship between $V_{3\omega}$ and I_0^3 into Eq. (18), the thermal conductivities of PANI films at different thicknesses are determined.

Fig. 3a shows the experimental results on electrical conductivity of polyaniline films as a function of film thickness. Very strong thickness effect is observed at the 1–100 nm length-scale, which can be attributed to the increasing packing density of the polymer as the thickness increases, leading to higher volumes of metallic transporting regions composed of polaronic conducting segments randomly oriented in the disordered matrix. There is a significant difference in the scattering mechanism in the PANI compared to metals, as shown by the difference between the dashed line (the Mayadas–Shatzkes [33] model for electron scattering in metals) and the solid line for the experimental results obtained in this study. This observation indirectly supports the polaron (electron in phonon cloud) model of conduction in polyaniline [34], where the electron–phonon scattering is more dominant compared to the electron surface/interface scattering as in metals.

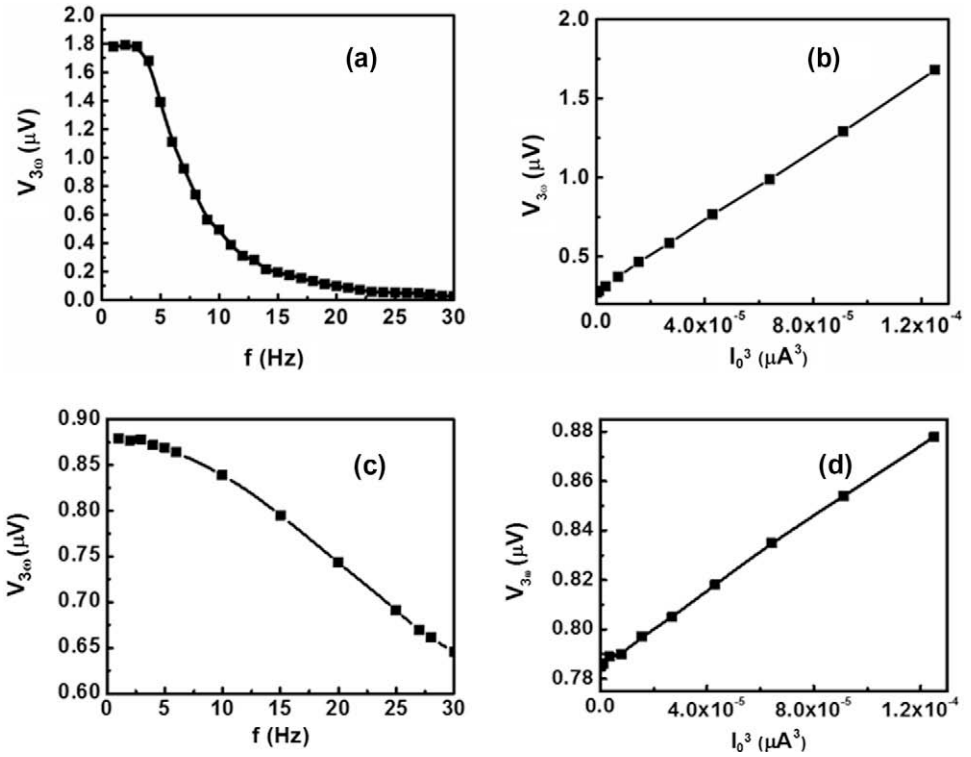

Fig. 2. Frequency dependence of the third harmonic in the range of 1–30 Hz of (a) 20 nm and (c) 110 nm thick PANI films. The amplitude I_0 of the supplied current is 0.05 μA. Dependence of the third harmonic on the applied current of (b) 20 nm and (d) 110 nm thick PANI films at 4 and 3 Hz, respectively.

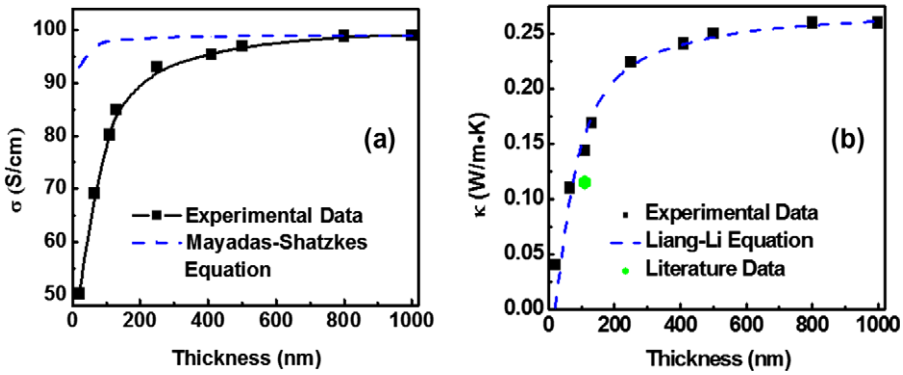

Fig. 3. (a) Electrical conductivity of PANI thin films as a function of film thickness. The dashed curve represents the analytical expression for metals. (b) Thermal conductivity of PANI thin films as a function of film thickness. The symbol ⬢ is the data of the thinnest film from literature [28]. The dashed curve represents the analytical expression [24].

Fig. 3b shows the thickness dependence of the thermal conductivity of polyaniline. Also shown is the data obtained for the thinnest specimen in the existing literature. The thinnest specimens (20 nm) exhibit the smallest value of thermal conductivity 0.0406 W/m K, and the thickest specimens (1 μm) presents the largest value of 0.26 W/m K. As the thickness increases from 20 to about 130 nm, the thermal conductivity increases rapidly from 0.0406 to 0.166 W/m K. Such strong thickness dependence diminishes rather dramatically after 130 nm thickness, and the values converge to the bulk value after 800 nm thickness.

Fig. 3b also shows a curve fitted to the experimental data according to Liang and Li [24] as shown below,

$$\kappa = \kappa_b p \exp\left(-\frac{l_0}{t}\right)\left[\exp\left(\frac{-(\alpha-1)}{t/L_0-1}\right)\right]^{\frac{3}{2}} \quad (\mathrm{W/m\,K}) \qquad (21)$$

where t is the thickness, k_b is the bulk value of thermal conductivity, p is the surface roughness parameter in the range of 0–1, and α is a material constant related to the atomic structure. For the phonon mean free path l_0, we use the estimated value 10 nm [28]. L_0 is a critical size of

material and is assumed as 10 nm in the fitted curve. The fitted results are the product of k_b and p is 0.2772 W/m K, and $\alpha = 4.135$. The analytical model [24] is derived based on the phonon surface scattering and the size confinement of phonon transport in the nanoscale semiconducting systems. Although the mechanism is not developed for polyaniline, its underlying phonon dominance agrees with our experimental data very well.

To explain the observed thickness dependence of thermal conductivity, we note that heat energy is transmitted via electrons and phonons in PANI [35]. The total thermal conductivity k comes from the contributions of those two heat carriers. The literature suggests that the phonon contribution to thermal conductivity may be predominantly high for thin films due to the polaron lattice imperfections in nano-scale films [20]. Therefore, the thermal conductivity can be expressed as

$$k = k_p + k_e \approx k_p = \frac{1}{3} c v l \tag{22}$$

where c is the phonon heat capacity, v is the phonon velocity and l is the phonon mean free path. Because heat conduction mainly depends on the phonon transport in nanometer film, the thermal conductivity is governed by the phonon heat capacity and mean free path. In ordered materials, it is reasonable to assume a constant heat capacity provided that the films are not as thin as atomic layers. However, for the case of disordered organic materials, the influence of structure and defect on volumetric heat capacity cannot be neglected. This is because the thermal properties of organic films are highly sensitive to their microstructural features [36]. With the reduction of film thickness, the volumetric heat capacity is decreased due to the interplay among atomic-scale disorder, porosity, partial crystallinity, and molecular orientation [28].

Another important reason leading to the size dependence of thermal conductivity is the phonon mean free path. On one hand, the collision probability of phonons increases with thickness reduction due to the confinement, which leads to the decrease of the efficiency in heat conduction. On the other hand, the heat conduction is greatly influenced by the nanometer film surface/interface. As the size decreases and the surface–volume ratio increases, the large surface and interface boundary scattering of phonons impose additional resistance to thermal transport and reduces the thermal conductivity of thin films. In addition, there is widespread acceptance that PANI forms a heterogeneous structure in its emeraldine salt (ES) form, in which small domains of highly ordered polymer are surrounded by less ordered material [10]. As PANI film becomes thinner, the amorphous regions are increased, hence the chains are more twisted or the polymer chain discontinues so that the mean free path of phonon is remarkably decreased. According to the classic kinetic theory, the mean free path of phonons in PANI thin films has been estimated to be on the order of 10 nm [28]. The thinnest specimen (20 nm) in our study approaches the mean free path. Therefore, phonon boundary scattering plays the most vital role in the significant reduction of the thermal conductivity of 20 nm thick films compared with thicker films. When the film thickness is between 20 nm and 130 nm, the thermal conductivity is greatly affected by the phonon–phonon scattering due to the confinement and phonon boundary scattering at the interface or surface. When the films are thicker than 130 nm, the nature of structural disorder, imperfection, molecular conformation leads to the increase of the thermal conductivity with the film thickness. When the films are 800 nm thick, the size effect of thermal conductivity is no longer observed, due to the constant phonon heat capacity and mean free path in the bulk films.

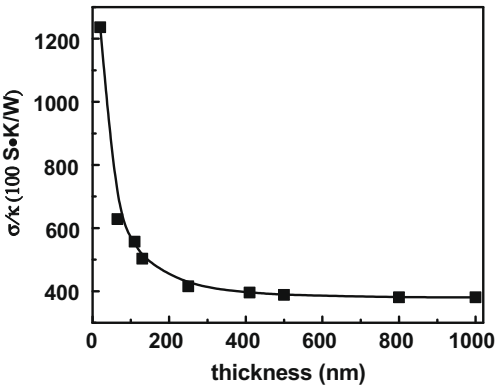

Fig. 4. Ratio of electrical to thermal conductivity (σ/κ) as a function of polyaniline film thickness.

The findings on length-scale effects on electrical and thermal transport in nanoscale polyaniline films predict unfavorable consequences of miniaturization, mainly because of the very low thermal conductivity. However, it also indicates promising performance enhancing aspects for thermoelectric applications. The efficiency of a thermoelectric material is reflected by the value of the dimensionless thermoelectric figure-of-merit (ZT) calculated according to the following equation,

$$ZT = S^2 T\left(\frac{\sigma}{k}\right) \tag{23}$$

where S is the Seebeck coefficient, σ is the electrical conductivity, T is the absolute temperature, and κ is the thermal conductivity. A good thermoelectric material has a high ZT value at the operating temperature, which is determined by the ratio of electrical conductivity and thermal conductivity, assuming S is constant. This ratio is shown as a function of film thickness in Fig. 4. Here, the length scale effect on the phonon dominated thermal transport outweighs the electronic conduction, hence the magnitude of the ratio is very large for the ultra-thin films. However, as the film thickness increases, thermal conductivity increases, thereby lowering the value of the conductivity ratio, which rapidly converges to the bulk value at 130 nm.

5. Conclusion

We present an experimental technique that allows simultaneous characterization of electrical and thermal conductivity and thermal contact resistance of ultra-thin film specimens on insulating substrates. The technique is based on a analytical model we developed to extend the conventional four-probe based (3ω) technique for thermal

characterization to specifically account for the heat loss to the substrate, which enables us to relax the freestanding specimen constraint. The model also allows the extraction of the thermal contact resistance of the specimen-substrate interface. Measurements on PANI thin films in the range of 20 nm −1 micron reveal a strong thickness dependence of thermal conductivity below 130 nm. The size effect rapidly diminishes for films thicker than 800 nm. The size effect on thermal conductivity is attributed to restrictions of the phonon mean free path length and heat capacity. The phonon boundary scattering is the major factor reducing the thermal conductivity of micro- and nanoscale films, and the trend for size effect is expected to be more significant for further reduced thicknesses. In addition, phonon–phonon scattering due to the confinement, structural factors including crystallinity, polymer chain orientation, molecular conformation and imperfection gradually increases, resulting in the decrease of thermal conductivity with the reduction in thin film thickness. The findings of this study suggest that the length-scale effects on electrical and thermal transport can be exploited for better performance thermoelectric applications.

ABSTRACT

A simple red phosphorescent organic light-emitting diode with a device structure of indium tin oxide (ITO)/single organic layer/Al was developed using a mixed host emitting layer of 2,7-bis(diphenylphosphoryl)spiro[fluorene-7,11′-benzofluorene] (SPPO21) and *N*,*N*′-di(1-naphthyl)-*N*,*N*′-diphenylbenzidine (NPB). Holes were directly injected from the ITO to the emitting layer through the NPB, while electrons were injected from the Al to the emitting layer through the SPPO21. The quantum efficiency of the simple device was comparable to that of the common red device.

1. Introduction

Phosphorescent organic light-emitting diodes (PHOLEDs) use triplet excitons for light emission and they have been known to be better than fluorescent organic light-emitting diodes (OLEDs) in terms of quantum efficiency. They showed four times higher quantum efficiency than the fluorescent OLEDs and a theoretical maximum internal quantum efficiency of 100% has already been reported [1–3]. Therefore, the PHOLEDs can replace the fluorescent OLEDs in practical applications.

Although the PHOLEDs are better than fluorescent OLEDs in terms of the quantum efficiency, the PHOLEDs have a complicated device structure to maximize the recombination efficiency of holes and electrons. Hole/exciton blocking layers have generally been used in the PHOLEDs to block the hole leakage and prevent the triplet exciton quenching by the electron transport layer [4,5]. Electron/exciton blocking layers were also critical to the quantum efficiency of the PHOLEDs and the quantum efficiency was greatly improved using the high triplet energy electron/exciton blocking layers [6–11]. Holes, electrons and excitons were confined inside the emitting layer in the device with the hole/exciton and electron/exciton blocking layers. The blocking layers were typically used in the PHOLEDs, but the high quantum efficiency could also be obtained in the PHOLEDs without the blocking layers by controlling the charge transport properties of the host materials [12,13]. It was reported that the hole/exciton blocking layer could be omitted by using the electron transport type host material with the recombination zone near the hole transport layer. The use of the high triplet energy hole transport material was effective to achieve high quantum efficiency without the hole/exciton blocking layers [9].

The device structure of the PHOLEDs could be further simplified by developing strong electron transport type host material which can transport electrons from the electron injection layer/cathode to the emitting layer [12,13]. The number of organic layers between the anode and the emitting layer could also be reduced by proper combination of the hole transport material and the triplet host material. A high triplet energy hole transport material with the highest occupied molecular orbital (HOMO) for efficient hole injection could play a role of the hole transport layer and the electron/exciton blocking layer [9]. It was

doi:10.1016/j.orgel.2009.09.019

reported that a single layer hole transport structure was enough to balance holes and electrons in the light-emitting layer. In this way, a simple PHOLED with three layers made up of the hole transport layer, the emitting layer and the electron injection layer between the anode and the cathode were developed [13]. However, it was difficult to further simplify the device structure due to high driving voltage and low quantum efficiency.

In this work, a single layer device with only the emitting layer between the anode and the cathode was developed using a novel phosphine oxide type host material. It was demonstrated that the combination of the hole transport type host material and the phosphine oxide type host material which can play a role of a host material and an electron injection material was effective to fabricate the single layer PHOLEDs. The device performances of the single layer red PHOLEDs were comparable to those of common red PHOLEDs with separate charge transport layers.

2. Experimental

The 2,7-bis(diphenylphosphoryl)spiro[fluorene-7,11′-benzofluorene] (SPPO21) was synthesized by the phosphonation reaction of the dibrominated spiro[fluorene-7,11′-benzofluorene]. The SPPO21 single layer device had a device configuration of indium tin oxide (ITO, 150 nm)/*N*,*N*′-di(1-naphthyl)-*N*,*N*′-diphenylbenzidine (NPB):SPPO21:iridium(III) bis(2-phenylquinoline)acetylacetonate (Ir(pq)$_2$acac, 100 nm, 2%)/Al (200 nm). A standard device with a device configuration of ITO (150 nm)/*N*,*N*′-diphenyl-*N*,*N*′-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (60 nm)/NPB(30 nm)/(4,4′-*N*,*N*′-dicarbazole)biphenyl (CBP):Ir(pq)$_2$acac (30 nm, 10% doping)/2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP, 5 nm)/tris(8-hydroxyquinoline)aluminum(Alq$_3$, 20 nm)/LiF (1 nm)/Al (200 nm) was also fabricated to compare device performances of the single layer devices. The relative ratio of the NPB to SPPO21 was 10:90, 25:75, 40:60 and 50:50 in weight ratio. Three devices were abbreviated as device I, device II, device III and device IV, respectively. Device structures and chemical structures of the emitting materials are shown in Fig. 1. Organic materials were deposited at a deposition rate of 0.1 nm/s and the relative composition of the host material was controlled by managing the deposition rate of each host material. The devices were encapsulated with a getter and a glass lid after cathode deposition. Voltage sweep of the single layer devices were carried out to obtain current density–voltage–luminance relationship. Energy levels of the materials were determined by cyclic voltametry and ultraviolet–visible absorption spectroscopy. Photovoltaic measurements of the devices were carried out with a solar simulator (Abet Co.) at AM 1.5 condition (100 mW/cm^2). The device performances of the blue PHOLEDs was measured with Keithley 2400 source measurement unit and CS1000 spectroradiometer.

3. Results and discussion

The phosphine oxide type host material, SPPO21, has the HOMO level of 6.12 eV, the lowest unoccupied molecular orbital (LUMO) level of 2.57 eV and the triplet energy level of 2.32 eV. The LUMO level of the SPPO21 is suitable for electron injection and the triplet energy of the SPPO21 is wide enough for efficient energy transfer from the SPPO21 to the red emitting triplet dopant materials. Therefore, it can be used as the electron transport type host material for red PHOLEDs. However, the HOMO level of the SPPO21 is not appropriate for hole injection from the anode to the SPPO21 layer. The hole injection can be improved by the hole transport type host material and

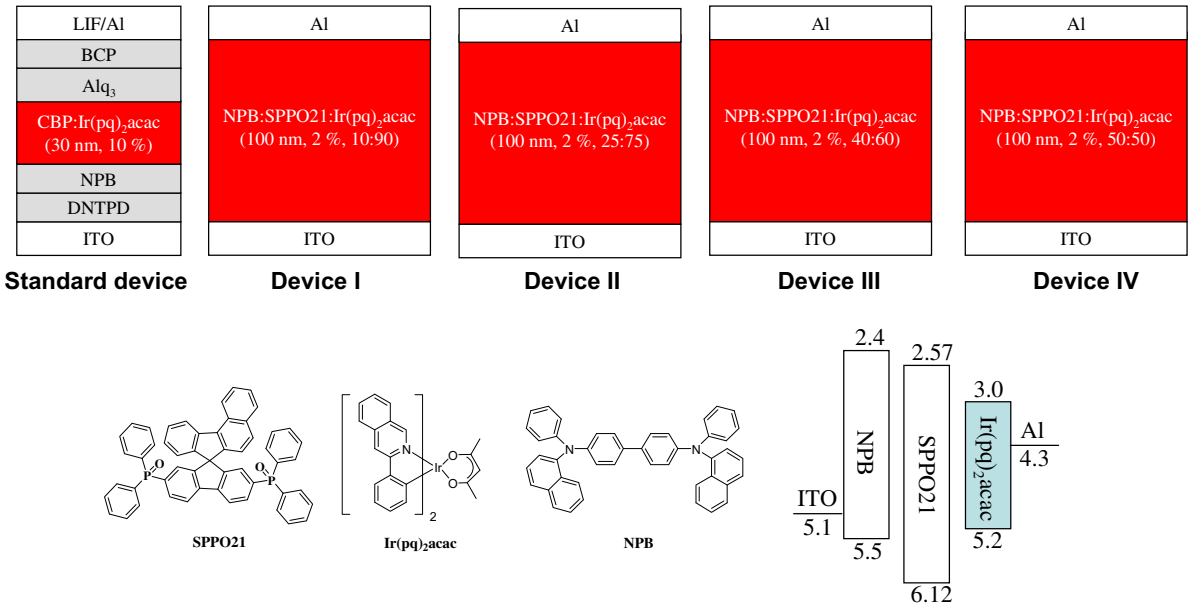

Fig. 1. Chemical structures of the organic materials and device structures of the single layer devices.

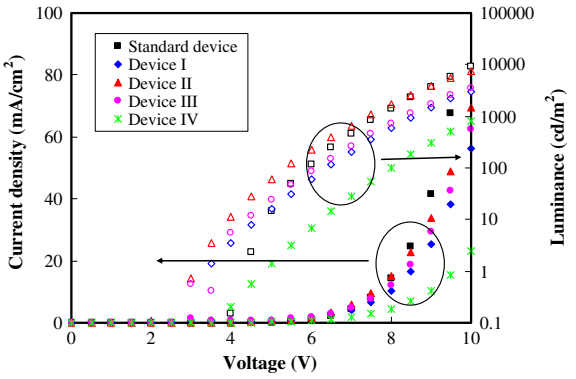

Fig. 2. Current density–voltage and luminance–voltage curves of the single layer red phosphorescent organic light-emitting diodes.

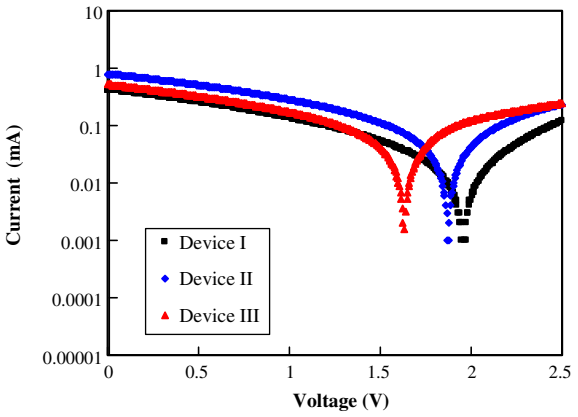

Fig. 3. Current–voltage curves of the single layer red phosphorescent organic light-emitting diodes under exposure to AM 1.5 solar simulator.

the mixing of the hole transport type host with the SPPO21 may enhance the hole injection from the anode to the emitting layer. NPB was chosen as the hole transport type host material due to its triplet energy of 2.3 eV for an energy transfer to the red triplet dopant and the HOMO level of 5.5 eV for direct hole injection from the indium tin oxide anode.

Fig. 2 shows the current density–voltage–luminance curves of the single layer PHOLEDs with different host compositions in the light-emitting layer. The highest current density was observed in the device II with the NPB:SPPO21(25:75) host in the light-emitting layer. There was little difference of the current density in the device I and device III. The high current density of the device II can be explained by the efficient hole injection from the ITO and electron injection from the Al electrode to the emitting layer. The hole injection is effective through the NPB material with strong hole transporting properties, while the electron injection is efficient through the electron transport type SPPO21 material. Therefore, both holes and electrons are effectively injected from the ITO and Al electrode to the emitting layer. In the case of the device I, poor hole injection from the ITO to the emitting layer reduces the current density of the device in spite of the high electron density. Similarly, poor electron injection from the Al cathode to the emitting layer may be responsible for the low current density of the device III. The current density of the device IV was even lower than that of the device III due to poor electron injection. This result implies that the probability for the formation of percolation path for the charge transport is high in the device II, while the percolation path is not formed in the device I, device III and device IV. The luminance of the single layer devices followed the similar relationship as the current density.

To investigate the origin for the direct electron injection from the Al to the emitting layer, the built-in potential of the device was measured using the photovoltaic experiments. The single layer device was exposed to the solar simulator at air mass (AM) 1.5 (100 mW/cm^2) condition and the open circuit voltage (Voc) of the device was measured. Fig. 3 shows the current density–voltage curves of the simple devices under exposure to AM 1.5 solar simulator. The Voc of the simple device I was 1.97 V and it was reduced in the device II (1.88 V) and device III (1.63 V). The Voc corresponds to the built-in potential of the device and it reflects the energy level difference between the anode and the cathode [14]. The ITO electrode has the work function of 5.1 eV from our photoelectron spectroscopic measurements and the Al has the work function of 4.3 eV. Therefore, the built-in potential of the device with the ITO anode and the Al cathode should be around 0.8 eV. However, the built-in potential was greatly increased in the simple device, indicating that the there is a band bending at the interface between the mixed host structure and the electrodes. The NPB does not form any complex with the ITO, while the SPPO21 can induce the band bending through the charge transfer complex formation between the phosphine oxide unit and the Al electrode [15]. Therefore, the work function of the Al is modified by the SPPO21 and the built-in potential is increased. The interface band bending is significant in the device with the high SPPO21 content due to the extensive interfacial contact between the SPPO21 and the Al. The built-in potential was greatly reduced in the device III due to low SPPO21 content, which explains the low current density of the device III. The high energy barrier for electron injection is one of the important reasons for the low current density. As a reference, the built-in potential of the NPB:Alq_3 single layer device was 0.9 eV.

Quantum efficiency of the single layer devices are shown in Fig. 4. High quantum efficiency was obtained in the device II, while the device I, device III and device IV showed much lower quantum efficiency than the device II. In general, the quantum efficiency of the PHOLEDs is determined by the charge balance and triplet exciton quenching by the charge transport layers or cathodes. In terms of the charge balance, the device II is better than the device I or device III because the hole and electron current density was similar in the device II. The electron carriers was much more than the hole carriers in the device I, while hole carriers are much more than the electron carriers in the device III and device IV. The holes and electrons unbalance in the light-emitting layer decreases the quantum efficiency of the device I, device III and device IV. This can be confirmed in the current density–voltage

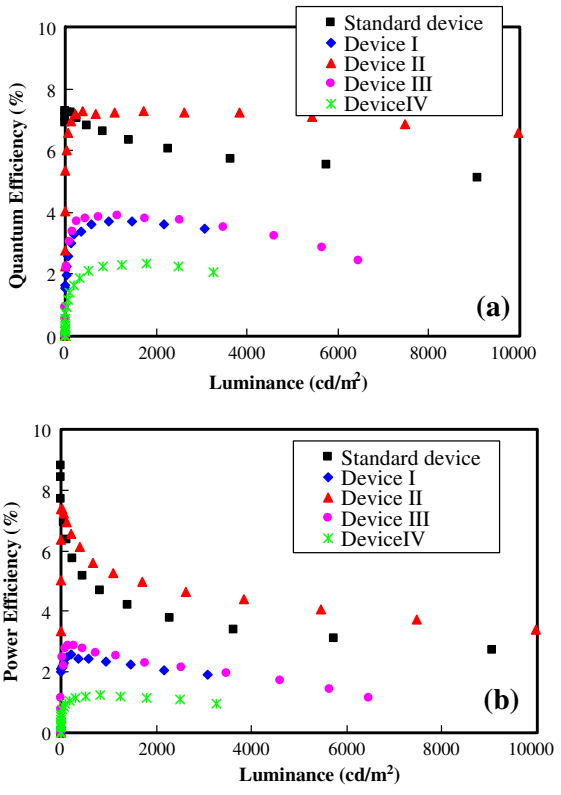

Fig. 4. Quantum efficiency–luminance (a) and power efficiency–luminance (b) curves of the single layer devices.

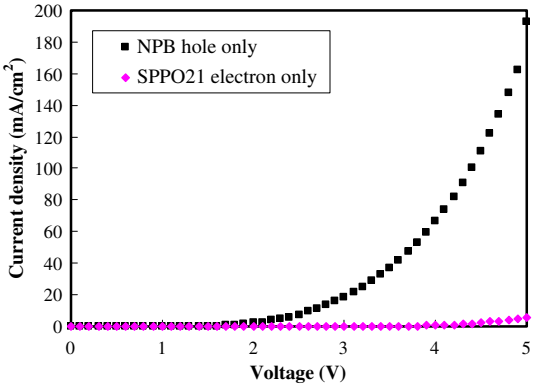

Fig. 5. Current density–voltage curves of the hole only device of the NPB and the electron only device of the SPPO21.

curves of the hole only device of the NPB and the electron only device of the SPPO21 (Fig. 5). The hole current density was much higher than the electron current density and the charge balance could be optimized in the device with high SPPO21 content. The other factor for the low quantum efficiency in the device I, device III and device IV is triplet exciton quenching by the anode and the cathode. It has been known that the recombination zone of the emitting layer in the PHOLEDs should be away from the cathode. As reported in the early work, the triple exciton quenching is significant in the device with the recombination zone near

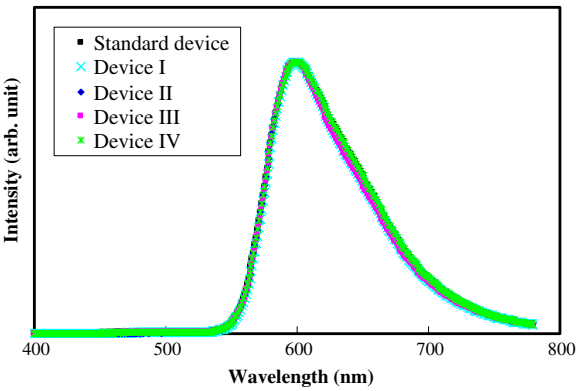

Fig. 6. Electroluminescence spectra of the single layer red PHOLEDs.

the electrode. The recombination zone of the device is close to the anode side when the electron transport type host material is rich in the mixed host structure, while the exciton formation zone is close to the electron transport layer side in the device when the hole transport type host material is rich in the mixed host structure. Therefore, there is a high probability for the exciton quenching by the electrode in the device I, device III and device IV. In the case of the device II, the exciton quenching by the electrode can be reduced due to broad recombination zone. The quantum efficiency of the device II was 7.3% at 1000 cd/m^2 and the current efficiency was 11.4 cd/A. The quantum efficiency of the device II was better than that of the standard device with CBP host in the light-emitting layer and common charge transport layers. The improved charge balance in the emitting layer and low probability for the triplet exciton quenching may be responsible for the high quantum efficiency of the device II compared with the standard device. The efficiency roll-off was also better in the device II, which may be due to broad recombination zone in the device II. Therefore, it was possible to develop the single organic layer PHOLEDs which show better performances than the common red PHOLEDs. The direct hole injection from the ITO to the NPB and direct electron injection from the Al to the SPPO21 were responsible for the high quantum efficiency and low driving voltage in the single layer device. The power efficiency of the devices followed the same trend as the quantum efficiency.

Electroluminescence (EL) spectra of the single layer red PHOLEDs are shown in Fig. 6. There was little difference of the EL spectra in the single layer devices with different host compositions in the emitting layer. This indicates that the same EL spectra as the standard device can be obtained in the single layer devices.

4. Conclusions

In conclusion, high efficiency single layer red PHOLEDs could be developed using the hole transport type NPB and the electron transport type SPPO21 as the host materials in the light-emitting layer. Holes were directly injected from the anode through the NPB and electrons could be directly injected from the cathode through the SPPO21 layer. Band bending at the interface between the

mixed emitting layer and the Al cathode by the SPPO21 layer was critical to fabricate the single layer devices without any electron injection layer and any charge transport layer. Therefore, the device structure of the PHOLEDs could be simplified without sacrificing the device performances by using the phosphine oxide type SPPO21 host material.

ABSTRACT

Two new coumarin derivatives containing an electron-transporting moiety (benzotriazole), 7-*N*,*N*-diethylamino-3-(benzotriazol-1-yl)coumarin (DABTC-1) and 7-*N*,*N*-diethylamino-3-(benzotriazol-2-yl)coumarin (DABTC-2), were synthesized and characterized by element analysis, ^{1}H NMR, FT-IR and UV–vis absorption spectra. Their structures were determined by X-ray crystallography single crystal analysis. The photoluminescent behaviors of the compounds in both solution and solid states were observed, they exhibit strong blue and blue–green emissions under ultraviolet light excitation, respectively. The energy levels of the HOMO and LUMO of the compounds have been calculated with density functional theory (DFT) and time-dependent density functional theory (TD-DFT) at B3LYP/6-31G(d) level. The electroluminescent devices with the compounds as the emitters were fabricated.

1. Introduction

Organic light-emitting diodes (OLEDs) based on organic materials are known to be highly efficient and are capable of producing a wide range of colors, which have attracted considerable interest and constitute a rapidly developing field due to their potential use in the development of energy-efficient, low-cost, full-color, flat-panel displays and other emissive products [1–4].

Coumarin derivatives exhibit not only excellent biological and medical activities [5], but also have super thermal stability and outstanding optical properties including an extended spectral response, high quantum yields, superior photostability. Optical applications of these compounds, such as laser dyes, nonlinear optical chromophores, fluorescent whiteners, fluorescent probes, polymer science, optical recording and solar energy collectors, have been widely investigated [6–12]. More important, coumarin dyes were used as blue, green and red dopants in organic light-emitting diodes (OLEDs) [13–15]. However, coumarin dyes are easily self-quenched in high concentration due to the intermolecular interactions and aggregations, so as the light-emitting materials they are always doped in the host materials at appropriate concentration to fabricate OLEDs with reasonable, luminant efficiency [16–19]. 7-*N*,*N*-diethylaminocoumarin dyes substituted at 3-position with an electron-withdrawing group are a typical class of D-A structure molecules and exhibit strong fluorescence [20–22]. So some of these coumarin derivatives have been used in the fabrication of OLEDs through doping in polymer matrix or Alq_3 thin layer as guest-emitting materials [23].

Recently, we synthesized two new coumarin derivatives, 7-*N*,*N*-diethylamino-3-(benzotriazol-1-yl)coumarin (DABTC-1) and 7-*N*,*N*-diethylamino-3-(benzotriazol-2-yl)-coumarin (DABTC-2), using the Knoevenagel type of condensation reaction (Scheme 1). The compounds exhibit strong blue and blue-green emissions under ultraviolet light excitation, respectively. Here, the photophysical properties of the compounds in diluted chloroform

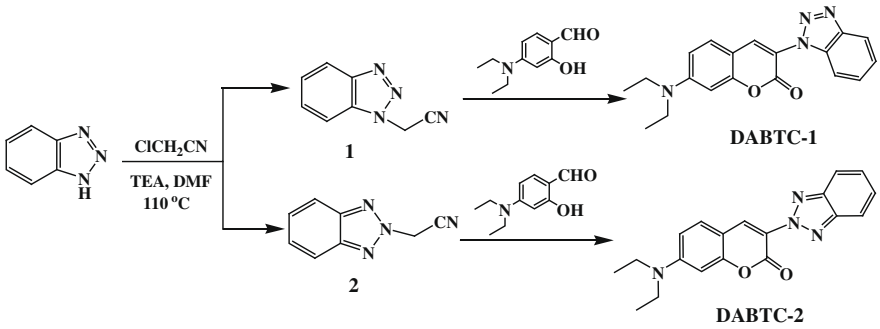

Scheme 1. Synthetic routes of 7-*N*,*N*-diethylamino-3-(benzotriazol-1-yl)coumarin and 7-*N*,*N*-diethylamino-3-(benzotriazol-2-yl)coumarin.

solutions and thin films were investigated in detail. We fabricated the electroluminescence devices by vacuum vapor-deposited film with doped with the compounds as emission materials and investigated the electroluminescent properties.

2. Experimental details

2.1. Materials and methods

4-(*N*,*N*′-diethylamino) salicylaldehyde from Zhejiang Huadee Dyestuff Chemical Co. Ltd. (China) was recrystallized from ethanol. 1H-benzotriazole (BTA) from Aldrich was used without further purification. Triethylamine, piperidine and chloroacetonitrile were analytical grade reagents from Tanjin Fuchen Chemical Reagent Factory. 4,4′-bis(9-carbazolyl) biphenyl (CBP), 2-(4-biphenylyl)-5-(4-tert-butylphenyl)-1,3,4-oxadiazole (Bu-PBD), 4,4′,4″-tris-N-naphthyl-*N*-phenylamino-triphenylamine (2-TNATA) and *N*,*N*′-bis-(naphthyl)-*N*,*N*′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB) were purchased from Electro-Light Technology Corp., Beijing. The other solvents were analytical grade reagents.

IR spectra (400–4000 cm^{-1}) were measured on a Shimadzu IRPrestige-21 FT-IR spectrophotometer. ^1H NMR spectra were obtained on Unity Varian-500 MHz. C, H, and N analyses were obtained using an Elemental Vario-EL automatic elemental analysis instrument. Melting points were measured by using an X-4 microscopic melting point apparatus made in Beijing Taike Instrument Limited Company, and the thermometer was uncorrected. UV–vis absorption and photoluminescent spectra were recorded on a Shimadzu UV-2550 spectrometer and on a Perkin–Elmer LS-55 spectrometer, respectively. The electroluminescent spectra were measured on a Hitachi MPF-4 spectrometer.

2.2. Synthesis and characterization of 7-N,N-diethylamino-3-(benzotriazol-1-yl)coumarin (DABTC-1) and 7-N,N-diethylamino-3-(benzotriazol-2-yl)coumarin (DABTC-2)

The synthetic routes were shown in scheme 1.

2.2.1. 2-(1H-benzotriazol-1-yl)acetonitrile (**1**) and 2-(1H-benzotriazol-2-yl)acetonitrile (**2**)

The intermediates **1** and **2** were synthesized by condensation of 1*H*-benzotriazole with chloroacetonitrile in DMF at reflux in the presence of triethylamine according to the method reported by Sanna et al. [24].

2.2.2. 7-N,N-diethylamino-3-(benzotriazol-1-yl)coumarin (DABTC-1)

1.93 g (10 mmol) of 4-(*N*,*N*′-diethylamino) salicylaldehyde, 1.67 g (10.6 mmol) 2-(1*H*-benzotriazol-1-yl)acetonitrile (**1**) were dissolved in 16 mL of anhydrous alcohol and treated with piperidine (0.6 mL). The reaction mixture was refluxed with stirring for 49 h, treated with HCl (3.5%), and boiled for 5 h. After the reaction was finished, the resulting mixture was poured into 50 mL of water and extracted with dichloromethane (3 × 50 mL). The organic phase was washed with water (2 × 50 mL) and dried over anhydrous $MgSO_4$. After filtering, the filtrate was evaporated to dryness under reduced pressure. The crude was purified by chromatography on silica gel using ethyl acetate/petroleum ether (1:6, v/v) as the eluent to give 7-*N*,*N*-diethylamino-3-(benzotriazol-1-yl)coumarin (DABTC-1) (1.12 g, 33.5%). m.p. 164–165 °C. 1H NMR: (500 MHz, $CDCl_3$, δ, ppm): 8.116 (d, J = 4.8 Hz, 1H, Aryl-H), 8.049 (s, 1H, 4-H), 7.619–7.594 (m, 1H, Aryl-H), 7.565–7.554 (m, 1H, Aryl-H), 7.540–7.516 (m, 1H, Aryl-H), 7.434–7.388 (m, 1H, Aryl-H), 6.678 (d, J = 7.9 Hz, 1H, Aryl-H), 6.608 (s, 1H, Aryl-H), 3.503–3.451 (m, 4H, $-CH_2-$), 1.261 (t, J = 6.4 Hz, 6H, $-CH_3$). IR (KBr pellet cm^{-1}): 3060 (Aryl-CH), 2971, 2929, 2891 (Alkyl-CH), 1728 (C=O, lactone), 1628 (C=C), 1590, 1524, 1421, 1250, 1121, 752. Anal. Calc. for $C_{19}H_{18}O_2N_4$ (%): C, 68.25; H, 5.43; N, 16.76. Found: C, 68.53; H, 5.57; N, 16.84.

2.2.3. 7-N,N-diethylamino-3-(benzotriazol-2-yl)coumarin (DABTC-2)

0.49 g (2.53 mmol) of 4-(*N*,*N*′-diethylamino) salicylaldehyde, 0.40 g (2.53 mmol) 2-(1*H*-benzotriazol-2-yl)acetonitrile (**2**) were dissolved in 12 mL of absolute alcohol, and then piperidine (0.2 mL) was dropped under ice bath. The mixture was stirred for 12 h at room temperature, treated with HCl (3.5%) and boiled for 5 h. After the reaction was finished, the resulting mixture was poured into 20 mL of water and extracted with dichloromethane (3 × 20 mL). The organic phase was washed with water and dried over anhydrous $MgSO_4$. After filtering, the filtrate was evaporated to dryness under reduced pressure. The crude was purified by chromatography on silica gel using ethyl acetate/petroleum ether (1:6, v/v) as the eluent to give 7-

N,*N*-diethylamino-3-(benzotriazol-2-yl)coumarin (DABTC-2) (0.63 g, 74.8%). m.p. 156–158 °C. ^{1}H NMR: (500 MHz, $CDCl_3$, δ, ppm): 8.280 (s, 1H, 4-H), 7.954 (d, J = 4.8 Hz, 2H, Aryl-H), 7.441–7.264 (m, 3H, Aryl-H), 6.682 (d, J = 8 Hz, 1H, Aryl-H), 6.608 (s, 1H, Aryl-H), 3.484–3.440 (m, 4H, $-CH_2-$), 1.255 (t, J = 5.2 Hz, 6H, $-CH_3$). IR (KBr pellet cm^{-1}): 3067 (Aryl-CH), 2975, 2925, 2871 (Alkyl-CH), 1731 (C=O, lactone), 1624 (C=C), 1573, 1517, 1421, 1233, 1125, 745. Anal. Calc. for $C_{19}H_{18}O_2N_4$ (%): C, 68.25; H, 5.43; N, 16.76. Found: C, 68.51; H, 5.72; N, 16.37.

2.3. Crystallography

Suitable crystals of DABTC-1 and DABTC-2 were obtained by evaporation of ethyl acetate solutions, respectively. The diffraction data were collected with a Bruker Smart Apex CCD area detector using a graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) at 20 °C. The structures of DABTC-1 and DABTC-2 were solved by using the program SHELXL and Fourier difference techniques, and refined by full-matrix least-squares method on F^2. All hydrogen atoms were added theoretically. The crystals and experimental data of DABTC-1 and DABTC-2 are shown in Table S1. The selected bond lengths and bond angles of DABTC-1 and DABTC-2 are listed in Tables S2 and S3, respectively.

2.4. Quantum chemical calculations

The structure of DABTC-1 and DABTC-2 were optimized by semiempirical density functional theory (DFT) using a B3LYP/6-31G (d) basis set. The structural energies of DABTC-1 and DABTC-2 were calculated at B3LYP/6-31G(d) levels. The structure optimization and energy calculations were performed with the GAUSSIAN 98 program.

2.5. OLEDs fabrication

The multilayer OLEDs were fabricated by vacuum-deposition method. ITO-coated glass with a sheet resistance $R_\square \sim 20\ \Omega/\square$ was cut into 3 cm × 3 cm plates and etched in dilute hydrochloric acid for 20 min. Then the ITO substrates were routinely cleaned by ultrasonic treatment in solvents and then cleaned by exposure to an UV–ozone ambient. All organic layers were sequentially deposited without breaking vacuum (2×10^{-4} Pa). Thermal deposition rates for organic materials, LiF and Al were ~2 Å/s, ~1 Å/s and 10 Å/s, respectively. The active area of the devices was 12 mm^2. The EL spectra were measured on a Hitachi MPF-4 fluorescence spectrometer. The characterization of brightness–current–voltage (B–I–V) were measured with a 3645 DC power supply combined with a 1980A spot photometer and were recorded simultaneously. All measurements were done in the air at room temperature without any encapsulation.

3. Results and discussion

3.1. X-ray crystal structures of DABTC-1 and DABTC-2

The crystal structures and packing diagrams of DABTC-1 and DABTC-2 are given in Figs. 1–4, respectively. The crystal data and experimental details are shown in Table S1. The selected bond lengths and bond angles of DABTC-1 and DABTC-2 are listed in Tables S2 and S3, respectively.

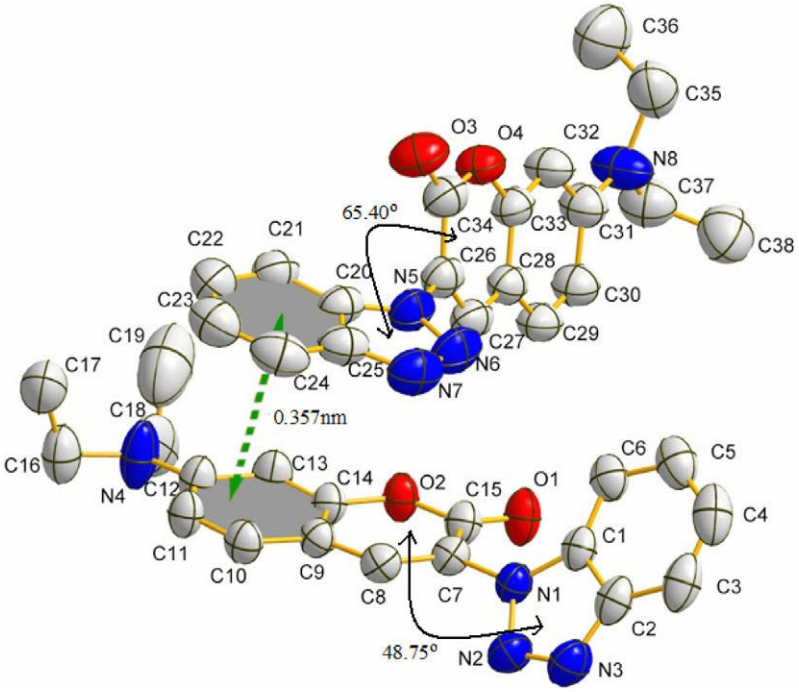

Fig. 1. Crystal structure of DABTC-1.

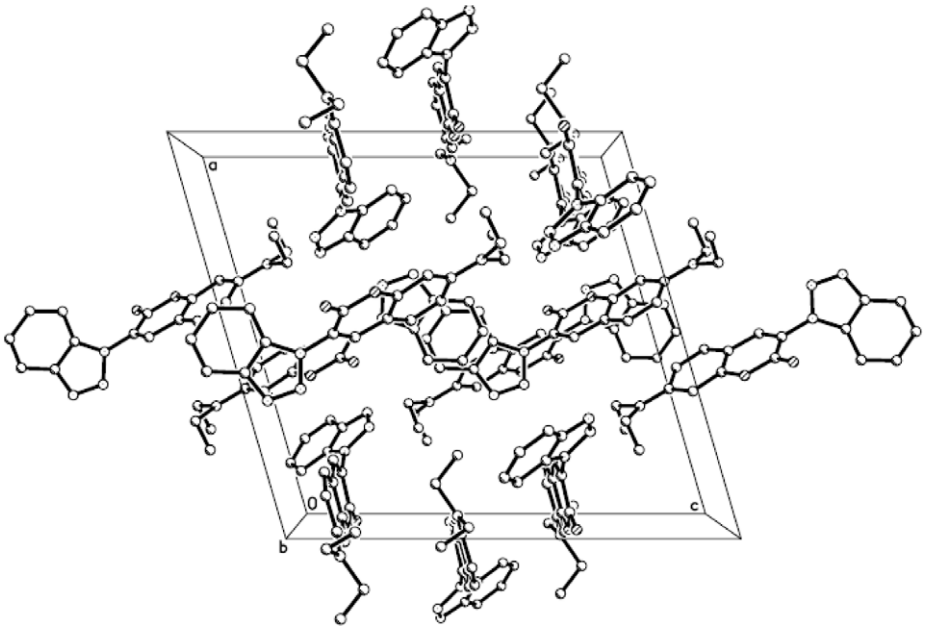

Fig. 2. Packing diagram of molecules of DABTC-1 along *a*-axis. H atoms are omitted for clarity.

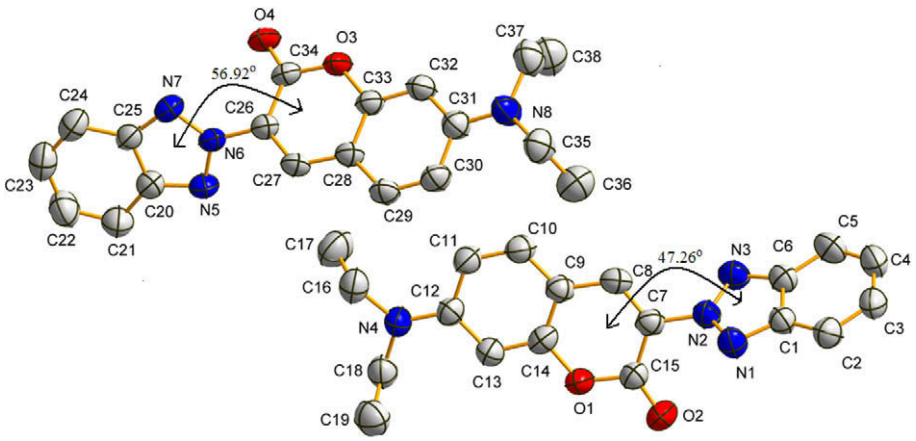

Fig. 3. Crystal structure of DABTC-2.

Acceptable crystals of DABTC-1 for X-ray analysis were obtained by slow evaporation of ethyl acetate solution, and the structure was measured by X-ray crystallography. The crystal of DABTC-1 belongs to the monoclinic space group $P2_1/c$, $a = 15.920(2)$ Å, $b = 12.8933(18)$ Å, $c = 17.083(3)$ Å, $\beta = 106.299(3)°$, $U = 3365.7(9)$ Å^3, $Z = 8$, $D_c = 1.320$ g cm^{-3}, $\mu = 0.089$ mm^{-1}. As shown in Fig. 1, there is an asymmetric unit consisted of two molecules in crystal structure of DABTC-1 due to the different space configuration of two ethylic groups of diethylamine in 7-position of coumarin ring. These two molecules are space conformers, the benzotriazole skeleton of one DABTC-1 molecule cross-paralleled and superposed with the coumarin ring of other DABTC-1 molecule, and the distance of the planes is about 3.6 Å. In addition, the benzotriazole skeletons are not coplanar with the coumarin rings in these two molecules, the dihedral angles are 65.40° and 48.75°, respectively.

The packing diagram for unit cell of DABTC-1 was shown in Fig. 2. There is cross ABAB-type stacking between the benzotriazole group of one DABTC-1 molecule and the coumarin ring of other DABTC-1 molecule, the interplanar (A···B) distance is approximately 3.6 Å, which means weak intermolecular π–π stacking interaction between DABTC-1 molecules in crystal lattice.

Acceptable crystals of DABTC-2 for X-ray analysis were also obtained by slow evaporation of ethyl acetate solution. The crystal of DABTC-2 belongs to the monoclinic space group $P2_1/c$, $a = 17.416(5)$ Å, $b = 12.743(4)$ Å, $c = 15.707(5)$ Å, $\beta = 102.527(5)°$, $U = 3403.1(18)$ Å^3, $Z = 8$, $D_c = 1.305$ g cm^{-3}, $\mu = 0.088$ mm^{-1}. Similarly, there is also an asymmetric unit consisted of two molecules in crystal structure of DABTC-2 due to the different space configuration of two ethylic groups of diethylamine in 7-position of coumarin ring (Fig. 3). Compared with DABTC-1, these

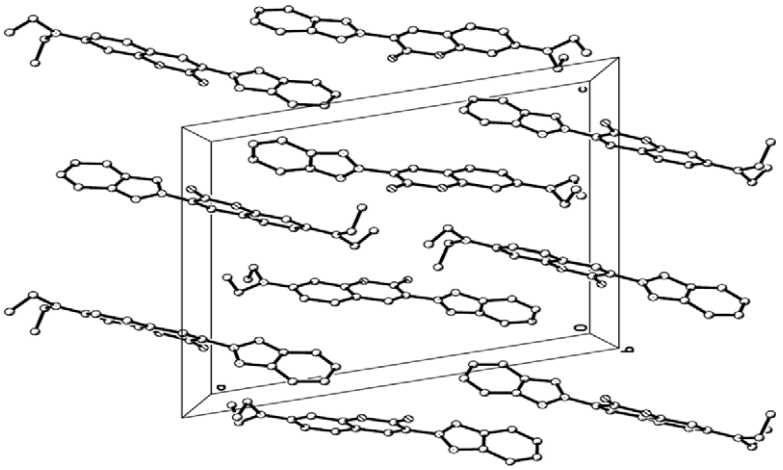

Fig. 4. Packing diagram of molecules of DABTC-2 along *c*-axis. H atoms are omitted for clarity.

space conformers did not neither parallel nor superpose each other. As shown in Fig. 4, there is no intermolecular π–π stacking interaction between DABTC-2 molecules in crystal lattice. From the crystal structure of DABTC-2, we can see that the benzotriazole skeletons are not also coplanar with the coumarin rings in these two molecules, the dihedral angles are 56.92° and 47.26°, respectively.

3.2. Absorption and fluorescence of DABTC-1 and DABTC-2

UV–vis absorption spectra of DABTC-1 and DABTC-2 in diluted chloroform solutions are given in Fig. 5. It is shown that the absorption spectrum of DABTC-1 exhibits absorptions at 253 nm and 414 nm, respectively. The absorption spectrum of DABTC-2 is similar to that of DABTC-1, there are two absorption at 253 nm and 424 nm. An important feature of the absorption spectrum of DABTC-2 is shown that the second absorption band at 424 nm was bathochromically shifted by about 10 nm with respect to that of DABTC-1 in which the second absorption band is at 414 nm, it can be generally deduced that the conjugative effect of the 2-substituted benzotriazole derivative (i.e. DABTC-2) is larger than that of the 1-benzotriazolyl isomer (i.e. DABTC-1).

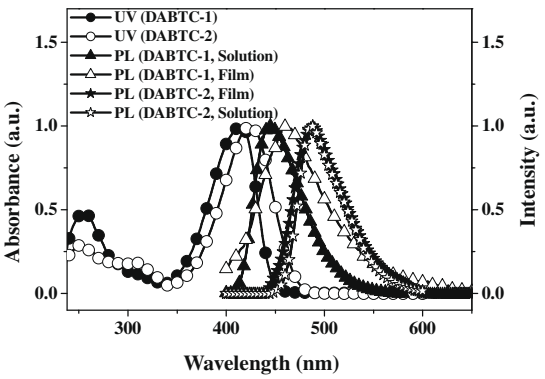

Fig. 5. UV–Vis absorption and photoluminescent spectra of the compounds in dilute chloroform solutions and the solid films.

Fig. 5 also shows the photoluminescent spectra of DABTC-1 and DABTC-2 in dilute chloroform solutions and the solid films. It is shown that DABTC-1 compound exhibits bright blue emission with peak at 447 nm and DABTC-2 compound exhibits bright blue–green emission at 485 nm in dilute solution, and the emission peak of DABTC-2 was red-shifted by about 38 nm compared with that of DABTC-1 due to the larger conjugation of molecule in DABTC-2. Compared with the emission spectra in the solutions, the emission peaks of the solid films of DABTC-1 and DABTC-2 are observed at 462 and 485 nm, respectively. The emission peak of DABTC-1 in the solid film was bathochromically shifted by 15 nm with respect to that in the solution, and much broader emission band of the solid film brought about the compact piling of the solids was occurred, suggesting that the compound in the solid film has more intermolecular interaction than that in solution situation, and thus may lead to change of the emission band. The emission spectrum of the film of DABTC-2 was similar to that of the solution, the emission peaks were at 485 nm, but the former was little broader than the latter. The differences between the films and the solutions were explained by the crystal structures of DABTC-1 and DABTC-2. There was weak intermolecular π–π stacking interaction between DABTC-1 molecules in crystal lattice, whereas no intermolecular π-π stacking interaction between DABTC-2 molecules existed in crystal lattice.

UV–vis absorption and photoluminescent spectra of coumarin 6 (C6) and 7 (C7) in diluted chloroform solutions show the maximum peaks at 456 nm (C6), 437 nm (C7), 490 nm (C6) and 491 nm (C7), respectively [25]. Compared with commercial coumarin 6 and 7, although the structure of DABTC-2 is similar to that of coumarin 6 and 7, UV–vis absorption and photoluminescent spectra of DABTC-2 shift to blue due to the electron-withdrawing benzotriazole substituents at 3-position.

The photoluminescence behaviors of DABTC-1 and DABTC-2 vs. the concentrations in chloroform solutions were shown in Fig. 6. It was found that the emission spectral features of DABTC-1 and DABTC-2 changed with the solution concentrations. The concentration required for

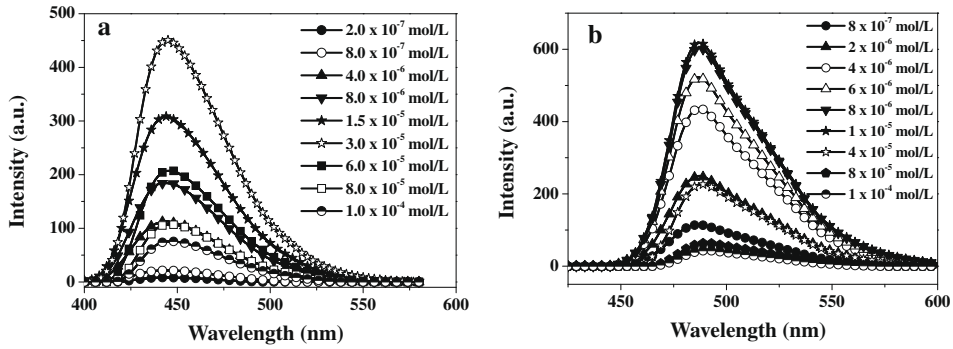

Fig. 6. The emission spectra of DABTC-1 (a) and DABTC-2 (b) in dilute chloroform solutions at room temperature.

the maximum emission intensity was different in DABTC-1 and DABTC-2, which implies that concentration plays an important role in the different dye molecules. There is the strongest blue emission at about concentration of 3.0×10^{-5} mol/L for DABTC-1 and 8.0×10^{-6} mol/L for DABTC-2, respectively. When the concentrations were lower than these concentrations, the relative emission intensities increased gradually with increasing the concentrations. When the concentrations were higher than these concentrations, the emission intensities were decreasing.

3.3. Fluorescence quantum yield of the compound **3** ($\Phi_{F,3}$)

Fluorescence quantum yields of DABTC-1 and DABTC-2 in chloroform solution were checked with anthracene, respectively. The quantum yield (Φ_F) were calculated according to the relationship [26,27]:

$$\Phi_F = \Phi_F^S \frac{\int_0^\infty I_F(\tilde{\nu})d\tilde{\nu}}{\int_0^\infty I_F^S(\tilde{\nu})d\tilde{\nu}} \left(\frac{1-10^{-A^S}}{1-10^{-A}}\right)\left(\frac{n}{n^S}\right)^2$$

where Φ_F^S is the quantum yield of anthracene as standard, which was assumed to be 0.25 for all environments [27]. The integral $\int_0^\infty I_F(\tilde{\nu})d\tilde{\nu}$ and $\int_0^\infty I_F^S(\tilde{\nu})d\tilde{\nu}$ are the areas under the emission curves of the investigated and standard compound, respectively. A and A^S are the absorbances at the wavelength of excitation, n and n^S are the refractive indices for the investigated and standard, respectively. In the research, the $\Phi_{F,\ DABTC\text{-}1}$ and $\Phi_{F,\ DABTC\text{-}2}$ are 0.53 and 0.69, respectively. Fluorescence quantum yields of Coumarin 6 ($\Phi_{F,\ Coumarin\ 6}$) in acetonitrile is 0.63 [28]. Fluorescence quantum yields of DABTC-1 and DABTC-2 are comparative to that of coumarin 6.

3.4. Quantum chemical calculations

From the crystal structures of DABTC-1 and DABTC-2 (Figs. 1 and 3), it was found that there were two molecules in the crystal structures. For the sake of quantum chemical calculations, we chose one molecule of them to optimize DABTC-1 and DABTC-2 geometrical structures, respectively. B3LYP/6-31G(d) optimized structures of DABTC-1 and DABTC-2 are close to their X-ray crystallographic data. The HOMO and LUMO levels of DABTC-1 and DABTC-2 were deduced using the DFT method as shown in Figs. S1 and S2, respectively. It can be seen that the levels of HOMO and LUMO of DABTC-1 were −5.510 eV and −1.589 eV, and the energy gap between HOMO and LUMO is about 3.921 eV. For DABTC-2, the data were −5.487 eV, −1.594 eV and 3.893 eV, respectively. It can be also found that the electron density distributions of the HOMO orbitals were different from that of the HOMO orbitals for DABTC-1 and DABTC-2.

The UV–vis absorption spectra of DABTC-1 and DABTC-2 were also calculated by the time-dependent density functional theory (TD-DFT) at the same level. The experimental and calculated data for the lower-lying singlet states of DABTC-1 and DABTC-2 were listed in Table 1. As shown in Table 1, there are some discrepancies between theoretical and experimental data due to several influencing factors, such as solvent effect and intermolecular interaction. It has been found that the lowest energy absorption at 414 nm for DABTC-1 or 424 nm for DABTC-2 was an excitation from the HOMO to the LUMO. The transition occurring at 253 nm was attributed to the electronic $\pi \rightarrow \pi^*$ transition from the HOMO to the LUMO+2 for DABTC-1 or from the HOMO−2 to the LUMO+1 for DABTC-2, respectively.

Table 1
Absorption spectra data of DABTC-1 and DABTC-2.

Compound	Transition character	OSC[a]	$\lambda_{max,\ cal.}$ (nm)	$\lambda_{max,\ exp.}$ (nm)[b]	Transition feature
DABTC-1	HOMO → LUMO	0.7397	369.32	414	$\pi \rightarrow \pi^*$
	HOMO → LUMO+2	0.1583	243.25	253	$\pi \rightarrow \pi^*$
DABTC-2	HOMO → LUMO	0.9473	378.24	424	$\pi \rightarrow \pi^*$
	HOMO−2 → LUMO+1	0.1778	233.37	253	$\pi \rightarrow \pi$

3.5. OLED performance

The molecular structures of the materials and the devices with the configuration of ITO/2-TNATA (5 nm)/NPB (40 nm)/CBP: DABTC-1 or CBP: DABTC-2 (× wt%, 30 nm)/PBD (30 nm)/LiF (1 nm)/Al (100 nm) were depicted in Fig. 7. DABTC-1: CBP or DABTC-2: CBP was employed as the emitter, 2-TNATA, NPB, and PBD were used as hole injection, hole transport and electron transport materials, respectively. LiF was used as the electron–injection layer.

Fig. 8 shows the EL spectra of the devices with DABTC-1 and DABTC-2 doped at concentrations of 1.0 wt% at different driving voltages. The intensities of EL emissions increase gradually with increasing the driving voltages, but the emission spectral features do not change. The devices of DABTC-1 exhibit blue emissions with the maximum peaks at ca. 462 nm, the devices of DABTC-2 exhibit blue–green emissions with the maximum peaks at ca. 485 nm. The EL spectra of DABTC-1 and DABTC-2 are identical to the PL spectra of them in the solid films, respectively. Such results indicate that these emissions take place from DABTC-1 and DABTC-2 molecules.

Fig. 9 shows the representative luminance-current density–voltage characteristics of the devices doped DABTC-1 with different concentrations. At the doped concentration of 1.0 wt%, the device shows a turn-on voltage about 12 V, and the luminance reaches as high as 40 cd/m^2 at 21 V. At the doped concentration of 2.0 wt%, a turn-on voltage of the device is about 8.5 V, and the maximal luminance reaches 48 cd/m^2 at 15 V.

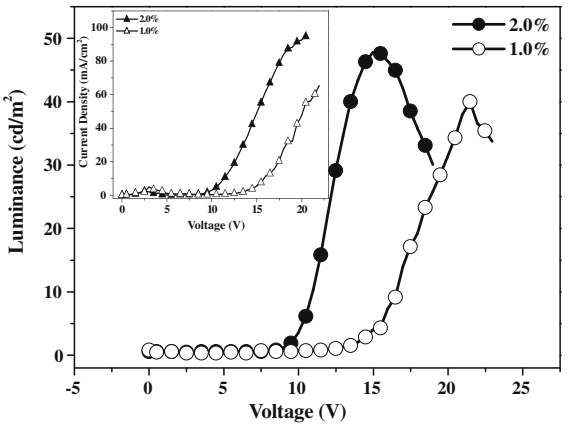

Fig. 9. The luminance vs. voltage and current density vs. voltage (inset) curves of the devices with different DABTC-1 concentrations.

Fig. 10 shows the representative luminance-current density–voltage characteristics of the devices doped DABTC-2 with different concentrations. The turn-on voltages of the devices at the doped concentrations of 1.0 wt% and 2.0 wt% were 10 V and 6 V, respectively. The maximal luminances were 371 cd/m^2 at 23 V for the device doped

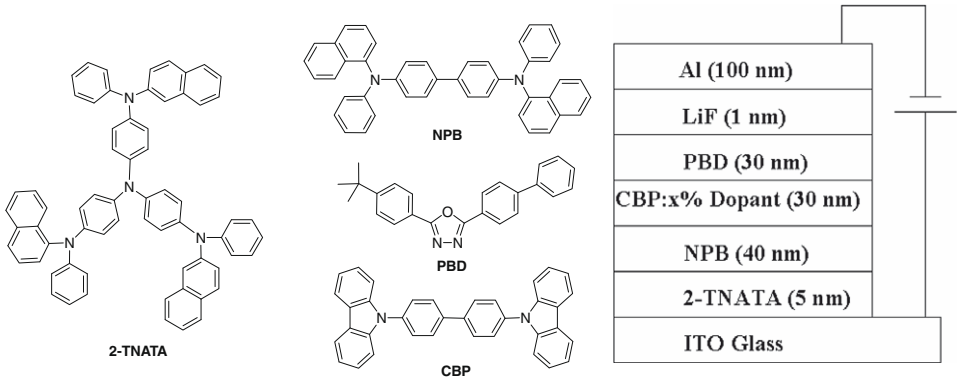

Fig. 7. The molecular structures of materials and the structure of EL devices.

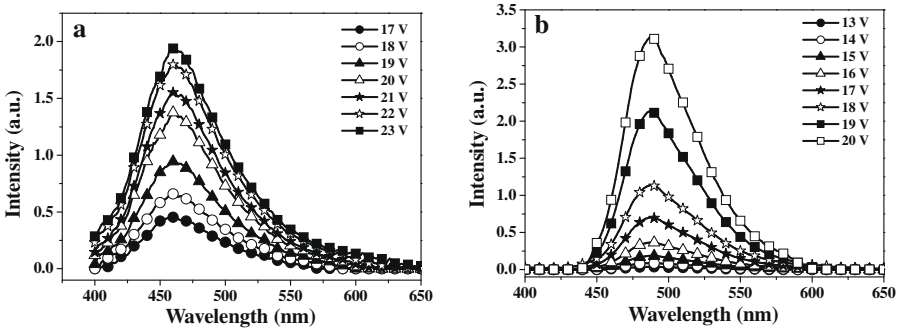

Fig. 8. EL spectra of the devices used DABTC-1 (a) and DABTC-2 (b) as dopants at different applied voltages. The devices with the configuration of ITO/2-TNATA (5 nm)/NPB (40 nm)/CBP: dopant (1.0 wt%, 30 nm)/PBD (30 nm) / LiF (1 nm)/Al (100 nm).

concentration of 1.0 wt% and 823 cd/m^2 at 17 V for the device doped concentration of 2.0 wt%, respectively.

Fig. 11 shows the relationships between current efficiency and the current density in the devices with various DABTC-1 and DABTC-2 doping concentrations. It is shown that all doped devices have higher efficiencies at low current densities, and then the efficiencies fall off at higher current densities. The above finding indicates that the electron hole recombination may not be effective under high current density, revealing that the present host, CBP, might not be an optimal host material. The present device performance could be further improved by substituting other host candidates. Table 2 summarized the performances of the devices with various DABTC-1 and DABTC-2 doping concentrations in CBP host. It was shown that the 2 wt% DABTC-1 and DABTC-2 doped devices had better efficiencies.

It was interesting to note that the turn-on voltages of the devices decreased with the increasing of compounds (DABTC-1 or DABTC-2) doping concentration in the CBP host from Figs. 9 and 10. In view of the structures of the two compounds, they were substituted by the electron-withdrawing benzotriazoles regarded as accptors [29] and used as electron-transporting materials [30]. Furthermore, the host material CBP can provide good hole-transporting properties [31]. With DABTC concentration

Table 2
EL performances of DABTC-1 and DABTC-2 doped devices.

Compound		Maximum efficiency (cd/A)	Efficiency at 20 mA/cm^2 (cd/A)
DABTC-1	1.0 wt%	0.33 @ 0.22 mA/cm^2	0.09
	2.0 wt%	0.60 @ 0.10 mA/cm^2	0.15
DABTC-2	1.0 wt%	1.81 @ 0.16 mA/cm^2	0.97
	2.0 wt%	1.63 @ 0.40 mA/cm^2	1.05

increasing, the conductive characteristics of the devices was considerably improved, and the turn-on voltages of the devices were reduced. It was shown that benzotriazole group had excellent electron-transporting ability in these EL devices. From Figs. 9 and 10, it was found that the luminance of DABTC-2 devices was very stronger than that of DABTC-1 devices due to the larger conjugation of molecule in DABTC-2. Similarly, it was found that the current efficiency of DABTC-2 devices was higher than that of DABTC-1 devices (Fig. 11).

From above results, it was indicated that the performance of the DABTC-2 doped devices is be superior to that of the DABTC-1 doped devices.

3.6. Conclusions

We designed and prepared two new coumarin derivatives containing an electron-transporting moiety (benzotriazole), 7-*N*,*N*-diethylamino-3-(benzotriazol-1-yl)coumarin (DABTC-1) and 7-*N*,*N*-diethylamino-3-(benzotriazol-2-yl)coumarin (DABTC-2). The photoluminescent behaviors of the compounds in both solution and solid states were investigated and discussed. The doped devices fabricated from DABTC-1 or DABTC-2 doped in CBP show the EL spectra of DABTC-1 or DABTC-2 is identical to the PL spectra of them in the solid films, respectively. The ITO/2-TNATA (5 nm)/NPB (40 nm)/CBP: DABTC-1 (2.0 wt%, 30 nm)/PBD (30 nm)/LiF (1 nm)/Al (100 nm) device displayed the pure blue emission, a maximum luminous efficiency of 0.15 cd/A at the current density of 20 mA/cm^2, and maximum luminance of 48 cd/m^2 at 15 V. At the same condition, the DABTC-2 doped devices exhibited the brighter blue–green emission, a maximum luminous efficiency of 1.05 cd/A at the current density of 20 mA/cm^2, and maximum luminance of 823 cd/m^2 at 17 V.

Fluorene–thiophene
Surface photovoltage
Diffusion length

ABSTRACT

The surface photovoltage method was used for the study of polymer layers made of copolymers based on fluorene and thiophene derivatives, particularly for the determination of exciton diffusion lengths. The surface photovoltage (SPV) in a polymer layer is the result of dissociation of photogenerated free excitons in electric field of the space charge region (SCR), which forms spontaneously at the surface. Our conception of the SPV calculates both currents from the bulk and currents from the SCR where recombination is considered. Fitting theory to the experimental data allows estimation of the diffusion length and the thickness of the SCR regardless of the thickness of the layers. Photovoltage spectra were measured under illumination from both the free surface (SPV_{fs}) and the substrate (SPV_{sub}) side of the layers. For the copolymers under study the diffusion length was determined to be 20–23 nm.

1. Introduction

Conjugated polymers such as polyfluorenes, polythiophenes and their derivatives are of interest as promising active materials for optoeletronic devices such as polymer light-emitting diodes (PLEDs), organic solar cells, and organic thin film transistors [1–4]. The use of semiconducting organic materials as an active layer in optoelectronic devices offers some advantages in processing and new possibilities of device fabrication. One very important parameter essentially influencing the operation of optoelectronic devices is the diffusion length of the excitons, which is connected with their lifetime and mobility. The exciton diffusion length in various conjugated polymers was reported to be in the range from 4 to 20 nm [5–17]. Quenching of luminescence is often used for diffusion length determination [5,6] but it requires the preparation of variously thick layers with exactly the same structure and also a quencher for which titania or C_{60} are mostly used. Another method, namely fitting of theoretical quantum efficiency to measured data needs complete cells [5,7]. On the other hand, the non-destructive surface photovoltage (SPV) method has been widely used for determination of diffusion length of minority charge carriers in thick samples of inorganic semiconductors [18]. It employs internal electric field of a space charge region spontaneously formed at the surface of the materials and is indicated also in organic semiconductors e.g. [19,20]. This region is consequence of surface states which arise e.g. due to oxygen adsorption or diffusion.

In this paper, we used this technique modified for determination of exciton diffusion length in thin polymer films made of two copolymers based on fluorene and thiophene derivatives in the main backbone (see Fig. 1), which differ each other in the substitution of thiophene ring in the position 3 by the alkyl chain (**FIPT**) or the pyrene derivative **FPyT**. Our model is performed assuming a layer with a neutral bulk and one space charge region (SCR) at the free surface. After illumination excitons are created both in the

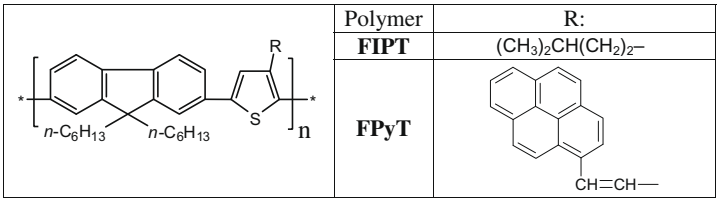

Fig. 1. Structure of alternating fluorene-thiophene copolymers under study.

bulk and in the SCR. The model considers that the bulk/SCR interface is the place where the charge separation occurs. The opposite surface is supposed to be a sink for excitons, which represents their losses by surface recombination.

To obtain the SPV signal from the bulk the continuity equation is solved. The second contribution to the signal comes from the SCR taking possible recombination in account. Total SPV signal is a sum of the both contributions. The SPV measurement at various wavelengths gives information on the diffusion length of excitons in the bulk and on the SCR thickness. The usual way of diffusion length evaluation by the SPV technique assumes a thin SCR with negligible losses of photogenerated carriers [21]. Consequently, it fails in samples with a thick SCR.

The advantage of our SPV model used here is its applicability to arbitrary thickness of the layers and its possibility to apply it to samples with arbitrary thickness of the SCR and of the bulk. From the photoelectric point of view the polymer layer acts as a thick or as a thin in different parts of the spectrum. For example if the polymer bulk thickness d is 100 nm, the exciton diffusion length L is 20–30 nm, and with the measured absorption coefficient α, there is a large wavelength region where the polymer layer cannot be considered as a thin layer according to the definition given by the following inequalities: $d \leqslant L$, $\alpha d \leqslant 1$ which hold for thin layers.

We have used our model to the evaluation of diffusion length in inorganic materials [22,23]. Recently, we have also applied the SPV method for characterization of organic layers made of fluorene–thiophene copolymer **FIPT**. We briefly reported the first result that the photovoltage consists from the contributions of thick SCR and thin neutral bulk and evaluated the diffusion length [24]. In this paper, we solved also the second case with thin SCR layer and a thick bulk region that is shown on the second fluorene–thiophene copolymer **FPyT**, which possesses similar absorption as **FIPT**, but differs in both SPV and photoluminescence spectra. Sensitivity of the SPV spectra to the diffusion length is demonstrated by a set of theoretical curves for the both cases i.e. for thick and thin SCR, and also for both cases of illumination (from the free surface and the substrate side).

2. Experimental

2.1. Samples and characterization

Alternating fluorene–thiophene copolymers, **FIPT** and **FPyT**, are displayed in Fig. 1. The copolymers were synthesized by Suzuki coupling reaction of 9,9-dihexylfluorene and 3-substituted (with 3-methylbutyl and 2-(pyren-1-yl)-vinyl, respectively) thiophene units. Detailed syntheses of monomers and polymers are described in our previous papers [25,26]. Average molecular weights of **FIPT** were $M_w = 26{,}250$, $M_n = 7800$, and **FPyT** $M_w = 26{,}460$, $M_n = 11{,}110$. Polymer films were prepared by spin coating from tetrahydrofuran solutions onto fused silica substrates for optical studies and onto indium-tin oxide (ITO) substrate for SPV study. All solutions were filtered with 0.45 μm Millex-FH13 Millipore syringe filters prior to spin coating. The films were dried in vacuum (10^{-3} Pa) at 353 K for 1 h. Thin polymer layers were prepared from good solvents under optimized conditions for spin coating and their homogeneity was checked by optical microscopy. Layer thicknesses were in the range 100–1000 nm as measured by KLA-Tencor P-10 profilometer. UV–vis spectra were measured on a Perkin–Elmer Lambda 35 spectrometer and PL spectra using a Perkin–Elmer LS55 spectrofluorometer.

2.2. Surface photovoltage measurement

The photovoltage generated in the polymer films was measured in a sandwich structure between two ITO electrodes with a Mylar sheet at the film surface serving as a dielectric layer. A capacitive couple is formed in this way. The sample was irradiated by low-intensity monochromatic light chopped with a low frequency of 11 Hz generating an alternating voltage which was measured between a transparent conductive electrode capacitively coupled to the sample and an appropriate back electrode by lock-in amplifiers Stanford SR 810 and SR 830. The SPV spectra were measured using a Jobin–Yvon H 25 spectrometer at constant impinging photon flux density ($\sim 10^{14}$ photons cm^{-2} s^{-1}) and subsequently corrected for the transparency of the electrodes. The light intensity was checked during the measurement by spectral independent Thermopile TS-100 (IPHT Jena). The SPV spectra were taken at room temperature and in air. Maximum values of the photovoltage were 30–50 μV.

3. Results and discussion

Typical SPV spectra of **FIPT** and **FPyT** samples under irradiation from the free surface (SPV_{fs}) and from the substrate (SPV_{sub}) are shown in Fig. 2. It can be seen that the SPV spectra of these two copolymers are significantly different, whereas the absorption spectra for the copolymers (see Fig. 3) are similar. The lowest-energy absorption maxima, corresponding to the absorption of the conjugated backbone, are located at 401 and 391 nm for **FIPT** and

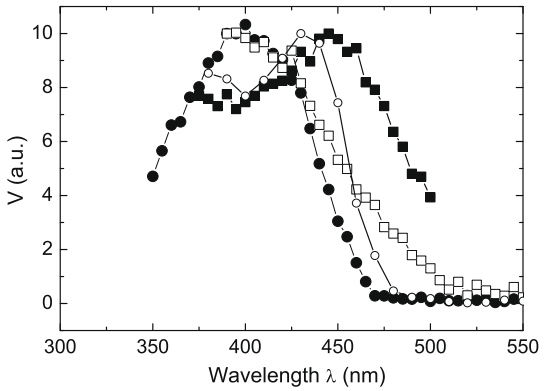

Fig. 2. Normalized SPV spectra measured for polymer layers under illumination from the free surface side: **FIPT** (open circles) and **FPyT** (open squares), and under illumination from the substrate side: **FIPT** (solid circles) and **FPyT** (solid squares).

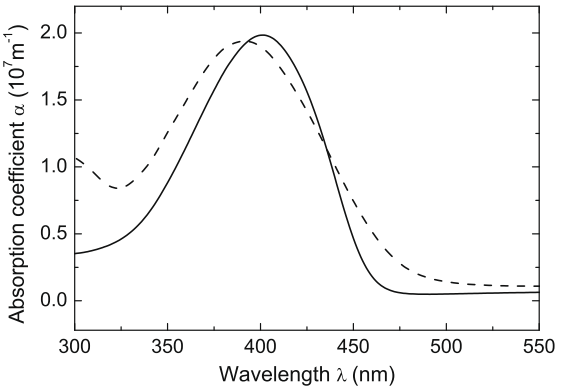

Fig. 3. UV-Vis absorption spectra of the copolymers **FIPT** (solid) and **FPyT** (dashed) measured in thin films prepared on fused silica substrate.

FPyT, respectively. The onset of the absorption is at about 470 nm for **FIPT** thin film, whereas for **FPyT** it is at a longer wavelength ca. 500 nm, which indicates a lower band gap value for **FPyT** than for **FIPT**. The optical energy band gap (E_g) was evaluated from the thin film absorption edge as 2.76 and 2.65 eV for **FIPT** and **FPyT**, respectively. The maximum of SPV_{sub} spectrum for **FIPT** is located at 400 nm similarly as the absorption one and also the shape is similar to that of the absorption spectrum, whereas the SPV_{fs} spectrum maximum is at 445 nm, i.e. shifted to longer wavelengths. In the case of **FPyT**, SPV_{sub} spectrum significantly differs from the absorption spectrum, with its maximum being shifted to longer wavelengths; on the other hand, SPV_{fs} spectrum follows roughly the absorption one.

Electronic structure of the copolymers was determined from electrochemical study. The onset of oxidation potential was nearly the same for both polymers. Using this value, HOMO levels E_{IP} at about 5.3 eV were estimated. From the onset of the reduction, electron affinity (LUMO level) of 2.8 eV was obtained for **FIPT** and a higher electron affinity of 3 eV was determined for **FPyT**. These results show that the condition on the interface substrate ITO-copolymer is similar for both materials under study.

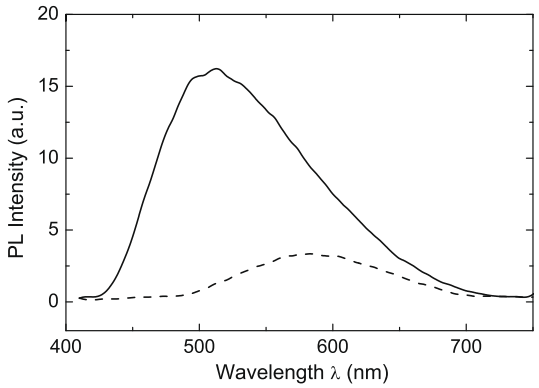

Fig. 4. Photoluminescence spectra of the copolymers **FIPT** (solid) and **FPyT** (dashed) measured in thin films prepared on fused silica substrate.

Photoluminescence (PL) of the two polymers in thin films significantly differs. As can be seen from Fig. 4, broad-band PL spectra were observed for both polymers, but the intensity and the position of their maxima significantly differ. The PL intensity is much lower in **FPyT** than in **FIPT**. The PL maximum for **FIPT** is located at 499 nm, whereas for **FPyT** it is at 580 nm, significantly red-shifted. This red-shift and a very large Stokes shift demonstrate more pronounced aggregation of **FPyT** molecules than **FIPT** ones.

To explain the SPV experimental data we use our earlier calculations [23,27]. The polymer layers under study were considered as homogenous medium for SPV study similarly as in other macroscopic optical or electrical studies. Results of SPV measurements performed on the different places of the samples did not show any non-homogeneity.

Measurements of photovoltage spectra show only one SCR and the polarity of the voltage indicates its position at the free surface (Appendix A). Hence, a structure with a bulk region and one SCR at its free surface is considered in the theoretical fitting (Fig. 5). Our measurements were performed in the ambient atmosphere; therefore the separation of charge carriers generated in the SCR is influenced by oxygen. The role of oxygen is not yet fully understood. Oxygen acts as an electron acceptor and may negatively charge the layer surface. The influence of oxygen on the charge separation and on the modulated SPV signal is discussed and shown by Zidon et al. [28]. In our case, oxygen molecules can catch electrons from the dissociated photogenerated excitons and shorten the drift length of these minority carriers. This causes a decrease in the probability of charge separation in the SCR and consequently the signal lowering. The excitons generated in the bulk, which

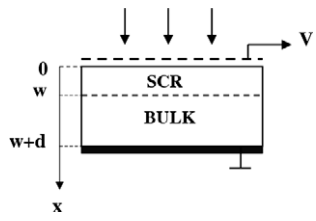

Fig. 5. Schematic view of the sample for SPV measurement.

diffuse to the SCR/bulk interface, are separated into free electrons and holes at the interface and contribute to the SPV signal that is added to the SPV from the SCR.

Let us note that the SPV measurement configuration does not allow for obtaining values of the quantum efficiency. It operates only with relative values that are proportional to the internal quantum efficiency.

Usually, there are several relaxation processes in the layers, influencing the form of the SPV pulses [29]. In our experiment the chopper frequency of 11 Hz was sufficiently low to obtain saturated pulses not influenced by relaxations. This fact together with experimentally verified linear relation between the photovoltage and the light intensity leads to proportionality between the photovoltage V and the photogenerated current J

$$V \sim J \tag{1}$$

Unit area of the samples is considered. The photogenerated current is formed both in the neutral bulk (thickness d) and in the space charge region (thickness w) at the free surface (Fig. 5). In the case of the free surface illumination the component from the neutral bulk is calculated by solving the usual diffusion equation

$$d^2\Delta p/dx^2 - \Delta p/L^2 = -\alpha I/D \exp(-\alpha[w+x]) \tag{2}$$

where Δp is the concentration of photogenerated free excitons, L is their diffusion length, and I is the density of the photon flux entering into the sample with the absorption coefficient α. The boundary condition characterizing sweep of excitons at the bulk-SCR boundary is

$$\Delta p(w) = 0 \tag{3a}$$

Another condition is represented by recombination at the bottom contact:

$$Dd\Delta p/dx|_{x=w+d} = -s\Delta p(w+d) \tag{3b}$$

where D is the exciton diffusion coefficient and s is the surface recombination velocity. Instead of s a dimensionless parameter $S \equiv sL/D$ is further used. Diffusion current J_b from the bulk can be simply obtained as

$$J_b = eDd\Delta p/dx|_{x=w}. \tag{4}$$

The component of the current from the SCR J_s is usually calculated as:

$$J_s = e\int_0^w g(x)dx = eI(1-\exp[-\alpha w]) \tag{5}$$

where $g(x) = \alpha I \exp(-\alpha x)$ is the generation rate. In the case of recombination in the SCR

$$J_s = e\int_0^w G(x)g(x)dx. \tag{6}$$

$G(x)$ is the gain factor characterizing losses by recombination in the SCR ($G \leqslant 1$) and according to Shockley–Ramo theorem [30] $G(x) = (l_n(x) + l_p(x))/w = (\mu_n\tau_n E(x) + \mu_p\tau_p E(x))/w$. $G(x)$ shows the contribution of each photogenerated carrier to the current J_s. $E(x)$ is the electric field in the SCR while $l_{n,p}$, $\mu_{n,p}$, $\tau_{n,p}$ are drift length, mobility and carrier lifetime of electrons and holes, respectively. A constant concentration of bound charges in the SCR is considered leading to linear electric field and a linear dependence of l_n, l_p versus x. The drift lengths at the surface are characterized by l_{n0}, l_{p0} values [23] and together with the thickness w of the SCR determine the drift lengths at arbitrary point in the SCR. Final equations for the currents J_b and J_s are shown in the Appendix B. As it was demonstrated in [22] the currents are mutually independent and can be added, giving the total photocurrent. Similar calculation can be made if illumination comes from the substrate side (Appendix B).

Let us assume and analyze two cases, which well applicable to our copolymers under study:

1. a thick SCR (w) and a thin bulk layer (d), i.e. $w > d$,
2. a thin SCR (w) and a thick bulk layer (d), i.e. $w < d$.

Theoretical SPV curves for the case 1 were calculated using absorption coefficients of **FIPT** (from Fig. 3) for $w = 100$ nm, $d = 25$ nm, $S = 1$, $l_{n0} = l_{p0} = 1$ nm and different L for illumination from the free surface side (Fig. 6) and substrate side (Fig. 7).

It can be clearly recognized from Fig. 6 that the shape of SPV_{fs} spectrum for illumination from the free surface side significantly depends on the value of exciton diffusion

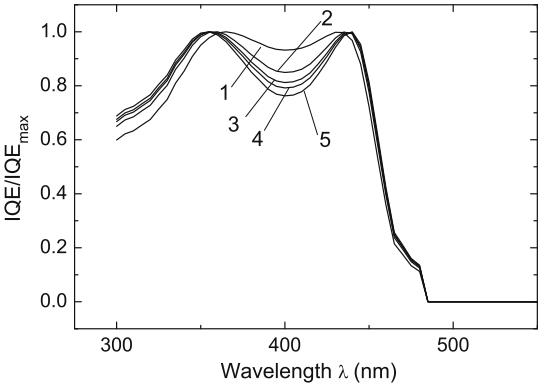

Fig. 6. Normalized theoretical SPV spectra for illumination from the free surface side calculated using $w = 100$ nm, $d = 25$ nm, $S = 1$, $l_{n0} = l_{p0} = 1$ nm and absorption coefficient values of **FIPT** for various diffusion length 1: $L = 5$ nm, 2: $L = 10$ nm, 3: $L = 15$ nm, 4: $L = 20$ nm, 5: L = 30nm.

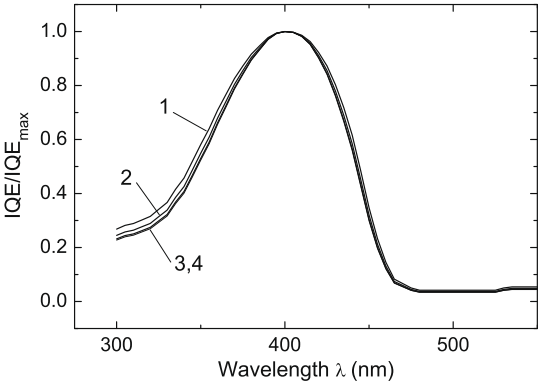

Fig. 7. Normalized theoretical SPV spectra for illumination from the substrate side calculated using $w = 100$ nm, $d = 25$ nm, $S = 1$, $l_{n0} = l_{p0} = 1$ nm and absorption coefficient values of **FIPT** for various diffusion length 1: $L = 5$ nm, 2: $L = 10$ nm, 3: $L = 20$ nm, 4: $L = 30$ nm

length L. As the diffusion length L increases the minimum of the signal becomes deeper in the region of maximum absorption. On the other hand, for illumination from the substrate side the SPV theoretical curves for various L values differ only slightly (Fig. 7) so that the diffusion length determination is not reliable.

Absorption coefficients for **FPyT** were used in the case of a thin SCR and a thick bulk layer. SPV theoretical curves for various L values differ only slightly for illumination from the free surface side and significantly for illumination from the substrate side (Figs. 8 and 9). In this case, the diffusion length can be determined from the SPV_{sub} spectra measured for the illumination from the substrate side. It should be stressed that using the absorption coefficient evaluated from the measurement in transmission the fitting is reasonable only in the spectral region of absorption because the absorption coefficient in the tail of the absorption differs from the intrinsic one. The reason for this is the fact that some fraction of the absorption in the tail of the absorption originates from reflection losses [31].

On the basis of theoretical analysis outlined above, SPV spectra measured for **FIPT** samples under irradiation from both sides are typical ones for the case 1 of a thick SCR (w) and a thin bulk layer (d), whereas SPV spectra measured for **FPyT** represent the case 2 of a thin SCR (w) and a thick bulk layer (d). The best theoretical fits to experimental data are shown in Figs. 10 and 11 for **FIPT** and **FPyT**, respectively.

For **FIPT** the diffusion length $L = 20$ nm was evaluated from the SPV_{fs} spectrum, whereas for **FPyT** from the SPV_{sub} one as $L = 23$ nm. For **FIPT**, the theoretical fit (solid lines) reveals that the SCR spreads across a greater part (100 nm) of the layer whereas the bulk region is very thin (25 nm). The SPV_{sub} signal is proportional to the absorption coefficient, which means that in this case the diffusion length modifies the spectrum only weakly. For **FIPT**, a low ratio of the drift lengths and thickness of the SCR that were evaluated by the fitting means that the SCR layer is not efficient. Absolute values of the SPV_{fs} were much lower than those of SPV_{sub}. This corresponds to a high recombi-

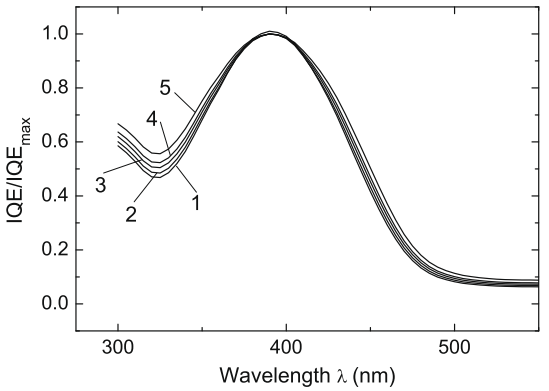

Fig. 8. Normalized theoretical SPV spectra for illumination from the free surface side calculated using $w = 2$ nm, $d = 137$ nm, $S = 1$, $l_{n0} = l_{p0} = 1$ nm and absorption coefficient values of **FPyT** for various diffusion length 1: $L = 5$ nm, 2: $L = 10$ nm, 3: $L = 15$ nm, 4: $L = 20$ nm, 5: $L = 30$ nm.

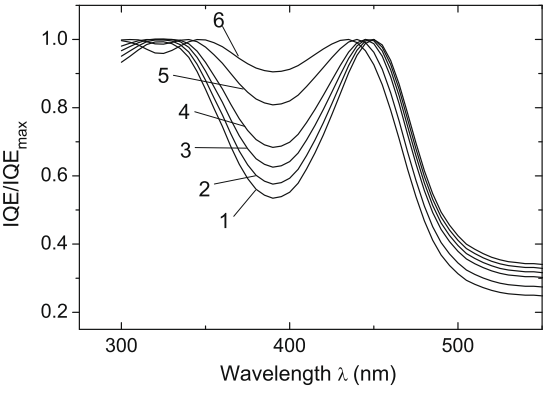

Fig. 9. Normalized theoretical SPV spectra for illumination from the substrate side calculated using $w = 2$ nm, $d = 137$ nm, $S = 1$, $l_{n0} = l_{p0} = 1$nm and absorption coefficient values of **FPyT** for various diffusion length 1: $L = 5$ nm, 2: $L = 10$ nm, 3: $L = 15$ nm, 4: $L = 20$ nm, 5: $L = 30$ nm, 6: $L = 40$ nm.

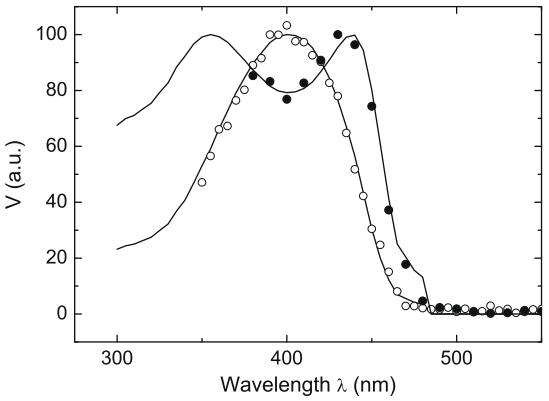

Fig. 10. Normalized SPV spectra measured on **FIPT** layers under illumination from the free surface side (solid circles) and from the substrate (open circles). Full lines are theoretical curves obtained as the best fit with $d = 25$ nm, $w = 100$ nm and $L = 20$ nm, $l_{n0} = l_{p0} = 1$nm.

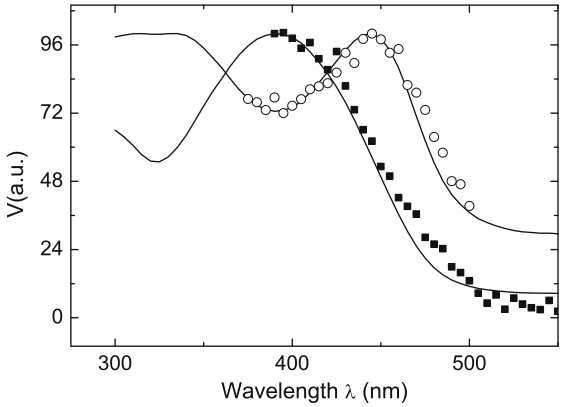

Fig. 11. Normalized SPV spectrum measured on **FPyT** layers under illumination from the substrate side (open circles) and from the free surface side (solid squares). Full lines are theoretical curves obtained as the best fit with $d = 137$ nm, $w = 2$ nm, $L = 23$ nm, $l_{n0} = l_{p0} = 1$nm.

nation rate in the SCR and a negligible contribution of this region to the SPV signal.

If the free surface is illuminated, weakly absorbed low energy photons penetrate deep into the material and generate a higher signal than the more absorbed photons in the SCR. This causes a local minimum in the region of the highest absorption.

In contrast to the **FIPT** samples, in **FPyT** the SCR is very thin (2 nm) in comparison with the thickness of the bulk (137 nm) as evaluated by fitting the theory to SPV_{sub}. Under illumination from the substrate side, and in the region of high absorption the excitons are generated far from the bulk/SCR interface and an SPV minimum appears. Higher signals correspond to weakly absorbed photons penetrating deeper into the material. All these spectra are in accordance with the theoretical results shown in Figs. 6, 7 and 9. The SPV_{fs} signals of **FPyT** were also measured (Fig. 11) but the spectrum did not correspond so well to the theory because most of the generated signal comes from the very thin SCR at the surface where a linear electric field cannot be assumed in general. The sum of thickness of the bulk and of the SCR agrees well with the thickness of the samples as measured with the profilometer, namely 125 nm for **FIPT** and 140 nm for **FPyT**.

For the **FIPT** samples with thin bulk region, the diffusion length value of 20 nm was estimated with 10% accuracy by fitting the theory to the SPV_{fs} spectrum measured under illumination from the free surface side of the samples. The accuracy of the thickness of the SCR was 6%. The diffusion length in the **FPyT** samples with relatively thick bulk region was 23 nm with 15% accuracy as estimated by fitting the theory to experiments carried out under illumination from the substrate side. The accuracy of the thickness of the bulk was 4%. In general, we have found that a satisfactory fit with the experiment cannot be attained with parameter combinations falling outside the frame of accuracy.

As already mentioned in Section 1 the exciton diffusion length in conjugated polymers according to the literature varies from 4 to 20 nm [5–17] depending not only on the material but also on the method applied for its measurement. The diffusion lengths in the range 17–23 nm as evaluated from SPV method for our copolymers belong to the higher ones determined for conjugated polymers. Such higher values were also obtained for MEH-PPV (20 nm) from the analysis of luminescence as a function of the film thickness [16] and was also reported in phenylene vinylene oligomers, where an estimate of the exciton diffusion range of 20 nm was obtained from the photoluminescence quenching at the Ca interface [17]. It should be noted that our SPV measurements were performed with much lower light intensity as compared with the measurements where lower diffusion lengths were determined. Our results show that SPV measurements are an alternative way of studying exciton diffusion and suitable method for the determination of the diffusion length.

The theoretical analysis of SPV experimental spectra measured for **FIPT** and **FPyT** within the frames of the model described in this paper is in very good agreement with the photoluminescence study on thin films. Thick SCR with short drift lengths found in **FIPT** samples show a high recombination rate in this region, which leads to higher PL intensity. On the other hand, thin SCR in **FPyT** material can yield only low PL intensity. Indeed, the PL intensity in **FPyT** is lower than in **FIPT**.

4. Conclusions

The surface photovoltage method was used for the photophysical study of copolymer layers. Measurement of photovoltage of **FIPT** and **FPyT** copolymer layers revealed that only one space charge region is present in the samples. This region, that is much thicker in **FIPT** than in **FPyT**, is localized at their free surface. Photovoltage spectra were taken under illumination of the free surface and substrate side. Their evaluation indicates a high recombination rate in quite thick SCR of the **FIPT** layers, which agrees with high PL intensity in these films. It was shown that the main contribution to the photovoltage comes from the bulk region because of a small signal from the SCR. The theory presented here was fitted to the spectra allowing evaluation of the exciton diffusion length and thickness of the space charge region. The diffusion length in the **FIPT** and **FPyT** layers was 20 ± 2 nm and 23 ± 3 nm, respectively.

Appendix A

Presence of two space charge regions, one at the free surface and another at the semiconductor/ITO interface would lead to two voltage signals of opposite sign generated after illumination. Change in the sign in the SPV spectrum would appear after illumination of the top or the bottom surface indicating two different SCRs in this way [27]. Such effect was not found in the measurement so that only one SCR was considered in our samples. The space charge regions at the ITO/molecular layers and at the free surface of the layers were demonstrated in [19] where only the latter significantly contributed to the photovoltage.

In our samples position of the SCR was determined from the direction of the photogenerated current influencing the phase of the signal measured by lock-in amplifier. Using Si solar cell for calibration, it was found that the SCR was at the free surface.

Appendix B

Electrons and holes from dissociated excitons create the current in the SCR, while minority carriers control the bulk current.

The illumination from the free surface side generates the current $J_1 = J_{s1} + J_{b1}$ [32,27] where

$$
\begin{aligned}
J_{s1} &= J_{ps1} + J_{ns1} \\
&= \frac{e\alpha I}{w}\int_0^w l_{p0}\left(1-\frac{x}{w}\right)\exp(-\alpha x)dx \\
&\quad + \frac{e\alpha I}{w}\int_0^{l_{n1}} x\exp(-\alpha x)dx \\
&\quad + \frac{e\alpha I}{w}\int_{l_{n1}}^w l_{n0}\left(1-\frac{x}{w}\right)\exp(-\alpha x)dx \\
&= \frac{eIl_{po}}{w}\left\{1+\frac{1}{\alpha w}(\exp(-\alpha w)-1)\right\} \\
&\quad + \frac{eIl_{no}}{w}\left\{\exp(-\alpha l_{n1})\left(1-\frac{l_{n1}}{w}-\frac{1}{\alpha w}\right)+\frac{1}{\alpha w}\exp(-\alpha w)\right\} \\
&\quad + \frac{eI}{\alpha w}(1-\exp(-\alpha l_{n1}))-\frac{eIl_{n1}}{w}\exp(-\alpha l_{n1})
\end{aligned}
$$

and

$$
\begin{aligned}
J_{b1} &= \frac{eI\alpha L}{1-\alpha^2L^2}\,\frac{\exp(-\alpha w)}{\{(1-S)\exp(-d/L)+(1+S)\exp(d/L)\}} \\
&\quad \times[(1+S)\exp(d/L)-(1-S)\exp(-d/L) \\
&\quad + 2\exp(-\alpha d)(\alpha L-S)]-eI\exp(-\alpha w)\frac{\alpha^2L^2}{1-\alpha^2L^2}
\end{aligned}
$$

I is the photon flux entering into the sample, l_{p0}, l_{n0} are the drift lengths corresponding to the maximum electric field in the SCR. The minority carriers drift length maximum is $l_{n1} = l_{n0}/(1 + l_{n0}/w)$, which follows from limitation by the SCR boundary [32].

The dimensionless surface recombination velocity is $S \equiv sL/D$ where D is the exciton diffusion coefficient and s is the surface recombination velocity at the substrate.

The illumination from the substrate side generates the current $J_2 = J_{s2} + J_{b2}$ where

$$
\begin{aligned}
J_{s2} &= J_{ps2} + J_{ns2} \\
&= \frac{e\alpha I}{w}\exp(-\alpha d)\int_0^w l_{p0}\frac{x}{w}\exp(-\alpha x)dx \\
&\quad + \frac{e\alpha I}{w}\frac{l_{n0}}{w}\exp(-\alpha d)\int_0^{l_{n1}} x\exp(-\alpha x)dx \\
&\quad + \frac{e\alpha I}{w}\exp(-\alpha d)\int_{l_{n1}}^w (w-x)\exp(-\alpha x)dx \\
&= \frac{eIl_{po}}{w}\exp(-\alpha d)\left\{\frac{1}{\alpha w}(1-\exp(-\alpha w))-\exp(-\alpha w)\right\} \\
&\quad + \frac{eIl_{no}}{w}\exp(-\alpha d)\left\{(1-\exp(-\alpha l_{n1}))\frac{1}{\alpha w}\right. \\
&\quad \left.-\frac{l_{n1}}{w}\exp(-\alpha l_{n1})\right\}+eI\exp(-\alpha d) \\
&\quad \times\left\{\exp(-\alpha l_{n1})(1-\frac{l_{n1}}{w}-\frac{1}{\alpha w})+\frac{1}{\alpha w}\exp(-\alpha w)\right\}
\end{aligned}
$$

and

$$
\begin{aligned}
J_{b2} &= \frac{eI\alpha L}{1-\alpha^2L^2}\,\frac{1}{\{(1-S)\exp(-d/L)+(1+S)\exp(d/L)\}} \\
&\quad \times\{2(\alpha L+S)+\exp(-\alpha d)[(1-S)\exp(-d/L) \\
&\quad -(1+S)\exp(d/L)]\}-eI\exp(-\alpha d)\frac{\alpha^2L^2}{1-\alpha^2L^2}
\end{aligned}
$$

Meaning of the symbols is the same as above.

ABSTRACT

We report on solution processed top-emitting organic light-emitting diodes (TEOLEDs) that are compatible with TFT- and CMOS-substrates, thus being applicable in full-color microdisplays. In this device geometry TEOLEDs offer highly tunable and controllable color-coordinates. Compared to the standard sRGB-colorspace the color gamut is increased by 18%. The CIE (*Commission internationale de l'éclairage)* color coordinates are more saturated in the red and green spectral region and comparable in the blue region. Brightness levels of 1000 cd/m^2 are reached at voltages below 7 V for all colors which is within the operating voltage range of CMOS-backplanes. The polymeric emitters are crosslinkable and can be patterned in a UV-lithography process. The achieved minimum feature size is suitable for high resolution microdisplays.

1. Introduction

For several years the interest in organic light-emitting diodes (OLEDs) has shifted from rather simple devices such as monochrome displays to complex full-color active-matrix displays. In this context, increasing amounts of money are invested in the commercialization of displays based on OLED-technology. As a preliminary highlight, this trend resulted in the implementation of an 11 in. OLED-TV (XEL-1) by Sony in 2007. The main effort in this field is to increase display sizes. However, there is also an ever increasing demand for mobile TV and video equipment. Here it is necessary to decrease pixel size in order to build very small displays (typically below 1.5 in. diagonal) with high resolution. These so-called microdisplays are the key components in video goggles. By use of magnifying optics an enlarged image of the display is projected directly into the human eye.

Today an overwhelming share of the display market is held by liquid crystal (LC)-technology and hence any new technology has to compete against it. In LC-displays white light from a backlight is converted into red, green and blue (RGB) by color filters laminated on top of the LC-cell. The gap between filter and LC-cells leads to partial illumination of adjacent sub-pixels and, therefore, to a loss in color gamut. This effect becomes worse with decreasing pixel size and hence puts a fundamental limit to the resolution of microdisplays. Underwood et al. [1] established a microdisplay in which the LC-cell was replaced by a white-emitting OLED (see Fig. 1a). This reduces the power consumption and simplifies the fabrication process of the microdisplays but does not solve the problem of the limited color gamut.

Here, we propose a process for the fabrication of a high resolution microdisplay in which red-, green- and blue-emitting OLEDs form the sub-pixels of the display. To achieve this, thin films of RGB-emitting materials will be deposited from solution and be structured via direct UV-lithography in order to define the color of corresponding sub-pixels (see Fig. 1b). The used electroluminescent materials are oxetane-functionalized and can be crosslinked through cationic ring opening polymerisation. In the presence of a photo acid generator (PAG) this reaction can be initiated by UV-light giving the material photoresist-like properties [2,3]. As light and color are generated in the same layer, crosstalk between sub-pixels is eliminated and a large color gamut is expected. The pixel size in a microdisplay

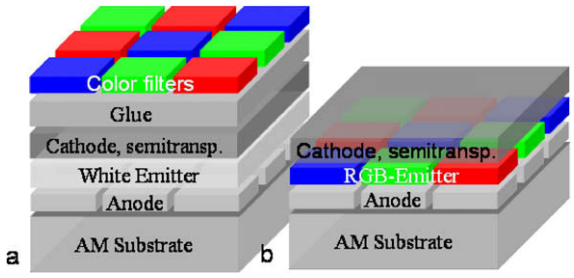

Fig. 1. (a) Schematic of a commercial OLED-based microdisplay using a polymeric white emitter and color filters. (b) RGB sub-pixel approach proposed here.

with VGA resolution (640 × 480 pixels) amounts to a few micrometers. We have already demonstrated that direct lithographic patterning of electroluminescent polymers yields minimum feature sizes down to 2 μm [3].

In contrast to direct lithography of solution processed OLED materials, vacuum deposition of small molecules through shadow masks is not a suitable option for the fabrication of microdisplays: The quality of the shadow masks suffers from material being deposited onto it over time. This leads to a gradual reduction of the actual pixel size and to an enhanced formation of disruptive particles on the OLED. For the small pixels of microdisplays, the required OLED quality is only ensured for very few evaporation procedures per shadow mask [4].

It is obvious that top-emitting OLEDs (TEOLEDs) are favorable over bottom-emitting ones (BEOLEDs) when working with opaque complementary metal oxide semiconductor (CMOS) backplanes. These active transistor backplanes are necessary to display complex content. There are two possible geometries for TEOLEDs: Inverted OLEDs with a transparent top-electrode [5–7] as well as cavity TEOLEDs [8–10]. The latter allow for better control of the emission characteristics due to the layer-thickness-dependent microcavity effect. Especially since many polymeric emitters show a broad emission spectrum (see Fig. 3c), the control of both, spectral width and peak wavelength, is beneficial to achieve primary color coordinates suitable for display applications.

In general, a cavity TEOLED consists of a metallic mirror which is usually the anode of the OLED, a stack of organic layers, and a semi-transparent metallic cathode. In this Fabry–Perot-cavity-like geometry, light is reflected between the two metallic layers. Light with wavelengths matching the criterion for constructive interference after reflection at each metal layer is amplified and emitted through the semi-transparent mirror. Light with other wavelengths is weakened or even suppressed from being coupled out [11–13]. As a consequence, the cavity thickness determines the emitted peak wavelength, and the cavity quality defines the spectral width.

2. Experimental

On CMOS surfaces, titanium nitride (TiN) is usually used as hole-injection layer (HIL). Due to its rather high work function of about −5 eV vs. vacuum [14], TiN is not capable of efficiently injecting holes to the electroluminescent copolymers used in this work (E_{HOMO} = −5.4 eV [15]). This problem can be circumvented by the addition of a molybdenum oxide (MoO_3)-layer (−5.3 eV [16]). When used in a cavity structure, MoO_3 is preferable to the commonly used 3,4-poly(ethylendioxythiophen)-poly(styrolsulfonat) (PEDOT) for transparency reasons.

We investigated TEOLEDs on glass substrates with a highly reflecting silver (Ag) anode due to our standard OLED processing. However, silver is not suitable in standard CMOS fabrication process. Thus, to demonstrate that the results are of relevance for a true CMOS process, we investigated in addition TEOLEDs containing an aluminum (Al)/(TiN)/(MoO_3) anode on a CMOS dummy substrate.

The silver anode, the HIL (MoO_3) and the cathode layers (barium and silver) were vacuum deposited in a Leybold Univex 450 chamber. The emitting polymers were spin-coated from solution in nitrogen atmosphere. Crosslinking was initiated by exposure to UV-light. A softcuring step at 90 °C on a hotplate is essential to allow chain propagation and promote further crosslinking. In crosslinked areas the polymer film becomes insoluble. Finally, the film is rinsed with toluene to remove non-exposed material. The subpixels in the future microdisplays will be developed in the same manner. Here, the entire layer is crosslinked to emulate the future conditions in microdisplays. At last, a postbaking step at 200 °C is applied.

For comparison of current–voltage–luminescence (*J–V–L*) curves and for color point characterization, OLEDs have been investigated in the top-emitting as well as in the bottom-emitting geometry. The cavity TEOLEDs consisted of the following layer stack:

Glass/Ag (150 nm)/MoO_3 (30 nm)//XR (90 nm) or
XG (70 nm) or XB (35 nm)//Ba (4 nm)/Ag (20 nm).

Using an Al mirror instead of an Ag mirror will change the optical characteristics of the cavity for a given layer thickness due to the difference in reflectivity. However, this can be compensated by re-adjusting the thickness of the emitting layer, thus, leading to identical spectral output. To study the influence on the OLED performance we fabricated a red-emitting device with Al mirror (CMOS dummy). The entire layer stack of the CMOS dummy was:

Si/Al (100 nm)/TiN (10 nm)/MoO_3 (30 nm)//
XR (100 nm)//Ba (4 nm)/Ag (20 nm).

The sequence of the BEOLED stack was:

Glass/ITO (160 nm)/MoO_3 (30 nm)//XR (80 nm) or
XG (80 nm) or XB (70 nm)//Ba (4 nm)/Ag (150 nm).

Each diode has an active area of 7.9 mm^2.

3. Results and discussion

3.1. Device performance

In Fig. 2 current density, luminance and current efficiencies are presented for TEOLEDs. Brightness levels of 1000 cd/m^2 for red and blue and 10,000 cd/m^2 for green

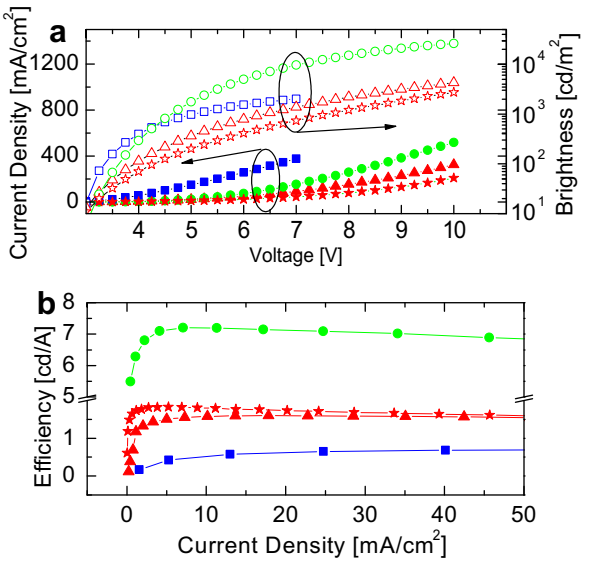

Fig. 2. (a) Current density (closed symbols) and brightness (open symbols) versus voltage, for red (triangles = Ag/MoO_3-anode, stars = Al/TiN/MoO_3-anode), green (circles) and blue (squares) TEOLEDs (b) Current efficiency versus voltage (symbols see (a)). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

were achieved at voltages of <7 V and a current density of <40 mA/cm^2. Comparing the efficiencies of the TEOLEDs and BEOLEDs, similar values are achieved for the red and the green emitter (see Table 1). In this case the losses due to absorption at the semi-transparent cathode are compensated by the light amplification in forward direction due to microcavity effects.

The decrease in efficiency of the blue emitter in the TEOLED case can be attributed to differences in optical and electrical device performance of TEOLEDs and BEOLEDs: the emission width of the polymeric blue emitter is broad with a significant amount of emission in the green region of the spectrum (see Fig. 3). In the BEOLED geometry this fraction of green leads to sky-blue emission. The layer thickness (70 nm) in this case is chosen to achieve optimum electrical performance (balancing efficiency and operating voltage). Deep blue emission with corresponding color coordinates is obtained in the TEOLED geometry at layer thicknesses of 35 nm (first maximum of emission) and 140 nm (second maximum). This is contrary to the optimum layer thickness in terms of efficiency and operating voltage. High leakage currents for the thin layers (35 nm) and high driving voltages for the thick layers (140 nm) are observed. Besides reducing the electrical performance, the spectral blue-shift leads to a decrease in current-efficiency as the brightness is corrected by the

η_{max} [cd/A] (CIE-values)	/	1.2 (0.65; 0.34)	9.4 (0.28; 0.58)	2.0 (0.18; 0.26)

sensitivity of the human eye. In order to distinguish the fractions of eye-sensitivity correction and electrical device performance, we normalized the device efficiency by the overlap integral of the EL-spectrum and the eye-sensitivity curve and then compared these "quasi quantum efficiencies". It turns out that 32% of the efficiency decrease can be attributed to the color shift to deeper blue. The remaining percentage (68%) of efficiency decrease has thus to be due to electrical device performance.

Comparing the red-emitting TEOLED device featuring an Ag/MoO_3 anode with the CMOS dummy (Al/TiN/MoO_3-anode), reduced current- and light output at a given voltage are observed in the latter case. This is mainly due to a decrease in electric field resulting from the enlarged layer thickness. The current efficiency is slightly increased while λ_{max} is red-shifted. The increase in efficiency is probably due to an enlarged internal quantum efficiency due to a better charge carrier balance in the CMOS dummy device. Optical simulations show that the expected output is even reduced by a factor of 0.45 (see Supplementary data). With respect to the electrical characteristics of green- and blue-emitting materials on a CMOS dummy device, we expect similar results.

3.2. Color characteristics

In Figs. 3b and 3c the electroluminance spectra of bottom- and top-emitting OLEDs are shown. The experimental spectra were confirmed by optical simulations using Fluxim Etfos 1.3 [17]. Assuming an exciton density that is maximum at the HIL/EML interface and decays exponentially towards the cathode with a 1/e width of 20 nm [18], simulation and experimental results are in excellent agreement. Due to microcavity effects, narrowband emission is achieved in case of the TEOLED devices. In comparison to the BEOLEDs, this results in a higher color purity and, therefore, better primary CIE-values (see also Fig. 3a). Especially for the blue emitter much better color coordinates are achieved. Overall, our TEOLEDs achieve better values than required by the sRGB color space which defines the limits for computer monitors and HDTVs. In particular, the red and green emission is more saturated than required. In this case the slightly red-shifted emission of the CMOS dummy device compared with our standard TEOLED has no significant effect on the color coordinate.

The blue nearly meets the sRGB specifications. By a comparison of the areas of the color triangles [19], we conclude that the color gamut is increased by 18% (see Fig. 3a).

Calculated from the primary color coordinates, the fraction of emission required from each of the RGB TEOLEDs to obtain white emission, i.e. CIE(x, y) = (0.33; 0.33) is (RGB) = (0.26; 0.61; 0.13). The corresponding maximum current efficiency for white light emission is 4.9 cd/A at a brightness level of 1000 cd/m^2. This corresponds to a value of 5 cd/A achieved in BEOLED geometry [3], i.e. the properties are fully conserved.

4. Summary

In conclusion, we investigated solution processed crosslinkable electroluminescent materials in top- and bottom-emitting OLEDs. We showed the advantages of TEOLEDs over BEOLEDs in terms of color tuning. We also demonstrated that our TEOLEDs are suitable for high color gamut and high brightness displays. Due to their photoresist like properties, they can be directly patterned via UV-lithography and hence will allow for high resolution microdisplays. The next step will be to process and investigate the TEOLED stack and arrays of RGB sub-pixels on CMOS-backplanes for microdisplays. We already demonstrated, that on a CMOS dummy substrate the electrical and optical characteristics are essentially preserved.

ABSTRACT

We present evidence that the photoluminescence (PL) spectrum, PL kinetics and PL efficiency of solution-cast films of a phosphorescent *fac*-tris(2-phenylpyridyl)iridium(III)-cored dendrimer are not affected by the choice of solvent and thermal annealing. In contrast, when the dendrimer is dispersed into a 4,4′-bis(*N*-carbazolyl)biphenyl (CBP) host, thermal annealing induces phase separation at a micrometer scale, which results in incomplete energy transfer from CBP to the dendrimer. The insensitivity of the dendrimer film morphology and PL properties to the casting conditions and thermal treatment shows the advantage of host-free electrophosphorescent dendrimers for the further development of light-emitting displays, whilst blended systems are potentially more suitable for photovoltaic applications.

1. Introduction

There has been considerable interest in the optical and electrical properties of conjugated dendrimers in the recent past owing to their prospective applications in organic light-emitting diodes (LEDs) [1–3], optical amplifiers and lasers [4]. In particular, phosphorescent dendrimers containing a *fac*-tris(2-phenylpyridyl)iridium(III) [Ir(ppy)$_3$] core have been used to make efficient solution-processable LEDs with external quantum efficiencies as high as 16% [1]. Iridium(III) complexes are capable of harvesting light from both singlet and triplet excitons [5] and internal electroluminescence quantum efficiencies of nearly 100% has been achieved [6]. In addition, these materials present good colour tunability and are attractive for display and lighting applications.

Solution processable materials such as conjugated dendrimers or polymers have the advantage over light-emitting small molecules of being suitable for simple solution processing techniques such as spin-coating and inkjet printing. It is now well established that the morphology and photophysical properties of conjugated polymer films are strongly affected by the solvent used for the spin-coating and also by thermal annealing [7–15]. They have to be carefully manipulated to achieve the best performance in devices. For instance, the interplay between film morphology and photophysical properties of polyfluorene has been investigated in detail [13] and strong variations of lasing performance with phase morphology were reported by Shkunov et al. [14]. In addition, the conformation of the molecules and the local morphology at the film/substrate interface can vary greatly with the solvent, depending on its polarity and its aromaticity [11]. Different experimental techniques including neutron reflectivity [16] and Fourier-transform infrared spectroscopy measurements [17] have also been performed to study the polymer film morphology and probe the interfacial interactions in order to relate

PL properties and film structure. In contrast, the influence of solution processing and thermal annealing on the molecular organization of phosphorescent [Ir(ppy)$_3$]-cored dendrimer thin films and their photophysical properties has not been investigated yet. In order to make further progress and guide future innovation in the field of phosphorescent dendrimer LEDs, it is now essential to identify the existence or not of such morphological effects and to improve our understanding of the structure–property relationships in these materials.

In this manuscript, we investigate how the photophysical properties of an [Ir(ppy)$_3$]-cored phosphorescent dendrimer with first generation phenylene-based dendrons and 2-ethylhexyloxy surface groups (IrG1) in neat films and blended into a 4,4′-bis(*N*-carbazolyl)biphenyl (CBP) host are affected by the film preparation conditions. In particular, we examine the influence of the solvent used for film deposition by spin-coating, the concentration of the dendrimer solution, the spin-speed and thermal annealing on the PL spectra, PL quantum yield (PLQY) and PL kinetics. Importantly, no significant changes in the PL properties of the neat film are observed with change in processing solvent or thermal annealing, indicating that the dendrimers form robust morphologically stable thin films. In contrast, annealing the blended film gives rise to a strong phase separation, which substantially modifies the PL properties. Using three different microscopy techniques, one measuring the photoluminescence [confocal laser scanning microscopy (CLSM)], one giving topographical information [atomic force microscopy (AFM)] and one observing the optical transmission of the sample [scanning near-field optical microscopy (SNOM)], we demonstrate the formation of large domains (up to 15 μm) rich in IrG1 dendrimer after the thermal annealing. The results are of strong interest for the development of efficient electrophosphorescent devices and support the desirability of developing solution-processed host-free phosphorescent dendrimer LEDs.

2. Experimental

The chemical structures of the materials used in this study are shown in Fig. 1. For the neat film preparation, IrG1 was dissolved into a range of organic solvents: chloroform, dichloromethane, tetrahydrofuran, chlorobenzene and toluene. Only chloroform was used to form the IrG1:CBP (20:80 wt.%) blended film due to the poor solubility of CBP in other solvents. The films were deposited by spin-coating onto precleaned quartz substrates with spin-speeds ranging from 1000 to 5000 rpm. Thermal annealing was carried out at 180 °C for 2 h in vacuum at 2×10^{-4} mbar. The thickness of the films was determined by spectroscopic ellipsometry and checked from the value of their absorbance. The absorption spectra were recorded by a Cary Varian model 300 absorption spectrophotometer and the PL spectra were measured by a Jobin Yvon Fluoromax 2 fluorimeter. Film PLQYs were determined using an integrating sphere under a flowing nitrogen atmosphere according to the method reported by Greenham et al. [18]. The samples were excited from a HeCd laser emitting at 325 nm with an excitation power of about 0.15 mW.

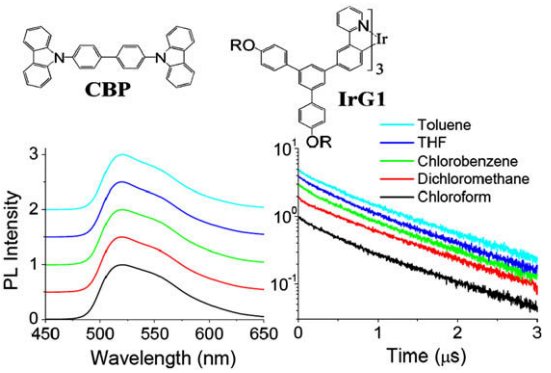

Fig. 1. PL spectra and PL kinetics detected at 520 nm of spin-coated IrG1 neat films prepared using a range of solvents. The spectra and kinetics are offset vertically for clarity. From top to bottom, the curves are obtained with films made from toluene, tetrahydrofuran (THF), chlorobenzene, dichloromethane and chloroform. The film thicknesses were in the range of 170–200 nm. The excitation wavelength was 355 nm. The chemical structure of the molecules used in this work is given in the inset. R = 2-ethylhexyl.

Time-resolved PL measurements were performed by a time-correlated single-photon counting system. Samples were excited at 393 nm by a pulsed laser diode (Picoquant) or at 355 nm by the third harmonic of a pulsed Nd:YAG laser. For the triplet–triplet exciton annihilation experiments, the 355 nm excitation light at a repetition rate of 10 kHz was focused onto the samples with a spot size of 0.3 mm diameter. All time-resolved PL measurements were carried out at room temperature and in a vacuum of $<8 \times 10^{-4}$ mbar. Spatially-resolved topographical, optical transmission and photoluminescence measurements were performed using a commercial microscope (alpha-SNOM, WITec GmbH) which allows scanning near field transmission measurements to be obtained simultaneously with AFM (contact or tapping mode) measurements. Simultaneous measurements of photoluminescence and topography are also possible using the light emanating from the tip as a near field excitation source. In addition the microscope can be used as a scanning laser confocal microscope. Sample topography was recorded simultaneously to the transmission mode data obtained at 393 nm with the Picoquant laser diode. CLSM and PL spectroscopy measurements were performed using the HeCd laser at 325 nm as excitation source. The PL signal was dispersed by a monochromator to allow wavelength discrimination. Both the transmission and the PL emission of the sample were detected by an avalanche photodiode.

3. Results and discussion

We have investigated the influence of the processing solvent on the PL properties of IrG1 neat films, using both non-aromatic and aromatic solvents. The films had thicknesses ranging from 170 to 200 nm. The green phosphorescent emission is due to the radiative decay of the metal-to-ligand charge transfer triplet state (^{3}MLCT) to the ground state [5,6,19,20]. As shown in Fig. 1, the PL spectra and the PL kinetics of IrG1 dendrimer neat films are independent of the solvent used for the spin-coating. The PLQYs

and the $1/e$ PL lifetimes measured for the films cast from a range of solvents were $65 \pm 5\%$ and 0.8 μs, respectively, with no significant difference between samples. This result clearly demonstrates that the photophysical properties of IrG1 neat films are insensitive to the processing solvents.

We have also studied the influence of the solvent on the triplet exciton diffusion in IrG1 neat films. Fig. 2a shows the PL decays measured in the neat film spin-coated from a THF solution for various excitation densities. As shown in previous work, triplet–triplet exciton annihilation processes [21–24] are responsible for the faster PL decays at high excitation densities. The density of triplet excitons $N(t)$ is proportional to the phosphorescence intensity and can be expressed by a rate equation: $dN/dt = -N/\tau - \gamma N^2$ where τ is the PL lifetime without annihilation and γ is the annihilation rate constant. If γ is time independent, a solution of this equation is:

$$\frac{1}{N(t)} = \left[\frac{1}{N_0} + \gamma\tau\right] \exp(t/\tau) - \gamma\tau \quad (1)$$

where the initial exciton density N_0 can be obtained from the energy density of the absorbed excitation laser pulse. In Fig. 2b, the inverse of the exciton density measured in the IrG1 neat film spin-coated from a THF solution is plotted as a function of $\exp(t/\tau)$. The γ value can be directly determined from the slope of the fitting curves calculated from Eq. (1). In the IrG1 neat films, the best fits were obtained with $\gamma = (6.3 \pm 1) \times 10^{-12}$ cm^3 s^{-1}, and did not depend on the solvent used for the film deposition. For diffusion limited annihilation in a three dimensional case, the exciton diffusion constant D can then be calculated from the annihilation rate constant using $\gamma = 4\pi D R_a$ where R_a is the reaction radius for which hopping is slower than annihilation and can be approximated as the core-core distance R_{eff} between neighboring phosphorescent emitters. This intermolecular distance can be estimated using a film density of 1.1 g/cm^3 [21] and assuming the molecules to be spherical. Our result leads to an exciton diffusion constant D equal to $(2.65 \pm 0.5) \times 10^{-6}$ cm^2 s^{-1} [21] and shows that the average intermolecular spacing between nearest neighbor chromophores and thus the molecular arrangement remain the same and independent of the processing solvent used to form the film.

Thermal annealing is another way to modify the morphology of polymer thin films. By heating the film near or above the glass transition temperature (T_g), macromolecules can in principle relax to more thermodynamically stable conformations and cause substantial changes in their electrical and optical properties [9,12]. We have examined the effects of thermal annealing on the photophysical properties of both the neat film of IrG1 and the 20 wt.% blend. Previous study has shown that the PLQY of 80% measured in films of this pristine (as deposited) blend is close to that of IrG1 in degassed solution [19], indicating that concentration quenching has been essentially suppressed. As shown in Fig. 3, heating the dendrimer neat film at 180 °C (which is around 50 °C higher than the T_g reported for the bulk [25]) for 2 h in vacuum does not induce any changes in the PL spectrum and the PL kinetics. It is worth noting that a similar thermal annealing in the presence of oxygen leads to a much faster PL decay and a strong

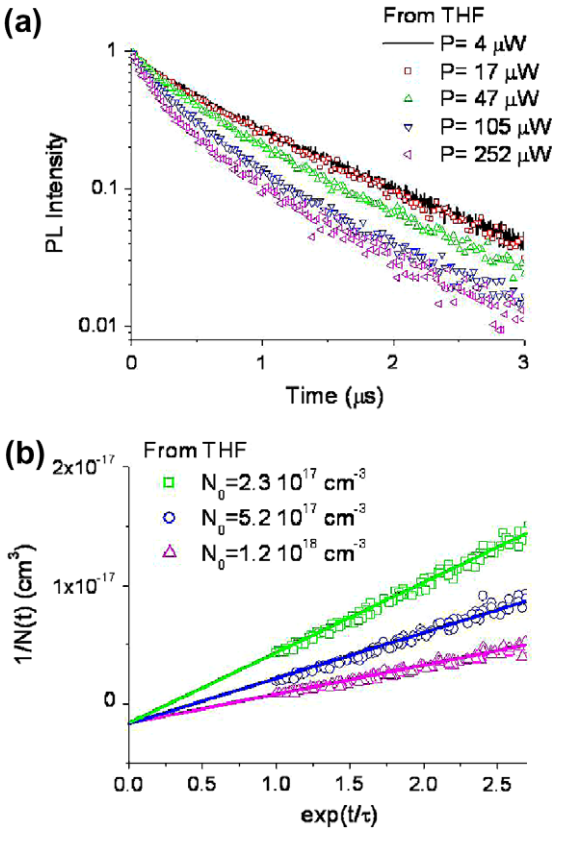

Fig. 2. (a) PL decays measured at 520 nm under different laser excitation densities in IrG1 neat film spin-coated from a THF solution. The initial intensities were normalized. (b) Plot of the reciprocal of the exciton density *versus* $\exp(t/\tau)$ in IrG1 neat film spin-coated from THF at various excitation densities.

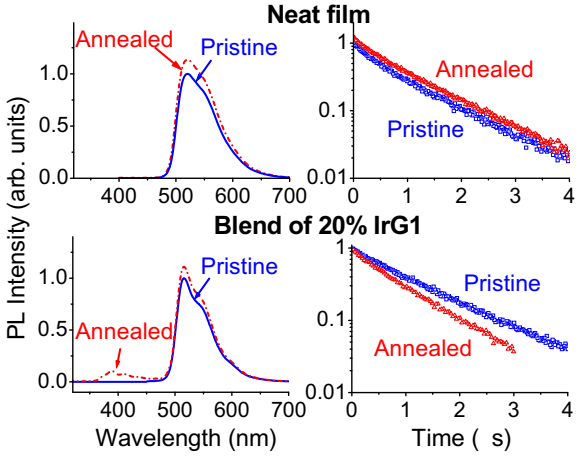

Fig. 3. PL spectra and kinetics of IrG1 neat films and IrG1:CBP (20:80 wt.%) blended films before and after a thermal annealing at 180 °C for 2 h in vacuum. The excitation wavelengths for the PL spectra were 390 and 310 nm for the neat film and the blend, respectively. The PL kinetics were measured at 520 nm with excitation at 393 nm. Spectra and kinetics are scaled vertically for clarity.

decrease in the phosphorescence efficiency due to photo-oxidation of the film. The PL spectrum of the pristine blend (before annealing) recorded with excitation at 310 nm, where CBP molecules have strong absorption, shows emission from IrG1 only, which indicates that excitation energy is transferred quickly from CBP to IrG1 (Fig. 3). In contrast, the annealed blend shows some blue fluorescence at around 400 nm from the CBP host, which suggests that energy transfer from CBP to IrG1 is much slower than in pristine blends (Fig. 3). The $1/e$ PL lifetime of IrG1 in the pristine blend of 1.1 μs is longer than that in the neat IrG1 film and can be explained by slower diffusion of triplets to any quenchers in the film [19,21]. The phosphorescence lifetime in the blend decreases to 0.8 μs with annealing and is the same as in the neat IrG1 film.

As a first step to investigate the change in blend morphology caused by thermal annealing, AFM and optical transmission measurements on a confocal microscope were performed to study the topography of the annealed blend. The blend before annealing is known to have a very smooth surface and to be homogeneous with no evident phase separation [19,21]. In contrast, the annealed blend (Fig. 4a) shows large domains (up to 15 μm) with a height variation profile of about a micrometer (Fig. 4c). The transmission signal shown in Fig. 4b was measured at 393 nm where only IrG1 absorbs significantly (see the absorption spectra of CBP and IrG1 in Fig. 4d) and correlates very well with the topography of the annealed blend. The transmission image shows exactly the same island distribution of the AFM image but with inverted contrast: low transmission of raised domains and higher transmission in inter-island regions. These results suggest that the islands are regions rich in IrG1.

Spatially-resolved PL spectroscopy using the CLSM technique was also performed to gain further insights into the molecular organization of the phase-separated annealed blend. An excitation wavelength of 325 nm was chosen in this experiment to observe the photoluminescence from both IrG1 and CBP. Note that the needs for different lasers (laser diode for the optical transmission image at 393 nm and HeCd laser for the fluorescence image) means that we were not able to probe exactly the same regions of the annealed sample using these two techniques. Fig. 5a show the CSLM fluorescence images at various emission wavelengths each of them with 10 nm bandwidth (FWHM). The images taken at emission wavelengths in the range from 480 to 600 nm show strong luminescence from the islands up to ~20 μm in size, whereas at 390 and 420 nm the islands are dark and some luminescence is observed in the regions between them. The PL spectrum of the islands (Fig. 5b) agrees well with the IrG1 emission in the bulk films (see Fig. 1), and shows no sign of CBP emission at wavelengths <430 nm, and hence the islands predominantly contain IrG1. The PL spectrum of the inter-island region shows only the blue fluorescence (<430 nm), indicating that the inter-island regions only

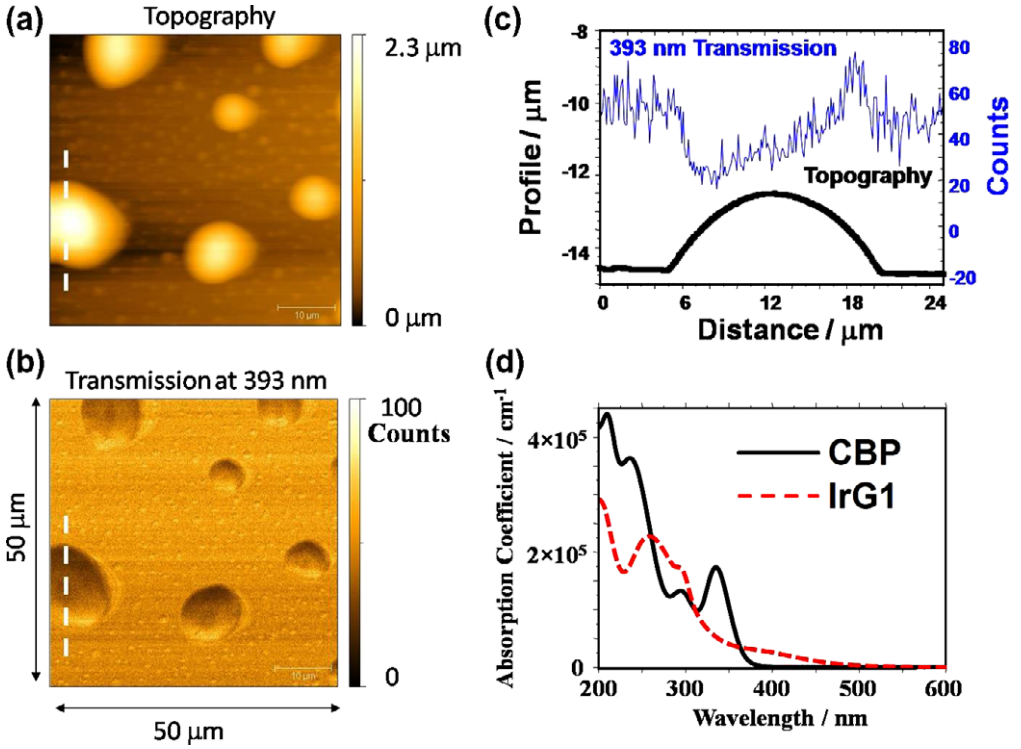

Fig. 4. SNOM micrographs demonstrating the phase separation between IrG1 and CBP after thermal annealing of the 20 wt.% blend. Panels (a) and (b) show the topography and the transmission mode measurement at 393 nm, respectively. Panel (c) gives the profiles of both the topography and the transmission mode measurement at 393 nm along the dashed white lines shown in (a) and (b). Panel (d) shows the wavelength-dependence of the absorption coefficients measured for IrG1 and CBP neat films determined by ellipsometry.

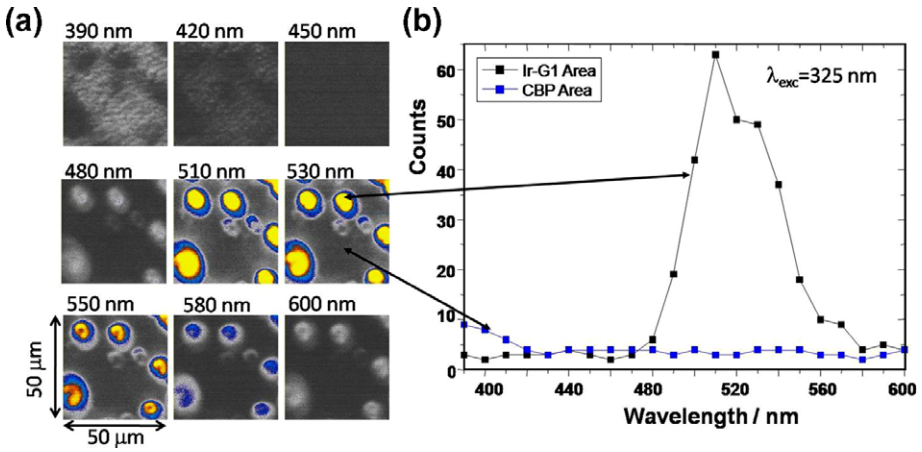

Fig. 5. (a) Photoluminescence images obtained with a confocal scanning laser microscope for the annealed 20 wt.% blend at different emission wavelengths varying from 390 to 600 nm. The excitation wavelength was 325 nm. (b) PL spectra recorded in IrG1-rich and CBP areas indicated by the arrows in (a).

contain CBP. However, it is possible that the island regions contain some CBP. If it is the case, no CBP fluorescence can be observed because the energy transfer from CBP to IrG1 is very fast in well-mixed blends. The images shown in Figs. 4 and 5 provide clear evidence of the phase separation into IrG1-rich and CBP domains when the phosphorescent blends are annealed. This work also demonstrates that spatially-resolved PL spectroscopy is a powerful tool to explore the morphology and the molecular organization of phosphorescent organic LED materials.

4. Conclusion

In summary, the effects of the solvent used for the film preparation by spin-coating and thermal annealing on the PL properties of neat and blended films of a phosphorescent [Ir(ppy)$_3$]-cored dendrimer have been investigated in detail. The results indicate excellent consistency of the properties of the film for a wide range of processing conditions for the neat films. We find that PL spectra, PL kinetics, PL efficiency and exciton diffusion of the neat films remain the same. This is potentially very attractive for applications as the need for complex process control is reduced. We also show that heating a phosphorescent dendrimer neat film at a temperature as high as 180 °C for several hours in vacuum does not alter its photophysical properties. Such thermal stability is another important factor for the choice of [Ir(ppy)$_3$]-cored dendrimers as light-emitting materials for the next generation of displays and lighting. In contrast, a strong phase separation was observed in the blend of the dendrimer with CBP and is likely to occur in other phosphorescent composite materials. Whilst phase separation may be useful for bulk heterojunction solar cells, our results strongly support the interest in developing host-free dendrimers for LEDs.

ABSTRACT

A study of one-dimensional exciton diffusion in tris(2-phenylpyridine) iridium(III) molecules as a function of intermolecular spacing is reported. We show for the first time the existence of an optimum intermolecular spacing that gives the longest diffusion length in [Ir(ppy)$_3$] molecules. When the intermolecular spacing is too short, the long-range excitonic quenching becomes dominant; on the other hand, when it is too long, the exciton energy transfer is miniscule. A specially-designed organic light-emitting diode with separate exciton formation and emission was constructed to measure the one-dimensional exciton diffusion length. The maximum one-dimensional exciton diffusion length for this material is around 8.5 nm for an inter-molecular separation of around 4.5 nm.

1. Introduction

Performance of organic light-emitting diodes (OLEDs) and photovoltaic (OPV) depends much on the dynamics of the exciton migration (diffusion). The relatively long exciton diffusion length (L_D) of triplet excitons enables a highly efficient white OLED with small electroluminescence efficiency roll-off by separating singlet and triplets into two independent channels [1]. In OPV devices, a longer L_D allows the utilization of a thick absorption layer that maximizes the light absorption. Although bulk-heterojunction OPV devices create donor–acceptor interface that is highly folded such that photogenerated excitons find an interface within a distance L_D of their generation sites [2,3], carrier transport is much obstructed by the multi-domains associated with the structure [4]. Therefore a longer L_D is still preferred. Understanding of exciton diffusion in organic semiconductor is therefore imperative.

Exciton diffusion in organic semiconductor has been subjected to theoretical and experimental studies for many years. Movaghar et al. [5,6] modeled the exciton diffusion and energy relaxation by both Monte Carlo simulation and a numerical analytic theory utilizing a Förster energy transfer between adjacent molecules. An improved model by Madigan and Bulovic is capable to fit very well with the experimental results [7] which shows that exciton diffusion in organics is truly governed by the long-range dipole–dipole interaction. These studies suggest that a more compact molecular material should posses a larger L_D due to a higher energy transfer rate.

Tris(2-phenylpyridine) iridium(III) [Ir(ppy)$_3$] has been used in organic light-emitting diode (OLED) to harvest the triplet excitons, which increases the efficiency by almost four times [8]. The emission layer of the OLED is normally formed by a host–guest system obtained by co-evaporating a small amount of guest molecule [Ir(ppy)$_3$] in the matrix of host material. Most excitons are formed in the matrix host which then transfers its energy to the guest molecules where final emission takes place. Recently, it was observed that Ir(ppy)$_3$ also suffers from a long-range excitonic quenching which is responsible for

doi:10.1016/j.orgel.2009.09.029

the concentration quenching [9–11]. Concentration quenching is represented by a persistent drop in quantum efficiency as the concentration of guest molecule increases. The quenching mechanism is reported to follow a similar Förster-type process with R^{-6} dependence, where R is the intermolecular spacing [9–11]. Correspondingly, our current understanding on exciton diffusion will be modified with the presence of this long-range quenching mechanism.

In this work we investigate the impact of the long-range quenching process to the exciton diffusion in $Ir(ppy)_3$. Exciton diffusion involves energy transfer to the adjacent molecules by Förster process [12]. In the presence of the long-range quenching there is an optimum value of intermolecular distance that gives the longest L_D. Besides demonstrating the first evidence of the existence of this optimum intermolecular spacing, we also present for the first time a direct method of measuring L_D in organic semiconductor.

2. Theory

To illustrate the effect of inter-molecular distance to the exciton diffusion, we utilized two models of exciton diffusion by adding in the long-range quenching process, as is shown in the following. The first one is based on the detailed-balance approach developed by Movaghar et al. [6]. The second one is based on the stochastic random flight model developed by Markov [13]. For the first approach, let's consider a one-dimensional molecular arrangement with a lattice spacing of R and exciton concentrations of (..., P_{i-1}, P_i, P_{i+1}, ...). We assume that the exciton transfer, which is governed by the Förster process, only occurs between adjacent molecules. This assumption is valid due to the R^n, ($n > 3$) dependence of the transfer rate. Based on this assumption, we can write the exciton (P) dynamics as,

$$\frac{dP_i}{dt} = -\frac{P_i}{\tau_r} + \{\chi_F P_{i-1} - 2\chi_F P_i + \chi_F P_{i+1}\} - 2\chi_{nr} P_i \quad (1)$$

where τ_r is the exciton lifetime, and χ_F is the Förster energy transfer rate, which can be written as [6]

$$\chi_F(R) = (1/\tau_r)(R_F/R)^6 \quad (1a)$$

For the case of a plane-to-plane interaction, Eq. (1a) should be integrated across the planar surface, thus we have $\chi_F(R) = \frac{2\pi\sigma R_F^6}{\tau_r}\int_0^\infty \frac{rdr}{(r^2+R^2)^3}$, which can be reduced to

$$\chi_F(R) = (1/\tau_r)\frac{\pi}{2}\sigma R_F^6 (1/R)^4 = (1/\tau_r)(R_{F2D}/R)^4 \quad (1b)$$

where σ is the plane surface density, R_F and R_{F2D} is the Förster radius and 2D modified Förster radius, respectively, and the long-range quenching rate is [9–11]

$$\chi_{nr}(R) = \begin{cases} (1/\tau_r)(R_{nr}/R)^6 \quad \text{for point-to-point} & (1.c) \\ (1/\tau_r)\frac{\pi}{2}\sigma R_{nr}^6 (1/R)^4 = (1/\tau_r)(R_{nr2D}/R)^4 & \\ \quad \text{for plane-to-plane} & (1.d) \end{cases}$$

where R_{nr} and R_{nr2D} is the lossy radius and 2D modified lossy radius, respectively. The steady state solution of Eq. (1) for the exciton distribution is $P_{i+1}/P_i = P_i/P_{i-1} = c = 1 + \Pi - \sqrt{\Pi}\sqrt{\Pi+2} \approx 1 - \sqrt{2\Pi}$, where $\Pi = \chi_{nr}/\chi_F + 1/2[\tau_r\chi_F]^{-1}$. At a distance x from the initial molecule, the exciton density becomes $P(x) = P(0)c^{\left(\frac{x}{R}\right)} = P(0)\exp^{\left(\frac{x}{R/\ln c}\right)}$. Hence the diffusion length can simply be written as $L_D = -R/\ln c \approx R/\sqrt{2\Pi}$.The second approach is based on Markov model where random flight of excitons in a lattice is considered [13]. In this case, the exciton diffusion occurs by incoherent hopping between the nearest-neighbor with a hopping rate (χ_F), which is related to the diffusion constant (D) by: $D = R^2(2\chi_F)/2$ [14]. The diffusion length can simply be written as $L_D = \sqrt{D\tau_t}$, where τ_t is the total exciton lifetime. Adding in the long-range quenching into the Markov isotropic model, the exciton lifetime can be written as $\tau_t^{-1} = \tau_r^{-1} + 2\chi_{nr}$. The exciton diffusion length can be written as:

$$L_D = \sqrt{\frac{R^2\chi_F}{(\tau_r^{-1} + 2\chi_{nr})}} = R/\sqrt{2\Pi} \quad (2)$$

For a plane-to-plane energy transfer, $L_D = R/\sqrt{2\left(\frac{R_{nr2D}}{R_{F2D}}\right)^4 + \left(\frac{R}{R_{F2D}}\right)^4}$. Both the Moghavar and Markov models yield the same result. Eq. (2) shows that there exists an optimum intermolecular spacing (R) that gives the longest L_D. When R is large, the energy transfer process between the molecules is miniscule. On the other hand, when R is small, the long-range quenching process takes place therefore reducing the L_D. It should be noted that Eqs. (1) and (2) only apply for one-dimensional exciton diffusion. However similar behavior is also expected in three-dimensional case.

It is worth mentioning that in the above analysis, we excluded the lateral long-range quenching interaction within the planar sheet of $Ir(ppy)_3$ and the non-radiative losses. This is meaningful as the lateral interaction only adds a constant value (independent of R) in the transfer rate, which can be absorbed in the equation as a non-radiative loss. Assuming the guest molecules in the planar layer are homogeneously distributed in a 2D square lattice with inter-molecular separation of a, the summation of the long-range quenching interaction within the planar guest layer (2D) can be written as:

$$\chi_{nr2D} = \int_a^\infty \frac{1}{\tau_r}\left(\frac{R_{nr}}{r}\right)^6 \sigma 2\pi r dr = \frac{2\pi\sigma R_{nr}^6}{\tau_r}\int_a^\infty \frac{rdr}{r^6} \quad (3)$$

where σ is the surface density of the guest layer (for the case of square lattice, $\sigma = a^{-2}$). The long-range quenching interaction within the guest layer is:

$$\chi_{nr2D} = \frac{\pi}{2\tau}\left(\frac{R_{nr}}{a}\right)^6 \quad (4)$$

The overall long-range quenching interaction is therefore,

$$\chi_{nr} = \frac{\pi}{2\tau}\left(\frac{R_{nr}}{a}\right)^6 + \frac{\pi}{2\tau}\sigma R_{nr}^2\left(\frac{R_{nr}}{R}\right)^4 \quad (5)$$

Addition of the lateral long-range quenching interaction will not affect the result shown in Eq. (2).

3. Experimental

To verify experimentally the variation of L_D as a function of intermolecular spacing, we investigated the exciton diffusion and quenching utilizing a blue OLED with a single exciton source [15]. The blue OLED has a structure of ITO/NPB/BCP/Alq_3/Mg:Ag, where ITO is indium–tin–oxide as the anode, NPB is N,N′-di(naphth-2-yl)-N,N′-diphenyl-benzidine as the hole transporting layer, BCP is 2,9-dimethyl-4,7-diphenylphenanthroline as the hole blocking layer, Alq_3 is tris-(8-hydroxyquinoline) aluminum as the electron transporting layer, and Mg:Ag is a mixture of magnesium and silver (ratio 10:1) as the cathode. Detail of the fabrication and measurement can be found elsewhere [15]. For this structure, the barriers for both hole and electron exist at the NPB/BCP interface. Since holes experience a larger barrier at BCP (1.1 eV) [16] than electrons at NPB (0.6 eV) [16], the recombination and exciton formation take place in the NPB layer.

Using the basic blue OLED structure, we shall study the exciton diffusion in Ir(ppy)$_3$ molecules in the following. As the exciton is absent at the BCP side, Ir(ppy)$_3$ was deposited as the guest molecule in the BCP-host by sequential doping [Ir(ppy)$_3$/BCP multiple-layer] [9]. In this system, the exciton from NPB transfers its energy to Ir(ppy)$_3$ nearest to the NPB/BCP interface (Fig. 1). The excitons then diffuse within the Ir(ppy)$_3$ molecules. To detect the exciton distribution, a thin sensing layer (red emission) of bis(2-phenylquinoline) (acetylacetonate) iridium(III) [Ir(2-phq)$_2$(acac)] is deposited after the Ir(ppy)$_3$. By varying the thickness of the BCP-host layer, the exciton diffusion as a function of intermolecular spacing in Ir(ppy)$_3$ can be studied.

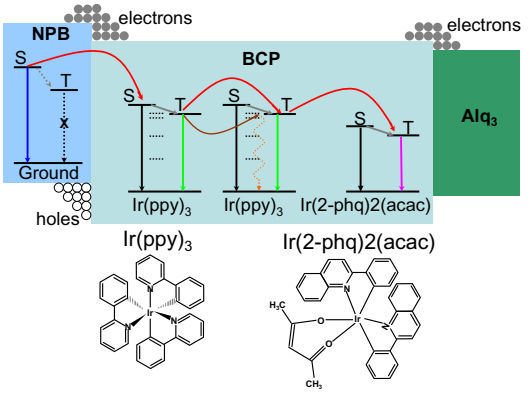

Fig. 1. Illustration of the OLED structure utilized to study exciton diffusion in Ir(ppy)$_3$. The excitons are formed at the NPB layer with a peak concentration at the NPB/BCP interface. The exciton in NPB transfers its energy to the nearest Ir(ppy)$_3$ molecules via Förster process (red arrow) [singlet–singlet (S–S)]. Due to a large inter-system crossing rate (grey arrow) because of the large spin–orbit coupling, the singlet exciton in Ir(ppy)$_3$ decays into a triplet state. The triplet (T) exciton then diffuses to an adjacent Ir(ppy)$_3$ molecule by Förster process (red arrow). However there is also a chance that the triplet exciton transfers via long-range quenching process (brown arrow) to the vibrational mode (dotted lines) of the adjacent Ir(ppy)$_3$, resulting in non-radiative decay (dotted orange arrow). To detect the exciton distribution, a Ir(2-phq)$_2$(acac) layer emitting red color (pink arrow) is deposited at the end. Also shown are the molecular structure of Ir(ppy)$_3$ and Ir(2-phq)$_2$(acac). 4. Result and discussion

4.1. Exciton distribution in blue OLED

Before we study the L_D, we shall first investigate the exciton distribution in the blue OLED. The inset of Fig. 2 shows the band energy of the blue OLED. The electroluminescence (EL) spectrum of the blue OLED is shown in Fig. 2. Also shown in Fig. 2 is the photoluminescence (PL) spectrum of the BCP. It can be seen that there is no BCP emission, thus the exciton is only formed at NPB layer.

To study the exciton distribution at NPB layer, we fabricated device with a structure of ITO/NPB (80-d nm)/DCJTB (0.1 nm)/NPB(d nm)/BCP (20 nm)/Alq_3 (50 nm), where DCJTB is 4-(dicyanomethylene)-2-tert-butyl-6-(1,1,7, 7-tetramethyljulolidin-4-yl-vinyl)-4H-pyran, and d varies from 10, 20, 30 to 50 nm as shown by the inset of Fig. 3a. DCJTB emits red light peaking at 590 nm. Fig. 3a shows the emission spectra for devices with various d's. It can be seen that the NPB (or DCJTB) peak increases (or decreases) with the increase of d. In Fig. 3b, we plotted the intensity of the NPB and DCJTB as a function of d. Also shown in the figure is the fitting curves that follows $(1 - \exp[-d/L_D])$ [red line] and $(\exp[-d/L_D])$ [blue line]. It can be seen that the fit and the data match well with $L_D = 22 \pm 3$ nm. This relatively long L_D may also indicate that the formation of exciton occurs throughout the NPB layer with the peak rate at the NPB/BCP interface.

4.2. Energy transfer rate between NPB, Ir(ppy)$_3$ and Ir(2-phq)$_2$(acac)

We then investigated the exciton energy transfer rate between NPB and Ir(ppy)$_3$. To do this, we deposited a thin layer of 0.5 nm Ir(ppy)$_3$ in the BCP layer with varying distance from NPB/BCP interface. The structure is NPB

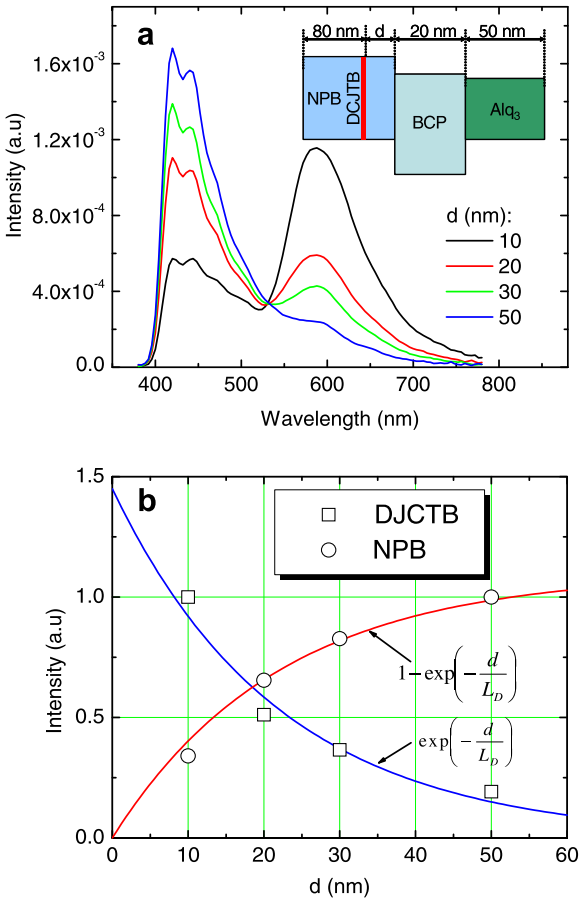

Fig. 3. (a) Emission spectra for devices with various *x*'s. The inset shows the energy diagram of the ITO/NPB/DCJTB/NPB/BCP/Alq_3/Mg structure. (b) Normalized peak intensity of DCJTB and NPB as a function of *x*. Also shown are the fitting curves which obey $(1-\exp[-d/L_D])$ and $\exp[-d/L_D]$.

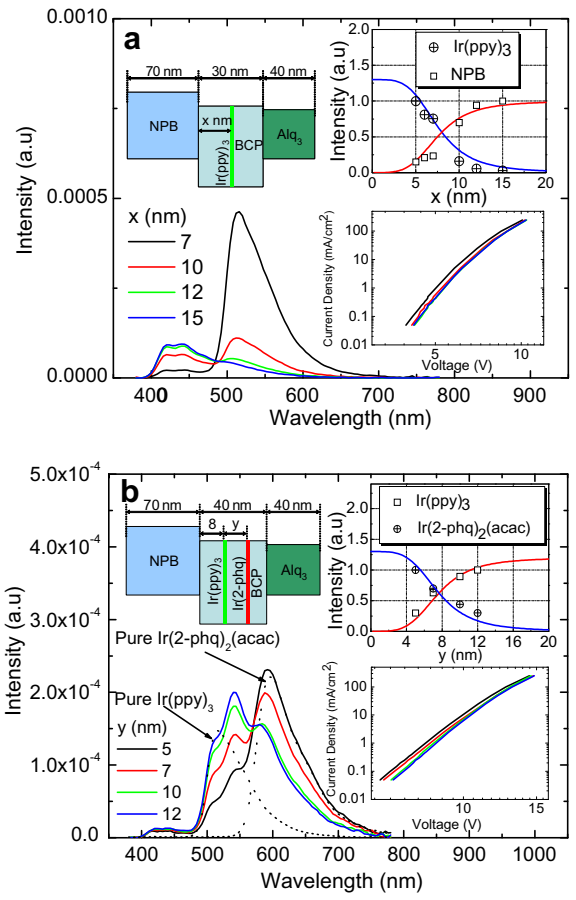

Fig. 4. (a) The emission spectra for devices with different values of *x*. The inset shows the normalized peak intensity of the NPB and $Ir(ppy)_3$ as a function of *x*. The lower inset shows the current density versus voltage curves for devices with different values of *x*. Also shown by the inset is the energy diagram of the corresponding device. (b) The emission spectra for devices with different values of *y*. Emission spectra of pure $Ir(ppy)_3$ and $Ir(2\text{-phq})_2(acac)$ are also shown. The inset shows the normalized peak intensity of the $Ir(ppy)_3$ and $Ir(2\text{-phq})_2(acac)$ as a function of y. The lower inset shows the current density versus voltage curves for devices with different values of y. Also shown by the inset is the energy diagram of the corresponding device.

(70 nm)/BCP (*x* nm)/$Ir(ppy)_3$ [0.5 nm]/BCP (30 − *x* nm)/Alq_3 (40 nm), where *x* varies from 5, 6, 7, 10, 12, to 15 nm as shown by the inset of Fig. 4a. Fig. 4a shows the emission spectra for device with different *x*'s. It can be seen that the $Ir(ppy)_3$ [or NPB] peak decreases [or increases] sharply with the increase of *x*. This is because the transfer rate from NPB to $Ir(ppy)_3$ exciton is distance dependent. The inset shows the peak intensity of NPB and $Ir(ppy)_3$ peaks as a function of *x*. The intensity of the $Ir(ppy)_3$ peak can be written as $\chi_F/(\chi_F+\tau_r^{-1}) = (1+(x/R_{F2D})^4)^{-1}$ [17]. It is clear that the $Ir(ppy)_3$ peaks can be fitted well using a plane-to-plane type Förster transfer rate [blue line]. The intensity of the NPB peak on the other hand can be written as $\tau_r^{-1}/(\chi_F+\tau_r^{-1}) = (1+(R_{F2D}/x)^4)^{-1}$ [17]. And similarly, the data are fitted well using a plane-to-plane type Förster transfer rate [red line], with R_{F2D} = 7.5 ± 0.6 nm. The lower inset in Fig. 4a shows the current density versus voltage relationship for devices with different values of *x*. It can be seen that there is no significant change in the current–voltage profile, which indicates that the variation of the emission spectrum is unrelated with charge trapping in $Ir(ppy)_3$ layer.

We then studied the exciton energy transfer rate between the $Ir(ppy)_3$ and the sensing layer $Ir(2\text{-phq})_2(acac)$. Devices with a structure of NPB (70 nm)/BCP (8 nm)/$Ir(ppy)_3$ [0.5 nm]/BCP(*y* nm)/$Ir(2\text{-phq})_2(acac)$ [0.1 nm]/BCP (32 − *y* nm)/Alq_3 (40 nm) was fabricated, where *y* varies from 5, 7, 10 to 12 nm as shown by the inset of Fig. 4b. Fig. 4b shows the emission spectra for different *y*'s. Similar to the results in Fig. 4a, there is a clear variation of emission spectrum due to energy transfer. The inset shows the peak intensities of $Ir(ppy)_3$ and $Ir(2\text{-phq})_2(acac)$ as a function of *y*. The simulation fits the experimental data well based on the Förster type of energy transfer with R_{F2D} = 7.5 ± 0.6 nm (as shown by the solid line). The lower inset in Fig. 4b shows the current density versus voltage curves for devices with different values of *y*. It can be seen that only slight shift in voltage is observed for different *y*'s. This indicates that the changes in the emission spectrum is not caused by direct exciton formation at $Ir(2\text{-phq})_2(acac)$. Exciton formation at $Ir(2\text{-phq})_2(acac)$ requires the presence

of both hole and electron carriers. Any variation of emission spectrum signifies changes in carrier flow within the device, hence should be reflected by the current density versus voltage curves.

4.3. Exciton diffusion length as a function of intermolecular spacing

Finally, to study the L_D in Ir(ppy)$_3$ molecules, we fabricated two different structures where Ir(ppy)$_3$ was deposited as the guest molecule in the BCP-host by sequential doping [Ir(ppy)$_3$/BCP multiple-layer] [9]. The thickness of the Ir(ppy)$_3$/BCP multiple-layer is fixed (Fig. 5a). The Ir(ppy)$_3$/BCP multiple-layer consists of [Ir(ppy)$_3${0.5 nm}/BCP(R nm)] N times/Ir(ppy)$_3$ [0.5 nm]. The BCP layer thickness determines the intermolecular spacing between the Ir(ppy)$_3$ molecules.

Structure A consists of NPB (70 nm)/BCP (7 nm)/{Ir(ppy)$_3$/BCP multiple-layer} [24 nm]/BCP (5 nm)/Ir(2-phq)$_2$(acac) (0.1 nm)/BCP (5 nm)/Alq$_3$ (40 nm). The (R, N) varies from (6 nm, 4), (8 nm, 3), to (12 nm, 2). For structure B, the thickness of the Ir(ppy)$_3$/BCP multiple-layer was fixed at 12 nm. Structure B consists of NPB (70 nm)/BCP (7 nm)/{Ir(ppy)$_3$/BCP multiple-layer} [12 nm]/BCP (7 nm)/Ir(2-phq)$_2$(acac) (0.1 nm)/BCP (5 nm)/Alq$_3$ (40 nm). The (R, N) varies from (2 nm, 6), (3 nm, 4), (4 nm, 3), to (6 nm, 2). For all devices in each structure, the sensing Ir(2-phq)$_2$(acac) layers are at the same distance from the NPB/BCP interface [18].

Fig. 5a shows the emission spectrum for structure A and B with different (R, N)'s. For structure A, it can be seen that the Ir(ppy)$_3$ peak increases with the increase of R. The Ir(2-phq)$_2$(acac) peak on the other hand is maximum for R = 6 nm. This shows L_D is the longest for device with (R, N) = (6 nm, 4) since the position of the Ir(2-phq)$_2$(acac) layer is approximately the same for all devices. The smaller Ir(2-phq)$_2$(acac) peak intensity for R > 6 nm can be understood due to a weak Förster energy transfer between the Ir(ppy)$_3$.

For structure B, it can be seen that the Ir(2-phq)$_2$(acac) peak decreases as R decreases. This shows the exciton diffusion to the Ir(2-phq)$_2$(acac) decreases with the decrease of R. The Ir(ppy)$_3$ peak decreases even more with the decrease of R. For device with R < 6 nm, the long-range quenching process increases, reducing the L_D as suggested in the beginning. The emission of the Ir(ppy)$_3$ molecule also reduces as a result of the increasing long-range quenching process. This agrees with our theory well for reduced L_D. Maximum exciton diffusion is obtained for R = 6 nm. The exciton distribution in the Ir(ppy)$_3$ layers can be written as $p(x) = L_D^{-1}\exp(-xL_D^{-1})$, where L_D is a function of intermolecular spacing R. In the case where there is an absorbing layer [Ir(2-phq)$_2$(acac)] with different emission spectrum positioned at a distance d from the boundary (x = 0), the emission will consist of that the original molecules [Ir(ppy$_3$)] and the absorbing molecules [Ir(2-phq)$_2$(acac)]. Unlike diffusion, where the energy transfers between different layers are unidirectional, the energy transfer from Ir(ppy)$_3$ to the Ir(2-phq)$_2$(acac) is one-way only, therefore the overall energy

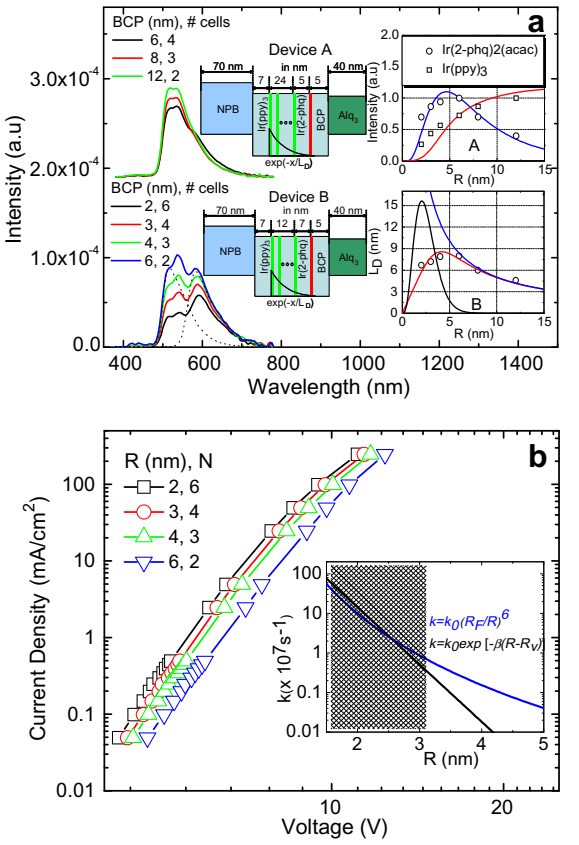

Fig. 5. (a) The emission spectra of devices with structure A (upper) and structure B (lower). The inset shows the respective energy diagram of structure A and B. Also shown in the energy diagram is the illustration of exponentially distributed excitons. The inset A shows the intensity of the Ir(ppy)$_3$ and Ir(2-phq)$_2$(acac) peaks as a function of thickness of BCP layer separating two adjacent Ir(ppy)$_3$ layers (R). Peak intensities of devices with structure A and B are normalized with respect to device with R = 6 nm. Inset B shows the corresponding L_D value for devices with different value of R. (b) Current density versus voltage curves for device B. Inset in (b) shows the exciton hopping rate as function of intermolecular spacing (R). Black and blue lines are the hopping rate based on Dexter and Förster processes, respectively. It can be seen that at the range of the data presented at Ref. [15] shown here inside the grid-box, both model show a similar characteristic. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

transfer to the [Ir(2-phq)$_2$(acac)] is much larger than the diffusion rate, hence the intensity can be written as:

$$I_{Ir(ppy)3} = \frac{\tau_r^{-1}}{\tau_r^{-1} + 2\chi_{Fnr}} \int_0^d p(x)dx = \frac{1}{(1 + 2\tau_r\chi_{Fnr})}\left(1 - \exp\left(-\frac{d}{L_D(R)}\right)\right) \quad (6)$$

$$I_{Ir(2\text{-}phq)2(acac)} = \int_d^\infty p(x)dx = \exp\left(-\frac{d}{L_D(R)}\right) \quad (7)$$

The inset A of Fig. 5a shows the intensity of the Ir(ppy)$_3$ and Ir(2-phq)$_2$(acac) as a function of BCP layer separating the Ir(ppy)$_3$ layers (R). It can be seen that the Ir(2-phq)$_2$(acac) peak intensity is maximum for R = 6 nm, which indi-

cates the longest L_D. The blue line shows the fit using Eq. (6) while the red line using Eq. (7). It can be seen that a reasonable agreement between the theory and experimental data were achieved. In the inset B of Fig. 5a, we plotted the corresponding L_D obtained from experimental data (open circle) and calculated from Eq. (2) with (red line) and without (blue line) the inclusion of the long-range quenching process. It should be noted that the large variation in the emission spectrum is only reflected by the small changes in the L_D value because of the logarithmic relation. Inclusion of the long-range quenching process is clearly necessary to fit the experimental data. For the fit, we used L_D = 8 nm for R = 6 nm (see below). From the fit in inset B, the Förster (R_{F2D}) and lossy (R_{nr2D}) radius are about 7.1 ± 0.3 nm and 3.5 ± 0.2 nm, respectively, with maximum L_D = 8.5 nm at R = 4.5 nm. The R_{F2D} value is close with that obtained for NPB–Ir(ppy)$_3$. On the other hand, the R_{nr2D} value is similar with that reported previously [9]. R_F and R_{nr} can be calculated assuming that the surface density of the planar 0.5 nm Ir(ppy)$_3$ layer is around (1^{-2}–2^{-2} nm^{-2}). Using the relation between R_F and R_{F2D} [Eq. (1)], R_F = 3.4–4.3 nm and R_{nr} = 2.1–2.7 nm were obtained. The R_{nr} value is very close with that reported previously [10].

Another point needs to be addressed is the possibility of Ir(ppy)$_3$ triplet exciton back-transferring the energy to the BCP triplet which then diffuses via BCP. Previous report has shown that the triplet energy of BCP (2.5 eV) is only slightly larger than that of Ir(ppy)$_3$ (2.4 eV) [19]. This small difference in the energy level suggests that the triplet is not well confined in the Ir(ppy)$_3$. The significance of the back-energy transfer from Ir(ppy)$_3$ to BCP can be seen by analyzing the experimental results. Let's examine Fig. 4b for example, where we showed the interaction between Ir(ppy)$_3$ and Ir(2-phq)$_2$(acac). A large back-energy transfer to BCP will lead to exciton diffusion directly via the BCP instead of Ir(ppy)$_3$. In this case, only the emission spectrum of the Ir(2-phq)$_2$(acac) is expected to vary, not the Ir(ppy)$_3$, since only the Ir(2-phq)$_2$(acac) layer is positioned differently. However, it is clear from Fig. 4b that both Ir(ppy)$_3$ and Ir(2-phq)$_2$(acac) peaks vary accordingly, which indicates that the energy transfer is mainly due to Förster process. Secondly, it can be seen for device B in Fig. 5 that the addition of the Ir(ppy)$_3$ layers is able to extend the exciton distribution up to 19 nm, which indicates that exciton diffusion is occurred between the Ir(ppy)$_3$ layers. Furthermore it has been well reported in the literature that BCP acts as a good exciton blocker [1,8]. In an OLED system that utilizes 4,4′-bis(N-carbazolyl)biphenyl (CBP) (with higher triplet energy of 2.6 eV [19]) as the host and with BCP as the exciton blocker, the triplet exciton is found to be efficiently confined within the CBP, which indicates effective exciton blocking by BCP [1]. Hence it is safe to say that the excitons are well confined within the Ir(ppy)$_3$ layer.

Fig. 5b shows the current–voltage characteristics for devices with various (R, N). It can be seen that despite of the large variation of R and N, the current–voltage profile is barely changed (maximum shift of 1 V). This signifies that the charge trapping at the Ir(ppy)$_3$ layers is minimum. The influence of charge trapping to the light emission can be further considered insignificant for the following reason. Charge trapping in Ir(ppy)$_3$ layer will cause devices with larger N to emit more green and red light. However, from the experimental result it can be seen that, N does not correlate linearly with the emission peak intensity. For device A, the highest N gives smaller green but larger red emissions. On the other hand for device B, the highest N gives smaller green and red emissions. Hence the consequence of charge trapping to the interpretation of our result can be neglected. Recently, Ribierre et al. studied the triplet–triplet exciton annihilation dynamics in Iridium(III)-centered dendrimers [11]. They discovered a similar Förster type of excitonic quenching, but discussed the exciton diffusion in term of a hopping (Dexter) process [20]. However, the limited range of intermolecular spacing (1.8–3.2 nm) available for the analysis could mislead to the conclusion that exciton diffusion is governed by Dexter process. In fact, at such intermolecular spacing (1.8–3.2 nm), the data can be fitted well with either Dexter or Förster (with R_F = 4.5 nm) processes. In inset of Fig. 5b we plotted the Dexter and Förster energy transfers as function of intermolecular spacing. It can be seen that at a small intermolecular spacing as reported by Ribierre et al. (1.8–3.2 nm), the data can be fitted with both Dexter and Förster processes. The data start to deviate at R > 3 nm. For the Förster transfer rate R_F = 4.5 nm. The fitted R_F is close to the value obtained experimentally (R_F = 3.4–4.3 nm). Moreover, exciton diffusion by Dexter process will lead to a non-monotonous L_D characteristic as a function of intermolecular spacing, which fails to fit the experimental data for a larger intermolecular spacing. Also shown in inset B of Fig. 5a is the L_D calculated by assuming that the exciton diffusion is governed by Dexter process (black line) with a hopping rate of $k = k_0 \exp[-\beta(R - R_v)]$ with $k_0 = 4\times 10^9\ s^{-1}$, $\beta = 0.33\ \text{A}^{-1}$ and $R_v = 1$ nm [11]. These parameters were directly taken from Ref. [12]. For the calculation, we modified the Dexter process for the case of plane-to-plane interaction. In plane-to-plane interaction, the Förster process decays as R^{-4} while the Dexter process decays as $R \cdot \exp[-\beta(R - R_v)]$. It can be seen that, due to the nature of the Dexter process, the L_D drops very fast as R increases, which cannot be fitted with the experimental data.

To confirm the value of L_D for the optimum intermolecular spacing, we then perform another experiment, by fabricating a structure with fixed intermolecular spacing with different values of N. The structure is NPB (70 nm)/BCP (7 nm)/[Ir(ppy)$_3$ {0.5 nm}/BCP (6 nm)]N times/Ir(ppy)$_3$ [0.5 nm]/BCP (5 nm)/Ir(2-phq)$_2$(acac) [0.1 nm]/BCP (28–6N nm)/Alq$_3$ (40 nm), where N is varied from 1 to 4. Fig. 6 shows the emission spectra for devices with various N's. The intensity of Ir(2-phq)$_2$(acac) and Ir(ppy)$_3$ as a function of N or thickness of Ir(ppy)$_3$/BCP multiple-layer is shown in the inset. The Ir(2-phq)$_2$(acac) and Ir(ppy)$_3$ peaks can be fitted with $(1 - \exp(-d/L_D))$ [red line] and $\exp(-d/L_D)$ [blue line], respectively. Based on the plot, the L_D is determined to be 8 ± 2 nm for R = 6 nm.

It is worth mentioning that the total thickness of our device is more than 120 nm, and a Ir(2-phq)$_2$(acac) was used as an absorber, so that surface quenching can be neglected [11]. In fact, there was no Alq$_3$ emission observed, indicating the absence of exciton diffusion toward the interface.

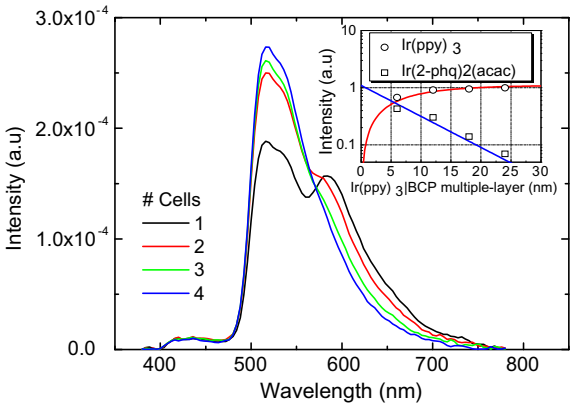

Fig. 6. The emission spectra for devices with different numbers of cells (N). The inset shows the normalized peak intensity of $Ir(ppy)_3$ and $Ir(2\text{-phq})_2(acac)$ as a function of the thickness of $Ir(ppy)_3$/BCP multiple-layer.

5. Conclusion

In conclusion, we have shown that there is an optimum intermolecular spacing that gives the largest L_D. This is because the exciton in organic semiconductor experiences two competing processes (Förster and long-range quenching processes). We found a good fit between theoretical and experimental data. This result will have tremendous impact to the development of OLED and OPV devices which rely heavily on exciton diffusion. Similar mechanisms are expected for other organic semiconductor and for singlets, though experimental verification is needed.

[18] To minimize the direct exciton energy transfer from NPB to Ir(ppy)3 to Ir(2-phq)2(acac) through Förster transfer (without diffusion), the first Ir(ppy)3 layer was deposited 7 nm away from NPB/BCP interface. Furthermore, the Ir(2-phq)2(acac) is deposited 7 nm from the final Ir(ppy)3 layer (structure B). This guarantees the contribution of direct exciton energy transfer from NPB to the first Ir(ppy)3 layer to Ir(2-phq)2(acac) to be close to zero, $\left[1+(7\text{ nm}/R_{F2D(\text{NPB}-\text{Ir(ppy)}_3)})^4\right]^{-1}\times[1+(19\text{ nm}/R_{F2D(\text{Ir(ppy)}-\text{Ir}(2-\text{phq}))})^4]^{-1}\sim 0.008$. A direct energy transfers from NPB to the Ir(2-phq)2(acac) sensing layer is also unlikely since they are separated by 26 nm.

ABSTRACT

A new X-shaped solution-processible oligomer with a glass transition temperature of higher than 200 °C based on an anthracene derivative was prepared, and it showed good hole-transporting ability in organic light-emitting diodes (OLED). Such oligomer was also employed as the emitting layer to give the devices showing blue emission.

1. Introduction

In the recent years, there has been an increasing interest in the synthesis and characterization of the π-conjugated molecules with topologically special structure such as cruciform or X-shaped [1–12]. Those molecules show highly electrochemical and photoluminescent activities, and easily form amorphous glass in the solid state. Moreover, some of them display sensitivity to proton and metals [2,3]. Such interesting properties of the molecules are desired for the application in optoelectronic field as the materials in non-linear optical device [4,5], light-emitting diodes [7,11], organic field-effect transistors [12] and chemical sensors [2,3].

Compared with the linear conjugated molecules, the conjugated cruciform compounds show spatially separated energy levels of HOMO and LUMO, and each branch of the molecules possess independent properties, which are suitable for the applications of chemical sensors [2]. It is more important the π-aggregation is depressed in the conjugated cruciform molecules due to the special 3D structure of the molecules [13], and such properties probably are useful for fabrication of the optoelectronic devices with excellent properties. Undoubtedly, investigation on the relationship between the chemical structure of the cruciform compounds and properties of the molecules is very necessary.

doi:10.1016/j.orgel.2009.09.030

It is noted that there are few building models for the cruciform compounds. E.g., the reported cruciform molecules are mainly formed by the models that each branch of the molecules is extended from a benzene (or a thiophene) ring [14,15]. Thus, exploring and developing new building models of the π-conjugated molecules with cruciform structure are desired.

To build a new structure of the cruciform compounds, a better choice is employing anthracene as a starting unit because an anthracene unit possesses four active positions, e.g., 2,6- and 9,10-positions, in which the covalent bonds are easily formed. When an anthracene unit contains π-conjugated substituted groups both at 2,6- and 9,10-positions, those molecules are topologically cross-shaped (or X-shaped). On the other hand, anthracene-based derivatives have been widely used as organic optoelectronic materials owing to their high fluorescence quantum yields [16], implying that studying the derivatives with new structure is helpful to find new kind of the anthracene-based materials. Hence, we designed and synthesized a new anthracene-based oligomer **8**, whose structure is shown in Scheme 1. Such oligomer shows good hole-transporting ability in organic light-emitting diodes. Moreover, employing the oligomer as the emitting layer gives the devices showing blue emission. Herein, we report the details.

2. Experimental

2.1. Materials

2,7-Dibromo-9,9-diethyl-fluorene (**1**) [17a], 2,6-dibromoanthraquinone (**4**) [17b], pinacol(4-(*N*,*N*-diphenylamino)l-phenyl)boronate (**6**) [17c] were prepared as previously reported. $[Bu_4N]ClO_4$ (Bu = butyl) was an industrial product and purified by recrystallized three times from a mixture of ethyl acetate and cyclohexane and dried over P_2O_5 under vacuum at room temperature for three days. All solvents were dehydrated and distilled under an inert atmosphere before use.

2.2. Instrumentation

Elemental analysis was taken with a Carlo Erba 1106 elemental analyzer. ^{1}H NMR spectra were carried out on a Bruker DRX 300 spectrometer and ^{13}C NMR spectra were carried out on a Bruker DRX 400 spectrometer. UV–Vis absorption and photoluminescence spectra were measured with a Hitachi U-2910 spectrophotometer and a Hitachi F-4500 fluorescence spectrophotometer, respectively. Cyclic voltammetry (CV) for the cast films were measured in an acetonitrile solution of $[Bu_4N]ClO_4$ (0.10 M, Bu = butyl) at a scan rate of 100 mV/s under argon using (0.10 M $AgNO_3$)/Ag and platinum wire as reference and counter electrodes, respectively. A CHI 600B analyzer was used for the measurements. DSC was determined with TA Instrument DSC Q200 at a heating and cooling rate of 10 °C min^{-1} under nitrogen flow.

2.3. LED device fabrication

On a cleaning ITO glass, a layer PEDOT-PSS (50 nm, Bayer AG) was applied. A layer of **11** (10 mg/mL in $CHCl_3$ for the application of hole-transporting layer, 20 mg/mL in $CHCl_3$ for the application of light-emitting layer) was then spin-coated on the substrate. After dried 2 h in a glove box at 60 °C, Alq_3 (30 nm), LiF, Ca (120 nm) and Al (100 nm) were deposited on the compound film by thermal evaporation, respectively, under a vacuum of 10^{-4} Pa. The measurements of the properties of the devices were operated at room temperature in air. The EL spectra were recorded on a photometer PR 705.

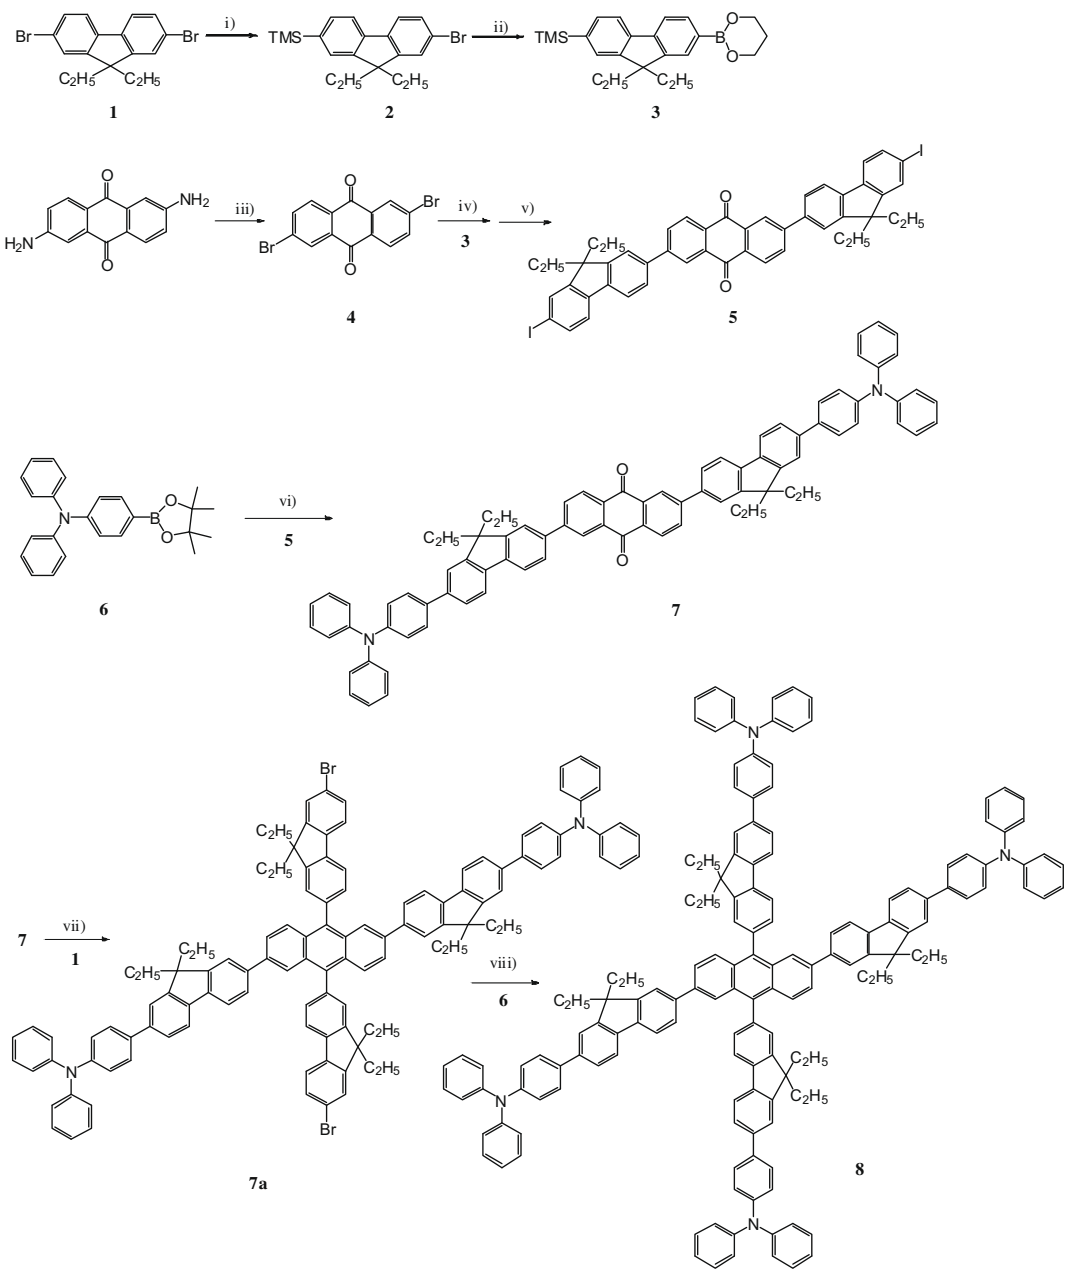
2.4. Synthesis of the compounds

2.4.1. Synthesis of (2-bromo-9,9-diethyl-9H-fluoren-7-yl)trimethylsilane (**2**)

Under an argon atmosphere, a solution of *n*-BuLi in hexane (1.6 M, 11.8 mL, 18.8 mmol) was added slowly at −78 °C to a solution of **1** in anhydrous THF. The mixture was stirred for 1 h at −78 °C before adding chlorotrimethylsilane (6.0 g, 55.3 mmol). The reactants were warmed to room temperature and stirred for 3 h, poured into water of 200 mL, and extracted with hexane. The organic layer was washed with water and dried over Na_2SO_4. **2** was obtained as a colorless oil by column chromatography on silica gel with hexane as the eluent. 6.80 g, yield of 99%. ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm): 7.68 (d, 1H), 7.69 (d, 1H), 7.52 (d, 1H), 7.46–7.49 (m, 3H), 2.04 (m, 4H), 0.33–0.38 (m, 15H).

2.4.2. Synthesis of (7-(1,3,2-dioxaborinan-2-yl)-9,9-diethyl-9H-fluoren-2-yl)trimethylsilane (**3**)

A solution of *n*-BuLi in hexane (1.6 M, 12.5 mL, 20.0 mmol) was added slowly to a solution of **2** (6.79 g, 18.2 mmol) in anhydrous THF (80 mL) at −78 °C. The mixture was stirred for 1 h at −78 °C before triisopropyl boronate (10.3 g, 54.6 mmol) was added. The reactants were warmed to room temperature, stirred for 24 h, poured into a large mount of water (200 mL), and extracted with ethyl acetate. The organic layer was washed with brine and dried over Na_2SO_4. After removal of the solvent under reduced pressure, the residue was obtained as the boric acid (6.05 g, yield of 98.4%) as white solid. To a solution of the boric acid (6.05 g, 17.9 mmol) in toluene (150 mL), 1,3-propanediol (4.15 g, 54.6 mmol) was added, and the mixture was stirred at 110 °C for 10 h. After being cooled to room temperature, the solution was washed with water, dried over Na_2SO_4, and evaporated to remove the solvent. The obtained crude product was purified by column chromatography using a mixture solvent of hexane and ethyl acetate (8:1, v/v) as the eluent to afford a white solid **3** (6.30 g, yield of 93.1%). ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm): 7.69–7.78 (m, 4H), 7.47 (m, 2H), 4.21 (t, 4H), 2.06 (m, 6H), 0.27–0.32 (m, 15H). ^{13}C NMR (100 MHz, $CDCl_3$, δ in ppm): 149.56, 149.13, 143.90, 142.11, 139.38, 132.46, 131.76, 127.91, 127.54, 119.22, 118.96, 62.02, 55.89, 32.60, 27.46, 8.59. FT-IR (KBr pellets, cm^{-1}): 2960, 2852, 1608, 1482,



Scheme 1. Synthetic procedure of the oligomer **8**. Reagents and conditions: (i) (1) *n*-BuLi, THF, −78 °C, (2) TMSCl, −78 °C to room temperature; (ii) (1) *n*-BuLi, THF, −78 °C, (2) (*i*-PrO)$_3$B, −78 °C to room temperature; (3) 1,3-propanediol, toluene, 110 °C; (iii) *t*-BuONO, $CuBr_2$, CH_3CN, 65 °C; (iv) $Pd(PPh_3)_4$, aq. K_2CO_3, toluene, 80 °C; (v) ICl, $CHCl_3$, 0 °C to room temperature; (vi) $Pd(PPh_3)_4$, aq. 2.4.3. Synthesis of 2,6-dibromoanthraquinone (*4*)

2,6-Diaminoanthraquinone (2.9 g, 12 mmol) was added to a solution of t-BuONO (3.62 mL, 2.8 g, 27 mmol) and $CuBr_2$ (6.0 g, 27 mmol) in CH_3CN (50 mL) at 65 °C. The mixture was stirred for 3 h and then slowly poured into 20% aqueous HCl solution (200 mL). The precipice was filtered, washed with water, CH_3CN, and benzene. Finally, the more pure product was obtained by washing with benzene. (3.75 g, yield of 84%).

2.4.4. Synthesis of 2,6-bis(9,9-diethyl-7-iodo-9H-fluoren-2-yl) anthraquinone (*5*)

Under an argon atmosphere, a mixture of **4** (1.85 g, 5.07 mmol), **3** (4.31 g, 11.4 mmol), $Pd(PPh_3)_4$ (0.29 g, 0.25 mmol) and K_2CO_3 (3.22 g, 23.3 mmol) in THF

(80 mL) and distilled water (40 mL) was stirred for 48 h at 80 °C. After being cooled to room temperature, the mixture was extracted with $CHCl_3$. The organic layer was washed with water and dried over with anhydrous Na_2SO_4. After removal of the solvents, the residue was recrystallized with a mixture solvent of toluene and ethanol to yield a yellow solid, which was dissolved in anhydrous $CHCl_3$ (3.02 g in 60 mL), and to the obtained solution was added a mixture of ICl in methylene chloride solution (1.0 M, 8.4 mL, 8.4 mmol) under an argon atmosphere at 0 °C. After warmed to room temperature, the reactants were stirred for 4 h, then poured into aqueous $NaHSO_3$ (5% w/w, 200 mL). The mixture was extracted with $CHCl_3$ and the organic layer was washed with water before being dried over with Na_2SO_4. After evaporated to remove the solvent, the residue was purified by recrystallization with toluene to give **5** as a crude product with a yield of 69%. ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm): 8.64 (s, 2H), 8.45 (d, 2H), 8.12 (d, 2H), 7.83 (d, 2H), 7.69–7.77 (m, 8H), 7.53 (d, 2H), 2.11 (m, 8H), 0.37 (t, 12H). ^{13}C NMR (100 MHz, $CDCl_3$, δ in ppm): 183.11, 152.75, 150.46, 147.25, 141.95, 140.36, 138.14, 134.12, 132.36, 132.28, 132.16, 128.18, 126.61, 125.51, 121.73, 121.62, 120.45, 93.26, 56.70, 32.73, 8.56. FT-IR (KBr pellets, cm^{-1}): 2958, 1672, 1592, 1453, 1399, 1313, 969, 816, 746, 479. MS (MALDF-TOF): 900.3 (M^+).

2.4.5. Synthesis of 2,6-bis(7-(4-(diphenylamino)phenyl)-9,9-diethyl-9H-fluoren-2-yl)-anthraquinone (7)

Under an argon atmosphere, a mixture of **5** (1.88 g, 2.08 mmol), **6** (1.70 g, 4.58 mmol), $Pd(PPh_3)_4$ (0.12 g, 0.10 mmol) and K_2CO_3 (1.32 g, 9.57 mmol) in THF (50 mL) and distilled water (25 mL) was stirred for 48 h at 80 °C. After being cooled to room temperature, the mixture was extracted with $CHCl_3$. The organic layer was washed with water and dried over anhydrous Na_2SO_4. After removal of the solvents, the residue was purified by column chromatography on silica gel using a mixture solvent of petroleum ether and CH_2Cl_2 (1:1, v/v) as the eluent to obtain **7** as an orange powder (1.98 g, yield of 83.8%). ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm): 8.67 (d, 2H), 7.46 (d, 2H), 8.14 (d, 2H), 7.23–7.88 (m, 8H), 7.27–7.32 (m, 8H), 7.17 (m, 12H), 7.05 (m, 4H), 2.16 (m, 8H), 0.42 (t, 12H). ^{13}C NMR (100 MHz, $CDCl_3$, δ in ppm): 138.41, 151.50, 151.31, 147.91, 147.68, 147.45, 142.55, 140.41, 139.79, 137.82, 135.62, 134.37, 132.51, 132.29, 129.53, 128.39, 128.06, 126.74, 125.89, 125.67, 124.62, 124.27, 123.19, 121.68, 121.31, 120.60, 120.50, 56.74, 33.14, 8.91. FT-IR (KBr pellets, cm^{-1}): 3032, 2962, 2874, 1673, 1591, 1514, 1492, 1464, 1377, 1310, 1281, 817, 747, 695, 497. MS (MALDF-TOF): 1136.0 (M^+). Elemental analysis: Calcd for $C_{84}H_{68}N_2O_2$: C, 88.86; H, 5.86; N, 2.47. Found: C, 88.77; H, 6.00; N, 2.13.

2.4.6. Synthesis of 2,6,9,10-tetra(7-(4-(diphenylamino)phenyl)-9,9-diethyl-9H-fluoren-2-yl)-anthracene (8)

A solution of *n*-BuLi (1.6 M, 1.38 mL, 2.21 mmol) in hexane was added slowly to a solution of **1** (839 mg, 2.21 mmol) in anhydrous THF (30 mL) at −78 °C, and the mixture was stirred for 1 h at the same temperature. Then a solution of **7** (627 mg, 0.55 mmol) in anhydrous THF was added to the mixture. The reactants were allowed to slowly warm to room temperature, stirred for 24 h and poured to water of 200 mL. The mixture was extracted with ethyl acetate, and the obtained organic layer was washed with brine and dried over Na_2SO_4. Column chromatography on silica gel with hexane:$CHCl_3$:ethyl acetate (30:10:4) as the eluent afford an intermediate (901 mg, yield of 93.8%) as an orange glass. ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm):7.86 (s, 2H), 7.41–7.72 (m, 32H), 7.25–7.30 (m, 8H), 7.16 (m, 12H), 7.04 (m, 4H), 3.36 (s, 2H), 1.96–2.11 (m, 16H), 0.27–0.41 (m, 24H). ^{13}C NMR (100 MHz, $CDCl_3$, δ in ppm): 152.76, 151.03, 149.60, 147.92, 147.32, 145.96, 142.06, 141.77, 141.10, 140.44, 140.05, 139.88, 139.81, 139.19, 135.75, 130.33, 129.51, 129.33, 128.03, 127.30, 126.50, 126.21, 125.83, 124.57, 124.31, 123.13, 121.75, 121.42, 121.35, 121.28, 121.21, 120.35, 120.08, 119.55, 76.94, 56.85, 56.44, 32.97, 8.88, 8.65. FT-IR (KBr pellets, cm^{-1}): 3543, 3033, 2963, 2920, 2875, 2852, 1592, 1514, 1493, 1464, 1377, 1313, 1279, 1006, 908, 815, 753, 734, 697. MS (MALDF-TOF): 1738.3 (M^+).

Under an argon atmosphere, the above mentioned intermediate (901 mg, 0.52 mmol), was added to a mixture of potassium iodide (861 mg, 5.2 mmol) and sodium hypophosphite hydrate (1.10 g, 10.4 mmol) in acetic acid (50 mL), and the mixture was stirred for 19 h at 120 °C. After being cooling to room temperature, the mixture was filtered and washed with water. The residue was purified by column chromatography on silica gel using a mixture of petroleum ether and $CHCl_3$ (2:1, v/v) as the eluent to give **7a** as a green–yellow powder, 658 mg, yield of 74.5%. ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm): 8.06 (s, 2H), 7.98 (d, 2H), 7.90 (d, 2H), 7.64–7.79 (m, 8H), 7.50–7.59 (m, 20H), 7.25–7.31 (m, 8H), 7.13–7.17 (m, 12H), 7.04 (m, 4H), 1.97–2.14 (m, 16H), 0.53 (m, 12H), 0.28–0.38 (m, 12H). ^{13}C NMR (100 MHz, $CDCl_3$, δ in ppm): 152.42, 150.87, 150.81, 149.78, 147.67, 147.05, 139.83, 139.54, 138.53, 137.57, 135.51, 130.40, 130.22, 129.60, 129.24, 127.74, 127.57, 126.33, 125.57, 125.45, 124.31, 124.05, 122.86, 121.48, 121.37, 121.17, 120.96, 119.96, 119.89, 56.72, 56.14, 32.82, 32.69, 8.70, 8.58. FT-IR (KBr pellets, cm^{-1}): 2962, 2918, 2974, 2851, 1592, 1541, 1493, 1455, 1377, 1313, 1278, 883, 812,752, 754, 696. MS (MALDF-TOF): 1702.8 ($(M-1)^+$). Elemental analysis: Calcd for $C_{118}H_{98}Br_2N_2$: C, 83.18; H, 5.80; N, 1.64; Br, 9.38. Found: C, 82.93; H, 6.10; N, 1.61; Br, 9.32.

The obtained green–yellow powder (200 mg, 0.12 mmol), mentioned above was added to a mixture of **6** (96 mg, 0.26 mmol), $Pd(PPh_3)_4$ (14 mg, 0.012 mmol) and K_2CO_3 (250 mg, 1.81 mmol) in THF (40 mL) containing distilled water (15 mL). The reactants were stirred for 48 h at 80 °C. After being cooled to room temperature, the mixture was extracted with $CHCl_3$. The organic layer was washed with water and dried over with anhydrous Na_2SO_4. After removal of the solvent, the residue was purified by column chromatography on silica gel using a mixture solvent of petroleum ether and CH_2Cl_2 (3:2, v/v) as the eluent to give **8** as a yellow–green powder, 190 mg, yield of 79.5%. ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm): 8.12 (s, 2H), 8.02 (d, 2H), 7.94 (m, 4H), 7.78 (d, 2H), 7.61–7.71(m, 14H), 7.49–7.58 (m, 14H), 7.23–7.33 (m, 18H), 7.12–7.22 (m, 22H), 7.05 (m, 8H), 2.17 (m, 8H), 1.99

(m, 8H), 0.54–0.60 (m, 12H), 0.28–0.38 (m, 12H). ^{13}C NMR (100 MHz, $CDCl_3$, δ in ppm): 150.91, 150.82, 150.33, 147.72, 147.68, 147.13, 147.03, 140.87, 140.62, 140.36, 139.92, 139.75, 139.65, 139.53, 137.81, 137.68, 135.62, 135.84, 130.51, 130.25, 129.71, 129.29, 127.84, 127.75, 126.18, 126.05, 125.74, 125.56, 125.36, 124.53, 124.34, 124.17, 124.08, 122.90, 122.86, 121.51, 121.05, 120.97, 120.10, 119.52, 119.91, 119.77, 56.48, 56.16, 33.12, 33.01, 8.84, 8.58. FT-IR (KBr pellets, cm^{-1}): 3036, 2961, 2917, 2873, 2851, 1592, 1513, 1492, 1467, 1376, 1313, 1279, 1177, 883, 813, 752, 695. MS (MALDF-TOF): 2033.0 (M^+). Elemental analysis: Calcd for $C_{154}H_{126}N_4$: C, 91.00; H, 6.25; N, 2.76. Found: C, 90.52; H, 6.56; N, 2.30.

3. Results and discussion

3.1. Synthesis

Oligomer **8** was built from 2,6-dibromoanthraquinone, fluorene boric ester and triphenylamine boric ester, and the synthesis procedure is shown in Scheme 1, and the detailed preparation and characterization of the oligomer are listed in experimental section. **8** was an amorphous powder and can easily form a film on a glass plate by using a spin-coating method, suggesting that the oligomer possesses good solution-processability, which is desire for the fabrication of the optoelectronic devices.

3.2. Thermal stability and optical properties

Thermal properties of **8** were characterized by differential scanning calorimetry (DSC), and the result is shown in Fig. 1. As can be seen from Fig. 1, **8** shows a glass transition temperature, T_g, of 223 °C, which is higher than those of most of the well-known small molecule materials used in optoelectronic fields [18], and even higher than those of some polymeric materials [19], indicating that the oligomer possesses high thin film morphological stability. Moreover, no obvious crystallization peak was observed during a scanning from 50 to 300 °C, demonstrating that **8** has a limited tendency to crystallize.

The basic photophysical properties of **8** were characterized by UV–Vis and photoluminescent (PL) spectra. The

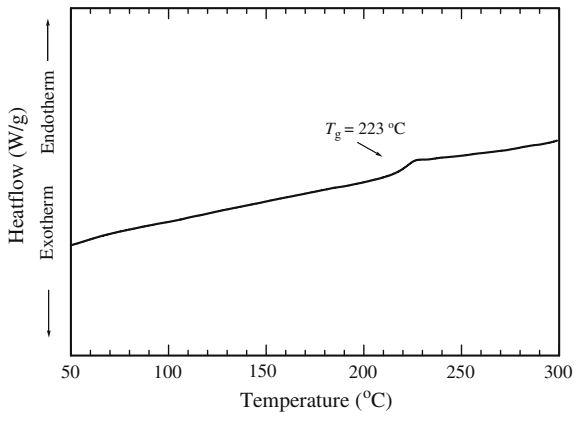

Fig. 1. DSC trace of **8**.

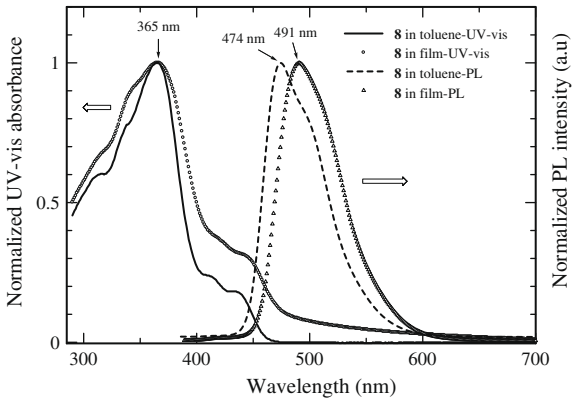

Fig. 2. UV–Vis and PL spectra of **8** in toluene and in the solid state.

spectra are displayed in Fig. 2. The oligomer exhibits a maximum absorption peak at 365 nm in both toluene and in the solid state, whereas the onset position of its absorption band in the solid state has a red-shift, suggesting the existence of part π-stacking structure in the oligomer. It is noted that a compound composed of a fluorene unit and two triphenylamine units showed an absorption peak at about 370 nm [20], thus, the maximum absorption peak at 365 nm in Fig. 2 is attributed to the electronic transition (π–π*) along the backbone of a fluorene unit linked with a triphenylamine group. The weak absorption peaks at 400–450 nm are also observed in Fig. 2, which are probably derived from the anthracene unit in **8**, the similar absorption peaks were found in our previous work concerning a polymer containing anthracene unit as side chain [21].

The photoluminescent (PL) spectrum of **8** in toluene shows a main peak at 474 nm with a quantum yield of 62% (estimated with a 0.5 M H_2SO_4 solution of quinine as a reference), similar to the PL spectra of poly(9,9-alkylfluorene-alt-triphenylamine) [22]. In the solid state, **8** gives a maximum emission peak at 491 nm with an absolute PL quantum yield of 24%, measured by using a calibrated integrating sphere. Here, the main emission peak of **8** has a red-shift of 17 nm relative to that in the solution, indicating the existence of the interaction between the molecules in the solid state, similar phenomena were also observed in poly(9,9-alkylfluorene-alt-triphenylamine) [23] and the fluorene–anthracene compounds [24].

3.3. Electrochemical properties

The electrochemical behavior of **8** was measured by cyclic voltammetry (CV) of its cast film on a Pt plate, and the result is shown in Fig. 3. The electrochemical oxidation (or p-doping) of **8** starts at about 0.60 V versus Ag^+/Ag, and gives a p-doping peak at 1.02 V. The corresponding reduction peak appears at 0.18 V. According to the relationship between the oxidation onset potential (E_{ox}^{onset}) and HOMO level value as $-(E_{ox}^{onset} + 4.4)$ [24], the HOMO energy level of **8** is estimated as $-(0.60 + 4.4) = -5.00$ eV. Relative to the triphenylamine derivatives with HOMO value of about 5.7 eV, that of **8** is close to the work function of ITO glass (4.5–4.8 eV) [25]. This result implies that **8** is very suitable for OLEDs as a hole-transport layer (HTL). Consequently,

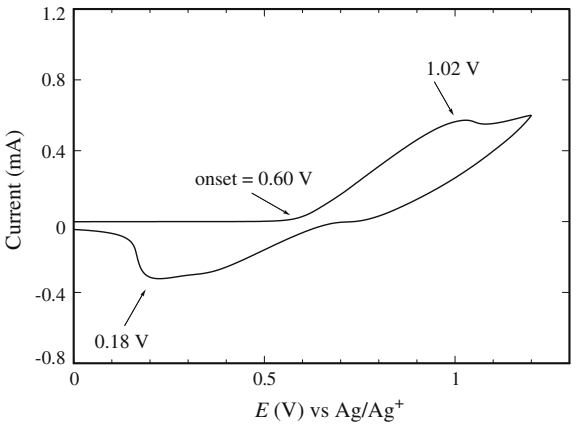

Fig. 3. CV curve of a cast film of **8** on a Pt electrode (wire) with a sweep rate of 100 mV s^{-1} in an acetonitrile solution of 0.10 M $[Bu_4N]ClO_4$. The applied potential is 0.0–1.5 V.

the LUMO value of **8** is calculated by subtraction of the optical bandgap E^{opt} (eV) from the HOMO value, given as −2.41 eV.

3.4. Electroluminescence properties

To evaluate the performance of **8** as a HTL in OLEDs, three non-optimized OLED devices were fabricated with

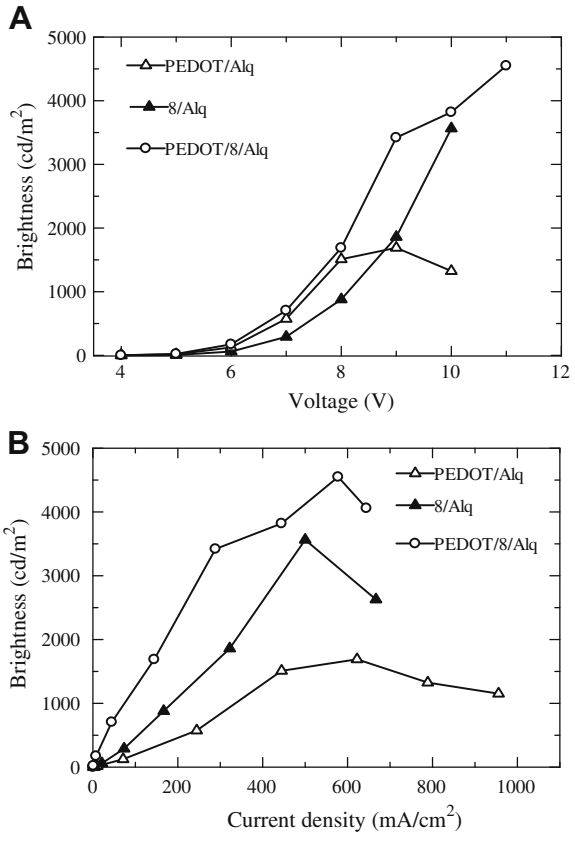

Fig. 4. *B–V* (A) and *B–I* curves (B) of the three devices.

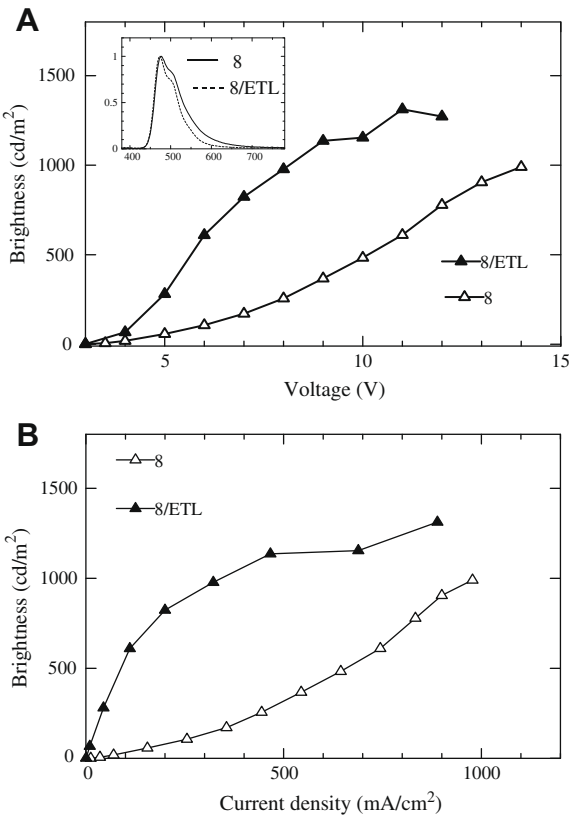

Fig. 5. *B–V* (A) and *B–I* curves (B) of a device based on **8.**

the following configuration: (1) ITO/PEDOT:PSS/Alq/LiF/Ca/Al (device PEDOT/Alq); (2) ITO/**8**/Alq/LiF/Ca/Al (device 8/Alq) and (3) ITO/PEDOT:PSS/**8**/Alq/LiF/Ca/Al (device PEDOT/8/Alq). Here, PEDOT-PSS was employed as a hole-injection material that had been widely used in OLEDs. Moreover, a commercially available electron transport material, Alq, was used as both electron transport layer and emitting layer. All devices showed green emission derived from Alq, illuminating that the holes from the anode (ITO) and the electrons from the cathode (Ca/Al) combine in the Alq layer. The *B–V* (brightness versus operation voltage) and *B–I* (brightness versus current density) characteristics of the devices shows in Fig. 4. As can be seen form Fig. 4, device 8/Alq shows a maximum brightness of about 3600 cd/m^2 at 10 V, which is much higher than that of the device PEDOT/Alq only with PEDOT as a hole-injection layer, suggesting that oligomer **8** shows good hole-transport ability. Interestingly, when **8** was used together with PEDOT-PSS, the device (PEDOT/8/Alq) shows higher brightness and luminous efficiency. Its maximum brightness was 4549 cd/m^2 at 11 V and the maximum current efficiency reached 2.32 cd/A. Moreover, the maximum external quantum efficiencies (Max EQE) of the devices showed an order of PEDOT/Alq (0.11%) < 8/Alq (0.26%) < PEDOT/8/Alq (0.57%). Those results indicate that a combination of **8** and a commercial PEDOT-PSS may obtain a better performance in OLEDs, and that oligomer **8** could be used as a new component in OLEDs.

The high absolute PL quantum yield of **8** inspired us to investigate its application in OLED as a light-emitting layer. A device was fabricated with the configuration of ITO/PEDOT:PSS/**8**/LiF/Ca/Al (device 8). The *B–V* curve and efficiency of the device are shown in Fig. 5. As shown in Fig. 5, device 8 shows light-blue emission with a maximum emission peak of 478 nm, which has a slight blue-shift relative to that of its PL emission in the solid state. Device 8 exhibits a low turn-on voltage of 3.5 V, whereas its efficiency is very low (maximum current efficiency = 0.1 cd/A, and Max EQE = 0.043%). This may be due to the unbalance between the hole-transport and the electron transport in the device, derived from the strong hole-transporting ability of **8**. Considering the good electron transport of a bitriazine derivative developed by our group [26], we designed a new configuration of the device using the bitriazine derivative as electron transport layer (ETL) to adjust the balance between the electron transport and the hole-transport in the device. The new device has a configuration of ITO/PEDOT:PSS/**8**/ETL/LiF/Ca/Al (device 8/ETL), and shows the same emission color as that of device 8 with a maximum emission peak of 474 nm (Fig. 5, the insert), but its efficiency is much higher than that of device 8 (for device 8/ETL, maximum current efficiency = 0.6 cd/A and Max EQE = 0.29%), implying that **8** also shows good emitting properties.

4. Conclusion

A new anthracene derivative containing four triphenylamine groups was prepared. Such oligomer is solution-processible with a glass transition temperature of higher than 200 °C, and it showed good hole-transporting ability in organic light-emitting diodes. Such compound was also employed as the emitting layer to give the devices showing blue emission.

ABSTRACT

This paper describes the fabrication of top-gate P3HT organic field effect transistors (OFETs) incorporating polymer/TiO_2 nanocomposite bilayer dielectrics. The TiO_2 nanocomposite comprised PVP, the cross-linking agent PMF, and TiO_2 nanoparticles (NPs), which possessed rod-like anatase structures and were solution-processable using polar solvents; thus, the composite dielectric solutions were easy to be prepared for the use in top-gate OFET devices without damaging and dissolution of the underlying P3HT film. SEM and AFM images revealed the high uniformity of the nanocomposite films. To determine the effects of the composite dielectrics with/without TiO_2 on the performance of the OFET devices, we inserted a buffer layer of PMMA between the semiconductor layer and the gate dielectric to maintain a constant semiconductor–dielectric interface. The device incorporating the PMMA/TiO_2 nanocomposite bilayer gate dielectric operated effectively at supply voltages within 20 V, with a good mobility (μ) of 1.5×10^{-2} $cm^2 V^{-1} s^{-1}$, which was three times greater than that of the devices featuring the PMMA/PVP/PMF dielectric; the on/off ratio of nanocomposite device (8.6×10^6) was significantly better than that of the PVP/PMF device (1.5×10^5). The PMMA/TiO_2 nanocomposite was also performed acceptably at supply voltages of less than 10 V. The performance of the OFET incorporating a single dielectric layer of the TiO_2 nanocomposite ($\mu = 0.001$ $cm^2 V^{-1} s^{-1}$; on/off ratio = 5.7×10^2) was inferior to those of the bilayer gate dielectric devices.

1. Introduction

During the past decade, organic field effect transistors (OFETs) have attracted a great deal of interest because of their potential use in such applications as radio frequency identification tags, flexible displays, and smart cards [1–4]. Although traditional OFETs must be operated at high voltage (usually exceeding 40 V) to output a high current, typical low-end applications would require very low available operating voltages. Recently, low-voltage OFETs have been reported that incorporate ultrathin high-capacitance gate dielectrics, such as self-assembled monolayers (SAMs) [5–8] and thin polymers [9–12], high-dielectric-constant (high-k) inorganic metal-oxide gate dielectrics [13–17], or polymer electrolyte dielectrics [18–20]. For example, Halik et al. [5] reported pentacene-based FETs employing SAMs as ultrathin gate dielectrics that operated at 2 V with a field effect mobility of 1 $cm^2 V^{-1} s^{-1}$. Although this approach shows great promise, the ability to integrate it into a large-volume coating process remains questionable. Ultrathin polymer dielectrics have the advantage that they could be applied through solution processing, but this technique remains problematic because of the generation of pinholes during the deposition process [10]. The films of high-k metal oxides, such as Al_2O_3, Ta_2O_5, and TiO_2,

are usually deposited using sputtering or high-temperature sintering processing, which are not compatible with low-cost, large-area plastic electronics. The combination of polymers and metal oxides is a relatively new development for the preparation of solution-processed high-*k* nanocomposite gate dielectrics for low-voltage OFETs [21–24]. The reported OFETs incorporating metal-oxide nanocomposite gate dielectrics have mostly been based, however, on thermally evaporated pentacene as the semiconductor layer and mostly based on bottom-gate OFET geometries. Little has been known about top-gate devices which were fabricated using solution-processed semiconductors and featuring metal-oxide nanocomposite gate dielectrics [24].

Top-gate OFET structures have many advantages over bottom-gate devices. For example, the gate dielectric and top-gate metal could also be used as the passivation layers to protect the devices from degradation by outdoor moisture, oxygen, and UV or visible light. In addition, the gate lines can be prepared conveniently and the channel length can be defined as small as is allowable photolithographically. Although top-gate architectures have great potential for use in the fabrication of low-cost, large-area OFETs on flexible substrates, their assembly remains very challenging because it requires successive multilayer depositions (semiconductor, gate dielectric, gate electrode) in which great care must be taken when selecting the materials and their processing solvents.

For the fabrication of top-gate OFETs, the first requirement is that the semiconductor layer remains intact during deposition of the overlying dielectric layers. Among the top-gate P3HT OFETs reported to date, the solvents that have been used to process the polymer gate dielectrics have been 2-butanone [25], ethyl acetate [26,27], *n*-butanol [27], and *N*-methylpyrrolidinone (NMP) [27], which are all polar solvents. Therefore, if we are to develop solution-processable polymer/metal-oxide nanocomposites from these solvents, the metal-oxides must be not only dispersible in polar solvents but also compatible with the selected polymers to prevent phase separation during the film formation process.

In previous studies, we demonstrated the blending of poly(vinyl phenol) (PVP) and poly(melamine-*co*-formaldehyde) (PMF) as the gate dielectrics for bottom-gate devices [28]. The transistors showed good performances, however, operated at high voltage (−40 V). We also demonstrated solution-processed oleic acid-capped TiO_2 (OA-TiO_2) dielectrics for low-voltage-driven bottom-gate devices [29]. We found, however, that the OA-TiO_2 was dispersible only in nonpolar solvents, such as toluene and xylene, which are good solvents for dissolving semiconductors; thus, the OA-TiO_2 can not be applied directly onto the semiconductor as the top-gate dielectrics nor homogeneously blended with the polar PVP polymer. In this present study, we modified the OA-TiO_2 nanoparticles (NPs) from hydrophobic to hydrophilic to improve both their solubility in polar solvents and their compatibility with the PVP polymer matrix. We then investigated the blending of the modified OA-TiO_2 NPs with polymers and studied their applicability as dielectrics in top-gate OFETs.

2. Experiments

2.1. Materials

Poly(vinyl phenol) (PVP) (M_w = 20,000), the cross-linking agent poly(melamine-*co*-formaldehyde) (PMF) (M_w = 511), poly(methyl methacrylate) (PMMA) (M_w = 540,000) and diethyl (2-cyanoethyl) phosphonate ($NC(CH_2)_2PO_2(OEt)_2$, DCP) were obtained from Sigma–Aldrich. Chlorobenzene, *n*-butanol, ethyl acetate, and acetone were also purchased from Sigma–Aldrich and used without further purification. The hydrophobic OA-TiO_2 NPs were obtained through the hydrolysis of titanium tetraisopropoxide using the literature procedure [30]. The hydrophilic TiO_2 NPs (DCP-TiO_2) were synthesized by heating a mixture of OA-TiO_2 (0.2 g) and DCP (0.1 g) in chlorobenzene (2 mL) at 100 °C for 24 h and then evaporating the solvent under vacuum. Regioregular P3HT was purchased from Aldrich and purified through Soxhlet extractions with hexane and CH_2Cl_2 to remove low-molecular-weight chains.

