The output characteristics showed very good saturation behavior and clear saturation currents that were quadratic to the gate bias (see Fig. 9). The saturated field-effect mobility μ_{FET} can be calculated from the amplification characteristics by using the classical equations describing field-effect transistors. [28] The mobility values obtained by measuring five different devices are listed in Table 2.Fig. 9 shows the typical drain current (I_{DC}) versus source-drain voltage (V_{DS}) plots at various gate voltages in accumulation mode for **4**- and **5**-based TFTs, respectively. When using OTS-treated SiO_2 insulators and annealing the OSC layer, the transistor devices made from **4** and **5** provided field effect mobilities of 0.020 and 0.023 cm^2/(Vs), respectively, as well as a high current on/off ratio (>10^5) and low threshold voltage ($V_{th} < -15$ V).

The molecules include alkyl chains in addition to the BTBT main structure; these chains enhance solubility and grasp adjacent neighboring molecules through molecular attractive interactions. Therefore, studies have shown that molecular distances are shorter for molecules with longer alkyl chains, resulting in the tendency of larger mobility in the TFTs. [29] The stronger attractive interaction also facilitates rapid crystal growth, so multi-domain thin films are easily fabricated on the substrates. [30] Our results are also consistent with the results in these studies.

Optical spectroscopy and GI-XRD results provided direct evidence of the strong intermolecular interaction and preferred molecular orientation of **4** and **5** in the thermally annealed crystalline film. Therefore, the predominant edge-on orientation of **4** and **5** can explain the higher values of the field effect mobilities as compared to that of as-spun molecular films, which exhibit random or less-ordered orientations of the chain molecules. For example, the unannealed film of **4** shows a mobility of the order of 10^{-3} cm^2/(Vs), which is one order of magnitude lower than that of a device with an annealed film; this can be attributed to liquid crystalline ordering under the annealing temperature. However, in this study, the mobility of the two molecules did not show significant differences, although they showed good film formation and liquid crystalline properties.

Table 2
TFT characteristics: μ_{FET} (cm^2/(Vs)) is the carrier mobility, $I_{on/off}$ is the on/off current ratio, V_{TH} (V) is the threshold voltage. *Samples: unannealed OSC layer and device with annealed OSC layer.

Molecule	Solvent	SAM	μ (cm^2/Vs)	V_{th} (V)	I_{on}/I_{off}
4[a]	MCB	OTS	0.002	−13.2	2.26×10^5
4[b]	MCB	OTS	0.020	−14.5	1.42×10^5
5[a]	MCB	OTS	0.001	−3.3	1.30×10^5
5[b]	MCB	OTS	0.023	−2.0	1.20×10^6

[a] Unannealed film.
[b] Annealed film.
* MCB, monochlorobenzene; OTS, octyltrichlorosilane.

4. Conclusions

We successfully synthesized and characterized new liquid crystalline molecules that are solution-processable. The molecules showed good film formation properties and a high degree of crystallinity in the solid states after thermal annealing. In addition to the molecular arrangement on the substrate in a predominant edge-on manner, the small crystallites of **4** and **5** covered the substrate uniformly and with good network interconnection between them; this is probably responsible for the moderately high carrier mobility in the solution-processed organic semiconductors for FETs. The field effect mobilities of TFT devices were measured to be around 0.02 cm^2/Vs, which indicates no effect of alkyl substituent in two molecules. The improved solution processability and high field-effect mobility make liquid crystalline **4** and **5** promising candidates for a new class of semiconducting materials meant for future flexible electronic devices.

Here, we synthesize a perfluoro-alkyl functionalized fullerene compound, *N*-methyl-2-(4-perfluorooctylphenyl)-fulleropyrrolidine (C60-F), and demonstrate that it is possible to pattern solution-processed C60-F films by a notably benign and scalable method. The patterning method encompasses an initial *direct* exposure of the semiconducting film to green laser light and a subsequent development by immersion into a heptane developer solution. By introducing a shadow mask between the laser and the C60-F film during the exposure step, we realize complex patterns with well-defined features. The patterned C60-F films have been utilized as the active material in field-effect transistors, and both the electron mobility ($>4 \times 10^{-2}$ cm^2/Vs) and the ambient stability are markedly improved in comparison to other more commonly employed fullerene materials, such as [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM). We further demonstrate that the crystallinity of the solution-deposited C60-F film increases during the exposure, presumably via thermal heating induced by the absorbed laser light, while its chemical properties remain unaffected. We propose that this ordering and related densification rationalizes the decreased solubility in the developer solution, the high electron mobility, and the improved ambient stability.

2. Experimental

2.1. Synthesis of N-methyl-2-(4-perfluorooctylphenyl)-fulleropyrrolidine

The fullerene *N*-methyl-2-(4-perfluorooctylphenyl)-fulleropyrrolidine (C60-F) was synthesized in accordance with a method reported in refs [27,28], and the synthesis can be divided into two major steps, as described below and depicted schematically in Scheme 1. ^{1}H NMR spectra were recorded on a Bruker DRX 400 or Bruker DRX 360 at 298 K. The MS analysis was performed with a triple quadrupole mass spectrometer (MS/MS) (API 2000 PE Bio system, Foster City, CA, USA) equipped with a Heated Nebulizer Ion Source (APCI) and a syringe pump. The quadrupole operated in a negative mode and the ion spray voltage was set to −4.2 kV.

2.1.1. Synthesis of 4-(perfluorooctyl)benzaldehyde

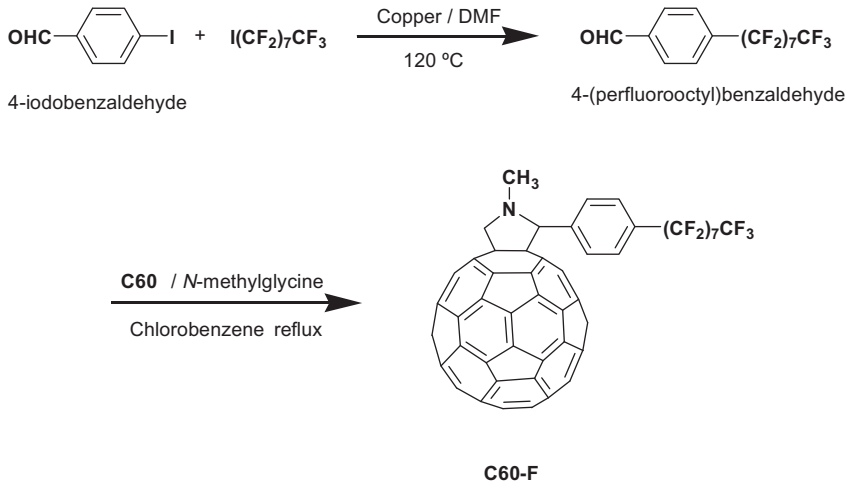
A mixture of 4-iodobenzaldehyde (800 mg, 3.45 mmol), $C_8F_{17}I$ (2 mL, 7.50 mmol) and copper bronze (2.60 g, 14.3 mmol) was dissolved in dimethylformamide (DMF) (20 mL) and stirred for 22 h at 120 °C. The mixture was subsequently filtered with Celite® and washed with Et_2O and H_2O. The aqueous layer was extracted with Et_2O (15 mL × 2). The organic layer was washed with H_2O and dried over $MgSO_4$. The evaporation of the organic phase gave the crude product, which was purified by silica gel column chromatography with n-hexane to afford 900 mg (50% yield) of 4-(perfluorooctyl)benzaldehyde. ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.80 (d, J = 8 Hz, 2H), 8.04 (d, J = 8.0 Hz, 2H), 10.12 (s, 1H).

2.1.2. Synthesis of N-methyl-2-(4-perfluorooctylphenyl)-fulleropyrrolidine (C60-F)

4-perfluorooctylbenzaldehyde (1.0 mmol, 524 mg) and *N*-methylglycine (2.5 mmol, 223 mg) were added to C_{60} (0.5 mmol, 360 mg) in 200 mL of chlorobenzene. The solution was heated to reflux for 20 h. The solvent was then condensed and the crude product was purified by long-path chromatography eluted by toluene/hexane (1:4). After evaporation of the solvent, 210 mg (33% yield) of the product C60-F (brown powder) was obtained. ^{1}H NMR (400 MHz, $CDCl_3$): δ 2.82 (s, 3H), 4.31 (d, J = 9.7 Hz, 1H), 5.02 (d, J = 9.7 Hz, 1H), 5.02 (s, 1H), 7.66 (d, J = 7.8 Hz, 2H), 7.97 (d, J = 7.8 Hz, 2H). LC–MS (m/z): calcd. $C_{77}H_{10}F_{17}N$ 1271.05; found 1271.0 (M^-).

2.2. Fabrication and patterning of fullerene films

The herein studied fullerene materials are the in-house synthesized C60-F, PCBM (≥99.5%, Solenne) and C_{60} (≥99.5%, SES research). The latter two were used as received. C60-F and PCBM were separately dissolved in chlorobenzene (99.8%, anhydrous, Sigma–Aldrich) in a



Scheme 1. Synthesis route and chemical structure of C60-F.

concentration of 20 g/l. The solutions were stirred at 333 K for 5 h on a magnetic hot plate, and filtered through a poly(tetrafluoroethylene) (PTFE) filter with a 0.45 μm pore size. The fullerene solution was thereafter spin-coated on top of a substrate (spin speed = 1400 rpm, spin acceleration = 1400 rpm/s, time = 60 s), and the resulting thin film, with a typical thickness of 100 nm, was annealed at 313 K for 5 h.

A green laser (λ = 532 nm) was utilized for the exposure of the C60-F films. The laser power intensity incident on the film was controlled by placing a negative lens at different positions in the optical path between the laser and the film. The emerging beam from the laser had a diameter of 0.8 mm, and the diameter of the incident beam on the C60-F film ranged between 2 and 10 mm in different experiments depending on the positioning of the lens. The exposure of the C60-F films was typically executed with an incident laser power intensity of p = 2.0 mW/mm^2 (corresponding to an incident laser beam diameter on the fullerene film of 5 mm) for 1 h, although other incident laser power intensities and exposure times (*e.g.,* p = 0.6 mW/mm^2 for 4 h) were also employed with a satisfying outcome. It is notable that other laser wavelengths are expected to be functional as well, but that we choose a green laser since C60-F exhibits an absorption peak at 520 nm in the visible range. The development was executed by immersing the C60-F film into a heptane developer solution for ~10 s. The resulting patterned film was dried at 333 K for 3 min before characterization. The patterning process of PCBM films in our lab has been described in detail in previous publications [29–31].

2.3. Transistor fabrication and measurements

Highly p-doped Si wafers (Cemat Silicon SA) were utilized as a combined substrate and gate electrode in transistor experiments. The wafers were coated on one side with a 200 nm thick layer of SiO_2, which functioned as the gate dielectric. The fullerene solution was spin-coated on top of the gate dielectric (as detailed in the previous section), and the resulting active material was annealed at T = 313 K for 5 h. Au source and drain electrodes (thickness = 40 nm) were deposited on top of the active material by thermal evaporation at $p = 10^{-6}$ mBar, using a shadow mask to define the electrode structure and the channel size (W = 1300 μm, L = 50 μm). The transistor characterization was performed using a Keithley 4200 semiconductor characterization system, with the source electrode grounded. All device fabrication and characterization were carried out under inert atmosphere in two interconnected N_2-filled glove boxes ([O_2], [H_2O] < 1 ppm) with an integrated thermal evaporation unit.

2.4. Characterization of the fullerene films during the patterning process

The IR vibrational spectra were recorded in attenuated total reflection Fourier transform IR (ATR-FTIR) mode. A horizontal single-reflection ATR accessory in the form of a ZnSe crystal was used as the internal reflection element (Harrick Scientific), and the spectra were collected with a Bruker IFS 66v/S spectrometer equipped with a deuterated triglycine sulfate (DTGS) detector and a water-cooled Globar source. The angle of incidence with respect to the ATR cell is ~45°, which is far above the critical angle of ~30°. The presented spectra are averages from 4096 scans, and the resulting resolution is ~2 cm^{-1}. All measurements were performed under vacuum (3 mbar) to eliminate undesired interfering contributions from H_2O(g) and CO_2(g). The samples for IR spectroscopy measurements were prepared by drop-casting a 10 g/l C60-F solution in chloroform onto the ZnSe crystal, and allowing the film to dry at room temperature in consideration of the heat-sensitive crystal substrate. A "patterned" C60-F film was prepared by first exposing a pristine film to the green laser (p = 0.6 mW/mm^2 for 4 h), and thereafter dropping heptane onto the exposed film from a pipette. A peak fit program (Seasolve, PeakFit v4.12) was used to deconvolute the IR absorption bands by symmetric Voigt type peaks for the analysis of sample crystallinity, as presented in Section 3.3.

The tapping mode AFM images were obtained on a MultiMode SPM microscope with a Nanoscope IV Controller (Veeco Metrology) operating under ambient conditions. LTESP Specialty Etched Silicon Probes with a nominal tip radius <10 nm, mounted on a 225 μm long, single-beam rectangular cantilever, were used. The probes were operated at driving frequencies in the range of 176.8–179.1 kHz, which is slightly below the resonance frequency of the cantilever.

The XRD data were recorded with a Siemens/Bruker D5000 diffractometer, using Cu Kα radiation (λ = 1.54 Å) as the probing beam. The probing beam was generated by an X-ray tube, with a typical applied voltage between the cathode and the Cu anode of 40 kV and with the current set to 30 mA. The XRD results were analyzed using the PeakFit v 4.12 software.

The absorption spectra were recorded using a high speed spectrometer (Ocean Optics, HR4000, entrance aperture = 5 μm, grating range = 200–1100 nm) and a tungsten halogen lamp (Ocean Optics, HL-2000-HP-232), both computer controlled with the Spectral Suite software via the RS232 port. The spectra were recorded with an integration time of 190 ms, and background effects (stemming, *e.g.,* from the influence of the substrate and stray light) were corrected for via the parallel acquisition of background spectra. A thicker drop-cast C60-F film deposited on a glass slide was utilized for the attainment of a stronger signal. The C60-F film did, however, not adhere as strongly on the glass (as on, *e.g.,* a SiO_2 layer), which resulted in that both the exposed and non-exposed film areas were removed during the development stage. We have therefore recorded absorption data for the exposed, and not the patterned, C60-F film.

The cyclic voltammetry (CV) measurements were carried out with a computer-controlled potentiostat/galvanostat (Autolab, PGSTAT302/FRA2, Eco Chemie) using the general Purpose Electrochemical Software (GPES, Eco Chemie). All of the measurements were performed in a N_2-filled glove box ([O_2] < 3 ppm, [H_2O] < 1 ppm). The solution for CV experiments comprised the "electrochemically active" fullerene (C60-F, PCBM or C_{60}) dissolved in a

concentration of 0.02 g/l in a mixture of anhydrous toluene and acetonitrile (v:v = 3:1) and with 0.1 M tetrabutylammonium hexafluorophosphate (TBAPF6, ≥99.0%, Fluka) as the inert supporting electrolyte. Two carefully cleaned platinum rods were utilized as the working and counter electrodes, and an Ag wire was used as the pseudo-reference electrode. The Ag wire was calibrated *vs.* the bis-(η-cyclopentadienyl)-iron (II)/bis-(η-cyclopentadienyl)iron(II)$^+$ ion (ferrocene/ferrocenium ion, Fc/Fc$^+$) reference redox couple (ferrocene, ≥98%; Fluka) at the end of each measurement by adding $\sim 10^{-5}$ mol of ferrocene into the solution and performing a sweep. The reduction onset potentials were defined to correspond to the crossing point between the baseline and the half-peak-height tangent line.

3. Result and discussion

3.1. Patterning of C60-F films

We have recently introduced a technique for the straightforward patterning of fullerene thin films, which comprises two main steps: A direct laser-light exposure of selected regions of the fullerene film, followed by development via immersion into a tuned development solution that solely removes (dissolves) the non-exposed regions of the film. The mechanism that allows the patterning has been established to be of a *chemical* origin for the up-to-now investigated fullerene materials, C_{60} [29] and PCBM [30], as photo-exposed C_{60} monomers transform into a low-solubility polymeric state via intermolecular bond formation, and exposed PCBM monomers connect chemically to form low-solubility dimers.

The patterning method has obvious similarities to the well-known and ubiquitous photo-lithography (in negative mode) in that the non-exposed areas of the film are selectively removed by the developer solution, but it is both notable and highly convenient that the sacrificial photo-resist material, which is a critical – and costly – component in photo-lithography, is completely absent in the herein presented patterning process. The fullerene material can accordingly be considered to have two parallel functions: (negative) photo-resist and semiconductor. This attractive opportunity is effectuated by that the semiconducting properties (notably the electron mobility) of the fullerene film are left essentially unaffected by the laser-light exposure, while its solubility in a tuned developer solution is drastically lowered in comparison to the non-exposed material. The merit of the technique has been demonstrated by the successful patterning of vacuum-deposited C_{60} films [29] as well as solution-processed PCBM films [30], and the subsequent realization of well-functioning arrays of n-type field-effect transistors and CMOS inverters based on such patterned fullerene films [31].

A drawback with the two up-to-now investigated fullerene materials is a very limited ambient stability. In order to address the stability problem, and to investigate whether the patterning opportunity for fullerene films is a generic feature, we have in this study synthesized and attempted to pattern thin films of a perfluoro-alkyl functionalized C_{60}-derivative, C60-F (see bottom part of Scheme 1 for chemical structure). C60-F is particularly interesting in this context as the pristine material is reported to exhibit a significantly improved ambient stability over other fullerenes, such as PCBM, presumably due to the existence of a crystalline C60-F structure comprising a dense packing of the perfluoro-alkyl side chains that functions as an effective gas barrier against an undesired and detrimental influx of oxygen and/or water molecules [32].

Fig. 1 presents optical micrographs of a spin-cast C60-F film before (a) and after (b and c) the patterning process. The resulting pattern demonstrates that it is indeed possible to pattern the C60-F film with the resist-free laser-patterning process. The Umeå University logo was defined during the exposure step by allowing the green laser light to pass through a shadow mask, while the subsequent development step was executed by dipping the entire film into a heptane developer solution for ~10 s.

Here, we want to call attention to two points: First, it was relatively difficult to find an appropriate developer solution that was capable of discriminating between the exposed and the non-exposed C60-F material, and that, *e.g.,* toluene (as used for C_{60} patterning) and mixtures of chloroform and acetone (as used for PCBM patterning) removed both the exposed and non-exposed C60-F film areas. Second, we anticipated problems with the patterning of C60-F films via the formation of intermolecular chemical bonds (*i.e.,* the mechanism in effect in the previously studied fullerene materials), as C60-F molecules within a crystalline matrix comprising aligned perfluoro-alkyl chains can be expected to be rotationally frozen-in-place, and since a free rotation has been considered to be a general prerequisite for the formation of intermolecular chemical bonds between adjacent fullerene molecules [33,34]. In contrast, films of C_{60} (crystalline but freely rotating molecules at room temperature, RT) [35] and PCBM (typically amorphous) comprise molecules that exhibit vibrant rotational motion at RT and, consequently, fulfill the prerequisites for intermolecular chemical bond formation.

3.2. Transistor performance and air stability of pristine and patterned C60-F

In order to establish the semiconducting performance and ambient stability of the C60-F fullerene during the patterning process, we have fabricated field-effect transistors (FETs) comprising a thin film of spin-cast C60-F as the active material. The performance of an FET can be quantified by establishing the electron mobility (μ_n) and the threshold voltage (V_T) in the saturation regime with the following equation:

$$I_D^{0.5} = \left(\frac{WC\mu_n}{2L}\right)^{0.5} \times (V_G - V_T) \quad (1)$$

where I_D is the drain current, W and L represent the transistor channel width and length, respectively, C is the capacitance per unit area of the gate dielectric, and V_G is the gate voltage [36]. We have further defined the on/off ratio ($I_{on/off}$) of the FET as the drain current at $V_D = 60$ V

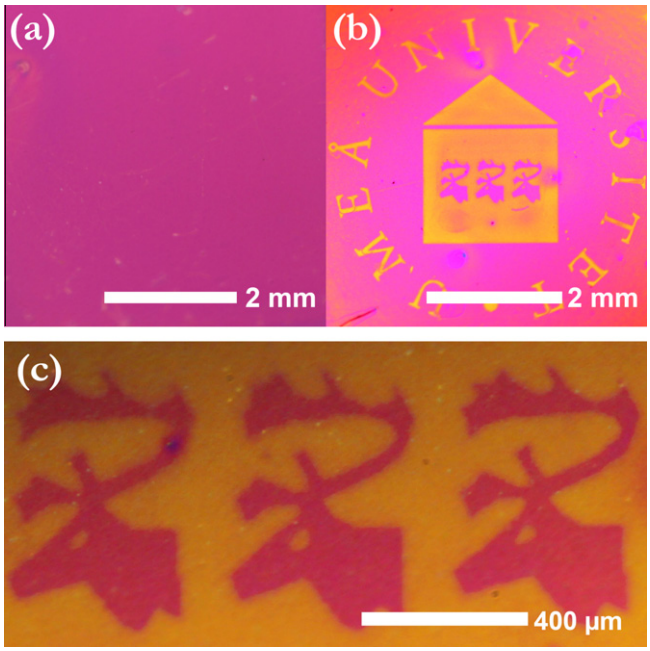


Fig. 1. Optical micrographs of a pristine spin-cast C60-F film (a) and the same C60-F film following patterning with the direct exposure-development technique (b and c). The pattern features were defined by positioning a shadow mask (with the shape of the logo of Umeå University) in conformal contact with the C60-F film during the laser exposure step.

and V_G = 60 V divided by the drain current at V_D = 60 V and V_G = 0 V.

We have fabricated and characterized >40 C60-F transistors in total, and the average performance values for FETs comprising pristine C60-F as the active material are: $\mu_n = 6.0(\pm 2.4) \times 10^{-2}$ cm^2/Vs, V_T = 15 V, and $I_{on/off} = 3 \times 10^3$. The highest mobility value within the group is: $\mu_n = 1.1 \times 10^{-1}$ cm^2/Vs. We note that our results are similar to those reported in a recent study on a pristine C60-F transistor ($\mu_n = 6.7 \times 10^{-2}$ cm^2/Vs) [32]. We have also tested >20 transistors with PCBM as the active material, and we find that such pristine PCBM-FETs exhibit average performance values of: $\mu_n = 2.0(\pm 1.0) \times 10^{-2}$ cm^2/Vs, V_T = 7 V and $I_{on/off} = 1 \times 10^3$. These results are also in reasonable agreement with previous literature reports (although the performance of the latter varies depending on the details of the preparation procedure) [16,17,30,31,37–41]. We call attention to that in our study the electron mobility of C60-F is distinctly higher by a factor of three over that of PCBM.

Fig. 2 illustrates the effects of the patterning of C60-F on the transistor performance. The transfer characteristics (left column) and the output characteristics (right column) of two representative C60-F transistors ("A" and "B") on the same substrate were recorded following the various stages of the patterning process, and the performance is quantified by calculating the electron mobility using Eq. (1). The mobility of the pristine C60-F material in transistor "A" is $\mu_n = 6.9 \times 10^{-2}$ cm^2/Vs (see Fig. 2a and b), but after the laser-light exposure the mobility has dropped to $\mu_n = 3.6 \times 10^{-2}$ cm^2/Vs (see Fig. 2c and d). Following the final development step, *i.e.*, at the end of the patterning cycle, the mobility of the patterned C60-F material in transistor "A" recovers somewhat to $\mu_n = 4.2 \times 10^{-2}$ cm^2/Vs (see Fig. 2e and f). A transistor "B" on the same substrate was also characterized during the patterning procedure, but with the notable difference that the exposure step for the C60-F material in the transistor channel was cancelled. The development step visually removed the non-exposed C60-F from the channel of transistor "B", and as expected the mobility for such a solely developed C60-F transistor is effectively zero (see Fig. 2g and h).

The air stability of pristine and patterned C60-F and PCBM films was estimated by exposing (a total of 80) transistors based on such films to ambient air for 24 h, and then returning them into a glove box for FET characterization after 5 min. For the pristine fullerene films, we find that the "ambient stability" of C60-F is better than that of PCBM, as quantified by that the former exhibits an average electron mobility of $\mu_n = 4.0 \times 10^{-3}$ cm^2/Vs and the latter exhibits $\mu_n = 2.0 \times 10^{-4}$ cm^2/Vs, following one day of air exposure. In relative terms, the average retained mobility is ~7% for the pristine C60-F film and ~1% for the pristine PCBM film. These results are in good agreement with a previous study performed by Chikamatsu et al. [32], which in combination with a small sample-to-sample variation yield support for that the employed measurement protocol is an appropriate indicator on the ambient stability.

For the patterned fullerene films, we find a markedly improved ambient stability, as the average retained mobility is ~24% for patterned C60-F films and ~16% for patterned PCBM films. In absolute terms, this corresponds to an average mobility of $\mu_n = 1.0 \times 10^{-2}$ cm^2/Vs for patterned C60-F and $\mu_n = 8.0 \times 10^{-4}$ cm^2/Vs for patterned PCBM following one day of air exposure. The results for

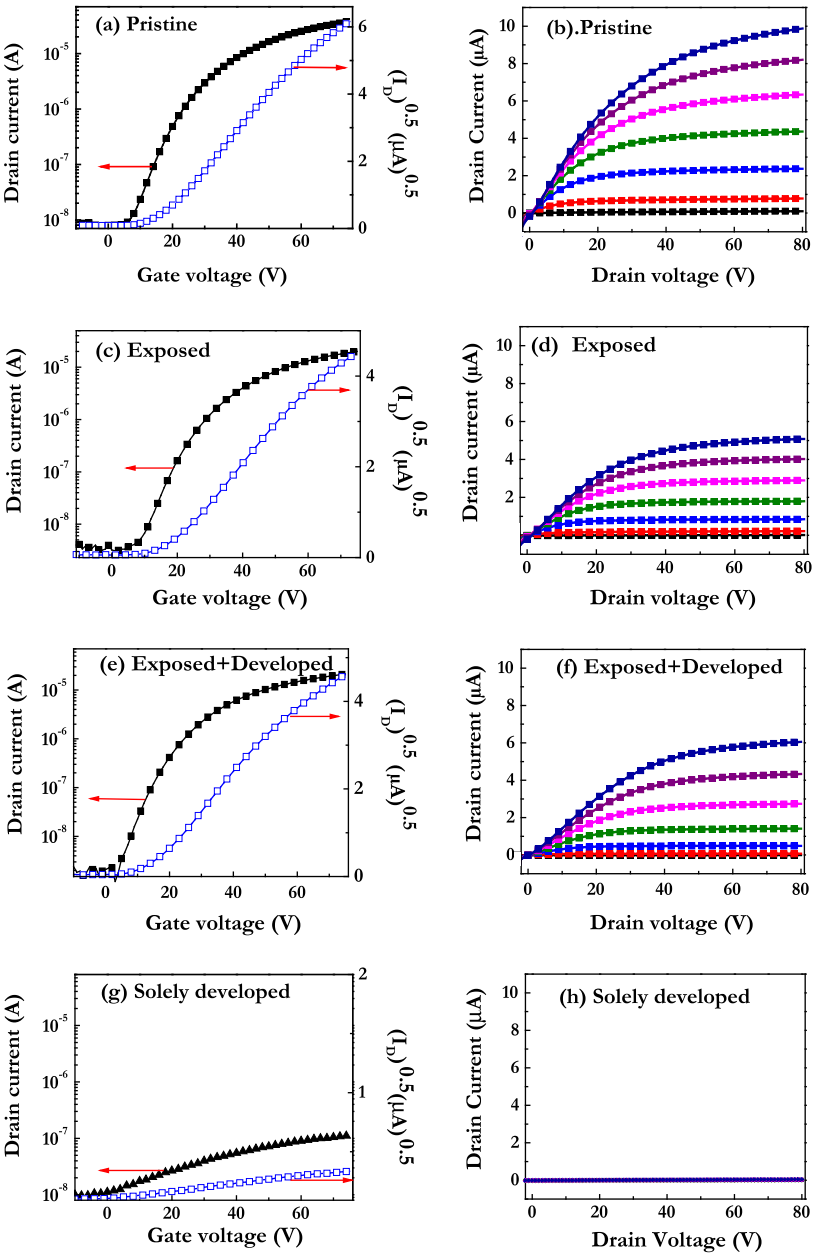

Fig. 2. Transfer (left column) and output (right column) characteristics of two representative C60-F transistors, as measured following the different stages of the patterning process. The data presented in (a–f) were recorded on the same transistor "A", while the data in (g and h) were recorded on a second transistor "B" on the same substrate. The transfer characteristics were measured at V_D = 60 V, and the output characteristics were measured at V_G ranging from 0 V (bottom trace) to 60 V (top trace), with a ΔV_G step of 10 V.

C60-F are promising in that they, for instance, suggest that it should be possible to perform processing and patterning of thin C60-F films for electronic applications in the ambient before a final encapsulation step.

3.3. Mechanism allowing for patterning and improved device performance

We now shift our attention to a material characterization of the C60-F material, with the goal of unraveling the mechanisms that allow the patterning as well as the improvement in electron mobility and air stability over PCBM. We start with an IR absorption spectroscopy study, and Fig. 3 presents data over various wave-number regions for a pristine C60-F film (bottom black trace i) and a patterned C60-F film (top red trace ii).

In our previous investigations on patterning of C_{60} and PCBM fullerene films, the fullerene breathing mode – the so-called $A_g(2)$-mode – was exploited as a qualitative indicator on the formation of new chemical bonds during the

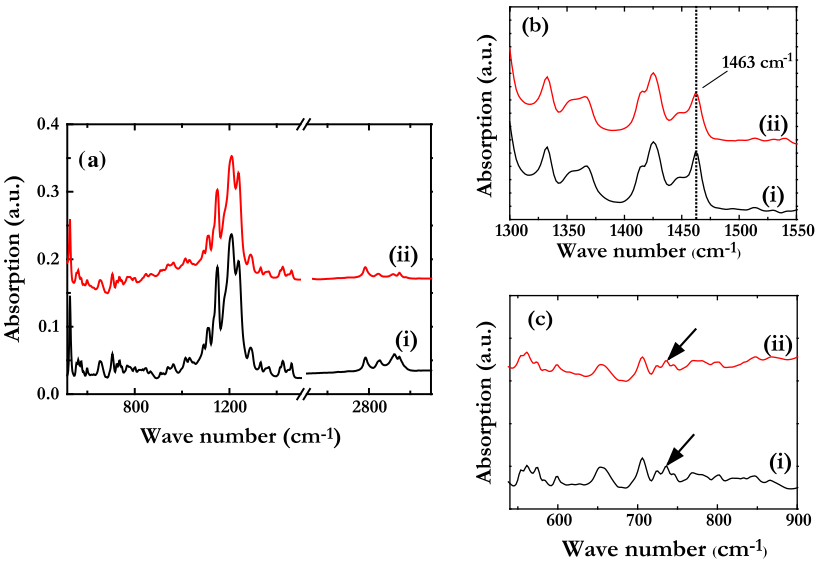

Fig. 3. IR absorption spectra for a pristine C60-F film (bottom black trace i) and a patterned C60-F film (top red trace ii) over an expanded wave-number range (a), over the $A_g(2)$-mode region (b), and over the "crystalline-indicator"-mode region (c).

patterning process, as it is well-established that this mode down-shifts in a regular fashion when new intermolecular chemical bonds are formed between the fullerene molecules. More specifically, it has been demonstrated that the $A_g(2)$-mode down-shifts with ~5 cm^{-1}/intermolecular bond/fullerene molecule [42–44]. Accordingly in PCBM, where dimers are formed during the laser-light exposure step, the $A_g(2)$-mode is down-shifted with 5 cm^{-1} following patterning [30], and in C_{60}, where preferentially linear polymers are created during the exposure, the $A_g(2)$-mode is found to down-shift by 9 cm^{-1} [29]. In the pristine C60-F film we find that the $A_g(2)$-mode, as expected, is positioned at 1463 cm^{-1}, but it is notable that the position of the $A_g(2)$-mode is unaffected by the patterning (see dotted line in Fig. 3b). This observation demonstrates that no intermolecular chemical bonds form during the laser-light exposure of the C60-F film, and also suggests that the *chemical* structure of C60-F – in contrast to its C_{60} and PCBM counterparts – remains intact during the patterning process.

Previous studies on polytetraflouroethylene materials (similar in structure to the perfluoro-alkyl side chain of C60-F) have shown that the IR absorption band at ~740 cm^{-1} is a useful probe of perfluoro-alkyl crystallinity, since this mode is completely absent in "perfectly" crystalline polytetraflouroethylene materials and since it increases in amplitude with increasing amorphicity [45,46]. Fig. 3(c) presents an enlarged view of this "crystallinity-indicator" region, where the data have been normalized by the strong IR absorption band at 1242 cm^{-1} (following the procedure outlined by Starkweahter et al. in Ref. 38). We find that the magnitude of the normalized 740 cm^{-1} peak decreases in magnitude by approximately 10% following patterning, and interpret this as an indication of increased C60-F side-chain crystallinity in the patterned film in comparison to the pristine film. We also note that the characteristic CH vibrations between 2850–3000 cm^{-1} decrease quite drastically in the patterned sample (see Fig. 3a), and that a similar observed decrease has been reported for a PMMA polymer gel during an amorphous–crystalline transition [47]. These observations indicate that the crystallinity of the C60-F film increases during the patterning process.

The notion that the spin-coated C60-F films are partially crystalline (or semi-crystalline) is supported by AFM and XRD studies. Fig. 4 presents AFM topographic images of a pristine C60-F film (a), a patterned C60-F film (b), and a pristine PCBM film (c). Both C60-F films exhibit a distinct surface morphology comprising a small number of micrometer-sized aligned rod-like grains as base units. In contrast, the PCBM film exhibits a completely flat surface morphology without any distinguishable features, which is a characteristic feature of an all-amorphous material and in agreement with previously published data [48]. A closer inspection of the AFM data for the pristine and patterned C60-F films reveals that the average grain size and the root-mean-square surface roughness are persistently larger in the patterned material over the pristine material; specifically, we find that the average grain size increases from 1.1 ± 0.16 to 1.9 ± 0.17 μm and that the surface roughness increases from 24.2 to 33.2 nm following patterning.

The conclusive evidence for that the spin-coated C60-F films indeed are crystalline and that the degree of crystallinity increases following patterning is provided by the XRD data presented in Fig. 5. Both the pristine C60-F film (Fig. 5a) and the patterned C60-F film (Fig. 5b) exhibit four distinct XRD peaks positioned at 6.4°, 9.6°, 12.8°, and 16.0°, corresponding to (0 0 2), (0 0 3), (0 0 4) and (0 0 5) reflections, respectively [32,49]. Moreover, the peak height increases and the full width at half maximum (FWHM) decreases following the patterning, as exemplified by that

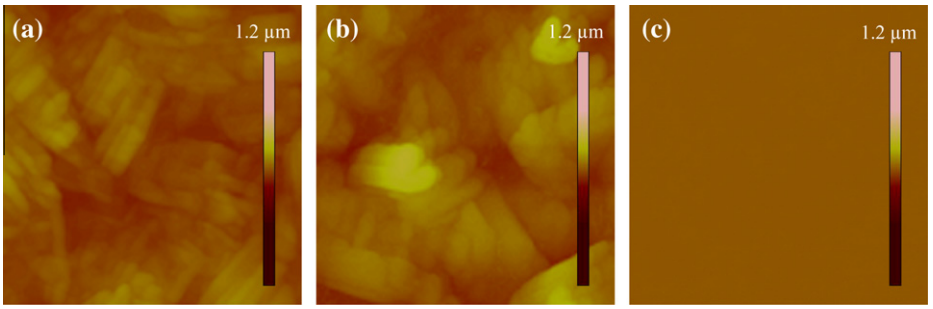

Fig. 4. Topographic AFM images recorded on a pristine C60-F film (a), a patterned C60-F film (b) and a pristine PCBM film (c). The scanning area is $4.4 \times 4.4\ \mu m^2$.

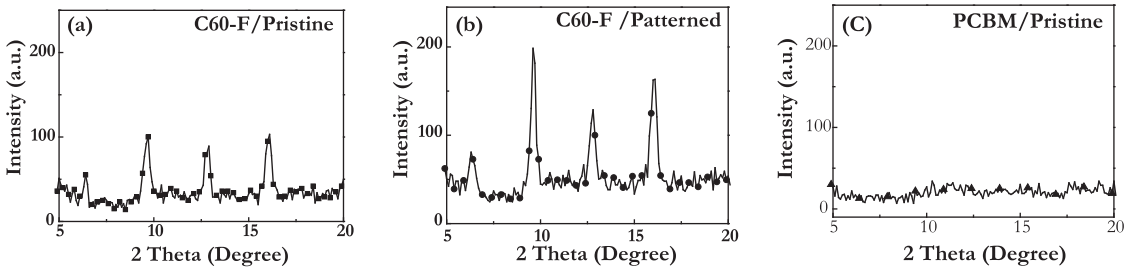

Fig. 5. XRD data recorded on a pristine C60-F film (a), a patterned C60-F film (b), and a pristine PCBM film (c).

the FWHM for the largest (0 0 3) peak at 9.6° is found to decrease from 0.43° to 0.28°. Both these trends are expected for a sample that increases its order and crystallinity. We also note that the PCBM film (Fig. 5c) exhibits no distinguishable XRD peaks, as should be the case for an all-amorphous material.

We have in addition performed complementary UV–vis absorption and CV measurements (data not shown), which verify that the patterning process indeed is effectuated by a physical ordering transition within the C60-F film and not by chemical changes. The UV–vis absorption spectra were recorded on pristine and exposed C60-F, either as dissolved in a toluene solvent or deposited as a spin-coated film. We find that the absorption spectra for the "free" C60-F molecules in solution are identical, regardless of whether the material had been exposed to laser-light or not before dissolution, which supports the notion that the pristine and exposed C60-F molecules have an identical chemical structure. In contrast, the absorption data for the spin-coated films differ in that the exposed film exhibits a more narrow and well-defined absorption profile over the pristine film, which is an expected signature change within a film that has increased its degree of crystallinity. The CV data demonstrates that the LUMO level of both pristine and exposed C60-F films is essentially identical and positioned outside the so-called "thermodynamic stability window" [22], which in turn implies that the observed improvement in air stability for the patterned C60-F film (see final paragraph in Section 3.2.) also can be traced to an increase in crystallinity. More specifically, and as discussed in Ref. [28], ordered and dense perfluoroalkyl layers within a crystalline C60-F matrix can be expected to function as an effective barrier towards an undesired influx of water and/or oxygen molecules.

At this point, it is relevant to include a brief discussion on the mechanism that provokes the observed increase in crystallinity of the C60-F film during the patterning process. First of all, as the pattern is defined during the exposure step, it is clear that it is the laser-light exposure that induces the order. A typical laser-light power intensity incident on the C60-F film surface is $\sim$2 mW/mm^2, and with a typical film thickness of 100 nm, this corresponds to approximately 20 W of irradiation that hits one cubic-millimeter of C60-F material for an extended time period of approximately 1 h during the exposure step. Moreover, as the wavelength of the incident laser light (λ_{laser} = 532 nm) is very close to the absorption peak (in the visible range) for the C60-F film ($\lambda_{abs\ peak}$ $\sim$520 nm), it is clear that a significant fraction of the incident photon flux is absorbed by the exposed areas of the thin C60-F film. With this information at hand, it is not difficult to realize that the exposed film areas become very hot, and we propose that such localized heating within the exposed regions is the cause for the increase in C60-F crystallinity via a thermal annealing process. In this context, we also note recent reports that show that perfluoro-alkyl-based materials are prone to the attainment of highly ordered structures [25,50,51].

Finally, as alluded to at the end of Section 3.1, it did not come as a complete surprise that the origin to the patterning of C60-F did not have a chemical origin, as the baseline criteria for the formation of chemical bonds between different fullerene molecules is that the individual molecules are rotating freely [33–35], which is a requirement that is

fulfilled for a crystalline C60 film [29] and an amorphous PCBM film [30], but not for a crystalline C60-F film.

4. Conclusions

We demonstrate that it is possible to pattern a solution-cast thin film of a perfluoro-alkyl functionalized fullerene compound using a resist-free laser-patterning technique. The patterning is done without use of a sacrificial photoresist material and comprises solely two steps: laser-light exposure and solution development. The exposure step selectively increases the crystallinity within the exposed fullerene regions, while the subsequent development removes the non-exposed fullerene material, so that a well-defined fullerene film structure emerges in reflection of the selected exposure pattern. We show that the patterned and crystalline fullerene film exhibits notably high electron mobility in transistor applications and a strongly improved ambient stability.

blue color of CIE_y = 0.09 than those of control devices (CIE_y = 0.13). These results show that the D-EML system containing 2-methyl-9,10-di(2-naphthyl)anthracene (MADN) and 4′-(dinaphthalen-2-yl)-1,1′-binaphthyl (DNBN) as hosts and 9-N-phenylcarbazole-3-vinyl-*p*-terphnyl (PCVtPh) as a dopant was employed to broaden the recombination zone and confine holes and electrons to that zone.

2. Experimental

2.1. Emitting material synthesis

All reactions were performed under nitrogen. Solvents were carefully dried and distilled from appropriate drying agents prior to use. Commercially available reagents were used without further purification unless otherwise stated. 4,4′-Dibromo-1,1′-binaphthyl [20], *p*-terphenylphosphonate [21], and 9-(4-*tert*-butylphenyl)-9H-carbazole [22] were prepared according to literature methods. ^1H and ^{13}C NMR were recorded on a Varian Unity Inova 300Nb spectrometer. FT-IR spectra were recorded using a Bruker VERTEX70 FT-IR spectrometer. EA was measured using an EA 1108 spectrometer. Low-resolution mass spectra were measured using a Jeol JMS-600 spectrometer in the EI mode. The UV–Vis absorption and PL spectra of DNBN were measured in CH_2Cl_2 (10^{-5} M) using a Shimadzu UV-1650PC and an Amincobrowman series 2 luminescence spectrometer. The fluorescent quantum yields were determined in CH_2Cl_2 solution at 293 K and compared with the host (Φ_{DPA} = 0.90) as a Ref. [23]. The energy level was measured with a low-energy photo-electron spectrometer (Riken-Keiki, AC-2). Thermal property was measured using thermogravimetric analysis (TGA) (DTA-TGA, TA-4000) under nitrogen at a heating rate of 10 °C/min.

A mixture of 4,4′-dibromo-1,1′-binaphthyl (1 g, 2.42 mmol), 2-naphthalene boronic acid (1.25 g, 7.28 mmol), tetrakis(triphenylphosphine)palladium(0) (0.112 g, 0.1 mmol), 2 M Na_2CO_3 (2.58 g, 24.2 mmol), toluene (24 mL) and EtOH (12 mL) were refluxed at 120 °C for 4 h. The crude solid product was filtered and then washed with water. The filtered solid was dissolved with CH_2Cl_2, dried over $MgSO_4$, filtered with silica-gel, and then the solvent was removed under reduced pressure to afford a crude product. The crude product was recrystallized from CH_2Cl_2/EtOH, affording 1.11 g (90.6% yield) of the white solid. ^1H NMR (300 MHz, $CDCl_3$, δ): 8.07 (d, J = 9.6 Hz, 4H), 8.01 (d, J = 8.4 Hz, 2H), 7.98–7.93 (m, 4H), 7.76 (dd, J = 1.5, 8.4 Hz, 2H), 7.68–7.55 (m, 10H), 7.40 (td, J = 1.5, 7.7 Hz, 2H), 7.34 (td, J = 1.2, 7.5 Hz, 2H); ^{13}C NMR (75 MHz, $CDCl_3$, δ): 140.4, 138.6, 138.5, 133.7, 133.5, 132.9, 132.1, 129.2, 128.9, 128.4, 128.1, 128.0, 127.8, 127.4, 127.1, 126.7, 126.6, 126.4, 126.3, 126.2; FT-IR [ATR]: ν = 3050, 1598, 1502, 843, 822, 769, 745 cm^{-1}; MS (m/z, EI^+) 506 (M^+); anal. for $C_{40}H_{26}$: C 93.30, H 5.15; found: C 94.83, H 5.17.

PCVtPh: To a mixture of 9-phenyl-9H-carbazole-3-carbaldehyde (170 mg, 0.627 mmol) and *p*-terphenylphosphonate (238 mg, 0.627 mmol) in 8.0 mL of anhydrous THF at 0 °C was added dropwise 0.70 mL of 1.0 M KO(*t*-Bu) (0.70 mmol) in THF under N_2. The reaction mixture was stirred for 10 min at 0 °C, followed by 1 h at room temperature and quenched with water. The solution mixture was filtered with water. The filtered solid was dissolved in CH_2Cl_2, dried over Na_2SO_4, filtered with silica-gel, and the solvent removed under reduced pressure to afford a crude product recrystallized from $CHCl_3$/EtOH, affording 290 mg (93.2%) of a yellow solid. ^1H NMR (300 MHz, $CDCl_3$, δ): 8.31 (s, 1H), 8.20 (d, J = 7.6 Hz, 1H), 7.43 (d, J = 4.7 Hz, 3H), 7.68–7.62 (m, 8H), 7.61 (d, J = 4.1 Hz, 3H), 7.51–7.31 (m, 10H), 7.26 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$, δ): 141.6, 141.0, 140.3, 140.0, 139.5, 137.8, 137.3, 130.2, 129.9, 129.8, 129.0, 128.4, 127.8, 127.7, 127.6, 127.5, 127.3, 127.2, 127.0, 126.4, 126.2, 125.1, 125.0, 124.1, 123.6, 120.6, 120.4, 118.8, 110.3, 110.2, 29.9, 1.2, 0.2; MS (FAB^+) m/z 497 (M^+); HRMS (FAB^+) calcd. for $C_{38}H_{29}N$: 497.6415 (M^+); found: 497.2139.

2.2. OLEDs fabrication

For the fabrication of OLEDs, indium tin oxide (ITO)-coated glass substrates were used, which have a sheet resistivity of 10 Ω per square and a thickness of 1500 Å. The ITO-coated glass substrates were cleaned in an ultrasonic bath in the following sequence: with acetone, methyl alcohol, distilled water, and isopropyl alcohol. The substrates were treated by O_2 plasma under conditions of 2×10^{-2} Torr at 125 W for 2 min. All organic materials and metals were deposited under high vacuum (5×10^{-7} Torr). The deposition rates were 0.1 nm/s for all organic materials and 0.01 nm/s for lithium quinolate (Liq). Without breaking the vacuum after the deposition of the organic layers, the Al cathode was deposited at a rate of 10 nm/s. The doping concentration of the emitters was optimized. Using DC voltage bias, the optical and electrical properties of OLEDs, such as the current density, luminance, current efficiency, external quantum efficiency (EQE), $CIE_{x,y}$ coordinates, and electroluminescence (EL) spectra of the emission, were measured with Keithley 2400 and Chroma Meter CS-1000A instruments. All measurements were carried out under ambient conditions at room temperature.

3. Results and discussion

Scheme 1 shows the synthetic route for DNBN and PCVtPh as the fluorescent emitter material and molecular structures of MADN as the fluorescent host materials used in this study. Horner–Emmons reaction between the *p*-terphenylphosphonate and the 9-phenyl-9H-carbazole-3-carbaldehyde afforded the PCVtPh as dopant material in moderate yields. DNBN host material was synthesized via the Suzuki Cross-Coupling reaction with moderate yields and was characterized by ^1H and ^{13}C NMR, FT-IR, elemental analysis (EA) and low-resolution mass spectroscopy. The various optical properties of the host materials, MADN and DNBN, are presented in Table 1. The decomposition temperature (T_d; corresponding to 5% weight loss) of DNBN (398 °C) was as high as that of MADN (397 °C). The HOMO energy level of DNBN was −6.0 eV as measured by a low-energy photo-electron spectrometer (Riken-Keiki AC-

2). The optical energy bandgap (E_g) of DNBN is 3.4 eV, as determined from the absorption spectrum. The lowest unoccupied molecular orbital (LUMO) energy level of DNBN, calculated as the difference between the HOMO levels and E_g, was −2.6 eV.

Fig. 1 shows PL emission spectra of the host materials, MADN and DNBN, and UV–Vis absorption spectra of dopant material, PCVtPh, where the main emission peaks of MADN and DNBN in the PL spectra are 425 and 412 nm, respectively. It was found that the introduction of the

(a) and (b) HODs and EODs structures of ITO (150 nm)/NPB (50 nm)/MADN:8% PCVtPh (HOD-1) or DNBN:8% PCVtPh (HOD-2) (8%, 30 nm)/NPB (30 nm)/Al (100 nm) and ITO (150 nm)/BAlq (50 nm)/MADN:8% PCVtPh (EOD-1) or DNBN:8% PCVtPh (EOD-2) (8%, 30 nm)/BAlq (30 nm)/Al (100 nm), respectively. (c) Current density versus voltage characteristics of HODs and EODs.

binaphthyl core between the terminal naphthalene as in DNBN results in a notable blue-shift in PL spectrum. Intriguingly, DNBN with 1,1′-binaphthyl core group showed a maximum emission wavelength that was blue-shifted (9 nm) in thin film compared to the solution. Therefore, it is shown in Fig. 1 that the PL emission peak of the DNBN overlapped more with the absorption peak of the PCVtPh than that of the host MADN. Moreover, DNBN has a higher energy bandgap (3.4 eV) than that of PCVtPh (3.1 eV), while the energy bandgap of MADN (3.0 eV) is smaller than that of PCVtPh (3.1 eV). These results indicate that the Förster-type energy transfer from the host to the emitter of PCVtPh may be more efficient in the DNBN host rather than the MADN host.

Fig. 2(a) shows seven device structures fabricated in this study, and the detailed structures are as follows: ITO/N,N′-bis-(1-naphthyl)-N,N′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB) (50 nm)/MADN (30 nm) (device A) or DNBN (30 nm) (device B) or PCVtPh (30 nm) (device C) or MADN:8% PCVtPh (30 nm) (device D) or DNBN:8% PCVtPh (30 nm) (device E) or MADN:8% PCVtPh (10 nm)/DNBN:8% PCVtPh (20 nm) (device F) or MADN:8% PCVtPh (20 nm)/DNBN:8% PCVtPh (10 nm) (device G)/bis-(2-methyl-8-quinolinolate)-4-(phenylphenolato)aluminum (BAlq) (30 nm)/Liq (2 nm)/Al (100 nm). Here, NPB, BAlq, and Liq were used as hole-transporting, hole-blocking and electron-transporting, and electron injection layers, respectively. The doping concentrations of PCVtPh in MADN or DNBN were optimized to 8%. Proposed energy level diagrams of devices F and G with D-EML are shown in Fig. 2(b). Devices A and D used MADN as an emitter and host, having the recombination zone (RZ) at the interface of EML and BAlq layer because there is no hole injection barrier between the highest occupied molecular orbital (HOMO) level of NPB and that of MADN, but there is an electron injection barrier of 0.4 eV between the LUMO level of BAlq and that of MADN. Moreover, NPB has a considerably higher hole mobility of 10^{-4} $cm^2/V\,s$ compared to BAlq, which has an electron mobility of 10^{-5} $cm^2/V\,s$ [25,26]. On the other hand, devices B and E used DNBN as an emitter and host, respectively, having RZ at the interface of the hole-transporting layer (HTL) and the EML because of the deep HOMO level (6.0 eV) of DNBN. Therefore, devices F and G with the D-EML system are expected to have an RZ at the interface of MADN and DNBN. When an RZ is generated at the interface of the HTL/EML or EML/electron-transporting

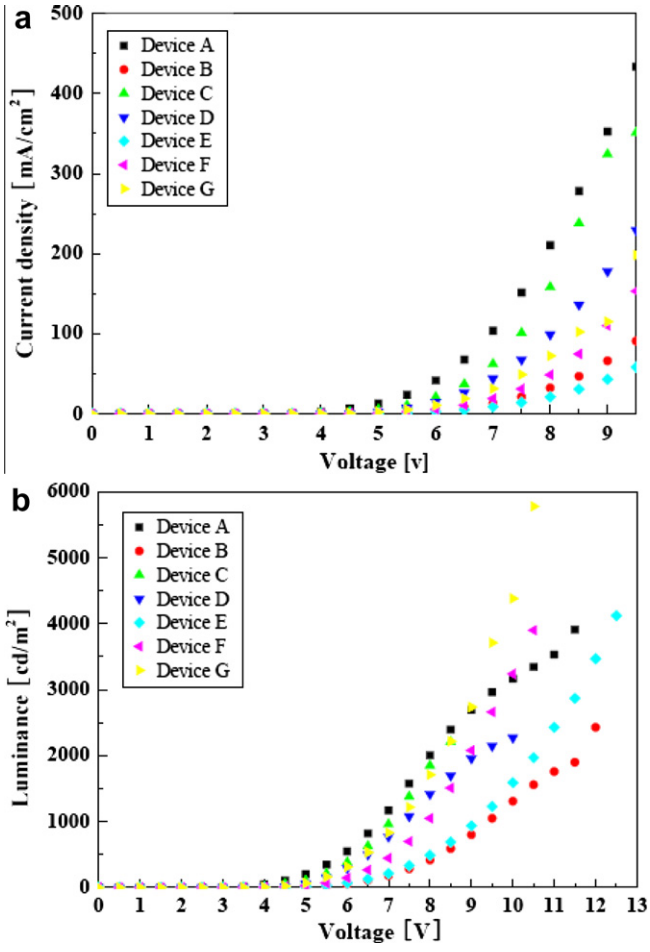

Fig. 4. (a) Current density versus voltage characteristics of all devices. (b) Luminance versus voltage characteristics of all devices.

layer (ETL), an emission zone is narrow and this produces a negative effect on the efficiency. On the other hand, the excitons of devices F and G with D-EML are generated from the interface of MADN/DNBN, i.e., in the middle of the EML, and are diffused in the direction of both anode and cathode sides, generating a wide RZ. Therefore, the D-EML system improves device efficiency effectively.

Hole-only devices (HOD) and electron-only devices (EOD) were fabricated to prove the previous assumption in Fig. 3(a) and (b) whose structures are as follows: ITO (150 nm)/NPB (50 nm)/MADN:8% PCVtPh (HOD-1) or DNBN:8% PCVtPh (HOD-2) (30 nm)/NPB (30 nm)/Al (100 nm) as HODs and ITO (150 nm)/BAlq (50 nm)/MADN:8% PCVtPh (EOD-1) or DNBN:8% PCVtPh (EOD-2) (30 nm)/BAlq (30 nm)/Al (100 nm) as EODs, respectively. It was found in Fig. 3(c) that HODs show current densities of 401.77 and 7.95 mA/cm^2 at 10 V and EODs also show current densities of 43.28 and 331.92 mA/cm^2 at 10 V. HOD-1 using MADN and EOD-2 using DNBN shows higher current density at the whole voltage than HOD-2 using DNBN and EOD-1 using MADN, respectively. This indicates that MADN and DNBN have excellent holes and electrons unipolar characteristics, respectively. Therefore, in order to maximize the efficiency by balancing charge carriers from both the anode and cathode, MADN and DNBN layers must be located near the anode and cathode sides, respectively, in the D-EML system.

Fig. 4(a) and (b) shows current density versus voltage characteristics and luminance versus voltage characteristics of all devices. It was found in Fig. 4(a) that the current densities for all seven devices were 433, 91, 351, 229, 58, 153, and 198 mA/cm^2 at 9.5 V. Devices A and C had the highest current densities due to the most efficient hole- and electron-pathways without trapping carriers in the EML. Device E, using the host of DNBN, showed lower current density at the operating voltage than device D, using the host of MADN. This indicated that DNBN has lower mobility than that of MADN. DNBN also has unipolar characteristics with excellent electron-transporting ability compared with MADN, which has good hole-transporting ability in our devices as shown in Fig. 3(c). Device G with MADN (20 nm)/DNBN (10 nm) showed a higher current density than device F with MADN (10 nm)/DNBN (20 nm), which also seems to be due to the MADN having

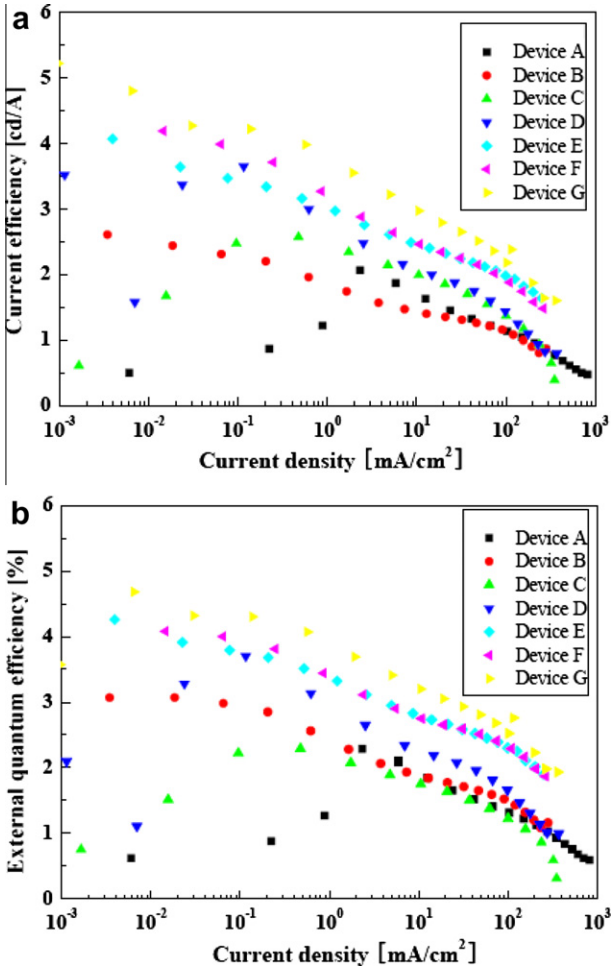

Fig. 5. (a) Current efficiency versus current density of all devices. (b) External quantum efficiency versus current density characteristics of all devices.

higher mobility than of DNBN. It is also found in Fig. 3(b) that the maximum luminances for all seven devices were 3910, 2430, 2210, 2270, 4120, 3900, and 5780 cd/m^2 at 11.5, 12.0, 8.5, 10.0, 12.5, 10.5, and 10.5 V, respectively, where device G showed the highest luminance among them. Devices E, F, and G, with the host of DNBN, tend to show higher luminance characteristics at operating voltages than devices C and D without the host of DNBN. Consequently, the large enhancement of luminance in devices containing DNBN seems to be due to the slowing down of hole mobility by the deep HOMO level of DNBN.

Fig. 5(a) and (b) shows current efficiency and EQE versus current density characteristics of all devices, where the maximum current efficiency values for all devices were 2.06, 2.61, 2.57, 3.65, 4.07, 4.19, and 5.22 cd/A at 2.336, 0.003, 0.476, 0.116, 0.004, 0.015, and 0.001 mA/cm^2, and

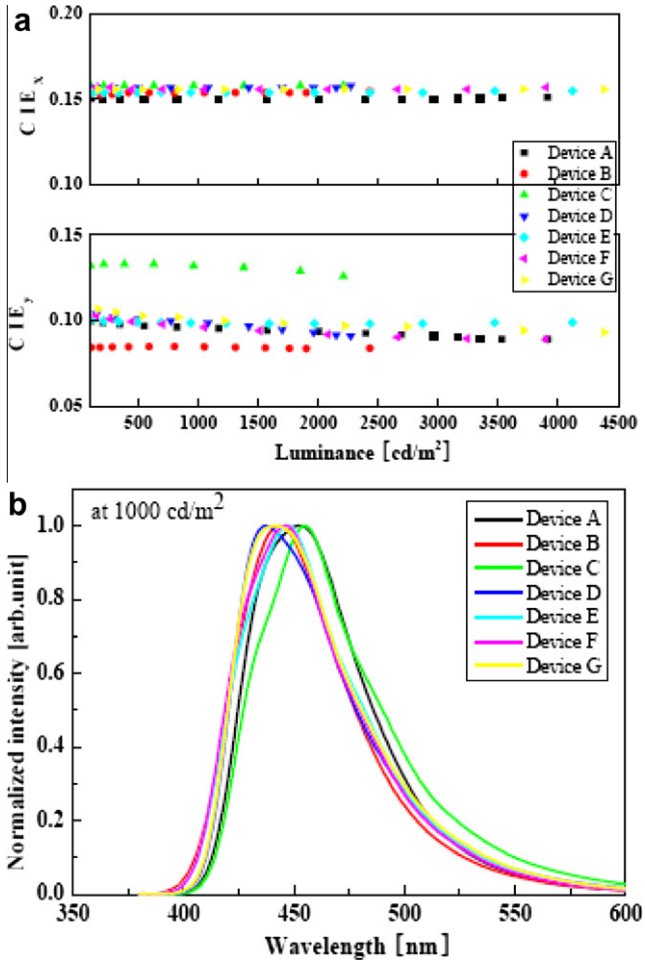

Fig. 6. (a) Commission Internationale d'Eclairage coordinates of all devices for luminance from 100 to 4500 cd/m^2. (b) Electroluminescence spectra of all devices from 350 to 700 nm at 1000 cd/m^2.

Table 2
Various characteristics of all devices, including a maximum luminance, current efficiency, power efficiency, EQE, and CIE$_{x,y}$ coordinates at 1 mA/cm^2, respectively.

Devices	Max. luminance (cd/m^2)	Current efficiency[a] (cd/A)	Power efficiency[a] (lm/W)	EQE[a] (%)	CIE$_{x,y}$[a]
A	3910	1.35	1.20	1.46	(0.15, 0.10)
B	2430	1.84	1.13	2.42	(0.15, 0.08)
C	2210	2.43	1.77	2.17	(0.15, 0.13)
D	2270	2.81	1.90	2.97	(0.15, 0.09)
E	4120	3.02	1.74	3.36	(0.15, 0.09)
F	3900	3.23	2.02	3.40	(0.15, 0.09)
G	5780	3.81	2.58	3.91	(0.15, 0.09)

[a] At a current density of 1 mA/cm^2.

the maximum EQE values for all devices were 2.28%, 3.07%, 2.29%, 3.70%, 4.26%, 4.08%, and 4.68% at 2.336, 0.003, 0.476, 0.116, 0.004, 0.015, and 0.006 mA/cm^2, respectively. The current efficiency values for all devices were also shown to be 1.35, 1.84, 2.43, 2.81, 3.02, 3.23, and 3.81 cd/A and 1.46%, 2.42%, 2.17%, 2.97%, 3.36%, 3.40%, and 3.91% at 1 mA/cm^2. Device G, with the D-EML system with MADN (20 nm)/DNBN (10 nm), exhibits EQE close to almost 5%, which is one of the highest EQEs previously reported on deep-blue OLEDs with CIE$_y$ < 0.10 to the best of our knowledge. This indicates that device G showed better carrier recombination zone in the D-EML system compared to other devices having a single-emitting layer (S-EML), where the RZ in the D-EML, when located far away from the interface of HTL/EML or EML/ETL, prevents excitons from approaching any quenching sites at these interfaces. Device G, with MADN (20 nm)/DNBN (10 nm), had higher efficiency than device F with MADN (10 nm)/DNBN (20 nm) since excitons are generated farther from the NPB layer in device G than in device F, where the NPB was known to have many quenching sites. Moreover, the devices in this study have hole-dominant characteristics due to higher hole mobility of the HTL than electron mobility of the ETL. In order to enhance the recombination of holes and electrons by charge balance, the MADN layer used as a hole-dominant EML should be thicker than the DNBN layer used as an electron-dominant EML. Therefore, although device F with MADN (10 nm)/DNBN (20 nm) had D-EML, it did not show higher performance compared to S-EML.

Fig. 6(a) shows CIE$_{x,y}$ coordinates versus luminance characteristics from 100 to 4500 cd/m^2 of all devices. They had emission characteristics of CIE$_{x,y}$ coordinates from (0.15, 0.10), (0.15, 0.08), (0.15, 0.13), (0.15, 0.10), (0.15, 0.10), (0.15, 0.10), and (0.15, 0.10) at 100 cd/m^2 to (0.15, 0.09), (0.15, 0.08), (0.15, 0.12), (0.15, 0.09), (0.15, 0.09), and (0.15, 0.09) at the maximum luminances (device A = 3910, device B = 2430, device C = 2210, device D = 2270, device E = 4120, device F = 3900, and device G = 5780 cd/m^2). Fig. 6(b) also shows the EL spectra of all devices from the wavelength of 350–600 nm at 1000 cd/m^2. All devices showed maximum peaks at 452, 444, 455, 437, 448, 446, and 440 nm. Various characteristics of all devices are summarized in Table 2, such as maximum luminance, current efficiency, EQE, and CIE$_{x,y}$ coordinates at 1 mA/cm^2.

4. Conclusions

In conclusion, a deep-blue OLED has been successfully demonstrated by introducing a novel emitter of PCVtPh, and the D-EML system consisted of MADN and DNBN. The D-EML system, with MADN (10 nm)/DNBN (20 nm), had good confinement of holes and electrons within the EML and good charge balance for carrier recombination. This optimized deep-blue OLED showed a maximum luminance of 5780 cd/m^2 at 10.5 V, a maximum EQE of 4.68%, a maximum current efficiency of 5.22 cd/A, and CIE$_{x,y}$ coordinates of (0.15, 0.09). This deep-blue OLED also showed higher efficiency by a factor of two and more deep-blue emission than the control device.

deposited on the surface of SiO_2 gate dielectric to isolate the electron traps. However, not all hydroxyl groups on polymeric dielectrics would trap electrons when OFETs were operated in the n-type regime. For example, by using polyvinyl alcohol (PVA) as gate dielectrics [14–16], ambipolar pentacene devices or the n-type only pentacene-based OFETs were demonstrated. Accordingly, correlations of the electron traps with the hydroxyl groups of the dielectric layer should be further studied.

In this study, pentacene-based OFETs were made with three kinds of polymer gate dielectrics, such as PVA, PVP, or PS, and with Ca, aluminum (Al), or gold (Au) metals as source-drain electrodes to investigate the mechanism of the n-type conduction in pentacene-based OFETs. The results show that the hydroxyl groups of PVP gate dielectric, trapping electrons as those of SiO_2 gate dielectrics, restrict n-channel formation in pentacene-based OFETs, but the hydroxyl groups of PVA don't. It could be clearly explained by the difference of the dissociation constant of protons on PVP and PVA. Additionally, while PS was used as the gate dielectric, the types of OFET conductive channels mainly depend on the charge injection conditions as determined by the work function of the source-drain electrodes. Finally, a pentacene-based OFET device using Ca as source-drain electrodes with PS as gate dielectric was fabricated, and its electron mobility could be up to 0.077 $cm^2s^{-1}V^{-1}$.

2. Experiments

The basic device in top contact bottom gate configuration herein, presented in Fig. 1a, comprises a pre-patterned indium–tin–oxide (ITO) on glass (RITEK Corp.) as the gate electrode that was sequentially coated with a thin layer of poly(3,4-ethylenedioxythiophene):polystyrenesulfonate (PEDOT:PSS Bayer Corp. VP-CH 8000), a double-layer gate dielectric (PS, PVA, or PVP on cross-linked PVP), a pentacene active layer, and metal source-drain electrodes. PEDOT:PSS layer was cast on a pre-patterned ITO glass substrate at 4000 rpm. The low conductivity PEDOT:PSS layer is used to smoothen the relatively rough ITO surface, which reduces the gate leakage current, improves the stabilities of devices during the long-term operation, and also increases the adhesion of PVP layer on the gate electrode. The bottom layer of gate dielectric was prepared by spin-coating (at 6000 rpm) the PVP (110 mg)/poly(melamine-*co*-formaldehyde) methylated (40 mg) in propylene glycol monomethyl ether acetate (PGMEA) solution (1 ml) on

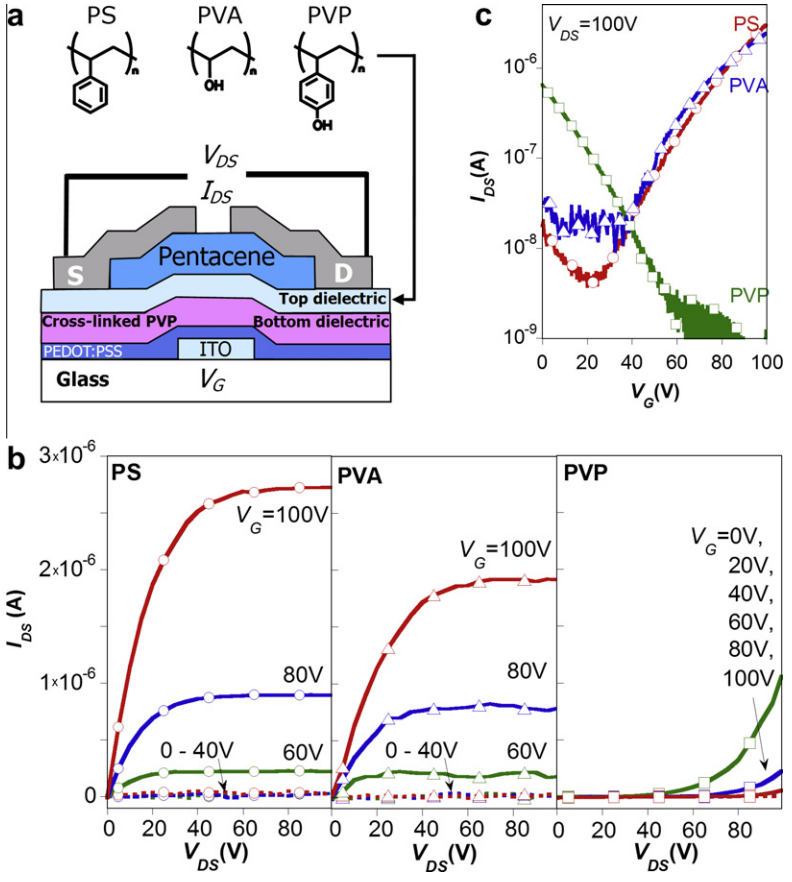

Fig. 1. (a) The structure of a pentacene-based OFET with metal electrodes, and PS, PVA, or PVP polymeric dielectrics spin-cast on cross-linked PVP as double-layer gate dielectrics. The chemical structures of PS, PVA, and PVP polymer are illustrated. (b)The output characteristics of I_{DS} vs. V_{DS} plot of pentacene-based OFETs with Ca source-drain electrodes, and three polymers as top gate dielectrics at V_G of 0 V to +100 V. (c) The transfer characteristics of I_{DS} vs. V_G plot of pentacene-based OFETs at a constant V_{DS} of +100 V with PS (○), PVA (△), and PVP (□) as the top gate dielectrics.

the PEDOT:PSS/ITO glass substrate. The substrate was baked at 120 °C for 5 min and then at 200 °C for 20 min to enable the formation of a cross-linked PVP dielectric [17]. The bottom dielectric provides good insulation and smooth surfaces which effectively reduced gate leakage currents. Next, the top dielectric made from one of three polymer solutions, PVA, PS, or PVP, was cast on the surface of the cross-linked PVP layer at 6000 rpm. PVA solution was made from 50 mg/1 ml de-ioned water solution, PS solution was made from 50 mg/1 ml toluene solution, and PVP was made from 50 mg/1 ml PGMEA solution. The substrate was heated to eliminate the residual solvent after spin-coating the second polymeric layer. The chemical structures of the three top dielectric polymers are shown in Fig. 1a. The pentacene (800 Å) active layer was deposited through a shadow mask on double-layer dielectric/PEDOT:PSS/ITO glass substrate inside the vacuum thermal evaporator (10^{-6} Torr). Through a shadow mask, a chosen metal material was thermally deposited on the surface of pentacene layer. The channel length (L) and width (W) of deposited electrodes in this work are 140 and 1000 μm, respectively. All of these steps were implemented inside a nitrogen-filled glove box, except for the preparation of the two layers of polymeric gate dielectrics and PEDOT:PSS/ITO glass substrate.

For studying the correlation of the different injection barriers of electrons or holes with device performance, Ca, Al, and Au, with work functions of 2.9, 4.2, and 5.1 eV, respectively, were selected as source-drain electrodes, respectively [11]. The electrodes of Ca are suitable for injection of electron carriers, for the smallest barrier height to the LUMO of pentacene molecules. For injection of hole carriers, the Au electrodes are suitable because of the matching of the work function of Au and the highest occupied molecular orbital (HOMO) of pentacene molecules (5.0). Then, the barrier heights from work function of Al to LUMO and to HOMO of pentacene are comparable, so ambipolar behaviors of OFETs with Al as source-drain electrodes are expectably observed.

Polymeric dielectrics, PS (M_w = 20,000), PVP (M_w = 20,000), PVA (M_w = 30,000–70,000, P8136), and cross-link agent, poly(melamine-*co*-formaldehyde) methylated, were purchased from Aldrich and used directly. Pentacene was also purchased from Aldrich without further purification.

The output and transfer characteristics of pentacene-based field-effect transistors were measured by HP 4145B semiconductor analyzer under N_2 environment. A pentacene-based field effect mobility with hole and electron mobility were extracted from the measured transfer curves according to the standard transistor's current–voltage equation in the saturation regime as follows: [18].

$$I_{DSsat} = (WC_i/2L)\mu(V_G - V_t)^2 \quad (1)$$

where W and L are the width and length of the channel, respectively, Ci is the gate dielectric capacitance, V_G is the gate voltage, and V_T is the threshold voltage. The μ value is field effect mobility for hole and electron conduction.

The capacitance–voltage (C–V) measurements were conducted with an HP 4284A Precision LCR meter. C–V measurements were carried out under biased voltage (−40–40 V) plus modulated voltage (100 mV) conditions. The alternate current responses versus bias voltages were measured to estimate the capacitance at the frequency modulated from 500 to 1 MHz. The device of metal–insulator-semiconductor (MIS) configuration as shown in the inset of Fig. 2 is composed of the ITO glass substrate, a PEDOT:PSS layer, a double-layer dielectric of cross-linked PVP with PVA, PVP, or PS, a pentacene active layer, and a metal (Ca) top electrode for the C–V measurements. The device area of MIS devices for the measurement of capacitance is of 2.0 mm^2. All MIS devices were measured inside a nitrogen glove box.

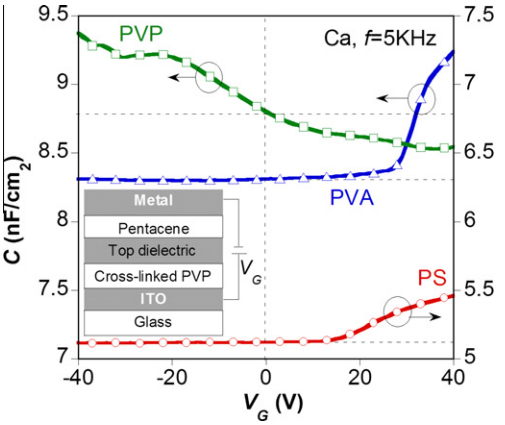

Fig. 2. Capacitance–voltage plots of the three devices with MIS configuration with PS (○), PVA(△), and PVP(□) as top dielectrics, respectively, and Ca metal as gate electrodes measured at the frequency of 5 KHz. The insert illustrates the device of MIS configuration.

3. Results and discussion

3.1. The influence of polymeric gate dielectrics on n-channel formation

In order to observe n-type conduction of pentacene-based OFETs, Ca was used as the source-drain metal electrodes of low work function (2.9 eV) for the injection of electrons to the LUMO level of pentacene molecules. Fig. 1b plots the output characteristics, drain current (I_{DS}) versus source-drain voltage (V_{DS}) of pentacene-based OFETs, which were operated at positive gate voltage from 0 to +100 V, n-channel accumulation regime. Three sets of curves represent three OFETs with PS, PVA, and PVP, as top gate dielectrics. OFETs with PS and PVA as top gate dielectrics performed the clear n-type channels with saturated and apparent pinch-off drain output currents. However, the OFET with PVP as top gate dielectric outputted diode-like currents. The currents are decreased as the gate voltage increased, which can be attributed to the hole flows. There was no n-channel formation in the OFET with PVP, although Ca electrodes were used for the efficient injection of electrons.

Fig. 1c plots the transfer characteristics of OFETs in Fig. 1b at V_{DS} of +100 V. The I_{DS} currents of OFETs with PS

or PVA are increased as the gate voltage increased, but the I_{DS} current of the OFET with PVP was declined as the gate voltage increased. It indicates that OFETs with PS or PVA are able to induce negative charges to form n-type channels, but the OFET with PVP is not. These results suggest that n-type channels of pentacene-based OFETs are correlated with both the effective injection of electrons from source-drain electrodes and the interfacial properties of gate dielectrics.

The *C–V* measurement was applied to investigate the types of accumulated charges between an organic semiconductor layer and a gate dielectric. The quasi-static capacitance per area versus bias voltage of devices of MIS structure is presented in Fig. 2. The pentacene was deposited on PS, PVA, and PVP top gate dielectric correspondingly with Ca as top electrodes. The baselines of capacitance curves of devices with PVP gate dielectric and PVA gate dielectric are higher than that of PS gate dielectric due to higher dielectric constants by the hydroxyl groups. Two of capacitance curves start to rise up when biased voltages are larger than +15 V for PS and +30 V for PVA, but the capacitance of devices with PVP gate dielectric drops as voltage bias increasing positively. The result of *C–V* measurements indicates that charge accumulation depends on the bias voltage applying to the interfaces of pentacene and polymer gate dielectrics, such as PS or PVA, when the n-type channel is formed. However, there is no n-type channel formation existing on the interface of pentacene and PVP gate dielectrics.

Accordingly, the functional groups on polymeric gate dielectrics should be the important parameters to determine the type of accumulated charge carriers, n-type or p-type accumulation. Comparing the chemical structures of the polymer gate dielectrics used in this study, firstly, both PVP and PS contain benzene rings attached on the side chain of polymers, but PVP has an additional hydroxyl group on the benzene ring. Secondly, both PVA and PVP are with hydroxyl groups. The chemical schematics of three polymers are shown in Fig. 1a. It is assumed that the hydroxyl groups on PVP interfere with the formation of n-type channel. The functionality of hydroxyl groups on PVA is different from that of PVP, because OFETs of PVA gate dielectrics present the decent n-type output characteristics.

3.2. The hydroxyl groups on PVP for n-channel formation

Fig. 3 demonstrates a transfer curve comparison of pentacene-based OFETs with different blend ratios of PVP and PS mixture as top layer of the double-layer gate dielectric at a constant V_{DS} of +100 V. The OFET structure with Ca electrodes was the same in Fig. 1a, and PVP:PS mixture was made from total 50 mg of PVP and PS in 1 ml PGMEA solution. When the ratio of PVP is 100%, a transfer characteristics curve is pure p-type. As decreased to 75% and to 50%, hole currents of devices are obviously decreased. Curves begin to appear ambipolar at 25% and to become n-type completely at 0%. Obviously, the transfer characteristics shifted from p-type to n-type depend strongly on the composition of PVP in the top gate dielectric. The ratio of PVP presents the percentage of hydroxyl groups on the interface of pentacene and the mixed PVP:PS gate dielectrics relatively. To further investigate the correlation between mixture ratio and surface hydroxyl groups, the result of contact angle measurements are presented in Fig. 3. As expected, an increase in contact angle of water from about 67° to about 94° when the portion of PVP decreases from 100% to 0%. The change of conductive channels from p-type to n-type suggests that hydroxyl groups on PVP dielectric cause the suppression of n-channel formation in pentacene-based OFETs. It agrees with the research reported by Chua et al. that the hydroxyl groups on the surface of silicon dioxide gate dielectric trap electrons and limit n-channel formation of OFETs [10]. However, PVA with hydroxyl groups had been reported as gate dielectrics for n-type or ambipolar pentacene-based OFETs [14–16]. The different functionalities of hydroxyl groups on PVP and PVA should be discussed.

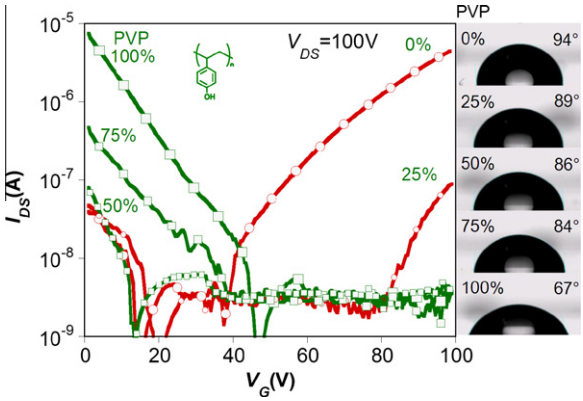

Fig. 3. The transfer characteristics of I_{DS} vs. V_G plot of pentacene-based OFETs with PVP and PS mixture as top gate dielectrics. PVP:PS mixture ratio is made from 100% of PVP to 0%. Currents of hole carriers are decreased gradually, and currents of electron carriers appear when PVP portion is less than 50%. The measurements of contact angles of water on the surfaces of PVP:PS mixture are presented.

3.3. The difference of hydroxyl groups on PVP and on PVA

The dissociation constants of protons for aliphatic alcohols are different from those of aromatic alcohols. The *pKa* value of methanol, ethanol, and 1-propanol are 15.5, 15.9, and 16.1, respectively. However, *pKa* value of phenol is about 9.5–10 [19,20]. Aromatic alcohols are mostly like a very weak acid because the negative charge after the dissociation of protons on the hydroxyl group can be stabilized by the conjugated molecule. Although both PVP and PVA have hydroxyl groups, the polymer of phenol, PVP, trends to lose its proton on the hydroxyl group as compared to PVA. Protons dissociated from PVP gate dielectrics result in the traps of electrons on the channels of OFETs. However, the hydroxyl groups in PVA have the minor effect on the generation of electron traps, because of the lower dissociation constant of protons. Fig. 4 illustrates a schematic drawing for the influence of dissociated protons on the electron channel in the pentacene active layer. When positive bias is applied on the gate electrode, an external electric field probably accelerate the dissociation of pro-

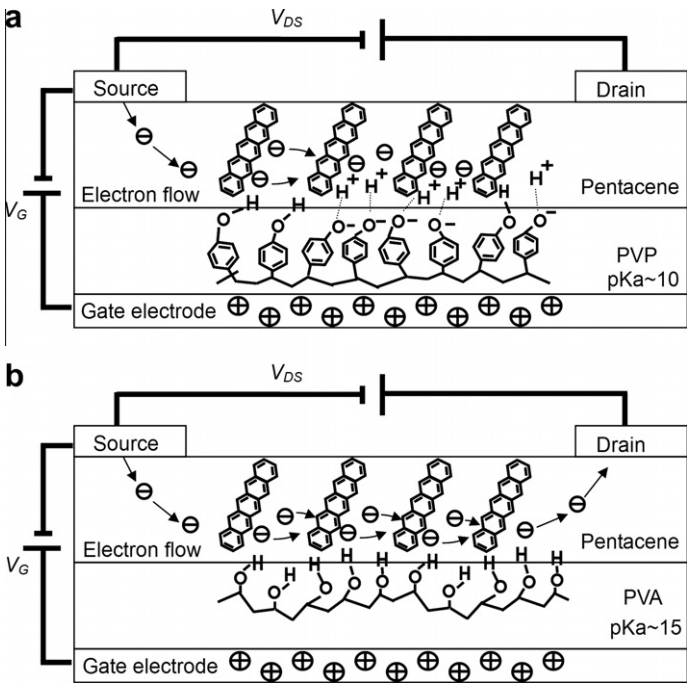

Fig. 4. A schematic demonstrates that electrons flow near the interface of pentacene and top gate dielectric. (a) Electrons are trapped by dissociated protons from PVP dielectric whose *pKa* is estimated around 9–10. (b) For PVA ($pKa \sim 15$) dielectric case, protons are not dissociated from hydroxyl groups, and electrons are not trapped.

tons on the hydroxyl groups of PVP gate dielectrics. Numerous traps of electrons are created to capture the injected electrons and block the electron flow. For OFETs of PVA ($pKa \sim 15$) as gate dielectrics, the influence of dissociated protons on the formation of the electron channel is minor, and characteristics of the n-type conduction can be observed as shown in Fig. 1b.

Dissociation of protons from PVP gate dielectrics was proposed to explain the output characteristics of OFETs. It was reported that PVP gate dielectrics output mobile ions, protons, in P3HT based OFETs when PVP gate dielectrics were exposed to moisture [21]. Additionally, the *pKa* value of hydroxyl groups on the surface of silicon dioxide was approximately 9–10 [22,23], which is similar to that of PVP. It might explain electron traps which are the dissociated protons on the surface of SiO_2 gate dielectrics. Without a modification layer on the SiO_2 gate dielectric, there is no n-type output characteristics in pentacene-based OFETs [10].

The different functionality of hydroxyl groups on PVP and PVA gate dielectrics can be detected by *C–V* measurements of devices with MIS configuration as shown in the insert of Fig. 2. For the MIS device made of PVP as the top layer of the double-layer dielectric, the magnitude of capacitance is decreased as the bias voltage operates from −40 to +40 V. This result interprets the accumulation of holes in the MIS device (probably at interface between pentacene and PVP) is favorable while the device is operated at negative gate voltage, p-type conduction regime. However, the accumulation of electrons is unfavorable while the MIS device is operated at positive gate voltage, n-type conduction regime. The magnitude of capacitance is decreased as the bias voltage increased. It is suggested that the n-type channel is inhibited by the dissociated protons from PVP gate dielectrics. We note that the magnitude of capacitance at $V_G = 0$ is higher than it at 20 V, which probably suggests the dissociation of protons in PVP gate dielectric, causing the interfacial doping effect. For MIS devices of PVA and PS as the gate dielectrics, the magnitudes of capacitance are increased while the devices are operated at the positive gate voltage, n-type conduction regime. The accumulation of electrons at the interface between pentacene and PVA or PS accounts for the n-type output characteristics of OFETs as shown in the Fig. 1b and c.

3.4. Influence of source-drain electrodes on the output characteristics of pentacene-based OFETs

The output performance of pentacene-based OFETs made of three metals (Au, Al, and Ca) of different work functions and three polymers (PVP, PS, and PVA) as the source-drain electrodes and top gate dielectrics, respectively, are summarized in Table 1. A comparison of OFETs of different source-drain metal electrodes provides the information regarding the correlations of the charge injection ability with n-type or p-type channel in OFETs. Additionally, OFETs of three different top gate dielectrics (PVP, PS, and PVA) are fabricated to investigate the influence of the top gate dielectrics on the formation of n-type or p-type channel.

In the case of OFETs with PVP as top gate dielectrics, there was no I_{DS} of n-type measured because the interface

* The channel length (L) and width (W) of source-drain electrodes are L = 140 μm and W = 1 mm.
** Capacitance values are obtained from capacitance–voltage measurement at +40 V for n-type and −40 V for p-type capacitance in driving frequency of 5 kHz.
*** I_{DS} (A) are measured in the saturation region at V_G of +100 V for n-type and at V_G of −100 V for p-type characteristics.

of pentacene and PVP interferes with the formation of n-type channel. However, the current I_{DS} of p-type is relatively higher than those with PS or PVA as top gate dielectrics which could be probably contributed to the larger size of pentacene grains on PVP [24,25]. Nevertheless, the intensity of the current I_{DS} went larger when the injection barrier from the work function of electrode metals to the HOMO level of pentacene molecules became smaller.

When top gate dielectrics of OFETs were replaced by PS, the type of conduction channel was highly correlated with the work function of source-drain electrodes. The operations of OFETs with PS are able to be the type of n-, ambipolar, or p-, while electrode metals of Ca, Al, or Au are adopted, respectively. In this case, the work function of metals simply determines the type of charge carriers in pentacene-based OFETs. It also indicates that the interface of pentacene and PS is likely trap-free for both hole and electron transport.

For the case of OFETs with PVA as top gate dielectrics, the output characteristics seem to prefer n-type operation. Using Ca as electrodes, the I_{DS} is about one third of that of the OFET using Al as electrodes. The cause of degradation could be the oxidization of Ca electrodes by water molecules attached on PVA. When adopting Al as source-drain electrodes, the OFETs only perform n-type behaviors which were also reported in our previous study [16]. When the OFETs use Au as electrodes, the output characteristic is ambipolar. The same ambipolar behaviors of pentacene-based OFETs with PVA as gate dielectrics and Au as source-drain electrodes agreed well with in the studies by Singh et al. [14,15]. These results could not explain by the barrier height of charge injection from the metal to the pentacene layer. So far, these extraordinary phenomena of OFETs with PVA are still under investigation.

In spite of the influence of gate dielectrics, the work function of source-drain electrode metals majorly determines the type of, negative, ambipolar, or positive, of output characteristics of pentacene-based OFETs. Further, the interface of pentacene and top gate dielectrics influences the conduction channels of OFETs which are related to charge transport through organic semiconductors. PVP gate dielectrics limit the formation of n-type channels regardless of metals of source-drain electrodes. PS gate dielectrics provide trap-free interfaces for both hole and electron carriers. For the case of PVA top gate dielectrics, the OFETs tend to operate rather in n-type channels than in p-type channels. To fabricate better n-type pentacene-based OFETs, it is suggested to adopt Ca as source-drain electrodes and PS as top gate dielectrics, and the n-type performance has achieved the electron mobility of 0.077 cm^{2}s^{-1}V^{-1}, which is a decent magnitude for pentacene-based n-type OFETs without further optimization.

4. Conclusions

In summary, this study presents the influence of polymer gate dielectrics and S-D electrodes on the formation of n-type channel in pentacene-based OFETs. For fabricating n-type pentacene-based OFETs, these gate dielectrics with hydroxyl groups and higher dissociation constant of protons, such as PVP or the surface of SiO_2, should not be considered because dissociated protons from dielectrics will trap electrons. It is recommended to employ Ca as source-drain electrodes and PS as top gate dielectrics, and its electron mobility could reach up to 0.077 cm^{2}s^{-1}V^{-1}. For further enhancing the n-type performance of pentacene-based devices, better charge transport quality will be required by improving crystallization of organic semiconductor material, such as optimizing deposition and post anneal treatments. In addition, favorable charge injection from metal electrodes to semiconductor material is also significant by minimizing injection barrier height. However, to balance low work function for n-type injection and air-stability of electrodes will be a challenge for n-type pentacene-based devices.

to be $\sim 0.2\ cm^2/V\,s$ at the highest [1]. The order of the air-stability in the family is naturally explained by difference in ionization potentials (IPs) of these compounds, where IP for pDA2T is reported to be 0.05–0.1 eV deeper than for pBTTT [1]. In this work, we employ surface modification with vapor-grown self-assembled monolayers (SAMs) of decyltriethoxysilane (DTS) and (heptadecafluoro-1,1,2,2-tetrahydrodecyl)triethoxysilane (FTS), with which we previously reported their effect of reducing the number of surface-trap levels and very high performance for organic single-crystal transistors [6,7]. In addition, the effect of prolonged annealing is investigated to maximize performance of the pDA2T TFTs, expecting improved ordering during the treatment above the glass-transition temperature. Moreover, lower surface energy on the SAMs-coated Si/SiO_2 substrates favors "edge-on" orientation of the thiophene chains, so that larger probability of the π-stacks orientated parallel to the channel can increase the mobility, as is argued in pBTTT devices [3].

Before depositing the SAMs, highly doped silicon substrates with thermally grown SiO_2 insulating layer (with the thickness of 100 nm) were carefully cleaned with acetone and isopropyl alcohol. The surface is ozone-treated for 2 min. We deposit hydrophobic organosilane SAMs of DTS or FTS by a vapor deposition process [8]. A *o*-dichlorobenzene solution of 10 mg/mL is prepared with pDA2T polymers. The polymer pDA2T was spun from the solution at a rate of 4000 rpm on the substrates in a relatively dry circumstances at less than 1%-humidity in a glove box at around 20 °C. The atmosphere is substituted to nitrogen gas with its content of more than 99%. The samples were dried and annealed at 100 °C, which is well above the glass-transition temperature of ~50 °C [9] in the glove box. In order to investigate the effect of the annealing time, we prepared samples annealed for 10 min, 120 min and

channel lengths L and the channel width W are 50–100 μm and 1500 μm, respectively. Electrical measurements of the transistors were carried out in ambient condition with a Keithley 4200 semiconductor parameter analyzer. To examine the air-stability, samples were stored in the conditions of 60%RH and the measurements were performed from time to time for over several weeks after the sample preparation. Fig. 1(a) shows schematic illustration of the devices.

Surface morphology is characterized by atomic-force microscopy. The samples with DTS and FTS with the annealing time of 120 min are shown in Fig. 1(b) and (c), respectively. As both surfaces are hydrophobic, the grain grew rather large. The grain size is typically ~100 nm, reproducing the morphology reported in [1]. We note that the morphology appears to be similar among samples with different annealing times.

Fig. 2(a) and (b) shows output characteristics of the samples with DTS and FTS, respectively. The results of the well-saturated characteristics indicate that both TFTs are typical field-effect transistors well approximated by the gradual-channel model with sufficiently long L (= 100 μm). Therefore, the use of the equation

$$I_D^{sat} = \frac{L}{2W}\mu C(V_G - V_{th})^2 \quad (1)$$

is fully guaranteed, where C is capacitance of the gate dielectric insulator (100-nm thick SiO_2). Therefore, mobility μ is evaluated from the plot of the saturation current $\sqrt{I_D^{sat}}$ *vs.* gate voltage V_G with the intercept of the threshold voltage V_{th}.

Such plots are given in Fig. 3(a) for the pDA2T sample with DTS SAMs annealed for 120 min. We keep the sample in a container with the humidity of ~60% and measured the characteristics after 1 day, 3 days, 8 days and 18 days. The nearly merged curves demonstrate that good stability in the humid air is indeed realized. Mobility is estimated to be ~ 0.13 $cm^2/V\,s$ using Eq. (1) from the slope of the linearly regressing part. The estimated μ is plotted as a function of time in Fig. 3(b) together with the results for similarly prepared samples with different annealing times. For all the samples, μ is essentially unchanged for more than 2 weeks, demonstrating significant improvement in the air-stability as compared to previous report [1]. We note that our present DTS SAMs are deposited from vapor, while mostly solution-processed SAMs are used in literatures [1–3], which could be related to the improvement in the stability. It is to be further investigated experimentally to elucidate the detailed mechanisms of the device instability in air.

The values of mobility are in the range of 0.08—0.17 $cm^2/V\,s$, which essentially reproduced the reported result for the same compound [1]. The tendency of higher μ with longer annealing time in the glass state suggests that the extent of ordering of the polymer chains can be improved slowly with time. A primitive X-ray diffraction scan did not show difference in the profiles, indicating that the difference is not due to obvious variation in their structures. It is to be further studied by low-angle X-ray diffraction using high-power light sources for more detailed structural change, for example.

Fig. 3(c) shows transfer characteristics of the sample with FTS annealed for 10 min, plotted similarly to Fig. 3(a). The mobility estimated by Eq. (1) is ~ 0.4 $cm^2/V\,s$. The air-stability for this sample is equally good as plotted together in Fig. 3(b). We have prepared other samples with different

annealing times, so that μ ranged in 0.4—0.8 $cm^2/V\,s$, though the variation is not correlated with the annealing times but film wettability. The larger mobility itself can be attributed to lower surface energy on the FTS substrate than on the DTS substrate, favoring better edge-on π stacks, as is argued formerly [3]. We note that the presence of larger dipole in the FTS layer accumulate carriers at the surface of the polymer semiconductor, which is responsible for the shift in V_{th} [6,10].

In conclusion, air-stability and high field-effect mobility comparable to amorphous silicon TFTs are simultaneously realized using high-IP compound pDA2T and employing fabrication processes of surface modification with SAMs and prolonged annealing. Since the polymer TFTs are of significant advantage in solution-based low-cost production for large-area electronics devices, the achievement of the high performance in practically applicable air-stable transistors further strengthens their material advantage and drives their future commercialization.

were considered ideal for host–guest relationship but their crystallization issues and non-uniform film thickness have aggravated as additional problems.

Generally, most of the host materials either transport holes or electrons in a device but unbalanced hole and electron currents makes the recombination zone narrower, thereby shifting it either close to hole transport layer (HTL) or electron transport layer (ETL). Thus narrower charge recombination zone in PHOLEDs are prone to triplet–triplet exciton quenching due to local high density of triplet excitons and also long diffusion of the triplet excitons [12,13]. Therefore, bipolar small molecule hosts can meet the requirements of balancing the charge density for making high performance simple device structure. For improving the charge-transferring capability of bipolar molecules, it is desirable to localize the highest occupied molecular orbital (HOMO) and lowest occupied molecular orbital (LUMO) level at their respective hole and electron transporting moieties. To the best of our knowledge very few devices based on solution process bipolar small molecules have been reported so far [14–16].

Typically, *N*,*N*′-diphenyl-*N*,*N*′-bis(1-naphthyl)(1,1′-biphenyl)-4,4′diamine (NPB) has bipolar characteristics in OLEDs with both hole and electron transporting property. It has 5.4 eV HOMO and 2.3 eV LUMO values and a low triplet energy (2.3 eV) [17]. For practical use of the host in PHOLEDs, its LUMO energy is too high compared with general host materials even though its electron mobility is good as 9×10^{-4} cm^2/vs [18]. In solution process devices, it forms non-uniform surface with high roughness due to crystallization of its molecules upon thermal treatment [19]. Therefore, NPB was reported as a hole-type host in the mixed host system [10]. In order to reduce the electron-injection barrier and enhancing the electron mobility of NPB molecule, we report, NPB modified two novel bipolar molecules, 4,4′-bis[*N*-(1-naphthyl)-*N*-(3-pyridinylamino]biphenyl (NPyB) and 4,4′-bis [*N*-(3-quinolinyl)-*N*-phenylamino]biphenyl (QuPB) with their synthetic method and material characteristics. We also employed NPyB and QuPB host materials for fabricating high-efficiency electrophosphorescent solution processed red OLEDs. The multilayered electrophosphorescent OLEDs fabricated from 1,2-dichlorobenzene solution containing spin-coated NPyB and QuPB hosts blended with a dopant, bis(2-phenylquinoline(acetylacetonate)iridium (Ir(phq)$_2$acac) emitted red phosphorescent light. The bipolar NPyB and QuBP hosts show good solubility and stability in 1,2-dicholobenzene solvent, uniform film growth characteristics without any crystallization issues, and good electron and hole-transporting properties. A luminance of 14,440 cd/m^2 at 8.4 V and luminous efficiency of 21.0 cd/A and 11.3 lm/W at 5.9 V are demonstrated in the NPyB host device.

2. Experimental details

2.1. Material synthesis

The compounds NPyB and QuPB were synthesized according to the procedure shown in Fig. 1. All reagents and solvents were purchased from Aldrich chemical Co. and Fluka. Other reagents in the scheme were used as from commercial sources.

2.1.1. 4,4′-Bis[N-(1-naphthyl)-N-(3-pyridinylamino]biphenyl (NPyB)

To a solid mixture of 1-naphthyl-3-pyridinylamine (3.0 g, 13.6 mmol) and 4,4′-dibromobiphenyl (2.0 g, 6.5 mmol), a solution of 50 ml toluene was added. It was degassed by bubbling nitrogen for 30 min. Additionally, 0.2 mmol of tris(dibenzylideneacetone)dipalladium(0) [$Pd_2(dba)_3$], 0.4 mmol of tri-*tert*-butylphosphine, and 20 mmol of sodium-*tert*-butoxide was added to the mixture. The mixture was vigorously refluxed under nitrogen for 24 h. When the reaction mixture was cooled down to room temperature, 30 ml of water was added to remove some salts. After separating the water, the solution was dried by $MgSO_4$, and then concentrated under reduced pressure. The mixture was purified by column chromatography on silica gel eluting with a 1:2 mixture of ethylacetate and hexane. By removing the eluting solvent, light yellow powder was obtained (2.5 g, 65%).

T_m 241 °C, T_g 93 °C, δ_H (500 MHz; $CDCl_3$; Me_4Si) 8.38 (2H, d, *J* 2.6), 8.16 (2H, d, *J* 4.5), 7.90 (4H, *J* 8.5), 7.49 (4H, m), 7.37 (8H, m), 7.28 (2H, d, *J* 8.7), 7.11 (6H, m). Elemental Analysis Calc. for $C_{42}H_{30}N_4$: C, 85.40; H, 5.12; N, 9.48%. Found: C, 85.54; H, 5.04; N, 9.47%. M/S (*m*/*z*, M$^+$). Found: 591.2543, Calc.: 591.2549.

2.1.2. 4,4′-Bis [N-(3-quinolinyl)-N-phenylamino]biphenyl (QuPB)

The synthetic procedure of QuPB is same except using 3-quinolinyl-phenylamine (3.0 g, 13.6 mmol) instead of 1-naphthyl-3-pyridinylamine. Yellow powder was obtained (2.3 g, 60%).

T_m 186 °C, T_g 94 °C. δ_H (500 MHz; $CDCl_3$; Me_4Si) 8.79 (2H, d, *J* 2.5), 8.03 (2H, d, *J* 8.3), 7.70 (2H, d, *J* 2.2), 7.59 (4H, m), 7.52 (4H, d, *J* 8.6), 7.46 (2H, t, *J* 7.7), 7.32 (4H, t, *J* 7.9), 7.20 (8H, d, *J* 8.4), 7.13 (2H, t, *J* 7.3). Elemental Analysis Calc. for $C_{42}H_{30}N_4$: C, 85.40; H, 5.12; N, 9.48%. Found: C, 85.49; H, 5.11; N, 9.45%. M/S: (*m*/*z*, M$^+$). Found: 591.2551, Calc.: 591.2549.

2.2. OLED fabrication and measurements

OLED devices were fabricated on the indium–tinoxide (ITO) glass having an emission area of 2 mm × 2 mm with a sheet resistance of 12 Ω/square. A line pattern of ITO was formed by the photolithography process. Before coating organic layers, the patterned ITO glasses were cleaned by sonification in isopropyl alcohol (IPA) and acetone, and then rinsed in deionized water; finally it was irradiated in a UV-ozone chamber. A 45 nm poly(ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) was spin-coated on the ITO substrates and then dried using a hot plate at 120 °C for 10 min to remove the solvent. A 40 nm thick emissive host system i.e. NPyB and QuPB doped with Ir(phq)$_2$acac in 1,2-dichlorobenzene was later spin-coated on the PEDOT:PSS layer. The spin-coated emissive layer was then baked on a hot plate at 120 °C for 10 min. The spin coating and baking process were carried out in a glove box with nitrogen ambient. Subsequently, 30 nm TPBI was

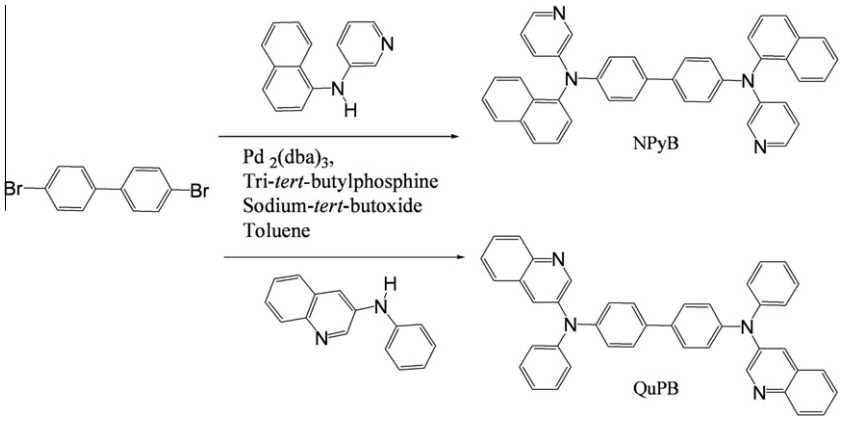

Fig. 1. Synthesis procedure of NPyB and QuPB.

deposited in an organic chamber using vacuum thermal evaporation at a base pressure of 10^{-7} Torr, while LiF (1 nm) and Al (100 nm) were deposited in an adjacent metal chamber without breaking the system vacuum.

Current density–voltage (*J*–*V*) and luminance–voltage (*L*–*V*) characteristics of the fabricated OLEDs were measured using a Keithley SMU 2635 and Konika Minolta CS-100A. Also, the electroluminescence (EL) spectra and CIE color coordinates were obtained using a Konika Minolta CS-1000A spectroradiometer. For optical measurements, UV–Visible absorption spectra of NPyB in dichloromethane solution were recorded with a Shimadzu 3100 UV–VIS–NIR spectrophotometer. In case of photoluminescence (PL) measurement, emission spectrum of NPyB and QuPB in dichloromethane solution, and deposited thin films on glass substrate were measured with a Jasco FP-6500 spectroflurometer. Low temperature emission spectra of NPyB and QuPB solutions were also recorded using liquid nitrogen at 77 K with Jasco FP-6500 spectroflurometer. For investigation of smoothness and homogenous surface of emissive layer, atomic force microscopy (AFM) was done.

Cyclic voltammetry (CV) was performed using EC epsilon electrochemical analysis equipment. Platinum wire and ITO film on glass were used as counter and working electrodes, respectively. Tetrabutylammonium perchlorate (Bu_4NClO_4) is used as a supporting electrolyte. Ag wire in 0.1 M $AgNO_3$ was used as a reference electrode. By means of internal ferrocenium/ferrocene (Fe^+/Fe) standard, the potential values were converted to the saturated calomel electrode (SCE) scale. The position of LUMO of each material is estimated from the optical band gap determined from the absorption onset of the spectra. The films that had been coated with the material were made on ITO glass through the solution drop coating and then dried in a vacuum oven at 80 °C. Solid-state electrochemistry was performed at a scan rate of 150 mV/s and start potential voltage have supplied from 0.5 eV for reducing potential damage.

3. Results and discussion

The chemical structure and synthetic route of 4,4′-bis[*N*-(1-naphthyl)-*N*-(3-pyridinylamino]biphenyl (NPyB) and 4,4′-bis [*N*-(3-quinolinyl)-*N*-phenylamino]biphenyl (QuPB) are shown in Fig. 1. The molecular structures of NPyB and QuPB were confirmed by ^{1}H NMR, mass spectrometry, and elemental analysis. Thermal properties of NPyB and QuPB were investigated by means of differential scanning calorimetry (DSC). A glass-transition temperature (T_g) was obtained from the second heating scan of the glassy samples cooled after the first heating up to melting temperature (T_m). The heating rate was 10 °C/min. The T_m's of NPyB and QuPB appeared at 241 and 186 °C, respectively. The crystallization temperature (T_c) of NPyB was observed about 180 °C by the second heating but no T_c of QuPB was found, which indicates that QuPB has more glass-like property. Considering the melting point of NPB about 280 °C, intermolecular dipole interaction is reduced in the order of NPB, NPyB, and QuPB. However, the glass-transition temperatures of both the molecules are around 93–95 °C which is about same as that of commercialized NPB (95 °C) [20]. NPyB and QuPB can readily dissolve in common organic solvents, such as 1,2-dichloromethane, 1,2-dichlorobenzene, toluene which enables the preparation of uniform thin film by solution processing such as spin coating.

AFM studies of NPyB and QuPB host materials with spin coating in 1,2-dichlorobenzene solution were carried out to investigate the surface morphology of thin films. As shown in Fig. 2, root-mean-square-roughness (rms) values are 1.90 Å and 1.89 Å for NPyB and QuPB. These results shows that both the host films were smooth and homogeneous without any crystallization issues by implementing the host compatibility with dopant material used in fabricating solution-processible devices.

The bipolar host materials, NPyB and QuPB having pyridine and quinoline units as electron transport moieties lead to bipolar charge transport property for both holes and electrons. The photophysical properties of NPyB and QuPB host materials were measured using UV–visible absorption and photoluminescence spectra as depicted in Fig. 3 and Table 1. The absorption and emission spectra of both the host materials were carried out in dilute dichloromethane solution. The absorption spectrum of NPyB has one absorption band from 305 to 360 nm which could be from π–π^* transitions of the conjugated π-electron system.

	NPyB	QuPB
Film		Rms roughness	1.90 Å	1.89 Å

Fig. 2. AFM image of host (a) NPyB and (b) QuPB.

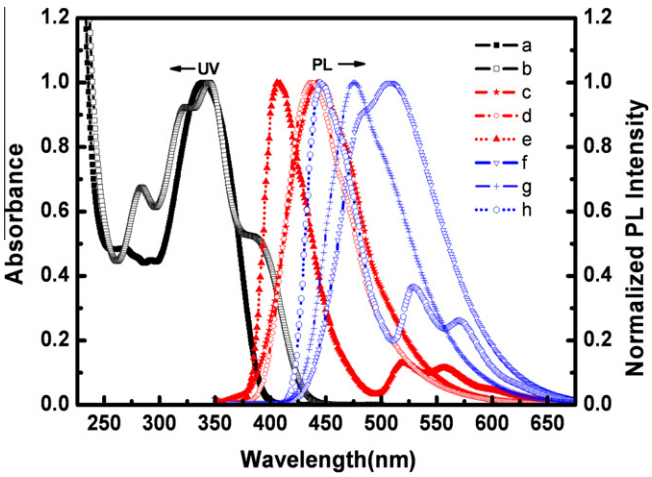

Fig. 3. UV spectra in dichloromethane (a) NPyB, (b) QuPB, and PL spectra in dichloromethane, (c) NPyB solution, (d) NPyB thin film, (e) NPyB low temperature (77 K), (f) QuPB solution, (g) QuPB thin film and (h) QuPB low temperature (77 K).

QuPB exhibits four vibronic absorption bands centered at 284, 320, 345 and 390 nm, respectively. The PL emission maximas of NPyB and QuPB in solution were observed around 442 and 510 nm, respectively. The PL emission spectra of NPyB and QuPB thin films were slightly blue shifted by 6 and 36 nm, respectively. The low temperature phosphorescent spectrum of the NPyB host, measured in 2-methyltetrahydrofuran (THF) solution at 77 K, revealed the shifting of main peak at 405 nm while a phosphorescent sub-band of two peaks with peak positions, 520 and 558 nm could also be noticed. Similarly, QuPB at 77 K shows the main peak at 446 nm and phosphorescent sub-bands with peak positions at 527 and 572 nm. From the phosphorescent spectra, triplet energies of 2.4 and 2.3 eV were calculated from 520 and 527 nm first peaks of NPyB and QuPB materials. It confirms that their triplet energies are in good agreement in transferring excitons from the bipolar hosts to $Ir(phq)_2acac$ dopant. In order to make appropriate comparisons of triplet energies, energy transfer experiments from the red dopant to NPyB and QuPB hosts were carried out in 1,2-dichlorobenzene solution. When NPyB was added to $Ir(phq)_2acac$ solution at different concentrations, the quantum efficiency did not change. However, addition of QuPB has decreased the quantum efficiency, significantly. These results indicate that NPyB triplet energy is higher than the red dopant while QuPB has a triplet energy similar to $Ir(phq)_2acac$ dopant. In order to obtain more accurate results, energy transfer rate of QuPB was calculated using Stern–Volmer plots and it came out $3 \times 10^9\ s^{-1}M^{-1}$, which is similar to diffusion rate of

Table 2
A summary of device performance as a function of doping concentration in NPyB and QuPB hosts.

Doping ratios of $Ir(phq)_2acac$	NPyB (1%)	NPyB (2%)	NPyB (3%)	QuPB (3%)	QuPB (5%)	QuPB (7%)	NPB:TPBI (7%)
Turn-on voltage (at 1 cd/m^2)	5.1	5.3	4.3	5.1	4.9	4.5	5.4
Operating voltage (at 1000 cd/m^2)	5.9	5.9	6.1	6.3	5.5	5.3	6.3
Luminance (max.) at voltage	12,820 (8.4 V)	14,400 (8.8 V)	14,190 (9.2 V)	7888 (8.2 V)	7714 (8.0 V)	8751 (8.6 V)	19,250 (9.2 V)
Maximum efficiency (cd/A , lm/W)	17.9, 9.21	21.0, 11.3	12.8, 5.8	6.9, 3.3	7.8, 4.5	7.2, 4.5	11.9, 5.8
Efficiency (cd/A, lm/W at 1000 cd/m^2)	17.6, 9.1	20.6, 10.8	11.6, 5.9	6.7, 3.3	7.6, 3.3	7.2, 4.2	11.9, 5.8
CIE (x, y) at 1000 cd/m^2)	0.57, 0.39	0.59, 0.39	0.59, 0.39	0.60, 0.38	0.60, 0.38	0.60, 0.38	0.61, 0.38
Emission peak (nm)	593	595	596	598	598	598	600

organic solvents. However, NPyB does not reach to such value. This proves that NPyB has higher triplet energy than $Ir(phq)_2acac$ and can be used with red dopant effectively.

In order to investigate the electrochemical properties of NPyB and QuPB, cyclic voltammetry experiments were performed to know HOMO levels. Table 1 summarizes the calculated and experimentally obtained energy levels values. The host materials showed reversible oxidation and reduction waves, indicating that these materials are quite relevant for bipolar transport in OLEDs. The HOMO energy levels for NPyB and QuPB were estimated to be 5.5 eV by cyclic voltammogram, which is considerably close to 5.4 eV HOMO of hole-transporting material, NPB [21]. The LUMO energy levels of both the hosts are at 2.4 and 2.7 eV which can be deduced from calculation of band gaps. The triplet energy values of host materials and NPB were estimated by molecular modeling with density functional theory (DFT) using DMOL3 program (version 4.2) [22–24]. The energy levels of phosphorescent dopant $Ir(phq)_2acac$ were reported to have approximately 2.2 eV triplet energy, 5.3 eV HOMO, and 3.1 eV LUMO energies [25], which allow to receive triplet energy from both the hosts. Our host materials are expected to be good agreement in confining triplet excitons on the guest molecule effectively.

A series of solution processed devices were fabricated by using a host/guest blend system and evaluated in terms of their J–V and L–V output characteristics. Devices A and B were fabricated using NPyB:$Ir(phq)_2acac$ (2 wt.%), and QuPB:$Ir(phq)_2acac$ (5 wt.%), respectively. These devices were fabricated on ITO with a multilayered structure of ITO/PEDOT:PSS (45 nm)/host:dopant (35 nm)/TPBI (30 nm)/LiF(1 nm)/Al(100 nm). For comparison, NPB:TPBI (1:1) type of mixed host device with 7 wt.% of $Ir(phq)_2acac$ concentration in similar experimental conditions was also fabricated [10] and its data is outlined in Table 2. Here PEDOT:PSS improves the hole injection as its HOMO level is 5.2 eV which is close to HOMO of NPyB and QuPB hosts. The operating conditions and characteristics of these devices with varying concentration ranges are compared and summarized in Table 2. Among all the prepared devices, devices A and B demonstrate their best performances with a dopant concentration of 2 and 5 wt.%.

Fig. 4 shows the current density–voltage (J–V) and luminance–voltage (L–V) characteristics of all three devices. Device A exhibited turn-on voltage of 5.3 V which is similar to hole transport NPB:TPBI mixed host doped device while lower turn-on voltage of 4.9 V was obtained in device B. It is interesting to note that NPyB type of device has similar current density compared to NPB:TPBI mixed host system. This clearly indicates that NPyB host has very good hole and electron transporting ability. Devices A and B have lower driving voltages compared to NPB:TPBI based device. It was observed that driving voltages to reach 1000 cd/m^2 were found to be 5.9 and 5.5 V for devices A and B, lower than 6.3 V for NPB:TPBI based device. Fig. 4 also shows L–V characteristics, exhibiting maximum brightness 14,440 cd/m^2 at 8.8 V for device A, and 7714 cd/m^2 at 8.0 V for device B, respectively. However, NPB:TPBI type of device exhibited slightly better maximum brightness compared to device A but overall performance of device A

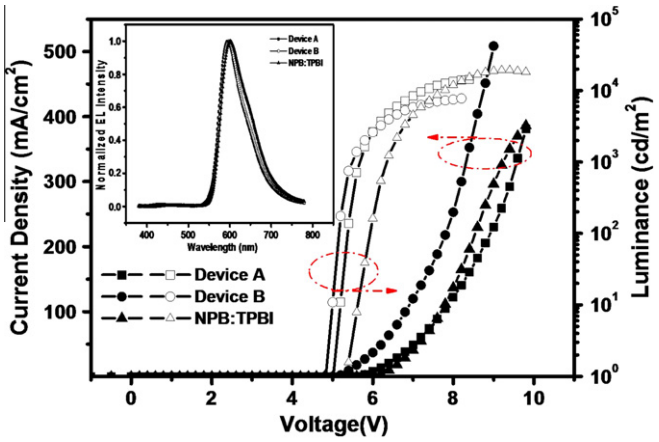

Fig. 4. Current–voltage and luminance–voltage of devices A, B and NPB:TPBI. Inset figure shows EL spectra of devices A, B and NPB:TPBI.

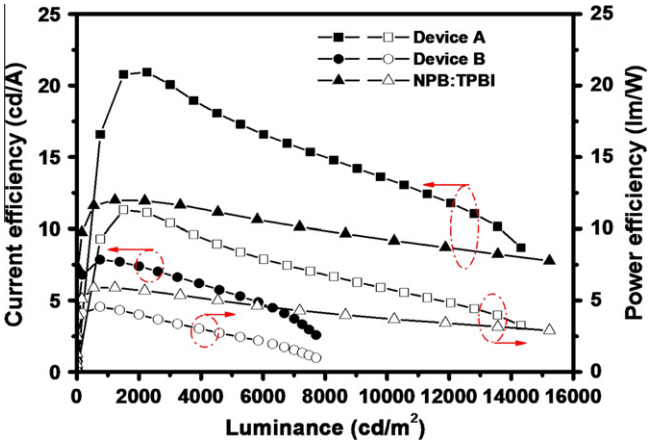

Fig. 5. Current and power efficiency characteristics of devices A, B and NPB:TPBI.

was found to be promising and convincing. This also signifies that NPyB host has better hole and electron transporting properties than NPB:TPBI type devices. Inset of Fig. 4 also shows the EL spectra of devices A and B exhibiting emissions in the red regions. It indicates complete energy transfer from the host materials to the guest due to confinement of triplet excitons at $Ir(phq)_2acac$ dopant molecule. The EL spectral peaks and CIE_{xy} coordinates of all devices are summarized in Table 2. At 1000 cd/m^2, the EL spectral peaks and CIE_{xy} coordinates of devices A and B were 595 nm/(0.59, 0.39) and 598 nm/(0.60, 0.38). The EL spectrum of each device does not change significantly with the applied voltage. It is manifested that phosphorescence photoluminescence quantum efficiency at high doping concentration tends to reduced inevitably due to self quenching or triplet–triplet annihilation by dopant molecules. In both the devices, efficiency decreases at high concentration of the dopant molecules.

The current and power efficiencies of devices A and B are depicted in Fig. 5 and Table 2. At a given constant lumi-

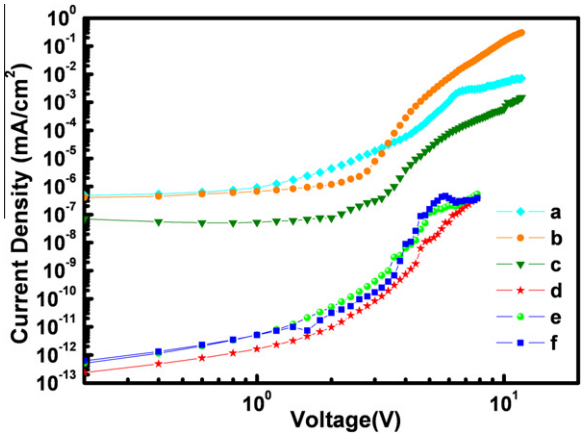

Fig. 6. *I–V* characteristics of the hole-only devices (a) NPB:TPBI, (b) NPyB, (c) QuPB, and electron-only devices (d) NPB:TPBI, (e) NPyB and (f) QuPB.

nance of 1000 cd/m^2, the current and power efficiencies of these devices were 20.6 cd/A and 10.8 lm/W for device A, and 7.6 cd/A and 3.3 lm/W for device B. Furthermore, the maximum current and power efficiencies obtained were 21.0 cd/A and 11.3 lm/W for device A, and 7.8 cd/A and 4.5 lm/W for device B. It clearly reveals that external quantum efficiency (EQE) of device A was 14.2%, which is nearly 40% higher than NPB:TPBI based device exhibiting EQE of about 8.6%. In case of device B, 5.2% of external quantum efficiency was achieved.

To examine the bipolar charge transport ability of NPyB and QuPB host materials, hole-only and electron-only devices were fabricated. For comparison, NPB:TPBI mixed host device as a reference was also fabricated. Fig. 6 shows the *J–V* characteristics of hole-only and electron-only devices. In case of hole-only device, the structure of ITO/PEDOT:PSS(45 nm)/host(35 nm)/sublimated NPB(60 nm)/Al(100 nm) was adopted in which a large barrier of NPB was used to block the electron-injection from Al [26]. The results clearly demonstrate that NPyB host has better hole conduction than NPB:TPBI type of hole-only device while QuPB shows the lowest hole current than that of NPB:TPBI reference. To evaluate the electron transporting performance of host materials, we adopted the device structure of glass/Al(100 nm)/PEDOT:PSS(45 nm)/host(50 nm)/LiF(1 nm)/Al(100 nm). It can be seen that electron transport property of NPyB and QuPB hosts are better than that of NPB:TPBI host system. This suggests that both NpyB and QuPB act as efficient bipolar materials because of comparable hole and electron mobility than that of reference. The above results confirm that NPyB and QuPB hosts have good bipolar charge transport properties.

4. Conclusions

We have synthesized and characterized two new bipolar host materials, NPyB and QuPB, containing both electron and hole-type of moieties. Their phosphorescence and electrochemical studies confirmed that both the hosts are capable of electron and hole-transport, suitable for harvesting red electrophosphorescence. The bipolar transport properties of NPyB and QuPB hosts were investigated by hole-only and electron-only devices. The multilayered solution-processed phosphorescent devices utilizing NPyB host was found superior in red electroluminescence performance. In particularly, this device exhibited a maximum brightness of 14,440 cd/m^2, with promising current and power efficiencies of 21.0 cd/A and 11.3 lm/W, and is considered an efficient bipolar host material for applications in low-cost electroluminescence devices. Consequently, this highly efficient promising red-emitting PHOLED have a possible space for improving its performance for further development of new generation OLEDs. Thus, the present investigation determined that new NPyB host material yielded a promising performance in terms of efficiency and color chromaticity for practical applications.

common approach has been to blend the polymer with [6,6]-phenyl-C61-butyric methyl ester (PCBM), a soluble C60 derivative [1,6].

The overall power conversion efficiency (PCE) has been steadily improving from an initial 1% via a blend of poly[2-methoxy-5-(30,70-dimethyloctyloxy)-1,4-phenylenevinylene] (MDMO-PPV) with PCBM [7] to an impressive ~5% achieved by poly(3-hexylthiophene) (P3HT):PCBM via extensive morphology optimization [8–10]. In order to further improve the efficiency of BHJ polymer solar cells, the research community is searching for new polymers. From the materials perspective, these donor polymers should not only have a low band gap, in order to increase the short circuit current (J_{sc}), but also bear a low energy level of the highest occupied molecular orbital (HOMO) to improve the open circuit voltage (V_{oc}) [11]. Typically, a low band gap polymer is designed via a "donor–acceptor" (D–A) approach, which is to incorporate electron-rich and electron-deficient moieties in the polymer backbone. The low band gap is mainly caused by the intramolecular charge transfer between donor and acceptor units [12]. Currently, state of the art polymer based BHJ solar cells have reached PCEs of more than 6% [13] and 6.7% [14] have been reported for single and tandem solar cells, respectively. However, these numbers are still significantly lower than the critical efficiencies of 10–15% [15].

In parallel efforts, organic solar cells (OSCs) based on small-molecules with vacuum evaporating interpenetrating multilayer structures have also reached PCEs as high as 5–6% [16]. Small-molecule donor materials can also form useable BHJ solar cells by solution processing, although it is more challenging to obtain high-quality films. The highest reported efficiencies for such devices have remained low (PCEs range from 0.3% to ~3.0%) relative to solution-processed solar cells using polymeric donor materials (~5%). Small-molecule materials, however, offer advantages over polymeric materials in terms of ease of synthesis and purification, which greatly improve fabrication reproducibility, as well as possessing a greater tendency to self assemble into ordered domains, which leads to high charge carrier mobilities [17]. Small-molecules do not suffer from batch to batch variations, broad molecular-weight distributions, end-group contamination, or difficult purification methods, which can be significant problems for polymeric materials. These considerations make small-molecules a promising class of donor material for BHJ solar cell applications [18–26]. Solution-processed small-molecules, which have been used for PV cells, have recently been reviewed [27]. Efficient BHJ PV solar cells based on symmetrical *D*–π–A–π–D organic dye molecules [28], squaraine [29,24], phthalocyanines [30,31], oligothiophene with dialkylated diketopyrrolopyrrole [32,33], 2-vinyl-4,5-dicyanoimidazole (vinazene) [34,35] and star-shaped molecules have very recently been reported [36–40]. The highest PCE reported to date for solar cells using solution-processable small-molecules is 3.0% [32].

On the other hand, cyano-poly(*p*-phenylenevinylene) (CN-PPV) and its derivatives with cyanovinylene moieties are one of the most important conjugated polymers with high electron affinity and promising materials used in polymeric light emitting diodes and polymeric PV devices [41–46]. Various low band gap small-molecules and polymers carrying 4-nitro-α-cyanostilbene units have been synthesized in our laboratory and used for BHJ solar cells [47] and dye-sensitized solar cells [48] with enhanced efficiency. In continuation of this research line, herein we describe the synthesis and characterization of two new symmetrical molecules **M1** and **M2** of low band gap with common structural segments. Both molecules contained a central spacer which was connected at both sides via ether bond with terminal 4-nitro-α-cyanostilbene units. The two ether bonds are expected to increase the flexibility of the molecules. Moreover, their aliphatic moieties render these molecules very soluble in common organic solvents thus allowing the facile preparation of thin films by spin casting. The molecules were successfully synthesized by a reaction sequence the last step of which included the condensation of a kye-dialdehyde with 4-nitrobenzylcyanide. We have used **M1** and **M2** as electron donor along with PCBM as electron acceptor for BHJ active layer for the fabrication of organic PV devices. The PCE for the devices based on pristine **M1**:PCBM and **M2**:PCBM blends, is 1.67% and 1.05%, respectively. We have investigated the effect of solvent vapor treatment of blend on the PV response of the BHJ devices and found that the PCE has been increased up to 3.05% and 1.90% for **M1**:PCBM and **M2**:PCBM blends, respectively. This improvement of PCE has been attributed to the increase in hole mobility and surface roughness, leading to better charge separation and collection efficiency. The PCE has been further increased up to 3.57% and 2.42% after thermal annealing of the solvent vapor treated **M1**:PCBM and **M2**:PCBM blends, respectively.

2. Experimental

2.1. Reagents and solvents

4-Nitrobenzylcyanide was synthesized from the nitration of benzyl cyanide with concentrated nitric and sulfuric acid [49]. It was recrystallized from ethanol. 4-Hydroxybenzaldehyde was recrystallized from distilled water. *N*,*N*-dimethylformamide (DMF) and tetrahydrofuran (THF) were dried by distillation over CaH_2. All other reagents and solvents were commercially purchased and were used as supplied.

2.2. Preparation of compounds

2.2.1. 1,4-Bis(p-formylphenoxymethyl)-2,5-bis(hexyloxy) benzene (3)

A flask was charged with a mixture of **2** (0.1650 g, 0.355 mmol), 4-hydroxybenzaldehyde (0.1042 g, 0.853 mmol), K_2CO_3 (0.15 g, 1.08 mmol) and acetonitrile (25 mL). The mixture was stirred and refluxed for 12 h under N_2. It was subsequently concentrated under reduced pressure. Water was added to the concentrate and then it was extracted with dichloromethane. The organic layer was dried (Na_2SO_4) and concentrated to afford **3** (0.1478 g, yield 76%).

FT-IR (KBr, cm^{-1}): 2930, 2870, 2854 (C–H stretching); 1684 (carbonyl of formyl); 3050, 1602, 1506, 1466 (aromatic); 1246, 1210, 1162 (ether bond).

^1H NMR ($CDCl_3$) ppm: 9.90 (s, 2H, formyl); 7.79 (m, 4H, aromatic ortho to formyl); 6.96–6.85 (m, 6H, aromatic

ortho to oxygen); 5.14 (s, 4H, OCH_2Ph); 3.96 (m, 4H, $OCH_2(CH_2)_4CH_3$); 1.81 (m, 4H, $OCH_2CH_2(CH_2)_3CH_3$); 1.37 (m, 12H, $O(CH_2)_2(CH_2)_3CH_3$); 0.91 (t, 6H, $O(CH_2)_5CH_3$).

Anal. Calcd. for $C_{34}H_{42}O_6$: C, 74.70; H, 7.74. Found: C, 74.32; H, 7.40%.

*2.2.2. Molecule **M1***

A flask was charged with a solution of **3** (0.1478 g, 0.270 mmol) and 4-nitrobenzylcyanide (0.0876 g, 0.540 mmol) in ethanol (20 mL). Sodium hydroxide (0.20 g, 5.00 mmol) was added to this solution. The reaction mixture was stirred for 1 h at room temperature under N_2 and then it was concentrated under reduced pressure. Water was added to the concentrate and **M1** precipitated as a dark green solid. It was recrystallized from ethanol/water (0.15 g, yield 66%).

FT-IR (KBr, cm^{-1}): 2922, 2852 (C–H stretching); 2170 (cyano); 1510, 1346 (nitro); 3075, 1600, 1454 (aromatic); 1258, 1162, 1106 (ether bond); 1016 (*trans*-vinylene bond).

^1H NMR ($CDCl_3$) ppm: 8.11 (m, 4H, aromatic ortho to nitro); 7.72 (s, 2H, cyanovinylene); 7.65 (m, 4H, aromatic meta to nitro); 7.26 (m, 4H, aromatic meta to oxygen); 6.88–6.85 (m, 6H, aromatic ortho to oxygen); 5.15 (s, 4H, OCH_2Ph); 3.97 (m, 4H, $OCH_2(CH_2)_4CH_3$); 1.80 (m, 4H, $OCH_2CH_2(CH_2)_3CH_3$); 1.38 (m, 12H, $O(CH_2)_2(CH_2)_3CH_3$); 0.90 (t, 6H, $O(CH_2)_5CH_3$).

2.3. Characterization methods

IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrometer with KBr pellets. ^1H NMR (400 MHz) spectra were obtained using a Brucker spectrometer. Chemical shifts (δ values) are given in parts per million with tetramethylsilane as an internal standard. UV–vis spectra were recorded on a Beckman DU-640 spectrometer with spectrograde THF. Elemental analyses were carried out with a Carlo Erba model EA1108 analyzer.

The electrochemical cyclic voltammetry was conducted with Pt disk, Pt wire and Ag/Ag^+ electrode as working electrode, counter electrode, and reference electrode, respectively, in a 0.1 mol/L tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) acetonitrile solution. The **M1** or **M2** films for the electrochemical measurements were coated from THF solution containing **M1** or **M2**.

2.4. Device fabrication and characterization

Organic solar cell devices with the structure ITO/PEDOT:PSS/**M1** or **M2**:PCBM (1:1)/Al were fabricated as follows: After spin-coating of 40 nm layer of poly (3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) onto a pre-cleaned ITO coated glass substrates and baking at 80 °C for 30 min, a 80 nm **M1**:PCBM or **M2**:PCBM blend layer in THF solution was deposited on the top of the PEDOT:PSS layer by controlled spin-coating rate. Finally, an Al electrode (50 nm) was deposited on the top of the active BHJ layer through the thermal evaporation method. The effective area of the each device is 0.08 cm^2. For the solvent treatment, the spin coated blends were transferred into a jar filled with THF. Pre-thermal annealing of the solvent treated active layers was carried out at 120 °C for 2 min on the hot plate before the deposition of the Al electrode. The devices based on pure **M1** or **M2** were also fabricated having structure ITO/PEDOT:PSS/**M1** or **M2**/Al.

Current–voltage (J–V) characteristics of the PV devices were measured using a computer controlled Keithley 238 source meter in dark as well as under illumination intensity of 100 mW/cm^2. A xenon light source (Oriel, USA) was used to give a simulated irradiance of 100 mW/cm^2 (equivalent to AM1.5 irradiation) at the surface of the device. The hole only device having ITO/PEDOT:PSS/**M1** or **M2**:PCBM/Au configuration using as cast the thermally annealed active layers, were fabricated and J–V characteristics in dark at room temperature, were recorded to estimate the hole mobility.

The incident photon to current efficiency (IPCE) of the devices was measured by illuminating the device with a xenon light source using monochromator and measuring the resulting photocurrent with a Keithley electrometer under short circuit conditions according to the following expression:

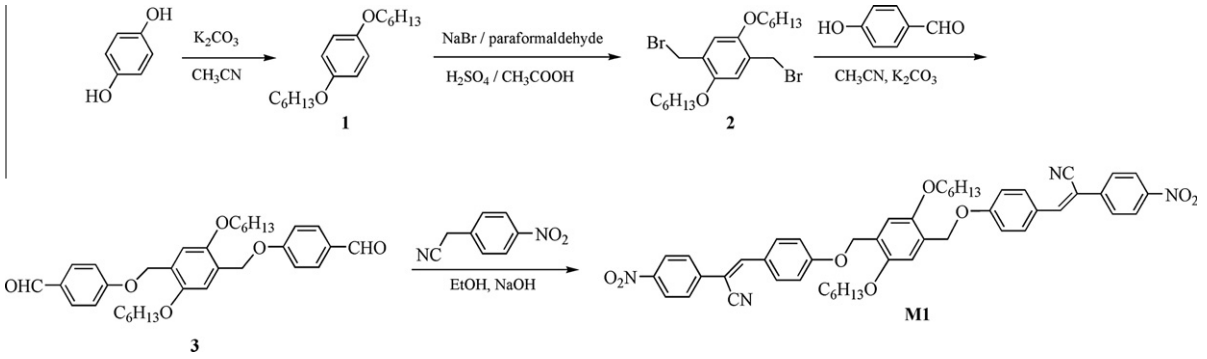
$$\mathrm{IPCE}(\%) = 1240 J_{sc}/\lambda P_{in}$$

where J_{sc} is the short circuit photocurrent and λ and P_{in} are the wavelength and illumination intensity of the incident light, respectively.

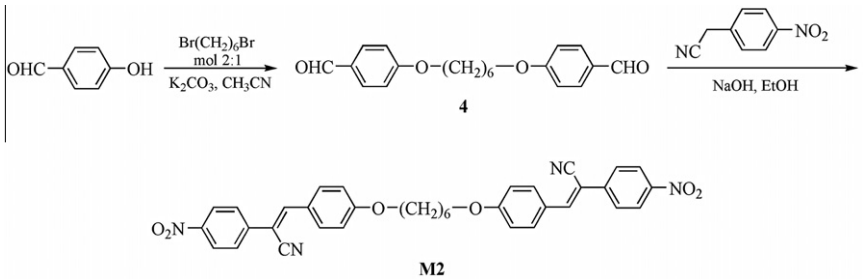
3. Results and discussion

3.1. Synthesis and characterization

Scheme 1 outlines the four-step reaction sequence applied for the synthesis of the target molecule **M1**. In particular, **1** [50] and **2** [50] were synthesized by reported procedures. The reaction of **2** with 4-hydroxybenzaldehyde in a mol ratio 1:2 afforded dialdehyde **3**. This reaction took place in acetonitrile in the presence of K_2CO_3. Finally, the Knoevenagel condensation [51] of **3** with a double molar amount of 4-nitrobenzylcyanide in ethanol in the presence of NaOH yielded **M1**. It is well known that this type of condensation forms double bonds which possess mainly *trans*-conformation [52]. The facile synthesis of the other target molecule **M2** was achieved in only two steps according to Scheme 2. Specifically, 4-hydroxybenzaldehyde reacted



Scheme 1. Synthesis of molecule **M1**.



Scheme 2. Synthesis of molecule **M2**.

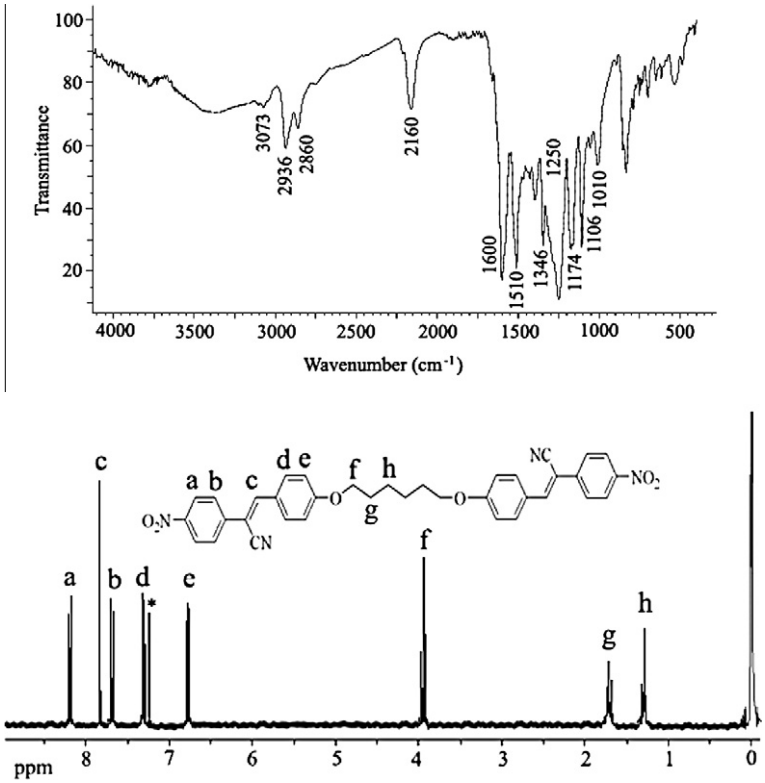


Fig. 1. FT-IR (top) and ^{1}H NMR in $CDCl_3$ solution (bottom) spectra of molecule **M1**.

with 1,6-dibromohexane to afford dialdehyde **4** [53]. The latter was subsequently condensed with 4-nitrobenzylcyanide to give **M2**. Both molecules were obtained in relatively high yields (66–70%) as dark green solids which were purified by recrystallization from ethanol/water. The two hexyloxy side chains of **M1** and the hexylene spacer of **M2** enhanced the solubility of these molecules. Particularly, both molecules were readily soluble in common organic solvents such as THF, dichloromethane, chloroform, acetone and toluene. Thin films of these molecules could be obtained by spin casting from the solutions despite their monomer nature.

Since the molecules have comparable chemical structures, their spectra showed certain common features. Fig. 1 presents the FT-IR and ^{1}H NMR spectra of **M2** as an example. The IR spectrum displayed characteristic absorption bands at 2936, 2860 (C–H stretching of hexylene); 2160 (cyano); 1510, 1346 (nitro); 3073, 1600 (aromatic); 1250, 1174, 1106 (ether bond) and 1010 cm^{-1} (*trans*-vinylene bond). The latter appeared at longer wavelength than usual *trans*-vinylene bonds (970–960 cm^{-1}) owing to the substitution by the electron-withdrawing cyano group. On the other hand, the ^{1}H NMR spectrum of **M2** showed upfield signals at 8.12 and 7.74 ppm assigned to the aromatic ortho to nitro and the cyanovinylene respectively. The other aromatic resonated at 7.66–6.80 ppm, while the aliphatic at 3.92–1.27 ppm.

3.2. Photophysical and electrochemical properties

Fig. 2 depicts the UV–vis absorption spectra of molecules in dilute (10^{-5} M) THF solution and thin film, which were normalized with respect to the long-wavelength absorption. Table 1 summarizes the photophysical and electrochemical characteristics of both molecules. Their absorption curves were broad and extended approximately up to 750 nm. This behavior is attributable to the terminal 4-nitro-α-cyanostilbene units as it has been well established in our previous publications [47,48]. The long-wavelength absorption maximum ($\lambda_{a,max}$) was located at 590–640 nm. The $\lambda_{a,max}$ of **M2** was red-shifted relative to that of **M1** in both solution and thin film. However, both molecules displayed the same thin film absorption onset at 742 nm which corresponds to an optical band gap (E_g^{opt}) of 1.67 eV. This value of E_g^{opt} conforms to those of other related materials [47,48].

Electrochemical cyclic voltammetry has been widely employed to investigate the redox behavior of organic materials and to estimate their HOMO and LUMO energy levels [54]. Fig. 3 shows the cyclic voltammograms of **M1** and **M2** films on Pt electrode in a 0.1 mol/L Bu_4NPF_6–acetonitrile solution. The results of the electrochemical measurements are listed in Table 1. It can be seen from Fig. 3 that there are reversible *n*-doping/depoping (reduction/reoxidation) and *p*-doping/depoping processes in both negative and positive potential range, respectively. The onset oxidation potential (E_{ox}) for **M1** and **M2** is 0.5 V and 0.7 V vs. Ag/Ag$^+$, respectively. The lower value of the oxidation potential for **M1** indicates higher electron donating ability of **M1** as compared to **M2**. In the reduction potential region, the onset reduction potential (E_{red}) is −1.21 V and −1.0 V vs. Ag/Ag$^+$ for **M1** and **M2**, respectively. From the E_{ox} and E_{red} of molecules **M1** and **M2**, their HOMO and

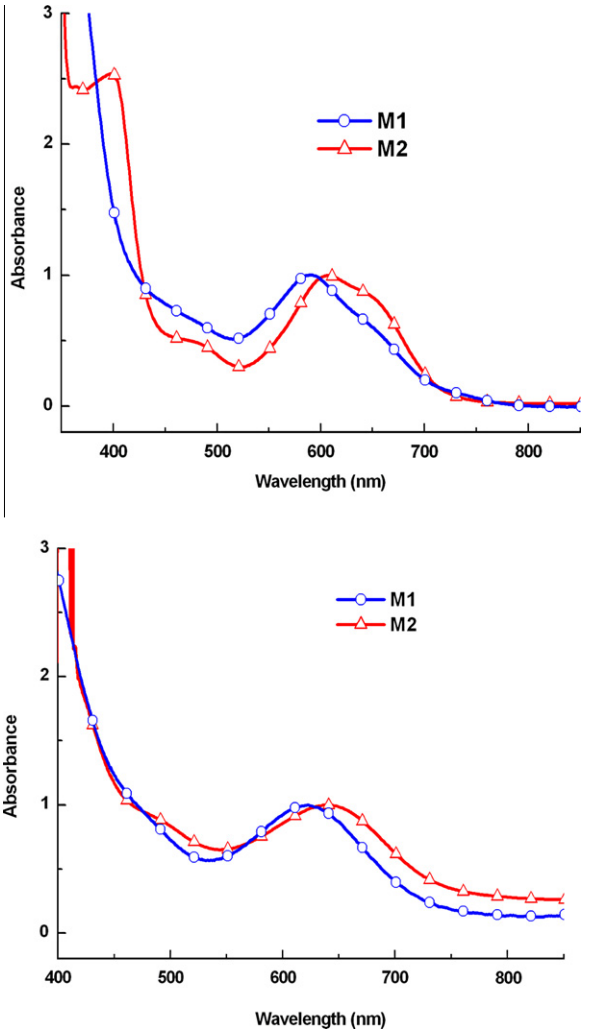

Fig. 2. Normalized absorption spectra of molecules in THF solution (top) and thin film (bottom).

Table 1
Optical and electrochemical properties of molecules.

Molecule	M1	M2
$\lambda_{a,max}$[a] in solution (nm)	590	607
$\lambda_{a,max}$[a] in thin film (nm)	622	640
Thin film absorption onset (nm)	742	742
E_g^{optb} (eV)	1.67	1.67
E_{onset}^{ox} (V)	0.5	0.7
E_{onset}^{red} (V)	−1.2	−1.0
HOMO (eV)	−5.2	−5.4
LUMO (eV)	−3.5	−3.7
E_g^{elc} (eV)	1.7	1.7

[a] $\lambda_{a,max}$: the long-wavelength absorption maxima from the UV–vis spectra in THF solution or in thin film.
[b] E_g^{opt}: optical band gap determined from the absorption onset in thin film.
[c] E_g^{el}: electrochemical band gap determined from cyclic voltammetry.

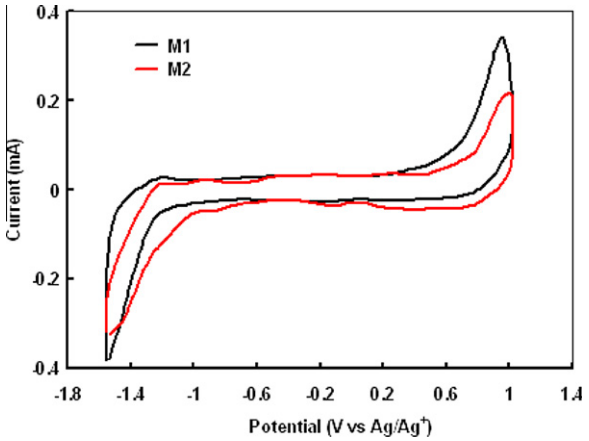

Fig. 3. Cyclic voltammetry data of **M1** and **M2**.

LUMO energy levels as well as their energy gaps were calculated according to equations:

$$\text{LUMO} = -q(E_{\text{red}} + 4.7)\ (\text{eV})$$
$$\text{HOMO} = -q(E_{\text{ox}} + 4.7)\ (\text{eV})$$

where the units of E_{ox} and E_{red} are V vs. Ag/Ag^{+}. The HOMO and LUMO values of these molecules are included in Table 1. It can be seen that the HOMO energy level of **M2** (−5.4 eV) is lower than that of **M1** (−5.2 eV). The LUMO level of **M2** (−3.7 eV) is higher than that of **M1** (−3.5 eV). However, the electrochemical band gap (E_g^{el}) (1.7 eV) is almost the same for both molecules. The E_g^{el} estimated from the electrochemical data is in good agreement with the E_g^{opt} estimated from the thin film absorption onset. The HOMO and LUMO levels of the PCBM were also estimated from the electrochemical data and were found to be −6.5 eV and −4.1 eV, respectively. The difference between the LUMO level of **M1** or **M2** and PCBM is about 0.6 eV and 0.4 eV, respectively, which indicates that the combination of **M1** or **M2** as donor with PCBM as an acceptor can be used for efficient BHJ organic PV devices.

3.3. Electrical and photoelectrical properties of *M1* and *M2*

The *J–V* characteristics of the ITO/PEDOT:PSS/**M1** or **M2**/Al devices in dark and under illumination are shown in Fig. 4. In these curves, the forward bias corresponds to the positive and negative voltage applied to PEDOT:PSS/ITO and Al electrode, respectively. It can be seen from these figures that the *J–V* characteristics show a rectification effect. The HOMO level of PEDOT:PSS (−5.2 eV) is very close to the HOMO level of both **M1** and **M2**. Therefore, this electrode behaves almost as an Ohmic contact for hole injection from the PEDOT:PSS into the HOMO of **M1** and **M2** in their respective devices. However, the LUMO level of both **M1** and **M2** is very far from the work function of the Al (−4.3 eV) and forms the Schottky barrier for the electron injection from the Al into the LUMO level of molecules. Hence, the rectification effect observed in the dark *J–V* characteristics is due to the formation of Schottky barrier at the Al–**M1** or Al–**M2** interfaces.

The charge carrier mobility of the PV materials is also an important factor which influences the performance of organic solar cells. We have measured the hole mobilities of these molecules using the hole only devices with ITO/PEDOT:PSS/**M1** or **M2**/Au structure using the SCLC model [55]. The *J–V* characteristics of the devices were plotted as $\ln[Jd^3/(V_{\text{app}} - V_{\text{bi}})]$ vs. $[(V_{\text{app}} - V_{\text{bi}})/d]^{0.5}$, and the hole mobilities of **M1** and **M2** calculated from the intercept of the corresponding lines are 2.3×10^{-6} and 5.1×10^{-6} cm^2/Vs for **M2** and **M1**, respectively.

The PV parameters, i.e. short circuit current (J_{sc}), open circuit voltage (V_{oc}), fill factor (FF) and PCE are summarized in Table 2. It can be seen from this table that the values of J_{sc} and PCE are higher for the device based on **M1** as compared to **M2**. This is attributed to the higher hole mobility of **M1** as compared to **M2**, since the E_g^{opt} and the absorption spectra

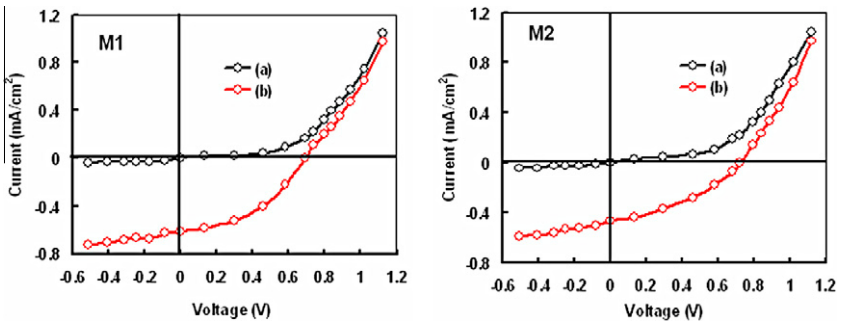

Fig. 4. Current–voltage characteristics of the devices based on pure **M1** and **M2** in dark (a) and under illumination (b).

Table 2
Summary of photovoltaic parameters of the ITO/PEDOT:PSS/**M1** or M2/Al devices.

Active material	Short circuit current (J_{sc}) (mA/cm^2)	Open circuit voltage (V_{oc}) (V)	Fill factor (FF)	Power conversion efficiency (PCE) (%)
M1	0.62	0.69	0.41	0.17
M2	0.47	0.72	0.40	0.13

of both molecules are identical. As the HOMO level of **M1** is very close to the HOMO level of PEDOT:PSS, the better hole collection in the device based on **M1** as compared to **M2**, may also be the reason for the higher PCE.

3.4. Photovoltaic properties of BHJ devices

The BHJ OSCs were fabricated with a structure of ITO/PEDOT:PSS/**M1** or **M2**:PCBM (1:1)/Al, where **M1** or **M2** were used as electron donor and PCBM was used as electron acceptor. Fig. 5 shows the *J*–*V* characteristics of the devices and Table 3 lists the corresponding PV parameters (J_{sc}, V_{oc}, FF and PCE) of the devices under illumination intensity of 100 mW/cm^2. It can be seen from Table 3 that the device based on the as cast **M1**:PCBM blend shows better PV response, having PCE of 1.67% as compared to 1.05% for the device based on the as cast **M2**:PCBM blend. The IPCE spectra of the devices (Fig. 6) show similar shape to the absorption spectra of the respective blends employed in the devices. This indicates that the visible light absorbed by the **M1**:PCBM or **M2**:PCBM photoactive layer in respective devices contributes to the J_{sc}. The maximum of IPCE for the as cast **M1**:PCBM and **M2**:PCBM based devices are about 55% and 42%, respectively at their absorption peak. The IPCE values are consistent with the higher values of J_{sc} and PCE of the **M1**:PCBM blend based organic solar cell.

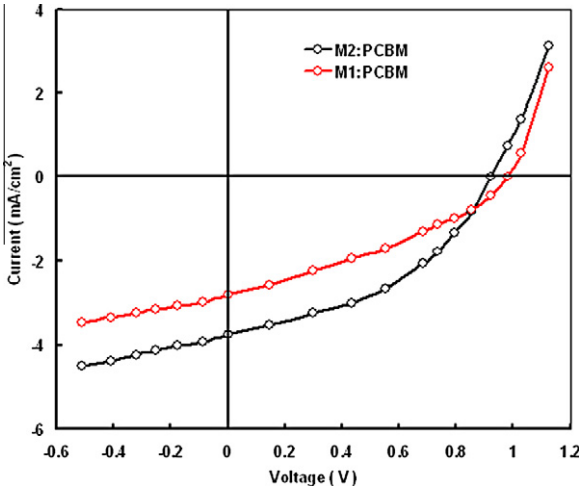

Fig. 5. Current–voltage characteristics of the devices based on pristine **M1**:PCBM and **M2**:PCBM blend under illumination intensity of 100 mW/cm^2.

Table 3
Summary of photovoltaic parameters of BHJ devices, using layer with different processing conditions.

Active material	Short circuit current (J_{sc}) (mA/cm^2)	Open circuit voltage (V_{oc}) (V)	Fill factor (FF)	Power conversion efficiency (PCE) (%)
M1:PCBM[a]	3.76	0.93	0.48	1.67
M1:PCBM[b]	6.4	0.90	0.53	3.05
M1:PCBM[c]	7.12	0.93	0.54	3.57
M2:PCBM[a]	2.38	0.98	0.45	1.05
M2:PCBM[b]	4.15	0.95	0.48	1.90
M2:PCBM[c]	5.16	0.98	0.48	2.42

[a] Pristine blend.
[b] Solvent vapor treated blend.
[c] Thermally annealed solvent treated blend.

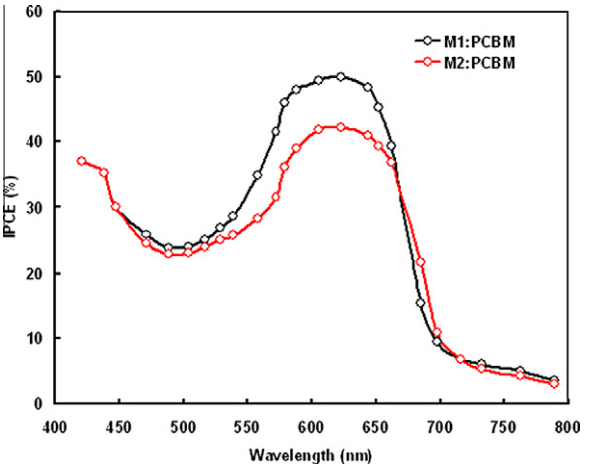

Fig. 6. IPCE spectra of BHJ devices based on pristine **M1**:PCBM and **M2**:PCBM blends.

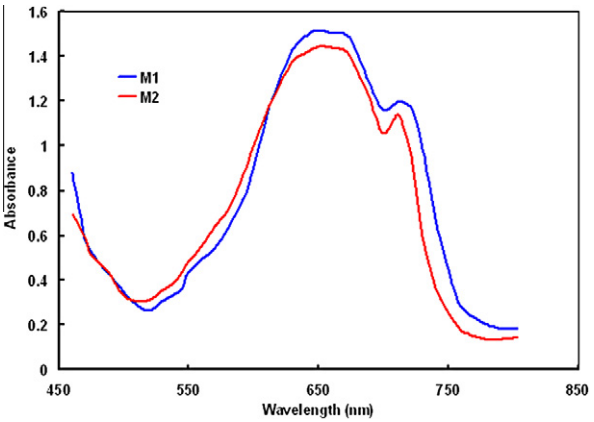

Fig. 7. Absorption spectra of solvent vapor treated **M1**:PCBM and **M2**:PCBM blends.

The J_{sc} is directly related to the product of absorbed photons and external quantum efficiency (EQE) [27]. Since the optical absorption of both **M1**:PCBM and **M2**:PCBM is almost the same, light absorption cannot be the factor for increased J_{sc} and PCE of the device based on **M1**:PCBM as compared to **M2**:PCBM. We assume that the difference in EQE of the devices is responsible for the higher photocurrent of the **M1**:PCBM blend. The EQE is determined by three processes: (i) migration/diffusion of photogenerated excitons towards the *D*/*A* interface, (ii) excitons dissociation and charge separation at the *D*/*A* interfaces, and (iii) collection of charge carrier at the electrodes. The process (i) depends on the nanoscale phase separation between the donor and acceptor components used in the BHJ active layer. It can be seen from the AFM images (Figs. 9 and 10)

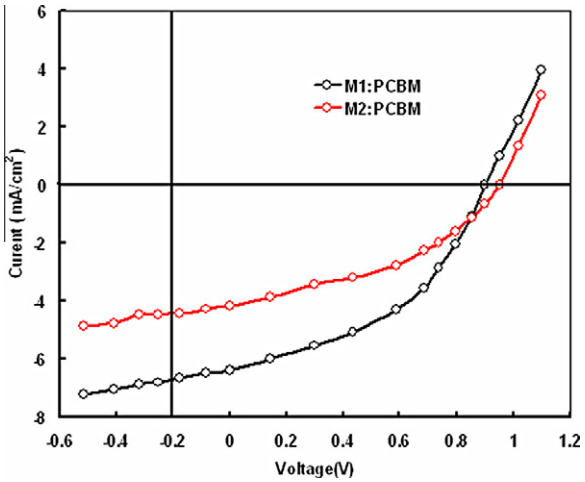

Fig. 8. Current–voltage characteristics of the devices based on THF treated **M1**:PCBM and **M2**:PCBM blend under illumination intensity of 100 mW/cm^2.

that the surface roughness is higher for **M1**:PCBM as compared to **M2**:PCBM, which indicates better nanoscale phase separation in **M1**:PCBM blend. Therefore, we assume that the contribution of EQE from the process (i) is higher for **M1**:PCBM. For process (ii) a sufficient large energy difference between the LUMO of the donor and acceptor material is required for ultra-fast photoinduced charge transfer. This difference is higher for **M1**:PCBM as compared to **M2**:PCBM blend. Photoinduced charge transfer is comparatively faster in the former blend, resulting in higher EQE for the device based **M1**:PCBM blend. Process (iii) depends on the percolated path for electrons and holes in BHJ active layer, mobility of electron and hole, and on the position of HOMO and LUMO level of the donor and acceptor materials, respectively, relative to the work function of anode and cathode. The HOMO level of **M1** is closer to the HOMO level of PEDOT:PSS indicating higher hole mobility for **M1**, which results in more efficient hole collection. Therefore, processes (i–iii) are responsible for the improved J_{sc} and PCE of the device based on **M1**:PCBM as compared to **M2**:PCBM.

Generally, the performance of the organic BHJ PV devices can be improved by controlling the morphology of the BHJ active layer, because efficient photoinduced charge generation, transport and collection of charge carriers at each collecting electrode crucially depend on the nanometer scale morphology of the films [56]. The crystallization of the organic materials improves the light harvesting property by extending the conjugation length and increases the charge carrier mobility, which is the limiting factor for the balance transport of the electrons and holes dissociated from the bound excitons. The increase in the PCE via thermal annealing is attributed to modified nanoscale morphology, enhanced crystallization of blend and improved transport of charges. It has also been reported that self-organization of organic material occurs not only under thermal annealing but also in proper ambience. Li et al. [9] and Zhao et al. [57] reported efficient PV cells based on P3HT/PCBM blend by controlling the growth rate of the active layer from solution to solid state. We have investigated the effect of thermal annealing, and combining solvent vapor treatment and thermal annealing on the PCE of PV devices based on **M1**:PCBM and **M2**:PCBM blends.

Fig. 7 shows the UV–vis absorption spectra of the solvent vapor treated **M1**:PCBM and **M2**:PCBM blends. For the untreated **M1**:PCBM blend film, the **M1** absorption peak is located at 620 nm with an absorption onset at 742 nm. Compared to the pristine **M1**:PCBM blend film, the absorption peak of the solvent treated **M1**:PCBM blend film shifted towards longer wavelength region and became much stronger in this region. In addition, the absorption spectra of the solvent treated **M1**:PCBM blend shows one vibronic absorption shoulder at 680 nm, which is attributed to an enhanced conjugation length and more ordered structure of **M1**. As the solvent molecules can penetrate into the film and increase the space between the molecular chains, the chains become mobile and self-organization can occur to form the ordering.

Fig. 8 shows the *J–V* characteristics of the devices under 100 mW/cm^2 white light illumination with THF treatment. The PV parameters for these PV devices are summarized in Table 3. It can be seen that the J_{sc} of the PV devices with THF vapor treatment increases to 6.4 mA/cm^2 and

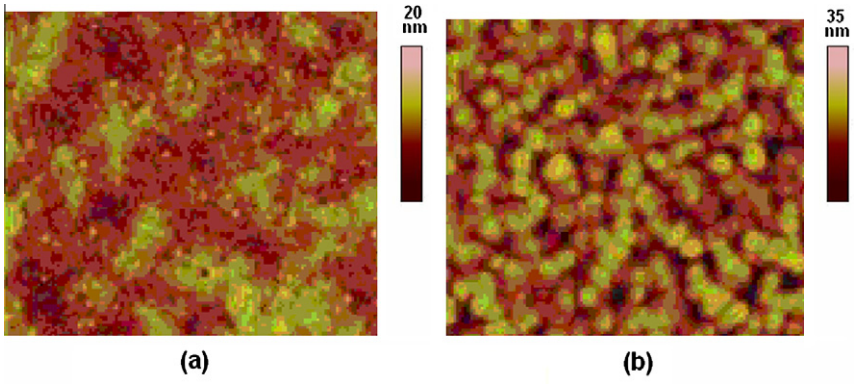

Fig. 9. AFM images of **M1**:PCBM as cast (a) and solvent treated (b) films.

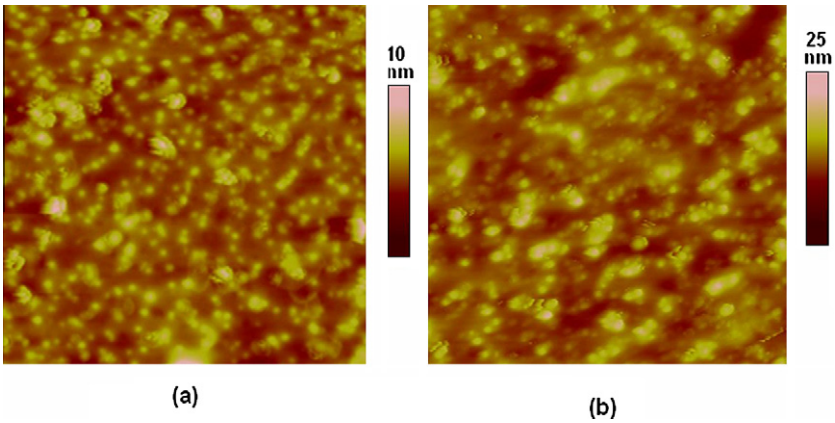

Fig. 10. AFM images of **M2**:PCBM as cast (a) and thermally annealed (b) films.

4.15 mA/cm^2 for **M1**:PCBM and **M2**:PCBM based devices respectively, which is a twofold increase compared to the as produced PV device. The overall PCE of the devices based on the solvent treated **M1**:PCBM and **M2**:PCBM has been increased up to 3.05% and 1.90%, respectively. This improvement is attributed to the self-organization of **M1** or **M2** induced by solvent vapor treatment which enhances the optical absorption and the hole transport. The PCE of the BHJ devices with THF treatment blends are higher than that of pristine blends. The J_{sc} of the organic BHJ PV devices is directly related to the product of light absorption by the photoactive blend used in the device, exciton diffusion, charge separation and charge collection efficiency. As it can be seen from the absorption spectra of the solvent vapor treated blends, the absorption coefficient has been increased as compared to the as cast blend films and also red-shifted. This indicates that more light is absorbed by the solvent vapor treated blends which generated more excitons in the photoactive blend. It is also observed that the IPCE spectra of the devices resemble the absorption spectra of the corresponding blend used in the device. This indicates that the J_{sc} is mainly attributed to the excitons generated because of the absorption of photons in **M1** or **M2**. The value of the IPCE is consistent with the values of J_{sc}. The IPCE is higher for the devices based on the solvent vapor treated blends as compared to the pristine blends, which is consistent with the increased values of J_{sc}.

The nanoscale morphology of the blend films has been investigated by the atomic force (AFM) experiment. Figs. 9 and 10 show the AFM images of the as cast and solvent vapor treated blend films. For the as cast films, an rms surface roughness of 4.2 nm and 3.2 nm, for **M1**:PCBM and **M2**:PCBM, respectively is observed. The solvent vapor treated films are much rougher that the as cast films. The solvent vapor treated **M1**:PCBM and **M2**:PCBM films show rms roughness of 7.6 nm and 5.6 nm, respectively at 5 μm × 5 μm scan sizes. The roughness is considered to be a signal of **M1** or **M2** chains self–organization and phase separation [57]. The increase of the roughness of the blend films after solvent vapor treatment is because of the **M1** or **M2** chains, self organize into ordered structure after solvent vapor treatment. The higher surface roughness of the blends support the increase in the phase separation of **M1**:PCBM or **M2**:PCBM after solvent vapor treatment. The increased phase separation leads to an increase in the *D*/*A* interfacial area for efficient charge separation, resulting in higher J_{sc} and PCE for BHJ PV devices based on the solvent vapor treated blend films.

The V_{oc} values of the devices based on the solvent vapor treated blend films is lower that that of the devices based on the as cast films. It is widely accepted that the energy difference between the HOMO and LUMO of the acceptor determines the V_{oc} value of the organic BHJ PV devices. We have already shown that the overall optical absorption spectrum of the solvent vapor treated blend films is red-shifted. This result can be interpreted assuming that the red-shifted spectrum results from a lower energy state of delocalized exciton in donor materials (**M1** or **M2**), as reported for conjugated polymers [58]. Therefore, the lowering of V_{oc} for devices based on the solvent vapor treated blends can be explained by reduced optical band gap of **M1** or **M2**.

We have investigated the charge collection efficiency by means of the space charge limited current (SCLC) measurements in dark. In the case of the devices based on the as cast blend films, the space charge limits the charge collection efficiency, because the hole mobility is lower than the electron mobility. According to the SCLC criteria, when there is a large difference between the hole and electron mobilities, the half power dependence of the photocurrent on the applied voltage takes place, and the FF can not exceed more than 0.40. Thus, in order to obtain high charge collection efficiency, it is necessary to balance the carrier mobility by enhancing the hole mobility in the blend. To investigate the space charge effects, we extract the hole and electron mobilities from the SCLC *J*–*V* characteristics obtained in the dark for hole and electron only devices [55a,57]. We have fabricated the hole- and electron-only devices having structure ITO/PEDOT:PSS/**M1** or **M2**:PCBM/Au and ITO/PEDOT:PSS/**M1**or **M2**:PCBM/Al, respectively. The hole and electron mobilities have been extracted from the *J*–*V* characteristics using the SCLC model [57] and they are listed in Table 4. It can be seen from this table that the hole mobility has been increased about 7–8 times for the devices based on

Table 4
Hole and electron mobility of **M1**:PCBM and **M2**:PCBM blends films evaluated using the SCLC model.

Film	Hole mobility (μ_h) (cm^2/Vs)	Electron mobility (μ_e) (cm^2/Vs)	μ_e/μ_h
M1:PCBM (as cast)	1.2×10^{-6}	6.4×10^{-5}	53
M1:PCBM (solvent vapor treated)	9.7×10^{-6}	6.5×10^{-5}	6.9
M1:PCBM (thermally annealed solvent vapor treated)	1.5×10^{-5}	6.9×10^{-5}	4.6
M2:PCBM (as cast)	0.96×10^{-6}	6.8×10^{-5}	71
M2:PCBM (solvent vapor treated)	6.8×10^{-6}	7.0×10^{-5}	10.3
M2:PCBM (thermally annealed solvent vapor treated)	9.6×10^{-6}	7.0×10^{-5}	7.3

the solvent vapor treated blend. Moreover, the electron mobilities with and without solvent annealing are almost the same. The increase in hole mobility after solvent vapor treatment is attributed to the enhance in the crystallinity and surface roughness of the **M1** or **M2** as indicated from the absorption spectra and AFM images. The mobility difference between the holes and electrons decreases remarkably and reduces the effect of space charge for the devices based on solvent vapor treated blends. Therefore, we assume that the charge collection efficiency has been increased for these devices resulting in improvement in the overall PCE of the devices.

Finally, we have investigated the PV response of the devices based on thermally annealed on the solvent vapor treated blends. The *J–V* characteristics of these devices are shown in Fig. 11. The PV parameters are summarized in Table 3. Both V_{oc} and J_{sc} have been increased for these devices as compared to devices based on solvent vapor treated blends. The PCE has been further increased up to 3.57% and 2.42% with the thermally annealed solvent treated **M1**:PCBM and **M2**:PCBM blend, respectively. This increase in PCE may be attributed to a further increase in the crystallinity of the blend upon the thermal treatment. We have also measured the hole and electron mobility for the devices based on the thermally annealed solvent vapor treated blends and found that the hole mobility has been further increased (as shown in Table 4). Moreover, the electron mobility has also been increased by 20 times as compared to the solvent treated blend, indicating that thermal annealing can effectively activate PCBM molecules to diffuse and aggregate into clusters for better charge transport. The increase in both electron and hole mobilities for the device based on the thermally annealed solvent vapor treated blends, further reduces the space charge effect, improves the charge transport and charge collection leading to the overall PCE of the device.

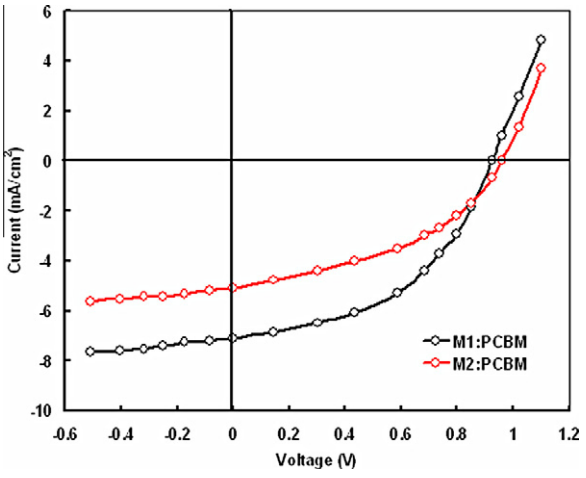

Fig. 11. Current–voltage characteristics of the devices based on THF treated and thermally annealed **M1**:PCBM and **M2**:PCBM blend under illumination intensity of 100 mW/cm^2.

4. Conclusions

Two new molecules **M1** and **M2** of low band gap which contained a central spacer and 4-nitro-α-cyanostilbene terminal units were synthesized. They were soluble in common organic solvents. Their long-wavelength absorption maximum was at 590–640 mm with thin film absorption onset at 742 nm corresponding to an optical band gap of 1.67 eV. The electrochemical band gap estimated from the cyclic voltammetery data is 1.70 eV, which is very close to the optical band gap. However, the HOMO and LUMO of **M1** and **M2** are at different energy levels. We have used both **M1** and **M2** as electron donor for BHJ PV devices along with PCBM as electron acceptor. The hole mobility of **M1** is higher than that of **M2**. The PCE for pristine **M1**:PCBM and **M2**:PCBM is 1.67% and 1.05%, respectively. The higher value of PCE for **M1**:PCBM is due to the higher hole mobility of this molecule. The devices with solvent vapor treated shows PCE 3.05% and 1.90% for **M1**:PCBM and **M2**:PCBM, respectively. The improved PCE has been interpreted in terms of more balanced charge transport due to the modified nanoscale morphology and increased crystallization of the blend. The PCE has been further increased up to 3.57% and 2.42% for the devices based on thermally annealed solvent vapor treated blend **M1**:PCBM and **M2**:PCBM, respectively. This has been attributed to the higher balance charge transport due to both increases in electron and hole mobilities in the blend. Our studies indicate that a combination of thermal annealing and solvent vapor treatment is an effective approach to improve the PCE of organic BHJ PV device.

Acknowledgement

We are thankful to Prof. Y.K. Vijay, for allowing us to undertake the device fabrication and characterization in his laboratory. We are also grateful to the Scientists in IUAC, New Delhi for recording the AFM images of the blend samples.

transport occurs far away from the quasi-equilibrium state. In such a case, analyzing the behavior of the device with the assumption that charge carriers have attained the quasi-equilibrium state may result in misleading conclusions. The uncertainty about the state of carriers in these organic photonic devices also raises doubt over the assumptions made in the analysis of the experiments like transient electroluminescence that the charge carriers are in true quasi-equilibrium [11]. Even in the case of well established time of flight mobility measurement technique, the deviation of the carriers from the true quasi-equilibrium is of great concern as far as the analysis of the transients and the extraction of the mobility value is concerned [3,12–14]. Thus, it is highly important to understand the characteristics of non-equilibrium transport and the influence of the same on device characteristics.

In this article we investigate the field dependence of mobility for different values of the sample thickness. By varying the thickness of the sample one can capture the different stages of carriers that approach towards the true quasi-equilibrium and the corresponding evolution of various characteristics such as field and temperature dependence of mobility. Our simulation studies, with zero positional disorder, show a negative field dependence of mobility (NFDM) at low field regime ($\sim < 3.6 \times 10^5$ V/cm) in samples of smaller thickness (of the order of few hundred nanometers). The observed NFDM at low field regime gradually vanishes with the increase of sample thickness. A clear saturation of mobility at low field regime is observed at large sample thicknesses (few microns), which is same as reported earlier [3]. In the present study the observed NFDM is explained on the basis of gradual reduction of carrier's ability to wander in the lattice to find out the least resistance paths when the carrier relaxes toward the bottom of the DOS so as to achieve the true quasi-equilibrium [3]. The dependence of observed results on sample thickness, energetic disorder and temperature is also explained.

Earlier studies [3,4] have reported NFDM at low field regime in thicker samples where carrier is believed to have attained a true quasi-equilibrium condition. It has been explained by GDM on the basis of high positional disorder [3,4] present in the sample. High positional disorder opens up numerous least resistant paths/faster routes to the carriers which enhance the mobility [3,4]. These paths may involve carrier jumps against the field direction that can help the carrier reach transport sites in the direction of the applied field faster than in the absence of positional disorder. The availability of these least resistant paths diminishes with increase of electric field strengths and gets totally eliminated at high field strengths. At higher fields, the field assisted barrier lowering becomes dominant and results in the increase of mobility in Poole–Frenkel fashion [3,4]. Thus, initially mobility decreases with increase of field strength and reaches a minimum before it starts increasing with increase of field in a $\log\mu$ Vs $E^{1/2}$ fashion. In addition, our earlier report has shown that a very low value of energetic disorder, which leads to saturation of drift velocity even at lower electric field strengths, can results in a total NFDM over the entire regime of electric field strength [15]. In this context, our present simulation study, with zero positional disorder, highlights another important fact that an NFDM at low field regime can also be observed if the carriers involved in the charge transport have not attained true quasi-equilibrium condition.

2. Details of simulation

The Monte Carlo simulation is based on the commonly used algorithm reported by Schönherr et al. [16]. A 3D array is considered as the lattice with size 70×70 along x and y direction. Along z direction, the direction of the applied field, various sizes are used for attaining the required sample thickness along this direction. The lattice constant a = 6 Å is used for the whole set of simulation. The site energies of lattice are taken randomly from a Gaussian distribution with a known standard deviation (σ). Throughout the simulation the positional disorder is neglected ($\sum = 0$). Simulation is always performed on this energetically disordered lattice with the assumption that the carrier hops among the lattice sites following Miller–Abrahams equation [17] in which the jump rate v_{ij} of the charge carrier from the site i to site j is given by,

$$v_{ij} = v_0 \exp\left(-2\gamma a \frac{\Delta R_{ij}}{a}\right) \begin{pmatrix} exp\left(-\frac{\varepsilon_j - \varepsilon_i}{kT}\right) & , \quad \varepsilon_j > \varepsilon_i \\ 1 & , \quad \varepsilon_j < \varepsilon_i \end{pmatrix} \tag{1}$$

where $\Delta R_{ij} = | R_i - R_j |$ is the distance between sites i and j, ε_j and ε_i represent the effective energy for the sites i and j, which includes the electrostatic energy due to the applied electric field, a is the inter-site distance, k is the Boltzmann constant, T is the temperature in Kelvin, v_0 is the jump frequency in a lattice without any disorder and $2\gamma a$ is the wave function overlap parameter which controls the electronic exchange interaction between sites. Throughout the simulation we have taken $2\gamma a = 10$ [3,16]. Transit time of a carrier is calculated by adding all the hopping times and averaging over few hundred carriers which are injected one at a time. The mobility is calculated using drift mobility equation. The electric field strengths ($>10^4$ V/cm) over which the simulations are performed is well above the field range ($\sim 10^1 - 10^2$ V/cm) for which the pure diffusion dominates the charge transport [18]. The lowest electric field used in this study ($\sim 4 \times 10^4$ V/cm) is well above the critical field required for the drift mechanism to dominate the charge transport even for the smallest thickness under study [18]. Hence the use of drift mobility equation over the field range of this study is appropriate. The position of the carrier as a function of time is recorded and is used to calculate diffusion co-efficient (D) by using the following formula [3],

$$D = \frac{\left\langle (x - \langle x \rangle)^2 \right\rangle}{2t} \tag{2}$$

Simulation is preformed for various values of energetic disorder (σ), electric field strengths and temperature. All the data presented in this article is simulated with uncorrelated site energies.

Simulations are also carried out using small polaron jump rates [19]. The main observations of this article, presence of NFDM at low field regime ($\sim < 3.6 \times 10^5$ V/cm) in samples of very small thickness and gradual reduction

with increase of thickness, are found to be independent of the choice of jump rate (Miller–Abrahams/small polaron) used for simulation. Even though the main findings of this article are independent of the choice of jump rate, jump rate based on Miller–Abrahams equation is considered to be more appropriate for the present study because the use of small polaron model requires unacceptable values of polaron binding energies or transfer integrals when site energies are uncorrelated [20]. Hence in this report we show the simulation results only for Miller–Abrahams jump rate equation, which is sufficient for demonstrating and explaining the main findings reported in this article.

3. Results and discussion

Fig 1(a-d) shows the field dependence of mobility parametric with thickness for various values of energetic disorder. When the sample thickness is small, for all values of energetic disorder under study, mobility first decreases with increase of electric field strength and reaches a minimum before it starts increasing with increase of electric field strength in a $\mathrm{Log}\mu \propto E^{1/2}$ fashion [3]. Thus, we observed a NFDM at low field regime ($\sim < 3.6 \times 10^5$ V/cm) for all values of the energetic disorder under study when the sample thickness is small. In order to quantify NFDM we define the strength of NFDM ($\Delta\mu_{\mathbf{NFDM}}$) as the difference between the mobility values for the lowest electric field strength under study and the observed minimum of the mobility at low field regime. As we increase the thickness of the sample, the strength of the observed NFDM gradually decreases and finally at large values of sample thickness mobility is nearly a constant at low field regime. For all values of energetic disorder under study, the value of mobility becomes independent of thickness (i.e. attaining true quasi-equilibrium value) in samples of large thickness ($\sim >$ few microns). The thickness of the sample at which the NFDM vanishes depends on the value of the energetic disorder. In case of $\sigma = 40$ meV, NFDM is observed even in micron thick samples while for the higher values of the energetic disorder ($\sigma = 75$ meV, 85 meV) the NFDM vanishes totally when the thickness of samples is increased to few hundreds of nanometers. In addition, for high values of the energetic disorder ($\sigma = 75$ meV, 85 meV), the observed NFDM vanishes before the mobility attaining the true quasi-equilibrium value (i.e. thickness independent mobility). On the other hand, for low values of energetic disorder ($\sigma = 40$ meV, 60 meV) the observed NFDM vanishes approximately at time of mobility reaching its true quasi-equilibrium value. Moreover, the strength of NFDM

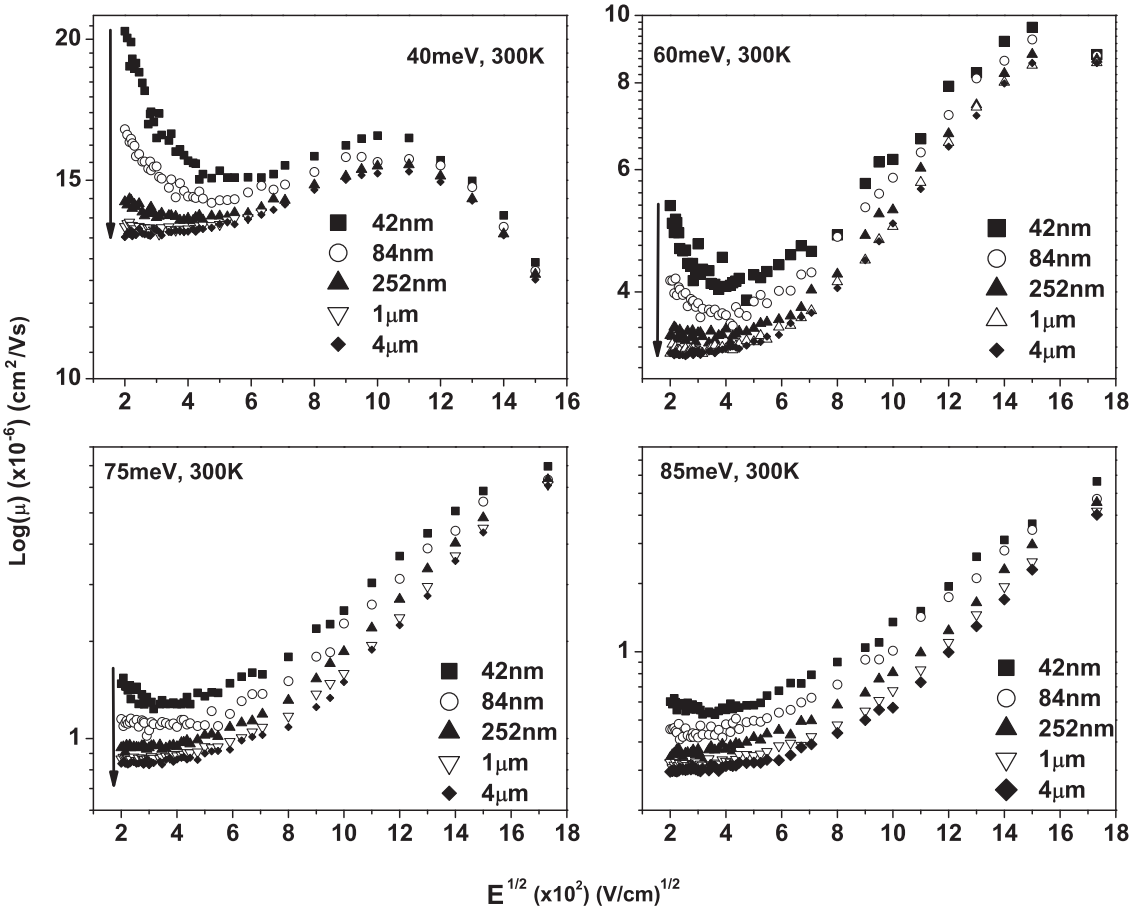

Fig. 1. Simulated field dependence of mobility, at $T = 300$ K, parametric with sample thickness for various values of energetic disorder. Value of energetic disorder is given in the respective figures.

is smaller for higher values of the energetic disorder and vice versa. The strength of the electric field at which the minimum of the mobility at the low field regime occurs also decreases with the increase in the sample thickness and the energetic disorder. In the intermediate field regime, magnitude of mobility decreases with the increase in the sample thickness but the nature of the field dependence of mobility remains same. Increase of mobility with the electric field strength in the Log$\mu \propto E^{1/2}$ fashion, observed in the intermediate field regime, is due to the tilting of density of states by the applied field that leads to the decrease of the energetic barrier seen by the charge carriers [3]. In the high field regime ($E > \sim 1 \times 10^6$ V/cm), we observed a NFDM for the low values of the energetic disorder (σ = 40 meV, 60 meV) under study. This is due to the saturation of drift velocity at high electric field strengths which results in the decrease of mobility with the further increase of electric field [3,21]. For higher values of the energetic disorder (σ = 75 meV, 85 meV), the saturation of drift velocity is not attained even for the highest value of the electric field strength in this study ($E = \sim 8 \times 10^6$ V/cm).

Our main findings which we try to explain here are the origin of the observed NFDM at low field regime in very thin samples and the dependence of the same on sample thickness, energetic disorder, temperature and strength of electric field. An NFDM at low field regime was earlier observed in samples with thickness of the order of few microns [3,4]. The reported data [3,4] establishes that a high value of positional disorder and a reasonable value of energetic disorder is indispensible for observing NFDM at low field regime. However, in our simulation we have considered *only* the energetic disorder ($\sum = 0$). The NFDM at low field regime observed in our simulation studies, even in the absence of any positional disorder, may be associated with non-equilibrium charge transport which need not be the case in the earlier reported data [3,4] where NFDM was observed in samples with thickness of the order of few microns. The similarity between the simulated data for micron thick samples and reported data in Refs. [3,4] supports this conjecture.

In order to understand the origin of the observed NFDM at low field regime, simulation is carried out to figure out as to when the carriers attain the quasi-equilibrium [3]. Coefficient of diffusion along the field direction is calculated as function of time [6,9]. Fig. 2 (a-d) shows variation of the coefficient of diffusion with time (*normalized with the dwell time of carrier in a lattice without disorder,* t_0 [2]), for various values of the energetic disorder and for

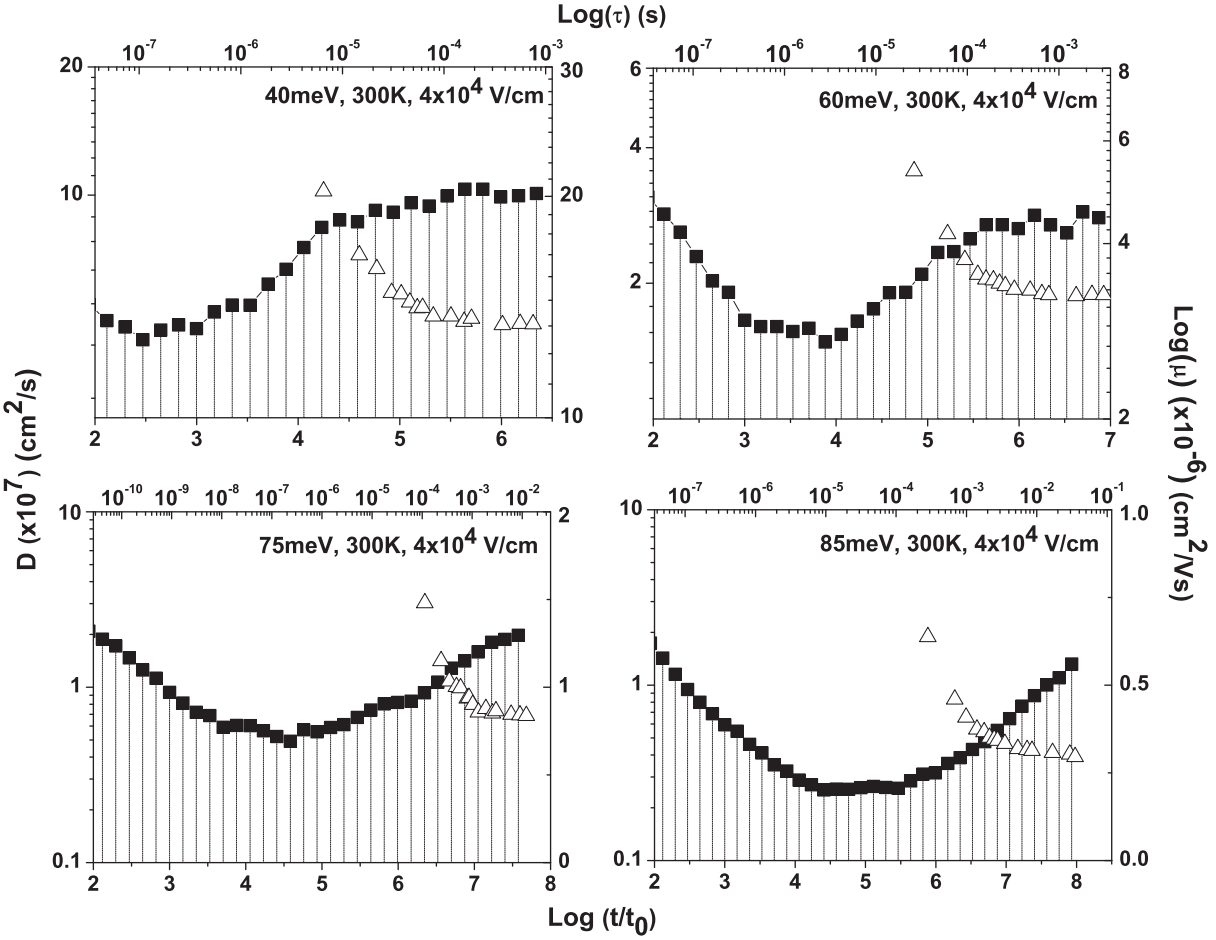

Fig. 2. Calculated coefficient of diffusion (D) of carriers while hopping in a Gaussian DOS, at T = 300 K and $E = 4 \times 10^4$ V/cm. Δ represents the variation of mobility with transit time (τ). t_0 is the dwell time of carrier in a lattice without disorder.

the lowest electric field strength under the study. Variation of mobility with transit time for the lowest electric field strength under study, effectively the variation of mobility with sample thickness, is also shown. For all value of energetic disorder, the coefficient of diffusion initially decreases with time and reaches a minimum before it starts increasing with time. The calculated value of diffusion coefficient contains the usual thermal energy contribution as well as the field and disorder dependent contribution. The field and disorder dependent part of the diffusion produces an additional non-thermal field assisted spreading of the carrier packet [6,22]. This is due to the wide difference in the distribution of jump rates of carriers that are temporally localized at the bottom and top of the DOS [6,22]. The increase in coefficient of diffusion with time is attributed to the non-thermal field assisted spreading of carrier packet. At long time the coefficient of diffusion is expected to attain a time independent value which is considered as the signature of the carriers attaining true quasi-equilibrium state. For low values of the energetic disorder (σ = 40 meV, 60 meV), diffusion coefficient has attained a time independent value in samples of large thicknesses. While for high value of disorder (σ = 75 meV, 85 meV), the diffusion coefficient has not attained a time independent value even for a thicker sample ($\sim$6 μm). For low value of energetic disorder (σ = 40 meV, 60 meV) mobility becomes independent of thickness only when the diffusion coefficient has attained a time independent value. For high value of energetic disorder (σ = 75 meV, 85 meV), mobility becomes independent of thickness even though the diffusion coefficient is not time independent.

So from Fig. 2 it is concluded that the carriers have not attained the true quasi-equilibrium when the thickness of the sample is very small. The decrease in mobility with increase in sample thickness even in the intermediate field regimes also suggests the same. Quasi-equilibrium condition is normally attained only in samples of very large thickness. The observed NFDM at low field regime that decreases with increase of sample thickness can be explained as follows. In case of samples with smaller thickness, at low electric field strengths, a carrier with the help of thermal energy finds numerous least resistance paths by which it can drift faster along the field direction, i.e. the carrier attains high mobility. These least resistance paths may involve carrier jumping against the field direction. Upon increasing the electric field strength these paths are gradually eliminated. Thus the carrier is forced to drift through the higher resistance paths with increase of electric field strength which in turn leads to the decrease of the carrier mobility. This results in an NFDM in low electric field regime in samples of smaller thickness. Similar explanation has been proposed earlier for explaining the observed negative differential hopping conductivity in doped inorganic semiconductors [23,24] and also for explaining NFDM observed at low field regime in thicker samples [3,4]. In the low field regime, in one way the increase of electric field strength decreases the carrier mobility while at the same time the tilting of DOS by the applied field, which reduces the effective barrier seen by the carrier, tends to increase the carrier mobility. Thus, in the low field regime, there exists a competition between the decrease and increase of the carrier mobility with increase of the electric field due to the respective mechanisms explained above. When the field is sufficiently strong the increase in the carrier mobility due to tilting of DOS by the applied field dominates and leads to the increase of the carrier mobility in a $\mathrm{Log}\mu \propto E^{1/2}$ fashion. This results in minimum of mobility in the low electric field regime. The dependence of the strength of electric field at which this minimum of mobility occurs on thickness, energetic disorder and temperature will be explained later. When we increase the thickness of samples, carriers tend towards attaining the quasi equilibrium. In this process they relax more towards the bottom of DOS [1,2,7]. More the carriers relax to the bottom of DOS higher is the required excitation energy to move around the lattice as before. Thus while covering more and more sample length the ability of the carrier to move around the lattice to find numerous least resistance paths diminishes. Thus, at short times carrier move through small resistance paths that results in high carrier mobility. However, as time advances these paths are not readily accessible to the carriers. So the average mobility of the carrier decreases with increase of sample thickness. This explains why the strength of the observed NFDM decreases with increase of thickness. Decrease of mobility with time has been shown analytically and experimentally in the recent reports as well [11,25–27].

In the present study, for small values of the energetic disorder (σ = 40 meV, 60 meV) the observed NFDM vanishes and the mobility attains the true quasi-equilibrium value almost simultaneously when the diffusion becomes time independent, i.e. only when the carriers have attained the true quasi-equilibrium. This suggests that at very large thickness the carrier attains the true quasi equilibrium and thus the positive influence of thermal energy on mobility at short times disappears resulting in the saturation of mobility at low electric field regime. However, for high values of the energetic disorder (σ = 75 meV, 85 meV) NFDM vanishes well before the carrier attaining the true quasi-equilibrium. From Fig. 1, it is clear that for high value of energetic disorder (σ = 75 meV, 85 meV) the mobility continue to decrease with increase of thickness even after the observed NFDM has totally vanished. This suggests that for the observed decrease in strength of NFDM and the subsequent vanishing of NFDM require only the reduction in the ability of the carrier to find the least resistance paths as the carrier relaxes towards the bottom of the DOS. When the value of the energetic disorder is very high, to effectively move around the lattice in search of least resistance paths the carrier requires high excitation energy even after a short relaxation. Once the carrier is not able to find the sufficient number of least resistance paths to keep the mobility high, the NFDM vanishes and a clear saturation of mobility can be observed. This explains why at high value of energetic disorder the observed NFDM vanishes in samples with thickness of few hundreds of nanometers while for low values of energetic disorder it persists even in micron thick samples (for example σ = 40 meV). In addition to this, for high value of energetic disorder the mobility nearly attains a thickness independent value (for example σ = 75 meV) while the calculated diffusion coefficient continues to increase with time. Thus, we have got a situation

where the mobility has nearly attained a quasi-equilibrium value while the diffusion coefficient continues to increase with time. This is termed as quasi-dispersive regime [9]. Our results suggest that quasi-dispersive regime may be observed only at very high value of energetic disorder.

In light of the above discussion it is also easy to understand why the strength of NFDM decreases with increase in energetic disorder. For high energetic disorder, the energetic barrier seen by the carrier is also high. Therefore carriers require high excitation energy to move around in the lattice. Thus at high value of energetic disorder the carrier will find less number of least resistance paths. This results in low carrier mobility which explains why, for a fixed and small enough value of sample thickness, the strength of observed NFDM in the low field regime decreases with increase of energetic disorder (shown in Fig. 1). Hence for any value of energetic disorder under study, if some extra energy is provided to the carrier a stronger NFDM can be expected. Fig. 3(a-c) shows the field dependence of mobility parametric with temperature for the smallest value of sample thickness under study. At high temperature the carrier gains more thermal energy which helps the carrier to find more number of least resistance paths. Thus the mobility of carrier will be high which in turn leads to the increase in strength of NFDM. Fig. 3(d) shows variation of the strength of NFDM ($\Delta\mu$) with temperature. The strength of NFDM is shown to vary linearly with temperature. The rate of increase of strength of NFDM with temperature decreases with increase in the energetic disorder. These observations assert the strong role of energetic disorder in the observed NFDM at low electric field regime in samples of smaller thickness. The decrease in the strength of NFDM with increase in energetic disorder and decrease of temperature supports our conjecture that decrease in strength of NFDM with increase of sample thickness is due to the relaxation of carriers towards the bottom of DOS.

The strength of electric field at which the minimum of the mobility occurs also depends on how far the carrier has approached towards attaining the true quasi-equilibrium or how close is the carrier from its quasi-equilibrium state. As explained above, in samples of smaller thickness carriers find a large number of least resistance paths and hence, these least resistance paths accessed by the carriers get eliminated only at higher electric field strengths. As we increase the sample thickness the effective number of least resistance paths accessed by the carrier reduces and thus the elimination of the least resistance paths occurs at

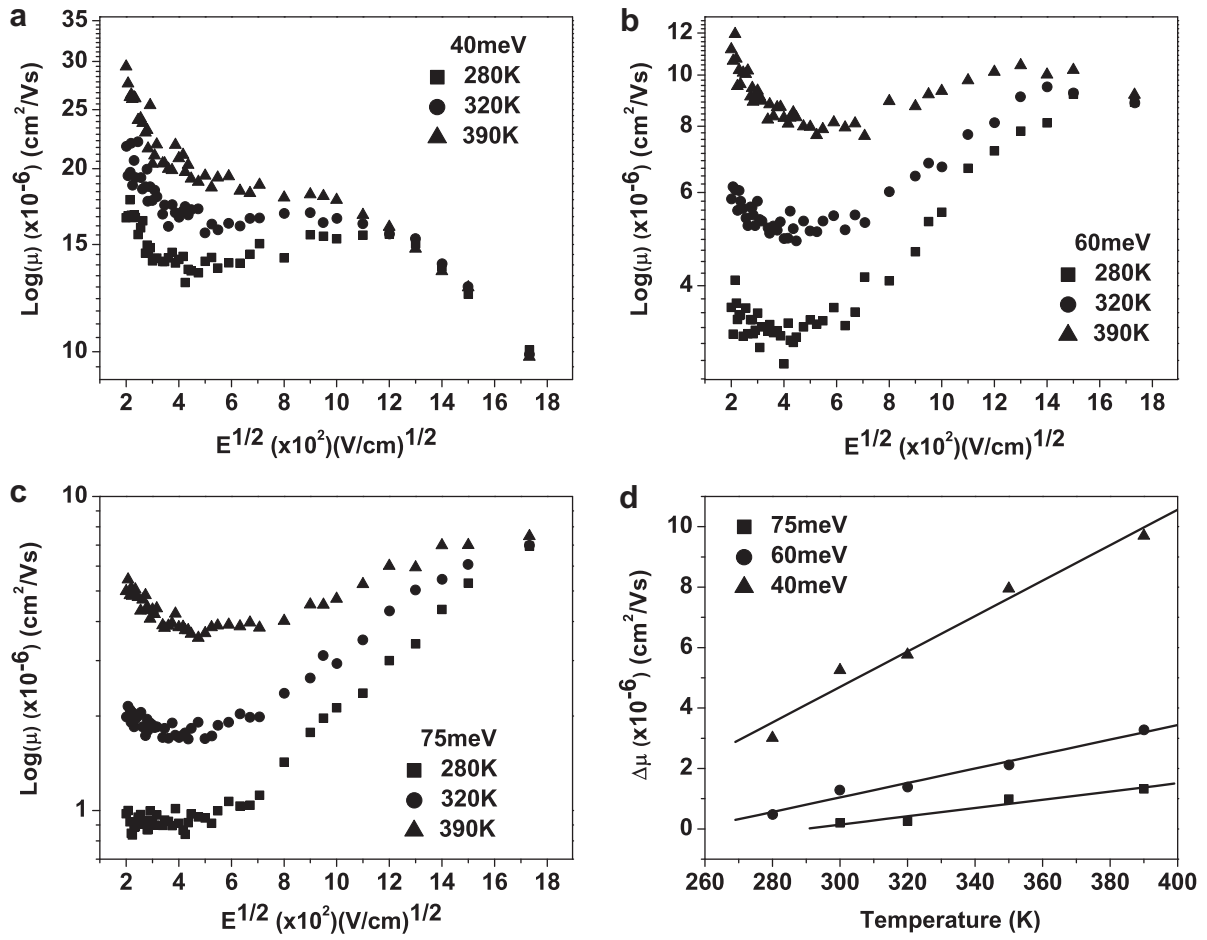

Fig. 3. (a-c) Simulated field dependence of mobility parametric with temperature for various values of energetic disorder. Value of energetic disorder is given in the respective figures. Simulations were carried out in sample of thickness ~ 42 nm. (d) Variation of strength of NFDM with temperature.

lower electric field strengths. Due to the elimination of the least resistance paths at low electric field strengths, the mechanism that leads to the increase of the carrier mobility in a $\mathrm{Log}\mu \propto E^{1/2}$ fashion could dominate at low electric field strengths. Hence, with increase of sample thickness the minima of the mobility at low field regime occur at lower electric field strengths. The occurrence of minimum of mobility at higher electric field strength upon decreasing the value of energetic disorder or increasing the temperature can also be explained in the similar manner.

4. Conclusion

Our simulation study clearly shows the influence of non-equilibrium charge transport on the nature of field dependence of mobility. Even in the absence of positional disorder an NFDM at low field regime is observed in samples of smaller thickness for all values of energetic disorder and temperature. The observed NFDM at low field vanishes with increase of sample thickness. The strength of the observed NFDM is found to be highly dependent on the value of energetic disorder and temperature. The observed NFDM is explained on the basis of carriers relaxing towards the bottom of the DOS in the process of attaining the true quasi-equilibrium. In brief, this study asserts that if the charge transport in the sample under study is not occurring under true quasi-equilibrium condition then an NFDM at low field regime can be observed where the role of the positional disorder as reported in Refs. [3,4] is not very crucial. The results may be relevant for organic photonic devices with active layer thickness in the order of few hundreds of nanometers where one expect non-equilibrium charge transport to take place.

promising properties with field-effect mobilities up to 1.0 $cm^2 V^{-1} s^{-1}$ from drop-cast films [18–20]. However, these molecules still exhibit stability issues. Some thiophene derivatives have also shown promising performances (up to 0.3 $cm^2 V^{-1} s^{-1}$) using alternative solution processing techniques [21,22]. Müllen and co-workers have developed new molecules based on dithieno[2,3-*d*;2′,3′-*d*′]benzo[1,2-*b*;4,5-*b*′]dithiophene that resulted in very good performances in solution processed devices (up to 1.7 $cm^2 V^{-1} s^{-1}$) [23,24]. Such wet processing is amenable to cheap high throughput fabrication using roll-to-roll or inkjet printing technologies. Thus, the overall goal remains the fabrication of stable, solution processable and high performance transistors.

In parallel, carbazole and indolo[3,2-*b*]carbazole derivatives represent a very promising class of materials for OFETs [25–27]. These compounds are good *p*-channel semiconductors, they are stable under ambient conditions and the addition of side chains on the nitrogen atoms results in highly soluble polymers and oligomers [25,28]. Relatively high performances have already been obtained with different carbazole derivatives [29,30]. For instance, hole mobilities as high as 0.3 $cm^2 V^{-1} s^{-1}$ have been obtained with evaporated thin films of 1,4-bis(vinylene-(*N*-hexyl-2-carbazole))phenylene (**CPC**). With indolo[3,2-*b*]carbazoles, the best performance was obtained from vapour deposited thin films of 3,9-diphenyl-5,11-dioctylindolo[3,2-*b*]carbazole [31] and 3,9-di(p-octylbenzene)-5,11-dihydroxyindolo[3,2-b]carbazole with a maximum field-effect mobility of 0.22 $cm^2 V^{-1} s^{-1}$ [32]. Other interesting small molecules have been developed based on the IC framework [33–35]. The only solution processed materials based on carbazole and indolo[3,2-*b*]carbazole are polymers and have shown field-effect mobility up to 0.02 $cm^2 V^{-1} s^{-1}$ [36–40].

New solution processable IC derivatives (Fig. 1) will be presented in this article. These compounds were synthesized based on the CPC class that has been developed by Morin et al. [29]. The synthesis of these new oligomers will be presented as well as their detailed characterization. We will show the influence of substituting the IC unit at the 2- or 3-position and the effect of adding vinylene moieties between the aromatic groups. Due to its high solubility in common organic solvents, 3POIND, whose synthesis and full characterization have been published elsewhere [31], will also be studied. The solution-processed thin films have been obtained by two different deposition techniques: drop-casting and shearing. By using polarized optical microscopy (POM) and XRD techniques, a better understanding of the relationship between the morphology and the performances of each material should be achieved.

2. Results and discussion

2.1. Synthesis of indolo[3,2-b]carbazole derivatives

As mentioned earlier, the synthesis of 3,9-diphenyl-5,11-dioctylindolo[3,2-*b*]carbazole has already been reported in the literature [31]. In order to obtain the four new indolo[3,2-*b*]carbazole derivatives shown in Fig. 1, 2-bromoindolo[3,2-*b*]carbazole and 3-bromoindolo[3,2-*b*]carbazole had to be synthesized. The synthetic pathway of these two unsymmetrical compounds was more complex than expected and is presented in Scheme 1. The first step involved the synthesis of the indole-2-carbonyl chloride (**2**) starting from the indole-2-carboxylic acid by treating it with thionyl chloride. This acid chloride was immediately used to perform an acylation reaction with either 5- or 4-bromoindole as described by Okauchi et al. and also by Wahlström et al. [41,42]. This led to compound (**5**) which was obtained with a 72% yield and compound (**6**) in a 67% yield. The ketone was then reduced into the corresponding alkyl group by simply

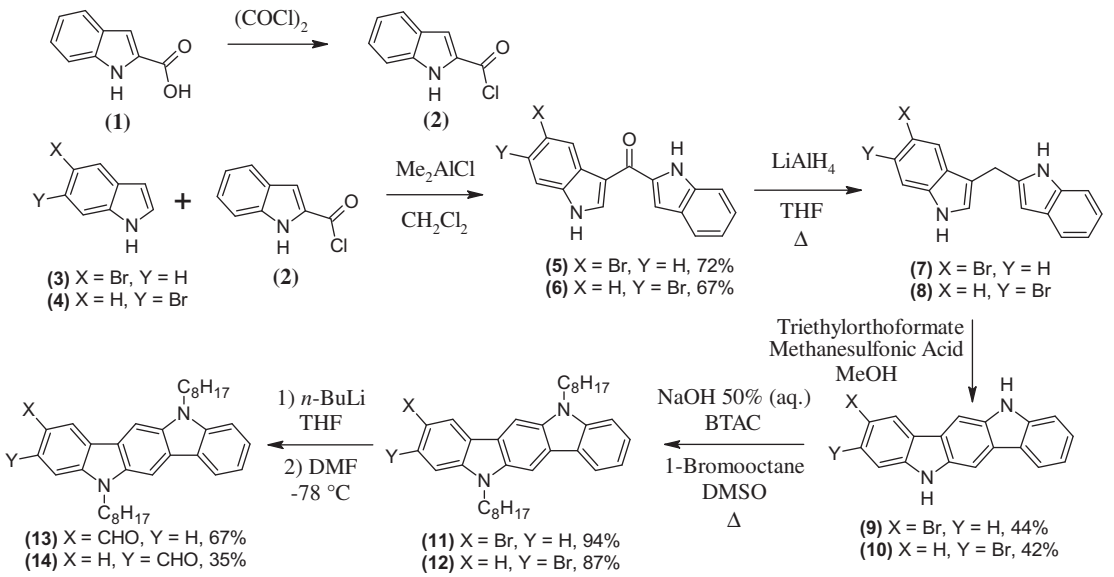
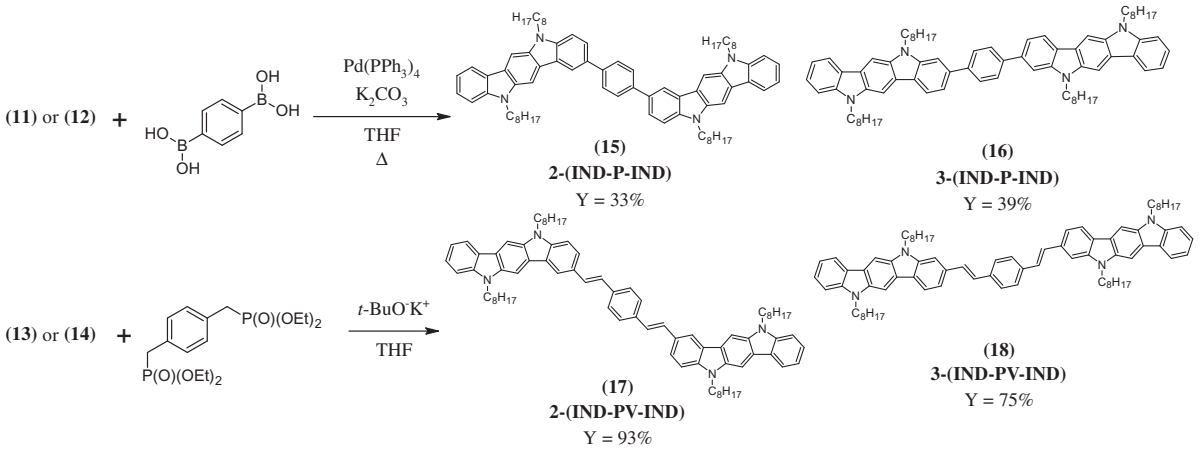


Scheme 1. Synthesis of the unsymmetrical indolo[3,2-b]carbazole. BTAC: benzyltriethylammonium chloride.

treating with lithium aluminum hydride in anhydrous THF. Compounds (**7**) and (**8**) were used without further purification with the following step being the formation of the IC framework. The cyclisation is performed by treatment with triethylorthoformate and catalytic amount of methanesulfonic acid in methanol [43]. Compounds (**9**) and (**10**) were obtained in 44% and 42% yields. Afterward, the 5,11-dihydroindolo[3,2-*b*]carbazole can be alkylated or arylated with different side chains.

Linear octyl side chains were added on both nitrogen atoms through a regular phase transfer condensation [31,34,35]. The starting compounds (**9**) and (**10**) are treated with aqueous sodium hydroxide, 1-bromooctane, and benzyltriethylammonium chloride as the phase transfer agent in DMSO. After heating at 65 °C for 4 h, compounds (**11**) and (**12**) were obtained in high yields (94% and 87%, respectively). These two compounds can be coupled via Suzuki cross-coupling with benzene-1,4-diboronic acid to obtain two new IC derivatives which should be highly soluble in organic solvents. The yields for the two reactions are 33% for 2-IND-P-IND (**15**) and 39% for 3-IND-P-IND (**16**). To achieve the syntheses of compounds (**17**) and (**18**), aldehyde functional groups had to be added instead of the bromine. This substitution is first performed by lithiation of compounds (**11**) and (**12**) and further treatment with N,N-dimethylformamide at −78 °C. Compounds (**13**) and (**14**) were successfully synthesized with 67% and 35% yields. Finally, those two compounds were mixed with 1,4-bis(methylphosphonate)benzene in anhydrous THF to perform Horner–Emmons reactions to obtain compounds (**17**) and (**18**) in 93% and 75% isolated yields. The final step of the synthesis of the materials is presented in Scheme 2.



Scheme 2. Synthesis of the four new indolo[3,2-*b*]carbazole derivatives.

2.2. Thermal properties

The thermal properties of the new derivatives were studied using thermogravimetric (TGA) and differential scanning calorimetry (DSC) analyses (Table 1). The full characterization of 3POIND has already been published elsewhere [31]. There were no degradation processes observed for all these indolo[3,2-*b*]carbazole derivatives below 440 °C under a flow of nitrogen. Moreover, the DSC curves do not show any particular thermal phenomenon, meaning that no glass transition temperatures were observed for any of these materials. Small peaks were obtained about 50 °C before the melting peak but those exothermic peaks are probably due to crystallization of the molecules during the heating process.

Table 1
Thermal properties of the oligomers.

Oligomer	T_d (°C)[a]	T_m (°C)[b]	T_c (°C)[b]
2-(IND-P-IND)	–	201	–
3-(IND-P-IND)	470	153	–
2-(IND-PV-IND)	440	212	193
3-(IND-PV-IND)	–	230	170
3POIND	410	237	196

[a] Degradation temperature (T_d) observed from TGA corresponding to 5% weight loss at 10 °C min^{-1} under nitrogen flow.
[b] Melting temperature (T_m) and crystallization temperature (T_c) observed from DSC at 10 °C min^{-1} under nitrogen flow.

2.3. Optical and electrochemical properties

The optical properties were characterized by UV–vis absorption spectroscopy and are summarized in Table 2. The solution and thin-film spectra of 2-(IND-P-IND) and 3-(IND-P-IND) are shown in Fig. 2. The data extracted from these spectra reveals a longer conjugation length for IC derivatives substituted at the 3-positions. It also shows that the addition of a second indolocarbazole into the material does not greatly affect the conjugation length of the molecule. The absorption maximum of the 3POIND is 366 nm compared to 368 nm for the 3-(IND-P-IND). This indicates that the phenyl group in the latter hinders the conjugation due to the phenyl-substituent bond which usually shows torsion angle of about 40° [44].

The UV–vis absorption spectra in the solid state were taken for 2-(IND-P-IND) and 3-(IND-P-IND) and not for the two other derivatives because it was very difficult to cast the films on quartz plates. The spectra exhibit a red shift compared to the solution spectra in CH_2Cl_2. This red shift is typically indicative of favourable interactions and stacking between the molecules in the solid state which leads to greater electron delocalization. A blue shift was observed in the case of 3POIND and it was attributed to

Table 2
Optical absorption maxima (λ_{max}) and electrochemical properties of the new materials.

Oligomer	λ_{abs} (nm) Solution[a]	λ_{abs} (nm) Thin film[b]	E_g (eV) Thin film [b]	$E_{peak\ ox}$ (V versus SCE)[c]	E_{HOMO} (eV)[d]
2-(IND-P-IND)	266, **349**, 401, 425	275, **353**, 409, 434	2.74	0.76 (0.69)	5.40

[a] Measurements performed in CH_2Cl_2.
[b] Measurements performed on 300 Å thin films vacuum-deposited on quartz.
[c] SCE: saturated calomel electrode. The values in parentheses correspond to the oxidation peak onset.
[d] Ionization potential (E_{HOMO}; HOMO: highest occupied molecular orbital) measured from the cathodic onset.

the formation of H-aggregates in the solid state is which often observed in closely packed structures [30,45]. The optical band gaps (E_g) were estimated from the onset of the absorption spectra in the solid state and the E_g for 2-(IND-P-IND) and 3-(IND-P-IND) are 2.74 and 2.68 eV, respectively. These values are very similar to the one obtained for 3POIND (2.65 eV).

Cyclic voltammetry experiments were also performed on the four new derivatives. They all showed one quasi-reversible oxidation process above 0.64 V versus SCE. 3-(IND-PV-IND) showed a second oxidation process at 1.00 V that was also quasi-reversible. The HOMO energy levels were calculated from the oxidation onset and varies from 5.40 to 5.65 eV [46]. The absolute values of these energy levels are higher than those observed for pentacene [47] and several thiophene derivatives [48] and should be high enough to avoid irreversible oxidation by the oxygen in air. Furthermore, the HOMO of the oligomers matches quite well the work function of a gold electrode (5.1 eV) [49].

2.4. Structural and morphological characteristics of Indolo[3,2-b]carbazoles

Because of the relatively large thickness of the solution-processed films for OFET applications, characterization techniques such as atomic force microscopy (AFM) and XRD do not provide any relevant information regarding the organization of the material in the first few layers on top of the substrate. These are the most significant layers since they are directly involved in the charge transport. The most interesting results were obtained by polarized optical microscopy (POM). This simple technique allows us to observe whether a crystalline or an amorphous film is present. One can also qualitatively measure the size of the crystallites. The first studied processing technique was the drop-casting of the films. Thin films were processed with different solvents and concentrations. As shown in Fig. 3, the main problem with this processing technique is the formation of a homogenous surface with large crystallites. In this case, a 2.0 mg/mL concentration in xylene was used. In order to evaporate the solvent left and trapped within the film, the device was heated at 100 °C for 30 min before the measurements. One of the main drawback of heating these type of film is that they tend to crack, resulting in smaller grain size and consequently, lower field-effect mobilities.

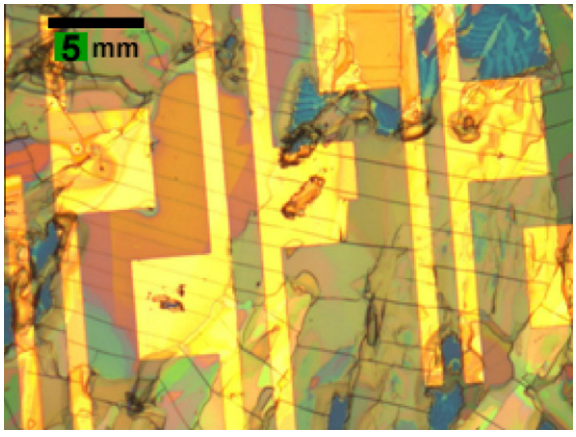

Fig. 3. Bright field micrograph of drop-cast 3POIND film. The gold channels are in yellow and under the organic material film (bottom-contact architecture).

From these observations on 3POIND, films processed by the shearing technique provide much larger crystalline grains than other technique such as drop-casting or spin-coating. As one can see in Fig. 4, by dragging a second substrate on top of the one containing the material in solution, it is fairly easy to obtain highly oriented films. Top-contact architecture was used for these devices since the shearing process could damage the quality of the gold channels. Because of the film orientation, it is very important to evaporate gold in a way that the device will be built along the crystalline grains and not perpendicular to them. With these two figures, it is obvious that the solution sheared will bring a higher crystallinity and therefore probably better performances.

The other four indolocarbazole derivatives led to amorphous-like films. Only small crystalline area could be found on the whole surface of the films. The low level of crystallinity observed by POM may be due to the length of these molecules along with the number of alkyl chains branched on the backbone. This molecular structure may not be adequate for efficient organization and packing. Furthermore, the presence of two IC moieties within each material produces disorder and consequently amorphous films. The addition of vinyl group between the ICs and the phenyl unit does not allow a better organization. Many conformations for this type of molecule create significant disorder which alters the efficient packing of the material. Therefore, it is believed that 3POIND has a great potential compared to the four other synthesized materials.

To prove that point furthermore, XRD experiments were performed to have a better idea of the organization within the films. However, no significant data could be extracted from the drop-cast films, most probably due to their thickness and heterogeneity. XRD experiments still showed out of plane ordering on the sheared films. Comparison with previous XRD experiments with vacuum evaporated thin film were performed [31]. As shown in Fig. 5, the sheared film adopts a very similar organization. The primary diffraction peak was observed at 5.52° which corresponds to a *d*-spacing of 16.0 Å. The second and third-order peaks are less intense than the primary peak but can still be found at 11.1° and 16.7°. The presence of these peaks indicates that the shearing technique gives rise to highly ordered films. This certainly means that the organization in three dimensions is very similar to what was observed for the sublimated thin film. Then, indolo[3,2-*b*]carbazole molecules should lay almost parallel to the substrate. The edge-on configuration have resulted in very promising performances in several studies [50].

2.5. Field-effect transistors

The field-effect transistors were fabricated from these drop-cast and sheared films. First, the drop-cast devices

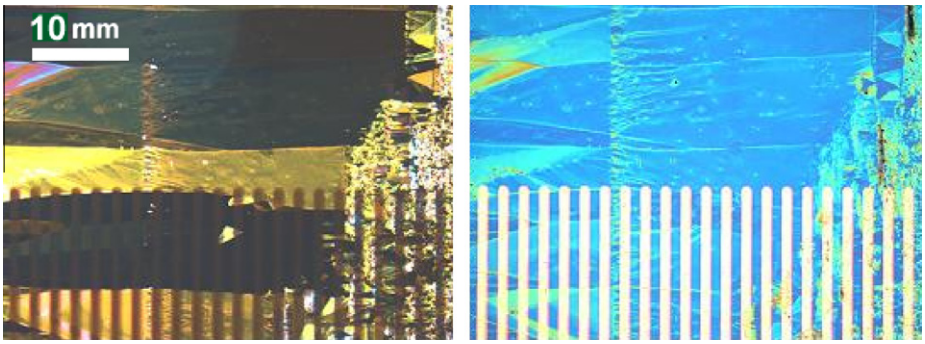

Fig. 4. (Left) Optical micrograph under cross-polarized optical microscopy of 3POIND using the shearing technique for film processing. (Right) The same film under bright-field.

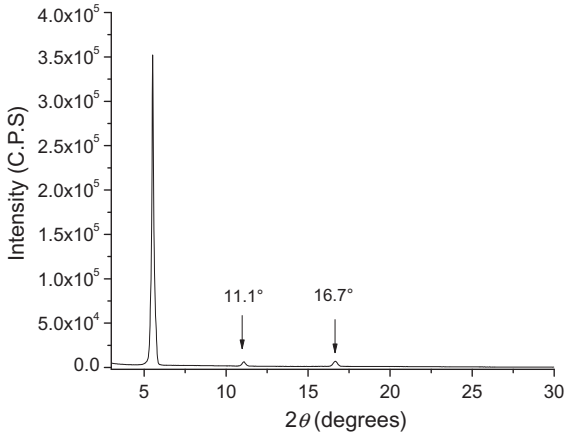

Fig. 5. XRD experiment on a sheared film of 3POIND.

were made in the bottom-contact architecture by vacuum evaporation of gold channels on OTS-treated Si/SiO_2 substrates. In order to obtain good quality films, the solution was deposited on the heated substrate which was covered with a funnel to decrease the evaporation rate of the solvent and promote larger crystal growth. Second, as described by Becerril et al. [21], the shearing technique leads to well-oriented crystals on the substrates. Higher field-effect mobilities can be obtained because the films have a much better uniformity. The sheared films were processed on phenyltrimethoxysilane (PTS)-treated substrates.

For vapour deposited thin films, plain and OTS-treated Si/SiO_2 substrates were used. It has been demonstrated that the treatment of bare Si/SiO_2 wafers has a great impact on the devices performances [51,52]. The addition of a hydrophobic layer on top of the silicon oxide decreases the number of surface hydroxyl groups which can either act as dopant (which increases off current) or act as trap sites [53]. As shown before, carbazole and indolo[3,2-*b*]carbazole derivatives typically behave as *p*-channel semiconductors when the electrode is gold. An example of the electrical measurements performed on the deposited thin films is shown in Fig. 6. A curve of the source–drain current (I_{DS}) versus source–drain voltage (V_{DS}) at various gate voltage is represented as well as I_{DS} versus the gate voltage (V_G) at a fixed V_{DS} (−100 V) both for a sheared film of 3POIND.

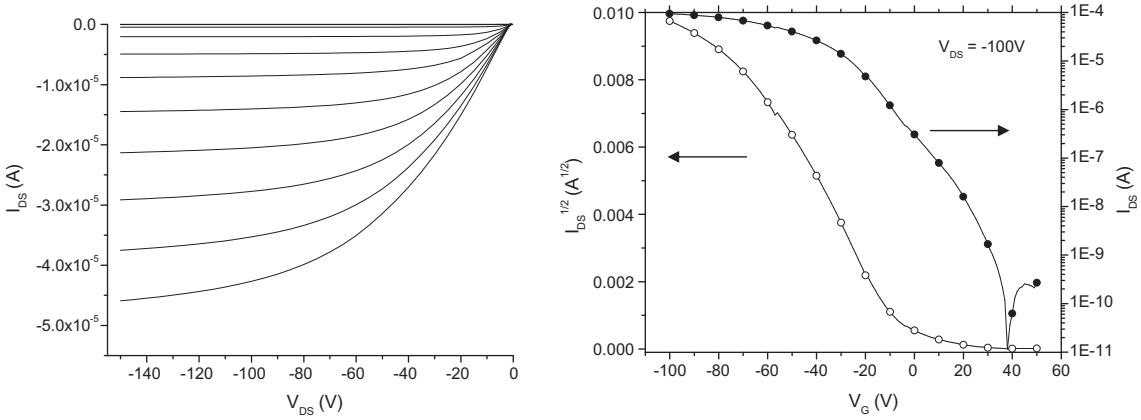

Fig. 6. Source–drain current (I_{DS}) versus source–drain voltage (V_{DS}) at various gate voltages (V_G) for top-contact field-effect transistors using solution processed 3POIND on PTS-treated SiO_2. The transfer characteristics in the saturation regime at a constant source–drain voltage (V_{DS}) −100 V) are also included.

Table 3
Field-effect mobilities, on/off ratios, and threshold voltages of solution processed indolo[3,2-*b*]carbazoles transistors prepared on SiO_2.

Compound	Solvent	[ ] (mg/mL)	T (°C)	μ ($cm^2\,V^{-1}\,s^{-1}$)	On/off	V_T (V)

3-IND-PV-IND	CB	2.0	75	4.7×10^{-4}	2.3×10^2	−32
2-IND-P-IND	CB	2.0	90	6.3×10^{-4}	1.4×10^4	−29
[a]	CB	6.0	85	7.0×10^{-4}	3.7×10^3	−21
3-IND-P-IND	CB	5.0	80	4.1×10^{-4}	1.0×10^2	−19
[a]	CB	5.0	75	5.9×10^{-4}	6.2×10^3	−32

[a] Obtained by the shearing technique on PTS functionalized substrates.

The promising performances previously obtained with 3POIND [31] were confirmed with the first performances obtained from a drop-cast film with field-effect mobility as high as 0.06 $cm^2\,V^{-1}\,s^{-1}$. The on/off ratio and the threshold voltage (V_T) were also good at 2.2×10^5 and −22 V, respectively. As described in Table 3, the parameters that allow the best performances for this compound are a concentration of 1.5 mg/mL in toluene with a thermal treatment at 80 °C in order to evaporate the solvent. Unfortunately, the new synthesized IC derivatives did not show great mobilities with a maximum of 7.6×10^{-4} $cm^2\,V^{-1}\,s^{-1}$ which is probably due to the very poor film-forming ability of these new materials. The on/off ratio was 1.0×10^4 and V_T was −24 V for that particular device. The maxima obtained with such technique are quite misleading, since it is difficult to repeat those performances with other devices and even within the same film because of their poor uniformity.

To solve this problem, the shearing deposition technique could to be useful. It will help to create a uniform film, with highly and oriented crystalline films. Consequently, the mobility observed for drop-cast films have been increased by a factor of 2 by using this new technique. The maximum observed goes from 0.06 to 0.12 $cm^2\,V^{-1}\,s^{-1}$ with an on/off ratio of 5.6×10^6 and a V_T of −31 V. The most efficient films were formed by solubilizing 6.0 mg/mL of material in toluene and heating the substrates at 70 °C. The main difference between the two techniques is that drop-cast films form randomly and discrete highly crystalline zones while sheared films are almost completely covered with oriented highly crystalline areas. For the newly synthesized oligomers, this technique is not so efficient. The highest mobilities observed are increased but not significantly. Furthermore, the problems observed in drop-cast films are recurrent meaning that the derivatives having vinyl link between the IC and the phenyl units hardly form any quality films.

In order to compare the performances of those newly synthesized materials, vacuum-deposited thin films have been tested at different substrate temperature (T_D). Although 3-IND-PV-IND and 2-IND-PV-IND could not be evaporated due to their low vapour pressure, the two molecules without vinyl links have been fully studied and the highest field-effect mobility was obtained with 2-IND-P-IND with $\mu = 7.4 \times 10^{-3}$ $cm^2\,V^{-1}\,s^{-1}$, on/off ratio = 6.4×10^3 and $V_T = -22$ V. For both compounds, the substrate temperature enabling the highest mobilities is 75 °C. The complete results of this study are detailed in Table 4.

Table 4
Field-effect mobility (μ), on/off current ratios, and threshold voltage (V_T) of indolocarbazole derivatives vacuum-deposited on OTS treated SiO_2 surfaces and at different substrate temperatures (T_D).

Compound	T_D (°C)	μ ($cm^2\,V^{-1}\,s^{-1}$)	On/off	V_T (V)
3-IND-P-IND	25	7.2×10^{-4}	2.5×10^4	−15
	60	5.9×10^{-3}	1.4×10^3	−51
	75	7.0×10^{-3}	2.4×10^3	−33
	90	3.7×10^{-3}	1.8×10^6	−4
	125	1.4×10^{-4}	3.0×10^1	−16
2-IND-P-IND	25	1.3×10^{-3}	2.9×10^2	−31
	50	5.3×10^{-3}	1.3×10^4	−31
	75	7.4×10^{-3}	6.4×10^3	−22
	100	No mobility	–	–

The performances of compound 2-IND-P-IND and 3-IND-P-IND are approximately one order of magnitude lower for solution-processed thin films. This is typically observed for organic semiconductors. As shown with 3POIND, the performances are much closer between vacuum-deposited and solution-processed thin films. The main reason could be this semiconductor has the ability to form highly crystalline thin films quite easily. By using sheared films, it was also possible to control the orientation of the crystallite which leads to higher hole mobility.

3. Conclusion

In this study, small molecules based on indolo[3,2-*b*]carbazole derivatives were used for solution processed field-effect transistors. Despite its rigid rod-like structure, it is possible to fine tune the structure to obtain materials with a high solubility. Using different synthetic strategies, 2- and 3-bromoindolo[3,2-*b*]carbazole were successfully obtained for the first time. Five materials were studied extensively through different solution processing techniques, namely drop-casting, shearing, and spin-coating. This last technique leads to the formation of completely amorphous thin films. Highly crystalline films were obtained using the other techniques. Finally, 3POIND shows great promises with a hole mobility of 0.12 $cm^2\,V^{-1}\,s^{-1}$ which is very close to the performances observed for the evaporated thin film (0.20 $cm^2\,V^{-1}\,s^{-1}$) [31]. For the four new materials, the performances were much lower even with evaporated thin films where the field-effect mobility only reached 10^{-3} $cm^2\,V^{-1}\,s^{-1}$. This is most probably due to the numerous conformations that can adopt the four

new derivatives which creates great disorder. Nevertheless, 3POIND has once again shown its great potential for OFET applications and further work on this particular molecule should be done to investigate further.

4. Experimental details

4.1. Characterization

^{1}H and ^{13}C NMR spectra were recorded on a Varian AS400 apparatus in appropriate deuterated solvent solution at 298 K. Chemical shifts were reported as δ values (ppm) relative to internal tetramethylsilane. Differential scanning calorimetry (DSC) analyses were performed on a Mettler Toledo DSC823^e instrument, calibrated with ultrapure indium. UV–vis absorption spectra were taken using a Varian Cary 500 UV–vis-NIR spectrophotometer. Cyclic voltammetry (CV) measurements were recorded on a Solartron 1287 potentiostat and C3 Cell Stand using platinum electrodes at a scan rate of 50 mV s^{-1} against Ag/Ag$^+$ (0.10 M of $AgNO_3$ in acetonitrile) reference electrode in an anhydrous and argon saturated solution of 0.1 M tetrabutylammonium perchlorate (TBAP) (10^{-1} M) in CH_2Cl_2. In these conditions, the oxidation potential (E_{Ox}) of ferrocene was 0.053 V versus Ag/Ag$^+$, whereas the E_{Ox} of ferrocene was 0.343 V versus saturated calomel electrode (SCE). Top contact devices were made according to a literature procedure [54,55]. Highly doped n-type (1 0 0) Si wafers (<0.004 Ω cm) were used as substrates for the devices. SiO_2 layers (unit area capacitance, C = 10 nF cm^{-2}), as gate dielectric, were thermally grown to 3000 Å thickness onto the Si substrates. The SiO_2/Si substrates were then cleaned with acetone and isopropyl alcohol. The wafers were then treated with octadecyl trimethoxysilane ($C_{18}H_{37}Si(OCH_3)_3$, OTS) in solution in dichloroethylene, which was spin-coated onto the substrates before treating with a saturated atmosphere of NH_4OH overnight. Organic films (40 nm) were vacuum-deposited on the treated SiO_2/Si substrates at room temperature and elevated temperatures, as denoted in the text, at a deposition rate of 0.4–0.5 Å s^{-1} and 10^{-6} Torr. The thin-film thickness of each derivative was determined in situ using a quartz-crystal microbalance (QCM). A top-contact thin-film transistor was used for measuring the charge mobility of the indolo[3,2-*b*]carbazole derivatives: gold source and drain electrodes (channel length (L) and width/length (W/L) of 200 lm and ca. 20, respectively) were vacuum-deposited through a shadow mask. The electrical characteristics of the organic field-effect transistors (OFET) devices were measured under accumulation mode using a Keithley 4200-SCS semiconductor parameter analyzer.

4.2. Materials

1,4-Bis(methylphosphonate)benzene was synthesized according to already published procedures [56]. All starting organic compounds were purchased from Aldrich, Alfa Aesar and TCI America and used without further purification. All reactions were carried out under argon at 1 atm unless mentioned otherwise. Some reaction solvents were distilled before use (THF from potassium/benzophenone; acetonitrile from CaH_2). Column chromatography was carried out on silica gel (Size 40–63 μm, pore size 60 Å, Silicycle). All other compounds have been synthesized following procedures described here.

4.2.1. (6-Bromoindol-3-yl)(indol-2-yl) (**5**)

In a flame-dried flask, 5-bromoindole (6.56 g, 33.4 mmol) was solubilized in dichloromethane (84 mL). Dimethylaluminum chloride (45 mL, 1 M in hexanes) was added at −10 °C and the mixture was stirred at 0 °C for 1 h. Afterward, freshly prepared indole-2-carbonyl chloride (33.4 mmol) was added to the mixture, it was allowed to warm up to room temperature and stirred for 12 h at this temperature. Crushed ice in water was then added to the resulting mixture before treating with ammonium chloride (50 mL). The precipitate was filtered and washed with water to afford 8.17 g of the title compound as a green powder. M.P.: 321 °C. (Yield: 72%).

^{1}H NMR (400 MHz, DMSO-d_6): 12.30 (s, 1H); 11.80 (s,1H); 8.54 (s, 2H); 8.09 (m, 1H); 8.43 (d, J = 1.6 Hz, 1H); 7.71 (d, J = 7.9 Hz, 1H); 7.51 (m, 2H); 7.40 (m, 2H); 7.27 (t, J = 7.4 Hz, 1H); 7.09 (t, J = 7.4 Hz, 1H).

HRMS: Calculated for $C_{17}H_{11}N_2OBr$: 338.0055. Found: 338.0046 ± 0.0010.

4.2.3. (6-Bromoindol-3-yl)(indol-2-yl)methane (**7**)

To a solution of compound **5** (0.500 g, 1.47 mmol) in anhydrous THF (4 mL) was added $LiAlH_4$ in THF (1.0 mol/L, 8.9 mL, 8.84 mmol). The reaction was refluxed for 1 h and then was allowed to cool down to room temperature before the addition of sodium potassium tartrate until no gas is generated from the reaction. The mixture was then filtered through Celite and washed with ether. This ethereal fraction was washed with water. The organic layer was dried over $MgSO_4$ and the solvent was removed under reduced pressure. The crude compound was used for the next step without any further purification.

4.2.4. (5-Bromoindol-3-yl)(indol-2-yl)methane (**8**)

This product was obtained (via compound **6**) following the same procedure used for the synthesis of compound **7** to afford the desired crude compound which was also used without any further purification.

*4.2.5. 2-Bromo-5,11-dihydroindolo[3,2-b]carbazole (**9**)*

To a solution of compound **7** (1.47 mmol) in methanol (3 mL) was added triethylorthoformate (0.109 g, 0.735 mmol) and methanesulfonic acid (0.014 g, 0.147 mmol). After 12 h of stirring at room temperature, the precipitate was filtered and washed with methanol to afford 0.213 g of the title compound as a brown powder. M.P.: >300 °C. (Yield = 44%).

^{1}H NMR (400 MHz, DMSO-d_6): 11.22 (s, 1H); 11.11 (s, 1H); 8.45 (d, J = 2.0 Hz, 1H); 8.21 (d, J = 7.9 Hz, 1H); 8.18 (s, 1H); 8.14 (s, 1H); 7.46 (m, 3H); 7.38 (m, 1H); 7.13 (m, 1H).

HRMS: Calculated for $C_{18}H_{11}N_2Br$: 334.0106. Found: 334.0100 ± 0.0010.

*4.2.6. 3-Bromo-5,11-dihydroindolo[3,2-b]carbazole (**10**)*

This product was obtained (via compound **8**) following the same procedure used for the synthesis of compound **9** to afford 0.207 g of the title product as a beige solid. M.P.: 275 °C (degradation). (Yield = 42%).

^{1}H NMR (400 MHz, DMSO-d_6): 11.20 (s, 1H); 11.09 (s, 1H); 8.21 (d, J = 7.9 Hz, 1H); 8.17 (d, J = 8.3 Hz, 1H); 8.14 (d, J = 2.9 Hz, 2H); 7.62 (dd, J = 0.4 et 1.8 Hz, 1H); 7.46 (m, 1H); 7.38 (m, 1H); 7.26 (m, 1H); 7.13 (m, 1H).

^{13}C NMR (100 MHz, DMSO-d_6): 141.94; 141.19; 135.33; 135.10; 125.70; 123.09; 122.45; 121.92; 121.88; 121.82; 120.35; 118.07; 117.76; 112.97; 110.55; 100.84; 100.73.

HRMS: Calculated for $C_{18}H_{11}N_2Br$: 334.0106. Found: 334.0100 ± 0.0010.

*4.2.7. 2-Bromo-5,11-dioctylindolo[3,2-b]carbazole (**11**)*

A freshly prepared 50% aq. NaOH solution (2.6 mL) was added to a well-stirred mixture of compound **9** (0.850 g, 2.54 mmol), benzyltriethylammonium chloride (0.120 g, 0.51 mmol), 1-bromooctane (1.97 g, 10.20 mmol), and DMSO (26 mL) in a 100-mL flask under an argon atmosphere. The mixture was stirred at room temperature for 1 h and then heated at 65 °C and maintained at this temperature for 4 h. Subsequently the reaction mixture was cooled down to room temperature and poured into 100 mL methanol with stirring. The precipitated yellow solid was filtered off and washed with water, and three times each with *N,N*-dimethylformamide and methanol to afford the desired compound. M.P.: 120–121 °C. (Yield = 94%).

^{1}H NMR (400 MHz, Acetone-d_6): 8.43 (s, 1H); 8.39 (s, 1H); 8.34 (s, 1H); 8.26 (d, J = 7.7 Hz, 1H); 7.52 (m, 4H); 7.19 (t, J = 7.3 Hz, 1H); 4.54 (t, J = 7.2 Hz, 4H), 1.98 (m, 4H); 1.33 (m, 20H); 0.83 (m, 6H).

^{13}C NMR (100 MHz, CD_2Cl_2): 142.36; 140.78; 136.70; 136.64; 128.50; 126.50; 12,506; 123.92; 123.24; 123.07; 121.98; 120.74; 118.53; 110.80; 110.47; 109.04; 99.56; 99.41; 43.95; 43.82; 32.39; 32.37; 29.99; 29.96; 29.80; 29.78; 29.29; 29.28; 27.91; 27.86; 23.19; 23.18; 14.41; 14.40.

HRMS: Calculated for $C_{34}H_{43}N_2Br$: 558.2609. Found: 558.2596 ± 0.0017.

*4.2.8. 3-Bromo-5,11-dioctylindolo[3,2-b]carbazole (**12**)*

This product was obtained (via compound **10**) following the same procedure used for the synthesis of compound **11** to afford 0.724 g of the title product as a yellow solid. M.P.: 128 °C. (Yield = 87%).

^{1}H NMR (400 MHz, CD_2Cl_2): 8.20 (m, 1H); 8.06 (m, 2H); 8.02 (d, J = 0.8 Hz, 1H); 7.59 (d, J = 1.7 Hz, 1H); 7.49 (m, 1H); 7.44 (m, 1H); 7.32 (dd, J = 1.7 et 8.2 Hz, 1H); 7.22 (m, 1H); 4.39 (m, 4H); 1.94 (m, 4H); 1.34 (m, 20H); 0.85 (m, 6H).

HRMS: Calculated for $C_{34}H_{43}N_2Br$: 558.2609. Found: 558.2602 ± 0.0017.

*4.2.9. 2-Formyl-5,11-dioctylindolo[3,2-b]carbazole (**13**)*

In a flame-dried flask, compound **11** (0.550 g, 0.983 mmol) was solubilized in anhydrous THF (25 mL) before cooling down to −78 °C. *n*-Butyllithium (2.5 M, 0.8 mL, 1.97 mmol) was then added dropwise and kept at this temperature for 2 more hours. After the treatment with dimethylformamide (0.11 mL, 1.47 mmol) the reaction was stirred at −78 °C for 1 h. The mixture was allowed to warm up to room temperature and was stirred overnight. The resulting mixture was extracted with dichloromethane and washed three times with water. The combined organic layers were dried over $MgSO_4$ and the solvent was removed under reduced pressure. The crude compound was purified by column chromatography with dichloromethane/hexanes (80/20) as the eluent. 0.424 g of the title compound is obtained as a yellow powder. M.P.: 132 °C. (Yield = 67%).

^{1}H NMR (400 MHz, Acetone-d_6): 10.10 (s, 1H); 8.83 (s, 1H); 8.52 (s, 1H); 8.43 (s, 1H); 8.29 (d, J = 7.7 Hz, 1H); 8.03 (dd, J = 1.2 et 8.4 Hz, 1H); 7.72 (d, J = 8.5 Hz, 1H); 7.60 (d, J = 8.3 Hz, 1H); 7.50 (t, J = 7.8 Hz, 1H); 7.21 (t, J = 7.4 Hz, 1H); 4.62 (t, J = 7.1 Hz, 2H), 4.58 (t, J = 7.1 Hz, 2H), 2.00 (m, 4H); 1.32 (m, 20H); 0.83 (t, J = 6.8 Hz, 6H).

^{13}C NMR (100 MHz, CD_2Cl_2): 191.81; 145.65; 142.31; 137.10; 136.81; 128.30; 127.85; 126.61; 123.89; 123.60; 123.06; 123.02; 120.77; 118.71; 109.16; 109.03; 100.15; 99.83; 44.08; 43.86; 32.38; 32.36; 30.00; 29.92; 29.80; 29.76; 29.34; 29.28; 27.92; 27.83; 23.19; 23.18; 14.41.

HRMS: Calculated for $C_{35}H_{44}N_2O$: 508.3453. Found: 508.3459 ± 0.0015.

*4.2.10. 3-Formyl-5,11-dioctylindolo[3,2-b]carbazole (**14**)*

This product was obtained (via compound **12**) following the same procedure used for the synthesis of compound **13** to afford 0.240 g of the title product as a yellow solid. M.P.: 119 °C. (Yield = 35%).

^{1}H NMR (400 MHz, CD_2Cl_2): 10.16 (s, 1H); 8.35 (d, J = 7.9 Hz, 1H); 8.23 (d, J = 7.6 Hz, 1H); 8.12 (s, 1H); 8.11 (s, 1H); 7.98 (s, 1H); 7.75 (d, J = 8.2, 1H); 7.49 (m, 2H); 7.24 (m, 1H); 4.50 (t, J = 7.3 Hz, 2H); 4.42 (t, J = 7.4 Hz, 2H); 1.97 (m, 4H); 1.32 (m, 20H); 0.85 (m, 6H).

4.2.11. 1,4-Bis(N-dioctyl-2-indolo[3,2-b]carbazole)benzene (2-IND-P-IND) (**15**)

Compound **11** (0.575 g, 1.03 mmol) and benzene-1,4-diboronic acid (0.080 g, 0.48 mmol) were solubilized in degassed THF (5 mL) and K_2CO_3 2 M (2 mL). $Pd(PPh_3)_4$ (0.023 g, 0.02 mmol) was added before refluxing the reaction for 10 h. The mixture was extracted with dichloromethane and wash with BRINE and water. The combined organic layers were dried over $MgSO_4$ and the solvent was removed under reduced pressure. The crude product was purified by column chromatography with hexanes/dichloromethane (75/25) as the eluent to afford 0.166 g of the desired compound. M.P.: 204 °C. (Yield = 33%).

^{1}H NMR (400 MHz, CD_2Cl_2): 8.56 (s, 1H); 8.23 (d, J = 7.6 Hz, 1H); 8.16 (s, 1H); 8.10 (s, 1H); 7.93 (s, 2H); 7.87 (d, J = 8.1 Hz, 1H); 7.50 (m, 3H); 7.23 (t, J = 7.1 Hz, 1H); 4.46 (m, 4H); 1.99 (m, 4H); 1.35 (m, 20H); 0.86 (m, 6H).

^{13}C NMR (100 MHz, Benzene-d_6): 142.74; 142.20; 141.34; 137.51; 137.17; 132.43; 126.51; 124.64; 124.11; 124.00; 121.10; 119.67; 109.60; 109.29; 99.88; 43.67; 32.57; 32.55; 30.12; 30.10; 29.92; 29.89; 29.47; 29.43; 38.00; 27.97; 23.37; 23.35; 14.67.

HRMS: Calculated for $C_{74}H_{90}N_4$: 1034.7165. Found: 1035.7183 ± 0.0030.

4.2.12. 1,4-Bis(N-dioctyl-3-indolo[3,2-b]carbazole)benzene (3-IND-P-IND) (**16**)

This product was obtained (via compound **12**) following the same procedure used for the synthesis of compound **15** to afford 0.290 g of the title product as a yellow solid. M.P.: 161 °C. (Yield = 39%).

^{1}H NMR (400 MHz, CD_2Cl_2): 8.30 (d, J = 8.1 Hz, 1H); 8.22 (d, J = 7.7 Hz, 1H); 809 (s, 1H); 7.94 (s,1H); 7.74 (s, 1H); 7.59 (d, J = 8.1 Hz, 1H); 7.48 (m, 2H); 7.23 (t, J = 6.9 Hz, 1H); 4.51 (d, J = 7.2 Hz, 2H); 4.44 (d, J = 7.1 Hz, 2H); 2.00 (m, 4H); 1.36 (m, 20H); 0.86 (m, 6H).

HRMS: Calculated for $C_{74}H_{90}N_4$: 1034.7165. Found: 1035.7183 ± 0.0030.

4.2.13. 1,4-Bis(N,N′-dioctyl-2-indolocarbazolene)phenylene (2-IND-PV-IND) (**17**)

To a solution of compound **13** (0.345 g, 0.678 mmol) and 1,4-bis(methylphosphonate)benzene (0.117 g, 0.308 mmol) in anhydrous THF (7 mL) was added potassium *t*-butoxide (0.294 g, 2.62 mmol). The mixture was stirred at room temperature for 12 h and was then dropped in water. The precipitate was washed with methanol and water. Afterward the product was washed by Soxhlet with methanol in order to obtain 0.313 g of the pure yellow compound. M.P.: 217 °C. (Yield = 93%).

^{1}H NMR (400 MHz, CD_2Cl_2): 8.40 (d, J = 1.7 Hz, 2H); 8.21 (d, J = 7.7 Hz, 2H); 8.12 (d, J = 0.6 Hz, 2H); 8.07 (d, J = 0.6 Hz, 2H); 7.73 (dd, J = 1.6 et 8.4 Hz, 2H); 7.63 (s, 4H); 7.45 (m, 8H); 7.23 (m, 4H); 4.44 (m, 4H); 1.98 (m, 4H); 1.36 (m, 20H); 0.87 (m, 6H).

^{13}C NMR (100 MHz, Benzene-d_6): 142.75; 142.46; 17.86; 137.45; 137.22; 130.35; 129.02; 127.48; 127.44; 126.58; 126.44; 125.76; 124.42; 124.13; 123.97; 121.12; 121.11; 119.51; 119.50; 109.40; 109.30; 99.94; 99.88; 43.76; 43.73; 43.72; 43.70; 32.56; 30.12; 30.08; 29.91; 29.46; 28.03; 27.98; 27.96; 23.36; 14.68.

HRMS: Calculated for $C_{78}H_{94}N_4$: 1086.7478. Found: 1086.7452 ± 0.0032.

4.2.14. 1,4-Bis(N-dioctyl-3-indolocarbazolene)phenylene (3-IND-PV-IND) (**18**)

This product was obtained (via compound **14**) following the same procedure used for the synthesis of compound **16** to afford 0.120 g of the title product as a yellow solid. M.P.: 230 °C. (Yield = 75%).

^{1}H NMR (400 MHz, CD_2Cl_2): 8.20 (t, J = 8.1 Hz, 4H); 8.05 (d, J = 7.0 Hz, 4H); 7.65 (s, 4H); 7.59 (s, 2H); 7.45 (m, 8H); 7.32 (d, J = 16.3 Hz, 2H); 7.22 (t, J = 7.8 Hz, 2H); 4.44 (m, 4H); 1.97 (m, 4H); 1.35 (m, 20H); 0.87 (m, 6H).

(PMMA), polystyrene (PS) and poly-4-vinylphenol (PVP) [24,25] and solid state polyelectrolytes which induce high charge carrier density due to the large electric fields created by ionic charge buildup in the electrolyte [26,27].

Barium titanate ($BaTiO_3$) is widely employed in various electronic and electro-optic applications due to its high dielectric constant [28–31]. Previously, $BaTiO_3$ nanoparticles have been synthesized hydrothermally at moderate temperatures and pressures. A method that has received much less attention is the glycothermal synthesis of $BaTiO_3$. Reports [32,33] have shown that glycothermal processing method provides a simple low temperature route for producing tetragonal $BaTiO_3$ nanoparticles. In addition to easy control over the size and shape of the nanoparticles, the glycothermal process significantly reduces the reaction pressure, which is a critical issue for large-scale production. The purpose of this study is firstly to investigate the optimum condition for preparation of uniform nano-size barium titanate particles by the glycothermal method and to employ these solution processable high-k $BaTiO_3$ nanoparticles as the dielectric layer in an organic field effect transistor to reduce the working voltages.

2. Experimental

2.1. Preparation of barium titanate nanocrystals

$BaTiO_3$ nanocrystals were synthesized from barium hydroxide ($Ba(OH)_2{\cdot}8H_2O$, 99.3%, Fisher chemical) and amorphous titanium hydrous gel precursors. The titanium hydrous gel was prepared by diluting the stoichiometric amount of titanium (IV) isopropoxide (Fluka) in 12.5 mL of 2-propanol (Pr^iOH, 99%, Sigma–Aldrich). A mixture solution of 2-propanol and deionized water (1:2, 1:1, 2:1 M ratios of H_2O:Pr^iOH) was added into the above solution to form a titania gel. The gel was washed with CO_2-free deionized water for three times and added into barium hydroxide solution (0.197 g of $Ba(OH)_2$ and 12.5 mL of 1,4-butanediol). The suspension was aged under vigorous stirring for 10 min before transferred to a Teflon-lined stainless steel autoclave. The sealed vessel was placed into the oven and heated at various reaction temperatures (180, 200, 220, 240 °C at fixed ramping rate of 3 °C/min) and times (5, 10, 16, and 20 h). After reaction, the product was cooled to room temperature and washed with pH-adjusted H_2O (CO_2-free deionized water with pH ~10, adjusted by concentrated ammonia solution) for three times to remove the unreacted barium precursor. $BaTiO_3$ powder was separated from the solution part by ultracentrifugation (9000 rpm for 5 min) and dried at 100 °C for 24 h.

2.2. Sol–gel silica synthesis

Sol–gel (SG) silica solution was prepared by a two-step acid–base catalyst procedure by mixing tetraethylorthosilicate (TEOS, 99.9% purity), ethanol, water and HCl in various molar ratios: 1:10:3.5:0.003. After stirring at room temperature for 90 min, 150 μl of the base catalyst (0.1 M NH_4OH) was then added into the solution. The solution was aged for three days under constant stirring at room temperature and was filtered through a 0.2 μm PTFE membrane filter before spincoating.

2.3. Structural characterization

The phase content of the $BaTiO_3$ nanocrystals was extracted from powder X-ray diffraction (XRD) patterns obtained with a Shimadzu diffractometer operating at 4 kW and using Cu Kα radiation. Materials were prepared for diffraction by packing the $BaTiO_3$ powder on a glass slide (2×2 cm) with diffracted intensity collected by step scanning over the 2θ range 10–140° in increments of 0.02° and a dwell time of 0.20 s per step. Rietveld refinement as implemented in TOPAS 3.0 was used for quantitative phase analysis with the starting model being $BaTiO_3$ [34], $BaCO_3$ [35], Ba_2TiO_4 [36] and $BaTi_4O_9$ [37]. For each analysis, a background polynomial, scale factor, cell parameters and zero point correction were refined, to determine phase content, check for mass balance, identify phase transformations and estimate crystal size. Transmission electron microscopy (TEM) was conducted in high resolution mode with a large objective aperture using a JEOL 2100F instrument operating at 200 kV. The TEM samples were prepared by immersion of a holey carbon coated copper grid in an ultrasonically treated $BaTiO_3$ suspension followed by dried at room temperature.

2.4. Device fabrication and electrical characterization

Organic transistors and capacitors were fabricated on highly doped silicon substrates which functioned as the gate electrode. The dielectric layer was prepared using $BaTiO_3$ nanoparticles dispersed in ethanol (99%, Fluka) at 5, 10 and 20 wt.% of $BaTiO_3$, spun coated on the substrate at a coating speed of 2000 rpm for 120 s. The specimens were calcined at 220 °C for 1 h before applying the surface modification layer of sol–gel silica. The original sol–gel silica solution was diluted (50%) and spun coated to form a layer ~150 nm thick. The samples were then dried at ambient conditions at 60 °C with slow heating rate. Gold electrodes (500 μm squares) were evaporated to form capacitor structures. A 45 nm pentacene (Sigma Aldrich) layer was evaporated on the dielectric as the organic semiconductor followed by gold source-drain electrodes to form organic field effect transistors. Capacitors and OFETs were also prepared without the sol–gel capping layer for comparison. I–V and C–V characteristics were measured using a Keithley 4200-SCS semiconductor parametric analyzer and a HP4284 LCR meter, respectively in a TTP-6 probe station at low vacuum.

3. Results and discussion

3.1. Synthesis of $BaTiO_3$ nanocrystals

3.1.1. Effect of reaction time

The influence of reaction time to the crystal structure and size of $BaTiO_3$ was studied at 5, 10, 16 and 20 h (reaction temperature 220 °C, 1:1 M ratio of H_2O:Pr^iOH). The

crystal structures of products were analyzed from their XRD patterns using the Rietveld refinement. The mixture phases of barium compounds ($BaTiO_3$, $BaCO_3$ and Ba_2TiO_4) were obtained from materials synthesized at 5–20 h, where cubic phase $BaTiO_3$ (Eq. (1)) is a major component (Table 1). The crystal size of products (10–13 nm) was not influenced by the variation of reaction time (Table 1 and Fig. 1).

Although CO_2-free DI-H_2O was introduced into the system to prevent the formation of $BaCO_3$, the reaction between $Ba(OH)_2$ and trace amount of CO_2 molecules from the air occurred during the transfer of suspension into the autoclave vessel (Eq. (2)). The formation of $BaCO_3$ can partially be prevented by performing the reaction at longer periods (reduced from 13% to 8% at 5 and 16 h, respectively) due to the reaction between $BaCO_3$ and some titania hydrous gel or synthesized $BaTiO_3$ product, forming the $BaTiO_3$ and Ba_2TiO_4 structures [38–40] (Table 1, Eqs. (3) and (4)). However, the amount of $BaCO_3$ phase became larger at reaction time 20 h (11%) through the reaction between Ba_2TiO_4 and free CO_2 molecules those were subsequently produced at long period (Eq. (5)). Thus, the reaction time 16 h was selected for further studies.

$$Ba(OH)_2 + TiO_2 \rightarrow BaTiO_3 + H_2O \quad (1)$$

$$Ba(OH)_2 + CO_2 \rightarrow BaCO_3 + H_2O \quad (2)$$

$$BaCO_3 + TiO_2 \rightarrow BaTiO_3 + CO_2 \quad (3)$$

$$BaCO_3 + BaTiO_3 \rightarrow Ba_2TiO_4 + CO_2 \quad (4)$$

$$Ba_2TiO_4 + CO_2 \rightarrow BaCO_3 + BaTiO_3 \quad (5)$$

3.1.2. Effect of reaction temperature

The reaction time which resulted in the highest percentage of $BaTiO_3$ (16 h) was selected for the variation of reaction temperature (180, 200, 220 and 240 °C) at fixed molar ratio of H_2O:Pr^iOH (1:1).

At low temperature (180 °C) where the energy is moderate for the reaction between $Ba(OH)_2$ and titania hydrous gel precursors, product with lowest percentage of $BaTiO_3$ (76%) and large amount of $BaCO_3$ (15%) was formed because of the reaction between $Ba(OH)_2$ and CO_2 molecules (Eq. (2)). When reaction temperature was increased to 220 °C, the improvement of $BaTiO_3$ phase (85%) was obtained with lower amount of $BaCO_3$ (8%). However, the development of $BaCO_3$ structure became higher with trace amount of Ba_2TiO_4 at 240 °C. This might occur due to the higher stability of $BaCO_3$ phase at high reaction temperature which reduces the number of $BaCO_3$ molecules reacting with $BaTiO_3$ (Eq. (3)).

3.1.3. Effect of H_2O:Pr^iOH molar ratio

The influence of H_2O:Pr^iOH molar ratio on the formation of titanium hydrous gel and $BaTiO_3$ nanocrystals was studied at 2:1, 1:1 and 1:2 M ratios (reaction temperature

Table 1
The influence of synthesis conditions on the crystal size and crystal structure of $BaTiO_3$ nanocrystals.

Sample	H_2O:Pr^iOH (molar ratio)	Reaction temperature (°C)	Reaction time (h)	% by weight of barium compound			Average crystal size[a] (nm)
				$BaTiO_3$	Ba_2TiO_4 (%)	$BaCO_3$ (%)	
BT1	1:2	220	16	78	11	11	12
BT2	1:1	220	16	85	8	8	10

220 °C and time 16 h). The optimal H_2O:Pr^{i}OH molar ratio for complete sol–gel process of titania hydrous gel was reported at 1:1 M ratio, in which the highest percentage of $BaTiO_3$ (85%) was obtained (Fig. 2). The incomplete formation of titania gel at less H_2O content causes the lower amount of Ti source for the synthesis of $BaTiO_3$, thus, reduces the amount of final product and increases the extra phases of barium compounds (78% $BaTiO_3$).

3.2. Application of $BaTiO_3$ nanoparticles in OFETs

3.2.1. Dielectric properties of $BaTiO_3$ nanoparticles

The dielectric properties of the as-synthesized nanoparticles (BT2, particle size ~10 nm) were measured by fabricating pellets of the material through compacting. The pellets were calcined at 220 °C for firming of the films before testing at room temperature. It has been shown previously that there is a relationship between the particle size and dielectric constant of $BaTiO_3$ [41–43]. It is generally recognized that the permittivity of $BaTiO_3$ ceramics increases with decreasing grain size at the micron level while it decreases with particle size in submicron ranges. Previous reports have indicated a dielectric constant of 15,000 at 68 nm and 5000 at 140 nm for impurity free $BaTiO_3$ synthesized by thermal decomposition method [41]. Fig. 3 illustrates the dielectric constant of the Barium titanate nanoparticle pellets measured at frequencies from 1 kHz to 1 MHz. The effective dielectric constant reduces from 3500 to 150 in this frequency range. The rather large frequency dispersion in the measured nanoparticles may be caused due to adsorbed molecules as well as the large number of interfaces in the pellet. The temperatures applied during the pellet fabrication (220 °C) is insufficient

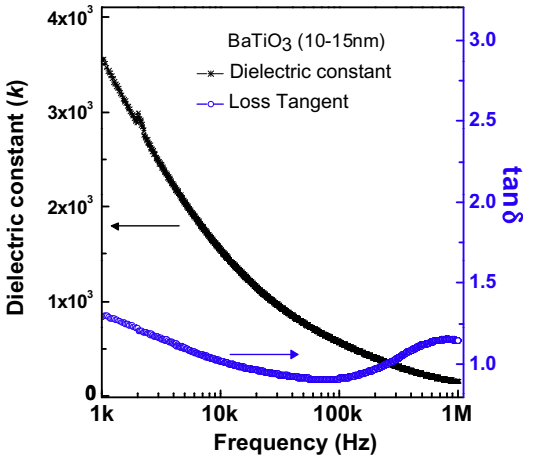

Fig. 3. The dielectric constant and loss tangent of barium titanate pellets measured from 1 kHz to 1 MHz.

to remove adsorbents [44] and maintains the nanocrystalline morphology. Adsorbed water molecules at the nanoparticles' surface can contribute to the total polarizability of the film through Maxwell–Wagner type interfacial polarization mechanism [45]. A k value of 150 for the 10–15 nm sized nanoparticles measured in this experiment is consistent with previous published reports [46] and is indicative of the size effect in barium titanate nanoparticles.

3.2.2. $BaTiO_3$ nanoparticle film as dielectric layer in OFETs

The dielectric layer was prepared using $BaTiO_3$ nanoparticles diluted in ethanol at three different concentrations,

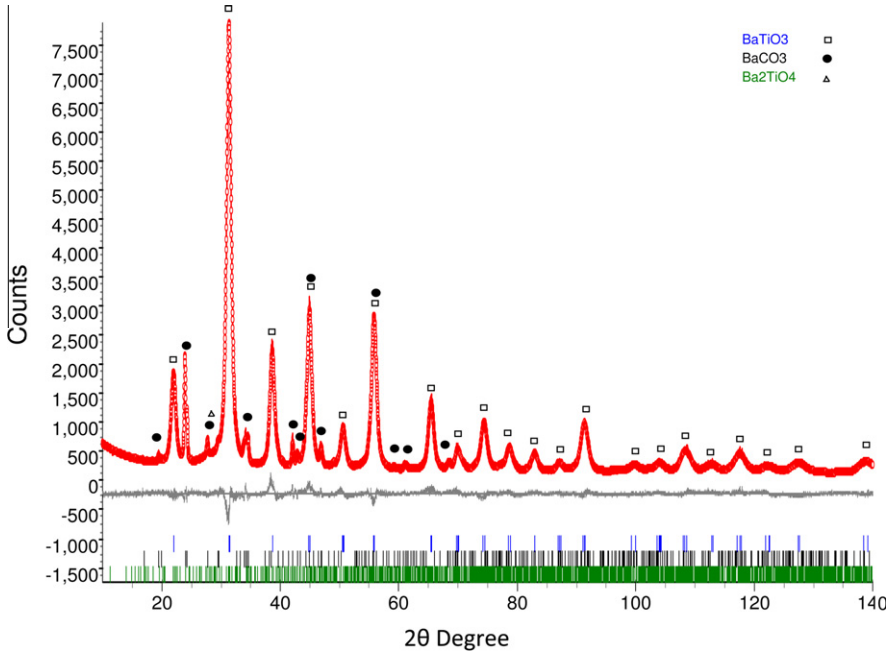

Fig. 2. X-ray diffraction profile of $BaTiO_3$ nanocrystals synthesized at 220 °C, 16 h and 1:1 M ratio of H_2O:Pr^{i}OH. The lower trace is the difference between the calculated and experimental intensities. The Bragg markers from upper to lower are cubic $BaTiO_3$, $BaCO_3$ and Ba_2TiO_4. The phase proportions are summarized in Table 1.

5 wt.% (*T*1), 10 wt.% (*T*2) and 20 wt.% (*T*3). The dielectric film thicknesses of *T*1, *T*2 and *T*3 are 1.2, 2 and 3 μm, respectively. As the concentration of $BaTiO_3$ increases, the surface becomes rougher due to agglomeration effects in the ethanol suspension. The calculated *k* value of the dielectric layer for each sample is shown in Table 2. The relatively lower dielectric constants of the spun coated films (in contrast to pellet measurements) may be attributed to poor film quality that can incorporate voids. Functional devices were obtained for samples fabricated from spin coating 5 wt.% solution and 10 wt.% solution of the $BaTiO_3$ nanoparticles as the dielectric layer (*T*1, *T*2, Table 2). However, devices fabricated from 20 wt.% solutions (*T*3) were not functional, which may be traced to the high surface roughness of the device. The thickness of the pentacene layer (45 nm) evaporated on the dielectric is not enough to form a continuous layer across the active area of the transistor.

From Table 2, we can distinguish that the capacitance per unit area of the device tends to increase with increasing amount of $BaTiO_3$ nanoparticles. Even though the *k* value increases substantially for the barium titanate nanoparticle dielectric, the mobility of the device is far lesser than that of pentacene devices fabricated on silicon dioxide substrates. In addition the on/off ratio decreases, while there is a slight improvement in the threshold voltage. The reduction in the mobility of the device with increasing $BaTiO_3$ concentration, illustrates the critical role played by the semiconductor–dielectric interface. The rough surface of the $BaTiO_3$ does not allow the pentacene molecules to form large grains, resulting in a large grain boundary density and charge traps. $BaTiO_3$ with high dielectric constant is a highly polar compound and is considered as a source of trap at the semiconductor/dielectric interface, which further affects charge carrier mobility adversely [17,47]. In order to improve the active layer morphology and to reduce the number of electrical traps, an insulating overlayer needs to be pursued.

We have previously studied sol–gel silica made from tetraethylorthosilicate precursor as an OFET gate dielectric and interfacial modification layer [8,48,49]. The low surface energy of the sol–gel silica induces crystalline growth of the organic semiconductor which results in enhancement of charge carrier mobilities. Thus the $BaTiO_3$ nanoparticle layer was covered by a second layer consisting of sol–gel silica, which also acts as the planarization layer (Fig. 4(a)). SEM was used to measure the cross sectional thickness of the devices. The dielectric layer thicknesses of *D*1, *D*2 and *D*3 were 1.3, 2.1 and 3.1 μm, respectively. It has already been shown that as the concentration of $BaTiO_3$ increases, the surface become rougher. Table 2 and Fig. 4(b)–(g) shows the improved electrical characteristics of transistors with the sol–gel silica layer. In contrast to the previous samples without the sol–gel layer, the devices possess higher mobility proving that the sol–gel silica can effectively act as planarization layer by reducing the surface roughness of the device. The higher mobility values can also be induced by the favourable low surface energy of the sol–gel silica. The output characteristics in Fig. 4(b)–(d) indicate that the devices have good saturation behaviour. Fig. 4(e) illustrates that there is a hysteresis in the transfer characteristics of the transistor, although no particular trend with the concentration of the nanoparticles is observed. The origin of the hysteresis is most likely from the localization of the charge carriers at the semiconductor–dielectric interface. As Fig. 4(g) illustrates, there is little hysteresis in the *C*–*V* characteristics of the dielectric, ruling out remnant polarization as a reason for the hysteresis.

Please note that the dielectric constant of the top sol–gel silica layer was measured by spin coating the layer on top of a silicon dioxide substrate to calculate the *k*. From Table 2, we find that the capacitance per unit area of the device does not vary much with the changing concentration of the $BaTiO_3$ nanoparticles However if we compare these devices to the *k* value of the samples without sol–gel planarization layer, it is considerably lower. This is caused by the lower capacitance of the device, which is affected by the lower dielectric constant of the additional sol–gel layer as well as the increased thickness. This leads to a reduction in the effective dielectric constants (k_{eff}). Despite this, the bilayer of the two solution processable dielectrics display dielectric constants of up to 44, indicating the advantages of this material combination. The mobility of these devices are much higher than the one without sol–gel planarization layer. Charge carrier mobilities in devices which incorporated 10 wt.% of $BaTiO_3$ in the dielectric layer increased by two orders of magnitude with the deposition of the sol–gel layer. The on/off ratio of the devices, which is critical for their application in logical circuitry, is also improved by the inclusion of the sol–gel layer. Another phenomenon observed is the decrease of the charge carrier mobility with increasing dielectric constant. This can be explained by the nature of polarons at the semiconductor/dielectric interface. Interface dipoles on the insulator surface distorts (polarize) individual electronic states of the HOMO of pentacene. At the interface, polar compounds cause dipolar disorder in the density of states (DOS) of the semiconductor leading to the broadening of the DOS. As a result, the temperature activation of carrier hopping is increased and the mobility is reduced

Table 2
Performance of transistors fabricated on single layer $BaTiO_3$ (*T*1–*T*3) and dual layer (*D*1–*D*3).

[17,47]. The electrostatic potential created by the induced polarization exerts an attractive force on the charge carrier itself that increases the tendency toward carrier self-trapping. This self-trapping tendency increases with increasing dielectric constant and leads to the reduction of mobility [6,50].

Despite the use of a high-*k* dielectric layer, the transistors described in this study require working voltages of about 20 V to obtain good drain currents. This is indicative of the important role played by the charge carrier mobility and the number of charge carrier traps at the semiconductor–dielectric interface. The use of a high dielectric constant layer has to be coupled with good surface properties to form favourable semiconductor morphologies that result in good mobilities. Another factor to consider here is the thickness of the dielectrics (ranging from 1 to 3 μm) used in this study. A reduction in the thicknesses of these dielectrics down to 300–400 nm range, while maintaining good dielectric integrity is necessary to realize low voltage operation. Efforts in this direction are underway.

4. Conclusions

In this research, $BaTiO_3$ single crystal nanoparticles were successfully synthesized using the glycothermal process. The experiments showed that the synthesized $BaTiO_3$ nanoparticles have the average particle size of 5–15 nm. It is exhibited that the size and purity of $BaTiO_3$ nanoparticles can be controlled by reaction condition, such as reaction temperature, reaction time and the ratio of hydrolysis agent. An optimum reaction temperature exists in producing nano-size particles, which is 220 °C based on this experimental conditions. However, for both reaction time and temperature, a compromise between the particle size and phase-purity should be considered when deciding the two parameters in order to produce the most desired properties of the nanoparticles.

The direct utilization of barium titanate particles as the dielectric was also partially successful. Too high a concentration of the nanoparticles, results in a rough surface that decreases mobility and has poor characteristics. The use of a sol–gel silica overlayer results in improvement of the device behaviour due to the planarization effects and better semiconductor dielectric morphology. Previous reports have shown that the application of a thin polymer layer planarizes the rough surface of nanocomposite layers and can improve the interfacial properties, including reducing the trap density and changing the relative surface energies between the layers [51–53]. However, the additional layer increases the thickness of the device, which then lowers the capacitance. In addition, these polymers have low dielectric constant thus reducing the effective capacitance. The final result is a high threshold voltage which is unfavorable to the device performance. The combination of the materials described in this manuscript, barium titanate nanoparticle layer with a sol–gel silica overlayer has many advantages. It helps to reduce the surface roughness, which then improves the mobility and on/off ratio of the

devices, while maintaining the high dielectric constant of the dielectric layer. It has already been shown that sol–gel silica has favourable surface properties that promote crystalline pentacene growth. Thus this combination of low temperature solution processable dielectrics is of potential for implementation in low voltage organic electronics.

processing is used most commonly in synthesizing PEDOT in the form of spin-coating, solvent-casting or ink-jet printing. However, these PEDOT systems are relatively insoluble in most solvents, making it necessary to attach soluble functional groups to the polymer or dope it with stabilizing polyelectrolytes [18]. An aqueous dispersion of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT-PSS), commercially available as Baytron P, is a stable polymer system with a high transparency up to 80% [7]. However, the PEDOT-PSS film exhibits relatively low electrical conductivity, 10–500 S/cm [7], which does not often meet the high conductivity required for most applications. In addition, scanning-tunneling microscopy, neutron reflectivity measurements, and X-ray photoelectron spectroscopy have revealed a PSS rich layer on the top of the spin-coated PEDOT-PSS films due to the phase separation [13,19,20]. Since PSS is an electrical insulator, excessive PSS can limit the film conductivity [19], and an acidic PEDOT-PSS dispersion can etch indium tin oxide (ITO) during the polymer spin-coating process. Moreover, the hydrolysis of the deposited PEDOT-PSS by moisture absorption can also etch ITO to cause indium and tin incorporation into the polymer [14].

For the PEDOT systems without using polyelectrolytes, PEDOT can be deposited directly on the substrate surface by several in situ polymerization techniques. One of the options is electrochemical polymerization, which has been reported to have higher electrical conductivity [21]. However, electrochemical polymerization results in a poor transparency and requires conducting substrates, which limits its practical applications. As an alternative, oxidative chemical polymerization either in the liquid or vapor phase is more versatile because it is not restricted by the substrates. In particular, one way of achieving a clear thin film with a smooth surface is to apply the oxidant using solvent coating processes and expose the coated surface to a reactive monomer vapor. This process is often referred to as vapor-phase polymerization (referred to herein as VPP) [4,5,22–26]. The PEDOT films by VPP have been reported to have conductivities of approximately 15 S/cm at a thickness of 300 nm without any additives [22]. Recently, a PEDOT film with high conductivity, exceeding 1000 S/cm, was reported using a base-inhibited VPP [3,4]. However, it should be noted that VPP PEDOT has a high bandgap and relatively low transmittance [23,24].

As another thiophene-based conducting polymer, poly(3-hexylthiophene) (P3HT) is also one of the most indispensable materials in OLEDs, OPVs, field effect transistors (FETs) and thin film transistors (TFTs) [12,17,27,28]. Over the last decade, blending or copolymerization techniques of conducting polymers have been investigated not only to overcome the drawbacks of a pristine conductive polymer, such as inadequate bandgap, rough surface, low conductivity and poor transmittance, but also to tailor the properties for various applications [29–31]. Recently, P3HT has been successfully fabricated by VPP [32] using a similar route to VPP of PEDOT choosing appropriate catalyst and solvent systems. Using the VPP technique, therefore, PEDOT and P3HT may be copolymerized in the state of vaporized monomers and subsequently polymerized to form, most probably, a PEDOT/P3HT copolymer structure. However, it should be mentioned that the traditional VPP route, where the monomer is maintained in the state of thermodynamic equilibrium, may not simply be applied because the vapor pressure and polymerization rate of the EDOT and 3HT are different and, thus, the relative composition of the VPP copolymer is not controllable.

Therefore, the PEDOT to P3HT ratio was kinetically controlled in this study by adjusting the relative feed amount of the evaporating monomers to the reaction chamber to fabricate the PEDOT/P3HT films containing different ratios of PEDOT to P3HT. The developed synchronous VPP technique successfully provided PEDOT/P3HT copolymer thin coatings with tunable bandgap and optoelectronic properties.

2. Experimental method

The main chemicals used in this study were 3HT (99%, Aldrich, St. Louis, MI USA), EDOT (99%, Aldrich, St. Louis, MI USA), iron (III) chloride hexahydrate ($Fe(III)Cl_3{\cdot}6H_2O$, 97%, Aldrich, St. Louis MI USA), MeOH (methyl alcohol anhydrous, 99.9%, Carlo erba reagenti) and EtOH (ethyl alcohol anhydrous, 99.9%, Carlo erba reagent). The substrate materials used in this study were plane glass (1.1 mm, Paul Marienfeld GmbH & Co. KG., Germany), ITO glass (indium–tin-oxide glass, 10 Ω, 185 ± 20 nm ITO thickness, 1.1 mm ITO glass thickness, U. I. D., Korea), PET (polyethylene terephthalate, 100 μm, Hwasung Co. Ltd., Korea) and a Si wafer (Thickness: 525 ± 25 μm, SEMI-MATERIAS Co. Ltd., Korea).

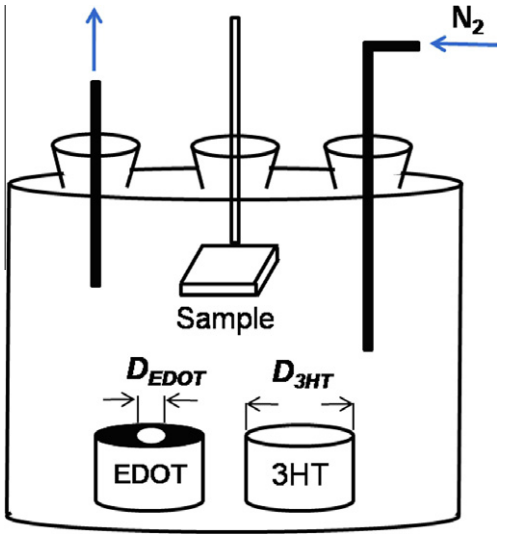
The substrates were washed and rinsed with DI-water and acetone and sonicated for 10 min to remove any organic contaminants. The glass substrates were plasma-treated (PLAMAX, SPS Co. Ltd., Korea) for 30 s, and the ITO glass substrates were UV-treated for 20 min. The oxidant was a mixture of MeOH and EtOH at a 1:1 ratio with iron (III) chloride hexahydrate. The wt.% ratio between the alcohol mixture and $FeCl_3 \cdot 6H_2O$ was 10:1, 5:1, and 3:1. A ratio of 10:1 was chosen to fabricate most thin films in this study. After sonicating the oxidant solution for 2 min at 40 °C, it was spin-coated onto the substrates at a speed of 500 rpm for 5 s and then at 1400 rpm for 5 s. The oxidized substrates were placed in the vapor-phase-polymerization (VPP) chamber, where the containers of 3HT and EDOT were also placed. The vaporized monomers were supplied into the chamber through the feed inlets, which were made at the center of the container ceiling with different inlet diameters of D_{3HT} and D_{EDOT} (Scheme 1). The flow rate of flowing nitrogen was kept constant during polymerization, and the feed ratio of 3HT and EDOT monomer vapors was adjusted by the inlet diameters of D_{3HT} (0, 2, 4, 6, and 8 mm) and D_{EDOT} (fixed at 20 mm). The EDOT and 3HT monomers in the VPP chamber were polymerized for 20 min, 30 min, or 1 h at 60 °C. After polymerization, the sample was soaked and washed sequentially with MeOH to eliminate the monomers and Fe(III) solution remaining on the substrate. The washed PEDOT/P3HT copolymer film was dried further using a hot-air gun for 1 min in an ambient atmosphere to remove the residual MeOH.

The thickness of the VPP PEDOT/P3HT was measured using an alpha step IQ (KLA Tencor corporate, the Yield Management company, San Jose CA, U. S. A.) and FE-SEM (Field emission scanning electron microscope, 1.0 nm guaranteed at 15 kV, JSM6700F, JEOL, Japan). The bandgap was determined by UV–vis-spectrophotometry (UV-3600, SHIMADZU, Japan). AFM (SPA-300HV, SII Nano Technology Inc., Tokyo Japan) was used to examine the surface morphology of the VPP-PEDOT/P3HT coating, where a 5×5 μm area was analyzed to determine the surface roughness. The AFM 3D images revealed the surface roughness of the copolymer films with a *z*-axis of 100 nm. X-ray photoelectron spectroscopy (XPS, ESCA2000, VG MICROTECH) equipped with an Al Kα radiation source ($h\nu = 1486.6$ eV) was used to analyze the components. Attenuated total reflection-Fourier transform infrared (ATR-FTIR) spectroscopy (Bruker IFS-66/S, Bruker, Massachusetts U.S.A.) was also used for component analysis of the VPP-PEDOT/P3HT copolymers. Contact angle measurements were performed using a Digi-drop contact angle goniometer (JinTech, Korea). A water droplet was dropped onto the surface of a small sample. The droplet shape was recorded by a camera and analyzed to determine the contact angle. The electrical conductivity of the synthesized films was measured using a four-point probe method (Keithley 236 current source and Keithley 617 electrometer). The film thickness for the measurement of electrical conductivities ranged 100–500 nm coated on a glass substrate in the area of 25×25 mm^2. The type of the four-probe point was a linear type with 1 mm tip spacing.

3. Results and discussion

The thin copolymers were fabricated by adding a small amount of EDOT monomer in the VPP chamber with excessive 3HT monomers because the polymerization rate of the EDOT monomers was faster than that of the 3HT monomers. More specifically, the composition was controlled by adjusting the feed amount of EDOT to the catalyst-coated layer placed in the reaction chamber, which complies with the typical steady-state plug-flow reactor system [33]. In this case, the feed ratio of EDOT to 3HT may be controlled by the inlet size of the vaporized monomers in the stream of purging nitrogen. Simply quantifying the feed composition, the feed ratio (r) may be defined by the feed inlet sizes of EDOT and 3HT, viz: $r = D_{EDOT}/D_{3HT}$, where D_{EDOT} and D_{3HT} are the cross-sectional diameters of the feeding hole on the ceiling of the EDOT and 3HT containers, respectively.

The ATR-FTIR spectroscopy results of the pristine PEDOT, pristine P3HT and PEDOT/P3HT copolymer films are compared in Fig. 1 at different feed ratios. As the characteristic peaks of each pristine polymer, the peak intensity of the aliphatic C–H bond stretching vibration corresponds to the 3-hexyl group in P3HT, and the C–O–C bond stretching vibration corresponds to the ethylenedioxy group in PEDOT. As seen in Fig. 1B, the aliphatic C–H bond stretching in the 3-hexyl group in P3HT appears at 2854, 2924, and 2954 cm^{-1}, and its peak intensity decreases with the feed ratio of r [34,35]. Assigning the bands at approximately 1058 and 1141 cm^{-1} to the stretching modes of the ethylenedioxy group [36,37], the intensity of these peaks increases with the increasing supply of the EDOT monomer. Consequently, the vapor-phase polymerization ratio of PEDOT appears to reflect the controlled supply of the EDOT monomer via the feed ratio of r. Fig. 1C compares the bands of the pristine PEDOT (doped with $FeCl_3 \cdot 6H_2O$) with the copolymers at different feed ratios of r, seemingly exhibiting a redshift due to copolymerization of 3HT and EDOT. The inset in Fig. 1A shows the camera images of pristine PEDOT, P3HT, and PEDOT/P3HT at different compositions coated on the ITO substrates. Since the colors of the pristine PEDOT and P3HT are blue and orange, respectively, the color of the PEDOT/P3HT copolymers changes gradually from orange to dark blue with the increasing EDOT feed ratio of r demonstrating that the ratio was successfully controlled by the feed ratio in our experiments.



Scheme 1. Schematic of experimental setup for synchronous polymerization of EDOT and 3HT monomers, where the monomer concentrations are controlled by the inlet sizes of monomers (D_{EDOT} and D_{3HT}) to the reaction chamber under the flowing inert gas.

For copolymers, the surface composition may be quantified using several surface-sensitive techniques, such as XPS and time-of-flight secondary ion mass spectrometry (ToF-SIMS) [38], XPS exhibiting somewhat better agreement with the theoretical compositions than ToF-SIMS [39]. Therefore, in this study, XPS was used to quantify the surface concentrations. The formation of PEDOT/P3HT copolymer films can be demonstrated by deconvoluting the XPS peaks at 285.0, 286.5, and 533.0 eV, as shown in Fig. 2. The XPS peaks at 285.0 and 286.5 eV in Fig. 2A can be assigned to C–C/C =C and C–O–C, respectively, corresponding to the spectra of the C(1s) core level [40,41]. Fig. 2A and Table 1 indicate that the intensity of the peak at 285.0 eV decreases with increasing r, whereas that at 286.5 eV increases, which agrees well with the chemical structures of PEDOT and P3HT, as shown in the inset in Fig. 2A. The O photoelectron spectrum in Fig. 2B and Table 1 shows that the O concentration increases with increasing r, as represented by the intensities of the XPS peak at

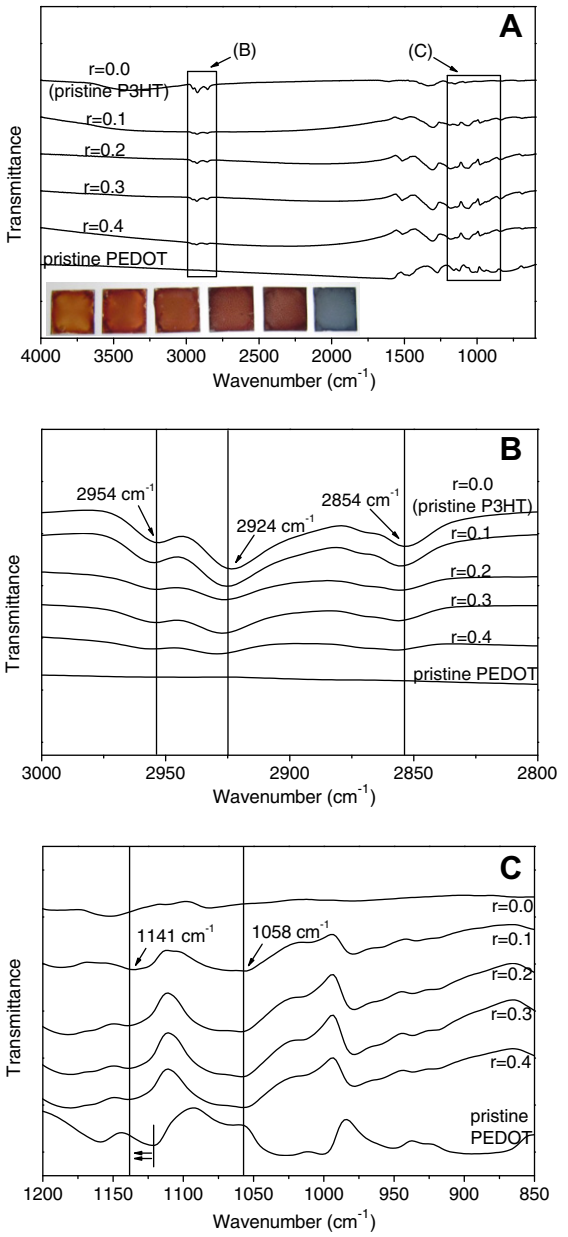


Fig. 1. Comparison of ATR-FTIR spectra of the PEDOT/P3HT copolymers at different feed ratio of *r*. (A) full spectral region: 4000–600 cm^{-1}, (B) enlargement of the region of 3000–2800 cm^{-1}, (C) enlargement of the region of 1200–850 cm^{-1}. The inset in (A) shows pictures of the PEDOT/P3HT copolymer films coated on ITO-coated glass using an oxidant at a 5:1 ratio of the alcohol mixture to ferric chloride hexahydrate, representing $r = 0$, 0.1, 0.2, 0.3, 0.4, and the pristine PEDOT film from left to right, respectively, with a thickness of 500 nm.

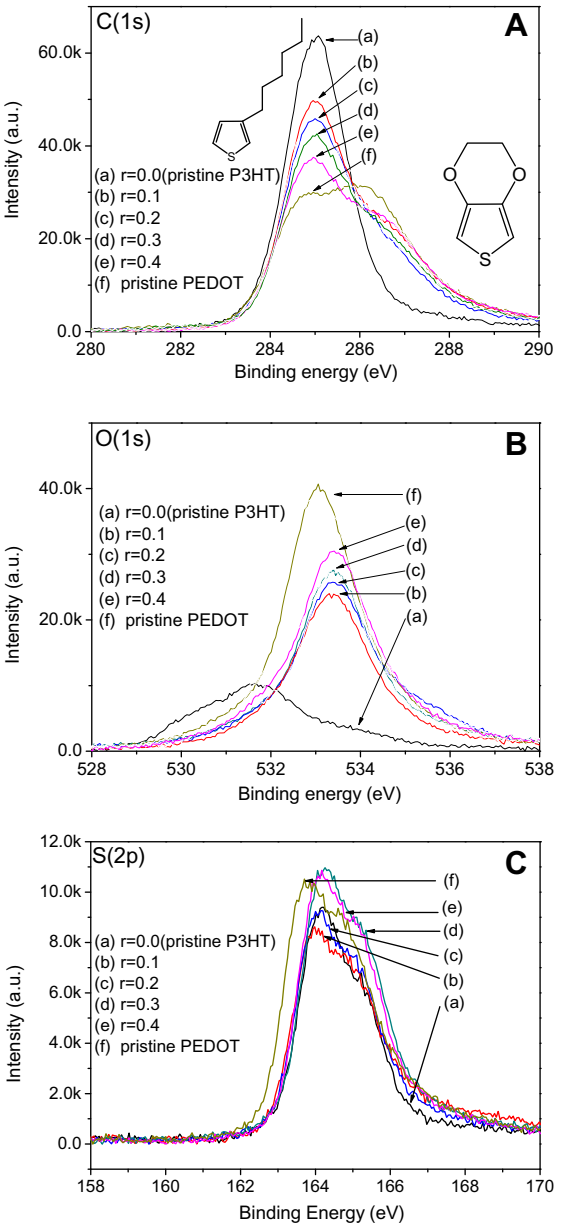

Fig. 2. Deconvolution of XPS spectra of (A) $C_{(1s)}$, (B) $O_{(1s)}$ core-level, and (C) $S_{(2p)}$ for PEDOT/P3HT copolymers at various feed ratio of *r*. The inset in (A) is chemical structures of PEDOT and P3HT, respectively.

533 eV, which can be assigned to the oxygen–ether group (C–O–C) [40,42]. The S photoelectron spectrum is shown in Fig. 2C and analyzed in Table 2. The S(2p) peak positions of pristine P3HT and PEDOT appear at 164.1 and 163.8 eV, respectively, and the peaks of their blend systems at different *r* values seem to appear between the two pristine polymers. Table 2 shows the elemental composition of the fabricated thin films demonstrating that the PEDOT to P3HT ratio increases with the EDOT feed ratio of *r*. As seen in Table 2, the concentration of S and the PEDOT to P3HT elemental ratio apparently increase with increasing *r*. Comparing the experimental and theoretical ratios of C/S, which may represent the ratios of P3HT to PEDOT, there are good agreements between the theoretical and experimental values. The slight discrepancy might be due to adventitious hydrocarbon contamination coming from the contact of the samples with the ambient atmosphere [39].

Fig. 3 presents the UV–vis absorbance spectra of VPP-PEDOT/P3HT films on glass substrates leading to changes of the bandgap of the VPP-PEDOT/P3HT copolymer at different feed ratio of r values. The bandgap was estimated to be 1.91, 1.98, 2.02, 2.07, and 2.16 eV for the specimens prepared with 0, 2, 4, 6 mm of feed diameters and the pristine VPP-PEDOT film, respectively, by taking the isobestic points at 650, 625, 615, 600, and 575 nm, respectively. The bandgap decreases gradually with decreasing EDOT monomer supply. Accordingly, the bandgap of the VPP-PEDOT/P3HT copolymer film can be desirably adjusted by changing the relative composition of PEDOT and P3HT, especially when a low bandgap is required in such applications as OLEDs and OPVs [16]. The inset in Fig. 3 shows the pristine PEDOT, P3HT and PEDOT/P3HT copolymers at different compositions coated on glass substrates. Similarly to Fig. 1, the color of the specimens clearly indicates that the compositions of PEDOT and P3HT vary with the fabrication conditions to give tunable bandgap.

Fig. 4 shows cross-sectional SEM images of pristine PEDOT, P3HT, and copolymerized PEDOT/P3HT films produced by the developed synchronous technique. In this experiment, the coating thickness of the oxidant was precisely controlled to be constant during the spin-coating process and the same VPP conditions were used. However, as can be seen, the final film thickness varies with the compositions because of the difference in polymerization rates of EDOT and 3HT. Fig. 4A, B, C, D, E and F show cross section images of pristine P3HT, copolymer films and pristine PEDOT, giving the final thicknesses of 52, 71, 87, 110, 131 and 153 nm at $r = 0$, 0.1, 0.2, 0.3, 0.4 and the pristine PEDOT film, respectively. The film thickness increases with increasing r due to the faster polymerization rates of EDOT than 3HT. It should be mentioned that the film thickness can also be controlled at a fixed r by changing the polymerization temperature [32].

Fig. 5 shows the electrical conductivity of the copolymers plotted as a function of r. The electrical conductivity increases from 3.0×10^{-2} S/cm for the pristine P3HT up to 6.28 S/cm for the copolymer with r at 0.4. The conductivity of PEDOT/P3HT copolymer can be increased up to 200 times higher than that of the pristine P3HT, which can be achieved by adjusting the EDOT feed ratio of r. In this study, the conductivity of the pristine VPP-PEDOT was similar to that reported elsewhere [22], where a $FeCl_3$-based oxidant solution was used without any additives. However, the addition of basic inhibitors, such as pyridine [4] and imidazole [25], has been reported to reduce the polymerization reaction kinetics and enhance the conductivity and transparency of the PEDOT film. Therefore, a weak base can be used to the PEDOT/P3HT copolymer systems to

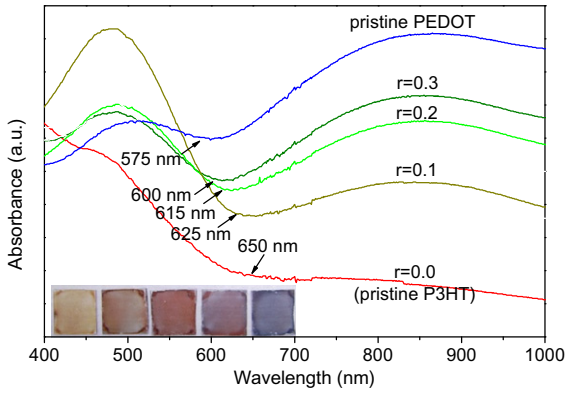

Fig. 3. UV–vis. absorbance spectra of the various PEDOT/P3HT copolymer films. The inset shows pictures of the PEDOT/P3HT copolymer films coated on ITO-coated glass using an oxidant at a 10:1 ratio of mixture to ferric chloride hexahydrate, representing $r = 0$, 0.1, 0.2, 0.3, 0.4, and the pristine PEDOT film from left to right, respectively, with a thickness of 300 nm.

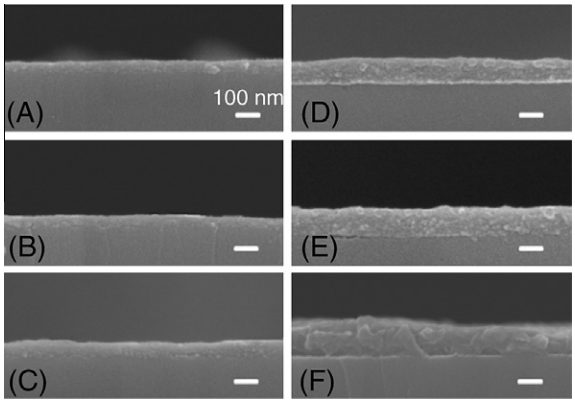

Fig. 4. Cross section of the PEDOT/P3HT copolymer films for (A) $r = 0.0$ (pristine P3HT), (B) $r = 0.1$, (C) $r = 0.2$, (D) $r = 0.3$, (E) $r = 0.4$ and (F) pristine PEDOT synthesized at 60 °C for 20 min. The scale bar is 100 nm in each.

achieve high conductivities, which is desirable for electrode systems in various electronic devices.

The polymerization rate of conjugated polymers, surface treatment and catalyst removal conditions were reported to affect the surface morphology of thin films substantially [5]. For example, the residual catalyst and monomers were removed successfully in order to synthesize smoother thin conducting polymer films [26]. Fig. 6 shows the surface morphology of the VPP-PEDOT/P3HT thin films in different polymerization conditions at different EDOT feed ratios of *r*. The surface roughness of the film increases with increasing *r*, as shown in Fig. 6A, B, C, D, and E, giving a RMS roughness of 4.88, 3.83, 8.66, 9.31, and 9.54 nm for $r = 0$, 0.1, 0.2, 0.3, and 0.4, respectively. This demonstrates that the surface roughness is affected by the incorporated EDOT monomers. The copolymerized film with $r = 0.1$ shows a lower RMS roughness than the pristine P3HT film (4.88 nm). However, the RMS roughness of the copolymer films increases gradually up to 18.3 nm with increasing *r*. The surface roughness of the pristine PEDOT is relatively high (ca. 18.3 nm) in Fig. 6F because no additional dopant was used in this study. Various additives are normally used to improve both conductivity and surface morphology of PEDOT, for example, such as glycerol, sorbitol and pyridine [5,43]. It should also be mentioned that $FeCl_3$ readily forms crystal-like structures as the

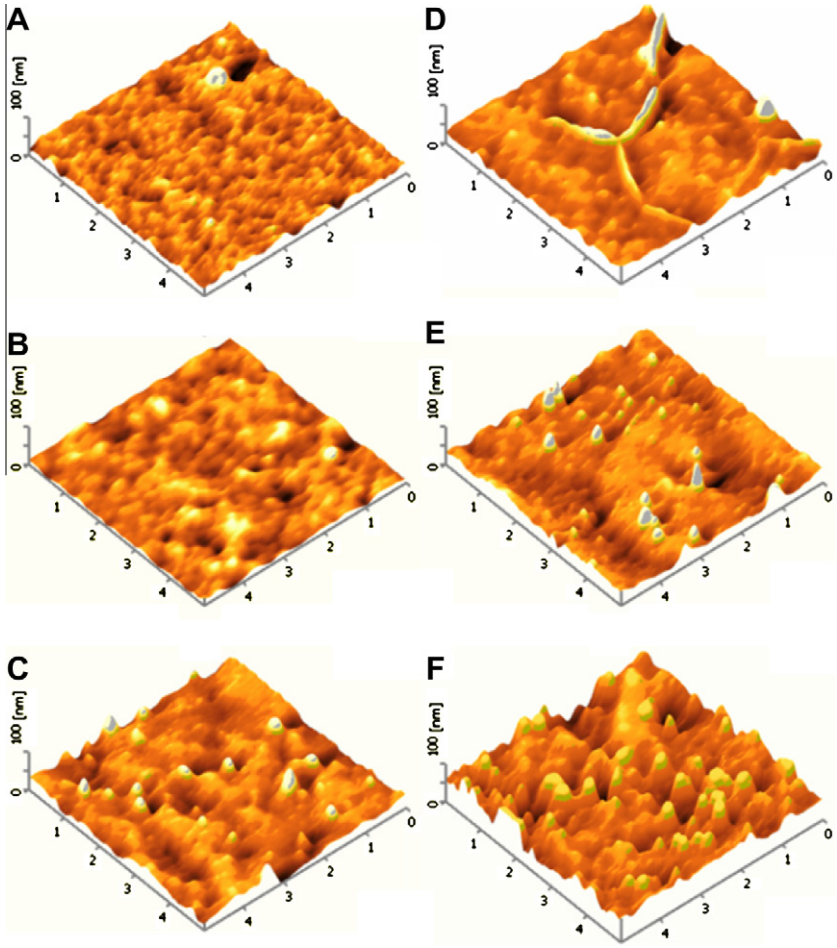

Fig. 6. AFM images of PEDOT/P3HT copolymers for (A) $r = 0.0$ corresponding to pristine P3HT, (B) $r = 0.1$, (C) $r = 0.2$, (D) $r = 0.3$, (E) $r = 0.4$ and (F) pristine PEDOT.

solvent evaporates to give grainy structures, which may act as a seeding template to cause discontinuous film formation [26]. Further work by Winther-Jensen et al. [4,26] shows that Fe(III) tosylate gives relatively smooth and homogeneous film surfaces, however, which often results in an undesirable polymerization route to give partially conjugated polymer chains. Therefore, further study of different additives and catalysts should be performed to enhance the surface morphology of VPP-PEDOT/P3HT.

Fig. 7 shows the water contact angle and RMS surface roughness of the copolymerized films coated on the glass substrates. Since a liquid makes contact with the outermost molecular layer of a surface, the contact angles represent the chemical and structural differences at the coating surface. Furthermore, the wettability of the thin coating is important in the fabrication of many optoelectronic devices, where multilayers should be fabricated in contact with heterogeneous layers. Since the contact angle of the pristine PEDOT at 36° is lower than that of the pristine P3HT at 54°, the PEDOT/P3HT copolymer films show a decreasing feature of the contact angle with a higher *r*, which is likely affected by the roughness of the coating since the water contact angle usually decreases with increasing RMS roughness. At a feed ratio of $r = 0.4$, however, the contact angle is slightly lower than the pristine PEDOT. Exhibited by the camera images of coating in the insets of Fig. 7, the color changes gradually from yellow to blue with the increasing EDOT feed ratio of *r*.

Overall, the developed VPP copolymerizing technique clearly demonstrates that the physicochemical properties of PEDOT/P3HT copolymers were successfully adjusted. Since the vapor pressure and polymerization rates of EDOT and 3HT monomers are different, the variation of the copolymer composition was ensured by adjusting the feed ratio of the monomers to the reaction chamber, which resulted in different reactant concentrations of EDOT and 3HT monomers. Different concentrations of reactants may well give different kinetic polymerization rates of EDOT and 3HT to provide a controllable synthesis route of PEDOT/P3HT copolymer coatings. Further study should be performed to identify the detailed copolymerization reaction and chemical structures of the VPP PEDOT/P3HT copolymer system.

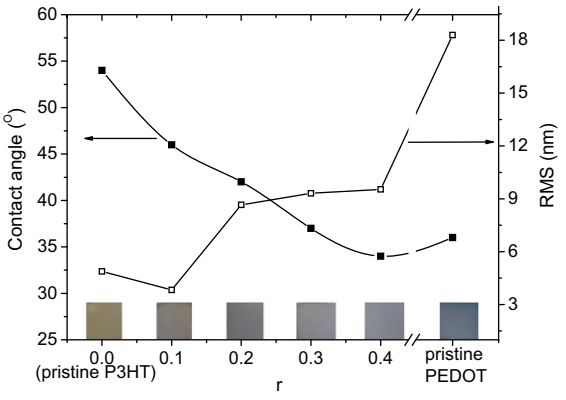

Fig. 7. Water contact angles and RMS surface roughness for different PEDOT/P3HT films. The inset shows the camera images of PEDOT/P3HT copolymer films with thickness of ca. 100 nm.

4. Conclusions

PEDOT/P3HT copolymer films were successfully fabricated as thin films on the glass, Si wafer, ITO-covered glass and PET film substrates using a vapor-phase polymerization technique. The ratios were kinetically controlled to ensure the tunable properties of bandgap, electrical conductivity, surface morphology and water contact angle of the thin copolymer films. The P3HT thin film incorporated with PEDOT may improve the mobility in OTFTs and charge extraction efficiency in OPVs. In addition to being used as a semiconductor with higher mobility, adding dopants to increase the electrical conductivity, P3HT/PEDOT copolymer films can also be used as a HIL in OLEDs with modified energy levels and properties.

However, these drawbacks can be overcome by applying an additional dielectric organic layer on top of the OLED stack [5–8]. This increases the transmittance through the top electrode, reduces microcavity effects, and alleviates the viewing angle dependence.

In this work, we demonstrate top-emitting white OLEDs based on a multilayer hybrid structure [11], simultaneously exhibiting high efficiencies and very good color coordinates. Furthermore, our devices show enhanced forward directed radiation, which is highly preferred for lighting applications such as ceiling mounted lighting panels. To clarify the mechanisms behind the electrical characteristics in our devices, we further performed UV photoelectron spectroscopy (UPS) and hole-only experiments. Finally, an efficiency analysis and comparison to a comparable bottom-emitting white OLED [11,12] is performed.

2. Material and measurements

2.1. Organic layer stack

The organic light-emitting devices are prepared by evaporating a 60 nm aluminum anode (Al) (device 1 and 2) on precleaned glass substrates (Princeoptics). Overall reflectivity can be enhanced by adding a 15 nm silver layer (Ag) (device 3 and 4). The organic layers are arranged in a p–i–n [13] architecture, starting with 20 nm *N*,*N*,*N*′,*N*′-tetrakis(4-methoxyphenyl)-benzidine (MeO-TPD) doped with 4 wt.% NDP2 provided by Novaled AG as hole transport layer. The following electron blocking layers (EBL) (10 nm), either *N*,*N*′-di(naphthalen-1-yl)-N,N′-diphenyl-benzidine (NPB) (device 1 and 3) or 2,2′,7,7′-tetrakis-(*N*,*N*-diphenylamino)-9,9′-spirobifluoren (S-TAD) (device 2 and 4) are tested with respect to the best device performance. The emission layers are formed by a 5 wt.% iridium(III)bis(2-methyldibenzo-[f,h]chinoxalin)(acetylacetonate) ($Ir(MDQ)_2(acac)$) doped NPB layer (10 nm), 4,4′,4″-tris(carbazol-9-yl)-triphenylamine (TCTA) (3 nm) doped with 5 wt.% tris(2-phenylpyridin)iridium(III) ($Ir(ppy)_3$) and 2-methyl-9,10-bis(naphthalen-2-yl)anthracene (MADN) (10 nm) doped with 1.5 wt.% 2,5,8,11-tetra-tert-butylperylene (TBPe) for orange-red, green and blue emission, respectively. The latter fluorescent emitter is chosen due to its better long-term stability compared to phosphorescent blue systems, which usually exhibit rather high efficiencies but very poor lifetime. Between the phosphorescent emitters and the fluorescent emitter, a 1.5 nm thin exciton blocking layer of TCTA and 2,2′,2″-(1,3,5-phenylen)tris(1-phenyl-1H-benzimidazol) (TPBi) (1:2) is added to avoid mutual exciton quenching of both systems [11]. Intrinsic and cesium (Cs) doped 4,7-diphenyl-1,10-phenanthroline (BPhen) is used as hole blocking (10 nm) and electron transporting layer (35 nm), respectively. Top electrical contacts are realized with a 1 nm thin Al layer for increasing stability reasons, followed by a semitransparent Ag layer (15 nm) to provide adequate conductivity and high transmittance. Finally, a dielectric capping layer of 50 nm NPB is added. The whole schematic layer structure is given in Fig. 1.

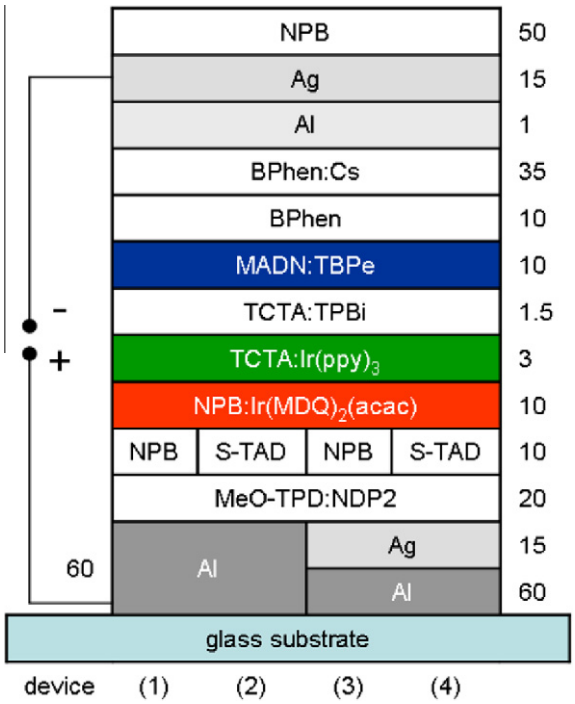

Fig. 1. Schematic layer structure of processed organic LEDs. Layer thicknesses are given in nm.

2.2. Preparation

Thin film evaporation of metals and organic semiconductor materials for the OLED devices is carried out under UHV conditions in a single chamber evaporation tool (K.J. Lesker) with a base pressure of 1×10^{-8} mbar. For the production of the hole-only devices as well as the single organic layers for UPS measurements, a multi chamber deposition tool (Bestec) ($p < 1 \times 10^{-8}$ mbar) is used. After processing, the devices are immediately encapsulated under nitrogen atmosphere.

2.3. Electrical and optical measurements

The current–voltage–luminance (*I*–*V*–*L*) and electroluminescent (EL) characteristics are determined at 0° viewing angle using an automated measuring setup consisting of an array-spectrometer (CAS 140CT-153) in combination with a Keithley 2400 SourceMeter. Since one generally cannot presume Lambertian emission characteristics for top-emitting devices, both luminous efficacy and external quantum efficiency are calculated considering the measured spectral emission at varied viewing angle. The emission characteristics of each device are determined employing a carefully adjusted goniometer setup. Light emitted from the active OLED area in the center of a rotary table is detected for angles θ from 0° to 90° with a spectrometer (USB4000). To avoid unwanted edge contributions, the substrates are covered with masks. Based on the angle dependent spectral radiation, luminous efficacies and external quantum efficiencies are calculated following the procedure given in [14].

2.4. UPS measurements

UPS measurements are carried out under ultrahigh vacuum ($p < 1 \times 10^{-9}$ mbar) with a Phoibos100 system from Specs (Berlin, Germany) using the He I line with an energy of 21.22 eV from a discharge lamp. The experimental error is below 50 meV and can be estimated from the reproducibility achieved in separate measurements. The organic layers for UPS measurements are grown in an UHV cluster tool, which is directly connected to the UPS chamber.

3. Results and discussion

3.1. Influence of different anode materials on the spectral emission

The reflectivity of the electrode mirrors plays an important role in cavity devices since it determines the cavity strength as well as the outcoupled spectra. To evaluate this effect, different metal electrodes have been chosen as described above. The emission spectra of the devices at a luminance of approximately 1000 cd/m^2 are shown in Fig. 2a and b. To verify the effect of different anodes and electron blocking layers, the forward directed cavity emission (Fig. 2c) of all four OLED systems as well as the reflectance of both highly reflecting anode mirrors (Fig. 2d) are additionally illustrated. The cavity emission was obtained by performing optical simulations based on thin film optics [8,15]. This quantity describes the ideal emission spectrum of an optical cavity as obtained by considering wavelength-independent intrinsic luminescence spectra of the emitters, thus providing information on the resonance behavior of the device under examination.

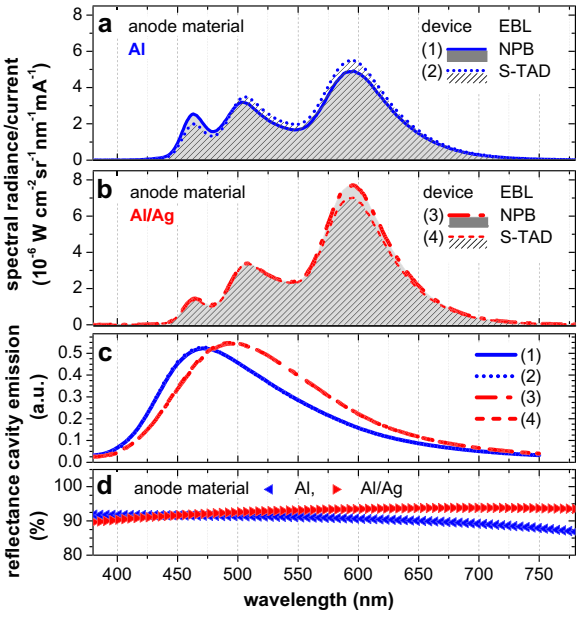

Fig. 2. (a and b) EL spectra of top-emitting white OLEDs containing different anodes (Al, Al/Ag) and different electron blocking layers (NPB, S-TAD). Spectra are measured in forward direction at approximately 1000 cd/m^2 and scaled to their driving current for better comparison. (c) Cavity emission of devices (1–4). The data for NPB and S-TAD fully coincide. (d) Reflectance of anode materials. Cavity emission and reflectance were determined via optical simulation.

The measured spectra of Al (device 1) and Al/Ag (device 3) based OLEDs reveal a dependence of the spectral emission shape on the anode reflectivity. This effect can be explained by a closer look on the cavity emission for Al and Al/Ag based devices and the associated reflectivity of their anode mirrors. The resonance wavelength of Al based devices (1 and 2) is calculated to be 470 nm, which is lower than for Al/Ag devices (495 nm). Accordingly, the cavity emission of Al based devices is enhanced for short wavelengths compared to Al/Ag devices. Therefore, the emission in the high energy region is enhanced, leading to larger contributions in the blue and decreased red emission. By using an Al/Ag anode (devices 3 and 4), the resonant wavelength of the cavity is red-shifted by 25 nm, leading to enhanced light emission in the low energy region. This is related to the larger reflectivity for composite Al/Ag anodes for wavelengths larger than 450 nm when compared to Al systems. Hence, devices with composite anodes present strongly enhanced red emission and suppressed blue contribution.

Due to the larger spectral contribution from the highly efficient phosphorescent orange-red emitting material Ir(MDQ)$_2$(acac), devices with the hybrid anode yield a higher luminous efficacy than OLEDs containing a pure Al anode (cf. Table 1). With the electron blocker NPB, 12.4 lm/W are achieved for device 3 compared to 8.0 lm/W (device 1), having a large spectral blue contribution from the fluorescent emitter TBPe with much lower efficiency. This corresponds to external quantum efficiencies of 5.3% and 3.8%, respectively.

3.2. Investigation of different electron blocking materials

To examine the influence of the electron blocking material on the device performance, we tested the materials NPB and S-TAD. Fig. 3 shows the current–voltage as well as the luminance–voltage characteristics for all processed devices. Devices using S-TAD as electron blocking layer material show steeper *I–V*-curves compared to NPB. Therefore, an approximately 0.5 V lower operating voltage is needed for S-TAD compared to NPB to reach a luminance of 1000 cd/m^2. Thus, the luminous efficacies can be enhanced to 10.4 lm/W (device 2) and 13.3 lm/W (device 4) employing S-TAD. However, the external quantum efficiency remains almost unchanged, as the spectra of the compared blocking materials – shown in Fig. 2a and b – do not show large variations for both cases of anodes.

The slight spectral changes cannot be attributed to a different optical behavior for different blocking materials, since for both anodes the cavity emission of the organic layers is practically independent from the EBL material (Fig. 2c), due to very similar optical constants. Therefore, the differences have to be attributed to the different electrical behavior, which slightly changes the electron–hole balance and therefore alters the emission spectra. A possible explanation for the altered *I–V*-characteristics might be found in different energy barriers from p-doped MeO-TPD to the applied electron blocking layer, S-TAD or NPB, respectively.

Table 1
Driving voltage V, luminance L, current efficiency η_c, luminous efficacy η_l and external quantum efficiency η_q as well as forward CIE coordinates and CRI values.

Device	Anode	EBL	V (V)	L (cd/m^2)	η_c (cd/A)	η_l (lm/W)	η_q (%)	CIE (x, y)	CRI
1	Al	NPB	3.5	1151	14.0	8.0	3.8	0.420, 0.407	75.6
2	Al	S-TAD	3.0	902	15.7	10.4	4.0	0.435, 0.429	74.8
3	Al + Ag	NPB	3.4	1037	20.0	12.4	5.3	0.472, 0.441	69.5
4	Al + Ag	S-TAD	3.0	1220	18.7	13.3	4.9	0.466, 0.444	70.4

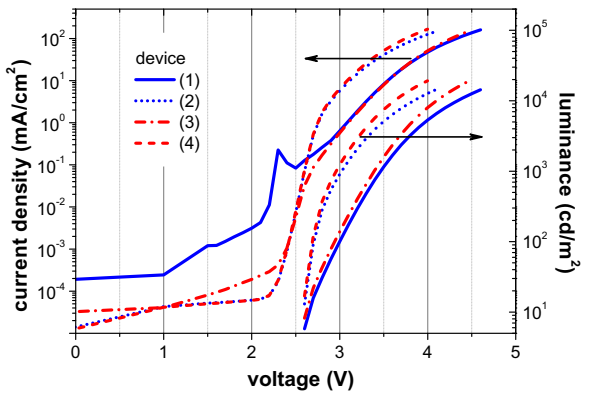

Fig. 3. Current–voltage and luminance–voltage characteristics of the produced devices. Using S-TAD as electron blocking layer leads to steeper curves and reduced driving voltage compared to NPB.

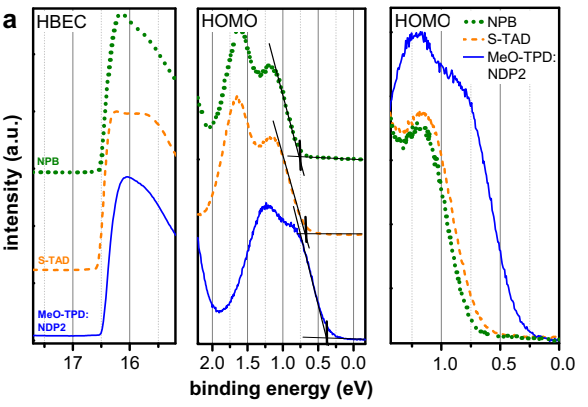

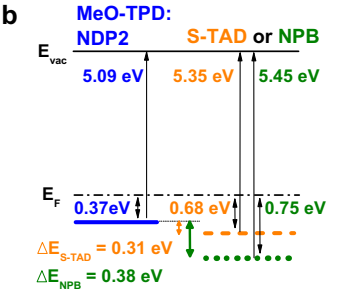

Fig. 4. Interface between NDP2 doped MeO-TPD (solid line) and the blocker materials S-TAD (dashed line) and NPB (dotted line), respectively. (a) High binding energy cutoff (HBEC) and HOMO region of the UPS He I spectra. The thick lines mark the HOMO cutoff positions. (b) Resulting schematic energy level diagram.

Therefore, we perform UPS measurements [16] at the interface of MeO-TPD:NDP2 to each blocker material to determine the hole injection barrier. The measurements and interface alignment between MeO-TPD:NDP2 and the applied electron blocking materials (NPB and S-TAD) are shown in Fig. 4. On top of two 10 nm thick 4 wt.% NDP2 doped MeO-TPD layers, either 5 nm S-TAD or 5 nm NPB are evaporated, respectively. Fig. 4a displays only one curve of MeO-TPD:NDP2, as both measurements show the same curve progression. Hence, for MeO-TPD:NDP2 a hole injection barrier from the Fermi level of 0.37 eV as well as a high binding energy cut-off of 16.50 eV is obtained, leading to an ionization potential (IP) of 5.09 eV. The following electron blocking layers show vacuum level alignment with the doped layer and the injection barriers to MeO-TPD are measured to be 0.31 eV for S-TAD and 0.38 eV for NPB with ionization potentials of 5.35 eV for S-TAD and 5.45 eV for NPB. Thus, the energy barrier for holes is 70 meV higher for NPB compared to S-TAD and is therefore just slightly larger than the experimental error of 50 meV.

Consequently, these small differences in the energy barrier for both electron blocking materials are unlikely to have such a strong influence on the electrical characteristics alone. Thus, it is more likely that the differences in the electrical characteristics are also influenced by an altered hole mobility within the blocking material.

To further investigate the origin of the deviating I–V-characteristics for both electron blocking materials, we additionally fabricate hole-only devices (p–i–p and p–i–i–i–p). In between two 50 nm thick hole transport layers of MeO-TPD:NDP2 (approximately 4 wt.%), the intrinsic material is inserted. For p–i–p devices either 100 nm NPB or 100 nm S-TAD are used as intrinsic layer. The p–i–i–i–p devices contain a layer sequence of 20 nm EBL and 30 nm NPB:Ir(MDQ)$_2$(acac), again followed by the electron blocking material (50 nm), which was used before. The organic p–i–p as well as the p–i–i–i–p stack is evaporated on top of an indium tin oxide (ITO) coated glass substrate and covered with 100 nm aluminum.

In Fig. 5, the forward and backward measured current density for both p–i–p and both p–i–i–i–p devices is shown. All four devices exhibit relatively symmetric I–V-characteristic, whereas the devices containing NPB as electron blocking material show lower current flow compared to the devices with S-TAD. As the current density for NPB at a fixed applied voltage is much lower than for S-TAD, the flow of holes is hindered.

Due to these different electrical characteristics of the device structure using either NPB or S-TAD as blocking

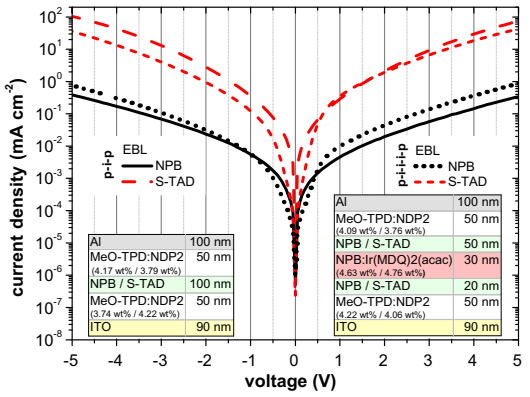

Fig. 5. Current density measured in backward and forward direction for the p–i–p as well as p–i–i–i–p devices. Layer structure for both hole-only devices (inset). The Ir(MDQ)$_2$(acac) doping concentrations for the central intrinsic layer of the p–i–i–i–p devices are 4.63 and 4.76 wt.%, using NPB or S-TAD, respectively, and are therefore almost identical. The slight differences in the p-doping concentration are due to processing.

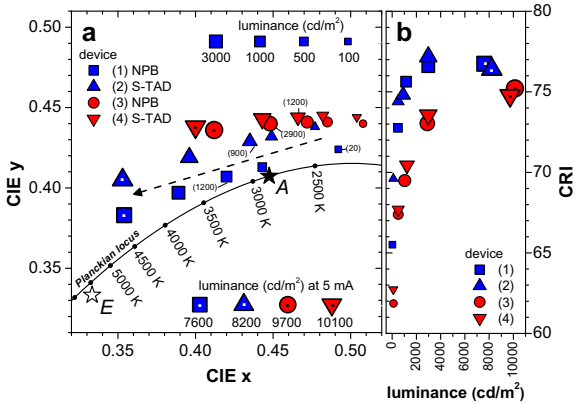

Fig. 6. (a) Color coordinates (CIE) and (b) color rendering indices (CRI) describing emission spectra at 0°. Values are calculated adapted from spectra measured at 100, 500, 1000, 3000 cd/m^2 and a driving current of 5 mA. Variant values are stated in brackets.

material, the electron–hole balance within the device is modified. Consequently, this has an influence on the emission spectra as well as on the OLED efficiency, as the distribution of exciton generation is also changed.

3.3. Chromaticity and color rendering

Based on the OLED spectra at angle of 0°, the chromaticity coordinates (CIE 1931) (Fig. 6a) and color rendering indices (CRI) (Fig. 6b) are calculated. As the organic stack comprises three separate emission layers, the charge carrier balance is modified due to a change in driving current. Hence, CIE and CRI change as a function of the device brightness. For all OLEDs, a shift towards the blue edge of the CIE coordinate diagram can be detected with increasing luminance. Aluminum based devices (1, 2) show a stronger change in both coordinates compared to devices 3 and 4. Furthermore, the CIE coordinates – especially for device 1 – are very close to the black body curve defining ideal white. The choice of the EBL modifies the distance to the Planckian locus, which is closest for device 1 at 500 cd/m^2 featuring a CRI of 73 and color coordinates of (0.44, 0.41) almost exactly matching the warm white standard illuminant A (0.45, 0.41). The color quality of the OLED emission steadily rises with brightness, possessing a stronger increase and higher CRI values for Al based devices, even reaching the highest CRI of 77 for device 2 at 3000 cd/m^2.

3.4. Emission characteristics

The angular emission characteristics of all four devices are comparable and only exhibit slight differences when different anode mirrors as well as electron blocking materials are applied. For the discussion, we take device 1 as representative, whose angular emission characteristics are shown in Fig. 7. Fig. 7a and c additionally provide data obtained via optical simulation based on thin film optics [8,15], which very well coincide with experimental measured data. In Fig. 7a the spectral radiance at different viewing angles is illustrated. The emission peak wavelength of spectral radiation is kept stable with increasing angle. However, the peak emission intensity of all three emission colors decreases with increasing viewing angle differentially for the three emitters, leading to a small blue shift of color (Fig. 7b). However, CIE coordinates exactly move along the Planckian locus.

The device radiance was calculated from the angular-dependent electroluminescence spectra (Fig. 7c). Usually, organic light-emitting diodes are presumed to show Lambertian emission with a cosine shaped decrease of intensity from 0° to 90°. Our devices, however, indicate considerably enhanced emission for small viewing angles. Compared to an ideal Lambertian emitter, featuring the same radiant power density per unit area (6.78 W/m^2 at 3.5 V forward bias), the device reveals larger radiance for viewing angles θ in the range of 0–50°.

In order to explain the observed small angular dependence and the enhanced emission in the forward direction, we evaluated the cavity resonance wavelength λ_R as a function of the viewing angle (Fig. 6d).

For device 1, the resonance wavelength λ_R equals 471 nm in forward direction ($\theta = 0°$). With increasing viewing angle θ, a blue shift in λ_R of 56 nm from 0° to 80° can be observed for TE-polarized radiation, whereas TM-polarized light does not show any change in the complete forward hemisphere. In comparison, the same device without a capping layer shows considerable shifts in both the TE- and TM-components (59 nm and 68 nm, respectively), featuring a resonance wavelength of 510 nm at an angle of 0°.

It can be concluded that the capping layer is very effective in suppressing the blue-shift of the TM-component, whereas the shift of the TE-component is left almost unchanged. Since the resonance conditions of the microcavity exhibit a rather small overall angular dependence, the corresponding color coordinates of the emitted radiations are stable with increasing viewing angle.

The observed forward directed emission feature of the device is as well related to the resonance wavelengths of

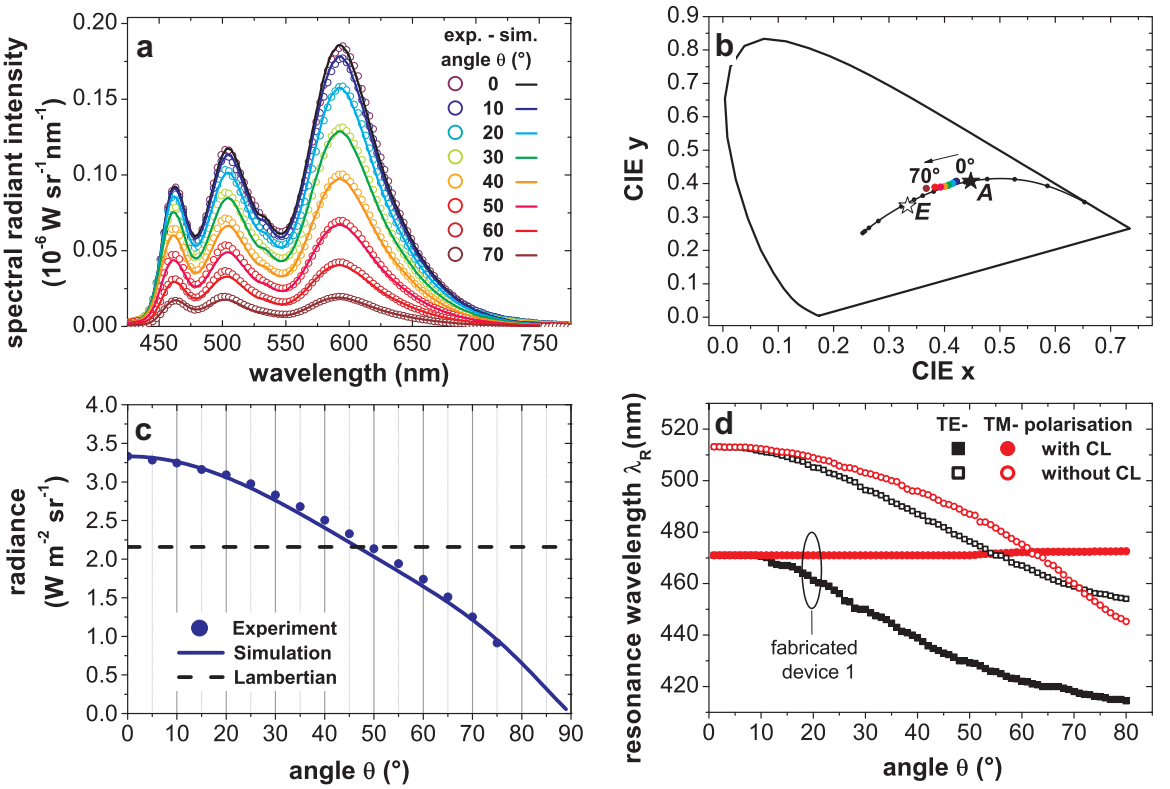

Fig. 7. Emission characteristics of device (1), driven at 3.5 V at a 0°-luminance of 1151 cd/m^2. (a) Experimental measured and simulated spectral emission and (b) measured color coordinate shift at different viewing angle. (c) Determined angular dependent radiance with an absolute radiated power of 6.78 W/m^2 compared to ideal Lambertian emission with the same total power. (d) Simulation of cavity resonance wavelength λ_R at different angles θ for the fabricated device with capping layer compared to a device without capping layer comprising the same layer stack.

the OLED microcavity. It can be observed that λ_R in the forward direction is smaller than the central emission wavelengths of both the green and orange-red emitters (525 nm and 610 nm, respectively) and slightly larger than the emission wavelength of the blue emitter TBPe (460 nm). With increasing viewing angle, the OLED cavity resonates at shorter wavelengths due to the blue shift in λ_R for TE polarized light (see Fig. 6d). Therefore the overlap between the intrinsic cavity emission and the luminescence spectra of the emitters is reduced, especially when considering TBPe. This leads to a consistent and fast reduction in radiated power when considering off-normal directions and, consequently, light emission from the device exhibits a rather strong directionality, rather than a Lambertian behavior [17].

3.5. Analysis of the device efficiency

An optical OLED model [18] is employed in this section to analyze the efficiencies of the OLEDs under examination. Similar calculations are performed for equivalent devices in bottom-emission configuration [11,12] in order to provide meaningful comparisons to existing literature data.

The first step of the modeling approach is the calculation of the outcoupling efficiency η_{out} [15] for each of the emitting layers in the OLED stack. An overall outcoupling efficiency for the white OLED is then derived as an averaged sum of the contribution of the three emitting units, the weights w being determined from the fitting of the electroluminescence spectrum of the device in the forward direction. As last step, an overall internal quantum efficiency η_{IQE} is obtained as the ratio $\eta_{IQE} = \eta_{EQE}/\eta_{out}$, where η_{EQE} denotes the measured external quantum efficiency of the device. This approach allows to obtain an approximate estimate of the internal efficiency of the device and therefore allows to quantify the optical and electrical/excitonic efficiencies of the OLED stack under study.

We consider in the remainder of this section device no. 3, exhibiting the maximum external quantum efficiency (5.3% at 1000 cd/m^2). The η_{out} values obtained for the red, green, and blue emitting layers are 6.9%, 19.9%, and 19.3%, respectively. The low value obtained for the red emitter is related to the fact the OLED cavity is strongly off-resonance for radiation at wavelengths in the range 600–700 nm, the resonance wavelength of the cavity being close to 490 nm. On the other hand, the OLED cavity resonates at wavelengths in the blue-green region of the visible spectrum and thus outcoupling of the green and blue components of the white OLED emission spectrum is favorable. The weights w of the three emitters in the OLED stack extracted from the forward emission spectrum of the device are equal to 0.72, 0.09, and 0.19 for the red, green, and blue emitter, respectively. From the analysis of the values quoted above, it is clear that most of the recombination

events are occurring within the red emitting layer, whereas only recombination within the green and blue emitting layers is comparably lower.

The overall outcoupling efficiency – defined as the total number of outcoupled photons to the total number of photons emitted inside the cavity – is finally evaluated as $\eta_{out} = w_{red} \times \eta_{out,red} + w_{green} \times \eta_{out,green} + w_{blue} \times \eta_{out,blue} =$ 10.4%. It is clear that such a relatively low value is related, on the one hand, to the low outcoupling efficiency of the microcavity for red light and, on the other hand, to the low number of recombination events occurring in the green and blue emitters. From the comparison of the measured η_{EQE} and the calculated η_{out}, the overall internal quantum efficiency equals to 50.8%.

For comparison purposes, we calculate the efficiencies of the white bottom-emitting OLEDs in Refs. [11,12]. These devices feature a very similar structure of the emission units, the main differences between the two stacks is the blue fluorescent emitter (Spiro-DPVBi instead of TPBe) and some of the organic functional layers. The best external quantum efficiency for these devices at 1000 cd/m^2 is $\eta_{EQE} = 7.4\%$ [12]. We calculate for these device an overall outcoupling efficiency $\eta_{out} = 19.6\%$. From the comparison of calculation and experiments, the internal quantum efficiency at 1000 cd/m^2 is estimated to be 37.8%, i.e. considerably lower than the η_{IQE} obtained for the devices presented in this work.

From the comparison of the estimated internal quantum efficiency values for the two device architectures, it can be concluded that the top-emission OLED presented here exhibits a performance superior to similar devices in bottom-emission configuration. The reasons for this can be ascribed to (i) a changed charge carrier balance and (ii) an improved efficiency for the blue fluorescent emitter used in this study.

4. Conclusions

In summary, we demonstrated white-emitting OLEDs with top-emission structure, showing enhanced forward emission up to angles of 50°. The emission maxima can be kept stable with a carefully adjusted optical design of the device. Different anode materials were tested revealing a considerable influence on the spectral emission shape of the devices, due to an altered cavity emission. By changing electron blocking materials the device performance could be enhanced due to a lowered driving voltage for S-TAD. The devices exhibit high efficiencies of 13.3 lm/W luminous efficacy (device 4) and 5.3% external quantum efficiency (device 3). In comparison to comparable bottom-emitting devices the presented top-emission devices feature superior internal quantum efficiency. Besides high efficiencies excellent color coordinates (e.g. (0.44, 0.41), device 1) near the warm white point A were achieved. The emission can be tuned along the Planckian locus via brightness and shows color rendering indices up to 77 (device 2).

ABSTRACT

We report on the development of a technique for the realization of source/drain electrodes of organic field-effect transistors (OFETs) with small channel length down to 10 μm. The process uses a combination of two different mass printing technologies (flexographic and gravure printing), which are both highly productive. In a first step a negative image of the electrode pattern was printed from an amorphous perfluorinated poly(alkenyl vinyl ether) (CYTOP™ CTL-809M), a material forming a surface of very low surface energy, followed by a full-tone-print of a conductive material, e.g. poly(3,4-ethylenedioxythiophene) doped with poly(styrenesulfonate) (PEDOT:PSS). Despite the full-tone-print the conductive ink was transferred in a patterned fashion due to the heterogeneous surface properties and formed very homogenous and smooth source/drain structures. On the basis of these source/drain electrodes OFETs, inverters and ring oscillators were realized by means of mass printing methods only.

1. Introduction

In the field of printed electronics, mass printing methods like offset, gravure or flexographic printing can play an important role because of their feasibility to produce electronic structures and films with extremely high throughput. Besides the significance of productivity, especially for low-cost products, it is essential to create structures with high resolution and homogeneity, even for simple integrated circuits. To find a solution for the combination of both demands new approaches have to be created.

Standard mass printing technologies have the potential to realize structures in the range of 20–50 μm in the field of graphic arts [1]. A better resolution is not necessary because of the limited ability of the human eye to differentiate between two points printed close to each other. One big challenge is to transfer these dimensions to printed electronics because of the different materials properties and higher quality requirements. However, substantial progress has been made in the last years. Offset printing was used to realize source/drain electrodes for OFETs with a channel length of 100 μm [2] and 50 μm [3], respectively. Flexography was used for this purpose as well, resulting in a channel length of 50–200 μm [4]. Finally, gravure printed source/drain electrodes with a channel length of 100 μm were used in order to set up a ring oscillator circuit with all other layers (semiconductor, insulator and gate) gravure printed too [5]. The usage of gravure printing to apply the active semiconductor was also reported for other electronic devices like rectifier diodes [6], OLEDs [7,8] and organic solar cells [9]. In spite of these promising results there are still no reports on successfully downsizing the channel length to and below values achievable with conventional printing of color inks.

In this paper we present a method to combine flexographic and gravure printing in order to achieve structural dimensions of 10 μm, which was derived from the process introduced in [10]. The technique uses the effect of wetting and dewetting of fluids on heterogeneous surfaces with different surface energy levels. Similar principles were

implemented by different research groups, either for the realization of source/drain electrodes [11–13] or for patterning of semiconductors [14,15]. However, in all of these cases a complicate and time-consuming pre-structuring of the substrate was necessary. Furthermore the application of the functional material was made by inkjet printing, which is a process of much lower productivity in comparison to mass printing, or by dip coating and spray coating [10], which tend to leave residuals on hydrophobic areas.

2. Experimental

The full roll-to-roll process for the realization of source/drain structures, called "Cyflex", is outlined in Fig. 1.

As substrate we used a commercially available smooth polyester foil (PET, DuPont Teijin Films) with a thickness of 100 μm and a surface roughness of 8 nm. After an inline corona pretreatment in order to enhance the surface energy from ~43 to ~60 mN/m, the pre-structuring of the substrate was performed by means of flexographic printing. In contrast to [10], an amorphous perfluorinated poly(alkenyl vinyl ether) (CYTOP™ CTL-809M, Asahi Glass) was transferred from an inked printing plate (Flint Group, FAH nyloflex). The most important reason for choosing this perfluorinated polymer was the ability of this material to generate a very smooth printed film ($R_a \approx 10$ nm, $R_z \approx 45$ nm) with an extremely low surface energy, measured to be $\sigma = 17.2$ mN/m ($\sigma_{pol} = 0.1$ mN/m). This results in a large contrast in terms of surface energy between covered and uncovered, areas of the substrate. Furthermore it was possible to print very thin (thickness $d_{CYTOP} = 10...60$ nm, depending on the polymer concentration) and small structures with a width between 100 and 10 μm. It should be noted that for the pre-structuring step a negative image of the source/drain electrodes had to be printed.

In order to form the electrodes themselves, a non-patterned full-tone gravure print of an in-house reformulated water-based dispersion of poly(3,4-ethylene dioxythiophene) doped with poly(styrene sulfonate) (PEDOT:PSS) formulation was applied. With this system smooth and homogenous layers could be printed on bare substrate areas, while no ink from the cells of the gravure cylinder was transferred to the areas with low surface energy. At least no residuals of the conductive ink could be detected on the CYTOP-structures. For a precise control of this separation process it is essential to optimize the interplay between the properties of the conductive ink (e.g. surface tension, viscosity) and the parameters of the printing process (e.g. cell volume and raster of the printing cylinder) together with the geometrical dimensions of the source/drain electrodes (finger width, channel length). In order to demonstrate the functionality of the printed source/drain structures top-gate OFETs, inverters and ring oscillators were built up using two different processes as depicted in Table 1. A spin-coating process was compared with a purely mass printing process using a roll-to-roll laboratory printing press. Details of the process steps and particularly the printing layout consisting of an endless repetition of source/drain fingers and self-aligned gates have been published elsewhere [5].

The surface tension of the PEDOT:PSS-formulations and the surface energy of the substrates were measured at room temperature on a OCA-20 contact angle meter from DataPhysics Instruments GmbH with the pendant and the sessile drop method, respectively. All geometrical values were determined using a profilometer Dektak 8 from Veeco. The transistors were electrically characterized by sweeping the gate voltage V_{GS} from +60 to −60 V with a constant source/drain-voltage of $V_{SD} = -60$ V under ambient conditions. The mobility was determined from the slope of the transfer curve by means of a standard procedure [16].

3. Results and discussion

As can be seen in Fig. 2, very smooth ($R_a \approx 10$ nm) and homogenous PEDOT:PSS–source/drain electrodes with a channel length of only 10 μm and a finger width of 90 μm were created by means of the "Cyflex" mass printing process. In order to achieve such small structures, all parameters involved were investigated carefully. Fig. 3 shows the relation between contact angle on CYTOP-layers and surface tension of different PEDOT:PSS-formulations, which were used to determine the optimum between good dewetting properties on CYTOP and good wetting behavior on uncovered foil. Micrographic images of examples for

different wetting behavior of the formulations are inserted into Fig. 3. The conductivity of the electrodes was measured to be ~30 S/cm, which represents an improvement of more than one order of magnitude in comparison to offset and inkjet printed PEDOT:PSS structures published in [3] and [17], respectively.

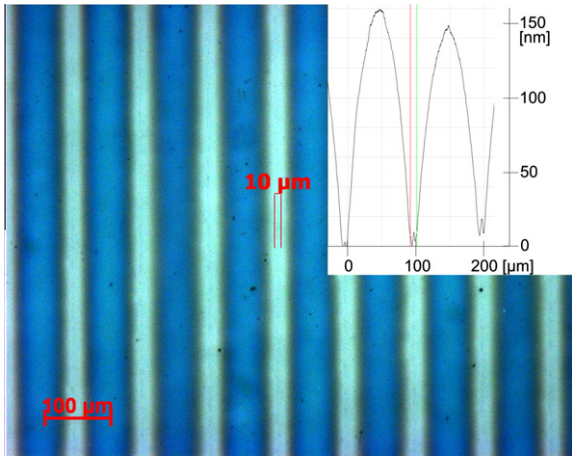

Fig. 2. Microscope image of source/drain electrodes with a channel length of 10 μm and a finger width of 90 μm; inset: profile of the structures.

The transfer characteristics of representative transistors based on "Cyflex"-printed source/drain electrodes with spincoated semiconductor and insulator and with different channel lengths are plotted in Fig. 4. For comparison the characteristics of fully mass-printed OFETs with the same channel length are shown as well. All transistors show good performance with an ON/OFF-ratio between 10^3 and 10^4, a threshold voltage of $-12\ldots-17$ V and a field-effect mobility in the range of $1\ldots3 \times 10^{-3}$ cm^2/Vs, respectively. These values are typical for fully mass-printed devices and the achieved mobility of the used semiconductor F8T2 is in the range of the results of other publications [2,20]. Higher mobility can be obtained using another semiconductor (e.g. TIPS-pentacene), but this would require significant effort in terms of optimization of the printing process. Hence, the more easily printable material was used here in order to demonstrate the structuring approach and leaving the introduction of a more advanced semiconductor for future work. There is, however, no significant difference between all-printed and spin-coated devices, demonstrating the compatibility of the "Cyflex"-process with subsequent printing steps. While the ON-current of the transistors increases nearly linear with decreasing channel length, the OFF-current for small channels of 10 μm is slightly

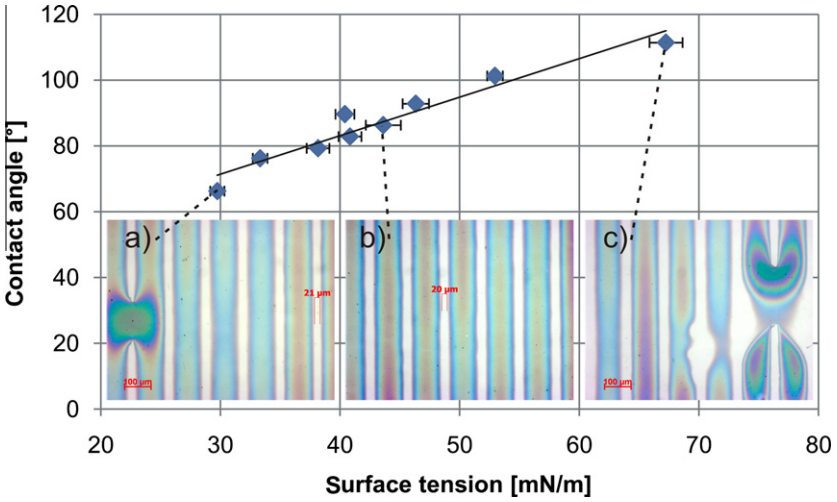

Fig. 3. Contact angle on CYTOP-layers vs. surface tension of different PEDOT:PSS-formulations. Inset: Optimization of the separation process by modification of the surface tension of the PEDOT:PSS formulation: (a) surface tension too low (shorts by bulges); (b) optimum formulation; (c) surface tension too high (dewetting of finger structures and shorts by bulges).

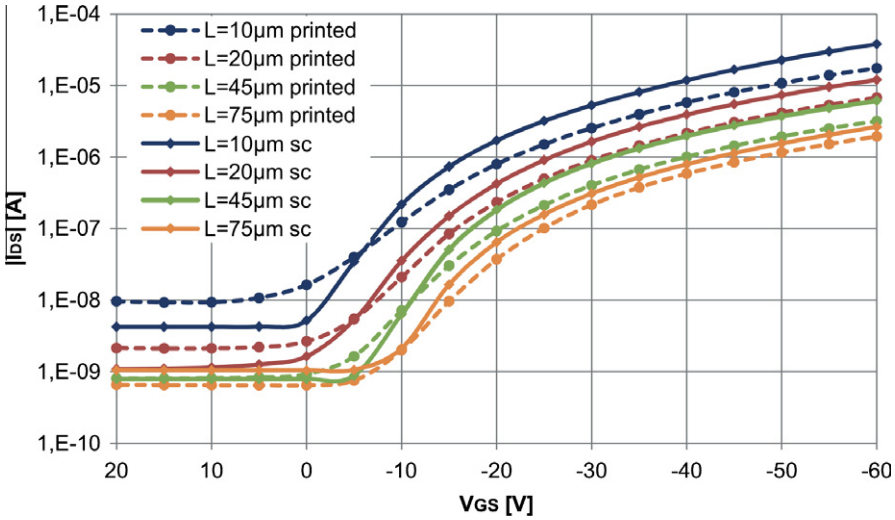

Fig. 4. Transfer characteristic of representative OFETs based "Cyflex"-printed source–drain electrodes with different channel lengths at $V_{DS} = -60$ V. OFETs were built up either by spin-coating (solid lines) or solely by means of mass printing techniques (dashed lines).

higher than the expected value. One reason for this result could be the increasing influence of the so-called short-channel effect [18]. It should be noted, that the thickness of the insulator remains constant while downsizing the channel length in our tests.

The broad range of channel lengths that can be created enables an interesting investigation concerning printed circuits. Ring oscillator circuits with five and seven inverter stages, respectively, were built up on source/drain electrodes with different channel lengths. The channel width

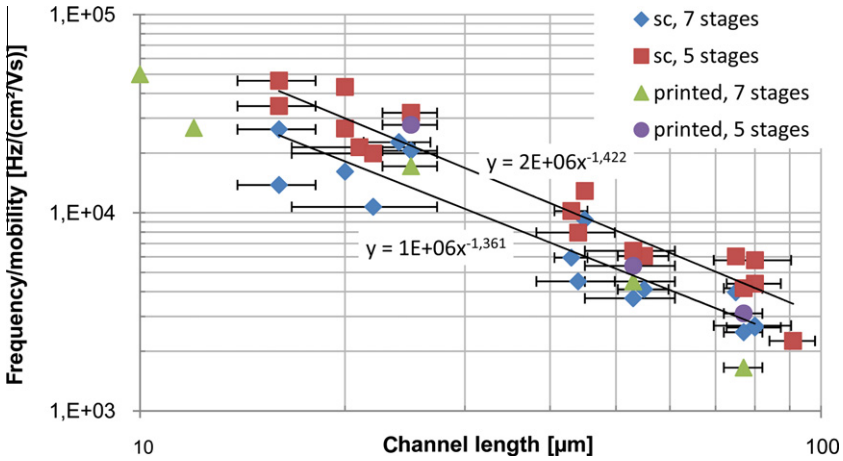

Fig. 5. Frequency–mobility-ratio of 5- and 7-stage ring oscillators made by spin-coating and mass printing techniques, respectively, as a function of the channel length at a supply voltage of $V_{DD} = -80$ V. The lines are power-law fits for the spin-coated devices.

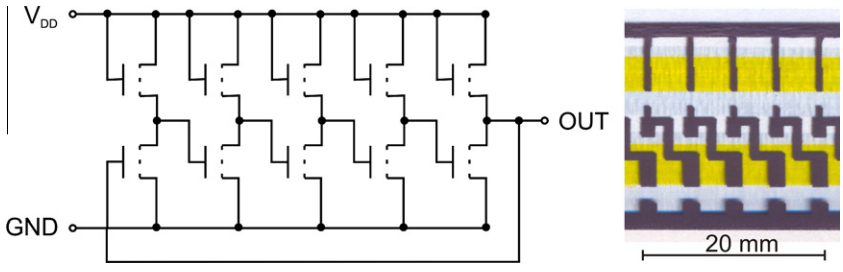

Fig. 6. Schematic circuit and photograph of the printed ring oscillator with five inverter stages.

of the drive and the load transistors was 30 and 6 mm, respectively. A printed circuit with five stages had a lateral size of 20 × 20 mm (Fig. 6). In the case of an ideal behavior of all components (i.e. no parasitic capacitances, no contact resistances, etc.) a quadratic increase of the frequency with decreasing channel length is expected according to

$$f = \frac{1}{2\pi} * \frac{\mu V_{DD}}{L^2} \quad (1)$$

where μ is the charge carrier mobility, V_{DD} is the supply voltage and L is the channel length. Experimental results obtained from spin-coated and all-printed ring oscillators are plotted in Fig. 5. In order to minimize the influence of mobility variations among the circuits, f/μ is plotted as a function of L. Here, μ is the mean mobility determined from the transistors of the respective circuit.

Fitting the data using a power-law dependence reveals that the behavior of all types of circuits is consistent with this kind of dependence. The exponent, however, is close to 1.4 in all cases. We ascribe the deviation from the expected quadratic behavior to parasitic (overlap capacitances, contact resistance, see [19]) and short-channel effects. Finally, we would like to point out that having created all-printed circuits with the up to now smallest channel length, we can extrapolate our data in order to estimate the oscillation frequency potentially achievable with all-printed organic materials. Based on our channel length of 10 μm and assuming a mobility of 1 cm^2/Vs – which can be reached with organic materials, but has not yet been demonstrated for printed devices – the estimation results in 80 kHz. It should be noted that this value can be improved by eliminating parasitic and short-channel effects.

4. Conclusions

The combination of the mass printing techniques flexography and gravure printing for the realization of source/drain electrodes by employing effects of surface wetting and dewetting on heterogeneous substrates turns out to be a promising solution. OFETs with channel length of 10 μm were produced solely by means of highly productive methods. The functionality of these structures was demonstrated with the help of spin-coated and mass-printed transistors and ring oscillators, which confirm a significant improvement of the geometrical and electrical properties in comparison to previous results of mass-printed devices. Fair values of switching frequencies can be expected provided that high-mobility semiconductors will be utilized for printed devices. Apart from further reducing the channel length, improvements are possible by reducing parasitic effects (e.g. by reducing overlap capacitances) and short-channel effects (by reducing the insulator layer thickness).

ABSTRACT

We report on the solution-processed thin-film transistors (TFTs) fabricated by the vertical flowing of the viscous 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) and isotatic (*i*-) poly-(methyl methacrylate) (PMMA) blend. According to the optical-absorption and X-ray diffraction spectra, the solution-processed film appeared self-assembled with TIPS-pentacene (up) and *i*-PMMA dielectric (down) layers on substrates. As fabricated on a highly capacitive 100 nm-thick AlO_x dielectric, our device displayed a high mobility of 0.34 cm^2/V s, a low operation voltage of −15 V, and little hysteresis.

1. Introduction

Organic thin-film transistors (TFTs) have attracted a great deal of attention over last decades, due to their advantage of low cost fabrication, which brings their research scope to solution processes, such as gravure printing, ink jet printing, and spin coating [1–4]. In order to meet the requirements for industrialization of organic TFTs, they should have performance uniformity over batch, a decent mobility at a low operational voltage, and electrical stability without gate hysteresis. A small-molecule semiconducting material, 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) has been demonstrated as one of the potential active materials for solution-based process, due to its good performance and solubility [4–10]. However, its device performance over batch is not uniform in general solution processes such as drop casting, ink jetting, and spin-casting [4–7]. Among above processes, spin-casting is more or less recommendable in terms of one batch uniformity but it usually brings a small grain size of TIPS-pentacene leading to poor device mobilities [4]. Furthermore, gate-bias hysteresis of TFTs with sole-TIPS-pentacene channel has rarely been reported but in fact a large hysteresis is often suspected [5,7]. In the present study, a possible solution for TIPS-pentacene based TFTs to be highly-performing hysteresis-free devices with batch-by-batch uniformity is suggested and was implemented by blending TIPS-pentacene and insulating isotatic (*i*-) poly-(methyl methacrylate) (PMMA), since the *i*-PMMA is reported to have good leakage-protecting and hysteresis-minimizing properties [11,12]. This type of blending has been recently implemented by other groups aiming at the self-assembly of the semiconductor/dielectric layers but is still worthy of re-evaluating. Our work uses "vertical flowing" technique of blend solution and is thus distinguished from the previously-reported works [4–9]. Our study scientifically reveals the layered channel/insulator structure in the organic thin-film, which was not clearly proved but only conjectured [6,8,9]. As a final result of our blending method, we demonstrate a hysteresis-free low-voltage-driven TIPS-pentacene TFT with a high mobility of 0.34 cm^2/V s operating at −15 V on glass substrate.

2. Experimental section

With purchased TIPS-pentacene (Polysis Pure Products Co.) and *i*-PMMA (Aldrich) 3–3.4 wt.% TIPS-pentacene/*i*-PMMA blend (1:1 weight ratio) was dissolved in cyclohexanone and toluene (Aldrich) co-solvent (weight ratio = 1.3:1), which makes a viscous solution to control the total thickness of TIPS-pentacene/*i*-PMMA blend on a substrate. The two mixed solvents were expected to properly increase the viscosity, simultaneously well dissolving the both of *i*-PMMA and TIPS-pentacene. A cleaned 200 nm-thick SiO_2 on p^+-Si was used as a substrate and common gate dielectric for a high voltage organic TFT, and hexamethyldisilazane (HMDS) was coated by spin-casting and annealed at 110 °C, to make the SiO_2 surface as hydrophobic as *i*-PMMA. TIPS-pentacene/*i*-PMMA blend solution was flowed through pipette on the upstanding SiO_2/p^+-Si substrate as shown in Fig. 1a. (Sole TIPS-pentacene solution without *i*-PMMA was not viscous enough to form a thin-film organic semiconductor on the substrates.) During the drying process, the substrate was kept in upstanding position and we could expect a directional crystallization of solid TIPS-pentacene (Fig. 1b), which was really observed by optical microscopy (Fig. 1c). Boiling point of a solvent cyclohexanone is known as 151 °C which is quite high. In general the high boiling point property of a solvent makes its evaporation slow, so helping solution-based TIPS-pentacene to be highly crystalline during the drying. [3–5,7] After drying the solution, the solution-deposited sample was placed in vacuum desiccators overnight for removal of solvents. The final thickness of our organic film was ~330 nm as its cross section was measured by scanning electron microscopy. The 200 nm-thick source/drain (S/D) Au electrodes were finally deposited on the processed TIPS-pentacene/*i*-PMMA blend by thermal evaporation (Fig. 1d); this TIPS-pentacene TFT has the nominal channel length (L) and width (W) of 90 and 1000 μm, respectively. For low-voltage TFTs on glass, a bottom gate electrode of 50 nm-thick Al was thermally evaporated to be patterned on the glass through a shadow mask. After that, 100 nm-thick AlO_x film was deposited by rf magnetron sputtering at room temperature (RT) [13]. HMDS coating on the oxide, the vertical flowing of TIPS-pentacene/*i*-PMMA blend layer, and S/D Au patterning were conducted on the AlO_x film with the same manner as implemented on the SiO_2/p^+-Si substrate. All electrical characterizations on devices were carried out in the dark at RT. Ultraviolet (UV)-absorption and X-ray diffraction (XRD) measurements were performed on TIPS-pentacene/*i*-PMMA films that was prepared on HMDS-coated glass.

3. Results and discussion

As observed in Fig. 1b and c, the viscous TIPS-pentacene/*i*-PMMA blend showed directional crystallization after vertically flowed on the HMDS-modified substrate. The nucleation and unidirectional growth of pentacene crystalline solid evidently began from the edge of the blend-strip. (In contrast to our vertical flow technique, a conventional drop casting method, where the dropped solution dries in a manner of more-or-less horizontal spreading, can hardly guarantee any uniform performance of OTFT devices, since in that case the crystallization direction of pentacene is not unidirectional but radial from the solution drop edge toward its center) [14]. Moreover, since the TIPS-pentacene/*i*-PMMA blend separated into two

Inset shows contact angle images of DI water on each film. (b) XRD spectra obtained from identical samples. Inset displays schematic structure of blend film before and after etching.

chemically different solid phases after solidification, it is likely that self-assembly (or segregation) of *i*-PMMA and TIPS-pentacene might take place on the HMDS-functionalized oxide substrate forming two separated layers, prior to the directional crystalline growth. Fig. 2a and b display UV-absorption and XRD spectra, respectively as obtained from our solution-processed TIPS-pentacene/*i*-PMMA film on HMDS-functionalized glass. According to UV-absorption

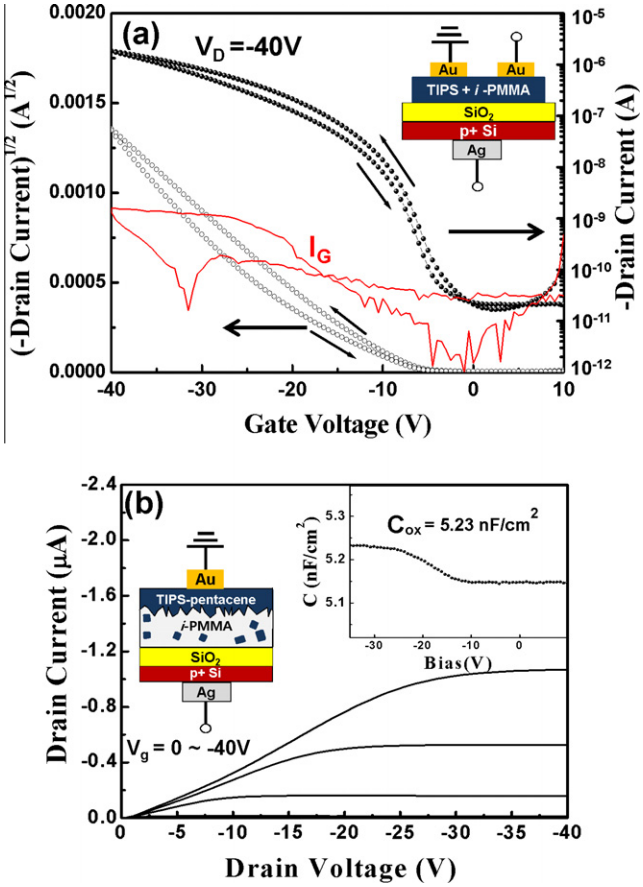

Fig. 3. $\sqrt{-I_D} - V_G$ and $\log_{10}(-I_D) - V_G$ plots obtained from our TFT based on TIPS-blend on SiO_2 (200 nm) gate dielectric. Inset shows schematic cross-section of our device. (b) $I_D - V_D$ curve obtained from the same device. Inset plot shows $C - V$ characteristic directly measured from MIS part of our TFT device. I_G means gate leakage current (<1 nA).

spectra, pristine thin-film exhibits strong absorption peaks at 644, 593.5, and 552 nm which are corresponding to those of reported TIPS-pentacene crystal [10]. However, after hexane-etching was carried out with the same sample, the peak intensities were considerably reduced and some amount of peak shift is also shown (see the arrows). This means that the hexane-etching very much removed the TIPS-pentacene layer [6], and the inset contact angles on the sample surfaces also proves this etching effect as measured before and after hexane-etching, because the surface of *i*-PMMA is less hydrophobic than that of TIPS-pentacene crystal. (It is also important to know that the hydrophobicity or surface energy of *i*-PMMA is somewhat similar to that of the HMDS-functionalized surface in view of contact angle, ~68° and that is why the *i*-PMMA moves down to be segregated on the HMDS-functionalized substrate surface.) The XRD spectra in Fig. 2b further support this hexane-etching effect. Pristine thin-film shows strong diffraction peaks that indicate a well-ordered pentacene crystalline structure with the interlayer spacing of 15.88, 8.11, 5.49, and 3.30 Å [4–8], while the same sample displays no peaks after hexane-etching. So, UV-absorption and XRD results may lead to the following scheme of solid TIPS-pentacene/*i*-PMMA structure; our TIPS-pentacene/*i*-PMMA film consists of two up/down-separated layers but a little amount of pentacene molecules are spatially embedded inside the *i*-PMMA film. The scheme is reasonable because the absorption peaks of hexane-etched film are closer to those of TIPS-pentacene molecules than to those of crystalline TIPS-pentacene.

Based on above understandings, we fabricated two types of TIPS-pentacene TFTs: TFTs on HMDS-functionalized 200 nm-thick SiO_2/p^+-Si and 100 nm-thick sputter-deposited-AlO_x/patterned Al (on glass). We surely expected the formation of bilayer dielectric (namely, *i*-PMMA/oxide bilayer) for the TFTs. Fig. 3a and b shows the transfer curves ($\log_{10}(-I_D) - V_G$) and output curves ($I_D - V_D$) of our devices fabricated on SiO_2/p^+-Si, respectively. Operation voltage was −40 V and the device hysteresis was not as large as ~1.5 V. Interesting to note is the inset *C*–*V* result from Au/TIPS-pentacene/*i*-PMMA-SiO_2 metal–insulator-semiconductor (MIS) sample. For the accumulation state, the *C* value turned out to be only 5.23 nF/cm^2, which is much lower than that of 200 nm-thick SiO_2 (~17 nF/cm^2), and this again proves that the insulator dielectric for the TFT is not just the SiO_2 but also contains thick *i*-PMMA. Adopting the total serial capacitance (5.23 nF/cm^2), the field effect mobility of our TFTs is estimated to be ~0.0324 ± 0.007 cm^2/V s with a high on/off ratio of ~10^5. (In order to confirm batch-to-batch uniformity, we fabricated the TIPS-pentacene devices based on SiO_2/p^+-Si taking three different batches under similar ambient conditions (temperature, humidity). Not quite a different mobility was obtained from all the

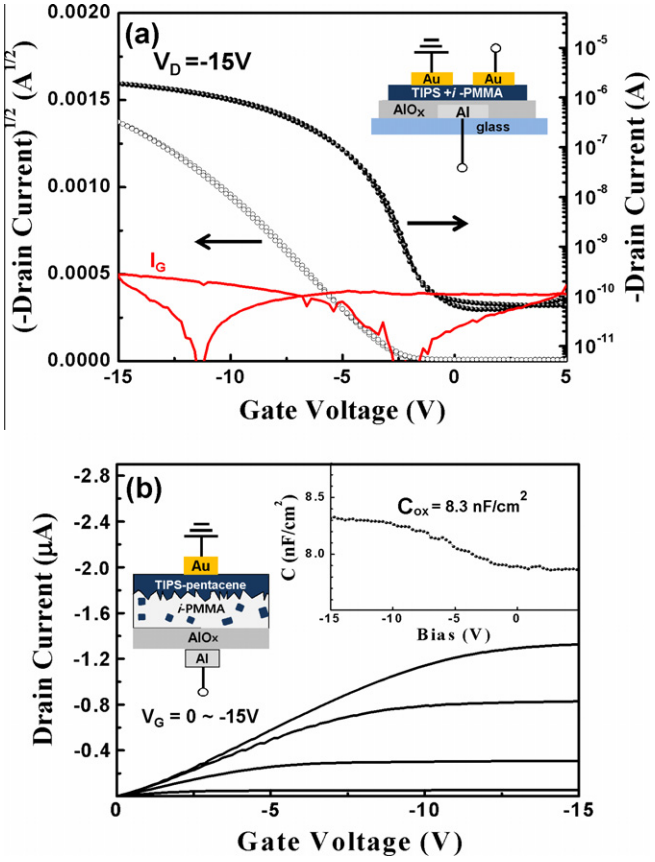

Fig. 4. (a) $\sqrt{-I_D} - V_G$ and $\log_{10}(-I_D) - V_G$ plots obtained from our TFT based on TIPS-blend on AlO_x (100 nm) gate dielectric. Inset shows the device schematic. (b) $I_D - V_D$ curve obtained from the same device. Inset plot shows *C*–*V* characteristic directly measured from MIS part of our TFT device.

batches (6 devices per batch) while the other performance parameters were very similar one another. Saturation mobility was estimated from each batch, to be 0.0319 ± 0.011, 0.0324 ± 0.007, and 0.0432 ± 0.009 cm^2/V s, respectively.

In the same manner of observation, Fig. 4a and b) display the transfer curves ($\log_{10}(-I_D)-V_G$) and output curves ($I_D - V_D$) of our devices fabricated on 100 nm-thick sputter-deposited-AlO_x/patterned Al, respectively. In this case, low-voltage device operation was possible at −15 V, which might be attributed to the dielectric capacitance (∼62 nF/cm^2) of 100 nm-thick AlO_x [13]. However, the total capacitance of Au/TIPS-pentacene/*i*-PMMA-AlO_x MIS capacitor was measured to be only ∼8.30 nF/cm^2 (Fig. 4b inset) due to the low capacitance value of thick *i*-PMMA (the value is 60% increased, compared to that of SiO_2/p^+-Si case). Nevertheless our device on AlO_x operates very well at −15 V without even hysteresis. We think that the 60%-improved dielectric capacitance was still effective to lower the operation gate voltage (from 40 to 15 V). The field effect mobility of this low-voltage TFT was estimated to be as high as ∼0.34 ± 0.03 cm^2/V s with an on/off current ratio over $\sim 10^4$, subthreshold swing of 0.8 V/dec and threshold voltage of −2.7 V. As a final analysis, we also calculated the capacitance of *i*-PMMA layer itself by considering serially connected capacitors (*i*-PMMA-oxide), and obtained the values of 7.6 and 9.5 nF/cm^2 for SiO_2 and AlO_x cases, respectively. Those two were not exactly identical but reasonably similar.

4. Conclusion

In summary, we have fabricated the solution-processed organic TFTs by the vertical flowing of the viscous TIPS-pentacene and *i*-PMMA blend. It was observed through the optical-absorption and X-ray diffraction that the solution-processed film consists of two separated layers of TIPS-pentacene and *i*-PMMA dielectric. When we fabricated the organic TFTs on HMDS-functionalized dielectric oxides, a high saturation mobility of ∼0.34 $cm^2/V{\cdot}s$ was achieved at only −15 V with little hysteresis. We thus conclude that our work and understanding are promising for the realization of stable solution-based low-voltage organic TFTs.

ABSTRACT

We investigated the influence of oxygen on the performance of P3HT:PCBM (poly(3-hexylthiophene):[6,6]-phenyl C61 butyric acid methyl ester) solar cells by current–voltage, thermally stimulated current (TSC) and charge extraction by linearly increasing voltage (CELIV) measurement techniques. The exposure to oxygen leads to an enhanced charge carrier concentration and a decreased charge carrier mobility. Further, an enhanced formation of deeper traps was observed, although the overall density of traps was found to be unaffected upon oxygen exposure. With the aid of macroscopic simulations, based on solving the differential equation system of Poisson, continuity and drift-diffusion equations in one dimension, we demonstrate the influence of a reduced charge carrier mobility and an increased charge carrier density on the main solar cell parameters, consistent with experimental findings.

1. Introduction

Power conversion efficiencies of almost 8% for organic solar cells have already been achieved, with growing tendency [1]. A critical issue yet to be addressed are the factors influencing the device lifetime. To gain a detailed understanding of the device stability, as well as the underlying degradation mechanisms and their impact on the solar cell performance is an important prerequisite for lifetime enhancements.

Organic solar cells undergo many degradation pathways during their lifetime. Efficiency losses due to light [2], oxygen [3,4] and water [5] are reported. The details of the degradation processes, however, are still not completely understood. Other studies, on the contrary, are only focused on the degradation of a single active material instead of the blend. For example for P3HT oxygen is known to form a charge transfer complex [6] resulting in *p*-doping of P3HT [7,8], which is also investigated theoretically by band-structure calculations [9]. Furthermore, oxygen induced degradation of P3HT is reported to result in decreased mobilities [6,10] and increased trap densities [10]. In the case of C60, oxygen also causes decreased electron mobilities [11,12] and increased trap densities [13], as demonstrated by investigations of C60 based field effect transistors.

This paper addresses the oxygen induced degradation of poly(3-hexylthiophene):[6,6]-phenyl C61 butyric acid methyl ester solar cells in the dark, as well as under simultaneous illumination. Detailed investigations including charge carrier mobility, charge carrier density and defect spectroscopic measurements are performed to get an insight of the degradation mechanism due to oxygen in P3HT:PCBM solar cells.

2. Experimental

The investigated bulk heterojunction solar cells were prepared by spin coating P3HT:PCBM (ratio 1:0.8) blends

made from solutions of 30 mg/ml in chlorobenzene on poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (Pedot:PSS) covered indium tin oxide/glass substrates. The active layer was about 240 nm thick. After an annealing step of 10 min at 130 °C, Ca (1.5 nm)/Al (60 nm) contacts were evaporated thermally (base pressure during evaporation $< 7 \cdot 10^{-7}$ mbar). The effective areas of the solar cells were 3 mm^2 and 9 mm^2.

PEDOT:PSS was purchased by H.C. Starck (CLEVIOS P VP Al 4083). P3HT was delivered by BASF (Sepiolid P200), PCBM (purity 99.5%) by Solenne. All materials were used without further purification. All preparation steps were performed in a nitrogen glovebox and an attached thermal vacuum evaporation chamber.

Initial current–voltage (IV) characteristics of the solar cells were measured in the nitrogen glovebox. For the illumination of the cells we used an Oriel 81160 AM1.5G solar simulator. The power conversion efficiencies of the investigated samples were 3–3.5%.

Degradation studies of the unprotected solar cells were performed in a closed cycle cryostat. During the thermally stimulated current (TSC), charge carrier extraction by linearly increasing voltage (CELIV) [14,15] and IV–measurements the cryostat was filled with helium as contact gas. To investigate the influence of oxygen on the solar cells, the helium was replaced with synthetic air ($80\%N_2, 20\%O_2, < 1$ ppm H_2O) for different degradation times. Thus, the effect of humidity was excluded. This exposure was always done at a constant temperature of 300 K. Two different degradation conditions were investigated: in synthetic air either in the dark or under illumination. For the latter we used a 10 W high power white light emitting diode (Seoul). The light intensity was adjusted to match the short circuit current of the non degraded cells obtained under the solar simulator. The LED was also used for the illuminated IV-curves in the cryostat.

For TSC measurements the trap filling was achieved by illumination of the samples at 18 K for 5 min using the 10 W LED. After a dwell time of five minutes the temperature was increased with a constant heating rate of 7 K/min up to 300 K. The TSC signals were detected by a Sub-Femtoamp Remote Source Meter (Keithley 6430) without applying an external field, implying that the detrapped charge carriers were extracted from the samples only due to the built-in voltage. Further details of the TSC measurements are described elsewhere [10].

CELIV measurements were performed at 300 K. The peak voltage of the triangular bias pulse in reverse direction was $V_a = 2$ V applied on the Ca/Al electrode. A voltage pulse width of 50 μs was chosen.

3. Results and discussion

3.1. Experimental results

The IV-curves for different degradation times between 0 and 120 h in synthetic air in the dark are shown in Fig. 1a. The obtained values for the power conversion efficiency (PCE), fill factor (FF), open circuit voltage (V_{oc}) and short circuit current (J_{sc}), normalized to the initial values are presented in Fig. 1b. The observed efficiency loss with dark degradation time is only due to J_{sc}, which decreases about 60% within 120 h, whereas V_{oc} and FF remain almost constant. Since the exposure of the samples to synthetic air in the dark results only in a loss in J_{sc}, a degradation of the electrodes being the origin of these findings can be excluded. Degradation (oxidation) of the Ca/Al electrode would result in the occurrence of an s-shaped IV-curve [16], at least in a strong loss in FF or V_{oc}. Neither of these effects was observed within the timescale of degradation considered here.

In contrast to degradation in synthetic air in the dark, the efficiency loss due to degradation in synthetic air and simultaneous illumination (Fig. 2a and b) occurs on a faster time scale – about 30% efficiency loss within 180 min – and is caused by a decrease of J_{sc}, as well as FF and V_{oc}, which all decrease about 10% within this time scale. Since, in the case of dark degradation, FF and V_{oc} are unaffected, the decrease of both during photodegradation is due to light in

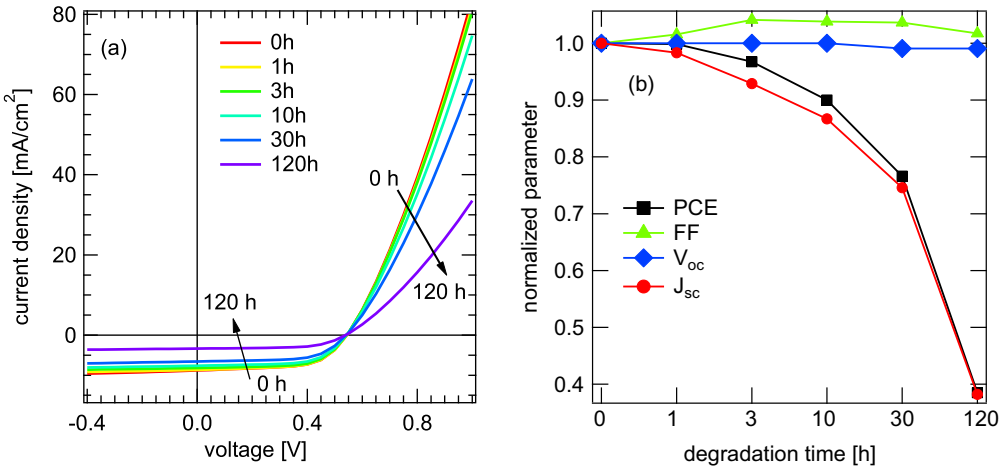

Fig. 1. Illuminated IV-curves of P3HT:PCBM solar cells for different dark degradation times in synthetic air (a) and the normalized values of the PCE, fill factor, open circuit voltage and short circuit current (b). The efficiency loss is due to the decrease of the short circuit current.

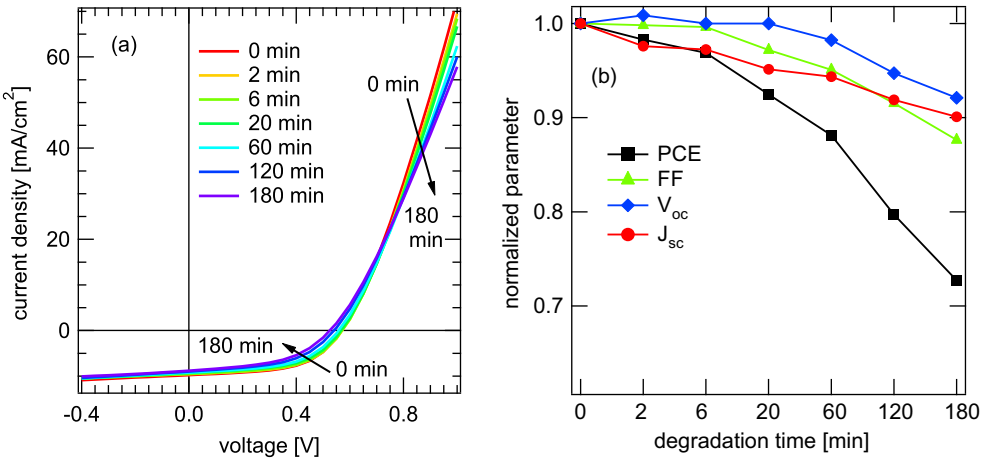

Fig. 2. Illuminated IV-curves of P3HT:PCBM solar cells for different degradation times in synthetic air under simultaneous illumination (a) and the normalized values of the PCE, fill factor, open circuit voltage and short circuit current (b). In contrast to dark degradation in synthetic air all parameters decrease.

the presence of oxygen, indicating an additional degradation path due to photooxidation in addition to doping as found under oxygenation in the dark.