2.2. Film fabrication and characterization

For the PVP dielectric, the weight percentage ratio of PVP and the cross-linking agent PMF in formulations (blends) was 8:4 in hexanol; for the TiO_2 nanocomposite, the weight percentage ratio of PVP, PMF, and DCP-TiO_2 was 8:4:12. Both formulations were spin-coated and the resulting films were then hardened through baking at 180 °C for 30 min. The thicknesses of the corresponding PVP films were determined using cross-sectional SEM. The morphologies of the TiO_2 nanocomposite films were evaluated using AFM (Nanoscope IIIa, Digital Instruments). The rms surface roughnesses were determined over an area of 9 μm^2. Absorption spectra of the corresponding films were measured using a Perkin–Elmer Lambda 950 UV–vis spectrometer. The phase of the crystalline TiO_2 NPs was analysed by powder X-ray diffraction (XRD: Philips Xpert XRD system), with Cu Kα radiation at a scanning speed of 10 min^{-1}. The dispersion characteristics of the TiO_2 NPs in organic media were evaluated by dynamic light scattering analyzer (DLS: Malvem Zetasizer Nano).TGA was performed using a Perkin–Elmer TGA 7.

2.3. Device fabrication and electrical measurements

A silicon wafer presenting thermally grown SiO_2 (d = 120 nm) was used as the substrate. The source and drain electrodes (Pt) having channel widths and lengths of 500 and 10 μm, respectively, were prepared using a photolithography/Pt (20 nm) deposition/lift-off (acetone) process. After spin-coating of P3HT as the semiconductor, the PMMA (1 wt.% in ethyl acetate) and the PVP or TiO_2 nanocomposite was then spin-coated onto the P3HT layer as a gate dielectric layer. Gold gate electrodes were deposited and patterned using the same methods used to prepare the source and drain electrodes. To characterize the leakage currents and capacitances of the PVP and TiO_2 nanocomposite films, metal–insulator–metal (MIM) capacitor structures were prepared by sandwiching the insulator

materials between the ITO and the Au electrode (dot area = 0.000415 cm^2). The capacitances were measured using a Keithley 590 CV capacitance analyzer operated at 100 kHz. All *I–V* measurements for our OFET and MIM devices were taken at room temperature under ambient conditions using an Agilent 4156C semiconductor parameter analyzer.

3. Results and discussion

This study began with the synthesis of TiO_2 NPs. The resulting OA-TiO_2 NPs have been reported to possess the anatase phase; our NPs were cylindrical in shape (20 nm long and 4 nm wide, as measured using transmission electron microscopy (TEM), Fig. 1a). The OA-TiO_2 film was solution-processable from toluene or chlorobenzene. We used scanning electron microscopy (SEM) imaging of the fracture edge to examine the uniformity of the OA-TiO_2 film. Fig. 1b reveals that the OA-TiO_2 layer exhibited good uniformity with a homogeneous NP dispersion. To synthesize hydrophilic TiO_2 NPs, we performed a surface modification of the OA-TiO_2 NPs by heating them in the presence of DCP in chlorobenzene at 100 °C for 24 h. The product DCP-TiO_2 NPs, which could be redispersed in polar solvents, such as isopropyl alcohol (IPA) and *n*-butanol, formed films that also exhibited good uniformity (Fig. 1c). Thus, we suspected that the DCP-TiO_2 NPs would be a good candidate material for use as a metal-oxide for mixing with a polymer matrix to form homogeneous nanocomposites that could be processed using polar solvents.

Because it is difficult to observe the modification layer on the surface of the TiO_2 NPs directly from TEM micrographs, we monitored the formation of the modification layer (DCP and OA) on the surface of the TiO_2 NPs using thermo gravimetric analysis (TGA). Fig. 2 presents typical TGA heating curves of the OA-TiO_2 and DCP-TiO_2 NPs. The mass profile reveals a major weight loss between 150 and 600 °C that is due to evaporation of the modification layer of the TiO_2. For OA-TiO_2 NPs, the TGA curve displays a ca. 43% weight loss (oleic acid), indicating a residue of ca. 57 wt.% inorganic TiO_2. For the DCP-TiO_2 NPs, the coverage of the NPs was ca. 54 wt.% (oleic acid and DCP), i.e., the inorganic TiO_2 residue was ca. 46 wt.%.

Fig. 3 displays the X-ray diffraction (XRD) patterns of the synthesized OA-TiO_2 and DCP- TiO_2 NPs. Both sets of

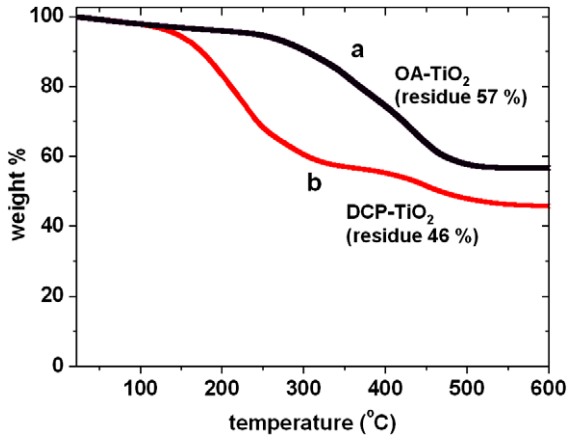

Fig. 2. Heating curves of OA-TiO_2 (curve a) and DCP-TiO_2 (curve b) nanoparticles.

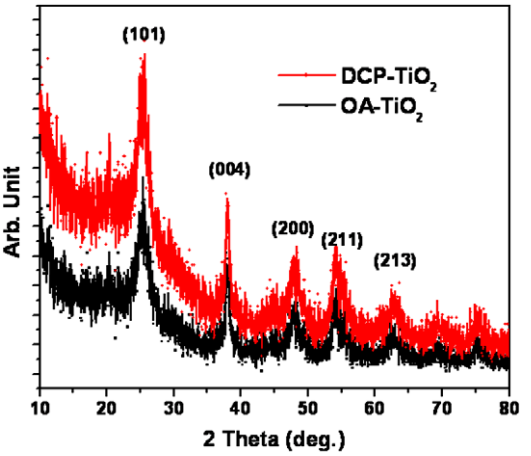

Fig. 3. XRD powder pattern of the OA-TiO_2 and DCP-TiO_2 nanorods.

reflections can be indexed to anatase; the (1 0 1), (0 0 4), (2 0 0), (2 1 1), and (2 1 3) planes provided the strongest reflections, indicating that the crystallinity of the TiO_2 was not changed after performing the surface ligand modification. The characteristic line broadening of diffraction peaks was consistent with the nanosized crystalline do-

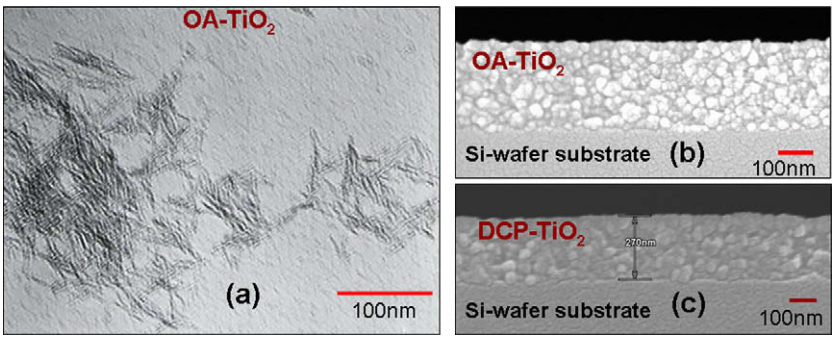

Fig. 1. (a) TEM image of the OA-TiO_2 nanorods, (b) cross-sectional SEM image of the OA-TiO_2 layer, (c) cross-sectional SEM image of DCP-TiO_2 layer. All scale bars are 100 nm.

mains and the sharp peak and narrow width of the signal for the (0 0 4) plane implied the formation of nanorods that grew anisotropically. These results are consistent with the TEM analysis.

Fig. 4 presents the particle size distributions of the DCP-TiO_2 NPs and OA-TiO_2 NPs that we measured using a dynamic light scattering (DLS) analyzer. The average particle size of the OA-TiO_2 NPs was ca. 35 nm in chlorobenzene, indicating that they were well dispersed in the organic medium (curve c). The DCP-TiO_2 NPs that we dispersed in *n*-butanol, a polar solvent, exhibited good dispersion stabilities with an average particle size of 22 nm (curve a), such that they have great potential for blending with polar polymer matrices. Interestingly, the DCP-TiO_2 NPs also displayed good dispersibility (102 nm) in chlorobenzene (curve d), although they had agglomerated to some extent relative to their dispersion in *n*-butanol. It thus implied that the DCP-TiO_2 NPs, resulting from the DCP ligands treated OA-TiO_2 NPs, still possessed small fraction of hydrophobic OA groups on their surfaces.

Among the polymer gate dielectrics reported in the literatures [7,31], the cross-linked PVP exhibits particularly good dielectric properties and high carrier mobilities of 3–5 $cm^2 V^{-1} s^{-1}$ when using pentacene as the semiconductor [32,33]. Hence, in this paper, we selected PVP as the polymer matrix for mixing with the DCP-TiO_2 NPs. For comparison, we prepared two types of gate dielectrics: a typical PVP/PMF blend gate dielectric (denoted "PVP/PMF"), which we obtained by mixing PVP (8 wt.%) with PMF (4 wt.%) in *n*-butanol, and a PVP/PMF/DCP-TiO_2 blend gate dielectric (denoted "TiO_2 nanocomposite") prepared at weight percentage ratio of 8:4:12 in *n*-butanol. We spin-coated these two dielectric films from solution and cured them at the temperature of 180 °C for 30 min. The DLS analysis in Fig. 4b reveals that the dispersibility of the TiO_2 nanocomposite was 35.2 nm in *n*-butanol, indicating that the NPs and polymers formed a uniform and homogeneous dispersion. In addition, the SEM cross-sectional image of the nanocomposite also displays a uniform NP/polymer blend (Fig. 5a); the tapping mode AFM image (Fig. 5b) exhibits the root-mean-square (rms) surface roughness of 2.29 nm, revealing the high uniformity of the PVP/PMF/DCP-TiO_2 blends, although the rms surface roughness of the neat PVP/PMF film was smaller at 0.58 nm (rms data from 3×3 μm scale). Thus, the TiO_2 nanocomposite in this study was not only soluble in polar solvents but also formed uniform films with homogeneous TiO_2 NP dispersion, all of which are desirable properties for solution-processable gate dielectrics for fabricating top-gate OFETs.

We measured the leakage currents and capacitances of the PVP/PMF and TiO_2 nanocomposite dielectrics using Au/

dielectric/ITO glass structures through capacitance–voltage (C–V) and current density–electric field (J–E) tests. Fig. 6 reveals that the PVP/PMF film exhibited a current density of 5×10^{-8} A cm^{-2} at 40 V, which is close to the value reported previously [32]. The current density of the TiO_2 nanocomposite (6×10^{-7} A cm^{-2} at 40 V) was only one order of magnitude higher than that of the low-k PVP film. The inset to Fig. 6 displays the C–V characteristics of the TiO_2 nanocomposite. From the capacitance (9.5 nF cm^{-2}) and the thickness (678 nm) of the film, we estimated the dielectric constant k to be 7.3. In contrast, the value of k of the PVP/PMF film was 4.9. Obviously, the increased value of k of the nanocomposite was due to the addition of the TiO_2 NPs in the polymer matrix of the PVP/PMF blends. Next, we deposited the TiO_2 nanocomposite and the PVP/PMF onto P3HT OFETs to study the effects of the high-k (k = 7.3) and low-k (k = 4.9) materials. We note that both the TiO_2 nanocomposite and PVP/PMF films exhibited excellent chemical resistance to the bases typically found in positive photoresist developers. Thus, we defined the region of the gate electrodes by using a photolithography/Au-deposition (50 nm)/lift-off process, rather than a traditional process of vacuum-deposition through a shadow mask.

All of the OFETs were fabricated with the top-gate geometry depicted in Fig. 7. A crystal silicon was used as a substrate. The semiconductor, P3HT, was spin-coated from a toluene solution and the resulting film was self-isolated between the source and drain electrodes (Fig. 7b) [34]. Because the performance of OFETs is influenced dramatically by the nature of the semiconductor–insulator interface [31,35], and because we expected the P3HT–high-k and P3HT–low-k dielectric interfaces to exhibited different morphologies and crystallinities, we capped the P3HT layer by spin-coating a buffer layer (d = 50–60 nm) of PMMA (k = 3.5) from ethyl acetate solution to maintain a constant semiconductor–dielectric interface and then spin-coated the two dielectrics from n-butanol solution

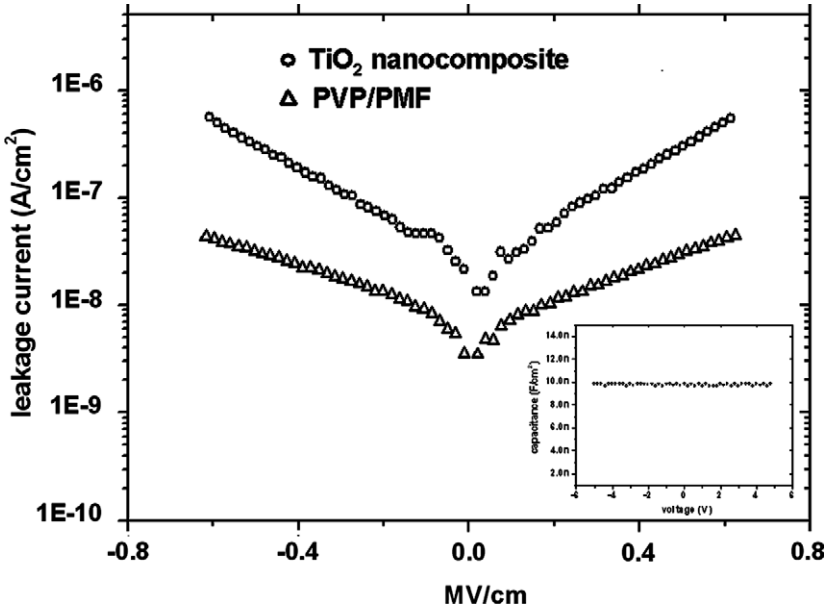

Fig. 6. Plots of current density and capacitance (inset) as a function of the applied voltage for the PVP/PMF and TiO_2 nanocomposite films.

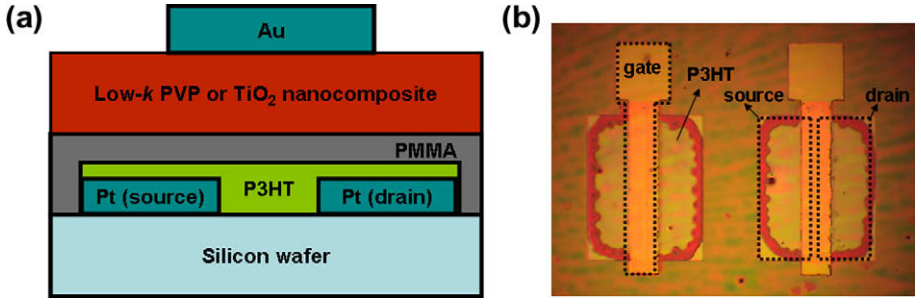

Fig. 7. (a) Device structure of the top-gate, bottom-contact configuration employed in this study. (b) Optical micrograph of stripe electrodes having a channel length of 500 μm and a width of 10 μm.

onto the resulting substrates. After deposition of the gate electrodes, we obtained two OFETs with stacked (bilayer) structures of the PMMA/TiO_2 nanocomposite and PMMA/PVP/PMF dielectrics, respectively, which allowed us to study the different effects of the high-k and low-k dielectrics. For convenience, we name the P3HT OFET incorporating the bilayer of PMMA/PVP/PMF (d = 420 nm) as "transistor 1"; the P3HT OFET featuring the PMMA/TiO_2 nanocomposite (d = 450 nm) is "transistor 2"; the P3HT OFET containing a single layer of the TiO_2 nanocomposite is "transistor 3." Using the following equation

$$1/C_{\text{total}} = 1/C_{\text{PMMA}} + 1/C_{\text{PVP}} \quad (1)$$

and the above dielectric constants k of the PVP/PMF and TiO_2 nanocomposite, we calculated the capacitances of the two bilayer dielectrics to be 8.12 and 11.1 nF cm^{-2}, respectively.

Fig. 8 displays the drain current–drain voltage curves (I_d–V_d) obtained from our P3HT OFETs incorporating the bilayer gate dielectrics. Both types of devices demonstrated desirable TFT characteristics at operating voltages of less than 20 V. To the best of our knowledge, this device is the first reported example of a top-gate P3HT OFET featuring solution-processed TiO_2 nanocomposites as gate dielectrics. From the output characteristics, the maximum saturation current of transistor 2 (PMMA/TiO_2 nanocomposite; 1.4 μA) under a gate bias (V_g) of −20 V was significantly greater that that of transistor 1 (PMMA/PVP/PMF; ca. 0.3 μA). These results clearly demonstrate the benefits that high-k TiO_2 NPs contribute to the performance of OFETs.

We used the following equation to determine the carrier mobility (μ) and the threshold voltage (V_{th}):

$$\sqrt{I_{D,SAT}} = \sqrt{\frac{W\mu C_{ox}}{2L}}(V_G - V_{th}) \quad (2)$$

where $I_{D,SAT}$ is the saturated drain current, C_{ox} is the gate capacitance per unit area, W and L are the conducting channel width and length, respectively, V_{th} is the threshold voltage, and V_G is the gate applied voltage. We extracted the mobilities from the slopes of the linear plots of the square root of the drain current versus the gate voltage (Fig. 9).

Table 1 lists all of the electrical parameters of these OFETs. When we operated transistor 1 (C = 8.12 nF cm^{-2}) within 20 V (V_{ds} = –20 V; V_{gs} = + 20 to −20 V), the mobility in the saturation region and the threshold voltage were 0.003 cm^2 V^{-1} s^{-1} and 1.43 V, respectively. The on/off ratio was ca. 1.5 × 10^5. For transistor 2 (C = 11.1 nF cm^{-2}), the mobility and threshold voltage were 0.015 cm^2 V^{-1} s^{-1} and −1.33 V, respectively, with an on/off ratio of 8.4 × 10^6; thus, the mobility of transistor 2 was ca. five times higher than that of transistor 1. This implies that the mobility of P3HT devices in this case is dependent of the capacitances of the gate dielectrics. The enhanced mobility obtained for devices with higher capacitance (i.e. higher field-induced carrier concentration in the conducting channel) indicated that the presence of a larger number of electronic defect states in the channel effectively trapping the carriers at small carrier concentration. Similar observations have been made in previous studies [36–38]. To achieve low-operating-voltage OFETs, we tested the performance of transistors 1 and 2 within 10 V (V_{ds} = −10 V; V_{gs} = +10 to −10 V). Fig. 9b reveals that transistor 1 exhibited a mobility of 0.002 cm^2 V^{-1} s^{-1} and a threshold voltage of 2.48 V, with an on/off ratio of 1.5 × 10^4; the mobility of transistor 2 (0.006 cm^2 V^{-1} s^{-1}) was three times better than that of transistor 1, and its on/off ratio (6.5 × 10^5) was 40 times better. These results clearly demonstrate the advantages that TiO_2 NPs materials provide toward improving the performances of OFETs in terms of their mobilities and on/off ratios.

For comparison, we investigated the performance of transistor 3, the P3HT OFET incorporating a single layer of the TiO_2 nanocomposite (C = 10.8 nF cm^{-2}) as the gate dielectric. When operated within 20 V, transistor 3 exhibited an acceptable mobility of 0.0011 cm^2 V^{-1} s^{-1} and a threshold voltage of 0.41 V, but its on/off ratio (5.7 × 10^2)

Table 1
Electrical characteristics of P3HT OFETs with bilayer (PMMA/PVP/PMF and PMMA/TiO_2 nanocomposite) and single layer (high-k nanocomposite) gate dielectrics.

Sample	Gate dielectric (bilayer or single layer)	C (nF cm^{-2})	Operating conditions	μ (cm^2 V^{-1} s^{-1})	On/off ratio	V_{th} (V)
Transistor 1	PMMA/PVP/PMF	8.12	$V_{ds} = -20$ V, $V_{gs} = +20$ to -20 V	3.1×10^{-3}	1.5×10^5	1.43
Transistor 2	PMMA/TiO_2 nanocomposite	11.1		1.5×10^{-2}	8.4×10^6	−1.33
Transistor 1	PMMA/PVP/PMF	8.12	$V_{ds} = -10$ V, $V_{gs} = +10$ to -10 V	1.9×10^{-3}	1.5×10^4	2.48
Transistor 2	PMMA/TiO_2 nanocomposite	11.1		6.1×10^{-3}	6.5×10^5	3.40
Transistor 3	TiO_2 nanocomposite (d = 600 nm)	10.8	$V_{ds} = -20$ V, $V_{gs} = +20$ to -20 V	1.1×10^{-3}	5.7×10^2	0.41

was dramatically inferior to those of the devices featuring bilayer gate dielectrics because its off-current (ca. 10^{-9} A) was ca. 2–3 orders of magnitude larger than those of transistor 1 (ca. 10^{-11} A) and transistor 2 (ca. 10^{-12} A). We suspect that the high off-current of transistor 3 might be due to the poor interface morphology induced by the relatively high-k material, the introduction of impurities at the interface during the preparation of the nanocomposite sample, or the high-temperature curing process having damaged the interface [26]. Therefore, the presence of PMMA as a buffer layer between the composite dielectric and the semiconductor was of vital importance to the high performance of these low-voltage top-gate transistors. Wang et al. [14] reported bottom-gate P3HT OFETs incorporating sputtered TiO_2 and bilayer SiO_2/TiO_2 gate insulators that operated within 10 V and exhibited mobilities of 0.005 and 0.032 cm^2 V^{-1} s^{-1}, respectively. Although our transistors operated with lower mobilities, they are the first examples of top-gate P3HT OFETs to have been prepared using simple, solution-processed TiO_2 nanocomposite gate dielectrics that had been fabricated at moderate temperatures.

4. Conclusions

We have synthesized novel DCP-TiO_2 NPs that are dispersible in polar solvents. Furthermore, the surfaces of these NPs are compatible with PVP, providing homogeneous polymer/NP blends, as evidenced from SEM and AFM images. The leakage current of the TiO_2 nanocomposite was only one order of magnitude larger than that of the PVP/PMF, suggesting again the uniformity of the organic/inorganic blends. We fabricated P3HT OFETs incorporating the PMMA/PVP/PMF and the PMMA/TiO_2 nanocomposite as bilayer gate dielectrics. When operated within 20 V, the OFET featuring the TiO_2 nanocomposite exhibited a higher mobility (0.015 cm^2 V^{-1} s^{-1}) and on/off ratio (8.5×10^6) than those of the PVP/PMF device. Furthermore, when operated within 10 V, this device retained a good mobility (0.006 cm^2 V^{-1} s^{-1}) and on/off ratio (6.5×10^5). Thus, our TiO_2 nanocomposite is a promising solution-processed gate dielectric for low-voltage top-gate OFETs.

Organic semiconductor
Injection efficiency

ABSTRACT

Oxygen or air exposure to transition metal oxides (TMOs) was demonstrated to be essential in improving the hole injection (HI) efficiency at the contact formed by TMOs and small organic hole transporter. Current–voltage (*J–V*) and dark-injection space-charge-limited current (DI-SCLC) techniques were used to cross-examine the TMO/organic contacts. The hole transporter under investigation was *N,N′*-diphenyl-*N,N′*-bis(1-naphthyl)(1,1′biphenyl)-4,4′diamine (NPB). The improvement was attributed to the reduction in the energy barrier at TMO/NPB interface, which was a consequence of the work function enhancement of TMO by the oxidation of oxygen in air.

1. Introduction

Organic semiconductors have received tremendous attention for optoelectronic applications in recent decades with various advantages such as low cost processing and structural flexibility [1,2]. Owing to the low intrinsic carrier concentration in organic semiconductors, external charge injection from a contact electrode is necessary for making the semiconductors electrically conducting. As a matter of fact, efficient carrier injection at electrode/organic contact is critically important in 'turning on' organic optoelectronic devices and thus realizing devices with high efficiency [3]. For hole injection, ideally, if interface dipole is negligible, the hole injection efficiency is mainly determined by the energy barrier between the work function of anode and the highest occupied molecular orbital (HOMO) level of organic hole transporting layer (HTL) [4]. A smaller barrier should result in a better efficiency. The most efficient injection contact, i.e. an Ohmic contact, appears in the absence of an injection barrier.

Indium tin oxide (ITO) is the preferred anode for organic optoelectronic devices due to its optical transparency in visible spectrum. However, with a work function of ~4.8 eV, a finite energy barrier always exists at ITO/HTL interface as most HT materials possess high-lying HOMO levels (>5.4 eV). To date, the most commonly used method to minimize the ITO/organic barrier is to insert a hole injection layer (HIL) between ITO and HTL [3,5]. Different HI materials were realized, such as copper phthalocyanine (CuPc) [3] and polyethylene dioxythiophene polystyrene sulfonate (PEDOT:PSS) [5], but an Ohmic contact has not been achieved yet. Recently, transition metal oxides (TMOs) with high work functions have been shown to be promising candidates to facilitate hole injection and improve the performance of organic optoelectronic devices [6–10]. Popular oxides include molybdenum trioxide (MoO_3), vanadium pentoxide (V_2O_5) and tungsten trioxide (WO_3). While most reports aim at showing the improved performance of devices by TMOs, a critical factor, the

preparation condition (substrate temperature and oxygen partial pressure, etc.) of TMOs, which strongly affects the stoichiometry of TMOs and their work functions, was neglected.

In this study, we address the injection problems encountered in using TMOs as HIL. We will show that the post-treatment of TMO films (MoO_3, V_2O_5, and WO_3) at different oxygen partial pressures before HTL deposition can affect the HI efficiency into an organic HTL, *N,N′*-diphenyl-*N,N′*-bis(1-naphthyl)(1,1′biphenyl)-4,4′diamine (NPB). NPB is a widely used amorphous HT material in OLEDs [11]. It has excellent film forming ability and air stability; it also exhibits trap-free HT property. Besides, similar to many common small-molecule HT materials, NPB has a high-lying HOMO level of 5.4 eV. Therefore, NPB is an ideal candidate for examining charge transport and injection mechanism in amorphous organic semiconductors [12,13]. Two electrical techniques, current–voltage (*J–V*) and dark-injection space-charge-limited-current (DI-SCLC) techniques, are employed to perform the examination. These techniques have been demonstrated to be valuable tools for injection contact examination [12,14,15]. Besides, carrier mobility of NPB can also be evaluated by DI-SCLC techniques [16]. The carrier mobility deduced from DI-SCLC technique will be compared to those obtained from independent time-of-flight (TOF) technique. In addition, X-ray photoemission spectroscopy (XPS) was employed to study the surface composition and the stoichiometry of TMO films.

2. Experimental

TMOs and NPB were purchased from Strem Chemicals and E-ray, respectively. Details of TOF experiments have been reported elsewhere [17]. For *J–V* and DI-SCLC experiments, samples have the general structures of ITO/TMO(20 nm)/NPB(~4 μm)/Ag. Prior to film deposition, ITO-coated glass slides were cleaned by using sequential baths of deconex, de-ionized water, and acetone. Subsequently, the ITO substrates were exposed to UV–ozone [18]. TMOs and NPB were thermally evaporated onto the substrates at rates of 0.05 and 1 nm/s, respectively. Since only hole injection was considered, 100 nm of Ag was used to be the hole collecting and electron blocking cathode. All films were deposited inside a high vacuum evaporator with a base pressure of about 10^{-6} Torr. In the following, instead of MoO_3, V_2O_5 and WO_3, we will use the notation of MoO_x, V_2O_x, and WO_x, to represent the stoichiometry of thermally evaporated TMOs film. Non-stoichiometric TMO films are usually obtained from thermal evaporation [19]. There are three kinds of devices used in this work. Their differentiation is based on how the TMO layer was modified prior to the deposition of the NPB layer. They are distinguished as follows: Method A – the TMO film was not modified, i.e., TMO and NPB were deposited sequentially under the same vacuum; Methods B and C – the TMO films were exposed to air and oxygen for 10 min, respectively, prior to the deposition of NPB. All film thicknesses were measured *in situ* by a quartz crystal sensor and *ex situ* by a step profilometer (Tencor Alpha-Step 500). After fabrication, the samples were immediately loaded inside a vacuum cryostat with a pressure of less than 10^{-3} Torr for measurements. All measurements were performed at room temperature. The *J–V* experiments were carried out with a computer-controlled Keithley Source-Measure Unit (model 236). For DI-SCLC experiments, the samples were subjected to a rectangular voltage pulse by using a pulse generator (HP model 241B) for injecting holes into the samples. A digital oscilloscope was used to capture the voltage across a current sensing resistor, which was connected in series to the samples. The current can be computed afterwards. For XPS, MoO_x was taken for surface composition study. Two samples were fabricated: Sample 1 – 20 nm MoO_x covered with 100 nm NPB, by which the two films were deposited sequentially on top of ITO in the same vacuum; Sample 2 – bare MoO_x film on top of ITO. The buried MoO_x film in sample 1 represents the MoO_x film without gas exposure, while the film in sample 2 corresponds to air-exposed oxide. The XPS experiment was performed inside Kratos AXIS ULTRA^{DLD} system using monochromic Al Kα radiation as the X-ray source and the surface composition can be determined. The surface composition of MoO_x in sample 1 can be characterized only after the removal of the NPB layer by Ar^+ ion sputtering.

3. Results and discussion

Fig. 1a shows the *J–V* characteristics for devices having the structure of ITO/HIL/NPB/Ag, where the HIL = PEDOT:PSS, TMOs with and without air exposure. Ideally, if an organic material is trap-free and under the condition of Ohmic injection contact, the steady-state current should follow the space-charge-limited current (SCLC) (J_{SCL}) [20]:

$$J_{SCL} = \frac{9}{8}\mu_0\varepsilon_0\varepsilon_r \exp(0.89\beta\sqrt{F})\frac{F^2}{d} \quad (1)$$

where ε_0 is the permittivity in free space, ε_r is the dielectric constant (~3 for organic materials), F is the applied electric field strength and d is the thickness of organic layer respectively. The factor β is the Poole–Frenkel slope, which indicates the sensitivity of carrier mobility of material with respect to applied electric field. Carrier mobility of materials with smaller β shows less field-dependence. On the other hand, μ_0 is zero-field mobility, i.e., the mobility when $F = 0$. Both β and μ_0 can be obtained from independent time-of-flight experiments, and were found to be $1.3 \times 10^{-3}(\mathrm{cm/V})^{-1/2}$ and $2.7 \times 10^{-4}\mathrm{cm}^2/\mathrm{Vs}$, respectively [21]. In addition, the HI efficiency (η_{INJ}), can be obtained from the *J–V* characteristics and is given by [22]:

$$\eta_{INJ} = J_{INJ}/J_{SCL} \quad (2)$$

where J_{INJ} and J_{SCL} are, respectively, the measured and computed hole current from Eq. (1).

The solid line in Fig. 1a is the computed theoretical J_{SCL} which serves as the upper bound for the experimental current density. PEDOT:PSS has been demonstrated to be an promising HIL for OLEDs. The *J–V* characteristic of device with PEDOT:PSS here is used as a reference showing how

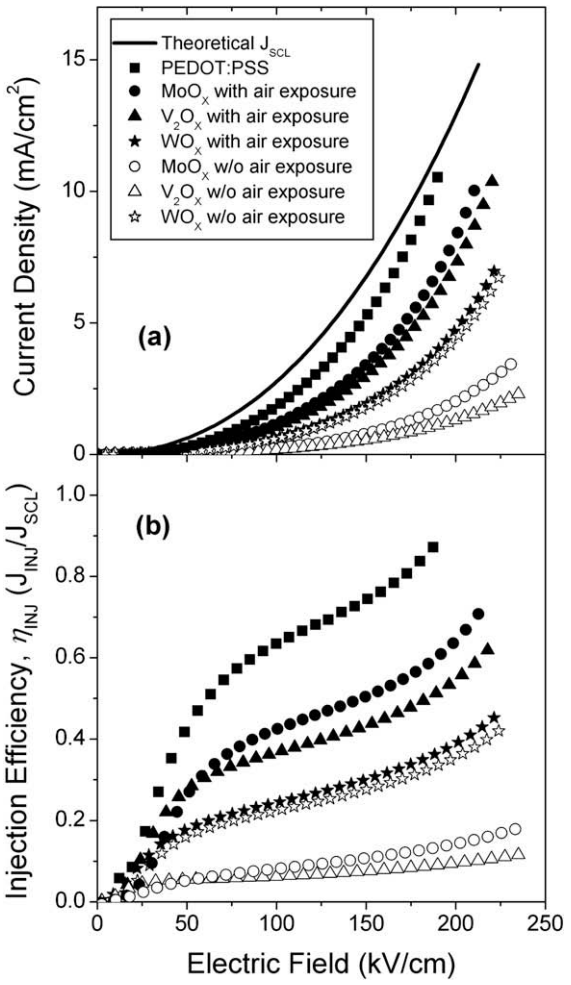

Fig. 1. (a) Current–voltage (J–V) characteristics and (b) injection efficiency plot of ITO/HIL/NPB/Ag devices using different HIL materials. The HILs are PEDOT:PSS, MoO_x, V_2O_x, and WO_x. For the TMOs, closed and open symbols correspond to the TMOs with and without air exposure, respectively.

an efficient HIL behaves. Clearly, at high field, the experimental J–V curves nearly overlap with the theoretical one for the PEDOT:PSS device, which indicates the HIL can form nearly Ohmic contact with NPB. On the other hand, those devices with HIL = air-exposed TMOs show larger deviations between experimental and theoretical J–V curves when compared to PEDOT:PSS device, indicating poorer injection condition. Furthermore, for those devices with HIL = TMOs without air exposure (except for WO_x), the measured J–V curves deviate substantially from the theoretical curve. This indicates the currents flowing through the devices are completely injection limited.

Substantial improvement in current density was observed from the devices with HIL = TMOs after air exposure. Fig. 1(b) shows the HI efficiency (η_{INJ}) plot of all the anodes. Same as J–V characteristics, when the TMOs are exposed to air, the HI efficiency has a marked improvement when compared to those without air exposure. About fivefold increase in η_{INJ} can be found when $F > 50$ kV/cm. The improvements clearly reveal that the hole injection at the TMO/NPB interface is enhanced upon exposing the oxides to air before the deposition of NPB, which is solely originated from the reduced injection barrier at TMO/NPB interface. The observations are, perhaps, not surprising. TMOs have been demonstrated to be the materials for gas sensors [23,24]. Their work functions change upon exposing to different gases. Exposing the oxides to oxidizing/reducing gases will result in an increase/decrease of their work functions. In air, the oxidizing constituent is oxygen. In order to verify if the improvement is solely originated from the oxygen exposure, samples with oxygen-exposed TMOs were fabricated.

Fig. 2a shows the J–V characteristics for NPB, with ITO/MoO_x as hole injecting anodes. The solid lines are the computed theoretical J_{SCL} using Eq. (1). In Fig. 2a, solid triangles (▲), open square (□) and open circle (○) represent the samples with no gas-exposed MoO_x (device A), air-exposed

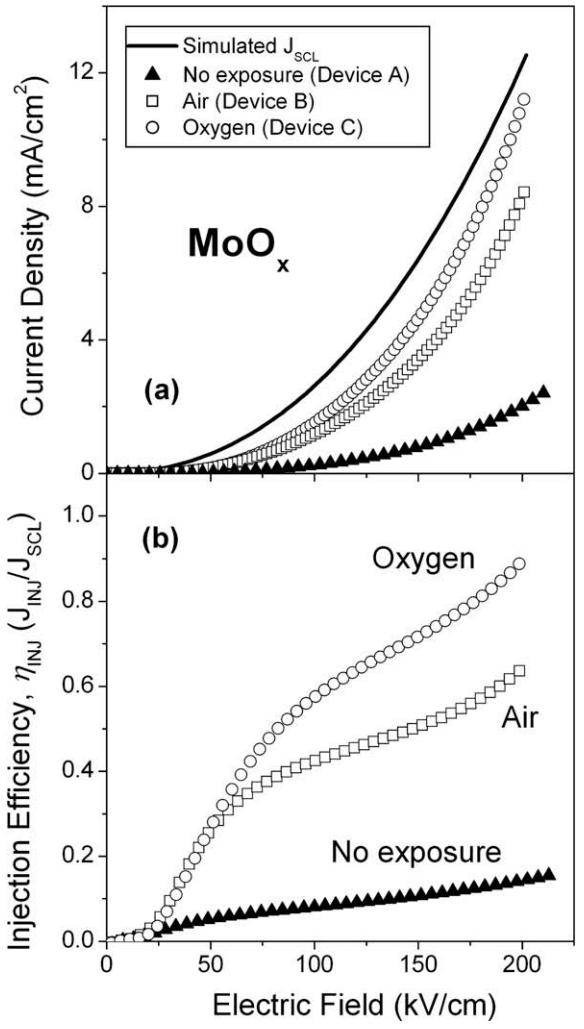

Fig. 2. (a) J–V characteristics and (b) injection efficiency plot of ITO/MoO_x/NPB/Ag devices. The MoO_x were treated differently in these devices: device A (▲) – no gaseous exposure; device B (□) – exposed to air for 10 min; device C (○) – exposed to oxygen for 10 min. In (a), the solid line is the simulated J–V curve using SCLC theory.

MoO_x (device B) and oxygen-exposed MoO_x (device C), respectively. Same as device B, substantial improvement in current density was observed from device C, when compared to that of device A. In addition, deviation between the theoretical fit and the experimental J–V curves from device C is smaller when compared to device B, in the entire range of electric field. Fig. 2b shows the HI efficiency plots for the corresponding TMOs containing devices. The results are consistent with the observations from the J–V plots, showing improved η_{INJ} from gas-exposed TMOs. The contacts of device C have the best η_{INJ} among all the devices, especially when $F > 50$ kV/cm. Analogous experiments were performed on V_2O_x, and the results are summarized in Table 1. The table shows η_{INJ} at two different applied electric field strengths, $F = 100$ kV/cm and 150 kV/cm. Same observation of η_{INJ} improvement can be found from V_2O_x containing devices. Since WO_x showed no effect upon air exposure, only MoO_x and V_2O_x were taken to be further investigated here. The discrepancy between η_{INJ} of oxygen-exposed and air-exposed TMOs is likely due to the presence of moisture in air, which acts as a reducing agent for TMOs [23]. Moisture counteracts the effect of oxygen and will reduce the effect of work function enhancement of oxides. In addition, the η_{INJ} of PEDOT:PSS/NPB contact were found to be 0.64 and 0.74 at $F = 100$ kV/cm and 150 kV/cm from Fig. 1b, respectively. Oxygen-exposed TMOs show comparable injection performance to PEDOT:PSS, which suggests that TMOs can be an alternative choice for HIL in OLEDs to replace PEDOT:PSS, with an additional advantage of being the top electrodes of organic thin film transistors (OTFTs).

Besides J–V characteristics, the injection behavior of TMO/NPB contacts was further examined by DI-SCLC experiment. Fig. 3a shows the DI signals at 100 V ($F = 250$ kV/cm) from all the devices (A, B and C). The signals from device B and C clearly exhibit the characteristics which resemble the ideal DI transient as shown in Fig. 3b, while the signal from device A is featureless. The ideal current transient reaches a maximum at a well-defined flight time τ_{DI} and decays to a saturated value after a long time. This transient can only be observed if the following conditions are satisfied: (i) anode/organic contact is Ohmic and (ii) organic/cathode contact is electron blocking. The transient current density $J(t)$ can be derived from Poisson's equation for a trap-free material under the condition of unipolar Ohmic injection. The carrier mobility μ_{DI} can be calculated as follows [25]:

$$\mu_{DI} = \frac{0.787 d^2}{\tau_{DI} \cdot V} \quad (3)$$

where τ_{DI} is the arrival time of the fastest carriers at the non-injecting electrode, and is related to the space-charge free carrier transit time τ by $\tau_{DI} = 0.787\tau$; d and V are the organic layer thickness and voltage applied across the sample. In Fig 3a, we can clearly extract the τ_{DI} from devices B and C while no distinct τ_{DI} appeared from device A.

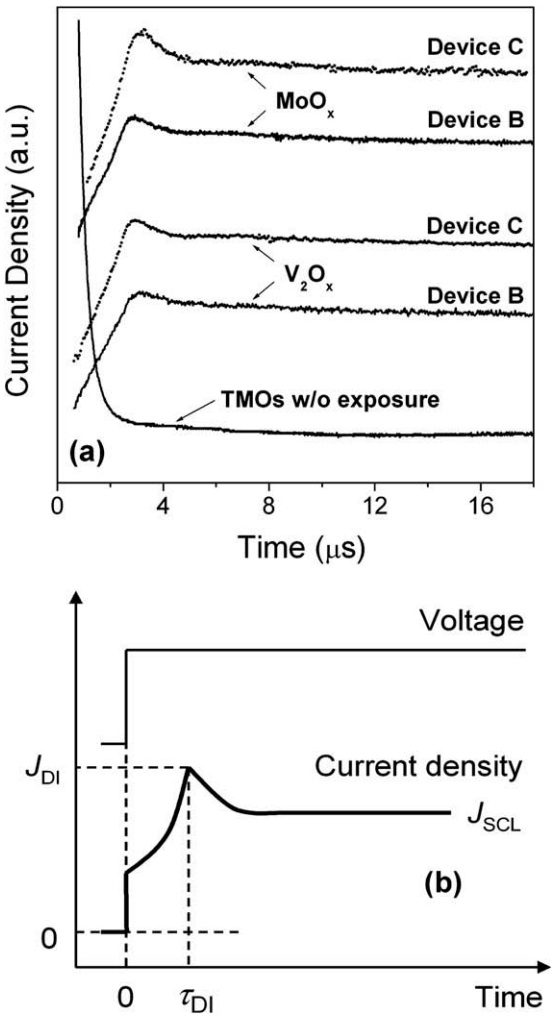

Fig. 3. (a) DI-SCLC transients from device A, B and C at 100 V ($F = 250$ kV/cm). (b) An ideal DI-SCLC transient.

Moreover, the DI transients under different applied voltages were measured. From Eq. (3), we can extract the hole transit time and hence the hole mobilities of NPB from the DI transients. The results from MoO_x containing devices are summarized in Fig. 4. The values of hole mobilities of NPB extracted from all the devices are consistent to the reported values [12,21]. In Fig. 4, device C (○) shows slightly higher hole mobilities than device B (■). Fig. 4 also

Table 1
Summary of HI efficiency (η_{INJ}) of different oxide contacts.

	MoO_x		V_2O_x	
	$F = 100$ kV/cm	$F = 150$ kV/cm	$F = 100$ kV/cm	$F = 150$ kV/cm
w/o gas exposure	0.08	0.11	0.06	0.08
Air exposure	0.43	0.51	0.37	0.43
O_2 exposure	0.58	0.72	0.6	0.75

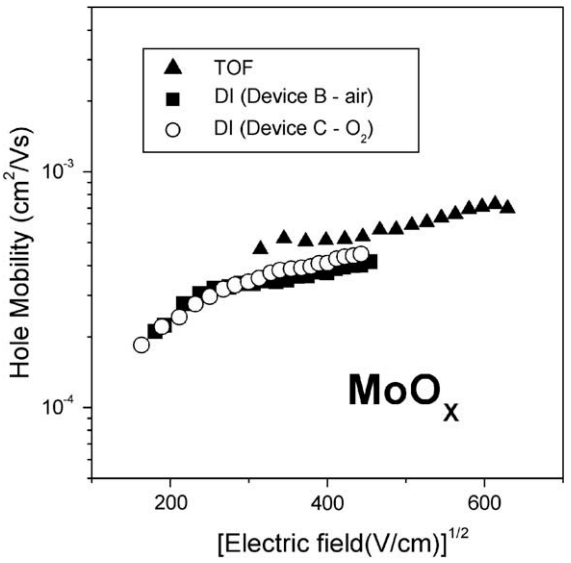

Fig. 4. The hole mobilities of NPB against the square root of the electric field at 290 K derived from DI-SCLC and TOF techniques for ITO/MoO_x/NPB/Ag devices.

shows the hole mobilities of NPB obtained from independent TOF experiment. In TOF, as the charge carriers inside NPB are optically generated by pulse laser, problems related to the injection contact can be neglected. Therefore, carrier mobility from TOF reveals the actual mobility of materials. The mobilities obtained from DI experiments are in good agreement to those from TOF. Same observation can also be found from V_2O_x containing devices. The small discrepancy can be originated from the imperfectly Ohmic injection from the oxides contact. Larger discrepancy can be found in the range of small electric field, as the injection barrier height is lowered upon increasing the applied voltages. The observation is consistent to that of *J–V* experiment showing incomplete overlap between the measured *J–V* curves and the theoretical fits, especially when *F* is small. Although significant difference cannot be found from the DI mobilities evaluated from the devices B and C, the observation of DI transients from those devices with gas-exposed TMOs indicate the contacts are nearly Ohmic. On the other hand, absence of DI transients and the large deviation between measured and theoretical *J–V* curve indicate the contacts formed by TMOs with no gas exposure and NPB (device A) are significantly injection limited. The contact transition from non-Ohmic to nearly Ohmic further verifies the air/oxygen exposure is essential for reducing the energy barrier at TMO/NPB interface.

Energy barrier reduction at the TMO/NPB interface after air/oxygen exposure is solely originated from the gas sensing properties of TMOs. As mentioned above, exposing the oxides to oxidizing gases will result in an increase of their work functions. The mechanism of work function enhancement in our case can be understood as follows. Under an oxygen deficient environment, i.e. low oxygen partial pressure (pO_2), TMOs undergo reduction by losing oxygen, which creates an oxygen vacancy and generates electrons contributing to *n*-type conductivity. This situation is similar to the case of doping donor atoms into an intrinsic inorganic semiconductor, which will shift the Fermi level of semiconductor towards the conduction band. Under this circumstance, non-stoichiometric TMOs are produced. While at high pO_2, oxygen is incorporated at an oxygen vacancy and takes two electrons from the valence band of TMOs, leaving two holes to contribute to *p*-type conductivity. This will shift the Fermi level to the valence band [26,27]. As the work function equals to the difference between the vacuum level and Fermi level, the shift of Fermi level results in the variation of work function. In order to

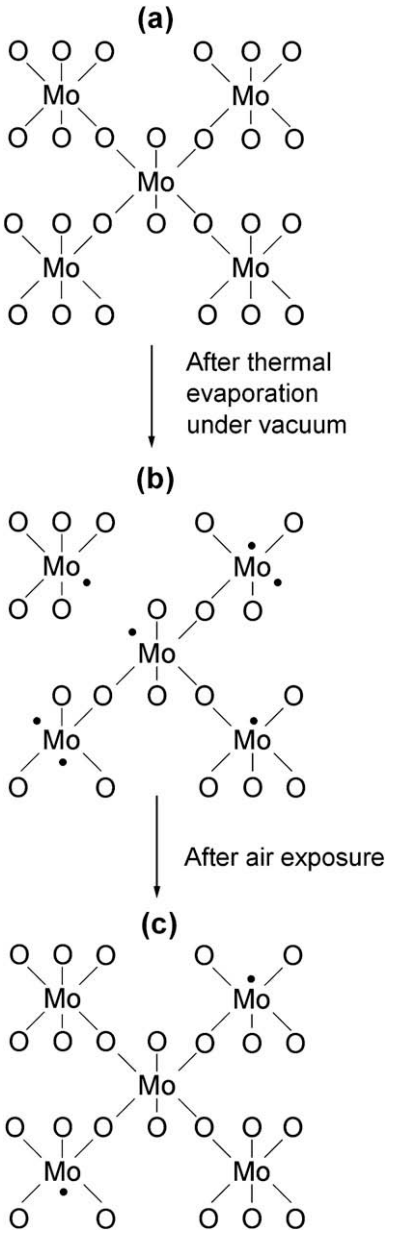

Fig. 5. Bond representation of (a) stoichiometric MoO_3 prior to evaporation; (b) thermally evaporated MoO_x film under vacuum; (c) MoO_x after exposing to air. The dots (●) denote the electrons left behind after the loss of O-atoms in the lattice.

verify if the air-exposed TMO film has different oxygen content to that without gas exposure, complementary X-ray photoemission spectroscopy (XPS) experiment was performed on MoO_x films. By monitoring the ratio of the peak areas of Mo 3d and O 1s, the values of x in the MoO_x films with and without air exposure were found to be 2.6 and 1.4 respectively, which suggests the oxygen content increases upon air exposure. The value of $x \sim 2.6$ from air-exposed MoO_x film is also consistent to the value from Kanno et. al. ($x \sim 2.7$) [19].

Fig. 5 shows a schematic diagram of the redox reactions of MoO_3 during our fabrication. In our case, the deposition of TMO film was carried out inside a vacuum evaporator, which provides an oxygen deficient environment. The outcome is the creation of oxygen vacancies inside the film, which shifts the Fermi level towards the conduction band and thus reduces the work function of the oxide as outlined above (Fig. 5b). However, upon air/oxygen exposure, oxygen will be incorporated back to the oxide films at the oxygen vacancies. For every oxygen vacancies, the process removes up to two electrons. The overall result is a net increase in the work function due to the lowering of the Fermi level of the oxide (Fig. 5c). As a result, the work function of oxide is enhanced, which reduces the energy barrier at TMO/NPB, and improves the HI efficiency.

In contrast to MoO_x and V_2O_x, WO_x behaves differently for the work function enhancement in this study. In this case, the *J–V* characteristics in Fig. 1 showed that only a small improvement can be found when WO_x is exposed to air. This is an indication that thermally evaporated WO_x film remains highly stoichiometric, with relatively few oxygen vacancies. According to the work of Molenda et al., a slightly non-stoichiometric species, $WO_{2.7}$, can only be created from WO_3 in ultra-high vacuum environment [28]. However, in our case, the film deposition was carried out under high vacuum ($\sim 10^{-6}$ Torr). So, it is unlikely that the non-stoichiometric oxide can be formed, and thus, the reduction of the oxide by oxygen does not occur. As a result, variation of the work function of WO_x cannot be observed and thus, the HI efficiency improvement cannot be found in WO_x. On the other hand, even in low vacuum environment, non-stoichiometric MoO_3 and V_2O_5 can be easily obtained [29], which are consistent to our observation as discussed above.

4. Conclusion

In conclusion, we demonstrate that exposing a TMO film to air can effectively reduce the energy barrier at TMO/NPB interface, and improve the HI efficiency. *J–V* and DI-SCLC techniques were used to cross-examine the injection behavior of the contacts. The origin of improvement is attributed to the oxidation of TMOs by oxygen upon air exposure. Finally, we emphasize that this improvement is not only valuable for enhancing the performance of organic optoelectronic devices, but also providing an insight for the fabrication of transition metal oxide films.

ABSTRACT

We report on the successful fabrication of full-swing charged organic inverter circuits by means of continuous mass-printing technologies. Using an electrostatic charged perfluorinated gate dielectric (Cytop™), we demonstrate depletion-mode and enhancement-mode transistors with the same organic semiconductor in top-gate device structure.

The threshold voltage of the printed p-type transistors can be shifted by injecting stable positive charges by means of a corona discharge or contact charging.

1. Introduction

The development of new cost-efficient applications like large area electronic circuits on flexible substrates requires solution-processing techniques. Several printing methods such as inkjet [1–3], screen printing [4] and pad printing [5] have been proposed. However, all of these techniques have limited throughput due to the slow process speed. In 2007, we demonstrated a fully integrated circuit completely manufactured by continuous mass-printing technologies [6]. The oscillator consisting of p-type enhancement-mode transistors only, was made by a single unipolar organic semiconductor (OSC), resulting in high circuit complexity and limited swing. While complementary circuits are desirable because of the high signal integrity and low power consumption, printable air-stable n-type semiconductors are rarely published yet [7,8].

One way to overcome these problems is the use of a so-called electret material as the dielectric in the organic field effect transistor (OFET). An electret is a type of dielectric that exhibits a quasi-permanent electric field due to dipolar polarization or trapped homopolar charge layers [9]. Corona charging, a common tool in xerographic printing processes, can be used to create electret properties in organic field-effect transistors and control their threshold voltage [10–12]. The high stability of the electret state, which is known to be higher than 10 years for some materials [13], makes electrostatic charging a promising technology for the realization of certain mass-printed circuits. Additionally, non-volatile transistor memories with long retention times could be realized. In this paper, we report on mass-printed full-swing inverter circuits based on positively charged top-gate-transistors with the perfluorinated material Cytop™ as the dielectric.

2. Experimental

For the preparation of the top-gate OFET's we used solution processable materials only, which allow the realization of mass-printed electronic devices.

The device architecture, the printable materials and the deposition method are summarized in Fig. 1. For material testing we prepared OFET's by a combination of gravure

printing, spin-coating and dispensing. As substrate we used a smooth commercially available (DuPont Tejin) polyester foil (PET) with a surface roughness of 8 nm.

Source–drain-electrodes are gravure-printed with an in-house reformulated water-based dispersion of poly (3,4-ethylenedioxythiophene) doped with poly (styrenesulfonate) (PEDOT:PSS), which is commercially available as Clevios P® from H.C Starck. The process speed was of the order of 1 m/s. The channel length was $L = 60$ μm and the channel width W was 30 mm. The layer thickness was measured to be 200 nm with a surface roughness $R_a = 20$ nm, determined using the profilometer Dektak 8 from Veeco. As active semiconductor (OSC) we used triisopropylsilyl (TIPS) pentacene, which was synthesized via standard methods published by the Anthony's group [14]. The OSC was spin-coated from a 0.5% toluene-solution with a spinning speed of 3000 rpm for 20 s and annealed for 5 min with a temperature of 120 °C. The resulting layer thickness was measured to be 80 nm. As organic dielectric we used the amorphous poly-perfluoro-alkenyl vinyl ether (Cytop CTL-809M, $\varepsilon_r = 2.1$), which is known for its excellent charge stability [15]. Cytop layers were prepared by spin-coating the 9% solution with a spinning speed of 1500 rpm for 20 s and a subsequent annealing step at 120 °C for 15 min. The thickness of the electret layer was measured to be 1.4 μm.

For electrostatic charging we tested the corona charging technique [16,17], as well as contact charging [18,19], to implant charges into the electret material.

Corona charging (wire-to-grid method) is done before dispensing the conductive gate on top of charged dielectric. Therefore we applied a corona voltage of +10 kV to a tungsten wire for a charging time of $t = 5$ min. The surface potential was controlled by the voltage of a metal grid, which is located above the test sample. After charging, the surface potential was measured with an electrostatic voltmeter (Trek model 368A). Due to the very low surface energy of the Cytop layer ($\sigma = 12$–14 mN/m), we used a mixture of a highly conductive PEDOT:PSS solution (Clevios FE) and the fluorinated surfactant DuPont Zonyl FSO for the gate electrode, which reduces the surface tension of the polymer solution and therefore improves the wetting properties on the insulating surface. The gate material was annealed for 5 min at 100 °C to remove the solvent. Contact charging was done by applying a high depletion voltage to the OFET for variable times, while the source and drain electrodes were grounded.

Fully mass-printed OFET's were realized by a combination of gravure printing and flexography in the same layer configuration under the same drying conditions as the spin-coated ones. Source–drain structures were gravure-printed on a flexible PET foil as described above. The OSC, organic dielectric and the gate electrode were applied by flexo-printing with a fixed process speed of 0.1 m/s. As printing form we used an anilox roll with a cell volume 24.9 ml. Optimized transistor performance was achieved by printing TIPS-pentacene from a 1% tetralin solution. To achieve insulating dielectric layers, we flexo-printed the 9% Cytop solution three times over the desired regions. The resulting layer thickness was measured to be 1.9 μm. For the gate layer we again used an in-house reformulated PEDOT:PSS solution mixed with the surfactant Zonyl FSO (0.5 mass %).

All devices were electrically characterized by sweeping the gate voltage V_{GS} from +60 to −60 V with a constant source–drain-voltage of $V_{SD} = -10$ V under ambient conditions. The threshold voltage is defined as the gate voltage at which the square root of the source–drain current begins to increase substantially and was extracted as the x-intercept of the transfer curve ($I_{DS}^{0.5}$ vs. V_G). The mobility was determined by a standard procedure from the slope of the transfer curve [20].

3. Results and discussion

Fig. 2 shows the transfer curves of corona charged top-gate OFET's with different surface potentials. We applied a positive corona voltage (V_C) of +10 kV to the tungsten wire, while the surface potential was controlled by the voltage of a metallic grid (V_{Grid}), which is located above the sample. Consequently, the free gate electrode side of the dielectric is charged positively. The charge density Uncharged transistors show typical p-type accumulation behaviour with a threshold voltage of $V_{th} = -5$ V. Under zero gate-voltage condition no charge accumulation can

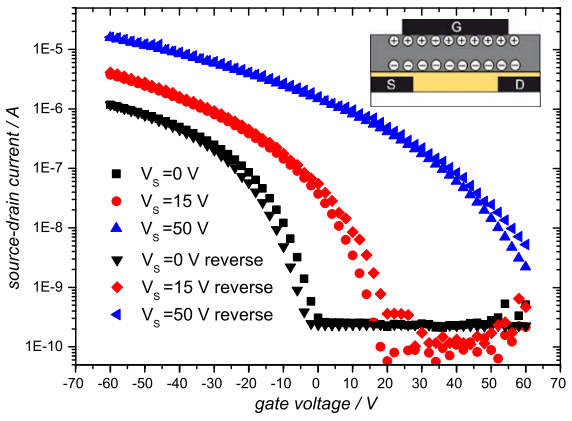

Fig. 2. Semilogarithmic I_{DS}–V_G curves of corona charged OFET's with different surface potentials measured at $V_{DS} = -10$ V. The inset shows the proposed mechanism of the threshold voltage shift. The transistors were prepared by spin-coating as shown in Fig. 1. W/L-ratio is 500 and the capacitance was measured to be 2 nF/cm^2.

be observed. With increasing surface potential V_S of the charged dielectric, the threshold voltage shifts towards higher positive gate voltages. Charged transistors show depletion mode characteristic with threshold voltages of V_{th} = +7 V (V_C = +10 kV, V_{Grid} = +20 V, V_S = +15 V) and of V_{th} = +37 V (V_C = +10 kV, V_{Grid} = +60 V, V_S = +50 V), respectively. The hysteresis observed in the transfer characteristic was <1 V. The mobility changes insignificantly from $1.3 * 10^{-2}$ cm^2/V s (uncharged sample) to $1.1 * 10^{-2}$ cm^2/V s (sample charged to V_S = 50 V). The charge density stored in the dielectric can be estimated to be $1.4 * 10^{-8}$ C/cm^2 for a surface potential of V_S = 15 V and $4.8 * 10^{-8}$ C/cm^2 for V_S = 50 V.

The gate leakage current did not exceed 10 nA for the uncharged as well as the charged transistors. The shift of the threshold voltage can be attributed to the presence of stored charge carriers in the dielectric. The result is an electrostatic induction effect at the interface of the dielectric and the semiconductor, increasing the number of hole carriers in the channel. Consequently the transistors reach on-state under zero gate-voltage condition.

Huang et al. reported positive threshold voltage shifts in bottom-gate devices with nonpolar dielectrics (SiO_2 and glass resin) by means of negative corona charging [10,11]. Scharnberg et al. [21] reported negative threshold voltage shifts for negative corona charging of the encapsulation layer (Teflon AF) in bottom-gate transistors. The mechanism behind the threshold voltage shift is explained by the electrostatic attraction or repellency of charge carriers on the semiconductor–dielectric interface caused by homopolar corona charges in the electret layer.

We observe positive threshold voltage shifts for positive corona charging in the top-gate architecture, indicating that in our case, the accumulation of majority charge carriers in the transistor channel cannot be explained by homopolar space charges residing completely in the dielectric. The result is consistent with previous observations, that positive threshold voltage shifts can be observed for negative corona charging of semiconductor side of the dielectric in bottom-gate architecture [10,11]. Consequently we can exclude, that the mechanism behind the threshold voltage shift is caused by a change of the surface chemistry at the semiconductor–dielectric interface.

However, we conclude that the corona discharge injects static charges somewhere between (or at) the surface of the dielectric and the dielectric–semiconductor interface. The charge may be in form of homopolar space charges that fill traps directly in the semiconductor, or oriented dipoles that have negative ends pointed toward the semiconductor, also causing the prefilling of traps in the semiconductor, and hence a threshold voltage shift in the transistor.

Due to the high complexity of corona discharges, we tested contact charging as another possibility to influence the threshold voltage of OFET's, which was first reported by Katz et al. [22]. Similar results, but with much smaller programming times, were reported by Baeg et al. [23,24]. By applying a high depletion voltage charge can be transferred from the gate electrode and/or the semiconductor to the electrets and stored at sites inside the dielectric.

In Fig. 3a the transfer curve of a transistor before and after applying a depletion voltage of V_{Write} = +200 V for t = 1 s is shown. The threshold voltage changes significantly from V_{th} = −2 V (pristine) to V_{th} = +40 V. Applying high accumulation voltages of V_{Write} = −200 V for up to 10 s results in threshold voltage shifts of <5 V towards lower positive gate voltages.

This applies for pristine as well as charged transistors.

The excellent charge stability is proved by repeated measurement of the transistor. After 1 month the threshold voltage reduces only by 5 V. Fig. 3b shows that the amount of transferred charge, and hence the threshold voltage shift, strongly depends on the applied electric field ($E = V_{Write}/d$) as well as on the writing time. By increasing the electric field, the necessary writing time to create a sufficient threshold voltage shift of about 10 V (transition from accumulation-mode to depletion mode) can be reduced to t = 10 ms, which makes this technology attractive for a possible roll-to-roll process. However, it is not clear

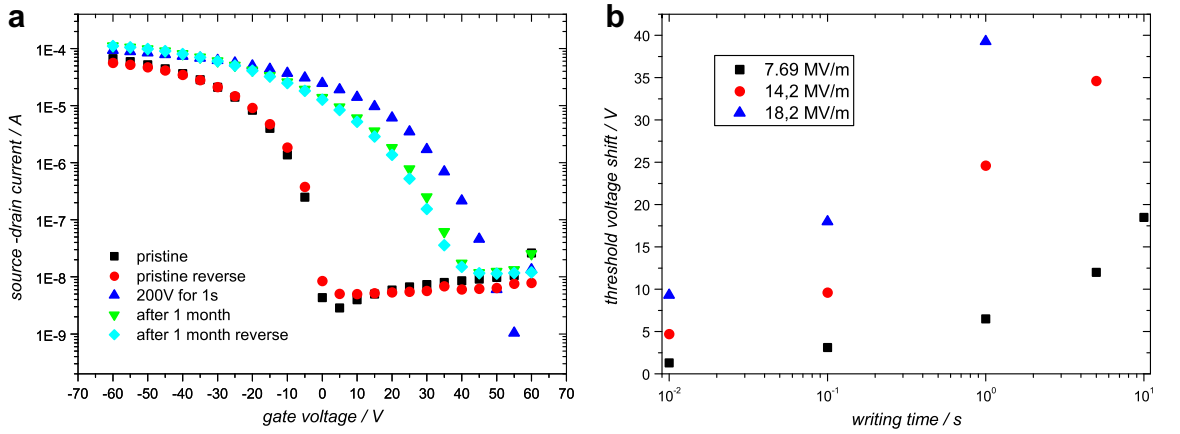

Fig. 3. (a) Semilogarithmic I_{DS}–V_G curve of a transistor before (pristine) and after contact charging with a writing voltage of V_w = 200 V for 1 s measured at V_{DS} = −10 V and (b) shows the threshold voltage shift of the contact charged OFET's depending on the applied electric field. The transistors were prepared by spin-coating as shown in Fig. 1.

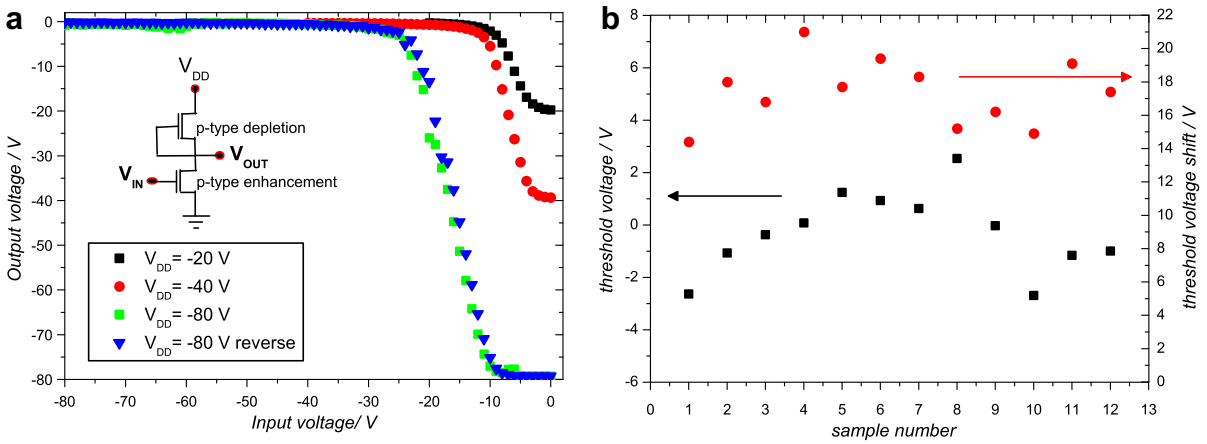

Fig. 4. (a) Static voltage transfer characteristic of a printed inverter device measured for supply voltages V_{DD} of −20 V, −40 V and −80 V. The inset shows the circuit diagram of the inverter comprising of a p-type depletion-mode load and a p-type enhancement drive transistor. (b) Statistical data of the printed transistors with the distribution of the threshold voltage (black squares) and their corresponding threshold voltage shifts (red dots) for a depletion voltage of 200 V for 1 s. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

whether the threshold voltage shift is caused by the injection of electrons from the semiconductor into the dielectric or due to charge transfer from the gate electrode to the dielectric.

Additionally, we demonstrate fully mass-printed organic inverters based on a contact charged Cytop layers. The printed transistors exhibit good electrical performance with a saturated mobility of $1–3 * 10^{-2}$ cm^2/V s, a threshold voltage between −3 and 2 V and On/Off-ratios of about 10^3. The capacitance was measured to be 2 nF/cm^2. Consequently, we built up inverters, which consists of a p-type accumulation-mode drive and a p-type depletion-mode load transistor (see inset Fig. 4a), each with the same geometrical dimensions (W/L-ratio = 500). The uncharged printed transistors were brought from accumulation-mode to depletion mode by applying a writing voltage of V_{Write} = +200 V for t = 1 s. The threshold voltage uniformity of the printed transistors, as well as their threshold voltage shift is illustrated in Fig. 4b. We observed threshold voltage shifts of 17.4 V with a standard deviation of 1.9 V for the tested transistors. The smaller threshold voltage shift in comparison to the spin-coated samples (Fig. 3b), can be explained by the higher dielectric layer thickness, resulting in a lower writing field for the same applied voltage.

The static voltage characteristic of a unipolar inverter device is shown in Fig. 4a. For negative values of drive voltages (V_{DD}) and input voltages (V_{IN}) the inverter works in the third quadrant of the output voltage (V_{OUT}) vs. (V_{IN}) plot. Our devices show nearly full-swing characteristic with a small hysteresis, similar to complementary inverters reported recently [25,26]. The voltage gain, which was measured to be 3.6 (V_{DD} = −20 V), 5.7 (V_{DD} = −40 V) and 7.2 (V_{DD} = −80 V), is comparable to results obtained in [10].

The gain can be increased by adapting the transistor dimensions [27], while using a symmetrical distribution of the threshold voltage (e.g. V_{th} = −5 V for the drive and V_{th} = +5 V for the load transistor). This can be done for instance by increasing the channel width of the drive transistor with respect to the load transistor. So the output current under zero gate-voltage condition of the load transistor can be tuned, to match the output characteristic of the drive transistor.

4. Conclusions

We successfully demonstrated fully mass-printed unipolar logic gates with improved device performance by using the electret Cytop as the gate dielectric for the OFET's. The threshold voltage of transistors can be shifted with the injection of electric charges into the dielectric by means of corona charging or contact charging. The injected charges exhibit excellent stability in comparison with other competing materials [21]. Full-swing inverters can be realized without using complementary semiconductors [8,25] or the use of competing technologies to influence the threshold voltage of the transistors [28–30]. In particular, the ability to charge the printed transistors within a few milliseconds makes this technology attractive for roll-to-roll processes, an application which is under investigation.

ABSTRACT

We present the extension of the organic vapor phase deposition technique to an in-line geometry, in which the sample travels underneath an elongated showerhead that sprays molecules transported by a stream of carrier gas. Highly uniform pentacene films are grown at web speeds of up to 2.1 m/min, equivalent to an average deposition rate of 105 Å/s in a static system. With transistor mobilities of up to 1.5 cm^2/V s, these pentacene films are of high electrical quality. Importantly, this quality is conserved up to the highest deposition speeds. We discuss the relationships between in-line deposition rate, morphology and crystallinity of the deposited pentacene films and their electrical characteristics.

1. Introduction

In the recent years, circuits based on organic field effect transistors (OFETs) have been investigated for potential applications such as back panels for flexible displays and transponder circuits for RFID tags. Two approaches have been explored for the processing of organic circuits at the lab-scale: (i) the first one, stimulated by the printing industry, based on printing technologies to apply and pattern films from soluble materials. (ii) the second one, inspired by the microelectronic industry, makes use of photolithography to pattern thin films often deposited by vacuum thermal evaporation (VTE). The former approach has the potential advantage of low-cost high-throughput production [1,2], while the latter approach has delivered the best performing organic circuits so far [3,4]. A future industrial scale roll-to-roll or sheet-to-sheet production of organic circuits would have to combine the advantages of both approaches: it should associate cost-effective processing steps to a sufficient performance of the final organic circuits.

The deposition of the organic semiconductor is a critical step in the fabrication sequence. The selected technique should deposit thin films at a high speed over large substrates with a well-controlled morphology, high uniformity and good reproducibility of the electrical characteristics. Due to its good electrical performance, pentacene is the small organic molecule that has attracted most of the attention. It is generally processed at the lab-scale by VTE. The maximum deposition rate that VTE can reach is set by the poor heat conductivity of the organic powder and is limited around ~2 Å/s. Above that value, the evaporated molecular flux fluctuates too much to guarantee reproducibility [5]. Such a deposition rate remains far away from the high speed constraint set by, for example, roll-to-roll processing, since the growth of a functional 30 nm thick pentacene film over a substrate of a limited area takes at least 150 s. In addition, using flash evaporation, Gundlach et al. demonstrated that pentacene thin film electrical characteristics greatly suffer from growth at too high rates [6]. This apparently sets a hard limit on

doi:10.1016/j.orgel.2009.10.005

the maximum deposition rate at which pentacene can be processed at the industrial scale.

An alternative to VTE for the growth of pentacene thin films is organic vapor phase deposition (OVPD) [7,8]. In OVPD, the source material is sublimed into a stream of hot carrier gas. The molecules undergo a convective transport through a hot-wall chamber to a cooled substrate on which they condense to form a film. OVPD has already been shown for the deposition of high quality pentacene thin films with rates of up to 10 Å/s [9,10]. This technique proves to be quite flexible in terms of tool design. The first instruments, inspired from purification systems, were based on a single differentially heated quartz glass tube containing both the source cell and the substrate [7]. Later on, OVPD instruments inspired from Chemical Vapor Deposition techniques were designed, where the evaporation and condensation steps are physically separated and the spreading of the process gas over the substrate is finely controlled by means of a showerhead [11]. As a result, OVPD presents a number of industrially important advantages [5,12]: (i) high material utilization efficiency and thickness uniformity; (ii) low vacuum operation; (iii) high deposition rates; (iv) fewer particles due to hot-wall chamber and gas flush; (v) flexibility in the design of the tool.

In this work, we demonstrate high performance pentacene thin films grown at unprecedented high speeds using a roll-to-roll compatible in-line OVPD tool. The relation between growth parameters, deposition speed and OFET mobility is discussed.

2. Experimental

2.1. In-line OVPD instrument

The in-line OVPD system used in this work was built in house and is schematically depicted in Fig. 1. The top part of the furnace encloses two gas lines: the source line and the dilution line. The amount of nitrogen carrier gas injected in each line is controlled by means of mass flow controllers. The source line comprises a source cell loaded with the organic powder. The bottom of the furnace envelops the deposition chamber. Injection of the process gas from the gas lines into the chamber is performed by an elongated showerhead whose appropriate design ensures a uniform distribution of the gas onto the susceptor passing several centimeters underneath. The susceptor consist of a trolley that is moving at a controlled speed along rails in a direction perpendicular to the long edge of the showerhead. Its temperature is controlled by means of a water chiller. The trolley top surface dimensions allow for the mounting of 4″ diameter substrates. This mobile trolley simulates well an infinitely-long continuously moving substrate, even though its finite size gives rise to edge effects that are absent in a roll-to-roll process. Finally, the deposition chamber is equipped on one side with a loadlock, allowing for fast loading and unloading of samples, and on the other side with a blind flange that would easily accommodate a second processing chamber.

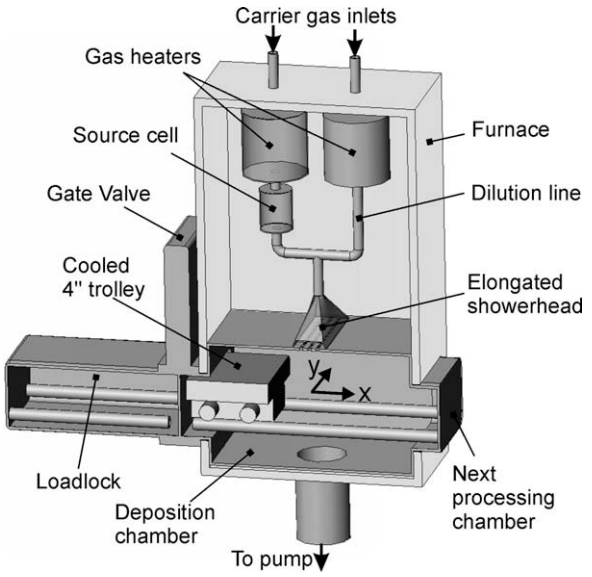

Fig. 1. Schematics of the OVPD tool used in this work. The *x* and *y* axis show the convention used in this work.

2.2. Pentacene deposition parameters

Pentacene is purchased from Aldrich and used as received without further purification. Approximately 500 mg of material powder is loaded into the source cell. For pentacene deposition, the furnace temperature is set between 260 and 320 °C and the carrier gas flow through the source cell is varied between 10 and 200 sccm. Using the dilution line, the total carrier gas flow injected in the chamber through the showerhead is set between 150 and 5000 sccm. The chamber pressure is regulated between 0.1 and 10 mbar independently of the total carrier gas flow by means of a flow control valve. The trolley is kept at a temperature between 50 and 80 °C. In order to meet the constraints of roll-to-roll processing, the trolley velocity is kept constant (between 0.1 and 10 mm/s) during a run and the travel distance is set to the maximum allowed by the dimensions of the chamber. Depending on the deposition speed, several passes under the showerhead can be needed to achieve the desired film thickness.

2.3. Thin film characterization

The film thickness is systematically measured post-growth using ellipsometry (SOPRA GES5). The morphology of the organic polycrystalline film is characterized by atomic force microscopy (AFM) operated in tapping mode (Agilent 5100). Finally, film crystallinity is characterized by XRD (PANalytical X'Pert Pro Materials Research Diffractometer).

The electrical characterization of the pentacene thin films is carried out through the fabrication of top contact OFETs. Fig. 2 shows schematically the structure of these devices. A highly doped n++ silicon wafer is used as gate. A 145-nm thick thermal SiO_2 layer serves as gate dielectric. Prior to pentacene deposition, the wafer is successively

rinsed in deionized water, acetone and isopropanol. It is further cleaned by a 2-min exposure to a 100-W O_2 plasma. Next, the clean gate dielectric is treated with a 10-nm thick poly-(α-methyl-styrene) (PαMS) film which is spin-coated at 4000 rpm for 30 s from a 0.1% solution in toluene, and let dried at 120 °C for 2 min. Then a 30-nm thick pentacene film is grown by in-line OVPD. Finally, gold source and drain contacts are deposited by evaporation through a shadow mask, delivering top contact OFETs with a channel width of 2000 μm and a channel length varying between 50 and 200 μm. Between pentacene deposition and device characterization, samples were often exposed to ambient for up to 12 h without noticeable damage.

These devices are characterized in a nitrogen atmosphere. The OFET transfer curves were typically measured in saturation mode, by sweeping back and forth the gate voltage between −20 and +5 V, while keeping a permanent voltage of −20 V between the source and drain electrodes. Thin film mobilities are extracted from these measurements as described in Ref. [13], using relative dielectric constant values of 3.9 for SiO_2 and 2.2 for PαMS.

3. Modeling of the growth

In in-line OVPD, the process gas injected by the elongated showerhead into the chamber undergoes a rapid relaxation, leading to a broadening of the flow of convectively transported organic species. As a consequence, the organic flux condensing on the substrate is a function of the position x relative to the showerhead long axis. By extension, we define the deposition rate profile $r(x)$ of an in-line instrument as the deposition rate experienced by a point on the susceptor as a function of its position x. Fig. 3 shows a profile $r(x)$ typically observed in our instrument. During a deposition run, a sample lying on the trolley sweeps the deposition rate profile, experiencing a varying deposition rate.

3.1. In-line deposition rate

In an in-line process, the average deposition rate r_{avg} can be evaluated by integrating the deposition rate profile $r(x)$:

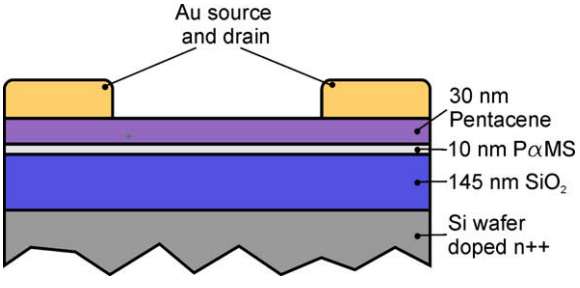

Fig. 2. Schematics of the top contact OFET devices fabricated for electrical characterization of pentacene thin film.

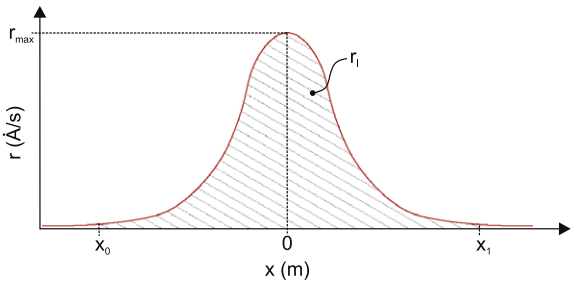

Fig. 3. Schematics of a deposition rate profile $r(x)$ typically observed in our in-line OVPD instrument. The central long axis of the showerhead is located in position $x = 0$, where the deposition rate is maximum (r_{max}). The area below the curve $r(x)$ and in this space interval defines the in-line deposition rate r_l.

$$r_{avg} = \frac{1}{x_1 - x_0} \int_{x_0}^{x_1} r(x)dx, \tag{1}$$

where x_0 and x_1 are, respectively, the starting point and the end point of the movement described by a considered substrate point under the showerhead. A practical way to evaluate r_{avg}, is to divide the final sample thickness d by its exposure time $t_1 - t_0$ to the incident organic flux, where t_0 is the starting time and t_1 the final time. Since the trolley is moving at a constant velocity v_t, there is a direct relationship between travel length and time. r_{avg} can be written:

$$r_{avg} = \frac{d}{t_1 - t_0} = \frac{d \cdot v_t}{x_1 - x_0}. \tag{2}$$

However, if the travel length $x_1 - x_0$ is longer than the width of the profile $r(x)$, the considered point is not permanently exposed to the incident flux. This leads to an underevaluation of r_{avg}. A correct evaluation requires the knowledge of $r(x)$ which depends on the system architecture and on processing parameters. A better parameter is the in-line deposition rate r_l defined by combining Eqs. (1) and (2):

$$r_l = \int_{x_0}^{x_1} r(x)dx = d \cdot v_t. \tag{3}$$

Indeed d and v_t are two easily accessible parameters, which renders r_l easily accessible for the experimentalist and comparable from system to system. As illustrated in Fig. 3, r_l also corresponds to the area under the deposition rate profile $r(x)$. A convenient unit for r_l is $\mu m^2/s$.

Industrially, the roll-to-roll processing speed is often expressed in terms of web speed (in m/min). This is the foil velocity needed to get a full functional coating. The roll-to-roll deposition of a 30-nm pentacene film at a web speed of 1 m/min requires a deposition rate $r_l = 500\ \mu m^2/s$.

However, as the community is using Å/s in order to qualify the deposition speed of a system, it is convenient to express r_l in this unit in order to convey a feeling for the growth speed. In the definition of r_{avg} in Eq. (2), $t_1 - t_0$, the time during which the sample is effectively exposed to the incident flux, is not an easily accessible parameter. However, another way to look at the problem is to simply take the time spent by the sample under the showerhead. This time is equal to the sample length l di-

vided by the trolley velocity. An average deposition rate in Å/s can then be expressed as:

$$r_{avg} \cong \frac{d \cdot v_t}{l}. \quad (4)$$

Calculated in this way, the deposition rate is inversely proportional to the substrate length. It is therefore important to specify the length on which this value is calculated. Since our trolley handles 4″ substrates, it is decided to use a l of 100 mm. This delivers a deposition rate comparable to the deposition rate reached in 4″ lab-scale VTE systems.

3.2. Finite element analysis of the deposition rate profile

The shape of the deposition rate profile is an important deposition characteristic that is unfortunately not easily accessible. A way to grasp it is a finite element analysis of the process gas flow within the chamber. Since the molecular mean free path remains small in comparison to the deposition chamber dimensions, the fluid behavior within this chamber can be accurately described using continuum models. The thermal nitrogen flow and the convective and diffusive transport of diluted organic species are solved on a geometry close to the actual in-line OVPD tool using a commercially available software.

The bulk properties and boundary conditions used to solve the nitrogen flow are similar to experimental operation conditions. The bulk properties and boundary conditions of the convective and diffusive transport model are the following: the diffusion coefficient of pentacene in nitrogen is calculated to be approximately 5e−3 m^2/s [14]; complete condensation is simulated by setting a concentration of 0 mol/m^3 as boundary condition on the susceptor surface; the flux of organic molecules at the inlet of the system is evaluated to be about 1e−4 mol/s at 300 °C [15]. In order to fit the experimental data, the numerically calculated deposition rate profile is multiplied by a single fitting parameter that covers the effects of out-of-equilibrium evaporation and non-complete condensation.

4. Results and discussion

4.1. Deposition rate profile and thickness uniformity

A way to measure the deposition rate profile of the in-line system is to grow a pentacene film over an immobile 4″ wafer lying right under the showerhead. The thickness is mapped by ellipsometry along a line crossing the center of the wafer along the x direction. The circles in Fig. 4 represent the deposition rate profile as measured on a film deposited in static conditions using typical growth parameters. Note that on the edges of the measured profile, the deposition rate profile has still a significant value. The reason for that is that for our system geometry and for the used parameters, the deposition rate profile is wider than the trolley length. Therefore, the static experiment can only capture the central part of the $r(x)$ peak represented in Fig. 3.

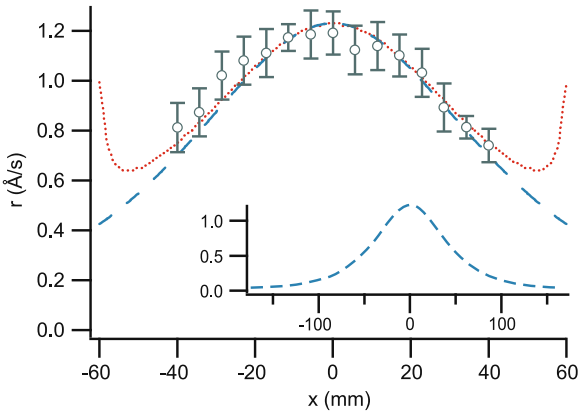

Fig. 4. Deposition rate profiles $r(x)$. Circles: as measured by ellipsometry along the central line of a typical pentacene film grown on an immobile 4″ wafer. Lines: numerically calculated profiles in conditions equivalent to the experimental ones. Dotted line: short susceptor geometry close to the trolley geometry. Dashed line: susceptor as long as the chamber dimensions. The inset shows the full width of the simulated profile on a long susceptor. Following Eq. (3), integration of this profile delivers a $r_l = 12.9\ \mu m^2/s$.

Fig. 4 also shows two deposition rate profiles obtained by numerical simulation and fitted to the experimental data. They were obtained by simulating the process gas flow around a "short" susceptor, similar to the real trolley, and around a "long" susceptor, as long as the chamber length. The strong increase in deposition rate on the edges of the short susceptor originates from the finite length of the susceptor: the thinning of the carrier gas boundary layer on the edges leads to an enhanced deposition. In the case of the long susceptor, the edge effects disappear and the deposition rate profile appears in its full extent. The in-line deposition rate r_l corresponding to this profile can be calculated from Eq. (3) by profile integration. Choosing experimental values as travel boundaries x_0 and x_1, we extract a $r_l = 12.9\ \mu m^2/s$.

Using the growth parameters of Fig. 4, we deposit pentacene on a susceptor travelling at constant speed underneath the showerhead. Fig. 5 shows a mapping of the thickness of a pentacene film grown in these conditions over a 4″ wafer. The standard deviation of the thickness over the whole wafer surface is low: 1.1%. The showerhead long axis is parallel to the vertical y direction of the image. Uniformity along this direction is optimized by carefully engineering the design of the showerhead. The smooth movement of the trolley ensures the uniformity along the horizontal x direction. However, in Fig. 5, the thickness on the left and right sides appears to be higher than in the center. This is a consequence of the edge effects revealed by the simulation on short susceptor in Fig. 4. In a roll-to-roll system with an infinite substrate, the uniformity along the horizontal direction should further improve. Following Eq. (3), the in-line deposition rate of the layer represented in Fig. 5 is calculated by multiplying the final thickness with the trolley velocity. A value of 13.2 $\mu m^2/s$ is extracted at the center of the wafer, which is close to the 12.9 $\mu m^2/s$ predicted by the long profile integration.

4.2. Growth speed optimization

A systematic study of the influence of in-line OVPD pentacene growth parameters on in-line deposition rate r_l has been carried out, the output of which is shown in Fig. 6. In OVPD, the organic flux condensing on the substrate is determined by the succession of evaporation and transport phenomena taking place within the system [15]. An analytical model of the evaporation exists [16] that can successfully explain the behavior of r_l as a function of the source flow n_s and the furnace temperature T_{fur} visible in Fig. 6a. This model also predicts that r_l drops with an increase in source cell pressure. Regarding the transport of organic species within the OVPD chamber, it can be shown by numerical simulation that conditions that favor an increase in carrier gas velocity also enhance convective transport of organic species towards the pump ports and therefore lower the chamber material utilization efficiency η_{ut}.

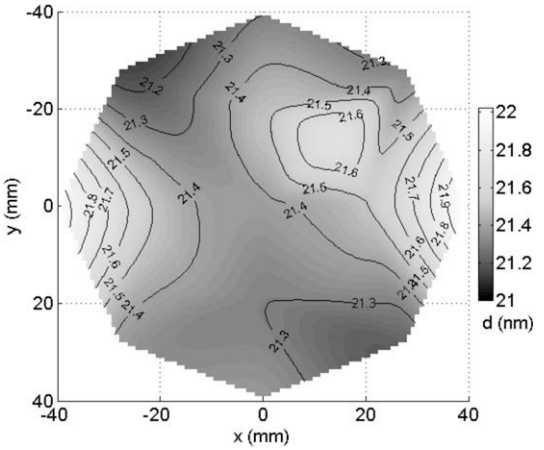

Fig. 5. Mapping of the thickness d of a typical pentacene film grown by in-line OVPD over a 4″ wafer. The thickness standard deviation over the wafer is ±1.1%. Following Eq. (3), multiplication of the layer thickness with trolley velocity delivers a $r_l = 13.2\ \mu m^2/s$.

An increase in total flow n_{tot} increases the source cell pressure and lowers chamber efficiency, explaining the important drop of r_l with n_{tot} in Fig. 6b. On the other hand, an increase of chamber pressure P slightly increases source cell pressure but improves chamber efficiency. These two effects counteract each other, explaining the limited effect of P on r_l seen in Fig. 6c.

Another studied parameter is the trolley velocity v_t depicted in Fig. 6d. A priori, an acceleration of the trolley should trigger an inversely proportional decrease of the fi-

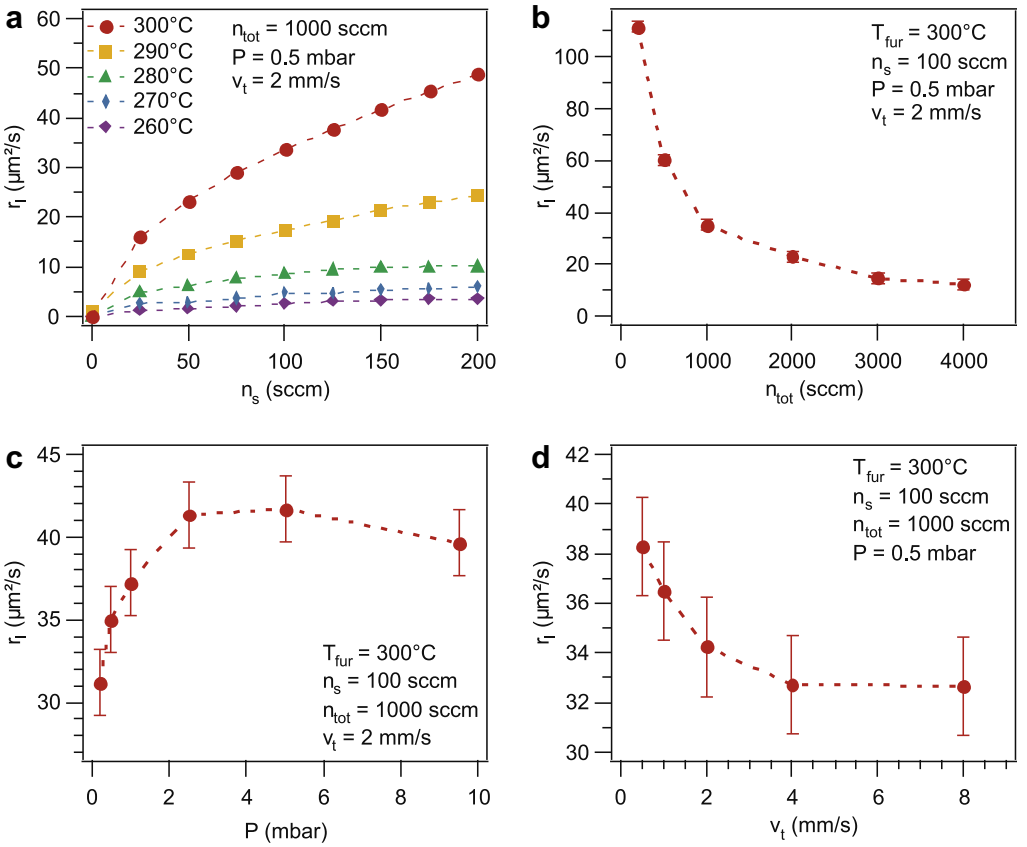

Fig. 6. Dependence of in-line deposition rate r_l on growth parameters. (a) r_l vs. source cell flow and furnace temperature; (b) r_l vs. total flow; (c) r_l vs. chamber pressure; (d) r_l vs. trolley velocity. The insets in each graph show the values of the growth parameters kept constant for all experimental points of the considered graph.

nal thickness d, leaving the in-line deposition rate r_l unchanged. However, r_l appears to be greater at low v_t. It is only at higher velocities that r_l becomes independent of v_t. The reason for the (small) decrease is unclear. It could be related to effects due to the finite size of the trolley.

As the main motivation of in-line processing is to enhance the production throughput, the OVPD growth parameters have been optimized to reach high in-line deposition rates. The graphs of Fig. 6 reveal that the two parameters that influence the most r_l are the furnace temperature and the total carrier gas flow. To reach the highest deposition speeds, T_{fur} is set at 320 °C and n_{tot} is decreased to 150 sccm. With these conditions, we reach an in-line deposition rate of 1055 μm²/s. This corresponds to a web speed of 2.1 m/min and to a 4″ static average deposition rate of 105 Å/s. Such a high speed is two orders of magnitude over what VTE usually reaches. Only Shtein et al., using organic vapor jet deposition could reach higher deposition rates for pentacene, but on dots with a diameter smaller than 100 μm [17].

4.3. Functional pentacene films grown at high speeds

In addition to deposition speed optimization, we studied the evolution of the electrical quality of pentacene thin films processed in-line and at high deposition speed. In order to establish a benchmark to assess our electrical results, control samples were fabricated, based on VTE-deposited pentacene layers. These samples have an OFET top-contact structure similar to the one displayed in Fig. 2. Two structural variations were simultaneously tested in this control experiment: (i) variation on the dielectric pretreatment: OFETs were fabricated with and without the PαMS layer on top of SiO_2; (ii) variation on pentacene deposition rate: both a low and a high rate were tested.

Measurement output for this set of VTE control samples is shown in Fig. 7. As expected, the pentacene layer deposited at a low rate (0.2 Å/s) on PαMS delivers the best transistor, with a saturation hole mobility μ_{sat} of 0.8 cm²/V s and a threshold voltage V_T of −0.6 V. In the absence of surface pretreatment, μ_{sat} is almost halved while other transistor characteristics remain good. This beneficial effect of PαMS on charge transport has also been observed by others [18] and justifies the systematic use of this pretreatment. Depositing pentacene at high rates (5.2 Å/s) results in an important worsening of transistor characteristics: μ_{sat} drops while V_T and the subthreshold slope greatly increase. These effects are attributed to a global increase of the trap density within the transistor channel [13]. This

points towards a very defective microstructure of the pentacene polycrystalline layer grown at high speed by VTE [19].

Fig. 8 shows typical transfer and output curves measured on a top contact OFET based on a pentacene thin film deposited by in-line OVPD. The transistor characteristics are apparently well-behaved: V_{ON} close to 0 V, the steep subthreshold slope (<0.4 V/dec) and the negligible hysteresis indicate high purity and low trap density. The saturation hole mobility μ_{sat} of this device is 1.01 cm^2/V s. These transistor characteristics advantageously compare to those of the best VTE control sample of Fig. 7. However, a major difference lies in pentacene growth speeds: $r = 0.2$ Å/s for the VTE control sample and $r_l = 431$ $\mu m^2/s$, equivalent to a $r_{avg} = 43$ Å/s, for the device shown in Fig. 8, which is based on an in-line OVPD-deposited pentacene film.

In fact, similar OFET characteristics were observed on most of the pentacene films prepared with the in-line OVPD, up to the highest speeds [20]. The observation that thin film electrical properties do not suffer from increased growth speeds contradicts previous reports [6]. It also opposes what we observed during the VTE control experiment of Fig. 7 according to which pentacene deposition at too high rates leads to inferior transistor characteristics. On the contrary, using certain conditions of in-line OVPD deposition, the opposite trend was even observed. Fig. 9a shows the evolution of the saturation mobility measured on thin films deposited at low total flow, with an increasing furnace temperature. This graph reveals that, in those conditions, the saturation mobility linearly increases with the logarithm of the in-line deposition rate. In order to study this effect in more details, three samples present in Fig. 9a are selected. They all have a pentacene thickness of 100 nm and are deposited with in-line deposition speeds of, respectively, I = 21, II = 343 and III = 961 $\mu m^2/s$. They are characterized by XRD in Fig. 9b and by AFM in Fig. 9c.

Pentacene growth on an inert substrate such as PαMS follows the description by Stranski–Krastanov [21]: after a two-dimensional layered growth, there is a transition towards a three-dimensional island growth, which, in the case of pentacene, appears to be mostly terraced. Such dendritic terraced islands are visible on all three AFM micrographs in Fig. 9c. Terrace step height is about 15 Å, indicating that the pentacene molecules are oriented with their long axis close to the normal direction of the substrate. In sample I, islands are larger than in other samples, but their center is often split into small high grains. Terraced islands are smaller in sample II and III but remain reasonably large considering the high growth speeds. At such speeds, a second mode of three-dimensional growth appears under the form of dispersed networks of fine needles, with a height of up to 200 nm. In VTE-grown pentacene films, bulkier needles become apparent with deposition rates above ~1.5 Å/s [22].

The XRD spectra of all three samples in Fig. 9b reveal the presence of a family of peaks attributed to reflection on the (0 0 1) planes. This confirms that *ab* planes of the crystal are parallel to the substrate. This is characteristic of layered and terraced growth. The interplanar distance d_{001} extracted from the spectra is 15.4 Å, typical of the "thin film" phase T of pentacene [23]. Moreover, a second family of peaks is also apparent on the three spectra, but with less intensity. It is also attributed to reflection on the (0 0 1) planes but with an interplanar distance of $d_{001} = 14.4$ Å, typical of the "bulk phase" B of pentacene [23]. The occurrence of such polymorphism within one pentacene thin film is usually thickness dependent, but can also be triggered by growth conditions [24]. Finally, two supplementary peaks at $2\theta = 19.3°$ and 24.0° are visible in the spectra of sample II and III. These correspond to interplanar distances of, respectively, 4.6 and 3.7 Å. These distances could be attributed to reflection on, respectively, (1 1 0) and (½ 0 0) planes in pentacene, revealing crystals with a different orientation relative to the substrate. These peaks could be characteristic of needles visible in the AFM micrographs of these two samples.

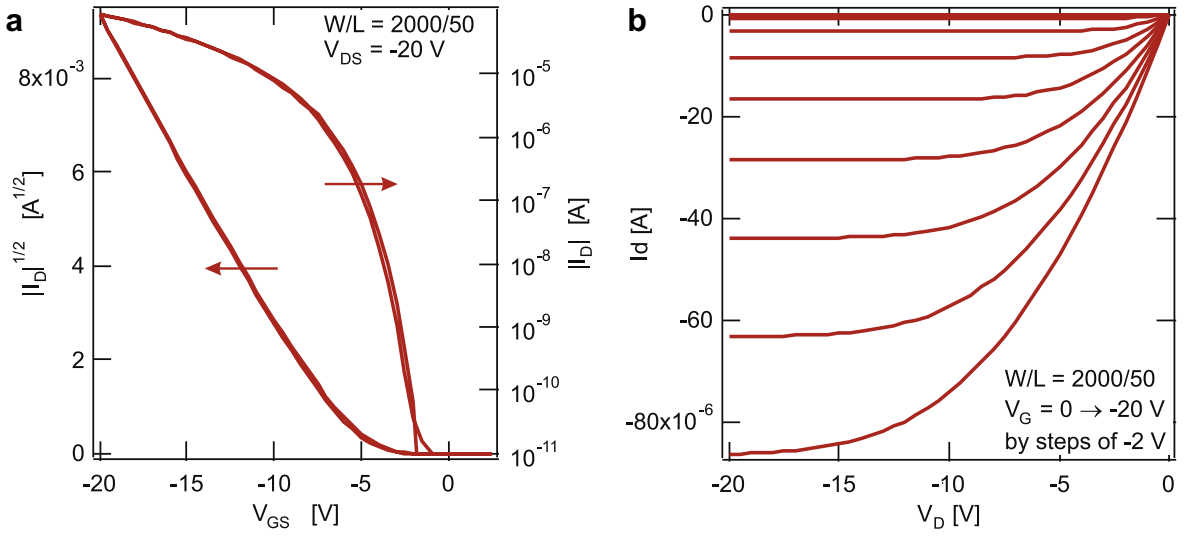

Fig. 8. Measurement of a typical top contact OFET based on a pentacene thin film deposited by in-line OVPD with a $r_l = 431$ $\mu m^2/s$, equivalent to a $r_{avg} = 43$ Å/s on a 4″ substrate. (a) Transfer curve measured in saturation; (b) output curve.

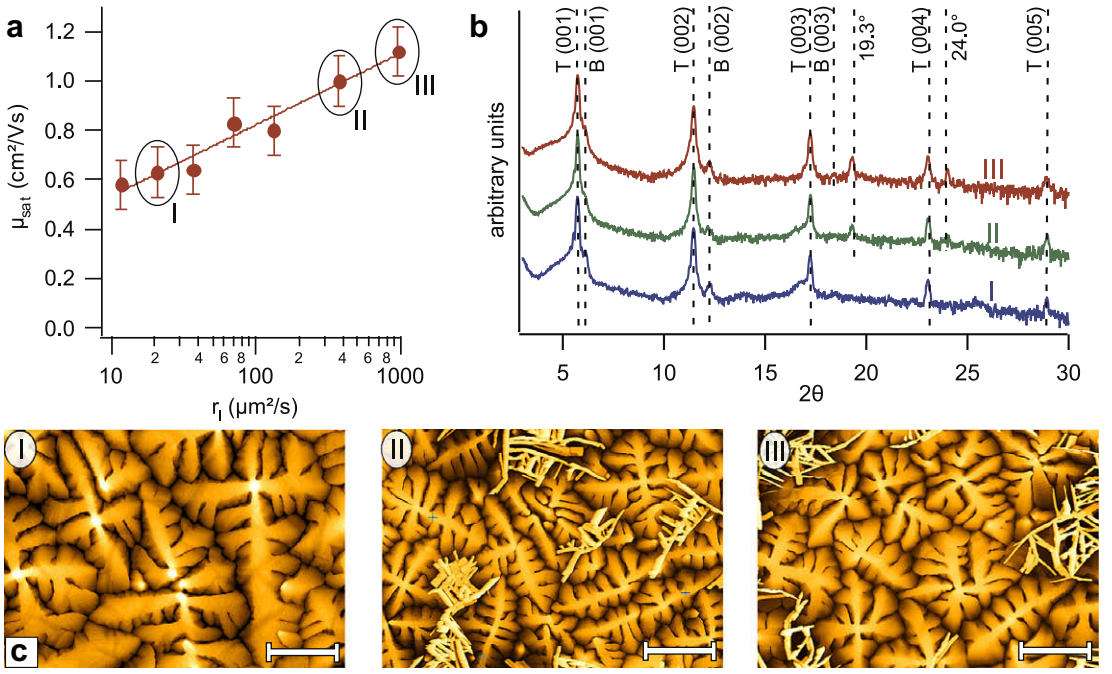

Fig. 9. (a) Top contact saturation mobility vs. logarithm of the in-line deposition rate. The linear fit is drawn as a guide for the eye. r_l of the selected samples are: I = 21, II = 343 and III = 961 μm^2/s. The selected samples have a pentacene thickness of 100 nm. (b) XRD spectra of the selected samples. T denotes thin film phase and B, bulk phase. (c) AFM images of the selected samples. Bars are 2 μm long.

The AFM and XRD data are not sufficient to clarify the improvement of the saturation mobility with the in-line deposition rate visible in Fig. 8a. The AFM data shows that, contrarily to what is usually observed in static systems [16], terraced island size does not drastically reduce upon an increase in deposition speed. The XRD data reveals that all three samples are of good crystalline quality, with T(0 0 l) peaks that are intense and repeated up to high orders [25]. Both characterization techniques show evidences that thin films conserve their good electrical performances up to the highest deposition rates. It is generally accepted that the electrical quality of a pentacene thin film is strongly dependent on the morphology of the first layered pentacene monolayers formed on the dielectric [26]. In in-line OVPD, considering the progressive deposition rate profile $r(x)$ measured in Fig. 4, these first monolayers are formed at low deposition rate. We tentatively attribute the good electrical performance of our pentacene films grown at high average speeds to this slow formation of the first monolayers.

Finally, other OVPD process parameters are equally important for the electrical properties of in-line deposited pentacene films. Electrical characteristics generally improve when the film is deposited at a lower pressure and at substrate temperatures above 60 °C. Furthermore, when growing at low in-line deposition rates, a too low total flow is harmful for the electrical characteristics. Using these basic rules, a sample grown at 41 μm^2/s, using a pressure of 0.5 mbar, a total flow of 1000 sccm and a substrate temperature of 65 °C reached a mobility of 1.4 cm^2/V s. At higher speeds, a mobility of 1.5 cm^2/V s is obtained on a sample grown at 751 μm^2/s, using a pressure of 0.1 mbar, a total flow of 350 sccm and a substrate temperature of 65 °C.

5. Conclusion

The OVPD technique has been successfully extended to an in-line geometry, with the susceptor undergoing a linear movement under an elongated showerhead. Experimental measurements reveal the spatial evolution of the deposition rate whose full profile is obtained by means of numerical simulations. As a consequence of the reduced dimensionality of the in-line system, the in-line deposition rate is defined that characterizes in-line growth speeds. A systematic parameter study using pentacene as a test material permits to draw calibration curves of the system and to define high deposition speed conditions. Pentacene is grown with thickness standard deviation as low as 1.1% over a 4″ substrate and an in-line deposition rate of up to 1055 μm^2/s. This corresponds to a web speed of 2.1 m/min and to a 4″ static deposition rate of 105 Å/s. Electrical properties of pentacene are probed via top-contact thin film transistors measurements. These transistors show high saturation mobilities (up to 1.5 cm^2/V s) and excellent characteristics that are conserved up to the highest deposition rates. This result opposes the usual observation that high pentacene deposition rates are very harmful to transistor characteristics. In contrast to pentacene layers deposited in static systems, the morphology of our pentacene films does not suffer from high growth speeds: grain sizes stay reasonable and crystalline order remains high. We attribute the conservation of excellent electrical prop-

erties up to the highest growth speeds to the progressive deposition profile that ensures a slow formation of the first pentacene monolayers. This work shows that in-line OVPD is a very promising candidate for the sheet-to-sheet and roll-to-roll processing of small molecular weight organic semiconductors.

ABSTRACT

We investigated the switching behavior of the polyfluorene-derivatives (WPF-oxy-F) with and without metal ions (Ca^{2+} and Na^{+}). Basic memory behavior (e.g., current–voltage sweep, cumulative probability and retention) was not significantly affected by the metal ions, and the materials displayed an on/off ratio of more than three orders of magnitude, as well as good device-to-device uniformity and $>10^4$ s of retention time. However, the threshold voltage of Na-WPF-oxy-F containing Na^{+} was found to be lower than that of Ca-WPF-oxy-F containing Ca^{2+}, due to the looser binding between the sodium ion and the ethylene oxide unit in Na-WPF-oxy-F. Both Ca-WPF-oxy-F and Na-WPF-oxy-F showed area dependence in the low resistance state, implying that localized current flow is assisted by metal ions. In addition, the response time of Ca- and Na-WPF-oxy-F was faster than that of WPF-oxy-F, suggesting possible modulation of memory performance by the addition of metal ions in the polymer layer.

1. Introduction

Recently, organic based electronic devices have been intensively studied due to their flexibility, low cost, ease of fabrication and printing capabilities [1–5]. With the rapid development of information technology, the demand for inexpensive and high density data storage media has increased. Organic non-volatile memory devices have been some of the most promising candidates for next generation storage media [6–17].

There have been many efforts to develop optimal structures and fabrication methods for organic non-volatile memory devices [6–17]. Many research groups have tried to develop novel organic materials or mixtures of host polymer material and metallic nanoparticles that exhibit good memory performance [13,15–17]. Recently, we demonstrated sub-micron scale polymer non-volatile memory devices fabricated using a scalable via-hole structure that showed potential for high density polymer non-volatile memory applications [18]. In addition, combined transistor and organic memory device (one transistor and one resistor, 1T-1R) and combined organic diode and organic memory device (one diode and one resistor, 1D-1R) structures were shown to prevent random accessibility in organic non-volatile memory applications [19,20]. Although they showed satisfactory switching behavior, the devices lacked the performance necessary for realistic memory applications without sophisticated control of the switching parameters or an understanding of the switching mechanism. Joo et al. determined operation voltage threshold behavior in organic based memory devices by controlling ionization of a copper electrode [21], and showed the memory behavior dependence on field strength and temperature. Ma et al. reported organic non-volatile memory devices with controlled copper–ion concentrations within the organic layer [22]. However, the specific effects of metal ions on the switching behavior of organic memory

devices have not been thoroughly investigated, and it is possible that addition of metal ions in organic memory devices could be used to control switching parameters.

In this study, the effects of metal ions on memory performance and specific switching parameters were investigated. Our results show that while the basic current–voltage characteristics of the polyfluorene-derivative were not significantly affected by the addition of metal ions, studies on the change in threshold voltage, area dependence of each resistance state and transient responses indicated that metal ions assisted localized conduction and induced faster responses.

2. Experimental

Single component polyfluorene-derivative memory devices were fabricated in metal–insulator–metal (MIM) structures on heavily doped p-type (1 0 0) silicon (p^+ Si) substrates (0.001–0.015 Ω cm). After the typical ultrasonic cleaning processes with acetone, methanol, and DI water, silicon wafers were treated with diluted HF to remove the native oxide layer and eliminate the possible role of interfacial SiO_2 layer on the switching behavior. Poly[(9,9-bis((6′-(*N*,*N*,*N*-trimethylammonium)hexyl)-2,7-fluorene)-alt-(9,9-bis(2-(2-methoxyethoxy)ethyl)-fluorene)] dibromide (denoted WPF-oxy-F) and its derivatives (Ca-WPF-oxy-F and Na-WPF-oxy-F) was used as an active layer, schematically shown in Fig. 1 [23]. The three kinds of polyfluorene-derivatives were first dissolved in methanol at a concentration of 10 mg/ml, and then were spin coated on the highly doped p-type silicon substrate. Typically, spin-coating was performed at 2000 rpm for 30 s, and the resulting thickness of the films was ~60 nm. To improve the film uniformity and eliminate the solvent from the films, the films were baked at 150 °C for 20 min on a hotplate in a nitrogen-filled glove box. The top electrodes of the MIM devices were patterned with a shadow mask with square patterns of four different sizes: $50 \times 50\ \mu m^2$, $100 \times 100\ \mu m^2$, $200 \times 200\ \mu m^2$ and $400 \times 400\ \mu m^2$. A 100 nm thick Ag layer was deposited as the top electrode using a thermal evaporator under a pressure of $\sim 10^{-6}$ torr. The memory device structure is schematically shown in Fig. 1d.

X-ray photoelectron spectroscopy (XPS) measurements were carried out using a MultiLab2000 (THERMO VG SCIENTIFIC) system equipped with monochromatised Mg Kα radiation at $h\nu = 1253.6$ eV at a pressure of 1×10^{-9} Pa ($\sim 7.5 \times 10^{-12}$ torr). The binding energies were calibrated to the C1s peak at 285 eV. Both room temperature current–voltage (*I*–*V*) measurements and pulsed *I*–*V* measurements were conducted using a semiconductor parameter analyzer (HP4155C). Additionally, transient voltage response tests were performed with a two-channel pulse generator (Agilent Technology 81104A) and a two-channel oscilloscope (Tektronix TDS 3054B), which were connected to a PC with a general purpose interface bus (GPIB) using a Labview program. The Ag top electrode was connected to a signal line, and the bottom electrode was used as a grounding electrode. All electrical characterization was performed under ambient conditions.

3. Results and discussion

To investigate the effect of metal ions on memory performance, we used WPF-oxy-F and its derivatives bound with mobile metal ions (sodium and calcium) [23]. Chemical structures are shown in Fig. 1. These materials were denoted Na-WPF-oxy-F when containing sodium ions and

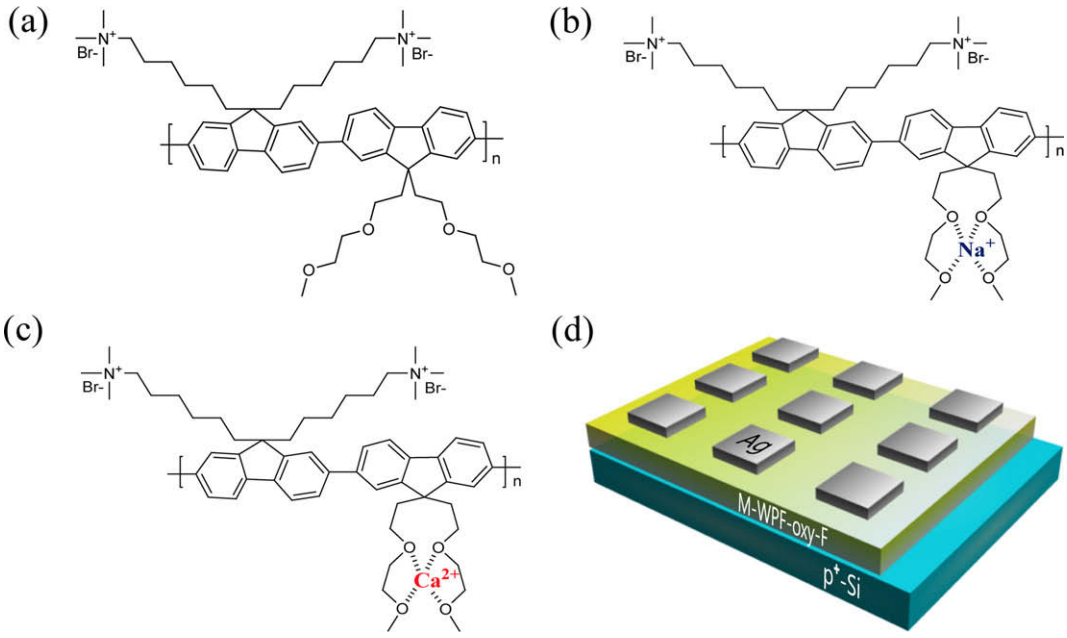

Fig. 1. Chemical structures of polyfluorene-derivatives (a) WPF-oxy-F, (b) Na-WPF-oxy-F and (c) Ca-WPF-oxy-F. (d) Schematic of MIM-type organic nonvolatile memory device.

Ca-WPF-oxy-F when containing calcium ions. The polyfluorene-derivatives with and without metal ions were used as active layers in metal–insulator–metal (MIM) type polymer non-volatile memory devices. To verify the existence of metal ions in M-WPF-oxy-F (where M indicates a metal ion), we performed X-ray photoelectron spectroscopy (XPS) analysis. Fig. 2 shows the XPS spectra of the oxygen 1s (O 1s) peak for each polyfluorene-derivative. For WPF-oxy-F, the O 1s peak equaled ~533 eV, indicating no binding between metal ions and the ethylene oxide unit. On the other hand, the M-WPF-oxy-F series with Na and Ca ions showed Na^+–O and Ca^{2+}–O binding in the O1s spectra as shown in Fig. 2, indicating binding between Na^+ or Ca^{2+} ions and the ethylene oxide unit [24,26]. Because Ca^{2+}–O has a higher binding energy than Na^+–O, binding between Ca^{2+} and the ethylene oxide unit is stronger than that of Na^+ [27].

The MIM polymer memory device structure is shown in Fig. 1d. In our previous work, we reported current–voltage (I–V) characteristics of WPF-oxy-F in an MIM structure [17]. Reversible switching behavior was observed within the range of 5 to −3 V. The initial state of the polymer memory devices was a high resistance state (HRS). When a positive bias was applied to the top electrode, the current began to increase gradually, and then abruptly jumped to around 3–4 V as the material changed from a HRS to a low resistance state (LRS), as shown in Fig. 3. Conversely, when a reverse voltage sweep was performed on the devices from 5 to −3 V, the current was maintained at a LRS and then decreased somewhat abruptly, indicating a change from a LRS to a HRS. Despite structural differences among these polyfluorene-derivatives, switching behavior was relatively uniform (Fig. 3).

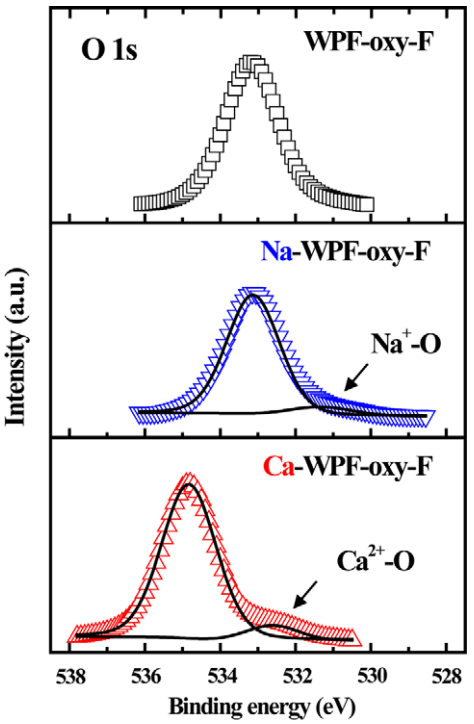

Fig. 2. XPS spectra of oxygen 1s peaks for WPF-oxy-F, Na-WPF-oxy-F and Ca-WPF-oxy-F.

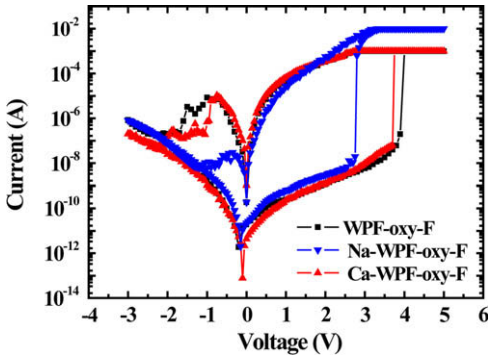

Fig. 3. Semi-log scale I–V characteristics of WPF-oxy-F, Na-WPF-oxy-F and Ca-WPF-oxy-F with a cell size of 50 × 50 μm^2.

To investigate the effects of metal ions on polyfluorene-derivatives, we characterized their basic memory performance. Fig. 4a shows the cumulative probability of resistance values (cell size of 50 × 50 μm^2). We measured a total of 81 memory devices (20 WPF-oxy-F devices, 37 Na-WPF-oxy-F devices and 24 Ca-WPF-oxy-F devices). The HRS of the three polymer memory devices showed very narrow resistance distributions. The distributions of the LRS were within two orders of magnitude, a slightly wider distribution than that of HRS. However, on/off ratios

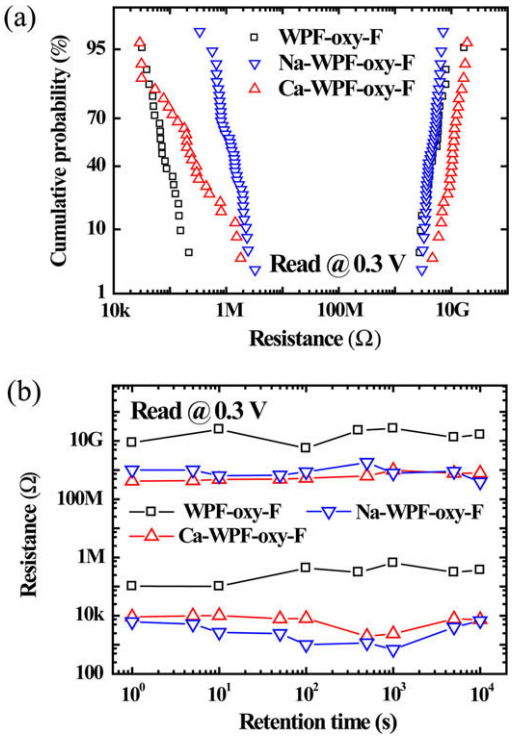

Fig. 4. (a) A Cumulative probability data sets of WPF-oxy-F, Na-WPF-oxy-F and Ca-WPF-oxy-F. (b) Retention characteristics of WPF-oxy-F, Na-WPF-oxy-F and Ca-WPF-oxy-F measured at room temperature.

of mean resistance values for each type of polymer memory devices were still more than three orders of magnitude, indicating excellent device-to-device uniformity in these polyfluorene-derivatives. Fig. 4b shows the retention characteristics of each polymer memory device. Written and erased data were held more than 10^4 s while maintaining on/off ratios of more than three orders of magnitude during the retention characterization. The metal ions did not show any distinct effects on basic memory performance (i.e., *I–V* sweeps, device-to-device uniformity and retention characteristics).

We also investigated the effect of metal ions on the threshold voltages and on/off ratios. Fig. 5a shows the distributions of threshold voltage (i.e., the voltage when changing from a HRS to LRS) for each polymer memory device. Although the three kinds of polyfluorene-derivatives had different average threshold voltages, most devices were within the voltage range of 2.5–4.0 V. For example, when we plot the histogram on the threshold voltage for Na-WPF-oxy-F (inset of Fig. 5a), we see a distribution of threshold voltages within 1 V around 2.8 V, indicating reliable switching performance. The other memory devices also showed similar distributions (data not shown). A previous study on the effect of metal ions on switching behavior reported that switching behavior is controlled by two processes: metal ionization and ion drift [21]. Electric field strongly influences the switching behavior, and the switching probability increases sharply around the threshold electric field [21]. In M-WPF-oxy-F containing metal ions, the metal ions are incorporated into the ethylene oxide side groups (see Fig. 1). It is well known that the ethylene oxide unit can be used as a channel for transport of mobile ions even in solid state [24,25]. Hence, when the devices are in the writing process, it is expected that the mobile ions in the ethylene oxide units are rearranged with an applied bias and form conducting current path [27]. This would affect the threshold voltage of the polymer memory devices. The looser bond between the ethylene oxide unit and Na^+ ion (as compared to Ca^{2+} ions, as explained in Fig. 2) results in Na^+ ions moving more easily than Ca^{2+} ions under the same bias conditions. Therefore, Na-WPF-oxy-F displayed a lower threshold voltage than Ca-WPF-oxy-F.

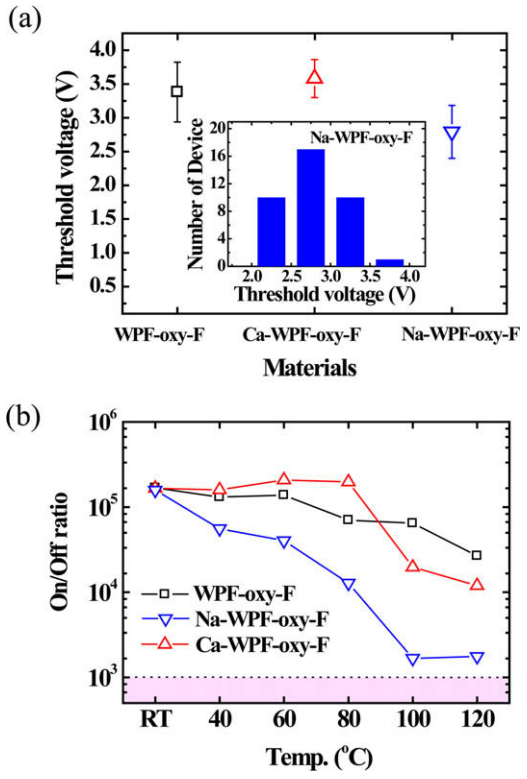

Fig. 5. (a) Distributions of threshold voltage of organic non-volatile memory devices with WPF-oxy-F, Na-WPF-oxy-F and Ca-WPF-oxy-F. Inset shows the histogram of threshold voltage for Na-WPF-oxy-F. (b) Comparisons of on/off ratios of three kinds of polyfluorene-derivatives measured at various temperatures.

Fig. 5b shows the on/off ratios of polymer memory devices at different temperatures. The on/off ratios were measured by the voltage sweep method and read at 0.3 V. In the initial state (at room temperature), all the memory devices showed on/off ratios of more than five orders of magnitude. Although the on/off ratios started to decrease after 60 °C, they retained on/off ratios of more than three orders of magnitude, indicating reliable switching behavior. Only WPF-oxy-F showed a gradual decrease in its on/off ratio. This decrease was due to the increase of leakage current in the HRS, which is enhanced by the hopping current as temperature increases [28]. The on/off ratios of Ca- and Na-WPF-oxy-F reduced considerably near 80 °C due to both hopping current increases and high-temperature activated metal ion movement through the ethylene oxide side groups. Na-WPF-oxy-F showed more rapid on/off ratio reduction with increasing temperature than Ca-WPF-oxy-F. This phenomenon is also related to the different binding energies between the ethylene oxide unit and the Na^+ and Ca^{2+} ions.

To help understand the switching mechanism, we characterized the size dependence of the resistance values of both the HRS and the LRS, as shown in Fig. 6a. The resistance of the polyfluorene-derivative with metal ions (Ca- and Na-WPF-oxy-F) clearly scaled with the reciprocal of the cell size, indicating that the current flowed through the whole cell area in the HRS [28]. This suggests that the metal ions, which exist in polymer layer randomly, allow the current to flow through the whole area in the HRS. On the other hand, dispersed metal ions in each polymer layer are arranged by applied bias and arranged metal ions act as a main current path in the LRS. Most of current flows happen through this current path. Hence the low resistance values of the two polymer materials with metal ions did not change significantly with cell size [29]. One should consider that ionic conduction also partially contributes to the current flow in metal ion based polymer materials. However, unlike Ca- and Na-WPF-oxy-F, the resistance of the WPF-oxy-F did not show any clear size dependence in both LRS and HRS, as can be seen in Fig. 6a. Especially, the slope of log (R)–log (area) at high resistance states observed below 1. This behavior implies that current flows in WPF-oxy-F are affected by not only localized current flows but also space charge limited conduction [17].

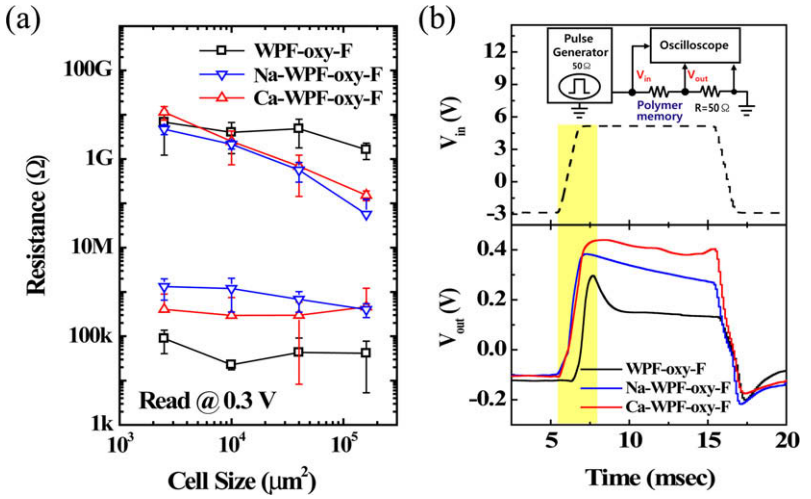

Fig. 6. (a) Resistance values of the on and off states of the three kinds of polyfluorene-derivative memory devices as a function of junction area. (b) Transient response characteristics of the three kinds of polyfluorene-derivative memory devices. The inset shows the circuit of measurement method.

Table 1
Summary of basic switching properties of organic non-volatile memory devices with WPF-oxy-F, Ca-WPF-oxy-F and Na-WPF-oxy-F.

	Band gap [24] [eV]	On/off ratio	*V*th [V]	Response time [μs]	Retention time [s]	Area dependence of HRS
WPF-oxy-F	~2.8	~10^4	3.4 ± 0.5	~2000	~10^4	No
Ca-WPF-oxy-F	~2.8	~10^4	3.6 ± 0.3	~10	~10^4	Yes
Na-WPF-oxy-F	~2.8	~10^4	3.0 ± 0.4	~10	~10^4	Yes

To further study the effects of metal ions on memory performance, we measured pulse delay times for the three kinds of polymer memory devices. The inset in Fig. 6b shows a schematic of the transient response measurements. We monitored input and output voltage pulses using an oscilloscope, and the data are shown in Fig. 6b. By monitoring output voltage (V_{out}) through a 50 Ω external resistor, we estimated the response times for each polymer memory device with cell size of 50 × 50 μm^2. In this analysis, the response time was the delay time between when an input voltage pulse was applied to the device in the HRS and when it switched to the LRS, as shown in the yellow region of Fig. 6b. The transient responses of Ca- and Na-WPF-oxy-F were very similar (~10 μs writing process). On the other hand, the transient response of WPF-oxy-F was ~2 ms, a much slower writing process response. This difference in response time is mainly due to the metal ions that make current paths in the polymer layer.

The properties of the three polymer memory devices are summarized in Table 1. While they show similar memory characteristics (e.g., similar *I*–*V* hysteresis, room-temperature on/off ratio and retention time), considerable differences can be seen in the threshold voltages, on/off ratios as temperature increases, area dependences and response times. Thus, metal ions in the polymer layer can play an important role in the design of polymer memory devices with low voltage operation and fast response. One can expect more sophisticated control of polymer memory device performance with use of various metal ions.

4. Conclusions

We synthesized polyfluorene-derivatives (WPF-oxy-F) with and without metal ions (Ca^{2+} and Na^+) and compared the switching behaviors of each polyfluorene-derivative. Although basic memory behavior (current–voltage characteristics, cumulative probability and retention) was not significantly affected by the metal ions, Ca-WPF-oxy-F and Na-WPF-oxy-F showed area dependence in the high resistance state, implying that metal ions assist localized current flow. The threshold voltage of Na-WPF-oxy-F was lower than that of Ca-WPF-oxy-F because of more efficient Na^+ movement in Na-WPF-oxy-F. In addition, the Ca- and Na-WPF-oxy-F response time was faster than that of WPF-oxy-F, indicating that memory performances could be controlled with the addition of metal ions in the polymer layer.

ABSTRACT

Amorphous AlQ_3 nanowires were fabricated by vapor condensation under a cold trap. Their diameter distributed in a small range of 35–60 nm, but their length was dramatically changed by working pressure. Longer and thinner nanowires could be obtained at a lower working pressure. The most appropriate condition to fabricate long and fine nanowires was to set boat temperature at 410 °C and to control the working pressure of Ar at 1.33×10^3–3.99×10^3 Pa. A higher density of nanowires was observed at a lower working pressure. The dendritic growth mechanism caused by a temperature gradient was proposed to explain the formation of branched nanowires. Due to the absence of quantum confinement effect, the nanowires did not exhibit a PL blue shift as their sizes shrank. When higher density of nanowires were formed at a lower working pressure, stronger PL intensity could be revealed on the emission spectra. The amorphous nanowires also exhibited field-emission behavior. Their $E_{turn\text{-}on}$ ranged from 3 to 20 V/μm and frequently approximated to 10 V/μm, comparable to those of most inorganic 1D nanostructures but somewhat larger than that of CNTs. Larger thickness caused by a higher deposition rate at a higher boat temperature could lead to a smaller $E_{turn\text{-}on}$.

1. Introduction

Nanostructures have received continuously growing interests owing to the peculiar and fascinating properties superior to their bulk counterparts. With a size between the molecules and bulk solid-state structures, nanostructured materials exhibit hybrid properties which are still not completely understood today. The small size of nanostructured materials may result in different electronic, optical, magnetic, chemical, and mechanical properties, and thereby they may be more suitable for noble applications. It is important to develop new advanced nanomaterials for electronics, biotechnology, environment or energy applications. Lots of effort has been devoted to the design and synthesis of new nanomaterials. However, most of the researches were concentrated on inorganic materials. By contrast, the studies related to organic or organometallic nanomaterials were comparatively fewer [1–19]. The development of "soft" nanomaterials is absolutely an inevitable tendency in future nanotechnology. Consequently, organic and organometallic nanomaterials merit more investigation due to their excellent flexibility, high photoconductivity, nonlinear optical effect and low cost [20–22].

It is generally accepted that one-dimensional (1D) nanomaterials such as wires, rods, belts and tubes, provide a good system for investigation of the dependence of electrical and thermal transports or mechanical properties on dimensionality. They are also expected to play important roles as interconnects and functional units in electronic and optoelectronic nanoscaled devices. Nevertheless, in comparison with quantum dots and wells, the advancement of 1D nanomaterials has been slow due to the difficulties associated with the synthesis and fabrication of 1D nanomaterials with well-controlled dimensions, morphology, phase purity, and chemical composition. In this study, we have demonstrated that an organometallic

doi:10.1016/j.orgel.2009.10.007

semiconductor named tris (8-hydroxyquinolinato) aluminium (AlQ_3), could be employed to fabricate long and fine amorphous nanowires under a cold trap by an accessible vapor condensation approach. Since the efficient electroluminescence (EL) from a bilayer organic light emitting device (OLED) was reported, AlQ_3 has become one of the most successful electron transport and emitting materials [23]. It offers the possibilities of flexible displays, more facile deposition of wide-area film, cheaper purification cost, and more versatile color specificity which most inorganic semiconductors do not have [24]. To generate AlQ_3 nanostructures with various geometries has become possible by adjusting the working parameters during the vapor condensation process [2–5]. Some interesting phenomena and optoelectronic properties have been discovered in this work. The growth mechanism of branched AlQ_3 nanowires could be explained by a temperature gradient and the presence of an interface allowed to move forward into sufficiently supercooled gaseous phase. Previously, the field emission of conjugated polymers and organic compound has been reported [25–27]. The amorphous AlQ_3 nanowires also exhibited field mission characteristics comparable to those of some inorganic nanostructures such as SiC or SiCN nanorods [28,29]. In addition, the low working temperatures for vapor condensation is compatible with most electronic processes. Thus this is a brand-new territory and of great potential for optoelectronic applications.

2. Experimental

AlQ_3 nanowires were fabricated by a vapor condensation system which mainly consisted of a process chamber, a pumping system, a heating system and a gauge system. The setup has been presented elsewhere previously [30]. The nanowires were grown on two kinds of substrates: *n*-type (1 0 0) silicon wafer and ITO-coated glass. The Si substrate was used mainly for SEM examination, whereas the conductive ITO-coated glass was employed for field-emission measurement. The morphology and size of the AlQ_3 nanostructures fabricated by vapor condensation were independent of substrate category. The pretreatment of substrates included two steps: rinse and drying. The silicon and ITO substrates were ultrasonically rinsed in acetone and then in isopropyl alcohol, respectively, for 15 min. Subsequently, they were taken out of the solvents and dried by purging with N_2 gas. Commercial AlQ_3 powder (TCI Ltd., T1527, purity >95.0%) was placed on the graphite boat. The silicon or ITO-coated glass substrates were stuck at the underside of the concave stainless steel plate which was 10 cm above the graphite boat. The DC current applied to the graphite boat was supplied by an AC transformer and modulated by the sensitive feedback through a thermocouple contact with the graphite boat. At first, the process chamber was evacuated to a vacuum of 2.7×10^{-4} Pa in 1 h, and then various pressures inside the chamber could be achieved by injecting Ar gas. The pressure was controlled in the range of 1.33×10^3–6.67×10^3 Pa. Subsequently, liquid nitrogen was poured into the concave stainless steel plate for rapid cold trap of the substrates. When the temperature of graphite boat reached 400–420 °C, the commercial AlQ_3 powder started to sublime to form amorphous nanowires on the cold substrates. Most impurities in the commercial powder could be eliminated in the evacuation and sublimation processes, so the nanowires obtained were much purer than the powder.

A field emission scanning electron microscope (FESEM, JEOL JSM-6330F) was used to examine the morphologies of the nanowires on silicon substrates. Due to the poor conductance of AlQ_3, an ultra-thin gold film was sputtered onto the specimen to get clearer image. A low angle X-ray diffraction spectrometer (MAC SIENCE MXP-18, Cu-Kα1) was employed to examine the crystallinity of the nanowires on silicon substrates. A photoluminescence (PL) system composed of a He–Cd excitation laser, a spectrometer and a photomultiplier was utilized to measure the PL spectra of the nanowires. The detection range of wavelength was from 350 to 1000 nm. The field-emission characteristics of the AlQ_3 nanowires were detected by a field emission measuring system mainly comprising a vacuum chamber, a power supply (Keithley 237) and a set of anode–cathode configuration. The anode was a small Pt sphere with a diameter of 650 μm. The specimen was placed on the cathode plate in the stainless steel holder. The movement and position of the anode sphere could be precisely controlled by a triple axis XYZ stage so that local measurement of emission current and a zero-point calibration were achievable. ITO-coated glasses were used as the substrates for field-emission measurement.

3. Results and discussion

3.1. Amorphous AlQ_3 nanowires

When the temperature of the graphite boat reaches 400 °C, AlQ_3 nanowires with an average diameter of 34, 42 and 45 nm are fabricated in Ar of 1.33×10^2, 1.33×10^3 and 3.99×10^3 Pa, respectively, as shown in Fig. 1. It is not easy to estimate the real lengths of the nanowires obtained in Ar of 1.33×10^2 and 1.33×10^3 Pa because they tangle and entwine together. Fig. 1a shows that the length is approximately several μm, whereas Fig. 1b reveals a smaller length than that in Fig. 1a. Nanowires with a length smaller than 1 μm are obtained in Ar of 3.99×10^3 Pa, as shown in Fig. 1c. Similar results are also observed as the temperature of the graphite boat is higher (410 and 420 °C). As displayed in Fig. 2, when the boat temperature is 410 °C, AlQ_3 nanowires with an average diameter of 35, 41, 46 and 60 nm are fabricated in Ar of 1.33×10^2, 1.33×10^3, 3.99×10^3 and 6.67×10^3 Pa, respectively. Fig. 2a–c reveal that the lengths of the nanowires is up to several μm, whereas that in Fig. 2d is smaller than 1 μm. If the boat temperature is further raised to 420 °C, AlQ_3 nanowires with an average diameter of 35 and 44 nm are obtained in Ar of 1.33×10^3 and 3.99×10^3 Pa, respectively, as shown in Fig. 2e and f. The length shown in Fig. 2e is estimated to be several μm, but that in Fig. 2f is smaller than 1 μm.

The above results illustrate that the boat temperature does not have a conspicuous influence on the dimension

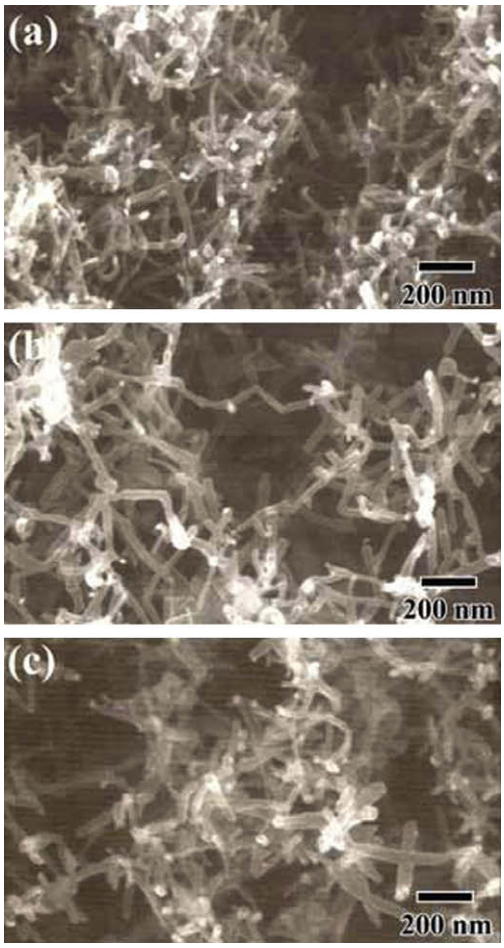

Fig. 1. AlQ_3 nanowires fabricated under a cold trap as the temperature of graphite boat is 400 °C in Ar of (a) 1.33×10^2 Pa, (b) 1.33×10^3 Pa, and (c) 3.99×10^3 Pa.

of nanowires. Unlike a wide distribution of the AlQ_3 nanoparticles [3], the diameter of the nanowires slightly increases with working pressure and its distribution is in a small range of 35–60 nm. On the other hand, the length of nanowires is dramatically changed by altering working pressure. Longer and thinner nanowires can be achieved at a lower working pressure. After the systematic studies, it is concluded that the most appropriate condition for fabrication of long and fine nanowires is to set the boat temperature at 410 °C and to control the Ar pressure at between 1.33×10^3 and 3.99×10^3 Pa. Moreover, a higher density of nanowires is observed at a lower working pressure, indicating that more nanowires congregate in the same area. Similar to AlQ_3 nanoparticles [3], the nanowires formed by vapor condensation are also amorphous, as demonstrated by the XRD pattern in Fig. 3, which shows the crystallinity of the commercial powder as well.

3.2. Growth mechanism

Unlike the fabrication of AlQ_3 nanoparticles in He [3], AlQ_3 nanowires were fabricated in Ar of various working pressures. Ar as well as He is inert gas, and they belong to the same group in the periodic table. Compared to the smaller He atom, an Ar atom has larger volume and weight. Probably due to the different size and gravity from the inert gaseous atoms, AlQ_3 nanostructures with dissimilar geometries could be fabricated in different working gases. How the atomic size and gravity influence the formation of various nanostructures should be further explored by theoretical calculation, which is not included in this work.

The growth of AlQ_3 nanowires is greatly related to the low temperature of the cold substrate and the working pressure in the process chamber. The Ar pressure should be controlled in the range of 1.33×10^2–6.67×10^3 Pa, otherwise abnormal nanostructures, rather than wire-like nanostructures, would be formed. It was found that the most appropriate Ar pressure for achieving fine and long nanowires was between 1.33×10^3 and 3.99×10^3 Pa. A dendritic growth mechanism caused by the temperature gradient is proposed to explain the formation of AlQ_3 nanowires during the vapor condensation process. When the graphite boat reaches the sublimation temperature, AlQ_3 molecules acquire enough energy to sublime and move upward to the cold substrate. As soon as they arrive at the substrate, the molecules freeze quickly and release the latent heat of fusion. Consequently, the temperature of the region where the molecules freeze on the substrate rises. However, the temperature ahead of this region drops because of a heat flow from the frozen solid into the gaseous phase, as schematically presented in Fig. 4. Subsequently, the condition becomes unstable. In the presence of any small perturbation, primary branches of nanowires may grow out from these positions into the gaseous phase. The resulting structures may also become quite complicated, with secondary branches forming on the primary ones, and possibly with tertiary branches forming on the secondary ones, ... and so on, as depicted in Fig. 4b and c.

The reason for the branched growth of AlQ_3 nanowires is not difficult to understand. As shown in Fig. 4b, section *aa* stands for the interface between the solid and gaseous phases where the primary branches start to form. On the other hand, the average temperature at section *bb* is lower than that at section *aa*, so a falling temperature gradient generates. The temperature gradient is responsible for the formation of primary branches. Once the primary branches have formed, the growth at section *aa* becomes slow because supercooling gets small here and the latent heat of fusion tends to further decrease its magnitude. Then secondary branches form because there is also a falling temperature gradient starting at point A on the primary arm and moving toward point B in front ($T_A > T_B$), as displayed in Fig. 4c. Tertiary branches also form for the same reason. Consequently, the branched growth of AlQ_3 nanowires can be attributed to the presence of an interface allowed to move forward into the sufficiently supercooled gaseous phase.

3.3. Photoluminescence

The same as AlQ_3 nanoparticles [3], the nanowires do not exhibit blue shift on their PL emission spectra when their sizes shrink because the molecules are bonded

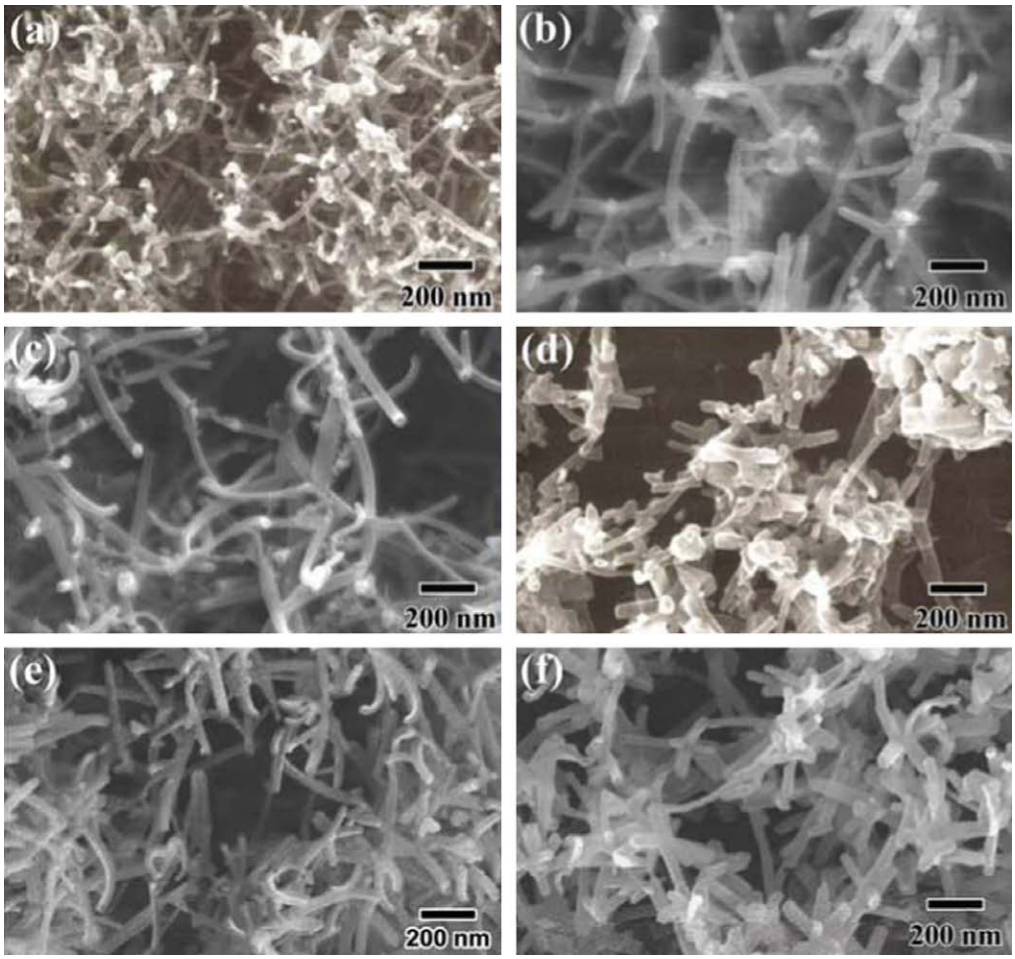

Fig. 2. AlQ_3 nanowires fabricated under a cold trap when the temperature of graphite boat is 410 °C in Ar of (a) 1.33×10^2 Pa, (b) 1.33×10^3 Pa, (c) 3.99×10^3 Pa, (d) 6.67×10^3 Pa, and when the temperature of graphite boat is 420 °C in Ar of (e) 1.33×10^3 Pa and (f) 3.99×10^3 Pa.

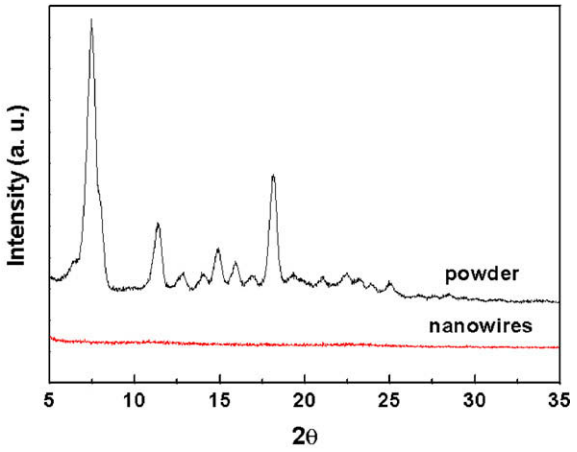

Fig. 3. XRD patterns of AlQ_3 nanowires and commercial powder.

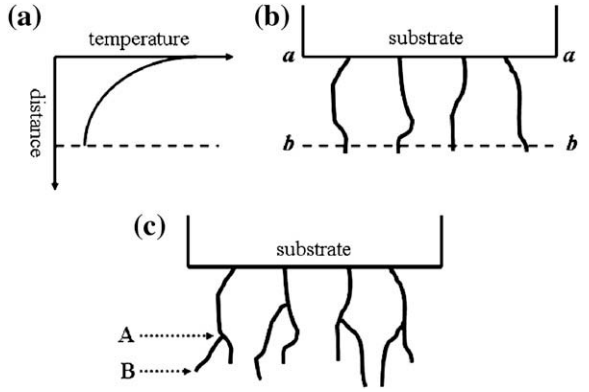

Fig. 4. Schematic growth mechanism of AlQ_3 nanowires. (a) The temperature in advance of section *aa* drops and a falling temperature gradient generates. (b) The primary branches of nanowires grow out. (c) T_A is higher than T_B so the secondary branches form.

together merely by weak van der Waals force. Quantum confinement effect is not expected to exist in this kind of organometallic material [31]. Previous literature has demonstrated that both AlQ_3 nanoparticles and nanowires ex-

hibit a stronger PL emission than that of AlQ_3 thin film [30]. Similar results are also demonstrated in this work. The specific surface area of nanowires is much larger than that of the film, so enhanced absorption of excitation light and a stronger PL emission are observed. The emission ranges of various nanowires are from 4400 to 7200 Å, and the maximum intensities are all located at around 5270 Å, as shown in Fig. 5. The PL spectra of the nanowires fabricated in Ar of 1.33×10^2, 1.33×10^3 and 3.99×10^3 Pa when the boat temperature is 400 and 410 °C are displayed in Fig. 5a and b, respectively. Stronger PL intensity is revealed from the nanowires fabricated at a lower working pressure. Unlike AlQ_3 nanoparticles [3], the nanowires have a narrow distribution of diameter, and a decreased diameter is not supposed to influence their PL property. The enhanced PL intensity can be attributed to the higher density of nanowires formed at a lower working pressure. Higher density indicates that more nanowires congregate in the same area and increases the absorption of excitation light, leading to a stronger PL emission accordingly.

3.4. Field emission

Thanks to the large aspect ratio and field enhancement factor (β) of 1D nanostructures, they have become promising candidates as the field-emission electron source for applications such as field-emission electron microscope, electron source of X-ray and field-emission displays, etc. Lots of effort has been devoted to 1D inorganic nanomaterials such as carbon nanotubes (CNTs), SiC nanowires and nanorods, SiCN nanorods, ZnO nanotips and nanowires, GaN nanorods and CuO nanofibers for a long time [32–42]. Among them, CNTs are one of the most widely investigated materials. It is demonstrated in this work that amorphous AlQ_3 nanowires fabricated by vapor condensation also exhibit field-emission behavior. Their low turn-on field ($E_{\text{turn-on}}$) and high current density are comparable to those of most inorganic 1D nanostructures.

The famous Fowler–Nordheim (F–N) equation [43] is also applicable to AlQ_3 nanowires. The straight line obtained by plotting $\ln(J/E^2)$ versus $1/E$ is regarded as a typical signature of field-emission phenomenon. According to the F–N equation, the slope (m) of the straight line is related to work function (ϕ) and β. As long as m is achieved, β can be calculated if ϕ is already known, or ϕ can be calculated if β is already known. The schematic energy diagram of bulk AlQ_3 material is depicted in Fig. 6a. The dissociation energy from the LUMO to vacuum is around 3.0 eV [44]. Because an exponential distribution of trap states with a characteristic energy 0.15 eV exists below the LUMO and the quasi-Fermi level lies in where the traps distribute, the ϕ of AlQ_3 bulk material is between 3.0 and 3.15 eV.

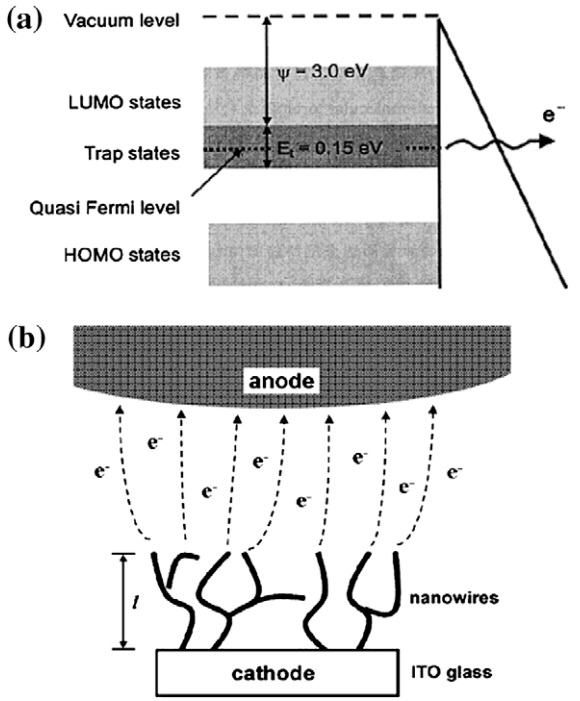

Fig. 6. (a) Schematic energy diagram of AlQ_3 bulk material. (b) Schematic electron emission process from the branched AlQ_3 nanowires.

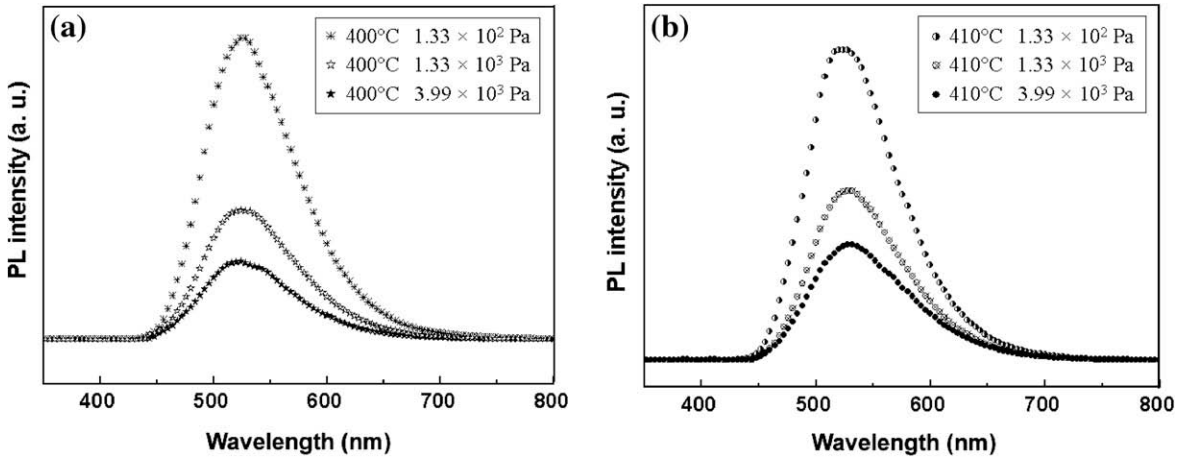

Fig. 5. PL spectra of the AlQ_3 nanowires fabricated in Ar of various working pressures when the boat temperature is (a) 400 °C and (b) 410 °C.

Thus $\phi = 3.15$ eV is used to calculate the β of AlQ_3 nanostructures. According to the report by Tarntair et al. [29], β is related to the geometry of nanostructures and can be expressed by the ratio of the length (l) and radius (r) of an individual nanostructure ($\beta = l/r$). A larger β can be obtained when a nanostructure has a larger l and a smaller r. That is, longer and thinner nanostructures should be more advantageous to field emission.

Fig. 7a shows the J–E curves of various AlQ_3 nanowires. As the applied field is 20 V/μm, the nanowires fabricated at a boat temperature of 400 °C in Ar of 1.33×10^2, 1.33×10^3 and 3.99×10^3 Pa can bear a current density of 31.90, 0.15 and 2.81 mA/cm^2, respectively (curves a–c). The nanowires fabricated at a boat temperature of 410 °C in Ar of 1.33×10^2, 3.99×10^3 and 6.67×10^3 Pa can bear a current density of 13.81, 12.42 and 44.27 mA/cm^2, respectively (curves d–f). With a boat temperature of 420 °C, the nanowires fabricated in Ar of 1.33×10^3 and 3.99×10^3 Pa can bear a current density of 6.25 and 32.49 mA/cm^2, respectively (curves g and h). Table 1 reveals that the current density of AlQ_3 nanowires can not be correlated to their geometries. The maximum current density can be as large as almost 50 mA/cm^2, implying the possibility of employing amorphous AlQ_3 nanowires as emitters with high bearing capacity.

Generally, the magnitude of $E_{\text{turn-on}}$ is regarded as an index of determining whether a nanostructure exhibits a good field-emission characteristic. The $E_{\text{turn-on}}$ is defined as the electric field required to reach a current density of 10 μA/cm^2, and it usually varies with different materials, structures, geometries or measuring instruments. In Fig. 7a, the $E_{\text{turn-on}}$ of curves a, b and c are 10.23, 19.91

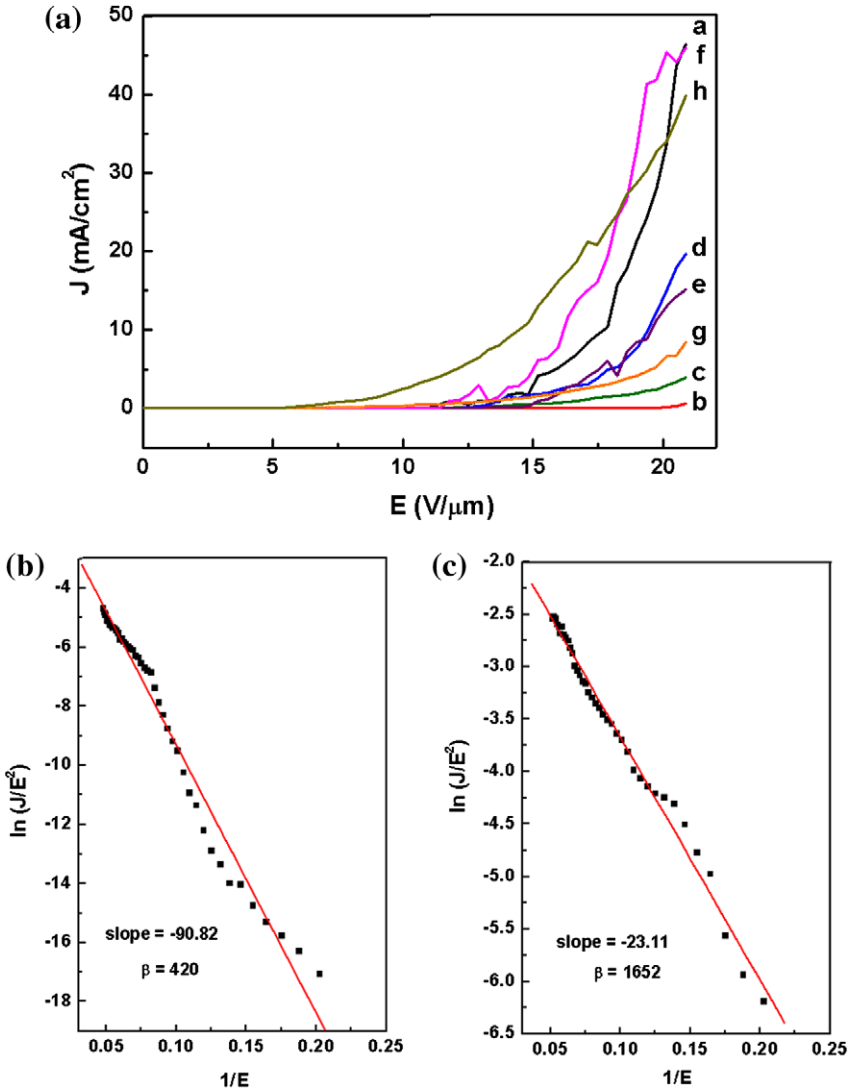

Fig. 7. (a) J–E curves of the AlQ_3 nanowires fabricated at a boat temperature of 400 °C in Ar of 1.33×10^2 (curve a), 1.33×10^3 (curve b), 3.99×10^3 Pa (curve c), at a boat temperature of 410 °C in Ar of 1.33×10^2 (curve d), 3.99×10^3 (curve e), 6.67×10^3 Pa (curve f), and at a boat temperature of 420 °C in Ar of 1.33×10^3 (curve g) and 3.99×10^3 Pa (curve h), respectively. (b) F–N plots transformed from the J–E curves c and h. The straight lines yielded from the high field region demonstrate the field-emission behavior of amorphous AlQ_3 nanowires.

Table 1
$E_{turn\text{-}on}$, $J_{E=20}$ (the current density when the applied field is 20 V/μm) and β estimated from curves a–h of Fig. 7a.

Sample	T (°C)	Ar pressure (Pa)	d (nm)	$E_{turn\text{-}on}$ (V/μm)	$J_{E=20}$ (mA/cm^2)	β
a	400	1.33×10^2	34	10.23	31.91	271
b	400	1.33×10^3	42	19.91	0.15	39
c	400	3.99×10^3	45	10.18	2.81	420
d	410	1.33×10^2	35	9.93	13.81	207
e	410	3.99×10^3	46	11.04	12.42	256
f	410	6.67×10^3	60	10.37	44.27	264
g	420	1.33×10^3	35	3.07	6.25	1445
h	420	3.99×10^3	44	3.21	32.49	1652

and 10.18 V/μm, respectively. For curves d, e and f, the $E_{turn\text{-}on}$ are 9.93, 11.04 and 10.37 V/μm, respectively, whereas for curves g and h, the $E_{turn\text{-}on}$ are 3.07 and 3.21 V/μm, respectively. Table 1 reveals that the $E_{turn\text{-}on}$ of the amorphous AlQ_3 nanowires ranges from 3 to 20 V/μm and frequently approximates to 10 V/μm. This is comparable to those of most inorganic nanostructures but somewhat larger than that of CNTs [32–42,45,46]. Table 1 also discloses that the magnitude of $E_{turn\text{-}on}$ does not correlate to the geometries (diameters) of the nanowires neither. It can be seen that the nanowires fabricated at a boat temperature of 420 °C exhibit a smaller $E_{turn\text{-}on}$. This may be ascribed to the larger film thickness caused by a higher deposition rate.

By plotting $ln(J/E^2)$ versus $1/E$, the *F–N* plots of various AlQ_3 nanowires are obtained. The *F–N* plots transformed from the *J–E* curves c and h in Fig. 7a are given in Fig. 7b and c, respectively, as examples to demonstrate the field-emission behavior of amorphous AlQ_3 nanowires. After obtaining the *F–N* plots, the slopes of the straight lines yielded from the high field region can be estimated, and the corresponding β can then be calculated by substituting the slopes into the *F–N* equation, as displayed in Table 1. According to the definition by Tarntair et al. [29], the l of nanowires can be obtained if the r and β are known, or the β can be calculated if the r and l of nanowires are known. However, the β obtained by estimating the l and r from the SEM micrographs (Figs. 1 and 2) does not match with those calculated from the slopes of the *F–N* plots. Therefore, the definition by Tarntair et al. has to be corrected herein in order to apply to AlQ_3 nanowires. As illustrated in Fig. 4, AlQ_3 nanowires have branched rather than well aligned structures. The process of electrons emitting from the nanowires can be proposed as follows. When an external voltage is applied, the electrons from the cathode are transported through the branches, and then emit from the tips of the branches to the anode, as depicted in Fig. 6b. Consequently, the "l" calculated by multiplying the β with r should be defined as the cross-section thickness of AlQ_3 nanowires, rather than the length of a branch or an individual nanowire. The total thickness of the nanowires deposited on the ITO substrate is calculated and ranges from 3.5 to 9.5 μm. However, the thickness of those fabricated at a boat temperature of 420 °C is over 25 μm, much longer than others. This can be attributed to a higher deposition rate as the boat temperature is higher. Thus larger total thickness of AlQ_3 nanowires results in not only a smaller $E_{turn\text{-}on}$ but also a larger β, which are beneficial for superior field emission.

The comparison in the field-emission properties of amorphous AlQ_3 nanowires with some inorganic and metallic nanomaterials were accomplished [29,32–36,41,45,46]. In terms of the above data and discussion, the $E_{turn\text{-}on}$ of the amorphous nanowires ranges from 3 to 20 V/μm and is usually close to 10 V/μm. Their filed emission characteristic is worse than CNTs, but is comparable to inorganic nanostructures such as SiC or SiCN nanorods [28,29]. The small $E_{turn\text{-}on}$ of some inorganic and metallic nanomaterials may be ascribed to their aligned structures [33–35,41,45,46]. If aligned AlQ_3 nanowires could be obtained, they may become more promising emitters for field emission. Moreover, AlQ_3 nanowires are prepared by a low temperature process, which is more compatible with most electronic processes, so they may find potential applications in electronic or optoelectronic devices.

4. Conclusions

AlQ_3 nanowires could be fabricated under a cold trap by vapor condensation. The diameter of the nanowires was slightly influenced by working pressure and its distribution was in a small range of 35–60 nm. Their length was dramatically changed by working pressure. Longer and thinner nanowires were obtained at a lower working pressure. The most appropriate condition for fabricating long and fine nanowires was to set boat temperature at 410 °C and to control Ar pressure at between 1.33×10^3 and 3.99×10^3 Pa. A higher density of nanowires was observed at a lower working pressure. By XRD analysis, it could be demonstrated that all the AlQ_3 nanowires were amorphous. Their growth was greatly related to the low temperature of substrate and the working pressure in the process chamber. A dendritic growth mechanism caused by a temperature gradient was proposed to explain the formation of AlQ_3 nanowires. The branched growth could be attributed to the presence of an interface allowed to move forward into sufficiently supercooled gaseous phase.

Quantum confinement effect was not expected to appear in AlQ_3 because the molecules were bonded together merely by weak van der Waals force. Thus the nanowires should not exhibit a PL blue shift as their sizes shrank. Stronger PL intensity was revealed when higher density of nanowires were formed at a lower working pressure. This work also demonstrated that AlQ_3 nanowires exhibited field-emission behavior. The $E_{turn\text{-}on}$ of the nanowires ranged from 3 to 20 V/μm and frequently approximated to 10 V/μm. Their low $E_{turn\text{-}on}$ were comparable to those

of most inorganic 1D nanostructures but somewhat larger than that of CNTs, implying the possibility of using them as emitters with high bearing capacity. The magnitude of $E_{\text{turn-on}}$ did not correlate to the geometries (diameters) of the nanowires. Larger film thickness caused by a higher deposition rate at a higher boat temperature led to a smaller $E_{\text{turn-on}}$. If aligned AlQ_3 nanowires could be obtained, they may become more promising emitters for field-emission applications.

ABSTRACT

An excellent gate dielectric of amorphous HfON (a-HfON) can be fabricated by flashing a Hf metal layer prior to a-HfON deposition. Nitrogen incorporation in the HfON film can reduce leakage current density from 8×10^{-7} to 10^{-7} A/cm^2. And surface roughness of a-HfON is reduced by the flash Hf metal layer from 1.9 to 1.2 nm. With the flash Hf metal layer, field effect mobility (0.17 cm^2/V s), threshold voltage (−0.3 V), subthreshold swing (−0.209 V/decade), and on/off current ratio (3.2×10^3) can be achieved for organic thin-film transistors with a-HfON gate dielectric.

1. Introduction

Organic thin-film transistors (OTFTs) have received attention in the applications of flat panel displays and flexible electronics [1–3]. Pentacene, a fused-ring polycyclic aromatic hydrocarbon, is one of the promising materials for the active layers in OTFTs since it exhibits high field effect mobility among organic materials [4,5]. For pentacene-based OTFTs, SiO_2 is frequently used as the gate dielectric and the threshold voltage is about 10 V for a SiO_2 layer of 100 nm thick. In order to lower the threshold voltage, two approaches have been often used. One is to reduce the thickness of the gate dielectric [6]. However, a very thin gate dielectric may have the leakage current problem [7]. The other is to use a high-*k* material as the gate dielectric [8,9]. Hafnium dioxide (HfO_2) is a high-*k* material with very good chemical stability, which has been used to fabricate pentacene-based OTFTs with a low threshold voltage [5,8,10]. The HfO_2 is in a form of amorphous since the deposition is operated at low temperature (150 °C). Nitrogen incorporated amorphous HfO_2 (a-HfO_2) is also an attractive material since it exhibits higher dielectric permittivity than intrinsic a-HfO_2 [11]. The a-HfON film can reduce further the threshold voltage. However, the amorphous HfON (a-HfON) film has been used as the gate dielectric in silicon-based thin-film transistors, rather than OTFTs.

In this article, we present an excellent gate dielectric film of a-HfON fabricated by flashing a Hf metal layer prior to a-HfON deposition. The requirements for a good gate dielectric are low leakage current density, low surface roughness and high-*k*. Low leakage current density can be achieved by the nitrogen incorporation in the HfON film. And surface roughness can be reduced by the flash Hf metal layer. The pentacene-based OTFTs with the a-HfON gate dielectric on a flash Hf metal layer exhibits very good device performance. Various OTFTs with different HfO_2-related gate dielectrics, such as a-HfO_2, a-HfON and a-HfON with a flash Hf metal layer, are fabricated for comparison.

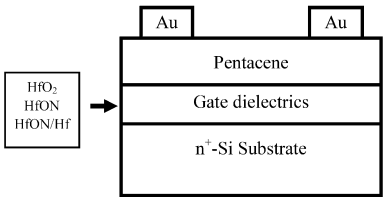

Fig. 1. Schematic showing the structure of an organic thin film transistor with bottom gate and top contact. An ultra-thin Hf metal layer is flashed onto Si(1 0 0) prior to the deposition of gate dielectric.

2. Experimental section

The HfON films with and without a Hf-flash metal layer were chosen as the gate dielectrics for pentacene-based OTFTs. Fig. 1 shows the schematic of a pentacene based OTFT structure. The n^+-Si(1 0 0) wafers were cleaned in the deionized water, and then ultrasonically cleaned in acetone. The n^+-Si(1 0 0) wafers were dipped in a dilute HF solution ($HF:H_2O = 1:100$) in order to remove the native oxide. HfON films of about 50 nm thick were then deposited on the as-dipped n^+-Si(1 0 0) wafers at low-temperature (150 °C) in a radio-frequency (RF) sputtering chamber. The as-dipped n^+-Si(1 0 0) wafers were first transferred to the RF sputtering chamber that was pumped down to a base pressure to 2×10^{-6} torr. The chamber was admitted with a mixing gas of Ar, O_2, and N_2. Mass flow controllers (MFCs) were used to monitor the flow ratio of the mixed gas. The working pressure was 0.25 mtorr. Before the HfON film deposition, a Hf metal layer was flashed onto n^+-Si(1 0 0) by RF sputtering. The Ar flow rate was set to 10 sccm and the RF gun power was operated at 100 W. The bonding characteristics of the HfON films were characterized using X-ray photoelectron spectroscopy (XPS; ESCA1600). With a shadow mask pattern, pentacene films were deposited onto the HfON gate dielectrics with or without a Hf-flash metal layer. The thickness of the pentacene film was about 80 nm and the deposition rate was 0.5 Å/s, which was monitored by a quartz crystal oscillator. The substrate temperature was heated to 50 °C, and work pressure was pumped to 1×10^{-6} torr. Finally, Au was deposited as the source/drain electrodes. Au film thickness was 100 nm, and the shadow mask was used to define the pad. The device channel width and length were defined as 1000 and 100 μm. A metal–insulator–metal (MIM) structure (Al/HfON/Al) with same film thickness of HfON (30 nm) was fabricated to measure the gate leakage current density and the dielectric constant. The area of the Al pad was 1650×1000 μm^2. All electrical characteristics were measured using Agilent 4155c and Agilent 4284 analyzers.

J_{leak} (A/cm^2)	8×10^{-7}	10^{-7}	10^{-7}

3. Results and discussion

Surface roughness and leakage current density (J_{leak}) are critical in the fabrication of an excellent gate dielectric for OTFTs [6,12]. Polycrystalline HfO_2 is not appropriate for gate dielectric since it exhibits high surface roughness and J_{leak} due to the existence of grain boundaries. Amorphous HfO_2 (a-HfO_2) film is a better choice for gate dielectrics since it may exhibit low surface roughness and J_{leak} by removing grain boundaries. In our work, three a-HfO_2 related materials (a-HfO_2, a-HfON, and a-HfON with a flash Hf metal layer) are compared and evaluated to be gate dielectrics in terms of surface roughness and J_{leak}. The evaluation results are listed in Table 1. The a-HfO_2 film was deposited onto Si(1 0 0) by magnetron sputtering Hf metal target in a chamber flowing with a mixed gas of Ar/O_2 (flow rate ratio = 2:4) at 150 °C and 30 W RF gun power. The surface roughness (*Ra*) is ~2.3 nm and J_{leak} is around 8×10^{-7} A/cm^2. By incorporating nitrogen into a-HfO_2 using the gas flow ratio $Ar:O_2:N_2 = 2:4:14$, the *Ra* value of the a-HfON film is reduced to 1.9 nm and the J_{leak} is lowered down to 10^{-7} A/cm^2 at an electric field of 1 MV/

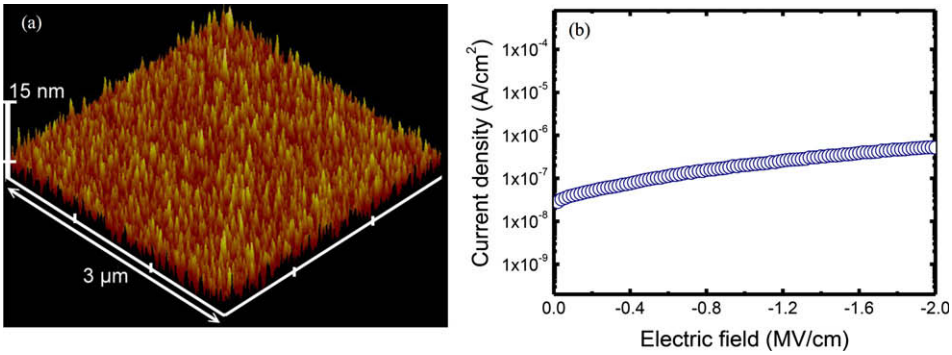

Fig. 2. (a) AFM image showing the 150 °C HfON film with a Hf-flash metal layer. The scanning size is 3×3 μm^2. (b) Leakage current density of the Al–HfON–Al structure as a function of electric field. The maximum bias voltage in OTFT operations corresponds to the electric field of 1 MV/cm.

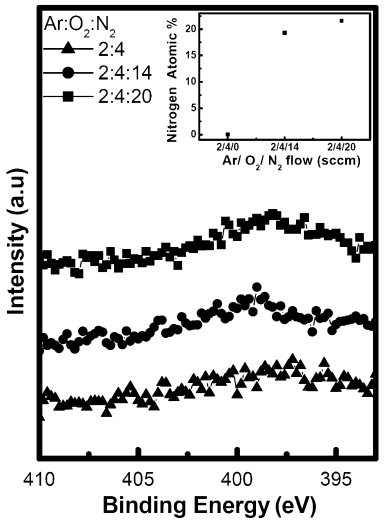

Fig. 3. XPS N 1s core levels excited from the HfON films deposited with different gas flow ratios. The gas flow ratios of $Ar/O_2/N_2$ are 2/4/0, 2/4/14 and 2/4/20. Inset shows the nitrogen atomic percentage at different gas flow ratio.

cm, in agreement with the previous observation reported by Kang et al. [11]. However, the surface roughness of the HfON film is not good enough for gate dielectric. When an ultra-thin Hf metal is flashed on Si(1 0 0) prior to the deposition of the a-HfON film, surface roughness can be reduced down to 1.2 nm shown in Fig. 2a. The corresponding J_{leak} remains at about the same magnitude as that of HfON, shown in Fig. 2b. This suggests that flashing Hf metal does not create more leakage paths.

The incorporation of nitrogen into a-HfO_2 is further characterized using XPS.

Fig. 3 shows the N 1s core electrons emitted different HfON films deposited at different gas flow ratio of $Ar/O_2/N_2$. The N 1s core level increases in intensity with the N_2 ratio, supporting that N incorporation occurs simply by adding N_2 in the mixed gas of Ar/O_2. The nitrogen concentration at different gas flow ratio of $Ar/O_2/N_2$ is estimated by the relative peak area of Hf 4f, O 1s, and N 1s and plotted in the inset in Fig. 3. Note that N 1s slightly shifts toward lower binding energy when gas flow ratio $Ar/O_2/N_2$ changes from 2:4:14 to 2:4:20. The slight energy shift is probably due to the change of the amorphous environment of nitrogen atom in a-HfON. Moreover, N_2 ratio should be higher than O_2 one for nitrogen incorporation to occur. This implies that the efficiency of nitrogen incorporation into a-HfO_2 is not high due to the stronger bond energy of Hf-O. The incorporation of nitrogen into a-HfO_2 is also confirmed by the increase of dielectric constant. The dielectric constants of different HfON films were measured using a test structure of Al/HfON/Al. The dielectric constants of HfON are determined to be 18, 21.1 and 21.3 for the gas flow ratio $Ar:O_2:N_2 = 2:4:0$, 2:4:14 and 2:4:20, respectively.

A 50 nm HfON film ($Ar:O_2:N_2 = 2:4:14$) with the Hf-flash metal layer was chosen as the gate dielectric to illustrate the electrical characteristics of pentacene-based OTFTs. Fig. 4a shows the transfer characteristics of the HfON–OTFT with a Hf-flash metal layer. The HfON–OTFT is saturated at a relatively low gate voltage (~3 V). The field effect mobility (μ_{FE}), threshold voltage (V_{TH}), on/off current ratio (I_{on}/I_{off}) and subthreshold swing (S.S.) are determined to be 0.17 $cm^2/V\,s$, −0.3 V, $\sim 10^3$ and 209 mV/decade, respectively. The subthreshold swing is close to the theoretical minimum value, $(kT/q \cdot \ln(10) = \sim 60$ mV/decade) [13]. The HfON–OTFT can be operated in the saturation region at low drain bias (~1.5 V), as shown in the output characteristics of the HfON–OTFT in Fig. 4b.

The electrical characteristics of pentacene-based OTFTs with different gate dielectrics (a-HfO_2, a-HfON, and a-HfON with a flash Hf metal layer) are determined for comparison and tabulated in Table 2. Among these three gate dielectrics, a-HfO_2–OTFT exhibits the lowest μ_{FE} value of 0.038 $cm^2/V\,s$. When nitrogen is incorporated into a-HfO_2, μ_{FE} increases to 0.086 $cm^2/V\,s$. For a-HfON with a flash Hf metal layer, μ_{FE} reaches to 0.17 $cm^2/V\,s$ much higher than that of a-HfO_2–OTFT. The enhancement of the μ_{FE} value is attributed to low surface roughness (1.2 nm) and low

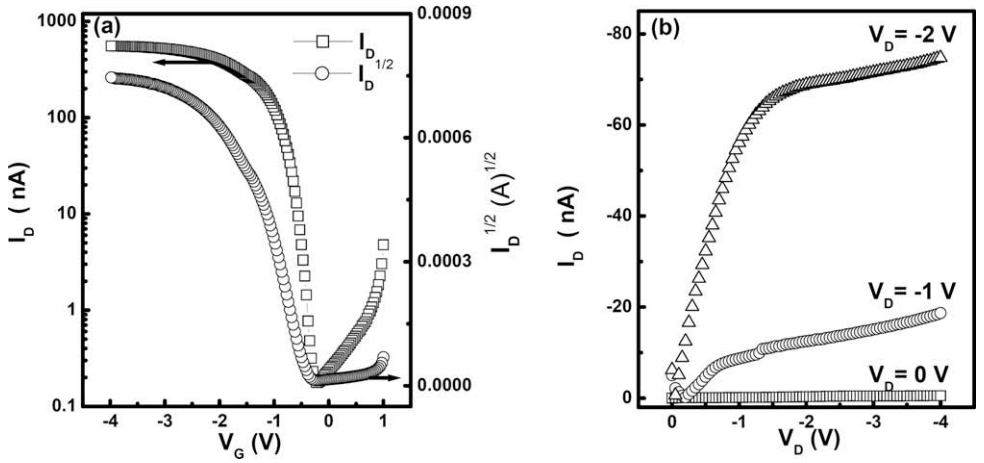

Fig. 4. (a) Transfer characteristics of the OTFT with HfON gate dielectric on a flash Hf metal layer. (b) The corresponding output characteristics.

Table 2
Electric properties of OTFTs with different gas flow ratio and Hf-flash metal layer.

	μ_{FE} (cm^2/V s)	V_{th} (V)	I_{on}/I_{off}	S.S. (V/decade)	Interface trap density (cm^{-2} eV^{-1})
a-HfO_2	0.038	−0.9	3×10^3	−0.319	3.14×10^{13}
a-HfON	0.086	−0.7	0.9×10^3	−0.368	3.8×10^{13}
a-HfON/Hf	0.17	−0.3	3.2×10^3	−0.209	1.9×10^{13}

leakage current density (10^{-7} A/cm^2). By lowering surface roughness, the scattering probably is reduced in the transport channel at the pentacene/a-HfON interface so that μ_{FE} is enhanced. Moreover, the reduction of leakage current density makes the drain current higher such that a higher value of μ_{FE} can be obtained. Similarly, the V_{TH} value of OTFTs reduces from −0.9 to −0.7 V when nitrogen is incorporated into a-HfO_2. The slight reduction of V_{TH} is attributed to the generation of negative fixed charges due to the replacement of oxygen by nitrogen. For a-HfON with a flash Hf metal layer, V_{TH} reduces further down from −0.7 to −0.3 V. The flash Hf metal layer is very thin, which is transformed into a-HfON at the interface during the deposition process of a-HfON. The extra formation of a-HfON due to the flash Hf metal layer is not expected to reduce V_{TH}. In 2008, Suemori et al. reported that the V_{TH} value of a pentacene based OTFT was reduced by smoothing the surface roughness of SiO_2 gate dielectric [14]. The V_{TH} shift was attributed to lattice distortion in pentacene layers deposited on rough SiO_2 surfaces. The V_{TH} shift is 0.4 V in our work that is thus attributed to the reduction of surface roughness. For OTFTs with either one of the three gate dielectrics (a-HfO_2, a-HfON, and a-HfON with a flash Hf metal layer), the I_{on}/I_{off} values are about the same. The I_{on}/I_{off} value of the a-HfON–OTFT with a flash Hf metal layer is slightly higher, which is attributed to its lowest leakage current density.

Since the subthreshold swing represents the interface quality and the trap behavior [15], the maximum interface trap density is approximated to be [16],

$$N_{SS} = \left[\frac{S \cdot \log(e)}{kT/q} - 1\right] \cdot \frac{C_i}{q}$$

where S is the subthreshold swing; C_i is the capacitance per unit area; k is Boltzmann's constant, and T is the absolute temperature. Substituting $C_i = 787$ nf/cm^2 and $S =$ 209 mV/decade, the approximate interface trap density is determined to be 1.9×10^{13} cm^{-2} eV^{-1} for the a-HfON–OTFT with the flash Hf metal layer. The trap density is lower than that of a-HfO_2–OTFT and a-HfON–OTFT. This indicates that the defects at the pentacene/a-HfON interface can be lowered by flashing a very thin Hf metal layer before depositing HfON film. Very probably, the defects at the pentacene/a-HfON are strongly affected by the surface roughness of a-HfON. With a smoother surface, a better quality of pentacence can be deposited on the surface of a-HfON at the beginning of the deposition. And the reduction of the interface trap density would speed up the carrier transport, which is in agreement with the increase of μ_{FE}.

4. Conclusion

In conclusion, a-HfON–OTFTs exhibits better device performance than a-HfO_2–OTFTs since nitrogen incorporation into a-HfO_2 can reduce leakage current density. The device performance of a-HfON–OTFTs can be further improved by flashing a very thin Hf metal layer on the bottom gate electrode before depositing the a-HfON gate dielectric. The flash Hf metal layer helps to reduce surface roughness of the a-HfON gate dielectric. The fabrication of the Hf flashed a-HfON gate dielectric is a low temperature process (150 °C), which may be applicable to either metal or polymer substrates and is potentially useful for soft organic electronics.

ABSTRACT

This paper investigates the dependence of organic thin film transistor (OTFT) characteristics with semiconductor (pentacene) thickness by way of two-dimensional drift–diffusion simulations. The extracted field-effect mobility of the as-measured top contact devices exhibits a variation as the pentacene thickness changes from 10 to 100 nm. Device simulation of an ideal OTFT does not exhibit any dependence on semiconductor thickness, as expected. Therefore, in simulations, the physical behavior related to charge transport at the pentacene–insulator interface and in the bulk is systematically introduced in order to model the experimentally observed device characteristics. These effects are simulated by incorporating a low-mobility-layer adjacent to the dielectric, and energy level shift in the same layer as compared to the bulk pentacene to induce confinement towards the insulator, and bulk donor traps in the pentacene film above a certain thickness (~35 nm). Finally, verification between the simulated and experimental device characteristics is obtained as a function of pentacene thickness.

1. Introduction

Thin film transistors using organic semiconductors as the active materials are considered to be an important component in low-cost, large-area applications such as active-matrix displays, identification tags, sensors and other low-end applications. Organic thin film transistors (OTFT) are also in competition with amorphous silicon TFTs because they demonstrate comparable performance level and better compatibility with the processing on flexible/plastic substrates [1,2]. OTFTs have shown impressive progress in the recent years, however, a lot of research is still needed to make these devices commercial grade and competitive to traditional inorganic-based transistors. It is now well realized that most of the room for improvement lies in understanding the interfaces and the physical properties (i.e., morphology) of organic semiconductors. Any inhomogeneity/defects at the interface or in the semiconducting film not only have adverse effect on the device performance but also hinder in determining the intrinsic properties of the organic semiconductor correctly.

One of the issues related to the above-mentioned effects is the dependence of device performance on the semiconductor thickness. In principle, the device mobility should be unaffected by the semiconductor thickness, because it is well known that most of the charge is accumulated in few nanometers of the semiconductor near the insulator, eliminating the effect of rest of the film [3,4]. However, several studies [4–15] have reported effects of

doi:10.1016/j.orgel.2009.10.009

active layer thickness on OTFT performance with a variety of organic semiconductors and in a range of semiconductor thickness (from ~2 nm to ~500 nm). The explanation of such behavior is often attributed to organic semiconductor morphology, semiconductor–insulator interfaces, and access resistances. Although efforts have been taken to describe it properly, comprehensive understanding is still lacking due to the experimental limitations in providing evidences. In this regard, physical modeling and simulation methods becomes utmost important to fully understand the device mechanisms and maximize their performances.

This paper builds on the previous efforts by combining the numerical simulation techniques with the experiments to fully understand the dependence of device characteristics with semiconductor thickness. The simulated results in the normal conditions did not show the experimentally observed thickness dependence, which was also expected as per the standard field-effect models. The physical behavior associated with the semiconductor–insulator interface and the morphology of the semiconductor in the simulation is then step-wise incorporated in order to model the device characteristics accurately. The pentacene film close to the insulator is simulated with different properties as compared to the bulk film in order to account for the known structural discontinuities and interaction of charge carrier with the surface polarons at the polar dielectric surfaces. The morphological dependence of pentacene film with thickness is simulated by including the bulk traps above a certain thickness of pentacene films. The simulated parameters are then adjusted to have a reasonable match with the experimental results.

2. Experiment and device simulation procedure

2.1. Experiment

Fig. 1a illustrates the schematic diagram of the top contact devices with the axes and dimensions as marked. A highly doped silicon wafer (n++) provides a common gate electrode and a uniform 200 nm thick layer of thermally grown SiO_2 on this wafer serves as a gate dielectric. The source and drain electrodes made of 50 nm thick gold are deposited through a shadow mask, which yield a channel length (L) of 30 μm and channel width (W) of 1.0 mm, respectively. Pentacene as the organic semiconductor film is deposited by thermal evaporation at the rate of 0.03–0.04 nm/s at substrate temperature of 65 °C.

2.2. Method of extraction of mobility

The prevalent method, for a grounded source, to extract the field-effect mobility is by using the expressions that describe the drain current (I_D) for crystalline MOSFETs [16]. From simple FET theory, the device characteristics is described by the following equation:

$$I_D = \frac{W\mu C_i}{L}\left[(V_G - V_T)V_D - V_D^2/2\right] \quad (1)$$

where V_D is (drain-source voltage, V_G is (gate-source voltage, μ is the field-effect mobility, V_T is the threshold voltage, and C_i is the capacitance per unit area of the gate insulator. In the linear regime, where $V_D \ll V_G - V_T|$) Eq. (1)) can be simplified to

$$I_D = \frac{W\mu C_i}{L}(V_G - V_T)V_D \quad (2)$$

The field-effect mobility in the linear regime is extracted from the transconductance, which is defined as

$$g_m = \frac{\partial I_D}{\partial V_G} \quad (3)$$

For small and constant V_D device, the mobility is calculated from the relationship

$$\mu = \frac{L \cdot g_m}{W \cdot C_i \cdot V_D} \quad (4)$$

It is to be noted that the mobility as a function of gate voltage can be obtained from Eq. (4) [16]. The threshold voltage is determined from the intercept of the fitting line used to extract the mobility in the linear regime (I_D–V_G) characteristics.

2.3. Device simulation procedure

The two-dimensional device simulator ATLAS (Silvaco) is used for numerical simulations. ATLAS incorporates the physics that govern charge carrier transport and applies it to the dimensions of the device being studied. Further details can be found in Ref. [17]. Although, its applicability to organic materials is limited, it can still predict the qualitative device characteristics correctly [17–20]. The bandgap of pentacene is taken as 2.2 eV, electron affinity (E_A) as 2.8 eV, density of states as 2×10^{21} cm^{-3}, doping concentration as 3×10^{16} cm^{-3}, and dielectric constant as 4. The work function of the source, drain and gate electrode is assumed to be 5.0 eV [17].

3. Results and discussion

3.1. Effect of pentacene thickness

Fig. 1b illustrates the experimental output curves for top contact devices at gate voltage, $V_G = -20$ V, for pentacene thicknesses of 10, 20, 35, 50, 80 and 100 nm, respectively. In order to make a comparison, the simulated curves for the same pentacene thicknesses are also superimposed on the experimental curves. The value of the mobility for the simulations is taken as 0.14 cm^2/Vs, which is equal to the value obtained experimentally for a device with pentacene thickness of 50 nm at $V_D = -5$ V and $V_G = -15$ V. Clearly, there is a mismatch in the trend of the drain current variation with pentacene thickness between experimental and simulated curves. According to the experiments, the drain current increases at any drain voltage (V_D) until a pentacene thickness of 35 nm, and then the

(b) A comparison of the output curves for the experimental (symbol) and the simulated (line) devices as a function of pentacene thickness (10–100 nm) at $V_G = -20$ V. (c) Extracted mobility of the devices as a function of gate voltage for pentacene thickness of 10, 20, 35, 50, 80 and 100 nm, respectively (at $V_D = -5$ V).

current decreases. However, the corresponding simulated drain current demonstrates a slight monotonic increase with the pentacene thickness.

The field-effect mobilities, according to the method described in Section 2.2, are also extracted as a function of gate voltage, and are plotted for various pentacene thicknesses at $V_D = -5$ V in Fig. 1c. It is evident from Fig. 1c that the mobility shows a variation with gate voltage, which is generally the case with organic transistors [3,21,22]. The reason for such a gate voltage dependence of mobility is often attributed to the organic material characteristics and also to the insulator–semiconductor interfaces [21,22]. As demonstrated in Fig. 1c, the trend of mobility variation with pentacene thickness is similar to the drain current for all gate voltages, where the values of mobility is highest for pentacene thickness of 35 nm. In order to make a comparison between the mobility obtained from the experimental data and from the simulated device characteristics, the mobility values at $V_D = -5$ V and $V_G = -15$ V are plotted as a function of pentacene thickness in Fig. 2a. Similar to the behavior of the drain current, the experimentally obtained mobility value peaks at 35 nm, whereas simulated data does not demonstrate a major effect of pentacene thickness.

It is clear that simulated device characteristics are only very slightly affected by pentacene thickness, and not to the extent of experimental observations. This small thickness dependence in the simulated results can be explained by the current density profile (Fig. 2b), which is taken across the pentacene at the center of the channel region (shown by a dashed vertical line in the inset of Fig. 2b). Fig. 2b shows that in all the devices with varying pentacene thickness, most of the current flows through a very thin region (called as accumulation region), approximately 5 nm, near the dielectric surface. The slight increase in the drain current with pentacene thickness is thus due to the increase in bulk current. However, its contribution to the total drain current is very little and hence no significant effect on the device characteristics could be observed by varying the pentacene thickness.

Since the experimentally obtained device mobility exhibits a significant pentacene thickness dependence, which is not adequately simulated, it is advisable to incorporate additional features in the simulation in order to model the device characteristics accurately. In the simulation, the physical behavior related to charge transport in the first few layers adjacent to the dielectric is not modeled. The first few layers, where most of the charge transport occurs, may have low mobility as compared to the bulk film. This low mobility may be caused by structural defects, discontinuities, low surface coverage or due to the charge-surface phonon interaction caused by the polar oxide dielectric [23–29]. Kirova and Bussac [26] and Hulea et al. [30] demonstrated through calculations that the charge carrier in the organic film interacts with the surface phonons of the polar dielectrics, which leads to its self-trapping and formation of the long range surface polaron. This result in increased effective mass and mid gap states, which tends to reduce the mobility of the material near the dielectric surface. The similar conclusion is also drawn by Houilli et al. [27], where they performed calculations on the bandwidth and effective mass of the organic semiconductor

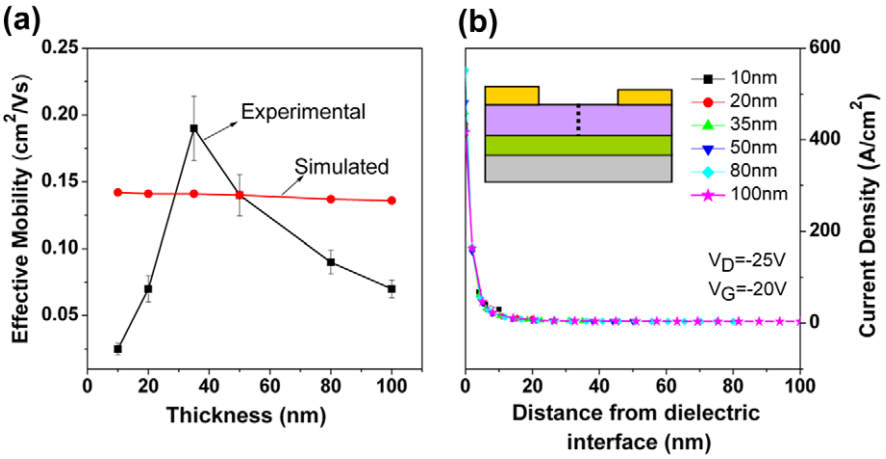

Fig. 2. (a) A comparison of the mobility values for the experimental and the simulated devices as a function of pentacene thickness at $V_D = -5$ V and $V_G = -15$ V. (b) Current density profile taken across the pentacene thickness in the center of the region between the source and drain contacts, as shown by a dashed vertical line in the inset.

layers near the polar dielectric by accounting for the dielectric polarizability and the charge-phonon interaction. They observed that the band-width of the organic semiconducting material near the gate dielectric decreases, while the effective mass increases, as compared to the bulk values. Through potentiometry studies on the pentacene monolayer on an oxide surface, Puntambekar et al. [25] also revealed potential drops in and between the pentacene grains, which also points that the region near the dielectric interface may have low mobility.

Apart from affecting the properties of the organic semiconductor film near the dielectric, the charge transport in this region may also get affected due to the inter layer surface potential differences in the pentacene film and charge distribution in the gate dielectric. Puntambekar et al. [25] demonstrated through surface potential studies that there exists a difference in potential between the first and the second monolayer of pentacene, forcing the mobile carriers more towards the vicinity of the dielectric. Huilli et al. [27] also showed this effect, where they study the polarizability of the channel and concluded that polarization interaction energy of the charge in the dielectric attract the mobile carriers towards it. Since the interface may be defective, this causes mobile charge carriers to probe all the non-idealities associated with the dielectric interface, which further affects the charge transport properties near the dielectric interface [25,27].

Based on this discussion, following two points emerge:

(a) A monolayer of pentacene may have low mobility in comparison to the bulk pentacene. Hereafter this layer is referred as low-mobility-layer.
(b) Mobile charge, for reasons not precisely understood, is preferentially forced to this low-mobility region.

Thus for the realistic simulations, these two effects should also be incorporated, which are systematically introduced in order to match with the experimental data.

3.2. Introduction of a low-mobility-layer at the pentacene–SiO_2 interface and its effect on the device behavior with pentacene thickness

To evaluate the effect of the low-mobility-layer at the insulator surface, we incorporated a 1.5 nm thick layer at the dielectric interface, as depicted in Fig. 3a. The thickness of this layer according to the pentacene crystal structure on SiO_2 is about one monolayer [31,32]. To observe the effect of the lower values of mobility of this layer as compared to the bulk mobility value on the device characteristics, we first reduced its mobility by 10 times as compared to the bulk mobility of 0.14 cm^2/Vs. It is found that the saturation current decreases approximately by 2.5 times with the introduction of a low-mobility-layer, which is due to the 10 times reduction in the drain current in the accumulation region. As already mentioned, the accumulation region is roughly 5 nm thick, therefore reducing the mobility of first 1.5 nm in this region by 10 times leads to a total reduction in the drain current approximately by 2.5 times.

The effective mobility extracted from the simulated curves for this device having a low-mobility-layer (mobility = 0.014 cm^2/Vs) is 0.08 cm^2/Vs at $V_D = -5$ V and $V_G = -15$ V, as compared to the bulk mobility value of 0.14 cm^2/Vs. However, the measured effective mobility of a similar device is 0.14 cm^2/Vs. Therefore, in order to achieve this effective mobility in simulations, we then need to increase the bulk mobility value to 0.28 cm^2/Vs. A good matching with the experiments and simulations could be established, by using the above mobility values. Lowering the mobility of this low-mobility-layer by a decade further causes the drain current to reduce by 1.3 times, while the effective device mobility reduces to 0.115 cm^2/Vs at $V_D = -5$ V and $V_G = -15$ V. Further reduction by a decade in the mobility of low-mobility-layer does not cause significant difference in the over-all device performance.

Next, a study on pentacene thickness dependence incorporating a 1.5 nm thick low-mobility-layer (mobil-

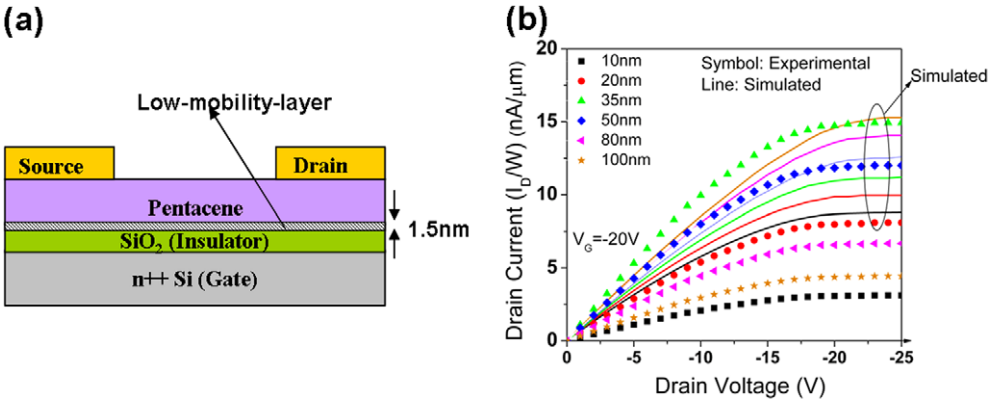

Fig. 3. (a) Schematic diagram of the device depicting 1.5 nm thick low-mobility-layer adjacent to the pentacene–dielectric interface. (b) A comparison of the output characteristics of the simulated devices with the low-mobility-layer at the dielectric surface and the experimental curves, as a function of pentacene thickness at $V_G = -20$ V. The mobility of the low-mobility-layer is 0.014 cm^2/Vs and bulk mobility is 0.28 cm^2/Vs, respectively.

ity = 0.014 cm^2/Vs) is carried out in order to accurately simulate the experimentally observed thickness dependence. Fig. 3b illustrates the superimposed experimental and simulated output characteristics at $V_G = -20$ V with pentacene thicknesses with the bulk mobility as 0.28 cm^2/Vs. It is clear from Fig. 3b that no similarity in the device characteristics between the simulated and experimental curves could be established as a function of pentacene thickness. When comparing with Fig. 1b, now the drain current depends more strongly on the pentacene thickness. However, the simulated device characteristics are still different in two ways from the measured results. First, the simulated drain current increases monotonically as thickness increases, whereas, as-measured drain current is maximum at pentacene thickness of 35 nm. Second, the drain current difference measured for various pentacene thicknesses is much greater than that simulated. Also, the extracted device mobility from the simulated curves shows different characteristics than the experiments. As shown in Fig. 4a the extracted mobility after a pentacene thickness of 35 nm becomes almost constant for simulated devices, whereas it starts decreasing in the as-measured ones.

The nature of the simulated device characteristics could be understood by considering the downwards vertical electric field (in y-direction), which decreases on increasing the pentacene thickness (illustrated in Fig. 4b, at the pentacene–insulator interface in the center of channel). The presence of low-mobility-layer at the dielectric interface and higher electric field for the thinner pentacene films forces more charge carriers to pass through this low-mobility-layer, causing greater reduction in the drain current for thinner devices. The initial increase in mobility with pentacene thickness is thus due to the reduced vertical electric field. However, after a certain value, the channel current is primarily conducted above the low-mobility-layer and the subsequent increase in the drain current is due to the increased bulk current. The above results clearly mark the fact that the incorporation of a low-mobility-layer at the dielectric interface has the greatest effect on thinner films, and after a certain thickness, it does not have any significant effect on the device mobility on increasing the pentacene thickness. Nonetheless, it is clear that the incorporation of low-mobility channel region alone does not allow us to simulate the measured results.

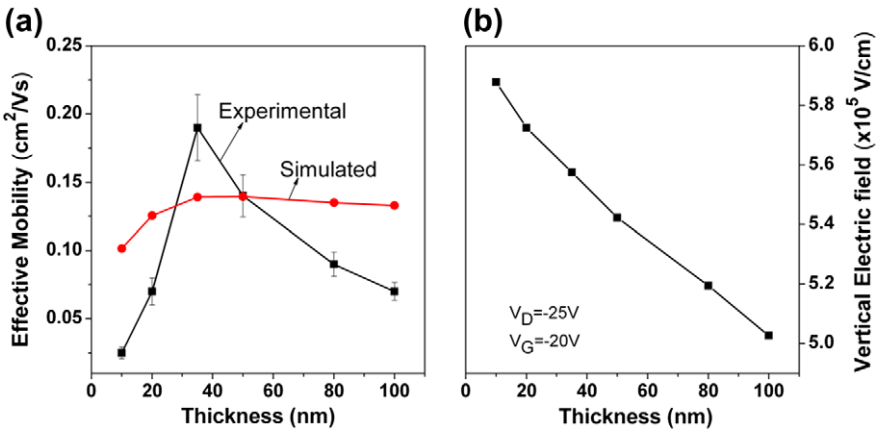

Fig. 4. (a) Extracted device mobility as a function of pentacene thickness for top contact devices on incorporating the low-mobility-layer at $V_D = -5$ V and $V_G = -15$ V, and (b) electric field at the pentacene–dielectric interface, in the middle of the channel. The mobility of the low-mobility-layer is 0.014 cm^2/Vs and bulk mobility is 0.28 cm^2/Vs.

Hence, it is important to include also the preferential forcing (confinement) of charge near the dielectric interface, as discussed in the next section.

3.3. Introducing charge confinement towards near semiconductor–dielectric interface

Since the insertion of the low-mobility-layer at the dielectric interface alone is not able to explain the observed pentacene thickness dependence on mobility values, the additional option of confinement of the mobile channel towards the low-mobility-layer is invoked. This could be accomplished in two ways. First, by the application of a negative charge at the semiconductor–insulator interface or secondly, by the introduction of an energy band offset in the low-mobility-layer with respect to the bulk film.

3.3.1. Negative interface charge

In order to induce confinement of the channel a negative interface charge of the magnitude $q \times 1 \times 10^{12}$ C cm^{-2} (q is the charge on an electron) is applied. On applying the interface charges, the drain current increases and shifts the threshold voltage towards negative gate voltages for all pentacene thicknesses, but does not impact the device mobility. Therefore, including a negative interface charge does not accomplish the objective of effective confinement of charge near the dielectric interface, and yet the threshold voltage shifts significantly. Therefore, confinement of charge near dielectric interface is simulated by another way, as discussed next.

3.3.2. Energy band offset between the low-mobility-layer and bulk pentacene

Based on observations discussed at the end of Section 3.1, electrostatic potential measurements indicated that carriers are preferentially forced in region near the dielectric interface. The reason for this behavior is not well established. Furthermore, the commercial simulator in use here does not contain any models to physically simulate the carrier confinement. Hence, to confine carrier near the dielectric interface, an energy band offset between the low-mobility-layer and bulk pentacene is introduced in such a way that it facilitates the charge migration towards the low-mobility-layer. Fig. 5a shows the energy band diagram of pentacene film depicting the energy band offset between the low-mobility-layer and the bulk pentacene. To force the mobile charge towards the low-mobility-layer, the electron affinity (E_A) value of the low-mobility-layer (E_{A1}) is reduced in comparison to its value in the bulk pentacene (E_{A2}), while keeping the band gap (E_g) value same for both the regions.

With this method of charge accumulation near the interface, the experimental and the simulated transfer curve with an energy band offset value of 0.1 eV between the low-mobility-layer and bulk pentacene is compared. The device characteristics are simulated with the mobility of the low-mobility-layer as 0.014 cm^2/Vs, bulk mobility as 0.28 cm^2/Vs, and pentacene thickness of 50 nm. As expected, the drain current is reduced on introducing this offset, which is due to the charge transfer from the bulk pentacene towards the low-mobility-layer. The effective device mobility reduces to 0.09 cm^2/Vs as compared to the mobility value of 0.14 cm^2/Vs. The threshold voltage shifts to −1.7 V (experimentally −1.9 V). Since the energy band offset produced the expected result of reducing the device mobility, without producing a significant change in the threshold voltage, this method of introducing energy band offset in the low-mobility-layer to confine the charge towards the dielectric interface is preferable.

The magnitude of band offset also affects the device characteristics, which is shown in Fig. 5b by the extracted mobility value with the offset values of 0.0, 0.1 and 0.2 eV, respectively. On increasing the energy band offset value, effective device mobility decreases, indicating more confinement of the mobile charges towards the dielectric interface. Additionally, on including the energy band offset, the mobility of the low-mobility region has much greater effect on the effective mobility of the device. This is illustrated by Fig. 5c which shows the change in over-all device mobility value as a function of the mobility of the low-mobility-layer with an energy band offset value of 0.1 eV.

Apart from the effective mobility value, the charge transport behavior also changes on reducing the mobility value of this low-mobility-layer. For the sake of illustration, the mobility value of this low-mobility-layer are taken as 1×10^{-2}, 1×10^{-3}, and 1×10^{-5} cm^2/Vs. Fig. 5d depicts the current density profile taken across the pentacene thickness in the center of the region between the source and drain contacts, as shown by a dashed vertical line in the inset of Fig. 5d. It is observed that on decreasing the mobility value of the low-mobility-layer by 10 times as compared to the bulk mobility value, the channel becomes very thin and confined to the low-mobility-layer, and the contribution of bulk current to the total current is insignificant. On decreasing the mobility value of the low-mobility-layer to 1×10^{-3} cm^2/Vs, the value of the current passing through the low-mobility-layer reduces. However, now the fraction of the current through bulk is significant. On further decreasing the value of the low-mobility-layer to 1×10^{-5} cm^2/Vs, we observe that current does not at all flow through the low-mobility-layer. Instead, the maximum drain current flows through the layer just above the low-mobility-layer. The bulk conduction also increases and it is almost half of the value of the maximum current density. Further decrease in the mobility value of the low-mobility-layer does not cause any significant difference in the current density profile.

3.3.3. Combined effect of energy band offset and mobility of low-mobility-layer: comparison with experiments

In this section, the simulation parameters that yield results similar to the measurements as a function of pentacene thickness are determined. To match the extracted mobility from the simulated curves with the experimental mobility values, the effect of the various mobility values of the low-mobility-layer and the values of the energy band offset are studied.

Fig. 6a illustrates the extracted effective mobility values as a function of pentacene thickness with a mobility value of 0.014 cm^2/Vs for the low-mobility-layer and the energy

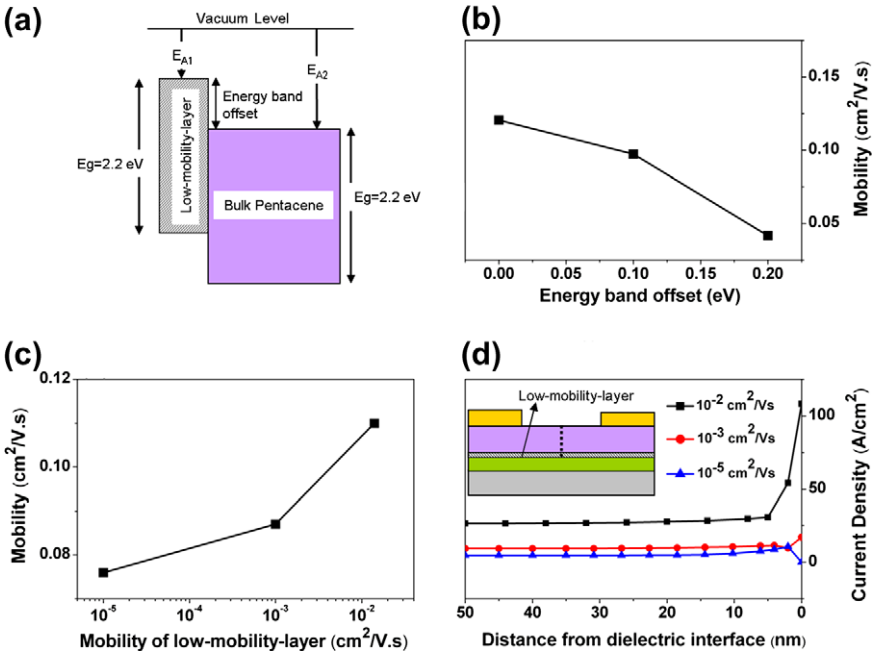

Fig. 5. (a) Schematic diagram of the energy levels in the low-mobility-layer and bulk of the pentacene film, (b) extracted mobility values as a function of the magnitude of energy band offset at $V_D = -5$ V and $V_G = -15$ V, (c) extracted mobility values as a function of the mobility of the low-mobility-layer at an energy band offset of 0.1 eV at $V_D = -5$ V and $V_G = -15$ V, and (d) current density profile in the cross-section of the device as a function of the mobility of the low-mobility-layer ($V_D = -40$ V and $V_G = -20$ V). The mobility of the low-mobility-layer is 0.014 cm^2/Vs and bulk mobility is 0.28 cm^2/Vs. Pentacene thickness is 50 nm.

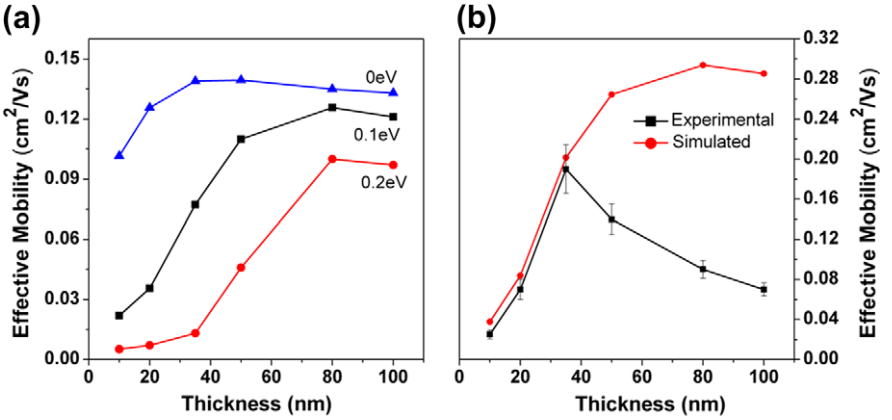

Fig. 6. (a) Effective mobility as a function of pentacene thickness for different values of the energy band offset between the low-mobility-layer and bulk pentacene at $V_D = -5$ V and $V_G = -15$ V. The mobility of the low-mobility-layer is 0.014 cm^2/Vs and bulk mobility is 0.28 cm^2/Vs. (b) Comparison of experimental and simulated mobility value as a function of pentacene thickness. The mobility of the low-mobility-layer is 1×10^{-4} cm^2/Vs and bulk mobility is 1.3 cm^2/Vs. The energy band offset value is 0.11 eV.

band offset value of 0.0, 0.1 and 0.2 eV. It can be seen that the variation in the magnitude of extracted device mobility with pentacene thickness increases when energy band offset between the low-mobility-layer and bulk pentacene is included. For energy band offset value of 0.1 eV, the mobility value increases gradually until 80 nm of thickness and then decreases slightly. While for an energy band offset value of 0.2 eV, device mobility value first increases slightly till 35 nm, then increases rapidly till 80 nm and then becomes almost constant. This variation with thickness as a function of energy band offset magnitude is a result of variations in electric fields, which vary with energy band offset magnitude as well as with the thickness. Whereas higher thickness reduces confinement, the higher energy offset promotes it.

The experimentally determined mobility, as in Fig. 2a increases up to a thickness of 35 nm and then decreases. In case of mobility determined from simulated curves

(see Fig. 6b), the quantitative behavior of mobility up to 35 nm is better matched for an energy band offset value of 0.11 eV, the mobility of low-mobility-layer as $\sim 1 \times 10^{-4}$ cm^2/Vs and bulk mobility as 1.3 cm^2/Vs. However, after 35 nm, no match could be obtained, which is discussed in the next section.

3.4. Introducing bulk traps for thicker pentacene films

After matching the mobility up to pentacene thickness of 35 nm, it is still found that mobility extracted from the simulated curves continued to increase till 100 nm. This would have been the case if the film growth was uniform along the thickness. It has been pointed out that the molecular crystal packing and grain size varies as the pentacene film thickness is increased [33–37]. Furthermore, pentacene films exhibit several crystal structures depending on the thickness [33–37]. Due to the variation in morphology with thickness, more grain boundaries begin to appear, which acts as trapping centers for the mobile charge [38,39]. Table 1 lists the grain size [recorded through atomic force micrographs (AFM)] variation with the pentacene thickness. It is found that until pentacene thickness of 35 nm, the average grain size remains ~0.85 μm. After further increasing the film thickness, the grain size reduces and reaches to 0.15 μm for the 100 nm thick pentacene films.

To explain the experimental results as a function of thickness, we then introduced bulk traps in the region above 35 nm of pentacene thickness, as illustrated in Fig. 7a. Fig. 7b shows a combination of bulk donor type trap concentration and its trap level from the valence band edge, which yields the drain current at $V_D = -25$ V and $V_G = -20$ V within 10% of the measured value in the same condition. Based on this figure, a trap level of 0.4 eV is selected, which produces a reasonable match between the experimental and simulated curves, if bulk donor trap concentration of 4×10^{16} cm^{-3} for 50 nm thick film and 6×10^{16} cm^{-3} for 80 and 100 nm thick films, are chosen.

Table 1
Average grain size as a function of pentacene thickness.

Thickness (nm)	Average grain size (nm)
10	0.8
20	0.85
35	0.85
50	0.55
80	0.3
100	0.25

The superimposed simulated and experimental output curves are depicted in Fig. 8a. The extracted mobility values from the experiments and simulations are also illustrated in Fig. 8b. The extracted mobility values from simulations after substituting these trap levels matches well with the experimentally determined mobility. This indicates that the devices face several non-regularities, which are expressed in the form of low-mobility of the pentacene layers that are associated with the dielectric, existence of energy band offset between the interface layers and the bulk, and the bulk traps due to the structural defects like grain boundaries. The combined effect of these features causes the extracted mobility to depend on the film thickness, which in an ideal case should have been absent. It also signifies the importance of optimizing the thickness of organic semiconductor in order to have enhanced as well as reliable device performance.

The effect of the bulk traps could be illustrated by the current density profile taken across a vertical section in the pentacene film in the center of channel. Fig. 9 illustrates the comparison of the current density profile in device with and without the bulk traps in pentacene film, taken across the pentacene in the middle of channel. It is found that on introducing the bulk traps, the bulk conduction reduces drastically. Since the bulk traps produce resistance, the current is less likely to flow through the bulk. This reduction in bulk current is proportional to the area in which these bulk traps reside. Since bulk traps reside in larger area in 100 nm thick film as compared to 50 and 80 nm thick films, the reduction in the drain current is highest for the 100 nm film. Therefore the bulk current which initially was a significant part of the drain current in thicker films has almost no contribution now. Due to this reduction in bulk current, the over-all drain current decreases.

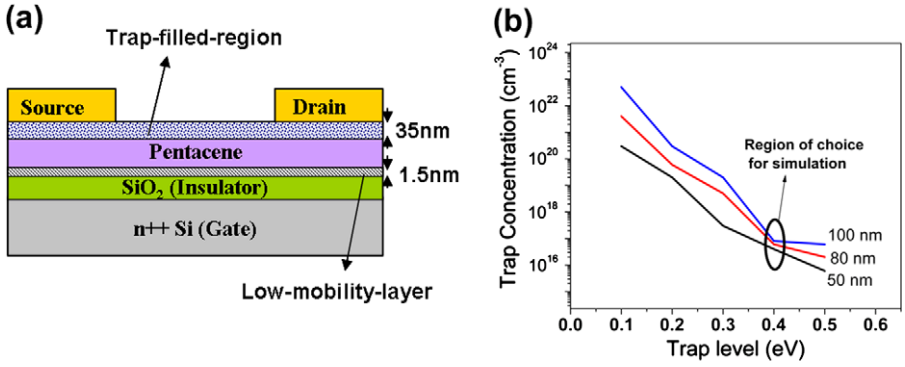

Fig. 7. (a) Schematic diagram of the device depicting low-mobility-layer, and trap filled region above the pentacene thickness of 35 nm. (b) Comparison of trap energy level and trap concentration for 50–100 nm thick pentacene films.

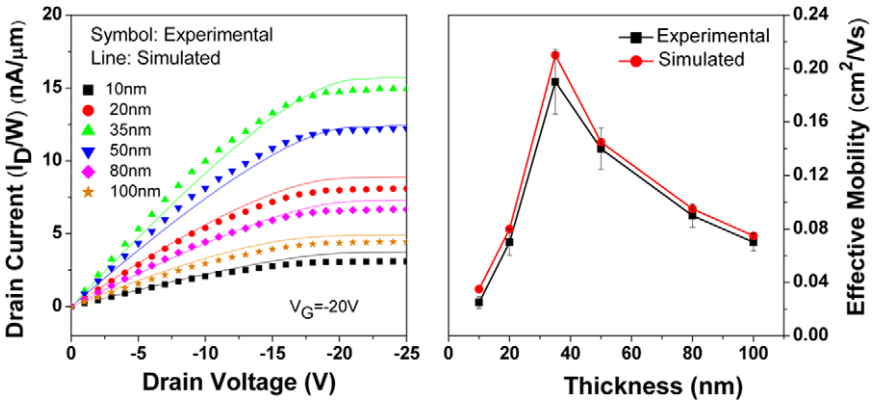

Fig. 8. A comparison of simulated and experimental (a) output curves and (b) mobility value (at $V_D = -5$ V and $V_G = -15$ V) as a function of pentacene thickness. The mobility of the low-mobility-layer and bulk pentacene is taken as 1×10^{-4} cm^2/Vs and 1.3 cm^2/Vs, respectively. The energy band offset value is 0.11 eV. The trap concentration is taken as 4×10^{16} cm^{-3} for 50 nm thick film and 6×10^{16} cm^{-3} for 80 and 100 nm thick films, respectively.

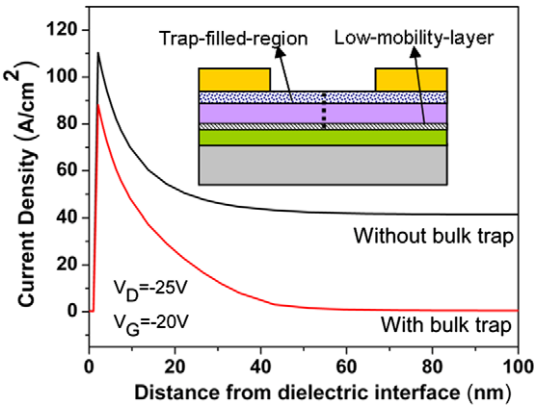

Fig. 9. Current density profile for 100 nm thick pentacene film showing the effect of traps above 35 nm thick pentacene.