To gain a deeper understanding of the underlying degradation mechanisms, we performed TSC measurements to obtain information about the electronic trap states of P3HT:PCBM solar cells for dark as well as photodegradation. First of all, the trap distribution of non degraded P3HT:PCBM solar cells was investigated by applying a fractional TSC measurement – the so-called $T_{start} - T_{stop}$ technique [10,17] – with T_{stop} varied between 25 and 150 K in steps of 5 K. The resulting density of occupied states (DOOS) distribution is shown in Fig. 3. The continuous activation energies of the traps range from 20 to 400 meV with the center of distribution at about 105 meV. For further

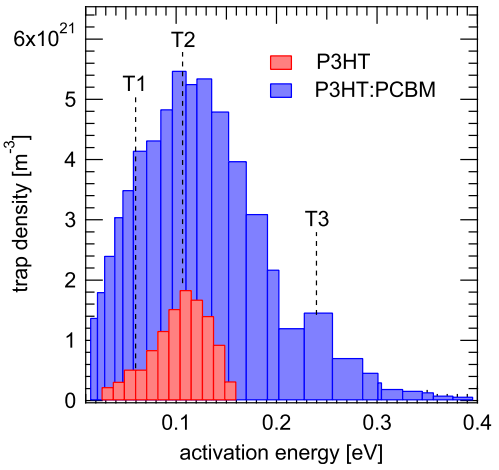

Fig. 3. Comparison of the DOOS distribution of P3HT and P3HT:PCBM blends, as obtained by TSC – $T_{start} - T_{stop}$ measurements. The DOOS of P3HT consists of two different traps (T1, T2), which both also contribute to the DOOS of the blend. Additionally to these two traps the DOOS of the blend features a third trap distribution (T3) with higher activation energy.

interpretation of the DOOS distribution of the blend, we consider the results for pure P3HT. For P3HT, the DOOS was related to two different overlapping traps with approximately Gaussian energy distributions [10], with the center of distribution of the dominant trap at about 105 meV (T2) and the other at about 50 meV (T1) (shoulder at the low energy side of the DOOS distribution) (Fig. 3). Since the centers of distribution for the blend as well as the pure P3HT are at 105 meV, we attribute the dominant trap to P3HT, although the distribution of the main trap in the blend is broadened as compared to the pure P3HT, indicating a higher disorder in the blend. Furthermore, the T1 can also be seen in the DOOS distribution of the blend in the steep onset of the distribution on the low energy side, but is less pronounced due to the higher concentration of the main trap T2, overlapping T1. Additionally to these two traps, the DOOS distribution of the blend features further trap states with activation energies of 200 to 400 meV which are not seen in pure P3HT, with the center at about 250 meV. We refer to the latter trap distribution as T3. Therefore we conclude that the DOOS of the blend consists of three different traps, with the dominant trap T2 at 105 meV. This interpretation is also supported by the TSC spectrum of pristine P3HT:PCBM solar cells, where T2 has a lower concentration compared to T1 and T3, so that T1, T2, and T3 can be clearly distinguished (data not shown). The trap density obtained from the TSC measurements of the investigated P3HT:PCBM solar cells is in the range of $6 - 8 \cdot 10^{22}$ m^{-3} which is considerably higher than the value obtained for P3HT ($1 \cdot 10^{22}$ m^{-3}) [10].

The TSC spectra of P3HT:PCBM solar cells for different dark degradation times in synthetic air are shown in Fig. 4a. Thermally stimulated current is observed between 18 and 160 K. At higher temperatures no additional TSC peaks can be observed up to 300 K. With exposure to synthetic air, a shoulder at about 100 K appears, which increases with longer degradation times within the investigated time scale up to 100 h. The appearance of a shoulder indicates an increase in density of the deeper

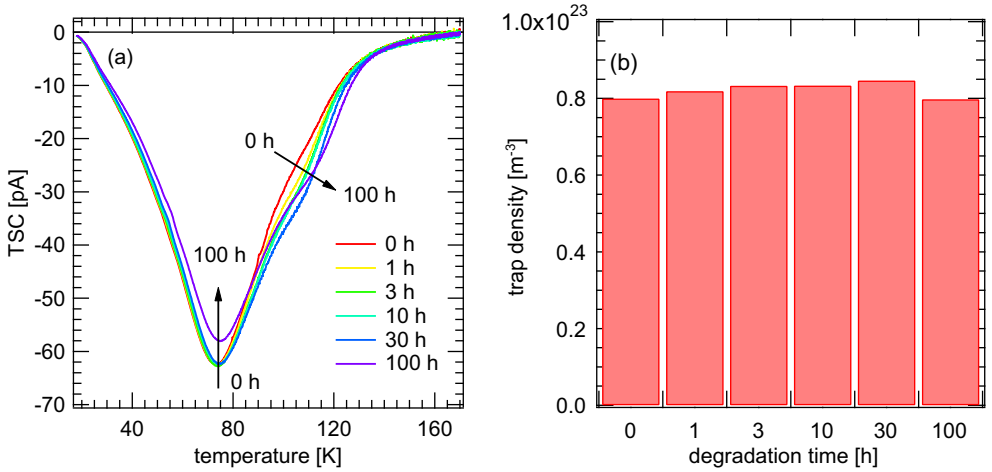

Fig. 4. TSC spectra of P3HT:PCBM solar cells for different dark degradation times in synthetic air (a) and the obtained trap densities (b). The trap density remains almost constant. The slight decrease of the trap density for 100 h degradation time is possibly due to recombination of the detrapped charge carriers.

traps or even the formation of additional traps. The main peak however decreases slightly. As a result the overall trap density of the blend obtained by the TSC measurements remains almost constant for the different degradation times (Fig. 4b). In this context it has to be mentioned that the determined trap density from the TSC spectra is only a lower limit of the actual trap density [18]. One reason is a possible recombination between electrons and holes after one of them got detrapped due to thermal activation. For degradation on synthetic air and simultaneous illumination we monitored almost the same behavior of TSC spectra, but on a faster timescale than during dark degradation.

To get further information about the influence of oxygen on the mobility and also the charge carrier concentration of the blend, we used the CELIV technique, which enables the simultaneous investigation of equilibrium charge carrier density and mobility by recording transient currents . The CELIV measurements for different degradation times in synthetic air in the dark are shown in Fig. 5a. The CELIV curves exhibit a high asymmetry, especially for longer degradation times, which might result from trapped charge carriers being extracted as the higher voltages at longer times promote emission from traps. This is in accordance with the increase of the deeper traps density as revealed by the TSC measurements. The mobility for different degradation times was calculated from the position of the current peak maximum according to Ref. [15]. Only a slight decrease of the mobility with degradation time can be observed (Fig. 5b), resulting in a decrease of about 50% after 120 h in synthetic air. The equilibrium charge carrier density, extracted by the CELIV measurements, however, increases about a factor of two within a degradation time of 120 h in the dark (Fig. 5c). We assign these additional charge carriers to oxygen doping of P3HT, which was also reported for P3HT diodes [10] and P3HT field effect transistors [8,7]. We note that the concentration of charges measured by CELIV provides only a lower limit of the actual charge carrier density, since only charge carriers extracted within the time scale of the experiment (voltage pulse width typically 50 μs) are observed. Thus, the experimental number includes charges from comparably shallow traps which can be emitted from them and then be extracted; charges in deeper traps as well as the ones lost within the sample (by recombination) are disregarded. The degradation on synthetic air and simultaneous illumination shows similar results for the changes in mobility and charge carrier concentration, but again the degradation is accelerated to a timescale of minutes instead of hours.

3.2. Simulation

In order to understand the influence of a decreased mobility as well as charge carrier doping on the solar cell parameters, we performed macroscopic simulations based on solving the differential equation system of the Poisson, the continuity and the drift–diffusion equations in one dimension [19,20]. In the simulation we accounted a bimolecular non-geminate recombination rate according to Langevin [21]. The charge carrier generation by light was assumed to create free polarons, neglecting any influence of electric field driven polaron pair dissociation. Furthermore the charge carrier mobilities of electrons and holes were set equal in the simulations. The used parameters are listed in Table 1. Using this approach we investigated the effect of charge carrier doping by oxygen on the solar cell parameters.

The simulated IV-curves for different hole doping levels are shown in Fig. 6a and the corresponding normalized solar cell parameters in Fig. 6b. For the given parameter set, doping concentration up to 10^{22} m^{-3} does not change the PCE, whereas for higher concentrations the PCE strongly decreases due to a decrease of J_{sc}. FF and V_{oc}, however, remain almost unaffected. This behavior is almost independent of the mobility (within changes of one order of magnitude) used for the simulations. The decreased J_{sc} due to doping can be explained by an increased

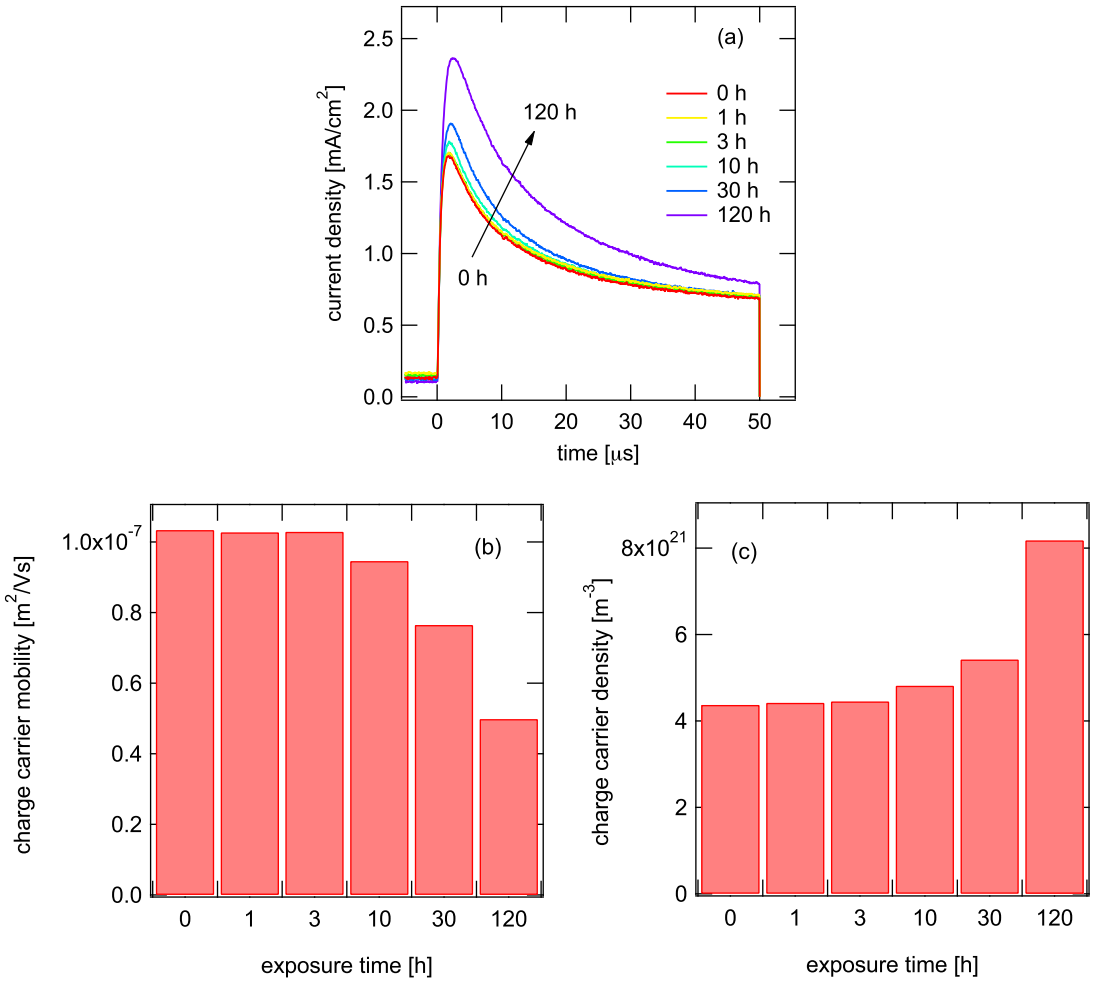

Fig. 5. CELIV measurements of P3HT:PCBM solar cells for different dark degradation times in synthetic air for offset bias of −0.3 V applied at the Ca/Al electrode (a) and the obtained mobilities (b) as well as the charge carrier densities (c). The charge carrier mobility slightly decreases with degradation time, whereas the charge carrier density shows an increase due to oxygen doping.

Table 1
Parameters used for simulation.

Parameter	Symbol	Value	Unit
Temperature	T	300	K
Effective band gap	E_g	1.30	eV
Relative dielectric constant	ϵ_r	3.6	
Active layer thickness	L	100	nm
Effective density of states	N_c, N_v	8×10^{25}	$1/m^3$
Generation rate	G	6.0×10^{27}	$1/m^3$ s
Injection barriers	Φ_a, Φ_c	0.1	eV

bimolecular recombination probability. Since doping implies additional charges within the device, it leads to less band bending and therefore a reduced electrical field within the solar cell. As a consequence the extraction time for the charge carriers increases leading to a higher recombination probability and thus to a lower short circuit current.

The influence of the mobility on the solar cell performance is shown in Fig. 6c and d, revealing a loss of J_{sc} and FF and a small increase of V_{oc} for decreased mobilities. A lower mobility leads to a higher extraction time for the charge carriers and therefore to an enhanced bimolecular recombination probability, which results in the decreased FF. At the same time, the charge extraction becomes less efficient. The slightly increasing open circuit voltage is due to a lower Langevin recombination rate due to decreased mobilities. The higher charge carrier densities and their more balanced distribution reduce the internal electric field and therefore increase the open circuit voltage [22,23]. If the field dependent polaron pair dissociation was also taken into account, it would mostly influence the FF and J_{sc} resulting in an even stronger decrease with lower mobilities.

3.3. Discussion

The influence of oxygen on P3HT:PCBM solar cells results in the case of dark degradation in a loss of J_{sc}, whereas photodegradation results in a decrease of all solar cell parameters. Further, the degradation due to oxygen is

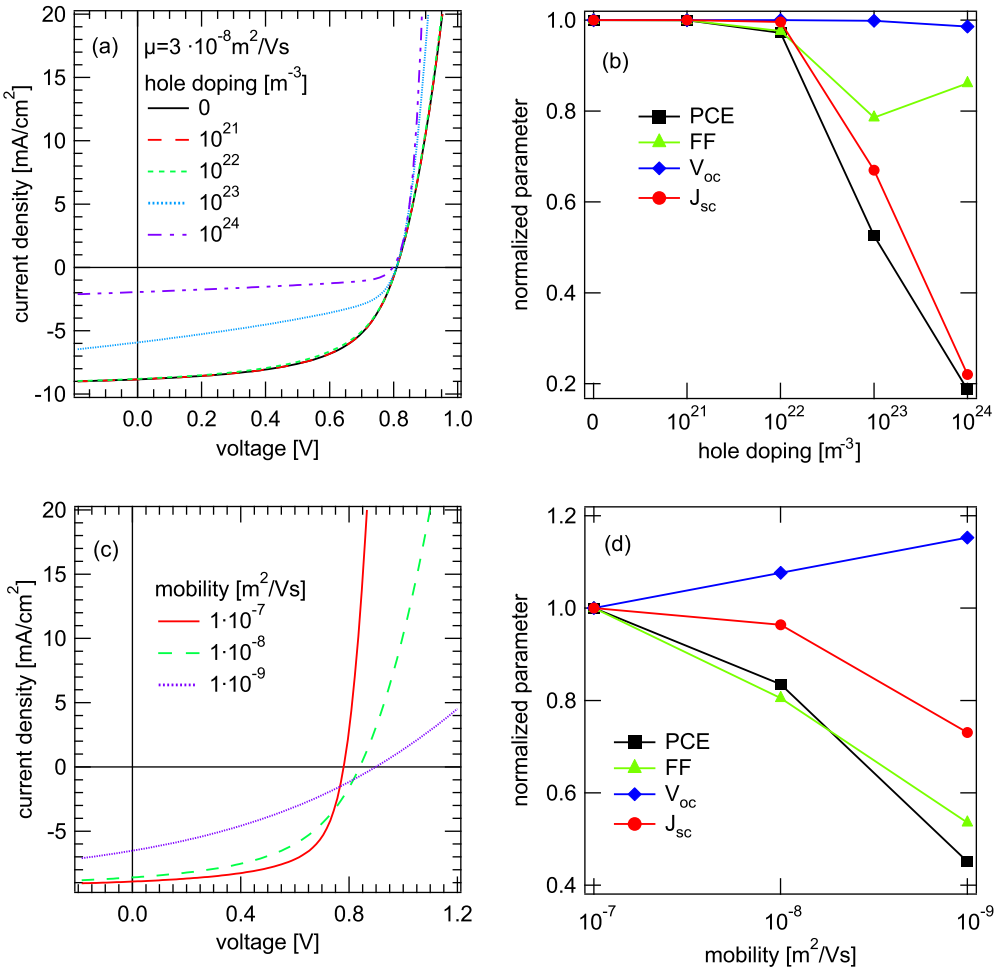

Fig. 6. Simulated IV-curves for different levels of hole doping (a) and the normalized values of the PCE, fill factor, open circuit voltage and short circuit current (b). An increased doping level results in a decrease of J_{sc}. A lowered charge carrier mobility (c) instead leads to a decrease of J_{sc} and FF (d).

accelerated by light. A similar behavior was recently reported for inverted P3HT:PCBM solar cells [3], where the efficiency yields almost no change for dark degradation within the investigated timescale of 1h, whereas a strong loss for photodegradation within 120 min is observed. The loss in J_{sc} can be explained by charge carrier doping, as we demonstrated by using macroscopic simulations. This interpretation is in accordance with the CELIV measurements, which show an increasing charge carrier concentration with degradation time. We attribute the increased charge carrier concentration to oxygen doping of P3HT [10,8,7]. The difference between the doping levels in the simulations and these determined by CELIV can be explained by the fact that the extracted charge carrier density by CELIV is only a lower limit of the actual charge carrier concentration, as mentioned before. The actual charge carrier density can be significantly higher. Furthermore, the accelerated increase of the charge carrier density in the case of photodegradation compared to the dark degradation is in good agreement with results of P3HT transistors, which also showed an expedited oxygen doping with light [7].

In addition to an increased charge carrier concentration, CELIV measurements reveal a decrease of the charge carrier mobility for the P3HT:PCBM blends due to oxygen. A decreasing mobility with degradation time is also reported for pure P3HT [10], but in contrast to pure P3HT, where the mobility decreases about two orders of magnitude within 100 h [10], only a slight decrease in the blend – by about 50% – can be observed. This difference could be due to a stabilization effect of PCBM for P3HT in analogy to findings for MDMO-PPV (poly(2-methoxy-5-(3′,7′- dimethyloctyloxy)-1,4-phenylene-vinylene)):PCBM solar cells [4]. The decreased mobility could also result from a degradation of PCBM due to oxygen. Decreased electron mobilities for C60 based field effect transistors after oxygen exposure have already been reported [11,12]. Since electron and hole mobilities can not be discriminated by CELIV, it is not possible to resolve which carrier mobility decreases.

A lower mobility leads to a decrease of FF and J_{sc}, as revealed by macroscopic simulations. Although our CELIV measurements show a slight decrease in mobility with degradation time, there are some facts indicating that the decreased mobility is not the origin of the FF loss in the

case of photodegradation. First of all the experimentally observed mobility reduction is too limited to have a strong impact on the FF. Furthermore, the mobility decreases in the same range for both dark and illuminated degradation, although the degradation in the illuminated case occurs on a faster timescale. In contrast, the loss in FF is only observed for photodegradation. Additionally, we experimentally observed also a decrease of V_{oc} for photodegradation, whereas a decrease in mobility should result in an increase of V_{oc} as exhibited by the simulation (Fig. 6d). Therefore, the decreased mobility is not the reason for the FF loss.

Another important factor which can negatively influence the solar cell performance are electronic trap states, since they lower the mobility, disturb the internal field distribution and can act as recombination centers. Exposure of P3HT:PCBM solar cells to oxygen results in a rise of the density of deeper traps for both dark and illuminated degradation. On the other hand, the main peak of the TSC slightly decreases due to oxygen exposure, which is in contrast to the observed increase of the main TSC peak of pure P3HT [10]. For comparison, the trap density in pure P3HT increases almost by a factor of three within 100 h under oxygen exposure [10]. In this context we want to mention again that the determined trap density from the TSC spectra is only a lower limit of the actual trap density [18].

The appearance of deeper traps due to oxygen exposure could also be the reason for the observed loss in fill factor, since they can disturb the internal field distribution and act as recombination centers, as mentioned before. Further investigations concerning the influence of deep traps on the solar cell performance have to be done, like the implementation of deep traps within the macroscopic simulation. Other crucial factors concerning FF and V_{oc} we want to address, are imbalanced electron – hole mobilities (resulting in the formation of space charges) and a field dependent photogeneration. These two factors have not been accounted so far and will be addressed in the future to completely clarify the origin of the loss of FF and V_{oc} in the case of oxygen induced degradation under simultaneous illumination.

4. Conclusions

We investigated the influence of oxygen on unprotected P3HT:PCBM solar cells by controlled exposure to synthetic air. Two different degradation conditions were used: in the dark and under simultaneous illumination. Exposure of the solar cells to synthetic air in the dark results in a loss of J_{sc} of about 60% within 120 h. In contrast, simultaneous illumination during oxygen degradation results in a loss of all solar cell parameters, yielding an efficiency loss of about 30% within only 3 h. Thus, the degradation of the P3HT:PCBM solar cells is strongly accelerated by light.

CELIV measurements revealed an increased charge carrier concentration after oxygen exposure for dark, as well as photodegradation. We attributed these additional charge carriers to oxygen doping, which is also known for pure P3HT. With the aid of macroscopic simulations we have shown that doping of the solar cells is the origin of the loss in J_{sc} for both degradation conditions.

Another impact of oxygen exposure on P3HT:PCBM solar cells is a slight decrease of the charge carrier mobility, as also revealed by CELIV measurements. Although a decreased mobility may result in a loss of the fill factor, as shown by macroscopic simulations, the experimentally observed mobility decrease is too small to be the origin of the FF drop in the case of photodegradation.

In addition to an enhanced charge carrier concentration, oxygen induced degradation results in an increase of the density of deeper traps, as was revealed by TSC measurements. These deep traps could be the origin of the decreased FF and V_{oc}, although further investigations to correlate the trap density to the solar cell performance are required for a verification.

for organic electronic applications, only a few studies up to date have investigated the electronic and optical properties and electron transfer characteristics of silyl-functionalized π-conjugated oligomers [9–11]. On the other hand, even though qualitative interpretations of the well-resolved absorption and emission spectra of oligoacenes can be found in the literature [12,13], to the best of our knowledge, a detailed analysis of the vibronic features in silyl end-capped oligothienoacenes has not yet been conducted.

In our previous studies, we analyzed the structural, electrochemical, and optical properties of a series of triisopropylsilyl end-capped oligothienoacenes to gain insight into the fundamental structure–property relationships with the addition of each fused-thiophene ring. We found that the selective enhancement of a very limited number of Raman scatterings is related to strong vibronic coupling between selected skeletal ν(C=C) stretching modes in the 1600–1300 cm^{-1} range and their respective frontier molecular orbitals [11]. Amplified spontaneous emission was observed in the pentathienoacene derivative doped into polystyrene films indicating that this material is a good candidate for active laser materials [14]. Cyclic voltammetry also reveals the formation of stable radical cations for all these oligothienoacenes, and the formation of dications only for the heptamer and the octamer [15]. The absorption and fluorescence spectra show partially resolved vibronic structures even at room temperature due to the absence of conformational disorder, at low temperature, the absorption spectra of all the series and the emission spectra recorded only for selected systems (i.e., for the pentamer and octamer) show two different vibrational progressions with an energy splitting, corresponding to vibrational modes with energies of $\nu_1 \sim 1530\ cm^{-1}$ and $\nu_2 \sim 490\ cm^{-1}$ [15]. In this contribution, we focus on the analysis of the vibronic structure and optical properties of a series of silyl end-capped oligothienoacenes (TIPS-T*n*-TIPS, where *n* indicates the number of fused-thiophene rings) ranging in length from the tetramer to octamer by using experimental spectroscopic data and quantum-chemical calculations (see Fig. 1). UV–vis absorption and fluorescence emission spectroscopy measurements are used to investigate the spectral profiles of all the series in the ground and first singlet excited-state at low (78 K) and room temperature.

We also employed density functional theory (DFT) and time-dependent DFT (TD-DFT) quantum–mechanical calculations to provide a detailed understanding of the electronic and vibrational interactions and their impact on the characteristics of the absorption and emission profiles of silyl end-capped oligothienoacenes. When compared against the non-silyl-functionalized oligothienoacenes, the DFT-calculated energies of the frontier molecular orbitals of the silyl-functionalized oligothienoacenes point to an effective silicon-induced hyperconjugation effect. Our calculations also reveal that the end-capping silyl groups have an almost negligible contribution to the total structural (intramolecular) reorganization energy upon electronic excitation. This finding suggests that although functionalization with TMS or TIPS groups may affect the overall charge carrier characteristics (mainly due to significant changes in the solid state packing induced by the presence of bulky end-capping silyl groups), to a large extent the vibronic coupling properties in silyl end-capped oligothienoacenes are mainly determined by their oligothienyl molecular backbone. Finally, the theoretically estimated vibrational frequencies and vibronic coupling constants of the silyl end-capped molecules are used to simulate their experimental absorption and emission spectral profiles.

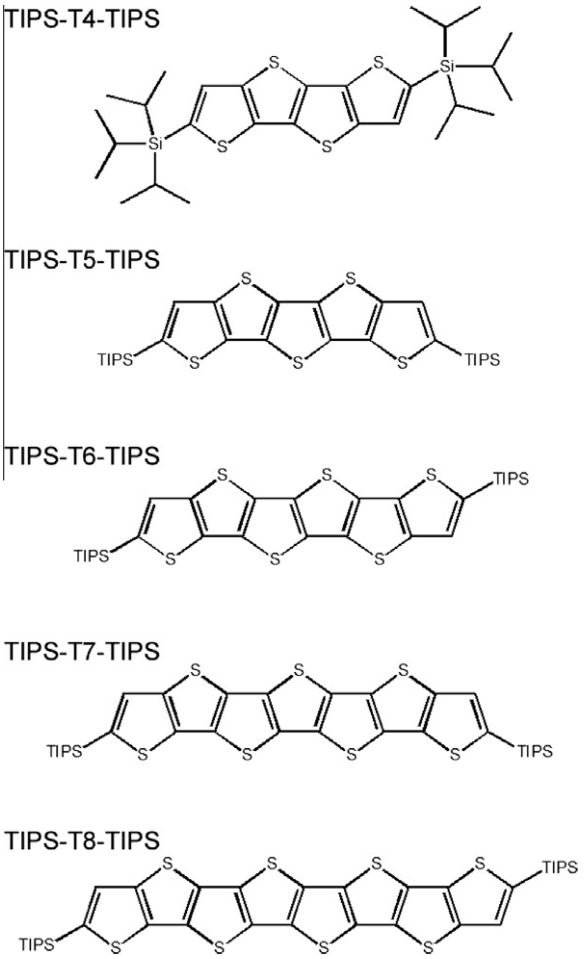

Fig. 1. Chemical structures of the series of end-capped oligothienoacenes investigated in this study (TIPS-T*n*-TIPS; where TIPS stands for triisopropylsilyl and *n* indicates the number of fused-thiophene rings).

2. Methodology

2.1. Experimental

UV–vis–NIR absorption spectra were recorded with a diode array Agilent 8453 instrument allowing for fast recording of all electromagnetic absorptions in the 190–1100 nm spectral region. Fluorescence emission spectra were measured using a FL920P spectrometer from Edinburgh Instruments. No fluorescent contaminants were detected upon excitation in the wavelength region of experimental interest. Solutions for emission measurements

were prepared with an absorbance in the visible spectral region between 0.1 and 0.2. 2-Methyltetrahydrofuran (MeTHF) was pre-dried over KOH for 3 days, filtered, distilled from CaH_2, and stored under inert atmosphere. Low-temperature spectra were recorded using an OptistatDN liquid nitrogen optical spectoscopy cryostat from Oxford Instruments.

2.2. Computational and theoretical methodology

Fig. 2 represents the potential energy surfaces (PES) for the electronic states S_0 and S_1 corresponding to the ground- and excited-state of the molecule, respectively. The intramolecular reorganization energy λ_{reorg} during an electronic transition consists of two terms related to the geometry relaxation energies upon going from the ground-state geometry to the excited-state geometry and vice versa,

$$\lambda_{reorg} = \lambda_{rel}^{(1)} + \lambda_{rel}^{(2)} \quad (1)$$

Here $\lambda_{rel}^{(1)}$ and $\lambda_{rel}^{(2)}$ represent the relaxation of a given molecule as it undergoes $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_0$ electronic transitions; $\lambda_{rel}^{(1)}$ is related to the relaxation of a molecular excited-state to its excited-state potential energy minimum while $\lambda_{rel}^{(2)}$ is related to the relaxation of the molecule to its ground-state potential energy minimum after emission. These two energy terms can be computed directly from the adiabatic potential energy surfaces, as schematically indicated in Fig. 2 and described in detail, e.g., in Refs. [16,17].

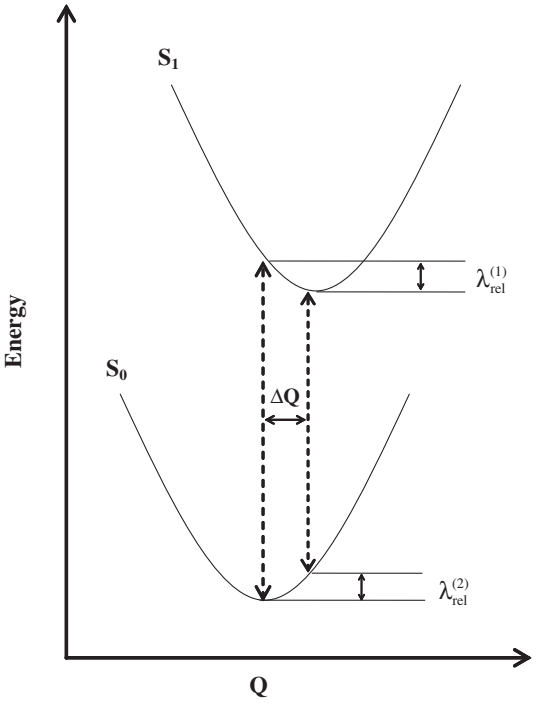

Fig. 2. Sketch of the potential energy surfaces for the molecular ground-state S_0 and excited-state S_1, showing the vertical transitions (dashed lines), the normal mode displacement ΔQ, and the relaxation energies $\lambda_{rel}^{(1)}$ and $\lambda_{rel}^{(2)}$.

The contribution of each vibrational mode to λ_{rel} was obtained by expanding the respective potential energy surfaces into a power series of the normal coordinates. In the harmonic approximation, the relaxation energy λ_{rel} is defined as [18,19]:

$$\lambda_{rel} = \sum \lambda_i = \sum \hbar\omega_i S_i \quad (2)$$

$$\lambda_i = \frac{k_i}{2}\Delta Q_i^2, \quad S_i = \frac{\lambda_i}{\hbar\omega_i} \quad (3)$$

Here, the summations run over the vibrational modes; ΔQ_i represents the displacement along the normal mode (NM) i between the equilibrium positions of the two electronic states of interest; k_i and ω_i are the corresponding force constants and vibrational frequencies; S_i denotes the Huang–Rhys factor (dimensionless electron–vibration coupling constant).

The Huang–Rhys factors S_i related to the S_0–S_1 transitions (and vice versa) were computed using a modified version of the DUSHIN program developed by Reimers [19]. The shapes of the emission and absorption spectra were simulated in the framework of the Born–Oppenheimer and Franck–Condon approximations according to the procedure described in detail elsewhere [17]. In these calculations, the B3LYP frequencies of both the ground- and excited-state have been scaled, according to the literature, with the same empirical factor of 0.9613 [20]. Note that for the simulation of the emission spectra the cubic frequency dependence was not taken into account; for specific details of this effect on π-conjugated molecular systems, see Ref. [21]. The convolution of the resulting spectra was carried out with Gaussian functions of uniform width (σ_{FWHM} = 0.03 eV). The onset of the simulated spectra was chosen to match the maximum of the first peak of the simulated spectrum with the maximum of the (0–0) absorption (emission) line found experimentally.

For the sake of computational convenience and efficiency, in all the quantum-chemical calculations the bulky triisopropylsilyl substituents shown in Fig. 1 were replaced by trimethylsilyl groups. First, the optimized equilibrium structure and vibrational normal modes of the S_0 state were obtained using DFT; for the S_1 state both the geometry optimization and vibrational normal modes calculations were obtained from TD-DFT [22,23]. Geometry determination at the TD-DFT level was recently shown to reproduce very well the vibronic structures in the absorption spectra of many large organic molecules [24,25]. In all cases, we employed the B3LYP exchange–correlation functional [26,27] and the 6-31G(d,p) [28–30] basis set, as implemented in the TURBOMOLE package [31].

3. Results and discussion

3.1. Experimental spectra

Fig. 3 displays the normalized UV–vis absorption and fluorescence spectra of TIPS-T*n*-TIPS recorded at low (78 K) and room temperature. Table 1 shows the wavelengths of the absorption and fluorescence emission maxima recorded at both temperatures.

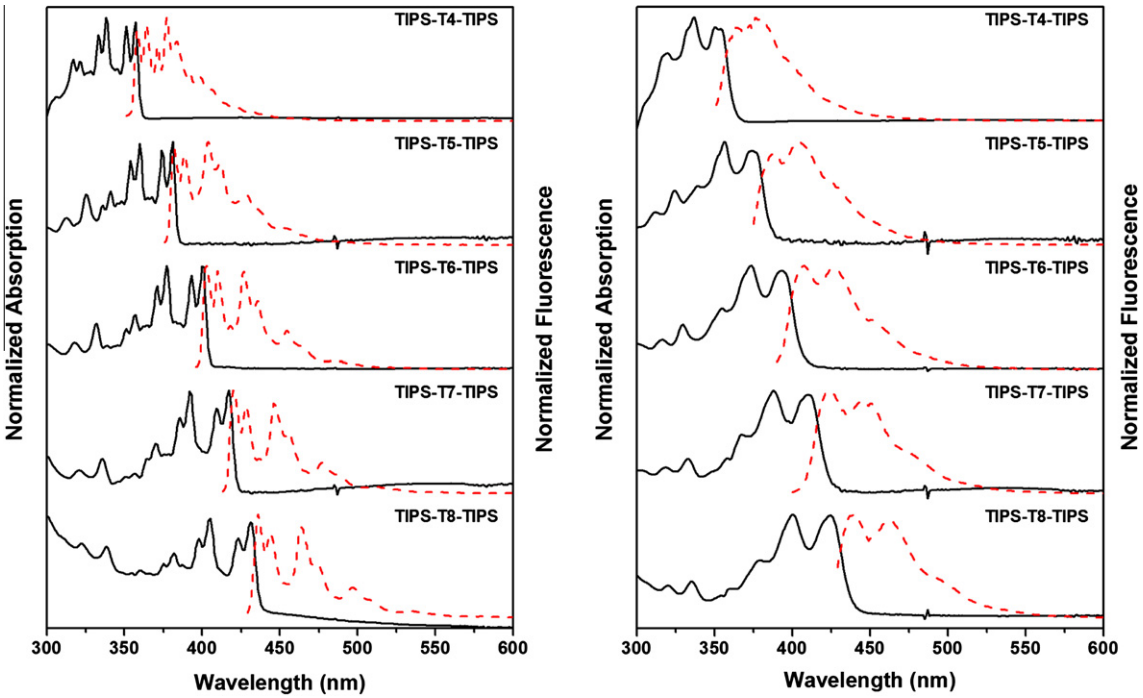

Fig. 3. Normalized UV–vis absorption (solid lines) and fluorescence emission (dashed lines) spectra of TIPS-T*n*-TIPS oligothienoacenes in MeTHF recorded at 78 K (left) and at room temperature (right).

At room temperature, the normalized absorption and fluorescence emission spectra of all the TIPS-T*n*-TIPS oligomers show a broad spectrum with partially resolved vibronic structures in good agreement with our previous data [14,15]. The appearance of vibrational fine structure in the absorption spectra in solution is a fairly unique property of oligothienoacenes, which is generally not observed in non-fused α-oligothiophenes [33]. This, in principle, is attributed to the rigidity of the fully-fused thiophene backbone, which drastically reduces the conformational disorder. In our previous work [15], the single excited electronic states of all these oligomers were calculated at the TD-DFT level. In good agreement with the experimental data, the existence of one strong electronic transition in the near-UV–vis range which undergoes a large bathochromic shift as the oligomer lengthens is predicted. This transition implies the excitation to the first excited-state S_1, which is shown to increase in intensity with the oligomer length. This agrees with the slight increase in the molar absorption coefficient. The fluorescence spectrum recorded at room temperature is also structured; a quite small shift is observed between the corresponding first peaks in UV–vis absorption and photoluminescence spectrum, which becomes smaller as the number of thiophene rings increases. As the π-conjugation is extended, the fluorescence quantum yield increases and the emission maximum shifts to longer wavelengths (i.e., from 363 nm and $\varphi_F = 0.08$ in TIPS-T4-TIPS to 440 nm and $\varphi_F = 0.39$ in TIPS- T8-TIPS, see Table 1).

In agreement with our previous data [15], the vibronic peaks in the UV–vis and fluorescence spectra of TIPS-T*n*-TIPS sharpen and become stronger upon cooling (see Fig. 3). The lowest-energy optical absorption clearly shows two different vibronic progressions with different energy splitting, for which up to three replicas are seen. The vibronic progression corresponds to the vibrational modes having frequencies of $\nu_1 \sim 1530\ cm^{-1}$ and $\nu_2 \sim 490\ cm^{-1}$. Two well-resolved vibronic progressions are also observed in the fluorescence spectrum at low temperature ($\nu_1 \sim 1400\ cm^{-1}$ and $\nu_2 \sim 450\ cm^{-1}$); while, a moderate energy-splitting is observed. In comparison to the UV–vis absorption spectrum, the energy-splitting is smaller. The changes accompanying cooling can be interpreted as a

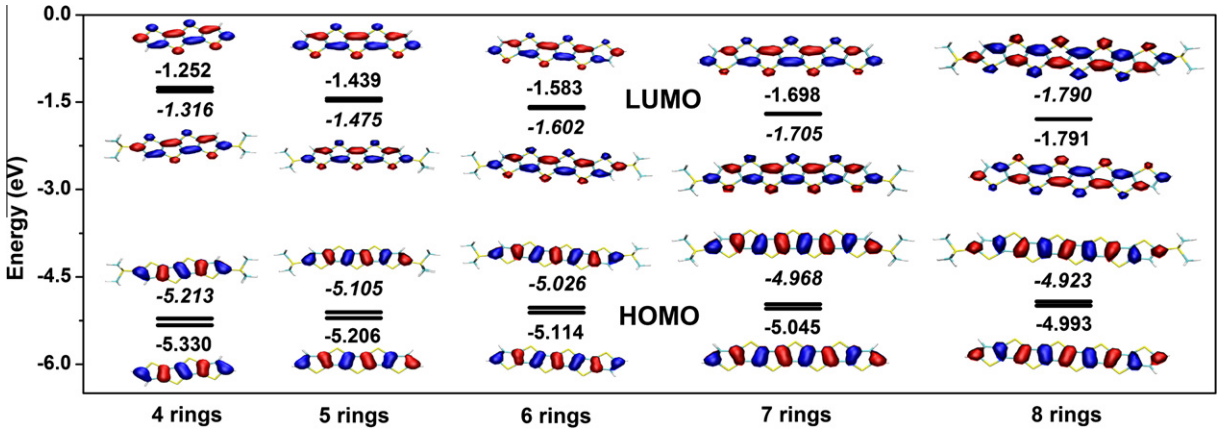

Fig. 4. DFT/B3LYP/6-31G(d,p) energy levels around the HOMO–LUMO gap region and molecular orbital topologies of the HOMO and LUMO of tetra(penta, hexa, hepta, and octa)thienoacene and TMS-T4(5, 6, 7, and 8)-TMS. The italicized energy values correspond to those of the TMS-T*n*-TMS oligomers.

consequence of a reduction in the inhomogeneous broadening induced by the considerable variation of local environments (i.e., the spectra of the individual molecules at low-temperature solids are much similar than in solution because of the loss of some conformational disorder) [34–36]. The resolution of the vibrational structure at low temperature is less pronounced for the longer oligomers (i.e., hexamer, heptamer and octamer) due to the fact that the coupling with low-frequency vibrations ca. 100 cm^{-1} becomes more significant, as discussed in more detail in Section 3.4.

Finally, we discuss the experimentally observed red-shift signatures of the UV–vis absorption peaks of the silyl end-capped oligothienoacenes as compared against their non-silyl-functionalized counterparts. This analysis was carried out by looking at the DFT-calculated energies (and topologies) of the molecular orbitals involved in the $S_0 \rightarrow S_1$ electronic transition of both sets of molecules. For a complete list of the UV–vis absorption peaks in unsubstituted oligothienoacenes see Table S1.

Silicon substituents are known to induce an effective hyperconjugation when coupled with carbon atoms [37]. In the case of organic semiconductors, this effect has been demonstrated both experimentally and theoretically for various silicon-containing π-conjugated organic systems [38,39], for which, the π^*-orbital of the aromatic system mixes effectively with the exocyclic Si–C σ^*-orbital to afford a low-lying lowest unoccupied molecular orbital (LUMO) and a relatively small band gap. In principle, a similar stabilizing effect is also expected for the case of the highest occupied molecular orbital (HOMO) in π-conjugated systems [40,41]. However, as recently observed by Lu et al. [40], the introduction of thiophene rings into the molecular core of silicon-containing organic semiconducting materials leads to an energetic destabilization of the HOMOs and stabilization of the LUMOs.

When compared against their non-silyl-functionalized counterparts, the silyl end-capped oligothienoacenes (except for the LUMO of TMS-T8-TMS) show the above-mentioned stabilization [destabilization] of the LUMO [HOMO] energy levels, as a result of an effective silicon-induced hyperconjugation effect (see Fig. 4). The energy difference between the LUMOs in the 8-ring systems is approximately 1 meV, which is too small to change the overall (observed) LUMO-stabilization trend of the TMS-T*n*-TMS oligomers. This effective silicon-induced hyperconjugation contributes then to the systematic reduction of the calculated HOMO–LUMO gaps and to the observed red-shift of the UV–vis absorption peaks in silicon-contain-

ing oligothienoacenes versus those measured in their unsubstituted counterparts. As an example of the silicon-induced effect, in Fig. S1, we report the UV–vis absorption and emission profiles of the pentathienoacene and TMS-T5-TMS molecules.

3.2. Ground- and excited-state structures

We investigate here the ground-state (S_0) and first excited-state (S_1) geometries obtained from DFT and TD-DFT calculations. The calculated bond lengths changes observed upon excitation for TMS-T4-TMS and TMS-T8-TMS are summarized in Table 2 (see Table S2 in Supporting information for the data of the rest of the compounds). The degree of aromatization/quinoidization of the conjugated backbone can be easily quantified by using the C–C bond-length alternation (BLA) parameter. The BLA parameter is computed for each thiophene ring as the difference between the length of the C_β–C_β and the average of the two C_α=C_β bonds. An aromatic ring is thus characterized by a positive BLA value, while a quinoid-like ring shows a negative BLA value. Table 3 collects the BLA values obtained for TMS-T*n*-TMS oligomers. In the ground-state, the thiophene rings display positive BLA values indicating that their molecular structure is of aromatic-type, in agreement with previous findings [7,15]. The geometry changes upon excitation from the S_0 state into the optimized S_1 geometry correspond to an elongation of the C_α=C_β double bonds and a shortening of the C_β–C_β single bonds, i.e., a switch in bond-length alternation. These C–C bond length changes are found to be more pronounced toward the molecular center (i.e., the BLA values computed for TMS-T8-TMS change from 0.034/0.023/0.021/0.020 Å in the S_0 state to 0.008/−0.019/−0.034/−0.042 Å in the S_1 state, going from the outer to the center rings). The change in sign in the BLA values clearly illustrates the quinoidization of the conjugated carbon skeleton. On the other hand, the C–S bond lengths are found to increase on going from S_0 to S_1, with a larger impact on the inner than on the outer rings. It is interesting to note that the geometrical changes upon electronic excitation are less pronounced in the longer oligomers in comparison with the shorter ones; for instance, the C–C bond length changes upon excitation are in the range of −0.039/0.048 Å in TMS-T4-TMS while they are in the range of −0.030/0.031 Å in TMS-T8-TMS (see Table 2 for TMS-T4-TMS and TMS-T8-TMS values and Table S2 for the rest of the compounds).

3.3. Reorganization energy

The intramolecular relaxation energies λ_{rel} related to the $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_0$ transitions for the series of silyl end-capped oligothienoacenes were obtained from potential energy surfaces calculations and by partitioning the intramolecular relaxation energy into the contribution of each normal mode according to Eqs. (2) and (3). The calculated values related to the $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_0$ transitions are listed in Table 4. Overall, we found a good agreement between the potential energy surface calculations and the normal mode approach. The results also show a monotonical reduction of the relaxation energies with the increase of the number of thiophene units in the oligomeric chain of the TMS-T*n*-TMS compounds. This observation is in good agreement with previous quantum-chemical studies of various aromatic-based chemical structures [7,16,42,43].

Also, we observed that along the series of end-capped oligothienoacenes there are only a couple of normal modes that mainly determine the vibronic progressions in spectra of these molecules (vibrational modes with energies of $\nu_1 \sim 1500\ cm^{-1}$ and $\nu_2 \sim 500\ cm^{-1}$). The qualitative characteristics of these vibrations are very similar in both electronic transitions. Thus, one could expect the UV–vis

Table 4

absorption and fluorescence spectra to be near-perfect mirror images; which, indeed, is the case for the series of TMS-T*n*-TMS oligothienoacenes considered in this study. However, we note that the spacing of the vibrational features is slightly larger in absorption than in emission; this agrees with the slightly larger Huang–Rhys factors (see Tables 5 and S3) found for the low-frequency modes (below 600 cm^{-1}) in the $S_0 \rightarrow S_1$ transition versus those observed for the $S_1 \rightarrow S_0$ transition. Additionally, the difference in spacing of the vibronic progression peaks in the spectroscopic profiles of these molecular structures is consistent with the widely accepted view that aromatic-like compounds assume a quinoidal form in the electronic excited-state. For example, we note that the excited-state properties of the silyl end-capped oligothienoacenes show the typical alternation of single and double carbon–carbon bonds and

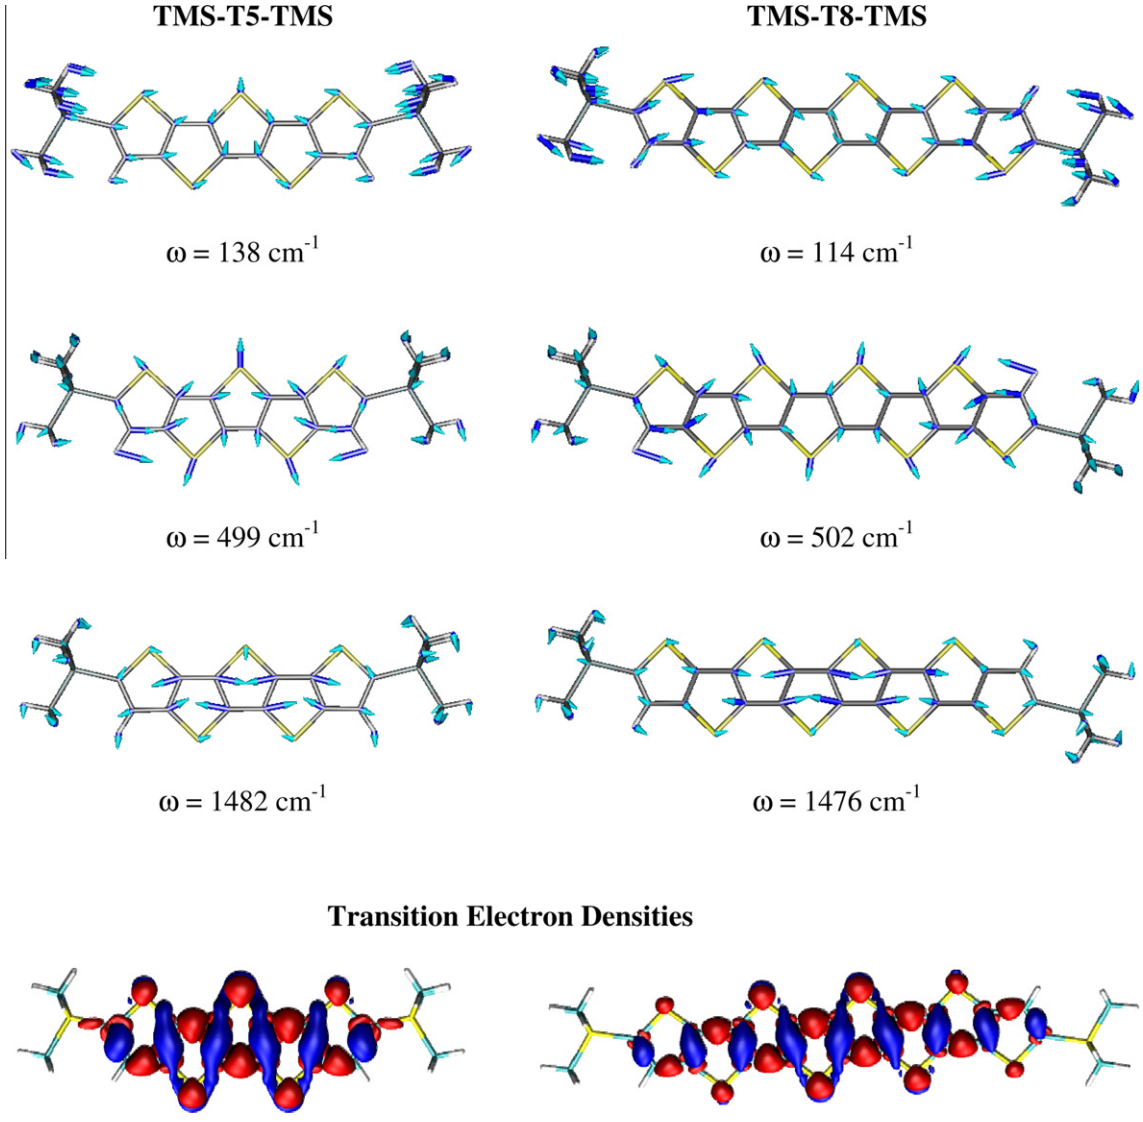

Fig. 5. (top) Illustrations of the normal modes yielding the largest Huang–Rhys factors and (bottom) electron density change in the S_0–S_1 electronic transition of TMS-T5-TMS and TMS-T8-TMS (left and right, respectively). The low-frequency modes involve mostly the sulfur atoms, whereas the high-frequency modes involve the carbon atoms.

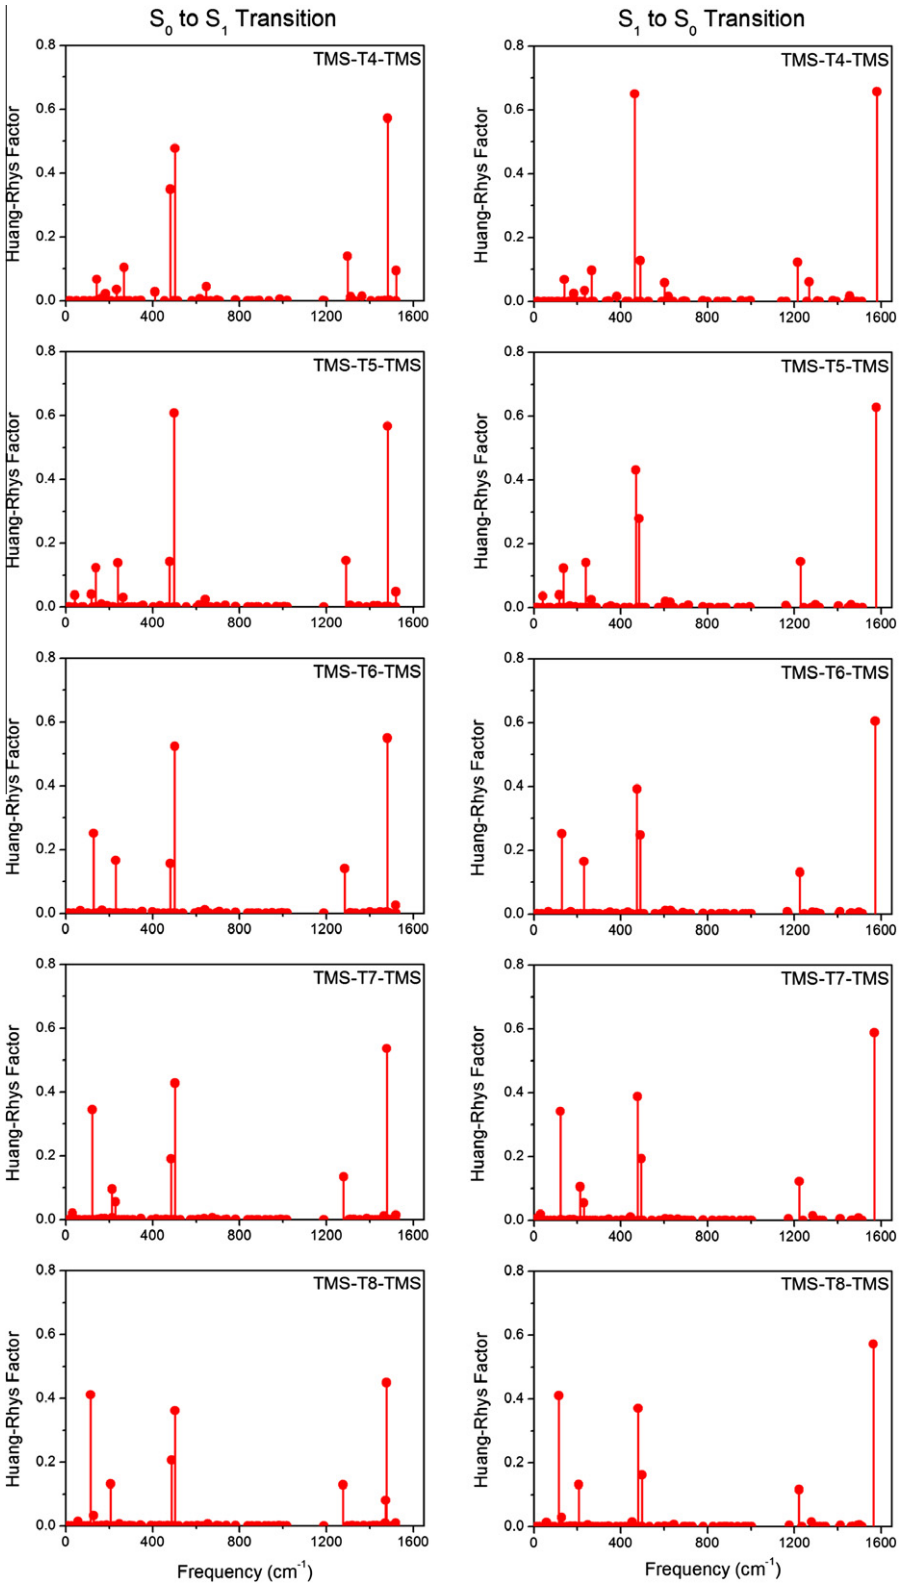

Fig. 6. DFT/TD-DFT/B3LYP/6-31G(d,p) Huang–Rhys factors related to the $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_0$ transitions of TMS-T*n*-TMS as a function of the normal mode frequency.

the characteristic shift of the ring C–C stretching mode toward the high-frequency region of the vibronic spectrum [44,45]. The change in sign of the BLA values reported in Table 3 (from positive to negative) is also in good agreement with the above arguments.

The decomposition of the value of the λ_{rel} into contributions of each normal mode for the TMS-T*n*-TMS oligothienoacenes permits an assignment of the contributions of the low- and high-frequency vibrations to the total value of the calculated relaxation energies. We found that for both electronic transitions approximately 70–75% of the relaxation energy comes from high-frequency vibrations in the range of 1200–1600 cm^{-1}; which include a particularly dominant vibration characterized by a C–C stretching of the inner-most rings (see Fig. 5). On the other hand, the contributions of low-frequency vibrations (below 600 cm^{-1}) account for only 25–30% of the total value of λ_{rel} and include vibrations that are near 500 cm^{-1} and characterized by stretches along the short molecular axis (i.e., via the C–S–C atoms of the thiophene rings). As an illustrative example of decomposition of the λ_{rel} into the normal mode contributions, the DFT/TD-DFT-derived (Huang–Rhys factors, S) related to the $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_0$ transitions in TMS-T5-TMS are shown in Table 5 (see Supporting information for the corresponding data of the other molecular structures investigated in this study).

In Fig. 6, we present the calculated vibrational coupling (Huang–Rhys factors, S) as obtained from DFT/TD-DFT for the complete series of TMS-T*n*-TMS compounds. The different plots of Fig. 6 show consistent vibronic–coupling interactions with both low- and high-frequency vibrations. Further inspection of the most-strongly coupled vibrations shows that the main distortions occur within the molecular backbone (i.e., the fused-thiophene rings) of the TMS-capped compounds. However, we also note that the vibronic–coupling interactions of the larger end-capped oligothienoacenes (TMS-T6-TMS, TMS-T7-TMS, and TMS-T8-TMS) involve a low-frequency vibration at around 100 cm^{-1}. This vibration (shown in Fig. 5) involves, for the case of TMS-T8-TMS, distortions of the silyl-based groups accompanied by lateral distortions of the outer-most thiophene rings; whereas for TMS-T5-TMS, this vibration mainly distorts the atomic positions of the silyl groups. This normal mode posses a large Huang–Rhys factor (i.e., 0.411 for the 114 cm^{-1} mode of TMS-T8-TMS, see Table S3 in Supporting information) and therefore has an effect in the absorption and emission spectra. As discussed in Section 3.4, this low-frequency vibration leads to an effective peak broadening of the absorption and emission profiles of the larger end-capped oligothienoacenes; in which, the extended motions of the outer-most rings distort significantly their respective transition electron densities (see Fig. 5 and Fig. S2).

Lastly, to investigate the effective contributions of the silyl groups to the overall intramolecular reorganization energy λ_{reorg}, we fixed the motions of the oligothienoacene molecular core in the series of TMS-T*n*-TMS oligomers, and computed again their respective λ_{reorg} values. We found that the contributions of TMS groups to the total value of λ_{reorg} upon an electronic excitation from the $S_0 \rightarrow S_1$ state and vice versa, is on the order of 1% (Table 6).

Table 6
Individual contributions of the oligothienoacene core and of the TMS substituents to the total intramolecular reorganization energy (λ_{reorg}) in the TMS-T*n*-TMS oligomers. Energy values are given in meV.

Molecule	TMS[a], λ_{reorg}	Oligothienoacene core[b], λ_{reorg}	Total, λ_{reorg}
TMS-T4-TMS	5	427	432
TMS-T5-TMS	3	395	398
TMS-T6-TMS	1	370	371
TMS-T7-TMS	1	352	353
TMS-T8-TMS	1	337	338

[a] The atomic coordinates of the oligothienoacene core were maintained fixed at the S_0 geometry positions during the optimization of the S_1 state.
[b] The atomic coordinates of the TMS substituents were constrained at the S_0 geometry positions during the optimization of the S_1 state.

3.4. Simulation of the UV–vis absorption and fluorescence

We employed the results of the normal mode analysis to simulate the shape of the absorption and emission profiles of the TMS-T*n*-TMS molecular compounds. Only vibrational modes with Huang–Rhys factors larger than 0.05 were used in these simulations since modes with smaller Huang–Rhys factors essentially do not contribute to the description of the electronic transitions of these almost-rigid molecular structures. The results of the simulation are presented in Fig. 7. The vibronic features of the experimental and theoretical profiles are in good agreement; highlighting the reliability of the DFT/TD-DFT-derived vibronic coupling constants and relaxation energies. However, the experimental intensity distributions cannot be perfectly reproduced by the simulated spectra; the calculated intensities of the (0–1) and (0–2) transitions are smaller with respect to the (0–0) peak than those observed experimentally. This underestimation is likely related to the amount of exact Hartree–Fock exchange in the B3LYP functional, as shown in previous studies [24,43,46].

Although, our quantum–mechanical calculations provide access to all of the predicted vibrational modes involved in the absorption and emission processes of the TMS-capped molecular structures, we have determined that at least for TMS-T4-TMS and TMS-T5-TMS, there are two vibrations that are the most relevant; the first one around 500 cm^{-1} and the second one in the region of 1450 cm^{-1} to 1600 cm^{-1}. However, the situation is different for TMS-T6-TMS, TMS-T7-TMS, and TMS-T8-TMS because, in these molecules, a low-frequency vibration at around 100 cm^{-1} also becomes important to the absorption and emission processes. This particular vibration, which shows a relatively large Huang–Rhys factor (see Table S3), introduces an effective spectral broadening of the absorption/emission features of these three compounds, which is in good agreement with previous reports (see for example, Ref. [44]). In order to account for the broadening effect of this low-frequency vibration, we have also simulated the absorption/emission spectroscopic profiles of the TMS-T*n*-TMS oligomers by introducing a frequency cut-off that only considers strongly coupled normal modes with frequencies larger than 400 cm^{-1}. The simulated spectral profiles are reported in Fig. S3. A simple comparison between the theoretically simulated

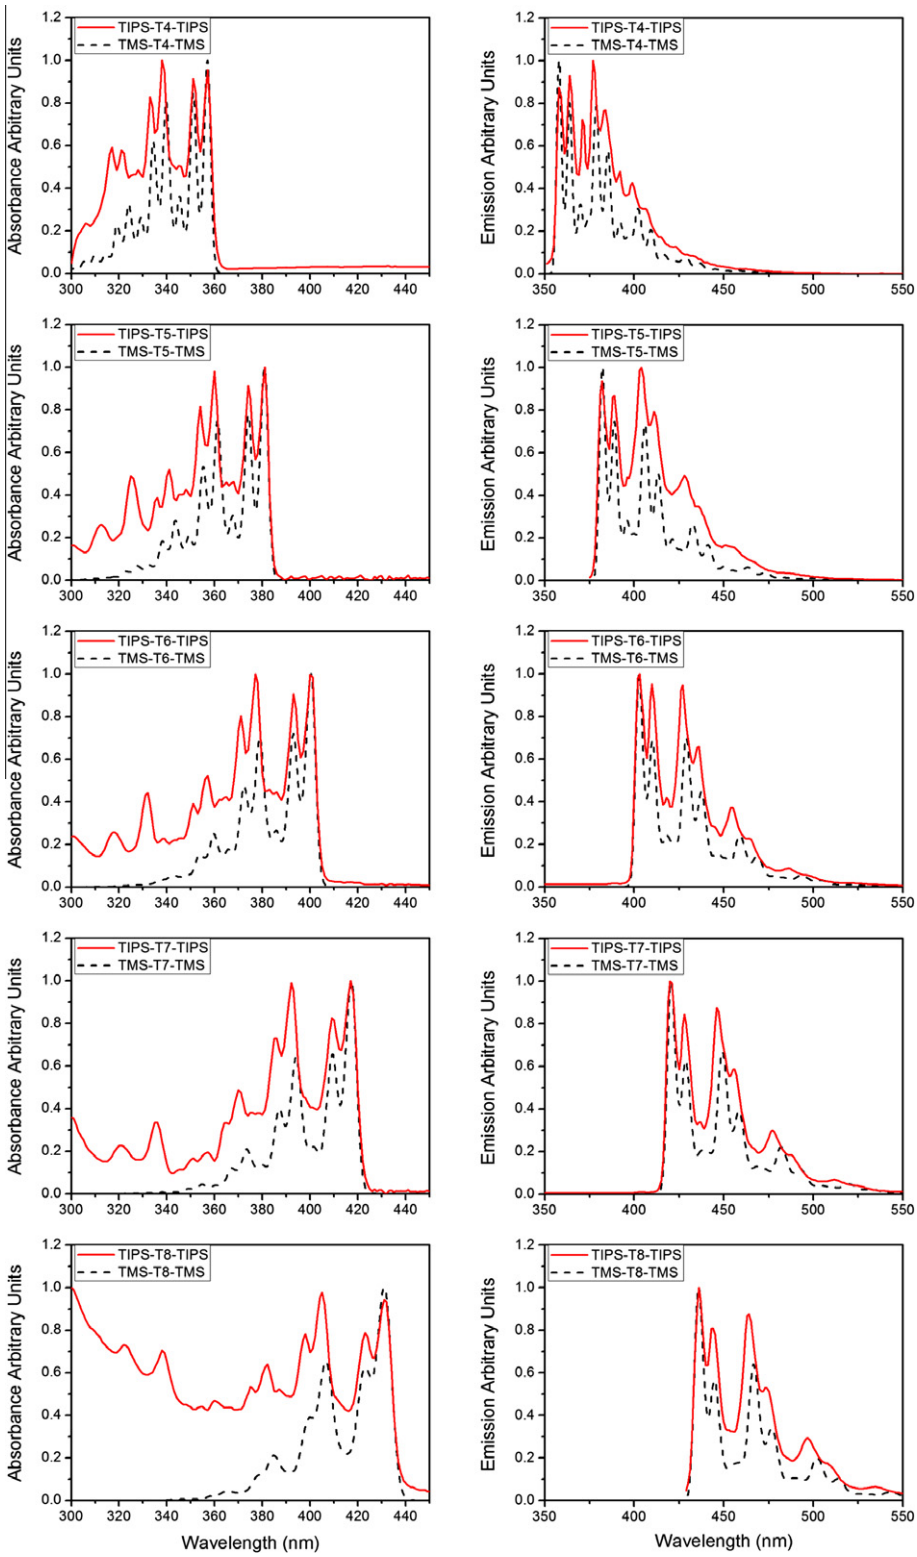

Fig. 7. Normalized UV–vis absorption and fluorescence experimental-spectra of TIPS-T*n*-TIPS (solid lines). The dashed lines represent the simulated (theoretical) spectra convoluted with Gaussian functions. Note that for computational efficiency, in all theoretical simulations we used TMS substituents instead of TIPS substituents. The onset of the simulated spectra is chosen to correspond to the experimental onset.

spectra that used both low- and high-frequency normal modes versus those that only incorporated normal modes with frequencies larger than 400 cm^{-1} reveals that for the shorter TMS-T*n*-TMS ($n = 4$ and 5) oligomers, their spectroscopic characteristics are mainly governed by the high-frequency normal modes (no significant differences between the two simulations, see Fig. S3). However, the simulation and comparison of their respective spectra suggest that, the larger TMS-T*n*-TMS ($n = 6$–8) oligomers require the inclusion of the low-frequency normal modes to account for the observed differences (see Fig. S3).

It is also important to note that the $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_0$ Huang–Rhys factors of ~100 cm^{-1} normal mode become larger as the number of thiophene rings increases. For example, the Huang–Rhys factors related to the absorption transition of this low-frequency vibration along the series of TMS-T*n*-TMS oligothienoacenes are: 0.067 (142 cm^{-1}), 0.122 (138 cm^{-1}), 0.251 (128 cm^{-1}), 0.345 (122 cm^{-1}), and 0.411 (114 cm^{-1}), ongoing from TMS-T4-TMS to TMS-T8-TMS, respectively. This low-frequency mode stretches the thiophene molecular backbone as a whole along the long molecular axis. However, these longitudinal stretches are only more pronounced in the larger end-capped oligothienoacenes ($n = 6$–8), in which the many more internal degrees of freedom, especially those of the outer-most thiophene rings, still distort their respective core-extended transition electron densities, as shown in Figs. 5 and S2.

4. Conclusions

This work presents a detailed joint experimental and theoretical analysis of the optical and electronic properties of a family of silyl end-capped oligothienoacenes, which have emerged as a novel class of solution-processable π-conjugated compounds for organic electronic applications. The experimental absorption and emission profiles showed well-resolved vibronic progressions at both low and room temperature, which is indicative of a minimal conformational disorder of the TIPS-T*n*-TIPS oligomers upon electronic transitions. Also, the systematic red-shift of the absorption maxima of the silyl end-capped oligothienoacenes with the extension of the π-conjugation is in good agreement with the systematic reduction of the calculated HOMO–LUMO gap along the series. When compared to the unsubstituted oligothienoacenes, the insertion of the silyl groups is found to destabilize/stabilize the HOMO/LUMO energies as a consequence of the silicon-induced hyperconjugation effect.

First-principles quantum–mechanical calculations have been used to characterize the experimental absorption and emission profiles of these novel molecular structures. For the smaller molecules (tetramer and pentamer), we found that the vibronic progression of their optical spectra are mainly determined by the presence of two normal modes with frequencies of ~1500 cm^{-1} and 500 cm^{-1}. However, the larger molecules (hexamer, heptamer, and octamer) are not only characterized by those frequencies but also by the presence of a low-frequency normal mode at around 100 cm^{-1}. We note that this particular vibration is responsible for the experimentally observed peak broadening of the vibrational absorption and emission features of these compounds. Also, our theoretical estimates of the intramolecular reorganization energies upon electronic transition reveal that the vibronic–coupling interactions in silyl end-capped oligothienoacenes are only associated with their respective oligothienyl molecular backbone.

Finally, our results suggest that a possible route to explore new soluble organic semiconducting materials should, in principle, include functionalization/modification of their respective molecular backbones. We hope that our results will trigger further experimental investigations for the design of new solution-processable organic semiconducting materials.

R.S.S.-C. thanks the Mary-Fieser Postdoctoral Fellowship at Harvard University. Financial support by the Ministerio de Ciencia e Innovación (MICINN) of Spain (Project CTQ2009-10098) and the Junta de Andalucia (Grant FQM-0159 and Project P06-FQM-1678) are greatly acknowledged. R.M.O. and C.C.F. are also grateful to the UMA and MICINN, respectively, for personal doctoral grants. We are grateful to Dr. Massimo Malagoli (Georgia Institute of Technology, USA) for making available a copy of the program used to simulate the optical spectra. We also thank Dr. Karin Zojer (Graz University of Technology) for adapting TURBOMOLE output files to the DUSHIN input. This work was also supported through a National Science Foundation grant via Harvard MRSEC, Grant No. DMR-08-20484. We thank the High Performance Technical Computing Center at the Faculty of Arts and Sciences of Harvard University for invaluable support.

Appendix A. Supplementary material

Figure for the normalized (low-temperature) UV–vis absorption and fluorescence emission spectra of TMS-T5-TMS and pentathienoacene in MeTHF. Supporting information also includes a table with selected bond lengths in the ground-state and excited-state of TMS-T*n*-TMS molecules with $n = 5$–7 as determined by DFT/TD-DFT/B3LYP calculations; DFT/TD-DFT/B3LYP estimates of frequencies, Huang–Rhys factors, and relaxation energies related to $S_0 \rightarrow S_1$ and $S_1 \rightarrow S_0$ transitions of TMS-T*n*-TMS ($n = 4$, 6, 7, and 8); and an illustration of the transition electron densities of TMS-T*n*-TMS ($n = 4$, 6, and 7). Finally, we have also included a figure that compares the effect of low- and high-frequency normal modes versus only high-frequency normal modes in the simulated absorption and fluorescence spectral profiles of the TMS-T*n*-TMS ($n = 4$–8) oligomers.

Threshold voltage

ABSTRACT

We report the effect of light illumination on the electrical characteristics of pentacene field-effect transistors with a large-bandgap conjugated polymer PFO as the interfacial layer. The nanostructured PFO servers as charge-trapping centers that capture charges injected from the pentacene active layer. When the device is under light illumination, the threshold voltage (V_{th}) can be modulated by varying positive gate biases such that the operation mode can be switched from the enhancement mode to the depletion mode. This light-programmable feature may motivate the development of this new type of organic memory devices.

1. Introduction

The organic field-effect transistor (OFET) has been envisioned as a promising candidate for commercial applications due to its demonstrated performance comparable to that of the amorphous silicon (*a*-Si) transistor, together with its potential low-cost fabrication [1–3]. To design and manufacture the integrated circuits (ICs) with organic transistors, a high mobility is required to increase the operation speed. Besides, the threshold voltage is another important parameter that needs to be controlled for the reliability of enhanced integrated circuits (ICs). In the case of silicon metal–oxide-semiconductor field-effect transistors (FETs), the threshold voltage, V_{th}, can be adjusted by doping the channel region and/or a second gate bias to tune the electrostatic potential and the carrier density in the channel [4,5]. The same techniques have not yet been well developed for OFETs, whereas great efforts have been made to develop a few methods to achieve the control of threshold voltage [6–11]. Nevertheless, little research has been done on employing light irradiation as a control apparatus to V_{th}, which will bring about light-controlled OFETs. Although a shift in V_{th} upon light illumination was observed, it was very difficult to strictly control V_{th} in a wide range for a single OFET device.

Previously, chargeable gate dielectrics (sometimes referred as "electrets") were employed to study the effect of photo-induced charge transfer on the shift of the field-effect onset [12,13]. The memory effect in the FET structure due to the photo-induced charge transfer was firstly studied by Dutta and Narayan [12]. It was found that the negative charges are severely trapped and lie in the deep-energy states in the depletion mode after being generated under illumination. Later, the rate of the charge transfer (both holes and electrons) was investigated in detail by Podzorov and Gershenson [13] which was determined by (i) the flux of photons with energies greater than the LUMO–HOMO gap of an organic semiconductor and (ii) the magnitude of the transverse electrical field applied at the semiconductor–dielectric interface. However, both works focuses on the charge transfer from an active layer to a gate dielectric. In this work, a conjugated polymer, poly(9,9-dioctylfluorene) (PFO), was selected to form type

I heterojunction (straddling gap) with pentacene to study the charge transfer effect, where the diagram of energy levels of PFO/pentacene was similar to that of PVA/P3AT or Parylene/rubrene, because of the presence of deep electron trapping states in PFO and the high room-temperature hole mobility with weak field dependence, which have been widely investigated as a hole-transport material in the fabrication of blue LEDs [14,15]. Besides, PFO will emit polarized light if they can be oriented, as it is an emissive liquid–crystal polymer [16]. Such a polarized emitter is of great interest for use as a backlight in a liquid–crystal display since it provides the replacement for the normal backlight and polarizer combination. For these reasons, high performance OFET devices with a pentacene active layer and nanostructured PFO dispersed in PMMA (or an ultrathin PFO film) were fabricated to study the effect of PFO. Under negative gate bias ($|V_g| > |V_{th}|$) in the dark condition, these FETs presented conventional p-channel behavior and operate in the enhancement mode, as the field-induced carriers are expected to be confined in the pentacene layer due to the HOMO offset between PFO (LUMO = −2.3 eV and HOMO = −5.8 eV) [14] and pentacene (LUMO = −3.2 eV and HOMO = −5.1 eV) [17,18]. On the other hand, when it is under illumination, non-equilibrium charge carriers (holes and electrons) are generated and separated under the influence of the electric field. By applying proper positive gate bias, i.e. operating in the depletion mode, electron carriers can be trapped by the nanostructured PFO and the interface, causing a shift in the threshold voltage. As we will show hereinafter, by varying the starting source–gate voltage V_{g_start} in the off-to-on transfer characteristics, V_{th} can be tuned through the effect of photo-induced charge transfer.

2. Experimental

A heavily doped n-type silicon wafer and a 500 nm-thick thermal oxide layer on the surface were used as the gate electrode and the gate dielectric layer, respectively. The interfacial layer, PFO, was deposited on the wafer after a wafer-cleaning process. It consisted of 10–15 nm nanostructured PFO dispersed in PMMA, referred as PFO&PMMA, or 10 nm PFO film in device 1, while another 10 nm-thick PMMA film was used to planarize the surface of PFO&PMMA (or PFO) film in device 2. PFO&PMMA (or PFO) film was spin-coated from toluene solution and the nanostructured PFO was formed during the annealing process at 105 °C for 10 min on a hotplate under the air ambient. PMMA planarizing layer was spin-coated from chlorobenzene solution and annealed at 105 °C for 10 min on the hotplate to remove the residual solvent. Subsequently, a 50–60 nm-thick layer of pentacene (used as received from Sigma–Aldrich) was deposited in a vacuum system by thermal evaporation at a background pressure of 10^{-5} Pa. The deposition rate was controlled at 0.2 Å/s and the substrates were maintained at room temperature. The transistors were completed by the deposition of a 30 nm-thick gold film as the source–drain contacts through a shadow mask. The channel length (L) and the width (W) of the devices are 100 μm and of 2 mm, respectively. To characterize absorption spectra, PFO&PMMA (or

(a) Molecular structure of poly(methyl methacrylate) (PMMA) and poly(9,9-dioctylfluorene) (PFO), and a schematic of the OFET device, (b) transfer characteristics of device 1 at V_{ds} = −100 V, where V_g = 200 V for 30 s was applied at V_{ds} = 0 V under white light illumination for inducing the shift in V_{th}.

PFO) film with the same thickness was prepared on the quartz substrate.

To investigate the effect of light illumination on the electrical performance of our devices, the devices were illuminated from the top from a halogen lamp, as shown in Fig. 1a. The characterization of the devices was carried out on a standard probe station with or without light illumination. The light intensity was preset using a neutral density filter. To clarify the charge transfer and trapping mechanism in these devices, a Dongwoo Optron TH3 arc lamp together with a Dongwoo Optron DM150i monochromator was used to conduct red light irradiation at a wavelength of 628 nm. The light was focused to a spot size approximately equal to the area of the device to cover the entire channel with an estimated light intensity of 1 mW/cm^2. Electrical characteristics were measured using a Keithley 4200 SCS semiconductor parameter analyzer under ambient condition at room temperature. AFM images were obtained using a Nanoscope IIIa AFM (Digital instrument) in trapping mode. Absorption spectrum was measured at room temperature using a Shimadzu UV–VIS spectrometer.

3. Results and discussion

Fig. 1b shows the device characteristics of p-type pentacene FETs, where the source–drain currents $|I_{ds}|$ are plotted in a logarithmic scale against the gate voltage, V_g, at a constant source–drain voltage of $V_{ds} = -100$ V for device 1. The source–drain current in the saturation region is described by

$$I_{ds} = \frac{W}{2L}\mu C_i (V_g - V_{th})^2, \quad (1)$$

where W and L are the channel width and length, μ is the field-effect mobility, and C is the capacitance per unit area of the gate dielectric layer. Thus, from linear curve fitting to the data of $\sqrt{I_{ds}}$ versus V_g in the saturation region (not shown here), V_{th} is obtained as the intercept to the X-axis of the linear fitting curve, whereas μ is derived from the slope. The evaluated values of the mobility μ, V_{th} and on/off current ratio are 0.028 cm^2/V s, –110 V and 10^3, respectively. By applying light illumination on the device at $V_g = 200$ V for 30 s, the entire curve was shifted to the positive side. The shift of the threshold voltage can be attributed to the trapping of photo-generated electrons and neutralize the positively charged states that contribute to the large initial negative threshold voltage. Therefore, the transferred carrier density Δn can be estimated by the follows:

$$\Delta n = \frac{Q_{\text{trap}}}{q} = \frac{C_i \Delta V_{th}}{q}, \quad (2)$$

where Q_{trap} is the amount of trapped charge and q is the charge of electron. The calculated Δn was around 3.75×10^{12} cm^{-2}. It is to say that the nanostructured PFO played as charge-trapping centers like silicon nanoparticles (NPs) distributed in the gate oxide [19]. In our case, the effect of field-induced electrons on inducing the shift of V_{th} under positive gate bias was suppressed because of (i) the low electron carrier density in the p-type pentacene layer and the large electron injection barriers (ii) between pentacene and Au and (iii) between pentacene and PFO. However, by applying light irradiation, the photo-generation process produced excess high-energy electron carriers, which was an important mechanism of boosting the amount of trapped electrons in nanostructured PFO and the interface, resulting in a significant shift of V_{th}. The calculated mobility was 0.026 cm^2/V s, which was in good consistence with that obtained in the dark condition.

Obviously, the obtained performance of device 1 was not satisfying, e.g. low mobility and terribly large threshold voltage. This might be due to the rough interface between the pentacene and the PFO&PMMA (or PFO) film, as shown in Fig. 2a, since PFO tends to crystallize to form nanostructures during annealing process. This rough interface brings a large amount of interfacial states that trap charge carriers, contributing to the large negative threshold voltage. Besides, the charge transport in the accumulation region became worse due to the charge scattering effect, thereby deteriorating the field-effect mobility. In order to improve the surface condition, a 10 nm-thick thin PMMA layer was employed for planarization, shown in Fig. 2b. The electrical characteristics of device 2 in the dark condition were presented in Fig. 3a. The device performance was greatly improved by the introduction of a 10 nm PMMA buffer layer, giving rise to a mobility of 0.35 cm^2/V s, V_{th} of -15 V and an on/off ratio of >10^5. On the other hand, when varying the starting gate voltage V_{g_start} from 0 to 200 V in the off-to-on transfer curve to induce the shift in threshold voltage in the dark condition, a shift in V_{th} (ΔV_{th}) of 6 V was obtained, namely, V_{th} varied from -15 to -9 V. It indicated that a small amount of field-induced electrons can be injected from pentacene active layer and trapped in nanostructured PFO and the interface, although the thin PMMA planarizing layer provided an additional tunneling barrier for electrons. It is thus expected that when the device is under illumination, the shift in transfer curves would become much more clear due to the participation of photo-excited high-energy electrons. As expected, the transfer curves systematically shifted toward the positive direction with increasing V_{g_start}, by applying light illumination on the channel region, as shown in Fig. 3b. It was observed that V_{th} remarkably shifted from -14.6 to 122.5 V when V_{g_start} changed from 60 to 200 V. It should be noted that the photo-induced threshold voltage shift was so significant that the operation mode can be changed from the enhancement mode to the depletion mode.

The photo-induced shift in V_{th} can be explained through the efficiency of the exciton separation in organic semiconductors and the electron trapping in nanostructured PFO and the interface. When light is absorbed, transitions between two molecular orbitals result in excitonic states with weak or strong Coulomb interaction binding electron and hole depending on photon energy. These paired electrons and holes are separated under proper gate bias. Detailed discussion of charge separation can also be found in studies of organic solar cells [20–22]. As shown in Fig. 4, V_{th} was almost unaffected till $V_{g_start} = 60$ V under light illumination. However, by applying $V_{g_start} = 200$ V, a conducting channel between the source and the drain

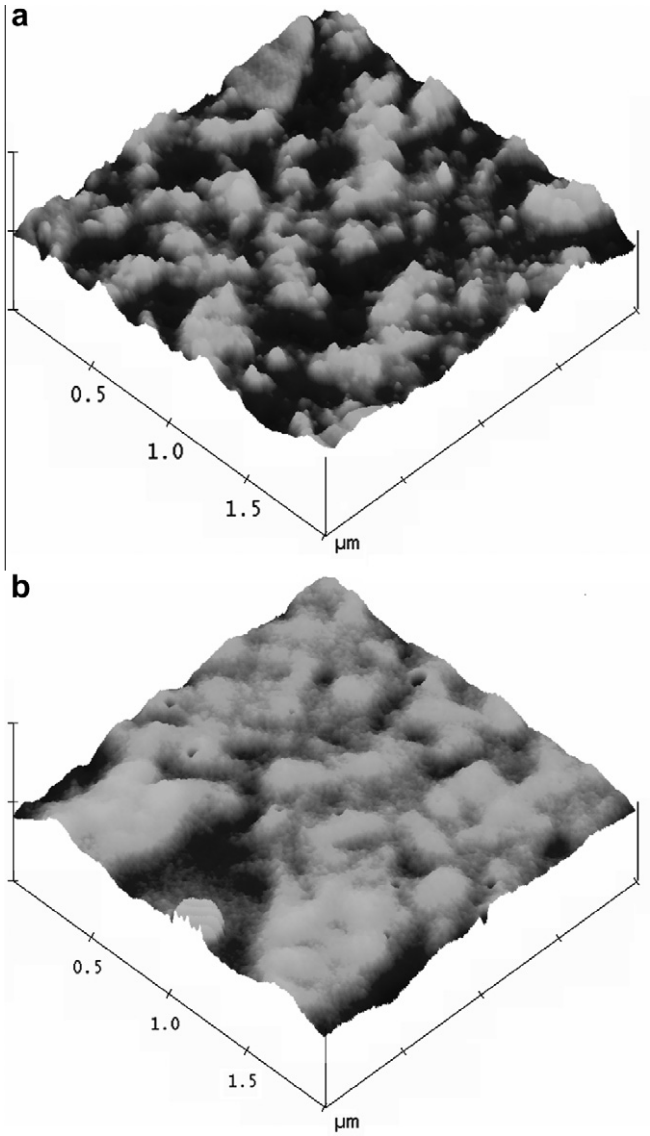

Fig. 2. Atomic force microscope images of surfaces of polymer: (a) PFO&PMMA spin-coated on SiO_2 surface (R_q = 4 nm), (b) PMMA film planarizing PFO&PMMA (R_q = 1.5 nm). Data scale is 50 nm and R_q represents RMS roughness.

began to form even at V_g = 150 V, indicating that a large amount of electrons were injected and trapped. Based on Eq. (2), the estimated density of transferred charges was around $5.14 \times 10^{12}\,cm^{-2}$. These trapped electrons were contributed from the excitonic states dissociated under the transverse electrical field determined by the applied gate bias. The efficiency of exciton dissociation and charge injection from the channel layer depends on the strength of the transverse electrical field and thus the threshold voltage can be set by V_{g_start}, whereas light illumination can be a control parameter for the modulation of the threshold voltage, as seen in response curves in Fig. 4.

In order to investigate the stability of a shifted V_{th}, we did the experiment on the lifetime of trapped charges in the dark. The device was programmed with red light (λ = 628 nm) under a gate bias of 200 V with respect to the short-circuited source and drain electrodes for a duration of 60 s. The considerably enhanced drain current was obtained at zero gate bias at $V_{ds} = -100$ V after programming, showing the "ON" state of the device. On the other hand, by applying an erasing voltage at $V_g = -200$ V at V_{ds} = 0 V in the dark to sweep away the trapped electrons, the transistor can be restored to the "OFF" state. The experiment result indicated that the trapped electrons were injected from the pentacene active layer, as the absorption spectrum of PFO mainly occurred in the blue light region (see the inset of Fig. 5) due to the large HOMO–LUMO bandgap while pentacene film was reported to be sensitive to red light [23]. A decay process in I_{ds} exhibited non-exponential characteristics with two distinguishable decay rates: (i) an initial rapid relaxation due to the recombination of closely packed holes and electrons and (ii) a subse-

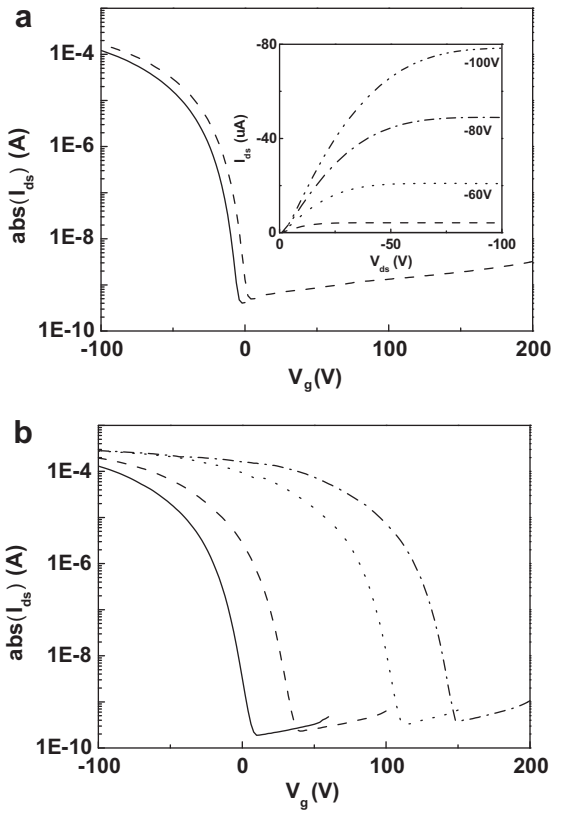

Fig. 3. Transfer characteristics of device 2 measured (a) in the dark condition with different V_{g_start}: 0 V (solid line) and 200 V (dash line), (b) under white light illumination with different V_{g_start}: 60 V (solid line), 100 V (dash line), 150 V (dot line), 200 V (dash dot line). The inset shows the sweeping characteristics with V_g starting from 0 V to −100 V in a step of −20 V in the dark condition.

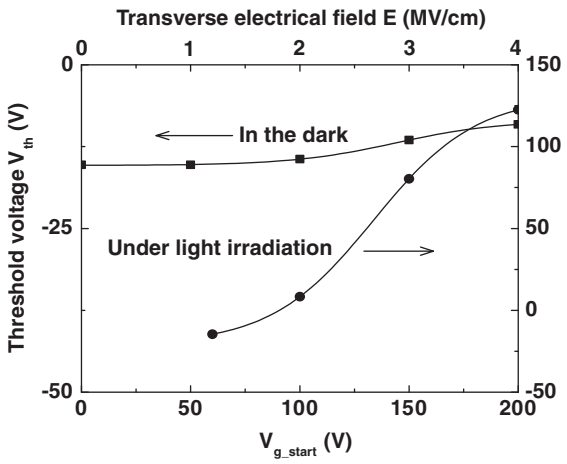

Fig. 4. V_{th} as a function of V_{g_start} with (circle)/without (square) white light illumination.

quent slower relaxation originated from deeply trapped carriers, depending on the quality of the PFO&PMMA (or PFO) film as well as the PMMA buffer layer. A charge storage lifetime of 60 min was obtained in this experiment. Due to the small, but non-zero leakage currents, these device in its current state needs to be refreshed every few hours, which might not reach the requirement for data storage application in organic electronics, but really motivating for the development of OFETs with tunable V_{th} through the photo-induced charge transfer.

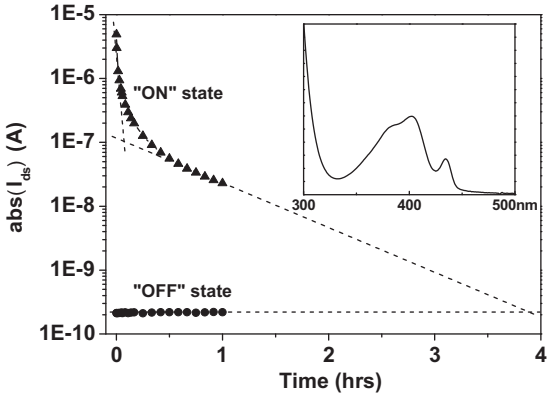

Fig. 5. Time evolution of I_{ds} measured at $V_{ds} = -100$ V and $V_g = 0$ V in the dark. The programming bias ($V_g = 200$ V and $V_{ds} = 0$ V) and erasing bias ($V_g = -200$ V and $V_{ds} = 0$ V) was applied to obtain the "ON"- and "OFF"-current states.

4. Conclusions

In conclusion, the charge transfer effect between pentacene and PFO in the FETs structure was studied and these devices presented a light-programmable electrical feature. The shift of the threshold voltage can be controlled in a wide range by varying V_{g_start} under light illumination, while the field-effect mobility and ON/OFF ratio were well maintained when the surface condition was optimized. It was ascribed to the charge-trapping ability of nanostructured PFO, whereas, to achieve a useful memory device, the improved performance is expected, in terms of charge retention and the operating voltage by introducing new combinations of various materials, smoother interface, along with optimization of geometrical parameters.

ABSTRACT

Here we report on low-supply voltage and high-performance regioregular poly-(3-hexythiophene) (P3HT) organic thin-film transistors (OTFT) using a thin atomic layer deposited (ALD) HfO_2 gate dielectric. For the capacitance–voltage characteristics, the measured gate capacitance was ~392 nF/cm^2 at 1 kHz and the dielectric constant was estimated ~18.5 for a 40 nm thick ALD HfO_2 gate dielectric. The gate dielectric showed breakdown fields >5 MV/cm with the leakage current density less than 10^{-7} A/cm^2 at 2 MV/cm. With octadecyltrichlorosilane-treated ALD HfO_2 gate dielectrics, P3HT OTFTs demonstrated high field-effect mobilities up to ~0.01 ± 0.002 cm^2/V s in the saturation region with the drain voltage of −5 V, which is at least one order of magnitude higher than typically reported mobilities particularly for low-voltage regioregular P3HT OTFTs using high-*k* inorganic gate dielectrics. The threshold voltage in the saturation region and on–off current ratio were measured to be −1.2 ± 0.2 V and ~1.1(±0.1) × 10^4, respectively.

1. Introduction

The performance of organic thin-film transistors (OTFT) have, in general, made tremendous progress in the last decade [1–3]. Using sublimed low molecular weight organic and solution-processed polymeric materials, excellent OTFT results have been reported paving the way for niche applications, such as radio-frequency technologies [4], and pixel drivers and switching elements for active-matrix displays [5,6].

Among the various conjugated polymers for the active channel layer in OTFTs, regioregular poly-(3-hexythiophene) (P3HT) has been one of the most popular channel materials in organic electronics due to its simple solution processibility and relatively high device performance. Stemming from its lamellar structure [7], P3HT films have reported relatively high carrier mobility (μ) in the range of ~0.1 cm^2/V s to ~0.3 cm^2/V s [8–11]. However, extremely high operating voltages persisting up to 60 V are often required to obtain saturation in OTFTs with low-dielectric constant (k) materials for the gate dielectric layer. Alternatively a variety of high-*k* gate dielectrics using inorganic, polymeric, and self-assembled monolayer or multilayer gate dielectrics, has been successfully implemented in OTFTs, greatly reducing OTFTs operating voltages and exhibiting excellent device performance [12,13].

For P3HT OTFTs particularly with metal oxide high-*k* dielectrics, high OTFT performance with low-supply operating voltages have been reported, as summarized in the Table 1 [14–17]. While hafnium-based oxide gate dielectrics were frequently employed in pentacene OTFTs [18,19], it has not yet been reported for regioregular P3HT OTFTs. In this article, we report low-voltage operation (sub −5 V) and high-performance P3HT OTFTs with an atomic layer deposited (ALD) HfO_2 gate dielectric.

2. Experimental

The HfO_2 films were deposited on silicon substrates with a commercial ALD reactor. During deposition, the ALD chamber temperature was set at 250 °C. All silicon substrates used in this study were processed through standard degreasing and RCA cleaning procedures prior to the deposition. The thicknesses (t) and the refractive index of the deposited films were estimated to be ∼40 nm and ∼2.07, respectively, as measured by single wavelength ellipsometry.

For capacitance–voltage (C–V) characteristics with an LCR meter (Agilent 4284A), the HfO_2 was deposited on p-type silicon wafers with a resistivity of ∼4.4 Ω cm for metal–oxide-semiconductor (MOS) capacitors. All HfO_2 gate dielectrics were used without any annealing. After deposition, MOS capacitors were completed by standard photolithography and lift-off of the Au (100 nm) gate, defining a square area of 80 μm by 80 μm. A Ti adhesive layer with a 15 nm thickness is used to increase the adhesion between the Au electrode and the ALD films. The final MOS structure fabricated was a p-Si/HfO_2/Ti/Au. The leakage current density through the MOS capacitors was measured with a semiconductor parameter analyzer (Agilent 4156) at room temperature and in darkness.

For the bottom contacted OTFTs, a heavily doped n-type silicon substrate with a resistivity of ∼0.003 Ω cm was used as the gate. The source and drain contacts are formed by standard photolithography and lift-off of the Au (100 nm) with a 15 nm Ti adhesive layer, defining a channel length of 7 μm and width of 115 μm atop the ALD HfO_2 layer. It should be noted that a Ti adhesion layer could affect the charge carrier transport between the source and the drain, requiring an optimized thickness [23]. In this work, the thickness of a Ti adhesive layer was not optimized. After photolithography and metal lift-off, the surface of the HfO_2 was plasma cleaned using an inductively coupled plasma reactive ion etching system with oxygen at an RF power of 20 W for 1 min. To modify the gate dielectric surface, a self-assembled monolayer (SAM) of octadecyltrichlorosilane (OTS; Aldrich, assay >90%) was then formed by immersing the ALD HfO_2 films in a 25 g/L solution of OTS dissolved in cyclohexane at ∼5 °C for 20 min, as described by Majewski et al. [20]. Thin films of the P3HT were then deposited by spin coating from a concentration of 8 mg/ml in chloroform in an inert glove box environment with ⩽1 ppm level of oxygen and moisture. The regioregular P3HT (Merck Chemicals, Ltd.) with 94.5% regioregularity was used without further purification. The P3HT used here has a weight-average molecular weight (M_w) of 26,200 g/mol, corresponding to a number-average molecular weight (M_n) of 13,000 g/mol, and with a polydispersity (M_w/M_n) of ∼2. The P3HT OTFTs were kept in a vacuum at pressures below 10^{-6} Torr for 10 h to remove any unintended doping. Prior to the measurement, the completed P3HT OTFTs were briefly annealed at 110 °C for 10 min in N_2 atmosphere. Small trenches in the P3HT film around the source and drain electrodes were created with a needle in order to minimize leakage currents [20]. Electrical characterizations of the P3HT OTFTs were performed with a semiconductor parameter analyzer (Agilent 4156) at room temperature under darkness in ambient air.

3. Results and discussion

In addition to the OTFTs, MOS capacitors were also studied as a control. Fig. 1 shows a typical C–V response of the ALD HfO_2 MOS capacitors at a frequency range from 1 kHz to 1 MHz at room temperature under darkness. The varying frequency response clearly shows accumulation at negative

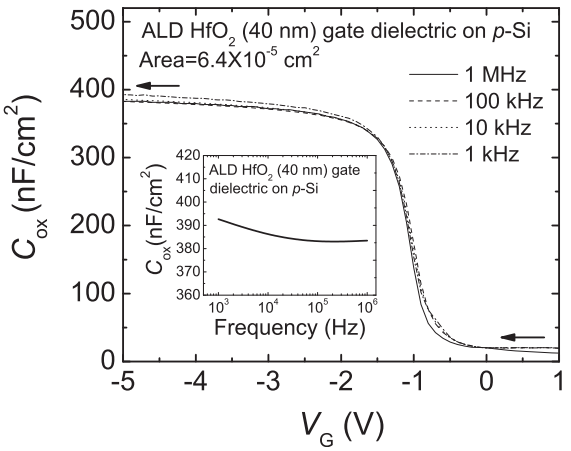

Fig. 1. Capacitance–voltage (C–V) characteristics of MOS capacitors at various frequencies for an atomic layer deposited HfO_2 (∼40 nm) gate dielectric (p-Si/HfO_2/Ti/Au). The inset shows frequency dependency of the gate capacitance per area (C_{ox}) in accumulation and the dielectric constant. The extracted k value at 1 kHz is ∼18.5.

gate bias voltages and depletion at positive gate bias voltages. The hysteresis behavior of the capacitor was observed, exhibiting ~0.5 V hysteresis at 1 MHz (not shown here). The trap charge density (N_t) in the gate dielectric layer is estimated to be $\sim 1.1 \times 10^{11}$ cm^{-2} using the relation $N_t = C_{ox} \cdot \Delta/q$, where C_{ox} is the measured gate capacitance per unit area (F/cm^2), Δ is a voltage shift (V), and q is the magnitude of electronic charge (C). The C_{ox} tends to shift to slightly higher values when decreasing the frequency for all capacitors, as shown in the inset of Fig. 1. No postdeposition heat treatment was used to densify, or passivate, the HfO_2 prior to OTFT fabrication. An observed frequency dependent dispersion in the accumulation region can be attributed to the slow polarization of the gate dielectric at higher frequencies and this polarization can lead to an increase in the induced charge at lower frequencies. The dielectric constant (k) of the ALD HfO_2 gate dielectric was calculated at four different frequencies using $k = C_{ox} \cdot t/\varepsilon_0$, where ε_0 is the permittivity in vacuum, and t is the thickness. The calculated dielectric constants varied from 18.1 at 1 MHz to 18.5 at 1 kHz. For the extraction of carrier mobility values of P3HT OTFTs, the C_{ox} equal to 392 nF/cm^2 at 1 kHz was considered. Upon the addition of the OTS SAM (k = ~2.4 and t = ~2.8 nm) [16], the total capacitance (C_{total}) is considered to be ~262 nF/cm^2 using $1/C_{total} = 1/C_{ox} + 1/C_{OTS}$.

Fig. 2 illustrates the leakage current density versus electric field for the ALD HfO_2 gate dielectric studied here. The dielectric layer shows breakdown fields >5 MV/cm with a leakage current density less than 10^{-7} A/cm^2 at 2 MV/cm for a ~40 nm thick film. The inset of Fig. 2 is the leakage current density versus the gate voltage characteristics for the MIS capacitors.

Fig. 3a shows the output characteristics for P3HT OTFTs with an applied drain voltage (V_D) ranging from 0 to −5 V with a gate bias (V_G) varying from 1 to −5 V in steps of −1 V. The output curves are typical for p-type OTFTs operating in an accumulation region. The OTFTs function well at low-supply voltages due to the high gate capacitance of HfO_2. The inset of the Fig. 3a is a photomicrograph of the Au source–drain contacts atop the ALD HfO_2 gate dielectric.

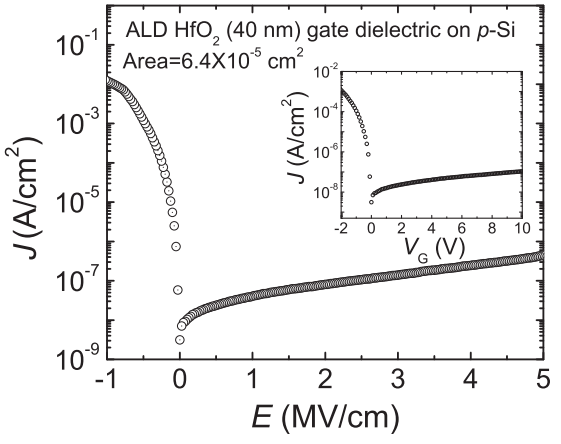

Fig. 2. The leakage current density (J) as a function of electric field (E) of MOS capacitors (p-Si/HfO_2/Ti/Au). The breakdown field is estimated >5 MV/cm. The inset shows current density–voltage characteristics of the devices.

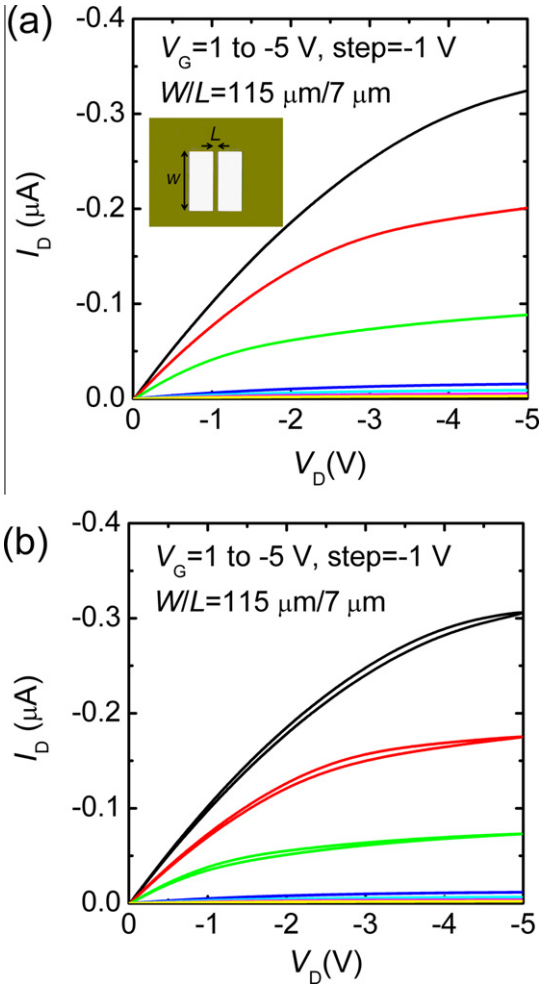

Fig. 3. (a) The output characteristics for P3HT OTFTs with the applied drain voltage (V_D) ranging from 0 to −5 V with gate biases (V_G) varying from 0 to −5 V in steps of −1 V. The inset is the image of the Au source–drain contacts atop the ALD HfO_2 gate dielectric using standard photolithography and lift-off process. (b) The hysteresis behavior of the output characteristic of P3HT OTFTs for an applied voltage V_D (0 → −5 V → 0 V).

At V_G = −2 V and V_D = 0 V, a very small positive I_D of $\sim 2.5 \times 10^{-11}$ A is observed, which increased with higher V_G due to a small drain-gate leakage current. For an applied voltage V_D (0 → −5 V → 0 V), a small hysteresis was observed at V_G > −3 V, and no significant hysteresis behavior was shown for gate voltages less than −3 V (Fig. 3b).

During the electrical measurements in ambient air, a variation of off-state I_D at V_G = 0 V and V_D = −5 V was carefully monitored. For fresh devices, a small off-state I_D (>$\sim 1 \times 10^{-11}$ A) was observed. However, an off-state I_D (>$\sim 1 \times 10^{-9}$ A) was increased by two orders of magnitude over the extended exposure (about 60 min) in ambient air due to the high bulk conductivity of P3HT attributed from unreduced P3HT and oxygen doping [21,22]. The devices exhibiting a high off-state I_D (>$\sim 1 \times 10^{-9}$ A) typically show significant hysteresis behavior at V_G > −3 V due to large excess drain current. Those devices are excluded from extraction of the performance of the OTFTs in this work.

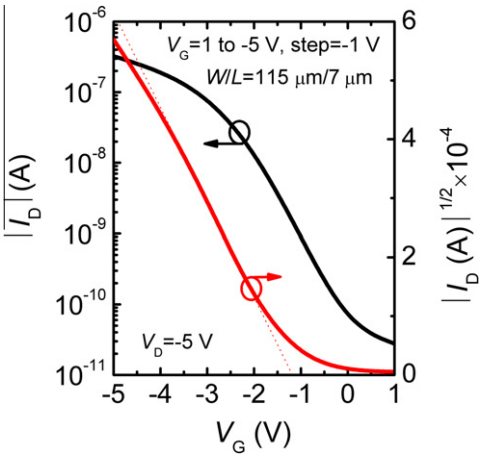

Fig. 4. The saturation region transfer characteristic for P3HT OTFTs with ALD HfO_2 gate dielectrics (~40 nm) with the applied gate voltage (V_G) ranging from 1 V to −5 V with the drain voltage (V_D) of −5 V.

For the transfer characteristics in the saturation region, the saturation mobility (μ_{sat}), the threshold voltage (V_T), and an on/off current ratio (I_{on}/I_{off}) are characterized. Fig. 4 shows the semilog plot of I_D–V_G and the square root of I_D–V_G at $V_D = -5$ V. The μ_{sat}, and the V_T are calculated from

$$I_D = \frac{W}{2L} C_{total} \mu (V_G - V_r)^2 \quad (1)$$

From the square root of I_D as a function of V_G, the maximum μ_{sat} was estimated to be $\sim 0.01 \pm 0.002$ cm^2/V s and the V_T was -1.2 ± 0.2 V. No significant variation of estimated μ_{sat} and V_T was recorded over more than 10 devices. The mobility obtained in this work is one to two orders of magnitude higher than the reported mobilities in low-voltage operating regioregular P3HT OTFTs specifically with metal oxide high-k gate dielectrics, such as ALD Al_2O_3 [15] and anodized Al_2O_3, but was the same order of magnitude mobility using electron-beam evaporated Ta_2O_5 [14], and TiO_2 [17]. Table 1 shows a summary of these gate dielectrics exclusively employed for P3HT OTFTs and their corresponding device performances. For the semilog plot of I_D–V_G at a fixed $V_D = -5$ V, an I_{on}/I_{off} as large as $\sim 1.1(\pm 0.1) \times 10^4$ was measured here, which is similar with previous values reported for P3HT OTFTs using high-k dielectric gate dielectrics (Table 1). From the subthreshold regime in the plot of log I_D as a function of V_G, the subthreshold swing (S) was calculated using $S = dV_G/d(\log I_D)$ and yielded a value of 0.803 ± 0.243 V/decade.

4. Conclusions

In conclusion, we have shown low-voltage operation and high-performance regioregular P3HT OTFTs using ALD HfO_2 gate dielectrics. For the C–V characteristics, the measured C_{ox} was ~392 nF/cm^2 at 1 kHz and the dielectric constant was estimated to be ~18.5 for a 40 nm thick ALD HfO_2 gate dielectric. The HfO_2 gate dielectric showed a breakdown field >5 MV/cm with a leakage current density less than 10^{-7} A/cm^2 at 2 MV/cm. With OTS-treated ALD HfO_2 gate dielectrics, P3HT OTFTs show high mobility up to $\sim 0.01 \pm 0.002$ cm^2/V s in the saturation region, which is at least one order of magnitude higher than typically reported mobilities for low-voltage operating regioregular P3HT OTFTs particularly with metal oxide high-k gate dielectrics. The V_T and I_{on}/I_{off} ratio are -1.2 ± 0.2 V and $\sim 1.1(\pm 0.1) \times 10^4$, respectively.

ABSTRACT

The authors report magnetic field (MF) induced grain growth of perylene polycrystalline films during vacuum deposition. It is clearly demonstrated that the grain size of perylene polycrystalline film was increased by 2.6 times with a 3.8 kG perpendicular MF to the substrate at the deposition temperature of 30 °C. In contrast, the grain size was decreased by applying a parallel MF to the substrate. This MF effect on the grain growth becomes stronger at higher deposition temperature. The mechanism of this MF effect is discussed through the diamagnetic property and the intralayer interaction of the perylene molecules during the nucleation process.

1. Introduction

Significant developments in organic thin-film transistors (OTFTs) have been made during the last two decades, and plenty of papers and books have been published [1–7]. Although there are still some debates on the detailed mechanism of charge transport in OTFTs, it is very clear that larger grain size in a deposited organic film leads to a higher charge carrier mobility of the device because the grain boundaries usually act as charge carrier traps [8–15]. In addition, the grain boundary is known to be deeply related to device degradation during operation by the bias stress or environmentally induced chemical reaction of materials [16–19]. Therefore, it is very important to make the grain size as large as possible in order not only to enhance the charge carrier mobility of OTFTs, but also to increase the reliability of the devices. To date, some approaches have been successfully applied to enlarge the grain size. For example, heating the substrate during film formation is very effective to increase the grain size, and is used as a popular method to enhance the charge carrier mobility of the devices [15,20–25]. Annealing after film deposition is also known as an effective method for some materials [26–28]. Surface modification of dielectrics and/or electrodes before film deposition, and solvent vapor treatment after film formation are also reported as effective methods [12,22,29,30]. Those reported methods, however, also have some drawbacks or distinct limits to their ability to enhance the charge carrier mobility of the devices. For example, thermal treatment at a somewhat high temperature usually results in the formation of cracks and/or gaps between the grains, which leads to a deterioration of the device performance even with a very large grain size [22,26,31].

Here we report a novel and very effective method to increase the grain size of organic films: applying a magnetic field (MF) during film deposition. The grain size of perylene polycrystalline film was increased by 2.6 times (from 1.59 to 4.14 μm in diameter) by applying 3.8 kG MF perpendicular to the substrate during vacuum deposition of perylene molecules at the deposition temperature of 30 °C. In contrast, the grain size was reduced by applying a MF parallel to the substrate. This is the first demonstration of the MF effect on the grain growth during vacuum deposition of purely hydrocarbon molecular materials without any metal atoms to the best of our knowledge.

2. Experimental

2.1. Material and film formation

Perylene of 99% purity was purchased from Aldrich, and purified once using the thermal gradient sublimation method before use. Perylene films were formed by thermal evaporation in vacuum with a base pressure of lower than 5.0×10^{-7} Torr. The perylene was sublimed from a cylindrical quartz crucible whose temperature was carefully controlled to get the deposition rate of 0.5 Å/s. The substrates of the O_2-plasma treated Si wafers with a 300 nm thick oxide layer were ca. 20 cm apart from the crucible. The substrate temperature was controlled from 20 to 40 °C by heating or cooling the substrate holder, and was detected from the surface and the inside of the substrate holder with two thermocouples. At the 40 °C deposition temperature, however, we could not get a homogeneous film but could only achieve discontinuous perylene domains with very large gaps between the domains, probably due to the low wettability onto the substrate and the resublimation of perylene molecules.

2.2. Application of magnetic fields

To apply MFs during deposition, we have used permanent NdFeB magnets whose coercivity of one piece is 11.9 kOe. For a uniform perpendicular MF to the substrate, we installed several magnets just above (top sets) and far below (bottom sets) the substrate for the formation of the sink and the source of MF, respectively, as shown schematically in Fig. 2a. The two magnet sets were separated by about 10 cm, and the size of the magnet sets was large enough to provide a uniform MF for all areas of the substrate. The MF strength was varied by changing the number of magnets of the top sets. For a parallel MF to the substrate, we installed magnets perpendicularly to the substrate on both sides of the substrate, as shown schematically in Fig. 2b. An inevitable problem of this configuration is that the MF strength is strongly dependent on the distance from magnets, and hence on the position of substrate. In our case, the MF strength was about 3.8 kG at the center of the substrate, and about 5.4 kG at the both sides of the substrate.

2.3. Film characterization

The surface morphology of the deposited films was examined with an Atomic Force Microscope (AFM, Digital Instruments Dimension 3100). We have used the contact mode AFM and acquired height images together with friction images for clearer observation of the grain boundaries. The domain size of the films is measured by counting the intercepts of the grain boundaries with 12 arbitrary straight (6 vertical and 6 perpendicular) lines in the AFM friction images of $20 \times 20\ \mu m^2$ size, from which we can calculate the average number of domains in those images. The crystal structure of the perylene films was determined with XRD (Rigaku Co., RU-300) with a Cu K_α (λ = 1.5418 Å) radiation.

3. Results and discussion

3.1. MF induced grain growth

Perylene (Fig. 1) was selected as the target material mainly because perylene and its derivatives have shown very high electron mobility [18,22–24,26,32–36], and partly because it is a simple and representative polycyclic aromatic hydrocarbon molecule. Fig. 1 shows the X-ray diffraction (XRD) pattern of a 100 nm thick perylene film deposited without MF. Four clear diffraction peaks can be assigned to different planes, which range from the (0 0 1) to (0 0 4) planes of the perylene film, respectively. The calculated d spacing of this perylene film is 10.13 Å, which is well matched with the spacing of the ab plane of the well known α-phase perylene crystal [37–39], indicating that the perylene molecules are almost upright standing and adopt a face-on-edge herringbone arrangement along the ab plane, and expected to show a high electron mobility along the parallel direction to the substrate [32–34,37–39].

For the application of MFs during perylene deposition, we have installed magnets around the substrate, as described in Section 2, which are shown schematically in Fig. 2. There was no difference in the MF strength in the temperature range from 20 to 30 °C used in this study. Fig. 3 shows the AFM topography (left column) and friction (right column) images of the perylene films deposited at 25 °C (a) without applying a MF, (b) with the application of a MF of 1.7 kG, and (c) with a 3.8 kG MF applied perpendicular to the substrate, respectively. It is very clear that the grain size increased with the increasing magnitude of the perpendicular MF. The grain size increased from 0.83 to 1.54 μm in diameter by applying a perpendicular MF of 1.7 kG, and even more, up to 1.68 μm by increasing the MF to 3.8 kG.

This MF effect on the grain growth of the perylene film becomes even more obvious when deposited at higher substrate temperatures, as can be seen in Fig. 4. At the deposition temperature of 20 °C, the grain size increased by only 23% by applying the MF of 3.8 kG. The grain size, however, doubled at 25 °C, and increased by 2.6 times at 30 °C. This result indicates that the MF effect on the grain

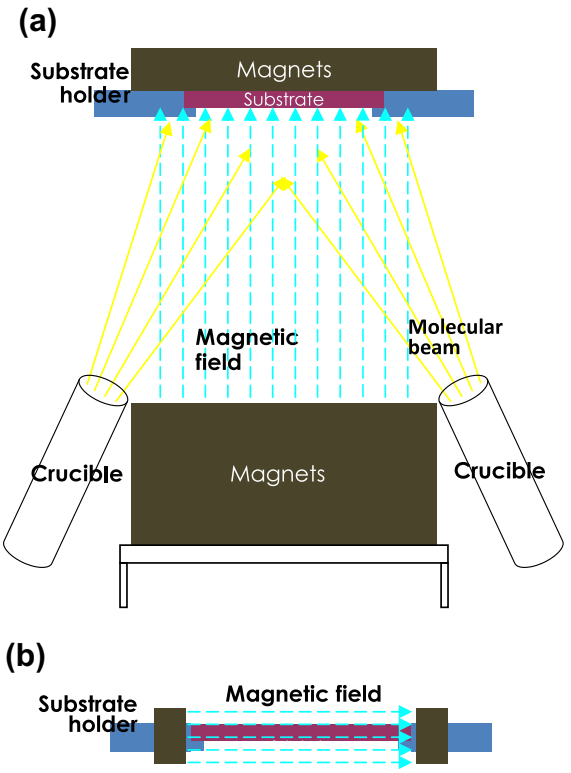

Fig. 2. Schematic illustrations of the deposition set-up with (a) a perpendicular MF and (b) a parallel MF. Note that these illustrations are not to scale.

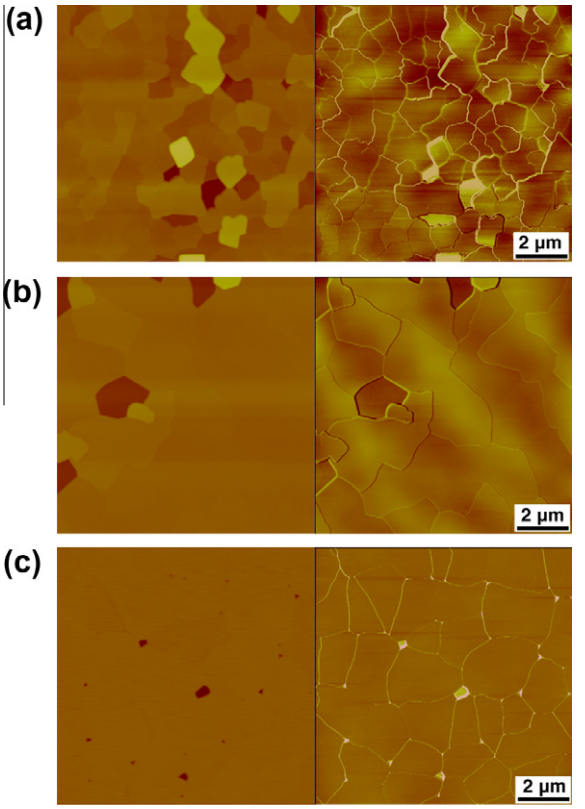

Fig. 3. AFM height (left column) and friction (right column) images of the perylene films deposited at 25 °C (a) without applying a MF, (b) with the application of a perpendicular MF of 1.7 kG, and (c) with the application of a perpendicular MF of 3.8 kG. The grains sizes measure 0.83, 1.54, and 1.68 μm in diameter, respectively.

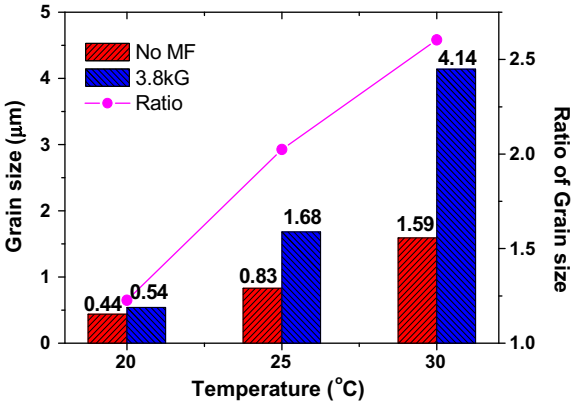

Fig. 4. Graphical comparison of the grain size of the perylene films deposited at various temperatures, and the ratio of the grain sizes. The numbers inserted above the graphic bars indicate the grain size in diameter, and the ratio of the grain sizes was calculated by simply dividing the grain size with the applying MF by the counterpart without the MF at each deposition temperature.

growth of the perylene polycrystalline film becomes stronger at higher deposition temperatures.

It seems that the perpendicular MF not only enlarges the grain size but also improves the crystal quality of the films. Fig. 5 shows the XRD patterns of the films deposited without applying an MF (black line) and with the application of a 1.7 kG perpendicular MF (red line) at 25 °C with the same film thickness. The peak positions are the same between the films, indicating that the lattice spacing is the same in both films grown with and without the MF. The peak intensities remarkably increased by 2.7 times by applying a 1.7 kG perpendicular MF even though the full-width-at-half maximum (FWHM) of the two peaks are almost the same with (FWHM = 0.37) and without (FWHM = 0.36) a magnetic field. This increase cannot be explained simply by the increase in the grain size but indicates an improved crystal quality, such as an increase in the crystal volume fraction of the grains or a more uniform perpendicular orientation of the grains. This proposed improvement of the crystal quality can be observed in the AFM friction images in Fig. 3, where a featureless frictional image, except for the grain boundaries, is obtained in the films grown under the perpendicular MF of 3.8 kG shown in Fig. 3c. In contrast, fluctuations in the friction image were observed not only between the grains but also within the grains, as shown in Fig. 3a when grown without MFs, indicating an inhomogeneity in the grains. This MF effect on the crystal quality of deposited film may be observed more clearly with further examination.

Application of a MF parallel to the substrate resulted in the reduction in the grain sizes, especially at high temperature as shown in Fig. 6. The average grain size in the film

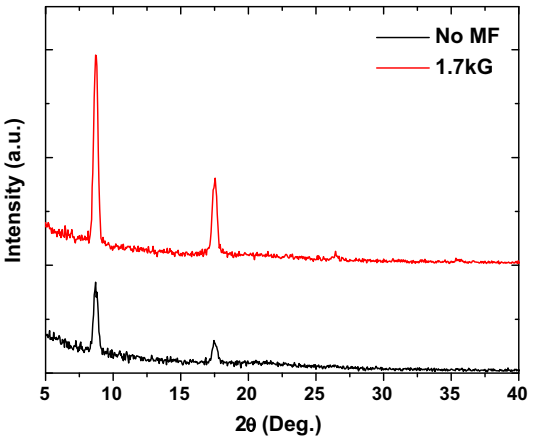

Fig. 5. XRD patterns of perylene films deposited at 25 °C without applying an MF (black) and with the application of a 1.7 kG perpendicular MF (red). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

was reduced from 1.59 to 0.98 μm at 30 °C when a parallel MF of 3.8 kG was applied during the growth. The grains have almost the same size of 0.85 μm if grown at 25 °C with and without the parallel MF. It suggests that a parallel MF to the substrate suppresses the grain growth, in contrast to a perpendicular MF.

From the results described so far, we can conclude that a perpendicular MF to the substrate has an effect of increasing the grain size and improving the crystal quality, but a parallel MF has an opposite effect. These MF effects become stronger at higher deposition temperatures.

3.2. Discussion

As a fundamental cause of this MF effect, we give consideration to the diamagnetic anisotropy of perylene molecules [40–43]. It is well known that liquid crystals (LCs) can be aligned by applying a MF due to the diamagnetic anisotropy of LC materials [44–47]. Similarly, the alignment of nanosized protein crystals in a strong MF was interpreted as being due to the diamagnetic anisotropy of the peptide groups in the amino acid sequence, and of aromatic residues in the protein molecules [48–50]. In those cases, the alignment of LCs and protein crystals was estimated to occur only in crystals or in domains larger than a critical size where the MF effect (or magnetic stabilization energy) can exceed the thermal fluctuation [45,48,49]. The MF effect is known to be negligibly small at the level of individual molecules, and cannot orient the individual molecules. The collective behavior of the molecules in a crystal or in a domain causes the molecular contribution to add up constructively, and the crystal or the molecular domain larger than a critical size can be

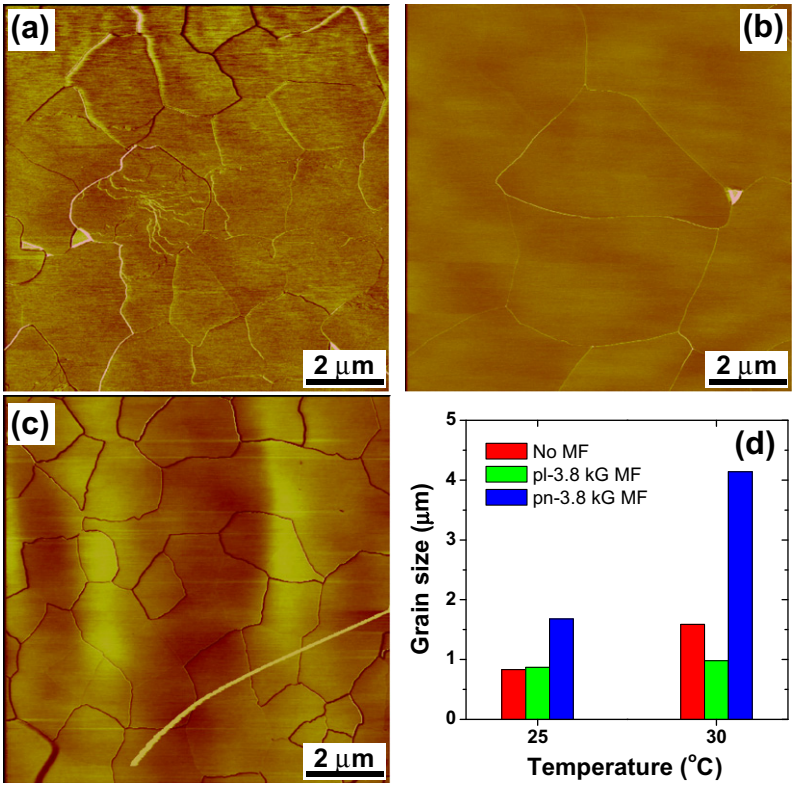

Fig. 6. AFM friction mode images of perylene films deposited at 30 °C (a) without applying MF, (b) with a perpendicular MF of 3.8 kG (pn-3.8 kG MF), (c) with a parallel MF of 3.8 kG (pl-3.8 kG MF), and (d) a graphical representation of the grain sizes of the perylene films deposited at 25 and 30 °C with the indicated deposition condition.

oriented as a whole. For example, it is calculated and proven experimentally that lysozyme crystals larger than 1.3 μm can be magnetically oriented when the magnitude of the MF exceeds 1 T, and most crystals larger than 0.3 μm are oriented when the magnitude of the MF is 10 T [48,49]. In recent years, it was also reported that perylene nanocrystals of 160 nm size can be oriented in a static MF of 2 T, which is interpreted with the same mechanism mentioned above [51].

In our case, however, there are some crucial differences in the detailed situation of the MF effect, although the fundamental cause lies with the diamagnetic anisotropy of the molecules in common. First, the MF effect was stronger at higher temperature in our case, which is completely opposite to the mechanism mentioned above. Second, almost all of molecules in a film align in the same direction, almost perpendicular to the substrate, regardless of the grain size in our case. Third, the subject of the MF effect is the "growth" of crystal domains in our case, which is totally different to the "alignment" of crystals or molecular domains. Therefore, it is not suitable to explain the MF effect of our case by adopting the mechanism mentioned above. It is necessary to consider the grain growth mechanism of perylene molecules in a vacuum deposition.

Perylene molecules are known to show a Stranski–Krastanov growth mode on various metals and on Si substrate during vacuum deposition [37,52–54]. In this growth mode, the perylene molecules usually form a few homogeneous monolayers in the first stage which is followed by the dewetting of multilayer films, which results in a formation of separated crystalline islands. The morphology and the size of the islands, hence the domain size, will be determined from a balance between the diffusion and nucleation of molecules if we rule out the effect of the surface free energy of the substrate, which is usually very important to explain the grain growth, but not in our case because we used the same substrate [25,37,55,56]. In our case, it is very difficult to consider the applied MF to have affected the molecular diffusion. Therefore, it is reasonable to think that the applied MF has affected the nucleation process of the perylene molecules. If the applied MF can reduce the nucleation rate, the grain size will be increased, and vice versa. For the nucleation of some organic semiconductors including perylene during vacuum deposition, Verlaak et al. have reported that the higher intralayer interaction leads to a higher energy of the nuclei which will result in a higher barrier against nucleation and thus contributes to a lower nucleation rate [55]. If we assume that the applied perpendicular MF increases the intralayer interaction of the perylene molecules, the resultant increased grain size obtained by applying a perpendicular MF can be accepted as a reasonable result. For the parallel MF effect, it is just the opposite situation: a decreased intralayer interaction and hence a reduced grain size. The problem is that the magnitude of the MFs in this study is not so large such that we can expect to have a strong effect on the intralayer interaction from the view point of the erstwhile mechanism of the diamagnetic anisotropy of perylene molecules. For the present, the detailed mechanism and the strength of this MF effect on the grain growth is now under further research.

4. Summary

It was clearly demonstrated that a perpendicular MF to the substrate increases the grain size of perylene polycrystalline film. The grain size was increased by 2.6 times (from 1.59 to 4.14 μm in diameter) with applying a 3.8 kG perpendicular MF to the substrate during vacuum deposition of perylene molecules at 30 °C deposition temperature. On the contrary, the grain size was reduced with applying a parallel MF to the substrate. This MF effect becomes stronger at higher deposition temperature in both of directions. We explained this MF effect with a diamagnetic property and the intralayer interaction of the perylene molecules during the nucleation process. This MF effect can be used widely in almost all OTFT materials because they usually have almost the same order of diamagnetic susceptibility with perylene due to benzene rings and/or thiophene rings for large conjugation length.

ABSTRACT

We present a comprehensive Kelvin probe force microscopy study of grain boundaries in pentacene transistors with different film thicknesses in combination with current–voltage measurements and 3D electrostatics simulations. It is found that in pentacene films thinner than approximately 30 nm, holes are accumulated in the grain boundaries due to negative trapped charge at the SiO_2–pentacene interface. On the other hand, in thicker films we observe hole depletion near the boundaries mainly due to positive charge trapping in the grain boundaries. The results are discussed in view of their effect on pentacene thin film transistors performance.

1. Introduction

The nature of grain boundaries (GBs) and their role in the charge transport in organic materials in general, and in pentacene in particular is of large interest in recent years. Horowitz and Hajlaoui [1] have shown that the carrier mobility increases with grain size in oligothiophene thin film transistors. Their model suggested that the charge transport is limited by trapping and thermal release at localized states located at the GBs. Other works also suggested that the main bottleneck for the charge transport in organic devices is due to potential barriers both in the GBs, and inside the grains [2–7]. The above works have used macroscopic measurements combined with simulations to study the GBs influence on the device characteristics. It is well known that in organic thin film transistors the current flows very close (few nm) to the gate dielectric interface, which makes the correlation between this accumulation current and the GBs properties extremely difficult.

Puntambekar et al. [8] have used Kelvin probe force microscopy (KPFM) to measure the GBs potential barriers in pentacene thin films (3–5 nm). They have found that the potential drop in the GBs is around 5–10 mV which is an indication of negative trapped charge at the GBs. They also observed that the surface-potential variations within the grains are comparable to the drops at the GBs making it ambiguous whether the GBs poses bottlenecks to hole transport. Wang et al. [9] also argued that the channel mobility and threshold voltage are limited by charged traps in the channel, most of which are not located in the grain boundaries but at the organic/insulating layer interface. Nakamura et al. [10] have shown that the GBs are not always a limiting factor for the carrier mobility, although the mobility had a correlation with the average grain size. Tello et al. [11] have also used KPFM to measure the surface potential in pentacene transistors under bias, and its correlation with the film morphology. They have found that most of the applied drain–source bias drops across a single well-defined grain boundary, which consequently acts as the bottleneck for charge transport. However, these features were scarce, indicating that there is generally sufficient connectivity through the GBs to transport the current.

The above studies indicate that the GBs role in pentacene charge carrier transport and their effect on the device

performance is not well understood. This is partially due to the lack of simulations combined with local GBs electronic measurements that can quantitatively reveal the effect of the GBs. We present here a comprehensive KPFM study of pentacene thin film organic field effect transistors (OFETs) with different film thicknesses combined with *i–V* measurements and 3D electrostatic simulations in order to reveal and quantify the GBs role on the device characteristics. We distinguish between two different charge trapping regions: the first is the SiO_2–pentacene interface where electrons are trapped, and the second is in the GBs that trap holes (the majority carriers). It is found that the bottom interface charge determines the GBs surface potential in thin layers, while the GBs trapped charge does it in thick layers. The results are discussed in view of their effect on pentacene thin film transistors performance.

2. Experimental

A heavily doped *n*-Si (1 0 0) wafer was used as the substrate and the gate electrode, and thermally oxidized SiO_2 (300 nm) served as the gate dielectric. The pentacene layer was deposited by using the molecular-beam deposition method [12] at a base pressure of 4×10^{-10} Torr and at a growth rate of 0.2 nm min^{-1} with a substrate temperature of 60 °C. The channel width and length of the pentacene transistor were 5 mm and 20 μm, respectively. The source and drain gold electrodes of pentacene TFT were deposited on the pentacene film in vacuum. Four transistors with pentacene layers in thickness of 100, 30, 10 and 5 nm were prepared and transferred to glove box where both the KPFM and electrical measurements were carried out. The KPFM measurements were conducted using a *Dimension 3100* atomic force microscopy (AFM) system in a controlled nitrogen environment glove box (less than ~5 ppm H_2O), in the lift mode where the first scan is a tapping mode topography measurement and in the second scan the tip is raised above the topography trajectory ~5 nm and measures the CPD.

3. Results and discussion

3.1. Thin pentacene layers

Fig. 1 shows topography (top row (a, d and g) and CPD images (second row (b, e and h) for 30, 10 and 5 nm thick pentacene transistors biased above the threshold voltage ($V_g = 0$), respectively. The measured CPD represents the difference between the tip work function (Φ_t) and sample work function (Φ_s) defined as:

$$\mathrm{CPD} = -\frac{1}{q}(\Phi_t - \Phi_s) \quad (1)$$

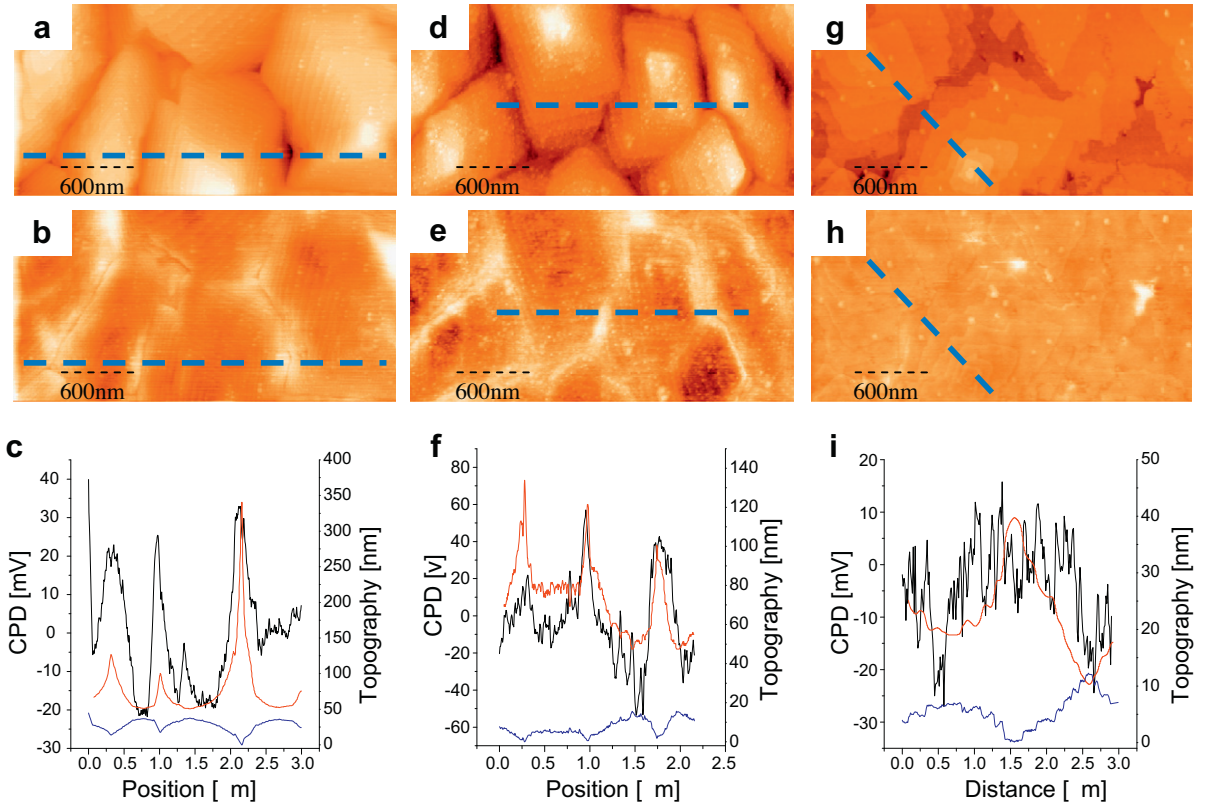

Fig. 1. (a, d and g) Topography of 30, 10 and 5 nm thick pentacene films, respectively. (b, e and h) CPD measurement of 30, 10 and 5 nm thick pentacene film respectively. (c, f and i) lines scans of the calculated and measured CPD of 30, 10 and 5 nm thick pentacene films, respectively. Black line represents the measured CPD, red line the calculated CPD and the blue line represents the measured topography. All the images were measured at $V_g = 0$. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

This means that larger CPD represents increase in the material work function. In the 30 and 10 nm thick samples the CPD is larger at the GBs (Fig. 1b and e) in comparison with the grain interior, which means that the Fermi-level at the GBs is closer to the highest occupied molecular orbital (HOMO) level. In the 5 nm thick sample (Fig. 1h) a minor CPD variation was observed between the GI and the GBs. The CPD is actually increased in the locations where the SiO_2 is exposed. The simulations represented by the solid red lines will be discussed later in this section.

It has been proposed that oxygen may induce new chemical species in pentacene films, shifting the Fermi-level (E_F) towards to the HOMO level, causing *p*-type behavior of the organic semiconductor [13,14]. In our samples the pentacene is assumed *p*-type due to unintentional doping by chemical impurities [15] or by reaction with ambient oxygen and/or H_2O [16]; therefore an upward band bending as shown in Fig. 1c and f represents hole accumulation.

In order to analyze the holes accumulation (CPD increase) in the GBs, we have to consider the charge distribution for the case where the pentacene film thickness (t) is much smaller than the space charge region (SCR) width (w); in such a case an "incomplete" SCR is formed [17]. The surface space charge is "incomplete" in the sense that there is deficiency of charges (dopants) in the film to balance the negative interface charge sheet. Fig. 2a shows schematics of the polycrystalline pentacene where the GBs thickness is smaller than the grains interior (GI) and only unintentional doping is assumed. Fig. 2b shows the corresponding band diagrams in the vicinity of a GB (red lines) and a GI (black lines), respectively. In the absence

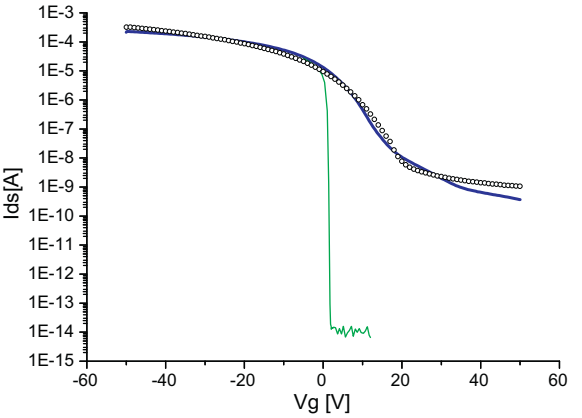

Fig. 3. Measurement (black dots) and simulations of source–drain current as a function of gate voltage of pentacene 30 nm thick film transistor. The simulation including interface traps (blue) is compared to the simulation without interface traps (green). The interface trap distribution responsible for the observed large V_t shift was calculated using: $N_0 = 5e12\ cm^{-2}$, $E_S = 0.22$, $E_0 = 0.55$ and the GBs trapped charge concentration was $N_{GB} = 3e11\ cm^{-2}$. It was assumed that the pentacene layer is compose of eight grains and their morphology was based on the AFM topography map.

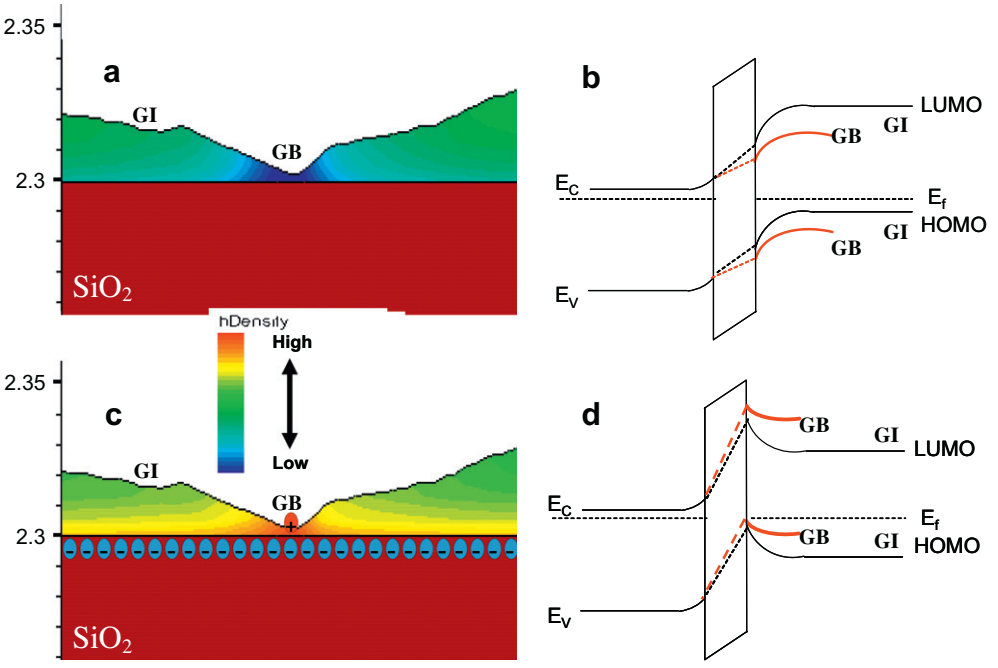

Fig. 2. Schematic charge distribution (a) and band diagram (b) for a pentacene transistor with no interface states and no trapped charge at the GBs. Schematic charge distribution (c) and band diagram (d) in the presence of interface states and trapped charge in the GB. The colour scale represents the mobile hole density in the pentacene film; the positive charge (red) represents trapped holes at the GB, and the negative charge (blue) represents trapped electrons. The grain boundary location is marked by (GB), and the grain interior location is marked by (GI). (a) and (c) clearly show that the space charge region at the vicinity of the GB is incomplete relative to the GI. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

of interface charge, there is a downward band bending in the pentacene layer due to the *n*-type Si substrate. This band bending is larger at the grain interiors *only because there are more acceptors there* (*due* to the pentacene thickness) *to accommodate a larger SCR*. This is clearly demonstrated by the different colours around the GBs in comparison with the GIs in Fig. 2a. Consequently, the SCR is smaller at the GBs leading to a local decrease in the work function and the measured CPD.

Based on these arguments a question arises why an upward band bending at the GBs (hole accumulation) is measured in the 10 and 30 nm thick pentacene films?

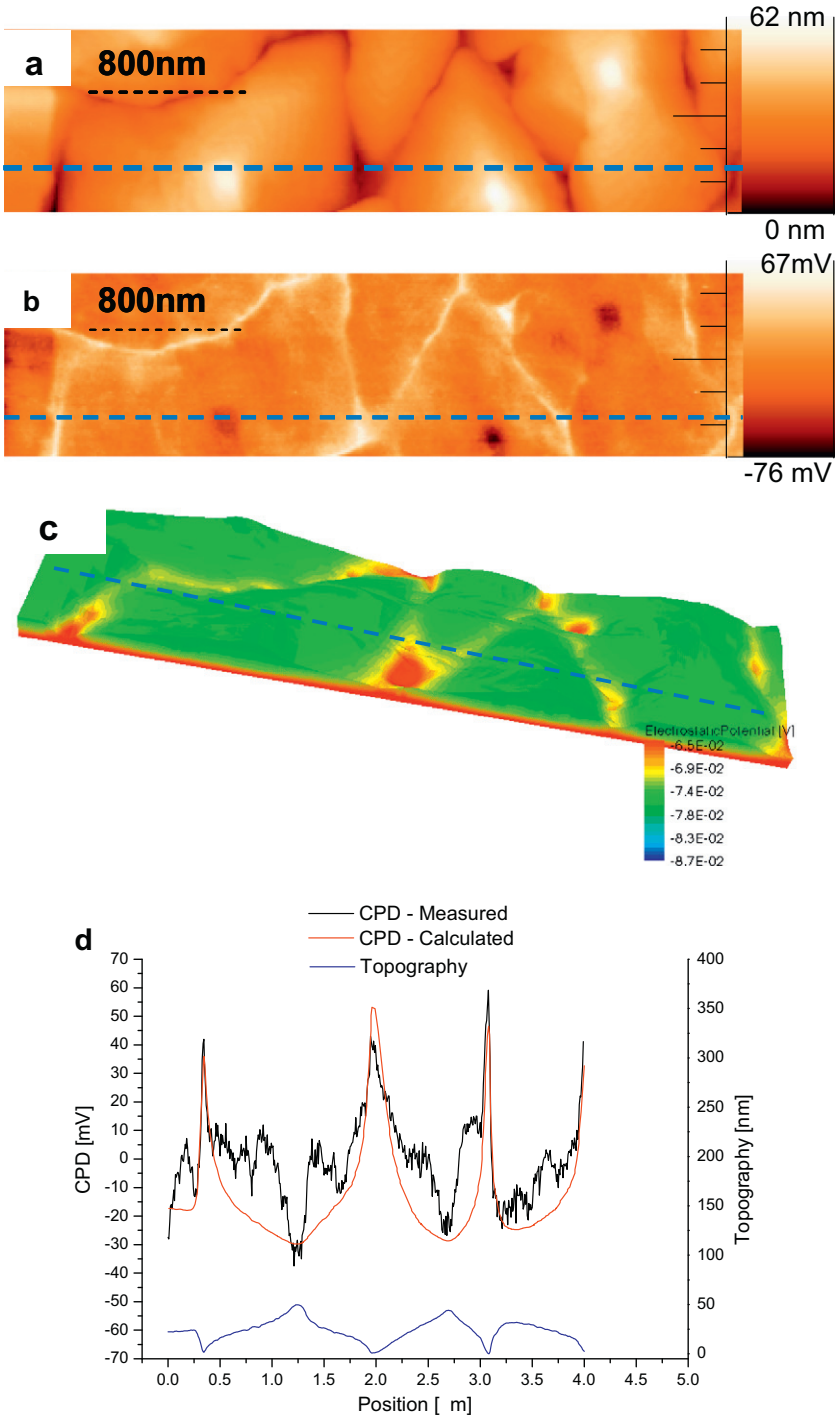

Fig. 4. (a) Topography, (b) measured CPD, (c) calculated CPD in 3D and (d) lines scans of the calculated and measured CPD of 30 nm thick pentacene film. The black line is the measured CPD, the red line is the calculated CPD and the blue line is the topography. The images were measured at $V_g = 0$. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

Below we show that this is due to the interface states present at the pentacene–SiO_2 interface. This interface state density is reported to be relatively high ($\sim 1 \times 10^{12}$ cm^{-2}) due to electron trapping by hydroxyl groups, present in the form of silanols at the SiO_2 pentacene interface [18]. The charge distribution is depicted in Fig. 2c where acceptor-like traps are present at the SiO_2–pentacene interface; the figure also shows the positive trapped charge in the GBs. The corresponding band diagram is shown in Fig. 2d. The negative interface charge induces accumulation of holes in the pentacene layer close to the interface, and consequently an upward band bending as shown in Fig. 2d. It should be noted that the effect of the GBs positive trapped charge is negligible in this case due to the short length of the boundaries, as will be discussed in more details later. In this case of upward band bending, the "incomplete" accumulation layer at the GBs leads to a larger work function and CPD at the GBs as shown schematically in Fig. 2d and by the KPFM measurement in Fig. 1. It should be mentioned that preferential oxidation at the GBs will increase the negative charge concentration there (ionized acceptors) [18] which will consequently reduce the CPD accordingly. However, this is in contrast to what is measured for thin films were the CPD is larger at the GBs. Moreover, this assumption alone cannot explain the CPD differences in the GBs between thin and thick samples demonstrated later on.

3.2. Electrostatic simulations

The simulations were calculated using a 3D device simulator TCAD Sentaurus (*Synopsys* Inc.) that solves the coupled Poisson and continuity equations for holes and electrons. We have assumed an exponential gap state distribution in the pentacene layer which was reported by several groups for thin amorphous organic films [19,20]. Our group have also measured such exponential density of state (DOS) by KPFM for an OFET structure [21]. Following Lang et al. [22] we have used an exponential trap distribution of the form:

$$g(E) = N_0 \exp\left(-\frac{|E - E_0|}{E_S}\right) \quad (2)$$

where E is the energy relative to the valence band edge, and N_0 and E_S are the coefficient and the characteristic energy width of the exponential trap distribution, respectively, and E_0 represents the energy of the conduction band minimum.

A unintentional dopant concentration of 5×10^{16} cm^{-3} was assumed in our simulations, although bulk traps may be present [19]. We have assumed that well-defined grain boundaries are present in the first few mono-layers of pentacene [23], although the evolution of GBs may be different compared with the upper part of the layer [24]. A positive trapped charge density at the GBs with constant energy distribution and with a concentration of $N_{GB} = 3 \times 10^{11}$ cm^{-2} was assumed. The physical parameters of the pentacene were taken from Ref. [25]. The pentacene layer morphology used in the simulations were based on the AFM measured topography.

The interface state density was obtained by comparing the transistor i–V curves to simulations conducted for the 30 nm thick transistor. The dotted line in Fig. 3a shows measured source–drain curve (I_{ds}) of a pentacene OTFT with a channel width of 5 mm and length L of 20 μm in the forward sweep (on to off) at an incremental gate voltage (V_{GS}) from −5 to 30 V in 1 V steps. The solid lines represent i–V simulations with (blue) and without (green) interface states, respectively. The observed large positive threshold voltage, V_{th}, shift is in agreement with previous studies [19,26] which showed that negatively charge interface traps are responsible for the large positive V_{th} shifts. The agreement between the simulation and the measured curve was obtained for an interface acceptor traps with $N_0 = 5 \times 10^{12}$ cm^{-2} eV^{-1}, $E_S = 0.22$ and $E_0 = 0.55$; the trap lateral distribution was assumed homogenous across the interface. We attribute the relatively high off current to the unintentional doping which takes place during the device preparation. Minor deviations in the i–V curves (not

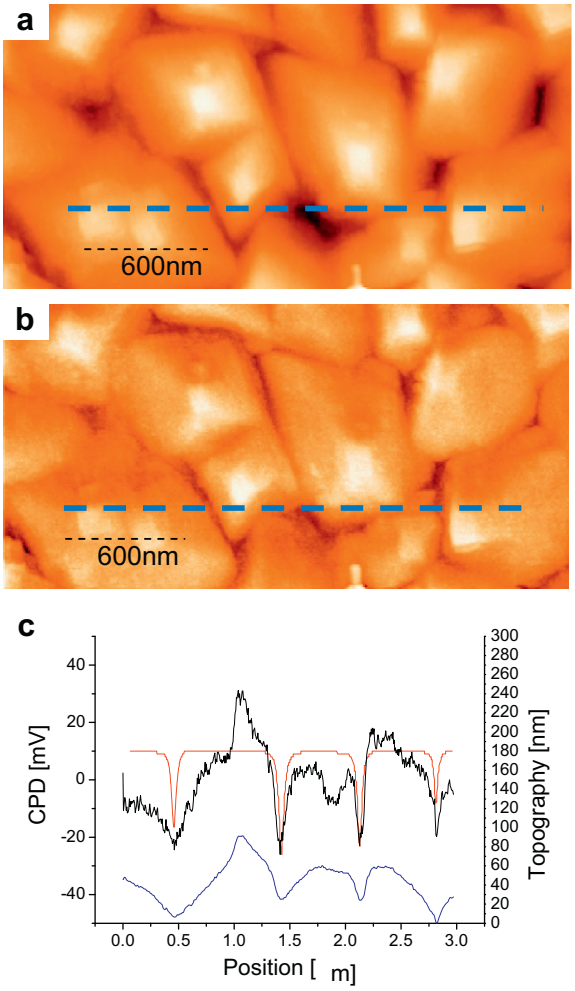

Fig. 5. (a) Topography, (b) measured CPD and (c) line scans of the calculated and measured CPD of 100 nm thick pentacene film. The black line is the measured CPD, the red line is the calculated CPD and the blue line is the topography. The images were measured at $V_g = 0$. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

shown) were observed as a function of trapped charge concentration in the GBs.

Fig. 1c, f and i summarizes the comparison between the simulated and the measured CPD for the 30, 10 and 5 nm thick samples, respectively. Some of the GBs at the 30 and 10 nm thick samples show larger CPD compared with the grain interior in qualitative agreement with the "incomplete" SCR phenomena described in details above. Fig. 1i shows that there are very small differences in the measured CPD between the GBs and grain interiors in the case of the 5 nm thick pentacene layer; this may be due to small variations in the film thickness between the GBs and the grain interior. The effect of trapping and accumulation of holes in the GBs was also reported recently by Hallam et al. [27] for conjugated polymers.

We may note that some GBs potential drops do not show good correlation with the simulated KPFM profile. This can be explained by differences in the local interface state density, different charge density in the GBs, variation in the GBs length and because the simulation are 2D. Since the CPD measurements at around the GBs are affected by the actual 3D electrostatic interactions, we have conducted 3D simulations on the 30 nm thick pentacene film as shown in Fig. 4. The figure shows the layer topography (a), measured CPD (b), calculated CPD (c) and line scan of the calculated and measured CPD (d). The calculations presented in (c) and (d) show that the CPD is larger at the GBs compared to the grain interior in a good agreement with the experimental results.

3.3. Thick pentacene layers

Fig. 5 shows topography (a) and KPFM (b) measurements conducted on a thicker (100 nm) pentacene layer. In such thick layers the interface charge is fully screened by the doped pentacene ($t \gg w$), and consequently the trapped holes in the GBs govern the surface potential rather than the interface states. This is demonstrated in Fig. 5b and c which shows that the CPD at the GBs is smaller than the GI; in the simulations shown in Fig 5c we have assumed that the GBs length is 30 nm. The CPD decrease in the GBs causes downward band bending and consequently hole depletion in the neighboring GIs. We argue that this is due to trapped holes in the GBs which are not screened as in the case of the thinner layers. Fig. 6 shows CPD calculation as a function of the GBs length for $V_g = 0$ V. The GBs length is define here as the distance between the GB surface and the pentacene–SiO_2 interface. The GBs length was varied from 2 to 30 nm while all the other parameters such as the GBs trapped charge, interface trap density and doping concentration were kept constant. The figure clearly demonstrates that for GBs length of less than 10 nm an upward band bending is predicted, while for thicker pentacene layers and longer GBs thickness a downward band bending is expected. This is in agreement with our assumption that for thin layers the GBs charge does not govern the measured CPD.

We have also simulated the effect of donor and acceptor type surface states. It was found that acceptor-like surface states decrease the potential drops in the GBs, while donor-like states increase it. Since the potential measured by the KPFM is affected by the overall charge distribution we cannot confirm or reject the presence of surface states at this stage. We emphasize that the density of surface states in organic materials is quite small because the molecules are typically closed-shell units with negligible concentration of dangling bonds. Based on all the above, we have not included surface states effects in the present study.

4. Summary and conclusions

We have presented a detailed experimental and numerical study of potential distribution at the GBs in pentacene thin film transistors. It was found that for thin film pentacene the CPD is larger at the GBs compare to the grain

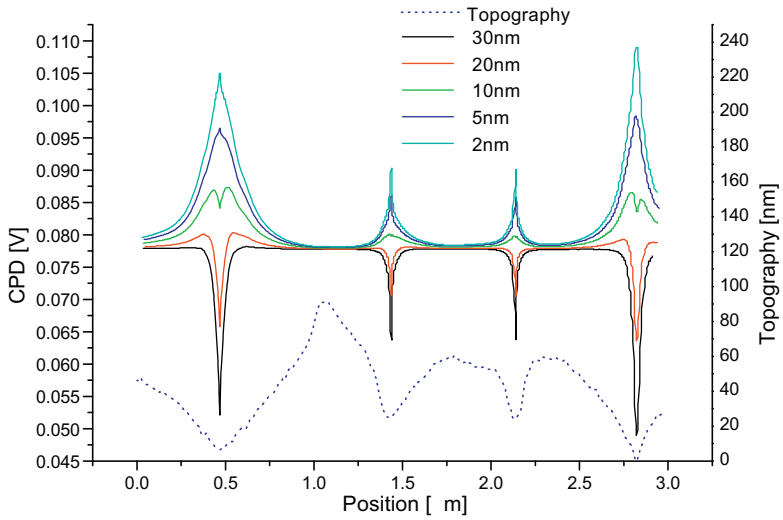

Fig. 6. Calculated potential profiles of different pentacene layers where the GBs length changes from 2 to 30 nm. The figure clearly shows that at a GB of around 10 nm the surface-potential change from accumulation to depletion.

interior. This phenomenon was attributed to interface trapped charge and to the "incomplete" accumulation in the GBs which consequently increases the local work function. On the other hand, in thick pentacene films we observed lower CPD at the GBs compared to grain interiors. In this case the trapped charge in the GBs governs the surface potential. The interface and the GBs trapped charge concentrations were evaluated by comparing the device transfer characteristics to the simulation and by solving the 3D electrostatic potential of pentacene GBs for different film thicknesses.

The effect of holes accumulation at the GBs in thin films may have a large effect on the carrier transport in such devices since it implies that the current density at the GBs may be larger compared to the grain interiors. This phenomenon is currently analyzed and will be the subject of future work.

Hydrostatic pressure sensor

ABSTRACT

We report on the preparation of hydrostatic pressure sensors, based on carbon sphere–polyvinyl alcohol composites deposited onto interdigitated electrodes, determining the pressure dependence of the conductance and capacitance of the devices. For these devices, we used carbon spheres with average diameter of 124 ± 13 nm at concentrations of 20%, 30% and 40%. The highest relative variation of conductance (0.69% kPa^{-1}) and capacitance (0.24% kPa^{-1}) was obtained using the composite with 30% carbon spheres.

1. Introduction

Pressure sensors are widely used in several different applications, like airflow measurement and in pressure control in confined vessels (for example tires, pipelines and microphones). Among the various existing pressure sensors [1–3], carbon black dispersed in a hosting polymer matrix has been demonstrated to constitute an interesting system due to the simple low-cost processes involved in their production, as well as their large and fast electrical response. Due to these advantages these systems have been applied to a number of pressure sensor systems, in most cases for uniaxial pressure measurement [4–7].

In conducting particles-host insulating polymer matrix composites, the pressure imposes changes on the average distance between the conducting particles mainly due to volume modification of the matrix, which changes the tunneling probability between conducting particles. By this mechanism, the conductance of the existing percolation paths is modified and new percolation paths may be created or suppressed, directly affecting the conductance of the medium. The capacitance of the system is also modified due to the variation of the separation distance of conducting particles by the insulating material.

In the past two decades a wide range of shaped carbon materials have been produced, including horns, onions, tubes, coils, etc. and many new methodologies to prepare the new and known shaped carbons have been extensively reported. This includes studies on spherical carbons (hollow, core/shell and fullerenes) [8] that are similar to the carbon blacks [9,10].

Herein we report on the use of carbon spheres (CSs) produced in a non-oxidizing environment, with a narrow size distribution, mixed with polyvinyl alcohol (PVA) as a hydrostatic pressure sensor. These CSs, with a narrow diameter range (124 ± 13 nm), are solid carbon balls made up of nanometric sized flakes, have a low surface area and are generally found accreted (Fig. 1). This means that clusters of the CSs are in contact with each other, similar to that found for carbon blacks. This accretion phenomenon should aid CSs in their ability to act in sensing devices.

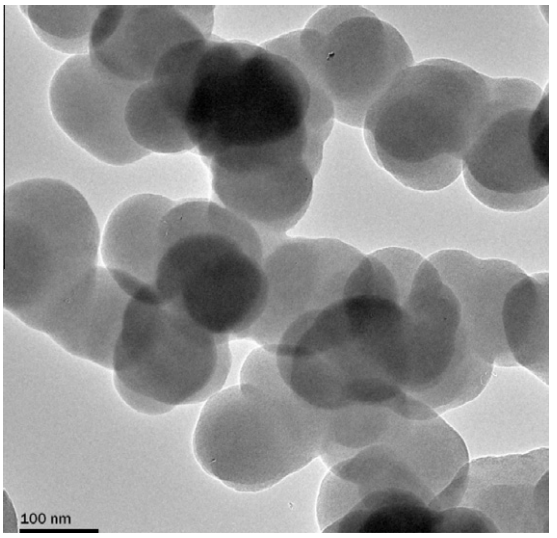

Fig. 1. Transmission electron micrograph of the carbon spheres.

2. Experimental

Polyvinyl alcohol was supplied by Sigma–Aldrich (average molecular weight 130,000) and used without further purification. The synthesis of the CSs was performed by passing a continuous flow of acetylene gas for 10 min at 900 °C, under an argon atmosphere through a quartz tube placed vertically inside a furnace. The acetylene and the argon gases were allowed to flow (100 mL/min each) from top to bottom through the quartz tube and the carbonaceous materials collected in a 500 mL round bottom flask, similar to that reported by Jin et al. [11]. The CSs were characterized by transmission electron microscopy (TEM) using a FEI Tecnai G2 Spirit electron microscope at 120 kV.

The devices were prepared as follows: PVA was added to 1,2-dichlorobenzene and the solution was heated to 80 °C and stirred for 30 min. This gave a homogeneous solution of PVA in the solvent (115 mg/mL). CSs were added to another sample of 1,2-dichlorobenzene, stirred for 30 min and ultrasonicated for 30 min at room temperature, using a 45 W ultrasonic bath, to obtain a uniform dispersion of CSs (2.2 mg/mL). Both solutions were then mixed at room temperature in a proportion chosen to give final solution compositions containing 20%, 30% and 40% CSs (w/w) concentration in the composite.

The pressure sensors used in this work were prepared by depositing the CS–PVA dispersion onto a $8 \times 9\ mm^2$ phenolite printed circuit board with nine pairs of 7.5 mm long tin-coated cooper interdigitated electrodes having a gap of 0.3 mm between them, in a rectangular geometry, as reported elsewhere [12,13]. A μL-pipette was used to deposit a CS–PVA dispersion by sequentially dropping 20, 30 and 35 μL (time interval of 60 min) onto the phenolite substrates.

The devices were then electrically characterized using a programmable Agilent 4284A LCR meter. An AC-signal amplitude of 500 mV was used as the operating voltage under environmental conditions. The pressure dependence measurements were made by placing the sensor in a cylindrical tube with a diameter of 44.5 mm in which the pressure was controlled manually with the aid of a piston (Fig. 2) following the relationship $h_i p_i = h_f p_f$, *i.e.*, the pressure in the cylindrical tube was varied by displacing the piston (h is the height, p is the pressure, i denotes initial and f denotes final) and neglecting the volume of the sensor.

3. Results and discussion

The transmission electron microscope (TEM) image of the CSs produced is shown in Fig. 1. From these TEM images it is evident that the solid CSs are accreted and have a narrow size distribution (diameter: 124 ± 13 nm). The synthesis of the spheres right from the beginning leads to accretion. Clustering of the spheres occurs either due to chemical interaction (accretion) or due to van der Waals interactions. The carbon chains involve from 2 to ~10

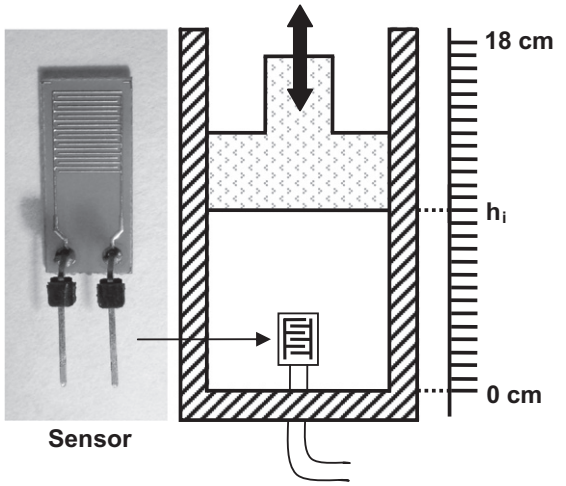

Fig. 2. Scheme of the experimental setup used for the pressure variation.

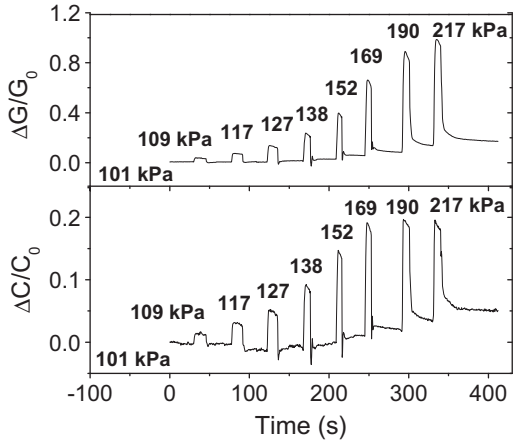

Fig. 3. Illustration of the electrical response of the device to pressure pulses of different magnitude.

spheres. The good yield and the simple production procedure constitute an advantage in using this material, when compared to other carbon materials that have been used in pressure sensors [2,14–16]. In addition, CSs are less expensive to synthesize than fullerenes and carbon nanotubes, and the synthesis constitutes a facile controllable synthetic methodology.

The current conductance G and capacitance C of the sensors were then measured as a function of applied hydrostatic pressure p at 27 kHz. This frequency was

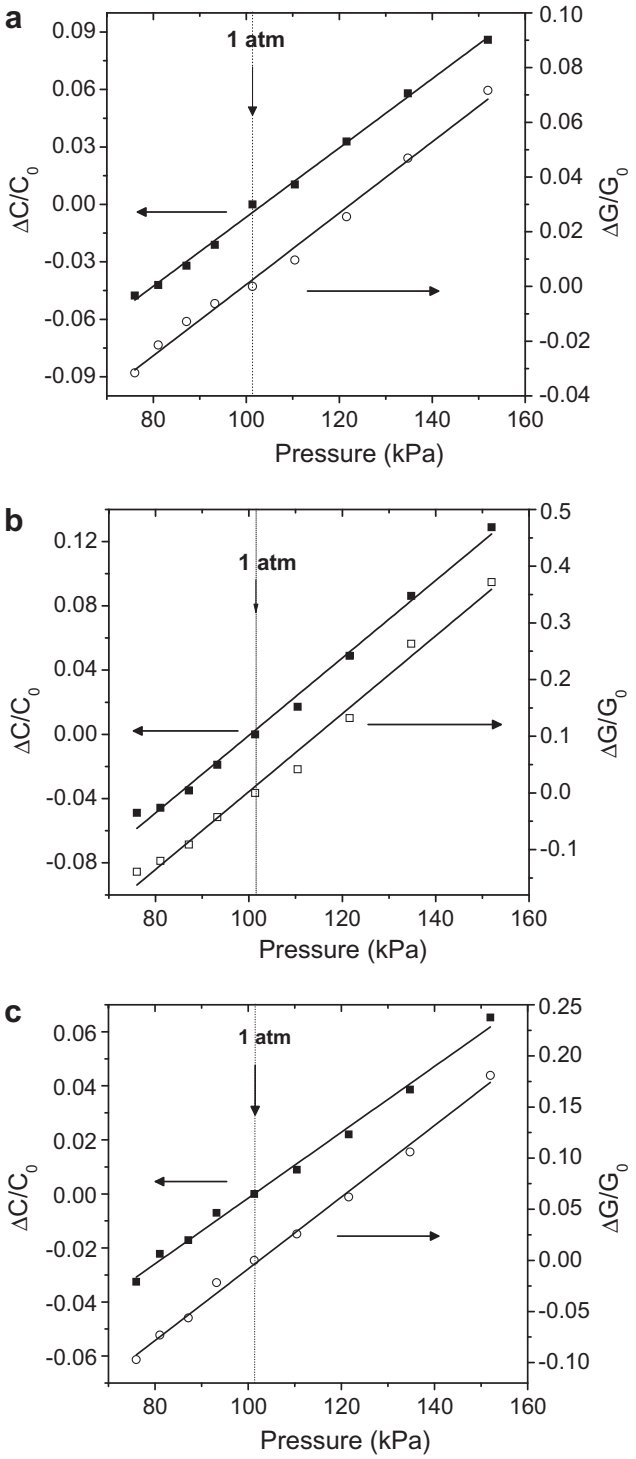

Fig. 4. Relative variation of the capacitance and conductance of devices prepared with different CS concentrations: (a) 20%; (b) 30%; and (c) 40%.

Table 1
Coefficients α_G and α_C as a function of the CS concentration in the device.

	CS concentration (w/w)		
	20%	30%	40%
α_G (kPa^{-1})	0.0013	0.0069	0.0035
α_C (kPa^{-1})	0.0018	0.0024	0.0012

chosen due to the low observed signal to noise ratio at this frequency. The data showing $\Delta G = G(p) - G_0$ and $\Delta C = C(p) - C_0$ (where the subscript 0 indicates initial value) were measured at $p_0 = 101.3$ kPa and are presented in Fig. 3.

It can be seen in Fig. 3 that the sensor responds to pressure variation in the range of atmospheric pressure to 217 kPa. In this experiment the pressure was periodically increased and then decreased back to atmospheric pressure, for different pressure pulse amplitudes. As can be observed, for pressure larger than *ca.* 150 kPa, the base line of the conductance was not recovered and for this reason the measurements were limited up to a maximum of 150 kPa. In the case of the capacitance measurements, the baseline problem was more pronounced and the relative capacitance variation due to pressure variation is small. As a consequence, the conductance was deemed to be more appropriate for measurements aimed at practical applications.

Figs. 4a–c shows the relative conductance variation and relative capacitance variation as a function of pressure, for CS concentrations of 20%, 30% and 40% (w/w). From this data, assuming a linearity of $\Delta G/G_0(p)$ and $\Delta C/C_0(p)$, the coefficients were calculated as follows:

$$\alpha_G \equiv \frac{\partial(\Delta G/G_0)}{\partial p} \tag{1}$$

$$\alpha_C \equiv \frac{\partial(\Delta C/C_0)}{\partial p} \tag{2}$$

The obtained coefficients are summarized in Table 1. It can be seen that both α_G and α_C showed higher values at a CS concentration of 30% and for this reason this is the most appropriate concentration to use for practical pressure sensors.

It is interesting to mention that these values are higher that those reported for carbon black or other polymer based sensors in the range of $p_0 \approx 100$ kPa. The estimate of α_C from the data reported by Arshak et al. for uniaxial stress gives $\sim 10^{-4}$ kPa^{-1} [6]. Wang et al. report $\alpha_G \approx 0.0012$ kPa^{-1} also for compressive stress [17]. From the data reported by Arshak et al. for polyvinylidene fluoride based sensors (in this case without carbon black) we also estimate $\alpha_C \approx 2 \times 10^{-3}$ kPa at $p_0 \approx 100$ kPa.

4. Conclusion

We have demonstrated that narrow size distribution CS–PVA composites at CS concentrations ranging from 20% to 40% are suitable for use as hydrostatic pressure sensors. In this particular work CSs with an average diameter of 124 ± 13 nm show promising results. Larger relative variation of the conductance was observed in devices with 30% CS concentration in both conductance and capacitance measurements.

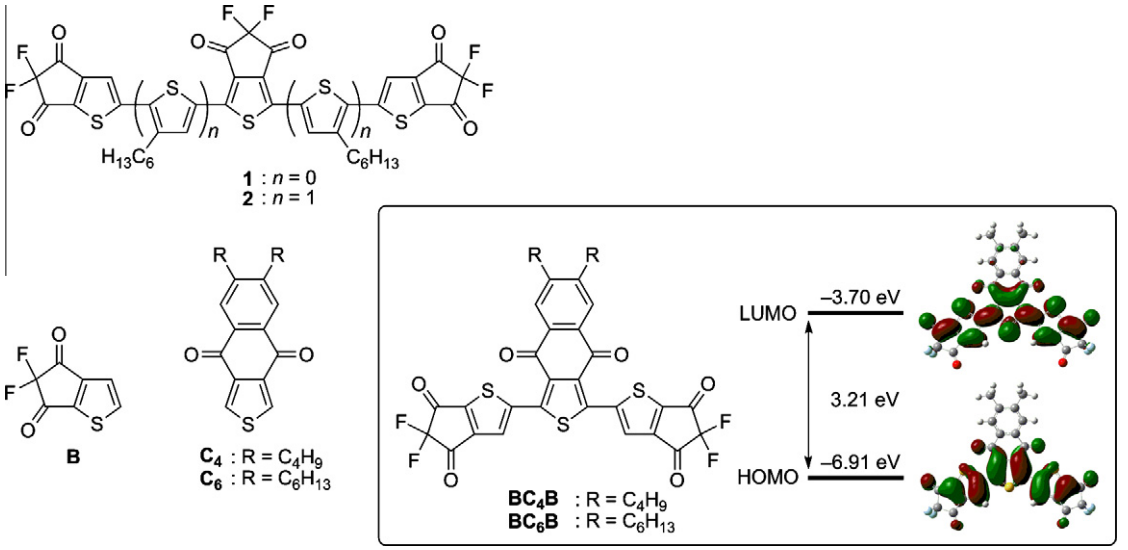

Fig. 1. Chemical structures of **1**, **2**, **B**, $\mathbf{C_4}$, $\mathbf{C_6}$, $\mathbf{BC_4B}$, and $\mathbf{BC_6B}$, and HOMO and LUMO energies of model compound (R=CH_3).

3-hexylthiophene [23]. It should be noted that the presence of electron-donating 3-hexylthiophene causes **2** to exhibit a relatively high LUMO energy level (−3.54 eV). In spite of this fact, OFETs fabricated using **2** by spin coating exhibited a field-effect electron mobility of $1.9 \times 10^{-4}\ cm^2\ V^{-1}\ s^{-1}$. Furthermore, X-ray diffraction (XRD) measurements indicated that the films fabricated using **2** were amorphous or less ordered. For further improving the electron mobility, it is important to both decrease the LUMO energy level and increase the efficiency of self-assembly in the solid state. Therefore, keeping this in mind, we have designed a dialkyl-substituted naphtho[2,3-*c*]thiophene-4,9-dione ($\mathbf{C_4}$ and $\mathbf{C_6}$) unit to be introduced into electronegative oligothiophenes. Herein, we describe the synthesis and properties of newly developed $\mathbf{BC_4B}$ and $\mathbf{BC_6B}$; we also report a substantial improvement in the performance of n-type OFETs, which is in the order of two orders of magnitude.

2. Material and methods

2.1. General Information

Preparative gel-permeation chromatography (GPC) was carried out with Japan Analytical Industry LC-908 equipped with JAI-GEL 1H/2H columns. ^{1}H NMR spectra were recorded on JEOL LA-400 in $CDCl_3$ with tetramethylsilane as an internal standard. Mass spectra were obtained on Shimadzu GCMS-QP-5050. UV–vis spectra were recorded on Shimadzu UV-3100PC. CVs were carried out on a BAS CV-620C voltammetric analyzer. Elemental analyses were performed on PerkinElmer LS-50B. The surface morphology of organic films was observed using an atomic force microscopy (Shimadzu, SPM-9600), and the film crystallinity was evaluated using an X-ray diffractometer (Rigaku, UltimaIV). X-ray diffraction patterns were obtained using Bragg–Brentano geometry with Cu Kα radiation as an X-ray source with an acceleration voltage of 40 kV and a beam current of 40 mA. $\theta - 2\theta$ scans were obtained between 2.5° and −30° a scanning step of 0.01°. The thickness of active-layer organic films was determined using a spectroscopic ellipsometer (HORIBA.UVISEL LT NIR-NNG).

2.2. Synthesis

4a: Compound **3** [24] (366 mg, 1.00 mmol) was placed in a two-necked round-bottomed flask, dissolved in CH_2Cl_2 (10 mL), and degassed with nitrogen. Next, anhydrous aluminum trichloride ($AlCl_3$) (533 mg, 4.00 mmol) was added to it at 0 °C. A solution of 1,2-dibutylbenzene (228 mg, 1.20 mmol) in CH_2Cl_2 (2 mL) was then added dropwise to the stirred mixture at 0 °C. After stirring the reaction mixture at 0 °C for 3 h, it was poured over ice and extracted with $CHCl_3$. The resulting organic layer was washed with water and dried over Na_2SO_4. After removal of the solvent under reduced pressure, the residue was purified by column chromatography on silica gel (hexane/ethyl acetate = 10/1) to yield **4a** (240 mg, 50%).

Yellow solid; Mp 133.5–134.5 °C; ^{1}H NMR ($CDCl_3$) δ 8.07 (s, 2H), 2.76 (t, 4H, J = 7.9 Hz), 1.62 (m, 4H), 1.45 (m, 4H), 0.97 (t, 6H, J = 7.3 Hz); MS (EI) *m/z* 484 (M^+); Anal. Calcd. for $C_{20}H_{20}Br_2O_2S_1$: C, 49.61; H, 4.16. Found: C, 49.89; H, 4.21.

4b: Compound **4b** was synthesized by following the procedure used for the preparation of **4a**, as a yellow solid with a yield of 74%. Mp 89–90 °C; ^{1}H NMR ($CDCl_3$) δ 8.06 (s, 2H), 2.74 (t, 4H, J = 7.9 Hz), 1.66 (m, 4H), 1.33 (m, 12H), 0.90 (t, 6H, J = 7.3 Hz); MS (EI) *m/z* 540 (M^+); Anal. Calcd. for $C_{24}H_{28}Br_2O_2S_1$: C, 53.35; H, 5.22. Found: C, 53.14; H, 5.08.

BC_4B: Compounds **4a** (58 mg, 0.12 mmol), **5** [22] (150 mg, 0.27 mmol), and tetrakis(triphenylphosphine)palladium(0) (25 mg, 0.02 mmol) were placed in a test tube; they were then dissolved in toluene (1 mL) and degassed with nitrogen. The resulting mixture was refluxed

for 15 h. After the removal of the solvent under reduced pressure, the residue was isolated by column chromatography on alumina ($CHCl_3$) to yield ketal-protected **BC_4B** (104 mg, 99%).

Yellow solid; Mp > 300 °C; ^1H NMR ($CDCl_3$) δ 8.06 (s, 2H), 7.66 (s, 2H), 4.30 (s, 16H), 2.75 (t, 4H, J = 7.9 Hz), 1.62 (m, 4H), 1.45 (m, 4H), 0.97 (t, 6H, J = 7.7 Hz); MS (EI) m/z 874 (M^+).

Ketal-protected **BC_4B** (104 mg, 0.12 mmol) was placed in a 50 mL round-bottomed flask and dissolved in THF (2 mL). Conc. H_2SO_4 (5 mL) was added to it, and the mixture was stirred at 60 °C for 12 h. The reaction mixture was poured over ice and extracted with ethyl acetate. The organic layer was washed with sat. $NaHCO_3$ aqueous solution and water and dried over Na_2SO_4. After the removal of the solvent under reduced pressure, the residue was first isolated by column chromatography on silica gel ($CHCl_3$), and then, the fraction containing **BC_4B** was further purified by GPC ($CHCl_3$) to obtain pure **BC_4B** (71 mg, 86%).

Yellow solid; Mp > 300 °C; ^1H NMR ($CDCl_3$) δ 8.08 (s, 2H), 8.05 (s, 2H), 2.80 (t, 4H, J = 7.9 Hz), 1.67 (m, 4H), 1.47 (m, 4H), 0.99 (t, 6H, J = 7.3 Hz); MS (EI) m/z 698 (M^+); Anal. Calcd. for $C_{34}H_{22}F_4O_6S_3$: C, 58.44; H, 3.17. Found: C, 58.72; H, 3.46.

BC_6B: Compound **BC_6B** was synthesized by following the procedure used for the preparation of **BC_4B**, as a yellow solid. Mp > 300 °C; ^1H NMR ($CDCl_3$) δ 8.08 (s, 2H), 8.05 (s, 2H), 2.79 (t, 4H, J = 7.9 Hz), 1.66 (m, 4H), 1.34 (m, 12H), 0.91 (t, 6H, J = 7.3 Hz); MS (EI) m/z 754 (M^+); Anal. Calcd. for $C_{38}H_{30}F_4O_6S_3$: C, 60.46; H, 4.01. Found: C, 60.42; H, 4.14.

2.3. Detailed device fabrication information

The field-effect mobility was measured using a thin-film field-effect transistor (FET) with bottom-contact geometry. A thermally grown silicon oxide (SiO_2) dielectric layer was formed on a gate substrate; this layer had a thickness of 300 nm and a capacitance of 10.0 nF cm^{-2}. An interdigital source and drain electrodes were constructed with gold (30 nm) that were formed on this SiO_2 layer. The channel width (W) and channel length (L) were 38 mm and 5 μm, respectively. The SiO_2 surface was washed with acetone and 2-propanol. It was then activated by ozone treatment and pretreated with octadecyltrichlorosilane (ODTS). The active layers were prepared by spin coating from 1.0 wt% chloroform solution at 1500 rpm for 1 min onto the substrate. Subsequently, the fabricated OFET devices were annealed at 200 °C for 30 min under a pressure of 10^{-3} Pa. Their current–voltage (I–V) characteristics were measured at room temperature under a pressure of 10^{-3} Pa or in air by using a KEITHLEY 4200 semiconductor parameter analyzer.

3. Calculation

All calculations were carried out using the Gaussian 03 program. The geometry of a model compound in which alkyl groups were replaced with methyl groups was optimized by the density functional theory (DFT) at the B3LYP/6-31G (d, p) level. As illustrated in Fig. 1, the highest occupied molecular orbital (HOMO) and LUMO are delocalized over the terthiophene-conjugated backbone. In addition, carbonyl groups are present in both the HOMO and LUMO, because of which these orbitals possess low-lying energy levels.

4. Results and discussion

The synthetic approach to our target compounds **BC_4B**, and **BC_6B** is depicted in Scheme 1. Friedel-Craft acylation of the corresponding 1,2-dialkylbenzene with 2,5-dibromo-3,4-thiophenedicarbonyl dichloride (**3**) in the presence of $AlCl_3$ yielded dioxo-substituted diboromothiophene **4a** or **4b** [24]. The ketal-protected counterpart **5** was synthesized by following the previously reported procedure [22]. The Stille coupling reaction of **4a** and **4b** with **5** and successive deprotection under acidic conditions afforded **BC_4B** and **BC_6B**, respectively, in moderate yields. The chemical structures of **BC_4B** and **BC_6B** were fully characterized by ^1H NMR, mass spectroscopy, and elemental analysis. As expected, these compounds were highly soluble in common organic solvents; therefore, they can be used to fabricate films by solution processing.

The data obtained from electronic absorption and electrochemical measurements provide important insights to ascertain the applicability of materials to organic electronic devices. As shown in Fig. 2a, the UV–vis absorption spectra of the oligomers in THF showed an absorption peak corresponding to the π–π^* transition band at 400–405 nm. Fig. 2b shows the results of CV carried out in fluorobenzene containing 0.1 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$). **BC_4B** and **BC_6B** show three reversible reduction waves with first half-wave potentials of −0.98 and −0.99 V, respectively; they do not show any oxidation wave within the potential window (+1.50 V). These measurements clearly indicate that the difference between the alkyl groups has little influence on the photophysical and electrochemical properties of **BC_4B** and **BC_6B**. Thus, the LUMO energy level of −3.8 eV for our π-conjugated system was calculated from the half-wave reduction potential of ca. −1.0 V, assuming that the energy level of ferrocene/ferrocenium (Fc/Fc^+) was −4.8 eV below the vacuum level [25]. This experimental estimate is in good agreement with the calculated values.

The electron mobilities of **BC_4B** and **BC_6B** were investigated by fabricating OFETs with a bottom-contact configuration. These OFETs were fabricated on the gate electrode of a p-doped silicon substrate. Source and drain gold electrodes with a channel width/channel length (W/L) of 38 mm/5 μm were prepatterned on a layer of SiO_2 dielectric. A thin film (650 nm thick) of **BC_4B** or **BC_6B** as an active layer was spin-coated from chloroform solution (1.0 wt%) on ODTS- treated SiO_2 dielectric. The electrical characteristics of the OFETs were measured under a vacuum condition (10^{-3} Pa). The field-effect mobility (μ) was calculated in the saturation regime at V_{DS} of 80 V using the equation $I_{DS}^{sat} = W/(2L) \cdot C_i \mu^{sat} (V_{GS} - V_{th})^2$, where C_i denotes the capacitance of SiO_2, and V_{th} the threshold gate voltage. Optimization experiments exploring annealing temperatures

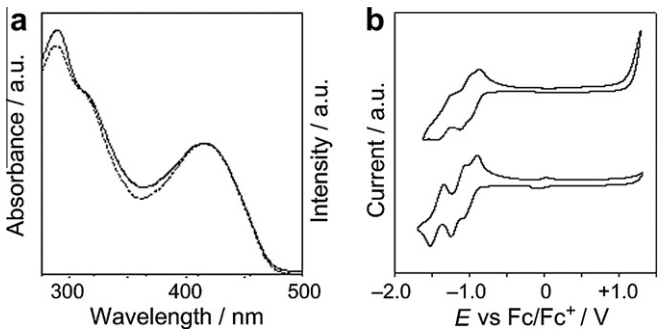

Fig. 2. (a) UV–vis spectra of **BC_4B** (dotted line) and **BC_6B** (solid line) in THF and (b) results of CVs of **BC_4B** (top) and **BC_6B** (bottom) in fluorobenzene containing 0.1 M $TBAPF_6$.

and surface treatments achieved a good electron mobility of 0.016 $cm^2 V^{-1} s^{-1}$. The extracted OFET parameters of the devices fabricated with **BC_4B** and **BC_6B** are summarized in Table 1, and the transfer and output characteristics of **BC_6B**-based device are shown in Fig. 3a and b, respectively. In order to investigate the stability of a **BC_6B** film under bias-stress conditions, we have also measured its source–drain current (I_{DS}) under continuous biases of gate voltage (V_{GS}) between −10 and 50 V with the source–drain voltage (V_{DS}) maintained constant at 50 V. As shown in Fig. 3c, the transfer characteristics exhibited a small degree of hysteresis even after 10 cycles under dual-sweep conditions, indi-

n-Channel field-effect characteristics of **BC_4B** and **BC_6B** in vacuum and air.

Compound	Measurement conditions	μ ($cm^2 V^{-1} s^{-1}$)	I_{on}/I_{off}	V_{th} (V)
BC_4B	Under vacuum	0.016	10^7	15
BC_4B	In air	5.3×10^{-4}	10^5	19
BC_6B	Under vacuum	0.014	10^6	10
BC_6B	In air	1.4×10^{-4}	10^5	18

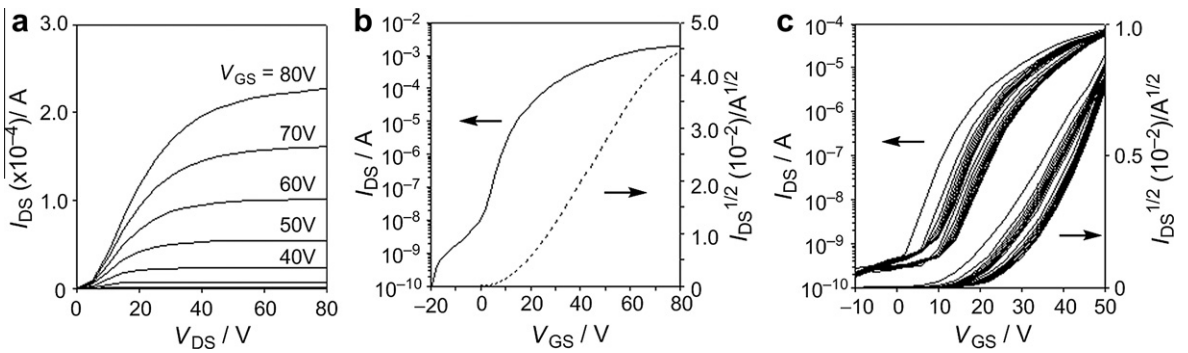

Fig. 3. (a) Output and (b) transfer characteristics of **BC_4B**-based OFET. (c) Transfer characteristics of **BC_4B**-based OFET with repeated biases for up to 10 cycles.

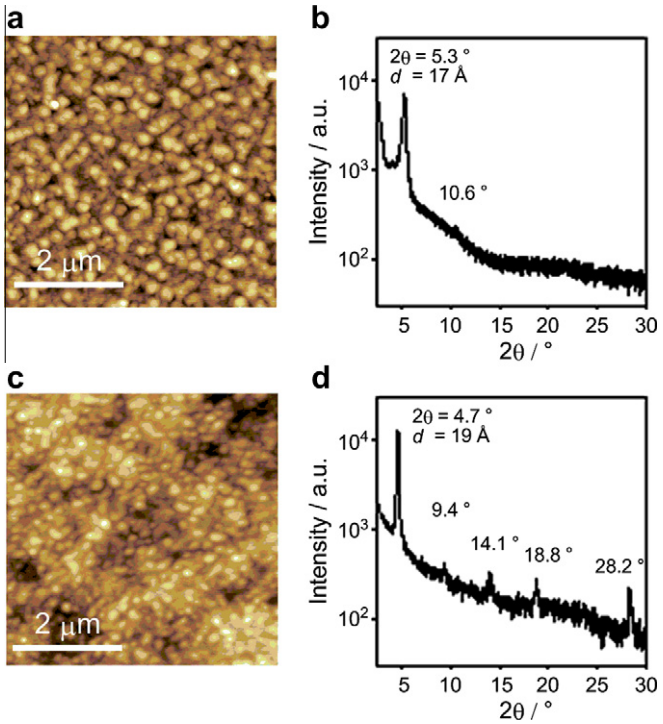

Fig. 4. (a) AFM images, (b) XRD data of a **BC_4B** film deposited on ODTS-modified SiO_2, (c) AFM images and (d) XRD data of a **BC_6B** film deposited on ODTS - modified SiO_2.

cating that this OFET possesses fair stability under switching operation. It is also important to note that **BC_4B-** and **BC_6B**-based OFETs can operate even after they are exposed to air for 1 h (Table 1). However, their performance was inferior to that obtained under vacuum conditions. This performance dependence on the operating conditions can be understood from the higher LUMO energy level (−3.8 eV) exceeding −4.0 eV, whose value is known to be on the borderline of gaining operational air stability [21,26,27].

In order to clarify the surface morphology and the alignment of molecules, AFM and XRD measurements have been performed on the **BC_4B** and **BC_6B** thin-films deposited on SiO_2 substrates. As shown in Fig. 4a and c, both the AFM images showed uniform deposition of the compounds over the SiO_2 surface with the formation of grains; segregation of the grains was not observed. XRD experiments revealed clear diffraction peaks (Fig. 4b and d), indicating that these molecules exhibited an ordered orientation in the solid state. These results clearly explain the formation of efficient electron-transporting pathways, which are responsible for improving the performance of the OFET.

5. Conclusion

In summary, n-type organic semiconductor materials comprising electronegative oligothiophenes have been successfully synthesized, and their electronic properties have been characterized. A combination of difluorodioxocyclopentene-annelated thiophene (**B**) and dialkyl-substituted naphtho[2,3-*c*]thiophene-4,9-dione (**C_4** and **C_6**) units ensured that an n-type OFET fabricated using the resulting terthiophene derivatives (**BC_4B** and **BC_6B**) not only exhibited solution processability but also good performance. An improvement in the performance of **BC_4B**- and **BC_6B**-based OFETs relative to that of the OFET fabricated using **2** can be rationalized on the basis of the low LUMO energy level and molecular ordering of these derivatives in the solid state. These results suggest that a sophisticated molecular design can pave a way for an improvement in the performance of OFETs.

ABSTRACT

The nonvolatile memory thin-film transistor (MTFT) using a solution-processed zinc–tin oxide (ZTO) semiconducting channel and a poly(vinylidene fluoride-trifluoroethylene) ferroelectric gate insulator was proposed. The crystalline phases of spin-coated ZTO films were essentially amorphous even when the films were annealed at 500 °C and the surface morphology was very smooth and uniform. Although the memory behaviors based on the ferroelectric field-effect were confirmed for all the fabricated MTFTs, the field-effect mobility, memory window, and the *on*/*off* ratio were markedly varied with the changes in annealing temperature and film composition of the ZTO channel. The origins for these differences were examined from the changes in electrical conductivities during the thermal process. The best device performances could be obtained for the MTFT using the 50/50 mol% ZTO channel annealed at 500 °C. The memory window at V_G sweep of ±15 V, field-effect mobility, subthreshold swing, and *on*/*off* ratio were obtained to be approximately 8.1 V, 15.8 $cm^2 V^{-1} s^{-1}$, 1.1 V/dec, and 6.4×10^7, respectively.

1. Introduction

Thin-film transistors (TFTs) using oxide semiconductors as active channel layers have attracted huge interest for use in the active matrix (AM) backplane of liquid–crystal display (LCD) [1] or organic light-emitting diode (OLED) display [2]. These technology trends are closely related to the fact that the oxide semiconductors with specified electronic configuration offer such features as high mobility, excellent uniformity, and robust stability, compared with the conventional TFTs using polycrystalline and amorphous Si. Requirements for flat-panel display with a larger size and a higher quality would accelerate the demand for the oxide TFTs. Although so many researches have not yet been reported [3–5], nonvolatile memory device application is also one of the most promising novel approaches employing the oxide TFT. The embeddable nonvolatile memory device having characteristics of mechanical flexibility and/or transparency to the visible light can provide us very interesting applications such as a lower-power display panel [6] and memory-embedded sensor sheet [7]. In enhancing the practical functionality of the next generation large-area electronics, this type of memory TFT (MTFT) can be an essential component, which can be realized by using the oxide TFT. Fully transparent nonvolatile memory transistors [8] and two-transistor-type memory cell composed of one access oxide TFT and one memory TFT [9] are good examples. In these approaches, the use of a ferroelectric copolymer as a gate insulator is desirable in the viewpoint of low-temperature process,

doi:10.1016/j.orgel.2010.08.002

because typical oxide ferroelectric material such as $Pb(Zr,Ti)O_3$ and $SrBi_2Ta_2O_7$ need a high temperature of more than 600 °C for their crystallization.

Solution-based process is an alternative powerful process for the large-area electronics, because it provides simpler process, lower cost, and higher throughput, compared with the vacuum-deposition-based process. A ferroelectric copolymer of poly(vinylidene fluoride-trifluoroethylene) [P(VDF-TrFE)], which has been typically employed for the memory application [10–12], can be simply formed by spin-coating method using precursor solution. As for the solution-processed oxide semiconductors, successful demonstrations were also reported for various materials of ZnO [13,14], indium–gallium–zinc oxide (IGZO) [15,16], indium–zinc oxide (IZO) [17,18], and aluminum–indium oxide (AIO) [19]. We have presented the device characteristics of the top-gate MTFT with P(VDF-TrFE)/IZO structure prepared by using the solution process [20]. Although the role of In is very important in order to achieve high field-effect mobility of the TFT, the use of In-free zinc–tin oxide (ZTO) is more preferable in viewpoints of resource shortage and eco-friendliness. ZTO has also been employed for the oxide TFT using vacuum-deposition [21–25] or solution-based processes [26–29] so far.

In this work, for the organic–inorganic hybrid-type MTFT application, solution-processed ZTO was chosen as a semiconducting active channel for the first time. The effects of the channel composition and process temperature on the memory and transistor behaviors were investigated for the fabricated MTFTs.

2. Experimental details

ZTO precursor solution was prepared by diluting and blending the commercial metal–organic solutions of 2.0 M ZnO and 0.5 M SnO_2 (SYM-ZN20 and SYM-SN05, Kojundo Chemical Lab. Co.). Firstly, each solution was diluted with n-butyl acetate [$CH_3COO(CH_2)_3CH_3$, CAS No. 123-86-4] to be 0.2 M, which was adjusted by considering the solution viscosity and the wettability on the substrate. Two final solutions with different molar ratios (Zn/Sn) of 83/17 and 50/50 were prepared by blending the previous diluted solutions. Dilution and blending processes were performed at 60 °C with stirring for more than 1 h. The solutions were filtered through a 0.45 μm syringe filter (cellulose) and then spin-coated on the substrates at 2500 rpm for 20 s. The thicknesses for the blended solutions with 83/17 and 50/50 molar ratios were obtained to be approximately 10 and 22 nm by one coating process, respectively. The thickness variation with the solution composition resulted from the viscosity difference between the initial solutions. The crystal structures of prepared films were investigated by using X-ray diffraction (XRD, Rigaku RU-200BH). The diffraction patterns were measured with Cu Kα radiation (40 kV/60 mA) at a scan rate of 2°/min. The surface morphology and roughness were examined by scanning electron microscopy (SEM) and atomic force microscopy (AFM), respectively. The sheet resistances of the prepared films were evaluated by the four-point probe method, which were measured with the temperature change in the range from room temperature (RT) to 400 °C.

The solution-processed MTFTs were fabricated using following procedures. Indium–tin oxide (ITO, 150 nm)-coated glass was prepared as a substrate. The ITO layer was patterned into the source/drain (S/D) electrodes using wet etchant. ZTO active layers with two molar ratios (83/17 and 50/50) were deposited by spin-coating method using the previously prepared precursor solutions onto the S/D patterned substrates. The coating processes were repeated twice with the interval of drying process at 250 °C for 10 m. After the ZTO channel regions were defined, thermal treatments were carried out in an oxygen ambient for 1 h, in which the annealing temperatures were varied to 400 and 500 °C in order to examine the temperature dependence for the solution-processed ZTO channels. P(VDF-TrFE) ferroelectric gate insulator was also deposited by spin-coating method using a 3 wt% diluted solution of P(VDF-TrFE) (70/30 mol%, Solvay Solexis) in methyl-ethyl-ketone (MEK). The coated film was crystallized at 140 °C for 1 h in an air ambient. The film thickness of P(DVF-TrFE) was approximately 200 nm. Then, the S/D contacts were opened by removing the given areas of P(VDF-TrFE) layer by using O_2 plasma with a reactive ion etching system (Samco RIE-10NL). The gate electrodes and S/D pads were finally formed by the deposition and patterning of Al film. The metal–ferroelectric–metal capacitors with the structures of Al/P(VDF-TrFE)/ITO were also fabricated through this series of fabrication process. The device properties of all fabricated MTFTs were characterized by using a semiconductor parameter analyzer (Agilent 4156 C). The ferroelectric behaviors of the P(VDF-TrFE) capacitor were examined by a ferroelectric capacitor evaluation system (FCE, Toyo Technica). All measurements were carried at RT in a dark box.

3. Results and discussions

3.1. Properties of solution-processed ZTO thin films

Fig. 1 shows the crystal structures of the prepared ZTO films and their variations with the changes in film composition and annealing temperature. In these evaluations, the film thickness of each film was intentionally increased to more than 100 nm to clearly compare the crystallinity and difference between the samples treated at different annealing temperatures. Feasible peaks for the ZTO can be referred from Joint Committee for Powder Diffraction Standards (JCPDS) File No. 24-1470, such as Zn_2SnO_4 (311) at $2\theta = 34.3°$, (400) at $2\theta = 41.7°$, (222) at $2\theta = 35.9°$, and (220) at $2\theta = 29.1°$. Any distinct peak was not detected over the range of annealing temperature from 250 to 500 °C for the ZTO films with 83/17 (Fig. 1(a)) and 50/50 mol% (Fig. 1(b)). Other phases corresponding to the $ZnSnO_3$ (JCPDS File No. 11-0274), ZnO (JCPDS File No. 36-1451), and SnO_2 (JCPDS File No. 41-1445) were also not detected. Although a tiny and broad peak of approximately 34°, which was observed for the 50/50 mol% film annealed at 400 or 500 °C, appeared, the obtained XRD patterns indicate that the solution-processed ZTO films are basically

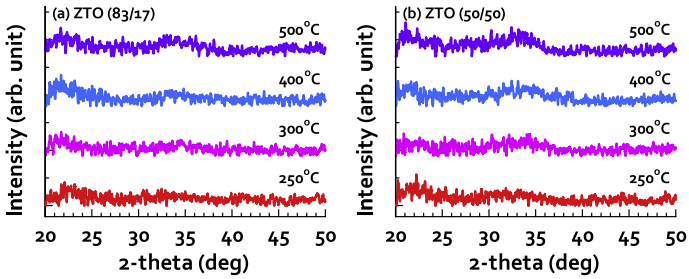

Fig. 1. X-ray diffraction patterns for the ZTO films with different molar ratios (Zn/Sn) of (a) 83/17 and (b) 50/50 at different annealing temperatures of 250, 300, 400, and 500 °C.

amorphous phases, which is consistent with the previous reports [21,27,28].

Fig. 2(a) and (b) shows top-view SEM images of the spin-coated 400 °C-annealed ZTO films with two compositions. The root-mean-square (rms) roughness was also evaluated by AFM, as shown in Fig. 2(c) and (d). The rms roughnesses were estimated to be approximately 0.39 and 0.44 nm for the ZTO films with 83/17 and 50/50 mol%, respectively. It was also found that the surface roughness was not degraded even after the 400 °C-annealing process. These results reveal that the ZTO films have very smooth and homogenous surface and shows no crystalline grains, which is in agreement with XRD results.

3.2. Device characterizations of memory TFT

Prior to the characterization of the fabricated MTFTs, the basic ferroelectric properties of the Al/P(VDF-TrFE)/ITO capacitors were confirmed, as shown in Fig. 3. Top electrode size was defined to be $50 \times 50\ \mu m^2$, which was comparable to the gate area of the memory transistors, by conventional patterning process performed on the P(VDF-TrFE) films. The remnant polarization (P_r) and coercive field (E_c) were typically measured to be approximately 9.6 $\mu C/cm^2$ and 930 kV/cm, respectively, at the frequency of 1 kHz. This result suggest that the prepared P(VDF-TrFE) thin film showed sufficiently good ferroelectric natures even when the ITO bottom electrode was employed and

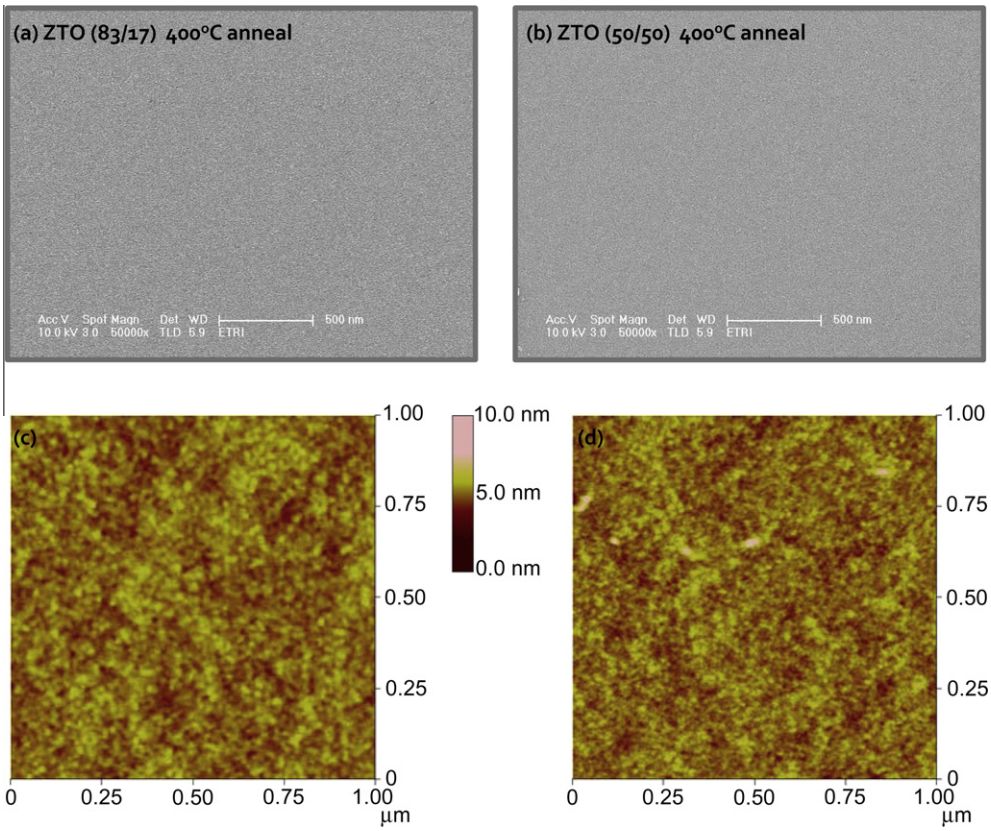

Fig. 2. SEM and AFM images of surface morphologies for the 400 °C-annealed (a), (c) 83/17 mol% and (b), (d) 50/50 mol% ZTO films, respectively. The rms values were evaluated by AFM images.

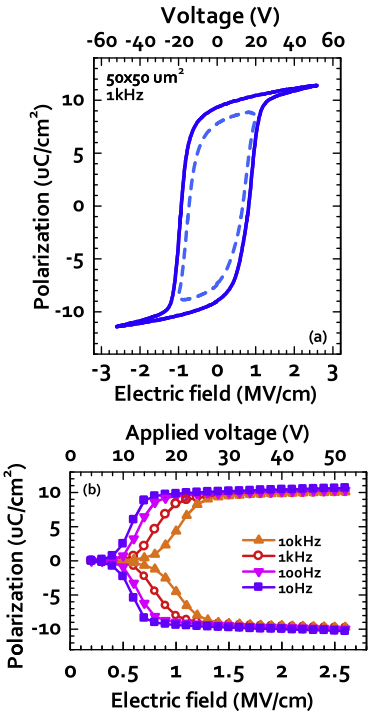

Fig. 3. (a) *P*—*E* characteristics of the Al/P(VDF-TrFE)/ITO capacitor with size of 50×50 μm^2, which was fabricated with the MTFTs on the same substrate. The measurement frequency was set to be 1 kHz. The solid and dotted curves correspond to the *P*—*E* hysteresis obtained at the electric field of 2.6 and 1.0 MV/cm, respectively. (b) Polarization saturation behavior with the increase of applied electric field at various measurement frequencies from 10 Hz to 10 kHz.

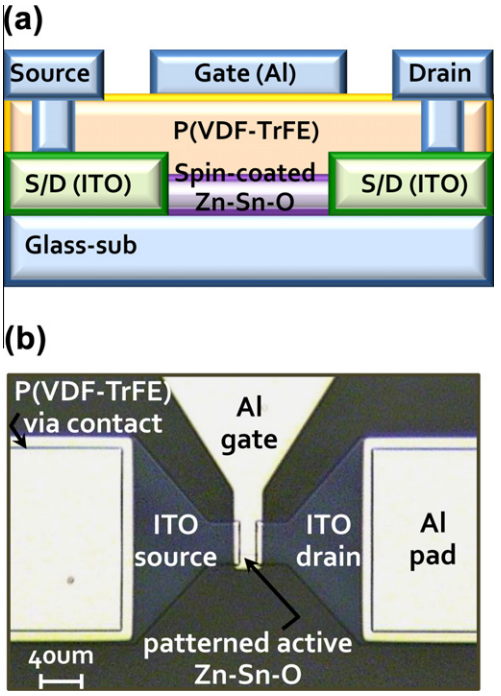

Fig. 4. (a) Schematic cross-sectional diagram and (b) photograph of the top-gate MTFT composed of the solution-processed ZTO active channel and the P(VDF-TrFE) gate insulator, respectively.

patterning process was conducted. It is also interesting to investigate the polarization saturation behavior with the increase of the electric field applied across the ferroelectric film, which provides useful criteria for determining the operation conditions of the MTFT. The electric field required to obtain the full saturation in the ferroelectric polarization decreased with the decrease in signal frequency. It means that the memory behaviors of the proposed MTFT may be sensitively influenced by the duration of programming voltage signals as well as the voltage amplitude [30–34]. The detailed discussions were described in another publication [35].

A cross-sectional schematic diagram and an optical microscope image of the fabricated solution-processed MTFTs using the ZTO channels were shown in Fig. 4(a) and (b), respectively. Fig. 5(a) and (b) shows the drain current (I_D)-gate voltage (V_G) characteristics of the MTFT employing the ZTO channel with 83/17 and 50/50 molar ratios, respectively, when the annealing temperature for the ZTO film was varied to 400 and 500 °C. Each transfer curve was measured in a double sweep mode of V_G (−15 to 15 V) at the drain voltage (V_D) of 5.0 V. The gate width (W) and length (L) of measured devices were 40 and 20 μm, respectively. Although the ferroelectric field-effect-driven counterclockwise hystereses in forward and reverse sweep of V_G were obtained for all devices, there are remarkable differences in device behaviors with the variations in channel composition and annealing temperature. The typical device characteristics such as threshold voltage (V_T), channel field-effect mobility (μ_{FE}), subthreshold swing (SS), and *on*/*off* ratio were summarized in Table 1. For the case of the MTFT using 83/17 mol% ZTO channel, the current drivability was absolutely insufficient. As results, the μ_{FE} and *on*/*off* ratio were no more than 0.02 $cm^2\ V^{-1}\ s^{-1}$ and 1.4×10^5, respectively, even when the annealing temperature increased to 500 °C. The Sn composition was increased to 50 mol% with all, the μ_{FE}, SS, and *on*/*off* ratio were at a standstill for the 400 °C-annealed ZTO channel. Dramatic improvement in TFT performances could be obtained for the 50/50 mol% ZTO channel annealed at 500 °C, that is, the μ_{FE} and *on*/*off* ratio were markedly enhanced to be 15.8 $cm^2\ V^{-1}\ s^{-1}$ and 6.4×10^7, respectively. It was also very inspiring that the *off* current was remained to be as low as 10^{-12} A.

Besides the TFT performances, there was an impressive variation in memory window (MW), which is defined as voltage width of turn-on voltage shift in transfer curve, among the evaluated controlled devices, as shown in Fig. 5(c). When the V_G sweep range was varied from ±10 to ±20 V, the MW for the MTFT using 83/17 mol% ZTO channel annealed at 400 °C increased from 2.4 to 5.9 V. On the contrary, for the MTFT using 50/50 mol% ZTO channel annealed at 500 °C, much larger value of MW was obtained to be in the range from 5.6 to 10.6 V. Because the E_c was estimated to be approximately 690 kV/cm at the applied voltage of ±20 V (dotted line in Fig. 3(a)), the MW was expected to be more than 25 V. However, this estimation cannot be generally applicable in the real

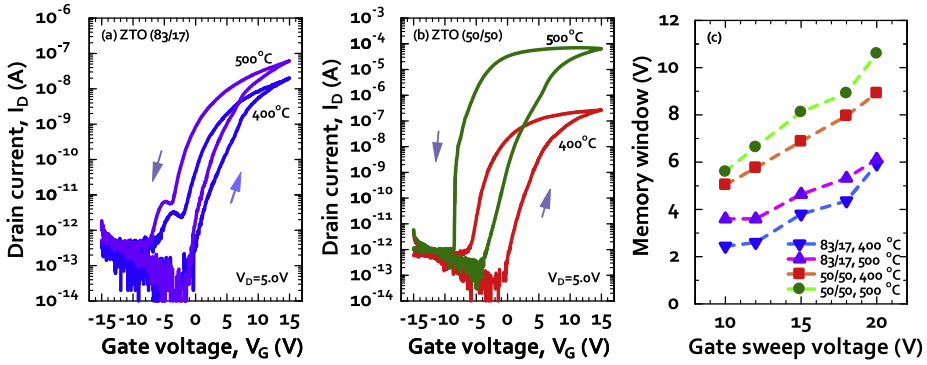

Fig. 5. I_D–V_G characteristics of the fabricated MTFT using the (a) 83/17 mol% and (b) 50/50 mol% ZTO channels. The annealing temperature for the ZTO channels were varied to 400 and 500 °C. All measurements were performed in a double sweep mode of V_G in the range of ±15 V at the V_D of 5.0 V. Arrows indicated in the plots represent the direction of hysteresis in I_D. (c) Variation of memory window for each MTFT when the sweep range of V_G was varied from ±10 to ±20 V.

Table 1
Summary of main process parameters and device characteristics of the fabricated MTFTs using the solution-processed ferroelectric P(VDF-TrFE) gate insulator and ZTO active channel.

Composition (Zn/Sn, mol%)	Annealing temp. (°C)	Threshold voltage (V)	Field-effect mobility (cm^2/V s)	S-Swing (V/dec)	Memory window (15 V) (V)	On/off ratio
83/17	400	4.7	0.007	2.85	3.8	4.3×10^4
	500	4.0	0.02	1.81	4.6	1.4×10^5
50/50	400	3.9	0.07	1.46	6.9	3.8×10^5
	500	4.0	15.8	1.07	8.1	6.4×10^7

situation. We have to remind couple of important issues for the device operation of the proposed ferroelectric-driven MTFTs. The first investigation is related to the fact that the oxide channel layer is fully or partially depleted at the negative V_G region (at *off* operation). Once the depletion layer is formed within in the channel, it remains an insulating layer at the *off* state, because the inversion carriers cannot be formed easily for the oxide semiconductor such as ZTO unlike the case of Si. Therefore, the voltage applied to the gate stack is distributed with the capacitance coupling. This feature of oxide semiconductor channel results in the second consideration. Considering that this MTFT operates in accumulation/depletion mode, it would be very difficult to establish the condition to fully compensate for the ferroelectric polarization charge at the ferroelectric/semiconductor interface. Moreover, because the film thickness of channel layer for this application is generally in the range of several nano-meters, only a small charge density is induced at the surface of semiconducting channel even for the accumulation state. Assuming that the carrier concentration (N_D) of the 40-nm thick ZTO film is $10^{18}/cm^2$, the induced semiconductor charge (qN_Dd, where d is semiconductor channel thickness) is roughly estimated to be approximately 0.6 μC/cm^2, which is much smaller than the ferroelectric P_r. Therefore, the channel thickness [5] and initial carrier concentration of the oxide channel layer have an important effect on the memory margin, which is expressed as the MW and memory *on*/*off* ratio. Actually, the variations in MW obtained for each device were observed to be sensitively affected by the differences of the ZTO channel conductance (Fig. 5(c)). Eventually, it was found that the solution-processed 83/17 mol% ZTO channels were not so suitable for a memory device as well as for a conventional TFT because of their too low carrier concentration and field-effect mobility.

In order to examine the differences in channel conductance and conduction mechanism of solution-processed ZTO channels with different film compositions, the variation in electrical conductivity (σ_c) was measured at the forward and reverse sweeps in temperature, as shown in Fig. 6. The ramping rate was set to be 5 °C/min. The σ_c typically increased and decreased with the increase and decrease of temperature, respectively, in the range from 250 to 400 °C. This reveals that the semiconducting behaviors of the prepared ZTO films appeared in this temperature range. However, obvious differences were observed with the changes in film composition, such as the activation energies of *in-situ* σ_c during the ramp-up ($E_{a,up}$) and ramp-down ($E_{a,down}$) periods, the value of σ_c at 400 °C, and the final σ_c after the ramp-down process. When the temperature approached to 400 °C, the σ_c's of 83/17 and 50/50 mol% ZTO films were approximately 1.4×10^{-5} and 7.3×10^{-5} S/cm, respectively. Although we could not increase the temperature up to 500 °C owing to the temperature limit of the measurement system, the σ_c difference between the films was expected to be much larger at 500 °C. It is also noticeable for the 50/50 mol% ZTO film that there was a significant variation between the $E_{a,up}$ and $E_{a,down}$ of *in-situ* σ_c, and that two distinct temperature region representing different values of $E_{a,up}$ ($E_{a,up1}$ and $E_{a,up2}$) were observed at

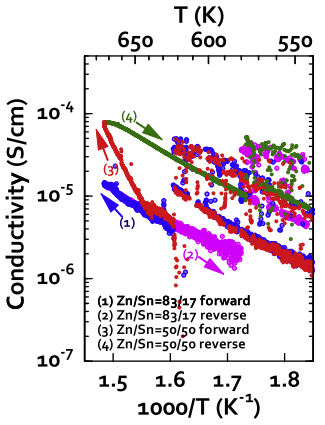

Fig. 6. Variation of electrical conductivity for the ZTO film with 83/17 and 50/50 mol% in terms of Arrhenius plot, which was *in-situ* measured for the forward and reverse directions in temperature from RT to 400 °C. The ramping rate was 5 °C/min. The data points of (1) in blue, (2) in pink, (3) in red, and (4) in green correspond to the forward and reverse sweeps for the 83/17 mol% and those for the 50/50 mol% ZTO film, respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

the vicinity of 370 °C. The values of $E_{a,up}$ and $E_{a,down}$ for each film were summarized in Table 2. For the case of 83/17 mol% ZTO film, the $E_{a,up}$ and $E_{a,down}$ were calculated to be similar values of 0.87 and 0.82 eV, respectively. While the $E_{a,up1}$ and $E_{a,down}$ for the 50/50 mol% ZTO film was also in the range from 0.80 to 0.77 eV, the $E_{a,up2}$ abruptly increased to 2.23 eV above the temperature of 370 °C. These results suggest some important insights related to the effect of annealing temperature and corresponding electrical behaviors of ZTO channel layers. The observed activation energies of lower than 1 eV can be mainly explained by the simple thermal excitation of the electrons in the semiconducting films [36], in which the conduction mechanism activated below the given critical temperature range was not so varied with the Zn/Sn compositions. On the contrary, the larger $E_{a,up2}$ values observed at higher temperature region for the 50/50 mol% ZTO film may result from the additionally generated free electrons. Consequently, the σ_c could be modulated by controlling the annealing temperature and film composition. The electronic configuration and effective density of states, which are intrinsically varied with the Zn/Sn molar ratio, have a critical impact on the semiconducting behaviors of the solution-processed ZTO films. Once free carriers are activated by the appropriate thermal treatment, they work even when the temperature was reversed to RT. The $E_{a,down}$ observed for the 50/50 mol% ZTO film well reflects this investigation. The second scenario is closely related to the fact that the H_2 and/or H_2O-based species incorporated in the ZTO films diffused out at high temperature. This process generates ionized oxygen vacancies and free electrons doped into the film [36]. These phenomena can be accelerated by the increase in Sn composition within the ZTO film.

Table 2
Summary of activation energies of *in-situ* electrical conductivity with the forward ($E_{a,up}$) and reverse ($E_{a,down}$) sweeps in temperature, which were calculated by Arrhenius plots for the solution-processed ZTO films with different compositions of 83/17 and 50/50 mol%.

	Zn/Sn (83/17)	Zn/Sn (50/50)
$E_{a,up1}$ (eV)	0.87	0.80
$E_{a,up2}$ (eV)	–	2.23
$E_{a,down}$ (eV)	0.82	0.77

As results, we can conclude that the most desirable behaviors for the proposed MTFT could be obtained when the ZTO channel composition was controlled to be 50/50 mol% and the annealing process was performed at 500 °C. In most previous literatures, the conventional oxide TFTs using the solution-processed ZTO channel were fabricated with the bottom gate structure, in which the μ_{FE} was reported to be in the range from 0.7 to 14 $cm^2\ V^{-1}\ s^{-1}$ at the annealing temperature of 500 °C [27–29]. The TFT *on/off* ratios of those devices were approximately from 10^7 to 10^8. Although a larger μ_{FE} of 16 $cm^2\ V^{-1}\ s^{-1}$ was obtained for the ZTO channel annealed at 600 °C, the *on/off* ratio was degraded to 10^5 owing to the marked increase of *off* current level (10^{-8}) [26]. Besides, the process temperatures of higher than 500 °C cannot be conventionally applicable for the large-area electronics employing low-cost glass substrates. From these investigations, we can say that the TFT performances obtained in this work were sufficiently good compared with those for the previously reported devices using the solution process for the ZTO channel layer.

4. Conclusions

The nonvolatile memory TFT using a solution-processed ZTO channel and a ferroelectric P(VDF-TrFE) gate insulator was fabricated for the first time. The spin-coated ZTO films were essentially amorphous phase and their surfaces were very smooth. The electrical natures of the ZTO films were found to be sensitively affected by the film composition and/or annealing temperature. Although all MTFTs exhibited ferroelectric field-effect-driven memory window in their I_D–V_G characteristics, there were marked variations in device performances. While the film composition of Zn-rich phase and the annealing temperature of lower than 500 °C were not so desirable in realizing the proposed MTFT with good performances, the excellent device characteristics of the MTFT were successfully confirmed when the 50/50 mol% ZTO channel was treated at 500 °C. The memory window at V_G sweep of ±15 V, μ_{FE}, SS, and *on/off* ratio were approximately 8.1 V, 15.8 $cm^2\ V^{-1}\ s^{-1}$, 1.1 V/dec, and 6.4×10^7, respectively. It is also inspiring that the *off* current could be suppressed as low as 10^{-12} A. A relatively high thermal budget is one of the issues to be considered as future works. We conclude that the electrical properties of the ZTO film could be improved by controlling the process conditions, and that the solution-processed amorphous ZTO film is very promising as a semiconducting channel for our proposed memory device using organic ferroelectric GI. These embeddable memory transistors fabricated via simple solution process could enhance the functionality of next-generation large-electronic devices and systems.

ABSTRACT

In this work we study the electric field dependence of mobility extracted from Electroluminescence Transient (ELT) measurements in both single carrier and double carrier Polymer Light emitting Diode (PLED) configurations by varying the cathode. We have chosen two different families of conjugated light emitting polymers (structurally different hole transporting materials). The Poole–Frenkel (P–F) plot of mobility μ as a function electric field F ($\log \mu \propto \sqrt{F}$) shows negative slope ($\beta < 0$) in the case of double carrier injection, while positive slope is observed as expected in the case of dominantly single carrier injection. The mobility values and their corresponding field dependent parameters for both the carriers are derived. It is shown that electrons injected to higher lying transport states can have high mobilities behaving as hot electrons. We propose a phenomenological model based on alignment of Gaussian local density of states (DOS) to explain the occurrence of reduction of mobility with increasing electric field for electrons, which do not fully relax into equilibrium distribution within the DOS in the timescales of transit time.

1. Introduction

Since the discovery of electroluminescence (EL) in conjugated polymers, both the science and technology of conjugate polymer based electronics have progressed unabated for the last two decades [1,2]. Their potential applicability in flat panel and flexible displays, lighting and thin film transistors motivate much of the current research. In these electronic systems, most of the opto-electronic processes and properties have been described using the framework of Gaussian density of states (DOS). The Bässler's Gaussian disorder model consisting of energetic and positional disorder have been successful in the interpretation and understanding of charge carrier transport in thin films of conjugated polymers, and specifically the temperature and electric field dependence of carrier mobility [3,4]. Carrier mobility, being one of the most significant parameters from both understanding and application points of view, has been studied by many methods. Often however, the results from different methods are not consistent and get mired in interpretative difficulties. In contrast to steady state methods involving J–V characteristics of specially designed samples [5], the most reliable methods of determination of mobility involve transient experiments such as Time-of-Flight (TOF) technique [6], transient current method [7], Charge Extraction by Linearly Increasing Voltage (CELIV) [8], and Electroluminescence Transient (ELT) [9]. The mobility in these cases is deduced from the transit time (t_{tr}) or delay time (t_d) for charge carrier in organic layer as

$$\mu = \eta \frac{d^2}{t \times V} \tag{1}$$

where t is the transit time or delay time observed, d is layer thickness of sandwiched device and V is the voltage drop

across it. Here η is a correction factor for different situations, for example, in case of TOF and ELT, the value of η is unity while for current transient $\eta = 0.786$.

The carrier mobility has been observed to increase with increasing electric field following Poole–Frenkel (P–F) model [5,10,11]. However, decrease in mobility with increasing electric field has also been observed for a variety of conjugated polymers [12,13], molecularly doped polymers [14,15], regioregular poly (alkylthiophenes) [8,16] polymer blends [17] etc., with Al or Au as cathode (except the case in Ref. [15] where Ca cathode was used). This phenomena has been sought to be understood using a variety of ideas such as Peled's empirical approach [14], Hirao's emphasis on correct determination of transit time free from field assisted diffusion [18], use of CELIV method [8,16], Marcus models in inverted regime [19], and Bässler's positional disorder formalism [19,20]. Among these, Bässler's positional disorder correction and their variants have been invoked most often to explain the occurrence of negative P–F coefficient in field dependence [21].

In this paper, we specifically focus on the occurrence of decrease in mobility with increasing electric field contrary to standard expectations. A coherent understanding of such observations is yet to emerge. Within the Gaussian disorder model, or their more refined correlated disorder versions, it is now widely recognized that diagonal disorder gives rise to P–F type electric field dependence of mobility (i.e. $\mu \propto \exp(\beta\sqrt{F})$), while a strong off-diagonal disorder yields a mobility that may decrease with electric field. However, there have been reports of observation of negative P–F coefficient in field dependence where nature of the disorder cannot be invoked as being responsible. We show that for two well characterized conjugate polymer systems the P–F coefficient (β) can be either positive or negative depending on different choice of cathodes even for the same material. This allows us to understand the dependence of mobility on the energy states to which the carriers are injected and the relaxation of carriers within the DOS. A phenomenological model is proposed to account for such observations which are both insightful and significant for applications.

2. Experimental

We have chosen two different families of conjugated polymers viz. *poly [2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene]* (MEH-PPV) and *Arylenevinylene-co-pyrrolenevinylene* with *octyloxy* side-chain (C8-AVPV) [22] in single layer LED configuration (Fig. 1(a) and (b)). All the devices were fabricated in controlled laboratory conditions to avoid as much as possible extrinsic effects on material's electronic property. Commercial ITO coated glass substrates were used to realize transparent anode. The patterned and RCA cleaned ITO substrates were subjected to 15 min ozone treatment followed by spin-coating of a thin layer of polyethylene dioxythiophene/polystyrenesulfonate (PEDOT:PSS) and dried at 120 °C for 1 h under 10^{-7} mbar vacuum. The PEDOT:PSS layer serves as conducting planar layer to avoid high electric field associated with roughness of the ITO substrates. The solution of MEH-PPV (commercial source, Sigma Aldrich) was prepared with concentration of 6 mg/cc in chloroform: toluene (50:50) mixture, which was optimized from the point of view of device fabrication in our laboratory [23,24]. C8-AVPV polymer solution is prepared in chlorobenzene with a concentration of 10 mg/cc. Active layers are spin-coated and dried under 10^{-7} mbar vacuum at 120 °C for 1 h. The thickness (~1000 Å) of the active layer was kept the same in all the devices. For single carrier and double carrier situations, we have used Al and Ca metals, respectively. A thick Al layer was deposited to cap the Ca layer in polymer/Ca devices. All the cathodes were deposited through shadow mask without breaking the vacuum to avoid any contamination at the active layer–cathode interface.

We have used ELT technique to monitor the electric field dependent transport parameters. The method is essentially based on monitoring time lag in EL on the application of a rectangular voltage pulse. Fig 1(c) and (d) show the schematics of the experimental setup and typical transients obtained in response to square voltage pulse, respectively. The carriers injected from the respective electrodes have to drift towards the other electrode, and give rise to exciton formation on meeting the opposite carriers. For a single layer of PLED, the fastest carrier controls the observed delay in luminescence in response to a rising edge of the voltage pulse, and the time delay (t_d) is given by

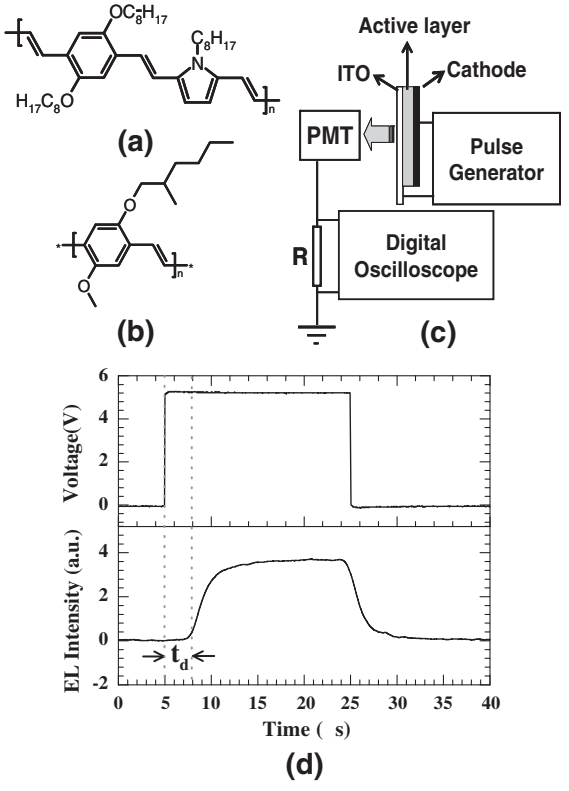

Fig. 1. (a) and (b) shows chemical structure of active material C8-AVPV and MEH-PPV, respectively. (c) Schematic diagram of experimental setup for measuring Electroluminescence Transient (ELT) for PLED device, and (d) typical ELT curve depicting the method of determining time delay (t_d).

$$t_d = \frac{d^2}{\mu_{eff} \times (V - V_{BI})} \quad (2)$$

where $\mu_{eff} = \mu_e + \mu_h$ is the effective mobility, V_{BI} is the built-in voltage and $(V - V_{BI})$ the corrected potential drop across the device.

The finished device was mounted on a home made copper sample mounting stage inside a vacuum chamber having an optical window. A 50 Hz HP 81101A pulse generator, with rise time 10 ns, was used to apply rectangular voltage pulses of different magnitude and pulse width across the devices. The pulse repetition rate was fixed 1 kHz to ensure no interference between the subsequent pulses and their corresponding ELT responses. A photomultiplier tube (S100 response) with time resolution < 1 ns was mounted near the optical window facing the emitting area of the device to detect the EL intensity. The PMT was connected to a 500 MHz digital oscilloscope (model HP 54615B) to record the time dependent EL signals. The RC time constant of the setup, including the PLED devices, was ensured to be smaller than the time scales of the transients.

3. Results and discussion

The effective mobility (μ_{eff}) as a function of electric field (F) was derived using Eq. (2) for two different materials viz. MEH-PPV and C8-AVPV. For each case, the electron injection into the single layer PLED was controlled by varying cathode material, aluminum (Al) to hinder electron injection and calcium (Ca) to provide copious electrons. The schematic band diagrams of the two types of devices are shown in the Fig. 2(a) and (b). The mobilities derived from time delay in each case are plotted as a function of $\sqrt{F}$, where F is the electric field taking into account correction for built-in voltage in Fig. 2(c). There are several important features in this plot as listed below:

- For both the materials, when Al is used as a cathode we obtain traditional P–F type behavior, in which $\mu_{eff} \propto e^{\beta\sqrt{F}}$, where β is positive, i.e. mobilities increase exponentially with increase in F as expected.
- For both the materials, when Ca is used as a cathode, the μ_{eff} decreases with β being negative in contrast to the Al case.
- The absolute values of μ_{eff} for Ca-cathode case is more than Al-cathode by an order of magnitude for lower electric fields, attaining similar values towards higher electric field.

In a typical determination of mobility using ELT, one assumes that the mobility of one of the charge carriers is higher by at least an order of magnitude than the other, and hence the measured mobility is that of the faster carrier. However, if they are comparable one would measure an effective mobility ($\mu_{eff} = \mu_e + \mu_h$). In this work, both the materials chosen are otherwise well characterized as hole transport materials. There is little doubt in ascertaining that for the case of Al-cathode, the transit time is dominated by the mobility of the holes. As expected we obtain

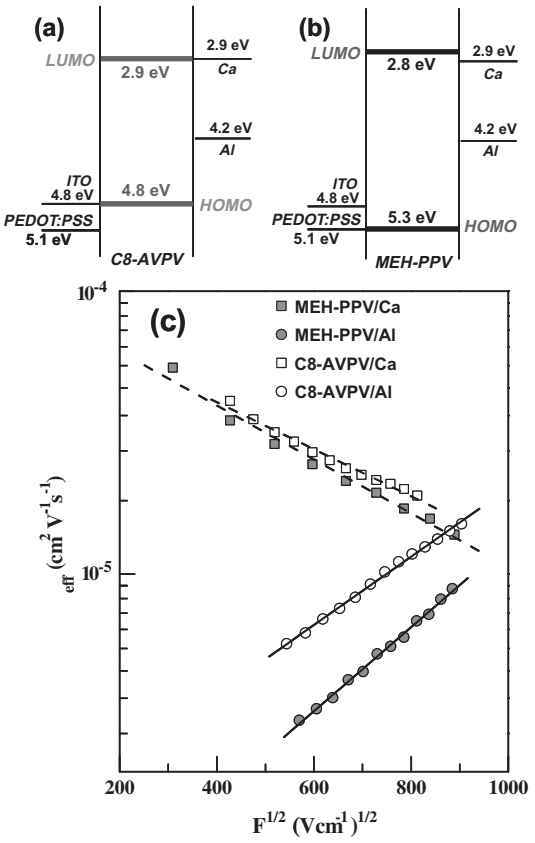

Fig. 2. The Schematic band diagram of PLED structures studied, (a) C8-AVPV/Ca, and (b) MEH-PPV/Ca. Note the energy barrier for electron injection is negligible for Ca in both polymeric systems. (c) Poole–Frenkel plots for charge carrier mobility in MEH-PPV/Ca (grey filled square), MEH-PPV/Al (grey filled circle), C8-AVPV/Ca (white filled square), and C8-AVPV/Al (white filled circle) device structures.

field activated dependence for hole mobility $\mu_h \propto e^{\beta_h\sqrt{F}}$. However, in both the cases when cathode is Ca, the field dependence is reversed. Ca being the low work-function cathode can inject electrons copiously without a barrier as shown in Fig. 2(a) and (b). Hence the measured mobility must be μ_{eff} due to both electrons and holes. In that case, the electron mobility must be unusually large and have negative field dependence. The values of $\mu_{0,eff}$, $\mu_{0,h}$, and $\mu_{0,e}$ along with their corresponding β_{eff}, β_h, and β_e can be determined using μ_h values obtained for the case of Al cathode [25]. The results so obtained are summarized in Table 1. Note that the P–F coefficients for Ca-cathode case (i.e. β_{eff} and β_e) are negative. The $\mu_{0,h}$ and β_h values for MEH-PPV agree well with the published literature. The reported hole mobility parameters ($\mu_{0,h}$) are 1.0×10^{-7} cm^2 V^{-1} s^{-1}–5.7×10^{-7} cm^2 V^{-1} s^{-1} [26–30]. There are only two reported measurements for electron mobility (μ_e) in MEH-PPV, in specially made electron-only structures using steady state J–V characteristics [5,30]. The values ($\mu_{0,e} \sim 1.0 \times 10^{-8}$ cm^2 V^{-1} s^{-1}–2.0×10^{-7} cm^2 V^{-1} s^{-1} and $\beta_e \sim 8.0 \times 10^{-3}$ cm$^{1/2}$ V$^{-1/2}$) are much lower than those obtained here. The fact that electrons can become the dominant carriers in single layer PLED of

MEH-PPV with Ca as the cathode has been noted earlier [31,32]. In Fig. 2, we also note that the μ_{eff} data has an upward curvature and is within a factor of two of the μ_h at higher electric fields. This clearly indicates that the μ_{eff} has an increasingly large contribution from holes at higher field thus tending to flatten the overall field dependence. This can be used to refine the fitting obtained though its effect in the values is small.

Our observations clearly indicate that electrons are involved and are responsible for the unusual behavior. Since the Ca work-function is much lower compared to that of Al, it is reasonable to assume that electrons being injected into the material occupy directly the transport states, and would need to relax within a Gaussian DOS to equilibrate. However, if this process of equilibration is slow, the injected electrons can be considered as hot and hence transport of such charge carriers within the transport states would be different. For equilibrium carriers, we observe P–F type activated transport due to existence of mobility-gap like barrier between localized states and transport states as is well known from Bässler formalism. This would be true for holes in both the polymer cases. This would also hold for electron mobility measurements reported in the literature using steady state techniques such as J–V characteristics in electron only devices and impedance analysis. The hot electron behavior can be observed only in transient experiments using sufficiently low work-function cathodes.

Further, we propose a phenomenological model to account for negative coefficient of field dependence for hot electrons through a series of schematics as shown in Fig 3. The injected electrons into the layers immediately in contact with the cathode have to tunnel into the transport states of the local DOS (shown as Gaussians) of the subsequent layer. However, because of the electric field the two Gaussian DOS would be misaligned in energy reducing the number of transport states accessible for transport in the subsequent layers. This misalignment increases further at higher electric field reducing probability of tunneling into the subsequent layers and hence the mobility of the hot electrons. However in case of Al, the concentration of electrons are low and are primarily injected into the localized/trap states and hence do not result in hot electrons. This is a scenario which provides a compelling rationale for observation of reduced mobility with increasing electric field. By changing the cathode only, we do not expect to alter the nature or degree of positional (i.e. off-diagonal) disorder, which are generally invoked to explain the negative coefficient of P–F field dependence in presence of dopants or other similar situations. However it is possible that at the microscopic level the hot electrons may be more sensitive to off-diagonal disorder—an effect that must be explicitly simulated to justify. In other words, our results indicate that in the case of Al-cathode, electrons are injected to localized states and hence are already equilibrated within the DOS with extremely low electron mobility. Effectively only holes move to recombine with electrons very near to the Al-cathode. The injected holes relax much faster within the DOS to obey the usual field dependence as predicted by Gaussian disorder model.

The above account that transport of electrons would involve simultaneously two processes – movement across the transport states towards the anode, and relaxation within the DOS towards the minimum of transport states and to localized states lying lower in energy. During the drift, the competition between the two processes would determine an effective mobility and hence a single value of mobility would loose its well-defined meaning. We believe that this is indeed the case for electrons in these materials. It is worth reemphasizing that this can only be observed in transient experiments with thin films as is typically used in OLED applications and any steady state experiment would completely miss this possible time dependent contribution to drift phenomena. Our results also indicate that the time-scale of relaxation of electrons is slower than that of the holes, and are longer than the transit time in our experiments which is in order of microseconds. This would need further empirical test. The mechanism of relaxation for holes and electrons seem to be very different probably owing to the nature and occupancy of localized/trap levels. It is plausible that electron trapping states get occupied very quickly and have low emission rates thus effectively getting eliminated as a source of equilibration in the timescales of the experiment.

In order to further test the idea that energetics and DOS play a crucial role in determining the behavior of injected electrons, we use a blend system in which C8-AVPV is blended with high gap non-luminescent PVK material as the active layer. The blend with PVK is uniformly miscible across the range. Ca as a cathode would not be able to inject electrons into LUMO bands of PVK. The mixtures of the two polymers only ensure that the local DOS corresponding to C8-AVPV gets decreased as compared to the pure C8-AVPV case. The comparison of results of pure C8-AVPV with blend of 60% PVK and 40% C8-AVPV is shown in Fig. 4. The negative field dependence occurs in both the devices except that the absolute value of mobility for corresponding electric field is decreased due to reduction in C8-AVPV local DOS, responsible for hot electron transport. This reinforced the idea that the occurrence of negative coefficient in P–F dependence of mobility using low work-function cathode is a robust phenomena and its origin can be traced to transport of hot electrons.

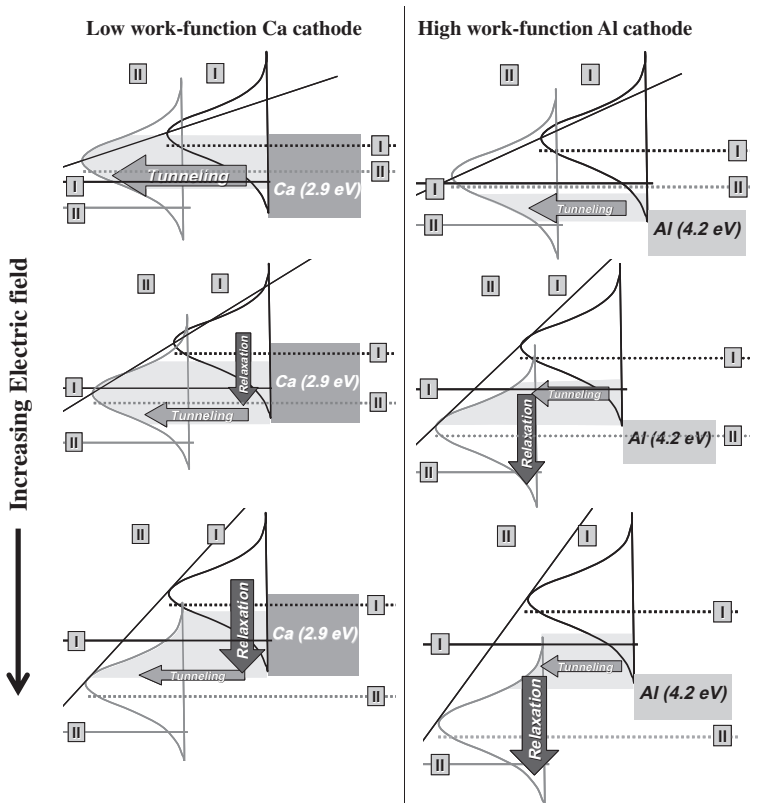

Fig. 3. Schematics (not to scale) depicting the transport mechanism for polymer/Ca (left column) and polymer/Al (right column) configuration. The dotted line represents lower edge of transport states and solid line represents upper edge of localized/trap states. Here shaded area shows overlapping of energy states between populated interfacial DOS and empty states in the localized DOS of next layer. The first interfacial and second next DOS are denoted as *I* and *II*, respectively. At low electric field (small band bending), for polymer/Ca, matching of Ca Fermi level with LUMO of polymer, favors electron population in transport states of interfacial DOS and subsequent tunneling to transport states of the next layer DOS. While due to limited injection efficiency and nature of band bending in case of Al, only localized trap states are filled first with very small tunneling probability to transport and trap levels of next DOS (first row). At moderate electric field (steeper band bending) (second row), for polymer/Ca, the probability of tunneling is slowly diminished. At higher electric field (steepest band bending) (third row), for polymer/Ca, the charge carriers' relaxation dominates over tunneling to next DOS, while in the case of Al the probability of tunneling from localized/trap states increase, i.e. trapping precedes tunneling to transport states of the next layer.

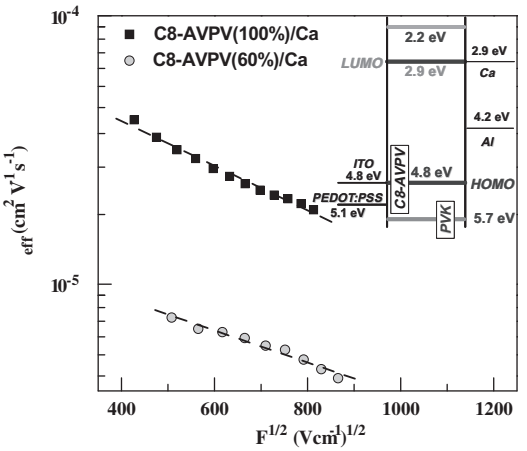

Fig. 4. log μ vs. $\sqrt{F}$ plot for blend of 60% (C8-AVPV: PVK) with Ca cathode (grey filled square). The 100% case is pure C8-AVPV (black filled square) showing the difference observed in magnitude for both the cases. Inset of the plot shows band diagram of the blended device.

4. Conclusions

In summary, we have demonstrated that the effective mobility and its field dependence measured in electroluminescence transient experiment can be strongly dependent on the nature of cathode used. The parameters describing field dependence for both carriers have been derived, and shown to have negative coefficient for electrons injected from Ca cathode. In this case carriers are injected into higher energies of transport states, and do not relax to equilibrium soon enough, the mobility of electrons can be significantly higher than the hole mobility even in traditional hole transporting layers. This is invoked to explain the occurrence of negative coefficient of field dependence for two different material systems (MEH-PPV and C8-AVPV) having Ca as the low work-function cathode. The proposed phenomenological model of field dependence is based on the idea that injected hot electrons are unable to find accessible transport states due to increasing misalignment of local DOS of subsequent layers with increasing electric field.

White organic light-emitting diodes
Various electron-transporting materials
Various 100% internal quantum efficiency

ABSTRACT

The authors have demonstrated white organic light-emitting diodes (WOLED) using all phosphorescent emitters for blue, green, and red, such as FCNIrpic, $Ir(ppy)_3$ and $Ir(pq)_2$(acac). Various electron-transporting materials such as $Bebq_2$, BPhen, TAZ, BAlq, and TPBI were also investigated for improving quantum efficiency of phosphorescence of WOLED by fabricating and characterizing white devices using these materials as an electron-transporting layer (ETL). It was found that WOLED with an ETL of TPBI exhibits a peak external quantum efficiency (EQE) of 19.5% and a peak power efficiency of 39.2 lm/W at very low light intensity. The optimized device also shows an EQE of 16.4% at 1000 cd/m^2. It was also found that the optimized white device with TPBI shows minimal change with Δ Commission Internationale de l'Eclairage coordinates of ±(0.02, 0.00) from 100 to 10,000 cd/m^2. In order to understand the mechanism for achieving nearly 100% IQE with this device structure, various analyses were also executed, such as UV/visible absorbance measurements of FCNIrpic and photoluminance (PL) measurements of mCP, fabrications of hole- and electron-only devices, UV/visible absorbance measurements of $Ir(ppy)_3$ and $Ir(pq)_2$(acac) and PL of FCNIrpic, and surface roughness measurements of various ETL films.

1. Introduction

White organic light-emitting diodes (WOLEDs) have drawn increasing attention as a solid-state light (SSL) source and backlights in liquid crystal displays and full-color OLEDs due to their light weight, low operating voltage, thinness, diffusiveness, and harmlessness for the restriction of certain hazardous substances directive/waste electrical and electronic equipment [1–6]. There are two ways of realizing WOLEDs as SSL in the aspects of materials used. One is phosphorescent WOLEDs (PHWOLEDs), which use all phosphorescent emitters, and the other is hybrid WOLEDs (HWOLEDs), which use fluorescent blue and phosphorescent red–green emitters. Sun et al. have demonstrated highly efficient HWOLEDs using fluorescent blue and phosphorescent red–green emitters, where a spacer of 4,4′-*N*,*N*′-dicarbazole-biphenyl was used in order to prevent singlet energy transfer from fluorescent blue emitter to phosphorescent red–green emitters; the exchange energy losses were minimized to increase the efficiency and lifetime [7]. Nevertheless, they showed low external quantum efficiency (EQE) and power efficiency (PE) to be about 10% and 14 lm/W at 500 cd/m^2, respectively [8]. PHWOLEDs have also been investigated intensively because we can harvest both singlet and triplet excitons with PHWOLEDs [9–11]. Unfortunately, PHWOLEDs, despite the possibility of achieving 100% internal quantum efficiency (IQE), do not yet have a proper phosphorescent blue emitter with high-energy gap, long life, or host materials for this emitter.

Nevertheless, lately, a few researchers have reported highly efficient phosphorescent deep-blue OLEDs and have also investigated the synthesis of novel blue Ir and Pt complexes [12,13].

White light emission can be obtained from monomeric or polymeric emitters [14,15], depending on molecular length, from all phosphorescent, fluorescent or hybrid phosphorescent–fluorescent materials [16–18], depending on the emission mechanism, and from single-emitting layer (EML) or multi-EML [19,20], excimer or exciplex [21,22], microcavity, down conversion, *p–i–n*, and tandem junction [23–26], depending on device structures. Among these options, we have investigated multi-EML junctions using all phosphorescent emitters in this paper.

Materials for hole-transporting layers (HTL) have been investigated widely in various aspects such as hole mobility, band gap, triplet exciton energy, and glass transition temperature. As a results, *N*′-bis-(1-naphyl)-*N*,*N*′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB) is now used as a common HTL material because it shows the most outstanding characteristics such as thermal stability, high hole mobility, and appropriate band gap. Even though there are many kinds of electron-transporting layers (ETL), such as bis(10-hydroxybenzo[h]quinolinato)beryllium complex ($Bebq_2$), 4,7-diphenyl-1,10-phenanthroline (BPhen), 3-(4-biphenylyl)-4-phenyl-5-tert-butylphenyl-1,2,4-triazole (TAZ), bis-(2-methyl-8-quinolinolate)-4-(phenylphenolato)aluminum (BAlq), and 2,2′,2″-(1,3,5-benzinetriyl)-tris(1-phenyl-1-H-benzimidazole) (TPBI), there were no systematic investigations to improve the efficiency of WOLEDs having multi-EML junctions using all phosphorescent emitters in the aspects of various physical properties. In this paper, we investigated the effects of photophysical analysis for host-dopant trade-off of 1,3-bis(9-carbazolyl)benzene (mCP) and iridium(III) bis[(5-cyano-4-fluorophenyl)pyridinato-N,C2′]picolinate (FCNIrpic) and various ETL materials on the efficiency of these WOLEDs by analyzing hole block ability, lowest unoccupied molecular orbital (LUMO) level, electron mobility, triplet energy level, and surface morphology of various ETL materials. Hence, 100% IQE and 19.5% EQE were achieved by using the optimized WOLEDs with TPBI as an ETL material.

The structure of all devices and energy level diagrams of WOLEDs fabricated in this study are shown in Fig. 1(a) and b), respectively, where the device structure was indium-tin oxide (ITO) (150 nm)/NPB (50 nm)/mCP (10 nm)/FCNIrpic:mCP (7 nm)/*fac*-tris(2-phenylpyridine)iridium ($Ir(ppy)_3$):iridium(III) bis(2-phenylquinoline) acetylacetonate($Ir(pq)_2(acac)$):TPBI (3 nm)/various ETLs (30 nm)/lithium quinolate (Liq) (2 nm)/Al (100 nm), respectively. $Bebq_2$, BPhen, TAZ, BAlq, and TPBI were used as ETL material in devices A, B, C, D, and E, respectively. The doping concentrations of FCNIrpic in mCP, $Ir(ppy)_3$, and $Ir(pq)_2(acac)$ in TPBI were optimized to 8%, 8%, and 3%, respectively. The thickness of EML was optimized to 10 nm since this thickness has many advantages such as low operating voltage, higher efficiency, and lower color shift [9]. NPB as an HTL, mCP as an exciton-blocking layer (XBL) and a phosphorescent blue host, FCNIrpic, as a phosphorescent blue emitter, TPBI as a phosphorescent red host and an ETL, $Ir(ppy)_3$, as a phosphorescent green emitter, $Ir(pq)_2(acac)$ as a phosphorescent red emitter, and Liq as an electron injection layer were also used in these device structures. In device E, TPBI was used as a red host and ETL simultaneously, for this set-up makes the fabrication process simple.

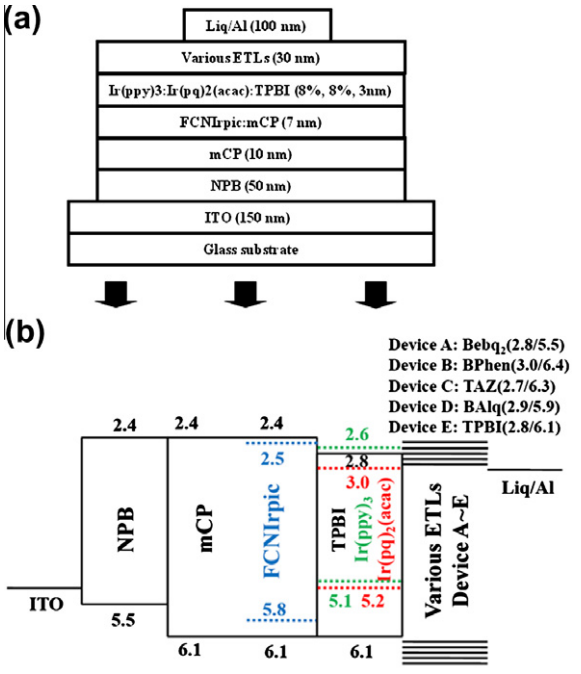

Fig. 1. (a) The structures of all devices fabricated in this study. (b) Energy level diagrams for all white devices. Numbers denote the energy level for the HOMO and LUMO of various materials used in this study, where the HOMO and LUMO of FCNIrpic, $Ir(ppy)_3$, and $Ir(pq)_2(acac)$ are presented by blue, green, and red dotted line, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The highest occupied molecular orbital (HOMO), LUMO, electron mobility, and triplet emission energy for various ETLs are listed in Table 1 [27–33]. It is clear in Table 1 that $Bebq_2$ and BPhen have a considerably higher electron mobility of 10^{-4} cm^2/V s compared to TAZ, BAlq, and TPBI, which has an electron mobility of 10^{-5} cm^2/V s. TAZ and TPBI have higher triplet emission energies than FCNIrpic (2.65 eV).

2. Experimental

An indium-tin oxide (ITO)-coated glass substrate was cleaned in an ultrasonic bath using the following sequence of solvents: acetone, methanol, distilled water, and isopropyl alcohol. Thereafter, a precleaned ITO layer was treated with O_2 plasma under the following conditions: 2×10^{-2} Torr and 125 W for 2 min. HWOLEDs were fabricated by the high-vacuum (5×10^{-7} Torr) thermal evaporation of organic materials onto the surface of the ITO-coated glass substrate (10 Ω/sq, emitting area was 3×3 mm^2). The deposition rates were 0.1 nm/s for all organic materials and 0.01 nm/s for Liq.

Without breaking the vacuum, after the deposition of the organic layers, the Al cathode was deposited at a rate of 1 nm/s. The ultraviolet (UV)/visible absorption and PL

Table 1
HOMO, LUMO, electron mobility, and triplet energy level of various electron transporting layers.

ETL	HOMO (eV)	LUMO (eV)	Electron mobility (cm^2/V s)	Triplet energy (eV)
$Bebq_2$	5.5	2.8	$\sim10^{-4}$ [27]	2.5 [28]
BPhen	6.4	3.0	$\sim10^{-4}$ [29]	2.5 [30]
TAZ	6.3	2.7	$\sim10^{-5}$ [31]	3.3 [28]
BAlq	5.9	2.9	$\sim10^{-5}$ [32]	2.6 [33]
TPBI	6.1	2.8	$\sim10^{-5}$ [31]	2.8 [27]

spectra were measured with HP-8453 (Hewlett Packard) and LS-55 (Perkin Elmer). In a presence of a DC voltage bias, the optical and electrical properties of WOLEDs such as the current density, luminance, PE, EQE, Commission Internationale de l'Eclairage ($CIE_{x,y}$) coordinates, and EL spectra of the emission characteristics were measured with Keithley 2400 (Keithley) and Chroma meter CS-1000A (Konica Minolta) instruments simultaneously. The films of various ETLs on silicon wafer substrates were used for atomic force microscopy (AFM) imaging. The various ETLs were deposited at a thickness of 20 nm at a rate of 0.1 nm/s. The AFM images were obtained with an XE-150 (Park Systems) instrument. The film conditions for the AFM measurements were kept the same as for OLEDs. All measurements were carried out under ambient conditions at room temperature.

3. Results and discussion

3.1. Photophysical analysis for host-dopant trade-off

Fig. 2 shows the UV/visible absorption spectrum of FCNIrpic and PL spectra of FCNIrpic, and of mCP in chlorobenzene, respectively. It was found in Fig. 2 that FCNIrpic shows the maximum UV/visible absorption peak at 250 nm with a sub-peak at 293 nm and peaks also at 375 and 413 nm, which are due to spin-allowed ^{1}metal–ligand charge transfer band (MLCT) and spin-forbidden ^{3}MLCT, respectively. It was also found in Fig. 2 that the PL emission peaks of FCNIrpic and mCP were located at 465.5 nm, with vibrational peaks at 492 nm and at 361.5 nm, respectively.

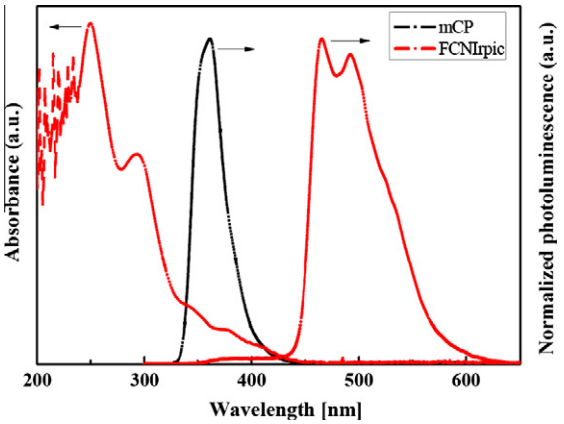

Fig. 2. UV/visible absorption spectrum of FCNIrpic and normalized PL spectra of mCP and FCNIrpic.

Since FCNIrpic is an iridium derivative having a strong electron-withdrawing substituent of CN at the position of fluorine in iridium(III) bis(4,6-(difluorophenyl)pyridinato-*N*,$C^{2'}$)picolinate (FIrpic), FCNIrpic has a wider bandgap (2.5/5.8 eV) than that of FIrpic (2.5/5.7 eV). It can be expected that the efficient Förster energy transfer would be possible from mCP to FCNIrpic since ^{1}MLCT and ^{3}MLCT absorption spectra of FCNIrpic has broader spectral overlap with fluorescence spectra of mCP from 330 to 450 nm. Efficient Dexter energy transfer is also possible from phosphorescence of mCP (430 nm) to ^{3}MLCT absorption of FCNIrpic (413 nm) [34]. Therefore, both Förster and Dexter energy transfers occur through the paths as follows; singlet excited state (S_1) of mCP → S_1 of FCNIrpic → intersystem crossing → triplet exited state (T_1) of FCNIrpic and T_1 of mCP → T_1 of FCNIrpic, respectively [19].

3.2. Mechanism analysis for achieving nearly 100% IQE of WOLEDs

Fig. 3(a) and (b) show EQE and PE-luminance characteristics of all devices, respectively. It was found in Fig. 3(a) and (b) that devices A, B, C, D, and E have peak EQEs of 8.9%, 11.8%, 12.0%, 15.1%, and 19.3% and peak PEs of 19.5, 28.9, 26.2, 33.5, and 39.2 lm/W at very low light intensities, respectively. The EQE of 19.3% and the PE 39.2 lm/W at very low light intensity are equivalent to nearly 100% IQE [35,13]. All devices also show EQEs of 7.2%, 9.1%, 9.1%, 12.0%, and 16.4% at 1000 cd/m^2. Device E, having TBPI as an ETL which is one of the highest values for the previously reported WOLEDs to the best of our knowledge. These excellent experimental results seem to be due to the following reasons: (1) blue device (10.70%) using FCNIrpic had an efficiency 1.5 times that of the control blue device (7.43%) using FIrpic [36] (see Ref. [36]); (2) TPBI as an ETL has an ideal hole-blocking property (see Section 3.2.2); (3) all the electrons injected into the EML pass without electron leakage since the same material was used as the red host and ETL (see Section 3.2.2); (4) since TPBI (2.8 eV) has a higher triplet energy than FCNIrpic (2.65 eV), device E, having TPBI as an ETL, can confine triplet energy of FCNIrpic to EML effectively (see Section 3.2.4); (5) TPBI film exhibits a very smooth surface with $\sigma \sim 0.14$ nm, which is the lowest value among those of $Bebq_2$, BPhen, TAZ, BAlq, and TPBI film (see Section 3.2.5). Thus, these five factors may contribute partially to the achievement of excellent efficiency in WOLEDs shown in this study. We will discuss some experimental results obtained by various analyses in detail in order to explain excellent efficiency in the next chapter.

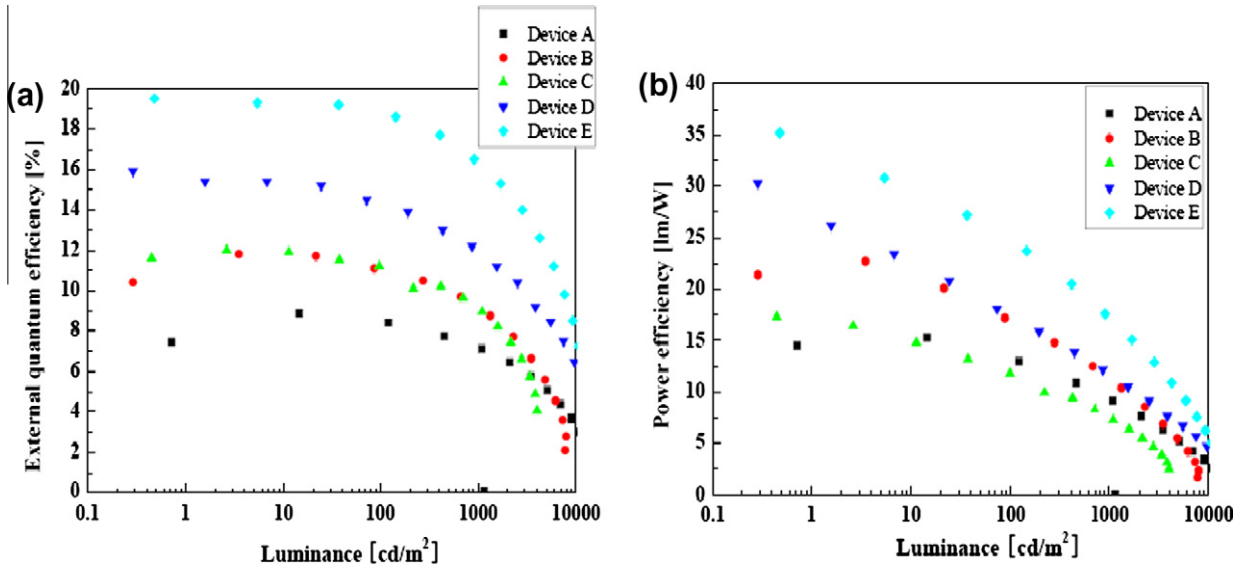

Fig. 3. (a) EQE versus luminance characteristics of all devices with various ETLs. (b) PE versus luminance characteristics of all devices with various ETLs.

3.2.1. Electrical and optical characteristics of WOLEDs using various ETLs

Fig. 4 and the inset in Fig. 4 show current density–voltage and luminance–voltage characteristics of all five devices, respectively. It was found in Fig. 4 that they have maximum current densities of 600, 143, 19, 64, and 113 mA/cm^2 at 10 V and luminances of 13,200, 7910, 2780, 9620, and 11,500 cd/m^2 at 10 V, respectively.

Device A shows the highest current density at operating voltages, which seems to be due to the inadequate role of $Bebq_2$ having the low HOMO (5.5 eV) as a hole-blocking layer. On the other hand, device C shows the lowest current density among other devices, which also seems to be due to the largest electron injection barrier between the Liq-Al and LUMO of TAZ and its lower electron mobility of 10^{-5} cm^2/V s compared to $Bebq_2$ and BPhen as shown in Table 1. It was also found that although BAlq in device D and TPBI in device E have the same electron mobility as shown in Table 1, device D shows lower current density than device E.

This can be explained as follows: device E did not have an electron injection barrier between the red EML and ETL because the same material, TPBI, was used for both the EML and ETL in device E. It is shown in the inset of Fig. 4 that devices A and B have similar saturation characteristics at driving voltages higher than 9.5 V, which seems to be due to the inadequate hole-blocking ability of $Bebq_2$ in device A and also bad surface morphology of the Bphen layer in device B (see Sections 3.2.2 and 3.2.5).

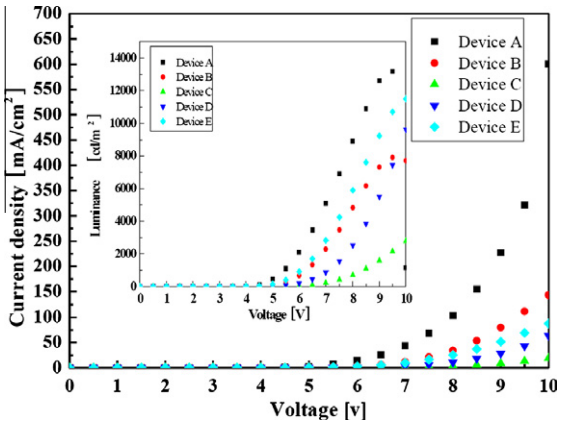

Fig. 4. Current density versus voltage characteristics of all devices. Inset: luminance versus voltage characteristics of all devices.

3.2.2. Fabrication and characterization of unipolar devices

Hole-only devices (HODs) and electron-only devices (EODs) were fabricated to prove the previous assumption. Fig. 5 and the inset of Fig. 5 show current density–voltage

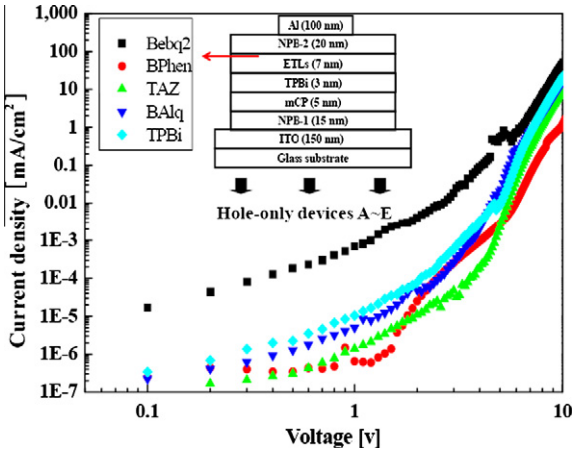

Fig. 5. Current density versus voltage characteristics of HODs. Inset: HODs structure which have five structures of ITO (150 nm)/NPB-1 (15 nm)/mCP (5 nm)/TPBI (3 nm)/various ETLs (7 nm)/NPB-2 (20 nm)/Al (100 nm).

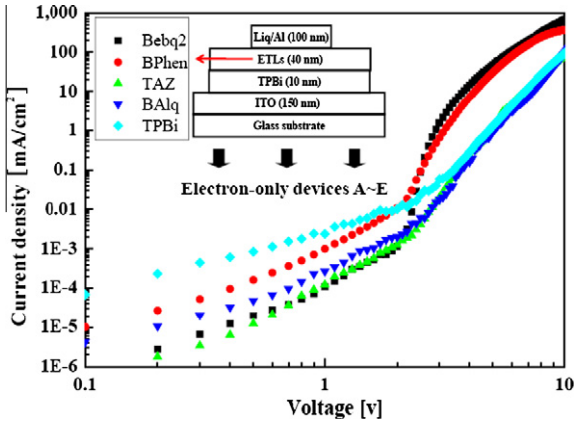

Fig. 6. Current density versus voltage characteristics of EODs. Inset: EODs structure which have five structures of ITO (150 nm)/TPBI (10 nm)/ETLs (40 nm)/Liq-Al (100 nm).

characteristics of HODs, and the device structure for five HODs is as follows: ITO (150 nm)/NPB-1 (15 nm)/mCP (5 nm)/TPBI (3 nm)/various ETLs (HOD-1–5) (7 nm)/NPB-2 (20 nm)/Al (100 nm), where various ETLs are $Bebq_2$ (HOD-1), BPhen (HOD-2), TAZ (HOD-3), BAlq (HOD-4), and TPBI (HOD-5). To maintain the same HOMO value in HODs as that of white devices, NPB-1, mCP, and TPBI were used as the HTL and NPB-2 was used as the electron-blocking layer. It was found in Fig. 5 that the HODs show current densities of 7.0×10^{-4}, 6.5×10^{-7}, 1.4×10^{-6}, 5.0×10^{-6}, and 9.0×10^{-6} mA/cm^2 at 1 V and also 0.538, 0.003, 0.002, 0.020, and 0.009 mA/cm^2 at 5 V. HOD-1 shows the highest current density at the whole voltage, and this trend becomes more conspicuous at a lower voltage. Therefore, this indicates that $Bebq_2$ could not play an adequate role of hole-blocking in device A. The lower the HOMO level of ETLs, the more holes that pass through toward the cathode; all ETLs except $Bebq_2$ can effectively prevent a hole from passing through an EML and, therefore, confine hole carriers within the EML.

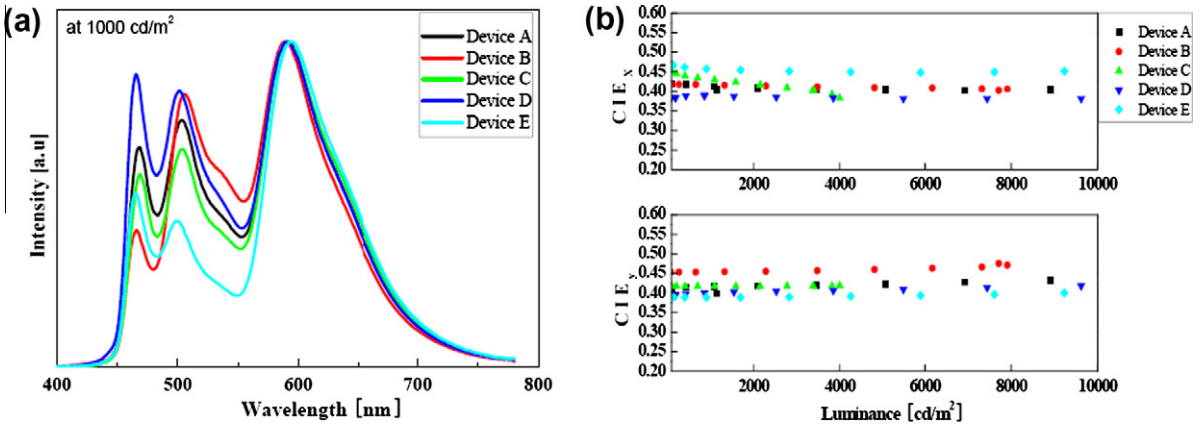

Fig. 7. (a) EL spectra of all white devices at 1000 cd/m^2. (b) CIE$_{x,y}$ coordinates versus luminance characteristics from 100 to 10,000 cd/m^2 of all white devices.

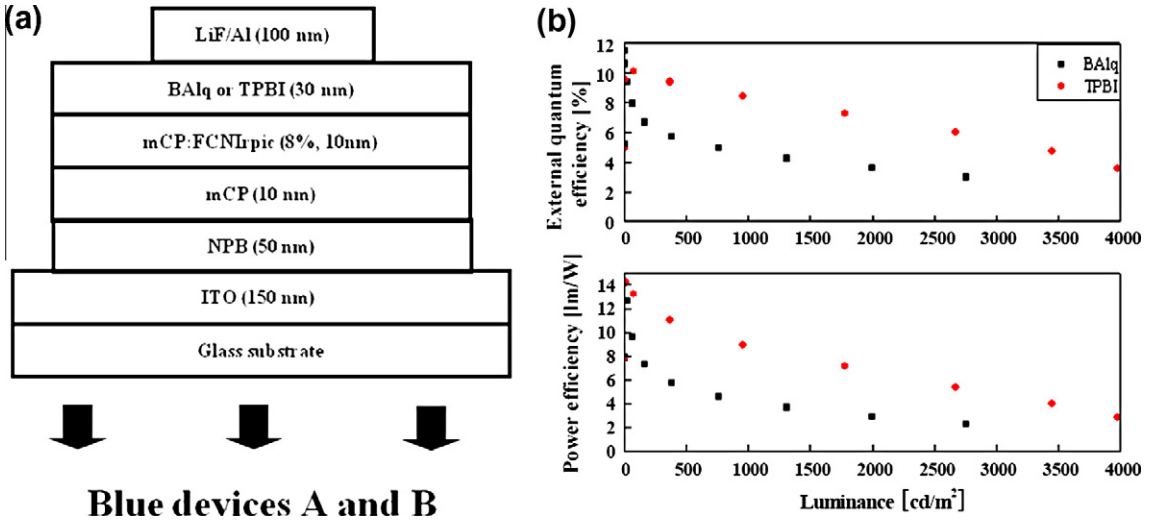

Fig. 8. (a) Blue device A and B where the device structures were ITO (150 nm)/NPB (50 nm)/mCP (10 nm)/FCNIrpic:mCP (8%, 10 nm)/BAlq (blue device A) or TPBI (blue device B) (30 nm)/LiF (2 nm)/Al (100 nm), respectively. (b) EQE and PE versus luminance characteristics of blue device A and B.

Fig. 6 and the inset of Fig. 6 show current density–voltage characteristics of EODs, and the device structure for five EODs is as follows: ITO (150 nm)/TPBI (10 nm)/various ETLs (40 nm)/Liq (2 nm)/Al (100 nm), where various ETLs are $Bebq_2$ (EOD-1), BPhen (EOD-2), TAZ (EOD-3), BAlq (EOD-4), and TPBI (EOD-5). To maintain the same LUMO value in EODs as that of white devices, TPBI was used as an HTL. It was found in Fig. 6 that the EODs show current densities of 1.54, 0.66, 0.02, 0.02, and 0.06 mA/cm^2 at 3 V and 47.8, 30.9, 1.2, 0.9, and 1.3 mA/cm^2 at 5 V, where the current densities of EODs having $Bebq_2$ and BPhen were much higher than those of other devices. This indicates that the electron mobility of ETLs plays a more important role in the current density of EODs than the LUMO value of ETLs.

3.2.3. EL characteristics of WOLEDs using various ETLs

Fig. 7(a) shows the EL spectra of five white OLEDs at 1000 cd/m^2. It was found in Fig. 7(a) that all devices have blue peaks at 465–469 nm, green peaks at 501–503 nm, and red peaks at 592–594 nm. Fig. 7(b) also shows $CIE_{x,y}$ coordinates-luminance characteristics from 100 to 10,000 cd/m^2 for all devices, where they have an emission of $CIE_{x,y}$ coordinates from (0.42, 0.41), (0.42, 0.45), (0.45, 0.42), (0.38, 0.40), and (0.47, 0.40) at 100 cd/m^2 to (0.40, 0.42), (0.41, 0.46), (0.38, 0.42), (0.38, 0.41), and (0.45, 0.40) at 5000 cd/m^2. It was found in Fig. 7(b) that device E has minimal change with $\Delta CIE_{x,y}$ of ±(0.02, 0.00) from 100 to 10,000 cd/m^2. It was also found in Fig. 7(a) that red peak intensity in devices C and E is enhanced compared to that in other devices, which means that devices C and E have more warmish white-emission characteristics rather than coldish white-emission characteristics compared to other devices.

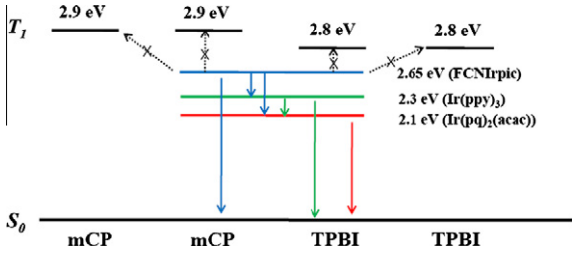

Fig. 9. Possible triplet energy transfer paths for all emitters in the two hosts and ETLs.

3.2.4. Efficiency comparison of white devices with BAlq and TPBI having different triplet energy

Device E with an ETL of TPBI showed higher efficiency than device D with an ETL of BAlq because TPBI (2.8 eV) has higher triplet energy than FCNIrpic (2.65 eV). On the other hand, BAlq (2.6 eV) has lower triplet energy than FCNIrpic as shown in Table 1. Therefore, device E could confine triplet energy in EML well. To confirm this result, as shown in Fig. 8(a), we fabricated blue devices A and B that had the following structure: ITO (150 nm)/NPB (50 nm)/mCP (10 nm)/FCNIrpic:mCP (8%, 10 nm)/BAlq (blue device A) or TPBI (blue device B) (30 nm)/LiF (2 nm)/Al (100 nm), where the doping concentrations of FCNIrpic in mCP were the same as those used for white devices. Fig. 8(b) also showed EQE and PE-luminance charac-

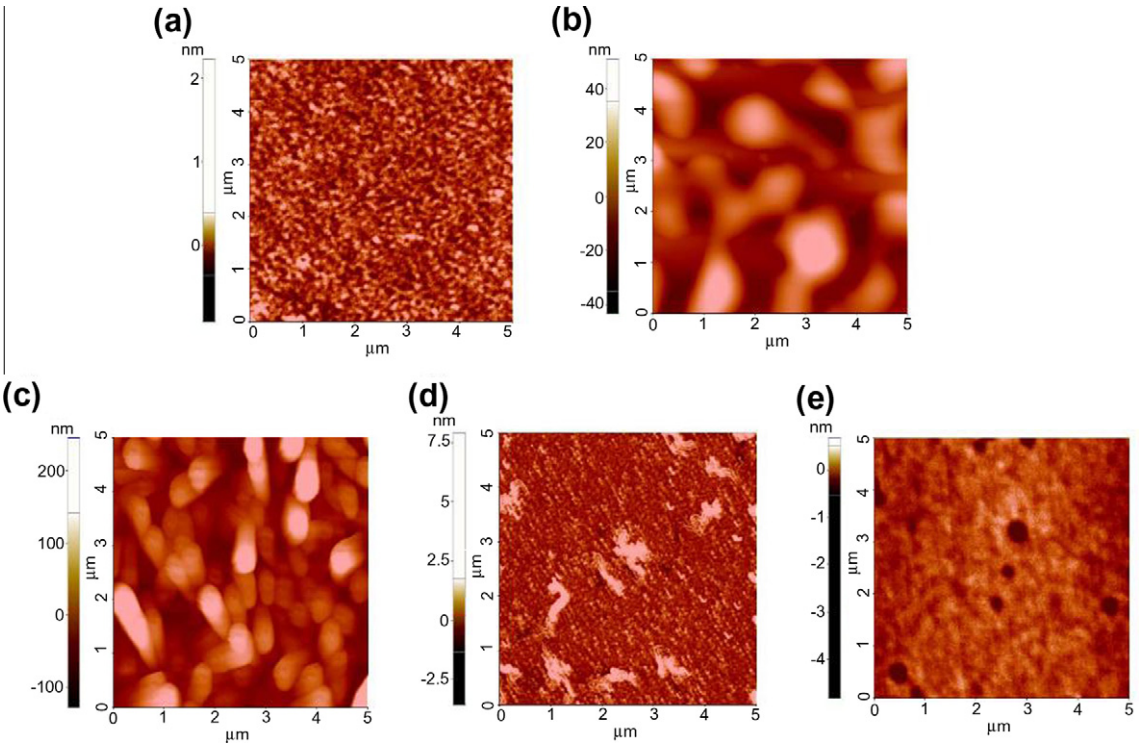

Fig. 10. AFM images of various ETLs. AFM images of various ETLs showing a 5 × 5 μm surface area: (a) $Bebq_2$, (b) BPhen, (c) TAZ, (d) BAlq, and (e)TPBI.

teristics of blue devices A and B, where an EQE of blue devices A and B was 7.55% and 10.01% at 100 cd/m^2 and 4.62% and 8.42% at 1000 cd/m^2, respectively. It was also found in Fig. 8(b) that a PE of blue devices A and B was 8.63 and 13.18 lm/W at 100 cd/m^2 and 4.16 and 8.94 lm/W at 1000 cd/m^2, respectively. Blue device B with an ETL of TPBI showed higher efficiency by a factor of 1.3 and two at 100 and 1000 cd/m^2 than blue device A with an ETL of BAlq, respectively. The efficiency difference between blue devices A and B explains the reason why device E has higher efficiency than device D. In other words, the ETL of TPBI, which has a higher triplet energy level than that of FCNIrpic, could confine triplet energy in EML well. Fig. 9 shows possible triplet energy transfer paths for all emitters in the two hosts and ETLs, where mCP used as a host for FCNIrpic and XBL, and TPBI, used as a host for Ir(ppy)$_3$ and Ir(pq)$_2$(acac), had higher triplet energy leading to effective confinement of triplet excitons in EML.

3.2.5. Surface morphology of various ETLs

Fig. 10 shows the AFM images of Bebq$_2$, BPhen, TAZ, BAlq, and TPBI films. It was found in Fig. 10 that for the films of BPhen and TAZ, the surfaces were very rough with r.m.s. roughness values (σ) of 14.75 and 54.60 nm, respectively. On the other hand, TPBI film showed the smoothest σ, at 0.14 nm, among them. Bebq$_2$ and BAlq films also showed σ of 0.15 and 0.56 nm, respectively. We can expect that the smooth surface of the film may be one of the important factors for achieving high efficiency in OLEDs due to less defective sites at the smooth interface of films. Therefore, the highest efficiency of device E with TPBI as the ETL may be partially due to the good film-forming property of TPBI.

4. Conclusions

WOLEDs were fabricated using blue, green, and red phosphorescent emitters such as FCNIrpic, Ir(ppy)$_3$, and Ir(pq)$_2$(acac) and various ETLs such as Bebq$_2$, BPhen, TAZ, BAlq, and TPBI. White devices with an ETL of TPBI exhibited nearly IQE of 100% and PE of 39.2 lm/W, which had a doubly higher efficiency than the control white device. Remarkably, it also showed high EQE of 16.4% at 1000 cd/m^2. In order to understand the reason why white devices with an ETL of TPBI exhibit nearly 100% IQE, many devices with various structures were fabricated and characterized in this study. In summary, the reasons for nearly 100% IQE are as follows: (1) high-efficiency phosphorescent blue emitter of FCNIrpic: the efficiency of phosphorescent blue emitters is generally lower than that of phosphorescent green and red emitters. But, the blue device with FCNIrpic in this study was found to have 1.5 times higher efficiency than the blue device with FIrpic; (2) good hole-blocking ability: TPBI has a deep HOMO value of 6.2 eV, which is similar to BPhen (6.4 eV) and TAZ (6.3 eV); (3) no electron leakage: no electron leakage can occur at the interface of red EML and ETL since the optimized white device E used TPBI as a host for the red emitter and also as ETL material; (4) higher triplet energy than blue emitter: TPBI can play the role of hole- and exciton-blocking layer simultaneously. Therefore, white devices with TPBI showed good confinement of triplet excitons within the EML; (5) a very smooth surface: TPBI has the smoothest morphology of $\sigma \sim 0.14$ nm among other ETLs. Thus, white devices with TPBI do not seem to show a saturated luminance–voltage curve at high voltage. We have exhibited high-efficiency PHWOLEDs along with a suggestion for the mechanism for achieving nearly 100% IQE. PHWOLEDs fabricated using device structures and materials described here may be expected to be applicable for SSL.

Table 2
Various characteristics of all devices, including, external quantum efficiency, current efficiency, power efficiency, and Commission Internationale de L'Eclairage (CIE$_{x,y}$) coordinates at 500 cd/m^2.

Device	External quantum efficiency (%)	Current efficiency (cd/A)	Power efficiency (lm/W)	CIE$_{x,y}$
A	7.70	17.14	10.87	0.42, 0.41
B	9.93	22.15	13.20	0.42, 0.45
C	10.04	24.46	9.07	0.44, 0.42
D	12.92	28.51	13.54	0.39, 0.40
E	17.47	35.74	19.85	0.46, 0.39

Various characteristics of all devices are summarized in Table 2, such as EQE, current efficiency, PE, and CIE$_{x,y}$ coordinates at 500 cd/m^2.

Organic thin-film transistor

ABSTRACT

A 10-layer stack of bipolar gate dielectric was formed by sequential layer-by-layer deposition using pulsed radio frequency (RF) plasma polymerization of allylamine and vinyl acetic acid monomers. Due to polar groups localized at the interfaces between each consecutive layer by alternating amine (–NH_2) and carboxylic acid (–COOH) functional groups, a 60 nm thick multilayer structure demonstrated relatively high dielectric constant of 4.4 with extremely smooth and crack/pin-hole free surfaces. Without any post-deposition thermal annealing, a 10-layer stack of bipolar dielectric layers shows a low leakage current density ($\sim 1 \times 10^{-6}$ A/cm^2 at 2 MV/cm) with high breakdown fields (>4 MV/cm). With a 10-layer stack of bipolar gate dielectrics, low supply voltage regioregular poly-(3-hexythiophene) (P3HT) organic thin-film transistors (OTFT) were tested. P3HT OTFTs demonstrated low-voltage operation and moderate field-effect mobility up to $\sim 3.4 \times 10^{-3}$ cm^2/V s in the saturation region with the drain voltage a −12 V. The threshold voltage in the saturation region and on–off current ratio were measured to be +1.4 V and $\sim 1.2 \times 10^2$, respectively.

1. Introduction

Organic-based gate dielectrics with high dielectric constant (k) have made remarkable progress toward high performance and low-voltage operation organic thin-film transistors (OTFT) in the last two decades [1–8]. Among various gate dielectric deposition methods, plasma polymerization has gained increasing interest for its ability to develop new thin gate dielectrics toward electronic application due to simple processing, wide selection of monomers, and low deposition temperature [9,10]. For example, both high- and low-k dielectric have been successfully plasma-polymerized using different monomers [11–15]. More recently, high-k gate dielectrics deposited under plasma polymerization have been implemented in OTFTs, greatly reducing OTFT's operating voltages while exhibiting good device performances [11,12].

Pulsed RF plasma polymerization can be employed to alter systematically the density of the monomer functional groups through controlled variation of the plasma on/off duty cycle. As a result, functional groups present in the monomer can be retained significantly in the polymerized films [13,14]. Under pulsed plasma polymerization conditions, the k values of deposited films can be tailored by employing different polarizability of monomer functional groups. Recently, a 50 nm thick multilayer structure demonstrated relatively high dielectric constant of ~6 without employing any post-deposition thermal annealing, which was attributed to the presence of polar groups, specifically ammonium ($-NH_3^+$) and carboxylate ($-COO^-$) localized at the interfaces between each consecutive plasma deposited

layer [14]. It should be noted that carbon-based materials, like polyimides, generally exhibit a dielectric constant of only 2.0–2.5.

The significant advantage of multistacked bipolar films is that the leakage current can be effectively suppressed, while the film can be synthesized thin, typically less than 50 nm [14]. In our previous study, we found the leakage current is decreased two orders of magnitude even though the total thickness of film is decreased while increasing the number of multilayers in the stack, indicating the number of interfaces within each deposited film is an important factor to control the leakage current in multilayer stacked bipolar polymer films [14].

In this article, we report low-voltage operation regioregular poly-(3-hexylthiophene) (P3HT) OTFTs with pulsed RF plasma-polymerized multistacked bipolar gate dielectric.

2. Experimental

A carboxylic acid (–COOH) containing monomer, vinyl acetic acid (VAA), and an amine ($-NH_2$) containing monomer, allylamine (AA), were polymerized under pulsed RF plasma operational conditions. The monomers were used as-received without further purification. A polymeric thin film of AA was first deposited by pulsed RF plasma polymerization on the substrate which was then followed by the deposition of a thin film of VAA. The sequential layer-by-layer deposition of these films was performed to obtain a total 10-layer stacked structure of pulsed RF plasma-polymerized AA (PP-AA) and VAA (PP-VAA), containing polar groups localized at the interfaces between each consecutive layer. For pulsed plasma deposition of VAA, a plasma duty cycle of 2/30 (plasma on-time, ms/plasma off-time, ms) was used at a monomer pressure 160 mTorr and 150 W power input. Allylamine was plasma polymerized at a duty cycle of 10/30, monomer pressure 70 mTorr and 100 W power input. Substrate temperature was nominally held at room temperature. Further details of condition for pulsed RF plasma polymerization of VAA and AA can be found elsewhere [14]. The nominal total thicknesses and the refractive index of the deposited films were estimated to be ~60 nm, corresponding to individual layers of ~6 nm, and 1.61, respectively, as measured by single wavelength ellipsometry. The surface morphologies of a 10-layer stack of polymeric films were studied using a Dimension 3100 atomic force microscopy (AFM) (Veeco Instruments) in tapping mode.

For capacitance–voltage (C–V) characterization with an LCR meter (Agilent 4284A), the polymer films were deposited on p-type silicon wafers with a resistivity of 4.4 Ω cm for metal–insulator–semiconductor (MIS) capacitors. After deposition of 10-layer stack of PP-AA and PP-VAA, the MIS capacitors were completed by shadowmask electron beam evaporation (~10^{-7} Torr) of a 100 nm thick Au gate metal, directly onto the multilayer stack surface. The final MIS structure fabricated was a p-Si/10-layer stack of PP-AA and PP-VAA/Au. The active area of each MIS capacitor studied was 0.283 mm^2. Leakage current density versus electric field characteristics ($J_{Leakage}$–E) of MIS capacitors were measured with a semiconductor parameter analyzer (Agilent 4156) at room temperature under darkness. All MIS capacitors fabricated were tested without any post-deposition annealing.

A 10-layer stack of film as the gate dielectric was used for a bottom contact OTFTs. The Si substrates were processed using standard silicon degreasing and RCA cleaning procedures prior to plasma polymerization. A heavily doped n-type silicon substrate with a resistivity of 0.003 Ω cm was used as the gate. After deposition of multilayer stacks of thin films, the Au source and drain contacts are formed by standard photolithography and lift-off, defining a channel length of 7 μm and width of 135 μm. It was shown that the plasma-polymerized multistacked gate dielectrics are resistant to immersion in typical chemical solvents for standard photolithography and lift-off. They are robust enough to withstand conventional photolithographic processing with no observable film shrinkage, warping or peeling.

Thin films of the P3HT were then deposited by spin coating from a concentration of 8 mg/ml in chloroform in an inert glove box environment with ⩽1 ppm level of oxygen and moisture. The regioregular P3HT (Merck Chemicals Ltd.) with 94.5% regioregularity was used without further purification. The P3HT used here has a weight-average molecular weight (M_w) of 26,200 g/mol, corresponding to a number-average molecular weight (M_n) of 13,000 g/mol, and with a polydispersity (M_w/M_n) of ~2. The P3HT OTFTs were kept in a vacuum at pressures below 10^{-6} Torr for 10 h to remove any unintended doping. Prior to the measurement, the completed P3HT OTFTs were briefly annealed at 110 °C for 10 min in N_2 atmosphere. Electrical characterizations of the P3HT OTFTs were performed with a semiconductor parameter analyzer (Agilent 4156) at room temperature under darkness in ambient air.

3. Results and discussion

The chemical structures of monomers used for plasma polymerization are shown in Fig. 1. Each AA and VAA monomer has the requisite monomer functionalities, $-NH_2$ and –COOH groups, respectively. Under pulsed plasma operational conditions, these functional groups in the monomer structure are retained significantly in the films. Explicit evidence for the presence of the $-COO^-$ and $-NH_3^+$ polar entities in the interface of the multilayer structure was provided using X-ray photoelectron spectroscopy and attenuated total reflectance Fourier transform-IR spectroscopy, described in detail elsewhere [14].

Fig. 2 shows the AFM tapping mode height images (1 μm × 1 μm) for a 10-layer stack of PP-AA and PP-VAA films deposited on a silicon substrate by pulsed RF plasma polymerization. The root-mean-square (RMS) roughness of the deposited film is ~0.129 nm in the image Z range of 1.703 nm, demonstrating pulsed RF plasma polymerization could be very effective for producing extremely smooth surfaces. In addition, no crack/pin-holes were observed over different positions on the surface scanned by AFM.

Fig. 3a shows a typical C–V response of an MIS capacitor (p-Si/10-layer stack of alternating AA and VAA/Au) at

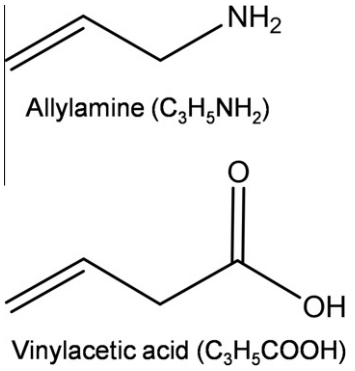

Fig. 1. Chemical structure of monomers used for polymerization under pulsed RF plasma condition: an amine ($-NH_2$) containing monomer, allylamine ($C_3H_5NH_3$), and a carboxylic acid (–COOH) containing monomer, vinyl acetic acid (CH_3COOH).

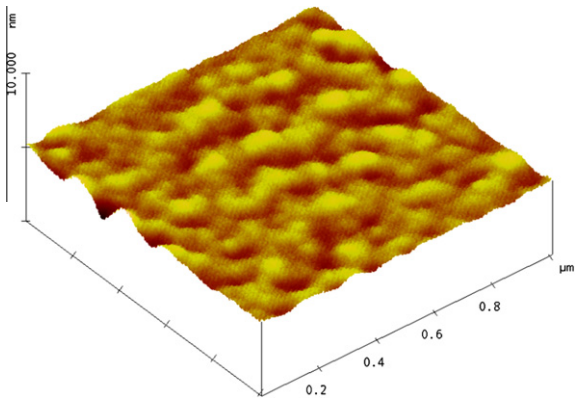

Fig. 2. AFM images (1 μm × 1 μm) for a 10-layer stack of gate dielectric layers deposited by pulsed RF plasma polymerization. The RMS roughness of the gate dielectric layers was 0.129 nm with the image Z range of 1.703 nm.

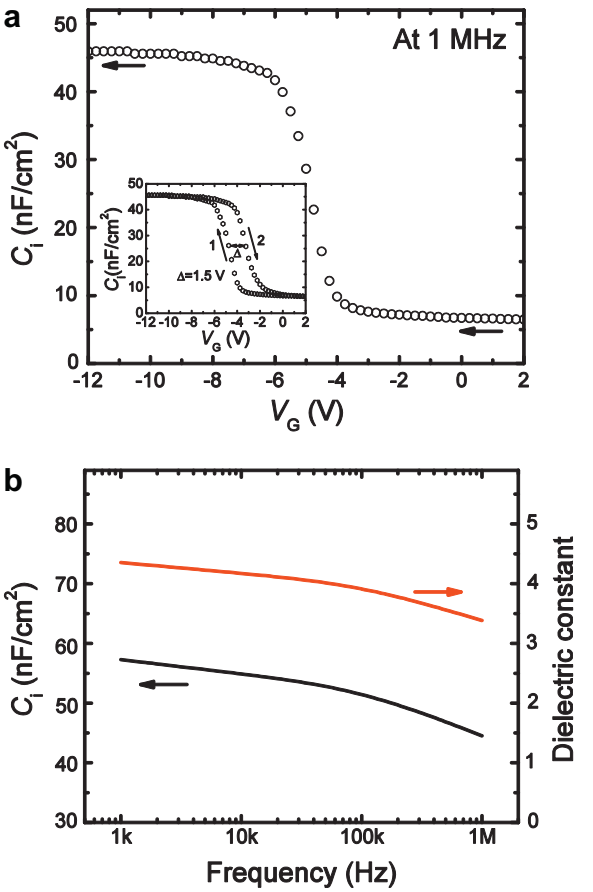

Fig. 3. (a) *C–V* characteristics of MIS capacitors at 1 MHz for a pulsed RF plasma-polymerized gate dielectric (~60 nm). The inset shows the hysteresis behavior of the MIS capacitor. (b) Frequency dependency of the gate capacitance per area (C_i) in accumulation and the dielectric constant. The dielectric constant extracted at 1 kHz is ~4.4.

1 MHz frequency clearly showing depletion at positive gate voltage (V_G) and accumulation at negative V_G when the V_G was swept from $+V_G$ to $-V_G$. It shows the shift to more negative values of V_G along the voltage axis of a *C–V* curves with respect to the ideal *C–V* curve due to uniformly distributed trapped charges during plasma polymerization process across the polymerized films thickness [15]. The inset of Fig. 3a shows the hysteresis behavior of the capacitor for a sweep of $+V_G$ to $-V_G$ and a return sweep $-V_G$ to $+V_G$, which exhibits a ~1.5 V voltage shift at 1 MHz. The voltage shift of the *C–V* curves could be attributed to positive mobile charges associated with the multilayered bipolar gate dielectric. For positive V_G, positive mobile ions drift to the insulator–semiconductor interface, giving a negative voltage shift. For large negative V_G, the positive mobile charges are attracted to the gate-insulator interface where it exhibits less influence upon the measured *C–V* curves. The total voltage shift, ΔV (V) is given as $\Delta V = -Q/C_i$ where Q is the effective net charge per unit area (cm^{-2}), and C_i is the measured gate capacitance per unit area (F/cm^2). The effective net charge density in the gate dielectric layer is estimated to be $\sim 4.4 \times 10^{12}\ cm^{-2}$. The C_i tends to shift to slightly higher values when decreasing the frequency for all capacitors, as shown in Fig. 3b. An observed frequency dependent dispersion in the accumulation region can be attributed to the slow polarization of the gate dielectric at higher frequencies and this polarization can lead to an increase in the induced charge at lower frequencies [16]. The k values of the multilayer gate dielectric were calculated at four different frequencies using $k = C_i \cdot t/\varepsilon_0$, where ε_0 is the permittivity in vacuum, and t is the thickness. The calculated dielectric constant was 4.4 at 1 kHz (Fig. 3b). For the extraction of field-effect mobility values of P3HT OTFTs in the saturation region, the C_i equal to 57.3 nF/cm^2 at 1 kHz was considered.

Fig. 4 illustrates the leakage current density versus electric field, $J_{Leakage}$–E, for the 10-layer stack of gate dielectric. The leakage current density was $7.34 \times 10^{-6}\ A/cm^2$ at 2 MV/cm. The breakdown field was estimated to be larger than 4 MV/cm. The inset of Fig. 4 is the leakage current density versus the voltage ($J_{Leakage}$–V) characteristics for the MIS capacitors. It should be noted that all the multilayer gate dielectrics in this study were measured without any post-deposition annealing.

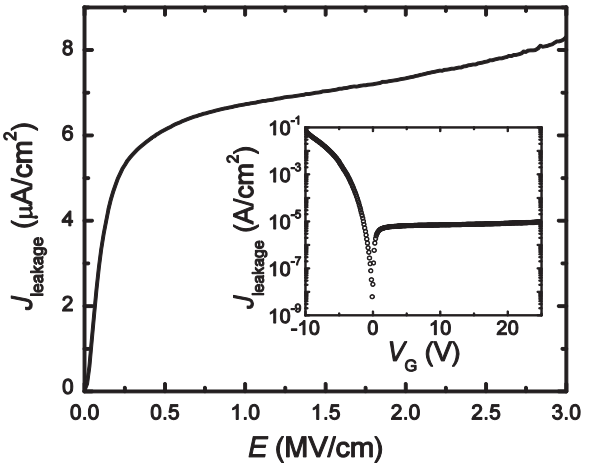

Fig. 4. $J_{Leakage}$–E characteristics of MIS capacitors. The breakdown field is estimated >4 MV/cm. The inset shows $J_{Leakage}$–V characteristics of the capacitors.

Fig. 5a shows the output characteristics for P3HT OTFTs with applied drain voltage (V_D) ranging from 0 to −15 V with V_G varying from 4 to −6 V. The devices operate at relatively low supply voltages. However, a large off-state I_D at the level of $\sim 1 \times 10^{-9}$ A at $V_G = 0$ was observed using fresh devices tested in air without any encapsulation immediately after completion of the fabrication process. Although a non-zero I_D could be reduced by applying a positive V_G, the I_D at $V_G = 4$ V was only one order of magnitude lower than that at $V_G = 0$ V. It has been known that an off-state I_D could increase over the extended exposure in ambient air due to the high bulk conductivity of P3HT attributed from unreduced P3HT and oxygen doping [17,18]. However, considering that the fresh devices were tested immediately after completion of fabrication, a high off-state I_D at a positive V_G could be due to doping to P3HT by oxygen from the surfaces of plasma-polymerized films since plasma-polymerized films have a strong affinity for oxygen and moisture [19]. For the transfer characteristic in the saturation region at $V_D = -10$ V and $V_D = -12$ V, the plot of $I_D^{1/2} - V_G$ is shown in Fig. 5b. The mobility in the saturation region (μ_{sat}), and the threshold voltage (V_T) are calculated from

$$I_D = \frac{W}{2L} C_{total} \mu (V_G - V_T)^2 \quad (1)$$

At $V_D = -12$ V, the μ_{sat} and V_T are estimated to be 3.4×10^{-3} cm^2/V s and +1.4 V, respectively, while $V_D = -10$ V, the μ_{sat} and V_T are 2.9×10^{-3} cm^2/V s and +1.5 V, respectively. The devices showed a dependence of μ_{sat} on V_G (not shown here). Due to a large off-state I_D, an on–off current ratio ($I_{on/off}$) of only $\sim 1.2 \times 10^2$ was measured. No significant variation of estimated μ_{sat}, V_T, and $I_{on/off}$ was recorded over more than 5 devices.

4. Conclusions

In conclusion, pulsed RF plasma polymerization could be very effective for producing extremely smooth and crack/pin-hole free gate dielectrics. It was shown that the plasma-polymerized multistacked gate dielectrics are robust enough to withstand conventional photolithographic processing with no observable film shrinkage, warping or peeling. Finally it was demonstrated that the P3HT OTFTs operate at low supply voltages due to high-k values of pulsed RF plasma-polymerized multistacked gate dielectrics, achieved without post-production annealing. Further work is required to reduce possible oxygen doping to P3HT from the surface of plasma-polymerized gate dielectrics through surface passivation.

Bulk-heterojunction solar cell
Low band-gap polymer
Poly(thienylenevinylene)

ABSTRACT

A new thienylenevinylene–benzothiadiazole copolymer, poly{1,2-(*E*)-bis[2-(5-bromo-3-dodecyl-2-thienyl)-5-thienyl]ethene-2,1,3-benzothiadiazole} (**PETVTBT**), was synthesized and characterized for potential use in solar cells. The polymer had broad absorption over the entire visible region and a low band gap of 1.57 eV. In addition, the polymer had a relatively low HOMO level of about 5.1 eV. Although **PETVTBT** was a donor–acceptor-type copolymer, the hole mobility reached 0.025 $cm^2/V\,s$ using field-effect transistors. Bulk-heterojunction solar cells that used a **PETVTBT**:$PC_{[71]}BM$ blend as the active layer showed a power conversion efficiency of 1.0% under a simulated AM 1.5 G solar irradiation at 100 mW/cm^2.

1. Introduction

Polymer solar cells (PSC) have attracted considerable attention recently because of their low manufacturing costs, solution processing and use in flexible devices [1]. Recently, the power conversion efficiencies (PCE) of bulk-heterojunction (BHJ) solar cells that are based on poly (3-hexylthiophene):[6,6]-phenyl-C61-butyric acid methyl ester (P3HT:$PC_{[61]}BM$) were reported to be approximately 5% [2]. Although P3HT is one of the most promising materials ever tested for use in polymer solar cells, P3HT absorbs only within the visible region of the solar spectrum, which limits device performance. To better match the solar spectrum, development of new low band-gap (LBG) polymers is critically important. The most successful approach to designing LBG-conjugated polymers is alternation of conjugated electron-rich and conjugated electron-deficient units within the polymer chain. These polymers have been termed donor (D)–acceptor (A) semiconducting polymers [3]. The D–A semiconducting polymers reduce the optical band-gap via intramolecular charge transfer (ICT) [4].

A large number of D–A-type LBG polymers have been reported by many research groups [5,6]. Among the various acceptor units, 2,1,3-benzothiadiazole and 4,7-di-2-thienyl-2,1,3-benzothiadiazole are most frequently used as acceptor molecules in the D–A-type LBG polymers [7]. For example, the silole-containing thiophene-2,1,3-benzothiadiazole copolymer PSBTBT has a high power conversion efficiency of 5.1% and a relatively high hole mobility of 3×10^{-3} $cm^2/V\,s$ [8]. Recently, Bazan and co-workers reported that modification of the alkyl side-chain of this polymer resulted in a very high efficiency of 5.9% when it was blended in a BHJ composite with $PC_{[71]}BM$ [9].

On the other hand, charge carrier mobility is also a very attractive feature that is critically important for high-performance solar cells [10]. The low hole mobility of the donor polymer is one of the limiting factors to achieve high efficient BHJ solar cells due to the efficient charge collection to each electrodes [11]. Therefore, high-mobility

LBG-conjugated polymers with broad absorption spectra are very attractive for PSC applications.

Recently, we reported a strong interchain interaction polymer in the solid state, poly(1,2-(*E*)-bis[2-(5-bromo-3-dodecyl-2-thienyl)-5-thienyl]ethene) (PETV12T) [12], which also had a high charge carrier mobility of 0.15 cm^2/V s. However, PETV12T has a relatively large band gap (~1.85 eV), which prevents its application as an absorber in a BHJ solar cell. To further enhance the absorption of sunlight, the band gap must be reduced.

The present study describes the synthesis of an alternating copolymer comprised of electron-rich 1,2-(*E*)-bis[2-(5-bromo-3-dodecyl-2-thienyl)-5-thienyl]ethene and electron-deficient 2,1,3-benzothiadiazole units, which was abbreviated as **PETVTBT**. This D–A copolymer had broad absorption over the entire visible region and a low band gap of 1.57 eV. In addition, this LBG polymer had a high hole mobility of 0.025 cm^2/V s. The BHJ solar cells that used a **PETVTBT**:$PC_{[71]}BM$ blend as the active layer showed a power conversion efficiency of 1.0% under simulated AM 1.5 G solar irradiation at 100 mW/cm^2. The relatively low power conversion efficiency, despite a low band gap and a high mobility, was due to a change in the electronic properties of **PETVTBT** that resulted from blending the polymer with the acceptor $PC_{[71]}BM$.

2. Experimental section

2.1. Materials

All starting materials were purchased from Aldrich Chemical Co., and were used without further purification. THF and diethyl ether were dried over calcium hydride. 1,2-(*E*)-bis[2-(5-bromo-3-dodecyl-2-thienyl)-5-thienyl]ethene and 4,7-dibromo-2,1,3-benzothiadiazole were prepared as previously described [12,13].

2.2. Synthesis

2.2.1. 4,7-Bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-2,1,3-benzothiadiazole (**2**)

A solution of 4,7-dibromo-2,1,3-benzothiadiazole (1.5 g, 5.1 mmol), bis(pinacolato)diboron (3 g, 11.81 mmol), PdCl2 (dppf)-MC complex (0.75 g, 0.92 mmol), and potassium acetate (3 g, 30.57 mmol) in degassed 1,4-dioxane (20 ml) was stirred at 80 °C overnight. The reaction was quenched by addition of water, and the resulting mixture was washed with diethyl ether, dried over $MgSO_4$, and concentrated *in vacuo* to yield a dark red solid. The solid was purified by silica gel chromatography using 3% ethyl acetate in hexane to give the desired compound as a pink solid. Yield: 21%. ^1H NMR ($CDCl_3$, 400 MHz, [ppm]): δ 8.12 (s, 2H), 1.43 (s, 24H). GCMS (EI): *m/z* 388, calcd 388.10.

2.2.2. Poly{1,2-(E)-bis[2-(5-bromo-3-dodecyl-2-thienyl)-5-thienyl]ethene-2,1,3-benzothiadiazole} (**PETVTBT**)

2 (0.31 g, 0.8 mmol) and 1,2-(*E*)-bis[2-(5-bromo-3-dodecyl-2-thienyl)-5-thienyl]ethane (0.68 g, 0.8 mmol), degassed K_2CO_3 (8 ml, 2 M) and 1 drop of Aliquat 336 (2 mol%) were dissolved in 10 ml of toluene in a 100-ml flask. The solution was purged with nitrogen for 30 m, and then tetrakis(triphenylphosphine)palladium (92 mg, 0.08 mmol) was added. The reaction was stirred at 100 °C for 48 h. After completion of the reaction, bromobenzene (0.1 equiv) was added to the reaction mixture, followed by stirring for 2 h. The resulting mixture was poured into a mixture of methanol and concentrated hydrochloric acid (2:1) and stirred overnight. The precipitated dark black solid was redissolved in THF and added dropwise to methanol (200 ml). The resulting solid was removed by filtration and then was subjected to Soxhlet extraction with methanol, acetone, and hexane to remove the low-molecular-weight fraction. The residue was extracted with chlorobenzene to give a dark black solid. Yield: 0.272 g (41%). ^1H NMR ($CDCl_3$, 400 MHz, [ppm]): δ 7.51 (s, 2H), 7.04–6.99 (br, 8H), 2.85 (br, 4H), 1.75 (br, 4H), 1.25 (br, 36H), 0.87 (br, 6H).

2.2.3. Characterization and measurements

Materials were characterized by ^1H NMR spectroscopy (JEOL JNM-LA300WB 400 MHz). Thermo-gravimetric analysis (TGA) was performed using a TA Instrument 2050 series. Differential scanning calorimetry (DSC) was performed using a TA Instrument 2010 series at a heating rate of 10 °C/min under a nitrogen atmosphere. Absorption spectra were measured using a UV–vis spectrophotometer (Lambda 750, Perkin–Elmer). Mass spectra were obtained by gas chromatography mass spectrometry (GCMS, Shimadzu GCMS-QP2010). The molecular weight of the polymer was confirmed by gel-permeation chromatography (GPC, Futecs, NS2001). Cyclic voltammetry (CV) was conducted using an Autolab, PGSTAT 30 Potentiostat/Galvanostat in an acetonitrile solution with 0.1 M tetrabutylammonium perchlorate (Bu_4NClO_4) as the supporting electrolyte, indium tin oxide (ITO) as the working electrode, a Pt wire as the counter electrode, and a Ag wire as the reference electrode at a scan rate of 50 mV/s. Atomic force microscopy (AFM) measurements were performed using an Autoprobe CP, PSI.

2.2.4. OTFT fabrication and characterization

The glass substrate was cleaned in an ultrasonic bath with DI water and acetone, followed by 2-propanol, and was then stored in a vacuum oven prior to electrode deposition. The source and drain electrodes were deposited on the cleaned glass substrates by thermal evaporation (Ni/Au = 5/30 nm). The channel length was 50 μm and the width was 1.0 mm. After deposition of the source and drain electrodes, the patterned surface was treated with 1H,1H,2H,2H-perfluorodecanethiol (PFDT) vapor to produce hydrophobic surfaces on the bottom-contact Au electrodes. **PETVTBT** films with a thickness of 80 nm were spin-coated from a 10 mg/ml solution in chlorobenzene and annealed at 130 °C for 10 min in a glove box. After annealing, 500-nm thick PMMA films, which served as gate dielectric layers, were spin-coated from an 80 mg/ml solution in *n*-butylacetate and baked at 80 °C for 2 h in a glove box. Subsequently, aluminium electrodes were deposited at a thickness of 30 nm by thermal evaporation. OTFT devices were characterized using a Keithley 4200-SCS characterization system under ambient conditions.

2.2.5. BHJ solar cell fabrication and characterization

The patterned indium tin oxide (ITO)-coated glass substrates were cleaned according to a conventional method. After cleaning the substrate, UV-O_3 treatment was carried out for 30 min prior to deposition of PEDOT:PSS (Baytron P VP AI4083). The PEDOT:PSS was spin-coated (5000 rpm, 1 min) onto the ITO-coated glass, which was then baked at 140 °C for 10 min in air before being transferred to an N_2-filled glove box for additional processing. The thickness, as measured with a surface profiler (Kosaka ET-3000i), was almost 25 nm. Films of **PETVTBT** blended with $PC_{[71]}BM$ (Nano-C) were used for the active layers of the solar cells. The weight ratios of **PETVTBT** to $PC_{[71]}BM$ in the blended solutions were 1:1, 1:2, 1:3, and 1:4. **PETVTBT** and $PC_{[71]}BM$ (total 25 mg) were dissolved in 500 μl of 1,2-dichlorobenzene and stirred at 60 °C overnight in an N_2-filled glove box. The active layers of each device were formed by spin coating, with the blended solutions passing through a 0.2-μm PTFE filter prior to deposition on the PEDOT:PSS layer. After spin coating, solvent annealing was performed at room temperature for 2 h in a jar. The Ca (25 nm)/Al (100 nm) top electrodes were deposited on the active layers by thermal evaporation under a high vacuum ($<3 \times 10^{-6}$ torr) with a shadow mask, and the area (4.66 mm^2) was defined as the photoactive area of the corresponding devices. *J–V* curves were measured with a Keithley 4200 source measurement unit. The solar cell devices were illuminated at an intensity of 100 mW/cm^2 using a 1-kW Oriel solar simulator with an AM 1.5 G filter in an N_2-filled glove box. For accurate measurements, the light intensity was calibrated using a radiant power meter and two reference silicon solar cells certified by the NREL.

3. Results and discussion

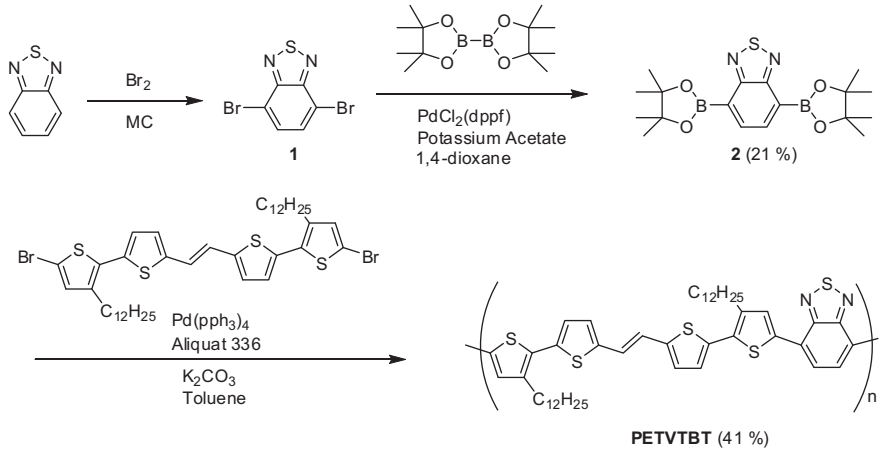
3.1. Synthesis and characterization

Scheme 1 shows the synthesis of **PETVTBT**. The monomer **1** was synthesized according to an established method [13]. The bromination of 2,1,3-benzothiadiazole with bromine to form **1** was performed at room temperature. The diboronic esters **2** were synthesized by the $PdCl_2$ (dppf)-catalyzed reaction of the corresponding dibromo starting material **1**, bis(pinacolato)diboron, and KOAc in degassed 1,4-dioxane [14]. The pure product **2** was isolated by chromatography on silica gel using a mixture of ethyl acetate and hexane as the eluent. After chromatography, **2** was recrystallized from dichloromethane/ethanol to afford the product as a pale pink solid. The D–A **PETVTBT** polymer was synthesized from a combination of diborolane 2 with a dibromooligothiophene 1,2-(*E*)-bis[2-(5-bromo-3-dodecyl-2-thienyl)-5-thienyl]ethane by Suzuki coupling in the presence of 10 mol% of $Pd(pph_3)_4$ as a catalyst, K_2CO_3 as a base, and 1 drop of Aliquat 336 as a phase-transfer catalyst. After polymerization, soxhlet extraction was performed using methanol, acetone, hexane and chlorobenzene in sequence. The **PETVTBT** in the chlorobenzene fraction gave a dark black solid in 41% yield. The molecular weight of the **PETVTBT** was estimated by gel-permeation chromatography (GPC) analysis in a THF solution relative to polystyrene standards. The number-average molecular weight (M_n) was 8000 with a polydispersity index (M_w/M_n) of 1.4.

TGA and DSC were used to investigate the thermal properties of the polymers. **PETVTBT** exhibited very good thermal stability, losing less than 5% of its weight on heating to 390 °C, as determined by thermo-gravimetric analysis (TGA) (Fig. 1a). The differential scanning calorimetry (DSC) thermogram for the polymer was determined to have a glass transition temperature of 149 °C (Fig. 1b).

3.2. Optical and electrochemical properties

The normalized UV–vis absorption spectra of a solution of **PETVTBT** in chlorobenzene, and films spin-coated from chlorobenzene onto a glass substrate are shown in Fig. 2. The dilute chlorobenzene solution of **PETVTBT** showed a broad absorption band, ranging from 350 to 700 nm. The absorption maximum (λ_{max}) located at 563 nm was due to the ICT transition [15]. The absorption maximum was accompanied by a strong absorption band at a shorter



Scheme 1. Synthetic scheme for **PETVTBT**.

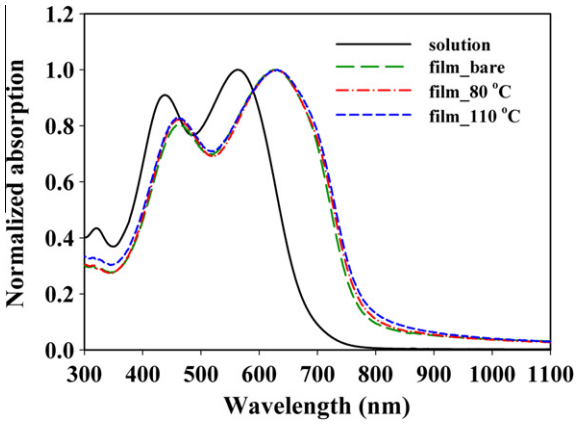

Fig. 2. UV–vis spectra of **PETVTBT** in chlorobenzene solution, unannealed thin film, and annealed film.

wavelength of 438 nm, which corresponded to the π–π^* transition of the quarterthiophene-vinylene units [16].

The normalized UV–vis absorption spectra of the **PETVTBT** films are also depicted in Fig. 2. Compared with the UV–vis absorption spectrum of the solution, the spectra of the polymer films showed pronounced peak broadening and a very large red-shift. When the thin film was annealed at 80 °C or 110 °C, the absorption maximum underwent an additional red-shift from 625 to 632 nm. This result implies that the polymer chains formed a more planar geometry with strong interchain interactions in the solid state

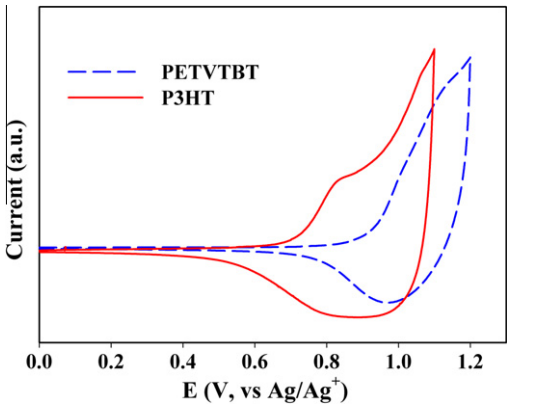

Fig. 3. Cyclic voltammogram of **PETVTBT** and P3HT.

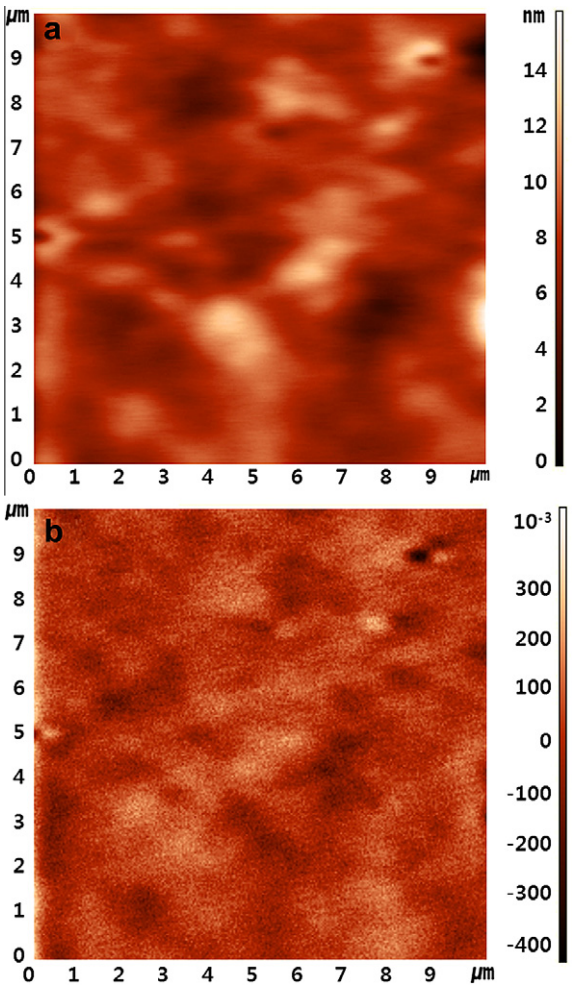

Fig. 4. AFM images of spin-coated **PETVTBT**:$PC_{[71]}BM$ (1:2, w/w ratio) films on silicon wafer; (a) topographic and (b) phase images.

[17]. More importantly, the UV–vis absorption spectrum of **PETVTBT** covered the entire visible region, which was indicative of a black polymer. This property is very attractive for fabrication of high-performance polymer solar cells due to the improved light harvesting. The optical band gap of the polymer was determined from the onset of UV–vis absorption in the solid state. The optical band gap of **PETVTBT** was 1.57 eV, which is very close to the ideal band gap for a polymer solar cell [18].

To investigate the electrochemical characteristics of **PETVTBT** and to estimate the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels of the polymers, cyclic voltammetry (CV) measurements were performed with 0.1 M tetrabutylammonium perchlorate ($Bu_4NC\,lO_4$) as the supporting electrolyte at a scan rate of 50 mV/s. To estimate the energy levels of the polymer from the vacuum energy level, we used the ferrocene/ferrocenium (Fc/Fc^+) redox couple as a calibration reference. The half-wave potential ($E_{1/2}$) for oxidation of the Fc/Fc^+ redox couple is 4.8 eV, below the vacuum level [19]. The HOMO level of **PETVTBT** was 5.1 eV (Fig. 3), which was 0.2 eV less than that of rr-P3HT (4.9 eV) when measured under the same conditions. The HOMO energy level of **PETVTBT** was lower than that of rr-P3HT, which is important for achieving large open-circuit voltage (V_{oc}) and high air stability.

3.3. Surface morphology of *PETVTBT*:$PC_{[71]}BM$ blend film

The roughness and surface morphology of the **PETVTBT**:$PC_{[71]}BM$ blend film were observed using atomic force microscopy (AFM). The blend film was prepared by spin coating from a 1:2 weight ratio of **PETVTBT**:$PC_{[71]}BM$ in 1,2-dichlorobenzene, and solvent annealing was performed at room temperature for 2 h in a jar. Fig. 4 shows the topographic and phase images of the blend film. The blend film was very smooth, and the root-mean-squared (RMS) surface roughness of the blend film was 1.58 nm, as shown in the topographic image.

3.4. Hole mobility

High hole mobility in the donor polymer is critically important for effective BHJ solar cells [20]. To characterize hole mobility, a **PETVTBT**-based organic thin-film transistor (OTFT) with a bottom-contact/top-gate (BC/TG) configuration was fabricated on a glass substrate. Before deposition of the active layer, the patterned substrate was treated with PFDT. The PFDT treatments reduced the contact resistance between the Au electrodes and the polymer active layer by increasing the Au electrode work function [21]. Fig. 5 shows transfer and output curves typical of a device with **PETVTBT** as the active layer. The hole

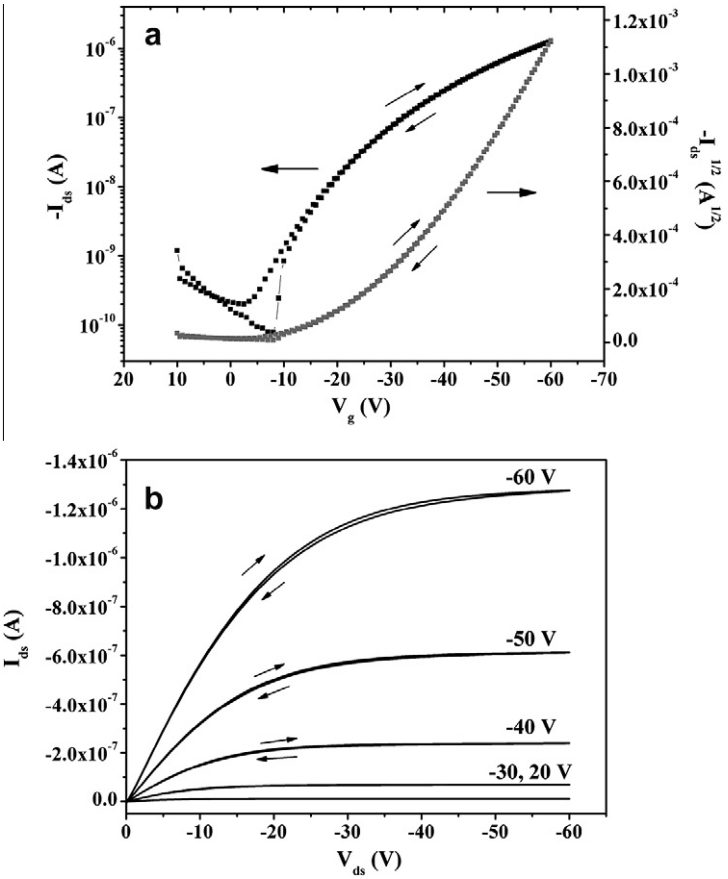

Fig. 5. *I–V* characteristics of a bottom-contact/top-gate (BC/TG) OTFT device of **PETVTBT** as semiconductor: (a) transfer curve at $V_d = -60$ V; (b) output curves at different gate voltages ($L = 50$ μm, $W = 1.0$ mm).

mobility was calculated from the slope of the linear fit of the transfer curve using the saturation regime. The hole mobility was 0.025 $cm^2/V\,s$, which was relatively high value than that of other D–A-type LBG polymers [22]. In addition, forward and reverse scans of the transfer curves showed that this polymer has very low hysteresis.

3.5. Photovoltaic performance

Bulk-heterojunction polymer solar cells were fabricated using **PETVTBT** as the donor, $PC_{[71]}BM$ as the acceptor, and Ca/Al as the negative electrode. The device structure was ITO/PEDOT:PSS/photoactive layer/Ca/Al. The active layer was spin-coated from a 1,2-dichlorobenzene solution, followed by solvent-assisted annealing at room temperature for 2 h in a jar [23]. The thicknesses of the thin film of the photoactive **PETVTBT**:$PC_{[71]}BM$ layer ranged from 60 to 100 nm. Although **PETVTBT** has a low solubility in 1,2-dichlorobenzene at low temperatures, the film morphology that formed upon heating a solution of **PETVTBT**:$PC_{[71]}BM$ was very smooth, as shown in the AFM images. Fig. 6 shows the current density–voltage characteristics of the photovoltaic cells fabricated using **PETVTBT**:$PC_{[71]}BM$ weight ratios of 1:1, 1:2, 1:3, and 1:4 under 1 sun AM 1.5 G of simulated irradiation at 100 mW/cm^2. Table 1 summarizes the photovoltaic characteristics as a function of $PC_{[71]}BM$ weight ratios. Maximal values of J_{sc}, and PCE were observed for the photovoltaic device with a 1:2 ratio of **PETVTBT**:$PC_{[71]}BM$. Both J_{sc} and PCE decreased at $PC_{[71]}BM$ weight ratios greater than 1:2. This result was attributed to increased aggregation of the $PC_{[71]}BM$, which would influence the separation of charges. Furthermore, an unbalanced charge transport was established due to the large fullerene ratio. Hence, both J_{sc}, and PCE decreased at higher fullerene weight ratios because of the two reasons described above. In addition, the values for V_{oc} decreased monotonically when the $PC_{[71]}BM$ content of the blend films was increased. A similar drop in the V_{oc} of MDMO-PPV/PCBM devices has been observed [24]. The decrease in V_{oc} could be explained by the formation of a charge-transfer complex (CTC) in a polymer/PCBM film, which reduces the effective LUMO level of PCBM [25]. Therefore,

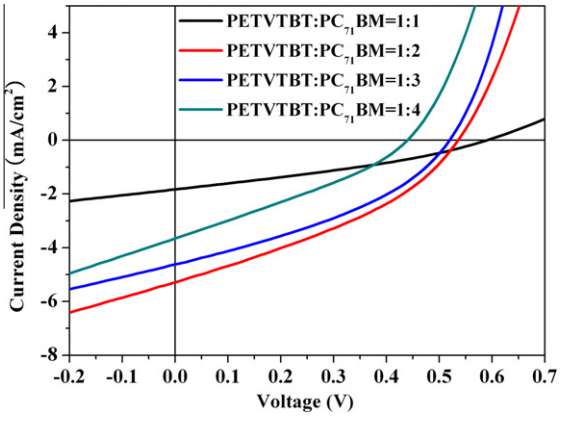

Fig. 6. The *J–V* curves of the **PETVTBT**:$PC_{[71]}BM$ based BHJ solar cell under 1 sun illumination. Device configuration – glass/ITO/PEDOT:PSS (25 nm)/**PETVTBT**:$PC_{[71]}BM$/Ca (25 nm)/Al (100 nm).

Table 1
A summary of the cell performance of parameters, indicating J_{sc}, V_{oc}, *FF* and PCE as functions of $PC_{[71]}BM$ concentration.

Device	Thickness (nm)	*FF* (%)	J_{sc} (mA/cm^2)	V_{oc} (V)	PCE (%)
1:1	100	32	1.83	0.59	0.35
1:2	80	35	5.29	0.54	1.00
1:3	60	37	4.62	0.52	0.88
1:4	80	30	3.66	0.44	0.49

the decrease in V_{oc} was proportional to the increase in the $PC_{[71]}BM$ concentration. The best performance was obtained with an active layer thickness of approximately 80 nm and a **PETVTBT**:$PC_{[71]}BM$ weight ratio of 1:2, which resulted in a J_{sc} of 5.29 mA/cm^2, a V_{oc} of 0.54 V, a *FF* of 0.35, and a PCE of 1.00%. These relatively lower efficiencies could be mainly attributed to the poor absorption and dissociation of low energy region excitons after blended with PCBM. Fig. 7 shows an incident photon-to-current conversion efficiency (IPCE) spectrum and UV–vis absorption spectrum of the 1:2 ratio of **PETVTBT**:$PC_{[71]}BM$ film. In contrast with the UV–vis absorption spectrum of the neat polymer, the IPCE spectrum of the **PETVTBT**:$PC_{[71]}BM$ blend film was decreased at longer wavelengths (~600–800 nm), and the absorption spectrum of the blend film was also diminished in the long-wavelength region unlike other high-performance polymers (Supplementary information, Fig. S1). These phenomena were also observed in

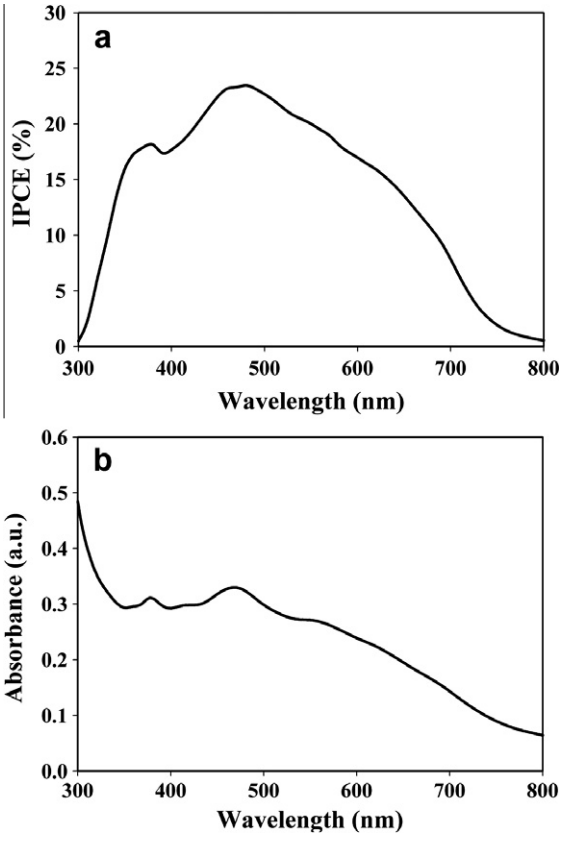

Fig. 7. The IPCE spectrum (a) and UV–vis absorption spectrum (b) of 1:2 ratio of **PETVTBT**:$PC_{[71]}BM$ film.

the UV–vis absorption spectrum of the **PETVTBT**:$PC_{[71]}BM$ solution (Supplementary information, Fig. S2). This result indicates that the electronic properties of **PETVTBT** were altered by blending with $PC_{[71]}BM$. Additional studies aimed at explaining this phenomenon are currently under way.

4. Conclusions

An alternating copolymer comprised of electron-rich thienylenevinylene and electron-deficient benzothiadiazole, **PETVTBT**, was synthesized. The thermal, optical, electrochemical, and photovoltaic properties of the copolymer were investigated in detail. The polymer was thermally stable with a decomposition temperature of 390 °C. The UV–vis absorption spectrum of **PETVTBT** covered the entire visible region, and the optical band gap of **PETVTBT** was 1.57 eV, which is very close to the ideal band gap for a polymer solar cell. In addition, the polymer had a low HOMO level of about 5.1 eV. Furthermore, the polymer had relatively high hole mobility of 0.025 cm^2/V s. These properties indicate that the polymer has potential for use in polymer solar cell applications. The photovoltaic properties of **PETVTBT** were investigated in a bulk-heterojunction solar cell that used $PC_{[71]}BM$ as the electron acceptor. A power conversion efficiency of 1.00% was achieved. In spite of the low band-gap, low HOMO energy level, and high hole mobility of the **PETVTBT**, the photovoltaic efficiency was relatively low, because the electronic properties of **PETVTBT** were changed after blending with $PC_{[71]}BM$.

ABSTRACT

This article focuses on the electronic structure of the poly(3-hexylthiophene):phenyl-[6,6]-C61 butyric acid methyl ester (P3HT:PCBM) blend, widely used in bulk heterojunction (BHJ) solar cells. Given the fact that the surface of the blend film is a nearly pure P3HT wetting layer, we use a lift-off method to access the originally buried surface, which is rich in both P3HT and PCBM and thus representative of the BHJ. The combination of direct and inverse photoemission spectroscopy on this surface leads to a determination of the energy gap between the lowest unoccupied molecular orbital (LUMO) of the acceptor and the highest occupied molecular orbital (HOMO) of the donor. The gap is ~1.4 eV, which implies a 0.5–0.6 eV interface dipole barrier between the two materials. The energy gap is found to be stable versus *in situ* annealing up to 100 °C.

1. Introduction

The ubiquity and fundamental role of organic–organic heterojunctions (OOH) in most organic-based devices have led to in-depth investigations of their molecular and electronic structures [1–4]. In organic photovoltaic (OPV) cells in particular, OOH molecular level offsets dominate exciton dissociation and charge transfer, and define open-circuit voltage and other characteristics of the device [5–7]. A detailed understanding of OOH electronic structure is therefore of general interest and is directly relevant to the control and optimization of these organic-based devices. A number of planar OOHs have been experimentally and theoretically investigated [7,8], and models have been proposed to provide a first-order evaluation of their electronic structure. Both experimental measurements and theoretical computations point out that vacuum level alignment generally does not describe OOHs adequately, and that interface dipoles should be taken into consideration for a proper description of their electronic structure [7–9]. Yet, in spite of their increasing popularity in high efficiency OPV devices, bulk heterojunctions (BHJ) have not received the same degree of scrutiny. The problem is both experimental and theoretical, given the difficulty in identifying molecular features of the various constituents and the complexity and lack of specific information on the molecular structure of the various phases of the film.

The present study focuses on the electronic structure of a BHJ system composed of a poly(3-hexylthiophene) (P3HT):phenyl-[6,6]-C61 butyric acid methyl ester (PCBM) blend. The P3HT:PCBM blend is widely used in BHJ solar cells, resulting in open-circuit voltages (V_{oc}) of the order of 0.6 V and power conversion efficiencies in the range of

4–6% [10–12]. The study combines structural and composition determination of the film via near edge X-ray absorption fine structure (NEXAFS) and X-ray photoemission spectroscopy (XPS), and electronic structure determination of filled and empty states via ultraviolet and inverse photoemission spectroscopy (UPS, IPES). The key result is the experimental determination of the fundamental gap between the lowest unoccupied molecular orbital (LUMO) and highest occupied molecular orbital (HOMO) of the blend. Comparison with the gap expected from the difference between the ionization energy (IE) and electron affinity (EA) of separated P3HT and PCBM, respectively, indicates a significant departure from vacuum level alignment at that interface, with formation of a 0.5–0.6 eV interface dipole barrier.

2. Experimental

In the course of this investigation, we measured (i) the main energy levels, i.e. HOMO and LUMO, of the separate constituents P3HT and PCBM, (ii) the electronic structure of the P3HT/C_{60} interface, and (iii) the electronic structure of the P3HT/PCBM blend. The organic films were formed on two different types of surfaces: silicon (Si) with a native oxide; and gold (Au, 30 nm) on Ti (2 nm)/Si. The Si substrates were cleaned by sonication in acetone and isopropyl alcohol, followed by a rinse of a few seconds in de-ionized water and a 10 min ultraviolet/ozone treatment to remove organic contaminants. The Au films were evaporated on Ti/Si shortly before use, without further treatment. The P3HT films prepared for spectroscopy were spin-coated from a 1 wt% P3HT chlorobenzene solution at 1000 rpm for 60 s. PCBM and 1:1 P3HT:PCBM blend films were prepared under similar conditions. C_{60} films were evaporated in a chamber connected to the photoemission analysis chamber.

All the films and heterojunctions were investigated with UPS and IPES to determine the vacuum level, the HOMO and LUMO positions, and the IE and EA. The resolution of the UPS measurements, using a He discharge lamp (HeI, 21.22 eV and HeII, 40.84 eV) and a double-pass cylinder mirror analyzer, was 0.15 eV, and the resolution of the IPES measurements was 0.45 eV [13]. *In situ* annealing of the blend films up to 100 °C was done to simulate post-fabrication processing of BHJ solar cells.

Samples prepared for NEXAFS analysis were spin-coated on glass substrates from a 24 mg/ml, 1:0.8 P3HT:PCBM solution, at 500 rpm for 2 min, yielding 150 nm thick films. NEXAFS experiments were carried out at the NIST/Dow soft X-ray materials characterization facility located at beamline U7A at the National Synchrotron Light Source at Brookhaven National Laboratories. Partial electron yield (PEY) NEXAFS spectra were acquired at the carbon K-edge per previously published procedures [14,15]. Step scans of 2 eV were used to acquire data between 250 and 270 eV; 0.5 eV increments between 270 and 280 eV; 0.1 eV increments between 280 and 300 eV; 0.5 eV increments between 300 and 330 eV; and 2 eV increments between 330 and 350 eV. The spectra were collected in vacuum (1×10^{-8} Torr) at ambient temperature. Raw PEY NEXAFS spectra were normalized by the corresponding incident beam intensity, I_0, obtained concomitantly from the photon yield of a freshly coated gold grid that is located upstream from the sample chamber. This normalization accounts for any incident beam intensity fluctuations and monochromator absorption features.

3. Results and discussion

The combined UPS and IPES spectra of separate films of pure P3HT and PCBM are shown in Fig. 1a. The vacuum level is used as energy reference, thus the IE and EA of the two materials (Fig. 1b and Table 1) can be directly obtained from the positions of the onsets of filled and empty states, respectively. The P3HT IE of 4.65 eV is consistent with data obtained by other groups [6,16,17], and the 2.5 eV transport gap is in good agreement with the UPS/IPES result by Deibel et al. [17]. Note that the assumption of vacuum

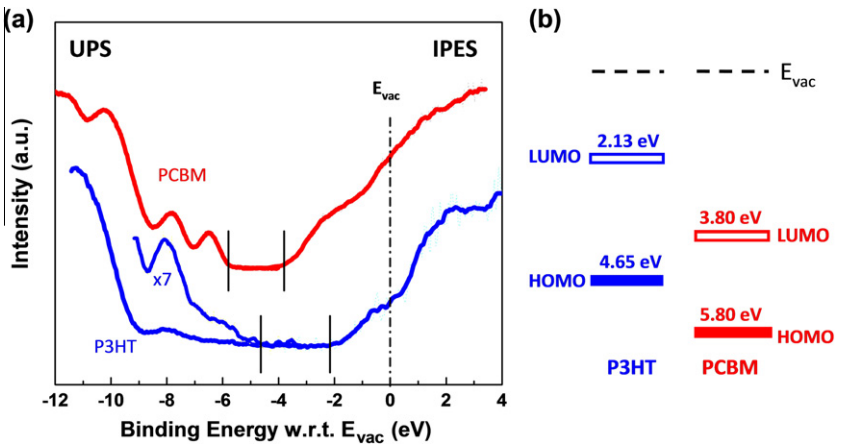

Fig. 1. The left panel shows the combined UPS and IPES spectra of pure P3HT (blue curves) and pure PCBM (red curves) with the energy position referenced to the vacuum level (E_{vac}, dash dotted line). HOMO and LUMO edges are shown in solid lines. The right panel presents the corresponding electronic structure with positions of molecular levels. Table 1
Measured ionization energy (IE), electron affinity (EA) and transport gap for all materials used in this work, as determined by UPS and IPES.

Materials	IE (eV)	EA (eV)	Gap (eV)
P3HT	4.65	2.13	2.52
PCBM	5.80	3.80	2.00
C_{60}	6.35	3.98	2.37
P3HT:PCBM top surface	4.69	2.14	2.55
P3HT:PCBM once-buried surface, on Si	5.22	3.76	1.46
P3HT:PCBM once-buried surface, on Au	4.63	3.29	1.34

level alignment between P3HT and PCBM would place the PCBM LUMO at 0.85 eV above the P3HT HOMO (Fig. 1b). OOHs with similarly small predicted LUMO (organic 2)–HOMO (organic 1) gap have been experimentally shown to display an interface dipole that increases this gap by several hundreds of millivolts [3,9]. No specific calculations have been done on these materials. However, electronic structure computations of OOHs comprising constituents with widely different EAs and IEs, based on the model of alignment of charge neutrality levels [9,18], have also predicted significant interface dipoles [3,9].

A first-cut approach to the actual electronic structure of the P3HT:PCBM blend is obtained by looking at the single heterojunction formed by vacuum deposition of C_{60} on a P3HT film (prepared *ex situ* by spin-coating). Obvious similarities between C_{60} and PCBM molecules in terms of molecular size and large IE and EA (Table 1) make C_{60} a good candidate for a first electronic structure evaluation. C_{60} films have been extensively investigated in the past via UPS and IPES [6,19,20], and electronic parameters like IE and EA are well established. Vacuum level alignment at the P3HT/C_{60} interface would place the fullerene LUMO only 0.65 eV above the polymer HOMO. In the present experiment, C_{60} is incrementally deposited on P3HT, and valence states and onset of photoemission are measured at each step. The spectra of the P3HT film, bare and covered with 80 Å C_{60}, are shown in Fig. 2a. The shift of the photoemission onset indicates a 0.5 eV dipole at the P3HT/C_{60} interface, which moves the C_{60} molecular levels upwards, toward lower binding energy with respect to those of P3HT (care was taken to ensure that P3HT molecular levels were not shifting during C_{60} deposition). This is in good agreement with results previously reported by Osikowica et al. [16]. The energy difference between the P3HT and C_{60} HOMO edges is 1.30 eV, and the energy difference between the LUMO edges is deduced from this value, using

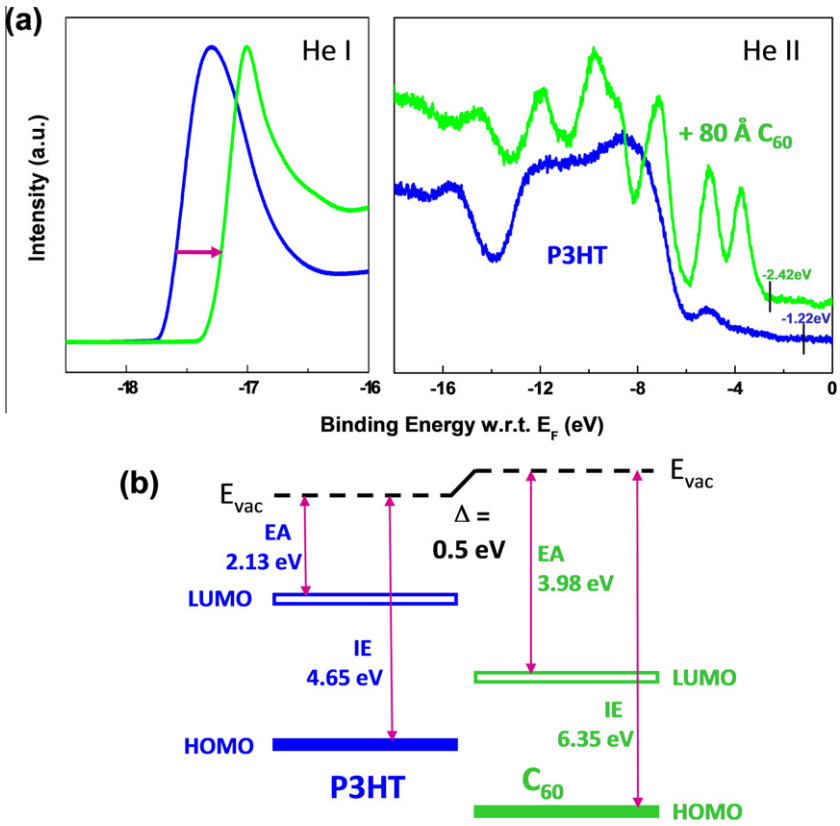

Fig. 2. (a) Valence UPS spectra of pure P3HT (blue curves) and 80 Å P3HT/C_{60} heterojunction (green curves). The right panel shows the different features of P3HT and P3HT/C_{60}, while the left panel shows the shift of the photoemission onset, indicating the presence of an interface dipole. All energies are taken Fermi level (E_F) as reference. (b) Corresponding schematic heterojunction energy diagram. The interface dipole is about 0.5 eV. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the transport gap of the two materials (Table 1). The energy diagram of the heterojunction is displayed in Fig. 2b.

The UPS and IPES spectra of the surface of a ~400 Å P3HT:PCBM blend film prepared on Si as described above are shown in Fig. 3a. Both spectra look remarkably similar to those of pure P3HT (Fig. 1), and the measurements of LUMO and HOMO positions yield IE, EA and energy gap identical to those of the pure polymer (Fig. 3b). In particular, the 2.55 eV gap is considerably larger than that anticipated between the PCBM LUMO and P3HT HOMO (Fig. 1b). This surprising result is explained by subsequent investigations of the vertical composition of the blend film by NEXAFS and XPS.

The pre- and post-edge normalized NEXAFS PEY spectra acquired at the carbon edge of thin films of PCBM, P3HT, as well as those of a film comprising P3HT:PCBM blended at 1:0.8 mass ratio are shown in Fig. 4. The spectra is magnified in the C1s – to – π^* transition region to facilitate discussion. The results of a full NEXAFS analysis of these films will be presented elsewhere [21]. Comparison of the NEXAFS spectra of PCBM and P3HT reveals C1s – to – π^* transitions occurring at different energies; these are highlighted in Fig. 4 for comparison. PCBM exhibits C1s – to – π^* transitions at 284.5 eV and 285.8 eV whereas the C1s – to – π^* transition of P3HT occurs at 285.13 eV [22]. Carefully monitoring the NEXAFS spectra in this region thus provides a unique fingerprint for the species in question. The NEXAFS spectrum acquired on the surface of the P3HT:PCBM film (labeled "Top", in Fig. 4) largely resembles that of neat P3HT. This observation is consistent with the presence of a thin P3HT wetting layer at the film surface [23,24] and explains why only the energy levels associated with P3HT are accessed when UPS and IPES measurements are conducted on the film surface (Fig. 3). The thickness of the P3HT wetting layer, estimated by NEXAFS, is around 5 nm [21].

Access to the blend, or mixed part of the film, was obtained in the following way. For UPS/IPES and XPS experiments, the P3HT:PCBM blend film was lifted off the substrate by soaking in water for a few seconds. The film was then picked up from the top with a second Si substrate and flipped over to expose the previously buried, PCBM-rich, surface of the film, referred to as "once-buried surface". The films for NEXAFS studies were delaminated using polydimethylsiloxane (PDMS) stamps. Note that the quality and composition of these films should not depend on the delamination method. The NEXAFS spectrum acquired on the once-buried surface of the P3HT:PCBM film (labeled "Bottom", in Fig. 4) reveals signatures of both P3HT and PCBM. In fact, quantitative analysis of the NEXAFS spectrum [21] indicates that this once-buried interface comprises 65 wt% P3HT and 35 wt% PCBM. It is thus the

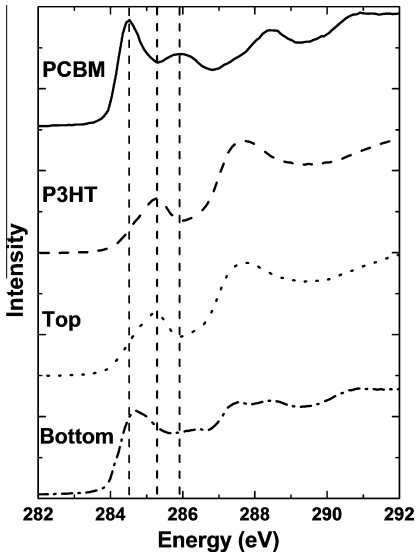

Fig. 4. Carbon-edge pre- and post-edge normalized NEXAFS PEY spectra of PCBM (solid), P3HT (dash), as well as those of a P3HT:PCBM blend taken at the original surface (dot) and the once-buried surface (dash dot) at 55°, the magic angle. The traces have been displaced along the *y*-axis for clarity.

characterization performed on this once-buried interface that provides a more realistic picture of the electronic structure of the polymer blend.

The chemical composition of the film was further analyzed via XPS on pure PCBM as well as on the original and once-buried surfaces of a 1:1 blend film formed on Si. The analysis of the O1s, C1s and S2p core levels measured from the blend film (Fig. 5) shows that the once-buried surface is richer in O than the top surface (Table 2), consistent with a larger concentration of PCBM. The O1s – to – C1s ratio is 1/20 for the once-buried blend surface, versus 1/15 for the pure PCBM film, as expected from the presence of the P3HT carbon in the blend. Furthermore, the original top surface yields no O signal, consistent with the fact that it contains very little PCBM, and in spite of the fact that the surface was exposed to air and water. An analysis of the line-shape of the oxygen core level on the PCBM and once-buried blend surface reveals the presence of two components, O=C–O (533.9 eV) and O–C=O (532.4 eV), corresponding to the two non-equivalent O species of the PCBM molecule [25]. Finally, the S2p – to – C1s ratio is at least in qualitative agreement with the compositions of the original and once-buried surfaces, when the enhancement in carbon content corresponding to PCBM is taken into consideration. All the XPS data confirm that the once-buried surface contains a mixture of the two molecules, although the precise ratio is difficult to establish with precision.

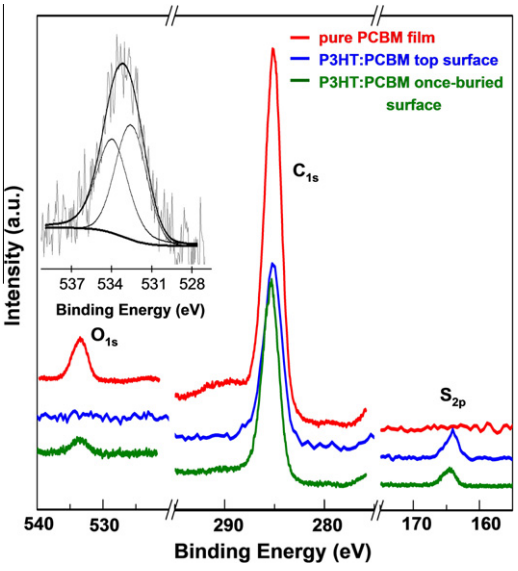

Fig. 5. XPS data of O1s, C1s and S2p core levels. The inset shows the detailed analysis of the O1s peak of the once-buried surface of the blend film. The two components correspond to the two different oxygen species of PCBM, indicating that there is no impact from H_2O on the increased O-signal.

Table 2
Normalized intensity of the O1s, C1s and S2p core levels measured from PCBM and the original and once-buried surfaces of the 1:1 blend P3HT:PCBM film.

Film	O1s	C1s	S2p
PCBM	1	15	0
P3HT:PCBM top surface	0	14	1
P3HT:PCBM once-buried surface, on Si	1	20	0.9

The UPS and IPES spectra of the once-buried surface of the blend film on Si are shown in Fig. 6a. This surface yields a significantly smaller transport gap (Fig. 6b) than the exposed surface (Fig. 3), i.e. 1.46 eV versus 2.55 eV, and an IE of 5.22 eV and an EA of 3.76 eV. Given that this part of the film is a true mixture of the two elements of the blend, and considering the electronic structure of the separate constituents (Fig. 1b and Table 1), we attribute the top of the filled states to the HOMO edge of the donor P3HT, and the bottom of the empty states to the LUMO edge of the acceptor PCBM. The energy gap is larger than would be expected from a simple vacuum level alignment between the donor and the acceptor phases in the blend (0.85 eV, Table 1), and fairly close to the LUMO(C_{60})–HOMO(P3HT) described above. This implies that a displacement of the PCBM molecular levels upwards with respect to those of P3HT has taken place. Such a displacement, which corresponds to the formation of a dipole at the interface between P3HT and PCBM, was expected from considerations of alignment of charge neutrality levels given above, and from the preliminary experiment with P3HT/C_{60}. The magnitude of the dipole is ~0.5–0.6 eV, and the electronic structure of the D/A interface in the blend is given in Fig. 6b. Note that the dipole value is in good agreement with the 0.4 eV value reported by Xu et al., who used a different experimental approach [24].

In the experiment described above, the Fermi level of the blend film (dashed vertical line in Fig. 6a) picked-up on the Si substrate is relatively high in the LUMO(PCBM)–HOMO(P3HT) gap. To verify that the substrate Fermi level did not have a significant impact on the molecular level alignment in the blend, and thus on the critical LUMO(PCBM)–HOMO(P3HT) gap, all experiments described above were repeated on Au (Au/Ti/Si) substrates. The energy levels of the separate constituents, i.e. P3HT and PCBM, and the electronic structure of the P3HT/C_{60} interface were re-measured on Au substrates (not shown here), and found in very good agreement with those obtained on Si. Measurements on the exposed surface of the blend film showed identical IE, EA and energy gap to those of pure P3HT, indicating here again the presence of a thin P3HT wetting layer at the film surface.

The UPS and IPES spectra of the once-buried surface of the blend film were also measured on a film picked-up on an Au sample following lift-off in water. As can be seen in Fig. 7a, the Fermi level is significantly lower in the LUMO(PCBM)–HOMO(P3HT) gap than in the Si substrate case. The IE and EA measured at this surface are different from those measured in the Si substrate case, indicating a different position of the overall vacuum level of the blend (issues related to the precise nature of the vacuum level at the surface of such a blend are complex, and beyond the scope of this work). Yet, the surface yields a 1.34 eV transport gap, nearly identical to that obtained on Si, implying

the existence of a similar dipole at the donor/acceptor interface. The electronic structure of the blend is given in Fig. 7b.

Annealing is known to improve the performance of P3HT:PCBM solar cells [26,27]. A series of *in situ* annealing steps at temperatures up to 100 °C for 10 min each were therefore performed to detect eventual changes in the electronic structure of the blend film on Si. Interestingly, the UPS and IPES spectra (not shown here) demonstrated that the position of the LUMO and HOMO edges with respect to the Fermi level, as well as the gap of the blend, remain the same as for the non-annealed film, which places origin of the improvement on something else than the donor/acceptor LUMO–HOMO gap. On the other hand, the work function of the blend film was reduced by 0.30 eV by annealing, possibly due to a change in film morphology, to an evolution of the phase separation between P3HT and PCBM [26,27], or simply to desorption of some contaminants from the surface.

Finally, the measurements presented here show that the donor/acceptor LUMO–HOMO gap is significantly larger than the best open-circuit voltage (V_{oc}) developed by a P3HT:PCBM cell: ~1.4 eV versus ~0.6–0.65 eV. Recent investigations of excitonic molecular and polymer cells have clearly established correlations between increase or decrease in the gap and in V_{oc} [28–32]. These correlations were coupled with models based on equivalent circuits of the cells, which include leakage and resistance paths for the photo-generated current, to explain the difference between the electronic structure of the donor/acceptor heterojunction and the cell performance. It is clear that further development of such models will be possible only if at least one of the most important parameters of the junction, i.e. the molecular level alignment at the OOH, is independently determined.

4. Summary

Measurements presented here have lead to the first direct determination of the donor/acceptor LUMO/HOMO energy gap in the widely used P3HT:PCBM bulk heterojunction. Using a lift-off technique to expose the once-buried surface of the thin blend film, and analysis with direct and inverse photoemission spectroscopy complemented by NEXAFS, we showed that this surface is rich in both donor (P3HT) and acceptor (PCBM) components, and thus representative of the blend. The LUMO/HOMO gap of the blend is found to be $\sim$1.4 eV, from which we infer a 0.5–0.6 eV interface dipole barrier between the donor and acceptor phases. This dipole widens the gap of the blend. The dipole and LUMO/HOMO gap are stable in a series of *in situ* annealing steps up to 100 °C.

ABSTRACT

The evolutions of the electronic structure in Cs-doped copper-phthalocyanine (CuPc) on different metal substrates have been investigated with photoemission spectroscopy. As the Cs doping ratio increases, the Fermi level of the system starts to shift towards the lowest unoccupied molecular orbital (LUMO) of CuPc, and then becomes saturated, as it aligns with the LUMO. The shift of all the energy levels has a linear dependence on the logarithm of the Cs doping ratio, with a slope of about 0.13 eV. By comparing the results of the samples deposited on different metal substrates, we found out that this slope indicates the broadening of the LUMO induced by alkali metal doping and is independent of the work-function of the metal substrate.

In the past few decades, there has been extensive interest in the development of semiconductor electronic devices based on organic molecules and polymers [1–3]. Organic semiconductors posses many potential advantages over their inorganic counterparts, which make them particularly attractive for large-area and low-cost applications [4]. In the development of organic electronics, many well-established techniques developed for inorganic semiconductors have been successfully adopted, such as doping. As for the inorganic semiconductors, doping has proven to be one of the most efficient techniques to adjust the electronic properties of the organic semiconductors [1,5,6]. However, due to the distinctive nature of the organic molecules, the understanding of the interactions between the organic host and the dopant is still quite limited, and the conventional doping theories based on the band structure in crystalline inorganic semiconductors are usually assumed without careful verification for the case of organic system. It is thus important to investigate the doping-induced evolution of the electronic structures of the organic molecules, in order to understand the fundamental mechanism of the interactions in the guest–host system. Such studies have been carried out by many groups for different kinds of dopants, such as oxygen [7], organic molecules [8], and alkali metals [9,10]. Among them, alkali metals, which donate their single outmost s-electrons, are usually considered as good candidates for prototypical studies, due to their simple electronic structures comparing to other possible dopants [11–14]. Generally, doping of the alkali metal atoms results in the energy level shift in the organic semiconductors [13,14]. Our previous studies suggest that such shift cannot be explained by the equations derived for crystalline inorganic semiconductors [15,16]. However, there is also doubt if the energy level shift is simply from the change of the substrate work-function by the alkali metals diffusing through the organic film. Therefore, it is interesting to investigate doping-induced electronic structure modification of organic thin films prepared on different metal substrates.

In this paper, we report our photoemission investigations on the evolution of the electronic structure for Cs-doped copper-phthalocyanine (CuPc) prepared on different metal substrate, such as Ag and Al. With ultraviolet and X-ray photoemission spectroscopy (UPS and XPS), we find out that, before saturation, the CuPc energy levels shift linearly as a function of the logarithm of the Cs doping ratio, with a slope of about 0.13 eV which is independent of the

substrate workfunction. The slope is much larger than k_BT as predicted by theory for inorganic semiconductors, and it can be understood as the broadening of the lowest unoccupied molecular orbital (LUMO) induced by metal–organic interaction.

The UPS and XPS studies were performed using a VG ESCA Lab system equipped with a He I (21.2 eV) gas discharge lamp and an Mg Kα X-ray source (1253.6 eV). The ultrahigh vacuum (UHV) system consists of a spectrometer chamber and an evaporation chamber, in which samples could be prepared in UHV and transferred directly into the spectrometer chamber. The base pressure of the spectrometer chamber is typically 8×10^{-11} torr. A fresh metal substrate (Ag or Al) was prepared inside the spectrometer chamber by thermal evaporation onto a Au-coated Si wafer cleaned with Ar^+ sputtering. The workfunction and the surface cleanness of the metal substrates were checked by UPS and XPS before the deposition of a 200 Å CuPc film. Cs was evaporated at 5.5 Amps from a SEAS getter source in the spectrometer chamber. The Cs doping ratio (R_{Cs}), calibrated as the number of Cs atoms per CuPc molecule, is derived from the XPS core level intensities with careful calibration of the atomic sensitive factor. The evolution of the doping ratio as a function of evaporation time (not shown) turns out to be very reliable for each experiment. The UPS spectra were recorded with the samples biased at −5.0 V to observe the low-energy secondary cutoff. The typical instrumental resolution for UPS measurements ranges from ∼0.03 to 0.2 eV with photon energy dispersion of less than 20 meV. The XPS resolution is ∼1.4 eV. All measurements were done at room temperature.

Fig. 1 shows the evolution of the UPS spectra of the highest occupied molecular orbital (HOMO) region of Cs-doped CuPc prepared on clean Ag (a) and Al (b) substrates as a function of R_{Cs}, the number ratio between the Cs atoms and the CuPc molecules. The workfunction of the metal substrate is measured with UPS (not shown), and is determined to be 4.32 eV and 4.09 eV for Ag and Al, respectively, which are consistent with the handbook values [17]. The spectra of the pristine CuPc films on both metal substrates agree very well with our previous observations [18] and those published in literature [13,14,19]. For the films prepared on Ag and Al substrates, the HOMO onset, which is usually determined by the linear extrapolation of the leading edge of the HOMO peak, is located about 1.2 eV and 1.4 eV below the Fermi level, respectively. The difference in the HOMO position at those two interfaces can be attributed mostly to the metal workfunction, which determines charge transfer at the interface and the formation of interface dipole. Other factors, such as push-back effect and screening, may also contribute in this case, as discussed in the review of metal organic interface [20]. Upon Cs doping, energy levels of the CuPc films prepared on both Ag and Al substrates start to shift towards higher binding energy, in other words, the Fermi levels of the two samples shift upwards inside the energy gap of the CuPc. This is in good agreement with our earlier studies of Cs-doped CuPc film prepared on Au substrate [15,21]. As the Cs doping ratio increases, the valence features of the CuPc molecules are well preserved, indicating that there is no destructive chemical interaction between the organic molecules and the doped alkali metal atoms. The full width at half maximum (FWHM) of HOMO in pristine CuPc film is estimated to be about 0.47 eV and 0.49 eV for films prepared on Ag and Al, respectively. Doping of Cs leads to a slight broadening of the HOMO peak. At higher doping ratios, the FWHM of the HOMO increases to about 0.50 eV for both samples. However, the shape of the HOMO peak remains symmetric and the simultaneous shift can also be noticed at the onset position. These observations rule out the presence of coexisting phases with different Cs stoichiometry. For both samples, the shift of the energy levels becomes saturated at higher doping ratios. However, the saturation occurs at different doping levels for the two

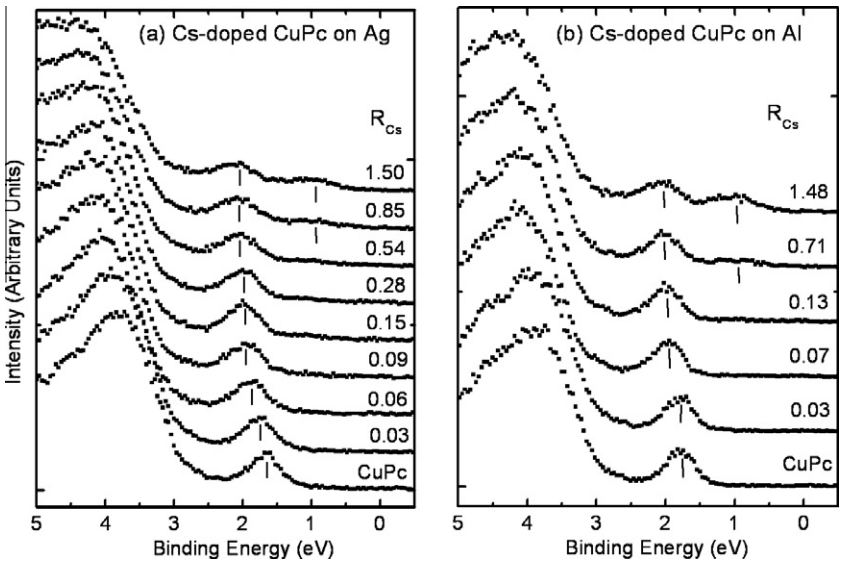

Fig. 1. UPS spectra of the HOMO region of Cs-doped CuPc film prepared on (a) Ag and (b) Al substrates as a function of Cs doping ratio R_{Cs}, derived from XPS core level intensities. The spectra are plotted in binding energy relative to the Fermi level.

samples prepared on different metal substrates. For the sample prepared on Ag, the shift of the HOMO peak becomes saturated after R_{Cs} reaches 0.25, when the total shift of the HOMO is about 0.4 eV. On the other hand, the saturation of the energy level shift happens much sooner when Al is used as the substrate. The HOMO shifts for a total of 0.2 eV and then becomes saturated at R_{Cs} equals 0.13. Those values are significantly different from our previous doping experiment on clean Au substrate, where the saturation occurs at R_{Cs} equals 0.4, and a much larger shift (0.8 eV) is observed before the saturation [15]. Another issue one should note here is that, at high Cs doping ratios, a new state emerges from the former energy gap in the UPS spectra, and its intensity increases monotonically as R_{Cs} increases. Similar to our earlier observation for samples prepared on Au substrate, the gap state lies about 1.1 eV above the HOMO peak. It is believed to be originated from the filling of the former LUMO in the CuPc molecules due to charge transfer [15]. For samples prepared on both metal substrates, the gap state can only be clearly identified after the saturation of the energy level shift and when the Cs doping ratio is large enough (0.54 for Ag and 0.71 for Al). Before that the features are too weak to be seen.

The evolution of the C 1s, N1s and Cu $2p_{3/2}$ core levels of Cs-doped CuPc prepared on Ag substrate are shown in Fig. 2. The C 1s core level spectrum of pristine CuPc (see bottom spectrum in Fig. 2(a)) consists of two main components: the leading peak C 1s(A), which can be easily associated with the aromatic carbon of the benzene rings, and the second peak C 1s(B) at 1.4 eV higher binding energy, which is due to the pyrrole carbon in contact with N [13]. A satellite of C 1s(A) overlaps with C 1s(B), whose contribution must be accounted for to get the proper intensity ratio of these two peaks. Both components shift simultaneously towards higher binding energy for about 0.4 eV at initial doping ratios, which is quite consistent with what has been observed for the valence features. After that, they merge into one broad and asymmetry peak, as a result of the slightly reverse shift of C 1s(B) towards lower binding energy. Both N 1s and Cu $2p_{3/2}$ core levels appear to have a single component in the XPS spectra. They shift towards higher binding energy for similar amount as that of C 1s core level for the initial doping ratios. A reverse shift can be identified for these two elements as the doping ratio is beyond 0.85, which coincides with the appearance of the gap state in the UPS spectra. This may be attributed to the correlation effect induced by the doped electrons, when they fill in the unoccupied sates of CuPc and become more localized at one molecular site. We have not observed any new components in the core level spectra, which further corroborate the absence of any strong chemical interactions, except for a doping-induced broadening. Finally, it has been reported that alkali metals readily diffuse into CuPc. For example, the Li diffusion length in CuPc has been measured to be 700 Å [22]. We therefore expect the distribution of Cs atoms inside CuPc reasonably uniform within the probing depth of photoemission (~15 Å for UPS and ~50 Å for XPS) [13,15].

The energy level shifts in Cs-doped CuPc film prepared on Ag and Al substrates are summarized in Fig. 3 (a) and (b), respectively. The vacuum level cutoff was obtained at the maximum of the differential curve of the UPS spectra. The core level shifts were deduced by fitting the spectra with Gaussian curves for C 1s, N 1s, and Cu $2p_{3/2}$ after careful deduction of the background. Note that R_{Cs} is in logarithmic scale to emphasize the initial shift. It has been reported that complete ionization of the doped Cs atoms can be easily achieved even at high doping ratios [15]. One can thus safely treat R_{Cs} simply as the electron doping density, as each Cs atom donates single electron to the organic molecules. The overall evolution of the electronic structure turns out to be similar to the case of the Cs-doped CuPc samples on Au substrate [23]. The energy level shift induced by Cs doping can be seen in two stages. At the first stage where the Cs doping ratio is low, all energy levels shift simultaneously and linearly towards higher binding

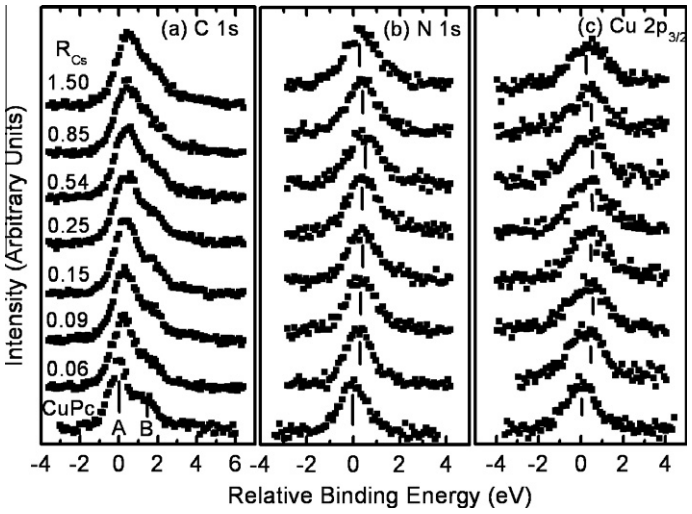

Fig. 2. XPS spectra of C 1s, N 1s and Cu $2p_{3/2}$ core levels as a function of the Cs doping ratio (R_{Cs}) for CuPc thin film prepared on clean Ag substrate. The peak positions are noted by short bars.

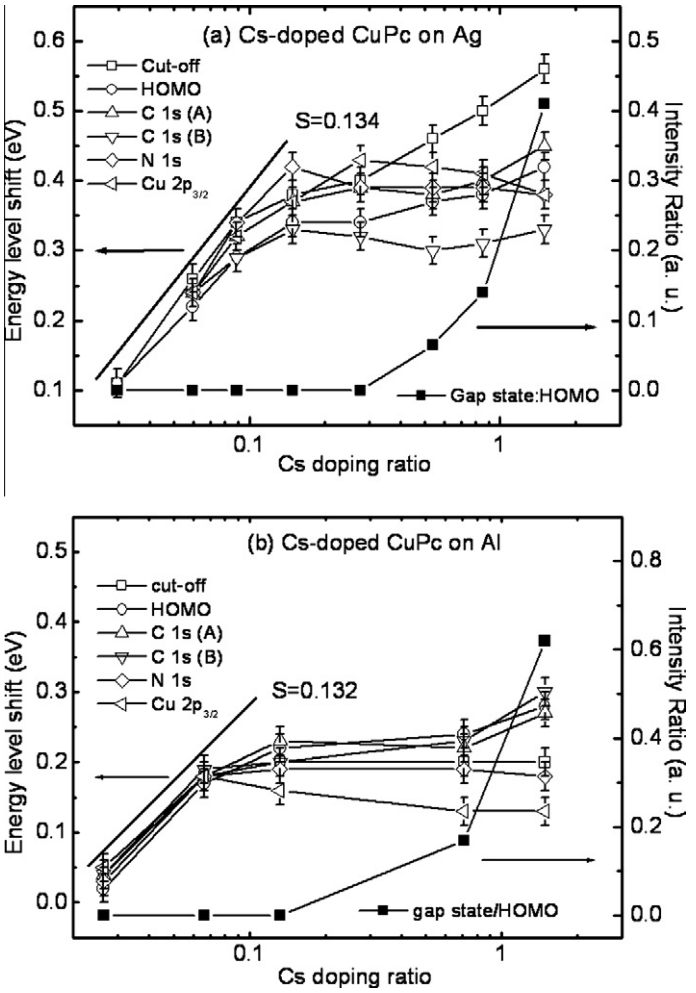

Fig. 3. The summary of the doping-induced energy level shift for CuPc samples prepared on (a) Ag and (b) Al substrates. Note that R_{Cs} is in logarithmic scale to emphasize the initial shift. For both samples, the doping-induced energy level shift can be seen in two stages, and the slopes of the initial stage are almost identical.

energy in the semi-log plot. As the doping density increases, the shift of the energy levels becomes diverse. For CuPc film prepared on Ag, the workfunction shift continuously, reaching 3.34 eV at $R_{Cs} = 1.50$, whereas the workfunction of the sample on the Al substrate becomes saturated quickly, leading to a final value of 3.28 eV. One should also note that both values are much larger than the workfunction of metallic Cs (2.14 eV), indicating strong intermixing at the sample surface, as suggested in our previous studies of intensive doping of CuPc with Na [18]. On the other hand, the shift of HOMO becomes saturated and a reverse shift can be observed for some core levels, such as N 1s and Cu $2p_{3/2,}$ for both samples. Such saturation and reversion have also been reported in our previous studies [14,15,24]. However, the saturation turns out to be substrate-dependent, as it occurs at different doping levels with different amount of shift for samples prepared on Ag, Al and Au substrates. To understand the discrepancy here, one needs to first learn about the energy level alignment at the interfaces between the pristine CuPc film and the metal substrates with different workfunctions. The location of the Fermi level inside the band gap of CuPc can be estimated by the HOMO energy shown in Fig. 1 and the gap energy of the pristine CuPc molecules, which is about 1.6 eV [25]. Thus, the energy separation between the Fermi level and the LUMO is derived to be 0.4, 0.2 and 0.8 eV for Ag, Al and Au substrates, respectively, which agrees very well with the total energy shift before saturation for doped-samples prepared on each of the three substrates. In fact, our previous inverse photoemission (IPES) studies also provide direct evidence that the doping-induced energy level shift becomes saturated as the Fermi level is aligned with the onset of the LUMO of the organic molecules [15]. We can then conclude that the amount of doping-induced energy level shift depends on the position of the Fermi level inside the energy gap of organic semiconductors. More importantly, despite of the workfunction difference of the metal substrates, the slopes derived from the linear shift region in the semi-log plot are in perfect agreement, being about 0.13 eV [15]. On one hand, this is

a clear indication that alkali metal doping-induced energy level shift is determined primarily by metal–organic interaction, which is independent from the choice of the metal substrates. On the other hand, it also suggests the failure of the predictions of the classical doping theories developed for inorganic semiconductors, as a slope of k_BT (0.026 eV) would be expected. The much larger slope in the case of Cs-doped CuPc should be attributed to the absence of the band structure in the amorphous organic thin films. However, if we first assume an infinitely sharp distribution of the molecular orbital, which can be simulated by a δ-function, the energy level shift will still be determined by the Fermi distribution, which again leads to a small slope of k_BT [23]. In order to have a large slope, as being observed in this experiment, a broadening of the LUMO has to be introduced, as one would actually expect when organic molecules are doped with impurities. In this context, the slope of 0.13 eV for Cs-doped CuPc may be used as an estimation of the broadening of the LUMO due to the presence of the excess electrons from alkali metals or other impurities. At a low doping ratio, the electronic structure of organic molecule remains almost intact, except for the rigid shift of all the energy levels. The absence of a discernable gap state suggests that the interactions between the dopants and the organic molecules are weak. Instead of the formation of a new state, the charge transfer at this stage is characterized by the partial occupation of the broadened exponential tail of the LUMO. It should be noted here that all energy levels shift simultaneously in the doping experiment at low doping ratios. No phase separation can be observed in the CuPc film, for the investigated doping ratios, which is much less than 1 at this stage. This suggests that the electronic structures of all CuPc molecules within the probing depth have been modified, and the doped electrons are shared by several surrounding molecules. The alkali metals are fully ionized even for moderately heavy doping ration ~1, another evidence that these dopants are not aggregated among themselves nor phase separated [15].

The independence of the slope of the energy level shift in the semi-log plot on the substrate workfunction indicates that the shift is the result of dopant-organic interaction instead of the substrate workfunction change induced by the alkali metal. Further assessment of the statement can be obtained from the Debye length considerations. As a measure of the screening of an electric field by a semiconductor, the intrinsic Debye length is inversely proportional to the doping density [26]. The Debye length for 1% doping, assuming 100% ionization, is about 7 Å in the organics, supporting the notion that the substrate contribution to the measured energy level shift is insignificant given the probing depth (~20 Å) and the film thickness (200 Å).