4. Conclusions

The observed pentacene thickness dependence on the device characteristics is attributed to the structural inhomogeneities of the region near pentacene/dielectric interface and in the bulk film. The interfacial region is modeled by assigning a 1.5 nm thick layer adjacent to the dielectric a lower mobility value as compared to the bulk pentacene and introducing an energy band offset between this layer and the bulk pentacene. The defects in the bulk film are modeled by introducing donor type traps above a certain thickness (~35 nm) of the pentacene film. The mobility of the low-mobility-layer is estimated to be $\sim 1 \times 10^{-4}$ cm^2/Vs with an energy level shift of the magnitude 0.11 eV. Based on these values, an optimum bulk mobility value of 1.3 cm^2/Vs for pentacene films is estimated, which is significantly higher than obtained from transistor measurements. It is also inferred that in the presence of the above-mentioned defects at the semiconductor–insulator interface and in the bulk of the film, the intrinsic mobility of the material is disguised and one is not able to measure the true mobility of the material through the field-effect measurements.

ABSTRACT

Two types of microcavity blue organic light-emitting diodes (OLEDs) with a dielectric Bragg mirror (two different center wavelengths, type-A ≈ 465, type-B ≈ 470 nm) were designed to achieve the color coordinates of NTSC blue standard and enhance the quantum efficiency in the normal direction. A moderate microcavity OLED was defined as a microcavity OLED with a single pair of TiO_2/SiO_2 high/low dielectric layers inserted between an indium tin oxide (ITO) layer and a glass substrate. The moderate microcavity blue OLED doped with 9,10-bis(3′,5′-diphenylphenyl)-10-(3″,5″-diphenylbiphenyl-4″-yl)anthracene (TAT) exhibited excellent color coordinates (type-A; $x = 0.143$, $y = 0.068$, type-B; $x = 0.139$, $y = 0.081$), which were better than the color coordinates of the NTSC standard (0.140, 0.080) and the TAT-doped conventional noncavity OLED (0.156, 0.094). There were approximately 60% and 54% improvement in the relative quantum efficiency of the type-B TAT-doped moderate microcavity OLED, respectively, compared to those of the conventional noncavity reference OLED (ITO = 150 nm) and other reference type-II with an identical ITO layer thickness (ITO = 85 nm). These improvements in color coordinates and the relative quantum efficiency were attributed to the optimization of narrowed spectrum bandwidth and enhanced integrated spectrum intensity in the TAT-doped blue OLED, resulting from the effective microcavity effect.

1. Introduction

Organic light-emitting diodes (OLEDs) are used widely as ideal emissive devices in lighting and flat panel displays on account of their low driving voltage, low power consumption, high color gamut, high contrast and rapid response [1–4]. For full color display applications, it is essential to develop high performance red-, green-, and blue-emitting OLEDs with high EL efficiency, good thermal properties, and long device lifetime as well as pure color coordinates (1931 Commission Internationale de l'Eclairage (CIE) x, y coordinates). To develop stable, efficient and saturated red to green and blue OLEDs, the general approach is to design and synthesize new organic small molecules as emitters in OLEDs. Many organic small molecules for red [5–7], green [8,9] and blue emitters [10–19] have been synthesized. Recently, high efficient and pure red fluorescent and green OLEDs have been developed with CIE x, y coordinates and electrical efficiencies of (0.67, 0.23) and 11 cd/A and (0.29, 0.64) and 21 cd/A, respectively. However, the color purity and efficiency of the blue-light emitters are still lower than the requirements for balancing with red and green emitters for full color displays. Therefore, improvements in the blue emitting performance are necessary, particularly for large display

applications, such as digital video displays (DVD) and laptop computer screens, which require a larger color gamut. In particular, blue emitters require the CIE x, y coordinates of the National Television System Committee (NTSC) blue color standard (0.14, 0.08). With this respect, synthesizing new blue emitters with a narrow band and saturated color might help in obtaining a deep blue color. Many types of blue emitters have been studied extensively, and considerable effort has been made to improve their blue EL performance [10–19]. Thus far, the best results of a deep blue-light emitter are anthracene-cored derivatives with excellent color coordinates (0.156, 0.088) and good electrical efficiency [19]. The color coordinates of anthracene-cored derivatives are still inferior to the NTSC blue color standard. Therefore, further improvements in blue color and luminescence efficiency are essential for applications to large display devices, such as televisions and computer screens. However, the broad emission spectra due to both vibronic transitions and strong inhomogeneous broadening of the transitions in various organic molecules make it difficult to develop deep blue color OLEDs using a new type of blue emitter only.

Another way of overcoming the problem of limited color purity of blue OLEDs is the optical modification of the OLED structure and filtering out the unwanted long wavelength emission. With this respect, a simple modification of the OLED structure, i.e. the insertion of organic layers into a microcavity structure has been investigated extensively in recent years owing to the enhanced luminescence, narrowing bandwidth, and tunable emission color [20–32]. Microcavity OLEDs can be divided into two categories: one is OLEDs embedded in a weak cavity structure [20], and the other is insertion into a strong cavity structure [21–32]. The former is a conventional OLED structure, in which the central organic layers are sandwiched between an aluminum (Al) metal cathode and an indium tin oxide (ITO) anode. On the other hand, the latter uses a conventional Al electrode and semitransparent metal mirror [21–24] or an ITO anode coated onto a dielectric Bragg mirror [25–32]. As previously reported, the weak microcavity has relatively minor effects on the electroluminescence (EL) performance [20]. However, the strong microcavity modifies the photonic mode density within the OLED significantly, improving the EL performance and tuning the color purity from a homogeneously broadened emitter at the microcavity resonance [21–32].

The use of metal mirrors enhances the EL efficiency and luminance in the top- or bottom-emitting OLEDs significantly but their narrowing capability of the emission spectrum from the metal mirror still does not satisfy the NTSC pure blue. Recently, Mudler et al. [21] obtained a high efficient and deep blue color (0.116, 0.136) OLED from a sky blue phosphorescent OLED using a strong microcavity structure with a semitransparent Ag anode. Although the color purity of the phosphorescent OLED was improved significantly using a strong metal mirror-based microcavity, it is necessary to control the detailed peak position and bandwidth of the emission spectrum in order to approach the NTSC blue color standard.

On the other hand, dielectric mirrors reduce the bandwidth of the EL spectrum considerably but the improvement in OELD efficiency is not as high as the metal-based strong microcavity. In the early stages of dielectric-based microcavity OLEDs, Tokito et al. [28,29] reported that the purity of red, green and blue obtained in microcavity OLEDs was superior to the NTSC standard. However, the total enhancement of their device by integration over all angles and wavelengths was not reported. Recently, Zhang et al. [30] and Jung et al. [31] reported the tuning of the emission color and improvement in EL efficiency simultaneously by simply adjusting the cavity length and carefully designing the device structures. They narrowed the emission spectrum of blue, green and red OLEDs significantly, but improved the green and red efficiency only. Quite recently, Cho et al. [32] reported that moderate microcavity formed by an Al cathode and one pair of high- and low-index (SiN_x/SiO_2) dielectric layers enhanced the efficiency of sky blue OLEDs (0.110, 0.216) by more than 26%. Although there are many papers on the enhanced output of the emission peaks from microcavity OLEDs, there are few reports on the high efficient and saturated blue OLEDs, which are more efficient than noncavity conventional OLEDs and have a deeper color than the NTSC blue color standard (0.14, 0.08). This paper reports microcavity OLEDs containing dielectric Bragg mirrors with a finely tunable peak position and a bandwidth of EL emission that achieves enhanced external quantum efficiency and a deep blue color ($y \leqslant 0.08$). The significant change in bandwidth, external quantum efficiency and color of the microcavity OLEDs with three different pairs and two lattice constants of high- and low-index dielectric layers was examined in order to gain a better understanding of the effect of the degree of microcavity TiO_2/SiO_2 layers on the efficiency and color purity of 9,10-bis(3′,5′-diphenylphenyl)-10-(3‴,5‴-diphenylbiphenyl-4″-yl)anthracene (TAT)-doped OLEDs. Among the various microcavity OLEDs, a moderate microcavity OLED was defined as a microcavity OLED with only a single pair of TiO_2/SiO_2 layers inserted between the indium tin oxide (ITO) layer and a glass substrate to achieve the NTSC blue standard and enhance the normally directed quantum efficiency.

2. Experimental

Fig. 1 shows a schematic diagram of the microcavity OLED with one, two and four pairs of high- and low-index pair of dielectric Bragg mirrors. Two types of reference blue OLEDs were fabricated with a commercialized emitter in the following configurations: ITO (150 nm or 85 nm)/4,4′,4″-tris(*N*-(2-naphthyl)-*N*-phenylamino)triphenylamine [2-TNATA] (49 nm)/*N*,*N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)benzidine [NPB] (12 nm)/9,10-bis(3′,5′-diphenylphenyl)-10-(3‴,5‴-diphenylbiphenyl-4″-yl)anthracene [TAT] (30 nm)/8-hydroxyquinolinealuminium [Alq_3] (24 nm)/LiF (1 nm)/Al (150 nm). The optical lengths of the type-A and type-B TAT-doped microcavity blue OLEDs were attributed to the different optimized structures summarized in Table 1. In the type-A microcavity blue OLEDs, one, two and four pairs of high-(TiO_2) and low-index (SiO_2) layers were placed between the ITO layer and glass substrate to control the top reflectivity of the reflection band.

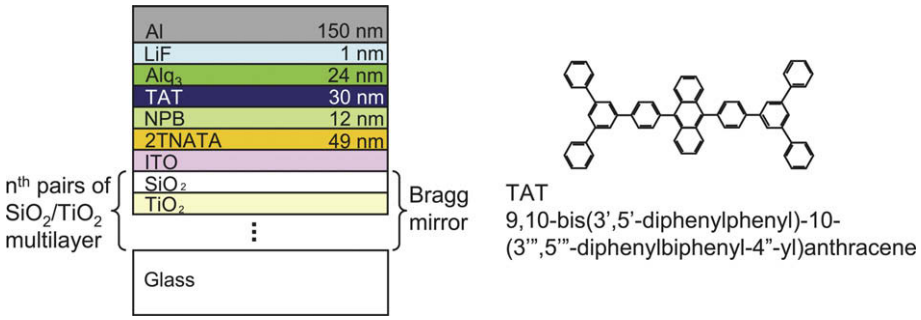

Fig. 1. Schematic diagram of a microcavity OLED device and chemical structure of TAT.

Fig. 1 also shows the chemical structures of the blue emitting material (TAT) in this experiment. As reported previously [19], TAT was purified employing a silica column and recrystallization, was characterized with nuclear magnetic resonance (NMR), Fourier transform infrared (FT-IR), and fast atom bombardment mass (FAB-MS) analysis. Boration and Suzuki aryl–aryl coupling reactions were used in all syntheses. The detailed synthesis route and characterization results of TAT are reported elsewhere [19].

To examine the effect of the dielectric Bragg mirrors experimentally, OLEDs were fabricated on two reference substrates (conventional reference (ITO = 150 nm) and reference type-II (ITO = 85 nm) and two types (type-A one pair and type-B one pair) of dielectric Bragg mirrors covering the substrates. Table 1 summarizes the thicknesses and sheet resistances of each sample. Mono-color OLED samples were fabricated with an active area of $2.0 \times 2.0\ mm^2$. High-index TiO_2 ($n = 2.3$) and low-index SiO_2 ($n = 1.46$) thin films were deposited alternatively on glass substrates in a single chamber using an e-beam evaporation technique [33]. The ITO layer was then deposited by magnetron sputtering with no intentional heating, and organic layers corresponding to 2-TNATA, NPB, TAT, and Alq_3 as well as a LiF film (as EIL) and aluminum metal cathode were evaporated sequentially to fabricate both the reference and microcavity devices. Finally the OLEDs were encapsulated with 0.7 mm Corning cover glass.

The current–voltage (I–V) characteristics of the electroluminescence (EL) devices fabricated were obtained using a Keithley 2611 electrometer. The EL spectra, EL brightness and color coordinates were obtained with a spectrophotometer (PSI Co., Ltd.) and a Minolta CS-1000A. The enhancement ratio of the quantum efficiency was obtained by comparing the normally directed light output of microcavity OLEDs at 10 mA/cm^2 to that of a conventional reference OLED (ITO = 150 nm).

3. Results and discussion

As reported previously [29–32], the electrical efficiency, relative quantum efficiency and color purity of the microcavity OLEDs depend on the thickness of the ITO, organic, low-index, and the high-index layers, respectively. The finite-difference time-domain (FDTD) simulations were used to determine the resonance wavelength of the cavity by varying the thickness of the ITO, low-index (SiO_2), and high-index layers (TiO_2). Dielectric Bragg mirrors with two different lattice constants were also inserted into the blue OLEDs in an attempt to tune the position of the blue emission peaks. Here, two types of quarter-wave stacks were designed to have center wavelengths of ≈465 (type-A) and 470 nm (type-B). The thicknesses of the ITO, low-index, and high-index layers are defined as the values when a deep blue color was realized. The reflectance (R) and transmittance (T) of the two types of quarter-wave stacks consisting of alternating low-index SiO_2 and high-index TiO_2 were measured as a function of the number of periods. As shown in Fig. 2, the reflectance of the type-A Bragg mirrors at the blue region increased with increasing periodic number of stacks. The central wavelength of the reflectance band shifted toward a bluish color with increasing number of high/low stacks, which is consistent with those in the calculation. The inset in Fig. 2 shows a side-view scanning electron microscopy (SEM) image of a real fabricated type-A dielectric multilayer comprised of alternate TiO_2 and SiO_2 quarter-wave films of the fourth periods. As shown in Table 1 and Fig. 2, the thicknesses

of the TiO_2/SiO_2 films match those of the dielectric films in the designed Bragg mirrors satisfactorily.

In order to compare the performance of the conventional noncavity OLED and the type-A microcavity OLEDs, the color coordinates, brightness, electrical efficiency and power efficiency should be considered. The normalized EL spectra of both type-A devices and the conventional reference (ITO = 150 nm) device (Fig. 3a) indicates that an increase in the periodic number of stacks decreases the full width at half maximum (FWHM) of the emission spectrum up to ~9 nm (four pairs) [29,30]. Single-mode blue emissions with peak wavelength of 460–466 nm with reduced FWHMs were realized by simply increasing the periodic number of SiO_2/TiO_2 stacks. Compared to the conventional noncavity devices with a broader EL spectrum (≈55 nm FWHM), controlling both the narrowness and position of the emissive spectrum will be of great benefit in optimizing the color purity of blue OLED for applications to display devices [32]. Fig. 3b shows the relative EL spectra of the conventional OLED and type-A OLEDs with the periodic number of stacks at a viewing angle of 0°. The intensity of the EL spectra increased with increasing periodic number of stacks up to two pairs and then decreased with further increases. This decrease in EL intensity in the four pairs of TiO_2/SiO_2 stacks was attributed to the increased reflectance and reduced transmittance of blue light, as shown in Fig. 2. The figure compares the normally directed emission spectra recorded at a constant current density (10 mA/cm^2) for the conventional noncavity OLED and type-A microcavity OLEDs with a periodic number of stacks. The results show that at the main peak wavelength, the emission intensity of the type-A microcavity OLEDs with one, two, and four pair stacks was 2.3, 3.3, and 2.2 higher than that of the conventional reference OLED, respectively. Moreover, the EL spectra of the microcavity OLEDs were narrowed and shifted, indicating the microcavity effect. Therefore, the thicknesses of the ITO, low- and high-index layer affect the spectral characteristics [30]. Our FDTD calculations were also used to determine

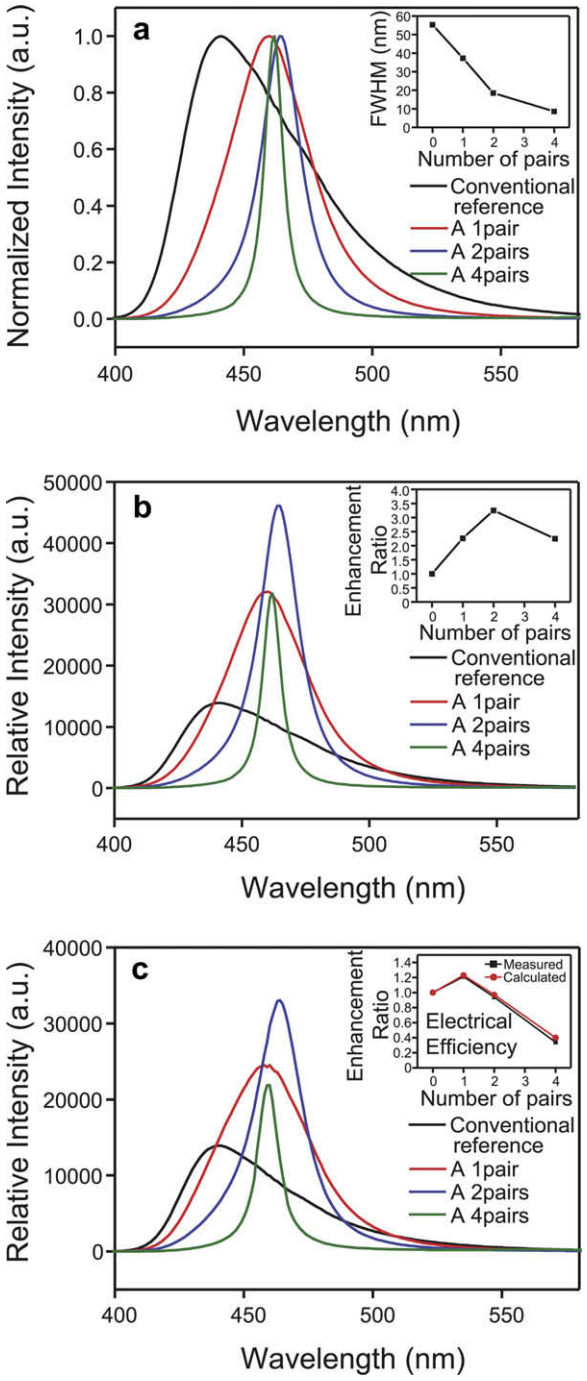

Fig. 3. (a) Normalized EL spectra and (b) relative EL spectra of the conventional reference OLED (ITO = 150 nm) and type-A microcavity OLEDs with the periodic number of high/low stacks at viewing angle of 0°. The inset in (a) shows the relationship between the full width at half maximum (FWHM) of the EL spectrum and the periodic number of high/low stacks, and the inset in (b) shows the relationship between the EL spectrum intensity and the periodic number of high/low stacks. (c) Calculated EL spectra of the conventional reference OLED (ITO = 150 nm) and type-A microcavity OLEDs with the periodic number of high/low stacks at viewing angle of 0°. The inset in (c) shows the relationship between the calculated and measured electrical efficiency along normal direction and the periodic number of high/low stacks.

the normally directed emission spectrum and electrical efficiency of type-A microcavity OLEDs with one, two and four pair stacks, indicating an improvement in the relative electrical efficiency of this device of ≈23%. Fig. 3c shows the calculated emission spectra and relative electrical efficiency of the type-A microcavity OLEDs. Fig. 3b and c confirm that the calculated shape of the emission spectra and the enhancement of the electrical efficiency are very similar to those of the measured spectra and electrical efficiency in the normal direction.

Fig. 4a and b shows the current density (J)–normal direction luminance (L)–voltage (V) characteristics of the conventional noncavity reference OLEDs and type-A microcavity OLEDs with the periodic number of stacks. The J of the conventional reference OLED increased faster with increasing voltage than those of all microcavity OLEDs. The superior J–V characteristics was attributed to the enhanced hole injection from the thicker ITO anode of the conventional OLED with a lower resistance, as summarized in Table 1. On the other hand, the dependence of J for all type-A microcavity OLEDs showed similar trends due to the similar sheet resistance of the ITO anodes, irrespective of the periodic number of stacks. Fig. 4b shows that the difference between the L–V curves of the conventional OLED

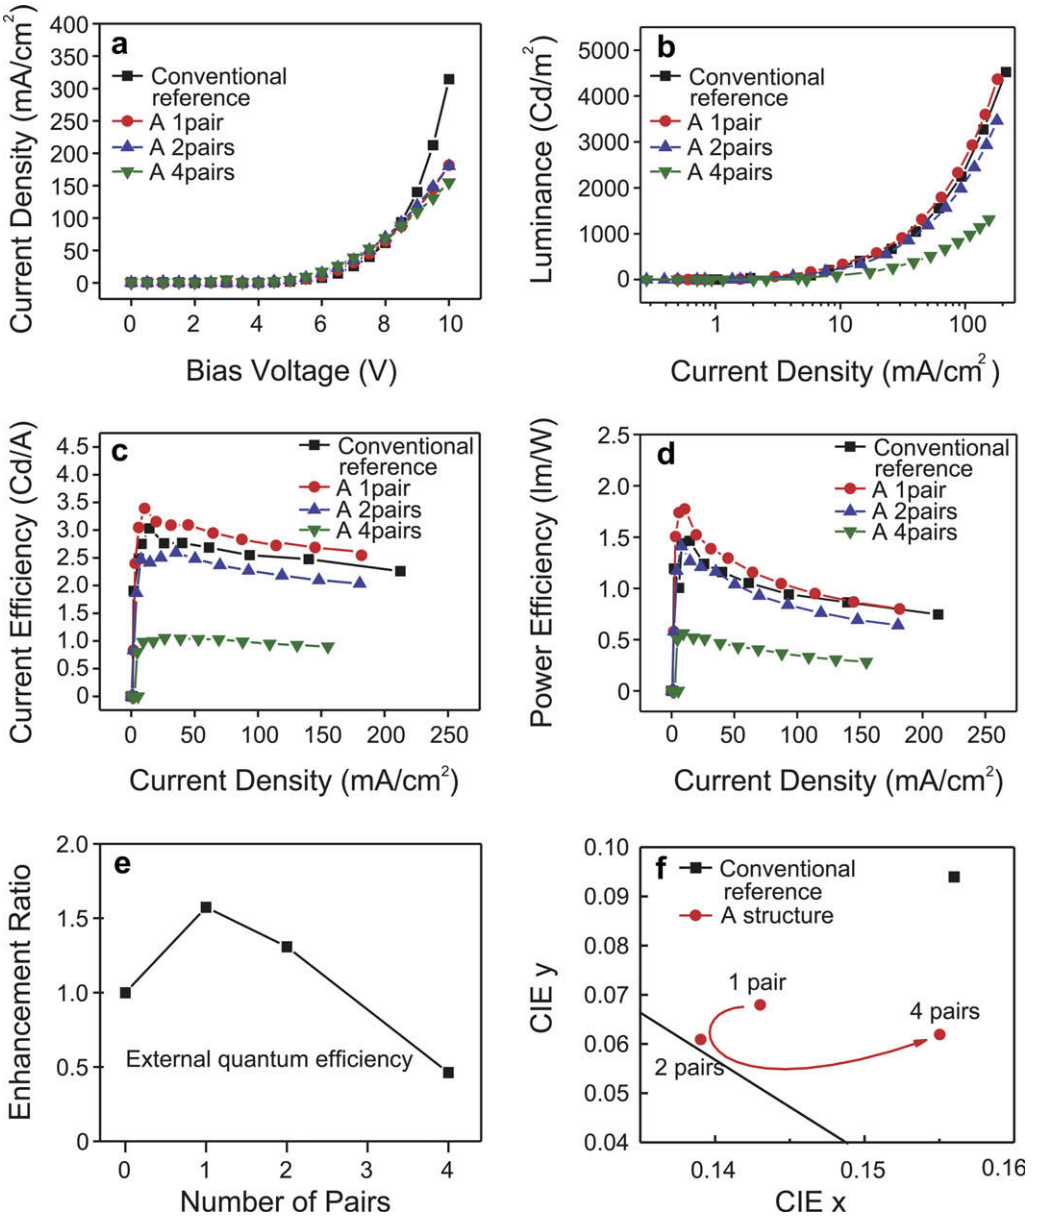

Fig. 4. (a) Current density–bias voltage characteristics, (b) current density–normal direction luminance characteristics, (c) current density–electrical efficiency characteristics, (d) current density–power efficiency characteristics (e) enhancement ratio of the quantum efficiency in the normal direction and (f) CIE color coordinates of the conventional reference OLED (ITO = 150 nm) and type-A microcavity OLEDs with a periodic number of high/low stacks at a viewing angle of 0°. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

and the microcavity OLEDs with the periodic number of stacks is larger than that between the *J–V* curves. This figure also shows the different trends of the *L–V* curves of the microcavity OLEDs as a function of the periodic number of stacks. The microcavity OLEDs with increasing number of quarter-wave stacks showed decreased brightness due to the different dependences of the microcavity effect on the periodic number of stacks. Although higher color purity was achieved by increasing the microcavity effect, the luminous efficiency was reduced despite the enhanced peak intensity due to the loss of light around the shoulder of the peak at 480 nm, which has high eye sensitivity. It appears that when dielectric mirrors are used, there is some trade-off between the color purity and luminance for blue-emitting materials.

Fig. 4c and d shows the relationship between the current efficiency–current density and power efficiency–current density of the conventional reference OLED and type-A microcavity OLEDs. The current efficiency at 10 mA/cm^2 in the normal direction for the conventional noncavity reference OLED was 2.8 cd/A, whereas the efficiencies for the type-A microcavity OLEDs with one, two and four pairs of quarter-wave stacks were 3.2, 2.4, and 1.0 cd/A, indicating that the current efficiency of conventional reference OLED in the normal direction is slightly lower than that in the type-A microcavity OLED containing a single pair of quarter-wave stacks. Fig. 4d also shows a similar relationship of power efficiency–current density with the number of quarter-wave stacks. Although the current and power efficiencies of the moderate microcavity blue OLED with one pair of high-low stacks is slightly higher than that of the noncavity blue OLED, the photons emitted from the microcavity blue OLEDs was significantly enhanced by the microcavity effect, as illustrated by the emission spectra in Fig. 3b.

For a systematic comparison of these OLEDs, the enhancement ratio of the quantum efficiency was defined as the ratio of the normally directed light output of microcavity OLEDs or other reference OLEDs to that of a conventional reference OLED (ITO = 150 nm). This enhancement ratio only shows how much the EL quantum efficiency at 10 mA/cm^2 of microcavity OLEDs was improved relative to that of a conventional noncavity reference OLED. Fig. 4e shows the enhancement ratio of the quantum efficiencies of each OLED. In contrast to the trends in current efficiency, the quantum efficiency of type-A microcavity OLEDs with a single pair of quarter-wave stacks was superior to that of the conventional reference OLED. However, the microcavity OLEDs with a higher number of pairs of quarter-wave stacks showed lower quantum efficiency. The normally directed quantum efficiency of the type-A microcavity OLEDs with a single pair of high and low-index layers was 1.57 higher than that of the conventional reference OLED. As expected, with the resonant wavelength set to 465 nm (19 nm longer than the PL peak of TAT), the type-A moderate microcavity device with a single pair of quarter-wave stacks showed the significantly enhanced quantum efficiency compared to the conventional reference OLED device. Even with brightness slightly higher than the conventional OLEDs, the quantum efficiency of the microcavity OLEDs with a single pair of quarter-wave stacks was significantly higher than that of the conventional OLED device. This was attributed to the lower eye sensitivity of more pure blue moderate microcavity OLEDs. In addition, Fig. 4f shows that the CIE color coordinates of the type-A microcavity OLEDs with a different number of quarter-wave stacks were purer than those of the conventional noncavity OLED. The increased color purity with the increasing number of high/low stacks was attributed to the blue shift and narrowing of the emission spectrum due to the enhanced microcavity effect. In particular, the moderate microcavity OLED with a single pair of high/low stacks showed a deeper blue and higher quantum efficiency than the conventional noncavity OLED.

The angular dependence of the emission spectrum was also examined because changes in color with changing viewing angle are undesirable for display applications [28,29]. Fig. 5a and b shows the angle dependence of the emission spectra of a conventional reference OLED (ITO = 150 nm) and a type-A microcavity OLED with a single pair of high/low stacks at room temperature, respectively. The figures show negligible angular dependence in the peak shape of the conventional reference OLED but a blue shift in the emission spectrum of the microcavity OLED with a single pair of high/low stacks. The CIE coordinates were used to assess the color changes in the OLEDs. Fig. 6 shows the angular dependence of the CIE color coordinates for the conventional reference OLED and type-A microcavity OLED with a single pair of high/low stack on a chromaticity diagram. When viewed from the normal direction, the CIE color coordinates for the conventional reference OLED and moderate microcavity OLED were $(0.156, 0.094)$ and $(0.143, 0.068)$, respectively. This suggests that the light emitted by the moderate microcavity OLED has deeper color purity than the conventional reference standard. The results also show that the color change ratio of the moderate microcavity OLED ($\Delta x = 13\%$, $\Delta y = 15\%$) became slightly worse than that of the conventional reference OLED ($\Delta x = 1\%$, $\Delta y = 31\%$) as the viewing angle was changed up to 60° of the normal. In contrast to the color change in the conventional reference OLED ($0.156, 0.094 \rightarrow 0.157, 0.123$) and the angular dependence of color purity of the moderate microcavity OLED ($0.143, 0.068 \rightarrow 0.161, 0.058$) showed improved color purity with increased viewing angle. The improved color purity and comparable angular dependence of the color purity are another advantage that the moderate microcavity OLEDs have over conventional reference OLEDs.

The far-field pattern of the integrated spectrum intensity was measured to determine the physical characteristics underlying the angular dependence of a single EL emission intensity. The far-field photon radiation from the OLED devices was measured directly with a photodiode, 1 mm^2 in area, which was located 10 cm from the radiation source. Fig. 7 compares the far-field profiles of the conventional reference and moderate microcavity OLEDs cut along the horizontal line. It shows that the noncavity OLED radiates into air in a manner consistent with a Lambertian source. It also suggests that the moderate microcavity OLEDs show only small variations in their angular radiation patterns over a large angular span. Therefore, the far-field profiles of the moderate microcav-

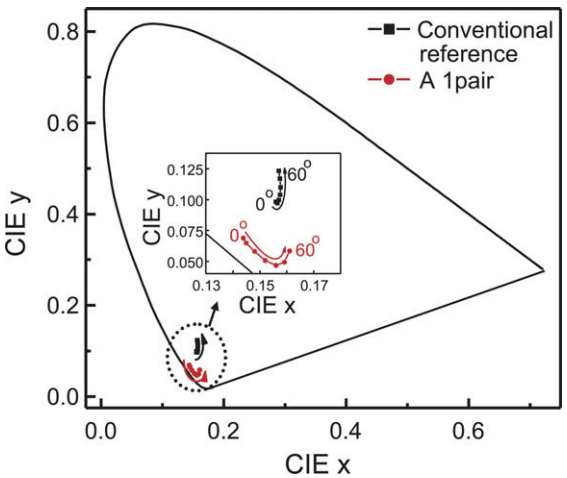

Fig. 6. Viewing angle dependence of the Commission Internationale de l'Eclairage (CIE) color coordinates of the conventional reference OLED (ITO = 150 nm) and type-A moderate microcavity OLED with a single pair of high/low stacks under 10 mA/cm^2 of current density.

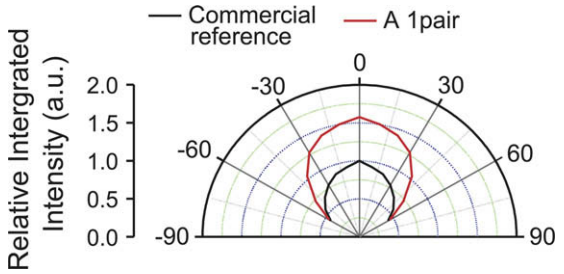

Fig. 7. The viewing angle dependence of integrated EL intensity profiles of conventional reference OLED (ITO = 150 nm) and type-A moderate microcavity OLED with a single pair of high/low stacks under 10 mA/cm^2 of current density.

ity OLEDs with a single pair of high/low stacks were similar to that of the conventional reference OLEDs.

To achieve the NTSC blue color from TAT-doped blue OLED, the tunable effects of the microcavity (type-A one pair and type-B one pair) on OLEDs were examined by controlling the central wavelength of the dielectric Bragg

mirror. OLEDs were fabricated on two reference substrates (conventional reference (ITO = 150 nm) and reference type-II (ITO = 85 nm)) and two moderate microcavity substrates (type-A: λ_{cen} = 465 nm, type-B: λ_{cen} = 470 nm) deposited with a single pair of high/low stacks, side by side for comparison. Consistent with the simulated results, Fig. 8 suggests that the emission spectrum of the type-B microcavity OLED was shifted slightly to a longer wavelength compared to that of the type-A microcavity OLEDs. This indicates that the emission spectra of two types of moderate microcavity OLEDs were narrower than those of the two reference OLEDs. Fig. 8 also shows the CIE color coordinates in the normal direction for the reference OLEDs and moderate microcavity OLEDs. The color coordinates of a thin ITO (85 nm) coated reference type-II OLED was slightly higher than that of the conventional reference OLED (ITO = 150 nm). This means that the reduced ITO thickness of the noncavity OLED have a minor effect in controlling the color purity and EL performance. As mentioned above, the light emitted from the moderate microcavity OLEDs had deeper color purity than that emitted by both types of reference OLEDs. The color coordinates (x = 0.139, y = 0.081) of the type-B moderate microcavity OLED with a single pair of high/low stacks was very close to the color coordinates of NTSC blue (x = 0.140, y = 0.080). Therefore, a pure blue color was obtained from TAT-doped blue OLEDs simply by introducing a single pair of TiO_2/SiO_2 high/low dielectric stacks on the substrate.

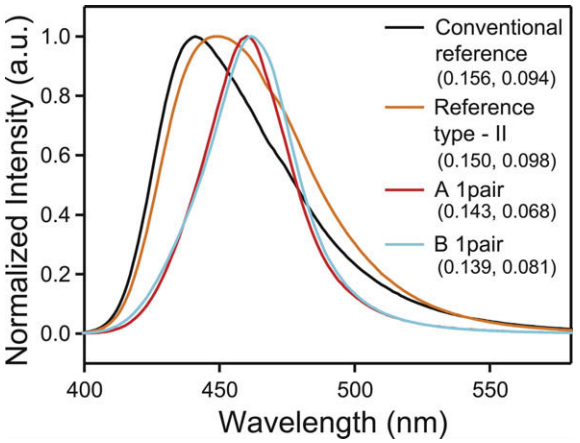

Fig. 8. The normalized EL spectra and CIE color coordinates of the conventional reference OLED (ITO = 150 nm), reference type-II OLED, type-A moderate microcavity, and type-B moderate microcavity OLED under a current density of 10 mA/cm^2.

The electroluminescence measurements showed the current density–luminance characteristics of the four types of OLEDs with and without the microcavity high/low stack. The luminance values of the two types of moderate microcavity OLEDs and reference OLEDs measured in the normal direction ($\theta = 0^\circ$) under dc excitation at 10 mA/cm^2 were 320 (type-A one pair, ITO thickness of 80 nm), 340 (type-B one pair, ITO thickness of 85 nm), 280 (conventional, ITO thickness of 150 nm), and 290 cd/m^2 (conventional, ITO thickness of 85 nm). Fig. 9 shows the current efficiency and enhancement ratio of the normally directed quantum efficiency for two conventional OLEDs and two types of moderate microcavity OLEDs. For the conventional OLEDs, the current efficiencies and relative quantum efficiencies at 10 mA/cm^2 in the normal direction were 2.8 cd/A and 1.00 (conventional reference) and 2.9 cd/A and 1.04 (reference type-II). By comparison, the current efficiencies and quantum efficiencies of the type-A and type-B moderate microcavity OLEDs were 3.2 cd/A, 1.57 and 3.4 cd/A, 1.60, respectively. This indicates that the current efficiencies of the moderate microcavity OLEDs in the normal direction are higher than those of the corresponding conventional OLEDs. Moreover, the relative quantum efficiencies of the type-A and type-B moderate microcavity OLEDs in the normal direction were 57% and 60% higher than those of the corresponding conventional reference OLEDs. This also suggests that the type-B moderate microcavity OLED with color purity close to the NTSC blue standard had higher efficiency than both conventional reference OLEDs and reference type-II with an ITO layer of identical thickness.

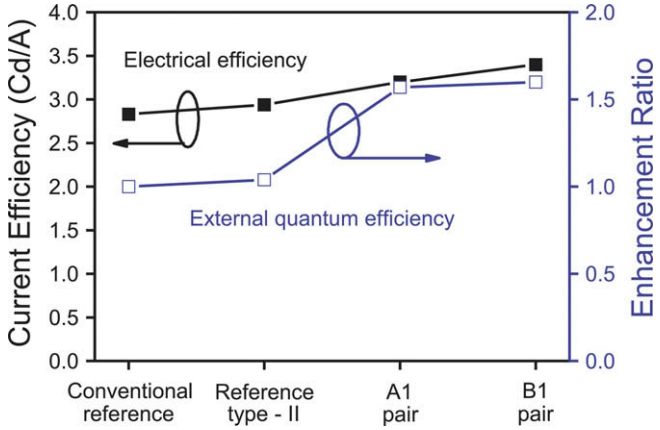

Fig. 9. Electrical efficiency and the enhancement ratio of the normally directed quantum efficiency of the conventional reference OLED (ITO = 150 nm), reference type-II OLED, type-A moderate microcavity, and type-B moderate microcavity OLED under current density of 10 mA/cm^2.

4. Conclusion

This study examined the effects of inserting dielectric Bragg mirrors in an OLED with the aim of achieving NTSC pure blue and enhancing its relative quantum efficiency. First the FDTD method was used to calculate the resonance wavelength of the cavity while varying the thickness of the organic and high/low dielectric layers. The introduction of a single pair of TiO_2/SiO_2 high/low stacks into the OLED structure (denoted as a moderate microcavity OLED) is an effective way of enhancing the quantum efficiency and achieving a NTSC pure blue color from a TAT-based blue OLED. It was demonstrated experimentally that the incorporation of two types of moderate microcavity OLEDs with a single pair of high/low stacks achieved pure blue CIE color coordinates (type-A; $x = 0.143, y = 0.068$, type-B; $x = 0.139$, $y = 0.081$). The type-A and type-B moderate microcavity OLED showed more than 57% and 60% improvement in relative quantum efficiency in the normal direction, respectively, compared to the conventional reference OLED (ITO = 150 nm) in the normal direction. They also improved the relative quantum efficiency by more than 51% and 54%, respectively, compared to the reference type-II (ITO = 85 nm). In addition, the moderate microcavity OLED is more favorable for the angular dependence of the color purity and EL intensity. This simple technique of introducing a dielectric Bragg mirror with a single pair of high/low dielectric stacks into a TAT-doped blue OLED can be generalized for the development of efficient and saturated blue OLEDs from the standpoint of realizing a deep blue color in computer and television screens, and for full color display applications.

ABSTRACT

The stability of molecular junctions is crucial for any application of molecular electronics. Degradation of molecular junctions when exposed to ambient conditions is regularly observed. In this report the stability of large-area molecular junctions under ambient conditions for more than two years is presented. Furthermore, the thermal stability of molecular junctions at elevated temperatures is investigated. A transition temperature at 50 °C was observed for molecular junctions based on self-assembled monolayers of alkanedithiols, above which the resistance decreases exponentially with temperature. This transition temperature limits the process window during fabrication and the temperature window during operation.

The field of molecular electronics has grown exponentially after the seminal theoretical paper of Aviram and Ratner [1], predicting that a single molecule can operate as a rectifying diode. Electronic transport through molecules has since then been investigated experimentally in many different device geometries [2,3]. The most studied systems are self-assembled monolayers (SAMs) of alkane(di)thiols on gold [4–6]. The resistance of Au/SAM Au junctions exponentially increases with increasing molecular length and is independent of temperature, indicating that charge transport is due to non-resonant tunneling [7–9]. Progress in the study of discrete devices is severely hampered by limited reliability, stability, and especially, yield. Electrical shorts in the SAM are readily formed upon vapor deposition of the top electrode [10]. An illustration is the statistical analysis which has been reported for manually measured molecular junctions with a diameter of 2 μm and evaporated metal top electrodes [11]. The yield of the functional junctions was 156 out of 13,440 junctions fabricated, or 1.2%. Formation of shorts can be prevented by applying a conducting barrier layer between the SAM and the top electrode. A yield of unity has been reported for discrete large-area junctions by using the conducting polymer poly(3,4-ethylene-dioxythiophene) stabilized with polystyrene sulphonic acid, henceforth abbreviated as PEDOT:PSS, as a barrier [12]. Even for devices as large as 100 μm in diameter, the PEDOT:PSS layer prevents shorts. The technology is suitable for upscaling, integration and incorporation of functionality. More than 20,000 molecular junctions, discrete and connected in series, were fabricated simultaneously on a single 150 mm wafer in a semi-automated process [13]. Functionality was demonstrated by switchable conductance realized with diarylethene molecular photoswitches

[14]. A prerequisite for any application is a shelf life extending years. Furthermore, the temperature window for operation needs to be determined. Here we investigate the electrical transport in molecular junctions as a function of storage time and at elevated temperatures.

Discrete large-area molecular junctions were fabricated according to previously published procedure [2,13–16]. By photolithography, vertical interconnects (vias) are created on top of the gold bottom electrodes. A monolayer of alkanedithiols is self-assembled on the exposed gold bottom electrodes within the vertical interconnects. The conducting polymer interlayer of PEDOT:PSS is spincoated on top after the self-assembly process. In the final step Au top electrodes are evaporated and the redundant PEDOT:PSS is etched away with reactive ion etching to prevent parasitic currents. The resulting molecular junctions have the SAM completely encapsulated by photoresist on the sides of the vertical interconnect and protected by the conducting polymer PEDOT:PSS on top. A schematic presentation of the device geometry and a micrograph of an actual junction are presented in Fig. 1.

The current density of C12-dithiol junctions as a function of bias is presented in Fig. 2a. The density is an average over 10 devices, half of them with a diameter of 40 μm and half of them of 80 μm in diameter. The *I–V* curves of the molecular junctions exhibit a super linear increase due to tunneling, as confirmed by low temperature measurements [7,12]. To investigate the stability of the molecular junctions, the samples were stored in air for subsequent measurements. Molecular junctions have been stored and remeasured after 2.5 years. There is only a minor change of a factor less than two after storage for 888 days, or 2.5 years. In Fig. 2b the resistances of the 10 discrete junctions are presented separately.

To determine the maximum operation temperature, the transport in the junctions was investigated as a function of temperature. The junctions are loaded in the probe station and set under vacuum. The temperature of the system was systematically increased up to 110 °C. The temperature was raised in steps of 10 °C and kept for 5 min at each temperature before performing *I–V* scans on 2 or 3 junctions at these temperatures. Subsequently, the temperature was raised and kept constant for 5 min again, before performing the next measurements.

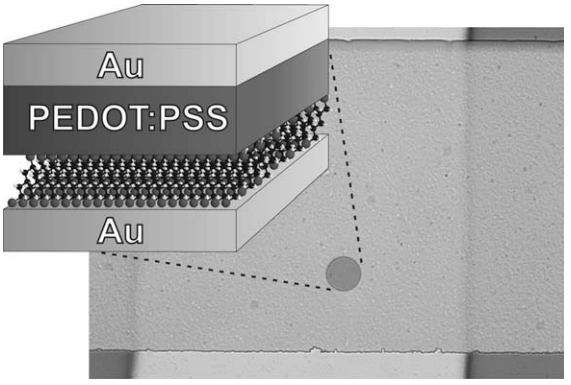

Fig. 1. A micrograph of a molecular junction of 100 μm in diameter. In this image the top Au electrode is 20 nm thick and therefore partially transparent. A schematic representation of the junction with the stacked layers of Au/SAM/PEDOT:PSS/Au is shown in the inset.

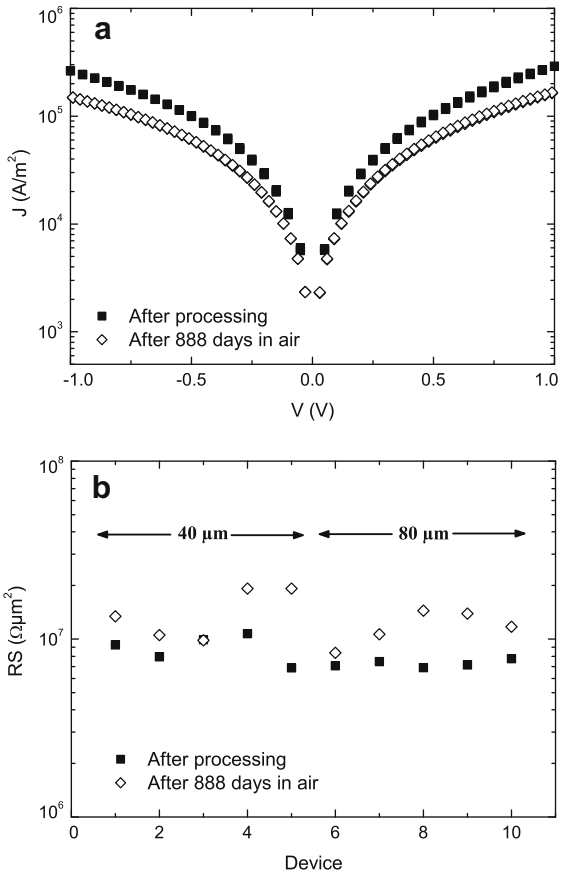

Fig. 2. Stability of large-area molecular junctions in ambient environment. (a) *J–V* traces of devices with a C12-dithiol self-assembled monolayer. The average current density is plotted of 10 junctions, where the *J–V* characteristics from the junctions after processing (■) are compared to the same junctions stored in air for 888 days (◇). The normalized resistance at 0.1 V for the 10 measured individual junctions of 40 and 80 μm in diameter is presented in (b). No dependence on device area is observed for the small increase in resistance after almost 2.5 years storage in air.

Fig. 3a shows the normalized resistance as a function of anneal temperature. Data are presented for different lengths of the alkanedithiols, *i.e.* C8, C10, C12, and C14. For comparison a junction without a SAM present (PEDOT:PSS-only device) is included. The resistances of all junctions decrease with increasing anneal temperature. We note that the change in resistance is irreversible. Since the maximum temperature inside the probe station is 110 °C, the samples were annealed at 150 °C and 200 °C for 15 min on a hotplate in air to investigate the decrease in resistance at higher temperatures. Towards high temperatures, all junctions approach the resistance value of a PEDOT:PSS-only device. The transition temperature is defined as shown in Fig. 3b, by the intercept between low and high temperature fits. Surprisingly, the transition temperature does not depend on the length of the molecules and is at 50 °C for all junctions. Below this temperature

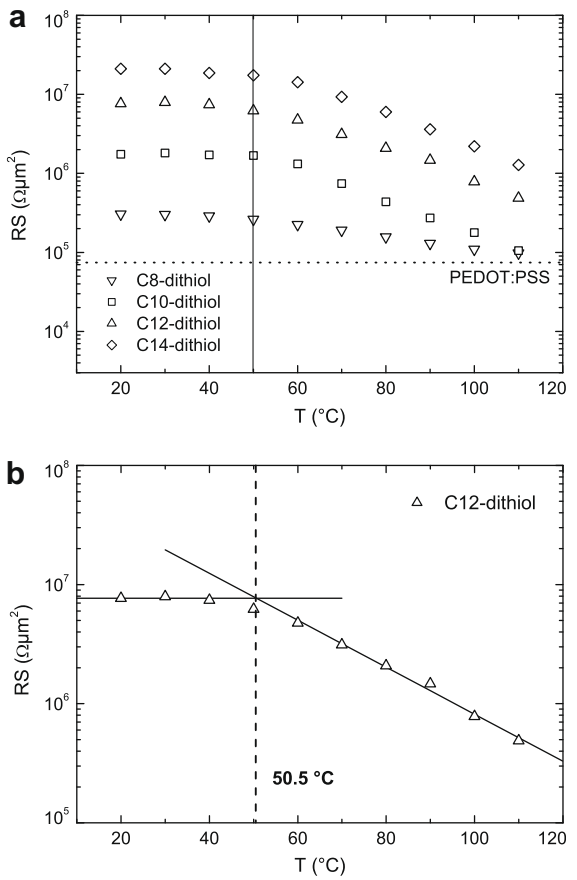

Fig. 3. (a) Normalized resistance at 0.1 V, *RS*, as a function of increasing temperature. For alkane(di)thiols with lengths C10, C12, and C14 a similar trend is observed with increasing temperature, independent of molecule length. C8 shows a different trend since the normalized resistance approaches that of PEDOT:PSS only junctions (represented by the dotted line) at higher temperatures. All SAMs show a transition temperature around 50 °C, after which the resistance is decreasing exponentially with increasing temperature. (b) The transition temperature is determined by calculating the intersection between the average *RS* value of 20–40 °C and the linear fit to the data for 70–110 °C.

no changes in resistance are observed. Above the transition temperature the resistance decreases exponentially with increasing temperature.

The formation of shorts due to PEDOT:PSS filaments can be excluded. When conducting filaments of PEDOT:PSS would form at a specific temperature, irrespective of the length of the SAM, the decrease in resistance would be more pronounced for higher resistances, hence longer molecules.

Thermal stability of SAMs on Au surfaces has been studied extensively [17–23]. Phase transitions and desorption of alkanethiol monolayers on Au(1 1 1) have been observed at elevated temperatures with STM [20,21,24–27]. The two dimensional melting temperature of alkanethiol SAMs increases with increasing chain length of the alkane backbone [22,23,27]. The transition temperature in the junctions being independent of chain length can therefore not yet be explained. The formation of an incommensurate phase as observed by Fenter and coworkers is similar to our observations [28]. While absolute transition temperatures are strongly dependent on coverage of the monolayer, the temperature for the commensurate–incommensurate phase transition is shown to be independent of molecular length, however, only for *n*-alkanethiols with $n \geqslant 14$.

To summarize, we investigated the stability of large-area molecular junctions at temperatures up to 110 °C. Long term stability at room temperature was demonstrated, when stored in ambient conditions. After 888 days in air without UV shielding or any other precautions, no significant change was observed in the current–voltage characteristics of molecular junctions. At elevated temperatures, a transition point was found at 50 °C, which is independent of the molecule length. Up to 50 °C no changes in resistance are observed, whilst above the transition temperature a decrease of the normalized resistance was observed. The observed exponential decrease in resistance for temperatures exceeding 50 °C is similar for all SAMs irrespective of the molecular length of the alkanedithiols. The upper limit of 50 °C is a strong limitation for the applicability of molecular electronics.

Memristor
Ionic transition metal complex

ABSTRACT

A light-emitting memristor (LEM) is reported based on a metal/mixed conductor/metal structure, where the mixed conductor is the ionic transition metal complex ruthenium(II) tris(bipyridine) with hexafluorophosphate counter ions. The device shows memory effects upon the application of an ac bias, in both current and electroluminescence intensity. The observation of memory in light emission offers the potential for optical read-out of the state of memristive devices.

1. Introduction

In 1971, Leon Chua introduced the concept of a missing fundamental passive element in electronics called the memristor (short for memory resistor) [1]. The prediction of the existence of the memristor was based on conceptual symmetry arguments which followed from the description of basic passive circuit elements as defined by the relation between two of the four fundamental circuit variables, namely voltage V, current I, charge q, and magnetic flux Φ. Chua demonstrated that memristors could not be obtained by any combination of the other three fundamental elements: resistors, capacitors and inductors. A memristor is characterized by its memristance $M(q)$, which is the time-dependent rate of change of the magnetic flux in respect to the electric charge:

$$M(q(t)) = \frac{\partial \Phi(t)}{\partial q(t)} \tag{1}$$

Since magnetic flux is the time integral of voltage and charge is the time integral of current I, one may write that:

$$M(q(t)) = \frac{V(t)}{I(t)} \tag{2}$$

which is more convenient since voltage and current can be easily measured in an experiment.

The essential property of a memristor is its memory – the dependence of resistance on the operational history of the device. At the time that the theoretical properties of a memristor were described, there was no experimental demonstration of a memristor as a two-terminal passive element. Chua proposed the modeling of a memristor with electric circuits, with at least 15 transistors and other passive elements [1]. Potential applications in programmable logic, signal processing, neural networks, and control systems have been proposed [2]. The ideal memristor response in terms of $M(q(t))$ is a step function at $q = 0$ between an "on" and an "off" state.

Interest in memristors was recently renewed when Williams et al. demonstrated the first memristor as a passive, two-terminal element made from a thin (5 nm) film of TiO_2 sandwiched between two Pt metal electrodes [3]. The

doi:10.1016/j.orgel.2009.09.015

memristance of the device was attributed to ion drift in the film and a subsequent modulation of the bulk conductivity [1]. It was further postulated that memristive behavior should be common in nanoscale electronics devices, in which high electric fields can induce ionic motion. In terms of response, this was not an ideal memristor, and there was a transition region between the "on" and "off" states, as one would expect for a realistic material.

In this vein, it is of interest to explore memristors from other materials, particularly materials that might offer enhanced functionality. Molecular electronic materials are currently being used in large-area flat panel displays and are also being developed for solar cells and memory devices. These materials offer unique properties such as solution processing, compatibility with mechanically flexible and large-area substrates, and wide tunability of properties through chemical synthesis [4]. As a result, they can bring new forms and functions to the memristor. In this letter, we report on a two-terminal memristor that is capable of electroluminescence (EL); hence the name light-emitting memristor (LEM). We use the well-studied ionic transition metal complex (iTMC) ruthenium(II) tris(bipyridine) with hexafluorophosphate counter ions, $[Ru(bpy)_3]^{2+}(PF_6^-)_2$, and demonstrate devices in which not only the current, but also the electroluminescence exhibits a memory effect. Light emission gives memristors new functionality, and might enable new features such as optical read-out.

$[Ru(bpy)_3]^{2+}(PF_6^-)_2$ is a mixed conductor, possessing the ability to conduct both ionic (the PF_6^- ions) and electronic (injected from metal electrodes) carriers under an applied bias [5–11]. In metal/{$[Ru(bpy)_3]^{2+}(PF_6^-)_2$}/metal devices, the redistribution of the PF_6^- ions upon the application of a bias creates an ionic space charge near each electrode (excess PF_6^- near the anode and uncompensated $[Ru(bpy)_3]^{2+}$ near the cathode). This assists in the injection of electrons and holes [7,10,11], which recombine in the bulk of the $[Ru(bpy)_3]^{2+}$ layer to form excitons, a fraction of which recombine radiatively to give rise to light emission.

2. Experimental

The LEM device was fabricated as follows: Stock solutions of 40 mg/ml of $[Ru(bpy)_3]^{2+}(PF_6^-)_2$ in acetonitrile and 25 mg/ml of poly(methyl methacrylate) (Aldrich; average $M_w \sim 300{,}000$) in acetonitrile were prepared separately and combined in a 1:1 volume ratio. A film was fabricated by spin coating onto a clean ITO glass slide at 1000 rpm for 60 s, to give a final film thickness of 120 nm. The film was baked for 2 h at 120 °C and a 300 Å-thick Au electrode was thermally evaporated on top of the films at a pressure of 3.0×10^{-6} Torr and at a rate of 1 Å/s. The devices were tested using a Keithley 236 source measure unit and a Labsphere modular integrating sphere with a calibrated Si photodetector. Fabrication and testing took place in a nitrogen glove box.

3. Results and discussion

The typical dependence of the current $I(t)$ under an applied harmonic bias $V(t)$ is shown in Fig. 1A. The observed time delay between the maxima in voltage and current is a result of memristive behavior. Fig. 1B shows the corresponding I–V plot, which follows Chua's prediction and corresponds to a Lissajous curve. Fig. 2A shows the time dependence of the intensity of electroluminescence ($L(t)$), which exhibits the same time delay with respect to voltage as did the current. Fig. 2B shows the corresponding plot of light intensity vs. voltage.

The highest occupied molecular orbital (HOMO) of $[Ru(bpy)_3]^{2+}$ is at 5.8 eV and its lowest unoccupied molecular orbital (LUMO) is at 3.2 eV. The large barriers from the ITO (work function ~4.3 eV) and Au (work function of ~5.1 eV) electrodes imply that there is little electronic charge injection immediately after the application of a bias. This is the OFF state where the electronic current is negligible and no light emission is observed. However, as the ions redistribute near the ITO/organic and organic/Au interfaces, charge injection commences and the ON state is reached [11]. The asymmetry in current and light intensity between positive and negative bias can be attributed to the difference in the work functions of ITO and Au, causing different injection barriers.

The memristive effect in these devices depends on the frequency of the applied signal. In order to illustrate this, Fig. 3 shows the frequency dependence of the phase shift – calculated by dividing the time delay between the maxima of $I(t)$ (or $L(t)$) and $V(t)$ peaks by the period of the ap-

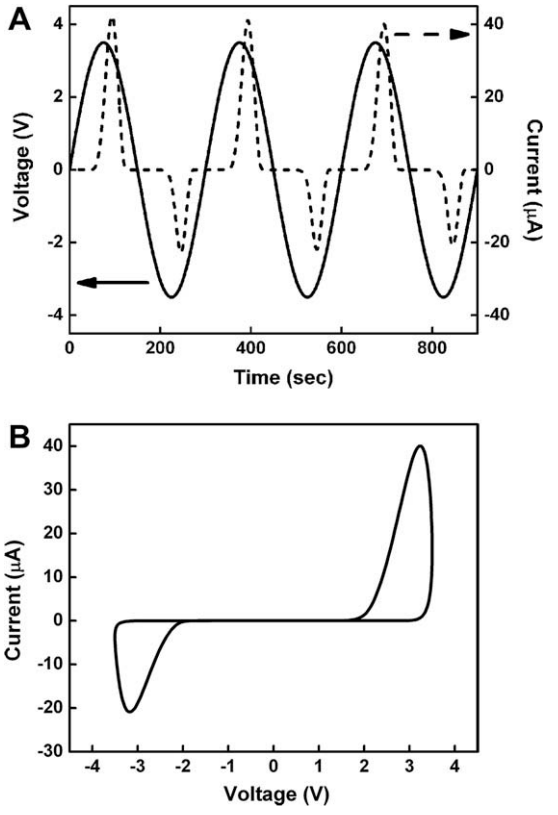

Fig. 1. (A) The applied bias at 3.33 mHz (solid line) and resulting current (dashed line) as function of time, and (B) the corresponding current vs. voltage plot. Bias applied with respect to ITO electrode.

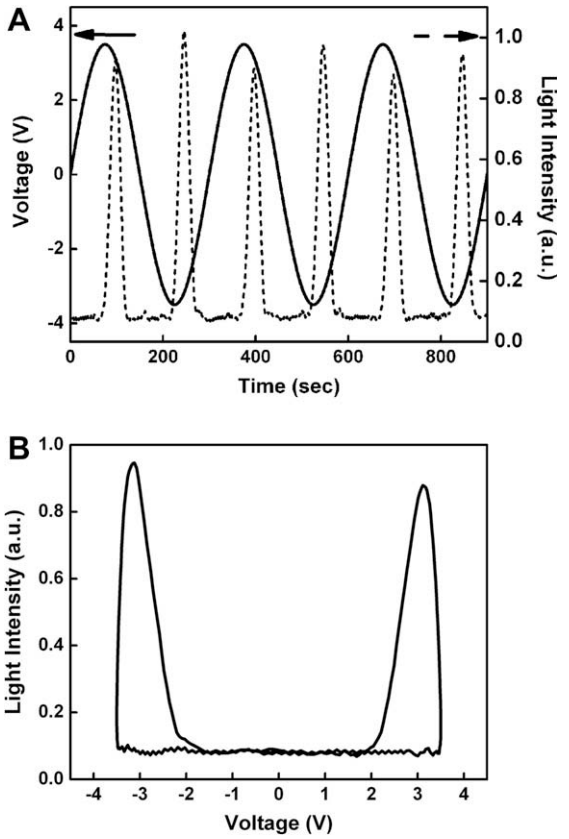

Fig. 2. (A) The applied bias at 3.33 mHz (solid line) and resulting electroluminescence intensity (dashed line) as function of time, and (B) the corresponding intensity vs. voltage plot.

plied signal. Interestingly, there is a phase shift maximum near 3.3 mHz, with decreasing phase shifts for lower and higher frequencies. We can account for this behavior by considering ionic space charge effects: at low frequencies, the ion movement is fast enough to follow the applied bias, so little memory effect is observed. The current (or light intensity) vs. voltage curves in this regime look qualitatively similar to the curves in Figs. 1B and 2B, but the magnitudes of both current and light intensity are higher and there is less hysteresis. In contrast, at high frequencies, the ions cannot respond fast enough to enable significant electronic carrier injection. Therefore, the current in this regime is mostly due to ionic displacement (hence there is no light emission) and follows the voltage signal without a time lag. The maximum phase shift corresponds to a time period around 300 s, consistent with the slow turn-on times of iTMC devices [11].

Due to the low ionic conductivity of PF_6^- ions, the time response of the memristor presented here is too slow for practical applications. However, there are several ways to improve the time response of devices made from iTMCs. For instance, decreasing the thickness of the iTMC layer makes the device turn-on faster. Unfortunately, this also lowers its efficiency, owing to exciton quenching at the electrodes [12]. Increasing the applied bias reduces the turn-on time but also leads to shorter device lifetime [5].

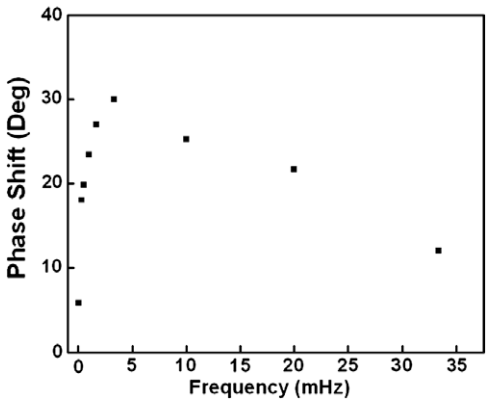

Fig. 3. Phase shift dependence on the frequency of the applied bias.

Changing the counter ion from PF_6^- to ClO_4^- or BF_4^- reduces the turn-on times but is also accompanied by a faster degradation of the device, as observed by the decreasing light output over time [6,13,14]. One of the most effective ways to improve the time response of iTMC light-emitting device is to increase the ionic conductivity [15–21]. For instance, incorporation of the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate enabled ac operation of $[Ru(bpy)_3]^{2+}(PF_6^-)_2$ devices at 60 Hz [19].

Even though the device presented here does not show non-volatility, it is still a memristor due to its strong dependence of resistance on charge. Upon application of a bias in a "rested" device, it takes several minutes to observe electroluminescence. The resulting ion distribution is retained for several minutes after the bias is removed. Therefore, if a bias is immediately reapplied, the time to observe electroluminescence would be much shorter. A memory switch could be fabricated using this device that would operate with a retention time/switching time ratio acceptable for some applications (e.g. for bio-inspired circuits). As was recently pointed out [22], thin metal oxide memristors are not completely non-volatile either, with their retention time depending on temperature, applied voltage and materials parameters.

The memristive behavior in electroluminescence observed here is not limited to $[Ru(bpy)_3]^{2+}(PF_6^-)_2$ light-emitting devices. Solid-state light-emitting devices possessing mixed ionic and electronic conductivity belong to a general class of devices termed light-emitting electrochemical cells, which have been studied for over a decade [23–28]. Virtually all of these devices should, likewise, exhibit memory effects. With recent advances in the understanding of their mechanism of device operation [10,23,24] and with better control of their turn-on time [15–21,29,30], these devices might contribute to data storage and computing.

ABSTRACT

In this article, low temperature processed, reactively evaporated titanium oxide layers were utilized as gate dielectrics for achieving low voltage driven transistors and complementary inverters. The surface of the gate dielectric was modified by an ultra thin (~30 nm) fluoropolymer Cytop® layer which partially helped to reduce the leakage in the dielectric films and also enhanced the organic transistor performance. The current investigation demonstrates the ability of these high capacitance bi-layer dielectrics ($k \sim 20$). The combined p-type and n-type field-effect transistors show similar saturation mobility ~0.3 cm^2/Vs to achieve low voltage driven complementary circuits with output gain of 22. Low temperature processing of these dielectric layers make them easily integrated.

1. Introduction

Recently, interest in organic electronics is rapidly emerging due to its easy processing routes and cheaper production costs. Organic solar cells, organic thin-film transistors (OTFTs), complementary inverters and light emitting diodes have been the focus of invention by majority of researchers in this area [1–3]. Various materials have been investigated as candidates for the active layers for organic/inorganic TFTs [4,5]. Among organic TFTs, Pentacene has derived much attention due to its planar structure and high mobility. Moreover, Pentacene can be easily evaporated so that the growth mechanisms are easily controlled through deposition rate, thickness and the substrate temperatures. When employed as active layers in a planar geometry, Pentacene based OTFTs have resulted in field-effect mobilities ~1 $cm^2/V\,s^{-1}$, ensuring that they can be the possible replacements for the amorphous Si transistors in near future [6,7]. However, one of the challenging issues in OTFTs is to reduce the operative voltages of the devices. Utilization of high dielectric constant oxides is the plausible route to achieve low voltage driven transistors and complementary inverters [8–10]. Some of the oxides which derived much attention as gate dielectrics are Ta_2O_3 [11,12], YO_x [13], TiO_2 [8,14,15], MgO [16] etc. Roughness, density of surface traps and dielectric constants of the dielectric layer are the key issues to be addressed while designing the OTFTs [11,17]. It is anticipated that surface of these oxides can be modified by a thin polymer layer coating which eventually smoothens the dielectric surface and helps in increasing the breakdown field [18]. Utilization of such bi-layer dielectrics is the main topic of current investigation [11,15]. Because of their highly hydrophilic surfaces, these oxide films are not suitable for direct growth of the organic semiconductor due to the probable undesirable interface modifications [19]. The polymer

layers atop gate oxide ensures organic–organic interface between the active layers and gate dielectrics which is of non-interacting nature and provide better interface [20]. Considering all these factors, in this study, we have grown low temperature processed titanium oxide (TiO_x) dielectric layers by a simple reactive evaporation process. The surface modification was achieved by a solution processed fluoropolymer Cytop® layers. We also have demonstrated the low-voltage operation of the complementary inverter consisting of Pentacene and PTCDI-C8 as p- and n-type semiconductors, respectively.

2. Experimental

The devices were fabricated on the indium tin oxide (ITO)-coated glass substrates (10–20 Ω/□, sheet resistance), acting as gate electrode. Prior to the device fabrication, the ITO substrates were cleaned by TFD4 detergent (Franklab, France) and deionized water in an ultrasonic bath and were treated with UV-ozone for 15 min. In order to implement low-voltage operation of the organic thin-film transistors, we used the high-k metal oxides TiO_x as gate insulators. The chamber was pumped down to $\sim 10^{-6}$ Torr before the TiO_x deposition. The films were deposited by reactive evaporation of Ti in an oxygen environment. The flow rate of the oxygen gas was maintained by means of a mass flow controller. During the TiO_x deposition process, the partial pressure was optimized at 2×10^{-4} Torr. The as-deposited films were subjected to post-deposition annealing process at a temperature of 150 °C, and the evaporation rate of 1.0 Å was fixed during the deposition. However, the resultant TiO_x dielectrics caused a high grain boundary leakage current. To reduce such leakage currents, a dilute 1 wt% Cytop® CTL-809 M (Asahi Glass, Tokyo, Japan) was spin-coated over the TiO_x-covered ITO glass substrates at a rotation speed of 2000 rpm for 60 s, followed by baking at 100 °C to remove the residual solvent. The spin coating process was carried out under nitrogen environment in glove box. In order to achieve the low-voltage complementary circuits, p-type Pentacene and n-type N-N′-dioctyl-3,4,9,10-perylene tetracarboxylic diimide (PTCDI-C8) were, respectively, patterned on the TiO_x layer using shadow masks by thermal evaporation.

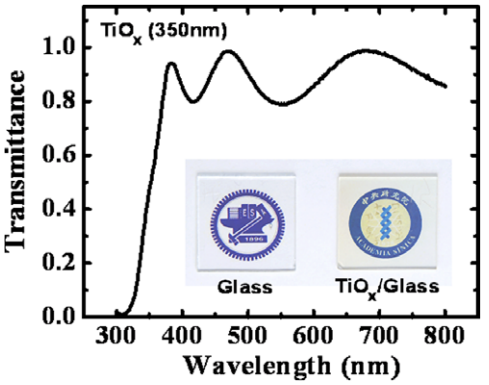

Fig. 1. UV–vis transmission spectra for TiO_x thin film. Inset: photographic images of the TiO_x films grown on glass and a bare glass.

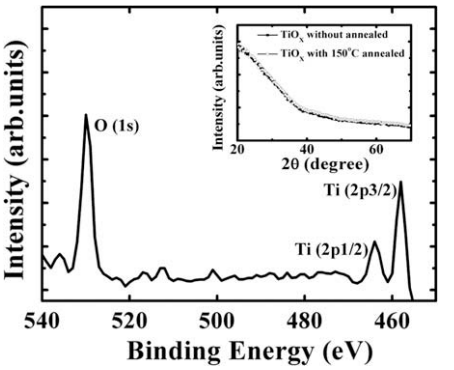

Fig. 2. X-ray photoelectron spectroscopic (XPS) spectra of TiO_x thin film. Inset: X-ray diffraction (XRD) spectra of TiO_x thin film with/without annealing.

The deposition rate was fixed to 0.5 Å/s for the evaporation of both Pentacene and PTCDI-C8 which were deposited onto the gate dielectric under a high vacuum 10^{-6} Torr. Both the thicknesses of Pentacene and PTCDI-C8 films were 50 nm. Finally, the metal (Au) was deposited on semiconductors through a shadow mask as the contact electrodes. The current–voltage (I–V) characteristics of OTFTs were measured in N_2 by Keithley semiconductor analyzer (4200-SCS). The C–V measurement was performed by a HP 4980A precision LCR meter. The films were subjected to X-ray diffraction (XRD) to ascertain nature of crystallinity

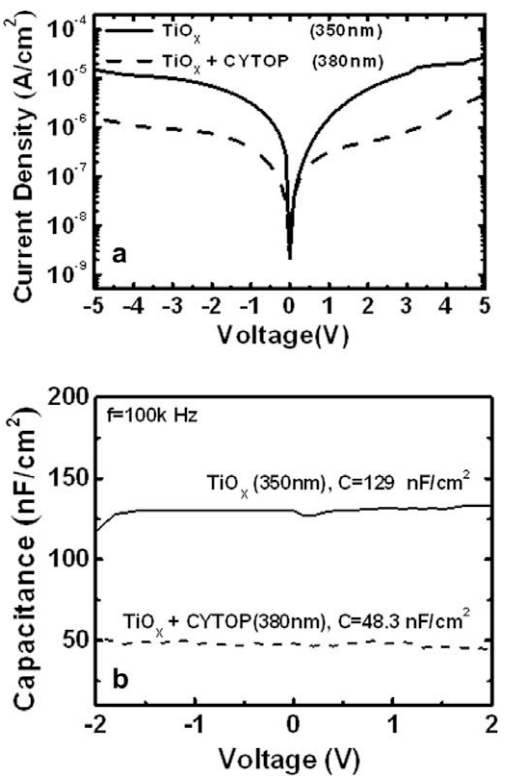

Fig. 3. (a) Current density vs. electric field characteristics of the TiO_x and TiO_x/polymer gate dielectrics. (b) Capacitance vs. voltage curves measured at 100 kHz for TiO_x and TiO_x/polymer.

in the films. The XRD measurements were performed using a Philips X' Pert-Pro diffractometer with Cu Kα radiation of wavelength $\lambda = 1.54$ Å.

3. Results and discussion

Optical band gap of TiO_x without intentional doping is ~3.4 eV [21]. Its wide band gap makes it transparent in the visible region of the electromagnetic spectrum and hence are suitable for the transparent electronics applications. Fig. 1 displays the transmission spectrum of the reactively evaporated TiO_x films grown on glass. Inset provides the photographic images of the TiO_x films grown on glass and that of a bare glass. The highly transparent nature of the films is clearly visible from the figure. Thickness of the layer was ~350 nm as measured from the thickness profilometer. The optical transmission spectra of the reactively evaporated TiO_x films are highly transparent (transmittance >78%) in the visible region. The high transmittances indicate fairly smooth surfaces and relatively good film homogeneity.

In order to further characterize the oxide films, X-ray photoelectron spectroscopy was carried out. Fig. 2 shows the high resolution XPS spectra of the TiO_x films deposited on glass substrate. As shown in the figure, titanium peaks were located 458 eV (Ti $2p_{3/2}$) and 464 eV (Ti $2p_{1/2}$), the oxygen peak (O 1S) was positioned at 530 eV. The elemental analysis of the films resulted in corresponding atomic composition of 66.3 and 33.7 for titanium and oxygen, respectively. Hence, it was found that the composition is

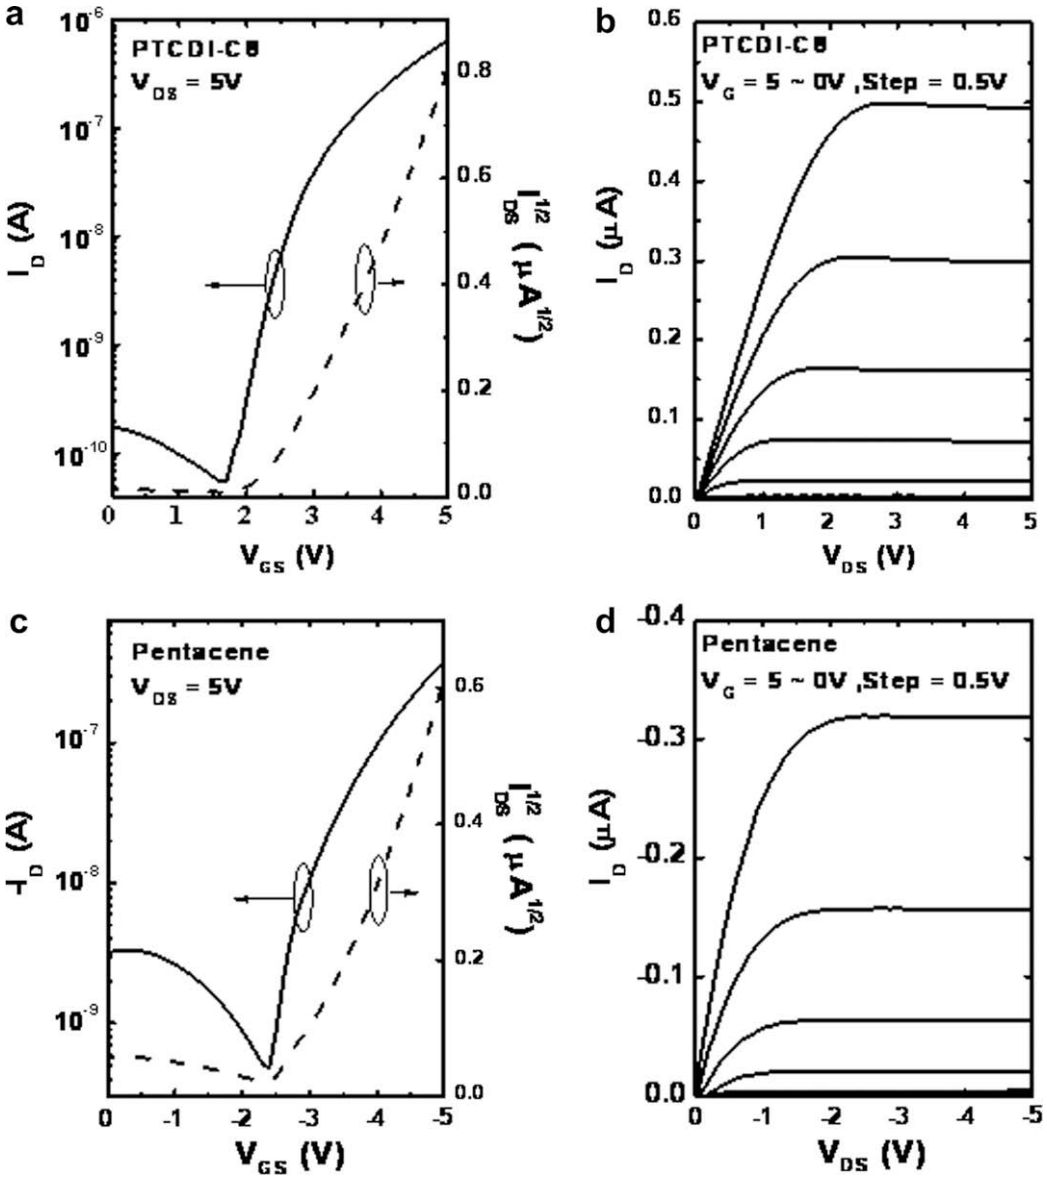

Fig. 4. (a) Transfer and (b) output characteristics of the n-type (PTCDI-C8) OTFTs. (c) Transfer and (d) output characteristics of the p-type (Pentacene) OTFTs.

close to the ideal value of 2, indicating that the films are stoichiometric in nature and the current reactive evaporation is desired for the effective conversion of Ti into TiO_x films at room temperature. Fig. 2 inset shows the X-ray diffraction pattern of TiO_x thin films grown on glass substrates by reactive evaporation. The absence of any well defined diffraction peaks indicates that the films are amorphous in nature. For comparison both unannealed and annealed films are shown in the figure. As can be seen from the figure, annealing at 150 °C did not help in inducing any crystallinity in the films. In the case of oxides, the grain size tends to increase with increasing annealing temperatures as a result of which the surface roughness also increases. Since the higher surface roughness is not desired for the gate dielectric applications, high-temperature annealing process was not carried out for the films. Amorphous nature of the oxide films ensures that the grain boundary effects will be minimal. Hence, it is expected to lead to reduced charge trapping at the interface. Amorphous nature of the gate dielectric films is also found in the literature.

In order to achieve low-voltage operation in OTFTs, the high-k materials are always used as the gate insulators, which can afford greater surface charge density and also reduce the operating voltages of OTFTs. The TiO_x has lately been used as a high-k gate dielectric material and many groups have researched about this metal oxide [14,15,20]. In general, the TiO_x films have usually fabricated through rf/dc sputtering, sol–gel, solution processing, and were used as dielectrics for OTFTs. However, almost such methods need to high-temperature annealing. Their dielectric constant values of the TiO_x films are in the range of 11–41. In the present study, the TiO_x films are deposited by reactive evaporation of Ti without any high-temperature treatment. The electrical properties of the films are investigated by current–density–voltage J–V and capacitance–voltage C–V characteristics of the Au/Cytop®/TiO_x/ITO sandwich structures. As shown in Fig. 3b, the TiO_x film has relatively high capacitance (Ci = 129 nF/cm^2) and the dielectric constant of the TiO_x extracted from capacitance–voltage (C–V) measurement is as high as 51. In order to avoid leakage current and surface modification, the fluoropolymer Cytop® thin film is used to stack on the TiO_x film through solution processing. The leakage current density of the bi-layer dielectric has successfully compressed than that of the single TiO_x layer as seen in Fig. 3a. For the bi-layer insulator, the bottom layer of the thick TiO_x enhances the dielectric constant of the insulator, and the top layer of the ultrathin Cytop® acts as a roughness-smoothing layer and hydrophobic surface treatment. As the metal–insulator–metal capacitors, we have measured the capacitance of 48.3 nF/cm^2 for an Au/Cytop®/TiO_x/ITO sandwich, and the total dielectric constant of the dual-layered gate dielectric was 20. Hence, in order to reconcile the advantages of high dielectric constant for operating at low operating voltages and polymer dielectric for better interface, it is desirable to employ bilayer gate dielectrics as demonstrated by the electrical properties.

OTFTs were fabricated using the above mentioned bilayer dielectrics using a top contact geometry with a channel length (L) of 120 μm and width (W) of 2 mm. While the

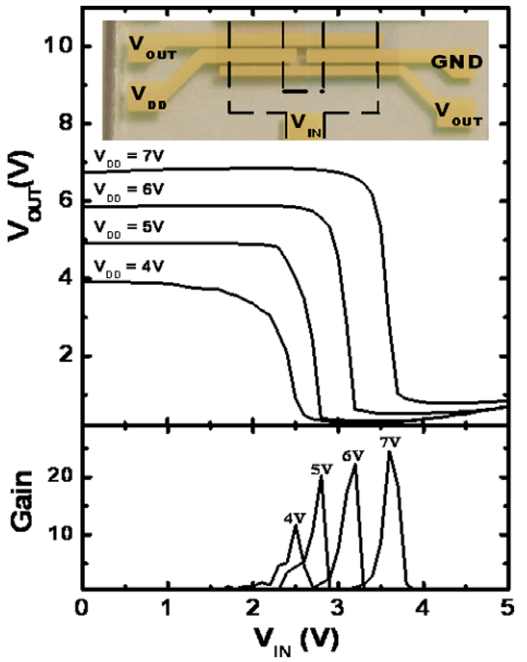

Fig. 5. Output voltage (top) and small-signal gain (bottom) plotted with respect to the input voltage for supply voltages between 4 and 7 V. Inset: photograph of a complementary Pentacene/PTCDI-C8 circuit.

Pentacene OTFTs exhibited a typical p-channel conduction, PTCDI-C8 OTFTs resulted in a n-type OTFT characteristics. It is worth noting that the operative voltages for both the devices is only 5 V depicting that these devices can be operated at low voltages. Output curves are the plots of drain current as a function of source to drain voltages are shown in Fig. 4b and d. Maximum saturation drain current of 0.5 μA for PTCDI-C8 transistor and 0.3 μA for Pentacene transistor are achieved under a gate bias of ±5 V. The field-effect mobility (μ) and threshold voltage (V_T) were extracted from the measured transfer curve (Fig. 4a and c) by comparing it with the standard current–voltage equation for a transistor in the saturation regime [22]. The PTCDI-C8 and Pentacene OTFTs had high field-effect mobilities of 0.33 and 0.31 cm^2/Vs, and exhibited low threshold voltage of 2.7 and −3.1 V, respectively. It reveals that the high-performance and low-voltage organic thin-film transistors can be accomplished though the high-k metal oxide. The PTCDI-C8 OTFTs exhibited a slightly higher on/off ratio ($\sim 10^4$) compared to the Pentacene OTFTs ($\sim 10^3$). Overall, the values of the filed-effect mobilities are relatively high both in n-channel transistors and p-channel transistors operating at low voltages, and the low threshold voltage will enable us to achieve the low-voltage operation of the inverter.

Finally, we have also demonstrated the organic complementary inverters with PTCDI-C8 and Pentacene OTFTs, fabricated on TiO_x/Cytop® double dielectric layers. The static inverter characteristic of a complementary Pentacene/PTCDI-C8 is shown in Fig. 5, and the inverter operated at low voltages (V_{DD}) in the range of 4–7 V. When the organic complementary inverters operated at a low voltage of 5 V, it shows a maximum voltage gain of 22. Thus, we conclude that our TiO_x/Cytop® double layer is a promising

new gate dielectric for realizing a low-operating-voltage PTCDI-C8 and Pentacene OTFTs and subsequent complementary inverters. Therefore, the logic circuits operating at low voltage can be realized by these low-voltage devices.

4. Conclusion

In summary, we have successfully implemented low-voltage operation organic thin-film transistors by using the high-k metal oxides TiO_x/thin polymer as gate insulators. The titanium oxide films are deposited by reactive evaporation of Ti in an oxygen environment without high-temperature annealing. The total dielectric constant of the dual-layered gate dielectric is 20 enabled us to achieve a high capacitance dielectric for low-voltage operation. By using TiO_x/Cytop® as insulator, we were able to manufacture high quality PTCDI and Pentacene organic OTFTs with exceptionally low leakage and relatively low operating voltage. The PTCDI-C8 and Pentacene OTFTs possess field-effect mobilities of 0.33 and 0.31 cm^2/Vs, and threshold voltage of 2.7 and −3.1 V, respectively. In addition, the organic complementary inverters operated at a low voltage of 5 V with a voltage gain of 22. Thus, we conclude that our TiO_x/Cytop® double layer is a promising new gate dielectric for realizing a low voltage driving OTFTs.

ABSTRACT

We report on the fabrication of ZnO-channel charge injection memory thin-film transistors (TFTs). Our non-volatile memory TFT has a thin pentacene on top of a dielectric sandwich which has 3 nm-thin inserted potential well as a hole trap layer. The thin pentacene in contact with Au top electrode supports effective hole injection from pentacene into the inserted well under +8 V programming gate pulse while those injected holes are effectively ejected out under −8 V pulse, so that ZnO channel below the dielectric may have two different current states: write and erase. Our device operates at less than 2 V and shows a retention time of about 1000 s after programmed at +8 V, along with an effective program/erase ratio of 5–20.

1. Introduction

Glass- or plastic-based electronics have steadily been developed with organic and oxide semiconductors as active channels for their thin-film transistor (TFT) component [1–3]. Since memory circuits with TFTs are regarded highly important for the future electronics on glass or plastics, non-volatile memory TFTs have been developed with ferroelectric polymers [4–7] or with charge injection gate [8–10] dielectrics. In the case of ferroelectric field effect transistors, however, the operating voltage was quite high ranging from minimum 15 to maximum 80 V, due to the thickness of the ferroelectric polymer. While the charge injection type memory TFTs operate at a little lower voltage of ~12 V than that of ferroelectric memory TFT, they expose a critical drawback: poor erase performance [8]. Low voltage-driven memory TFTs with good program/erase properties using charge-injection mechanism has thus hardly been reported. Here, we have fabricated ZnO-channel non-volatile memory TFT with unique top gate structure, as an effort to resolve such issues: good erase performance and low voltage switching. Our charge injection memory TFT has thin pentacene layer on top of oxide-organic nanohybrid dielectric sandwich which has 3 nm-thin inserted oxide-organic nanohybrid potential well. The thin pentacene in contact with Au top electrode supports effective hole injection from pentacene into the inserted dielectric well under +8 V programming gate pulse, while those injected holes are effectively ejected out under −8 V pulse for erase, so that ZnO channel below the dielectric may have two different current states.

2. Experimental section

On a clean glass substrate (Corning Eagle 2000), Al source/drain electrodes were patterned by thermal evaporation. Then, a 70-nm-thick ZnO film was deposited at room temperature (RT) by rf sputtering, to be active patterned channel. After that, nanohybrid dielectric multi-layers were deposited on ZnO channel by repeating a cyclic molecular layer deposition (MLD), which is a deposition

doi:10.1016/j.orgel.2009.09.021

process to achieve multi-units of inorganic (AlO_x or TiO_x) monolayer-organic self-assembled monolayer (SAM), e.g., $1AlO_x$–SAM = 1 molecular unit with 1.1 nm thickness; the details of the oxide–SAMu formation and MLD were very recently reported [11], while the molecular units of AlO_x-SAM and TiO_x –SAM were described in Fig. 1a. Our organic–inorganic hybrid (e.g., oxide–SAMu) dielectric has a specifically designed sandwich structure that includes a trap layer of TiO_x–SAMu (3.3 nm) between a 2.2 nm AlO_x–SAMu for gate charge tunneling and an 11 nm-thick AlO_x–SAMu for blocking the ZnO-channel charges. After the definition of sandwich dielectrics, 15–50 nm-thick pentacene (Aldrich Chem. Co., ~99% purity) as hole injection layer was deposited on the dielectric. Finally, the Au top-gate electrode was patterned on pentacene by thermal evaporation. The nominal channel length (L) and width (W) were 90 and 500 μm, respectively. Top-gate flash memory transistor has three layers in its general dielectric structure: tunneling layer in contact with channel, trapping layer, and blocking layer beneath the gate electrode [12–15]. However, in contrast to general flash memory transistor scheme, our memory device has an opposite dielectric layer stacking, as shown in the device cross-section of Fig. 1a. Plan view of the device is also shown in the right-side photograph (Fig. 1b). All of our device characterizations, except memory dynamics, were carried out in the dark at RT by using a semiconductor parameter analyzer (HP 4155C, Agilent Technologies). Memory dynamics were measured by a setup using a function generator (AFG310, Sony/Tektronix) and an oscilloscope (TDS210, Tektronix).

3. Results and discussion

Fig. 1c is absorption spectra as the plots of the squared angular frequency absorption coefficient ($\alpha^2\omega^2$) with respect to photon energy, that were obtained from 20 nm-thick TiO_x–SAMu and identically-thick AlO_x–SAMu layers deposited on sapphire substrates. According to the spectra, the optical bandgap of TiO_x –SAMu is estimated to be ~3.9 eV while that of AlO_x –SAMu appeared greater than 7 eV. We thus expect that the accumulated holes would tunnel from pentacene into the TiO_x–SAMu quantum well through the thin AlO_x–SAMu under a strong (+) gate pulse, to be confined there as illustrated in the band diagram of Fig. 1d. As a result, non-volatile memory effects are induced. The holes injected by the (+) pulse would induce the increase of channel electron density and drain current at the bottom ZnO channel while those holes may tunnel back to pentacene by (−) pulse resulting in the decrease of channel electron density.

The charge injection memory effects are clearly displayed in the transfer curves of Fig. 2. Considerable memory window appears through the gate voltage (V_G) sweep that ranges from −4 to 7 V and this window was again proved by pulsing our pristine TFT device with ±8 V. We applied +8 V write-pulse (pulse condition: V_G = +8 V 1 s with ground source/drain, $V_D = V_S = 0$ V) onto the gate to achieve blue color transfer curves in a low voltage range (−1 to +2 V) and then applied −8 V erase-pulse to get green curves in the same low voltage range. It is interesting to note that the write- and erase-levels are quite well

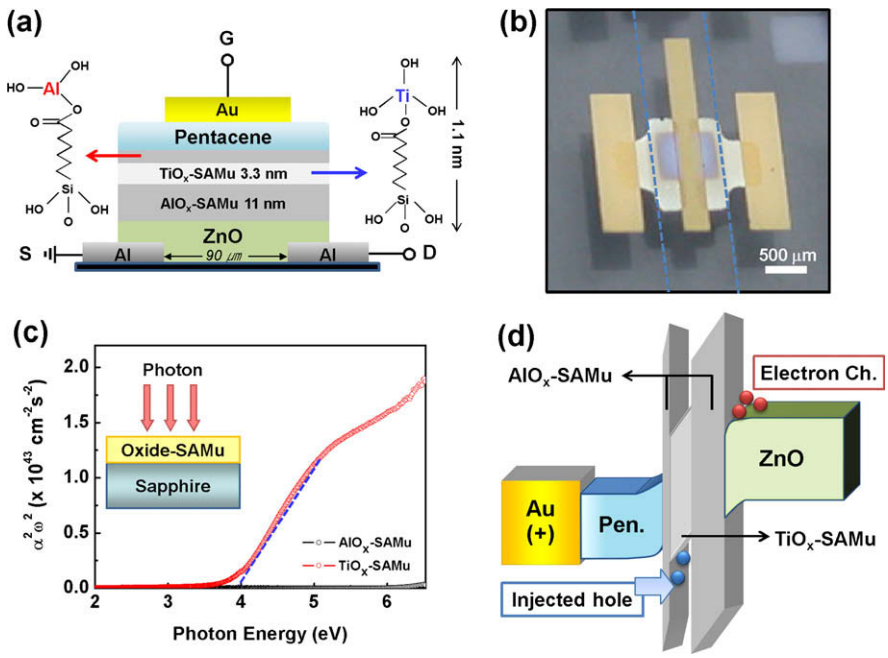

Fig. 1. (a) Schematic cross-section of our hole injection memory TFT using ZnO channel and pentacene top layer. The sandwich dielectric is composed of organic–inorganic hybrid multi-layers: 2.2 nm-thin AlO_x–SAMu, 3.3 nm-thin TiO_x–SAMu, and 11 nm-thin AlO_x–SAMu. (b) Photographic image of the top-view ZnO–TFT. (c) Absorption spectra of our dielectric materials of 20 nm-thin AlO_x–SAMu (black line) and the same thin TiO_x–SAMu (red line) layers. (d) Band diagram of our memory TFT.

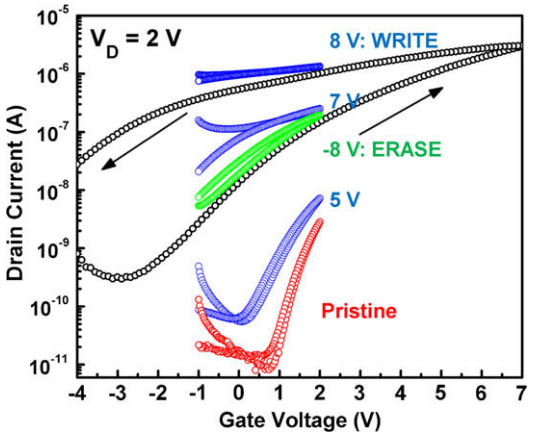

Fig. 2. Main transfer characteristics of the memory TFT were achieved from a gate voltage (V_G) sweep between −4 and +7 V, while low voltage transfer curves between −1 and 2 V gate bias were also obtained after write (+8 V) and erase (−8 V) pulses. Program (write) characteristics depend on the gate voltage; optimum was 8 V.

matched to those (black curves) from large gate-bias sweep. The red transfer curves are for the pristine device, whose initial device performance is not good (with a saturation mobility ~0.05 $cm^2/V\,s$) because we intentionally use Au (high work function ~5.1 eV) as top-gate electrode, which is largely mismatched with the Fermi level of ZnO (~4.3 eV) [16]. However, when +8 V gate pulse is applied, the drain current increases drastically to 10^{-6} A level (saturation mobility ~0.3 $cm^2/V\,s$) and it decreases to about 10^{-8} A with −8 V pulse. This write–erase switching was repetitively observed. These memory behaviors with the pulse are again confirmed in the transistor output curves of Fig. 3a and b. The drain current (I_D) obtained by +8 V 1 s gate pulse for program (write) appears ~10 times higher than that of erase state (by −8 V pulse).

The reason why the current at the erase state does not turn back to the original pristine state in Fig. 2 is because −8 V does not make the same electric field for the dielectric as +8 V does. Instead, the −8 V makes lower electric field for the dielectric itself, since the depleted ZnO and pentacene layers take part in the voltage dividing under

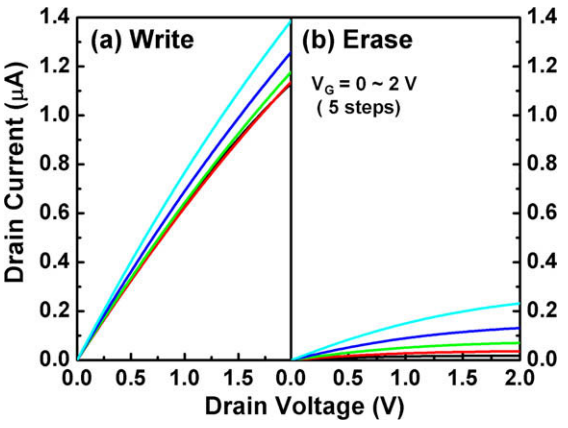

Fig. 3. Drain current–drain voltage (I_D–V_D) output curves of ZnO–TFT after ±8 V 1 s pulses for (a) write and (b) erase.

the negative gate bias. Nevertheless, our results for erase are relatively much effective compared to those of the previously reported ZnO-based memory TFTs with normal floating gate structures, where the carrier ejection performance (erase) was very poor [8,17]. In our present device, 8 V turned out to be an effective value for hole tunneling. As shown in the figure, 5 and 7 V were not large enough to fully turn on the memory device. We thus regard 8 V as a critical value. The maximum gate leakage current was ~2 nA for our memory TFT devices (not shown here). In addition, all the transfer curves have displayed quite stable operations in a low voltage range (−1 to +2 V), hardly showing any hysteresis. It is because the interface between our AlO_x–SAMu dielectric and channel semiconductors (either ZnO or pentacene) is very stable as we previously reported [18,19].

Fig. 4a shows the capacitance–voltage (C–V) measurement results from pentacene-semiconductor/dielectric insulator/metal (MIS) structure, confirming that some of the accumulated holes are really injected from the thin pentacene into the inserted TiO_x–SAMu dielectric well. Some of the accumulated interface holes tunnel into the inserted dielectric layer at a high (+) voltage in the end of the up-arrow process. Once the inserted thin dielectric becomes electrically positive by the hole injection, the hole depletion process of pentacene (down-arrow sweeping) becomes easier with the well-confined holes than without. But then, all of the confined holes are ejected into the pentacene through the down-arrow sweeping at a high (−) voltage. These hole injection and ejection, causing a memory window, were almost exactly repeated without much deviation as shown in the figure. The right and left insets illustrate the hole injection (at +4 V) and ejection (at −4 V), respectively. The memory window approximately deduces the (+) hole charge density difference $\Delta Q_{h(+)}$ between write and erase states by the following equation [13]:

$$\Delta V_{FB} = -\frac{\Delta Q_h}{C_{ox}} \times \frac{x_{(+)}}{x_{tot}},$$

where ΔV_{FB} is the flat band voltage shift obtained from the memory window (~2 V), C_{ox} is total capacitance of the dielectric (~127 nF/cm^2), $x_{(+)}$ is the thickness of injected (+) charge location (=5.5 nm, sum of inserted and tunneling layer thickness) and x_{tot} is 16.5 nm as the total dielectric thickness. Now ΔQ_h is deduced as $\sim 5 \times 10^{12}\ e/cm^2$, where e is electron charge and the ΔQ_h value is regarded reasonable in light of usual charge injection carrier density [20].

Based on these non-volatile memory properties of Figs. 2 and 4a, we set up a non-volatile memory inverter with 22 MΩ load-resistance as shown in the inset of Fig. 4b. According to the input gate voltage sweep (from −4 to +8 V), the memory inverter displays permanent hysteresis window and transition voltage shift (~5 V) with the voltage gain of ~5. For instance, two different output voltages (V_{out}) exist at an input voltage (V_{in}) of 1 V; the two V_{out} states (=1.5 and 7.5 V) after the respective write (+8 V) and erase (−8 V) pulses were substantially displayed along with the memory inverter curves. (See the results from V_{in} sweep in the range from 0 to 1.5 V, as blue and green curves.) This means that our memory device approaches

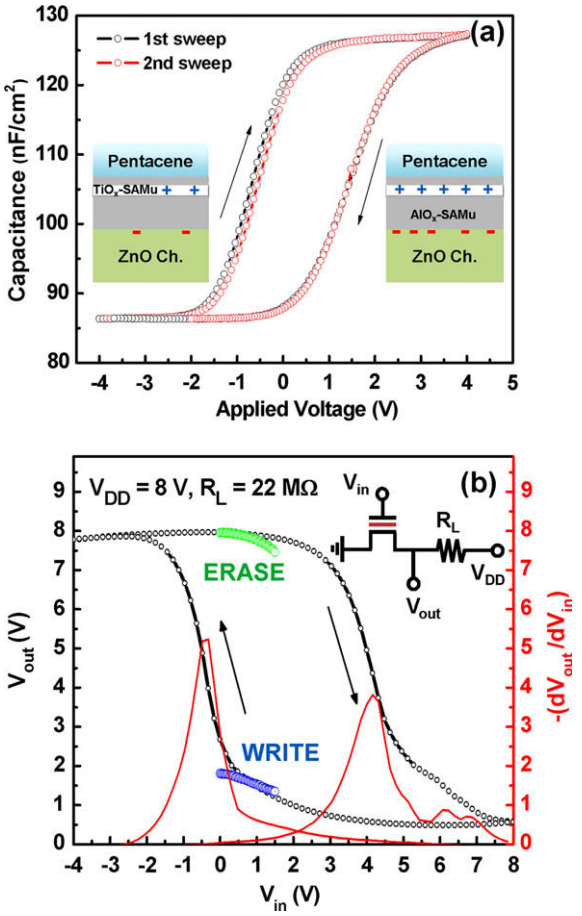

Fig. 4. (a) *C–V* curves of our sandwich structured dielectrics with 15 nm-thick pentacene layer. The holes injected from the accumulated pentacene induce a hysteresis. The inset briefly shows the injection and ejection mechanism. (b) Static voltage transfer characteristics (VTC) of our ZnO–TFT connected to load resistor (R_L) of 22 MΩ. Due to the large window, we clearly obtain two V_{out} states at 1 V (=V_{in}) (blue:+8 V pulsed; green: −8 V pulsed).

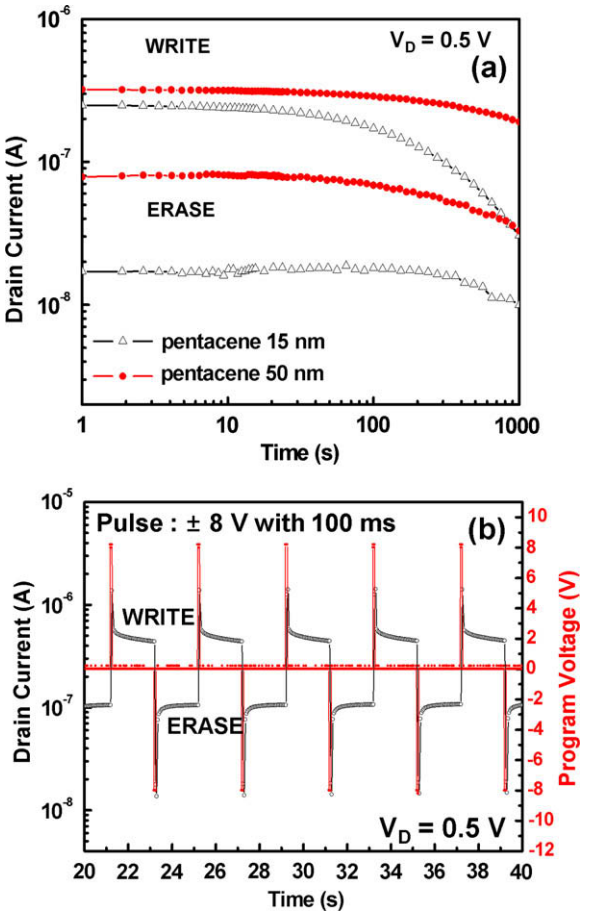

Fig. 5. (a) Retention of the write and erase state for our memory TFT with 15 nm- and 50 nm-thick pentacene. (b) Dynamic retention behavior observed under periodic pulses.

to practical applications readily demonstrating the write and erase states.

Retention properties at static and dynamic switching were measured under a condition of $V_G = 0$ V and $V_D = 0.5$ V as shown in Fig. 5a and b, respectively. For the static retention properties of the ZnO-channel flash memory TFT, ±8 V 1 s pulses were applied onto the gate of the devices with 15 nm- and 50 nm-thin top pentacene. Large on/off (=write/erase) ratio of ∼20 was observed from the TFT with 15 nm-thin pentacene although its effective retention time was only as long as approximately few hundred seconds (Fig. 5a). This short retention was lengthened to higher than ∼1000 s adopting a little thick pentacene top layer (∼50 nm) but then on/off ratio was reduced to ∼4. Fig. 5b shows the dynamic retention properties with the ZnO device with 15 nm-thin pentacene top layer when the write/erase current ratio was measured by alternating ±8 V 100 ms pulses in 4 s period. Write/erase states were clearly distinguished and the ratio was persistent to be ∼5, which is still effective to resolve the two states.

Fig. 6a and b displays the results from subsidiary experiments on ZnO memory TFT without pentacene top layer. As shown in the transfer curves of Fig. 6a, memory hysteresis window was relatively narrow and in particular, +8 V pulse could not make high on-state current unlike the case with pentacene top layer. It seems that without top pentacene the embedded TiO_x–SAMu in the ZnO–TFT has only minor density of injected holes. In other words, the Au gate electrode could not effectively supply high density holes into the embedded well without the assistance of pentacene interlayer and it is understandable. The retention curves of Fig. 6b again reflect the low write-state current, which is an order of magnitude lower than that of ZnO–TFT with pentacene top layer as observed in Fig. 5a. Retention time also appeared much inferior to the case with pentacene top layer (Fig. 5b), that may now play as a buffer to keep the trapped hole charges from occasional recombining with the electrons in gate electrode. We regard that this is a reasonable explanation, since according to Fig. 5b the ZnO device with 50 nm-thick pentacene buffer shows improved retention time property compared to that with 15 nm-thin buffer which may allow some regional contact between Au electrode and dielectric surface [21].

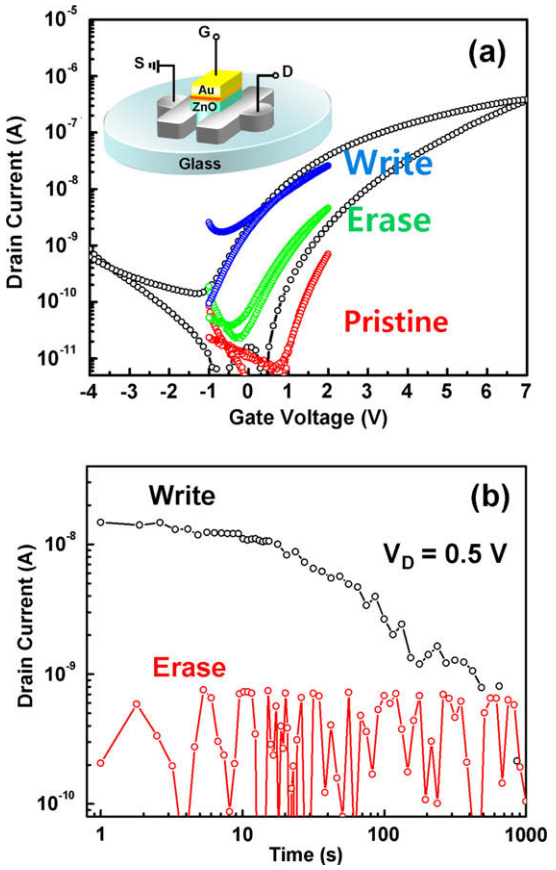

Fig. 6. (a) Transfer (V_G–I_D) and (b) retention characteristics of ZnO–TFT without pentacene top layer. Reduced memory window size and write-state current were observed.

4. Conclusion

In summary, we have fabricated non-volatile flash memory TFTs with ZnO layer for electron channel and with pentacene top layer for gate hole injection. With the assistance of 15–50 nm-thin pentacene, the accumulated holes were effectively injected into inserted TiO_x–SAMu potential well. The repetitive injection and ejection processes were very stable at ±8 V showing good memory window in light of memory transfer curves, memory inverter curves, and dynamic retention curves. Although the retention time after 8 V 1 s pulse appears not that long, our flash memory TFT demonstrates a promising non-volatile memory effects operating at low voltages.

ABSTRACT

The interface between Al and tris-(8-hydroquinoline) aluminum (Alq_3) was studied using *in situ* medium energy ion scattering spectroscopy. We compared two interfaces of Al/LiF/Alq_3 and Al/Alq_3 with the elemental depth profile of each interface. The thin LiF changes the interfacial structures significantly; the excess Li in the LiF layer diffuses into Alq_3 while F does not. In addition, the Al diffusion into the Alq_3 layer during the initial stages of Al deposition is reduced significantly compared to the interface without the LiF interlayer. The LiF interlayer makes a more abrupt metal–organic interface, which would contribute to the efficiency and stability of the organic light-emitting device.

Organic electronic devices are promising candidates which can substitute for the Si-based electronic devices because of their simple fabrication process, flexibility and cheap manufacturing cost. For instance, the development of organic light-emitting diodes (OLED) has already reached the level for mass production. However, fundamental understanding of organic devices has not kept pace with the development of the manufacturing process. One of these issues is the physical structures of the interface between the metal electrode and the organic material layer. Various groups have studied the metal–organic interface, which has revealed that the interface has a crucial role in the performance and lifetime of such devices. In 1997, Hung et al. [1] reported the LiF electron injection layer (EIL) in the OLED which initiated research on the insulator EILs in the organic devices. The LiF EIL at the interface between the metal electrode and the organic layer has shown good device performance. The introduction of LiF EIL is regarded as a key architecture for the advanced OLED. Thus, many reports about this EIL have been published.

There have been many efforts to find the mechanism of how a thin LiF layer – or other EIL materials such as NaCl, CsCl and NaF – enhances the performance of OLED. The photoemission measurements have been mainly performed to reveal the interfacial electronic structure which is responsible for the enhancement [2,3]. EILs reduce the work function of the metal electrode, and so lower the electron injection barrier at the interface. Thus it improves the electron injection efficiency dramatically. Though the LiF shows device performance enhancement clearly, its distribution inside the device and the chemical interaction with other materials in the device are still in discussion. In previous studies, the chemical interaction in Al/LiF/tris-(8-hydroxyquinolate) aluminum (Alq_3) has been explained by the reaction of $Al + 3LiF + Alq_3 \rightarrow AlF_3 + 3Li^{+} + Alq_3^{-}$ [4].

However, there is no clear report for the Li liberation and the behavior of free Li in the device. In another viewpoint, it has been suggested that the presence of the LiF interlayer prevents Al diffusion into Alq_3 [5]. However, these results are not very clear because of the destructive analysis such as secondary ion mass spectroscopy (SIMS) or X-ray photoemission spectroscopy (XPS) depth profiles. Recently, we showed the suitability of the medium energy ion scattering spectroscopy (MEIS) technique for studying the organic thin films and obtained good results for Al diffusion into the Alq_3 layer [6].

In this letter, we studied the physical structures of LiF film deposited on the Alq_3 layer and its behaviors during the initial stage of the Al layer formation on it. We chose the Al/LiF/Alq_3 system since they are the most widely used materials in organic devices, and their characteristics are well known. We measured the MEIS spectra before and after depositing Al on bare Alq_3 and after each stepwise deposition of Al on LiF-covered Alq_3. To analyze the MEIS data, an ion scattering simulation code was used [7]. All film preparation and MEIS measurements were carried out *in situ*. We obtained information about the behavior of Li in the Al/LiF/Alq_3 structure and the effect of LiF layer on Al diffusion into Alq_3 layer.

Alq_3 (Sigma–Aldrich) and LiF (99.99%, Sigma–Aldrich) were thermally deposited (~1.0 nm/min) from an alumina crucible heated with Ta wire. Al metal was thermally evaporated from an Al wire (99.9999%, Nilaco) inserted into the alumina tube wound with Ta wire. Al metal was deposited on Alq_3 or LiF/Alq_3 film at the rate of 0.05 nm/min. All samples were prepared on Si (1 0 0) substrates having a natural oxide layer (SiO_2). The Si substrates were cleaned by ultrasonication in acetone and rinsed with deionized water. The thickness of the film was monitored with a quartz microbalance and confirmed with an α-step and the simulation of the MEIS spectra. All film depositions were conducted in the preparation chamber with a pressure of 1×10^{-7} torr at room temperature.

The quantitative elemental analysis and depth profile of the films were investigated by MEIS. A detailed measurement setup is described in a previous report [6]. In this study, we used two scattering geometries. Generally, we used a H^+ ion beam with an incident angle of 54.7° ([1 1 1] direction of the Si substrate) and an exit angle of 0° ([1 0 0] direction of the Si substrate) from the surface normal ([1 0 0] exit geometry). A different geometry was set with an identical incident angle but an exit angle of 54.7° ([1 1 1] exit geometry). In this geometry, the energy splitting between different elements decreases, while the scattering cross section increases. Consequently, it is possible to get the spectrum of light elements with much better statistics. All measurements were carried out in the scattering chamber with a pressure of 1×10^{-9} torr.

First, we analyzed the single LiF layer deposited on the Si substrate quantitatively. In Fig. 1, the MEIS spectrum is obtained from the sample LiF (1 nm)/SiO_2. The gray symbol is the measured spectrum and the red line is the simulated result. Five peaks are lined up in the order of elemental number. Si and O peaks originated from the native oxide (SiO_2) on the Si substrate and the C peak from the carbon contamination on the SiO_2 surface. To confirm the composition of the LiF film, we simulated the spectra with a composition ratio of Li:F = 1:1 (green line). However, the simulated spectrum, especially on the F height, does not fit with the experimental spectrum. The F concentration is rather small (red line for the best fit) compared to the stoichiometric LiF. We obtained a concentration ratio of Li:F = 1:0.8 from the fitting parameters. This excess Li might have originated from the partial dissociation of LiF during the deposition process.

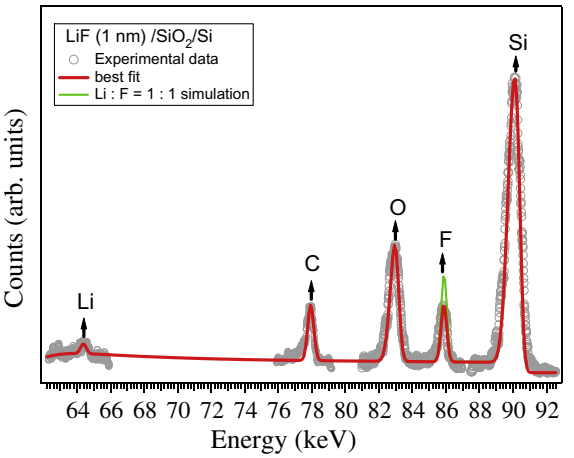

Fig. 1. Measured MEIS spectrum from the sample of LiF/SiO_2/Si versus simulated result. Traces of open symbol are measured spectrum, and the red line is the simulated result. The green line indicates the shape of the F peak when Li:F = 1:1. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 2 shows the Li and F spectra of LiF (1.5 nm)/Alq_3 (6 nm)/SiO_2 and Al (1 nm)/LiF (1.5 nm)/Alq_3 (6 nm)/SiO_2 measured with [1 1 1] exit geometry. We chose thin LiF thickness known for the optimum device performance [1]. The Li and F peaks show different shapes. While the Li peak shows tails at the lower energy side, F shows only a single peak without following tails. (The F tail region is seen in the Fig. 3. The F peak in Fig. 2 seems to be overlapped with another peak at lower energy side, but the lower energy overlap is nothing more than the SiO_2 substrate signal in [1 1 1] exit geometry.) These indicate that Li diffuses into Alq_3 significantly but F does not. The diffused Li could be the excess Li shown in Fig. 1 or liberated Li by the chemical interaction with Al and Alq_3 [4].

With the Al deposition (red line), the amount of the F peak shift to lower energy is smaller than that of the Li peak. (The energy resolution of MEIS is about 100 eV.) This means that some part of Li diffuses into the Alq_3 layer, but F remains at the surface region relatively. This is consistent with the previous SIMS study showing that Li and F have maximum density at different positions [8]. One possible driving force for the F immobilization could be the Al–F interaction forming the AlF_3 species [4].

In Fig. 3, the MEIS spectra measured in [1 0 0] exit geometry are presented as a function of Al thickness. Each spectrum corresponds to the sample of Al (1, 2, and 4 nm)/LiF (1.5 nm)/Alq_3 (10 nm) deposited on the SiO_2 substrate. While the surface Al and O peaks increase as Al is deposited, the C, F and Si peaks are shifted to low energy because

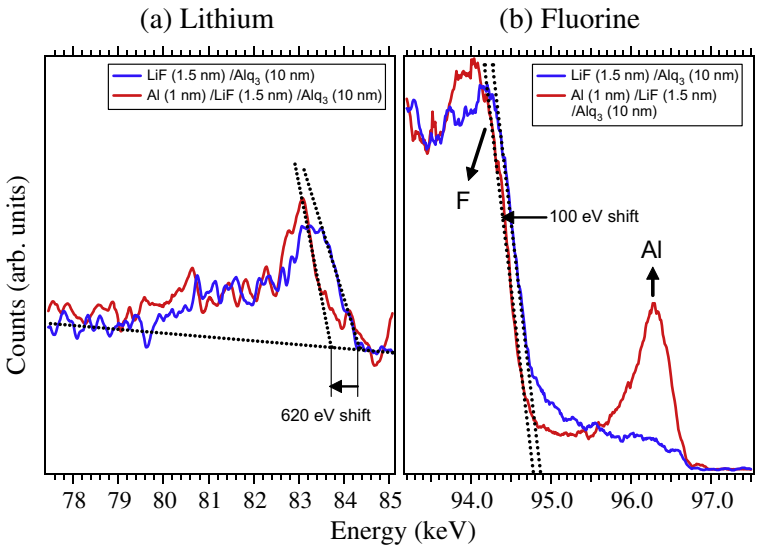

Fig. 2. Li and F spectra measured from the sample of LiF (1.5 nm)/Alq_3 (6 nm) (blue) and Al (1 nm)/LiF (1.5 nm)/Alq_3 (6 nm) (red) with [1 1 1] exit. (a) Li spectrum spreads from surface to the region of Alq_3, indicating the Li diffusion into Alq_3 layer. (b) The low energy shift of the F peak is smaller than the Li peak, implying negligible F diffusion. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

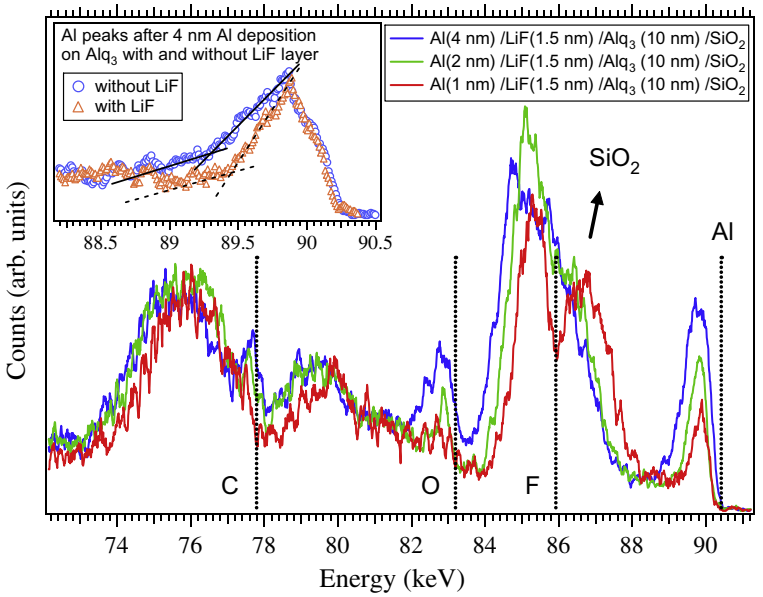

Fig. 3. Measured MEIS spectra from the sample of Al (1, 2, and 4 nm)/LiF (1.5 nm)/Alq_3 (10 nm)/SiO_2 with the step-by-step deposition. The inset shows the different Al peak width according to the existence of LiF interlayer.

they are buried under the surface Al layer. As mentioned in Fig. 2, F shows a sharp peak without significant tails on the low energy side, meaning negligible diffusion. The inset shows the Al peak after 4 nm Al deposition on Alq_3 (10 nm)/SiO_2 (orange) and on LiF (1.5 nm)/Alq_3 (10 nm)/SiO_2 (blue). It clearly shows the different Al peak width between the two interfaces. With the LiF layer, the peak width is reduced significantly, implying that the interfacial diffusion of Al decreases significantly. That is, Al makes a more abrupt interface with the LiF interlayer.

In Fig. 4A, the depth profile of each element is presented in order to see the changes of the Al/LiF/Alq_3 interface with successive Al deposition. Thus, they show the evolution of elemental depth profile during the initial Al layer formation. We also presented control experiment of Al/Alq_3 interface in Fig. 4B from our previous results [6]. We fitted all spectra in Fig. 3 and used the Alq_3 density of 1.3 g/cm^3 [6] to convert the area density to the depth dimension. Each diagram represents the interface of (a) 1 nm, (b) 2 nm and (c) 4 nm Al deposited on LiF (1.5 nm)/Alq_3

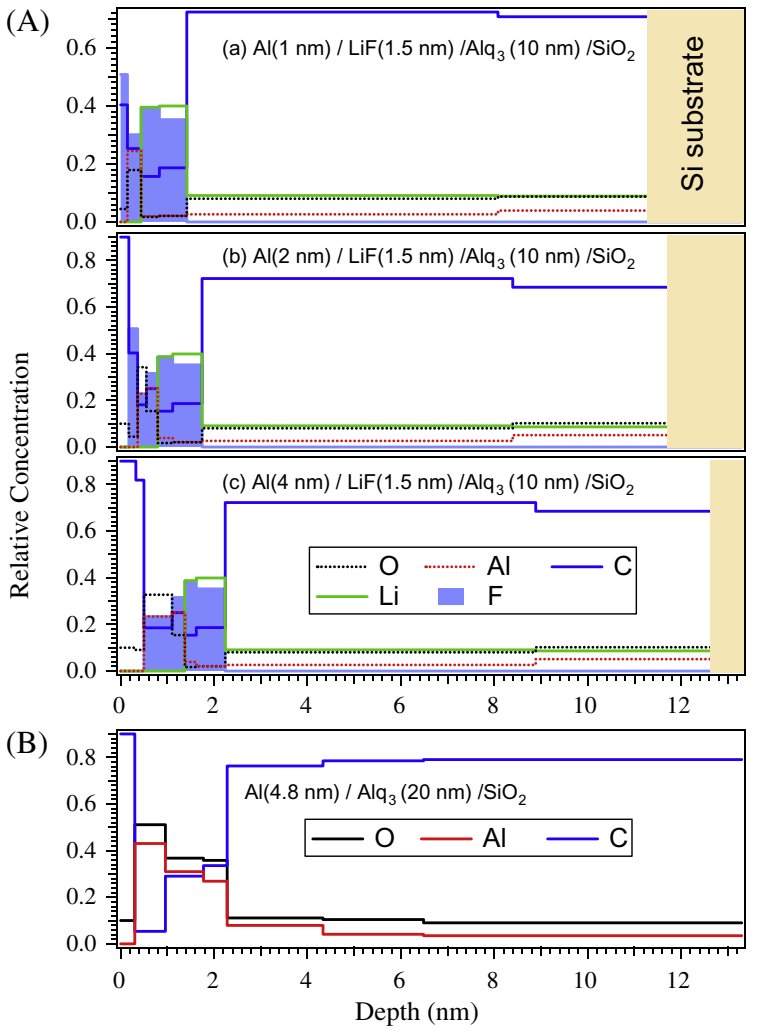

Fig. 4. (A) Depth profiles of key elements (C, O, Al, F and Li) during the Al deposition. (a–c) Indicates successive deposition of Al on LiF/Alq_3/SiO_2 corresponding to the Fig. 2. (B) The depth profile of Al on Alq_3 without LiF layer [6].

(10 nm)/SiO_2 which correspond to the spectra in Fig. 3. At the initial deposition stage (a), small amounts of Al diffuse into the Alq_3 layer and reach the SiO_2 interface. However, the Al diffusion into Alq_3 layer is highly diminished compared to the interface without the LiF interlayer (B). The diffused Li into the Alq_3 layer is clearly seen as explained in Fig. 2. After this stage, Al is only stacked on the LiF layer without significant penetration into Alq_3 (b). Then, the Al forms a thick layer and is oxidized with residual water or oxygen from the vacuum chamber (c). The oxidation of Al is also decreased compared to the interface of (B) Al/Alq_3. The F species in the vicinity of Al could prevent Al oxidation, which could be caused by the interaction between Al and F [4]. That is, the metallic Al is consumed to be reacted into AlF_3 and there are little metallic Al atoms to be reacted with residual oxygen/water. However, further studies for the detailed interaction mechanism and the effect of oxidation on the diffusion are needed. These reduced diffusion and oxidation would contribute to the improvement of device performance in terms of luminescence quenching site elimination [9] and interfacial resistance reduction [10].

In summary, we studied the interface structure of LiF/Alq_3 and Al/LiF/Alq_3 with *in situ* medium energy ion scattering spectroscopy. Excess Li was found in the single LiF layer deposited on the SiO_2 substrate and some Li diffused into the Alq_3 film when LiF was deposited on the Alq_3 layer. The Al diffusion into the Alq_3 layer was significantly diminished with the LiF interlayer compared to the case without LiF. That is, a more abrupt interface is formed at the Al/LiF/Alq_3 than at the Al/Alq_3 surface. The reduction of Al diffusion and abrupt interface formation attributes to the enhancement of device performance.

ABSTRACT

We report on p-channel depletion mode organic inverter composed of two pentacene thin-film transistors (TFTs), which have different channel thickness each other. Adopting thin hydrophilic AlO_x as dielectric, the 25 nm-thin channel pentacene TFT showed lower threshold voltage (V_{TH}) than that of 50 nm-thick channel-TFT, while on hydrophobic poly-4-vinyphenol (PVP) dielectric the results became opposite. We utilized the different V_{TH} caused by different channel thickness to operate the inverter that consists of driver- and load-TFTs. The 50 nm-thick pentacene operated as the channel layer of driver-TFT on AlO_x, but on PVP dielectric the 25 nm-thin pentacene layer played as the driver channel. Maximum voltage gain of ~22 under −8 V supply voltage was achieved when the dielectric layer was optimized.

1. Introduction

Pentacene-based thin-film transistors (TFTs) have attracted much attention due to their potentials use in transparent, flexible and low cost electronics circuits: sensors, display backplane and rectifiers for radio frequency identification (RFID) [1–6]. Pentacene inverter has thus been studied and fabricated with several methodologies as a fundamental element of conventional integrated circuit on glass or plastic. Among the methodologies, using different W/L ratios for the load- and driver-TFTs [7], changing the dielectric surface of load- or driver-TFTs [8], adopting different polymer dielectrics for load and driver [9,10], and even using dual-gate for the driver-TFTs [11] have been reported for pentacene inverter, all of which were based on the effort to change threshold voltage (V_{TH}) of load- or driver-TFTs; the main concept of organic inverter implemented by previous researchers was to make the V_{TH} of load-TFT smaller than that of driver-TFT, so that the effective channel resistance of load-TFT might be smaller for desirable inverter operation. In the present study, we adopt another but more simple way to change the V_{TH} of load-TFTs and achieve an organic inverter: changing the channel thickness, since we observed the change of V_{TH} and drain current (I_D) (or effective channel resistance) with varying thickness of pentacene channel on both hydrophilic oxide and hydrophobic polymer dielectrics [12]. We have thus fabricated the depletion-mode inverters, where pentacene channel of load-TFT has different thickness from that of driver on hydrophilic or hydrophobic dielectric surfaces.

2. Experimental

For OTFT substrates, we used indium-tin-oxide (ITO)/glass that was cleaned with acetone, methanol, and de-ionized water, in that order. ITO gate electrodes were patterned by wet etching. Then we deposited three kinds of dielectrics: sputter-deposited AlO_x [13], optimally-cured poly-4-vinyphenol (PVP) [14,15], and AlO_x–PVP bilayer [8]. Pentacene (Aldrich Chem. Co., 99% purity, no other distillation) active channel layers were patterned on the dielectric layers through a shadow mask by thermal evaporation at room temperature (RT). We fixed the pentacene deposition rate to 1 Å/s. For source/drain (S/D) of the pentacene TFTs

and also for inverter connection, Au was evaporated onto the pentacene channels at RT. Nominal channel length (L) and width (W) of our pentacene TFTs were 90 and 500 μm, respectively. We used two different pentacene-thicknesses for load- and driver-TFTs: 25 and 50 nm for OTFT inverter with dielectric AlO_x, but vice versa for other

devices with PVP dielectric. Fig. 1a shows the three-dimensional schematic of our inverter while Fig. 1b does its cross-section.

3. Results and discussion

3.1. Organic inverter with hydrophilic AlO_x dielectric

Fig. 2a shows the I_D versus gate voltage (V_G) transfer curves of two pentacene TFTs with 100 nm-thick AlO_x dielectric that was deposited by 50 W rf sputtering of Al_2O_3 target (~99.999%) at RT. Both OTFTs with 25 and 50 nm-thick channel appear very stable with little hysteresis, but one with 25 nm-thin channel displays smaller V_{TH} and higher on-state current [13]. Since we previously observed the similar results from pentacene TFTs on hydrophilic SiO_2 dielectric where I_D and mobility gradually decreased with pentacene thickness due to thickness-induced resistance [12] (the parasitic resistance through thickness between the metal/pentacene interface and the channel), we set-up a TFT inverter utilizing the thickness effects on hydrophilic AlO_x in the present study [13]; 25 nm-thin pentacene channel was used for load-TFT due to its lower effective channel resistance, (which can be defined by channel resistance + thickness-induced resistance) while 50 nm-thick channel for driver-TFT. Driver-TFT shows a good saturation mobility (~0.5 $cm^2/V\,s$) and high on/off current ratio (~5×10^5), also displaying $V_{TH} = -3$ V in a low operating V_G range below −8 V. Load-TFT displays similar saturation mobility of ~0.46 $cm^2/V\,s$ and the same decent on/off ratio (~5×10^5) but with smaller $V_{TH} = -2.2$ V. As a result from the two OTFTs, we obtained a high gain inverter, whose voltage transfer curves (VTCs) are displayed under a constant supply voltage (V_{DD}) of −8 V but in the different sweep ranges of driver input (V_{IN}, from −3 to 2 V, −4 to 2 V, −6 to 2 V, and −8 to 2 V) in Fig. 2b. Starting V_{IN} is indicated by arrows and a maximum output voltage gain ($-dV_{OUT}/dV_{IN}$) was ~18. VTCs show some hysteresis at output voltage (V_{OUT}) switching, and all the hysteresis appears almost the same regardless of V_{IN} range when the sweep started from negative voltages to reach the positive values. During V_{IN} sweep, electron injection from ITO gate electrode into AlO_x or time-dependent charge trapping at the pentacene/

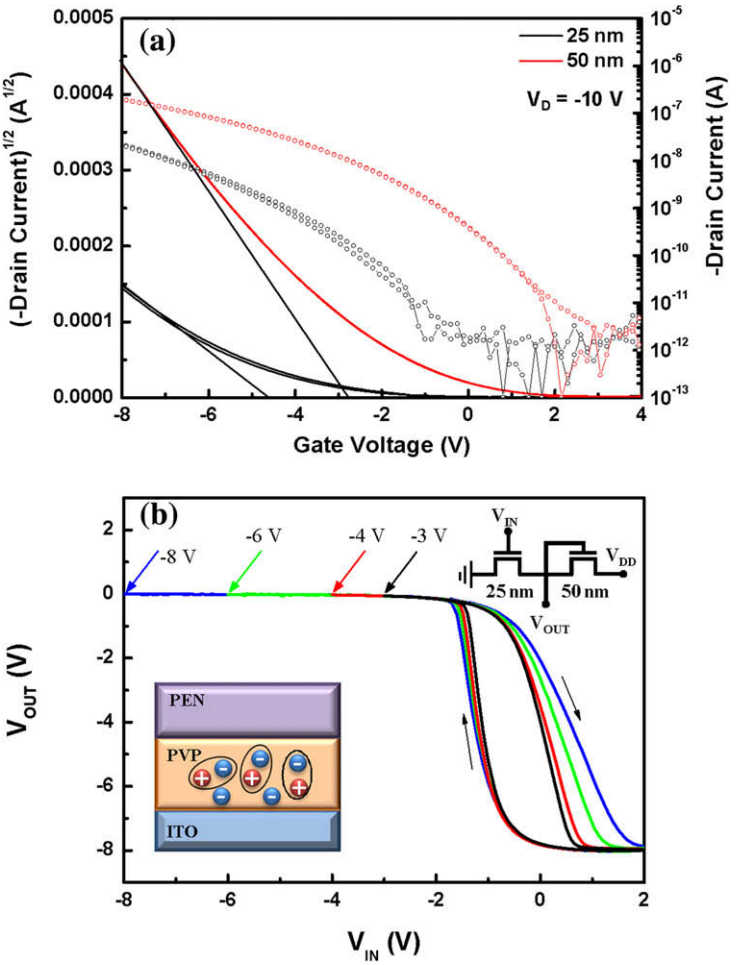

Fig. 3. (a) $\sqrt{-I_D}$–V_G and $\log_{10}(-I_D)$–V_G plots obtained from our pentacene TFTs with 230 nm-thick PVP dielectric at $V_D = -10$ V. (b) VTC of the inverter on PVP as obtained under various V_{IN} ranges. Arrows indicate the starting V_{IN} for sweep (−3, −4, −6, and −8 V). Driver-OTFT has 25 nm-thin pentacene channel while load-OTFT does 50 nm-thick pentacene.

dielectric interfaces are expected and such mobile charge behavior causes the visible hysteresis in the driver-TFT side [14–18]. If our pentacene TFT driver of this inverter was influenced by time-dependent charge trapping at the pentacene/dielectric interfaces, the hysteresis direction would appear opposite to the present direction [7]. (See the hysteresis arrows.) Therefore, the observed VTC hysteresis is attributed to the electron injection from the ITO gate as illustrated in the inset in Fig. 2b [19]. (It is also to be kept in mind that unlike the V_G sweep of transfer curve, the V_{IN} sweep exerts serious gate bias-stress onto the driver-TFT because V_{OUT} maintains 0 V during some time of V_{IN} sweep.) However, when we swept the V_{IN} from +2 V to reach −8 V, the VTC hysteresis direction changed opposite to that of Fig. 2b as shown in another VTC of Fig. 2c. This means that other hysteresis mechanism due to electron trapping also exists for this inverter with thin AlO_x dielectric whose surface is strongly polar and hydrophilic to trap some density of electrons [7,17,18]. We regard that both electron trapping and gate electron injection exist for this inverter probably competing each other.

3.2. Organic inverter with hydrophobic PVP dielectric

We also tested the case of PVP polymer for an inverter dielectric, on which OTFT with 25 nm-thin pentacene channel has lower on-state I_D and larger V_{TH} than that with 50 nm-thick channel. The transfer curves of Fig. 3a show the very results, supporting previous reports that a hydrophobic dielectric surface has an optimum pentacene channel thickness around 50 nm [12]. Unlike the case on hydrophilic oxide of large surface energy, the pentacene channel on hydrophobic dielectric does not have perfect coverage if it is too thin [12], so that the effective channel resistance of 25 nm-thin pentacene must be larger than that of 50 nm-thick channel which may perfectly cover the PVP dielectric making good channel/dielectric interface. In this case, we set-up an inverter taking 50 nm-thick pentacene as the channel of load-TFT because this TFT with 50 nm-thick channel has lower V_{TH} (−3.6 V) than that (−6 V) with 25 nm-thin pentacene channel, which is now contrary to the case on hydrophilic AlO_x. Although OTFTs with this polymer dielectric did not show any gate-bias

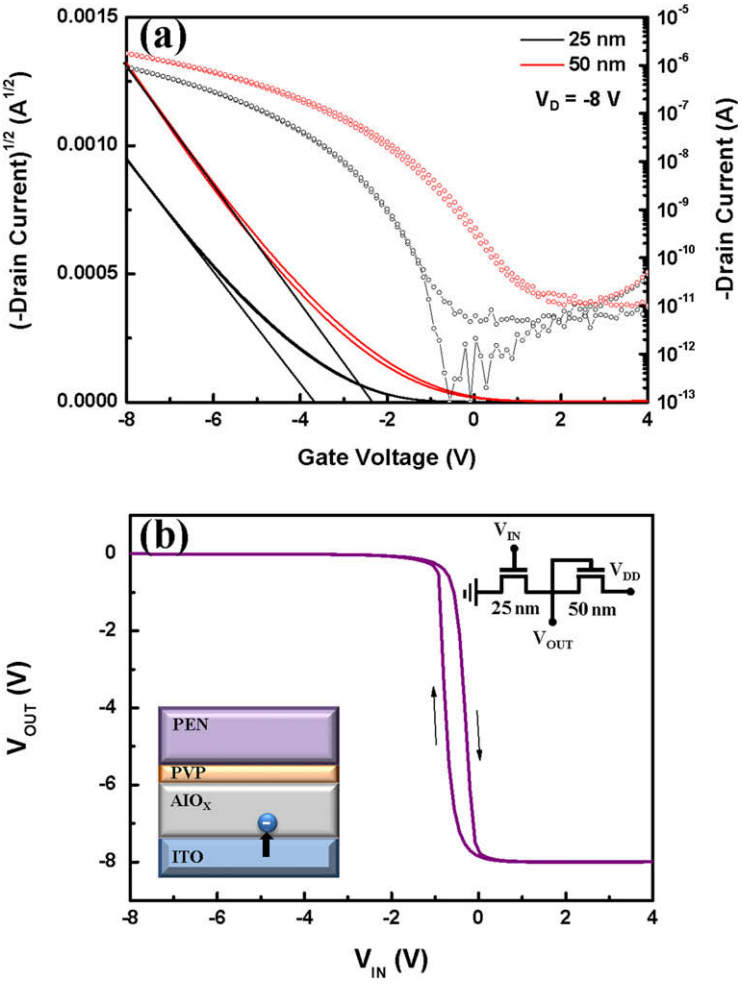

Fig. 4. (a) $\sqrt{-I_D}$–V_G and $\log_{10}(-I_D)$–V_G plots obtained from our pentacene TFTs with AlO_x–PVP bilayer dielectric at $V_D = -8$ V. (b) VTC of the inverter on AlO_x–PVP bilayer. VTC behavior was improved in respects of voltage gain and hysteresis. (V_{IN} starts at −8 V.)

hysteresis in their transfer curves, our inverter VTCs behavior displayed very large hysteresis depending on V_{IN} sweep range. (Fig. 3b) Thickness of the PVP film was approximately 230 nm as measured by optical method (model ST2000DLXn, K-MAC) and we attribute the large hysteresis to the gate-bias stress on driver-TFT. The stress would easily cause gate electron injection into the thick PVP as well as cause electric dipoles in PVP. The dipoles in PVP are slowly depolarized even at a positive (+) V_{IN} during the sweep. We explained this slow polarization effects in previous reports [14,15]. Due to this effect added to the gate electron injection, the size of hysteresis appears large and evidently increases with the V_{IN} range increase. The inset of Fig. 3b illustrates the remnant dipoles and remnant electrons.

In order to minimize such V_{IN}-induced hysteresis that we observe from electron injection, slow polarization, and electron trapping, we prepared another inverter with 45 nm-thin PVP/100 nm-thick AlO_x double layer dielectric. Fig. 4a shows the I_D versus V_G transfer curves obtained from the OTFTs with 45 nm-thin PVP/100 nm-thick AlO_x double layer dielectric. Since pentacene channel was in contact with hydrophobic PVP surface, the device of 50 nm-thick pentacene channel showed higher on-state I_D and lower V_{TH} than those of 25 nm-thin channel. According to $\sqrt{-I_D}$–V_G curve, the pentacene TFT with 25 nm-thin channel has a saturation mobility of ~0.5 cm^2/V s and a high on/off current ratio of $\sim 10^6$ with $V_{TH} = -4$ V while the other one with 50 nm-thick pentacene shows a little higher saturation mobility (~0.6 cm^2/V s) and lower $V_{TH} = -2.5$ V. We thus took the TFT with 25 nm-thin channel as driver-TFT and the other one as load-TFT. The VTCs of this inverter with PVP/AlO_x double dielectric are displayed in Fig. 4b and show improved features in respects of voltage gain ($-dV_{OUT}/dV_{IN} = \sim 22$) and the size of hysteresis, compared to those of other inverters with AlO_x or with PVP single layer (Figs. 2b and 3b). Through the organic/inorganic double layer approach, we may reduce the hysteresis induced by gate electrons injected into AlO_x because electric field stress is divided into PVP and AlO_x, simultaneously minimizing the slow polarization effects in PVP which is now thin enough to neglect the effect [8,15].

3.3. Device statistics on the V_{TH} values of driver- and load-TFTs

Fig. 5a shows the V_{TH} values of our TFTs as the functions of thickness and substrate. We randomly selected at least 12 pentacene TFTs consisting 6 pairs of inverter for this statistic plot. As shown in the plot, the V_{TH} of 25 nm-thin channel-TFT appeared always lower than that of 50 nm-thick channel-TFT on hydrophilic AlO_x dielectric, to be −2.5 V as an average value while that of 50 nm-thick channel-TFT was −3.4. (Deviation bar is also noted.) In contrast, the situation becomes opposite when we use PVP dielectric surface for pentacene channel. In this case, the V_{TH} of 25 nm-thin channel-TFT appeared always larger than that of 50 nm-thick channel-TFT as we expected from previous results. It is also noted that our V_{TH} values obtained from our optimized devices on PVP/AlO_x dielectric has much reduced deviations. Our pentacene inverters with the PVP/AlO_x dielectric have also been tested for their aging properties. Fig. 5b displays two VTC curves of a random selected organic inverter with the PVP/AlO_x dielectric; one of the curves was obtained after 3 months passed since initially measured. As shown in the figure, our device displayed almost the same VTC characteristics except a little shift of transition voltage even after 3 months, implying that this organic inverter is relatively stable in aging (as long as we have kept the device in 1 Torr desiccator for the time).

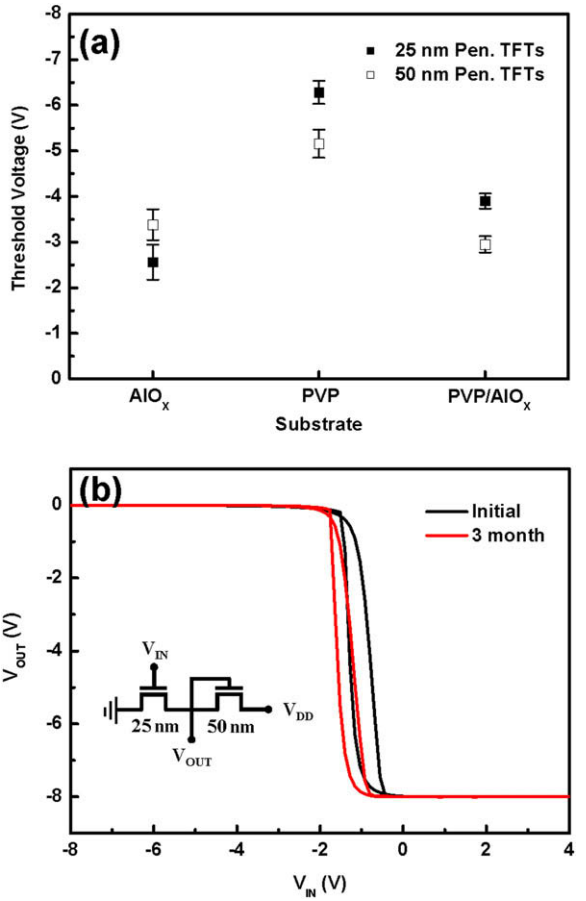

Fig. 5. (a) V_{TH} values of our TFTs as the functions of thickness and substrate. (b) VTC curves of a random selected organic inverter with the PVP/AlO_x dielectric; one of the curves was obtained after 3 months passed since initially measured. Our organic inverter appears relatively stable in aging (as long as we have kept the device in 1 Torr desiccator for the time).

4. Conclusion

We have fabricated p-channel depletion mode inverter using two pentacene TFTs with different channel thicknesses. Since on hydrophilic AlO_x dielectric the V_{TH} of 25 nm-thin channel-TFT is lower than that of 50 nm-thick channel-TFT, the thinner channel-TFT was used as load while the thicker channel-TFT became driver in the inverter. The driver and load set-up for inverter became opposite on hydrophobic PVP dielectric surface, where the V_{TH} of thinner channel-TFT is larger. Our optimized inverters

with 45 nm-thin PVP/100 nm-thick AlO_x double layer dielectric demonstrate a high voltage gain of ~22 under −8 V supply voltage, since the double dielectric layer effectively prevents the slow polarization and gate electron injection. We conclude that this channel thickness approach is quite a promising way to achieve organic inverter without complexity.

Integration

ABSTRACT

We demonstrate a vacuum deposited molecular organic photodetector (OPD) integrated with a top gate, bottom-contact, pentacene-based organic thin film transistor (OTFT) for use as a switchable organic passive pixel sensor in focal plane imaging arrays. The heterojunction OPD consists of a 110 Å thick film of the donor, boron subphthalocyanine chloride, and a 325 Å thick film of the acceptor, C_{60}. The OTFT switch allows the photodetector to be switched between an active (ON) state with a light intensity dependent photocurrent peaking at 20 nA, and an inactive (OFF) state with current <50 pA, corresponding to an 8-bit dynamic range. The integrated device has a spectral coverage from wavelengths of 400–600 nm, and a pixel switching frequency >400 kHz. The integrated structure is fabricated at room temperature, making this circuit compatible with low cost, flexible plastic substrates.

Recent interest in organic semiconductors has led to the development of many devices and applications opportunities previously unattainable with inorganic semiconductors. Inexpensive organic materials can be readily deposited onto transparent and flexible substrates, and in non-planar geometries with potential uses in, for example, displays, imaging, and solar energy harvesting [1]. In particular, organic photodetectors (OPD) have been demonstrated with broad spectral coverage and high specific detectivity [2], while simple passive-matrix OPD focal plane arrays have been fabricated on such non-planar surfaces as hemispheres [3,4]. A second component required for many electronic applications is the organic thin film transistor (OTFT), demonstrated using an organic semiconductor channel [5]. Examples of integrated circuits that combine electrical and optical functions include drive transistors combined with organic light emitting devices (OLEDs) [6]. Hybrid [7] and monolithic [8] photodetectors [7] or photoconductors [8] integrated with transistors have also been demonstrated for scanning and imaging applications using complex laser drilling [7] or lithographic processes and inkjet printing [8] techniques.

Here, we demonstrate a boron subphthalocyanine chloride (SubPc)/C_{60} photodetector monolithically integrated in series with a top gate, pentacene OTFT switch for use as a passive pixel sensor [9] in imaging focal plane array applications that require a low OFF current [3,4]. The integrated structure is fabricated by sequential layer growth using vacuum thermal evaporation of the small molecular weight organic materials. The pixel is activated using the OTFT by applying a negative gate voltage which turns the transistor to the ON (i.e. conducting) state, permitting photocurrent from the OPD to be collected at the source. The device has an 8-bit dynamic range and allows for >400 kHz switching.

A cross-section of the integrated circuit is shown in Fig. 1a. The OPD was fabricated by vacuum thermal evaporation onto a commercially patterned 200 μm wide stripe of 100 nm thick, 20 Ω/sq. indium tin oxide (ITO) precoated on a glass substrate. Prior to organic thin film deposition, the substrate was solvent cleaned and UV ozone treated as described elsewhere [10]. All organic materials were

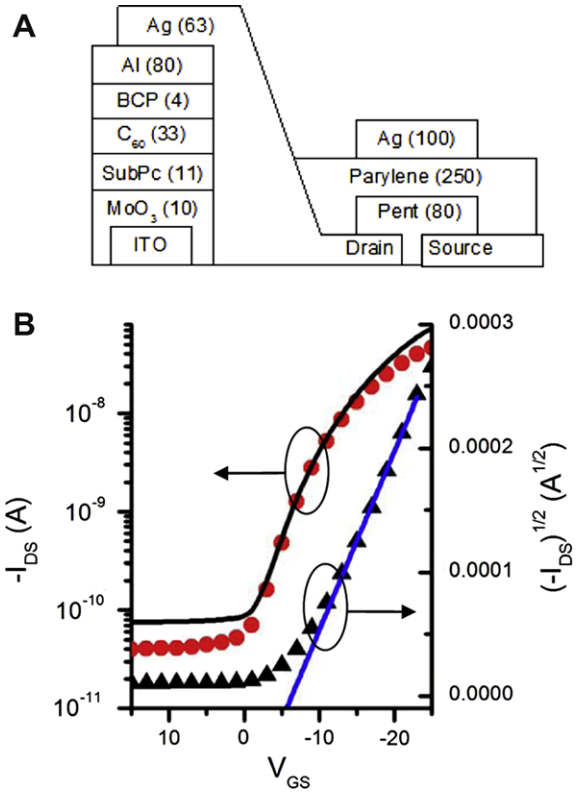

Fig. 1. (a) Schematic cross-section of the integrated pixel structure. Layer thicknesses in parentheses are in nanometers. (b) Top gate pentacene OTFT transfer characteristic at a drain-source voltage of $V_{DS} = -17.5$ V (solid line) and -7.5 V (circles) for a 500 μm wide by 25 μm long channel. Also shown is the square root of drain-source current, $(I_{DS})^{1/2}$, (triangles) with fit to pinch-off region (straight solid line).

purified by vacuum thermal gradient sublimation and were deposited at 1 Å/s in a vacuum chamber with a base pressure of 1×10^{-6} torr unless otherwise stated. Prior to deposition of the photoactive layers, a 10 nm thick MoO_3 film was deposited onto the ITO at 0.2 Å/s as a hole transport and electron blocking layer that reduces photodetector dark current [11]. The active layers consisted of a 110 Å thick film of SubPc followed by a 325 Å thick film of C_{60}. Subsequently, a 40 Å thick layer of exciton blocking and electron transporting bathocuproine was deposited [12]. The cathode, an 800 Å thick Al stripe that was either 100 or 500 μm wide, was deposited through a shadow mask aligned with the ITO anode across the anode stripe defining the detector area. The top gate OTFT was subsequently grown adjacent to the detector with the drain connected to the detector cathode, forming the passive pixel sensor circuit [9]. The OTFT layers were also grown by vacuum thermal evaporation except for the gate insulator. Here, parylene-C gate dielectric was deposited at room temperature after vaporization and pyrolysis [13] to prevent any damage to the pentacene channel. The OTFT structure consists of (from substrate to top gate): a 625 Å thick Ag layer for the drain and source contacts deposited through a second, aligned mask, an 800 Å thick pentacene channel layer (deposited at 0.2 Å/s for the first 300 Å, and 0.5 Å/s for the remainder), and a 250 nm thick parylene-C insulator followed by a 1000 Å thick Ag top gate electrode. Channel widths of 100 μm and 500 μm were employed, each with gate lengths of 25 and 50 microns. During deposition the device was kept in vacuum or in an ultrahigh purity (<1 ppm O_2 or H_2O) N_2 glovebox except when exposed to air after the cathode, pentacene, and parylene-C deposition steps.

Independent steady state electrical characterizations of both the OTFT and OPD were obtained using a semiconductor parameter analyzer. The OPD was tested in the dark and under illumination at powers as high as 0.33 mW/cm^2, at a wavelength of $\lambda = 578$ nm using a Hg lamp with a notch filter. A quartz-tungsten lamp chopped at 190 Hz synchronized with a lock-in amplifier, and filtered by a monochromator was used to determine the detector spectral response. Optical power intensity was measured using a calibrated Si photodetector. The optical pulse response was measured using a N_2 pumped dye laser at $\lambda = 581$ nm with a pulse energy of 5 μJ and duration of 1.5 ns. The switching response of the OTFT was measured using an oscilloscope and a pulse generator connected to the OTFT gate.

The OTFT with a gate width to length ratio of $W/L = 20$ for a gate width of $W = 500$ μm had a drain-source current, I_{DS}, ON/OFF ratio of 700 when the gate-source voltage, V_{GS}, was varied from -25 V to +15 V (voltages are relative to the source at ground) and at a drain-source voltage of $V_{DS} = -17.5$ V. The OFF current was approximately $I_{OFF} = 80$ pA as shown in the transfer characteristics of Fig. 1b. At low V_{DS}, I_{OFF} is reduced but more slowly than the reduction in the ON current resulting in a reduced ON/OFF ratio. Analysis of the transfer characteristics in the pinch-off regime yields a pentacene mobility of $\mu = 0.0025$ cm^2/V s and threshold voltage of $V_{th} = 7$ V according to: $I_{DS} = \frac{1}{2}\frac{W}{L}\mu C_i(V_{GS} - V_{th})^2$, where $C_i = 8$ nF/cm^2 is the capacitance of the parylene-C gate dielectric. The resistance of the OTFT, extracted from I_{DS} vs. V_{DS}, is 220 MΩ at $V_{DS} = -5$ V with $V_{GS} = -20$ V. The relatively high resistance and low mobility of the OTFT is due to the top gate, bottom-contact configuration, and air exposure between the pentacene and parylene depositions. Growth of the pentacene channel at elevated temperatures also is known to increase the hole mobility [14].

The current–voltage (I–V) characteristic of a 200 μm × 500 μm OPD at a wavelength of $\lambda = 578$ nm is shown in Fig. 2, with the wavelength-dependent external quantum efficiency (EQE) shown in the inset. The SubPc response peak at $\lambda = 580$ nm and the broader C_{60} peak at $\lambda = 450$ nm are apparent [15]. Under reverse bias, the C_{60} peak increases significantly relative to that of SubPc due to increased field-induced exciton dissociation in the thin film bulk [16].

The anode-source current, I_{AS}, of the integrated device is shown in the inset of Fig. 3 for $V_{AS} = -5.0$ V. In the ON state at $V_{GS} = -20$ V, the pixel provides an intensity dependent photocurrent that is suppressed in the OFF state. The ON state photocurrent is plotted in Fig. 3 as a function of power intensity and shows an 8-bit dynamic range of $DR = \Delta I_{max}/\Delta I_{min} = (I_{max} - I_{dark})/(I_{min} - I_{dark}) = 300$, where I_{max} is the current that is reduced by 1 dB from the linear

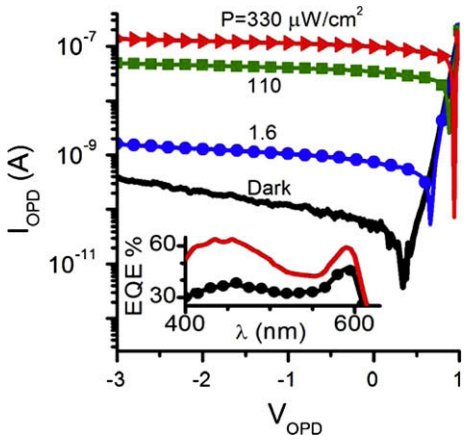

Fig. 2. Steady state current–voltage (I_{OPD}–V_{OPD}) characteristics for a 200 μm × 500 μm SubPc/C_{60} based OPD in the dark (solid line) and illuminated at a wavelength of $\lambda = 578$ nm at 1.6 μW/cm^2 (circles), 110 μW/cm^2 (squares), and 330 μW/cm^2 (triangles). Inset: Spectral dependence of external quantum efficiency (EQE) of the OPD, at 0 V (solid line) and at −2.5 V (circles).

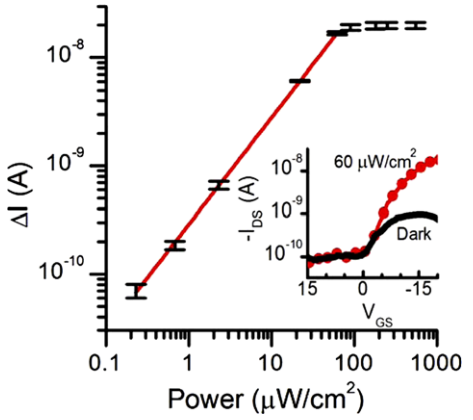

Fig. 3. Power intensity dependent photocurrent of an integrated pixel with a 200 μm × 500 μm OPD, and a 500 μm wide × 25 μm long OTFT channel, illuminated at a wavelength of $\lambda = 578$ nm. The photocurrent, ΔI, is the illuminated current minus the dark current. The pixel is in the ON state, with gate-source voltage of −20 V, and the anode-source voltage is $V_{AS} = -5$ V. The line is a linear fit of log(ΔI) to log(P) with a slope of 1.01 ± 0.02 and an intercept corresponding to a responsivity of 0.29 A/W. Inset: The anode-source current, I_{AS}, in the dark (solid line) and illuminated at 60 μW/cm^2 (circles) for $V_{AS} = -5$ V with V_{GS} varied from +15 V to −20 V.

response of current vs. incident optical power, I_{dark} is the OPD dark current, and I_{min} is the minimum current distinguishable from I_{dark}. This *DR* is lower than expected from the transfer characteristic since $V_{AS} = -5.0$ V is restricted to low voltage to avoid damaging the OPD. The line is a fit of log(ΔI) to log(P) and yields a slope of 1.01 ± 0.02 and intercept of −6.54 ± 0.06, corresponding to a responsivity of 0.29 A/W at $\lambda = 581$ nm.

The response of the pixel to a 1.5 ns optical pulse at $\lambda = 581$ nm is shown in Fig. 4 with $V_{GS} = -20$ V and OPD-anode to OTFT-source voltage, V_{AS}, of −5 V. The signal is

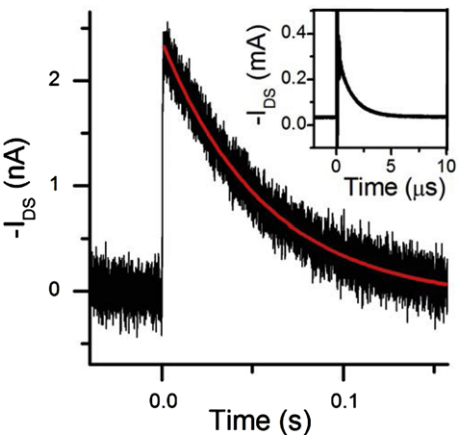

Fig. 4. Optical pulse response through a 1 MΩ load of an integrated pixel, with a 200 μm × 100 μm OPD and a 500 μm wide × 25 μm long OTFT channel. The optical pulse is 1.5 ns long with a pulse energy of 5 μJ centered at a wavelength of $\lambda = 581$ nm. The anode-source current, I_{AS}, decays exponentially with a 60 ms time constant, shown by the fit (red line). Inset: OTFT switching response of the pixel with 5 kΩ load due to a 800 ms long, gate-source voltage pulse of −20 V. The response time of 1.3 μs corresponds to a frequency response of >400 kHz. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

measured on an oscilloscope with a 1 MΩ load that is much less than the channel resistance, and an exponential fit has a decay time of 60 ms. The response time of the OPD alone is approximately 10 ns [2], and the long response time corresponds to discharge through the OTFT. Improving the mobility of the OTFT by improving molecular ordering of the pentacene film and preventing air exposure between the channel and gate insulator deposition steps can reduce the time required to extract photogenerated charge from the pixel. The electrical pulse response of the integrated device under illumination is shown in the inset of Fig. 4, with $V_{AS} = -10$ V and with a 50 ms long pulse of $V_{GS} = -20$ V applied to the transistor gate. A resistance–capacitance (RC) time of 1.3 μs is required to charge the OTFT using a 5 kΩ load, resulting in a switching frequency of 400 kHz.

The OPD has a linear response over more than 5 decades in power intensity, so the *DR* is limited by the performance of the OTFT which limits the photocurrent of the OPD at high light intensity. For small photocurrents, the OTFT operates in a linear, resistive regime where $V_{DS} \propto I_{DS}$, and all the photocurrent can be extracted through the transistor. For large currents, the OTFT saturates and the forward bias on the OPD is diminished since the total voltage across the circuit, $V_{AS} = V_{OPD} + V_{DS}$, is fixed. This restricts the photocurrent to the ON current of the OTFT. The OTFT ON current could realistically be improved toward reported values of 10^{-6} A by improving fabrication techniques [17]. This would result in a dynamic range of 13 bits for the same dark current.

This device has applications in systems that require low dark current, for example, sensors with multiple detectors sharing a common output as is typical of most imaging focal plane arrays. The integrated OTFT in the OFF state re-

duces the OPD dark current by a factor of 10, enabling the fabrication of a sensor comprised of 10×10 array blocks with integrated OFF currents comparable to that of a single detector. Optimization of the OTFT performance to reported OFF currents <4 pA characteristic of discrete, top gate pentacene OTFTs can extend array sizes to $>100 \times 100$ [18]. Since the vertical integration achieved using layer-by-layer growth requires no complex patterning processes, it preserves the potential low cost of organic electronics. In addition, the room temperature processing including gate insulator deposition makes this process compatible with flexible plastic substrates.

In conclusion, we have demonstrated a monolithically integrated, small molecular weight OPD plus OTFT passive pixel sensor circuit with an 8-bit dynamic range, a switching time of >400 kHz, and an OFF current of <50 pA. This circuit has applications in focal plane detector arrays for high sensitivity imaging applications.

ABSTRACT

We report simple red phosphorescent devices comprising single layer configuration using a tris[1-phenylisoqunolinato-C2,N]iridium (III) ($Ir(piq)_3$) dopant concentration as low as 1 wt.% in mixed host systems. The driving voltage of 5.4 V to reach the brightness of 1000 cd/m^2 in the mixed emitting layer of *N*,*N*′-diphenyl-*N*,*N*′-bis(1,1′-biphenyl)-4,4′-diamine (NPB) and bis(10-hydroxybenzo[h]quinolinato)beryllium ($Bebq_2$) is reported. Maximum current and power efficiency values of 9.44 cd/A and 10.62 lm/W are obtained in this single layer structure PHOLEDs, respectively. It is believed that the direct injection of charge carriers to the organic layer and high carrier mobility therein are the keys to the simplification of the device structure.

1. Introduction

Organic light-emitting devices (OLEDs) have made significant stride in recent days [1] and the technology has already been commercialized to mobile flat panel display applications. In phosphorescent OLEDs (PHOLEDs), required for high brightness and display applications, almost maximum theoretical limit of external quantum efficiency (EQE) has been achieved in several color devices [2–4]. Thermal evaporation technique and complicated fabrication process consisting of multiple layers for charge carriers balancing and exciton confinement [5–7] are employed in highly efficient phosphorescent OLEDs. In order to overcome such complex device architecture, many good approaches are enduring until now. High efficiency devices with pure organic bi-layered OLEDs have been reported by several researchers [8–10]. Furthermore, bi-layered devices consisting of an organic single layer with a buffer layer on the electrode have also been reported without any significant improvement of the device performances [11–14]. However, truly organic single layered approach is almost rare. To date, only an exclusive article on the red emitting PHOLED single layer device with a tris[1-phenylisoqunolinato-C2,N]iridium (III) ($Ir(piq)_3$) (21 wt.%) doped in TPBi (100 nm) with low values of current and power efficiencies under 3.7 cd/A and 3.2 lm/W at 1 cd/m^2 have been reported, respectively [15].

In this paper, we have demonstrated efficient and simple red PHOLEDs with only single organic layer using thermal evaporation technique. The key to the simplification is the direct injection of holes and electrons into the mixed host materials through electrodes. In conventional OLEDs, usually the Fermi energy gap between cathode (~2.9 eV) and surface treated anode (~5.1 eV) is about 2.0–2.2 eV which is close to the red light emission energy (1.9–2.0 eV). As a consequence, red devices do not at all require any charge injection and transporter layer if the host material has proper HOMO (highest occupied molecular orbital) and

doi:10.1016/j.orgel.2009.10.010

LUMO (lowest unoccupied molecular orbital) energy levels. However, such host materials are very rare. The most suitable option to address such issues is to employ the mixed host system to adequately match the energy levels between emitting host and electrodes. Mixed host system of electron transporting and hole transporting materials to inject electrons and holes from electrodes into the organic layer without any barrier has been studied, respectively and employed for the charge balance. Thus, hole type host materials are required to have HOMO energy levels at 5.1–5.4 eV to match with the Fermi energy of surface treated ITO (5.1 eV). While 2.8–3.0 eV LUMO energy levels of electron transporting host materials are necessary to match the Fermi level of cathode. 4,4′,4″-Tris(*N*-3-methylphenyl-*N*-phenyl-amino)triphenylamine(m-MTDATA) and *N*,*N*′-diphenyl-*N*, *N*′-bis(1,1′-biphenyl)-4,4′-diamine (α-NPB) were used as the hole transporting host materials. Bis(10-hydroxybenzo[h]quinolinato)beryllium ($Bebq_2$) with 2.8 eV LUMO energy was used as the electron transport host material and $Ir(piq)_3$ was employed as a red phosphorescent guest.

2. Experimental

m-MTDATA and α-NPB as hole transporting host materials, $Bebq_2$ as an electron transporting host material, and $Ir(piq)_3$ as a red dopant were purchased from Gracel Corporation. To fabricate OLED devices, clean glass substrates precoated with a 150-nm-thick indium tin oxide (ITO) layer with a sheet resistance of ~20 Ω/sq were used. Line patterns of ITO were formed on glass by photolithography process. The ITO glass was cleaned by sonification in an isopropylalcohol and acetone, rinsed in deionized water, and finally irradiation in a UV-ozone chamber. All organic materials were deposited by the vacuum evaporation technique under a pressure of $\sim 2.0 \times 10^{-7}$ Torr. The deposition rate of organic layers was about 1 A/s. Subsequently, LiF and Al were deposited in another vacuum deposition system without breaking vacuum. Deposition rates of LiF and Al were 0.1 and 5–10 A/s, respectively. The current density–voltage (*J*–*V*) and luminance–voltage (*L*–*V*) data of red PHOLEDs were measured by Keithley 2635 A and Minolta CS-1000A, respectively. The red PHOLED emitting area was 2 mm^2 for all the samples studied in the present work.

3. Results and discussion

Fig. 1 shows the energy band-diagram of the single layer red PHOLEDs used in the present work. For the evaluation of single layer with different mixed host systems, the following devices were fabricated:

Device A: ITO/m-MTDATA:$Bebq_2$:$Ir(piq)_3$ [1–4 wt.%, 100 nm]/LiF (0.5 nm)/Al (100 nm).
Device B: ITO/α-NPB:$Bebq_2$:$Ir(piq)_3$ [1–4 wt.%, 100 nm]/LiF (0.5 nm)/Al (100 nm).

The ratio of the hole and electron transporting hosts was fixed to 1:1. The doping concentrations were varied

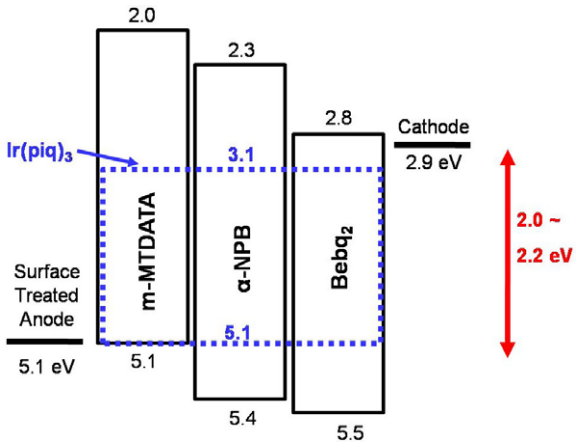

Fig. 1. Energy band-diagram of the single layer red PHOLEDs.

from 1% to 4% to optimize the device performance. Table 1 shows the performance of red PHOLEDs devices comprising a single emitting layer. The current and power efficiencies values of 7.44 cd/A, and 3.43 lm/W at 1000 cd/m^2 brightness value are reported in 4 wt.% doped device A, respectively. The driving voltage (to reach 1000 cd/m^2) is 6.9 V. Very similar device performances are obtained in 2 wt.% doped device A. The optimum doping condition for device A seems to be 4 wt.% as the highest efficiency is observed at an acceptable brightness value (1000 cd/m^2). Whereas, the driving voltage, current and power efficiencies values of 5.4 V, 9.02 cd/A, and 5.25 lm/W at brightness value of 1000 cd/m^2 are reported in device B with 1 wt.% of optimum doping condition, respectively. Maximum current efficiency for devices A and B were appeared for the 4 and 1 wt.% of $Ir(piq)_3$ doped mixed hosts, respectively. The color coordinates are (0.66, 0.33) or (0.67, 0.32) for all devices. Even in 1% doped device, a good red emission color is observed. The results of device B (1 wt.%) is significantly superior to $Ir(piq)_3$ doped multilayer red PHOLEDs [16]. In our previous study, the doping concentration in PHOLEDs can be reduced until 1–2% range with higher efficiency when HOMO–HOMO and LUMO–LUMO differences between host and dopant molecules are provided within ~0.3 eV [17]. Device B displays exactly similar behavior although HOMO–HOMO gap is relatively higher than device A. However, unlike device B, similar device properties in device A regardless of doping condition from 1% to 4% are obtained. The self quenching by dopants seems to be not so serious in this device A. This indicates that the emission zone of device A is very broad and the charge balance is also relatively poor. As a result, the efficiency of device A is low compared to device B and 4% doped condition in device A seems to have a little better charge balance.

The *J*–*V*–*L* curve and efficiency characteristics of devices A and B are shown in Fig. 2. The best efficiency yields of 9.44 cd/A (EQE 14.6%) and 10.62 lm/W are noticed in the device B as shown in Fig. 2b. As seen from the results of Fig. 2a, the driving voltage in device A with m-MTDATA:$Bebq_2$:$Ir(piq)_3$ [4 wt.%] is 6.9 V at the bright-

ness of 1000 cd/m^2. The device B with α-NPB:Bebq$_2$:Ir(piq)$_3$ [1 wt.%] shows a driving voltage of 5.4 V at 1000 cd/m^2. In m-MTDATA, no barrier for hole injection from the surface treated ITO (5.1 eV) to the HOMO (5.1 eV) of the m-MTDATA exists. Further, this energy level matches with the HOMO (5.1 eV) of the Ir(piq)$_3$. While, electrons injected from the cathode move freely on the LUMO energy of Bebq$_2$. In case of the device B, the HOMO energy in the α-NPB material at 5.4 eV as against 5.1 eV in the surface treated ITO (HOMO difference ~0.3 eV) offers some barrier to the hole injection into the emitting layer. While electrons injected from cathode move freely over the LUMO energy of Bebq$_2$. In order to understand the injection barrier situation in m-MTDATA and α-NPB, J–V of hole only devices were investigated. An ideal Ohmic contact [18] at ITO and m-MTDATA interface was reported. Whereas, the NPB hole only device had reported to have injection limited current behavior. When a buffer layer like PEDOT:PSS (poly(3,4-ethylenedioxythiophene)-poly(4-stylenesulfonate) or C60 was introduced at ITO interface, the Ohmic characteristic was observed in this device [19,20]. Form these previously reported results, a high value of driving voltage in the α-NPB mixed device B due to the high barrier to hole injection into the emitting layer was expected. However in reality, the device B with α-NPB hole transporting host shows a lower driving voltage implying a low resistance to the current flow. Here, devices A and B were realized using two different hole transporting host materials having different charge carriers transport abilities, particularly the hole mobility. α-NPB has an ambipolar transporting ability with the hole mobility faster than that of m-MTDATA [21]. Thus, mobilities of hole carriers in these mixed host single layer systems rather than hole injection barrier at the ITO/mixed host interface seems to be crucial in deciding the driving voltage. In order to elucidate the conduction and emission processes in single layer devices, we have fabricated following several devices and investigated.

We have made devices C and D without Ir(piq)$_3$ dopant and results were compared with those of devices A and B, respectively. Fig. 3 shows J–V characteristics of devices A, B, C, and D. Results on bi-layered ITO/α-NPB (40 nm)/Bebq$_2$:Ir(piq)$_3$ (10 wt.%, 50 nm)/LiF (0.5 nm)/Al (100 nm) red emitting PHOLEDs [16], reproduced here for better

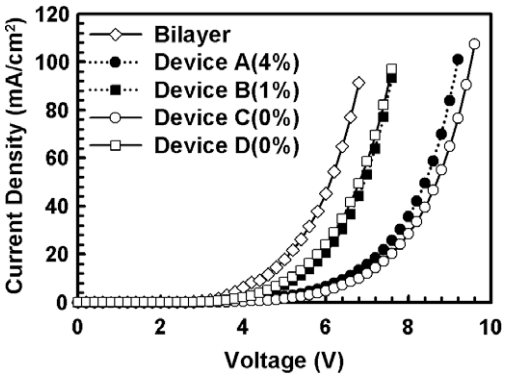

Fig. 3. J–V characteristics of bi-layered ITO/α-NPB (40 nm)/Bebq$_2$:Ir(piq)$_3$ (10 wt.%, 50 nm)/LiF (0.5 nm)/Al (100 nm) red emitting PHOLED and devices A–D.

comparison, show a low driving voltage value of 4.5 V to reach a luminance of 1000 cd/m^2. As displayed in Fig. 3, both devices C and D (undoped) show *J–V* characteristics similar to Ir(piq)$_3$ doped devices A and B, respectively. Furthermore in our devices A and B, hole and electron injection barriers by dopant molecules are negligible due to no barrier at ITO and cathode interfaces, respectively. Doping in the device may affect carrier mobility due to carrier trapping by dopant molecules. Usually, *J–V* characteristics of PHOLEDs are changed significantly by adding dopant molecules when HOMO–HOMO and LUMO–LUMO differences between host and dopant molecules are high over 0.3 eV. In device A and B, these energy differences are within 0.3 eV. In this case, the change of *J–V* characteristic is very small because trapped charges in dopant molecules easily overcome to host energy level by thermal energy. Such behavior is already reported in our previous study [17]. Described results demonstrate that the conduction of current in a hole and electron transporting mixed host layer is almost independent of (i) the charge trapping at dopant molecules and (ii) hole injection barrier at the ITO/mixed host interface. Further, all mixed single layer devices offer a high resistance to current flow than bi-layered red device with hetero junction (see Fig. 3). The interesting and intriguing results on *J–V* in mixed host single layer devices may be explained on the basis of existing knowledge on carrier mobilities in organic materials. α-NPB exhibits an ambipolar transporting ability with electron and hole mobility values of 9×10^{-4} and 6×10^{-4} cm^2/Vs, respectively [22], while the hole mobility value in m-MTDATA is 3×10^{-5} cm^2/Vs. Earlier, it was shown that the charge transport behaviors in mixed thin films of α-NPB and Alq$_3$ are sensitive to (i) compositional fraction, and (ii) charge carriers mobilities of neat compounds [22]. The 1:1 mixed layer of α-NPB and Alq$_3$ appeared to give lower charge carrier mobility of 10^{-2}–10^{-3} order than neat films [22]. As a consequence, the fast current flow in the device B despite the large hole injection barrier is attributed to the high hole mobility value and ambipolar nature of α-NPB. Higher driving voltage of single layer devices compared to the bilayer device is also well understood by the decrease in carrier mobility in the mixed host system.

Since the charge transport behaviors in mixed hosts are sensitive to the composition and intrinsic mobilities in neat films, the location of the recombination region may be important to understand the device efficiency. To investigate the recombination zone position, we have evaluated three devices with doped emissive layer located at different positions as:

(1) Device A-(L): ITO/m-MTDATA:Bebq$_2$:Ir(piq)$_3$ [4 wt.%, 30 nm]/m-MTDATA:Bebq$_2$ [70 nm]/LiF (0.5 nm)/Al (100 nm).
(2) Device A-(C): ITO/m-MTDATA:Bebq$_2$ [35 nm]/m-MTDATA:Bebq$_2$:Ir(piq)$_3$ [4 wt.%, 30 nm]/m-MTDATA:Bebq$_2$ [35 nm]/LiF (0.5 nm)/Al (100 nm).
(3) Device A-(R): ITO/m-MTDATA:Bebq$_2$ [30 nm]/m-MTDATA:Bebq$_2$:Ir(piq)$_3$ [4 wt.%, 70 nm]/LiF (0.5 nm)/Al (100 nm).

Similarly, devices B-(L), (C) and (R) were fabricated using α-NPB instead of m-MTDATA and 1 wt.% of Ir(piq)$_3$. The doping region was fixed to 30 nm in all devices. The anode side doped devices show the best current efficiency performance as displayed in Fig. 4 (devices A-(L) and B-(L)), indicating that the recombination zone is around the ITO/mixed host interface. Further, the emission efficiency performance deteriorates as the doped region is moved toward the cathode side. High current efficiency in α-NPB/Bebq$_2$ mixed host system is the consequences of the better charge balance in the recombination zone. Fig. 5 shows electroluminescence (EL) spectra dependence on the emission zone location in doped and undoped devices. Broad and clean EL peak at 620 nm in undoped mixed m-MTDATA/Bebq$_2$ host organic device C is due to exciplex emissions. While the strong and asymmetric EL emission peak at 620 in devices A-(L) to A-(R) due to emissions of exciplex and Ir(piq)$_3$ red phosphorescent dopant are noticed. In these devices, exciplexes are formed as the energy difference between HOMO of m-MTDATA and LUMO of Bebq$_2$ is about 2.3 eV. Whereas in case of fully doped (device B) and undoped (device D) α-NPB/Bebq$_2$ mixed devices, clean peaks at 510 and 620 nm due to strong emission of Bebq$_2$ and Ir(piq)$_3$ dopant are appeared, respectively. Upon moving the doped region toward the anode side, EL spectra show both emission peaks at 510 and 620 nm due to Bebq$_2$ host and Ir(piq)$_3$ dopant, respectively, but with the reduced intensity of 510 nm emission peak of Bebq$_2$. The electron charge carriers are transported over the LUMO of Bebq$_2$ through the doped region and reach the anode side, resulting in the emission due to Bebq$_2$ host. Although holes are easily injected into the m-MTDATA/Bebq$_2$ organic layer (device A), they are slowly transported due to low hole mobility in m-MTDATA which is further reduced in the mixed host system. While transport behavior in α-NPB/Bebq$_2$ mixed host system is relatively better due to the high hole mobility in α-NPB. Whereas, electrons in both doped devices A and B are transported freely over the LUMO of the Bebq$_2$. These results corroborate that the recombination zone in devices A and B are located between the anode and the center of the emitting layer.

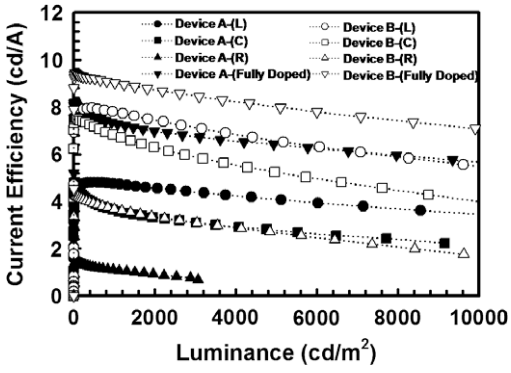

Fig. 4. *L*-Efficiency characteristics of various single layer devices fabricated with different locations of doped regions.

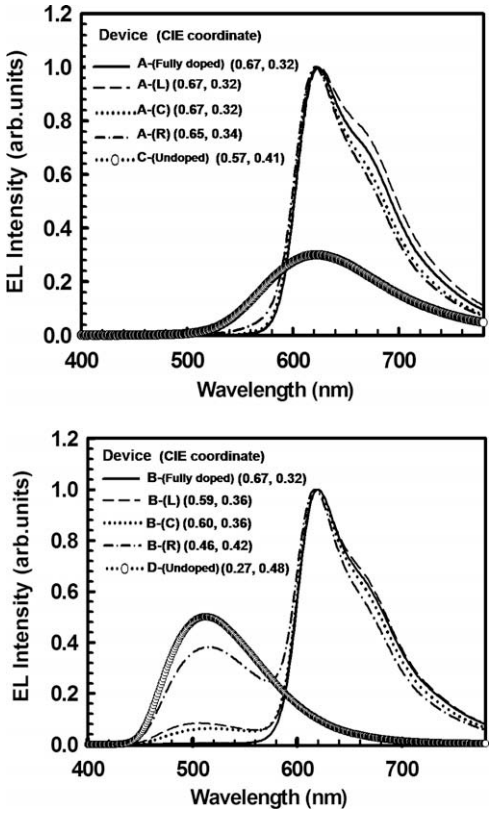

Fig. 5. Electroluminescence (EL) spectra of various single layer devices fabricated with different locations of doped regions at the brightness of 1000 cd/m^2.

4. Conclusions

In conclusion, we have demonstrated high efficiency red PHOLEDs comprising only single emitting layer. The key to the simplification is the direct injection of holes and electrons into the mixed host materials through electrodes. The driving voltage of 5.4 V to reach the 1000 cd/m^2 and maximum current and power efficiency values of 9.44 cd/A and 10.62 lm/W, respectively, in the α-NPB/$Bebq_2$ mixed single layer structure PHOLEDs with the $Ir(piq)_3$ dopant as low as 1 wt.% are obtained. We found that carrier mobility is significantly important parameter to simplify the device architecture. The obtained characteristics of red PHOLEDs pave the way to simplify the device structure with reasonable reduction in the manufacturing cost of passive and active matrix OLEDs.

ABSTRACT

Solution processed multilayer stacked white polymer light-emitting diodes (WPLEDs) with small molecule based interlayer for color and charge balance management were developed. The multilayer stacked WPLEDs were fabricated by a stamp transfer printing method and a mixed interlayer of 4,4′,4″-tris(N-carbazolyl)triphenylamine (TCTA) and 3-(biphenyl-4-yl)-4-phenyl-5-(4-tert-butylphenyl)-1,2,4-triazole (TAZ) was inserted at the interface between a yellow and a blue emitting layer. Electroluminescence spectra and efficiency of the multilayer stacked WPLEDs could be effectively managed by changing the composition of the TCTA:TAZ mixed interlayer.

1. Introduction

White polymer light-emitting diodes (WPLEDs) are promising as devices for applications in displays, light sources and general lighting because of their advantages such as simple processing and simple device structure. However, the device performances of the WPLEDs are inferior to those of small molecule based white organic light-emitting diodes fabricated by a vacuum thermal evaporation [1,2]. Many factors such as purity of the polymer material, corrosion of the indium tin oxide (ITO) by an acidic hole injection layer, electron leakage to the hole transport layer and limitation of multilayer stacking of polymer materials have been proposed as the main reasons for the poor device performances of the polymer based devices [3,4]. In particular, the limitation of the multilayer stacking of polymer materials is one of important factors for the poor device performances in WPLEDs.

There have been several studies to fabricate multilayer stacking structures in the PLEDs. An alcohol soluble or water soluble emitting material was developed to prepare multilayer structures and the WPLEDs with the alcohol soluble emitting material were reported [5]. Crosslinkable polymer emitting materials were also synthesized to fabricate multilayer stacked PLEDs and they were effective to prepare the WPLEDs with multiple emitting layers [6]. However, these approaches require the synthesis of functionalized or crosslinkable materials and common polymer or soluble materials cannot be used.

A method to fabricate multilayer structures with common polymer materials is to apply dry patterning method to form a thin film. A laser induced thermal imaging was effective to deposit polymer films on the substrate and a stamp transfer printing method could be used to make polymer thin film without any damage to the polymer film underneath [7]. Polydimethylsiloxane (PDMS) stamp has been typically used for the stamp transfer printing and polymer films could be transferred from the PDMS to the substrate by heat and pressure during contact [8–10]. Our group already demonstrated that the stamp transfer printing method could be utilized for the preparation of multilayer device structure [11,12].

In this work, color tunable multilayer stacked WPLEDs were fabricated by the stamp transfer printing and the device performances of the multilayer stacked WPLEDs

were investigated according to the interlayer structures. An efficient color control of the WPLEDs by the small molecule interlayer was demonstrated.

2. Experimental

A device structure of indium tin oxide (ITO, 150 nm)/polyethylene-3,4-dioxythiophene:polystyrenesulfonate (PEDOT:PSS, 60 nm)/yellow emitting layer(15 nm)/4,4′,4″-tris(N-carbazolyl)triphenylamine (TCTA):3-(biphenyl-4-yl)-4-phenyl-5-(4-tert-butylphenyl)-1,2,4-triazole (TAZ) (10 nm)/blue emitting layer (60 nm)/LiF/Al was used. The interlayer was a mixed layer of the TCTA and TAZ. The relative compositions of the TCTA:TAZ interlayer were 100:0 (device I), 90:10 (device II) and 75:25 (device III). A polyfluorene based Blue C polymer from Dow chemical was a blue emitting material, while polyphenylenevinylene based supper yellow polymer from Merck was a yellow emitting material. The yellow emitting material was spin-coated from a 0.2 wt% toluene solution, while the blue material was spin-coated from a 0.5 wt% toluene solution. The blue material was spin-coated on a Si substrate and then it was transferred to the substrate coated with the yellow polymer and the TCTA:TAZ interlayer using a PDMS stamp. Detailed procedure for the preparation of the PDMS stamp was reported in previous work [12]. Device structures and energy levels of the materials are shown in Fig. 1. Current density–voltage–luminance and electroluminescence (EL) characteristics of the devices were obtained by Keithley 2400 source measurement unit and a Minolta CS 1000 spectroradiometer.

3. Results and discussion

The interlayer in the white organic light-emitting diodes (WOLEDs) is important for the color management and charge balance control and it was generally used in small molecule based WOLEDs [1]. However, the interlayer could not be used in the WPLEDs as it was difficult to fabricate multilayer stacked structures in the WPLEDs. Film orthogonality could not be guaranteed due to the intermixing of the polymer materials during spin coating of one polymer on the other polymer. The problem can be solved by utilizing the stamp transfer printing method and the WPLEDs with controlled light emission were fabricated using the small molecule interlayer structure.

Fig. 2 shows the current density–voltage–luminance curves of the multilayer stacked WPLEDs with the small molecule interlayer. The current density of the device was dependent on the interlayer structure and the WPLED with the TCTA:TAZ (75:25) interlayer showed the highest current density. The current density of the WPLED with the pure TCTA interlayer was much lower than those of other devices with the mixed interlayer structure. The current density of the white device with multiple emitting layers is generally determined by the energy levels of the emitting layers and the interlayer. Efficient hole and electron transport in the emitting layer lead to high current density, while energy barrier within the emitting layer reduces the current density of the device. In the case of the interlayer, a bipolar type interlayer is usually effective to improve the current density because holes and electrons can be transported through the interlayer. In the device I

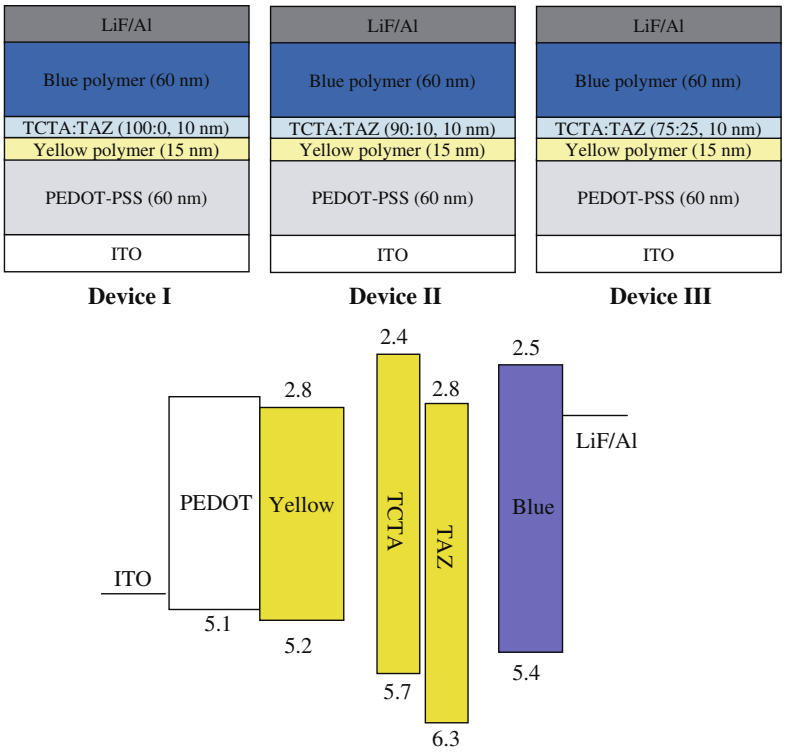

Fig. 1. Device structures and energy levels of the white polymer light-emitting diodes fabricated in this work.

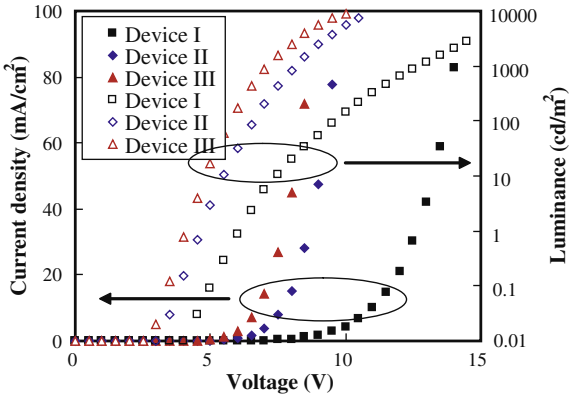

Fig. 2. Current density–voltage–luminance curves of the white polymer light-emitting diodes with the TCTA:TAZ interlayer.

with the TCTA interlayer, the holes can be transported from the yellow emitting layer to the blue emitting layer, while electrons are blocked by the TCTA interlayer due to the lowest unoccupied molecular orbital (LUMO) of 2.4 eV. The poor electron transport through the TCTA interlayer reduces the current density of the WPLED in spite of the efficient hole transport. The current density was greatly improved in the device II and device III because both the hole transport type TCTA and electron transport type TAZ were used in the interlayer. The holes can be transported through the TCTA, while electrons can be transported through the TAZ, resulting effective holes and electrons transport through the interlayer. The rather high current density of the device III compared with the device II is due to better electron transport through the TAZ. High TAZ content in the interlayer facilitates the electron transport though the interlayer. The luminance of the WPLEDs followed the similar trend as the current density.

The quantum efficiency and current efficiency of the WPLEDs are shown in Fig. 3. The quantum efficiency of the WPLED with the mixed interlayer was much higher than that of the WPLED with the TCTA interlayer. The mixed interlayer balances the transport of the holes and electrons through the interlayer, resulting in charge balance in the yellow and blue emitting layer. However, the TCTA blocks electron injection from the blue emitting layer to the yellow emitting layer, leading to poor charge balance in the emitting layer. Compared with the quantum efficiency of the yellow and blue single layer devices [13], the quantum efficiency of the WPLED was rather high due to efficient charge transport control through the interlayer. The quantum efficiency of the WPLED with the TCTA:TAZ interlayer was even higher than that of the stacked WPLEDs reported earlier [11,13]. This indicates that the light emission of the multilayer stacked WPLEDs can be effectively managed by the TCTA:TAZ interlayer. The current efficiency of the WPLEDs was also improved by the TCTA:TAZ interlayer and a current efficiency of 6.1 cd/A was obtained in the device III with the TCTA:TAZ (75:25) interlayer. The efficiency roll-off was also improved in the mixed interlayer devices due to the balance charge injection through the interlayer.

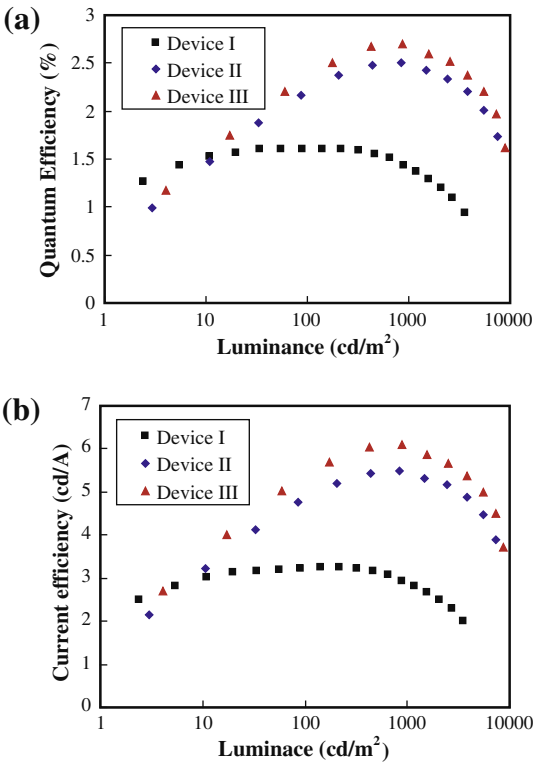

Fig. 3. Quantum efficiency–luminance (a) and current efficiency–luminance (b) curves of the white polymer light-emitting diodes with the TCTA:TAZ interlayer.

The EL spectra of the WPLEDs with the TCTA:TAZ mixed interlayer are presented in Fig. 4 according to the composition of the interlayer. The increase of the TAZ content in the interlayer strengthens the yellow emission due to strong electron transport properties of the TAZ. The emission zone is shifted from the blue emitting layer to the yellow emitting layer due to more electron injection through the interlayer. The use of the TCTA interlayer increases the

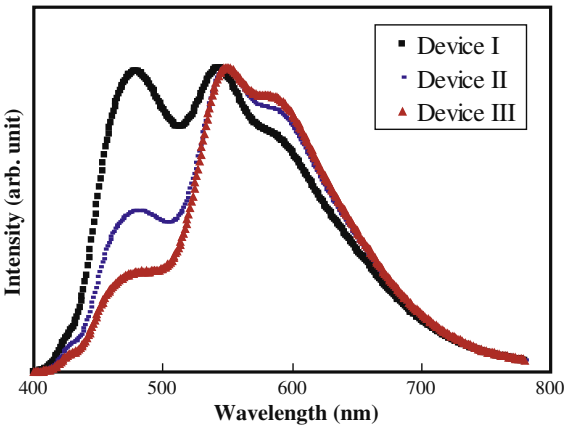

Fig. 4. Electroluminescence spectra of the white polymer light-emitting diodes with the TCTA:TAZ interlayer. The spectra were obtained at 1000 cd/m².

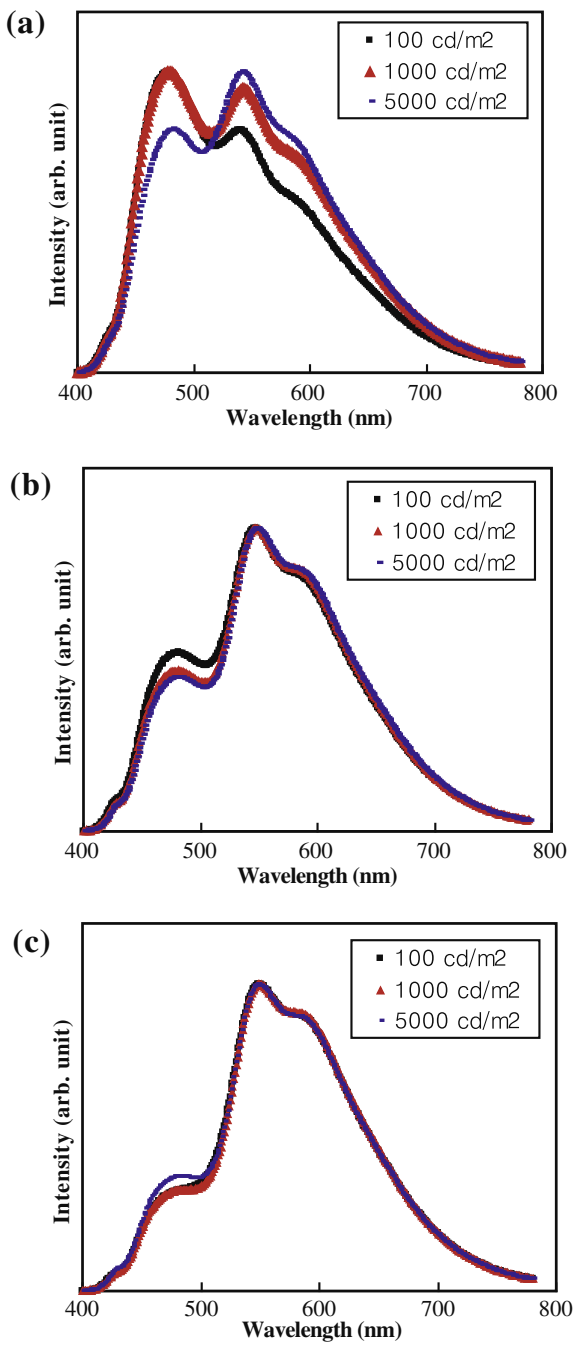

Fig. 5. Electroluminescence spectra of the white polymer light-emitting diodes with the TCTA:TAZ interlayer according to the luminance of the devices. (a) Device I, (b) Device II and (c) Device III.

blue intensity because of more hole injection from the yellow emitting layer to the blue emitting layer. The yellow and blue emission was balanced in the device II with the TCTA:TAZ (9:1) and a color coordinate of (0.38, 0.43) was obtained. The color coordinates of the device I and device III were (0.32, 0.39) and (0.41, 0.46).

The color change of the WPLEDs was measured according to the luminance of the devices (Fig. 5). The color change of the WPLEDs was minimized in the device III with TCTA:TAZ (75:25). The color change depends on the recombination zone shift according to the driving voltage of the devices. The use of the mixed interlayer in the WPLEDs balanced the hole and electron injection at low and high luminances, leading to the stable EL spectra in the device III. Similar result was reported in the small molecule based white devices in our previous work [14]. The color change was significant in the device I with only TCTA interlayer.

4. Conclusion

In summary, the device performances of the multilayer stacked WPLEDs could be effectively managed by the small molecule based TCTA:TAZ interlayer. The emission zone of the WPLEDs could be controlled by managing the composition of the interlayer and the efficiency of the device was also improved by the mixed interlayer. The interlayer approach can be useful in the fabrication of the multilayer stacked WPLEDs in the future because of balanced charge transport and effective color control.

MoO_3
Oxygen vacancy
Ultraviolet photoemission spectroscopy
Inverse photoemission spectroscopy

ABSTRACT

The electronic structure at the α-NPD/MoO_3/Au interfaces has been investigated with ultraviolet photoemission spectroscopy (UPS), X-ray photoemission spectroscopy (XPS) and inverse photoemission spectroscopy (IPES). It was found that the MoO_3 layer contains some number of oxygen vacancies prior to any treatment and gap states are induced by the partial filling of the unoccupied 4d orbitals of molybdenum atoms neighboring oxygen vacancies. The α-NPD thickness dependence of XPS spectra for the α-NPD/MoO_3 system clearly showed that molybdenum atoms at the surface of the MoO_3 film were reduced by α-NPD deposition through the charge-transfer interaction between the adsorbed α-NPD and the molybdenum atoms. This reduction at the α-NPD/MoO_3 interface formed a large interface dipole layer up to −1.79 eV. The deduced energy-level diagram for the α-NPD/MoO_3/Au interfaces describes the energy-level matching that explains well the significant reduction in the hole-injection barrier due to the MoO_3 buffer layer.

1. Introduction

MoO_X was first introduced as a buffer layer in an organic electroluminescent device (OLED) by Tokito et al. in 1996 [1]. By placing the MoO_X layer between the hole-transporting layer (HTL) and anode, the operational voltage of the device was reduced and its efficiency was enhanced. These improvements were attributed to the lowering of the hole-injection barrier at the HTL/MoO_X interface. Since the first report by Tokito et al., similar improvements in device efficiency have been reported for OLEDs with both small molecule and conducting polymer layers [2–9]. Moreover, the MoO_3 buffer layer also offers advantages over the lifetime of the device, such as less contamination of anode surface which significantly improves stability of anode interface. The improvement of device performance has been attributed to the enhancement of the hole-injection and recombination efficiencies at the HTL/MoO_X interface. Recently, Wang et al. reported the electronic structure at the *N*,*N*′-di(naphthalene-1-yl)-*N*,*N*′-diphenyl-benzidine (α-NPD)/MoO_3/indium tin oxide (ITO) interface, as observed by ultraviolet photoemission spectroscopy (UPS) [10]. They concluded that the reduction in the hole-injection barrier is due to the formation of an interfacial dipole layer at the MoO_3/ITO interface, which shifts the vacuum level upward. Consequently, the highest occupied molecular orbital (HOMO) of the α-NPD layer becomes relatively close to the Fermi level (E_F) of ITO. However, it has been observed that device efficiency improves over a wide range of MoO_3 thickness [9]. Even for devices with a thick MoO_3 buffer layer up to 20 nm, the device efficiency and lifetime are significantly improved. To interpret these results, it is necessary to better understand the hole-transport mechanism through the MoO_3 layer. In previous reports, information is lacking on the hole-transporting levels of

doi:10.1016/j.orgel.2009.10.013

the MoO_3 layer. The topmost valence band of the MoO_3 layer remains far below E_F of the anode and HOMO of the α-NPD layer since MoO_3 is an insulator with a wide band gap of about 3.1 eV; such a wide band gap would be expected to result in a large hole-injection barrier at the MoO_3/ITO interface.

In this study, we used UPS, X-ray photoemission spectroscopy (XPS) and inverse photoemission spectroscopy (IPES) to systematically investigate the details of the electronic structure of the α-NPD/MoO_X/Au interfaces. It was found that gap states, which are generated by partial filling of unoccupied 4d orbitals of molybdenum atoms neighboring oxygen vacancies, are formed within the energy gap of the MoO_3 layer. The gap states align with the topmost hole-transporting states of the α-NPD layer and play an important role in energy-level matching at the α-NPD/MoO_3/Au interfaces.

2. Experimental

α-NPD and MoO_3 samples were purchased from Aldrich Chemical Co. and Mitsuwa Chemicals Co. Ltd., respectively. The purity of the α-NPD and MoO_3 samples were 99% and 99.9999%, respectively. Silicon substrates with an atomically flat surface were used for the measurements of thickness dependence. The MoO_3 film was evaporated onto a clean Au-coated Si substrate. Then, α-NPD film was evaporated onto the MoO_3 film in a stepwise fashion. The evaporation rates for MoO_3 and α-NPD were about 0.3 nm/min and 0.1 nm/min, respectively. The rates were constant over the course of the evaporation. Annealing of MoO_3 film was performed at 300 °C for 10 min under an ultrahigh vacuum (UHV). The evaporation of the materials was performed under UHV (base pressure $<1 \times 10^{-7}$ Pa). The specimens were transported to the analysis chamber without being exposed to air. The UPS and XPS measurements were performed in an analysis chamber (base pressure $<5 \times 10^{-8}$ Pa), using an electron spectrometer (Omicron spectrometer, EA125). The He I resonance line at 21.22 eV was used as the excitation source for UPS measurements. IPES measurements were performed in the analysis chamber (base pressure $<1 \times 10^{-7}$ Pa), using a home-made electron-gun and a band-pass-type photon-detector with a combination of a SrF_2 window and KCl-coated channeltron [11].

3. Results and discussion

Fig. 1 displays the XPS spectra of MoO_3 films for Mo 3d core levels. The thickness dependence of the spectra for as-grown MoO_3 films is shown in Fig. 1a. The numbers on the right axis denote the MoO_3 film thickness t. The spectrum of the MoO_3 film with thickness of 20 nm shows a single Mo $3d_{3/2}$ and $3d_{5/2}$ doublet, which indicates the presence of only one type of molybdenum(VI) oxo-species. The binding energies of the Mo $3d_{3/2}$ and $3d_{5/2}$ doublet are 235.6 eV and 232.5 eV, respectively, which are lower than those of the MoO_3 crystal [12]. The observed values of the binding energy are close to the reported values for the MoO_3/Al_2O_3 system [13]. The discrepancy in the binding energy between the MoO_3 film and crystal reflects the presence of two-dimensional or monomeric molybdenum(VI) oxo-species in the film. From a fitting analysis with a Gaussian/Lorentzian mixing function, it was found that a single doublet could not resolve the observed XPS spectra of the films with thickness less than 15 nm. On the other hand, the fitting results are of sufficient quality when a second doublet is introduced. The binding energies of the two individual doublets are almost constant for all the spectra of the MoO_3 films, regardless of film thickness. The doublet at the lower binding energy (234.4 eV and 231.3 eV for Mo $3d_{3/2}$ and $3d_{5/2}$, respectively) corresponds to molybdenum(V) oxo-species [14], which indicates that reduced molybdenum is present in the evaporated MoO_3 film. The area of the doublet at lower binding energy decreases with increasing MoO_3 thickness. This reflects the decrease in reduced molybdenum with increasing the MoO_3 thickness. The reduced molybdenum could not be detected in film with thickness of 20 nm. In order to confirm the assignment of the doublet at the lower binding energy, XPS spectra of annealed MoO_3 films were acquired for comparison. The top spectrum in Fig. 1a was obtained for the MoO_3 film (t = 20 nm) annealed at 300 °C for 10 min. It is known that annealing induces the reduction of the molybdenum of MoO_3 by the introduction of the oxygen vacancies [12]. In fact, the spectra of the molybdenum(V) species were significantly enhanced after annealing. The fitting analysis shows that the binding energy of the doublet at the lower binding energy agrees with that of the as-grown films. From the XPS results, it can be concluded that oxygen vacancies are present in the evaporated MoO_3 film. Fig. 1b shows the α-NPD thickness dependence of the XPS spectra. α-NPD was deposited onto the annealed MoO_3 film in a stepwise fashion. By increasing the α-NPD thickness, the contribution to the spectra from the molybdenum(V) species increases, indicating that the surface molybdenum atoms are reduced by the adsorption of α-NPD. As discussed later, this electron donation from the adsorbed α-NPD to the MoO_3 surface induces a large dipole layer at the α-NPD/MoO_3 interface.

The UPS-IPES spectra of the as-grown and annealed MoO_3 films are shown in Fig. 2a. The density of states (DOS) calculated by the "density functional theory (DFT) + U" method is also shown for comparison [15]. The UPS-IPES spectra of the as-grown and annealed films are well explained by the calculated DOS, showing that the films mostly consist of stoichiometric MoO_3. The occupied band labeled "A" just below the energy gap is mainly composed of oxygen 2sp orbitals, and the unoccupied band labeled "B" just above the energy gap is mainly composed of molybdenum 4d orbitals. The energy gap is defined as the energy difference between the top of the O 2sp valence band and the bottom of the Mo 4d conduction band, which are indicated by vertical lines in the figure. The deduced energy gap of the as-grown film is about 3.2 eV. It was found that the energy gap decreased slightly to 3.1 eV upon annealing. In the spectra of both the as-grown and annealed films, there are small peaks just below E_F, which are denoted by asterisks. The calculated DOS does not explain these peaks. Fig. 2b shows the MoO_3 thickness dependence of the UPS spectra for the as-grown MoO_3 film in the vicinity of E_F. The peak around 1 eV decreases with increasing film thickness and is

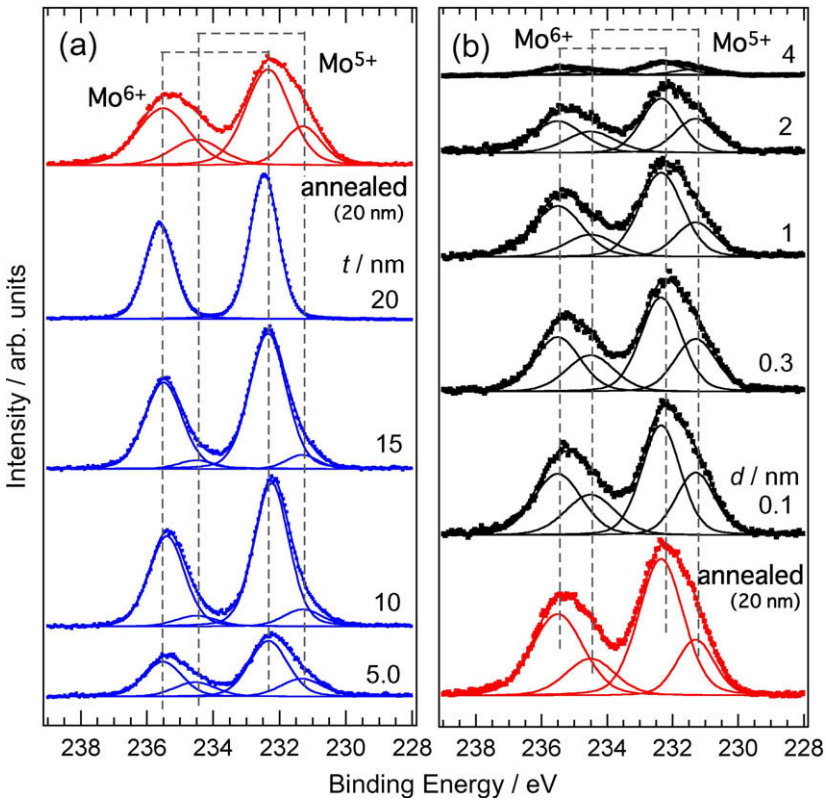

Fig. 1. XPS spectra of MoO_3 films for Mo 3d core levels. Bottom axes represent binding energy with respect to E_F of the substrate. (a) MoO_3 thickness (t) dependence of the XPS spectra for MoO_3 film deposited on Au substrate in a stepwise fashion. (b) α-NPD thickness (d) dependence of the XPS spectra for α-NPD film deposited on annealed MoO_3 film (t = 20 nm) in a stepwise fashion. Solid lines represent Gaussian/Lorentzian mixing functions for fitting analysis and resultant curves of the fitting on the experimental data. Full width at half maximum for fitting functions is 1.2 eV. Binding energies for fitting functions for the two doublets are constant.

almost completely obscured in the spectrum of the film with thickness of 2.0 nm. On the other hand, a new shoulder structure appears at around the 1.9 eV in the spectra of films with thickness of 1.5 nm and 2.0 nm, as indicated by vertical lines. In order to investigate the nature of the peak observed at 1 eV, we re-examined the effect of annealing on the spectrum. The top spectrum in Fig. 2b was obtained for the annealed MoO_3 film (t = 20 nm). A prominent peak appears at around 1 eV. This peak appears to be associated with the oxygen vacancies introduced by annealing. A similar peak was observed in the UPS spectra of the intermediate molybdenum oxide crystals, Mo_4O_{11} and $Mo_{18}O_{52}$ [12]. From DFT cluster studies, this peak was found to correspond to the gap state caused by partial filling of unoccupied 4d orbitals of molybdenum atoms neighboring oxygen vacancies [12]. When oxygen is removed to yield a neutral final product, it leaves a negative charge behind, which is distributed over the atoms close to the vacancy and compensates for some of the positive charge of the molybdenum atoms. Thus, the oxygen vacancy increases the occupancy of local molybdenum 4d orbitals. In fact, as can be seen in Fig. 2a, the unoccupied Mo 4d orbitals contribute less to the IPES spectra after annealing. As discussed in regards to Fig. 1a, the XPS spectra indicate the presence of the oxygen vacancies in the MoO_3 films up to the thickness of about 15 nm. On the other hand, the UPS results in Fig. 2b show that the gap states disappear in the thinner film with thickness of 2.0 nm. One possible reason for this inconsistency between the XPS and UPS results is the difference in their probing depth. UPS measurement possesses higher sensitivity to the surface states of the sample than XPS. However, roughly speaking, the probing depths of UPS and XPS are not much different in this experiment. The typical probing depths of XPS and UPS in this experiment are 2 nm and 1 nm, respectively, and thus both measurements are sufficiently surface sensitive. It has been reported that MoO_3 crystals with oxygen vacancies introduced by mild ion bombardment have a gap state at the 2.1 eV [12]. It should be noted that the binding energy of the shoulder structures in the UPS spectra of as-grown films with thickness of 1.5 nm and 2.0 nm is very close to the gap states of the above mentioned MoO_3 crystal containing oxygen vacancies. Therefore, the shoulder structures can possibly be assigned to the gap states that result from the oxygen vacancies that differ from those in the thinner films. The studies of the intermediate molybdenum oxide crystals showed that the nature of the gap states strongly depends on the chemical state of the oxygen vacancy [12]. The gap states at around 1.9 eV are present even in MoO_3 films with thickness up to 20 nm, although they are very small.

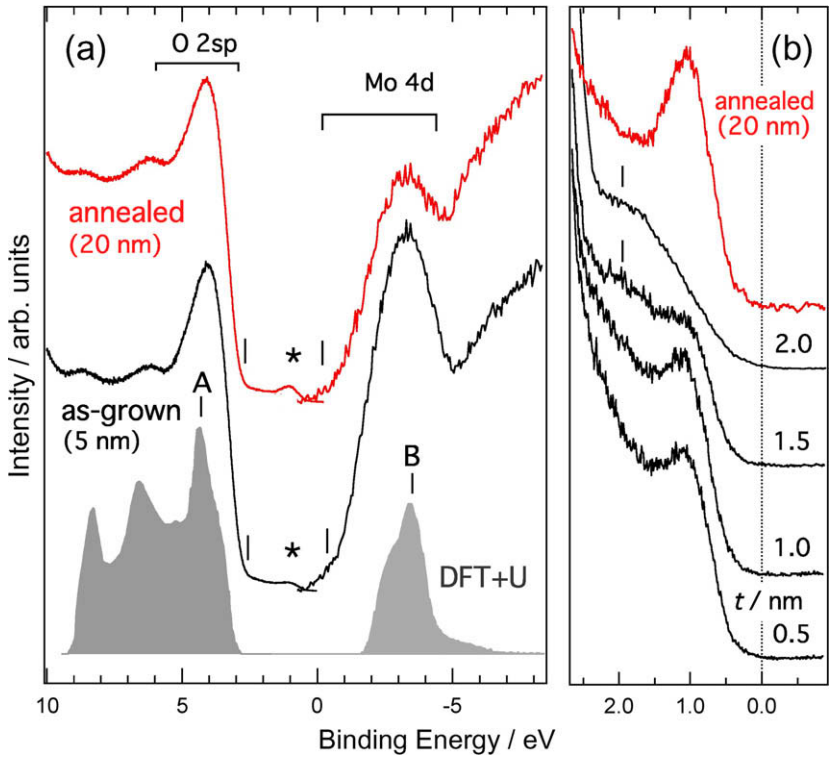

Fig. 2. (a) Combined UPS-IPES spectra for as-grown MoO_3 film (t = 5 nm) and annealed MoO_3 film (t = 20 nm). Bottom axis: binding energy with respect to E_F. Calculated DOS (filled spectra at bottom) calculated by DFT + U method is displayed for comparison. DOS data are cited from Ref. [15]. Energies for occupied and unoccupied parts of DOS were individually shifted to reproduce the observed spectra. (b) MoO_3 thickness (t) dependence of UPS spectra of as-grown MoO_3 film near E_F. Top spectrum shows UPS spectrum of annealed MoO_3 film. The top of the O 2sp valence band and the bottom of the Mo 4d conduction band are indicated by vertical lines. Asterisks denote the gap states which are caused by oxygen vacancies.

Fig. 3 shows the α-NPD thickness dependence of the UPS spectra. The results for the α-NPD films deposited on the as-grown (t = 20 nm) and annealed MoO_3 films (t = 20 nm) are shown in Fig. 3a and b, respectively. The numbers on the right axes denote the α-NPD thickness d. As discussed above, the gap states exits within the energy gap of the MoO_3 films even in the case of the as-grown film. The gap states can be seen at around 1.9 eV in the spectrum of the as-grown MoO_3 film in Fig. 3a. Both in the cases of the as-grown film (a) and the annealed MoO_3 films (b), the spectral features of α-NPD appear in the spectra of films with thickness greater than 4.0 nm. The spectra of films with thickness of 4.0 nm and 10 nm are in reasonably good agreement with the reported α-NPD spectrum [16]. On the other hand, differing spectra were obtained for films with thickness less than 1 nm. For example, the spectrum of the film for which d = 1.0 nm on the as-grown MoO_3 has a single broad peak at around 0.9 eV, while the spectra of the films for which d = 4.0 and 10 nm show two peaks around the 1.2 eV. These results indicate that there is a characteristic electronic structure right at the α-NPD/MoO_3 interface through the interaction between adsorbed α-NPD and the MoO_3 surface. Neither DFT calculations for anion nor cation of α-NPD reproduce the spectra. Although we have lacked detailed information regarding the chemical species produced at the interface until now, based on the XPS results shown in Fig. 1b, it was found that the molybdenum atoms at the MoO_3 surface are reduced by the deposition of α-NPD. Therefore, the cationic species of α-NPD must be generated by a charge-transfer interaction between the adsorbed α-NPD and molybdenum atoms at the MoO_3 surface. The vertical lines in the figures indicate the onset positions of the spectral peaks, which correspond to the topmost hole-transporting states of the films. It should be noted that the onset positions of the α-NPD films are very close to those corresponding to the gap states of MoO_3 films.

Fig. 4 summarizes the α-NPD thickness (d) dependence of the vacuum level (VL), HOMO and C 1s core level energies for α-NPD films on the as-grown and annealed MoO_3 films. As d increases, the VL sharply decreases at the α-NPD/MoO_3 interface, which represents the formation of an interfacial dipole layer. Here, the magnitude of interfacial dipole layer is defined as the energy difference between the VL of the MoO_3 film (d = 0 nm) and that of the α-NPD film with thickness of 4 nm. The magnitudes of interfacial dipole layers of the as-grown and annealed MoO_3 films are denoted as Δ and Δ', respectively. The deduced values of Δ and Δ' are −1.79 eV and −1.54 eV, respectively. Assuming that there is a weak interaction between the adsorbed organic molecule and the substrate surface such as van der Waals interactions, the typical magnitude of the interfacial dipole layer has been found to be less than −1 eV [17]. The large negative values of Δ and Δ' at the α-NPD/MoO_3 interface indicates that a charge-transfer interaction between the adsorbed α-NPD

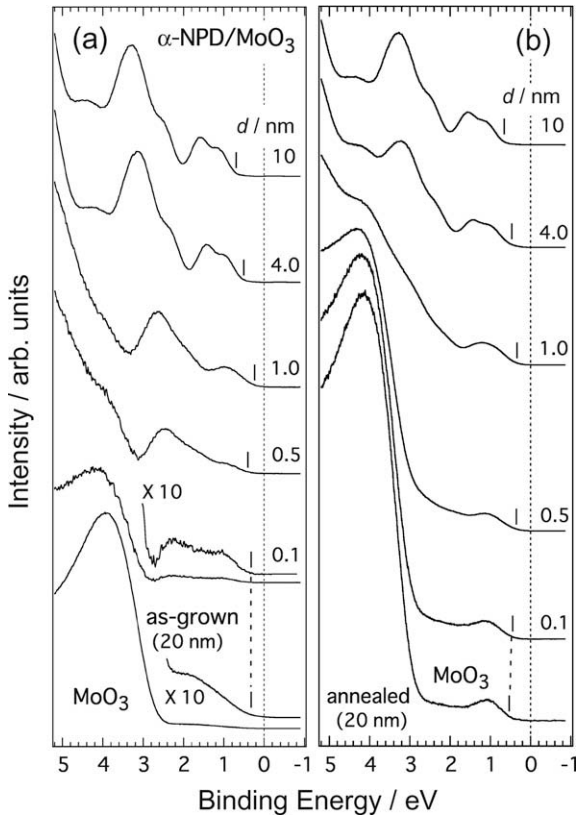

Fig. 3. α-NPD thickness (d) dependence of UPS spectra for α-NPD film deposited on as-grown MoO_3 film (t = 20 nm) (a) and annealed MoO_3 film (t = 20 nm) (b). Vertical lines denote onset position of the spectra.

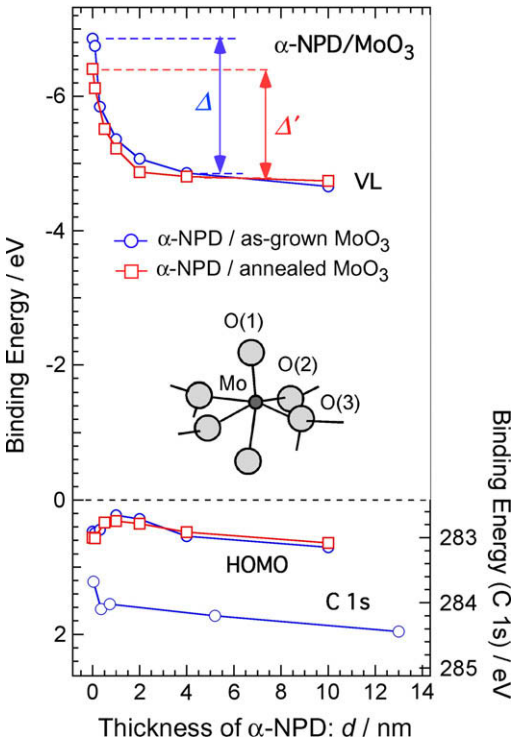

Fig. 4. α-NPD thickness (d) dependence of VL, HOMO and C 1s core level energies for α-NPD film deposited on as-grown MoO_3 film (open circle) and annealed MoO_3 film (box). Bottom axis: α-NPD thickness d. Left axis: binding energies of VL and HOMO. Right axis: binding energy of C 1s core level. Inset: octahedral MoO_6 cluster which is a building unit for MoO_3 crystal.

and MoO_3 film surface forms a cationic α-NPD layer at the interface. This is consistent with the α-NPD thickness dependence of the XPS spectra shown in Fig. 1b, which shows the reduction of the molybdenum atoms at the MoO_3 surface as a result of α-NPD deposition. The difference between Δ and Δ' is primarily due to the difference of the VL between the as-grown and annealed MoO_3 films (d = 0 nm). The inset in Fig. 4 depicts an octahedral MoO_6 cluster, which is the building unit of the MoO_3 crystal. The different oxygen sites are labeled as O(1), O(2) and O(3), respectively. If the O(1) site is removed by annealing, an electric dipole would form pointing outward. This scenario explains well the observed decrease in the VL of the MoO_3 film due to annealing. However, the vacancy formation energy for the removal of an oxygen is about 7 eV for each of the oxygen sites [12]. This means that it is quite difficult to remove oxygen from the fully stoichiometric MoO_3 surface by annealing at 300 °C. These oxygen vacancies can be produced only on a reduced MoO_3 surface already containing oxygen vacancies. As discussed with regard to Fig. 2, some vacancies are already present in the evaporated MoO_3 film, and thus it is possible to produce additional oxygen vacancies by annealing. However, it is difficult to specify the site of the oxygen vacancy. The difference in VL between the as-grown and annealed film indicates only that annealing induces the formation of the interfacial dipole by the introduction of oxygen vacancies, where the outside of the MoO_3 film is positively charged. In films with thickness greater than 4 nm, the energies of VL, HOMO and C 1s core level monotonically decrease as thickness increases.