As doping density increases, the energy level shift saturates because of the pinning of the Fermi level at the LUMO [25]. Further doping leads to the second stage of charge transfer, when the doped electron concentrates at the center of CuPc and a strong correlation of the electronic states takes place [13,14,18,27]. This leads to the reversed shift of core levels of atoms at the center, including those of Cu and N, as well as the growth of the gap state. When low workfunction metal is used as the substrate, the energy level shift becomes saturated at much smaller doping ratio, comparing to the case of Au. In the UPS measurements, the gap state may not be clearly identified at this time, due to the weak signal intensity. However, as the LUMO now is aligned with the Fermi level, the doped electrons can easily fill in the unoccupied sates in organic molecules and stay localized at a single molecular site, leading to a strong correlation that can effectively modify the electronic structure of the doped molecule. The charge transfer at the second stage is therefore characterized by the formation of gap and strong correlation of the organic energy levels.

In conclusion, the evolution of the electronic structure of Cs-doped CuPc prepared on different metal substrates has been investigated with UPS and XPS. We found out that the shift of the energy levels depend on the energy level alignment at the interface between the pristine CuPc film and the metal substrate. However, the slope of the shift in the semi-log plot is independent of the substrate metal workfunction, being about 0.13 eV, which is much larger than the prediction by inorganic semiconductor theory. This is attributed to the doping-induced broadening of the CuPc LUMO.

ABSTRACT

An ion-sensitive organic field-effect transistor (ISOFET) has been fabricated by using poly(3-hexylthiophene) as the semiconductor and polymethylmethacrylate as the gate insulator. With the gate metallization replaced by an Ag/AgCl reference electrode, and following suitable encapsulation, the ISOFETs exhibit transistor behavior in an aqueous environment. Moreover, the devices are shown to respond to changes in pH of the solution. A significant increase in the sensitivity of the ISOFET to H^+ ions was found by depositing a Langmuir–Blodgett film of arachidic acid on top of the gate insulator.

1. Introduction

The development of effective devices for the identification and quantification of chemical and biochemical substances for process control and environmental monitoring is a growing need. Many sensors do not conform to existing or forthcoming legislation; some systems are too bulky or expensive for use in the field. The ion-sensitive field-effect transistor (ISFET) has been developed since the 1970s [1,2]. In essence, the ISFET is a metal-oxide field-effect transistor (MOSFET) in which the gate connection is separated from the silicon substrate in the form of a reference electrode.

The field of organic electronics is concerned with replacing the 'traditional' inorganic materials used in electronic devices (e.g. Si, SiO_2) with their organic counterparts. This technology should allow for the fabrication of organic ISFETs (ISOFETs) which are cheap, relatively easily to fabricate and offer additional advantages such as mechanical flexibility [3,4]. To date, most work in this area has been reported for devices in which an organic semiconductor has been combined with an inorganic gate dielectric, e.g. Si_3N_4 or Ta_2O_5, to provide hydrogen ion selectivity [5,6]. Here, we fabricate ISOFET structures in which both the semiconducting layer and the gate insulator are organic materials, and show that their pH sensitivity can be enhanced by coating the gate insulator with a few layers of a fatty acid Langmuir–Blodgett (LB) film.

2. Experiment

The devices use poly(3-hexylthiophene) (P3HT) as the semiconductor and polymethylmethacrylate (PMMA) as the gate insulator. We have previously described the incorporation of PMMA into organic FETs and inverter structures [7,8]. This particular insulator exhibits low leakage currents and can be used to produce devices with high carrier mobility and minimal hysteresis.

PMMA (molecular weight 93,000) and P3HT were purchased from Sigma–Aldrich. The PMMA was dissolved in anisole (methoxybenzene) to a concentration of 42 mg ml^{-1}, while the P3HT was dissolved in chloroform to a concentration of 10 mg ml^{-1}. A standard silver/silver chloride (Ag/AgCl) reference electrode was used as the gate electrode to provide a stable electrical contact in the solution. The pH of the solution in contact with the ISOFET surface was changed by adding quantities of acetic acid (buffers containing Cl^- ions were avoided); the pH was

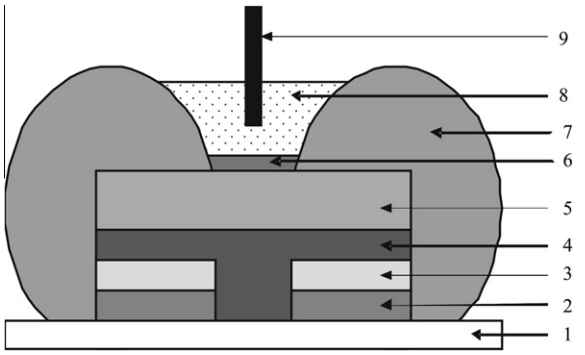

Fig. 1. A typical structure for ISOFET; 1 – glass substrate, 2 – chromium, 3 – gold, 4 – P3HT, 5 – PMMA, 6 – LB film, 7 – epoxy resin, 8 – electrolyte solution, 9 – reference (gate) electrode.

monitored using a Philips PW9420 pH meter. The electrical characteristics of the ISOFET were recorded using an HP 4140B picoammeter/voltage source. All the measurements were undertaken at room temperature and with the devices in the dark.

Fig. 1 shows a schematic diagram of the top-gate ISOFET structure. After cleaning in an ultrasonic bath, the glass substrate was rendered hydrophobic by immersion in dimethyldichlorosilane solution. An interdigitated pattern of source and drain electrodes, formed using conventional photolithographic methods, was used; the channel width, W, and length, L, were 22,000 μm and 25 μm, respectively. The electrode materials were deposited by the thermal evaporation of Cr (20 nm) followed by Au (20 nm). The P3HT (thickness about 55 nm) was deposited using spin-coating at a spin speed of 5000 rpm for 45 s. This was followed by spin-coating the PMMA (thickness approximately 130 nm) using a two-step process: spinning at 500 rpm for 10 s followed by 3000 rpm for 50 s. The resulting device structure was baked in a vacuum oven at 135 °C for 120 min. For some devices, 10 LB layers of arachidic acid were deposited on top of the PMMA (Y-type deposition, with the first layer transferred on the initial downward traversal of the substrate through the air/water interface). An epoxy resin was used to encapsulate the final device by hand. This allowed the electrolyte solution to come into direct contact with only the gate insulator.

3. Results and discussion

The electrical measurements were first undertaken with the device in deionized water (pH 5.5) and at source-to-drain voltages, V_d, and gate-to-source voltages, V_g, below 1 V to prevent the occurrence of unwanted electrolytic processes, which led to device instability. The device was normally left in solution for about 2 h before the measurements were started. If the ISOFET bias conditions were changed (V_g and/or V_d), relatively long current transients generally resulted. For example, Fig. 2 shows the effect of changing the value of V_g. During this measurement, V_d was scanned over the range 0 V → −1 V → 0 V in 50 mV steps, while the source-to-drain current, I_d, was monitored. Fig. 2 reveals that, following a decrease in the

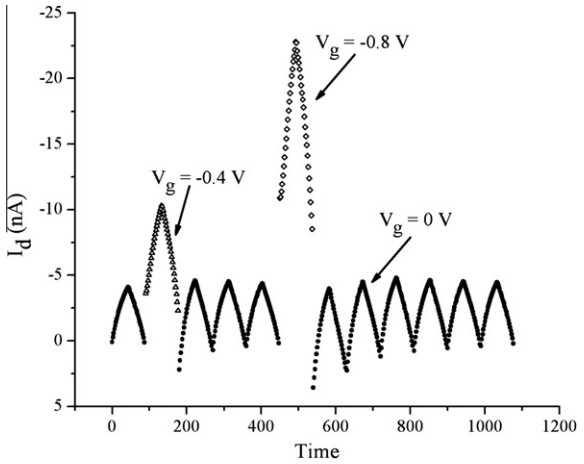

Fig. 2. Effect of changing the gate bias V_g on the drain current I_d of the ISOFET (without LB layer). The increase and decrease of I_d correspond to a scan in V_d over the range 0 V → −1 V → 0 V. Measurements in the dark at room temperature.

magnitude of the gate voltage (e.g. −0.8 V → 0 V), the drain current initially changed polarity and took several cycles (each cycle of V_d lasted approximately 90 s) to stabilize at its new value. This recovery time increased with increasing magnitude of the change in V_g. These effects were attributed to the charging and discharging of the surface of the PMMA resulting from changes in the gate voltage (applied via the reference electrode). Consequently, a systematic method of recording the electrical characteristics of the ISOFET was devised to avoid ambiguous results.

Fig. 3 shows the output currents of the P3HT/PMMA ISOFET (the basic structure without the LB layer). Each I_d versus V_d curve was recorded following the stabilization of I_d using the procedure discussed above. Results for both increasing and decreasing V_d (at a constant value of V_g) are included in Fig. 3. The data reveal that the ISOFET is work-

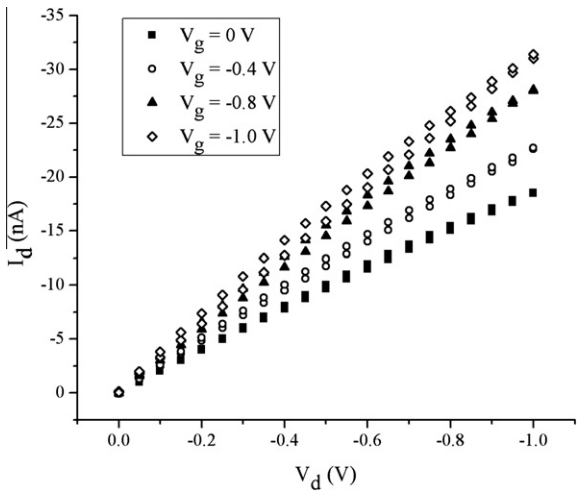

Fig. 3. Output characteristics of ISOFET (without LB layer). Voltage scans are shown for both increasing and decreasing V_d. Measurements in the dark at room temperature.

ing as a transistor in the linear regime, with very little hysteresis evident on reversing the drain voltage scan [9].

To investigate the pH response of our ISOFETs, acetic acid was added to samples of deionized water; the solutions were stirred and left overnight to provide a series of test solutions at different pHs. The ISOFET was placed initially in deionized water for 2 h, removed and immersed in the highest pH test solution. The drain voltage was then scanned over the range 0 V → −0.2 V → 0 V, with V_g = 0 V in 20 mV steps until the I_d values were stable; this process generally took 5 min. The gate voltage was then changed to V_g = −0.2 V and the drain voltage scanned between 0 V and −0.20 V until I_d was again stable. The ISOFET was removed from the solution, placed in a different pH test solution and the measurement procedure repeated. Results for V_g = −0.2 V and V_d = −0.2 V are summarized in Fig. 4a; the error bars reflect the average of 5 measurements at each pH value. The magnitude of the drain current clearly decreases with increasing acidity of the solution. This is similar to the pH effects reported other ion-sensitive transistors based on P3HT [4].

The pH response of the ISOFET with the LB film deposited on the gate insulator, Fig. 4b, shows a similar trend to

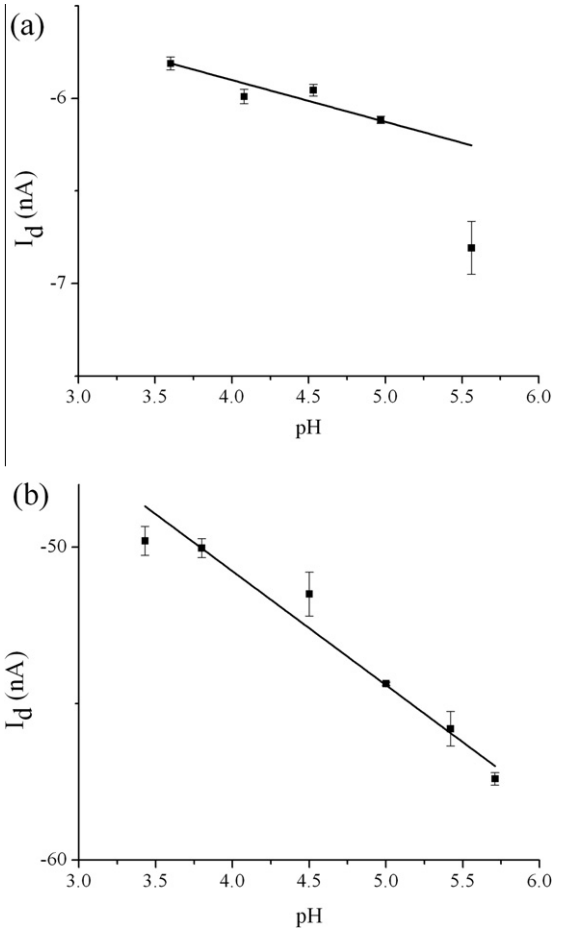

Fig. 4. (a) pH response of the ISOFET without the LB layer (V_g = −0.2 V, V_d = −0.2 V). (b) pH response of the ISOFET with the LB layer (V_g = −0.2 V, V_d = −0.2 V).

that of the uncoated device. However, the drain currents are significantly larger and the hydrogen-ion sensitivity (slope of the graph) has increased by about an order of magnitude. Osa has reported a similar result by depositing LB layers onto both Si_3N_4 and parylene gate ISFETs [10].

In the linear regime, the dependence of the FET drain current I_d on the drain to source voltage V_d is given by [9]

$$I_d = \frac{\mu C_i W V_d}{L}\left[(V_g - V_t) - \frac{V_d}{2}\right] \quad (1)$$

where V_t is the threshold voltage of the transistor. In the case of the ISFET, the introduction of new interfaces between the solution and the gate insulator leads to the modification of Eq. (1) [9]. If the gate insulator is assumed to be ideal (i.e. no charge can cross it and it is thicker than the electron tunneling distance) and that the interface between the solution and the gate insulator can be considered to be non-polarized (i.e. ions can permeate reversibly into and out of the insulator) the relevant equation is

$$I_d = \frac{\mu C_i W V_d}{L}\left[(V_g - V_t^*) - \frac{V_d}{2} \pm \frac{RT}{z^i F}\ln a^i - E_{ref}\right] \quad (2)$$

where V_t^* is the modified threshold voltage for the ISFET, a^i is the activity of the ion in solution, z^i is the number of charges per ion, E_{ref} is the reference electrode potential, T is the temperature, R is the gas constant and F is Faraday's constant. The effect of the ion concentration on the drain current is provided through the term containing the activity in Eq. (2).

Based on the site-binding model [5,11], the charges at the surface of the insulating layer are affected directly by the H^+ concentration in solution; this in turn changes the drain current of the ISOFET. An increase in the pH (i.e. to a more basic solution) will decrease the positive charge density, leading to an increase in the density of holes in the accumulation layer of the P3HT. As a consequence, the magnitude of the drain current increases, as observed in Fig. 4a and b. The opposite effect occurs when the solution is made more acidic. The change in the drain current with pH for our P3HT/PMMA ISOFET is approximately 0.5 nA per pH unit. This is significantly smaller than the variation of 30–40 μA/pH reported for Si/Si_3N_4 ISFETs [12], and also much less than figures reported for devices based on $P3HT/Ta_2O_5$ (0.3 μA/pH) [6] and those based on $P3HT/Si_3N_4$ (25 nA/pH) [5]. The low sensitivity is directly related to the small transconductance, $\left(\frac{\partial I_d}{\partial V_g}\right)_{V_d=\text{constant}}$, of the organic-based ISOFET and to the low affinity of the ester groups in the PMMA to hydrogen ions.

By coating 10 LB layers on the PMMA layer of the ISOFET, the change in the drain current with pH is approximately 3.5 nA per pH unit, an increase of almost an order of magnitude. We suggest that the enhanced drain current and increased pH response of the LB film-coated ISOSFET both arise from the presence of the carboxylic acid head groups in the LB film. These will become ionized on the surface of the aqueous subphase during monolayer formation and will subsequently be incorporated into the ISOFET structure [13]. The increased negative charge increases the conductivity of the channel, thereby increasing I_d. A variation in

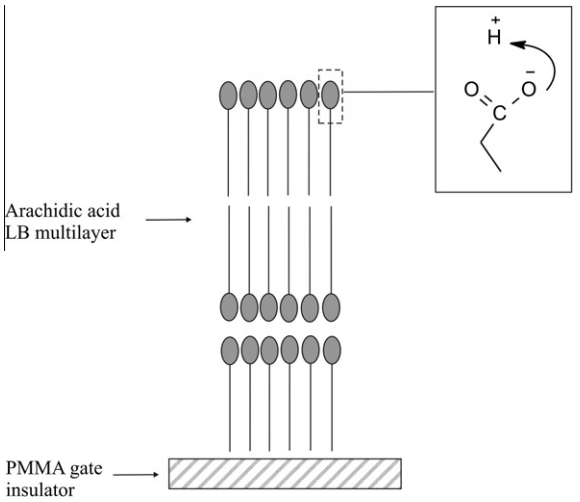

Fig. 5. Schematic diagram showing ionization of carboxylic acid head-group in outer layer of LB multilayer.

the solution pH subsequently changes the degree of ionization of the carboxylic acid head groups, as depicted in Fig. 5 (although the alkyl chain will be outermost for the LB film in air, it is likely that the top monolayer is removed following immersion of the LB film-coated ISOFET in the test solution). These groups more readily dissociate (lower pK_a) in the solution than the ester groups in the PMMA.

The sensitivity of the LB film-modified ISOFET is also less than that of its inorganic counterpart. However, it is anticipated that higher values can be obtained using an improved device design (e.g. larger W/L ratios, thinner gate dielectrics). The organic device offers significant advantages in terms of mechanical flexibility, cost and potential biocompatibility. Moreover, the LB layer, to some extent emulates a biological membrane. It should therefore be possible to incorporate additional components in the fatty acid matrix (e.g. ionophores) to sensitize the ISOFET to other species.

4. Conclusions

An organic field-effect transistor, fabricated by using P3HT as the semiconductive layer and PMMA as the gate insulator, has been shown to operate in an aqueous environment, with the metallic gate electrode replaced by an Ag/AgCl reference electrode. The resulting device exhibits a small sensitivity to hydrogen ions and indicates that such transistor structures might form the basis of organic-based chemical sensors. Furthermore, results with Langmuir–Blodgett film-coated devices suggest a strategy to make the ISOFET more sensitive and more selective to the target ions in a solution.

ABSTRACT

In the letter, a conductor/insulator/semiconductor (CIS) polymer solar cell was demonstrated with higher performance and stability than standard polymer solar cell. The random copolymer, poly(styrene-co-methyl-methacrylate) (PS-r-PMMA), was used as the insulator. By control the annealing temperature, a 2 nm-thick insulator could provide dark current suppress function and ensure carrier tunneling simultaneously. The efficiency of the CIS solar cell was improved from 2.09 to 2.37%, around 11% improvement. Meanwhile, the half-efficiency lifetime increase from 58 to 97 h by the applying of PS-r-PMMA protection layer.

1. Introduction

The solar cell based on polymer material is an attractive technology for developing low cost and large area renewable energy because of its solution process and simple cell structure [1–3]. The structure of the polymer solar cell consists of a polymer photoactive layer placed between anode and cathode electrodes [4]. The photoactive layer for the most efficient polymer solar cell is based on a bulk hetero-junction (BHJ) structure [5,6]. The BHJ intermixes the polymer donor and acceptor materials to form a percolated conducting network. The excitations generate by photon absorption in photoactive material and separate at BHJ interfaces into holes and electrons, transporting through the percolation-conducting path toward the anode and cathode [7]. The generally used polymer donor and acceptor is poly-3-hexthiophene (P3HT) and [6,6]-phenyl-C61 butyric acid methyl ester (PCBM) [8,9]. A conducting polymer, poly(3,4-ethylenedioxythiophene)/poly(styrenesulfonate), abbreviated as PEDOT:PSS is generally inserted between the anode electrode and the active layer as a buffer layer to improve device performance, increasing and modifying the work function and surface morphology of the indium-tin oxide (ITO) anode [10]. The interface between ITO/PEDOT:PSS and BHJ is not stable because the moisture and oxygen in PEDOT:PSS oxidizes the photoactive polymer [11,12], forming poor contact that reduces the fill factor (*FF*) and opens the circuit voltage (V_{oc}) after high temperature annealing or storage in air for a period of time [13].

This work places an ultra-thin polymer insulator between PEDOT:PSS and the photoactive layer to make a conductor/insulator/semiconductor (CIS) solar cell. The polymer insulator may improve the interface, blocking the dark current that improves the V_{oc} and *FF*. This research uses the poly(styrene-co-methyl-methacrylate) (PS-r-PMMA) for this concept. The PS-r-PMMA is a copolymer randomly combines polystyrene (PS) and poly methyl methacrylate (PMMA) in which some PS-r-PMMA contains the hydroxyl group (OH–) after copolymer formation. The

hydrophobic surface of the PS-r-PMMA may cause better surface morphology and better P3HT/PCBM phase separation in the active layer to form an efficient percolation-conducting path. Research on the organic thin film transistor has demonstrated that the PS-r-PMMA attaches on the hydroxyl surface forming a very thin polymer layer in amorphous form by a condensation process. An adequate solvent removes the excess un-attached PS-r-PMMA material. The amounts of attached PS-r-PMMA vary with thermal annealing time and temperature, controlling the thickness of the PS-r-PMMA film on silicon oxide from 2 to 6 nm [14]. A thin enough PS-r-PMMA ensures photocurrent tunneling, as in the inorganic metal–insulator–semiconductor solar cell, and serves as a protection layer for the photoactive layer. This layer could suppress oxygen and moisture penetration from PEDOT:PSS into the photoactive layer.

2. Experimental

Fig. 1(a) shows the device structure of the conduction/insulator/organic semiconductor (CIS) solar cell. A pre-patterned ITO glass was cleaned by acetone, DI water, and isopropanol sequentially, for 10 min. After cleaning, the ITO surface was treated by UV-ozone for 30 min. The conducting layer, PEDOT:PSS was spin coated on the ITO substrate and thermally dried at 140 °C for 10 min. The thickness of the dried PEDOT:PSS layer was about 40–50 nm. The polymer insulator, PS-r-PMMA was applied on the PEDOT:PSS. Fig. 1(a) depicts the chemical structure of PS-r-PMMA. To prepare the PS-r-PMMA solution, the PS-r-PMMA random copolymer (Aldrich, M_w = 1000.000–150.000) was dissolved in toluene in a concentration of 10 mg/ml and stirred overnight. Fig. 1(b) shows the formation procedure of ultra-thin PS-r-PMMA film. The PS-r-PMMA solution was first spin coated on the PEDOT:PSS layer at 500 rpm for 60 s. Three temperatures, 140, 180, and 220 °C were used to anneal PS-r-PMMA film for 2 h. After annealing, the samples were rinsed in toluene for 10 s. Since the toluene removes the un-attached PS-r-PMMA polymer to form a flat film, the thickness of the remained PS-r-PMMA film was approximately 2, 3, and 6 nm for the 140, 180, and 220 °C annealed sample. The thickness of the PS-r-PMMA layers was determined by measuring the thickness of PS-r-PMMA on the silicon oxide with the same processes by an ellipsometer with calibrated parameters [15]. The photoactive layer was a mixed solution of P3HT and PCBM organic semiconductors. The P3HT and PCBM were dissolved in 1,2-dichlorobenzene (DCB) separately in a concentration of 16 mg/ml. The photoactive layer solution was achieved

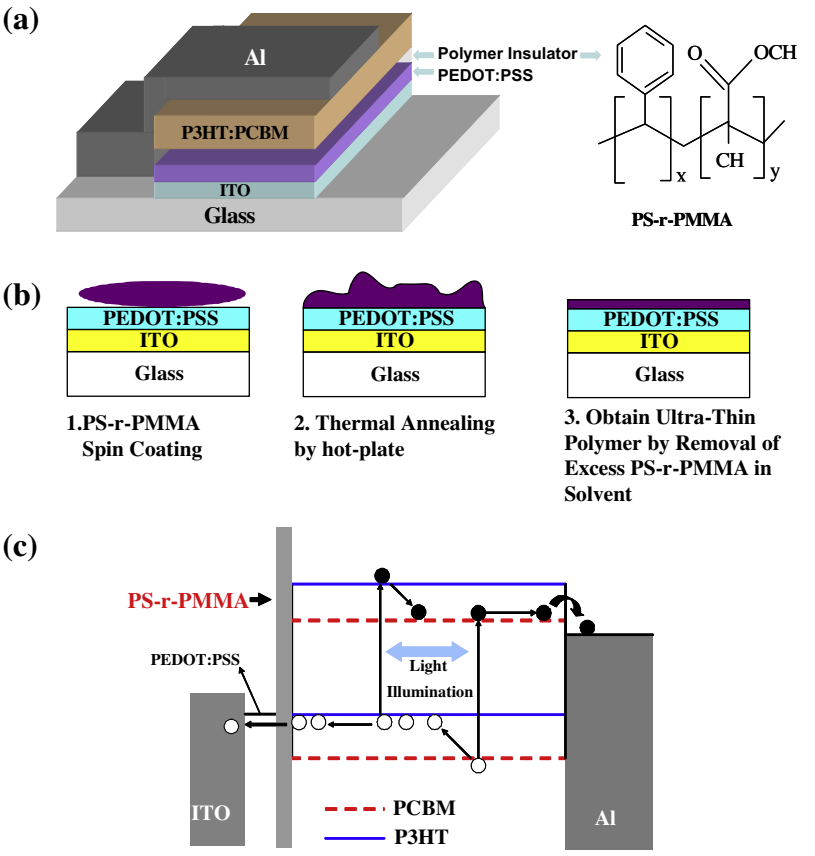

Fig. 1. (a) The schematic diagram of CIS solar cell with ultra-thin PS-r-PMMA random copolymer as insulator. The chemical structure and processing for PS-r-PMMA layer is also shown. (b) The coating process for ultra-thin PS-r-PMMA. After rinsed in toluene, a smooth and ultra-thin PS-r-PMMA was obtained. (C) The band alignment of CIS polymer solar cell.

by mixing P3HT and PCBM solution in a 1:1 ratio. The active layer was spin coated on the PS-r-PMMA layer at 500 rpm for 60 s and naturally dried in a glove box. Finally, a 100 nm thick Al layer was deposited on the photoactive layer as the cathode electrode and annealed at 110 °C for 10 min in a N_2 filled glove box. The active area for all devices was 4 mm^2. The photovoltaic effect was performed by a (Peccell-PEC-L11) solar simulator under AM1.5G illumination (100 mW/cm^2), calibrated by a reference silicon solar cell. The atomic force microscopy (AFM) images were obtained using a PicoPlusII scanning probe microscope. All device characterizations were performed under an ambient condition.

3. Results and discussion

Fig. 1(c) sketches the band alignment of the CIS cell and an ultra-thin PS-r-PMMA layer between PEODT:PSS and the photoactive layer. Inserting a thick layer of PS-r-PMMA might blocks the hole transport, reducing the dark saturation current since PS-r-PMMA is an insulator. However, if the thickness of PS-r-PMMA is thin enough, the holes can transport through it with less reduction. After light illumination, the photo-generated holes could tunnel through the ultra-thin insulator to the anode to achieve high photocurrent [16]. To find the appropriate thickness of PS-r-PMMA, the dark current for polymer solar cells with several PS-r-PMMA thickness was shown in Fig. 2(a). The reverse saturation leakage current for 2 nm thick PS-r-PMMA in CIS solar cell is slightly less than standard solar cell. The reduction of dark leakage saturation current is not clear. This reverse saturation leakage current decreases obviously for the CIS solar cell with 3 and 6 nm thick PS-r-PMMA layer. This implies the thickness of PS-r-PMMA less than 2 nm might be suitable for carrier transport with less blocking effect. However, for PS-r-PMMA graft to the hydroxyl group (OH–) of the underlying OH– surface, the temperature equal or higher than 140 °C is required [14]. Further decrease the thickness less than 2 nm is hardly to obtain and control. Compare the dark current at the forward bias, the current for the CIS solar cell with 2 nm thick PS-r-PMMA is also slightly less than standard cell. However, for CIS solar cell with 3 and 6 nm thick PS-r-PMMA, the forward current is strongly blocked which would not have acceptable photovoltaic performance. Fig. 2(b) shows the photovoltaic effect of the four polymer solar cell conditions. The standard cell denotes the polymer solar cell without the PS-r-PMMA protection layer. The J_{sc}, V_{oc} and fill factor (*FF*) for the standard cell is 8.90 mA/cm^2, 0.48 V and 0.49, respectively, leading to a 2.09% power conversion efficiency (PCE). With 2 nm thickness of the PS-r-PMMA insulator layer, the J_{sc}, V_{oc}, and *FF* of a polymer solar cell increase to 9.11 mA/cm^2, 0.52 V and 0.50, leading to a 2.37% PCE, around 11.26% enhancement, compared to a standard cell. The Fig. 2 inset shows the J_{sc} and V_{oc} for several CIS and standard cells. In general, CIS cells exhibit higher J_{sc} and V_{oc} than standard cells. Inserting an ultra-thin layer of PS-r-PMMA, slightly decreases the leakage current and enhances photocurrent leading to an slightly increase of V_{oc} by the following equation:

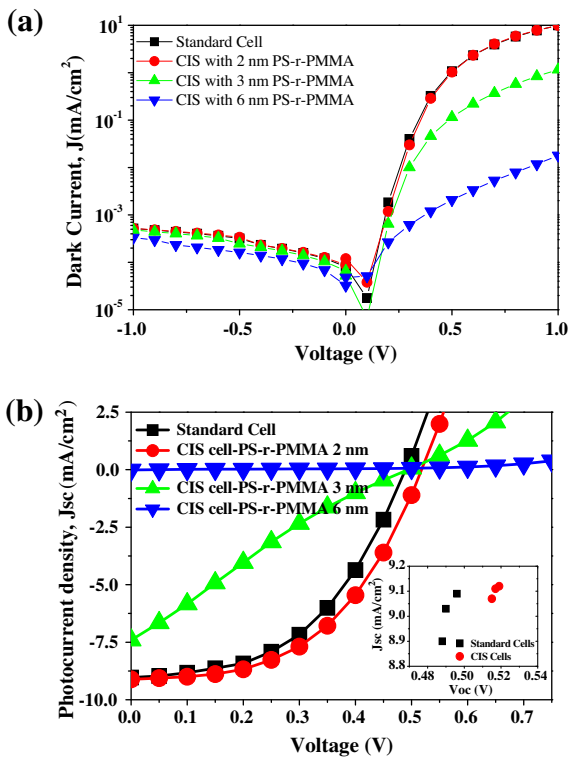

Fig. 2. (a) The dark saturation leakage current density–voltage characteristic for standard solar cell and CIS solar cells with 2, 3, and 6 nm thick PS-r-PMMA insertion layer. (b) The photo-current density–voltage characteristics for the polymer solar cell with standard and CIS structure under AM1.5 illumination. Inset shows the J_{sc} and V_{oc} of several standard and CIS polymer solar cells.

$$V_{oc} = \frac{nKT}{q} \ln\left(\frac{J_{sc}}{J_0} + 1\right)$$

in which n is the ideal factor, K is the Boltzman constant, T is the absolute temperature, J_{sc} is the photocurrent, and J_0 is the dark current [17]. The V_{oc}, J_{sc}, *FF*, PCE, series resistance and shunt resistance for standard solar cell, and CIS solar cells with 2, 3, and 6 nm thick PS-r-PMMA were listed in Table 1. From the table, the insertion of 2 nm thick PS-r-PMMA will not increase the series resistance extensively. This agrees well with the similar current density–voltage (*J–V*) characteristics of standard and CIS (2 nm) solar cell. However, increase the thickness of PS-r-PMMA to 3 nm, the series resistance increase dramatically from 11.89 to 93.6 Ω cm^2. Further increase the thickness of PS-r-PMMA to 6 nm, no photovoltaic effect was observed. We could still try to extract the series resistance. It increases to 468 Ω cm^2, which is around 42 times higher than CIS solar cell with 2 nm thick PS-r-PMMA. With insertion a layer of PS-r-PMMA with thickness higher than 3 nm, the carriers will be blocked cause high series resistance and poor photovoltaic performance. By the mechanism for CIS solar cell described above, the J_{sc} should decrease instead of increase, compared to a standard cell. This could be explained by the surface of the photoactive layer deposition. Inserting an ultra-thin layer of PS-r-PMMA

Table 1
Photovoltaic performance parameters for standard and CIS polymer solar cells with 2, 3, and 6 nm thick PS-r-PMMA.

	J_{sc} (mA/cm^2)	V_{oc} (V)	Fill factor (%)	Efficiency (%)	Series resistance (Ω cm^2)	Shunt resistance (Ω cm^2)
Standard cell	8.90	0.48	49	2.09	11.63	862

PS-r-PMMA (6 nm)	–	–	–	0	468	20,846

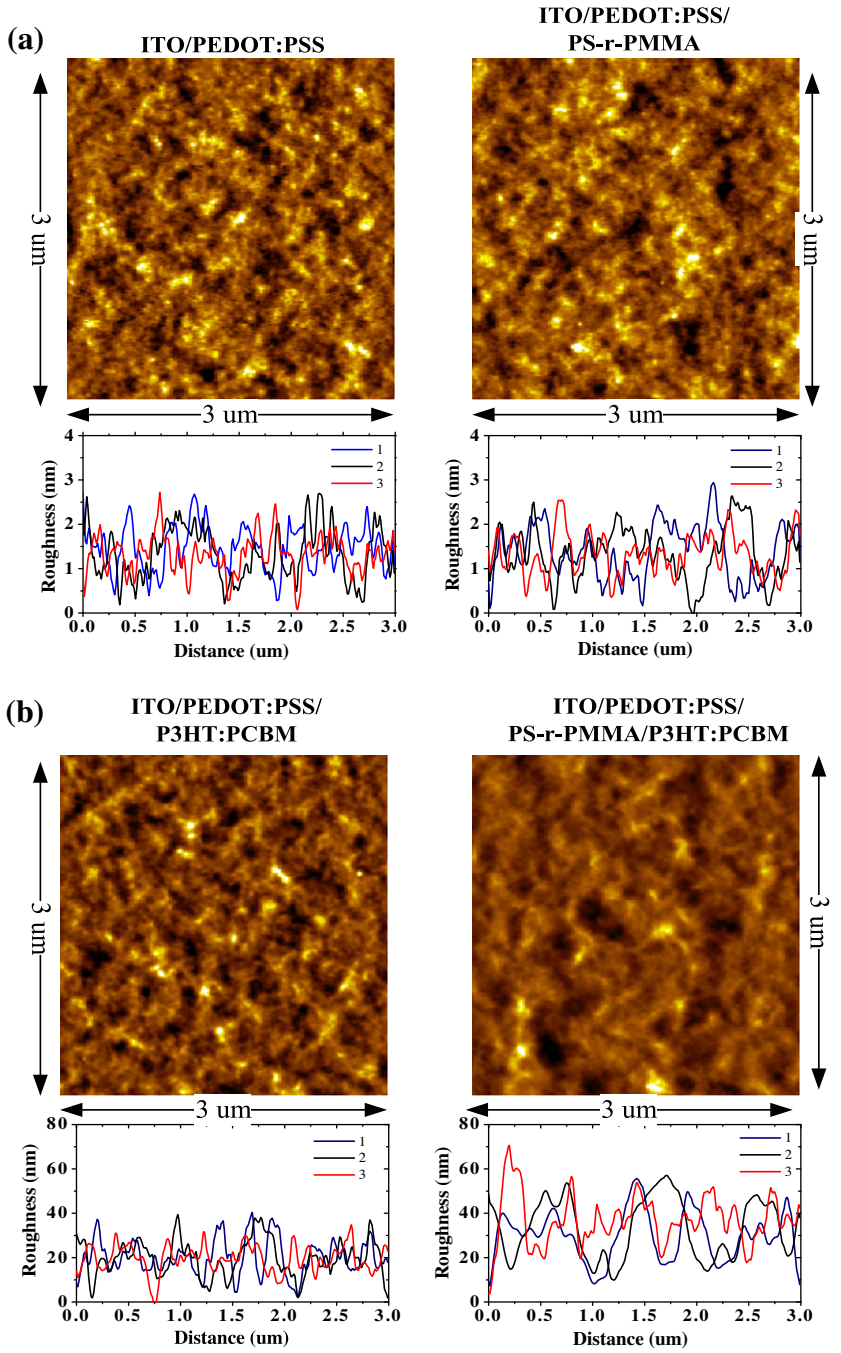

Fig. 3. The atomic force microscope (AFM) surface morphology on (a) PEDOT:PSS and PS-r-PMMA surface. The scales are 3 μm × 3 μm. The roughness is similar for both surface, (b) on P3HT/PCBM with PEDOT:PSS and PS-r-PMMA underlying layer. The roughness of the P3HT:PCBM layer on the PEDOT:PSS layer exhibits rms around 18.7–19.5 nm with small P3HT and PCBM domains. In comparison, the roughness of the P3HT:PCBM film on the PS-r-PMMA surface exhibits rms around 23.75–32.5 nm with a large P3HT and PCBM domain.

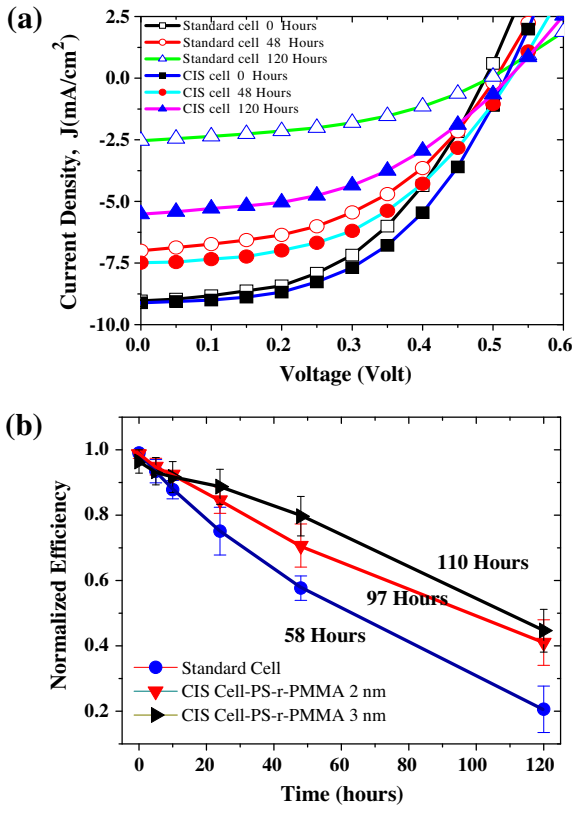

Fig. 4. (a) The photo-current density–voltage characteristic for standard and CIS (2 nm PS-r-PMMA layer) solar cells after storage in ambient for 0 (pristine), 48, and 120 h. (b) The normalized efficiency respect to the storage time for standard and CIS solar cells. The half-efficient for standard, CIS (2 nm) and CIS (3 nm) polymer solar cell are 58, 97, and 110 h, respectively.

modifies the surface from hydrophilic to hydrophobic. The hydrophobic surface is favorable for better P3HT/PCBM growth and phase separation [18]. The increase in the photocurrent due to better morphology of the active layer compensates for photocurrent reduction by the ultra-thin insulator, resulting in obtaining a similar J_{sc} in CIS and the standard cell. Further increases in the thickness of PS-r-PMMA causes a current density leakage far below the photocurrent of the polymer solar cell. Carrier blocking makes the J_{sc} of the polymer solar cell too small to have good photovoltaic performance. Fig. 3(b) shows a totally blocked photocurrent by a 6 nm thick PS-r-PMMA film.

To verify modification in the P3HT/PCBM active layer on different underlying layers, the surface morphology was measured by AFM on the area of $3 \times 3\ \mu m^2$. Fig. 3(a) shows the surface for PEDOT:PSS film and PS-r-PMMA covered PEDOT:PSS film. The roughness of the PEDOT:PSS/ITO surface is flat with a root-mean-square (rms) approximately 1.1–1.3 nm. Covering with PS-r-PMMA does not alter uniformity of the rms at approximately 1.1–1.5 nm. This indicates the uniform coverage of the PEDOT:PSS surface by PS-r-PMMA. The PS-r-PMMA layer also modifies the surface energy. The contact angle measurements determine the surface energy of a material surface [19]. The aqueous contact angle increases from 25° of PEDOT:PSS to around 62°, meaning that the hydrophilic surface modifies to slightly hydrophobic. Fig. 3(b) shows the AFM surface morphology for the P3HT:PCBM layer on PEDOT:PSS and on PS-r-PMMA. The roughness of the P3HT:PCBM layer on the PEDOT:PSS layer exhibits rms around 18.7–19.5 nm with small P3HT and PCBM domains. In comparison, the roughness of the P3HT:PCBM film on the PS-r-PMMA surface exhibits rms around 23.75–32.5 nm with a large P3HT and PCBM domain. This indicates that the P3HT and PCBM on PS-r-PMMA separate well into a better percolation path for electron and hole-conduction by a self-organization process. The rough surface also enhances internal light scattering and light absorption, leading to higher J_{sc}, resulting in the J_{sc} for the CIS cell not less than the standard cell [20].

For the lifetime measurement, this research encapsulated the polymer solar cell at the cathode side by covering it with a glass sheet and sealing with epoxy. Fig. 4(a) shows the photo-current density–voltage (J–V) characteristic of standard and CIS cells. The measurement time is 0 (pristine), 48, and 120 h after cell fabrication. The J_{sc} of the standard cell decreased from 8.90 to 7.00 mA/cm^2, for the first 48 h, and decreased rapidly from 7.00 to 2.53 mA/cm^2 from 48 to 120 h. Within 120 h, the J_{sc} decreased around 72%. In comparison, the J_{sc} in the CIS cell with 2 nm PS-r-PMMA protection layer reduced from 9.11 to 7.48 mA/cm^2 in 48 h, and further decreased to 5.51 mA/cm^2 after 120 h. Within 120 h, the J_{sc} decreased only 39.5%. Table 2 lists the details. Fig. 4(b) shows the efficiency trend to a prolonged time. Efficiency for the standard and CIS cells decreases along the store time. The half-efficiency lifetime for the standard cell is around 58 h and around 97 h for the CIS cell. The lifetime for the CIS cell exceeds the standard cell by 40 h, around 67% enhanced. The half-efficiency lifetime further increases to 110 h when using the 3 nm thick PS-r-PMMA layer. Although J_{sc} and efficiency for both

Table 2

	48	7.48	0.52	43	1.67	18.30	701
	120	5.51	0.52	34	0.97	32.94	386

the standard and CIS cell decrease with time, the trend is different. The efficiency decreases faster than the short circuit current, explained by the series resistance (R_s). Table 1 shows that the R_s for the pristine standard cell is 11.63 and 11.82 $\Omega\,cm^2$ for the CIS cell. After 120 h, the R_s for the standard cell increases to 56.30 $\Omega\,cm^2$. The R_s for the CIS cell only increases to 32.94 $\Omega\,cm^2$, far smaller than the standard cell. The increase in R_s causes the decrease of the *FF*, with efficiency decreasing faster than J_{sc}. This is because the moisture and oxygen in the PEDOT:PSS film that oxidizes the photoactive polymers decreases conductivity to enhance the R_s device. Inserting a layer of PS-r-PMMA may help block the oxygen and moisture penetration. Only 2 nm thick PS-r-PMMA has significant effect in oxygen and moisture blocking. To explain this effect, this study measured the water vapor transmission rate (WVTR) of PS-r-PMMA. The WVTR is around 0.9676 (gm/m^2 day) at 22 h in the H_2O 90 RH% environment [21]. In polymer materials, insulator materials are more stable than conductive materials in an atmosphere environment. PS-r-PMMA as an insulator material is rather stable in an oxygen and moisture environment. In the AFM measurement, the P3HT and PCBM form a better percolation loop on the PS-r-PMMA surface to resist oxidation longer to preserve the conduction path, which is indicated by R_s measurement as in the table.

4. Conclusion

This study demonstrates a conductor/insulator/organic semiconductor solar cell by covering PEDOT:PSS with an ultra-thin polymer, PS-r-PMMA. The 2 nm thick PS-r-PMMA improves the *FF* and V_{oc} leading to improving efficiency from 2.13 to 2.37%, around 11% enhancement. This research extends the lifetime of the polymer solar cell from 58 to 97 h. This technique provides higher performance and longer lifetime for the polymer solar cell, compatible to the roll-to-roll large area printing process on a plastic substrate.

ABSTRACT

Polymer composites with metal nanoparticles have attracted considerable attention over the past years due to numerous solid state potential applications in organic electronics and microelectronic devices. Here we report the first example of a novel, rapid and convenient self-directed dual surface nano-silvering of a polymer film by a simple single-stage process of free-radical photopolymerisation (UV-curing). The major component of the composite is bisphenol A ethoxylate dimethacrylate (BEMA) which can be photopolymerised by a photo-reactive initiator (Darocur 1173) under UV light. Under the same conditions of UV irradiation, silver nitrate decomposes and the silver ion is deposited as metal while the pyrrole is oxidised to polypyrrole. It is demonstrated that this versatile method can open up promising prospective in obtaining innovative composite polymeric capacitors for highly flexible and/or non-planar electronics application. The obtained films are characterised by Scanning Electron Microscopy (SEM) and electrical measurements.

1. Introduction

The rapid development of portable electronic devices has increased the demand for compact, lightweight, high capacity electronics [1–3]. Capacitors are important elements in electrical circuits. In this context, polymer networks offer the obvious advantages of being light in weight, flexible, elastic, and less fragile with respect to other inorganic supports such as glasses, ceramics, or native metals. Silver has been a material of great interest as it has the highest electrical and thermal conductivity among the metals. Metal–polymer and ceramic–polymer composites are being studied as embedded capacitors in organic substrates [4–7]. In particular, polymer composites with silver nanoparticles are receiving considerable attention due to numerous solid state potential applications in many fields, e.g. organic electronics, catalysts, plasmonics, coatings, antimicrobials, etc., [8–14]. Very often the polymeric capacitors are prepared by multi-step methods like spin or spray coating, layer by layer deposition or Langmuir–Blodgett techniques followed by vapour deposition of a metal for conducting contacts [15–18].

Free-radical photopolymerisation (UV-curing) is a well established polymerisation technique which takes place at room temperature under UV light. Upon irradiation, a liquid poly-functional monomer containing a proper photo-initiator forms a solid highly cross-linked film. A typical formulation may consist of more than one monomer and oligomer, but is usually solvent free. The irradiation time ranges from few seconds to few minutes and light is the only energy source for building up the polymeric thermo-set matrix. Therefore, the process is well known for being fast and environmentally friendly, as the energy consumption is low and there is no emission of

doi:10.1016/j.orgel.2010.08.003

volatile organic compounds [19]. For these reasons the UV-curing is a consolidated technique for the production of coatings and inks; it is widely applied in the field of photolithography for the production of electronic and optical devices and is gaining interest in other areas, such as biomedical applications. We have previously demonstrated the use of this versatile technique to prepare in a single-step plasticized polymer electrolyte membranes for Li-based batteries application [20–22].

There is abundant literature on one side metalised polymeric films for various applications [23–27]. Southward and Stoakely [23] have reviewed the single-stage thermal curing of selected Ag^+ containing poly(amic acids) leading to cyclo-imidization of the polyimide precursor with concomitant Ag^+ reduction and surface aggregation of the metal, yielding a reflective and/or conductive silver surface. They have also highlighted the disadvantages of multi-stage processes like chemical vapour deposition, sputtering, electroless plating, etc. which often result in poor adhesion at polymer–metal interface. Photo-induced (mainly UV) polymerisation has been used to obtain silver nanoparticles in different polymer composite matrices like trisacrylates [8], acrylamide cryogels [28] and also polypyrrole [29,30]. However, all these methods involved time-consuming multiple steps in preparation.

Recently we had reported a simple single-step UV-curing method to obtain conducting polymer surfaces with silver nanoparticles [31]. Here we report the first example of dual surface nano-silvering of a polymer film by a simple single-stage process of UV-curing. The term "single-stage" refers to a procedure in which the metallised film is directly developed from a single homogeneous solution that contains both the metal precursor and the desired reactive precursors of the final polymeric network. That is, the sample is obtained in a single-stage and no subsequent distinct metallisation stage is involved, as is the usual route to prepare metallised films/coatings [23]. To the best of our knowledge, such an approach to dual surface metallisation has not been reported so far. This kind of polymeric film metalised on both sides is conceived to be, in principle, a capacitor.

2. Experimental section

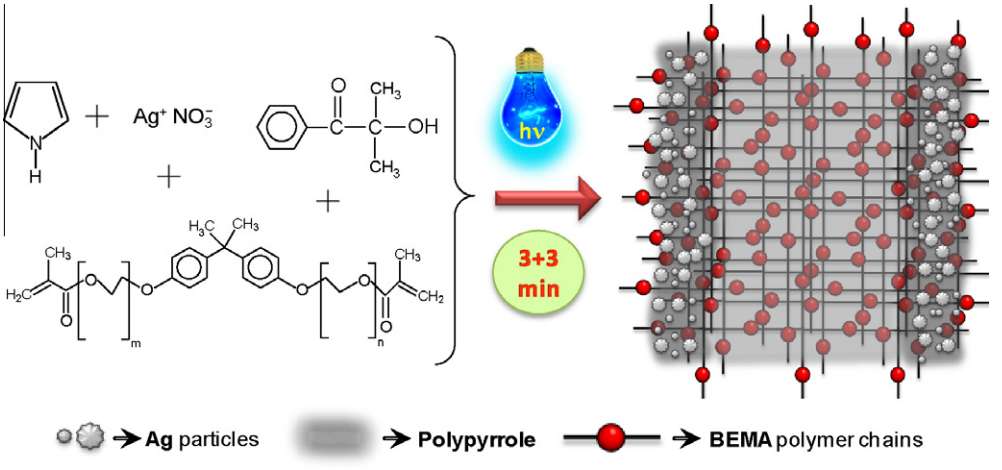
2.1. Materials

The reactive formulation for the preparation of the dual-surface conducting polymer composite membranes was based on bisphenol A ethoxylate (15 EO/phenol) dimethacrylate (BEMA), a methacrylic-based di-functional oligomer having an average molecular weight of 1700, obtained from Aldrich. The free radical photo-initiator was 2-hydroxy-2-methyl-1-phenyl-1-propanone (Darocur 1173/D1173) provided by Ciba Specialty Chemicals. Silver nitrate ($AgNO_3$, 99.5%), methanol (CH_3OH, 99.8%) and pyrrole (C_4H_5N, $\geqslant$98%) were obtained from Aldrich and used as such.

2.2. Procedure

$AgNO_3$ (1.27 g) was dissolved in 5.00 g of 50% (v/v) $CH_3OH + H_2O$ mixture. This methanol + distilled water mixture enabled the dissolution of silver nitrate and pyrrole and homogenized the mixture with BEMA and the photo-initiator. To this solution, 7.43 g of BEMA, 1.00 g of pyrrole and 0.30 g of initiator were added subsequently and mixed thoroughly. This gives a molar ratio of 2:1 for pyrrole to silver nitrate, and ensures complete reduction of Ag^+ to its metallic form [31]. The mixture was then poured into Petri dishes and then exposed to UV irradiation for 3 min on each side (sample A) and for 3 min on only one side (sample B). The photochemical curing was performed by using a medium vapour pressure Hg UV lamp (Helios Italquartz, Italy), with a radiation intensity on the surface of the sample of 28 ± 2 mW cm^{-2}. For this process, the samples were held under a pure N_2 atmosphere in small sealed boxes equipped with a quartz window. These conditions assure maximum curing (disappearance of the band attributable to the double bonds of the methacrylate groups at 1630 cm^{-1}, checked by real time FT-IR spectroscopy) [20]. Free composite polymer films were then easily detached from the dishes.

In the absence of UV light (i.e., under ambient laboratory conditions), the reaction between silver nitrate and



Scheme 1. Schematic illustration of the single-stage UV-curing process to self-directed dual surface polymer metallisation.

pyrrole is very slow, and the black colour of polypyrrole formation starts to be visible after about an hour. Also, there is no film formation as BEMA does not polymerise in absence of UV.

Experiments were repeated at least three times and were found to be reproducible.

2.3. Instrumental techniques and characterisation

Morphological characterisation of the films was performed employing a FEI Quanta Inspect 200 LV Scanning Electron Microscope (max magnification of 1.5×10^5). Scanning Electron Micrographs were obtained using a microscope operated at an accelerating voltage of 15.00 kV, both as secondary and backscattered electron images. The samples for the cross-sectional Scanning Electron Microscopy (SEM) images were prepared by fracturing the given film in liquid nitrogen in order to avoid any change in the morphology.

The surface resistances of the films were calculated from the current–voltage (I–V) curves recorded at ambient temperature over the voltage range of ±1.0 V by a CHI 760 D Electrochemical Workstation, with constant pressure spring loaded gold-plated pin probes (spring force 1.26 N,

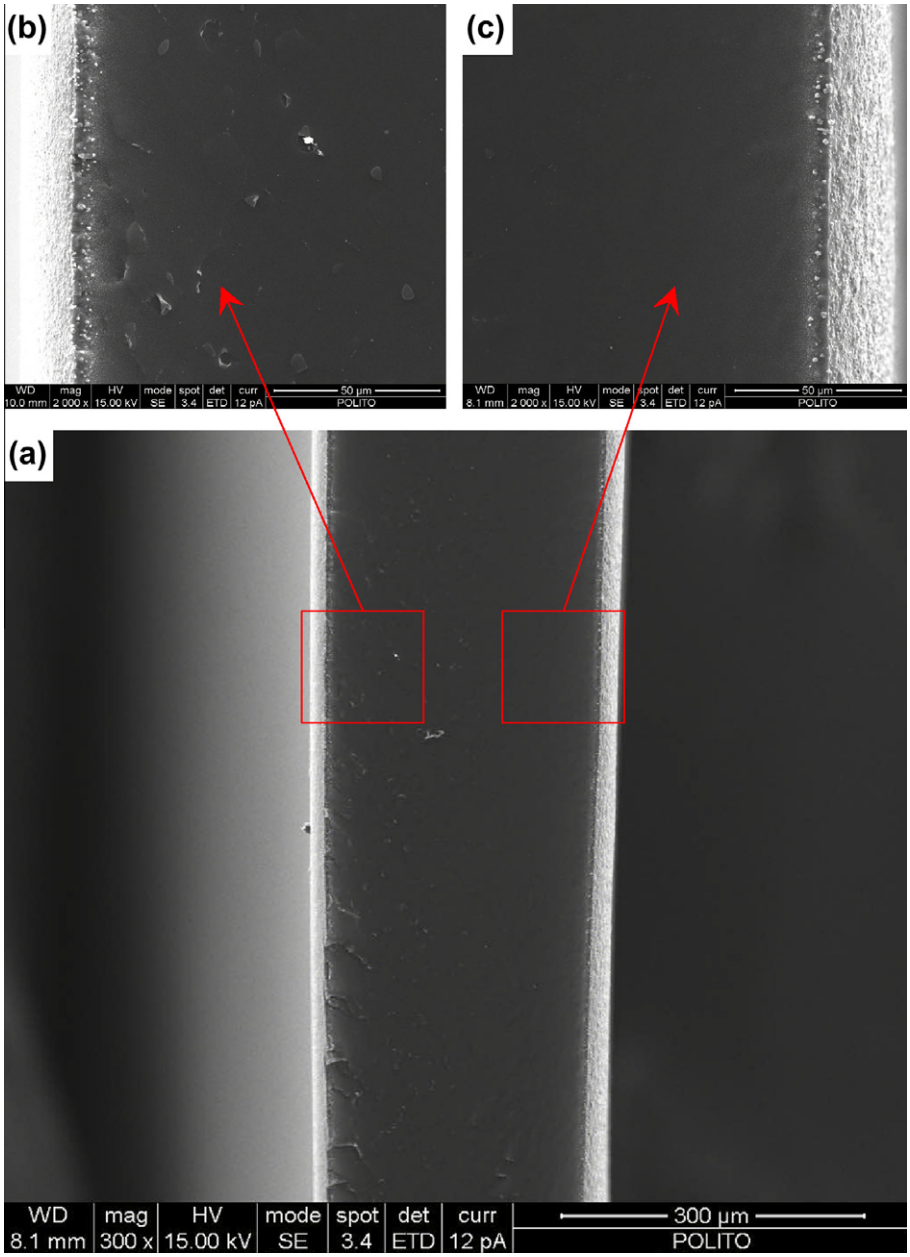


Fig. 1. SEM micrographs of sample A (UV exposed on both sides) at different magnifications: (a) cross-sectional image, (b) cross-section left edge (upper side, exposed first) and (c) right edge (lower side).

contact resistance 50 mΩ, P25-0822 Flat Head, Harwin). There was a fixed distance of 1.0 cm between the probes, and measurements were made at five different points on the surface of the films.

The same CHI 760 D Electrochemical workstation was used to obtain the capacitance versus voltage plot. Two-electrodes Teflon-made Swagelok test cells were assembled by sandwiching discs of 0.785 cm^2 of the given film (sample A: average thickness ≅ 500 μm, average weight ≅ 50 mg) between two stainless-steel 316 (SS-316) cylindrical blocking electrodes (1.0 cm in diameter and resistance of less than 1 Ω).

3. Results and discussion

The major component of the composite is bisphenol A ethoxylate dimethacrylate (BEMA) which can be photopolymerised by a photo-reactive initiator under UV light. The complete process involves multiple reactions, simultaneously. A schematic representation is shown in Scheme 1. On irradiation with UV, the initiator generates radicals by intramolecular scission. Then, the monomer BEMA undergoes free radical polymerisation, the details of which have been already discussed [20]. Under the same conditions of UV irradiation, silver ion is reduced to metallic form while the pyrrole is oxidized to polypyrrole. All these reactions occur within few minutes. This process gave methacrylate films with one side conducting surface of 7–10 μm composed mostly of silver nanoparticles and polypyrrole. Interestingly, when the sample is turned over to expose the other surface to UV light we get a polymer film with both sides silvered to more or less the same extent. It is this interesting and intriguing phenomenon that forms the core of this communication.

Two kinds of samples have been prepared, namely sample A (UV irradiated on both sides) and sample B (irradiated only on the top surface). The obtained samples were then characterised by Scanning Electron Microscopy (SEM) and electrical measurements.

Fig. 1 shows the cross-sectional SEM micrographs of the film that was exposed on both sides (sample A). It is clearly evident that the silvered layer is present on both sides, extending to about 8 ± 2 μm into the interior. In Fig. 2, the SEM micrographs are reported of the cross-section of sample B (UV exposed only on top side). Clearly it is seen that only the top surface is silvered, even when checked in backscattered mode. Correspondingly, the electrical measurements show low resistances on both surfaces for the sample exposed to UV light on both sides; whereas the sample exposed on only one side demonstrated a high resistance on the unexposed surface, as shown in Table 1.

Table 1
Average surface resistance values.

Sample	Resistance [Ω]	
	Upper surface[a]	Lower surface[a]
A	256 ± 8	201 ± 9
B	326 ± 15	>620 K

[a] Values obtained as an average from *I–V* curves recorded at five different point on the surface of the samples. One example is reported in Fig. 3.

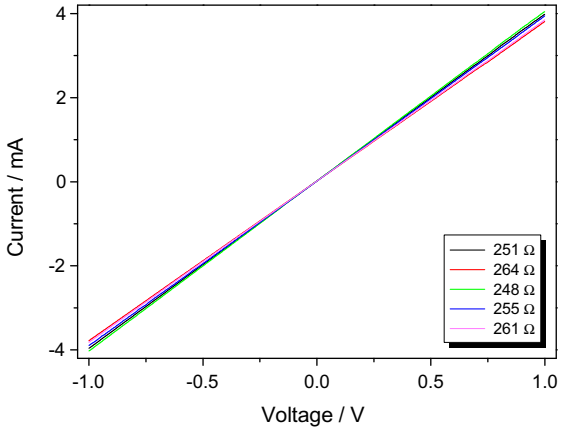

Fig. 3. Current–voltage (*I–V*) plots at five different locations on the upper surface (exposed first) of sample A.

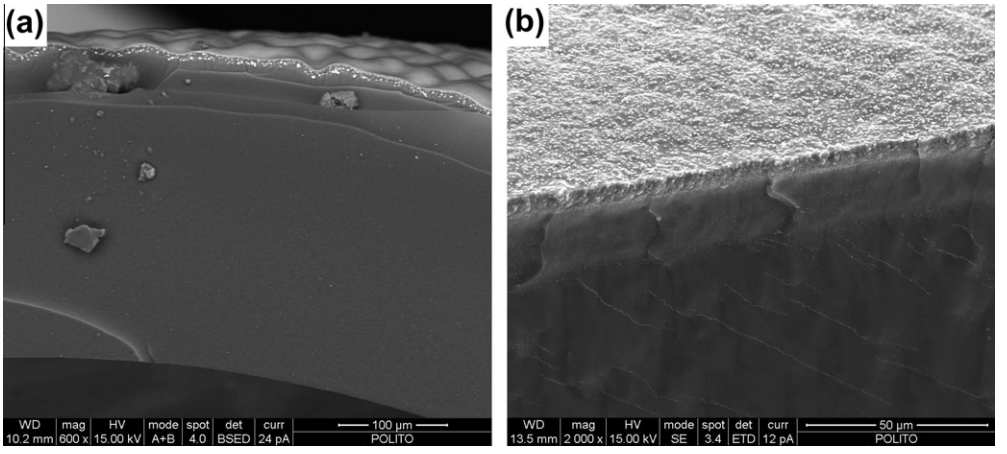

Fig. 2. SEM micrographs of sample B (UV exposed only on the top side) at different magnifications: (a) backscattered electron mode and (b) secondary electron mode.

The surface resistances of the films were calculated from the current–voltage (I–V) curves recorded at ambient temperature over the voltage range of ±1.0 V, with constant pressure spring loaded gold-plated pin probes. There was a fixed distance of 1.0 cm between the probes, and measurements were made at five different points on the surface of the films. An example of the results obtained for sample A is shown in Fig. 3. As the five curves are nearly

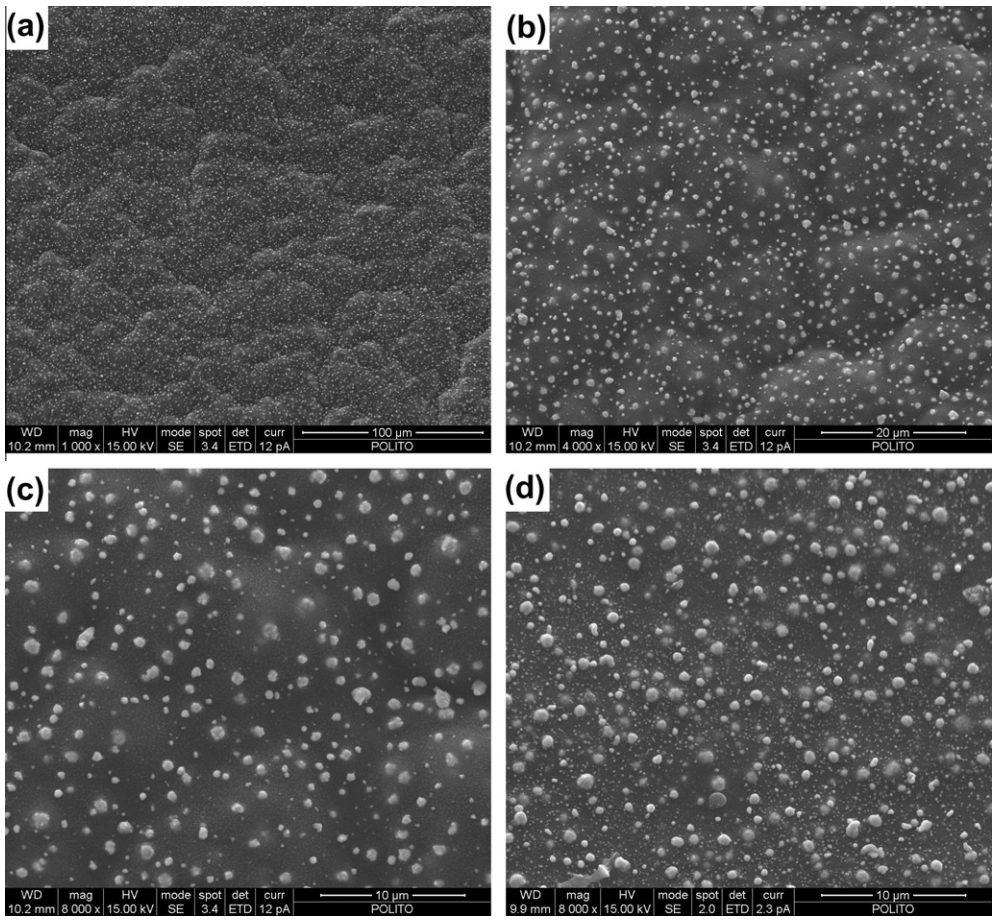

Fig. 5. SEM micrographs of sample A: (a, b, c) top surface (exposed first) at different magnifications and (d) lower surface (exposed next). Ag nanoparticles embedded in polypyrrole are clearly visible on both surfaces.

overlapping, it indicates highly homogenous conductivity all over the surface of the film.

We found a large variance associated with the resistance values measured on the unexposed side which is indicative of several non-homogeneities on the surface. This is somewhat expected due to some random reduction of silver ions with large areas of non-conducting material. The same is confirmed from Fig. 4, which illustrates the comparison between the SEM micrographs of the exposed (Fig. 4a) and unexposed (Fig. 4b) surfaces of sample B. In fact, the exposed side shows homogenous distribution of Ag nanoparticles, whereas no such particles can be seen on the unexposed surface.

On the contrary, in the case of sample A there is formation of well-distributed Ag nanoparticles on both the surfaces (see Fig. 5). Moreover, at low magnifications, the characteristic wrinkles of polypyrrole are clearly visible with Ag nanoparticles studded more or less uniformly, as shown in (Fig. 5a and b) [32]. The silver particles on the surface have an average size of 150 nm, while the agglomerates were of the order of 700 nm. Uniformity in high conductivity is maintained all over the surface by the conducting polymer polypyrrole studded with the Ag nanoparticles.

The formation of silvered layers on both surfaces indicates that there is migration of silver ions and pyrrole towards both surfaces under UV irradiation. From complexation studies and the "hard and soft acid–base" (HSAB) concept [33], it is known that transition metal ions (viz. silver) being a soft acid would form stronger complex with nitrogen-containing pyrrole than the polyether oxygen of BEMA, and hence both silver and pyrrole migrate together to the surfaces. The causes for such migration are not clear yet. We hypothesize that since the photo-initiated reaction of BEMA [20] is much faster than the redox reactions of pyrrole and Ag^+, the formation of cross linked BEMA polymer pushes out the Ag^+ and pyrrole contained in aqueous domains.

Southward and Stoakley reported the observation of such migration in thermally cured polyimides, and it seems there is still no explanation as to why and how it

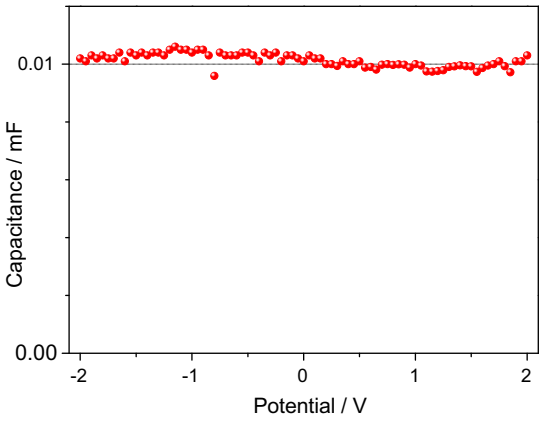

Fig. 7. Capacitance versus voltage plot of sample A at a frequency of 100 Hz.

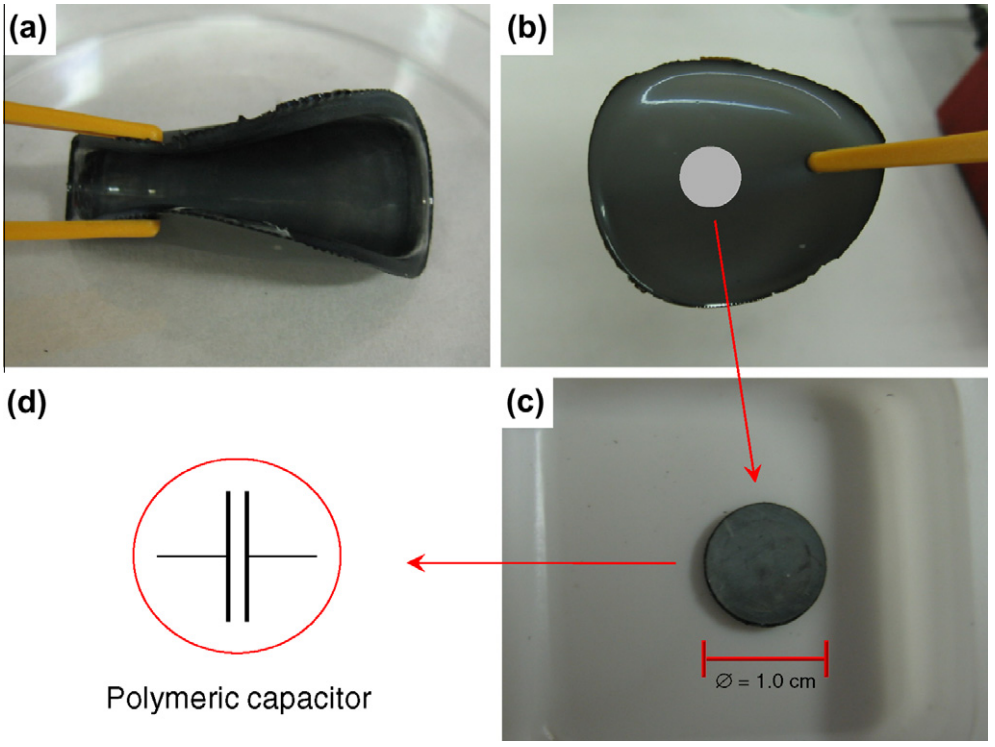

Fig. 6. (a) Illustration of the flexibility of the polymer composite (highly suitable for flexible and/or non-planar electronics application); (b, c, d) a disc of 1.0 cm in diameter is cut out to be used as a capacitor (results obtained are shown in Fig. 7).

happens [23]. However, they discussed about migration of silver towards only one surface. Probably, we are the first to observe this intriguing migration towards both the surfaces of the composite polymer films and we are now trying to ascertain its exact mechanism and causes by changing various preparation conditions and compositions of the materials. Nevertheless, the formation of two conducting layers on either sides of an insulating polymer in a single-step opens up possibilities of rapid production of highly flexible polymeric capacitors, which until now are made by time-consuming multiple steps procedures. In this respect, Fig. 6 shows the bendability of the film. Circular discs of 1.0 cm in diameter were cut out from the master film, as shown in the figure, and tested for capacitive properties. Fig. 7 shows the capacitance versus potential curve for sample A at a frequency of 100 Hz. A two-electrode Teflon-made Swagelok test cell was used for this experiment, which was assembled by sandwiching a 0.785 cm^2 disc of the given film between two SS-316 cylindrical blocking electrodes. The capacitance behaviour over the voltage range of ±2.0 V is similar to the curve reported by Liu et al. for their polymer capacitor made by multi-step inkjet printing [18]; however, the capacitance value obtained for our sample is rather high (about 0.01 mF) compared to what is reported in the reference above. We suspect this could be because of the presence of a very small amount of Ag nanoparticles and/or conducting polymer trapped in the bulk of the insulating (BEMA) polymer matrix, which act as multiple nano-capacitors thus leading to a huge increase in the overall capacitance value. Work is in progress to get a deeper insight into this aspect.

4. Conclusions

In summary, we have successfully introduced a novel but simple and efficient method that allows excellent dual surface metallisation of a methacrylic-based polymer network, in a single-stage. The whole process is remarkably convenient, with short reaction time, ‘‘environmentally friendly”, and no need for any complex equipment or manipulation. For certain applications, such an approach can increase the production efficiency when compared to traditional multistage techniques. We believe that exploiting the potential and versatility of UV-curing technique can open up promising perspectives in obtaining innovative polymeric capacitors with high flexibility, which is well suited for flexible and/or non-planar electronics application. In this respect, further work and optimization is currently directed towards a better understanding of the silver migration phenomenon and extending the method to other metals and polymer matrices.

Eumelanin layer
Hysteresis effect
Memory device

ABSTRACT

Hysteresis behaviour of the current–voltage characteristics collected on spin coated synthetic eumelanin layer embedded in the Au/eumelanin/ITO/glass structure is shown. The effect has been observed under dark both in air and vacuum environment and its magnitude has been found related to the eumelanin hydration state. Moreover, in vacuum and under white light illumination, enhancement of the hysteresis loop area respect to those collected under dark has been observed. Space charge storage and charge trapping/detrapping as possible mechanisms responsible of the observed current–voltage behaviour are discussed. Preliminary experimental results have evidenced the possible integration of eumelanin layers in electro-optical charge storage based memory devices.

1. Introduction

Eumelanins are ubiquitous pigments present throughout nature responsible for the color of hair, skin and eyes ranging from red, yellow, brown to black. It is ascertained worldwide that eumelanins exert several functions such as photoprotection, photosensitization, antibiotic activity and thermal regulation. A pioneering work by Mc Ginnes et al. disclosed that eumelanin electrical properties are similar to those of amorphous semiconductors and envisaged its possible implementation as active material in switching devices [1]. Following this original hint, a great deal of work is currently in progress in order to investigate the various optoelectronic properties and possible technological applications of eumelanins. Most research efforts mainly concerned the investigation on synthetic eumelanin powders or pellets: absorption coefficient, dark electrical conductivity, photoconductivity and ac response were explored [2–9] but all of them under the picture of eumelanin as an amorphous semiconductor. However, its broadband absorption that does not strictly follow a Tauc law [5,6,10] pointed out also that the picture of eumelanin as an amorphous structure has to be taken with care [11–13] and the chemical disorder model has been invoked to explain the α vs λ behaviour [3]. The eumelanin conductivity is furthermore strongly related to the hydration state and external environment and can lowers several order of magnitude when water is desorbed [8,9]. The dependence of conductivity on the humidity degree stems in the presence of two forms of water bonded to the macromolecules: one adsorbed on the surface and easily removable under vacuum or by drying, and the other incorporated in the inner polymer

structure. In the last case the removal can require thermal treatments. The presence of these two kind of water bonding has been assessed by several studies and mainly on pellets [[8,9] and Ref. therein]. Specifically, in air water bridges and/or hydrogen bonds between individual molecules and carboxy, hydroxyl and amino groups are present but, during dynamic vacuum treatment, weakening or partial breaking of hydrogen bonds between planar layer occurs influencing (i.e. lowering) then the conductivity. The residual conductivity is then due to the remaining strong bonded water. Eumelanin is nowadays recognized as primarily formed by various combinations, still unknown at this stage, of 5,6-dihydroxyindole (DHI or HQ) and 5,6-dihydroxyindole-carboxylic acid (DHICA) and their corresponding redox forms.

One of major drawbacks in the application of melanin as active material in electronic devices is represented by its scarce solubility in common solvents, preventing easy deposition of homogeneous layers. As a consequence, in recent years, the focus is on eumelanin layer deposition on various substrates in order to better study electrical properties aiming to foresee a possible integration of this intriguing material in hybrid optoelectronic devices [2,14]. To date, eumelanin layer has been electrochemically deposited on gold, or spin coated and/or spray coated on quartz substrates [2,14,15].

To the best of our knowledge, no paper has been published so far concerning the study of the electrical properties of eumelanin layers on ITO/glass substrates. While, in our opinion this approach is a priority in the view of technological applications. It is well known, in fact, that ITO/glass is a widely used conductive support for organic semiconductors, and the feasibility of building up such a eumelanin/ITO junction, opens the possibility to witness the intriguing electrical properties of eumelanin and to compare its behaviour with that of the widely studied layer of organic molecular or polymeric semiconductors.

Up to now the electrical characterization of eumelanin layers have been interpreted under the picture of melanin as an amorphous semiconductor [14]. However, it was stated that in order to perform conductivity measurements on melanin under stationary conditions, the current should be collected after a certain time interval thus evidencing the presence of transient phenomena which cannot be overcome in any way [14]. However, such effects can be useful to shed light on the nature of a carrier (electron or hole) dominating the transport which is still an open issue. As a matter of fact, current relaxation phenomena have been well known and studied in several organic Au/polymers/ITO/glass interfaces and ascribed to space charge storage or to trapping/detrapping mechanisms under voltage application. Based on these phenomena, a possible integration of these materials in memory devices has been foreseen [16–18]. The experimental evidence of space charge storage or charge trapping effect is the hysteresis-type behaviour of current–voltage (I vs V) characteristics [16,17]. This communication shows for the first time similar hysteresis behaviour in I vs V characteristics observed in Au/eumelanin/ITO/glass interfaces and a first insight on the mechanisms responsible of this behaviour will be discussed.

2. Materials and methods

Eumelanin layers have been spin coated on ITO/glass substrates starting from synthetic melanin powder (140 mg, Sigma–Aldrich) dissolved in water (1 mL) and 28% aq. ammonia solution (2 mL). The solution was stirred and sonicated for 1 h, and subsequently centrifuged at 3500 rpm for 15 min. Before layer deposition, ITO/glass substrates were submitted to an oxygen plasma treatment (30 min, room temperature), in order to improve the adhesion of organic layers onto ITO/glass substrates [19].

AFM measurements were performed in air, in the weak repulsive regime of contact mode. Gold coated Si_3N_4 cantilevers with a force constant of 0.05 N/m and a statistical apical radius of 5–20 nm were used. Constant force images were acquired with a scan rate of 3.0–4.0 s/row.

The optical absorption spectrum has been calculated following the Ritter–Weiser expression on reflectance (R) and transmittance spectra (T) collected in air in the wavelength range $\lambda = 400$–800 nm by using a Perkin–Elmer Lambda 9 spectrophotometer [20]. The chosen wavelength range was dictated by the glass absorption at $\lambda < 330$ nm and high ITO reflectance at $\lambda = 800$ nm. Moreover, T and R spectra were collected from both the film and substrate side to estimate the film roughness and scattering effects on the absorption [21]. The film thickness was estimated from reflectance interference fringes.

Current–voltage (I vs V) characteristics have been performed on Au/eumelanin/ITO/glass structure at room temperature by using an electrometer and a power supply. For these measurements an Au slab ($0.25 * 0.25$ cm^2) has been gently placed on top of the melanin layer in order to avoid possible macromolecule modification induced by metal evaporation contacting procedure. The I vs V loops have been collected in air and in vacuum ($p = 10^{-5}$ mbar), and waiting several minutes between consecutive sweeps, under dark and white light irradiation at different voltage sweep speed starting from zero bias to a maximum positive value $+V_L$, and then alternating back and forth between $+V_L$ and $-V_L$. A halogen lamp simulating the solar spectrum at a power of AM 1.5 (100 mW/cm^2) was used for white light irradiation.

3. Results and discussion

The optical absorption spectra (Fig. 1(a)) display the characteristic broadband absorption observed in spin coated 400 nm thick eumelanin layer on quartz [2,3,7]. The α values have been found varying between 5×10^5 m^{-1} and 3×10^6 m^{-1} in the wavelength range $\lambda = 400$–800 nm, thus confirming the good film density. Also the calculated surface roughness (10 nm) agrees with values observed by AFM measurements. The estimate of the scattering coefficient was around 2–3% in the range 400–700 nm, i.e. <6% in the overall λ range, so that scattering has practically no influence in determining the layer broadband absorption [22]. AFM acquisitions (see Fig. 1(b and c) and inset herein) show that the surface of eumelanin layer is homogeneous, with a RMS roughness [23] of about 7 nm estimated over the entire area imaged in

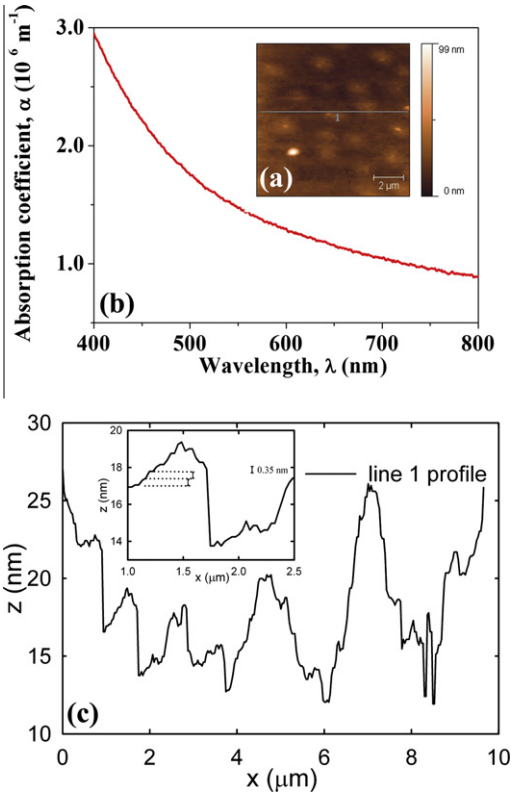

Fig. 1. (a) AFM height image acquisition and (b) broadband optical absorption spectra of a 400 nm thick eumelanin layer deposited by spin coating on ITO/glass substrate and corresponding (c) typical cross-section of the film height profile as derived from AFM height image acquisition. The profile refers to scan along the line 1 corresponding to the same region indicated in the AFM image (see inset).

Fig. 1(c) and a stacked structure about 0.35 nm apart, as illustrated in the inset. This supports the expected structural organization of eumelanin, consisting of stacked layers of several DHI- and DHICA-based monomers self assembled forming the so called eumelanin 'protomolecule' [24]. A strong anisotropy in the conduction has been also found thus validating the model that the melanin structure can be considered similar to that of graphite-like materials [25]. In fact, the in plane layer dark conductivity at room temperature was of 10^{-7} $(\Omega\,\mathrm{cm})^{-1}$ in air and of 10^{-12} $(\Omega\,\mathrm{cm})^{-1}$ in vacuum respectively, while the transverse conductivity was found 10^{-15} $(\Omega\,\mathrm{cm})^{-1}$ in air and 10^{-19} $(\Omega\,\mathrm{cm})^{-1}$ in vacuum, respectively. It can be noted that the transverse conductivity has been found around height order of magnitude lower than the planar conductivity both in air and in vacuum. While both the in plane and transverse conductivity decrease of around four order of magnitude under vacuum.

Fig. 2(a.1) and (b.1) shows the hysteresis loop of the current–voltage (I vs V) characteristics on Au/eumelanin/ITO/glass structure in the voltage range (−1 V, 1 V) in air under dark only and at different voltage sweep speed (Fig. 2(a.1)) and the hysteresis behaviour which occurs in vacuum, under dark and white light illumination at a sweep rate of 9 mV/s (Fig. 2(b.1)). This because in air, no relevant modification on the hysteresis curves has been evidenced under white light irradiation. Similar hysteresis behaviour has been observed on several conjugated polymers [16–18].

The origin of the hysteresis loop lies in the presence of a displacement current I_d adding to the conductive part I_r and shifting upwards or downwards the I vs V characteristics. The $I_d = d(CV)/dt$ is due to both voltage variation ($C dV/dt$) and capacitance variation $V(dC/dt)$. The first contribution is typically due to voltage sweep speed (dV/dt)

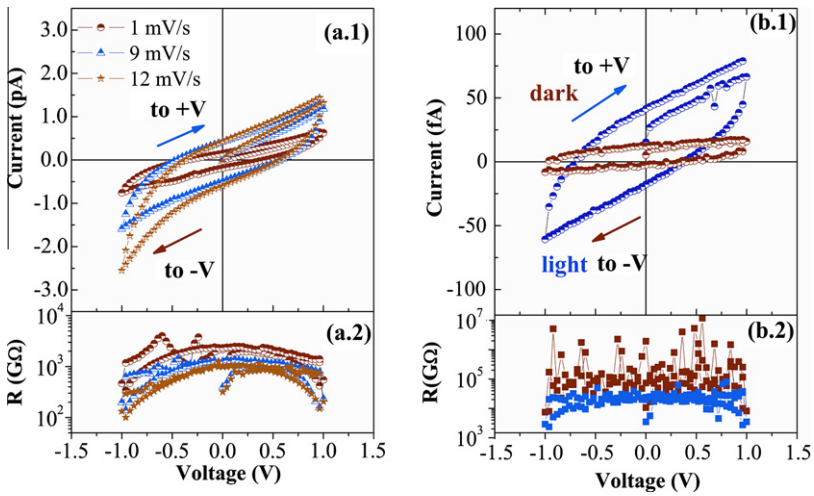

Fig. 2. (a.1) Hysteresis-type current–voltage (I vs V) characteristics collected in air of Au/eumelanin/ITO/glass structure at different voltage speed rate for 1 V loop amplitude at a voltage speed rate of 1 mV/s, 9 mV/s and 12 mV/s. (a.2) Corresponding semilog plot of $(dI/dV)^{-1} = R$ vs V. (b.1) Hysteresis-type current–voltage (I vs V) characteristics of Au/eumelanin/ITO/glass structure collected in vacuum under dark (red circles) and white light exposure ($P = 100$ mW/cm^2) (blue circles) at a voltage speed rate of 9 mV/s. The I vs V characteristics collected in vacuum have been magnified by a factor of 50 for sake of clarity. (b.2) Corresponding semilog plot of $(dI/dV)^{-1} = R$ vs V. The red and blue arrows show the reverse (towards negative voltages) and forward (towards positive voltages) voltage sweep direction. (For interpretation of color in this figure readers are referred to web version of this article.)

whereas the second one $V(dC/dt)$, is more or less enhanced by the hysteresis loop amplitude (i.e. voltage interval). The magnitude of these contributions determines the total value of the detected current.

In Fig. 2(a.1) the hysteresis curves in air show asymmetry and higher current values in the negative voltage bias region while in vacuum are rather symmetric, but with different V_{oc} values in the two voltage branches and I_{sc} values lower than in air. As for other metal/polymer interfaces the mechanisms generating the hysteresis behaviour in present case could be ascribed to the space charges accumulation at metal/polymer interface, screening the applied electric field and limiting further carrier injection in the eumelanin layer [16,24]. As a matter of fact the asymmetry observed in Fig. 2(a.1) indicates that the space charge accumulates mainly near one of the electrodes (Au or ITO) depending on carrier signs (electron or holes) which at this stage is still unknown. Also, one cannot exclude the presence of layer defect sites producing trapping centres, so that, the hysteresis behaviour could be due to trapping (i.e. charge reduction) or detrapping (charge release) mechanisms as well [18]. The amount of space charges or effectiveness of a trapping mechanism can both have a fundamental role in determining the hysteresis behaviour and conversely affect the possible device operation.

Under the hypothesis of stored charges, carriers injection occurs when increasing the applied voltage from 0 V to $+V_L$ and space charges accumulate at one of the eumelanin/electrode (Au or ITO) and then spatially distributed in the structure [16]. By reversing the voltage sweep (from positive voltage to 0 V) the device retains its charges with no further carriers injection due to screening effect, so that, the device current decreases. During the reverse sweep and at a certain value of the applied voltage (called open circuit voltage $V_{oc}(+)$) a balance establishes between the external and the electric field due to space charge and a zero current is detected. At zero voltage a non zero current is observed (short circuit current $I_{sc}(-)$) representing the flowing back of the stored charges through the external circuit. In a similar way, charge storage occurs when the voltage is swept from 0 V to negative voltage and in the subsequent forward sweep direction (i.e from negative to 0 V) an open circuit voltage ($V_{oc}(-)$) and short circuit current ($I_{sc}(+)$) are again observed. The magnitude of I_{sc} and V_{oc} in both sweep directions depends on the amount of stored charges at electrode/polymer interface and may differ in the two hysteresis branches due to the different electrodes (Au and ITO) work functions [16].

Hysteresis curves can be also the effect of carrier trapping/detrapping mechanisms within the organic layer [17,18]. A hint of the presence of such a mechanism is the dependence of the hysteresis curve from the voltage sweep speed [17]. But, mostly to discriminate between the prevalence of this mechanism or space charge accumulation, an useful method is the analysis of the oscillation in the resistance vs voltage $R(V)$ characteristics (where $R = (dI/dV)^{-1}$) [18]. These oscillations have been observed on several materials, from layered to structure embedding nanoclusters and have been ascribed to discrete (single electron for example) carrier transport or trapping and emission of carriers [25,26].

The hysteresis loop parameters (i.e. $V_{oc}(+)$, $V_{oc}(-)$, $I_{sc}(+)$, $I_{sc}(-)$, loop area A_L) extracted from in air *I vs V* of Fig. 2(a.1) have been summarized in Table 1. Also the parameters observed by performing the *I* vs *V* in air at the same sweep speed (9 mV/s) and for different V_L values (*I vs V* loops not shown) have been reported. Moreover, the V_{oc} values have been found in the range of those observed on other conjugated polymers [16,18]. Respect to what has been assumed and observed elsewhere, the loop area shrinks at low speed rate evidencing that the current component depending on voltage sweep speed also contributes to the displacement current [17,19]. However, loop parameters values are only slightly dependent on the sweep rate and, apart $I_{sc}(-)$, they saturate when increasing the voltage sweep speed. Conversely, when maintaining the same voltage sweep speed (9 mV/s) a general linear increase of all loop parameters has been observed for increasing values of V_L.

The loop parameters extracted from the dark *I vs V* collected under vacuum ($p = 1 \times 10^{-5}$ mbar, see Table 1) shows values of V_{oc} higher than those collected under light exposure. Interestingly, *I vs V* collected under white light illumination proves a detectable increase of the loop area (about four times of those collected under dark), together with higher values of the I_{sc} in both voltage sweep direction and lower values of the V_{oc}. The large enlargement of the hysteresis curve areas indicates the presence of a displacement current adding to that measured under dark together with a DC photocurrent effect producing the rotation of the hysteresis axis. This conversely explains also the observed V_{oc} values lower than those seen under dark.

Table 1
Open circuit voltage (V_{oc}), short circuit current (I_{sc}), and loop area (A_L) values extracted from the hysteresis loops collected: (a) in air, at different voltage sweep speeds and 1 V loop amplitude; (b) in air, at a voltage sweep speed of 9 mV/s and different loop amplitudes; (c) in vacuum under dark and white light irradiation at a voltage sweep speed of 9 mV/s and 1 V loop amplitude.

Voltage sweep speed (mV/s)	Measurements conditions	$V_{oc}(+)$ (V)	$V_{oc}(-)$ (V)	$I_{sc}(+)$ (pA)	$I_{sc}(-)$ (pA)	A_L (10^{-12} a.u.)
1	Air/dark	0.41	−0.35	0.15	−0.19	0.88
9	Air/dark	0.56	−0.46	0.42	−0.49	2.16
12	Air/dark	0.55	−0.39	0.40	−0.61	2.43
Voltage loop amplitude V_L						
(−1 V, 1 V)	Air/dark	0.56	−0.46	0.42	−0.49	2.16
(−2 V, 2 V)	Air/dark	1.00	−0.92	1.27	−1.02	15.0
(−3 V, 3 V)	Air/dark	1.47	−1.50	3.83	−1.27	50.7
(−1 V, 1 V)	Vacuum/dark	0.44	−0.98	1.2×10^{-2}	-2.3×10^{-3}	3.8×10^{-2}
(−1 V, 1 V)	Vacuum/light	0.36	−0.78	1.8×10^{-2}	-4.2×10^{-2}	1.5×10^{-1}

As stated above two principal mechanisms can be responsible for hysteresis behaviour: space charge storage and/or trapping/detrapping mechanisms at organic layer defect sites that can be discriminate by the presence/absence of conductivity oscillation when representing the $R = (dI/dV)^{-1}$. The $R(V)$ characteristics shown in Fig. 2(a.2) and (b.2) clearly indicate that under dark carrier flow due to trapped/detrapped charges at layer defect sites is detectable in vacuum while in air space charges are mostly stored at the Au/ or ITO/eumelanin interface, although with a different density. In air, this has been furthermore observed also when changing the voltage sweep speed. In vacuum and under white light exposure, although a certain amount of detrapped charges can be also released, the large enhancement of the loop area (about a factor of four) and absence of (or not detectable) trapping/detrapping mechanisms (see Fig. 2(b.2)) indicates that space charge storage is still the predominant mechanism. In order to explain the predominant space charge effect in air and discrete charge trapping/detrapping mechanisms in vacuum we refer to the dependence of melanin transport properties on hydration states. As state before, the water weakly bonded to carboxy, hydroxyl and amino groups can be responsible of a continuous distribution of trap across the layer and promote the charge injection from the contact inside the melanin layer. In vacuum, these traps are removed and only a discrete trap distribution is expected so that trapping/detrapping mechanisms are present explaining the conductivity oscillation behaviour.

Eumelanin memory capabilities have been verified by preliminary tests. Fig. 3(a) shows that a writing stage occurs at a voltage of −3.7 V and −2.8 V in air and vacuum respectively; however, no erasing voltage has been till now clearly identified. The current on/off ratio has been found of around 100 in both cases and consistent with similar ones observed in other organic polymers [27]. The charge storage effect under white light has been evidenced by the reduction of the photocurrent collected under consecutive light pulse switches (Fig. 3(c)). This because during the first light pulse the photo-generated space charges are stored in the eumelanin layer; during the second light pulse the space charges oppose to the further photo-carrier injection resulting in a decrease of the detected photocurrent.

In conclusion, this work represents a first experimental insight into the electrical transport in Au/eumelanin/ITO/glass structure. The good optical quality and staking of eumelanin layers have been evidenced by optical absorption spectra and AFM characterization. The hysteresis loops when performing I vs V measurements suggest that space charges are retained in the layer and the charge storage is the predominant mechanism in air and in vacuum also under white light irradiation whereas trapping/detrapping generates the loop in vacuum. More experiments are in progress aiming to better clarify first the nature of the majority carriers (holes or electrons) and the characteristics of memory effect under voltage or light pulses and possible erasing procedure. At this stage, the

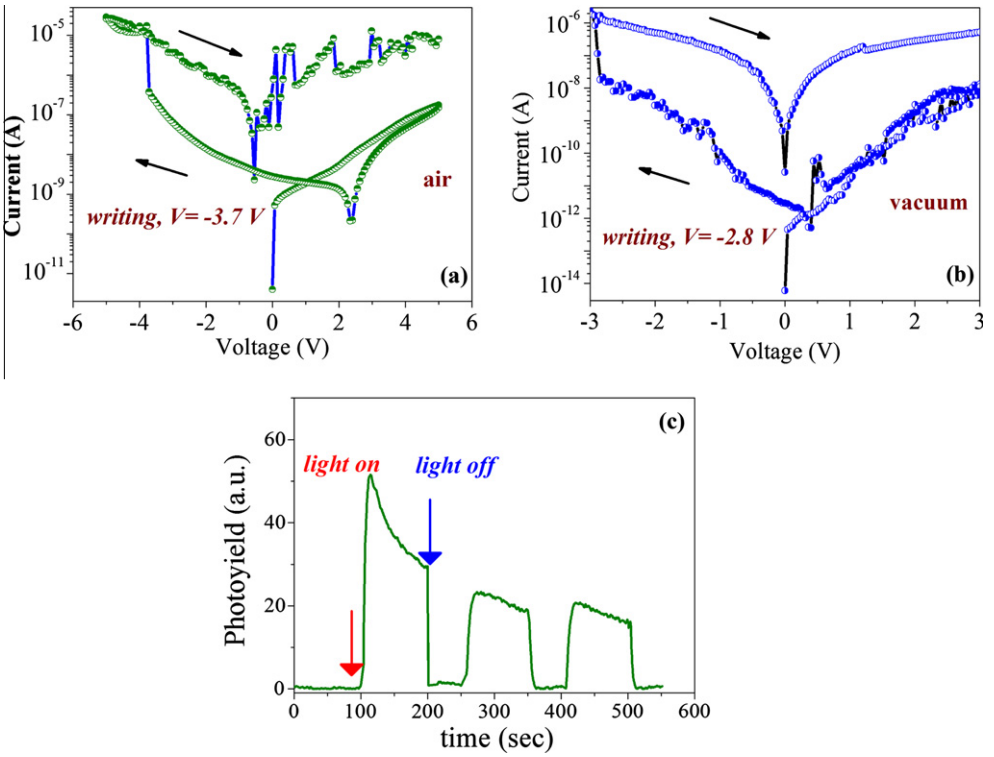

Fig. 3. (a) I vs V characteristics collected in air on Au/eumelanin/ITO/glass structure showing a writing state at −3.7 V. (b) I vs V characteristics collected in vacuum on Au/eumelanin/ITO/glass structure showing a writing state at −2.8 V. The arrows indicate the voltage sweep direction. (c) Transient photoresponse (Y vs t) determined under consecutive white light pulse switches. The light pulses duration and delay between consecutive light switching was of 60 s.

above results aim to foresee a possible of integration of eumelanin layer in voltage or light sensitive memory devices in a fashion similar to conjugated polymer or molecular materials layers.

Low temperature process

ABSTRACT

The present work demonstrates organic circuits on a new class of substrate, silicone elastomers. The fabrication method relies on dry, additive processes performed at ultra-low substrate temperature (<100 °C). P-type pentacene and n-type C_{60} organic thin-film transistors (TFTs) in a bottom gate, top contact architecture are prepared directly on polydimethylsiloxane (PDMS) membranes without any surface pre-treatment. Simple logic elements including complementary inverters and ambipolar transistors patterned on PDMS perform similarly to their counterparts fabricated on substrates thousands times stiffer. The processing options and mechanical compliance of the elastomeric substrate combined with organic device materials open new opportunities for compliant, lightweight, low-power and large area thin-film circuitry.

1. Introduction

Organic materials have been successfully employed for CMOS-circuitry [1]. Their applications stand in circuits of low complexity such as RF ID tags [2] or in active matrices for displays [3] and electronic skins [4]. Complementary organic electronics have been reported on silicon, polyimide or polyethylene naphtalate (PEN) substrates [5,6]. Non-volatile memories and non-volatile memory transistors for flexible sensor arrays have recently been demonstrated by Sekitani [7,8].

To date, polydimethylsiloxane (PDMS) elastomers are mainly used in microfabricated devices for microfluidics, sensors, MEMS and biomedical applications [9–13]. Their implementation as substrates for microelectronics is a recent evolution. When integrated circuits, first manufactured on and cut into small silicon [14] or plastic [15] platforms, are transferred onto an elastomeric wiring board, the electronic circuit becomes mechanically compliant and even stretchable. The results provide unique electronic systems, which can integrate clothes [16], conform spherical surfaces [14] and more recently organs [17]. Several strategies for elastic interconnects have been developed and patterned directly onto the elastomeric substrates [14,18–21]. We now propose to also fabricate the electronic circuits directly onto PDMS employing organic small molecules semiconductors. The device process flow is straightforward [22] and compatible with organic thin-film electronics manufacturing.

2. Experimental

PDMS substrates of 1 mm thickness are prepared by casting polydimethylsiloxane (PDMS, Sylgard 184, Dow Corning) in a 10:1 mixing ratio into Petri dishes and curing at 65 °C for 24 h. Alternatively 1 mm thick PDMS membranes (Speciality Manufacturing Inc., MI, USA) are leached for 48 h in isopropanol alcohol followed by blow-drying with nitrogen. A bilayer of 5 nm/50 nm thick Chromium/Gold films is thermally evaporated (rate ~0.1 Å/s) to form the transistor bottom gate electrode. The gate dielectric is formed by vapour deposition of 600 nm thick poly-para-xylylene (Parylene C) film with a capacitance of 4.6 μF/cm^2 using a Labcoater 2010 (Speciality Coating Systems, UK). Organic semiconductor films of 50 nm

pentacene (Sigma Aldrich, 98% purity) (p-type) and C_{60} (MER Corp., 99% purity) (n-type) respectively are evaporated with a rate of $r = 0.4$ Å/s, followed by 30 nm of gold to form the source and drain electrodes for the top contacts. Pentacene and C_{60} TFTs have identical channels with $W/L = 3000\ \mu m/200\ \mu m = 15$. Complementary organic inverters are further prepared by patterning adjacent p-type and n-type transistor channels. Fig. 1a presents 18 complementary inverters on a transparent 1 mm thick PDMS substrate. Each pair of TFTs shares a common 1 mm gate electrode. The n-type and p-type devices are clearly distinguished from their resulting multilayer colour (Fig. 1b). Fig. 1c shows the schematic view of the inverter. For ambipolar TFTs, the semiconductor layer is formed by evaporating a 50 nm thick pentacene film on a 50 nm thick C_{60} film (C_{60}/pentacene device) or vice versa (pentacene/C_{60} device). Channel dimensions for ambipolar TFTs are $W/L = 3000\ \mu m/150\ \mu m = 20$. Electrodes and the semiconductor layer are patterned through stainless steel shadow masks; the gate dielectric deposited through a PDMS shadow mask. The devices are not annealed.

AFM micrographs of the topography of the thin films on PDMS are obtained using a Pico Plus AFM system (Molecular Imaging) and an NSC36noAl cantilever (MikroMasch) with a 1.75 N/m force constant.

TFTs and inverter circuits are characterised in a nitrogen environment using an HP4155 semiconductor parameter analyser.

3. Results and discussion

Fig. 2 summarizes the electrical response of n-type, p-type TFTs and complementary inverters on PDMS. The transfer and I(V) characteristics of a p-channel pentacene TFT on PDMS are shown in Fig. 2a and b. The TFT channel is 3000 μm wide and 200 μm long ($W/L = 15$). The off state current is below 5 nA and the on/off ratio is 10^4 for $V_{GS} \cdot \varepsilon \cdot [-60\ V;\ 10\ V]$. Low leakage gate current is maintained during linear and saturation TFT operation with $I_{GS} < 1$ nA. The threshold voltage is −4 V, and carrier mobility in the saturation regime is 0.16 cm^2/V s. Symmetric results are obtained for the n-type C_{60} TFT on PDMS (Fig. 2c and d) with equal channel dimensions ($W/L = 15$). Saturation electron mobility and threshold voltage are measured to be 0.16 cm^2/V.s and 12 V, respectively. On current at $V_{DS} = 60$ V is 10 μA. Both n-type and p-type TFTs show negligible hysteresis suggesting good gate stability.

C_{60} and pentacene TFTs are then integrated into complementary inverters (Fig. 1). Fig. 2e shows the transfer curves of an inverter with equally sized n- and p-type channels ($W/L = 3000\ \mu m/200\ \mu m$) and for supply voltages V_{DD} of 40, 50 and 60 V. The gate is common to both transistors and is the circuit input node V_{in}. The circuit exhibits sharp switching at nearly $V_{DD}/2$. In the off state ($V_{in} = 0$ V), V_{out} matches V_{DD}. Voltage gains as high as 21 are recorded from the inverter. This confirms that both transistors have matching performance (Fig. 2f).

Small tensile flexion (bending radius of 6.5 cm) is then applied to the inverters on PDMS. The circuits remain functional inverters after one bending cycle but their performance degrades quickly with further bending. This is expected because the TFT stack is sitting on top of the PDMS membrane without any encapsulation, i.e. away from the mechanical neutral plane, where the tensile strain is about one percent [23].

Ambipolar transistors and inverters based on heterojunctions of pentacene/C_{60} or C_{60}/pentacene semiconductor films are prepared as an alternative to complementary TFT inverters. Fig. 3a and d show the transfer characteristics for transistors with pentacene/C_{60} or C_{60}/pentacene semiconductor channels for V_{DS} at 10 V and 60 V. Their channel is 3000 μm wide and 150 μm long ($W/L = 20$). Both devices exhibit a typical ambipolar response with V-shaped transfer curves. On currents for both device configurations are in the micro ampere range, and gate leakage currents are below 10 nA. In the electron accumulation mode, the pentacene/C_{60} device has a threshold voltage $V_{Th,n}$ of 40 V and yields a saturation electron mobility of 0.12 cm^2/V.s, close to that of the C_{60} TFT (Fig. 2c). In the hole accumulation mode, the device's threshold voltage $V_{Th,p}$ is −30 V and the corresponding hole mobility is low, 3×10^{-2} cm^2/V.s. The C_{60}/pentacene transistor presents poorer performance with electron mobility of 0.02 cm^2/V s and $V_{Th,n} = 12$ V, and hole mobility of $\sim 6.5 \times 10^{-3}$ cm^2/V s and $V_{Th,p} = -40$ V.

The obtained mobilities for either of our ambipolar device configurations are higher than those reported for similar devices fabricated on Si/SiO_2 or Mylar substrates

(c) Transfer and (d) output curves for a C_{60} TFT on PDMS with similar but opposite V_{DS} and V_{GS}. (e) Transfer characteristics of a pentacene and C_{60} complementary inverter for V_{DD} = 40, 50, 60 V and (f) corresponding inverter gain.

[24,25]. Clearly, the semiconductor stack construction, C_{60} on pentacene or vice versa, affects the resulting carrier mobilities and overall device performance. Several studies have reported on the electronic structures on the pentacene/C_{60} interfaces [26,27]. In particular, Kang et al. have measured the HOMO and LUMO offsets at the pentacene/C_{60} interface as a function of the stack preparation (pentacene on C_{60} versus C_{60} on pentacene) and showed the offsets are minimal when C_{60} is deposited on pentacene films [27]. This may therefore result in better carrier injection in the pentacene/C_{60} device and higher mobilities than in the pentacene/C_{60} device. Further investigation of the electronic properties of the pentacene/fullerene interfaces grown on parylene on PDMS will help analysing the electrical performance of the devices.

Complementary inverters are prepared using two identical ambipolar transistors where the common gate is the input voltage. Channels' geometry is $W/L = 20$. Typical transfer curves of pentacene/C_{60} or C_{60}/pentacene ambipolar inverters are shown Fig. 3b, c, e and f. The pentacene/C_{60} device performs well. In the first quadrant, a voltage gain of up to 20 is measured for V_{DD} = 60 V. Negligible hysteresis is observed. In the third quadrant, the hysteresis is more pronounced and probably indicates charge trapping at the parylene/pentacene interface. Nevertheless, the ambipolar inverter has a gain of 20 for $V_{DD} = -60$ V. The C_{60}/pentacene ambipolar inverter also presents reliable switching in the first and third quadrants. High inverter gains are measured (gain ~25 for $V_D = 60$ V). However the threshold voltages in both quadrants are low, much lower than half of V_{DD}, possibly due to the poor and unbalanced hole and electronic mobilities. In both ambipolar inverter configurations, low V_{out} never reaches 0 V when V_{in} is high. This is explained by the fact that the individual ambipolar devices never fully turn off (as shown Fig. 3a and d).

The morphology of each layer of the devices' stack was analysed using scanning electron (SEM) and atomic force microscopies (AFM). Fig. 4a shows an SEM image of the gold gate electrode on PDMS. The film has a complex topography where gold ligaments are separated by short, micro-scale cracks [28]. A 9 μm × 9μm scan is recorded on each layer of the TFT stack. Representative AFM micrographs are presented in Fig. 4b. Overall the topography of the thin films deposited on PDMS is complex and rough. The as-prepared PDMS surface is smooth with an RMS roughness of 5 nm (Fig. 4b-i).

After deposition of the gate electrode (Fig. 4b-ii), the RMS roughness increases to 16 nm as a result of the built-in micro-crack network in the gold film on PDMS

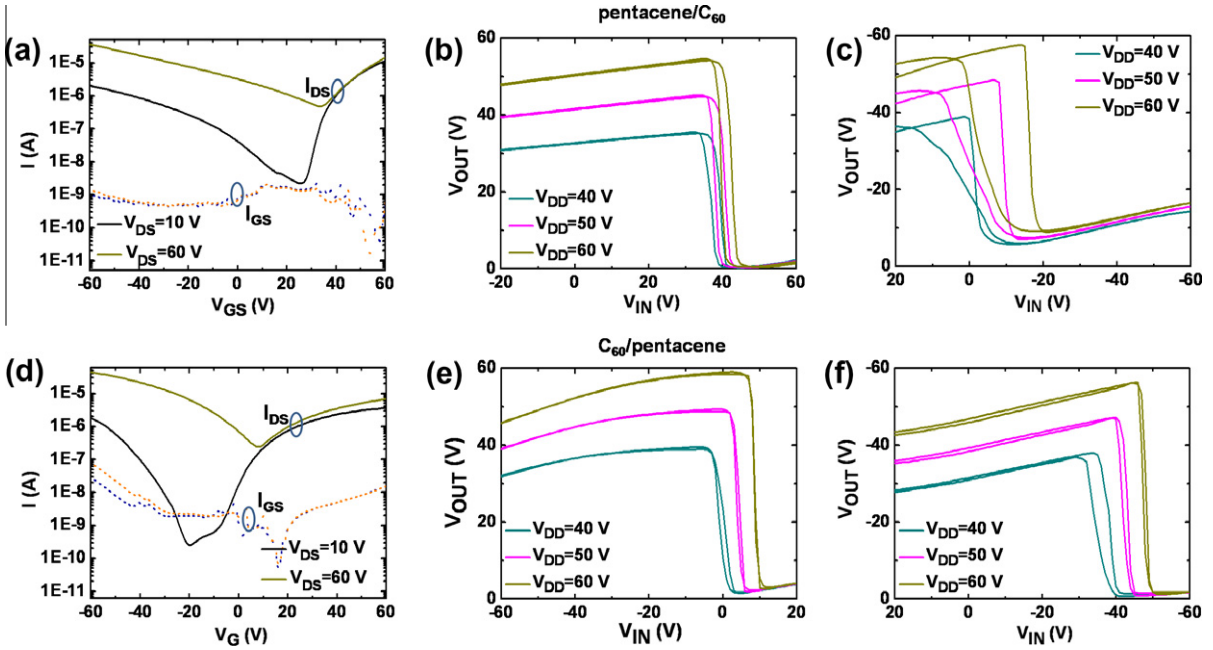

Fig. 3. (a) Transfer characteristics of an ambipolar pentacene/C_{60} TFT on PDMS; V_{DS} is 10 V and 60 V. (b) First and (c) third quadrants $I(V)$ curves of a pentacene/C_{60} inverter on PDMS; V. (d) Transfer characteristics of the ambipolar C_{60}/pentacene TFT; V_{DS} is −10 V and −60 V. (e) First and (f) third quadrants I(V) curves of a C_{60}/pentacene inverter on PDMS. V_{DD} is 40 V, 50 V and 60 V for all transfer characteristics.

(Fig. 4a). AFM micrographs (Fig. 4b-iii) and (Fig. 4b-iv) show that the parylene film grows differently on the bare PDMS substrate than on the gate gold electrode. On PDMS, the parylene forms a smooth coating with an RMS roughness of 12 nm and features or grains of 100 nm diameter and 5 nm height. On the microstructured gold film, the parylene appears very rough with a resulting RMS roughness of 16.2 nm and raised features as tall as 100 nm are observed. Metallic surfaces, including gold, inhibit parylene deposition [29,30]. Vaeth et al. reports that the resulting polymer film grows into large and sparse grains rather than small and uniformly distributed grains, thereby leading to films with high roughness [30]. Parylene growth inhibition combined with the initially micro-cracked gold film on PDMS lead to a gate dielectric surface with a chaotic and rugged topography showing features of 0.5–1 μm width and 20–100 nm height. The roughness of the parylene film is therefore significantly higher than that of typical polymer dielectrics with RMS roughness between 0.2 nm and 2 nm [31]. As a result, the parylene's morphology sets that of the subsequently deposited films of pentacene (Fig. 4b-v) and C_{60} (Fig. 4b-vi). For pentacene, grains with 100–300 nm diameter superimposed onto a complex wavy topography are observed (Fig. 4b-v); the RMS roughness is 16.7 nm. For the C_{60} devices, no grain is clearly visible (Fig. 4b-vi) and the film RMS roughness is 17 nm. Finally, the source/drain metal film conforms the semiconductor surface (RMS roughness = 18.9 nm, AFM micrograph not shown).

The channel surface of the ambipolar devices is shown Fig. 4b-vii and Fig. 4b-viii. Grains of 100–300 nm in diameter are observed in the C_{60} films grown on pentacene. Pentacene films grown on C_{60} exhibit significantly smaller grains with 50–100 nm in diameter. Surface RMS roughness is about 17 nm for both stacks of organic semiconductors. Further investigation on the structural and electrical properties of the semiconductor bi-layers is now required to explain the different electrical performance of the pentacene-on-C_{60} and C_{60}-on-pentacene devices.

4. Conclusion

In summary, we have demonstrated that complementary organic field-effect transistor circuits can be manufactured on ultra-compliant silicone substrate. Their process flow is straightforward and does not require extensive substrate or dielectric surface treatment or annealing to obtain devices with carrier nobilities in the 0.2 $cm^2/V\,s$ range. Only modest bending can be sustained by the devices on PDMS but various strategies including placing the device stack in the neutral plane of the structure or onto rigid platforms embedded in the silicone matrix, can be readily implemented to add flexibility and even stretchability to the organic CMOS-like circuits on PDMS.

The ability of depositing and patterning active device materials directly onto silicone elastomers is a promising and exciting opportunity for the fabrication of truly integrated circuits on elastomers. Our results clearly show that organic circuitry on elastomer is feasible and competitive with organic electronics on plastic. Thin-film circuitry on elastomer promises diverse and multiple applications in the fields of microfluidics, active matrices for sensory platforms and large-area electronics. With optimised mechanical design, TFT circuits on PDMS will become flexible and even fully elastic.

ABSTRACT

Polymer solar cells based on the polyfluorene copolymer poly[9,9-didecanefluorene-alt-(bis-thienylene) benzothiadiazole] (PF10TBT) and the fullerene derivative [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM) exhibit a power conversion efficiency of 4%. However, the optimum thickness of the photoactive layer is only 80 nm, such that these solar cells absorb only half of the photons available in their absorption bandwidth. Thicker cells are subject to electronic losses due to space charge effects and recombination. We demonstrate both from simulations and experiments that the optical and electronic losses can be decoupled in a double junction solar cell. For the PF10TBT:PCBM blend, the integration of two thin cells in a double junction device leads to an enhancement of the measured power conversion efficiency with 13% up to a value of 4.5%.

1. Introduction

The active layer of the most efficient polymer solar cells to date consists of a bulk heterojunction (BHJ) of a conjugated polymer with the buckminster fullerene derivative [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM). Such a bulk heterojunction is characterized by nanoscale intermixing of the electron donor and acceptor materials in order to maximize their cross-sectional area [1]. Compared to inorganic solar cells, thin film polymer devices produce high photovoltages. However, the power conversion efficiency is limited by a relatively low photocurrent as a result of a higher bandgap and narrower absorption bandwidth. Efforts to increase the efficiency are therefore primarily focused on the harvesting of more photons.

The most direct way to increase absorption is increasing the thickness of the photoactive layer. However, in many polymer:fullerene systems the combined effects of charge carrier recombination and the formation of space charge reduce the fill factor and consequently the overall device efficiency of thick cells [2]. In a BHJ solar cell the reflective back electrode introduces optical interference effects inside the photoactive layer between incoming and reflected light [3]. Therefore, it has been suggested that the photocurrent can be increased by introducing an optical spacer that enhances light absorption in thin polymer solar cells by redistributing the optical electric field [4,5]. However, the spacer effect is only beneficial if the BHJ film thickness does not coincide with a local maximum of optical power dissipation [6].

Alternatively, the optical properties of the photoactive materials can be tuned. Promising results have been reported for solar cells in which narrow bandgap polymers were introduced in order to absorb low-energy photons [7–9]. The electron-accepting material can be modified as well: substitution of PCBM with its more strongly absorbing C_{70}-analogue generally results in a larger contribution to the photocurrent [10]. A further improvement of the spectral coverage of the solar irradiance spectrum can be realized by incorporation of multiple heterojunctions with complementary absorption spectra in a tandem solar cell [11–13].

In this paper we present an alternative approach to improve the performance of thin film polymer photovoltaics. As a model system we use polymer solar cells based on the

polyfluorene copolymer poly[9,9-didecanefluorene-alt-(bis-thienylene) benzothiadiazole] (PF10TBT) and PCBM with a power conversion efficiency of 4%. An efficiency increase of 13% is realized by combining two optimized PF10TBT:PCBM solar cells in one double junction device, without any change to the constituents of the photoactive layer. The approach concurrently utilizes the enhanced absorption of thick films and the superior electronic performance of thin films.

2. Experimental

2.1. Device fabrication

ITO patterned glass substrates were thoroughly cleaned with soap water, acetone, propanol and a UV ozone treatment before application of a layer of PEDOT:PSS (Clevios VP AI4083 SG, H.C. Starck). PF10TBT (TNO, M_w = 1.9 $\times$ 10^5 g/mol, PDI = 3.5) and PCBM (Solenne) were used as received. Photoactive layers were spin coated under ambient conditions from hot (90 °C) chlorobenzene solutions of PF10TBT:PCBM in a 1:4 weight ratio and capped with a 1 nm LiF/100 nm Al cathode. For the middle electrode of double junction devices, ZnO nanoparticles with a diameter of 5–10 nm were synthesized in methanol via hydrolysis and condensation of zinc acetate dihydrate by KOH, as described elsewhere [14,15]. After centrifugation, the ZnO gels were dispersed in acetone [16], followed by sonication and filtration. The acidity of PEDOT:PSS (Clevios PH500, H.C. Starck) was tuned by addition of a 1:8 dilution of 2-dimethylaminoethanol in water [17]. Nafion perfluorinated resin solution (5 wt% in a mixture of lower aliphatic alcohols and water, Aldrich) was diluted 1:20 with ethanol before spin coating at high rpm on top of pH-modified PEDOT:PSS layers in a nitrogen-flushed compartment under ambient atmosphere.

2.2. Characterization

Current–voltage characteristics were recorded with a Keithley 2400 SourceMeter. The results of Fig. 1 were recorded under illumination from a Steuernagel SolarConstant 1200, producing white light with an intensity of 1.3 kW/m^2. The light intensity was determined by (a) comparison of the measured J_{sc} with the expected short-circuit current density as calculated from the convolution of the spectral responsivity curve with the AM1.5 global reference spectrum, taking into account the linear dependence of J_{sc} on light intensity and (b) the deviation of the setpoint of a multicrystalline silicon reference cell from the value determined using accurate mismatch correction [18]. The same lamp was used for the measurements of Fig. 6, using spectral mismatch correction (M = 1.40) and a GG385 filter, resulting in a light intensity equivalent to 0.9 sun. Contributions to the photocurrent from regions outside the anode/cathode overlap area were eliminated using illumination masks with slightly smaller apertures. Incident photon to current conversion efficiency (IPCE) spectra were measured from 400 to 1100 nm using a custom-built setup comprising a 50 W quartz tungsten halogen lamp, 28 narrow band-pass interference filters, a transimpedance amplifier and a lock-in amplifier. The spectral response was measured relative to that of a calibrated monocrystal-

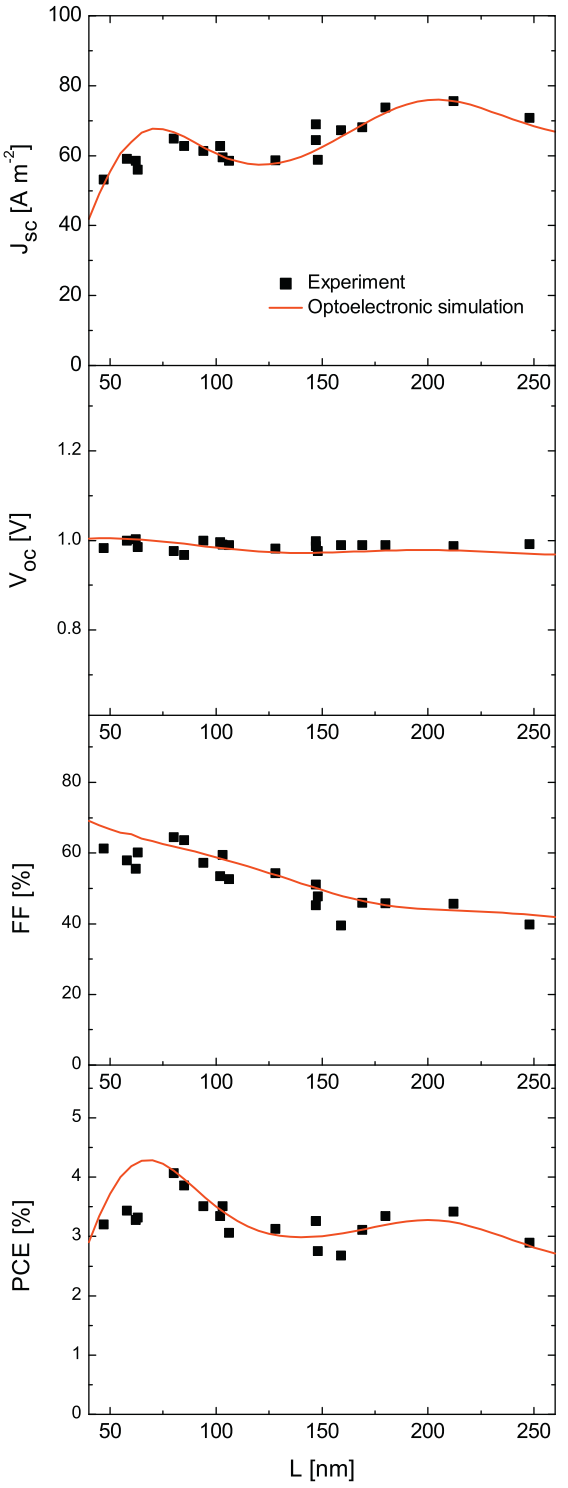

Fig. 1. Squares: experimental photovoltaic data of PF10TBT:PCBM solar cells with varying active layer thickness. The lines denote the result of the combined optoelectronic simulation.

line silicon photodiode (Newport 818-SL). Layer thickness measurements were done with a Veeco Dektak 6 M or 150 profilometer. Optical absorbance was measured with a Perkin–Elmer Lambda 900 spectrophotometer.

3. Results and discussion

3.1. Single junction solar cells

The efficiency of PF10TBT:PCBM solar cells is known to increase with the molecular weight of the polymer. This is caused by a reduced recombination rate of bound electron–hole pairs at high molecular weights, which leads to more efficient generation of free charges [19]. Therefore, the solar cells studied here are based on bulk heterojunctions of PCBM and high molecular weight PF10TBT. The donor/acceptor weight ratio was fixed to the optimum of 1:4 and all devices were processed from hot chlorobenzene solutions.

The variation of the short-circuit current density J_{sc}, open-circuit voltage V_{oc}, fill factor FF and power conversion efficiency PCE with photoactive layer thickness L is displayed in Fig. 1. Each data point (squares) represents the average of three or more current density–voltage (J–V) measurements. The values of J_{sc} and PCE were corrected for spectral mismatch of the lamp with the solar spectrum (see Section 2.2). Noticeable is the oscillatory behavior of J_{sc}, characterized by maxima at L = 80 nm and L = 210 nm. Thicker cells clearly absorb more light as J_{sc} is highest for L > 150 nm. However, since the open-circuit voltage is virtually independent of layer thickness and the fill factor strongly decreases with increasing L, the overall experimental PCE reaches its highest value of 4.0% already at L = 80 nm.

Next, we use combined optoelectronic modeling to gain insight in the major limitations of PF10TBT:PCBM solar cells of varying thickness. In order to describe the experimental results, we use an optical model based on the transfer matrix formalism in combination with a numerical electronic device model [20].

3.1.1. Optical simulations

Most conjugated polymers exhibit strong absorption with a high peak absorption coefficient [21]. As a result, layers as thin as several hundreds of nanometers can effectively absorb most solar photons with energy higher than the bandgap of the polymer. Since the wavelength of the incoming light is of a similar length scale and the back electrode in polymer solar cells is usually highly reflective, optical interference effects have to be taken into account in the description of the photocurrent of such devices [3].

As input for the optical model, the index of refraction n, extinction coefficient k and thickness of each layer in the device architecture are used. The optical constants were determined previously using variable-angle spectroscopic ellipsometry [19]. The light intensity $I(\lambda,x)$ is calculated for each wavelength and position inside the entire layer stack, taking into account the optical properties of each layer as well as the interference of light that is incident on the device (AM1.5G, 1000 W/m^2) with light that is reflected by the back electrode. The exciton generation rate at each position in the polymer:fullerene layer is given by the convolution of the local spectral photon flux and the absorption spectrum of the active layer [20]. In the calculation the relevant wavelength range is discretized at exponentially equidistant values λ_i and the integral is consequently replaced by a summation:

$$G(x) = \sum_i \frac{4\pi k(\lambda_i)}{hc} I(\lambda_i, x)\Delta\lambda_i \quad (1)$$

where $G(x)$ is the exciton generation rate at position x, h is Planck's constant, c is the speed of light and $I(\lambda_i,x)$ is the light intensity at wavelength λ_i and position x. The exciton generation profiles $G(x)$ are used below as an input for the electronic device model. A final integration of $G(x)$ over the position in the device gives the total generation rate G_{tot} of excitons inside the photoactive layer.

By definition, the amount of absorbed photons is equal to the amount of photogenerated excitons G_{tot}. For the AM1.5G reference spectrum, the number of *incident* photons with wavelengths within the effective absorption bandwidth of PF10TBT:PCBM layers, i.e., 300 < λ < 650 nm, is $N_{ph} = 1.05 \times 10^{21}$ m^{-2} s^{-1}. A measure of the absorption efficiency is now given by the ratio of G_{tot} to N_{ph}, which is plotted versus layer thickness in Fig. 2 (solid line). At L = 80 nm, which is the point of the first maximum of the experimental J_{sc}, only 48% of the available photons are absorbed. Poor light absorption thus strongly limits the current these thin PF10TBT:PCBM solar cells can produce. As expected, this conclusion is not altered by the introduction of an optical spacer in the form of a thin ZnO layer between the active layer and the cathode, since the incoupling of light is already optimal, giving a local maximum of the dissipated optical power at L = 80 nm. At the other local maximum of the experimental short-circuit current density, L = 210 nm, two-thirds of the available photons are absorbed. This shows that the available light can be used more efficiently in order to increase cell performance, without reducing the bandgap of the polymer.

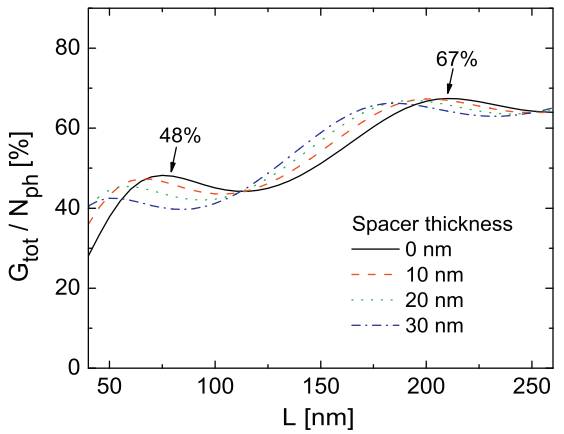

Fig. 2. Ratio of photogenerated excitons G_{tot} to the amount of photons N_{ph} with wavelength between 300 and 650 nm as a function of layer thickness. The lines denote different optical spacer thicknesses as indicated in the legend.

3.1.2. Electronic simulations

In polymer:fullerene solar cells, photogeneration of excitons is followed by diffusion of the excitons towards a donor–acceptor interface, charge transfer at the interface, dissociation of the resulting bound electron–hole (e–h) pair and charge carrier transport to and extraction at separate electrodes. Each of these processes generally introduces electrical losses that reduce the amount of extracted charges. The cumulative effect of these losses at short-circuit conditions is represented in the internal quantum efficiency, defined as the number of electrons in an external circuit per absorbed photon, or IQE = J_{sc}/qG_{tot}, where q is the elementary charge. The IQE can thus directly be determined from the measured J_{sc} (Fig. 1) and calculated G_{tot} (Fig. 2). In Fig. 3, the resulting IQE is plotted versus photoactive layer thickness. Approximately 80% of the absorbed photons contribute to the photocurrent in thin cells. For thicker layers this fraction decreases monotonically to around 70%, which is in good agreement with previously reported results [22].

Next, the current–voltage characteristics are simulated for each L in the range of experimental layer thicknesses. Here we use our numerical device model that includes drift and diffusion of charge carriers, a temperature- and field-dependent generation rate of free carriers, bimolecular recombination and the effect of space charge on the electric field in the device [23]. Ultrafast electron transfer from the photoexcited polymer to PCBM is assumed to occur with unity quantum yield, i.e., each exciton generates a bound e–h pair at an interface of donor and acceptor molecules. The dissociation rate of bound pairs into free carriers is described by Onsager–Braun theory [24,25], using an initial e–h separation distance a with a Gaussian distribution in energy and a bound pair decay rate k_f to parameterize the dependence of the dissociation probability P on electric field and temperature. Recombination of free carriers is assumed to be of the Langevin type, with a recombination constant dominated by the slowest carrier [26], and results in a bound pair that can either dissociate again or decay to the ground state. Other relevant parameters are the electron and hole mobilities μ_e and μ_h, the spatially averaged relative dielectric constant ε_r and the effective energy gap E_{gap} between the highest occupied molecular orbital (HOMO) energy of the donor and the lowest unoccupied molecular orbital (LUMO) energy of the acceptor.

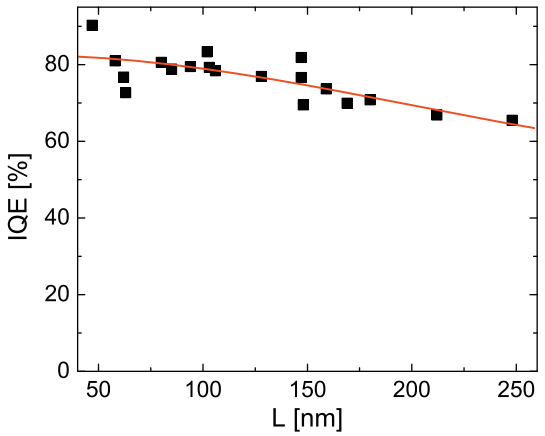

Fig. 3. The internal quantum efficiency IQE = J_{sc}/qG_{tot} versus photoactive layer thickness. The line serves as a guide to the eye.

The exciton generation profiles obtained by optical modeling are used as an input for the electronic model. The values that were used for the parameters in the electronic model are in excellent agreement with those previously derived for high molecular weight PF10TBT:PCBM cells [19] and are summarized in Table 1. In Fig. 1, the results of the optoelectronic simulations are depicted by the solid lines. Clearly, the oscillations of the short-circuit current density and power conversion efficiency with thickness are reproduced, as well as the strongly decreasing fill factor. The simulations indicate an optimal thickness of around 70 nm, which is close to the experimental value of 80 nm. The ratio of the amount of excitons that are lost due to quenching at the electrodes to the total amount of photogenerated excitons is large in very thin cells. As this quenching effect is not incorporated in the model, the calculations slightly overestimate the fill factor and short-circuit current in thin cells and, consequently, the predicted value of the maximum PCE of 4.3% is somewhat higher than the optimal experimental value.

Based on the optical simulations of Section 3.1.1, a relative increase of 40% in J_{sc} would be expected for a 210 nm thick cell compared to the 80 nm thick device. As can be seen in Fig. 1, enhanced absorption in thicker cells does indeed enable the extraction of a higher current. However, limited by the combined effects of space charge and recombination, the short-circuit current at L = 210 nm is only 16% higher than that at L = 80 nm. The same limitation causes the fill factor to drop considerably, resulting in a reduction of the PCE to 3.2%.

This clearly demonstrates that the increased absorption in thick cells is opposed by less favorable electronic properties. As a result the processing window for optimized solar cells is limited to thin layers. In the following section, the interlocking of optics and electronics is reduced by using double junction solar cells consisting of two optimized thin layer devices.

3.2. Double junction solar cells

Multijunction solar cells are generally used to compensate for the relatively narrow absorption bandwidth of conjugated polymers. By inclusion of a second bulk heterojunction with a lower optical bandgap, photon harvesting

Table 1
Overview of the model parameters used in the simulations.

Parameter	Symbol	Value
Bandgap	E_{gap}	1.37 eV
Electron mobility	μ_e	1×10^{-7} m^2 V^{-1} s^{-1}
Hole mobility	μ_h	6×10^{-9} m^2 V^{-1} s^{-1}
Effective density of states	N_c	2.5×10^{25} m^{-3}
Relative dielectric constant	ε_r	3.6
Initial e–h pair distance	a	2.2 nm
e–h Pair decay rate	k_f	5×10^5 s^{-1}

can be extended from the visible towards the near infrared. However, as discussed above, thin solar cells based on high bandgap materials fail to absorb a lot of photons with sufficient energy. In this section we therefore choose to investigate the possibility to enhance absorption of these high energy photons.

The photovoltaic properties of a multijunction solar cell depend on the method of interconnection of the subcells. A polymer tandem cell containing two subcells in a parallel configuration is feasible and is generally capable of producing higher currents [27]. However, charges need to be extracted at the middle electrode, which should consequently be based on materials with high sheet conductivity, such as metals. So far this has been incompatible with processing from solution. A much more practical approach is the series-connected multijunction, in which an increase in the amount of absorbed photons is utilized to deliver a higher photovoltage rather than a high current. As conduction now mainly occurs perpendicular to the interface, less conductive materials such as conjugated polymers and metal oxides are suitable candidates for the interlayer as well.

Here, we employ a previously reported device architecture in which the two subcells are connected in series by a composite middle electrode of ZnO nanoparticles and pH-modified PEDOT:PSS [16]. For practical reasons, the thicknesses of these layers are fixed to 20 and 30 nm, respectively.

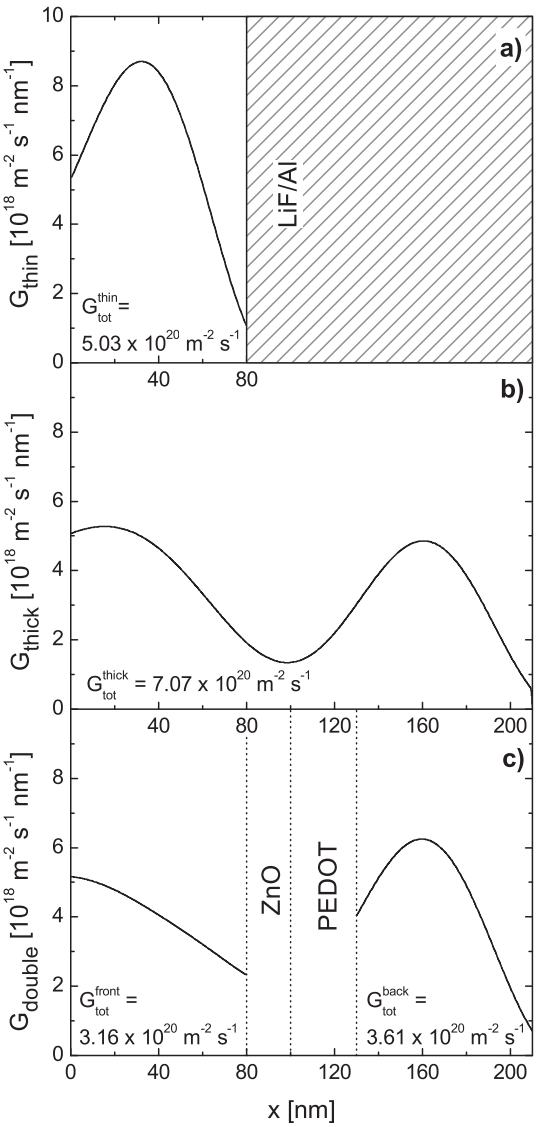

Fig. 4. Calculated exciton generation rate profiles plotted versus the position x in (a) a thin, (b) a thick and (c) a double junction solar cell. The total (integrated) exciton generation rate G_{tot} for each profile is indicated in the relevant figure panel.

3.2.1. Simulations

As a reference, we first take a step back to examine the exciton generation profiles of a thin and a thick device, as shown in Fig. 4a and b. Again we consider the layer thicknesses at the maxima of the experimental J_{sc} and PCE, i.e., L = 80 nm and L = 210 nm. Position x = 0 corresponds to the interface of PEDOT:PSS with the photoactive layer and the cathode is located at $x = L$. The light can thus be considered incident from the left side of the figure. As expected, both profiles show excellent incoupling of the incident light. Furthermore, as discussed above, the ratio of the total exciton generation rates amounts to $G_{tot}^{thick}/G_{tot}^{thin} = 1.40$, which means that the thick cell absorbs 40% more photons than the thin one.

In Fig. 4c, the exciton generation profiles inside the two subcells of a double junction device are plotted. As a one-to-one extension of the optimized single layer cell, the tandem device is chosen to incorporate two thin PF10TBT:PCBM cells of 80 nm thickness. These are separated by a ZnO cathode (20 nm) for the front cell and PEDOT:PSS anode (30 nm) for the back cell, which results in a

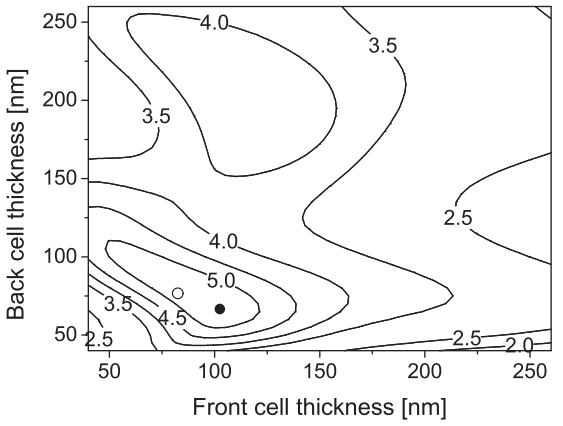

Fig. 5. Layer thickness dependence of the efficiency of a double junction device (labels) as predicted by combined optoelectronic simulations. For each combination of layer thicknesses, the exciton generation profiles inside the subcells were calculated and used as an input for our numerical device model. The J–V curves of tandem cells were constructed from the subcell characteristics [28]. The symbols indicate the optimal combination of subcell thicknesses (filled circle) and the case of two 80 nm thick subcells (open circle).

total device thickness of 210 nm. It can be seen that the shape of the generation profile in the back cell is similar to the one of the single thin layer because it is closest to the reflective cathode. As expected the magnitude of $G(x)$ in the back cell is lower than in the single layer thin cell due to optical interference effects and absorption in the front cell. However, *in total* the double junction absorbs more photons, in fact nearly as much (96%) as the 210 nm thick single layer device. In contrast, a single layer of 160 nm thickness absorbs only 81% of G_{tot}^{thick}. In other words, the double junction device absorbs more photons per nanometer of photoactive material than thick single layer cells due to the presence of the transparent middle electrode.

In order to predict the photovoltaic properties of the double junction device, we consider the general properties of a series-connected tandem cell. First, since each subcell is as thick as the thin single layer device and based on the same donor–acceptor system, it is reasoned that they will exhibit a similar IQE, FF and V_{oc}. Similarly, this also means that the FF of the double junction device will be the same as the FF of the subcells whereas its V_{oc} will be twice as large. Of the two subcells in the particular device considered in Fig. 4c, the front cell produces the least amount of excitons ($G_{tot}^{front} < G_{tot}^{back}$). As the IQE is invariant, this subcell will be current-limiting under short-circuit conditions and thus determine J_{sc} of the double junction device. Then, the ratio of the short-circuit current densities of the double junction cell and the thin, optimized single layer cell is close to $G_{tot}^{front}/G_{tot}^{thin} = 0.63$. It is thus predicted that a stack of two thin cells produces a J_{sc} that amounts to ca. 63% of the value for the single layer device. Combined with a doubled V_{oc} and an unchanged FF, an ideal double junction device is expected to have a 26% higher efficiency than the optimized single layer device.

The efficiency increase that is obtained with the use of a double junction structure can be enlarged slightly when the layer thicknesses of the subcells are chosen such that light absorption is more balanced. As indicated in Fig. 5, combined optoelectronic simulations of double junction devices predict that the highest performance would be expected for a device with a front cell thickness of 100 nm and a back cell thickness of 70 nm. However, since a more straightforward double junction device with two 80 nm thick subcells should perform much better than a single junction cell as well, we will employ this structure in the experimental section below.

3.2.2. Comparison with experiment

To determine the advantageous effect of a double junction structure on the performance of a real device, a slight modification to the anode of the back cell was necessary. The work function of pH-modified PEDOT:PSS is lower than that of unmodified PEDOT:PSS, which would result in a reduction of the open-circuit voltage of the back cell. To prevent this, an ultrathin layer of a perfluorinated ionomer was spin coated on the middle electrode [17]. Since the perfluorinated ionomer layer is presumably only a few monolayers thick, it is not expected to affect the optical properties of the layer stack. Fig. 6 shows the measured and simulated J–V curves of single and double junction cells with active layers of 80 nm thickness. At a light intensity of 0.9 sun, the experimental double junction device delivers a J_{sc} of 34.9 A/m^2 compared to 56.0 A/m^2 for the 80 nm thick single layer cell. The J_{sc} ratio thus amounts to 62%, which is in excellent agreement with the calculated value of 63%. At 1.92 V the V_{oc} of the double junction cell is very close to but slightly lower than the sum of the subcell voltages (1.94 V). Unfortunately, the fill factor shows a small drop as well, from 66% to 61%, which is most probably caused by an additional series resistance due to the thin insulating layer between the back photoactive layer and its anode. Nevertheless, the power conversion efficiency increases with 13% from 4.0% for the optimized single layer device to 4.5% for the double junction device. The decoupling of optical and electronic limitations thus clearly enables an enhancement of the photovoltaic performance. The working principle is therefore generic to all polymer:fullerene systems that show optimum performance at small layer thicknesses.

4. Conclusions

The photovoltaic properties of PF10TBT:PCBM solar cells are described with combined optoelectronic modeling to identify the processes that limit the power conversion

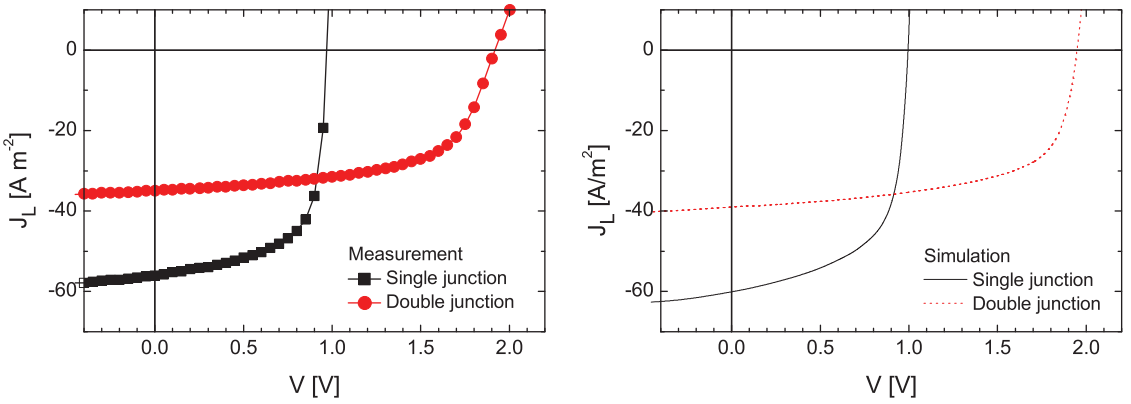

Fig. 6. Experimental (left) and calculated (right) current density versus voltage curves of a single and a double junction cell at a light intensity of 0.9 sun. The (sub)cells are all 80 nm thick.

efficiency. It is shown that 4%-efficient solar cells with an optimized layer thickness of 80 nm absorb only 48% of the photons that are available within the absorption bandwidth. Optical modeling reveals that this figure can be increased to 67% if the PF10TBT:PCBM layer is made 210 nm thick. However, a concurrent decrease in fill factor limits the efficiency of thick cells to 3.2%. It is shown that a double junction solar cell consisting of two optimized PF10TBT:PCBM layers absorbs photons more efficiently than thick single layer cells, as its structure disentangles the optical and electronic limitations. Simultaneously, the subcells have the high internal quantum efficiency and fill factor associated with thin cells. Overall, the power conversion efficiency is improved from 4.0% for an optimized single layer cell to 4.5% for the double junction device.

ABSTRACT

We have used sol–gel derived copper oxide (CuO_x) thin film as an interlayer at the organic/metal interface to improve the performance of the inverted P3HT:$PC_{61}BM$ solar cells. The resulting interlayer can form an ohmic contact between the P3HT:$PC_{61}BM$ and electrode. Due to the formation of the ohmic contact, the series resistance of device has been decreased from 2.77 to 1.29 (Ω/cm^2). Simultaneously, the CuO_x interlayer can redistribute the light intensity to enhance light absorption and thereby increases the current density form 11.0 to 11.9 (mA/cm^2). Thus, the power conversion efficiency (PCE) is improved from 3.11% to 4.02%.

1. Introduction

Polymer solar cells (PSCs) have great potential for renewable energy due to their low cost, mass production and low temperature fabrication. Recently, the conventional bulk-heterojunction solar cells, which consist of donor and acceptor blend inserted between a high work function transparent semiconducting oxide anode and a low-work-function metal cathode with PCE of 7.73%, have been reported [1]. However, the conventional structures of PSCs have the drawback of fast degradation partly due to the poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and the low-work-function metal cathode. The PEDOT:PSS layer will etch the ITO and cause interface instability due to its acidic nature. The low-work-function metals are easily oxidized, increasing the series resistance (R_s) at the metal/organic layer interface. Hence, the inverted structures are used to overcome the above deficiencies. They reverse the nature of charge collection and replace both the PEDOT:PSS and the electrode. This significantly improves the life time of the solar cells [2,3].

Generally, the metal electrodes used in most studies are Ag or Au for effective hole collection [4,5]. However, the work function of Au will decrease in the air due to the contamination by carbon and oxide [6]. This will lead to the degradation in the device's performance. Nevertheless, in the case of the Ag electrode, the oxidization of Ag will increase its work function from 4.3 to 5.0 eV [2,7], which will benefit the hole transportation from P3HT to Ag and improve the device's performance. Thus, in this study, we choose Ag metal as the anode electrode.

In order to further increase the efficiency of the inverted structure device, the oxide interlayer, such as P–NiO [8], V_2O_5 [9], WO_3 [10], Cs_2CO_3 [11], ZnO [12], and MoO_3 [13] have been applied to the organic solar cell as a blocking layer. They are mostly deposited by using vacuum evaporation. Nevertheless, the process of vacuum evaporation is expensive. Consequently, low-cost solution process becomes the strategic principle for the preparation of metal oxide interlayer on polymer solar cell.

Using solution-processed metal oxide as an anode interlayer is challenging because of the hydrophobicity of the polymer active layer [2]. Therefore, the selection of solvent for sol–gel is an important issue. 2-methoxyethanol (2MOE) is usually used as the solvent in sol–gel methods [14]. However, to be compatible with the polymer active layer, we use isopropanol (IPA) instead of 2MOE as the solvent. In addition to the solvent selection, the metal selection is also critical. We found that the copper oxide is a good choice for the metal oxide layer. The highest occupied molecular orbital (HOMO) energy of P3HT is located at 5.2 eV [15]. The work function of copper oxide is about 5.3 eV [16,17] which is close to HOMO of P3HT. This leads to the better hole transportation at the organic/inorganic interface. Therefore, copper oxide complexes have great potential to function as hole transportation layer. Here, we have fabricated CuO_x interlayer on P3HT:$PC_{61}BM$ blend by using low-cost sol–gel process in inverted structure device.

The CuO_x film which mainly consists of Cu_2O can form an ohmic contact between P3HT:$PC_{61}BM$ blend and metal because the Cu_2O can modulate the barrier height of schottky contact and form an ohmic contact at P3HT:$PC_{61}BM$ blend/metal interface. With the CuO_x interlayer, the device increases the shunt resistance (R_{sh}) from 412.42 to 1030.71 (Ω/cm^2) and decreases the R_s from 2.77 to 1.29 (Ω/cm^2). In addition, the photocurrent density (J_{sc}) also enhances from 11.0 to 11.9 (mA/cm^2). Thus, the FF (fill factor) of our device is dramatically improved from 53.4% to 63.7% while the efficiency of device increases from 3.11% to 4.02%.

2. Experimental details

The inset of Fig. 1 is the structure of the inverted polymer solar cell with CuO_x. The devices were fabricated on cleaned ITO-coated glass substrates (~7 Ω/sq.). The ZnO seed layer (50 nm) was spin-coated from a 0.5-mol solution of zinc acetate in 2MOE. Then, a blend of P3HT:$PC_{61}BM$ (1:1 by weight) was prepared on the ZnO seed layer by spin-coating a 1.5-wt.% dichlorobenzene solution. After spinning the active layer, the CuO_x layer was spin-coated from a 0.25-mol solution of copper (II) acetate monohydrate in IPA mixed with monoethanolamine and deionized water. For comparison, another sample without the CuO_x layer was also prepared. Finally, silver film (~250 nm) was deposited on top of the blend under high vacuum ($\sim 3 \times 10^{-6}$ torr). The electrical measurements were carried out with the devices under air atmosphere at room temperature. Fig. 1 is the current density–voltage (J–V) curve of the devices illuminated at 100 mW/cm^2 from a 150 W Oriel solar simulator using an air mass 1.5 global (AM 1.5G) filter. The R_s and R_{sh} of the devices are obtained from the J–V curve. The R_s and the R_{sh} are calculated by the $(slope)^{-1}$ of curve at $V = 1$ and $V = 0$, respectively. The reflectance spectrum of the devices with the CuO_x layer was obtained by using a Perkin–Elmer Lambda 35 UV–vis spectrophotometer with an integrating sphere. To investigate the sol–gel derived thin film, the scanning electron microscopy (SEM) and Fourier Transform Infrared Spectroscopy (FTIR) were used for identifying the thickness and structure.

3. Results and discussion

To characterize the contact behavior between the CuO_x and electrode, we measure the surface J–V characteristic of metal/P3HT:$PC_{61}M$ [18], as shown in Fig. 2(a). The inset of Fig. 2(a) shows the device structure for surface J–V curve measurement. It can be seen that the schottky barrier formed between P3HT:$PC_{61}BM$ and aluminum (black line). The schottky contact may lead to the decrease in V_{oc} (open-circuit voltage) of the device [19]. However, the sample with CuO_x shows good ohmic contact at the interface (red line). The CuO_x can be applied to modulate schottky barrier as the oxide of Cu_2O in CuO_x is very easily reduced and a copper rich phase will form near the Cu_2O/metal interface [20]. These decrease barrier height and result in an ohmic contact between P3HT:$PC_{61}BM$ and aluminum.

On the other hand, ohmic contact has also established at the interface between the P3HT:$PC_{61}BM$ and silver

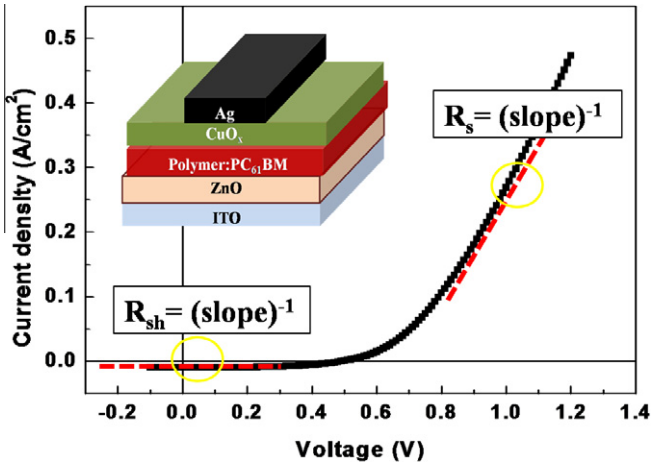

Fig. 1. Device structure and the J–V curve of the device illuminated at 100 mW/cm^2 from a 150 W Oriel solar simulator using an air mass 1.5 global (AM 1.5G) filter.

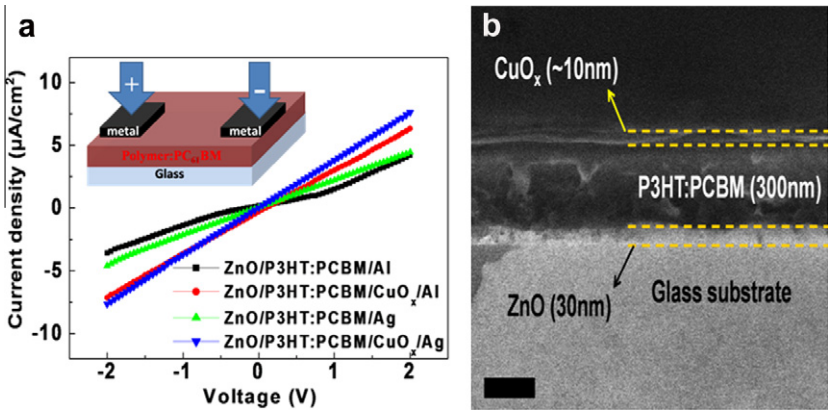

Fig. 2. (a) The structure diagram for surface *J–V* measurement and the surface *J–V* curve of the contact between P3HT:$PC_{61}BM$ and electrode with and without the CuO_x interlayer. (b) SEM cross-sectional image of Si/ZnO/P3HT:$PC_{61}BM$/ CuO_x, scale bar: 200 nm.

electrode (green line). In this case, the slope for CuO_x/Ag contact at the interface is 77% higher than that on P3HT:$PC_{61}BM$ /Ag contact (blue line). It reveals that the devices with CuO_x interlayer have low-resistance ohmic contact to the Ag electrode, which makes the R_s decrease.

The R_s in the solar cell is attributed to the conductivity of each layer and the contact resistance between them. The materials with high charge carrier mobility and ohmic contact at the interfaces are required to obtain high J_{sc} values [19]. Although the ohmic contact has formed at active layer/Ag interface, by introducing the CuO_x interlayer, the R_s and R_{sh} can still be dramatically improved due to the low-resistance ohmic contact. This will lead to the increase in the J_{sc} and the FF. However, since the ohmic contact has formed, there will be no V_{bi} at the interface. As a result, the contributions to the performance of devices by the CuO_x are mainly on FF, J_{sc} and efficiency [21]. In addition, by introducing the CuO_x, the Fermi levels of electrodes are close to the HOMO of donor and LUMO of acceptor due to the energy level alignment between CuO_x interlayer and the Ag anode, which can slightly increase the V_{oc}.

Fig. 2(b) shows the SEM cross-sectional image of the Si/ZnO/P3HT:$PC_{61}BM$/CuO_x. The thicknesses of ZnO film and active layer are about 30–50 and 300 nm, respectively. The sol–gel derived CuO_x thin film (10 nm) can cover the active layer well, preventing the organic layer from oxygen and moisture which can lead to the degradation of active layer.

To further clarify whether the CuO_x protect the polymer blend underneath against moisture and oxygen, we investigate the FTIR spectrum of the polymer thin films with and without CuO_x prepared and placed in the air for 9 days as shown in Fig. 3(a) and (b). In the Fig. 3(a), it is observed that the C=O peak at 1740 cm^{-1} [22,23] of the sample with oxide layer appears clearly after 3 days and then becomes stable, revealing that the CuO_x can prevent the polymer

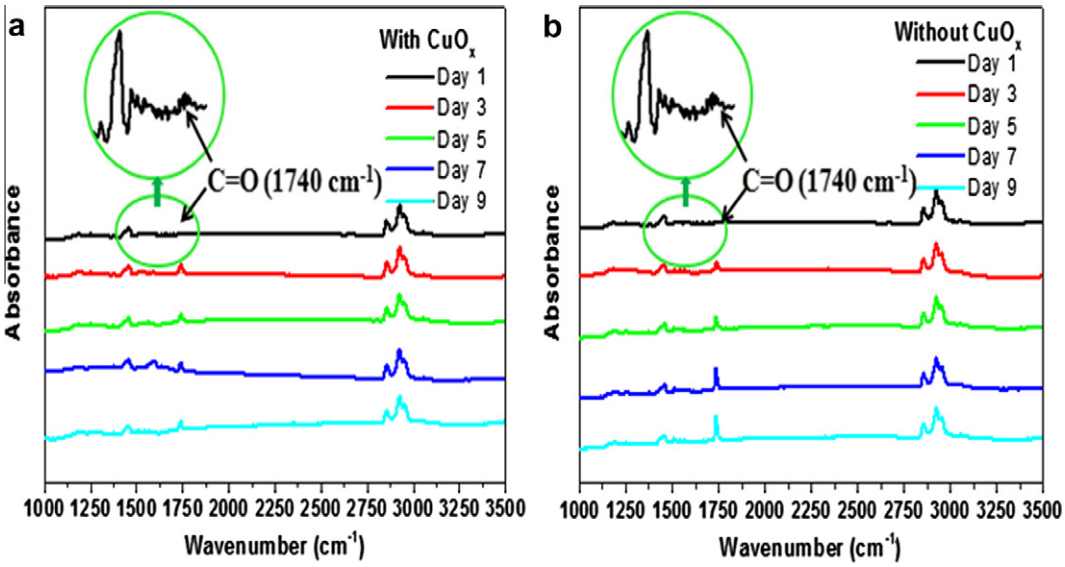

Fig. 3. (a) The FTIR spectrum of the polymer thin film with CuO_x in the air for 9 days. (b) The FTIR spectrum of the polymer thin film without CuO_x in the air for 9 days.

layer from oxygen. In the Fig. 3(b), the peak at 1740 cm^{-1} of the sample without oxide layer gradually enhances as the time increases, revealing that the thin film is continually oxidized. It implies that the CuO_x can prevent the photoactive from oxygen.

Irradiation of inverted polymer solar cells at ambient air leads to the formation of oxidation products attributed to P3HT and to $PC_{61}BM$. The variation of the peak at 1740 cm^{-1} can be observed in the FTIR spectrum. As a result, we need to further identify the peak derived from P3HT or $PC_{61}BM$. The C=O peak observed at 1740 cm^{-1} in IR spectrum can be assigned to be carbonyl part of $PC_{61}BM$ [23]. The carbonyl group of $PC_{61}BM$ has been found to be sensitive to local environments [23]. Therefore, it implies that oxidation products in this study may be attributed to $PC_{61}BM$.

In order to observe the variation of $PC_{61}BM$ in ambient environment, we performed atomic force microscopy (AFM) examinations of the surface morphology of the $PC_{61}BM$ thin film which was only spin-coated from a 20 mg mL^{-1} solution of $PC_{61}BM$ in dichlorobenzene. Moreover, we measured the FTIR spectra to identify whether or not $PC_{61}BM$ is oxidized in the air. The course of photo- and thermo-oxidation was followed by FTIR spectra monitoring the increase of carbonyl absorption at 1740 cm^{-1}, caused by oxidation products [24]. Fig. 4 is the AFM and FTIR spectra of the $PC_{61}BM$ thin film observed with aging. The AFM images show root-mean-square (rms) roughness values of 1.05 nm at day 1, 2.35 nm at day 3, 3.51 nm at day 5, 6.89 nm at day 7 and 7.32 nm at day 9. The surface roughness of $PC_{61}BM$ thin film increases from day 1 to day 9, revealing $PC_{61}BM$ may be deteriorated with aging. Furthermore, the peak at 1740 cm^{-1} also becomes stronger from day 1 to day 9, representing that oxidation products in devices should be attributed to $PC_{61}BM$.

Fig. 5 is the device performance of unencapsulated inverted PSCs with and without the CuO_x interlayer over 1000 h in air. The device without CuO_x reaches a maximum PCE of ~3.1% and then reduces to ~1.5% after 1000 h, a ~51% degradation. In contrast, the PCE of the device with the CuO_x interlayer reaches a maximum of ~4.0% and then declines to ~3.5% after 1000 h, only 13% degradation. The improved stability is mainly attributed to the CuO_x

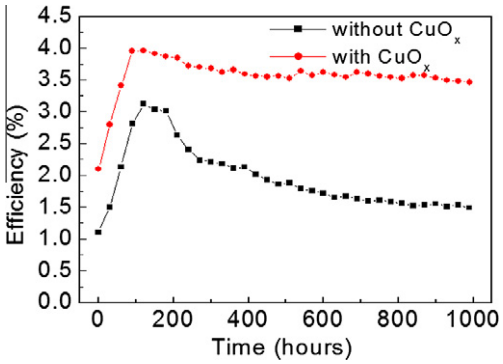

Fig. 5. The device performance of unencapsulated inverted polymer solar cells with and without the CuO_x interlayer over 1000 h in air.

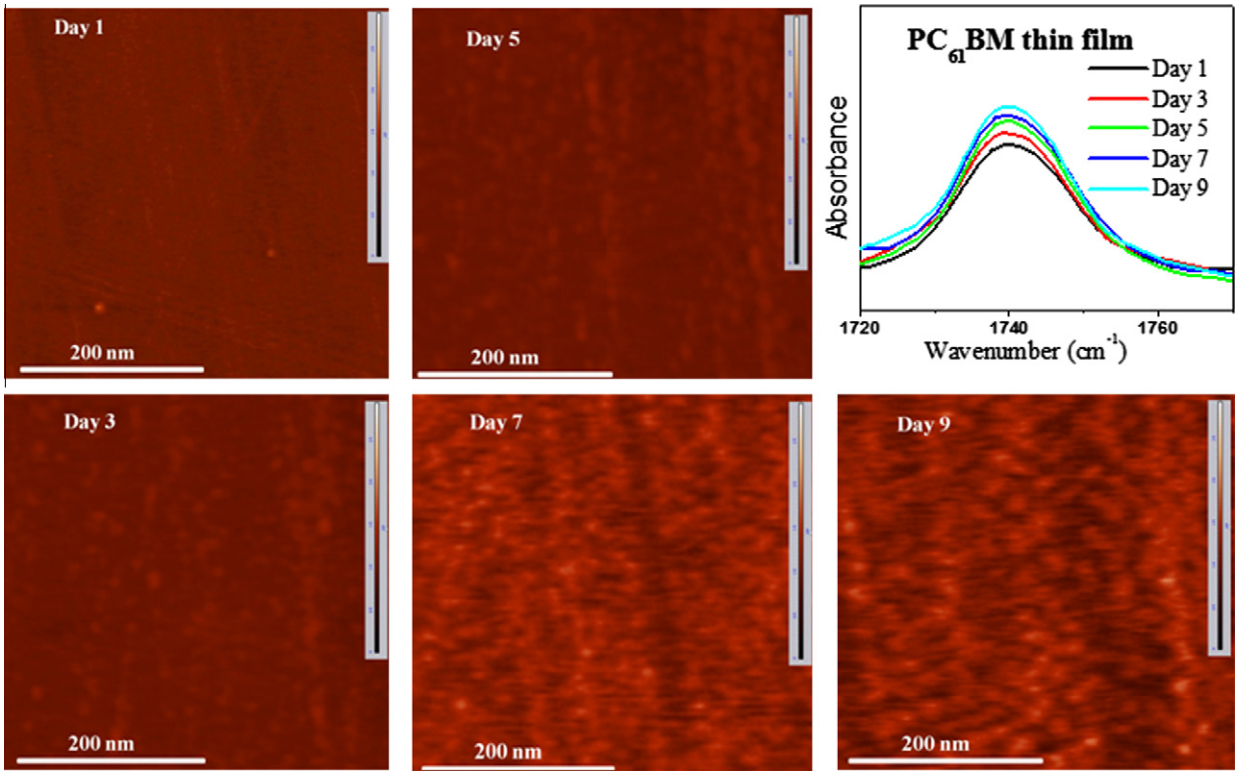

Fig. 4. The AFM and FTIR spectra of the $PC_{61}BM$ thin film observed with aging.

interlayer. Furthermore, in both devices, the maximum performance is only obtained by 100 h of storage in air after device preparation. This phenomenon has also been observed in previous report [25]. In this study, it is found that the oxidization of the photoactive layer may result in the variation in morphology of photoactive layer with aging, which may lead to the improvement in efficiency.

In order to identify the thin film composition, we further compare the FTIR spectrum with and without CuO_x, as shown in Fig. 6(a). The CuO_x film consists of Cu_2O (630, 606 and 588 cm^{-1}) [26,27], Cu_2S (617 cm^{-1}) [28] and CuO_2 (646 cm^{-1}) [29]. The CuO_x may react with S atom of the P3HT at the interface, resulting in the peak at 617 cm^{-1} [28]. The weak signal at 646 and 617 cm^{-1} indicate that the CuO_2 and Cu_2S contained in the CuO_x thin film are both rare.

To further clarify the containment of CuO_2 and Cu_2O in the CuO_x thin film, we simulated the spectra by the Gauss function with 588, 630 and 646 cm^{-1} peak, as shown in Fig. 6(b). By calculating the area under the individual peak, we can roughly estimate the containment of variety structures [30]. Here, the containment of CuO_2 in CuO_x is about 1%, which is much smaller than the Cu_2O.

To realize the role of the CuO_x interlayer, we measured the reflectance spectrum of the devices with and without the CuO_x interlayer. Perkin–Elmer Lambda 35 with an integrating sphere was used to measure the reflectance of devices. Since the two devices are identical except the addition of the interlayer, we can compare the reflectance yield information on the additional absorption. Fig. 7(a) is the absorption spectra through the equation: $A = 1 - R - T$. The CuO_x interlayer enhances the absorption of the devices at 400–600 nm and only slightly increases the absorption above 600 nm. The increased photogeneration of charge carriers are resulted from the spatial redistribution of the light intensity. To further identify the function of CuO_x, the additional absorption, $\Delta\alpha(\lambda)$, as a result of spatial redistribution of light intensity by the CuO_x interlayer is estimated by [9,15].

$$\Delta\alpha(\lambda) \cong (-1/2d)\ln(I'_{out}(\lambda)/I_{out}(\lambda)) \quad (1)$$

where $I'_{out}(\lambda)$ is the reflection from a device with the CuO_x interlayer, $I_{out}(\lambda)$ is the reflection from a device without the CuO_x interlayer, and d is the thickness of the photoactive layer (d is ~300 nm in both). Fig. 7(b) is the change in the absorption spectrum $\Delta\alpha(\lambda)$ resulting from the Eq. (1). The result shows a clear increase in absorption over the spectral region. Furthermore, this spectrum reveals four peaks at 450, 512, 556, and 602 nm, respectively. It implies that the contribution of the CuO_x interlayer in photocurrent is

Table 1
The device performance of inverted P3HT:$PC_{61}BM$ bulk-heterojunction solar cells.

Device	V_{oc} (V)	J_{sc} (mA/cm^2)	FF (%)	PCE (%)	R_s (Ω/cm^2)	R_{sh} (Ω/cm^2)
No CuO_x	0.53	11.0	53.4	3.11	2.77	412.42
CuO_x 500 rpm	0.54	11.1	63.5	3.81	1.88	446.42
CuO_x 1000 rpm	0.53	11.6	64.2	3.93	1.73	473.91
CuO_x 2000 rpm	0.53	11.9	63.7	4.02	1.29	1030.71
CuO_x 3000 rpm	0.53	11.5	59.5	3.63	1.46	431.32
CuO_x 4000 rpm	0.53	11.3	54.3	3.25	2.12	382.48

mainly at these peaks which are vibronic features from the P3HT molecules [31,32].

Fig. 8(b) shows energy band diagram for the photovoltaic cells in this study. The conduction band and the valence band of Cu_2O are located at near 3.1 and 5.2 eV, respectively [33,34]. The HOMO of P3HT is 5.2 eV [35], which is similar to the valence band energy of Cu_2O. Thus, the interface between the P3HT:$PC_{61}BM$ blend and CuO_x can easily form an ohmic contact. To optimize the device efficiency, we controlled the thickness of the oxide by varying spin rate from 500 to 4000 rpm. The oxide film with lower spin rate has the higher thickness. Fig. 8(a) is the *J–V* curve of the photovoltaic devices with different spin rates of the oxide layer under 100 mW/cm^2 AM 1.5G irradiation. The higher thickness of CuO_x does not only contribute to the R_s of the device but lead to a lower photocurrent. In contrast, the thinner CuO_x film has higher photocurrent and lower R_s. These results are similar to the previous reports [13,36].

Table 1 illustrates the efficiency of unencapsulated inverted P3HT:$PC_{61}BM$ bulk-heterojunction solar cells using CuO_x film as an interlayer with different spin rates. The efficiency initially increases as the spin rate increases from 500 to 2000 rpm. Nevertheless, the efficiency starts to decline at 3000 rpm. When the spin rate of the CuO_x film is 2000 rpm, the devices exhibit a PCE of 4.02% with J_{sc} of 11.90 mA/cm^2 and V_{oc} of 0.53 V. The R_s and the R_{sh} are also improved. As the spin rate reaches over 2000 rpm, the high spin rate could result in the broken CuO_x film that leads to a lower PCE.

Furthermore, the devices with CuO_x all have higher FF value than the device without CuO_x. Except for the better ohmic contact formation at the interface, the other reason for these is because the states of Cu_2O at the top of valence band are derived from fully occupied Cu 3d states and are more mobile when converted into holes [35], which makes it a great hole transportation layer.

4. Conclusions

In conclusion, we have fabricated the CuO_x film well on P3HT:PC61BM blend of inverted structure by all solution process. The CuO_x has similar valence band energy with the HOMO of P3HT and serves as an interlayer which modulates the ohmic contact at the organic/metal interface. This leads to the better transportation that causes the improvement in FF, R_{sh} and R_s of the device. Hence, the PCE is improved from 3.11% to 4.02%. Moreover, the CuO_x layer can redistribute the light intensity to enhance the light absorption and increase current density. Furthermore, the CuO_x interlayer can prevent the organic layer from oxygen and moisture, which can cause the degradation of active layer.

Space-charge-limited conduction
Disordered films

ABSTRACT

The charge transport properties of 100 nm thick cobalt phthalocyanine (CoPc) films grown on single crystal Al_2O_3 (0 0 0 1 oriented) and quartz substrates using molecular-beam epitaxy, have been investigated as a function of applied bias (±50 V) and temperature (300–75 K). Films grown on Al_2O_3 are highly ordered and exhibited non-hysteretic current–voltage (*J–V*) characteristics. The *J–V* characteristics in this case are well described by space-charge-limited conduction (SCLC) mechanism. On the other hand, films grown on quartz substrates are highly disordered and exhibited hysteretic *J–V* characteristics. Analyses of complex hysteretic *J–V*'s in disordered films indicated a transition from trap-controlled SCLC mechanism to Poole–Frankel emission with lowering temperature. Various parameters, such as, hole density, trap concentration and space charge limited motilities have been estimated. X-ray photoelectron spectroscopy data show that charge trapping centers in the films grown on quartz substrates are created by chemisorbed oxygen.

1. Introduction

Molecular organic semiconductors (OSC) are promising materials for future low cost and large area electronics. Among various OSCs, metal phthalocyanines (MPcs) due to high mobility, high thermal and chemical stability and ease of preparation make them suitable for a wide range of applications, such as, dyes, light emitting diodes, solar cells, field effect transistors, gas sensors, field emission applications etc. [1–4]. However, in order to estimate a full potential of these materials, a better understanding of charge transport mechanisms in thin films forms is needed. The charge transport in OSC's is either electrode-limited (due to a mismatch of energy levels between the electrode work function and the corresponding transport levels of the OSC) or bulk-limited. If an ohmic contact is established between OSC and electrode material, then the current is dominated by bulk transport. Efficient charge transport in a film requires that charges move from molecule to molecule and do not trap or scatter. Therefore, charge carrier mobility is influenced by several factors, including molecular packing or crystallinity, disorders, temperature, electric field and charge-carrier density. In literature, several experimental studies have been reported on the understanding of the impact of these parameters on charge transport in OSCs. Unfortunately, such studies are made on films having different OSC materials (e.g., phthalocyanines, pentacene etc.), which were grown on substrates of different materials as well as crystallinity under varying experimental conditions [5]. Several interesting findings have been reported. These include: (i) an enhancement of mobility by nearly six orders in magnitude in pentacene thin films by controlling the substrate temperature, nature of substrate and films thickness [6]; (ii) a

doi:10.1016/j.orgel.2010.08.014

systematic decrease of mobility with increasing background pressure/deposition rates ratio in copper phthalocyanine thin films, which has been attributed to an increase in trap concentrations [7]; (iii) presence of hysteretic current–voltage (J–V) characteristics along with a negative differential resistance (NDR) in copper phthalocyanine thin films, which depend on the deposition parameters etc. [8]. Such a high sensitivity of transport properties essentially depends on the disorders created in the films due to deposition conditions and/or the substrates employed [9–12]. Generalization of disorder induced charge transport in OSC films by comparing data of different groups can be tricky as films of different OSCs are prepared on different substrate materials with varying deposition conditions. Therefore, in order gain an insight into the role of disorders in the charge transport of OSC films, it is essential to delineate the origins of disorders created in the films due to substrates and processing conditions. This demands that films of a particular OSC are grown on different substrates under identical conditions and their charge transport studies are investigated.

In this work, we present results of a detailed investigation carried out on the role of substrate-induced disorders in charge transport properties of cobalt phthalocyanine (CoPc) films. For this purpose, 100 nm CoPc films were deposited under identical conditions on amorphous quartz and crystalline (0 0 0 1 oriented) Al_2O_3 (sapphire) substrates using molecular-beam epitaxy. We demonstrate that films grown on quartz substrates exhibit the J–V characteristics with a pronounced hysteresis, whereas those grown on Al_2O_3 substrates exhibit J–V without any hysteresis. The hysteresis in films grown on quartz substrates is attributed to the deep traps created by chemisorbed oxygen.

2. Experimental

CoPc films (thickness ~100 nm) were deposited on quartz and (0 0 0 1 oriented) Al_2O_3 substrates using molecular-beam epitaxy, MBE, (RIBER system, model EVA 32) under identical conditions. The details of the deposition process are described in our earlier paper [13]. Briefly, cleaned quartz and sapphire substrates were introduced in the introduction chamber of the system and heated at 300 °C under 10^{-8} torr vacuum for removal of moisture and impurities present at the surfaces. The substrates were then transferred in situ to the deposition chamber and CoPc films were deposited using an effusion cell loaded with pure α-CoPc powder (Aldrich make, which was purified by thermal gradient sublimation technique as described in the literature [14]). Prior to the film deposition, the loaded material was heated at 300 °C for 2 days to remove the moisture. All the films were grown at a substrate temperature of 200 °C using a deposition rate of 2 Å/s under a base vacuum of better than 10^{-8} torr. The X-ray photoelectron spectroscopy (XPS) of the deposited films was carried out in situ using MgK_α (1253.6 eV) source and a MAC-2 electron analyzer. The binding energy scale was calibrated to Au $4f_{7/2}$ line at 83.95 eV. The C 1s peak from the adventitious carbon-based contaminant, with the binding energy of 285 eV, was used as the reference for calibration of the charging effect. The structure of the grown films was determined by grazing incidence X-ray diffraction (GIXRD) using CuK_α radiation (Seifert-XRD 3003TT) in out-of-the-plane geometry with an incidence angle of 0.1°. The surface morphology of the films was studied by scanning electron microscopy, SEM, (Tescan make VEGA MV2300T/40 system).

The charge transport measurements were carried out using in-plane electrode geometry. For this purpose, two planar gold electrodes of length 3 mm, width 2 mm separated by 12 μm were thermally deposited onto films using a metal mask and silver wires were attached to the gold pads with silver paint. We may like to add that we have varied the width of gold electrode from 1 to 5 mm, and no significant effect of width on the J was observed. The in-plane geometry has following distinct advantages over out-of-plane geometry (i.e., electrodes are made across the film thickness). (i) In the out-of-plane geometry, metal ions can get incorporated in the films, which can act as the charge trapping centers and hence can create hysteresis in the J–V characteristics [15]. This can make it difficult to differentiate intrinsic origin of hysteresis. This problem will not arise in the in-plane geometry, as the electrodes are far apart (12 μm). (ii) Larger electrode spacing also indicates that the contribution of contact resistance is very small as compared to the film resistance. The J–V measurements were carried out using Keithley 6487 picoammeter/voltage source and computer based data acquisition system. The measurements at low temperatures (20–300 K) were carried out using a closed cycle cryostat. All measurements were carried out in dark to avoid the problem of photoconductivity. In order to rule out the effect of film inhomogeneities, J–V measurements were carried out using at least three pairs of electrodes deposited on a film at different locations.

3. Results

The morphology and GIXRD spectra of the 100 nm CoPc films grown under identical conditions on Al_2O_3 and quartz substrates are shown in Fig. 1. The morphology of films grown on Al_2O_3 substrates has a very dense structure, whereas for quartz substrates the film morphology is granular with a rough surface. For films grown on Al_2O_3 substrates, the presence of GIXRD peaks at $2\theta = 6.94°$, 15.56° and 22.23° indicate that the film is polycrystalline. The least-square fitting of the XRD pattern indicated the monoclinic unit cell structure with lattice parameters $a = 2.58(8)$ nm, $b = 3.75(3)$ nm and $c = 2.40(8)$ nm, $\beta = 90.2°$, which is in agreement with the reported values [16,17]. On the other hand, for quartz substrate presence of only one peak at $2\theta = 6.94°$ (i.e., (2 0 0) orientation) with very low intensity, along with granular morphology, indicates weak crystallization of the film. This difference in CoPc film morphology and structure on two different substrates is attributed to the interaction between the CoPc molecules and the surface of the substrates. On Al_2O_3 substrates, due to strong reactivity of Al-terminated surface, the CoPc molecules initially stack with face-on configura-

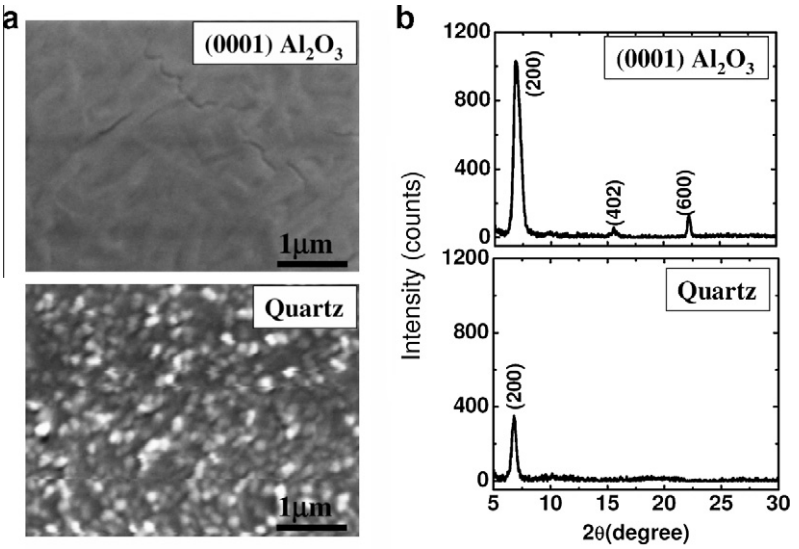

Fig. 1. GIXRD patterns (a) and scanning electron micrographs (b) for the films grown on (0001) Al_2O_3 and quartz substrates.

tion [18,19]. However, as the thickness increases the substrate-molecule interaction weakens, which allows other planes to grow and, in turn, a polycrystalline film is grown. On the other hand, due to inert nature of quartz substrates, the CoPc molecules stack randomly on the substrate resulting in a more disordered state.

The in situ XPS data of CoPc films grown on both substrates indicated absence of oxygen and presence of cobalt in Co^{2+} state. However, exposing films to ambient conditions for 24 h showed a marked difference in the XPS spectra, as shown in Fig. 2. For CoPc films grown on Al_2O_3, O-1s spectrum exhibited single peak at 531 eV (corresponding to physisorbed oxygen) [20]. This indicates that films on Al_2O_3 substrates are not reactive with atmospheric oxygen, which is attributed to a dense packing of the molecules. On the other hand, CoPc films on quartz substrates are found to be reactive with atmospheric oxygen. This is evident from the O-1s spectrum, which has two distinct components at binding energies of 531 and 535 eV, corresponding

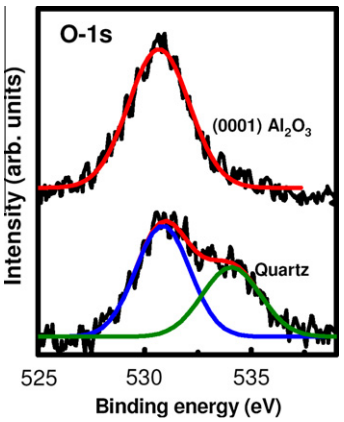

Fig. 2. O-1s XPS spectra recorded for the films grown on Al_2O_3 and quartz substrates.

to physisorbed and chemisorbed oxygen, respectively [21]. The XPS data, therefore, indicates that the charge transport properties of the CoPc films grown on Al_2O_3 and quartz substrates are likely to be very different, which is in agreement with transport properties discussed in the following.

The *J–V* characteristics recorded for films grown on Al_2O_3 and quartz substrates in the bias range of ±50 V are shown in Fig. 3a and b, respectively. The striking difference between the two films is that while for films on Al_2O_3 substrates the *J–V* characteristics are non-hysteretic and highly reproducible with repeated bias scans; for films on quartz substrates a hysteresis in *J–V* characteristics is observed it increases with number of scans. However, hysteresis becomes highly reproducible after 12th scan. Before making further analysis, we would like to mention that space-charge-limited conduction (SCLC) is a commonly reported charge transport mechanism in the OSC films. In the case of ohmic interface between the metallic electrodes and organic films, if the density of injected carriers is lower than the thermally generated carriers in the films (as occurs at low bias) one expects an ohmic (linear *J–V*) behavior. The *J* in this case is given by [22]:

$$J = n_0 e \mu V / d \tag{1}$$

where J is the current density, n_0 is the concentration of thermally generated holes, e is the electronic charge, μ is the hole mobility and V is the applied bias and d is the electrode separation. At sufficiently high bias, concentration of injected carriers exceeds the thermally generated carrier density and SCLC mechanism becomes dominant. In the presence of shallow traps, the SCLC is described by [22]:

$$J = \frac{9\varepsilon_0 \varepsilon_r \theta \mu V^2}{8d^3} \tag{2}$$

where ϵ_0 is the permittivity of free space, and ϵ_r is the static dielectric constant of the film and θ is the ratio of free to total (trapped and free) charge-carrier density.

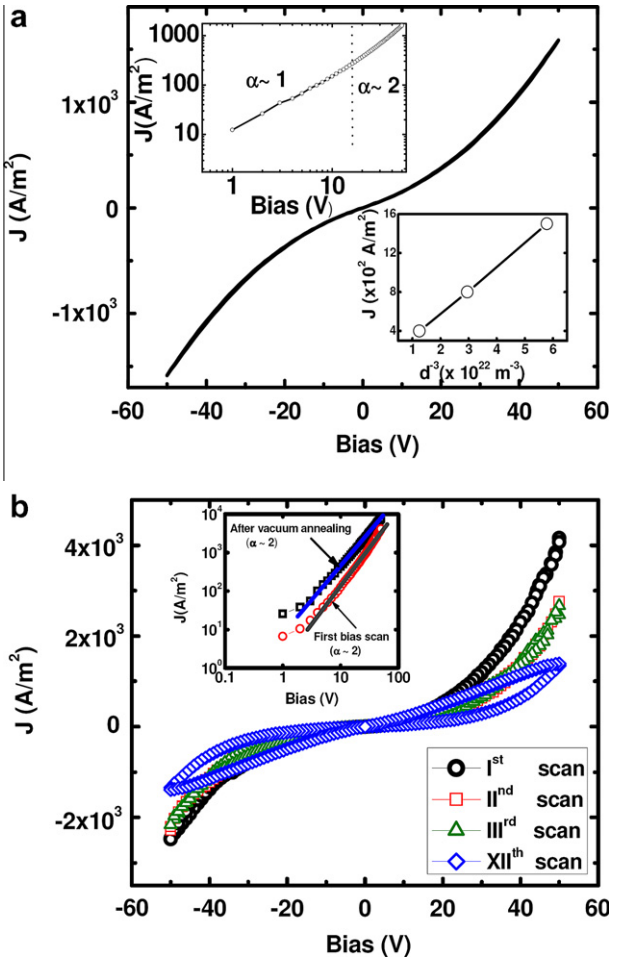

Fig. 3. Room temperature J–V characteristics recorded for the films grown on (a) Al_2O_3 and (b) quartz substrates (for repeated bias scans). Inset of Fig. 3(b) shows the J–V plots for the first bias scan and for the vacuum annealed films on Quartz substrate.

A large amount of structural disorder in films can result in high concentration of trapping centers. Often, the disorder does not have a uniquely defined environment and results in a broad smearing of the trap level distribution. In many cases an exponential distribution of trap levels with a maximum at valence band edge has been reported. In such a case, the J–V characteristics are described by [22]:

$$J = e\mu N_V \left(\frac{\varepsilon_0 \varepsilon_r}{eP_0 kT_t}\right)^l \frac{V^{l+1}}{d^{2l+1}} \tag{3}$$

Where N_V is the effective density of states in the valence band, P_0 is the trap density per unit energy at valence band edge, $l = T_t/T$, where T is the measurement temperature and T_t is the temperature characterizing the trap distribution. Current–voltage characteristics with exponent $(l+1) > 2$ suggest SCLC mechanism in the presence of exponentially distributed traps. We may add that SCLC (Eqs. (2) and (3)) assumes field independent mobility. In case of field dependent mobility, the expressions for J–V characteristics will be modified [23]. In case of exponential distribution of traps, total trap density is given by:

$$N_t = P_0 kT_t \tag{4}$$

In the light of above discussion, we make interpretation of the data presented in Fig. 3 and will first analyze data on sapphire. It is known that the energy barrier at Au/CoPc interface is very small (0.2 eV), which indicates an ohmic contact between Au and CoPc film [24]. For films on Al_2O_3 substrates, a log–log plot of data, as shown in inset of Fig. 3a, indicates a power law behavior of J–V characteristics, i.e., J–V^α, with a crossover in exponent (α) from 1 to 2 at a bias of ~20 V. This indicates that charge transport is ohmic in the bias range 0–20 V, and at higher bias the transport mechanism changes to shallow trap mediated SCLC [22] as described by Eq. (2). In case of SCLC mechanism with shallow traps, linear dependence of J on d^{-3} has been predicted. Therefore, we had made measurements on a single film with different spacing between electrodes (d = 12, 15 and 20 μm) and the results shown in the lower inset of Fig. 3a confirm the validity of SCLC mechanism. Using slope of J–V^2 plots and assuming literature value of $\varepsilon_0\varepsilon_r$ (2.43×10^{-11} F/m), value of mobility (μ) was determined (using Eq. (2)) to be 9.8×10^{-5} m^2/Vs [22]. Using this value of μ, we find (using Eq. (1)) the thermally generated hole concentration (n_0) of 9.6×10^{18} m^{-3} (at 300 K). Here, we have assumed $\theta = 1$ (as justified later, by

very low trap density found for sapphire substrate). Values of different parameters calculated above are given in Table 1.

We can estimate the injected carrier concentration n_{inj} as well as show field independent mobility (assumed in above analysis on sapphire substrate) using the approach of Wu et al. [25]. Under SCLC conditions, Eq. (1) with carrier density n_{inj} may be written as:

$$J = n_{inj}(x)e\mu E(x) \tag{5}$$

Electric field $E(x)$ is related to injected carrier density by:

$$\frac{\varepsilon}{e}\frac{dE(x)}{dx} = n_{inj}(x) \tag{6}$$

We define a function $g = g(E)$ satisfying $\mu(E)E = dg(E)/dE$ with $g(0) = 0$. For an ohmic contact at $x = 0$ and $E = 0$ (at $x = 0$) we obtain:

$$\frac{J}{\varepsilon}x = g(E) \text{ or } E = g^{-1}\left(\frac{J}{\varepsilon}x\right) \tag{7}$$

Where g^{-1} is the inverse function of g. We define another function $F = F(y)$ such that $dF/dy = g^{-1}(y)$ and integration of Eq. (7) with respect to x from $x = 0$ (injecting electrode) to $x = d$ (collecting electrode) gives:

$$\frac{VJ}{\varepsilon} = \left[F\left(\frac{dJ}{\varepsilon}\right) - F(0)\right] \tag{8}$$

Taking derivative of Eq. (8) with respect to J, we get:

$$G\left(\frac{V}{d} + \frac{J}{d}\frac{dV}{dJ}\right) = \frac{dJ}{\varepsilon} \tag{9}$$

Using Eq. (9) and experimental J–V characteristics, one can calculate the g as a function of E. For a fixed value of J, we can also find (from Eq. (7)) the $g(E)$ for different x. By comparing these two data set for $g(E)$, we can find out E as a function of x. The $n_{inj}(x)$ can be calculated using Eq. (6). Mobility (μ) as function of E can be determined using:

$$\mu = \frac{1}{E}\frac{dg(E)}{dE} \tag{10}$$

It can be seen from the Fig. 4, the mobility is field independent and very closely matches with earlier derived SCLC mobility assuming θ as 1. The field independent mobility confirms application of SCLC model to data on sapphire. Further, as required for SCLC mechanism, injected carrier density (at bias of 50 V) shown in the inset of Fig. 4a is significantly larger than thermally generated carrier density (Table 1).