The deduced schematic energy diagrams for α-NPD/MoO_3/Au interfaces are shown in Fig. 5. Fig. 5a depicts the energy diagram of α-NPD/Au as previously reported [16]. The hole-injection barrier of the α-NPD/Au interface was reported to be 1.4 eV. The large Δ formed at the interface results in a very large hole-injection barrier. The energy diagrams of the as-grown and annealed MoO_3 buffer layers are depicted in Fig. 5b and c, respectively. The following points should be emphasized here: (1) the positive interfacial dipole Δ at the MoO_3/Au interface is canceled out by the negative dipole Δ' at the α-NPD/MoO_3 interface, (2) the gap states nearly align with the topmost hole-transporting states of the α-NPD layer at the α-NPD/MoO_3 interface. As a result of (1) the HOMO position in the α-NPD/MoO_3/Au system is much closer to E_F of the substrate compared with that of the α-NPD/Au system, in which α-NPD is in direct contact with the substrate surface. The gap states provide hole-transporting levels from the substrate to the α-NPD layer through the MoO_3 layer. There is a small injection barrier of 0.28 eV (0.32 eV) at the as-grown (annealed) MoO_3/Au interface, and there is a negligibly small barrier at the α-NPD/MoO_3 interface as a result of (2). These results reasonably explain the improved hole-injection efficiency due to the MoO_3 buffer layer as well

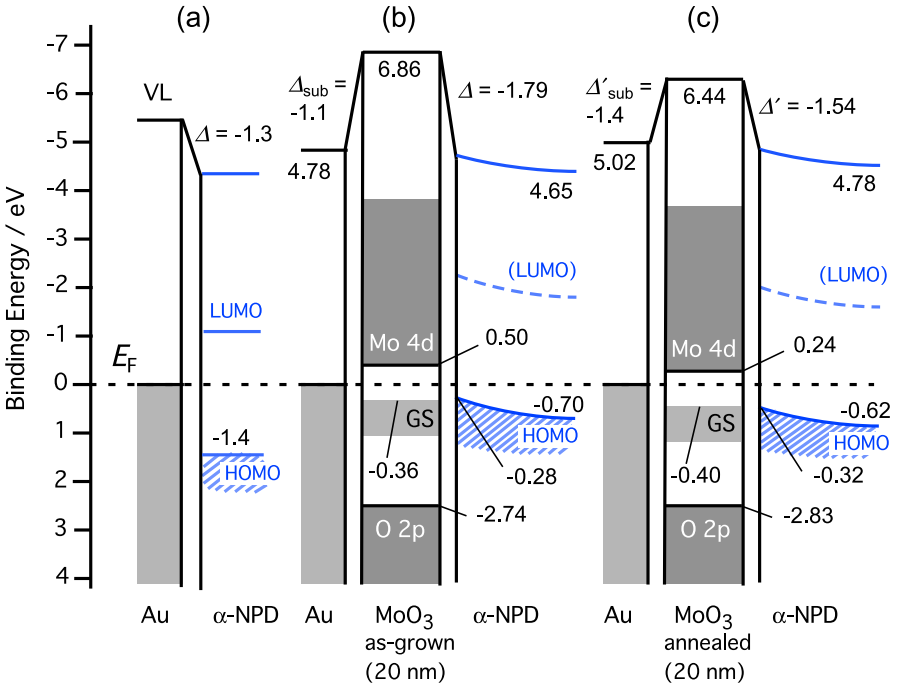

Fig. 5. Schematic energy diagrams for α-NPD/Au (a), α-NPD/as-grown MoO_3/Au (b) and α-NPD/annealed MoO_3/Au (c) interfaces. Left axis: binding energy with respect to E_F. Δ_{sub}, Δ, Δ'_{sub} and Δ' represent values of interfacial dipole layers estimated by UPS experiments. Numbers written in the figures are binding energy based on UPS and IPES results. Data for α-NPD/Au (a) were cited from Ref. [15]. "GS" in (a) and (b) refers to gap states.

as the hole-transport mechanism through the thick MoO_3 layer. Although the difference between the as-grown and annealed MoO_3 films is small, the density of gap states in the annealed film is larger than that in the as-grown film. Thus, the gap states are located at higher binding energy and the hole-injection barrier is slightly larger.

Finally, it should be noted that the interfacial dipoles (Δ_{sub}, Δ, Δ'_{sub} and Δ') observed in this work are much larger that those reported by Wang et al. [10]. For example, their reported value of Δ_{sub} for the MoO_3/ITO interface was −0.5 eV, which is much smaller than the value of Δ_{sub} obtained for the MoO_3/Au interface (Δ_{sub} = −1.1 eV) in this work. It can be reasonably assumed that this difference is due to differences in substrate material. On the other hand, their reported value of Δ for the α-NPD/MoO_3 interface (Δ = −0.05 eV) is also much smaller than that observed for the same interface in this work (Δ = −1.79 eV). However, the hole-injection barriers at the α-NPD/MoO_3 interface are nearly identical in both works. The hole-injection barrier observed by Wang et al. was 0.25 eV, while in this work it was found to be 0.28 eV. This strongly suggests the alignment of E_F between the substrate and α-NPD through the MoO_3 buffer layer. The gap states located just below E_F of the MoO_3 film are possibly impurity states that donate electrons to the conduction band since the molybdenum atoms neighboring oxygen vacancies are accepting some amount of electrons. Thus, such an "*n*-doped MoO_3 film" has some electron carriers that are thermally activated and can achieve the alignment of E_F with the substrate. Charge-transfer between the α-NPD and MoO_3 surfaces might occur, allowing the α-NPD/MoO_3 interface to reach thermal equilibrium.

4. Conclusion

The electronic structure at the α-NPD/MoO_3/Au interfaces was investigated with UPS, XPS and IPES. It was found that the MoO_3 layer contains some number of oxygen vacancies prior to any treatment and gap states are induced by the partial filling of the unoccupied 4d orbitals of molybdenum atoms neighboring oxygen vacancies. The α-NPD thickness dependence of XPS spectra for the α-NPD/MoO_3 system clearly showed that molybdenum atoms at the surface of the MoO_3 film were reduced by α-NPD deposition through the charge-transfer interaction between the adsorbed α-NPD and the molybdenum atoms. This reduction at the α-NPD/MoO_3 interface formed a large interface dipole layer up to −1.79 eV. The deduced energy-level diagram for the α-NPD/MoO_3/Au interfaces described the energy-level matching that explained well the significant reduction in the hole-injection barrier due to the MoO_3 buffer layer. In particular, it was found that the gap states align with the topmost hole-transporting states of the α-NPD layer and there is almost ohmic contact between them. The MoO_3 layer is possibly "*n*-doped" by the electron-rich molybdenum atoms neighboring the oxygen vacancies, and this might be the origin of the energy-level alignment at the α-NPD/MoO_3/Au interfaces.

Heteroepitaxy
Organic thin film transistors
Weak epitaxy growth

ABSTRACT

High performance films of phenyl substituted perylene diimide are obtained by heteroepitaxy growth through Weak Epitaxy Growth technique. As epitaxially grown on the *para*-sexiphenyl (*p*-6P) ordered layers, the *N*,*N*′-di-phenyl perylene tetracarboxylic diimide (PTCDI-Ph) grows to form continuous and highly oriented films with large grain size, which possess low density of grain boundary and smooth surface. This quality films bring about improvement of two orders of magnitude in mobility compare to the traditional films, and present relative good air stability. Ambipolar transport behavior was also observed as tuning the thickness of *p*-6P.

1. Introduction

Organic semiconductors have attracted considerable interest for several decades, owing to their various applications in organic thin film transistors, organic light-emitting diodes, and organic solar cells [1–4]. Some of the applications such as complementary integrated circuits, organic p/n junction devices, both hole-transporting (p-type) and electron transporting (n-type) materials are needed. However, performance of n-type materials is being challenge because most of organic semiconductors usually present hole-transporting property. During the past decades, much progress has been made in exploiting high performance n-type materials, typical material families are C_{60} and its derivatives [5–7], Perylene and naphthalene diimide derivatives [8–13], substituted oligothiophene derivatives [14,15], substituted pentacene derivatives [16], and some metal phthalocyanine compounds [17–19]. Among them, perylene diimide derivatives (PTCDIs) bear most attention for their good performance, high electron affinities and good chemical stability. In addition they are commercial pigments which can be readily synthesized [20]. According to recent works, strategy from materials design has been widely studied and significantly promotes the performance of PTCDIs [21–27]. However, the film growth of PTCDIs has received less attention [12,28,29] and work had scarcely paid close attention on film growth strategy, which affects the device performance to a great extent. Most of the PTCDIs growing on amorphous substrate (SiO_2) present small grain size with random orientation. Even large grain size has obtained at high temperature, concomitant cracks result in poor film continuity. Besides, it is known that the performance of flexible alkyl substituted PTCDIs (0.6–2.1 cm^2/Vs) is quite better than the PTCDIs bearing phenyl or methyl substituent (10^{-5}–10^{-2} cm^2/Vs) [10,22,30]. The reason of this is unclear so far but it might greatly relative to the film quality, since the PTCDIs with flexible alkyl end groups usually are liquid crystals which possess the ability to self-organize into highly ordered structure [31]. Recent work proposed that the film quality also influenced the air stability which is a grave problem of n-type materials [32]. Hence, study on achieving high quality film is

important for the further development of perylene diimides derivatives.

Organic-organic heteroepitaxy is an effective approach to grow highly ordered films with controlled orientation and morphology [33,34]. However, most studies of heteroepitaxy growth are based on the single-crystal substrate. It greatly limited their applications on the devices. Recently, a method named "Weak Epitaxy Growth" made the heteroepitaxy can be realized on the ordinary amorphous substrate e.g. SiO_2, polymer, on which an ordered layer of rod-like molecule was introduced between the substrate and organic semiconductor films, and high substrate temperature was applied [35,36]. The rod-like molecules possess the layer-by-layer growth manner and easily to form large-area crystalline domains, which benefit the overlayer growth. Previous work has also pointed out that inserting an ordered buffer layer (such as pentacene) can increase the molecular wettability of the substrate, and thus improve the crystalline of the overlayer, leading to high performance [7,37]. Here, we explore the heteroepitaxy growth of one of perylene diimides derivatives, *N*,*N*′-diphenyl perylene tetracarboxylic diimide (PTCDI-Ph), on the crystalline layer of rod-like molecules *para*-sexiphenyl (*p*-6P). The results displayed that the PTCDI-Ph was successfully heteroepitaxially grown on the *p*-6P layers, forming highly oriented single-crystal-like films. Organic transistors with the epitaxial films as the active layer exhibit electron mobility up to 0.2 cm^2/Vs in the ambient condition, which is two orders of magnitude higher than common films, simultaneously show relative good air stability.

2. Experimental

2.1. Materials and samples preparation

The *p*-6P was synthesized according to Ref. [38], and *N*,*N*′-di-phenyl perylene tetracarboxylic diimide (PTCDI-Ph) was synthesized according to Ref. [39]. All the materials were purified twice by thermal sublimation prior to experiments. A heavily doped n-type silicon wafer with a 300 nm thermal oxidation SiO_2 layer (dielectric capacitance $C = 10$ nF cm^{-2}) was used as the substrates. The *p*-6P of various thicknesses was deposited on the previously cleaned SiO_2 substrate, and PTCDI-Ph with different thicknesses were then deposited on the *p*-6P thin films. The deposition was performed under a pressure of 10^{-4}–10^{-5} Pa at a rate of about 1 nm/min with a substrate temperature at 180 °C. For the transistor fabrication, Au was deposited on the organic films by thermal evaporation as the source and drain contacts with a shadow mask in vacuum at 10^{-4} Pa. The channel length and width are 200 μm and 6000 μm, respectively.

2.2. Characterization of organic films and transistors

2.2.1. Atomic force microscopy

Film morphology was imaged by a SPI 3800/SPA 300HV (Seiko Instruments Inc., Japan) with tapping mode. A 150 μm scanner and a commercially available SiN4-cantilevel with a spring constant of 2 N/m were used. *X-ray diffraction measurements*: The wide angle XRD pattern were taken from a D8 discovery thin film diffractometer with Cu Kα radiation (=1.54056 Å). The selected voltage and current were 40 kV and 35 mA, respectively.

2.2.2. Transmission electron microscope measurements

Organic films of PTCDI-Ph/*p*-6P were deposited on the SiO_2 substrate, subsequently a carbon thin film which was used as support layer was deposited on the films. The films were separated from SiO_2 surface by floating from 10% HF solution, and then transferred to a copper grid for measurements. The selected area electron diffraction was performed by JEOL JEM-1011 transmission electron microscope operated at 100 kV. In order to provide weaker-intensity beam and high contrast, dark field was used for experiments.

2.2.3. Transistor measurements

Current–voltage tests were performed with the two keithley 236 source-measurement unit under ambient conditions at room temperature.

3. Results and discussion

3.1. Film morphologies and structural properties

Molecular structures of PTCDI-Ph and *p*-6P are given in Fig. 1. Fig. 1a and b show morphologies of 2 nm PTCDI-Ph grown on *p*-6P with thickness of 2 nm. Domains of *p*-6P monolayer were clearly observed (details of the growth of *p*-6P have been published else where [40,41]), and differences of film morphology of PTCDI-Ph grown on *p*-6P domain and on bare SiO_2 are obviously displayed. On the *p*-6P monolayer islands, large size ribbon-like crystals of PTCDI-Ph with several preferred orientations were formed (Fig. 1b), which is much better than that on the bare SiO_2 (Fig. 1g and h). As the thickness of *p*-6P increased to 5 nm, bilayer domains of *p*-6P were formed (Fig. 1d). On the *p*-6P bilayer islands, as Fig. 1e shows, all ribbon-like crystals nearly show one orientation, implying well-defined epitaxy relation exists between the *p*-6P and PTCDI-Ph. All the crystals on the *p*-6P layers show layer-by-layer growth fashion at the early stage, whereas additional readily coalescence between adjacent grains, leading to smooth and continuous films with low density of grain boundaries. As the thickness of PTCDI-Ph increases to 20 nm, morphology is the same as the film at the early stage except appearance of some needle-like crystals originated from the island growth manner (Fig. 1c and f). This is greatly different from the morphology of PTCDI-Ph directly grown on the SiO_2 substrate, which shows small size and randomly oriented (Fig. 1l). The epitaxial films with large size and continuous grains greatly decrease the grains boundaries which is the primary limit to high performance.

The out of plane X-ray diffraction of the films present strong intensity diffraction peaks, revealing highly order (Fig. 2). PTCDI-Ph films grown on SiO_2 and *p*-6P monolayer present a primary peak with a d spacing of 17.17 Å, slightly different from the (1 0 0) peak of bulk phase (with

a lattice spacing of 16.60 Å). On the *p*-6P bilayer, besides the diffraction peak with the d spacing of 17.17 Å, the PTCDI-Ph films mainly present another strong diffraction peak with a d spacing of 16.10 Å. This result implies that different polymorphs exist in the epitaxial films. Here different d spacing imply tilt angle between the molecular long axis and the substrate is variant. Detailed information about this was being investigated. Nevertheless, the (1 0 0) orientation corresponds that PTCDI-Ph molecule upright on the substrate, meaning the π–π stack direction parallel

to the film plane, which is ideal for the in-plane charge transport.

Selected area electron diffraction was performed to investigate the epitaxy relationship between PTCDI-Ph and *p*-6P. On the *p*-6P monolayer, in the selected area with a diameter of 3.5 μm, diffraction pattern consists of one (0 0 1) zone of *p*-6P, demonstrating that each domain of *p*-6P presents single-crystal structure. (Fig. 3a) However, several sets diffraction of PTCDI-Ph appearance indicated that several orientations coexist on the *p*-6P monodomain, agreed well with the AFM results and the corresponding electron micrograph. The reciprocal vectors of PTCDI-Ph shows featureless relation with the *p*-6P, implied incommensurate growth of PTCDI-Ph on the *p*-6P monolayer. On the *p*-6P bilayer domain, besides the diffraction pattern of *p*-6P, only one set of in-plane orientation of PTCDI-Ph presents, indicating the PTCDI-Ph grown on each *p*-6P island shows only one orientation, consistent with the AFM results (Fig. 3b). Clear and strong intensity of the diffraction spots of PTCDI-Ph reveal that the epitaxial films present single-crystal-like structure. In-plane parameters of PTCDI-Ph calculated from diffraction pattern are: $d_{(010)} = 4.98$ Å, $d_{(002)} = 7.96$ Å, $\alpha = 90^{o}$. The lattice parameters are greatly different from the bulk phase, it can ascribe to "thin film phase". What's more, the lattice vectors of two materials are perfectly coincidence. The c* axis of PTCDI-Ph is parallel to the a* axis of *p*-6P, and the b* axis of PTCDI-Ph parallel to the b* axis of *p*-6P. In addition, along the a* direction, there exists a perfect lattice match relationship: $d_{(002)\text{PTCDI-Ph}} = d_{(100)p\text{-6P}}$, along the b* axis of *p*-6P, the lattice mismatch between $d_{(010)p\text{-6P}}$ and $d_{(010)\text{PTCDI-Ph}}$ is about 10%. All the results suggest information of commensurate epitaxy between the PTCDI-Ph and *p*-6P. Fig. 3c gives the model of the commensurate epitaxy, the epitaxy relationship is: $(1\,0\,0)_{\text{PTCDI-Ph}}//(0\,0\,1)_{p\text{-6P}}$, $[0\,0\,1]_{\text{PTCDI-Ph}}//[1\,0\,0]_{p\text{-6P}}$, $[0\,1\,0]_{\text{PTCDI-Ph}}//[0\,1\,0]_{p\text{-6P}}$. Additionally, large discrepancy of PTCDI-Ph on *p*-6P monolayer and bilayer was found in the morphology and structure, which might attribute to the difference of the phase and structure between *p*-6P monolayer and bilayer [42]. Combined the electron diffraction pattern and corresponding morphology, the PTCDI-Ph crystal anisotropic grown along the b axis direc-

tion, owing to the strong π–π interaction. Such growth behavior is desired for the organic thin film transistors.

3.2. Transistor performance based on the epitaxial films

Top-contact bottom gate transistors with the epitaxial films as the active layer were fabricated to investigate the performance of the PTCDI-Ph films, the device configuration was shown in Fig. 4a. For comparison, devices with different thicknesses of *p*-6P and no *p*-6P were fabricated. The field-effect mobility was summarized in Table 1, the thickness of PTCDI-Ph is 20 nm of all the devices. The devices basing the epitaxial films show extraordinary performance improvement compare to the device with traditional film (no *p*-6P). For PTCDI-Ph directly grown on SiO_2/Si substrate, a field-effect electron mobility of about 0.001 cm^2/Vs was obtained, while as the 1 nm *p*-6P inserted, the electron mobility increases to 0.01 cm^2/Vs. As the thickness of *p*-6P increase to 2 nm, the electron mobility is up to 0.1 cm^2/Vs, which can be compared with most fashion n-type materials. Fig. 4b shows the typical transfer curve of devices with and without *p*-6P, besides the enhancement in mobility, the threshold voltage and current on/off ratio are also greatly improved. As the *p*-6P thickness up to 3 nm, the *p*-6P domains impinge with each other, forming a continuous film, which results in the formation of a hole transport channel (the *p*-6P is a p-type materials). Hence, the transistors present ambipolar transport behavior. Fig. 4c and d gives the output characteristics of ambipolar transistors with PTCDI-Ph (20 nm)/*p*-6P (3 nm), its hole mobility and electron mobility extract from the transfer characteristics is 0.09 cm^2/Vs and 0.17 cm^2/Vs, respectively. Its notable that the enhanced hole mobility is nearly 3 times higher than the *p*-6P single component (0.02 cm^2/Vs), which is similar to the phenomenon observed in 2,5-bis (4-biphenylyl) bithiophene (BP2T)/copper-hexadecafluoro phthalocyanine ($F_{16}CuPc$) system [43,44]. It implies that effect like charge transfer may be occurs in the interface of *p*-6P/PTCDI-Ph, which favored the charge transport in the interface. Details of the effect need further study. Continuing to increase thickness of *p*-6P, ambipolar charge transport dominate, but the hole mobility reduced. The thicken of *p*-6P causing the influence from the effect of organic-organic interface on the hole transport decreases, led to a mobility nearly equal to *p*-6P single component (0.02 cm^2/Vs). The electron mobility of ambipolar transistors slightly increases as the *p*-6P thickness increase. The maximum mobility of PTCDI-Ph

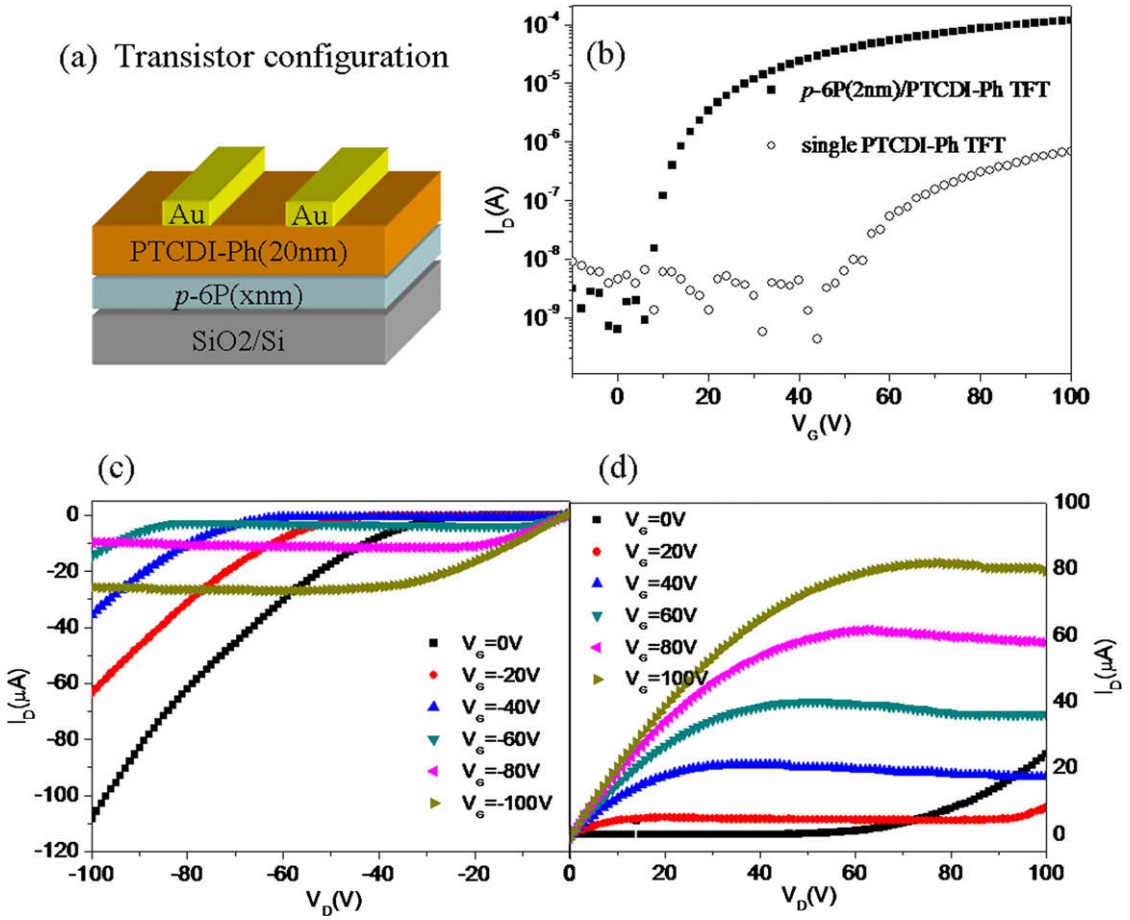

Fig. 4. (a) The transistors configuration, (b) the transfer characteristics of transistors of based on PTCDI-Ph films grown on 2 nm *p*-6P and bare SiO_2, V_{DS} = 100 V, (c), (d) output characteristics of ambipolar transistor basing on PTCDI-Ph (20 nm)/*p*-6P (3 nm) for positive and negative gate biases.

Table 1
The mobility of transistors based on PTCDI-Ph grown on *p*-6P with various thicknesses.

Devices	Hole mobility (cm^2/Vs)	Electron mobility (cm^2/Vs)
PTCDI-Ph	–	0.001–0.002
p-6P (1 nm)/PTCDI-Ph	–	0.01
p-6P (2 nm)/PTCDI-Ph	–	0.1–0.15
p-6P (3 nm)/PTCDI-Ph	0.06–0.09	0.1–0.17
p-6P (5 nm)/PTCDI-Ph	0.02	0.15–0.2

can be up to 0.2 cm^2/Vs, which is the best performance of this material in ambient condition until now.

The great improvement in electron mobility of the epitaxial films is consistent with the morphology results. Comparing to the non epitaxial films, the epitaxial films with lager grain size are highly oriented and continuous, which is benefit to the carrier transport. In addition, the low density of grain boundary of the epitaxial films is responsible for the increased electron mobility. The thickness of *p*-6P increasing means the coverage of *p*-6P on substrate increase, via, the coverage of epitaxial films increase. Owing to the oriented, large size and continuous crystals of epitaxial films, the grain boundary decreased dramatically, led to high electron mobility and low threshold voltage. On the other hand, recent studies reveal that the Si–OH groups on the bare SiO_2 substrate are the efficient traps for electrons but not for holes [45]. These interface traps greatly affect the n-channel field-effect, thus the inserted *p*-6P layer maybe reduced the traps on the SiO_2 surface worked as a buffer layer [46–49]. However, compare to the performance of PTCDI-Ph grown on the substrate modified with OTS which shows a mobility of 0.017 cm^2/Vs in glove box (The OTS treatment was an efficient method to reduce the traps and improve the mobility) [22], the electron mobility of epitaxial films is also one order of magnitude higher. Hence, the improvement mainly attribute to the good film morphology, although the *p*-6P may be play a role in reducing the electron traps originating from the Si–OH groups on the bare SiO_2 substrate.

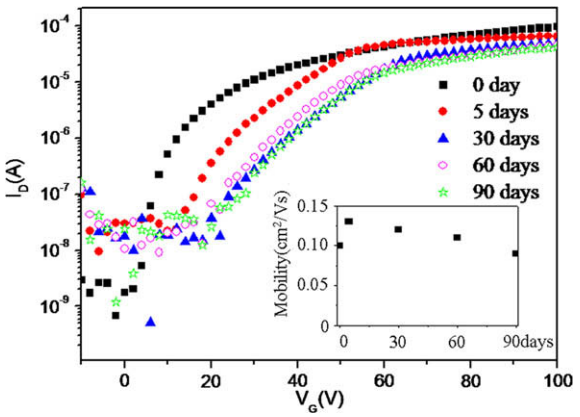

Fig. 5. Air-stability measurements of transistors based on PTCDI-Ph (20 nm)/*p*-6P (2 nm), V_{DS} = 100 V, the inset gives the mobility evolution as the function of time.

Performance evolution of the epitaxial film TFTs as the function of time exposing in ambient condition was carried out by tracking the transfer characteristics. In the first 5 days, the mobility slight increased from 0.1 cm^2/Vs to 0.13 cm^2/Vs, and then gradually decreased (Fig. 5). After exposing in ambient for 90 days, the mobility still retain as high as 0.09 cm^2/Vs, which is rarely for the n-type materials. The good stability of the mobility might attribute to the few grain boundaries and smooth interface in the epitaxial films, which effectively decrease the physical absorption of the environment gases. On the other hand, the inserted *p*-6P layer which might reduce the electron traps on the SiO_2 substrate is also responsible for the good stability. The threshold voltage shifts from 5 V to 18 V after exposure for 5 days, but remains at 20–30 V as exposing more time, and the current on/off ratio slightly decreases from 10^5 to 10^4.

4. Conclusions

In summary, we have obtained high mobility films of PTCDIs by heteroepitaxy growth using the Weak Epitaxy Growth technique. Through epitaxial grown on the *p*-6P ordered layer, the PTCDI-Ph films present highly crystalline, oriented and continuous morphology, and commensurate epitaxy relationship was found between PTCDI-Ph and *p*-6P. The high quality films, which possess low density of grain boundary and smooth surface, bring about improvement of two orders of magnitude in the mobility, simultaneously exhibit relative good stability in ambient condition. Hence, the organic–organic heteroepitaxy provide a new path to achieve high performance films of perylene diimides derivatives.

ABSTRACT

Microcavity top-emitting white organic light-emitting devices (TEWOLEDs) with M/(Alq_3/Ag)$_2$ anode (M = Ag, Au or Al, Alq_3 is tris (8-hydroxyquinoline) aluminum) were investigated. All devices show white emission and the optical properties of the anode play an important effect on the efficiency and contrast of the devices. The maximum efficiencies of the top-emitting devices are comparable to the corresponding bottom one and the contrasts of top-emitting devices are much higher than that of the bottom one. The results indicated that such TEWOLEDs are compatible with complementary metal oxide semiconductor or organic thin film transistor techniques which using Au or Al as electrode.

1. Introduction

Top-emitting organic light-emitting devices have attracted intense attention because of its enormous potential in flat-panel displays, especially for microdisplays on opaque silicon substrate. Top-emitting white organic light-emitting device (TEWOLED) combined with color filter and driving circuit [such as organic thin film transistor (OTFT) or complementary metal oxide semiconductor (CMOS)] is the most effective method to obtain high-resolution displays. In addition, TEWOLEDs will be superior to bottom one because they can fabricate on opaque and flexible substrates such as metal foils, which is cheaper than ITO. However, it remains a challenge to generate white light in TEOLEDs because of the strong microcavity effects in the devices and there are a few reports on TEWOLEDs [1–6]. In our previous work [7], the TEWOLED with one-dimensional metallic-dielectric photonic crystal (MDPC) comprised of Ag/Alq_3 (Alq_3 = tris (8-hydroxyquinoline) aluminum) as anode are investigated. A two-peak or three-peak TEWOLED could be achieved by adjusting the thickness of the Alq_3 layers in the MDPC.

Ag is used as the anode in TEOLEDs due to its lower absorption loss in the visible range and highest conductivity among electrode materials, while Au or Al was used as electrode in OTFT [8–10] or CMOS [11–13], usually. Thus, TEWOLED with appropriate electrode will simplify the fabrication process of the integrated device. In this letter, we report the TEWOLEDs based on microcavity effect with M/(Alq_3/Ag)$_2$ anode (M = Ag, Al, or Au). The effect of the different M on the performance of the device is discussed. The result indicated such TEWOLED is compatible with CMOS or OTFT techniques.

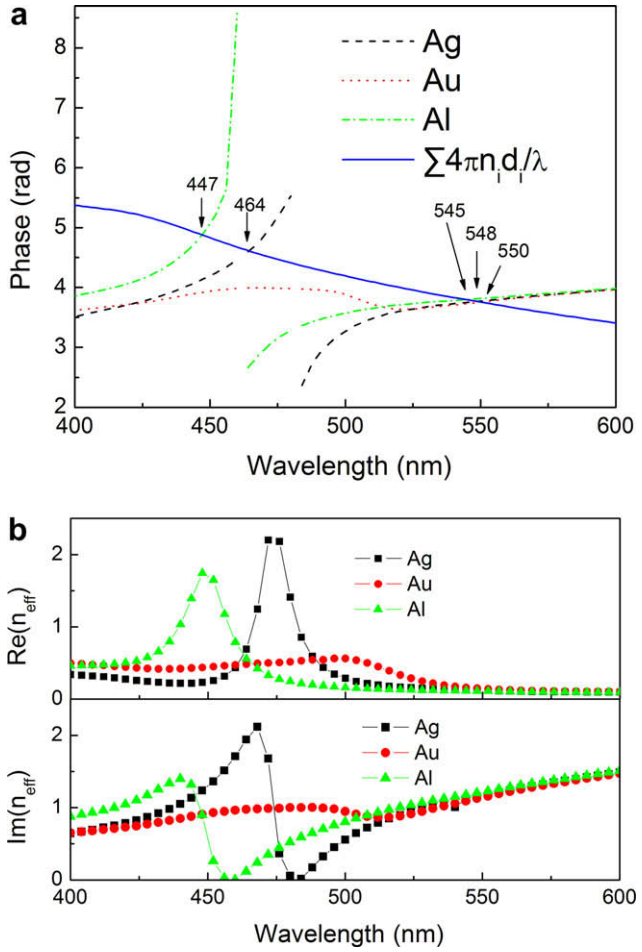

Fig.1. (a) The calculated round-trip phase changes for 95 nm organic layers between two electrodes and the phase changes on two electrodes for normal incidence; and (b) the calculated effective refractive index of three anodes.

1,1-biphenyl-4,4'-diamine (NPB, 10 nm)/4,4′-bis(2,2′-diphenylvinyl)-1,1′-biphenyl (DPVBi, 15 nm)/4,4-*N*,*N*-dicarbazole-biphenyl (CBP, 3 nm)/CBP:bis(2-(2-fluorphenyl)-1,3-benzothiozolato-N,C2′) iridium(acetylacetonate) [(F–BT)$_2$Ir(acac)] (7 nm)/4,7-diphenyl-1,10-phenanthroline (Bphen,30 nm)/LiF (1 nm)/Al (1 nm)/Ag (20 nm)/MoO_x (35 nm) were fabricated. 1.5 nm MoO_x, m-MTDATA, NPB, DPVBi, CBP:(F-BT)$_2$Ir(acac), Bphen, LiF/Al/Ag and 35 nm MoO_x were used as buffer layer, hole injection layer, hole transporting layer, blue emitting layer, orange emitting layer, electron transporting layer, cathode and light out-coupling layer, respectively. M = Ag, Au, or Al for devices A, B, or C, respectively. For comparison, the bottom-emitting device (ITO glass substrate) with the same organic layers (device D) was fabricated. All films were deposited at pressure below 4×10^{-6} Torr. Detailed processes of fabrication and measurement for OLEDs have been described in previous paper [5].

3. Results and discussion

The resonant wavelength (RW) conditions of the microcavity for normal incidence is determined by the Fabry–Perot peak condition [14]. Fig. 1a shows the calculated round-trip phase changes for 95 nm organic layers sandwiched between two reflection electrodes (i.e., $\varphi_1(0,\lambda) = \sum_i \frac{4\pi d_i n_i(\lambda)}{\lambda}$, where λ is the emission wavelength, $n_i(\lambda)$ and d_i are the refractive index and thickness of organic layers), and the phase changes at two reflective electrodes (i.e., $\varphi_2(0,\lambda) = \varphi_{\text{cathode}}(0,\lambda) + \varphi_{\text{anode}}(0,\lambda)$, $\varphi_{\text{cathode}}(0,\lambda)$ and $\varphi_{\text{anode}}(0,\lambda)$ are the angle- and the wavelength-dependent phase changes on reflection from top cathode and bottom anode, respectively; incidence medium is Bphen and m-MTDATA for cathode and anode, respectively). The points of the intersection of $\varphi_1(0,\lambda)$ and $\varphi_2(0,\lambda)$ are the RWs of the devices. As can be seen, the RWs were different for M = Ag (464 and 548 nm), Al (447 and 545 nm), and Au (550 nm). Two resonant emission peaks were achieved in the devices with M = Ag and Al. But only one intersection was observed for M = Au anode. To explain this phenomenon, we calculated the effective refractive index of the anodes with the transfer matrix theory [15]. The results are shown in Fig. 1b. The phase change on reflection is relative to the refractive index of the incidence and reflectance medium. For the anode with M = Au, the real part and imaginary part of n_{eff} is flat rela-

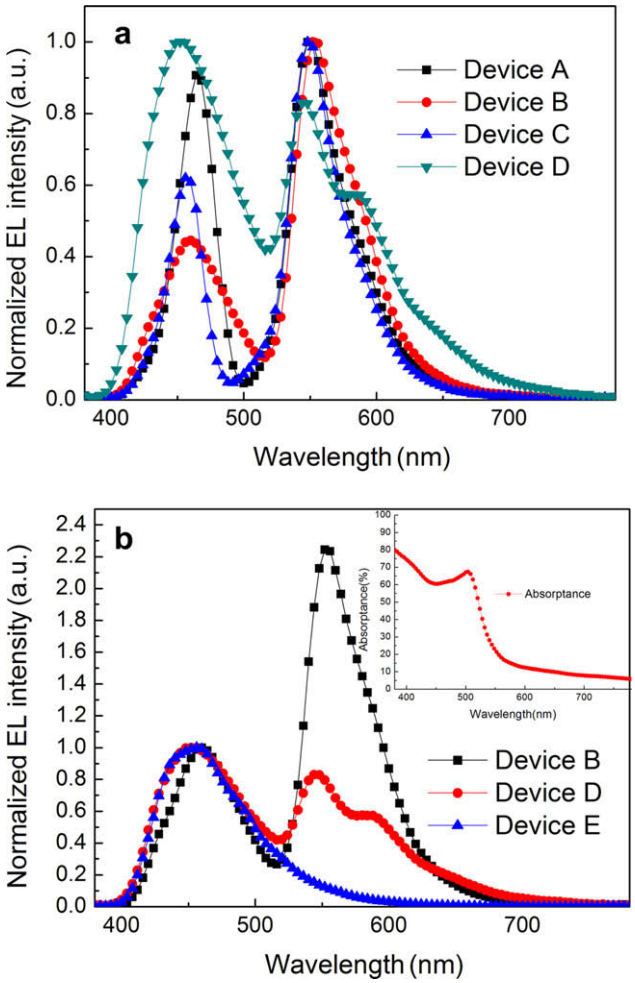

Fig. 2. (a) The normalized measured EL spectra of devices A, B, C and D at voltage of 8 V, and (b) the normalized measured EL spectra of devices B, D, and E at voltage of 8 V. Insert is the absorption for anode with M = Au.

tive to that of other two anodes. As a result, the reflection phase changes were also flat for anode with M = Au. So one intersection was obtained for device with M = Au, and two intersections for the other two.

Fig. 2a shows the normalized measured EL spectra at voltage of 8 V and viewing angle of 0° for devices A, B, C, and D. The spectrum of the device D shows two main peaks at 452 and 544 nm originating from DPVBi and $(F\text{-}BT)_2Ir(acac)$. As can be seen, the spectrum of the devices show two emission peaks, 464 and 548 nm, 460 and 552 nm, 456 and 548 nm for devices A, B, and C, respectively. The emission peaks of all the devices are in excellent agreement with calculated results. The narrowness of the full width at half maximum (FWHM) of the DPVBi and $(F\text{-}BT)_2Ir(acac)$ emission in devices A and C is observed. These results indicated that microcavity effect, which will produce a narrowing of the emission spectra of the device [16], was occurred in device A and C.

The distinct narrowness of the FWHM is only observed for $(F\text{-}BT)_2Ir(acac)$ emission in device B. We presumed that the microcavity effect was almost eliminated for blue emission in this device. To further prove this, we built the bottom-emitting device (ITO glass substrate, device E) with the same organic layers except using 10 nm DPVBi replacing CBP (3 nm) and CBP: $(F\text{–}BT)_2Ir(acac)$ (7 nm) layers. Fig. 2b shows the normalized measured EL spectra at voltage of 8 V for devices B, D, and E. We can see that the blue emission for device D is the same as that for device E. This implied that the blue emission of device D originating from DPVBi. Similarly, device B showed almost the same blue emission as device E except slight red shifts at short wavelength. Insert is the absorption for anode with M = Au. As can be seen, for the wavelength less than 450 nm the absorption is higher. We attribute the red shifts to the absorption of the anode. And the low reflection of this anode at short wavelength zone as shown in Fig. 3 almost eliminates the microcavity effects for the blue emission.

Fig. 4a–c shows the normalized measured EL spectra at voltage of 6 V and viewing angle of 0°, 30°, and 60° for devices A, B, and C, respectively. Obvious change of the blue emission is observed in devices A and C. However, it is inconspicuous for device B. This is also a proof that the microcavity effect is almost eliminated for the blue emis-

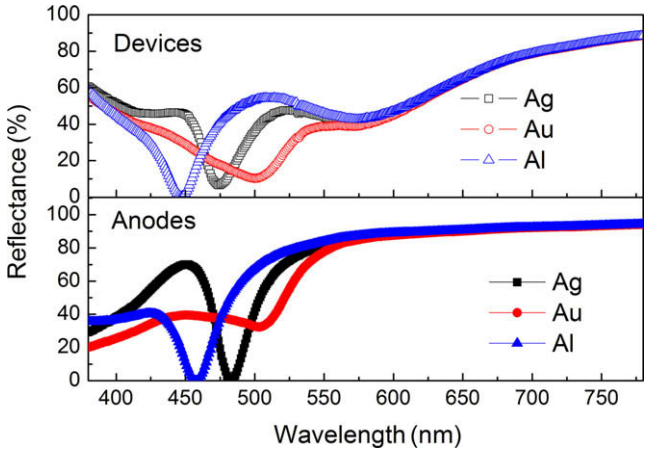

Fig. 3. The reflectance of the devices (top) and anodes (bottom).

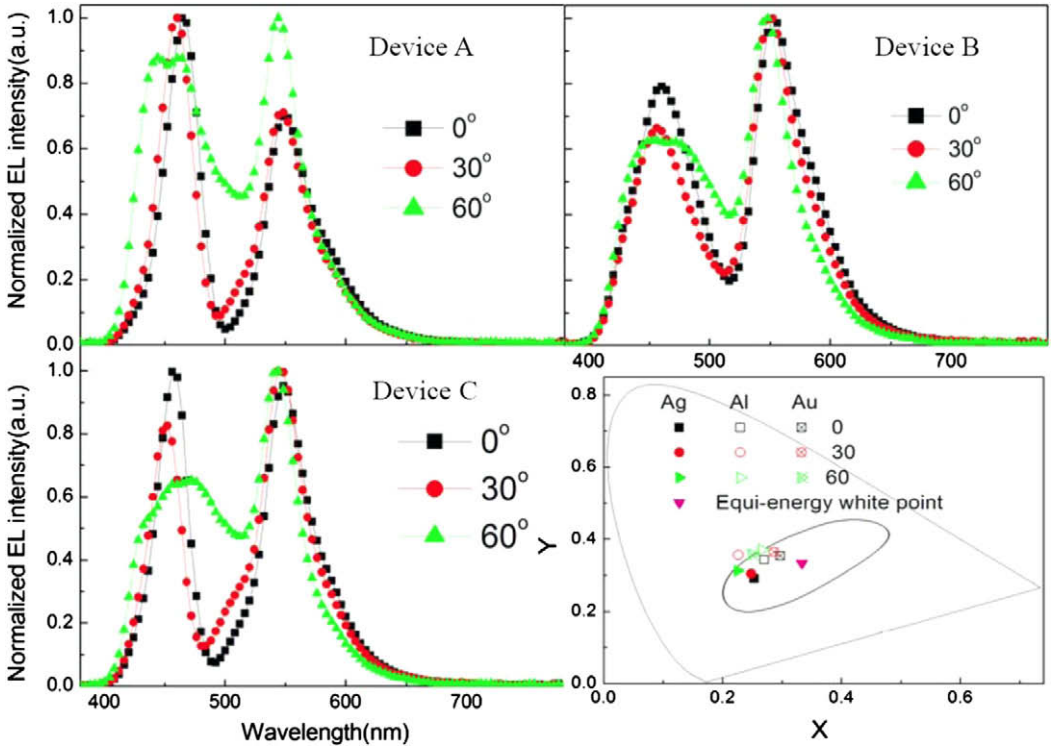

Fig. 4. The normalized EL spectra of the white TEOLED at viewing angle of 0°, 30°, and 60° for devices A, B, and C and the CIE coordinate of devices at different viewing angles.

sion in device B. Fig. 4d is the CIE coordinates of devices at viewing angle of 0°, 30°, and 60° (at a driving voltage of 6 V). We can see that a warm white emission at viewing angle of 0°, 30°, and 60° was obtained.

Fig. 5 shows the voltage–current density–luminance characteristics of the devices A, B, and C. The luminance of the devices A, B and C is 7565, 8335, and 8936 cd/m^2 at 11 V, respectively. Insert is the efficiencies versus voltage characteristics of the devices. The maximum current efficiency of the devices are 8.2, 7.7, 8.4, and 7.3 cd/A for devices A, B, C, and D, respectively. The high efficiency of top-emitting device can attributed to the microcavity effect in the devices.

The pixel contrast ratio (PCR) of devices is investigated as depicted in Refs. [17,18]. The light source D65 is utilized for calculation. In the calculation, the brightness of the devices at on- and off-state is set to be 1000 and 0 cd/m^2. The PCR of devices A, B, and C is 52:1, 63:1, and 48:1 under an ambient illumination of 140 lx, corresponding to an enhancement of 86%, 104% and 79% over that of device D.

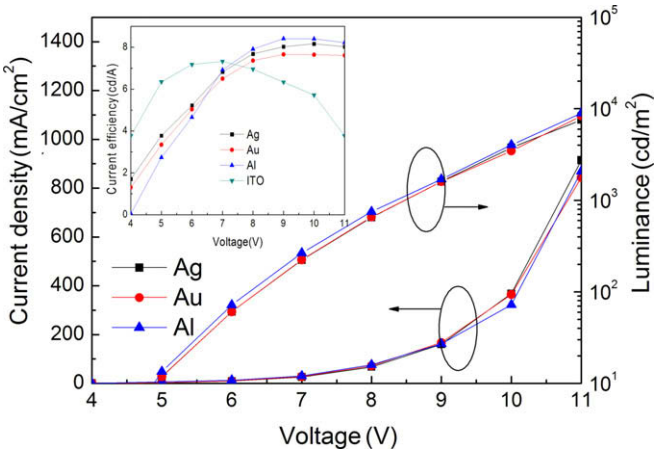

Fig. 5. The voltage–current density–luminance characteristics of the devices. Insert the efficiency–voltage characteristics of the white devices.

The obvious improvement of PCR in devices A, B, and C originates from the reduction of reflectance in the whole visible region and the anode plays an important role in the absorption of ambient light, especially for the device with M = Au (Fig. 3).

4. Conclusion

In summary, the top-emitting white organic light-emitting devices with a M/(Alq_3/Ag)$_2$ (M = Ag, Au, or Al) anode are demonstrated. The device with M = Al shows the highest efficiency and device with M = Au gives the highest contrast. The results indicated M/(Alq_3/Ag)$_2$ is an effective anode for top-emitting white OLED and is compatible with CMOS or OTFT techniques.

Threshold voltage shift

ABSTRACT

Here the device performance is shown to be directly related to the measured electronic level alignment at the dielectric interface in C_{60} organic field effect transistors (OFETs). We compare C_{60} on two dielectrics: Al_2O_3 and a divinyltetramethyldisiloxane-bis(benzocyclobutene) (BCB)–Al_2O_3 bilayer. The improved transistor performance and the lowering of the threshold voltage by 0.8 V due to the BCB interlayer are reflected in the ultra-violet photoemission data. These show a 0.8 eV difference in the work function and a concomitant shift in the C_{60} valence band. By following the work function the improvement is shown to be due to the dipole at the organic BCB–C_{60} interface.

1. Introduction

Interface engineering in organic field effect transistors (OFETs) has become the key issue in designing devices with acceptable electrical transport properties. The crucial part is to design the interface between the dielectric and the organic semiconductor [1]. It has been demonstrated that by introducing a polymeric layer on an oxidic dielectric surface the overall device performance can be enhanced. Recent publications demonstrate well performing transistors with passivation layers of various thin polymeric insulators as well as transistors with self assembled molecules (SAMs) grown on silicon dioxide and Al_2O_3 [2–6]. Factors ranging from film morphology through to issues of electronic level alignment could all be playing a role. While device activity has concentrated on modifying the inorganic dielectric surface with SAMs or polymer dielectrics, little work has considered the possibility of charge rearrangements at the interface of such modifiers with the organic semiconductor. Recently theoretical modelling has suggested that improvements in transfer characteristics and rigid shifts of the threshold voltage can result from the introduction of permanent space charge or dipole layers at the organic semiconductor/dielectric interface [7]. In particular the introduction of a BCB divinyltetramethyldisiloxane-bis(benzocyclobutene) interlayer between the inorganic dielectric (Al_2O_3, SiO_2) and the organic semiconductor has been reported to yield low operating voltages and high mobilities [2–4]. Apart from suggestions of it acting as a passivation layer removing hydroxyl groups from the semiconductor dielectric interface little is known of the function of BCB interlayers. Till now very few combined studies of device characteristic and photoemission investigations of the energy level alignment of device structures can be found in literature [8]. Moreover, to our knowledge there have been no such studies where a

doi:10.1016/j.orgel.2009.10.017

comparison of device structures with and without interlayer has been made.

In this work transistors using C_{60} and a bilayer of BCB–Al_2O_3, which has been reported to have low operation voltage (~1 V) and high mobilities (<3 $cm^2 V^{-1} s^{-1}$) [2,3], were used to explore the role in the improved performance due to the BCB interlayer. Here a systematic study of two insulator-C_{60} structures, with and without BCB, is made. We compare the performance of the field effect transistors and show that the improvement of the OFET with BCB can be directly related to the differences in energy level alignment as measured by ultra-violet photoemission spectroscopy (UPS). Moreover, from studies of each interface the improvement in device performance arising from the polymeric interlayer is shown to be generated by an in-built potential at the BCB-interlayer/organic semiconductor interface.

2. Experimental section

Here we use the same OFET system as Zhang et al. [3] and we systematically compare the interface of C_{60} and BCB–Al_2O_3 to the interface of C_{60} and Al_2O_3 alone to understand its role in the improved performance. To allow meaningful comparison we fabricated two bottom-gate/top contact transistors, such that both the Al_2O_3 alone and the bilayer Al_2O_3–BCB exhibit the same geometric capacitance, as depicted in Fig. 1. Additionally using 55 nF cm^{-2} dielectric layers provide transistors operating at gate voltages in the range of 1 V and a mobility of 1 $cm^2 V^{-1} s^{-1}$. To combine the transistor with the photoemission spectroscopy the same MIS structures are studied by UPS with the samples prepared in a controlled way using the same batch at once and a blind sample as a reference for the surface characterization.

2.1. OFET fabrication and characterization

BCB precursor solution and C_{60} was purchased from Aldrich and Merck respectively. The C_{60} was purified in a further re-sublimation process before evaporation. 200 nm of Al are deposited on a glass substrate at a rate of 10 Å s^{-1}. For the Al_2O_3 gate insulator a 145 nm and an 85 nm film respectively is electrochemically grown on the Al following the instructions from Majevski et al. [9] and Schröder et al. [10]. The generated oxide was then rinsed and treated with distilled water at 80 °C in the ultra sonic bath and finally dried at 200 °C. For the polymer layer a 1 wt% BCB precursor solution in mesitylene was spun onto the 85 nm thick aluminium oxide film at 1500 rpm and afterwards annealed at 150 °C for cross linking. By controlling the Al_2O_3 thickness we obtained two systems (Al_2O_3 layer and Al_2O_3–BCB bilayer) with similar surface roughness of 1.5 nm RMS and with the same measured geometric capacitance C_p of 55 nF cm^{-2}. The thicknesses were measured by capacitance measurements (Al–Al_2O_3–Al) and checked by cross section scanning electron microscopy. For the semiconductor a 300 nm C_{60} film was deposited in high vacuum using hot wall epitaxy technique at a substrate temperature of 140 °C and a growth rate of 0.5 Å s^{-1} [11]. The morphologies, as determined by AFM of the C_{60} films on the two substrates are found to be similar. For the source-drain contacts LiF/aluminium (0.6 and 50 nm) [12] was evaporated using a 70 μm shadow mask for the channel and a channel width W of 2 mm. The OFETs were characterized using Agilent E5273A 2-channel-source unit.

2.2. UPS measurements at dielectric-semiconductor interface

For the UV photoemission spectroscopy metal–insulator–semiconductor structures were prepared in the following way: A 5 nm thin layer of aluminium oxide was electrochemically grown on aluminium and treated afterwards as mentioned in Section 2.1. For the BCB surface, the 1% precursor solution was directly spun onto oxidized aluminium and cured at 200 °C as for the transistor. In a further step the C_{60} was deposited by thermal evaporation at a rate of 1 A s^{-1} at a substrate temperature of 78 K in order to guarantee homogenous covering. The thickness of the C_{60} is 2 nm (3–4 molecule layers) as determined by a quartz microbalance calibrated for C_{60}. The samples were then characterized by HeI (21.2 eV) UPS in ultra high vac-

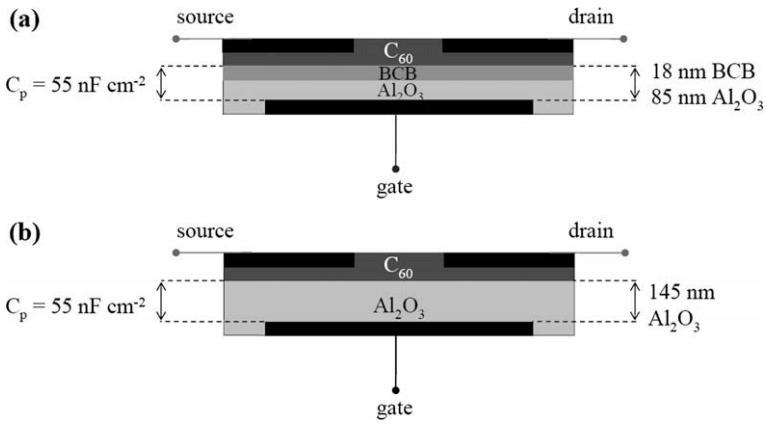

Fig. 1. Schematic of the OFET structures studied with (a) and without (b) a BCB layer on Al_2O_3. Both structures exhibit the same geometric capacitance of 55 nF cm^{-2}.

uum using a Specs PHIOBOS hemispherical energy analyser. The valence band spectra were recorded in both normal and 45° off normal emission angles and the work functions were determined from the secondary electron cut off in normal emission with a bias of 10 V. For all films XPS spectra were taken and no significant contamination was observed.

3. Results and discussion

3.1. OFET characterization

The device characteristic with and without BCB are compared in Fig. 2a and b which show the output characteristics and the transfer characteristics taken in the linear regime ($U_{gate} > U_{drain}$), respectively. Data presented here are recorded when the gate voltage U_{gate} as well as the drain voltage U_{drain} are applied in ascending and descending mode with 1 s integration time per step. Both figures reflect the same trend, however, the transistor with the BCB interlayer performs significantly better in all respects. It has a higher source-drain current I_{ds}, a higher depletion and accumulation amplitude, a sharper onset, a higher on/off ratio and a lower hysteresis. The observed hysteresis in the transfer curve is reduced for the BCB–C_{60} and the charge charier mobility μ in the range of 1 $cm^2 V^{-1} s^{-1}$ is in good agreement to earlier results of C_{60} on BCB [2,13,14].

The most striking difference of the two systems is the tremendous change in the threshold voltage U_{th}: To extract the exact threshold value in the linear regime, the transconductance change or second derivative (SD) method is selected [15]. The method estimates U_{th} as the gate voltage at which the derivative of the transconductance (dI/dU_{gate}) is maximum [16]. It works around the problem of series resistances and is shown to give reliable values for organic (*n*-channel) systems [17]. In Fig. 3a, the second derivative of the transfer characteristics d^2I/dU^2_{gate} is presented showing two maxima. The device with BCB shows a distinct and sharp peak, whereas for the device without BCB the peak is rather broad and ill-defined.

The peak maximum corresponds to the threshold voltage U_{th} of the transistor system which shifted from +725 mV in the Al_2O_3–C_{60} interface system to −75 mV in the BCB–C_{60} interface system. The device with the BCB interlayer has a 0.8 V lower U_{th}.

The shift in the HOMO and in the secondary electron cut-off $\Delta\Phi$ is indicated.

3.2. Photoemission studies

Photoemission measurements of ex situ prepared films on dielectric substrates are particularly challenging as contamination and charging effects can be misleading and care has to be taken. In Fig. 3b the UPS spectra of $Al/Al_2O_3/BCB/C_{60}$ and $Al/Al_2O_3/C_{60}$ thin film structures are shown referenced to the Fermi energy obtained from a metal substrate. In both cases the valence band fingerprint of the uppermost C_{60} layer is well defined with a quality approaching that of in situ UHV prepared C_{60} films [18]. This, combined with the fact that the ionisation potential of C_{60} in both cases are in agreement with literature values [18], shows that contamination and charging effects are minor.

The comparison of Fig. 3a and b illustrates the link between the device thresholds U_{th} and the electronic level alignment observed in the UPS spectra with BCB and without BCB. Clearly, introducing the BCB interlayer leads to a rigid shift of the entire photo emission spectrum to lower binding energy relative to the Fermi level. The shift of the HOMO-peak is measured to be 0.6 eV whereas the shift in the secondary cut-off, the change in the work function, is 0.8 eV. Thus the change in the measured C_{60} electronic level alignment induced by the BCB layer is the same as the lowered threshold voltage measured in the device with BCB.

To determine where and why the BCB has lowered the threshold voltage UPS spectra were measured at each layer in the device. This is summarized in Fig. 4 where the energy relations of the studied metal–insulator–semiconductor (MIS) systems for all interfaces with the work function measured for each layer are indicated. For the pure inorganic dielectric device without BCB (Fig. 4a) we measured a large work function drop to 2.7 eV on oxidation of the aluminium surface followed by a very small increase of the work function to 2.9 eV when the C_{60} film is grown on the oxide. Similar changes have been observed in in situ model studies [19,20]. In contrast, what is seen in Fig. 4b, is that on applying BCB to the Al_2O_3 surface the work function drops further to 2 eV. Then when C_{60} is grown on the BCB surface there is a large increase of the work function to 3.7 eV. At both BCB interfaces (Al_2O_3 and C_{60}) significant dipoles are formed and clearly BCB cannot be considered simply a passive spacer layer. The large work function increase at the BCB–C_{60} interface is the prime determinant of the improved device performance.

The result suggests that a significant interface dipole is formed at the BCB–C_{60} interface. This is surprising as generally organic–organic interfaces display vacuum level alignment with no significant interface dipoles. However in recent model studies [21] significant interface dipoles at organic–organic interfaces have been observed and were attributed to integer charge transfer (ICT) that is the formation of polaronic charge transfer states. Indeed the observed work function increase for C_{60} on P3HT has been attributed to this effect [21].

The C_{60} level alignments on the two gate dielectrics measured in the UPS are consistent with the two threshold voltages measured for the OFETs. Gate voltages of −0.075 V (BCB–C_{60}) and +0.725 V (Al_2O_3–C_{60}), would shift the HOMO level in both cases to around 2.8 eV below the Fermi level of the source. As C_{60} is a *n*-type semiconductor it is the LUMO relative to the Fermi energy of the source that is critical. Given a C_{60} affinity level of ~2.5 eV above the HOMO [21,22] one sees that the device threshold is obtained when the electron affinity is positioned slightly below the Fermi level of the source.

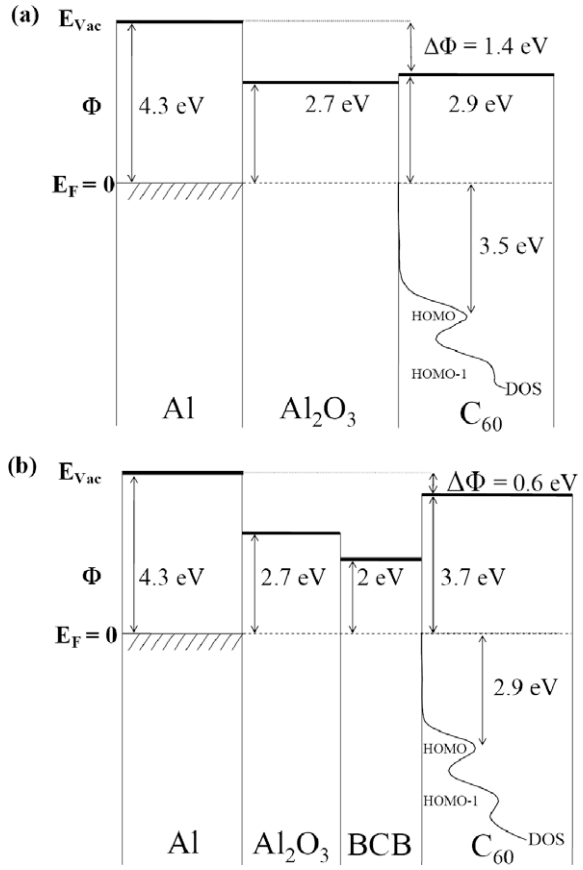

Fig. 4. Measured energy level diagrams of the two metal–insulator–semiconductor (MIS) structures studied without (a) and with (b) BCB between C_{60} and Al_2O_3. The Fermi level is the reference level and the work function at each layer are indicated. Note the large work function change at the BCB–C_{60} interface (b) and that the difference in the final work function between the two structures is 0.8 eV.

4. Conclusion

To conclude we studied two different interfaces between an organic semiconductor (C_{60}) and oxide (Al_2O_3) and an organic polymer (BCB) respectively. At the BCB interlayer dipoles are formed, which lower the threshold voltage and improve the transistor performance. The 0.8 V difference in the threshold voltage of the two device structures has been shown to be directly related to the 0.8 eV work function differences and is consistent with the band offset of C_{60} in each device. Photoemission investigations at all interfaces clearly indicate that the dipole formed at the BCB–C_{60} interface is the prime determinant for the improved device threshold. The magnitude and mechanism of this shift suggests detailed studies into tailoring

organic–organic interfaces on the gate dielectric could be very promising for optimizing device performance.

ABSTRACT

Organic hetero-junctions in multi-layered thin film stacks comprising alternate layers of the molecular donor – tetrathiafulvalene (TTF) and the acceptor – tetracyanoquinodimethane (TCNQ), have been studied by ultraviolet photoelectron spectroscopy (UPS). We show that the energy level alignment at the organic–organic interfaces in the stacks depends only upon the relative energy structure of the donor and acceptor molecules, in particular, the molecular integer charge transfer (ICT) states. The observed interfacial dipoles, across the multi-layered organic stacks, correspond to the difference in energy between the positive and the negative charge transfer states of the molecules constituting the interface. Consequently, Fermi level across the multi-layer system is pinned to those states, since the energetic conditions for the charge transfer across the interface are fulfilled. Hence the energy level alignment at donor–acceptor interfaces studied can be rationalized on the basis of integer charge transfer model (ICT-model). Moreover, we present the photoelectron spectra where 0.85 eV shift of the highest occupied molecular orbital (HOMO) of TTF during formation of TCNQ over-layer is directly observed. These studies contribute to the understanding of the nature of the offset between the frontier electronic levels of the donor and acceptor components which is of high importance in the engineering of efficient organic solar cells.

1. Introduction

The understanding of electronic structure of organic materials and energy level alignment at all-organic and hybrid interfaces is the subject of many recent extensive research efforts. In particular, photoelectron spectroscopy has been a very fruitful tool for elucidation of the electronic properties of thin organic films [1]. A detailed knowledge of the electronic structure of condensed molecular solid films and even conjugated polymers has contributed significantly to emerging industrial applications in the area of organic electronics.

Organic electronic devices are usually composed of several thin film layers that facilitate various functionalities, *e.g.,* charge injection and transport, recombination/extraction of charges, as discussed elsewhere [2–4]. Within such multilayer thin film architectures are contained interfaces, the properties of which influence and control device operational characteristics. Consequently, a detailed understanding of the interfaces involved in organic electronic devices is critical for improvement of device performance. Particularly important for device operation is electronic level alignment. The significance of this topic is related to the fact that interfacial energetics determines the conditions for the injection of charges from electrodes and charge transport across the device. According to a simple model, energy level alignment at given interface can be estimated by simply lining up the separately observed

doi:10.1016/j.orgel.2009.10.018

electronic structures of organic layers. However, as found by Seki and co-workers, this assumption is not valid in many cases [5]. It has been shown that various phenomena, *e.g.* formation of chemical bonds, charge transfer, "push-back effect" or adsorption of molecules, result in the formation of interfacial dipoles, which result in a vacuum level offset [6]. Such vacuum level discontinuity imposes a relative shift between the energy levels of materials constituting interface. Hence the magnitude of the interfacial dipole is an essential parameter to fully characterize interface energetics. The interfacial dipole can be used as a tool to enhance charge injection properties of an electrode. The magnitude of the dipole can be engineered through various surface modifications [7–9]. However, a complete and systematic understanding of energy level alignment has not yet been achieved. Interfacial interactions have been addressed by a large number of theoretical and experimental studies [10–14]. The concept of induced density of interface states (IDIS), based on the interaction between metals and organics has been developed to predict trends in the magnitude of interfacial dipole [15]. For a class of weakly interacting interfaces, the integer charge transfer (ICT) model was recently proposed [16,17]. This semi-empirical model originates from the photoelectron spectroscopy, which reveals characteristic trends in energy level alignment of various organic semiconductors [18–20]. The model predicts that for a large-enough range of work functions, a "Z" shaped ("Mark of Zorro") type of dependence between substrate work function and the work function of the organic layer adjacent to the substrate should be obtained. Hence, for a range of substrates with different work functions, and a given organic material, a transition between vacuum level alignment and Fermi level pinning should occur if the substrate work function enables charge transfer between the substrate and the organic over-layer. The interface will then be in equilibrium when the Fermi level of the conductive substrate is pinned at interfacial states in the organic layer, near the HOMO or LUMO levels of the molecular material. The pinning levels are determined by properties of the organic layer, defined by the nature of the charge transfer states. According to the experimental data, when the Fermi level of the metallic substrate falls within the gap (vacuum level alignment regime) any barriers for charge injection (or lack thereof) are dependent of the work function of the electrode and follow Schottky–Mott limit behavior, *i.e.,* they scale linearly with the work function of the electrode. Within the pinning regimes, when the electrode work function enables interfacial charge transfer, the barriers, if any, has a constant value determined by energy of integer charge transfer states [16–22]. In the context of device engineering, the model predicts that the charge injection barriers can be modified by changing the work function of an electrode only within certain limits [20,23–26]. Considerable interest has been also directed toward more complex systems, containing more than one organic over-layer [27–31]. Such multi-layered structures can help understanding the electronic processes in organic electronic devices.

Recently we have shown that the energetics across a multi-layered structure depends on the interplay between

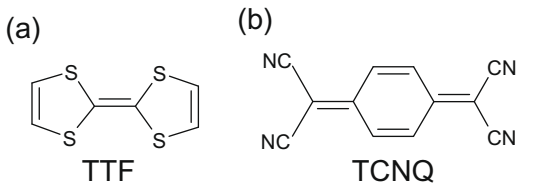

Fig. 1. The molecular structures of the organic molecules studied: (a) tetrathiafulvalene (TTF), (b) tetracyanoquinodimethane (TCNQ).

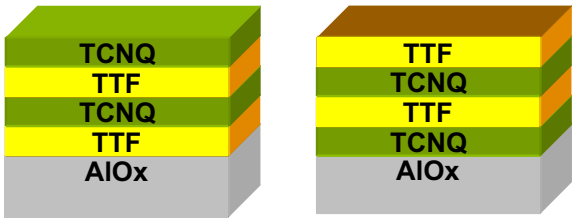

Fig. 2. Schematic drawing illustrating the molecular stacks studied.

electrode work function and the charge transfer states in organic over-layers [32]. Consequently, the magnitude of the dipole may be dependent on the sequence in which adjacent layers are present in the stack of thin film layers. Those points out the complexity of the interfacial energetics that must be addressed in the consideration of real organic-based devices.

In this report, we focus on the energy level alignment at interfaces in a multi-layer donor–acceptor organic stack. Organic donors and acceptors are commonly used in various applications where their unique properties associated with high electron affinity alternatively low ionization potential are exploited. They are often utilized to form charge-transfer complexes that are used to enhance electronic properties or they serve as the active entity to facilitate charge separation in photovoltaic cells [33,34]. In the present case, the molecular donor–acceptor pair of tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ) (see Figs. 1 and 2), has been studied [35,36]. The stacks of up to four layers have been prepared in different deposition sequences. In addition, particular attention has been paid to whether TTF or TCNQ is adjacent to the substrate, as shown in Fig. 3. The results obtained on such stacks revealed that the influence of the substrate on the organic–organic interfaces is confined to the first two organic layers, and that subsequent layers exhibit exactly the same interfacial off-sets, independent of the substrate. Moreover by a careful choice of the substrate work function the position of HOMO level of the molecular donor (TTF) at the interface with the acceptor (TCNQ) could be directly observed by photoelectron spectroscopy.

2. Experimental

The multilayer stacks comprising thin films of TTF and TCNQ were prepared in situ under ultra high vacuum (UHV) conditions by physical vapor deposition (PVD). The

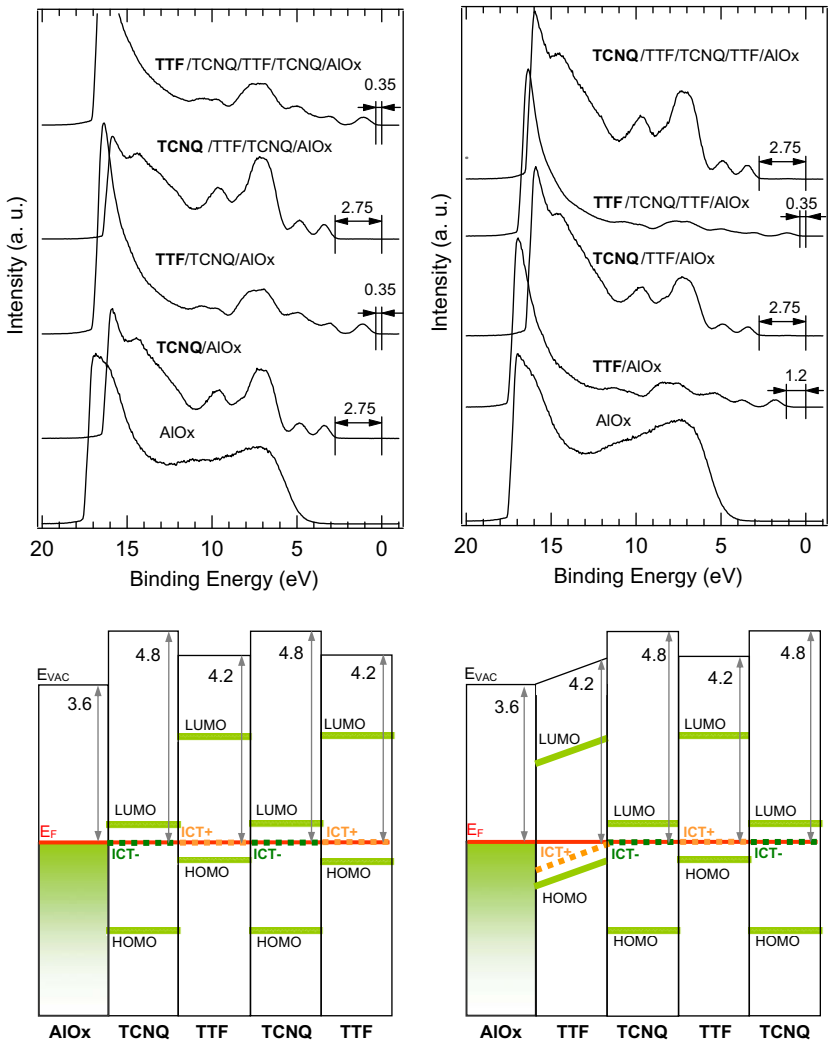

Fig. 3. UPS spectra and the corresponding diagrams of energy level alignment of interfaces at multilayer stacks of TTF and TCNQ.

molecules: TTF and TCNQ were purchased from Sigma–Aldrich. The deposition rate was set to approximately: 5 Å/min, as calibrated from the attenuation of the Au(4f) core level line of a gold substrate, measured by X-ray photoelectron spectroscopy (XPS). The aluminium substrate with a native oxide has been used. During the film growth and measurement, the substrates were cooled to −100 °C.

Ultraviolet photoelectron spectroscopy (UPS) was used to examine the correlation between the substrate work function and the energy level alignment at the organic–organic interfaces formed upon deposition of the donor and acceptor molecules. This technique is especially suited for such studies, since it enables direct probing of the occupied valence electronic levels as well as the vacuum levels, and therefore also of vacuum level shifts, upon forming the interface. The value of the vertical ionization potential (IP) is measured as the onset of the HOMO edge versus the vacuum level. UPS measurements were performed using monochromatized HeI radiation ($h\nu$ = 21.2 eV) in a spectrometer of our own design and construction [37]. The measurement sequence involved characterization of the bare substrates followed by stepwise deposition and characterization of molecular add-layers.

3. Results and discussion

Thin films of the molecular donor – TTF and the acceptor – TCNQ, have been subsequently deposited onto AlO*x* substrate. As shown in Fig. 2, the deposition sequence has been varied so either TTF or TCNQ has been put in direct contact with AlO*x*. In both cases there are four molecular layers deposited on the substrate in order to study the energy level alignment across the multi-layered organic stack.

As shown in Fig. 3, upon deposition of TCNQ onto AlO*x*, the dipole of 1.2 eV is present at the interface. Consequently, this dipole shifts the vacuum level (E_{VAC}) from 3.6 eV, as observed for AlO*x*, to the value of 4.8 eV. This shift sets the substrate Fermi level (E_F) in the vicinity of

LUMO of TCNQ that is located at 4.5 eV [R. Murdey, private commun.]. The obtained result is in line with the previously reported energy level alignment of TCNQ on the various substrates [38]. In those cases, the interfacial dipole scales with substrate work function in such a manner that the substrate Fermi level stayed pinned at about 4.8 eV. In the case reported here, the low work function of the AlO*x* (3.6 eV) also enables charge transfer between the substrate and the TCNQ molecules. In this process, it is expected that charges are transferred to the LUMO-derived states and the substrate Fermi level is pinned in the vicinity to LUMO [39].

The Fermi level, which is pinned at 4.8 eV upon deposition of TCNQ, is the reference level for TTF over-layer. As TTF is deposited onto TCNQ to form TTF/TCNQ/AlO*x* stack, the interfacial dipole appears but in the reverse direction with respect to the TCNQ/AlO*x* interface. This can be rationalized on the basis of integer charge transfer model. Since the charge transfer state of TTF is at 4.2 eV it is then 0.6 eV lower than the position of Fermi level (4.8 eV). In order to reach equilibrium, the Fermi level aligns with the TTF pinning level and the interfacial dipole is formed. The magnitude of the dipole corresponds directly to the difference between the Fermi level and the positive pinning level of TTF. As revealed by UPS and shown in Fig. 3, the same mechanism is observed when the next molecular layers are deposited. The Fermi level stays aligned to the positive integer charge transfer state (ICT+) of TTF and the negative charge transfer state (ICT−) of TCNQ. Consequently the vacuum level shift is equal to the energy difference of those charge transfer states. There are alternating positive and negative dipoles of the same magnitude equal 0.6 eV at each consecutive interface.

The stack of TTF and TCNQ layers has been also studied in the configuration where TTF layer has been deposited first onto AlO*x*. As shown in Fig. 3 the deposition of the first layer does not change vacuum level and there is no dipole at the interface. This situation is apparently different from the cases studied by Murdey et al. when TTF was deposited on the substrates with work function ranging from 4.3 to 5.1 eV. As depicted in Fig. 4, within this range of work functions, the magnitude of the dipole scales with the substrate work function in such a way that the substrate Fermi level is pinned at the constant distance from HOMO level of TTF. The lack of interfacial dipole in the case of TTF/AlO*x* indicates that there is no charge transfer between TTF and AlO*x*. This can be rationalized on the basis of the ICT-model. Since the work function of AlO*x* substrate (3.6 eV) is lower than the positive pinning level of TTF (4.2 eV), there is no favorable condition for charge transfer between organic layer and the substrate. Consequently, the lack of interaction does not alter the electronic conditions at the interface and leads to the observed vacuum level alignment. In the next step, a thin layer of TCNQ has been deposited onto TTF/AlO*x*. As shown in Fig. 3, this leads to a large work function shift of 1.2 eV (the vacuum level is lifted upward to the value of 4.8 eV). The observed energy level alignment at this organic–organic interface is attributed to the favorable energetic conditions for charge transfer between those two organic materials. Even though TTF does not alter the vacuum level position set by AlO*x*, the

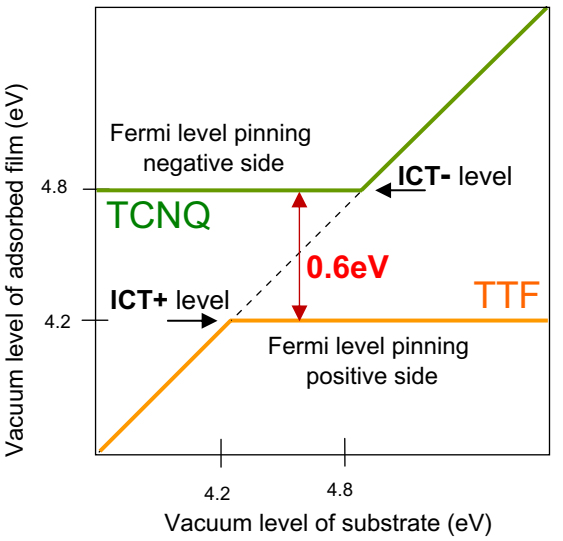

Fig. 4. Schematic drawing presenting energy level alignment regimes for TTF and TCNQ as a function of substrate work function.

Fermi level, which is set at 3.6 eV versus vacuum level, enables charge transfer between TTF and TCNQ. Consequently, upon deposition of TCNQ, the vacuum level observed for TTF is shifted to the value of the pinning level of TCNQ (4.8 eV). Note that the work function shift (1.2 eV) is larger than the interface dipole of 0.6 eV obtained at the TTF/TCNQ and TCNQ/TTF interfaces (0.6 eV being the difference between the ICT+(TTF) and ICT−(TCNQ) energies). Hence additional charge must be transferred across the interface to bring the system into equilibrium. This may be facilitated by transferring charge from the AlO*x* substrate through the TTF layer to the TCNQ at the TCNQ/TTF interface, which would lead to a linear potential gradient over the TTF layer, as schematically pictured in Fig. 3. More charges could be transferred from the TTF layer extending further away from the interface, creating a "band-bending-like" potential gradient over that region. Alternatively, some contribution to the observed work function shift may originate from the polarization effect, as suggested in the recent work of Avilov et al. [40].

On such TCNQ/TTF/AlO*x* structure the third and fourth organic layer was deposited to finally form the stack in the following configuration: TCNQ/TTF/TCNQ/TTF/AlO*x*. As revealed by the photoelectron spectra the two top most interfaces follow the path of alternating vacuum level shifts that correspond to the 0.6 eV difference between the pinning levels of TTF and TCNQ. Hence the energy level alignment of those top interfaces is invariant versus the deposition sequence. This, in turn, leads to the conclusion that the influence of the substrate work function on the energy level alignment at organic ad-layers is confined to the first two layers in a multi-layered stack *e.g.* where the first layer is adjacent to the substrate.

The direct observation of HOMO level of a molecular layer, while building the interface with another organic material, is often obscured by the similarity in the binding energies of those levels. The overlapping contributions in photoelectron signal introduce apparent ambiguity in

interpretation of the spectra. This problem is circumvented in the present studies: when TCNQ layer is deposited on TTF/AlO*x* the onset of HOMO level of TCNQ is present at 2.75 eV. In the case of the TTF layer, when deposited on AlO*x*, the HOMO onset is at 1.2 eV. Hence, the large difference in the binding energy of HOMO peaks gives a unique opportunity for a direct observation of the position of HOMO level of the molecular donor – TTF versus Fermi level, upon building the interface with TCNQ.

As shown in Fig. 5, the HOMO level of TTF deposited on AlO*x* moves towards Fermi level as the coverage of TCNQ increases. At the same time, the gradual shift of vacuum level at this interface, from 3.6 to 4.2 eV, has been observed. The total shift of HOMO level of TTF, measured between the neat TTF film and the TTF film with 8 nm thick overlayer of TCNQ is 0.85 eV. With the increasing thickness of TCNQ the HOMO peak of TTF becomes less intense, as shown in Fig. 5. This is the effect of the gradually prevailing contribution to the photoelectron signal from TCNQ. The leading edge of the highest molecular orbital of TTF is finally observed at 0.35 eV from Fermi level. As shown in Fig. 6, this value is already reached for the less than 8 nm thick TCNQ. This new position of HOMO edge (0.35 eV) is similar to the position observed when the TCNQ layer obeys the Fermi level pinning regime. Note that the HOMO leading edge of TTF does not reach the Fermi level which could be an expected result in the scenario of charge transfer. However, for a very small molecule strong localization of transferred charges could lead to Coulomb gap that would prevent appearance of the density of states at the Fermi level.

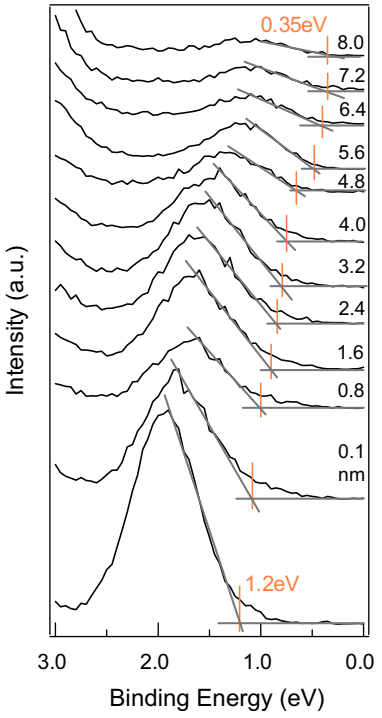

Fig. 5. UPS spectra of HOMO of TTF for different thickness of TCNQ overlayer.

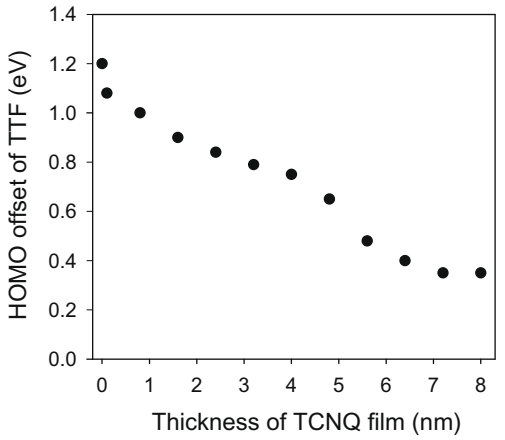

Fig. 6. Binding energy shift of HOMO edge versus thickness of TCNQ overlayer.

Recently, Duhm et al. reported that for the ordered film of α,ω-dihexyl-sexithiophene (DH6T), energy level alignment can be dependent on the orientation of the molecules due to the collective electrostatic effect of the highly anisotropic intramolecular charge distribution [41]. This dependence is manifested by the changes in ionization potential of the molecular film that for DH6T riches value of 0.6 eV. In the case of TTF/TCNQ interface, we do observe a difference between vacuum level shift (0.6 eV) and HOMO shift of TTF (0.85 eV), which points out that the ionization potential of TTF molecules in vicinity of TCNQ over-layer is changed by 0.25 eV. This, in turn, would suggest reorientation of some TTF molecules as the effect of changes in electrostatic field caused by charge transfer at the interface. To clarify this issue, however, the further research including assessment of the molecular orientation of the TTF and TCNQ films is needed.

In theory, the evolution of the TTF HOMO edge upon TCNQ deposition could be used to differentiate between the linear potential drop or "band-bending-like" potential gradient over the TTF layer (discussed in connection with Fig. 3) as the UPS signal is attenuated by the TCNQ overlayer and we are hence probing more and more shallow into the TTF layer as the TCNQ thickness increases. However, as we do not believe that the TCNQ over-layer grows uniformly, we refrain from attempting such an analysis, leaving the question open until more reliable techniques such as energy dependent depth probing at a synchrotron radiation light facility has been performed.

4. Summary

The interfaces between thin films of donor – TTF and acceptor – TCNQ have been studied by means of ultraviolet photoelectron spectroscopy. We demonstrated that the energy level alignment across the multilayer stack of thin films of molecular donor and acceptor is interdependent on the molecular integer charge transfer states and the sequence in which the layers are deposited on the substrate. These results are reminiscent to the previously studied interfaces of CBP and m-MTDATA deposited on the high

work function polymer: PEDOT-PFESA [32]. Since the studied structures include four organic layers, we have verified that across the stack of those layers, the observed interfacial dipoles (0.6 eV) are such that the Fermi level stays pinned to either positive or negative charge transfer state of TTF and TCNQ, respectively. There is however an exception to this scenario. When TTF layer is adjacent to the aluminum substrate, the work function increase upon TCNQ deposition has the magnitude of 1.2 eV. This result is rationalized on the basis of integer charge transfer model with an additional potential gradient over the TTF layer, supported by the experimental results on the TTF HOMO evolution. These studies contribute to the understanding of the nature of the offset between the frontier electronic levels of the donor and acceptor components which is of high importance in the engineering of efficient organic solar cells.

Excitonic emission

ABSTRACT

We propose electronic and excitonic emission models for the quantitative simulation of organic light emitting diodes comprising host–guest system in emission layer. The electronic model contains the thermionic injection at the electrodes, the charge transport with the field- or doping-dependent mobility, and Langevin's recombination. The excitonic emission model includes radiative (or nonradiative) decay, exciton diffusion, singlet–triplet intersystem-crossing, exciton annihilation, and polaron quenching. Förster and Dexter energy transfers as well as exciton blocking are also added to the excitonic emission model for the simulation of phosphorescent host–guest system. When these models are applied to a series of tris(2-phenylpyridine) iridium ($Ir(ppy)_3$)-doped 4,4′-bis(*N*-carbazolyl)-1,1′-biphenyl (CBP) devices with various doping concentration, the simulated electronic and excitonic emission properties are in good agreement with experimental results. The real devices show gentle efficiency roll-off at high $Ir(ppy)_3$ concentration and current efficiency reversion between 10% and 15% doping concentrations at over 20 mA cm^{-2}, which are successfully realized by the proposed models in which triplet–triplet annihilation in host sites is considered. It is also numerically demonstrated that exciton confinement in emitting layer by controlling the energy, lifetime, and diffusion of exciton results in improvement of luminance efficiency of the devices.

1. Introduction

Since the first appearances of a bi-layer organic light emitting diode (OLED) [1], electrochemical doping (host–guest system) has been widely used to improve the efficiency of multi-layer OLEDs. Understanding carrier injection, transport, and exciton formation in the doped system is the important issue for optimizing the devices and requires in-depth study of electronic and excitonic emission mechanisms. There have been proposed several theoretical models for OLEDs, but most of them are focused on the simple devices without doping [2–6] and only few reported on host–guest system [7–9], in which guests were simply treated as trap sites and carrier transport through guest sites were not considered. The carrier transport through both host and guest sites have been reported [10–13], however, there is no study in which the mechanism is applied to the simulation of the electronic properties of OLEDs. Meanwhile, simple excitonic emission models have been applied for the simulation of OLEDs, considering radiative (or nonradiative) decay, and exciton diffusion [3,5]. The concept of intersystem-crossing (ISC), exciton annihilation, and polaron quenching were often added to those models [14–17]. In some cases, Förster and Dexter energy transfers [18,19] were also included for the excitonic mechanisms, but unclearly implemented in a diffusion term [20] or limitedly applied to studies of transient photo-luminescence [15–17]. There was a case in which the Förster energy transfer is used in an excitonic emission model of steady state device simulation [9], however, exciton blocking phenomena [21,22] were not

considered in the studies because the model dealt with only fluorescent dopant.

In this paper, we propose electronic and excitonic emission models for the simulation of electrochemically-doped OLEDs. The electronic model basically contains the thermionic injection at the electrodes, the charge transport with field-dependent mobility, and Langevin's recombination. For the calculation of the electronic properties in electrochemically-doped layer, hopping and trapping with field- and doping-dependent mobility in host and guest sites are also considered. For the simulation of excitonic emission, Dexter energy transfer as well as Förster energy transfer between host and guest excitons is added into the model proposed by Baldo et al. [14] and exciton blocking is treated as diffusion-like transfer containing Boltzmann factor at organic/organic interfaces. In order to verify our electronic and excitonic emission models, a series of green-emitting phosphorescent OLEDs are prepared by varying doping concentration from 1% to 15%. The experimentally-obtained current density(J)–voltage(V)–luminance(L) characteristics of the devices are compared with the theoretically-calculated ones.

2. Theory

2.1. Electronic model

Fig. 1 schematically shows the proposed hole/electron transport mechanism in undoped and doped layers. The carriers injected from electrode move along the hopping distance (d_o) in the undoped layer with a field-dependent mobility, experiencing trapping and detrapping between transport and trap sites. At the interface between undoped layers, the carriers penetrate the barriers between the layers with the probability related with energy difference and energetic disorder [3]. At the interface between undoped and doped layers, the carriers penetrating into host sites move along the host hopping distance (d_h), whilst the carriers penetrating into guest sites move along the guest hopping distance (d_g). These carriers also experience trapping and detrapping between transport and trap sites of host (or guest), and at the same time, trapping and detrapping between transport sites of host and guest.

The field-dependent mobility at room temperature in undoped layer is expressed as below from Bässler's Gaussian disorder model [3,23]

$$\mu(F)_{RT} = \mu_{o,RT} \cdot \exp(C_{RT} \cdot \sqrt{F}), \tag{1}$$

where F is electric field, $\mu_{o,RT}$ and C_{RT} are zero-field mobility and electric-field-activation parameter at room temperature, respectively. In doped layer, the effective mobilities in host and guest can be modified by considering the decrease of wavefunction overlap factor [23], and the change of field dependency [24] with increasing hopping distance

$$\mu_h * (F)_{RT} = \mu_{ho,RT} \cdot \exp\left[2\left(1 - \frac{d_h}{d_{ho}}\right)\right] \cdot \exp\left[\left(\frac{d_h}{d_{ho}}\right)^{\alpha} C_{hRT} \cdot \sqrt{F}\right], \tag{2.1}$$

$$\mu_g * (F)_{RT} = \mu_{go,RT} \cdot \exp\left[2\left(1 - \frac{d_g}{d_{go}}\right)\right] \cdot \exp\left[\left(\frac{d_g}{d_{go}}\right)^{\alpha} C_{gRT} \cdot \sqrt{F}\right], \tag{2.2}$$

where subscript o means the condition of zero concentration of guest and d is doping-dependent hopping distance. We use the host hopping distance, $d_h = d_o/(1-c)^{1/3}$ and the guest hopping distance, $d_g = d_o/c^{1/3}$, $d_o = d_{ho} = d_{go} = 1$ nm and $\alpha = 0.5$, where c is doping concentration (c = 0–1).

The numerical framework for steady state simulation is based on conventional drift-diffusion models [5,7,9]. In this study, we consider the transport and recombination in guest site in addition to those in host site. The electronic properties are then described with the following Poisson's, current continuity, and current equations:

$$\nabla^2 V = -\frac{q}{\varepsilon_r \varepsilon_o}\left(p_h + p_{ht} - n_h - n_{ht} + p_g + p_{gt} - n_g - n_{gt}\right), \tag{3}$$

$$\nabla \cdot J_{p_h} + U^t_{p_h p_{ht}} + U^f_{p_h p_g} + U^r_{p_h n_h} + U^r_{p_h n_{ht}} = 0, \tag{4.1}$$

$$\nabla \cdot J_{n_h} - U^t_{n_h n_{ht}} - U^f_{n_h n_g} - U^r_{p_h n_h} - U^r_{n_h p_{ht}} = 0, \tag{4.2}$$

$$\nabla \cdot J_{p_g} + U^t_{p_g p_{gt}} - U^f_{p_h p_g} + U^r_{p_g n_g} + U^r_{p_g n_{gt}} = 0, \tag{4.3}$$

$$\nabla \cdot J_{n_g} - U^t_{n_g n_{gt}} + U^f_{n_h n_g} - U^r_{p_g n_g} - U^r_{n_g p_{gt}} = 0, \tag{4.4}$$

$$J_{p_h} = -q\left(D_{p_h}\nabla p_h + \mu^*_{p_h} p_h \nabla V\right), \tag{5.1}$$

$$J_{n_h} = q\left(D_{n_h}\nabla n_h - \mu^*_{n_h} n_h \nabla V\right), \tag{5.2}$$

$$J_{p_g} = -q\left(D_{p_g}\nabla p_g + \mu^*_{p_g} p_g \nabla V\right), \tag{5.3}$$

$$J_{n_g} = q\left(D_{n_g}\nabla n_g - \mu^*_{n_g} n_g \nabla V\right), \tag{5.4}$$

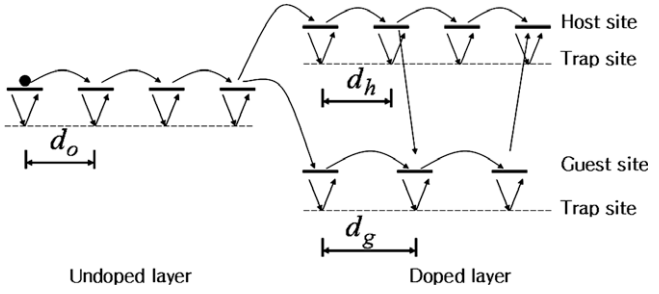

Fig. 1. Proposed electron transport mechanism in undoped and doped layers.

where V is externally-applied voltage, q is electronic charge, ε_r is relative permittivity, ε_o is permittivity of free space, p is hole density, n is electron density, t is trap, J is current density, U^t is trapping rate between transport and trap sites, U^f is trapping rate between host and guest transport sites, U^r is Langevin's recombination rate, and D is carrier diffusion constant obtained from Einstein relationship ($D = \mu \cdot k_BT/q$, where k_BT is the thermal energy).

In Eq. (4.1), the hole trapping rate between host transport and trap sites is given by [3]

$$U^t_{p_h p_{ht}} = \mu^*_{p_h} F \sigma_t \left[p_h (N_{tp_h} - p_{ht}) - p_{ht} (N_{\mathrm{hHOMO}} - p_h) \exp\left(-\frac{E_{tp_h}}{k_B T} \right) \right], \tag{6}$$

where σ_t is cross section for carrier trapping, N_t is density-of-states (DOS) of trap, E_t is trap energy level, and N_{HOMO} is DOS of the highest occupied molecular orbital (HOMO). In this study, we use $\sigma_t = 5d_o^2$ and $N_{\mathrm{hHOMO}} = d_h^{-3}$ [3]. The electron trapping rate in host or the hole and electron trapping rates in guest can be derived as an equivalent form to Eq. (6).

The hole trapping rate between host and guest transport sites is driven by

$$U^f_{p_h p_g} = \mu^*_{ph} F \sigma_t \left[p_h (N_{\mathrm{gHOMO}} - p_g) - p_g (N_{\mathrm{hHOMO}} - p_h) \exp\left(-\frac{\Delta E^H_{hg}}{k_B T} \right) \right], \tag{7.1}$$

or

$$U^f_{p_h p_g} = -\mu^*_{pg} F \sigma_t \left[p_g (N_{\mathrm{hHOMO}} - p_h) - p_h (N_{\mathrm{gHOMO}} - p_g) \exp\left(-\frac{\Delta E^H_{hg}}{k_B T} \right) \right], \tag{7.2}$$

where ΔE^H_{hg} is energy difference between host and guest HOMO levels. We set $N_{\mathrm{gHOMO}} = d_g^{-3}$. Eq. (7.1) is used when the guest HOMO level is energetically above the host HOMO level and vice versa for Eq. (7.2). The electron trapping rate between host and guest transport sites is equivalent to Eqs. (7.1) and (7.2).

The host recombination rates considering free-free and free-trap cases are given by [3]

$$U^r_{p_h n_h} = \frac{q}{\varepsilon_r \varepsilon_o} \left(\mu^*_{p_h} + \mu^*_{n_h} \right) p_h n_h, \tag{8.1}$$

$$U^r_{p_h n_{ht}} = \frac{q}{\varepsilon_r \varepsilon_o} \mu^*_{p_h} p_h n_{ht}, \tag{8.2}$$

$$U^r_{n_h p_{ht}} = \frac{q}{\varepsilon_r \varepsilon_o} \mu^*_{n_h} p_{ht} n_h. \tag{8.3}$$

The guest recombination rates are equivalent to Eqs. (8.1)–(8.3). The source terms for exciton rate equations are then considered to be only the free-free recombination rates ($U^r_{p_h n_h}$ and $U^r_{p_g n_g}$: see Eq. (11)) because it was reported that the exciton by a free-trap recombination has the other bound state of electron [25]. In this study, we exclude the recombination rates between charges in host and guest because exciton is supposed to be Frenkel exciton rather than charge-transfer exciton or Mott–Wannier exciton.

For device simulation, additional information is necessary: (1) boundary condition, (2) injection model. Here, Schottky contact boundary condition [26] is adopted. The potential at anode and cathode (V_{anode} and $V_{cathode}$) can be written as

$$V_{anode} = \frac{1}{q} \left(\phi_p - \frac{E_g}{2} + qV \right), \tag{9.1}$$

$$V_{cathode} = \frac{1}{q} \left(\frac{E_g}{2} - \phi_n \right), \tag{9.2}$$

where E_g is energy gap of the material adjacent to the electrode and ϕ is barrier height at the electrode. For injection model, we use Scott's injection model [27],

$$J_{INJ} = 4\psi^2 N_o q \mu F \exp\left(\frac{-\phi}{k_B T} \right) \exp(f^{1/2}), \tag{10.1}$$

$$\psi(f) = \frac{1}{f} + \frac{1}{\sqrt{f}} - \frac{1}{f} \left(1 + 2\frac{1}{\sqrt{f}} \right)^{1/2}, \tag{10.2}$$

$$f = \frac{q^3 F}{4\pi \varepsilon_r \varepsilon_o (k_B T)^2}, \tag{10.3}$$

where N_o is density of charge hopping sites, ψ is slowly varying function of electric field, and f is the usual Schottky barrier lowering effect. Here, we set $N_o = d_o^{-3} = 10^{21}$ cm^{-3}.

Finally, by self-consistent calculation using Eqs. (3)–(5), the local recombination rate for excitonic emission properties as well as the spatial distribution of charge carriers and current density in the device comprising host–guest system is obtained.

2.2. Excitonic emission model

The rate equations for singlet density (S) and triplet density (T) use Langevin's recombination rate (U^r) as a source, and include radiative (r) and nonradiative (nr) decay, exciton diffusion, singlet–triplet ISC, exciton annihilation (T–T,S–S,S–T), and polaron (P) quenching (S–P and T–P) mechanism [14–17]. Additionally, the exothermic energy transfers are implemented in host–guest system as shown in Fig. 2: (1) Förster energy transfer between host singlet and guest singlet, (2) Dexter energy transfer between host singlet and guest singlet, and (3) Dexter energy transfer between host triplet and guest triplet. The final form of exciton rate equations in steady state are

$$\frac{3}{4} U^r_{p_h n_h} - K^{h\to g}_{DET:T} T_h + K^{g\to h}_{DET:T} T_g + k^h_{\mathrm{ISC}} S_h - \frac{T_h}{\tau^h_{rT}} - \frac{T_h}{\tau^h_{nrT}} - \kappa^h_{TP}(n_h + p_h) T_h - \kappa^h_{TT} T_h^2 - \nabla\left(\tilde{D}^h_T \nabla T_h \right) = 0, \tag{11.1}$$

$$\frac{1}{4} U^r_{p_h n_h} - K^{h\to g}_{FET} S_h + K^{g\to h}_{FET} S_g - K^{h\to g}_{DET:S} S_h + K^{g\to h}_{DET:S} S_g - k^h_{\mathrm{ISC}} S_h + \frac{1}{5} \kappa^h_{TT} T_h^2 - \frac{S_h}{\tau^h_{rS}} - \frac{S_h}{\tau^h_{nrS}} - \kappa^h_{ST} T_h S_h - \kappa^h_{SP}(n_h + p_h) S_h - \frac{\kappa^h_{SS}}{2} S_h^2 - \nabla\left(\tilde{D}^h_S \nabla S_h \right) = 0, \tag{11.2}$$

$$\frac{3}{4} U^r_{p_g n_g} + K^{h\to g}_{DET:T} T_h - K^{g\to h}_{DET:T} T_g + k^g_{\mathrm{ISC}} S_g - \frac{T_g}{\tau^g_{rT}} - \frac{T_g}{\tau^g_{nrT}} - \kappa^g_{TP}(n_g + p_g) T_g - \kappa^g_{TT} T_g^2 - \nabla\left(\tilde{D}^g_T \nabla T_g \right) = 0, \tag{11.3}$$

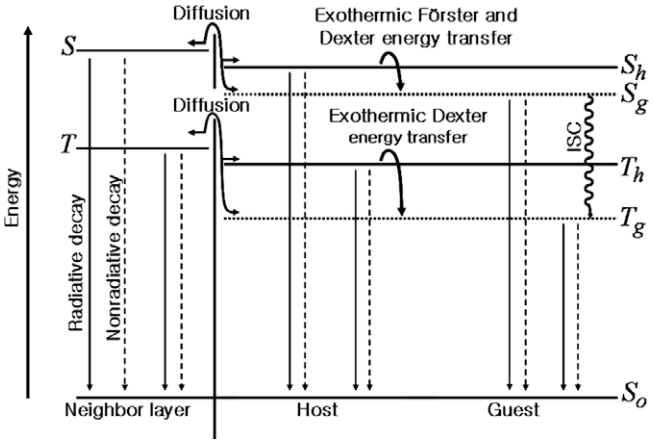

Fig. 2. Proposed excitonic emission mechanism in undoped and doped layers.

$$\frac{1}{4}U^r_{p_g n_g} + K^{h\to g}_{FET}S_h - K^{g\to h}_{FET}S_g + K^{h\to g}_{DET:S}S_h - K^{g\to h}_{DET:S}S_g - k^g_{ISC}S_g + \frac{1}{5}\kappa^g_{TT}T^2_g - \frac{S_g}{\tau^g_{rS}} - \frac{S_g}{\tau^g_{nrS}} - \kappa^g_{ST}T_gS_g - \kappa^g_{SP}(n_g + p_g)S_g - \frac{\kappa^g_{SS}}{2}S^2_g - \nabla\left(\tilde{D}^g_S\nabla S_g\right) = 0, \quad (11.4)$$

where K is energy transfer rate, k is decay rate, κ is annihilation or quenching rate, τ is exciton lifetime, $\tilde{D}$ is exciton diffusion constant. *FET*, *DET*:*S*, and*DET*:*T* denote Förster energy transfer, Dexter energy transfer for singlet and triplet, respectively.

In doped layer, the exciton diffusion constant is assumed to be changed by doping ratio-dependent hopping distance [14], and therefore, modified by multiplying exp[2(1 − d/d_o)]. As the exciton energy can be transferred to adjacent layers by an energy transfer mechanism, we assume that the exciton diffuses to the adjacent layers with the probability expressed as Boltzmann factor, exp(−$\Delta E/k_BT$), where ΔE is the difference of exciton energy between two layers. The average exciton diffusion constant at the interface is obtained by multiplying the probability.

In Eqs. (11.1)–(11.4), Förster energy transfer rate from host singlet to guest singlet is given by [18]

$$K^{h\to g}_{FET} = \frac{1}{\tau^h_{rS}}\left(\frac{R_F}{R}\right)^6, \quad (12)$$

where τ^h_{rS} is radiative lifetime of host singlet, R is average separation distance between host and guest sites, and R_F is Förster radius.

Dexter energy transfer is regarded as a purely quantum-mechanical effect, therefore, does not have a classical analogy [18,19]. We relate Dexter energy transfer rates from host singlet (or triplet) to guest singlet (or triplet) to the lifetime of exciton, the average separation distance of host and guest sites (R), effective Bohr radius (R_B), and Dexter radius (R_D) as the following rate model:

$$K^{h\to g}_{DET:S} = \frac{10^3}{\tau^h_{tS}}\exp\left[\frac{2(R_D - R)}{R_B}\right], \quad (13.1)$$

$$K^{h\to g}_{DET:T} = \frac{10^3}{\tau^h_{tT}}\exp\left[\frac{2(R_D - R)}{R_B}\right], \quad (13.2)$$

where τ_t is total lifetime ($\tau_t^{-1} = \tau_r^{-1} + \tau_{nr}^{-1}$). R_B is $0.053(\varepsilon^h_r + \varepsilon^g_r)/2$ nm, and R_D is a critical distance at which energy transfer rate reaches maximum (3 orders of magnitude higher than the other decay rates) when Dexter radius is same as the separation distance of host and guest sites.

Finally, the singlet and the triplet densities of host (or guest) are calculated by using Eq. (11), and then the luminance from guest singlet and triplet can be obtained as follows [3]:

$$L^S_g = \frac{1}{\varepsilon_r}k_m h\nu\frac{1}{\pi}\sum\frac{S_g}{\tau_{rS}}d_o, \quad (14.1)$$

$$L^T_g = \frac{1}{\varepsilon_r}k_m h\nu\frac{1}{\pi}\sum\frac{T_g}{\tau_{rT}}d_o, \quad (14.2)$$

where k_m is constant for daylight-adopted human eye (k_m = 683 lm/W), $h\nu$ is the energy of the emitted photons.

3. Experiments

In order to verify the proposed electronic and excitonic emission models, a series of green-emitting phosphorescent OLEDs were prepared by varying doping concentration of tris(2-phenylpyridine) iridium ($Ir(ppy)_3$) from 1% to 15%. The green phosphorescent devices (4 mm^2 active area) were fabricated with the configurations of ITO (150 nm)/DNTPD (60 nm)/NPB (30 nm)/CBP:$Ir(ppy)_3$ (30 nm)/BCP (5 nm)/Alq_3 (20 nm)/LiF (1 nm)/Al (200 nm), where ITO, DNTPD, NPB, CBP, BCP and Alq_3 are indium tin oxide, *N*,*N*′-diphenyl-*N*,*N*′-bis-[4-(phenyl-*m*-tolyl-amino)-phenyl]-biphenyl-s′4-diamine, *N*,*N*′-di(1-naphtyl)-*N*,*N*′-diphenylbenzidine, 4,4′-bis(*N*-carbazolyl)-1,1′-biphenyl, 2,9-dimethyl-4,7-diphenyl-phenanthroline and tris(8-hyroxyquinloine) aluminum, respectively. $Ir(ppy)_3$ was doped in CBP with the ratio of 1%, 5%, 10% and 15% and the thickness of CBP:$Ir(ppy)_3$ was maintained constant (30 nm). ITO glass substrates with a sheet resistance of 10 Ω/sq were cleaned successively with acetone and isopropyl alcohol in an ultrasonic bath for 10 min and dried at 120 °C for 2 h before set in a vacuum evaporator (~10^{-4} Pa). DNTPD, NPB, EML, and Alq_3 were thermally deposited at a rate of 1.0 Å/s. The deposition rate of $Ir(ppy)_3$ was adjusted according to the doping ratio (1%, 5%, 10% and 15%). After

deposition of organic materials, LiF and Al were successively deposited at a deposition rate of 0.1 Å/s and 2.0 Å/s, respectively. The *J–V–L* characteristics of the devices were measured with Keithley 236 source measurement unit and PR650 Spectrascan® colorimeter (Photoresearch, Inc.) at room temperature.

4. Input parameters

For the calculation of electronic and excitonic emission properties, many kinds of input parameters are required. The material properties used in the simulation are listed in Table 1, where the experimentally-obtained and theoretically-calculated data are highlighted by underline and double underline, respectively. As many different values of HOMO and LUMO for a material are shown in several articles [28–30] and there is little information of *S*, *T* energy in published articles, we theoretically-calculated those parameters using quantum-mechanical methods. The calculation processes are: firstly, all reported molecular structure was optimized at a DND/GGA(P91) level of theory using Dmol3 module (Material Studio, Accelrys software) and secondly, time-dependent density functional theory calculation was performed at a B3LYP/6-31G* level of theory using the Gaussian03 code to obtain the data of HOMO, LUMO, *S* and *T* energy. Most of carrier mobility are extracted from the published experimental results [31–33]. It is assumed that $100\mu_{n_NPB} = \mu_{p_NPB}$, $\mu_{DNTPD} = \mu_{NPB}$, $\mu_{BCP} = 100\mu_{Alq_3}$ (the electron mobility of BCP is reported to be at least an order of magnitude higher than that of Alq_3 [34]). Considering low mobility of Ir complex, we use $\mu_n = \mu_p = 10^{-7}\exp(10^{-3}\sqrt{F})$ for the mobility of $Ir(ppy)_3$ [35].

As there is also little information for exciton lifetime and diffusivity except those for $Ir(ppy)_3$ and CBP [17,29], we set the properties of materials as follows: (1) $\tau^S_r = 10^{-9}$ s, $\tau^S_{nr} = 10^{-7}$ s for CBP and $Ir(ppy)_3$ and $\tau^S_r = 10^{-7}$ s, $\tau^S_{nr} = 10^{-9}$ s for the other materials, (2) $\tau^T_r = 10^{-4}$ s, $\tau^T_{nr} = 10^{-6}$ s for non-phosphorescent materials and $\tau^T_r = 10^{-6}$ s, $\tau^T_{nr} = 10^{-4}$ s for $Ir(ppy)_3$, (3) $\widetilde{D}_S = 10^{-4}(cm^2/s)$ and $\widetilde{D}_T = 5 \times 10^{-6}(cm^2/s)$ for all materials, which implies that the diffusion lengths are 3 nm and 22 nm for singlet and triplet, respectively. (4) $k_{ISC} = 10^{-11}\ s^{-1}$ for metal complex material ($Ir(ppy)_3$) in order to apply strong spin–orbit coupling. The rates of polaron quenching and exciton annihilation are extracted by fitting the simulations to experimental results. For the other parameters such as trap information, injection barrier heights, etc., we use the common values as shown in Table 2. As LiF can be regarded as a barrier for electron injection from cathode, its contribution is included in ϕ_n (for the calculation of luminance (Eq. (14)), ITO and Al are assumed to be completely transparent and reflective, respectively).

Table 2
Common material parameters.

Parameter	Value
$N_{tp} = N_{tn}$	$1.0 \times 10^{18}\ cm^{-3}$
$E_{tp} = E_{tn}$	0.2 eV
ϵ_r	3
n_i	$1.0 \times 10^{11}\ cm^{-3}$
$\phi_p = \phi_n$	0.3 eV
V_{bi}	4.7 V
R_F	3.2 nm
R_D	1.12 nm

5. Results and discussion

Understanding distributions of charge carrier densities and recombination rates (or exciton densities) makes physical interpretation of the different behaviors of devices possible. Fig. 3 shows the simulated spatial distributions of electron and hole densities and recombination rates in the devices doped with 1% and 15% $Ir(ppy)_3$ at an applied voltage (9 V) (the zero position is anode). The carriers injected from the electrodes move along with different mobility in each layer and pile up at the interface between layers or penetrate into the adjacent layers. The simulation results show that (1) electrons and holes are abundant at both edges of EML, where the recombination rate is highest, (2) inside EML, the density of electrons and holes in host are higher than that in guest due to the high DOS of host, and consequently, recombination occurs mainly in host, and (3) as the concentration of $Ir(ppy)_3$ in EML is increased, the density of electrons and holes in guest is increased and therefore, the recombination in guest is increased.

The calculated *J–V* curves for the devices doped with 1%, 5%, 10%, and 15% of $Ir(ppy)_3$ are compared with experimentally-obtained ones in Fig. 4, which shows that the theoretical *J–V* curves are reasonably in good agreement with experimental ones. There is little difference in *J–V* characteristics of the devices with various

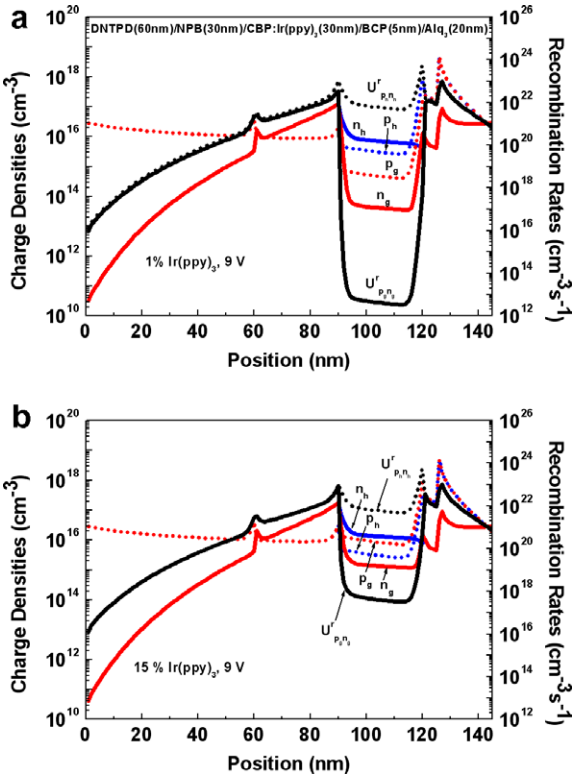

Fig. 3. Spatial distributions of the carrier densities and recombination rates of the device doped with $Ir(ppy)_3$: (a) 1% and (b) 15%.

doping concentrations, even though the real devices show relatively large variations compared with the simulated results. The similar *J–V* characteristics irrespective of doping concentration is assumed to be because most of voltage is dropped in Alq_3 layer due to the very low mobility of Alq_3 (see Table 1) and the thickness of EML is too thin (30 nm) to affect the total current of the device. Consequently, overall current density is not significantly affected by the mobility change of host and/or guest material as shown in Eq. (2) (the variations in the *J–V* curves of the real devices could be ascribed to the experimental deviations resulted from the parameters such as trap density, built-in potential, effective barrier height at EML interface, trap activation energy, etc. [36]).

As described in Eq. (14), luminance is related to exciton densities per radiative lifetime (i.e. emission rate). The simulated spatial distributions of the recombination and emission rates of the device doped with 1% and 15% $Ir(ppy)_3$ are shown in Fig. 5. The emission rates are very low in all layers except EML, which can be ascribed to fast nonradiative decay, low charge confinement, and charge unbalance in the layers. In EML, the recombination rate in host is much higher than that in guest, however, the emission from guest triplet is dominant. This is because: (1) the singlet and triple emission in host are reduced by Förster and Dexter energy transfers and nonradiative decay, and (2) the guest singlet emission is suppressed by the decay through ISC. Increase of $Ir(ppy)_3$ concentration in EML results in increase of guest emission rate, which could be simply ascribed to increase of recombination in guest. However, considering that the singlet and triplet emission rates of host are largely decreased at 15% of $Ir(ppy)_3$, the high guest emission rate at high $Ir(ppy)_3$ concentration is assumed to be due to the increase of energy transfer from host. The triplet emission is more broadly distributed in EML due to long diffusion length of triplet, and is sharply decreased at both end of EML due to exciton diffusion (triplet energy of $Ir(ppy)_3$ is 0.172 eV higher than NPB and only 0.077 eV lower than BCP as shown in Table 1).

From the fitting process of energy transfer radius (Fig. 6a), we obtain R_D = 1.12 nm for 5% $Ir(ppy)_3$:CBP device

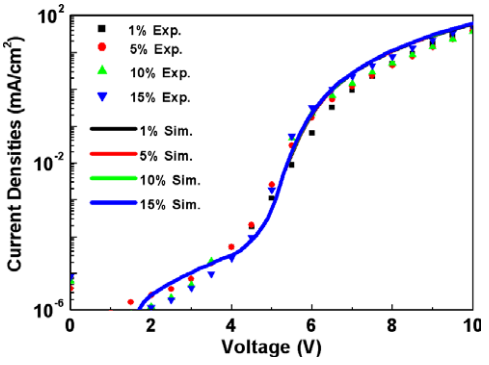

Fig. 4. Experimental and calculated current densities with voltage for the devices doped with 1%, 5%, 10%, and 15% of $Ir(ppy)_3$.

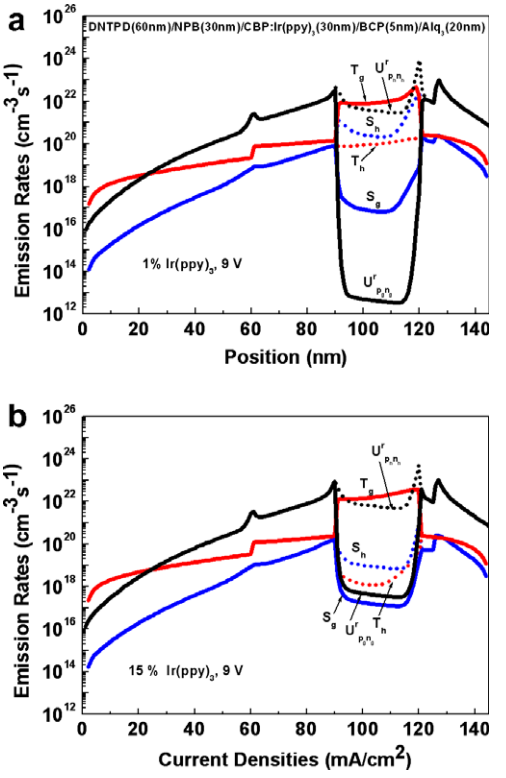

Fig. 5. Spatial distributions of the recombination and emission rates of the device doped with $Ir(ppy)_3$: (a) 1% and (b) 15%.

at a fixed value of R_F (3.2 nm [37]) (the current efficiency–current density curve at R_D = 1.12 nm is not fitted well in high current density region because exciton quenching or annihilation is not considered yet. The curve fitting in high current density region will be discussed later). Fig. 6b shows the doping concentration dependencies of energy transfer rate ratio ($K \cdot \tau$) for various Förster and Dexter radius, which is obtained by using the energy transfer rate equations (Eq. (12) and (13)). In Fig. 6b, $K \cdot \tau = 10$ implies that the energy transfer rate is 10 times higher than radiative or nonradiative decay rates. For example, Förster (at R_F = 3.2 nm) and Dexter (at R_D = 1.12 nm) energy transfers occur fast enough at over 2.5% and 9% doping concentration, respectively. The average separation distance of host and guest sites (R) can be obtained from the analytic form $R = 2.6603(100c)^{-0.25}$ nm for Förster energy transfer (which is extracted from the exact distances for the several doping concentration under the condition of crystal structure with the hopping distance of d_o = 1 nm) and $R = 1.7136\exp(-1.53c)$ nm for Dexter energy transfer (which is modified in order to avoid overestimation (underestimation) for smaller (larger) R than R_D in the simple Perrin model [38]).

In Fig. 7a, the current efficiency data simulated at R_F = 3.2 nm and R_D = 1.12 nm are compared with experimental results for all doping concentrations (1%, 5%, 10%, and 15%). The simulated results are in good agreement with experimental ones in low current density region. Overall, the current efficiency is increased with doping concentration, which is due to increase of energy transfer. The reason for higher current efficiency at 10% $Ir(ppy)_3$ than at 15% $Ir(ppy)_3$ is assumed to be because: (1) Förster and Dexter energy transfers sufficiently occur at over 9% $Ir(ppy)_3$ as shown in Fig. 6b, (2) host recombination rate decreases as guest concentration increases due to the reduction of host DOS, and (3) exciton blocking decreases as guest concentration increases due to the increase of guest exciton diffusivity as described in Eq. (11). In high current density region, there is typical efficiency roll-off

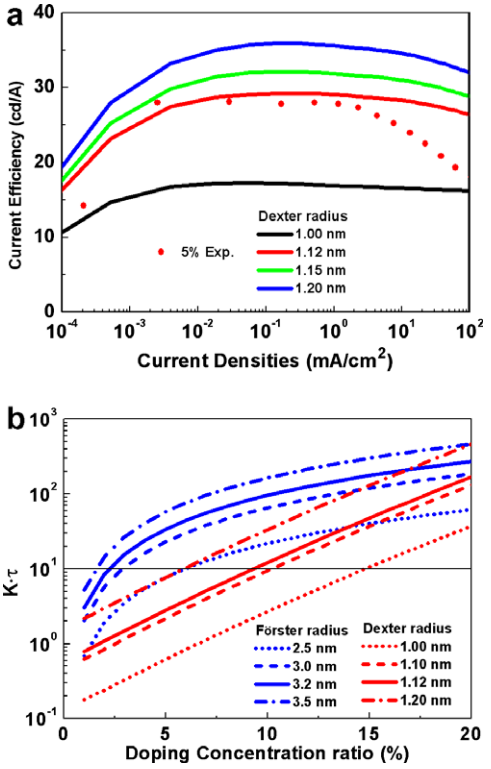

Fig. 6. (a) Dexter radius dependency of current efficiency for the device with 5% $Ir(ppy)_3$. (b) Doping concentration dependency of the energy transfer rate ratio ($K \cdot \tau$) for various Förster and Dexter radius. The horizontal solid line is $K \cdot \tau = 10$.

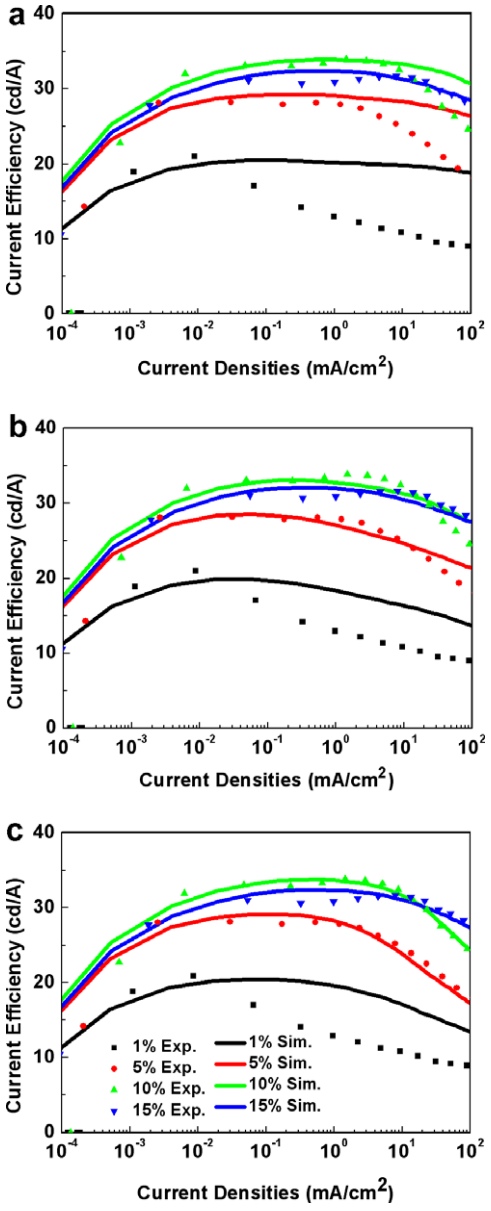

Fig. 7. Comparison of experimental and calculated current efficiency as a function of current density under the condition of (a) no quenching or annihilation, (b) host triplet–polaron quenching ($\kappa_{TP}^h = 3\times 10^{-11}$ cm^3 s^{-1}), and (c) host triple–triplet annihilation ($\kappa_{TT}^h = 2\times 10^{-9}$ cm^3 s^{-1}) for the devices doped with 1%, 5%, 10%, and 15% $Ir(ppy)_3$.

irrespective of doping concentration. Interestingly, the roll-off starting points of experimental curves are shifted to higher current density with increasing doping concentration and the roll-off slope becomes gentle at 15% Ir(ppy)$_3$, which consequently brings about the reversion of current efficiency between 10% and 15% at over 20 mA cm^{-2}. Such tendency of current efficiency roll-off can be fitted by considering polaron quenching or exciton annihilation, which is supposed to mainly occur in host sites because host recombination decreases as the doping concentration increase. The gentle roll-off at 15% Ir(ppy)$_3$ is assumed to be due to higher energy transfer rate compared with other decay rates (radiative, nonradiative, and annihilation decays). When the host *T*–*P* quenching ($\kappa^h_{TP} = 3 \times 10^{-11}$ cm^3 s^{-1}) is included to calculation, the current efficiency roll-off becomes too gentle to fit experimental results and the current efficiency reversion between 10% and 15% Ir(ppy)$_3$ is not expected as shown in Fig. 7b. This implies that polaron quenching is not the main reason for the current efficiency roll-off. When host *T*–*T* annihilation ($\kappa^h_{TT} = 2 \times 10^{-9}$ cm^3 s^{-1}) is considered, the steep roll-off and the current efficiency reversion are successfully realized except 1% Ir(ppy)$_3$ as shown in Fig. 7c. For 1% Ir(ppy)$_3$, it seems that the current efficiency roll-off cannot be obtained using common annihilation parameters, which is assumed to be because host emission (which generally shows low quantum efficiency) occurs significantly in high current density region due to very low DOS of 1% guest. Fig. 8 shows that emission at 460 nm is increased as the current density is increased, supporting that the steep efficiency roll-off at 1% Ir(ppy)$_3$ is ascribed to host emission.

In Fig. 9, several approaches to obtain high current efficiency are presented. Firstly, when the radiative lifetime of guest triplet is set to be reduced by 1 order (from 10^{-6} to 10^{-7} s), the shorten diffusion length (7.1 nm) leads to the increase of maximum current efficiency by more than 1.3 times compared with experimental result (case I). This implies that the use of the material with short triplet lifetime could be an efficient way to improve device efficiency. Meanwhile, there is no change in the roll-off tendency irrespective of the lifetime of guest, which is because *T*–*T* annihilation occurs mainly in host site (if the origin of *T*–*T* annihilation were guest site, the current efficiency roll-off

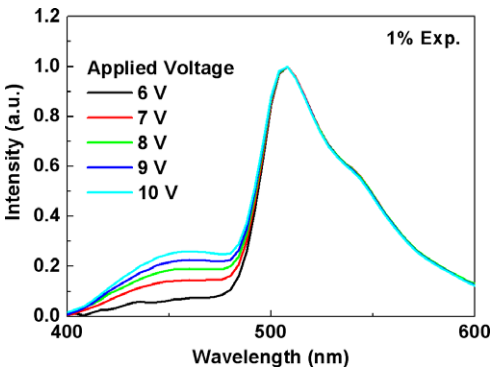

Fig. 8. Electroluminescence spectra for the device doped with 1% Ir(ppy)$_3$ according to voltage.

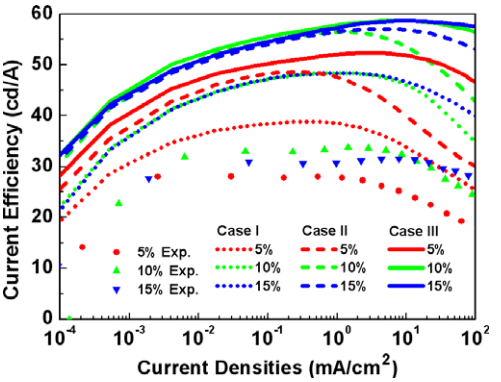

Fig. 9. Current efficiency as a function of current density, simulated under the condition of case I (1 order reduction of radiative lifetime of guest triplet), case II (reduction of *S* and *T* wavelength in HTL and ETL (λ_S = 350 nm, λ_T = 400 nm)), and case III (1 order reduction of radiative and nonradiative lifetime of host triplet) for the devices doped with 5%, 10%, and 15% Ir(ppy)$_3$.

should be gentle). Secondly, when the singlet and triplet wavelength in HTL and ETL are reduced (λ_S = 350 nm and λ_T = 400 nm), the maximum current efficiency is calculated to be about 1.8 times higher compared with experimental result (case II), which implies that hole transporting and/or electron transporting materials with high singlet and/or triplet energy could block exciton diffusion at the end of EML, consequently, increasing current efficiency. Finally, the current efficiency roll-off in high current region is improved by one order-reducing radiative and nonradiative lifetime of host triplet ($\tau^T_r = 10^{-5}$ s $\cdot$ $\tau^T_{nr} = 10^{-7}$ s), i.e. increase of energy transfer results in reduction of *T*–*T* annihilation in host [see Eq. (13)] (case III).

6. Summary

We propose electronic and excitonic emission models for organic light emitting devices comprising a host–guest system in emission layer. The basic electronic model contains thermionic injection at the electrodes, charge transport, and Langevin's recombination. Especially, charge transport mechanisms in organic host–guest systems are described as (1) hopping through the transport sites of host and guest with field- and doping-dependent mobility, (2) trapping between host (or guest) transport and trap sites, and (3) trapping between host and guest transport sites. Then, the spatial distribution of carriers, current density, and local recombination rates in host and guest sites is obtained from self-consistent calculation using Poisson's, current continuity, and current equations. The excitonic emission model includes (1) radiative and nonradiative decay, (2) exciton diffusion by exciton energy difference between materials, (3) singlet–triplet intersystem crossing, (4) Förster energy transfer between host singlet and guest singlet, (5) Dexter energy transfers between host singlet and guest singlet, or host triplet and guest triplet, (6) singlet–singlet, singlet–triplet, and triplet–triplet annihilation, (7) singlet–polaron and triplet–polaron quenching. Then, the spatial distributions of exciton and luminance

are obtained from the calculation of exciton rate equations and the summation of emission rate in EML, respectively.

In order to verify the proposed electronic and excitonic emission models, the simulated results are compared with experimental data of a series of phosphorescent (Ir(p-py)$_3$:CBP) organic electroluminescent devices with various doping concentration. When Förster and Dexter radius is set to be 3.2 nm and 1.12 nm, respectively, the simulated current density–current efficiency curves are in good agreement with experimental data for various doping concentration (5%, 10%, 15%), proving the validity of our model. It is also numerically demonstrated that (1) efficiency roll-off in high current density region is resulted from triplet–triplet annihilation (dominant) and triplet–polaron quenching, (2) exciton confinement in emission layer by controlling lifetime, diffusion constant and energy of exciton is important to improve device efficiency, (3) it is necessary to maximize energy transfer and intersystem-crossing in order to increase current efficiency. Finally, it is concluded from these results that the proposed models can be powerful simulation tools to analyze experimental data and design optimized device structures.

ABSTRACT

We report on the effect of the deposition of self-assembled monolayers (SAMs) on the source and drain electrodes on the contact resistance and mobility in organic thin film transistors (OTFTs). Ultraviolet photoelectron spectroscopy (UPS) shows a variation of the work function of the electrodes depending on the SAM. OTFTs were fabricated with solution processible Polyera ActivInk™ N1400, TIPS-pentacene and TFB, giving access to both polarities of transistors and to both crystalline and amorphous materials. The transfer line method (TLM) was used to separately estimate the contact resistance and mobility. A clear correlation is found between the work function of the modified electrodes and the corresponding contact resistance. The effect on mobility is more puzzling, and tentatively attributed to morphological effects.

1. Introduction

During the last decade, the development of new organic materials with enhanced electrical properties and ease of processing have led to organic field-effect transistors (OTFTs) with higher electrical performance [1–5]. More and more works report on mobility higher than 1 $cm^2/V\,s$ for both n- and p-channel OTFTs.

With the emergence of more robust materials, processible from solution, and with higher electrical properties, reduction of the transistor channel length is becoming one of the major challenges for the future years. Smaller transistors would help in designing circuits with higher working frequencies [6].

As performance is improving and channel length is decreasing, charge injection at source and drain electrodes is becoming the major impediment to further improvements [7–10]. For practical reasons, the vast majority of OTFT have contact electrodes made of gold. The high work function of atomically clean gold (5.2 ± 0.2 eV) matches most of the p-channel organic semiconductors Highest Occupied Molecular Orbital (HOMO) energy level [11–13]. For n-channel OTFTs however, a lower work function electrode is required to optimize electron injection in the Lowest Unoccupied Molecular Orbital (LUMO).

Some works have been reported on transistors fabricated using low WF metals such as calcium [14,15]. However, low WF metals tends to oxidize very quickly in ambient atmosphere. Process under high vacuum is needed for the fabrication and the characterization of such devices. For the fabrication of organic circuits, the use of the same metal is preferred to reduce the number of fabrication step.

An elegant way for tuning the work function of gold is the use of self-assembled monolayers (SAM) [16–22]. Since the first report by Campbell and coworkers [16], several works have been reported, mostly on p-channel OTFTs.

Yet, the effect of modifying gold with SAM on electrical performance of OTFTs is still controversial. Several works have attributed the improvement resulting from a modification of the source and drain electrodes by SAMs to a morphological effect [22,23]. However, more recent results tend to indicate that the mechanism of barrier height reduction described by Campbell may also lead to a modulation of the contact resistance in transistors.

In this paper, we investigate the effect of various SAMs on both n- and p-channel OTFTs, including polycrystalline and amorphous semiconductors. Ultraviolet photoelectron spectroscopy (UPS) is used to validate the concept in terms of work function of the modified gold electrodes. Transistors are then fabricated and characterized with various SAMs. The transfer line method (TLM) [19–21] is used to investigate and separate the effect of the SAMs on both the contact resistance and mobility. Results show that the contact resistance varies with the electrode work function (WF) and in agreement with the UPS data. Variations in the charge carrier mobility in the case of polycrystalline semiconductor are attributed to morphological effects, which are investigated by atomic force microscopy (AFM).

2. Experimental

2.1. Samples for SAMs characterization

Substrates were prepared by evaporating 200 nm of Au on Si, rinsing in acetone under nitrogen atmosphere and heating at 120 °C for 2 min. 4-Methyl(sulfanyl)thiophenol (MeSTP), 4-methoxythiophenol (MeOTP), 4-methylthiophenol (MeTP), 4-aminothiophenol (ATP), 4-nitrothiophenol (NOTP), cysteamine (CT), 1-decanethiol (DT), 1H,1H,2H,2H-perfluorooctanethiol (PFOT), and 1H,1H,2H,2H-perfluorodecanethiol (PFDT) were bought from Sigma–Aldrich. One millimolar solutions in ethanol were prepared, in which samples were immersed at room temperature for a period of 5 h. They were then rinsed thoroughly with pure ethanol and dried in a N_2 gas stream before being transferred into the vacuum system.

2.2. UPS

Measurements were performed in ultra-high vacuum (base pressure 10^{-10} Torr) using both He I and He II lines (21.22 and 40.81 eV, respectively) from a He discharge lamp. The photon flux was kept low to prevent photon-induced sample damage. The energy resolution was 0.15 eV.

2.3. Transistor fabrication and characterization

Polyethylene naphthalate (PEN) films were used as flexible substrates (Fig. 1). Thirty nanometer thick Au source and drain electrodes were deposited by plasma vapour deposition and patterned by photolithography. Transistors with a width of 1 cm and channel length of 5, 10, 20, 40, and 100 μm were fabricated.

Self-assembled monolayers were deposited the same way as for UPS and contact angle samples. For n-channel transistors, a *N,N*-dialkylsubstituted-(1,7&1,6)-dicyanoperylene-3,4:9,10-bis(dicarboximide) derivative (Polyera ActivInk™ N1400) bought from Polyera Corporation was diluted in 1,2-dichloro-benzene at a concentration of 8 mg mL^{-1} and spin-coated at 1200 revolutions per minute (rpm). For p-channel transistors, poly[9,9-dioctyl-fluorene-

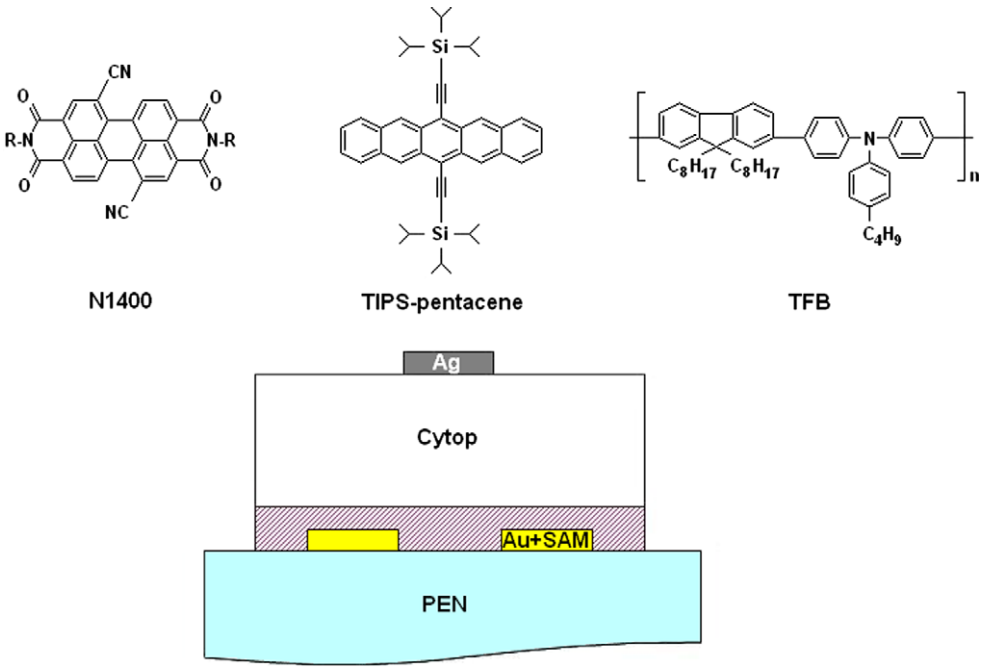

Fig. 1. Formula of the different semiconductor used in the study, and schematic of the fabricated devices.

co-*N*-(4-butylphenyl)-diphenylamine] (TFB) and 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) were used as the active layer at a concentration of 16 and 12 mg mL^{-1} in mesythylene and toluene, respectively. Solutions were spin-coated at 1000 rpm. In all cases, the semiconductor films were cured for the three materials at a temperature of 115 °C for 5 min to eliminate the solvent. For all the spin-coating steps of the process, the plastic substrates were mounted on a silicon wafer using a drop of ethanol.

Cytop™ dielectric was then spin-coated on top of the semiconductor and cured at 100 °C for 20 min. The thickness of the layer was measured with a profilometer around 1.2 μm. To promote adhesion of the gate electrode on the highly hydrophobic insulating layer, solution of Nafion diluted at 30 mg mL^{-1} in isopropanol was spin-coated at 1000 rpm. Finally an Ag ink gate electrode was printed by ink-jet using a Dimatix set up.

Electrical measurements were performed at room temperature in air by using a parameter analyser (HP4145, Hewlett-Packard). Morphological characterization was carried out with an Innova AFM operating in the intermittent contact mode on samples specifically prepared for that purpose. The substrates consisted of PEN and patterned gold electrodes with the different SAMs that were prepared exactly the same way as for the transistors and on top of which the semiconductor was spin-coated.

2.4. Electrical parameters extraction

The transfer characteristic in the linear regime (V_D = 1 V for Polyera ActivInk™ N1400, V_D = 5 V for TIPS-pentacene, and V_D = 10 V for TFB) was measured on devices with various channel length (L = 5, 10, 20, 40, and 100 μm) prepared in the same run. From these characteristics, the threshold voltage was first extracted from the peak of the second derivative of the gate voltage dependent drain current, as described previously [21]. The next step consisted of calculating the width corrected total resistance as a function of $V_G - V_T$. According to the TLM, this resistance can be decomposed into the contact resistance R_C in series with the channel resistance. A representative example of the channel length dependent resistance for various values of $V_G - V_T$ is shown in Fig. 2. The contact resistance corresponds to the extrapolation of the straight line to zero channel length.

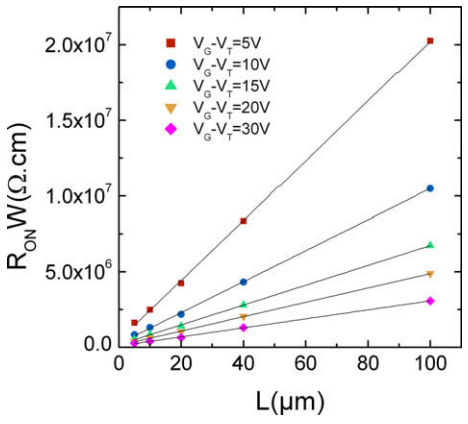

Fig. 2. Representative example of width normalized resistance versus channel length curves. The resistance is computed from the transfer characteristic at a drain voltage of 1 V.

3. Results

3.1. SAMs characterization

Fig. 3 gives the chemical structure of the different molecules used for the SAMs. To understand the effects of the different SAMs on transistors performance, we characterized them by UPS and contact angle measurements.

The UPS spectra of three representative samples are shown in Fig. 4. The work function, defined as the energy difference between the vacuum level (E_{vac}) of the film and the Fermi level (E_F), was determined from the secondary electron cut-off energy. The WF of the bare Au reference was 4.75 eV, which is a standard value for an Au surface exposed to the ambient. The WF of the SAM-modified Au was found to range from 4.18 to 5.44 eV. For example, the WF of the Au modified by PFDT SAM was measured at 5.44 eV, in good agreement with previous results [20], and 0.69 eV higher than that of bare Au. On the other hand, the work function of gold modified with MeTP was 4.28 eV, 0.47 eV lower than that of Au.

The contact angle with water (Table 1) is an indication of surface energy, and in turn depends on the nature of the terminal group of the SAM. We first note that the contact angle is smaller for the thiophenol molecules than for the corresponding alkanethiolate, which has been attributed to the polar nature of the phenol adsorbate [24]. The effect of the terminal group on the contact angle allows us to classify their impact on surface energy as follows (listed in order of decreasing surface energy): $NH_2 = NO_2 > OCH_3 > SCH_3 > CH_3 > CF_3$. We finally note that the very low contact angle found with cysteamine can be attributed to a poorly organized layer, due to the very short alkyl chain and the resulting low interchain coupling.

3.2. N-channel polycrystalline OTFTs

For each semiconductor, transistors were fabricated with various electrodes and channel lengths. We first report the results on n-channel transistors. Fig. 5 gives the transfer characteristic of some of the devices.

For long channel transistors, the devices with PFDT exhibit the largest ON current and the highest mobility, as shown in Fig. 5b. Interestingly, the transistors fabricated with hydrophobic DT and PFOT also exhibit a larger mobility than others. When the channel length decreases down to 5 μm, the transistors with PFDT deliver the lowest current, which can be attributed to a high contact resistance. Similarly, the low WF of the gold + MeOTP system can be associated with the corresponding high current at short channel length. We also note that electrodes made of bare gold and gold + CT, which show almost the same WF, yield very similar transfer characteristics.

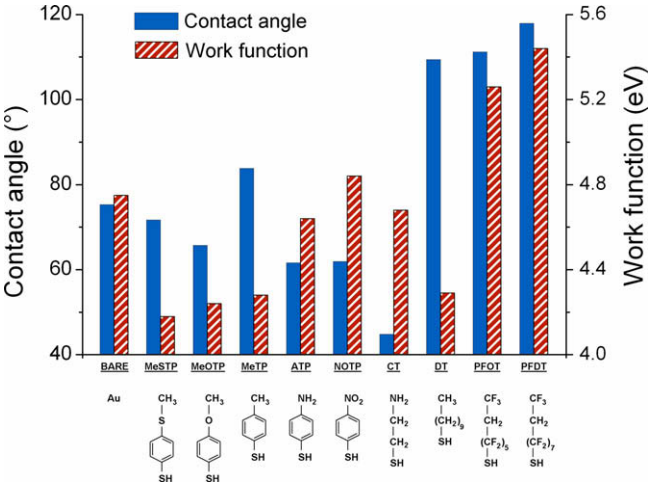

Fig. 3. Molecules used in the SAMs and corresponding Au/SAM work function measured by UPS and contact angle measured with water. Name of the molecule from left to right: 4-(methylsulfanyl)-thiophenol (MeSTP), 4-methoxythiophenol (MeOTP), 4-methylthiophenol (MeTP), 4-aminothiophenol (ATP), 4-nitrothiophenol (NOTP), cysteamine (CT), 1-decanethiol (DT), 1H,1H,2H,2H-perfluorodecanethiol (PFDT), 1H,1H,2H,2H-perfluorooctanethiol (PFOT).

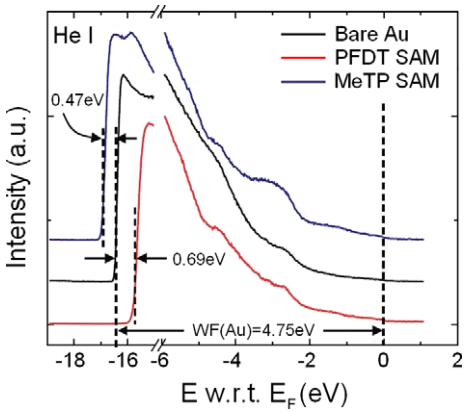

Fig. 4. He I UPS spectra of the bare Au substrate and of the PFDT and MeTP SAMs on Au samples.

The main electrical parameters of each device are listed in Table 1. For short channel, the high work function electrodes PFDT, PFOT and NOTP produce transistors with low effective mobility.

We also shown in Fig. 6 the output characteristics for source/drain electrodes modified with MeTP and PFOT. It has been reported [25,26] that transistors suffering from very high contact resistance present some non-linearity at the origin of the I_D–V_D curves. Interestingly, Polyera ActivInk N1400™ does not seem to give rise to such non-linearity.

We estimated the contact resistance R_C with the transfer line method (TLM) as described in the Section 2. Because none of the devices was affected by non-linearity at the origin, we were able to work with drain voltages as low as 1 V. For each SAM, eight transistors of each length were fabricated and characterized. The contact resistance and mobility are reported in Fig. 5. We note that R_C varies linearly with $1/(V_G - V_T)$, which is a

common feature in transistors with staggered configuration [27].

The extracted contact resistance nicely matches the WF of the corresponding electrodes. The LUMO of Polyera ActivInk™ N1400 is given by the supplier at around 4.3 eV. Electrodes with DT, MeTP, MeOTP and MeSTP have respective WF equal to 4.29, 4.28, 4.24, and 4.19 eV, respectively, which adequately match the LUMO

level. It is therefore not surprising that they offer the lowest contact resistance. Electrodes made of bare gold, gold + CT and gold + ATP have similar WF and exhibit almost the same contact resistance. Finally, the higher WF of gold + NOTP, gold + PFOT and gold + PFDT leads to devices with the highest contact resistance.

Interestingly, transistors fabricated with highly hydrophobic SAMs exhibit higher mobility when corrected for the contact resistance. This was already reported [28] and was attributed to morphological effects. We carried out AFM and optical polarized microscope imaging on the semiconductor films deposited on various SAMs. Representative pictures are given in Fig. 7.

Optical microscope images of films grown on gold + CT show a very small grain size. This can also be seen on the corresponding AFM picture. When the contact angle increase (from 45° for gold + CT to 84° for gold + MeTP), grains become larger, leading to an increase in mobility. The effect on the grain size is even more pronounced for very hydrophobic SAMs as shown in Fig. 7c for gold + PFOT (111°). The mobility corrected for the contact resistance for transistors made with DT, PFOT, and PFDT was found the highest among all the SAMs tested.

3.3. P-channel polycrystalline OTFTs

The effect of the SAMs on transistors made with the polycrystalline small molecule TIPS-pentacene are presented next. We limit ourselves to the most relevant SAMs. Table 2 reports the main electrical parameters for the different device fabricated.

Fig. 8 shows the output characteristics of transistors with the high WF PFOT (Fig. 8a), and low WF MeOTP (Fig. 8b). We note some non-linearity at the origin of the curves in the case of MeOTP. For this reason, TLM measurements were conducted at a drain voltage of 5 V.

The parameters extracted from TLM on TIPS-pentacene transistors are displayed in Table 2 and Fig. 9 Like for Polyera ActivInk™ N1400, the contact resistance and WF are closely correlated.

The mobility corrected for the contact resistance increases with the contact angle, the most hydrophilic surfaces corresponding to the highest mobility. A similar effect of surface energy on semiconductor morphology was already reported [29]. Optical microscope images of the semiconductor films are presented in Fig. 10. With hydrophilic surfaces, TIPS-pentacene forms very large grains offering the highest mobility when corrected for the contact resistance. When deposited on hydrophobic SAMs, the semiconductor adopts a very different morphology, which can account for the lower mobility. We finally note that, like for Polyera ActivInk™ N1400, the threshold voltage seems to be independent of the SAM.

3.4. P-channel amorphous OTFTs

Lastly, we investigated the influence of the SAMs on transistors made with amorphous TFB. As in the case of TIPS-pentacene, we limited the study to the most relevant SAMs. In Fig. 11, the output characteristics of transistors with two different SAMs are presented. The HOMO level of TFB was reported in the literature to be between 5.3 and 5.5 eV [30]. With high WF source and drain elec-

trodes, the onset of the characteristics is highly linear. However, with low work-function electrodes, the characteristics are affected by a significant non-linearity at the origin.

The transfer characteristics in the saturation regime ($V_D = 100$ V) and the corresponding square root of the drain current as a function of the gate voltage are given in Fig. 12.

The saturation mobility is computed from the slope of the curves in Fig. 12b as:

$$\mu_{SAT} = \frac{2 * \text{slope} * L}{W * \text{Cox}} \quad (1)$$

Interestingly, when the applied gate voltage is large enough, all the devices have similar mobility (curves on

Fig. 12b have similar slope). In the case of amorphous TFB, morphological effects are non-existent. The threshold voltage extracted in the saturation regime (using the linear extrapolation of the curves in Fig. 12b) is strongly affected by the WF of the source and drain electrodes. Table 3 sums up the main electrical parameters of the different devices.

Because of the large non-linearity observed in Fig. 11b, we conducted the TLM investigation at an applied drain voltage of 10 V to ensure that transistors were operating in the linear regime. Compare to polycrystalline materials, amorphous TFB presents a huge dependence of the contact resistance with the drain voltage. This is reflected by an increased of the threshold voltage with the contact resistance, and a more and more pronounced non-linearity at the origin of the output characteristics. At a drain voltage of 10 V, we found a linear dependence of the drain current with the gate voltage for each SAM ensuring the validity of the transfer line method. The contact resistance and mobility are drawn in Fig. 12c and d.

The evolution of the contact resistance is in agreement with the WF of the respective source and drain electrodes. The lower mobility found for low WF electrodes cannot be explained by morphological effects like in the case of the polycrystalline materials. Because of the very high threshold voltages and higher applied drain voltages (10 V), TLM results for low WF electrodes are given for a smaller range of $V_G - V_T$. Mobility in TFB semiconductor was previously reported to be highly gate voltage dependent [31,32]. Due to variation of the threshold voltage, the extracted mobility is lower.

4. Discussion

Charge injection at metal-organic semiconductor interfaces is mainly controlled by the alignment of energy level at both sides of the interface [12]. Using SAMs, it is possible to tune the barrier at the interface and thus tune the contact resistance. However, several studies have also attributed the improvement resulting from a modification of the source and drain electrodes by SAMs to a morphological effect [9,10,33].

Using the TLM method, we were able to separate the effect of the SAMs on mobility and contact resistance in both n-channel and p-channel polycrystalline OTFTs. Fig. 13 shows the variation of the contact resistance as a function

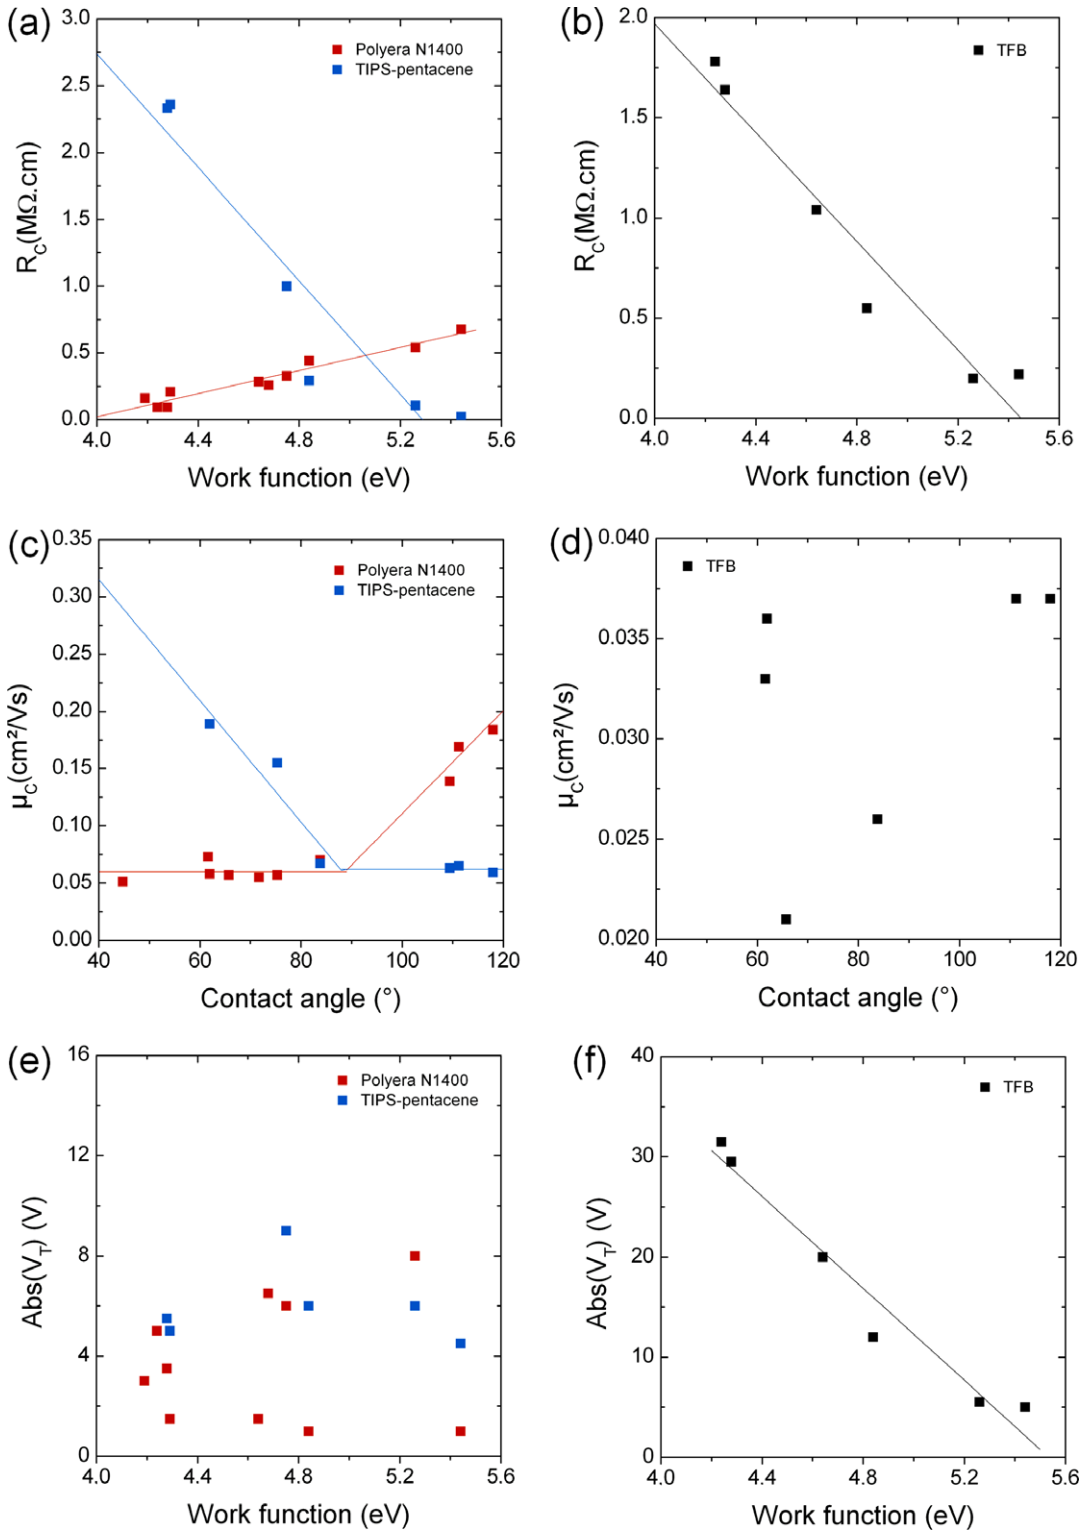

Fig. 13. (a and b): Contact resistance as a function of the work function of the modified electrodes for the different studied semiconductor. (c and d): Mobility corrected for the contact resistance as a function of the contact angle of the modified electrodes for the different studied semiconductor. (e and f): Threshold voltage as a function of the work function of the modified electrode for the different studied semiconductor. Experimental data are linearly fitted when relevant.

of the work function of source/drain electrodes. For both Polyera ActivInk N1400™ and TIPS-pentacene, the clear correlation between the two parameters presents strong evidence for the effect of the SAMs on the injection barrier height at the interface. A similar behaviour was found for amorphous TFB as already reported in the literature [34]. Of importance is the fact that the trend reverses when passing from the n-channel to the p-channel devices. That is, the contact resistance increases with the WF in the first case, while it decreases in the second one. These trends are in perfect agreement with an increase of the electron barrier in n-channel devices, and a reduction of the hole barrier in p-channel transistors.

The effect of the SAMs on the mobility is less clear and seems to largely depend on the nature of the semiconductor. Fig. 13 also reports on the variation of the mobility as a function of the contact angle. For TIPS-pentacene, the mobility is constant for contact angles lower than 90°, and linearly increases above this value. A similar behaviour has been reported for evaporated pentacene [29]. Surprisingly, a reverse trend is observed with Activink N1400, indicating that in this case, a more hydrophilic substrate yields a better morphological organisation in the semiconductor film. This unexplained discrepancy deserves further investigation. We finally note that the contact angle has practically no effect on the mobility of TFB, which can be attributed to the amorphous (isotropic) character of this compound. We also found a clear interdependence between the threshold voltage and the work function of the electrodes for the amorphous material (Fig. 13). In the case of the polycrystalline materials, we did not find any obvious dependence for the threshold voltage.

5. Conclusion

We have characterized a set of 10 SAM-modified source/drain electrodes and investigated the effect of the different SAMs on electrical performance of OTFTs. For the first time, the work was conducted on both n- and p-channel semiconductors. The use of TLM measurements allowed us to separate the effect of SAMs on contact resistance and channel mobility. We found a clear relationship between the contact resistance and the work function of source/drain electrodes for each semiconductor.

In the case of polycrystalline semiconductor, the mobility corrected for contact resistance is linked to the surface energy of the electrodes, as measured by the contact angle with water. For n-channel (p-channel) transistors, mobility was found constant for contact angles smaller (larger) than 90° and linearly increasing when the surface became more hydrophobic (hydrophilic). Optical microscope and AFM images were used to link this variation of mobility to the morphology of the semiconductor. In the case of amorphous TFB, the most affected parameter is the threshold voltage. We find a linear dependence between the threshold voltage and the work function of the electrodes.

ABSTRACT

By wisely utilizing combinations of exciton-managed orange-phosphorescence/sky blue-fluorescence, we report on high-efficiency white organic light-emitting diodes (WOLEDs) with high color-stability together with reduced efficiency roll-off. Two WOLEDs with the peak current efficiencies of 34.5 and 42.5 cd A^{-1} which slightly shift to 34.2 and 40.0 cd A^{-1} at 1000 cd m^{-2} are demonstrated. Systematic investigations focused on the effects of hole-injection buffer layer, thickness of emitting-layer (EML) and the stepwise-doping profile of orange phosphorescent EML on the device performance have been performed. It is evidently shown that careful management of the triplet/singlet excitons and charge-carriers is key to realizing such high performance of the devices. The results will beyond doubt be helpful to the design of both material and device structure for high-performance WOLEDs and next-generation solid-state lighting sources.

1. Introduction

White organic light-emitting diode (WOLED) technology is one of the most stormy developing classes of organic photonic devices nowadays due to its merits of high resolution and possible flexibility for large-scale production of solid-state lighting sources and full-color OLEDs [1]. Among the various methods that have been proposed to realize WOLEDs [2–9], electrophosphorescence is outstanding due to its demonstrated potential for achieving unity internal quantum efficiency through the simultaneous harvesting of both singlet and triplet excitons [8–10]. Accordingly, all-phosphorescence-based WOLEDs often have the highest reported efficiencies because of their possibility to achieve up to 100% internal quantum efficiency (IQE). However, problems in this architecture remain in terms of the undesired color-stability over the entire process associated with the short operational lifetime of blue phosphor, and the significant efficiency roll-off at high brightness observed due to the strong triplet–triplet or triplet-charge annihilation [11]. Furthermore, the approximate 0.8 eV exchange energy losses in power efficiency resulted from the energetic relaxation following intersystem crossing from the conductive host into the blue emissive triplet state represent another drawback. Although all-fluorescence-based WOLEDs can give less pronounced efficiency roll-off and eliminate the unfavorable exchange energy losses, the obtained maximum IQE based on this only-singlet-harvesting system is limited to 25% by quantum statistics [6,7].

An effective method to solve this conflict is by introducing both fluorescent (F) and phosphorescent (P) emitters into one WOLED, in particular the combination of high-efficiency red and green (or orange) P emitters with blue

F dye. Recent conceptual advancement leads to several types of P/F architectures [12–15]. One exciting example is via the combination of stacked F–P–F emitters in an ambipolar host proposed by Sun et al. [12a]. It is unique in that the singlets and triplets are harvested along independent channels, and hence nearly resonant energy transfer (either from the singlet or triplet) from the host to dopants for both species can be realized, and meanwhile eliminating the 0.5–1.0 eV exchange energy losses. Accordingly, their demonstrated WOLEDs exhibited very high efficiency together with reduced efficiency roll-off [12b].

As the efficiency of WOLEDs has experienced step-by-step increase over the past years, the research focus is now shifting towards the issues such as reducing the efficiency roll-off at high luminance and enhancing the device color-stability in order to satisfy the future lighting requirements [16,17]. A lot of endeavors in improving these issues have been made, e.g., manipulating singlet and triplet excitons within an ambipolar host [12], the design of exciton-confining structure [16], broadening the exciton formation zone [9], the utilization of single host system [9e,f] or p–i–n junction [13] architectures. However, we note that these elegant and high-performance WOLEDs need somewhat complicated fabrication processes, limiting their further practical applications. In general, highly efficient WOLEDs with high color-stability and reduced efficiency roll-off based on a simpler structure seem more promising but examples that can greatly resolve this issue are still very limited.

To loosen this bottleneck, we have recently reported on a novel organometallic phosphor **Ir(Cz–CF$_3$)** (see Fig. 1 for its structure) with its intrinsic multifunctional features that can yield very high-efficiency orange emission [15]. Furthermore, a simple two-wavelength P/F WOLED by combining this orange phosphor and a sky blue fluorophore was successfully fabricated. However, as compared to the previously reported all-phosphor WOLEDs, the efficiency of this P/F WOLED is yet unsatisfactory (~26 cd A^{-1}). Besides, in order to give a further performance improvement for the WOLEDs before real commercialization, a deep understanding of the device operational mechanism is still needed. Aiming at both issues, we extend here our previous work by largely enhancing the efficiency (up to ~42 cd A^{-1}) of this simple P/F white emission device, cooperating both the improvement in color-stability and efficiency roll-off. Comprehensive studies correlating the influence of the P emitting-layer (EML) thickness, hole-injection buffer layer and stepwise-doping profile in orange EML to the device performance are subsequently carried out, from which a complete scenario of the working principle of this unique P/F WOLED is clearly depicted. It is noted that carefully managing the triplet transfer and charge-transport via the introduction of such multifunctional material and smart device engineering are essential to the realization of such high electroluminescence (EL) performance. Such knowledge would undoubtedly provide a new avenue for the rational design of heavy metal electrophosphors together with the device structure for ultra-high performance WOLEDs in the future.

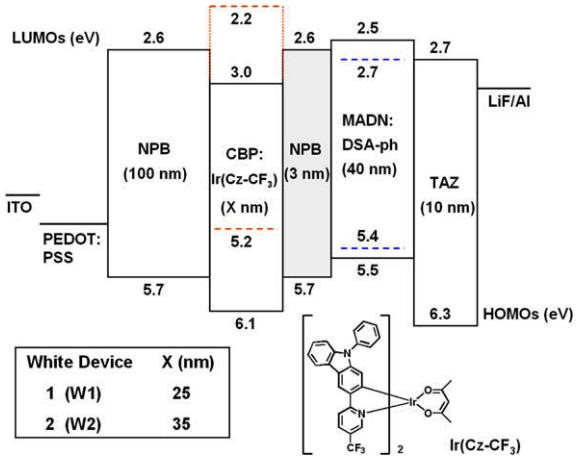

Fig. 1. Configuration (and the energy-level diagram) of the WOLED and molecular structure of **Ir(Cz–CF$_3$)**. The energy levels (in eV) are taken from Refs. [9g,h,18,19].

2. Experimental

The synthesis of **Ir(Cz–CF$_3$)** followed the procedures as described previously [15]. The fabricated devices were grown on clean glass substrates pre-coated with a 180 nm thick layer of indium tin oxide (ITO) with a sheet resistance of 10 Ω per square. The ITO surface was treated by oxygen plasma for 2 min, following degreased in ultrasonic solvent bath and then dried at 120 °C before it was loaded into an evaporator. All layers were grown by thermal evaporation in a high vacuum system with pressure of less than 5×10^{-4} Pa without breaking the vacuum. The various device structures were described in the text. In the deposition of the doping layers, deposition rates of both host and guest were controlled with their correspondingly independent quartz crystal oscillators. The evaporation rates were monitored by frequency counter, and calibrated by Dektak 6 M Profiler (Veeco). The overlap between ITO and Al electrodes was 4×4 mm^2 as the active emissive area of the devices. Current density–voltage–brightness characteristics were measured by using a Keithley source measurement unit (Keithley 2400 and Keithley 2000) with a calibrated silicon photodiode. The EL spectra were measured by JY SPEX CCD3000 spectrometer. All the measurements were carried out in ambient conditions.

3. Results and discussion

3.1. Design and fabrication of P/F hybrid WOLEDs

Several strategies are employed to enhance the EL performance of our WOLEDs. First, in common OLEDs the free electrons will combine with holes to form excitons with a singlet-to-triplet formation ratio of χ_S/χ_T in the vicinity of the main exciton-recombination zone. To effectively harvest the singlet excitons with relatively short diffusion length, the blue F layer is placed adjacent to this region, allowing for a resonant singlet energy transfer via Förster

process onto the fluorophore. On the other hand, the generated non-radiative triplets, however, which have lifetimes that are several orders of magnitude larger than singlets, typically have long diffusion lengths, and hence can migrate into the P region which is separated from the main exciton formation zone by a thin interlayer to ensure orange emission. According to this assignment, singlets and triplets can be channeled to their respective emitting species (F and P) through parallel pathways, thus greatly avoiding the exchange energy losses suffered in all-phosphor white emission devices, although some unavoidable energy losses associated with the long triplet diffusion cannot be totally eliminated.

Secondly, in conventional electrophosphorescent OLEDs one main drawback is the large efficiency roll-off at high brightness values due to the strong triplet–triplet or exciton-charge annihilations associated with the intense exciton pile-up or the intrinsically narrow exciton-recombination zone at the EML side(s) [9c]. One powerful method to solve this problem is to lower the triplet density by expanding the exciton formation region. Here, we introduce an ambipolar host for P dopant that allows a distributed exciton formation region across the full EML width to realize this goal. Furthermore, as discussed above, the process of the triplet diffusion between layers is also greatly beneficial to the formation of an extended emission zone, hence decreasing the efficiency roll-off by reducing exciton quenching [9a–f].

Next, it is noted that both careful control of triplet diffusion and wise management of electron- or hole-charges distribution provide good means of achieving a balanced white emission [3,4,9]. Therefore, in this hybrid WOLED a thin (~3 nm) hole-transporting interlayer is introduced between P and F layers to facilitate the hole injection into F layer and block electrons on this side to guarantee blue emission, maintaining the balanced white light, on the one hand. It can also prevent backward triplet energy transfer to F dopant which would otherwise decay non-radiatively, on the other hand (see Section 3.5). Finally, to achieve high color-stability in our WOLEDs, we utilize the energy-level difference between the P dopant and the host, which can lower both electron and hole mobility in the device to maintain the recombination ratio constant, thus stabilizing the EL spectrum with changing operational voltage (see Section 3.5).

Given these considerations, we put forward the structure of the hybrid WOLEDs in Fig. 1. The blue layer is composed of 0.75 wt.% *p*-bis(*p*-*N*,*N*-diphenyl-aminostyryl)benzene (DSA-Ph) doped 2-methyl-9,10-di(2-naphthyl)anthracene (MADN) [18], while 4 wt.% **Ir(Cz–CF$_3$)** doped 4,4′-*N*,*N*′-dicarbazole-biphenyl (CBP) constitutes the orange layer. Here, we choose *N*,*N*′-diphenyl-*N*,*N*′-bis(1-naphthylphenyl)-1,1′-biphenyl-4,4′-diamine (NPB) as the thin interlayer between F and P regions. 3-(4-Biphenyl)-4-phenyl-5-(4-*tert*-butylphenyl)-1,2,4-triazole (TAZ) is selected as the electron-transporting layer. To further improve the hole injection from the indium tin oxide (ITO) anode into the hole-transporting layer (HTL) of NPB, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) is introduced, which is important to the realization of high EL performance (see Section 3.3).

3.2. Orange EML-thickness dependent EL performance

We first examine the influence of phosphor-layer thickness on the EL efficiency and spectrum of the device by fabricating two WOLEDs, that is, W1 with 25 nm-thick orange EML while 35-nm thick orange EML for W2, as shown in Fig. 1. The dopant concentrations were optimized in their respective monochromatic devices before WOLED fabrication. From Fig. 2a, as compared to W1, W2 gives more intense orange emission relative to its blue counterpart, which suggests that more excitons will be trapped or harvested by **Ir(Cz–CF$_3$)** with increasing its thickness (to be discussed in detail below). Since this orange phosphor is much more efficient than the blue fluorophore, W2 exhibits the maximum forward viewing current efficiency (CE) and power efficiency (PE) of 42.5 cd A^{-1}and 24.9 lm W^{-1}, while W1 gives the maximum CE and PE of 34.5 cd A^{-1}and 17.0 lm W^{-1}, respectively (Fig. 2b). We note that these results outperform in efficiency some of the best reported all-phosphor WOLEDs in the literature [8,9a–d].

Besides the realization of high efficiency, we note here that issues on the simultaneous chromatic stability and efficiency roll-off are well resolved in this P/F hybrid WOLED. As seen from Fig. 2a, when the voltage increases from 8 to 12 V, the variations of the Commission Interna-

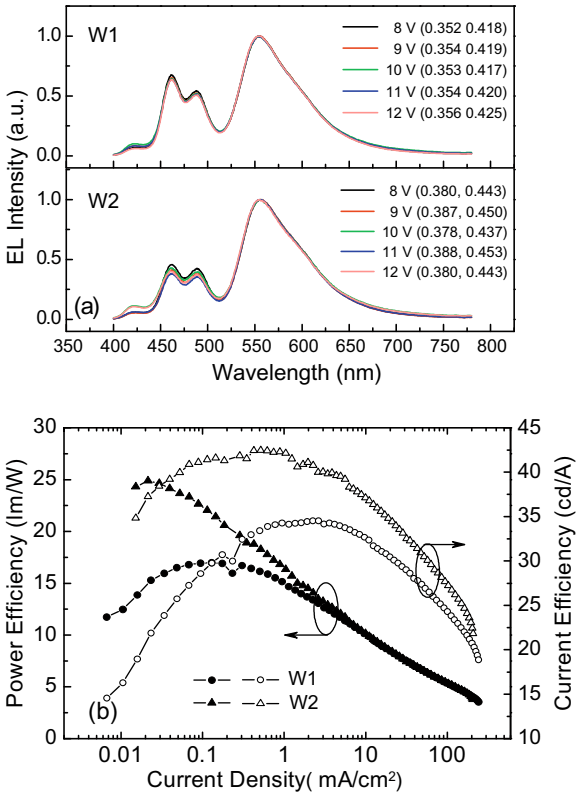

Fig. 2. (a) Electroluminescent (EL) spectra of W1 and W2 at different voltages. (b) Power and current efficiencies as a function of current density for W1 and W2.

tionale de L'Eclairage (CIE) coordinates of W1 and W2 are (0.004, 0.007) and (0.008, 0.010), respectively, which are comparable to or even much smaller than some of the high-performance single- or multi-EML WOLEDs demonstrated before [5–9]. Furthermore, as shown in Fig. 2b, this P/F WOLED exhibited less pronounced efficiency roll-off, yet at an illumination-relevant brightness of 1000 cd m^{-2}, the CE of W1 and W2 can still reach 34.2 cd A^{-1} and 40.0 cd A^{-1}, respectively, while the PE are 12.6 lm W^{-1} for W1 and 13.5 lm W^{-1} for W2. Overall, this P/F-based WOLED can reveal a better trade-off among efficiency/reduced efficiency roll-off/color-stability, demonstrating its great potential for lighting applications. Table 1 summarizes the EL efficiencies of W1 and W2 at different brightness values.

3.3. The influence of hole buffer layer

In OLEDs, an effective way to enhance the EL performance is by modifying the electrodes via the addition of buffer layer(s) to improve the charge injection and the stability of the electrode interfaces [19]. For our WOLED a proper selection of hole buffer layer is of vital importance. To give a clear illustration, a control device with CuPc modified ITO anode was fabricated. Fig. 3 depicts the device structure and its EL performance.

The maximum CE and PE of the control device dramatically decrease to 15.1 cd A^{-1} and 5.3 lm W^{-1} (Fig. 3a), with the CIE coordinates ranging from (0.382, 0.447) at 7 V to (0.374, 0.457) at 14 V (Fig. 3b). In this case, one would assume an efficiency enhancement via increasing the thickness (e.g., expanded to 25 or 35 nm as in W1 or W2) of the P layer in the control device. However, this straightforward method proved to be ineffective since any thicker phosphorescent layer (>20 nm) will render the orange emission overwhelm its blue counterpart, and hence we cannot even get yellowish-white emission as was found in the control device. Besides, we note that the thickness of HTL (NPB) also strongly influences the EL spectrum of the device. The thicker the NPB layer, the more the orange emission. Hence, we optimized the thickness of NPB as 50 nm in CuPc modified device (Fig. 3a) considering the issues of both device efficiency and EL spectrum performance.

Apparently, the introduced PEDOT:PSS buffer layer is essential in realizing the high EL performance (consider W2 with its highest CE of 42.5 cd A^{-1}, and its nearly the same EL spectral shape as the control device). Fig. 4 compares the current density–voltage characteristics of the device with CuPc or PEDOT:PSS modified anode. It is clear that the current density is enhanced dramatically in PEDOT:PSS modified device as compared to its CuPc counterpart, which indicates that the hole-injection barrier between ITO and NPB can be lowered by introducing the PEDOT:PSS buffer layer in order to facilitate the hole injection and transportation in the device. We note that this greatly benefits to the enhancement of device PE by reducing the driving voltage. Moreover, according to the previous reports, this hole buffer can smooth the anode surface and efficiently block the electrons within the device to reduce the current leakage, which contribute to the enhancement of device performance as well [20].

Table 1
EL efficiencies of W1 and W2 at different brightness values.

Brightness (cd m^{-2})	EQE (%)[a]	CE (cd A^{-1})	PE (lm W^{-1})
100	11.4, 14.0[b]	32.4, 41.9	16.1, 20.0
500	12.1, 13.9	34.2, 41.5	14.3, 15.8
1000	12.0, 13.4	34.2, 40.0	12.6, 13.5

[a] EQE: external quantum efficiency; CE: current efficiency; PE: power efficiency.
[b] The former value is from W1 whereas the latter belongs to W2.

3.4. Stepwise-doping profile in orange emissive region

In OLEDs the charge or exciton transport inside the EML is one of the most important issues for determining the EL performance, especially in the host–guest doped system [9a–f,12]. Therefore, a deep understanding of the underlying carrier transport or exciton diffusion characteristics is essential in revealing the device operational mechanism [21]. In order to understand how the introduced **Ir(Cz–**

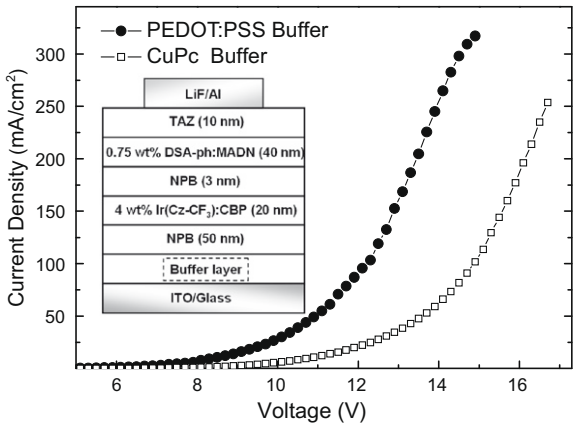

Fig. 4. Current density–voltage characteristics of the devices with CuPc or PEDOT:PSS modified anode.

CF_3) dopant functions on hole charges in this P/F WOLED, a stepwise-doping profile in the orange EML is proposed [22].

To give a clear illustration, two types of devices (Devices A and B) with an opposite stepwise-doping sequence in the orange EML were fabricated, as depicted in the upside of Fig. 5. Also shown are their corresponding EL spectra at different voltages (Fig. 5a and 5b). Apparently, in Device A the orange emission is increased dramatically relative to the blue with increasing voltage, while in Device B a completely opposite result is observed upon increasing the voltage. Fig. 5c depicts the variations of the CIE coordinates of the two devices. Evidently, a visible red-shift is observed in Device A while a large blue-shift appears in Device B with increasing voltage. Furthermore, it is found that the color-shifts in both devices are much larger than that of W2 in which the 4 wt.% doped **Ir(Cz–CF_3)** is uniformly distributed within the whole orange region (see the enlarged image in inset of Fig. 5c).

Several key issues should be clarified before our further analyses. Firstly, in a doped system the dopant may influence the charge-transportation behavior in different ways depending on its energy-level relative to the host. If the dopant has a higher-lying highest occupied molecular orbital (HOMO) with respect to the host HOMO, the dopant molecules can then act like hole-traps [23,24]. Secondly, it has been demonstrated that CBP exhibited bipolar transport property and relatively higher hole mobility [25]. Therefore, in this P/F WOLED, the main exciton formation region should be located close to the NPB/MADN interface, considering the dominant hole and electron transport characteristics of NPB and MADN, respectively. Finally, for organic semiconductors, we assume that the charge transportation is governed by hopping model between dopant sites [23].

According to the device energy-level diagram (Fig. 1), the HOMO level of **Ir(Cz–CF_3)** is much higher than that of CBP, indicating that the phosphor may act as good hole trappers, thanks to the presence of the electron-rich carbazolyl ring. In this case, some mobile holes transported in the orange EML would be trapped by the dopant molecules. Given the deep hole-trapping depth (~0.9 eV) which is defined as the HOMO energy-level difference between **Ir(Cz–CF_3)** and CBP, the detrapping probability is low, and hence the hole mobility will be lowered. Besides, since the hole mobility of CBP is nearly one order of magnitude higher than its electron counterpart, the hole charges should be distributed rather uniformly throughout the orange EML, except for the sudden rise and fall at the junctions [25]. Combining both results, the hole-trapping effect of **Ir(Cz–CF_3)** in CBP host is quite anticipated and shown to be efficient [9e,f,21–24].

Therefore, in the case of Device A, when the stepwise-doping profile in orange EML is arranged by a 4 wt.%–3 wt.%–2 wt.%–1 wt.% sequence towards the blue-layer side, an internal electric field guided to the blue-layer direction (see Device A in Fig. 5) is subsequently formed across the orange EML, considering that a higher concentration of **Ir(Cz–CF_3)** will capture more holes than its lower counterpart and the potential drop is most related to the total amount of charges inside the layer [26]. Accordingly, this internal electric field formed will significantly facilitate the electron injection across the thin NPB layer into the orange EML to combine with the trapped holes, forming excitons which then are available for **Ir(Cz–CF_3)** molecules as the voltage increases. The overall results are the continuous shift of the recombination distribution away from the main exciton formation zone (i.e., NPB/MADN interface) towards the orange-layer side [21c], resulting in a large increase in orange emission relative to blue emission with increasing voltage, consistent with the experimental results (Fig. 5a). However, when the stepwise-doping profile is arranged by a 1 wt.%–2 wt.%–3 wt.%–4 wt.% sequence, as shown in Device B, an internal electric field with the opposite direction as compared to Device A is subsequently formed across the orange EML. In this case, the formed internal electric field will tremendously retard the electron injection into the orange layer, leading to a reduction of orange emission with respect to its blue counterpart with increasing voltage (Fig. 5b). The overall results evidently reveal the hole-trapping character of **Ir(Cz–CF_3)** in CBP host.

On the other hand, as shown in Fig. 1, **Ir(Cz–CF_3)** has a higher-lying lowest unoccupied molecular orbital (LUMO) with respect to CBP. This large LUMO level difference (~0.8 eV) can effectively block the direct injection of electrons into **Ir(Cz–CF_3)** sites, preventing the shift of recombination zone as the operational voltage increases. Furthermore, the electrons tunneled into the CBP layer can be scattered at the dopant sites. Then the average free path of electrons is shortened and the electron drift velocity becomes lowered, leading to a reduction of electron mobility [24]. Direct experimental evidence for this hypothesis is provided by examining the current density–voltage characteristics of electron-only devices with or without **Ir(Cz–CF_3)** dopant in the CBP layer. As shown in Fig. 6, the significant decrease of current density in **Ir(Cz–CF_3)** doped device strongly proves that the orange dopant can indeed induce a reduced electron mobility in the CBP host.

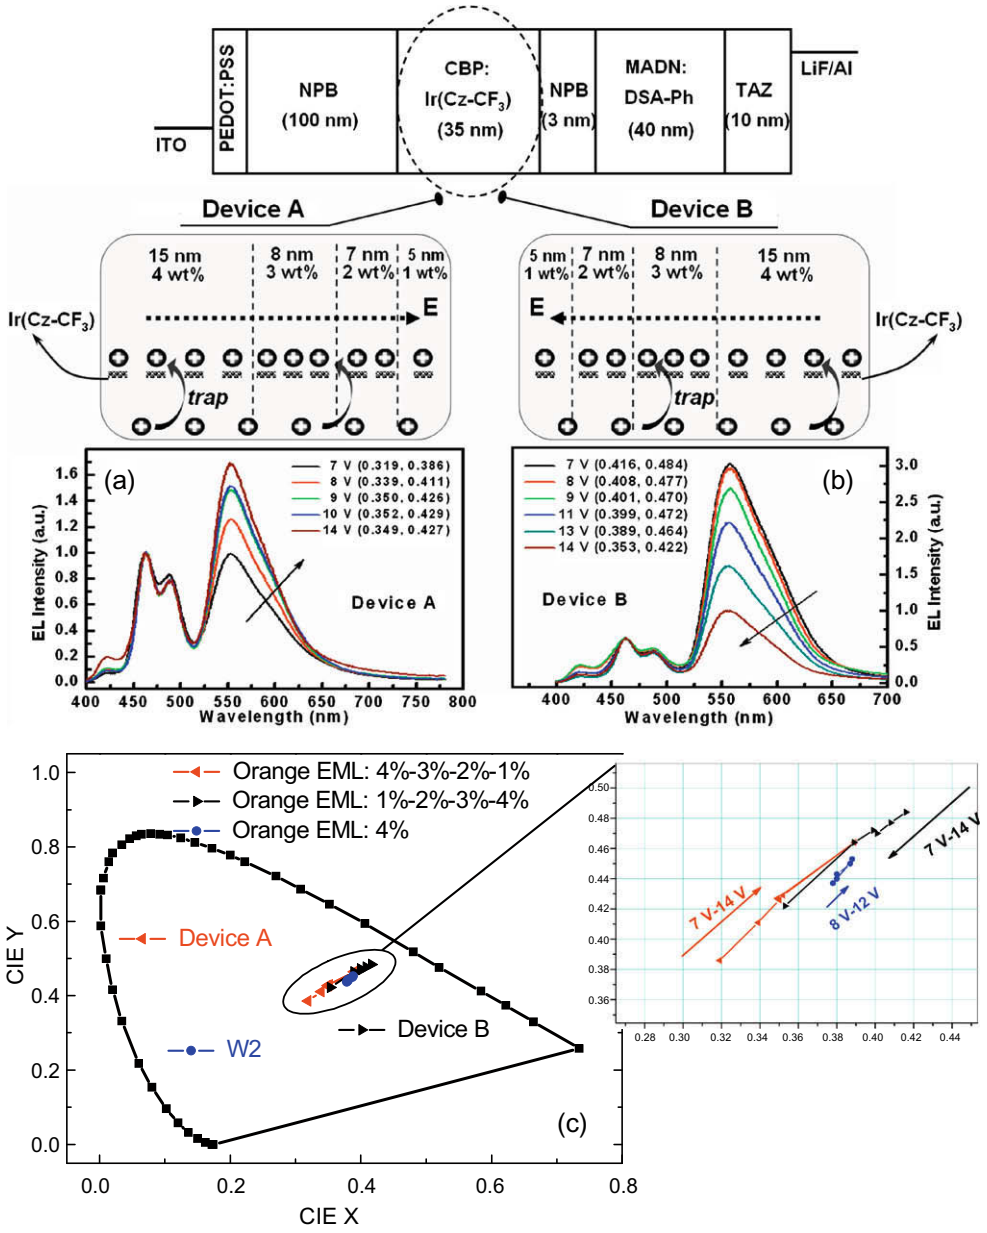

Fig. 5. Configuration of WOLEDs with stepwise-doping profile in orange EML. Device A follows 15 nm–4 wt.%, 8 nm–3 wt.%, 7 nm–2 wt.%, and 5 nm–1 wt.% doped **Ir(Cz–CF$_3$)** sequence towards the CBP/internal-NPB interface, while Device B follows a reverse sequence of doping concentration, that is, 5 nm–1 wt.%, 7 nm–2 wt.%, 8 nm–3 wt.%, and 15 nm–4 wt.% originated from the NPB-HTL/CBP interface. The formed internal electric field (E) across the orange region is also shown (dotted lines). EL spectra of Devices A and B with different voltages are depicted in (a) and (b), respectively. (c) Summarizes the variations of the CIE coordinates of Devices A, B, and W2.

3.5. Origin of the high EL performance

As illustrated above, the energy-level difference between **Ir(Cz–CF$_3$)** and CBP enables the dopant to play different roles on holes and electrons in the device. Acting as deep hole-traps, they may capture hole-carriers and then lower the hole-transport across the orange EML. Alternatively, due to the large LUMO level difference between **Ir(Cz–CF$_3$)** and CBP, the electrons injected may collide with the positive barriers and be scattered by these barriers, leading to a reduction of the drift velocity due to an increase of the total transit path [23]. Therefore, the mobilities of both holes and electrons are reduced in the white light-emitting device.

It has been evidently demonstrated that the reduction of charge mobility associated with this host–guest energy-level difference will lead to the recombination ratio to be constant in each EML, thus greatly stabilizing the EL spectrum with a change of voltage [24]. As mentioned earlier, the large host–guest LUMO difference can prevent

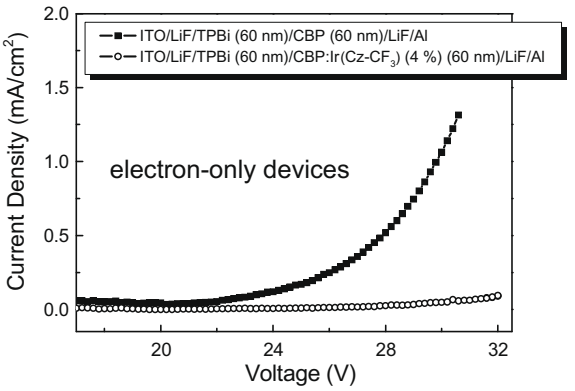

Fig. 6. Current density–voltage characteristics of electron-only devices with or without **Ir(Cz–CF$_3$)** dopant in CBP layer. Here, the addition of an electron-transporting layer 2,2′,2″-(1,3,5-phenylene)tris-(1-phenyl-1*H*-benzimidazole) (TPBi) with high electron mobility serves to block the hole diffusion into the CBP (or doped CBP) layer and prevent the breakdown of the tested film with increasing operational voltage.

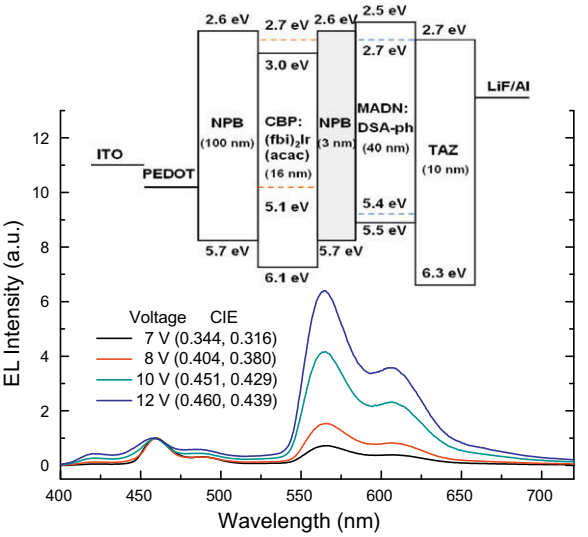

Fig. 7. EL spectrum of the device with (fbi)$_2$Ir(acac) dopant in CBP (see inset for its structure) instead of **Ir(Cz–CF$_3$)** at different voltages.

the direct electron injection into **Ir(Cz–CF$_3$)** sites, which maintains the stability of exciton-recombination zone in the device. From Fig. 5c, the rather small color-shift even in a wide range of operational voltages observed in W2 provides a strong evidence for the above analysis. Furthermore, we note that the carrier trapping process is also beneficial to the device performance since the trapped exciton fraction is not subject to diffusive transport loss, and the reduced triplet accumulation at the orange EML edges can decrease the triplet quenching, thus representing a trade-off between high color-stability and reduced efficiency roll-off. Herein, the tiny spectral variation in W2 is attributed to the asymmetric electron and hole mobility values. The relatively low electron mobility increases rapidly with the electric field. Therefore, more electrons can move throughout the CBP/internal-NPB heterojunction continuously, inject into the orange EML, and combine with the trapped holes to form excitons which are then available for **Ir(Cz–CF$_3$)** molecules, leading to more intense orange emission relative to the blue one. Clearly, the notorious voltage-dependent-color-shift problem can be solved by using this smart method which can bear the critical demands of commercial lighting applications.

Recall that a thicker orange EML in WOLEDs leads to more orange emission with respect to its thinner counterpart (compare W2 with W1). Given the unique property of **Ir(Cz–CF$_3$)**, there should be more electrons and holes captured and then they recombine to form excitons on the multifunctional dopant sites with increasing its thickness, thus making more orange light contribution, as illustrated in Fig. 2a.

To further demonstrate the importance of **Ir(Cz–CF$_3$)** in this hybrid WOLED, another device was fabricated by replacing this orange dopant with another iridium phosphor bis(2-(9,9-diethyl-9*H*-fluoren-2-yl)-1-phenyl-1*H*-benzoimidazole-*N*,C^3)iridium(acetylacetonate) (fbi)$_2$Ir(acac) [27]. Fig. 7 shows the device structure and its corresponding EL spectrum at different voltages. The LUMO offset between (fbi)$_2$Ir(acac) and NPB is rather small (~0.1 eV), indicating that the electrons tunneled from the internal-NPB layer could inject resonantly into the (fbi)$_2$Ir(acac) LUMO and transport by hopping on dopant sites [9e,f,18,28]. In this case, the fraction of excitons (singlets or triplets) directly formed on (fbi)$_2$Ir(acac) molecules via the combination of the trapped holes and the channeled electrons will be markedly increased, leading to overwhelmed orange emission with respect to the blue with increasing voltage, as shown in Fig. 7. In particular, the variations of the CIE coordinates of (fbi)$_2$Ir(acac) based device are $\Delta X = 0.116$ and $\Delta Y = 0.123$, which are nearly one order of magnitude larger than that of W1 or W2. This fact evidently demonstrates that the introduced **Ir(Cz–CF$_3$)** is important to achieve the rather high color-stability in the resulting WOLED.

Furthermore, it is noted that the smart device engineering is essential to the realization of a high EL efficiency together with a reduced efficiency roll-off. As discussed above, the added hole-type NPB interlayer between P and F regions plays an important role in maintaining the balanced white emission. Besides, this interlayer, with high triplet energy ($T_1 \sim 2.29$ eV), can suppress triplet quenching between phosphorescent and fluorescent regions. Experimental evidence to support this point is provided here, in which it is found that the PL intensity of a 30 nm layer of 4 wt.% **Ir(Cz–CF$_3$)** doped CBP is nearly unchanged, if a 4 nm layer of NPB is evaporated directly on top [13c]. Since NPB does not absorb the photon energy in the spectral range of **Ir(Cz–CF$_3$)** emission together with the fact that the triplet energy of NPB (~2.29 eV) is higher than that of **Ir(Cz–CF3)** (~2.24 eV), this result clearly demonstrates that the generated triplet excitons can flexibly transport across this thin spacer bridge into the orange EML and then decay radiatively, without being absorbed by the triplet state of the internal-NPB or backward-energy-transferred to the blue F dopant which would otherwise decay non-radiatively. In such device the blue fluorescent dopants harvest a majority of singlet energy, with the remainder of triplets diffusing into the **Ir(Cz–CF$_3$)** doped CBP layer to

excite the orange phosphor. Herein one assumption for the above analysis is that the triplet energy of MADN is larger than that of **Ir(Cz–CF3)**, rendering the triplet diffusion into the phosphorescent region can possibly happen. On the other hand, because of the rather low doping concentration of DSA-ph (0.75 wt.%), the generated triplets near the NPB/MADN interface cannot efficiently energy transfer to the fluorophore by either Förster or Dexter mechanism. Besides, direct singlet transfer from the blue species to the lower-energy orange phosphor is forbidden because of their inherently short diffusion lengths [12]. This architecture is unique in that the singlet and triplet excitons can be harvested along completely independent channels which avoids the exchange energy losses, allowing for increased power efficiency. Additionally, as expected, the process of the extended triplet diffusion and the introduction of ambipolar CBP host both allow a distribution of excitons to form in the multiple regions, thus achieving a rather small efficiency roll-off at high current density (Fig. 2b) by decreasing the exciton-charge or exciton–exciton quenching which is yet the main bottleneck to be addressed in the development of today's phosphorescent WOLEDs [11]. Overall, by virtue of the multifunctional iridium phosphor combined with the smart device engineering, we can carefully control the charge-carrier transport and diffusion of singlet or triplet excitons between or within layer(s) to reveal a better trade-off for the EL efficiency/reduced efficiency roll-off/color-stability which is necessary for constructing high-performance WOLEDs.

4. Conclusions

We report on simple and color-stable two-wavelength WOLEDs with high efficiency together with reduced efficiency roll-off at high luminance. The devices exploit a blue fluorescent dopant in exchange for a phosphorescent species to avoid the exchange energy losses and create parallel pathways to channel nearly all of the triplet energy to orange phosphor while retaining the singlet energy exclusively on the blue-fluorescence. Systematic studies on the device working mechanism have been subsequently performed from which the origin of the high EL performance of the WOLED is clearly revealed. We note that the wise management of charge-carrier transport coupled with triplet diffusion in the device is key to enhancing the device performance. Given the good compromise among the efficiency, color-stability and reduced efficiency roll-off, the present study can act as a good benchmark to resolve the trade-off hurdle of these issues. Besides, this study can also make a positive impact on the advance of both the development of new host–guest system and of efficient white emission device structures, which will excel in the realization of next-generation solid-state indoor lighting sources [29].

ABSTRACT

The combination of white organic light-emitting devices (OLED) and color filters is one of the most promising technologies for full-color OLED displays. Yet, the transmission spectra of most available color filters are broad and poorly match the electroluminescence spectra of white OLEDs, yielding less saturated filtered colors and small color gamut for displays. In this work, we report that by employing the microcavity structure only in green pixels for such OLED display technology, one can simultaneously achieve simplification the manufacturing process, enhancement of color performances, and enhancement in efficiencies for OLED displays.

1. Introduction

White organic light-emitting devices (WOLEDs) have attracted wide attention due to their potential applications in displays and solid-state lighting (SSL) [1,2]. For full-color display applications, the combination of WOLEDs and color filters is one of the most promising technologies, since it avoids the precise shadow-masking often used in the separate red–green–blue (RGB) pixilation, and thus is beneficial to realizations of higher display resolutions and large-area scale-up. However, for this technique challenges exist in generation of white electroluminescence (EL) with wide visible spectra and their perfect match with the transmittance of color filters (CFs) [3–5]. Typically, broad EL spectra of white emission can be achieved either by mixing two complementary colors or three primary colors. Yet, the transmission spectra of most available CFs are broad and poorly match the EL spectra of WOLEDs. Hence, the filtered EL usually exhibit poorly saturated colors and yield small color gamut than the NTSC standard.

In 2004, Sony reported that the white emitter with pixilated microcavity structures combined with CFs can achieve high brightness and good color saturation in full-color active-matrix OLED displays [6]. In general, microcavity OLEDs consist of a highly reflective back mirror electrode and a semi-transparent output mirror electrode. When appropriately tailored, microcavity OLEDs can produce narrowed/more saturated EL and brightness enhancement [7–9], useful for constructing energy-efficient displays with color saturation comparable to the NTSC standard. In Sony's configuration, WOLEDs were embedded in the microcavity structure and individual RGB emissions from RGB sub-pixels were created by adjusting the microcavity resonant wavelength of each sub-pixel. It was accomplished through depositing and patterning the indium–tin-oxide (ITO) layers of different thicknesses for the respective RGB sub-pixels. The schematic configuration is shown in Fig. 1a. Depositing and patterning ITO into different thicknesses, however, complicates the fabrication and thus is not convenient for mass production [10].

In the WOLED + CF display technology, the most significant issue resulting from residual emission with the imperfect filtration is unsaturated green emission. With

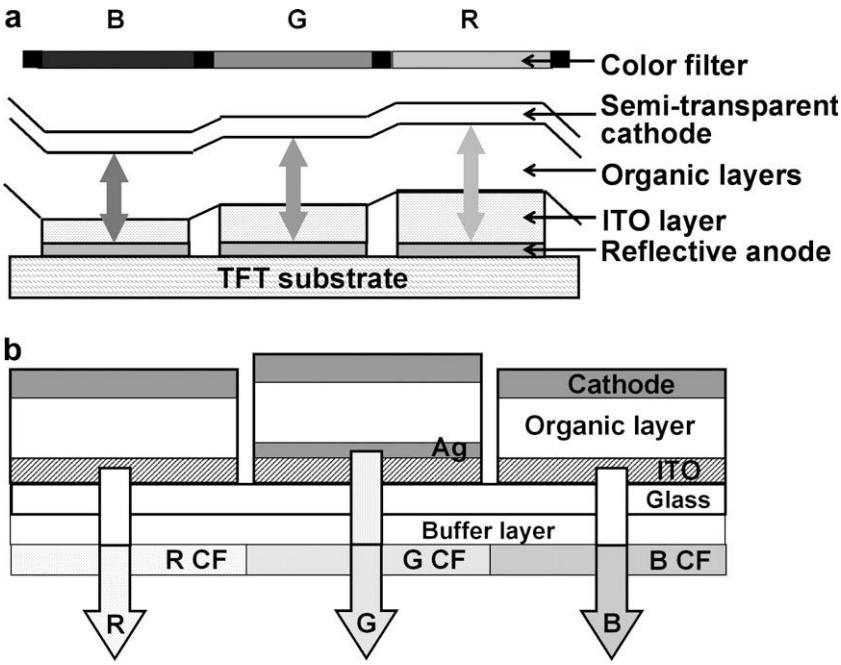

Fig. 1. (a) The schematic diagram of the WOLED + CF display with pixilated microcavity developed by Sony in 2004 and (b) the schematic diagram of the WOLED + CF display by using microcavity green pixels. The buffer layer in (b) could be an index-matching adhesive.

the band-pass nature of green color filters, modifying optical properties of CF or OLED materials would give only limited improvement and shall not solve the problem completely. Nevertheless, by employing the microcavity structure only in green pixels may compensate this weakness and also substantially simplify the manufacturing process (versus Sony's configuration). For instance, one possible WOLED + CF configuration with microcavity green pixels is schematically shown in Fig. 1b. In such an approach, a thin metal layer of one thickness is deposited and patterned only on the ITO anode of green pixels, and then the fabrication of WOLEDs of a same structure for all RGB pixels can be carried out simultaneously.

2. Experimental

2.1. OLED fabrication

All compounds used were subject to temperature-gradient sublimation under high vacuum before use. OLEDs were fabricated on the ITO-coated glass substrates with multiple organic/metal layers sandwiched between the transparent bottom indium–tin-oxide (ITO) anode and the top metal cathode. The organic and metal layers were deposited by vacuum evaporation in a vacuum chamber with a base pressure of $<10^{-6}$ Torr. The deposition system permits the fabrication of the complete device structure in a single vacuum pump-down without breaking vacuum. The deposition rate of organic layers was kept at ~0.2 nm/s. The active area of the device is $2 \times 2\ mm^2$, as defined by the shadow mask for cathode deposition.

2.2. Device characterizations

Current–voltage–luminance (I–V–L) characterization of the devices was measured using an Agilent 4155B semiconductor parameter analyzer and a Si photodiode calibrated with Photo Research PR650. EL spectra of devices were collected by a calibrated CCD spectrograph. To measure the EL spectra of WOLED + CF, color filters were attached to the devices by employing index-matching oil. Transmission spectra of CFs were measured using a spectrophotometer.

3. Results and discussion

Two types of WOLEDs were fabricated and tested. In Type-I devices (Devices A and B, Fig. 2a), the emissive dopants of two complementary colors (red and blue) were used to form a two-component white EL. In Type-II devices (Devices C and D, Fig. 2b), the emissive dopants of three primary colors (red, green, and blue) were used to form a three-component white EL. Both Type-I and II devices used two different anodes, i.e. ITO for non-cavity Devices A/C and ITO/thin Ag (30 nm) for microcavity Devices B/D, respectively. In Devices B and D, the thin silver was chosen as semi-transparent reflective anode for the microcavity structure because of its low absorption/high reflection in the visible range and the lowest resistance among electrode materials [11,12]. By controlling the thickness of anode and organic layers, the resonant wavelength was adjusted to match the transmittance of the green color filters. The transmission spectra of RGB color filters used in this study (micrometer-thick color filters coated on the glass substrate) are shown in Fig. 3.

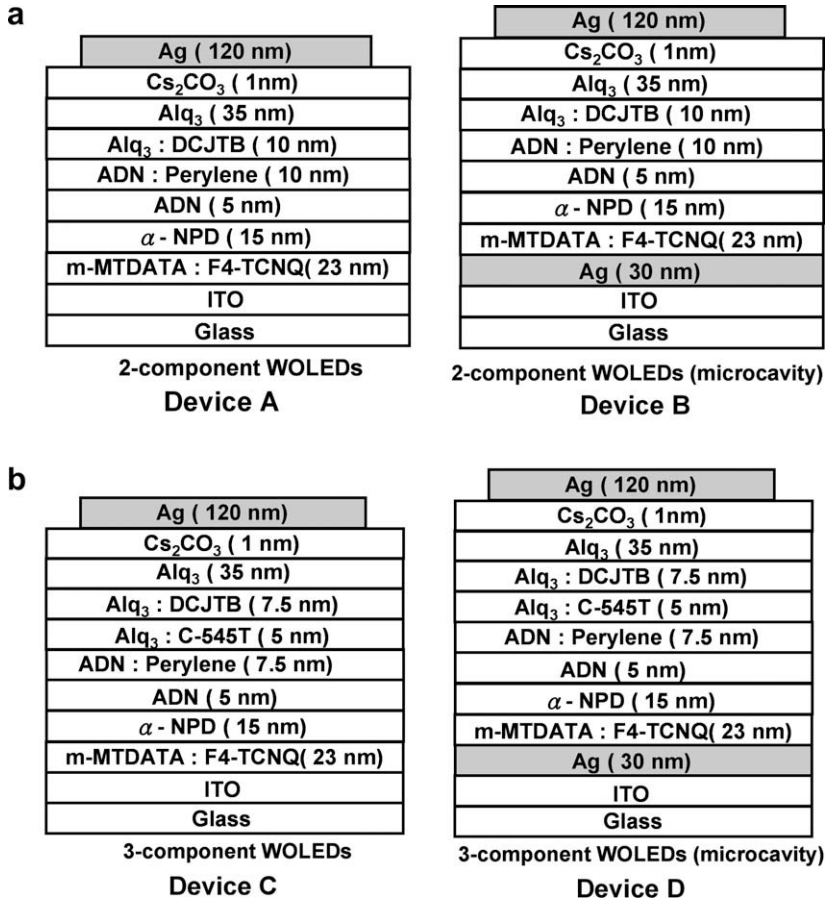

Fig. 2. (a) The structures of two-component WOLEDs (Type-I devices): non-cavity Device A and microcavity Device B and (b) the structures of three-component WOLEDs (Type-II devices): non-cavity Device C and microcavity Device D.

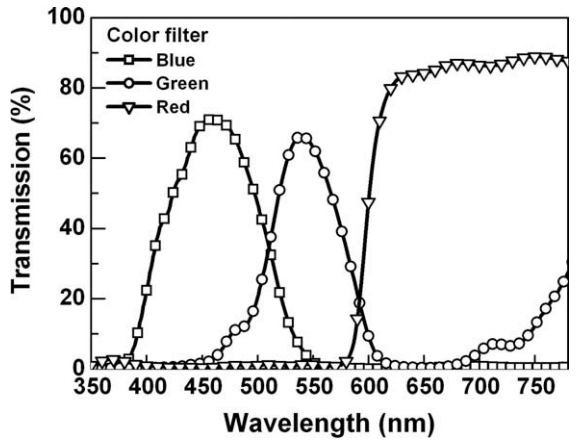

Fig. 3. Transmission spectra of color filters used in this study (micrometer-thick RGB color filters coated on the glass substrate).

3.1. Color performances of two-component white OLEDs + CFs

In Type-I devices, the organic layers and the cathode were: m-MTDATA: F4-TCNQ 2.0 wt% (23 nm)/α-NPD (15 nm)/ADN (5 nm)/ADN: Perylene 1.0 wt% (10 nm)/Alq_3: DCJTB 0.3 wt% (10 nm)/Alq_3 (35 nm)/Cs_2CO_3 (1 nm)/Ag (120 nm). In these devices, 4,4′,4″-Tris(N-3-methylphenyl-N-phenyl-amino) triphenylamine (m-MTDATA) doped with 2 wt% of 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) was used as the *p*-doped hole-injection layer (HIL) [13–15]. The p-type doping (F4-TCNQ) facilitates carrier (hole) injection between anode (ITO or silver) and organic materials. N,N′-bis(naphthalen-1-yl)-N,N′-bis(phenyl)-benzidine (α-NPD) and Tris(8-hydroxyquinolinato) aluminium (Alq_3) were used as the hole-transport layer (HTL) and electron-transport layer (ETL), respectively. A 5 nm-thickness 9,10-Di(naphth-2-yl)-anthracene (ADN) layer was used as a buffer layer between HTL and emitting layers [16,17]. The blue emitting layer was composed of 9,10-Di(naphth-2-yl)anthracene (ADN) doped with 1.0 wt% Perylene; the red emitting layer was composed of Alq_3 doped with 0.3 wt% 4-(Dicyanomethylene)-2-tert-butyl-6-(1,1,7,7-tetramethyljulolidin-4-yl-vinyl)-4H-pyran (DCJTB) [18–20]. Cs_2CO_3 and Ag were used as the electron-injection layer (EIL) and cathode, respectively [21,22]. Two types of anodes, ITO for non-cavity Device A and ITO/thin Ag (30 nm) for microcavity Device B, were used, respectively. The layer thickness and the doping concentration were adjusted to achieve white EL for non-

cavity WOLEDs and the wavelength-selected green emission for the microcavity structure (i.e. match the resonant wavelength with the green CF) simultaneously. All the materials used in devices are shown in Fig. 4.

The EL spectra of Type-I devices at 1000 cd/m^2 are shown in Fig. 5a. With carefully adjusting the relative ratio of the two complementary colors in Type-I devices, the EL spectrum of Device A exhibited a white emission with CIE coordinates of (0.34, 0.30), which is close to the equal-energy white at $CIE_{x,y}$ = (0.33, 0.33). One notices that there is absence of the green part in EL of Type-I Devices A. In microcavity Device B, to ensure sufficient light emission through the thin Ag anode, the thickness of silver was set at 30 nm to avoid serious power loss. As such, the microcavity effect is not strong enough to remove completely residual emission in the blue and red ranges, but they are already largely suppressed. The resonant wavelength of Device B was set at 531 nm and the device showed green emission with $CIE_{x,y}$ = (0.23, 0.65).

To measure the EL spectra of WOLED + CF, color filter plates were attached to the devices by employing index-matching oil. Fig. 5b and c show the filtered normalized EL spectra and the color gamut of Type-I Devices (A and B) when combined with CF. In Device A, the filtered EL spectra exhibited rather saturated blue and red colors at $CIE_{x,y}$ = (0.13, 0.11) and $CIE_{x,y}$ = (0.67, 0.32), respectively. On the contrary, the weak intensity in the green region broadened the filtered green emission and produced an unsaturated green color at $CIE_{x,y}$ = (0.28, 0.61). In Device B, the residual blue and red emission was further suppressed by the green CF and the filtered green EL was further narrowed. As shown in Fig. 5c, with the microcavity structure, the filtered green emission (along the normal direction) shifted from $CIE_{x,y}$ = (0.28, 0.61) (Device A) to $CIE_{x,y}$ = (0.25, 0.70) (Device B). By adopting the microcavity green pixel, the color gamut of the WOLED + CF display could be enlarged from 74.6% NTSC (Device A) to 91.2% NTSC (using the microcavity Device B for the green pixel)

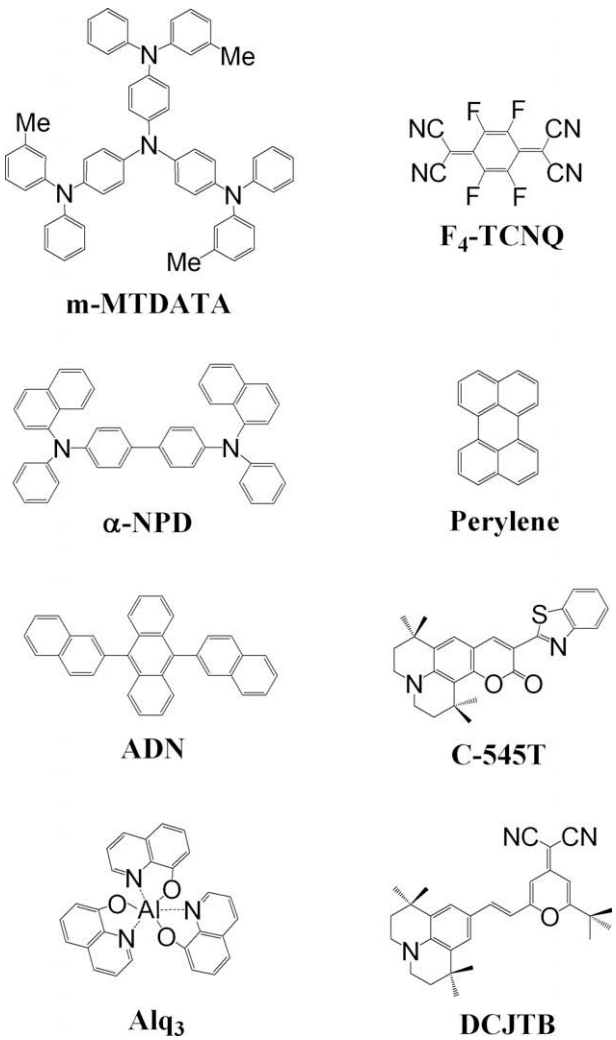

Fig. 4. Chemical structures of materials used in devices.

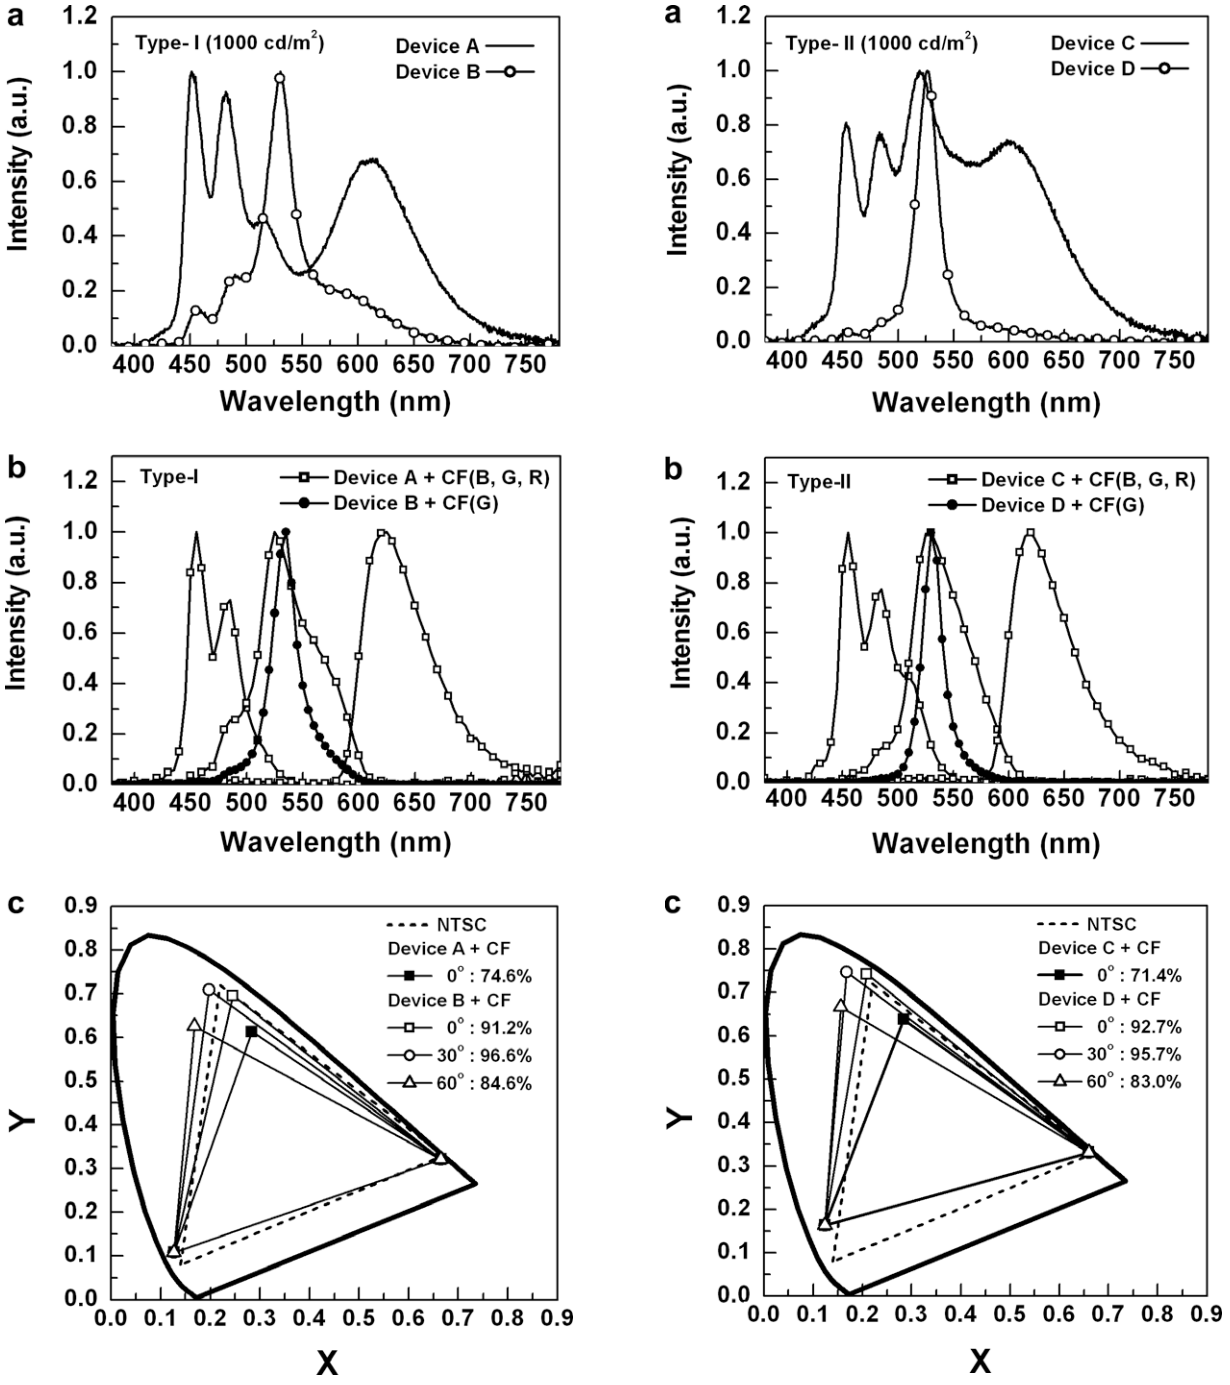

Fig. 5. (a) The normalized EL spectra of Type-I devices in the normal direction, (b) the normalized EL spectra of Type-I devices coupled with CF, and (c) color gamut of Type-I devices coupled with CF at different viewing angles.

Fig. 6. (a) The normalized EL spectra of Type-II devices in the normal direction, (b) the normalized EL spectra of Type-II devices coupled with CF, and (c) color gamut of Type-II devices coupled with CF at different viewing angles.

in the normal direction. Fig. 5c also shows the CIE coordinates of EL of microcavity Device B at different viewing angles, which shows slight blue shift with viewing angles. As such, the color gamut of the WOLED + CF display employing the microcavity green pixel would vary from 91.2% NTSC at 0°, to 96.6% NTSC at 30°, and to 84.6% NTSC at 60°. Therefore, enlarged color gamuts could be obtained over wide viewing angles. In general, the microcavity effect induces slight blue shift of the EL spectrum/peak (color) of the microcavity green pixel with viewing angles [9]. Near the viewing angle of 30°, the EL happens to reaches the

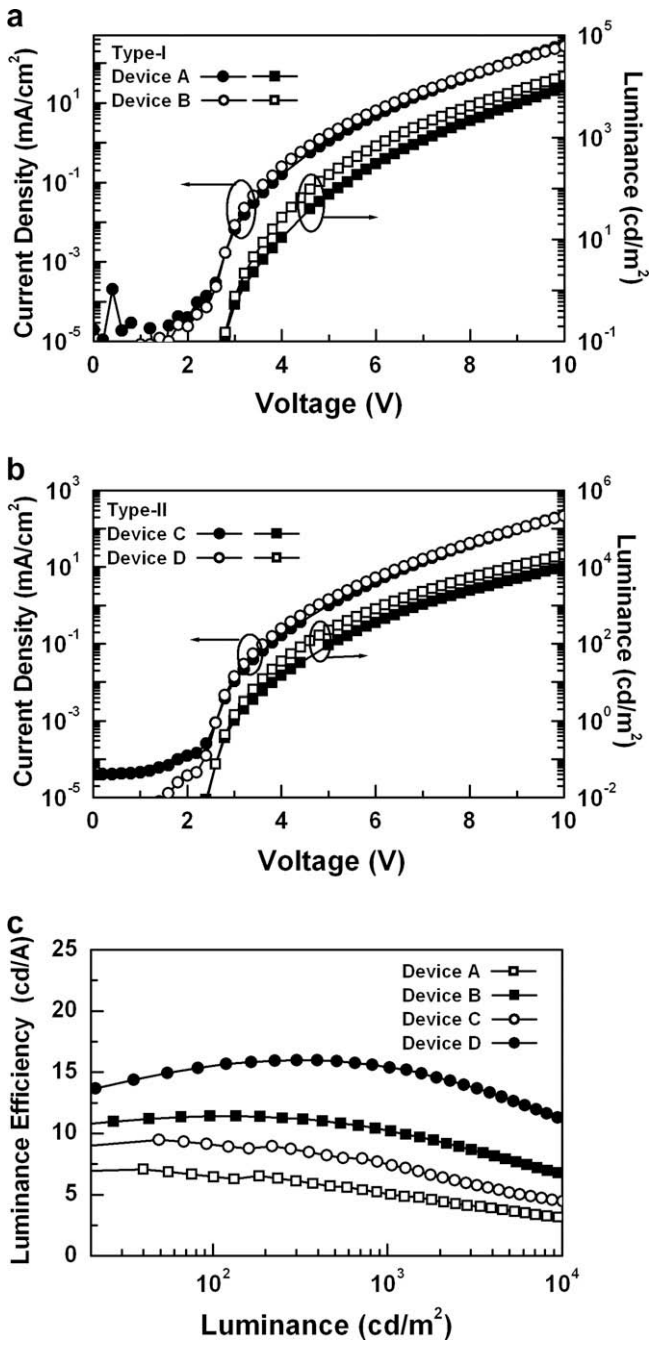

Fig. 7. (a) Current–voltage–luminescence (*I–V–L*) characteristics of Type-I devices, (b) current–voltage–luminescence (*I–V–L*) characteristics of Type-II devices, and (c) luminance efficiency vs. luminance of Type-I and II devices.

most saturated green, thus giving the largest color gamut. We also checked the viewing-angle characteristics of microcavity Device B without CF. Without green CF, the color gamut of the WOLED + CF display would have a significant variation from 89.54% NTSC at 0° to 29.14% NTSC at 60°. Therefore, the results indicate that the CF not only purifies emission colors but also reduces the color shift with viewing angles in the current technology.

3.2. Color performances of three-component white OLEDs + CFs

Triple emission layers were used in Type-II devices. The organic layers and cathode in Type-II devices were: m-MTDATA: F4-TCNQ (23 nm)/α-NPD (15 nm)/ADN (5 nm)/ADN: Perylene 1.0 wt% (7.5 nm)/Alq_3: C545T 1.0 wt% (5 nm)/Alq_3: DCJTB 0.3 wt% (7.5 nm)/Alq_3 (35 nm)/Cs_2CO_3

(1 nm)/Ag (120 nm). In Type-II devices, Alq_3 doped with 2,3,6,7-Tetrahydro-1,1,7,7,-tetramethyl-1H,5H,11H-10- (2-benzothiazolyl) quinolizino-[9,9a,1gh] coumarin (C545T) was used as the green emitting layer (Fig. 4) [23,24]. ITO was used as the anode for the non-cavity device C and ITO/thin Ag (30 nm) was used as the composite anode for the microcavity Device D.

Fig. 6a shows the EL spectra of Type-II devices at 1000 cd/m^2. With the addition of the green emitting layer and the emphasis of green emission, the EL spectrum of Type-II Device C exhibited a greenish white color with $CIE_{x,y}$ = (0.34, 0.40). The larger EL intensity in green wavelengths of Type-II devices enhances the microcavity effect in the microcavity Type-II Device D, giving a much sharper green EL. Comparing the EL spectra of microcavity devices of both types (Devices B and D), one notices that the residual blue and red emissions were much more suppressed in Device D. The resonant wavelength in Device D was set at 526 nm and the device showed more saturated green EL at $CIE_{x,y}$ = (0.22, 0.67).

Fig. 6b and c shows the normalized filtered EL spectra and the color gamut of Type-II Devices (C and D) when combined with CF. Compared to the two-components WOLED Device A, the additional green emitter in Device C does not improve color gamut of the WOLED + CF (71.4% NTSC for Device C vs. 74.6% NTSC for Device A; partially due to the degradation of the filtered blue color in addition to the broad filtered green color). In microcavity Device D + CF, the filtered green emission produced even more saturated green color at $CIE_{x,y}$ = (0.21, 0.74), and the color gamut of the WOLED + CF display could be enlarged from 71.4% NTSC to 92.7% NTSC (using microcavity Device D for the green pixel) in the normal direction. As in the previous case, the microcavity structure combined with CF could mitigate the color shift with viewing angles. The color gamut of the WOLED + CF display employing the microcavity green pixel vary from 92.7% NTSC at 0°, to 95.7% NTSC at 30°, and to 83.0% NTSC at 60°, still showing enlarged color gamuts over wide viewing angles. In general, the microcavity effect induces slight blue shift of the EL spectrum/peak (color) of the microcavity green pixel with viewing angles [9]. Near the viewing angle of 30°, the EL happens to reaches the most saturated green, thus giving the largest color gamut.

3.3. Current–voltage–luminescence (I–V–L) characteristics of all devices

Current–voltage–luminescence (*I–V–L*) characteristics of Type-I and Type-II devices are shown in Fig. 7a and b, respectively. For both types of devices, both the non-cavity and microcavity devices show similar *I–V* characteristics, indicating the effectiveness of the p-type conductive doping (in the hole-injection layer) for facilitating hole injection from the Ag anode. The luminance efficiency vs. luminescence for all Type-I and Type-II devices are shown in Fig. 7c. The non-cavity Type-II device (Device C) shows higher luminance efficiency than the non-cavity Type-I device (Device A), partly because the green dopant was used in Type-II devices. For the same type of devices, the microcavity device also shows higher luminance efficiency than the non-cavity device (Device B vs. Device A and Device D vs. Device C), partly due to eyes being more sensitive to the green color and partly due to microcavity effects on brightness enhancement.

Table 1
Luminance efficiency of WOLED + CF.

Device	Luminance efficiency (cd/A) (at 10^3 cd/m^2)			
	Original	+CF_Blue	+CF_Green	+CF_Red
Type-I				
A	5.49	0.56	1.57	1.33
B	10.23	—	5.10	—
Type-II				
C	7.72	0.70	2.89	1.28
D	14.96	—	8.08	—

The luminance efficiencies of all the devices with/without color filters are listed in Table 1. For Type-I devices, the efficiencies of filtered green EL (at 1000 cd/m^2) for Devices A and B are 1.57 and 5.1 cd/A, respectively. For Type-II devices, the efficiencies of filtered green EL (at 1000 cd/m^2) for Devices C and D are 2.89 and 8.08 cd/A, respectively. It is interesting to note that owing to the better match between the EL spectra of the microcavity OLEDs (B and D) and the transmission of the green color filter, the efficiency loss caused by the color filter (for green pixels) is substantially lower, compared to the case of the conventional WOLED. Hence, by employing the microcavity structure merely in green pixels of the WOLED + CF technology, one can simultaneously achieve simplification the manufacturing process, enhancement of color performances, and enhancement in efficiencies for OLED displays.

4. Conclusions

The combination of WOLEDs and color filters is one of the most promising technologies for full-color OLED displays. Yet, the transmission spectra of most available CFs are broad and poorly match the EL spectra of WOLEDs, yielding less saturated filtered colors and small color gamut. In this work, we report that by employing the microcavity structure only in green pixels for the WOLED + CF display technology, one can simultaneously achieve simplification the manufacturing process, enhancement of color performances, and enhancement in efficiencies for OLED displays.

ABSTRACT

We investigated charge transports in *N,N′*-diphenyl-*N,N′*-di(*m*-tolyl)benzidine (TPD), a well-known hole-transport material for organic light-emitting diodes (OLEDs), in the orthorhombic and monoclinic polymorphs. Based on Marcus theory, charge-transfer rate constants in both the polymorphs were investigated by calculating the reorganization energies and charge transfer integrals. The rate constants for hole transfers, k_{CT}^{+}, were calculated to be two to three orders of magnitude larger than those for electron transfers, k_{CT}^{-}, for both the polymorphs. The small k_{CT}^{-} values result not only from the large reorganization energies for electron transfers but also from the small electron transfer integrals. To investigate the charge transfer integrals in more detail, the contributions of respective moieties of TPD molecules, nitrogen, central biphenylene, outer phenyl, and outer tolyl moieties, to charge transfer integrals were analyzed separately. From the analysis, the small electron transfer integrals compared to hole transfer integrals were found to originate from little contribution of LUMO to the outer phenyl and outer tolyl moieties, which has close intermolecular contacts. In contrast, HOMO spreads over these moieties, which results in relatively large hole transfer integrals. Holes can transport through these moieties with close contacts. Percolated hole-transport paths, consisting of consecutive molecular pairs with large hole transfer integrals, and therefore, large k_{CT}^{+}, exist in both the polymorphs, showing the good hole-transport property.

1. Introduction

Charge transports in organic materials are of immense interest for device applications such as organic light-emitting diodes (OLEDs) [1,2], organic field effect transistors [3,4], and organic solar cells [5,6], and intensive studies have been carried out to understand the charge transport properties [7–47]. Charge transports in several organic crystals with particularly strong intermolecular interactions were reported to be described by the band theory at low temperatures [7,8]. In contrast, organic materials with weak intermolecular interactions, including materials for OLEDs, are known to transport charges by the hopping mechanism [9–13]. The hole- and electron-transfer processes are described by the following Eqs. (1) and (2), respectively

$$M_A + M_B^+ \rightarrow M_A^+ + M_B \quad (1)$$

$$M_A + M_B^- \rightarrow M_A^- + M_B \quad (2)$$

The charge-transfer rate constant, k_{CT}, for each process can be given by Marcus theory [9,10] as

$$k_{CT} = \frac{4\pi^2}{h} H_{AB}^2 \frac{1}{\sqrt{4\pi\lambda k_B T}} \exp\left(-\frac{\lambda}{4k_B T}\right) \quad (3)$$

doi:10.1016/j.orgel.2009.11.003

where λ is the reorganization energy, H_{AB} is the charge transfer integral (or the electronic coupling matrix element) between the relevant two molecules, and T is the temperature. The h and k_B are the Planck and Boltzmann constants, respectively. The parameters of key importance for charge-transfer processes are λ and H_{AB}. The value of λ is the sum of internal and external reorganization energies. The former has been quantified by quantum chemical calculations for an isolated molecule [14–17], as the summation of λ_1 and λ_2, both of which are represented by the energy differences as follows

$$\lambda_1 = E(\text{charged state in neutral geometry}) - E(\text{charged state in charged geometry}) \quad (4)$$

$$\lambda_2 = E(\text{neutral state in charged geometry}) - E(\text{neutral state in neutral geometry}) \quad (5)$$

The external reorganization energy is related to intermolecular interaction and the contribution to the total reorganization energy has been considered to be small [18,19].

To quantify H_{AB} values, geometrically symmetric neutral dimers have been often considered [20–25]. Halves of the splittings of HOMO and LUMO caused by intermolecular interactions in the dimer system correspond to H_{AB} values for the hole transfer, H_{AB}^{+}, and electron transfer, H_{AB}^{-}, respectively. However, this method is ineffective when the geometry of the dimer is asymmetric and the HOMO or LUMO is unequally distributed between the two molecules. In contrast, the following equations provide the H_{AB}^{+} value, irrespective of the symmetry

$$\begin{vmatrix} \alpha_A - E & \beta - ES \\ \beta - ES & \alpha_B - E \end{vmatrix} = 0 \quad (6)$$

Here, $\alpha_A = \langle \Phi^A_{HOMO} | \mathbf{H} | \Phi^A_{HOMO} \rangle$, $\alpha_B = \langle \Phi^B_{HOMO} | \mathbf{H} | \Phi^B_{HOMO} \rangle$, $\beta = \langle \Phi^A_{HOMO} | \mathbf{H} | \Phi^B_{HOMO} \rangle$, $S = \langle \Phi^A_{HOMO} | \Phi^B_{HOMO} \rangle$, and E is the energy. $\mathbf{H}$ is the electronic Hamiltonian. Φ^A_{HOMO} and Φ^B_{HOMO} are HOMOs of isolated molecules, A and B, respectively. Noting that Φ^A and Φ^B are a non-orthogonal basis set, an effective electronic coupling value, H_{AB}^{+}, is given by Eq. (7) through Löwdin's transformation [26,48].

$$H_{AB}^{+} = \frac{\beta - \frac{\alpha_A + \alpha_B}{2} S}{1 - S^2} \quad (7)$$

For the calculations of H_{AB}^{-} values, LUMOs of isolated molecules, Φ^A_{LUMO} and Φ^B_{LUMO}, are used instead of Φ^A_{HOMO} and Φ^B_{HOMO}.

Until now, the evaluations of H_{AB} values have been performed for several asymmetric organic molecular pairs [27–30]. However, the evaluations of H_{AB} values for OLEDs materials have not been carried out, except for tris(8-hydroxyquinoline) aluminum(III) (Alq_3) [30]. To estimate H_{AB} values for materials in OLEDs, investigations of the amorphous structures are desired; however, they have been difficult to access so far. Therefore, in Ref. [30], the β-Alq_3 crystalline structure was used for the calculations of H_{AB}, assuming that the relative geometries of molecular pairs in the amorphous state are similar to those in the β-crystalline state.

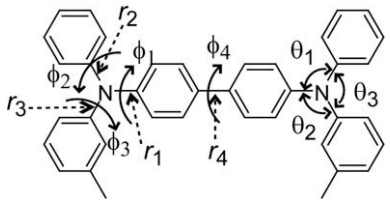

Fig. 1. The chemical structure of TPD. The θ, ϕ, and r represent respective bond angles, torsion angles, and bond lengths, respectively.

In this paper, we focus on charge transports in *N*,*N*′-diphenyl-*N*,*N*′-di(*m*-tolyl)benzidine (TPD) (Fig. 1), considering "*percolation paths*" for charge transports. TPD is a well-known hole-transport material for OLEDs [2,31–45]. Its reorganization energies for hole transfer, λ^+, and electron transfer, λ^-, have been evaluated by density functional theory (DFT) calculations, revealing that the value of λ^+ (0.28 or 0.29 eV) is much smaller than that of λ^- (0.56 eV) [15,16]. The calculations result in the ratio of the hole-transfer rate constant and electron-transfer rate constant, k_{CT}^{+}/k_{CT}^{-}, of 21 when we assume $H_{AB}^{+} = H_{AB}^{-}$ in Eq. (3) [16]. The value has been used to qualitatively explain the results of time-of-flight experiments [37,45] that TPD is superior for hole transports. However, the experimental results, that the electron mobility of TPD is a few or several orders of magnitude smaller than the hole mobility [37,45], cannot be explained by the ratio, $k_{CT}^{+}/k_{CT}^{-} = 21$. To quantify the k_{CT} values and to understand its charge transport property in more detail, the estimation of H_{AB} values is inevitable. In this paper, we evaluate the H_{AB} values using relative intermolecular geometries in TPD crystals as in the above case of Alq_3, because there have been also no data concerning the amorphous structure of TPD, except for the intramolecular structural parameters [44]. For TPD crystals, two different polymorphs, orthorhombic [41] and monoclinic [42], have been reported. We calculate H_{AB} values for both the polymorphs. To understand the charge transports in devices, percolated charge transport paths between the electrodes should be considered. We also investigate the percolation paths for charge transports, which consist of consecutive molecular pairs with large k_{CT} values. Only when percolation paths do exist, charges can be transported from one electrode to the counter electrode by the hopping mechanism [9–13].

2. Computational details

The molecular structures of TPD in its neutral, cationic and anionic states were optimized by DFT method using the B3LYP functional, which employs the gradient correction of the exchange functional with three parameters by Becke [49,50] and the correlation functional by Lee et al. [51]. The 6-31G(d) basis set was used. The values of λ^+ and λ^- were calculated for the DFT-optimized structures by both B3LYP/6-31G(d) and extended Hückel levels. As described above, the contribution of the external reorganization energy to the total reorganization energy has been considered to be small [18,19], and has been neglected [14–16,19]. Similarly, we only considered the internal

reorganization energy in the calculations of the reorganization energy, according to these preceding studies.

For the calculations of H_{AB} values, we used packing structures in the orthorhombic and monoclinic polymorphs of TPD described in Refs. [41,42], respectively. All the pairs of neighboring two molecules were taken from respective polymorphs, and the values of H_{AB} were calculated for the pairs from Eq. (7), using the values of α_A, α_B, β, and S. The calculations of H_{AB}^{+} and H_{AB}^{-} values by *ab intio* and DFT methods have sometimes failed [25] and semi-empirical calculations have been often performed [21–26]. Following these preceding studies, we used extended Hückel method to calculate H_{AB} values. All the calculations were carried out with Gaussian 03 program [52].

3. Results and discussion

3.1. Reorganization energies

For the reorganization energy calculations, TPD in the neutral, cationic, and anionic states were optimized by DFT method. Important optimized parameters, the bond angles, θ_1, θ_2, and θ_3, the torsion angles, ϕ_1, ϕ_2, ϕ_3, and ϕ_4, and the bond lengths, r_1, r_2, r_3, and r_4 (see Fig. 1), are listed in Table 1. The magnitude of geometrical change by anionization is larger than that by cationization, especially concerning the torsion angles. Table 2 shows the calculated λ values. Reflecting the torsion angle differences between the neutral and charged states, the λ^{-} value was calculated to be larger than λ^{+} value for both the DFT and extended Hückel calculations. The DFT-calculated λ values in this study are almost consistent with a previous report [16] as shown in Table 2. Although the extended Hückel calculations provide smaller λ values for both the hole and electron transports, the values of k_{CT}^{+}/k_{CT}^{-} at 300 K under the assumption of $H_{AB}^{+} = H_{AB}^{-}$, are almost consistent between the DFT and the extended Hückel results; hole-transfer rate constants are 20–30 times larger than the electron-transfer rate constants.

3.2. Frontier orbitals

Fig. 2 illustrates the HOMO and LUMO of TPD in the neutral state calculated at DFT B3LYP/6-31G(d) and extended Hückel levels for the above DFT-optimized geometry. Table 3 shows the square of the MO coefficients of respective segments in percentage. In Table 3, the respective segments, the nitrogen, biphenylene, phenyl, and tolyl moieties, are represented as "N," "BP," "Ph," and "To," respectively. The subscript of "L" or "R" means left or right part of the molecule in Fig. 2. For example, "N_L" indicates the left nitrogen of the molecule. For the HOMO, the DFT and extended Hückel results are almost equivalent. The contributions from one nitrogen, N_X, (X = L or R) and one benzene-ring in biphenylene parts, BP_X, are 15 and 16–18%, respectively. The contributions from one benzene-ring in phenyl, Ph_X, and tolyl, To_X, are 9% for both the moieties. On the other hand, the LUMO is more

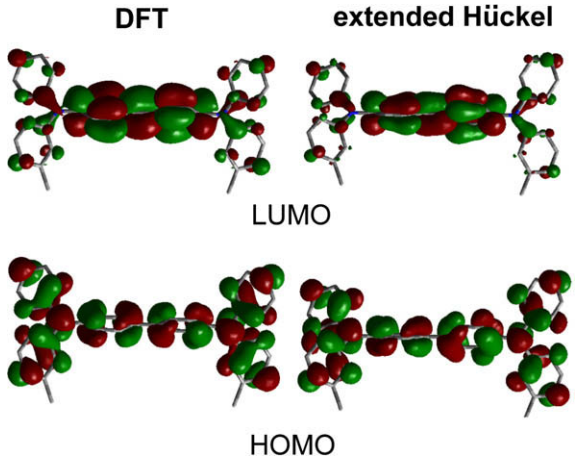

Fig. 2. The HOMO and LUMO of TPD calculated by DFT B3LYP/6-31G(d) and extended Hückel methods for the DFT-optimized geometry. The value for the surfaces is 0.02 a.u.

Table 1
Optimized parameters of TPD in its neutral, cationic, and anionic states. The parameters are defined in Fig. 1.

	θ_1 (°)	θ_2 (°)	θ_3 (°)	ϕ_1 (°)	ϕ_2 (°)	ϕ_3 (°)	ϕ_4 (°)	r_1 (Å)	r_2 (Å)	r_3 (Å)	r_4 (Å)

	LUMO	0.5	0.5	42.6	42.6	3.7	3.7	3.1	3.1

localized on the biphenylene part and contributions from the other parts are notably small, although some difference is found between the DFT and extended Hückel results for the LUMO. For the extended Hückel calculations, the contribution from BP_X is 42.6%, whereas those from N_X, Ph_X, and To_X, are 0.5, 3.7, and 3.1%, respectively.

3.3. Molecular pairs in TPD crystals

Fig. 3a and b shows the unit cell of TPD in the orthorhombic and monoclinic polymorphs reported by Kennedy et al. [41] and Zhang et al. [42], respectively. We designate four molecules in respective unit cells as I, II, III, and IV. We define the cell in Fig. 3 as cell (0 0 0), and neighboring cells at the $+a$, $-a$, $+b$, $-b$, $+c$, and $-c$ directions are represented as (1 0 0), (−1 0 0), (0 1 0), (0 −1 0), (0 0 1), and (0 0 −1), respectively. We refer to a molecule X (X = I, II, III, or IV) in the cell (abc) (a, b, c = −1, 0, or 1) as X(abc). For example, I(0 0 0) denotes molecule I in the cell (0 0 0). In the orthorhombic polymorph, as shown in Table 4, I(0 0 0) is surrounded by two molecules of I, four molecules of II, two molecules of III, and eight molecules of IV. Except for the above pairs between I and II, II(0 0 0) is surrounded by two molecules of II, eight molecules of III, and two

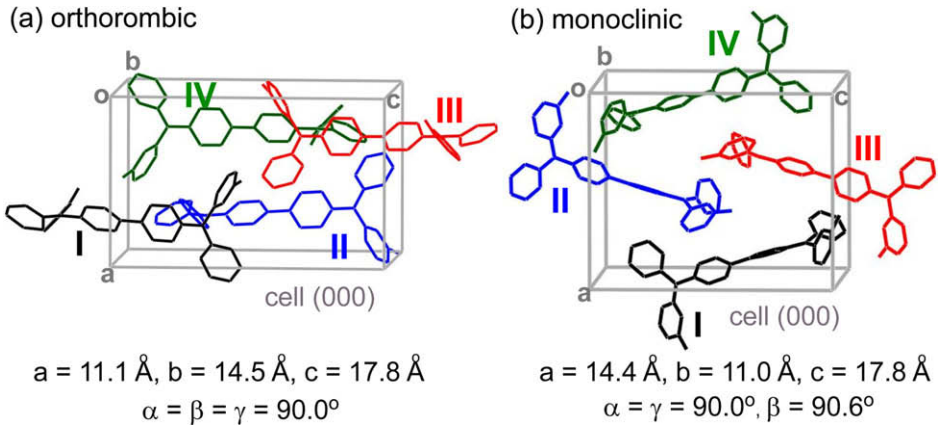

Fig. 3. Four molecules classified into the unit cell (0 0 0) in (a) orthorhombic and (b) monoclinic polymorphs of TPD. For each polymorph, the molecules are designated as I, II, III, and IV.

Table 4
Molecular pairs in the *orthorhombic* polymorph of TPD.

I	II	III		IV	
Pairs with I(0 0 0)					
1. I(0 0 1)	3. II(0 0 0)	7. III(0 0 −1)		9. IV(0 0 0)	13. IV(1 −1 0)
2. I(0 0 −1)	4. II(0 −1 0)	8. III(1 0 −1)		10. IV(1 0 0)	14. IV(1 0 −1)
	5. II(0 0 −1)			11. IV(0 −1 0)	15. IV(0 −1 −1)
	6. II(0 −1 −1)			12. IV(0 0 −1)	16. IV(1 −1 −1)
Pairs with II(0 0 0)					
–	17. II(0 0 1)	19. III(0 0 0)	23. III(1 1 0)	27. IV(0 0 0)	
	18. II(0 0 −1)	20. III(1 0 0)	24. III(1 0 −1)	28. IV(1 0 0)	
		21. III(0 1 0)	25. III(0 1 −1)		
		22. III(0 0 −1)	26. III(1 1 −1)		
Pairs with III(0 0 0)					
–	–	29. III(0 0 1)		31. IV(0 0 0)	33. IV(0 0 1)
		30. III(0 0 −1)		32. IV(0 −1 0)	34. IV(0 −1 1)
Pairs with IV(0 0 0)					
–	–	–		35. IV(0 0 1)	
				36. IV(0 0 −1)	

molecules of IV. Also except for above pairs between I and III, and II and III, III(0 0 0) is surrounded by two molecules of III and four molecules of IV. As the rest, IV(0 0 0) is sandwiched by two molecules of IV. In total, thirty-six pairs, numbered from 1 to 36 in Table 4, were considered for the calculations of H_{AB} values. Likewise, H_{AB} values were calculated for thirty-six pairs in the monoclinic polymorph, which are numbered from 37 to 72 in Table 5.

3.4. "Hole" transports in orthorhombic TPD

The H_{AB}^{+} values for the orthorhombic polymorph are represented in Fig. 4a as filled squares. The H_{AB}^{+} values are notably large for the pairs of 7 (I(0 0 0)–III(0 0 −1)), 8 (I(0 0 0)–III(1 0 −1)), 27 (II(0 0 0)–IV(0 0 0)), and 28 (II(0 0 0)–IV(1 0 0)). Since all these pairs are geometrically equivalent, their H_{AB}^{+} values are the same, 6.4 meV. The pairs are illustrated in Figs. 5a and 6a. The second largest H_{AB}^{+} values are for the pairs of 4 (I(0 0 0)–II(0 −1 0)), 6 (I(0 0 0)–II(0 −1 −1)), 31 (III(0 0 0)–IV(0 0 0)), and 33 (III(0 0 0)–IV(0 0 1)). They are also geometrically equivalent with each other, and all the H_{AB}^{+} value are 4.5 meV. Figs. 5b and 6b show the pairs. For the remaining pairs, the values are 6.4×10^{-2}–1.8 meV.

By using the H_{AB}^{+} values, the k_{CT}^{+} values were calculated at $T = 300$ K, according to Eq. (3). Here, we used the above-mentioned λ^{+} value of 0.148 eV. The results are shown in Fig. 4b as filled squares. The k_{CT}^{+} values are 4.2×10^{7}–4.3×10^{11} s^{-1}. The maximum value is for the pairs of 7, 8, 27, and 28, reflecting their large H_{AB}^{+} values. It can be expected that holes are favorably transported along the *a*-axis through the periodic pairs of 7 and 8, or 27 and 28, as shown in Fig. 5a. The k_{CT}^{+} values in the pairs of 4, 6, 31, and 33 are also in the same order, 10^{11} s^{-1}. Using the periodic pairs of 4 and 6, or 31 and 33, holes can be transported macroscopically along the *c*-axis (see Fig. 5b). Combinations of the pairs in Fig. 5a and b can be also used for effective hole-transport paths in the *a*–*c* plane. For hole transports in the *b*-direction, the pairs of 3, 4, 5, and 6, or 31, 32, 33, and 34 can be used as shown in Fig. 7. The k_{CT}^{+} values for the pairs of 3, 5, 32, and 34 are smaller than those for the pairs of 7 and 4 by about one order of magnitude. Therefore, the hole transports along the *b*-axis are expected to be ineffective compared with those along the *a*- and *c*-axes.

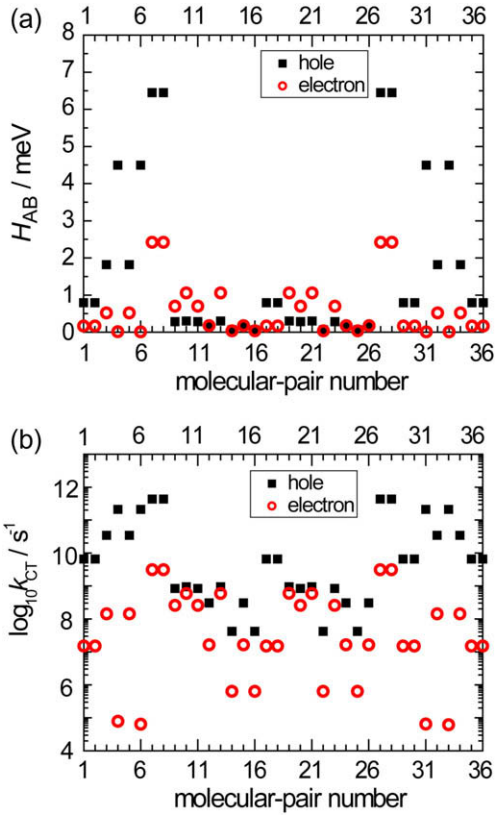

Fig. 4. (a) The values of hole transfer integrals, H_{AB}^{+}, and electron transfer integrals, H_{AB}^{-}, calculated by extended Hückel method for the thirty-six molecular pairs in the orthorhombic polymorph of TPD. (b) The values of hole-transfer rate constants, k_{CT}^{+}, and electron-transfer rate constants, k_{CT}^{-}, at 300 K calculated using the H_{AB} values in (a). For the calculations, the reorganization energies of $\lambda^{+} = 0.148$ and $\lambda^{-} = 0.404$ eV were used, which were calculated by extended Hückel method.

Table 5
Molecular pairs in the *monoclinic* polymorph of TPD.

I	II	III		IV	
Pairs with I(0 0 0)					
37. I(0 0 1)	39. II(0 0 0)	43. III(0 0 0)	47. III(1 1 0)	51. IV(1 0 0)

				72. IV(0 0 −1)	

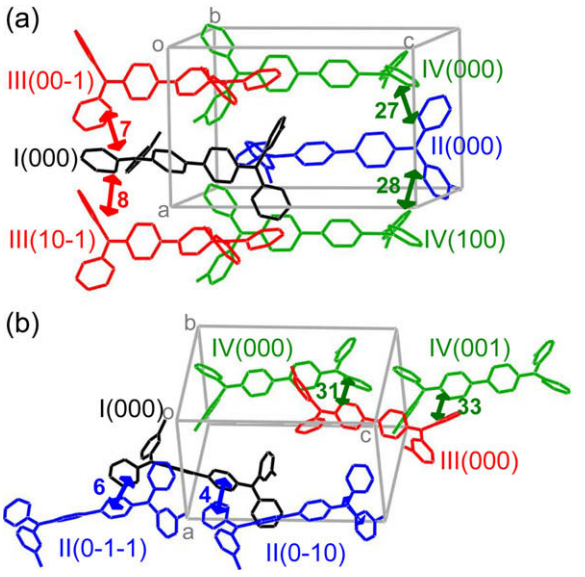

Fig. 5. (a) Representations of the molecular pairs with the largest hole-transfer rate constant in the orthorhombic polymorph, 7 (I(0 0 0)–III(0 0 −1)), 8 (I(0 0 0)–III(1 0 −1)), 27 (II(0 0 0)–IV(0 0 0)), and 28 (II(0 0 0)–IV(1 0 0)). Percolation paths for hole transports along the *a*-axis can be formed by the periodic pairs of 7 and 8, or 27 and 28. (b) The pairs with relatively large hole-transfer rate constants, 4 (I(0 0 0)–II(0 −1 0)), 6 (I(0 0 0)–II(0 −1 −1)), 31 (III(0 0 0)–IV(0 0 0)), and 33 (III(0 0 0)–IV(0 0 1)). The periodic pairs of 4 and 6, or 31 and 33 can be percolation paths for hole transports along the *c*-axis.

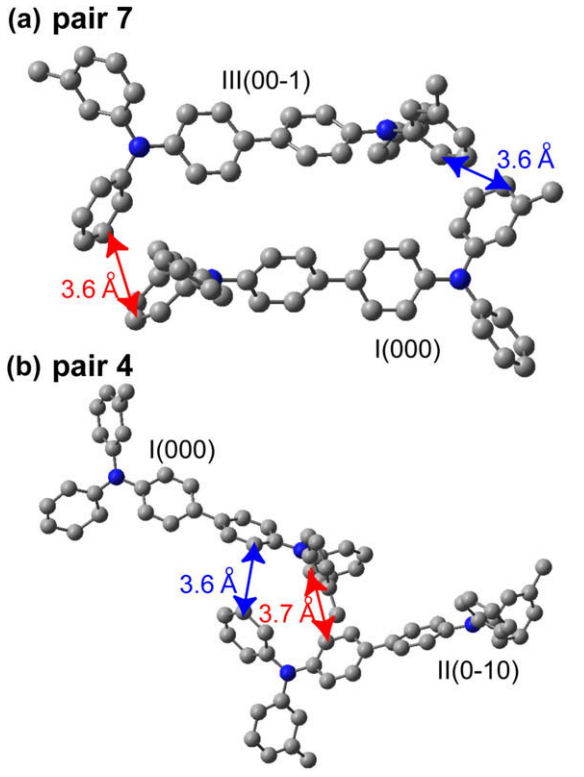

Fig. 6. Representations of short inter-segment C–C distances for the molecular pairs of (a) 7 (I(0 0 0)–III(0 0 −1)) and (b) 4 (I(0 0 0)–II(0 −1 0)).

From the calculations, the values of S in Eq. (7) were found to be small, which results in $1 \gg S^2$. Therefore, Eq. (7) can be reduced to $H_{AB}^{+} = |\beta - \{(\alpha_A + \alpha_B)/2\}S|$. Moreover, H_{AB}^{+} is found to be almost proportional to β, due to the well-known relation, $\beta \cong K\{(\alpha_A + \alpha_B)/2\}S$, where $K = 1.75$ is a Wolfsberg–Helmholz constant [53,54]. Therefore, the contribution of respective segments, the nitrogen, biphenylene, phenyl, and tolyl, for the H_{AB}^{+} values can be investigated by "*segmental β values*", calculated as $\langle \Phi_{HOMO}^{segA} | \mathbf{H} | \Phi_{HOMO}^{segB} \rangle$. Here, Φ_{HOMO}^{segA} and Φ_{HOMO}^{segB} are linear combinations of atomic orbitals in the respective segments of the molecules A and B. Tables 6 and 7 summarize the segmental β values for hole transfer, β^{+}, for respective segmental pairs in the pair of 7 and 4, respectively. Both the positive and negative values appear in the Tables, but the signs are not important and the absolute values are compared in the following discussion.

It is found from Table 6 that the following segment pairs provide large segmental $|\beta^{+}|$ values for the pair 7; (i) the pair of Ph_L of I(0 0 0) and Ph_L of III(0 0 −1), (ii) that of To_L of I(0 0 0) and Ph_L of III(0 0 −1), and (iii) that of To_R of I(0 0 0) and To_R of III(0 0 −1). For the pair 4, as shown in Table 7, followings are notable; the pair of BP_R of I(0 0 0) and Ph_L of II(0 −1 0), (ii) that of Ph_R of I(0 0 0) and BP_L of II(0 −1 0), (iii) that of To_R of I(0 0 0) and BP_L of II(0 −1 0), and (iv) that of To_R of I(0 0 0) and BP_R of II(0 −1 0). Tables 6 and 7 also show the inter-segment distances. It is found that segment pairs with short inter-segment distances generally provide large segmental $|\beta^{+}|$ values. Note that the inter-segment distances in Tables 6 and 7 are the shortest internuclei distances (here, we neglect the hydrogen nuclei). When we use the centers of gravity of each segment as the

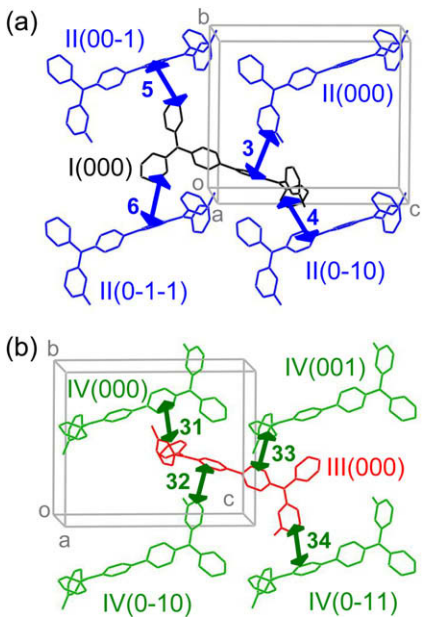

Fig. 7. Molecular pairs of (a) 3 (I(0 0 0)–II(0 0 0)), 4 (I(0 0 0)–II(0 −1 0)), 5 (I(0 0 0)–II(0 0 −1)), and 6 (I(0 0 0)–II(0 −1 −1)) and (b) 31 (III(0 0 0)–IV(0 0 0)), 32 (III(0 0 0)–IV(0 −1 0)), 33 (III(0 0 0)–IV(0 0 1)), and 34 (III(0 0 0)–IV(0 −1 1)) in the orthorhombic polymorph of TPD. They can convey holes in the direction of the *b*-axis.

inter-segment distance instead, distinct relationship between the segmental $|\beta^+|$ value and the inter-segment distance was not found. Although the inter-segment distance is one of the most crucial factors to provide large segmental $|\beta^+|$ values, they are also affected by other factors. For example, relatively large segmental $|\beta^+|$ value of 1.6 meV is found for To_L of I(0 0 0) and BP_L of III(0 0 −1) in the pair 7 (the inter-segment distance is 4.1 Å). In contrast, the pair of To_R of I(0 0 0) and Ph_R of III(0 0 −1) provides only 0.3 meV, although the inter-segment distance is as short as 3.8 Å. One of the other factors, which affect segmental $|\beta^+|$ values, will be relative orientations between the segments. Another factor is the localization of frontier orbitals. The above results suggest that the phenyl and tolyl rings have great significances to the H_{AB}^+ in both the pairs of 7 and 4, originating from the relatively large contributions to the HOMO and the short inter-segment distances. The situation is substantially different for electron transport in spite of the same intermolecular geometry. This is due to the localization of LUMO as shown later.

3.5. "Electron" transports in orthorhombic TPD

Fig. 4a also shows the H_{AB}^- values for the orthorhombic polymorph as open circles. It is found that the values are smaller than those for HOMOs; all the values are smaller than 2.4 meV. From the H_{AB}^- values, the k_{CT}^- values in Eq. (3) were calculated at $T = 300$ K, using the λ^- value of 0.404 eV. The results are shown in Fig. 4b as open circles. It is clearly shown that the maximum k_{CT}^- value, 3.1×10^9 s^{-1} is two orders of magnitude less than the maximum k_{CT}^+ value. The minimum k_{CT}^- value, 6.2×10^4 s^{-1} is two to three orders smaller compared to the minimum k_{CT}^+ value. The smaller k_{CT}^- values explain the poor electron-transport property of TPD, which is found in this study to originate from the small H_{AB}^- values as well as the large λ value.

The segmental β values for the electron transfer, β^-, in the pairs of 7 and 4 are also shown in Tables 6 and 7, respectively. For the segment pairs with large segmental $|\beta^+|$ values, such as the pair of Ph_L of I(0 0 0) and Ph_L of III(0 0 −1), the segmental $|\beta^-|$ values are found to be small, although the relative geometry of the molecular pairs are the same. The difference originates from the difference of HOMO and LUMO; LUMO is localized on the biphenylene part and the contributions of the other segments are small as shown above (see Fig. 2 and Table 3). Instead, the pair of BP_L of I(0 0 0) and BP_R of III(0 0 −1) provides the segmental $|\beta^-|$ value of 5.0 meV, which is larger than that of the corresponding segmental $|\beta^+|$ value, 0.4 meV. This is also due to the localization of LUMO on the biphenylene part.

3.6. "Hole" transports in monoclinic TPD

Filled squares in Fig. 8a represent the H_{AB}^+ values for the monoclinic polymorph of TPD. It is found that the values in the pairs of 51 (I(0 0 0)–IV(1 0 0)), 52 (I(0 0 0)–IV(1 1 0)), 55 (II(0 0 0)–III(0 0 −1)), and 56 (II(0 0 0)–III(0 1 −1)) are remarkable. These pairs are shown in Figs. 9a, 10a, and 10b. The geometries of the former two pairs, 51 and 52, are equivalent with each other. Also, those of the later two pairs, 55 and 56, are equivalent. The difference between the former two pairs and latter two pairs is slight, which originates from the lower symmetry of the monoclinic polymorph compared with the orthorhombic polymorph. It is also found from Fig. 8a that the H_{AB}^+ values for the pairs of 39 (I(0 0 0)–II(0 0 0)), 41 (I(0 0 0)–II(0 0 1)), 67 (III(0 0 0)–IV(0 0 0)), and 69 (III(0 0 0)–IV(0 0 1)) are relatively large. These pairs are illustrated in Figs. 9b, 10c, and 10d. The geometries of the pairs, 39 and 67, are equivalent and those of the pairs, 41 and 69, are also equivalent.

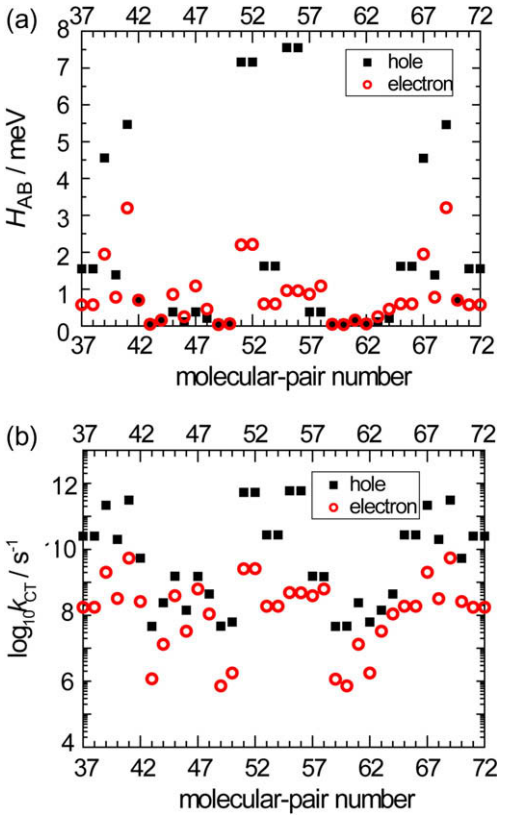

Fig. 8. (a) The values of hole transfer integrals, H_{AB}^+, and electron transfer integrals, H_{AB}^-, calculated by extended Hückel method for the thirty-six molecular pairs in the monoclinic polymorph of TPD. (b) The values of hole-transfer rate constants, k_{CT}^+, and electron-transfer rate constants, k_{CT}^-, at 300 K calculated using the H_{AB} values in (a). For the calculations, the reorganization energies of $\lambda^+ = 0.148$ and $\lambda^- = 0.404$ eV were used.

It should be noted that the pairs of 51, 52, 55, and 56 are similar to the pair 7 (and 8, 27, 28) in the orthorhombic polymorph, as shown in Figs. 6 and 10. Therefore, large segmental $|\beta^+|$ values are obtained for the same segmental pairs between spatially close Ph_X and/or To_X rings in the pairs of 51, 52, 55, and 56, as in the case of the pair 7 (see Tables S1 and S2 in the supporting information). The pairs of 39, 41, 67, and 69 are similar to the pair 4 (and 6, 31, 33) in the orthorhombic polymorph, also as shown in Figs. 6 and 10. Therefore, as in the case of the pair 4, the dominant contribution for the intermolecular HOMO coupling is provided for the segmental pairs between spatially close BP_X and Ph_X, or BP_X and To_X (see segmental $|\beta^+|$ values in Tables S3 and S4 in the supporting information).

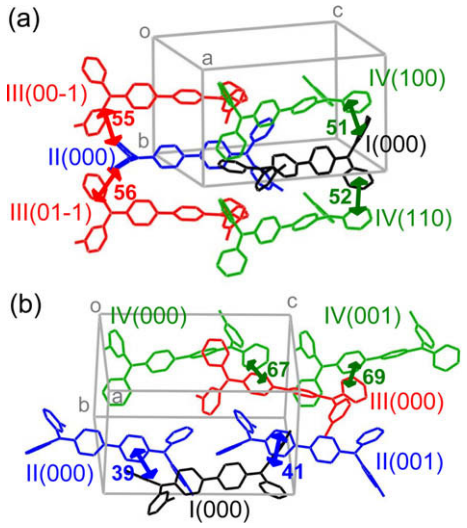

Fig. 9. (a) Representations of the molecular pairs with large hole-transfer rate constants in the monoclinic polymorph, 51 (I(0 0 0)–IV(1 0 0)), 52 (I(0 0 0)–IV(1 1 0)), 55 (II(0 0 0)–III(0 0 −1)), and 56 (II(0 0 0)–III(0 1 −1)). Percolation paths for hole transports along the *b*-axis can be formed by the periodic pairs of 51 and 52, or 55 and 56. (b) The pairs with relatively large hole-transfer rate constants, 39 (I(0 0 0)–II(0 0 0)), 41 (I(0 0 0)–II(0 0 1)), 67 (III(0 0 0)–IV(0 0 0)), and 69 (III(0 0 0)–IV(0 0 1)). The periodic pairs of 39 and 41, or 67 and 69 can be percolation paths for hole transports along the *c*-axis.

The k_{CT}^{+} values at $T = 300$ K are shown in Fig. 8b as filled squares. Large k_{CT}^{+} values in the order of $10^{12}\,s^{-1}$ are obtained for the pairs of 51, 52, 55, and 56, reflecting the H_{AB}^{+} values. Therefore, holes can be conveyed along the *b*-axis through the periodic pairs of 51 and 52, or 55 and 56, as illustrated in Fig. 9a. Also, the periodic pairs of 39 and 41, or 67 and 69, which provide the k_{CT}^{+} values larger than $10^{11}\,s^{-1}$, can transport holes macroscopically along the *c*-axis, as illustrated in Fig. 9b. Combinations of these pairs can also convey holes effectively in the *b* and *c* plane. For hole transports in the *a*-direction, the pairs of 39, 40, 41, and 42, or 67, 68, 69, and 70 can be used as illustrated in Fig. 11. However, the transports are expected to be inferior to those along the *b*- and *c*-axes due to the smaller k_{CT}^{+} values for these pairs.

3.7. "Electron" transports in monoclinic TPD

The H_{AB}^{-} values for the monoclinic polymorph of TPD are also shown in Fig. 8a as open circles. All the H_{AB}^{-} values are less than 3.2 meV, meaning the small intermolecular electronic couplings of LUMOs. The segmental β values for the pairs of 51, 55, 39, and 41 are shown in Tables S1–S4 in the supporting information. As in the case of the orthorhombic polymorph, the intermolecular LUMO couplings between the Ph_X and/or To_X rings are small due to the localization of LUMO on the biphenylene moiety, which results in the small H_{AB}^{-} values.

The k_{CT}^{-} values at $T = 300$ K are represented in Fig. 8b as open circles. The values, which results in 10^{5}–$10^{10}\,s^{-1}$, are found to two to three orders smaller than the k_{CT}^{+} values, as

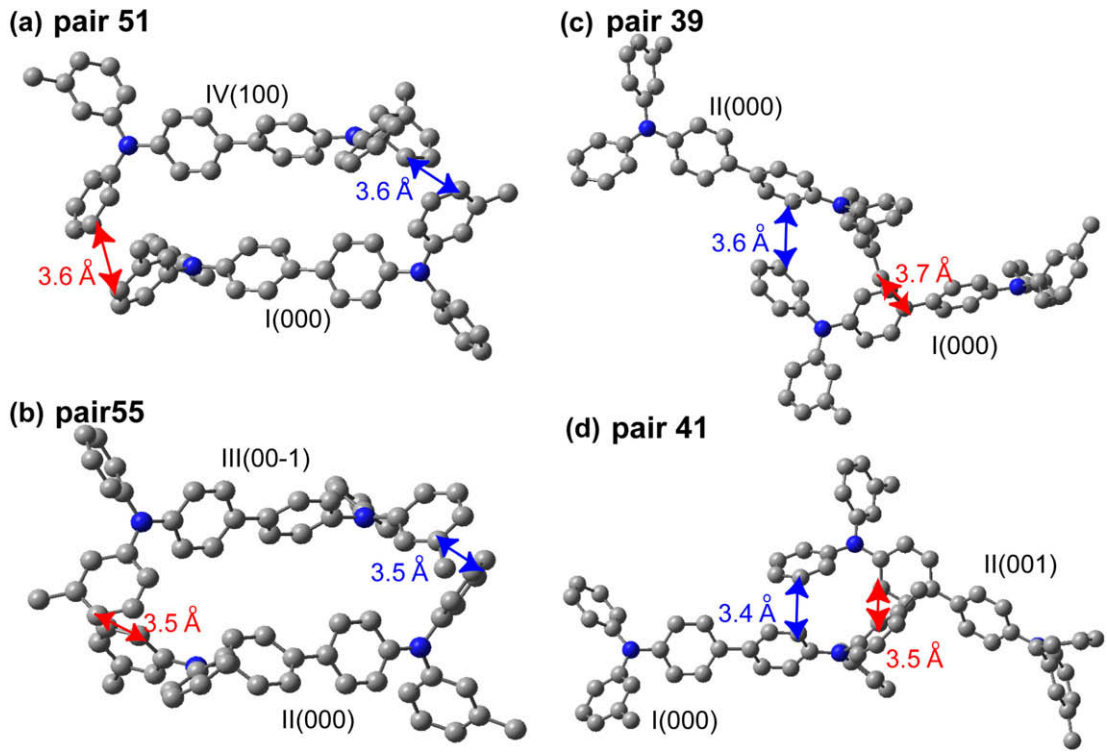

Fig. 10. Representations of some short inter-segment C–C distance for the molecular pairs of (a) 51 (I(0 0 0)–IV(1 0 0)), (b) 55 (II(0 0 0)–III(0 0 −1)), (c) 39 (I(0 0 0)–II(0 0 0)), and (d) 41 (I(0 0 0)–II(0 0 1)).

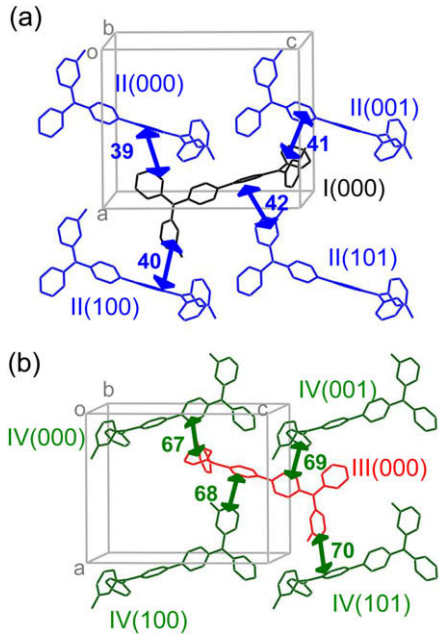

Fig. 11. Molecular pairs of (a) 39 (I(0 0 0)–II(0 0 0)), 40 (I(0 0 0)–II(1 0 0)), 41 (I(0 0 0)–II(0 0 1)), and 42 (I(0 0 0)–II(101)) and (b) 67 (III(0 0 0)–IV(0 0 0)), 68 (III(0 0 0)–IV(1 0 0)), 69 (III(0 0 0)–IV(0 0 1)), and 70 (III(0 0 0)–IV(1 0 1)) in the monoclinic polymorph of TPD. They can convey holes in the direction of the *a*-axis.

in the case of orthorhombic polymorph. Therefore, the electron-transport property of TPD is poor due to the small H_{AB}^{-} values as well as the large λ^{-} value also for the monoclinic polymorph, which is the same conclusion for the orthorhombic polymorph.

4. Conclusion

We have calculated the rate constants for Marcus-type charge transfers and have investigated percolation paths for charge transports in both the orthorhombic and monoclinic polymorphs of TPD. For hole transports, it was found that effective percolation paths exist along specific directions in both the polymorphs. HOMO of TPD delocalizes over the whole molecule, and the outer phenyl and tolyl rings of TPD were found to play an important role for the intermolecular hole transfer integrals due to the inter-segmental close contact between molecular pairs. In contrast to hole transfers, the electron-transfer rate constants are much smaller in both the polymorphs. The smaller electron-transfer rate constants originate not only from the larger reorganization energy but also from smaller electron transfer integrals. LUMO of TPD localizes on the central biphenylene segments, which results in small inter-segmental charge transfers between outer phenyl and tolyl rings in molecular pairs, in spite of the close segmental contacts.

We showed that the shape of HOMO and LUMO and intermolecular packings are crucial for charge transfer integrals. In OLEDs, TPD is used in the amorphous state. This study on the segmental contribution to charge transfer integrals shows that the intermolecular packing is crucial for charge transports. Electron transport properties would be better, if paths consisting of consecutive molecular pairs with close contact at the biphenylene segments are percolated. To be exact, information on intermolecular packing in the amorphous state is necessary to quantify the charge transfer integrals. In order to clarify the amorphous structure and to discuss the charge transports in the amorphous state, two-dimensional double-quantum solid-state NMR experiments [55–58] are now in progress in our laboratory.

ABSTRACT

We report successful fabrication of high-color-rendering pure-white phosphorescent organic light-emitting devices (OLEDs) by employing a true-blue iridium complex Ir(dfbp-py)(fbppz)$_2$ and a wide-bandwidth yellow emitting osmium complex Os(bptz)$_2$(dppee). The two-component phosphorescent white OLED exhibited a high color rendering index (CRI) of 81 and CIE$_{x,y}$ coordinates close to the ideal white emission (0.33, 0.33). By doping the yellow phosphors into the hole-transport layer and the electron-transport layer adjacent to the blue-emitting layer and thereby forming a triple-emitting-layer device structure, we obtained WOLED which exhibited rather stable colors at different biases/brightnesses. Such high-CRI pure-white two-component WOLEDs yielded EL efficiencies of up to 9.5%, 22.9 cd/A, and 20 lm/W for the forward directions.

1. Introduction

With intrinsically high quantum efficiency, white-emitting organic light-emitting devices (WOLEDs) incorporating phosphorescent emitters have become the most promising candidates for meeting the stringent efficiency requirements in lighting applications [1,2]. For high-quality white-light illumination, WOLEDs with CIE$_{x,y}$ coordinates similar to those of the blackbody radiation (with a correlated color temperature (CCT) between 2500 and 6500 K), and a color rendering index (CRI) above 80 are required [3]. Intuitively, the CRI can be enhanced by increasing the number of dopants to extend the spectral range of the electroluminescence (EL). For instance, in 2002, D'Andrade et al. demonstrated that the CRI of phosphorescent WOLEDs could be greatly improved from 50 to 83 by using three (red, green and bluish-green) phosphorescent dopants instead of two complementary (red and bluish-green) dopants [4]. As another example, in 2006 the same group combined blue fluorophors and red/green phosphors to generate white EL, in which deeper blue emission was obtained from the singlet emission of the fluorophors (to relax the requirement for the more challenging true-blue phosphors with high emission efficiencies) while red/green emission was obtained from the triplet emission of the phosphors [5]. In such hybrid WOLEDs, the CRI was improved to 85. In 2007, Schwartz et al. also successfully demonstrated high-CRI WOLEDs (CRI = 86) using a similar hybrid fluorophor/phosphor approach [6]. However, the adoption of a larger number of emissive dopants not only complicates device fabrication, but also renders the color control in WOLEDs fraught with difficulties. In addition, most reported phosphorescent WOLEDs yielded warm white, which would limit their applications in lighting.

As such, generating white electrophosphorescence using less dopants (e.g. two complementary colors) while retaining a useful CRI is highly desired, since it would

doi:10.1016/j.orgel.2009.11.004

vastly simplify the device structures of WOLEDs. To achieve such a goal, it is necessary to develop complementary-color phosphors with extended bandwidths as well as good color rendering capabilities. Until recently, one of the major bottlenecks in implementing high-CRI two-component phosphorescent WOLEDs was the lack of efficient blue phosphors generating enough light output in the shorter wavelength region. For instance, the adoption of the common bluish-green phosphor FIrpic in the two-component WOLEDs generally yielded a poor CRI of <70 due to deficient color rendering in the blue region [7–9]. However, this can be compensated by adopting novel true-blue organic phosphors developed recently [10–13]. On the other hand, from the perspective of color mixing, wide-bandwidth complementary yellow phosphors are also needed to generate white emission with high CRI. In this paper, through the employment of a recently developed true-blue iridium complex Ir(dfbppy)(fbppz)$_2$ and a newly developed wide-bandwidth yellow osmium complex Os(bptz)$_2$(dppee) in appropriate device architectures, we report two-component pure-white phosphorescent WOLEDs with CRI of >80 and CIE coordinates close to the ideal equal-energy white emission (0.33, 0.33).

2. Experimental

2.1. Materials

The blue phosphorescent iridium complex Ir(dfbppy)(fbppz)$_2$, where dfbppy and fbppz stand for 4-*tert*-butyl-2-(2,4-difluorophenyl)pyridinato and 3-(trifluoromethyl)-5-(4-*tert*-butylpyridyl) pyrazolate, and the yellow phosphorescent osmium complex Os(bptz)$_2$(dppee), where bptz and dppee stands for 3-*tert*-butyl-5-(2-pyridyl)-1,2,4-triazolate and cis-1,2-bis(diphenylphosphino) ethene, whose chemical structures are shown in Fig. 1a, were employed in the preparation of two-component WOLEDs. As shown in literature, the heteroleptic Ir^{III} complex Ir(dfbppy)(fbppz)$_2$ revealed true-blue phosphorescence with CIE$_y$ of ~0.2 [10,13]. In particular, placing bulky tertiary butyl substituents around the chelates had improved dispersion of dopant in the host matrix and reduced back energy transfer from dopant to host due to their increased spatial separation [13,14]. On the other hand, the yellow emitting Os(II) complex Os(bptz)$_2$(dppee), showing a featureless emission peak centered at λ = 611 nm, phosphorescence lifetime τ_{obs} = 1 μs and emission quantum yield ϕ = 0.3 in degassed CH_2Cl_2 solution, was synthesized from treatment of $Os_3(CO)_{12}$ with bptzH and dppee in sequence, employing the synthetic methodology that described in literature [15].

Selected spectral data of Os(bptz)$_2$(dppee): MS (FAB, ^{192}Os): *m*/*z* 990 (M^+). ^{1}H NMR (500 MHz, d_6-acetone, 298 K): δ8.04 (t, J_{HH} = 9.0 Hz, 4H), 7.83–7.71 (m, 2H), 7.59–7.55 (m, 4H), 7.36 (dd, J_{HH} = 7.5, 7.0 Hz, 2H), 7.29 (dd, J_{HH} = 8.0, 7.0 Hz, 4H), 7.05–7.03 (m, 4H), 6.85 (dd, J_{HH} = 7.5, 7.3 Hz, 4H), 6.79–6.75 (m, 6H), 1.46 (s, 18H). ^{31}P NMR (202 MHz, d_6-acetone, 298 K): δ31.04 (s). Anal. Calcd. for $C_{48}H_{48}N_8OsP_2$: C, 58.29; N, 11.33; H, 4.89. Found: C, 58.26; N, 11.24; H, 4.85.

2.2. OLED fabrication

All synthesized compounds were subject to temperature-gradient sublimation under high vacuum before use. OLEDs were fabricated on the ITO-coated glass substrates with multiple organic layers sandwiched between the transparent bottom indium–tin–oxide (ITO) anode and the top metal cathode. The organic and metal layers were deposited by thermal evaporation in a vacuum chamber with a base pressure of <10^{-6} torr. The deposition rate of organic layers was kept at ~0.2 nm/s. The deposition system permitted the fabrication of the complete device structure in a single pump-down without breaking vacuum. The active area of the device was 2 × 2 mm^2, as defined by the shadow mask for cathode deposition.

2.3. Device characterizations

Current–voltage–luminance (*I–V–L*) characterization of the devices was measured using an Agilent 4155B semiconductor parameter analyzer and a Si photodiode calibrated with Photo Research PR650. EL spectra of devices were collected by a calibrated CCD spectrograph. Total photon output from the device (either from the viewing direction or from all directions of the device) was measured in an integrating sphere containing a calibrated photodetector.

3. Results and discussions

3.1. Emission properties of the Ir and Os complexes

Photoluminescence (PL) of Ir and Os complexes were measured using a Charge-Coupled Device (CCD) spectrograph and the 325 nm line of the He-Cd laser as the excitation source. For determining PL quantum yields, the samples were mounted in a calibrated integrating sphere coupled with the CCD spectrograph. By comparing the spectral intensities of the excitation laser and the PL emission, quantum yields (PLQY) were determined [16].

The structural drawings, PL spectrum of Ir(dfbppy)(fbppz)$_2$ and Os(bptz)$_2$(dppee) in CH_2Cl_2 and their corresponding CIE coordinates are shown in Fig. 1a–c, respectively. The PL quantum yield of Ir(dfbppy)(fbppz)$_2$ in degassed CH_2Cl_2 is calculated to be 0.68, for which true-blue emission showed a CIE$_y$ close to 0.2, while the PL spectrum of Os(bptz)$_2$(dppee) in CH_2Cl_2 revealed a yellow–orange emission with a quantum yield of 0.3.

With the CIE coordinates shown in Fig. 1c, these two phosphors are indeed quite complementary in colors and appropriate combinations of these two colors could possibly generate nearly ideal white emission with CIE coordinates close to (0.33, 0.33) (Fig. 1c). The main PL peak of Ir(dfbppy)(fbppz)$_2$ locates at 449 nm and is accompanied by the vibronic bands peaking at 479 and 507 nm and extending into the blue–green region, which together would provide color rendering in the shorter wavelength region. The yellow emitter Os(bptz)$_2$(dppee) exhibits a

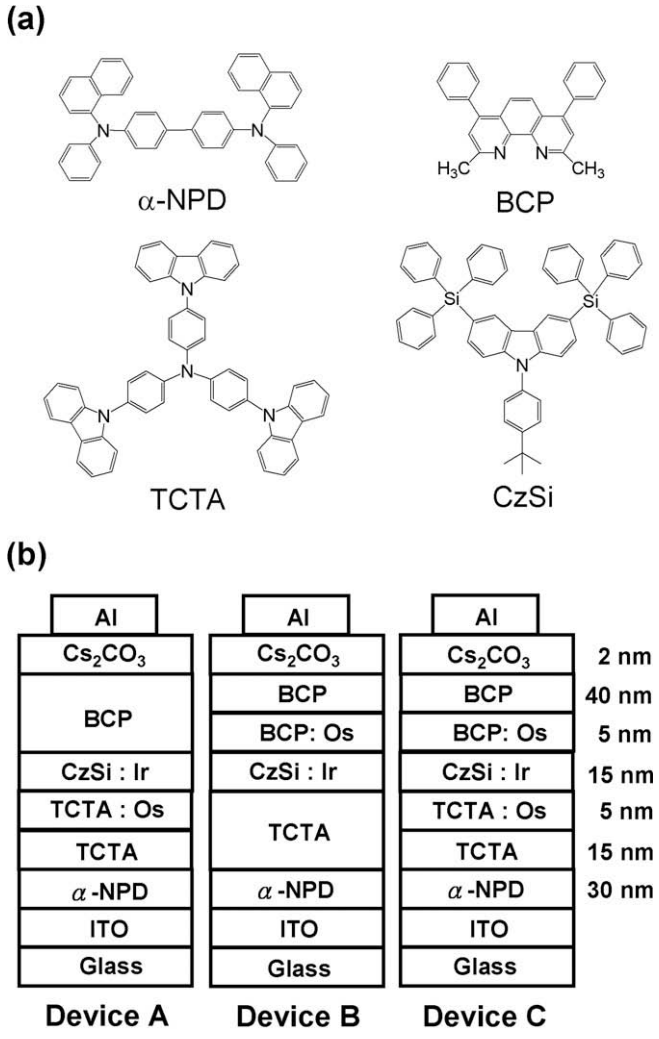

Fig. 2. (a) Structural drawings of materials used in the fabrication of OLEDs; (b) Schematic structures of the various OLED devices.

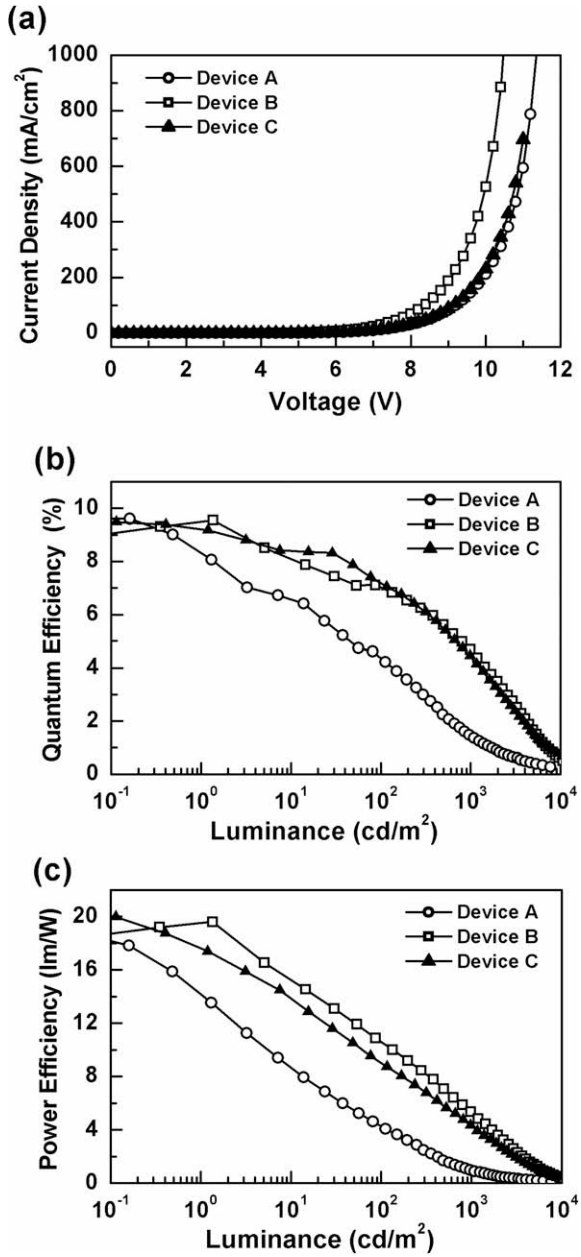

Fig. 3. (a) Current–voltage (*I–V*) characteristics, (b) external quantum efficiency versus luminance, and (c) power efficiency versus luminance for devices A, B and C.

broad PL peak at 611 nm and full-width at half-maximum (FWHM) of 120 nm, covering the spectral range all the way to saturated red. The exceeding large FWHMs of both the blue and yellow emission render possible fabrication of two-component phosphorescent WOLEDs with high CRI, if appropriate color mixing could be implemented by certain device architectures.

3.2. WOLEDs with double emitting layers

In general, the WOLED device structures can be roughly classified into single- and multiple-emitting-layer (EML)

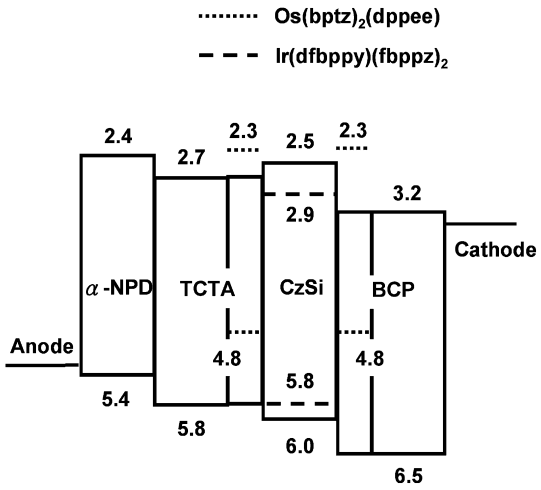

Fig. 4. The energy levels of different materials used in devices.

architectures. The fabrication of WOLEDs with the single EML is usually difficult because the multiple dopants and the host have to be evaporated simultaneously with precise ratio control. Furthermore, the relative intensities of the different emissions might vary upon variation of the operational biases. On the other hand, the device structure with multiple EMLs sometimes suffers from shifting of the recombination zone (RZ) upon increasing the biases. As such, the buffer layer is often inserted between the EMLs to prevent the RZ shift and to stabilize the emission color [17,18]. However, the hindered carrier transport at the buffer layer might degrade the power efficiency. In this work, without adopting the buffer layer, we studied various architectures for multiple-EML WOLEDs, with the aim of achieving stabilized colors. Three multiple-EML WOLED structures without the buffer layer were fabricated in this study (Fig. 2).

To prevent the back transfer of the triplet excitons from the blue phosphors to the host material, a wide-gap host 9-(4-*tert*-butylphenyl)-3,6-bis(triphenylsilyl)-9*H*-carbazole (CzSi), with a large triplet energy of 3.02 eV, was adopted for the blue-emitting layer [19]. In considering the carrier-transport properties and the energy-gap matching, both the hole-transport material 4,4′,4″-tris(carbazole-9-yl)-triphenylamine (TCTA) and the electron-transport material 2,9-dimethyl-4,7-diphenyl-1,10-phenanhroline (BCP) were tested as the host for the yellow emitting layer. Both are commonly used in green to red phosphorescent OLEDs [20]. From the phosphorescence measurements at 77 K, triplet energies of TCTA and BCP were determined to be 2.79 and 2.54 eV, respectively, both larger than that of $Os(bptz)_2(dppee)$. Hence, the yellow emitter was doped in the carrier transport layer (BCP or TCTA or both) next to the blue EML.

We first tested two architectures with double EMLs. The first device configuration (device A, in which the blue phosphor was doped into the CzSi, while the yellow phosphor was doped into TCTA) was: ITO/α-NPD (30 nm)/TCTA (10 nm)/TCTA doped with 1 wt.% of $Os(bptz)_2(dppee)$ (5 nm)/CzSi doped with 6 wt.% of $Ir(dfbppy)(fbppz)_2$

(15 nm)/BCP (50 nm)/Cs_2CO_3 (2 nm)/Al (150 nm). 4,4′-bis[N-(1-naphthyl)-N-phenyl-amino]biphenyl (α-NPD) and TCTA were used as the hole-transport layer (HTLs), BCP as the electron-transport layer (ETL), and Cs_2CO_3 as the electron-injection layer (EIL). ITO and Al were used as the anode and cathode respectively. In device B, the yellow emitter was doped into the electron-transport layer BCP. The configuration of device B was: ITO/α-NPD (30 nm)/TCTA (15 nm)/CzSi doped with 6 wt.% of Ir(dfbppy)(fbppz)$_2$ (15 nm)/BCP doped with 2 wt.% of Os(bptz)$_2$(dppee) (5 nm)/BCP (45 nm)/Cs_2CO_3 (2 nm)/Al (150 nm). The chemical structures of the materials used and the device structures are shown in Fig. 2.

The current–voltage (*I–V*) characteristics of devices A and B are shown in Fig. 3a. From the *I–V* curves, the lower voltage of device B compared to that of device A suggested hole trapping associated with the yellow emitter in TCTA. Fig. 4 depicts the energy levels of materials used in the devices. The energy levels of hosts and carrier-transport materials were collected from the literatures while energy levels of the phosphorescent dopants [Os(bptz)$_2$(dppee), Ir(dfbppy)(fbppz)$_2$] were determined by cyclic voltammetry (CV) [10,19,21,22]. The ionization potential of Os(bptz)$_2$(dppee) (4.8 eV) is substantially lower than those of TCTA, CzSi and Ir(dfbppy)(fbppz)$_2$ (all of which range between 5.8 and 6.0 eV). In view of such an energy-level relationship, it is expected that the Os complexes will function as effective hole traps in TCTA in device A [23–28], but less likely as electron traps in BCP in device B.

The EL spectra of devices A and B at different brightness levels are shown in Fig. 5a and b, respectively. With more contribution from the blue Ir complex and significantly less emission from the yellow Os complex, device A exhibited a bluish-white EL. Such EL characteristics indicated that the exciton formation occurred predominantly inside the CzSi layer, perhaps closer to the CzSi/BCP interface (even though the Os complex in TCTA demonstrated certain hole-trapping characteristics), since the CzSi was dominated by hole-transporting [19,29]. The significant efficiency roll-off in device A might also be associated with such a scenario, since the electron-transporting BCP (with lower triplet energy of 2.54 eV) can quench the high-energy triplet excitons of Ir(dfbppy)(fbppz)$_2$) (2.8 eV) near the interface. On the other hand, doping the yellow Os complex into the electron-transporting BCP near the CzSi/BCP interface (device B) greatly enhanced the yellow emission from the Os complex, resulting in a white EL with CIE coordinates close to (0.33, 0.33) (Table 1). This was due to the fact that the exciton formation zone was almost entirely located at the CzSi/BCP interface. Thus, the increased yellow emission was likely the result of both the direct exciton formation on the Os complex and the energy transfer from the Ir complex (or host) to the Os complex. Furthermore, although both devices A and B exhibited similar EL efficiencies at low current densities (peak external EL quantum efficiencies of 9% and 9.6% for devices A and B, respectively; Fig. 3b and Table 1), the efficiency roll-off in device B was nevertheless much less pronounced.

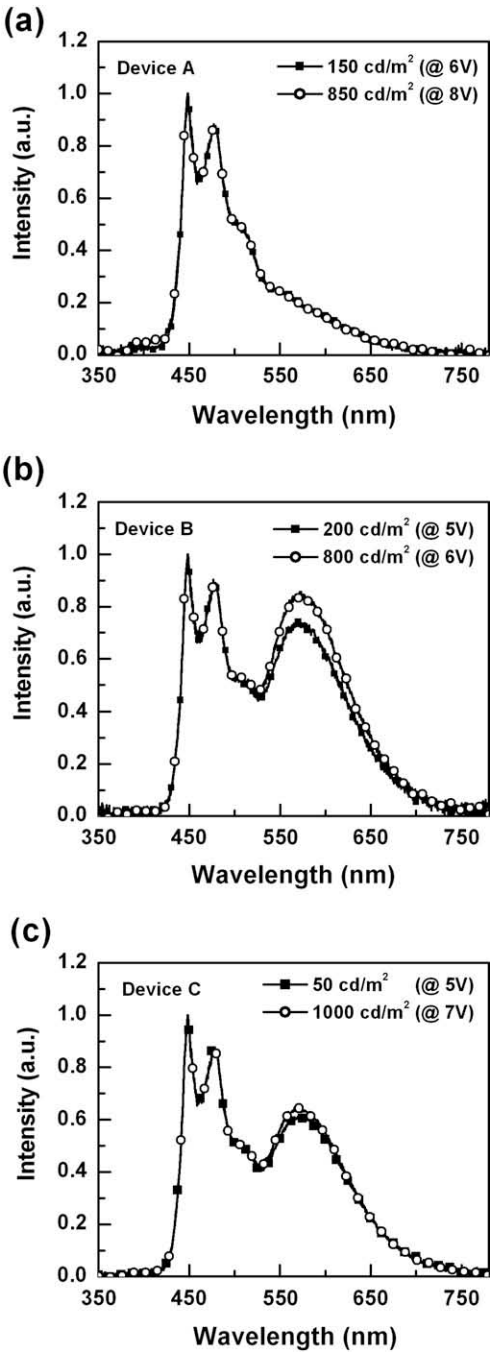

Fig. 5. Normalized EL spectra of OLED devices A, B and C at different brightness levels. EL spectra of all devices were collected at some fixed driving voltages (e.g. 4, 5, 6, 7, 8, 9 V, etc.), and the EL spectra shown in a–c represent those observed at the voltages giving brightness levels closest to 100 and 1000 cd/m^2 for each device.

3.3. WOLEDs with triple emitting layers

Although device B yielded nearly pure white EL, its CRI value was still below 80 and the color variation with brightness levels was noticeable. For device B, the intensity

EL characteristics of devices A, B and C.

		Device A (2 EML)	Device B (2 EML)	Device C (3 EML)
External quantum efficiency (%)	Peak	9.6	9.6	9.5
	10^2 cd/m^2	4.2	6.8	7.0
Luminance efficiency (cd/A)	Peak	21.5	22.5	22.9
	10^2 cd/m^2	7.5	15.3	15.0
Power efficiency (lm/W)	Peak	18.8	19.6	20.0
	10^2 cd/m^2	4.1	10.0	8.7
Max. brightness (cd/m^2) (V)		7731 (11.6 V)	13368 (10.8 V)	10271 (11.0 V)
CIE coordinates	$\sim10^2$ cd/m^2	(0.211, 0.249)	(0.324, 0.343)	(0.311, 0.327)
	$\sim10^3$ cd/m^2	(0.208, 0.245)	(0.339, 0.354)	(0.314, 0.332)
CRI/CCT (K)	$\sim10^2$ cd/m^2	–	79 / 5861	81 / 6592
	$\sim10^3$ cd/m^2	–	78 / 5229	81 / 6400

of yellow emission grew relative to the intensity of the blue emission and the CRI dropped with the bias/brightness. It might imply that the exciton recombination zone migrated towards the BCP EML when the bias was increased, leading to larger contribution from the yellow emission of the Os complex. Such effects may be suppressed or reduced by utilizing the hole trapping phenomenon in the device structure A; the hole-trapping mechanism might be used to retard the shift of the recombination zone toward the BCP interface and thus to stabilize EL colors with biases.

Based on these considerations, we further tested a device C with the yellow Os complex doped into portions of both the hole-transport layer TCTA and electron-transport layer BCP adjacent to the blue-emitting layer. The configuration of device C with triple EMLs was: ITO/α-NPD (30 nm)/TCTA (10 nm)/TCTA doped with 1 wt.% of $Os(bptz)_2(dppee)$ (5 nm)/CzSi doped with 6 wt.% of $Ir(dfbppy)(fbppz)_2$ (15 nm)/BCP doped with 2 wt.% of $Os(bptz)_2(dppee)$ (5 nm)/BCP (45 nm)/Cs_2CO_3 (2 nm)/Al (150 nm) (shown in Fig. 2). In Fig. 3a, one observed that device C exhibited *I–V* characteristics very similar to those of device A (and higher voltage than device B), indicating similar hole-trapping effects from the $Os(bptz)_2(dppee)$ doped TCTA. Fig. 5c shows the EL spectra of device C at different brightness levels. The corresponding CIE coordinates of the EL spectra are tabulated in Table 1. For the brightness from <10^2–10^3 cd/m^2, the device exhibited nearly pure white EL with CIE coordinates of (0.311, 0.327)–(0.314, 0.332), which are close to the ideal equal-energy white (0.33, 0.33). With a color variation of only about (0.003, 0.005), the color was rather stable, indicating the effectiveness of the aforementioned device strategy and architecture. Furthermore, the CRI of device C at different brightness levels (Table 1) were higher than 80 (81 indeed). To the best of our knowledge, reports of two-component pure-white phosphorescent OLEDs with a CRI of >80 are very rare.

The EL efficiency characteristics of device C were similar to those of device B (Fig. 3(b), 3c and Table 1). The device C exhibited peak EL efficiencies of 9.5% photon/electron, 22.9 cd/A, and 20 lm/W for the forward directions. At the practical brightness of 100 cd/m^2, the forward efficiency remained high at around 7.0%, 15.0 cd/A, and 8.7 lm/W. For lighting applications, the light emitted from all surfaces of the substrate can in principle be redirected to the forward direction via certain lighting fixtures; hence the total efficiency of the device was also characterized by using an integrating sphere setup [30]. The total quantum and power efficiencies measured in our sphere setup were about 1.7× larger than the forward viewing efficiencies, which were consistent with previous reports [3,31–33]. In this regard, device C indeed had a total peak external quantum efficiency and a total power efficiency of 16.2% and 34 lm/W, respectively.

4. Conclusions

In conclusion, by utilizing a true-blue iridium complex $Ir(dfbppy)(fbppz)_2$ and a wide-bandwidth yellow osmium complex $Os(bptz)_2(dppee)$, we obtained a highly efficient phosphorescent WOLEDs. The two-component phosphorescent WOLED exhibited a high CRI of 81 and CIE coordinates close to the ideal white emission (0.33, 0.33). By doping the yellow phosphors into the hole-transport layer and the electron-transport layer adjacent to the blue-emitting layer and thereby forming a triple-emitting-layer device structure, we obtained WOLED which exhibited rather stable colors at different biases/brightnesses. Such high-CRI pure-white two-component WOLEDs yielded EL efficiencies of up to 9.5%, 22.9 cd/A, and 20 lm/W for the forward directions.

Photocurrent spectroscopy

ABSTRACT

We used photocurrent spectroscopy to study the electronic density of states distribution in thin films of sexithiophene and an alkylated analog, both at the band edge and inside the band-gap. The presented photocurrent spectroscopy analyses provide direct experimental evidence for a modification of the distribution of the electronic density of states in an organic field effect transistor (OFET) channel induced by the modulation of the effective carrier density by the gate voltage. We observe a correlation between a gate voltage induced increase of the carrier density in the channel and a broadening of the distribution of the electronic states around the band edge. We also detected the formation of deep electrically active states within the band-gap of sexithiophene OFETs, induced by the exposure to air and light. These results are in good agreement with the evolution of the macroscopic transport parameters of the devices, i.e., carrier mobility and threshold voltage, as a function of the exposure time to light and atmosphere.

1. Introduction

Organic semiconducting materials offer the possibility of implementing innovative applications, such as flexible light emitting diodes, photovoltaic cells, and organic field effect transistors (OFETs). The determination and the understanding of organic semiconductor charge transport properties and the electronic states energy distribution are important for further improving device performance. However, these issues are still not unequivocally resolved [1–4]. Since most organic electronic devices rely heavily on the electrical conduction properties of the material, it is necessary to achieve a thorough understanding of the physical mechanism of charge carrier (photo-) generation, transport, trapping and recombination. Charge transport in organic semiconductors can be impacted by different, often interdependent parameters. For instance, the carrier mobility (the transport parameter that can be directly derived from electrical characterization of an OFET) is affected by temperature, electrical field, and, in particular, by the charge carrier density, because charge transport at room temperature in most organic semiconductors occurs *via* carrier hopping through an energetically disordered manifold of localized states [1,2,5,6]. The energy distribution of the states that dominate the transport processes has been shown to have a Gaussian shape with its width σ [5,7,8]. It has been show from theoretical models [9] and quantum chemical calculations [10] that the presence of charged species on a molecule causes a major modification of the electronic energetic structure due to the formation of polarons. Also, the presence of a high charge carrier

doi:10.1016/j.orgel.2009.11.005

density has the effect of increasing the disorder of the energy landscape within the organic semiconductor, thus broadening the Gaussian density of states (DOS) distribution [7,11–13].

The exposure of OFETs to atmosphere and a prolonged operation are two factors known to affect the macroscopic transport parameters of the devices (i.e., mobility and threshold voltage) by introducing deep electrically active trapping states [14–17]. Photocurrent (PC) spectroscopy [18] provides information on the density of states distribution inside the forbidden gap (deep states) and near the band edge, where the photocurrent follows the classical power function of the photon energy, as does the absorption coefficient α, $I_{PC}(\hbar\omega) \sim \alpha \sim (\hbar\omega - E_G)^2$, where E_G is the energy gap, I_{PC} is the collected photocurrent and $\hbar\omega$ is the photon energy, even if for energies above the band-gap the condition $I_{PC}(\hbar\omega) \sim \alpha$ becomes invalid due to the strong increase in optical absorption [19,20].

The goal of the present work is twofold: (i) to investigate how the effective distribution of the electrically available states near the band edge is affected by the modification of the DOS due to variation of the charge carrier density and (ii) to characterize the formation of deep electrically active states within the band-gap.

For that purpose, we fabricated various p-type OFETs with sexithiophene (6T) or α,ω-dihexylsexithiophene (DH6T) as the active semiconductor, and measured the key macroscopic transport parameters, i.e., the hole mobility μ and the threshold voltage V_T. Moreover, we investigated the distribution of the electrically active states by spectral photocurrent (PC) analyses as a function of the carrier concentration in the channel, which was modified by varying the applied gate voltage. We observed a modification of the photoresponse induced by the electrically active states distribution (their energy and width) as a function of the charge carrier concentration in the OFET channel. In addition, we studied the effects induced by prolonged exposure to air and light at room temperature on the transport properties (μ and V_T) and the PC spectra of 6T OFETs.

2. Experimental

OFET devices were fabricated by evaporating gold contacts on a heavily doped *n*-Si/SiO_2 substrate (the *n*-Si is the gate of the transistor) with a 0.5 μm thick SiO_2 dielectric layer. The Au source and drain contacts defined the OFET channel width (50 μm) and length (5 mm). Typically 30 nm thick layers of 6T (Sigma Aldrich) or DH6T (H.C. Stark GmbH) were then thermally evaporated (pressure below 2×10^{-7}mbar, deposition rate ca. 4 Å/min; for final device structure see Fig. 1). An Agilent HP 4155 Semiconductor Parameter Analyzer, provided with gold tips for contacting the electrodes, was used to carry out drain-source current (I_{ds}) measurements as a function of gate voltage (V_G).

Photocurrent spectroscopy measurements were carried out on these OFET structures in air and at room temperature. A low bias was applied to the drain electrode (<2 V) and the current was measured through a load resistance. The light source was a 150 W Quartz Tungsten Halogen lamp coupled to a Jarrel monochromator and mechanically chopped at low frequency (<20 Hz). The photocurrent was measured as a function of light wavelength (varied in the range λ = 300–750 nm) using a current amplifier connected to a digital lock-in amplifier (Stanford Research 850). The energy resolution was 0.01 eV at 2.40 eV. The photon flux was measured with a calibrated Si photodiode. PC measurements were done at low-level injection conditions (1×10^{13} photons/cm^2 at λ = 450 nm). No indications for sample degradation were observed in the PC spectra during experiments, as assessed by comparing consecutively acquired spectra.

3. Results and discussion

The average values of the key transport parameters of OFETs with 6T and DH6T are summarized in Table 1. Despite the very similar molecular structure of the conjugated part of the two employed molecules, two striking differences can be noted: (i) DH6T devices exhibit a higher hole mobility than 6T devices; (ii) 6T devices show a negative threshold voltage, whereas DH6T devices have a positive threshold voltage. Therefore, DH6T features an accumulation layer of charge carriers (holes) at the semiconductor/dielectric interface even at zero gate bias, and a high positive bias is needed to completely deplete the channel (OFET "off-state"). These observations were highly reproducible, and were measured for both bottom contact and top contact control-device configurations, and for OFETs fabricated on a flexible substrate (Mylar®) [22].

The observed difference in hole mobility between 6T and DH6T OFETs is likely due to a better structural and morphological quality of DH6T layers [21,22]. The terminal hexyl groups of DH6T enable an improved long range molecular ordering on the substrates [21–24], resulting in a lower density of grain boundaries in thin films [12]. The substantial number of holes present in DH6T OFET channels at zero gate voltage has been explained by a high susceptibility of this material to p-type doping by oxygen

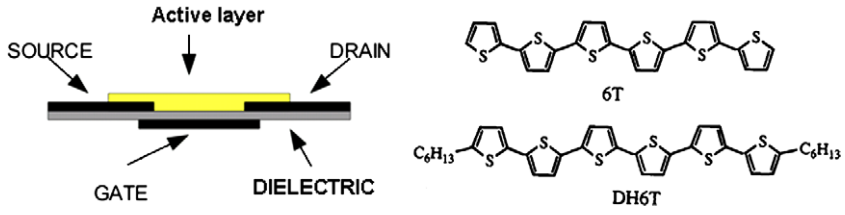

Fig. 1. Schematic layout of the OFET devices, and chemical structure of 6T and DH6T.

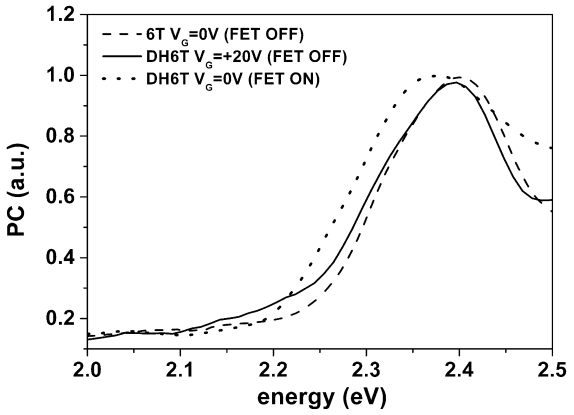

Fig. 2. Photocurrent yield (electron/photon) spectra of 6T and DH6T OFETs for different gate voltages, normalized to each curve maximum.

(*e.g.*, due to air exposure) due to its 0.2 eV lower ionization energy than 6T [21].

Fig. 2 shows the PC spectra near the fundamental optical transition (at 2.4 eV [25]) of 6T and DH6T OFETs. The almost coinciding position of the strong absorption band indicates that the effective conjugation length of the substituted DH6T molecules essentially equals that of 6T [26]. V_T values of these devices were −4 V (6T) and +12 V (DH6T). Therefore, PC measurements were done by applying V_G = 0 V (6T) and V_G = +20 V (DH6T) in order to have both OFETs in the "off-state". In this state, both organic materials exhibit a similar onset of electrical transport at *ca.* 2.25 eV. The energy distribution of the electrically available states has an almost Gaussian-like shape for both devices in the "off-state". For comparison, Fig. 2 also shows the PC spectrum of DH6T in an "on-state", i.e., for V_G = 0 V, thus with a much higher density of holes in the channel. PC spectra of DH6T OFETs in the "on-state" show a modification in the distribution of the density of the electronic transport states with the onset of the electrical transport shifting to lower energies (*ca.* 2.18 eV).

More insight into the effects of varying the charge carrier density in the OFET channel on the occupation of the electronic states distribution is provided by the PC spectra reported in Fig. 3, which zooms in on the band edge DOS distribution of a 6T OFET under different gate bias voltages (V_G = +20 V, V_G = 0 V and V_G = −20 V; i.e., going from "off-state" to "on-state"). It is evident that the energy distribution of the electrically active states varies, shifting towards lower energy when the device is turned on (V_G = −20 V). Fitting the PC spectra at the band edge of 6T OFETs with a Gaussian-like curve yields that its width increases by 0.12 eV when it passes from the "off–state" to the "on-state".

A similar behavior was reported for chemically doped organic semiconductors where the width of the Gaussian shaped density of states was assumed to increase as the charge carrier density increases [7,11] due to the local electric field induced by the presence of charges. This local electric field is responsible for the alteration of the potential landscape in the active material. The increase in energetic disorder due to the presence of charges may broaden

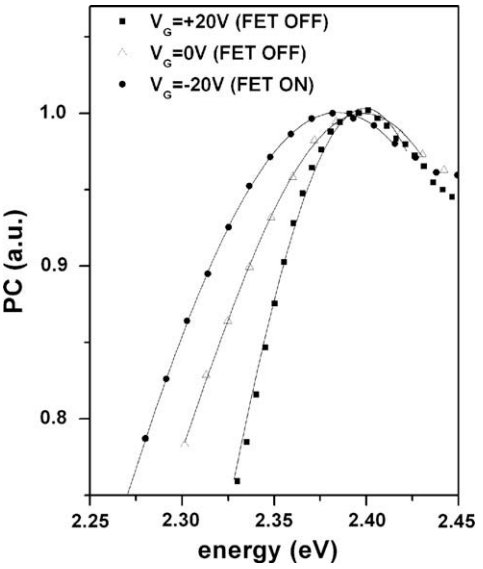

Fig. 3. Band edge details of the photocurrent yield (electron/photon) spectra of a 6T OFET for different gate voltages, normalized to each curve maximum (solid curves). The Gaussian fits to the experimental data are the dashed curves.

the effective DOS distribution by increasing the available and effective transport states in the band tails [7,12,13].

The polaronic nature of mobile charges has also the effect of modifying the energy levels of the molecules on which they are located: the presence of the polaron induces the formation of levels between the HOMO and LUMO gap and modifies the band edge shape. These effects, quantitatively predicted using quantum chemical calculations [10], have been investigated on thiophenes by Charge Modulation Spectroscopy (CMS) measurements [27], showing an induced absorption below the HOMO–LUMO transition, and a bleaching of the neutral π–π^* transition. The rearrangement of the molecular energy levels can create additional disorder in the energy landscape of the 6T layer.

Another noteworthy factor that has to be taken into account when interpreting photoconductivity spectra in organic materials is the efficiency of charge generation, which is usually low due to strong exciton effects. The presence of a larger concentration of charge carriers in the channel and of a stronger electric field when the OTFT is in the on-state, might affect the processes of light absorption and photogeneration of carriers, enhancing the photoconductivity response below the band edge region. Our results, reported in Fig. 3, suggest that this effect is not highly correlated to the presence of intense electric fields in the active material, since we observe a decrease in the DOS broadening (i.e. a decrease in the PC signal) when the OTFT is strongly depleted of charges in the off-state (V_G = +20 V).

We now turn towards the effects induced by prolonged exposures to air and light, at room temperature, on the transport properties and on the PC spectra of 6T OFETs. Two sets of 6T samples, labeled A and B, respectively, were

exposed to different ambient conditions: set B was exposed to atmosphere and light while set A was exposed to light while kept under vacuum. The change of the transport parameters and of the PC spectra was monitored after one month and after three months and the results are shown in Fig. 4. Samples A, exposed to light in vacuum, exhibit a moderate variation of the PC spectrum, the relative amplitude of the two major peaks (at 2.4 eV and at 2.8 eV) decreases from 1.5 to 1.1, mainly due to the marked decrease of the peak at 2.8 eV More pronounced modifications occur in samples B, where the relative amplitude of the two major peaks markedly decreases, due to the almost complete disappearance of the peak at 2.8 eV. At the same time, an interesting feature appears below the band-gap, where the behavior of the PC signal at ca.1.55 eV indicates the onset of photoemission of carriers from deep levels [18], that were not present in fresh as-deposited devices, but become electrically active after one month and more of exposure to air and light.

The macroscopic effects of such modifications can be monitored following the evolution of the main transport parameter of the OFETs, namely, the mobility and the threshold voltage, which are reported in Table 2 for samples A and B. Since the mobility remains almost constant for A samples, while it clearly decreases in the B ones, we assume a correlation between this behavior and the modifications observed in the corresponding PC spectra and discuss the origin of these effects.

The features that appear below the band-gap can be explained by the interaction of oxygen with organic semiconductors: it is known that oxygen diffuses into organic semiconductors, where it has recently been proposed to act as a dopant through the formation of electrically active deep states, induced by an electrochemical process during the interaction with the host organic molecule. These deep states have been theoretically modeled for pentacene where they should be located at about 0.29 eV from the valence band [31]. The slope variation that we observe in the PC spectra of the aged 6T devices and that indicates the onset of emission of carriers from trapped states is associated to an optical absorption at about 1.6 eV, i.e. much deeper in the gap.

Indeed, a strong increase in the doping level of organic materials induces an increase in the below band-gap transitions associated to polaron states, as observed by IR analyses on Ion Gel-gated polymer thin-film transistors [32]. It has been reported that polarons in photoexcited 6T are characterized by two electronic transitions (detected by photoinduced absorption) below the band-gap, i.e., at 0.8 eV and 1.54 eV [25]. The PC spectra of aged devices indicate the onset of emission of carriers from trapped states that could be attribute tosingly charged polaron

DH6T	+12	6.8×10^{-2}

Table 2
Extracted parameter values (mobility and threshold voltage) for 6T OFETs following exposure to light in vacuum (set of samples A) and in air (set of samples B).

	6T			
	A		B	
	V_T (V)	μ (cm^2/Vs)	V_T (V)	μ (cm^2/Vs)
As deposited	+28	2×10^{-3}	+20	2×10^{-3}
1 Month	−18	3×10^{-3}	+7	8×10^{-4}
3 Months	−20	4×10^{-3}	0	7×10^{-4}

states [18], also in good agreement with the polaron induced absorption observed with Charge Modulation Spectroscopy [27]. Indeed, not all doping-induced polarons in the ground state contribute to mobile charge carriers at room temperature, because of notable Coulomb interactions. However, after optical excitation of a polaron to a higher lying state the charge carrier can more easily overcome the Coulomb attraction of the dopant and thus becomes a mobile charge; i.e., photoconductivity is enhanced.

Our PC results thus indicate that one month and longer exposure to air and light enhances the formation of bound polaron states (i.e., charged states) in 6T films, likely due to oxygen adsorbed from atmosphere (note that we cannot formally rule out similar effects due to water), interacting with the 6T chain and changing its charge state.

The increase in polaron concentration affects the charge carrier transport and induces a marked reduction of the carrier mobility by trapping and enhanced scattering effects [11], as reported in Table 2.

The threshold voltage shifts to more negative values in both sets of samples, and this effect normally attributed to bias stress [14] when a negative gate voltage is applied. In our case we can assume the same mechanism acting in both sets of devices [28] as, during PC analyses the gate voltage is kept at 0 V while V_{DS} = +10 V, thus inducing an effective negative potential difference between the gate and the channel. It is noteworthy that the decrease is less marked in samples B, intentionally exposed to oxygen, with respect to samples A, possibly due to oxygen doping effects that may shift the threshold voltage towards more positive voltages, thus balancing the negative V_T drift. However, the behavior of V_T under bias stress and atmosphere exposure may be affected by a number of different factors that are still being debated [15–17].

In addition, the exact nature of the broad band at 2.8 eV is still under discussion [29,30], but its modification, clearly observed in both samples A and B, is not related to a reduction of the carrier mobility, since the peak markedly decreases with aging in samples A while the mobility remains almost constant (Table 2).

4. Conclusions

In conclusion, we carried out photocurrent spectroscopy analyses on 6T and DH6T OFETs and we directly assessed a correlation between the distribution of the electronic density of states and the charge carrier population in the channel. We induced a modulation of the occupation of the density of states at the electrical band edge by varying the charge carrier concentration in the OFET channel, through applying an external voltage to the gate. As the carrier density in the OFET channel increases, the distribution of the electronic density of states is modified and the Gaussian-like shape of the transport states increases in width by 0.12 eV. We studied the effects induced by a prolonged exposure to air and light on 6T OFETs. The observed changes of the macroscopic transport parameters (reduction of the mobility and shift of the threshold voltage) were correlated to the modifications of the distribution of the electronic density of states at the band edge and in the activation of deep trapping states attributed to the formation of polaron states. PC analyses provide thus a useful tool for the in the investigation of transport phenomena in organic thin-film transistors. Table 1.

Bipolarons

ABSTRACT

We simulate the scattering processes between a negative polaron and a positive bipolaron in a conjugated polymer chain using mixed quantum classical molecular dynamics. The simulations are performed based on the Su–Schrieffer–Heeger (SSH) model modified to include electron–electron interactions, a Brazovskii–Kirova symmetry-breaking term, and an external electric field. It is found that there exist a critical electric field, below which the polaron and bipolaron can scatter into an excited polaron. If the external electric field is higher than the critical electric field, the polaron and bipolaron will pass through each other and continue moving as isolated ones. Because the excited polaron can decay to the polaron state through emitting a photon, our results indicate that the interactions between polarons and bipolarons can open a channel for electroluminescence.

1. Introduction

Since the discovery that a conjugated organic polymer, poly(paraphenylene vinylene) (PPV), can be used as the active component in light-emitting diodes (LEDs) [1], much effort has been devoted to the study of the properties of organic conjugated materials. Conjugated polymers, as quasi-one-dimensional materials, have property that their structure can be easily distorted due to the strong electron-lattice interaction [2]. As a result, charges added to the polymer chain by doping, charge injection, or photoexcitation will induce self-localized electron states called polarons or bipolarons. A polaron has a spin $\pm 1/2$ and a charge ±e, whereas a bipolaron is spinless with charges ±2e [3]. It has been generally accepted that the polarons can recombine to form singlet and triplet excitons, in which the singlet exciton is radiative. However, to our knowledge, less attention has been paid to the recombination and products of polarons and bipolarons.

Bipolarons were hypothesized to exist in conjugated polymers almost 30 years ago [2] and studied extensively over the years. It was well accepted that bipolarons can be formed in doped polymers [4–7], while their formation in pristine photoexcited polymers was still an open question [8]. In addition, in studies on bipolarons it appeared that the stability of a bipolaron is questionable in the absence of oppositely charged ions [9]. In this paper, we are interested in the recombination processes between a polaron and a bipolaron with opposite charges. Total energy estimates indicate that two extra electrons may go either into two independent polarons or into a bipolaron [10]. There is a subtle balance between the two situations. The optical data of some polymers showed clearly signals involving polarons and bipolarons [3,11], which testifies the coexistence of polarons and bipolarons in conjugated polymers. Therefore, there is a possibility that polarons collide with bipolarons, and investigating the interactions between polarons and bipolarons seems to be necessary and significant.

doi:10.1016/j.orgel.2009.11.006

Recently, Kadashchuk and coworkers reported an experimental study of trions in a PPV derivative [12]. They pointed out that the capture of a positive bipolaron by a deeply trapped negative polaron is one of the mechanism of trion formation. Onodera [13] investigated the interactions among polaron and bipolaron excitations within the framwork of the Brazovskii and Kirova continuum model of *cis*-polyacetylene. The results showed that polarons and bipolarons can freely pass through each other without attractive or repulsive interactions. Swanson et al. [14] pointed out that a positive (negative) polaron and a negative (positive) bipolaron produce a polaron and phonons. However, the results are simply based on a conjecture, not be convinced yet. Very recently, Ge et al. [15] theoretically investigated the scattering process between a negative polaron and a positive bipolaron in a single polymer chain. They employed an adiabatic molecular dynamics method (in which the electrons are in their eigenstates at any instant), and thought the reaction between a polaron and a bipolaron produces a positive polaron and emits a photon. From these works, we can see that all the results for the polaron–bipolaron interaction are not consistent, so that further investigations are needed.

In this paper, we present results from a numerical study of the dynamics of scattering between a negative polaron and a positive bipolaron in a polymer chain under the influence of an external electric field. The dynamics is performed by using a nonadiabatic evolution method where electron transitions between instantaneous eigenstates are allowed in contrast to the so-called adiabatic dynamics with fixed level occupation. We mainly give our attention to the products and their yields for the polaron–bipolaron reaction.

The paper is organized as follows. Section 2 describes the model and parameters used. The results are presented in Section 3. The summary and conclusions are given in Section 4.

2. Model and method

We use the following model Hamiltonian:

$$H = H_{\mathrm{SSH}} + H_{ee} + H_E. \tag{1}$$

The first term of Eq. (1) expresses the Su–Schrieffer–Heeger (SSH) Hamiltonian [16]:

$$H_{\mathrm{SSH}} = -\sum_{i,s} t_{i,i+1}\left(c^{\dagger}_{i,s}c_{i+1,s} + c^{\dagger}_{i+1,s}c_{i,s}\right) + \frac{1}{2}K\sum_i (u_{i+1}-u_i)^2 + \frac{1}{2}M\sum_i \dot{u}_i^2, \tag{2}$$

where $t_{i,i+1} = t_0 - \alpha(u_{i+1}-u_i) + (-1)^i t_e$, t_0 is the transfer integral of π electrons in a regular lattice, α is the electron-lattice coupling constant, and u_i is the lattice displacement of the i-th site from its equidistant position. t_e is introduced to lift the ground-state degeneracy for non-degenerate polymers. The operator $c^{\dagger}_{i,s}(c_{i,s})$ creates (annihilates) a π electron with spin s at the i-th site. The last two terms on the right hand side of Eq. (2) represent the lattice harmonic potential energy and the lattice kinetic energy, where K is the elastic constant of a σ bond and M the mass of a CH group.

The second term of Eq. (1) expresses the electron–electron interactions:

$$H_{ee} = U\sum_{i,s}\left(c^{\dagger}_{i,s}c_{i,s} - \frac{1}{2}\right)\left(c^{\dagger}_{i,-s}c_{i,-s} - \frac{1}{2}\right) + V\sum_{i,s,s'}\left(c^{\dagger}_{i,s}c_{i,s} - \frac{1}{2}\right)\left(c^{\dagger}_{i+1,s'}c_{i+1,s'} - \frac{1}{2}\right), \tag{3}$$

where U and V are the on-site and nearest-neighbor Coulomb repulsion strengths, respectively. In this paper, these extended-Hubbard-type interactions are treated within the unrestricted Hartree–Fock approximation.

The electric field is included in the Hamiltonian as a scalar potential, which gives the following contribution to the Hamiltonian:

$$H_E = |e|E\sum_{i,s}(ia + u_i)\left(c^{\dagger}_{i,s}c_{i,s} - \frac{1}{2}\right). \tag{4}$$

The model parameters we use in this work are those generally chosen for polyacetylene, [2] $t_0 = 2.5$ eV,$\alpha = 4.1$ eV/Å, $t_e = 0.05$ eV, $K = 99.0$ eV/Å^2, $M = 1349.14$ eVfs^2/Å^2 and $a = 1.22$ Å. As for the electron–electron interaction, $U = 0.5t_0$, $V = U/3$.

Within the unrestricted Hartree–Fock approximation, the time-dependent Schrödinger equations for one-particle wave functions are expressed in the following form:

$$i\hbar\frac{\partial}{\partial t}\psi_{k,s}(i,t) = H^s_{i,i+1}(t)\psi_{k,s}(i+1,t) + H^s_{i,i-1}(t)\psi_{k,s}(i-1,t) + H^s_{i,i}(t)\psi_{k,s}(i,t), \tag{5}$$

with

$$H^s_{i,i+1}(t) = -t_{i,i+1} - V\tau_s(i,t), \tag{6}$$

$$H^s_{i,i-1}(t) = -t_{i-1,i} - V\tau^*_s(i-1,t), \tag{7}$$

$$H^s_{i,i}(t) = U\left[\rho_{-s}(i,t) - \frac{1}{2}\right] + V\sum_{s'}[\rho_{s'}(i+1,t) + \rho_{s'}(i-1,t) - 1], \tag{8}$$

where the density $\rho_s(i,t)$ and bond density $\tau_s(i,t)$ are expressed as

$$\rho_s(i,t) = \sum_k{}'\psi_{k,s}(i,t)\psi^*_{k,s}(i,t), \tag{9}$$

$$\tau_s(i,t) = \sum_k{}'\psi_{k,s}(i,t)\psi^*_{k,s}(i+1,t). \tag{10}$$

Here the sum over the index k is over those occupied single-particle states. The equation of motion for the lattice is

$$M\ddot{u}_i = -K[u_{i+1}(t) - u_{i-1}(t) - 2u_i(t)] + \alpha\sum_s\{[\tau_s(i,t) - \tau_s(i-1,t)] + H.c.\} + |e|E\sum_s\left[\rho_s(i,t) - \frac{1}{2}\right]. \tag{11}$$

The above set of equations are numerically solved by discretizing the time with an interval Δt which is chosen

to be sufficiently small so that the change in the electronic Hamiltonian during that interval may be negligible small. For all the results presented below, we choose a time step of $\Delta t = 0.005$ fs.

By introducing electron eigenstates at each moment, the solutions of the time-dependent Schrödinger equations can be put in the form:

$$\psi_{k,s}(n,t_{j+1}) = \sum_l \left[\sum_m \phi^*_{l,s}(m)\psi_{k,s}(m,t_j)\right] \times e^{-i(\epsilon_l \Delta t/\hbar)}\phi_{l,s}(n), \quad (12)$$

where $\{\phi_{l,s}\}$ and $\{\epsilon_{l,s}\}$ are the eigenfunctions and the eigenvalues of the electronic part in the Hamiltonian H at a given time t_j. The lattice equations are written as

$$u_i(t_{j+1}) = u_i(t_j) + \dot{u}_i(t_j)\Delta t + \frac{F_i(t_j)}{2M}(\Delta t)^2, \quad (13)$$

$$\dot{u}_i(t_{j+1}) = \dot{u}_i(t_j) + \frac{F_i(t_{j+1}) + F_i(t_j)}{2M}\Delta t. \quad (14)$$

Hence, the electronic wave functions and the lattice displacement at the $(j+1)$th time step are obtained from the jth time step.

At time t_j, the wave functions $\{\psi_{k,s}(i,t_j)\}$ can be expressed as a series expansion of the eigenfunctions $\{\phi_{l,s}\}$ at that moment:

$$\psi_{k,s}(i,t_j) = \sum_{l=1}^{N} C^s_{l,k}(t_j)\phi_{l,s}(i), \quad (15)$$

where $C^s_{l,k}$ are the expansion coefficients. The occupied number for eigenstate $\phi_{l,s}$ is

$$n_{l,s}(t_j) = \sum_k{}' |C^s_{l,k}(t_j)|^2. \quad (16)$$

$n_{l,s}(t_j)$ contains information concerning the redistribution of electrons among the energy levels.

It is well known that removing or adding electrons to conjugated polymers creates lattice distortion in the form of polarons or bipolarons [17,2]. The formation of a polaron or bipolaron state not only induces lattice distortion but also lets the highest occupied molecular orbit (HOMO) and the lowest unoccupied molecular orbit (LUMO) enter the original energy gap and become localized deep levels [2]. In Fig. 1, we show the schematic diagram of energy levels for a polymer chain containing a negative polaron and a positive bipolaron. We can see that there are four levels in the gap. The left two levels ε^u_p and ε^d_p come from the polaron, in which the upper one is occupied by one electron and the lower one occupied by two. The right two levels ε^u_{bp} and ε^d_{bp} come from the bipolaron, and they are empty.

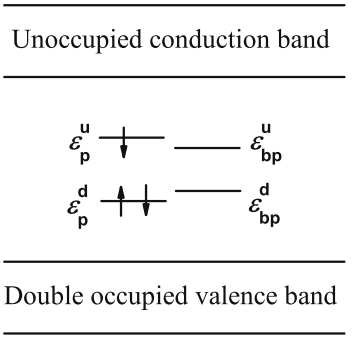

Fig. 1. The schematic diagram of energy levels for a polymer chain containing a negative polaron and a positive bipolaron.

In our simulations, a 200-site chain is considered, which is long enough to contain two independent excitations at the beginning. Before the external electric field turns on, a negative polaron is located at the 60th site while a positive bipolaron at the 140th site. They are well enough separated to ensure that they are non-interacting at the beginning. Starting from the initial conditions, the scattering processes between them driven by the external electric field are investigated.

In the following, we will focus on the evolution of the staggered lattice configuration $r_n(t)$ as

$$r_n(t) = (-1)^n \frac{u_{n-1}(t) + u_{n+1}(t) - 2u_n(t)}{4}. \quad (17)$$

3. Results and discussion

Simulations are carried out for a number of different field strengths. In these simulations, a critical electric field strength, $E_C = 0.8 \times 10^5$ V/cm , is found corresponding to markedly different behavior of the polaron and bipolaron dynamics. If the external electric field is lower than the critical electric field, the polaron and bipolaron scatter into a new state. If the external electric field is higher than the critical electric field, the polaron and bipolaron pass through each other, and continue moving in more or less the same way as before.

Fig. 2 shows the lattice evolution for the polaron–bipolaron scattering process in the external electric fields of 0.7×10^5 V/cm and 0.8×10^5 V/cm. As shown in Fig. 2a, driven by the external electric field, the polaron and bipolaron are accelerated and quickly approach their saturation velocity. At about 160 fs, they begin to contact. Due to the high kinetic energies of them, the polaron first passes through the bipolaron. However, after that, the polaron turns around and moves back following with the bipolaron. This explicitly shows that there is a strong attraction between the polaron and bipolaron. A short time later at about 300 fs, the polaron and bipolaron recombine into a new state. We can see that such a state corresponds to only one lattice deformation. What are the characteristics of this new state? We will analyze it later.

In a slightly higher electric field, as shown in Fig. 2b, the polaron and bipolaron simply pass through each other when they come into collide. After that, they recollect and continue moving as a polaron and a bipolaron along the chain.

We also find that the critical electric field is sensitive to the electron–electron interaction parameters U and V. The critical electric field strength increases as the electron–electron interaction parameters increase. This is easy to be understood. As U and V increase, the attraction between electron and hole gets strong, i.e., the attraction between the polaron and bipolaron becomes strong. Thus, passing through each other becomes difficult for the polaron and bipolaron.

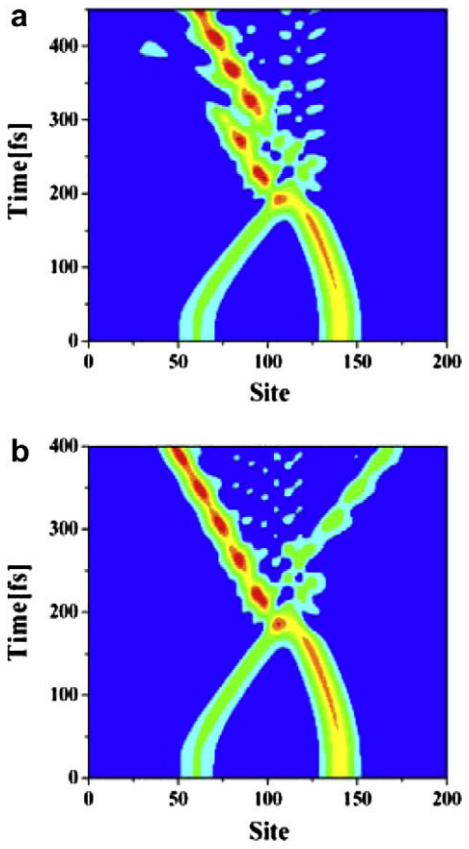

Fig. 2. Time dependence of r_n for the polaron–bipolaron scattering in different external electric fields, (a) $E = 0.7 \times 10^5$ V/cm and (b) $E = 0.8 \times 10^5$ V/cm.

In addition, if the electron–electron interaction is neglected ($U = V = 0$), we find that the polaron and bipolaron can easily pass through each other even in very weak electric fields. These results are quite consistent with the results obtained by Onodera [13].

To recognize the new state formed after the polaron–bipolaron collision, we first display the time evolution of occupied number of the intragap levels ε_p^u, ε_p^d, ε_{bp}^u and ε_{bp}^d in Fig. 3. Before 300 fs, the occupied numbers of the four levels are almost invariable, which means that the polaron and bipolaron all keep their isolation. After 300 fs, however, the occupied number of level ε_p^u rapidly drops to about zero, while the occupied number of level ε_{bp}^u quickly increases to about 0.3. At the same time, the occupied number of the other two levels ε_p^d and ε_{bp}^d still remain invariable. These results indicate that the reduced electrons in level ε_p^u may transfer to level ε_{bp}^u or level in conduction band with some probability after collision. Explicitly, electron transfer from polaron level ε_p^u to bipolaron level ε_{bp}^u and levels in conduction band will induce forming excited polarons and free carriers.

As shown above, the polaron–bipolaron interaction induces electron redistribution among levels. It also can be said that there are other electronic states mixed into the initial electronic state after the polaron–bipolaron collision. As indicated by the results displayed in Fig. 3, we found that there are mainly three electronic states mixed together after collision, which are shown in Fig. 4. State (a) denotes the initial electron distribution. So this state still contains a polaron and a bipolaron. State (b) denotes the electron in level ε_p^u transferred to level ε_{bp}^u. This state actually contains an excited polaron. As for state (c), it denotes the electron in level ε_p^u being excited to the conduction band. So this state contains a free carrier and a bipolaron. We do not draw the other possible states as we have found that the yields of other states are very small compared with these three states.

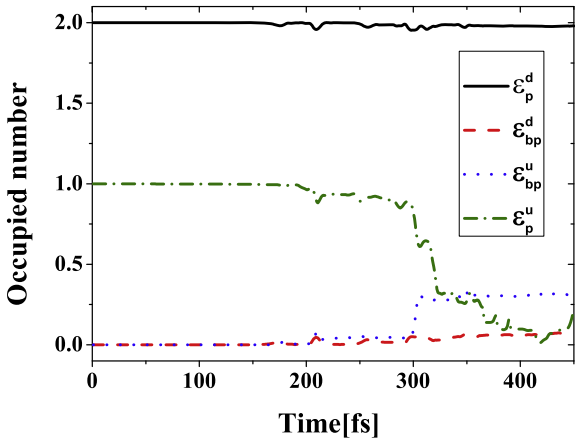

Fig. 3. Time evolution of the occupied number of the intragap energy levels, $E = 0.7 \times 10^5$ V/cm.

In the following, we will calculate the yields for these three states using a projection method [18]. The evolved wavefunction of the whole system $|\Psi(t)\rangle$ can be constructed by the single electron evolutional wavefunction $\{\psi_k(n,t)\}$ as a Slater determinant. After each evolution step, the evolved state $|\Psi(t)\rangle$ is projected onto the space of eigenstates of the system. The relative yield $I_K(t)$ for a given eigenstate $|\Phi_K\rangle$ is then obtained from:

$$I_K(t) = |\langle \Phi_K | \Psi(t) \rangle|^2. \tag{18}$$

The eigenstate $|\Phi_K\rangle$ is constructed by $\{\phi_{l,s}(n)\}$ which are the eigenfunctions of the electronic part of the Hamiltonian H. $|\Phi_K\rangle$ can be any state of interest, e.g., the states (a), (b) and (c).

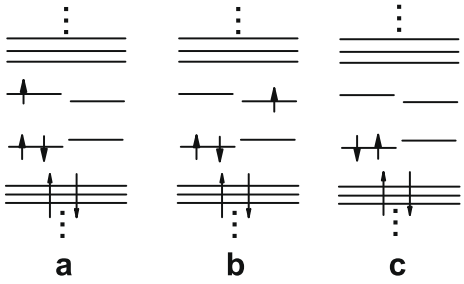

Fig. 4. The initial states and other mixed states after the polaron–bipolaron collision.

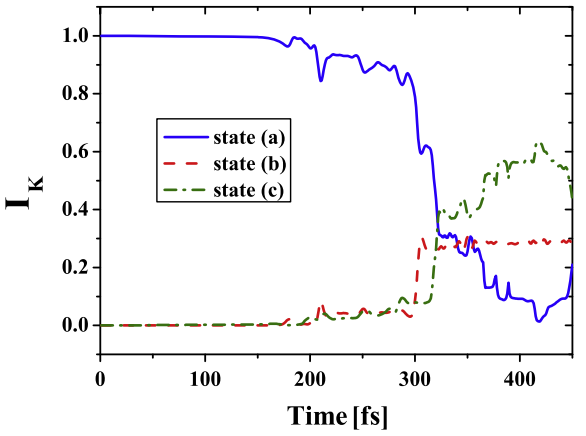

Fig. 5. Time dependence of the yields for states (a)–(c) which are shown in Fig. 4, $E = 0.7 \times 10^5$ V/cm.

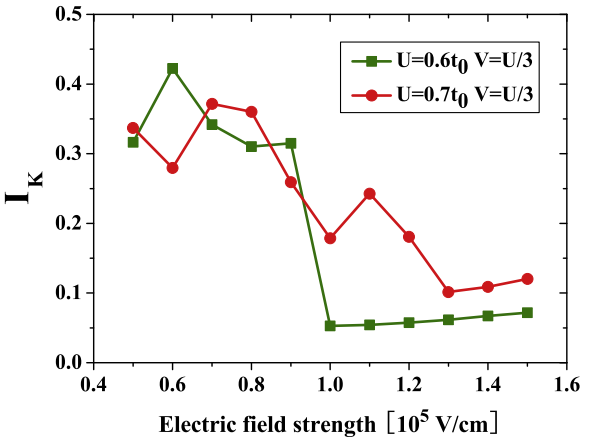

Fig. 7. Average yields of state (b) as a function of electric field strength for different electron–electron interactions.

Fig. 5 shows the time dependence of the yields for states (a), (b) and (c) during the polaron–bipolaron interaction. It can be seen that the yield of state (a) keeps 100% before 200 fs. This is because the polaron does not interact with the bipolaron before this time. From 200 to 300 fs, the yield of state (a) drops about 10%, which means that some other states, e.g., states (b) and (c), must mix into state (a). After 300 fs, the yield of state (a) sharply drops. At the same time, the yields of states (b) and (c) increase to about 30% and 40%, respectively. This explicitly shows that states (b) and (c) appear after the collision. As we have known, state (b) contains an excited polaron, and state (c) contains a free carrier. Thus, the results indicate that excited polaron and free carrier can be produced by the polaron–bipolaron interaction.

We also calculate the yields of states (a), (b) and (c) for different electric fields. We average the yields for these three states over the last 200 fs since their yields distinctly increased. The results are displayed in Fig. 6. Below the critical electric field strength, the yields of states (a), (b) and (c) oscillate in a large scope. It shows that the attraction between the polaron and bipolaron dominates their motions.

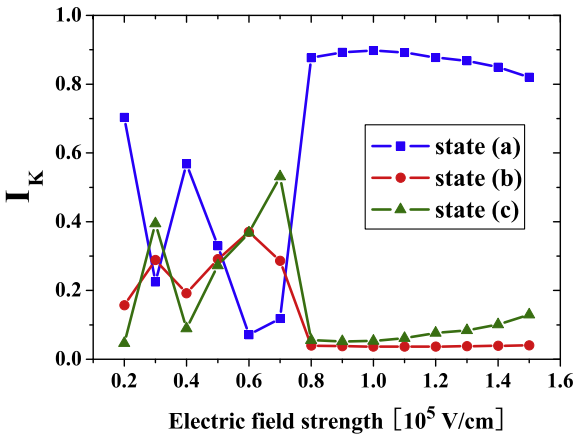

Fig. 6. Average yields for states (a)–(c) as a function of electric field strength.

However, just above the critical electric field strength, the yield of state (a) sharply increases to about 90% , while the yields of states (b) and (c) decrease quickly all to about 4%. As we have known from Fig. 4(a), state (a) contains a polaron and a bipolaron. It shows that the external field dominates the motion of the polaron and bipolaron in this case.

In Fig. 7, we display electric field dependence of the average yields of state (b) for different electron–electron interactions. It can be seen that the variation of the electron–electron interaction parameters U and V does not lead to significant change in the qualitative behavior of the yield of state (b). In addition, the results also show that the critical electric field increases as the electron–electron interaction parameters increase: $E_C = 1.0 \times 10^5$ V/cm for $U = 0.6t_0$ and $V = U/3$, $E_C = 1.3 \times 10^5$ V/cm for $U = 0.7t_0$ and $V = U/3$.

From the results above, an important channel for the polaron–bipolaron reaction can be written as

$$P^- + BP^{2+} \rightarrow P^{*+}, \tag{19}$$

where P^- denotes a negative polaron, BP^{2+} a positive bipolaron, and P^{*+} an excited positive polaron. It is worth noting that the excited polaron can decay to the polaron state through emitting a photon. Therefore, it is expected that the polaron–bipolaron reaction can contribute to electroluminescence in conjugated polymers.

From the above results, it can be seen that the electronic state of the system also have large probability to keep the initial state especially under weak electric fields, as shown in Fig. 6. In this condition, the polaron and bipolaron coalesce into a bound state due to the electron–phonon interaction and the Coulomb interaction between them. The bound state formed by a polaron and a bipolaron with opposite charges is called a trion [12] or a charged exciton [19]. Obviously, the polaron–bipolaron bound state has lower energy than separate ones so that it is more stable.

4. Conclusion

We have investigated the scattering processes between a negative polaron and a positive bipolaron in a conjugated

polymer chain. This study was carried out through numerical calculations using an improved version of the SSH model modified to include electron–electron interactions via an extended Hubbard Hamiltonian, a symmetry-breaking term and an external electric field. The time-dependent unrestricted Hartree–Fock equation and the equation of motion for the time-dependent lattice displacements form a coupled set that was numerically integrated over the time in a self-consistent way.

Initially, the negative polaron and the positive bipolaron are accelerated by an external electric field. They quickly approach saturation velocity before collision. A critical electric field is found corresponding to markedly different behavior of polaron and bipolaron dynamics. Below the critical electric field, the polaron and bipolaron can scatter into an excited polaron with high yield. The excited polaron can decay to the polaron state through emitting a photon, so that the polaron–bipolaron reaction shows a contribution to the electroluminescence in conjugated polymers beside the polaron recombination. Above the critical electric field, the polaron and bipolaron will pass through each other and continue moving as isolated ones.

Nano-pattern

ABSTRACT

A patterned conducting IZO film with well-ordered periodic dot-structures with 50 or 200 nm deep features has been constructed by nanoimprinting technique as the anode of an organic solar cell. The use of the patterned anode leads to an increase in the short circuit current (J_{sc}) from 7.03 to 8.94 mA/cm^2 and the power conversion efficiency (PCE) from 1.05 to 1.71% compared to the flat anode. The open circuit voltage (V_{oc}) is also affected by nano-patterned structure. The PCE is also influenced by the aspect ratio of the pattern structure.

1. Introduction

Research into the development of thin film photovoltaic devices based on a polymer-fullerene heterojunction as an active layer has progressed in recent years [1–6]. From [6,6]-phenyl C61-butyric acid methyl ester (PCBM) and conjugated polymers in bulk-heterojunction (BHJ) polymer solar cells, worldwide interest related to enhancing device performance has increased. The positive impact of polymer-based solar cells make them suitable for low-cost processes involving solution-based spin casting, realizing large area processability, and a flexible device with a polymer property [7]. Device performance is closely connected to the external photocurrent density, which is affected by photo-generated free electrons and holes from exciton in active layer systems. Another factor is the method of transferring the charges through the donor and acceptor phases smoothly toward each electrode [8]. Therefore, the introduction of nanostructured architecture in organic solar cells, which assists exciton generation as well as the transport of electrons-holes, is critical for an increase of the photocurrent density, resulting in an enhancement in device performance.

Generally, the most extensively used anode in optoelectronic devices has been indium tin oxide (ITO) because of its high conductivity, high transparency, and ability to match the work function of polymer films [9]. ITO, however, is weak in continuous bending tests and requires high-temperature processing conditions during sputtering operations. On the other hand, indium zinc oxide (IZO) can be prepared easily in room-temperature processing. This implies that IZO can be applied onto polymer films with various nano-patterns owing to its low-temperature processability.

Recently, a photovoltaic device containing patterned PEDOT:PSS as a hole transporting layer using polydimethylsiloxane (PDMS) stamps was reported, showing improved charge extraction and optical absorption due to the light trapping and scattering of reflected light by the imprinted patterns [10]. Another approach has been reported related to the vertical structure of the active layer, which facilitates charge transport as well as charge separa-

tion with patterned TDPTD (thermally deprotectable polythiophene derivative) using Si molds in a nanoimprinting operation [11].

This study presents the effect of a highly ordered 2D-dot nano-patterned anode fabricated in a simple process with UV-curable PUA [poly(urethane acrylate)] resin. PUA resin is characterized by its large-area replication capabilities, good detachment properties with low surface energy from a releasing agent, and clearly formed 2D patterns [12]. Particularly, a patterned anode also allows well-ordered periodic structures in the upper spin-coated layer. This continuous patterned anode in a polymer solar cell can induce an increase in the interfacial area between the active layer and the anode, contributing to more effective charge harvesting.

2. Experimental details

First, patterned IZO glass was cleaned by acetone and isopropanol to remove residual organic matter. Before use, it was treated with oxygen plasma. Poly(3,4-ethylene dioxythiophene:Poly(styrene sulfonate) (PEDOT:PSS, Baytron P), well known as hole a transporting material, was spin-coated to a thickness of ~35 nm. The devices were uniformly heated using a digital controlled-hotplate at 100 °C for 5 min. An active layer consisting of P3HT and PCBM at a ratio of 1:0.6 was then spin-coated at 900 rpm for 5 s in a glove-box using chlorobenzene solvent. The average thickness of the bilayer with active layer and PEDOT:PSS confirmed by Focused Ion Beam (FIB) images was approximately 240 nm (See Supplementary material). Subsequently, a metal electrode (Al) with a thickness of 150 nm was thermally deposited under a high vacuum pressure of 6.0×10^{-7} torr. The active device area with the deposited Al electrode was confirmed in the range of 4–6 mm^2. A solar simulator with a 2500 W Xenon lamp and air mass 1.5 global (AM 1.5G) filter was used to evaluate the performance of the solar cells. The light intensity was calibrated using a silicon reference cell (Fraunhofer ISE, Certificate No. C-ISE269). *J–V* curves were measured by a Keithley 2400 source measure unit under 1 sun (100 mW/cm^2) light intensity condition. The surface morphology and the roughness of the patterned IZO glass were observed by Atomic Force Microscope (AFM) made by Veeco (USA) (non-contact tapping mode, D3100). The incident photon to current conversion efficiency (IPCE) as a function of excitation wavelength (nm) was measured with a 300 W xenon lamp (Newport) and a monochromator (Model, Newport 260). Diffuse reflectance spectra were plotted by using a UV–Visible Spectrophotometer (CARY, 100 Conc) with an integrating sphere.

3. Results and discussion

Fig. 1 shows a schematic of the fabrication sequence of the highly ordered 2D-dot nano-patterned anode for poly-

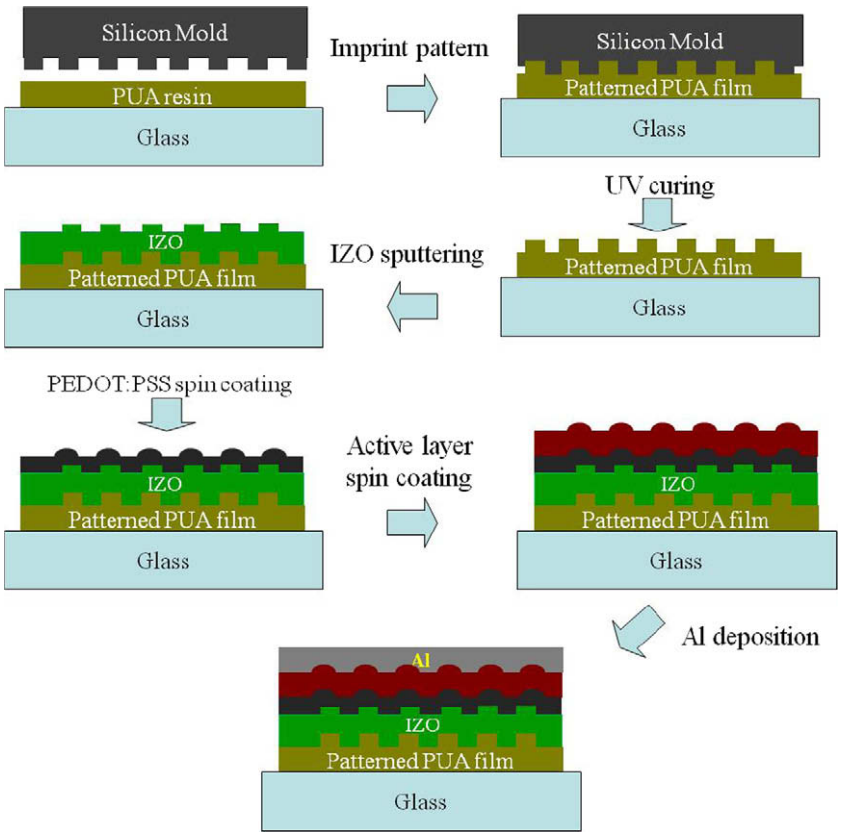

Fig. 1. Schematic of the fabrication sequence of highly ordered 2D-dot nano-patterned anode for polymer solar cells.

mer solar cells. This patterned anode was fabricated via simple imprint techniques using two different silicon master molds with heights of 50 or 200 nm and a dot space of 265 nm on a glass substrate with UV-curable PUA resin. The PUA resin was composed of tri(propylene glycol) diacrylate, trimethylolpropane triacrylate as a monomer, and 2,2-dimethoxy-2-phenylacetophenone as a photoinitiator (Aldrich). Acrylate polysiloxane (TEGO Rad 2200 N) was added as a releasing agent (1–4%). The patterned PUA film had a regular pitch size and a periodic height of the dot patterns form the UV-curing process. IZO was deposited on the patterned PUA film up to a thickness of 300 nm by RF-sputtering using a shadow mask at 400 W. The resistivity was defined to 25 Ω/□ as measured by four-point probe microscope.

To confirm of patterned PUA film and the anode for polymer solar cells, SEM images of the patterned PUA film and the IZO-coated PUA film were obtained. These are presented in Fig. 2. Fig. 2a is an top view image of an original flat PUA film on a glass substrate, and Fig. 2b and c shows top view images of a patterned PUA film with heights of either 50 or 200 nm, respectively, on glass substrates. Fig. 2d shows the side view image of a patterned IZO-coated PUA anode with a height of 200 nm. These SEM images confirm that the fabrication of the 2D-dot nano-patterned PUA films was highly ordered with a simple imprint technique. Moreover, the patterns are retained after the IZO sputter process, as shown in Fig. 2d. Fig. 2e and f are top view images of an active layer with highly ordered 2D-dot patterned PUA, 50 or 200 nm in height, respectively, with IZO after the spin coating of PEDOT:PSS (~35 nm). The surface morphology in Fig. 2e and f shows the retained well-ordered embossing structures after the spin-coating process of the P3HT/PCBM layer.

Fig. 3a–d shows AFM images of PEDOT:PSS layer with two different height patterns of the surface morphologies. From the AFM images in Fig. 3a–d, the surface morphologies of the patterned shapes retained entirely throughout the PEDOT:PSS spin-coating process. Also to confirm the patterned sequential structure of the PEDOT:PSS layer, IZO, and PUA film, we used a FIB (Focused Ion Beam) instrument. It was found that the surface morphologies retained the embossing structures after the spin-coating of PEDOT:PSS layer on the patterned IZO (See the Supplementary material, Fig. S1). Fig. 3e and f shows 52° tilted images of the entire inner structure of film prepared using a patterned anode at a height of either 50 nm or 200 nm from the FIB, respectively. These figures also show clearly sustained periodic structures from the patterned PUA up to the interfaces between the PEDOT:PSS and the active layer. The interfacial area between the PUA substrate and the anode, the anode and the PEDOT:PSS, and the PEDOT:PSS and the active layer increase in the order of precedence as they follow the first patterned structure. Therefore, the highly ordered 2D-dot nano-patterned anode from the PUA films influences the enhancement of the interfacial area between the active layer and the anode.

Fig. 4 shows the *J–V* curves of devices fabricated with IZO-coated PUA film without patterns as well as 50 or 200 nm PUA film patterned with IZO. After spin coating

the active layer and Al deposition, thermal treatments such as pre-annealing or post-annealing were not performed to maintain the stable property of the PUA films. In the case of the device composed of flat PUA film with IZO in the reference device, the performance level was approximately 1.05%. However, as the patterned height of the PUA film increases, the performance of the device also increases. The factor that critically increased the efficiency of the devices with the PUA film patterned with IZO was J_{sc}. As Fig. 4 shows, the photocurrent values of the nanostructured devices were 8.67 and 8.94 mA/cm^2 at heights of 50 or 200 nm, respectively, which are larger than the 7.03 mA/cm^2 value of a cell without nano-patterns, suggesting increased the number of created charges that are collected at the electrodes. The number of charges depends on the fraction of photons absorbed (η_{abs}), the fraction of electrons-hole pairs that are dissociated (η_{diss}), and finally the fraction of charges that reach the electrodes (η_{out}) determining the overall photocurrent efficiency (η_j):

$$\eta_j = \eta_{abs} \times \eta_{diss} \times \eta_{out}$$

First possible effect for the increased photocurrent is increased optical absorption due to the dot-patterned anode. Recently, Curry's group suggested the possibility of in-

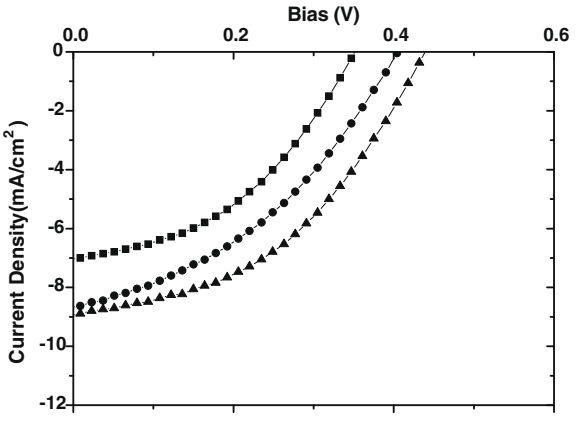

Fig. 4. *J–V* curves of devices made with flat PUA film with highly ordered patterned PUA with IZO (-■- Solar cells with IZO without patterns, -●- Solar cells with 50 nm PUA patterned film with IZO, -▲- Solar cells with 200 nm PUA patterned film with IZO).

creased optical absorption due to light trapping or scattering of reflected light by the imprint pattern when they prepared organic photovoltaic devices with patterned PEDOT:PSS layers [10]. When periodic patterns are provided on the anode of the organic solar cell, reflected light from Al electrode might be scattered or trapped in the active layer by the imprint patterns in the same manner as Curry's system. To confirm this hypothesis, optical absorption spectra were examined. The optical absorption cannot be determined directly because Al is not transparent. Instead of optical absorption, diffuse reflectance spectra were examined to measure the fraction of incident photons absorbed by the device. Fig. 5a shows diffuse reflectance spectra of the devices fabricated with IZO-coated PUA film without patterns as well as 50 nm PUA film patterned with IZO. The lower reflectivity for the device with nano-patterned anode indicates stronger absorption influencing η_{abs}. Fig. 5b shows IPCE spectra. The difference of J_{sc} between the reference device without nano-pattern and the device with 50 nm nano-pattern can be explained by this IPCE spectrum. However, the ~30% increased photocurrent cannot be fully explained by the light scattering effect. Another possible reason for the enhanced external quantum

efficiency is a reduced dead ends and/or a decrease of contact resistance. In the case of BHJ cells, absorption throughout the whole P3HT/PCBM layer can generate the photocurrent, due to the efficient exciton dissociation everywhere in the BHJ layer [13]. However, it is found that

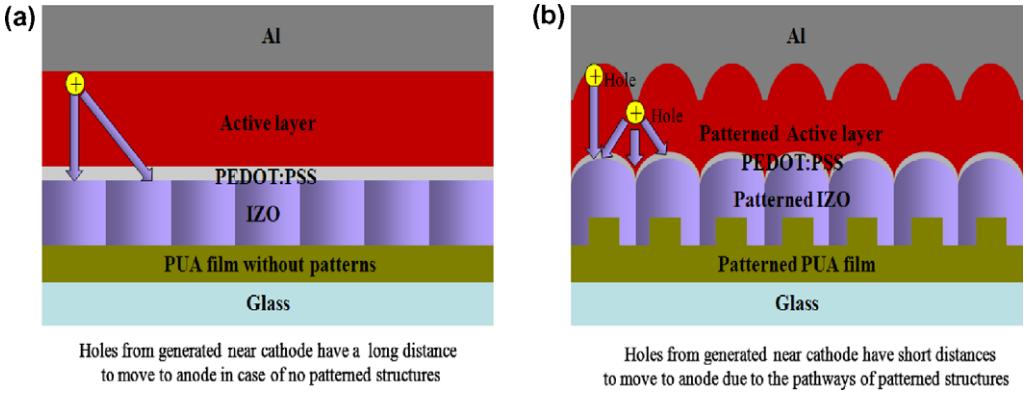

Fig. 6. Schematic diagram of the proposed devices fabricated with IZO-coated PUA film without patterns as well as IZO-coated PUA film with 2D-dot nanopatterns.

the J_{sc} increases upon increasing the temperature in the polymer/fullerene BHJ devices [14,15]. This means that a thermally activated hopping transport mechanism is obvious in the disordered morphology [16]. Therefore, the J_{sc} strongly depends on the charge-carriers mobility. Unfortunately, organic semiconductors generally have low mobilities, ranging between 10^{-5} and 10^{0} cm^2/V s [17]. Well-ordered embossing anode structures can assist with extraction of electrons and holes as it will in some regions reduce the distance they have to travel to the electrode, as shown in Fig. 6. In addition, the enlarged contact area between the active layer and the embossed pattern also might assist an efficient carrier collection. By implementation of the mechanisms discussed above, it is possible to explain the increase of PCE of a BHJ photovoltaic cell with 2D-dot nano-patterned anode.

4. Conclusion

In conclusion, P3HT/PCBM-based organic solar cells were fabricated on highly ordered 2D-dot nano-patterned anodes prepared by a nano-imprinting method. It was found that a highly ordered 2D-dot nano-patterned anode can enhance the device performance due to the large interfacial area between both of the electrodes and the active layer. This is possible because the nano-patterned structures can efficiently harvest electrons and holes from the active layer to each electrode in the IZO anode and Al cathode. Moreover, increased optical absorption due to light trapping or scattering of reflected light by the imprint pattern was also expected. A polymer solar cell based on an IZO anode makes its feasible to produce in a low-cost, room-temperature process. This technology is confidently expected to play an important role in the creation of efficient flexible polymer solar cells via nano-imprinting for practical applications in future.

Contact resistance
Semi-conductor thickness

ABSTRACT

In this study, we report on the influence of the semi-conductor thickness on organic thin-film transistors (OTFTs). Devices are fabricated with a top gate/bottom contact geometry on plastic substrates. Both n-channel and p-channel OTFTs made, respectively, from a *N,N*-dialkylsubstituted-(1,7&1,6)-dicyanoperylene-3,4:9,10-bis(dicarboximide) derivative (Polyera ActivInk™ N1400) and from 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) are studied and compared. Impact of the active semiconducting layer thickness on both contact resistance and mobility are uncorrelated by the use of the transfer line method (TLM). When increasing the thickness of the semi-conductor, we find an increasing contact resistance and a decreasing channel mobility for both n- and p-channel OTFTs. The loss of mobility with increased thickness is attributed to a degradation of the interface between the semi-conductors and the dielectric, and is studied by atomic force microscope (AFM).

1. Introduction

The emergence of new solution processible materials with higher electrical performance has led to significant progress in the field of OTFTs during the last decade [1–5]. Among the different transistor geometries, the staggered top gate configuration presents several technical and physical interests for solution processible organic transistors [6–9]. In this configuration, the active semiconducting–dielectric interface, where charge carriers are transported, is separated from the source and drain electrodes by the semi-conductor layer. The thickness and quality of this layer is thus of crucial importance for device performance.

Most of the works reported in the literature focused on evaporated materials [10–17] and on p-channel OTFTs. In the field of solution processed materials, Richards et al. gave a detailed study of contact resistance in top gate staggered transistors made with amorphous semiconducting polymer. Their work shows that the main cause of contact resistivity comes from the transport through the bulk film rather than injection process from gold electrode into the semi-conductor. Impact on the channel mobility and the threshold voltage was however not discussed. Recently, Verilhac et al. reported [8] an optimum thickness around 200 nm when working with staggered top gated amorphous p-channel transistors. The threshold voltage and subthreshold slope were the most affected parameters whereas the mobility was found almost constant by varying the thickness among two orders of magnitude. Huge non-linearity at the origin of the output characteristics were reported when increasing the thickness. This effect was attributed to the access resistance through the semiconducting layer which is inherent to the staggered geometry. Pesavento et al. compared [11] the impact of the

doi:10.1016/j.orgel.2009.11.008

evaporated crystalline pentacene layer on bottom gated top contact and bottom contact transistors. In the staggered top contact configuration, for thickness higher than 100 nm, they found an increasing contact resistance and a decreasing mobility. They did not report however on the threshold voltage evolution.

From these previous works, it seems that the thickness influence may change depending on the amorphous or crystalline nature of the semi-conductor. Moreover, to our knowledge no detailed report has been published where the effect of the thickness on both contact resistance and mobility were separated in the staggered top gate configuration in the case of poly-crystalline small soluble molecules.

In this study, we fabricated both n-channel and p-channel transistors made from spin-coated small molecules (see Fig. 1). For the realization of complex organic circuits, the understanding of transistors of both polarities is necessary. To simplify the design of such circuits, similar electrical performance for n- and p-channel OTFT would be beneficial. It is also important to verify that the injection and transport mechanisms are not affected by the nature of the charge carriers.

When the semi-conductor is deposited from solution, the mechanisms of the film formation are very different from evaporated thin films. In that case, the surface morphology and roughness of the active layer are affected by parameters such as the solvent boiling point [18], the annealing temperature [19], and the surface energy of the substrate [20]. When working with very thick semi-conductor layer, a fast evaporation of the solvent can dramatically impact the roughness and the morphology of the layer, which will in turn affect the electrical performance of the devices.

In this paper, we chose the transfer line method (TLM) [21,22] to study the effect of increasing the active layer thickness on the contact resistance and the mobility. We also discussed the variation of the threshold voltage. Interestingly we found very different electrical behaviour on poly-crystalline small molecules from what was reported on amorphous polymer TFB and PTAA with the same device architecture [8].

The first part of the paper describes the fabrication process. In a second part, we report the electrical impact of increasing the semi-conductor thickness on small molecule n-channel and p-channel OTFTs. The last section is dedicated to discuss the experimental results. To account for the mobility degradation, AFM and optical microscope inspections were also conducted to get an insight at the interface between the semi-conductor and the organic insulator.

2. Materials and samples preparation

2.1. Transistor fabrication and characterization

Polyethylene naphthalate (PEN) films were used as flexible substrates. 30 nm thick Au source and drain electrodes were deposited by sputtering and patterned by photolithography. Transistors with a width of 1 cm and channel length of 5, 10, 20, 40, and 100 μm were fabricated.

In the case of n-channel transistors, 1 mM solutions of 4-methylthiophenol in ethanol were prepared, in which samples were immersed at room temperature for a period of 5 h. They were then rinsed thoroughly with pure ethanol and dried in a N_2 gas stream before semi-conductor deposition. For p-channel transistors, we followed the same procedure with 1H,1H,2H,2H-perfluorodecanethiol [23].

For n-channel transistors, a *N*,*N*-dialkylsubstituted-(1,7&1,6)-dicyanoperylene-3,4:9, 10-bis(dicarboximide) derivative (Polyera ActivInk™ N1400) [24] bought from Polyera Corporation was diluted in 1,2-dichloro-benzene at a concentration of 8 mg mL^{-1}. For p-channel transistors, 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) [25] was used as the active layer at a concentration of 20 mg mL^{-1} in 1,2,3,4-tetrahydronaphthalene. Solutions were spin-coated at different speed to obtain different film thicknesses. The semi-conductor films were cured for both materials at a temperature of 115 °C for 5 min. Thicknesses of the active layer were measured with an alpha step profilometer.

Cytop™ dielectric [26] was then spin-coated on top of the semi-conductor and cured at 100 °C for 20 min to reach a thickness of 1.2 μm. To promote adhesion of the gate electrode on the highly hydrophobic insulating layer, solution of Nafion [27] diluted at 30 mg mL^{-1} in isopropanol was spin-coated at 1000 rpm. Finally an Ag ink gate electrode was printed by ink-jet using a Dimatix tool.

Electrical measurements were performed at room temperature in air by using a parameter analyser (HP4145, Hewlett–Packard). Morphological characterization was

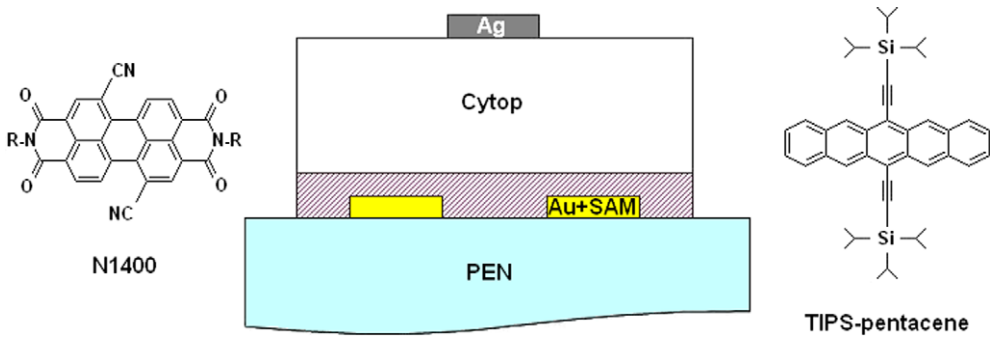

Fig. 1. Schematic of the fabricated transistors and formula of the semi-conductors used in the study.

carried out with an Innova AFM operating in the intermittent contact mode on samples specifically prepared for that purpose. The substrates consisted of Silicon on top of which the semi-conductor was spin-coated in the same condition as in the transistor fabrication.

2.2. AFM measurement

For TIPS-pentacene, 50 μm wide pictures were taken at a speed of 0.5 Hz with 256 lines. For Polyera ActivInk™ N1400, 10 μm wide pictures were taken in the same scan conditions. Roughnesses Ra and RMS were computed after a levelling of the pictures. Ra is defined as the arithmetic average of the average value roughness and is computed as Eq. (1):

$$R_a = \frac{1}{n}\sum_{i=1}^{n}|y_i| \quad (1)$$

RMS is defined as the root mean square roughness and is described by Eq. (2):

$$R_{RMS} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}y_i^2} \quad (2)$$

Five pictures on five different regions of the samples were taken for each semi-conductor thickness. The reported roughness was taken as the mean value of the different scans.

2.3. Electrical parameters extraction

The transfer characteristic in the linear regime (V_D = 1 V for Polyera ActivInk™ N1400, V_D = −1 V for TIPS-pentacene) was measured on devices with various channel lengths (L = 5, 10, 20, 40, and 100 μm) prepared in the same run. From these characteristics, the threshold voltage was first extracted from the peak of the second derivative of the gate voltage dependent drain current, as described previously [7]. The next step consisted of calculating the width corrected total resistance as a function of V_G–V_T. According to the TLM, this resistance can be decomposed into the contact resistance R_C in series with the channel resistance from which the corrected mobility can be extracted. A representative example of the resistance for various values of V_G–V_T is shown in Fig. 2. The contact resistance corresponds to the extrapolation of the straight line to zero channel length.

3. Results

Fig. 3 shows the transfer characteristics in the linear regime of 20 μm long transistors for n- and p-channel OTFTs at different active layer thicknesses. Main Electrical parameters are also reported in Table 1.

Fig. 4 shows the extraction of the threshold voltage (V_T) by means of two different methods. The extrapolation in the linear region (ELR) finds the gate-voltage axis intercept of the linear extrapolation of the I_D–V_G curve at its minimum first derivative (slope) point. The value of V_T is calculated by adding $V_D/2$ to the resulting gate-voltage

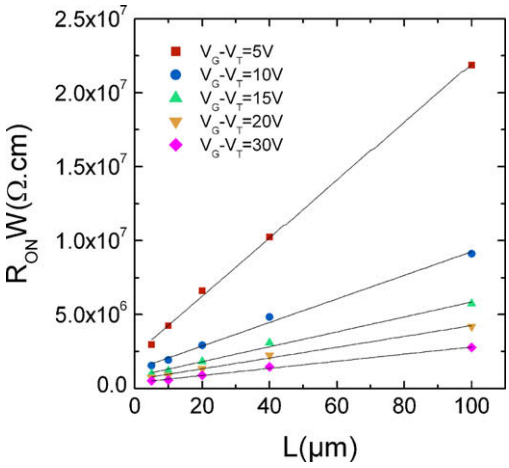

Fig. 2. Representative example of width normalized resistance versus channel length curves for n-channel OTFT. The resistance is estimated from the transfer characteristic at a drain voltage of 1 V.

intercept. We found a value of 0.5 V. The second derivative method which estimates V_T as the gate voltage at which the derivative of the transconductance (i.e., dg_m/dV_G) is maximum also gave a value of 0.5 V. In a previous study [7], we reported that for short channel OTFT, the ELR method tends to give overestimated values of V_T. As a consequence we chose to use the SD method.

V_T is not much affected by the semi-conductor thickness. Other groups also reported similar trend [13,15]. We also notice a small variation of the onset voltage (V_{ON}) defined as the lowest absolute current in the transfer characteristic from devices to devices. Variation of doping levels between the different fabricated transistors was previously reported as the origin of such variations [13,28].

We obtained very low leakage current through the gate dielectric in our transistors, leading to low OFF current and high ON/OFF ratio. Interestingly, output characteristics were not affected by the semi-conductor thickness (not shown here): we did not observe any major non-linearity at the origin of the curves for all the fabricated devices.

Fig. 5a gives the contact resistance extracted from the TLM (as described in the experimental section) with the applied gate voltage for different layer thickness. We note that R_C varies in a linear way with $1/(V_G–V_T)$ and increase for thicker film, in agreement with previous reports [9]. In a staggered geometry were charge carriers have to travel through the active layer before reaching the channel, this effect can be attributed to a smaller mobility in the normal direction of the semi-conductor [29–31].

Mobilities computed with the classical equations and extracted from the TLM method (corrected for the contact resistance) as a function of semi-conductor thickness are compared in Fig. 5b. We observe in both n-channel and p-channel OTFTs a huge drop when the semi-conductor layer becomes thicker.

4. Discussion

The almost constant threshold voltage we found in our devices tends to indicate that this parameter is not affected

by the semi-conductor thickness in the case of both n- and p-channel solution processed small molecule transistors. In poly-crystalline OTFTs a huge variation on V_T is generally achieved by modifying the chemical properties at the interface between the semi-conductor and the dielectric as widely reported in the literature [32,33]. Kuo et al. previously reported [15] a constant threshold voltage when changing the semi-conductor thickness in amorphous silicon devices with staggered geometry, in good agreement with our results.

Verilhac et al. on the other hand, recently reported [8] a very different trend for amorphous polymer with the same exact transistor configuration. Two distinct regimes in semi-conductor thickness were identified with an optimum for V_T around 200 nm. The authors attributed these variations to source and drain induced topologic effect and to access resistance, respectively, for low and high thickness regimes. Dependence of V_T on the semi-conductor thickness was also reported [12] on poly-crystalline pentacene by Schröeder et al.

The fact that we found an almost constant threshold voltage with the active layer thickness seems to indicate

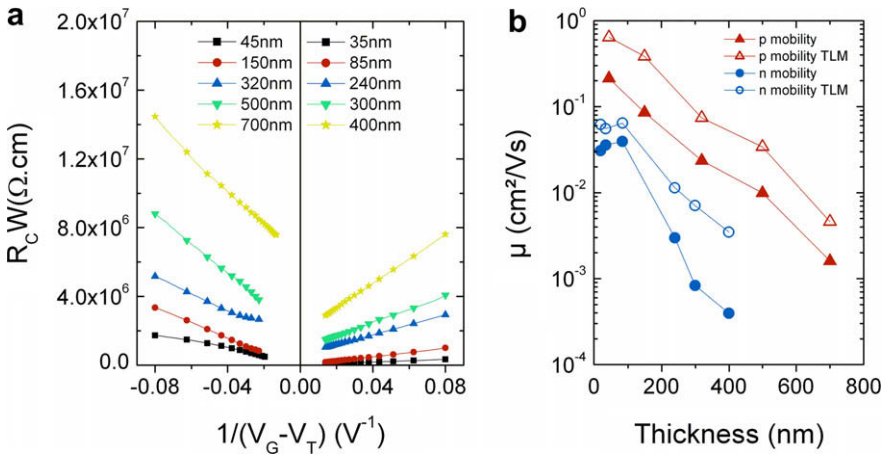

Fig. 5. (a) Contact resistance extracted from TLM measurements (left panel for p-channel OTFTs, right panel for n-channel OTFTs), and (b) comparison of the mobility corrected from contact resistance and computed from the classical equation.

that this parameter is dependent to both the geometry of the device and the nature of the semi-conductor.

In an other study where we modified the gold source and drain electrodes with self-assembled monolayers, we also found very different behaviour between amorphous poly[9,9-dioctyl-fluorene-co-*N*-(4-butylphenyl)-diphenyl-amine] (TFB) and poly-crystalline N1400 and TIPS-pentacene [23]. Variation of V_T was found dependant on the barrier height between the electrode work function and the highest occupied molecular orbital (HOMO) for amorphous TFB. In the case of poly-crystalline materials we did not find any link between these two parameters. These combined results highlight very different transport and injection mechanisms in amorphous and poly-crystalline materials.

Fig. 6a, shows the evolution of the contact resistance (R_C) as a function of the semi-conductor thickness. For both n- and p-channel OTFTs, we observe an increase in R_C with the active layer thickness. Mariucci et al. previously reported [14] that the variation of R_C was closely dependant of the device geometry. In coplanar configuration, they found an almost constant R_C, whereas this parameter was increasing with the semi-conductor thickness in the case of a staggered configuration. For thicker semiconducting films, the path that charge carriers have to cross before reaching the channel is increased which lead to a higher contact resistance. This increase in the contact resistance in staggered devices is also generally attributed to diffusion limited charges transport in thicker layer between the electrodes and the active interface [8].

From our results, and contrary to what has been previously observed for amorphous polymer, we found a huge variation in mobility with the active layer thickness. As the mobility calculated has been corrected from contact resistance, such dependence could be mainly attributed to morphological or topological effects at the semi-conductor surface.

Fig. 7 shows optical polarized microscope of both semiconductor for different thickness. In the case of TIPS-pentacene, clear change in the morphology is observed. When the layer thickness is increased, the morphology is changing from clear spherulite structure to a rod like crystallization.

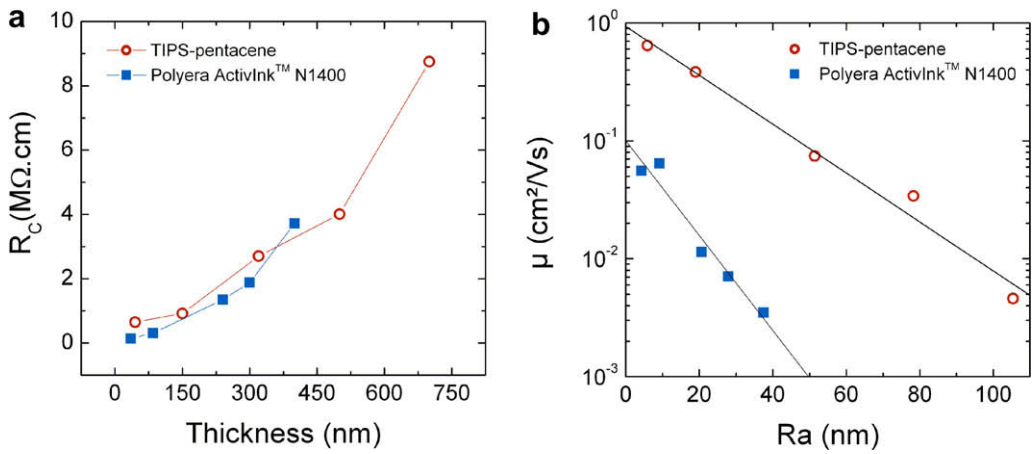

Fig. 6. (a) Variation of the contact resistance as a function of the semi-conductor thickness for both n- and p-channel devices. (b) Variation of the mobility corrected from the contact resistance as a function of the semi-conductor layer roughness (Ra) for both transistors polarity.

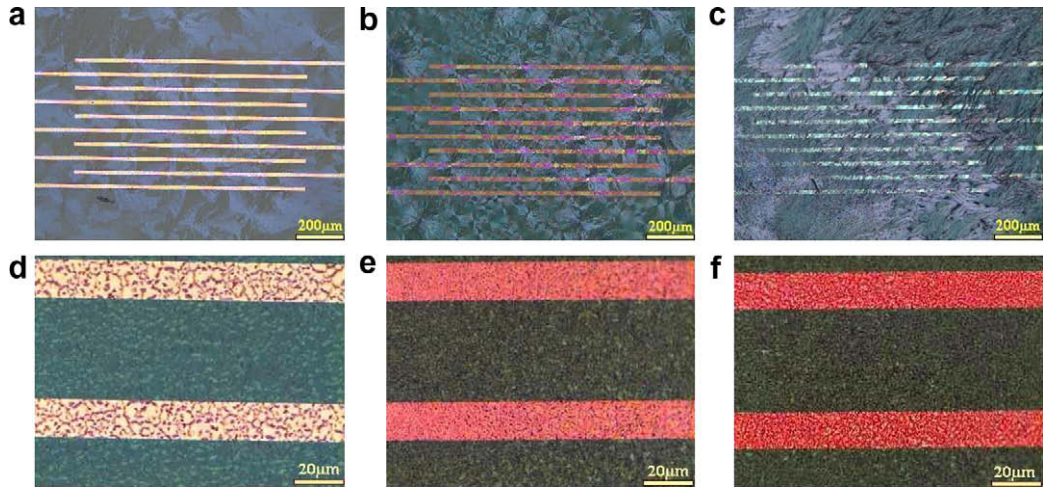

Fig. 7. Optical polarized microscope pictures on TIPS-pentacene for thicknesses of (a) 45 nm, (b) 320 nm, and (c) 700 nm and on Polyera ActivInk™ N1400 for thicknesses of (d) 35 nm, (e) 240 nm, and (f) 400 nm.

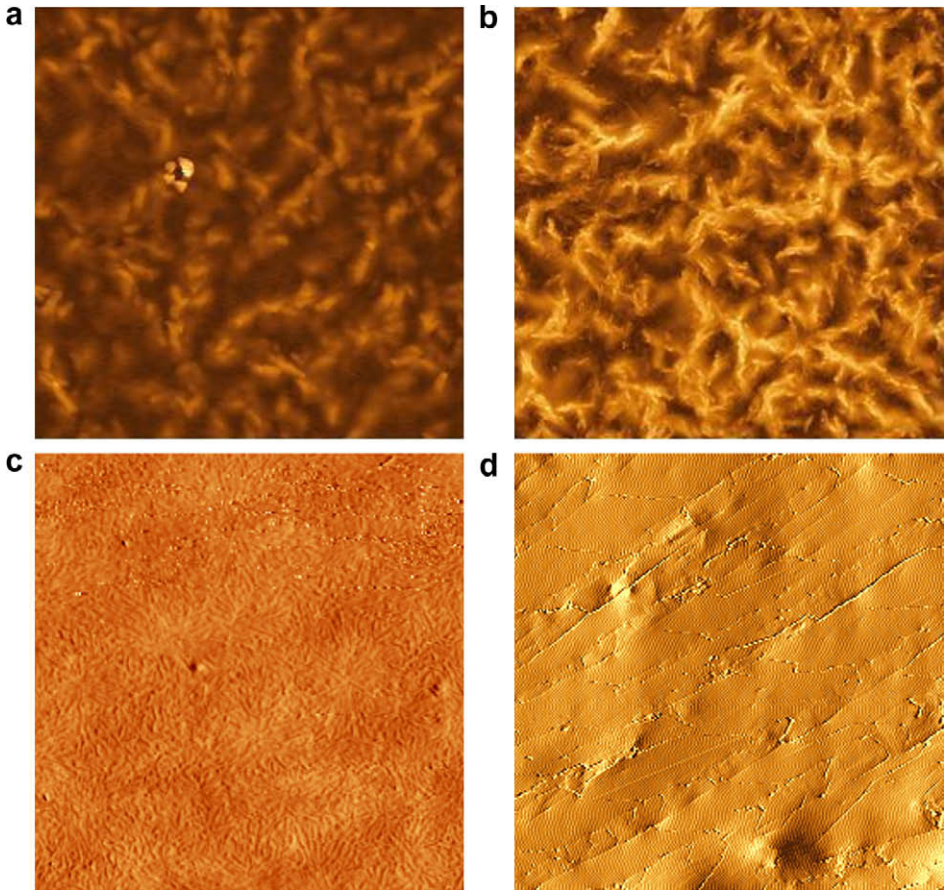

Fig. 8. AFM pictures on (a) 35 nm thick, and (b) 400 nm thick Polyera ActivInk™ N1400, and (c) 45 nm thick, and (d) 500 nm thick TIPS-pentacene. For N1400, pictures are 10 µm wide, for TIPS-pentacene, pictures are 50 µm wide.

AFM pictures on thick TIPS-pentacene also evidence cracks on top of the layer, which may be caused by solid state phase transition in the TIPS-pentacene crystals [34] and can account for the lower channel mobility. Note that in the case of n-channel OTFTs, change of optical visible variation of the morphology with the semi-conductor thickness is less clear. Complementary X-ray diffraction measurements could be processed in order to give a clearer vision

Table 2
Influence of the active layer thickness on roughness and mobility.

Semi-conductor	Thickness (nm)	Ra[a] (nm)	RMS[b] (nm)	μ (cm^2/Vs)[c]

[c] Mobility from TLM measurements at $V_G - V_T = 40$ V.

of morphological aspects. However such experiments tend to be difficult on PEN due to the huge features of the substrate on X-ray spectrum.

The morphological variations come with a degradation of the semi-conductor surface smoothness which is confirmed by roughness analysis made by AFM measurement. In the bottom contact staggered geometry, the roughness of the semiconducting surface is of major importance and may impact significantly the performance of the transistor. Fig. 8 reports AFM pictures for both materials at different thicknesses. Corresponding roughnesses are reported in Table 2. For both materials, as the semi-conductor layer thickness is increased, the roughness was found higher. As an example, the 700 nm thick TIPS-pentacene film has a very high average roughness of Ra = 105 nm, while the 45 nm thick film showed much lower values around Ra = 6 nm. The very high roughness obtained can be attributed to a too fast evaporation of the solvent, which in turn leads to a poorly organized layer. In Fig. 6b we plotted the variation of the mobility as a function of the roughness Ra of the semi-conductor surface. An exponential dependence was found between the two parameters. The corresponding drop in mobility was more than two orders of magnitudes, from 0.6400 to 0.0046 cm^2/Vs. Such a trend has already been reported [35] for amorphous polymer but for another scale of roughness variation which were in the order of 1–2 nm. Such a degradation of roughness could explain the drop in contact corrected mobility as the accumulated charge carriers which are localized in a thin (~5 nm) layer at the semi-conductor–dielectric interface may be disturbed by these nano-topological effects.

5. Conclusion

We investigated the influence of the semi-conductor layer thickness on electrical performance on both n- and p-channel OTFTs. Results on both polarities followed the same trends. The threshold voltage was found constant with the active layer, opposite to other reports on amorphous semi-conductors. We believe that this parameter is dependant on both the geometry of the device and the nature of the semi-conductor.

For both types of device, contact resistance was found higher with thicker film. This result confirms the hypothesis of a diffusion limited charge transport mechanism across the semi-conductor layer.

Finally, even when corrected for the contact resistance, we found a huge decrease in the mobility when the active layer was thicker. We attributed this loss to a degradation of both the film morphology and the roughness at the interface with the dielectric, evidenced by AFM.

ABSTRACT

Two series of red and blue electrochromic aromatic poly(azomethine ether)s (PAMEs) containing electroactive triphenylamine (TPA) moieties in the backbone were prepared from the high-temperature polycondensation reactions of newly azomethine–triphenylamine (AM–TPA)-based biphenol monomers, 4,4′-di(4-hydroxybenzylideneamino)triphenylamine (**3**) and 4,4′-di(4-hydroxybenzylideneamino)-4″-methoxytriphenylamine (**4**), with difluoro compounds, respectively. The obtained polymers were readily soluble in many organic solvents and showed useful levels of thermal stability associated with high softening temperatures (215–240 °C) and high char yields (higher than 64% at 800 °C in nitrogen). In addition, the polymer films showed reversible electrochemical oxidation with high contrast ratio and unique anodic blue/red electrochromic behaviors.

1. Introduction

Electrochromic materials exhibited a reversible optical change in absorption or transmittance upon electrochemically oxidized or reduced, such as transition-metal oxides, inorganic coordination complexes, organic molecules, and conjugated polymers [1]. In general, the investigation of electrochromic materials had been directed towards optical changes in the visible region proved especially useful for variable reflectance mirrors, tunable windows, and electrochromic displays.

Poly(azomethine)s (PAMs) or poly(Schiff-base)s with aromatic backbones were considered as high performance polymers [2] due to their high thermal stability [3], excellent mechanical strength [4], and good optoelectronic properties [5]. In recent years, PAMs had also been explored for applications in organic electronics, such as light-emitting materials [6], pH sensors [7], and metal-collecting polymers [8]. However, their insolubility in common organic solvents limited their processability and application [9]. One of the common approaches for increasing the solubility and processibility of PAMs without sacrificing high thermal stability was the introduction of various substituted aromatic ring into the polymer backbone [10], by using monomers with thiophene [11], phenylquinoxaline ring [12], cardo-structure [13], tetraphenylethene [14], and others [15]. Though PAMs made by vapor deposition of the monomers in a vacuum chamber have also been used as electron transporting layers in polymer light-emitting diodes [16], the preparation by solution-processable PAMs is beneficial for their fabrication of large-area, thin-film photonic devices.

The anodic oxidation pathway of electroactive TPA always associated noticeable color changed was well reported, and the electrogenerated TPA cation radical could be dimerized to form tetraphenylbenzidine (TPB), which

doi:10.1016/j.orgel.2009.11.009

was more easily oxidized than the original TPA moieties [17]. Recently, we have reported some organo-soluble and high T_g aromatic polymers bearing TPA units in the main chain [18]. Because of the incorporation of bulky and three-dimensional TPA units along the polymer backbone, all the polymers were amorphous with good solubility in many aprotic solvents and exhibited excellent thin-film-forming capability.

In this contribution, we therefore synthesized the azomethine–triphenylamine (AM–TPA)-based aromatic poly(azomethine ether)s (PAMEs) from the new (AM–TPA)-based diol monomers, 4,4′-di(4-hydroxybenzylideneamino)-4″-triphenylamine (**3**) and 4,4′-di(4-hydroxybenzylideneamino)-4″-methoxytriphenylamine (**4**), with difluoro compounds, respectively. Incorporation of preformed TPA units into PAMEs allowed the retention of some of the favorable properties of polymers such as high thermal stability and glass transition temperature, whereas the ether linkages increase the solubility and enhance the film-forming ability. In addition to the general properties (such as inherent viscosities, solubility, and thermal properties), the electrochemical and electrochromic behaviors of these polymers were also investigated.

2. Experimental section

2.1. Materials

4,4′-Diaminotriphenylamine [19] (**1**) (mp: 186–187 °C), 4,4′-diamino-4″-methoxytriphenylamine [20] (**2**) (mp: 150–152 °C) and 2,5-bis(4-fluorophenyl)-1,3,4-oxadiazole [21] (**5b**) (mp: 205–206 °C) were synthesized according to a previously reported procedure. 4,4′-Difluoro-benzophenone (**5a**) (ACROS) was purified by recrystallization. Tetrabutylammonium perchlorate (TBAP) (ACROS) was recrystallized twice from ethyl acetate under a nitrogen atmosphere and then dried in vacuo prior to use. All other reagents were used as received from commercial sources.

2.2. Monomer synthesis

The general procedure is as follows: To a solution of 30.10 mmol of diamino compound was stirred in 85 mL of ethanol and heated to 70 °C under nitrogen atmosphere. After the diamino compound was dissolved, 90.40 mmol of 4-hydroxybenzaldehyde was added and the mixture was then heated to reflux. After a further 15 h of reflux, the solution was cooled and poured slowly into 300 ml of stirred methanol, and the product was collected by filtration and dried *in vacuo* at 80 °C to give yellow powders.

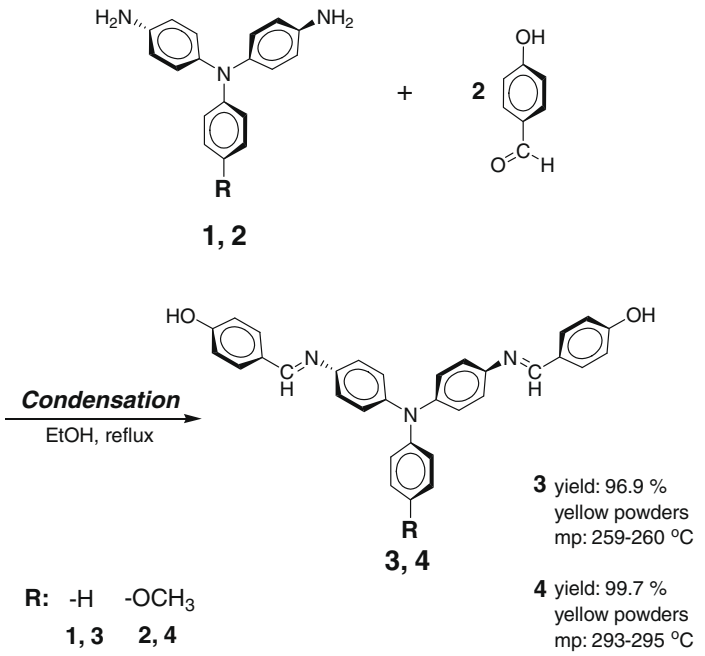
2.3. Polymer synthesis

The synthesis of PAME **Ia** was used as an example to illustrate the general synthetic procedure. To a two necked 50 ml glass reactor was charged with diol monomer **3** (0.97 g, 2 mmol), **5a** (0.44 g, 2 mmol), and 4 ml *N*-methyl-2-pyrrolidinone (NMP), 2 ml of toluene, and an excess of potassium carbonate (0.41 g, 3 mmol). The reaction mixture was heated at 150 °C for 3 h to remove water during the formation of phenoxide anions, then heated at 170 °C for 1 h, 180 °C for 3 h, and finally heated at 190 °C for 1 h. After the reaction, the obtained polymer solution was poured slowly into 400 ml of acidified methanol/water (v/v = 1/1). The precipitate was collected by filtration, washed thoroughly with hot water and methanol, and dried under vacuum at 100 °C. Reprecipitations of the polymer by NMP/methanol were carried out twice for fur-



Scheme 1. Synthesis of AM–TPA-based diol monomers.

ther purification. The inherent viscosity of the obtained PAME **Ia** was 0.20 dl/g (measured at a concentration of 0.5 g/dl in NMP at 30 °C). Anal. Calcd (%) of **Ia** for $(C_{47}H_{37}N_3O_3)_n$ $(691.81)_n$: C, 81.60; H, 5.39; N, 6.07. Found: C, 79.70; H, 5.61; N, 5.90. Anal. Calcd (%) of **IIa** for $(C_{48}H_{39}N_3O_4)_n$ $(721.84)_n$: C, 79.87; H, 5.45; N, 5.82. Found: C, 77.97; H, 5.33; N, 5.89. The other PAMEs were prepared by an analogous procedure.

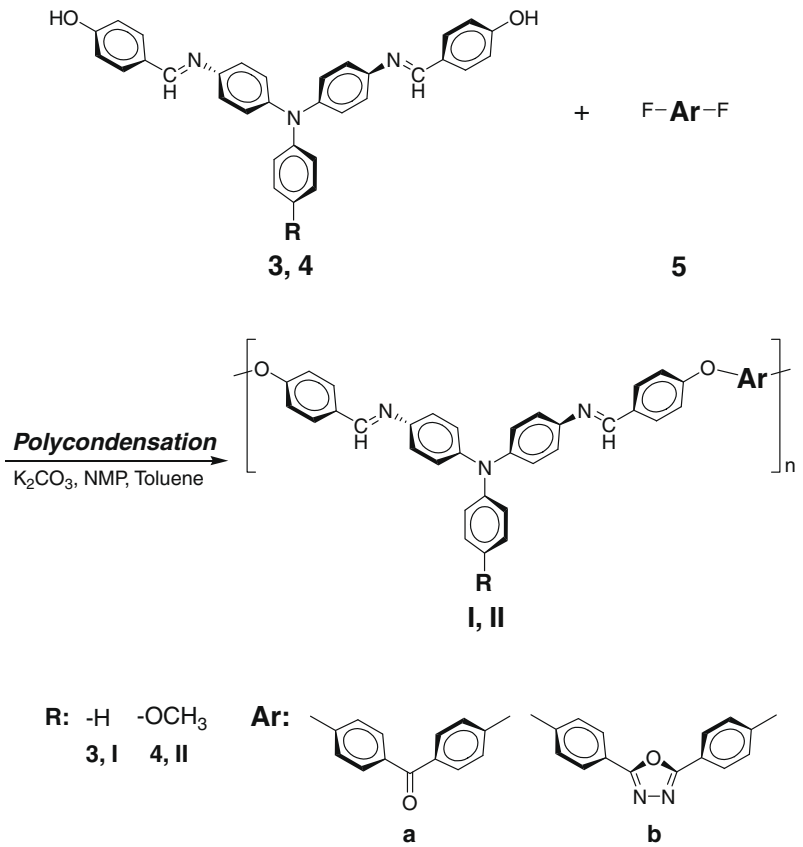

Scheme 2. Synthesis of aromatic PAMEs.

2.4. Preparation of the poly(azomethine-ether) films

A solution of polymer was made by dissolving the poly-ether sample in NMP. The homogeneous solution was poured into a glass Petri dish, which was placed in a 90 °C oven for 5 h to remove most of the solvent; then the semidried film was further dried *in vacuo* at 160 °C for 8 h. The obtained films were used for solubility tests and thermal analyses.

Table 1
Inherent viscosity[a] and solubility behavior of PAMEs.

Polymer	η_{inh} (dl/g)	Solubility in various solvent[b]						
		NMP	DMAc	DMF	DMSO	*m*-cresol	THF	$CHCl_3$

[b] Softening temperature measured by TMA with a constant applied load of 10 mN at a heating rate of 10 °C/min.
[c] Temperature at which 5% and 10% weight loss occurred, respectively, recorded by TGA at a heating rate of 20 °C/min and a gas flow rate of 30 cm^3/min.
[d] Residual weight percentages at 800 °C under nitrogen flow.

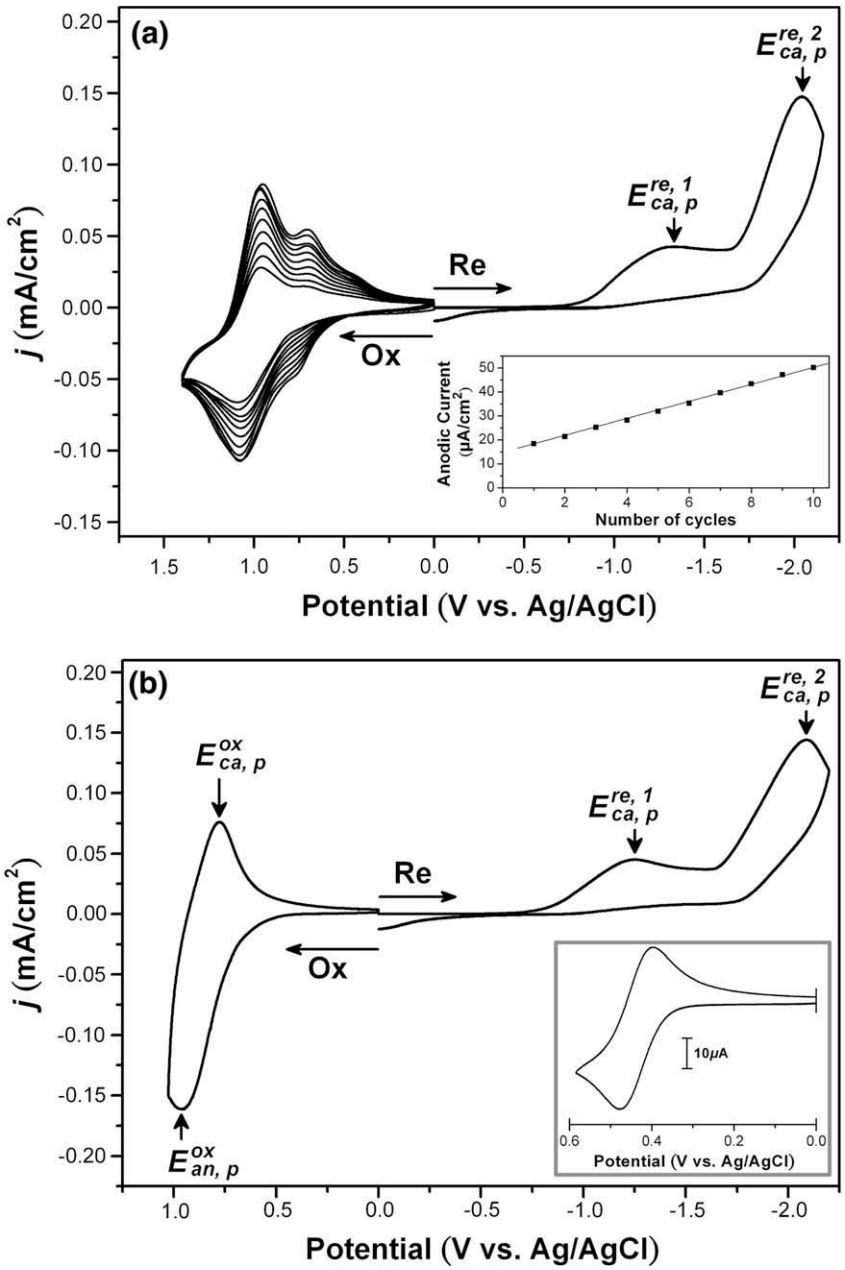

Fig. 5. Cyclic voltammogram of: (a) **Ia** and (b) **IIa** films on ITO-coated glass substrate in CH_3CN (oxidation) and DMF (reduction) solutions containing 0.1 M TBAP at scan rate of 50 and 100 mV/s, respectively. The inset showed a linear plot of the anodic current grown at 0.80 V vs. the number of scans and ferrocene, respectively.

2.5. Measurements

Elemental analyses were run in a Heraeus VarioEL-III CHNS elemental analyzer. Electrospray ionization (ESI) mass spectra were measured on LCQ Advantage mass spectrometer. NMR spectra were measured on a Bruker AC-300 MHz spectrometer in $CDCl_3$ and DMSO-d_6, and peak multiplicity was reported as follows: s, singlet; d, doublet; m, multiplet. The inherent viscosities were determined at 0.5 g/dl concentration using Tamson TV-2000 viscometer at 30 °C. Thermogravimetric analysis (TGA) was conducted with a PerkinElmer Pyris 1 TGA. Experiments were carried out on approximately 6–8 mg film samples heated in flowing nitrogen or air (flow rate = 20 cm^3/min) at a heating rate of 20 °C/min. Softening temperatures (T_s) were taken as the onset temperatures of probe displacement on the TMA traces. Electrochemistry was performed with a CH Instruments 611B electrochemical analyzer. Voltammo-

grams were presented with the positive potential pointing to the left and with increasing anodic currents pointing downwards. Cyclic voltammetry (CV) was conducted with the use of a three-electrode cell in which ITO (polymer films area about 0.5 cm × 1.6 cm) was used as a working electrode. A platinum wire was used as an auxiliary electrode. All cell potentials were taken by using a homemade Ag/AgCl, KCl (sat.) reference electrode. Spectroelectrochemical experiments were carried out in a cell built from a 1 cm commercial UV–visible cuvette using Hewlett–Packard 8453 UV–Visible diode array and Hitachi U-4100 UV–vis-NIR spectrophotometer. The ITO-coated glass slide was used as the working electrode, a platinum wire as the counter electrode, and Ag/AgCl cell as the reference elec-

trode. The thickness of the PAME thin films was measured by alpha-step profilometer (Kosaka Lab., Surfcorder ET3000, Japan). Colorimetry measurements were obtained using a Minolta CS-100A Chroma Meter. The color coordinates were expressed in the CIE 1931 *Yxy* color spaces.

3. Results and discussion

3.1. Monomer Synthesis

The new AM–TPA-based diol monomers **3** and **4** were synthesized by condensation reaction of the diamino compounds **1** and **2** with 4-hydroxybenzaldehyde, respectively (Scheme 1). Elemental analysis, MS, and NMR spectroscopic techniques were used to identify structures of the target diol monomers. Fig. 1 illustrates the ^{1}H NMR and ^{13}C NMR spectra of the diol monomer **4**. The ^{1}H and ^{13}C NMR chemical shift of CH=N at 8.46 and 158.1 ppm, respectively, were consistent with the previous reports (Fig. 1) [6b,18d]. The ^{1}H NMR chemical shift of Ar–OH shifts to low field at 10.08 ppm due to its acidity increased by the introduction of azomethine moiety. Assignments of each carbon and proton were assisted by the two-dimensional NMR spectra shown in Fig. 2, and these spectra agreed well with the proposed molecular structure.

3.2. Polymer synthesis

A series of newly TPA-based PAMEs were synthesized from the biphenol monomers **3** and **4** with corresponding difluoro compounds **5** (Scheme 2). The polymerization was carried out via potassium carbonate-mediated nucleophilic substitution reaction. All polymerization reactions proceeded homogenously and the obtained PAMEs had inherent viscosities in the range of 0.20–0.32 dl/g (Table 1). All the polymers could afford transparent and tough films via solution casting implying the formation of polymers with high molecular weight. Typical ^{1}H NMR spectrum of PAME **Ib** is illustrated in Fig. 3, and the hydroxyl group of diol monomer around 10 ppm disappeared for PAMEs confirming the completion of polymerization.

3.3. Polymer properties

3.3.1. Basic characterization

The solubility behavior of the PAMEs was investigated qualitatively, and the results were also summarized in Table 1. The TPA-based PAMEs showed good solubility in polar organic solvents such as NMP, *N,N*-dimethylacetamide (DMAc), and *m*-cresol. The enhanced solubility made these polymers as potential candidates for practical applications by spin-coating or inkjet-printing processes to afford high performance thin films for optoelectronic devices.

The thermal properties of PAMEs were examined by TGA and TMA and the typical TGA and TMA curves of representative PAME **Ia** were shown in Fig. 4, and the data were also listed in Table 2. All the prepared PAMEs exhibited good thermal stability with insignificant weight loss up to 400 °C under nitrogen or air atmosphere. The 10% weight loss temperatures of these polymers in nitrogen and air were recorded in the range of 485–540 and 495–550 °C, respectively. The concentration of carbonized residue (char yield) of these polymers in a nitrogen atmosphere was more than 64% at 800 °C. The high char yields of these polymers can be ascribed to their high aromatic content. The softening temperatures (T_s) of the polymer film samples were determined by the TMA method with a loaded penetration probe. They were obtained from the onset temperature of the probe displacement on the TMA traces and recorded in the range of 215–240 °C, depending upon the stiffness of the polymer chain.

3.3.2. Electrochemical properties

The electrochemical properties of the PAMEs were investigated by cyclic voltammetry (CV) conducted for the cast film on an indium–tin oxide (ITO)-coated glass substrate as working electrode in anhydrous CH_3CN and

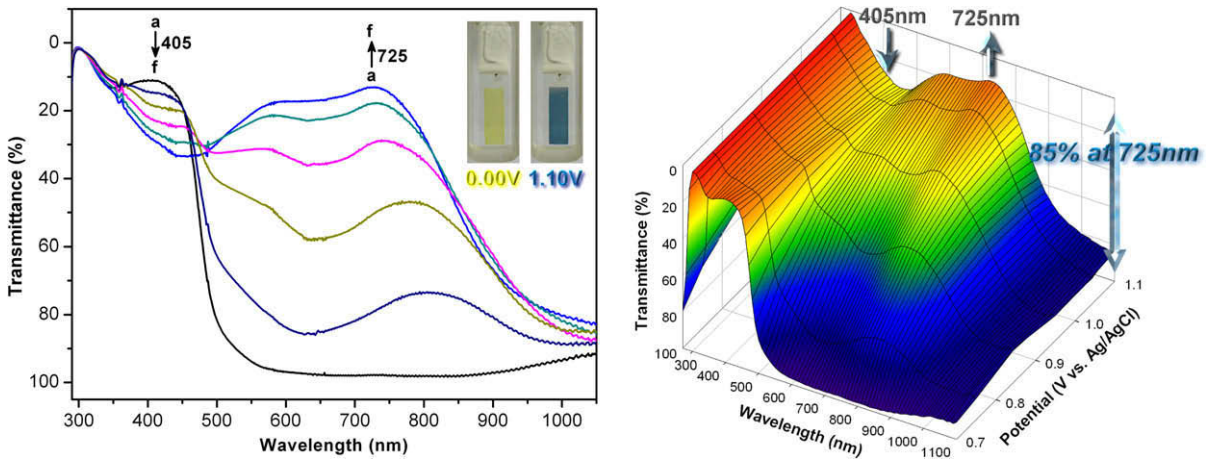

Fig. 7. Electrochromic behavior (left) at applied potentials of: (a) 0, (b) 0.75, (c) 0.85, (d) 0.95, (e) 1.05, (f) 1.10 (V vs. Ag/AgCl), and 3-D spectroelectrochemical behavior (right) from 0.70 to 1.10 (V vs. Ag/AgCl) of PAME **IIa** thin film (~160 nm in thickness) on the ITO-coated glass substrate in 0.1 M TBAP/CH_3CN.

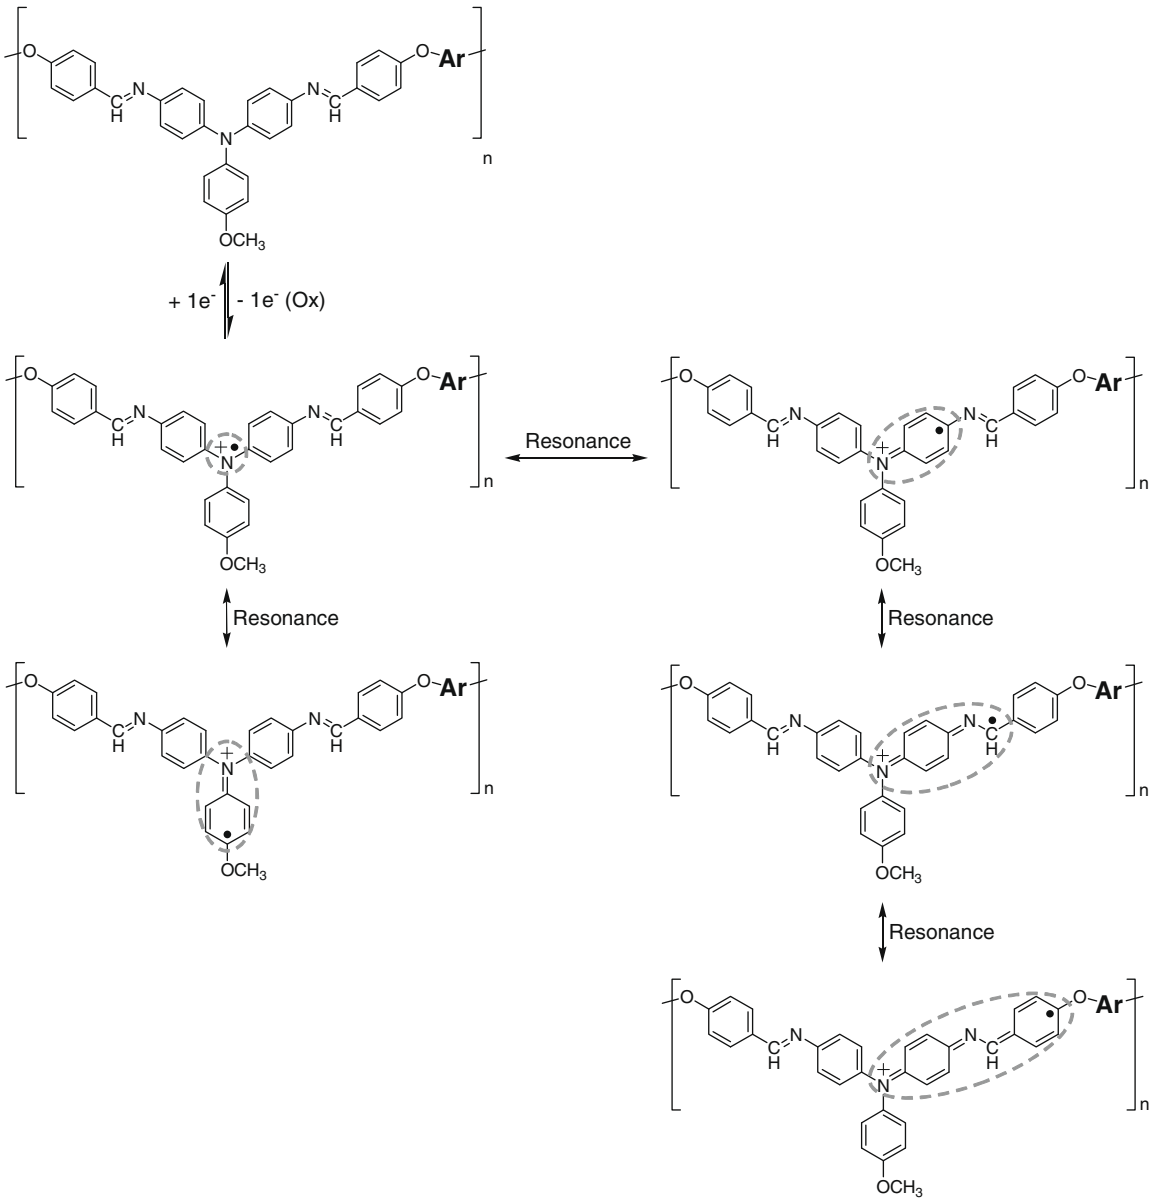
DMF containing 0.1 M of TBAP as an electrolyte under nitrogen atmosphere for oxidation and reduction measurements, respectively. The typical CV for PAMEs **Ia** (without 4-methoxy-substituted) and **IIa** (with 4-methoxy-substituted) are shown in Fig. 5 for comparison, the results revealed one oxidation and two reduction processes for all the PAMEs. The PAME **IIa** (with 4-methoxy-substituted) exhibited lower oxidation potential than the corresponding **Ia** (without 4-methoxy-substituted) [20]. The cyclic voltammogram of PAME **Ia** indicated that TPA without 4-methoxy-substituted unit was irreversibly oxidized at applied potential range from 0 to 1.4 V upon repetitive scanning. A new pair of redox peaks corresponding to TPB was observed around 0.80 V from the second scan in Fig. 5a indicating the TPB formation during oxidation of the TPA moieties of PAME **Ia** (Scheme 3). As shown in the inset of Fig. 5a, the plot of the anodic current at 0.80 V was linearly proportional to the number of scans confirming the occurrence of the oxidative coupling at the *para*-position of TPA in PAME **I** main chains. As summarized in Table 3, the reduction behavior of PAMEs **Ia**, **IIa** and **Ib**, **IIb** were attributed the methanone and oxadiazole groups in the polymer main chain, respectively. In addition, the second reduction stage around −2.05 V could be assigned to the imine (CH═N) groups in the polymer main chains [22], and the mechanism for the electrochemical reduction of PAMEs could be depicted as in Scheme 4. During the electrochemical oxidation scanning of the PAME thin films, the color of



Scheme 5. Mechanism of the electrochemical oxidation for PAMEs **II**.

the film changed from yellow to red and blue for PAMEs **I** and **II**, respectively. The redox potentials of the PAMEs as well as their respective highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) (on the basis of ferrocene/ferrocenium is 4.8 eV below the vacuum level with E_{onset} = 0.36 V) estimated from the onset of their oxidation or reduction in CV experiments were summarized in Table 3.

3.3.3. Spectroelectrochemical and electrochromic properties

Spectroelectrochemical experiments were used to evaluate the optical properties of the electrochromic films. The PAME film was cast on an ITO-coated glass slide, and was placed in the optical path of the light beam from a UV–vis-NIR spectrophotometer, which allowed us to acquire electronic absorption spectra under potential control in a 0.1 M TBAP/MeCN solution. The UV–vis-NIR absorbance curves correlated to applied potentials and three-dimensional transmittance-wavelength-applied potential correlation of after-oxidized **Ia** film were depicted in Fig. 6. The strong absorption at around 396 nm, characteristic for the charge-transfer complex (CTC) formation between the electron-donating TPB group and the strongly electron-accepting AM group in the neutral form (0 V), decreased and new peaks at 493 and 717 nm grew up steadily upon electrochemical oxidation (increasing applied voltage from 0 to 1.00 V). The one-electron oxidation product, a stable monocation radical TPB, exhibited absorption at 493 nm. As the anodic potential higher than 1.00 V, the absorption peak at 717 nm corresponding to the formation of a dication of TPB unit grew up. From the inset shown in Fig. 6, the PAME **Ia** film switched from a transmissive neutral state (light-yellow; *Y*: 74; *x*, 0.372; *y*, 0.444) to a highly absorbing oxidized state (red; *Y*: 13; *x*, 0.601; *y*, 0.351) with an high optical transmittance change ($\Delta\%T$) of 84%.

On the other hand, the spectroelectrochemical behavior of PAME **IIa** film shown in Fig. 7 also exhibited strong absorption at around 405 nm in the neutral form (0 V). Upon oxidation (increasing applied voltage from 0 to 1.10 V), the intensity of the absorption peak at 405 nm decreased while a new peak at 725 nm gradually increased in intensity due to the formation of a stable monocation radical of the AM–TPA unit. Furthermore, the broadened absorbance band was because of the monocation radical of AM–TPA unit having more extended conjugation length than TPA (Scheme 5), which resulted different and unique coloration from other TPA-based electrochromic materials [20,23]. From the inset shown in Fig. 7, the PAME **IIa** film switches from a transmissive neutral state (light-yellow; *Y*: 70; *x*, 0.374; *y*, 0.453) to a highly absorbing oxidized state (blue; *Y*: 10; *x*, 0.246; *y*, 0.305) with an high optical transmittance change ($\Delta\%T$) of 85% at 725 nm. Besides, the distribution of coloration across these polymer films was very homogeneous with high electrochemical stability.

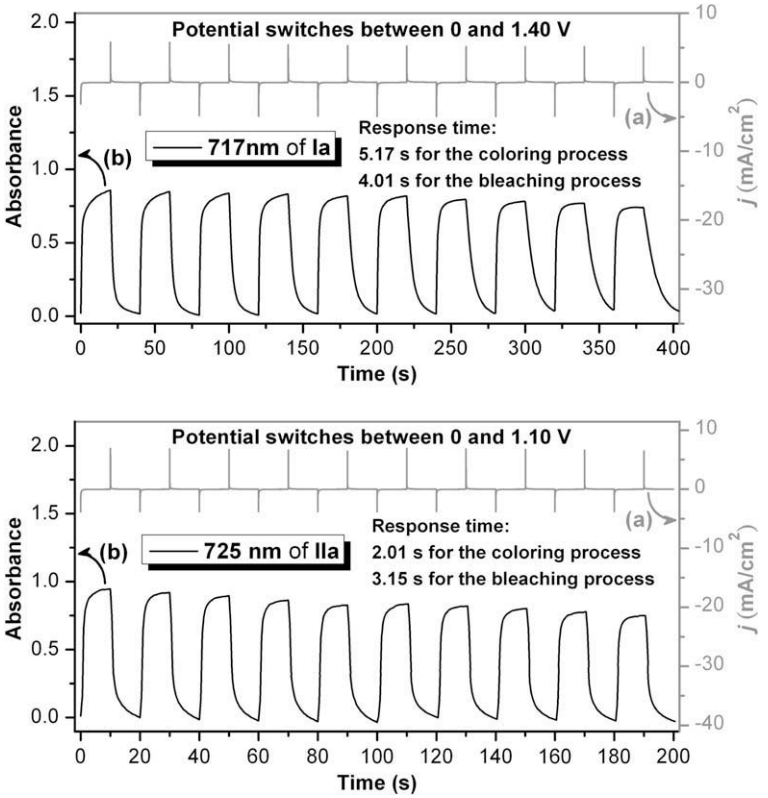


Fig. 8. (a) Current consumption and (b) electrochromic switching and absorbance change monitored for PAME thin films (~160 nm in thickness) on the ITO-coated glass substrate (coated area: 1.6 cm × 0.5 cm) in 0.1 M TBAP/CH_3CN.

For electrochromic switching studies, polymer films were cast on ITO-coated glass slides in the same manner as described above, and chronoamperometric and absorbance measurements were performed. While the films were switched, the absorbance at the given wavelength was monitored as a function of time with UV–vis-NIR spectroscopy (Fig. 8). The switching time was calculated at 90% of the full switch because it is difficult to perceive any further color change with naked eye beyond this point. The electrochromic coloration efficiency ($\eta = \delta OD/Q$) of PAMEs **Ia** and **IIa** are calculated as 162 and 195 cm^2/C, respectively [18j]. After several coloring/bleaching cyclic scans, the polymer films still exhibited good stability of electrochromic characteristics.

4. Conclusion

Two series of blue and red electrochromic aromatic PAMEs containing electroactive TPA moieties in the backbone were prepared from the potassium carbonate-mediated nucleophilic substitution reaction of newly azomethine–triphenylamine (AM–TPA)-based biphenol monomers with difluoro compounds. Introduction of electron-donating TPA groups to the polymer main chain not only afford high T_g and good thermal stability but also leads to good solubility of the PAMEs. All the obtained polymers revealed valuable electrochromic characteristics such as high contrast in visible region and unique blue/red electrochromic behavior, indicating the incorporation of azomethine groups into TPA-based polymers is a new approach for tuning the coloration changed.

Bulk heterojunction

ABSTRACT

A new low-band gap small molecule (Se-SM), which contains dithyenyl-benzoselenadiazole as central unit and terminal cyanovinylene 4-nitrophenyls, was synthesized. In addition, a new phenylenevinylene copolymer (P) containing dithyenyl-dinitrobenzothiadiazole moieties was synthesized by Heck coupling. Se-SM showed broad absorption band with long-wavelength absorption maximum ($\lambda_{a,max}$) at ~640 nm and optical band gap (E_g^{opt}) of 1.67 eV. Copolymer P had $\lambda_{a,max}$ around 420 nm and E_g^{opt} of 2.31 eV. The dark current–voltage characteristics and incident photon to current efficiency spectra of the devices based on copolymer P and Se-SM indicates that both materials behave as p-type organic semiconductors. The power conversion efficiency (PCE) of the photovoltaic devices based on these materials is low. However, the PCE of the devices fabricated with the blends of copolymer P or Se-SM with PCBM, was improved significantly. The increase is attributed to the formation of bulk heterojunction with increased interfacial area. The effect of the incorporation of Se-SM molecule on the photovoltaic properties of copolymer P:PCBM blend has been also investigated. The overall PCE of the copolymer P:PCBM:Se-SM device is approximately 2.24%, which is further enhanced up to 3.16%, when the thermally annealed blend is used. Therefore, we conclude that the Se-SM molecule increases the light harvesting property of the blend and also provides efficient path for holes and electron in copolymer and PCBM phases, respectively.

1. Introduction

Conjugated polymer/fullerene bulk heterojunction (BHJ) solar cells have received increased attention because of their promising energy conversion efficiencies, solution processability, and their low cost of fabrication [1–14]. Power conversion efficiencies (PCEs), more than 5% have been reported for BHJ cells, incorporating a blend of conjugated polymer poly(3-hexylthiophene) (P3HT) as donor and fullerene derivatives as electron acceptor [5–14]. However, to achieve PCE values higher than 10%, nanoscale morphology of blend, transport properties in the device, band gap, band alignment, and device architecture must be optimized [4,15,16].

Since P3HT (with a band gap of about 1.9 eV) only absorbs up to 22% of the incident photons of solar spectrum [17], low-band-gap materials were expected to harvest more incident photons to further improve the efficiency of organic solar cells. However, BHJ devices made from

doi:10.1016/j.orgel.2009.11.010

these materials with PCBM are usually show low power conversion efficiency (<1%), with only a few of them demonstrated efficiencies in the range of 3–6% [18–27,9,28–35]. Most of them suffer from either (a) unmatched energy levels with respect to PCBM and thereby a low open circuit voltage (V_{oc}) or (b) low hole mobility and un-optimized morphology, leading to a low short circuit current (J_{sc}) and a small fill factor (FF).

Recently, several low-band gap conjugated polymers ($E_g < 1.8$ eV) have been employed as electron donor materials in BHJ solar cells [36,32]. Among these, benzothiadiazole-based copolymers were the most successful, showing a PCE in the range of ~1.0–5.5% [22,24,25,32]. The reasons for such high performance might be ascribed to the material properties, such as high hole mobility, structural stability in the charged state, as well as a broad absorption spectrum (E_g ~1.38 eV) [22]. Moreover, a possible route to overcome the low photovoltaic performance observed in a polymer solar cell may be the incorporation of a low-band gap small molecule [37,38]. Small molecules generally have high charge carrier mobility, monodispersity and relatively simple synthesis [39].

Color tuning to the deep-red and near-infrared (NIR) region in conjugated polymers can be also achieved by incorporating low-band gap Se-containing comonomer into the polymer backbone. Cao et al. first reported a polyfluorene copolymer with Se-containing heterocycle, benzoselenadiazole (BSeD), a selenium analogue of benzothiadiazole in different compositions [40]. He found out that incorporating Se-containing heterocycle (BSeD) into the polyfluorene main chain resulted in a significant red shift in comparison with its sulfur analogue. He also reported the synthesis and properties of the polyfluorene copolymer with another Se-containing heterocycle, 2,1,3-naphthoselenadiazole as a narrow band gap component [41]. Finally, Cao et al. reported the synthesis of two conjugated Se-containing heterocyclic monomers and their copolymerization with 9,9-dioctylfluorene. The copolymers derived, which had optical band gap of ~1.80 eV, were used for BHJ solar cells with PCBM and gave energy conversion efficiency up to 1% [42]. These results indicate that synthesizing Se-containing heterocycles with a narrower band gap moves the absorption band edge to a further deep-red or even NIR region without using the metallic complex ions.

Very recently, we have shown that the addition of a low-band gap benzothiadiazole-based small molecule in a conjugated phenylenevinylene copolymer:PCBM bulk heterojunction solar cell improves the photocurrent and power conversion efficiency [43]. In extension of this research line, we have synthesized a new low-band gap benzoselenadiazole-based small molecule (Se-SM) and incorporated it with a novel phenylenevinylene copolymer (P) for BHJ solar cells. The phenylenevinylene copolymer is a dithyenyl-dinitobenzothiadiazole derivative which was successfully synthesized by Heck coupling. The structures of Se-SM and P were designed so that the energy levels of the Se-SM lie between those of P and PCBM, in order to avoid a charge trapping in the small molecule. Both samples contain nitro groups in the terminal or the central units to broadening their absorption band [43,44]. Moreover, Se-SM contains two cyano-substituted vinylene bonds. The very strong electron withdrawing effect of the cyano group significantly affects the charge separation and charge transfer processes as well as the band gap energy of the molecule [45]. Copolymer P carries solubilizing hexyloxy side chains. The current–voltage characteristics and the incident photon to current efficiency (IPCE) spectra of the devices based on either copolymer P or Se-SM reveal that both materials behave as p-type organic semiconductors. The PCE of the devices based on blends with PCBM is about 0.52% and 1.30 for copolymer P and Se-SM, respectively. We have shown that the addition of the Se-SM small molecule in the copolymer P:PCBM bulk heterojunction solar cell increases the efficiency of the device, which is further improved up 3.16%, when thermally annealed P:PCBM:Se-SM blend is used as active layer in the device.

2. Experimental

2.1. Characterization methods

IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrometer with KBr pellets. ^{1}H NMR (400 MHz) spectra were obtained using a Brucker spectrometer. Chemical shifts (δ values) are given in parts per million with tetramethylsilane as an internal standard. UV–vis spectra were recorded on a Beckman DU-640 spectrometer with spectrograde THF. TGA was performed on a DuPont 990 thermal analyzer system. Ground samples of about 10 mg each were examined by TGA and the weight loss comparisons were made between comparable specimens. Dynamic TGA measurements were made at a heating rate of 20 °C/min in atmospheres of N_2 at a flow rate of 60 cm^3/min. Thermomechanical analysis (TMA) was recorded on a DuPont 943 TMA using a loaded penetration probe at a scan rate of 20 °C/min in N_2 with a flow rate of 60 cm^3/min. The TMA experiments were conducted at least in duplicate to ensure the accuracy of the results. The TMA specimens were pellets of 10 mm diameter and ~1 mm thickness prepared by pressing powder of sample for 3 min under 8 kp/cm^2 at ambient temperature. The T_g is assigned by the first inflection point in the TMA curve and it was obtained from the onset temperature of this transition during the second heating. Elemental analyses were carried out with a Carlo Erba model EA1108 analyzer.

2.2. Reagents and solvents

1,4-Divinyl-2,5-bis(hexyloxy)-benzene was prepared by Stille coupling reaction of 1,4-dibromo-2,5-bis(hexyloxy)-benzene with tributylvinyltin [46]. *N,N*-Dimethylformamide (DMF) and tetrahydrofuran (THF) were dried by distillation over CaH_2. Triethylamine was purified by distillation over KOH. All other reagents and solvents were commercially purchased and were used as supplied.

2.3. Synthesis of compounds and copolymer

2.3.1. Compound 4

A flask was charged with a solution of **3** (0.38 g, 1.09 mmol) in 1,2-dichloroethane (30 mL). DMF (0.26 g,

3.61 mmol) and $POCl_3$ (0.55 g, 3.61 mmol) are added dropwise and the mixture was refluxed for 17 h under N_2. After cooling to room temperature and addition of dichloromethane (20 mL) and a saturated aqueous solution of sodium acetate (30 mL), the mixture was stirred for 2 h at room temperature. The organic phase was then washed with water and dried over $MgSO_4$. Solvent removal and column chromatography (silica gel/dichloromethane) gave 4 (0.27 g, 61%).

FT-IR (KBr, cm^{-1}): 1630, 1588, 1412, 1338, 1266, 1160, 1074, 1016, 908, 780, 670, and 614.

^1H NMR ($CDCl_3$) ppm: 9.90 (s, 2H, CHO); 7.80 (m, 2H, benzoselenadiazole); 7.23 (m, 4H, thiophene).

Anal. Calcd. for $C_{16}H_8N_2O_2S_2Se$: C, 47.65; H, 2.00, N, 6.95. Found: C, 46.20; H, 1.74, N, 6.37.

2.3.2. Compound Se-SM

A flask was charged with a solution of 4 (0.75 g, 1.09 mmol) and 4-nitrobenzyl cyanide (0.35 g, 2.18 mmol) in anhydrous ethanol (20 mL). Sodium hydroxide (0.20 g, 5.00 mmol) which was dissolved in anhydrous ethanol (20 mL) was added portionwise to the stirred solution. The mixture was stirred for 1 h at room temperature under N_2 and then was concentrated under reduced pressure. Compound Se-SM precipitated as a dark-green solid by concentration and subsequent cooling into a refrigerator. It was filtered off, washed thoroughly with water and dried. The crude product was purified by dissolution in THF and precipitation in methanol (0.43 g, 57%).

FT-IR (KBr, cm^{-1}): 2154, 1654, 1586, 1522, 1440, 1344, 1288, 1184, 1106, 1016, 854, 702.

^1H NMR ($CDCl_3$) ppm: 8.15 (m, 4H, phenylene ortho to nitro); 7.81 (m, 2H, benzosenadiazole); 7.70 (s, 2H, olefinic); 7.46 (m, 4H, phenylene meta to nitro); 7.22 (m, 4H, thiophene).

Anal. Calcd. for $C_{32}H_{16}N_6O_4S_2Se$: C, 55.57; H, 2.33, N, 12.15. Found: C, 54.73; H, 2.12, N, 11.85.

2.3.3. Copolymer P

A flask was charged with a mixture of 9 (0.4887, 0.891 mmol) 1,4-divinyl-2,5-bis(hexyloxy)benzene (0.2944 g, 0.891 mmol), $Pd(OAc)_2$ (0.0083 g, 0.037 mmol), P(*o*-tolyl)$_3$ (0.0624 g, 0.205 mmol), DMF (5 mL) and triethylamine (3 mL). The flask was degassed and purged with N_2. The mixture was heated at 90 °C for 24 h under N_2. Then, it was filtered and the filtrate was poured into methanol. The precipitate was filtered and washed with methanol. The crude product was purified by dissolution in THF and precipitation in methanol (0.46 g, 72%).

FT-IR (KBr, cm^{-1}): 2956, 2926, 2868, 1592, 1538, 1464, 1378, 1270, 1210, 1156, 1064, 962, 874, and 702.

2.4. Electrochemical characterization

The position of the HOMO and LUMO energy levels were estimated by cyclic voltammetry measurements. This was performed on an Autolab Potentiostat PGSTAT-10, equipped with a three electrode system, in an acetonitrile solution (0.1 M) of 4-tert-butylpyridine at a potential scan of 0.05 V/s at room temperature. Three electrode systems were composed of a glassy carbon electrode coated with a thin film of copolymer P, Se-SM and PCBM, Pt and Ag electrode. The electrochemical potential was calibrated against ferrocene/ferrocenium (Fc/Fc^+).

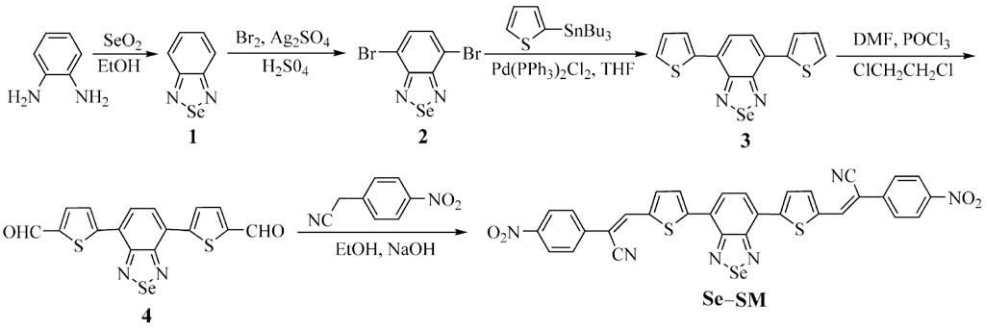
2.5. Device fabrication and characterization

For the photovoltaic device fabrication, indium tin oxides (ITO) coated glass substrates were cleaned with detergent, de-ionized water and acetone and then dried at room temperature. The PEDOT:PSS was spin coated upon the ITO coated substrates and then dried at a temperature of 60 °C. Then the active layers copolymer P, Se-SM, P:PCBM (1:1), Se-SM:PCBM (1:1) and P:Se-SM:PCBM (1:0.5:1) were spin coated on PEDOT:PSS coated ITO substrates from a THF at 1500 rpm. The thickness of the photoactive layers is about 100 nm. Finally, the Al electrode was thermally evaporated on the top of the photoactive layer under vacuum ($\sim 10^{-5}$ Torr) to make the sandwiched structure ITO/PEDOT:PSS/organic photoactive layer/Al. The effective area of the devices is about 25 mm^2. For the thermal annealing of photoactive layer, photoactive layer deposited on the PEDOT:PSS coated ITO substrate was placed on a hot plate at 100 °C for 10 min and then cooled up to room temperature, before the final Al electrode was deposited. Current–voltage characteristics of the devices were recorded with a Keithley electrometer with a built-in power supply in the dark and under a white light illumination intensity of 100 mW/cm^2. The 100 W halogen lamp calibrated for 1.5 AM sunlight spectrum was used as light source. The intensity of the lamp was calibrated and adjusted using a energy meter equipped with silicon detector. The incident photon to current efficiency (IPCE) of the devices was measured by illuminating the device with a halogen lamp using a monochromator and measuring the resulting photocurrent with a Keithley electrometer under short circuit conditions. All the fabrications and characterization were performed in an ambient environment.

3. Results and discussion

3.1. Synthesis and characterization of small molecule Se-SM

The Se-containing small molecule (Se-SM) was synthesized by a five-step reaction sequence which is outlined in Scheme 1. Specifically, compounds **1** [47], **2** [48] and **3** [48] were synthesized according to reported methods. Dialdehyde **4** was prepared by formylation of **3** using DMF and $POCl_3$. Finally, the condensation of **4** with 4-nitrobenzyl cyanide in ethanol in the presence of NaOH afforded Se-SM. It precipitated from the reaction mixture as a dark-green solid and was purified by dissolution in THF and



Scheme 1. Synthesis of small molecule Se-SM.

precipitation into methanol. Se-SM was soluble in THF, dichloromethane, chloroform and other common organic solvents. Thin films of Se-SM could be obtained from its solution by spin-coating even though it was a small molecule.

Table 1
Thermal, optical and electrochemical properties of Se-SM and P.

Sample	Se-SM	P
T_d[a] (°C)	517	413
Y_c[b] (%)	76	57
T_g[c] (°C)	68	56
$\lambda_{a,max}$[d] in solution (nm)	650	422
$\lambda_{a,max}$[d] in thin film (nm)	640	426
E_g^{opt}[e] (eV)	1.67	2.31
E_{onset} (red) (V)	−1.15	−1.95
HOMO (eV)	−5.25	−5.1
E_{onset} (ox) (V)	0.55	0.40
LUMO (eV)	−3.55	−2.75
E_g^{el}[f] (eV)	1.70	2.35

The HOMO and LUMO energy levels were calculated according to the equation: $-E_{LUMO} = E_{onset}$ (red) + 4.7 eV and $-E_{HOMO} = E_{onset}$ (ox) + 4.7 eV, where E_{onset} (ox) and E_{onset} (red) are the onset potentials for the oxidation and reduction processes of sample thin films vs. Ag/Ag^+ electrode.

[a] Decomposition temperature corresponding to 5% weight loss in N_2 determined by TGA.

[b] Char yield at 800 °C in N_2 determined by TGA.

[c] Glass transition temperature determined by TMA.

[d] $\lambda_{a,max}$: the absorption maxima from the UV–vis spectra in THF solution or in thin film.

[e] E_g^{opt}: optical band gap determined from the absorption onset in thin film.

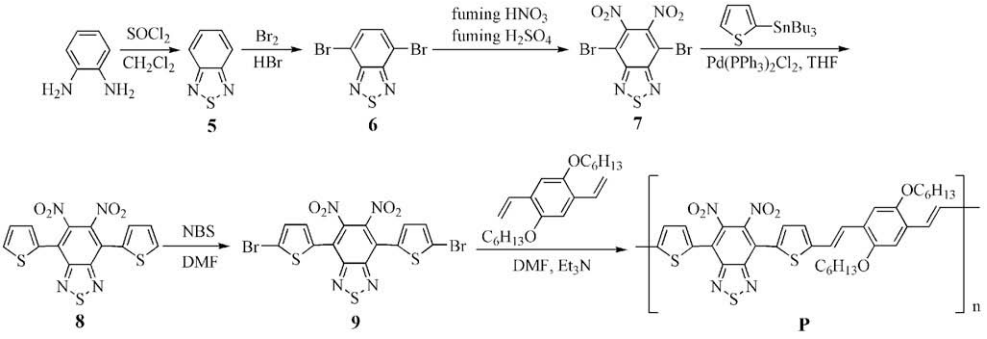
[f] E_g^{el}: electrochemical band gap determined from cyclic voltammetry. $E_g^{el} = E_{LUMO} - E_{HOMO}$.

The FT-IR and ^1H NMR spectra confirmed the chemical structure of Se-SM (see Section 2). In particular, it showed characteristic absorption bands at 2154 (cyano group); 1586, 1440 (aromatic); 1522, 1344 (nitro group); 1654 (C=C olefinic stretching vibration); 1288, 854, 702 (thiophene) and 1016 cm^{-1} (cyano-substituted trans olefinic bond). The ^1H NMR spectrum of Se-SM displayed upfield signals at 8.15 (phenylene ortho to nitro) and 7.81 (benzoselenadiazole). Finally, the olefinic, the aromatic meta to nitro and the thiophene protons resonated at 7.70, 7.46 and 7.22 ppm, respectively.

Se-SM exhibited high thermal stability, which was comparable with that of heat-resistant materials, due to the absence of aliphatic moieties. In particular, it had decomposition temperature (T_d) of 517 °C, char yield (Y_c) at 800 °C of 76% in N_2, by TGA, and glass transition temperature (T_g) of 68 °C, by TMA (Table 1).

3.2. Synthesis and characterization of copolymer P

Copolymer P was synthesized by a six-step reaction sequence which is presented in Scheme 2. Particularly, compounds **5** [49], **6** [49], **7** [50], **8** [50] and **9** [51] were synthesized according to the literature. The Heck coupling of dibromide **9** with an equivalent amount of 1,4-divinyl-2,5-bis(hexyloxy)benzene gave P. This reaction took place in DMF utilizing palladium catalyst and triethylamine as acid scavenger. The hexyloxy side chains enhanced the solubility of P making it very soluble in common organic solvents. The number average molecular weight (M_n) was 12,300, by GPC, with polydispersity of 2.6.



Scheme 2. Synthesis of copolymer P.

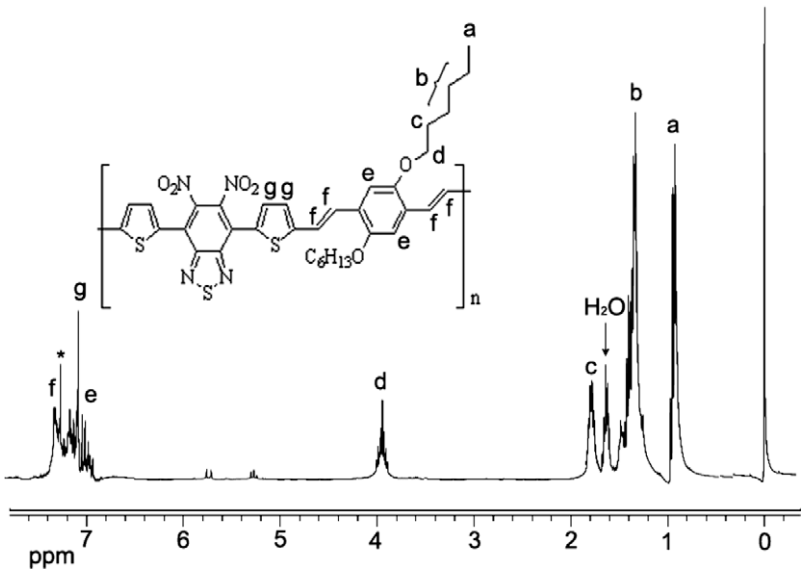


Fig. 1. ^{1}H NMR spectrum of copolymer P in $CDCl_3$ solution. The solvent peak is denoted by an asterisk.

The FT-IR spectrum of P showed characteristic absorptions at 2956, 2926 (C–H stretching of aliphatic segments); 1592, 1492, 1464 (aromatic); 1538, 1378 (NO_2); 1210, 1156 (ether bond); 1270, 874, 702 (thiophene) and 962 cm^{-1} (trans olefinic bond). The ^{1}H NMR spectrum (Fig. 1) displayed multiplets at 7.33, 7.08 and 7.04 ppm assigned to the olefinic, thiophene and phenylene protons, respectively. Finally, the aliphatic protons labelled "d", "c", "b" and "a" resonated at 3.94, 1.80, 1.33 and 0.92 ppm, respectively. The small peaks between 5 and 6 ppm are assigned to the terminal CH_2 = CH– groups.

Fig. 2 presents the TGA and TMA traces of P. No weight loss was observed up to ~300 °C. The T_d and Y_c were 413 °C and 57%, respectively (Table 1). Finally, the T_g, which was determined by TMA, was 56 °C. P exhibited lower thermal stability and T_g than Se-SM owing to the presence of the hexyloxy side chains in the former.

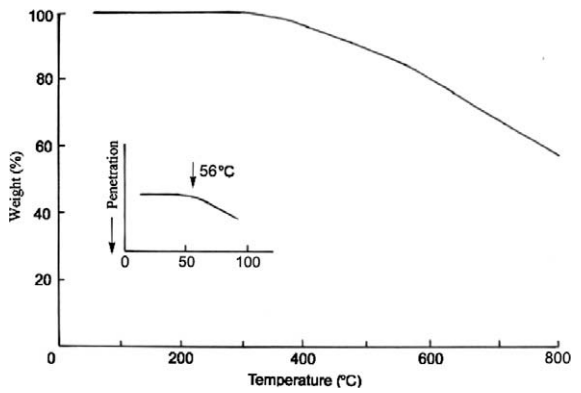

Fig. 2. TGA thermogram of copolymer P in N_2. The inset shows the TMA trace of this copolymer. Conditions: N_2 flow, 60 cm^3/min; heating rate, 20 °C/min.

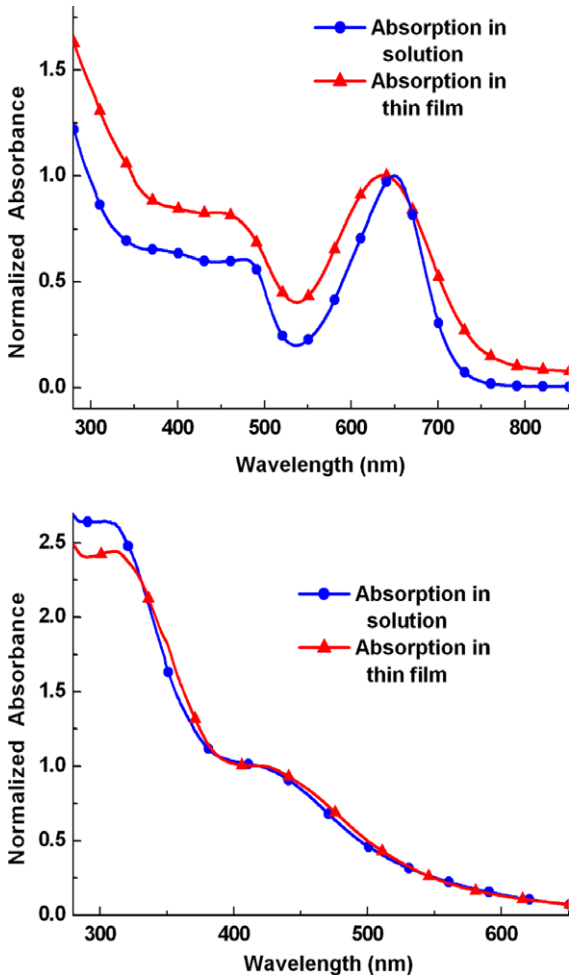

Fig. 3. Normalized UV–vis absorption spectra in solution and thin film of small molecule Se-SM (top) and copolymer P (bottom).