In order to estimate the concentration of shallow traps, we have measured J–V characteristics for films on sapphire substrates at lower temperatures and results for temperatures in 300–75 K range are shown in Fig. 5a. It is seen that the J–V characteristics are non-hysteretic even at low temperatures though the value of J decreases significantly. In Fig. 5b, we plot the data's of Fig. 5a in log–log scale. It is seen that J–V characteristics at different temperatures converge to $V_c = 460$ V, indicating that the current is temperature independent (for $V = V_c$) and the activation energy is zero. The voltage V_c is related to trap density N_t by equation: $V_c = qN_t d^2/2\varepsilon_0\varepsilon_r$ [26]. Using this equation, we obtain $N_t = 9.8 \times 10^{20}/m^3$. The trap characteristic temperature T_t can be determined using exponent of J–V characteristics ($\alpha = l + 1$) determined at different temperatures from data of Fig. 5b. A plot of α versus $1/T$ is shown in the inset of Fig. 5a. Using $\alpha = l + 1 = T_t/T + 1$, the slope of the curve gives the value of T_t (~236 K). Using the values of N_t and T_t, we determine the value of P_0 using Eq. (4) as 1.9×10^{22} eV^{-1} m^{-3}. A transition from trap free SCLC regime at room temperature to exponentially distributed trap-controlled SCLC at low temperature can occur due to free carrier density at room temperature being higher than the trapped

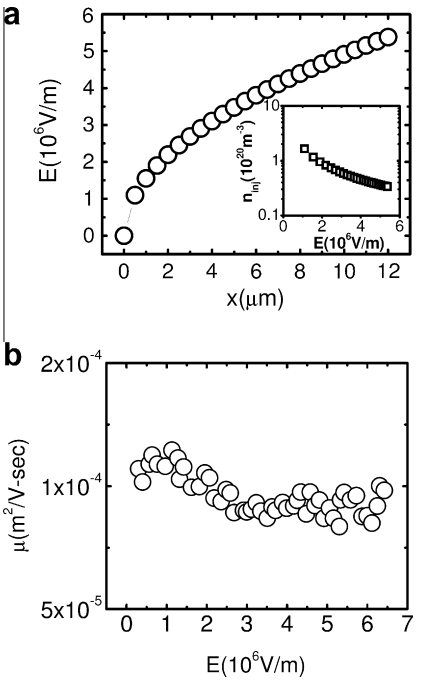

Fig. 4. (a) Spatial distribution of the electric field E at bias voltage of 50 V, inset shows the injected hole concentration n_{inj} (at bias of 50 V) as a function of field and (b) Field dependence of mobility for the films on Al_2O_3 substrates.

Table 1
Values of hole concentration (n_0), trap characteristics temperature (T_t), trap concentration per unit energy at valence band edge (P_0) and Mobility (μ), determined using J–V characteristics for CoPc films grown on (0001) Al_2O_3 and quartz substrates.

Films	n_0 (m^{-3})	T_t (K)	N_t (m^{-3})	P_0 (eV^{-1} m^{-3})	μ (m^2/Vs)
Quartz					
Increasing bias (12th scan)	2.5×10^{18}	600	4.5×10^{23}	8.7×10^{24}	
1st scan	4.5×10^{18}				1.2×10^{-4}
Vac. Ann.	5.5×10^{18}				1.9×10^{-4}
Al_2O_3 (0001)	9.6×10^{18}	236	9.8×10^{20}	1.9×10^{22}	9.8×10^{-5}

carrier density. However, as the temperature is reduced the free carrier density is reduced and the trapped carrier density increases, resulting in exponentially distributed trap-controlled SCLC characteristics.

The value of Fermi energy E_F (at room temperature) may be determined [using $n_0 = N_v \exp[-(E_v - E_F)/kT]$ from free carrier density (n_0) and literature value of effective density of states in valence band $N_V = 10^{27}\ m^{-3}$ to be 0.46 eV above valence band edge [22]. Schematic of trap distribution and band diagram is shown in Fig. 6. It is seen that the traps are on the average at $E_t \sim 0.1$ eV from E_v. Density of trapped carriers (n_{t0}) can be estimated from $n_{t0} = N_t \cdot \exp\{(E_t - E_F)/kT\}$ to be $\sim 5.5 \times 10^{14}/m^3$. A very small concentration of trapped carriers compared to n_0 justifies use of $\theta = 1$ in our analysis earlier.

Now we analyze room temperature data of J–V characteristics measured on quartz substrate [as shown in Fig. 3b]. As seen from Fig. 3b, the current reduces as J–V characteristics are scanned repeatedly. The hysteresis in characteristics is negligible for 1st scan, increases on further scans and characteristics stabilize after about 12 scans. In each scan, the current during increasing voltage is smaller than that during decreasing voltage. The results indicate that trap states are created (on application of voltage) as the J–Vs are measured resulting in reduced current

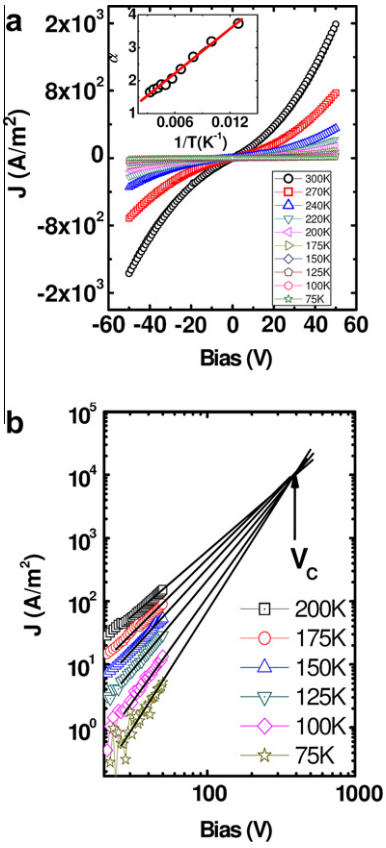

Fig. 5. (a) Temperature dependence of J–V characteristics for films on Al_2O_3 substrate. Inset shows the temperature dependence of exponent (α, J–V^{α}) (b) Power law fit of data of Fig. 5(a). The fits meet at cross over voltage $V_c = 460$ V.

after each scan. Similar bias dependent generation of charge traps has been reported in the other organic semiconductors, such as, pentacene single crystals, polyfluorene etc. [27–29]. Fig. 7a shows the stability of the room temperature J–V characteristics obtained after 12th scan. Higher current during reducing voltage (12th scan) is attributed to filling of deep trap states during increasing current part of scan. This is also indicated by V^2 dependence of current on voltage during reducing voltage scan in Fig. 7b, as the deep traps are filled and shallow trap characteristics (of Eq. (2)) are realized. To confirm that the traps are created by adsorbed oxygen, film was vacuum annealed and characteristics were measured in vacuum. The results are shown in the inset of Fig. 3b. It is found that the current density is higher than in 1st scan in air, due to annealing of trap states on removal of oxygen (removal of oxygen was independently confirmed by XPS, data not shown here).

Now we analyze the J–V characteristics of 1st scan and vacuum annealed sample. We note that the current density at each voltage is quite large (similar to that on sapphire) and V^2 dependence of current indicates SCLC mechanism with shallow traps (shown in the inset of Fig. 3b). This is also indicated by absence of hysteresis that arises on filling of deep traps. Analysis of linear and SCLC characteristics (assuming $\theta = 1$) using Eqs. (1) and (2) yield mobility and free carrier density as given in Table 1. The trap distribution during 12th scans can be estimated using the increasing part of J–V characteristics shown in Fig. 7b. We find that in the bias range >25 V, exponent $\alpha = l + 1 = 3$. This implies that the value of trap characteristic temperature T_t (defined as: $l = T_t/T$) is 600 K. The value of the trap density per unit energy range at valence band edge (P_0), estimated (using Eq. (3)) from slope of J–V plot and literature value of $N_V = 10^{27}\ m^{-3}$ [22], is $8.7 \times 10^{24}\ eV^{-1}\ m^{-3}$. We have used mobility value as determined from characteristics of 1st scan. The mobility for 12th scan may not be calculated as there could be large number of trapped carriers and value of θ is not known. Value of $\theta\mu$ may however be calculated using slope J–V^2 part of the characteristics and Eq. (2). This is found to be nearly five times lower at $2.5 \times 10^{-5}\ m^2/V\text{-}s$ and is minimum value of mobility assuming limiting value of $\theta = 1$. Using this value of mobility, estimated trap density is $2.6 \times 10^{25}\ eV^{-1}\ m^{-3}$, i.e., a factor of nearly 3 higher compared to that given earlier and this is maximum possible error in calculation of trap density. Total concentration of traps (N_t) given in Table 1, has been calculated from the value of P_0 and T_t using Eq. (4) [22]. Thermally generated hole concentration (n_0) for increasing current (of 12th scan) has been estimated from ratio of conductivity of 1st and 12th scan and the hole concentration of 1st scan. Values of parameters T_t, N_t and P_0, as given in Table 1, are within the range of reported values for various metal phathalocyanines [22]. A significantly smaller value of n_0 for 12th scan (compared to first scan) indicates large number of trapped carriers in this case.

As seen by data of Fig. 7c, the hysteresis in J–V characteristics is a function of maximum bias applied. This is understandable as with the increasing applied bias more and more traps gets filled, which results in increase in the hysteresis. As seen earlier, application of bias also re-

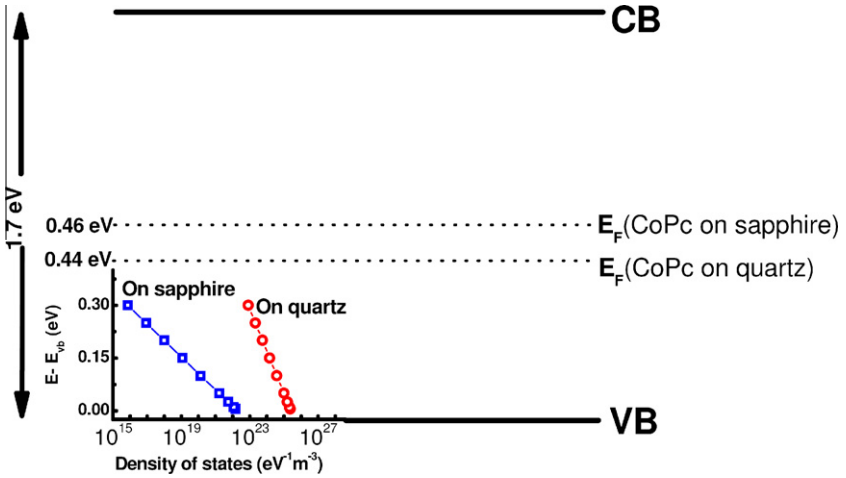

Fig. 6. Fermi energy levels (E_F) position is shown with respect to the conduction band and valence band for films grown on sapphire and quartz. In the left side show the plot of density of traps states as a function of energy.

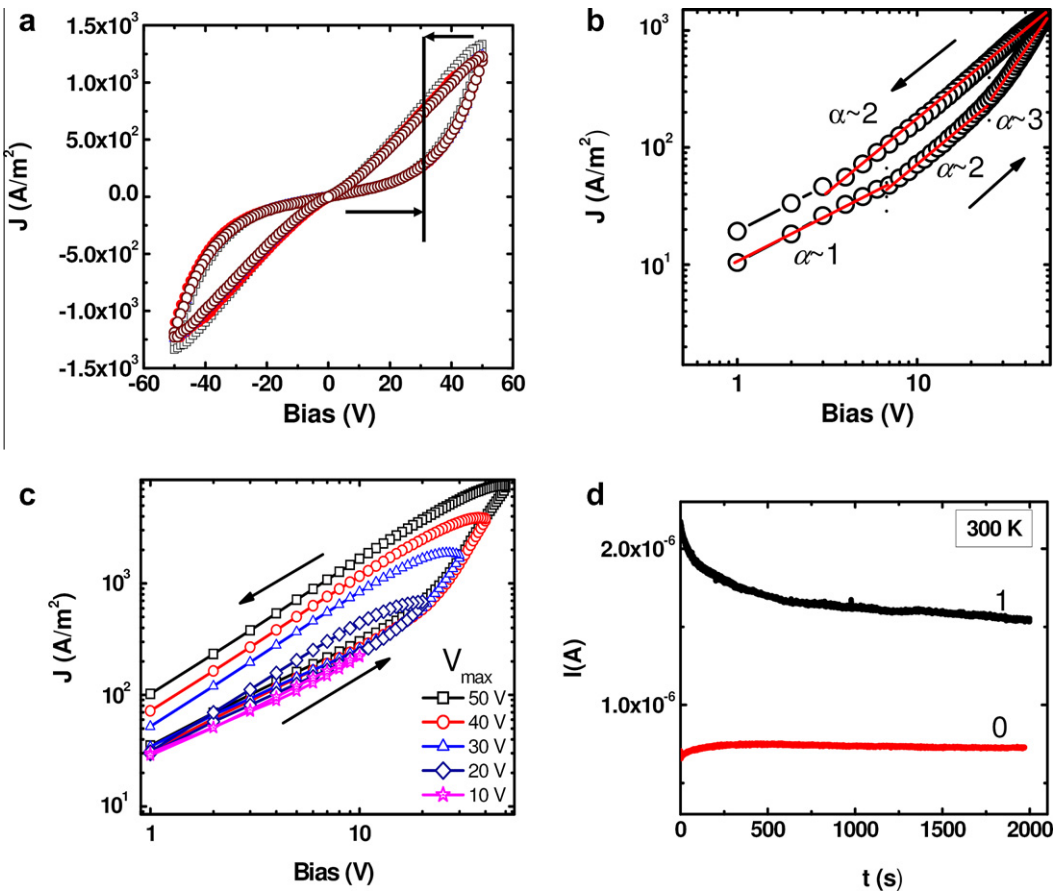

Fig. 7. (a) Stable *J–V* data (obtained after12th bias scan) for CoPc films on quartz substrates; (b) log *J* – log *V* data (at 300 K) plot for data of Fig. 7(a); (c) *J–V* characteristics for different voltage sweep range (as indicated in the figure). (d) High (i.e. denoted by 1) and low conducting state (i.e. denoted by 0) of the CoPc films on quartz substrate. 1 state is obtained by application of + 50 volts for 100 s. and read at + 30 volt, 0 state is obtained by application of 0 volts and read at + 30 volt. The arrow marked in Fig 7(a) shows the bias sequence applied to obtain 1 and 0 states.

sults in creation of traps and some increase in hysteresis on increasing bias could be due to such additional traps. Stability of two high and low conduction states was studied by measurement of time dependence of current at 30 V by ramping bias from 50 to 30 V and 0 to 30 V and the results are shown in Fig. 7d. We may like to add

that hysteresis with current ratio of 10^9 has been reported in the organic semiconductors based devices. In most of these devices the metal nano-particles have been embedded in organic/polymer matrix to achieve the bistability [30]. Hysteresis in the present case is intrinsic to the films and arises due to oxygen induced deep traps in the films on quartz.

For films grown on quartz substrates, as shown in Fig. 8a, the hysteresis decreases systematically with lowering temperature, and eventually vanishes at 220 K. Moreover, below 150 K, films do not transport any current. As shown in the inset of Fig. 8a, the value of α decreases with lowering temperature and becomes <2 for temperatures below 230 K. This implies in the temperature range 230 – 150 K, the SCLC transport mechanism is not valid. This is because due to disorder present in the films, at low temperatures there is strong charge localization, density of free carriers is very small and conduction occurs by hopping of trapped charges.

The charge transport mechanisms in temperature range 230–150 K were analyzed using Poole-Frankel (PF) and Schottky-emission (SC) models. The PF effect essentially is a field-assisted lowering of the coulomb potential barrier of the trap levels, which is given by the expression: $\Delta\phi = \beta_{PF}V^{1/2}/d^{1/2}$ where $\beta_{PF} = (e^3/\pi\varepsilon_0\varepsilon_r)^{1/2}$ is the PF field lowering coefficient. The J–V characteristics in this case are described by [22]:

$$J = J_0 \exp(-\frac{\beta_{PF}V^{1/2}}{kTd^{1/2}}) \tag{11}$$

The electrode-limited analogue of PF effect is Schottky effect [22]. In this case due to field-assisted lowering of a potential barrier at the injection electrode J–V characteristics are given by:

$$J = AT^2 \exp(-\frac{\phi_0}{kT}) \exp(\frac{\beta_s V^{1/2}}{kTd^{1/2}}) \tag{12}$$

Where A is Richardson constant $A = \frac{4\pi mk^2e}{h^3}$ $\mathrm{Am^{-2}K^{-2}}$, m and e are the mass and charge of the charge carries, h is the Planck constant, φ_0 is the Schottky barrier height at injecting electrode interface, k is boltzmann constant and, β_S is the Schottky field lowering coefficient. In principle the Schottky and PF effects can be distinguished by the measured value of field lowering coefficient, which is twice as high in the PF case as in Schottky case.

$$2\beta_S = \beta_{PF} = (\frac{e^3}{\pi\varepsilon_0\varepsilon_r})^{1/2} \tag{13}$$

For phthalocyanines, the theoretically determined values for PF and Schottky field lowering coefficients are $\beta_{PF} \sim 4 \times 10^{-5}\ \mathrm{eVm^{1/2}\,V^{-1/2}}$ and $\beta_S \sim 2 \times 10^{-5}\ \mathrm{eVm^{1/2}\,V^{-1/2}}$ [22].

Linear dependence of $\ln J$ on $V^{1/2}$ for $T < 220$ K, as shown in Fig. 8b, indicates agreement with PF or SC model. Average value of β determined from slopes of characteristics at different temperatures was found to be $\sim 3.5 \times 10^{-5}\ \mathrm{eVm^{1/2}\,V^{-1/2}}$. Value of β was also calculated from the slope of $\ln J$ versus $1/T$ (measured at 50 V) characteristics shown in inset of Fig. 8b to be $4.7 \times 10^{-5}\ \mathrm{eVm^{1/2}\,V^{-1/2}}$. These values of β indicate PF mechanism of charge transport. We may note that contact dominated SC mechanism, if present, should be more dominant for films on sapphire substrates due to higher current density (at low temperatures). The absence of SC transport in sapphire supports absence of SC and presence of PF mechanism for quartz substrate.

4. Conclusions

By carrying out the temperature dependent J–V measurements of 100 nm thick CoPc films grown under identical conditions on single crystal Al_2O_3 and quartz substrates – we have demonstrated that charge transport is strongly governed by the structural disorders present in the films. The films grown on Al_2O_3 are polycrystalline and have densely packed molecules, which exhibit non-hysteretic J–V characteristics. On the other hand, films grown on quartz substrates are more disordered and exhibit hysteretic J–V characteristics. This difference in charge transport is attributed to the chemisorbed oxygen present in the films grown on quartz substrates owing to the disordered nature. The chemisorbed oxygen acts as charge traps. For films grown

on Al_2O_3, the *J–V* characteristics are well described by SCLC mechanism in the temperature range of 300–75 K. However, for the films grown on quartz substrates, a change in charge transport mechanism from SCLC to PF with lowering temperature has been observed.

ABSTRACT

The deep blue fluorescent spiro-type dopant materials *N,N,N′,N′*-tetraphenylspiro[fluorene-7,9′-benzofluorene] (**SFBF**)-5,9-diamine (BD-6DPA), *N,N′*-di-(2-naphthyl)-*N,N′*-diphenyl-**SFBF**-5,9-diamine (BD-6NPA), *N,N′*-diphenyl-*N,N′*-di-*m*-tolyl-**SFBF**-5,9-diamine (BD-6MDPA) and *N,N′*-diphenyl-*N,N′*-bis(4-(trimethylsilyl)phenyl)-**SFBF**-5,9-diamine (BD-6TMSA) were designed and successfully prepared by amination reactions. The EL characteristics of MADN as the blue host material doped with the above blue dopant materials were evaluated. The electroluminescence spectra of ITO/*N,N′-diphenyl-N,N′*-bis-[4-(phenyl-*m*-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD/*N,N′*-di(1-naphthyl)-*N,N′*-diphenylbenzidine (NPB)/2-methyl-9,10-di(2-naphthyl)anthracene (MADN):BD-6MDPA/tris(8-hydroxyquinoline)aluminum (Alq_3)/LiF/Al devices show a narrow emission band with a full width at half maximum of 48 nm and a $\lambda_{max}(\varepsilon)$ = 463 nm. The device obtained from MADN doped with BD-6MDPA showed a good color purity (0.135, 0.156), high luminance efficiency (9.11 cd/A at 6.5 V) and high external quantum efficiency (8.16%).

1. Introduction

Organic light emitting diodes (OLEDs) have attracted considerable attention due to their many advantages for commercial applications, such as their high brightness, low power consumption, capability of emitting a wide range of colors, and applications in full color organic displays [1]. For full color displays, three primary colors (red, green, blue) are necessary. Many new materials with red, green, and blue emitting colors have been developed to meet these requirements [2]. Developing blue light emitters is essential for the development of full color displays. In spite of the considerable advances that have been made in the field of OLEDs, it is difficult to find appropriate blue emitting materials because of their low solution and low solid-state photoluminescence (PL) quantum yields [3]. OLED devices have a short lifetime because of the deterioration of the luminescent layers. Their lifetimes can be lengthened by the introduction of thermally stable substituents on the host and dopant materials [4]. Generally, host and supporting layer materials having a high glass transition temperature are needed to obtain a long lifetime. Especially, the lifetime of the luminescent layers is closely related to the specific host material in use [5].

The color purity of a blue light emitter is determined by the dopant, and is improved by shifting the emission region to a shorter wavelength. The maximum emission range of some commercial dopant materials are close to the blue sky region (450–470 nm), but wavelengths lower than 450 nm are also considered to have reasonable color purity [6,7]. In addition, many problems still remain to be solved regarding durability over time due to long-term usage, and deterioration caused by oxygen and moisture in air. In addition, many other problems remain related to the need for good color purity of blue luminescence in applications such as full color displays [8].

On the other hand, spiro compounds with specific steric configurations has been attracting attention as an organic functional material because of the specific physical properties of the material, such as high glass transition temperature, which makes them a very promising approach for optoelectric materials [9]. Much of the recent research into blue light-emitting materials has centered on spiro-based derivatives because of their high solution and solid-state photoluminescence quantum yields [10]. Representative organic spiro materials as blue light-emitting materials include spiro-oligophenyl [11], spirofluorenes (**SFs**) with asymmetric substitution [12],spiro-substituted **SF** [13], **SF**-linked phenylanthracene [14] and anthracene [15], heteroatom-substituted spiro compounds [16], pyrene-substituted **SFs** [17] and difluorene-indenofluorene compounds [18]. Many studies have dealt with the spiro[fluorene-7,9′-benzofluorene] (**SFBF**) as organic electroluminescent host materials. The performance of OLEDs (the color purity and luminescence efficiency) based on **SFBF** was determined by the position of substitution and aryl moieties with a variety of conjugation chain length [19].

In this study, we report the synthesis of a series of new deep-blue emitting dopant materials, *N,N,N′,N′*-tetraphenyl-**SFBF**-5,9-diamine(BD-6DPA), *N,N′*-di-(2-naphthyl)-*N,N′*-diphenyl-**SFBF**-5,9-diamine (BD-6NPA), *N,N′*-diphenyl- *N,N′*-di-*m*-tolyl-**SFBF**-5,9-diamine (BD-6MDPA) and *N,N′*-diphenyl-*N,N′*-bis(4-(trimethylsilyl)phenyl)-**SFBF**-5,9-diamine (BD-6TMSA) by amination reactions of both 5- and 9-positions on the **SFBF**. Multilayered OLEDs were fabricated by using these deep-blue materials as the emitting layer and the dopant for MADN. A high quantum efficiency of 8.16% with CIE coordinates of (0.135, 0/156) was achieved, and this is one of the best efficiency value of deep blue fluorescence OLEDs ever reported in the literature.

2. Experimental

2.1. Materials and measurements

Tetrakis(triphenylphosphine)palladium(0) and bromine (Aldrich Chem. Co.) were used without further purification. Diphenyl-[4-(2-[1,1;4,1]terphenyl-4-yl-vinyl)-phenyl]-amine (BD-1) and 2-methyl-9,10-di(2-naphthyl)anthracene (MADN) were prepared using a method reported elsewhere [22]. Tetrahydrofuran and toluene were distilled over sodium and calcium hydride. Diphenylamine, *N*-phenyl-2-naphthylamine and 3-methyldiphenylamine (Aldrich Chem. Co.) were used as received. *N*-phenyl-4-(trimethylsilyl)aniline was prepared by the literature method previously reported [23]. Tri-*t*-butylphosphine, potassium *t*-butoxide (Aldrich Chem. Co.), palladium(II) acetate (TCI Co.) were used as received for amination. 5-Bromo-**SFBF** and 5,9-bromo-**SFBF** [19] were prepared as previously reported.

The FT-IR spectra were obtained using a Biorad Excaliber FTS-3000MX spectrophotometer, and the ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker Avance 500 (500 MHz for ^{1}H and 125 MHz for ^{13}C) spectrometer. The photoluminescence (PL) spectra were recorded on a fluorescence spectrophotometer (Jasco FP-6500) and the UV–vis spectra were obtained using a UV–vis spectrophotometer (Shimadzu, UV-1601PC). Elemental analyses were performed using a CE Instrument (EA1110), and the differential scanning calorimetry (DSC) measurements were performed using a Mettler DSC 822^{e} under nitrogen at a heating rate of 10 °C/min. The low and high resolution mass spectra were recorded using a mass spectrometer (JEOL, JMS-AX505WA) in FAB mode. The energy levels were measured using a low energy photoelectron spectrometer (Riken-Keiki AC-2). The current–voltage characteristics of the encapsulated devices were measured using a Keithley 2400 source measurement unit and CS 1000 spectroradiometer.

2.2. General procedure for the coupling reaction

The 5,9-dibromo-**SFBF** (**1**) (5 g, 9.53 mmol), diarylamine derivative (24.79 mmol) and palladium acetate (0.150 g, 0.67 mmol) were dissolved in anhydrous toluene under nitrogen atmosphere. To the reaction mixture was added a solution of tri-*t*-butylphosphine (1 M, 0.42 g, 1.91 mmol) and potassium *t*-butoxide (4.28 g, 38.15 mmol) dropwise slowly. The reaction mixture was stirred for 12 h at 100 °C. The mixture was diluted with dichloromethane and washed with distilled water (150 mL) three times. The organic layer was dried over anhydrous $MgSO_4$ and evaporated in vacuo to give the crude product, which was purified by column chromatography by *n*-hexane. The final product was obtained, a yellow-green powder.

2.3. OLED fabrication

A basic device configuration of indium tin oxide(ITO, 150 nm)/*N,N′*-diphenyl-*N,N′*-bis-[4-(phenyl-*m*-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD, 60 nm)/*N,N′*-di(1-naphthyl)-*N,N′*-diphenylbenzidine (α-NPB, 30 nm)/2-methyl-9,10-di(2-naphthyl) anthracene (MADN): dopant (30 nm, x%)/tris(8-hydroxyquinoline)aluminum (Alq_3, 20 nm)/LiF (1 nm)/Al (200 nm) was used for device fabrication. All organic materials except for dopants were deposited at a deposition rate of 1 Å/s. The doping concentration of the dopant materials was varied at 3, 5 and 7%. The devices were encapsulated with a glass lid and a CaO getter after cathode deposition. Current density–voltage-luminance and electroluminescence characteristics of the blue fluorescent OLEDs were measured with a Keithley 2400 source measurement unit and CS 1000 spectroradiometer. Lifetime measurement of the blue OLEDs was carried out at a luminance of 5000 cdm^{-2} at constant current mode.

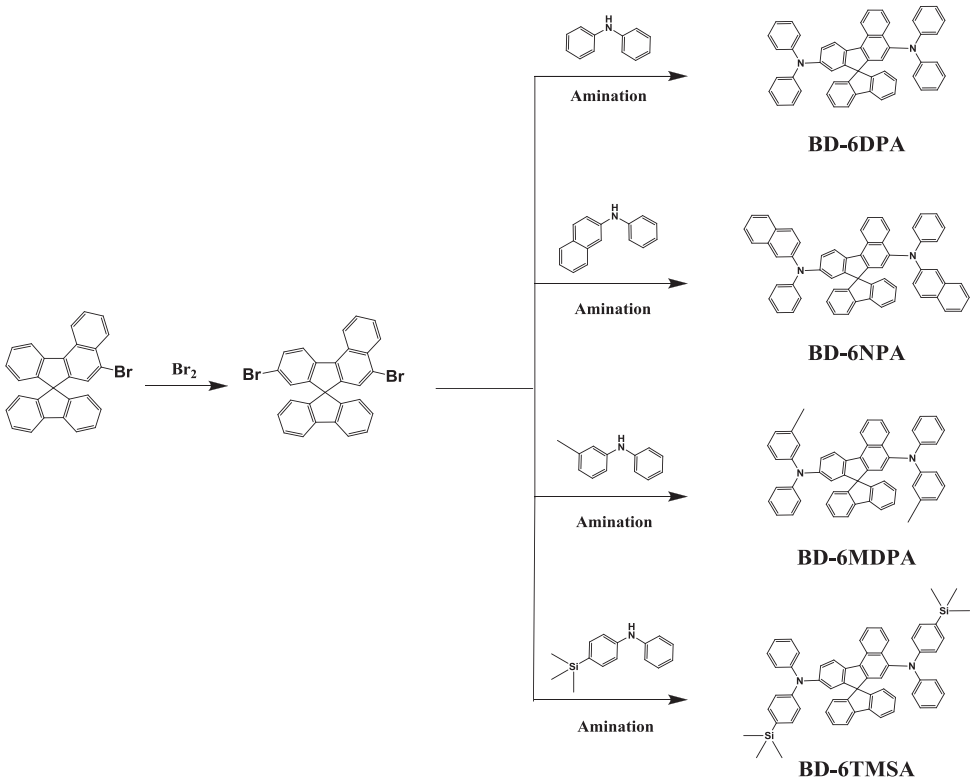
3. Results and discussion

3.1. Synthesis and characterization

The key intermediate in this synthesis is the introduction of diarylamine substituents into the 5- and 9-position of the **SFBF** by amination reactions, to tune the electro-optical properties of the deep-blue emitting dopant materials. 5,9-Dibromo- **SFBF** (**1**) was prepared by selective bromination of **SFBF** via 5-bromo-**SFBF** using carbon tetrachloride and chloroform solvent as shown in Scheme 1. The dopant materials *N,N,N′,N′*-tetraphenyl-**SFBF**-5,9-diamine (BD-6DPA), *N,N′*-di-(2-naphthyl)-*N,N′*-diphenyl-**SFBF**-5,9-diamine (BD-6NPA), *N,N′*-diphenyl-*N,N′*-dim-tolyl-**SFBF**-5,9-diamine (BD-6MDPA) and *N,N′*-diphenyl-*N,N′*-bis(4-(trimethylsilyl)phenyl)-**SFBF**-5,9-diamine (BD-6TMSA) were prepared by amination reactions of compounds **1** with diphenylamine, *N*-phenyl-2-naphthylamine, 3-methyldiphenylamine and *N*-phenyl-4-(trimethylsilyl)aniline in the presence of a palladium catalyst. The synthetic routes to the four dopant materials are described in Scheme 1. The chemical structures and compositions of the resulting precursor and spiro-compounds were characterized by ^{1}H NMR, ^{13}C NMR, FT-IR and GC–MS.

3.2. Optical properties and energy levels

Table 1 shows the UV–vis absorption and photoluminescence (PL) spectra data of the dopant materials, respectively. The solution absorption maxima of BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA showed at 407, 411, 408 and 407 nm, respectively, whereas the BD-6 series showed at 416, 421, 416 and 413 nm in film. The emission maximum of BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA were located at 478, 464, 468 and 459 nm in solution, respectively, whereas the BD-6 series showed an absorption maximum at 484, 491, 487 and 484 nm in film. The introduction of a diphenylamine group to both the 5- and 9-positions in **SFBF** caused a significant red-shift in



Scheme 1. Synthetic scheme and chemical structure of dopant materials.

Table 1
UV absorption, PL, energy levels and thermal properties of four dopant materials.

Properties	Abs (nm)		PL (nm)		Energy level (eV)		Thermal properties (°C)			Φ_f[a]
Sample	Solution	Film	Solution	Film	HOMO	LUMO	T_g	T_m	T_d	
BD-6DPA	407	416	478	484	5.48	2.77	120	270	429	0.747
BD-6NPA	411	421	464	491	5.44	2.77	154	295	477	0.656

[a] Fluorescence quantum efficiency, relative to 9,10-diphenylanthracene in cyclohexane (Φ_f = 0.90).

the PL spectrum of BD-6DPA to 478 nm as a result of increased electron donation. The solution fluorescence quantum efficiency (Φ_f) of dopant materials are 0.65 and 0.75, which were determined relative to 9,10-diphenylanthracene in cyclohexane (Φ_f = 0.90). The relatively higher fluorescence quantum efficiency values of BD-6DPA and BD-6MDPA compared to those of BD-6NPA and BD-6TMSA is due to the introduction of the phenyl and tolyl group, which maintains the intermolecular interaction between the emitting materials. A molecular simulation of DPA, NPA, MDPA and TMSA was carried out to understand the physical properties of DPA, NPA, MDPA and TMSA at the molecular level. Density functional theory (DFT) calculations have also been performed to characterize the three-dimensional geometries and the frontier molecular orbital energy levels of DPA, NPA, MDPA and TMSA at the B3LYP/6-31G* level [20] by using the Gaussian 03 program. The optimized structures and the HOMO/LUMO orbitals for DPA, NPA, MDPA and TMS are shown in Fig. 2. Energy gaps for DPA, NPA, MDPA and TMSA were calculated as 3.31 eV, 3.25 eV, 3.31 eV, and 3.30 eV, which corresponded to the absorption wavelengths of 416, 421, 416, and 413 nm, respectively. The calculated geometries of DPA, NPA, MDPA and TMSA in Fig. 1 show that the fluorene and benzofluorene are significantly twisted against each other because of the spiro center, resulting in a non-coplanar structure in each molecule. These geometrical characteristics can effectively prevent intermolecular interactions between π-systems and, thus, suppress molecular recrystallization, which improves the morphological stability of these molecules. Calculated highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) density maps of DPA, NPA, MDPA and TMSA are also included in Fig. 1. The electron densities of the HOMOs and

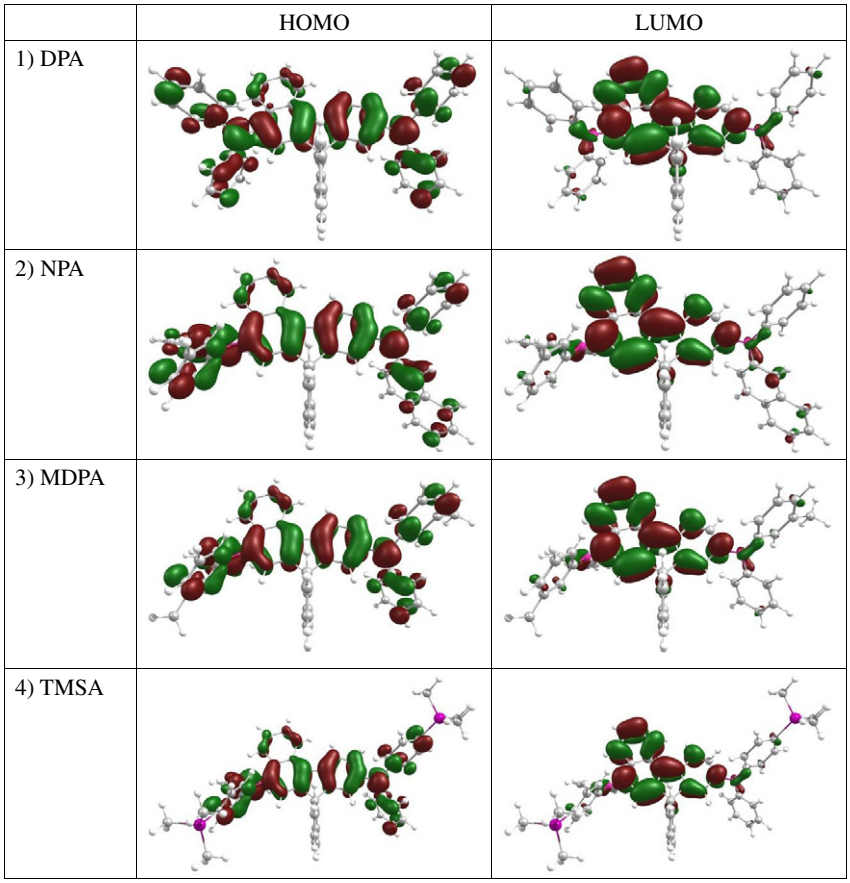

Fig. 1. Molecular simulation results of (a) DPA, (b) NPA, (c) MDPA, and (d) TMSA , showing the HOMO and LUMO orbital distribution (calculated at the DFT/B3LYP/6-31G* for optimization and Time Dependent DFT (TDDFT) using Gaussian 03).

LUMOs are mostly localized on the benzofluorene unit, implying that the absorption and emission processes can only be attributed to the π–π^* transition centered at the benzofluorene unit. As a result, the molecular orbital analysis clearly indicates that the substituents in fluorene unit do not influence the blue emission at all.

3.3. Thermal properties

The thermal properties of the resulting deep-blue emitting materials were characterized with DSC and TGA in a nitrogen atmosphere. The onset decomposition temperatures were 429, 477, 436 and 437 °C for BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA, respectively. Table 1 summarizes the DSC and TGA data for four dopant materials. The purified samples of BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA showed a melting point (T_m) of 270, 295, 248 and 256 °C, respectively. On the second heating, no melting points were observed, even though it was given enough time to cool in air. Once it becomes an amorphous solid, it does not revert to the crystalline state at all. After the sample had cooled to room temperature, a second DSC scan performed at 10 °C/min revealed a high glass transition temperature (T_g) between 120 and 154 °C because of their rigid spiro-type backbone. As a result, the amorphous glassy state of the transparent film of the four dopant materials was a good candidate as an EL material. This suggests that thermal stability was improved significantly by the introduction of various diarylamine groups.

3.4. EL properties

In order to find an optimized dopant concentration, EL spectra were gathered of MADN doped by BD-6 series dopants with different weight concentrations. The emission band increases with the increase of dopant concentration from 3 to 7% by weight. However, it is noted that CIE color coordinates of blue emission did not deviate from deep blue when the doping concentration of BD-6MDPA dopant increases from 5 to 7%. The CIE coordinates of the four devices made of MADN: 7%, 5%, 3%, 0% BD-6MDPA were (0.135, 0.153), (0. 135, 0.156), (0.138, 0.144) and (0.154, 0.164), respectively. It was found that sufficiently deep-blue emission was obtained in the sample with 5% concentration of BD-6MDPA with the CIE coordinates (0.135, 0.156).

OLEDs were fabricated by thermal evaporation onto a cleaned glass substrate precoated with transparent and conductive indium tin oxide (ITO). All the organic layers were grown by thermal evaporation at a deposition rate

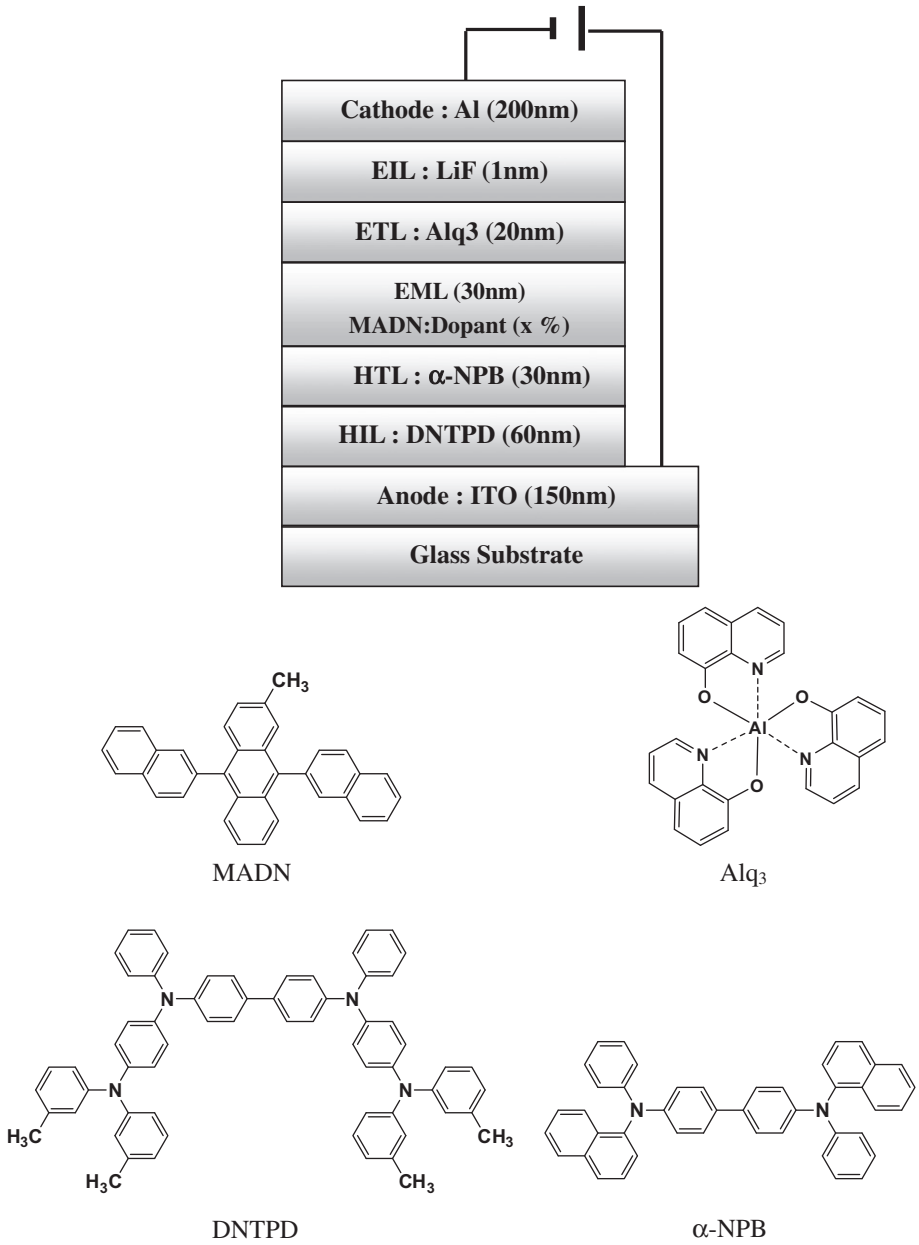

Fig. 2. The device configuration and the chemical structure of the materials used in the devices.

of 1 Å/s. The EL properties of the BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA dopant materials were examined by fabricating multilayer devices with the following configuration: glass ITO anode/HIL/HTL/EML/ETL/EIL/Al cathode. DNTPD was used as the HIL, α-NPB as the HTL, MADN:5% dopant as the EML and Alq3 as the ETL; a 10 Å LiF layer was used as the EIL, as shown in Fig. 2.

Fig. 3 shows the normalized EL spectra of a device composed of MADN doped with BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA at 7 V. All the devices showed intense blue emission in the EL spectra at 465, 463, 462 and 462, respectively. The maximum wavelength of the EL spectra varied significantly according to the dopant material. Based on the EL spectrum, the CIE coordinates of the emitting layer MADN doped with 5% BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA were measured to be (0.135, 0.175), (0.134, 0.168), (0.135, 0.156) and (0.135, 0.151), respectively.

3.5. OLED device properties

Figs. 4 and 5 shows the luminance–voltage and current density–voltage characteristics of the OLEDs with MADN:5% dopant as the EML. The threshold voltage for

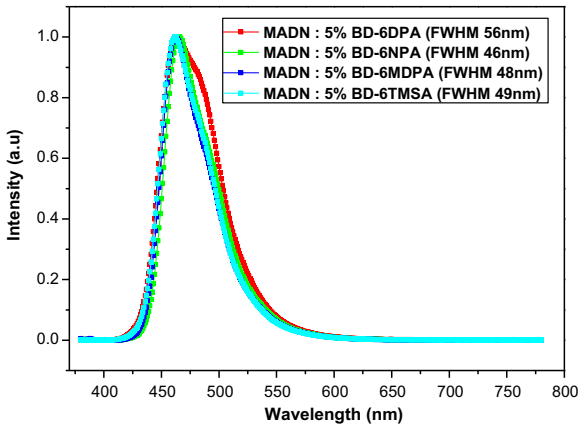

Fig. 3. EL spectra of the devices obtained from MADN host doped with various dopant materials.

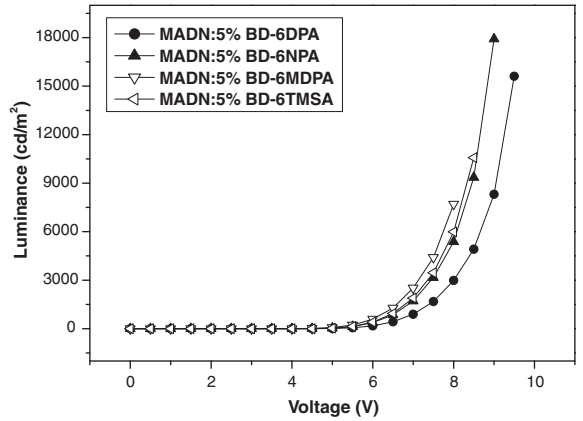

Fig. 4. Luminance–voltage characteristics of the device using MADN:5% dopant.

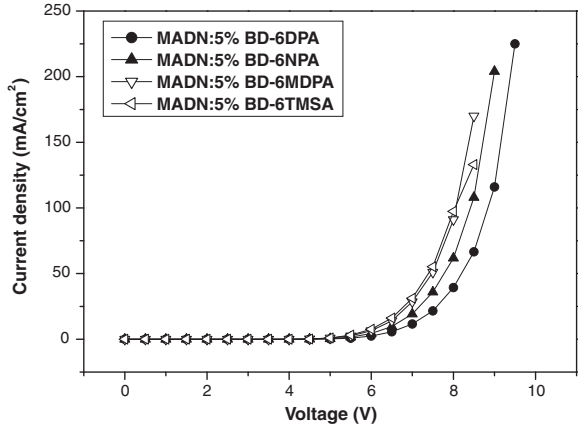

Fig. 5. Current density–voltage characteristics of the device using MADN:5% dopant.

luminescence was about 4.5 V in all the devices. In the case of the device using MADN doped with 5% BD-6MDPA, the maximum brightness of 7699 cdm^{-2} occurs at approximately 8.0 V. Table 2 summarizes the device characteristics at 7 V.

The luminance efficiency of the devices made using MADN:5% dopant were more than 4–6 times higher those of the device without the dopant. This suggests that the dopant is significantly effective in enhancing the EL properties of the spiro-type emitting layer.

The maximum power efficiency of the device obtained from MADN doped with 5% BD-6MDPA was 6.13 l mW^{-1}, which is five times that of the device without the dopant (1.28 l mW^{-1}). The device shows the maximum EQE of 7.95% and the efficiency increased rapidly to a maximum of approximately 8.84 cd A^{-1} at a low current density of 28.50 mA cm^{-2} at 7 V. The holes injected from α-NPB as HTL is transferred to the blue lighting layer and can be trapped to dopant sites. HOMO values of four dopant materials decreased in the order of BD-6DPA (5.48) > BD-6TMSA (5.45) > BD-6NPA (5.44) > BD-6MDPA (5.42). In the case of BD-6DPA having a little difference between the HOMO values of dopant and host materials, the holes from NPB were transferred to ETL as well as EML to causing the loss of holes. However the BD-6MDPA have the large capacity to catch the holes strongly, they minimized the loss of holes to result in the good electroluminescent efficiency. Thus the HOMO level of BD-6MDPA is suitable for holes trapping and the hole transporting properties of the dopant and MADN host is appropriate for balancing holes and electrons in the emitting layer. There was a large difference in EL efficiency between BD-6DPA and BD-6MDPA, even though both materials have almost same PL efficiencies and spectra.

Fig. 6 shows the dependence of luminescence efficiency on the current density of four devices. It can be seen that MADN doped with 5% BD-6NPA shows high efficiency and a small decrease of efficiency as the current density increased from 0 to 175 mA cm^{-2}, *i.e.*, a weak-current-induced fluorescent quenching. It reached a current efficiency of 8.56 cd A^{-1}. This suggests that an exciton is formed and light is emitted at specific thresholds. It should be noted that the efficiencies of these devices remained stable when the current density was increased to 175 mA cm^{-2}. The PL spectrum of MADN overlaps with a major portion of the absorption spectrum of BD-6MDPA. This indicates that BD-6MDPA can effectively accept energy from the host through Förster energy transfer or function as a direct recombination center due to the higher HOMO levels [21]. By using BD-6TMSA as the fluorescent dopant, the PE was successfully enhanced to 5.12 l mW^{-1}, which is four times higher than that of the undoped device. The EQE of OLEDs using BD-6TMSA as the fluorescent dopant with a doping concentration of 5 wt.% was 7.43% with CIE coordinates of (0.135, 0.151).

The device with MADN:5% BD-6-MDPA as EML shows the maximum EQE 8.16% at a current density of 14.0 mA cm^{-2} (6.5 V, 1275 cd m^{-2}) with an luminance efficiency of 9.11 cd A^{-1}, power efficiency of l mW^{-1} and the CIE coordinates of (0.135, 0.157). To our knowledge, this is one of the highest EQE in deep-blue OLEDs. Combined

good efficiency and color purity enables the dopant materials to be a good candidate as a deep-blue emitter for OLEDs.

Among synthesized compounds, the lifetime of BD-6MDPA, which showed the best EL efficiency in this series, was measured as the operational lifetime ($t_{1/2}$) of the blue devices under initial luminance of 5000 cd/m^2 at a constant current. Its lifetime (168 h@2.33 mA) was more than that of MADN:5% BD-1 (154 h@2 mA) as shown in Fig. 7.

4. Conclusion

A series of new deep-blue light emitting spiro-type dopant materials (BD-6DPA, BD-6NPA, BD-6MDPA and BD-6TMSA) were successfully prepared by amination reactions of 5,9-dibromo-**SFBF** with various diarylamines. When the device configuration of ITO/DNTPD/NPB/MADN:dopant/Alq_3/LiF/Al was constructed, the EL emissions of the devices (doped with 5% BD-6MDPA) are observed at 463 nm. In optimized structures, the device obtained using MADN:5% BD-6MDPA had greatest resulted in high performance OLEDs with a high external quantum efficiency of 8.16% and deep-blue emission, having CIE coordinates (0.135, 0/156). According to these characteristics, these deep-blue emitting materials have sufficient potential for display applications.

ABSTRACT

Blends of copper phthalocyanine (CuPc) and fullerene (C_{60}) have successfully been used for organic field-effect transistors and photovoltaic cells. In this work we investigate the unoccupied states of CuPc/C_{60} blends by inverse photoemission spectroscopy. The energies of the lowest unoccupied molecular orbitals of CuPc and C_{60} vary linearly with the mixing ratio, which is consistent with the energy shifts of the vacuum level, the highest occupied molecular orbitals and core levels. The observed results can be interpreted as unchanged electron affinities of CuPc and C_{60} in the blended films due to nano-phase separation.

1. Introduction

Donor/acceptor (DA) blends have been used for improving the performance of various organic electronic devices so far. For example, DA blended films were introduced in organic photovoltaics (OPVs) as an active layer. Using blends the power conversion efficiency of small molecule-based OPVs has been improved significantly [1–4]. The success in employing DA blends for OPVs is due to an increase in the magnitude of the DA interface and improved efficiency of exciton dissociation, which consequently enhances the photocurrent. DA blended films have also been used in organic field-effect transistors (OFETs) leading to ambipolar character, where balanced mobility can be adjusted by the mixing ratio of the DA blend [5].

For understanding and describing the performance of these devices, knowledge on the electronic structure of the DA blend is important. Previously, Opitz et al. investigated the occupied states of CuPc/C_{60} blends with ultraviolet photoelectron spectroscopy (UPS) and X-ray photoelectron spectroscopy (XPS) [6]. It was found that the vacuum level, the highest occupied molecular orbitals (HOMOs) and core levels vary linearly with C_{60} concentration. Recently, the investigation of the electronic structure in occupied states has also been extended to P3HT/PCBM blended films for bulk heterojunction OPVs by Xu et al. [7]. However, the unoccupied states in DA blends have been elusive. So far, the energies of the lowest unoccupied molecular orbitals (LUMOs) in the blended films have only been estimated using the band gaps of neat films of donor and acceptor, which assume that the energy shift of the LUMO is the same as that of the HOMO. However, recently, it was found that the change in the polarization energy leads to the opposite shift of the LUMOs and HOMOs at the planar C_{60}/CuPc interface [8]. These results suggest that the constant band gap is not always a valid assumption at

an interface, and that the direct measurements of the energies of the LUMOs for donor and acceptor are important to understand the dominant factor which determines the electronic structure.

In this letter, we have investigated the LUMO energies in CuPc/C_{60} blends with various mixing ratios by inverse photoemission spectroscopy (IPES), which can detect the energies of unoccupied states, directly [9]. We found that the LUMOs of CuPc and C_{60} vary linearly with increasing C_{60} concentration. This trend is consistent with the results on the vacuum level, the HOMOs and the core levels. The observed results indicate that electron affinities of CuPc and C_{60} are the same in the blend as in the neat film, which can be attributed to phase separation between CuPc and C_{60} in the blend, as observed by atomic force microscopy and X-ray scattering.

2. Experimental

As substrates we used clean polycrystalline Au films prepared by thermal evaporation on naturally oxidized Si (100) substrate in ultra-high vacuum (base pressure $< 1 \times 10^{-7}$ Pa). The CuPc/C_{60} mixed films were fabricated in situ on the Au substrate by co-evaporation using two glass cells with different evaporation rates to achieve the required mixing ratio. The thickness of the blended films was monitored by a quartz microbalance and adjusted to be 10 nm. IPES measurements were performed in situ in the isochromat mode using a home-made apparatus [10]. The band-pass type detector for photons with an energy of $h\nu = 9.3$ eV consists of a channeltron coated with KCl and is placed behind a SrF_2 window. A low energy electron gun was used to produce a mono-energetic electron beam. The substrate temperature during sample preparation and measurement was kept at room temperature. The morphology of blended films were also analyzed by atomic force microscope (AFM, Seiko Instrument: SPA300) in non-contact mode under ambient atmosphere.

3. Results and discussion

Fig. 1 shows the IPES spectra of the CuPc/C_{60} blend films as a function of C_{60} concentration. The abscissa is energy measured from the Fermi level (E_F) of clean Au substrates. Peaks marked with horizontal lines or solid filling are assigned to unoccupied states of CuPc and C_{60}, respectively. The composition of the blended films were determined by fitting each spectra with Voigt functions using the spectral shapes of neat CuPc and C_{60} films. Here, Gaussian width was set to be 0.75 eV including the total energy resolution of IPES measurements at room temperature. Lorentzian widths were properly taken to fit each peak. The spectra of the neat films (0% and 100% C_{60}) are in good agreement with the reported results [11–14]. The spectra of the mixed films in Fig. 1 can be described by a superposition of the spectra for neat CuPc and C_{60} films with proper energy shifts. No additional features are required in the fitting procedure, which indicates that there is no strong interaction between CuPc and C_{60}. From Fig. 1, it was found that

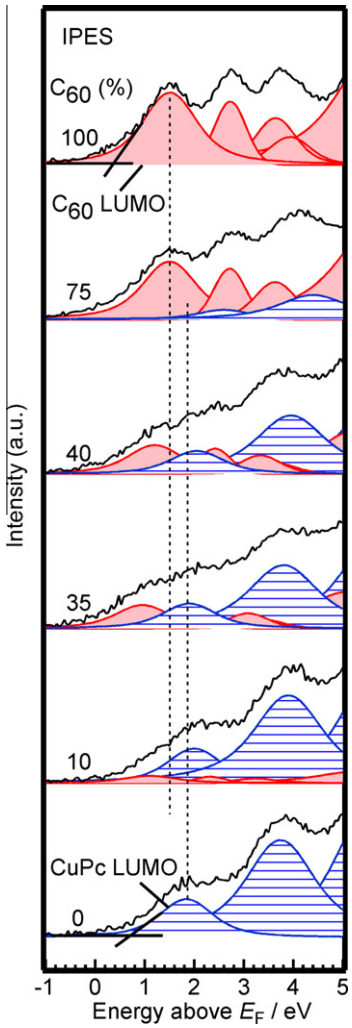

Fig. 1. The IPES spectra of blended films are shown as a function of C_{60} concentration. Peaks marked with striped lines or solid filling are assigned to unoccupied states of CuPc and C_{60}, respectively. Dashed lines are visual aids for recognizing the energy shifts of the LUMOs. The onsets of the LUMO peaks were determined from the cross-point as indicated by solid lines in neat CuPc and C_{60} films (0% and 100% C_{60}).

the LUMO peaks of CuPc and C_{60} move away from E_F with increasing C_{60} concentration.

The energy shifts of the LUMOs are consistent with those of the vacuum level and the HOMOs. Fig. 2 shows the concentration dependence of the observed energies for vacuum level (triangles in Fig. 2(a)), HOMO (squares in Fig. 2(a)) and LUMO (Fig. 2(b)). The upper and lower axes are CuPc and C_{60} concentrations, respectively. The energies of the HOMOs and LUMOs were deduced from the peak onsets. The data of vacuum level and the HOMOs were taken from the UPS spectra that the Augsburg group reported in Ref. [6]. Considering mixed films, the LUMOs of CuPc and C_{60} shift upward by 0.7 and 0.5 eV, respectively, with increasing C_{60} concentration, which is close to the shift of the vacuum level and the HOMOs.

Important to mention are the differences of the two analyses. Whereas the study presented here was carried

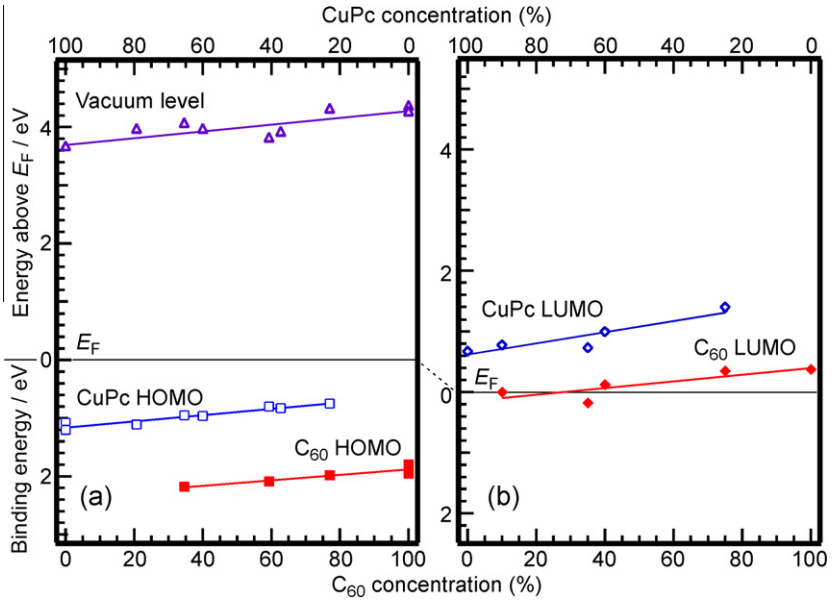

Fig. 2. Dependence of vacuum level and the HOMO (a) and LUMO (b) energies of CuPc and C_{60} on different mixing ratio. The data of vacuum level and HOMOs are deduced from the UPS spectra reported in [6]. Error bars in the LUMO data of CuPc in (b) are derived from an uncertainty of spectral fitting. The lines are linear fits of the corresponding energy levels. The data in (a) and (b) are collected on thin films prepared on contaminated and clean Au substrates, respectively. For a clearance of the difference in work function, *y*-axis in (b) is shifted by 0.35 eV.

out on a clean gold surface (Fig. 2(b)) the substrate of the previous study was contaminated with hydrocarbons (Fig. 2(a) and [6]). After deposition of CuPc and C_{60} on contaminated-Au substrate, the vacuum levels of CuPc and C_{60} films are found at 3.8 and 4.3 eV from E_F, respectively [6]. On the other hand, the vacuum levels of CuPc and C_{60} films prepared on clean Au surfaces are located at 4.21 and 4.63 eV, respectively [15]. Thus a difference in the Fermi levels should be taken into account for the analysis of the energy values of the materials. Assuming a difference of 0.35 eV in the vacuum levels for the semiconducting films, the HOMO–LUMO gap determined from the onset of the peaks is 2.2 eV for CuPc and 2.6 eV for C_{60}, respectively. These values are in between the energy gap derived from peak maxima and onsets which were reported in the literature [11–14]. The differences to the values in the literature are based on the experimental broadening of the peak width which is not accounted here and which is in the range of 0.3–0.4 eV in total for both experiments, UPS and IPES.

Even though different substrates were used for UPS and IPES measurements, similar energy shifts were observed in the vacuum level, HOMO and LUMO. Thus, the difference in substrate work functions can be neglected to discuss nature of electronic properties in the blended films. The similar shift of all levels indicates that the ionization energies and electron affinities of CuPc and C_{60} are constant even in their blended film. The observed constant ionization energies and electron affinities as well as the common vacuum level can be related to nano-phase separation in the mixed film (see below) [16].

In Fig. 3, AFM images of the mixed films with C_{60} concentration of 10%, 35% and 75% are shown. The maximum height increases with increasing C_{60} concentration, which can be attributed to higher roughness of C_{60} films than CuPc films [13]. We also notice that the maximum height exceeds the nominal thickness of the mixed films (10 nm), which also reflects the growth of C_{60} grains. These results can be related to phase separation between CuPc and C_{60} in the blend. Actually, X-ray diffraction (XRD) measurements of a CuPc/C_{60} blend with mixing ratio of 1:1 show the formation of the α-phase of CuPc and the *fcc*-phase of C_{60} even in the blended film [13]. The results of the XRD study indicate that both CuPc and C_{60} crystallites formed in blends are similar to neat films, and that phase separation occurs between the two materials. This can explain the fact that the ionization energies and electron affinities of CuPc and C_{60} in the mixture are similar to those of neat films in the whole range of concentration (Fig. 2). Nevertheless, phase separation occurs only on a length scale of about 10 nm which allows for the preservation of a common vacuum level [6,16–17].

The behavior of the energy levels in planar and bulk heterojunction solar cells is reported in the literature [18] for layers grown on the device relevant electrode PEDOT:PSS. It was found that the energy gap between the HOMO of CuPc and the LUMO of C_{60} is comparable for blended films and planar heterojunctions in contrast to our previous expectation [6]. This is because the HOMO of CuPc stays constant and the LUMO of C_{60} is also expected to be located at the same energy in the planar heterojunction and blended films [18]. As for CuPc, the hole polaron level of CuPc is pinned to the Fermi level of the electrode material [19] which prevents changes by the variation of the blend ratio. One can therefore expect that the open circuit voltage in planar heterojunction, whose value

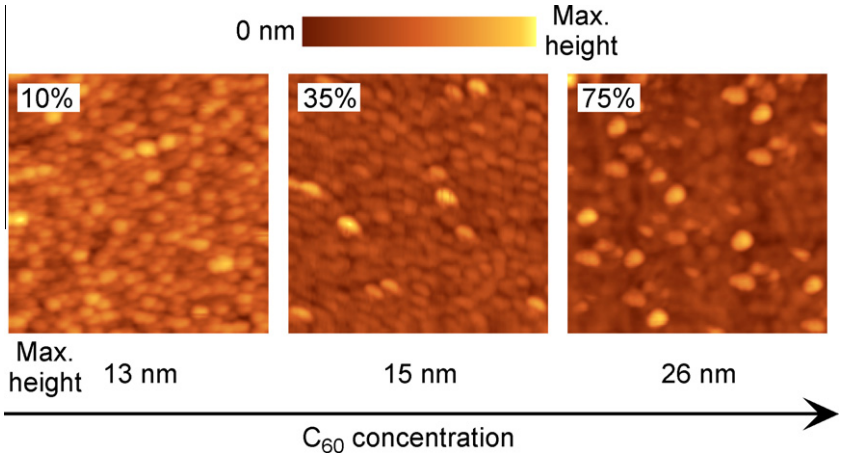

Fig. 3. AFM images for CuPc/C_{60} blends with C_{60} concentration of 10%, 35% and 75%. The maximum heights of each film were deduced from the lowest and highest values in each image. The image size is 1 μm^2.

can be related to the energy gap between the HOMO of the donor and LUMO of the acceptor [20], will be similar to that in blended films. However, this expectation contradicts with the fact that the open circuit voltage in blended films is by 0.2 V smaller than that in planar heterojunction [16–17]. The reduced open circuit voltage in bulk heterojunction solar cells in comparison to planar heterojunction cells are reported to be explained with additional recombination losses [21] or insufficient energy level alignment at contacts [22].

It is also noted that in the case of CuPc/Au interface the Fermi level seems to be near mid-gap of CuPc (Fig. 2(a)), similar to various phthalocyanines/Au substrate interfaces [23], when the work function difference in Au substrates between UPS and IPES studies is considered. However, the pinning of the energy levels is not expected at the present CuPc/Au interface, since Kelvin probe study indicated that the interfacial dipole induced by the push-back effect lowers the energy levels of CuPc on Au substrate and no band bending was observed up to CuPc thickness of 20 nm [24]. On the other hand, for C_{60} films, the energy level pinning occurs at 10–50 nm thickness on Au substrate [25]. This can be attributed to the pinning of the LUMO edge of C_{60} to the Fermi level of Au substrate [26]. Actually, the LUMO edge of C_{60} at C_{60} concentration = 100% is very close to the Fermi level of Au substrate as shown in Fig. 2(b). With increasing C_{60} concentration in CuPc/C_{60} blended films, the energy level alignment gradually changes between CuPc/Au and C_{60}/Au systems.

4. Conclusion

We performed the first investigations on the LUMO energies of CuPc and C_{60} in blends of both materials using inverse photoemission spectroscopy. It was found that the LUMOs of CuPc and C_{60} shift away from E_F by 0.7 and 0.5 eV, respectively, which is similar to the energy shifts of the vacuum level and the HOMO peaks. The coincidence of the energy shifts for the LUMOs with the vacuum level indicates that the electron affinities of CuPc and C_{60} are unchanged in blended films as compared to the neat materials. This can be attributed to nano-phase separation between CuPc and C_{60}, which is indicated by AFM measurements of the blended films. The present results provide information on unoccupied states in DA blends, which will be beneficial for understanding the energetics in DA solar cells.

WORM memory

ABSTRACT

We report on the electrical properties of a thin film of carbon spheres and cross-linked poly(4-vinylphenol) composites, sandwiched between an Al bottom contact and a Au or Al top contact. These simple sandwich structure memory devices show write-once-read-many-times (WORM) characteristics with an ON/OFF current ratio of 10^8 at 1 V bias when Au is used as top contact and the write operation corresponding to an OFF/ON transition can be made at low voltages, of *ca.* 2 V.

1. Introduction

There is an always increasing need to enhance data processing and data storage in our society, which imposes higher demands for memory devices. In some electronic devices used for this purpose the information is written or erased by changing the conductivity through an external input. This input changes the device conductivity in order to achieve a stable state different from the initial one, characterizing bistability. This bistability allows the introduction of binary information that can then be read by measuring the current that flows through the device submitted to a known voltage [1].

In the last years several attempts have been made to substitute inorganic semiconductors and related processes by simpler processes and device architectures using organic semiconductors [2–19], motivated by the perception that existing technologies are inadequate in one or more memory operating parameters [20]. Additionally, there is a need for memories whose production processes are compatible with generally adopted procedures in organic device based circuits, in order to allow simple incorporation of memories in organic electronics.

In this letter we report on the electrical non-volatile memory properties of a thin film of carbon spheres (CSs) and cross-linked poly(4-vinyl phenol) (CPVP) composites, sandwiched between an Al bottom contact and a Au or Al top contact layer. These simple memory devices show write-once-read-many-times (WORM) characteristics, *i.e.*, if the device is turned from the OFF to ON-state, the change is irreversible.

Despite the fact that there are several groups working on CS synthesis, characterization and applications [21], the use of CSs in electronic devices has been under reported.

2. Experimental

All chemicals, except the carbon spheres, were obtained from Sigma–Aldrich and used without further purification. Carbon spheres (see Fig. 1) were synthesized by passing a continuous flow of acetylene gas (100 mL/min) for

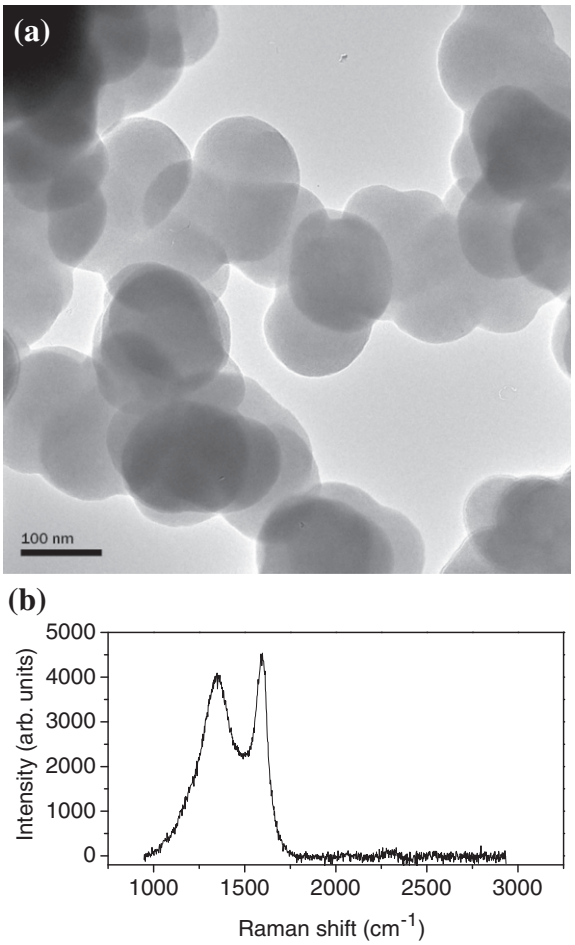

Fig. 1. (a) Transmission electron micrograph and; (b) Raman spectrum of the carbon spheres.

10 min at 900 °C under an argon atmosphere (100 mL/min) through a quartz tube placed vertically in a furnace. The acetylene and the argon gases were allowed to flow from top to bottom through the quartz tube and the carbon material collected in a 500 mL round bottom flask. This synthesis is based on a process reported by Jin et al. [22].

The carbon spheres thus synthesized were characterized by transmission electron microscopy (TEM) using a FEI Tecnai G2 Spirit electron microscope at 120 kV. Raman spectroscopy (J-Y T64000) was used to measure the intensity of the D and G bands of the CSs.

The memory device was prepared by the simple construction of ~450 nm (composite A) and ~300 nm (composite B) thick CPVP-CS composite film sandwiched between a 100 nm thick Al bottom electrode and a 100 nm thick, either Au or Al, top electrode (Al/CPVP-CS/Au or Al), as schematically represented in Fig. 2. The device active area, corresponding to the overlap of the top and bottom electrode, was 4 mm^2. The thickness of the PVP film was estimated by the capacitance measurements of the CPVP film, assuming a relative dielectric constant equal to 3.5 [23].

For the fabrication of the devices, poly(4-vinylphenol) (PVP) and methylated poly(melamine-*co*-formaldehyde) (PMF) as a cross-linker, were dissolved in propylene glycol monomethyl ether acetate, at concentrations equal to 11% and 4%, respectively (sample A), and 7% and 2.5%, respectively (sample B). The concentration was varied in order to vary the viscosity of the solution to obtain spin-coated films with different thickness, while maintaining the same PVP/PMF w/w ratio. CSs were then added to these two solutions (A and B), to prepare devices with four different ratios of CS to host polymer matrix, specifically [CS]/[PVP + PMF] w/w concentrations of 5%, 10%, 15% and 20%), as summarized in Table 1.

The composite mixtures were sonicated for *ca* 3 h at room temperature and 100 μL of suspension, in each case, were then spin-coated onto an Al electrode at 2000 rpm.

Table 1
PVP and PMF concentrations used for the preparation of solutions before CS addition; and the relative CS to PVP + PMF concentration in the solutions after CS addition. This is also the concentration in the prepared films.

Sample	Solution		Film
	PVP concentr. (w/w%)	PMF concentr. (w/w%)	[CS]/[PVP + PMF] (w/w%)

B-20	7.0	2.5	20

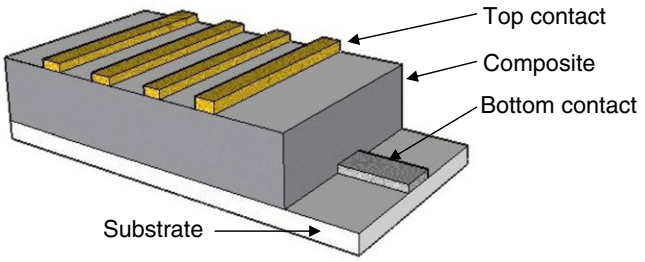

Fig. 2. Schematic representation of the memory device structure.

The devices were then annealed in air at 200 °C for an hour in order to cross-link the polymer [24–26]. Then, either Au or Al metal was thermally evaporated onto the composite surface at 10^{-6} Torr base pressure using a shadow mask for device patterning. The devices, 8 for each concentration, were characterized using a programmable Keithley 2602. The OFF–ON transition time was determined measuring the voltage drop in a 10 Ω resistor in series with a 81101A Agilent pulse generator (50 MHz) and the memory device. The voltage drop in the resistor was measured with a DSO 6104A Agilent 4-channel oscilloscope (1 GHz).

3. Results and discussion

Fig. 1a shows the transmission electron microscope (TEM) image of the CSs. The synthesized carbon spheres were obtained in good yield (about 250 mg) and size distributions (diameter: 124 ± 13 nm). The Raman spectrum of the CSs (Fig. 1b) shows two bands at 1356 cm^{-1} (D band) and at 1595 cm^{-1} (G band), indicating that the synthesized material is graphitic in nature. The good yield and the simple production procedure constitute an advantage in using this material, when compared to more expensive carbon materials such as carbon nanotubes and fullerenes, which have been also demonstrated to be suitable for memory devices [9],[27]. As a consequence, the CS-CPVP composite, constitutes a very cheap material option as active layer in memory devices.

Current–voltage (I–V) measurements were carried out to investigate the electrical properties of the devices. The I–V characteristics of devices made from composites A and B are qualitatively similar, both displaying distinctly bistable electrical conductivity states. Starting with a low-conductivity (OFF) state in the devices containing composite A and B (Fig. 3a–b, and Fig. 4a–b, respectively) the current increases gradually with an the increase in applied negative voltage (bottom Al electrode negatively biased). The current density, J, remains in the low 10^{-9}–10^{-7} A cm^{-2} range, corresponding to sweep 1 (up to −2 V in Fig. 3a-b), until the threshold voltage of about −4 V is reached. At the threshold voltage, J increases suddenly from 10^{-4}–10^{-1} A cm^{-2} (sweep 2), indicating a device transition from the low-conductivity OFF-state to the high conductivity ON-state. A similar OFF–ON transition occurs if a threshold voltage is achieved at positive applied voltage (not shown here).

However, there is a quantitative difference between devices shown in Figs. 3 and 4. In the case of Fig. 4, the ob-

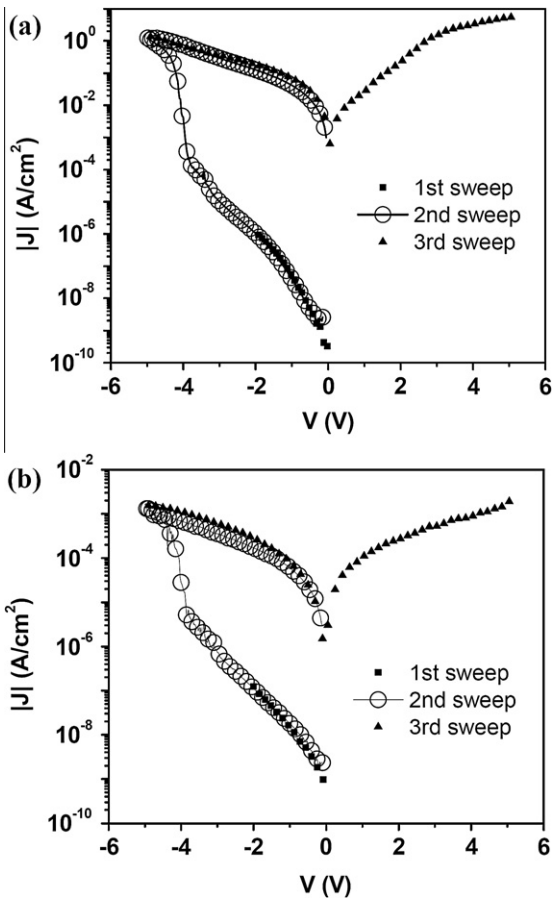

Fig. 3. $J(V)$ characteristic of the: (a) Al/CPVP-CS(A-10)/Au device; (b) Al/CPVP-CS(A-10)/Al devices.

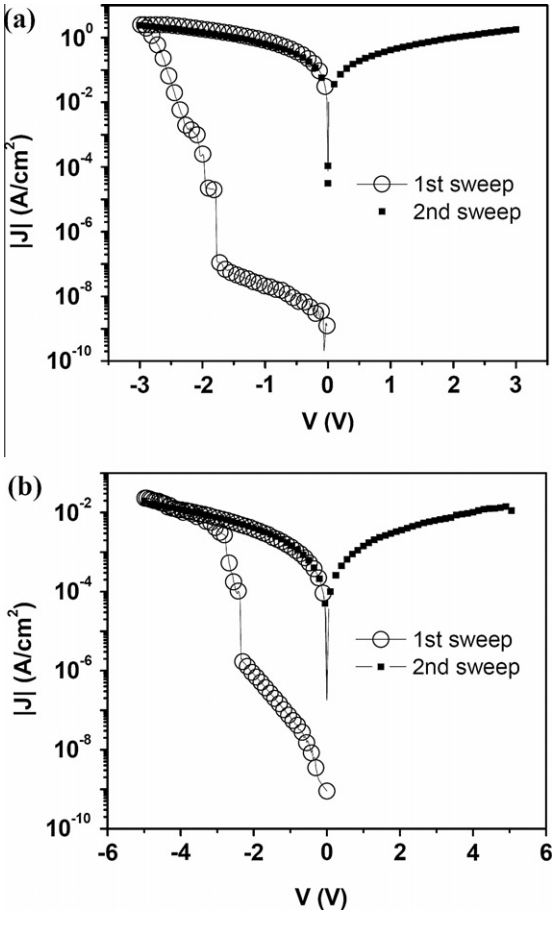

Fig. 4. $J(V)$ characteristic of the: (a) Al/CPVP-CS(B-15)/Au; (b) Al/CPVP-CS(B-15)/Al.

served threshold voltages are around −1.8 and −2.3 V for the Au and Al electrodes, respectively, values that are much lower than the ∼−4 V value obtained for devices like that of Fig. 3. This presumably relates to the different thickness of the two composites.

For the composites used in the samples, whose data are presented in Figs. 3 and 4, the device readily transformed from a low-conductivity state (OFF-state) to a high conductivity state (ON-state). The ON/OFF current ratio at $V = -1$ V is of the order of $\sim 10^6$ and $\sim 10^4$ for the Au and Al electrodes (Fig. 3a–b), respectively for composite A −10; and $\sim 10^8$ and $\sim 10^4$ for Au and Al electrode, respectively, for composite B-15 (Fig. 4a–b).

For comparative purposes, devices having a structure of Al/CPVP/Au or Al were also fabricated. The *J–V* characteristics of the devices are shown in Fig. 5. The Al/CPVP/Au or Al devices show low-conductivity, corresponding to an OFF-state, in the full voltage range used for CS-CPVP composite devices. This implies that the memory effect is due to the presence of carbon spheres in the polymer composites.

When Au was used as top metal electrode, the device performed better than when Al metal was used, showing a higher ON/OFF current ratio. Moreover, according to our results, even using a relatively thin film in a simple device architecture, permits control of the threshold voltage and the ON/OFF current, through top electrode material choice and thickness of the composite film. In the case of composite B-10, these values were measured to be *ca.* −2 V and $\sim 10^8$, respectively. This constitutes a very simple strategy for adjustment of the device characteristics, representing a big advantage when a production process is considered. Furthermore, this threshold voltage is low and the ON/OFF ratio high enough to allow compatibility with most conventional electronics and available circuitry, without further need of sophisticated improvements.

The relative concentration of CSs in the composites used in our devices influence the electrical characteristics trends, as shown in Fig. 6a and b. When the CS relative concentration increases (15% CS and 20% CS) there is an increase in the OFF current density while the ON current density is lowered when low CS concentration (5% CS) is used. As a consequence, the highest ON/OFF current density ratio is always observed in samples with a 10% CS concentration (A-10 and B-10, in Table 1). The variation of the threshold voltages with CS concentration is small, of the order of 0.5 V, which is similar to the maximum dispersion of values observed in a set of 8 different devices prepared at the same CS concentration.

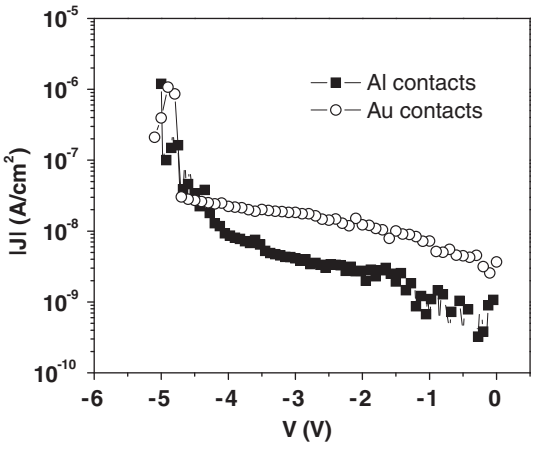

Fig. 5. *J*(*V*) characteristic of the Al/CPVP/Au and Al/CPVP/Al device.

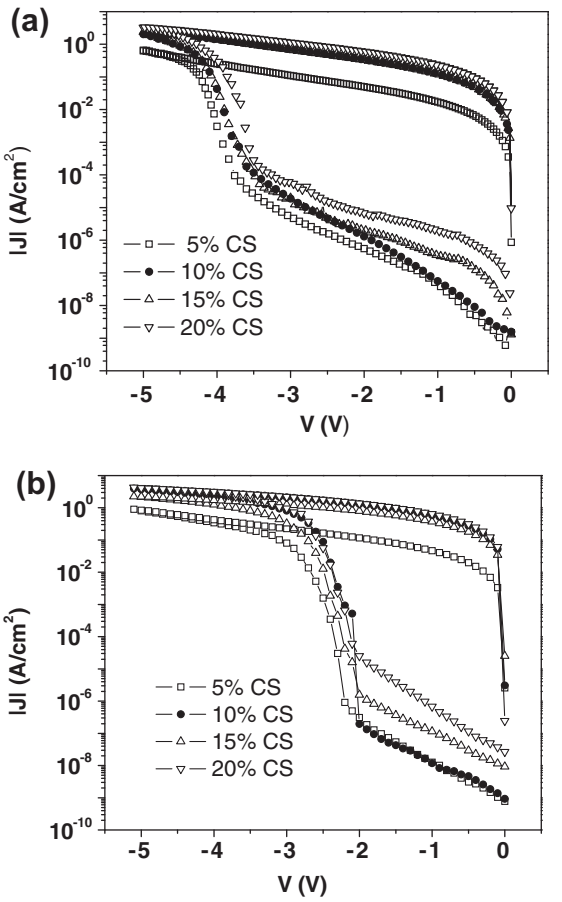

Fig. 6. *J*(*V*) characteristic of Al/CPVP-CS/Au devices prepared with (a) composites A and; (b) with composites B, for different relative CS concentrations.

This electrical transition voltage threshold from the OFF-state to the ON-state, considering the absolute values, serves as the lowest limit of the voltage applied during the "write" operation for the memory device. In contrast, the "read" operations have to be performed in the range below the threshold voltage, where the two states are clearly separated. The "0" and "1" can be encoded from the low-conductivity state and high conductivity state, respectively, allowing application of Boolean algebra.

The most interesting feature of these memory device is that it remains in the ON-state even after turning off the power and in the subsequent voltage scans. Thus the devices exhibit write-once-read-many-times (WORM) memory behavior. The current and WORM memory effect of these memory devices are largely dependent on the type of metal electrode used, as also observed by other authors [28,29]. Moreover, the devices exhibit stability in the OFF-state as well as in the ON-state during the subsequent for-

ward and reverse voltage scans. The stability of the devices is demonstrated in Fig. 7. In Fig. 7(a) the device current density is presented as a function of time for a device which was biased at the READ voltage (−1 V), before and after the application of the WRITE voltage (two pulses). It can be seen that the current density value is stable. In Fig. 7(b) and (c) we present the current obtained from devices that were periodically submitted to the READ voltage for 24 h (see inset for pulse characteristics and measurement moment). The higher current density corresponds to the current during the READ condition (−1 V), whereas the bottom curve corresponds to the current of the device at rest (0 V) for devices in both states: a device in the OFF-state (Fig. 7(b)) and a device in the ON-state (Fig. 7(c)). The ON-state device current density during the READ operation decays by ~50%, following a simple exponential decay with time constant of 7 h. The variation of the *J(V)* characteristics of the device with temperature (between 20 and 70 °C) is not significant for its use as memory, as illustrated in Fig. 8. The most important finding is that the threshold voltage is only slightly displaced and the ON/OFF current ratio remains almost the same.

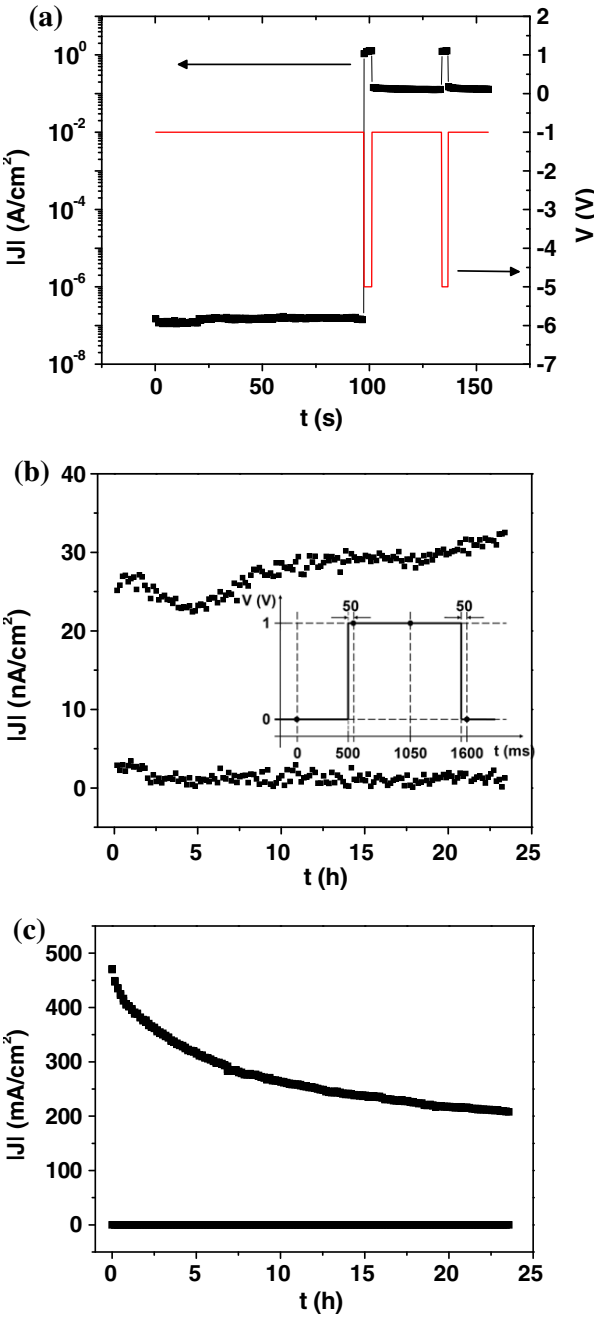

Fig. 7. (a) *J*(*t*) behavior of a Al/CPVP-CS(A-05)/Au device at READ voltage (−1 V) in the OFF-state (up to ~100 s), during and after a WRITE pulse (−5 V) and the subsequent ON current at READ voltage. (b) Long term measurement applying a pulse every 10 min for a Al/CPVP-CS(B-10)/Au device in the OFF-state [inset: pulse form indicating the time for the four measurements made during every pulse, as full circles]. (c) Same as in (b), after application of the WRITE pulse, *i.e.*, ON-state.

The slight threshold displacement that occurs with an increase in the relative CS to CPVP composite concentration in the composite and with temperature, as well as the strong threshold voltage displacement with device thickness, suggests that the OFF–ON transition is controlled by the thickness of the composite film. This threshold then occurs at a critical electrical field strength. However, since the relationship between these two quantities is not a simple proportionality, this subject must be investigated in more details. This observation is under investigation and will be reported in due course.

The formation of percolation paths throughout the CSs inside the CPVP insulator layer is easier when the relative amount of CSs is equal to or larger than 10% (Fig. 6). Percolation paths may be formed through the displacement of the CSs at the high fields achieved in the device, which are larger than 10^6 V/m. The irreversible character of the OFF–ON transition suggests again that the new CS positions are stabilized after high current passage, which also leads to higher local temperatures facilitating molecular conformation modification. Even at the high ON-state current, fusion of CSs occurs, leading to the formation of permanent conducting filaments [19]. In the case of the formation of a filamentary current, high temperatures are easily achieved since the current density is then locally

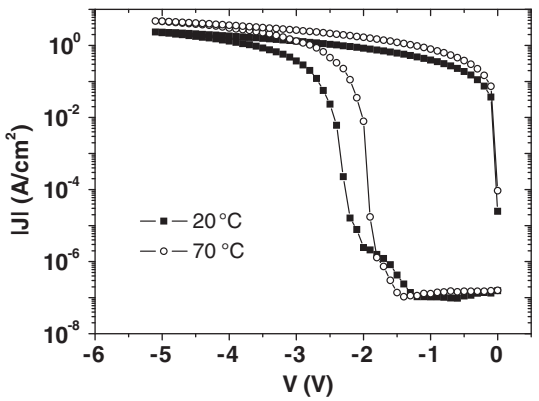

Fig. 8. *J*(*V*) characteristics of two Al/CPVP-CS/Au devices of the same sample prepared with composite B-10, measured at different temperatures.

much higher than the value calculated for the average device current density considering the superposition of top and down electrodes. And it is important to remember that even this value is very high for organic devices, in some cases achieving more than 1 A/cm^2, which corresponds to more than 2 W/cm^2 in the ON-state.

The reproducibility of the results is very good, since from 64 prepared devices all demonstrated the OFF–ON transition, except three devices that presented short-circuit between the electrodes.

We measured the transition time from the OFF to the ON-state during the WRITE operation. In all measurements made using 10 devices prepared with composites B-05, B-10, B-15, B-20 and A-10 the current stabilizes at the ON value in less than 2 μs.

Simple memory elements have been developed for organic electronics, such as conducting polymer strips that make a conducting bridge between metal electrodes. When a current above a certain threshold passes through this bridge, the Joule heat degrades the polymeric material producing at least a partial interruption of the bridge, and in this way the current state is modified [30]. Compared to such devices, our memory elements have the advantage offered by the vertical architecture, which allows smaller device size and consequently a higher integration level.

In summary, we have demonstrated WORM memory devices made using a thin film of a composite of carbon spheres and cross-linked poly(vinylphenol) sandwiched between two metallic electrodes, which show OFF/ON transitions at low voltages and show ON/OFF current ratios $\sim 10^8$.

ABSTRACT

We present the results of applying multi-layer graphene (MLG) films as transparent conductive electrodes in organic photovoltaic devices (OPVs). The MLG films synthesized at different growth temperatures by chemical vapor deposition were applied to OPVs. The performance of OPVs with 1000 °C-grown MLG films was found to be the best with a power conversion efficiency (PCE) of ~1.3%. The PCE was further enhanced when a hole-blocking TiO_X layer was inserted in the device structure, resulting in a PCE of ~2.6% which is a significantly higher efficiency compared to other previously reported graphene-adopted photovoltaic cells. Our demonstration of the PCE-increase in the graphene-electrode OPVs may foster the application of the fast-progressing graphene technology toward more practical OPV technology.

1. Introduction

Graphene, a two-dimensional sheet of covalently bonded carbon atoms, has been attracting great attention in the field of optoelectronics of organic and inorganic materials. This is because of its outstanding electronic, optical, and mechanical properties, such as quantum electronic transport properties, transparency, mechanical and chemical stability, stretchability, and flexibility [1–6]. Currently, graphene films that can be deposited on arbitrary substrates are prepared by various techniques, including mechanical exfoliation of graphite crystals, reduction of graphene oxide films, and growth by chemical vapor deposition (CVD) [6–11]. In this study, we used the CVD method for graphene production. This method offers several advantages, including the capability to grow large and continuous uniform films with low sheet resistances, transferability to arbitrary substrates, and controllability of the synthesized film properties. It has been reported that the graphene films produced by CVD typically have sheet resistances of 300–1000 Ω/□ and mobilities of 300–4000 $cm^2/V\,s$ [4,8,9].

In this work, our focus is on the application of graphene films as the electrodes in organic photovoltaic cells. In the optoelectronics, the need for a noble material to replace indium tin oxide (ITO) that can be produced cheaply while providing high transparency and conductivity has emerged [12,13]. Graphene films potentially fulfill all of these required properties and are therefore currently being vigorously researched [4,5,10,11,14–23]. Wang et al. [11] first reported the application of graphene films in dye-sensitized photovoltaic cells and obtained a power conversion efficiency (PCE) of 0.26%. A number of reports followed.

Tung et al. [5] reported organic bulk-heterojunction (BHJ) photovoltaic cells with modified graphene films composited with carbon nanotubes and demonstrated a 0.85% PCE. More recently, Wang et al. [14] used functionalized graphene films in organic BHJ photovoltaic cells and reported an improved PCE of 1.71%. Overall, BHJ photovoltaic cells with graphene electrodes have exhibited PCEs below 2% to date [5,11,14–17]. These PCEs are only proof-of-concept and are far below the best performance obtained from organic solar cells made with ITO electrodes. Values of 6.1% [24], with a BHJ structure, and 6.5% [25], with a tandem cells structure, have both been reported by the research group of Heeger and Lee, one of co-authors of this paper. Recently, a PCE of 6.7% has been reported from an organic BHJ structure with low bandgap polymers having an enhanced open-circuit voltage [26,27]. On the contrary, the poor performance of photovoltaic cells incorporating graphene electrodes is apparently due to the poor quality of graphene films: high sheet resistances and interfacing problems with the active layers.

In this paper, we report an application of CVD-synthesized multi-layer graphene (MLG) films incorporated as transparent and conductive electrodes of organic BHJ photovoltaic cells (OPVs). Particularly, the growth temperature of the graphene films was studied as a control paramter on the PCE of the graphene-OPVs. Overall, the MLG films showed good performance as electrodes for OPVs, and among tested graphene-OPVs the1000 °C-grown MLG films were found to yield the best PCE. Furthermore, when a thin sol–gel processed titanium sub-oxide (TiO_X) layer was inserted in the cell, the PCE was further increased to ~2.60%. Our results show the control of the graphene film quality and the cell structure optimization with a TiO_X layer can increase the performance of OPVs beyond the proof-of-concept level.

2. Experimental

The device structure of a photovoltaic cell with graphene as a transparent and conducting electrode is shown in Fig. 1(a). To synthesize graphene films, 300 nm thick Ni-deposited substrates were placed into the CVD chamber and heated to 800, 900, or 1000 °C under the flow of a 4% H_2 in Ar gas mixture. Then, a graphene film was grown by adding CH_4 gas to the flow. After growth, the substrate was rapidly cooled to room temperature (>200 °C/min initially and slower later) to suppress excessive precipitation of carbon atoms. Finally, the graphene film was released from the Ni substrate by etching Ni in an aqueous solution of iron chloride ($FeCl_3$) [4]. The CVD-synthesized MLG film was transferred onto a glass substrate to form the anode for OPV. Before a poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS) layer was spin coated on top of the graphene film, the graphene film was undergone an ozone treatment to produce the hydrophilic surface, which was a necessary step to increase the coating efficiency of PEDOT:PSS on graphene. Next, the photoactive BHJ composite of poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl-C61 butyric acid methyl ester (PCBM) was spin coated on top of the PEDOT:PSS layer. Then, a TiO_X film was spin coated for some devices. Finally, aluminum was thermally evaporated to form the cathode. A cross-sectional high-resolution transmission electron microscopy (HRTEM) image of a prepared photovoltaic cell (Fig. 1(b)) clearly shows that the individual layers were nicely formed with distinctive interfaces; the TiO_X film and MLG film are shown in the upper and lower inset of Fig. 1(b), respectively.

3. Results and discussion

3.1. Characteristics of multi-layer graphene films

Before applying the MLG films in photovoltaic cells, we investigated the properties of these films using various techniques. To determine the morphological features and thicknesses of the MLG films, we used an atomic force microscope (AFM) to image a transferred MLG film on a 300-nm-thick SiO_2 layer on a Si substrate, as shown in Fig 2(a). The thinnest part measured on our graphene film is 1.13 nm, as shown in the cross-sectional profile in Fig. 2(b). This thickness corresponds to the thickness of a monolayer; due to the chemical contrast between graphene and substrate, the monolayer thickness has been measured as ~1 nm by AFM [7,9,28–30]. Fig. 2(c) shows the TEM images for a graphene film. Our graphene films consisted of mono to multi-layer regions and contained rippled regions, as marked by a square in the lower image. By counting the number and the distance of the bright and dark stripes in the rippled region, the number of

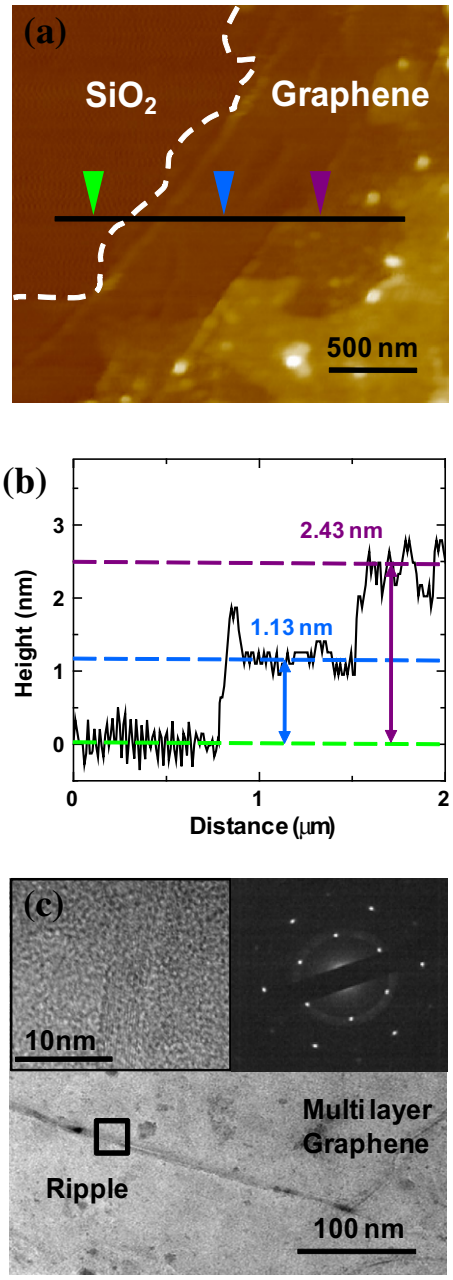

Fig. 2. (a) AFM image of a MLG film showing the edge of the MLG layers (dashed) on a SiO_2 substrate. (b) Topographic height profiles across the solid line indicated in (a). (c) TEM image of a region of MLG. The insets show an HRTEM image of the rippled region (top left) and an electron diffraction pattern (top right) of MLG.

graphene layers (~15) and the interlayer distance (3.5 ± 0.1 Å) were obtained; the results were found consistent with values reported previously [9,31]. The electron diffraction (ED) pattern (upper right inset, Fig. 2(c)) taken on a monolayer region shows a hexagonal spot pattern, confirming the threefold symmetry of the arrangement of carbon atoms in the graphene film.

Raman spectroscopy using the 514 nm line of an Ar+ laser was used to analyze the properties of MLG films grown at three different temperatures (Fig. 3). Raman spectroscopy is a non-destructive analysis tool which provides high-throughput and unambiguous identification of the properties of graphene films with three most intense peaks: D peak at ~1350 cm^{-1}, G peak at ~1580 cm^{-1}, and 2D peak at ~2700 cm^{-1} [32–34]. Our CVD-grown graphene films typically showed multi-layer-type Raman features (i.e., G-peak intensity > 2D-peak intensity) and small D peaks that were related to defects on MLG. The integrated intensity ratios of the observed Raman peaks are shown in Fig. 3(b) and (c). The ratios of the G-peak intensity to the 2D-peak intensity (I_G/I_{2D}) shown in Fig 3(b) indicate that the average thickness of the graphene film increased as the growth temperature increased since the higher ratio corresponds to the thicker graphene film. The ratios of the D-peak intensity to the G-peak intensity (I_D/I_G) shown in Fig. 3(c) correspond with the average density of defects [33–35], and these ratios indicate that the defect density decreased as the growth temperature increased. From the comparison of Raman peak ratios, we conclude that the growth temperature significantly affects the properties of the graphene in terms of the film thickness and defect density.

Furthermore, the film property that is directly relevant to the performance of the organic photovoltaics was investigated: the optical transmittances and the sheet resistances of the MLG films synthesized at three different growth temperatures. Results are summarized in Fig. 4. Fig. 4(a) shows the representative transmittances of MLG films prepared at different growth temperatures and the inset shows the transmittance of 90.7 ± 1.5, 88.8 ± 2.2, and 86.9 ± 1.2% at 515 nm wavelength according to the growth temperatures of 800, 900, and 1000 °C, respectively. The plot of mobility versus resistance, shown in Fig. 4(b), was obtained by taking the statistical means and standard deviations of 8–10 synthesized-MLG films at each growth temperature. As expected from Raman analysis, higher temperature grown thicker MLG films yielded less transparency and lower sheet resistance. Specifically, MLG films prepared at growth temperatures of 800, 900, and 1000 °C showed the sheet resistances of 1730 ± 600, 990 ± 400, and 610 ± 140 Ω/□, and the mobility of 660 ± 270, 1030 ± 440, and 1180 ± 260 $cm^2/V\,s$ respectively. Furthermore, we measured the work function of the MLG films by using a Kelvin probe measurement system. As shown in Fig. S2(b) in Supplementary material, the work function of the graphene films was 4.45 ± 0.04 eV and did not change significantly with the growth temperature change.

3.2. Performance of the organic photovoltaic cells with graphene electrode

Fig. 5(a) shows the representative current density–voltage (*J–V*) data of the fabricated OPVs without TiO_X layers under AM 1.5 G irradiation by a solar simulator with an irradiation intensity of 100 mW/cm^2. The three different MLG films prepared at different growth temperatures (800, 900, and 1000 °C) were used to compare the performance as electrodes in OPVs. The best performance was achieved from the devices using MLG films that were

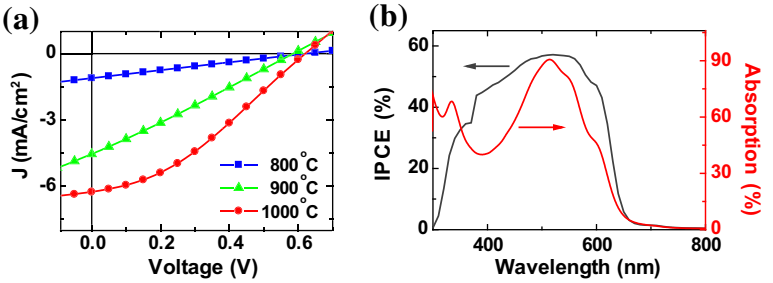

Fig. 5. (a) J-V curves of photovoltaic cells with MLG films grown at different growth temperatures under AM 1.5 G irradiation conditions. (b) Incident photon-to-current efficiency (IPCE) and absorption spectra of a photovoltaic device fabricated with a 1000 °C-grown MLG film.

prepared at 1000 °C. Specifically, for the case of the 1000 °C-graphene OPV, the representative parameters obtained were short-circuit current density (J_{SC}) of 6.25 mA/cm^2, open-circuit voltage (V_{OC}) of 0.62 V, and fill factor (FF) of 0.35. These values yielded PCE = $J_{SC}V_{OC}$FF/P_{inc} (here P_{inc} is the intensity of incident light) of 1.34%. The parameters for the devices with graphene films prepared at 800 and 900 °C are summarized in Table 1. Fig. 5(b) compares

Table 1
Summary of the performance parameters of graphene-electrode organic photovoltaic devices fabricated with graphene films that were synthesized at different growth temperatures (800, 900, and 1000 °C) and ITO-electrode devices. Short-circuit current density (J_{SC}), open-circuit voltage (V_{OC}), fill factor (FF), and power conversion efficiency (PCE) are listed. The improvement of the performance parameters by the insertion of the TiO_X layer as a hole-blocking layer (HBL) was compared in all the device types.

Temp. (°C)	HBL	V_{OC} (V)	J_{SC} (mA/cm^2)	FF	PCE (%)
800	–	0.62	1.11	0.25	0.17
800	TiO_x	0.59	6.45	0.32	1.22
900	–	0.59	4.54	0.26	0.70
900	TiO_x	0.62	7.57	0.46	2.13
1000	–	0.62	6.25	0.35	1.34
1000	TiO_x	0.60	9.03	0.48	2.60
ITO	–	0.63	7.50	0.50	2.34
ITO	TiO_x	0.63	9.02	0.67	3.80

the incident photon-to-current collection efficiency (IPCE) spectrum and absorption spectrum of a device fabricated using MLG films prepared at 1000 °C. The graphene-electrode photovoltaic cell without a TiO_X layer showed the typical spectral response of P3HT:PCBM composites with a maximum IPCE of approximately 57% at 515 nm.

The performance of the graphene photovoltaic devices was further enhanced when a TiO_X film was added between the aluminum cathode and the photo-active layer. Fig. 6(a) compares the *J–V* curves of the photovoltaic devices with 1000 °C-grown MLG electrodes and with ITO electrodes with and without the TiO_X layer. The performance parameters obtained from the MLG-electrode devices with the TiO_X layer shown in this figure are J_{SC} of 9.03 mA/cm^2, V_{OC} of 0.60 V, and FF, which was dramatically increased, of 0.48. The corresponding PCE was significantly increased to 2.60%. Such performance enhancement by adding a TiO_X film was also observed in photovoltaic cells with ITO electrodes. The representative parameters obtained for the case of the ITO-electrode devices with the TiO_X layer were J_{SC} of 9.02 mA/cm^2, V_{OC} of 0.63 V, and FF of 0.67, and the PCE was determined as 3.80%. The enhancement of PCE for our graphene-electrode and ITO-electrode photovoltaic devices by inserting a TiO_X layer can be explained by the role of the TiO_X layer that creates a higher density of photo-generated charge carriers as an optical spacer [36,37] and facilitates better transport of charge carriers to each electrode as a hole-blocking layer [24,25,38,39], thereby increasing J_{SC}. Recently, Roy et al. [37] have compared the calculated and the experimentally measured total absorption spectra of photovoltaic devices with and without the TiO_X layer and confirmed the effect of the TiO_X layer as an optical spacer. Also, Cho et al. [38] have demonstrated the hole-blocking property of TiO_X using multilayer bipolar field-effect transistors (FETs). In their device, the TiO_X layer was inserted to separate the n-channel material and the p-channel material. Because the TiO_X layer retained the injected holes within the p-channel material and transferred the injected electrons into the n-channel material, their device successfully showed the *J–V* characteristics. As a result, the PCE of our photovoltaic devices with TiO_X was improved by the effects of the TiO_X layer both as an optical spacer and as a hole-blocking layer. Moreover, the TiO_X layer reduced the contact resistance between the aluminum cathode and the P3HT:PCBM photo-active layer, consequently increasing the FF in the device. Fig. 6(b) presents detailed statistical data for PCE values that were statistically determined from all the measured graphene-electrode devices in comparison with the ITO-electrode devices, with and without the TiO_X layers. Each statistical value in Fig. 6(b) was extracted from all the measured devices shown in the Supplementary material (Fig. S1). For devices without the TiO_X layer, the PCEs (the mean and standard deviation) of the photovoltaic devices were determined as 0.19 ± 0.08, 0.56 ± 0.10, and 1.38 ± 0.35% with the graphene-electrodes grown at 800, 900, and 1000 °C, respectively, in comparison to 1.20 ± 0.27, 1.79 ± 0.31, and 2.58 ± 0.45% for the devices with TiO_X layer and the graphene-electrodes grown at 800, 900, and 1000 °C, respectively. Also, we found that the PCE of the ITO-electrode photovoltaic devices without TiO_X was 2.53 ± 0.42% compared to 3.74 ± 0.31% of those with TiO_X. It can be noticed that the PCEs for ITO-electrode devices were higher than those for graphene-electrode devices, partly due to higher conductivity of ITO film than that of graphene films. Furthermore, the best PCE observed was 3.63% from a 1000 °C-grown graphene-electrode device with the TiO_X layer. However, this value was outside of the one sigma criterion, i.e., the 3.63% value was beyond

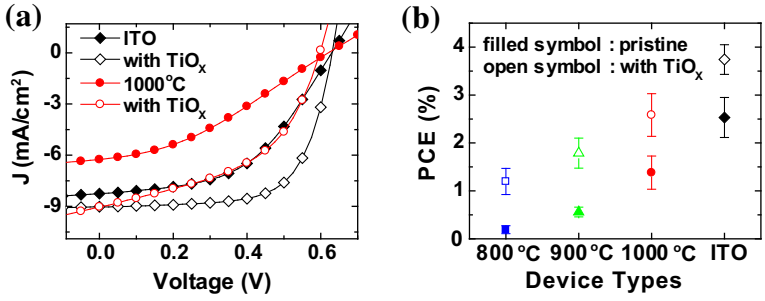

Fig. 6. (a) *J–V* curves of photovoltaic devices with 1000 °C-grown MLG electrodes (circles) and with ITO electrodes (diamonds). The curves without the TiO_X layer (filled symbols) are compared to the ones with the TiO_X layer (open symbols). (b) The PCEs for graphene-electrode photovoltaic devices in comparison with those for the ITO-electrode photovoltaic devices with the TiO_X layers and without the TiO_X layers (pristine). This statistical means and standard deviations were extracted from Supplementary material. The types of the devices are indicated on the *x*-axis (800, 900, and 1000 °C: graphene-electrode devices, ITO: ITO-electrode devices).

one $\sigma = 0.45\%$ (standard deviation) from the mean of $m = 2.58\%$. The performance parameters for all types of photovoltaic devices measured in this study are summarized in Table 1. Although our results indicate that the efficiency of OPVs can be significantly enhanced by graphene film quality control and by inserting a TiO_X layer, there are rooms for improvements to compete with the efficiency of ITO-electrode OPVs. With more research to further enhance the graphene film quality and to further optimize the device structure, graphene films may soon be widely used as an alternative material to ITO films in organic photovoltaics.

4. Conclusions

In summary, we reported the application of MLG films grown by chemical vapor deposition to organic photovoltaic cells. The effect of graphene synthesis temperature on the performance as anode in OPVs was studied. The 1000 °C-grown MLG films, that possessed sheet resistances of ~606 Ω/□ at transmittances of ~87%, showed the best performance as electrodes in OPVs. Furthermore, a cell structure optimization with an inserted TiO_X layer enhanced the observed power conversion efficiency up to $2.58 \pm 0.45\%$. Our demonstration of efficiency improvements in graphene-adopted photovoltaic cells may foster the application of fast-progressing graphene technology into the practical realm of organic photovoltaic cells.

of the adjacent layers when the environmental temperature changes [5]. External stress comes from the application of an external bending moment [6]. For example, when the FOLED device is bent, strain is introduced in the thin-films and stress is generated. Stress can make each film to crack or buckle when the deformation exceeds what it can bear. In a conventional multilayer OLED device structure, the indium-tin-oxide (ITO) is the most vulnerable film with the Young's Modulus of 120 GPa and yield stress of 1.2 GPa. Mechanical studies of ITO under external stress have been widely conducted [7]. Stretching-type stress can cause ITO to crack and increase its sheet resistance [8]. However, compression-type stress could promote buckling at first, and eventually crack or delaminate when the stored energy exceeds what the film can bear. When the ITO/plastic composite film is bent, the ITO film can suffer from either compressive or tensile stress, and this depends on the way it is bent.

Comparing these two types of strain conditions, people have found the increase in sheet resistance behaves asymmetrically. This might arise from the residual stress of the ITO/plastic composite, which is usually compressive in terms of the ITO layer [9] or the different course for the cracking or buckling to the electrical resistance. Thus the two different types of stress may also change the electroluminescence (EL) of OLED device differently. Apart from these stress effects, creep [10] (which is more likely to happen to the metal thin-film and plastic substrate) and film delamination [11] are two other key factors which affect soft multilayer thin-film structures.

2. Experimental

The ITO/polyethylene terephthalate (PET) composite substrate used in this study was purchased from Sigma–Aldrich, with the ITO thickness to be 100 nm and sheet resistance to be 60 Ω/□. The substrate was then cleaned with acetone and isopropanol in the ultrasonic bath for 7 min each, and exposed in the UV–Ozone Oven for another 7 min.

The component layers of the OLED device with the structure aluminum (100 nm)/lithium fluoride (0.8 nm)/tris–(8-hydroxyquinoline) aluminum (Alq_3) (40 nm)/*N*,*N*′-bis(naphthalen-1-yl)–*N*,*N*′-bis(phenyl)benzidine (NPB) (50 nm)/ITO (100 nm)/PET (0.127 mm) were deposited by evaporation under vacuum (2×10^{-7} mbar) using the Kurt J. Lesker small molecule deposition system. The FOLED device was mounted on the sample holder and the brightness was measured by the Konica-Minolta LS-110 Luminance meter as shown in Fig. 1a. The holder enables the device to be bent about one axis with three different conditions: R_1 = position A, R_2 = position B, and R_3 = position C in both concave and convex directions. Furthermore, the device pattern (as shown in Fig. 2) was designed in order that during the bending tests, the active area (5 mm × 10 mm) was located around the furthest point of the curve from the electrical contact caused by bending, i.e., the axis referred to above was parallel to the short side and the area between the electrical contacts and the active area was relatively flat.

In order that uninterrupted optical access can be made in the "bent" positions, a 2-point bending method was used. However, this method has the disadvantage of having to define the radius of curvature at the device position (R_c). Two methods were applied to estimate R_c for bending

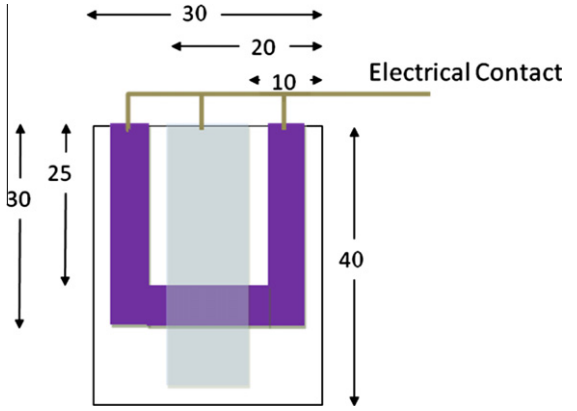

Fig. 2. The FOLED device plan. The darker area is the ITO layer. The lighter oblong shape covered on it is the aluminum layer. The dimensions are in unit of mm. The OLED is thermal evaporated everywhere on the 40 mm × 30 mm PET substrate and between these two electrodes. The OLED active area is 10 mm × 5 mm.

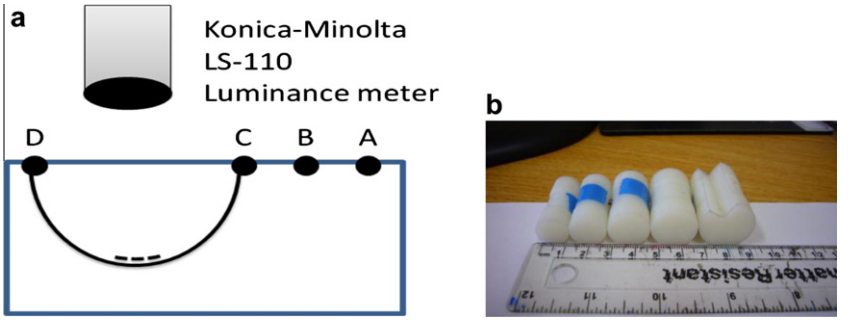

Fig. 1. The FOLED device was mounted and bent on the sample holder to be measured by the Konica-Minolta LS-110 Luminance meter fixed above the sample holder as shown in (a). The curved line is the FOLED device. It is fixed at the left end of the long side (position D). The dash line is the active OLED area which emits light. The right end is to be fixed at the positions A, B, and C for different radius of curvature. $\overline{DC}$ = 25 mm, $\overline{DB}$ = 35 mm, $\overline{DA}$ = 45 mm. (b) The cylindrical rods used to estimate the bending radius of curvature of the device.

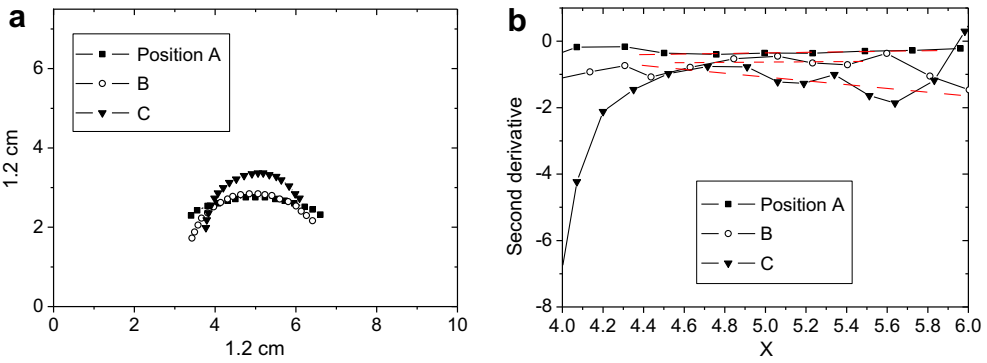

Fig. 3. Traced curves (a) from the 2.5× images of the FOLED device bent with positions A, B, and C. (b) Their second derivative around the active OLED area ($x = 5$).

Table 1
The radius of curvature (R_c) of the devices investigated in each of the test runs.

Test run	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
R_c of FOLED in Expt. 1	N/A	R_1	R_2	R_3	R_2	R_1	N/A	R_1	R_2	R_3	R_2	R_1	N/A	R_3	N/A
R_c of FOLED in Expt. 2	N/A	R_1	R_2	R_3	N/A	R_3	N/A								
R_c of FOLED in Expt. 3	N/A	R_3	N/A	R_3	N/A										
R_c of FOLED in Expt. 4	N/A	R_3	N/A	R_3	N/A										

R_1 = position A, R_2 = position B, and R_3 = position C.

positions A, B, and C. First, five cylindrical rods were fabricated with radius 7 mm, 8 mm, 9 mm, 10 mm, and 12 mm as shown in Fig. 1b, and used to compare with the curvature at the three positions. As a result, R_c for positions A, B, and C are approximately 12 mm, 10 mm, and 8 mm. For confirmation, the second method was also applied in each case, but is more complicated. Images of the FOLED devices bent at the three positions were taken separately and input to the software Origin 7.0 with a magnification of 2.5. Three curves were then traced and centered on $x = 5$ as shown in Fig. 3a, and the second derivative was calculated and plotted in Fig. 3b. The semi-circle as a function of x centered on (x_0, y_0) is:

$$y(x) = y_0 + \sqrt{R_c^2 - (x - x_0)^2} \quad (1)$$

and the second derivative of (1) when $x = x_0$ is:

$$y''(x_0) = \frac{-1}{R_c} \quad (2)$$

From Fig. 3b, the average of the second derivative of bending positions A, B, and C between $x = 4.4$ and 5.6 are about −0.37, −0.68, and −0.8. Therefore, the R_c of Fig. 3a are 3.2 cm, 1.9 cm, and 1.5 cm. But because the curves were traced from a 2.5× image, so the real R_c of the FOLED device of bending positions A, B, and C are 12.8 mm, 7.6 mm, and 6 mm.

Finally, when the device was bent, the focus of Konica-Minolta LS-110 Luminance meter was adjusted in order to focus on the active area and make the accurate measurement of the device brightness.

3. Results and discussion

The experiments included several runs with different R_c and bending stress type as listed in Table 1. It is to be noticed that the device in Expt. 1, 2, 3, and 4 are not the same device in order to control the defect type caused by each direction of stress. Second, the device was not encapsulated, which means the EL efficiency would decay with time under normal operation in the air, even without bending. Consequently, the EL lifetime experiment was first conducted at a current density of 9.4 mA/cm^2 (about 4.6 V and 100 cd/m^2) as shown in Fig. 4. It showed that after about 10 min, the device was relatively stable at least for the next 50 min. Therefore, the bending experiments were only conducted after the fresh devices were operated

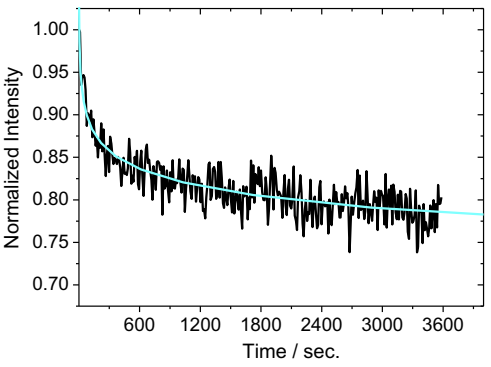

Fig. 4. The lifetime measurement of the non-encapsulated FOLED device under constant current supply at 9.4 mA/cm^2.

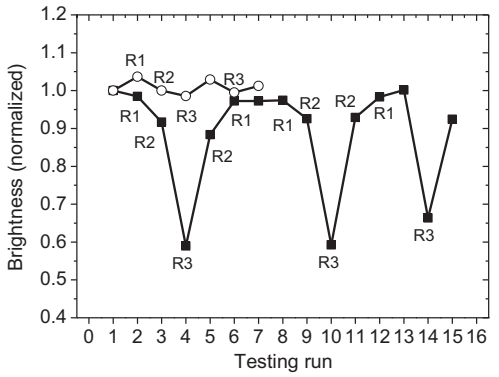

Fig. 5. The brightness of the FOLED device against the testing runs. In the Expt. 1 (filled square), the OLED device was given a stretched stress while in the Expt. 2 (open circle), a compressive stress. R_x denotes the radius of curvature: R_1 = position A, R_2 = position B, and R_3 = position C.

at 9.4 mA/cm^2 after 10 min and did not extend beyond 1 h in duration. This ensured that the EL performance change in the experiment was mainly caused by the mechanical bending process.

Fig. 5 shows how the brightness (normalized) of the OLED device changed with the different bending conditions. The OLED was stretched in Expt. 1 (filled square), and compressed in Expt. 2 (open circle). With the constant current supply at 9.4 mA/cm^2, the brightness of the device in Expt. 1 reduced slightly first when being stretched with R_c = position A, and lowered to 90% with R_c = position B. When it was bent more tightly with R_c = position C, the brightness drops dramatically to under 60%. It seemed that the device was sustainable under the strain up to a critical point: in this case R_c between positions B and C. The strain of the thin-film caused by bending can be calculated by Eq. (3) if the bending is homogeneous and R_c is known.

$$\varepsilon = \frac{y}{R_c} \tag{3}$$

ε is the strain, and y is the distance between the layer and the neutral axis (the layer-element within the complete stack that is neither stretched nor compressed in the bending). With the condition of the described 2-point bending method, it is assume that over the small area of the device, the strain produced is homogeneous. It is also assumed that the position of the neutral axis was at the midpoint of the substrate (as the substrate is much thicker than the coated films) → y = 0.0635 mm. Therefore, for the case of R_c = 10 mm and 6 mm for bending positions B and C, the strain of the OLED layers ~0.65–1%, respectively. After this point, one or more layers appear to crack. Candidate layers could be the ITO anode, as it is the most brittle material of the device, or the ductile aluminum cathode layer as the yield stress decreases dramatically when being as thin as 100 nm [12], or even the organic layers, of which the Young's modulus is between 60 and 120 GPa when being coated on a harder substrate such as the silicon waver [13]. Surprisingly, this damage was reversible as shown in the testing runs 5–7 where the device was relieved gradually until completely flattened. The cycle was then repeated one more time. The brightness again was decreased to lower than 60% after the critical bending point and recovered to almost 100% in run 13 when the bending was relieved again. In the third cycle, the device was bent with R_c = position C directly and relieved again in the next run. It shows that although the brightness did not drop as much as the previous two cycles, the recovery was nevertheless not complete. The damage caused by sudden hard bending seems to be more pronounced. On the other hand, when comparing run 2 and run 8 (with R_c = position A in both runs), although the run 8 was after a likely severe damage to the device that had been caused in run 4, the brightness of each run was not too different. This may be due to the fact that when the device was operated, the higher temperature allowed the layers to creep when the strain was less severe. When the OLED was compressed as in Expt. 2, the brightness was almost unchanged even when R_c = position C.

In order to confirm this result, two more devices were tested and measured by the integrated sphere (Labsphere LMS-100), which had been calibrated according to the FOLED sample holder, as Expt. 3 and Expt. 4 in Table 1. The integrating sphere is a hollow spherical chamber with

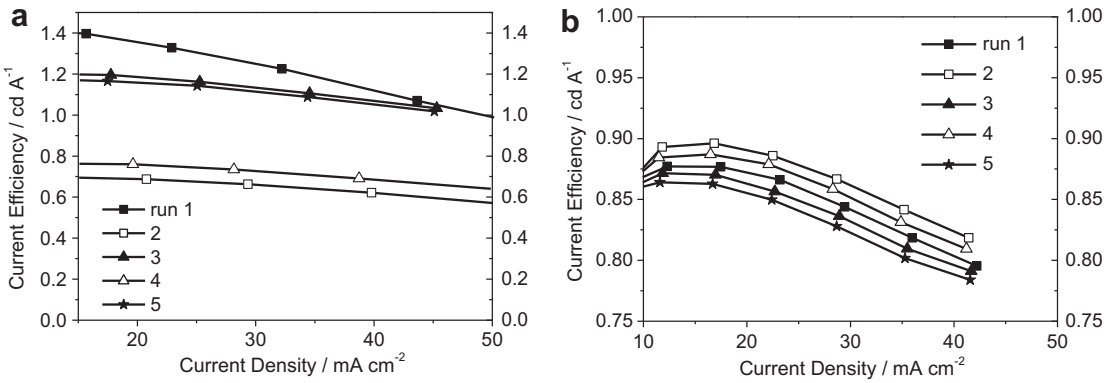

Fig. 6. The current efficiency of the FOLED device against the current density. In the Expt. 3 (a), the OLED device was given a tensile stress while in the Expt. 4 (b), a compressive stress. The filled symbols plots the runs when the device was unbent, while the open symbols plots the runs when the device was bent such that R_c = position C.

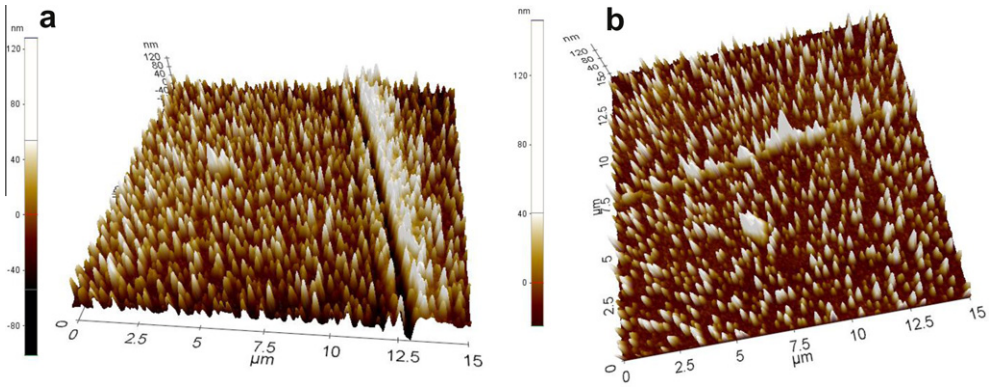

Fig. 7. The AFM images of the aluminum surface of the Expt. 1 (a) and Expt. 2 (b) FOLED device after the bending tests.

a highly reflective material coated on the inner surface and a small photodiode. The sample to be measured is mounted in the middle of the chamber so that ideally all the out-coupled light can be collected by the photodiode. In Fig. 6a (Expt. 3), the device was bent in a concave manner to produce a tensile stress with R_c = position C in the runs 2 and 4, and relieved in the runs 1, 3, and 5. In Fig. 6b (Expt. 4), on the other hand, the device was bent in a convex manner to produce a compressive stress with R_c = position C in the runs 2 and 4, and relieved in the runs 1, 3, and 5. Both experiments repeated the two important results observed by the luminance meter in Fig. 5: the recovery of EL when tensile stress was removed and the different response of the device EL to the opposite direction of the stress.

To understand more about these observations, the devices were examined by atomic force microscopy (AFM) immediately after the bending experiments, and the images are shown in Fig. 7a (Expt. 1) and 7b (Exp. 2). The rough surfaces in the images were the typical thermal evaporated aluminum layer surface as it was the outmost layer of the device. Although it was reported that for a free-standing or polymer-supported aluminum thin-film, the rupture strain is normally between 1% and 2% [14], which is about the maximum strain caused by bending position C in Expt. 1 (~1%). Therefore, the deep and clear cracks were observed in Fig. 7a. On the other hand, in the Fig. 7b only some buckle-like lines were observed, and these lines were merely rougher surfaces with taller spikes, and this may explain why the EL brightness of the Expt. 2 and Expt. 4 remained relatively unchanged as shown in Figs. 5 and 6b. Although the AFM images could only reveal the surface of the aluminum layer as it was the outermost layer, the other layers of the OLED, notably the ITO layer, might have the same types of defects, cracks or buckling, as the aluminum layer. One thing to be noticed here is that these AFM measurements were not conducted during the bending experiments but 1–2 h after, therefore, some cracks or buckles might recover already thus were not observable, but they still provide some information about how these two kinds of stress damaged the devices differently. It is also worth mentioning here that although the compressive strain looks harmless to the FOLED device, it did, however, cause the outermost aluminum layer to detach initially. It means the device completely failed when being bent tighter than some critical radius. This is a known issue for multilayer thin-films when adherence of the layers is poor. But as long as the whole active area did not completely delaminate, and it was still adherent in the flat regions either side of it, i.e., it was still held in place, the layers would come back into contact when the bending moment was removed. Nevertheless, creep, which accelerates as the temperature rises as a result of the resistive heating while the device is operated, would improve the adherence. This process only takes 10s of seconds. For example, the Expt. 2 device would completely fail initially when under a compressive strain with R_c = position C. On removing the bending moment, the device would come back to work with the original EL efficiency. By operating the device for 10–20 s further at the current density of 9.4 mA/cm^2 (about 4.6 V), and then bending the device with R_c = position C again, the device would then not fail but would perform as well as before the bending, as shown in curve Expt. 2 of Fig. 5.

4. Conclusion

It has been shown here that the conventional bottom emitting FOLED device can work with at least 90% of the original efficiency when the OLED layers were subjected to bending in a cylindrical sense about one axis and given a tensile stress with R_c = position B, and almost 100% of the original efficiency when given a compressive stress with R_c = position C. The damage caused by the bending is reversible. For the case of tensile stress (stretching), the device recovered better when bending was applied slowly and step by step from R_c = positions A–C. When it was bent with R_c = position C directly, the device only recovered to 95% after the bending was removed. For the case of compression, one possibility may be that the aluminum cathode detaches initially when being bent with R_c = position C. But after the bending is relieved and the device operated for another 20 s at the current density of 9.4 mA/cm^2 (about 4.6 V), thus giving the aluminum layer enough time to creep, the device could function while being bent with

R_c = position C, and with the same efficiency as before the bending. In both situations, the results give reason to be optimistic about FOLEDs, provided the bending radius of curvature does not fall below 10 mm. To reduce the critical bending radius of curvature further would require a modified substrate architecture. In addition, to avoid delamination when a compressive stress is applied, the adhesion of the OLED layers needs to be improved.

ABSTRACT

A benzothiadiazole bearing donor–acceptor–donor (D–A–D) type monomer (M_3) was synthesized using the combination of 3, 4-ethylenedioxythiophene (EDOT) and thiophene donor units to understand the effect of donor strength on the optoelectronic and electrochemical properties. The resulting monomer was polymerized electrochemically (P_3) and compared with its symmetrical thiophene (P_1) and EDOT (P_2) bearing homologues whether there exists a combination of the electrochemical and optical characteristics. Also, copolymer studies were performed with symmetrical thiophene (M_1) and EDOT (M_2) containing monomers in order to compare the results with P_3. Cyclic voltammetry (CV) and spectroelectrochemistry results revealed that P_3 is a low band gap polymer (1.18 eV) having both p-and n-type property which is superior to the copolymers synthesized using M_1 and M_2.

1. Introduction

Due to their favorable electronic, optical and mechanical properties conductive polymers (CPs) are used in a wide range of applications such as photovoltaics [1], light-emitting diodes [2], field-effect transistors [3], sensors [4], and electrochromic devices [5]. CPs as a class of electrochromic materials have attracted great interest due to several superior properties over their inorganic counterparts such as coloration efficiency [6], fast switching ability [7], multiple colors with the same material [8], and fine-tuning of the band gap with small structural modifications [5b,6–9]. Due to the fact that electrochromic and non emissive applications of CPs provide stimuli effect (viewing angle, light intensity or sunlight exposure) free, light-weight and flexible displays, their development is considered to be important for future display technologies [10].

In order to use CPs in electrochromic devices, there are two issues to be resolved; to have a low band gap to maximize the conductivity of the polymers and satisfy three additive colors in the neutral state to obtain full color space [11]. Approaches to achieve RGB (red, green, blue) colors with CPs have become the subject of many studies; however, only handful of them revealed true red [12], blue [13] or green [14] neutral state polymers. Up to date, donor–acceptor–donor (DAD) route has been considered as the most effective way to obtain low band gap polymers with desired neutral state colors. DA structured monomers are usually obtained with electropolymerizable heterocycles as the end group in order to achieve the necessary polymers electrochemically [15].

Electrochemical copolymerization is also a facile method to obtain desired neutral state colors for these types of materials. In copolymerization, electroactive monomers are polymerized from a bulk containing the co-monomers. Resulting polymer generally shows unique optical and electronic properties with enhanced mechanical and kinetic properties compared to those of the homo-polymers [16]. Fine tuning in the band gap and neutral state color

can be achieved by tailoring the co-monomer feed ratio as well as the working potential of copolymerization [17]. However, exact structures of electrochemical copolymers are hard to determine due to the insolubility of the deposited films which hinders the solution characterizations.

Recently, poly(4,7-di(2,3-dihydro-thieno[3,4-b][1,4]dioxin-5-yl)benzo[1,2,5] thiadiazole) [14d] (P_2) was characterized in terms of its electrochromic properties in our group. It was shown to be the first green to transmissive electrochromic material with two simultaneous maximum absorptions placed at around 400 and 750 nm. Its homologue with lower electron density, poly(4,7-dithien-2-yl-2,1,3-benzothiadiazole) [18] (P_1) has an absorption maximum at around 560 nm where its second transition is in UV region. At the first glance, it seems that a copolymer obtained from these two monomers should have an absorption covering the entire visible region, but the copolymers reported in this manuscript revealed neutral state colors in between the two, since absorption maximum of the copolymer usually lies between the two homo-polymers.

Herein, we report our approach to explain the effect of different donor groups on the electronic and optical properties of DAD type polymers. An asymmetric monomer having both 3,4-ethylenedioxytiophene and thiophene as the donor groups was synthesized and electrochemically polymerized. Since the monomer contains two different donor units, we anticipated that its polymer may behave as a copolymer of the symmetric monomer having the same donor groups. Hence, the properties of copolymers achieved with the co-monomers having either thiophene or 3,4-ethylenedioxythiophene as the donor group were also reported.

2. Results and discussion

2.1. Synthesis

Donor–acceptor–donor type materials 4,7-di(thiophen-2-yl)benzo[c][1,2,5]thiadiazole (M_1) [18,19], 4,7-di(2,3-dihydro-thieno[3,4-b][1,4]dioxin-5-yl)benzo[1,2,5]thiadiazole (M_2) [14d,20] and 4-(2,3-di hydrothieno[3,4-b][1,4]dioxin-5-yl)-7-(thiophen-2-yl)benzo[c][1,2,5]thiadiazole (M_3) were synthesized as shown in Scheme 1 according to previously reported methods. In order to synthesize the asymmetric monomer (M_3) 4,7 dibromobenzothiadiazole was first coupled with tributyl(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)stannane and then the isolated compound was coupled with tributyl(thiophen-2-yl) stannane.

2.2. Cyclic voltammetry

M_3 was polymerized potentiodynamically between −0.3 V and 1.5 V vs. Ag wire pseudo reference electrode (0.3 V vs. Fc/Fc^+) in a 0.1 M dichloromethane (DCM)/acetonitrile (AN) (5:95, v:v) / tetrabutylammonium hexafluorophosphate ($TBAPF_6$) solution onto ITO-coated glass slides in order to observe the polymer characteristics. During polymerization, a characteristic oxidation peak of monomer was observed at 1.2 V accompanied by a reversible redox couple of the polymer. In Fig. 1, the increase in current density with the number of scans clearly shows the deposition of an electroactive film of P_3 on ITO. The resultant polymer revealed reversible p-type doping properties where the p doping/de-doping was indicated by the peaks at 1.06 V and 0.85 V, respectively. The P_3 film is blue in its neutral state and reveals light blue color when oxidized.

Generally, EDOT bearing DAD type molecules have lower monomer oxidation potentials than thiophene bearing ones under identical experimental conditions owing to the electron rich ethylenedioxythiophene group. As reported M_1, revealed a monomer oxidation at 0.85 V in 0.1 M DCM/AN (5:95, v:v)/$TBAClO_4$ vs. the Ag/Ag^+ reference electrode and its EDOT bearing homologue M_2 has a monomer oxidation at 0.95 V in DCM/$TBAPF_6$. In order to have a reliable comparison with M_3, we performed all experiments in DCM/AN/$TBAPF_6$ system vs. Ag wire pseudo reference electrode. As a result, M_3 revealed a monomer oxidation at 1.2 V vs. Ag wire pseudo reference electrode which was lying between the two others. Since M_3

Scheme 1. Synthesis scheme of the monomers; M_1, M_2 and M_3.

contains both ethylenedioxythiophene and thiophene groups, its oxidation potential value is between the values of the monomers containing only EDOT or thiophene as shown in Fig. 2.

Since the polymer structure consists of electron withdrawing benzothiadiazole units, a rare property; n-type doping was observed for P_3 with reversible peaks at −1.6 V and −0.9 V vs. the same reference electrode (Fig. 3). Oxidation and reduction onset values were used to determine the band gap energies for P_1, P_2 and P_3 since all the polymers are both p- and n-type dopable. HOMO and LUMO energies were calculated as −5.75 and −4.65 eV, respectively for P_3 (the value of NHE was used as −4.75 eV throughout this study) [1j]. As seen from Table 1, the LUMO levels of three polymers are same since benzothiadiazole was used as the acceptor unit. However, as the donor strength increases the HOMO energy levels decrease due to the electron rich EDOT units incorporated into the polymer structure. Calculated optical and electrochemical band gap values for P_1 (1.65 eV), P_2 (1.1 eV) and

Table 1
Monomer oxidation, corresponding polymer redox potentials, band energies (HOMO/LUMO values), optical and electronic band gap values of P_1, P_2 and P_3.

Polymer	E_m^{ox} (V)	E_p^{ox} (V)	E_p^{red} (V)	HOMO/LUMO energies (eV)	Optical band gap (eV)	Electrochemical band gap (eV)
P_1	1.36	1.09	0.61	−4.85/−3.75	1.50	1.65
P_2	1.07	0.90	0.70	−5.40/−3.75	1.20	1.10
P_3	1.20	1.06	0.85	−5.00/−3.75	1.18	1.20

P_3 (1.2 eV) are in good agreement confirming the identical electrochemical processes for both methods (CV and spectroelectrochemistry).

The scan rate dependence of the P_3 film was investigated using CV. A direct proportionality between the scan rate and the current intensity indicates a well adhered electroactive film on ITO and a non-diffusion controlled electrochemical process. The linear relationship can be seen even at very low and high scan rates which demonstrates that the number of electrons in the diffusion layer is always constant during the scans but increases as the scan rate increases [21] (Fig. 4).

Copolymer studies were performed with M_1 and M_2 in order to observe whether the resulting copolymer will have the same properties with P_3. Since M_3 has both thiophene and EDOT units on its polymer backbone, its polymer P_3 may reveal the similar electrochemical and optical characteristics with the copolymer (M_1 and M_2 as the co-monomers). A three-electrode cell with ITO working electrode was used to deposit polymers potentiodynamically. Oxidative polymerizations were achieved by repeated cycling between −0.3 V and +1.5 V with different feed ratios. For 1:1 (M_1:M_2) ratio 10^{-6} moles of each co-monomers were used and the other ratios were determined according to the mole ratios. DCM/AN (5:95 v: v)/ $TBAPF_6$ solvent-electrolyte system was used for polymerization at a scan rate of 100 mV s^{-1} for 1:1, 1:2, 1:4, 1:10 and 2:1 (M_1:M_2) ratios. Table 2 summarizes the monomer and polymer redox potentials for electrochemically prepared copolymers. During potentiodynamic scans, two monomer oxidations were observed for M_1 and M_2 distinctively and reversible redox peaks were determined for the copolymers. As the amount of M_1 was increased in the feed, the polymer redox peaks were slightly shifted to higher potentials due to the increased amount of thiophene units on the polymer backbone. Likewise, P_3 showed similar electrochemical properties with those of the copolymers prepared from different feed ratios.

2.3. Optical studies

In its neutral state, P_3 showed maximum absorption at 408 nm and 642 nm in the visible region which resulted in a greenish-blue color. Likewise P_2 also has two absorption maxima due to π–π^* transition at around 428 nm and 755 nm corresponding to green color in its neutral state. In order to have a green color, there should be two transitions at around 400 nm and 700 nm in the visible region. P_1 has only one transition at 560 nm whereas its second transition is not in the visible region. As we incorporated EDOT moieties into the P_3 polymer structure the absorption in the UV region shifts to 408 nm which is

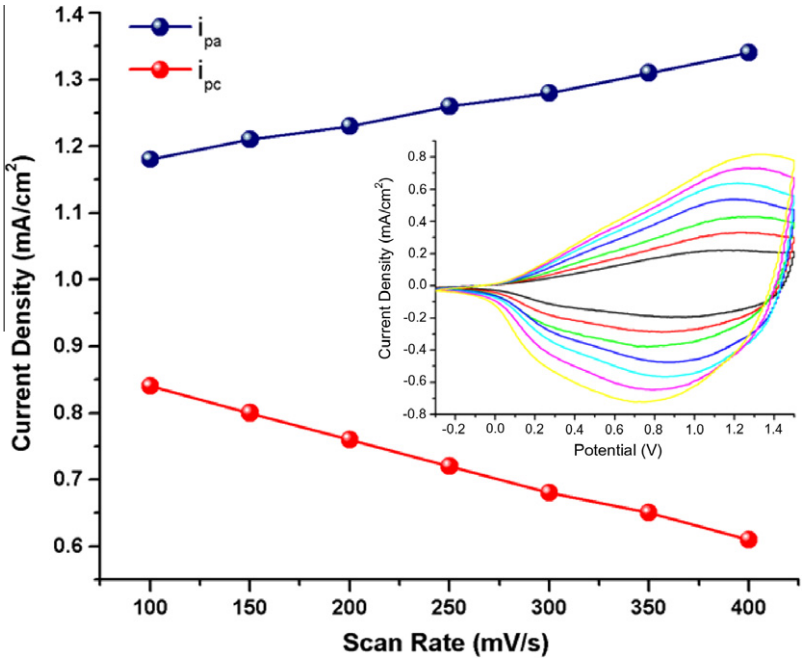

Fig. 4. Scan rate dependence of P_3 film for p-doping in 0.1 M AN/$TBAPF_6$ solvent-electrolyte couple at 100, 150, 200, 250, 300, 350 and 400 mV s−1.

Co-monomer composition	$2M_1$:$1M_2$	$1M_1$:$1M_2$	$1M_1$:$2M_2$	$1M_1$:$4M_2$	$1M_1$:$10M_2$
E^{ox}_{poly} (V)	1.34	1.30	1.28	1.28	1.26
E^{red}_{poly} (V)	0.94	0.91	0.85	0.75	0.58

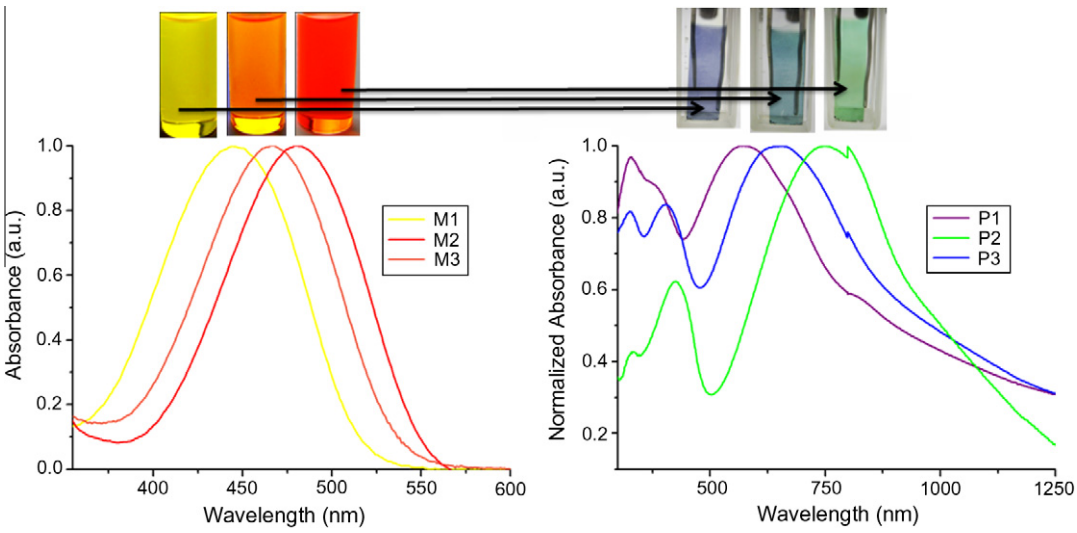

Fig. 5. Electronic absorption spectra of monomers M_1, M_2 and M_3 (left) in $CHCl_3$ and polymers P_1, P_2 and P_3 in thin film form (right).

in the visible region but still does not correspond to green color since the second π–π^* transition is not at around 700 nm. The normalized monomer and resulting polymer film absorptions of P_1, P_2 and P_3 are shown in Fig. 5. It can be seen that when thiophene units were replaced by EDOT units, monomer absorbance values were shifted to lower energies. This trend was also observed in the absorbance values of polymer films. Also, since the conjugation

length was increased, all dominant wavelengths were shifted to right for polymers P_1, P_2 and P_3 compare to the ones for their monomers.

Fig. 6 displays the normalized absorbance of each copolymer film in neutral state prepared from different compositions. P_1, P_2 and P_3 demonstrate a clear shift in the dominant wavelength as the co-monomer composition is varied from pure P_1 to pure P_2. As the concentration of M_2 is increased in the copolymer chain, the π–π^* absorptions of the copolymers were shifted to lower energies from 391 nm to 422 nm and 596 nm to724 nm. The observed red shift indicated a "tunable" electrochromic material can be synthesized by varying the amount of any monomer in the copolymer backbone. Here, it is noteworthy to emphasize that P_3 showed the electrochemical and optical properties of the copolymer (1:4, M_1:M_2 ratio) hence P_3 can be used like a copolymer. Most of the copolymer studies in the literature state that the copolymerization of two co-monomers often results in a random copolymer. However, we achieved a controlled polymerization with similar properties to that of copolymers using M_1 and M_2 as the co-monomers. Table 3 summarizes λ_{max} values and band gap energies for P_1, P_2, P_3 and the copolymers obtained from M_1 and M_2. The band gap of P_3 was calculated as 1.18 eV from the lowest π–π^* transition which is very similar to the one reported for the copolymer obtained using 1:4 M_1:M_2 ratio.

In order to probe the spectral response of P_3 upon applied potential spectroelectrochemical studies were performed in 0.1 M AN/$TBAPF_6$ solvent-electrolyte couple. During stepwise oxidation, the potential was gradually increased from −0.3 V to 1.2 V and the absorbance changes were observed for P_3. In its neutral form P_3 revealed only two transitions with no absorbance in NIR region. Upon p-type doping, as the peaks at 408 nm and 642 nm were decreased new bands in near-IR region intensified due to the charge carrier formation such as polarons and bipolarons (Fig. 7). Since P_3 still absorbs after 600 nm in its doped

state, the polymer was light blue. To have a transmissive state in the doped form the bands in the visible region should have depleted completely [13b].

Transmittance changes and switching abilities of P_3 were determined while sweeping the potentials between its fully oxidized and reduced states within 5 s time intervals. The studies were performed in a monomer free 0.1 M AN/$TBAPF_6$ solvent-electrolyte system. P_3 revealed 22% transmittance change upon doping/de-doping process at 408 nm, 14% at 620 nm and 46% at 1050 nm (Fig. 8). Switching time is the duration for the polymer to switch between the two extreme states and it was calculated as 0.6 s, 0.75 s and 0.8 s at corresponding wavelengths.

3. Conclusion

An EDOT, thiophene and benzothiadiazole bearing donor–acceptor type monomer was synthesized and

polymerized electrochemically as an alternative to copolymer studies. The polymer was characterized by electrochemically and optically. The resulting polymer is both p- and n-type dopable and showed the characteristics of a copolymer where two monomers are required. The results revealed that P_3 can be synthesized and its polymerization can be controlled to avoid the formation of a random copolymer.

4. Experimental

4.1. General

All chemicals were purchased from Aldrich except THF (tetrahydrofuran) which was purchased from Acros. Tributyl(thiophene-2-yl)stannane [22] and tributyl(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)stannane [23] were synthesized according to a previously described method. All reactions were carried out under argon atmosphere unless otherwise mentioned. All electrochemical studies were performed under ambient conditions using a Voltalab 50 potentiostat. Electropolymerizations were performed in a three-electrode cell consisting of an indium tin oxide doped glass slide (ITO) as the working electrode, platinum wire as the counter electrode, and a silver wire pseudo reference electrode. After each measurement the reference electrode was calibrated with ferrocene. The potential of quasi reference electrode was determined as 50 mV vs. the normal hydrogen electrode (NHE).

^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Bruker Spectrospin Avance DPX-400 Spectrometer. Chemical shifts are given in ppm downfield from tetramethylsilane. A Varian Cary 5000 UV–Vis spectrophotometer was used to perform the spectroelectrochemical studies of the polymer at a scan rate of 2000 nm/min. Column chromatography of all products was performed using Merck Silica Gel 60 (particle size: 0.040–0.063 mm, 230–400 mesh ASTM). Reactions were monitored by thin layer chromatography using silica gel coated aluminum sheets. Solvents used for spectroscopy experiments were spectrophotometric grade.

4.2. Synthesis of 4,7-dibromobenzo[c] [1,2,5] thiadiazole

A mixture of hydrobromic acid (16 ml) and bromine (2 ml) was added slowly to a mixture containing hydrobromic acid (36 ml) and benzothiadiazole (2.0 g, 0.015 mol) via continuous stirring at 150 °C. The reaction was left for overnight reflux. Then, the mixture was kept in ice bath; orange crystals were produced in 3–4 h. The crystals were filtered, and dissolved in dichloromethane. The organic phase was extracted by two portions of sodium bisulfide solution, and then with saturated sodium chloride solution. After the washing process, mixture was dried over $MgSO_4$ and the solvent DCM was evaporated by rotary evaporator. The yellowish solid was collected after drying in oven for overnight. ^{1}H NMR (400 MHz, $CDCl_3$): δ(ppm) 7.65 (s, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ(ppm) 152.75, 132.13, 113.70.

4.3. Synthesis of 4-bromo-7-(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)benzo[c][1,2,5]thiadiazole

4,7-Dibromobenzo[c] [1,2,5] thiadiazole (1.5 g, 5.1 mmol) and tributyl(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)stannane (3.3 g, 7.7 mmol) were dissolved in dry tetrahydrofuran (THF) (60 ml) and set for refluxing under argon atmosphere. The catalyst, dichlorobis(triphenylphosphine)-palladium(II) (60 mg, 0.085×10^{-3} mmol) was added and the mixture was stirred at 100 °C under argon atmosphere for 16 h while monitoring the reaction with TLC. At the end of 16 h, the mixture was cooled and THF was removed from the mixture by rotary evaporator. Then the residue was subjected to column chromatography (Chloroform: Hexane, 3:1) to afford a purple solid, 4-bromo-7-(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)benzo[c][1,2,5]thiadiazole. ^{1}H NMR (400 MHz, $CDCl_3$): δ(ppm) 7.77 (d, 1H), 8.16 (d, 1H), 6.54 (s, 1H), 4.24 (m, 2H), 4.34 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ(ppm) 61.95, 62.73, 100.63, 105.36, 115.65, 123.47, 124.02, 127.67, 127.84, 130.21, 139.34, 151.15.

4.4. Synthesis of 4-(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)-7-(thiophen-2-yl)benzo[c][1,2,5]thiadiazole (M_3)

4-Bromo-7-(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl) benzo[c][1,2,5]thiadiazole (1 g, 2.8 mmol), and tributyl(thiophen-2-yl)stannane (2.1 g, 5.6 mmol) were dissolved in THF (60 ml) and dichlorobis(triphenylphosphine)-palladium(II) (50 mg, 0.071×10^{-3} mmol) was added at room temperature. The mixture was refluxed for 12 h under argon atmosphere. Solvent was evaporated under vacuum and the crude product was purified by column chromatography (Cholorform: Hexane, 3:1) to obtain a dark red solid, 4-(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)-7-(thiophen-2-yl)benzo[c][1,2,5]thiadiazole (M_3) . ^{1}H NMR (400 MHz, $CDCl_3$): δ(ppm) 6.5 (s, 1H), 7.8 (d, 1H), 6.9 (s, 2H), 8.3 (d, 1H), 8.0 (m, 1H), 7.1 (m, 1H), 7.4 (m, 1H), 4.3 (m, 2H), 4.2 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$): δ(ppm) 151.56, 151.38, 140.70, 140.66, 140.37, 139.21, 138.32, 126.64, 125.90, 125.11, 124.92, 124.85, 123.51, 101.13, 63.75, 63.04.

4.5. Electrochemical polymerization of M_3

For electrochemical polymerization, anodic electrodeposition of the polymer was performed from a dichloromethane (DCM) and acetonitrile (AN) mixture (5/95, v/v) with 0.1 M $TBAPF_6$ (tetrabutylammonium hexafluorophosphate) solvent-electrolyte couple at a scan rate of 100 mV s^{-1}. ITO-coated glass slides, Pt wire and Ag wire were used as working, counter and pseudo reference electrodes, respectively. The potentiodynamic scans were carried out between −0.3 and 1.5 V. After polymerization, the film was washed with ACN to remove the unreacted monomers and the supporting electrolyte.

4.6. Synthesis of copolymers

A three-electrode cell containing ITO-coated glass slide as the working electrode was used to deposite copolymer films potentiodynamically. 4,7-Di(thiophen-2-yl)benzo[c]-

[1,2,5]thiadiazole (M_1) and 4,7-bis(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)benzo[c][1,2,5]thiadiazole (M_2) were synthesized according to the previously reported method [14d,18,20b]. The oxidative electrochemical copolymerizations were achieved by repeated potential cycling in different solutions. M_1 and M_2 were used as the co-monomers in 0.1 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$)/acetonitrile (AN)/dichloromethane (DCM) (95:5, v: v) solvent-electrolyte couple at a scan rate of 100 mV s^{-1}. All polymerizations were done under the same conditions for comparison purposes. For 1:1 (M_1:M_2) ratio 10^{-6} moles of each co-monomer were used and the other ratios; 1:2, 2:1, 1:4 and 1:10 (M_1:M_2) were determined accordingly to mimic M_3. Potentiodynamic runs were between −0.3 and 1.5 V for all copolymer depositions with a scan rate of 100 mV s^{-1}. After electrolysis, the films were washed with ACN to remove the supporting electrolyte and the unreacted monomers.

Surface free energy
Carbonyl-bridged bithiazole

ABSTRACT

The effects of adding solution-processed polyfluorene derivatives as buffer layers between the polymer insulator and active layer of n-channel organic field-effect transistors (OFETs) containing a carbonyl-bridged bithiazole derivative were investigated. The surface free energy was modified by the polyfluorene derivatives. A poly(9,9-dioctylfluorene) (F8) buffer layer, which has a hydrophobic nature, a low surface free energy, and consists almost entirely of a dispersion component, improved the growth morphology of the OFET active layer. An OFET with an F8 buffer layer exhibited n-channel characteristics, and an electron field-effect mobility of 0.025 $cm^2 V^{-1} s^{-1}$.

1. Introduction

Organic semiconductors have attracted considerable attention due to their simple, low-cost processing and potential electronic and optoelectronic applications. They have potential application as electronic and optoelectronic devices, especially when fabricated by solution processing for large-area, flexible devices. Recently, organic field-effect transistors (OFETs) have been extensively studied for their potential application in low-cost, large-area, flexible electronics [1–9]. However, most of the high field-effect-mobility OFETs have been based on p-channel materials. Although n-channel semiconductor materials are important in the manufacture of ambipolar transistors and complementary circuits, they are relatively rare compared to p-channel materials. N-channel OFETs containing carbonyl-bridged bithiazole derivatives have been reported to have a relatively high electron field-effect mobility [10]. These n-channel OFETs, fabricated on organic self-assembled monolayer (SAM)-treated SiO_2, had an electron mobility on the order of 10^{-2} $cm^2 V^{-1} s^{-1}$.

Recently, polymer gate insulators have attracted attention due to their novel properties, such as solution-processed fabrication, smooth surface, optical transparency, and thermal stability. The electrical characteristics of OFETs depend on the interface state between the organic active layer and the gate insulator, so the choice of gate insulator is important. Chua et al. demonstrated that hydroxyl bonds at the interface between SiO_2 and the organic active layer interfered with n-type carrier transport [8]. On the other hand, Nakayama et al. also demonstrated that insertion of an electronically active interfacial layer of an organic semiconductor is more effective in eliminating electron traps at the insulator surface [11]. Therefore, surface treatment could be an effective means of improving the performance of OFETs. In general, the application of an organic SAM, such as octadecyltrichlorosilane ($C_{18}H_{37}SiCl_3$, OTS) or hexamethyldisilazane ($(CH_3)_3$-Si-NH-Si-$(CH_3)_3$, HMDS), forms an effective channel coating

[8,12,13]. However, because the SAM is only a monolayer, it is difficult to quantify its formation, and the surface treatment time required to form the SAM is relatively long.

Fluorene-type polymers have emerged as an important class of conducting polymers, due to their efficient emission, high stability, and relatively high mobility [8,14,15]. Various characteristics, such as electrical and optical properties, of polymers can be modified by copolymerization with fluorene units and various functional groups.

In this study, we anticipated that a fluorene-type polymer could be utilized as a hydroxyl-bond-free solution-processable buffer layer, instead of a SAM. We investigated the interface effect of adding polyfluorene derivatives as solution-processable buffer layers between the polymer insulator and the active layer in n-channel OFETs containing a carbonyl-bridged bithiazole derivative.

2. Experimental procedure

Fig. 1 shows the device structure, with a polyfluorene derivative buffer layer, and the molecular structure of the active layer used in this study. Poly(9,9-dioctylfluorene) (F8), which has a fluorene backbone and alkyl side-chains, and fluorene copolymers of poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-bithiophene] (F8T2) and poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-(1,4-benzo-{2,1′,3}-thiadiazole)] (F8BT) were used as buffer layers. Polished indium tin oxide (ITO), commercially pre-coated on a glass substrate, was used as the gate electrode. The surface morphology was observed by atomic force microscopy (AFM; JEOL JSPM-5200), from which the average surface roughness of the ITO was estimated to be about 0.5 nm. The polyvinylphenol (PVP) and poly(methyl methacrylate) (PMMA) used to make the insulator were spun onto a patterned ITO-coated glass substrate, and then baked above 150 °C in air. To form the buffer layer, polyfluorene derivatives with a 15 nm thickness were spun onto PVP and baked at 70 °C. The typical thickness of the gate insulator was about 400 nm.

It is well-known that the electrical properties of OFETs are strongly affected by the surface roughness of the gate insulator. The average surface roughness of gate insulators

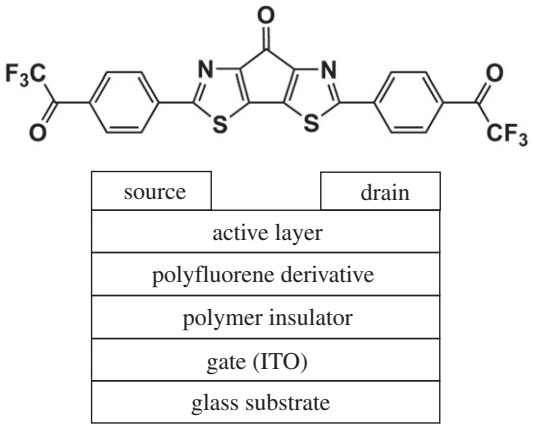

Fig. 1. The device configuration and the molecular structure of the active layer used in this study.

and buffer layers was estimated to be less than 0.3 nm from AFM images. The gate leakage of the PVP was on the order of 10 nA/cm^2 at a gate bias of 50 V. An electric permittivity of 5.3 for the PVP insulator was calculated from capacitance measurements. Material containing trifluoroacetyl groups at the terminal positions of a π-conjugated oligomer was observed to lower the lowest unoccupied molecular orbital energy level and invoke strong intermolecular interactions [16,17]. The material shown in Fig. 1 was synthesized using a previously published procedure [10], and used as the organic active layer in an OFET. An organic active layer 15 nm thick was deposited by organic molecular beam deposition, without substrate annealing, at a background pressure of about 10^{-5} Pa. The growth rate was monitored using a quartz crystal oscillator, and was on the order of 1 Å/min. 30-nm-thick source and drain Au electrodes were evaporated at a background pressure of about 10^{-4} Pa. The channel length and width were 0.1 and 2 mm, respectively. All measurements of electrical characteristics of the OFETs were performed at room temperature in a vacuum chamber at a background pressure of about 10^{-4} Pa. The current–voltage characteristics were obtained using 2400 and 6517A source meters (Keithley). To analyze the surface state of the buffer layers, the surfaces were characterized by measuring the contact angles with distilled water, ethylene glycol, and diiodomethane [18,19].

3. Results and discussion

PVP, which has a relatively high electric permittivity, is a candidate polymer insulator for p-channel OFETs [20]. In OFETs, it is well-known that the charge carriers run a few nm around the insulator/semiconductor interface, and OH groups at the interface between the polymer gate insulator and the organic active layer interfere with n-type carrier transport [8]. Therefore, OFETs with unmodified PVP gate insulators cannot exhibit good electron transport, because the hydroxyl groups trap electrons. PMMA, which contains no electron trapping groups, has also been used as a gate insulator for n-channel OFETs [9,15].

Carrier mobility depends on the microstructure and morphology of the organic layer. Moreover, the surface morphology of the first few layers, where charge transport occurs, can strongly influence the mobility. Fig. 2a–c show phase images of organic layers on PVP, PMMA, and PVP/F8, respectively, with deposited organic active layers approximately 1 nm thick. As shown in Fig. 2, AFM images demonstrated that larger monolayer grains grew on the F8 buffer layer, compared to PVP and PMMA. That is, the molecular ordering in the initial layer was better on the F8 buffer layer.

It is widely known that the growth of organic thin films is highly sensitive to the surface free energy of the substrate. Thus, the optimization of surface free energy by SAMs influences the two-dimensional growth of the organic layers. In the initial stage of vacuum deposition of the semiconductor, crystal growth is affected by the surface free energy of the insulator or buffer layer. We investigated the surface free energy to determine why polymer insula-

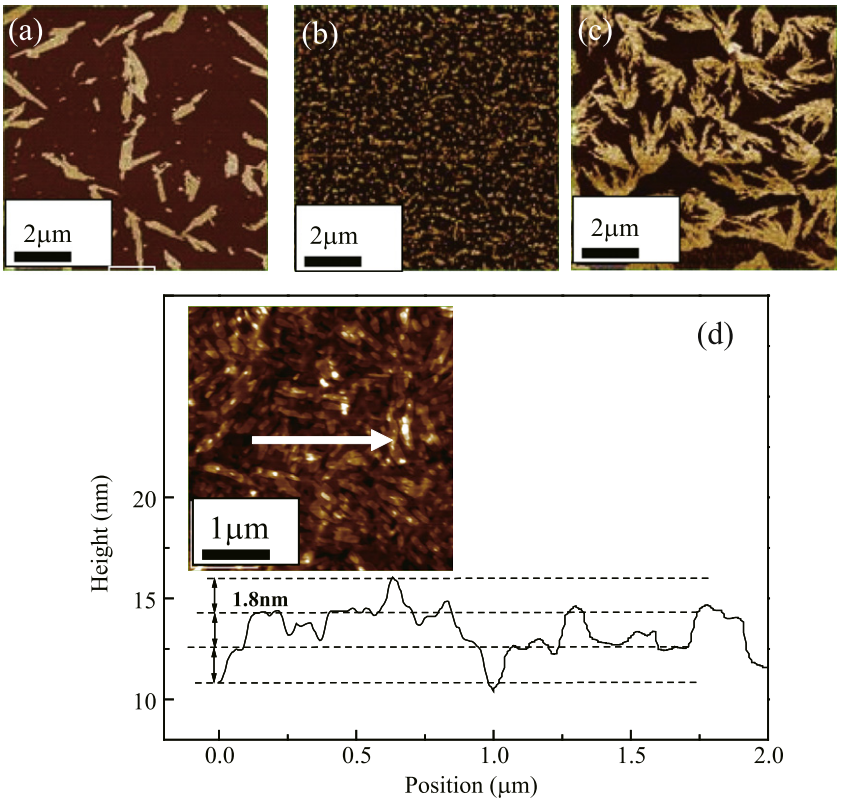

Fig. 2. Phase images of 1-nm-thick active layers on (a) PVP, (b) PMMA, and (c) PVP/F8, and (d) cross-sectional profile along the arrow shown in the inset. The inset shows a topographic image of a 15-nm-thick active layer on PVP/F8.

tor and polyfluorene derivatives yielded different morphologies. The surface free energy was estimated from contact angle measurements using distilled water, ethylene glycol ($C_2H_6O_2$), and diiodomethane (CH_2I_2). To calculate the surface free energy, we employed a solid–liquid adhesion (W) equation based on Owen's theory [18] as follows,

$$W = \gamma_{LV}(1+\cos\theta) = 2(\gamma_s^d\gamma_{LV}^d)^{1/2} + 2(\gamma_s^p\gamma_{LV}^p)^{1/2}, \quad (1)$$

where the superscript d refers to the dispersion (non-polar) component, and p refers to the polar (non-dispersion) component including all interactions established between the solid and liquid, such as dipole–dipole, dipole-induced dipole, and hydrogen bonding. γ_s and γ_{LV} refer to the solid and liquid surface free energies, respectively.

Since it contains OH groups, PVP is hydrophilic. The static contact angles of polyfluorene derivatives were larger than those of polymer insulators. Unsaturated hydrocarbons tend to exhibit $\gamma_s^p = 0$ [18]. PVP and PMMA have both dispersion and polar components, as shown in Table 1. The surfaces of polyfluorene derivatives are believed to be hydrophobic because of their alkyl side-chains, which have $\gamma_s^p = 0$. Their surfaces consist almost entirely of a dispersion (non-polar) component, as shown in Table 1. The characteristics of surfaces consisting almost entirely of a dispersion component are the same as those of OTS [12]. The F8 buffer layer had a lower surface free energy than the polymer insulators, and its surface free energy was lower than that of HMDS (~40 mJ/m^2) and close to that of OTS (~30 mJ/m^2) [12,13]. Therefore, fluorene-type polymers without OH could be applied to the buffer layer to modify the surface free energy at the interface between the insulator and the active layer, as an alternative to an SAM.

The low surface free energy and predominant dispersion component of F8 resulted in improved molecular ordering in the initial layer. The differences in the phase images were consistent with the differences in surface states of the insulators and F8. In a 15-nm-thick film on F8, crystal growth was governed by a layer-by-layer mechanism, as shown in Fig. 2d. The step size of a grain was estimated to be approximately 1.8 nm, and the molecules were oriented parallel to each other, with their long axis tilted away from normal to the substrate plane [10]. The grain structure of the active layer favored current flow, with a nearly upright orientation of molecules on the substrate, when the maximum change transport was realized in the direction perpendicular to the plane of the bithiazoles. Therefore, n-channel OFETs with an organic layer on the polyfluorene buffer layer should be expected to have a high mobility.

The output characteristics, at various gate voltages, of OFETs containing different polyfluorene derivatives as buffer layers are shown in Fig. 3. For all devices, the saturation characteristics were typical of an n-channel OFET function-

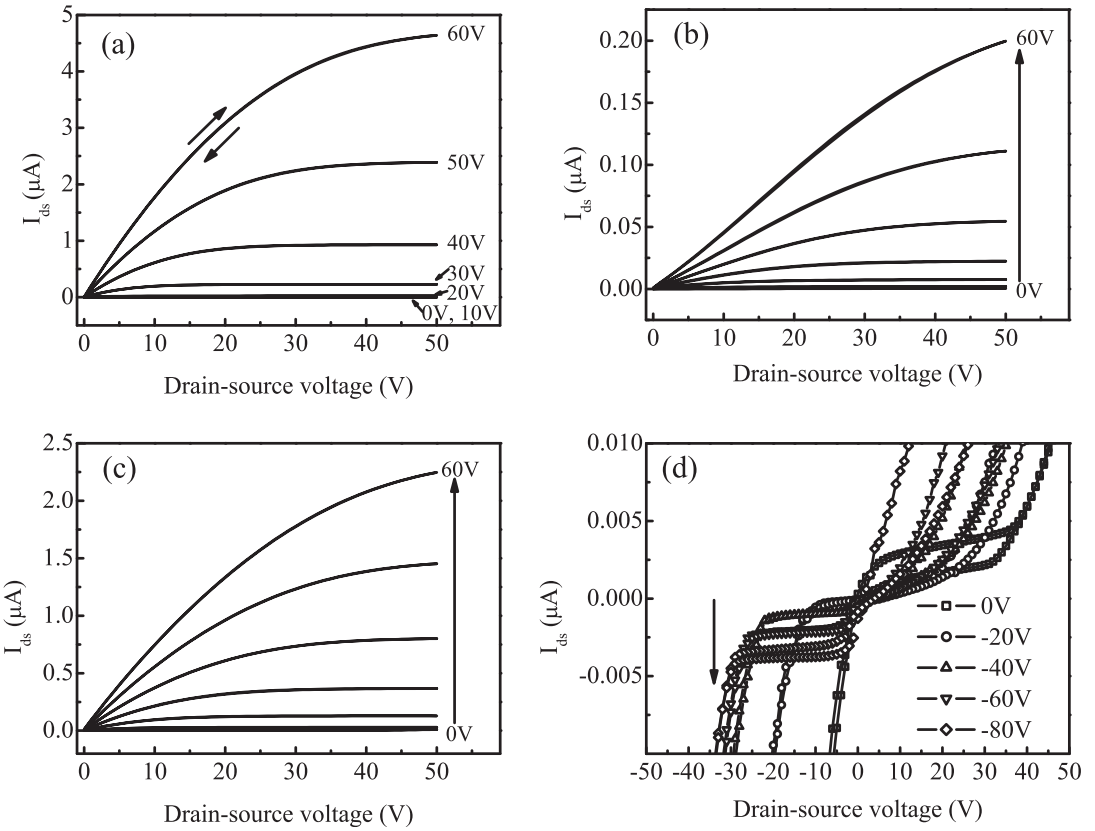

Fig. 3. Output characteristics of OFETs with F8 (a), F8BT (b), and F8T2 (c), (d) buffer layers at different gate voltages.

ing in electron enhancement mode. However, for a device with F8T2, the saturation characteristics of a p-channel OFET functioning in hole enhancement mode were also observed. Therefore, the F8T2 layer functioned as a p-channel active layer.

Fig. 4 shows transfer characteristics of OFETs with F8, F8T2, and F8BT buffer layers at a drain voltage of 50 V. The field-effect mobility and threshold voltage were estimated from the square root of the drain current versus gate voltage, by plotting the saturated drain current at a drain voltage of 50 V. The field-effect mobilities, threshold voltages, and current on/off ratios of various OFETs are summarized in Table 1. The OFET with an F8 buffer layer had a field-effect electron mobility of 0.025 cm^2 V^{-1} s^{-1}, and a threshold voltage of 23 V. The current on/off ratios of OFETs with F8, F8T2, and F8BT buffer layers at a drain voltage of 50 V were about 10^4, 10^3, and 10^3, respectively, as shown in Fig. 4 when the gate voltage was scanned from 0 to 100 V. The carrier mobility and current on/off ratio of an OFET with an F8 buffer layer, which had the lowest surface free energy, were higher than those of OFETs with F8T2 and F8BT layers. One possible explanation for this is that the effect of grain boundaries was dominant in determining the electron mobility in OFETs, since the hydrophobic surface of the F8 improved the molecular ordering in the initial layer. It is also possible that the mobility of an OFET with an F8T2 buffer layer decreased because the F8T2 also functioned as the active layer. The interface between the insulator and organic layer encountered problems, not only with the growth morphology of the

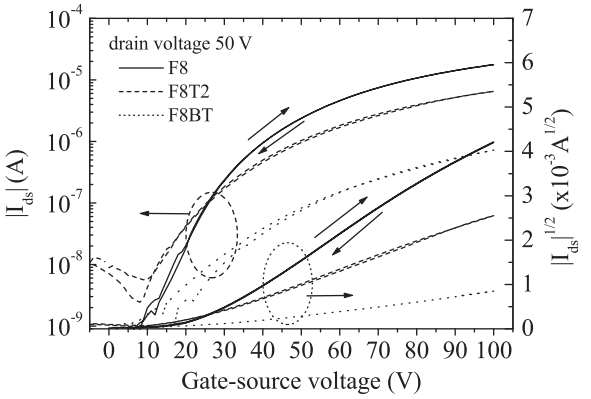

Fig. 4. Transfer characteristics of OFETs with F8, F8T2, and F8BT buffer layers at a drain voltage of 50 V.

overlaying films, but also with carrier traps. Since PVP insulator with OH groups has a hydrophilic nature, the OFETs had hysteresis characteristics related to carrier traps at the interface [21]. For an F8 device, no significant hysteresis was observed in the output or transfer characteristics. This suggests that the carrier traps decreased due to the hydrophobic surface of the F8. Due to the presence of alkyl groups on the F8 surface, instead of an SAM, devices with an F8 buffer layer would have performed comparably to those fabricated on SAM-treated surfaces [10].

4. Conclusions

We investigated the effect of inserting solution-processable polyfluorene derivatives as buffer layers between the insulator and the active layer in n-channel OFETs containing a carbonyl-bridged bithiazole derivative. The surface free energy was modified by the polyfluorene derivatives. An F8 buffer layer with a hydrophobic nature, low surface free energy, and consisting almost entirely of a dispersion component improved the growth morphology of the active layer. An OFET with an F8 buffer layer exhibited n-channel characteristics, with an electron field-effect mobility on the order of 10^{-2} cm^2 V^{-1} s^{-1}. The combination of a polymer insulator and F8 exhibited the same order of n-type performance as a conventional SiO_2-SAM system, demonstrating that our findings may help enable an all-OFET device. Polyfluorene derivatives, the characteristics of which can be modified by copolymerization of fluorene units with various functional groups, can be applied as a solution-processable buffer layer to modify the surface free energy at the insulator to active layer interface.

Anodic buffer

ABSTRACT

Highly efficient top-emitting organic light-emitting devices (TOLEDs) using a Fe_3O_4 modified Ag anode have been demonstrated. The tris-(8-hydroxyquinoline) aluminum-based TOLEDs exhibit a very low turn-on voltage of 2.5 V and a high current efficiency of 8.1 cd/A. The improved properties for the TOLEDs is mainly due to the enhanced hole injection by introducing the anodic buffer. The mechanism of this enhanced hole injection is studied by the X-ray and ultra-violet photoemission spectroscopy, which demonstrated that the dipole layer is formed at the anode/organic interface and the hole-injection barrier is therefore reduced after introducing the thin Fe_3O_4 film between the Ag anode and the hole-transport layer.

1. Introduction

Top-emitting organic light-emitting devices (TOLEDs) are of considerable interest for their application in high resolution active matrix display because they provide better image quality, higher aperture ratio and allows fabrication on an opaque substrate, such as Si wafers [1]. The bottom anode with both high reflectivity and high work function are essential for achieving efficient TOLEDs. Ag is an excellent candidate due to its highest reflectivity in visible light range among various metals. However, its work function (4.3 eV) [2] is not sufficient high for efficient hole injection. Serious efforts, therefore, have been devoted to overcome the problem. For example, MoO_x [3], Ag_2O [4], V_2O_5 [5], CFx [6], etc. have been reported to modify the Ag anode and improve the hole injection from the Ag anode. A self-assembled monolayer appears to be another way of tuning the work function of the Ag anode [7]. Therefore, using an anodic buffer in the TOLEDs is effective in realizing its high performance, and more works are needed to explore other materials as the anodic buffer to further improve the performance of the TOLEDs.

In previous work [8,9], we have reported that Fe_3O_4 is not only an effective buffer on the ITO anode but also an effective p-dopant in hole-transport layer in bottom emitting OLEDs. In this work, the application of the Fe_3O_4 was further explored into the TOLEDs and much improved performance due to the anodic modification of the Fe_3O_4 on the Ag anode was observed. Systematic investigation on the role of Fe_3O_4 as the buffer in the TOLEDs was performed by *in situ* ultra-violet photoemission spectroscopy (UPS) and X-ray photoemission spectroscopy (XPS) measurements, as well as the characteristics of the hole-only devices. These studies reveal that the hole-injection efficiency is enhanced due to the reduction of the injection barrier after introducing the ultra thin film of Fe_3O_4 at the Ag anode and the hole-transport layer interface. As a

result, the brightness, the current density and the efficiency of the TOLEDs are highly improved.

2. Experimental details

The TOLEDs were fabricated by depositing 80 nm thick Ag as the reflective anode onto 1600 nm thick SiO_2-covered Si substrate. An ultra thin film of Fe_3O_4 as the anode buffer with the different thickness changing from 1 nm to 4 nm was then deposited, followed by deposition of 50 nm thick hole-transporting layer of *N*,*N*′-diphenyl-*N*,*N*′-bis(1,1′-biphenyl)-4,4′-diamine(NPB), 50 nm thick emitting layer of tris-(8-hydroxyquinoline) aluminum (Alq_3), and semi-transparent cathode of LiF (1 nm)/Al (1 nm)/Ag (20 nm). Here, all layers were prepared by thermal evaporation in a high vacuum system with the pressure of less than 5×10^{-4} Pa. The active area of the devices was 2×2 mm^2. Their current density–luminance–voltage (*J*–*L*–*V*) characteristics were measured by Keithley 2400 programmable voltage–current source and Photo Research PR-655 spectrophotometer. The UPS data were measured with a Thermo ESCALAB 250, and the samples were biased at −4.0 V to observe the low energy secondary cutoff during the measurement. The XPS measurements were performed with Mg Kα X-ray source (1253.6 eV) (Specs XR50).

3. Results and discussion

3.1. Effects of Fe_3O_4 modified Ag anode on electroluminescence performance of TOLEDs

The *J*–*L*–*V* characteristics of the TOLEDs with the various thickness of Fe_3O_4 as the anodic buffer are shown in Fig. 1. The inset of Fig. 1a shows the electroluminescence (EL) spectra of the TOLEDs at viewing angle of 0°, 20°, and 40° off the surface normal. The EL spectra of the TOLEDs with the various Fe_3O_4 thickness are similar, and the TOLEDs show narrowed and angular shift of the peak wavelength and intensity of the EL spectra due to the existence of microcavity effects. Both the current density and the luminance in the normal direction are strongly dependent on the presence and the thickness of the Fe_3O_4 buffer layer. They markedly increase when increasing the Fe_3O_4 thickness, and reach the maximum at 3 nm. With further increment of the Fe_3O_4 layer thickness, the current density and the luminance are decreased. The devices without the buffer layer shows much lower EL properties compared to the Fe_3O_4 buffered devices. The turn-on voltage of 2.5 V to obtained the luminance of 1 cd/m^2 and the maximum luminance of 108,297 cd/m^2 at 14 V have been observed from the TOLEDs with an optimum Fe_3O_4 thickness of 3 nm, while it is 5.0 V and 13,680 cd/m^2 at 13 V for the TOLEDs without the anodic buffer. The current efficiency versus voltage in the normal direction of these TOLEDs shows a similar behavior to that of *J*–*L*–*V* performance (Fig. 2b), and also exhibits an optimum thickness of 3 nm. The maximum current efficiency is around 8.1 cd/A for the Fe_3O_4 buffered TOLEDs, while it is only around 4.0 cd/A for the devices without the anodic buffer. These results indicate

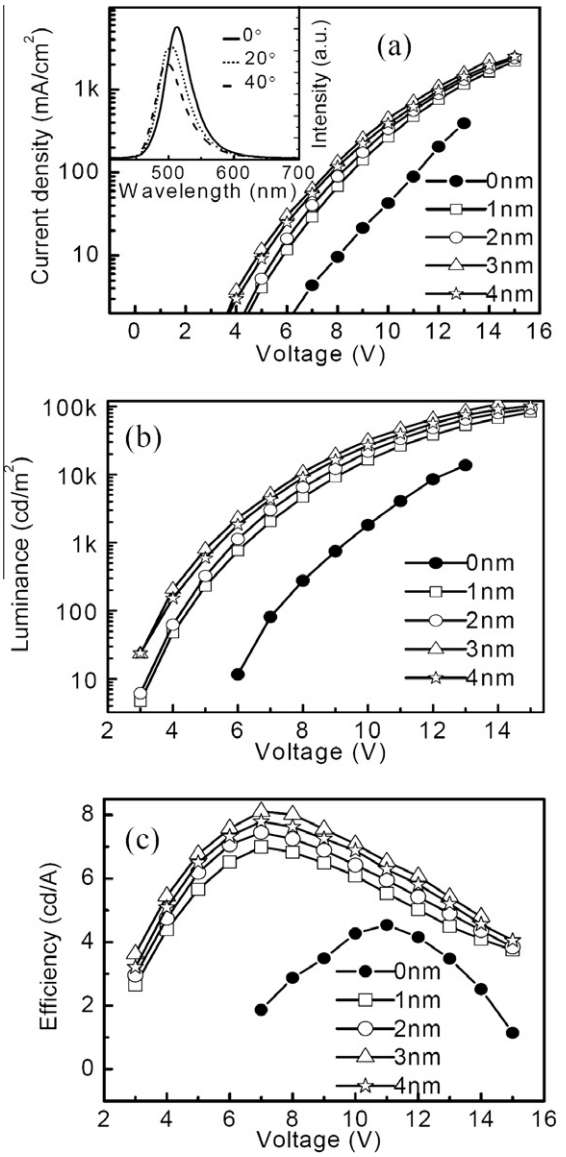

Fig. 1. EL performance of the Fe_3O_4 buffered OLEDs. (a) Current density–voltage, (b) luminance–voltage, and (c) current efficiency–voltage characteristics of the devices with various thickness of Fe_3O_4 film as the buffer layer. Inset in (a) shows the EL spectrum of the Fe_3O_4 buffered device at different observation angle.

that high EL performance of the TOLEDs is obtained by employing the Fe_3O_4 modified Ag anode.

Various metal oxides have been demonstrated as effective anodic buffer in the TOLEDs [3–5]. In order to study the relative effectiveness of the anodic modification of the Fe_3O_4, we have fabricated the devices with MoO_3 as the buffer layer for comparison, which is one of the most effective anodic buffer for the Ag anode [3,10]. The *J*–*L*–*V* characteristics of both Fe_3O_4 and MoO_3 buffered TOLEDs with the same device structure and optimized thickness of the buffer layer are compared in Fig. 2a. The optimized thickness is 3 nm and 4 nm for the buffer of Fe_3O_4 and MoO_3, respectively. The operating voltage at the current

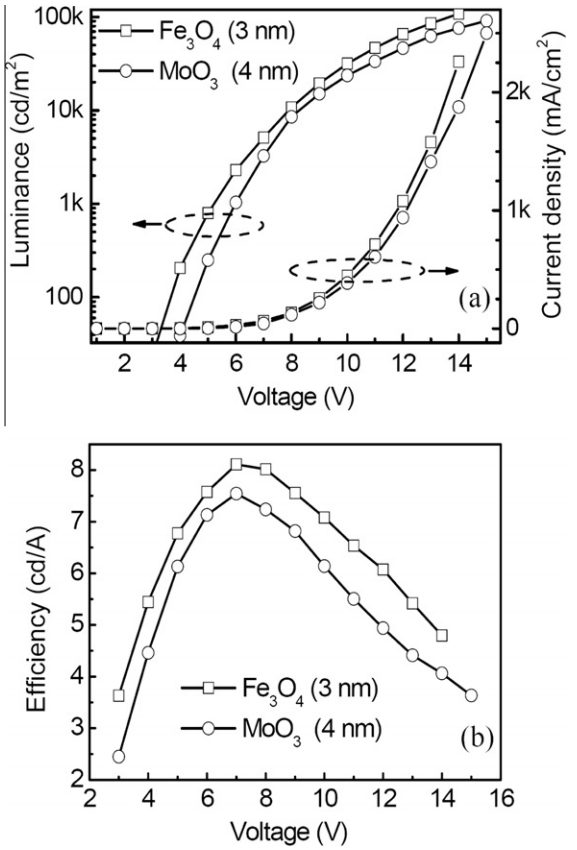

Fig. 2. (a) Current density–luminance–voltage and (b) current efficiency–voltage characteristics of the Fe_3O_4 and MoO_3 buffered devices.