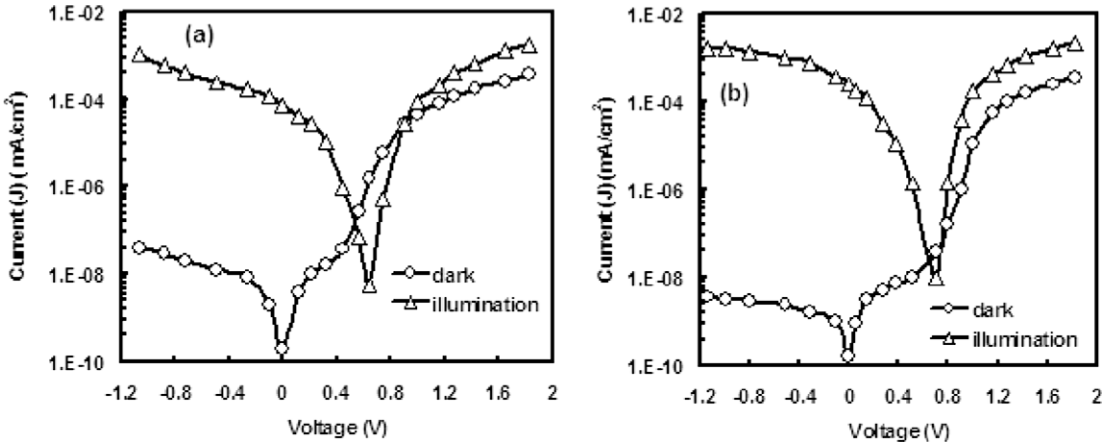

Fig. 4. Current–voltage characteristics in dark and under illumination for (a) ITO/PEDOT:PSS/copolymer P/Al and (b) ITO/PEDOT:PSS/Se-SM/Al devices.

3.3. Photophysical properties

Fig. 3 presents the UV–vis absorption spectra of Se-SM and P in both dilute (10^{-5} M) THF solution and thin film. They were normalized with respect the long-wavelength absorption peak. Table 1 summarizes all photophysical characteristics of these samples.

Se-SM showed a broad absorption bands (Fig. 3a) which were extended up to ~750 nm with long-wavelength absorption maximum ($\lambda_{a,max}$) at 650 for solution and 640 nm for thin film. This $\lambda_{a,max}$ was attributed to an intramolecular charge transfer between the central 4,7-di-2-thienyl-2,1,3-benzoselenadiazole and the terminal cyanovinylene 4-nitrophenyls. Similar absorption curves were obtained from other related compounds which have been synthesized in our laboratory [43,44]. The thin film absorption onset of Se-SM was located at 741 nm which corresponds to an optical band gap (E_g^{opt}) of 1.67 eV. The relatively low E_g^{opt} value of Se-SM suggests that this small molecule is attractive for photovoltaic applications.

Copolymer P displayed similar absorption curves (Fig. 3b) in solution and thin film which were extended about up to 500 nm with $\lambda_{a,max}$ at ~420 nm. The thin film absorption onset was at 536 nm corresponding to E_g^{opt} of 2.31 eV.

3.4. Electrical and photovoltaic properties of copolymer P and Se-SM

The current–voltage (J–V) characteristics of the ITO/PEDOT:PSS/copolymer P/Al and ITO/PEDOT:PSS/Se-SM/Al devices in dark and under illumination intensity of 100 mW/cm^2 are presented in Fig. 4. In these curves, the forward bias corresponds to the positive and negative voltage applied to ITO and Al electrode, respectively. It can be seen from this figure that the J–V characteristics show rectification effect. This can be explained by the high work function of ITO coated PEDOT:PSS and p-type semi-conductivity of both copolymer P and Se-SM. This indicates that the ITO/PEDOT:PSS/ and Al form Ohmic and Schottky barrier with both copolymer P and Se-SM, respectively. Since the HOMO level of both the copolymer P (−5.1 eV) and Se-SM (−5.25 eV) are very close to the Fermi level of PEDOT:PSS (−5.0 eV), forms a potential barrier of about 0.10 and 0.25 eV for hole injection from PEDOT:PSS into the HOMO of copolymer P and Se-SM, respectively, in their devices. This results in the formation of nearly Ohmic contact at ITO/PEDOT:PSS-organic layer. However, the Fermi level of Al (−4.3 eV) is very far from the LUMO of copolymer P (−2.8 eV) and Se-SM (−3.60 eV) thus forming a potential barrier of 1.5 and 0.9 eV for electron injection from Al to LUMO of the copolymer P and Se-SM, respectively, resulting a Schottky barrier contact. Therefore, the copolymer P behaves as p-type organic semiconductor.

We have estimated the hole mobility of copolymer P and Se-SM using the space charge limited current (SCLC) method [52]. The J–V characteristics of ITO/PEDOT:PSS/copolymer P/Au and ITO/PEDOT:PSS/Se-SM/Au devices in dark on log–log scale are shown in Fig. 5. It can be seen from this figure that in low voltage region, the log J is linearly dependent on the log V with a slope of unity. In the relatively high voltage region, the log J is also linearly

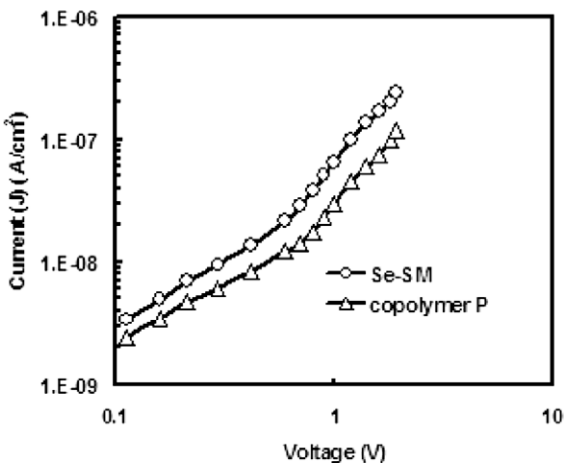

Fig. 5. Current–voltage curves in for devices based on copolymer P and Se-SM sandwiched between PEDOT:PSS coated ITO and Au electrodes in log–log scale.

dependent on the log V with a slope of two. The J–V curves in this region correspond to the trap free SCLC behavior. We estimated the hole mobility of the corresponding copolymer P and Se-SM, according to equation

$$J = \frac{9}{8}\varepsilon_r\varepsilon_o\mu_h\frac{(V - V_{bi})^2}{d^3} \quad (1)$$

where V is the applied voltage, J is the current density, ε_r and ε_o are the relative dielectric constant and permittivity of free space (8.85×10^{-12} F/m), respectively, μ_h is the hole mobility and d is the thickness of the organic layer and V_{bi} is the built-in potential which is determined by the difference between the work function of the electrodes. Using $\varepsilon_r = 3.5$, $d = 100$ nm and $V_{bi} = 0.8$ eV and fitting the curve in high voltage region with Eq. (1), the values of hole mobility are 2.3×10^{-5} cm^2/Vs and 3.4×10^{-4} for copolymer P and Se-SM, respectively.

The photovoltaic parameters, i.e., short circuit current (J_{sc}), open circuit voltage (V_{oc}), fill factor (FF) and power conversion efficiency (η) for the devices are listed in Table 2. It can be seen from this table that the open circuit voltage for both devices is almost the same and the J_{sc} for the ITO/PEDOT:PSS/Se-SM/Al device is higher than that for ITO/PEDOT:PSS/copolymer P/Al device. The V_{oc} for a Schottky barrier device is approximately equal to the work function difference between the electrodes used. In these devices we have used same electrodes and therefore the V_{oc} is quite similar. The higher value of the J_{sc} for the device based on Se-SM is attributed to the broad band absorption spectra and the low-band gap as compared to the copolymer P. The higher value of the hole mobility for the Se-SM also contributes to the higher photocurrent, resulting better charge transport in the device.

Table 2
Photovoltaic parameters of the devices using different photoactive layers sandwiched between ITO/PEDOT:PSS and Al electrodes.

Photoactive layer	Short circuit current (J_{sc}) (mA/cm^2)	Open circuit voltage (V_{oc})	Fill factor (FF)	Power conversion efficiency (η) (%)
P	0.07	0.64	0.31	0.014
Se-SM	0.25	0.74	0.38	0.07
P:PCBM	1.30	0.93	0.43	0.52
Se-SM:PCBM	2.7	0.98	0.49	1.30

In order to get more information about the formation of Schottky barrier, we measured the incident photon to current efficiency (IPCE) of both devices. The values of IPCE have been estimated using the following expression

$$\mathrm{IPCE}\,(\%) = 1240 J_{sc}/\lambda P_{in} \quad (2)$$

where J_{sc} (mA/cm^2) is the short circuit photocurrent, P_{in} (W/m^2) and λ (nm) is the illumination intensity and wavelength of the monochromatic light, respectively. The IPCE spectra of the ITO/PEDOT:PSS/copolymer P/Al and ITO/PEDOT:PSS/Se-SM/Al devices, illuminating through the Al and ITO side are shown in Fig. 6a and b. It can be seen from these figures that the shape of IPCE spectra of the devices, illuminating through the Al side closely follow the absorption spectra of the organic materials used in the device as photoactive layer. In organic photovoltaic devices, the photocurrent is due to the exciton generation upon the photoexcitation and their subsequent dissociation into free carrier at the Schottky barrier or p–n junction. Since the exciton diffusion length in most of organic semiconductors is in the range of 10–15 nm, the excitons that reaches the interface, only contributes to the photocurrent. When the device is illuminated through the Al electrode, photons corresponding to the absorption peaks of copolymer P and Se-SM are absorbed near the Al/copolymer P and Al/Se-SM in their respective devices due to the high absorption of photoactive material, generate the excitons in this region and subsequently dissociate into free carries due to the built-in field at the interface, resulting IPCE. However, photons corresponding to the low absorption coefficient of the organic materials, penetrate more into the bulk of the material. As a result, they are absorbed far from the Schottky barrier and generate excitons there. Therefore, only excitons that are generated within the distance 10–15 nm from the Schottky barrier (Al–organic layer interface), are able to reach the Schottky interface, contributes to the photocurrent. In this case only few excitons reach to the Schottky barrier and results low photocurrent in comparison to earlier case. On the other case, when the devices are illumi-

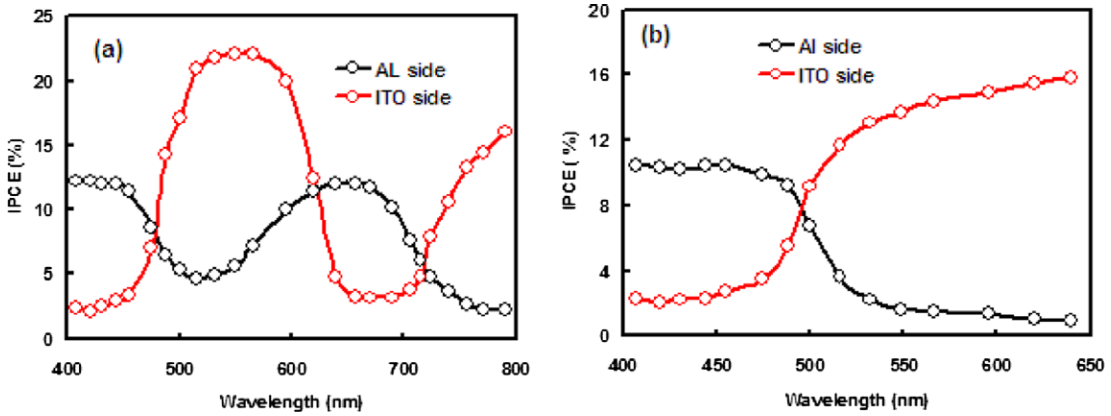

Fig. 6. IPCE spectra of (a) ITO/PEDOT:PSS/Se-SM/Al and (b) ITO/PEDOT:PSS/copolymer P/Al devices, illuminating through ITO and Al electrodes.

nated through the ITO side, only a few of the photons are able to reach the Schottky barrier, and therefore, cause limited generation of excitons leading to low photocurrent at the wavelength where the absorption coefficient is low. The excitons generated near to the Ohmic contact, i.e., ITO/PEDOT:PSS disappear due to recombination or trapping during their transportation through the organic layer towards the Schottky barrier. At the wavelengths where the absorption of the active layer is minimum, the light can penetrate deeper, allowing more excitons to be generated near the Schottky barrier, leading to higher photocurrent.

3.5. Photovoltaic properties of copolymer P or Se-SM blended with PCBM

The energy levels for the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of copolymer P and Se-SM were obtained by cyclic voltammetry with the method described by Bredas et al. [53] and are summarized in Table 1. The crucial factor for the effective photoinduced charge transfer in bulk heterojunction is the difference between the LUMO level of the donor and acceptor components used in the bulk heterojunction photoactive layer. This difference should be larger than that of the exciton binding energy, i.e., 0.3 eV. The difference in the LUMO levels of PCBM (acceptor) and copolymer P or Se-SM is higher. Therefore, the combination of PCBM and copolymer P or Se-SM is suitable for the photoactive layer to be used in a BHJ PV device.

Fig. 7 shows the *J–V* characteristics of the devices fabricated with copolymer P:PCBM and Se-SM:PCBM blends under the illumination intensity 100 mW/cm^2. The photovoltaic parameters of both devices are given in Table 2. The values of the power conversion efficiency of both devices are higher than those obtained for the devices fabricated with pristine copolymer P and Se-SM. This indicates that a BHJ is formed in the blend that increases the interfacial interface between the donor and acceptor. It can be seen from Table 2 that both short circuit current and open circuit voltage for the device using Se-SM:PCBM are higher than that for fabricated with copolymer P:PCBM. The higher short circuit current is attributed to the low-band gap and broad band absorption extending up to 800 nm of Se-SM and higher hole mobility in comparison to that for copolymer P, resulting to greater exciton generation in the Se-SM phase and better hole transport in the device.

In BHJ devices, if both electrodes form the Ohmic contact with the photoactive layer, the open circuit is mainly governed by the difference between the LUMO level of acceptor and HOMO level of the donor used in the device [54,55]. The work function of PEDOT:PSS almost matches the HOMO level of copolymer P or Se-SM, resulting in nearly ohmic contact for holes in the their respective BHJ devices, under the forward bias condition. On the other hand, the Al makes nearly Ohmic contact electron injection in the LUMO of PCBM. For this case the open circuit voltage is given by [54]

$$q(V_{oc} - \Delta V_b) = (\mathrm{HOMO})_{donor} - (\mathrm{LUMO})_{acceptor} \quad (3)$$

where ΔV_b is the sum of the voltage losses at each contact due to the band bending. The observed experimental values of V_{oc} for both devices are in agreement with Eq. (3). Since the position of the HOMO level for Se-SM (−5.25 eV) is more negative than that for copolymer P (−5.1 eV), results higher value of V_{oc} for device employing Se-SM:PCBM blend as compared to the device with copolymer P:PCBM blend.

3.6. Effect of incorporation of Se-SM in the copolymer P:PCBM blend

The photovoltaic performance of the photovoltaic devices using copolymer:PCBM and Se-SM:PCBM blends is low. A possible route to overcome this low performance

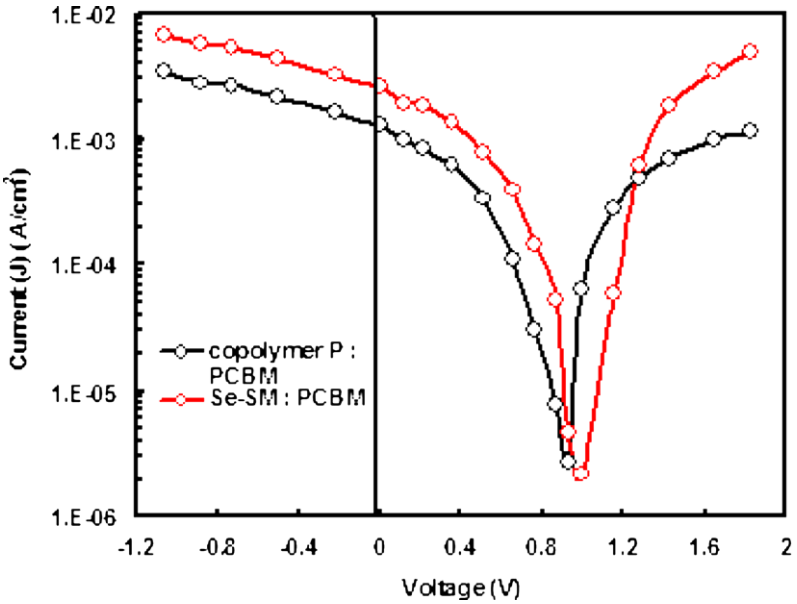

Fig. 7. Current–voltage characteristics of devices fabricated with copolymer:PCBM and Se-SM:PCBM blends under illumination.

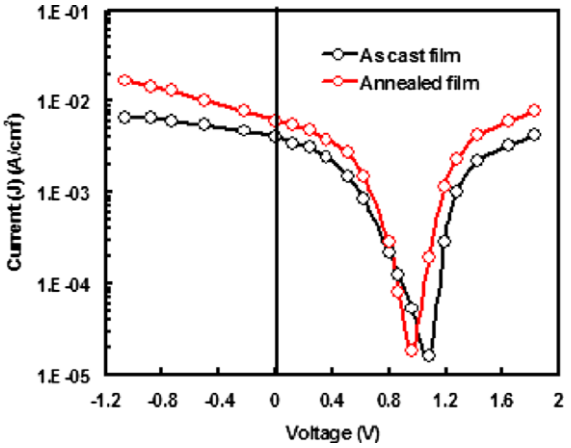

Fig. 8. Current–voltage characteristics of ITO/PEDOT:PSS/copolymer P:PCBM:Se-SM/Al devices.

might be to incorporate a low-band gap small molecule donor in the blend of polymer P:PCBM [56,57] blend with energy levels intermediate to those polymer and PCBM, in order to avoid the charge trapping in the small molecule. Since the energy levels of the Se-SM are located between the energy levels of copolymer P and PCBM, we have incorporated Se-SM in the copolymer P:PCBM blend to increase the power conversion efficiency.

Fig. 8 shows the *J–V* characteristics of the devices based on as cast and annealed copolymer P:PCBM:Se-SM blends under illumination intensity of 100 mW/cm^2. The photovoltaic parameters of the devices are summarized in Table 3. The incorporation of Se-SM in the blend improves both the short circuit current (J_{sc}) and the open circuit voltage (V_{oc}). However, the V_{oc} decreases when the annealed photoactive blend is used. This may be due to the increase in the crystalline nature of the copolymer that results in a decrease of V_{oc} because of the rise of HOMO level of the copolymer P. The rise in the HOMO level occurs as a result of increased inter-chain orbital delocalization [58]. The increase in J_{sc} with the addition of Se-SM is a result of increased absorption at the longer wavelength region, which is absent in the case of the copolymer P:PCBM blend. The absorption at the wavelength region leads increased exciton generation in the blend, and their subsequent dissociation into free charge carriers at the donor–acceptor (D–A) interfaces formed in the blend. Since Se-SM also acts as a donor, its incorporation also increases number of D–A interfaces in the blend that also increases the photoinduced charge separation.

In order to get more information about the origin of the increase in J_{sc} upon the addition of Se-SM in the copolymer P:PCBM blend, we have measured the IPCE spectra of the devices which are shown in Fig. 9. In the case of photovoltaic device based on blend without Se-SM, the IPCE peak is only in the region of 380–500 nm corresponding to the absorption spectrum of copolymer P. The increase in the IPCE of device with copolymer P:PCBM (Fig. 9b) upon thermal annealing is attributed to the increase in crystallization of the copolymer. On the other side, the device with copolymer P:PCBM:Se-SM exhibits two IPCE peaks appearing in the wavelength region of copolymer P absorption and also in the longer wavelength region of Se-SM absorption.

When the Se-SM is incorporated in copolymer P:PCBM blend, Se-SM may be located between (i) copolymer P and PCBM phases, (ii) PCBM phases and (iii) copolymer phases. The energy level diagram of the copolymer P, Se-SM, and PCBM is shown in Fig. 10. As shown in this figure, the excitons generated in Se-SM, when Se-SM is located between copolymer P and PCBM, inject electrons into PCBM and holes into copolymer P because the HOMO level of Se-SM is more negative than the HOMO level of copolymer P. However, when Se-SM is located at PCBM domain, Se-SM can only inject electrons into the PCBM domain but cannot inject holes into surrounding PCBM domain because of more negative HOMO level of PCBM. Similarly, when Se-SM is located between the copolymer P domains only holes are injected into the surrounding copolymer P. Therefore, only the Se-SM molecule, which is located between the copolymer P and PCBM, can contribute to the photocurrent.

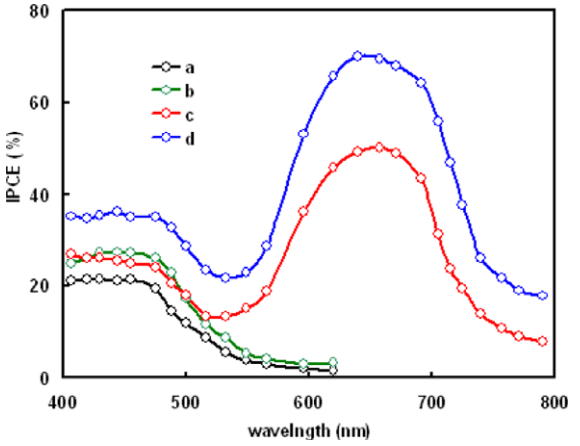

Fig. 9. IPCE spectra of the photovoltaic devices based on different blends (a) copolymer P:PCBM (as cast), (b) copolymer P:PCBM (annealed), (c) copolymer P:PCBM:Se-SM (as cast) and (d) copolymer P:PCBM:Se-SM (annealed).

Table 3
Effect of Se-SM incorporation in the copolymer P:PCBM blend on photovoltaic parameters.

Photoactive layer	Short circuit current (J_{sc}) (mA/cm^2)	Open circuit voltage (V_{oc}) (V)	Fill factor (FF)	Power conversion efficiency (η) (%)
P:PCBM:Se-SM (as cast)	4.1	1.05	0.52	2.24
P:PCBM:Se-SM (annealed)	6.1	0.92	0.54	3.16

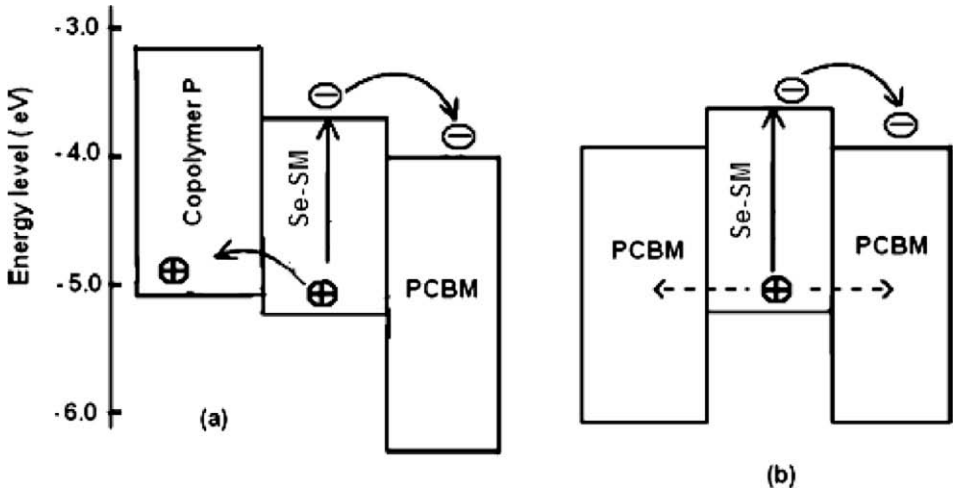

Fig. 10. Energy level diagram of Se-SM and surrounding materials: (a) Se-SM molecule is located between copolymer P and PCBM and (b) Se-SM molecule located in between two PCBM domains.

As can be seen from the IPCE spectra of the devices, the IPCE value at 640 nm increases from 48% to 70%, when the thermally annealed copolymer P:PCBM:Se-SM blend is used. However, it was observed that the optical absorption spectra do not change upon the thermal annealing. The increase in the IPCE may be attributed to the enhanced charge collection efficiency, which is improved by the formation of more crystalline nature interpenetrating network, upon thermal annealing. In addition to that, the number of the Se-SM molecules in between copolymer P and PCBM may increase upon thermal annealing because of the increased crystalline nature of the conjugated polymer and aggregation of the nano-crystalline PCBM domain. The Se-SM molecules located in the copolymer P or PCBM domain may be expelled from these domains into the interface between copolymer P and PCBM, upon thermal annealing. The combined effect of additional absorption at longer wavelength region by Se-SM molecules and Se-SM molecules located in between conjugated copolymer P and PCBM results the improvement in the J_{sc}, thereby increases the power conversion efficiency.

4. Conclusions

A new low-band gap Se-containing small molecule (Se-SM) and a phenylenevinylene copolymer (P) based on dithyenyl-dinitrobenzothiadiazole were synthesised and used for BHJ solar cells. The current–voltage characteristics in dark and IPCE spectra of devices using these materials show that both copolymer P and Se-SM behave as p-type organic semiconductor forming Ohmic and Schottky barrier with ITO coated PEDOT:PSS and Al electrodes, respectively. The power conversion efficiency of the devices based on Se-SM and copolymer P is low. However, both materials can be used as donors for bulk heterojunction with PCBM due the suitable position of their LUMO level. However, when P or Se-SM blended with PCBM, the power conversion efficiency was significantly improved resulted from the formation of bulk heterojunction between copolymer P or Se-SM and PCBM in their respective devices. The effect of the incorporation of the Se-SM on the photovoltaic properties of vinylene copolymer P:PCBM solar cell was investigated. The broader absorption of Se-SM molecules at the longer wavelength region effectively harvests the photon in this region. Moreover, the Se-SM molecules located between the copolymer P and PCBM contribute to the enhancement in the power conversion efficiency due to the effective dissociation of the generated excitons in the copolymer P phase at shorter wavelength region. A further improvement in the power conversion efficiency (3.16%) of the device based on thermally annealed copolymer P:PCBM:Se-SM is attributed to the increase in the number of Se-SM molecules in between copolymer P and PCBM domain due to increased crystallization of the copolymer P.

ABSTRACT

In this study, we examine organic light emitting diodes (OLEDs) having Al top electrodes deposited on organic layers by direct-current magnetron sputtering. The OLEDs consisted of electronically doped transport layers and phosphorescent emission layer were characterized by typical current–voltage–luminance measurement. They showed higher leakage currents, decreased forward currents, and corresponding increases of driving voltage after the sputter deposition on the organic layers. The OLEDs exhibited randomly distributed bright spots on the active area, and the bright spots were investigated by scanning electron microscopy/energy-dispersive X-ray spectroscopy. In order to prove the origins of sputter damage, simple organic/Al layer samples were made and investigated by ellipsometry and laser-induced desorption/ionization time-of-flight mass spectrometry. The results are compared with previous works addressing the fundamental phenomena of magnetron sputtering. We conclude that the high leakage current originated from a penetration of sputtered metal atoms into the underlying organic layers, and the decrease of forward current resulted from an interface degradation caused by the radiation of plasma, which reduces charge carrier injection preferentially at the Al/organic layer interface.

1. Introduction

Organic light emitting diodes (OLED) are excellent optoelectronic devices for various applications like display and general lighting due to their self-emissive characteristics, natural color expression, and comparably simple device structure. Since a multilayered organic electroluminescence device was reported [1] , its efficiency has been tremendously improved by introducing highly efficient and functional organic materials and stack optimization [2–5]. Fabrication technologies as well as organic materials also achieved great progress on large area substrates, although high deposition rate and stability of top electrode deposition are still a challenge. The top electrodes, e.g. Al or Ag, are evaporated at two or threefold higher temperature than organic materials. For this purpose, metal boats made of Ta or W are generally used to heat the electrode materials. However, such metal boats are supplied with a high power in order to exceed the vaporizing temperature of the electrode metals, which causes a gradual degradation of the boat materials. In particular, molten Al can easily wet the boat surface, resulting in a serious damage due to an extremely high current. In OLED mass production, this problem is still a critical issue in the metal electrode deposition, because it leads to a shorter equipment uptime. Due to those problems, the development of an alternative deposition method has been strongly urged by the OLED industry, especially for large area OLEDs. Magnetron sputtering method is still the best candidate for the metal

deposition. Much works were done in order to apply magnetron sputtering for the top electrode deposition on organic layers [6–8], but serious damages in device were reported unfortunately. However, a positive result was also reported by Guenther et al. that only a slight voltage increase of less than 1 V was observed in case of sputtered Indium–Tin–Oxide (ITO) top electrode with a device optimization, keeping the efficiencies and the lifetime similar as for a device having a evaporated metal top electrode [9].

The first part of this study is therefore devoted to examine the OLEDs fabricated with Al cathodes by direct-current (DC) magnetron sputtering and to identify the origins of damage, especially leakage currents. In the Al sputter depositions, only the Ar flow rate was varied to alter the process pressure, which affects sputter deposition significantly. Since the process pressure plays a decisive role in changing kinetic energy of atomic particles by collisions with background Ar gases, a corresponding variation in damages of OLEDs can be expected. The fabricated OLEDs were characterized by current–voltage–luminance (I–V–L) measurements. The results are discussed on the basis of the fundamental phenomena of magnetron sputtering, and a possible damage source responsible for the high leakage current is inferred from it. Simple structures were made in order to prove a change of the electronic level structure in an organic layer after Al cathode deposition by sputtering. Each sample consisted of a single organic and Al layer deposited with the same process parameters as for the OLED fabrications. The samples were examined by ellipsometry which allows an easy access to optical constants of the materials. We employed laser desorption/ionization time-of-flight mass spectrometry (LDI–TOF–MS), which is a useful tool to detect chemical mixtures via their mass-to-charge ratio, in order to identify materials responsible for the high leakage current [10].

In the second part, radiation effects from plasma on the metal/organic interface are examined. If a substrate is immersed into the plasma, the surface of the substrate experiences impingement of radiative particles including electrons, ions and photons. The former two particles have energy corresponding to plasma potential, but the latter photons range from ultra-violet (UV) to infrared. In particular, the high-energy photons ($h\nu > 10$ eV) generated from the energy transition of excited or ionized atoms have been examined in various plasma-associated processes because the photon radiation is quite intensive in glow discharge plasma and affects a device performance significantly. While radiation-induced material damages have been studied widely in semiconductor devices, e.g. metal–oxide-semiconductor devices and bipolar transistors, or a surface modification engineering of polymers using plasma [11–13] , such effects have been rarely discussed in OLED field. During magnetron sputtering, those particles are also generated from the bulk plasma and the surface of sputter cathode considerably. Therefore, we will examine resulting influences from the plasma radiation on OLED characteristic by considering an radiation energy, which the underlying organic layer suffers differently according to the variation of sputter process parameters.

2. Experimental preparation

The samples listed in Table 1, except for the reference OLED, were fabricated in VES400 vertical In-line OLED deposition system (Applied Materials, GmbH & Co. KG) [14,15] . The VES400 consists of several vacuum chambers as shown in Fig. 1, and all the organic materials are thermally evaporated in linear type sources.

The stacks of the samples are listed in Table 1. Substrates used for OLED fabrications were cleaned with isopropanol, acetone and deionised water ultrasonically. Afterwards they were heated at 120 °C for outgassing. The substrate loading to a transport carrier was carried out in the nitrogen ambient glove box 1, and the carrier moved from glove box 1 into the loadlock chamber. The deposition processes were performed at high vacuum of 10^{-7} mbar range by passing all the process chambers. In the substrates, indium tin oxide (ITO) was predeposited on glass as a transparent anode material. For all the OLEDs including the reference OLED and the OLEDs from A to C, doped transport layers (Novaled AG.) were employed to achieve low driving voltage and high carrier transport. These organic layers, NHT5:NDP2 and NET5:NDN1, have electrical conductivity above 10^{-5} S/cm which are electrically approximately equivalent to MeO—TPD : F_4–TCNQ and BPhen:Li, respectively [4] . The emission layer consisted of 4,4-bis [N-(1-naphtyl)-N-phenyl-amino] biphenyl (α-NPD) and Iridium(III)bis(2-methyldibenzo-[f,h] quinoxaline)(acetylacetonate) ($Ir(MDQ)_2(acac)$) as a host and orange–red phosphorescent dye dopant, respectively. This emitting system allows an effective energy transfer from the host to the guest dopant because the HOMO/LUMO positions of α-NPD and the triplet energy state of $Ir(MDQ)_2(acac)$ are quite well matched. Hence an effective energy transfer of the singlet and triplet excitons from the

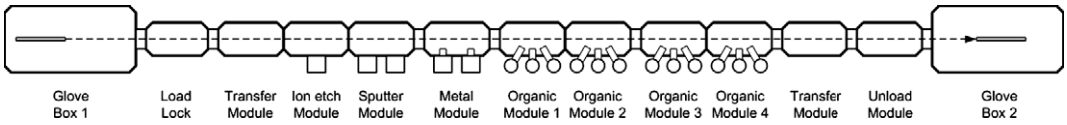

Fig. 1. Schematic illustration of In-line machine implemented for the experiments.

host to the phosphorescent dye dopant is accomplished [16].

The reference OLED was fabricated in a cluster equipment with same organic stack in order to deposit Al cathode by thermal evaporation. The Al cathodes of the sample A/B/C are deposited in the sputter chamber after depositions of organic layers. The sputter chamber equipped with two conventional magnetron sputtering cathodes is also located in the middle of the In-line machine so that Al cathodes were subsequently deposited on organic layers without vacuum break. The process parameters for Al sputtering are listed in Table 2. As indicated, three different Ar flow rates (100, 300 and 500 sccm) were selected with an equal DC power 500 W. After all the film depositions, the substrates were encapsulated in a nitrogen-filled glove box with glass including getter inside to protect the OLEDs from oxygen and water vapors. *I–V–L* characteristic of the fabricated OLEDs was measured by DMS 101 (Autronic Melchers, GmbH). The samples from D to H were made on different substrates prepared with the same preparation sequence for ITO substrates. The samples for ellipsometry and LDI–TOF–MS measurements were put into a nitrogen-filled carrier with O-ring seal directly after film deposition in order to prevent them from ambient before the measurements.

The basic setup of ellipsometry is depicted in Fig. 2. The measurements were performed twice on both sample sides. In the first measurement, linearly polarized light emitted from light source fell onto the Al film at an incoming angle $\theta = 65°$, and the optical constant of the Al film was obtained first after eliminating the constant of a thin surface aluminum oxide. Afterwards, the film-coated side of the sample was set above like Fig. 2, and the measurement was performed once more with the setup. In this case, the polarized light is reflected at the Al/organic layer interface and escapes from the sample. The light undergoes phase delays by passing through the glass and the organic layer because the refractive indices of glass and most organic materials are higher than air. The light escaping the sample is then falls onto the detector. Since the optical constants of Al films processed at different parameters were almost identical, we assumed that the optical properties of the Al film at the interface agreed with those at the air side. Since the refractive index of the glass is already known ($n \cong 1.5$), that of the organic layer is able to be extracted. By means of iterative fits, the thickness as well as the index of the organic layer was successfully obtained. The thickness of the organic layer exhibited approximately 5% deviation from the value measured by a profilometer, proving that the sample preparations were very reproducible. As an organic interlayer, NET5 (Novaled AG, Dresden) was deposited on the glass because this material undergoes sputter damage firstly in OLED.

Table 2
Process parameters for Al sputter depositions and corresponding deposition rates.

Process parameter	DC power (W)	Ar flow rate (sccm)	Pressure (mbar)	Deposition rate (nm/speed.oscillation)
1	500	100	0.001	24.86
2	500	300	0.003	18.70
3	500	500	0.005	14.75

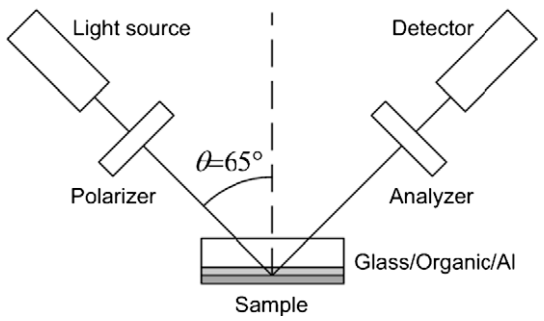

Fig. 2. Ellipsometry scheme on the sample for measurement. The optical constants of organic layer after sputter deposition are obtained from this setup.

The samples for LDI–TOF–MS were prepared on well-cleaned stainless plates. The instrument was described well by Scholz et al. [10]. The samples were placed in the analysis chamber under a vacuum of 10^{-7} mbar during measurement. The wavelength of the laser was 337 nm and the total laser intensity was 129.2 μJ/pulse. The spectra were taken at positive detection mode at a laser intensity of 75%. Three different positions at one sample were measured, and 60 spectra were gathered from each position to obtain one spectrum.

3. Results and discussion

3.1. Origin of leakage current in OLED

In Fig. 3, the *I–V–L* characteristics of the reference OLED and the OLED samples A to C are shown. Notable are high current densities at low forward voltage under 2 V and negative voltage regions in the OLEDs having sputtered Al cathode while the reference OLED shows very low current. According to the transport theory in a dielectric layer, the current at those regions exhibits $I \propto V$ characteristic in a well-fabricated device. This current obeys Ohm's law, and this ohmic current is controlled by thermally generated charges [17] . The current level is usually much lower than the trap-filled space charge limited current at higher

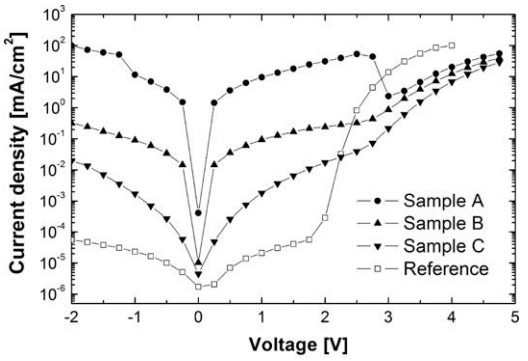

Fig. 3. *I–V* Characteristics of fabricated OLEDs. The OLEDs show high leakage currents after the Al top contact deposition using magnetron sputtering. Remarkable point in the graph is that the leakage current decreases as the process pressure increases.

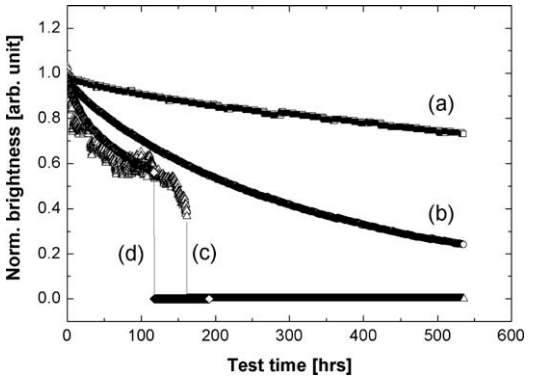

Fig. 4. Lifetime results of the fabricated OLEDs. (a) and (b) are the normalized brightness of reference OLED measured at 10 and 30 mA/cm^2, respectively. (c) From the sample B measured at 10 mA/cm^2, and (d) from the sample C measured at 30 mA/cm^2.

voltage region. When the low current density of around 10^{-4} mA/cm^2 at between ±2 V in the reference OLED is considered, the higher currents in the OLED samples A to C seem to be defects caused by sputtering deposition on the organic layers. There can be other possible reasons like shortcuts due to ITO roughness or particle contamination. However, it is certainly sputter-induced damage because an identical procedure for substrate preparation was carried out for all the samples including the reference OLED. Similar phenomena have been examined by Kim et al. for Al top electrode deposition using facing target sputter (FTS) apparatus [8] . In that study, the reason for high leakage current was explained with a formation of a metallic surface due to bombardment of energetic particles and with a current path at the interface between metal and organic layers due to local damage, quoting the study of Liao et al. and Gu et al., respectively [18,19] . In the Liao's study, the effect of energetic Ar^+ ion bombardment on tris-(8-hydroxyquinoline) aluminum (Alq_3) molecules has been examined in order to simulate sputtering deposition. They explained that the bombardment of high energetic particles destroyed molecular band structure, resulting in a formation of a metal-like conducting surface consequently. However, their experiment was not carried out by a substantial sputtering deposition, and employed an intentional 100 eV Ar^+ which is scarcely generated in Al target sputtering with Ar^+ ion at a discharge voltage around 300 V [20] . Furthermore, only a metallic surface is not thought to induce such high leakage current because the bombarded surface of organic layer makes contact with a deposited Al layer, which is incomparably more conductive.

Since these high leakage currents often result in an unstable device operation or sudden death, lifetime measurement must be performed to evaluate the stability of OLED. The measurement is also necessary to turn out a correlation between the leakage current and the lifetime. Fig. 4 contains four graphs of normalized brightness obtained from lifetime measurements. OLEDs, the reference and sample A/B/C, are supplied with the current density of 10 and 30 mA/cm^2. It should be noted in advance that the sample A, which has shown the highest leakage current, exhibited extremely short lifetime, only a few minutes, so the result is not included. As expected, the results of the reference OLED in Fig. 4a and b shows curves stably decaying in brightness at the both current densities. In contrast with the reference OLED, the sample B from Fig. 4c measures at 10 mA/cm^2 showed a faster decay, fluctuating until the sample resulted in sudden death eventually. Whereas, the sample C in Fig. 4d shows relatively more stable decay than the sample B. This result is attributed to the lower leakage current of the sample C. It is therefore manifested that the leakage current and the lifetime have an intimate correlation.

In order to compare the previous explanations of Liao et al. with our results, simple structures (samples D–G) were made for an investigation on optical properties of the organic material by ellipsometry. In Fig. 5, the curves of the optical constants obtained for NET5 layers are shown. Interestingly, there were no significant differences in the optical properties of the organic layers in spite of the high leakage currents in the OLEDs. In particular, the optical bandgaps of NET5 layers from the extinction coefficients

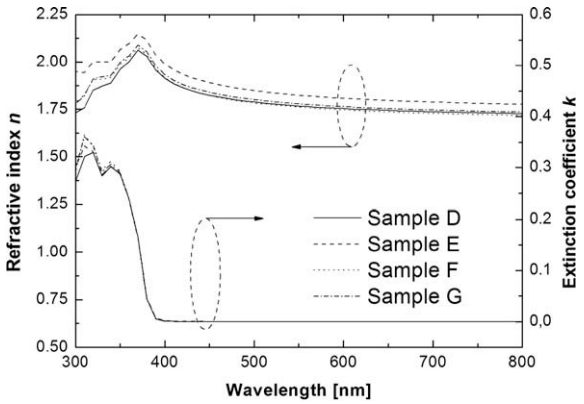

Fig. 5. Comparison of refractive indices and extinction coefficients of the samples from D to G. The NET5 layers show an identical optical gap of 3.26 eV despite of different leakage currents in the sample A–C.

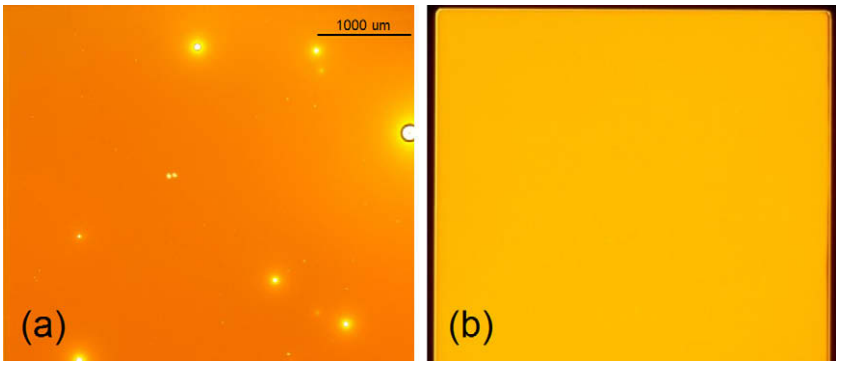

Fig. 6. Observation of the lighting surface of OLEDs at identical magnification, (a) having sputtered Al cathode and (b) evaporated Al cathode. The operation voltage was 3 V, and the resulting luminance was 160 (a) and 2700 cd/m^2 (b). Many bright spots are observed in the OLED having the sputtered Al top electrode while the reference OLED shows a homogenous lighting area.

are explicitly identical and clearly observable at 3.26 eV (λ = 380 nm); the results were also equal in other measure points as well. This means that the electronic band structure of the entire organic layer was not significantly changed after the Al sputtering and the previous explanations are not satisfactory to explain the leakage currents in our OLEDs.

The active surfaces of operating OLEDs were also observed by optical microscopy in order to find clues in detail. The surface images are shown in Fig. 6. In contrast to the results of Kim et al. [8] , the OLEDs having sputtered Al cathodes showed many localized bright spots while the reference OLED had no such spots. These bright spots indicate that more charge carriers flow through such small areas due to the higher electric field or parasitic current paths and that the charge carriers are transported not by conventional hopping conduction between organic molecules over highest occupied molecular orbital (HOMO)/lowest unoccupied molecular orbital (LUMO) level. Such current paths are therefore thought to be responsible for the high leakage currents, and it may be caused by other highly conductive species like metal filaments.

We also examined the core of the bright spots by means of scanning electron microscopy/energy-dispersive X-ray spectroscopy (SEM/EDX) after removing encapsulation glass. Fig. 7 contains two SEM images of the bright spots and EDX element map obtained from the core and the outer area of the damages. It is seen in Fig. 7a and b that the center of the bright spots was seriously destroyed and that the total OLED structure was completely molten and agglomerated again. The destroyed core was analyzed by EDX at the X-ray energy of 5 kV. The solid line spectrum is from the outer area of the center, and the filled spectrum is from the center. It is quite interesting that the element map showed similar intensities of the elements consisting of OLED. This result gives important information that such damages were not induced by external particle contamination but by existing elements in OLED. Also, these damages were not observable in an as-made device, and they were all generated during the *I–V–L* measurement. This means again that materials inside OLED like conductive metallic particles must have generated such damages, and it supports the presence of metallic current paths.

Interestingly, the leakage currents in Fig. 3 shows a decreasing trend as the process pressure increases. To understand this result, energy transfer onto the substrate from all the energetic particles generated in magnetron sputtering should be taken into account. In sputtering processes, various kinds of energetic particles are generated simultaneously from the sputtering cathode and bulk plasma, for example, ions, secondary electrons, sputtered target atoms, neutrals and also radiation particles [21–22]. The energy and the production of each particle depend on the kind of discharge gas, target material, process parameters, and power source. Such complications made the identification of dominant damage sources quite difficult and prevented the understanding of the exact damage mechanisms up to now. So we attempt to investigate the generation mechanisms referring to other researches. The highly energetic atomic particles include recoiled Ar neutrals, ions and sputtered particles. Among them, the recoiled neutrals can be either generated or not depending on the masses of incident ion and target material. Sputtering mechanism is based on atomic momentum transfer between incident and target atoms. In case of Al sputtering with Ar gas, the mass of Ar (39.95) is heavier than that of Al (26.98) so that a perfect energy transfer is accomplished. The fraction of energy lost by the incident particle is obtained as [23]

$$\zeta_L = \frac{E_t}{E_i} = \frac{\frac{1}{2} m_t v_t^2}{\frac{1}{2} m_i v_i^2} = \frac{4 m_i m_t}{(m_i + m_t)^2} \cos^2 \theta \qquad (1)$$

where E_t and E_i are respectively the kinetic energy of target and incident particles, m_t and m_i are the mass of target and incident particles, v_t and v_i are the velocity of target and incident particles. θ is the incident angle, and is assumed to be 90° in plasma sheath. If the mass relation of Ar and Al is applied in Eq. (1), ζ_L is derived as 0.962 which states an almost perfect energy transfer from the incident Ar to the Al target atoms. It means that no Ar neutrals are generated theoretically and that the energy term of Ar neutrals is neglected. Accordingly, energy variations of other components and their energy transfer are taken into account.The total energy generated from magnetron sputtering was estimated by Ekpe as

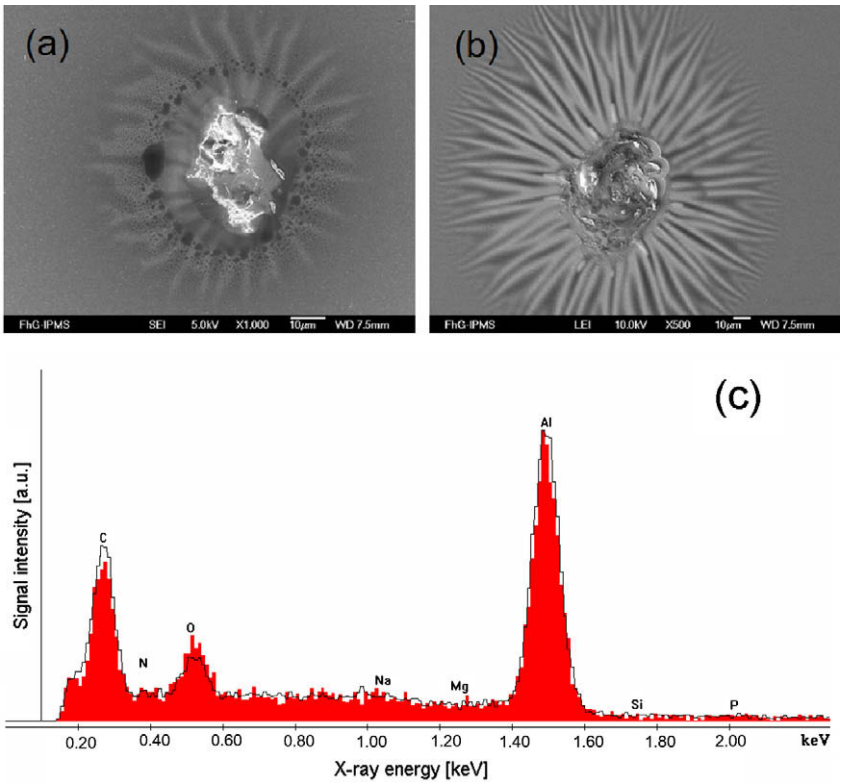

Fig. 7. SEM images of bright spots after *I–V–L* measurement and EDX element map from the core and the vicinity: (a) and (b) destroyed OLED structures through melting and agglomeration. EDX element map in Fig. 6c shows two spectra obtained from the degradation core (filled) and outer the degradation (solid line), non-destroyed region. Two spectra exhibit almost identical signal intensities throughout the elements consisting of OLED.

$$E_{\text{total}} = U + E_k + E_0\frac{R_E}{Y} + E_p + E_e + E_t \tag{2}$$

where U and E_k represent the heat of condensation and the average kinetic energy of the deposited atoms, respectively [24]. The third term represents the contribution of the reflected gas neutrals determined per sputtered atoms in terms of the yield Y. As discussed already, this term is eliminated. E_p represents the contribution of photonic radiation generated from excited atoms within plasma. E_e and E_t are the contributions of electron and thermal radiation, respectively. In this equation, however, the contribution of ions from plasma bulk onto the substrate is absent, and it should be added. Therefore, Eq. (2) is modified into

$$E_{\text{total}} = U + E_k + E_p + E_e + E_t + E_i \tag{3}$$

It is then essential to know which energy terms or elements in Eq. (3) vary with respect to process pressure. Firstly, the kinetic energy of the sputtered atoms and its changes on the process pressure is discussed. The energy and direction of the sputtered target atoms arriving at the substrate is related to the transport process from the target to the substrate. Each energy term in Eq. (3) is significantly affected by process parameters like power and operating pressure. Pressure-dependent deposition rate or film uniformity changes have been described by many researchers [25–27], and the average energy of the sputtered Al atoms was also reported to reach 19.2 eV at process conditions similar to our study. In magnetron sputtering, the transport from the sputter target to the substrate plays a significant role in film deposition and properties. Collisions and mutual energy transfer between sputtered atoms and discharge gases, depending on their energies, masses and densities, are the key factors in determining the transport process. A mean free path is introduced primarily to explain the effect of collision between particles. Since the energetic particles generated collide with the background gas atoms, the energy of the background gases should be taken into account. The mean free path λ_m is then expressed as

$$\lambda_m = \frac{k_B T}{p\sigma} \tag{4}$$

where k_B is the Boltzmann constant, T is the temperature of the sputtering gas. p is the pressure of the sputtering gas, and σ is the collision cross section for momentum transfer [28]. Referred to Eq. (4), the λ_m is decreased reciprocally with an increase of pressure. This effect is due to increase of collision frequency which can lead to a deviation of the direction by scattering and a loss of kinetic energy of the sputtered atoms, so-called thermalization. Therefore, the deposition rate decreases at higher process pressure as indicated in Table 2, and a decrease of the kinetic energy

of the sputtered atoms is thus expected.Secondly, the energy transfers by other energy terms (E_p, E_e and E_t) are discussed. In contrast to the energy of sputtered atoms, their energy transfer is increased at higher process pressure because the process time to deposit film of a same thickness becomes longer and accordingly the surface of organic layer is exposed to the plasma longer. Those plasma components are particles which change internal energy of organic molecules or deposited Al film by ionization and excitation. By continuous irradiation on the surface of organic layers or on the initial thin metal layer previous to a high reflection or screening against such irradiation, other degradation at the interface of metal and organic layer can occur. However, it is believed that they are not the major source to give rise to a high leakage current because their masses are extremely small to deliver a sufficient kinetic energy for a formation of metallic current paths.

When comparing these explanations with the OLED *I–V–L* results in Fig. 3, one can recognize that only the energy variation of the sputtered Al atoms in good agreement with the change of leakage current in OLEDs. Considering their masses and energies, the sputtered Al atoms are supposed to penetrate into the underlying organic layers much deeper than the evaporated Al atoms. Moreover, if energy is transferred further by collision cascades due to continuous atomic bombardments, highly conductive current paths can be formed locally through the organic layers. As a similar phenomenon, it was reported that even evaporated metal atoms deposited at an elevating substrate temperature up to 70 °C were also able to diffuse into a single crystalline organic diindenoperylene (DIP) film [29]. A high electric field can be then induced through the localized paths caused by metal diffusion, and it leads to highly localized currents through the OLED even at a low operation voltage, as shown in Fig. 3. The substrate temperature during deposition was measured on glass substrate by Super mole™ (ECD, Inc.). Highest temperature during Al depositions in the In-line machine was however only 26 °C as shown in Fig. 8, so the thermal energy seems not to play a significant role in producing such highly conductive paths resulted from penetration or diffusion.

By LDI–TOF–MS, we were able to identify the presence of metal particles deep in the organic layer. There are several methods to detect atomic elements in thin films like depth profiling X-ray photoemission spectroscopy (XPS) and depth profiling secondary ion mass spectrometry (SIMS). However, these instruments require an additional ion gun in order to sputter the surface of specimen. This is a quite destructive method, and the bombarded surface element can also penetrate deeper into the underlying film. In case of organic films, the intermolecular bonding is in general held by a weak van der Walls force so that such energetic metal atoms can easier penetrate through organic molecules than inorganic molecules. Therefore, it is difficult to distinguish whether such metal atoms originate from sputtering damage or depth profiling in those instruments. On the other hand, the LDI–TOF–MS can also provide in-depth information by laser-induced desorption. One

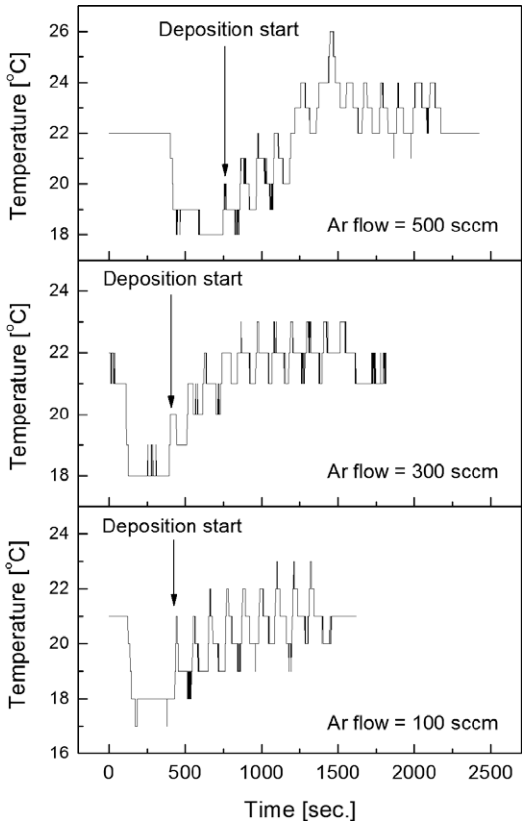

Fig. 8. Temperature variations during Al depositions at different Ar flow rates. The highest temperature is found as 26 °C at the Ar flow rate of 500 sccm which showed the longest deposition time.

important thing is that the laser intensity must be controlled at a threshold level to avoid an excess of ionizations and corresponding chemical reactions.

A shallow doping of metal atoms was reported to be beneficial to improve charge injection into the organic layers by a self-doping effect at the metal/organic layer interface [30]. However, if metal atoms exist in a deep area of organic layer, they will provide current paths interconnecting the two electrodes of OLED. The organic material BPhen used for the measurements is reported to produce a complex with Al or Ag metal atom by donor–acceptor interaction. Hence one can recognize the presence of those metal atoms from the detection of metal–organic complexes. Additionally, the quantity of the metal atoms can be compared by the intensity of spectra. Its depth resolution is unknown, but the deposited 10 nm think Al layer of the sample H and I is certainly transparent for the wavelength of the laser. Hence the given condition for the laser irradiation was same, and it enables a relative comparison of the both samples. Nevertheless, the technique is suitable to give quantitative statement about incorporated compounds and reacted molecules, even for metal on organic hetero structures [30].

In Fig. 9, two spectra of the sample H and I are shown. It is clearly seen that the sample H contains much more Al adduct ions, $[BPhen + Al]^+$ at $m/z = 359$ amu and [2BPhe-

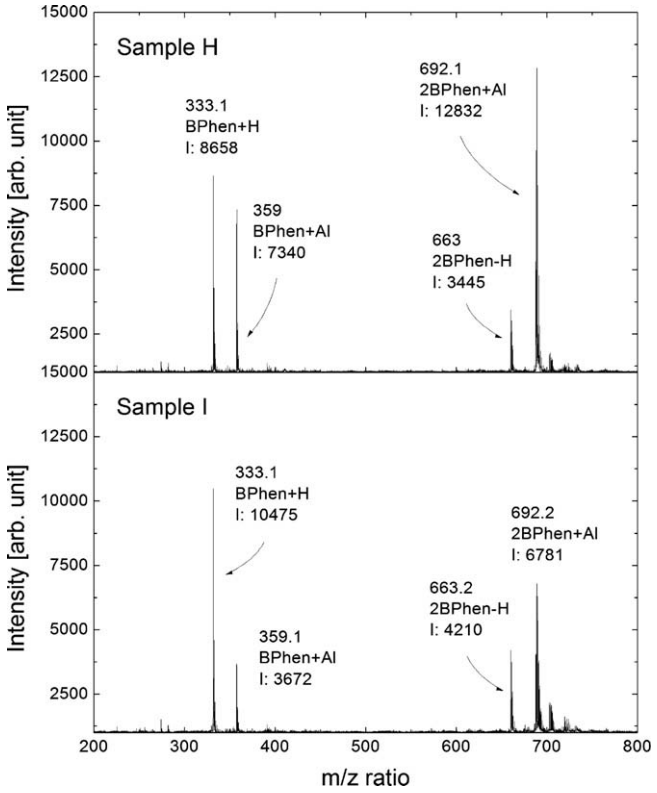

Fig. 9. LDI–TOF–MS results of sample H and I. The sample H shows much higher intensities of BPhen + Al and 2BPhen + Al complexes than the sample I, representing the existence of Al atoms inside of the BPhen layer.

n + Al]$^+$ at m/z = 692.1 amu, than the sample I. The ratios of the spectrum intensities from the existing molecules are tabulated in Table 3. This result gives a decisive evidence to clarify that more metal atoms existed inside the BPhen layer of the sample H than the sample I, supporting the penetration effect of Al atoms due to continuous bombardment effect with high-energy. Therefore, we can conclude that the penetrated Al atoms resulted in high leakage current flowing through the organic layers.

3.2. Radiation effects in OLED

The forward *I–V* in the linear scale and *L–V* characteristics of the OLEDs are plotted again and shown in Fig. 10a and b. The reference OLED exhibits a high forward current density of 100 mA/cm^2 at 4 V. On the other hand, the forward current density of the OLED from the sample A–C decreases with increasing process pressure. The forward current in OLED is the summation of hole and electron currents. The decrease of the forward current reflects a poor charge carrier injection, especially electrons from the Al cathode. It is probably due to generation of different electronics states or charge traps at the top metal/organic layer interface generated by the irradiation from plasma. Several mechanisms can be introduced to explain the degradation of interface property due to plasma radiation. Electrons fall onto a substrate faster than ions when the substrate is immersed in the plasma. The electrons can be accumulated on the surface making the interface of metal/organic layer negatively charged. Such localization of electrons can possibly modify electronic structure of organic molecules [31]. The photons with energies higher than the band gap of organic material can excite bound electrons to LUMO or higher states, generating electron–hole pairs (EHPs) [32]. When the organic molecules are excited, they may dissipate the excess energy by emitting photons as it returns to a lower energy level and eventually to the ground state. The energy can also be emitted irradiatively forming fragmented and reactive species by the opening of a bond structure and the detachment of hydrogen or an organic ligand. It is because the photon energy in plasma ranges much exceeding the binding energy of carbon–carbon covalent bonds or carbon–hydrogen bonds of organic molecules, and such unbound sites are then able to act as charge trapping sites which hinder the injection of charge carriers from the electrode.

Table 3
Calculated ratios from the spectrum intensities of the sample H and I.

Molecules for comparison	Sample H (Ar = 100 sccm)	Sample I (Ar = 500 sccm)
BPhen/BPhen-Dimer	2.51	2.488
BPhen + Al/2BPhen + Al	0.57	0.54
BPhen/Al + BPhen	1.18	2.85
BPhen-Dimer/2Bphen + Al	0.268	0.62

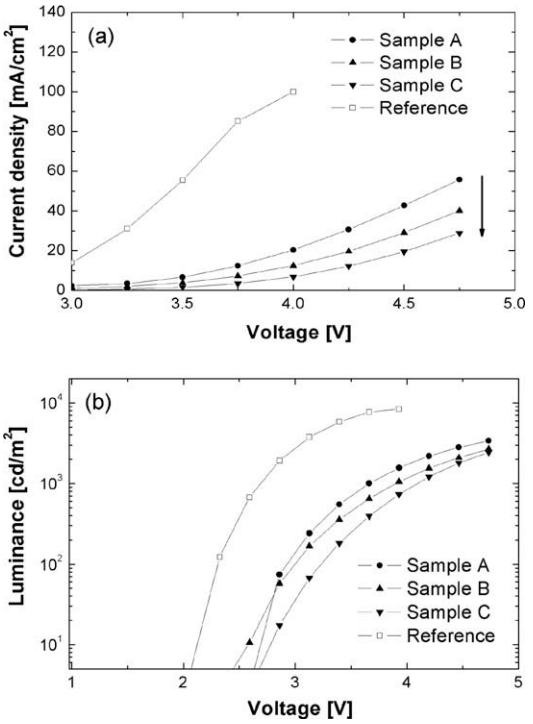

Fig. 10. Rescaled *I–V* and *L–V* characteristics of the OLEDs. The forward current and corresponding luminance decrease as the irradiative energy increases, resulted from the decrease of the deposition rate.

The generation of such degradations can be related with a total radiation energy, which is estimated as a product of radiation flux from plasma and exposure time of the organic layers. As discussed briefly in former section, the total radiation energy comprising E_p, E_e, E_t and E_i in Eq. (3) becomes larger at higher process pressure because the process time to deposit 100 nm thick Al layer in the sample C was roughly two times longer than A. Corresponding effect is clearly seen in Fig. 10a that the forward current of the sample C decreased from 57 mA/cm^2 at 4.75 V to 30 mA/cm^2 of the sample A, which is well matched with the increase of the process time. Therefore, the decrease of the forward current can be ascribed surely to the radiation out of plasma. It should be mentioned one more that this radiation effect should be separated from that of the leakage current, because the tendency of the both effects with respect to the variation of the process pressure was obviously opposite. The luminance of the OLED is undoubtedly decreased, and this yielded also a shift of driving voltage from 2.7 V of the reference OLED to almost 4 V of the other OLEDs for 1000 cd/m^2.

4. Conclusions

We demonstrated OLEDs having Al top electrode deposited by a conventional magnetron sputtering system. The Al sputtering deposition on organic layers resulted in high leakage current and lower forward current in the OLEDs fabricated. The OLEDs possessing high leakage current showed many bright spots on active area, which are thought as the result from the leakage current. The optical constants of the organic layers obtained from ellipsometry showed no changes in the optical gap of the organic layers. This means that the organic layer was not damaged seriously after Al sputter deposition and that other sources might have caused the high leakage currents. Based on the operating principle of magnetron sputtering, we concluded that the high kinetic energy of sputtered Al atoms was the dominant source responsible for the leakage current, resulting in a metal penetration into the underlying organic layers. In order to prove the metal penetration, we employed LDI–TOF–MS. At the same process parameter that OLED showed highest leakage current, the obvious existence of Al atoms deeper inside the organic layer was identified as a form of metal–organic complex. It assured that the high leakage current was caused by conductive metallic paths provided by penetrated Al metal particles into organic layer.

The effect of plasma radiation on the metal/organic layer interface was also examined. The forward current density showed a decreasing trend, as the process time became longer. This result was explained well with the increase of the radiation energy that influences the generation of the interface degradation.

We note that if the process pressure is increased further in order to reduce the leakage current in OLED, the interface will be degraded more, which leads to a higher operating voltage. Therefore, the two damages caused by magnetron sputtering are in a trade-off relation, and a thick buffer layer or modified organic layers based on *p–i–n* OLED would be helpful to obtain comparable leakage current, efficiency and lifetime with OLED having evaporated metal electrode.

Self-interaction correction

ABSTRACT

A C_{60} molecule sandwiched between two Au(1 1 1) based tips is used as a model system to analyze the formation of nanogap molecular junctions including charging effects and self-interaction corrections. In our approach, we combine a DFT-LDA calculation of the structural and electronic properties of the system with an analysis of the interface barrier formation based on the charge transfer and the organic Charge Neutrality Level, as described by the Induced Density of Interface States model. This allows us to determine, as a function of the tip/C_{60} distance, the self-interaction correction to the frontier molecular orbitals levels, the transport energy gap and the metal/organic barrier height. Our approach offers a fully consistent technique for analyzing a metal/organic interface at the molecular level.

1. Introduction

One of the most ambitious objectives in Nanoscience is to build electronic devices using individual molecules. In order to achieve this goal, a lot of work has been addressed to investigate the nanocontact between metal electrodes and a single molecule [1–14]. For example, mechanically controllable break junctions or scanning tunneling microscope tips have been used to deposit inorganic and organic molecules [15–17] between two metals, forming in this way a typical quantum dot (QD) as a possible component of a molecular electronic device.

From a fundamental point of view, the energy levels of the frontier orbitals of the molecule relative to the interface Fermi energy determine the electronic, transport and optical properties of the system [18]. Those levels depend on the detailed atomic geometry of the nanocontact, but also depend sensitively on self-interaction corrections, polarization effects and the charging energy of the molecule [19–21] and therefore cannot be determined accurately using standard density functional theory (DFT) calculations [22]. Thus, there is a critical need for the development of practical procedures to properly include those effects in a simulation of a realistic molecule/metal nanocontact.

In the last few years, a lot of experimental and theoretical work has been done to explain the mechanism responsible of the barrier height formation (and interface electrostatic dipole) between a metal and an organic monolayer. Chemical reactions [23–27], induced "pillow" (or Pauli exclusion) dipole [26,28,29], or intrinsic molecular dipoles [26,28–30] have been proposed as the main mechanisms operating at the metal organic (MO) interface. The Unified Induced Density of Interface States (IDIS)-model [30,31] combines the "pillow" and the intrinsic molecular dipoles with the charge transfer between the materials forming the interface to explain the barrier formation. Although in these studies typically a full monolayer of the organic material is assumed to be deposited on the metal, one can expect that a similar mechanism should be operative at the molecular level.

The C_{60} molecule has been widely studied deposited on metals [21] or forming interfaces [33,34] and it has been encapsulated as a film between two metal electrodes as part of a solar cell [35]. Some work has also been addressed to understanding the QD formed by an isolated C_{60}–molecule located between two metallic tips [12–14], but in these references those many-body corrections have been neglected.

In this paper we analyze theoretically a C_{60} sandwiched between two Au(1 1 1) based tips, as a model system for understanding the nanocontact between a metal and an organic molecule, including the many-body corrections mentioned above. We study the fully relaxed nanocontact with variable tip/tip distance, combining a DFT calculation in the local density approximation (LDA) of its geometrical and electronic properties with the induced interface potential associated with the charge transfer as described by the IDIS-model. In particular, we show how the barrier formation at the molecular level can be related to the effective intrasite charging energy of the molecule, this quantity allowing us to obtain the transport energy gap of the molecule, and the frontier molecular orbital levels, as a function of the tip–molecule distance [19,32]. In a further step, we combine the calculation of the effective on-site coulomb repulsion with a "scissor" hamiltonian [19,36] to determine selfconsistently the transport energy gap for each tip/C_{60}/tip geometry. Finally, we make contact with other theoretical and experimental approaches by analyzing the case of a single C_{60} molecule on a Au-surface.

2. Model and mechanical study

In our DFT simulations, the Au-tips consist of pyramidal-shape clusters of 46 Au atoms in a (1 1 1) geometry, with 3, 6, 10 and 27 atoms in the first, second, third and last layer respectively [38] (see Fig. 1). The Au/C_{60} interface is analyzed using the FIREBALL code [37], with a LDA-exchange correlation functional and a basis set of short-range numerical atomic-like orbitals (NAOs); the carbon atoms are described in terms of an optimized sp^3 NAOs basis [40] with cut-off radii (in a.u.): 4.5 (s), 4.5 (p), while for the Au atoms we use a sp^3d^5 basis defined with the following cut-off radii (in a.u.): 4.6 (s), 5.2 (p) and 4.1 (d) [36]. This DFT-LDA technique has been slightly modified by shifting the metal energy levels in order to have an appropriate MO level alignment before the contact is established [30,36]: in this paper we have taken initially the Au work-function 0.3 eV above the gas-phase C_{60}-midgap [34]. In addition to this shift, we have also introduced in the molecule a "scissor" operator to calculate the molecule energy gap selfconsistently (see below). The contact formation is analyzed by approaching each Au-tip in steps of 0.1 Å; after each step the atoms are relaxed to their corresponding minimum energy positions, excepting the atoms in the last Au-layer of both tips, which are fixed. The electrical conductance of the system is calculated at each step of the deformation using a Keldish–Green's function approach [41,42], together with the first-principles hamiltonian obtained after the relaxation.

Fig. 1 shows the calculated geometry of the tip/C_{60}/tip contact as a function of the distance, d, measured between the fixed Au-layers of both tips. Initially (Fig. 1A), C_{60} is attracted by the tips, its diameter increasing along the tip–tip direction (see Fig. 2b). The buckyball suffers, however, a slight rotation (Fig. 1B) in the attractive region between distances d = 23.7 and 26.4 Å, where the molecule jumps between different minima in such a way that the force cannot be calculated as the derivative of the energy (in Fig. 2a this is represented by a dashed line for the force which is only a guide to the eye, calculated smoothing the energy curve). When the force is $\sim$0, the C_{60} returns to its original orientation, and after that, the molecule starts to be compressed (Fig. 1C), shortening its diameter along the tip–tip direction. Eventually, the tips starts to break (Fig. 1D). Notice also that the maximum attractive energy for one interface is 2.2 eV, and that the maximum attractive force is (probably) in the order of 3.8 nN; as expected, this force is around twice the one calculated for a tip/nanotube contact of the same diameter [38]. Van der Waals forces are found to be small (less than 0.5 nN) and are not discussed here (see [38]).

The conductance at the Fermi level of the tip/C_{60}/tip contact (Fig. 2b) shows a maximum of $1.8G_0$ ($G_0 = 2e^2/h$) in the compressive region, while it is $\sim 0.8G_0$ for the equilibrium position. For long distances, $d > 25.7$ Å, 3 channels contribute equally to the conductance, as corresponds to the three orbitals of the lowest unoccupied molecular orbital (LUMO) level while, due to the symmetry breaking of LUMO level, only two channels contribute at short distances. At intermediate distances only one channel dominates the conductance due to the rotation of the molecule.

3. Electronic analysis: unified IDIS-model and self-interaction correction

Fig. 3 shows the density of states projected on the C_{60} orbitals for the cases A, B and C of Fig. 1. For each case, the LUMO and highest occupied molecular orbital (HOMO) levels, the molecule Charge Neutrality Level (CNL), the Fermi energy E_F (zero energy) and the metal (effective) work-function, Φ_M ($\widetilde{\Phi}_M$, see below), are shown. The CNL is calculated integrating the C_{60}-DOS up to charge neutrality conditions; as in a typical MO interface [30], the tip/C_{60}/tip contact reacts creating a mean potential, V^t, between the tips and the molecule that tries to align the organic CNL and the metal work-function: notice that Φ_M and E_F define respectively the initial and final metal Fermi energy with respect to the molecular levels.

In case A for which the "pillow" potential (associated with the compression of the metal electron tails at the MO interfaces due to the Pauli repulsion [30]) is negligible, that potential is created by the charge transfer between the two materials and, following the IDIS-description of MO interfaces [43], it can be identified with V^{IDIS} ($V^t = V^{IDIS}$, case A) such that:

$$eV^{IDIS} = (1 - S)(CNL - \Phi_M); \tag{1}$$

S being the interface screening parameter [30]. Notice also that:

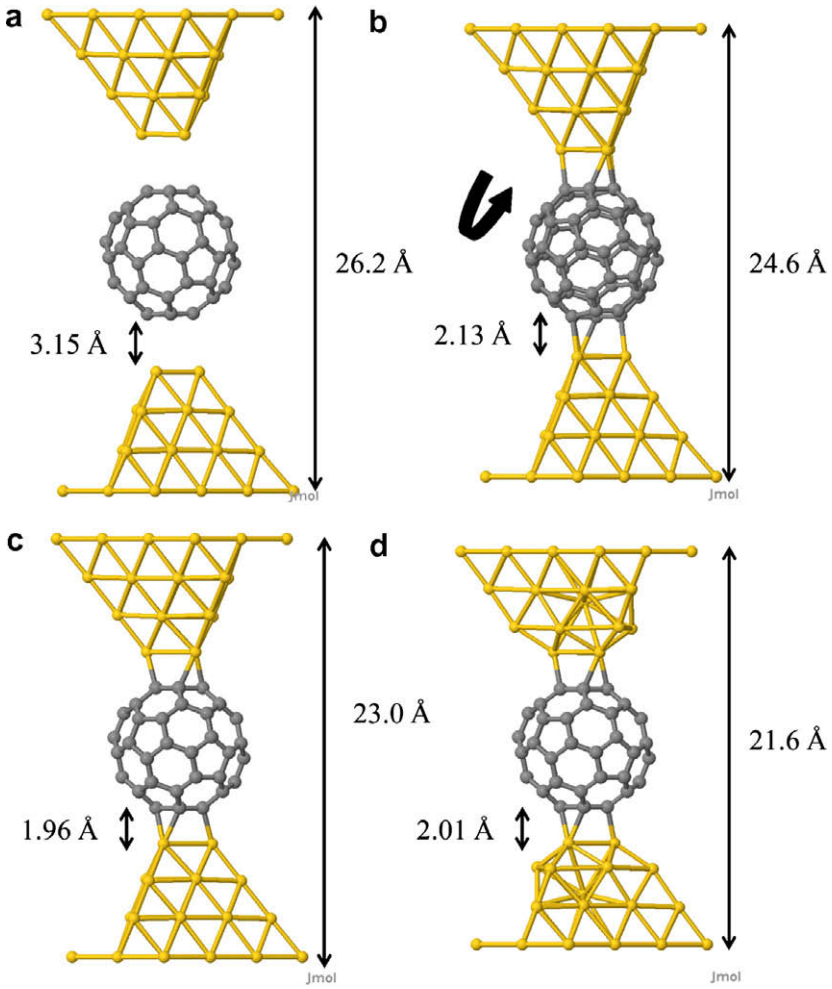

Fig. 1. (color online). Geometry of the tip/C_{60}/tip system for different values of the distance d between the fixed Au-layers. The arrow in case B suggests how the molecule rotates. (images created with Jmol [39]).

$$(CNL - E_F) = S(CNL - \Phi_M); \tag{2}$$

this equation describing how that parameter "screens" $(CNL - \Phi_M)$ to $(CNL - E_F)$.

In Fig. 3a, $CNL - \Phi_M$ = 1.1 eV and eV^{IDIS} = 0.34 eV, so that S = 0.7. We have checked, by changing in our code Φ_M fictitiously, that S is practically independent from moderate changes of the work-function value. In these calculations, the transport energy gap (the HOMO–LUMO energy difference) has been fitted to 3.6 eV (see below) moving in an opposite way the filled and empty states using a "scissor" operator, described in Ref. [36]: we stress that in $H^{scissor} = \sum_{\mu=occ.} - \Delta|\mu\rangle\langle\mu| + \sum_{\nu=empty}\Delta|\nu\rangle\langle\nu|$, $|\mu\rangle$ and $|\nu\rangle$ are the molecular orbitals of the non-interacting molecule with the deformed geometry of Fig. 1. As shown in Fig. 3a, the effect of the metal/C_{60} interaction is to broaden the HOMO and LUMO levels, in addition to the creation of V^{IDIS}: the effect of this induced potential is to shift rigidly the HOMO and LUMO levels, as well as the CNL, with respect to the metal Fermi energy. This suggests to calculate the charging energy of the molecule (the effective on-site coulomb interaction, U^{eff}) by dividing eV^{IDIS}, by the number of electrons transferred to the molecule (δn):

$$U^{eff} = \frac{eV^{IDIS}}{\delta n} = \frac{(1-S)(CNL - \Phi_M)}{\delta n} \tag{3}$$

a similar equation for the LUMO and HOMO levels has also been reported by Sau et al. [22]. Considering that $\delta n = (CNL - E_F)\widetilde{D}$, $\widetilde{D}$ being the mean density of states between the Fermi level and the CNL in the organic molecule, one can easily find that:

$$S = \frac{1}{1 + U^{eff}\widetilde{D}}; \tag{4}$$

in this equation $U^{eff}\widetilde{D}$ plays the same role that the term $4\pi e^2 D(E_F)\delta/A$ does in the elementary theory of Schottky-barriers [30,44].In our calculations, δn has been calculated using Löwdin population analysis [37] of C_{60} and Au orbitals and the CNL has been obtained by integrating the molecule DOS up to charge neutrality condition.

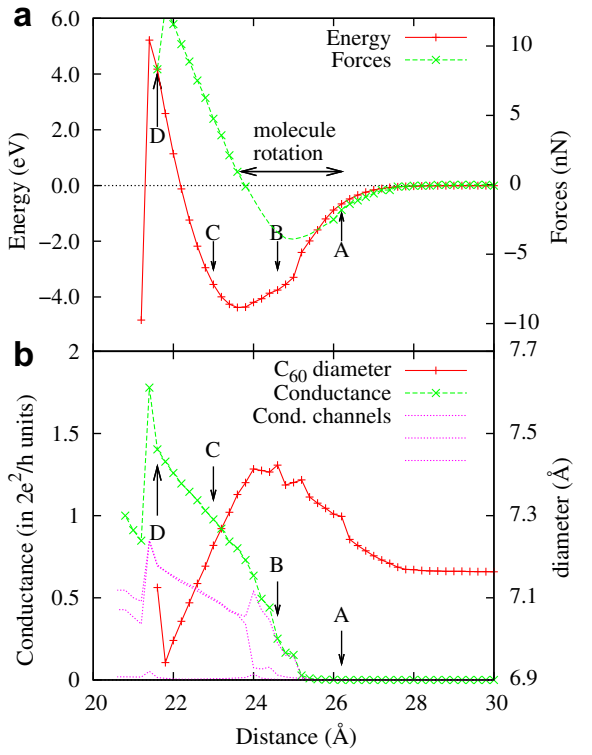

Fig. 2. (color online) (a) Energy, forces and (b) conductance at the Fermi level and the diameter of C_{60} along the contact direction, for the system shown in Fig. 1 as a function of the distance *d*.

Let us now discuss how to calculate selfconsistently the C_{60}–molecule transport energy gap. The first point to realize is that for an isolated molecule, the appropriate transport energy gap is given by the (underestimated) Kohn–Sham gap plus the self-interaction correction [19]:

$$E^t_{mol} = E^{KS}_{mol} + E^{SI}_{mol} \text{ (isolated molecule)}; \quad (5)$$

where E^{SI}_{mol} can be viewed as due to the self-interaction energy associated with the orbital charge distribution for either the HOMO or the LUMO levels [19], which we have found, for C_{60}, to be very similar. This suggests that, for a very weak MO interaction (where image potential effects are negligible), the self-interaction correction for the metal charge tunneling into the organic gap should also be the same E^{SI}_{mol}

On the other hand, image potential effects at the MO-interface induce on the metal side an opposite charge to the one appearing in the molecule, and reduce E^t_{mol} compensating partially for the self-interaction correction. Both effects taken together can be added to yield an effective charging energy that we identify with U^{eff}, as given by Eq. (3), since in this equation we include in V^{IDIS} both the self-interaction energy of the extra charge and its interaction with the opposite charge induced in the electrodes. This allows us to write for the MO-interface:

$$E^t_{mol} = E^{KS}_{mol} + U^{eff} \quad (6)$$

with U^{eff} given by Eq. (3) [22].

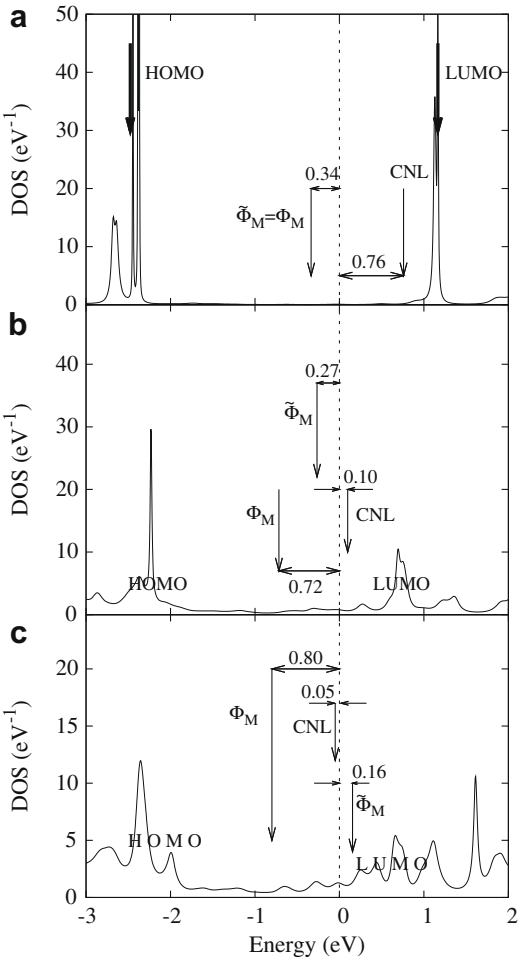

Fig. 3. (a–c) DOS (per spin) as a function of energy for geometries (A–C) in Fig. 1. Each case shows: HOMO, LUMO levels and Fermi energy (E_F, origin of energies), as well as the CNL and the (effective) work-function, ($\tilde{\Phi}_M$) Φ_M.

Then, in our calculations we determine U^{eff} and E^t_{mol} selfconsistently, using the "scissor" operator mentioned above.

1. In a first step, we define an "input" E^t_{mol} using $H^{scissor}$. This transport gap is then used in the DFT calculation.
2. From this calculation and Eq. (3) we obtain U^{eff}.
3. Then, using Eq. (6) we calculate an "output" E^t_{mol}; this new transport gap is then used to define a new "input" E^t_{mol} (step 1), defining a selfconsistent cycle.

Regarding the cases shown in Fig. 3b and c, the main difference with case A is due to the "pillow" effect that creates a potential V^{pillow} between the tips and the molecule. Then, the total potential between the two materials, V^t, can be decomposed into the IDIS, V^{IDIS}, and the "pillow", V^{pillow} potentials:

$$V^t = V^{IDIS} + V^{pillow} \quad (7)$$

V^{IDIS} being, as in case A, associated with the misalignment between the CNL and Φ_M (see Eq. (1)).

The "pillow" potential, V^{pillow}, is also the result of screening the bare one V_0^{pillow}, $V^{pillow} = SV_0^{pillow}$ [30], in the same way as $(CNL - \Phi_M)$ is screened to $S(CNL - \Phi_M) = (CNL - E_F)$. Then Eq. (7) can be rewritten as follows:

$$\begin{aligned} eV^t &= (1-S)(CNL - \Phi_M) + SeV_0^{pillow} \\ &= (1-S)(CNL - \tilde{\Phi}_M) + eV_0^{pillow} \end{aligned} \quad (8)$$

this equation shows that eV^t has a bare component, eV_0^{pillow}, independent from the interface screening, and another one, $(1-S)(CNL - \tilde{\Phi}_M)$, associated with the charge transfer between the tips and the molecule. In this component, there appears an effective metal work-function: $\tilde{\Phi}_M = \Phi_M + eV_0^{pillow}$, such that $(CNL - \tilde{\Phi}_M)$ is related to the total charge transfer between the tips and the molecule. In this way of thinking, the "Pauli exclusion" potential, V_0^{pillow}, is fully incorporated in the effective work-function $\tilde{\Phi}_M$; notice, in this regards, that the bare potential, eV_0^{pillow} in Eq. (8) also shifts the metal work-function from Φ_M to $\tilde{\Phi}_M = \Phi_M + eV_0^{pillow}$.

Fig. 3b and c shows both Φ_M and $\tilde{\Phi}_M$: the corresponding values of eV_0^{pillow} are 0.45 eV and 0.96 eV respectively. In addition to this new effect appearing in cases b and c, we also find an important broadening of the HOMO and LUMO levels that cannot be so sharply defined as in case A. This is the reason why it is necessary, in our procedure, to consider the relative shift of the metal Fermi level with respect to the CNL, instead of the metal Fermi level and either the LUMO or the HOMO levels, to define the charge transfer induced potential and calculate U^{eff}.

In our calculations for cases B and C, the initial values of $(CNL - \tilde{\Phi}_M)$ [0.37 eV (B); −0.21 eV (C)] are reduced to $(CNL - E_F) = S(CNL - \tilde{\Phi}_M)$ [0.10 eV (B); −0.05 eV (C)], yielding the following values of S: 0.26 (B) and 0.24 (C), indicating that in these two cases, for small tip–C_{60} distances the interface screening is much more effective than in case A, saturating around the energy minimum. Moreover our selfconsistent calculations yield the following values of U^{eff}: 1.6 eV (B) and 1.3 eV (C), and the following transport energy gaps: 3.2 eV (B) and 2.9 eV (C), as can be approximately appreciated from the strongly broadened HOMO and LUMO levels of those figures.

We have also calculated the case of C_{60} on a Au(1 1 1)-surface as shown in the inset of Fig. 4 in order to compare our model with other theoretical and experimental results. The DOS projected on the C_{60}–molecule for this case yields the following results: $CNL - E_F = 0.10$ eV; $E_F - \Phi_M = 0.72$ eV; and $S = 0.35$, not far from the values found for cases B and C above; we also find $U^{eff} = 1.6$ eV. Notice that in our calculations, the HOMO–LUMO gap as estimated from the calculated DOS is around 3.2 eV, slightly larger than the one measured by Lu et al. [21] using STS: 2.7 eV with an error bar of 0.3 eV, this might be due to the screening effects associated with the STS tip. It is interesting to mention that calculations of Sau et al. [22] using a GW-like approach yield $E_{gap}^{trans} = 2.5$ eV, a little too small. On the balance, we believe that the comparison with the experimental data offers a reasonable confirmation of the validity of the calculations presented here.

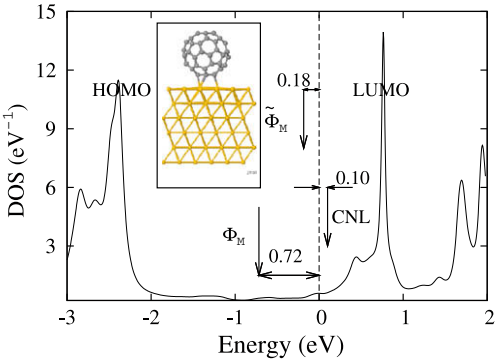

Fig. 4. (color online). DOS (per spin) as a function of energy for a single C_{60} molecule adsorbed on Au(1 1 1)-surface. Shows HOMO and LUMO levels, Fermi energy (energy origin) and (effective) metal work-function. Inset: geometry of the interface.

4. Conclusion

In conclusion, a new method is introduced to analyze the formation of a nanogap organic molecular junction, including charging effects and self-interaction corrections. In our approach, we combine a DFT-LDA calculation of the structural and electronic properties of the nanocontact with an analysis of the interface charge transfer and metal/organic molecule barrier height formation, as described by the IDIS-model. In this way, we obtain the on-site coulomb interaction, U^{eff}, associated with the injection of an electron in the molecule and calculate selfconsistently its frontier molecular orbital levels and the transport energy gap. We have illustrated this new approach, by analyzing a C_{60} molecule between two Au(1 1 1) based tips as a function of the tip–molecule distance. Our approach offers a practical fully selfconsistent technique for studying realistic single molecule nanocontacts.

Self-assembled monolayers
Low contact resistance

ABSTRACT

This paper reports the fabrication of organic thin film transistors (OTFTs) with conducting poly(3,4-ethylenedioxythiophene) (PEDOT) electrodes using a bottom-up process consisting of the selective growth of PEDOT on a pre-patterned (3-aminopropyl)trimethoxysilane (APS) monolayer. The newly developed bottom-up process produced strongly adherent, selectively and uniformly patterned PEDOT films on oxidized substrates. In addition, the PEDOT/APS double structure showed an approximately one order of magnitude lower leakage current and contact resistance than the Au/Ti electrodes. The lower leakage current was due to the additional blocking effects by APS monolayer in the PEDOT/APS structure; the lower contact resistance was attributed to the better quality of pentacene films formed on PEDOT electrodes than that of the gold electrodes.

1. Introduction

Organic thin film transistors (OTFTs) have attracted considerable attention for their potential applications to low cost and low temperature fabrication of flexible devices [1–5]. Significant improvement in the performance of organic semiconductor materials, especially pentacene, has been reported [6–11]. In addition, the recent development of highly conducting π-conjugated polymers provided the possible replacement of gold electrodes, which has further reduced the material and processing cost. Conducting polymer electrodes provide a low contact resistance to semiconducting polymers due partly to the lower barrier height for hole injection, and the negligible interface morphological discontinuity at the organic–organic interface [12–14]. Among these polymers, poly(3,4-ethylenedioxythiophene) (PEDOT) has attracted particular attention as a potential electrode of OTFT and organic light emitting diodes (OLED) on account of its low band gap (1.5–1.7 eV), as well as its excellent electrochemical stability and transmittance in the visible range [15–19]. To date, a variety of methods, such as polymer dispersion with a water soluble polyelectrolyte [20], electropolymerization [21] and direct oxidative polymerization [22], have been used to produce PEDOT thin films. However, there are no reports of the production of pure thin films. Recently, Winther-Jensen and West and Kim et al. [23,24], reported that 3,4-ethylenedioxythiopene (EDOT), a monomer of PEDOT, can be vaporized simply by increasing the temperature, and these molecules can be polymerized rapidly on an oxidizing agent (for example, $FeCl_3$) – coated substrate, thereby producing pure films. However,

in order to implement a vapor phase-polymerized PEDOT film in conventional TFTs, several issues, such as the poor adhesion of PEDOT films to the oxide substrate [25] and the lack of a scalable, simple, and inexpensive patterning method, needs to be addressed.

We previously reported [25,26] a method to pattern PEDOT thin films by the selective growth of PEDOT on a pre-patterned APS monolayer, which had been self-assembled on OTS monolayers microcontact-printed on an oxidized silicon wafer. This bottom-up process can produce a strongly adhered, selectively patterned PEDOT thin film on an oxidized Si wafer surface through the chemical bonds between the polymer and APS monolayer [26]. The strong tendency of the lone pair electrons on the N–H groups of APS monolayer to bind Fe (III) leads to a uniform distribution of ferric chloride on the APS monolayer, and can provide excellent selectivity in the presence of an OTS monolayer [25,26]. Therefore, this simple, scalable and inexpensive PEDOT patterning method was used to fabricate PEDOT bottom contact (BC) pentacene TFTs. The electrical performance of the OTFTs was also investigated. In addition, the Au BC OTFTs were fabricated and compared. Furthermore, the degree of crystallinity of pentacene thin films deposited on PEDOT electrodes as well as on gold electrodes was examined by using XRR to find out the dependence of crystallinity of pentacene on substrate materials and its effects on contact resistances.

2. Experimental

The thermally grown SiO_2 (100 nm) coated n^+-Si substrates (resistivity < 0.005 Ω cm) were cleaned using the Piranha cleaning method (H_2SO_4:H_2O_2 = 4:1), and then exposed to UV illumination to create hydroxyl (–OH) groups that can form a siloxane bond with the OTS monolayer [27]. A polydimethylsiloxane (PDMS) stamp was then used for microcontact printing to transfer the OTS SAM patterns to the SiO_2 surface, leaving a hydrophobic stamped area. The OTS coated area showed a typical water contact angle of approximately 109°. After OTS patterning, a negative pattern was formed with APS monolayers by dipping it into a silane solution (0.1 mM APS + 1 μM acetic acid in 50 ml ethyl alcohol) for 30 min. After rinsing with ethyl alcohol followed by drying with blowing N_2, a 3 wt.% $FeCl_3$ solution was spread over the monolayer surface and spun at 2500 rpm using a spin coater for 90 s. The $FeCl_3$-coated sample was placed on the top sample holder with the surface facing down in a hot wall oven. EDOT was then placed in a container. The EDOT was vaporized for 3 min at 80 °C to selectively form PEDOT films on the pre-patterned APS monolayer. The sample was rinsed with methanol, and dried in a desiccator before depositing the pentacene semiconductor layer. A 70 nm-thick pentacene layer was thermally evaporated in a vacuum of 7×10^{-6} Torr at a substrate temperature of 60 °C. The deposition rate was approximately 1 Å/s. Fig. 1 shows the fabrication sequence for the bottom contact pentacene TFTs formed on the n^+-Si substrate.

The transmission line model (TLM) patterns were used to characterize the bottom contact resistance of the PEDOT BC pentacene TFTs. The width of the TLM patterns measured from the optical images was 51 μm and the length was varied; 8, 14, 25, 46, and 84 μm. The polymer thickness and sheet resistance was measured using an ellipsometer (Sentech SE-800) and a four point probe (Chang Min Co., Ltd, Korea). The static water contact angles were measured with a goniometer (Phoenix 300, Surface Electro Optics Co. Ltd, Korea) and recorded with a CCD camera. Atomic force microscopy, AFM (SPA 400 Seiko, Japan; trapping mode, scan speed: 0.5–0.6 Hz, scan size: 10×10 μm^2) was used to measure the surface morphology. X-ray reflectivity (XRR) measurement was done at 5A HFXS beamline of Pohang Light Source with the X-ray energy of 11.6 keV in order to get information about the structures of pentacene thin films deposited on PEDOT or gold electrodes. These structures were compared with that of pentacene on OTS monolayer. Finally, a semiconductor parameter analyzer (HP4155C) was used to determine the electrical properties.

3. Results and discussion

Fig. 2a shows an optical image of a selectively formed PEDOT source and drain electrodes on a SiO_2-coated n^+-Si substrate (gate electrode). The patterned PEDOT electrodes had a defined channel width and length between 70 and 15 μm, respectively. The AFM image in Fig. 2b shows the edge of the PEDOT pattern with a tapered, smooth surface. The thickness and sheet resistance of the PEDOT thin film were 133 nm and 18 Ω/□, respectively.

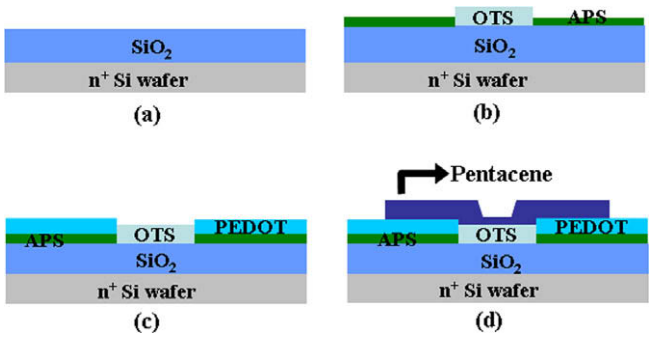

Fig. 1. Schematic diagram showing the fabrication of pentacene OTFTs of (a) dry oxidation of n^+-Si, (b) micro contact printing of OTS and then formation of APS monolayers by dipping it into silane solution, (c) selective vapor deposition of PEDOT and (d) deposition of pentacene.

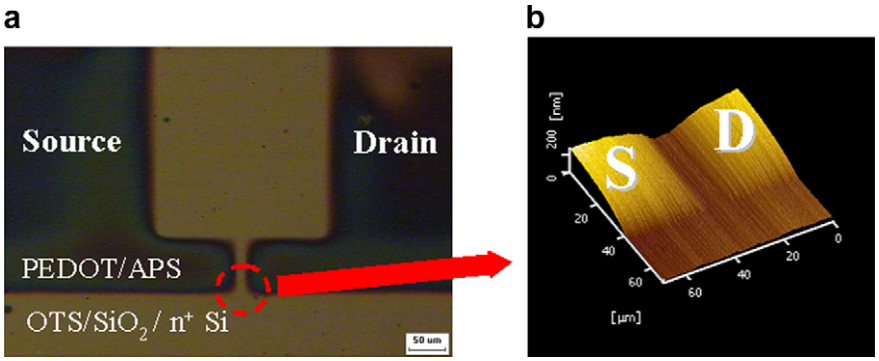

Fig. 2. (a) Optical image of selectively deposited PEDOT on APS patterns, and (b) AFM images of the gap between the source and drain electrodes of PEDOT.

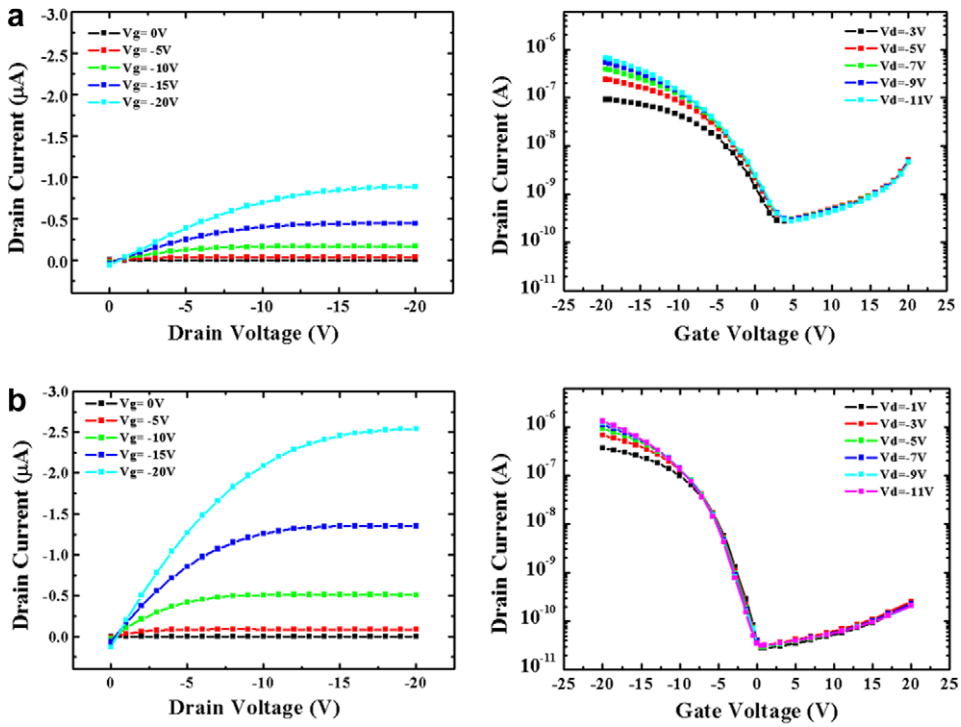

Fig. 3. Electrical characteristics of pentacene-based OTFT with (a) Au/Ti electrodes and (b) with PEDOT electrodes, respectively.

Fig. 3 shows the typical electrical output and transfer characteristics of the BC pentacene TFTs with (a) Au/Ti electrodes and (b) PEDOT electrodes, respectively. The field-effect mobility, on/off current ratio, subthreshold slope and threshold voltage of the gold BC pentacene TFTs with a channel length of 70 μm were 0.1 $cm^2/V\,s$ in the saturation regime ($V_{DS} = -11$ V), 2.4×10^3, 3.6 V/decade and −1.4 V, respectively. On the other hand, the PEDOT BC OTFTs with a channel length of 25 μm showed an improved field-effect mobility, on/off current ratio, subthreshold slope and the threshold voltage of 0.13 $cm^2/V\,s$, 1.2×10^5, 2.04 V/decade, and 0.527 V, respectively, as shown in Fig. 3b. In some OTFTs, for small V_{DS} a large fraction of V_{DS} may be dropped across the contact resistance rather than the intrinsic field-effect transistor, while at larger V_{DS} the fraction of V_{DS} dropped across the contacts may decrease and the contact resistance is less significant. Since small values of V_{DS} are used to extract linear mobility, the measured mobility may be significantly smaller than the measured saturation mobility in the case of high contact resistance. The linear mobility of the PEDOT-electrode and gold-electrode TFTs was calculated to be 0.128 $cm^2/V\,s$ and 0.058 $cm^2/V\,s$, respectively. Significantly smaller linear mobility than the saturation mobility in the gold-electrode OTFT was compared with the similar value of the linear and saturation mobility in the PEDOT-electrode device. Much higher contact resistance of gold-electrode transistor than that of PEDOT-electrode one was responsible for the decreased linear mobility. It was also noted that the significantly increased on/off current ratio for the PED-

OT contact OTFT was attributed to both the decrease in leakage current and increase in on-current. The PEDOT/APS BC OTFTs showed an approximately one order lower leakage current than the Au/Ti BC OTFTs. This was attributed to the presence of an APS monolayer between the PEDOT layer and SiO_2, which acts as an additional blocking layer to effectively reduce the leakage current [28]. The total resistance is the sum of the channel resistance and contact resistance, and the channel resistance for the two types of OTFTs is similar. Therefore, the increased on-current for the PEDOT OTFTs can be understood by comparing the contact resistance between pentacene and the electrodes (both gold and PEDOT).

The contact resistance was evaluated by fabricating TLM patterns using a selectively deposited PEDOT on a microcontact-printed APS monolayer followed by the deposition of a pentacene layer. Gold TLM patterns were fabricated using a lift-off technique for the patterning of gold pads followed by the deposition of a pentacene layer. Fig. 4 shows a plot of the corresponding resistance as a function of the distance between the pads and the voltages applied to the n^+-Si substrate. For the PEDOT TLM patterns, stable electrical *I–V* curves were measured at gate voltage of −20 V, providing contact resistances, R_C, of $1.8 \times 10^6\ \Omega$. The normalized contact resistances, R_C' (=$R_C \times W$, *W*: channel width), was 9.2 k Ω cm, which are similar to those of gold TC pentacene TFTs [29].

For the gold TLM patterns, the electrical *I–V* curve was measured at a gate voltage of −20 V, providing a slope (R_S/*W*) of $4.5 \times 10^5\ \Omega/\mu m$, which is similar to that of the PEDOT TLM structures. This suggests that the channel resistance is similar irrespective of the contact resistance. However, the corresponding contact resistance of the gold TLM was increased to $1.3 \times 10^7\ \Omega$, which is approximately one order of magnitude higher than that of the PEDOT contacts to pentacene. The increased contact resistance can be a main contributor to the decreased on-current and reduced linear mobility. In an OTFT device, the barrier height between semiconductor and electrode, and the crystalline quality of semiconductor on the electrodes are major factors determining the contact resistance. As a result, we have used XRR to determine the quality of pentacene deposited on the electrodes (PEDOT and gold) and then compared with the pentacene on OTS monolayer. We have measured X-ray specular scans of the three samples: pentacene/OTS/Si (POS), pentacene/PEDOT/Si (PPS), and pentacene/Au/Ti/Si (PATS), all of which were deposited at 60 °C. The experiment was performed at 5C2 of the Pohang Light Source (Korea). The X-ray energy was 10 keV. Fig. 5a shows true specular scans in which the background signals from the substrate are removed. True specular scans probe density variation in the normal direction to substrate surface. POS shows the typical pentacene peaks at $q = 0.41\ Å^{-1}$ from the film phase, $0.44\ Å^{-1}$ from the bulk phase and their second order peaks [30], where $q = 4\pi/\lambda \times \sin\theta$, λ is the X-ray wavelength, and θ is the incident angle to the sample surface. PPS shows a very weak and broad diffraction peak near $q = 0.41\ Å^{-1}$, but PATS does not. This difference can be more easily noted in the Patterson function which is simply the Fourier transformation of the true specular scans in normalized form [31]. It can be shown that the peak positions in the Patterson functions indicate the distances between regions where the density is changing rapidly. Fig. 5c shows the resulting Patterson functions and POS shows the typical layer spacing of pentacene 15.3 Å, in good agreement with previous reports. The Patterson function of PPS is different to that of POS, but shows four peaks (marked by the arrows) separated by 11, 14, and 13 Å which would indicate pentacene molecules tilted to the surface normal direction. The Patterson function of PATS, however, only shows the peaks corresponding to the interfaces between pentacene/Au, Au/Ti and Ti/Si; it does not indicate any layered pentacene molecules at all.

Another structural aspect of the films can be found from the off-specular scans by +0.07° and −0.07° from the specular direction as shown in Fig. 5b. These scans probe the average crystallinities of the films. The two peaks for POS are from the film phase and the bulk phase of pentacene as in the true specular scans of Fig. 5a, while PPS shows a weak peak but broad enough to include both of the pentacene phases. PATS also show a peak but the bulk phase peak is significantly suppressed. This suppression would be due to the fact that the pentacene thickness of PATS is much thinner than those of POS and PPS. Usually the film thicknesses would be estimated from the Kiessig fringes in XRR data, but the three XRR data do not show the Kiessig fringes corresponding to the thicknesses of pentacene films. The reason would be the large surface roughness of the pentacence films. The obvious Kiessig fringes in the PATS data are just from the metallic layers, Au/Ti. We, therefore, measured the thicknesses of pentacene films using AFM. The POS and the PATS were scrubbed several times with Q-tips soaked in methanol; the PPS was scrubbed just once not to remove PEDOT. The thicknesses were found to be 82.1, 83.6 and 71.1 nm for POS, PPS and PATS, respectively. Although PATS is ∼10% thinner than two others, it is still thick enough to show the bulk phase peak. A similar trend was obtained for the three films deposited at room temperature. The Patterson functions and the off-specular scans for the three films indicate that the structures of POS and PPS are the more similar than that of PATS.

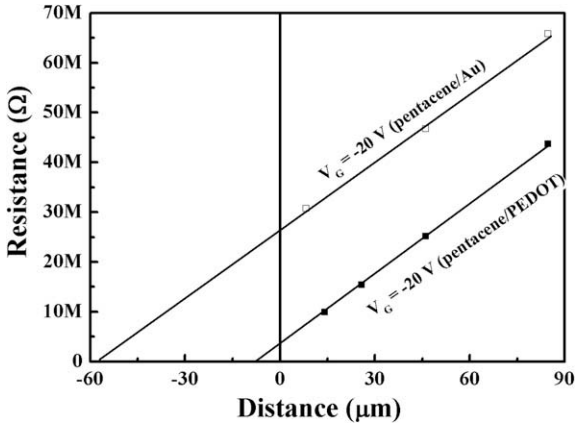

Fig. 4. The resistance as a function of the distance between the pads for gate voltage of −20 V applied in both pentacene/PEDOT structure and pentacene/Au structure.

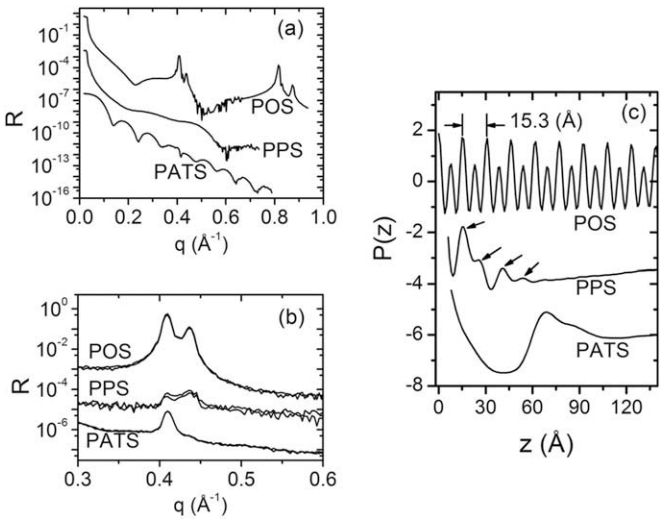

Fig. 5. (a) The true specular scans, (b) the off-specular scans and (c) the Patterson functions corresponding to (a) for three types of films: POS, PPS and PATS. Error bars are not shown in (a) and (b) for clarity. The two lines in each case of (b) represent the off-specular scans by +0.07° and −0.07° from the specular direction. POS, PPS and PATS curves in each of (a–c) are shifted vertically for clarity.

It can be concluded that the pentacene thin film evaporated on PEDOT shows better crystallinity in a region of 0–60 Å, compared with that on gold electrodes. The current flowing from the electrode-semiconductor lines to the active channel regions must be transported from the electrode–pentacene interface to the edge of the channel through the source or drain regions. Current enters the contact perpendicular to the pentacene surface and then travels through the pentacene on the electrode to reach the channel. The contact resistance from the contact to the edge of the channel can be the sum of the contact resistance between the electrode and the source/drain region of pentacene, and the sheet resistance of the pentacene of the source or drain. As a result, the better crystalline structure of pentacene on the PEDOT reduces the sheet resistance, thus leading to the lower contact resistance in PPS.

4. Conclusions

In summary, a bottom-up process was developed using a negative SAM patterning method combined with the selective growth of conducting polymer PEDOT electrodes for BC OTFTS. The negatively patterned APS monolayer provides chemically robust templates for the selective and uniform coating of $FeCl_3$ on the APS–SAM surface. This allows for the formation of highly selective patterns of PEDOT films with a smooth surface and strong adhesion to the oxide substrates. In addition, XRR analysis revealed the better crystalline structures of pentacene thin films grown on PEDOT electrodes than that on gold ones. This may be a main contributor to the lower contact resistance obtained in PPS. Furthermore, the PEDOT/APS structure effectively reduces the leakage current and provides a low contact resistance, resulting in excellent electrical characteristics. Overall, this chemically active SAM patterning and the selective growth of a conducting polymer is quite suitable for the fabrication of bottom contact TFTs.

ABSTRACT

The electrical performance of organic thin film transistors (OTFTs) is profoundly affected by organic semiconductor crystal formation and molecular ordering. The molecular ordering induced by self-assembly mechanisms can improve carrier mobility by a few orders of magnitude. In this work, the dielectric surface was modified to obtain preferred chemical functional groups that promote semiconductor ordering on the dielectric surface. OTFTs were fabricated using heavily p-doped silicon wafers as the gate electrode and thermally grown SiO_2 as the dielectric. Organosilanes, (3-mercaptopropyl)triethoxysilane and p-tolyltrimethoxysilane were used to modify the dielectric surface. Organic semiconductor, bis(triisopropylsilylethynyl) pentacene, was solution-cast as the semiconductor layer. X-ray photoelectron spectroscopy was used to characterize the modified dielectric surface. The analysis from atomic force microscopy indicated improved ordering in the semiconductor layer on silane treated dielectric surfaces. Electrical characterizations showed that the field-effect carrier mobility was enhanced by two orders of magnitude with dielectric surface modifications.

1. Introduction

During the past decade, organic thin film transistors (OTFTs) have been studied extensively for printed integrated circuits (p-ICs) as an alternative to traditional inorganic based (e.g., silicon) ICs. Compared to traditional inorganic TFTs, OTFTs have lower mobilities and slower switching speeds; therefore, OTFTs are more likely to suit applications requiring large area circuit distribution, structural flexibility, and low product cost. Commonly used organic semiconductors are conjugated polymers, oligomers, and small molecules [1,2]. The highest reported field-effect mobility for an OTFT was 6 cm^2/V s for a pentacene and C_{60} based OTFT fabricated using vacuum deposition [3]. High vacuum deposition processes are costly and the size of the substrate is limited by the dimensions of the vacuum chamber. Thus, these inherent limitations make this method unsuitable to meet the attributes of many OTFTs applications, such as large area and low cost. Pentacene cannot be solution processed; however, bis(triisopropylsilylethynyl) pentacene (TIPS) is a solution processable pentacene that shows great promise [4–8]. In this study, we investigate the performance of OTFTs fabricated using TIPS semiconductor material.

Previously conducted studies have demonstrated that OTFT electronic properties, such as the threshold voltage, device mobility and on/off current ratio, are strongly dependent on the preparation of the surface on which the organic film material is deposited [9–19]. Thus, surface modification is important in enhancing the electronic

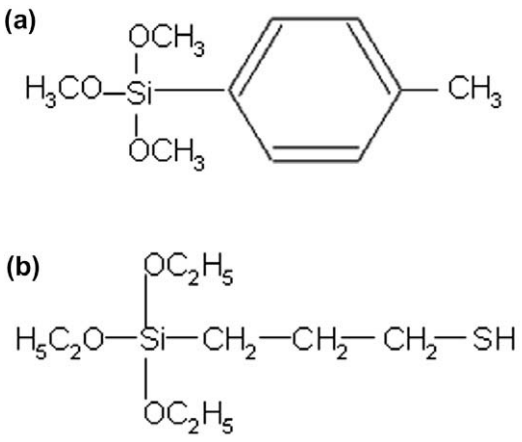

Fig. 1. Molecular structures of TTMS (a) and MPTES (b).

properties of OTFTs. During the surface modification process, a chemical moiety is selected as a self-assembling monolayer (SAM) that is applied to enhance π–π conjugation during organic semiconductor film formation [10] and to induce the local electrical field for carrier accumulation [14]. Organosilanes, such as hexamethyldisilazane (HMDS) and octyltriethoxylsilane (OTS), are commonly used SAM materials for pentacene [9–11]. These organosilanes are terminated with hydrophobic functional groups to decrease the surface energy and to enhance the ordering of pentacene molecules deposited by vacuum deposition [14,18].

In this study, for our solution-processed semiconductor material, organosilanes having hydrophilic terminal groups, such as (3-mercaptopropyl)triethoxysilane (MPTES), and organosilanes similar in chemical structure to TIPS, such as p-tolyltrimethoxysilane (TTMS), were selected as SAM candidates. The molecular structures for TTMS and MPTES are shown in Fig. 1. After surface modification with MPTES, the dielectric surface was hydrophilic which was suitable for deposition of the semiconductor film via solution processing. The existing SAM layer assisted molecular ordering of the semiconductor which in turn enhanced the field-effect mobility. The dielectric surface modified by TTMS was less hydrophilic but still enhanced semiconductor molecular ordering. It is believed that the enhanced ordering is partially due to the presence of a benzene ring in both TTMS and the semiconductor film; the benzene ring facilitates the compact alignment of the different molecules at the interface [20]. This, in turn, results in the enhancement of the field-effect mobility.

2. Experiment – device fabrication

Heavily doped p-type silicon samples (resistivity, 0.005 V cm/A) were cleaned using piranha solution, followed by rinsing in deionized (DI) water and nitrogen blow-drying. Next, the wafers were oxidized in dry oxygen at 1000 °C for 150 min resulting in the growth of a SiO_2 layer. The thermally grown SiO_2 was 150 nm-thick, measured using ellipsometry (J.A. Woollam Co., Inc., Model M-44). These samples were subjected to a second piranha treatment to obtain –OH groups on the surface of the grown SiO_2 layer. The –OH groups were required to aid the bonding of organosilanes to the surface during the subsequent processing steps [21,22]. The samples were then dipped in the organosilane solutions (10% in toluene) at room temperature for 60 min. After this step, the samples were rinsed sequentially with toluene, isopropyl alcohol (IPA) and DI water to remove excess organosilane solution followed by blow-drying with nitrogen. A gold (Au) source (S) and drain (D) of 50 nm thickness were deposited by e-beam evaporation using a shadow mask. A titanium (Ti) layer of 5 nm thickness was used as the adhesion layer. The channel length and width were 70 and 600 μm, respectively. Finally, the semiconductor precursor solution (1% TIPS in toluene) was rod-coated on the S/D to complete the fabrication of the bottom-gate field-effect transistors.

Contact angle measurements using Drop Shape Analysis Software (Version 1.00.17.0) were carried out to assess the hyrdrophobicity of the surfaces. X-ray photoelectron spectroscopy (XPS) was used to investigate the chemical composition and elemental bonding states of the dielectric surface – Kratos AXIS-165 spectrometer with a monochromatic Al Kα (1486.6 eV) X-ray source. Atomic force microscopy (AFM; Veeco MultiMode III) in the contact mode was used to probe the morphology of the semiconductor film. The OTFT electrical characterization was conducted using a Keithley 4200 Semiconductor Characterization System. The test was conducted in dark and in a nitrogen purged environment.

3. Results and discussion

The hydrophilicity of the treated surfaces was characterized by surface contact angle measurements of a water droplet on the SiO_2 surface before and after surface treatment. Initial studies were performed using HMDS and OTS; however, since surfaces treated with these organosilanes are strongly hydrophobic, they are incompatible with the selected solution-processed semiconductor films (e.g., TIPS). The incompatibility was observed during the inhomogeneous crystal formation of TIPS when rod-coated on surfaces treated by HMDS and OTS; contact angle measurements showed that the surfaces were higher than 80°. The resulting high contact angles did not enable fabrication of top contact mode transistors. TIPS material did not spread evenly over the device layer surfaces and it preferentially formed as a drop prior to solvent evaporation and therefore did not result in the formation of a continuous film. Therefore, MPTES and TTMS were selected as surface modification agent in this study.

As it is shown in Fig. 2a, MPTES and TTMS surface treatments resulted in higher surface contact angles for a water droplet than that on an untreated SiO_2 surface. This increased hydrophobicity was expected for the MTPES and TTMS-treated surfaces, because after surface modification alkyl groups are added onto the surface [16,18]. Further, the terminal group $–CH_3$ in TTMS is more hydrophobic than –SH in MPTES, which further suggests why the contact angle is larger on TTMS-treated surfaces than that on MPTES-treated ones. The capacitance values for the dielectric film modified with the different organosilanes are

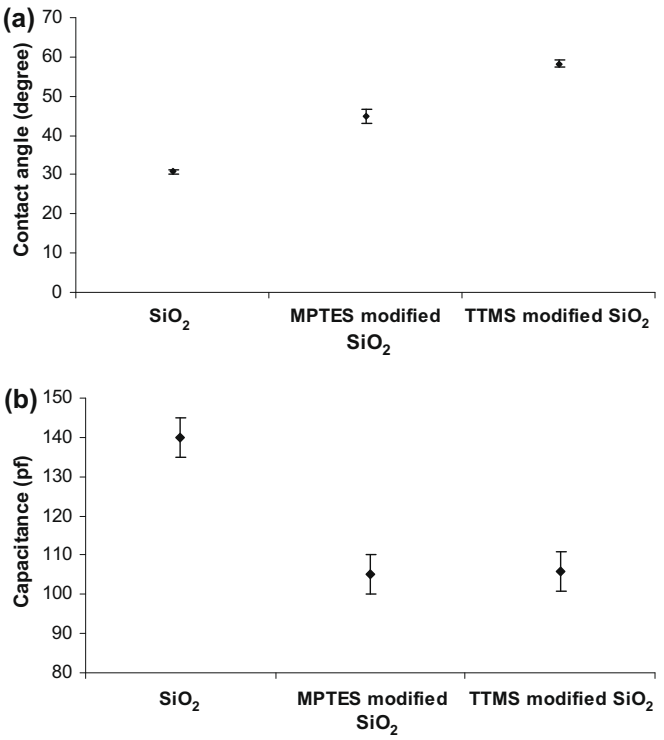

Fig. 2. DI water contact angles (a) and capacitances (b) of dry oxygen-grown SiO_2 surface, and SiO_2 surfaces modified with MPTES and TTMS.

shown in Fig. 2b; they are lower than that of the untreated SiO_2 devices. This decrease in the capacitance may be attributed to the increased overall dielectric layer thickness and the formation of the low dielectric constant (<3) [23] organosilane layer on the SiO_2 dielectric layer.

Fig. 3 shows the transfer characteristics for the OTFTs fabricated with untreated SiO_2 dielectric, and the SiO_2 dielectric modified with MPTES and TTMS. It is observed that MPTES and TTMS treatments on the SiO_2 surface improve the electrical performance of the resulting

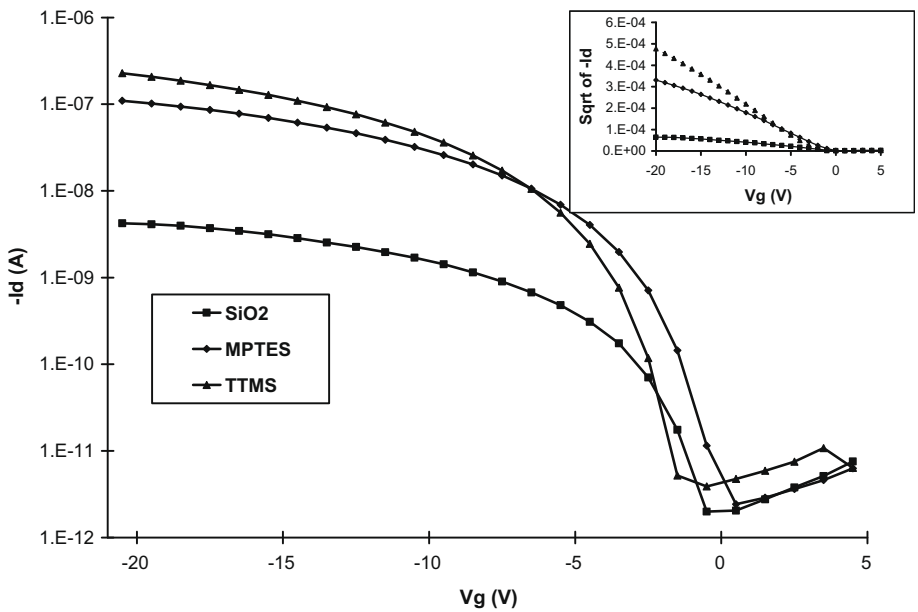

Fig. 3. Transfer curves of OTFTs with SiO_2, and SiO_2 surfaces modified with MPTES and TTMS.

transistors, as indicated by the higher measured 'on currents' and 'on/off ratios'. The field-effect mobility (μ) calculated from the transfer curves using the method published by Horowitz [24] are 4.2×10^{-5} cm^2/V s for devices with untreated SiO_2, and 0.002 and 0.005 cm^2/V s for devices with MPTES- and TTMS-treated dielectric, respectively. Devices with treated dielectric have on/off ratios that increased by at least one order of magnitude when compared to devices with untreated SiO_2. MPTES dielectric surface modification tended to shift the OTFT threshold voltage to the positive regime, while there was no apparent shift for the TTMS dielectric surface modified OTFTs. This observed shift is due to the electron accumulation properties of the terminal group on the organosilane molecule. For MPTES which has a –SH terminal group, electrons from the TIPS film are attracted by the SAM and leave behind mobile holes in the channel. Therefore, a higher positive gate bias is needed to switch off the device [16]. This electron accumulation effect is less pronounced when using TTMS which has a $–CH_3$ terminal group. Table 1 summarizes the results of the electrical parameters for these devices.

The enhanced performance of devices fabricated with TTMS and MPTES-treated dielectrics is attributed to the improvement in TIPS crystal formation when compared to TIPS crystal formation on untreated dielectrics, as seen in the AFM images presented in Fig. 4. TIPS crystals show greater ordering and alignment between the source and drain on the devices with modified dielectric surfaces (Fig. 4c and d) as compared to the randomly oriented crystals that formed on the devices fabricated with untreated SiO_2 surfaces (Fig. 4b). In the case of MPTES-treated dielectric based devices, the self-assembling layer with the hydrophilic terminal group (–SH) seemed to improve the ordering of TIPS molecules while not negatively affecting the surface wetting properties. Grazing Incidence X-ray Diffraction data seems to corroborate this conclusion. Similar to TIPS, TTMS has a benzene ring in its molecular structure, and as shown in previously published articles

Table 1
Electrical characteristics of the OTFTs with treated and untreated SiO_2 dielectric surfaces.

	Mobility (cm^2/V s)	On–off ratio	Threshold voltage (V)	Capacitance (pf)
SiO_2	0.42×10^{-4}	0.21×10^4	−0.7	140
MPTES-treated SiO_2	20×10^{-4}	4.5×10^4	0.1	105
TTMS-treated SiO_2	50×10^{-4}	5.8×10^4	−0.9	106

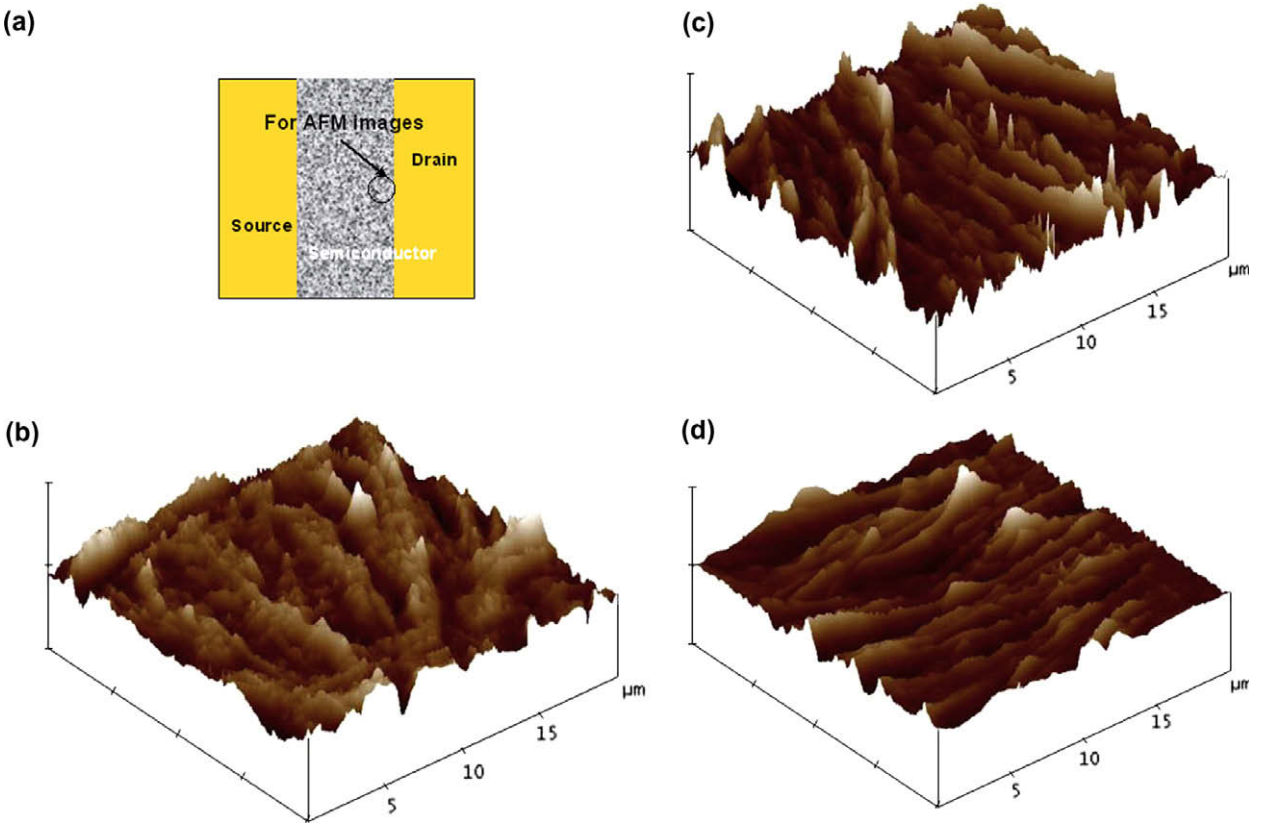

Fig. 4. AFM images of TIPS on different surfaces: top view of the OTFT and location at which the AFM images were taken from (a); atomic force micrographs of the semiconductor in the channel with SiO_2 dielectric surface untreated (b), and treated with MPTES (c) and TTMS (d). The full vertical range is 600 nm.

molecules having similar chemical structures typically, when processed, result in films with greater alignment. Therefore, improved ordering of TIPS molecules on TTMS-treated surfaces is achieved. For organic semiconductors, π–π conjugation can be enhanced by the improvement of molecular ordering which thereby increases the carrier mobility [10]. This might explain the higher field-effect mobility observed for OTFTs with the treated dielectric surfaces studied.

While contact angle measurements showed the physical property modification results after the SAM successfully bonded onto the SiO_2 surface, XPS characterization was necessary to reveal information about the chemical bonding changes at the surface before and after SAM treatments. XPS is a surface sensitive technique and chemical changes upon successful surface modification would manifest as additional peaks in the core level element scans. Based on the molecular structure shown in

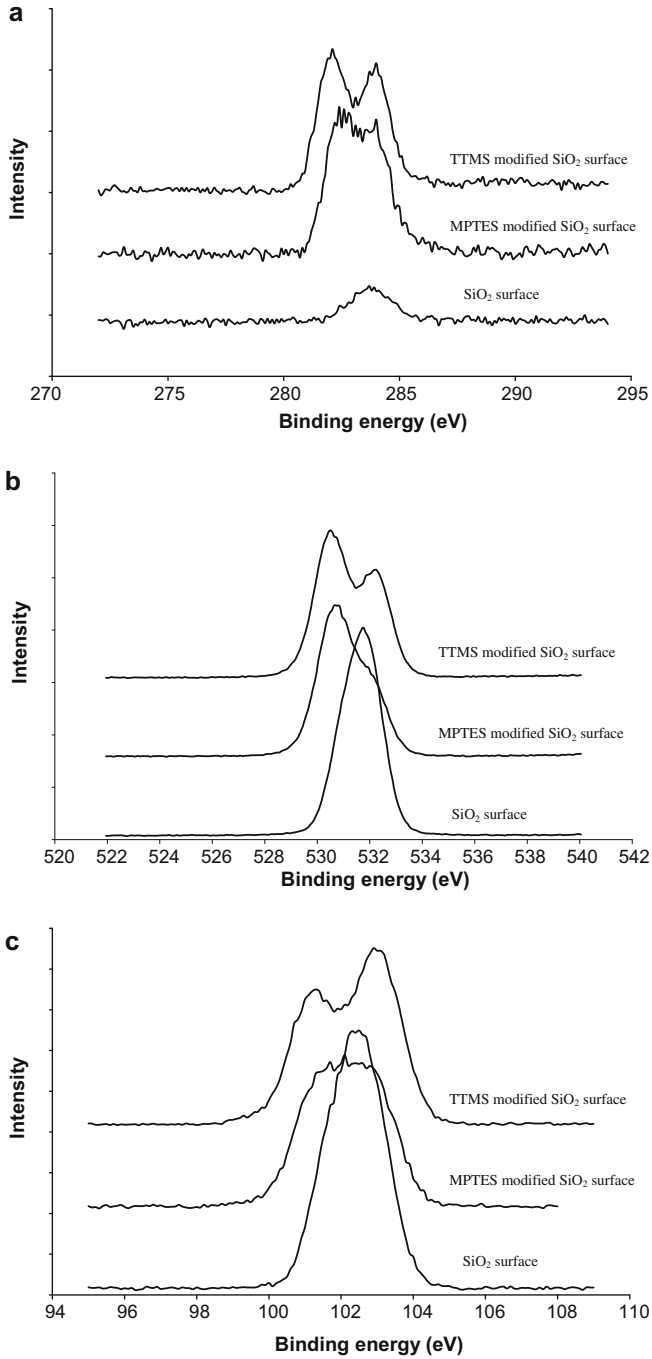

Fig. 5. XPS spectra (a) C 1s, (b) O 1s, and (c) Si 2p for SiO_2 surface, and SiO_2 surfaces treated with TTMS and MPTES.

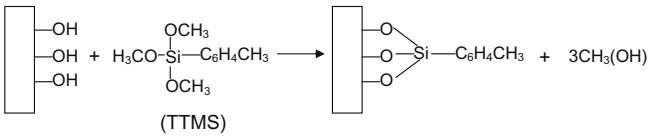

Fig. 6. Schematic chemical reaction for the surface modification of the OH-terminated SiO_2 surface using TTMS.

Fig. 1, after successful surface modification the organosilane was bonded onto the silicon oxide surface, therefore introducing, additional chemical bonds on the surface such as Si–C–C and C–Si(–O)$_3$. Fig. 5a shows the C 1s core level for the different SiO_2 surfaces. The peak at 284 eV in the case of untreated SiO_2 is attributed to carbon contamination from the ambient since there is no carbon in the silicon oxide film. Following MPTES and TTMS treatment, additional peaks appear at lower binding energy. The bonds with more electronegative atoms result in greater positive XPS chemical shift [25]. The newly formed carbon bonds, C–C, having weaker electronegativity compared to C=O appear at lower binding energy. Similarly, silicon bonds Si(–O)$_3$ from organosilanes molecules which are weaker than the bonds in SiO_2 (Si(–O)$_4$) shift towards lower binding energies, by more than 1 eV, in the Si 2p core regions [22,26] (Fig. 5c). The reaction corresponding to surface modification could be represented as indicated in Fig. 6. Based on such a reaction, if there is a monolayer formation, the chemical environment of oxygen atoms would essentially be the same as that before the reaction. But in the spectra for O 1s shown in Fig. 5b, an additional peak at a lower binding energy is observed indicating the presence of weaker bonds such as C–O besides Si–O. This could indicate that some alkoxy groups remain in the film. They are either present in the form of excess organosilanes remaining on top of the surface or in the form of incompletely removed leaving groups, probably due to steric hindrance effects from the bulky tolyl and mercaptopropyl groups.

4. Summary – conclusion

Arrays of OTFTs were fabricated using solution processable TIPS semiconductor and electrically characterized. The OTFT performance was significantly influenced by dielectric surface modifications. The SAM layers formed on the dielectric surfaces using organosilanes with polarized or aromatic functional groups improved the maximum on-current and the on/off current ratio of the fabricated OTFTs. Also, the field-effect mobility increased by two orders of magnitude resulting in a average mobility of 0.005 cm^2/V s. In addition, a shift in the threshold voltage was observed for OTFTs fabricated with dielectric surfaces modified using MPTES.

Air stability

ABSTRACT

Organic field-effect transistors (OFETs) based on regioregular poly(3-hexyl-thiophene) (P3HT) have been demonstrated with improved ambient-air stability. Substrates of untreated SiO_2, octadecyltrichlorosilane (OTS)-treated SiO_2, and SiO_2 coated with a thin layer of polymethylmethacrylate (PMMA) were compared in terms of OFET electric performance and air stability. We are able to show virtually no change in transistor on/off ratio over a 3-day period in ambient air in OFETs fabricated on SiO_2-PMMA substrates. We also studied devices based on OTS-treated PMMA interface. By analyzing the surface morphology, possible mechanisms of the enhanced air stability are discussed.

Organic semiconductors offer the potential as a low-cost alternative to silicon in applications such as active-matrix backplanes for displays, photovoltaics, sensors and radio-frequency identification (RFID) tags [1,2]. Among the many soluble polymers, regioregular poly(3-hexyl-thiophene) (rr-P3HT) has been extensively studied in organic field-effect transistors (OFETs) due to its comparatively high hole carrier mobility, simple solution processability, and commercial availability [3–6]. However, P3HT-based OFETs typically show relatively poor ambient stability, which has limited its use in industrial applications. Experimentally, it has been shown that increased humidity, oxygen, ozone, UV light exposure as well as other species present in ambient air, could result in degradation of P3HT device performance [7–9].

In order to overcome the air stability limitations of polythiophenes, a number of approaches have been pursued. Several groups have attempted to optimize the chemical structures so as to lower the highest occupied molecular orbital (HOMO) level [10–13]. This enabled improved stability against oxidative doping, but often somewhat lowered the solubility and hence printability. Furthermore, efforts have devoted to understanding the physical mechanisms of the susceptibility of P3HT to air [7–9,14]. Holdcroft et al. reported that oxygen could form a weak charge-transfer complex with P3HT, which increases the carrier concentration and hence conductivity [7]. In contrast, Hoshino et al. reported that atmospheric water content had a greater effect on the susceptibility of the device operation to air than oxygen [8]. Interestingly, Chabinyc et al. reported that oxygen is not a strong dopant for polythiophenes in the absence of light, but ozone may have a much greater influence [9]. It is noted that less effort has so far been undertaken to enhance the air stability of actual polythiophene devices, when compared with the work to improve the carrier mobility. Recently, we reported that the stability of rr-P3HT devices were improved by utilizing a combination of a high-boiling point solvent 1,2,4-trichlorobenzene (TCB), highly hydrophobic interface treatment with a self-assembled monolayer (SAM) octadecyltrichlorosilane (OTS), and a thermal annealing process [15]. Devices fabricated using this method showed stable operation in air for a few hours. Interestingly, the same fabrication procedures also enabled P3HT devices to survive in de-ionized water for periods as long as 20 h, showing a much better stability than in ambient air [16]. The

experiments demonstrated that the stability of OFETs may not only be improved by optimization of the chemical structures of the organic semiconductor but also by refining the detailed device fabrication processes.

In this paper, we report that the interface between the gate dielectric and P3HT film plays a significant role in the device performance and stability. Four different interfaces were studied: bare SiO_2, SiO_2 modified with OTS (referred to as SiO_2-OTS), SiO_2 coated a thin polymethylmethacrylate (PMMA) layer (SiO_2-PMMA), and SiO_2 substrate coated with PMMA and subsequently treated with OTS (SiO_2-PMMA-OTS). Very different air stability was observed by modification of the interface. Whereas the devices on bare SiO_2 degraded rapidly within 30 min, the OFETs based on SiO_2-PMMA substrates showed virtually no change in characteristics even after exposure in ambient air for 3 days.

Fig. 1 shows the chemical structure of rr-P3HT and a schematic of the top-contact OFETs in this study. In all cases, highly n-doped silicon wafers with a thermally grown SiO_2 (300 nm) were used. Some of the substrates were modified by OTS and/or PMMA before spin coating the organic semiconductor material. PMMA (*Mw*: 950,000, purchased from Microchem Corp, 3% in anisole) was spin coated at 4000 rpm for 2 min and a thickness of approximately 150 nm obtained. Subsequently, the sample was hard baked at a high temperature of 220 °C for 30 min in nitrogen gas environment. The hard baking process enabled PMMA films to be resistant to swelling and dissolution by TCB over the time scale of the experiment. Without such hard baking, we observed significant color change of the PMMA films once we spin coated TCB. To be more certain, we have also carried out atomic-force micrograph studies, which showed that hard baked PMMA films remained very smooth after spin coating of TCB solvent. For PMMA films only baked 180 °C, a spin-coating of TCB solvent significantly increased the film roughness. OTS was evaporated onto the sample in a nitrogen gas chamber at 140 °C for 1 h. Ellipsometry shows that the OTS layer was composed of a single monolayer with thickness approximately 2.65 nm [17]. For the substrates prior to P3HT deposition, we have imaged bare SiO_2 (RMS: 0.6 nm) and SiO_2/PMMA (RMS: 0.79 nm). In fact, the RMS values are similar to reported in literature [18]. Regioregular P3HT (purchased from Rieke Metals, and used as received) was dissolved in TCB at a concentration of 10 mg/ml and spin coated on top of the substrate at 3000 rpm for 3 min in air. The samples were then annealed at 100 °C for 2 h in nitrogen gas environment. Finally, gold source and drain electrodes, which define a channel length $L = 60$ μm and a channel width $W = 2$ mm, were deposited through a shadow mask. All P3HT devices were stored and measured in air in a 3-day period in room light.

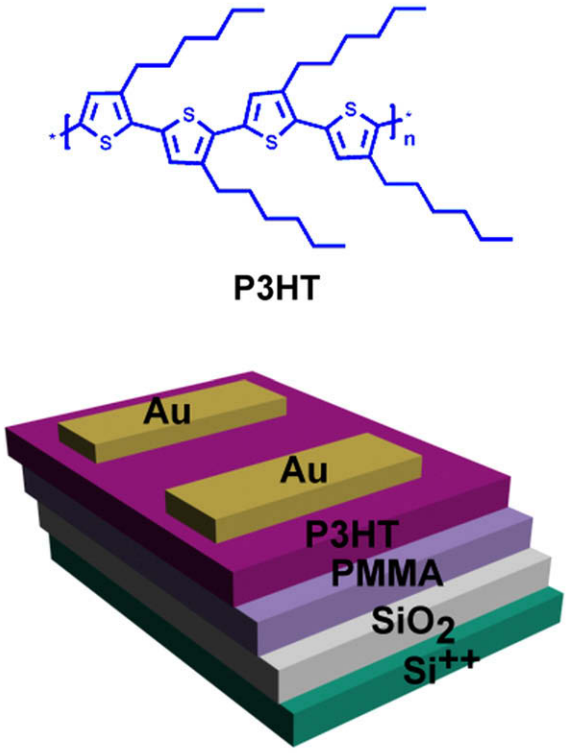

Fig. 1. The chemical structure of rr-P3HT and a schematic of the bottom gate, top-contact OFETs used in this study.

The transfer characteristics of four typical P3HT devices in the saturated regime at a drain–source voltage $V_D = -80$ V are shown in Fig. 2. A summary of the performance of the P3HT FET over time is given in Table 1. For each gate interface structure, we measured the total gate dielectric capacitance using an Agilent E4980 LCR meter and the values (10^6 Hz) are shown in Table 1. Fig. 2a shows the transfer characteristics of a P3HT FET based on a bare SiO_2 substrate after different exposure times in air. Before the first measurement, the sample was subjected to air exposure for about 15 min due to the sample transfer from the cleanroom and setting up the electrical measurement. The transfer curve indicates that the device was already severely doped as seen by a large positive threshold voltage ($V_T = 20$ V). Further doping clearly occurred after 30 min and the on/off ratio was reduced from 7×10^3 to 1×10^2 (the on/off ratio values are taken at the gate voltages of -100 V and 40 V). After the first 30 min, the rate of deterioration seemed to have significantly reduced. The on/off ratio only changed moderately in the next 3 days largely due to the increase of both the on current and off current. It is also noted that the hole mobility increased slightly after 3 days, from 0.013 to 0.019 cm^2/V s. The relatively high mobility on a bare SiO_2 substrate without any SAM treatment is most likely a result of the air doping. Recently, mobility values up to 1.8 cm^2/V s have been demonstrated in electrolyte-gated P3HT FETs with very high carrier concentrations [19–21].

Fig. 2b shows the transfer characteristic of a P3HT device based on a OTS-treated SiO_2 substrate. Here, OTS was used to promote the edge-on orientation of P3HT, which could enhance carrier mobility. For the initial measurement, the mobility was calculated to be 0.02 cm^2/V s and remained almost constant for 9 h in air. However, the on/off ratio decreased from 3×10^6 to 1.9×10^6 and the threshold voltage changed from 11 V to 18 V, indicat-

		1	0.005	4×10^4	13
		2	0.005	4.4×10^4	13
		3	0.005	5.5×10^4	13
SiO_2-PMMA-OTS	5.40	0	0.005	1×10^5	11
		1	0.005	6×10^4	16
		2	0.005	6×10^4	16
		3	0.005	8×10^4	16

[a] The on/off ratios for all devices were calculated at the gate voltages of −100 V and 40 V.

ing the occurrence of air doping. After the first day, the device characteristics became relatively stable, with the on/off ratio reducing from 5×10^4 to 1.5×10^4 and the threshold voltage increasing from 23 V to 27 V over the following 2 days. The air stability is clearly much better than the P3HT FET based on bare SiO_2 substrates shown in Fig. 2a. This is most likely due to the highly hydrophobic interface resulted by the OTS treatment, which inhibits water molecules being adsorbed at the interface and therefore severely affecting the device performance.

PMMA is often used in OFETs as a dielectric material, especially for oligomers [22]. By inserting a thin layer of PMMA on top of the SiO_2 prior to coating of P3HT, we found that the devices showed dramatically improved stability, with the on/off ratio virtually unchanged even after exposure in air for 3 days, as shown in Fig. 2c. The thresh-

old voltage was calculated to be 12 V, similar to the value of as-fabricated OTS-treated device. When compared to the bare SiO_2 substrate, a very different stability was obtained. We believe the improved stability arising from PMMA treatment is a consequence of H-bonding interactions arising from acid–base interactions between the acidic OH groups on the silica surface and the basic carbonyl groups on PMMA [23–25]. It has previously been reported that poly(styrene-methyl methacrylate) statistical copolymers when spin coated onto silica and heated above the glass transition temperature (T_g) of the copolymer give polymer chains that are permanently attached to the silica surface [26]. Whereas it has been previously reported that PMMA and P3HT solutions are both soluble in DCB [27]. We believe the hard bake conditions employed here give rise to high molecular weight PMMA which is strongly bound to the silica surface and which is not removed under the short contact times arising from the spin coating of the P3HT/TCB solution.

Interface plays an important role to determine the properties of OFETs. Some groups have suggested that the interface hydrophobicity could affect the device stability. A recent paper by Chen and Liao reported that the air stability of n-channel OFETs based on N,N′-dioctyl-3,4,9,10-perylene tetracarboxylic diimide was significantly improved after they modified the dielectric surfaces with hydroxyl-free polymers [28]. It was suggested that the enhanced hydrophobicity of the interface limited the absorption of humidity, and thereby retarded the degradation of the OFETs under ambient condition. In our work, the PMMA surface is also far more hydrophobic than bare SiO_2 surface, because of the lack of hydroxy groups. This may make it difficult for water molecules to attack and attach to the PMMA interface.

Since both OTS treatment and PMMA coating seemed to improve the P3HT OFET stability, we have also tried OTS treatment on PMMA-coated SiO_2 substrates. The device measurement results are shown in Fig. 2d. The resulted mobility of 0.005 $cm^2/V\,s$, on/off ratio of 1×10^5, and threshold voltage of 11 V of the as-fabricated device were almost the same as that based on the SiO_2-PMMA substrate. By considering the performance alone, the data suggest that the extra OTS treatment on PMMA layer did not improve the mobility. Meanwhile, the device stability actually reduced, although it was still much better when compared to the bare-SiO_2 device in Fig. 2a and slightly better than the device on OTS-treated SiO_2.

In order to gain an insight into the differences in ambient stability, the morphology of the P3HT films on the four different substrates were studied by using an atomic-force microscope (AFM). Comparing the AFM micrographs in Fig. 3a and b, no significant differences were observed. The values of the maximum peak-to-valley fluctuation (Z_{max}) and root-mean-square (RMS) are similar. However,

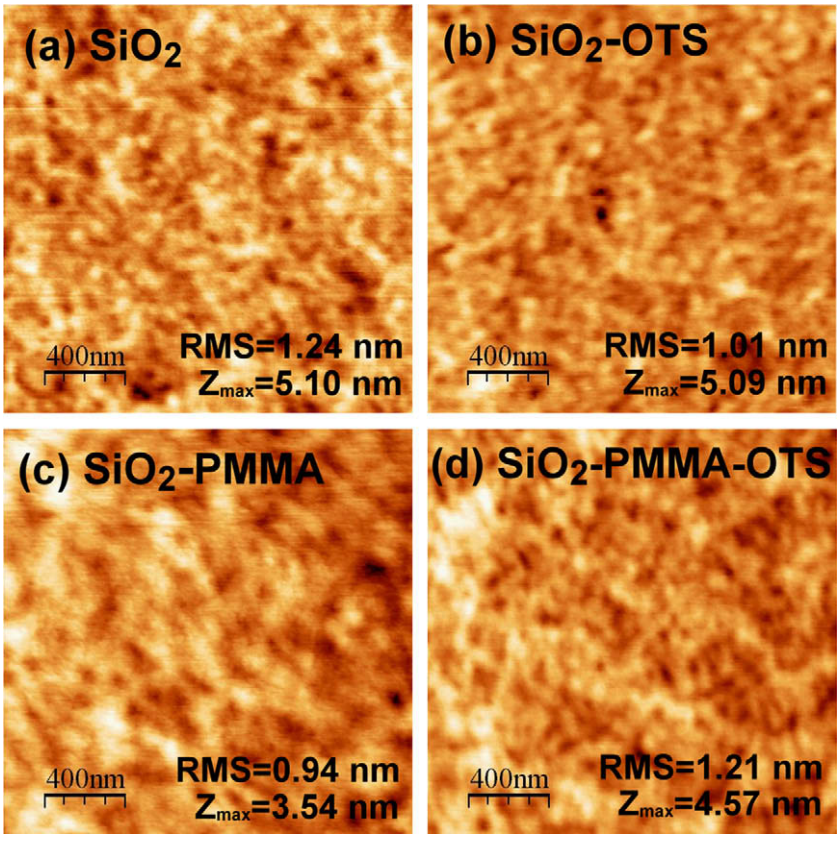

Fig. 3. AFM images of P3HT thin films on the four different dielectric-semiconductor interfaces.

both the surface roughness (RMS = 0.94 nm) and the fluctuation (Z_{max} = 3.54 nm) of P3HT on PMMA-coated SiO_2 in Fig. 3c were reduced. This suggests that the P3HT molecules are slightly more densely packed, and hence slow down the diffusion of oxygen and moisture to the gate dielectric interface where the hole transport takes place. This may also contribute to the improved stability for the P3HT devices based on PMMA-coated substrates. In Fig. 2d, it was shown that OTS treatment on PMMA surface did not improve the device stability. The corresponding AFM image in Fig. 3d indicates that the domain sizes of P3HT were similar when compared with case in Fig. 3b, which may be the reason for the reduced stability.

In summary, regioregular-P3HT devices with four different interfaces were studied. We were able to demonstrate virtually no change in the OFET electrical characteristics over a 3-day period in air, by inserting a thin PMMA buffer layer between the P3HT film and gate insulator. Such stability may have important implications in practical applications by enabling a long process window before, e.g., the encapsulation or packaging steps are applied.

ABSTRACT

We demonstrate that it is possible to fine-tune the photocurrent action spectrum of an organic photodiode, based onto a prototype semiconducting polymer, simply varying the active layer thickness and properly exploiting the filter effect of the optical absorption. The theory adopted to model the experimental data represents a useful tool to predict with accuracy the position and the spectral shape of the photovoltaic current. Based on this result, we apply our method in the colorimetric field, where a simple way to tune the spectral response of the detector unit is highly desired: we realize an organic color sensor device without any optical filtering.

1. Introduction

Over the last three decades, there has been a continuously increasing interest in organic photovoltaics (oPVs) research, especially focused onto the realization and the development of efficient solar cells [1–6]. Only more recently, the same attention has been deserved to organic photodetectors (oPDs) as well [7,8]. In particular, photosensors working in photovoltaics conditions may find useful application not only in technology, but also, for instance, in diagnostics, in biometry, in humanoid sciences [9,10].

Although oPV cells and oPDs share many similar features and definitely are, under many respects, similar devices, they nevertheless have to fulfill a different set of requirements. In photovoltaics, tremendous efforts have been done by many groups in order to pursue two main objectives, the improvement of the overall power conversion efficiency and the extension of the absorption range towards the near infrared. Important results have been obtained by blending conjugated polymers with high-electron affinity molecules, such as C_{60} and its soluble derivative, PCBM [3]. So, as far as photovoltaics is concerned, the main issue is to convey as much as possible the solar spectrum.

On the other side, the key parameters for photodetection are the photocurrent and the dark current intensities; state-of-the-art P3HT:PCBM bulk heterojunction diodes have been recently reported, with external quantum efficiency between 60% and 70% and dark current densities below 10 nA/cm^2 at −1 V [11]. In addition to the most conventional architectures, hybrid devices, based onto the contemporary employ of organic conjugated polymers and inorganic semiconductors as active materials, have been recently extensively explored, due to the exciting opportunity to combine the valuable properties of both materials groups, in particular in terms of charge generation and transport (see [12] for a recent review). Another fundamental factor to be considered in photodetection is represented by the spectral selectivity. The opportunity to tune and properly, finely adjust the spectral response of photodetectors within the visible range is one of their most attractive properties, which does not have a counterpart in the silicon-based technology.

Organic materials can be chemically tailored, by changing the molecular structure in order to adjust the band gap, and therefore the optoelectronic properties; anyway, this

doi:10.1016/j.orgel.2009.11.013

approach is often too expensive and time-consuming. A second, well-known method [13,14] to tune the spectral response consists in applying various difference potentials (which is anyway strictly required for sensitive and fast photodetection, [11]). Nevertheless, for many applications in the colorimetric and bioengineering fields (for instance in spectral biological imaging) photodiodes working at zero bias are preferable.

In this work, we use the well-known internal filter effect in order to fine-tune the spectral response of a prototype conducting polymer, simply varying the active layer thickness. We analyze the data within the framework of the Ghosh–Feng model [15]; the good agreement between the experimental action spectra and the theory provides us with a simple way to predict and/or to tune with accuracy the position and the spectral shape of the photovoltaic current, just relying onto the optical absorption and the active layer thickness. Finally, we describe an interesting application of the organic photodiodes in the colorimetric field, where the spectral tuning plays a fundamental role: it has a significant technological value, since it avoids the use of optical filters in front of the detector, and, even more importantly, it can account for a more bio-mimetic color perception, offering a simpler and direct response to the problem of metamerism (i.e., different combinations of the reflected light from two (different) objects produce the same color perception; sets of metameric colors vary in a considerable way among different sets of color-matching functions).

2. Materials and methods

The photodetectors were realized in the usual sandwich structure, adopting for simplicity a single layer approach and using as active polymer a prototype material, regioregular poly(3-hexylthiophene-2,5-diyl) (rr-P3HT). P3HT was supplied by Sigma–Aldrich with a regio-regularity of 99.5%, a molecular weight of 17,500 g/mol, and it was used without any further purification. We used glass substrates precoated with ITO as the anode; special care was taken of careful cleaning, rinsing the substrates in ultrasonic bath with (i) specific detergent in 3% water solution, (ii) deionised water, (iii) pure acetone and (iv) isopropyl alcohol. The substrates were then dried by a nitrogen flux and finally cleaned by oxygen plasma. 1,2-Dichlorobenzene solutions (concentration range between 5 and 40 g/l) of P3HT were heated at 50°, stirred and finally deposited by spin coating on pre-heated substrates, properly adjusting the parameters, in order to obtain a film of good optical quality. After deposition films were not thermally annealed. The aluminium cathodes were deposited by thermal evaporation, through shadow masks. The metal thickness was determined by a quartz microbalance; suitable values are about 120 nm. Finally, electrical contacts were realized through Au wires. Pixel area is 2×3 mm^2. The devices were realized and immediately tested in air, at room temperature. Degradation of the optoelectronic properties was observed after a week, as a $\sim$50% reduction in the measured photocurrent values.

Active film thickness for different concentrations was carefully measured by a step profiler (ALPHA STEP IQ, KLA TENCOR): obtained values are, respectively, 30, 75, 250, 340, and 440 nm; for each device we measured the photocurrent action spectrum, in photovoltaic conditions.

In action spectra measurements, the light from a tungsten lamp passes through a monochromator and is focused onto the photodiode, at 0° incidence, through the ITO electrode. The light is chopped by a mechanical chopper (operating frequency 130 Hz) and the reference signal is fed to a lock-in amplifier. System calibration was performed by replacing the organic photodiode with a silicon photodiode of known efficiency, taking into account the dark current and the spectral response of the light source and the monochromator gratings.

For the measurements of colorimetric coordinates of standard objects, the source light (whose spectral emission is close to the standard illuminant A) is focused onto calibrated color samples (LABSPHERE, SPECTRALON® color standards), and the diffused radiation is detected by the organic photodiodes at an angle of 45°, following the CIE (Commission International d'Eclairage) prescriptions. All measurements were performed in air and at room temperature.

3. Results and discussion

Measured photocurrent action spectra on different thickness photodiodes are shown in Fig. 1a, as dotted black lines. The optical absorption spectrum is also shown for comparison (dashed green line). The latter shows a weak structure probably due to the vibronic lineshape convoluted by the disorder distribution in the polymer film. In the considered range, the spectral responsivity (Fig. 1b) of the organic photodiodes changes as the active layer thickness is increased, and it presents two main features:

- A narrowing of the lineshape.
- A pronounced shift of the peak, from 560 nm (matching the absorption spectrum) to 625 nm.

The highest responsivities are obtained for 30 and 250 nm-thicknesses; the photodiode with 75 nm active layer thickness is characterized by an intermediate value, while for active layers thicker than 250 nm the measured responsivities are considerably reduced.

Maxima external quantum efficiencies (EQE) are low, as expected in pristine rr-P3HT photodiodes, with a not-optimized structure. Moreover, they critically depend on the layer thickness. Calculated values are reported in Table 1. In this work, we mainly focused onto the spectral shape, aiming at finding a simple method to predict, at a discrete level of accuracy, the photocurrent action spectrum, with the final goal of reproducing the standard observer color-matching functions (see Section 4). For practical colorimetric application it will be possible to increase the EQE of the devices, if required, by using an external signal amplifier, without affecting the optimized spectral matching and properly selecting the amplifying factor.

Traditionally, the relationship between the photocurrent and the absorption spectra has been classified as either symbatic or antibatic [14]. If the maximum photo-

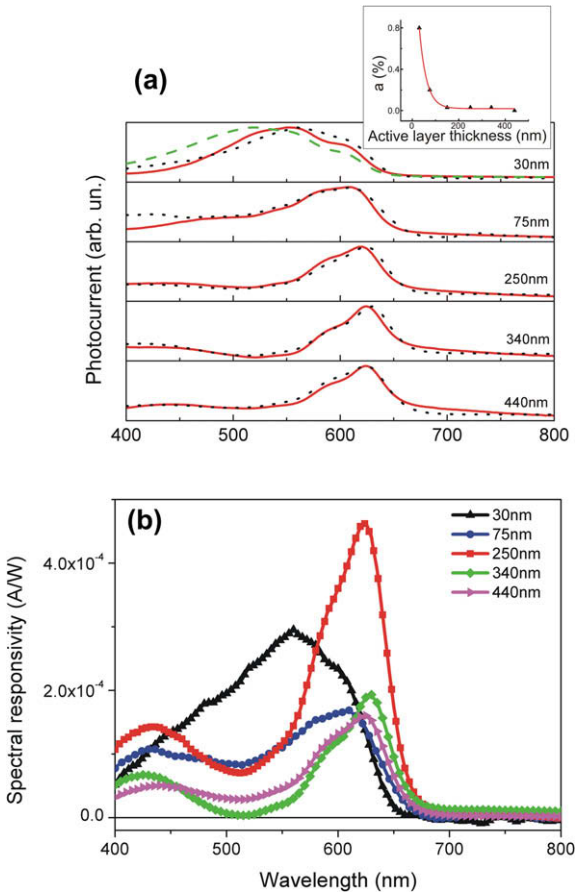

Fig. 1. (a) Normalized photocurrent action spectra of sandwich photodetectors ITO/rr-P3HT/Al, for different active layer thicknesses (dotted black lines), and theoretical spectra, as predicted from the Ghosh–Feng diffusion model (solid red lines). For comparison, the optical absorption spectrum of the polymer is also shown (dashed green line). The model reproduces with good accuracy the transition from a symbatic to an antibatic behaviour, in photovoltaic conditions. The inset reports the percentage weight of the symbatic component *a*, as obtained from the simulation procedure, as a function of the polymer thickness. (b) Measured spectral responsivities for different active layer thicknesses. 30	0.07
75	0.03
250	0.09
340	0.04
440	0.03

current coincides with the strongest photon absorption, the photocurrent response is said to be symbatic with the absorption spectrum. If the maximum of the photocurrent spectrum occurs at photon energy where the optical absorption is weakest, i.e., if the photocurrent and the absorption are almost complementary, the photocurrent response is said to be antibatic. Fig. 1 clearly shows the transition from the symbatic response to the antibatic one, for increasing active film thickness.

The antibatic behaviour has been previously reported for various polymer-based sandwich cells and attributed to the internal filter effect [13,14,16–20]: carriers are predominantly generated close to the electrode, which is opposite to the contact through which light enters the active layer. In other words, the material below the aluminium does not contribute to current generation within the device and acts solely as an optical filter, filtering out the useful light from reaching the only active charge generation region in the device. In this case the photocurrent is expected to decrease in the wavelength range of high absorbance.

Several models have been developed in the past in order to relate the photocurrent action spectrum to the optical absorption spectrum, based onto the self-absorption within the film [21–24]: all of them assume an exponential decay of the incident radiation with the distance (i.e., the Lambert–Beer law), but differ from each other in the assumed mechanisms of charge separation and transport. In this work, we use the model originally due to Simpson [25], and then applied for the first time to organic, merocyanine solar cells materials by Ghosh and Feng [15].

Two main hypotheses are assumed:

i. The absorption of the light creates excitons, that *diffuse* towards the organic material–electrode interfaces;
ii. Dissociation of the excitons into free carriers takes place *only* in proximity of the interfaces, within few exciton diffusion lengths, and not in the bulk (as in doped organic photodiodes).

Under the first assumption, the transport of excitons from the generation to the dissociation site is treated by the standard diffusion equation:

$$\frac{dn(x,t)}{dt} = \Phi N \alpha e^{-\alpha x} - \frac{dJ}{dx} - \frac{n(x,t)}{\tau} \quad (1)$$

where n is the number of excitons, Φ is the quantum efficiency of exciton generation, N is the number of incident photons per unit area per second, α is the absorption coefficient, as a function of the radiation wavelength, J is the exciton current and τ is the mean exciton lifetime.

First term on the right hand side of Eq. (1) describes exciton photogeneration, the second one is due to the exciton diffusion, while the last one is a recombination term. J is proportional to the diffusion coefficient D, and can be expressed as:

$$J = -D\frac{dn(x,t)}{dx} \quad (2)$$

Since we are interested in steady-state photocurrent, we only consider equation at equilibrium ($dn(x,t)/dt = 0$):

$$0 = D\frac{d^2n}{dx^2} - \frac{n}{\tau} + \alpha\Phi N \exp(-\alpha x) \quad (3)$$

Adopted boundary conditions are $n(x) = 0$ at $x = 0$ and $x = L$, where L is the thickness of the active layer. In this way the two electrode–organic interfaces can be both

recombination and dissociation sites for the excitons. In other words, we assume that free carriers are generated only if the excitons reach one of the two electrodes (no bulk photogeneration), so that interfaces with aluminium and ITO can be seen as 'infinite sink' either for exciton dissociation or for exciton recombination. With these boundary conditions, general solution of Eq. (3) is given by (4):

$$n = \frac{\gamma}{\beta^2 - \alpha^2}\left(\frac{e^{\beta L} - e^{-\alpha L}}{e^{-\beta L} - e^{\beta L}}\right)e^{-\beta x} - \frac{\gamma}{\beta^2 - \alpha^2}\left(\frac{e^{-\beta L} - e^{-\alpha L}}{e^{-\beta L} - e^{\beta L}}\right)e^{\beta x} + \frac{\gamma}{\beta^2 - \alpha^2}e^{-\alpha x} \tag{4}$$

where Λ is the diffusion length of excitons and:

$$\beta \equiv (\Lambda)^{-1} \equiv (D\tau)^{-1/2} \quad \text{and} \quad \gamma \equiv \frac{\alpha N \Phi}{D} \tag{5}$$

The exciton current at interfaces with ITO and aluminium, J_{ITO} and J_{Al}, is thus simply obtained by relation (2) in correspondence, respectively, to the extremes $x = 0$ and $x = L$ (for illumination from the ITO side):

$$J_{ITO} = -D\frac{dn}{dx}\bigg|_{x=0} \quad \text{and} \quad J_{Al} = -D\frac{dn}{dx}\bigg|_{x=L} \tag{6}$$

For a p-conducting material and for illumination from the ITO side, the dependence of J_{ITO} and J_{Al} on the incident photon energy gives rise, respectively, to the symbatic and antibatic response in the photocurrent action spectrum. In our case, at zero bias, the photocurrent spectra cannot be described simply by a symbatic or an antibatic response alone, but it is necessary to consider the combination of both contributions [14–20]. The two limiting cases are for thicknesses comparable to the exciton diffusion length Λ, when the spectral response is mainly symbatic, and for thicknesses much greater than Λ, when it is almost completely antibatic. For intermediate thicknesses, one should consider both the symbatic and the antibatic response. We assume that the total photocurrent J can be simply written as a linear combination of J_{ITO} and J_{Al}:

$$J = (1 - a)J_{Al} + aJ_{ITO} \tag{7}$$

where a ($0 < a < 1$) is the contribution due to the symbatic response.

Using this model, we were able to reproduce with good accuracy the experimental photoaction spectra, for different values of the active layer thickness. In the simulation procedure we first optimized the exciton diffusion length Λ, and we fixed it to $\Lambda = 10$ nm. This value has anyway to be considered as a rough estimate, since it probably slightly overestimates the recently reported values, in the range (8.5 ± 0.7)nm, obtained by specific and more precise technique [26,27]. Considering that the exciton lifetime τ is in the order of ~400 ps [27], we can give an estimation for the diffusion coefficient, D ~25E–4 cm^2/s, five times larger than the value estimated by Luer et al. [28], which anyway was to be considered as a lower limit, since they estimated D from kinetics measurement of fluorescence quenching upon exposure to oxygen. Within the framework of the Smoluchowski model [29], they assumed that the fluorophores are instantaneously deactivated upon contact with the quencher (oxygen), and that each encounter leads to quenching, with a reaction radius R = 500 pm. If these conditions are not met, or R is smaller, one obtains higher values for D.

For fixed Λ, the only free parameter is a, which has been varied between 0 and 1. Results of the simulation are shown in Fig. 1, as solid, red lines. The slight deviations of the experimental spectra from the model, more evident at the lowest and the highest wavelengths, may find an explanation taking into account that:

1. We assume the exciton dissociation efficiency as independent from the excitation wavelength;
2. We do not consider any length distribution in the polymeric chains, which would determine different exciton lifetimes.

The inset in Fig. 1 shows the best values obtained for the percentage weight of the symbatic component a, as a function of the active layer thickness. It is possible to note that the weight of the symbatic component decreases in an exponential way with the thickness, and indeed it plays a real role just in the first one hundred nanometers. For thickness ~440 nm it is almost zero, and the photocurrent is dominated by the antibatic behaviour. This is due to the unbalance in mobility (holes mobility is bigger than electrons mobility) and only a small fraction of the electrons generated near the ITO reaches the aluminium electrode and can contribute to the current. We see that the spectral response of the photodiodes stems for both charge generation and transport phenomena.

The well accordance between the experimental data and the model allows us to conclude that the interfaces at the electrodes play a fundamental role, without any relevant contribution from the bulk photogeneration: the exciton dissociation is a fully extrinsical phenomenon.

The model gives us a useful tool to predict with accuracy the photocurrent action spectrum of an organic photodetector, just on the base of its optical absorption, the exciton diffusion wavelength (which is known for many, commercial materials) and the active layer thickness. In addition, it suggests that fine tuning of the spectral response can as well be obtained using a single material and different thickness. This can be done simply changing the processing conditions (polymer concentration and/or spinning parameters). In the following, we describe an application, where the spectral tuning of the photoresponsivity is of fundamental importance, thus exploiting the thickness dependence.

4. Color measurement

Organic photodetectors may find useful applications in the colorimetric field, as color sensor devices [30]; the great advantage of the organic semiconductors technology is the possibility to reproduce the three standard observer color-matching functions (CMFs), traditionally named as Z, Y and X [31], without using any optical filtering, but simply exploiting the tunability characteristics of the active materials. To this respect a simple way to properly tune the spectral response is of crucial importance.

In this work, we exploit the symbatic/antibatic behaviour of the photocurrent in rr-P3HT sandwich devices in order to reproduce the standard colorimetric curves *Y* and *X*. More in detail we choose two different solution concentrations, corresponding to active layers of, respectively, 50 nm (mainly symbatic-type photocurrent action spectrum) and 200 nm (mainly antibatic-type). The CMF *Z* is reproduced by selecting a second material, namely methyl-substituted ladder-type *para*-polyphenylene (m-LPPP), doped with PCBM (1:1 concentration, in weight). Measured EQE at 470 nm is 1.1%. Fig. 2 shows the comparison between the experimental photocurrent action spectra and the standard CMFs (respectively, dashed and solid lines). Even if the spectral agreement is not yet fully satisfactory, nonetheless these results represent a proof of concept of the reliability of our approach. In order to directly test the possibility to use organic photodiodes as color sensor devices, we measured the colorimetric coordinates of some calibrated color standard. Obtained values are displayed in Fig. 3 (white triangles) in comparison with the calibration values in the standard system (black dots). Even if the organic color sensor devices at the present still do not meet the requirements for a commercial application, due to the spectral mismatch between the experimental and the standard CMFs, these results demonstrate the capability of organic photodiodes to measure the color of a diffusing object, representing a valuable alternative to the existing technology.

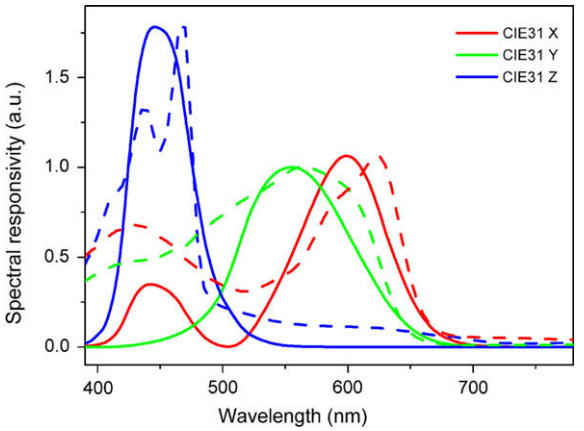

Fig. 2. Comparison between the two sets of colorimetric functions, the standard observer CIE31 (solid lines) and the experimental photocurrent spectra, properly normalized (dashed lines).

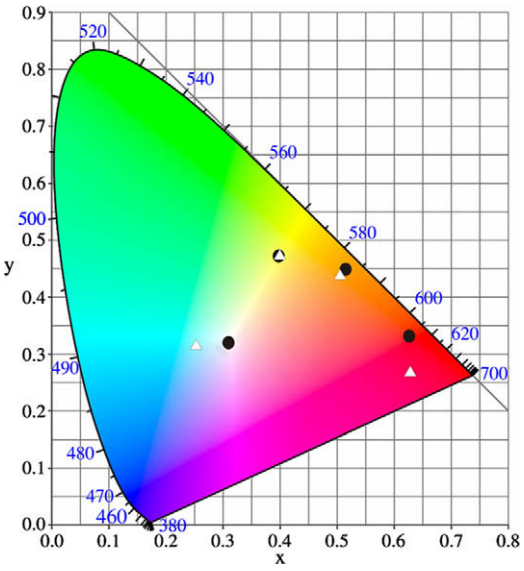

Fig. 3. Chromaticity coordinates of four calibrated color samples, as measured by organic color sensors (white triangles), in comparison with the calibration values (black dots) in the standard system CIE31. The observed deviations are due to the mismatch between the standard observer colorimetric functions and the experimental ones; nevertheless, these results can be considered as a direct proof of the capability of organic photovoltaic devices to detect and measure color stimuli. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

5. Concluding remarks

In this work, we demonstrated that, exploiting the internal filter effect, it is possible to fine-tune the photocurrent action spectrum of an organic photodiode simply varying the active layer thickness. The theory adopted to model the experimental data represents a useful tool to accurately predict the action spectrum shape, just relying onto observation of the material optical absorption and properly selecting the active layer thickness. We applied our method to a specific purpose, i.e. the realization of a color sensor device without any optical filtering, whose spectral response closely resembles the standard observer CMFs.

ABSTRACT

We have fabricated the flexible field-effect transistors based on the liquid crystalline phenylterthiophene derivative via a solution process. A dielectric layer of polyvinyl alcohol (PVA) are deposited on a polyimide sheet substrate by a spin-coating method and then the thin film of 5-propyl-5″-(4-pentylphenyl)-2,2′:5′,2″-terthiophene is fabricated from its chlorobenzene solution on the dielectric layer by spin-coating or solution sheared deposition method. The fabricated devices exhibit good electrical performance with a hole mobility of up to 0.05 $cm^2 V^{-1} s^{-1}$ as well as excellent mechanical flexibility. The performance does not degrade at the external strain reached 3%. Our results demonstrate that liquid crystalline semiconductors are promising materials for low-cost flexible electronic devices.

1. Introduction

Organic field-effect transistors (FETs) exhibit high carrier mobility which can be comparable to that of amorphous silicon field-effect transistors. In general, organic FETs utilize the vacuum-deposited polycrystalline thin films of molecular crystals such as pentacene [1–3]. In contrast to expensive vacuum process, a few solution-processable organic semiconductors forming high quality polycrystalline thin films have been designed and applied to FETs [4,5]. The soluble precursors which can be converted to insoluble organic semiconductor materials, as well as the pentacenes bearing bulky substituents are the typical examples [6,7]. However the control of crystal growth in the solution processes is generally difficult and the device performances are inferior to those of the devices fabricated by vacuum process. A few conjugated polymers have been applied to the FETs with high performance [8]. However the performance significantly depends upon the crystallinity and morphology of the thin films [9].

In addition to the solution-processability, one of the recent research topics is the development of the flexible FETs. Such devices are the key components, e.g. in the electronic papers [10,11] and in the large-area active-matrix pressure sensors for artificial skin [12,13]. Someya et al. prepared the flexible FETs based on the vacuum-deposited pentacene films and fabricated the transistor arrays on flexible polymer substrates which were applied to pressure sensors [12,13]. Bao et al. fabricated the transistor arrays consisting of rubrene single crystals on the plastic substrates [14,15]. However, molecular crystals have a relatively rigid structure and the device performance degrades when a large strain is applied e.g. by bending. Moreover the fabrication of polycrystalline thin films generally needs vacuum process. It should be noted that the flexible organic FETs fabricated by solution process have been very limited.

In this paper, we report the fabrication and characterization of the flexible FETs using liquid crystalline (LC)

doi:10.1016/j.orgel.2009.11.014

semiconductors by solution process. The LC semiconductors exhibit good carrier transport characteristics in their mesophases because of their crystal-like molecular packing structures and the low defect density [16–22]. In the columnar and smectic phases, the LC molecules self-organize into large domains with crystal-like molecular ordering. The close molecular packing structure and small energetic disorder in the LC phases leads to efficient intermolecular charge carrier transport. In addition, the defect density at the domain boundaries is sufficiently suppressed because of a self-healing effect by molecular thermal motion.

Fast electronic charge carrier transport has been confirmed in the discotic columnar [23–30], smectic [31–37], nematic and cholesteric phases [38–40]. The time-of-flight (TOF) measurement revealed high drift carrier mobilities exceeding 0.1 $cm^2 V^{-1} s^{-1}$ in highly ordered smectic phases of alkynylquaterthiophene [35] and bisthienylbenzene derivatives [36] as well as in the discotic columnar phases of hexaalkylthiotriphenylene derivatives [26], respectively. Time-resolved pulse-radiolysis microwave conductivity indicates high microscopic carrier mobilities comparable to molecular crystals in columnar phases of hexabenzocoronene derivatives [27–29].

Recently a few solution-processable LC semiconductors have been developed and applied to the electroluminescence devices [41–44], solar cells [45], and FETs [46–52]. The disk-like hexabenzocoronene derivatives exhibiting columnar phases were applied to the FETs in which the columns are aligned parallel to the substrates by the friction transfer [46] and zone-cast methods [47]. In contrast, it is relatively easy to control the molecular alignment of the rod-like LC molecules in the smectic phases. Oligothiophene derivatives which exhibit the highly ordered smectic phases have been applied to the FETs [48–52].

Moreover, the LC semiconductors possess not only efficient carrier transport characteristics but also softness even in the highly ordered smectic phases owing to molecular thermal motion [53]. The thermal movement of the LC molecules enables self-healing of dynamic positional disorders (which act as carrier trapping sites) within the LC material, resulting in a low defect density [54]. These LC semiconductors are expected to be conformable to the deformation made by the external strain, and therefore the formation of the defects and disorders will be suppressed. These characteristics are highly desirable in flexible electronics. However the fabrication of the flexible FETs based on the liquid crystalline semiconductors by the solution process has not been reported yet.

Recently, we have developed a LC semiconductor, 5-propyl-5″-(4-pentylphenyl)-2,2′:5′,2″-terthiophene (3-TTPPh-5); its molecular structure is shown in Fig. 1a. 3-TTPPh-5 exhibits a nematic phase between 216 °C and 202 °C and a highly ordered smectic phase below 202 °C. This compound does not crystallize when it is cooled to −50 °C. A time-of-flight measurement revealed a fast ambipolar transport in the bulk state at room temperature [49]. Hole mobility of more than 0.04 $cm^2 V^{-1} s^{-1}$ in ambient air was achieved in its FETs [50]. It should be noted that the active layers of such FETs are in the highly ordered smectic phase and not in the crystalline state when the devices are functioning. This highly ordered smectic phase should be more flexible and softer than the crystalline films. Most of the FETs based on liquid crystalline semiconductors are operated in the crystalline states [46–48,52]. The highly ordered smectic phase has a layer structure with long-range molecular ordering within the smectic layers, while there is degree of freedom for molecular thermal movement around the long axis of the LC molecules. The LC films are expected to be softer and more flexible than those based on molecular crystals.

2. Experimental

2.1. Material synthesis

3-TTPPh-5 was synthesized by a previously reported method [49]. Before the fabrication of the devices, the material was purified by silica gel column chromatography and recrystallized from cyclohexane.

2.2. Fabrication of the OFETs on the polyimide (PI) films

A 60 nm-thick Au film with a 5 nm MoO_x adhesive layer was vacuum-deposited on the surface of a 0.3 mm-thick PI sheet, and this Au film acted as the gate electrode. The dielectric layer was spin-coated (at 1500 rpm) on the Au-deposited PI sheet from a 10% aqueous solution of polyvinyl alcohol (PVA) (Tokyo Kasei, Japan) and baked overnight in a vacuum oven at 80 °C. The average thickness of the resulting PVA layer determined using a surface profiler was ca. 2.0 μm. The PVA-coated PI sheet was then immersed into a 10 mM toluene solution of octyltrichlorosilane (OTS-8) at 65–70 °C for 25 min and rinsed four times with toluene. Then a 50 nm thin film of the LC 3-TTPPh-5 was prepared by spin-coating the 0.7% solution in chlorobenzene on the PVA surface and annealed at 100 °C for 10 min in vacuum. Finally, a 60 nm-thick Au source/drain electrode was deposited under high vacuum using a shadow mask to define a top-contact FET structure with a channel length of 20–30 μm (width: 5 mm).

2.3. Fabrication of the liquid crystalline thin film of 3-TTPPh-5 by the solution sheared deposition

A few droplets of chlorobenzene solution of 3-TTPPh-5 (0.6 wt.%) were placed on a PVA-coated PI sheet which was kept at 80 °C in air, so that the solution should cover the whole surface of the substrate. Then a hydrophobic Si wafer whose surface was pretreated by the OTS-8 self-assembled monolayer was put on the surface of the solution. Drawing the upper wafer in one direction (shearing the solution) slowly, leaving the film on the PVA surface by solvent evaporation on the heated substrate.

2.4. Electrical measurement of the flexible field-effect transistors

The transistor characteristics were measured by a two-channel source meter (Kethley source meter 2612). The transistors were placed in a light-shielded box under ambi-

ent condition with low humidity. The strain was applied to the flexible transistors by attaching them around glass cylinders. All the electrical measurements were performed at room temperature.

3. Results and discussion

The flexible thin film transistors were fabricated on the polyimide sheets with a device structure as shown in Fig. 1b. The capacitance of the PVA dielectric was estimated to be 3.5 nF cm^{-2} from its thickness by assuming the relative permittivity of the PVA as 8. Such a capacitance value was confirmed by the capacitance–frequency measurements and this value was used to calculate the hole mobility below.

The morphology and structure of the LC 3-TTPPh-5 thin films grown on the PVA surface were investigated by atomic force microscopy (AFM) and X-ray diffraction (XRD). The AFM observation revealed that the film consists of large-size plate-like grains (10–50 μm) with a lamellar structure, similar to the films formed on the SiO_2 surface [50]. Fig. 1c shows a tapping-mode AFM image within a grain exhibiting the atomically flat terraces on the surface. The films formed on the PVA surface also showed the same XRD pattern as those on the SiO_2 surface, exhibiting a highly ordered layer structure [50].

Fig. 2a and b show the output and transfer characteristics of the flexible FET using 3-TTPPh-5, measured in ambient air, respectively. The device exhibits a clear *p*-type operation. The hole mobility and current on/off ratio were found to be ca. 0.01 $cm^2 V^{-1} s^{-1}$ and 10^4, respectively. This mobility value is lower than that of the FETs of 3-TTPPh-5 formed on the rigid SiO_2/Si substrate (0.04 $cm^2 V^{-1} s^{-1}$) [50]; however, this value is comparable to that of the normal solution-processed organic FETs [55]. The unsaturation of the drain current was found to occur at the higher drain voltage in the output curves, and the threshold voltage V_T was found to shift slightly toward the positive direction with time. We propose that these phenomena are due to the presence of trace amounts of mobile sodium ions in the commercially available PVA, as recently demonstrated by Egginger et al. [56]. The movement of such ionic impurities in the PVA dielectric induces an additional electric field in the dielectric layer by gate bias; this leads to the shift of V_T and a large off-current (thereby, a low on/off ratio). However, we observed that such impurities do not significantly

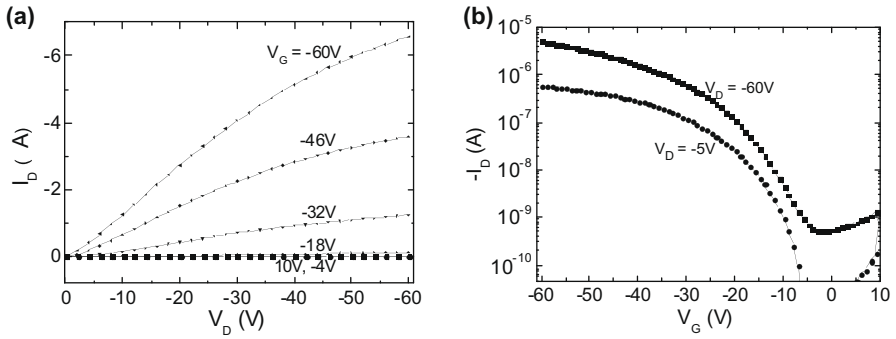

Fig. 2. (a) Output characteristics and (b) transfer curves of the flexible FET of 3-TTPPh-5 film on the bare PVA dielectric surface at room temperature. The channel length of the FET is 30 μm.

affect the value of carrier mobility in our devices. Residual water contained in the PVA layers may also influence on the unsaturation in the drain current and the shift of V_T.

In order to further improve the device performance, we carried out surface modification of the PVA dielectric using silane agents. This was owing to the presence of hydroxyl groups (–OH) on the PVA surface, similar to the SiO_2 surface. First hexamethyldisilazane (HMDS) was spin-coated on the PVA-coated PI sheets. However, there was no notable enhancement in the hole mobility in the devices. This was probably due to a weak interaction between the PVA surface and the HMDS molecules and thus the insufficient surface coverage by the alkyl chains. In the next approach, we grew a self-assembled monolayer (SAM) of octyltrichlorosilane (OTS) on PVA. The PVA-coated PI sheet was immersed into a 10 mM toluene solution of OTS at 65–70 °C for 25 min and rinsed four times with toluene. After this treatment, the contact angle of water droplets on the PVA surface increased from 30–40° (for the bare PVA) to 90°, indicating the sufficient coverage of the OTS on the PVA surface.

The OTS-treatment enhances the hole mobility, as shown in the transfer curves of the flexible 3-TTPPh-5 FETs (Fig. 3). Hole mobility of up to 0.036 $cm^2 V^{-1} s^{-1}$ has been achieved, which is close to that observed for the 3-TTPPh-5 devices on the OTS-treated SiO_2/Si substrates. The on/off ratio keeps nearly constant (10^4). We did not observe any change in the surface morphology and structure of the LC films after the OTS-modification of the PVA surface. Therefore, the mobility enhancement should be attributed to the favorable interaction between the long alkyl chains of the OTS molecules and those of the 3-TTPPh-5 molecules near the initial 2–3 layers of the LC film [57]; however, further investigation must be carried out in this regard. The off-current is slightly higher possibly due to the residual impurities introduced by the OTS-treatment of the PVA surface.

The hole mobility increases further when the liquid crystalline thin films are formed by a solution sheared deposition (SSD) method. High performance FETs based on some of solution-processable oligothiophene derivatives were produced by this method [58]. In our study, the thin film of 3-TTPPh-5 was deposited on the PVA-coated PI sheets which were kept at 80 °C in air. From optical microscopic observation, the resulting films exhibit a better film coverage on the substrate as well as the more homogenous film morphology, compared to the films deposited by spin-coating (not shown here). Moreover the films also show some degree of macroscopic orientation, similar to the observation by Bao et al. on oligothiophene films produced by the SSD method [58]. However, crystal structure of the films formed by the SSD shows no obvious change compared to those by spin-coating from the XRD results.

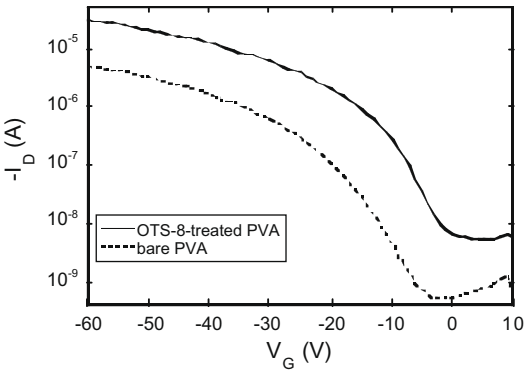

Fig. 3. Transfer curves of flexible 3-TTPPh-5 FET on the bare surface (dotted line) and on OTS-treated surface (solid line) at room temperature. The channel length of the FET is 30 μm.

Fig. 4a and b show the output and transfer characteristics of the FET prepared by the solution sheared deposition. The hole mobility and on/off ratio reach up to 0.05 $cm^2 V^{-1} s^{-1}$ and 10^5, respectively. The threshold voltage value is reduced from −18 V (for the FET prepared by spin-coating) to ca. −8 V. It should be noted that the mobility approaches the value in the bulk state (0.07 $cm^2 V^{-1} s^{-1}$) from the TOF measurement [49], which represents the upper limit of carrier transport.

We tested the mechanical flexibility of the FETs by bending the PI substrate to various radii. The flexible FETs fabricated by the solution sheared deposition on the PVA layer (on a PI substrate) exhibits the hole mobility of 0.05 $cm^2 V^{-1} s^{-1}$ and the on/off ratio of 10^5 before the application of the strain. The extent of bending was measured by attaching the flexible transistor around the cylindrical bars with different radii R, as shown in the inset of Table 1. The derived mobility and threshold voltage are shown as a function of the strain in Fig. 5. The relation between the strain ε and the bending radius R is given as $\varepsilon = d_s/2R$ for our devices. Here, d_s is the substrate thickness (PI sheet) [14,15,59]. Table 1 lists the bending radii used in our experiment and the corresponding strain values. Our flexible devices can be bent to a radius of less than 5 mm. The carrier mobility shows a slight increase with the strain and then remains constant at a high strain of 2.7%. The slight decrease in V_T with strain may be attributed to the effect of mobile ionic impurities in the dielectric layer, as mentioned above. Bending measurements could not be carried out at the smaller bending radii because of the large-size of the device and the relative rigidity of the thick PI sheet (thickness: 0.3 mm) which makes the bending difficult. However, we believe that our LC transistors are capable of functioning even under the higher strain. In addition, the AFM observation did not reveal any marked difference between the film morphologies of the bent FETs and those prior to bending.

Our results are very encouraging when compared to the data on the flexible FETs presented by the other groups [11,12,14,15]. Someya's group has fabricated the flexible pentacene TFT arrays, whose mechanical flexibility represents the best values till date [12]. However, though these devices can be operated under a strain of 2.7%, their hole mobility is decreased by 40%. Therefore, the flexible properties of our devices are comparable to and even better than the OFETs with the best flexibility available at present. It should be mentioned that these authors used the thin polymeric substrates (thickness: 0.1–0.14 mm). The substrates with a thickness of less than 0.3 mm can effectively absorb the mechanical stress and prevent mechani-

cal degradation of the active layer. Our PI substrates are relatively thick (0.3 mm), which may be detrimental to the flexibility of the FETs. However, our flexible LC FETs also exhibit the excellent mechanical flexibility. Better results can be expected from bending measurements if the thinner substrates are used. The excellent mechanical flexibility of LC FETs can be attributed to the inherent softness of liquid crystals. The thermal movement and self-assembling capability of the LC molecules enables self-healing of the dynamic positional disorders (carrier trapping sites) caused by mechanical deformation, and thus, carrier transport in LC semiconductors is not significantly affected by the external strain.

Besides, the large-area homogenous LC 3-TTPPh-5 thin films can be fabricated by a simple spin-coating process. The film morphology and structure are unaffected by the nature of the substrate materials and surface chemistry; these properties facilitate the fabrication of these device by practical methods such as roll-to-roll printing or ink-jet processing. Moreover, all the device fabrication steps were carried out at a low temperature (below 100 °C). These characteristics make the 3-TTPPh-5 a good candidate for large-area, low-cost flexible electronics.

4. Conclusions

In conclusion, we have fabricated the flexible FETs based on the LC 3-TTPPh-5 via solution process. The fabricated devices exhibit good electrical performance with a hole mobility of up to 0.05 $cm^2 V^{-1} s^{-1}$ and mechanical flexibility superior to the normal polycrystalline OFETs. Our results demonstrate that the LC semiconductors are promising materials for the low-cost flexible electronic devices.

Acknowledgements

This study was financially supported by the NEDO Industrial Technology Research Grant, Association of New Chemistry, and Sumitomo foundation. We thank Dr. H. Minamikawa and the Nano-Processing Facility in AIST for providing the XRD apparatus. We also thank Dr. M. Chikamatsu and Dr. R. Azumi from the Photonics Research Institute of AIST for their fruitful advice on fabrication and characterization of FET devices and Prof. T. Kato for the valuable discussion on the material design. We also thank Mitsui Chemicals for providing the polyimide sheets.

ABSTRACT

Two structurally simple Iridium(III) complexes with pyrimidin-imidazole derivatives as the ancillary ligands (Ir**1** and Ir**2**) were synthesized. Photophysical studies showed that the iridium complexes have suitable triplet energy levels for sensitizing Nd^{III}. The efficient energy transfer from Ir^{III} moiety to Nd^{III} is observed in both solutions and films. Utilizing co-deposition film of Ir–Nd assemblies as the emitting layer, nondoped OLEDs were fabricated. EL devices with a structure of NPB (1,4-bis((1-naphthylphenyl)amino)biphenyl, 30 nm)/Ir**1**-Nd(PMIP)$_3$ (1-phenyl-3-methyl-4-isobutyryl-5-pyrazolone, 1:1, 40 nm)/BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline, 10 nm)/Alq_3 (tris(8-hydroxyquinoline), 30 nm) exhibited a NIR emission from Nd^{III} ions. The highest EQE achieved is 0.3%, with a maximum radiance of 6.1 μW cm^{-2} at the main emission wavelength of 1060 nm. This result provides a useful guidance for the future work of lanthanide complexes based NIR OLEDs.

1. Introduction

Organic light-emitting diodes (OLEDs) have been the subject of a significant research effort from both the academic and industrial communities because of their advantages in emission in a wide visible region and great potential to serve in flat-panel displays [1,2]. Near infrared (NIR) OLEDs have many potential applications such as optical communication [3,4], night-vision readable displays [5], and sensors [6]. To date, attempts to achieve NIR electroluminescence (EL) have primarily focused on low band-gap organic chromophores [7–12], polymers [13–19], transition metal complexes [6,20–24], and lanthanide complexes [25–41]. Among many low band-gap organic compounds, π-conjugated donor–acceptor (D–A) type of chromophores and polymers have been investigated for NIR materials. Yang et al. reported D–A–D oligomers that displayed the EL spectra at 815 nm [12]. OLEDs based on polymers were also developed with peaks ranged from 670 nm to 790 nm and an external an quantum efficiency (EQE) of 1.1% and 0.3%, respectively [19]. Recently Qian et al. reported the well designed D–π–A–π–D type chromophores in the OLEDs that displayed emission exclusively at 1080 nm with an EQE of 0.28% [10,11]. On the other hand, the efficiency of OLEDs is markedly improved when fluorescent emissive chromophores are replaced by phosphorescent complexes which can harvest both the singlet and triplet excitons [42–45]. The highest quantum efficiency in NIR OLEDs published so far is about 8% by Borek et al. using a Pt-based porphyrin complex. However, this OLED emits at a peak of 765 nm, which is still far away from the telecommunication window (1310 nm or 1550 nm) [22,23]. Lanthanide complexes based NIR OLEDs have shown NIR EL at a number of important wavelengths (e.g., 890, 977, 1064, 1346, and 1560 nm), being the potential candidates in optical fiber applications. It has got a great development since Curry et al. reported electroluminescence of ErQ complex [25]. Schanze et al. fabricated devices utilizing lanthanide cations in conjunction with a porphyrin/polystyrene matrix by spin-coating. The EQE ranged from 8.0×10^{-4} to 2.0×10^{-4}% [33].

$Ln(diketonate)_3$ units with neutral N,N-bidentate chelates or phosphine oxide ligands were also developed as NIR emitting material [26–29,35–37,41]. Zhang et al. observed an EL intensity enhancement by introducing an iridium complex in emitting layer but the efficiency was not given [38]. To date, most EL performances obtained with Ln^{III} complexes had an irradiances of less than 1 $\mu W\,cm^{-2}$ and an EQE of less than 0.1%. Therefore, it is still a challenge to develop Ln^{III} based NIR OLEDs with a high efficiency for both science and technological applications.

Lanthanide emissions need to be sensitized *via* antenna chromophores because their intra-configurational 4f–4f transitions are forbidden and absorptions are very weak. The use of strongly absorbing d-block chromophores as sensitizers for the NIR emissions from f-block lanthanides has attracted more and more attentions since van Veggel and co-workers reported the first example of Nd^{III} and Yb^{III} luminescence sensitized by the transition metal complexes $Ru(bpy)_3^{2+}$ and ferrocene [46]. Subsequently, many d-block chromophores, based on related transition metals were extensively studied [47–54]. Recently our group reported the characterization of dinuclear Ir–Ln complexes that display NIR emission [55]. As most of the energy levels of these d-block chromophores are around 13,000–18,000 cm^{-1}, energy transfer from the transition metal to the lanthanide ion is most efficient and the characteristic emission from these NIR lanthanides are successfully obtained. But the application of multimetallic assembles on OLEDs has not been reported. In this contribution, we report the design and synthesis of a structurally simple Ir^{III} complex with a suitable triplet energy level for sensitizing Nd^{III}. Efficient energy transfer was observed when Ir^{III} complex served as the neutral ligand for Nd^{III} ions in both solutions and films. As the high molecular weight of the complex precludes direct thermal evaporation, we utilized co-deposition film of Ir^{III} complex and Nd^{III} complex as the emitting layer to fabricate NIR OLEDs. The highest EQE achieved was 0.3%, with a maximum radiance of 6.1 $\mu W\,cm^{-2}$ at the main emission wavelength of 1060 nm. These values are a significant improvement over previously reports.

2. Experimental

2.1. General Information

Alq_3 was synthesized according to literature procedures and sublimed twice prior to use [56]. NPB and BCP were purchased from Aldrich and used after a single sublimation. $Tb(PMIP)_3(H_2O)_2$, $Tb(PMIP)_3(TPPO)_2$ and $Tb(PMIP)_3$ Bath (PMIP = 1-phenyl-3-methyl-4-isobutyryl-5-pyrazolone; Bath = bathophenanthroline; TPPO = triphenylphosphine oxide) were synthesized according to our previous report [56]. Chromatographic separation was carried out on silica gel (200–300 mesh). The ^1H NMR spectra were recorded on a Varian 400 MHz instrument using Me_4Si as an internal reference. Mass spectra were recorded on a ZAB-HS and BIFLEX III. Elemental analyses were performed on a VARIO EL analyzer. Photoluminescence spectra and phosphorescence decay lifetimes were recorded with an Edinburgh Analytical Instruments FLS920 spectrometer after removing oxygen in the solution by a vacuum technique (3 or 4 freeze–pump–thaw cycles) [57]. EL spectra were measured by using liquid-nitrogen-cooled germanium detector on FLS 920. Absorption spectra were measured on a Shimadzu UV-3100 UV–vis spectrometer. Cyclic voltammetry was performed with a computer controlled CHI600C electrochemical workstation. The measurement was carried out at room temperature with a conventional three electrode configuration consisting of a one compartment electrolysis cell with a platinum button, a platinum wire, an Ag/AgCl working electrode, counter electrode and reference electrode. Cyclic voltammograms were obtained at a scan rate of 50 mV s^{-1} in dichloromethane after removing oxygen. The concentration of the complexes was 1.0 mM and each solution contained 0.1 M tetrabutylammonium hexafluorophosphate (TBAP) as an electrolyte.

2.2. OLED fabrication and measurement

OLED devices were fabricated by sequentially depositing organic layers using thermal evaporation in one run under high vacuum ($<8 \times 10^{-5}$ Pa) onto a pre-cleaned indium tin oxide (ITO) glass substrate with a sheet resistance of 7 Ω/sq. A shadow mask with rectangular (3×3 mm) openings was used to define the cathode of a 200 nm thick layer of $Mg_{0.9}Ag_{0.1}$ alloy with an 80 nm thick Ag cap. The thickness of the deposited layer and the evaporation speed of the individual materials were monitored in a vacuum with quartz crystal monitors. Deposition rates were maintained at 0.05–0.2 nm s^{-1} for organic materials and 0.2–0.3 nm s^{-1} for the $Mg_{0.9}Ag_{0.1}$ alloy. The visible EL spectra were measured with a Spectra Scan PR650. The current–voltage (I–V) characteristics were measured with a computer controlled Keithley 2400 Sourcemeter unit. The NIR EL irradiance was measured by using a UDT Model 261 Germanium Detector (calibrated by National Institute of Metrology PR China). A 720 nm filter SCF-50S-72R, purchased from Sigma, was used to preclude the effect of visible light. All the measurements were carried out under ambient atmosphere at room temperature. The EQE of the NIR emission was obtained by measuring the irradiance in the forward direction and assuming the external emission profile to be Lambertian.

l is the distance between the OLED and the detector (1.7 cm), e is the charge of an electron, λ is the emission wavelength (1060 nm), P_{det} is the power that the detector measures, S_1 is the area of the detector (0.25 cm^{-2}), S_2 is the area of the device (0.09 cm^{-2}), h is Planck's constant, c is the speed of light in a vacuum and I is the current injected. According to the literature, [11,58] the flux leaving the device directly, F_{ext}, can be calculated as follows:

$$F_{ext} = \int_0^{\pi/2} 2\pi L_0 \cos\theta \sin\theta d\theta = \pi L_0,$$

where L_0 is the flux per solid angle of light leaving the device directly in the forward direction.

The solid angle from the detector to the light source is as follows:

$$\omega = \frac{S_1}{l^2}$$

$$L_0 = \frac{P_{det}}{\omega}$$

So the irradiance of the device, R ($\mu W\ cm^{-2}$), can be calculated as follows:

$$R = \frac{F_{ext}}{S_2} = \frac{\pi P_{det} l^2}{S_1 S_2}$$

The number of photons can be calculated as follows:

$$N_p = \frac{F_{ext}}{h\nu} = \frac{\pi P_{det} l^2 \lambda}{S_1 hc}$$

The number of electrons can be calculated from the current injected as follows:

$$N_e = \frac{I}{e}$$

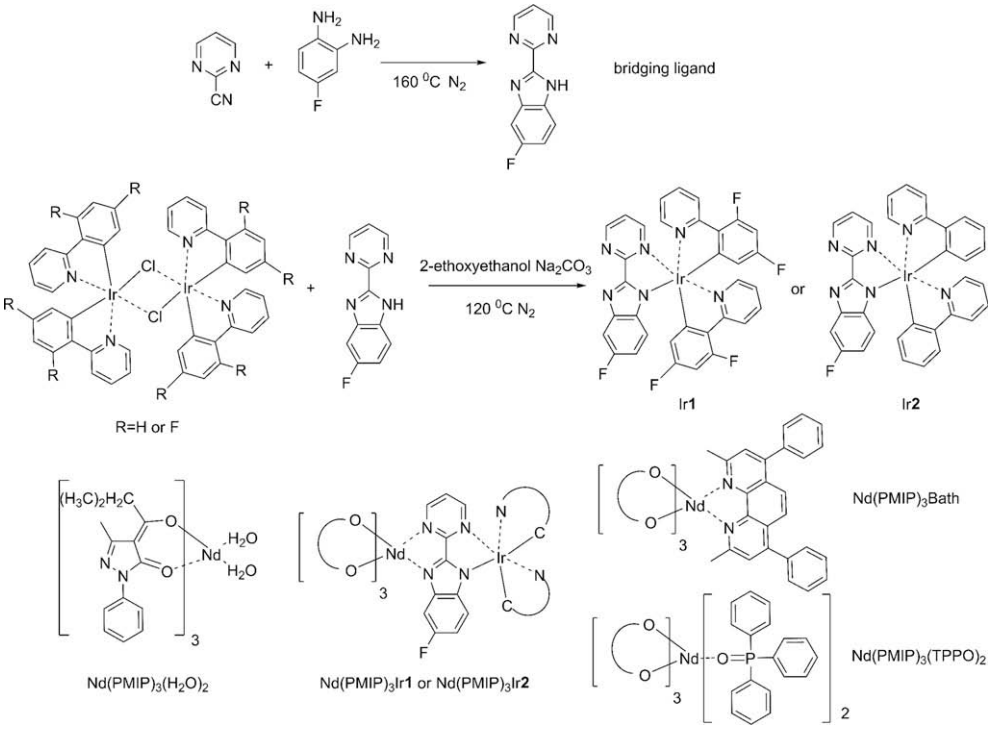
So the EQE was calculated as follows:

$$\eta_{ext} = \frac{N_p}{N_e} = \frac{\pi P_{det} l^2 \lambda e}{S_1 hcI}$$

2.3. Materials

Scheme 1 shows the synthetic route to the Ir^{III} complexes and chemical structures of Nd^{III} complexes. The bridging ligand was obtained by a one-step reaction of pyrimidine-2-carbonitrile and 4-fluorobenzene-1,2-diamine at 160 °C for 2 h [59]. Complex Ir**1** or Ir**2** was prepared from a reaction of the bridging ligand with the corresponding chloride-bridged Ir^{III} dimer: $(dfppy)_2Ir(\mu\text{-}Cl)_2Ir(dfppy)_2$ or $(ppy)_2\ Ir(\mu\text{-}Cl)_2Ir(ppy)_2$, respectively, (dfppy = 2-(4′,6′-difluorophenyl)-pyridinato-N,$C^{2'}$, ppy = 2-phenylpyridinato-N,$C^{2'}$). The iridium ion was coordinated to one N^N site of the bridging ligand, leaving the other N^N site free for chelating with Ln^{III}. PMIP was chosen as the anion ligand because it has shown good thermal-evaporation ability and sensitization ability to Ln^{III} ions in previous reports [37,60,61]. Reaction of $Nd(PMIP)_3(H_2O)_2$ with Ir**1** or Ir**2** in ethanol and recrystallization afforded the dinuclear adducts by displacement of two water ligands from the lanthanide. This synthesis is based on the well-known formation of eight-coordinate adducts between $Ln(diketone)_3$ units and N,N-bidentate chelates. Similar d–f dinuclear complexes have been described by others [49,50,53]. $Nd(PMIP)_3Bath$ and $Nd(PMIP)_3(TPPO)_2$ were also synthesized as reference materials because most reports on lanthanide based NIR OLEDs have used Bath or TPPO as the neutral ligands [27–29,34,35,37,38,41].

Synthesis of Iridium(III) bis(2-(4′,6′-difluorophenyl)-pyridinato-N,$C^{2'}$) (5-fluoro-2-(pyrimidin-2-yl)-benzo[d] imidazole) (Ir**1**): Ir**1** was synthesized in two steps. A mixture of pyrimidine-2-carbonitrile (2 mmol) and 4-fluorobenzene-1,2-diamine (2 mmol) was heated under a N_2 atmosphere at 160 °C for 2 h. The product was purified by recrystallization from ethanol with a yield of 80%. Then the mixture of this compound (1.1 mmol), anhydrous sodium carbonate (5 mmol) and $(dfppy)_2Ir(\mu\text{-}Cl)_2Ir(dfppy)_2$ (0.5 mmol) was refluxed in 2-ethoxyethanol under a N_2 atmosphere for 12 h. After cooling to room temperature, the mixture was poured into water. The crude product was obtained by filtration and then dissolved in $CHCl_3$. The solution was dried in anhydrous sodium sulfate overnight. After evaporation of the solvent, the residue was



Scheme 1. Synthetic route to Ir^{III} complexes and chemical structures of the Nd^{III} complexes.

purified *via* chromatography, using a methanol–CH_2Cl_2 mixture as the eluent. The pure product was obtained as a yellow powder. Yield: 40%. HRESI (*m*/*z*, Ir**1**H$^+$, 100%): calcd. 787.11423, found 787.11771. ^{1}H NMR (400 MHz, $CDCl_3$, δ): 8.96 (s, 2H), 8.28–8.26 (d, J = 8 Hz, 4H), 7.95–7.94 (d, J = 4 Hz, 2H), 7.76–7.52 (m, 10H), 7.18 (s, 2H), 6.99–6.92 (m, 5H), 6.67–6.51 (m, 5H), 6.19–6.16 (q, 1H), 5.87–5.80 (m, 5H).

Synthesis of Iridium(III) bis(2-phenyl)-pyridinato-N,C$^{2\prime}$) (5-fluoro-2-(pyrimidin-2-yl)-benzo[d]imidazole) (Ir**2**): Ir**2** was synthesized using a procedure similar to that used for Ir**1**. Yield: 35%. HRESI (*m*/*z*, Ir**1**H$^+$, 100%): calcd. 715.15975, found 715.16000. ^{1}H NMR (400 MHz, $CDCl_3$, δ): 8.87 (s, 2H), 7.93–7.91 (m, 2H), 7.85–7.81 (t, 4H), 7.70–7.58 (m, 12H), 7.08–7.05 (m, 4H), 7.00–6.98 (m, 2H), 6.92–6.90 (m, 4H), 6.87–6.84 (m, 6H), 6.59–6.53 (t, 1H), 6.47–6.42 (m, 4H), 6.05–6.02 (q, 1H), 5.71–5.69 (q, 1H).

Synthesis of Nd(PMIP)$_3$Ir**1**: to a 1.0 mmol solution of Nd(PMIP)$_3$(H_2O)$_2$ in 20 mL ethanol 1.0 mmol Ir**1** in 50 mL ethanol was added (drop wise) while stirring and the mixture was heated to reflux for 2 h. The yellow solid was collected by filtration and purified by recrystallization from ethanol with a yield of 50%. HRESI (*m*/*z*, Nd(PMIP)$_2$Ir**1**$^+$, 100%): calcd. 1418.26432, found 1418.27013. Anal. Calcd. for $C_{77}H_{72}F_5IrN_{12}NdO_7$ (Nd(PMIP)$_3$Ir**1** + C_2H_5OH) C 54.12, H 4.25, N 9.84, found C 54.03, H 4.19, N 9.91.

Synthesis of Nd(PMIP)$_3$Ir**2**: Nd(PMIP)$_3$Ir**2** was synthesized using a procedure similar to that used for Nd(PMIP)$_3$Ir 1 with a yield of 52%. HRESI (*m*/*z*, Nd(PMIP)$_2$Ir**2**$^+$, 100%): calcd. 1344.30200, found 1344.30398. Anal. Calcd. for $C_{77}H_{76}FIrN_{12}NdO_7$ (Nd(PMIP)$_3$Ir**2** + C_2H_5OH) C 56.50, H 4.68, N 10.27, found C 56.41, H 4.59, N 10.34.

3. Results and discussion

3.1. Absorption, fluorescence and phosphorescence

The absorption spectra of Ir**1** and Ir**2** in CH_2Cl_2 (Fig. 1) show high energy bands from 220 to 380 nm, which are attributed to the π–π^* transitions of the ligand centered states. The weaker absorption bands at longer wavelengths are due to the singlet and triplet metal-to-ligand charge transfer (^{1}MLCT and ^{3}MLCT) transitions. The photoluminescence (PL) spectra of Ir**1** and Ir**2** in CH_2Cl_2 are observed as broad peaks centered at 535 nm and 565 nm, respectively. The lifetimes of the excited state (τ) for Ir**1** and Ir**2** are 1.8 μs and 1.1 μs, respectively, consistent with the emission from the triplet excited state. According to our previous study on Ir–Ln assembles [55], triplet excited energy levels of Ir**1** and Ir**2** are both suitable for Ln^{III} ions with NIR emissions.

The spectroscopic titration of addition of ND(PMIP)$_3$ (H_2O_2) into a solution of Ir**1** in ethanol (Fig. 1b) and PL spectra of films containing a 1:1 ratio of co-deposited ND(PMIP)$_3$(H_2O)$_2$ and Ir**1** or Ir**2** (Fig. 2) both show the efficient energy transfer from the d-block to the f-block. When increasing amount of Nd(PMIP)$_3$(H_2O)$_2$ is added to a solution of Ir**1** in ethanol, the intensity of iridium moiety centered emission decrease. The luminescence intensity at 535 nm of the Nd-Ir**1** (1:1) complex is 10 times lower than that of Ir**1**, indicating efficient energy transfer from Ir**1** to Nd^{III} ions. The PL spectrum of vacuum co-deposited film of Ir**1** and Nd(PMIP)$_3$ (molar ratio = 1:1) also shows strong emission from the $^4F_{3/2} \rightarrow {}^4F_{j/2}$ (j = 9, 11, 13) transitions of Nd^{III} ions (Fig. 2) while the emission from Ir**1** is quenched.

PL quantum efficiency of the emitting material is a key factor for its EL performance. Due to the relatively low efficiency and lack of a sensitive power meter working with an integral sphere at NIR wavelength, we compared the PL intensity of the following films: Nd(PMIP)$_3$, Nd(PMIP)$_3$Ir**1**, Nd(PMIP)$_3$Ir**2**, Nd(PMIP)$_3$Bath and Nd(PMIP)$_3$(TPPO)$_2$ (Fig. 2). Nd^{III} complexes with an Ir complex as the have higher PL intensity, which can be attributed to the more suitable triplet energy levels of iridium complexes for sensitizing Nd^{III} ions. All the complexes with the neutral ligand have higher PL intensity compared to that of Nd(PMIP)$_3$ because the neutral ligand offers the coordination number to the Nd^{III} ions to prevents the quenchers enter the coordination sphere and also help to harvest the light to improve the fluorescence [32].

3.2. Cyclic voltammetric studies

Cyclic voltammetry (CV) was conducted to investigate electrochemical properties of the compounds. The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of the materials were estimated by CV and absorption spectra. The

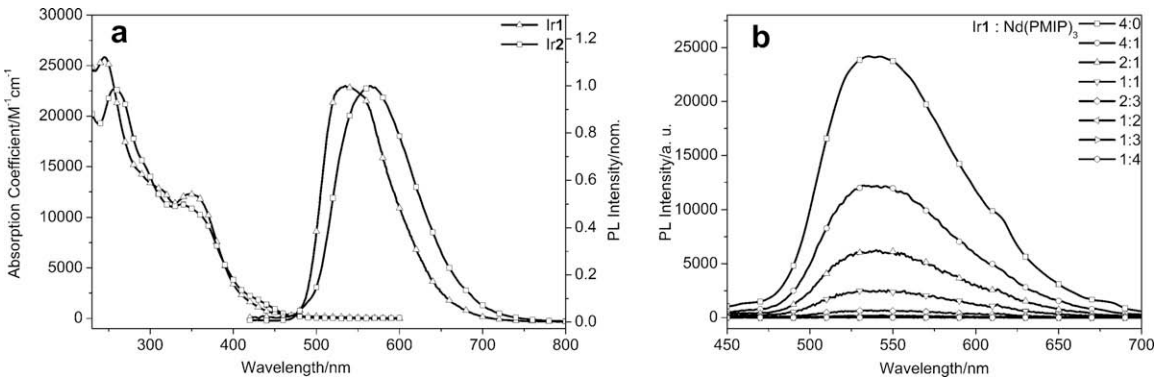


Fig. 1. (a) Absorption and PL spectra of Ir**1** and Ir**2** in dichloromethane (10^{-5} M). (b) Spectroscopic titration by dropping Nd(PMIP)$_3$(H_2O)$_2$ solutions into Ir**1** solution in ethanol (10^{-5} M).

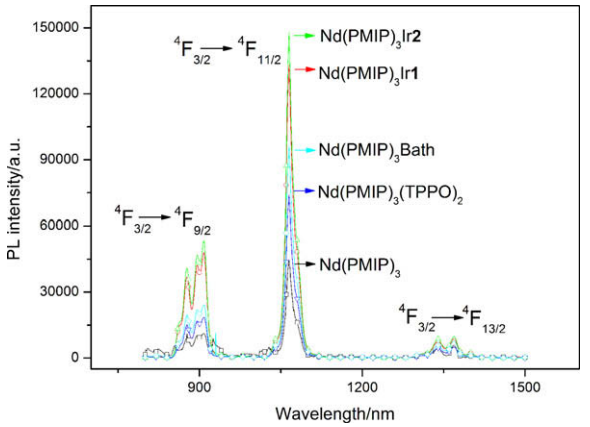

Fig. 2. PL spectra of Nd^{III} complexes at maximum exciting wavelength, measured from their 50 nm vacuum deposited films on quartz slides.

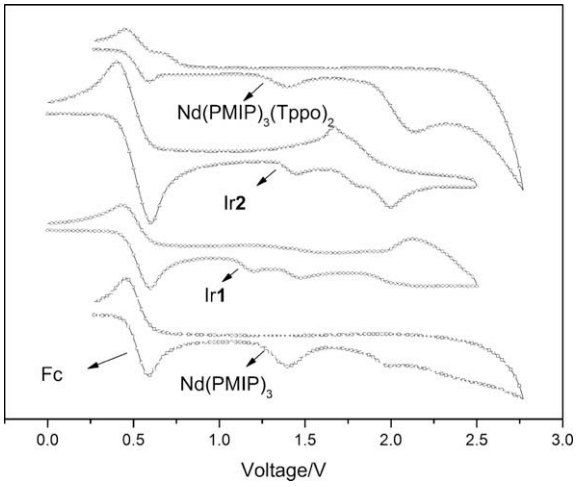

Fig. 3. Cyclic voltammograms of Ir^{III} and Nd^{III} complexes.

highest occupied molecular orbital (HOMO) energy level was calculated from the oxidation potentials by reference to the ferrocene/ferrocenium energy level of −4.8 eV. The energy gap (Eg) between HOMO and LUMO was estimated from the UV–vis absorption spectra. The LUMO energy level was deduced from the HOMO energy level and Eg. The cyclic voltammograms were shown in Fig. 3. $Nd(PMIP)_3$ and $Nd(PMIP)_3(TPPO)_2$ exhibit similar HOMO (−5.4 eV) and LUMO (−2.1 eV) energy level. The HOMO energy level of Ir**1** and Ir**2** was calculated to be −5.4 eV and −5.8 eV. The LUMO energy level was −2.5 eV and −3.1 eV, respectively.

3.3. Electroluminescence properties

All of the Nd^{III} complexes were further evaluated as emitters in NIR OLEDs. 4,4′-bis[N-(1-naphthyl)-N-phenylamino]biphenyl, (NPB), tris(8-hydroxyquinolinato) aluminum^{III} (Alq_3) and 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) was chosen as the hole transporting, electron transporting and hole blocking materials, respectively. A Mg/Ag cathode is used to aid the electron injection and ITO anode for the hole injection. The device configuration is: ITO/NPB (30 nm)/emitting layer (40 nm)/BCP (10 nm)/Alq_3 (30 nm)/$Mg_{0.9}Ag_{0.1}$ (200 nm)/Ag (80 nm). The EL spectra are shown in Fig. 5 and the devices' performance are summarized in Table 1 and Fig. 4. Firstly, we made device A with $Nd(PMIP)_3$ as the emitter. An irradiance of 0.28 μW cm^{-2} at 14.0 mA cm^{-2} and an external quantum efficiency of 0.02% are obtained. This result is of the same order of magnitude with that of previous reports [36,41]. Then the co-deposited film, $Nd(PMIP)_3$:Ir**1** (1:1), is applied as the emitting layer of device B. Compared with device A, device B has a maximum irradiance of 6.1 μW cm^{-2}, 20 times enhancement on intensity, and an EQE of 0.3%, 15 times increase on efficiency. With $Nd(PMIP)_3$:Ir**2** (1:1) as the emitter, Device C shows an irradiance of 5.6 μW cm^{-2} and an EQE of 0.1% at low voltage. The result is lower than that of device B in some extent. Such a phenomenon is likely originated from the different highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels that the complexes exhibit (Fig. 4). In device B the LUMO energy level of Ir**1** moiety is −2.5 eV, which is lower than that of $Nd(PMIP)_3$ (−2.1 eV) and the HOMO energy level of Ir**1** moiety is −5.4 eV, higher than that of $Nd(PMIP)_3$ (−5.6 eV). When electrons and holes are injected into the emitting layer, they are both trapped on the d-block moiety providing excitons. The energy is then transferred to Nd^{III} ions leading to an efficient NIR emission. However, in device C, the HOMO energy level of Ir**2** is −5.8 eV, which is 0.2 eV lower than that of $Nd(PMIP)_3$. So the holes are more likely to be injected onto the $Nd(PMIP)_3$ while electrons are trapped on the d-block moiety. Thus the exciton recombination in device C is not so efficient as that in device B. Meanwhile, device C has a larger current density at each voltage than that of device B. It can be explained by the fact that Ir**2** has a much lower LUMO energy level than that of Ir**1**, which makes electrons easier to be injected

Table 1
Electroluminescent data of NIR OLEDs based on Nd^{3+} complexes.

Device	Emitting Complex	Irradiance (μW cm^{-2})	EQE (%)		
			Highest value	J = 0.1 mA cm^{-2}	J = 10 mA cm^{-2}
A	$Nd(PMIP)_3$	0.28	0.02	0.005	0.002
B	$Nd(PMIP)_3$:Ir**1** (1:1)	6.1	0.3	0.1	0.05
C	$Nd(PMIP)_3$:Ir**2** (1:1)	5.6	0.1	0.07	0.03
D	$Nd(PMIP)_3(TPPO)_2$	2.4	0.01	NA	0.003

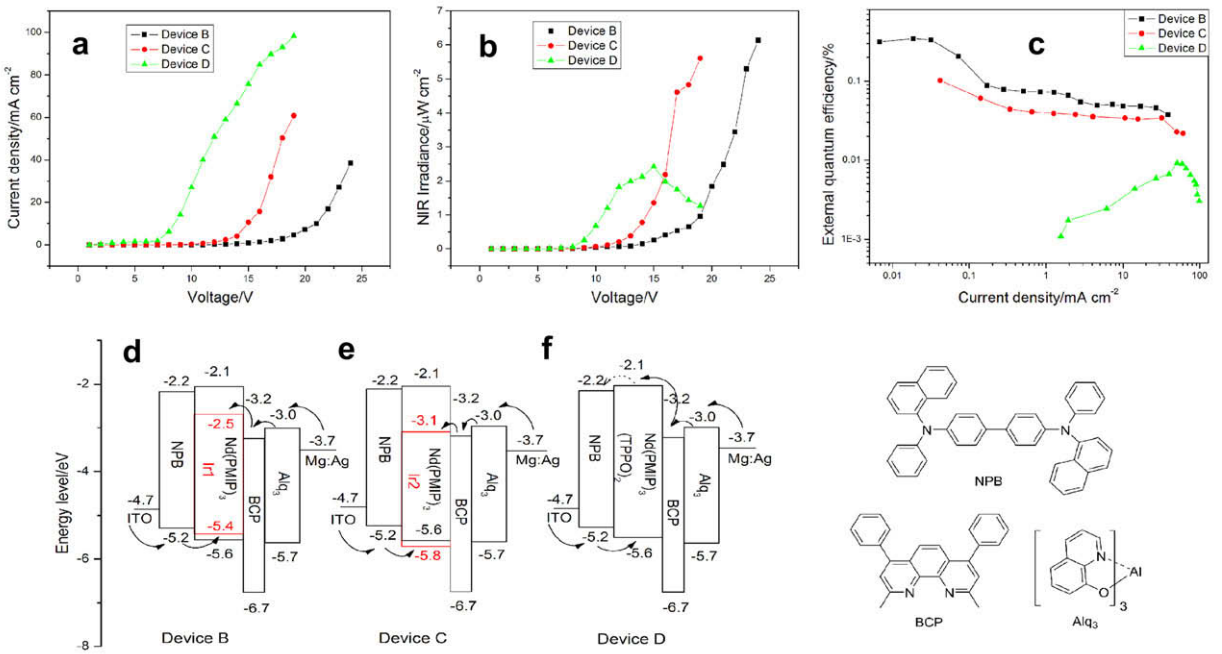

Fig. 4. (a) Current density versus voltage. (b) NIR irradiance versus voltage. (c) EQE versus current density of device B, C and D. (d), (e) and (f) Energy diagrams of device B, C and D.

from BCP layer. Strong roll-off characteristics of efficiencies at high current density are observed in all devices. The phenomenon is thought to be a result of some processes quenching the excited states [57,62,63].

To determine the difference between Ir^{III}-based antenna and traditional small molecular in serving as the neutral ligand, device D with $Nd(PMIP)_3(TPPO)_2$ as the emitter was fabricated. Surprisingly this device does not show much improvement compared to device A. Introducing TPPO moiety into the complex improves the charge-transfer ability of the emitting layer as TPPO is widely used as an electron transporting group. Thus the turn-on voltage, maximum current density and maximum irradiance of device D is improved to 6 V, 98.34 mA cm^{-2} and 2.4 μW cm^{-2}, respectively. However the highest EQE is only 0.01%. It is possible due to excitons not confined well in the emitting layer. Because of the large energy gap between the LUMO energy level of BCP and that of $Nd(PMIP)_3(TPPO)_2$ (Fig. 4f), electrons are difficult to be injected into the emitting layer at low voltages. Meanwhile holes may tunnel through the thin layer of BCP into Alq_3 layer. Thus electrons and holes are mainly combined in Alq_3 layer at low voltages. On the other hand, electrons are easy to be transferred into NPB layer at high voltages because $Nd(PMIP)_3(TPPO)_2$ have a 0.1 eV higher LUMO energy level than that of NPB. Thus as the voltage increases in device D, the combining zone for excitons moves from Alq_3 layer to Nd^{III} complex layer, and then to NPB layer. We measured the visible EL spectra of device D at different voltages. The changing of emitting zone, from Alq_3 layer to NPB layer, was observed (Fig. 6). This phenomenon is accordant with the fact that the NIR irradiance increases and then decreases as the voltage increases (Fig. 4b). The brightness of this visible emission in device D was 269 cd m^{-2} (measured without the filter), five times higher than that of device B. However the NIR EQE measured (with the filter) of device B was 10 times higher than that of device D, indicating that the 720 nm filter precluded the effect of visible light. When Bath is used instead of TPPO as the neutral ligand, device only shows blue emission from NPB. The NIR efficiency is still low (0.02%). These results

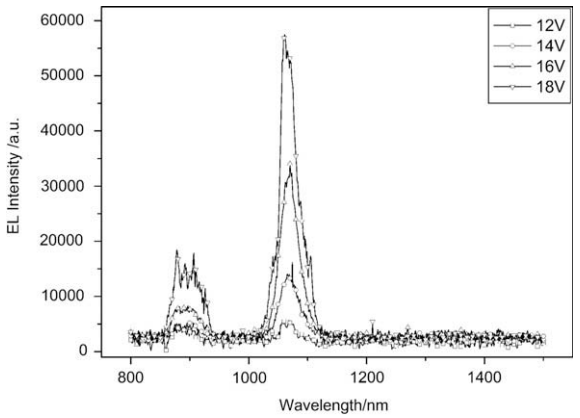

Fig. 5. EL spectra at different voltages of device B (inset: EL spectra at visible region with 720 nm filter).

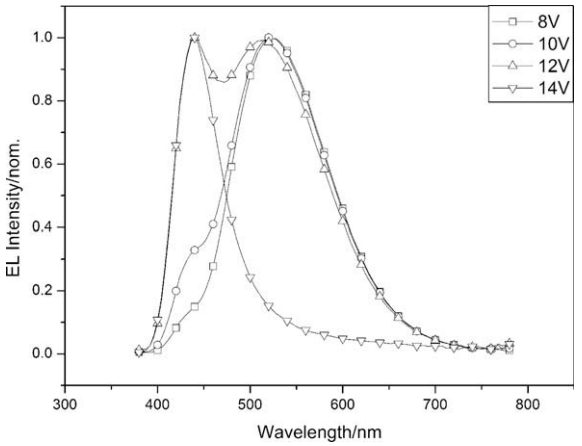

Fig. 6. EL spectra of device D at different voltages (without the 720 nm filter).

indicate that the improvements achieved in device B and C are contributed to both higher PL intensity and more suitable energy levels leading to well confined excitons.

In summary, two structurally simple iridium complexes with suitable triplet energy levels for sensitizing Nd^{III} ions have been synthesized. Efficient energy transfer from Ir^{III} moiety to Nd^{III} is observed in both solutions and films. Utilizing co-deposition film of Ir–Nd assemblies as the emitting layer, nondoped OLEDs were fabricated. The highest EQE achieved is 0.3%, with a maximum radiance of 6.1 $\mu W\,cm^{-2}$ at the main emission wavelength of 1060 nm. Further modifying on transition metal-based antenna and device optimization to further improve the performance of Ln^{III} based NIR OLEDs are in progress.

Crystal structure
Solid state fluorescence and absorption
Ligand–metal exchange coupled states

ABSTRACT

An investigation on the MPc series (M = Zn, Cu, Ni, Fe) targeted at a fundamental understanding of the physical origin of their different performance in organic solar cells is presented. MPc/C_{60} based bilayer hetero-junction (HJC) devices were built and analyzed. The crystal structure in thin films of MPc's was explored by high resolution XRPD and AFM measurements and compared to powder data. The absorption spectra of the evaporated MPc films was observed to differ only slightly, while there was a strong fluorescence quenching for M = Cu, Ni, Fe as opposed to ZnPc. The differences in the solid state fluorescence were further explored by high-level quantum mechanical calculations. Thus, the calculations of the lowest excited states show, that there are intermediate states below the Q-band (π–π^*) excitation for all of the MPc series but ZnPc. It will be discussed, that these states are ligand–metal exchange coupled states, which are treated at the multi-reference configuration interaction (MR-CI) level, in order to account for multi-configurational mixing and double excitations. The implications of these electronic effects on exciton diffusion are discussed and related to device performance.

1. Introduction

Organic photovoltaic could be one solution for future energy supply because of low production costs, light weight of devices and the processibility on flexible substrates. Since Tang [1] presented a 1% efficient bilayer solar cell based on copper phthalocyanine (CuPc) and a perylene tetracarboxylic derivative (PTCBI) in 1986, enormous progress was made in research. The introduction of bulk heterojunction [2,3] and tandem device architectures [4–7] led to devices with power conversion efficiencies close or even higher than η = 6%. For a successful commerzialisation of organic photovoltaic devices it is necessary to increase the power conversion efficiency further. One possibility could be the development of new photoactive materials based on metal phthalocyanine derivatives. Therefore, it is crucial to understand the influence of the central metal atoms on the optical and electrical behavior in solar cell devices on a microscopic level.

Although metal phthalocyanines (MPc) were one of the first compounds used in organic photovoltaics, 20 years later they are still first choice due to their special physical and chemical properties, investigated by numerous experimental and theoretical [8–17,60,61] studies. Depending on the nature of the central metal atom, MPc based solar cells exhibit markedly different device performance. In this

publication, an experimental and theoretical study on zinc (Zn), copper (Cu), nickel (Ni) and iron (Fe) phthalocyanines is presented in which the fundamental physical origin of their characteristic performance in organic solar cells (Fig. 1b) was investigated. We restrict the study to metal phthalocyanines, having the same molecular structure and symmetry (D_{4h}). Thus, a straightforward comparison of their electronic structure was possible.

Since charge transport properties were supposed to depend sensitively on the thin film structure, atomic force microscope (AFM) and high resolution X-ray powder diffraction (XRPD) measurements were carried out. In the course of these investigations the relation between the known crystal structure of α-CuPc [18] and the molecular packing in vacuum deposited thin films was clarified. This relation was described incorrectly in previous publications [19–21]. The optical properties of the respective metal phthalocyanines were experimentally investigated by solid state fluorescence and absorption measurements. Significant differences in the solid-state fluorescence intensity prompted us to undertake an in-depth quantum mechanical study on the excited states of the present MPc series. Details are presented in Section 3. It will be shown, that there are states below the Q-band (π–π^*) excitation for all of the MPc series but ZnPc. These states arise from d–d excitations and ligand–metal exchange coupling. We present for the first time a treatment of these states at the ab initio multi-reference configuration interaction (MR-CI) level. Finally, the implications of these excitation effects on the exciton diffusion capabilities of the respective metal phthalocyanines will be discussed and related to device performance.

2. Experimental and results

2.1. Device setup and characterization

Hetero-junction solar cells were produced using FePc, NiPc, CuPc and ZnPc, respectively, as p-conducting and C_{60} as *n*-conducting organic layers (see Section A for sample preparation). The layer sequence ITO/MPc (10 nm −60 nm)/C_{60} (10 nm −60 nm)/Bphen (6 nm)/Ag (100 nm) was used in the present device setup. The structure of the molecules used as well as the device setup are depicted in Fig. 1. The open circuit voltage V_{oc}, the short circuit current I_{sc}, the fill factor FF and the power conversion efficiency η were obtained under simulated 100 mW/cm^2 AM 1.5 white light illumination. The illumination intensity was adjusted with a calibrated Si detector. Fig. 2 shows the *I–V* characteristics for HJC's with optimized layer setups. The respective layer parameters and key characteristics are depicted in Table 1. With an open circuit voltage V_{oc} of 550 mV, a short circuit current I_{sc} of −5.15 mA/cm^2 and an efficiency η of 1.77%, ZnPc was identified to be the best performing metal phthalocyanine in our bilayer HJC's. All other MPc's showed reduced device performance in the ordering ZnPc → CuPc → NiPc → FePc.

While the thickness of C_{60} has its optimum at 40 nm for all devices, the optimal layer thickness of the metal phthalocyanines varied from 40 nm for ZnPc to 10 nm for FePc. A complete thickness dependence of I_{sc} is depicted in Fig. 2b.

2.2. High resolution X-ray powder diffraction (XRPD)

High resolution X-ray powder diagramms were recored in order to look for a correlation between device performance and the crystal structure of vacuum deposited ZnPc, CuPc, NiPc and FePc films with thicknesses of 1 μm and 30 nm (for details see Section B). As a result, the XRPD diagramm of all investigated materials turned out to be almost identical. For the 1 μm films seven reflection peaks (Fig. 3, Table 2) were observed. At layer thicknesses of 30 nm only the strongest peak at $2\Theta = 6.8°$ could be measured. The peaks at $2\Theta = 21.27°$ and 30.17° are attributed to [2 1 1] and [2 2 2] reflections of the ITO substrate [25]. Comparing the observed reflections with previously published results of MPc films, the crystalline polymorph could be identified as α-phase [26–28] (Table 2). In agreement with present fundamental crystallographic studies [29,30], our observations show, that the crystal structure of the investigated MPc films exhibit the α-form [18], e.g. have a triclinic unit cell. Therefore, it became obvious, that

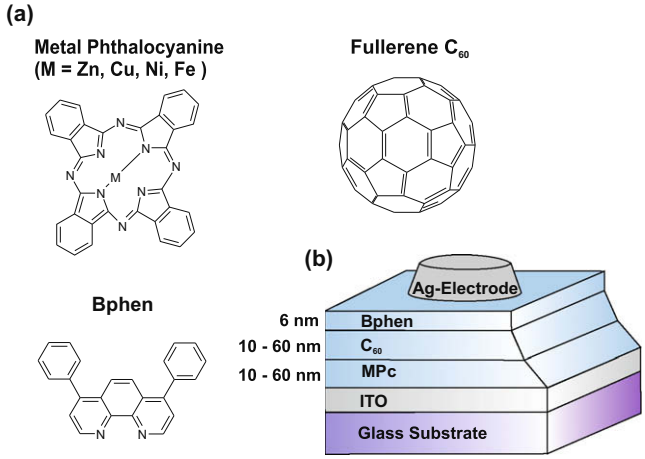

Fig. 1. (a) Chemical structure of the materials used in our bilayer hetero-junction solar cell (HJC). (b) Schematic device structure of the HJC.

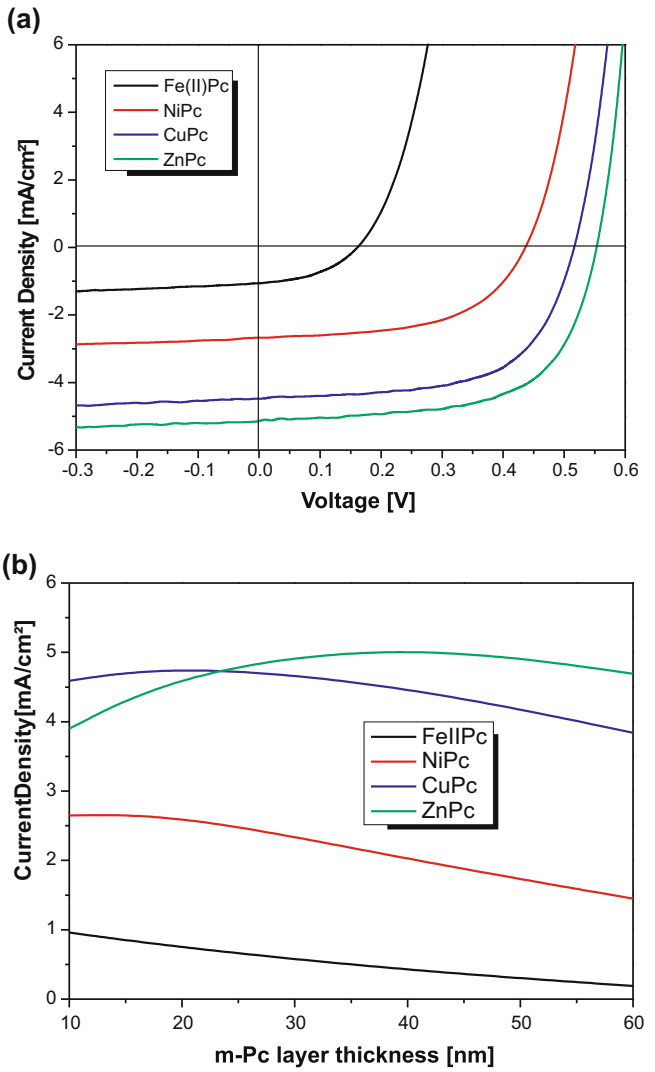

Fig. 2. (a) *I–V* curves of the investigated bilayer hetereojunction solar cells: ZnPc/C_{60}, CuPc/C_{60}, NiPc/C_{60} and FePc/C_{60}. The corresponding device data are given in Table 1. (b) Thickness dependence of the short circuit current I_{sc} (absolute value) of the MPc/C_{60} hetero-junction devices: The layer thickness of the phthalocyanines was varied from 10 nm to 60 nm, while the C_{60} layer was kept constant at 40 nm.

Table 1
Key device characteristics measured for the optimal thickness combination of the MPc and C_{60} layer. The corresponding *I–V* curves are shown in Fig. 2.

MPc	MPc/C_{60} (nm)	V_{oc} (mV)	I_{sc} (mA/cm^2)	FF (%)	η (%)
ZnPc	40/40	550	−5.15	63	1.77
CuPc	40/40	520	−4.48	61	1.42
NiPc	20/40	440	−2.67	55	0.64
FePc	10/40	160	−1.06	42	0.07

the monoclinic β modification [23], having a completely different arrangement shown in Fig. 3c, has been erroneously used to describe the crystal packing in previous publications [19–21].

For the 30 nm vacuum deposited MPc films the calculated crystallite sizes, based on the [0 1 0] reflection peak, were found to be identical to the film thickness. For the 1 μm films no domain sizes >50 nm were observed in agreement with complementary AFM studies (Fig. 4, details in Section C): With a diameter of (27.6 ± 8.7) nm NiPc shows the largest grains followed by ZnPc with (23.6 ± 8.91) nm, FePc with (22.2 ± 6.5) nm and CuPc with (21.1 ± 8.5) nm.

As no significant differences regarding packing and grain size in the different metal phthalocyanines were found, the performance variation (Table 1) of the fabricated devices is assigned tentatively to electronic properties.

2.3. Absorption and fluorescence of vaccum deposited metal phthalocyanine films

The optical absorption of all investigated MPc films was measured on quartz glass. As depicted in Fig. 5a, the 30 nm thick phthalocyanines films showed similar spectra with slight characteristic differences. With respect to the

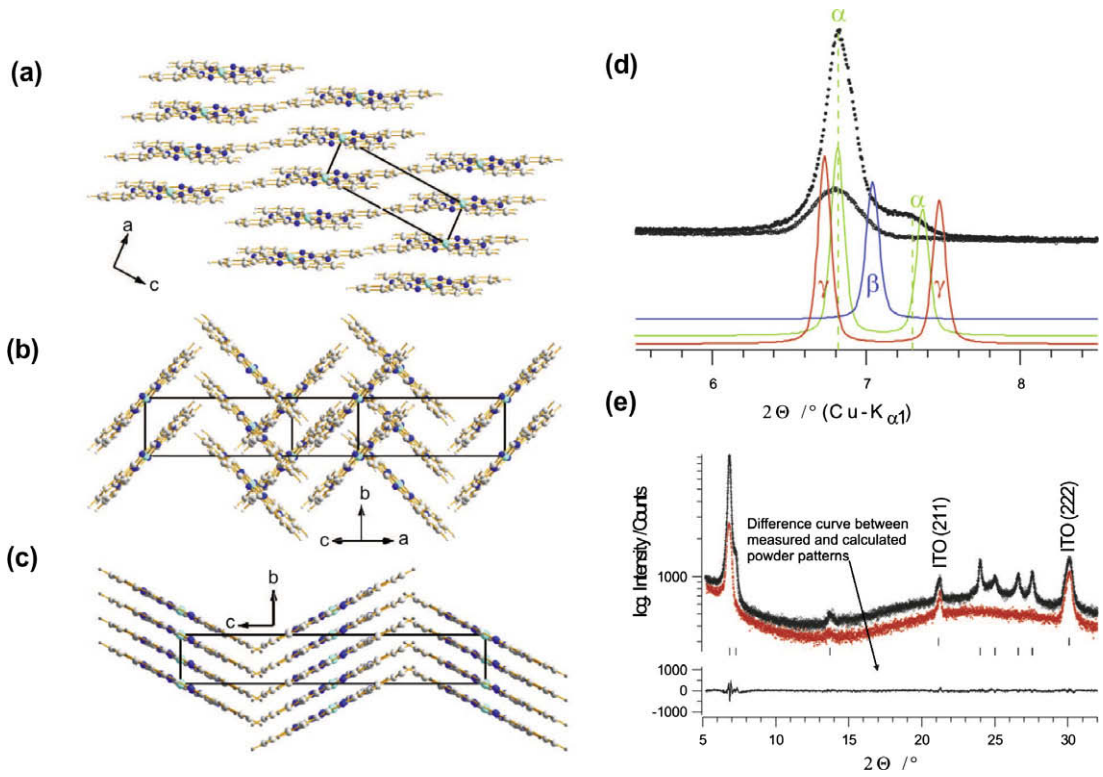

Fig. 3. (a–c) Crystal packings of three polymorphic forms of CuPc showing different arrangements of the CuPc molecules: (a) triclinic α-phase [18] showing parallel stacks in a single orientation. (b) Monoclinic β-phase [22] exhibiting a herringbone arrangement and (c) the also monoclinic γ-phase [23] with parallel stacks in a zigzag fashion with a dihedral angle of 54.8° between neighboring stacks. (d) Low angle region of powder patterns of 1 μm and 30 nm thick, vacuum deposited CuPc films on ITO, compared to calculated powder patterns of α-, β-, and γ-CuPc. (e) Full powder patterns of the 1 μm and 30 nm thick films shown partly in (d) in logarithmic intensity scale. For the 1 μm film, a calculated profile is given, consisting of a LeBail fit [24] of the ITO substrate and seven individually fitted peaks of α-CuPc. The peaks markers of the two phases and the difference curve between measured and calculated powder patterns are given below.

Table 2
Observed reflections of the 1 μm CuPc films in values of 2Θ compared with the calculated powder pattern of α, β, and γ-forms obtained from the CCDC data base. For the 30 nm films only the first reflection at $2\Theta = 6.85°$ could be detected.

Observed peaks	α-Form [18]		γ-Form [23]		β-Form [22]

27.56	27.55	12-1	27.53	31-3	27.65	60-2

[a] The large deviation from the theoretical peak position could be explained by the strong overlap with the first reflection.

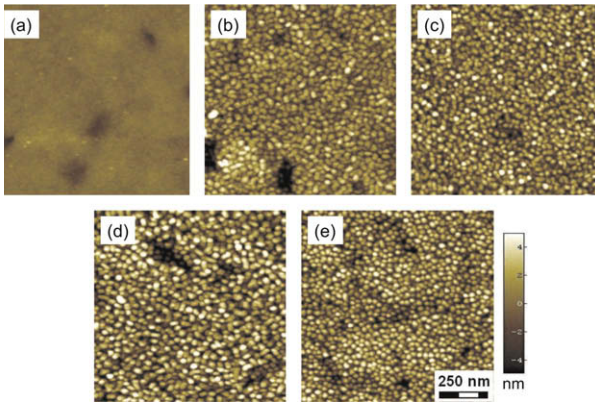

Fig. 4. AFM images of 30 nm thin films of (b) ZnPc, (c) CuPc, (d) NiP and (e) FePc grown on ITO coated glass. The used ITO (a) is in average very smooth (RMS = 0.48 nm), however slight hight differences of up to 3 nm could be detected (dark parts in the SEM picture).

current-thickness dependence shown in Fig. 2b it is concluded, that the absorption strength, which varied at most by a factor of two, could not explain the five times higher current of ZnPc compared to FePc in the present solar cells. Thus, the differences in absorption cannot account for the huge differences in the device performance of the MPc's.

The fluorescence spectra of evaporated ZnPc, CuPc, NiPc and FePc films were also measured on quartz glass. The applied technique is explained in Section D. As depicted in Fig. 5b, the fluorescence intensity of ZnPc was measured to be ninety times stronger than that of CuPc. The fluorescence of NiPc and FePc was below the detection limit. Interestingly, in contrast to the very similar structure and

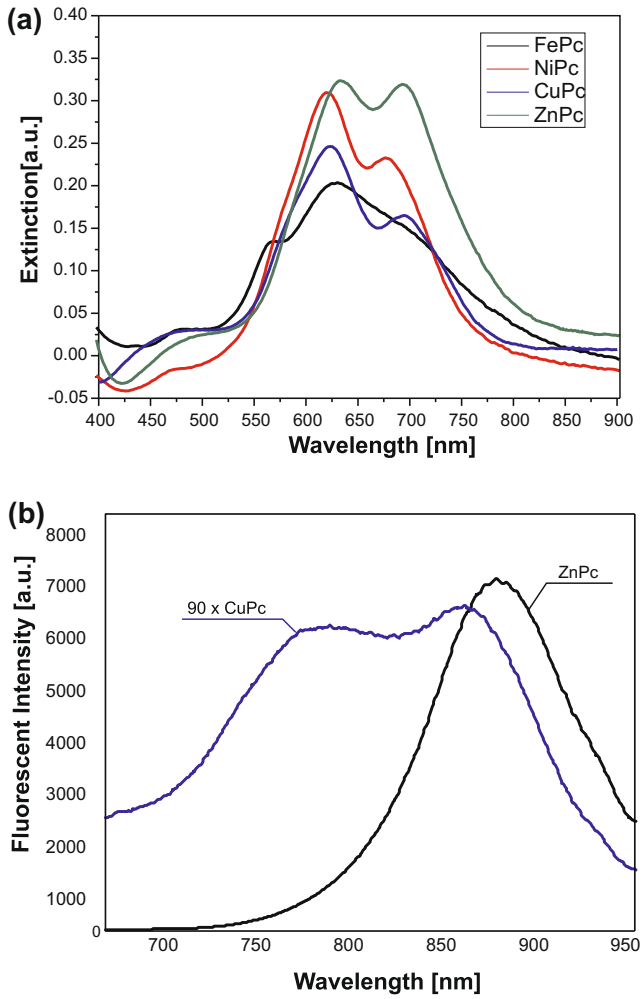

Fig. 5. (a) Absorption spectra of 30 nm thick evaporated films of ZnPc, CuPc, NiPc and Fe(II)Pc. (b) Fluorescence spectra of vacuum deposited films of CuPc and ZnPc with a thickness of 800 nm. The films were excited at a wavelength of 532 nm. The fluorescent quantum yield of CuPc is measured to be ninety times weaker than for ZnPc. The broad shape of the CuPc spectra has its origin in impurities of the vacuum deposited film.

absorption characteristics, the fluorescence quantum yield of the investigated MPc films differed tremendously from each other. These variations of the solid state fluorescence were further explored by high-level quantum mechanical calculations.

3. Computational results of ligand–metal exchange coupled states

Electronic ligand–metal exchange coupling is a general phenomenon observed in many transition metal complexes. An excellent introduction to this subject is given in Ref. [31].

It was demonstrated already in early theoretical work, e.g. on CuPc [33], that exchange coupling of the metal center with ligand triplet states gives rise to spin-allowed transitions at low energy [31], i.e. a doublet (tripdoublet) [34] state in CuPc. Results from ultrafast spectroscopy indicate that this state is responsible for efficient fluorescence quenching and intersystem crossing to the quartet [35]. While there are a number of more recent theoretical studies on the excited states of MPc's [8–17,60,61], a rigorous theoretical treatment of the ligand–metal exchange coupled states (LMEC states) is lacking to this date. Herein, we calculated the low-energy LMEC states by an *ab initio* multi-reference configuration interaction technique (MR-CI) [36], specifically the Spectroscopy-Oriented CI (SORCI) approach by Neese [32]. Our calculations explicitly take into account double-excitations and multi-configurational mixing. In the case of FePc, NiPc, and CuPc, LMEC states are located energetically well below the Q-band excitation on the phthalocyanine ligand at around 1.7 eV. Because the oscillator strength of a transition from ground state to the LMEC state is zero, the corresponding absorption features are not obvious. However, it is important to note that the LMEC states considered here are of the same spin as the respective ground states. Therefore, they may be populated on the femto- to picoseconds timescale by internal conversion from the initial ligand excited state. This process is expected to lead to a fast de-population of the initial excited

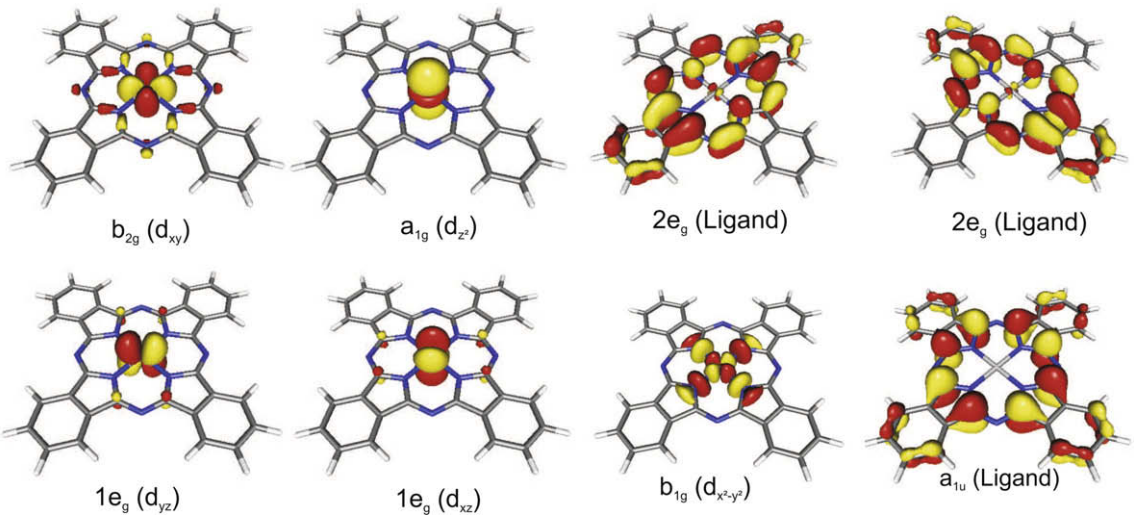

Fig. 6. Relevant frontier orbitals of the MPc's considered in the present study. Shown orbitals are state-averaged natural orbitals from a DDCI2 calculation [32] on FePc. The corresponding orbitals of ZnPc, NiPc and CuPc are qualitatively the same, with a somewhat larger admixture of ligand π and metal d_{xz}/d_{yz} orbitals.

state, and could therefore influence effectively the solid state fluorescence of the corresponding MPc's.

3.1. Relative energy of ligand–metal exchange coupled excited states

The electronic structure of the MPc series (M = Fe, Ni, Cu, Zn) in their ground and excited states is defined by differential occupations of the representative molecular orbitals (MOs) depicted in Fig. 6. Three points have to be emphasised:

1. The metal *d* orbitals give rise to the following MOs, classified according to their irreducible representation in D_{4h} symmetry: $b_{2g}(d_{xy}), a_{1g}(d_z^2), 1e_g(d_{xz,yz}), b_{1g}(d_{x^2-y^2})$.
2. The relevant ligand-based orbitals for the low-energy excitations are the a_{1u} orbital and the set of degenerate $2e_g$ orbitals.
3. The mixing of ligand and metal MOs is quite small, hence the picture of weakly exchange coupled electronic systems is justified.

Because we did not aim for the calculation of the higher-energy B-band region, the a_{2u} MO has not been included into the reference space of our calculation.

Ligand–metal exchange coupled (LMEC) states which have the same spin as ground state, and which are lower in energy than the optical excited state (the Q-band, i.e. the ligand based $a_{1u} \rightarrow 2e_g$ excitation) were found to be present for all molecules under study but ZnPc. An increasing number of electronically excited states was obtained energetically below the initially excited ligand-based π–π^* state (Q-band) going from ZnPc (zero) → CuPc with one → NiPc with two → FePc with over six excited states. In Table 3 the MR-CI ground state configurations are summarized, while the excited states are listed in Table 4. In the following, we have adopted the nomenclature for LMEC states from Ref. [31], where $^{2S+1}L(M_s)^{2S'+1}M(M'_s)$ denotes a LMEC state with a ligand L of multiplicity $(2S + 1)$ and magnetic spin quantum number M_s and a metal *M* of multiplicity $(2S' + 1)$ and magnetic spin quantum number $M_{s'}$. The nature of the LMEC states are assigned in Table 4 accordingly, where we give appropriate linear combinations to account for the correct symmetry of the wavefunctions, but have dropped orthonormality coefficients for the sake of brevity. A pictorial representation of the leading configurations is given in Fig. 7. Detailed information of the respective calculated excited states of each of the MPc's are presented in the supporting information.

4. Discussion

The similar molecular structure, packing and grain size of the MPc's as well as their absorption offers no explanation for the huge performance variation in organic solar cells. However, the solid state fluorescence spectra of the

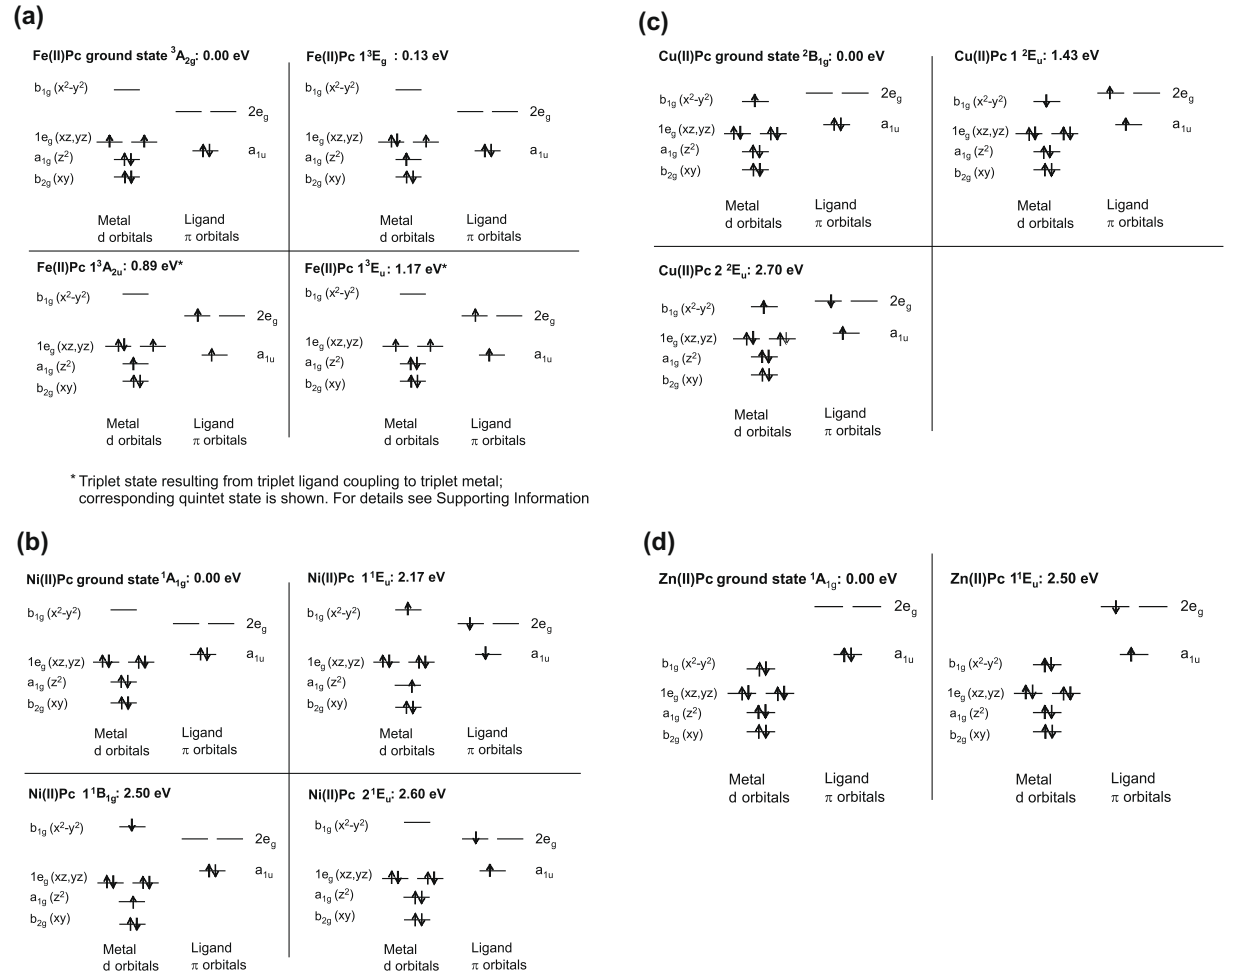

Fig. 7. Leading electronic configurations of the ground states and lowest excited states of the same spin manifold obtained from SORCI calculations for (a) FePc, (b) NiPc, (c) CuPc and (d) ZnPc. For FePc, the configuration $1\,^3B_{2g}$ (d–d excitation) state has been omitted.

investigated MPc films were shown to differ significantly from each other. Based on the quantum mechanical calculations of the excited states in the MPc's, there is a strong evidence, that the different fluorescence behaviors are based on characteristic ligand–metal exchange coupled states (LMEC states).

To correlate the influence of the LMEC states with the device performance of the respective phthalocyanines,

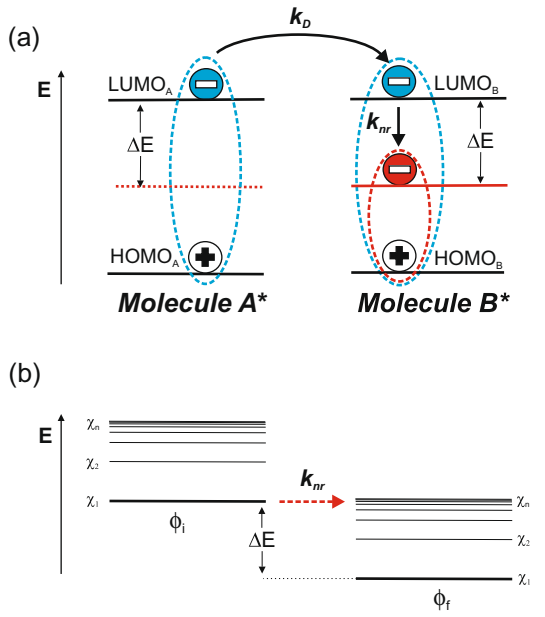

Fig. 8. (a) Schematic picture describing the influence of the calculated LMEC-state of CuPc (Table 4) on the exciton transport: CuPc has one additional calculated excitation which is lowered by a ΔE of 1.27 eV compared to the π–π^* Q-band excitation. This intermediate state has the same spin as the respective initial state and therefore may be populated on the femto- to picoseconds timescale by internal conversion. Thus, excitons moving with a rate k_D from molecule A to B (the * at A and B in the picture should indicate that the molecules are not charged but excited) towards the donor–acceptor (DA) interface could concurrently relax non-radiative with a rate k_{nr}. These relaxed excitons are now either trapped or they cannot split at the DA interface due to their strong binding. Hence, they cannot contribute to the current in an organic solar cell. (b) None radiative energy conversion in a polyatomic molecule. The rate of the none radiative deactivation processes k_{nr} depends on the density of the states ρ_v as well as on the overlap of the vibronic wavefunctions in the final and initial state.

one has to consider, that excitons diffuse after their generation towards the donor–acceptor interface[1] with a certain rate k_D. Concurrently, these excitons could relax nonradiatively with a rate k_{nr} by increasing their binding energy (Fig. 8). In case of the presence of LMEC-states below the Q-band excitation ($a_{1u} \rightarrow 2e_g$) this relaxation process is supposed to become very likely.

Therefore, it has to be discussed whether the exciton diffusion rate k_D or the none radiative relaxation k_{nr} is dominant and therefore formative for the device performance of the investigated metal phthalocyanines.

4.1. Implications of the excitation effects on the excitation energy transfer

Incoherent exciton hopping is described in the weak coupling limit, which means that interchromophore electronic coupling is weaker than the donor excited state vibrational reorganisation energy. In this case, the bimolecular rate k_D for excitation energy transfer takes the form [37]

$$k_D = \frac{2\pi}{\hbar} V_{DA}^2 F_{DA}, \tag{1}$$

where V_{DA} is the electronic coupling integral for excitation energy transfer and F_{DA} the overlap between donor emission and acceptor absorption spectra, normalized on an energy scale (derived from the Franck–Condon weighted density of states, the product of the density of vibrational states in the initial and final states and their overlap). Under the assumption of separate chromophores, V_{DA} is dominated by the Coulomb integral

$$J = \frac{1}{4\pi\varepsilon_0} \int dr_1 dr_2 \phi_A^{HO}(r_1)\phi_A^{*,LU}(r_1)\frac{1}{r_{12}}\phi_B^{HO}(r_2)\phi_B^{*,LU}(r_2). \tag{2}$$

$\phi_A^{HO}(\phi_A^{*,LU})$ is the HOMO (LUMO) on the donor molecule A and $\phi_B^{HO}(\phi_B^{*,LU})$ is the HOMO (LUMO) on acceptor molecule B. This integral may be approximated by a simple dipole [38,39] or even multipole [40–42] interaction energy. It is noted that a quantitative estimation of intermolecular coupling between closely packed molecules requires also the inclusion exchange and penetration terms [43–46]. We consider excitation energy transfer only between the ($a_{1u} \rightarrow 2e_g$) excited states for all investigated MPc's.[2] Because a_{1u} and $2e_g$ are essentially unaffected by the metal center (depicted in Fig. 6), the electronic coupling integral, described in Eq. (2), and therefore V_{DA} will be equal for all MPc's.

With respect to the analogy of the absorption and normalized fluorescence spectra (Fig. 5), F_{DA} is expected to be similar as well. Based on these perceptions k_D can assumed to be similar for all MPc's.

4.2. Implications of the excited state spectrum on the non-radiative deactivation

Non-radiative deactivation processes within molecules can be characterized by matrix elements derived from the time-dependent pertubation theory. Under the assumption of weak coupling, the wavefunctions ψ can be divided (Born–Oppenheimer approximation) in an electronic ϕ and a vibrionic χ part. Therefore, the rate for non-radiative deactivation k_{nr} can be written [47] as

$$k_{nr} \sim \frac{2\pi}{\hbar} \left\langle \phi^f | H' | \phi^i \right\rangle^2 \langle \chi_i | \chi_f \rangle^2 \rho_v, \tag{3}$$

where H' is the pertubation operator. In the case of internal conversion between states of equal multiplicity (which is the case here) it has been shown, that H' is the operator of the kinetic energy of the cores [47]. Based on Eq. (3) it becomes obvious that the excitation energies (Table 3) of the respective phthalocyanines must have a significant influence on the radiationless deactivation processes described by k_{nr}: As depicted in Fig. 8b the density of states

[1] Valid in vacuum deposited organic bilayer and bulk heterojunction solar cells.

[2] To split excitons at the donor–acceptor interface into free charge carriers it is widely accepted, that the present energetic offset between the HOMO of the donor (metal phthalocyanines) and the LUMO of the acceptor (C_{60}) have to be equal or somewhat larger than the exciton binding energy. Thus, only Q-band excitons are considered to be able to split at the MPc/C_{60} interface.

ρ_v in the final state increases with the size of the energy gap ΔE between the final and initial state. At the same time the electronic excitation energy which has to be absorbed by the lattice vibration is also rising. Thus, $\langle \chi_i | \chi_f \rangle^2$ decreases due to the lower overlap of the vibrational wavefunctions with different vibrational quantum numbers. Concerning the investigated metal phthalocyanines this means, that k_{nr} depends on the number as well as on the energetic difference of the LMEC-states lying in between the initially excited state and the ground state: As more LMEC-states are available and as closer their energetics are, k_{nr} will increase due to Eq. (3). Thus, FePc is expected to have the highest relaxation rate k_{nr} and ZnPc the lowest.

4.3. Relation between device performance and excited state spectrum

Exciton transport is in general characterized by the effective exciton diffusion length L_{ex}

$$L_{ex} = \sqrt{D \cdot \tau}. \quad (4)$$

The lifetime τ is related to k_{nr} as

$$\tau \sim \frac{1}{\sum_i k_{i,nr}}, \quad (5)$$

while D is directly proportional to k_D,

$$D \sim k_D. \quad (6)$$

Based on the presented experimental and theoretical results (*vide supra*) D is assumed to be similar while an increasing number of intermediate states leads to a decreasing τ depending on the metal phthalocyanine of interest. Obviously, the differences in lifetime τ will lead to different values of L_{ex} in the present MPc series. This is in agreement with experimental results [48–51]. Furthermore, the optimized thickness of the MPc layer in the device decreases in the series ZnPc → CuPc → NiPc → FePc which is another indication that L_{ex} decreases in same series, as less excitons are able to reach the donor–acceptor-interface.

Besides the specific exciton diffusion length L_{ex}, also the hole mobility μ is considered to have an influence on I_{sc} and the fill factor. Therefore, the electronic effects which affect the characteristic hole mobility still have to be elucidated; work in this regard is currently on going in our laboratories.

5. Conclusion

In summary a study on different metal phthalocyanines (MPc's with M = Zn, Cu, Ni, Fe) was presented in which the fundamental physical origin of their characteristic performance in organic solar cells was investigated under a structural, optical and electronic point of view. MPc/C_{60} based bilayer hetero-junction solar cells exhibited a clear dependence of the optimal layer thickness and overall performance on the employed MPc material. The origin of these differences were explored by AFM and high resolution XRPD measurements on powder and evaporated thin films. In the course of these measurements it was found, that all MPc's exhibit a similar thin film crystal structure. Furthermore, the relation between the known crystal structure of α-CuPc [18] and the molecular packing of vacuum deposited thin films was clarified.

The optical properties of the metal phthalocyanines were investigated by solid state fluorescence and absorption measurements. While the MPc molecules under study have similar absorption characteristics, they differ markedly by their fluorescence spectra. Based on this finding, the lowest excited states of the MPc series were explored by correlated multi-reference ab inito calculations. An increasing number of excited states is obtained energetically below the initially excited ligand-based π–π^* state (Q-band) going from ZnPc (zero) → CuPc with one → NiPc with two → FePc with over six excited states. These states arise from d–d excitations and ligand–metal exchange coupling. It is argued that an increasing number of intermediate states lead to increasing rates for non-radiative relaxation. This will directly affect the lifetime and therefore the diffusion lengths L_{ex} of photoelectrically active excitons in the present MPc series. Thus, the effect offers a straightforward explanation for the experimentally observed reduced device performances from ZnPc to FePc.

Acknowledgments

We acknowledge the financial support of the Fonds der chemischen Industrie (FCI) and the Bundesministerium für Bildung und Forschung (BMBF) within the project OPEG, Förderkennzeichen F13N9714. Furthermore we thank Erwin Thiel for the solid state fluorescence measurements. We would also like to thank Frank Neese for helpful discussions.

Appendix A. Sample preparation of the metal phthalocyanine/C_{60} bilayer hetero-junction (HJC) solar cells

To ensure a reproducible purity of the used phthalocyanines all compounds were gradient sublimed before they were used in devices. A bilayer phthalocyanine/C_{60} heterojunction cell architecture was used for all devices to guarantee a defined layer structure and a high reproducibility of the solar cell performance.

A prestructured ITO covered glass substrate with an active area of 31.5 mm^2 was exposed to UV-light during 30 min, to lower the ionisation potential (IP) of the ITO. The substrate was then transferred into a high vacuum evaporation chamber (2×10^{-6} mbar). At first the metal phthalocyanines were evaporated with rates of 2 Å/s and layer thicknesses of 10–60 nm. This was followed by a C_{60} layer (2 Å/s, 10–60 nm) and a 6 nm thick Bphen (4,7-diphenyl-1,10-phenanthroline) layer (0.6 Å/s). The active area of our device was defined by a 100 nm thick silver electrode (5 Å/s) which was evaporated on top of the organic layers. A schematic picture of the layer setup is depicted in Fig. 1b.

Appendix B. High resolution X-ray powder diffraction

B.1. Sample preparation and measurement setup

Fe, Ni, Cu and Zn-Phthalocyanine layers of 30 nm and 1 μm thickness were vacuum deposited (2×10^{-6} mbar) with a rate of 2 Å/s on precleaned ITO covered glass substrates. High resolution X-ray powder diffraction patterns of thin films were recorded at room temperature. A laboratory powder diffractometer (D-8, Bruker, Cu Kα_1 radiation from primary Ge(1 1 1) Johannson monochromator; Lynx-Eye position sensitive detector (PSD) with an opening angle of 3°) in Bragg–Brentano mode was used. The sample was loaded on a plexiglas sample holder with a 2 mm deep cavity of 32 mm diameter. The samples were aligned such to minimize sample height errors and rotated during measurement for better particle statistics. Data were generally taken in steps of 0.009° [2Θ] from 2.0°–62.0° [2Θ] at a scanning speed of 0.5°/min.

B.1.1. Sample height correction

To account for the small but (almost) unavoidable sample displacement error, a glass substrate with a sole ITO thin film was aligned carefully in a previously calibrated sample holder and used as reference standard. The (2 2 2) reflection as the strongest reflections of ITO turned out to be largely insensitive to peak shifts and could thus be used as a suitable reference for correcting the sample height error. This approach is based on the assumption that the position of the (2 2 2) reflection of ITO is constant throughout all samples under investigation which seemed to be reasonable [52]. The calculated cubic lattice parameter was fixed to 10.28104 Å. LeBail fits [24] using exclusively the (2 2 2) reflection of ITO for all samples containing ITO, immediately revealed individual sample displacement parameters and allowed the angular correction of the reflections of the different phthalocyanine samples.

B.2. Determination of domain size

The fundamental parameter (FP) approach [53] was used to describe the peak profile of our 1 μm and 30 nm thick evaporated MPc films using direct convolutions of wavelength distribution, the geometry of the diffractometer and the microstructural properties like domain size and microstrain. Due to the fact that the geometry of the Lynx-Eye position sensitive detector is not fully characterized by FP's, fine tuning of the available parameters was performed by using refined values of the FP's from a precise measurement of the NIST line profile standard SRM 660a (LaB_6) measured in a silicon (9 1 1) low background sample holder over the full 2Θ range of the diffractometer.

Appendix C. Estimating the grain size from the AFM images

The morphology of 30 nm thick films of different metal phthalocyanines vacuum deposited on ITO coated glass was investigated with an atomic force microscopy (AFM) with Si-tips (resonance frequency 68 kHz, force constant 1,3 N/m) used in tapping mode. As shown in Fig. 3, the used ITO is very smooth (RMS = 0.48 nm) but with height differences of up to 3 nm not completely flat. This influences the further film growth of the organic materials, resulting in dints in the Pc film (Fig. 3). All Pc's show a similar topography and their crystallite sizes are only slightly different. For estimating the grain size from the AFM images a threshold method was used. First, the images were flattened with a third grade polynomial fit. Only structures higher than the threshold level of the geometrical mean were taken into account and the average diameter d of their 2D projection was calculated.

Appendix D. Fluorescence measurement technique

Due to the in general low fluorescent quantum yield of the measured phthalocyanines the smallest and almost unavoidable amount of fluorescence light coming from impurities became significant. To get still a clear and reliable measurement signal the ZnPc and CuPc films were exposed with a 532 nm laser which describes a significant shift to the maximum absorption regime of the respective phthalocyanines. Using this technique we were able to avoid overlap coming from parasitaric impurities within the phthalocyanine films by shifting their fluorescence peaks to shorter wavelength than the fluorescence of the MPc's.

Appendix E. Theoretical methods

The metal basis set was triple-ζ quality with polarization functions (TZVP [54]). The ligand heavy atoms were treated with a split valence basis and polarization functions, while hydrogens do not carry polarization functions (SV(P) [54]). This basis set leads to overall 625 basis functions, and is expected to give qualitatively meaningful results in a correlated ab initio calculation.

Geometry optimizations were carried out under D_{4h} symmetry constraints at the B3LYP [55–57] density functional theory (DFT) level, using TURBOMOLE, v5.10 [58]. All molecules were optimized in the respective ground states that are indicated in the main text.

The multireference-configuration-interaction (MRCI) calculations were done with the the spectroscopy oriented CI (SORCI,[32]) procedure as implemented in ORCA [59].

The reference wavefunctions were built by the complete-active-space (CAS) technique, involving the relevant frontier orbitals n, containing m electrons – CAS(n,m) – of the molecule under study. In order to keep the MR-CI calculation tractable and balanced, we have chosen CAS(n,m) to be for ZnPc: CAS(2,3); CuPc: CAS(3,4); NiPc: CAS(8,7); FePc: CAS(8,7).

Following [32,60], the initial orbitals for the MR-CI calculation were quasi-restricted orbitals from an unrestricted DFT calculation, obtained at the B3LYP [55–57] level. This approach leads in the present case to the expected energetic order of the relevant orbitals (the metal d-block and the ligand a_{1u} and e_g orbitals), that were chosen to belong to the active space. We have also used Hartree–Fock orbitals as initial orbitals, however, this made

it necessary to re-order the relevant orbitals in the definition of the active space of the MR-CI procedure (see above). The energies of the resulting MR-CI excited states agrees between both alternatives to within 0.1 eV.

In all MRCI calculations, the thresholds T_{sel}, T_{pre} and T_{nat} defined previously [32] and introduced to enhance computational efficiency at small loss of accuracy were set to 10^{-6} Eh, 10^{-4} Eh and 10^{-5} Eh, respectively.

ABSTRACT

We report highly efficient, variable-color light-emitting diodes (LEDs) realized via mixing of molecular exciton and excimer phosphorescent emissions from a new organic phosphor platinum N^C^2^N-[1,3-di(4-methoxy-pyrid-2-yl)-4,6-difluorobenzene] chloride (PtL^{26}Cl), a member of the Pt(N^C^N) complex series, where N^C^N represents a cyclometallating tridentate ligand based on 1,3-dipyridylbenzene, *L*. PtL^{26}Cl-doped TCTA blends [TCTA = 4,4′,4″-tris(*N*-carbazolyl-triphenylamine)] have been used as either the low-concentration bluish-green (molecular) phosphorescence emitter or high-concentration red (excimer) phosphorescence emitter. By adjusting the relative amount of blue and red emissive species, the color of the light emission was tuned from bluish-green through green and white up to red. The concentration-optimized devices can easily reach high brightness up to B = 10,000 cd/m^2, achieving extremely high external quantum efficiency (EQE) up to 20% at low-current densities (<10^{-2} mA/cm^2) and up to 17% at B = 500 cd/m^2. High purity white light emission [CIE coordinates (x = 0.34, y = 0.35)] was realized at this B, QE = 11.5%, power efficiency of 6.8 lm/W and color rendering index (CRI) = 74, though CRI = 81 has been achieved with CIE coordinates (x = 0.42, y = 0.38). The reported performance data are among the best achievements reported for color and white emission organic LEDs.

1. Introduction

Organic light-emitting diodes (OLEDs) [1] have been intensively studied due to their potential in next generation full-color displays [2] and solid-state lighting [3–6]. Various strategies have been used to fabricate full-color displays. For example, fluorescent color-changing medium arrays were used to change blue OLED emission into red or green fluorescent colors [7]. Other approaches involve the use of patterned lateral red, green, and blue (RGB) emitters [8], stacked RGB emitters [9], patterns by photo-bleaching [10] or ink-jet printing [11]. Several routes have been employed to realize white light-emitting OLEDs (WOLEDs). Typically, the fabrication of stacked [4] or multilayer [12] LED structures with separated molecular emitters, that is, blue, green and red has been realized. However, the OLEDs with the most impressive characteristics are those based on a single emissive dopant, where molecular excitons are harnessed to form triplet excimers in addition to molecular excited states [13–17].

Electrophosphorescence from cyclometallated Pt(II) complexes has recently received broad attention due to their potential for tailoring the emission color and efficiency of organic LEDs [18–22]. Many of the Pt(II) complex blend-based emitters show two phosphorescence bands located in the bluish-green and red regions of the visible spectrum. Their contribution to the total emission output can be controlled by the concentration of the Pt(II) com-

plex in a host matrix used for the preparation of blend emissive layers of the LEDs. This feature has been employed in the fabrication of very high efficiency organic white [16] and color [22] LEDs. Pursuing this strategy, we now report a significant improvement in efficiency and white color purity of organic LEDs based on a new metallo-organic phosphor, platinum N^C^2^N-[1,3-di(4-methoxy-pyrid-2-yl)-4,6-difluorobenzene] chloride (PtL^{26}Cl) – a new member of the Pt(N^C^N) complex series, where N^C^N represents a cyclometallating tridentate ligand based on 1,3-dipyridylbenzene, *L*. PtL^{26}Cl-doped TCTA blends [TCTA = 4,4′,4″-tris(*N*-carbazolyl-triphenylamine)] have been used as either the low-concentration bluish-green (molecular) phosphorescence emitter or high-concentration red (excimer) phosphorescence emitter. By adjusting the relative amount of blue and red emissive species, the color of the light emission was tuned from bluish-green through green and white up to red. The concentration-optimized devices can easily reach high brightness (up to 10,000 cd/m^2), and extremely high external quantum efficiencies (QE) of up to 20% achieved. High purity white light emission [the Commission Internationale de L'Eclairage (CIE) coordinates (x = 0.34, y = 0.35)] was realized at 500 cd/m^2, QE = 11.5%, power efficiency of 6.8 lm/W and color rendering index (CRI) of 74. The reported performance data are among the best performance achievements reported for color and white emission organic LEDs. Although a very high external QE (up to 34% at 1000 cd/m^2) has recently been achieved by improving light outcoupling of WOLEDs [23], the purity of their white light (x = 0.43, y = 0.49), with a lower CRI = 72 was much worse, placing these emitting devices beyond the warm incandescent lamp light (x = 0.41, y = 0.41) towards the red.

2. Experimental

2.1. OLED structures

In Fig. 1 the structure of the organic LEDs studied is schematically presented. The devices consist of an indium tin oxide (ITO) coated glass anode transparent to the light generated in the emitter layer (EML) which consists of a PtL^{26}Cl (x wt.%) – doped TCTA blend. Holes are injected from the ITO anode, and pass through (TPD:PC) and TCTA hole-transporting layers (HTL), and recombine in the EML with electrons that were injected from an Al/LiF cathode and transported through the electron transporting layer (ETL) of a triazole derivative (TAZ). The 10 nm-thick TCTA layer, characterized by a triplet exciton energy E_T of 2.85 eV, has been used to block triplet exciton transfer from the Pt complexes (E_T = 2.60–2.65 eV) to the non-radiative triplet of TPD (E_T = 2.45 eV). The 30 nm-thick layer of TAZ (E_T = 2.75 eV) plays a similar role of inhibiting quenching of the Pt complex triplet excitons at the cathode while at the same time blocking holes, both properties that enable the recombination process to be confined to a 30 nm-thick EML layer. Such a LED architecture allowed us to maximize its performance parameters (for general electronic mechanisms of organic LED function see e.g. Ref. [1]). The PtL^{26}Cl has been shown to reveal the best performance and all the presented OLEDs are based on this compound.

2.2. LED preparation and experimental procedures

LEDs were fabricated by growing a sequence of thin layers on clean glass substrates pre-coated with a 150 nm-thick layer of indium tin oxide (ITO) with a sheet resistance of 20 Ω per square. A 60 nm-thick (TPD:PC) blend hole-transporting layer was deposited on top of the ITO by spin coating from a 10 mg/ml dichloromethane solution at room temperature. All remaining organic layers were deposited in succession by thermal-evaporation under vacuum of $\sim 10^{-4}$ Pa, followed by high vacuum ($\sim 10^{-4}$ Pa) thermal-evaporation of the cathode layer consisting of 0.5 nm-thick LiF and by a 100 nm-thick Al cap. The EML was evaporated by co-deposition of the phosphor and TCTA to form a 30 nm-thick blend film. We have chosen a monomer/excimer emitting dopant PtL^{26}Cl (Fig. 1) from a group of highly efficient N^C^N-coordinated platinum (II) complex phosphors, PtL^nCl, where L^n represents cyclometallating tridentate ligands with various substituents in either the central phenyl ring (e.g. F atoms for both L^{22} and L^{26}) or in the pyridine rings (e.g. methyl for L^{23} and methoxy for L^{26}), and fabricated a four-layer LED. The photoluminescence (PL) quantum efficiency (QE) (φ_{PL}), emission lifetimes (τ) along with redox potentials of PtL^{26}Cl are summarized in Table 3. We note the unusually high red excimer phosphorescence quantum yield for neat films of PtL^{26}Cl (0.74), which probably exceeds that for the blue monomolecular phosphorescence of this complex in solution (0.71). Solid-state absorption and emission measurements were made using a Perkin–Elmer Lambda 9 UV/Vis/NIR spectrometer and a StellarNet spectroradiometer, respectively. The current–voltage characteristics were measured with a Keithley Source-Measure unit, model 236, under continuous operation mode, while the light output power was measured with an EG&G power meter. All measurements were carried out at room temperature under argon atmosphere and were reproduced for many runs, excluding any irreversible chemical and morphological changes in the devices. The performance of the emissive layer has been optimized by locating the EML between exciton blocking layers of TCTA and TAZ, the latter acting also as an electron transporting and hole-blocking layer.

2.3. Procedure for synthesis of the platinum phosphors

The platinum complexes PtL^nCl are readily prepared in one step from the respective ligands HL^n, in yields of up to 80%, upon treatment with K_2PtCl_4 in refluxing acetic acid. The ligands themselves are best accessed by cross-coupling procedures. For HL^{26}, a mixture of 4-methoxy-2-(tri-*n*-butyltin)pyridine (0.80 g, 2.02 mmol), 1,5-dibromo-2,4-difluorobenzene (0.25 g, 0.92 mmol), Pd(PPh$_3$)$_2$Cl$_2$ (30 mg, 3.8 μmol) and LiCl (0.27 g, 6.44 mmol) in toluene (6 mL) was degassed by five freeze–pump-thaw cycles, and then heated at reflux under an atmosphere of nitrogen gas for 72 h. After cooling to room temperature, saturated aqueous KF (10 mL) was added and the mixture stirred for 30 min.

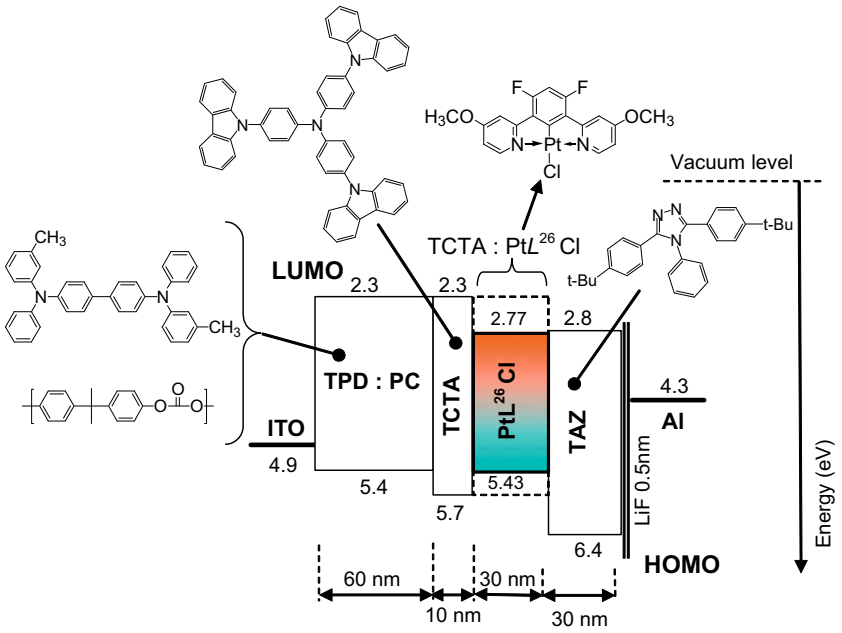

Fig. 1. The architecture of the LEDs manufactured, and molecular structures of the materials used. These are complemented by an energy level diagram shown for understanding the exciton and electronic traffic within the devices. The highest occupied molecular orbital (HOMO) obtained for each material corresponds to its ionization potential. The lowest unoccupied orbital (LUMO) is equal to the molecular electronic affinity, estimated from the reduction potential. The Fermi level positions for ITO and Al electrode contacts are added for completion. The positions of all the levels are indicated by the numbers in electronvolts relative to the vacuum level at energy zero.

The precipitated solid was removed by filtration and washed with water (25 mL) and toluene (30 mL). The filtrate was added to $NaHCO_3$ solution (10%, 50 mL) and the resulting mixture extracted with dichloromethane (2×100 mL). The organic phase was dried over $MgSO_4$, and the solvent was removed under reduced pressure to leave a pale brown residue. Purification by column chromatography (alumina, hexane/ethyl acetate, from 100/0 to 0/100) led to the desired product as a colourless solid (120 mg, 44%). $R_f = 0.35$ (alumina, hexane/ethyl acetate 60/40). NMR (500 MHz, $CDCl_3$) $\delta_H = 3.89$ (6H, s, OCH_3), 6.79 (2H, dd, $J = 5.5$ and 2.5, H^5), 7.00 (1H, t, $^3J_{F\text{-}H} = 11$, $H^{5\prime}$), 7.28 (2H, d, $J = 2.5$, H^3), 8.52 (2H, d, $J = 5.5$, H^6), 8.56 (1H, t, $^4J_{F\text{-}H} = 9.0$, $H^{2\prime}$). $\delta_C = 55.5$ (OCH_3), 105.2 (t, $^2J_{F\text{-}C} = 27$, $C^{5\prime}$), 108.9 (s, C^5), 110.7 (s, C^3), 124.7 (s, $C^{1\prime}$), 133.9 (s, $C^{2\prime}$), 151.1 (s, C^6), 154.2 (s, C^2), 160.7 (dd, $^1J_{F\text{-}C} = 255$, $^3J_{F\text{-}C} = 13$, $C^{4\prime}$), 166.2 (s, C^4). $\delta_F = -113.0$ (dd, $^3J_{F\text{-}H} = 11$, $^4J_{F\text{-}H} = 9.0$). HRMS (ES^+) $m/z = 329.1098$ ($M+H^+$); calc. for $C_{16}H_{10}$- $F_2N_2 = 329.1102$.

Platinum N^C^2^N-[1,3-di(4-methoxy-pyrid-2-yl)-4,6-difluorobenzene] chloride (PtL^{26}Cl) was prepared from a mixture of the ligand HL^{26} (30 mg, 0.091 mmol) and K_2PtCl_4 (38 mg, 0.091 mmol) in acetic acid (2 mL). The mixture was degassed by three freeze–pump-thaw cycles, and then heated at reflux under a nitrogen atmosphere for 72 h. The resulting precipitate was separated by centrifugation and washed successively with water, ethanol and diethyl ether (3×5 mL of each). The residue was extracted into dichloromethane, filtered, and the solvent removed under reduced pressure to give the product as a very pale yellow solid (21 mg, 44%). NMR (500 MHz, $CDCl_3$) $\delta_H =$ 3.98 (6H, s, OCH_3), 6.68 (1H, t, $^3J_{F\text{-}H} = 11$, $H^{5\prime}$), 6.78 (2H, dd, $^3J = 6.7$, $^4J = 3.0$, H^5), 7.39 (2H, d, $^3J = 3.0$, H^3), 9.08 (2H, d, $^3J = 6.8$, $^3J_{H\text{-}Pt(195)} = 39$, H^6). $\delta_F = -108.8$ (d, $^3J_{F\text{-}H} = 11$). MS (MALDI) $m/z = 557$, M^+; 522, ($M-Cl^+$).

3. Results and discussion

3.1. Electroluminescence spectra

Fig. 2 shows EL spectra and the CIE coordinates (x, y) of LED structures from Fig. 1 for different PtL^{26}Cl complex dopant concentrations. It is clear that a reduction in its concentration leads to a relative increase of the blue light emission band originating from the radiative decay of molecular triplet excitons of the isolated phosphorescent molecules of the Pt complex while increasing dopant concentration increases the contribution of the broad red light band emanating from the emission of triplet Pt complex excimers or aggregates that comprise two closely associated molecules. They have main maxima at $\lambda \approx 465$ and 620 nm, respectively. The EL spectrum of a neat film of the Pt complex (100%) is practically devoid of blue monomer emission, as in the case of OLEDs based on the unsubstituted parent complex PtL^1Cl, and simple derivatives [16,24]. Fig. 3 shows the voltage dependence of luminance for the devices with different PtL^{26}Cl concentrations. Luminance (B) increases monotonically with increasing dopant concentration (up to ca. 10,000 cd/m^2 for neat phosphor films), showing in all cases a tendency to saturation associated with high-voltage (high brightness) roll-off in the EL quantum efficiency [1]. A detailed examination of the B (V) characteristics shows a distinct increase in luminance between 25 and 35 wt.% PtL^{26}Cl concentrations except for

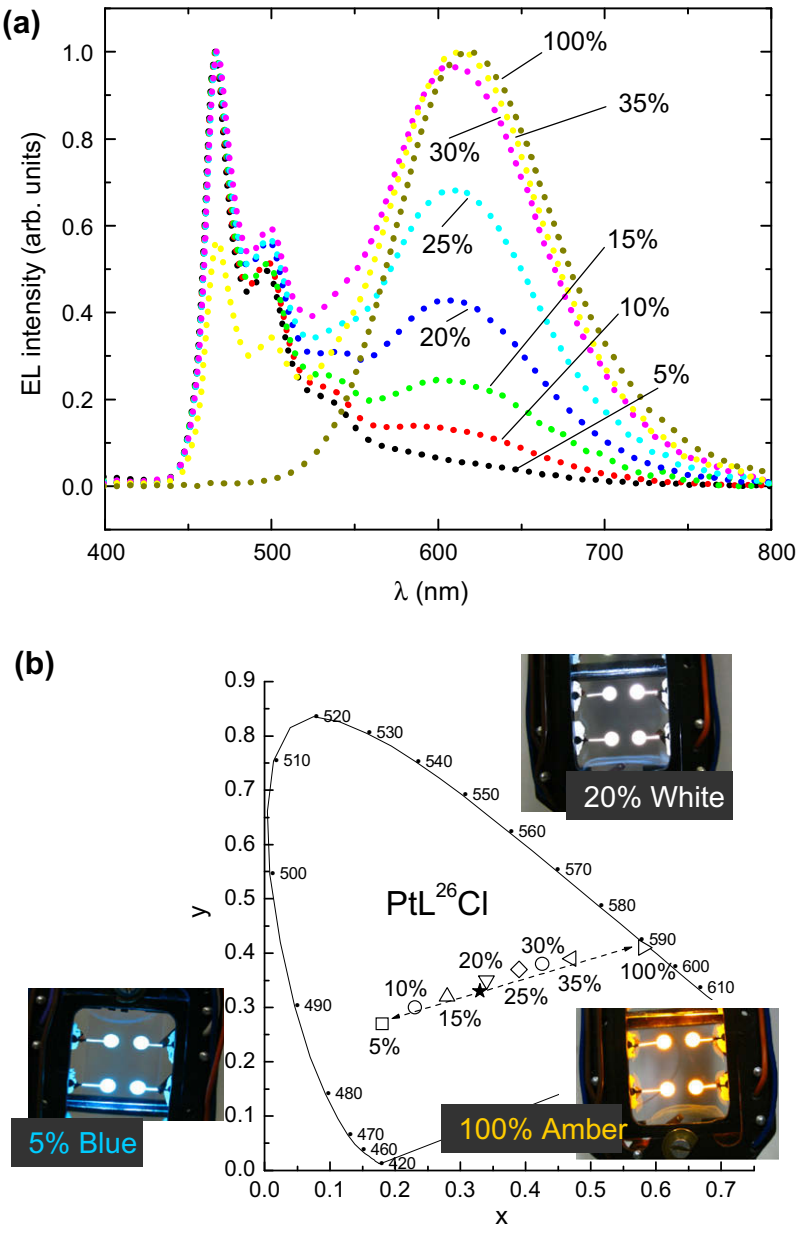

Fig. 2. EL spectra (a), and CIE diagram (b) for LEDs with emitters of varying concentrations of PtL^{26}Cl. At low concentrations of the phosphor the LEDs are "blue-biased" (dominated by emission from the molecular triplet excitons), at high phosphor concentrations the LEDs become "red-biased" being dominated by the emission from phosphor excimers. The blue emission band practically disappears for 100% phosphor emitter (neat PtL^{26}Cl films). The LED with a 20 wt.% content of the phosphor approaches closely a white light with CIE coordinates (0.33, 0.33). Examples of emission colors at various phosphor concentrations are given by photographs in the CIE diagram in part (b). (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

the highest voltage (>15 V) region, where, surprisingly, neat films reveal the highest light output.

3.2. Dimers vs excimers

The nature of bi-molecular emissive states is a challenging question concerning all planar organometallic platinum complexes. Are they excited states of dimers that pre-exist in the ground-state, or excimers (bi-molecular emissive species not having a bi-molecular ground-state)? Based on the close similarity of absorption and excitation spectra of neat PtL^{26}Cl films shown in Fig. 4, we believe that the long-wavelength broad EL bands at 620 nm, emanating from PtL^{26}Cl-based devices, have purely excimeric character. An important point to note here is that the QE and purity of white light (CIE coordinates) emanated from Pt complex-based LEDs depend on the substituents at the central ring and lateral rings of the Pt complex. The excel-

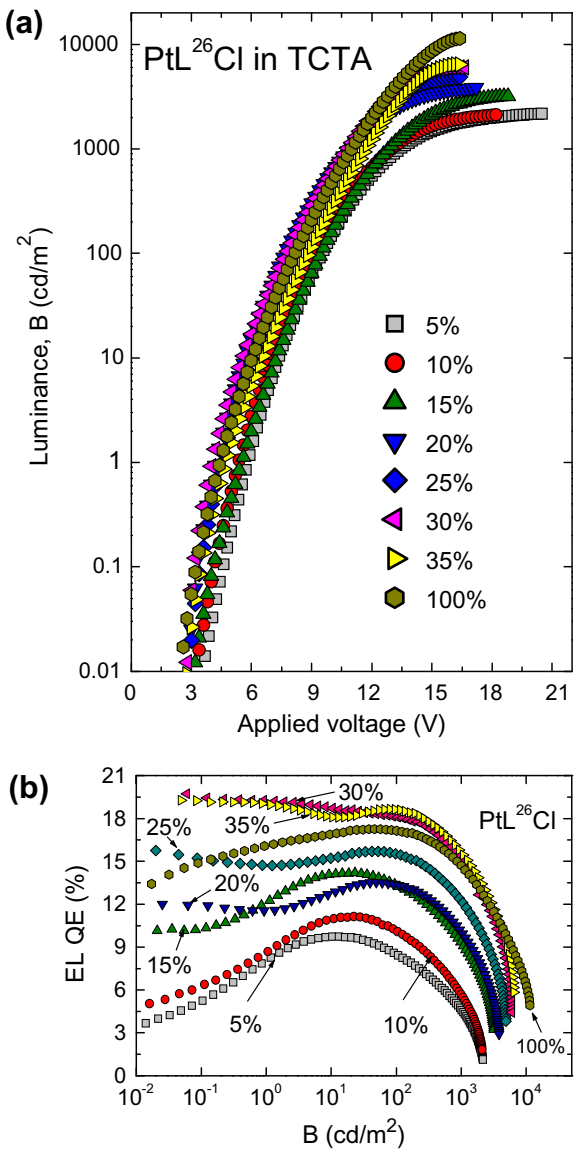

Fig. 3. Luminance (B) vs applied voltage (a) and EL QE vs B (b) at varying PtL^{26}Cl concentration in EML of devices from Fig. 1.

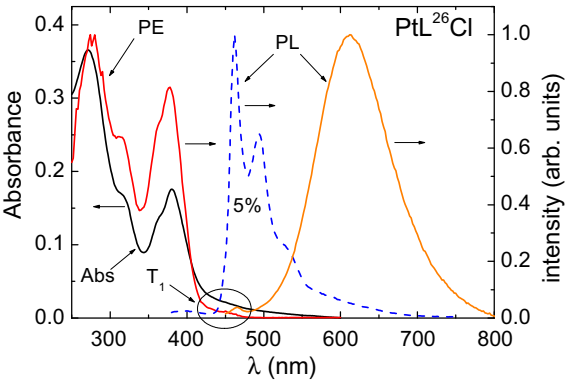

Fig. 4. Absorption (Abs), photoluminescence (PL) at λ_{exc} = 380 nm, and excitation (PE) detected at λ_{det} = 600 nm spectra of a 50 nm-thick film of pure PtL^{26}Cl. The PL spectrum at λ_{exc} = 350 nm of a 30 nm-thick TCTA film containing 5 wt.% of PtL^{26}Cl is reported for comparison (dashed line). The close similarity of Abs and PE spectra indicates the PL spectrum to be underlain by the excimer rather than dimer emission.

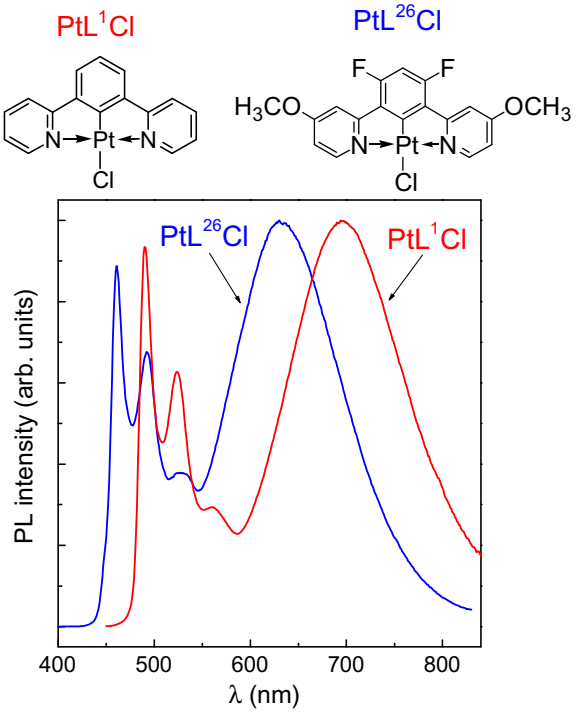

Fig. 5. PL spectra of a substituted (PtL^{26}Cl) and unsubstituted (PtL^{1}Cl) Pt(II) complex in solution (CH_2Cl_2) showing the effect of a blue shift due to the substituents. For explanation see text. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

lent performance of the present complex PtL^{26}Cl-based LEDs (as reported in Section 3.3) is associated with the combination of fluorine atoms in the cyclometallating phenyl ring and methoxy substituents in the pyridyl rings leading to a blue shift in both molecular exciton and excimer emission, as shown in Fig. 5 in comparison with the unsubstituted Pt(II) complex, PtL^{1}Cl. Obviously, these substituents cause a rise in energy of the molecular excited state, which can be understood in terms of the frontier orbitals involved in the excited state, as obtained from recent TD-DFT calculations [25,26]. They show that the HOMO in this series of complexes is largely based on the metal and the cyclometallating ring, whereas the LUMO is essentially localized on the pyridyl rings. Thus, the electron-withdrawing influence of F atoms meta to the C–Pt bond will serve to lower the energy of the HOMO but not the LUMO. Conversely, the electron-donating methoxy groups will have the effect of raising the LUMO energy without significantly destabilizing the HOMO. The net effect is a substantial increase in the HOMO–LUMO gap, and a shift of the excited state to higher energy. The excimer is similarly destabilized and its emission maximum shifted away from the NIR, where energy is wasted in the case of PtL^{1}Cl.

Finally, we note that, in general, the bi-molecular excited triplet state is a result of excitonic and charge-transfer resonances [1]. The relation between their contributions to the function describing the overall excimer state and thus the excimer energy depend on the distance and mutual orientation of interacting molecules. The states with a negative CT-resonance energy component have the lowest energies [1]. The direct electron–hole recombination mechanism of the excimer formation in the EL favors the low-energy CT states to dominate the excimer character, observed as a red shift in the EL spectrum compared with that of PL [24]. This shift is not too big in case of PtL^{26}Cl (cf. Figs. 2 and 4), suggesting the exciton resonance to dominate the excimer structure under both optical and electrical excitation of the emission. On the other hand, the EL–PL maxima red shift of 80 nm has been ascribed to the difference between the spectral locations of the emission peaks originating from dimer and excimer in neat films of Pt(II) (2-(4′,6′-difluorophenyl) pyridinato-*N*,C^2) acetyl acetonate (FPt1) [27]. Since, however, the excitation and absorption spectra of solid FPt1 have not been reported, one cannot firmly distinguish the dimer emission from that of a second excimer or electromer [28]. Moreover, the absence of molecular exciton emission, reported for solid FPt1 [27], does not have to be a rule. Its occurrence may be expected in organic solids with large intermolecular separation distance (ca. 0.4 nm or so) and configurations impeding the formation of a facially oriented molecular pair.

3.3. OLEDs performance

The physical characteristics of PtL^{26}Cl-based LEDs are collected in Table 1 and Figs. 2 and 3. An apparent monotonic trend towards red CIE coordinates is accompanied by increasing external QE, power efficiency (PE), luminous efficiency (LE) and the color rendering index (CRI), following the concentration of the phosphor dopant except for the remarkable decrease in correlated color temperature (CCT). The emission color of all the low PtL^{26}Cl concentration emitter LEDs is blue–green-biased while the neat PtL^{26}Cl film emitter LEDs fall in the red region. The CIE coordinates for the LEDs of intermediate concentrations (10%, 15%, 20%, 25%, 30%) of PtL^{26}Cl in their emitters (0.23, 0.30), (0.28,0.32), (0.34,0.35), (0.39,0.37), (0.42,038), respectively, lie on the line joining blue–green to red in the CIE color diagram (see Fig. 2b), and show how varying the doping provides a simple way of tuning color over a wide range from white to amber-orange. The color of emission from each blend does not change significantly in the brightness range studied of [100–10,000] cd/m^2. The external EL QE ranges between 0.5% and 1.0% at low-current densities ($<10^{-4}$ mA/cm^2) for the lowest phosphor concentration (5%) and as high as 20% at low-current densities for optimized phosphor concentration of 30–35% with the power efficiency (PE) reaching 9.6 lm/W. We note that the external EL QE value of 20% corresponds to 100% (80%) internal EL QE for the commonly assumed light outcoupling factor 0.2 (0.25). The luminous efficiency (LE) falls in the range 10.7–30 cd/A for the 5 and 35 wt.% PtL^{26}Cl-doped emitter LEDs, respectively. The light turn-on voltage (0.01 cd/m^2) for all the devices was ca. 3 V and the operating voltage at 500 cd/m^2 was ca. 10 V (cf. Fig. 3a). Hence, the electrical properties are only slightly sensitive to the EML composition, and good performance is achieved for almost all the devices. The EL QE evolves with luminance showing typical roll-off at high luminance values (Fig. 3b).

The CRI quantifies the eye's ability to distinguish color under illumination by the light source. Thus, the LEDs with a higher phosphor dopant concentration, giving high CRI, can serve as a good starting point for the manufacture of white LEDs. Among a series of the devices characterized in Table 2, the 20%-doped device stands for the highest-purity white light. Its CIE coordinates ($x = 0.34$, $y = 0.35$) are very close to the pure white color defined by ($x = 0.33$, $y = 0.33$), but its CRI = 74, though high enough, is still far from the desired upper limit of 100. The CRI of our LEDs reaches a maximum high value of 81 at the 30 wt.% phosphor content in the emitter. However, this improvement of CRI is achieved at the expense of the white color purity of the device (0.42, 0.38) which, still being considered as white light, is shifted towards the warm incandescent lamp light ($x = 0.41$, $y = 0.41$). In Table 2, characteristics of selected most advanced WOLEDs are presented and compared with the present results. It is seen that the color purity, EL QE and CRI of our present 20%-doped emitter device fall in the two highest-purity white light OLEDs. However, since no data on efficiencies of the exciplex-driven WOLED reported in Ref. [31] are available, the overall performance advantage of one of these two devices cannot be assessed.

It is important from both device engineering and device physics perspectives to understand the mechanism

Table 1
OLED[a] performances[b]. Each device is listed by concentration (x) of the PtL^{26}Cl complex in the emitting layer. At ca. 500 cd/m^2.

[a] Calculated using integrating sphere and the calculation method described in Ref. [34].
[b] τ For samples aerated.
[c] Electrochemical data in dimethyl sulfoxide (DMSO) solution owing to the low solubility in more usual solvents (DCM or MeCN). Measured using platinum working, reference and counter electrodes, and employing the ferrocene/ferrocenium coupled as an internal reference. Irreversible peak potentials are reported vs Saturated Calomel Electrode (SCE).
[d] Calculated as a sum of the monomer (M) and excimer (EX) quantum efficiencies according to: φ_{PL}(wt.% dopant) = $\varphi_{PL}^{(M)}$(5% dopant) × EL$^{(M)}$/EL$^{(tot)}$ + $\varphi_{PL}^{(EX)}$(100% dopant) × EL$^{(EX)}$/EL$^{(tot)}$. This is an approximation assuming the monomer (blue)-to-excimer (red) contribution ratio in PL to follow that for EL as in Fig. 2. EL intensities were taken suitably from the EL spectra as the blue band, red band and total under-curve areas.
[e] Highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital LUMO levels (eV) as calculated from the redox potentials.
[f] Calculated employing the optical gap (E_O) as E(LUMO) = E(HOMO) + E_O = 5.43–2.66 = 2.77 eV. It correctly falls above the value of 2.5 eV – a lower limit predicted from the reduction potential (row 1). Its exact value could not be determined because the reduction wave of the complex is obscured by the solvent. Thus, this value is not certain as indicated by the question mark.

governing the enhancement in WOLEDs efficiency. To understand the general trend of the EL external quantum efficiency (EL EQE) increasing as PtL^{26}Cl concentration increases (see Table 1), we recall that the EL EQE (φ_{EL}) is simply proportional to the recombination probability (P_R) of holes injected from TCTA into the emission layer with electrons injected into it from TAZ (cf. Fig. 1) and to the total emission efficiency (φ_{PL}). Thus, $\varphi_{EL} = \xi P_R \varphi_{PL}$, where ξ is the light output coupling factor. Using the data of Tables 1 and 3, we find $\xi P_R(5\%) = 0.12$ and $\xi P_R(35\%) = 0.25$. From these numbers it is seen that a two fold increase of the product ξP_R when going from a 5% to a 35%-doped blend finds only partial correspondence in the increased PL efficiency, $\varphi_{PL}(35\%)/\varphi_{PL}(5\%) = 1.37$. Furthermore, if we reasonably assume ξ to be only a slightly varying function of the dopant concentration, the difference must be attributed to the concentration increasing recombination probability, P_R. This probability is given by [1]

$$P_R = \frac{1}{1 + (\tau_{rec}/\tau_t)} \quad (1)$$

where τ_{rec} is the recombination and τ_t the faster carrier transit time through the emitter layer, respectively. Assuming reasonably that hole mobility substantially exceeds electron mobility in the blend EMLs, we arrive at

$$\tau_{rec} = \frac{1}{\gamma n_e} \quad \text{and } \tau_t = \frac{d_{em}^2}{\mu_h U} \quad (2)$$

where τ_{rec} is the recombination time of holes captured by PtL^{26}Cl-located electrons with a second order recombination rate constant γ, the latter acting as negative recombination centers PtL^{26}Cl$^-$ of concentration n_e; τ_t is the hole transit time through the EML of thickness d_{em} dependent on its mobility, μ_h, and applied voltage, U. Obviously, increased concentration of the phosphor dopant increases n_e, but reduces μ_h. Consequently, the decreasing τ_{rec}-to-τ_t ratio in (1) leads to increasing P_R and, following it, increase in EL efficiency. For a concentration dopant high enough to make $\tau_{rec}/\tau_t \ll 1$, $P_R \to 1$ that is all injected holes recombine with injected electrons, the EL efficiencies tend to saturation as observed (Table 1).The situation changes with neat PtL^{26}Cl film emitters since electron mobility may be comparable with or even exceed the hole mobility in this molecular solid. Then, P_R may differ from unity by an amount reducing slightly EL efficiency at low and moderate current densities, but its enhancement can be expected at high current densities (high voltages). The latter may be due to the fact that only emissive excimers are generated in neat film EMLs, and these emissive species are subject to weaker quenching as compared with quenching of monomolecular excitons similar to the situation discussed earlier to understand the electric field effect on exciplex luminescence in electron donor–acceptor organic solid films [33]. Indeed, the luminance of neat PtL^{26}Cl film-based devices is greater than that for PtL^{26}Cl blend-based ones at high voltages as shown in Fig. 3a. A detailed investigation of the current density evolution of the EL QE at different concentrations of PtL^{26}Cl dopant is underway and will be reported in a forthcoming paper.

4. Concluding remarks

We have shown that by varying the concentration of a Pt(II) organic complex, PtL^{26}Cl, in blends of (TCTA:PtL^{26}Cl) used as single-dopant EMLs in four-layer LEDs, their performance parameters can be effectively tuned. The good color tuning from bluish-green to reddish-yellow has been attributed to the mixing of the molecular (blue) and excimer (red) phosphorescence, the emission from excited ground-state molecular aggregates shown to be disregarded. Amongst the series of fabricated LEDs, the 20 wt.% PtL^{26}Cl content EML-based device is a high purity white LED with CIE coordinates (0.34, 0.35) and CRI = 74, which render it one of the best achievements reported for WOLEDs. The external EL efficiency has been shown to follow the dopant content, reaching a maximum at concentrations between 30 and 35 wt.%. This correlation is explained in terms of increasing phosphorescence efficiency and electron–hole recombination probability within EMLs due to the dopant-induced increase of the negative PtL^{26}Cl$^-$ recombination centers and a reduction in the hole mobility. The extremely high external EL QE of ca. 20% has then been obtained at low-current densities, which corresponds to an internal EL QE of almost 100%. The composition of monomer and excimer emissions has shown an interesting impact on the overall emission output: the luminance of the neat PtL^{26}Cl film EML-based LED exceeds those for blend EML-based devices, the effect being attributed to the different sensitivity of monomer excitons and excimers to quenching processes operating effectively at large driving current densities.

Double emission

ABSTRACT

In typical organic light-emitting devices (OLEDs), a significant portion of internally generated radiation is trapped into the surface plasmon polariton (SPP) modes, in general not accessible for external use. By thinning the metal electrode, the SPP modes can be coupled to the outside surface of the device. As such, one can recycle a portion of SPPs by capping the thinned metal electrode with an appropriate absorbing/re-emission medium, inducing SPP-mediated energy transfer and re-emission. Such an approach may be used for implementing double-emitting OLEDs with different emission colors on two sides and with a broad color tuning capability.

1. Introduction

Surface plasmon polaritons (SPPs) are guided electromagnetic waves propagating at the interface between a dielectric and a conductor, which arise via the coupling of the electromagnetic fields to oscillations of the conductor's electron plasma and are evanescently confined near the interface [1–8]. In typical organic light-emitting devices (OLEDs), emitters are located close enough to the metal electrode, and thus a large portion of internally generated radiation is trapped into SPP modes (20–40%, depending on the device structure) and is not available for external use [9,10]. Thus an effective approach/structure that is able to access/recycle SPP modes for external use and compatible with typical OLED fabrication is certainly desired.

In a conventional OLED with a thick top metal electrode, the SPP modes are mainly distributed from the bottom surface of the metal layer downward into the organic layer, therefore making it difficult to access/manipulate the SPP modes from the outside of the device. Some periodically corrugated structures were proposed previously to out-couple SPPs [11]; yet they in general are less compatible with typical OLED fabrication and also result in strong wavelength and angular dependence in emission characteristics. In extensive studies of SPP optics in recent years, it has been shown that by thinning the thickness of a metal layer, the originally independent SPPs on two sides of a metal layer could interact with each other, resulting in coupled SPPs that have modal field distributions spanning on two sides of the metal layer [5,6]. As such, by making OLEDs with thinner metal electrodes, SPPs of the devices could exhibit a significant field distribution outside the devices, giving a possibility to access/manipulate SPPs from outside of the device for external emission. In this work, we adopt such a principle to manipulate SPPs of OLEDs for external use. We performed electromagnetic simulation/analysis of the SPPs of OLEDs with thin metal electrodes and investigated double-emitting OLEDs with a wide range of color tunability.

2. Experimental

2.1. OLED device structures investigated

Two types of OLED devices were studied in this work (Fig. 1): one based on green-emitting OLEDs (Types-IA

and IB) and one based on blue-emitting devices (Type-II). The Type-I OLED device structures (Fig. 1) studied in this work were: glass substrate/ITO (120 nm)/m-MTDATA (30 nm)/α-NPD (20 nm)/Alq_3:C545T (1 wt.%, 20 nm)/Alq_3 (35 nm)/LiF (0.5 nm)/Al (1 nm)/Ag (*X* nm)/Alq_3 (80 nm, for Type-IA devices with non-doped capping) or Alq_3:DCJTB (1 wt.%, 80 nm, for Type-IB devices with doped capping). Indium–tin–oxide (ITO) was used as the bottom anode, 4,4′,4″-tris(3-methylphenylphenylamino)triphenylamine (m-MTDATA) as the hole-injection layer [12], α-naphthylphenylbiphenyl diamine (α-NPD) as the hole-transport layer [13], tris-(8-hydroxyquinoline) aluminum (Alq_3) doped with the fluorescent dye C545T [(10-(2-benzothiazolyl)-1,1,7,7-tetramethyl-2,3,6,7-tetrahydro-1H,5H,11H (1) benzopyrano (6,7,8-ij) quinolizin-11-one)] as the emitting layer [14,15], undoped Alq_3 as the electron-transport layer, thin LiF/Al as the electron injection layer [12], Ag as the top cathode, and non-doped or doped Alq_3 as the capping layer. The thickness of Ag cathode (*X* = 20, 30, 40, 50, 120 nm) was varied to investigate the SPP properties. The Alq_3 was used as the capping so that the dielectrics on both sides of the metal layer would have same/similar refractive indices to ensure effective generation of coupled SPP modes [4,5]. The 1 wt.% DCJTB [4-(Dicyanomethylene)-2-tert-butyl-6-(1,1,7,7-tetramethyljulolidin-4-yl-vinyl)-4H-pyran] doped in the Alq_3 capping is used to absorb the SPPs propagating in the capping layer for re-emission (i.e. recycling SPPs), thus inducing the donor–acceptor (C545T–DCJTB) energy transfer mediated by coupled SPPs across the metal layer [4]. The thickness of the electron-transport layer (undoped Alq_3) was adjusted in a way to increase fraction of internally generated radiation coupled into SPP modes and to make the SPP effects more easily observable [8,14].

The Type-II OLED device structure (Fig. 1) studied in this work was: glass substrate/ITO (120 nm)/m-MTDATA (30 nm)/α-NPD (20 nm)/ADN:perylene (1 wt.%, 20 nm)/Alq_3 (35 nm)/LiF (0.5 nm)/Al (1 nm)/Ag (*X* nm)/Alq_3:rubrene (1 wt.%, 80 nm), where the thickness of the Ag cathode was varied (*X* = 15, 20, 25, 30, 40, and 50 nm). The Type-II device structure is similar to that of Type-I, except that the emitting layer is replaced by blue-emitting ADN:perylene [where ADN is 9,10-di-(2-naphthyl) anthracene] and that the capping is replaced by Alq_3:rubrene. Therefore, the donor–acceptor system in the SPP-mediated energy transfer is switched from (C545T, DCJTB) to (perylene, rubrene).

2.2. Electromagnetic simulation of OLEDs

The optical model used for performing the analysis adopts a rigorous and classical electromagnetic model based on the equivalence between the emission of a photon due to an electrical dipole transition and the radiation from a classical electrical dipole antenna, which can take into account losses due to absorption and electromagnetic interaction with metals (e.g. SPPs) [14–20]. With plane-wave expansion of the dipole field, the full-vectorial electromagnetic fields generated by a radiation dipole embedded in a layered structure is calculated, from which the distribution of the radiation power into different plane-wave modes and the far-field radiation related to emission characteristics of an OLED are obtained [14–20]. In the plane-wave expansion, each plane-wave mode can be characterized by an in-plane wave vector k_t, where k_t is the component of the wave vector parallel to the layer surface. To model emission characteristics of a real OLED, one treats the emitting layer as an ensemble of mutually incoherent dipole radiators with distributions in dipole orientations (a random isotropic distribution in the present study), locations (assuming a decaying exponential distribution from the hole-transport layer/emitting layer interface into the emitting layer with an exciton diffusion length of 10 nm in the present study [21]), and frequencies (using the photoluminescence (PL) spectrum of the emitting layer as the intrinsic spectral distribution of the dipole radiators). It has been shown that the quantum efficiency of the emitter might influence the simulation results and the power dissipation into different modes [22]. The optical model adopted here indeed has included the influences of the optical structures on the quantum yields of the emitters and the internal quantum efficiencies of OLEDs. Yet, since the donor (C545T) used in this work has very high fluorescent quantum yield (0.95 in solution) [23], an emitter quantum efficiency of 100% is assumed for simplicity of the simulation. The total emission intensity *I* from the OLED as a function of the wavelength λ and the viewing angle θ (i.e. $I(\theta, \lambda)$, with θ measured relative to the surface normal) is then obtained by averaging contributions over these distributions.

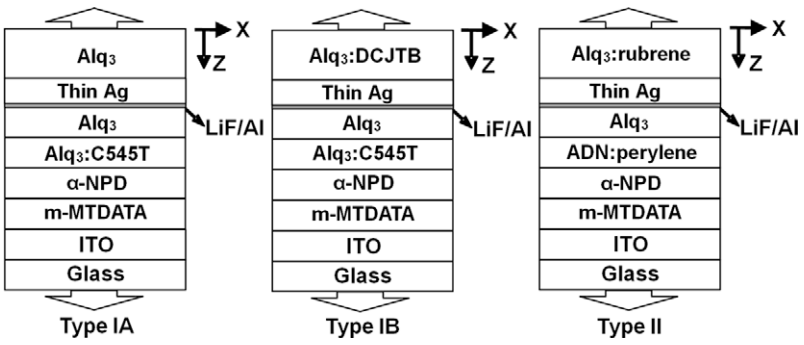

Fig. 1. Schematic device structures under investigation.

2.3. OLED fabrication and characterization

OLEDs were fabricated on the ITO-coated glass substrates with multiple organic layers sandwiched between the transparent bottom indium–tin–oxide (ITO) anode and the top metal cathode. The organic and metal layers were deposited by thermal evaporation in a vacuum chamber with a base pressure of $< 10^{-6}$ torr. The deposition rate of organic layers was kept at ~0.2 nm/s. The deposition system permitted the fabrication of the complete device structure in a single pump-down without breaking vacuum. The active area of the device was 1×1 mm^2.

Current–voltage–luminance (I–V–L) characterization of the devices was measured using an Agilent 4155B semiconductor parameter analyzer and a Si photodiode calibrated with Photo Research PR650. EL spectra of devices were collected by a calibrated CCD spectrograph. The total external quantum efficiencies of devices were determined from the measured angular dependence of emission intensity and spectra.

3. Results and discussion

3.1. Electromagnetic simulation of SPP modes in OLEDs

In the following, we use simulation results of Type-I devices (C545T-based devices) to illustrate characteristics of the SPP modes. Fig. 2a shows the calculated mode distributions (fraction of radiation coupled into different modes) of internally generated radiation (at 525 nm) as a function of k_t/k_0 (k_t is the in-plane component of the wavevector and

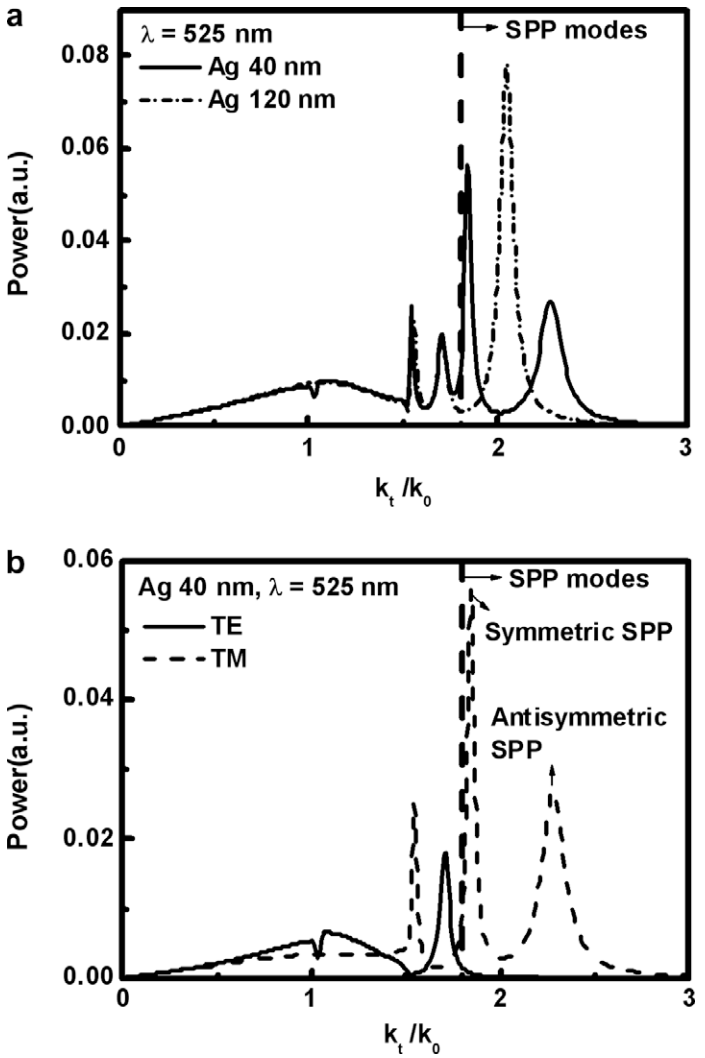

Fig. 2. (a) Calculated mode distributions (power dissipation) of internally generated radiation ($\lambda = 520$ nm) as a function of the normalized in-plane wavevector k_t/k_0 for a conventional OLED with thick Ag cathode (120 nm) and for a Type-I double-emitting OLED with thin Ag cathode (40 nm). (b) Calculated mode distributions (power dissipation) for the same Type-I double-emitting OLED with thin Ag cathode (40 nm), with TE and TM modes separated.

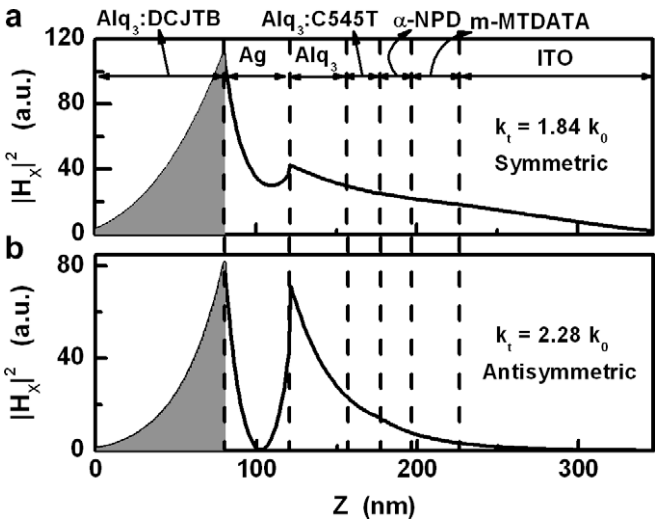

Fig. 3. The distributions of the field intensity for the (a) symmetric and (b) antisymmetric SPP modes of the Type-I double-emitting OLED with thin Ag cathode (40 nm), at the wavelength of 525 nm, and along the z-axis. The transverse magnetic field H_x is shown, since SPP modes are of TM nature.

k_0 is the free-space wavevector) from a conventional OLED with thick Ag cathode (i.e. 120 nm Ag) and from an OLED with thin Ag cathode (40 nm). With the confining nature of the SPPs, modes with $k_t/k_0 > 1.75$ (where $n \sim 1.75$ is the refractive index of the bounding medium of Alq_3 at 525 nm) are associated with the SPP modes [3,5]. The conventional OLED with the thick Ag cathode (120 nm) has only one major SPP mode peaking at $k_t = 2.05\ k_0$, which is the typical SPP having only one-side distribution (i.e. from the Ag/Alq_3 interface downward into the Alq_3). The OLED with thin Ag (40 nm), on the other hand, has two major SPP modes peaking at $k_t = 1.84\ k_0$, and $k_t = 2.28\ k_0$. These two modes, one with k_t lower than $2.05\ k_0$ and one with k_t higher than $2.05\ k_0$ indeed are the coupled SPP modes resulted from interaction and splitting of two one-side SPP modes (i.e. one above and one below the metal cathode) [4]. Further analyses on polarization properties (Fig. 2b) reveal that these coupled SPP modes associated with thin Ag are mainly of TM (transverse magnetic mode) nature, similar to conventional one-side SPP modes associated with the thick metal layer. The distributions of the field intensity for these two modes (transverse magnetic field H_x, since they are of TM nature) along the z-axis (from the Alq_3/air interface downward as shown in Fig. 1) are shown in Fig. 3a and b. From Fig. 3, it is seen that the mode at $k_t = 1.84\ k_0$ is of symmetric nature and the mode at $k_t = 2.28\ k_0$ is of antisymmetric nature (i.e. with a node located within the thin metal layer). Both modes span from the inside to the outside of the thin Ag cathode and exhibit significant distributions in the capping layer.

In Table 1, the peak k_t/k_0 values for symmetric SPP modes and antisymmetric SPP modes associated with different Ag thicknesses are listed. The peak k_t/k_0 values for these two types of SPP modes are splitted farther away from each other when the Ag thickness is reduced (that is, the coupling/interaction between SPPs on two sides of the metal layer increases).

Table 1
SPP characteristics of Type-I devices versus Ag thickness.

Ag (nm)	Symmetric SPP(k_t/k_0)	Antisymmetric SPP (k_t/k_0)	ET_{d-a} (%)
20	1.75	2.94	5.29
30	1.79	2.49	6.77
40	1.84	2.28	6.43
50	1.89	2.17	4.92

3.2. Color-tunable double-emitting devices: Type I

Since these symmetric or antisymmetric modes propagate horizontally and have rather long propagation lengths (of micrometer scale), in Type-IB devices, by doping into the capping layer a small amount of DCJTB dyes (e.g. 1 wt.%) whose absorption matches C545T emission, the SPPs in the capping can be effectively absorbed and then be re-emitted, thus recycling a portion of SPPs for external emission. In each of Fig. 4a–d, the (0°) EL spectra with relative intensities measured from the top side of the Type-IA device (with non-doped capping) and the Type-IB device (with doped capping) are compared for each of the Ag cathode thickness (20, 30, 40, 50 nm), respectively. Without DCJTB dopants in the capping, pure C545T emission is observed, while with DCJTB dopants in the capping, the emission combines both DCJTB and C545T emission. The observed DCJTB emission from the top side of Type-IB devices cannot not be completely due to re-absorption/re-emission of the directly out-coupled top (donor) emission, since for each Type-IB device C545T emission from the top side only drops slightly compared to those of Type-IA devices. Instead, the significant DCJTB emission from the top side is mainly due to recycled SPPs, which in some sense can be regarded as the SPP-mediated energy transfer from the C545T donor to the DCJTB acceptor and is a rather long-range energy-transfer process. Fig. 4e shows the (0°)

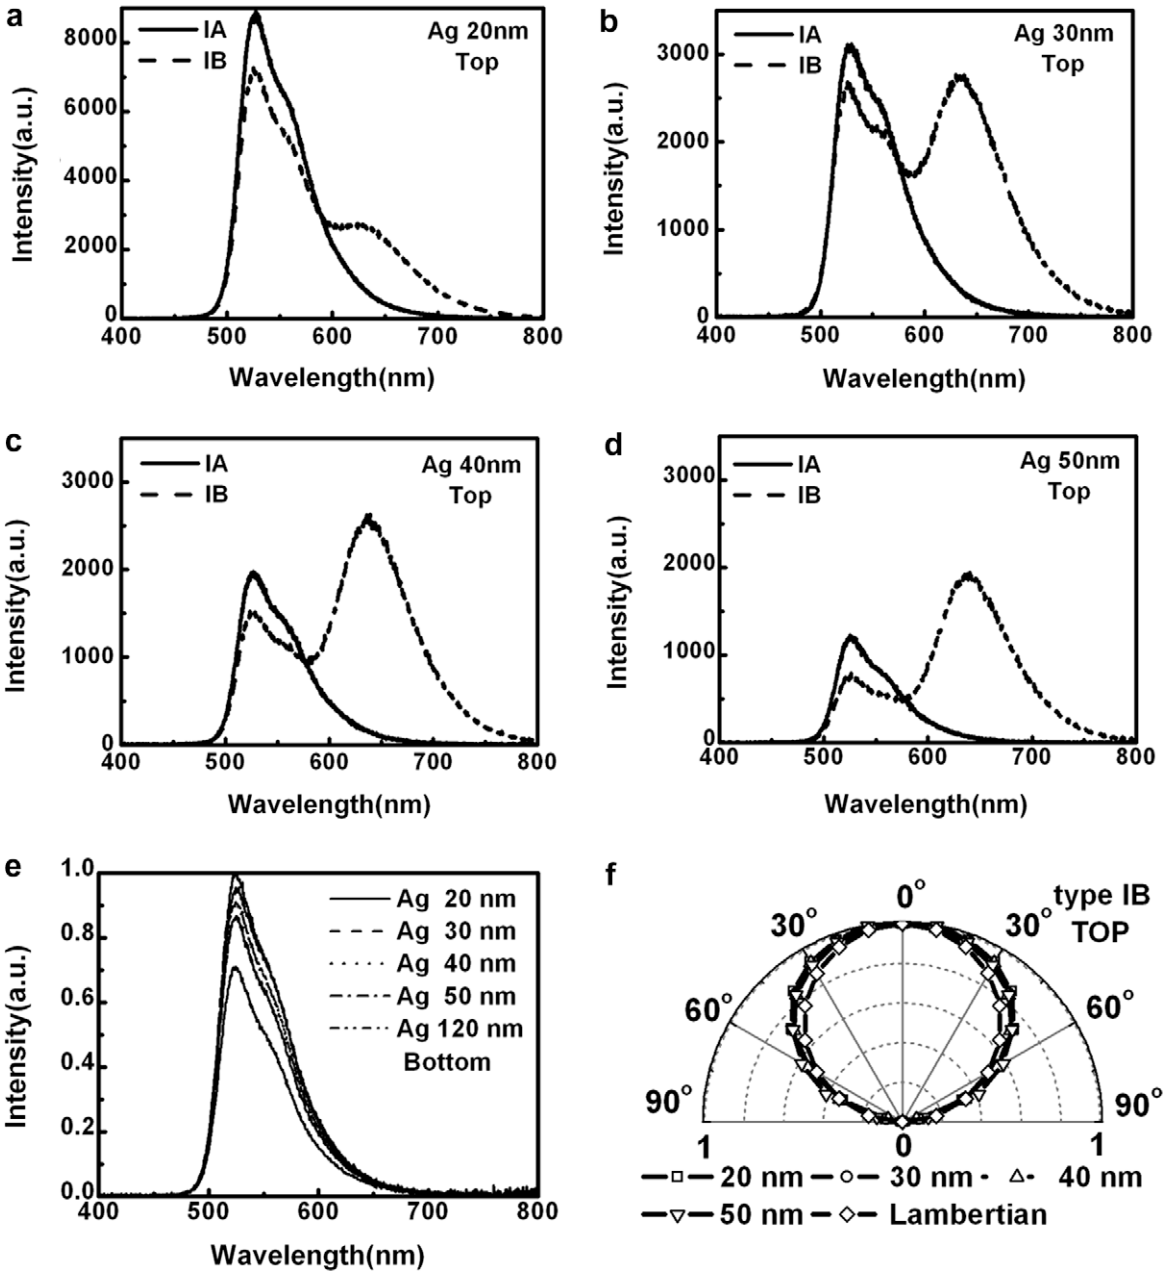

Fig. 4. The (0°) EL spectra with relative intensities measured from the top side of the Type-IA device (with non-doped capping) and the Type-IB device (with doped capping) are compared for each of the Ag cathode thickness: (a) 20, (b) 30, (c) 40, (d) 50 nm. (e) (0°) EL spectra with relative intensities for bottom emission of Type-IB devices with different Ag cathode thicknesses (20, 30, 40, 50 nm), compared to that of the conventional bottom-emitting device (Ag = 120 nm). (f) Polar plots of the top-emission intensity for Type-IB devices with different Ag cathode thicknesses (20, 30, 40, 50 nm), compared to the Lambertian pattern. For (a)–(f), measurements were performed at a current density of 100 mA/cm^2.

EL spectra with relative intensities for bottom emission of Type-IB devices (with doped capping) with different Ag cathode thicknesses (20, 30, 40, 50, 120 nm). The EL spectra are basically the same as those of Type-IA devices and are not dependent on the Ag thickness. Yet in general, the intensity of bottom emission (for both Types-IA and IB) drops gradually with reducing the Ag thickness, mainly due to lowered reflection of the Ag cathode. Fig. 4f shows the polar plots of the top-emission intensity for Type-IB devices (similar for Type-IA devices, data not shown), which are all nearly Lambertian regardless of the Ag thickness (since there is no strong microcavity structure in these devices).

In Type-IB devices, as the Ag thickness increases, the directly out-coupled top radiation (C545T emission) decays rapidly due to reduced transmission of the semi-transpar-

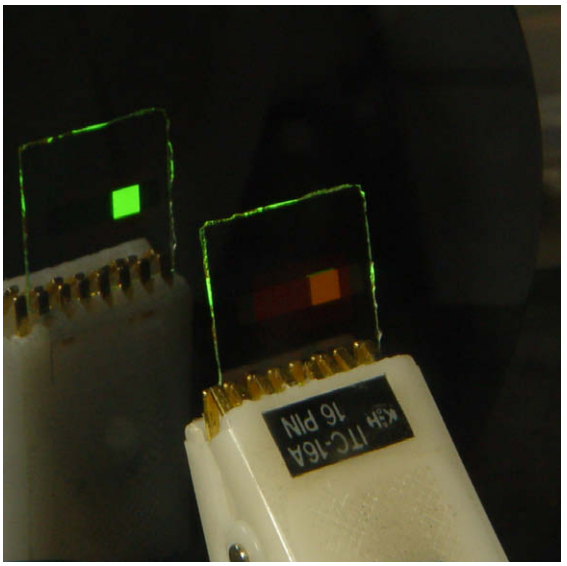

Fig. 5. Photo of a Type-IB double-emitting device with the Ag thickness of 40 nm (i.e. the device shown in Fig. 4c), where green emission is observed from the bottom side (the reflected image appearing in the reflecting mirror) and orange-like emission is observed from the top side. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

ent cathode. Yet, interestingly the intensity of the SPP-recycled top emission (DCJTB emission) stays rather constant versus the Ag cathode thickness (which will be explained later in this section). As such, for the top emission, the ratio of the DCJTB emission relative to the directly out-coupled C545T emission rises when the Ag thickness increases, providing a capability of color tuning. Due to the capability to tune emission colors with the metal thickness, the SPP-mediated energy transfer can be used for implementing double-emitting OLEDs with different emission colors on two sides or with color tuning capability. For instance, Fig. 5 shows a photo of a Type-IB double-emitting device with the Ag thickness of 40 nm (i.e. the device shown in Fig. 4c), where green emission is observed from the bottom side (the reflected image appearing in the reflecting mirror) and orange-like emission is observed from the top side.

Fig. 6a and b shows the external quantum efficiencies for bottom emission and top emission of Type-IA devices (with non-doped capping), respectively. Fig. 6c and d shows the external quantum efficiencies for bottom emission and top emission of Type-IB devices (with doped capping), respectively. Magnitudes and trends of efficiencies (versus Ag thickness) for bottom emission of both Type-IA/Type-IB devices are basically same; yet they differ for top emission of Types-IA and IB devices. The top-emission quantum efficiency of Type-IA devices drops rapidly with increasing the Ag thickness, but the efficiency drop is more gradual for Type-IB devices. In Table 2, measured the quantum efficiencies of the bottom emission, the top emission, and the total emission (including both top and bottom emission) for both Type-IA/Type-IB devices are listed and are compared to those of the conventional bottom-emitting device (with Ag = 120 nm). All these efficiencies are also plotted in Fig. 7 as a function of the Ag thickness for comparison. For Type-IA devices (with non-doped capping), the total efficiency drops monotonically in reducing the Ag thickness. Yet for Type-IB devices (doped capping) enhanced total efficiency is observed for Ag = 50 and 40 nm, although the enhancement by up to 3% is modest. It however should be noticed that the present devices have not gone through thorough optimization yet. For instance, with changing the top mirror structure/property of the devices, the organic layer structures in the device should be modified accordingly for maximizing optical output. Preliminary analyses show that further enhancement should be achievable.

In Fig. 7, the measured quantum efficiencies are also compared with the calculated out-coupling efficiencies for top emission ($\eta_{device,top}$), bottom emission ($\eta_{device,bot}$) and total emission ($\eta_{device} = \eta_{device,top} + \eta_{device,bot}$). $\eta_{device,top}$ is calculated by $\eta_{device,top} = \eta_{d\text{-}out,top} + ET_{d-a} \times QY_a \times \eta_{a\text{-}out,top} + A_{d-a,direct} \times QY_a \times \eta'_{a\text{-}out,top}$. $\eta_{d\text{-}out,top}$ is the direct out-coupling efficiency for donor (C545T) top emission. By taking into consideration of the complex optical index (i.e. both n and k) of the DCJTB-doped Alq_3 capping, the $\eta_{d\text{-}out,top}$ for Type-IB devices would suffer ~10% decrease compared with $\eta_{d\text{-}out,top}$ for Type-IA devices due to direct absorption by acceptors, which is consistent with the experiment results shown in Fig. 4a–d). ET_{d-a} is the efficiency of the donor (C545T)-to-acceptor (DCJTB) energy transfer mediated by coupled SPPs for Type-IB devices (for instance, ~6.43% for the OLED with Ag = 40 nm, Table 1). QY_a is the emission quantum yield of the acceptor (1 wt.% DCJTB doped in the Alq_3 capping, ~70%). $\eta_{a\text{-}out,top}$ is the out-coupling efficiency for acceptor top emission (through SPP-mediated energy transfer). $A_{d-a,direct}$ is the efficiency of the donor (C545T)-to-acceptor (DCJTB) energy transfer through direct absorption for Type-IB devices ($\sim 0.1 \times \eta_{d\text{-}out,top}$). $\eta'_{a\text{-}out,top}$ is the out-coupling efficiency for acceptor top emission (through direct acceptor absorption). Since $\eta_{d\text{-}out,top}$ is much larger than $A_{d-a,direct} \times QY_a \times \eta'_{a\text{-}out,top}$, indeed it results in $\eta_{device,top} = \eta_{d\text{-}out,top} + ET_{d-a} \times QY_a \times \eta_{a\text{-}out,top} + A_{d-a,direct} \times QY_a \times \eta'_{a\text{-}out,top} \approx \eta_{d\text{-}out,top} + ET_{d-a} \times QY_a \times \eta_{a\text{-}out,top}$. In calculating ET_{d-a}, the emission properties of the donor emitter, the SPP modal field distribution, the propagation properties of the SPP modes, and the complex dielectric constants of related media are used. The calculated ET_{d-a} values (for C545T donor and DCJTB acceptor) for different Ag thicknesses are listed in Table 1, which are basically consistent with the variation of the DCJTB top-emission intensity versus Ag thickness shown in Fig. 4a to d. The ET_{d-a} values do not vary significantly versus the Ag thickness (20–40 nm) till the Ag thickness increases to 50 nm. Meanwhile, the transmission of thin Ag drops significantly when its thickness increases from 20 to 50 nm. These explain why the intensity of the SPP-recycled top emission (DCJTB emission) stays rather constant versus the Ag cathode thickness, in contrast with that of the directly out-coupled C545T top emission. On the other hand, $\eta_{device,bot}$ is calculated by $\eta_{device,bot} = \eta_{d\text{-}out,bot} + ET_{d-a} \times QY_a \times \eta_{a\text{-}out,bot}$, where $\eta_{d\text{-}out,bot}$ is the direct out-coupling efficiency for donor bottom emission, and $\eta_{a\text{-}out,bot}$ is the out-coupling efficiency for acceptor bottom emission. Since $\eta_{d\text{-}out,bot}$ is much larger than $ET_{d-a} \times$

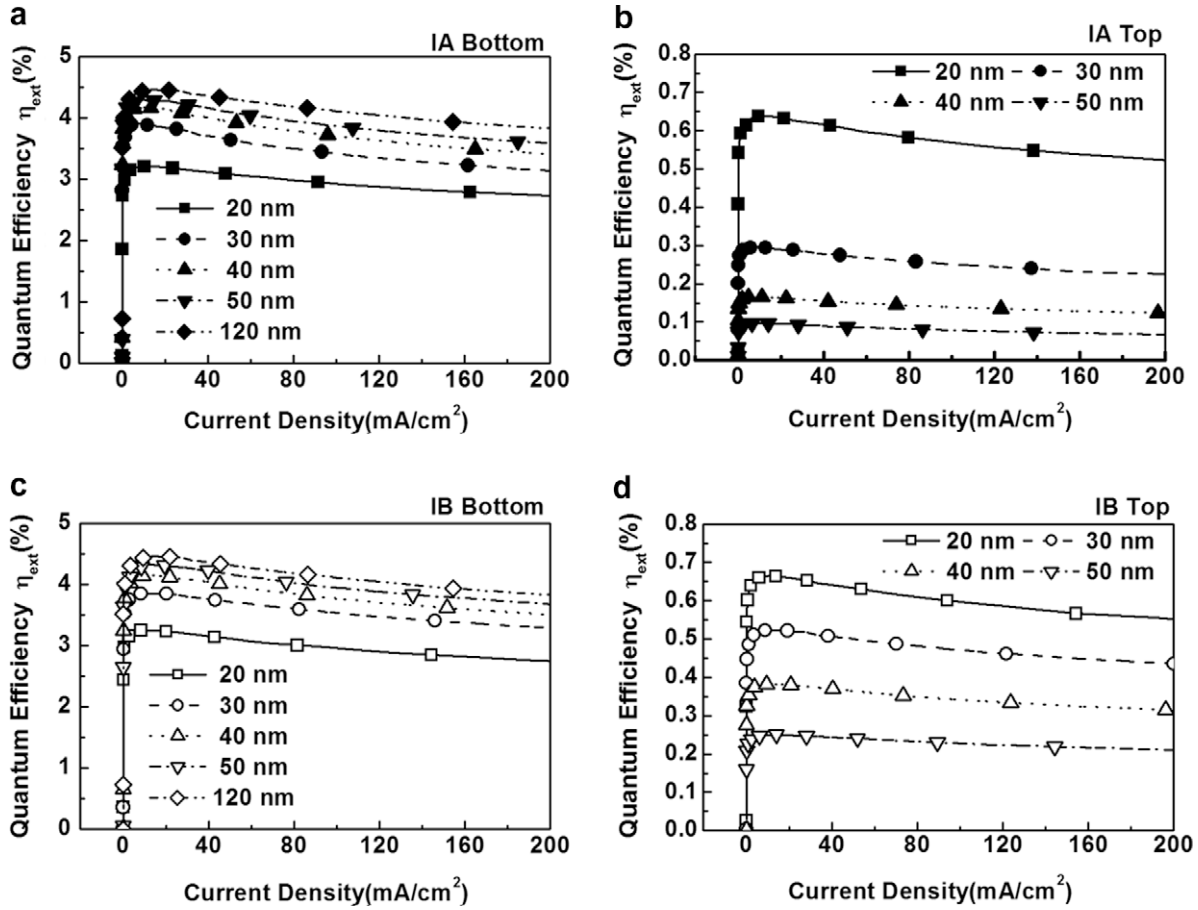

Fig. 6. (a) and (b) show the external quantum efficiencies for bottom emission and top emission of Type-IA devices (with non-doped capping), respectively. (c) and (d) show the external quantum efficiencies for bottom emission and top emission of Type-IB devices (with doped capping), respectively.

Table 2
The measured external quantum efficiencies of various devices. "Enhancement" indicates the ratio of the total efficiency of various devices relative to that of the conventional bottom-emitting device (Ag = 120 nm).

Ag (nm)	IA				IB			
	Bottom (%)	Top (%)	Total (%)	Enhancement	Bottom (%)	Top (%)	Total (%)	Enhancement
20	3.21	0.64	3.85	0.86	3.25	0.68	3.93	0.88
30	3.90	0.3	4.20	0.94	3.85	0.52	4.37	0.98
40	4.17	0.17	4.34	0.97	4.14	0.38	4.53	1.014
50	4.30	0.10	4.40	0.99	4.3	0.3	4.6	1.03
120	4.46	0.0	4.46	1.00	4.46	0.0	4.46	1.00

$QY_a \times \eta_{a\text{-out,bot}}$, ($\eta_{d\text{-out,bot}} \gg ET_{d-a} \times QY_a \times \eta_{a\text{-out,bot}}$), indeed it results in $\eta_{device,bot} = \eta_{d\text{-out,bot}} + ET_{d-a} \times QY_a \times \eta_{a\text{-out,bot}} \approx \eta_{d\text{-out,bot}}$. Thus in bottom emission of all Type-IB devices (Fig. 4e), the DCJTB acceptor emission (recycled SPP emission) is hardly visible. As can be seen in Fig. 7, overall rather good agreement between calculation and experiment results of efficiencies is obtained.

3.3. Color-tunable double-emitting devices: Type II

As has been demonstrated in the previous section, by varying the metal cathode thickness, the SPP-mediated energy transfer (or SPP recycling) can be used for implementing double-emitting OLEDs with different emission colors on two sides or with color tuning capability. As another instance of such implementation, in Type-II devices, by adopting a blue-emitting layer in the device (i.e. using the blue-emitting perylene dopant in ADN) and a yellow dopant (i.e. rubrene that can absorb perylene emission) in the capping, double-emitting devices with blue emission from the bottom side and white emission from the top side were realized.

In Fig. 8, the (0°) EL spectra measured from the top side of Type-II devices with different Ag cathode thick-

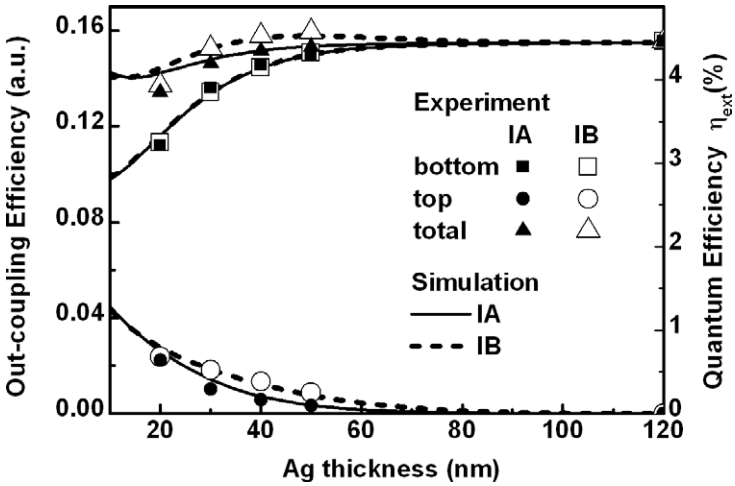

Fig. 7. The measured quantum efficiencies of the bottom emission, the top emission, and the total emission (including both top and bottom emission) as a function of the Ag cathode thickness for both Type-IA/Type-IB devices, compared with the calculated out-coupling efficiencies for top emission, bottom emission and total emission.

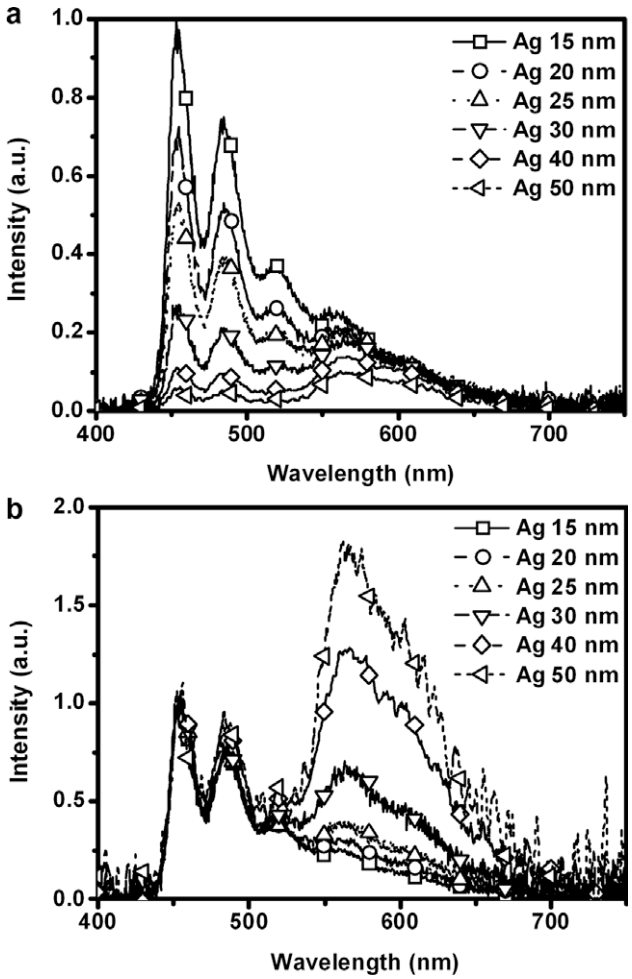

Fig. 8. The (0°) EL spectra measured from the top side of Type-II devices with different Ag cathode thicknesses (X = 15, 20, 25, 30, 40, and 50 nm) at a fixed current density: (a) with relative intensities, and (b) normalized to the blue perylene emission peak.

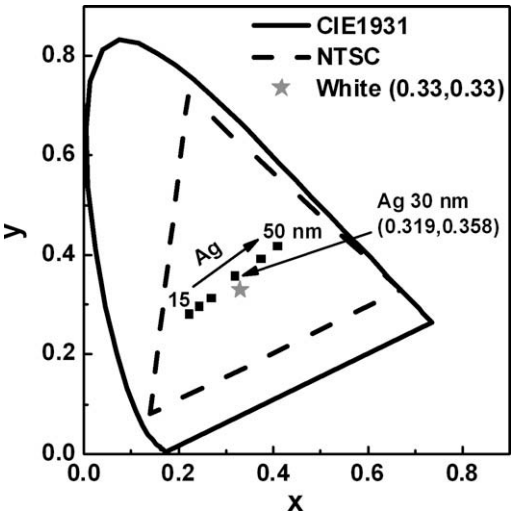

Fig. 9. 1931 CIE coordinates of top-emission EL of Type-II devices with different Ag cathode thicknesses (X = 15, 20, 25, 30, 40, and 50 nm).

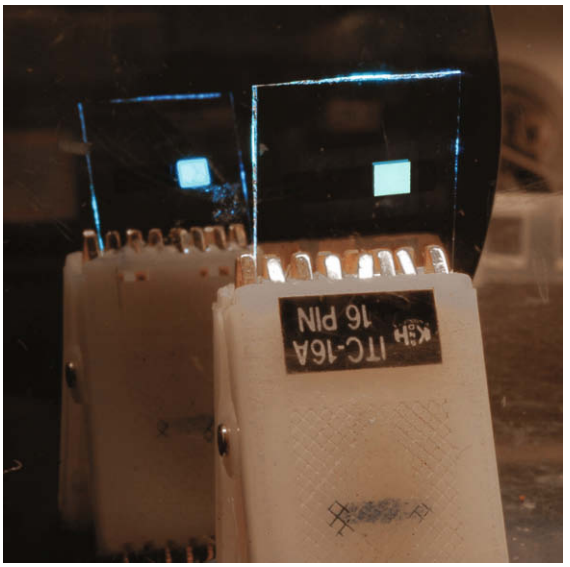

Fig. 10. Photo of the Type-II double-emitting device with the Ag thickness of 30 nm, where blue emission is observed from the bottom side (the reflected image appearing in the reflecting mirror) and white emission is observed from the top side. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

nesses (X = 15, 20, 25, 30, 40, and 50 nm) are shown. Fig. 8a shows the EL spectra with relative intensities at a fixed driving current, while Fig. 8b shows the EL spectra normalized to the perylene emission peak. For the top emission of Type-II devices, the ratio of the yellow rubrene emission relative to the directly out-coupled blue perylene emission rises when the Ag thickness increases, yielding white emission with a wide range of complementary color compositions. Although the total top and bottom emission intensities decrease with increasing the Ag thickness (as in Type-I devices), yet it clear indicates the possibility of color tuning with this approach. Fig. 9 shows the 1931 CIE coordinates of top-emission EL of these Type-II devices, demonstrating that a wide range of white colors (from bluish white to yellowish white) can be tuned simply by adjusting the metal cathode thickness. In particular, the Type-II device with a Ag thickness of 30 nm gives CIE coordinates of $(x, y) = (0.319, 0.358)$, very close to the ideal equal-energy white at $(x, y) = (0.33, 0.33)$. Fig. 10 shows a photo of the Type-II double-emitting device with the Ag thickness of 30 nm, where blue emission is observed from the bottom side (the reflected image appearing in the reflecting mirror) and white emission is observed from the top side. Such a scheme of white emission has a particular advantage that the EL spectra/white color would not change with the driving currents/biases. These double-emitting OLEDs with color tunability may have some interesting applications, such as one single backlight panel for two touch pads requiring different backlight colors.

4. Conclusions

In typical OLEDs, a significant portion of internally generated radiation is trapped into the surface plasmon polariton modes, in general not accessible for external use. By thinning the metal electrode, the SPP modes can be coupled to the outside surface of the device. As such, one can recycle a portion of SPPs by capping the thinned metal electrode with an appropriate absorbing/re-emission medium, inducing SPP-mediated energy transfer and re-emission. Such an approach may be used for implementing double-emitting OLEDs with different emission colors on two sides and with a broad color tuning capability.

ABSTRACT

An efficient top-emitting organic light-emitting diode (TEOLED) achieving high luminance at very low voltage and enabling the integration of organic light-emitting diodes (OLEDs) with silicon-based driving circuits to realize high resolution and low power consumption OLED microdisplay is introduced. One of the key features is a p doped hole injecting layer (HIL) significantly reducing the driving voltage matching with that of silicon-based driving circuits without a high-voltage option. A well modulated interface is introduced to reduce the quenching of the excitons, and direct charge trapping effect in the emitter layer (EML) also play a role in balancing the charges in EML. We have demonstrated a TEOLED achieving a brightness of about 2500 cd/m^2 at 4 V and a maximum power efficiency of 28.8 lm/W at 1000 cd/m^2, which are ones of the best results of fluorescent emitters reported in literatures. Our OLED microdisplays without a high-voltage CMOS process show potentially low cost for commercial production.

1. Introduction

OLEDs have attracted intensive attention during the past two decades due to their potential applications in flat panel displays and lighting [1–5]. TEOLEDs have the advantage of easy integration with opaque substrates, such as silicon wafers with active matrix driving circuits [6–10]. TEOLEDs on CMOS substrates, including peripheral row and column driving part as well as pixel, contribute to the emergence of OLED microdisplays which have great promising applications in military and commercial productions. However, it's not easy to drive an OLED emitting enough brightness to the response of human eyes with the conventional logic MOSFET due to the difference of the driving voltage of these two components. One possible approach is to adopt a high-voltage CMOS process which requires additional mask steps to form the drift region to disperse the strong electric field [10]. In this approach, the additional mask steps entail process complexity and high cost [10]. An alternative approach is to reduce the driving voltage of OLEDs to match with that of conventional silicon-based active matrix circuits ($\leqslant$5 V). The introduction of the concept of electrical doping would reduce the driving voltage of OLEDs to be compatible with that of CMOS circuits. Recently, electrical doping [11] technology containing p doping or n doping or p–i–n structure was introduced in OLEDs to achieve low driving voltage and high power efficiency. Note that the devices with state-of-the-art performances were fabricated with p–i–n architectures [2,4,12–19].

In this paper, we report OLED microdisplays by introducing TEOLEDs, on CMOS substrates, with MoO_x ($2 < x < 3$) [20] p doping strategy accompanied with highly efficient fluorescent dye doped emitting layer to achieve

low voltage and high power efficiency, aiming for low-cost mass production. We investigate the effect of MoO_x p doping. Due to this unique electrical doping strategy, which leads to the formation of charge transfer (CT) complexes and subsequently an increased conductivity in the injecting layer, we meet the requirement of driving an OLED with silicon-based CMOS circuits, which could be readily obtained from a foundry, without a high-voltage option.

2. Experimental

2.1. TEOLEDs fabrication and measurement

TEOLEDs on pristine 1-mm-thick Si substrates covered with 340 nm SiO_2 were fabricated in the same batch. All the materials were used as purchased. The OLED microdisplays shared common cathodes were fabricated in the same run with TEOLEDs except for the anodes. All the devices were transferred to the glove box (MBRAUN) and then encapsulated under a nitrogen atmosphere using slow setting two-part epoxy resin adhesives (Araldite Precision – Syringe Pack) mixed with Syringe A and Syringe B and covered with glass lids. The glue solidification process would take couples of hours. TEOLEDs were kept in the glove box till measured in air after a 24 h break with a PR650 spectrascan spectrometer and a Keithley 2400 programmable voltage–current source. The external quantum efficiency, weighted according to the response of the human eyes, was determined in an integrating sphere (Jm-3200, Jm-smart Technology) calibrated by a halogen lamp (Halostar, OSRAM).

2.2. Morphology characterization

An atomic force microscopy (SII NanoTechnology) and an Olympus BX51M model optical microscope equipped with a CCD camera were used to characterize the morphologies. The heat treatment processes were carried out in a low vacuum oven (DZF-6021, Yiheng Instruments). In the first half an hour, the temperature was maintained at 150 °C, and then cooled down to the ambient temperature for 6 h.

2.3. Chip fabrication

Here, CMOS refers to complementary metal oxide semiconductor, and MOSFET for metal oxide semiconductor field effect transistor. The 320 × 240 pixel silicon driving circuit, containing a novel three-transistor voltage-programmed pixel driver, was implemented using the standard 0.5 μm CMOS process (CSMC, Central Semiconductor Manufacturing Corporation), then a newly developed Ag chemical mechanical polishing (CMP) process. Both the 4 bit D/A converter and the pixel driver were implemented with pMOS devices. The pixel area was 28.4 × 28.4 μm^2 and the display area was 10.7 × 8.0 mm^2 with a diagonal of about 13 mm.

Fig. 1a presents a schematic illustration of our OLED microdisplay and a finished chip is shown in Fig. 1b after tape out in the wafer foundry. After a chemical mechanical polishing (CMP) process (Fig. 1d and e), the large steps at the pixel edges (not shown here) fabricated in the CMOS foundry would be smoothed for OLED fabrication.

3. Results and discussion

For comparison, we fabricated two kinds of TEOLEDs on silicon substrates without circuits and the structures are as follows: Si/SiO_2/Ag (60 nm)/MoO_x (2 nm)/4,4′,4″-tris (N-3-methylphenyl-N-phenyl-amino)triphenylamine (m-MTDATA) (45 nm)/N,N′-bis(naphthalene-1-yl)-N,N′-bis (phenyl)-benzidine (NPB) (5 nm)/tris(8-hydroxy-quinolinato)aluminium (Alq_3): 10-(2-benzothiazolyl)-1,1,7,7-tetramethyl-2,3,6,7-tetrahydro-1H,5H,11H-benzo[*l*]-pyrano[6,7,8-*ij*]quinolizin-11-one (C545T) (20 nm, 100:1)/4,7-diphenyl-1,10-phenanthroline (BPhen) (40 nm)/LiF (1 nm)/Al (2 nm)/Ag (20 nm), and Si/SiO_2/Ag (60 nm)/m-MTDATA:MoO_x (10 nm, 3:1)/m-MTDATA (35 nm)/NPB (5 nm)/Alq_3:C545T (20 nm, 100:1)/BPhen (40 nm)/LiF (1 nm)/Al (2 nm)/Ag (20 nm). Fig. 2 shows the brightness-voltage–current density characteristics of these two TEOLEDs. It is obvious that the one with MoO_x doped HIL shows better performance regarded to the luminance and current. TEOLED with MoO_x doped m-MTDATA reaches a luminance of about 2 cd/m^2 at 2.30 V, compared to that of 1 cd/m^2 at 2.35 V with MoO_x buffer. The luminance at 4 V for the one with MoO_x buffer and MoO_x doping, respectively, are 579 and 2500 cd/m^2. The shadow and the dash line in Fig. 2 indicate the output voltage range of our microdisplay driver with 2.0 V reference voltage of D/A convertor. The p doped device proves steeper brightness–voltage curve, which is the prerequisite to realize high gray-resolution image in OLED microdisplays. The benefits of our structures will be discussed in detail in the followings.

As known, a balanced injection of the carriers would improve the efficiencies and reduce the efficiency roll-off [21]. As shown in Fig. 3, we observed no efficiency loss in p doped TEOLED in spite of the imbalance injection of holes and electrons from counter electrodes according to our previous study of the single carrier devices [22]. While TEOLEDs without and with MoO_x doping show no difference in current efficiency (Fig. 3a), the p doped device exhibits significantly improved power efficiency (Fig. 3b), due to the reduction of driving voltage. A high power efficiency of 28.8 lm/W is achieved at a luminance of 1000 cd/m^2, compared to that of 22.7 lm/W at the same luminance for the one with MoO_x buffer. We ascribe these properties to the well modulated interfaces suppressing the quenching of the emitters and emitter doping-induced carrier trapping [23] reducing carrier imbalance in the EML. By introducing this MoO_x doping strategy, monochromatic green OLED microdisplays (see the inset of Fig. 3a) are demonstrated by using the TEOLED stacks mentioned above, while those with MoO_x buffer are too dim to be visible due to the unavoidable luminance loss on the rough CMOS substrate caused by the complicated chip processing.

The elimination of excess charge accumulation at the emitter's interfaces will reduce the quench of the excitons,

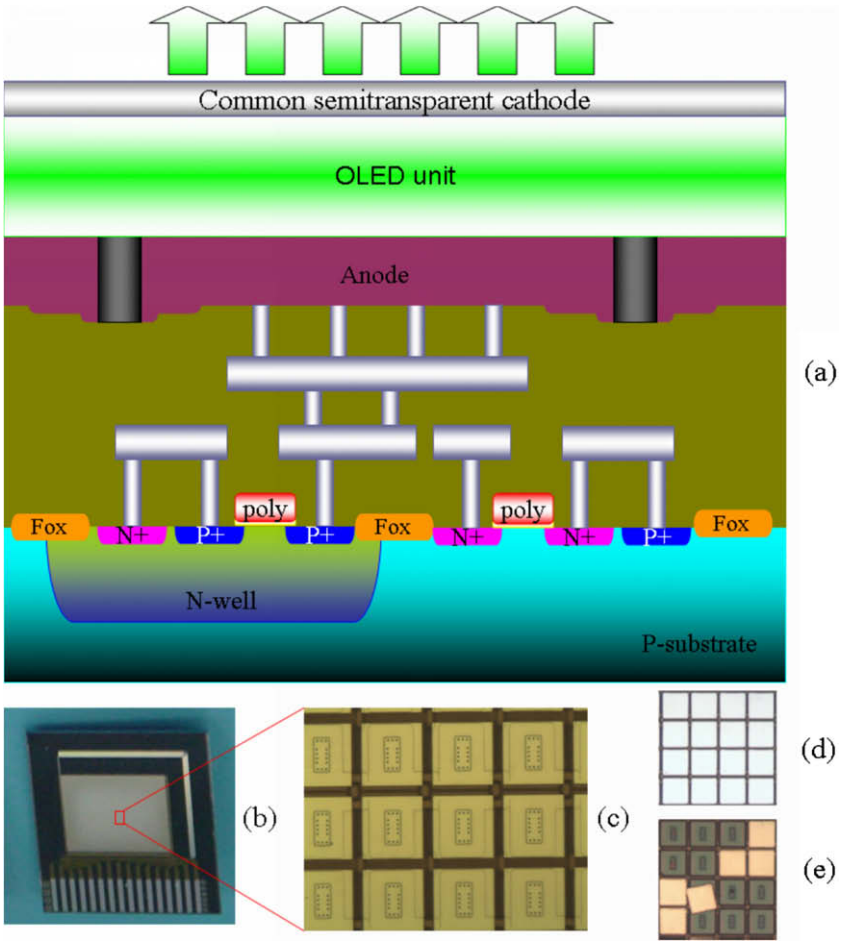

Fig. 1. (a) Schematic diagram of OLED microdisplay. (b) A chip from the foundry before CMP process. (c) a magnified view of the pixels. (d) pixels after Ag CMP process. (e) defects made to characterize the topography after CMP process.

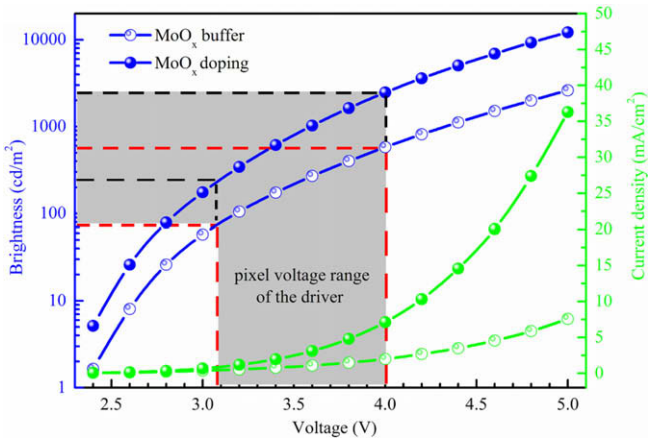

Fig. 2. Brightness–voltage–current density characteristics of the devices without and with MoO_x doping.

thereby maintain high efficiency at high luminance. The 5-nm-thick NPB also serves as an electron blocking layer (EBL) as its high lowest unoccupied molecular orbital (LUMO) level hinders electrons from reaching m-MTDATA and anode. Meanwhile, the EBL prevents excitons generated in the emission layer from drifting and diffusing into the highly conducting HIL where non-radiative quenching might occur [2]. We consider that the excess positive charges, due to efficient hole injection by p doping, tend to accumulate at the interface of m-MTDATA/NPB, but

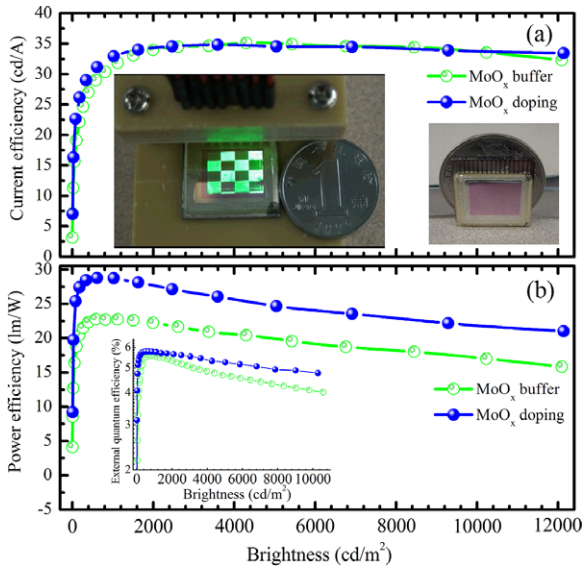

Fig. 3. (a) Current efficiency–brightness characteristics. (b) power efficiency–brightness characteristics of the devices with MoO_x buffer and MoO_x doping, respectively. The insets of (a) shows a snap of the unpackaged OLED microdisplay (left-hand side), on a home-made 16-pin probe testing platform, playing the ANSI [8] contrast ratio pattern, and a photograph of the chip with a coin of 1 Yuan RMB (right-hand side), respectively. The inset of (b) exhibits the external quantum efficiencies (5.6% for the one with MoO_x buffer and 5.8% for the one with MoO_x doping at a luminance of 1000 cd/m^2, respectively.).

not at the interface of NPB/EML. The thin NPB layer followed by the pristine m-MTDATA not only results in the energy level alignment but also dissipates the accumulated holes at the interface of EBL/EML. These conclusions are likely consistent with the result reported in the literature [24].

Another benefit of our structure is the highly efficient emitter, C545T, which also plays a role of hole and electron traps in Alq_3 [25–27]. The trapped holes will decrease free hole distribution in the EML, and hence a reduction of current density [26]. It is pointed out that imbalance between the numbers of holes and electrons in the EML are one of the sources of efficiency roll-off at high intensities [21]. By introducing electron transporting layer (ETL) BPhen owning relatively high electron mobility and low highest occupied molecular orbital (HOMO) level (as hole blocking layer, HBL) which can confines the excitons in the EML, we can avoid a vast imbalance of holes and electrons in the EML, in spite of the imbalance injection from the electrodes. In our structures, not only charge carrier trapping but also direct exciton recombination on the fluorescent dopants are responsible for the high efficiencies, and the energy transfer followed by Förster energy transfer process from the host molecule to the dopant molecule can also play a role.

In the stage of OLED microdisplays package for practical utility, wire-bond [28,29] is needed to connect to the external circuits on a holder. During the wire-bond process, the temperature of the substrate will rise, which might affect the reliability of OLEDs. Here, we demonstrated that MoO_x could also help to improve the stability of TEOLEDs. Apparent differences of the morphologies and topographies of 10 nm neat m-MTDATA and m-MTDATA doped with MoO_x on Ag (60 nm) after a heat treatment at 150 °C for half an hour, shown in Fig. 4, can be seen. The surface morphology of pristine m-MTDATA (Fig. 4c) is damaged by thermal annealing due to the crystallization. In contrast, that of MoO_x doped m-MTDATA (Fig. 4d) ap-

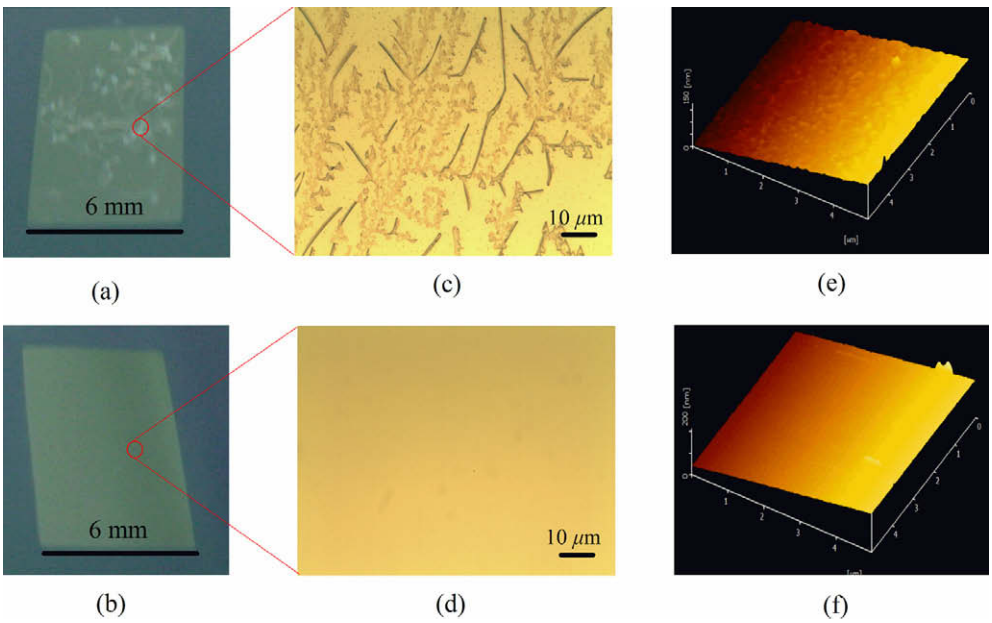

Fig. 4. (a and b) Photos of 10 nm pristine m-MTDATA and MoO_x doped m-MTDATA on 60 nm Ag on the Si/SiO_2 substrate, respectively. (c and d) microscopical images of the above two devices after annealing. (e and f) AFM topographic images of the above devices after annealing at 150 °C.

pears to be no significant change after annealing, which is consistent with the AFM measurement (Fig. 4f). This result suggests that MoO_x in m-MTDATA not only leads to an increase of the conductivity, but also contributes to an improvement of the stability of TEOLEDs.

4. Conclusions

In summary, we have succeeded in reducing the operating voltage of TEOLEDs emitting high brightness to below 5 V, resulting in the possibility of introducing cost-effective CMOS substrates without high-voltage option from the foundry. The high conductivity of the p doping layer contributes to a decrease in driving voltage as well as an increase in the reliability of TEOLEDs. The p doped TEOLED with highly efficient C545T fluorescent dye exhibits high brightness of 10,000 cd/m^2 at 4.9 V and a maximum power efficiency of 28.8 lm/W at 1000 cd/m^2. The highly conductive p doped layer also allows the introduction of thicker TEOLEDs, which effectively reduces pixel defect formation caused by electrical short circuits between the bottom and top electrodes, on the CMOS substrates with rough surfaces. OLED microdisplays are demonstrated by combining the low voltage and highly efficient TEOLED with MoO_x p doping layer. We speculate that a controlled n doping, a highly efficient phosphorescent emitter and a carefully designed outcoupling scheme will result in a higher power efficiency [14]. Low power consumption microdisplays based on the efficient TEOLEDs introducing the inexpensive and readily available MoO_x p dopant, combined with the mature and cheap CMOS technology, show potentially low cost for commercial use.

ABSTRACT

By utilizing a newly developed deep-blue iridium complex along with efficient green and orange-red phosphors, we have successfully demonstrated efficient three-component phosphorescent white-emitting organic light-emitting devices (WOLEDs) with excellent performances. Such WOLEDs were based on the deep-blue phosphorescent OLEDs architecture with double emitting layers and double confining layers; portions of the deep-blue phosphors were selectively replaced with green and orange-red phosphors, thereby forming a structure with the green/orange-red emitting layers sandwiched between the two deep-blue emitting layers. Such three-component phosphorescent WOLEDs yielded a high color rendering index (CRI) of up to 94 and Commission Internationale de l'Eclairage (CIE) coordinates close to the ideal equal-energy white (0.33, 0.33). Furthermore, they exhibited rather stable colors and high CRI over a wide brightness range of 10^2–10^4 cd/m^2 and yielded electroluminescence efficiencies of up to 10.3%, 24.0 cd/A and 16.4 lm/W for the forward directions.

1. Introduction

With intrinsically high quantum efficiency, white-emitting organic light-emitting devices (WOLEDs) incorporating phosphorescent emitters have become the most promising candidates for meeting the stringent efficiency requirements in lighting applications [1,2]. For high-quality white-light illumination, WOLEDs with CIE$_{x,y}$ coordinates similar to those of the blackbody radiation (with a correlated color temperature (CCT) between 2500 K and 6500 K), and a color rendering index (CRI) above 80 are required [3]. While simply mixing two complementary colors can effectively produce white light, the CRI of such two-component WOLEDs are usually rather mediocre. Intuitively, the CRI can be enhanced by increasing the number of dopants to extend the spectral range of the electroluminescence (EL). For instance, in 2002, D'Andrade et al. demonstrated that the CRI of phosphorescent WOLEDs could be greatly improved from 50 to 83 by using three (red, green and greenish-blue) phosphorescent dopants instead of two complementary (red and greenish-blue) dopants [4]. As another example, in 2006, the same group combined blue fluorophors and red/green phosphors to generate white EL, in which deeper blue emission was obtained from the singlet emission of the fluorophors (to relax the requirement for the more challenging true-blue phosphors with high emission efficiencies) while red/green emission was obtained from the triplet emission of the phosphors [5]. In such hybrid WOLEDs, the CRI was improved to 85. In 2007, Schwartz et al. also successfully demonstrated high-CRI WOLEDs (CRI = 86) using a similar hybrid fluorophor/phosphor approach [6].

Although the hybrid fluorophor/phosphor approach has achieved certain success in raising the CRI of phosphor-incorporated WOLEDs, the inherent singlet/triplet branch-

ing ratio in OLEDs may nevertheless still limit the color tuning, thereby reducing the CRI or resulting in color-efficiency tradeoffs for phosphor-incorporated WOLEDs. As such, the fabrication of WOLEDs using all red/green/blue phosphors is still highly desired, since it would yield the greatest flexibility in tuning the color of WOLEDs. Until recently, one of the major obstacles in implementing high-CRI three-component phosphorescent WOLEDs was the lack of efficient true-blue phosphors, giving insufficient light output in the shorter wavelength region. For instance, the adoption of the common greenish-blue phosphor FIrpic in the three-component phosphorescent WOLEDs generally yielded a warm white and a CRI of only up to ~80 due to deficient color rendering in the blue region [7], which would limit the applications of such WOLEDs in lighting. However, such deficiency may be compensated by adopting novel true-blue organic phosphors developed recently [8–10]. In this paper, through employment of a recently developed true-blue iridium phosphor $Ir(fppz)_2(dfbdp)$ together with efficient green/red phosphors in appropriate device architectures, we report three-component pure-white phosphorescent WOLEDs with CRI of up to 94 and with CIE coordinates close to the ideal equal-energy white emission (0.33, 0.33).

2. Experimental

2.1. Materials

We employed the deep-blue iridium phosphor, $Ir(fppz)_2(dfbdp)$ (Fig. 1a) [13], where fppzH and dfbdpH stand for 5-(2-pyridyl)-3-trifluoromethylpyrazole and (2,4-difluorobenzyl)diphenylphosphine, respectively. It has been shown that 2-pyridyl azole chromophores possess a very large intraligand $\pi\pi^*$ energy gap [11]. By reacting the chromophores with the third-row transition metals and the employment of appropriate ancillary chelates with sufficient $\pi\pi^*$ gaps, one can effect the isolation of a true-blue phosphors [12]. In our recent work [13,14], we have shown that the employment of non-conjugated ancillary chelates, such as the benzylphosphine chelate used in the present complex, not only greatly restricts their participation in the lowest-lying electronic transition but also enhances the coordination strength, leading to effective confinement of the lowest energy transition over the unique 2-pyridyl azole moiety and successful tuning of the phosphorescence toward authentic blue. Fig. 1b shows the photoluminescence (PL) spectrum of the heteroleptic Ir^{III} complex $Ir(fppz)_2(dfbdp)$ in CH_2Cl_2 solution. The lowest-energy PL peak locates at 431 nm, corresponding to a triplet energy of 2.87 eV. The PL spectrum clearly demonstrates its deep-blue phosphorescence, corresponding to $CIE_{x,y}$ of (0.162, 0.138) (Fig. 1c). It also exhibited rather high PL quantum yields when doped into the host materials used in this study [10]: 0.73 in 9-(4-tert-butylphenyl)-3,6-bis(triphenylsilyl)-9H-carbazole (CzSi, Fig. 2a) [15,16], and 0.58 in *p*-bis(triphenylsilyl) benzene (UGH2, Fig. 2a) [17].

On the other hand, the highly efficient green and red phosphors, tris(2-phenylpyridine)iridium(III) ($Ir(ppy)_3$) (Fig. 1a) and $Os(bpftz)_2(PPh_2Me)_2$ (Fig. 1a) [where bpftz stands for 3-trifluoromethyl-5-(4-tert-butyl-2-pyridyl) triazolate, PPh_2Me represents a monodentate phosphine ligand], were adopted in this study [18]. The widely used green phosphorescent emitter, $Ir(ppy)_3$, exhibits very high PL quantum efficiency (>90%) in wide-gap hosts [19]. On the other hand, the Os complex $Os(bpftz)_2(PPh_2Me)_2$ with high steric hindrance exhibits orange-red emission at around 603 nm, short excited-state lifetime (0.97 μs) and high PL quantum yield of ~90% in solution [20]. Fig. 1b shows their PL spectra along with those of the deep-blue complex $Ir(fppz)_2(dfbdp)$, while the corresponding CIE coordinates [(0.317, 0.616) for $Ir(ppy)_3$ and (0.624, 0.374) for $Os(bpftz)_2(PPh_2Me)_2$] are shown in Fig. 1c. The PL spectra of these B, G and R emitters cover most of the visible wavelengths, meaning that in principle, white emission with pure white colorant and high color rendering should be attainable with appropriate mixing of these phosphorescent emitters.

2.2. OLED fabrication

All synthesized compounds were subject to temperature-gradient sublimation under high vacuum before use. OLEDs were fabricated on the ITO-coated glass substrates with multiple organic layers sandwiched between the transparent bottom indium-tin-oxide (ITO) anode and the top metal cathode. The organic and metal layers were deposited by thermal evaporation in a vacuum chamber with a base pressure of $<10^{-6}$ torr. The deposition rate of organic layers was kept at ~0.2 nm/s. The deposition system permitted the fabrication of the complete device structure in a single pump-down without breaking vacuum. The active area of the device was 2×2 mm^2, as defined by the shadow mask for cathode deposition. Organic materials (other than phosphorescent emitters) and device structures used in this study are shown in Fig. 2a and b, respectively.

2.3. Device characterizations

Current–voltage–luminance (*I–V–L*) characterization of the devices was measured using an Agilent 4155B semiconductor parameter analyzer and a Si photodiode calibrated with Photo Research PR650. EL spectra of devices were collected by a calibrated CCD spectrograph. Total photon output from the device (either from the viewing direction or from all directions of the device) was measured in an integrating sphere containing a calibrated photodetector.

3. Results and discussion

For OLEDs incorporating deep-blue phosphors, one of the key challenges is the acquisition of effective device architectures. Deep-blue phosphors usually require large triplet energy hosts to prevent the reverse energy transfer from dopants to hosts [21]. Effective confinement of excitons in the emitting layer is also a critical issue. The excitons formed in the emitting layer would have high energy, and would therefore easily diffuse to adjacent layers and result in a decrease of the device efficiency or suffer

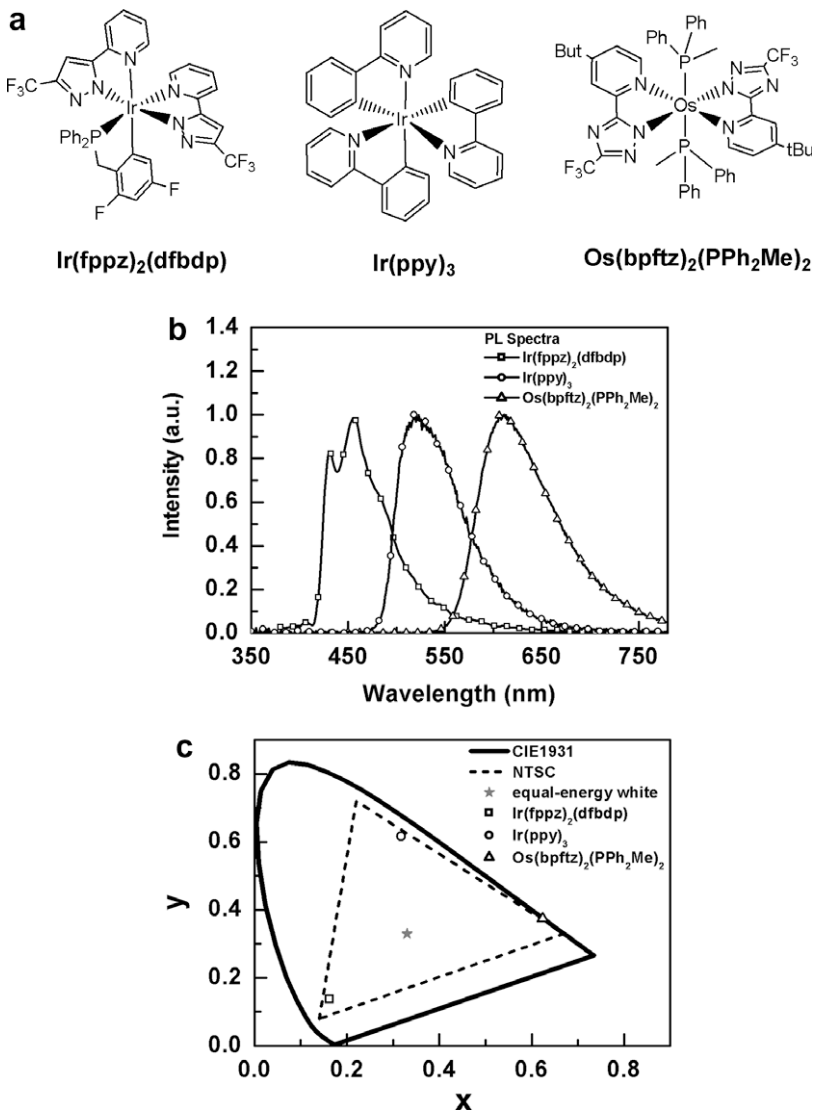

Fig. 1. (a) The structural drawings, (b) PL spectra, and (c) CIE coordinates of $Ir(fppz)_2(dfbdp)$, $Ir(ppy)_3$ and $Os(bpftz)_2(PPh_2Me)_2$ measured in CH_2Cl_2 solution.

from unwanted color degradation. Since the hosts of deep-blue phosphors generally have large triplet energy as well as larger HOMO/LUMO energy gaps, finding suitable blocking materials for exciton/carrier confinement is generally more difficult [22]. Besides, as with other OLEDs, charge balance is also important to ensure high efficiencies [23]. In this work, since we want to focus on WOLEDs incorporating deep-blue phosphors, prior investigations on the OLED structures incorporating the deep-blue phosphor $Ir(fppz)_2(dfbdp)$ deemed necessary.

For WOLEDs, device structures can be roughly classified into single- and multiple-emitting-layer (EML) architectures. The fabrication of WOLEDs with a single EML is usually difficult because the multiple dopants and the host have to be evaporated simultaneously with precise ratio control. Furthermore, the relative intensities of the different emissions might vary upon variation of the operational biases [24]. On the other hand, the device structure with multiple EMLs sometimes suffers from shifting of the recombination zone (RZ) upon increasing the biases [25]. As such, the buffer layer is often inserted between the EMLs to prevent the RZ shift and to stabilize the emission color [26,27]. However, the hindered carrier transport at the buffer layer might degrade the power efficiency. In this work, by using the developed deep-blue phosphorescent OLED device structure as a template, we implemented multiple-EML WOLEDs with pure white colorant and unprecedented high CRI value by selectively incorporating green and red phosphors, yet without inserting buffer layers between EMLs.

3.1. Blue OLEDs with different architectures

To prevent the back transfer of the triplet excitons from the deep-blue phosphors to the host material, the wide-gap materials, CzSi with a large triplet energy of 3.02 eV

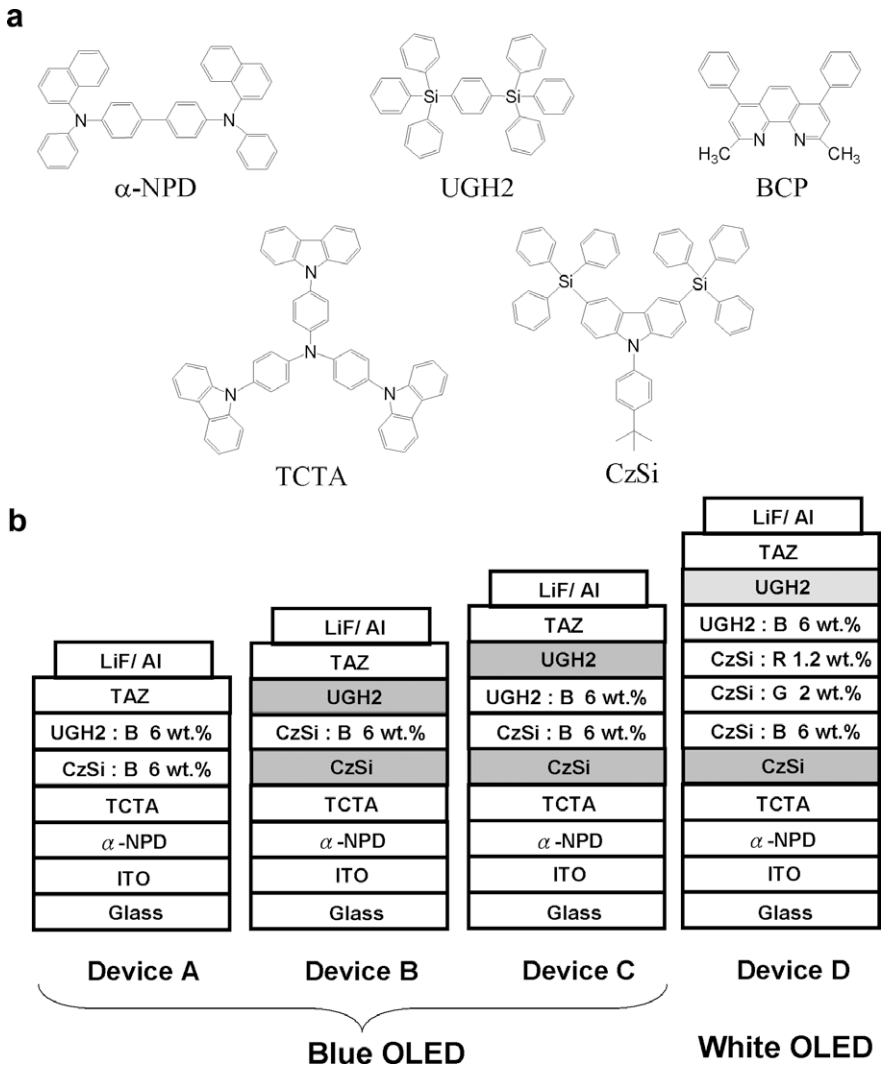

Fig. 2. (a) The structural drawing of materials used in OLEDs; and (b) schematic structures of blue and white OLEDs.

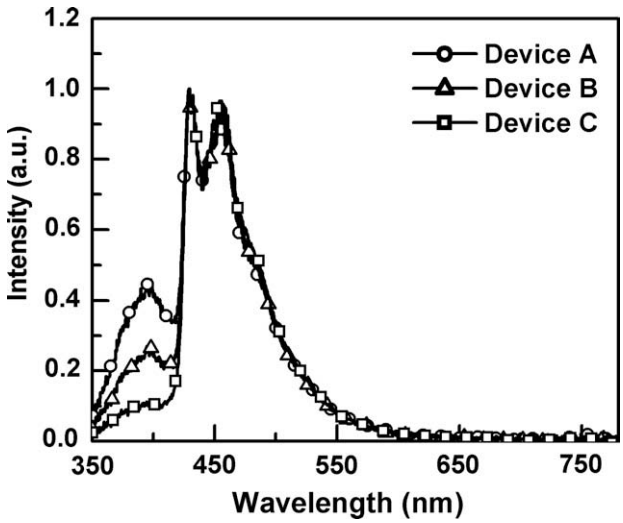

Fig. 3. EL spectra of Devices A–C at 1000 cd/m^2.

and UGH2 with a large triplet energy of 3.18 eV [15–17], were adopted as the hosts for the deep-blue phosphors. CzSi is of hole-transport nature, while UGH2 is of electron-transport nature [8]. Three different device architectures (Fig. 2b) for deep-blue OLEDs were investigated to examine the characteristics of carrier balance and carrier/exciton confinement. The first device structure (Device A) was composed of: ITO/α-NPD (30 nm)/TCTA (20 nm)/CzSi doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ (23 nm)/UGH2 doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ (3 nm)/TAZ (40 nm)/LiF (0.5 nm)/Al (150 nm). The second device (Device B) was composed of: ITO/α-NPD (30 nm)/TCTA (20 nm)/CzSi (3 nm)/CzSi doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ (23 nm)/UGH2 (2 nm)/TAZ (40 nm)/LiF (0.5 nm)/Al (150 nm). The third device (Device C) was composed of: ITO/α-NPD (30 nm)/TCTA (20 nm)/CzSi (3 nm)/CzSi doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ (23 nm)/UGH2 doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ (3 nm)/UGH2 (2 nm)/TAZ (40 nm)/LiF (0.5 nm)/Al (150 nm). In all these devices, 4,4′-bis[N-(1-naphthyl)-N-phenyl-amino]biphenyl (α-NPD) and 4,4′,4″-tris(carbazol-9-yl)-triphenylamine (TCTA) were used as the hole-transport layers (HTLs) [28], 3-(4-biphenylyl)-4-phenyl-5-(tert-butylphenyl)-1,2,4-triazole (TAZ) as the electron-transport layer (ETL) [29], LiF as the electron-injection layer [30], and aluminum as the cathode. The materials and device architectures are shown in Fig. 2.

In Device A, double emission layers (23-nm hole-transporting CzSi and 3-nm electron-transporting UGH2 doped with 6 wt.% $Ir(fppz)_2(dfbdp)$) were used to achieve balance between the hole and electron injection/transport and thus to shift the exciton formation zone away from the interfaces between the carrier-transport layers, taking advantage of the inherent physical nature of both CzSi and UGH2. Since the electron-transport capability of UGH2 is poorer than the hole-transport capability of CzSi, a relatively smaller thickness was used for the UGH2 emitting layer to avoid the degradation of device performances that may be induced by un-balanced carrier-transport properties. Device B consisted of a single emitting layer (23-nm hole-transporting CzSi doped with 6 wt.% $Ir(fppz)_2(dfbdp)$), and a thin layer of non-doped CzSi (3 nm) and UGH2 (2 nm) were inserted between the emission and hole-transport layers and between the emission and electron-transport layers, respectively. The hole-transporting CzSi possesses high-triplet-energy and is thus capable of blocking the high-energy triplet excitons (on the dopants) from migrating to TCTA (with a lower triplet energy than the dopant) [28]. On the other hand, the electron-transporting UGH2 with high-triplet-energy is expected to retard the high-energy triplet excitons (on the dopants) from migrating to TAZ (with a lower triplet energy than the dopant). For Device C, the double emission layers and the high-triplet-energy buffer layers on the two opposite sides of the emitting layers were simultaneously adopted for better confinement of triplet excitons and carriers.

Fig. 3 shows the EL spectra of these three blue-emitting devices. Device A exhibited EL predominantly from the deep-blue phosphor $Ir(fppz)_2(dfbdp)$, but a notable emission in the near-UV region was also observed, showing carrier recombination in the charge-transport layers (TCTA

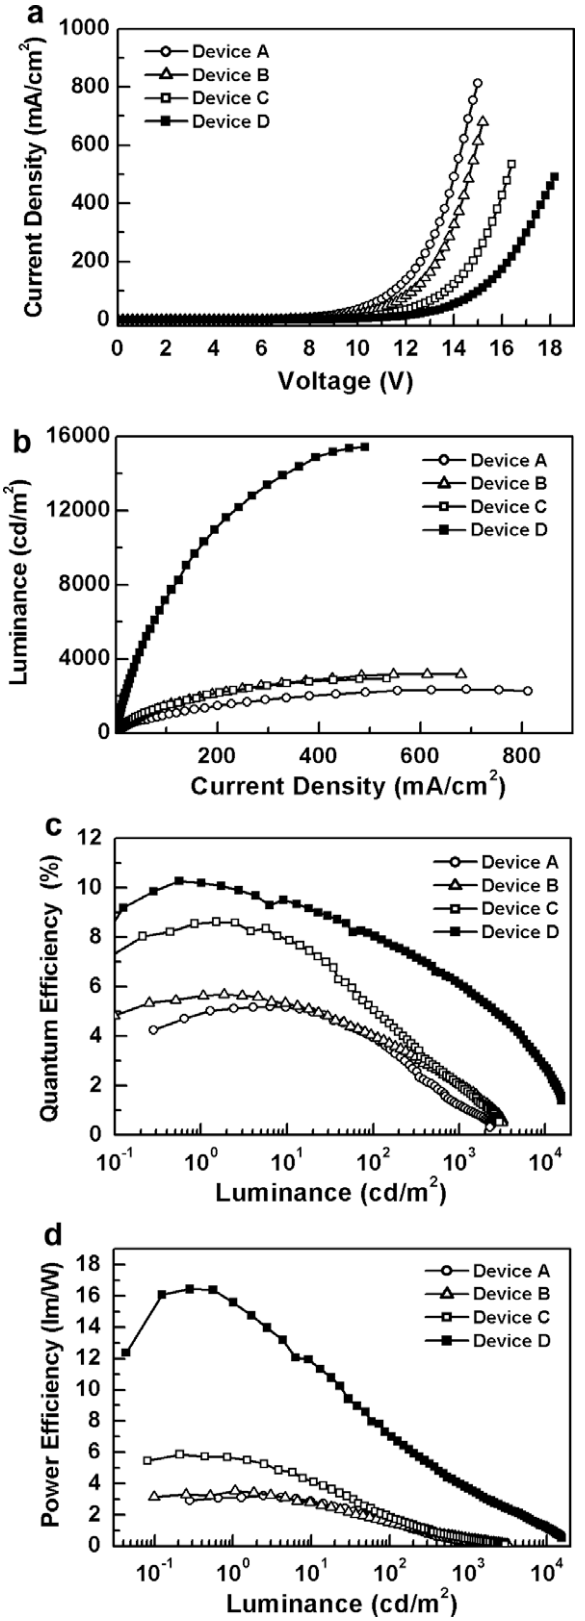

Fig. 4. (a) Current–voltage (*I–V*) characteristics, (b) luminance–current (*L–I*) characteristics, (c) external quantum efficiency versus luminance, and (d) power efficiency versus luminance for the Devices A–D.

and/or TAZ, both of which are known to exhibit near-UV emission at ~400 nm) [22]. With the employment of the two high-triplet-energy buffer layers on the opposite sides of the emitting layers (Devices B and C), the near-UV emission generated from TAZ or TCTA in Device A was significantly reduced. Such results indicated that the two buffer layers (confinement layers) could effectively hinder the carrier recombination in, or the exciton diffusion into, the charge-transport layers adjacent to the emitting layers.

The EL characteristics of the three blue-emitting devices are shown in Fig. 4, with quantitative data summarized in Table 1. The peak external quantum efficiencies for Devices A–C were 5.2%, 5.7% and 8.6%, respectively. Thus, Device C exhibited a significant efficiency improvement (1.5–1.7 times) in comparison with Devices A and B. Therefore, these results confirmed the effectiveness of the double emitting layer and double buffer layer structure for achieving efficient deep-blue electrophosphorescence.

3.2. WOLEDs with four emitting layers and double buffer layers

Based on the deep-blue phosphorescent OLED structure described in the previous section, we then studied the incorporation of green and red phosphors in the device structure to implement the desired white emission (Device D, Fig. 2b). The architecture of Device D consisted of four emitting layers and double confining layers: ITO/α-NPD (30 nm)/TCTA (20 nm)/CzSi (3 nm)/CzSi doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ (16 nm)/CzSi doped with 2 wt.% of $Ir(ppy)_3$ (3 nm)/CzSi doped with 1.2 wt.% of $Os(bpftz)_2(PPh_2Me)_2$ (4 nm)/UGH2 doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ (3 nm)/UGH2 (2 nm)/TAZ (40 nm)/LiF (0.5 nm)/Al (150 nm). The green-emitting phosphor $Ir(ppy)_3$ and the orange-red-emitting phosphor $Os(bpftz)_2(PPh_2Me)_2$ were selectively doped into portions of the CzSi emitting layer (replacing the deep-blue phosphor $Ir(fppz)_2(dfbdp)$), forming a structure with the green/orange-red emitting layers sandwiched between the two blue-emitting layers [CzSi doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$ and UGH2 doped with 6 wt.% of $Ir(fppz)_2(dfbdp)$].

The EL characteristics of Device D are shown in Fig. 4 and the respective data are summarized in Table 1. The peak external quantum efficiency, luminance efficiency and power efficiency of Device D (along the forward viewing directions) were 10.3%, 24.0 cd/A and 16.4 lm/W, respectively. The efficiencies at the practical luminance of 100 cd/m^2 remained at around 8.0%, 17.4 cd/A and 7.0 lm/W, respectively. The maximum luminance reached 15,428 cd/m^2 at a driving voltage of 18.2 V. For lighting applications, the light emitted from all sections of the substrate can in principle be redirected to the forward direction via certain lighting fixtures; hence the total efficiency of the device was also characterized by using an integrating sphere setup [31]. The total quantum and power efficiency measured in the sphere were about 1.7 times larger than the forward viewing efficiency, which is consistent with previous reports [32]. Thus, the total peak external quantum efficiency and power efficiency were 17.5% and 27.9 lm/W, respectively. On closer inspection of Devices D, which was formed by replacing some deep-blue emitters in Device C with red and green emitters, one can clearly see the improvement of efficiency (vs. Device C efficiency). This efficiency enhancement might have resulted from the higher QY of red and green emitters than that of deep-blue emitters. Moreover, the relative higher driving voltage of Device D suggested that the lower-energy emitters (e.g. $Os(bpftz)_2(PPh_2Me)_2$) doped in Device D may have induced a significant amount of carrier trapping, which could in turn reduce the leakage of carriers into adjacent carrier-transport layers (e.g. TCTA and TAZ) and improve the carrier balance [20]. Indeed, comparison of the EL spectra of Devices D (Fig. 5a) and C (Fig. 3) revealed that the near-UV emission from TAZ or TCTA in Device D had reduced significantly.

The normalized EL spectra and corresponding CIE coordinates of Device D at different luminance levels are shown in Fig. 5, while quantitative data are summarized in Table 1. Device D exhibited a rather pure white emission with the CIE coordinates close to the ideal equal-energy white of (0.33, 0.33). Furthermore, the EL spectra and colors were stable at all brightness levels ranging from 10^2 to 10^4 cd/m^2, with the color variation (variation of the CIE coordinates) being as small as $\Delta(x,y) = (0.014, 0.028)$. The WOLEDs generated balanced white light over a wide range of brightness. The FWHM (full width at half maximum) of the EL spectra was measured as wide as ~210 nm at different luminance levels. Such wide EL emission effectively cover visible spectral region and largely enrich the color rendering capability. The maximum CRI of Device D

reached as high as 94 (around the luminance of 1000 cd/m^2). It is also worth mentioning that the CRI remained above 90 throughout the wide brightness range of 10^2–10^4 cd/m^2 investigated.

4. Conclusions

In conclusion, by utilizing a newly developed deep-blue iridium complex along with tailor made green and orange-red phosphors, we successfully demonstrated efficient three-component phosphorescent WOLEDs with high color performances and stable colors. Such WOLEDs were based on the deep-blue phosphorescent OLED structure with double emitting layers and double confining layers; portions of deep-blue phosphors were then selectively replaced by green and orange-red phosphors, thereby forming a structure with the green/orange-red emitting layers sandwiched between the two deep-blue emitting layers. Such three-component phosphorescent WOLEDs yielded a high CRI of up to 94 and CIE coordinates close to the ideal white emission (0.33, 0.33). Furthermore, these devices exhibited stable colorant and high CRI over a wide brightness range of 10^2–10^4 cd/m^2 and yielded EL efficiencies of up to 10.3%, 24.0 cd/A and 16.4 lm/W for the forward directions.

ABSTRACT

A contact free method of surface potential measurement using scanning Kelvin-probe microscopy (SKPM) was conducted to probe the nature of nanocrystalline TiO_2/dye interface. In combination with electrical measurements an effort has been made to establish a correlation between the nature of sensitizing dye and observed surface potential with open circuit voltage (Voc) after dye-sensitized solar cell (DSSC) fabrication. Effect of chenodeoxycholic acid (DCA) as co-adsorbent with dyes upon the enhancement of DSSC efficiency has been probed by SKPM, which revealed a positive shift of surface potential upon treatment of thin films of TiO_2 with DCA. The enhancement of DSSC performance upon DCA introduction has been explained by upward shift of TiO_2 conduction band edge leading to enhanced Voc along with the prevention of π-stacked aggregation resulting in enhanced short-circuit current density.

1. Introduction

Silicon solar cells are presently playing a pivotal role in harvesting the solar energy efficiently but their high cost of production is one of the major stumbling blocks towards their reach at common mass level as a clean energy substitute. Dye-sensitized solar cells (DSSC) are a cheap alternatives to silicon solar cells for efficient conversion of solar energy into electrical energy and has attracted the attention of material science community in the recent past [1,2]. Although, DSSC based on organic dyes giving a respectable photoconversion efficiency of 10–11% which is still lower than the efficiency obtained by silicon solar cells (20%) [3,4]. One of the most important and challenging factor attributed to the lower efficiency of the DSSC, is the narrower optical absorption window (400–800 nm) of organic dyes, which is narrower than the optical absorption window of crystalline silicon (500–1100 nm). Recently, Inakazu et al. have proposed the extension of optical absorption window by selective adsorption of two dyes on nanoporous titania under pressurized CO_2 atmosphere leading to the enhancement in photoconversion efficiency [5]. Over all photoconversion efficiency of a DSSC is basically decided by the short-circuit current density (Jsc), open circuit voltage (Voc) and fill factor (FF). There are reports about a number of organic dyes giving very high Jsc but over all poor photoconversion efficiency of the cell was mainly attributed to small observed Voc [6,7]. Voc plays an important role in controlling the photoconversion efficiency and is basically decided by the difference in the conduction band level of TiO_2 and potential of I_3^-/I^- redox couple in DSSCs. In an interesting report O'Regan and Gratzel [8] advocated the role of electron recombination in governing the Voc based on their transient photovoltage and photocurrent measurements in the DSSC.

Several approaches such as introduction of nitrogen containing heterocyclic additives like pyrimidine, alkyl pyridine, etc. [9,10], molecular modification of TiO_2 surface by dipolar carboxylic acid derivatives [11,12], coating of

TiO_2 surface with a very thin conformal overlayers of insulators like silica, alumina, strontium titanate, etc. [13–15], lithium intercalation of TiO_2 particulates [16] and introduction of chenodeoxycholic acid (DCA) [17] in electrolyte solution have been utilized to improve the Voc of DSSC. Kelvin probe method is a very sensitive non-invasive technique which finds versatile application in determining the relative work functions of metals and semiconductors by measuring the contact potential difference between a reference surface and a material under investigation. It has been successfully used to determine the band offsets in heterojunction solar cells [18], change in the work functions of the metal and semiconductors after molecular adsorption [19] and determination of work functions of organic molecular semiconductors like porphyrins, phthallocyanines and perrylenes [20].

Ruhle and Cahen [21] have extensively studied the conducting F-doped Tin oxide and nanocrystalline mesoporous TiO_2 interface using Kelvin probe method and reported a macroscopic band bending due to Fermi level equilibration. Organic sensitizing dyes used for the fabrication of DSSC possess some finite dipole moments and hence are supposed to create a band offsets after their attachment to TiO_2 surface, therefore, are expected to af-

fect the Voc of the DSSC. Present article deals with the measurement of surface potentials of a number of sensitizing dyes adsorbed on to the nanocrystalline titania surface in order to delineate the dye surface potential with Voc. At the same time, the role of DCA in the enhancement of the photovoltage was also investigated since it is believed to suppress the back electron transfer or recombination [22].

2. Experiment

Ruthenium based two inorganic dyes N3 and N719 were purchased from Solaronics Corporation, Switzerland while organic dye NK3628 was purchased from Hayashibara Tokyo, Japan. Organic dyes D77 and D102 were purchased from Mitsubishi Paper Mills Company limited and used as supplied. Squaric acid based sensitizing dyes SQ-A, SQ-B and SQ-C used in the present study have been synthesized following the methods by Oswald et al. [23] and Matsui et al. [24]. Structures of these SQ dyes have been shown in Fig. 1(a).

To prepare samples for surface potential measurement by the Kelvin probe method, a thin layer of dense TiO_2 was applied on glass slides by spin coating followed by their calcination at 450 °C having film thickness of about 100 nm. Adsorption of the organic and inorganic sensitizing dyes on TiO_2 thin film was performed by dipping the calcinated titania coated glass slides in the ethanolic solution of the dyes (0.25 mM) for 3 h and 24 h respectively. To study the effect of DCA on Voc in the case of organic sensitizing dyes, it was dissolved in the similar solvent used for making the dye solution for its adsorption on the titania thin film. Surface potential measurement was performed using scanning Kelvin probe microscope (SKPM model JSPM 5200, JEOL Datum). Measurements were done in non-contact mode using a platinum probe for scanning under vacuum. First of all, surface potential of only TiO_2 thin film on glass was measured and its value was taken as reference followed by measurement of surface potential of dye adsorbed on titania film for comparison and study of influence of nature of dye adsorption on observed surface potential. Schematic representation of SKPM has been shown in Fig. 1(b).

DSSC were fabricated using Ti-Nanoxide D paste (Solaronix SA) which was coated on a Low E glass (Nippon Sheet Glass Co., Ltd.) by a doctor-blade. The substrate was then baked at 450 °C to fabricate TiO_2 layers of about 12 μm thickness. The substrate was dipped in a solution containing dye in the presence and/or absence of DCA. Concentration of DCA in the organic dye solution was 2.5 mM. A Pt sputtered SnO_2/F glass substrate was employed as the counter electrode. Electrolyte (WWS30) containing LiI (500 mM), iodine (50 mM), *t*-butylpyridine (580 mM), MeEtIm-DCA (ethylmethylimidazolium dicyanoimide) (4:6 wt/wt) (600 mM) in acetonitrile, was used to fabricate the DSSC. A Himilan film (Mitsui-DuPont Polychemical Co., Ltd.) of 25 μm thickness was used as a spacer. The cell area was 0.25 cm^2. Performance of the solar cells was evaluated using a metal mask on the solar cell in order to remove the effect of the optical reflection under the irradiation of 100 mW/cm^2 at AM 1.5.

The molecular dipole moments of the sensitizing dyes used in the present investigation were calculated after structural optimization of the dye using time dependent density functional theory (TD-DFT) calculations on Gaussian G03 program package with B3LYP functional and 6–311 g basis set.

3. Results and discussion

Fig. 2(a) shows the surface potential profile of sensitizing dyes adsorbed on a thin film of nanocrystalline TiO_2 measured using the Kelvin probe microscope. Considering

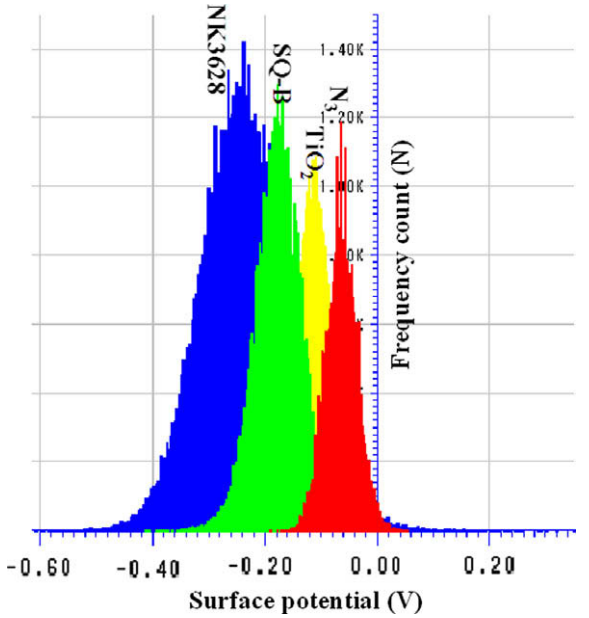

Fig. 2a. Surface potential histogram of inorganic and organic sensitizing dyes adsorbed on thin film of nanoporous TiO_2.

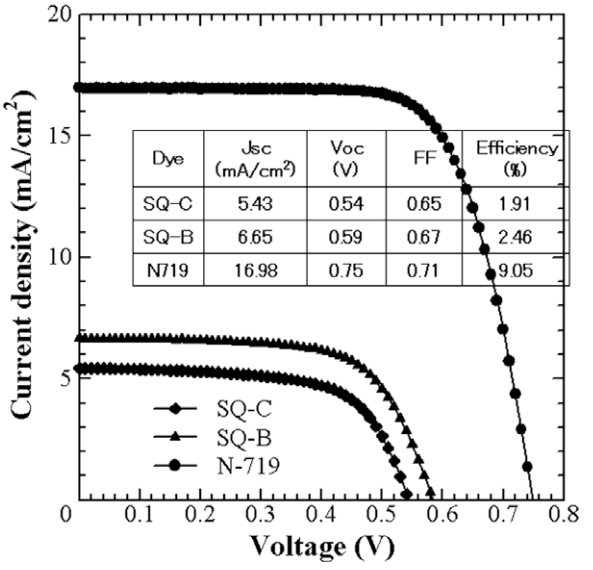

Dye	Jsc (mA/cm²)	Voc (V)	FF	Efficiency (%)
SQ-C	5.43	0.54	0.65	1.91
SQ-B	6.65	0.59	0.67	2.46
N719	16.98	0.75	0.71	9.05

Fig. 2b. Photovoltaic characteristics of DSSC based on organic (SQ-B, SQ-C) and inorganic (N-719) dyes.

the surface potential of bare TiO_2 surface as reference, a perusal of the surface potential profile corroborates that the work functions of organic and ruthenium based inorganic dyes differ distinctively. Surface potentials of organic dyes show a negative shift while ruthenium based inorganic dye N3 shows a positive shift of surface potential as compared to that of the reference TiO_2 surface. As shown in Fig. 2(b), experimentally observed value of Voc of the organic dyes SQ-B and SQ-C (0.59 V and 0.54 V) have been found to be lower than that of ruthenium based inorganic dye N-719 (0.75 V), which is also one of the reasons for their lower photoconversion efficiency. Zhan et al. reported appreciably very high short-circuit current density for the DSSC based on their newly synthesized organic dye but the cause of the observed lower photoconversion efficiency was attributed to very low Voc [25]. This indicates that probably nature of the adsorbed dye on the TiO_2 surface leads to differential shifting of the conduction band in the case of organic and inorganic dyes due to band alignment after dye adsorption.

This can be attributed to the formation of different kind of dipoles being formed at TiO_2/dye interface upon dye adsorption since these sensitizing dyes possess some finite dipole moments leading to differential nature of band alignments as shown schematically in Fig. 3. Ruthenium dye (N719) has relatively positive shift in the surface potential as compared to that of bare TiO_2 surface probably forms the negative dipole i.e. dipole moments pointed towards TiO_2 surface, shifting the TiO_2 conduction band edge upwardly leading to higher observed Voc. At the same time, lower Voc observed for the organic dyes could be explained considering formation of positive dipole by organic dye at TiO_2/dye interface. Similar trends of differential shifting of TiO_2 conduction band upon treatment of TiO_2 surface by organic carboxylic and phosphonic acids has also been reported by Ruhle et al. [11]. Passivation effect of metal/semiconductor junction by monolayer of polar organic molecules has also been investigated in detail by Vilan et al. [26] using the Kelvin probe method where they have emphasized that polar organic molecules led to the change of the barrier height of the junction systematically in the order of the dipole moments of the free molecules.

Using the Kelvin probe method, surface potentials of a number of ruthenium based inorganic and organic dyes adsorbed on TiO_2 surface were measured along with the fab-

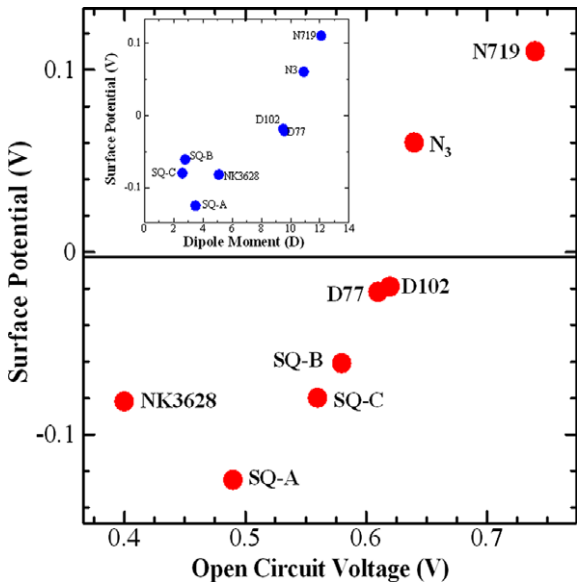

Fig. 4. Surface potential vs Voc for some sensitizing dyes. Surface potential shown here are potential with respect to bare TiO_2 surface measured as the reference. Inset shows relationship between calculated dipole moment and measured surface potential of dyes used in the present study.

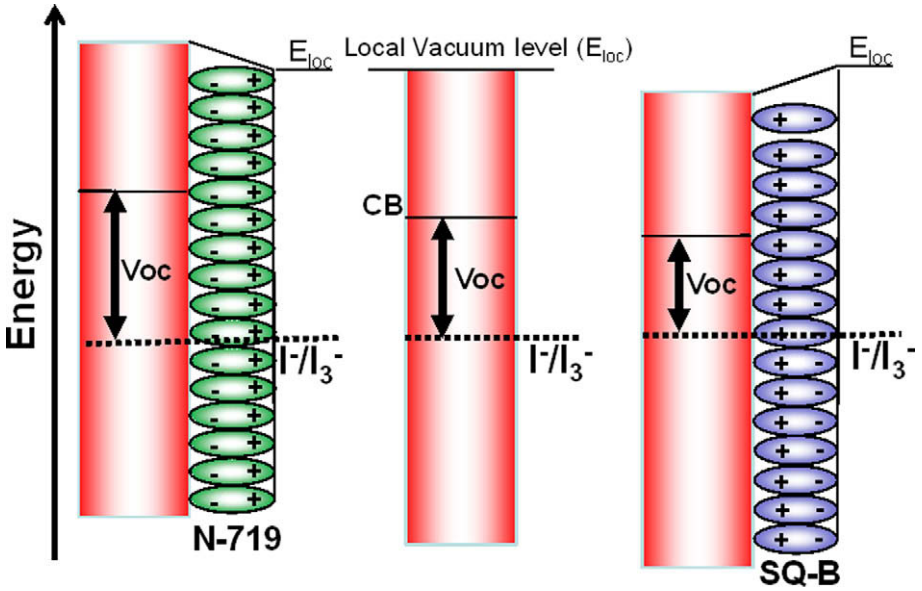

Fig. 3. Schematics of energy band diagram of nanoporous TiO_2/electrolyte interface with inorganic and organic dye adsorbed on thin TiO_2 film.

rication of DSSC and an effort was made to study the effect of surface potential on the observed Voc. Fig. 4 represents the effect of measured surface potential of dyes on the observed Voc. As can be seen clearly from this figure that dyes having high Voc (ruthenium based inorganic dyes) have the positive surface potential as compared to that of the reference surface potential of the nanoporous TiO_2 film. This positive shift in the surface potential of ruthenium dyes indicates that most likely the vicinity of TiO_2 is negative leading to the downward shift of the vacuum level of titania followed by an upward shift in the conduction band edge. Since Voc is governed by the difference in the conduction band of TiO_2 and redox energy level of I_3^-/I^- redox couple, this upward shift of conduction band edge leads to the higher observed Voc. In a similar manner, low Voc in the case of organic dyes can also be explained by downward shift of TiO_2 conduction band edge due to negative shift of surface potential by organic dyes as compared to that of bare TiO_2 surface. It is interesting to note that relatively positive shift in surface potential for both of the organic as well as inorganic dyes led to an increase in the observed Voc. Kruger et al. [27] have studied the effect of molecular dipole moment on the contact potential difference and emphasized that molecular species having higher dipole moment results into enhanced band bending at the interface.

To get further insight about the TiO_2/dye interface, we calculated the dipole moments of the dyes used in the present investigation after optimization of the dye structure using Gaussian G03 program package. Inset of Fig. 4 shows the correlation between the measured surface potential and calculated dipole moments of the dyes under investigation. A perusal of Fig. 4 (inset) indicates that dyes having higher dipole moment show relatively positive shift in the surface potential which could be attributed to the enhanced band bending at TiO_2/dye interface leading to higher observed Voc. Therefore, surface potential measurement using Kelvin probe method seems to be an important diagnostic tool to predict whether a given sensitizing dye will give higher/lower Voc prior to DSSC fabrication. At the same time it is also helpful to design an efficient dye giving positive shift in the surface potential.

A number of cholic acid derivatives have been frequently employed as co-adsorbent along with sensitizing dyes for the enhancement of efficiency of DSSC [28–31]. The exact role of cholic acid towards enhancement of DSSC performance is not yet completely clear, however, Kay and Gratzel [28] proposed the four possible roles played by cholic acid viz. (a) suppression of dye aggregation, (b) positive shift of the TiO_2 conduction band edge, (c) decrease in leakage current by adsorbed dyes and (d) tuning of redox potential of sensitizing dyes. Using various cyanine dyes Sayama et al. [32] have advocated the predominance of factor (c) as the key role played by the cholic acid for enhancement of their DSSC efficiency. On the other hand, Kopidakis et al. [33] emphasized that incorporation of DCA is associated with the upward shift of TiO_2 conduction band edge leading to enhancement of Voc and thus DSSC performance based on their transient photovoltage measurements.

To investigate the role of DCA on DSSC performance, surface potential measurement was conducted on thin nanoporous TiO_2 films in the presence and absence of DCA using the Kelvin probe method. Fig. 5 shows the surface potential profile of TiO_2 thin film in the presence and absence of DCA and clearly corroborates that there is a positive shift of surface potential in the presence of DCA as compared to reference surface potential of bare titania surface. This suggests that presence of DCA leads to the nega-

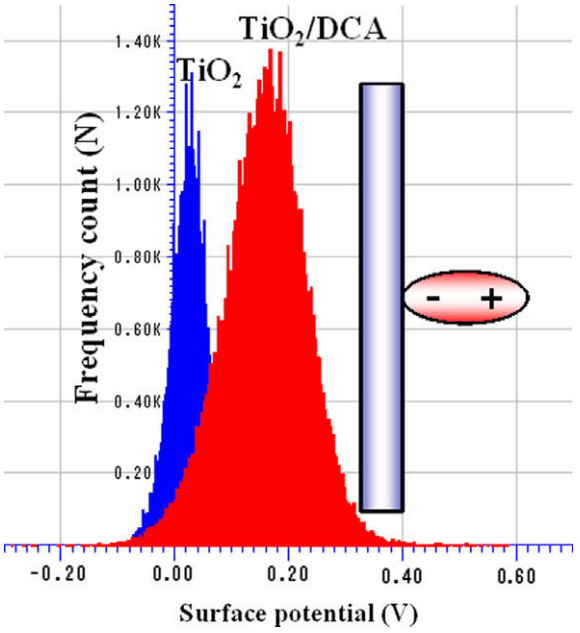

Fig. 5. Surface potential histogram of nanoporous titania film in the presence and absence of DCA.

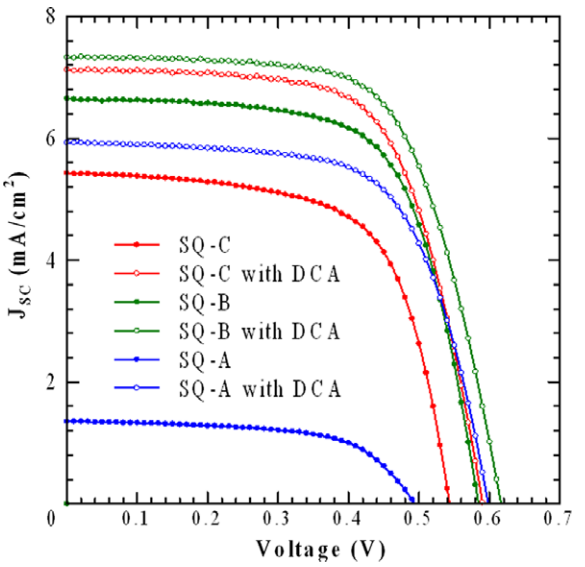

Fig. 6. Photovoltaic performance for DSSCs containing squaric acid based organic dyes in the presence and absence of DCA. Cell area 0.2115 cm^2, AM 1.5, 100 mW/cm^2.

tive shift of TiO_2 vacuum level followed by upward shift of its conduction band edge leading to the enhancement of Voc. Similar observation of enhancement of DSSC efficiency in the presence of DCA as co-adsorbent along with the Ruthenium dye has also been observed by Neale et al. [30] who emphasized the predominance of the shift of TiO_2 conduction band edge leading to overall improvement in the photovoltage.

To verify the role of DCA in efficiency enhancement of DSSC based on organic dyes as sensitizer, three squaric acid based organic dyes viz SQ-A, SQ-B and SQ-C have been utilized for the DSSC fabrication and their current–voltage (*I–V*) curve upon irradiation of 100 mW/cm^2 simulated solar light has been shown in Fig. 6. It clearly shows that introduction of DCA as co-adsorbent leads to the enhancement of cell efficiency by increasing both of the Voc and Jsc in the case of the all of the organic SQ dyes. A similar observation has also been made by Wang et al. [34] where both of Jsc and Voc were found to be increasing upon increase in the DCA concentration in the case of their coumarin based organic dyes.

A careful perusal of Fig. 6 clearly corroborates that although both Voc and Jsc are getting improved upon introduction of DCA in the case of the SQ dyes but improvement is much pronounced for the dye SQ-A as compared to that of SQ-B and SQ-C. To understand this observation, surface potential measurement using the Kelvin probe method was conducted upon thin films of nanoporous titania adsorbed with these dyes in the presence and absence of DCA. The measured surface potential profile of SQ dyes in the presence and absence of DCA has been shown in Fig. 7. As clearly evidenced by this figure, there was a marked positive shift of surface potential in the case of dye SQ-A as compared to that of SQ-B after introduction of DCA, which could probably be responsible for the pronounced enhancement of Voc for the sensitizing dye SQ-A.

Upon adsorption of dye in the presence of DCA there is a dynamic competition between the dye molecule and DCA for their attachment on the total available sites on the TiO_2 particle surface. Based on dye desorption studies, Neale et al. [35] have reported that adsorption of ruthenium dye in the presence of DCA led to the reduction of dye loading up to 60% and emphasized that even the reduction at such extent has not affected over all photovoltaic performance. A perusal of Figs. 5 and 7 indicates that the shift in the surface potential in the presence of DCA only was 0.13 V, while this shift was 0.06 V for SQ-B and 0.08 V for SQ-A in the presence of DCA. This indicates a differential competition of DCA for its attachment on TiO_2 surface in the presence of these dyes. Considering the 0.13 V shift associated with 100% adsorption by DCA molecules, the relative abundance of SQ-A and SQ-B in the presence of DCA, could be approximated to be 38% and 54%, respectively, which is in similar range as observed by Neale et al. Presence of relatively larger extent of DCA (62%) in the case SQ-A could be attributed to the formation of larger π-aggregates which probably hinders their attachment and favours the attachment for DCA molecules.

Another role of DCA has been reported to suppress the dye aggregation resulting into the suppression of charge recombination between the injected electrons and I_3^- ions of the electrolyte. Khazraji et al. have also emphasized that

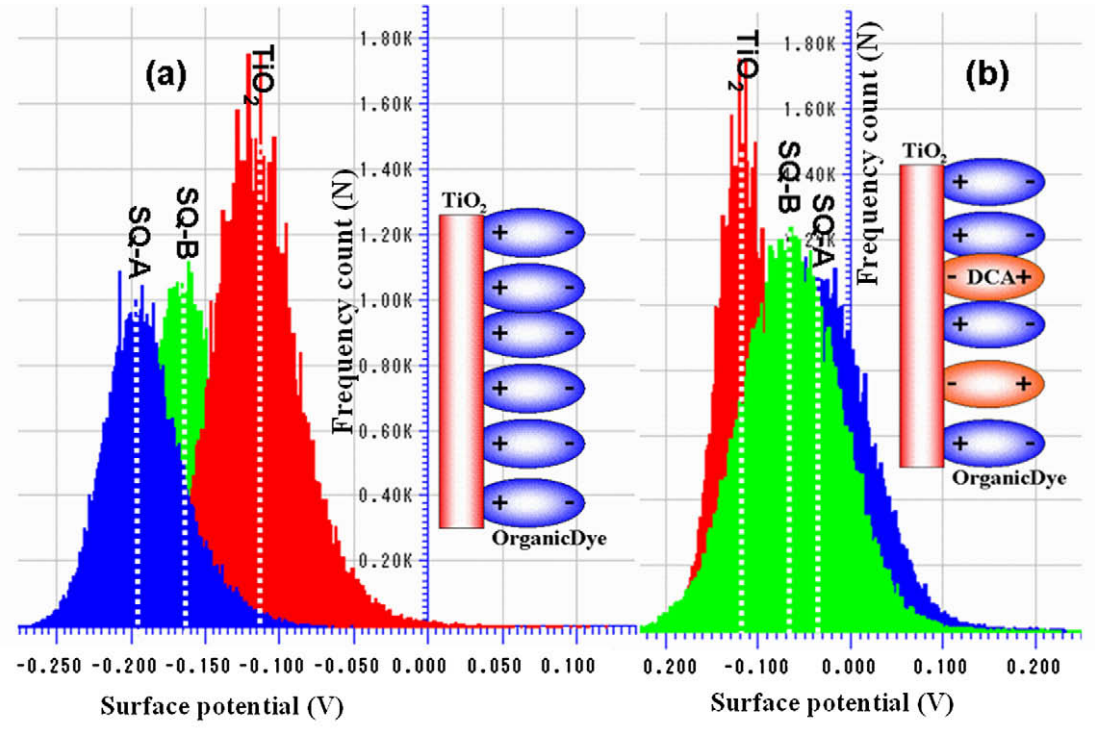

Fig. 7. Surface potential histogram of organic SQ dyes in the absence (a) and presence (b) of DCA.

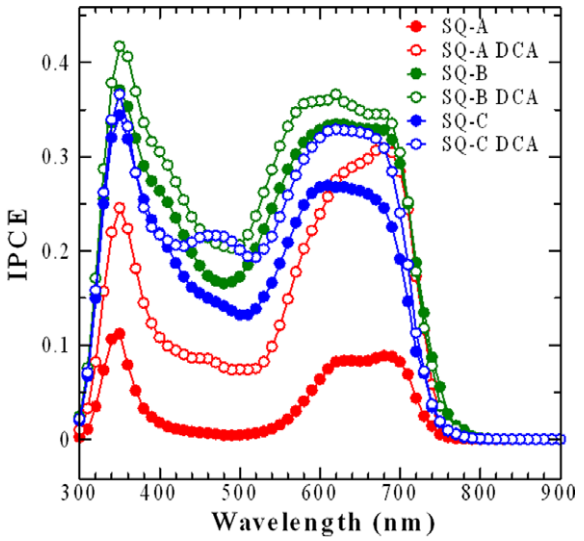

Fig. 8. IPCE as a function of the wavelength of incident monochromatic light for TiO_2 electrodes in the presence and absence of DCA for SQ dyes.

as compared to the dye aggregates, monomers can inject electrons to TiO_2 more efficiently [36]. A perusal of dye structures of SQ dyes as shown in Fig. 1(a) clearly indicates that SQ-A having increased aromatic ring is relatively prone to form π-stacked dye aggregates as compared to that of SQ-B where the reduced number of aromatic ring along with the very long alkyl chain (Octadecyl) resists the easy dye aggregation. In the presence of DCA these π-stacked aggregates get broken leading to facile electron injection yield and thus Jsc. Presumably this prevention of dye aggregation is responsible for the pronounced effect of DCA in the case SQ-A.

Incident photon to electron conversion efficiency (IPCE) as function of wavelength (action spectrum) is basically measured to evaluate the photoresponse of photoelectrode under investigation in the whole spectral region. Fig. 8 shows the action spectra of SQ dyes in the presence and absence of DCA. A perusal of action spectrum clearly indicates that there is a clear enhancement of IPCE maximum upon the introduction of DCA for all of the SQ dyes. Following a similar trend as observed in the *I–V* characteristics as shown in Fig. 6, there was pronounced enhancement of IPCE for SQ-A (9–31%) as compared to the IPCE enhancement for SQ-B (34–36%) in the presence of DCA. SQ-C having identical structure of SQ-B differing only in the length of alkyl substituent viz. butyl in place of octadecyl also shows relatively enhanced IPCE (27–33%) as compared to that of SQ-B upon DCA introduction. This further supports that inclusion of DCA leads to the breaking of π-stacked aggregates followed by facile electron injection resulting in to pronounced enhancement of Voc in the case of SQ-A.

4. Conclusions

It has been shown that surface potential measurements using SKPM is an important probing tool to get the initial idea about the Voc to be observed after DSSC fabrication. Lower Voc in the case of organic dyes under investigation has been attributed to the formation of positive dipole at TiO_2/dye interface leading to the negative shift of surface potential and downward shift of the conduction band edge of TiO_2 owing to a decrease in the overall observed Voc. The role of DCA in the enhancement of Voc by the upward shift of the titania conduction band edge has been clearly shown by surface potential measurement, which gives a positive shift after DCA introduction. The use of DCA as co-adsorbent with newly synthesized organic dyes SQ-A, SQ-B and SQ-C also give the positive shift in measured surface potential, which was much pronounced for dye SQ-A. This positive shift in the surface potential in the presence of DCA was also in accordance with the DSSC performance, where both of the Voc and Jsc were found to be increased after DCA incorporation. Pronounced improvement of device performance in the case of SQ-A as compared to that of SQ-B in the presence of DCA has been attributed to the enhanced shift of the surface potential and prevention of dye aggregation owing to its molecular structure.

ABSTRACT

We have investigated the effect of hole transporting materials in phosphorescent white polymer light-emitting diodes. The doping of a hole transporting material TCTA (4,4′,4″-tris(N-carbazolyl)-triphenylamine) resulted in enhanced luminance and efficiency while the doping of other hole transporting materials degraded the device performance. The effect of hole transporting materials on the performance of the device has been explained with the triplet energy level, HOMO (highest occupied molecular orbital)/LUMO (lowest unoccupied molecular orbital) level, and hole mobility of the materials. The doping of TCTA into an emissive layer increased the maximum current efficiency by 43%. Simultaneous utilization of TCTA both as an interlayer and a dopant in an emissive layer has been found to enhance the device performance further. The optimized phosphorescent white polymer light-emitting device showed the current efficiency of 20.5 cd/A with the luminance of 1800 cd/m^2 at an operating voltage of 11.5 V.

1. Introduction

White organic light-emitting diodes (WOLEDs) have been studied due to their potential applications in full-color flat panel displays, back-lighting sources for liquid-crystal displays, and solid-state lighting [1–3]. High-efficiency WOLEDs are important since they can save electrical energy and have longer lifetime by reducing heat generation from the devices. In order to achieve highly efficient WOLEDs, multilayer structures have been commonly utilized to realize both the minimized electron/hole injection barriers and the optimized electron–hole balance in the devices. Highly efficient multilayer WOLEDs have been fabricated by vacuum deposition using various low molecular weight organic materials. In contrast, as another type of WOLEDs, white polymer light-emitting diodes (WPLEDs) utilize polymers instead of low molecular weight organic materials and have much simpler structures, e.g. single emissive layer since the structures can only be fabricated by solution processes which are difficult to avoid the dissolution of the layer underneath. As the result, WPLEDs have usually exhibited much lower efficiencies compared with multilayer WOLEDs with low molecular weight organic materials. In order to achieve white emission from polymer light-emitting diodes (PLEDs), single emissive layer structure with a polymer host such as PVK (poly(N-vinylcarbazole)) doped with two or three phosphorescent dyes has been studied most frequently. A WPLED with two or three iridium-cored phosphorescent dyes doped into PVK:OXD-7 (1,3-bis[(4-*tert*-butylphenyl)-1,3,4-oxadiazolyl]phenylene) matrix was reported to show the maximum luminous efficiency (LE) of 21.9 cd/A [4]. In the study, OXD-7 was included into the host PVK to facilitate electron transport. More recently, a WPLED with the maximum LE of 36.1 cd/A has been reported [5]. The device utilized a separate water/alcohol-soluble electron transport layer doped with Li_2CO_3 salt for efficient electron transport and hole blocking. The WPLED

doi:10.1016/j.orgel.2009.11.022

has also been fabricated with PVK:OXD-7 matrix doped with two phosphorescent dyes. High-efficiency PLEDs reported to date have not utilized a small molecular hole transporting material other than PVK as a hole transporting polymer host. However, most of recent reports on WOLEDs with low molecular weight organic materials have proved the effectiveness of the inclusion of hole transporting TCTA in the device structure [6–10]. Since the hole transporting TCTA has relatively higher triplet energy level (2.8 eV) and lower HOMO level (5.9 eV) than those of most phosphorescent emitters, the inclusion of TCTA into the emissive layer or as an interlayer results in beneficial effect on the device performance [6,7].

In this study, we introduced a hole transporting TCTA into WPLEDs for the first time and investigated the effect of the introduction on the device performance. In order to examine the effect of TCTA in detail, we have compared the results with other hole transporting materials such as TPD (N,N′-diphenyl-N,N′-bis(3-methylphenyl)-1,1′-diphenyl-4,4′-diamine) and α-NPD (4,4′-bis[N-(1-naphthyl)-N-phenylamino]biphenyl). We have found the optimal concentration of TCTA in single emissive layer and also showed the effect of TCTA on the device performance when used as an interlayer.

2. Experimental details

For the preparation of WPLEDs, commercial ITO (indium tin oxide) glass substrates with a sheet resistance of 10 Ω/square were used. The ITO glass was cleaned by sonification in an isopropyl alcohol (IPA) and acetone, and finally rinsed in deionized water. The line pattern of ITO was prepared by conventional photolithography process. After the plasma treatment of ITO surface at 100 W oxygen plasma for 3 min, PEDOT:PSS (poly(3,4-ethylenedioxythiophene) doped with poly(styrene sulfonate); Baytron P AI4083) was spin-coated on the ITO surface to have the thickness of 40 nm and baked at 110 °C for 5 min. Subsequently, single emissive layer was spin-coated with a premixed organic solution to have the thickness of 50 nm. The organic solution was composed of a host PVK, an electron transporting OXD-7, a blue phosphorescent FIrpic (bis(3,5-difluoro-2-(2-pyridyl)phenyl-(2-carboxypyridyl)iridium)), a green phosphorescent Ir(mppy)$_3$ (tris(2-(4-toltyl)phenylpyridine)iridium), and a red phosphorescent Ir(piq)$_2$(acac) (bis (1-(phenyl)isoquinoline)-iridium acetylacetonate), which were dissolved in chlorobenzene solvent. The composition was pre-optimized and fixed in all experiments with 50:40:9.6:0.2:0.2 for PVK:OXD-7:FIrpic:Ir(mppy)$_3$:Ir(piq)$_2$(acac). For investigating the effect of hole transporting TCTA, TPD and α-NPD on the performance of the devices, some devices were fabricated using an organic solution in which TCTA, TPD, or α-NPD (0–10 wt.% of the amount of PVK) was added additionally to the premixed solution with the fixed composition. After the single emissive layer was formed, the layer was dried at 80 °C for 30 min. Finally, the device was completed by thermal evaporation at a pressure of 2×10^{-6} torr of lithium fluoride (LiF) and aluminum (Al), of which the thicknesses are 1 and 100 nm, respectively. In order to fabricate devices with a TCTA interlayer, a solution containing 0.5 wt.% TCTA in toluene was spin-coated on PEDOT:PSS surface. The interlayer was dried at 180 °C for 30 min on a hot plate prior to the spin coating of single emissive layer.

Active area of all fabricated devices was 9 mm^2 and all electrical measurements were performed under ambient condition without encapsulation. The current–voltage–luminance (*I–V–L*) characteristics were measured using a source measure unit (Keithley 2400) and using a luminance meter (Minolta CS100). The electroluminescence (EL) spectra and device efficiencies of the devices were recorded by using Minolta CS1000.