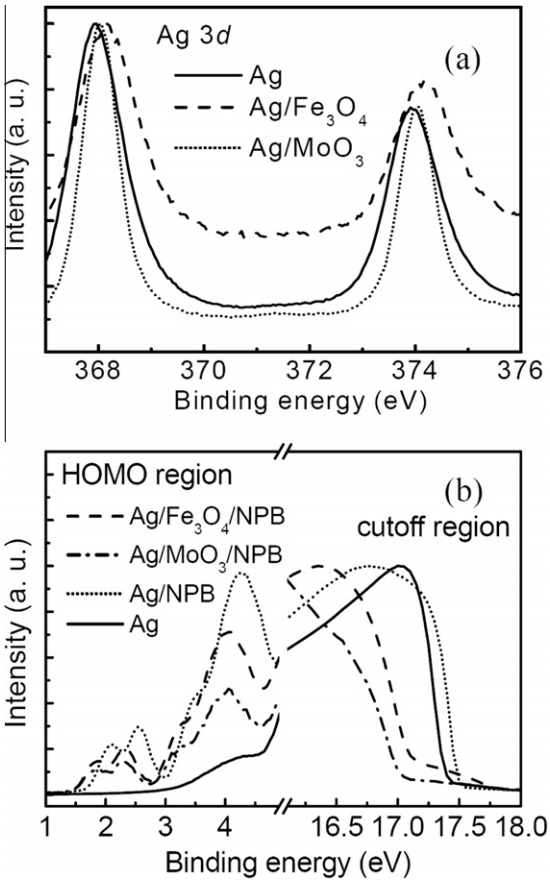

Fig. 3. (a) XPS spectra of Ag (80 nm) and Ag (80 nm)/Fe_3O_4 (3 nm). (b) UPS spectra of Ag (80 nm), Ag (80 nm)/NPB (15 nm) and Ag (80 nm)/Fe_3O_4 (3 nm)/NPB (15 nm).

density of 100 mA/cm^2 is 9.1 V and 9.3 V, and the operating voltage for obtaining a luminance of 300 cd/m^2 is 4.3 V and 5.1 V for the Fe_3O_4 and MoO_3 buffered devices, respectively. The turn-on voltage of the Fe_3O_4 buffered devices (2.5 V) is 0.2 V lower than that of the MoO_3 buffered devices (2.7 V), and its current efficiency is also higher than that of the MoO_3-based device as shown in Fig. 2b. These results indicate that Fe_3O_4 has comparable and even appreciably superior effect in modifying the Ag anode and improving the properties of the TOLEDs to the MoO_3.

3.2. Effects of Fe_3O_4 as anodic buffer on hole injection of TOLEDs

Generally, the reduced operating voltage and enhanced EL performance in OLEDs with the insertion of the anodic buffer are attributed to the reduced hole-injection barrier and therefore enhanced hole-injection efficiency. We have carried out the XPS measurements to analyze the interface between the anode and the hole-transport layer. The XPS spectra of the Ag 3*d* peaks are measured from the bare Ag (80 nm), Ag (80 nm)/Fe_3O_4 (3 nm) and Ag (80 nm)/MoO_3 (2 nm) as shown in Fig. 3a. It can be seen that the Ag 3*d* peaks shift towards higher binding energy by approximately 0.25 eV after depositing the ultra thin Fe_3O_4 layer on the Ag film, while it is ~0.15 eV in case of MoO_3 buffered Ag film. The peak shift indicates an electron transfer from Ag to Fe_3O_4 at the interface [10], which would result in a formation of a dipole layer at the interface and leading to an abrupt shift of the potential across the dipole layer [11,12]. Therefore, the hole-injection barrier is reduced as a result of the potential shift.

To further clarify the effects of the Fe_3O_4 on the hole injection, UPS spectra are investigated to evaluate the reduction of the hole-injection barrier. Fig. 3b shows the UPS spectra of the Ag (80 nm), Ag (80 nm)/Fe_3O_4 (3 nm)/NPB (15 nm), Ag (80 nm)/MoO_3 (4 nm)/NPB (15 nm) and Ag (80 nm)/NPB (15 nm). There are clear spectra changes after the insertion of the ultra thin film of Fe_3O_4 or MoO_3 between Ag and NPB compared to that of Ag/NPB sample. Both the highest occupied molecular orbital (HOMO) onset position and the cut off position shift towards the lower binding energy. The shift of the HOMO onset position indicates that the HOMO level of NPB is reduced after introducing the Fe_3O_4 or MoO_3 buffer layer, which will result in the reduction of the hole-injection barrier [12]. Moreover, it is noticeable that the shift of the secondary electron cutoff position indicates the formation of the interface dipoles at the Ag/NPB interface, which is coincident with the XPS results. The energy diagrams of the Ag/NPB, Ag/Fe_3O_4/

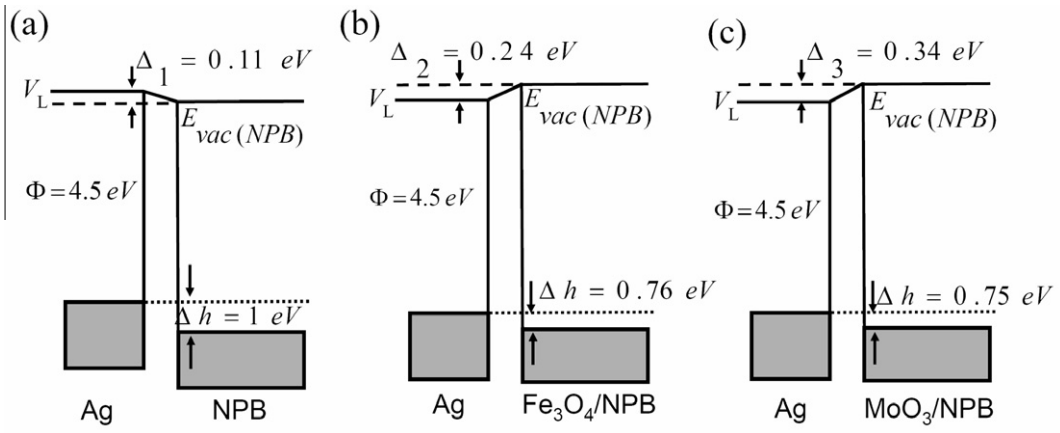

Fig. 4. Schematic energy diagram of Ag/NPB (a), Ag/Fe_3O_4/NPB (b), and Ag/MoO_3/NPB (c).

NPB, Ag/MoO_3/NPB extracted from the UPS spectra [13–15] are shown in Fig. 4. The work function of Ag is calculated to be 4.5 eV from the UPS spectra. The hole-injection barrier from Ag to NPB is reduced by 0.24 eV after inserting the Fe_3O_4 buffer. While in case of the MoO_3, the injection barrier is reduced by 0.25 eV. Both the XPS and UPS results demonstrate that the Fe_3O_4 as the anodic buffer has similar effect to MoO_3 in lowering the energy barrier of the hole injection at the interface, which should contribute to the reduction of the operating voltage and the improvement of the EL efficiency.

The efficient hole injection of the Fe_3O_4 modified devices are further confirmed by the *J–V* characteristics of the hole-only devices [16,17]. The hole-only devices with and without the anodic buffer were fabricated to demonstrate the role of the anodic buffer in the hole-injection ability of the TOLEDs. Fig. 5 shows the current density versus voltage characteristics of the hole-only devices with the structures of Ag (80 nm)/Fe_3O_4 (3 nm)/NPB (80 nm)/Ag (20 nm), Ag (80 nm)/MoO_3 (4 nm)/NPB (80 nm)/Ag (20 nm) and Ag (80 nm)/NPB (80 nm)/Ag (20 nm). The electron injection from the Ag cathode to the NPB is prohibited, because the work function of Ag is around 4.5 eV while the lowest occupied molecular orbital level of the NPB is around 2.4 eV, and there exists very large injection barrier. It can be seen that the current density of the hole-only devices with the anodic buffer is obviously higher than that of the device without the buffer, and the Fe_3O_4 buffered devices shows even higher current density than that of the MoO_3 buffered devices. It further confirms that Fe_3O_4 is an efficient anodic buffer in enhancing the hole injection of the TOLEDs.

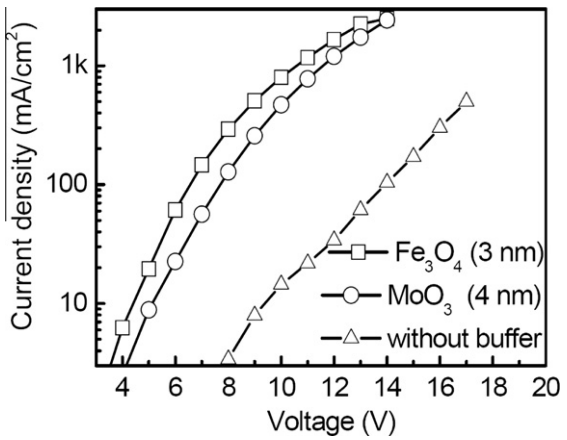

Fig. 5. The current density–voltage characteristics of the hole-only devices with and without the anodic buffer.

4. Conclusions

In summary, we report the thin film of Fe_3O_4 as the Ag anodic buffer for efficient TOLEDs. The Fe_3O_4 exhibits its effect in lowering the driving voltage and improving the brightness and current efficiency of the TOLEDs. The XPS and UPS measurements indicate that the introduction of the thin film Fe_3O_4 can greatly reduce the hole-injection barrier, and the enhancement of the hole injection has been further confirmed by the investigation of *J–V* characteristics of the hole-only devices. Our results reveal that Fe_3O_4 is a prospective material in modifying the Ag anode and realizing the high performance of the TOLEDs.

ABSTRACT

Ultrathin Al_2O_3 layers, deposited using atomic layer deposition (ALD), have been utilized as the primary barrier layers for encapsulation of organic solar cells. This work shows that the encapsulation characteristics of a barrier layer can be accentuated by replacing H_2O with O_3 as the ALD oxidant. The Al_2O_3 layers deposited using O_3 offered superior device encapsulation compared to the films deposited using H_2O. The organic solar cell efficiency has also been studied as a function of Al_2O_3 thickness and effective encapsulation has been monitored for two different ALD temperatures.

1. Introduction

Organic solar cells comprising conjugated polymer–fullerene bulk heterojunctions (BHJs) have the potential of becoming ubiquitous sources of renewable energy owing to their cost-effectiveness and ease of fabrication on lightweight, flexible substrates [1–4]. However, these cells have primarily been tested in controlled laboratory environment as they undergo rapid degradation upon exposure to oxygen and water [5,6]. Therefore, adequate encapsulation from ambient oxygen and water is an essential requirement for the commercial viability of organic photovoltaic (OPV) cells. The encapsulating layer in turn should be thin, defect-free, light weight, and offer ease of processing. Amongst various methods reported in literature, the ultrathin barrier layers grown by atomic layer deposition (ALD) have emerged as promising candidates for device encapsulation [7,8]. ALD is particularly suitable for organic and flexible electronics as passivation layers with excellent film conformity can be grown at low temperatures. In this regard, the encapsulation of OPVs by ALD has been reported using Al_2O_3 [7] and Al_2O_3/HfO_2 nanolaminates [8]. However, both approaches use H_2O as the oxidant along with trimethylaluminum (TMA) as the precursor for Al_2O_3 or tetrakis(dimethylamido) for growing HfO_2 layers. It is well known that films deposited by ALD using H_2O as oxidant have high impurity content, especially hydrogen [9]. Also, it takes longer time to purge out water molecules from the surface as water has a high surface affinity owing to its large dipole moment [9,10]. This reduces throughput of the process especially when lower temperatures are used for deposition and high aspect ratio structures are in consideration [10]. In the current semiconductor technology, O_3 is the preferred oxidant for growing dielectric layers by ALD [9–11]. The MIS (Metal–Insulator–Semiconductor) capacitors with Al_2O_3 films grown using O_3 (O_3–Al_2O_3) show a smaller hysteresis, lower leakage current density, and higher breakdown field strength compared to the Al_2O_3 films grown using H_2O (H_2O–Al_2O_3) at the same growth temperature [9,11]. O_3-based ALD offer higher throughput as the time required for surface reactions and purging out of the unreacted surface adsorbed species is much shorter than H_2O-based processes. This is because

doi:10.1016/j.orgel.2010.08.020

of the high chemical reactivity between TMA and O_3 and that O_3 can be purged out more efficiently than H_2O [9–11]. O_3–Al_2O_3 film also shows a smaller residual hydrogen concentration as compared to H_2O–Al_2O_3 film [9]. This work describes how encapsulation of OPVs with ultrathin Al_2O_3 layers is significantly improved by replacing water with ozone as the oxidant in ALD. Unlike previous reports, this work utilizes only Al_2O_3 as the primary barrier layer and does not require a UV-curable epoxy resin film as an additional sealant for protecting OPVs from ambient moisture or oxygen. The OPV efficiency has been studied as a function of Al_2O_3 thickness and effective encapsulation has been monitored for two different ALD temperatures – 140 °C and 150 °C.

2. Experimental

Fig. 1a shows schematics of the encapsulated OPV structure discussed in this work. The pre-patterned indium tin oxide (ITO) coated glass substrates [12] were cleaned by ultrasonic treatment in acetone and isopropyl alcohol followed by a UV–ozone treatment. These substrates were then spun coated with poly-3,4-ethylenedioxythiophene–poly-styrenesulphonate (PEDOT:PSS, Aldrich) at 4000 rpm for 40 s and annealed at 120 °C for 1 h. For the active layer, 1 wt% of poly-3-hexylthiophene-2,5-diyl (P3HT, Rieke Metals) was blended with 0.8 wt% of 6,6-phenyl-C61-butyric acid methyl ester (PCBM, Nano-C) in 1,2-dichlorobenzene for 12 h inside a N_2-filled glovebox. The PEDOT-coated ITO substrates were transferred into the glovebox and spun coated with the P3HT/PCBM blend at 600 rpm for 60 s [13]. Immediately after spin casting, these films were dried in a covered Petri dish for 20 min to yield 100 nm of the active layer. The samples were then briefly exposed to ambient air while being transferred into the thermal evaporator. Al was deposited through a shadow mask to define an active device area of 10 mm^2. An unencapsulated OPV (control sample) underwent post metal anneal for 20 min at 150 °C in order to increase the device efficiency [14]. Thermal annealing induces aggregation of the P3HT and PCBM domains, which facilitates transport of charge carriers through these domains and increases the device efficiency [14]. No post metal anneal was done for the samples that were encapsulated using ALD as the ALD process also served as the annealing step. For ALD encapsulation, the devices were again briefly exposed to the ambient conditions while being transferred into the ALD chamber (Savannah100, Cambridge Nanotech, Inc.). A typical ALD cycle comprised an initial pulse of TMA for 0.015 s followed by a 5 s purge with N_2 and a subsequent pulse of O_3/H_2O for 0.015 s followed by a 5 s purge with N_2. The growth rates for Al_2O_3 using O_3 and H_2O at 140 °C are 0.85 Å and 1.05 Å per cycle, respectively. The encapsulated devices were stored outside the glovebox under ambient conditions. The current density–voltage (J–V) characteristics were measured with a Keithley 2400 source meter under simulated AM1.5G illumination (100 mW/cm^2) using Oriel solar simulator. All electrical measurements were done in ambient conditions and averaged over six devices patterned on a single substrate.

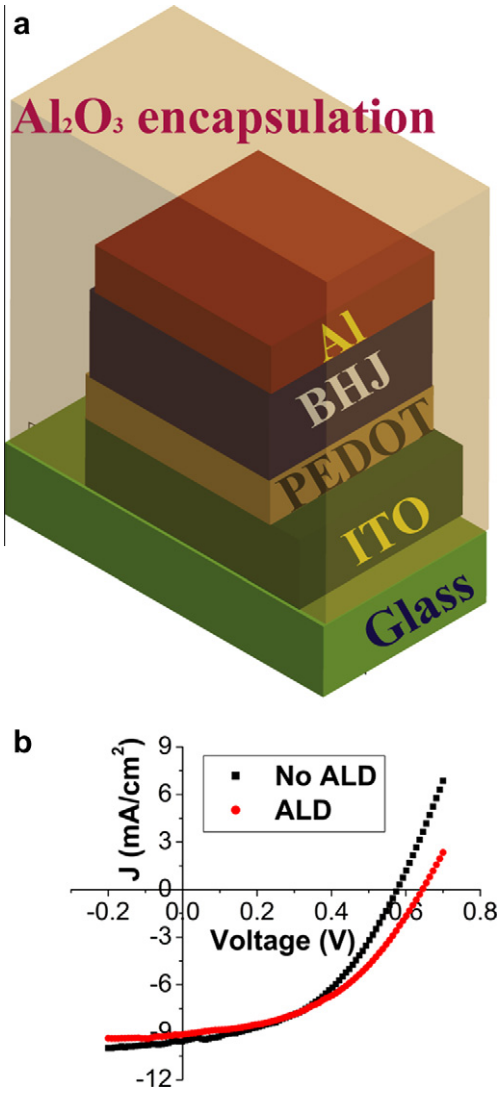

Fig. 1. (a) Schematics of the device structure encapsulated with Al_2O_3. BHJ signifies the P3HT–PCBM bulk heterojunction layer. (b) J–V characteristics of the control device (black squares) and an OPV encapsulated with 210 cycles of Al_2O_3 deposited at 140 °C (red circles) under illumination. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

3. Results and discussion

Fig. 1b shows the J–V characteristics under illumination for a control device (black squares) and an OPV encapsulated with O_3–Al_2O_3 (red circles). The open circuit voltage (V_{OC}), short circuit current (J_{SC}), efficiency (η), and fill factor (FF) for both the devices are listed in Table 1. The FF and η

Table 1
The performance characteristics of OPVs with and without Al_2O_3 encapsulation based on J–V characteristics in Fig. 1b.

	J_{SC} (mA/cm^2)	V_{OC} (V)	FF (%)	η (%)
Control device	9.58	0.574	46	2.54
Encapsulated device	9.15	0.646	45	2.7

for the control device is lower than that is typically reported [7,8,13,14] because of the following reasons (i) these devices were exposed to ambient conditions while being transferred into thermal evaporator and (ii) electrical measurements were done outside the glovebox. After ALD encapsulation, the V_{OC} increased from 0.57 V to 0.64 V and η increased from 2.54% to 2.7% as seen in Table 1. Additionally, there was a minimal change in the FF and J_{SC} for the encapsulated device as compared to the control sample. This indicates that ALD precursors, especially O_3 that is known to be highly reactive, did not cause any damage to the organic layer. This is primarily because the organic layer is initially exposed to O_3 for a short period of 0.015 s per cycle however, as Al_2O_3 continues to grow on top of the organic layer, the effect of this exposure gets severely attenuated with each ALD cycle. When stored outside the glovebox, the control sample underwent severe degradation and the device efficiency reduced by more than 80% in less than 24 h. This further highlights the importance of OPV encapsulation.

The efficiency for two sets of encapsulated OPVs were tested over time, where one set was encapsulated with O_3–Al_2O_3 and the other with H_2O–Al_2O_3 as shown in Fig. 2a and b. Four different thicknesses of Al_2O_3, i.e., 90, 120, 150, and 210 cycles of ALD were deposited for each set at 140 °C. The encapsulating ability of Al_2O_3 in both sets increased with increase in ALD thickness, which is expected (Fig. 2a and b). The most effective encapsulation was offered by 210 cycles of O_3–Al_2O_3 (210-O_3–Al_2O_3) as the efficiency for that device reduced by just 20% over a period of 500 h (Fig. 2c). In contrast, efficiency for OPV encapsulated with 210-H_2O–Al_2O_3 decreased by 67% within 350 h (Table 2). The efficacy of O_3-based ALD for device encapsulation is further highlighted by the fact that even 10.2 nm of O_3–Al_2O_3 (120 cycles) offers better encapsulation than 20 nm of H_2O–Al_2O_3 (210 cycles). Hence, this work shows that O_3–Al_2O_3 offers excellent device encapsulation for a much lower effective oxide thickness when compared with the H_2O–Al_2O_3 layer. This is further substantiated when the blocking characteristics observed in the present work is compared with that reported in literature. Potscavage et al. [7] required a thick film of 200 nm for an effective protection of OPV from ambient conditions and they deposited Al_2O_3 layer using H_2O at a growth rate of 10 nm/h. In another work, Chang et al. [8] did employ a thinner capping layer (26 nm of Al_2O_3) for OPV encapsulation. However, they reported a 60% degradation in device efficiency within 100 h, indicating extremely poor encapsulation by the Al_2O_3 layer grown using H_2O. In comparison, a device capped with 18 nm of O_3–Al_2O_3, in the present work, showed 80% retention of the initial efficiency in over 500 h. Hence, an ultrathin barrier layer of 18 nm offers excellent blocking for OPVs from ambient conditions. As the market for organic solar cells is growing, the importance of having a more effective encapsulation with a thinner capping layer can be readily realized. This would bring down the fabrication time and manufacturing cost, thereby making organic solar cells commercially more viable. The more effective blocking behavior offered by O_3–Al_2O_3 layer is attributed to higher density, lesser defects, lower leakage current and higher breakdown field as compared to the H_2O–Al_2O_3 layer [9,11].

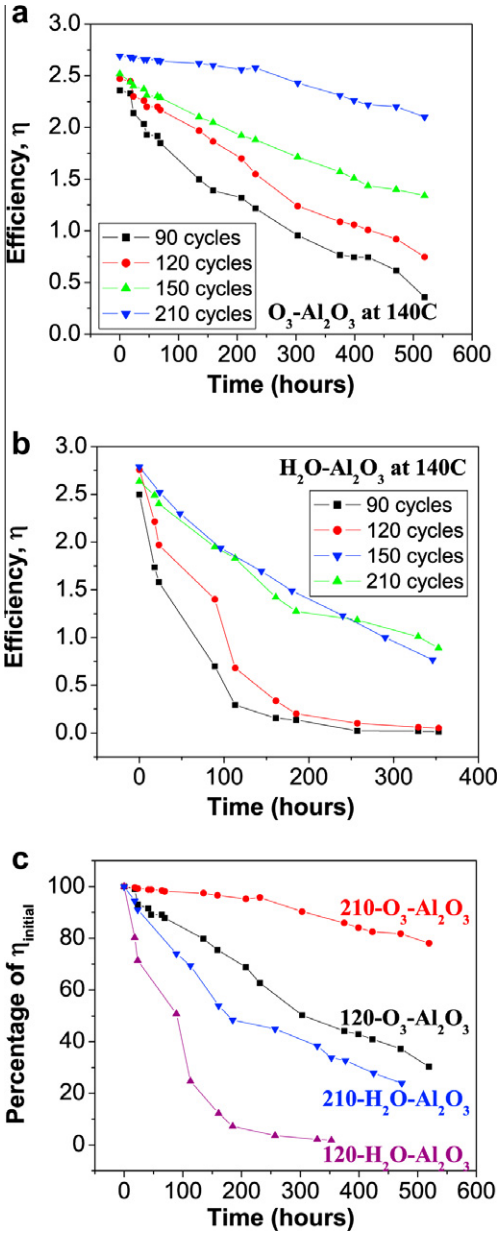

Fig. 2. (a) A time dependent study of efficiency for OPVs encapsulated with four different thicknesses of Al_2O_3 deposited using O_3 at 140 °C. (b) The degradation profile of device efficiency over time for OPVs capped with four different thicknesses of H_2O–Al_2O_3 deposited at 140 °C. (c) A comparison of the percentages of initial efficiencies studied over time for four different organic solar cells encapsulated with 120 cycles of O_3–Al_2O_3 (black squares), 210 cycles of O_3–Al_2O_3 (red circles), 120 cycles of H_2O–Al_2O_3 (purple triangles), and 210 cycles of H_2O–Al_2O_3 (blue inverted triangles). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

In literature, the efficiency of a polymer solar cell is typically enhanced by doing a post metal deposition anneal at either 140 °C or 150 °C [8,13,14]. Since the anneal

Table 2
The initial efficiency ($\eta_{initial}$), efficiency after 350 h ($\eta_{350\ h}$) and percentage of initial efficiency retained after 350 h (% $\eta_{retention}$) for OPVs encapsulated with 90, 120, 150, and 210 cycles of Al_2O_3 deposited at 140 °C.

ALD cycles	O_3–Al_2O_3			H_2O–Al_2O_3		
	$\eta_{initial}$	$\eta_{350\ h}$	% $\eta_{retention}$	$\eta_{initial}$	$\eta_{350\ h}$	% $\eta_{retention}$
90	2.36	0.82	35	2.50	0.01	0.4
120	2.47	1.13	46	2.76	0.05	2
150	2.52	1.61	64	2.64	0.74	28
210	2.69	2.35	87	2.78	0.91	33

temperature is key in determining the BHJ morphology and device efficiency, ALD encapsulation of OPVs was also studied at 150 °C. This is particularly because the process of ALD also serves as a thermal anneal step. Four different OPVs were encapsulated with 90, 120, 150, and 210 ALD cycles of O_3–Al_2O_3. Chang et al. [8] reported that device efficiency increases with increase in anneal time, typically peaking at 30 min for 150 °C but the trend reverses after reaching the maximum value. A similar trend was also observed here as the thermal budget was increased by 10 °C. The η at 150 °C peaked at 120 cycles with a marginal change at 150 cycles but decreased for the device encapsulated with 210 cycles. The peak value of η obtained at 150 °C is about 20% lower than that obtained at 140 °C. The effectiveness of encapsulation by O_3–Al_2O_3 increased with increase in number of ALD cycles with the exception of 210-O_3–Al_2O_3 (Fig. 3a). The deterioration of device characteristics for the OPV capped with 210-O_3–Al_2O_3 is attributed to prolonged heating of the solar cell at 150 °C. Prolonged heating causes over aggregation of the P3HT and PCBM domains, reducing the effective BHJ area that is critically required for charge generation [8]. Amongst the different Al_2O_3 thicknesses deposited at 150 °C, 150-O_3–Al_2O_3 offered the most effective encapsulation and the device retained 60% of the initial efficiency after 500 h. As a comparison, three other OPVs were also encapsulated with 90, 120, and 150 cycles of H_2O–Al_2O_3 at 150 °C and their efficiencies were monitored over time. As seen in Fig. 3b, devices capped with H_2O–Al_2O_3 showed rapid degradation in efficiencies as compared to devices capped with O_3–Al_2O_3. Hence, independent of anneal temperature, Al_2O_3 films deposited using O_3 offer superior encapsulation characteristics as compared to the films deposited using H_2O.

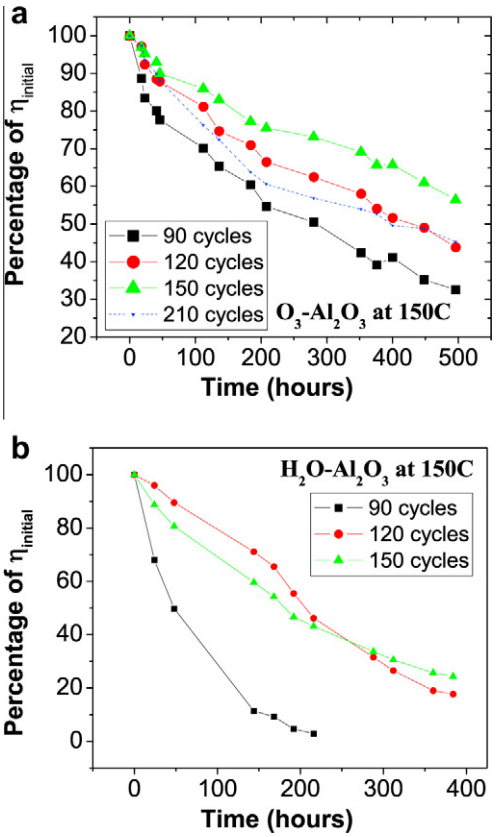

Fig. 3. (a) Percentages of initial efficiencies monitored over time for four OPVs capped with four different thicknesses of Al_2O_3 deposited using O_3 at 150 °C. (b) A time dependent study of the percentage of initial efficiencies for OPVs encapsulated with three different Al_2O_3 layers deposited using H_2O at 150 °C.

4. Conclusions

This work shows that encapsulation behavior of ultrathin Al_2O_3 films is significantly enhanced by replacing H_2O with O_3 as the ALD oxidant. This work utilizes Al_2O_3 grown using O_3 as the primary barrier layer without the requirement of any additional UV-curable epoxy resin film as a sealant for protecting OPVs from ambient moisture or oxygen. Amongst the various Al_2O_3 thicknesses monitored, 210 cycles of O_3–Al_2O_3 offered the best device encapsulation and the OPV retained 80% of its initial efficiency over a period of 500 h. The barrier layer thickness of 18 nm, utilized in the present work, provides excellent protection from ambient water and oxygen. Since ALD also serves as the annealing step, the effective encapsulation was studied for two different ALD temperatures. Irrespective of the anneal temperature, the O_3–Al_2O_3 layers showed superior encapsulation as compared to the H_2O–Al_2O_3 film. The device efficiency was studied as a function of Al_2O_3 thickness. The O_3–Al_2O_3 films demonstrated excellent encapsulation characteristics for a much lower effective oxide thickness compared to the H_2O–Al_2O_3 films.

ABSTRACT

In this work, the impedance spectroscopy was adopted to characterize conductively doped organic hole-transport layers. We performed comparative studies of the impedance spectroscopy of undoped and doped hole-transport materials, by both experiment and simulation approaches. The impedance spectroscopy of the non-doped hole-transport material can be well understood by simply adopting the conventional RC equivalent circuits and considering the dielectric response frequency-independent. For the conductively doped organic hole-transport materials, however, successful modeling of the impedance spectroscopy results need to take into account the more complicated situations: including the difference between the bulk region and the depletion region near the electrode, and dispersion (i.e. frequency dependence) in the dielectric response of the conductively doped transport layer. As such, it is found necessary to include the complex dielectric response and the non-conventional complex impedance element in the equivalent circuit to achieve tight matching of simulated results with experiment results over wide bias and frequency ranges.

1. Introduction

Since first reports of efficient organic light-emitting diodes (OLEDs) in 1980s [1], OLEDs have attracted substantial research efforts and have now become one of the most promising technologies for displays and solid-state lighting [2–5]. To further enhance OLED performances, conductive doping of carrier-transport materials in OLEDs has been adopted and is becoming an important technology due to their various merits [6–12]. Conductive doping of carrier-transport materials in OLEDs could largely facilitate carrier injection and increase the conductivity of organic semiconductors, both capable of reducing operation voltages and increasing efficiencies of OLEDs. Thus, more detailed understanding of the operation mechanisms and electrical properties of conductively doped organic carrier-transport materials could be of use to applications and advancement of such technologies.

Impedance spectroscopy has been a useful tool for probing the electrical/dielectric properties and operation mechanisms of organic and inorganic semiconductors/devices [13–16]. With the aid of impedance spectroscopy, one in principle can construct the equivalent circuits of the devices and thereby obtain more insights about the operation of the materials and devices [17–19]. In this work, we adopted the impedance spectroscopy to characterize conductively doped organic hole-transport layers for OLEDs. We performed comparative studies of the impedance spectroscopy of undoped and doped hole-transport materials, by both experiment and simulation approaches. The impedance spectroscopy of the non-doped hole-transport material can be well understood by simply

adopting the conventional RC equivalent circuits and considering the dielectric response frequency-independent [18]. For the conductively doped organic hole-transport materials, however, successful modeling of the impedance spectroscopy results need to take into account the more complicated situations: including the difference between the bulk region and the depletion region near the electrode, and dispersion (i.e. frequency dependence) in the dielectric response of the conductively doped transport layer. As such, it is found necessary to include the non-conventional complex impedance element in the equivalent circuit to achieve tight matching of simulated results with experiment results over wide bias and frequency ranges.

2. Experimental: sample preparation and characterization

The organic carrier-transport material studied in this work is the widely used hole-transport/hole-injection material 4,4′,4″-tris(3-methylphenylphenylamino)triphenylamine (*m*-MTDATA) [20]. For comparative studies, *m*-MTDATA was vacuum-deposited as an intrinsic non-doped layer or with 2 wt.% p-type conductive dopants 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F_4-TCNQ) [21]. F_4-TCNQ is a very strong electron acceptor that can act as effective p-type dopant materials. The undoped device structure for impedance spectroscopy was ITO/*m*-MTDATA (100 nm)/Ag (100 nm), while the doped device structure was ITO/*m*-MTDATA: F_4-TCNQ (2 wt.%, 100 nm)/Ag (100 nm). The LUMO level of *m*-MTDATA is 1.9 eV [20] while the work function of silver is around 4.28 eV. Such a difference in energy levels results in a large barrier for electron injection. Together with the much better hole-transport capability vs. electron-transport capability in *m*-MTDATA, both undoped and doped *m*-MTDATA devices were mainly single-carrier (hole-only) devices.

The devices were fabricated on the ITO (indium tin oxide)-coated glass substrates with organic layers sandwiched between the bottom anode and the top metal cathode. ITO was cleaned and UV–ozone-treated before use. All the organic and metal layers were deposited by thermal evaporation in a vacuum chamber with a base pressure of $<10^{-6}$ torr. The F_4-TCNQ-doped *m*-MTDATA layer was deposited by co-evaporation. The deposition rate of organic layers was kept at ~0.2 nm/s. The deposition system permitted the fabrication of the complete device structure in a single pump-down without breaking vacuum. The active area of the device was 1×1 mm^2, as defined by the shadow mask for cathode deposition. The impedance spectroscopy was measured by an impedance analyzer (Wayne Kerr 6440B) together with a dc power supply used to provide the dc bias voltage. For all measurements, the amplitude of ac signals was kept at 0.1 V. The frequency range of the generated impedance data was from 20 to 3×10^6 Hz.

3. Results and discussions

The *I*–*V* curves of the undoped and the doped devices are shown in Fig. 1. With the conductive doping, the current is increased by orders of magnitude (vs. the undoped device) and the current rises sharply with the bias.

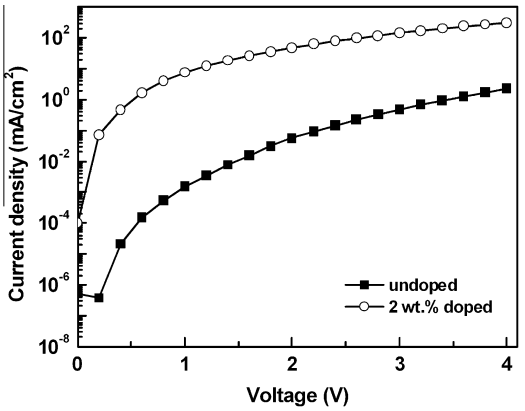

Fig. 1. *I*–*V* characteristics of ITO/*m*-MTDATA: F_4-TCNQ (0 wt.%, 2 wt.%, 100 nm)/Ag (100 nm).

Fig. 2 shows the measured Cole–Cole plots of the undoped *m*-MTDATA device under different dc bias voltages. The Cole–Cole plot depicts the imaginary part of the impedance (i.e. Im(*Z*)) versus the real part of the impedance (i.e. Re(*Z*)) when continuously sweeping the small-signal frequency (under a particular dc bias) [17]. Under each dc bias, the Cole–Cole plot of the undoped device resembles a single-semicircle in continuously sweeping the frequency, which is typical for a single-layer single-carrier device [18]. Such single-semicircle impedance characteristics in the Cole–Cole plot can usually be reproduced with an equivalent circuit as shown in Fig. 3. In Fig. 3, the series resistance R_s is associated with the contribution from the electrode. The parallel resistance R_p in the parallel RC network is associated with the layer resistance (i.e. *m*-MTDATA), while C_p is associated with the geometric capacitance of the *m*-MTDATA layer. As also shown in Fig. 2, by carefully adjusting the parameters (R_s, R_p, C_p), each curve in the Cole–Cole plot (each associated with a particular bias voltage) can be well reproduced using the equivalent circuit of Fig. 3. The parameters (R_s, R_p, C_p) used

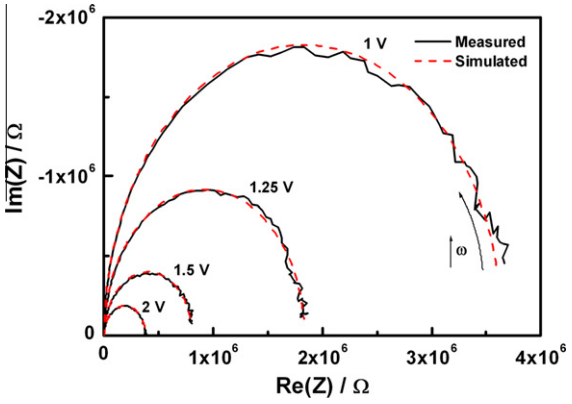

Fig. 2. Measured and simulated Cole–Cole plots of the undoped *m*-MTDATA device, ITO/*m*-MTDATA (100 nm)/Ag (100 nm), under different dc bias voltages. The simulated curves are generated using the equivalent circuit shown in Fig. 3 and parameters listed in Table 1.

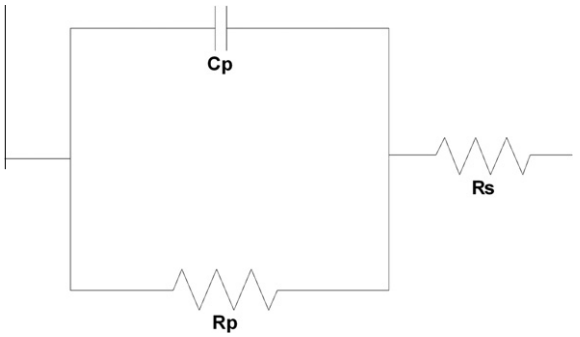

Fig. 3. The equivalent circuit used to simulate impedance characteristics shown in Fig. 2 for the undoped *m*-MTDATA device.

to fit the curves under different bias voltages are shown in Table 1. In Table 1, one sees that C_p remains rather constant versus bias voltage for the frequency range measured (as the geometric capacitance is supposed to be) and R_p drops significantly as the bias voltage increases. It makes sense since more carrier are injected into the device (leading to higher carrier concentrations) and thus the layer resistance drops when the dc bias voltage is raised. By assuming a nominal dielectric constant of ~3 typical for organic layers, the thickness of the *m*-MTDATA film is estimated to be 107 nm from the C_p value, which is consistent with the deposited m-MTDATA thickness verified by ellipsometry.

Fig. 4 shows the measured Cole–Cole plots of the F_4-TCNQ-doped (2 wt.%) *m*-MTDATA device under different dc bias voltages. In contrast to the undoped device, the doped device exhibits two semicircle-like features, particularly at lower dc bias conditions. When the dc bias increases, one feature shrinks quickly and the two semicircles appear to merge together. The difference in impedance spectroscopy for undoped and doped devices can be further manifested by comparing Re(Z) and Im(Z) of both devices as a function frequency. Fig. 5a and b shows Re(Z) versus frequency under different bias voltages for undoped and doped devices, respectively. Fig. 6a and b shows $-$Im(Z) versus frequency under different bias voltages for undoped and doped devices, respectively. From results of Figs. 4–6, one sees that under a similar dc bias, in general the doped device exhibits a much smaller (absolute) magnitude of the impedance (much smaller semicircles in the Cole–Cole plots, much smaller Re(Z) and Im(Z) at lower frequencies). It manifests that with the conductive doping, the carrier conduction in the carrier-transport layer is largely enhanced.

For Cole–Cole plots containing two semicircles, an equivalent circuit consisting of series connection of two parallel RC circuits, like that shown in Fig. 7, is often effective. A series connection of two parallel RC circuits is usually associated with a device containing two layers or two regions of different electrical characteristics. For the present case, although the organic layer was deposited as a single doped layer, yet Riess et al. [13] previously reported that in the conductively doped organic carrier-transport layer, a depletion region could occur near the electrode with larger energy level mismatch. Thus, for the present F_4-TCNQ-doped (2 wt.%) *m*-MTDATA device,

two regions of different electrical characteristics, a depletion region near the Ag electrode and a more conducting bulk region near the ITO electrode, might occur and the equivalent circuit in Fig. 7 might be appropriate. In such a case, in Fig. 7, R_B and C_B represent the resistance and capacitance of the conducting bulk region, while R_J and C_J represent the resistance and capacitance of the depletion region. The optimized fittings to the measured Cole–Cole plots (under different dc biases) using such an equivalent circuit and the parameters listed in Table 2 are shown in Fig. 8. In assigning fitting values of equivalent circuit elements to the bulk or the junction under different biases (throughout this whole work), particular attention was paid to the consistency of the characteristic frequency ranges and their transitions vs. biases with the frequency responses of corresponding circuit elements. From Fig. 8, one sees that even in the optimized case, it is difficult to

obtain satisfactory fittings for a wide range of dc biases and frequencies. The simulated curves have the difficulty to truthfully follow the shapes/forms of the measured

curves, indicating the equivalent circuit in Fig. 7 is not good/complete enough. Also, with the circuit model of Fig. 7, one would expect a dependence of C_J on the bias [13]. Yet from the fitting values shown in Table 2, one notices that the junction capacitance C_J does not show a strong dependence on biases. This is partially due to the limited bias range shown (more significant increase of C_J can be seen at higher forward biases). On the other hand, with doubts on the accuracy and completeness of the simple RC model, one suspects how much the extracted C_J values reflect the real situations.

Riess et al. [13] also similarly observed significant deviations in fittings of impedance spectroscopy results of the conductively doped carrier-transport layer using the equivalent circuit of Fig. 7. Riess el al. [13] mentioned that the imperfect fittings might result from the frequency (ω) dependence of the conductivity $\sigma(\omega)$ and dielectric constant $\varepsilon(\omega)$ and spatial inhomogeneities in the thickness and dopant concentration etc., whose effects are not included in the simple equivalent circuit of Fig. 7. Thus, a more accurate and physically meaningful equivalent circuit/model is needed to reproduce impedance characteristics of the conductively doped organic transport layer. Later, Leo et al. [22] suggested the adoption of a distributed circuit element called constant phase element (CPE) [17,23,24] to replace the regular capacitance, for taking into account the dispersive properties (e.g. frequency dependence of the dielectric properties) and for better modeling impedance characteristics of conductively doped organic carrier-transport films. The impedance of a CPE has the general form of $Z(\omega) = Q(j\omega)^{-\alpha}$, where Q is a constant parameter and the parameter α can assume values between 0 and 1. The parameter α describes the degree of the capacitive character; when $\alpha = 1$, the CPE is like a regular capacitance. The introduction of this CPE distributed element may include effects of the distribution of energy states and/or spatially distributed conductivity etc. By replacing the regular capacitances in Fig. 7 with the corresponding CPE elements, the modified equivalent circuit is shown in Fig. 9. The optimized fittings to the measured Cole–Cole plots (under different dc biases) of the F_4-TCNQ-doped *m*-MTDATA device using such an equivalent circuit and the parameters listed in Table 3 are shown in Fig. 10. Compared to results of Fig. 8 using the equivalent circuit of Fig. 7, the fittings are improved, but still deviations from measured curves are apparently visible and there is room for further improvement of the model/equivalent circuit.

Results of Fig. 10 based on the equivalent circuit of Fig. 9 indicate that simply replacing regular capacitances

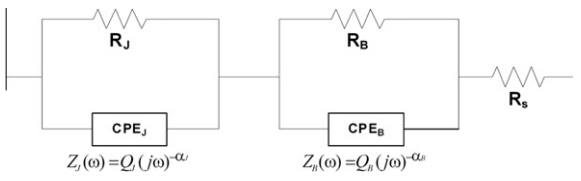

Fig. 9. An equivalent circuit consisting of a series connection of two parallel *R*/CPE circuits, (which is modified from Fig. 7 by replacing regular capacitances with constant phase elements).

with the CPE elements is not sufficient (or accurate enough) to model dispersive characteristics of the conductively doped organic carrier-transport layers. A more complete/accurate model is needed. A more general formula for including the dispersion in the dielectric constants, that was first reported by Cole and Cole [25] and is found to well represent dielectric properties of many inorganic and organic electrochemical systems, has the complex form of:

$$\varepsilon - \varepsilon_\infty = \frac{(\varepsilon_s - \varepsilon_\infty)}{[1 + (j\omega\tau_0)^{1-\alpha}]} \quad (1)$$

In this formula, ε is the dielectric constant at a angular frequency ω, ε_∞ is the high-frequency dielectric constant, ε_s is the static (low-frequency) dielectric constant, and τ_0 is the average relaxation time. The parameter α can assume values between 0 and 1. ε_∞ represents the non-dispersive component of ε, which remains from low-frequencies to high frequencies. Meanwhile, $(\varepsilon_s - \varepsilon_\infty)/[1 + (j\omega\tau_0)^{1-\alpha}]$ represents the dispersive part of ε, the transition of ε from the static dielectric constant ε_s to the high-frequency dielectric constant ε_∞.

When an electric field is applied to an electrochemical system, an almost instant polarization due to the displacement of electrons with the respect to the (molecular) nuclei, which corresponds to the high-frequency dielectric constant ε_∞. If there is reorientation of electric dipole moments associated with the applied electric field (often associated with complexes, defect electronic species, ionic interstitials etc.), a time-dependent polarization (at the time-scale of interest) and dispersion in dielectric responses, however, could occur. In such a case, the static dielectric constant ε_s is associated with the total polarization if the electric field remains in place for long enough time. As for the detailed dispersion characteristics, it depends on the detailed relaxation processes. For instance, if the polarization process can be described by a single relaxation time, a Debye dispersive relation is usually derived [17,25]. On the other hand, when there is a distribution in the relaxation times, the dispersion behaviors in the dielectric response are most widely described by Eq. (1), in which τ_0 represents the average of the relaxation times, not the single relaxation time. For the present F_4-TCNQ-doped *m*-MTDATA, the p-type conductive doping (increase of hole carriers) is based on the ground-state electron transfer between host and dopant molecules. If for some of the molecules the electron transfer is not complete (due to energetic and spatial distributions associated with the amorphous/disordered morphology), then charge-transfer complexes (between donor host *m*-MTDATA and acceptor dopant F_4-TCNQ) with electric dipole moments could form. F_4-TCNQ dopant molecules are surrounded by much more *m*-MTDATA host molecules and thus reorientation of electric dipole moments of the complexes could very possibly occur when an ac field is applied. Since the present F_4-TCNQ-doped *m*-MTDATA is an amorphous system, the corresponding polarization relaxation could also very possibly exhibit a distribution in the relaxation times, showing a dielectric dispersion like Eq. (1).

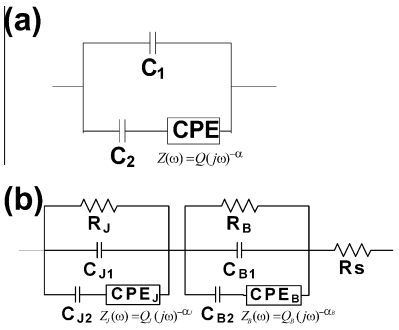

Fig. 11. (a) The equivalent circuit for a material layer having a dispersive dielectric response like Eq. (1). (b) The equivalent circuit modified from Fig. 7 by replacing regular capacitances with the equivalent circuit of Fig. 11a.

For a material layer having a dispersive dielectric response as described by Eq. (1), in impedance spectroscopy, such a dispersive dielectric response represents a more complicated equivalent circuit as shown in Fig. 11a [17,25]. The equivalent circuit in Fig. 11a can be understood by considering a general capacitance that is equal to the complex dielectric constant multiplied by the area *A* and divided by the layer thickness *d*. As such, the effects of dielectric response function of Eq. (1) can naturally be decomposed into an equivalent circuit like Fig. 11a. $C_1 = A\varepsilon_\infty/d$ represents the geometric layer capacitance associated with the non-dispersive component of ε in Eq. (1) (i.e. ε_∞, which remains same from low-frequencies to high frequencies) [17]. Meanwhile, $C_2[=A(\varepsilon_s - \varepsilon_\infty)/d]$ in series with the constant phase element [CPE, $Z = Q \times (j\omega)^{-\alpha}$, $Q = (\tau_0^{1-\alpha} \times d)/(\varepsilon_s - \varepsilon_\infty)/A]$ represents the contributions from the dispersive part of ε in Eq. (1), i.e. $(\varepsilon_s - \varepsilon_\infty)/[1 + (j\omega\tau_0)^{1-\alpha}]$.

By replacing the regular capacitances in Fig. 7 with the circuit of Fig. 11a that now gives more general/complete description of dispersive characteristics, the equivalent circuit for the conductively doped carrier-transport-layer device is modified as Fig. 11b. The optimized fittings to the measured Cole–Cole plots (under different dc biases) using such an equivalent circuit and parameters listed in Table 4 are shown in Fig. 12. As shown in Fig. 12, nearly perfect matching between the measured and simulated results is

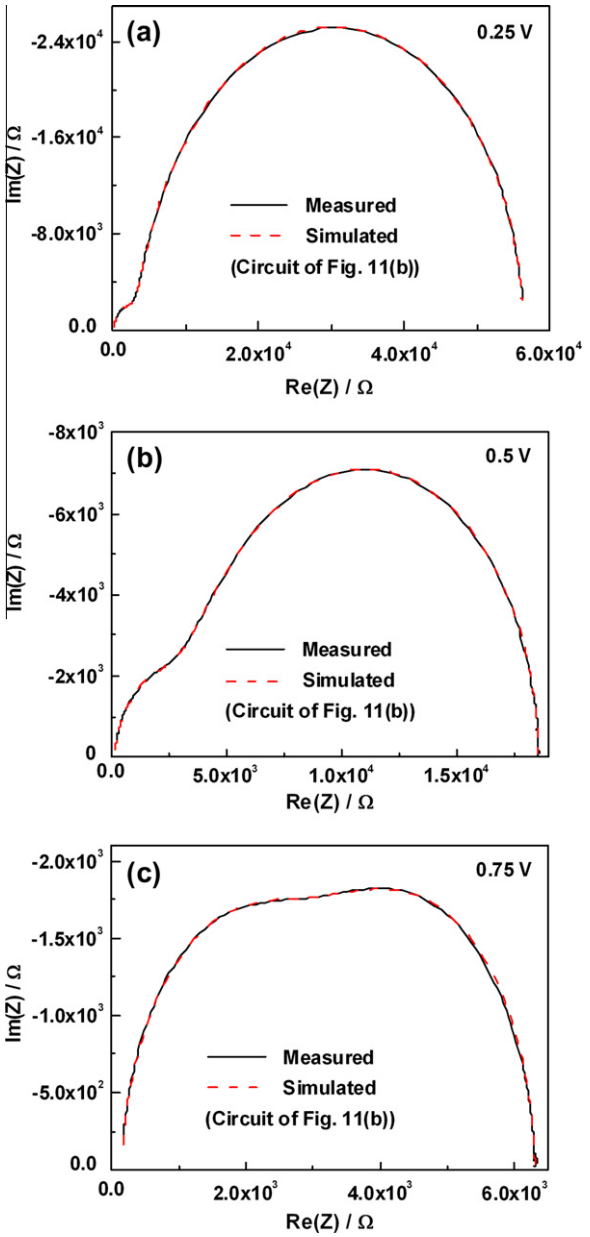

Fig. 12. The optimized fitting to the measured Cole–Cole plots of the 2 wt.% doped device in Fig. 4 using the equivalent circuit in Fig. 11b and parameters listed in Table 4 (for different bias voltages): (a) 0.25 V, (b) 0.5 V, and (c) 0.75 V.

obtained over a wide bias and frequency range by using the equivalent circuit of Fig. 11b. These results indicate the effectiveness of the equivalent circuits of Fig. 11a and b for the conductively doped organic carrier-transport layer. In Table 4, one notices that the CPE for the depletion region (CPE_J) has the α value significantly lower than 1, suggesting of more dispersive character. One also notices that the layer resistances of doped devices are much smaller than R_P in the non-doped device. With increasing bias, the resistance of the depletion region (R_J) decreases significantly. From the extracted values of equivalent circuit elements (e.g. comparing C_J and C_B) in Table 4, one can estimate the thicknesses of the bulk region and the junction region to be 70–90 nm and 10–30 nm, respectively, for the bias range shown. From the Q and capacitance values, one can also estimate the average relaxation time τ_0 to be on the order of 10^{-5} s, which is within the frequency range studied here and thus has noticeable influences on impedance spectroscopy.

The impedance spectroscopy of conductively doped hole-transport layers in this work indicates that a higher-impedance depletion region would occur when the energy level of the conductively doped hole-transport layer does not well match that of the adjacent layer in the OLED device (e.g. undoped hole-transport layer, emitting layer, electrode etc.). If occurring, that might degrade benefits provided by the conductively doped hole-transport layer (improved injection and conductivity, lowered operation voltage etc.). Thus to optimize OLED performances, even with adoption of conductively doped carrier-transport layers in devices, it is still worthy of carefully considering matching of energy levels of relevant materials layers to avoid/minimize such depletion phenomena. Furthermore, the dispersive dielectric responses induced by the conductively doping (and corresponding polarization relaxation) could have impacts on high-frequency operation (e.g. >10 kHz) of organic devices, in addition to regular RC effects.

4. Conclusions

In summary, the impedance spectroscopy was adopted to characterize conductively doped organic hole-transport layers for OLEDs. We performed comparative studies of the impedance spectroscopy of undoped and doped hole-transport materials, by both experiment and simulation approaches. The impedance spectroscopy of the non-doped hole-transport material can be well understood by simply adopting the conventional RC equivalent circuits and considering the dielectric response frequency-independent. For the conductively doped organic hole-transport materials, however, successful modeling of the impedance spectroscopy results need to take into account the more complicated situations: including the difference between the bulk region and the depletion region near the electrode, and dispersion (i.e. frequency dependence) in the dielectric response of the conductively doped transport layer. As such, it is found necessary to include the complex dielectric response and non-conventional complex impedance element in the equivalent circuit to achieve tight matching of simulated results with experiment results over wide bias and frequency ranges.

ABSTRACT

Small molecules have a great potential in developing organic solar cells owing to their well-controlled structure and tunable electronic properties by functionalization. Here, we use a classical fluorescent dye with a D-π-A structure, 4-(dicyanomethylene)-2-methyl-6-(4-dimethyl-aminostyryl)-4H-pyran (DCM), as an efficient light absorption layer with sensitivity at wavelengths of 400–600 nm where the aromatic amine/C_{60} cells have low absorbance. Combined with a p-type transporting layer of selected aromatic amines, the much improved layer and interface morphology yield solar cell power conversion efficiency up to 1.68% under AM 1.5 and 100 mW cm^{-2} illumination. The morphology of active organic layers, their interface, and the influence on the cell performance have been systematically studied.

1. Introduction

Organic solar cells (OSCs) have the potential to offer device flexibility and inexpensive power generation [1–4]. Developing materials with useful physical properties and exploring novel device architecture have been a general strategy in improving the power conversion efficiency of OSCs [5–7]. Small molecules with π-conjugated donor–acceptor (D-π-A) structure constitute an important group of material that possess many distinct advantages in the design and fabrication of OSCs [8,9]. The intramolecular charge transfer between π-conjugated electron donating and accepting units results in reduced optical band gap and enhanced light absorption in solar spectrum. Small molecules offer great flexibility in modifying the molecular structures and tailoring the electronic properties, and can be processed (e.g. by vacuum evaporation) into high-purity thin films consisting of mono-dispersed molecules. Recently, there has been increasing interest in studying new D-π-A type materials and their potential application in making bulk-heterojunction OSCs. Current results show that slight modification of the molecular structure by reducing the linker length could lead to nearly 2-fold increase of cell efficiency [10,11]. Despite these progresses, it remains a great challenge in developing D-π-A molecules with appropriate structures and optimizing device configuration for substantial improvement of OSC performance.

Here, we show that a commercially available dye, 4-(dicyanomethylene)-2-methyl-6-(4-dimethyl-aminostyryl)-4H-pyran (DCM), which has a simple D-π-A structure with an electron-rich dimethylamino group linked to two electron-withdrawing cyano groups, can be used as photoactive materials in OSCs. One of the advantages is that DCM has high absorption coefficient to visible light (42,000 M^{-1} cm^{-1} at 468 nm) [12], thus DCM layers can be made into very small thickness (less than 10 nm) for exciton transport but still have strong light absorption. Previous study on laboratory-synthesized materials consisting of triphenylamine and DCM moieties has shown promising results including high open-circuit voltages

(>0.9 V) and efficiencies in the range of 0.79–1.5% [10,11], however, OSCs directly using DCM have not been reported. Our devices were made by stacking electron accepting (C_{60}), photoactive (DCM), and selected p-type transporting layers into a heterojunction structure. Systematic study reveals that the DCM layer morphology, thickness, and interface with underlying layers are critical factors that dominate the cell performance. A combination of 10 nm thick DCM with 4,4′-bis[*N*-(1-naphthyl)-*N*-phenyl-amino]biphenyl (NPB) yields uniform layers with smooth interface, and cell efficiencies up to 1.68%.

2. Experimental

All materials were purchased from Sigma–Aldrich. Except for C_{60} (99%), they were purified by thermal gradient sublimation before deposition.

All devices were fabricated on indium tin oxide (ITO) coated glass substrates with an ITO thickness of 600 Å. The substrates were routinely pre-cleaned using isopropanol, ethanol and de-ionized water. PEDOT:PSS was spun onto the ITO anode at 4500 rpm for 60 s and then it was annealed at 120 °C for 15 min under atmosphere to form a 600 Å thick film. Organic layers were deposited at a 0.2 Å s^{-1} rate by thermal evaporation under high vacuum (7×10^{-7} Torr). Organic layers were annealed at 140–160 °C before Al electrodes were evaporated on their surfaces, followed the work of Osasa et al. [13]. Then the Al cathode was thermally evaporated on the top through a shadow mask giving an active device area of 5 mm^2. The film thicknesses were monitored by a quartz-crystal microbalance. The *J*–*V* characteristics were recorded using a Keithley 4200 Semiconductor Characterization System under ambient conditions. An Oriel 300W solar simulator (Thermo Oriel 91160-1000) with AM 1.5 G filter provides 100 mW cm^{-2} illumination, determined using a standard silicon solar cell.

Except where noted, all samples were prepared identically to the cells and all measurements were performed under ambient conditions. AFM images were obtained in the taping model using an SPA400 SPM (Seiko Instrument Inc.). The cross-section images of samples were observed using SEM (SIRION, FEI, USA). PL and polarized PL spectra were obtained using a Spectrometer FLS920 equipped with excitation and emission polarizers. The absorption spectra were recorded on a UV-3100 spectrophotometer (Shimadzu, Japan).

3. Results and discussion

A typical cell structure (from bottom to top, shown in Fig. 1a) is described as ITO/PEDOT:PSS (60 nm)/NPB (or TPD) (10 nm)/DCM (10 nm)/C_{60} (50 nm)/BCP (10 nm)/Al (80 nm) (here ITO, PEDOT:PSS, BCP and TPD denote indium tin oxide, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate), bathocuproine and *N*,*N*′-diphenyl-*N*,*N*′-di(m-tdyl)benzidine, respectively. BCP serves as an exciton-blocking layer [5]). A proposed energy level scheme is shown in Fig. 1b, where the highest occupied molecular orbital levels are measured by cyclic voltammetry. The band gap energies are estimated from optical absorption edge of each material (Table S1). Here, the energy levels of the materials measured under the same condition are not absolute values but on trend in the energy diagram.

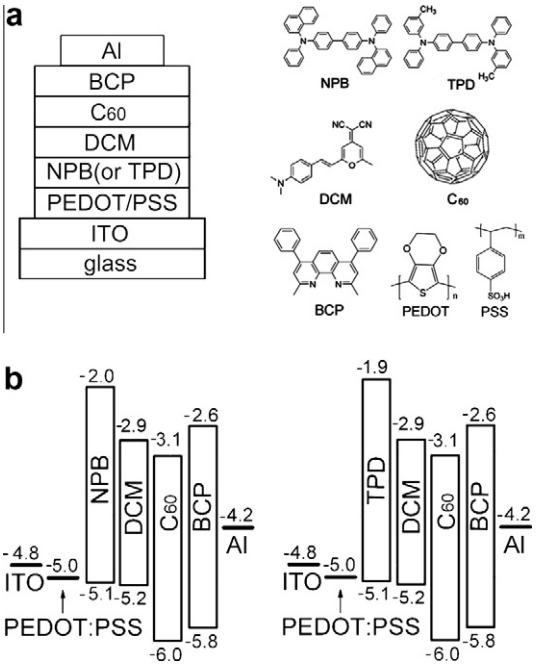

Fig. 1. Illustration of solar cell structure and energy level. (a) (Left) Illustration of a heterojunction cell with ITO/PEDOT:PSS/NPB (or TPD)/DCM/C_{60}/BCP/Al structure. (Right) The chemical structure of materials used in this work. (b) Energy level diagram for NPB (or TPD)/DCM/C_{60} cells assembly as determined by cyclic voltammetry.

Fig. 2a and b show the *J*–*V* characteristics of the NPB/DCM/C_{60} and TPD/DCM/C_{60} cell, respectively. The NPB/DCM/C_{60} cell (DCM thickness = 10 nm) annealing at 160 °C shows an open-circuit voltage (V_{oc}) of 0.75 V, a short-circuit current density (J_{sc}) of 4.62 mA cm^{-2}, a fill factor (*FF*) of 48.4%, and a power conversion efficiency (η) of 1.68% under AM 1.5, 100 mW cm^{-2} simulated solar light (Fig. 2a). The cell efficiency is higher or comparable to OSCs based on the similar materials TPA–DCM–TPA or DADP reported by other groups (0.79% and 1.5%, respectively) [10,11]. At the same condition, control sample of NPB/C_{60} (without DCM layer) shows slightly higher V_{oc} (0.86 V) but much decreased J_{sc} (2.47 mA cm^{-2}) and efficiency (0.81%). It was reported that OSCs made of α-NPD (NPB) or TPD layers in combination with C_{60} showed a large open-circuit voltage (>0.8 V) and maximum cell efficiency of about 1% [3,13]. This indicates that the incorporation of DCM is essential for improving the cell efficiency from 0.81% to 1.68%. In our cells, *J*–*V* curves from a comparative study demonstrate that annealing process has a favorable effect on the V_{oc} and fill factor (Fig. S1). The enhanced cell performance is most likely attributed to the improvement of carrier mobility in the organic layers [14,15].

Compared with the NPB/DCM/C_{60} structure, the TPD/DCM/C_{60} cell (DCM thickness = 10 nm) annealing at 140 °C shows significantly reduced V_{oc} (0.25 V) and

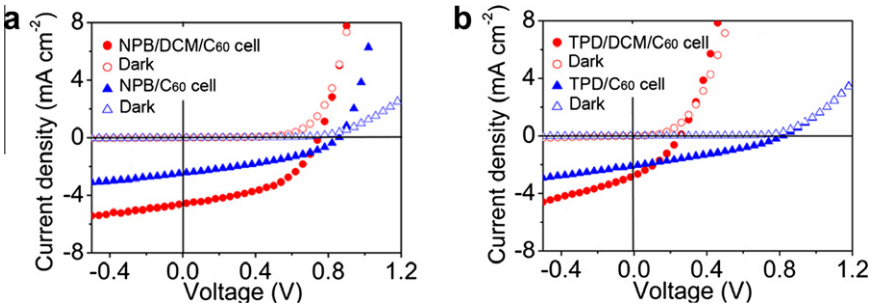

Fig. 2. *J–V* characteristics of solar cells. Dark (open) and photo (solid) current density–voltage characteristics of (a) the NPB/C_{60} cell (up triangle) and NPB/DCM (10 nm)/C_{60} cell (circle), and (b) TPD/C_{60} cell (up triangle) and TPD/DCM/C_{60} cell (circle).

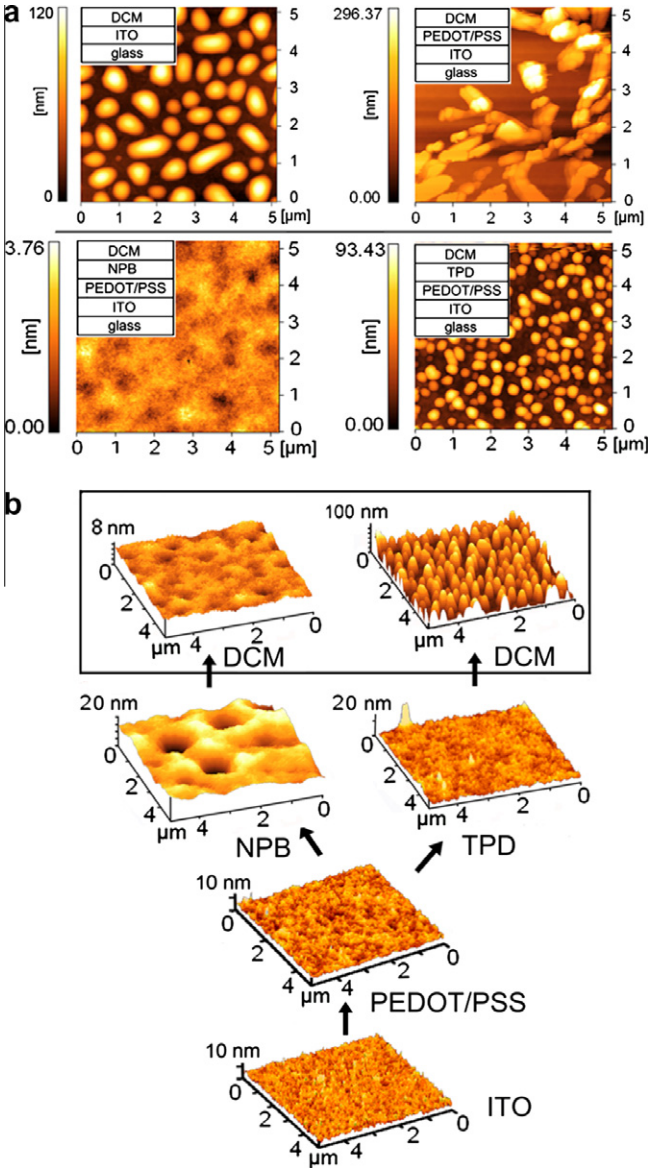

Fig. 3. Characterization of DCM film morphology. (a) Illustration of multi-layer film deposition where DCM was vacuum evaporated onto ITO/glass substrates with various pre-deposited organic layers, including bare ITO and PEDOT:PSS (top panel), NPB and TPD (bottom panel), and AFM images of the corresponding DCM film morphology. (b) AFM characterization and film roughness of each layer from the ITO to the DCM layer: ITO (roughness ~8.0 nm rms), PEDOT/PSS (roughness ~6.9 nm rms), NPB (roughness ~15.0 nm rms), TPD (roughness ~11.2 nm rms), DCM (on NPB layer, roughness ~10.1 nm rms), DCM (on TPD layer, roughness ~93.4 nm rms). AFM image scans are 5 × 5 μm.

efficiency (0.24%) (Fig. 2b and Table S2). It is known that V_{oc} strongly depends on HOMO–LUMO offset between donor and acceptor materials [16]. Since NPB and TPD only has slight difference in their energy levels, the energy band diagrams (Fig. 1b) of NPB/DCM/C_{60} and TPD/DCM/C_{60} heterojunctions indicate that both configurations are favorable for exciton dissociation and transport to outer electrodes in theory. In other words, there is no significantly different between TPD/DCM/C_{60} and NPB/DCM/C_{60} heterojunctions in their energy levels, which means there are other reasons leading to the different results. In practice the morphology of active layers and their interface are important factors because processes such as exciton transport and dissociation occur at these sites in a heterojunction cell structure [14].

We characterized the morphology of DCM deposited on substrates with different pre-deposited layers. Atomic force microscopy (AFM) images show that the layer and interface morphology of DCM is strongly influenced by the underlying substrate, and can be tuned from separated small islands to a uniform thin film by introducing an NPB layer. DCM molecules directly deposited on ITO or PEDOT:PSS substrates aggregate into microscale islands with irregular shapes, which is undesirable for subsequent device fabrication (Fig. 3a, top panel). A DCM layer deposited on TPD pre-deposited on PEDOT:PSS/ITO still shows island-like morphology, with considerable surface roughness of 100 nm. In contrast, deposition of DCM on NPB pre-deposited on PEDOT:PSS/ITO resulted in a smooth layer with a surface roughness of <10 nm (Fig. 3a, bottom panel and Fig. 3b). The surface morphology of DCM films largely depends on the wettability of the underlying layer to DCM molecules. These wetting process are determined by many factors related to the hydrophilic–hydrophobic property of materials (Table S3) at the macroscale (larger than 1 μm) and the long range force (e.g. van der Waals force) at the microscopic level (from 3 nm to 1 μm) [17].

We also characterized the interface morphology between active layers by means of scanning electron microscopy (SEM) and atomic force microscopy (AFM). The cross-section of the NPB/DCM/C_{60} cell shows a compact structure that is efficient for carrier transport and collection

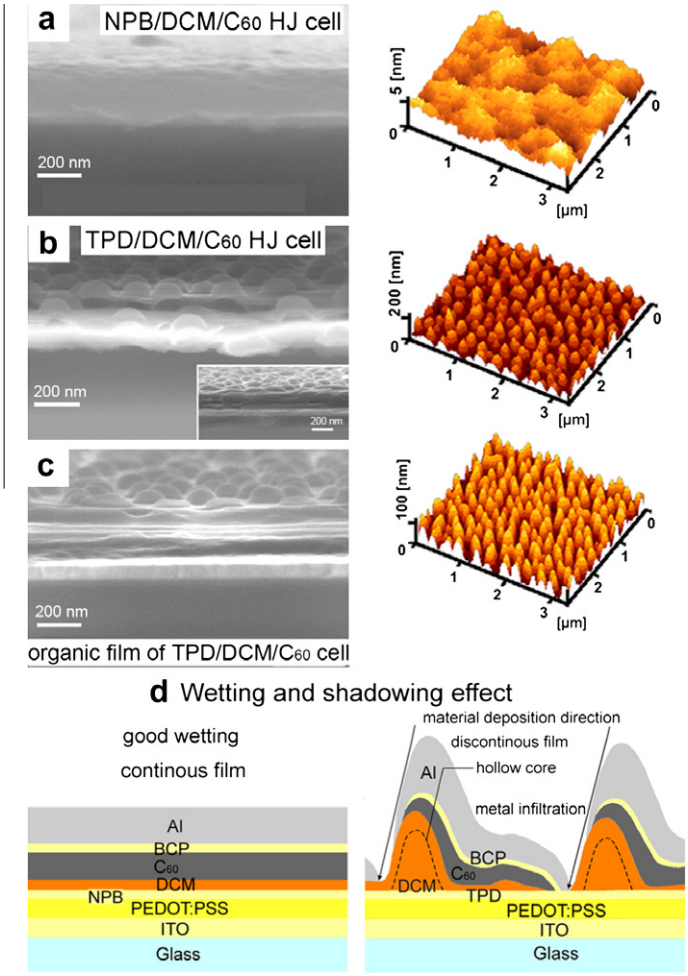

Fig. 4. Interface morphology of solar cells. Cross-sectional SEM and the film surface AFM images of (a) the ITO/PEDOT:PSS/NPB/DCM/C_{60}/BCP/Al cell, (b) the TPD/DCM (10 nm)/C_{60} cell after and (c) before Al electrode deposition. (d) Illustrations of the interface structure of the NPB/DCM/C_{60} cell with continuous and uniform layers (left), and the TPD/DCM/C_{60} cell with discontinuous layers and penetration of Al electrode due to shadowing effect (right).

(Fig. 4a). In contrast, the TPD/DCM/C_{60} cell shows an uneven layer interface with many structural defects like encapsulated hollow spheres. The formation of these defects can have significant influence on cell performance. First, the shadowing effect [18] can give a reasonable explanation for the lower V_{oc} of the TPD/DCM/C_{60} cells. The DCM film deposited on the TPD substrate shows an "island-like" morphology with a roughness of about 100 nm. After deposition of a 50 nm thick C_{60} layer and 10 nm thick BCP layer, the surface roughness is still about 100 nm (Fig. 4c). The DCM islands were too high to be completely covered by the subsequent organic layers, therefore cannot form a continuous layer to prevent penetration of Al electrode into the bottom organic layers. Fig. 4b shows that the surface roughness increased to 200 nm after depositing 80 nm Al as the top electrode. The shadowing of the high DCM islands could cause nonuniform organic layer deposition, and in some areas (e.g. around the islands) the organic layer might be very thin. In this case Al electrode could easily penetrate into deeper layers (even contact ITO/PEDOT:PSS anode), as illustrated in Fig. 4d, thus promote charge recombination in the organic layers and result in shortage of current and decrease of V_{oc}.

Although the TPD/DCM/C_{60} cell has a relatively large interface area similar to the bulk-heterojunction solar cells [6] the presence of structural defects is detrimental for exciton dissociation. In comparison, the results show that a smooth, continuous DCM film deposited on NPB is important for high performance of the heterojunction cells.

In addition to the layer morphology, the thickness of DCM film also determines the cell performance. Systematic study on the NPB/DCM/C_{60} cell with a DCM thickness in the range of 0–20 nm shows that the cell efficiency reaches maximum value (1.68%) at a DCM thickness of 10 nm (Fig. 5a). The increase of efficiency is accompanied by simultaneous increase of J_{sc} and *FF* due to improved light absorption and more exciton generation. The hole mobility of DCM derivatives is around 10^{-6}–10^{-5} $cm^2\,V^{-1}\,s^{-1}$ [10,11]. The highest *FF* is achieved through control of DCM layer thickness so that the low hole mobility does not significantly impact the cell performance. However, the cell efficiency drops monotonically from 1.68% down to <0.7% with increasing film thickness from 10 to 20 nm, indicating that the DCM thickness is limited to 10 nm therefore a film thicker than that is not favorable for good charge transport. At the same time, V_{oc} shows little change with DCM thickness in the range of 5–15 nm, since the HOMO–LUMO offset of DCM/C_{60} is similar to that of NPB/C_{60} heterojunction.

For the TPD/DCM/C_{60} cell in which the active layers formed islands during deposition, the efficiency–thickness relationship is very different compared with the NPB/DCM/C_{60} cell with smooth layers. There is no optimized layer thickness for maximum cell efficiency as V_{oc} drops significantly from 0.8 V to below 0.4 V when the thickness of DCM increases to >5 nm, and the cell efficiency drops to only 0.24% at a DCM thickness of 10 nm (Fig. 5b). In comparison, a uniform 10 nm DCM layer in the NPB/DCM/C_{60} cell has improved the efficiency by 2-fold (Fig. 5a).

The optimized DCM layer morphology and thickness (10 nm) suggests that incorporating DCM with appropriate structure is helpful for achieving maximum efficiencies in energy conversion processes such as photon absorption, exciton diffusion, and carrier collection. Such processes in both NPB/DCM/C_{60} and TPD/DCM/C_{60} cells have also been studied by the absorption and photoluminescence spectrum.

First, we show that the combination of a DCM and NPB (or TPD) layer has extended the photo absorption to UV and visible region (Fig. 6a). Without DCM, NPB or TPD

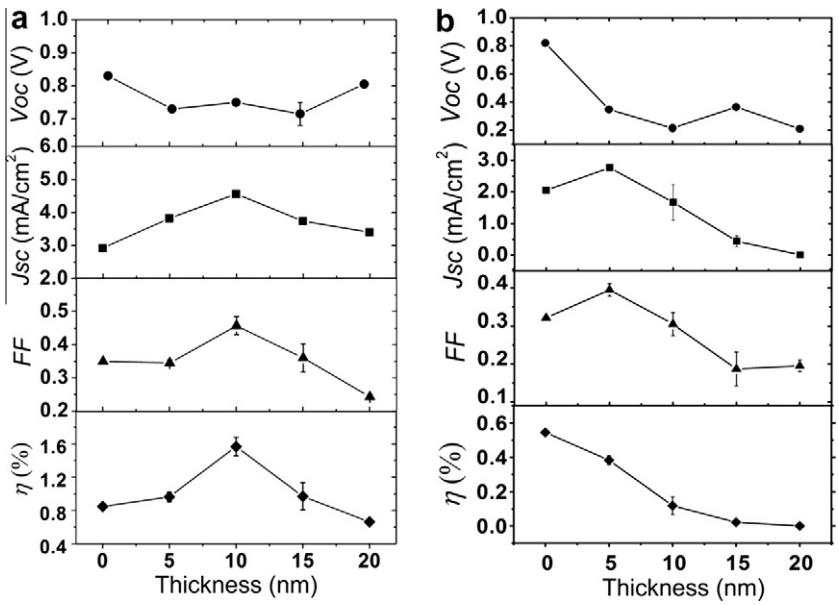

Fig. 5. Effect of DCM thickness on PV performance. (a) Photovoltaic response (e.g. V_{oc}, I_{sc}, *FF* and η, respectively) of the NPB/DCM/C_{60} cell with varying DCM thickness from 0 to 20 nm. (d) Photovoltaic response of the TPD/DCM/C_{60} cell with varying DCM thickness.

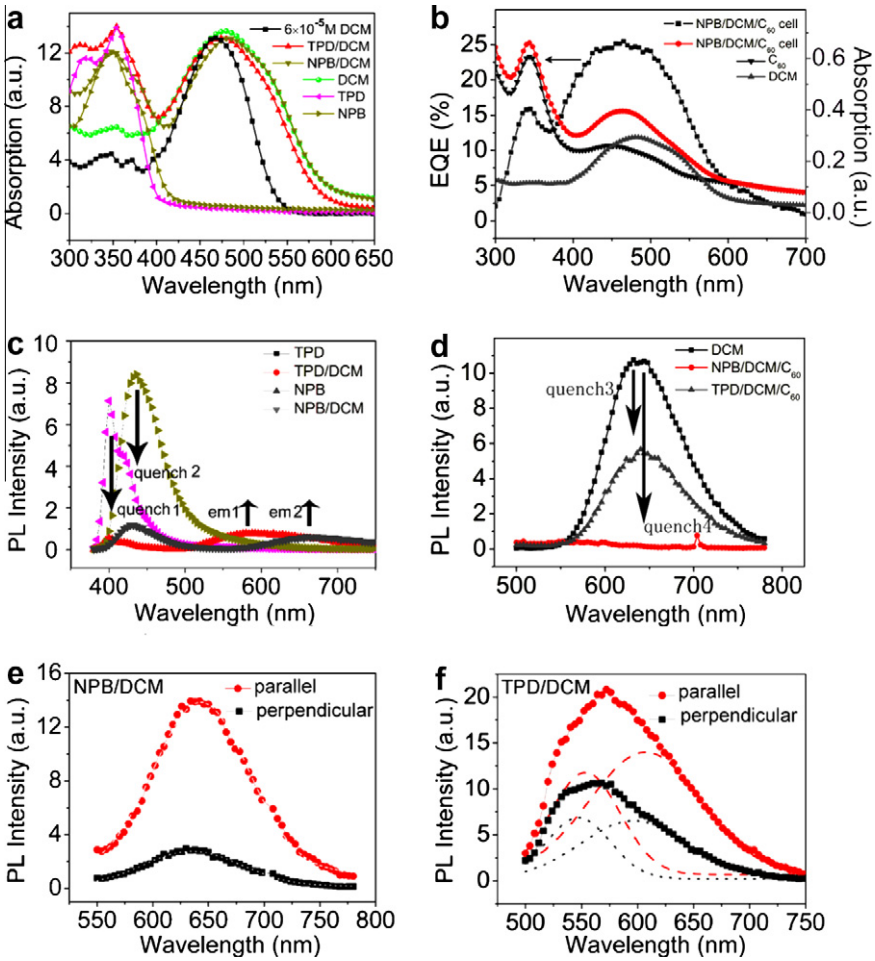

Fig. 6. Absorption and photoluminescence characterization. (a) UV absorption spectra of DCM, TPD, NPB, TPD/DCM and NPB/DCM films on ITO and 6×10^{-5} M DCM solution in CH_2Cl_2. (b) External quantum efficiency (EQE) spectrum and absorption spectra of NPB/DCM/C_{60} cell, C_{60} and DCM films. (c) PL spectra of NPB, TPD, NPB/DCM and TPD/DCM films on the ITO/PEDOT:PSS substrates (λ_{ex} = 352 nm). (d) PL spectra of DCM, NPB/DCM/C_{60} and TPD/DCM/C_{60} films (λ_{ex} = 467 nm). Polarized PL spectra for DCM deposited on (e) NPB, (f) TPD films, respectively, in parallel and perpendicular to the substrate under 352 nm polarized excitation, in which the parallel (dash lines) and perpendicular (dot lines) emissions were both fit with Gaussian. (The thicknesses of NPB, TPD, DCM and C_{60} are 10, 10, 10 and 50 nm, respectively.)

layers show little absorption in the range of 400–600 nm. Second, the order and interaction of DCM molecules in the film could be inferred from the absorption peak positions. In a diluted CH_2Cl_2 solution (6×10^{-5} M), DCM monomers show a relatively narrow absorption peak centered at λ_{max} = 468 nm (Fig. 6a). For DCM (islands) deposited on ITO substrate by vacuum evaporation, the absorption spectrum was broadened and red-shifted about 10 nm, indicating the formation of *J* aggregates [19]. Since the absorption band of TPD/DCM is slightly broadened on the blue-side compared with the NPB/DCM film, the DCM intermolecular interactions in these two films could be different, which is also verified by the PL spectra. The external quantum efficiency (EQE) of the NPB/DCM/C_{60} cell is shown in Fig. 6b followed absorptions of the cell and constituent photoactive materials with the photocurrent contribution from C_{60} generated between $320 < \lambda < 550$ nm, while DCM layer contributes from $400 < \lambda < 600$ nm.

Fig. 6c shows the emission spectra of the TPD and NPB films with maxima at λ_{max} = 400 nm and λ_{max} = 436 nm, respectively, under excitation at 352 nm. After depositing 10 nm DCM, the emission maxima of the TPD/DCM and NPB/DCM layer were mostly quenched. Since there is an overlap between the emission band of TPD (or NPB) and the absorption band of DCM, the energy transfer occurred from TPD (or NPB) to DCM via the Förster mechanism is responsible for the quenching of emission [20]. At the same time, new emissions originating from the DCM layer with maximum at λ_{max} = 586 nm (for TPD/DCM) and λ_{max} = 671 nm (for NPB/DCM) were observed. The emission maximum of the NPB/DCM film at λ_{max} = 671 nm was close to that of DCM crystal at λ_{max} = 693 nm [19] and red-shifted by ca. 100 nm compared with that of DCM in CH_2Cl_2 solution (λ_{max} = 582 nm). It is suggested that the intermolecular force of DCM in NPB/DCM films is high, close to the force in the crystal of DCM. On the other hand, the

emission band of the TPD/DCM film is very broad, overlapping both the band of DCM in CH_2Cl_2 solution and that of the NPB/DCM film, which means that the DCM molecules existed in the form of both monomers and aggregates after deposition on TPD. The emission from excited DCM layers was thoroughly quenched by the C_{60} layer in the NPB/DCM/C_{60} cell indicating an electron donating and accepting process occurred across their interface (Fig. 6d). While the emission of DCM was only half quenched in the TPD/DCM/C_{60} cell, since DCM layer is too rough (roughness around 100 nm) to be completely covered by C_{60} in the TPD/DCM/C_{60} cell (Figs. 3a and 6d).

Fig. 6e and f show polarized PL spectra for NPB/DCM and TPD/DCM films, respectively, excited at 352 nm. For the NPB/DCM film, both emission peaks in parallel and perpendicular polarization could be fitted with one Gaussian peak (around 634 nm) (Fig. 6e). The polarization ratio (parallel to perpendicular) was estimated to be 5.0, and the molecular order degree (R) was estimated to be 0.57 (see Table S4). These values suggest that most DCM molecules deposited on the NPB surface packed in an order form. However, the polarized emission peaks from TPD/DCM film are broad and can be fitted with two Gaussians centered at 553 and 607 nm, respectively, with smaller polarization ratios (1.7 and 2.1) and molecular order degrees (0.19 and 0.27). This result indicates a disorder form of DCM molecules on the TPD surface without obvious polarization. It can be seen that increasing order (alignment) of DCM molecules would cause their PL emission more red-shifted. The alignment of DCM molecules allows fast exciton diffusion to the interface through the ordered pathway, and also can significantly influence the optical and electrical properties of the devices [21].

4. Conclusions

To summarize, we demonstrated the application of a classical small molecule D-π-A material, DCM, in making heterojunction OSCs. Combined with appropriate underlying p-type layers, the cell efficiencies reach 1.68% due to extended solar spectrum coverage and improved exciton dissociation and transport path. We show that in the design and fabrication of OSCs, a smooth morphology of active layers and their interface is important for preventing device short-circuiting and achieving higher efficiencies. Simple small molecules such as DCM therefore are promising materials to make inexpensive OSCs.

ABSTRACT

We show the need for a quantity that describes the angular dependence of the chromaticity emitted from organic light-emitting diodes (OLEDs), present different quantities that may be suitable for describing this color stability and compare these quantities to ratings obtained from a perception test to determine which quantity correlates most strongly with the observer ratings.

© 2010 Elsevier B.V. All rights reserved.

1. Introduction

In the past years, organic light-emitting diodes have undergone significant development towards becoming a new generation of light source for general illumination. Not only are monochromatic OLEDs available, white OLEDs are also starting to enter the markets [1]. Due to the completely novel nature of these two-dimensional light sources, some challenges that are not present in previous luminaires must still be overcome. One such challenge is the angular dependence of the chromaticity. This angular dependence is especially prevalent in microcavity OLEDs [2], but also significantly distracting in white non-microcavity OLEDs.

Before attempting to reduce the angular color dependence, a quantity is required that successfully describes how strong the angular dependence is. While quantities like a shift in the peak wavelength [2,3] can be used for monochromatic OLEDs, this does not work well for white non-microcavity OLEDs where multiple emission-peaks are present that change their relative intensity but whose peak wavelengths do not shift significantly.

Because humans will ultimately decide whether the color shift is acceptable for use as a luminaire, the figure of merit against which color dependence must be judged should always be the color stability as perceived by a human observer. For this reason we have focused our research on finding a quantity that will successfully predict, from the measurement results, how a human observer judges the color stability with viewing angle of an OLED.

Several quantities that might describe the angular color stability well were identified. These quantities were calculated for a range of different color gradients (Fig. 1) and compared to observer ratings to determine which, if any, showed the best correlation.

2. Color difference

As stated above, the figure of merit must be the perceived color stability for a human observer. This means that color must be described in a suitable color space. David MacAdam showed that the CIE 1931 *xy* color space is not suited for comparing color differences [4] and it has been an ongoing effort to find a uniform color space that is perfectly equidistant with respect to perceived color difference. Albeit far from perfect, one such color space is the CIE (comission international de l'eclairage) 1976 $u'v'$ color space [5].

While still not perfectly uniform, it seems nonetheless justified to use the $u'v'$ color space because the OLEDs to be studied only exhibit a relatively small variation in color and OLEDs that are compared to each other will have a similar chromaticity (in the direction of the surface nor-

doi:10.1016/j.orgel.2010.08.022

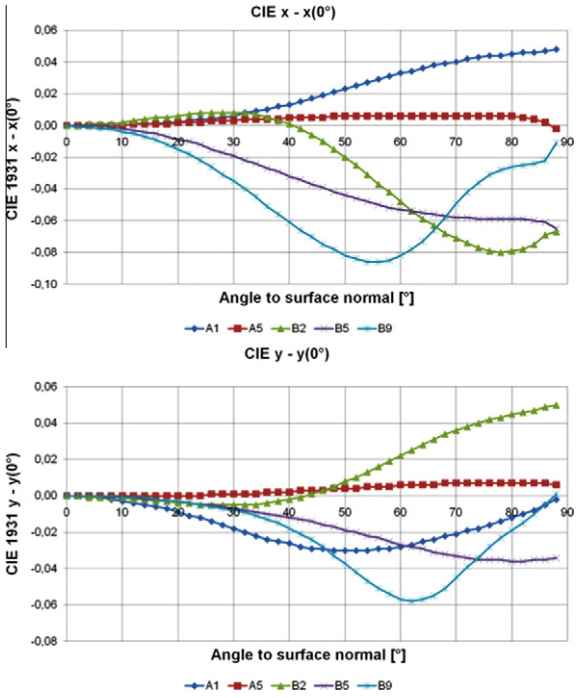

Fig. 1. Relative change of CIE x and y coordinates for selected samples. All samples had a chromaticity near color point A (≈ 0.44/0.40).

mal). Comparisons between OLEDs with similar color are, therefore, feasible with a color difference based on the CIE 1976 $u'v'$ color space.

Luminance changes with viewing angle are not taken into account in order to focus solely on the color. As OLEDs are (almost) Lambertian emitters, the luminance does not vary significantly with viewing angle, which allows for this simplification.

Color differences in a uniform color space, which the CIE $u'v'$ color space is assumed to be for our purposes, can simply be calculated as the Euclidean distance between two color points. This distance is calculated as

$$\Delta E_{i,j} = \sqrt{(\Delta u')^2 + (\Delta v')^2} \tag{1}$$

$$= \sqrt{\left(u'(\vartheta_i) - u'(\vartheta_j)\right)^2 + \left(v'(\vartheta_i) - v'(\vartheta_j)\right)^2} \tag{2}$$

where ϑ_i, ϑ_j denote the angles under which the chromaticity is measured with $i,j = 1,2,\ldots n$ and $0^\circ \leqslant \vartheta_i \leqslant 90^\circ$.

The color difference Eq. (2) can be used to describe the difference between two colors, for example an OLED under different viewing angles. It is not yet, however, suitable for judging the continuously changing color of an OLED viewed under varying angles. The color difference is, therefore, not the final solution for determining the color stability. Instead, it forms the basis for the following formulae that take into account the gradual change with viewing angle.

2.1. Maximum color difference

The maximum color difference is the largest value of ΔE that occurs between any two angles ϑ_i, ϑ_j and can be expressed as

$$CD_{max} = max(\Delta E_{i,j}). \tag{3}$$

2.2. Maximum color difference to vertical

Similarly, the maximum color difference to the color emitted in the direction of the surface normal can be calculated as

$$CD_{vert} = max(\Delta E_{1\,j}) \tag{4}$$

where $\vartheta_1 = 0^\circ$.

2.3. Average color difference to vertical

Rather than determining the maximum value of the color difference between the vertical direction and any angle, as calculated in Eq. (4), one can also calculate the average color difference to the vertically emitted color:

$$CD_{avg,vert} = \frac{1}{n-1}\sum_{j=2}^{n} \Delta E_{1,j}. \tag{5}$$

2.4. Average color difference between all angles

Similar to the average color difference to the vertical, an average color difference between all viewing angles ϑ_i, ϑ_j, $i \neq j$ can be calculated as

$$CD_{avg} = \sum_{1 \leqslant i \leqslant n} \sum_{i < j \leqslant n} \frac{\Delta E_{i,j}}{\frac{n(n+1)}{2} - n}. \tag{6}$$

2.5. Maximum rate of change

The previous concepts have focused on the absolute values of color difference only. An aspect that can also influence perceived color stability is the rate at which a color changes. The rate of color change might, therefore, also give an indication of the perceived color stability. The maximum rate of change is defined as

$$ROC_{max} = max\left(\frac{\Delta E_{i-1,i}}{\vartheta_i - \vartheta_{i-1}}\right). \tag{7}$$

2.6. Average rate of change

As the maximum rate of change might be high, even if only a small but very rapid color change is present, a more relevant quantity could be the average rate of change

$$ROC_{avg} = \frac{1}{n-1}\sum_{i=2}^{n} \frac{\Delta E_{i-1,i}}{\vartheta_i - \vartheta_{i-1}}. \tag{8}$$

2.7. Average rate of change between angles with maximum color difference

As a last quantity that might describe the perceived color stability well, we have identified the average rate of change between the angles with maximum color difference. The angles with maximum color difference are the angles ϑ_i, ϑ_j for which Eq. (3) yields the maximum. The average rate of change between these angles is

$$ROC = \frac{\Delta E_{ij}}{|\vartheta_i - \vartheta_j|}. \quad (9)$$

To determine which of these formulae is best suited for describing the perceived color stability, a perception test was carried out.

3. Perception test

A number of participants were shown different OLEDs with different color gradients (Fig. 1) at a luminance of 1000 cd/m^2. These OLEDs were attached to a goniometer and could be viewed under angles between 0° and 90°. Participants were free to adjust the angle as they desired. The participants were first shown the worst (i.e. with the largest angular color dependence) sample that would be used during the test. They were then asked to judge the following samples on a scale from 1 (good, no visible color change) to 6 (bad). They were only told to pay attention to the color change, but were otherwise not pointed to any details (i.e. rate of change, range of colors etc.). The group of participants consisted of men and women and people with and without experience in judging colors and working with OLEDs. The test was later repeated with a different set of OLEDs with different (more noticeable) color gradients and a different group of participants.

A repeatability and reproducibility study was carried out to judge how suitable this test is. The difference between a first and second rating of an OLED by the same observer was, on average, lower than 0.5, which is acceptable for such a visual perception test. As for the reproducibility, a difference was observed between different observers, as also expressed by the standard deviation on the average ratings. However, most participants put the OLEDs in the same order and only the absolute values of the ratings differed. This error is minimized by averaging over a large number of observer ratings.

4. Results

The participant ratings and calculated results are given in Tables 1 and 2. A scatter plot of CD_{avg} versus participant rating is shown in Fig. 2. A linear fit is applied to the data and the coefficient of determination, R^2, is used to judge how well the formula compares to the observer ratings. The results for all formulae are summarized in Table 3. The threshold for R^2, above which the correlation is statistically significant, is 0.36 for eight samples and a significance level of 95%.

From these results it is clear that ROC_{max} shows no or very little correlation with the perceived color stability. This is to be expected, because a very small color change that happens rapidly will significantly affect this quantity but will be hardly noticed by a human observer. ROC and ROC_{avg} must also be eliminated as quantities to describe the color instability of an OLED because the correlation with the ratings was weak on at least one test. CD_{vert} and CD_{avg}, on the other hand, are more promising quantities and CD_{max} and $CD_{avg,vert}$ can also not be ignored completely. From these findings it is suggested that CD_{avg} is used as a measure for OLED color instability. This quantity can be

used to compare different OLEDs to each other, characterize, for example, outcoupling structures, or serve as an optimization target for computer simulations.

It is also interesting to note that the quantities that performed worst were the ones that incorporated the rate of change in some way, indicating that the absolute color difference is more distracting to the human observer than the rate at which this change occurs.

To summarize these conclusions, the procedure for calculating the angular color stability of an OLED can be broken down into the following steps:

1. Measure the angle-dependent chromaticity of an OLED using a goniophotometer.
2. Ensure that color points are expressed in CIE 1976 $u'v'$ color space; convert measurement results if necessary. The $u'v'$ color space must be used as it is more equidistant with respect to perceived color difference than the widely used CIE 1931 xy color space.
3. Calculate color difference Eq. (2) for every pair of color points (with $i \neq j$) once.
4. Average over these color differences. This average value quantifies the angular color instability.

Steps three and four correspond to Eq. (6).

The following should be observed when using this procedure to rate OLEDs:

- Angular color instabilities of different OLEDs *should not* be compared if different measurement resolutions are used (e.g. color points measured every 2° or 5°). Higher resolutions yield more accurate results.
- Color instability *cannot* be compared for different angular ranges (e.g. measurements from 0° to 70° or 0° to 90°). Ideally, measurements should be conducted from 0° to 90° to cover all directions of emission.

5. Outlook

In the future, further perception tests must be performed before a definitive quantity for OLED color stability can be agreed upon. Once these tests have been carried out, it might also be worthwhile to look at combinations of the above formulae, like, for example, the product of the maximum color difference and a rate of change. The quantity that turns out to have the highest correlation with observer ratings should then be normalized to a range that is easier to handle and understand for people unfamiliar with the involved procedures.

6. Summary

In summary, we have explained why a quantity describing angular color stability of an OLED is required. We have compared several potentially suitable quantities to observer ratings of the color stability. From these results, the average color difference between all angles was determined to show the best agreement with the perceived color stability as rated by observers. Some other quantities may also be able to describe the color stability well although they performed slightly worse, while others can be eliminated completely.

ABSTRACT

In this paper, we analyze the variation of the threshold voltage V_T and carrier mobility μ_{fet} with the active layer thickness of polymer thin film transistors (PTFTs). The value of V_T was observed to become more negative as the active layer thickness decrease, while mobility slightly increased. Simulations obtained for different active layer thickness were first validated with experimental data from measured devices with known active layer thickness. Then using the calibrated simulator, it was found that as the semiconductor thickness decreased, the charge per square units in the active layer changes, establishing the cause of both of these behaviors.

1. Introduction

During the past decade, organic and polymeric materials have received increased attention from the research and industrial communities, particularly for application as electronic devices for low-cost, flexible, large-area displays. Among these devices, small molecules organic thin film transistors (OTFTs) already reached performance similar to amorphous silicon TFTs, especially OTFTs based on pentacene [1]. Polymeric TFTs (PTFTs) are also been intensively studied, with poly (3-hexyl-thiophene) (P3HT). P3HT has attracted considerable interest because it can be solution-processed and has been reported to show the highest reported field effect mobility, up to 0.1 $cm^2/V\,s$ [2–7].

It has been observed that the structure and ordering of the organic active layer has a great impact on the value of the mobility [3,6,8], which is related to the charge carrier transport mechanism. The increase in mobility with charge carrier concentration is described in many publications, for example in [9–11].

Another factor that may affect mobility is the interface between the dielectric and the semiconductor polymer, which is much related to the threshold voltage, V_T, as well as to its stability [12,13]. For the above reasons, the device current voltage characteristics and mobility are related to many factors, which include the characteristics of the active layer material, its interface with the dielectric, as well as details of the fabrication process [14] and the device structure [6–8].

Less attention, however, has been dedicated to the optimization of device geometry for a more efficient device operation, where the thickness of the active layer has been reported to affect in different ways device characteristics. In [15] the effect of the active layer thickness on-current–voltage characteristics for pentacene bottom gate and top drain and source contacts devices was studied. It was reported that drain current and mobility (determined from the square root of drain current vs. gate voltage curve) increased as active layer thickness t_S is reduced down to 16 nm. However, it was observed that the on/off-current ratio reduced with t_S, which they associated with an off-state leakage that was not clearly understood. On the other hand, the authors in [16] observed that the

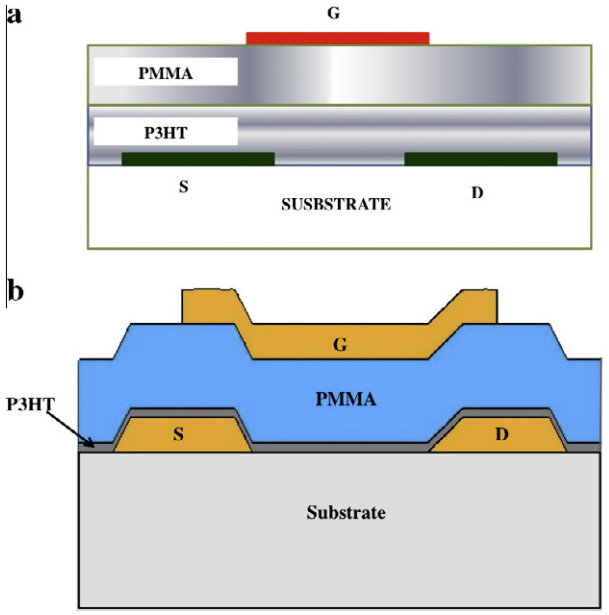

Fig. 1. Device structure of the P3HT-based PTFTs used in simulations. (a) Planar structure in ATLAS and (b) real structure in ATHENAS.

gate current decreased as pentacene thickness was reduced from 80 to 10 nm, which they found related to the presence of series resistance. Also, the thickness of the pentacene layer has been observed to affect device stability [17,18].

For polymer active layers, variation of drain current and mobility with active layer thickness was observed as early as 1988 [19], when quality of the P3HT and optimization of the fabrication processes were still in their infancy. Since then, much work has been done regarding PTFTs with different structures and materials. The effect of ambient conditions on the stability of PTFTs has been investigated [13,18]. More recently the dependence of organic thin film transistor characteristics with pentacene thickness was analyzed [20], they observed that the drain current increases at any drain voltage until a pentacene thickness of 35 nm, and then the current decreases; they show that in all the devices with varying pentacene thickness, most of the current flows through a very thin region, approximately 5 nm, near the dielectric surface.

In this work, we report and analyze the effect of the active layer thickness on the current voltage characteristics of top gate P3HT-based PTFTs. First, we validate results from a two-dimensional simulation in ATLAS [21] with measured characteristics of PTFTs fabricated with PMMA on P3HT, as reported in [4,5]. This was done to confirm the simulation, with the structure and input parameters to represent correctly the behavior of measured devices. With this calibration completed, simulation to study the effect of t_S on threshold voltage and mobility can be performed. The structure and geometrical input parameters were taken from measurements on fabricated devices. Other parameters were extracted using the procedure described in [22]. Since, as indicated above, the PTFT electrical characteristics depend on many technological parameters and conditions, and then using simulation allows for the separation of the effect of layer thickness from the effect of other factors (source/drain contact resistances, surface roughness, etc.) that may arise from processing conditions during the fabrication process, either intentionally or non-intentionally. Simulation also allows for fixing with precision the desired device dimensions. At the same time, simulation provides the means to determine charge carrier distribution, electric fields and other physical parameters for a given operating condition of the device, thus making it is possible to better understand the observed electrical behavior.

2. Experimental part

A schematic cross section of the TFTs under study is depicted in Fig. 1. Upper gate polymer TFTs were fabricated with a PMMA layer on top of a P3HT layer, both deposited by spin coating. Transistors with the following dimensions were fabricated, channel width W of 210, 150 and 110 mm and channel length L = 50 mm, L = 30 mm, L = 20 mm and 10 mm. The PTFTs with expected thickness of the P3HT layer of 80, 30 and 16 nm and the above dimensions, were fabricated. Details on their fabrication can be found in [4,5].

3. Simulation

For simulation, we have used the commercial device simulator ATLAS. The band gap for P3HT was taken as 1.8 eV as provided by supplier Sigma Aldrich. The dielectric constant of P3HT and PMMA was taken as 6.5 and 2.6, respectively, as obtained in [4]. The density of states *gdo* and the characteristic temperature T_o were extracted from

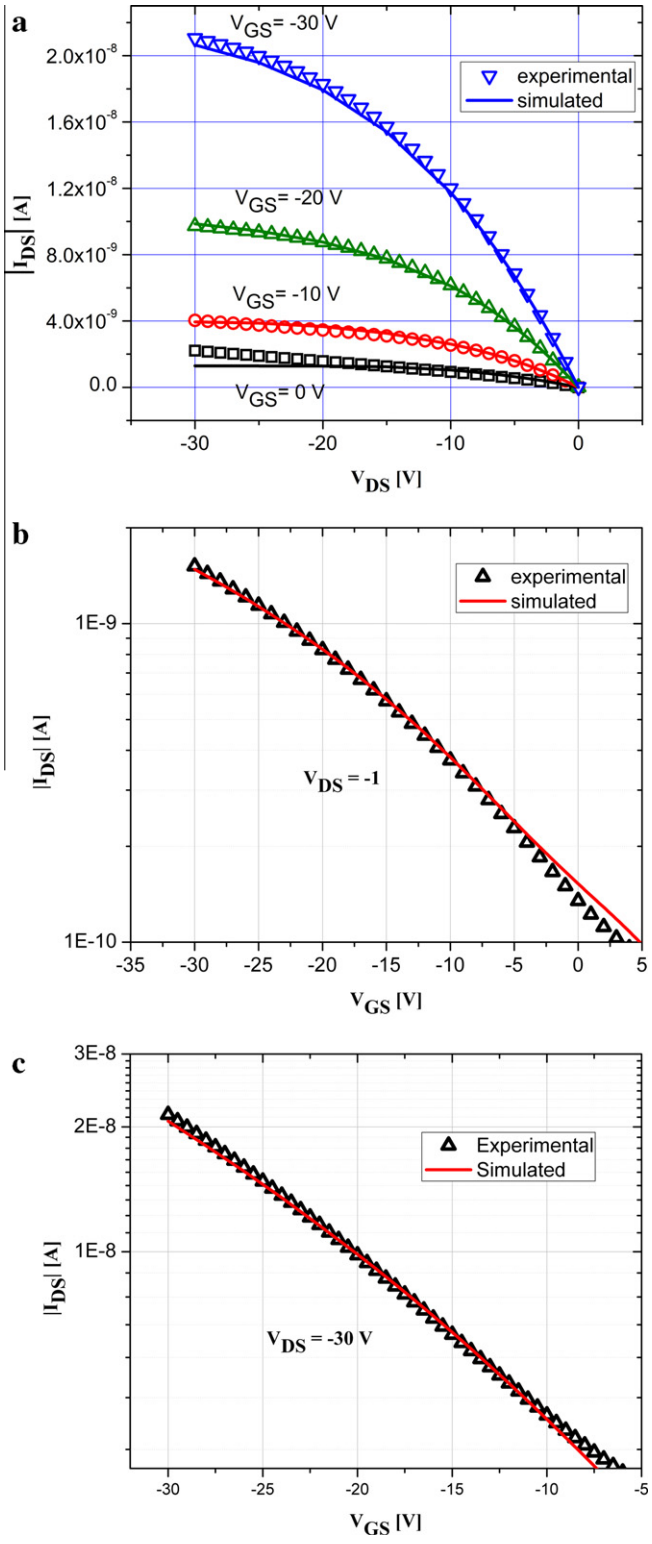

Fig. 2. (a) Output, (b) linear transfer and (c) saturation transfer characteristics for top gate PMMA on P3HT transistor, measured and simulated.

measurements following the procedure described in [22]. The P3HT film was considered non-intentionally doped *p*-type, with a concentration in the range of 5×10^{16} to 1×10^{17} cm^{-3}, as was determined in [22]. The effective density of states in the conduction band N_C and valence band N_V were both assumed to be 1×10^{21} cm^{-3}, which

is a typical value considered for organic materials. Simulations were done using a planar structure in ATLAS, where drain and source were located at the bottom and the gate on top, and also using the more real representation done in ATHENAS, as indicated in Fig. 1(a) and (b), respectively.

4. Results and discussion

Fig. 2 shows the good agreement obtained between simulated and measured characteristics, indicating that simulations, with the extracted parameters, can be used to study the effect of active layer thickness on the device parameters. It is worth to remark, that for this device, with active layer thickness of 80 nm, the I_{DS}–V_{DS} curve for V_{GS} = 0 V is the same as reported in [4], a drain current is present due to the conductivity of the P3HT layer between drain and source, which depends on the non-intentional doping of the P3HT layer.

The output characteristics of the TFTs with a P3HT active layer of 20, 30, 40, 80, 120 and 160 nm, simulated with the extracted parameters indicated above are shown in Fig. 3 for two gate voltages. In Fig. 3(a) can be observed that the drain current increases with the P3HT thickness, the same behavior was observed in [23,24], for P3HT film thickness below 200 nm.

Reducing the P3HT layers thickness can eliminate the drain current related to the conductivity of the unintentionally doped P3HT, Fig. 3(a). For 20 nm thickness there is no effect, while for 160 nm thickness, the effect is much more pronounced than the observed for 80 nm, this was also obtained experimentally in [23].

The transfer characteristics of the TFTs with a P3HT layer for the same thicknesses above were simulated with V_{DS} = −1 V and −30 V, Fig. 4. An important effect observed, that is also related with the unintentional doping of the P3HT layer, is that decreasing the active layer thickness, t_S, leads to a lower off-current.

The on/off ratio was calculated from the highest on-current and the lowest off-current from the transfer curve of the P3HT PTFTs (V_{GS} = + 7 to −30 V at V_{DS} = −30 V), Fig. 5.

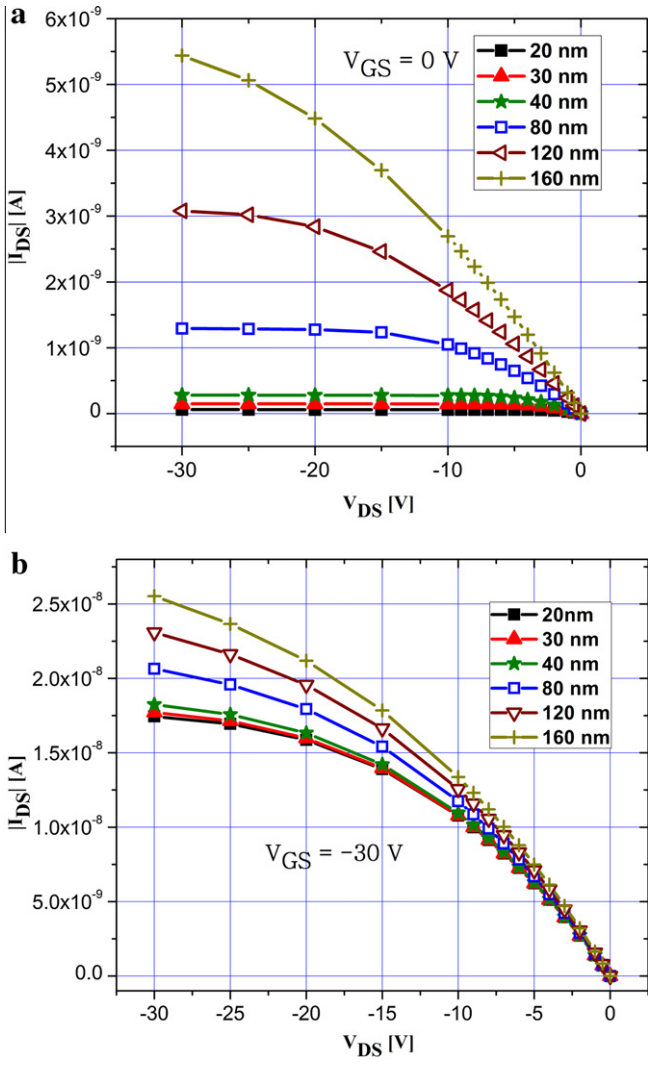

Fig. 3. Simulated output characteristic for the PTFT transistor (a) *VGS* = 0 V and (b) V_{GS} = −30 V.

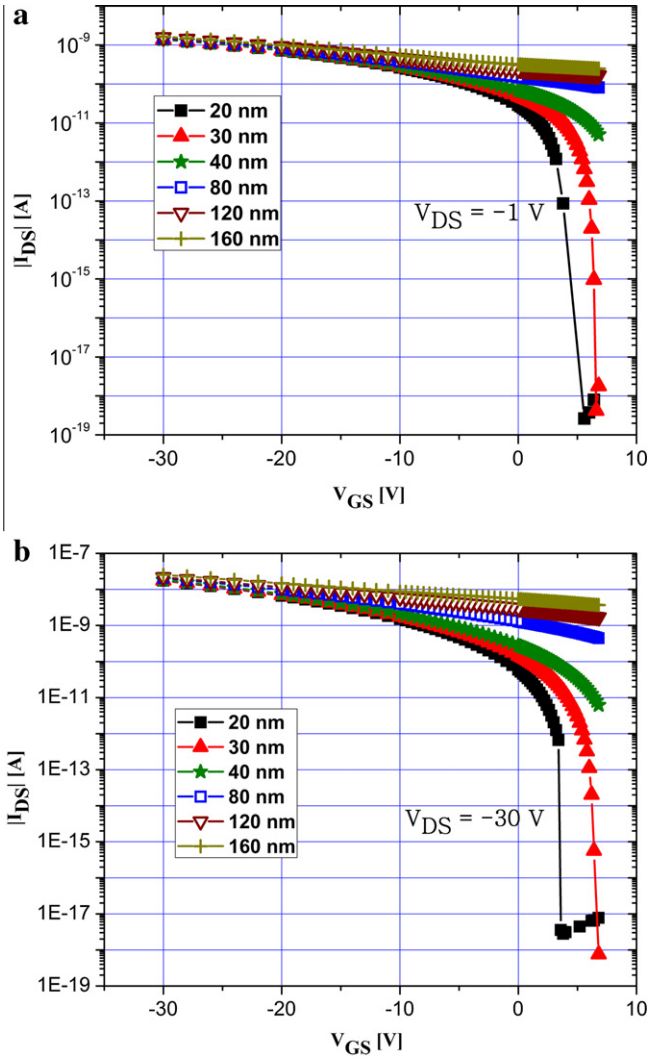

Fig. 4. Simulated transfer characteristics for PTFTs with various active layers thickness, (a) $V_{DS} = -1$ V and (b) $V_{DS} = -30$ V.

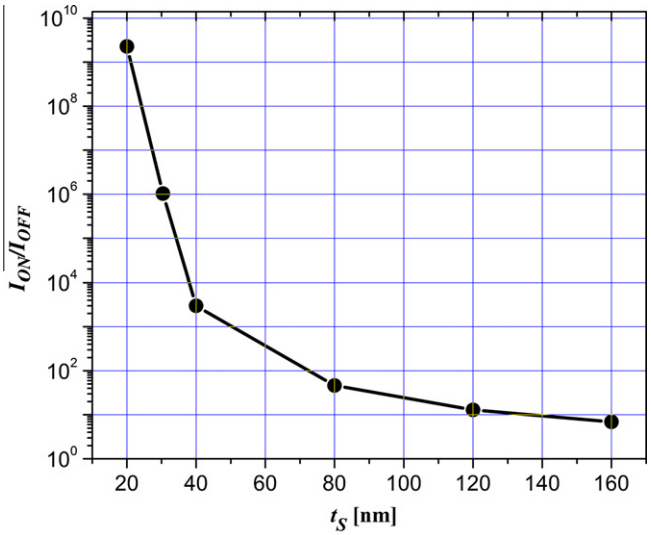

Fig. 5. P3HT film thickness dependence of on/off ratio in P3HT devices.

The devices with thicker films have lower on/off ratios. Since the on-current slightly increases, the reason for low on/off ratios is the faster increase of the off-current.

For the same operating conditions used to simulate the transfer and output characteristics, the charge per unit area in the active layer was analyzed, and the results are shown in Fig. 6. It was observed that for V_{GS} below V_T, active layers with thickness smaller than 40 nm are fully depleted, and for this reason, the off-current is low. For active layers with thickness greater than or equal to 80 nm, at some depth, the charge per unit area is high enough to provide current path between drain and source even for V_{GS} below V_T. As the active layer thickness increases, the part of the layer where current can flow increases, and so the off-current also increases.

In Fig. 4(a) and (b), it is seen that the on-current also increases as the thickness of the active layer increases, for same reason described above. At high values of V_{GS}, the active layer surface will be accumulated. The charge per unit area in the active layer in a plane near the drain, for $V_{GS} = -30$ V is shown in Fig. 7 as function of film depth.

For further analysis, we calculated the V_T for each active layer thickness using the procedure described in [22] and the simulated current–voltage curves. It can see in Fig. 8, there is a variation in the curvature of the $I_{DSsat}^{1/1+\gamma}$–V_{GS} profiles in the low V_{GS} region, suggesting that the deviation of the drain current from the potential law of V_{GS} has influence on the determination of the V_T values, and has been ascribed to a decrease in the field effect mobility at low V_{GS} values [25].

The variation of V_T with t_S is shown in Fig. 9, where V_T becomes more positive as t_S increases. As the semiconductor layer becomes thinner, the charge per square units decreases, so there is less charge to compensate, Fig. 6 [6].

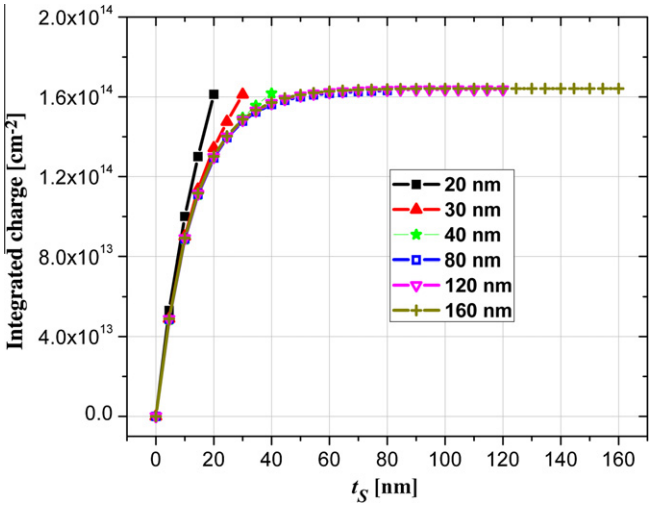

Fig. 6. Charge per square unit in the active layer in a plane located near the drain, obtained from simulation for $V_{DS} = -1$ V and $V_{GS} = 0$ V.

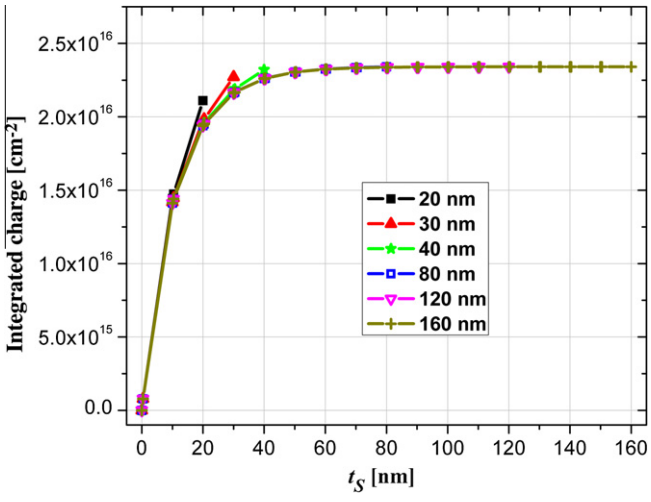

Fig. 7. Charge per square unit in the active layer in a plane located near the drain, obtained from simulation for $V_{DS} = -1$ V and $V_{GS} = -30$ V.

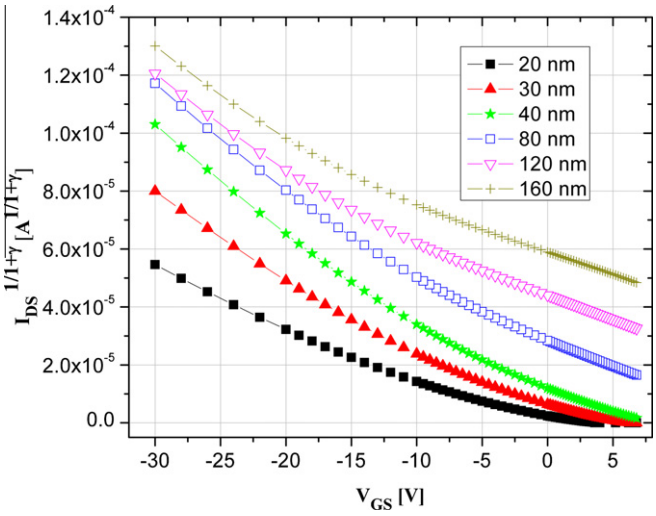

Fig. 8. $I_{DSsat}1/1+^{\gamma}$–V_{GS} curves (V_{DS} = −30 V) of PTFTs with various P3HT thicknesses.

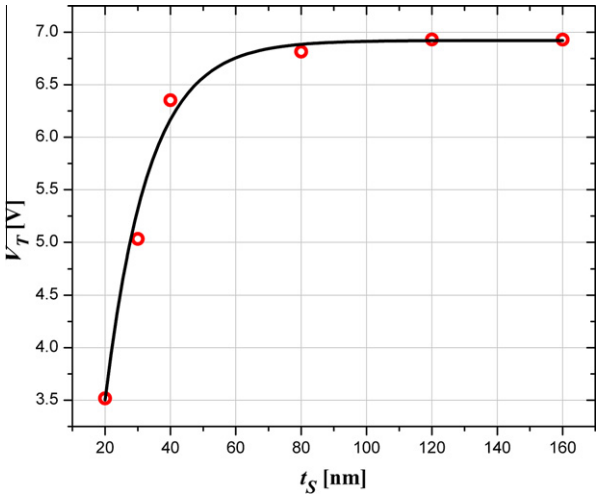

Fig. 9. Variation of threshold voltage [22] with the active layer thickness.

Table 1
Mobility values for different active layer thickness.

t_s (nm)	m_{fet}
160	1.762e−3
120	1.764e−3
80	1.770e−3
40	1.788e−3
30	1.835e−3
20	1.919e−3

This however cannot explain the behavior of I_{DS}, if the drain current increase is solely because of the bulk conductance increase, the output characteristic would not saturate, so other factors must be present.

Finally, the field-effect mobilities (μ_{fet}), according to the method described in [22] were extracted, the behavior of mobility with active layer thickness is shown in Fig. 10 and Table 1, where it is observed, as the active layer

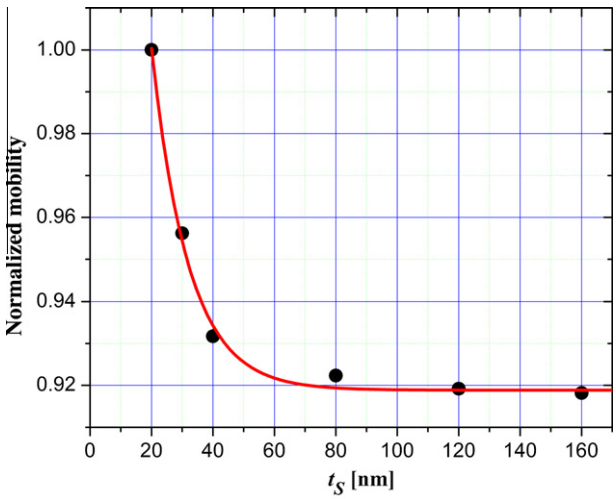

Fig. 10. Variation of normalized field effect mobility (calculated as in [22]) with the active layer thickness.

thickness decreases, the mobility slightly increases. The degeneration of mobility seems to be dependent on thickness, as seen in Fig. 8, this behavior can be caused by the increase of the average value of the charge, as the thickness of the active layer decreases, which is confirmed by simulation.

5. Conclusions

In this paper, we studied the dependence on thickness of V_T and mobility in PMMA on P3HT PTFTs. The value of V_T was observed to become more positive as the active layer thickness is increased, while mobility slightly decreased. Using simulation we confirmed that, as the semiconductor layer becomes thinner, the charge per square units decreases, which can explain the observed shift of V_T. The increase in mobility can be explained by the increase of the average value of the charge as the thickness of the active layer decreases, which was confirmed from simulations.

ABSTRACT

The mobility of rubrene single-crystal field-effect transistors has been measured in the presence of hydrogen and oxygen gas. The mobility of as-grown crystals is ~10 cm^2/V s but falls to 0.01 cm^2/V s during reduction in a hydrogen environment, and returns to nearly its original value in oxygen. Several cycles of surface reduction and oxidation have been done, which indicates that the surface reactions are reversible and the mobility can be changed to any value between that of the oxidized surface (10 cm^2/V s) and that of the reduced surface (0.01 cm^2/V s). Fourier-transform infrared (FTIR) spectroscopy and photoluminescence (PL) spectroscopy have been applied to examine the oxidized and reduced surface of the rubrene single crystal. FTIR, Raman and PL spectroscopies reveal differences between the rubrene surface and bulk depending on the state of surface oxidation. We conclude that high field-effect mobility in rubrene crystals is a result of surface doping by an oxidized layer on the crystal surface and not due to the intrinsic molecular and crystal structure of rubrene.

1. Introduction

Fundamental studies over the past 50 years [1–3] of carrier transport properties in organic semiconductors have led to applications in low cost, flexible organic electronics such as foldable displays, organic solar cells and printed microelectronic circuits. In particular, the increase in electron and hole mobilities from the range of 10^{-5} to above 10 cm^2/V s achieved as a result of the exploration of new and higher-quality crystalline materials promises numerous new applications, especially in high-frequency electronics.

Single crystals provide a good platform for studying the fundamental physics of the charge transport mechanism and to evaluate its limits in organic semiconductors. Numerous studies have been done on single crystals of polycyclic aromatic hydrocarbons such as tetracene [4,5], pentacene [6], anthracene [7] and similar compounds [8,9]. However, the transport mechanism is still controversial and the limit of the charge-carrier mobility, a parameter critical for device applications, is not yet known due to the presence of impurities and other defects at far higher levels than in typical inorganic semiconductors. Despite dramatic improvements in the mobility measured in field-effect transistors made from organic semiconductors from initial levels in the 10^{-5} cm^2/V s range, during the last few years improvements in the mobility have stagnated in both thin films and single crystals at values of order 10 cm^2/V s.

Rubrene (5,6,11,12-tetraphenylnaphthacene) appears to be an exceptional material in this regard, as very high values for its mobility have been consistently reported [10–12]. However, the composition and the molecular and crystalline structure of rubrene are in no way excep-

doi:10.1016/j.orgel.2010.08.019

tional compared with other organic semiconductors, although the intermolecular coupling is known to be extremely low, and so the origin of this high mobility remains a subject of controversy.

Conduction in FET devices takes place in a shallow surface channel, which in rubrene is subject to oxidation under ambient conditions. Photo-oxidation of rubrene in solution has been reported since the compound was first synthesized [13], and a red toluene solution of rubrene fully bleaches in the presence of air and light, forming an endoperoxide of rubrene that is not very stable. The dry endoperoxide loses oxygen during heating and decomposes back to rubrene. However, bulk rubrene single crystals appear not to bleach, presumably due to steric obstacles in the crystalline lattice because the formation of the endoperoxide requires bending of the tetracene backbone of the molecule. Materials with large surface area such as commercial powders have been shown to contain endoperoxide, and the oxide has also been detected on the surface of single crystals [14]. To date a connection between the transport properties and the oxidation state of the rubrene surface has not been directly established.

In the present paper, we report the growth of rubrene single crystals from the gas phase and measurements of conductivity, field-effect mobility, infrared transmission and reflection, and photoluminescence on the crystals during oxidation in an oxygen atmosphere and reduction in hydrogen atmosphere. We observed significant changes in the transport parameters due to oxidation and reduction of the rubrene single-crystal surface. The field-effect mobility of a rubrene single-crystal transistor decreased by at least three orders of magnitude, from 10 to 10^{-2} cm^2/V s, during reduction of the rubrene surface. Upon re-oxidation the mobility returned to close to the original value of 10 cm^2/V s. We have shown that the process is repeatable and reproducible. Our measurements of IR transmission and reflection, photoluminescence, Raman scattering and chemical purity all indicate that surface oxidation and reduction change the doping of the active layer in a rubrene field-effect transistor. We explore here whether surface doping is the primary parameter producing the high mobility of organic semiconductors, with the structure–property relations being a secondary factor in the search for high-performance organic semiconductors.

2. Experimental

Rubrene single crystals were grown by the physical vapor transport (PVT) technique [15,16], using hydrogen, forming gas (4% H_2 and 96% N_2) or argon (Ar) for transport of the rubrene molecules in the gas phase. The rubrene source powder (purchased from Sigma–Aldrich) was purified by sublimation before crystal growth. The temperature of two-zone furnance was set to 300 and 260 °C, respectively. The carrier gas hydrogen was produced by a hydrogen generator via electrolysis of water. Before using it, water was eliminated by passing it through a dry column. After growth, the furnace was cooled to room temperature without any additional temperature control, keeping the carrier gas flowing throughout the cooling process. We collected the crystals from the furnace in laboratory atmosphere and evaluated their quality under a polarized microscope, selecting some for further measurements.

Two-terminal devices were fabricated with contacts made with Ag paint. A Keithley 6517 electrometer was used to make two-point current vs. voltage measurements. The sample was kept in oxygen or hydrogen atmosphere at 100 °C overnight before the room-temperature conductivity measurements were made.

Rubrene air-gap field-effect transistors (FET) were fabricated by gently pressing the smooth surface of the rubrene crystal onto a pre-fabricated polydimethylsiloxane (PDMS) stamp [17]. The air gap was 4.2 μm thick. We deposited a 20-nm layer of Au on the PDMS stamps at rate of 0.2 Å/s by an electron beam evaporator, forming the source, drain and gate electrodes and allowing us to achieve adhesion of the rubrene crystals to the source and drain electrodes. A schematic of a transistor is shown in the insert of Fig. 1. After the transistors were fabricated we placed them inside a quartz tube of a transparent tube furnace where the temperature, pressure and gas atmosphere could all be controlled. Electrical wires attached to transistor led to the measurement instrument outside the furnace, allowing us to make transport measurements while using oxygen and hydrogen gas in the oxidation and reduction process. To study the reproducibility of the oxidation/reduction process, we cycled the gas flow between oxygen and hydrogen repeatedly, measuring the output and transfer characteristics of the transistors continuously during processing, using a Keithley 4200-Semiconductor Characterization System.

Perkin–Elmer FTIR spectrum GX was used to perform FTIR measurement on rubrene crystals in both transmission and attenuated total reflection (ATR) modes. We selected thin flexible rubrene single crystals (approximately 20 μm thick) for the ATR-FTIR measurement, as the

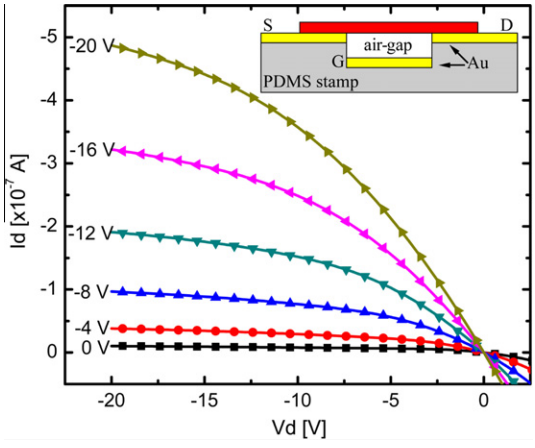

Fig. 1. Output characteristics of an air-gap rubrene single-crystal FET used in this study. The numbers at the end of curves indicate the corresponding gate voltage (V_g). The inset is a schematic of the air-gap rubrene single-crystal FET. The red part represents the rubrene single crystal. The yellow part represents the 20 nm gold film. The grey part represents the polydimethylsiloxane (PDMS) stamp.

measurement required good adhesion between a quartz window and the rubrene single-crystal surface. For transmission-mode measurements we used crystals a few hundred micrometers in thickness. The crystals used in infrared experiments were grown in Ar and stored in dry air for several days. Photoluminescence spectrum were collected using a confocal photoluminescence spectroscope, the Witec α-300. Excitation was provided by the 488-nm wavelength of an Ar+ laser focused through a 100× objective (N.A. 0.95) onto the rubrene single-crystal surface. Laser power is of approximately 15 μW/cm^2 to avoid damaging the sample.

3. Results and discussion

Charge-carrier transport in an FET takes place in the near-surface region, therefore any modification of the chemical or physical properties of this region in an organic semiconductor affects the transport properties of the device [18,19]. In order to demonstrate that the oxidation state of the semiconductor surface controls the mobility of a rubrene FET, we have conducted two types of transport experiments in which the crystal is cycled between the oxidized and reduced state while the surface conductivity or the charge-carrier mobility is measured.

Our first measurements were of conductivity, using samples prepared with two electrodes painted on the surface of the as-grown crystals. We observed a significantly larger current in the oxidized samples than in the reduced. The largest currents were observed in the as-grown samples, which we assume were already oxidized from extended contact with air. The change in the conductivity upon oxidation or reduction is shown in Fig. 2. Since silver (Ag) was used as a contact material, there were concerns that changes affecting only the contacts might have occurred, especially since contacts always play a large role in charge injection and thus in conductivity measurements of organic semiconductors. We therefore produced additional samples with silver paste, evaporated Ag, copper (Cu) and aluminum (Al) as contacts. We observed changes in the conductivity of the same order of magnitude for oxidation and reduction in all of the crystals regardless of the type of contacts. While highly suggestive, these experiments did not allow us to distinguish between changes in the charge injection and changes in the doping of the conduction channel as potential causes of the dramatic change in conductivity observed upon oxidation and reduction. We therefore performed FET measurements to resolve this ambiguity.

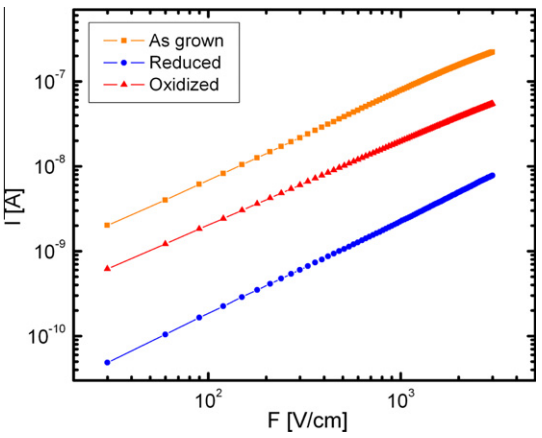

Fig. 2. Change of rubrene single-crystal surface conductivity under different conditions. The oxidation and reduction were done in O_2 and H_2 environment at 100 °C, respectively. The measurements were done at room temperature.

To measure the charge-carrier mobility we fabricated rubrene FETs with air-gap dielectric where the conduction channel is accessible to flowing oxygen or hydrogen gas, as shown in the insert of Fig. 1. At the start of the experiment in our FET measurements of transistors made on as-grown crystals, we observed a typical output characteristic as shown in Fig. 1. In the low source-drain voltage (V_d) range (−1 to 1 V), the source-drain current (I_d) shown a symmetric and linear curve crossing the origin, which indicates good contact between the Au electrode and the rubrene crystal with low contact resistance. In the higher V_d region the current saturated.

We placed the device in a quartz tube with pure oxygen or pure hydrogen gas flowing at room temperature and connected the source, drain and gate terminals to the measurement apparatus. We observed significant changes in the FET characteristic curves with time during hydrogen or oxygen treatment, as shown in Fig. 3. During the reduction process the source-drain current I_d decreased by almost three orders of magnitude within 1 h. When the

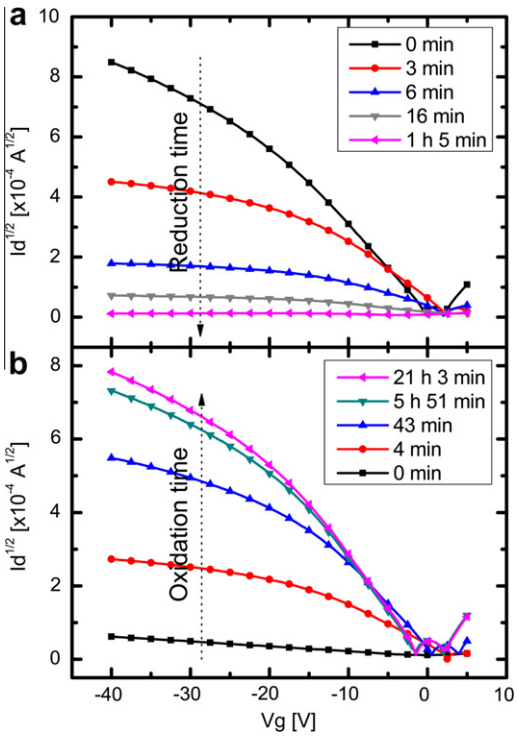

Fig. 3. Transfer characteristic with $V_d = -8$ V, V_g swept from 5 to −40 V. (a) Shows the reduction process. (b) Shows the oxidation process. The measurements are done at 1 atm, 25 °C.

same device was subsequently put through the oxidation process under flowing oxygen gas in the quartz tube, I_d returned to almost its original magnitude over a period of about 20 h.

The mobility of a typical rubrene FET measured in air before oxidation or reduction treatment did not depend on the carrier gas used in crystal growth. Because the FET was fabricated in air, we assume that the surface of the rubrene FET channel area was always oxidized in the initial measurement. The devices always shown relatively high initial mobility in the range of >1 cm^2/V s, and in some samples above 10 cm^2/V s, before the reduction/oxidation cycle was begun.

The field-effect mobility was extracted from the transfer characteristic using the equation

$$\mu = \frac{L}{CWV_d} \cdot \frac{dI_d}{dV_g}.$$

Fig. 4 shows the mobility change with time in three reduction/oxidation cycles. In the presence of hydrogen the mobility drops steeply from its initial value of ~10 to ~0.01 cm^2/V s in less than 1 h. When the flowing gas is switched to oxygen, the mobility increases rapidly in the first few minutes, followed by slow saturation in the next 20 h. The mobility never fully recovered to its original value in this time period, rather the saturation value decreased a little in each cycle. In a chemical reaction resulting from the oxygen or hydrogen treatment, water molecules would be formed. Therefore we suspect that build-up of defects may occur after repeated cycling and may interfere with the charge flowing in the channel area.

The three-order-of-magnitude change in the hole mobility observed in this experiment between the reduced and the oxidized state is surprising, since conventional wisdom from studies of transport properties of inorganic semiconductors suggests that in order to observe the intrinsic (or at least as high as possible) mobilities of charge carriers it is necessary to remove defects and dopants. Our previous work [15] shows that multiple sublimations of rubrene may remove solvent molecules or other molecules used for synthesis, but the dominant contaminants, which are oxidized forms of rubrene, need to be removed from the growth environment to avoid oxidization of the purified materials during the crystal growth process. The recent literature on rubrene transport properties indicates that the room-temperature mobility of rubrene may be as high as 20 cm^2/V s [9], or perhaps even higher [12]. All of those reports claim very high quality and purity of rubrene single crystals used in the measurement, but our analysis of the details given in those reports does not allow us to exclude the possibility of surface oxidation of the crystals during handling or contact preparation. It is not clear if the oxide is fully removed when the surface of the device is exposed to vacuum at room temperature, but it appears that the mobility changes slowly, if at all [10].

In order to examine that surface more closely, and to distinguish its state from that of the bulk crystal, we conducted two types of optical measurements: Fourier-transform infrared (FTIR) and photoluminescence (PL). We performed transmission FTIR measurements to examine the bonds in bulk rubrene (~300 μm in thickness), and attenuated total reflection (ATR) FTIR measurements to analyze the surface region (to a depth of ~700 nm). The results are shown in Fig. 5, in which selected peaks are magnified for clarity. We observed new peaks at the rubrene surface, and those are indicated by black arrows in the figure. The changes we have observed in the oxidized rubrene surface indicate the formation of oxidized species such as rubrene endoperoxide, rather than just intercalation of O_2 into the rubrene crystal. This conclusion is consistent with our previous observation of the endoperoxide in our chemical analysis of rubrene crystals [15].

To explore the effect of oxidation on the electronic states of rubrene, we performed photoluminescence measurements. Immediately after the crystal growth, the

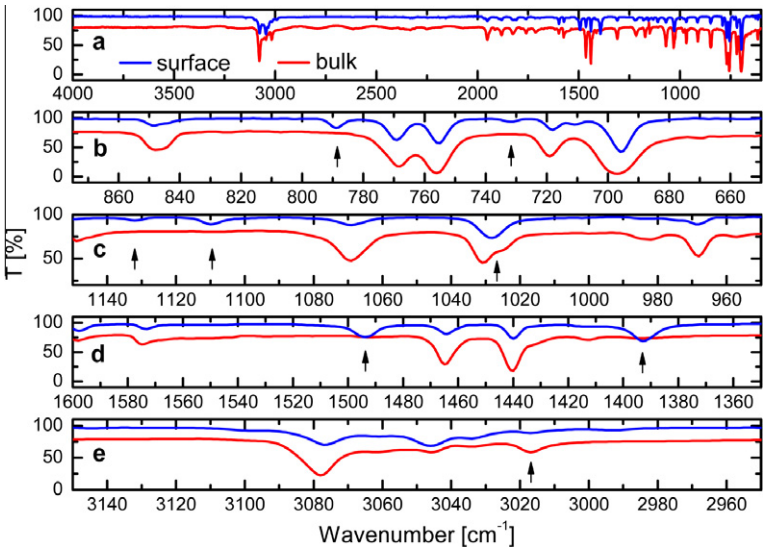

Fig. 5. Fourier-transform infrared spectroscopy (FTIR), (a) complete spectra, (b)–(e) magnification of selected areas. Arrows are to guide the eye. The blue line is the spectrum from the rubrene surface, collected by attenuated total reflection (ATR) FTIR. The red line is the bulk spectrum, collected by transmission FTIR.

room-temperature PL spectrum (measured in laboratory air) of rubrene crystals grown in a hydrogen atmosphere shows two peaks, one at near 570 nm (2.18 eV) and the other near 600 nm (2.06 eV) [20]. These emissions, which are intrinsic to rubrene, most likely result from molecular (Frenkel) excitons [21]. For the rubrene crystals grown in air or oxidized in air at a temperature of approximately 100 °C, the intrinsic rubrene peaks at 570 nm are reduced in intensity in comparison with the peaks at 650 nm (1.91 eV) and 700 nm (1.77 eV). Fig. 6 shows the PL spectrum observed during a dynamic process of oxidation of an ultra thin (<100 nm) rubrene single crystal on a SiO_2 substrate. It illustrates the change of intensity of the aforementioned three peaks during oxidation at 100 °C. However it is worth noting that the intensities of these peaks do not change significantly after growth of rubrene single crystals and storage for several weeks in a laboratory-air atmosphere, suggesting that the oxidation is confined to the surface at room temperature. However, the excitation wavelength for the PL measurement was 488 nm and the optical absorption coefficient for rubrene at this wavelength means that the incident beam intensity will decay to half its initial value by a depth of approximately 1.1 μm [22]. The PL measurement will therefore not be sensitive to a few layers (<10 nm) of oxidation product which may be formed at room temperature over a period of a few weeks. However at elevated temperature and over a longer time the oxidation may proceed deeper into the crystals (for example along dislocations or other structural defects) and therefore be detected by PL measurements. Similarly, Raman measurements performed with long-wavelength excitation that penetrates deeply into the crystal [21] do not display vibrational modes attributable to oxide molecules. However, those measurements were likewise performed on rubrene crystals stored in laboratory air, not those oxidized at higher temperatures in pure oxygen. It is likely that Raman measurements made with short wavelength on crystals oxidized at high temperature would display such modes, as do the ATR infrared measurements shown in Fig. 5.

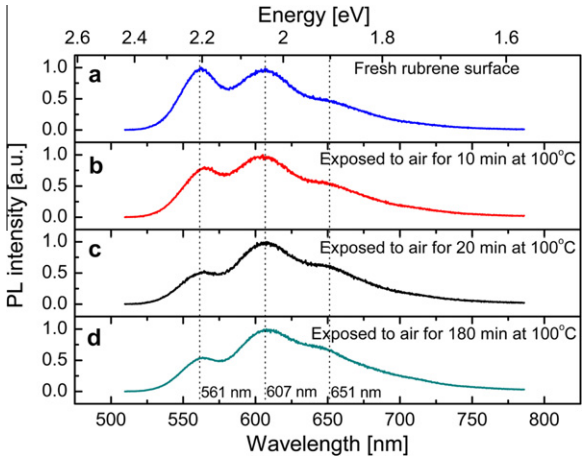

Fig. 6. Photoluminescence spectrum of rubrene showing change with time. (a) Pristine rubrene at room temperature, (b) pristine rubrene heated in air at 100 °C for 10 min, (c) for 20 min, (d) for 180 min. The thickness of the rubrene crystal is less than 100 nm, cleaved on a clean SiO_2 substrate.

Because the mobility measurement in an FET is determined by only the conditions in the near-surface region, it is not necessary for the entire crystal to be oxidized in order to observe the dramatic effect shown in Fig. 4. To examine the fraction of the material that is oxidized, we performed X-ray powder diffraction measurements on our oxidized and reduced crystals. The diffraction patterns of both oxidized and reduced rubrene were identical to

that of the published structure [23]. Assuming that impurities need to constitute approximately 1% of the volume of the substance to be detected in our routine X-ray powder diffraction measurements, this suggests that only the thin surface layer may be oxidized and the bulk of the crystal was composed of pristine rubrene.

Our results, in which we achieve the highest mobility in oxidized samples, may appear to be in contradiction with a long series of reports by the group of Prof. N. Karl of the University of Stuttgart [24]. The group measured carrier transport in very-thoroughly-purified single crystals of organic semiconductors (though not in rubrene) by time-of-flight methods and shown that the lifetime of the charge carriers increases significantly if impurities are removed from the crystal. We believe that this observation is general for all organic semiconductors. However, field-effect measurements of mobility probe only the very shallow channel on the surface of the semiconductor and therefore do not measure bulk mobility. This can be seen by the different mobilities recorded for FETs made from rubrene but with different dielectric layers [25,26]. However, our mobility values measured in rubrene crystals reduced in a hydrogen environment, as well as the value reported by Iwasa and co-workers [27] for ambipolar transport measured in vacuum and the value measured by Podzorov et al. [28] under vacuum in the presence of a hot-cathode vacuum gauge are likely to be closer to the intrinsic value than are the maximum values measured on samples in which significant surface oxide is present. It appears that the high value of the mobility measured in FET structures results from the presence of the oxidized layer at the surface, perhaps through radical cation hole carriers doping generated by oxygen assisted electron transfer mechanism [29] at the interface with the pristine rubrene.

4. Conclusion

We have grown rubrene single crystals in flowing hydrogen, argon or air. The mobility measured in FET structures made from as-grown crystals was more than 10 $cm^2/V\,s$ at room temperature. When the FET was treated with flowing hydrogen gas the mobility decreased by more than three orders of magnitude as a result of reduction of the rubrene surface. The mobility increased back to nearly its original value when the crystal was subsequently oxidized, a cycle that could be repeated multiple times. Fourier-transform infrared spectroscopy confirmed that oxidation appears only at the surface, and changes in the photoluminescence spectrum resulting from oxidation or reduction were also observed. We conclude that the high value of the mobility reported for rubrene is not an intrinsic property of the bulk crystal but is determined by the oxidation state of the rubrene surface. Therefore we believe that the current effort to tailor the molecular structure of organic semiconductors to achieve high-mobility charge-carrier transport should be complemented by efforts to control the state of the surface of organic semiconductors by defect control, and doping by electron transfer through interfaces or in binary organic compounds.

ABSTRACT

High efficiency inverted regioregular poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM)-based polymer solar cells (PSCs) using an indium tin oxide (ITO) cathode, modified with a solution-processed ionic liquid-functionalized carbon nanoparticles (ILCNs) layer, was demonstrated. ILCNs-modified ITO cathode has a very good thermal stability and a superior surface electronic property suited for application in polymer solar cells. A power conversion efficiency (PCE) of 3.2% was obtained for inverted PSCs measured under AM1.5G illumination of 100 mW/cm^2, which is comparable to PCE of a reference P3HT:PCBM-based solar cell having a conventional structure. There was almost no deterioration in the performance of inverted PSCs that were aged over a post-annealing temperature range from 100 to 200 °C. The work function of ILCNs-modified ITO cathode annealed at different temperatures was also measured using ultraviolet photoelectron spectroscopy. It was found that the work function of 4.4 eV, measured for a bare ITO electrode, decreased to 3.8 eV when it was modified with ILCNs, and was not dependent on the post-annealing temperature.

1. Introduction

The development of the emerging polymer solar cell technology has attracted a lot of interests due to its great potential of low-cost non-vacuum process photovoltaic technology. Polymer solar cells (PSCs) can be flexible, large-area and prepared using solution processable technologies. PSCs have enjoyed significantly development in the past decades. The power conversion efficiency (PCE) of 4–5% for bulk heterojunction (BHJ) PSCs using regioregular poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM) blend system has been achieved. A PCE of 6.0% was reported for BHJ polymer solar cells using low-bandgap alternating co-polymers of poly (2,7-carbazole) derivatives with deeper highest occupied molecular orbital (HOMO) energy and [6,6]-phenyl C_{70}-butyric acid methyl ester [1]. PCE of 6.77% was reported recently for heterojunction PSCs [2]. New device processes based on the control of film morphology, optimization of the active layer thickness [3], modification of electrode using surface plasmonic effect to boost the light absorption [4,5], and use of p- and n-types metal oxides [6–11] to improve the charge collection efficiency were demonstrated.

In a conventional P3HT:PCBM-based polymer solar cell, the hole-transporting layer, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) is spin-coated on top of indium tin oxide (ITO) surface to prevent electron leakage and to aid in hole extraction. The active layer of P3HT:PCBM is sandwiched between an ITO/PEDOT:PSS anode and a low work function metal cathode. However,

PEDOT:PSS layer is detrimental to ITO anode and the active polymer layer due to its acidic nature. In conventional PSCs, the top cathode, often made with a low work function metal cathode, such as calcium or barium cathode, is easily oxidized even with a delicate encapsulation, leading to reduced device lifetime [12]. The p- and n-types transparent metal oxides have been recently introduced as anode and cathode contacts in PSCs, providing greater process freedom for new device structures including inverted PSCs [6–8,10,11]. The use of transparent metal oxides can also offer a better choice to fabricate inverted PSCs. More importantly, the inverted PSCs can overcome some disadvantages of the regular PSCs with PEDOT:PSS anode contact layer. Therefore, several inverted polymer solar cell structures have been developed. For example, p-type metal oxide, such as vanadium oxide (V_2O_5) [11,13] and molybdenum trioxide (MoO_3) [10] were deposited on top of the active layer as a hole selective layer before a less air-sensitive and high work function metal was deposited as a back hole collecting electrode [8,10]. Solution-processed ZnO [7] and TiO_x [6] when applied as electron selective layer have been reported to achieve 2.58% and 3% PCE, respectively. However the high temperature annealing needed to improve the film properties of these metal oxides is not compatible with the active polymer layer.

Liao et al. [14] demonstrated that work function of ITO electrode was decreased from 4.5 to 3.06 eV by spin-coating an ultrathin cesium carbonate (Cs_2CO_3) onto ITO surface. The Cs_2CO_3 layer can be decomposed into low work function cesium oxide by annealing under 150 °C, which is consistent with the fabrication procedures of the active polymer layer. The PCE of inverted PSCs with Cs_2CO_3-modified ITO cathode reaches 4.2% after annealing, which is comparable to the regular structure device on the same system. However, Cs_2CO_3 is very sensitive to moisture and the property of Cs_2CO_3-modified ITO cathode can be easily degraded due to air-leakage through the edges of the encapsulation. Solution-processed V_2O_5 as an anode interlayer without annealing have been reported, the PCE of devices made with V_2O_5 modified ITO anode was shown to increase from 2.5% to 3.56% compared to PSCs without the V_2O_5 interlayer [11]. This solution-processed V_2O_5 is relatively insensitive to moisture and oxygen and its advantage of non-annealing treatment, as compared to a post-annealing treatment required for solution-processed TiO_x [6] and ZnO [7], offers a simple and effective approach for fabrication of low-cost and large-area PSCs.

In this work, a thermally stable, transparent cathode of ionic liquid-functionalized carbon nanoparticles (ILCNs)-modified ITO was developed. A layer of ILCNs was solution-processed and its low annealing temperature offers additional advantage for fabrication of PSCs. The ILCNs was used to modify ITO electrode; the work function of the modified ITO electrode decreased from 4.5 to 3.8 eV after spin-casting a ~1–3 nm thick ILCNs film on top of the ITO electrode. The PCEs of inverted PSCs made with modified ITO cathode increased to 3.2%, after post-annealing at a temperature of 120 °C, which is comparable to that of a reference PSC using the same system [15,16].

2. Experimental

The ILCNs was synthesized by the electrochemical exfoliation of graphite electrode in 1-butyl-3-methylimidazolium tetrafluoroborate ($[C4mim]^+[BF4]^-$) and water mixture [17]. The ILCNs consists of ionic liquid molecules and graphite-like carbon nanoparticles held together by hydrogen bonding, van der Waals forces, $\pi-\pi$ stacking interactions or/and covalent interactions in a gel-like matrix. The transmission electron microscopy image shows that the average size of ILCNs is below 4 nm [15]. The details of ILCNs synthesis and its properties have been reported [15,17]. In this work, the ILCNs layer was spin-coated on the surface of ITO-coated glass substrates (15 Ω/sq), pretreated with UV-ozone, and followed by annealing with different temperature in the glove box with an O_2 level and a H_2O level <2 ppm. P3HT (Sigma–Aldrich) and PCBM (American Dye Source) were dissolved in 1,2-dichlorobenzene with 1:0.8 wt. ratio. ILCNs were dissolved in ethanol. P3HT:PCBM film was spin-coated on top of the ILCNs-modified ITO in the glove box. The P3HT:PCBM film was spin-coated at 800 rpm for 60 s, and then kept in a petri dish for slow growth. After 12 h, P3HT:PCBM films were annealed at 120 °C for 10 min. The 5 nm thickness MoO_3 and 100 nm Al metallic layers were thermally deposited with a background pressure of 5×10^{-7} Torr. The active area of PSCs is 3.0 mm × 3.0 mm. Current density–voltage (J–V) characteristics of PSCs were measured in nitrogen under AM1.5G illumination of 100 mW/cm^2 (SAN-EI Electric Xe-Lamp controller). The surface work function of bare ITO and ILCNs-modified ITO cathode was examined using ultraviolet photoelectron spectroscopy with Helium line (21.2 eV).

3. Results and discussion

The atomic force microscopy (AFM) image measured for ILCNs layer on ITO surface is shown in Fig. 1(a). The ILCNs film was spin-coated at the speed of 1500 rpm for 60 s. The average thickness of the ILCNs layer was estimated to be 2.8 nm with corresponding rms roughness of ~0.85 nm, as shown in Fig. 1(b). The optical transmission spectra of ILCNs films spin-coated at 1500 and 2500 rpm, respectively onto ITO/glass substrates are shown in Fig. 1(c). The transmission spectra measured for ILCNs-modified ITO glass substrate show a slight decrease in the light wavelength range from 350 to 450 nm, as the thickness of ILCNs over layer increases. The overall transparency of the ILCNs-modified ITO glass substrates is almost identical to that of the bare ITO glass over the light wavelength from 450 to 800 nm. This reveals clearly that modification of the ILCNs layer on ITO electrode does not affect its transparency. This is in agreement with the results showing that absorption in PSCs made with ILCNs-modified ITO glass is almost the same as PSCs with bare ITO glass.

In order to carry out a systematic study of the effect of the ILCNs-modified ITO cathode on the performance of inverted P3HT:PCBM-based PSCs, a set of structurally identical polymer solar cells made with ITO cathode modified differently by ILCNs was fabricated. To get optimal

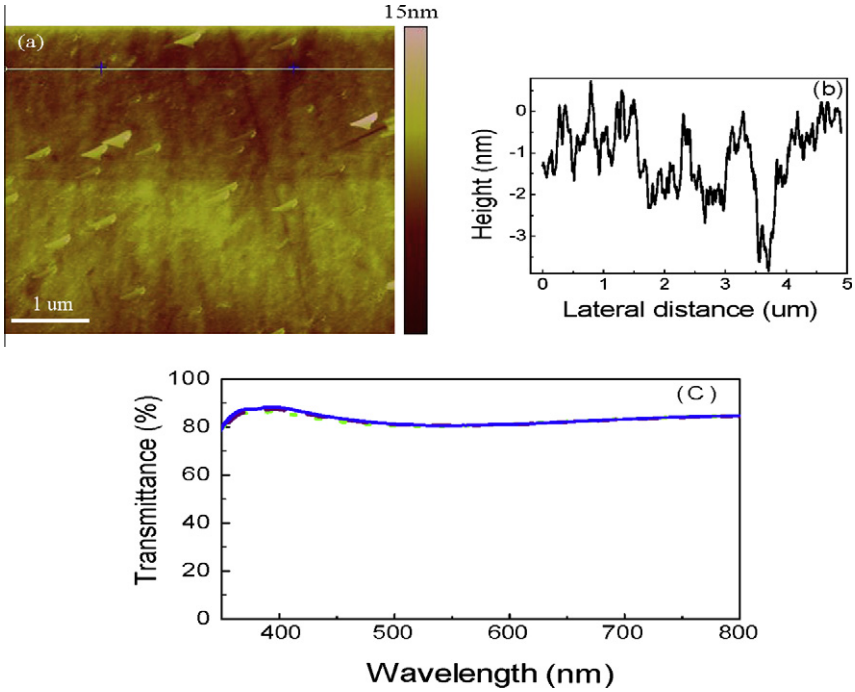

Fig. 1. (a) AFM images measured for ILCNs-modified ITO surface. (b) Topographical height of ILCNs layer on ITO. (c) Optical transmission spectra measured for ITO surface modified with ILCN layers prepared at different spin-coating speeds of 1500 rpm (dot), 2500 rpm (dash) and pure ITO (solid).

thickness of ILCNs layer, the ILCN films were spin-coated at 1500, 2000 and 2500 rpm for 60 s, respectively, followed by annealing at 120 °C for 10 min. The layer thickness of ILCNs prepared at different spin-casting speeds was estimated to be 1–3 nm using AFM. However, the PCE of devices within these spin-coating speed range is close and the optimal device of PCE is 3.20% at the spin-coating speed of 2000 rpm. The results reveal that the PCE of devices is insensitive to thickness of ILCNs layer. This is probably attributed to the sp^2-bonded aromatic structure of carbon nanoparticles and the formation of the electric double layers between ITO and the active layer. The sp^2-bonded aromatic structure of carbon nanoparticles can transport electrons and decrease tunneling barrier height at the interfacial contacts [18]. The ions of ILCNs are expected to form electric double layers with large polarization fields at the interface between the active layer and ILCN, as well as between ILCN and ITO cathode [19]. The presence of electric double layers and carbon nanoparticles helps to reduce the electron injection/extraction barrier and, unlike the tunnel theory [20], is not significantly sensitive to barrier height and tunnel thickness.

The schematic energy diagram of an inverted PSC is shown in the inset of Fig. 2a. The thickness of P3HT:PCBM blend layer and MoO_3 is 200 and 5 nm, respectively. Fig. 2a shows *J–V* characteristics corresponding to PSCs prepared with ILCNs-ITO cathode that was pre-annealed at different temperatures. The ILCNs films were annealed at 120 °C (device A), 160 °C (device B) and 200 °C (device C) for 10 min after spin-casting ILCNs solution at 2000 rpm for 60 s. As-prepared ILCN-ITO cathode, which was done at room temperature (RT) without the post-annealing treatment, was also used for the control PSC (device D) for comparison study. The PCE of PSCs with ITO-only cathode is far lower than that of PSCs with ILCNs-ITO cathode, which is attributed to the higher interface barrier and the elevated reverse saturation current, as shown in Fig. 2(b). Fig. 3 presents the statistical graph of PCE of PSCs made with ILCNs-modified cathode that was annealed at different temperature. The PCE of inverted PSCs made with ILCNs-modified ITO under optimum annealing temperature of 120 °C can reach up to 3.2% and the highest efficiency of 3.37% was obtained for PSCs made with ITO-cathode pre-annealed at 160 °C. The PCE of PSCs made with ILCNs-modified ITO cathode that was annealed over the temperature from 120 and 160 °C is slightly higher than efficiency of PSCs made with the cathode that was at 200 °C (device C). It is noted that PCE of device C is comparable to the efficiency of devices A, B and D, suggesting that ILCNs-modified cathode has a very good thermal stability suitable for application in inverted PSCs. In addition to its thermal stability, the nature of the solution processability also makes ILCNs practically more attractive over the materials commonly used for electrode modification, such as TiO_x, ZnO and Cs_2CO_3. This is because the performance of inverted PSCs made with ITO, modified with these materials, is very sensitive to the annealing temperature. The solution-processed ILCNs-modified ITO can be also easily integrated with the fabrication of PSCs using solution processable materials.

In order to understand the changes in the surface properties of ILCNs-modified ITO cathode, the surface hydrophobic property of ILCNs-modified ITO was measured using contact angle measurement, and the ILCNs-modified

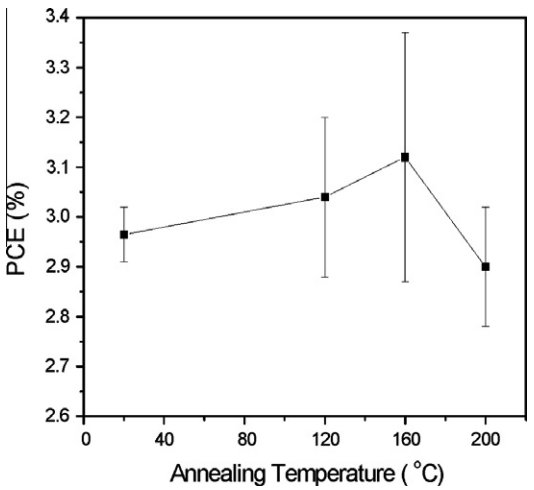

Fig. 3. PCE of devices made with ILCNs-modified ITO cathode as a function of pre-annealing temperature.

ITO cathode was studied using UPS measurements to determine the electronic structures on both bare ITO and ILCNs-modified ITO surfaces. Fig. 4(a) shows the secondary electron edge in UPS spectra measured for ILCNs-modified ITO surface, which can provide information of the work function of ILCNs-modified ITO surface. The work function of modified ITO cathode as a function of ILCNs annealing temperature is further presented in Fig. 4(b). As shown in Fig. 4(b), the surface hydrophobic property of ILCN films gradually increased with the post-annealing temperature. The increase in the contact angle seen in ILCNs surface is ascribed to the ionic liquid deficiency in ILCNs, due to the increase in the annealing temperature. The work function of UV-ozone treated ITO surface was 4.4 eV. The work function of the bare ITO decreased to about 3.8 eV when its surface was modified with a thin layer of ILCNs. The 0.6 eV decrease in work function of ILCNs-modified ITO electrode suggests that ILCNs-modified ITO can be an effective cathode for application in inverted PSCs. It was found that the work function of ILCNs-modified ITO further decreased to 3.7 eV after annealing at 200 °C for 10 min. However, the PCE of device C annealed at 200 °C was a little lower, which means that other possible factors such as hydrophobic property may affect the morphology of the

active polymer layer and the interface barrier between cathode electrode and P3HT:PCBM blend layer [14].

4. Conclusion

In summary, a high performance solution processable ILCNs-modified ITO cathode was developed. ILCNs-modified ITO cathode has very good thermal stability and a surface work function of 3.8 eV. Transparent ILCNs-modified ITO cathode was used for P3HT:PCBM-based inverted polymer solar cells, resulting in a PCE of 3.2% measured under AM1.5G illumination of 100 mW/cm^2. The device performance of the inverted PSCs is comparable to that of a reference PSC having the same material system and device structure [15,16]. The ILCNs-modified ITO cathode developed here has the advantages of solution processability, thermal stability and the desired electronic properties, and is superior to the cathode contacts that are modified using traditional materials such as TiO_x, ZnO and Cs_2CO_3, for application in inverted polymer solar cells.

Functionalized anthradithiophene
Solvent–vapor annealing
Organic field effect transistor

ABSTRACT

Solvent–vapor annealing was used to increase the field-effect mobility of soluble triethylsilylethynyl anthradithiophene spin-coated on organosilane-terminated silicon dioxide, yielding a high value of 1.2 $cm^2 V^{-1} s^{-1}$. The cause of improvement was investigated by atomic force microscopy, X-ray diffraction, and near-edge X-ray absorption fine structure spectroscopy. Vapor annealing exerts little effect on the molecular tilt and the crystallinity normal to the surface, but improves the film morphology significantly, yielding larger grains with perhaps better in-plane crystallinity.

1. Introduction

Solution-processable organic semiconducting materials have gained tremendous popularity in recent years due to the anticipated low-cost and flexible engineering approaches to electronic device fabrication [1–4]. Organic field effect transistors (OFETs) have been envisaged to have active applications in the fields of radio-frequency identification tags [5], active matrices displays [6], and smart cards. For practical usage, OFET should have mobility comparable to that of amorphous silicon, i.e., 1 $cm^2 V^{-1} s^{-1}$, an on/off ratio larger than 10^6, and an operational stability in ambient [1,7,8]. Solvent–vapor annealing has been demonstrated to improve the electrical performance of organic electronics materials via the recrystallization induced by solvent vapor [9–11]. However, the effect of the vapor annealing on the molecular orientation and the crystalline state remains to be elucidated.

Due to a favorable two-dimensional π-stacking, solution-processable triethylsilylethynyl-anthradithiophene (TESADT) was demonstrated to yield a hole mobility of 1 $cm^2 V^{-1} s^{-1}$, based on a bottom contact OFET with TESADT spread across the device surface [12]. However, the typical processing techniques like spin-coating only produce OFET of low mobility, which can be remedied by vapor annealing. Improved mobility values of 0.11 and 0.43 $cm^2 V^{-1} s^{-1}$ have been reported [13,14]. The modification of SiO_2 dielectric surface with self-assembled monolayers (SAM) of organosilanes has established itself as an effective means of improving the field-effect mobility of OFET via improved thin film quality and better interfacial property [15]. Along the line, a phenyl-terminated SAM of phenethlytrichlorosilane grown on SiO_2 was reported to increase the mobility and also improve the air-stability of pentacene OFET [16].

In this report, we used a phenyl-SAM-modified SiO_2 as the substrate for growing TESADT and the as-grown films were further subject to the solvent–vapor annealing to accelerate the grain growth, thereby achieving an OFET saturation mobility higher than what have been reported so far. By combining several structural characterization

techniques, we offer a plausible explanation for the mobility enhancement.

2. Experimental

The *n*-type heavily-doped silicon wafer capped with 300 nm thick thermally-grown SiO_2 served as a gate dielectric. The wafer was cleaned by hot Piranha solution, an acid mixture of H_2SO_4 and H_2O_2 at a volume ratio of 7:3, heated through water bath for 3–5 h to remove the organic contaminants, and then thoroughly rinsed with deionized water and dried with nitrogen gas before use. TESADT films were grown on two types of substrates: SiO_2 and SiO_2 terminated with 4-phenylbutyltrichlorosilane (4-PBTS) SAM. As-produced samples were labeled as **I** and **II**, respectively. For growing SAM, the SiO_2 was placed in a 1 wt.% solution of 4-PBTS in toluene for 1 h. TESADT was spin-coated using a 20 μl of 1 wt.% solution of TESADT in toluene at two speeds, 1000 rpm for 2 s and then 1500 rpm for 28 s. The thickness of as-produced films was estimated as 30 nm by Atomic Force Microscopy (AFM). Afterward, vapor-annealing was performed by separately placing samples **I** and **II** faceup near the bottom of a 100 ml PFA bottle filled with 50 μl dichloromethane solvent with its vapor agitated by a Teflon bar spinning at 120 rpm for 15 min. These samples were labeled as **III**, and **IV**. The fabrication of top-contact, bottom gate OFETs was complete by forming Au electrodes on top of TESADT films via vacuum-depositing gold through a shadow mask patterned with a fixed channel length of 80 μm, but variable channel widths of 400, 800, and 1600 μm, respectively.

The morphology of the organic films was characterized by AFM operated in contact mode (Digital instruments, NanoScope E). X-ray diffraction (XRD) study was carried out using MAC MXP-18 and BRUKER AXS D8 ADVANCE diffractometer with Cu K_α radiation. The Near-Edge X-ray Absorption Fine Structure (NEXAFS) spectroscopy were performed in Wide-Range beamline (BL24A) of NSRRC based on Auger-electron yield (AEY) detection mode with an electron energy analyzer (SPECS PHOBOIS 150). The output characteristics of the OFETs were measured in ambient condition using a Keithley 2636A dual-channel source-meter instrument.

3. Results and discussion

Fig. 1 shows a set of AFM images for samples **I**–**IV**. The SiO_2 surface in sample **I** is covered by small TESADT grains uniformly, producing a film with an rms roughness of 1.0 nm (Fig. 1a). In comparison, a growth of larger grains up to several hundred nm is noted in sample **II**, yielding a roughness of 1.8 nm (Fig. 1b). As a reference, the typical roughness values for the SiO_2 after Piranha cleaning and after 4-PBTS modification are 0.9 and 0.6 nm, respectively. After the vapor annealing, a dramatic change of surface morphology is observed. For sample **III** (Fig. 1c), mound-like structures with sizable voids in-between are formed, resulting in a larger roughness of 2.4 nm. Meanwhile, for sample **IV** (Fig. 1d), continuous, platelet-shaped structures are produced with a reduced roughness of 1.0 nm.

Fig. 2 shows the θ–2θ XRD patterns obtained for samples **I**–**IV**. The diffraction patterns consist of (0 0 *l*) reflections only as the 2θ angle is varied between 3° and 18°. A (0 0 1) reflection at $2\theta = 5.34°$ corresponds to an interlayer spacing of 16.54 Å, given the X-ray wavelength of 1.5406 Å. The numerical closeness between the interlayer spacing and the *c* axis value [17] together with the observation of (0 0 *l*) reflections only strongly indicate that TESADT crystallites are oriented with silyl group in close proximity to the surface and *a*, *b* crystallographic axes are parallel to

the substrate surface within a few degrees. This finding corroborates with the results deduced from NEXAFS data (*vide infra*). Sample **IV** has the strongest (0 0 1) reflection as compared with the weakest reflection for sample **I**, yielding a 2:1 intensity ratio but similar peak width. Sample **IV** is deemed to possess the best out-of-plane crystallinity, but perhaps not by much. Moreover, the distribution of sub-grain tilt is assessed by measuring the ω-scan rocking curve of (0 0 1) peak and two types of slightly misoriented crystallites are identified (data not shown).

The intermolecular carrier transport crucially depends on the molecular orientation ordering, a physical parameter amenable to the NEXAFS techniques. Briefly speaking, the carbon *K*-edge NEXAFS spectroscopy measures the transition probabilities of an electron from the C1s core level into its various unoccupied molecular orbitals with the transitional intensity (I) dependent on the X-ray incidence angle (θ), and the orientation of transitional dipole

moment investigated. For the molecules adsorbed on a surface, the dependence on the azimuthal angle often vanishes due to the crystallographic symmetry exhibited by the surface atomic plane and the tilt angle of the dipole moment (α) becomes the remaining angle dependent term. The angular dependence is expressed in the following equation:[18]

$$I(\theta,\alpha) \propto P\cos^2\theta\left(1-\frac{3}{2}\sin^2\alpha\right)+\frac{1}{2}\sin^2\alpha, \quad (1)$$

where P is the polarization factor and determined to be 0.85 for carbon K-edge energy at a bending beamline of NSRRC, and θ and α are measured from the surface plane and surface normal, respectively. For the π-conjugated molecule investigated here, the lower-energy X-ray absorption peaks are due to the transitions from C1s to π* orbitals with the transition dipole moment vectors perpendicular to the aromatic-ring plane of the molecule. Therefore, by analyzing how the intensity of X-ray transition depends on the X-ray incidence angle, the molecular tilt angle can be inferred.

Fig. 3a–d show four sets of polarization-dependent carbon NEXAFS spectra for samples **I–IV**. The major spectral features and their angular dependence are all similar despite the different surface treatment. Also shown for comparison are the spectra of 4-PBTS (Fig. 3e) and multilayered anthradithiophene (ADT), a five-member-ring constituent of TESADT, grown on SiO_2 (Fig. 3f). The contribution of 4-PBTS SAM to the total signal is found to be negligible owing to its attenuation by the TESADT overlayer. The spectroscopic assignment of the salient features of TESADT spectra is relatively straightforward.[18] The first region from 284 to 287 eV containing several sharp absorption peaks is assigned to the transitions from C1s core level to the lower unoccupied orbitals of π character; the second region from 287 to 290 eV is assigned to the transitions form C1s to mostly π* states but perhaps mixed with some σ^*_{C-H} and σ^*_{C-S} characters [19]; the broad absorption features from 290 to 320 eV are due to the transitions from C1s to various σ^* states.

For the determination of inclination angle of the ring plane of TESADT, the total intensity of sharp1s to π* transitions located in the spectral region from 284 to 287 eV is included in the analysis. These peaks bear strong resemblance with those of ADT and the anthracene [20] and can be regarded as originated from ADT in spite of slightly larger transitional energy for TESADT. Note that the dependence of NEXAFS signal on the X-ray incidence angle for an amorphous sample like SiO_2 used here is the same as that for a substrate possessing 3-fold symmetry like fcc(1 1 1) [21]. A fitting of the intensity of the X-ray transition to the theoretical curves described by Eq. (1) is presented in Fig. 4a in which an inclined angle of 72° is concluded. The ADT rings of samples **I–IV** are found to be inclined from the surface plane by 70°, 71°, 68°, and 72°, respectively. The derived inclination angles agree closely with the 71° tilt of the ADT ring from the surface to the *a*, *b* plane of the crystallographic unit cell [12], as presented in Fig. 4b. The close similarity among these tilt angles suggests that *a*, *b* plane of the TESADT crystallites aligns

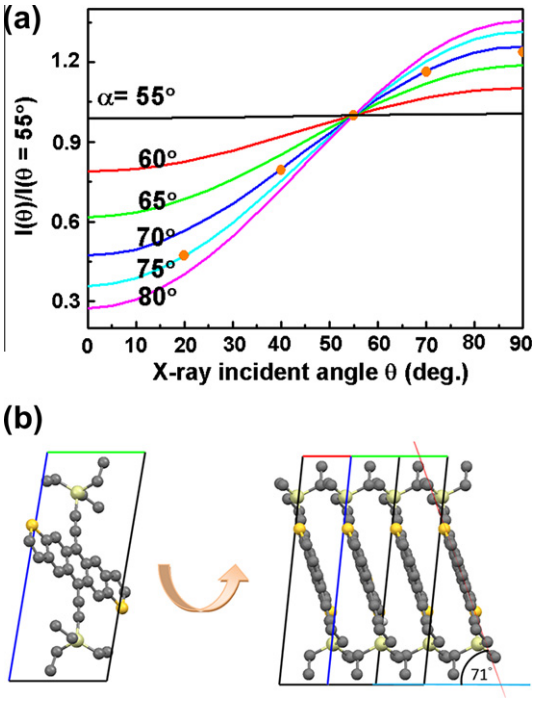

Fig. 4. (a) Angle-dependent intensity of 1s to π* transition for the sample **IV** (solid dots) plotted against the theoretical curves generated from Eq. (1). The intensity of each curve, corresponding to a given inclination angle of aromatic ring made with the surface, is normalized to its intensity at the so-called magic angle of $\theta = 54.7°$. (b) (Left) view of TESADT unit cell along the *a*-axis with crystallographic data taken from Ref. [12]. (Right) The 71° inclination angle of ADT ring made with the *a*, *b* plane is revealed by rotating the unit cell in the *a*, *b* plane.

closely with the substrate surface. It is worth noting that the NEXAFS and XRD data corroborate with each other despite their different structure sensitivity. Whereas XRD is sensitive to long-range structural ordering, NEXAFS technique has no direct bearing on the structural ordering other than yielding an averaged molecular tilt from the surface normal because the azimuthal dependence is often averaged out.

The electrical properties of the samples were assessed by measuring their OFETs characteristics. The field-effect mobility (μ) is extracted from the saturation regime using the relationship:

$$I_{DS} = \frac{W}{2L}\left[C_i\mu(V_{GS}-V_T)^2)\right] \quad (2)$$

where I_{DS} is the source-drain saturation current, W and L are channel width and length, respectively, C_i is the capacitance per unit area of the gate dielectric (= 10.8 nF/cm^2) [14], V_{GS} is the gate voltage relative to source electrode, and V_T is the threshold voltage. The latter can be estimated as the x intercept of the linear section of the plot of $(I_{DS})^{1/2}$ vs. V_{GS}. Fig. 5 shows the typical output characteristics (left) of the OFETs fabricated from samples **I–IV** and the corresponding transfer characteristics evaluated at V_{GS} of −50 V are shown in the right. The distribution of the

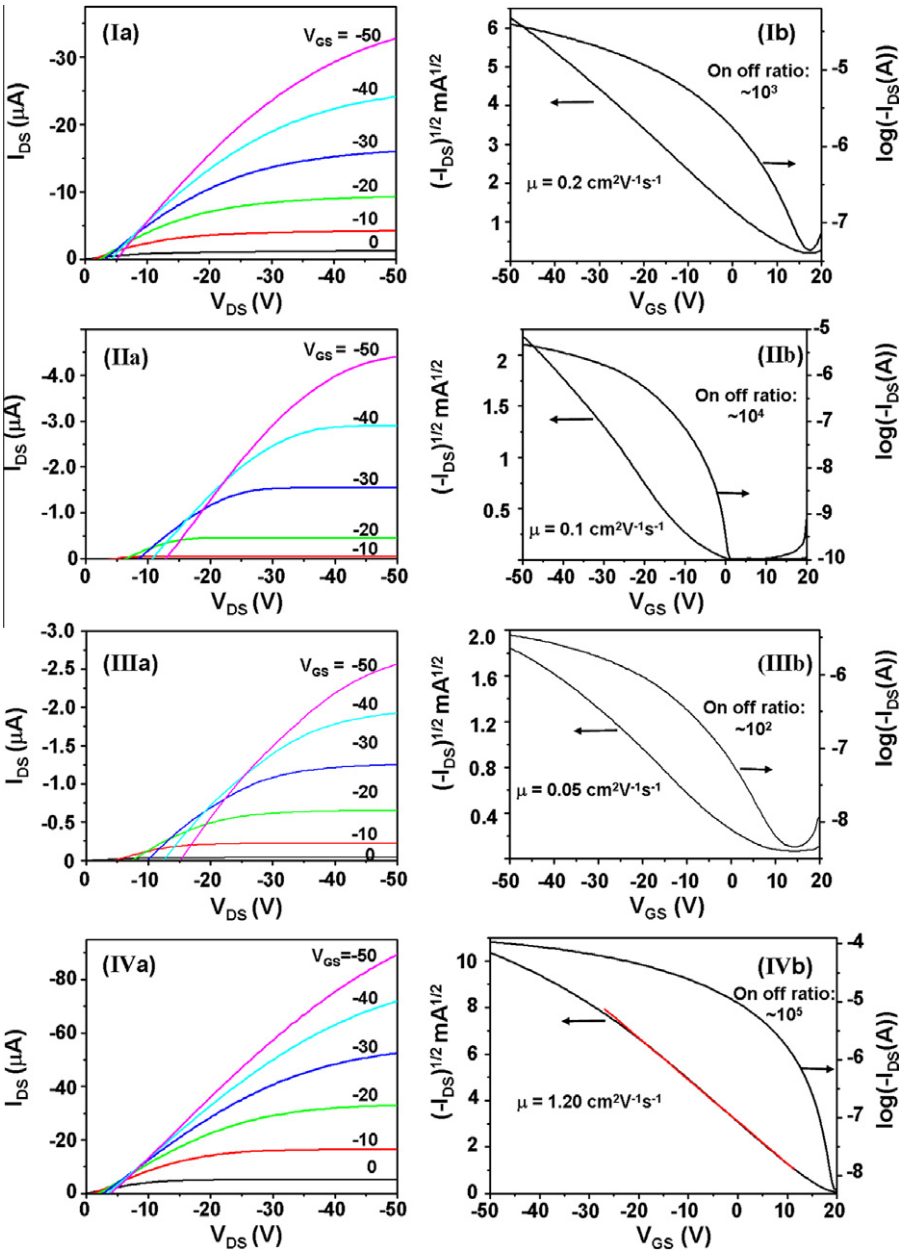

Fig. 5. (Left) output characteristics of the OFETs fabricated from samples **I–IV**; (right) saturated transfer characteristics ($I_{DS}^{1/2}$ vs. V_{GS}) of the corresponding OFETs. *W/L* for samples **II–IV** OFETs is 400 μm/80 μm, whereas *W/L* for sample **I** OFET is 800 μm/80 μm. For each device, the output curves were first acquired by having V_{GS} varied by a 10 V step between 0 and −50 V, and for each V_{GS}, the V_{DS} was swept from 0 to −50 V and back to 0 V. The transfer curves were next obtained by keeping V_{DS} at −50 V with V_{GS} swept from 20 to −50 V (off-to-on).

mobility values determined for all devices is presented in a linear scatter plot shown in Fig. 6. Note that the mobility for samples **I–III** OFETs ranges from several hundredths to several tenths of a $cm^2\,V^{-1}\,s^{-1}$; and a number of data points clustered around $\mu = 0$ are omitted for clarity in Fig. 6. In stark contrast, the sample **IV** OFET yields a consistently larger mobility, though of a broader spread, and averages 0.46 $cm^2\,V^{-1}\,s^{-1}$ over ten devices. The highest mobility obtained is 1.2 $cm^2\,V^{-1}\,s^{-1}$ and the on/off ratio is 10^5. The output and transfer characteristics of this device are shown in Fig. 5-IVa and 5-IVb. We note that our value tops the mobility list of TESADT OFETs reported so far [12–14]. The performance of OFETs fabricated with samples **I–IV** is compiled in Table 1. The gate induced leakage current, or drain current offset, signaled by non-zero drain current at zero V_{DS} in the output characteristics curve [22], is sometimes found in devices such as those shown in Fig. 5-IIa and 5-IIIa. This undesirable feature can be greatly reduced by spatially confining the semiconducting materials in the intended channel region.

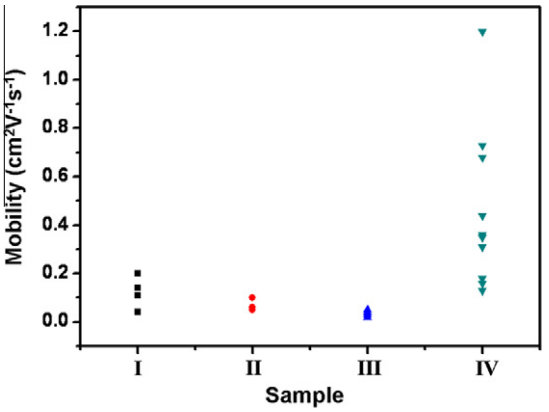

Fig. 6. Distribution of OFET mobility determined from the devices fabricated with samples **I–IV**.

Table 1
Performances summary of the OFETs fabricated from samples **I–IV**.

Sample	Sample condition	μ ($cm^2\ V^{-1}\ s^{-1}$)		Avg. on/off ratio
		Avg.	Max.	
I	TESADT/SiO_2	0.11	0.20	4.84×10^2
II	TESADT/4-PBTS/SiO_2	0.08	0.10	5.94×10^4
III	TESADT/SiO_2 (p.a.s.v.)	0.03	0.05	4.18×10^4
IV	TESADT/4-PBTS/SiO_2 (p.a.s.v.)	0.46	1.20	1.17×10^5

p.a.s.v., Post-annealed with solvent vapor.

Here we digress to examine the hysteresis in current–voltage characteristics in the devices. For example, in the sample **IV** OFET, the last measurement in the output-curve scan ($V_{GS} = V_{DS} = -50$ V) gives an I_{DS} of 89 μA, but in the subsequent transfer-curve scan with the transistor changing from the off-to on-mode (V_{GS} swept from 20 to −50 V while V_{DS} fixed at −50 V), the corresponding I_{DS} increases to 107 μA. The increase of I_{DS} for the off-to-on sweep in the transfer characteristics has been reported for the pentacene OFET, with the hysteresis accounted for by the formation of long-lifetime traps at pentacene–dielectric interface [23,24]. Since the present study is focused on the investigation of origin of high mobility in solvent-annealed TESADT films, the hysteresis is not pursued further. How the saturation mobility, determined by the rate of change of $(I_{DS})^{1/2}$ with the V_{GS}, is affected by the hysteresis must await further studies. However, it is interesting to note that for the typical pentacene OFET with hysteresis, as reported in the Fig. 1 of Ref. [23], the saturation mobility determined from the off-to-on scan is estimated to be lower by ~10% than that from an on-to-off scan, despite a higher I_{DS} produced from the off-to-on scan. Linear mobility determined from the on-to-off scan also increases by ~25%, counter to the effect of decreasing I_{DS}.

We now return to the discussion of origin of mobility enhancement. Samples **I–IV** are all crystalline, and even more interesting is that sample **I** possesses crystallinity and thus fares better than the amorphous samples reported earlier [13]. The similar tilt angle between samples I–IV and TESADT single crystal, inferred from NEXAFS data, suggests that all four samples have adopted a favorable cofacial π–π stacking characteristic of a single crystal. As a result, the intermolecular transfer integral that is crucial in charge transport should be similar if the molecular spacing in all four samples is close [25]. Moreover, considering that samples **I–IV** are all crystalline and terminated with TESADT of the same orientation, there is no a prior reason not to expect the formation of similar metal–semiconductor interface that gives rise to equivalent charge injection as Au is deposited on TESADT. The presence of 4-PBTS creates a permanent interface dipole that changes the surface potential and shifts the threshold voltage of OFET but not the carrier mobility [26].

Because the charge injection and the transfer integral for samples **I–IV** are argued to be similar in quantity, the size of crystallite distribution should be scrutinized next because the carrier transport critically depends on the carrier scattering at the grain boundary. It has been well established that a smaller crystal grain decreases the carrier transport efficiency [25]. AFM image of sample **III** is typified by an increasing number of disconnected, mound-like features after annealing; therefore, a mobility increase is not to be expected. In stark contrast, sample **IV** forms smooth, continuous, platelet-like structures after annealing, thereby leading to a tenfold increase in mobility.

Why is there such a difference in the regrowth initiated by solvent vapor? An effective vapor annealing depends complicatedly on many parameters including solubility, solvent vapor pressure, spreading of solution on surface, interfacial free energy, recrystallization rate, to name a few. We speculate that different interfacial interaction between TESADT and the substrate might be responsible for the morphology difference that in turn affects the mobility. TESADT interacts with 4-PBTS more strongly than with SiO_2 due to the phenyl termination in the former. As a result, more two-dimensional-like growth of TESADT on 4-PBTS is favored due to the stronger interfacial interaction. In comparison, three-dimensional mound-like formation is found for TESADT on SiO_2.

In conclusion, we have used a phenyl-terminated SAM on SiO_2 to enable a larger grain growth of TESADT. Dichloromethane-vapor annealing promotes the formation of better-connected, platelet-shaped crystallites, thereby increasing the saturation OFET mobility to 1.2 $cm^2\ V^{-1}\ s^{-1}$. The formation of TESADT crystallites on SiO_2 is noted in the present study, which paves the way for growing larger crystallites during vapor annealing. Vapor annealing neither changes the molecular orientation nor improves the out-of-plane crystallinity markedly, but significantly improves the morphology and yields larger grains with perhaps better in-plane crystallinity.

ABSTRACT

To explore the influence of molecular structure on formation excimers and obtain high-efficiency white polymer light-emitting devices, two novel blue-emitting cyclometalated platinum (II) complexes of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) have been successfully synthesized and characterized, where dfppy is 2-(2,4-difluoro-phenyl)pyridine, C_{16}dfppy is 5-hexdecanyl-2-(2,4-difluorophenyl)pyridine and Tfl-pic is alkyltrifluorene-containing picolinic acid derivative. Compare to (dfppy)Pt(pic), both of platinum (II) complexes exhibited high thermal stability, good solubility and excellent photoluminescent quantum efficiency (about 94% ± 10%) at room temperature. Deep blue emission at about 418 nm in dilute dichloromethane (10^{-5} M) and red-shifted emission at about 619 nm in the neat film were observed under opto-excitation. Pure white light with a CIE coordinates (0.33, 0.33) at 10 V was obtained in the (dfppy)Pt(Tfl-pic)-doped devices and a red emission was obtained in the (C_{16}dfppy)Pt(Tfl-pic)-doped devices with the same device configuration using a blend of polyvinylcarbazole and 2-(4-biphenyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole as a host matrix, respectively.