3. Results and discussion

In order to investigate the effect of hole transporting materials in single emissive layer PLED, we have tested three different materials of TCTA, TPD, and α-NPD. In the single emissive layer, the compositions of other constituents, PVK, OXD-7, FIrpic, Ir(ppy)$_3$, and Ir(piq)$_2$(acac) are fixed for a meaningful comparison of the hole transporting materials. Hole drift mobility of TCTA, TPD, and α-NPD is known to be 2.0×10^{-5}, 1.1×10^{-3}, 8.8×10^{-4} cm^2 V^{-1}s^{-1}, respectively [11], which means that the drift speed of holes in TCTA is the lowest when compared with those in TPD and α-NPD at a fixed electric field. By analyzing the *I–V–L* characteristics and efficiencies of the devices doped with a fixed amount of the materials, we could estimate how hole mobility affects the performance of the devices from the experimental results. As another factor to affect the device performance, the HOMO and LUMO levels of the hole transport materials are shown in Fig. 1a, along with those of other constituents in the device. An important thing

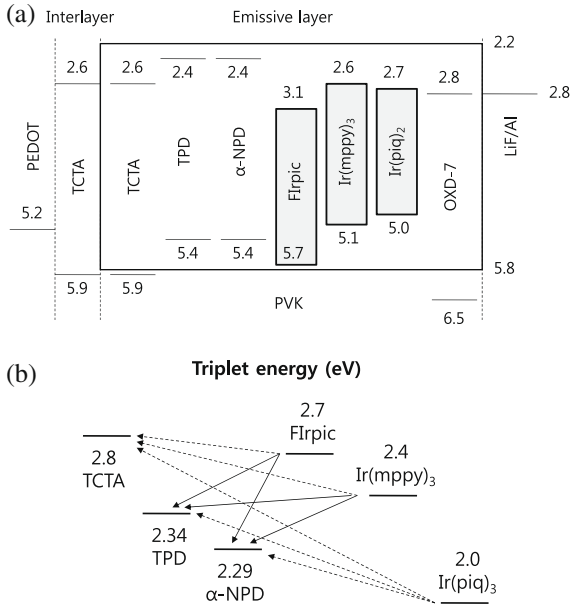

Fig. 1. (a) Energy level diagram showing HOMO/LUMO levels of constituent materials for the devices and (b) triplet energy levels (T_1) of hole transporting materials and phosphorescent emitters.

we can notice from the figure is the fact that the emission from FIrpic could be hindered upon the inclusion of TPD and α-NPD since the materials should act as competitive hole traps due to their higher HOMO levels than that of FIrpic. We think that it should be the reason why the previous studies reporting single layer PLEDs doped with FIrpic [4,5] have not utilized the hole transport materials other than the hole transporting host PVK in their devices. In single layer PLEDs doped with $Ir(mppy)_3$ only, however, the effective utilization of TPD and α-NPD has been reported in the literature [12,13]. Since HOMO levels of TPD and α-NPD are lower than that of $Ir(mppy)_3$, TPD and α-NPD do not act as efficient hole traps preventing the formation of excitons at the phosphorescent emitter. Moreover, higher hole mobility of TPD and α-NPD than that of the host PVK can enhance the performance of the devices upon the doping of the materials. Even though the hole mobility and HOMO/LUMO levels of the hole transporting materials can affect the device performance, the most important factor affecting the performance of the devices upon the utilization of hole transporting materials should be the triplet energy of the materials. The utilization of TPD and α-NPD has been examined with multilayer phosphorescent OLEDs doped with FIrpic or $Ir(mppy)_3$ in the literature [14,15]. They found that exciton energy could transfer from FIrpic or $Ir(mppy)_3$ to TPD and α-NPD since the triplet energies of the hole transporting materials are lower than those of FIrpic or $Ir(mppy)_3$. The triplet energies of hole transporting TCTA, TPD, α-NPD are 2.8 [7], 2.34 [14], 2.29 eV [14], respectively and the energies of phosphorescent FIrpic, $Ir(mppy)_3$, and $Ir(piq)_2(acac)$ emitters are 2.7 [14], 2.4 [6], 2.0 eV [16], respectively. As shown in Fig. 1b, it is expected

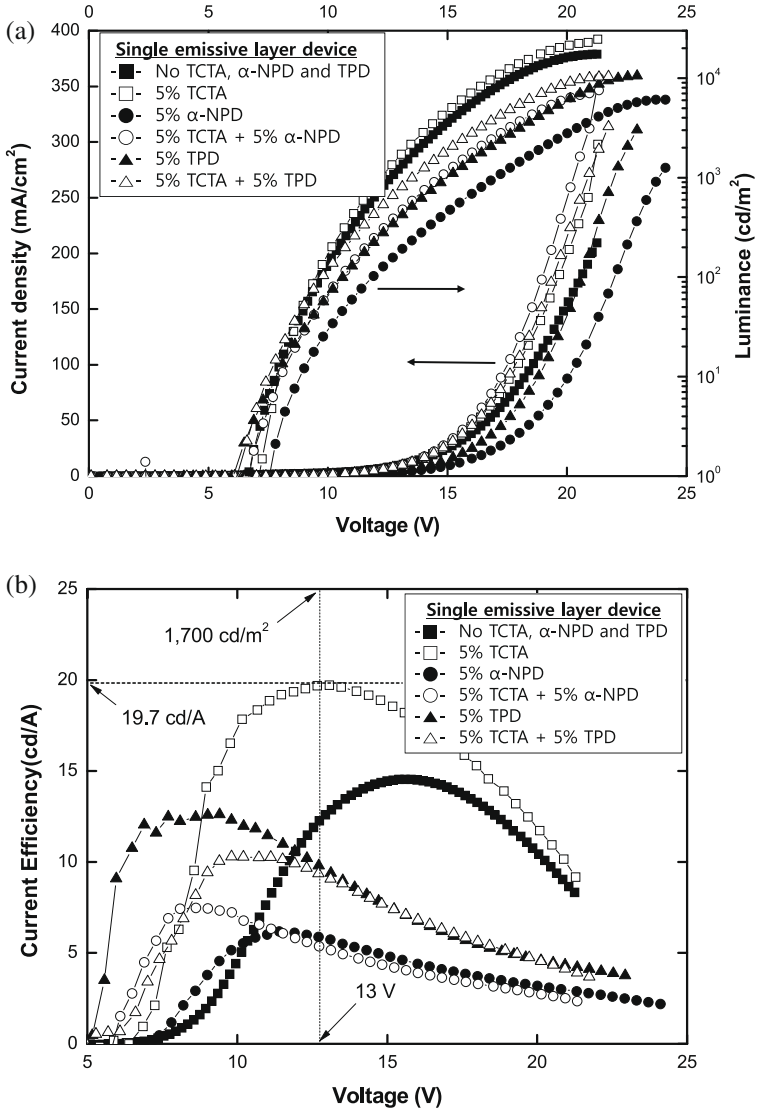

Fig. 2. (a) Current–voltage–luminance (*I–V–L*) curves of WPLEDs with different hole transporting materials and (b) current efficiency characteristics of the devices.

that low triplet energies of TPD and α-NPD should provide non-radiative paths for exciton quenching and reduce the phosphorescent light emission from FIrpic and $Ir(mppy)_3$. Since the triplet energy of TCTA is higher than those of three different phosphorescent emitters, however, TCTA is not expected to cause the exciton quenching. In addition, the lowest HOMO level of TCTA compared with those of other constituents could enhance the performance of the devices.

As expected, we indeed have found the reduced efficiency upon the doping of TPD or α-NPD into emissive layer as shown in Fig. 2a and b. On the other hand, the doping of TCTA into the emissive layer was found to increase the highest current efficiency by 43% along with the decrease in the voltage at the highest current efficiency as shown in Fig. 2b. The result indicates that TCTA confines the triplet excitons within the emissive layer effectively while TPD or α-NPD acts as centers for the excitons to be transferred readily. As shown in Fig. 2b, the devices singly doped with TPD or α-NPD exhibited the lower efficiencies compared with that of undoped device. Specially, the doping of α-NPD lowers the efficiency most significantly. We think that it is mainly because the triplet energy is the lowest for α-NPD. However, the doping of TCTA enhances both luminance and efficiency of the device due to the enhanced exciton confinement. The co-doping of TCTA with TPD or α-NPD results in the increases in the efficiency compared with the singly doped cases but the resulting efficiency still does not exceed that of undoped device. It is worth to mention that the voltages at the highest efficiencies are in order of TPD, α-NPD, and TCTA which is the same as in descending order for the hole mobilities of the three compounds. Since the hole mobility of PVK is $2.5 \times 10^{-6}\ cm^2\ V^{-1}s^{-1}$ [17] which is the lowest compared with those of TCTA,

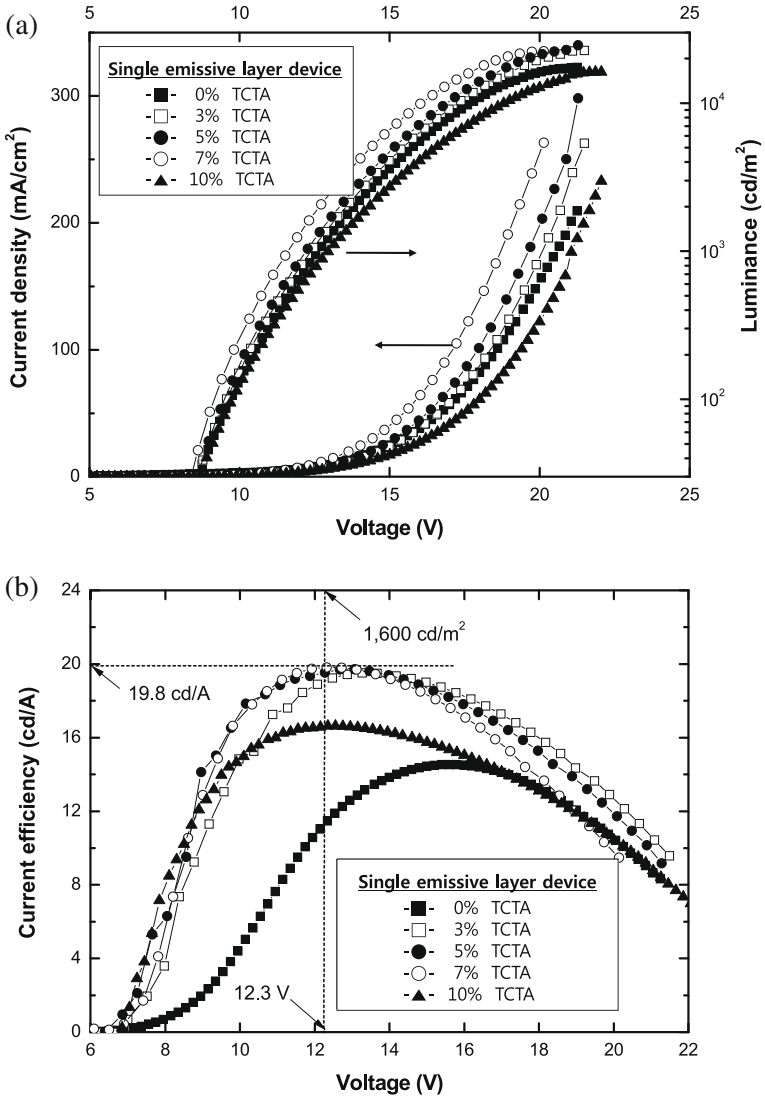

Fig. 3. (a) Current–voltage–luminance (*I–V–L*) curves of WPLEDs with different TCTA concentrations and (b) current efficiency characteristics of the devices.

TPD, and α-NPD, the voltage at the highest efficiency was found the highest for the undoped device. This result suggests that the addition of hole transport material in single layer PLEDs affect the operating voltages giving the highest efficiency of the devices due to their different hole mobility. Another thing to be noticed from Fig. 2a is that the current density is always higher whenever TCTA exists in the emissive layer. We attribute it to the lowest HOMO levels of TCTA close to that of PVK.

In order to optimize the concentration of TCTA, we have varied the TCTA concentration in single layer WPLEDs and measured the performance of the devices as shown in Fig. 3a and b. The highest efficiency was obtained at TCTA concentration of 7 wt.%. As can be seen from the figure, however, the highest efficiency of the devices with a TCTA concentration range from 5 to 7 wt.% was found close to be around 20 cd/A at a voltage around 12 V. The voltage giving the highest efficiency was found to decrease as the TCTA concentration increases. We attribute it to the fact that the hole mobility of TCTA is higher than that of PVK. After optimization, the voltage showing the highest efficiency was reduced from 13 to 12.3 V even though the

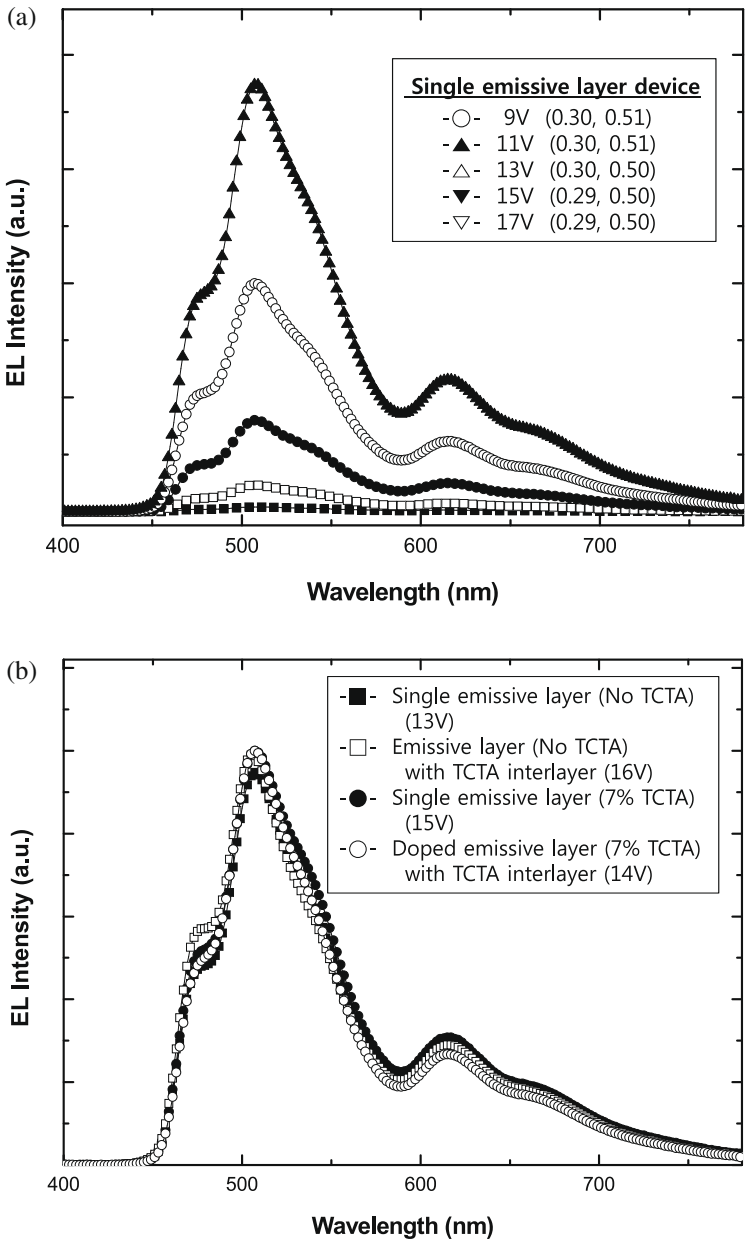

Fig. 4. (a) Electroluminescence spectra of WPLEDs with the 7 wt.% doping of TCTA and the corresponding color coordinates at different applied voltages and (b) electroluminescent spectra of WPLEDs of four different structures.

luminance and current efficiency were almost the same as shown in Figs. 2b and 3b. We have shown the EL spectra of the TCTA-doped single emissive-layer device in Fig. 4a. As the driving voltage increases, the spectra and color coordinate were not found changed significantly. The color coordinate was (0.30, 0.50) which corresponded to greenish white emission.

When TCTA is separated as an interlayer instead of the doping into the emissive layer as a hole transporting constituent, the role of TCTA can be examined more clearly. Since HOMO levels of TCTA and PVK are very close, the hole injecting property to the emissive layer should be almost the same. We expect that the difference in hole mobility between TCTA and PVK can give different device property. More importantly, the triplet exciton confinement given by TCTA interlayer enhances the device efficiency more pronouncedly than that by TCTA addition in the emissive layer. In the literature [6], TCTA interlayer has been introduced by a wet process to enhance the device efficiency greatly. The same experimental procedure was followed in this study.

We have measured the current efficiency to compare the performance between devices of different structures. In order to compare the device performance with the current efficiency, the emission spectra should be the same for all the devices in the comparison. We have fabricated four different kinds of devices which are the followings: (1) conventional single emissive-layer device without TCTA doping; (2) single emissive-layer device (without TCTA) with a TCTA interlayer; (3) TCTA-doped single emissive-layer device; (4) TCTA-doped emissive-layer device with a TCTA interlayer. We have measured the emission spectra for the devices and shown the data in Fig. 4b. As shown in the figure, the emission spectra were found almost the same for the four different devices.

As shown in Fig. 5a and b, the introduction of TCTA in the devices both as an interlayer and a co-dopant showed

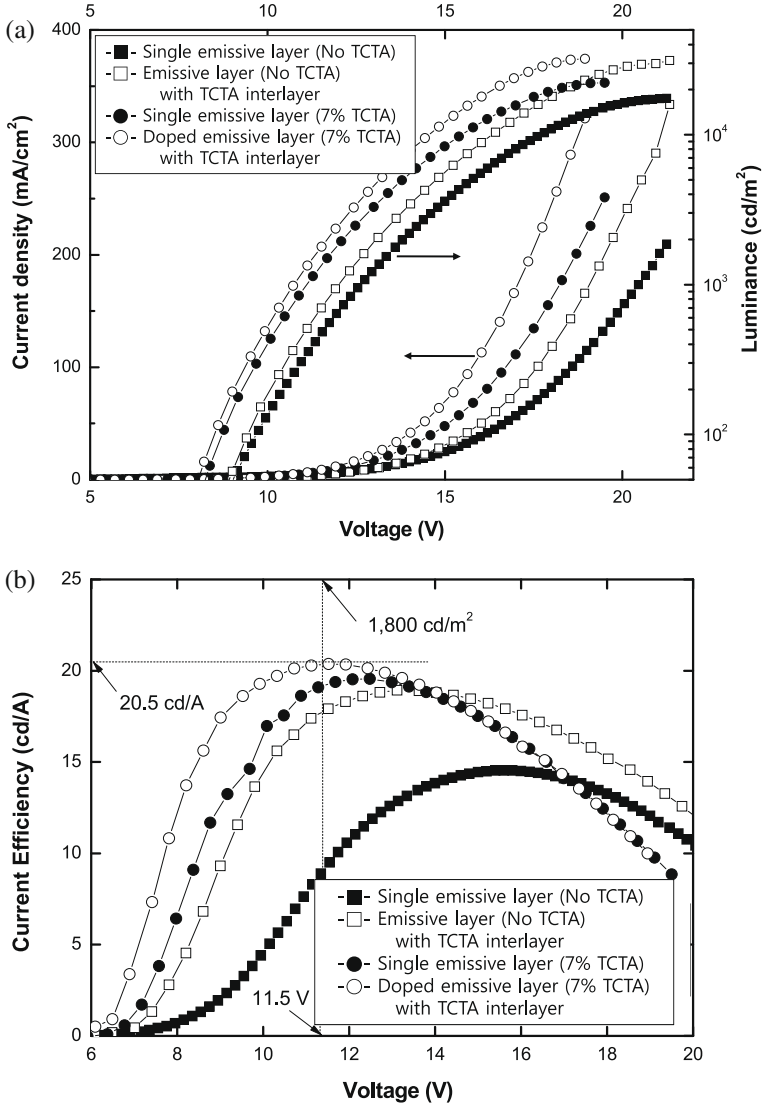

Fig. 5. (a) Current–voltage–luminance (*I*–*V*–*L*) curves of WPLEDs with a TCTA interlayer and (b) current efficiency characteristics of the devices.

the increase in the current efficiency of the devices. Relative to the current efficiency of the single emissive-layer device (without TCTA) without the interlayer, the utilization of TCTA as a co-dopant into the single emissive layer showed the higher increase in the current efficiency compared with the utilization of TCTA as an interlayer. Simultaneous utilization of TCTA both as an interlayer and as a dopant in the emissive layer can enhance the device performance further. The simultaneous utilization of TCTA is found to maximize the current efficiency. It should be mentioned here that the utilization of TCTA interlayer has not only increased the current efficiency but also increased the luminance significantly as shown in Fig. 5a. The optimized phosphorescent white polymer light-emitting device with TCTA showed the current efficiency of 20.5 cd/A with the luminance of 1800 cd/m^2 at an operating voltage of 11.5 V. The performance of WPLEDs in this study is comparable to the performance of previously reported WPLEDs [4,5] which showed the best efficiency to date.

4. Conclusions

We have investigated the effect of hole transporting materials in phosphorescent white polymer light-emitting diodes. The doping of a hole transporting material TCTA resulted in the enhanced luminance and efficiency while the doping of other hole transporting materials degraded the device performance. We have revealed that the doping of hole transporting TPD and α-NPD into an emissive layer gave a harmful effect on the device performance due to their low triplet energies compared with those of phosphorescent emitters. On the other hand, the utilization of TCTA as an interlayer or as a dopant in an emissive layer enhanced the luminance and current efficiency of the devices. The results were explained with the triplet energy level, HOMO/LUMO level, and hole mobility of the materials. The optimized phosphorescent white polymer light-emitting device showed the current efficiency of 20.5 cd/A with the luminance of 1800 cd/m^2 at an operating voltage of 11.5 V.

ABSTRACT

Spun films of novel thermotropic liquid crystalline lutetium bisphthalocyanine sandwich complexes substituted with sixteen octyl chains are employed as active organic semiconducting layers in the fabrication of organic field-effect transistors (OFET). When the device is annealed under vacuum at 70 °C, an increase in the field effect mobility in the saturated regime by a factor of five is observed while the threshold voltage is reduced to half the value obtained for as-deposited films. The annealed devices exhibit an increase in on/off ratio by two orders of magnitude. An improvement in performance of OFETs annealed above the crystal to mesophase transition temperature is consistent with atomic force microscopic images indicating increases in grain sizes and decreases in mean surface roughness of the organic bisphthalocyanine films.

1. Introduction

Metallated phthalocyanines (MPcs) are organometallic macrocycles that typically comprise the usually planar organic ligand (Pc^{2-}) and a metal ion or metalloid within the central cavity of the ring. Common examples are 1:1 complexes of ligand and a metal ion and particular compounds have found applications that include their use as commercial blue/green dyes and pigments, charge generators and carriers in electrophotography and laser printing [1], singlet oxygen photosensitisers for photodynamic therapy [2] and the active layer in a number of optical data recording systems [3]. Detailed studies of their electrical properties have given values for room temperature. Values of the electrical conductivity of undoped samples lie typically within the range 10^{-7} Scm^{-1} to 10^{-15} Scm^{-1} depending upon the polymorphic form of the sample [4]. Complexes of lanthanide metallated Pcs are interesting for a number of reasons. Examples include 2:1 complexes with Pcs, ($Ln^{(III)}Pc_2$), in which the metal ion is sandwiched between two Pc ligands [5,6]. The redox and electrochromic properties of the sandwich compounds have been much investigated [7] and the electrical properties of the so-called 'green' redox state are of particular interest because it is a neutral free radical structure. The conductivity of this free radical state of the lutetium complex, $Ln^{(III)}Pc_2$, has been especially well studied and results led to its description as the first organic semiconductor [8]. In particular, $Lu^{(III)}Pc_2$, and the scandium and tantalum analogues, have been investigated as the electroactive component of thin film field-effect transistors, the films being formed by vapour phase deposition methods [9]. $Lu^{(III)}Pc_2$, substituted with alkylthio groups are soluble in most common organic solvents and values of the dc conductivity were estimated to be in the range of 10^{-8} Scm^{-1} to 10^{-5} Scm^{-1} depending on alkyl chain lengths. The conductivity was also found to be sensitive to the presence of volatile organic compounds

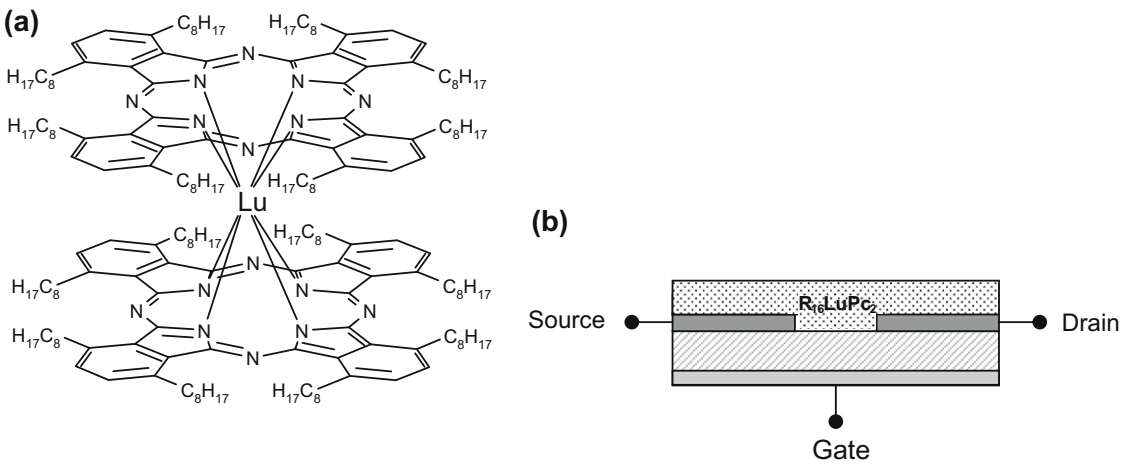

Fig. 1. (a) Structure of $R_{16}LuPc_2$. In this notation, each R refers to a C_8H_{11} (octyl) chain; and (b) schematic cross-sectional view of the bottom gated field-effect transistors used for measurements.

in the ppm range [10]. The conductivity of spun films of liquid crystalline alkyl-substituted dysprosium phthalocyanine $[(C_6S)_8Pc]_2Dy$ derivatives was dependent upon the heat treatment and exhibited directional anisotropy, values varying between 2.76×10^{-5} Scm^{-1} and 2.91×10^{-11} Scm^{-1} [11].

The present paper reports an investigation of the transistor properties of a novel derivative of $Lu^{(III)}Pc_2$. The compound bears eight octyl chains on each of the two rings, i.e. $R = C_8H_{17}$ in Fig. 1a, that render it soluble in organic solvents and we refer to it hereafter as $R_{16}LuPc_2$. The solubility enabled it to be deposited readily as films by the spin coating method [12], a methodology ideal for simple device fabrication [13]. As with similarly substituted 1:1 metallated Pcs [14], the presence of alkyl substituents on the new compound leads to thermotropic liquid crystal properties, in this case a mesophase is exhibited above 62 °C, which allows for a convenient low temperature annealing of the film structure. A bottom gated organic field-effect transistors (OFET) has been fabricated on heavily doped silicon substrates using spin coated films of $R_{16}LuPc_2$ molecules. The electrical behaviour of OFETs is studied with a view to determining the influence of annealing on the transistor characteristics. The surface morphology of the $R_{16}LuPc_2$ is found to be responsible for improvement of the device parameters when an OFET is heated at 70 °C above the crystal to mesophase transition temperature.

2. Experimental details

Heavily doped n-type silicon (1 0 0) wafers having resistivity of 5 μΩ m were covered with 250 nm thick plasma enhanced chemical vapour deposited silicon dioxide (SiO_2) as gate dielectric. Using photolithographic and sputtering techniques, the source and drain contacts were then prepared on the oxide layers in interdigitated gold (50 nm thick)/Cr (10 nm thick) electrode configurations. The octadecyltrichlorosolane (OTS) monolayer was self-assembled on the oxide layer by dipping the substrates in 1% solution of OTS in ethanol in order to improve the quality of the interface between the organic semiconductor and gate dielectric layers. As shown in Fig. 1b, the structure of the bottom-gated thin film organic transistors was then accomplished by depositing a ~100 nm thick $R_{16}LuPc_2$ film at room temperature as an active semiconducting layer on the gate dielectric with the electrode systems. The deposition technique used was to spin coat a small volume of the spreading solution of $R_{16}LuPc_2$ in chloroform (5 mg ml^{-1} concentration) at 2000 rpm for 30 s. The film thickness t was estimated to be 100 nm using the Dektak 6M stylus profilometer. Prior to the deposition of the organic layers, the transistor substrates were ultrasonically cleaned and degreased in acetone and iso-propanol and finally washed in Millipore Milli-Q (resistivity of 18 MΩ cm). The native oxide layer on the reverse side of the silicon wafer was removed by the dry etching method and a layer of Ga–In eutectic was then applied in order to form an ohmic gate terminal. The gate capacitance C_i per unit area of the oxide was estimated to be 9 nF cm^{-2}. Values of the transistor channel length L and W were found to be 10 μm and 2000 μm, respectively. Using a microprocessor controlled Keithley 93 I-V measurement system, the characteristics were obtained at room temperature and in air for the transistors consisting of as-deposited $R_{16}LuPc_2$ films. Measurements were repeated under identical conditions to examine the effects of thermal annealing on the transistor characteristics. For this purpose, the devices were heated to 70 °C in a tubular furnace under vacuum of $\sim 2 \times 10^{-7}$ torr and then gradually cooled down to room temperature at the rate of 1 °C min^{-1}. The surface morphology of the organic $R_{16}LuPc_2$ films was investigated in the tapping mode using a Nanoscope III multimode scanning probe microscope. The atomic force micoscopic images (AFM micrographs) of the $R_{16}LuPc_2$ surfaces were collected over a scan area of 5 × 5 μm for both as-deposited and annealed devices.

3. Results and discussion

The synthesis and structural characterisation of the compound $R_{16}LuPc_2$ will be reported elsewhere [15]. In

summary, the compound was prepared by reacting metal-free 1,4,8,11,15,18,22,25-octakis(octyl)phthalocyanine with lutetium acetate in an octanol solution using DBU as promoter. $R_{16}LuPc_2$ was shown to exhibit a crystal to columnar mesophase transition at 62 °C. The compound is soluble in various hydrocarbon solvents as well as chloroform, the solvent selected for spin coating the material as films.

The AFM micrographs in Fig. 2 show the spin coated deposition of fairly compact, significantly void-free organic $R_{16}LuPc_2$ active layers with uniform thickness and good film adhesion to the silicon substrates. The presence of randomly oriented disc like structures of dimensions between 50 nm and 100 nm was observed on the as-deposited $R_{16}LuPc_2$ film surface. The agglomeration of small size grains is apparent following heat treatment at 70 °C, i.e. at a temperature within the mesophase range exhibited by the compound in the form of bulk material. Following this annealing process, relatively large size clusters with dimensions of the order of 150–200 nm are formed. Values of the average surface roughness were found to have decreased from 30 nm for as-deposited films to 2.2 nm for annealed $R_{16}LuPc_2$ films.

A set of reproducible, hysteresis-free output characteristics are shown in Fig. 3 for both as-prepared and annealed $R_{16}LuPc_2$ field-effect transistors in terms of the drain-to-source current I_{DS} as a function of the drain-to-source voltage V_{DS} for different values of the gate voltage V_{GS} ($0V \leqslant V_{GS} \leqslant -50$ V). The output characteristics were typical of behaviour of a p-type OFETs operating in an accumulation mode. The conductance of the annealed devices was found to be greater than that of as-deposited devices. Values of 1.5 μA and 5 μA for the as-prepared and annealed devices, respectively indicate more than three times increase in the maximum saturation current at $V_{GS} = -50$ V over the same range of V_{DS}. Furthermore, the drain-to-source current in heat treated devices was found to saturate at a drain-to-source voltage lower than the corresponding value for the as-deposited devices.

The graph in Fig. 4 of $\sqrt{I_{DS}}$ as a function of V_G corresponding to $V_{DS} = -45$ V was found to be linear, giving the well known quadratic behaviour:

$$I_{DS(sat)} = \frac{W}{2L}\mu_{(sat)}C_i(V_{GS} - V_T)^2 \quad (1)$$

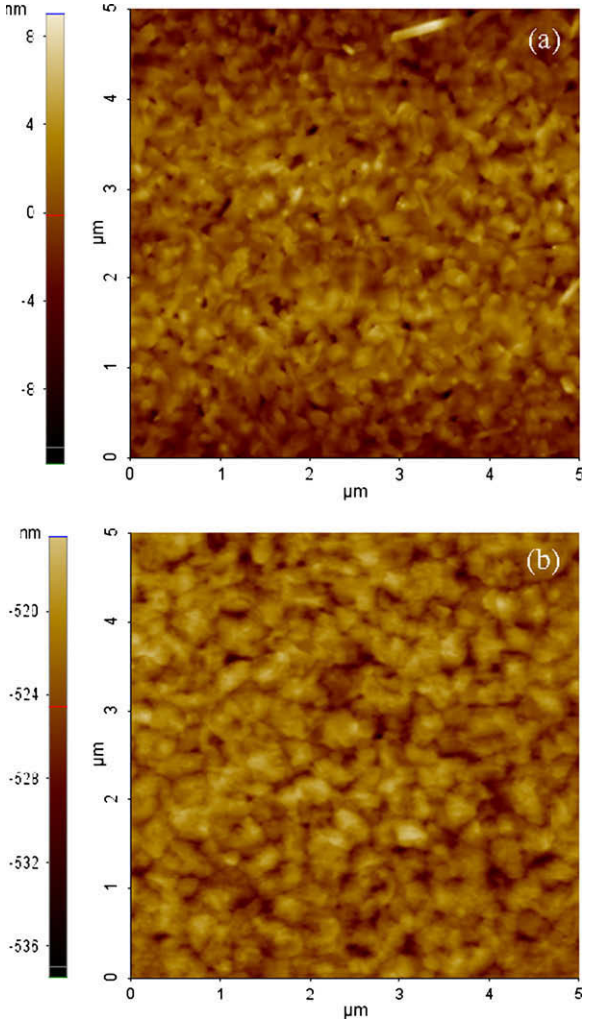

Fig. 2. Micrograph AFM images of (a) as-prepared and (b) annealed $R_{16}LuPc_2$ active layers.

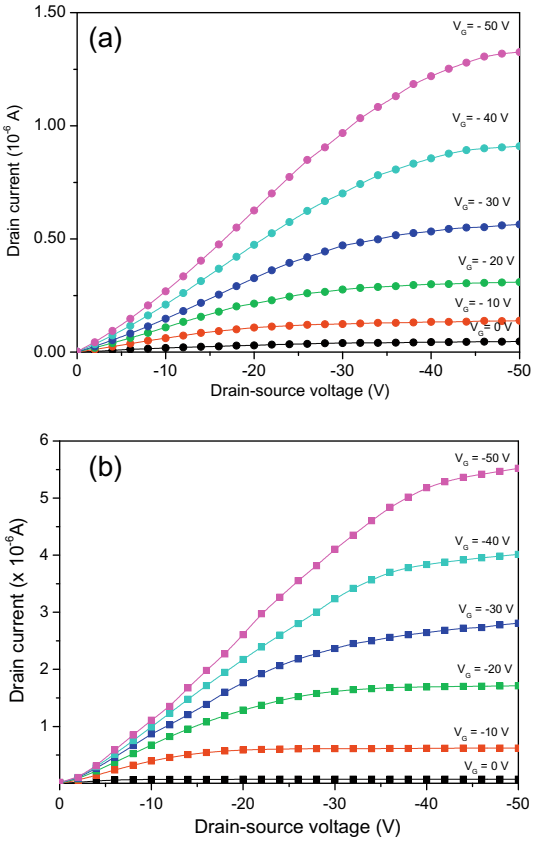

Fig. 3. Output characteristics: drain-to-source current (I_{DS}) as a function of the drain-to-source voltage (V_{DS}) at various drain-to-source voltages of channel length (L) 10 μm and channel width (W) 2000 μm.

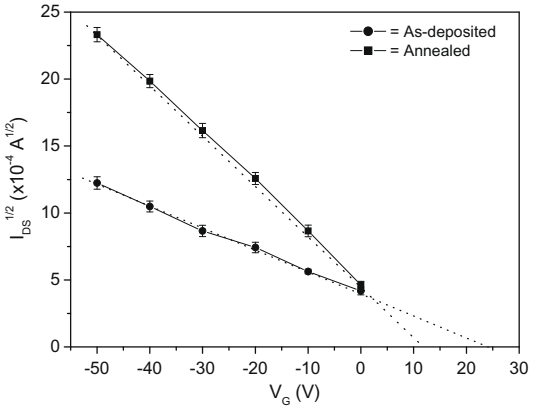

Fig. 4. The square root of drain current as a function of gate voltage in the saturation regime (V_{DS} = −45 V).

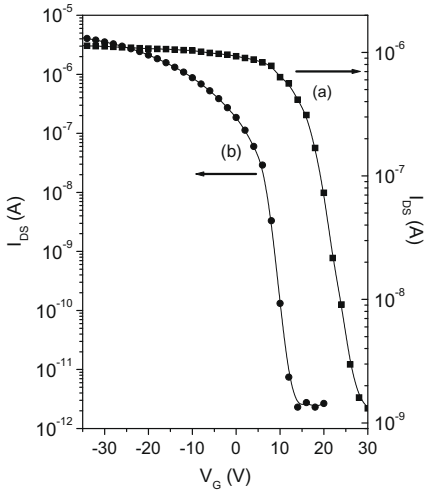

Fig. 5. Transfer characteristics: drain-to-source current (I_{DS}) as a function of gate-to-source voltage (V_G) recorded for (a) as-prepared and (b) annealed $R_{16}LuPc_2$ transistors. Drain-to-source voltage was kept constant at −45 V.

Values of the field effect mobility $\mu_{(sat)}$ in the saturated regime and threshold voltages V_T were estimated from the slope and the intercept at $I_{DS} = 0$ of the linear graphs, respectively. Values of the on/off current modulation ratio were estimated from the transfer characteristics in Fig. 5 in terms of the dependence of the drain-to-source current I_{DS} on the gate voltage V_{GS} at a fixed drain–source voltage of $V_{DS} = -45$ V. Calculations were performed for the transistors using both as-prepared and annealed $R_{16}LuPc_2$ active layers and the results were summarised in Table 1. Values of the mobilities are found to be two orders of magnitude higher than those recently reported for a lutetium (III) bisphthalocyanine derivative substituted with hexylthio groups [16].

The transistor parameters are believed to be dependent upon the $SiO_2/R_{16}LuPc_2$ interface and the grain boundaries in the polycrystalline $R_{16}LuPc_2$ films [17,18]. A value of 2.8×10^{12} cm^{-2} is obtained for the density N_t of traps at the interface between the as-deposited $R_{16}LuPc_2$ layer and the gate SiO_2 dielectrics using the equation [19]:

$$N_t = \left[\frac{S\log(e)}{\left(\frac{KT}{q}\right)} - 1\right]\frac{C_i}{q} \tag{2}$$

where k, T and q are the Boltzmann constant, the operating temperature and the electronic charge, respectively. S, the sub-threshold voltage swing defined as the voltage V_{GS} required to increase the drain-to-source current I_{DS} by a factor of 10 was calculated using the following equation:

$$S = \frac{dV_{GS}}{d(\log I_{DS})} \tag{3}$$

Values of S were found to be 3.8 V/decade and 1.6 V/decade from the transfer characteristics for as-deposited and heat treated transistors, respectively. A similar calculation for the annealed $R_{16}LuPc_2$ layer produced a reduced value of 1.4×10^{12} cm^{-2} for the density N_t of traps at the interface between the annealed $R_{16}LuPc_2$ and SiO_2 layers. The origin of this reduction of the interface traps may possibly attributed to the decrease in surface roughness of the annealed $R_{16}LuPc_2$ layer and the increase in the interfacial bonding between the active organic layer and the gate dielectric.

As observed earlier in AFM images in Fig. 2, the grain boundaries in the $R_{16}LuPc_2$ layer are expected to influence the transistor characteristics. The effect of grain-boundary potential barriers is usually explained in terms of the Levinson model which describes the dependence of the drain-to-source current (I_{DS}) in the linear regime on the density N_g of traps at the grain boundaries in the form [20]:

$$I_{DS} = \mu_0 V_{DS}\frac{W}{L}C_i V_G \exp\left(-\frac{q^3 N_g^2 t}{8\varepsilon_0\varepsilon kTC_i V_G}\right) \tag{4}$$

where μ_0 and ε are the trap free mobility and the dielectric constant of $R_{16}LuPc_2$, respectively. This model has been applied to determine charge transport in polycrystalline semiconductor thin films including organic films [21]. Fig. 6 shows the Levinson plots of $\ln(\frac{I_{DS}}{V_G})$ as a function of $\frac{1}{V_G}$ for the devices using both as-deposited and annealed $R_{16}LuPc_2$ films. Values of 1.2×10^{12} cm^{-2} and

7.6×10^{11} cm^{-2} for N_g were obtained from the slopes of the best linear fits for as-deposited and annealed samples.

4. Concluding remarks

Organic thin film transistors have been fabricated using the solution processable spin coating technique for depositing newly synthesised the lutetium phthalocyanine complexes $R_{16}LuPc_2$. The improvement in transistor performance by annealing the devices at 70 °C under vacuum demonstrates the importance of heat treatment above the crystal to mesophase transition temperature. An increase in the value from 1.5×10^{-3} cm^2/Vs for as-deposited films to 8.0×10^{-3} cm^2/Vs for annealed films is achieved for the field effect mobility in the saturated regime. Simultaneously, the threshold voltage is reduced from −25 V for the as-deposited device to −12.5 V for the annealed device while the decrease in the sub-threshold voltage swing is observed from 3.8 V/decade to 1.6 V/decade for corresponding devices. The improved transistor parameters measured for heat treated devices are attributed to the reduction in effective grain boundaries, grain-boundary trap densities and a substantial decrease in the average surface roughness of the $R_{16}LuPc_2$ films.

ABSTRACT

We investigated the temporal coherence properties of organic light-emitting devices (OLEDs) by characterizing their coherence lengths. The interferometry based on the Newton's rings apparatus was adopted to characterize the coherence lengths of various OLEDs, including non-doped/doped OLEDs and non-cavity bottom-emitting/cavity top-emitting OLEDs. The types of OLEDs investigated exhibit coherence lengths of 3–10 μm, depending on the device structures/emitters and spectral bandwidths of the OLED emission. OLEDs using emitting molecules with more limited number of allowed vibronic transitions give narrower-band and more coherent emission. Introducing the microcavity into the device structure to induce resonance also narrows the emission spectra and meanwhile increases the coherence length. Such information may be useful for modeling, design, and optimization of optical properties of OLEDs.

1. Introduction

Organic light-emitting diodes (OLEDs) are becoming increasingly important because of their applications in flat panel displays and lighting [1,2]. Along with the advancement of the OLED technology, demands in precise and detailed adjustment and optimization of optical properties of OLEDs are also increasing [3,4]. For OLEDs with multiple material layers, optical coherence properties of the devices influence various optical phenomena, such as interference, propagation, and distribution of radiation generated by the emitter. Thus, for optical modeling and designs of OLEDs, information regarding the coherence properties of OLEDs would become more essential and indispensible. Coherence properties of various Lambertian and non-Lambertian emitters/light sources had been studied conventionally [5]; yet only recently had people started to investigate coherence properties of OLEDs [6].

There are two kinds of optical coherence properties associated with a light source: temporal coherence and spatial coherence [7]. Temporal coherence is a measure of the phase correlation between different points along the propagation direction of a light wave [8]. Spatial coherence is a measure of the phase correlation between different points transverse to the propagation direction of a light wave [9]. Spatial coherence tells how uniform the phase of the wave front is. In recent studies of optical coherence of OLEDs, mainly the spatial coherence was reported [10]; yet the temporal coherence of OLED light sources has not been well investigated. In this work, we performed investigations on the temporal coherence properties of various OLEDs.

One typical parameter to characterize the temporal coherence of a light source is the coherence length [11]. The coherence length is the propagation distance from a light source to a point where the electromagnetic wave still maintains a specified degree of coherence (phase cor-

doi:10.1016/j.orgel.2009.11.024

relation). In interference experiments, it corresponds to a maximal optical path difference at which two originally coherent beams can still exhibit distinguishable interference [12]. That is, within the coherence length of a light source, the interference of two beams from a same light source will remain detectable, but not distinguishable beyond the coherence length. In interference experiments with varying the optical path difference, in principle, the coherence length can be determined. In this work, by adopting interferometry based on the Newton's rings apparatus [13], we characterized the coherence lengths of various OLEDs.

2. Experimental

2.1. Newton's rings apparatus

The arrangement of the experiment setup is shown in Fig. 1. The setup was comprised of a light source O_1 (e.g. an OLED), the Newton's rings apparatus N_1, a silicon photodetector D_1, a motorized linear stage M_1, and two focusing lens (the convex L_1 and the parabolic lens L_2). The OLED emission was first collimated by the convex lens L_1 (with a focal length of 5 cm). Under the illumination of a collimated OLED emission, a series of concentric rings of interference induced by the Newton's rings apparatus would occur nearby. A parabolic lens L_2 was used to image such interference patterns near the apparatus onto a convenient surface for detection. A silicon photodiode detector D_1 mounted on the motorized linear stage M_1 was used to record the pattern of interference rings (i.e. the interferogram), upon moving the stage. A 0.3-mm-width slit was placed in front of the silicon photodiode for enhancing the measurement resolution. Upon moving the motorized linear stage with a velocity of 48 μm/s, the photodiode detected the variation of the light intensity and converted it into a current signal. A galvanometer with pico-ampere resolution was used to measure the current signal. A computer was used to control the motorized stage/the galvanometer and was used to record the data.

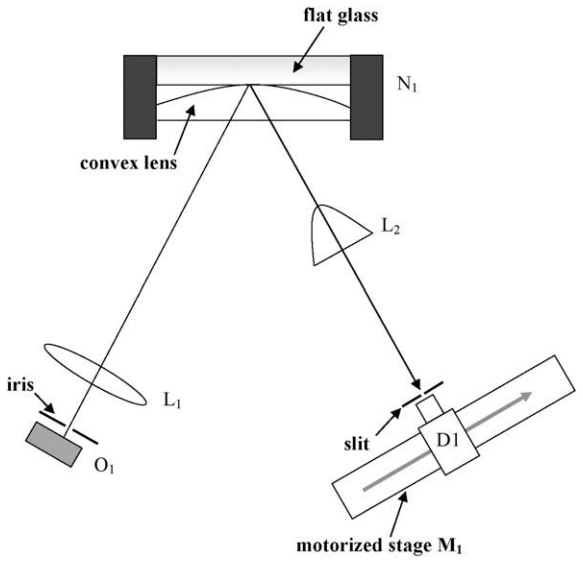

Fig. 1. The experiment setup used for characterizing the coherence lengths of light sources, based on the Newton's rings apparatus.

The Newton's rings apparatus in Fig. 1 was comprised of a long-focal-length convex lens and a flat glass surface, as shown in Fig. 2. It provided a continuous variation of the air gap between the convex and flat glass surfaces. As shown in Fig. 2, there are four surfaces (S_1, S_2, S_3, and S_4) in the Newton's rings apparatus. Under the illumination of a collimated OLED emission, mainly reflection beams from the two surfaces S_2 and S_3 (i.e. R_2 and R_3) would induce distinguishable interference. Reflection beams from the other two surfaces S_1 and S_4 (i.e. R_1 and R_4) would not contribute to the interference patterns, since the thicknesses of the glass plate and the convex lens are much larger than the coherence length of OLEDs studied in this work (of μm scale, as will be seen later).

As shown in Fig. 3, the two reflected beams from S_2 and S_3 will meet again (either in the real space in front of the air gap or virtually behind the air gap) and induce interference if the optical path difference is within the coherence length of the light source. As shown in Fig. 3, the interference would occur in a region near the air gap (i.e. the area F_1 as indicated in Fig. 3). As illustrated in Fig. 3, some interference occur in front of the air gap (e.g. P_1 and P_2) and form a real image of interference patterns; meanwhile some occur behind the air gap (e.g. P_3 and P_4) and indeed form a virtual image of interference patterns. Such interference patterns (i.e. Newton's rings, a series of alternately bright and dark concentric rings) formed near the air gap are called localized fringes [14]; in order to measure the interference patterns formed near the Newton's rings apparatus, it is necessary to project the image in the F_1 region onto a convenient detecting surface for recording.

2.2. OLED fabrication and characterization

OLEDs were fabricated on the ITO-coated or metal-coated glass substrates with multiple organic layers sandwiched between the bottom anode and the top metal cathode. Cleaned and UV-ozone-treated indium tin oxide (ITO) was used as the bottom anode for bottom-emitting OLEDs, while the reflective metal was used as the bottom

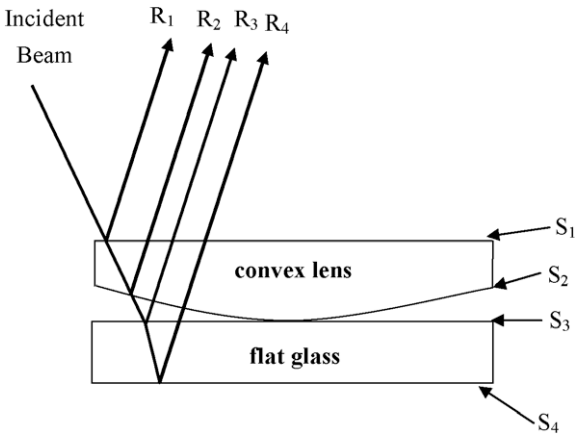

Fig. 2. Schematic illustration of the Newton's rings apparatus.

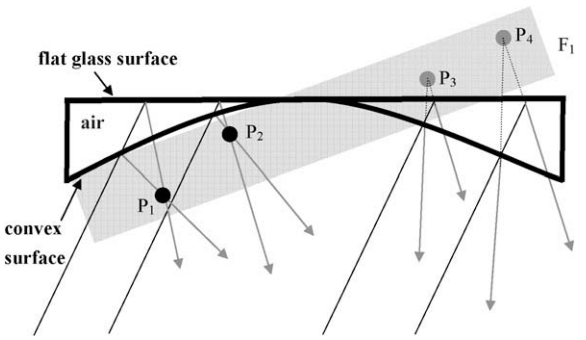

Fig. 3. Schematic illustration of the formation of localized interference fringes (Newton's rings) near the air gap of the Newton's rings apparatus.

anode for microcavity top-emitting OLEDs. All the organic and metal layers were deposited by thermal evaporation in a vacuum chamber with a base pressure of $<10^{-6}$ torr. The deposition rate of organic layers was kept at ~0.2 nm/s. The deposition system permitted the fabrication of the complete device structure in a single pump-down without breaking vacuum. The active area of the device was 2×2 mm^2, as defined by the shadow mask for cathode deposition. After the device deposition, the devices were encapsulated with a cover glass under dry nitrogen atmosphere. Electroluminescence (EL) spectra of devices were collected using a calibrated CCD spectrograph.

3. Results and discussion

3.1. OLED structures and characteristics

Three types of OLEDs (devices A, B, and C) were prepared for studies of coherence properties. These devices were all green-emitting OLEDs based on the typical tris-(8-hydroxyquinoline) aluminum (Alq_3) [15]. Their device structures were:

Device A: Glass/ITO/m-MTDATA (30 nm)/α-NPD (20 nm)/Alq_3 (60 nm)/LiF (0.5 nm)/Al (1 nm)/Ag (150 nm).
Device B: Glass/ITO/m-MTDATA (30 nm)/α-NPD (20 nm)/Alq_3:C545T (1 wt.%, 20 nm)/Alq_3 (40 nm)/LiF (0.5 nm)/Al (1 nm)/Ag (150 nm).
Device C: Glass/Ag (80 nm)/m-MTDATA:F_4-TCNQ (2 wt.%, 30 nm)/α-NPD (20 nm)/Alq_3:C545T (20 nm)/Alq_3 (30 nm)/LiF (0.5 nm)/Al (1 nm)/Ag (20 nm)/Alq_3 (70 nm).

Device A is an Alq_3 bottom-emitting OLED. Device B is an Alq_3 bottom-emitting OLED doped with the green dye C545T [10-(2-benzothiazolyl)-1,1,7,7-tetramethyl-2,3,6,7-tetrahydro-1H,5H,11H (1) benzopyrano (6,7,8-ij)quinolizin-11-one] [16]. Device C is a top-emitting microcavity OLED based on the Alq_3:C545T emitter [17]. The bottom-emitting OLEDs (Devices A and B) adopted the transparent ITO as the bottom anode and the thick Ag as the reflective top cathode, while the microcavity top-emitting OLED (Device C) used the thick Ag as the reflective bottom anode and the thin Ag as the semi-transparent top cathode. In the microcavity top-emitting OLED, the thin Ag cathode is further capped with a 70 nm Alq_3 to form a low-absorption high-reflection composite mirror for maximizing optical output of cavity OLEDs [18]. In these devices, the organic multilayer structure consists of un-doped 4,4′,4″-tris(3-methylphenylphenylamino)triphenylamine (m-MTDATA) or m-MTDATA doped with 2 wt.% of the p-type dopant tetrafluorotetracyano-quinodimethane (F_4-TCNQ) as the hole-injection layer [19], α-naphthylphenylbiphenyl diamine (α-NPD) as the hole-transport layer [20], un-doped Alq_3 or Alq_3 doped with C545T as the emitting layer, and un-doped Alq_3 as the electron-transport layer. Ultrathin layers of LiF (0.5 nm) and Al (1 nm) serve as the electron-injection layers [21,22]. For the microcavity top-emitting OLED (Device C), the resonant wavelength was set around the intrinsic emission peak wavelength of C545T by adjusting the thicknesses of organic layers and the capping layer. During the coherence length measurements, the devices were driven by a fixed dc bias.

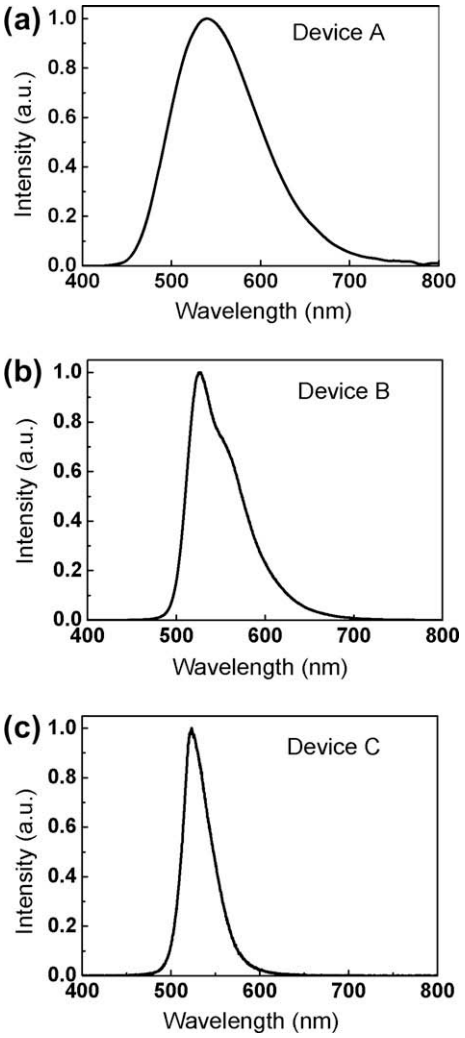

Fig. 4. EL spectra of the OLEDs under investigation: (a) Device A (FWHM ~110 nm), (b) Device B (FWHM ~60 nm), and (c) Device C (FWHM ~40 nm).

Fig. 4a shows the EL spectrum of un-doped Alq_3 Device A, which exhibits an EL peak at 540 nm and a full width at half maximum (FWHM) of ~110 nm, a typical broad-band emission of Alq_3. Fig. 4b shows the EL spectrum of the C545T-doped Device B, which exhibits an EL peak at 525 nm and a smaller FWHM of ~60 nm due to the narrower emission spectrum of the green dopant C545T. Fig. 4c shows the EL spectrum of microcavity top-emitting Device C (doped with C545T), which exhibits an EL peak at 523 nm and a further reduced FWHM of ~40 nm due to the microcavity effects induced by the microcavity structure.

3.2. Characterization of coherence lengths

In order to verify the effectiveness of the coherence length measurement using the Newton's rings apparatus we set up, we first used it to measure the coherence length of a commercial red LED based on $GaAs_{0.6}P_{0.4}$/GaP (model: 204URC, Everlight Electronics Co., Ltd.). The EL spectrum of the red LED is shown in Fig. 5a[1], which exhibits an EL peak at 665 nm and a full width at half maximum (FWHM) of ~24 nm. Then the LED was investigated by the Newton's rings apparatus. Upon illuminating the collimated LED emission onto the Newton's rings apparatus, a series of concentric rings of constructive and destructive interference, as shown in Fig. 5b, could be observed at the detecting surface (via the aid of a white paper). Fig. 5c shows the corresponding interferogram recorded by scanning the photodiode D_1 from the center of the concentric rings to the edge.

The Newton's rings (i.e. alternately bright and dark rings centered around a dark spot) are induced by interference of two beams reflected from surfaces S_2 and S_3, i.e. the curved convex surface and the adjacent flat glass surface. The dark spot at the center of the Newton's rings is associated with the contact point between the convex lens and the flat glass plate, at which the air gap is nearly zero but the two reflected beams S_2 from the convex surface and S_3 from the flat glass surface has a phase difference close to 180°. The bright rings are induced by constructive interference between these two reflected beams, while the dark rings are induced by destructive interference. The mth dark ring ($m = 1,2,3,\ldots$, excluding the central dark spot) from the center corresponds to the mth-order destructive interference (minimum) in the interferogram, which is associated with a phase difference of $(2m + 1)\pi$ and an optical path difference of $\Delta d = m\lambda$. The optical path difference of course increases with the air gap. As the air gap between surface S_2 and surface S_3 increases, the visibility of the interference fringes decreases due to reduced coherence between two reflected beams. The fringe visibility is defined as [23]:

$$V = \frac{I_{max} - I_{min}}{I_{max} + I_{min}}, \quad (1)$$

where I_{max} and I_{min} are the neighboring maximum (peak) and minimum (valley) in the interferogram. In principle, the coherence length can be defined as the optical path difference at which the interference fringe visibility drops to

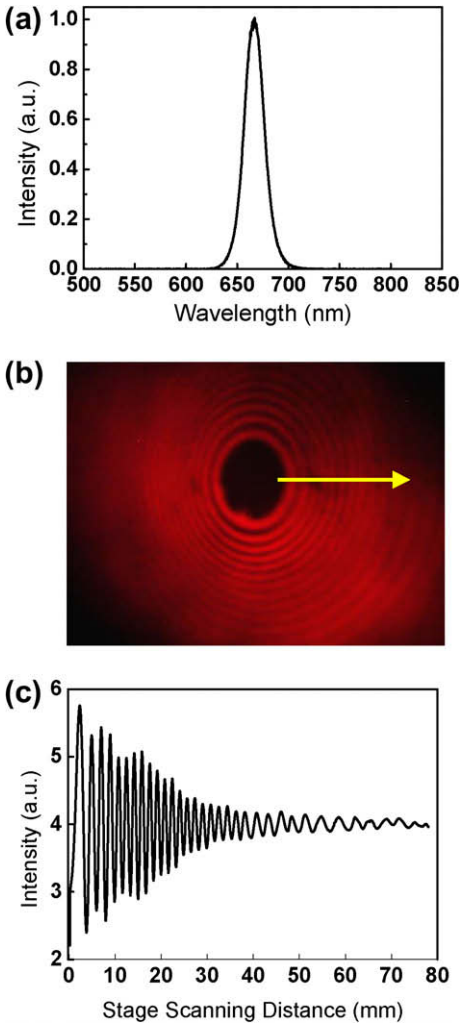

Fig. 5. (a) EL spectra of the $GaAs_{0.6}P_{0.4}$/GaP LED under investigation, (b) image of Newton's rings for emission of the $GaAs_{0.6}P_{0.4}$/GaP LED appearing at the detection surface, (c) the corresponding interferogram recorded at the detection surface. The arrow in (b) indicates the scanning path of the recording photodiode D_1.

1/e of the peak value [24]. In practical measurements of real light sources, when approaching the coherence length, the visibility may drop rapidly to nearly zero, and thus the coherence length may be alternatively/roughly defined as the optical path difference at which the interference fringe visibility drops to nearly zero [25]. Thus in the interferometry based on the Newton's rings apparatus, the coherence length of a light source like a LED or OLED could be estimated by counting the number of distinguishable interference rings in the interferogram and then multiplying the number with the major wavelength of the light source [26].

In Fig. 5c, about 32 minima can be distinguished in the interferogram. Thus the coherence length of this red LED is estimated to be about 21.3 μm (665 nm × 32). The coherence length determined this way is consistent with that of the same type of LED reported previously by other researchers [27], indicating the effectiveness and accuracy

[1] For interpretation of color in Fig. 5, the reader is referred to the web version of this article.

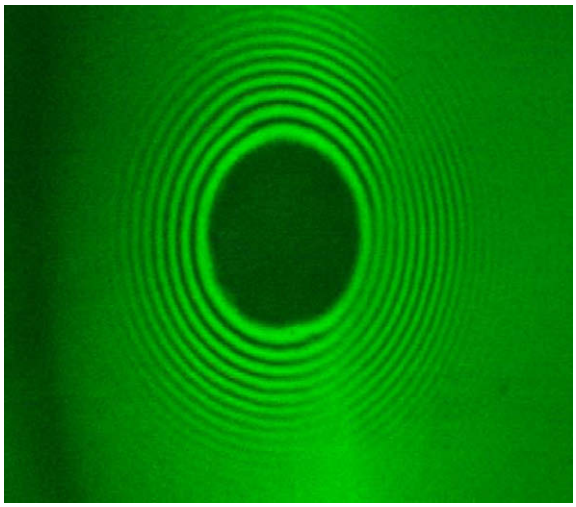

Fig. 6. Image of Newton's rings for emission the OLED under investigation (Device B) appearing at the detection surface.

of the current Newton's rings apparatus for determining the coherence length of a light source.

Similarly, Fig. 6 shows one example image of Newton's rings for one of the OLED light sources under investigation (Device B). Correspondingly, Fig. 7a–c show the corresponding interferograms for Device A, Device B, and Device C, respectively. In Fig. 7a, about six distinguishable minima can be observed in the interferogram of Device A, from which a coherence length of ~3.2 μm (540 nm × 6) is estimated. In Fig. 7b, about 14 distinguishable minima can be observed in the interferogram of Device B, from which a coherence length of ~7.4 μm (525 nm × 14) is estimated. In Fig. 7c, about 18 distinguishable minima can be observed in the interferogram of Device C, from which a coherence length of ~9.4 μm (523 nm × 18) is estimated.

The results show that the three types of OLEDs under investigation have coherence lengths of 3–10 μm, depending on the device structures/emitters and thus spectral bandwidth of the OLED emission. OLEDs with broader EL spectra appear to have longer coherence lengths. Such trend is consistent with that observed in various light sources. For example, in various lasers, the positive feedback and stimulated emission are induced by the cavity structures, resulting in highly coherent and spectrally narrowed emission. As such, the coherent lengths of various laser systems could range from tens of m (e.g. helium–neon laser) [28], to tens/hundreds of m (e.g. some semiconductor lasers) [29], to well over km (e.g. some fiber lasers) [30]. On the other hand, the less coherent and broader-bandwidth emitters like semiconductor LEDs have much smaller coherent lengths (micrometer scale, like the one shown in Fig. 5). Unlike the semiconductor LEDs whose emission mechanism is mainly band-edge emission, for OLEDs, the emission mechanism is mainly due to the radiative relaxation of excitons (molecular excited states generated by electrical excitation) [31]. The molecular exciton relaxation could occur via coupling different molecular vibration states (between electronic excited states and ground states) [32], usually resulting in much

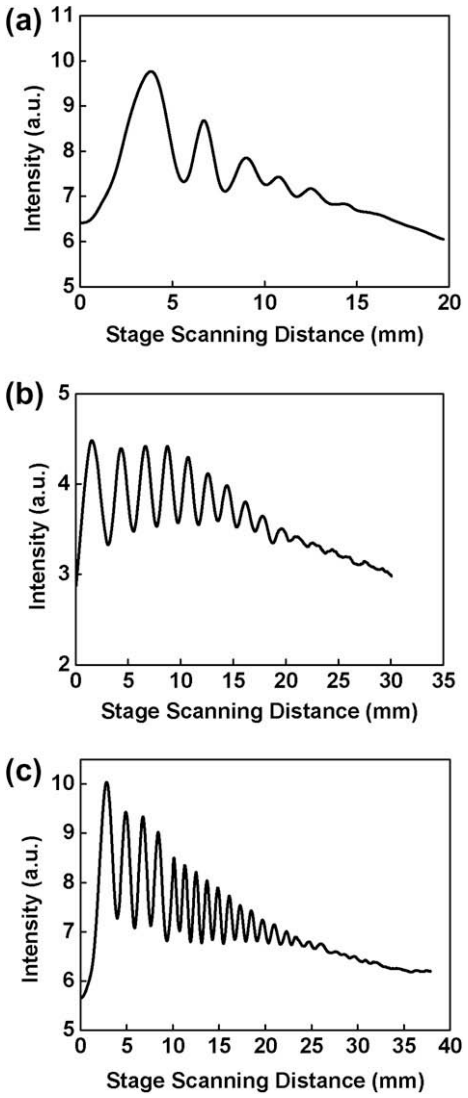

Fig. 7. Interferograms for emission of OLEDs in the Newton's rings experiment: (a) Device A, (b) Device B, (c) Device C.

broader-band and less coherent emission compared to the band-edge emission of semiconductor LEDs. For emitting molecules which inherently have more limited number of allowed vibronic transitions would naturally give narrower-band and more coherent emission. The emission and coherence characteristics of Device B (using narrower-band emitter C545T) vs. those of Device A (using broad-band emitter Alq_3) give a good example. When further introducing the microcavity into the device structure to induce resonance around some wavelengths, like in Device C, it is seen that the emission spectra could be further narrowed and meanwhile the coherence length is increased.

4. Conclusions

In conclusion, we performed investigations on the temporal coherence properties of OLEDs by characterizing

their coherence lengths. The interferometry based on the Newton's rings apparatus, which is convenient and effective, was adopted to characterize the coherence lengths of various OLEDs, ranging from non-doped to doped OLEDs and from non-cavity bottom-emitting to cavity top-emitting OLEDs. The results show that the types of OLEDs under investigation have coherence lengths of 3–10 μm, depending on the device structures/emitters and thus spectral bandwidths of the OLED emission. OLEDs using emitting molecules with more limited number of allowed vibronic transitions give narrower-band and more coherent emission. Introducing the microcavity into the device structure to induce resonance also narrows the emission spectra and meanwhile increases the coherence length. Such information may be useful for modeling, design, and optimization of optical properties of OLEDs.

ABSTRACT

The improvement of current injection efficiency in organic light emitting diodes is demonstrated with incorporation of SubPc-doped NPB as hole injection layers. The photoemission spectra illustrate the presence of gap states and the occurrence of axial reaction on SubPc with NPB. Quantum chemistry calculation provides simulated valence-band spectra indicating that the formation of gap states is due to the HOMOs of new complexes created from the reaction of SubPc and NPB, which facilitate the hole injection at the anode interfaces.

1. Introduction

Organic light emitting diodes (OLEDs) receive great attention in recent years due to applications in lighting and future display technology [1]. In typical multi-layer OLEDs, carrier injection at anodes is a crucial issue in improvement of electrical characteristics. There are many techniques to enhance the hole injection efficiency, e.g. oxidation of ITO [2,3] and electrical doping of hole injection layers with oxidizing regents [4,5] or tetrafluoroteracyanoquinodimethane (F_4TCNQ) [6]. Among electrical doping materials, phthalocyanine derivatives (Pcs) are frequently studied due to some of their physical properties, such as high mobility in ordered thin films, self-assembling behaviors, and n-type doping effect by incorporating alkali atoms [7–9]. One of the pc-related compounds, chloro[subphthalocyaninato]boron(III) (SubPc), is also widely investigated for their non-linear optical property [10,11]. Some research groups have employed SubPc in photovoltaic devices to improve the solar cell performance, including open circuit voltage, power conversion efficiency, and quantum efficiency, owing to better energy level alignment at the abrupt junction of donor/acceptor interfaces [12,13]. In this paper, we report the enhanced current injection efficiency of OLEDs using SubPc-doped hole injection layers (HILs) and the studies of mechanisms leading to such improvement.

2. Experimental and theoretical method

In this study, OLEDs were fabricated with SubPc-doped *N,N′*-di(naphthalene-1-yl)-*N,N′*-diphenyl-benzidene (NPB) as HILs and the electrical characteristics of devices with various HILs were measured with Keithley 2636A. Compared to the metal oxides usually used in OLEDs as HILs, e.g. MoO_x and WO_3 [14], SubPc can be evaporated with stable deposition rate at relatively low temperature of about 220 °C. Photoemission experiments were performed at the National Synchrotron Radiation Research Center (NSRRC) in Hsinchu, Taiwan, Republic of China. The valence-band and core-level photoemission spectra were measured at U5 beamline, which can provide photons with energy range from 100 eV to 1000 eV [15]. Photoelectrons

emitted from samples were collected with a 125 mm hemispherical analyzer in an UHV chamber. Procedures of sample preparation and organic material evaporation were described in the previous report [16].

To identify the origins of the gap states found in valence band, theoretical simulation with density functional theory methods were used to compute the molecular orbitals (MOs) and simulated density of states. The optimized geometric structures were obtained with the method of B3-LYP and the basis set of 6-31G, and the single-point energy was then applied to retrieve the detail information of molecular energy using Gaussian03 software [17]. The simulated valence-band spectra using calculated MOs was extracted via GaussSum [18] with full-width-at-half-maximum of 0.4 eV.

3. Results and discussion

A series of devices with SubPc-doped NPB as HILs were fabricated to investigate hole injection efficiency. The device structures are UV-ozone-cleaned indium tin oxide (ITO)/HIL (5 nm)/NPB (35 nm)/Alq3 (40 nm)/LiF (0.5 nm)/Al (150 nm). Various doping levels of SubPc in NPB were tested and thickness of HILs was optimized for best current density. The reference device was fabricated with MoO_x as the HIL for comparison. Fig. 1(a) shows the *J–V* characteristics of devices with different HILs in both linear and semi-log scales and the result reveals that the performance of SubPc-doped devices are all much improved. The device with 5–10% SubPc-doped NPB shows the best current injection efficiency as compared to those with other doping concentrations and is also superior to the devices with MoO_x, which has been widely used as HILs. At higher concentration of SubPc doped in NPB, the current density of devices decrease, which is probably due to the decrease of mobility of NPB with too many foreign molecules. Fig. 1(b)–(d) shows the luminance vs. voltage, luminous efficiency characteristics, and electroluminance (EL) spectra, respectively, of the devices with SubPc doped in NPB. As indicated from these data, the device with 5% SubPc-doped NPB also demonstrates the best brightness at the same voltage, whereas the luminance efficiency and EL spectra are almost the same for all devices. The results illustrate that SubPc doped in NPB promotes hole injection capability between ITO and NPB.

In order to identify the role of SubPc in NPB as HILs, photoemission experiments were carried out *in situ* at synchrotron radiation center. Fig. 2(a) shows the valence-band spectra of pristine NPB, pristine SubPc, and 1:1 mixture of these two molecules, respectively. The vicinity of HOMO regions are enlarged and shown in Fig. 2(b). For pristine NPB and SubPc, there is no detectable density of states within 1 eV below the Fermi level. However, states extended in the forbidden gap from HOMO to the Fermi level are emerged with mixing of NPB and SubPc. The formation of the gap states has been observed at the interface of the

Pc-derivatives and metal electrodes [19–21]. However, the studies of interfaces between Pc-derivatives with other organic molecules are relatively sparse in literatures [22–25] and there is no report on the formation of gap states. These gap states between the HOMOs of the organic materials and the Fermi level at the anode interfaces could provide extra states for holes and facilitate the hole injection, resulting in the enhancement of current density of devices when SubPc is doped into NPB. To find out the origins of these gap states, the interfacial chemistry between NPB and SubPc was further studied with core-level photoemission spectra.

The carbon 1*s* and boron 1*s* core-level spectra of SubPc with incremental deposition of NPB were measured with excitation photon energy of 350 eV and 250 eV, respectively. In order to extract detailed chemical information from XPS, all the core-level spectra were subtracted by the Shirley background, and then analytically fitted with the Voigt profile. The carbon 1*s* core-level spectra of pristine SubPc shown at the bottom of Fig. 3(a) consists of four major features, which are similar to those of other Pc-derivatives from previous reports [26–28]. The main peak C1, at 284.8 eV, is attributed to the 18 carbon atoms in benzene rings and the next prominent peak C2, at 286.4 eV, is contributed by the remaining 6 pyrrole carbons. Whereas C3 and C4 peaks are the shake-up structures of carbon element in benzene and pyrrole rings, respectively. With as little as 0.5 angstroms of NPB deposition, the rapid smear of C2 component implies that the chemical reaction happens around the center of SubPc. The evolution of boron 1*s* core-level on SubPc substrates with NPB coverage is demonstrated in Fig. 3(b). The binding energy of boron 1*s* peak in pristine SubPc is 191.8 eV and a new feature appears at the low binding energy side with increasing NPB

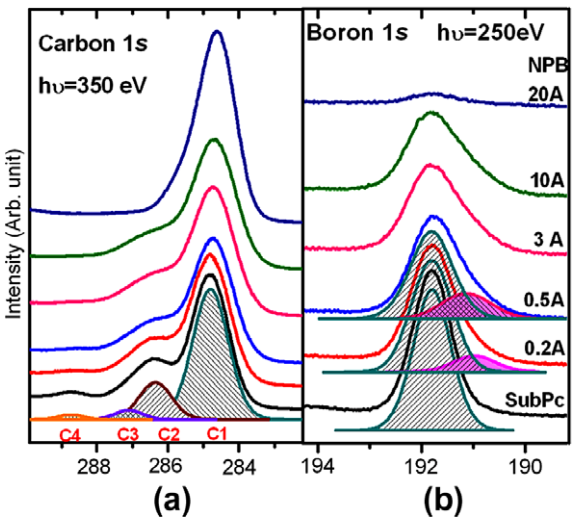

Fig. 3. (a) Carbon 1*s* core-level spectra of SubPc with incremental deposition of NPB. (b) Boron 1*s* core-level spectra of SubPc with incremental deposition of NPB.

coverage, which indicates that boron atoms in some of the SubPc molecules are gaining extra portion of electrons in the deposition process. The possible reaction of SubPc has been discussed and characterized into three categories: axial reactivity, peripheral reactivity, and ring expansion reaction [11]. From the result of core-level photoemission spectra, it can be assumed that the appearance of the new feature in boron 1*s* core-level is attributed to an axial reaction process on SubPc with deposition of NPB. The axial reaction in this case means that elimination of the axial ligand (chlorine) of SubPc forms a meta-stable

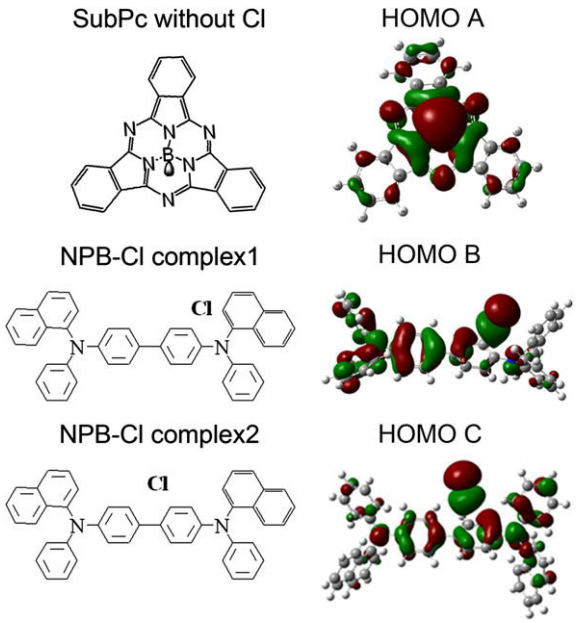

Fig. 4. Chemical structures of complexes resulting from the reaction of SubPc and NPB and their frontier molecular orbitals.

intermediate structure, with chlorine atoms detached from SubPc molecules [29]. Quantum chemistry calculation were then carried out to verify the occurrence of axial reaction and to identify the correlation between this reaction and the gap states detected in UPS experiments.

In axial reactivity, chlorine would dissociate from SubPc and form a new complex with NPB molecules. The calculated Gibbs free energy is about −440 kcal/mol if chlorine and NPB form a complex. A similar case can be found in Li and Alq_3 [30,31] or in $FeCl_3$ and NPB [32]. From energy calculation, two geometrical arrangements with similar energy would possibly be formed as chlorine-NPB complex. The molecular structures of these two chlorine-NPB complexes and a SubPc molecule with chlorine detached, which are the species in the NPB/SubPc mixed films, are shown on the left hand side of Fig. 4. The spatial distributions of HOMOs of these three species are shown on the right hand side of Fig. 4.

To investigate the correlation of molecular structures and electronic structures, the molecular energy levels and simulated valence-band spectra were calculated. Fig. 5(a) shows the simulated spectra of pristine NPB and SubPc, which agree fairly well with the experimental UPS results. The vertical bars under the simulated spectra are the molecular levels of single molecule. In both simulated and experimental data, we can see that there is no energy level within 1 eV below the Fermi level in either pristine SubPc or NPB. Fig. 5(b) is the re-drawn of Fig. 2(b) with calculated molecular energy levels shown under the associated experimental valence-band spectra. As shown in the spectrum of NPB-SubPc mixture in Fig. 5(b), there are three new energy levels at the top of valence band corresponding to HOMO A, HOMO B, and HOMO C in Fig. 4, respectively. From the comparison of calculated energy levels and experimental spectra, it is clear that the gap states are attributed to the HOMOs of the new complexes resulting from the axial reaction of SubPc with deposition of NPB.

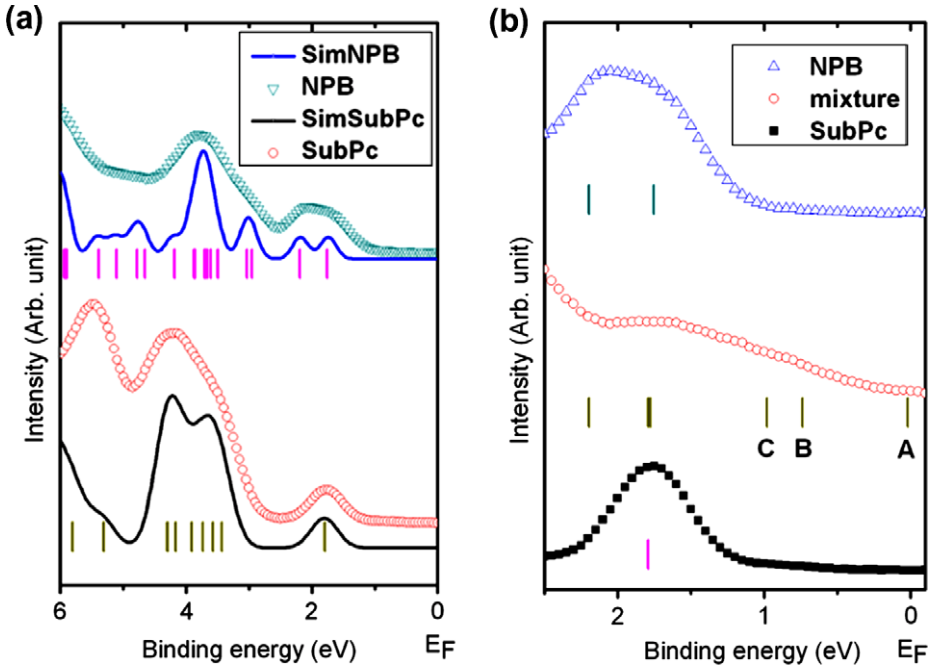

Fig. 5. (a) The experimental and simulated valence-band spectra of pristine NPB and SubPc. The vertical bars under the simulated spectra are the molecular levels of single molecule. (b) Comparison of experimental HOMO spectra and calculated molecular levels of pristine NPB, pristine SubPc, and NPB/SubPc, respectively.

4. Conclusion

In conclusion, we demonstrated the enhancement of current injection efficiency in OLEDs with incorporation of SubPc-doped NPB as HILs. The origins of enhanced current efficiency were investigated via photoemission spectroscopy and quantum chemistry calculation. The corresponding core-level spectra indicate the occurrence of axial reaction on SubPc with NPB. Furthermore, simulated valence-band spectra show that the formation of gap states is due to the HOMOs of new complexes created from the reaction of SubPc and NPB, which facilitate the hole injection at the anode interfaces.

ABSTRACT

Two of the commonly-used Organic Light Emitting Diode (OLED) materials tris-(8-hydroxyquinoline) aluminum (Alq_3) and *N*,*N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)benzidine (NPB) are thermally evaporated as thin-films on two kinds of substrates with different hardness. By using nano-indentation techniques, the reduced elastic modulus of each of the coatings is measured. The data are carefully analysed through the standard Oliver and Pharr method, and the recently developed critical indentation depth method which takes the effect of the substrate more into account.

1. Introduction

Thin-films of organic luminescent molecules have been used in Light Emitting Diodes (LED) for two decades. Applications for lighting and small size displays are said to be approaching the cost and lifetime requirements of the electronics consumer market. Comparing their relatively low power consumption with other rivals such as inorganic LEDs in lighting or backlit liquid crystal devices in flat panel Liquid Crystal Displays (LCDs), the Organic Light Emitting Diode (OLED) distinguishes itself by having the potential to be mechanically flexible. Unlike LCDs and inorganic LEDs, OLEDs or printable polymer LEDs can be fabricated on a plastic substrate to make the device flexible, and amenable to roll-to-roll manufacture. It is therefore essential to understand how this rolling process might mechanically damage the multi-layer structured OLED, and studies towards this aim have appeared in the last 5 years. Most of these studies, however, have focused on what was estimated to be the most brittle layer in the structure – the commonly-used Indium Tin Oxide (ITO) layer as the anode [1,2]. However, study of the elasticity properties of the organic conducting and emissive layers is still rare in literature [3]; to obtain such information from a 100 nm thick thin-film is not a simple task. One method potentially able to perform this task is nano-indentation.

Nano-indentation has been used routinely in the mechanical characterization of thin-films and thin-surface layers in recent years [4]. The technique applies a programmed function of increasing and decreasing load to the surface of interest with an indenter of well-defined shape and continuously measures the indenter displacement. The advantage of this method is that mechanical information, such as elastic modulus, can be obtained through the analysis of the load–displacement behaviour alone with a coating of the material to be tested on a substrate made from different material. This makes it an ideal

tool for our task. The technique has been used to assess the elastic and plastic properties of micron thick coatings on a range of substrates but there are limitations in measuring the properties of much thinner coatings, particularly when elastic properties are required [5,6]. For coatings of a few hundred nano-metres thickness it has been suggested that extrapolating the properties determined at a range of peak loads or indenter displacements to zero load/depth can be used to determine the coating only properties. With high quality, sharp indenters it is possible to assess coatings down to 100 nm thick by this method [7]. This has been attempted in this study.

2. Experimental

Among all the small molecules used in OLEDs, tris-(8-hydroxyquinoline) aluminum (Alq_3) (Fig. 1a) and *N*, *N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)benzidine (NPB) (Fig. 1b) are two of the most popular materials. Because of the relatively high stabilities of the structures during operation and good electrical conductivities, they can be found in almost every OLED device structure. Therefore it is reasonable to expect that they would be used in the flexible OLED devices, too. So it is important to understand their elastic characteristic. In order to evaluate the effect of the substrate [8], two different kinds of substrates were used: polyethylene terephthalate (PET) supplied from DuPont Teijin Films and standard silicon wafers. All the substrates were cleaned in an ultrasonic bath with acetone, and then isopropanol for 5 min each. The substrates were then loaded into the Kurt J. Lesker Spectros II Deposition System. The tested materials were deposited under a vacuum of 5×10^{-7} mbar. Finally, the samples with 100 nm of Alq_3, 200 nm of Alq_3 and 200 nm of NPD on three individual PET substrates and samples with 100 nm of Alq_3, 100 nm of NPD on two silicon wafers were prepared, respectively (see Table 1).

The Young's moduli of the samples were measured by standard nano-indentation techniques. For each material nano-indentation tests were performed under open loop, load and displacement control with maximum displacements (h_{max}) from 10 nm to 1000 nm using a Hysitron Triboindenter fitted with a sharp Berkovich diamond indenter (tip end radius ~50 nm). In open loop control the indentation loading and unloading segments were controlled by timed ramps whereas in the other loading schemes feedback loops were used to ensure that the desired peak loads and displacements were achieved. The indentation systems frame stiffness and the diamond tip shape was carefully calibrated with a fused silica test sample, using the standard Oliver and Pharr method [9], before and after measurements with no change in either recorded. Nano-indentation load (P) *vs.* displacement (h) curves were then recorded for each indent and only those where evidence of plastic deformation was observed (i.e. the loading and unloading curves are different) were used in the analysis of Young's modulus by the Oliver and Pharr method [9]. The indenter displacement is in fact made up of two components: the plastic depth of the indent, or contact depth, and the elastic deflection of the surface at the edge of the contact. The relationship between the contact depth (h_c) and the maximum displacement (h_{max}) can be determined from Eq. (1):

$$h_c = h_{max} - \varepsilon \frac{P_{max}}{S} \tag{1}$$

where, P_{max} is the maximum loading, and ε is a constant that depends on the shape of the indenter [10]. Empirical studies have shown that for a Berkovich indenter, the typical value of ε is about 0.75. S is the unloading stiffness, which comes from:

$$S = \frac{dP}{dh}\Big|_{h=h_{max}} = mB(h_{max} - h_f)^{m-1} \tag{2}$$

where, m and B are fitting parameters, and h_f is the final displacement after completely unloading.

In this approach, S, the initial slope of the unloading curve, can finally be used to determine the reduced elastic modulus of the sample (effectively from the recovery of the elastic deflection of the surface) based upon the Sneddon flat punch solution [11] and the following equation:

$$E_r = \frac{1}{\beta}\frac{\sqrt{\pi}}{2}\frac{S}{\sqrt{A}} \tag{3}$$

where, A is the contact area which can be deduced from h_c based upon an accurate knowledge of the tip end shape, and β is a constant also depends on the geometry of the indenter (β = 1.034 for the Berkovich indenter) [10].

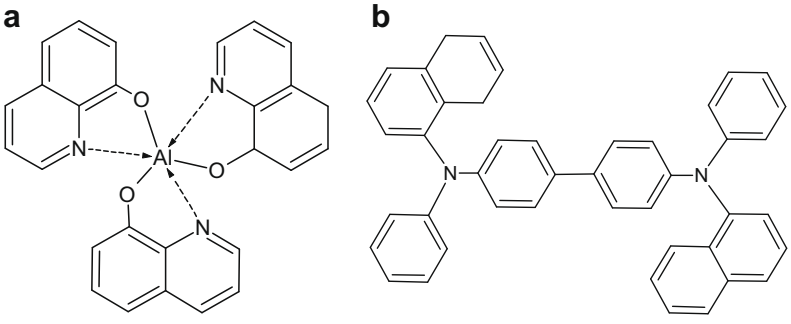

Fig. 1. (a) Structure of tris-(8-hydroxyquinoline) aluminum (Alq_3) and (b) *N*,*N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)benzidine (NPB).

Table 1
Samples investigated.

Sample ID	Ia	Ib	Ic	IIa	IIb
Substrate material	PET	PET	PET	Silicon wafer	Silicon wafer
Substrate thickness/mm	0.1	0.1	0.1	1	1
Coating material	Alq3	Alq3	NPD	Alq3	NPD
Coating thickness/nm	100	200	200	100	100

3. Results and discussion

Fig. 2 shows one example of our load–displacement curve for the sample Ic obtained under open loop control at h_{max} = 475 nm. There is little difference to curves obtained by the other control schemes (load or displacement control) showing that time dependent deformation (creep viscoelasticity) is not significant in this sample. The load-unload curve shows the typical behaviour of a material undergoing a nano-indentation test. The initial slope (~4.4 μN/nm) of the unloading process is used to deduce the reduced elastic modulus of the coating material (in this case, NPB) at the specific h_c. There are a number of jumps (pop-ins) in the loading curve initially. These are most likely related to through-thickness cracking in the coating. Once the coating cracks it no longer supports as much load and the load support is transferred to the substrate – hence the behaviour is dominated by substrate deformation. The cracked coating will also have a lower effective Young's Modulus. The reason for the cracking is probably the mismatch in properties between substrate and coating; a lower Young's modulus substrate material will expand elastically more than the coating for a given contact stress and the as the coating tries to follow this expansion (because it is adhered to it) it is stretched beyond its fracture strain.

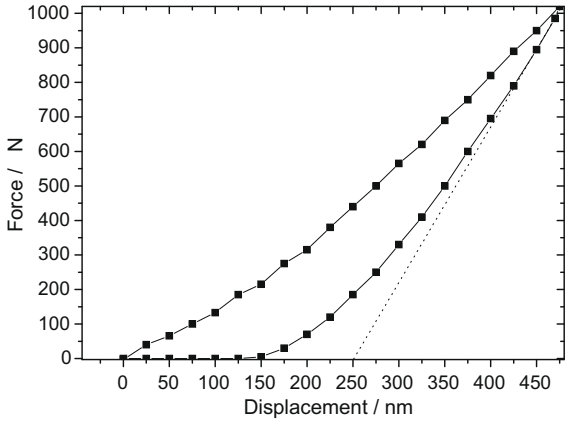

Fig. 2. Load–displacement curve for the 200 nm thick NPB coated on a PET film obtained under open loop control at maximum indenter displacement (h_{max}) = 475 nm.

The reduced elastic modulus of samples Ia, Ib and Ic against the contact depth are shown in Fig. 3a. It is clear that the Alq_3 coating has a greater stiffness than the NPD coating. Since the coating thicknesses of all the samples are ~100 nm all the values of reduced elastic modulus are expected to be affected by the substrate material. Therefore the value when the contact depth is extrapolated to zero should approximate the reduced elastic modulus of the coating layer deposited (ISO 14577-4 (2007)). From Fig. 3a, all the three samples have a Young's Modulus between 9 GPa and 13 GPa when h_c approaches zero. Fig. 3b, however, shows a completely different result when using a silicon wafer as the substrate. The reduced elastic modulus of Alq_3 and NPD are over 160 GPa and 100 GPa, respectively, as h_c approaches zero which seems too large for a molecular film. If we omit the data when h_c < 5 nm because of the effect of surface roughness, and do the extrapolation of the curve only between h_c = 5 nm and 10 nm as shown in Fig. 4, the reduced elastic modulus would become about 100 GPa (Alq_3) and 60 GPa (NPD). All the different reduced Young's moduli obtained from different substrate materials and different analysis methods are listed in Table 2.

There is a question about the validity of the data when h_c < 25 nm since the accuracy of the measurement depends

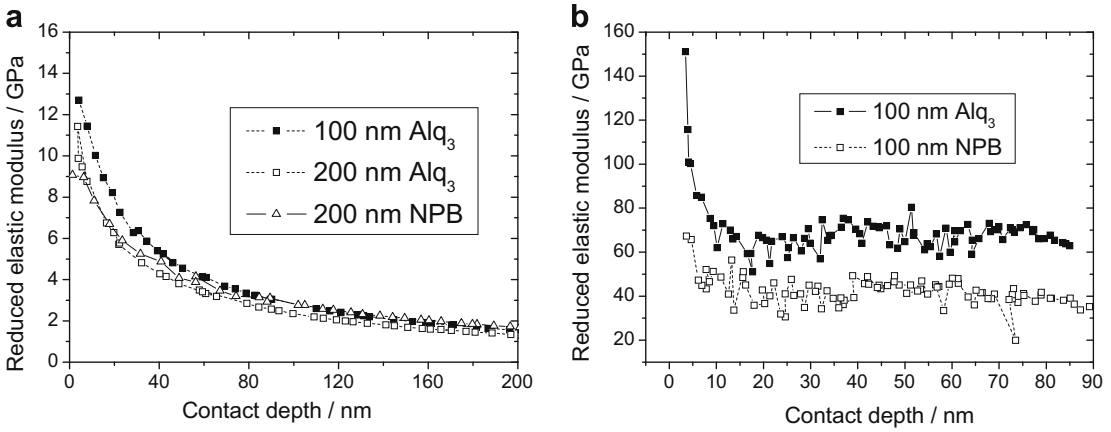

Fig. 3. Reduced elastic modulus against contact depth for the samples Ia, Ib and Ic (a) and of samples IIa and IIb (b).

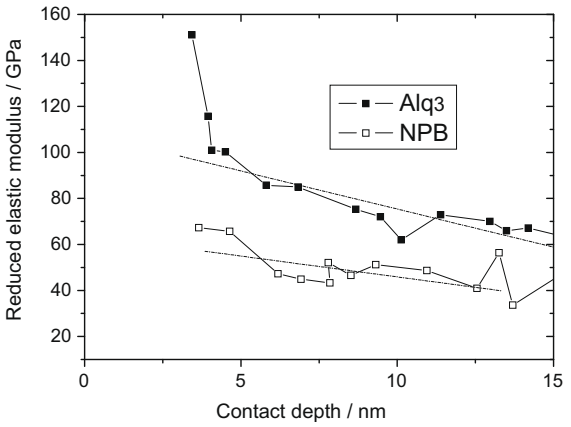

Fig. 4. Extrapolation to zero depth of the curve in Fig. 3b when considering the contact depth from 5 nm to 10 nm.

Table 2
Reduces elastic moduli of samples determined by different methods.

Reduced elastic modulus/GPa	Sample ID				
	Ia	Ib	Ic	IIa	IIb
Data analysis method					
Extrapolation to 0	13	12	9	100	60
Series of springs – Eq. (4)				123.5	61
Plateau in measured value as function of RID				70	40

on the relative indentation depth (RID, i.e. the penetration divided by the coating thickness). This is due to the fact that for a blunt conical indenter there is a transition from spherical contact to conical contact behaviour – for the Berkovich indenter used here this transition occurs at h_c = indenter radius/4, i.e. 12 nm and data at lower depths should be treated with caution as it has been shown that the contact modulus measured varies considerably with tip radius under spherical contact conditions [12]. The decrease in Modulus as h_c increases to 20 nm could be due to this but may also be due to the fracture of the thin coating. It is not likely that the measured values in this depth range are due to an increasing contribution from the substrate since the plateau in Modulus at greater contact depths is not equal to the Young's Modulus of the substrate.

When a coating/substrate system is compressed between the indenter and sample support the measured reduced elastic modulus can be regarded as a combination of springs in series via, to a first approximation,

$$\frac{1}{E_{reduced}} = \frac{1}{E_{indenter}} + \frac{1}{E_{substrate}} + \frac{1}{E_{coating}} \quad (4)$$

Given the indenter properties (E = 1141 GPa) and silicon wafer substrate properties (E = 130 GPa) and the plateau values of measured modulus above h_c = 20 nm using the Eq. (4), Alq_3 would have a Young's modulus of 124 GPa and NPD of 61 GPa which are similar to the values produced by extrapolation of the data to zero contact depth. This gives us some confidence in the measured values.

However, as mentioned previously, the ratio of the indenter tip end radius (IR) to the coating thickness (t) also plays an important role in nano-indentation data analysis [12]. For IR = t, the data can only be reliable when the penetration depth is equal to or greater than half the thickness of the coating material. For IR down to 0.1t, the reliable data can extend to RID = 0.05. If we use this concept to examine our experimental data, with the IR of the indenter about 50 nm, and the thickness of the small molecule coatings between 100 nm and 200 nm, the range would sit between IR = 0.25t and 0.5t. In such circumstances the critical RID to achieve reliable data would be 0.25 for the 100 nm coating and 0.125 for the 200 nm coating – i.e. the contact depth of 25 nm as identified above. The reduced elastic modulus of the samples is plotted against RID in Fig. 5a (Ia, Ib, Ic) and 5b (IIa, IIb). In both cases the reliability of the data at RID < 0.1 used in extrapolation to zero contact depth for coating property assessment is questionable and the Young's Modulus data should be determined by different methods to ensure good accuracy.

The fact that the measured Young's Modulus values do not converge to the Modulus of the substrate in either case shows that the indenter/coating/substrate system must be considered as a set of springs in series as described by Eq.

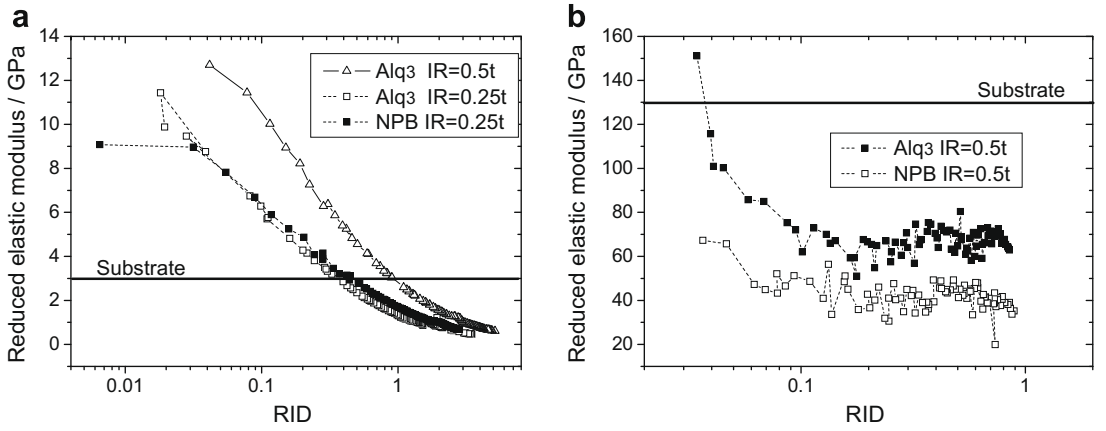

Fig. 5. Reduced elastic modulus against relative indentation depth (RID) for the samples Ia, Ib and Ic (a) and for samples IIa and IIb (b).

(4). It is well known that the properties of a low modulus gasket will dominate the elastic properties of a bolted joint and in a similar manner a low modulus coating or substrate will dominate the properties of the system. The load jumps in the loading curve show that through-thickness fracture occurs at very low loads and the coating stiffness will depend on such cracking. The cracks are approximately parallel to the loading direction during indentation and are expected to have a relatively small effect on the Young's Modulus measured in this direction. However, the Young's Modulus necessary for OLED bending calculations is that in the direction perpendicular to these cracks which could be dramatically affected by cracking. The knowledge of the strain to failure in the film, as well as the knowledge of the modulus of uncracked material would be necessary to determine the bending resistance of these materials.

In systems where the elastic properties of the coating are well known and the coating is deposited on a stiff and a polymer substrate (e.g. in the case of copper on sapphire and polyimide in Fig. 6) the analysis methods used here only give the correct Young's modulus for coatings on the stiff substrate. Thus for design purposes the properties of the films on a hard, stiff substrate should be used as these are more likely to be correct. The deposition of relatively stiff, stressed films on a polymeric substrate can lead to enhanced deformation of the substrate which cannot be accounted for by the simple, time-independent analysis that has been used here. Given the different results from the two substrates (Table 2), we note first that the density of the thin-film, or the way it is grown might be different when deposited onto different materials, and both the film density and the structure of the aggregation can alter the elastic response of the thin-film. The mobility of added species on polymer substrates is often low when compared to materials like silicon leading to the formation of less dense coatings with lower elastic moduli. Thus the properties on silicon may not be totally correct for the films deposited on PET but are a better first approximation to the real properties than the values measured on the PET substrate unless a better model is developed to account for substrate deformation during indentation.

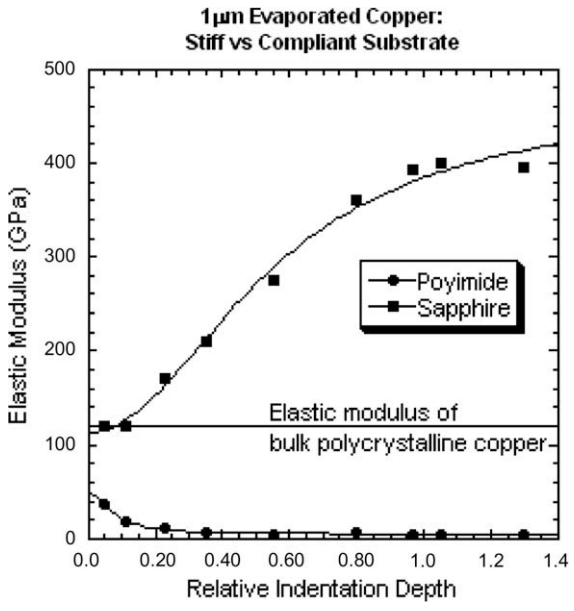

Fig. 6. Elastic modulus against relative indentation depth (RID) for the polycrystalline copper coated on softer (polyimide) and stiffer (sapphire) bases.

4. Conclusion

For such a thin coating on a compliant substrate (i.e. the samples Ia, Ib, Ic) it is difficult to completely filter out the effect of the substrate and there may be considerable scatter in the extrapolated modulus due to the quality of the data available for extrapolation. Fig. 5a actually show a monotonic increase in Reduced Modulus with relative indentation depth and there is considerable agreement between the samples with different coatings but the same thickness. An increase in coating thickness results in an increase in measured Reduced Modulus at a given depth which implies that differing substrate contributions have been recorded. However, on the silicon substrate there is much greater discrimination between the properties of the individual coatings as the results are dominated by the coatings rather than the substrate material.

To conclude, in this work the reduced elastic modulus of the Alq_3 and NPD thin-films used in the OLED devices are measured with different substrates using the nanoindentation method developed by Oliver and Pharr. Different methods of analysis have been applied. When measured on silicon, the reduced elastic modulus of Alq_3 and NPD are in the range of 60–120 GPa, which is similar to values obtained for amorphous carbonaceous coatings and heavily cross-linked materials where density is high. When the film is deposited on the PET film, however, the Young's Modulus is much smaller (~13 GPa) due to changes in film density and structure.

ABSTRACT

Printed organic electronic is believed to be one of the next major technological breakthroughs in the field of microelectronic. The use of high throughput standard graphic arts printing to process organic field-effect transistors (OFETs) opens promising perspectives for low cost, large area and flexible circuits. Nevertheless, these techniques are commonly known to produce relatively thick (>1 μm) layers and to require complex inks formulations composed of several additives. In this paper, we demonstrate that screen printing and gravure printing may be highly versatile and could be well appropriate to deposit organic semi-conducting layers. These fast "single step" processes combined with amorphous semi-conducting polymer give thin, uniform and reproducible layers. The performances of printed or spin-coated films are similar and lead to robust and reliable full printed transistors and logic functions. Moreover, the capability of screen printing and gravure to deposit small patterns of semiconductor is discussed. Lines and spaces down to 500 μm are reported without specific inks and tools optimizations.

1. Introduction

During the past decade, huge understanding of physical process in the field of organic field-effect transistors (OFET) [1] combined with tremendous progress on chemistry design and synthesis of solution-processed organic semiconductors [2], have led to demonstrations of high-performance solution-processed organic transistors with electrical properties and stability closed to amorphous Si [3–5]. One of the next challenges is now to demonstrate the robustness and reliability of OFETs to support the realization of circuits and active matrixes with several hundreds of connected transistors. The benefit of organic electronics is usually associated to the possibility to formulate inks that are compatible with conventional graphic arts printing processes. These techniques are well appropriate for large area, flexible substrate and for the high throughputs required to decrease production cost. When looking at the severe specifications in terms of thickness or resolution of the semi-conducting layers and also in term of viscosity of the associated formulations, the most intuitively adapted printing technique is inkjet. By the use of appropriate nozzle, small volumes of droplet from 100 pL down to 1 pL are afforded and have led to small pattern resolution down to few μm and thicknesses below

100 nm [6]. Another advantage of inkjet is the ability to generate patterns by digital proofing, without any physical mask, thus reducing the cycle time for prototyping and manufacturing. For these reasons, inkjet printing has been the most widely studied technique for the deposition of the organic semi-conducting layer and has demonstrated promising results. Nevertheless, this process suffers form relatively low deposition speed and low throughput capability compared to other printing techniques [7]. This could be detrimental when working on large area because it could generate non uniform drying of the layer and could lead to non homogenous transistors performances. Even if digital circuits may be tolerant enough to support small variations from transistor to transistor, it is obvious that the next generation of analogue circuits, used for example in sensors applications, will be highly sensitive to any deviations. To overcome this issue the use of high cadence printing techniques that afford a fast "single step" deposition similar to spin-coating process, are of interest. For this purpose, Offset printing, Pad printing, Gravure printing, Flexography or Screen printing may be well appropriate, but have been poorly studied [8–10]. This is mainly due to common statements coming from conventional graphic arts printing, such as printed layer thicknesses in the range of 1–10 μm, spatial resolution adapted for the human eye (∼100 μm) and high ink viscosity requirement [11]. In this paper, we aim to demonstrate that these techniques-namely, focusing on gravure printing and screen printing-could be highly versatile and that when combined with amorphous organic semiconductors, could yield to robust and reliable full printed transistors and circuits.

2. Material and methods

For the active semi-conducting layer, we use a triarylamine copolymer, proprietary polymer from Merck Chemicals, which is a well known family of air stable and solution-processed P-channel semiconductor [12]. The nonplanar conformation of the triarylamine prevents the polymer from crystallization. The lack of supramolecular order makes this class of semi-conducting material robust against the deposition and annealing processes. In the present report, we use a 3 wt% formulation of an amorphous polytriarylamine derivative in mesitylene. This formulation was deposited as blanket layer by an industrial semi-automatic screen printing apparatus from EKRA and by gravure printing with a Labratester I automatic tool from Schläfli. The bottom contacts staggered field-effect transistors performances have been compared with layer realized by spin-coating. T-shape gold source and drain contacts were patterned either by standard photolithography or by laser ablation on a plastic PEN substrate (Dupont Teijin) sputtered with 30 nm of gold. Laser ablation is a powerful tool for the realization of source and drain electrodes as it enables a single step direct patterning contrary to photolithography which requires several steps and is more time consuming. This technique is well adapted for roll to roll or sheet to sheet industrial manufacturing. In counterpart, laser ablation could damage the underlying layer – in our case the PEN substrate – which could be detrimental for the transistor performances. In this study, both photolithography and laser ablation are compared. The gold source and drain surface were cleaned with a Reactive Ion Etching oxygen plasma (Nextral) and subsequently treated with a 10^{-3}mol/L solution of pentafluorobenzene thiol (PFBT) in ethanol for 1 min and then rinsed with pure ethanol. Layers on top of the semiconductors are composed of a 1 μm thick low k perfluoropolymer dielectric layer (Cytop®) [13] inkjet printed with an Altadrop equipment from Altatech. Cytop formulations suffer from high viscosities (∼100 cPs) which make them poorly compatible with conventional inkjet printing processes. In our case, a dilute 0.7 wt% solution of Cytop in its solvent (CT-Solv.100 from Asahi Glass) was used. The solution was inkjetted with a single piezoelectric printhead from Microfab (60 μm diameter) drive at a voltage >80 V. Finally, a silver conductive gate (Cabot®) has been deposited by inkjet with a Dimatix printer. Each 5 × 5 cm test sheet is composed by 27 transistors with channel lengths of 50 μm and 100 μm and channel widths ranging from 500 μm to 2 mm.

AFM measurements were carried out in tapping mode with a Veeco dimension 3000. Ellipsometric measurements were done by a GESP 5 model apparatus made by SOPRA. Measures of tan (ψ) and cos (σ)-corresponding to the change of amplitude and phase of the reflection on the sample, which are specific to the sample, were done at 72° (for maximum intensity) and for a wide range of wavelength: from 250 nm to 800 nm, with an interval of 10 nm.

Electrical characterizations of the OTFTs were performed in air without encapsulation, using a HP4156 semiconductor analyzer combined with an automatic prober. Transistor parameters such as saturation mobility, threshold voltage and $I_{ON/OFF}$ ratio were extracted following the 1620™ IEEE standard test procedure.

3. Results and discussions

Recently, we have reported [14] that the thickness of amorphous semiconductor in top gate staggered transistors has a significant influence on the device properties such as the threshold voltage and the subthreshold slope. Variation of these parameters has been attributed to topological effect induced by the source and drain electrodes and by diffusion limited charge transport through the semiconductor bulk, respectively at low and high thickness regime. This result emphasizes the importance of thickness homogeneity in order to decrease the spread of device parameters within a sheet and from sheet to sheet. In this study, we target a semi-conducting layer thickness of 100 nm which is the optimum values, taking into account the 30 nm source and drain step height. For this purpose, we kept the low viscosity (∼10 cPs) of the 3 wt% formulation in mesitylene and we adapted the printing tools parameters in order to achieve 100 nm thick layers. Note that we observed previously [15,16] that the formulation viscosity may have a significant impact on the morphology of semi-crystalline polymers such as regioregular poly(3-hexylthiophene). In particular, higher solution viscosity

leads to poorer supramolecular organization. In the case of amorphous semi-conducting polymers, this argument is not relevant and this family of materials could be formulated in large range of inks viscosity without impacting the transistor performances.

Fig. 1 shows the calibration curves of the semiconductor thickness as a function of process parameters for spin-coating, gravure and screen printing. In the case of spin-coating, we used a 2 wt% formulation and we observe the well known dependence of thickness with rotating speed. For gravure and screen printing, we tuned the thickness by changing, respectively the cell density (number of lines/cm) and the squeegee pressure (N). We observe a linear dependence for both parameters. For screen printing, the thickness increases when increasing the squeegee pressure due to a higher volume of ink transferred through the meshes. In the case of gravure printing, higher cell density gives lower thickness. This could be explained as the cell depth/volume ratio increases when the cell density decreases which leads to higher dry film thickness. We evaluated the thickness non-uniformity of the semi-conducting layer on 5 × 5 cm substrate area by ellipsometric measurements. The results are listed in table 1. We obtained very uniform layers with typical standard deviation less then 5%, yielding a low spread of transistors performances within a sheet. Values from sheet to sheet are also very similar as could be seen from the two screen printed samples. This is not surprising as similarly to spin-coating, gravure and screen printing are fast deposition processes typically with speed in the range of several centimeters to meters per second. The fast coating combined with the use of high boiling point solvent such as mesitylene (BP = 160 °C) enable a homogenous drying process for all the printed area.

Fig. 2 shows Atomic Force Microscopy images of the treated PEN substrates and the amorphous polymer surface for all the deposition techniques investigated. The RMS roughness values are summarized in Table 1. The PEN substrate with gold source and drain patterned by photolithography or laser ablation was cleaned with an oxygen Reactive Ion etching plasma before Self-Assembled Monolayer (SAM) deposition. Gold cleaning such as oxygen plasma or UV-Ozone are well known to improve the quality of the SAM treatment [17]. Such plasma activation leads to a rough PEN surface with RMS ~ 20 nm. Deposition of the semi-conducting layer tends to planarize the surface and the roughness drops to RMS values of 5 nm, excepted for the gravure deposited layer for which we measure a value of 1.4 nm. This smoother surface in the case of gravure is not yet fully understood, and is still under investigation. The semi-conducting top surface does not show any evidence of periodic micro-patterning that may originated from the printing tools, such as gravure cells or screen meshes. This is due to the ink viscosity which is sufficiently

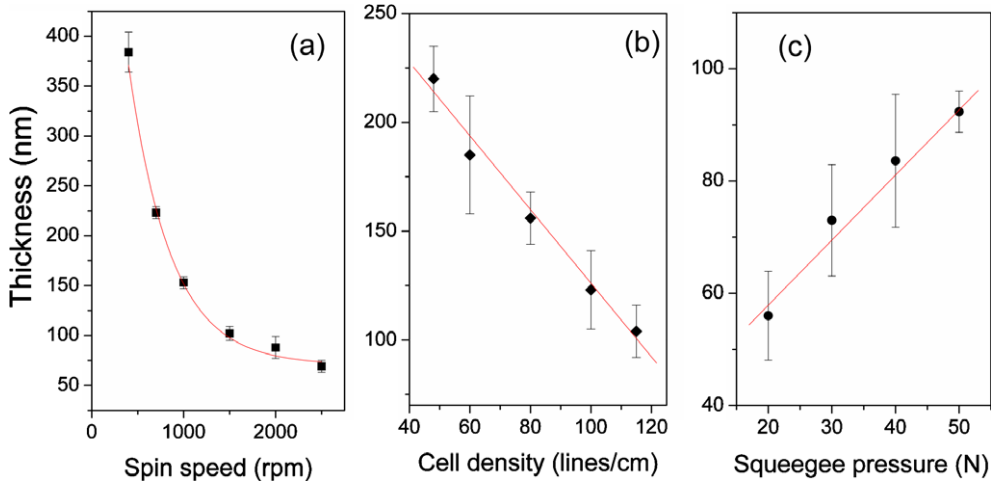

Fig. 1. Dependence of the semi-conducting layer thickness as a function of (a) the rotating speed (rpm) for the spin-coating deposition, (b) the Anilox cell density (lines/cm) for the gravure printing deposition and (c) the squeegee pressure (N) in the case of the screen printing deposition. The solution concentration in mesitylene is 2 wt% for the spin-coating and 3 wt% for the printing techniques.

low to spread the ink formulation on the substrate surface. In the staggered transistor geometry studied, the semiconductor surface roughness may have an impact on the transistor mobility [18]. In our case, we do not observe significant difference in mobility for the three deposition conditions used (Table 1). The average mobility taken from 27 transistors per sheet is ranging from 0.025 cm^2/V s to 0.035 cm^2/V s which is the current state of the art mobility for amorphous semi-conducting polymer [12]. Such a non dependence of the mobility with the semi-conducting roughness may be attributed to the presence of some randomly dispersed peaks (average height ~50 nm) which increase the RMS roughness values without impacting the charge carrier's transport at the semiconductor–dielectric interface.

Fig. 3a shows typical output and transfer characteristics of all printed transistors with amorphous semiconductor. The gold source and drain electrodes treated with a perfluorobenzene SAM give good ohmic contact for all the devices tested. The OFF current in the order of 1–10 pA is an indication of a poorly doped semi-conducting layer which is a specific feature of this class of amorphous polymer with high ionization potential and narrow density of states (DOS) [1,12]. Comparison of saturation mobility, threshold voltage (extracted in the saturation regime) and I_{ON}/I_{OFF} ratio are summarized in Table 1. It is remarkable to see that the transistors have similar properties for all the deposition techniques used. Moreover, no differences are observed between source and drain patterned by photolithography or laser ablation. The high stability of the transistors is shown in Fig. 3b. The devices have been cycled at room temperature between $V_{gs} = -40$ V and $V_{gs} = +5$ V with no noticeable degradation of the ON current or the $I_{ON/OFF}$ ratio over a 80 h period (more than 3 days without discontinuity). Moreover, small bias stress time of 1000 s with high gate bias ($V_G = -40$ V) and low drain bias ($V_{DS} = -1$ V) gave threshold voltage shift $\Delta V_T < 1.5$ V which is comparable with a-Si TFT [19]. Variation in ON and OFF current and the standard deviation mobility from on sheet to another is depicted in Fig. 3c and d. More than 50 sheets have been processed with the same transistor geometry and with the semi-conducting layer deposited independently by spin-coating, gravure or screen printing. The I_{ON}/I_{OFF} ratio is typically higher than 10^4 and the mobility could be fitted by a Gaussian law centered on 0.026 cm^2/V s with a width of 0.009 cm^2/V s. Subsequent technology optimization leads to a yield of functional transistors close to 100%. We believe that the robustness and reliability of this technology is due to a combination of appropriate fast deposition printing tools with the use of amorphous semi-conducting polymer. For example, in the case of high mobility transistors made with solution processed semi-conducting small molecules [3] or polymers [20], the deposition process could impact significantly the morphology and change the mobility by several orders of magnitude. The mobility of the triethylsilylethynyl anthradithiophene (TES-ADT) can vary by more than two orders of magnitudes when moving from amorphous to polycrystalline morphology [21]. Even in the polycrystalline form, the mobility could vary from 0.005 cm^2/V s to 0.36 cm^2/V s just by changing the crystal size [22]. This variety of crystalline materials may be more sensitive with the deposition process, and contrary to amorphous polymer, they will require specific optimizations of solvents

formulation, surface treatment and annealing procedure to give their best properties.

In order to further demonstrate the good performances of our transistors, full printed unipolar basic logic functions such as organic inverters and ring oscillators, have been realized on PEN foil. In that case, the semi-conducting layer has been deposited by screen printing. An image of a five-stage ring oscillator is shown in the inset of Fig. 4b. The oscillators are made of connected inverters composed of drive OFET with channel length L = 40 μm and channel width W = 10 mm and a load OFET with channel length L = 40 μm and channel width W = 2 mm. The output characteristics of inverters behave properly with maximum gain values of 5 for V_{DD} = 40 V (Fig. 4a). The oscillation frequency (Fig. 4b) tends to increase with supply voltage up to a maximum frequency of 300 Hz at 50 V. The amplitude of the oscillations is rather low around 12 V for a supply voltage V_{DD} = 50 V. This is a typical feature of unipolar inverters. As the load transistor acts as a resistor, the current is never completely blocked and the residual small leakage current decreases the amplitude of the oscillations. Moreover, the choice of transistors W/L layout has not been optimized to reach the fastest switching of the circuits, many improvements may still be done in order to get higher performances.

The best improvement for organic circuits will be to switch from unipolar to complementary logic functions. Combination of P channel and N channel transistors leads to more robust circuits with higher gain and lower noise margin, static consumption and driving voltage [23]. Realization of such circuits implies the local patterning of each

semiconductor. In order to investigate the patterning capability of gravure and screen printing, we use specific anilox

or screen with various lines of 500 µm to 5 mm and spaces ranging from 500 µm to 3 mm. The definition of the patterns and the minimum separation distance between them depend greatly on the nature of solvents, the substrate surface tension and the annealing process. The spatial resolution of the patterns is enhanced when the ink does not spread, which is generally favored by the use of low substrate surface tension and high solvent surface tension. Drying time and annealing temperature should also play a crucial role. For this study, all these parameters have not yet been optimized and we use the standard process conditions describe earlier to check the patterning capability of the screen printing and gravure printing processes. Fig. 5 shows images of semi-conducting square plot patterned by screen printing. The patterns are 750 × 750 µm and they are separated by 300 µm. The combination of solvent and surface treatment used leads to a small spread of the ink of around 200–300 µm from the targeted dimensions. This spread is independent of the pattern size which enables similar spatial resolution between patterns from various dimensions. Semi-conducting squares of 500 µm, 1 mm, 3 mm and 5 mm have been printed with same separation of 300 µm. This non desirable spread could be further reduced by working on ink and surface engineering. Although the resolution is isotropic for screen printing, the resolution of patterns made by gravure is slightly anisotropic, with the higher resolution normal to the drawing direction. Nevertheless, similar size and separation of the patterns have been found for screen and gravure printing techniques. They are also in the same order of what have been obtained with inkjet printing of such formulation. Most often, applications such as active matrix for electrophoretic display or organic circuits require currents in the order of µA to be operational. The use of mobility in the range of 0.03 $cm^2/V\,s$ implies to use W/L ratio above 30. Taking into account a medium channel length of 40 µm, this leads to channel width of around 1–2 mm and pattern area around 0.2 mm^2. This is in the capability offers by screen or gravure printing and it indicates that the patterning step with these techniques is not the limiting factor of the current technology. Moreover, taking into account that further process optimizations may lead to lower spatial resolution between printed patterns, this opens promising perspectives to increase the device density of organic circuits.

Another figure of merit of printed patterns is their 3D topography. In particular, when decreasing the size of the patterns, edge effect becomes a non negligible part of the area. For direct patterning, the difference of solvent evaporation rate in the center or at the edge of the deposited ink generates a gradient of concentration which gives higher thickness at the frontier of the patterns. This phenomenon-the so-called coffee-stain effect- is depicted in Fig. 5b for a printed pattern of amorphous polymer in mesitylene solvent and it is poorly dependent on the printed technique used. The border effect has a width around 100–200 µm and a thickness typically two or three times higher than in the center of the pattern. This smooth over-thickness could have detrimental effects for printed Organic Light Emitting Diodes (OLED) as it gives pixels with non homogenous brightness, but in the case of OFETs the impact is lower. Nevertheless, the coffee-stain effect could be reduced by the use of appropriate solvents formulation or substrate surface tension. Transistors made with direct patterning of the amorphous semiconductor gave identical performances ($\mu = 0.03 cm^2/V\,s$, I_{ON}/I_{OFF} ratio $>10^4$ and $V_T = -9$ V) than similar transistors with full sheet printed semi-conducting layer. These P channel transistors have been combined with N channel transistors in a full printed process flow and give efficient CMOS-like 5–11 stages ring oscillators.

4. Conclusions

In summary, we have demonstrated that standard industrial tools such as Gravure printing or Screen printing could be highly versatile. In particular, we showed that they could match the severe specifications required for the deposition of the semi-conducting layer in organic field-effect transistors. Low thickness of 100 nm with high uniformity has been reached without specific optimization of the ink formulation. We realized both blanket and direct patterning of the semiconductor material with lines and spaces around 500 µm. Further ways of optimization could still be investigated in order to achieve smaller spatial resolution. The combination of these fast single step printing techniques with amorphous semi-conducting polymer leads to robust and reliable full printed transistors, inverters and oscillators. The lack of supramolecular organization makes this family of materials almost process independent and well suited for the field of printed electronics. Nevertheless, their low mobility will limit the field of applications. In that sense, taking into account the semiconducting layer, strong efforts should be done on the development of high mobility ($>1\ cm^2/V\,s$) small molecules and polymers, in order to move toward high-performance transistors and circuits. Even if the feasibility of printed high mobility transistors has already been demonstrated, they show more pronounced sensitivity to process variations, and strong developments are still requested in order to reach acceptable reliability and uniformity on large area. This will go through a careful control of the crystal growth, as well as optimized ink formulation and stable roll to roll or sheet to sheet manufacturing processes.

ABSTRACT

A composite silver–indium zinc oxide (Ag–IZO) layer is deposited on a polyethylene naphthalate (PEN) film by DC and RF sputter respectively. Tof–SIMS and XPS studies showed that an interface was formed when Ag has successfully plugged into the softer layer of IZO forming a composite Ag-IZO layer to achieve a water vapor transmission rate (WVTR) of $\sim 1.6 \times 10^{-4}$ g/day/m^2. Poly (3-hexylthiophene) (P3HT) based organic thin-film transistors (OTFT) encapsulated with the Ag–IZO–PEN film kept in glove box and ambient condition are tested and shown that this film is capable to provide the OTFT with adequate protection against moisture and oxygen for more than 3600 h. Mechanical bending tests on the Ag–IZO film also revealed that it has only 0.9% increase in sheet resistance after 10,000 cycles of bending which make this barrier film very suitable for encapsulation of flexible OTFT devices.

1. Introduction

Organic thin-film transistors (OTFTs) have the potential application for use on low-cost electronic devices such as flexible solar cells, disposable electronic tags and flexible displays [1]. However, the performance of OTFTs and flexible electronic devices are adversely affected when exposure to various elements in the environment inclusive of light exposed, oxygen and moisture [2]. Therefore, in many applications, OTFTs need to be protected from these elements in the environment with an effective protecting barrier or encapsulation layer [3,4].

For low-cost OTFTs, a liquid-processable barrier layer would be preferable to lower manufacturing cost. But, additional 3–5 inorganic inter layers (e.g. Al_2O_3) are required to improve the gas and water permeability properties of such barrier layer.

In this paper, our barrier layer consists of a DC sputtered Ag and RF sputtered IZO on a PEN film. We measure the WVTR of the barrier film by calcium test [5–7] and study lifetime of the barrier film in relation to the on/off ratio of the encapsulated devices inside a nitrogen glove box and in air. Furthermore, we characterize the barrier film using Tof–SIMS and XPS to have more in-depth understanding on the formation of an interface between the Ag and the IZO and how this interface may affect the film's WVTR and bending properties. Ag is selected as part of the barrier component because its cost and properties is optimized as compared to Au and Al.

2. Materials and methods

2.1. Fabrication of P3HT OTFT

The bottom-gate, bottom-contact OTFT was fabricated as follows: first, 200 nm of SiO_2 gate dielectric was deposited on a heavily doped n-type silicon wafer. Second, the gold drain and source channels and electrodes were formed by thermal evaluation of gold through shadow mask. A thin layer of Chromium was used to provide the adhesion between the gold and the dielectric layers. The channel length/width (L/W) was 10 μm/2 mm. Third, the dielectric layer was treated with octadecyltrichlorosilane

doi:10.1016/j.orgel.2009.11.028

(OTS) to form a self-assembled monolayer (SAM). This SAM allows edge-on orientation of P3HT by replacing the hydroxyl groups at the SiO_2 surface with alkyl groups capable of attracting the hexyl side chains of P3HT [8]. Finally, the P3HT layer was spin-coated from a 0.08 wt.% chlorobenzene solution at 3500 rpm for 60 s, followed by 10 min of hot plate baking at 120 °C. The thickness of the P3HT is ~350 nm.

2.2. Encapsulation of P3HT OTFT

The Ag–IZO–PEN barrier film as fabricated at room temperature (~22 °C and substrate's temperature is <50 °C after sputtering process) as follows: First, 90 nm of IZO was sputtered on the PEN substrate by 75 W RF, 82 V_{bias}, Ar:H_2 is 10:1 sccm and process pressure of 3×10^{-3} torr. Second, 300 nm of Ag was sputtered on the IZO by 100 W DC, Ar 10 sccm and process pressure of 4.3×10^{-3} torr. Third, the film was adhered directly on the OTFT with a thin layer of adhesive. A UV curable epoxy sealant was then applied around the edges of the barrier film and cured under UV radiation for 20 s. This epoxy sealant is to enhance the adhesion between the barrier film and the silicon wafer. The encapsulation process was done in a Nitrogen filled glove box where the O_2 and H_2O were controlled below 2 ppm.

2.3. Characterization methods

The *I–V* characteristics of the devices were measured in air by an Agilent 4156C Precision Semiconductor Parameter Analyzer. The on/off ratio was directly extrapolated from the plot of log I_{ds} versus V_g at $V_{ds} = -40$ V, where I_{ds} is the drain–source current, V_g is the gate voltage and V_{ds} is the drain–source voltage. WVTR of the Ag–IZO–PEN barrier film was measured by calcium test conducted at 60 °C 90%RH. The interface of Ag–IZO composite barrier was studied using time of flight-secondary ion mass spectroscopy (Tof–SIMS, ION TOF SIMS IV) and X-ray photoelectron spectroscopy (XPS, ESCA-LAB-220i XL VG Scientific). Bending test was conducted on a 5 cm × 5 cm barrier film using a radius of curvature of 12.5 mm at 1 cycle per second. The sheet resistances (in Ohm/sq) of the barrier films were measurement by a four-pin probe of Loresta-EP tester after 1 k, 5 k, 10 k, 20 k and 60 k of bending cycles. The schematic diagram of the bending tester and the detail calculation of achieving 12.5 mm radius of curvature is described in detail else where [9,10].

3. Results and discussion

The calcium test of Ag–IZO–PEN was done at 60 °C 90%RH over a period of 1200 h. As shown in Fig. 1, the WVTR of 1.6×10^{-4} g/m^2/day was calculated from the slope of the plot of calcium conductance versus test duration. In contrast, this result was far better than the WVTR (by Mocon tester) of 0.8–1.2 and 0.65×10^{-2} m/m^2/day of the bare PEN and IZO coated PEN substrate respectively. This result is also comparable or better than other types of encapsulation layer such as PECVD deposited SiO_x–PEN

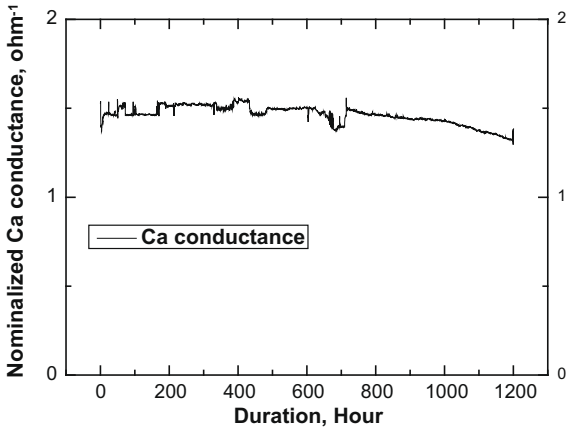

Fig. 1. Permeation rate of Ag–IZO–PEN film as a function of Ca conductance over the duration of 1200 h at 60 °C 90%RH.

(<5×10^{-3}) by Dennler et al. [11]. The improvement in WVTR is come from depositing a layer of Ag on top of the IZO layer.

In order to have better understanding of the contribution of the Ag layer to the barrier properties, we conducted Tof–SIMS and XPS analysis on the interface of Ag–IZO and the result is shown in Figs. 2 and 3 respectively. The Tof–SIMS depth profile of Ag has a distinguish peak immediately after the rise of the In, Zn and O depth profiles in which ZnAg and InAg profile formed a similar plateau as the Ag profile. The similar decay profile of Ag and InAg indicates that an interface is formed between Ag and IZO layer. This interface was formed during the sputtering of Ag onto the IZO surface and some Ag atoms penetrated and/or migrated into the IZO layers. The XPS scans on the same film confirmed that there is no doping or oxidation of Ag to the IZO layers but rather an Ag–IZO interface was formed between the pure Ag and IZO layer. As from the WVTR result, IZO alone has a high water permeation rate 6.5×10^{-2} g/m^2/day implies that this IZO layer is not sufficient to block the migration of water molecules to the other side of the layer [12]. It is most possible due to

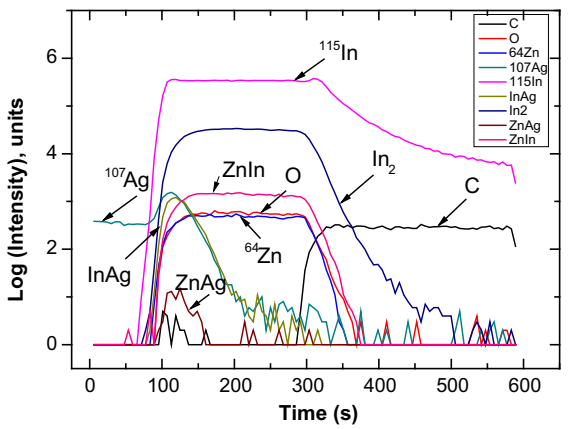

Fig. 2. Tof–SIMS depth profile of Ag–IZO–PEN film.

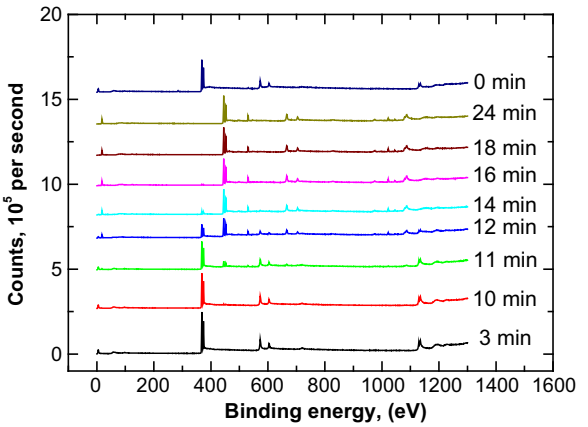

Fig. 3. XPS scan on the Ag–IZO–PEN film at various time intervals. The peak of Ag3d, In3d, Zn2p and O1s are 368.3 eV, 444.9 eV, 1022.2 eV and 530.3 eV respectively. Notice that the peak of Ag3d vanished at 16 min and In3d peak appeared after 10 min of Ar sputtering indicates that there is an interface at Ag and IZO layer.

vacancies between the IZO clusters (as shown in Fig. 4) still large enough that allow water permeation. The situation with the Ag–IZO film is different, as the Ag molecules are incorporated to the interstitial or grain boundaries of IZO forming a much denser interface which could reduce the migration of the water molecules much more effectively, hence the WVTR of the Ag–IZO–PEN film decreased to a value of 1.6×10^{-4} from the 6.5×10^{-2} of IZO–PEN. The atomic ratio plots showed in Fig. 5 further reveals the migration pattern of Ag in the IZO layer is homogenous and decrease gradually (~20% per minute of Ar sputtering during the XPS scan) as the sputter energy decreases with the distance from the sputter target during the Ag deposition process. Fig. 6 shows a schematic diagram of the formation of Ag–IZO interface. Smaller molecules such as H_2O which pass through the pin holes in the Ag layer are blocked by the denser Ag–IZO interface resulting in better barrier performance.

In order to further prove that our Ag–IZO–PEN barrier film is suitable for OTFT application, we fabricated and encapsulated the OTFT device as described in the earlier part of the paper. We measured and calculated the on/off ratio of the encapsulated devices in air and at the same time for the encapsulated devices kept inside the Nitrogen filled glove box. The change in on/off ratio versus the life time (in days) is showed in Fig. 7. The changes in on/off ratio of both samples (i.e. inside glove box and in air) did not varies (~50% higher than the initial value) significantly over the period of >3600 h show that the encapsulation of the Ag–IZO–PEN barrier film provide adequate protection against moisture for the sample kept in air so that its on/off performance over time was similar to that of samples kept in the N_2 glove box.

Finally, we also conduct a bending cycle testing to the Ag–IZO–PEN film and the result is comparable to other flexible substrate such as CNT–PEN [13]. From Fig. 8, only a 0.9% increase in sheet resistance was observed after 10,000 cycles of bending. We believe that the interlayer at the Ag–IZO interface helps to reduce the bending stress and preventing crack formation [14] of the barrier film during the bending cycles. More studies are still required to investigate the impact of bending test on the Ag–IZO interface such as any further migration of Ag into the IZO layer due to the mechanical interactions and the changes (if any) in the life time performance of the barrier film after bending stress.

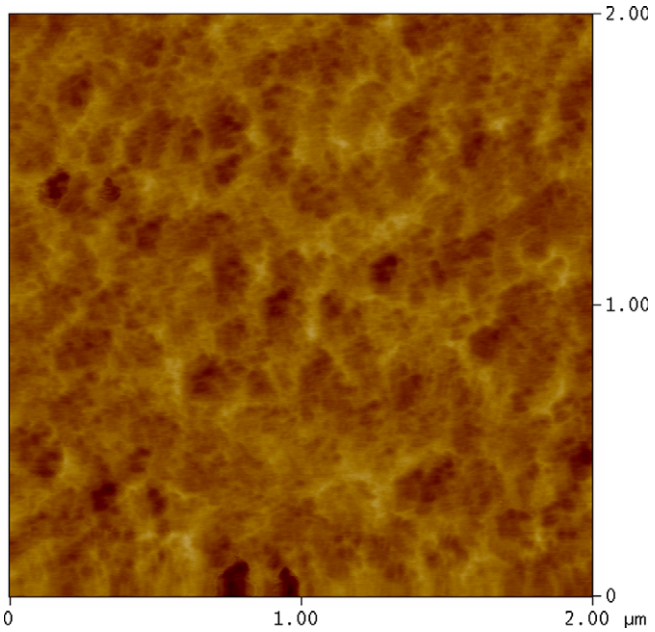

Fig. 4. AFM images of IZO–PEN shows the formation of IZO clusters and surface roughness (RMS) is 1.072 nm. The scan area is 2 μm × 2 μm.

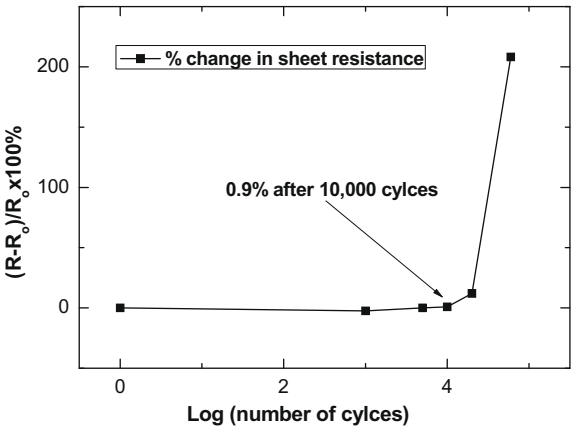

Fig. 8. Changes in sheet resistance of Ag–IZO–PEN film after bending cycles of 1 k, 5 k, 10 k, 20 k and 60 k of bending cycles.

4. Conclusions

We have fabricated an Ag–IZO–PEN barrier film for effective encapsulation of P3HT OTFT devices. The low water permeation rate of 1.6×10^{-4} g/m^2/day allows the device to survive more than 3600 h. Further investigation using Tof–SIMS and XPS reveals that there is a dense interlayer at the interface between the Ag and the IZO layers where the Ag atoms migrated into the IZO layer. This interface layer also helps to prevent and reduce the cracks formation when the film undergoes mechanical bending cycles. We will continue to investigate the possibilities of using different metal–metal oxide barrier films instead of inorganic–organic or metal oxide–organic barriers for flexible OTFT devices.

Charge generation layer

ABSTRACT

The problem that conventional time of flight (TOF) mobility measurements are made on much thicker films than typically used in organic optoelectronic devices is investigated by comparing the mobility of thick and thin films of the poly(phenylenevinylene) based copolymer "SuperYellow". We report for the first time mobility values perpendicular to the substrate for this widely used material and find them to be of the order of 10^{-6}–10^{-7} cm^2/V s for both spin-coated and drop-cast films. A high photoluminescence quantum yield (PLQY) of 60 ± 5% is measured for both types of films. The results indicate a trade-off between PLQY and charge transport in poly(arylenevinylene)s. The insensitivity of the charge transporting and photophysical properties to the film preparation procedure and thickness is a desirable characteristic that may result from the bulky side groups of "SuperYellow".

1. Introduction

The time of flight (TOF) technique is one of the most widely used methods to study charge carrier drift mobility in low mobility materials such as organic semiconductors [1]. This technique has been successfully applied in a wide range of organic materials such as small molecules [2,3], polymers [4,5] and dendrimers [6,7] to study both hole and electron transport. An important feature of TOF is that it measures mobility in the direction perpendicular to the substrate. This direction is of crucial importance for optoelectronic devices such as organic light emitting diodes (OLEDs), organic solar cells (OSCs) and (in the future) electrically pumped lasers.

However, in such devices the organic semiconductors usually have a thickness of 100–200 nm, whereas the TOF method is normally applied to films of thickness several micrometers. The reason TOF is only used for relatively thick films is that charge carriers must begin from a well-defined region and so in conventional TOF the excitation light must be absorbed in a layer much thinner than the film thickness. However, it is known that photophysical properties are strongly influenced by choice of solvent and deposition conditions [8–10]. An important question arises of whether conventional TOF measurements are relevant to thin film devices such as OLEDs. In this work, we address this issue by comparing TOF measurements on both thick and thin films of the same material – the poly(phenylenevinylene) (PPV) based copolymer "SuperYellow". "SuperYellow" (SY) is a widely used yellow emitting copolymer that has successfully been employed in polymer light emitting devices such as PLED [11] and LEFET [12]. Previous studies of this material have focused only on its electroluminescence properties including material stability, and efficiency [13] but so far nothing has been reported about charge transport in the direction perpendicular to the substrate and its photoluminescence quantum yield, which are key parameters for understanding structure–property relations of materials and device operation.

A range of methods including steady state current–voltage measurements, dark-injection space charge limited current (DI-SCLC) [14,15], and charge extraction in a linearly increasing voltage (CELIV) [16,17] have been applied to study charge mobility in the direction perpendicular to the substrate in thin films. In the present work we use the charge generation layer (CGL) TOF technique to

doi:10.1016/j.orgel.2009.11.030

measure thin films, and conventional TOF for thick films. In CGL-TOF a strongly absorbing layer is photoexcited, leading to charge injection into the test film [18,19]. We note that Bässler and co-workers [20], have used TOF and CGL-TOF technique to measure hole mobility on a PPV-ether, but the samples studied were a few microns thick, leaving open the question of whether the measurements were relevant to thin film devices.

2. Experimental

SuperYellow (PDY-132) was obtained from Merck and used as received, its molecular structure is shown in Fig. 1a. Lumogen Red (a perylene dye) was supplied by BASF and was used as the charge generation layer for CGL-TOF measurements. Films for both absorption and photoluminescence quantum yield (PLQY) measurements were prepared at the same time from the same solution, by dissolving SY in chlorobenzene at 5 mg/ml and spin coating onto quartz substrates in a glovebox. The spin speed was 2000 rpm giving a thickness of about 150 nm. The film PLQY was determined using a He–Cd laser operating at 442 nm to excite the sample in an integrating sphere purged by nitrogen, following the method of Greenham et al. [21].

For both TOF and CGL-TOF measurements, solutions of SY were made with concentrations of 10 mg/ml in chlorobenzene. Films for TOF measurements were drop cast onto an ITO substrate and left to dry overnight inside a glovebox. The resulting films had thicknesses in the range 4–8 μm, and were then transferred to an evaporator where under high vacuum a 30 nm semi-transparent aluminum film was deposited through a shadow mask to define an active area of approximately 6 mm^2. Films for the CGL-TOF measurements were spin-coated onto an ITO substrate at a speed of 1000 rpm, giving films of thickness close to 300 nm. The samples were then transferred to an evaporator where under high vacuum a 10 nm layer of Lumogen Red followed by 150 nm of aluminum was deposited through a shadow mask.

Both TOF and CGL-TOF measurements were performed at room temperature and in vacuum using 500 ps light pulses from a dye laser for excitation. For TOF measurements (Fig. 2a) the SY was excited at 470 nm through the semi-transparent Al layer. CGL-TOF measurements were performed by exciting the charge generation layer through the ITO and polymer layers (Fig. 2b). The excitation wavelength was 580 nm, which is the peak of the absorption spectrum of Lumogen Red (see Fig. 1b). At this excitation wavelength the SY is completely transparent. The HOMO of the Lumogen Red lies 6.2 eV from the vacuum level [22] enabling hole injection into the polymer layer (HOMO = −4.8 eV) [23].

In both cases the photogenerated packet of charge carriers is then swept through the device under an applied field, and the transit time (t_{tr}) measured using a digital storage oscilloscope (Tektronix TDS 3032). The aluminium electrode was biased positively and the photocurrent signal detected from the ITO. The applied bias led to the photogenerated electrons being removed from the device at the aluminium electrode and holes being swept across the device to be collected at the ITO electrode. Thus the

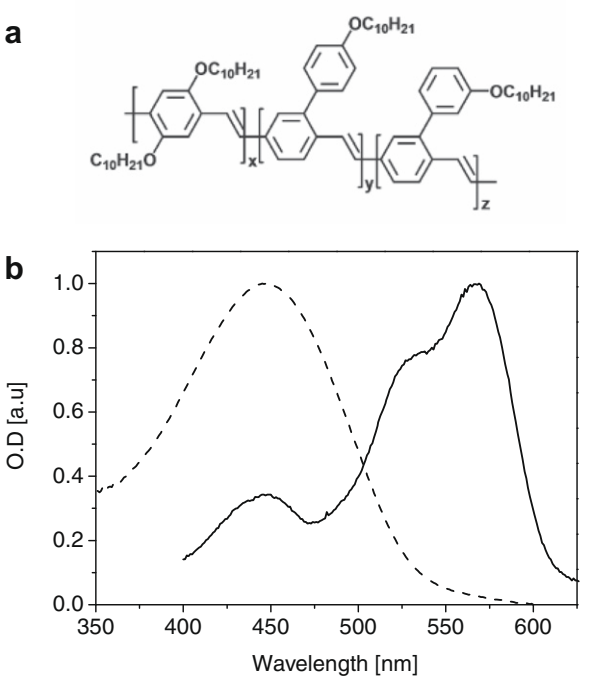

Fig. 1. (a) SuperYellow molecular structure. (b) Normalized SY (dashed line) and Lumogen Red (solid line) absorption spectra.

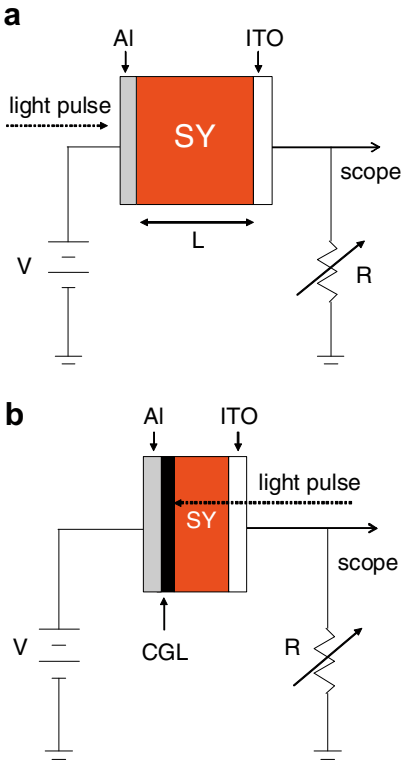

Fig. 2. Schematic of TOF set-up: (a) standard TOF configuration and (b) CGL-TOF configuration. SY denotes SuperYellow. CGL denotes charge generation layer.

measured photocurrent transients are hole currents. Hole mobilities, μ, were deduced from the transit times t_{tr} via the relation $\mu = d^2/(Vt_{tr})$ where d is the film thickness and V is the applied voltage. The time resolution is determined by the RC time constant of the measurement circuit, which was selected to be $\leqslant 20$ t_{tr}. The total charge injected into the film was kept around 2–3% CV in all cases, where C is the capacitance of the device and V is the applied voltage.

3. Results and discussion

Fig. 3a shows the hole photocurrent transient on a linear scale for a drop-cast film, at room temperature measured for an applied electric field $E = 4.2 \times 10^5$ V/cm. The signal has a distinct plateau indicative of non dispersive charge transport, followed by a shoulder and a long tail. The well defined change in the slope of the photocurrent transient allows a clear measurement of the transit time ($t_{tr} = 3.5 \times 10^{-3}$ s) which corresponds to the intersection of asymptotes to the plateau and the tail on a log–log plot. The transit time corresponds to a mobility of 5.4×10^{-7} cm^2/V s. The results of CGL-TOF measurements on the spin-coated sample are shown in Fig. 3b. The transit time (under the same experimental conditions of temperature and electric field) is 6.7×10^{-5} s which corresponds to a mobility of 1.2×10^{-6} cm^2/V s.

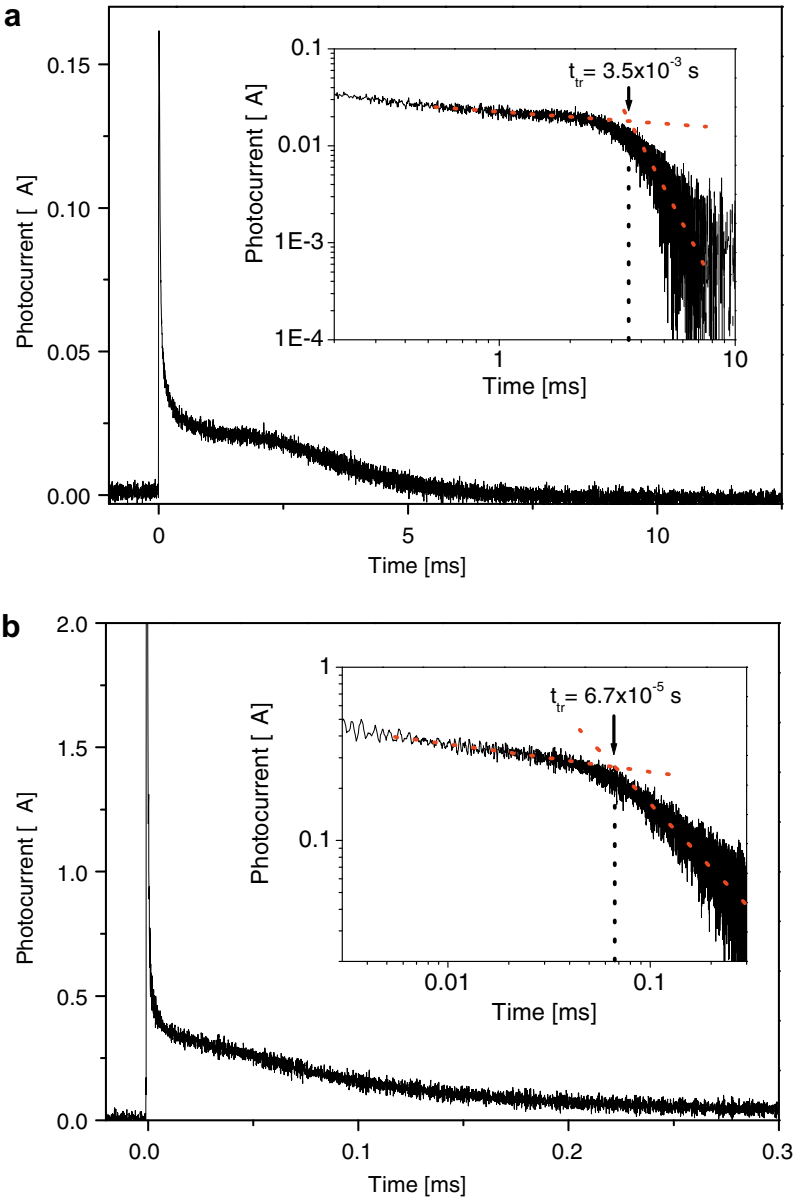

Fig. 3. SY room temperature hole photocurrent transient taken at an applied electric field $E = 4.2 \times 10^5$ V/cm. Data are plotted in both linear and log–log (inset) scale for (a) drop-cast film and (b) spin coated film.

Our measurements give the hole mobility in the direction perpendicular to the substrate, and we have studied its field dependence, as shown in Fig. 4. As the electric field is increased from 1.7×10^5 to 5.4×10^5 V/cm, the hole mobility increases from 5.6×10^{-7} to 6.7×10^{-7} cm^2/V s for the drop-cast film, and from 6.5×10^{-7} to 1.4×10^{-6} cm^2/V s for the spin-coated sample. Our results show that the casting conditions have only a modest effect on the mobility – although the spin-cast film has a stronger field-dependence of mobility, the mobility values for the two samples are within a factor of two of each other.

Variations in mobility values of over an order of magnitude or in charge transport behaviour, such as dispersive or non dispersive, have been observed in polymers of the PPV family as a result of molecular weight [24], solvents [25,26], side-chains [27,28], and annealing [29]. These differences are normally attributed to intrinsic factors, such as chain packing. However, extrinsic factors such as environmental conditions during sample fabrication, (air or in inert atmosphere), or chemical purity also have a marked impact on charge mobility [30,31]. In our study we have removed such factors by using the same high quality material from Merck, preparing samples in a glove box, and measuring them in vacuum for both thick and thin films. The non dispersive nature of the photocurrent transients also suggests the good chemical purity of the material under investigation [2].

Although recently hole mobility values up to 10^{-4} cm^2/V s have been reported for a PPV derivative polymer prepared by a precursor route [32], our mobility values are within the range of others polymers of the PPV family (10^{-6}–10^{-7} cm^2/V s) [28]. We have made a direct comparison by measuring MEH–PPV. Fig. 4 shows the results of TOF measurements on drop-cast films of MEH–PPV (~5 μm) made from a solution with concentration of 10 mg/ml in chlorobenzene and it can be seen that the hole mobility is an order of magnitude higher than for SY. This result shows that the very bulky sidegroups of SY do reduce charge mobility. It is also consistent with the observation of lower mobility in PPV copolymers than homopolymers [33].

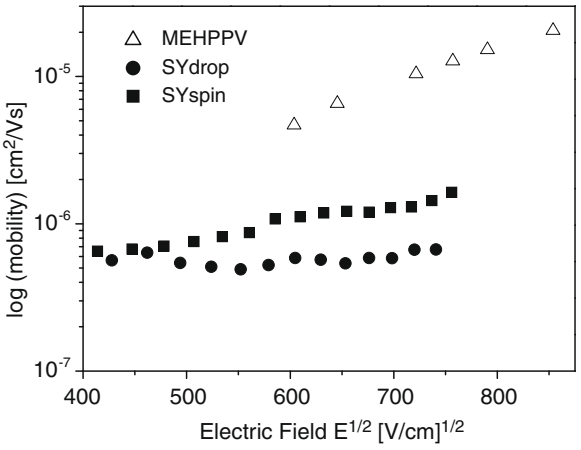

Fig. 4. Field dependent hole mobilities at room temperature. Filled symbols are experimental data for SuperYellow drop-cast film (circle) and spin coated film (square), also are shown MEH–PPV data (triangle) for a direct comparison.

It is also instructive to explore the impact of the sidegroups and film preparation conditions on the photoluminescence quantum yield. We measure the PLQY value of 60 ± 5%, for both types of film. This value is 4–5 times higher in the solid state than the reported values for the related homopolymers: 10–15% for MEH–PPV [21] and 12% for BEH-PPV [34], showing that the particularly bulky sidegroups of SY are effective in controlling intermolecular interactions which can quench photoluminescence. Our results show that SY has much higher PLQY, but much lower mobility than MEH–PPV. However overall SY has substantially better OLED performance than MEH–PPV. Single layer SY based OLEDs have been reported having an External Quantum Efficiency (EQE) of 5.3%, max Power efficiency of 10 lm/W and 11 cd/A [35]. Meanwhile similar single layer OLEDs based on MEH–PPV have shown EQE values of 1–2% and Luminous efficiency of 3 lm/W [36–38]. The above results show that high mobility is not essential for good OLED performance.

4. Conclusions

In summary, we have reported for the first time the charge mobility perpendicular to the film and photoluminescence quantum yield for drop-cast (thick) and spin-coated (thin) films of the widely used PPV copolymer SuperYellow. We find that TOF and CGL-TOF measurements on thick and thin films give similar mobilities in the range 10^{-7}–10^{-6} cm^2/V s, depending on the electric field. This suggests, in the case of this material, at least, conventional TOF measurements do give information relevant to the much thinner films used in devices. We find that the high photoluminescence quantum yield of 60% is achieved at the expense of reduced charge mobility, indicating a trade-off relevant to the development of organic optoelectronic devices. Our results suggest that the bulky side groups of SY cause a highly amorphous film to form over a wide range of preparation conditions, and therefore suggest that the use of such bulky sidegroups could be a useful strategy for the preparation of materials insensitive to processing conditions.

Humidity sensor
Irreversible
Functional dopant

ABSTRACT

We present a new concept for a humidity sensor based on doped poly(aniline) that shows irreversible changes of its sheet resistance and capacitance upon exposure to humid conditions, *i.e.* a humidity memory. Therein humidity triggers an irreversible dedoping process, which results in a phase separation and crystallization of the hydrated form of its protonating agent, as suggested by combining FT-IR and UV–Vis-NIR spectroscopies, optical microscopy, dc-conductivity, and frequency dependent capacitance measurements. We also introduce a simple concept to activate the sensor and to monitor it through non-contact capacitance measurements. We anticipate that the proposed concept could be implemented for functional packaging to qualitatively detect whether their contents have been exposed to humidity during their transportation and storage history.

1. Introduction

π-Conjugated polymers have attracted considerable interest as materials for organic and soft electronics [1–3], such as field-effect transistors [4–8], light-emitting diodes [9–13], photovoltaic cells [14–21], lasers [22–24], and sensors [25–27]. One of their advantages is that they can allow simple processing *e.g.* by printing and that several of their properties can be tuned by chemical modification of the polymer backbone, side-chains, or incorporating functional counter-ions [28]. For example, solubility or dispersibility in solvents [29–32] enables printing techniques to process semi-conducting or conducting poly(aniline), poly(thiophene), and poly(pyrrole). In their doped conducting state, the structural organization depends critically on the counter-ions, which have a major effect on the dc-conductivity [33–35] and mechanical properties, such as Young modulus and elongation at break [36]. Sensors for specific molecules or environmental conditions comprise one of the most promising applications of conducting polymers, enabling detection and monitoring of *e.g.* carbon dioxide gas [37], TNT vapor [38], moisture [39–42], temperature [43], and biological moieties, like antigens [44], glucose [45] or DNA [46]. Functionalization of the counter-ions provides one general strategy to construct efficient, reliable, specific, and yet simple sensors based on conducting polymers.

The characteristic response of doped PANI to humidity is an increased dc-conductivity, as water molecules absorbed from the surrounding atmosphere and those trapped within its semi-crystalline structure impact the conduction mechanism [47–51]. This enhancement is typically reversible, as dc-conductivity decreases again upon drying. This allows reversible moisture sensors that can measure the instantaneous prevailing moisture conditions [26,39–42]. On the other hand, guaranteeing the authenticity and quality of selected products is increasingly required in some high-end consumer applications. This requires follow-up of the storage and transportation history. For example, low moisture content may need to be demonstrated throughout the product history. In several com-

doi:10.1016/j.orgel.2009.11.031

monplace applications only qualitative but very simple indication of the history suffices without a need to know the exact level of humidity. Such a sensor could be denoted as a humidity memory; the sensor should remember if the package content has been exposed to moisture at any stage during transportation and storage. Only a few examples of such smart materials exist capable of irreversible moisture sensing, for example based on water absorption, which leads to increase in capacitance [52] or aggregation of dyes, which results in a change in fluorescence and absorption spectrum [53].

We present here a novel type of conducting poly(aniline) (PANI) complex, which utilizes a functional polar counter-ion that phase separates and crystallizes irreversibly due to humidity probably due to hydration, and therefore works as an irreversible humidity sensor, *i.e.* a humidity memory. Therefore it can sense whether the material has been exposed to humid conditions during its history. Thus it can be considered as a sensor analogue to an electrical WORM-type (write-once-read-many-times) memory [54–56]. The concept is based on a surprising observation that upon exposure to humidity, PANI doped with the 5-formyl-2-furansulfonic acid (FFSA: see Fig. 1a) protonating agent experiences irreversible loss in dc-conductivity, which is in contrast to the characteristic reversible increase of conductivity. Here, we will first explore the optimum degree of protonation, investigate the electrical and spectroscopic response to humidity, demonstrate a method to trigger and to read the memory, and finally propose tentative explanations for this complicated process.

2. Experimental

2.1. Materials

Panipol Ltd. (Finland) provided the emeraldine base (EB) form of PANI and it was used without further purification. The sodium salt of 5-formyl-2-furansulfonic acid (Na-FFSA, 98 %) was purchased from Chemos Ltd. and the formic acid (>98 %) from Riedel de Haën. The Dowex Marathon C cation-exchange resin, used for converting Na-FFSA in its sulfonic acid form (FFSA), was purchased from Aldrich.

2.2. Sample preparation

PANI-EB was dissolved in formic acid and the solution was filtered through a 1 μm filter. Na-FFSA was ion-exchanged to its acidic form (FFSA) in formic acid in order to use it as a protonating agent for PANI-EB. Complexation of PANI-EB and FFSA was performed immediately after the ion exchange procedure by combining the formic acid solutions of the corresponding starting materials to obtain PANI[FFSA]$_x$ ionic complexes, where x denotes the nominal ratio of the sulfonic acid group *vs.* nitrogen atom of the repeating units of PANI-EB (see Fig. 1). Samples were prepared with x = 0.1, 0.3, and 0.5. All the samples were spin-coated in a nitrogen glove box (oxygen and moisture levels below *ca.* 0.1 ppm) and subsequently the thin films were dried either in a vacuum oven (with a base pressure lower than *ca.* 10^{-2} mbar) or in a high vacuum oven (base pressure lower than *ca.* 10^{-7} mbar) at 60 °C for at least 48 h before performing the electrical measurements. The thicknesses of the thin films were measured with an Optical Profiler (Veeco) from dried films.

2.3. Electrical measurements

The dc-conductivity measurements were performed online with a digital multimeter (Keithley 2001) in an environmental chamber (Espec), in which relative humidity and temperature were simultaneously controlled. The sheet resistance R_s [Ω/□] was measured from spin-coated samples with a two-probe configuration, instead of using the conventional Valdes method [57,58] in which four probes are arranged in a collinear way, due to size restrictions imposed by the environmental chamber. The gold electrodes, spaced by a *ca.* 1 mm distance and allowing the measurement of R_s [Ω/□] were evaporated through a metal mask on a glass slide before spin-coating the thin films of conducting PANI[FFSA]$_x$.

2.4. UV–Vis-NIR spectroscopy

UV–Vis-NIR spectra of thin films spin-coated on microscope glass slides were recorded in the 275–1050 nm wavelength range using an AvaSpec-USB2 spectrophotometer (Avantes).

2.5. Fourier transform infrared (FT-IR) spectroscopy

The infrared spectra were obtained using a Nicolet 380 FT-IR spectrometer with an attenuated total reflection (ATR) setup. A minimum of 64 scans were averaged at a resolution of 2 cm^{-1}.

2.6. Optical microscopy

The optical microscopy pictures where taken with a digital camera connected to an optical microscope (Olympus BX60) utilizing the differential interference contrast (DIC) setup.

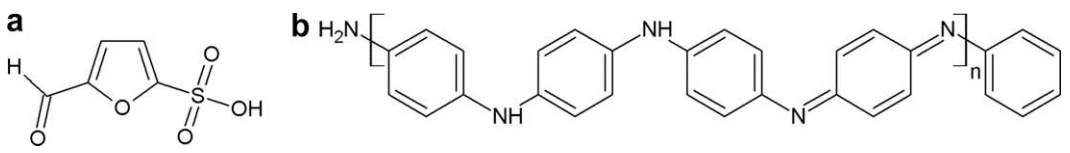

Fig. 1. Chemical structures of (a) 5-formyl-2-furansulfonic acid (FFSA) and (b) poly(aniline) in its Emeraldine Base (PANI-EB) state.

2.7. Capacitance

The frequency dependent capacitance of doped PANI[FFSA]$_x$ thin films was measured as a function of the elapsed time following the exposure of the sensor to humid conditions using two lateral electrodes and an AC LF-impedance analyzer (HP 4192A). The continuous capacitive measurements utilized two stationary aluminium electrodes attached on the outer side of the sensor element. Fig. 6a demonstrates how the sensor can be placed inside a package to allow detection by the non-contact capacitance measurements.

3. Results and discussion

Fig. 2a displays the response of the PANI[FFSA]$_x$ sheet resistance R_s to humid (RH = 50%) or dry (RH = 1%) air using films of *ca.* 70 nm thickness and different nominal doping ratios x = 0.1, 0.3, and 0.5. The films were kept in an environmental chamber with temperature and humidity control and the changes in the resistance were followed online. The nominally fully-doped case, *i.e.* PANI[FFSA]$_{0.5}$ containing one FFSA per iminic (—N=) sites of PANI-EB, showed the highest conductivity but only minor dependence on the humidity. Slightly reduced doping level, *i.e.* x = 0.3, allowed a clear humidity response while still showing a sufficiently high dc-conductivity level for a sensor. Very small doping levels (x = 0.1) showed very large dependence on humidity but the conductivity level was very low. Finally, an undoped PANI-EB thin film spin-coated from a formic acid solution was measured as a reference, also to ensure that formic acid can be removed from the films. Drying for 48 h at 60 °C in a vacuum oven was enough to essentially remove the formic acid, as the dc-conductivity remained out of the measuring range of our dc-conductivity setup and neither UV–Vis nor FT-IR spectroscopic investigations showed evidence of formic acid doping. To even more ascertain removal of the potential traces of formic acid, the samples were further dried in a high vacuum oven at 60 °C for several days maintained at a base pressure of *ca.* 10^{-7} mbar. Therefore, formic acid residuals cannot act as secondary protonation agents within the samples.

PANI[FFSA]$_{0.3}$ was chosen for detailed investigations due to its feasible combination of response to humidity and conductivity. Fig. 2b shows R_s as a function of the elapsed time after its initial contact with a 50% RH atmosphere at 25 °C using films of thicknesses of *ca.* 40 nm and 80 nm. First, the films were kept for a few hours under dry conditions at 25 °C, during which the sheet resistance did not essentially increase. Then, the films were transferred to a humidity chamber (50% RH and 25 °C), where the sheet resistance started to rapidly increase as a function of time. After 2 days at 50% RH we checked that the above-mentioned change was not reversible and we transferred the thin films back to the dry conditions (RH = 1%). This led to a small but abrupt increase of R_s, as is expected due to the generic classical response of conducting PANI-based materials upon decrease of humidity. Finally, the samples were again transferred to humid air (RH = 50%) where R_s values started to further rise (see Fig. 2b).

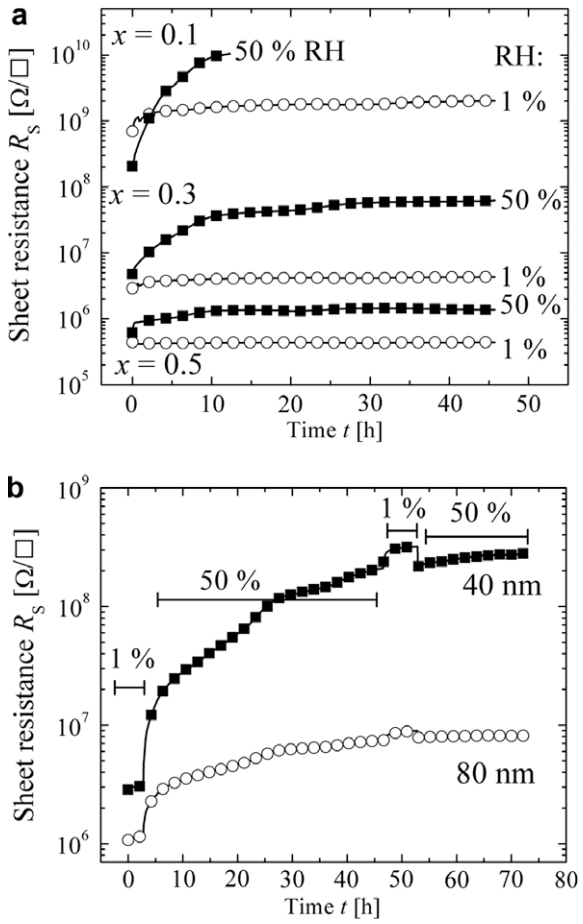

Fig. 2. Evolution of the sheet resistance R_s of thin films of PANI[FFSA]$_x$ as a function of the elapsed time after the initial contact with a humid atmosphere. (a) R_s for thin films of *ca.* 70 nm thickness with doping ratios x = 0.1, 0.3 or 0.5 under constant humidity. (b) R_s for PANI[FFSA]$_{0.3}$ when the humidity was switched between two constant values 1% and 50% at 25 °C using *ca.* 40 and 80 nm films. This indicates the irreversible nature of the conductivity loss due to exposure to humidity.

UV–Vis-NIR spectroscopy was used to investigate the effect of moisture on the electronic transport properties of PANI[FFSA]$_x$ thin films, as it allows sensitive optical probing of the state of doping and the polaron delocalization of doped PANI solutions [59] and thin films [60,61]. Conducting PANI shows three bands in its UV–Vis-NIR absorbance spectrum with maxima located at *ca.* 350, 420, and 800–880 nm [59,60]. They are related to π–π^*, polaron–π^*, and π–polaron electronic transitions, respectively. On the other hand, the UV–Vis spectrum of undoped PANI-EB shows two bands: one with a maximum at *ca.* 320–330 nm and second one with a maximum at *ca.* 600–650 nm [62], which are ascribed to its π–π^* and n–π^* electronic transitions, respectively. Fig. 3 shows the UV–Vis-NIR spectra of PANI[FFSA]$_{0.3}$ in the dried state and after a 3-day humidity treatment (50% RH and 25 °C) for thin films of thicknesses of *ca.* 40 nm and 80 nm. The films ex-

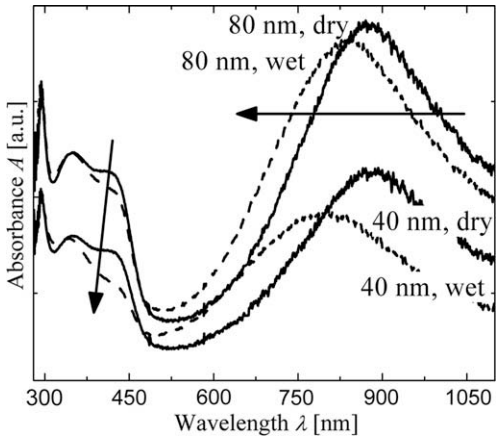

Fig. 3. UV–Vis-NIR spectra of PANI[FFSA]$_{0.3}$ thin films in their pristine states (solid line) and after a 3-day humidity treatment at 50% RH and 25 °C (dotted line) using two film thicknesses 40 nm and 80 nm. Do note that the black arrows are only guidelines for eyes.

posed to the humidity show a decrease of the intensity of the band associated with the polaron–π^* transition. This optical change happens concomitantly with a hypsochromic shift of the maxima of the band related to the π–polaron electronic transition of doped PANI, which moved from 875 nm to 835 nm, and from 875 nm to 790 nm for the two film thicknesses, 80 and 40 nm, respectively. These two spectral changes suggest humidity-induced partial dedoping, which further converts the doped PANI form into its semi-conducting PANI-EB one.

In optical microscopy, the dry PANI[FFSA]$_{0.3}$ films are structureless and homogeneously green whereas exposure to humidity leads to inhomogeneity where small crystal/particle-like dispersion emerges and the sample shows some bluish[1] color (see Fig. 4a). Even more striking effects take place when water is dropped directly on top of a PANI[FFSA]$_{0.3}$ film. After the water evaporation, large phase separated domains with sharp boundaries and edges are observed as well as strongly blue color (see Fig. 4b), which indicates PANI dedoping and suggests phase separation to form large crystals. The only available mechanism for phase separation is that the FFSA counter-ions form separate crystals and simultaneously PANI becomes at least partly dedoped. The conclusion would be that under dried conditions FFSA is bound to PANI due to protonation, whereas under humid conditions their mutual protonation interaction is suppressed allowing the phase separation. The latter phenomenon is not surprising due to the strong aggregation tendency of the relatively rigid PANI chains, if the binding strength of the additive becomes reduced. A question arises, what is the characteristic property of FFSA to promote this observed behavior. There have been numerous functionalized counter-ions already incorporated to protonate PANI [28,29,33–36]. Typically they have contained bulky or spacer-like groups to promote solubility or fusibility, thus

[1] For interpretation of color in Figs. 4 and 6, the reader is referred to the web version of this article.

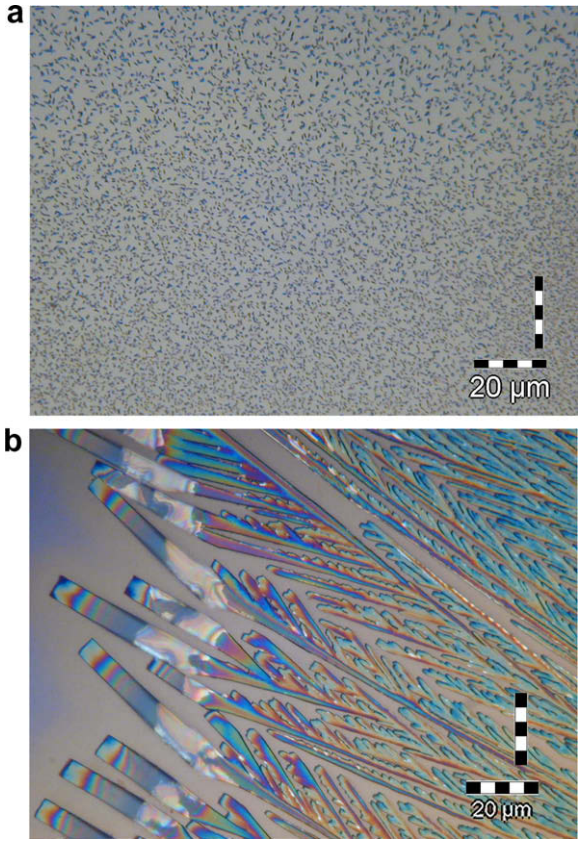

Fig. 4. Optical micrographs of a PANI[FFSA]$_{0.3}$ thin film spin-coated on a glass substrate showing phase-separated hydrated FFSA crystals resulting from (a) a few days humidity treatment in a humidity chamber [50% RH at 25 °C] or (b) the deposition of water on top of its free surface.

indirectly also promoting hydrophobicity. By contrast, FFSA contains five electronegative oxygen atoms and it is quite hydrophilic. Therefore, under humid conditions, it could be expected to easily trap water and to form hydronium salts instead of protonating PANI. In this case, the strong ionic interaction between PANI and FFSA is suppressed, as evident from UV–Vis-NIR (Fig. 3), and the hydrated FFSA phase separates as separate crystals.

In order to shed further light for the proposed mechanism, FT-IR spectroscopy was incorporated. Often in PANI complexes a detailed interpretation of FT-IR absorption has shown to be challenging, but in the present case we expected that the carbonyl >C=O band could be diagnostic [63], as it is known to be sensitive for hydrogen bond formation [64]. Accordingly, the strong FT-IR band of Na-FFSA near 1680 cm^{-1} is assigned to the carbonyl absorption, see Fig. 5b. Therein this band is particularly prominent, as each FFSA contains a carbonyl group. In agreement, in PANI[FFSA]$_{0.3}$ the band is smaller due to concentration effects. But interestingly, in wet PANI[FFSA]$_{0.3}$ the band is particularly narrow and centered at 1680 cm^{-1}, whereas in dry PANI[FFSA]$_{0.3}$ it is slightly down-shifted to 1677 cm^{-1} and it becomes considerably broadened towards lower wavenumbers. We suggest that this downshift in dry PANI[FFSA]$_{0.3}$ is due to hydrogen bonding of the hydrogen bond

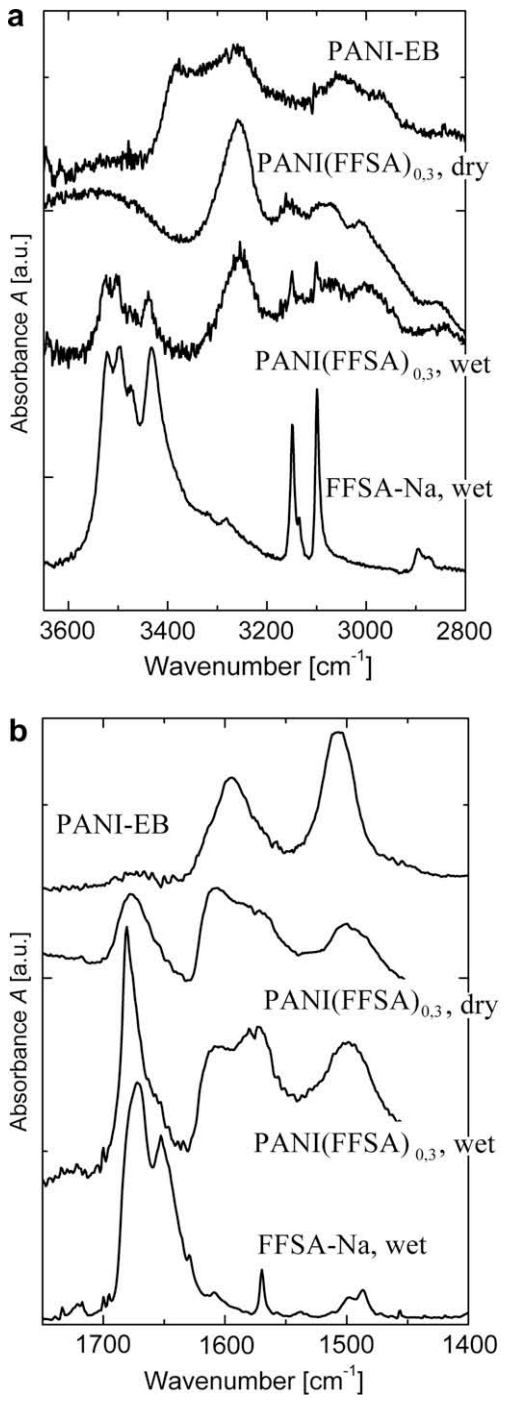

Fig. 5. FT-IR spectra of PANI[FFSA]$_{0.3}$ thin films in their dried states and after a 3-day humidity treatment at 50% RH and 25 °C, of PANI-EB thin films, and of FFSA-Na in the (a) 3600–2800 cm^{-1} and (b) 1750–1400 cm^{-1} wavenumber range.

accepting carbonyl group of FFSA to the secondary amines ≥N—H of the PANI backbones of the neighboring chains, as they are the only hydrogen bond donors available in large quantities. As UV–Vis-NIR, dc-conductivity, and the characteristic green color indicate that in the dried state the sulfonic acid groups protonate the iminic nitrogen groups, the FFSA molecules therefore connect two neighboring PANI chains by the ionic interaction at one end to the imines and hydrogen bond to the amines at the other end. This FFSA-induced networking between the PANI chains could also explain the slightly unexpected 1610 cm^{-1} peak in PANI[FFSA]$_{0.3}$, see Fig. 5b. In principle, the 1610 cm^{-1} band could originate from the furan rings of FFSA, but it is unlikely, since there is no such band in the FFSA-Na spectrum. Previously, the *ca.* 1610 cm^{-1} band has been assigned to a usually IR-inactive band of the quinoid ring, which can become active due to protonation-induced conformational changes [65]. Therefore we suggest that the band represents the quinoid rings of doped PANI, especially since the humidity-induced decrease in its intensity is in line with the suggested partial dedoping reaction, based on the electrical and UV–Vis-NIR measurements. Also in the previous literature, upshifting of the quinoid ring FT-IR band of a modified PANI chain has been presented (*e.g.* *N*-grafting of the PANI chain [62,66]).

Effect of humidity is considered next: in humid PANI[FFSA]$_{0.3}$ the carbonyl band of the FFSA dopant at 1680 cm^{-1} becomes sharp, suggesting suppression of hydrogen bonds. This would indeed be expected if the hydrated FFSA molecules phase separate and the hydrogen bonds to the PANI secondary amines are opened. Also, the intensity of the band at 1610 cm^{-1} decreases upon the humidity treatment, which could be expected if the FFSA-induced PANI-to-PANI connections are opened and the conformational stresses within PANI chains are relieved. Additionally, the spectrum of wet PANI[FFSA]$_{0.3}$ in Fig. 5a shows also that humidity initiates the formation of new bands, compared to the spectra of dry PANI[FFSA]$_{0.3}$: peaks located at 3150 cm^{-1} and 3101 cm^{-1} and bands in the 3400–3500 cm^{-1} wavenumber range. All of these bands are similar to the Na-FFSA spectrum. This also suggests that humidity triggers a partial dedoping reaction, after which the hydrated dopant phase separates from the PANI matrix and crystallizes.

Even if we expect that the above-mentioned humidity-induced phase separation concept is a plausible explanation for the observed effects, it still remains somewhat speculative. Therefore, for completeness, also other scenarios can be mentioned. The aldehyde (CHO) groups of FFSA might react with the secondary amine (—NH) groups of the PANI backbone through *e.g.* a Leuckart–Wallach reaction [67,68], leading to *N*-grafted PANI. Even though this reaction might explain the 1610 cm^{-1} peak, the irreversible nature of the suggested reaction conflicts with the results. The aldehyde group might also react with the primary amine (—NH$_2$) end-groups of the PANI chain to form a Schiff base [69]. This reaction would indeed lead to a moisture-sensitive bond [70,71], but since the breaking of the bond should not affect the conductivity significantly, it is not likely that this reaction is dominating the humidity-induced reaction leading to decreased dc-conductivity.

Based on the above observations, we finally demonstrate in the following that PANI[FFSA]$_x$ thin films can be used for electrically responsive active layers in sensors, which are sensitive to humidity and which report whether a package has been opened under humid conditions, see Fig. 6a. First, a PANI[FFSA]$_{0.3}$ thin film was spin-coated from a formic acid

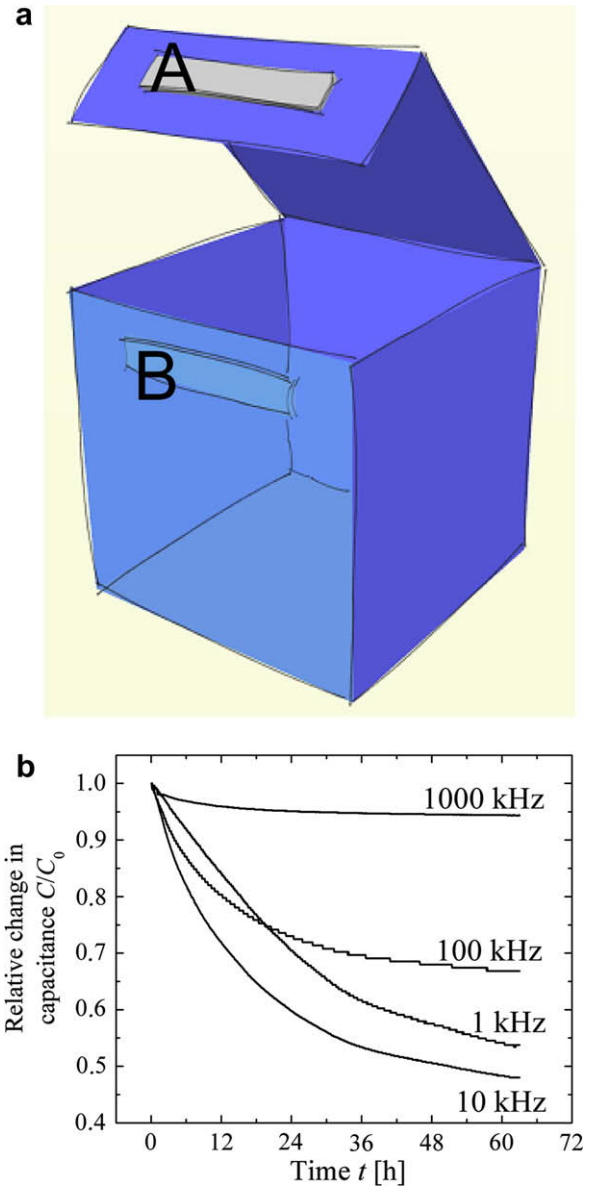

Fig. 6. (a) Schematic representation of the structure and the operating principle of the humidity memory as the seal of quality showing the adhesive tape (A) located on the lid and the PANI(FFSA) sensor (B) located inside the package. The sensor is activated when the protective layer (*i.e.* the tape) is peeled off. (b) Evolution of the reduced capacitance C/C_0 of PANI[FFSA]$_{0.3}$-based sensor (at four different frequencies) as a function of the elapsed time after its contact with the *ca.* 20% RH atmosphere of the VTT laboratory, in which the *ca.* 2.5 days tests were performed. Note that C_0 indicates the capacitance value before the activation of this humidity sensor.

solution onto a PET substrate (Melinex ST504) and dried in a vacuum oven at 60 °C for at least 48 h. Then, the samples were simply covered with a protective layer, consisting of a two-sided adhesive tape (3M 9415PC) having high and low adhesion sides, in order to protect the film against spurious humidity. The low adhesion side was pressed on the sensor element right after drying and the highly adhesive side was pressed against a paperboard, simulating a package lid. The sensor can be attached inside a package on the package wall opposing the package lid. Opening the package causes the low adhesion side to detach from the sensitive and electrically responsive PANI[FFSA]$_{0.3}$ layer. On the other hand, closing the lid does not attach the protective layer on the sensor anymore.

Moisture of the surrounding atmosphere triggers the dedoping of the conducting PANI[FFSA]$_{0.3}$ active layer of the sensor when the protecting layer is peeled off, impacting simultaneously its sheet resistance and capacitance. Due to the chosen design (see Fig. 6a), lateral electrodes on the outer side of the sensor advantageously enable a non-contact measurement of the capacitance through the package without the necessity of additional wiring. Fig. 6b shows the change in the reduced capacitance C/C_0 as a function of elapsed time after the activation of the sensor, which consisted of removing of the protective layer and exposure to a laboratory atmosphere showing a *ca.* 20% RH content. Fig. 6b demonstrates that the proposed capacitance measurement allows for simple yet unequivocal and precise follow-up of the dedoping reaction of this PANI[FFSA]-based humidity sensor, as water absorption usually causes an increase of the dielectric constant, which, in turn, leads to an increase of the capacitance value [42,52]. While the best responses achieved so far with the presently developed prototypical sensor are the ones obtained within the 1–100 kHz frequency range, one can easily anticipate that accurate capacitance measurements will become within reach with a portable meter, usually operating in the 0.1–100 kHz range, thanks to the easy control of the intrinsic dc-conductivity level (through the x doping ratio of the PANI[FFSA]$_x$ thin films) and of the film thickness of this conducting PANI-based humidity sensor.

4. Conclusions

We have presented a concept for an irreversible humidity sensor, *i.e.* a so-called humidity memory. PANI is partially protonated using a highly polar dopant 5-formyl-2-furansulfonic acid (FFSA), which upon humidity exposure phase separates from PANI, obviously due to hydration, and causes dedoping. Subsequently the sheet resistance increases and the capacitance decreases, as well as the PANI layer turns from light green to blue. The sensor detects and remembers any presence of moisture; however, the exact humidity level can not be quantitatively detected. Thus the sensor can be utilized in applications where it is enough to simply distinguish between completely dry and humid past conditions. The sensor can *e.g.* be attached to a package as a seal of quality, and we demonstrate activation when and only when the protective layer is peeled off. Sheet resistance or non-contact capacitive measurements allow humidity detection and easy operation. We expect that the concept can be tuned and generalized using other highly hygroscopic counter-ions.

ABSTRACT

Hole-transporting arylamino-9,10-diphenylanthracene derivatives were synthesized by C–N cross coupling with palladium catalyst. The materials showed higher glass transition temperatures (135–177 °C) than that of a conventional hole-transporting material, *N*,*N*'-bis(naphthalen-1-yl)-*N*,*N*'-bis(phenyl)benzidine (NPD). The compounds all showed higher hole mobilities than that of NPD, with one of the compounds showing a much higher hole mobility of $\sim 1.0 \times 10^{-2}$ $cm^2 V^{-1} s^{-1}$. Tris-(8-quinolinolato) aluminum (Alq_3)-based green light emitting devices containing the arylamino-9,10-diphenylanthracene derivatives as hole transport layers were fabricated. The devices containing the anthracene derivatives showed lower driving voltages and higher efficiencies compared with those of the equivalent device containing NPD. The anthracene derivative with a dibenzofuran substituent was also used as the emitting material in a device. This device emitted blue light with high efficiencies of 5.0 lm/W and 6.3 cd/A at 4.0 V and 1000 cd/m^2, respectively.

1. Introduction

Organic light emitting devices (OLEDs) have attracted a great deal of attention because of their application in flat panel displays [1] and general lighting [2,3]. Since organic electroluminescence was first reported by Pope et al. from a single crystal of anthracene [4], thousands of π-conjugated molecules have been developed as charge transport and/or light emitting materials for OLEDs. Among these numerous compounds, 9,10-diphenylanthracene derivatives have played a leading role as host or emitting materials in highly efficient and long-lived state-of-the-art OLEDs [5–10]. 9,10-Diphenylanthracene itself shows strong blue emission but it has high crystallinity, which is a severe drawback for device stability in OLED applications. To make 9,10-diphenylanthracene amorphous, arylamino substituents were introduced and blue emission from OLEDs containing these arylamino-9,10-diphenylanthracene derivatives was reported [11,12]. Generally, arylamine groups increase the hole-transporting ability of the compounds [13], so arylamino-9,10-diphenylanthracene derivatives are expected to exhibit good hole transport properties. High hole mobility, in addition to a small hole injection barrier, is an important parameter in reducing the energy consumption of OLEDs because it reduces the required driving voltage. 9,10-Diphenylanthracene derivatives **1**–**6** containing bulky π-conjugated arylamino groups were synthesized. Their glass transition temperature, hole mobilities and performance as a hole-transporting material in OLEDs were investigated. The compound with a dibenzofuran substituent **5** exhibited high efficiency as a blue emitting material in OLEDs.

2. Results and discussion

2.1. Synthesis and thermal properties

Arylaminoanthracene derivatives **1**–**6** were synthesized by the Pd(0)-catalyzed C–N cross-coupling reaction of 9,10-bis(4-(phenylamino)phenyl)anthracene and an arylhalide (Scheme 1). Purification of the compounds was made difficult by their poor solubility in common organic solvents. Diethylfluorene-substituted compound **4** showed

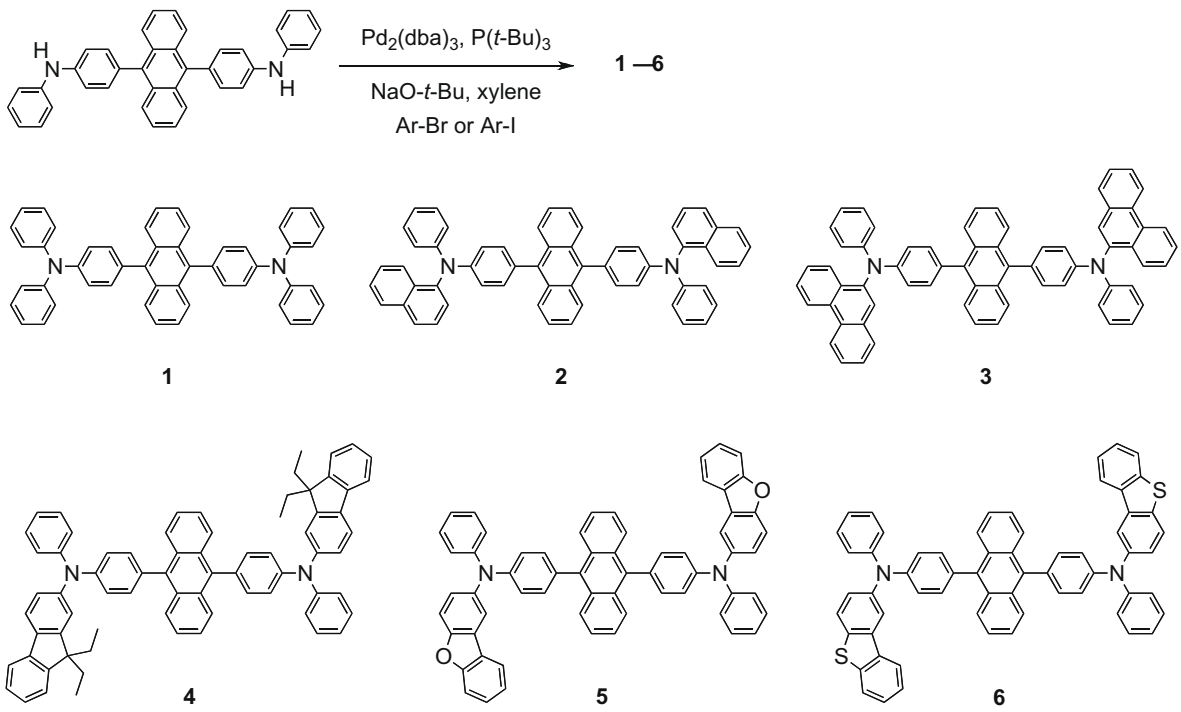

Scheme 1. Synthetic route and chemical structure of compounds **1**–**6**.

the best solubility in chloroform, and **1** and **2** were also soluble in chloroform. The compounds with bulky aryl groups (**3**, **5** and **6**) showed poor solubility, especially **3** which contained a bulky phenanthrene substituent. Only **3** was not able to be purified by column chromatography with chloroform; a solution of **3** in hot dichlorobenzene was passed through a short silica column to remove highly polar impurities. After column chromatography, all of the compounds were further purified by train sublimation with two heating zones at pressures under 5.0×10^{-2} Pa for **1** and **2**, and under 5.0×10^{-4} Pa for **3**–**6**. Thermogravimetric analysis (TGA) showed that the decomposition temperatures (T_d) with loss of 5 wt% of the compounds were over 400 °C. Differential scanning calorimetry thermograms of the compounds are shown in Fig. 1. The glass transition temperatures (T_g) of **2**–**6** (Table 1) were higher than the T_g of 100 °C of *N*,*N*'-bis(naphthalen-1-yl)-*N*,*N*'-bis(phenyl)benzidine (NPD). Compound 3 showed the highest T_g of 177 °C because of the bulky phenanthrene substituent. On the other hand, a T_g for 1, which has a symmetrical structure and simple phenyl substituent, was not observed in our experiment, probably because of its high crystallinity.

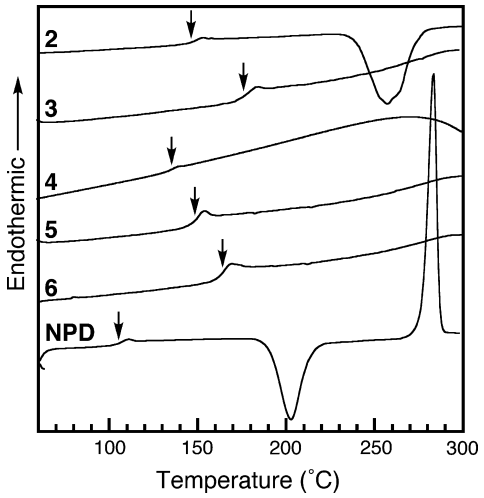

Fig. 1. DSC thermograms of the compounds.

2.2. Photophysical and electrochemical properties

UV absorption and PL spectra of solutions and films on a quartz substrate of **1**–**6** were measured (Fig. 2). All of the compounds except **4** showed three absorption peaks between 360 and 400 nm which were ascribed to the vibrational structure of the central anthracene moiety. All of the compounds **1**–**6** exhibited blue emission with wavelength maxima located around 480–490 nm. The PL quantum efficiency (PLQE) of 1 wt% doped polymethylmethacrylate (PMMA) films and neat films of the anthracenes were determined using an integrating sphere. All the compounds showed a high PLQE of around 80% in a diluted film, which suggests that these anthracene compounds should be useful as emitting dopants in OLEDs. The ionization potential (I_p) of each compound, which generally corresponds to the energy level of the highest occupied molecular orbital (HOMO), was measured by

photoelectron yield spectroscopy. The electron affinity (E_a), which generally corresponds to the energy level of the lowest unoccupied molecular orbital (LUMO), was tentatively estimated from the difference between I_p and the optical energy gap (E_g). All of the compounds showed similar I_p and E_a, meaning the HOMO and LUMO energy levels were almost independent of the attached substituents. The I_p of 1 was a little higher than the other compounds because its phenyl substituent is less electron-donating than the other aryl substituents.

2.3. Hole mobilities and OLED characteristics

The hole mobilities of the compounds were estimated by time-of-flight (TOF) measurements (Fig. 3). Compounds **1**, **3**, and **6** exhibited slightly higher mobilities of around 10^{-3} cm^2 $V^{-1}s^{-1}$ than that of NPD, and diethylfluorene-substituted **4** exhibited much a higher mobility of close to 10^{-2} cm^2 $V^{-1}s^{-1}$ (Fig. 4). The detailed condition and nondispersive photocurrents of **4** at 10 different electric fields are shown in Supporting information.

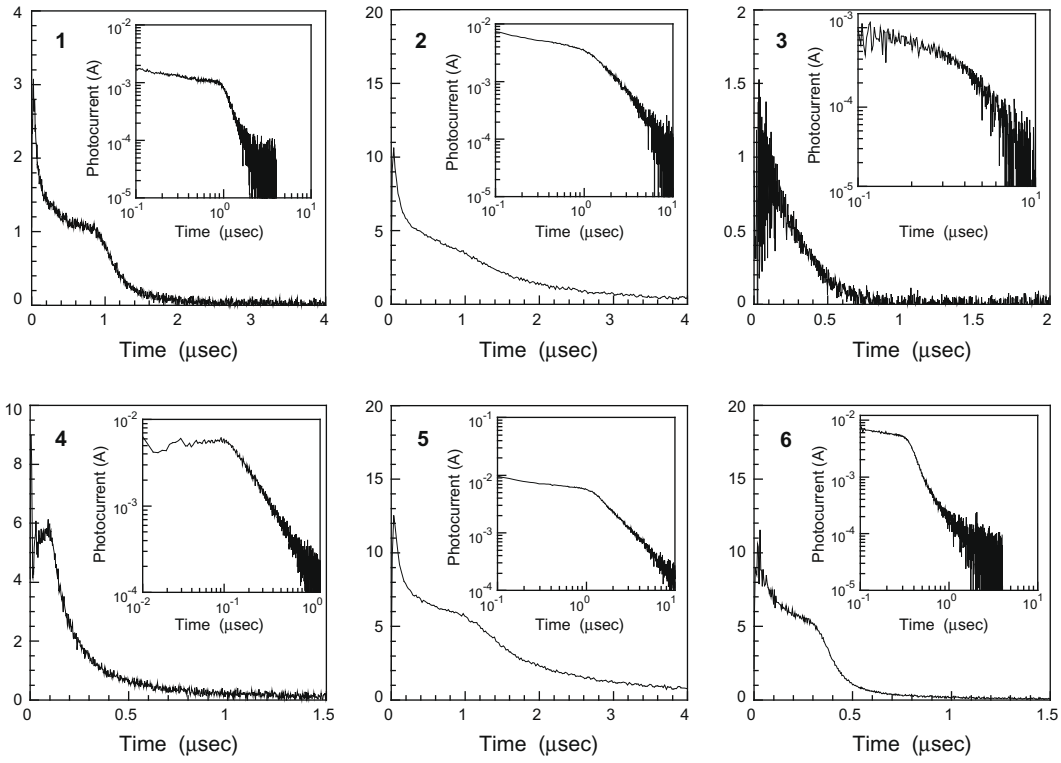

Fig. 3. Transient photocurrents obtained from TOF measurements. (Inset) Double logarithmic plot of the TOF data.

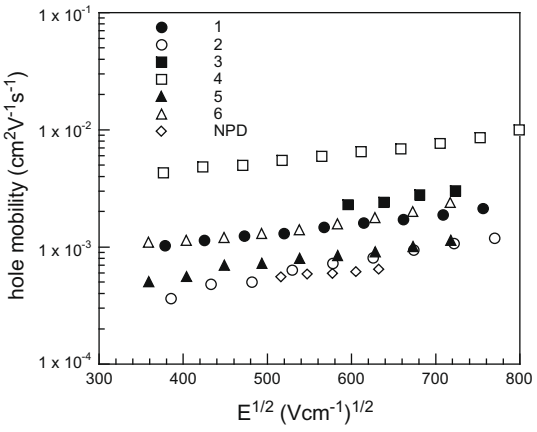

Fig. 4. Hole mobilities of compounds **1**–**6**.

OLEDs with the configuration of ITO/HTL: **1**–**6** or NPD (40 nm)/Alq_3 (60 nm)/LIF (0.5 nm)/Al (100 nm) were fabricated. The luminance–voltage and current density–voltage plots are shown in Fig. 5, and the device efficiencies are summarized in Table 2. OLEDs containing **1**–**6** showed comparable driving voltages and efficiencies to those of NPD. The OLED containing naphthalene-substituted **2** exhibited a lower driving voltage by 0.6 V and 1.4 times higher efficiency at 1000 cd/m^2 than those of the device containing NPD. No correlation between the device efficiency and the high hole mobility of the compounds was observed for these devices. The hole injections from ITO to the compounds should be poor because of their large I_ps, and those hole injection abilities mainly determined the device performance rather than the hole mobilities. To explain the device performance from the perspective of the materials in the HTL, the hole injection ability from ITO in a hole-only device has to be taken into account. Dibenzofuran-substituted **5** was used as a blue emitter in a device with the configuration of ITO/NPD (50 nm)/2-methyl-9,10-bis(naphthalen-2-yl)anthracene (MADN): 5 (10 wt%) (30 nm)/1,4-di(1,10-phenanthrolin-3-yl)benzene (DPB) (20 nm)/LiF (0.5 nm)/Al (100 nm). The device exhibited blue emission from **5**, with a maximum wavelength of 468 nm and Commission Internationale de L'Éclairage (CIE) chromaticity coordinates of (0.14, 0.21). The device efficiencies were as high as 5.0 lm/W and 6.3 cd/A at 1000 cd/m^2, meaning that these arylaminoanthracene derivatives could be useful as not only hole-transporting materials but also as blue emitting dopants in OLEDs. (Fig. 6).

3. Conclusion

Arylamino-9,10-diphenylanthracene derivatives were synthesized and purified by train sublimation. Their T_g ranged from 135 to 177 °C because of their bulky aryl substituents. The compounds all showed higher hole mobilities than that of NPD, and diethylfluorene-substituted **4** showed a much higher hole mobility of

$\sim 1.0 \times 10^{-2}$ cm^2 $V^{-1}s^{-1}$. Lower driving voltages and higher efficiencies compared with those of NPD were achieved in devices containing the anthracene derivatives as the HTL. Dibenzofuran-substituted **5** was also used as a blue emitting dopant, and a high device efficiency of 5.0 lm/W and blue emission of CIE (0.14, 0.21) was achieved.

4. Experimental

4.1. Characterization and OLED Fabrication

^{1}H NMR spectra were measured in deuterated solvents on a JEOL ECX 400 MHz spectrometer. Elemental analyses

were carried out by the Elemental Analysis Service, Yamagata University, Japan. Mass spectra were obtained on a JEOL JMS-K9 mass spectrometer. TGA was performed on a Seiko SII EXSTAR 6000 and TGA/DTA 62000 analyzers. DSC was performed on a Perkin–Elmer Diamond DSC7 calorimeter. Ionization potentials were measured on a photoelectron yield spectrometer (RIKEN KEIKI AC-3). UV–visible absorption spectra were recorded of solutions in chloroform or of film on quartz with a Shimadzu UV-3150 spectrometer. PL spectra were recorded using a Jobin Yvon Fluoromax-4 fluorometer. PL quantum efficiencies were measured on a Hamamatsu C9920–01 integral sphere system under nitrogen. TOF measurement was performed on OPTEL TOF-401 system with N_2 laser. OLEDs were fabricated on ITO-coated glass substrates, which were provided by AGC Display Glass Yonezawa Co., Ltd. and cleaned by ultrasonication sequentially in detergent, methanol, 2-propanol and acetone, then exposure to UV-ozone under ambient conditions for 20 min. Organic materials were deposited by thermal evaporation at pressures less than 2×10^{-4} Pa. Lithium fluoride and aluminum were deposited at a pressure less than 1×10^{-3} Pa through a shadow mask to form a cathode. The active area of each device is 2×2 mm^2. Layer thickness calibration was performed using a Dektak 3 surface profilometer. EL spectra were measured on a Hamamatsu PMA-11 photonic multichannel analyzer. The current–voltage characteristics and luminance of the OLEDs were measured using a Keithley 2400 Source Meter and Konica Minolta CS-200 chromameter, respectively. External quantum efficiencies were calculated assuming a Lambertian emission pattern and considering all spectral features in the visible region.

4.2. Synthesis

9,10-*bis*-(4-(Phenylamino)phenyl)anthracene was purchased from Wakayama Seika Kogyo Co., Ltd. All other compounds were purchased from a general chemical company or synthesized.

Compound ***1***: A mixture of 9,10-bis(4-(*N*-phenylamino)phenyl)anthracene (2.00 g, 3.90 mmol), bromobenzene (1.84 g, 11.7 mmol), sodium *t*-butoxide (1.12 g, 11.7 mmol), tris(dibenzylideneacetone)dipalladium (28 mg, 0.031 mmol), tri-*t*-butylphosphine (8 mg, 0.04 mmol) and xylene (200 cm^3) was heated at 100 °C under nitrogen for 15 h. The mixture was allowed to cool to room temperature, then the organic layer was washed with water, dried over magnesium sulfate and filtered. The solvent was removed and then the residue was purified by column chromatography on silica gel using *n*-hexane/chloroform (2:1), followed by train sublimation at 5.0×10^{-2} Pa with the zone temperatures set at 300 °C and 250 °C . Yield: 1.3 g, 51%. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ 7.08 (4H, td, J = 0.9, 7.25 Hz), 7.25–7.36 (24H, m), 7.40 (4H, dd, J = 3.2, 6.8 Hz), 7.84 (4H, dd, J = 3.2, 6.8 Hz). EI-MS m/z Calcd: 664.8. Found: 665. Anal. Calcd for $C_{50}H_{36}N_2$: C, 90.33; H, 5.46; N, 4.21. Found: C, 90.43; H, 5.54; N, 4.23.

Compound ***2***: **2** was prepared in the same manner as **1**, using 1-iodonaphthalene instead of bromobenzene. The residue was purified by column chromatography on silica gel using *n*-hexane/chloroform (3:2), followed by train sublimation at 5.0×10^{-2} Pa with the zone temperatures set at 330 °C and 310 °C . Yield: 0.63 g, 21%. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ 6.99 (2H, td, J = 1.4, 7.25 Hz), 7.20–7.61 (28H, m), 7.80 (4H, dd, J = 3.2, 6.8 Hz), 7.86 (2H, d, J = 8.2 Hz), 7.96 (2H, d, J = 8.6 Hz), 8.12 (2H, d, J = 8.2 Hz). EI-MS m/z Calcd: 765.0. Found: 765. Anal. Calcd for $C_{50}H_{40}N_2$: C, 91.07; H, 5.27; N, 3.66. Found: C, 91.05; H, 5.35; N, 3.62.

Compound ***3***: A mixture of 9,10-bis(4-(*N*-phenylamino)phenyl)anthracene (2.00 g, 3.90 mmol), 9-bromophenanthrene (3.01 g, 11.7 mmol), sodium *t*-butoxide (1.12 g, 11.7 mmol), tris(dibenzylideneacetone)dipalladium (28 mg, 0.031 mmol), tri-*t*-butylphosphine (8 mg, 0.04 mmol), and xylene (100 cm^3) was heated at 100 °C under nitrogen for 15 h. The mixture was allowed to cool to room temperature, and the organic layer was washed with water, dried over magnesium sulfate, and filtered. The solvent was removed and the residue was dissolved in hot dichlorobenzene. This solution was passed through a short silica column and then the solvent was removed. Finally, the product was purified by train sublimation at 5.0×10^{-4} Pa with the zone temperatures set at 327 °C and 317 °C. Yield: 0.57 g, 17%. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ 6.99–7.03 (2H, m), 7.24–7.39 (20H, m), 7.59–7.89 (16H, m), 8.23 (2H, d, J = 8.6 Hz), 8.75 (2H, d, J = 8.2 Hz), 8.81 (2H, d, J = 8.2 Hz). EI-MS m/z Calcd: 865.1. Found: 865. Anal. Calcd for $C_{66}H_{44}N_2$: C, 91.64; H, 5.13; N, 3.24. Found: C, 91.48; H, 4.83; N, 3.19.

Compound ***4***: **4** was prepared in the same manner as **1**, using 2-bromo-9,9-diethylfluorene instead of bromobenzene. The residue was purified by column chromatography on silica gel using *n*-hexane/chloroform (2:1), followed by train sublimation at 5.0×10^{-4} Pa with the zone temperatures set at 316 °C and 296 °C. Yield: 0.41 g, 11%. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ 0.39 (12H, t, J = 7.3 Hz), 1.99 (8H, q, J = 7.3 Hz), 7.08 (2H, td, J = 1.4, 6.9 Hz), 7.23–7.43 (30H, d, J = 8.2 Hz), 7.67–7.71 (4H, m), 7.88 (4H, dd, J = 3.2, 6.4 Hz). EI-MS m/z Calcd: 953.3. Found: 953. Anal. Calcd for $C_{72}H_{60}N_2$: C, 90.72; H, 6.34; N, 2.94. Found: C, 90.94; H, 6.34; N, 2.99.

Compound ***5***: **5** was prepared in the same manner as **1**, using 3-iododibenzofuran instead of bromobenzene. The residue was purified by column chromatography on silica gel using *n*-hexane/chloroform (3:2), followed by train sublimation at 5.0×10^{-4} Pa with the zone temperatures set at 320 °C and 290 °C. Yield: 0.63 g, 19%. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ 7.07 (2H, t, J = 7.02 Hz), 7.28–7.52 (26H, m), 7.58–7.61 (4H, m), 7.86–7.95 (8H, m). EI-MS m/z Calcd: 845.0. Found: 845. Anal. Calcd for $C_{62}H_{40}N_2O_2$: C, 88.13; H, 4.77; N, 3.32. Found: C, 88.05; H, 4.76; N, 3.29.

Compound ***6***: **6** was prepared in the same manner as **1**, using 3-iododibenzothiophene instead of bromobenzene. The residue was purified by column chromatography on silica gel using *n*-hexane/chloroform (3:2), followed by train sublimation at 5.0×10^{-4} Pa with the zone temperatures set at 340 °C and 324 °C. Yield: 0.38 g, 11%. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ 7.10 (2H, t, J = 7.02 Hz), 7.31–7.50 (26H, m), 7.84–7.90 (8H, m), 8.07–8.10 (4H, m). EI-MS m/z Calcd: 877.1. Found: 877. Anal. Calcd for $C_{62}H_{40}N_2S_2$: C, 84.90; H, 4.60; N, 3.19. Found: C, 84.85; H, 4.66; N, 3.19.

ABSTRACT

The effect of host organic semiconductors on electrical doping has been investigated. Electrical conductivities and carrier densities in various hosts are increased by doping with ReO_3. The degree of carrier generation by the *p*-doping is, however, different for different host organic semiconductors and depends on the energy difference between the HOMO level of the hosts and the Fermi energy level of the dopant ($\Delta E = E_{HOMO,host} - E_{F,dopant}$). The larger ΔE resulted in increased carrier generation. In contrast, hole mobilities were reduced by the doping if the organic semiconductors are heavily doped with a doping concentration of 25 mol%. The reduction of the mobilities is also different for different organic semiconductors and is not inversely proportional to the generated carrier densities.

1. Introduction

Electrical doping in organic semiconductors is an important technique to reduce the driving voltage and improve the power efficiency in organic light emitting diodes (OLEDs) and other organic electronic devices [1]. Electrical doping in charge transporting materials can reduce the contact resistance between the electrodes and organic materials and can enhance the electrical conductivity. Recently, various types of dopants have been developed for *n*- and *p*-doping in organic materials. Lithium in tris(8-quinolinolato)aluminum (Alq_3), cesium, cesium carbonate (Cs_2CO_3), rubidium carbonate (Rb_2CO_3) and cesium nitride (CsN_3) in 4,7-diphenyl-1,10-phenanthroline (BPhen) have been commonly used as *n*-type dopants [2–7]. Various combination of *p*-type dopants and host organic semiconductors have been reported to increase the conductivity of doped organic molecules, including tetrafluoro-tetracyano-quinodimethane (F_4-TCNQ) in 4,4′,4″-tris(*N*,*N*-diphenyl-amino)triphenylamine (TDATA), metal halides such as antimony pentachloride ($SbCl_5$) in *N*,*N*′-diphenyl-*N*,*N*′-bis(3-methylphenyl)-1,1′-biphenyl-4,4′-diamine (TPD), ferric chloride ($FeCl_3$) and copper iodide (CuI) in 1,4-bis[*N*-(1-naphthyl)-*N*′-phenylamino]-4,4′ diamine (NPB), and metal oxides such as tungsten oxide (WO_3) in 4,4′,4″-tris(*N*-(2-naphthyl)-*N*-phenyl-amino)-triphenylamine (2TNATA), vanadium oxide (V_2O_5), molybdenum oxide (MoO_3) and rhenium oxide (ReO_3) in NPB or *N*,*N*′-dicarbazolyl-4–4′-biphenyl (CBP) [8–17]. These papers observed that the *p*-dopants form CT complexes with the hole transporting organic materials to increase the conductivity [8–18]. In our previous report, we demonstrated that dopants having a larger work function are more effective in generating holes for a host [19]. To our best knowledge, however, there has been no systematic study on the effect of host materials on electrical conductivity, generation of carriers and carrier mobility by doping.

In this letter, we report the effect of host materials on the electrical conductivity of the doped semiconductors. We selected several hosts having different highest occupied molecular orbital (HOMO) levels to investigate the effectiveness of doping. ReO_3 was selected as the dopant since its work function is very high (>6 eV) [20]. We will demonstrate that higher carrier densities are generated in the host possessing higher lying HOMO level (smaller

absolute HOMO energy). In contrast, however, hole mobilities are reduced by doping in all the hosts when the doping concentration is very high.

2. Experimental

ReO_3 was used as the *p*-dopant and four different organic semiconductors of 2TNATA, NPB, 1,1-Bis-(4–methylphenyl)-aminophenyl-cyclohexane (TAPC), and CBP were used as the hosts. The doped organic layers were formed by the coevaporation of the dopant and each host by thermal evaporation in high vacuum. The doping concentration was controlled by the evaporation rate of the dopant in the range of 0.02∼0.32 Å/s under a constant evaporation rate of 2 Å/s for the organic hosts. The carrier density in the doped films was obtained from the capacitance–voltage (*C–V*) measurement of the metal-insulator-doped organic semiconductor (MIS) structure. A LiF (50 nm), doped organic semiconductor (50 nm) and an Ag electrode (50 nm) were successively deposited on indium tin oxide (ITO) coated glass substrates for the purpose. The *C–V* measurements were carried out by a 1260 impedance/gain-phase analyzer and a 1287 electrochemical interface (Solartron). Electrical conductivities of the doped films were measured using the four leads method. For the measurements, 1000×1000 μm^2 sized organic layers were thermally evaporated on a 200 nm thick SiO_2 covered *p*-type Si wafer. Then four strips of 50 nm thick gold electrodes were deposited on the organic layers. The size of the strip was 50×1100 μm^2 and the gap between the strips was 55 μm. The conductivity was measured using a Suss PM8 probe station with an Agilent 4155C semiconductor parameter analyzer. 50 nm thick doped organic films evaporated on glass substrates were used for the ultraviolet–visible–near infrared (UV–Vis–NIR) absorption measurement (Varian, Cary 5000).

From the references and the measured data by cyclic voltammetry in our laboratory, we confirmed the HOMO level of 5.0 eV for 2TNATA, 5.4 eV for NPB, 5.8 eV for TAPC and 6.0 eV for CBP, respectively [11,21,22]. The HOMO level of the hosts are located higher than the work functions of the ReO_3 (6.0 eV) based on the assumption that the Fermi level of a metal oxide dopant is the same as that of the bulk semiconductor [23]. Therefore, the hosts and the dopant are expected to form CT complexes in the doped films by transferring electrons from the host molecules to the dopant.

3. Results and Discussion

The formation of CT complexes can be easily detected by the appearance of new absorption peaks in the Vis–NIR region which are not shown by either component alone. Fig. 1a shows the difference in the UV–Vis–NIR absorption spectra between 25 mol% ReO_3 doped host films and undoped films. The additional peaks appeared in the doped films at 467 and 1226 nm for 2TNATA, 500 and 1352 nm for NPB, 455 and 691 nm for TAPC and 454 nm for CBP, respectively. These additional peaks are generated at the expense of the $\pi-\pi^*$ transition of undoped films, indicating that these peaks originated from the characteristic absorption peaks of the charge transfer complexes or the radical cation host molecules ($Host^+$) formed by doping [24]. The absorption intensities of the CT complexes increased with the doping concentration as shown in Fig. 1b. However, the intensity of the CT peaks becomes smaller as the HOMO level of the hosts becomes lower. ReO_3 doped 2TNATA showed the highest intensity of CT complex absorption in the full doping concentration range, followed by NPB, TAPC and CBP in sequence.

The carrier density generated by the doping was estimated by the *C–V* measurement using the MIS devices [25]. Details of the sample preparation and the carrier density measurements were described in a previous report [26]. The carrier density increased with an increase in the doping concentration of ReO_3, as shown in Fig. 2. Again, the host having a higher lying HOMO level generates a larger carrier density than the host with a lower lying HOMO level. For instance the ReO_3 doped 2TNATA film with a 25 mol % doping concentration has the higher carrier density of 6.2×10^{18} cm^{-3} than CBP films which have a carrier density of 7.3×10^{17} cm^{-3}. The charge generation efficiency, defined as the ratio of the carrier density to the number of dopant molecules in the doped films, is reduced in the following sequence: 2TNATA (3.8%) > NPB (0.75%) > TAPC (0.38%) > CBP (0.29%). These carrier generation efficiencies follow a similar trend as the absorption intensity of CT complexes (Fig. 1b). From Figs. 1 and 2, we could conclude that the hosts with higher HOMO levels result in higher doping efficiencies. In other words, a larger energy difference between the HOMO level of an organic host

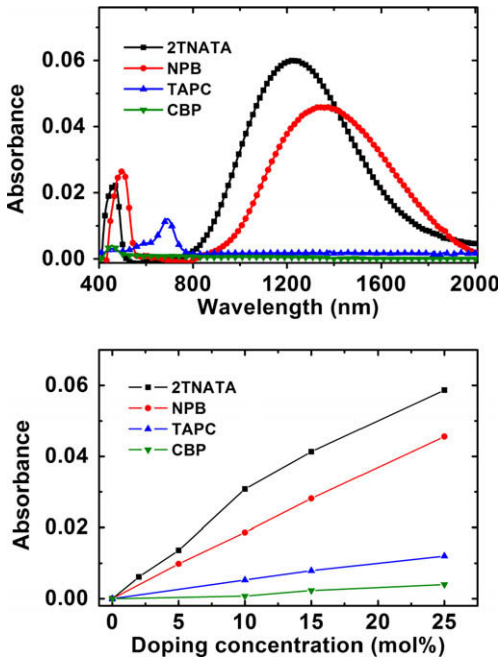

Fig. 1. (a) The difference in the absorption spectra between the 25 mol% ReO_3 doped film and undoped film. (b) The intensity of the CT complex absorption peak vs doping concentration for ReO_3 doped 2TNATA (square), NPB (circle), TAPC (triangle) and CBP (inverse triangle), respectively.

and the Fermi level of a *p*-dopant ($\Delta E = E_{HOMO,host} - E_{F,dopant}$) facilitates the formation of more CT complexes at the same doping concentration. These results are consistent with previous results of the energy difference of ΔE by using different *p*-dopants having different Fermi levels in a host [19]. This doping efficiency was calculated on the assumption that the dispersion of ReO_3 is the same for all the molecular films if the doping concentration is the same in each film. Even though there are good possibilities of the formation of dopant aggregates in the films, this assumption is expected to be valid in these systems since the chemical structure of all the hosts are based on the triphenylamine group [16,27].

In order to investigate the relationship between the carrier density and electrical conductivity, we measured the electrical conductivity of the doped films. The four leads method was used to measure the conductivity to avoid the problem of the contact resistance between the metal electrode and the organic layer in a sandwich type hole only device or in a two parallel electrodes structure [28]. The scheme of four leads measurement is shown in the inset of Fig. 3. During the primary current flows through the outer electrode i.e., between electrodes 1 and 4, we measured the voltage drop between the inner electrodes 2 and 3 with the small secondary current. The current density–electric field (*J*–*E*) characteristics of the 2TNATA, NPB, TAPC and CBP films doped with 25 mol% of ReO_3 are shown in Fig. 3. The linear region in the *J*–*E* graph corresponds to the region where the secondary current becomes negligible to the primary current and we could measure the conductivity from the slope in the region with negligible effect to the contact resistance.

The electrical conductivity and the mobility of doped and undoped films are shown in Fig. 4. The conductivity of the doped films is the highest for NPB, followed by 2TNATA, CBP and TAPC. This sequence was different from the trend of the generated carrier density by doping. This difference comes from the characteristics of the mobility of the doped organic semiconductors.

The mobility of a doped organic semiconductor is obtained from the following equation,

$$\mu_h = \frac{\sigma}{qN_h},$$

where σ is the conductivity, q is the electronic charge, and N_h is the carrier density. The measured conductivity by the four leads method and the carrier density by *C*–*V* measurement were used for the calculation. The mobility of ReO_3 doped host films are compared with that of the undoped host films in Fig. 4. The mobility of the undoped film was measured using the time-of-flight method. ReO_3 doped NPB has the highest mobility of 2.3×10^{-6} cm^2/Vs followed by CBP, TAPC and 2TNATA. These hole mobilities of the doped host films are 1∼2 orders of magnitude lower than the undoped host films.

The drift mobility of the doped NPB film with 25 mol % of ReO_3 is almost the same as the field effect mobility of the same film. The sample for the four leads method was directly used for the measurement of the field effect mobility. P doped Si substrate was used as the gate, and electrodes 2 and 3 as the source and drain electrodes, respectively. The channel length and width were 55 and 1000 μm, respectively. The hole mobility of the ReO_3 doped NPB film was measured to be 3.0×10^{-6} cm^2/Vs in the saturation region, which is almost the same as the previous drift mobility. The consistency of the separately measured hole mobilities of the ReO_3 doped NPB film confirms the validity of the con-

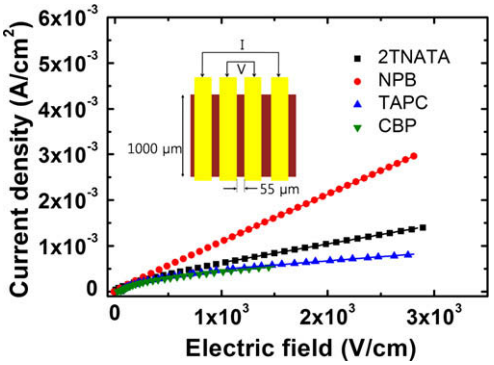

Fig. 3. The current density–electric field characteristics of devices with 25 mol% ReO_3 doped 2TNATA (square), NPB (circle), TAPC (triangle) and CBP (inverse triangle), respectively. Inset: scheme diagram of the four leads method.

ductivity measured by the four leads method and of the carrier density by the *C–V* measurement.

The reduction of the hole mobilities by the doping observed in the system is consistent with the previous report in the F_4-TCNQ doped NPB system [29], but is contradictory to the F_4-TCNQ doped ZnPc system [30]. In F_4-TCNQ doped ZnPc, the mobility was increased from 3×10^{-4} to 1×10^{-3} cm^2/Vs as the doping concentration increased from 0.002 to 0.04 mol%. In contrast, the hole mobility was reduced from 1.6×10^{-5} to 4.3×10^{-6} cm^2/Vs when the same dopant F_4-TCNQ is doped into NPB with the doping concentration of 4 mol %. In our experiment, the doping concentration is even higher with 25 mol%.

The mobility of *p*-type dopant doped organic semiconductors could be interpreted by a form of charge transport in a disordered hopping system with the trap states correlating to the charged dopants. At a low doping concentration, generated hole carriers fill the trap states of intrinsic host organic materials to enhance the mobility of doped films. At a high doping concentration, however, large number of charged dopants form deep trap states to interrupt the hole transport. Different doping concentrations and different distributions of the density of states in disordered hopping systems could cause this contrary behavior of mobility depending on the doping concentration [31,32]. Therefore, in our results, it is reasonable to understand that the negatively charged dopant, ReO_3 reduced the mobility of holes in the doped organic semiconductors at the high doping concentration.

4. Conclusion

In summary, we investigated the host effect on the electrical properties of ReO_3 doped organic semiconductors such as 2TNATA, NPB, TAPC and CBP possessing different HOMO energy levels [CBP (6.0 eV) > TAPC (5.8 eV) > NPB (5.4 eV) > 2TNATA (5.0 eV)]. Through the UV–Vis–NIR spectroscopic measurements and the *C–V* measurements, we demonstrated that the doped host with a larger energy difference of $\Delta E = E_{HOMO,host} - E_{F,dopant}$ facilitates to form more CT complexes and a higher carrier density due to the doping. High doping of ReO_3 reduced the hole mobility for all the hosts. The degree of reduction, however, is different for different hosts and is not proportional to the generated carrier density in the hosts.