1. Introduction

Recently, white organic light-emitting devices (WOLEDs) have attracted much increasing interest because of their potential applications in full color displays, back lighting of flat-panel displays and solid-state lighting [1–16]. An ideal white emission is generally composed of three primary colors (blue, green and red) and covers the whole visible range from 400 to 700 nm. So far, most of the reported white-emitting devices were multilayer configuration fabricated by consecutive evaporations or co-evaporation of different emission compounds [6–8]. However, this class of multilayer devices requires complicated processes, high cost and high turn-on voltage. Compared to the multilayer devices, the single-layer devices fabricated by a blend of different emitters with three primary colors have a more cost-effective. Nevertheless, this class of single-layer devices could have poor stability and can hardly get pure white emission due to phase separation and undesired Förest energy transfer from the high-energy emitter to the low-energy one. In order to obtain high-efficiency single-layer WOLEDs, an effective method, in which planar blue-emitting platinum (II) complexes were used as emitter, has been developed in these years. The white emission results from a blend of itself blue short-wavelength emission and excimer's long-wavelength emission in these devices [3,17,18]. For example, Forrest et al. made a WOLED using a bidentate platinum (II) complex (FPt) doped into 1,3-bis(N-carbazolyl)-benzene (mCP) with a power efficiency of 8.1 lm W^{-1} [17]. Jabbour et al. used the same FPt complex as dopant to fabricate similar WOLEDs using a 2,6-bis

(N-carbazolyl)pyridine (26mCPy) as a host with external quantum efficiency (*EQE*) of 15.9% and a power efficiency of 12.6 lm W^{-1} [18]. However, to our best knowledge, the reports on the platinum (II) complex-doped white polymer light-emitting devices (WPLEDs) are very rare [19–21].

With this mind, to study the influence of cyclometalated platinum (II) complexes on formation excimers in polymer host and obtain high-efficiency WPLEDs, we designed and synthesized a new ancillary ligand of the oligomer-fluorene-based picolinic acid derivative (Tfl-picH) and its heteroleptic platinum (II) complexes of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic), where dfppy is 2-(2,4-difluorophenyl)pyridine and C_{16}dfppy is 5-hexadecanyl-2-(2,4-difluorophenyl)pyridine. The synthetic route of two platinum (II) complexes is shown in Scheme 1. As oligomer-fluorene possesses a rigid π-π aryl system and good solubility [22], it is expected to facilitate its square-planar platinum (II) complexes to form excimers in high concentration, even in thin films [23–25]. As expected, intense excimers's emissions were observed for these two platinum (II) complexes in their neat films under photo-excitation and in their-doped PLEDs under electronic-excitation. Significant influence of cyclometalated ligand on the excimer emission of its platinum (II) complexes was presented. Employing (dfppy)Pt(Tfl-pic) as guest, a blend of polyvinylcarbazole (PVK) and 2-(4-biphenyl)-5-(4-*tert*-butylphenyl) -1,3,4-oxadiazole (PBD) as a host matrix, the simple single-layer PLEDs exhibited pure white emission with the CIE coordinates (0.33, 0.33) at 10 V. In contrast, the (C_{16}dfppy)Pt(Tfl-pic)-doped PLED with the same device configuration displayed only red emission with the CIE coordinate around (0.40, 0.41).

2. Results and discussion

2.1. Synthesis

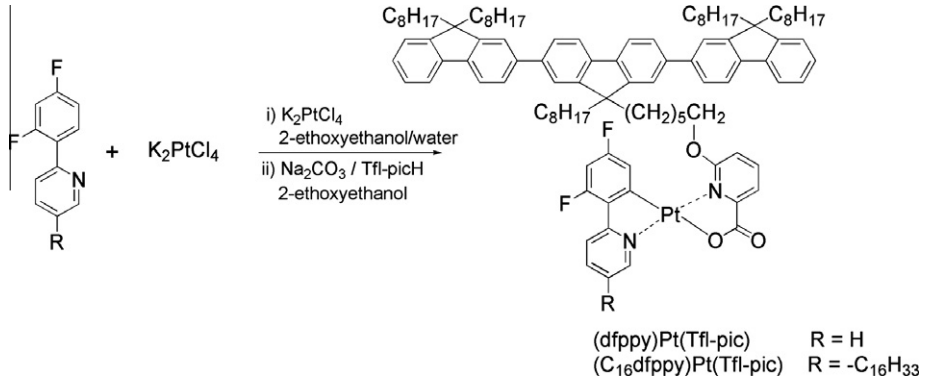
The trialkyl-fluorene-based picolinic acid (Tfl-picH) was prepared with a moderate yield based on the procedures [26]. The platinum (II) complexes of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) were synthesized by two-step procedures with a chloride-bridged process of K_2PtCl_4 with cyclometalated ligand and a chloride cleavage of the resulting chloro-bridged dimmers with the ancillary ligand of Tfl-picH in a moderate condition based on the literatures [27,28].

As this trifluoene-based ancillary ligand has a steric block and the platinum atom has a planar structure with a bigger atom radius, it was more difficult to gain (dfppy)-Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) than (dfppy)Pt(pic). Both of platinum (II) complexes have been confirmed with ^{1}H NMR and elemental analysis.

2.2. Optical analysis

Fig. 1 shows the UV–vis absorption spectra of platinum (II) complexes in dilute dichloromethane (DCM, 10^{-5} M) at room temperature and their UV absorption data are summarized in Table 1. As shown in Fig. 1, a moderate high-energy UV absorption band at 267 nm and much intense low-energy absorption bands at about 354 nm were observed for each of two alkyltrifluorene-based platinum (II) complexes. The influence of alkyltrifluorene-based picolinic acid on UV–vis absorption property of its platinum (II) complex is similar to that of its iridium (III) complex reported in our previous work [26]. Compared to UV–vis spectrum of (dfppy)Pt(pic), the high-lying absorption band is assigned to the intraligand-based π–π* transitions, and the low-lying absorption band is attributed to the mixed single and triplet metal-to-ligand charge transfer transitions (MLCT) for these alkyltrifluorene-based platinum (II) complexes [29]. Furthermore, the low-energy absorption of both alkyltrifluorene-based platinum (II) complexes are more intense than that of (dfppy)Pt(pic). This means that incorporating alkyl-trifluorene group into the common ancillary ligand of picolinic acid is available for enhancing UV absorption of its platinum (II) complexes and enlarges spectral overlap between UV absorption of platinum (II) complexes and PL of PVK employed as host matrix in the latter devices.

The photoluminescence (PL) spectra of these three platinum (II) complexes are shown in Fig. 2 and their emission data are summarized in Table 1. Nearly identical PL profiles containing an emission peaks at 396 nm with a shoulder at 418 nm are exhibited for these two alkyltrifluorene-based platinum (II) complexes (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)-Pt(Tfl-pic) in dilute DCM (10^{-5} M). Compared to PL spectrum of (dfppy)Pt(pic) in dilute DCM (10^{-5} M), these two deep blue emission peaks are attributed to the emission



Scheme 1. Synthesis route of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic).

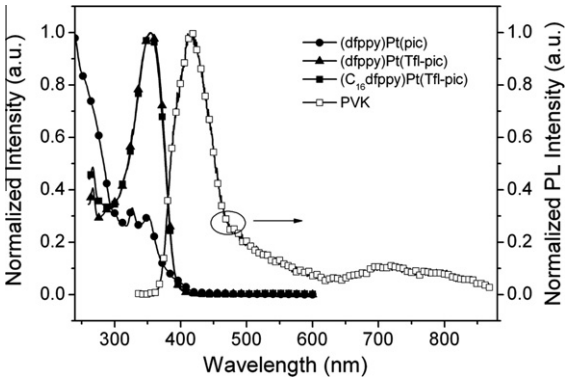


Fig. 1. Normalized UV–vis absorption spectra of (dfppy)Pt(pic), (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) in dilute DCM (10^{-5} M) and PL spectrum of PVK film at room temperature.

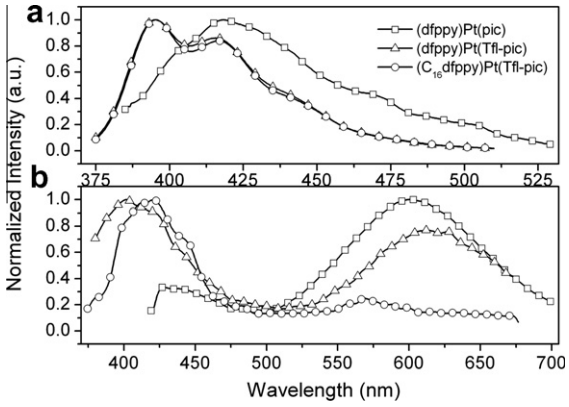

Fig. 2. Normalized PL spectra of (dfppy)Pt(pic), (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) in dilute DCM (10^{-5} M) (a), and their neat films at room temperature(b).

of platinum (II) complexes. However, these two trifluorene-based platinum (II) complexes exhibited higher photoluminescent quantum yield (Φ_f) than (dfppy)Pt(pic) in degassed DCM at room temperature. The Φ_f was determined to be 0.94 for (dfppy)Pt(Tfl-pic), 0.81 for (C_{16}dfppy)Pt(Tfl-pic) and 0.58 for (dfppy)Pt(pic) by using 9,10-diphenylanthrancene as the standard (Φ_f = 0.9) [30]. Therefore, an introduction of alkyl-trifluorene group into the ancillary ligand of picolinic acid did improve the PL quantum efficiency of its platinum (II) complexes obviously.

In contrary, the PL spectra of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) in their neat films exhibit two emission peaks, respectively. The high-energy emission peak locates at 402 nm for (dfppy)Pt(Tfl-pic) and 421 nm for (C_{16}dfppy)Pt(Tfl-pic) while the low-energy emission peak locates at 619 nm for the former and 569 nm for the latter. They are different from the PL spectrum of (dfppy)Pt(pic) in the neat film which exhibit only an emission peak at 601 nm. As we know, platinum (II) complexes have a planar molecular configuration and have a potential to form excimers and give the excimers emission in their neat film [31]. Compared to (dfppy)Pt(Tfl-pic), (C_{16}dfppy)Pt(Tfl-pic) with a substituted alkyl chain in 2,4-difluorophenylpyridine presented obviously weak emission in long-wavelength area. The weak low-energy emission for (C_{16}dfppy)Pt(Tfl-pic) may be relative to the excimer emission quenching resulting from facile aggregation by the flexibility of long alkyl chain in 2,4-difluorophenylpyridine core.

2.3. Thermal property

The thermal stability of platinum (II) complexes was evaluated by thermogravimetric analysis (TGA) under N_2 stream with a scanning rate of 20 °C/min and their TGA curves are shown in Figure S1. The decomposition temperature (T_d) values are 292 °C for (dfppy)Pt(Tfl-pic), 295 °C for (C_{16}dfppy)Pt(Tfl-pic) and 294 °C for (dfppy)Pt(pic), which correspond to a 5% weight loss. This result suggests incorporating a trifluorene group into picolinic acid has a minor effect on thermal stability of its platinum (II) complexes.

2.4. Electrochemical property

The electrochemical behavior of these cyclometalated platinum (II) complexes was studied by cyclic voltammetry using ferrocene as the internal standard and their data are listed in Table 1. Irreversible oxidation peaks were found from each compound. On the basis of these onset oxidation potentials (E^{ox}) and formula $E_{HOMO} = E^{ox} + 4.34$ eV, the highest occupied molecular orbital energy levels (E_{HOMO}) of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) were calculated as −6.28 and −5.94 eV, respectively. The lowest unoccupied molecular orbital energy levels (E_{LUMO}) of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) were −2.23 and −2.0 eV based on the equation $E_{LUMO} = E_{HOMO} + E_g$, respectively, in which energy band gap (E_g) was estimated from the UV–vis absorption threshold[32]. Compared to (dfppy)Pt(pic) complex, (dfppy)Pt(Tfl-pic) present an increased energy gap due to introduction of trialkylfluorene group into picolinic acid. Moreover, an additional introduction of alkyl to the cyclometalated ligand further results in energy gap decrease of (C_{16}dfppy)Pt(Tfl-pic).

Table 1
Optophysical, electrochemistry and thermal stability data of (dfppy)Pt(pic), (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic).

Compounds	UV–vis (nm)	Emission[a](nm)	Emission[b](nm)	Φ_{em}	HOMO (eV)	LUMO(eV)	E_g (eV)
(dfppy)Pt(pic)	264, 325, 350, 404	418	601	0.58	−6.63	−3.46	3.17
(dfppy)Pt(Tfl-pic)	354, 266, 404	396, 418	402, 616	0.94	−6.28	−2.23	4.05
(C_{16}dfppy)Pt(Tfl-pic)	354, 266, 404	396, 418	421, 569	0.81	−5.94	−2.0	3.94

[a] measured in DCM at room temperature.
[b] measured in the neat film at room temperature.

2.5. Electroluminescent property

To investigate electroluminescence (EL) properties of these platinum (II) complexes, the single-layer devices were fabricated with a structure of ITO/PEDOT : PSS (50 nm)/dopant + PVK–PBD (45 nm)/Ba (4 nm)/Al (150 nm), in which ITO is used as the anode, PEDOT:PSS is used as a hole-injection layer and Ba/Al is employed as a cathode. The emitting layer is consist of the dopant of platinum (II) complexes and host matrix of PVK-PBD blend, in which doping weight concentration of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) is 10 wt.%, respectively, PBD weight ratio is 30% in the PVK–PBD blend.

The EL spectra of the (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic)-doped PVK–PBD devices at different applied voltage are shown in Fig. 3. EL spectrum of the (dfppy)Pt(Tfl-pic)-doped device covers whole visible range from 400 to 700 nm (Fig. 3a). Two emission peaks at about 590 nm and 418 nm are observed. Compared to PL spectrum of the (dfppy)Pt(Tfl-pic)-based neat film, the high-energy emission is attributed to itself blue emission and the low-energy emission is assigned to its excimer's emission. With increasing applied voltage, the low-energy emission intensity become stronger and the high-energy emission intensity turn weaker. Their CIE 1931 chromaticity diagram is shown in Figure S2. While the driving voltage increases from 7 V to 13 V, CIE coordinates of the (dfppy)Pt(Tfl-pic)-doped device vary from (0.27, 0.22) to (0.39, 0.41), which locates in white area. At 10 V, this (dfppy)Pt(Tfl-pic)-doped device displayed bright white light with a CIE coordinate of (0.33, 0.33). The luminance was 650 cd m^{-2} and current efficiency 0.40 cd A^{-1} were obtained in this situation. As far as we know, this is the purest white emission ever reported for platinum (II) complex-doped single-layer PLEDs. However, (C_{16}dfppy)Pt(Tfl-pic)-doped device only presented red emission at the different applied voltages in the same device configuration (Fig. 3b). The CIE coordinates of the (C_{16}dfppy)Pt(Tfl-pic)-doped device have a minor change around (0.40, 0.41) with increased bias from 7 V to 13 V. This implies that a hexadecyl group attached into 5-position of 2-(2,4-difluorophenyl)pyridine plays an positive role in facilitating the excimer's formation for its trialkylfluorene-based platinum (II) complexes under electric-excition. In order to explain why the trifluorene-based platinum (II) complexes-doped PLEDs exhibit different EL spectra, we measured the surface morphologies of (dfppy)Pt(Tfl-pic) and (C_{16}dfppy)Pt(Tfl-pic) in PVK–PBD film by atomic force microscopy (AFM) as shown in Fig. 4, respectively. The (dfppy)Pt(Tfl-pic)-doped film displayed a significantly decreased roughness with R_a = 1.79 nm (a) while the (C_{16}dfppy)Pt(Tfl-pic)-doped film exhibited a roughness with R_a = 46.0 nm (b). It indicates that (dfppy)Pt(Tfl-pic) has a better dispersibility than (C_{16}dfppy)Pt(Tfl-pic). It may be attributed to that the hook junction effect of this flexible hexadecyl chain can make easily the (C_{16}dfppy)Pt(Tfl-pic) molecules aggregation in the host matrix.

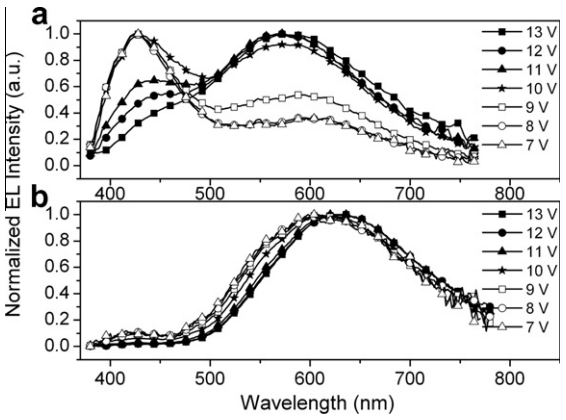

Fig. 3. (a) EL spectra of the (dfppy)Pt(Tfl-pic)-doped PVK–PBD device at 10% dopant concentration under different applied voltages; (b) EL spectra of the (C_{16}dfppy)Pt(Tfl-pic)-doped PVK–PBD device at 10% dopant concentration under different applied voltages.

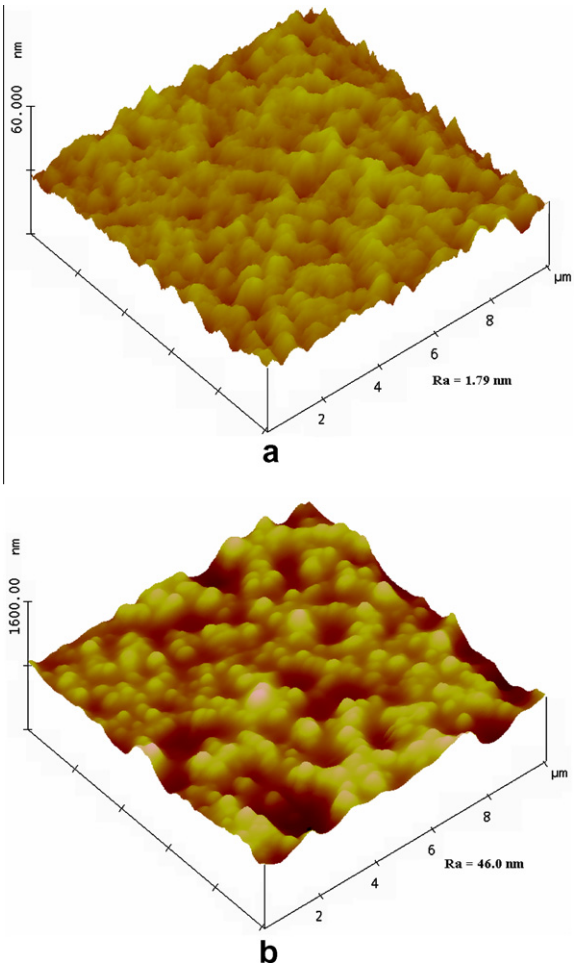

Fig. 4. Atomic force microscope images for: (a) the (dfppy)Pt(Tfl-pic)-doped PVK–PBD film; (b) the (C_{16}dfppy)Pt(Tfl-pic)-doped PVK–PBD film. The film thickness was about 80 nm.

3. Conclusion

In summary, two alkyl trifluorene-based cyclometalated platinum (II) complexes were obtained. The alkyl-

trifluorene group in ancillary ligand and hexadecyl chain in cyclometalated ligand present significantly influence on optophysical and EL properties of its cyclometalated platinum (II) complexes. The device using (dfppy)Pt(Tfl-pic) as dopant presented a white emission with CIE coordinate of (0.33, 0.33) at 10 V, but the other device using (C_{16}dfppy)Pt(Tfl-pic) as dopant displayed a red emission with the same single layer device configuration. This work provide an improved approach to control formation excimers of platinum (II) complex by tuning molecular structure with alkyl-trifluorene group in ancillary ligand and long alkyl chain in cyclometalated ligand. The pure white PLEDs can be obtained using this kind of platinum (II) complex as dopant.

4. Experimental

All solvents were carefully dried and distilled prior to use. Commercially available reagents were used without further purification unless otherwise stated. Tfl-picH was prepared according to the reported process [26]. All reactions were performed under nitrogen atmosphere and were monitored by thin-layer chromatography (TLC). Flash column chromatography and preparative TLC were carried out using silica gel from Merck (200–300 mesh). All ^{1}H NMR spectra were acquired at a Bruker Dex-400NMR instrument using $CDCl_3$ as a solvent. Elemental analysis was performed on a Harrios elemental analysis instrument. The UV absorption and photoluminescence spectra were measured with a Varian Cray50 and Perkin-Elmer LS50B Luminescence Spectrometer, respectively. EL spectra were recorded with an Insta-Spec IV CCD system (Oriel). Luminance was measured with a Si photodiode and calibrated by using a PR-705 spectrascan spectrophotometer (Photo Research).

4.1. Synthesis of (dfppy)Pt(Tfl-pic)

To a mixture of K_2PtCl_4 (0.3 g, 0.84 mmol) and water (5 mL) was added 2,4-difluoropyphenylpyridine (0.4 g, 2.1 mmol) and 2-ethoxyethanol (15 mL). The mixture was stirred vigorously under inert gas atmosphere for 20 h. After cooled, the colored precipitate was filtered off, washed with water and hexane, respectively. A red solid of dimmer of $[(dfppy)PtCl]_2$ was obtained (0.42 g, 78.0%). Then a mixture of the dimmer (0.2 g, 0.24 mmol), compound Tfl-picH (0.75 g, 0.60 mmol) and sodium carbonate (90 mg, 0.85 mmol) in 2-ethoxyethanol (15 mL) at about 80–90°Cwas stirred vigorously under inert gas atmosphere for 24 h. After cooling to room temperature, the mixture was extracted with DCM and the resulting organic layer was dried over anhydrous magnesium sulfate and distilled to gain black fused liquid. This crude product was purified by a dry flash silica gel column using DCM as eluent to gain the goal product (0.28 g, 53.0%) as a brown red solid. ^{1}H NMR ($CDCl_3$, 400 MHz), δ (ppm): 9.19–9.20 (1H, d, J = 5.2), 7.82–7.64 (16H, m), 7.37–7.33 (9H, m), 7.12–7.10 (1H, t), 6.90–6.85 (1H, t), 6.47–6.42 (1H, t), 4.10–4.06 (2H, t), 2.07–2.03 (12H, m), 1.26–1.01 (56H, m), 0.81–0.71 (27H, m). Anal. Calcd for $C_{102}H_{126}F_2N_2O_3Pt$: C 73.75, H 7.65, N 1.69. Found: C 73.48, H 7.60, N 1.73%.

4.2. Synthesis of (C_{16}dfppy)Pt(Tfl-pic)

It was prepared according to the synthetic procedure of (dfppy)Pt(Tfl-pic). A brown red solid was obtained with a yield of 36.0%.δ (ppm): 9.98 (1H, s), 7.82–7.63 (16H, m), 7.38–7.32 (9H, m), 6.89–6.85 (1H, t), 6.45–6.40 (1H, t), 4.09–4.04 (2H, t), 2.64–2.62 (2H, t), 2.08–2.03 (12H, m), 1.25–1.07 (84H, m), 0.81–0.78 (30H, m). Anal. Calcd for $C_{118}H_{158}F_2N_2O_3Pt$: C 75.16, H 8.45, N 1.49. Found: C 75.08, H 8.53, N 1.55%.

Spray-coating

ABSTRACT

We report on high performance organic thin-film transistors fabricated by spray-deposition, an innovative coating technique for organic electronic devices. This method is simple and inexpensive, compatible with room-temperature processing and easily scalable from laboratory-based devices to large-area electronics. Our spray-deposited 2,8-difluoro-5,11-bis (triethylsilylethynyl) anthradithiophene transistors show very good homogeneity, with mobilities of 0.2 cm^2/V s, and on/off ratios of 10^7. This performance is comparable to that of our best spin-coated devices fabricated on the same substrate type, while offering additional advantages such as using 20 times less organic semiconductor and facilitating fast coating of large-areas.

1. Introduction

The scope of applications emerging from large-area electronics has broaden considerably with the latest successes demonstrated in the field of organic electronics [1–4]. Organic devices offer an attractive balance between cost and performance, complemented by versatility and functionality accomplished by means of molecular engineering. The applications envisioned for organic semiconductors have expanded beyond conventional silicon, and include flexible displays, chemical and biological sensors, wearable electronics, medical applications, etc. The fabrication methods presently employed in research labs, such as spin-coating or drop-casting, offer advantages of low cost and allow demonstration of very good device performance [5–7]. Nevertheless, they are not compatible with large-areas, and thus present limited usability. New methods have emerged to design alternative processing routes that can meet the manufacturing requirements for large-area electronics, and at the same time maintain the cost-efficiency. Several techniques such as inkjet printing [8], screen printing [9], or doctor blading [10] have endeavored to deliver fast deposition over large-areas. In the frame of these efforts, spray-coating captures increasing attention, with both organic semiconductors [11–17] and contact materials [18,19] spray-deposition being demonstrated. However, while an intense effort is involved in developing spray-deposition technologies for manufacturing organic photovoltaics (OPVs) and organic light emitting diodes (OLEDs) [11–15], to the best of our knowledge, with the exception of a few reports [16,17], little attention is given to designing and developing methods that match organic thin-film transistors (OTFTs) materials and device structures.

In this article we report on high performance OTFTs fabricated by spray-deposition of organic semiconductor layer and demonstrate the viability of this approach by comparing the performance of spray-deposited devices with that of the spun-coated devices. While previous reports presented a detailed study of the spray-deposition of polymer semiconductors [16,17], here we demonstrate for the

doi:10.1016/j.orgel.2010.09.008

first time spray-deposited small molecule OTFTs. In spite of the impressive electronic properties measured in single crystals of materials from this class [20–22], their use in combination with cost-effective fabrication techniques was inhibited by their poor solubility. Recently, various molecular design approaches have succeeded in increasing solubility, allowing for demonstration of solution deposited OTFTs [5,6,23]. In this study we use 2,8-difluoro-5,11-bis (triethylsilylethynyl) anthradithiophene (diF-TES ADT) [5](chemical formula shown in the inset of Fig. 1) and demonstrate that spray-coating is a processing technique suitable for fast large-area coating, while maintaining device performance of small molecules organic TFTs. DiF-TES ADT has received much attention lately given the high performance it demonstrated in thin films [6] and single crystals devices [24], as well as the interesting film forming properties which allow low-cost, room-temperature patterning approaches [25]. Charge mobilities as high as 6 cm^2/V s have been demonstrated in field-effect transistors of vapor grown single crystal diF-TES ADT, together with large current on/off ratios ($I_{on}/I_{off} = 10^8$), small subthreshold slopes (S = 1 V/dec) and negligible hysteresis in the current–voltage characteristics [24]. In solution deposited devices, mobilities of 1.5 cm^2/V s have been reported in films drop-casted from a chlorobenzene solution [5], 0.2 cm^2/V s in diF-TES ADT TFTs, when the organic material was spun-casted from a chlorobenzene solution on pentafluorobenzenethiol (PFBT) treated contacts, and 0.4 cm^2/V s for PFBT treated contacts and hexamethyldisilazane (HMDS) modified gate dielectric [26]. Our spray-deposited diF-TES ADT TFTs exhibit performance comparable with spun-deposited devices on the same substrate (mobilities as high as $\mu = 0.2$ cm^2/V s, and $I_{on}/I_{off} = 10^7$ for PFBT treated contacts), while offering the advantage of being faster and less complex to manufacture on any size device structure, and utilizing 20 times smaller the amount of organic semiconductor.

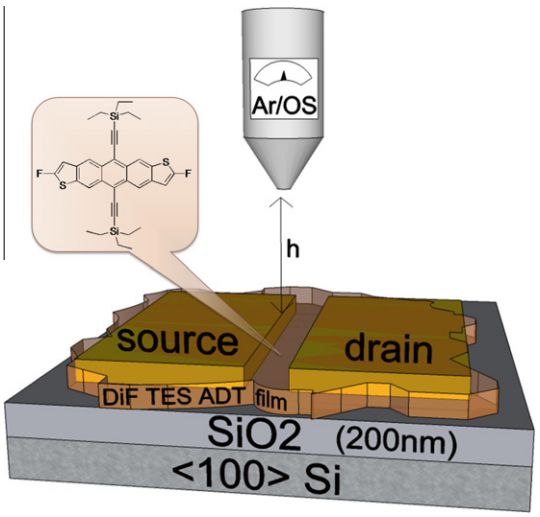

Fig. 1. Schematic drawing of the spray-deposition system. Organic semiconductor solution (OS) was sprayed under argon directly onto the device structure. h is the distance between the sample and airbrush. Field-effect transistor device structure is also shown, as well as the chemical formula of the organic semiconductor used in this study.

2. Experimental

A schematic of our spray-deposition system is presented in Fig. 1. We have used an Iwata Kustom TH K9200 airbrush with a nozzle diameter of 0.50 mm and pressurized argon as the carrier gas (5N purity). The organic semiconductor solution in chlorobenzene was aerosolized under high pressure argon, and the droplets were collected on the device structure, positioned at distance h below the airbrush. The concentration of the organic solution was carefully controlled, and systematically modified to improve transistor performance. The spray process was performed in ambient conditions, under the hood. Argon pressure, as well as the aforementioned distance h, were accurately adjusted, as they are critical parameters that dictate thin-film quality and, consequently, device performance, as we will demonstrate later. The airbrush was set in a fixed position, aiming perpendicular towards the sample. The sample and the airbrush were held steady during the spraying process, and the deposition time was monitored. Typical spraying times were in the order of 20–30 s (continuous spraying).

We have fabricated bottom-contact TFTs (see cross-section of the device structure in Fig. 1) by spraying the organic semiconductor solution over the 1.2 cm × 1.2 cm substrate containing 63 pre-fabricated device structures. We used a heavily doped Silicon wafer as the substrate and gate electrode with a 200 nm thermally grown SiO_2 layer that served as the gate oxide. The source and drain Ti/Au contacts (5 nm Ti/45 nm Au) were deposited by e-beam evaporation. Discrete devices had well defined geometries by using photolithography and lift-off, with channel lengths L between 5 and 100 μm and channel widths W between 200 and 1000 μm. Prior to spray-deposition of the organic semiconductor, the substrates were cleaned by soaking in hot acetone, isopropyl alcohol, followed by UV ozone cleaning and DI water rinse. The contacts were chemically treated by immersing the substrates for 30 min in a $5 \cdot 10^{-2}$ mol/L PFBT solution in ethanol. The fabrication parameters have been optimized by performing systematic tests and correlating processing parameters with resulting device performance. We have investigated the electrical properties of our transistors in ambient air and at room temperature, using a commercially available probe station, and an Agilent 4155C Semiconductor Parameter Analyzer. A minimum number of 50 devices were fabricated and characterized for each set of parameters that were investigated in this study. Optimum spraying parameters were found to be: argon pressure 5 psi, spray distance 13 cm, solution concentration $c = 0.1$ wt% (1.1 mg/mL), and spray time 30 s. In parallel with spray-deposited devices, spin-coated TFTs were also fabricated for comparison studies. These devices were fabricated in air, on the same substrate type (held at room temperature), from a solution in room-temperature chlorobenzene. No subsequent thermal treatment was applied to the spray or spin-coated samples.

3. Results and discussion

Fig. 2 shows the current–voltage characteristics of a device having channel length $L = 20$ μm, and channel width $W = 200$ μm. It can be observed from these graphs that the drain current I_D increases with increased negative gate–source voltage V_{GS}, typical for a hole-transporting organic layer. In the upper panel of Fig. 2 we plot the $\log(I_D)$ vs. V_{GS} (right axis) and $\sqrt{I_D}$ vs. V_{GS} (left axis) graphs in the saturation regime (drain–source voltage $V_{DS} = -40$ V).

The mobility for this device was calculated to be $\mu = 0.2$ cm^2/V s by using the following expression:

$$I_D = \frac{W}{L}\frac{C_i}{2}\mu(V_{GS} - V_T)^2 \quad (1)$$

where V_T is the threshold voltage, C_i is the gate oxide capacitance per unit area ($C_i = 1.7 \times 10^{-4}$ F/m^2), and W and L are the channel width and length, respectively. We have estimated the threshold voltage $V_T = 4.4$ V by extrapolating the linear fit of $\sqrt{I_D}$ vs. V_{GS} plot to $I_D = 0$ A (intercept with V_{GS} axis). The current on/off ratio for this device was $I_{on}/I_{off} = 10^7$. The evolution of the drain current (I_D) with the drain voltage (V_{DS}) is presented in the lower panel of Fig. 2 for different gate voltages (V_{GS}). The gate voltage was varied in 10 V steps from 0 to −40 V. A strong field-effect modulation of the channel conductance can be observed in this plot, with a linear variation of I_D with V_{DS} at small voltages and reaching saturation regime at high voltages. The performance of this OTFT is clearly altered by contact effects. This observation is supported by the current compression in the linear regime [27,28]. We have previously demonstrated using scanning Kelvin probe microscopy (SKPM) that such a current compression in the linear regime is accompanied by a several volts potential drop at the electrode/organic semiconductor interface [29]. Therefore, only a small fraction of the applied voltage is gradually dropped across the organic semiconductor itself, indicating that the electrical performance of the devices is contact-limited. The potential profile gives valuable insight into device operation, and we believe higher mobilities can be achieved in air-brushed diF-TES ADT TFTs, by improving device contacts.

The promise for low-cost electronics converges expectations of cost efficiency in processing, as well as materials used in devices. Spray-deposition is more efficient than spin-coating, where most solution is wasted during spinning. With spray-coating, the waste is highly minimized and most of the starting material is efficiently used to fabricate the active film. To increase the material usage efficiency even further, we have investigated the effect of the concentration of the organic solution used for spraying, with the goal of determining the minimum amount of material required to fabricate high-mobility devices. Fig. 3 presents the effect of the concentration of the solution on the properties of the devices, for diF–TES ADT TFTs fabricated from a chlorobenzene solution, under constant flow rate, 5 psi argon carrier gas pressure, spray time 30 s, and spraying distance of 13 cm. The plot in the lower panel of this figure suggests the presence of three distinct

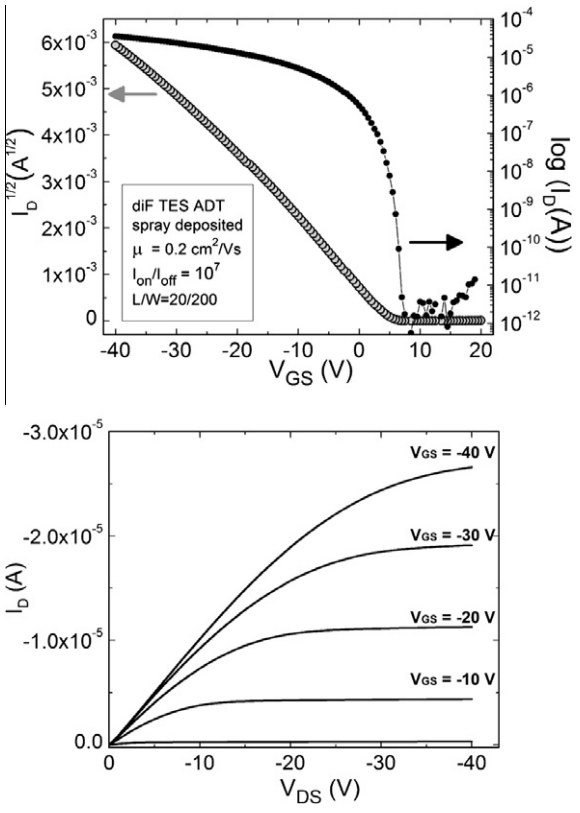

Fig. 2. Electrical characteristics of a spray-deposited diF-TES ADT TFT. Upper graph: current–voltage characteristics ($\log(I_D)$ vs. V_{GS}) in the saturation regime, at $V_{DS} = -40$ V. Left axis: $\sqrt{I_D}$ vs. V_{GS} plot used to calculate the mobility. Lower graph: Source–drain (I_D) current vs. drain voltage (V_{DS}) measured at different gate voltages (V_{GS}). The dimensions of channel length (L) and channel width (W) are indicated.

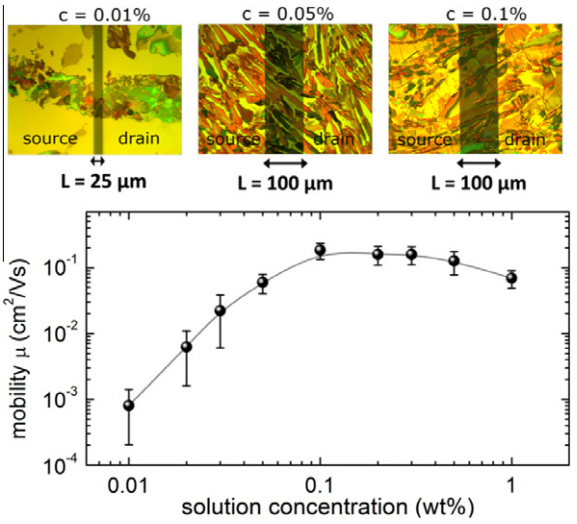

Fig. 3. Upper panel: Optical micrographs of the spray-deposited thin-film transistors, showing the difference in coverage for three different concentrations. The concentration of the organic semiconductor solution used for fabrication is indicated above each photo. Lower panel: Variation of mobility with the concentration of the solution.

regimes: mobility increases with concentration (regime I), it reaches the highest value for $c = 0.1$ wt% (1.1 mg/mL – regime II), and it decreases slightly after that (regime III). We believe the improved mobility as a function of concentration for the first segment of this graph is a result of better coverage achieved at higher concentrations. Our observations are supported by the optical micrographs presented in the upper panel of Fig. 3. At $c = 0.01$ wt% (0.11 mg/mL) the coverage is very poor, consistent with the low average mobility of 8×10^{-4} cm^2/V s. As the concentration increases, the coverage gradually improves and consequently the mobility increases, reaching the value of 0.06 ± 0.02 cm^2/V s for $c = 0.05$ wt% (0.55 mg/mL), and 0.18 ± 0.05 cm^2/V s at $c = 0.1$ wt%. With further increase in concentration, for $c > 0.1$ wt%, a small decrease in mobility is observed (regime III). This behavior may stem from anisotropy in mobility [30,31], a non-uniform vertical structural profile in the film structure or/and the presence of the structural phase transition around room-temperature, which was found in diF–TES ADT, and which leads to the existence of two polymorphs with different inter-layer spacings and distinct electrical properties [32].

Fig. 4 reveals the channel length dependence of the mobilities measured in the saturation regime for spray- (black circles) and spin-coated (red squares) films of diF-TES ADT from chlorobenzene, on PFBT treated contacts, for comparison. Here we focus on the values of mobilities in the saturation regime, to minimize contact effects. For each of the two techniques, the fabrication process has been extensively optimized, and the conditions that promoted the best performance are presented. We recall the parameters for the spray-deposited films, which include $c = 0.1$ wt%, argon pressure 5 psi, spray distance 13 cm, spray time 30 s. For the spun-coated devices, a concentration of $c = 2$ wt%, and spinning speed of 1000 rpm were used. Devices fabricated on the same substrate presented very little spread in performance for a given channel length, and devices fabricated on different days, following the same conditions, demonstrated good reproducibility. The mobilities at small channel lengths are similar for spray- and spin-deposited devices. Nevertheless, the newly introduced spray-deposition uses 20 times diluted solution, thus a considerably smaller quantity of organic semiconductor material to achieve the same performance, allowing impressive cost reduction for organic devices fabricated by spray-coating. While this achievement is itself remarkable, it presents additional advantages over spin-coating, such as offering the opportunity of being used in fast large-area coating. Another notable aspect is that the entire fabrication process takes place in air, at room temperature, with no high-temperature steps involved. The modest thermal budget required by our method opens new routes towards fabrication of large-area, light-weight, low-cost flexible electronics on plastic substrates. Both device types exhibit increased mobility with decreasing channel length. This behavior seems to contradict our earlier statement of contact-limited devices, which would lead to lower mobility for short channel length due to the fact that contact resistance effects are more severe here [27]. However, it was previously demonstrated that with diF-TES ADT devices, microstructure effects play an important role in the device operation [25,26]. Organic thin-film microstructure and contact effects are competing effects in this case. For short channel devices, only a small number of grains/grain-boundaries are necessary to bridge the channel, but barriers at the organic/electrode interfaces dominate the charge transport. For long channel length devices, film microstructure governs the electrical properties, in agreement with Ref. [29]. It is clear from this behavior of mobility with channel length that both contacts and microstructure act simultaneously, and the interplay between the two effects is complex. A detailed model of the effect of microstructure and contact effects is currently under development. A closer look over Fig. 4a reveals a very distinct behavior for the two types of devices. For spray-coated films the mobility changes from $\mu = 0.18$ (± 0.05) cm^2/V s at $L = 5$ μm to $\mu = 0.05$ (± 0.01) cm^2/V s at $L = 100$ μm. On the contrary, for spun films, the mobility starts from roughly the same value, $\mu = 0.16$ (± 0.03) cm^2/V s at $L = 5$ μm, but decreases more abruptly, to $\mu = 0.001$ ($\pm 4.02 \times 10^{-4}$) cm^2/V s at $L = 100$ μm. Optical microscopy performed on films consisting of 100 μm

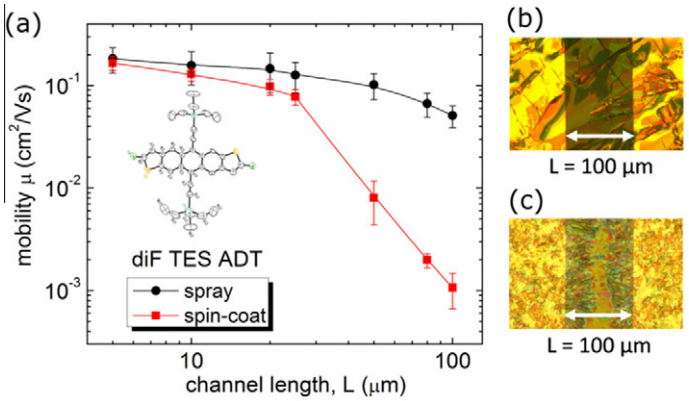

Fig. 4. (a) Saturation mobility μ vs. channel length L for diF-TES ADT TFTs fabricated by spray-deposition (black circles) and spin-coating (red squares). Optical micrograph of a spray-deposited device (b) and spin-coated device (c) with channel length L = 100 μm. (For interpretation of references to colors in this figure legend, the reader is referred to see the web version of this article.)

channel length TFTs of diF-TES ADT deposited by spray- and spin-deposition, respectively, on PFBT treated Au contacts (Fig. 4b and c) shows very different structural features characteristic for the two types of fabrication approaches, and elucidate the origin of the differences measured in electrical properties. In the spray-deposited devices, the mobility varies monotonically with L, pointing to an uniform film structure in the transistor channel [33,34]. This behavior is consistent with the optical micrograph in Fig. 4b, which shows that both the channel and contacts are covered with a nominally continuous, uniform film consisting of large plate-like crystals. The large crystalline grain size obtained in spray-deposited films is controlled by the fabrication conditions such as gas pressure, solvent boiling point, solution flow, surface tension, and more importantly, the distance h between the spray nozzle and the substrate [17]. For short distances the solution is easily blown away by the incoming flow. On the contrary, for large h distances, the solvent present in small aerosolized droplets, with large solution-air surface contact area, will evaporate before the solution reaches the substrate. For intermediate distances, which we have determined to be $h = 13$ cm for our system, the droplets will reach the substrate, coalesce there, and the organic semiconductor film will grow from the nucleation sites that form here. For the spin-coated devices, the film formation is very different. Here, the solvent evaporates almost instantaneously. This effect, together with the interactions present at the surface of the chemically treated contacts, leads to formation of a very distinct film microstructure. As a result of this microstructure, the mobility vs. channel length graph shown in Fig. 4 kinks at $L = 25$ μm. This behavior is in good agreement with our earlier reports on diF-TES ADT thin-film devices fabricated on PFBT treated contacts, and is a result of a transition between two distinct channel microstructures [26]. Following PFBT treatment, spin-coated devices consist of unique structural features, with plate-like crystals covering the contact area and extending into the channel, and small grains in the middle of the channel. We have demonstrated that these contact-nucleated features form a highly ordered film, consisting of co-facially packed molecules, with the long axis of the ADT core forming the π stacking along the charge transport path and, consequently, exhibiting high mobility. In TFTs with sufficiently short channels, the contact-nucleated features bridge the source and drain contacts and a high mobility is observed. At long channel lengths the mobility dramatically decreases as a result of the formation of a poorly ordered film within the channel consisting of mixed molecular orientations and promoting low mobility regions [25]. Fig. 4c shows the unique film microstructure at large channel lengths, consisting of the two different film types and provides an explanation for this peculiar behavior.

4. Conclusions

In summary, we have fabricated high performance organic thin-film transistors by using spray-deposition. We have shown that the electrical performance of our devices is strongly dependent on solution concentration, with the best TFTs exhibiting mobilities of $\mu = 0.2$ cm^2/V s, and current on/off ratios of 10^7. Our results demonstrate the viability of spray-deposition, a low-cost, high-throughput method that provides a robust route to fabricating reliable organic TFTs, with remarkable properties, and open new routes to low-cost fabrication of organic electronic devices.

ABSTRACT

We demonstrated that 1,3,5-tris([2′,2″]bipyridin-6′-yl)benzene (BpyB) and 1,3,5-tris([2′,2″,6″,2‴]terpyridin-6'-yl)benzene (TpyB) are good electron-transport (ET) layer materials for organic light-emitting devices (OLEDs). The new materials exhibit high electron mobilities of around 10^{-4} cm^2 V^{-1} s^{-1}, and OLEDs comprising the materials operate at lower voltage than the OLEDs with tris(8-hydroxyquinolinato) aluminum (Alq) as an ET material. The new materials are also useful for phosphorescent OLEDs in blue-, green-, and red-light-emitting devices, where they function as both electron-transporting and hole-blocking materials. Phosphorescent OLEDs with the new materials operate at lower voltage (while maintaining comparable external quantum efficiencies of electroluminescence) than does the corresponding reference device with bathocuproine/Alq as electron-transporting and hole-blocking layers.

1. Introduction

Organic light-emitting devices (OLEDs) are of interest for potential application in various fields such as flat televisions, mobile displays, lights, and optical communication light sources. OLEDs generally comprise functionally divided organic multilayers – for example, hole-transporting (HT), emissive, and electron-transporting (ET) layers [1,2]. In the last decade, many kinds of amorphous molecular semiconductor materials [3,4], HT materials [5–12], and ET materials [13–23], have been proposed. Among these, HT molecular semiconducting materials have become practical due to their high charge-carrier mobility and excellent operational durability, but few reports exist to date on ET organic semiconducting amorphous materials that perform well in terms of high-speed transport of electrons, easy injection of electrons from the cathode, and good operational durability [16]. Tris (8-hydroxyquinolinato) aluminum(III) (Alq) was used in the first bright OLED reported by Tang and VanSlyke in 1987 [1]; it is still conventionally used as an ET material, despite its slow electron mobility [24], because of its relatively good operational durability. However, as a reflection of the imbalanced performance between ET and HT materials, electron-feeding from the cathode into an emissive layer controls device characteristics. As a result, the development of efficient ET organic amorphous semiconducting materials remains an important challenge.

ET materials with high electron mobilities provide some advantages, including lower operating voltage and lower power consumption. Moreover, if ET materials have wide band gaps – that is, deep highest occupied molecular orbitals (HOMOs) – they can also work as hole-blocking (HB) materials. Hole-blocking is desirable because complete confinement of holes in emissive layers by the HB layer raises the quantum efficiency (QE) of electroluminescence (EL). Furthermore, when considering phosphorescent OLEDs (PHOLEDs) that can theoretically provide the 100% internal electron–photon conversion efficiency theoretically [25], a complete confinement for triplet exciton energies of phosphorescent light-emitters also becomes important to attain extremely high QE.

We have frequently reported on ET materials with high electron mobilities based on one molecular design concept: hybridizing bipyridine with common ET units such as oxadiazole or triazole [26–28]. Can we now make good ET materials based on bipyridine only? Bathophenanthroline, a common good ET material, is similar in structure to bipyridine. Kido et al. recently reported that tris-pyridine-substituted triphenylbenzenes exhibit very good electron-transport properties, with electron mobilities as high as 7.9×10^{-3} cm^2 V^{-1} s^{-1} [29]. As a result, we can assume that the tris-bipyridine-substituted benzene (BpyB) and tris-terpyridine-substituted benzene (TpyB) examined in this study will be good ET-layer materials for OLEDs. As described herein, OLEDs with these new materials clearly operate at lower voltage than do OLEDs with Alq, a conventional ET material. The new materials are also useful for phosphorescent OLEDs, where they work not only as ET but also as HB materials.

2. Experimental

2.1. Materials

Fig. 1 shows chemical structures of the newly developed materials BpyB and TpyB, synthesized from bipyridine or terpyridine bromides with tris(pinacolboryl) benzene by Suzuki–Miyaura coupling reaction. BpyB and TpyB were purified, before evaluation and measurements, by temperature-gradient sublimation in a flow stream of pure Ar gas. Other OLED materials were obtained from industrial companies as sublimation grades and used without further purification.

2.2. Synthesis

2.2.1. 6-Bromo[2,2′]bipyridine (Br-Bpy)

Br-Bpy was synthesized from 2,6-dibromopyridine (11.8 g, 52.8 mmol) and 2-pyridyl zinc bromide (55.0 mmol) that was contained in 110 ml of its tetrahydrofuran (THF) solution (0.5 M) using 50 ml of THF as additional solvent and tetrakis(triphenylphosphine)Pd(0) (1.7 g, 2.5 mmol) as catalyst. With the reaction solution kept below 10 °C with an ice bath, the 2-pyridyl zinc bromide solution was added dropwise. The ice bath was removed and the solution was stirred continuously for 48 h. Then, 10 wt.% ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid, disodium salt (EDTA 2Na) aqueous solution (500 ml) was added in small steps. Chloroform extraction and distillation of the solvent gave a crude brown powder. Purification by silica gel chromatography with a toluene/ethyl acetate mixture as eluent yielded Br-Bpy as white powder (7.0 g; 54% yield). δ_H (600 MHz, $CDCl_3$): 8.67 (d, 1H, J 4.8 Hz), 8.41 (d, 1H, J 7.8 Hz), 8.38 (d, 1H, J 8.4), 7.82 (dd, 1H, J 8.7 Hz), 7.67 (dd, 1H, J 7.8 Hz), 7.49 (d, 1H, J 7.2 Hz), 7.32 (dd, 1H, J 6.3 Hz).

2.2.2. 6-Bromo[2,2′,6′,2″]terpyridine (Br-Tpy)

Br-Tpy was synthesized from 6,6′-dibromo[2,2']bipyridine (10.0 g, 31.4 mmol) essentially as described for Br-Bpy to yield a white powder (5.2 g; 52.4% yield). δ_H (600 MHz, $CDCl_3$): 8.70 (d, 1H, J 4.8 Hz), 8.58 (d, 1H, J 6.6 Hz), 8.57 (d, 1H, J 9.0 Hz), 8.46 (m, 2H), 7.95 (dd, 1H, J 7.8 Hz), 7.85 (dd, 1H, J 6.0 Hz, J 7.8 Hz), 7.70 (dd, 1H, J 8.1 Hz), 7.50 (d, 1H, J 7.2 Hz) 7.34 (m, 1H).

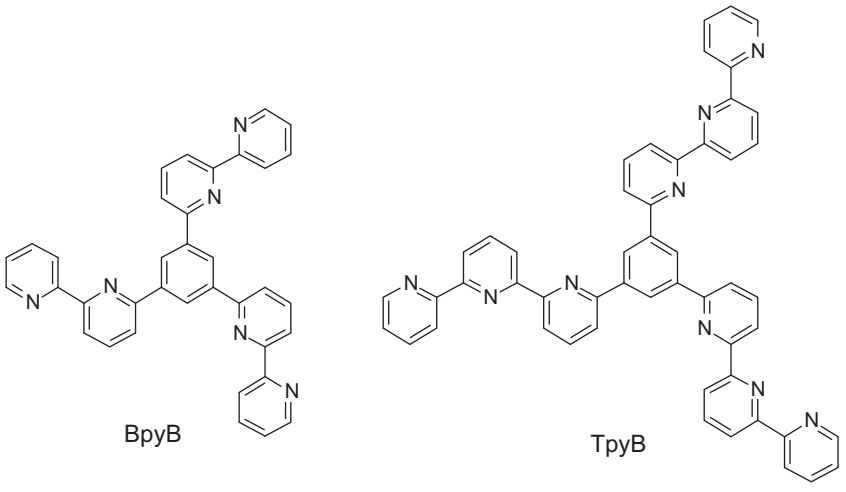

Fig. 1. Chemical structures of BpyB and TpyB.

2.2.3. 1,3,5-Tris(pinacorato boryl)benzene ((PinB)$_3$B)

(PinB)$_3$B was synthesized by Suzuki–Miyaura coupling reaction using 1,3,5-tribromobenzene (8.6 g, 27.3 mmol), bis(pinacorato)diboron (25.0 g, 98.4 mmol), potassium acetate (24.1 g, 245.7 mmol), and [1,1′-bis(diphenylphosphino)ferrocene] dichloropalladium(II) as catalyst in dimethyl sulfoxide. The reaction mixture was refluxed for 21 h, and then cooled to room temperature. Pure water (1000 ml) was added and the mixture was stirred for 30 min and filtered to remove precipitates. Addition of methanol gave a crude white crystalline powder, which was dissolved in ethyl acetate, filtered to remove the catalyst, and distilled to yield pure (PinB)$_3$B (7.1 g; 57% yield). δ_H (600 MHz, $CDCl_3$): 8.37 (s, 3H), 1.33 (s, 36H).

2.2.4. 1,3,5-Tris([2′,2″]bipyridin-6′-yl)benzene (BpyB)

BpyB was synthesized from (PinB)$_3$B (2.5 g, 5.5 mmol) and Br-Bpy (3.8 g, 15.0 mmol) by Suzuki–Miyaura coupling reaction using 1 M K_2CO_3 aqueous solution (32.4 ml, 32.4 mmol) as base, tetrakis(trisphenylphosphine)palladium(0) (0.32 g, 0.28 mmol) as catalyst, and 135 ml of a 4/1 ethanol/toluene mixture as solvent. The reaction mixture was refluxed with stirring for 33 h, and then cooled to room temperature. Pure water (500 ml) was added and the mixture was stirred for 30 min. Extraction by chloroform, drying with $MgSO_4$, filtration to remove precipitates, and distillation to remove the chloroform gave a crude brown powder. Purification by silica gel column chromatography with a 1/3 chloroform/hexane mixture as eluent yielded BpyB as a white crystalline powder (1.1 g; 41% yield). δ_H (600 MHz, $CDCl_3$): 9.01(s, 3H), 8.76 (d, 3H, J 7.2 Hz), 8.74 (d, 3H, J 4.8 Hz), 8.47 (d, 3H, J 7.2 Hz), 8.01 (dd, 3H, J 8.7 Hz), 7.98 (d, 3H, J 7.8 Hz), 7.88 (dd, 3H, J 7.8 Hz), 7.36 (dd, 3H, J 6.3 Hz). δ_C (150 MHz, $CDCl_3$): 156.43, 156.31, 155.90, 149.14, 140.43, 137.82, 136.82, 126.25, 123.78, 121.37, 120.65, 119.65.

2.2.5. 1,3,5-Tris([2′,2″,6″,2‴]terpyridin-6′-yl)benzene (TpyB)

TpyB was synthesized by Suzuki–Miyaura coupling reaction using (PinB)$_3$B (2.4 g, 5.26 mmol) and Br-Tpy (5.0 g, 16.0 mmol) essentially as described for BpyB using 1 M K_2CO_3 aqueous solution (32.3 g, 32.4 mmol), tetrakis(trisphenylphosphine)palladium(0) (0.32 g, 0.28 mmol), and 150 ml of a 4/1 ethanol/toluene mixture. The reaction mixture was refluxed for 3 h, cooled, and then filtered. Recrystallization from *o*-dichlorobenzene solution yielded TpyB as a white powder (2.7 g; 67% yield). δ_H (600 MHz, $CDCl_3$): 9.06 (s, 3H), 8.81 (d, 3H, J 7.8 Hz), 8.73(d, 3H, J 3 Hz), 8.68 (d, 3H, J 8.4 Hz), 8.67 (d, 3H, 7.8 Hz), 8.50 (d, 3H, J 8.4 Hz), 8.03 (m, 9H), 7.89 (dd, 3H, J 7.8 Hz), 7.35 (d, 3H, J 7.8 Hz). δ_C (150 MHz, $CDCl_3$): 156.21, 155.85, 155.54, 155.30, 149.15, 140.28, 137.77, 136.87, 130.51, 127.70, 126.17, 123.75, 121.26, 121.21, 121.05, 120.60, 119.69.

2.3. Device fabrication and measurements

All OLEDs were fabricated on 150-nm-thick layers of indium-tin oxide (ITO) that were commercially precoated onto glass substrates with a sheet resistance of 14 Ω/sq. The solvent-cleaned ITO surface was treated with O_2 plasma for 5 min and then the substrate was immediately loaded into a high-vacuum chamber (base pressure below $\sim 6 \times 10^{-4}$ Pa) where organic layers, 0.5-nm-thick LiF, and 200-nm-thick aluminum cathode layers were deposited by thermal evaporation. Deposition rates were 0.6 Å/s for organic materials, 0.1 Å/s for LiF, and 6 Å/s for Al. The current density-applied voltage–luminance (*J–V–L*) characteristics of the OLEDs were measured with a commercial OLED-characteristics measurement system (Precise Gauge EL1003) and a source meter (Keithley 2400). Electroluminescence (EL) spectra were recorded simultaneously with the EL1003 during *J–V–L* measurements.

^{1}H- and ^{13}C NMR spectra were recorded on an FT–NMR spectrometer (JEOL JNM-ECA600). Thermal analyses were performed on a differential scanning calorimeter (Seiko Instruments DSC-6200) at a heating rate of 10 °C/min under N_2 gas. Ultraviolet (UV) and visible absorption spectra were recorded with a spectrophotometer (Shimadzu UV-3150); photoluminescence (fluorescence and phosphorescence) spectra were recorded with a spectrofluorometer (Horiba FluoroMax4P). HOMO energy was determined with a photoelectron emission yield spectrometer (Riken Keiki AC-3), and the HOMO energy was defined as being equal to the ionization potential measured by photoelectron emission spectroscopy. Optical band gaps were determined by the spectral onset of each UV–visible absorption spectrum; the lowest unoccupied molecular orbital (LUMO) energy was then estimated to be the difference between the HOMO energy and the optical bandgap. Spectroscopic measurements were conducted with thin films prepared by thermal evaporation on quartz substrates.

Electron mobility was measured by conventional time-of-flight (TOF) techniques. The excitation light was a 500-ps-duration optical pulse from an N_2 gas laser (λ = 337 nm, Usho Optical Systems KEN-150). Test samples were prepared by thermal evaporation in vacuum and encapsulated with fresh desiccant under a highly inert atmosphere of N_2 at the dew point of almost −60 °C and O_2 concentration of <10 ppm. A 100-nm-thick fullerene C_{60} layer was used as a charge-generation layer for optical excitation [27].

Computational chemistry was conducted with commercial software (Wavefunction Spartan 06W) on a personal computer with a dual-core processer. Density function theory (DFT) was used to determine conformations, with a B3LYP hybrid functional and a 6-311G* basis set for determining optimized geometries and estimating activation energies for conformation change. During the estimation of activation energies, we constrained the dihedral angle that was responsible for the conformation change and conducted each geometry optimization with the dihedral constraint at several angles.

3. Results and discussion

3.1. Thermal and electronic properties

Fig. 2 shows differential scanning calorimetry (DSC) curves for BpyB and TpyB. During the first heating procedure, endothermic peaks due to melting are observed for

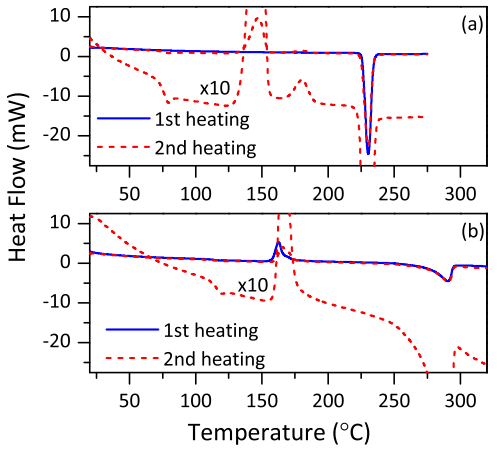

Fig. 2. DSC curves of BpyB and TpyB during first and second heating procedures.

the two powders at 240 °C and 305 °C, respectively. For BpyB, during the second heating procedure, a baseline shift due to glass transition and an exothermic peak at 146 °C due to recrystallization are observed; the glass transition temperature T_g is 75 °C. For TpyB, during the second heating procedure, the same transitions occur: recrystallization at 166 °C and T_g at 110 °C. These results confirm that both powders can form stable glassy thin films by vacuum evaporation. T_g is higher for TpyB (110 °C) than for NPB (94 °C), a practical HT material (Fig. 5).

Fig. 3a shows the optimized geometry for BpyB, obtained by means of computational chemistry. The geometry shows C3 symmetry and resembles a three-blade propeller. The dihedral angle between the center phenyl ring and the adjacent pyridine ring is 23° because of steric hindrance between the two hydrogen atoms at the ortho position of each ring. In contrast, the pyridine units are coplanar. These angles are reasonable from the viewpoint of general chemistry. Fig. 3b shows a bipyridyl wing of BpyB rotated 180° around the single bond that connects the bipyridine unit with the center phenyl ring, significantly changing the molecular geometry. Note that the energy of this rotated geometry is the third lowest and the energy difference ΔE between the two conformers is estimated to be only 1.77 kJ mol^{-1}. Such rotation is known to occur easily in the case of conformation with a single bond that links two aromatic rings. Fig. 3c shows the energy profile for dihedral rotation. Through computational chemistry, we estimate the activation energy to be 15.5 kJ mol^{-1}, only ~6 times larger than the thermal energy at room temperature (2.48 kJ mol^{-1}). This result indicates that conformation change between the two conformers occurs frequently, and a population of the higher energy conformer must be defined by the Boltzmann distribution with the energy difference ΔE. The exact population must depend on the energy distributions of all the

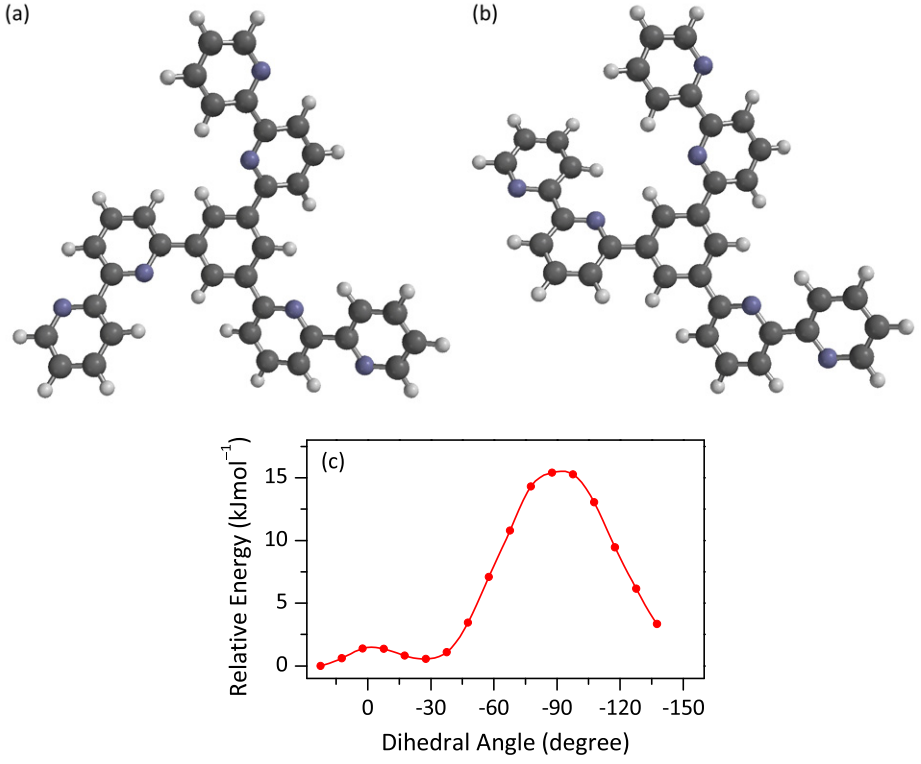

Fig. 3. (a) and (b) Lowest-energy and third-lowest-energy computational optimized geometries, respectively, of BpyB. (c) Energy profile of the conformation change between these two geometries. Another local minimum exists at a dihedral angle of 30°. The structure of the second-lowest-energy geometry is close to that of (a).

conformers of BpyB, but this small ΔE suggests that a large number of BpyB molecules exist as conformers other than the lowest energy one, and thus thin films of BpyB are composed of several conformers. We believe that this is one reason why BpyB displays an amorphous nature [27].

Fig. 4a shows UV–visible absorption and fluorescence spectra of neat thin films of each material. The absorption maxima are at 274 nm for BpyB and 293 nm for TpyB, and both materials emit bright UV fluorescence. Optical interference by the sample thin film causes broad absorption around 500–600 nm. The band gaps (E_g = 3.60 eV) for both BpyB and TpyB from the absorption spectra are clearly wide.

Fig. 4b shows phosphorescent spectra of dilute 2-methyltetrahydrofuran (meTHF) solutions of BpyB and TpyB at liquid-nitrogen temperature (77 K). We determined the triplet bandgap energy E_g^T from an apparent peak at the shortest wavelength, indicated by an arrow in the figure; for BpyB, $E_g^T = 2.77$ eV and for TpyB, $E_g^T = 2.79$ eV. For BpyB, the LUMO level (2.85 eV) in neat solid is low enough to easily accept electrons from a cathode metal. For TpyB, the LUMO level is deeper (3.00 eV) due to three additional pyridine units, implying easier injections of electrons from a cathode metal. In addition, for both materials, the HOMO levels (6.45 eV for BpyB and 6.60 eV for TpyB) are sufficiently deep to suppress hole leakages from the emissive layer, and hole confinement in the emissive layer leads to high QE of EL. As a result, BpyB and TpyB can be used as efficient ET and HB materials. The thermal and electronic properties of BpyB and TpyB are summarized in Table 1.

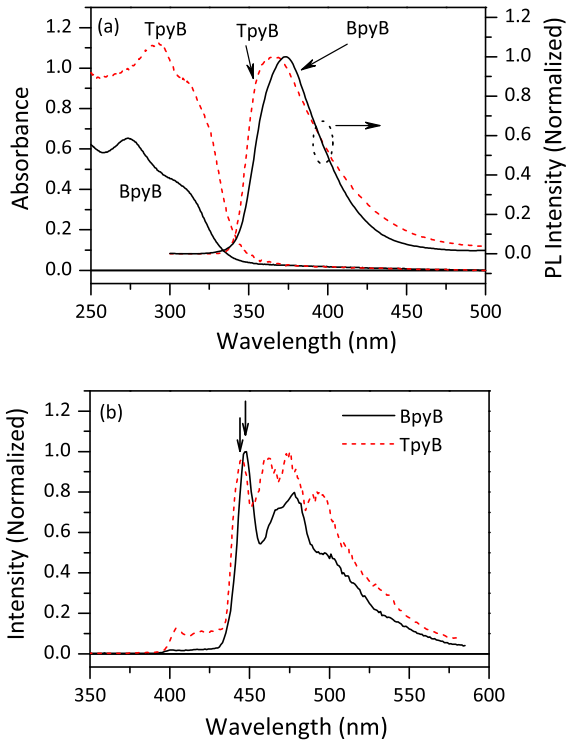

Fig. 4. (a) UV and visible absorption spectra (left axis) and PL spectra (right axis) of thin films of BpyB (thickness 77 nm) and TpyB (thickness 88 nm). (b) Phosphorescence spectra of meTHF solutions of the materials at liquid-nitrogen temperature (77 K). Weak bands around 400–425 nm are assigned to phosphorescence from the stabilizer contained in meTHF, 3,5-di-*tert*-butyl-4-hydroxytoluene (BHT).

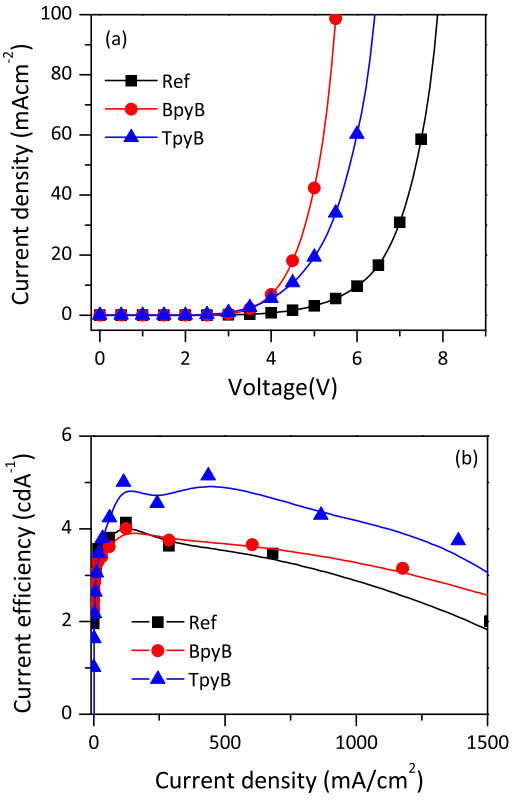

Fig. 5. *J–V–L* characteristics of OLEDs with BpyB or TpyB as electron-transporting materials and of a reference OLED with Alq: (a) Current density as a function of voltage (*J–V*); (b) Luminous current efficiency as a function of current density (*L–J*).

Table 1
Thermal and electronic properties of BpyB and TpyB.

	I_p (eV)	E_a (eV)	E_g (eV)	E_g^T (eV)	T_m (°C)	T_g (°C)
BpyB	6.45	2.85	3.60	2.77	240	75
TpyB	6.60	3.00	3.60	2.79	305	110

3.2. OLED properties

Fig. 5 shows the current density–applied voltage (*J–V*) characteristics of OLEDs with BpyB or TpyB as an ET material as well as of a reference device without the new materials. Fig. 6 shows the structure of the associated OLED and the various chemicals used in it. OLEDs with the new materials perform better (operate at lower voltage) than a reference OLED with Alq. Therefore, we conclude that we can make a good ET material with bipyridine and/or terpyridine only. The BpyB device shows almost the same luminous efficiency (4.0 cdA^{-1}) as does the reference device with Alq. The TpyB device shows even higher luminous efficiency (5.0 cdA^{-1}), probably due to the deeper HOMO

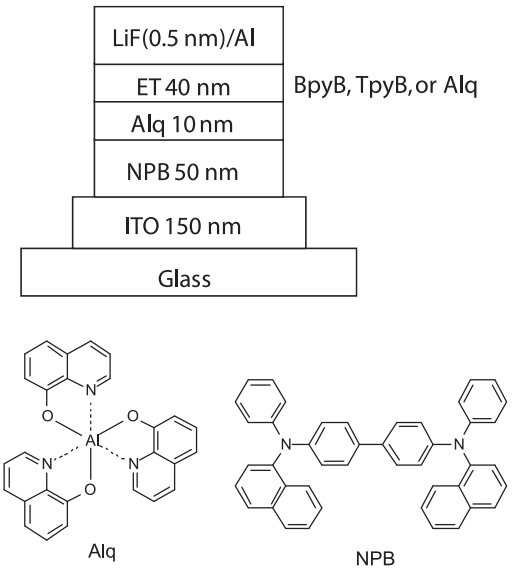

Fig. 6. OLED device: (top) device structure; (bottom) chemical structures of two of the materials used in the device.

of TpyB, which is effective for preventing hole leakages from the emissive layer. As noted earlier, hole-blocking is important for attaining high QE of EL. While we observed no increase in efficiency for BpyB, the lower operation voltage of the device with BpyB implies high electron mobility of BpyB, and the high mobility might move the electron–hole recombination zone for the NPB/Alq interface. The move of the recombination zone is probably a reason no increase of the QE because a very recent report indicated that an interaction between NPB and Alq apparently reduces the luminescence efficiency of Alq [30]. We believe that BpyB should also have HB properties because of its sufficiently deep HOMO.

Because BpyB and TpyB perform well not only as ET materials but also as HB materials, we investigated their use as double-function ET/HB materials. Recent highly efficient phosphorescent OLEDs have both an HB layer and an ET layer. In particular, an HB layer is important for obtaining high QE because hole leakage seriously reduces efficiency. Moreover, it is more important to consider triplet energy dissipation from the emissive layer to the hole-blocking layer for attaining high QE. At present, only a few materials are used as HB materials for phosphorescent OLEDs, including bathocuproine (BCP) and bis (2-methyl-8-quinolinolato) (*p*-phenylphenolato) aluminum (BAlq).

Fig. 7 shows the *J*–*V* characteristics of phosphorescent OLEDs with BpyB or TpyB as a double-function ET/HB material as well as of a reference OLED. Fig. 8 shows the structure of the associated phosphorescent OLED and the various chemicals used in it. Phosphorescent OLEDs with both new materials perform better (operate at much lower voltage) than a conventional double-layer reference OLED comprising BCP and Alq layers [31]. Since devices with both new materials show high external QE (almost 10%), BpyB and TpyB are both useful as double-function ET/HB materials for phosphorescent OLEDs. As shown in Table 1, the E_g^T for each new material is so large that no triplet en-

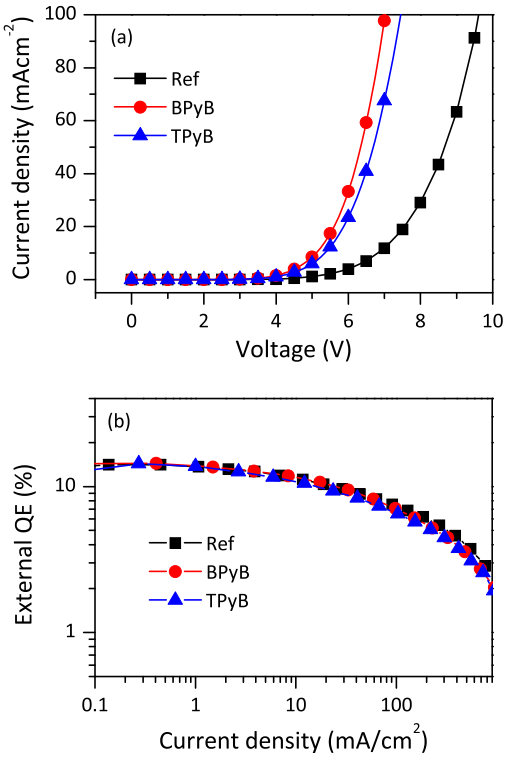

Fig. 7. *J*–*V*–*L* performance characteristics of phosphorescent OLEDs with BpyB or TpyB as dual-function hole-blocking and electron-transporting materials and of a reference OLED with the conventional structure: (a) current density as a function of voltage (*J*–*V*); (b) external quantum efficiency (QE) as a function of current density.

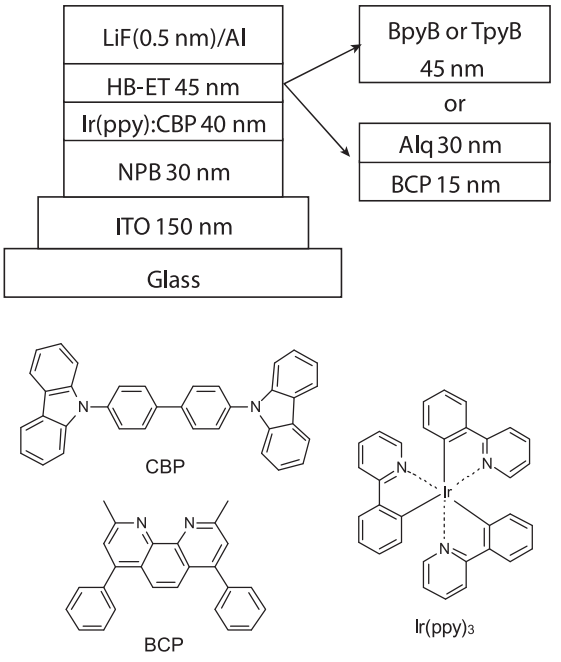

Fig. 8. Phosphorescent OLED device: (top) device structure; (bottom) chemical structures of three of the materials used in the device.

ergy leakage from the Ir-complex phosphorescent light emitter occurs.

The new materials appear to be effective even for blue-light-emitting Ir complex because the E_g^Ts of the materials are sufficiently large enough to prevent leakages of the triplet energy in blue-lights-emitting Ir complexes such as Ir(III) bis(2-(4,6-difluorophenyl)pyridinato-N,C^2)picolinate (FIrpic) of which E_g^T is 2.62 eV [32]. This is clearly evident from Fig. 9, which shows the *J*–*V*-external QE characteristics of blue- and red-light-emitting PHOLEDs with the corresponding dopants (Ir(III) bis(2-(4,6-difluorophenyl)pyridinato-N,C^2)picolinate (FIrpic) for blue and Ir(III) bis(2-(2′-benzothienyl)pyridinato-N,$C^{3'}$)acetylacetonate (BtpIracac) for red. Note that we fabricated those devices based on the same structure shown in Fig. 8 except for the dopants. Fig. 9 clearly shows that using the new materials reduce operation voltages in both colors. In addition, as one can see from Fig. 9, the devices comprising the new materials in both luminescent colors showed comparable external QEs to the corresponding reference devices with BCP and Alq. However, a slight but obvious difference in the QEs between the BpyB and TpyB devices could be observed in the blue devices. Because both E_g^Ts are almost the same, the difference probably results from a change of the recombination zone due to higher electron mobility of BpyB – the triplet energies of FIrpic and also maybe CBP possibly leak to NPB. The lower operation voltages and the comparable external QEs indicate that both BpyB and TpyB are also useful for phosphorescent OLEDs in both colors. Further optimization of device structures, including changes of host and other materials, should lead to higher external QEs at low operating voltage.

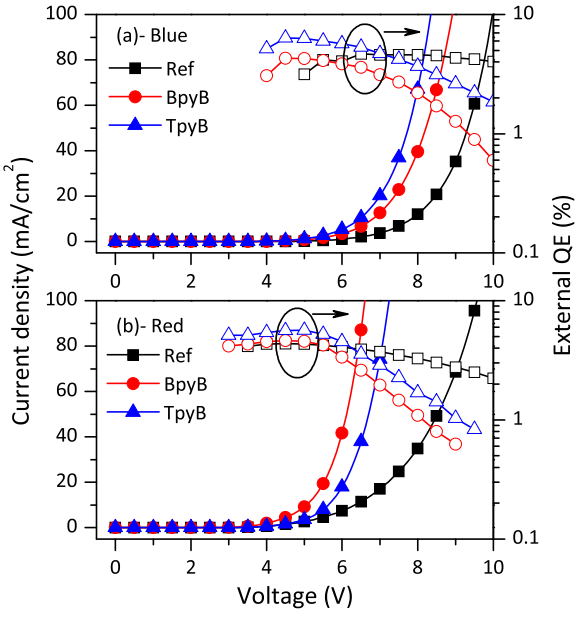

Fig. 9. *J*–*V*-external QE characteristics of phosphorescent OLEDs with BpyB or TpyB as dual-function hole-blocking and electron-transporting materials and of a reference OLED with the conventional structure: (a) blue-light-emitting phosphorescent OLED with FIrpic as the dopant; (b) red-light-emitting phosphorescent OLED with BtpIracac as the dopant. Device structures are the same as shown in Fig. 8 except for the dopants.

3.3. Electron mobility

Finally, we would like to briefly discuss electron mobility in the new materials. Fig. 10 shows the transient electron photocurrent waveform with double logarithmic scale, obtained by TOF measurement, for the BpyB film. Although each photocurrent waveform was not clear non-dispersive, we could clearly see that the transits of photogenerated charge carriers – electrons in this case become faster with increasing applied voltages because the photocurrents decayed faster with the increasing. In accordance with the conventional method to determine a transit time (t_T) for dispersive transportations, we drew the two auxiliary straight lines as shown in the figure and determined the t_T at the crossing point of the auxiliary lines. Note that the two slopes of the two auxiliary lines for each photocurrent are almost the same as each other, and this also endorses that the observed photocurrents are due to drift motions in the film. If we take electron mobility μ to be.

$$\mu = Dd/(t_T V) \tag{1}$$

where D is the distance between the two electrodes (4.0 μm), d is the thickness of the prepared BpyB layer (3.9 μm), and V is the applied voltage, we can determine, for example, that $\mu = 2.6 \times 10^{-4}$ cm^2 V^{-1} s^{-1} at the electric field $E = V/D = 1.13 \times 10^6$ V cm^{-1}. This mobility is two orders of magnitude higher than that for Alq (1.3×10^{-6} cm^2 V^{-1} s^{-1}) at approximately the same electric field [33]. This high mobility probably accounts for the better *J*–*V* curve for the OLED with BpyB than for the OLED with the corresponding reference.Fig. 11 shows electron mobility as a function of the square root of the applied electric field for several materials, including BpyB and TpyB. Both BpyB and TpyB show mobility that is at least an order of magnitude higher than that of Alq. This high mobility is comparable to that of a representative ET material with high electron mobility: a silole derivative, 2,5-bis(6′-(2′,2″-bipyridine))-1,1-dimethyl-3,4-diphenylsilole (PyPySiPyPy) [33,34]. The

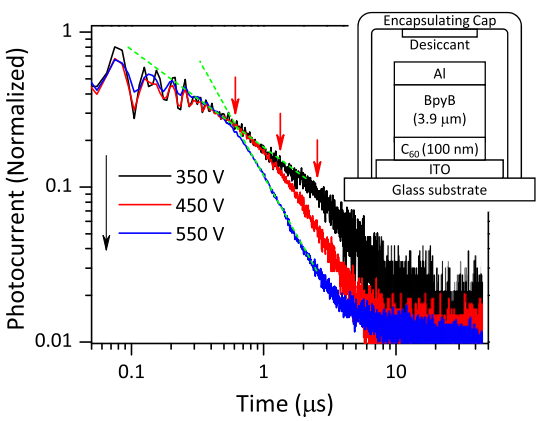

Fig. 10. Electron transient photocurrent for time-of-flight measurements of BpyB at applied voltages, to the Al cathode, of 350, 450, and 550 V. The dashed lines in green are for guides to determine the transit time of the photocurrent at 550 V and the three short red arrows represent each transit time. The inset shows the structure of the OLED device used.

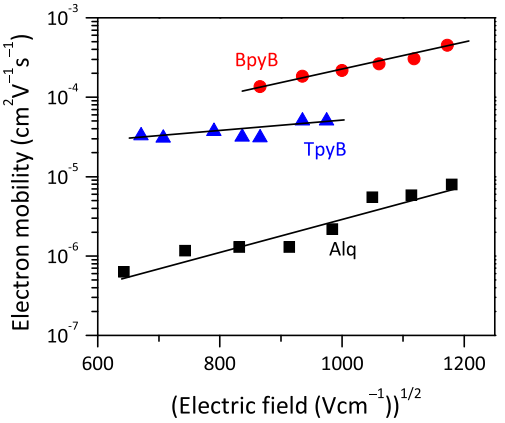

Fig. 11. Electron mobility as a function of electric field for BpyB, TpyB, and Alq. Data for Alq are from Murata (refer text).

mobility was relatively high but lower than that (1.0×10^{-3} cm^2 V^{-1} s^{-1} at 6.4×10^5 V cm^{-1}) of tris-pyridyl substituted 1,3,5-triphenylbenzene (TmPyPB) reported by Kido et al. [29] of which structure was similar to BpyB, and we are unsure about the reasons for the difference at present. In addition, mobility is lower for TpyB than for BpyB. Although we are also not sure at present about the reason, the lower mobility reflects the higher operating voltages for TpyB devices than for BpyB devices, as shown in all of the figures showing *J–V* characteristics.

4. Conclusion

We demonstrated that tris-bipyridine-substituted benzene (BpyB) and tris-terpyridine-substituted benzene (TpyB) are good ET-layer materials for OLEDs. Electron mobilities for these new materials ($\sim 10^{-4}$ cm^2/Vs) are much higher than that for Alq and almost the same as that for conventional high-mobility ET materials such as bathophenanthroline and silole derivatives. OLEDs with these new materials operate at lower voltages than does an OLED with Alq as an ET material. The new materials are also useful for phosphorescent OLEDs in blue-, green-, and red-light-emitting devices, where they work as both electron-transporting and hole-blocking materials. Phosphorescent OLEDs with the new materials operate at lower voltage (while maintaining comparable external quantum efficiencies) than do the corresponding reference devices with BCP/Alq as electron-transporting and hole-blocking layers.

ABSTRACT

Environmentally sustainable systems for the design, production, and handling of electronic devices should be developed to solve the dramatic increase in electronic waste. Sustainability in plastic electronics may be the production of electronic devices from natural materials, or materials found in common commodity products accepted by society. Thereby biodegradable, biocompatible, bioresorbable, or even metabolizable electronics may become reality. Transistors with an operational voltage as low as 6 V, a source drain current of up to 0.5 μA and an on–off ratio up to four orders of magnitude, with saturated field effect mobilities in the range of 1.5×10^{-4} to 2×10^{-2} cm^2/V s, have been fabricated with such materials. Our work comprises steps towards environmentally safe devices in low-cost, large volume, disposable or throwaway electronic applications, such as in food packaging, plastic bags, and disposable dishware. In addition, there is significant potential to use such electronic items in biomedical implants. As such, organic materials offer a unique opportunity to guide electronics industry towards an environmentally safe direction.

1. Introduction

Two major concerns in the world nowadays are plastic consumption and waste. Due to the economic growth and the increased demand in developing countries, plastics consumption is projected to increase by a factor of two to three during the current decade [1]. A consequence of this incessant demand of plastics in the world is the accumulation of non-biodegradable solid waste and plastic litter with negative effects on our environment. As an example, the amount of municipal solid waste per person per year averages ~440 kg/yr for China, ~550 kg/yr for the European Union and ~790 kg/yr for the United States, with roughly half of the waste being electronic products and plastics [1,2]. Taking into account the expected increase of plastic electronics in low-cost, large volume, disposable or throwaway applications, plastic waste problems may become even more dramatic. More effort will be necessary in order to minimize the negative impact of the increasing production, consumption and disposal of both polymer materials and electronic circuits [3].

There have been so far several initial reports addressing the use of biodegradable substrates in organic electronics, such as poly (L-lactide-co-glycolide) [4], paper [5–9],

leather [10] or even silk [11,12]. Here we present an initial study of using natural, nature-inspired and common commodity materials which are widely accepted by society for sustainable electronics. The rationale for choosing materials from sugar family, small molecular nucleobases, beta-carotene, indigo, food colors (indanthrenes) and cosmetic colors (perylene diimide) on substrates such as glucose, hard gelatine and biodegradable polymers is to show how large the materials base may become for organic electronics, when low cost and sustainability is a concern. We limit our work to the electrical characterization of these materials and to the demonstration of field-effect transistors, a first step towards building more complex electronic integrated circuits. We consider unusual substrates, such as Ecoflex, hard gelatine capsules and caramelized glucose, to enhance the substrate materials base for organic electronics. High-performance, biocompatible and biodegradable organic field-effect transistors operating at low voltages are demonstrated by the evaporation of ultrathin layers of natural nucleobase dielectrics (adenine and guanine) on inorganic oxide dielectrics, a viable alternative to the passivation of such oxide dielectrics with self-assembled monolayers [13,14]. Semiconductors chosen include natural compounds like beta-carotene and indigo, as well as perylene diimide (a lipstick colorant), indanthrene yellow G and indanthrene brilliant orange RF, colorants used for example in textile and food industry. Having identified natural and nature-inspired p- and n-type semiconductors, opens ways to fabricate integrated circuits, based on inverters, ring oscillators, logical elements, etc. We hope that this initial study initiates an intense search for new materials and material combinations to finally end up with sustainable plastic electronic products.

2. Experimental

2.1. Preparation and/or purification of materials

Dielectric and semiconductor compounds employed (adenine, guanine, cytosine, thymine, caffeine, indigo, indanthrene yellow G) were purchased from Sigma–Aldrich and additionally purified by two vacuum sublimation cycles performed in a closed quartz tube. Indanthrene brilliant orange RF was purchased from Shanghai Jucheng Chemical Co., and purified by three vacuum sublimation cycles; its chemical composition was proven by mass spectrometry. Poly (vinyl alcohol) (Mowiol®40-88, electronic grade) was purchased from Kuraray Specialities Europe GmbH and used as received. D-(+)-glucose, lactose, and beta-carotene were purchased from Sigma–Aldrich and used without further purification. Ecoflex foil was purchased from BASF and hard gelatine capsules from a local pharmacy in Linz, Austria.

2.1.1. Perylene diimide: synthesis and analysis

Perylene diimide (EH-PDI) was synthesized as shown in Scheme 1. Perylene-3,4,9,10-tetracarboxylic acid dianhydride (5 g, 12.8 mmol) was mixed with 60 ml of freshly distilled quinoline, 15 g (116 mmol) of 2-ethylhexylamine and ca. 100 mg of $Zn(OAc)_2 \cdot H_2O$.

The obtained mixture was heated at reflux for 2 h, cooled down to room temperature and poured into 600 ml of 10% aqueous hydrochloric acid. The precipitate formed was removed by filtration, extracted with methanol and dried in air. The resulting crude sample of perylene diimide was purified by column chromatography. Elution with a CH_2Cl_2–methanol mixture (95.5:0.5 v/v) produced a pure compound EH-PDI. The final purification was performed by sublimation at 450–500 °C under a reduced pressure of $\sim 10^{-2}$ mbar. The yield of EH-PDI was in the range of 45–55%.

The NMR and FTIR spectra are summarized below:

^{1}H NMR (400 MHz, $CDCl_3$,) δ = 8.83 (d, 4H, *H*-Ar), 8.75 (d, 4H, *H*-Ar), 4.31 (m, 4H, NCH_2), 2.14 (m, 2H, C*H*), 1.58 (m, 8H, CH_2), 1.50 (m, 8H, CH_2), 1.13 (t, 6H, CH_3), 1.06 (t, 6H, CH_3), ppm. Chemical analysis: $C_{40}H_{42}N_2O_4$.

Calculated: C, 78.15; H, 6.89; N, 4.56. Found: C, 77.95; H, 6.97; N, 4.61.

IR spectrum (KBr pellet): ν = 745, 809, 1178, 1247, 1308, 1346, 1380, 1403, 1441, 1577, 1594, 1615, 1650, 1695, 2859, 2873, 2930, 2958 cm^{-1}.

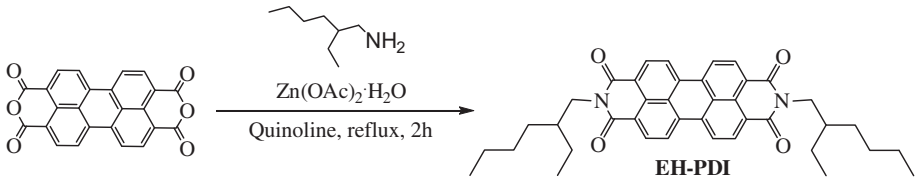
2.2. Device fabrication

2.2.1. Glucose/caffeine-beta-carotene OFET on glass

Precursor solution of D-(+)-glucose (0.9 g/ml) and caffeine (0.02 g/ml) was prepared in deionized water (~18 MΩ cm). The mixture was stirred for 60 min at 60 °C. Beta-carotene solutions (10 mg/ml in chloroform) were prepared under inert atmosphere in a glove bow. Thin films of glucose containing also caffeine were spun at 2000 rpm on top of a 100 nm thick patterned aluminium gate on a 1.5 × 1.5 cm glass substrate. The spun samples were dried overnight in a vacuum oven at 55 °C. Beta-carotene thin film was spin coated at 2000 rpm for 60 s under inert atmosphere. A 100 nm thick gold layer was evaporated through a shadow mask to pattern the top source and drain electrodes. The channel dimensions (length and width) was L = 100 μm, and W = 1 mm. The measured capacitance per unit area (by impedance spectroscopy) of a 3.1 μm thick dielectric film of glucose with caffeine was C_{0d} = 1.9 nF/cm^2. The measured unit capacitance of a 2.6 μm thick film cast from glucose solution (0.9 g/ml in deionized water, with no caffeine addition) was 2.15 nF/cm^2.

2.2.2. PVA/Indigo OFET on glass

Precursor solution of PVA (0.08 g/ml) was prepared in deionized water (~18 MΩ cm) and the mixture was stirred for 24 h at 90 °C. Thin films of PVA were spun at 2000 rpm on top of a 100 nm thick patterned aluminium gate on a 1.5 × 1.5 cm glass substrate. 100 nm thick indigo layer was vacuum processed in an Edwards evaporator. A 100 nm thick aluminium layer was evaporated through a shadow mask to pattern the top source and drain electrodes. The evaporation rate of indigo was 0.1 nm/s. The channel dimensions (length and width) was L = 100 μm, and W = 1 mm. The measured capacitance per unit area (by impedance spectroscopy) of a 2 μm thick dielectric film of PVA was C_{0d} = 3.1 nF/cm^2.



Scheme 1. Fabrication route of the perylene diimide semiconductor.

2.2.3. Glucose/C_{60} and lactose/C_{60} OFET on glass

Precursor solutions of D-(+)-glucose (0.9 g/ml in deionized water) and lactose (0.3 g/ml in DMSO) were spun at 2000 rpm on top of a 100 nm thick patterned aluminium gate electrodes on 1.5 × 1.5 cm glass substrates. Thick film of fullerene (100 nm), C_{60}, was evaporated in an Edwards vacuum evaporator. Thick aluminium (100 nm) was evaporated through a shadow mask to pattern the top source and drain electrodes. The evaporation rate of fullerene was 0.1 nm/s. The channel dimensions (length and width) was L = 100 μm, and W = 1 mm. The measured capacitances per unit area (by impedance spectroscopy) for a 2.6 μm thick dielectric film of glucose, C_{0d}, was 2.15 nF/cm^2 and for a 0.85 μm thick dielectric film of lactose was 6.8 nF/cm^2.

2.2.4. Guanine–C_{60} OFET on glass

A 1 mm wide-100 nm thick aluminium was evaporated onto 1.5 × 1.5 cm^2 glass slides to pattern the gate electrode. Thick guanine (425 nm) and C_{60} (100 nm) formed the organic dielectric and semiconductor layers, respectively, whereas 100 nm aluminium was used to pattern the source and drain electrodes. The evaporation rates of guanine and fullerene were 0.75 nm/s and 0.1 nm/s, respectively. The channel dimensions for the source and drain electrodes were: L = 100 μm and W = 1 mm. The measured unit capacitance of the dielectric was C_{0d} = 9.25 nF/cm^2.

2.2.5. Cytosine–C_{60} OFET on glass

A 1 mm wide-100 nm thick aluminium was evaporated onto 1.5 × 1.5 cm^2 glass slides to pattern the gate electrode. Thick cytosine (300 nm) and C_{60} (100 nm) were vacuum deposited to form the organic dielectric and semiconductor layers, respectively, whereas 100 nm aluminium was used to pattern the source and drain electrodes. The evaporation rates of cytosine and fullerene were 2 nm/s and 0.1 nm/s, respectively. The channel dimensions for the source and drain electrodes were: L = 100 μm and W = 1 mm. The measured unit capacitance of the dielectric was C_{0d} = 13.8 nF/cm^2.

2.2.6. Aluminium oxide–adenine–C_{60}/pentacene OFET on glass

A 1 mm wide-100 nm thick aluminium gate was evaporated onto 1.5 × 1.5 cm^2 glass slides and subsequently anodized by immersing in citric acid solution and passing a step voltage (up to a maximum of 40 V) at a constant current of 0.06 mA. Adenine (i.e., 10 nm thick for the sample with C_{60} and 150 nm thick for sample with pentacene) was vacuum deposited on top of AlOx to form the combined inorganic–organic dielectric. A 100 nm thick C_{60} and 100 nm pentacene, respectively, formed the organic semiconductors for the n- and p-type of OFETs. A 100 nm thick aluminium formed the source and drain electrodes for the sample with fullerene semiconductor; a 100 nm thick gold formed the source and drain electrodes for the sample with pentacene semiconductor. The evaporation rate of adenine was 3 nm/s, whereas pentacene and C_{60} and were evaporated at 0.1 nm/s, respectively. The channel dimensions for the source and drain electrodes were: L = 100 μm and W = 1 mm. The measured unit capacitances of the dielectrics were C_{0d} = 99 nF/cm^2 for the dielectric built for the n-type sample, and 19.55 for the dielectric of the p-type OFET.

2.2.7. Aluminium oxide–thymine–C_{60} OFET on glass

A 1 mm wide-100 nm thick aluminium gate was evaporated onto 1.5 × 1.5 cm^2 glass slides and subsequently anodized using the same method as described above. Thymine (i.e., 75 nm thick) was vacuum deposited on top of AlOx to form the combined inorganic–organic dielectric. A 100 nm thick C_{60} formed the organic semiconductor. A 100 nm thick aluminium formed the source and drain electrodes. The evaporation rate of thymine and C_{60} was 0.1 nm/s. The channel dimensions for the source and drain electrodes were: L = 100 μm and W = 1 mm. The measured unit capacitances of the combined dielectric was C_{0d} = 23.6 nF/cm^2.

2.2.8. Aluminium oxide–guanine/adenine–indanthrene yellow G OFET on glass

A 1 mm wide-100 nm thick aluminium gate was evaporated onto 1.5 × 1.5 cm^2 glass slides and subsequently anodized by immersing in citric acid solution and passing a step voltage (up to a maximum of 40 V) at a constant current of 0.06 mA. A transmission electron microscopy (TEM) picture of a cross-section of the anodized electrode revealed a thickness of ~55 nm of aluminium oxide. Two alternating layers of guanine and adenine (i.e., 2.5 nm thick guanine and 15 nm thick adenine) were vacuum deposited on top of AlOx to form the combined inorganic–organic dielectric. A 100 nm thick indanthrene yellow G and 100 nm aluminium formed the semiconductor and source/drain electrodes, respectively. The evaporation rates of adenine, guanine and indanthrene yellow G were 3 nm/s, 0.75 nm/s and 0.1 nm/s, respectively. The channel dimensions for the source and drain electrodes were: L = 100 μm and W = 1 mm. The measured unit capacitance of the dielectric was C_{0d} = 81.6 nF/cm^2.

2.2.9. Aluminium oxide–adenine/guanine–perylene diimide OFET on glass

A 1 mm wide-100 nm thick aluminium gate was evaporated onto 1.5 × 1.5 cm^2 glass slides and subsequently anodized by immersing in citric acid solution and passing

a step voltage (up to a maximum of 40 V) at a constant current of 0.06 mA. Two alternating layers of guanine and adenine (i.e., 2.5 nm thick guanine and 15 nm thick adenine) were vacuum deposited on top of aluminium oxide to form the combo inorganic–organic dielectric. A 100 nm thick perylene diimide and 100 nm aluminium patterned the semiconductor and source and drain electrodes, respectively. The evaporation rates of adenine, guanine and perylene diimide were 3 nm/s, 0.75 nm/s and 0.1 nm/s, respectively. The source and drain electrodes had the channel dimensions: $L = 100$ μm, $W = 1$ mm. The measured capacitance per unit area of the combined dielectric was $C_{0d} = 81.6$ nF/cm^2. The measured capacitance per unit area of the plain AlOx was 140 nF/cm^2.

2.2.10. Aluminium oxide–adenine/guanine–indanthrene brilliant orange RF OFET on glass

A 1 mm wide-100 nm thick aluminium gate was evaporated onto 1.5×1.5 cm^2 glass slides and subsequently anodized by immersing in citric acid solution, using the method described. Two alternating layers of guanine and adenine (i.e., 2.5 nm thick guanine and 15 nm thick adenine) were vacuum deposited; followed by 100 nm thick indanthrene brilliant orange RS and 100 nm gold source and drain electrodes. The source and drain electrodes had the channel dimensions: $L = 35$ μm, $W = 7$ mm. Gold, rather than aluminium, was used for contacting the n-type semiconductor. Adenine was evaporated at a rate of 3 nm/s, guanine at 0.75 nm/s and indanthrene brilliant orange RF at a rate of 0.1 nm/s. The measured capacitance per unit area of the dielectric was $C_{0d} = 81.6$ nF/cm^2.

2.2.11. Adenine–perylene diimide OFET on Ecoflex

Aurin (0.1 g/ml in pure ethyl alcohol) was spun at 2000 rpm for 60 s onto 1.5×1.5 cm^2 Ecoflex foils to act as a smoothening layer. A 1 mm wide-100 nm thick aluminium gate was evaporated through a shadow mask; A 1.1 μm thick adenine and 100 nm thick perylene diimide were evaporated in an Edwards high vacuum evaporation system at a pressure of 10^{-6} torr to pattern the gate dielectric and semiconductor, respectively. A 100 nm thick aluminium layer formed the top drain and source electrodes. The evaporation rate was 3 nm/s for adenine, and 0.1 nm/s for perylene diimide. The channel dimensions were $L = 100$ μm, $W = 1$ mm. The measured capacitance per unit area of the dielectric was $C_{0d} = 3.1$ nF/cm^2.

2.2.12. Adenine/guanine–indanthrene yellow G OFET on caramelized glucose

As received powder of D-(+)-glucose was melted on top of a hot plate at ~225–250 °C and droplets were deposited with a glass rod on aluminium foil wrapped around 1.5×1.5 cm glass slides. Wrapping aluminium around the glass slides was necessary to prevent the solidified glucose from cracking during cooling to room temperature. A thin layer of rosolic acid (50 nm) was vacuum evaporated to serve a double role: (1) to act as a smoothening layer and (2) to prevent the caramelized glucose substrate to swollen during the gold gate electrode patterning. A 100 nm thick-1 mm wide gold gate electrode was evaporated in a metal evaporator. The gate dielectric was formed by four alternating layers of guanine and adenine (75 nm thick each of the first three layers of guanine and adenine, and 400 nm thick adenine-the fourth layer), and 100 nm indanthrene yellow G was used as organic semiconductor. Adenine was evaporated at a rate of 3 nm/s, whereas guanine and indanthrene yellow G at a rate of 0.1 nm/s. A 100 nm thick layer of gold patterned the source and drain electrodes. The channel dimensions were: $L = 100$ μm and $W = 1$ mm. The measured unit capacitance of the combined dielectric was $C_{0d} = 5.6$ nF/cm^2.

2.2.13. Adenine/guanine–perylene diimide OFET on hard gelatine capsules

Hard gelatine capsules were cut open and stuck with the aid of a double-side scotch tape on 1.5×1.5 cm^2 glass substrates in order to force the gelatine substrate remain in a flat-open position. Rosolic acid (0.1 g/ml in pure ethylalcohol) was spun at 2000 rpm for 60 s on top of capsule substrates to act as a smoothening layer. A 1 mm wide-100 nm thick gold gate was evaporated through a shadow mask followed by four alternating layers of guanine and adenine (75 nm thick the first and the third layer of guanine, 100 nm and 500 nm thick the second and fourth layer of adenine) to form the gate electrode and gate dielectric, respectively. A 100 nm thick perylene diimide was evaporated to pattern the semiconductor layer and a 100 nm thick gold source and drain electrodes were subsequently evaporated. The evaporation rate was 1 nm/s for guanine, 3 nm/s for adenine, and 0.1 nm/s for perylene diimide. The source and drain electrodes had the channel dimensions: $L = 100$ μm, $W = 1$ mm. The measured capacitance per unit area of the dielectric was $C_{0d} = 5.1$ nF/cm^2.

2.3. Device characterization

Steady state current–voltage measurements were performed with an Agilent E5273A instrument. Both transfer and output characteristics were measured at a sweep rate of 66 mV s^{-1}, with 1 s for each of the hold, delay and step delay times, respectively.

Dielectric characterization of the gate dielectrics was performed with metal–insulator–metal capacitors using a Novocontrol Alpha Analyzer. X-ray diffraction was performed using a Bruker AXS X-ray Diffractometer (Cu Kα) X-ray Diffractometer. AFM investigation was performed using a Digital Instruments Dimension 3100 microscope working in tapping mode.

3. Results and discussion

3.1. Field effect transistors

Field effect transistors rely on an electric field (supplied by the gate voltage, V_{gs}, applied between the grounded source and the gate) to control the conductivity of a channel at the interface between the semiconductor and the insulator, and hence the current between source and drain contacts I_{ds}. A measure of the quality of the dielectric is given by the leakage current from the gate to the source contacts through the insulator layer, I_{gs}. Field effect

transistor preparation requires substrates, smoothing layers when the substrate is rough, metal electrodes, gate dielectrics and organic semiconductors. Fig. 1 illustrates such a transistor with all the components employed in this work presented in the schematic form. In the following, we start discussing first substrates, then gate dielectrics and

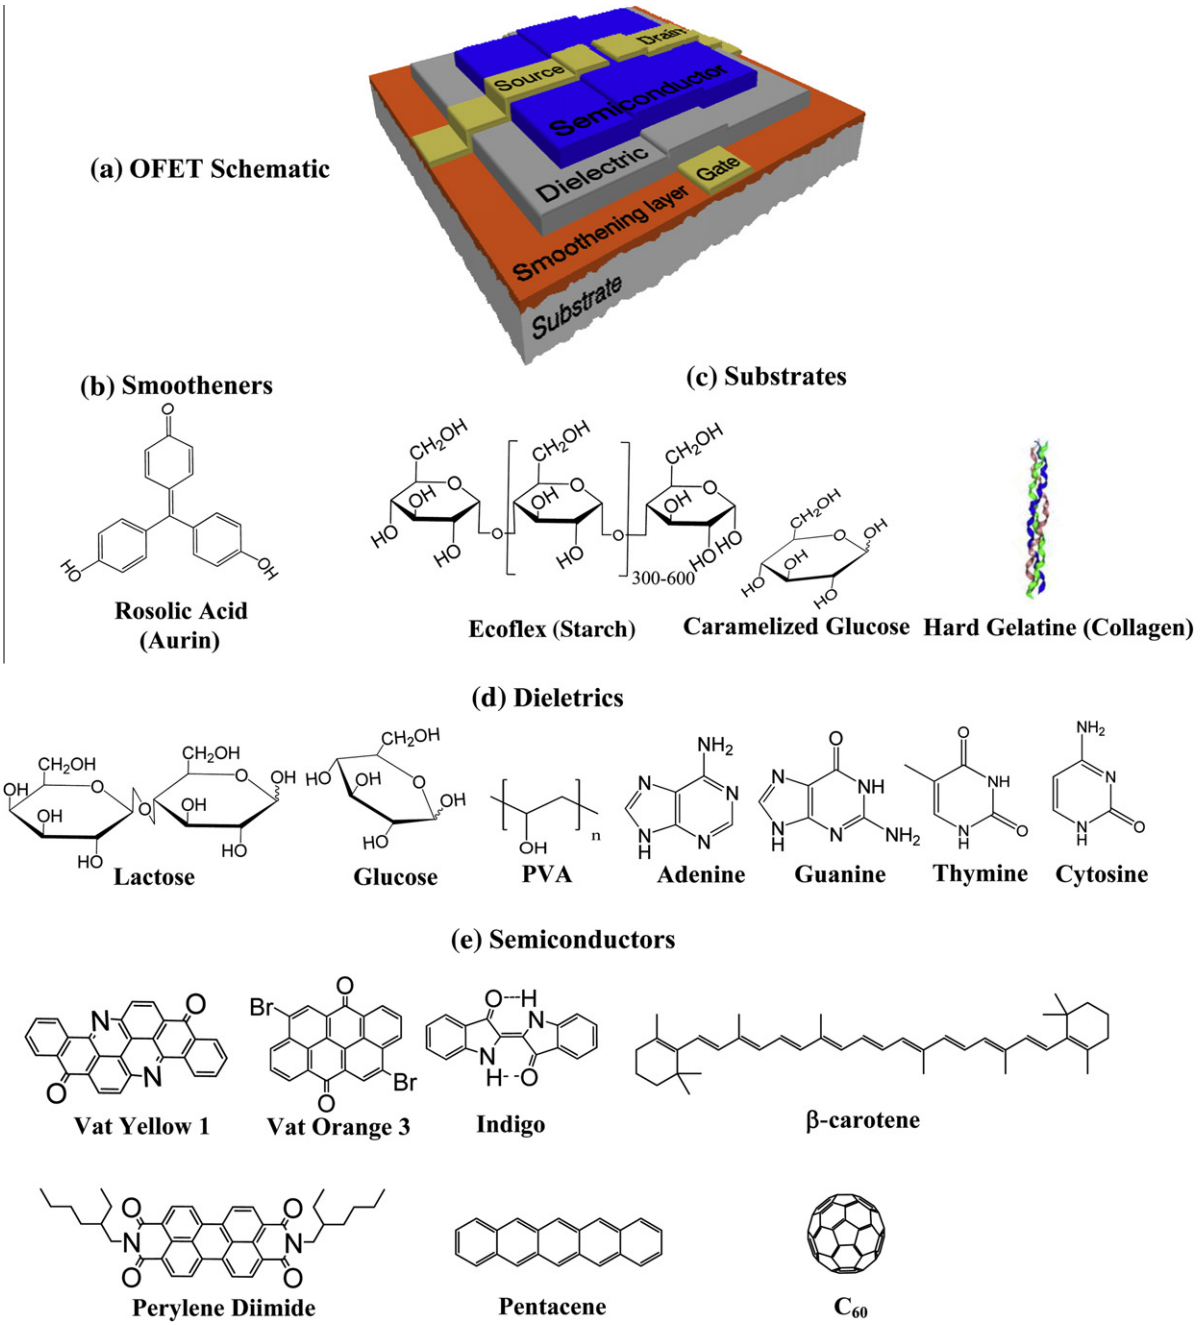


Fig. 1. Natural materials or materials inspired by nature used for fabrication of environmentally sustainable organic field effect transistors. (a) Schematic of bottom-gate, top-contact OFET employed in this work; (b) schematic of rosolic acid (aurin), used here as smoothener; (c) substrates investigated: Ecoflex produced from potato and corn starch, hard gelatine capsule originating from collagen and caramelized glucose; (d) natural dielectrics materials in the nucleobase and sugar families: adenine, guanine, cytosine, thymine glucose and lactose; (e) semiconductor materials: β-carotene and indigo are natural p- and n-type organic semiconductors; indanthrene yellow G and indanthrene brilliant orange RF are semiconductors derived from natural anthraquinone and perylene diimide, a cosmetic color. Glass, aluminium oxide, poly(vinyl alcohol), C_{60} and pentacene are examples of workhorse substrate, dielectric and semiconductor materials widely employed in the field, used here for comparison. Transistors and integrated circuits produced from natural or nature inspired materials may ultimately provide the basis for "sustainable green electronics".

organic semiconductors, together with examples of field-effect transistors built on either glass or biodegradable/biocompatible substrates.

3.1.1. Substrates for sustainable electronics

Fabric, hot-pressed cotton-fiber paper, leather and silk have been recently reported as examples of biodegradable and biocompatible-sustainable substrates for organic field effect transistors [4,5,10,11]. Other examples of such substrates are presented here; they include hard gelatine, commercially available biodegradable polymers and even caramelized sugar for edible devices.

Hard gelatine capsule is a fully biocompatible and biodegradable substrate employed extensively in the pharmaceutical field for oral drug delivery. Gelatine capsules are made from pork skin and bones and may contain small additions of plasticizers (e.g., glycerin and sorbitol), preservatives, colors, flavors (e.g., ethylvanilin and essential oil), sugars, etc. Their widespread availability, the ease of production in various forms and the complete biodegradability make gelatine capsules an interesting substrate for electronics. Such electronics may even be ingested in the body in biomedical applications. Ecoflex is a commercially available (BASF) biodegradable polymer based on potato starch, corn and polylactic acid. Ecoflex degrades in compost in 6 months without leaving any residue [15]. Since the use of such polymers for various low-end, biodegradable applications will most likely increase, it is interesting to explore them also as a substrate for organic electronics. Caramelized glucose is employed as another example of substrates for the preparation of OFETs; it allows for the

Table 1
Dielectric performance of investigated materials.

Material	Dielectric constant (at 1 kHz)	Breakdown field (MV/cm)	Loss tangent (at 100 mHz)
Dielectrics			
Adenine	~3.85	~1.5	$\sim 4 \times 10^{-3}$
Cytosine	~4.65	~3.4	$\sim 5 \times 10^{-3}$
Guanine	~4.35	~3.5	$\sim 7 \times 10^{-3}$
Thymine	~2.4	~0.9	$\sim 1 \times 10^{-2}$
Glucose	~6.35	~1.5	$\sim 5 \times 10^{-2}$
Lactose	~6.55	~4.5	$\sim 2 \times 10^{-2}$
Caffeine	~4.1	~2	$\sim 9 \times 10^{-2}$
PVA	~6.1	~2	$\sim 4 \times 10^{-2}$
AlOx	~9	~3.5	$\sim 4 \times 10^{-3}$

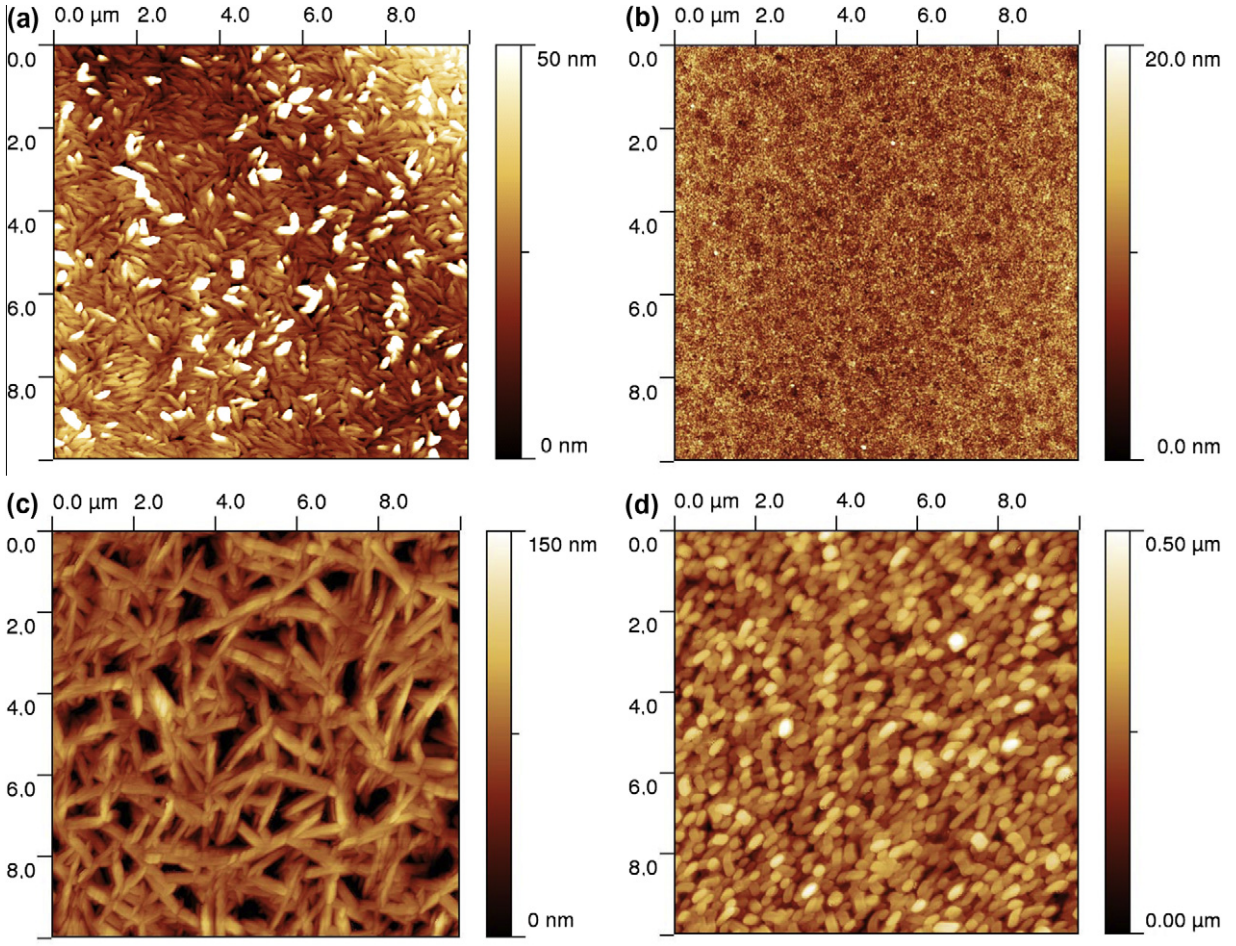

Fig. 3. AFM of nucleobase thin films on aluminium covered glass a) 1000 nm adenine (rms ~14.5); (b) 425 nm guanine (rms ~3); (c) 350 nm cytosine (rms ~24); (d) 450 nm thymine (rms ~65).

fabrication of bio-metabolizable (edible) electronics. All substrates mentioned here have large surface roughnesses, with root-mean-square (rms) values between 30 nm and 80 nm, necessitating the addition of a smoothing layer in order to decrease their roughness to values that allow fabrication of electronic components on such materials.

3.1.2. Smoothening layer

Initial work on paper substrates employed a smoothening layer formed by a thin spin-coated polymer film (polydimethylsiloxane, PDMS) to reduce the inherent roughness of the substrate [5,10]. While being biocompatible and solution processible, the polymer film required thermal cross-linking to render the structure amenable for the patterning of electrodes and further device preparation. Aurin (rosolic acid), a compound with a simple synthetic chemistry (i.e., produced by the reaction of phenol with oxalic acid in concentrated sulfuric acid bath) and which occurs also naturally (being extracted from the rhizomes of a free growing plant (*Plantago asiatica* L.)) [16,17] is used here as a smoothing layer. In traditional Chinese medicine, *Plantago asiatica* L. is known for its medicinal properties, used as anti-inflammatory, antiseptic, diuretic, expectorant, etc. [18]. In the medical and pharmacological fields, aurin is currently explored as heme-oxygenase activity regulator in aortic endothelial cells or as a generator of androgen receptors in binding assays that mimic the functions of natural hormones [17,19]. Being a naturally occurring compound with a simple chemistry and easy biodegradability, aurin represents an interesting candidate for the smoothening layer of various rough substrates. Fig. 2a and c shows the surface roughness of Ecoflex and gelatine capsules, with rms roughness values of ~70 nm and ~30 nm, respectively. As presented in Fig. 2b and d, the substrate roughness, rms, is reduced to 8 nm for Ecoflex and 9 nm for hard gelatine after spin-coating aurin, solution processed in ethyl-alcohol.

3.1.3. Natural dielectrics for sustainable organic field effect transistors

Nature provides an overwhelming number of materials that are degradable, so looking for natural dielectrics appears to be a promising route for sustainability in organic electronics. We first describe dielectrics from the sugar family, followed by dielectrics from the nucleobase family, both groups comprising naturally occurring-biodegradable

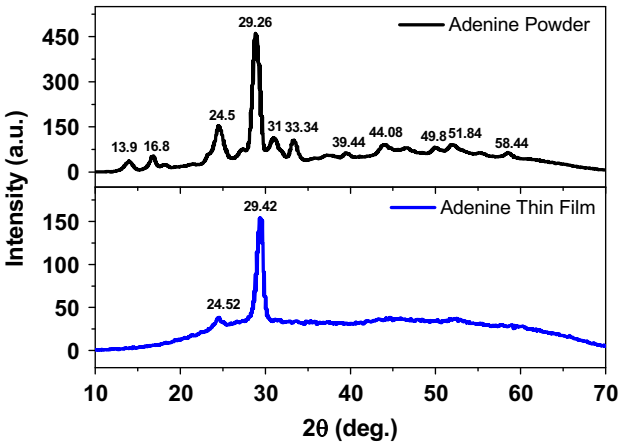

Fig. 4. X-ray diffraction profiles of precursor adenine (a) and evaporated adenine (b); the corresponding crystallographic planes are conforming to the pattern in a standard card.

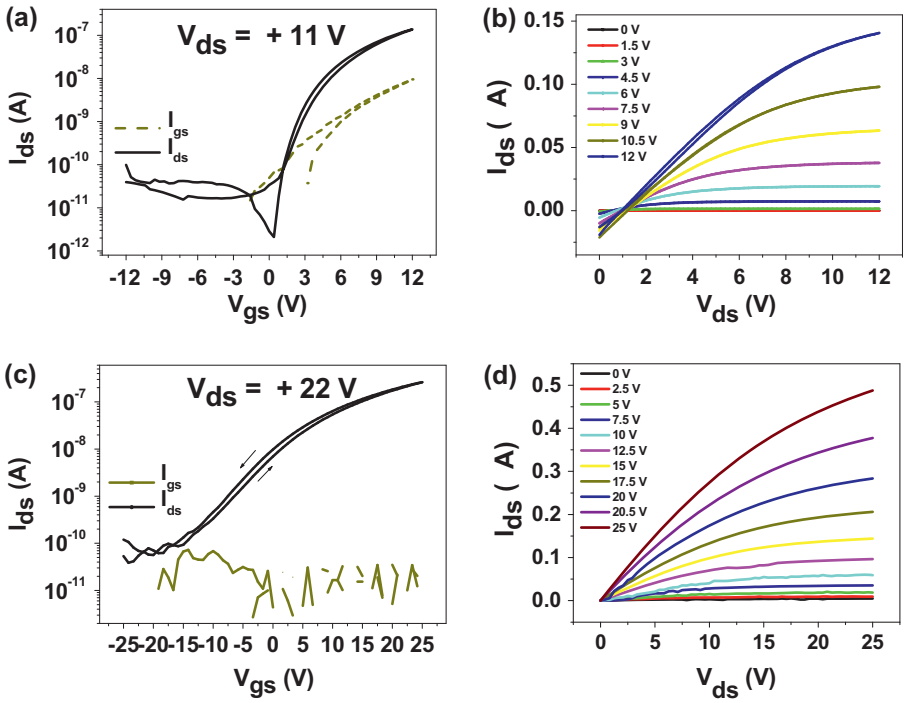

Fig. 5. Transfer and output characteristics of OFETs with (a and b) solution processed lactose gate and C_{60} semiconductor channel; capacitance per unit area, C_{0d} = 6.8 nF/cm^2, field-effect mobility μ = 0.055 cm^2/V s, subthreshold swing S = 2 V/dec and normalized subthreshold swing S_n = 13.6 V nF/cm^2 dec; (c and d) solution processed glucose gate and C_{60} channel. Capacitance: C_{0d} = 2.15 nF/cm^2, field-effect mobility μ = 0.085 cm^2/V s, subthreshold swing S = 6.2 V/dec and normalized subthreshold swing S_n = 13.3 V nF/cm^2 dec.

compounds with a long history in chemistry or biochemistry.

3.1.3.1. Dielectrics from the sugar family (lactose, glucose). Glucose and lactose are two of many other simple small molecules in the sugar family. They are industrially produced on a very large scale, are non-toxic and have excellent film forming properties, when solution processed from water and/or DMSO. The measured dielectric properties of films of glucose and lactose (dielectric constant, breakdown field and loss tangent) are displayed in Table 1. AFM graphs of the spin-cast films are essentially featureless and display a root-mean-square (rms) roughness in the range of 0.5–1 nm. In addition to their excellent film

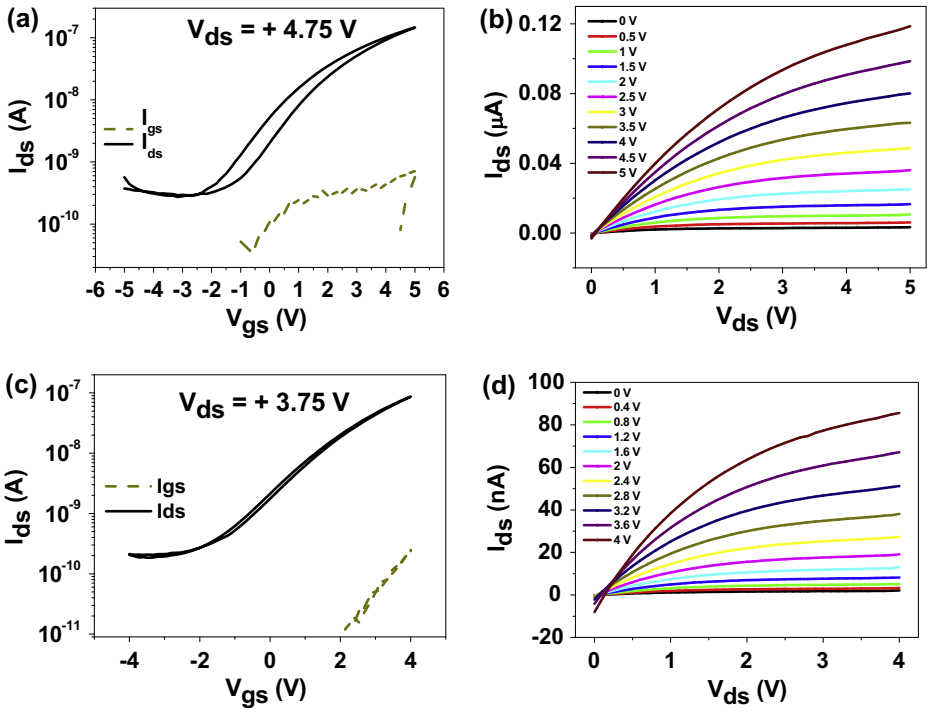

Fig. 6. Transfer and output characteristics of OFETs with (a and b) Guanine gate and C_{60} channel. Capacitance per area, C_{0d} = 9.25 nF/cm^2, field effect mobility μ = 0.12 cm^2/V s, subthreshold swing S = 1.4 V/dec and normalized subthreshold swing S_n = 12.9 V nF/cm^2 dec; (c and d) cytosine gate and C_{60} channel. Capacitance per area, C_{0d} = 13.8 nF/cm^2, field effect mobility μ = 0.09 cm^2/V s, subthreshold swing S = 1.2 V/dec and normalized subthreshold swing S_n = 16.6 V nF/cm^2 dec.

forming properties, the two small molecules are good insulators as shown by the low dielectric losses measured over a wide frequency range (10 kHz to 10 mHz). In addition, glucose and lactose have relatively high breakdown voltages of ~1.5 MV/cm and ~4.5 MV/cm, respectively.

3.1.3.2. Dielectrics from the nucleobase family (adenine, guanine, cytosine and thymine). DNA, recently considered for photonics as well as other electronic applications [20,21], has been employed also as gate dielectric in organic field effect transistors [22–24]. The main drawback of the use of DNA as an organic dielectric is the occurrence of hysteresis in the transfer characteristics of organic field effect transistors [22–24], probably caused by the presence of mobile ionic impurities in the natural DNA dielectric. However, DNA is composed of alternating sequences of four nucleobases (adenine, guanine, cytosine and thymine). Being small molecules, nucleobases are amenable for scrupulous purification and can be vacuum processed in thin films of thicknesses scaled down to 2.5 nm, as it will be shown in this work. Their natural abundance, low cost and low toxicity make these materials interesting candidates for organic electronics. Guanine and adenine, for example, occur naturally in many biological systems. Guanine can be extracted from bat droppings, as well as fish skin and scales [25]. Currently, the cosmetic industry relies on small additions of guanine into shampoo, facial creams and nail enamels to render them an iridescent bluish-white tint. Adenine is also a natural product, freely produced in most of the fruits, whole grains, raw honey and propolis, etc.

The dielectric properties of thin evaporated films of adenine, guanine, cytosine and thymine presented in Table 1 show low losses and featureless dielectric functions over a wide frequency window, ranging from 10 kHz to 10 mHz. The breakdown voltage of the four investigated nucleobases ranges from 0.9 MV/cm to 3.5 MV/cm, which makes these materials suitable for use as gate dielectric in field effect transistors.

AFM surface investigations of thin films of adenine, guanine, cytosine and thymine are presented in Fig. 3a–d. Vacuum processed nucleobase thin films show a tendency for crystallization, with increasing surface roughness starting from guanine (rms ~3 nm) to adenine (rms ~14.5 nm), cytosine (rms ~24 nm) and thymine (rms ~65 nm). The investigation of the fifth nucleobase, uracil, proved difficult because of its extreme tendency for crystallization. With this respect, thin films of uracil displayed pin-holes, whereas thicker films had a roughness with root-mean-square values greater than 100 nm.

An example of the X-ray diffraction investigation for adenine in the forms of precursor powder and 1 μm thick evaporated film on aluminium coated glass slide is presented in Fig. 4. The crystallographic planes are conforming to the pattern available in the standard card (JSPDS no. 24-1654) of the instrument. As shown in Fig. 4, adenine thin films display crystallinity and preferred orientation compared to precursor powder, as it is suggested by strong

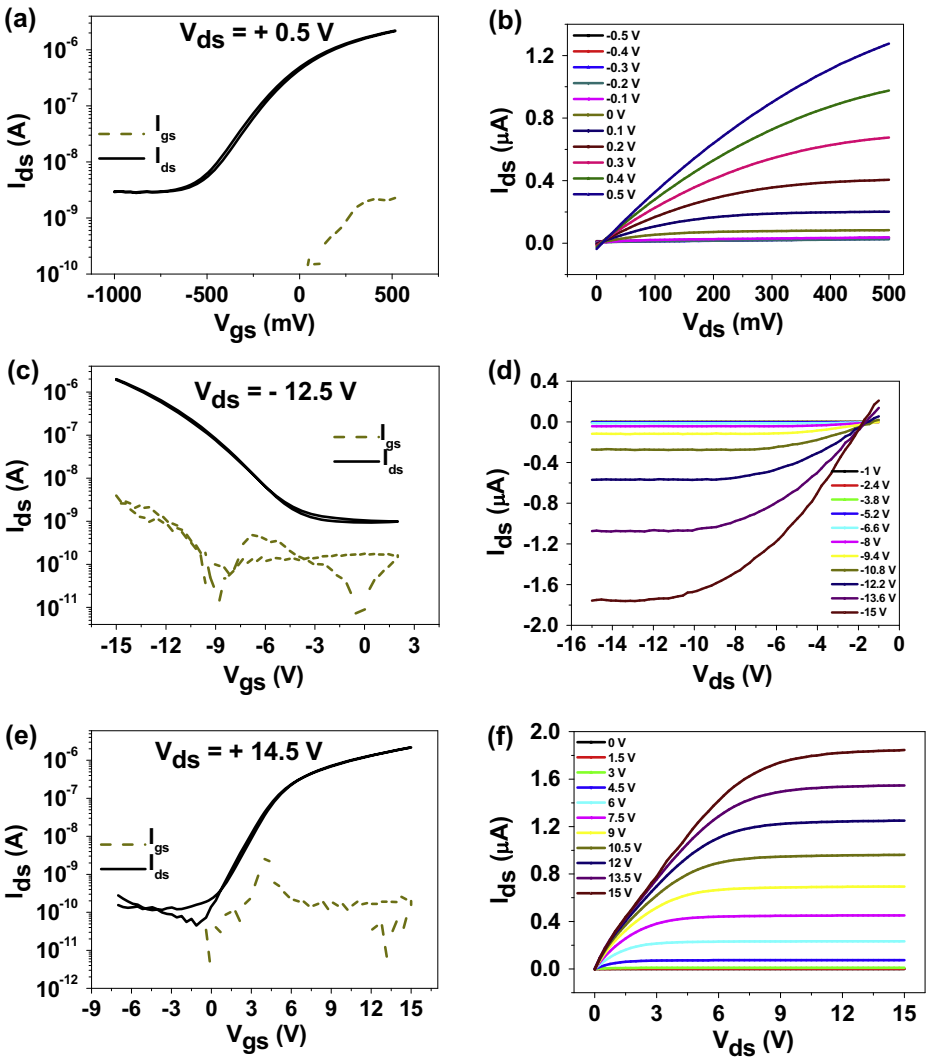

Fig. 7. Transfer and output characteristics of OFETs with (a and b) an AlOx–adenine gate and hot-wall epitaxial deposited C_{60} channel. Capacitance per area, C_{0d} = 99 nF/cm^2, field effect mobility μ = 5.5 cm^2/V s, subthreshold swing S = 0.25 V/dec and normalized subthreshold swing S_n = 24.7 V nF/cm^2 dec; (c and d) AlOx–adenine gate and pentacene channel. Capacitance per area, C_{0d} = 19.6 nF/cm^2, field effect mobility μ = 0.35 cm^2/V s, subthreshold swing S = 2.5 V/dec and normalized subthreshold swing S_n = 49 V nF/cm^2 dec; (e and f) AlOx–thymine gate and C_{60} channel. Capacitance per area, C_{0d} = 23.6 nF/cm^2, field effect mobility μ = 0.5 cm^2/V s, subthreshold swing S = 2 V/dec and normalized subthreshold swing S_n = 47.2 V nF/cm^2 dec.

domination of the peak centered at $2\theta = 29.42°$. Nevertheless, more work is required to understand the mechanisms of film growth in nucleobase materials.

3.1.3.3. Natural dielectrics-based OFETs. Organic field effect transistors with solution processed thin film gate dielectrics of glucose (in deionized water) and lactose (in DMSO) and vacuum processed fullerene, C_{60}, as semiconductor are presented in Fig. 5a–d. The transfer and output characteristics display a minimal hysteresis, which being counterclockwise can be attributed to the finite presence of mobile ionic impurities in the two dielectric films [26,27]. The field effect mobility of the organic semiconductor, C_{60}, deposited on lactose and glucose dielectrics was in the range of 5.5×10^{-2} to 8.5×10^{-2} cm^2/V s, and the capacitances per area of the two dielectrics employed were 6.8 nF/cm^2 for lactose and 2.15 nF/cm^2 for glucose dielectric. The method used to calculate the field effect mobility was reported in Ref. [28]. The measured subthreshold swing values of the fullerene were 2 V/dec for the OFET with a lactose dielectric and 6.2 V/dec for the glucose dielectric device. As described in the review article (Ref. [28]), the normalized subthreshold swing (the product of the dielectric capacitance per area and the subthreshold swing) is a more useful metric of comparison of semiconductor films deposited on different dielectrics or on dielectrics of various thicknesses. The values of the normalized subthreshold swing (S_n) for fullerene grown on lactose and glucose dielectrics are 13.6 V nF/cm^2 dec and 13.3 V nF/cm^2 dec, respectively. The saturated electron mobility of C_{60} deposited on solution processed small molecules in the sugar family is somewhat lower compared to

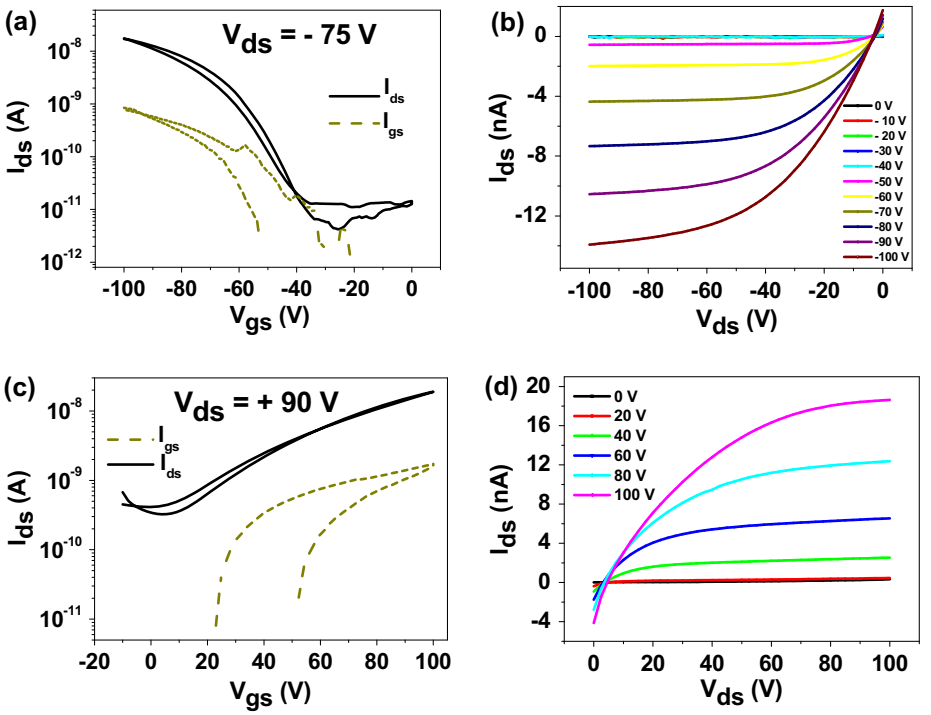

Fig. 8. (a and b) Transfer and output characteristics of organic field effect transistors with glucose and caffeine gate and solution processed beta-carotene (from chloroform) channel. Capacitance per unit area, C_{0d} = 1.9 nF/cm^2, field effect mobility $\mu = 4 \times 10^{-4}$ cm^2/V s, subthreshold swing S = 11 V/dec and normalized subthreshold swing S_n = 21 V nF/cm^2 dec; (c and d) transfer and output characteristics of organic field effect transistors with poly(vinyl alcohol) (PVA) gate and vacuum processed indigo organic semiconductor channel. Capacitance per unit area C_{0d} = 3.1 nF/cm^2, field effect mobility $\mu = 1.5 \times 10^{-4}$ cm^2/V s, subthreshold swing S = 34 V/dec and normalized subthreshold swing S_n = 105.4 V nF/cm^2 dec.

values reported elsewhere for fullerene semiconductors [29,30]. This lower electron mobility may be explained by the finite presence of moisture in the two dielectric films.

Vacuum processed organic dielectrics on the other hand allow fabrication of OFETs operating at low voltages [31,32]. Organic field effect transistors with vacuum processed guanine and cytosine gate and C_{60} channel are displayed in Fig. 6a–d, for transistors operating at voltages as low as 4–5 V. The measured saturated field effect mobility of C_{60} vacuum processed on cytosine and guanine dielectrics was 0.09 cm^2/V s and 0.12 cm^2/V s, respectively; the dielectric capacitance per area was 9.25 nF/cm^2 for guanine and 13.8 nF/cm^2 for cytosine. The measured subthreshold swing and normalized subthreshold swing values for the structure built on guanine were S = 1.4 V/dec and S_n = 12.9 V nF/cm^2 dec, respectively; the respective values for the fullerene film grown on cytosine were 1.2 V/dec and 16.6 V nF/cm^2 dec.

Higher operating currents as well as higher saturated field effect mobilities are possible when organic and inorganic dielectrics (i.e., anodized aluminium) are combined in hybrid structures [33]. Transistors with such hybrid gate structures are shown in Fig. 7a–f where thin layers of adenine (a–d) and thymine (e and f) were evaporated on aluminium oxide electrochemically grown in citric acid to produce high performance gate dielectrics. The calculated field effect mobility of transistors with hot-wall epitaxially deposited C_{60} and the hybrid gate (capacitance per area, C_{0d} = 99 nF/cm^2) listed in Fig. 7a and b was 5.5 cm^2/V s, with a calculated subthreshold swing of 0.25 V/dec and a normalized subthreshold swing of 24.7 V nF/cm^2 dec. The operating voltage of the respective device was as low as 500 mV. It is important to note that all the vacuum processed nucleobase dielectrics are also amenable to work in combination with p-type semiconductors (e.g., pentacene); an example of such an OFET is shown in Fig. 7c and d. In the latter case, 150 nm adenine was vacuum processed on 55 nm aluminium oxide (AlOx with a capacitance per unit area, C_{0d} = 140 nF/cm^2). The field effect mobility in the saturation regime of pentacene was 0.35 cm^2/V s, subthreshold swing S = 2.5 V/dec and normalized subthreshold swing S_n = 49 V nF/cm^2 dec, for a capacitance per unit area of the combined dielectric C_{0d} = 19.6 nF/cm^2. Despite its relatively low dielectric constant (i.e., 2.4 as shown in Table 1) and its high tendency of crystallization that renders films of high roughness (Fig. 3d), thymine passivates aluminium oxide very well. In the transistor shown in Fig. 7e and f, a 75 nm thick thymine film was vacuum processed on top of anodized aluminium, and vacuum processed C_{60} was used for the organic semiconductor. The respective OFET was hysteresis free in both transfer and output characteristics, while displaying a C_{60} mobility of 0.5 cm^2/V s, a subthreshold swing of 2 V/dec and a normalized subthreshold swing of 47.2 V nF/cm^2 dec, for a capacitance per unit area of

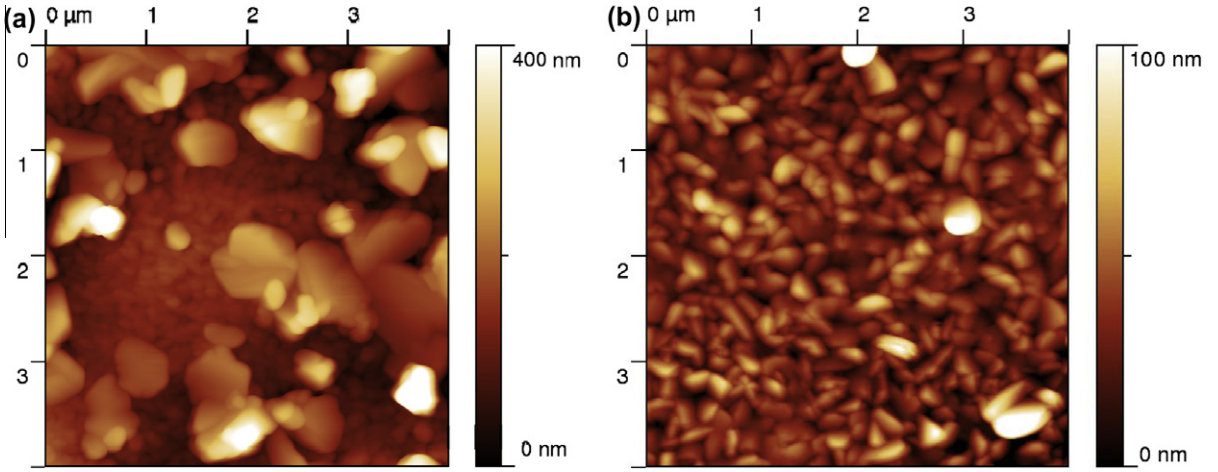

Fig. 9. AFM of natural semiconductor thin films (a) solution processed beta-carotene in chloroform on glucose + caffeine dielectric. Average roughness, rms = ~19 nm, measured in the shallow region of small grains; (b) vacuum processed indigo on poly(vinyl alcohol) dielectric. Average roughness, rms = ~17 nm. Measurements were recorded in the channel of OFETs devices displayed in Fig. 8.

23.6 nF/cm^2 of the hybrid gate dielectric. Surprisingly, the extreme roughness of vacuum processed small molecule dielectrics described here (adenine, cytosine and thymine), as well as in our previous work (melamine), Ref. [32]), was not a deterrent in generating hysteresis-free devices. The only exception was guanine. Interestingly, guanine formed smoother films when compared with adenine, cytosine, thymine or even melamine. We presume that the intimate binding that occurs at the interface between the dielectric and the semiconductor layers generates the occurrence of hysteris-free behavior in various OFETs. Further investigations at the molecular level are required to elucidate the mechanism of hysteresis formation in transistors with vacuum processed small molecules dielectrics and semiconductors of high purity.

3.1.4. Semiconductors for sustainable electronics

Encouraged by the performance of our transistors based on vacuum processible sustainable dielectrics and traditional workhorse semiconductors we went on identifying organic semiconductors, which may be viewed sustainable. A short, and by no means comprehensive list of such semiconductors, includes natural (indigo, beta-carotene), nature-inspired (anthraquinone vat dyes), and common commodity materials (perylene diimide). All these semiconductors have in common large scale production, ease of synthesis and low price, coupled with low toxicity, biodegradability and wide social acceptance [34].

3.1.4.1. Natural semiconductors for organic field effect transistors. Beta-carotene is a material with an old history. It was first reported by the German chemist Hernan Wachenroder, who in 1831 extracted red crystals from carrot roots, that he ultimately called "carotene" [35]. Until now, applications of beta-carotene and related products have been limited to the medical/biomedical field, as anti-aging and heart-disease prevention drug [36]. However, the optical, non-linear optical, fluorescence and even semiconducting properties of beta-carotene have been recently investigated by various groups [37–41].

Indigo is a naturally occurring compound, which has historically been extracted from plants in the *Indigofera* genus. Nowadays the synthetic production of indigo (initiated by Adolf Baeyer in 1882) has made possible high scale production of blue cotton yarn cloths with the main application of the compound remaining in the blue jeans industry [42]. Although the electronic and energetic levels of indigo were recently investigated, no report of using indigo as organic semiconductor in field effect devices appeared so far [43,44].

Organic field effect transistors with solution processed p-type beta-carotene and vacuum processed n-type indigo as organic semiconductors are presented in Fig. 8a–d. The organic dielectrics are glucose with small additions of caffeine in a and b and poly(vinyl alcohol) in c and d. The AFM investigations of the two dielectrics (glucose + caffeine and PVA) revealed featureless surfaces with rms ~1.5 nm and ~1 nm, respectively. The calculated field effect mobilities of the two natural semiconductors were 4×10^{-4} cm^2/V s for beta-carotene and 1.5×10^{-4} cm^2/V s for indigo for capacitances per area C_{0d} = 1.9 nF/cm^2 for glucose and caffeine dielectric and C_{0d} = 3.1 nF/cm^2 for PVA dielectric. The calculated subthreshold swing and normalized subthreshold swing values of the two natural semiconductors were 11 V/dec and 21 V nF/cm^2 dec for beta-carotene; 34 V/dec and 105.4 V nF/cm^2 dec for indigo, respectively. Higher performance may be achieved by optimizing transistor design and fabrication, corroborated with scrupulous purification of the chemicals.

AFM measurements of beta-carotene and indigo, performed in the channel of the measured devices shown in Fig. 8, are depicted in Fig. 9. The top surface of beta-carotene revealed small grains with a diameter in the range of 60–150 nm and an average size of 105 nm. However, in all the locations investigated (like for example the region shown in Fig. 9a), large grains were also visible, with diameters scaling up to 900 nm. The average roughness, rms, of

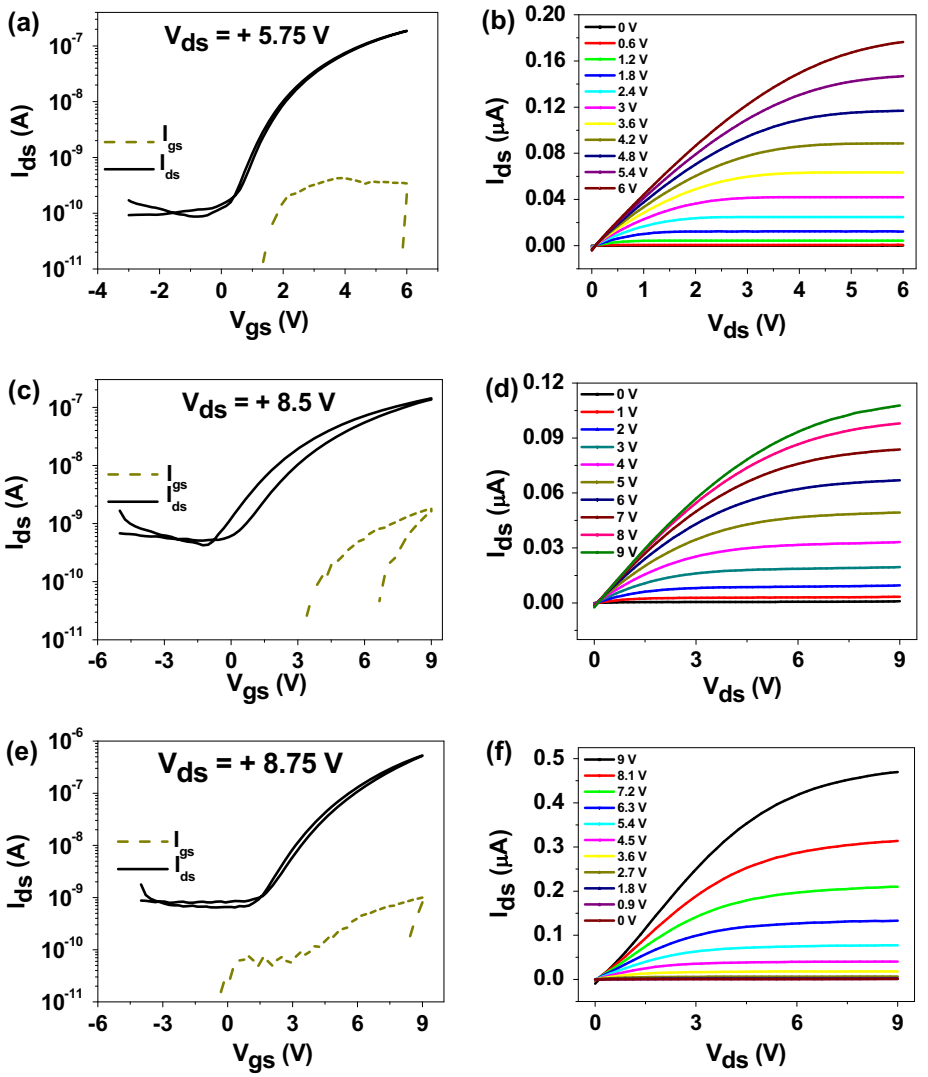

Fig. 10. (a and b) Transfer and output characteristics of organic field effect transistors with AlOx–guanine–adenine gate and perylene diimide channel. Capacitance per unit area C_{0d} = 81.6 nF/cm^2, field effect mobility μ = 0.016 cm^2/V s, subthreshold swing S = 1.5 V/dec and normalized subthreshold swing S_n = 122.4 V nF/cm^2 dec; (c and d) OFET with AlOx–guanine–adenine gate dielectric and indanthrene yellow G channel. Capacitance per unit area C_{0d} = 81.6 nF/cm^2, field effect mobility μ = 0.01 cm^2/V s, subthreshold swing S = 2.4 V/dec and normalized subthreshold swing S_n = 196 V nF/cm^2 dec; (e and f) OFET with AlOx–guanine–adenine gate and indanthrene brilliant orange RF channel. Capacitance per unit area C_{0d} = 81.6 nF/cm^2, field effect mobility $\mu = 1.9 \times 10^{-3}$ cm^2/V s, subthreshold swing S = 1.9 V/dec and normalized subthreshold swing S_n = 155 V nF/cm^2 dec.

beta-carotene measured in the shallow regions of small grains was ~19 nm. Indigo on the other hand displayed a more uniform surface in terms of grain size and distribution. Most of the indigo grains were elongated in shape and had a diameter in the range of 150–550 nm, with an average of 250 nm.

3.1.4.2. Nature-inspired semiconductors for organic field effect transistors. Indanthrene yellow G and indanthrene brilliant orange RF (derivatives of natural occurring anthraquinone-a well known laxative drug [45]) are both used widely in textile industry as vat dyes for fabrics coloring as well as in electronics industry as color filter in image forming applications [46,47]. However, their low toxicity [48], biodegradability [49,50] and ability to metabolize [51] has led to these compounds being proposed for coloring sausage skin in food industry [52,53].

Although having a synthetic route that can be distantly considered as starting from natural naphthalene, perylene diimide is not a truly nature-inspired compound [54]. Nevertheless, we want to list it here as environmentally sustainable material. The chemical inertness of perylene diimides is a prerequisite for their very low acute toxicity that opens up numerous applications in cosmetic industry as red pigments for hair colorants, nail enamels and lipsticks. Nowadays many perylene dyes are produced on an industrial scale and commercially available under trade names such as Red Dye 190 or Lumogen®F [55]. Perylene

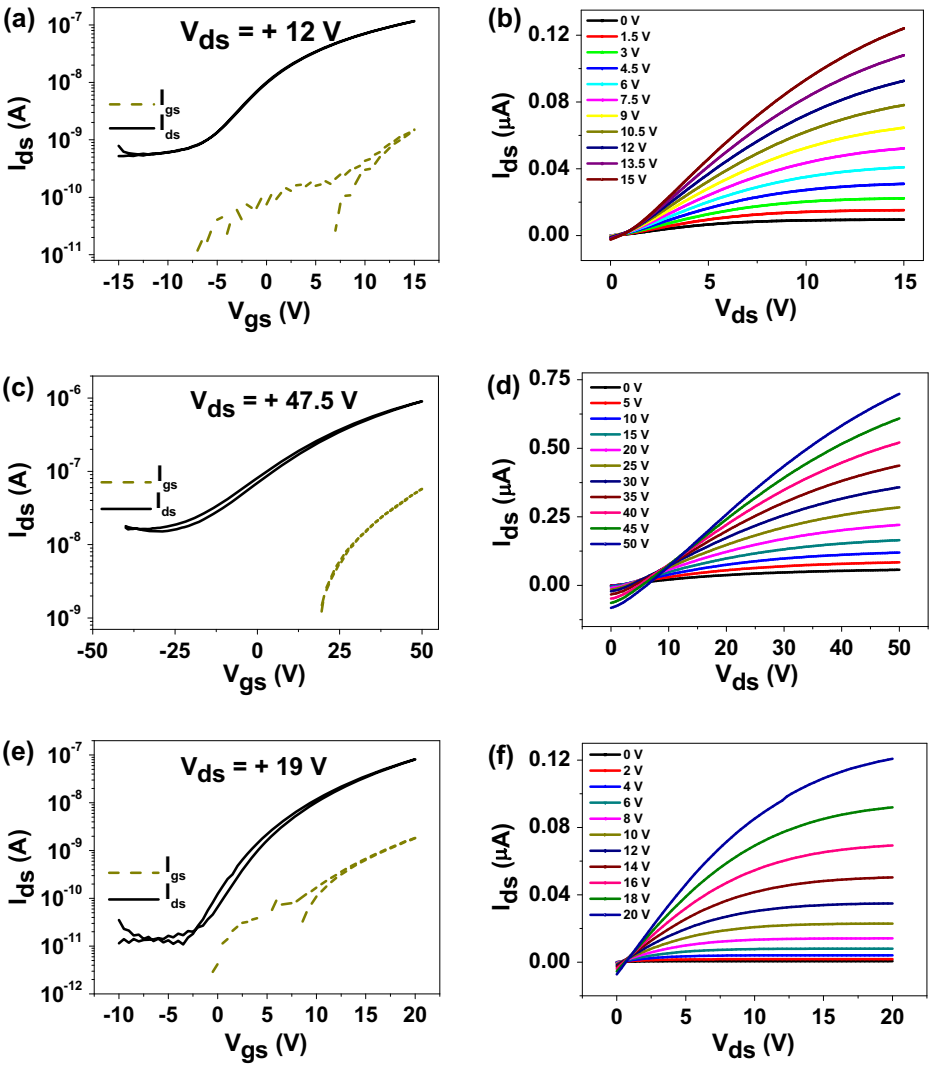

Fig. 11. (a and b) Transfer and output characteristics of an OFET on a biodegradable Ecoflex substrate; the roughness of the Ecoflex foil is reduced with a smoothing layer of aurin. Adenine forms the dielectric and perylene diimide is the semiconductor; C_{0d} = 3.1 nF/cm^2, μ = 0.01 cm^2/V s, S = 3.6 V/dec and S_n = 11.1 V nF/cm^2 dec; (c and d) Transfer and output characteristics of biocompatible and biodegradable OFETs on caramelized glucose substrates; guanine and adenine form the gate dielectric and indanthrene yellow G is the organic semiconductor. C_{0d} = 5.6 nF/cm^2, $\mu = 8 \times 10^{-3}$ cm^2/V s; (e and f) Transfer and output characteristics of an edible OFET on a hard gelatine capsule substrate; adenine and guanine form the gate dielectric and perylene diimide is the organic semiconductor; C_{0d} = 5.1 nF/cm^2, μ = 0.02 cm^2/V s, S = 3.1 V/dec and S_n = 15.8 V nF/cm^2 dec. Electrodes are aluminium (a and b) and gold (c and f).

diimides are also known as good n-type organic semiconductors widely used in organic solar cells [56].

3.1.4.3. OFETs with sustainable semiconductors on glass substrates. After having shown a large number of potential low cost organic semiconductors, we now proceed by presenting field effect transistors of these materials on glass substrates. Fig. 10a–f display transistors formed with indanthrene yellow G and indanthrene brilliant orange RF, as well as perylene diimide. Thin layers of these organic semiconductors have been evaporated on hybrid inorganic–organic gate dielectrics (55 nm aluminium oxide and thin alternating layers of guanine (2.5 nm) and adenine (15 nm), with a total capacitance per area of 81.6 nF/cm^2. The reason for using different organic dielectric layers was the intention to produce dense and pinhole free layers at lower thickness than using one organic dielectric layer alone. The saturated field effect mobilities of perylene diimide and indanthrene yellow G were ~0.015 cm^2/V s, indanthrene brilliant orange RF had a mobility of $\sim 2 \times 10^{-3}$ cm^2/V s. The mobilities of these materials of low cost and large scale availability are on par with mobilities reported recently for synthetic poly(p-phenylene vinylene) or for ambipolar polyselenophene organic semiconductors [57,58]. The calculated subthreshold swing values for the investigated nature-inspired semiconductors fell in a close range: 1.5 V/dec for perylene diimide, 2.4 V/dec for indanthrene yellow G and 1.9 V/dec for indanthrene brilliant orange RF. The OFET devices in Fig. 10 have been fabricated using identical

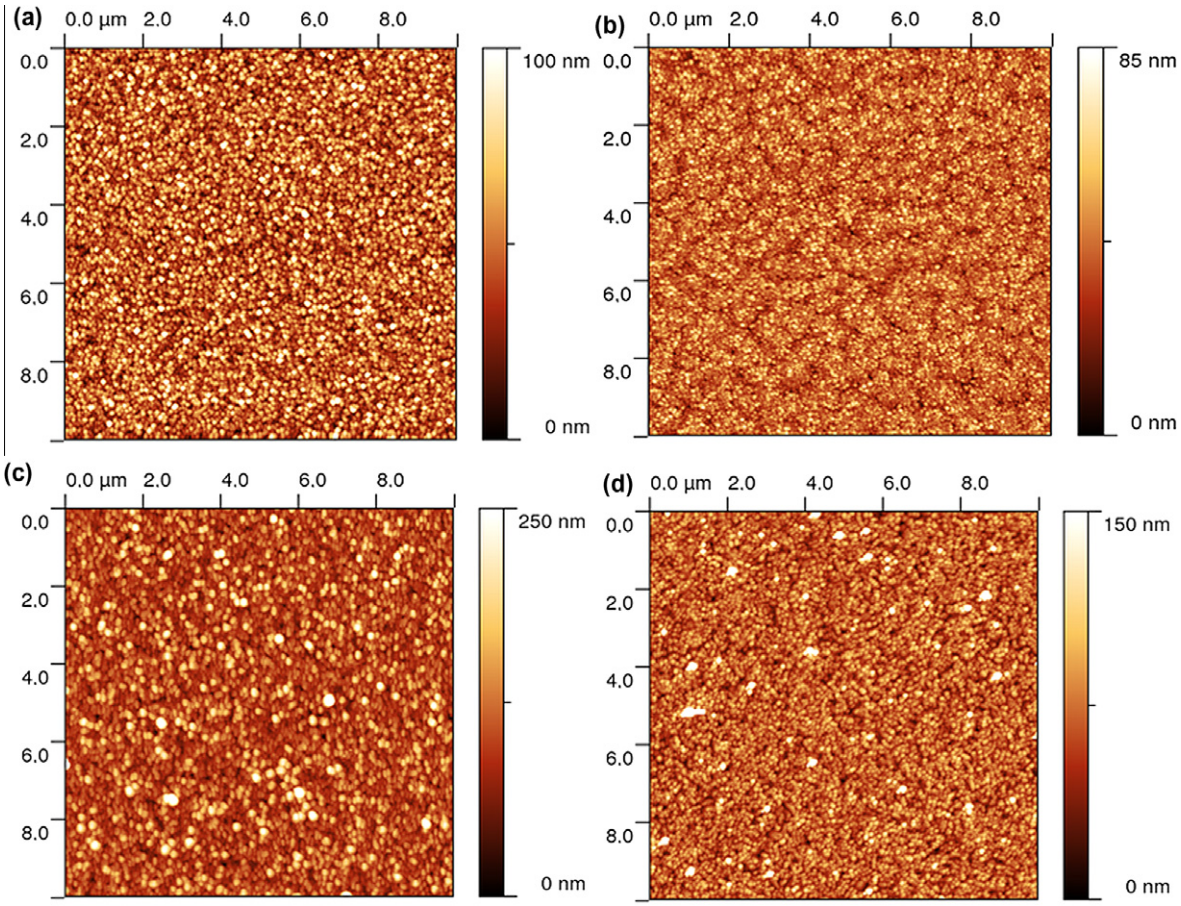

Fig. 12. AFM of various nature-inspired semiconductors employed in this work. Measurements were performed in the channel of the OFET devices shown here; (a) perylene diimide displayed in Fig. 10a and b; average surface roughness, rms ~17.5 nm (b) indanthrene yellow G displayed in Fig. 10c and d; average surface roughness, rms ~10.5 nm; (c) indanthrene brilliant orange RF displayed in Fig. 10e and f; average surface roughness, rms ~34 nm; (d) indanthrene yellow G displayed in Fig. 11c and d; average surface roughness, rms ~22 nm.

dielectric material (a hybrid inorganic–organic layer, having a capacitance per area $C_{0d} = 81.6$ nF/cm^2). The much lower values of the subthreshold swing recorded for the nature-inspired semiconductors displayed in Fig. 10, compared to the respective values of the natural semiconductors (beta-carotene and indigo) shown in Fig. 8, are not a surprise, since the subthreshold swing is highly dependent on both the semiconductor mobility and the dielectric capacitance per unit area [28]. It also shows the need for more detailed investigations on naturally occurring organic semiconductors.

3.1.4.4. OFETs with sustainable semiconductors on biodegradable and biocompatible substrates. Having been able to demonstrate transistors with sustainable gate dielectrics and semiconductors, we have tried to fabricate such devices also on natural caramelized glucose, biodegradable Ecoflex and biocompatible hard gelatine capsule substrates. OFET transfer and output characteristics for such devices are presented in Fig. 11a–f where small molecule-vacuum processed nucleobases (adenine in Fig. 11a and b or alternating layers of adenine and guanine in Fig. 11c–f) have been used for gate dielectrics; perylene diimide and indanthrene yellow G have been used for organic semiconductors. The on–off ratio of transistors fabricated with these sustainable materials ranged from 10^2 to 10^5, whereas the mobility of organic semiconductor was 8×10^{-3} for indanthrene yellow G and $\sim 1 \times 10^{-2}$ to 2×10^{-2} cm^2/V s for perylene diimide. The calculated subthreshold swing values of the perylene diimide semiconductor employed in Fig. 11a, b e, and f were 3.6 V/dec and 3.1 V/dec, respectively; the normalized subthreshold swing values were 11.1 V nF/cm^2 and 15.8 V nF/cm^2. The recorded values of normalized subthreshold swing show a good correlation of its dependence on mobility and dielectric capacitance (i.e., 3.1 nF/cm^2 for adenine dielectric in Fig. 11a and b and 5.1 nF/cm^2 for guanine and adenine in Fig. 11e and f).

AFM investigations of the nature-inspired semiconductors employed here (perylene diimide, indanthrene yellow G and indanthrene brilliant orange RF), performed in the channel of the measured devices presented in Figs. 10a–f and 11c and d are displayed in Fig. 12. The grain size of uniformly distributed perylene diimide (Fig. 12a) is in the range of 80–160 nm, with an average size of 125 nm. Indanthrene yellow G and indanthrene brilliant orange

RF form also grains with a uniform distribution (Figs. 12b and c, respectively). The indanthrene yellow G grain size spans the range from 60 nm to 130 nm, with an average size of 90 nm, whereas the indanthrene brilliant orange RF grains are somewhat larger, ranging from 100 nm to 300 nm, with an average grain size of 200 nm. Fig. 12d) shows the surface of indanthrene yellow G deposited on alternating layers of guanine and adenine on caramelized glucose substrate, the OFET device displayed in Fig. 11c and d). The surface of the latter material shows a uniform grain distribution, with grain diameters from 70 nm to 190 nm, and an average grain size of 125 nm.

It is interesting to observe that the grain sizes of the two semiconductor materials displaying on par mobilities in Fig. 10 (perylene diimide and indanthrene yellow G) were also comparable, whereas materials that rendered films of larger grain sizes (indanthrene brilliant orange RF, beta-carotene and indigo) recorded significantly lower mobilities. Moreover the subthreshold swing of various OFET devices was in the same range for devices showing similar semiconductor mobilities and having dielectrics of comparable capacitances per unit area.

4. Conclusions

In this work, we have initiated a search on low cost materials that may find applications in sustainable biodegradable and biocompatible organic field effect transistors. We have shown that different gate dielectrics from sugars and nucleobases can be used in field effect transistors based on workhorse p and n-type organic semiconductors such as C_{60} and pentacene. Large volume prepared dyes used in textiles, cosmetics or food industry have shown surprisingly large mobilities in field effect devices on glass and biodegradable/biocompatible substrates. Transistors on degradable substrates, such as Ecoflex, gelatine and caramelized sugars, could be operated with voltages around 15–20 V and source drain currents of 0.15 μA. We hope to have initiated with this work an intense search for new materials for organic electronics, to make the vision of sustainability in plastics electronics coming closer to reality.

ABSTRACT

The influence of structural ordering in a blend of rrP3HT polymer and C_{60} molecules has been investigated with first principles DFT calculations. An increasing packing density of rrP3HT chains and C_{60} component favors an increasing open-circuit voltage (V_{oc}), leaving the absorption properties of rrP3HT nearly intact. In contrast, an increasing size of π-crystal domains of rrP3HT within the blend tends to strongly enhance the magnitude of π-electron delocalization, leading to a decrease of both the rrP3HT band gap and V_{oc}.

1. Introduction

The development of clean, renewable and sustainable energy sources considers multiple technologies, including photovoltaic cells, with the aim of replacing more traditional energy sources. A large-scale implantation of photovoltaic cells that would sustain the actual energetic demand is strongly hindered by their manufacturing cost [1]. The use of organic semiconductors to manufacture photovoltaic devices with large-scale and low-cost printing techniques associated with the facility to process polymer could overcome the cost limitation of traditional inorganic photovoltaic cells [2–5]. However, the power conversion efficiency of organic photovoltaic cells has to reach a minimal 10% target in order for such devices to be economically competitive [6,7]. State-of-the-art organic photovoltaic cells, presently achieving power conversion efficiencies up to 7.9% [8,9], rely on a bulk heterojunction (BHJ) made of π-conjugated polymer acting as electron donor and fullerene derivative acting as electron acceptor [10–12]. Therefore, before attaining the 10% target with high-efficiency BHJ organic photovoltaic cells, more experimental and theoretical efforts are needed to provide a comprehensive representation of the electronic properties of the blend at the donor–acceptor interface.

The present work is a theoretical investigation of the electronic properties of an important BHJ model system in which we focus on the influence of structural order at the donor–acceptor interface. In the investigated BHJ models, regioregular head-to-tail poly(3-hexylthiophene-2,5-diyl) (rrP3HT) polymer is used as electron donor and buckminsterfullerene (C_{60}) molecule as electron acceptor. The photophysical interest for such rrP3HT/C_{60} blend is mainly motivated by an ultrafast electron transfer that occurs between the conjugated polymer and the C_{60} moiety [2,13,14]. Due to its significant solubility [15], [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM) molecule is more often used in high-efficiency organic photovoltaic cells [4]. Nevertheless, one may assume that the physical characteristics of a BHJ containing C_{60} are similar to one with PCBM because the side chain attached to C_{60} in PCBM does not actively participate in the electron transfer process, and

hence does not modify the electronic properties of frontier orbitals. Experimentally, an improved solubility translates into a better film morphology which in turn leads to an improved efficiency of the photovoltaic cell [14]. However, an appropriate use of recent fabrication techniques can improve the morphology of BHJ made of C_{60} without requiring the use of PCBM [16]. Finally, considering the high electron mobility of C_{60} networks ($\sim 1\ cm^2/Vs$) [17] over PCBM networks ($\sim 10^{-3}\ cm^2/Vs$) [18], BHJs based on C_{60} would lead to organic photovoltaic cells with higher efficiency.

Concerning the rrP3HT polymer, it is composed of a rigid π-conjugated backbone combined with alkyl side chains providing the required solubility to polythiophene for the processing steps used to build the devices [19]. A high degree of regioregularity in the polymer favors the self-assembly of the rrP3HT chains into microcrystalline domains through a π-stacking of the polythiophene backbones [20,21]. This self-assembly leads to an highly anisotropic mobility for the two-dimensional charge transport observed in high-performance organic field-effect transistors. The charge carrier mobility reaches $0.1\ cm^2/Vs$ for transport in the plane containing the π-conjugated backbone and π-stacked directions, while a mobility more than a 100 times smaller is observed for transport in the plane containing the π-conjugated backbone and alkyl side chains directions [22,23]. The influence of ordering on the photophysical properties of P3HT have been extensively studied at both theoretical [24] and experimental [25] level. The existence of structural ordering in rrP3HT solution is usually associated to the formation of H-aggregate nanostructures that lead to the emergence of new absorption bands that are significantly redshifted with respect to the main absorption peak observed in diluted and disordered solution [25]. From these observations, we may then anticipate that well-ordered rrP3HT polymer have a higher band dispersion and a smaller optical band gap than the disordered phase.

In this paper, we first briefly describe the computational details considered in the study of organic BHJ. These BHJs were constructed by varying the domain size of the rrP3HT π-crystal region in the rrP3HT/C_{60} blend. Then, we discuss the geometry optimization of the BHJs, analyze their electronic properties and compare the results with the electronic properties previously obtained for pure rrP3HT π-crystals [26]. Finally, we examine the influence of interface between domains of rrP3HT and C_{60} on the electronic properties of the BHJs.

2. Computational details

We have performed first principles density functional theory (DFT) computations with the SIESTA software package [27] to determine the structural and electronic properties of different rrP3HT/C_{60} blends. The DFT calculations were mostly performed within the local density approximation (LDA), which still remain an adequate approach to determine accurate equilibrium distances in periodic π-stacked systems even though it does not formally consider dispersion interactions [26,28]. In fact, computations performed on graphite involving π—π interactions show a small underestimation of the interlayer separation with LDA compared to a large overestimation with the generalized gradient approximation (GGA) [29]. Our interpretation based on the comparison of relative energies and electronic properties of different BHJs drastically reduces the importance of artifacts related to well-known shortcomings of LDA, such as the underestimation of the band gap, on the general conclusions of this work. Nevertheless, we also tested the approach of Dion [30,31] (vdW-DF) to evaluate the magnitude of van der Waals interactions for the rrP3HT/C_{60} blend.

All computations were performed using periodic boundary conditions in conjunction with norm-conserving Troullier–Martins pseudopotentials and double-ζ polarized linear combination of numerical atomic orbitals basis sets. The pseudopotentials generated with the ATOM software [27] for the different atomic species reproduce the all-electron eigenvalues and excitation energies of multiple atomic configurations within a 1 mRy error. The geometry of the BHJs studied were optimized using the DFT-LDA calculated forces and stresses within a quasi-Newton method updating the Hessian matrix with a Broyden–Fletcher–Goldfarb–Shanno (BFGS) procedure. The geometry optimizations were stopped when the maximum force in the unit cell was less than 7.5 meV/Å (20 meV/Å for the largest systems) and the total energy variation between two iterations was less than 0.5 meV.

3. Results and discussion

3.1. Structural properties of well-organized blend

In experimental rrP3HT/C_{60} BHJ, suitable electronic coupling exists between C_{60} and rrP3HT frontier states to establish charge transfer across the interface. Considering that the rrP3HT crystal frontier states are centered on the π-conjugated backbones while the alkyl side chains states are further away from the Fermi level, we built the BHJ by placing C_{60} between rrP3HT backbones in the π-stacked direction in order to promote electronic donor–acceptor coupling. As shown in Fig. 1, the BHJ unit cell used to model an amorphous disordered blend is composed by one C_{60} and one rrP3HT chain containing four hexylthiophene monomers. We define the three orthogonal vectors **a**, **b** and **c** lying, respectively, in the alkyl side chains, the π-stacked and the π-conjugated backbone directions. The unit cell vectors **a** and **c** are fixed at the optimized values for a pure rrP3HT π-crystal [26], that are $|\mathbf{a}| = 15.82$ Å and $|\mathbf{c}| = 15.66$ Å. The dimension of $|\mathbf{b}|$, as well as the orientation and relative position of the C_{60} along the rrP3HT chain were fully optimized. In order to appropriately describe the C_{60}—rrP3HT interface, the geometry optimization was performed for the four different configurations illustrated in Fig. 1 as a function of the distance d ($d = |\mathbf{b}|/2$) separating the rrP3HT chain from the center of the C_{60} molecule. Configuration I, the most stable configuration found at DFT-LDA level, gives a cohesive energy ($E_{rrP3HT} + E_{C_{60}} - E_{BHJ}$) of 1.87 eV. This value compares well to the cohesive energy 1.55–1.99 eV reported for solid C_{60}

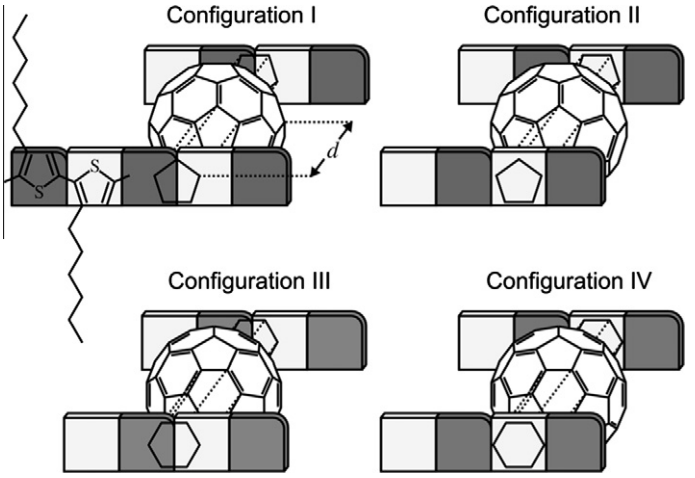

Fig. 1. Representation of the four rrP3HT/C_{60} BHJ configurations studied.

Table 1
Equilibrium distances and relative stabilities of optimized BHJ configurations with LDA and vdW-DF.

	LDA		vdW-DF	
	d (Å)	ΔE (meV)	d (Å)	ΔE (meV)
Conf. I	6.35	0	6.68	0
Conf. II	6.43	4	6.71	−109
Conf. III	6.35	24	6.56	57
Conf. IV	6.47	75	6.63	−12

[32], but is significantly lower than the cohesive energy of 3.50 eV previously calculated for bulk rrP3HT with a DFT-LDA approach [26]. This result indicates that the formation of ordered rrP3HT/C_{60} BHJ is favorable even though the interactions between component are relatively weak.

As reported in Table 1, the energy differences (ΔE) between the four configurations considered with LDA and vdw-DF are within nearly 100 meV, indicating that C_{60} is almost free to rotate and to move along the rrP3HT chain in the backbone direction. The LDA method seems to favor configurations for which a pentagon of C_{60} is facing the rrP3HT chain, while the vdw-DF method favors configurations where C_{60} is simply aligned with an hexylthiophene ring. The energy difference between configurations where pentagon or hexagon of C_{60} is facing the hexylthiophene chain is similar to the calculated value obtained by Kanai and Grossman with a similar DFT-LDA approach [33].

The equilibrium distances given in Table 1 also differ for both computational approximations, the vdw-DF giving larger separation between rrP3HT chain and C_{60} than LDA. The periodicity of the BHJ crystal given by the value of 2d varies from 12.70 to 13.42 Å for both LDA and vdW-DF, which is shorter than the summation of individual bulk distances for C_{60} (10.02 Å) [34] and P3HT (3.42–3.60 Å) [26,35–38]. This result is fully consistent with a previous work on rrP3HT/C_{60} system [33]. As mentioned above, these dimensions are coherent with rather weak interactions between the rrP3HT and C_{60} in the BHJ crystal. In addition, considering the very good agreement between LDA and experimental values we previously obtained for the equilibrium distance between rrP3HT chains in a rrP3HT crystal [26], and including the fact that this not well tested vdw-DF approach tends to overestimate equilibrium distances [30,31], we believe that LDA results remain the most reliable.[1] Therefore, configuration I, the LDA most stable configuration, will be used in further calculations.

It is well accepted experimentally that annealing of a rrP3HT/C_{60} blend leads to the crystallization of domains made of pure polymeric or molecular phase [39–42]. Even with this partial phase segregation, the overall physical and electrical characteristics of the blend are usually enhanced with respect to mixed and disordered phase by allowing higher charge carrier mobilities [43–45]. Those variations should also be somehow related to the quality of the interface between C_{60} and rrP3HT domains. Hence, from the most stable configuration I at LDA level, we have studied the influence of the domain size of the π-crystal, or in other words the size of H-aggregates of rrP3HT, by introducing C_{60} within the rrP3HT crystal network. This would contribute to describe the variation of C_{60}—rrP3HT interface properties when the blend becomes gradually well-organized with a demixing of the two components. The different BHJ unit cells studied, illustrated in Fig. 2, are composed of 1, 2, 3 or 4 chains of rrP3HT in the π-stacked direction where each chain is made of four hexylthiophene monomers in the conjugated backbone direction. The distance between the center of C_{60} and the nearest rrP3HT chain is set at 6.35 Å with the shortest distance between the hydrogens of the alkyl side chains and the C_{60} carbons at approximatively 2 Å, as in configuration I. Furthermore,

[1] We have also compared LDA and PBE-vdW energies with the help of NwChem software on finite models of configuration I–IV where P3HT oligomers where considered instead of a periodic polymer. For these test cases, we found similar ordering in stability between LDA and PBE-vdW approaches, but where, as expected, the stability is increasing with consideration of dispersion corrections.

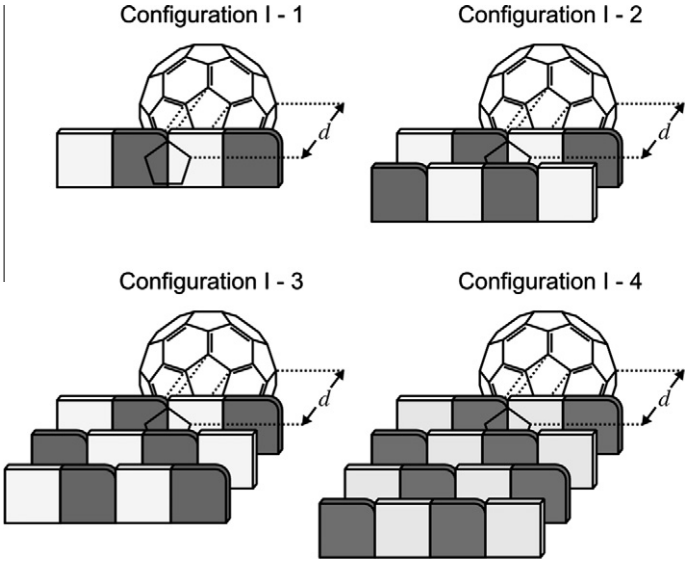

Fig. 2. Illustration of configuration I-*X* where *X* indicates the number of rrP3HT chains per unit cell considered in the π-crystal domain.

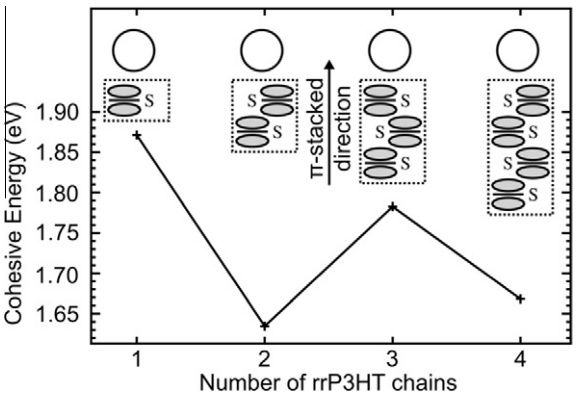

Fig. 3. Cohesive energy of the BHJ as a function of number of rrP3HT chains between C_{60} in the π-stacked direction. A representation of the HOMO wavefunction is illustrated above the curve.

the distance between rrP3HT chains in the π-stacked direction is fixed at 3.42 Å as in the periodic rrP3HT π-crystal [26].[2]

After full relaxation of the atomic coordinates inside the fixed unit cell, the cohesive energy of the BHJ is evaluated as a function of number of the rrP3HT chains in the unit cell. The variation of cohesive energy reported in Fig. 3 clearly shows an oscillation between 1.63 and 1.87 eV, with values greater for odd numbers of rrP3HT chains than for even numbers. This stability oscillation is related to boundary conditions in the π-stacked direction where an odd number of rrP3HT chains allow the formation of symmetric delocalized wavefunctions through the thiophene units (A, ABA, ABABA,...) that stabilize the system. This contrast with an even number of stacked chains (AB, ABAB,...) that does not allow the formation of symmetric delocalized wavefunctions which leads to a less stable system.

3.2. Electronic properties of nanostructured blend

In this section, we first present the electronic structure properties of a BHJ in configuration I with a rrP3HT/C_{60} ratio of 1 (see configuration I-1, Fig. 2). Such rrP3HT/C_{60} mixture can be compared to a disordered blend in which there is no H-aggregates or domains of rrP3HT nanocrystallite. The band structure of this BHJ is displayed in Fig. 4a for the π-stacked direction from Γ to $X = (0, \pi/\mathbf{b}, 0)$ and for the π-conjugated backbone direction from Γ to $X' = (0, 0, \pi/\mathbf{c})$. As illustrated by the three shaded areas in Fig. 4a, the presence of C_{60} in the polymer has few impacts on the band structure of rrP3HT in the π-stacked direction. C_{60} mainly introduces three nearly degenerate states in the rrP3HT band gap defined by the position of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO). These three empty states are originating from the threefold degenerate t_{1u} state of isolated C_{60}, and are weakly dispersed in both $X\Gamma$ and $\Gamma X'$ directions of the blend. Those results suggest that C_{60} interacts weakly with rrP3HT and other C_{60} molecules forming the crystal blend. As revealed by the wavefunctions in Fig. 4b, the C_{60} acceptor states remain strongly localized in the blend and no overlap between rrP3HT and C_{60} states can be clearly identified.

Similarly, as observed for an isolated rrP3HT chain, the dispersion of both HOMO and LUMO bands of rrP3HT in

[2] In a previous DFT study, the rrP3HT crystal configuration was determined the most stable configuration among multiple probable configurations. We consider this configuration to be highly probable since it allows an uniform distribution of the alkyl side chains in a structure similar to a polyethylene crystal ($|\mathbf{a}| = 7.46$ Å and $|\mathbf{b}| = 4.98$ Å [46]) with comparable lattice parameters ($|\mathbf{a}| = 6.83$ Å and $|\mathbf{b}| = 5.72$ Å). Furthermore, we view this configuration as truly representative of real rrP3HT crystal samples considering the very good agreement between calculated and experimental results [37,47–49].

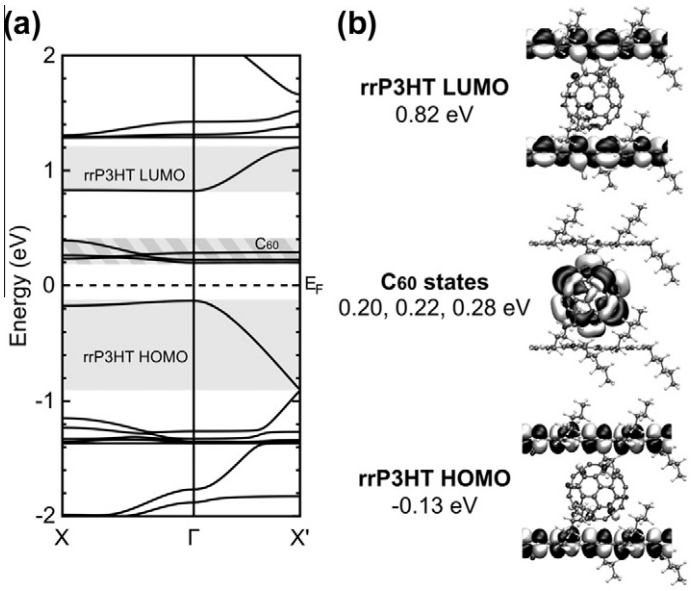

Fig. 4. (a) Band structure of BHJ in configuration I. (b) Wavefunction contours of frontier orbitals in a configuration I BHJ with the energy levels taken at Γ point.

the π-stacked direction ($X\Gamma$) is nearly zero while it is significantly larger in the π-conjugated backbone direction ($\Gamma X'$) [26]. The calculated HOMO–LUMO gap at Γ-point for rrP3HT (0.97 eV) is substantially lower than the experimental band gap ($\sim$ 1.9 eV), as generally observed with an DFT-LDA approach. A similar trend is observed for C_{60} where the calculated HOMO–LUMO gap (1.60 eV) is lower than the experimental value (2.6 eV) [50]. Although band gaps are usually underestimated with DFT-LDA, the relative alignment of HOMO–LUMO bands between rrP3HT and C_{60} are more appropriately described. For example, the calculated energy shift between LUMOs of rrP3HT and C_{60} is 0.62 eV as compared to 0.50 eV observed experimentally [51,52]. A similar trend is observed between HOMO's where the calculated value (1.13 eV) is in good agreement with experimental value (1.00 eV) [51,52]. Hence, the relative variation of electronic properties observed in this study and their impact on our general conclusions should not be affected by the absolute band gap values.

The two diagrams in Fig. 5 show the position of HOMO and LUMO of rrP3HT along with the three C_{60} energy levels in different BHJ systems. The position of HOMO and LUMO taken at Γ are clearly identified by a thick line located at, respectively, the top of the valence band and the bottom of the conduction band. The dispersion of these bands is represented by the shaded area. The influence of the distance d separating the nearest rrP3HT chain from the C_{60} on the electronic properties of the BHJ is presented in Fig. 5a. The effect of the domain size of rrP3HT crystal on the position of frontier orbital is reported in Fig. 5b.

The most noticeable impact of modulating the unit cell dimension in the π-stacked direction (see Fig. 5a), or in other words in varying the rrP3HT/C_{60} packing density, is to modify the position of energy levels. A decrease in d causes a simultaneous displacement of HOMO and LUMO levels of rrP3HT toward higher binding energy (BE) by approximately the same amount, while the splitting between the three C_{60} states increases with their shift toward lower BE. These energy shifts are consistent with the trend and magnitude of the total induced dipole moment variation observed at a pentacene–fullerene heterojunction upon reduction of the intermolecular distance [53]. The direct consequences of these shifts are (1) a decrease of $\Delta\epsilon_{LUMO}$ for the blend when d decreases, i.e. a decrease in the energy offset between LUMOs of the donor (rrP3HT) and the acceptor (C_{60}) and (2) an increase in energy separation between $HOMO^{rrP3HT}$ and empty states of C_{60} ($LUMO^{C60}$) with a decreasing d. Finally, energy shifts observed for HOMO and LUMO of rrP3HT with a variation of d leave the band gap of rrP3HT nearly constant.

The band gap of rrP3HT and the $HOMO^{rrP3HT}$—$LUMO^{C60}$ separation have their own importance in the photovoltaic process : the rrP3HT band gap is an approximation of the optical gap for the photon absorption by the donor component in the BHJ; and the $HOMO^{rrP3HT}$—$LUMO^{C60}$ separation is proportional to the maximum theoretical open-circuit voltage (V_{oc}) of the organic photovoltaic cell [54]. To maximize the efficiency of the device, the optical gap has to be minimized to allow the harvesting of a broader range of the solar spectrum while V_{oc}, which limits the efficiency of state-of-art bulk heterojunction organic photovoltaic cells, has to be maximized. Although a concurrent optimization of both parameters remains a difficult task, it is facilitated by employing a bulk heterojunction to decouple the optical band gap from V_{oc} [55]. For example, new acceptor materials are being developed to raise their LUMO level in order to optimize simultaneously both parameters [56].

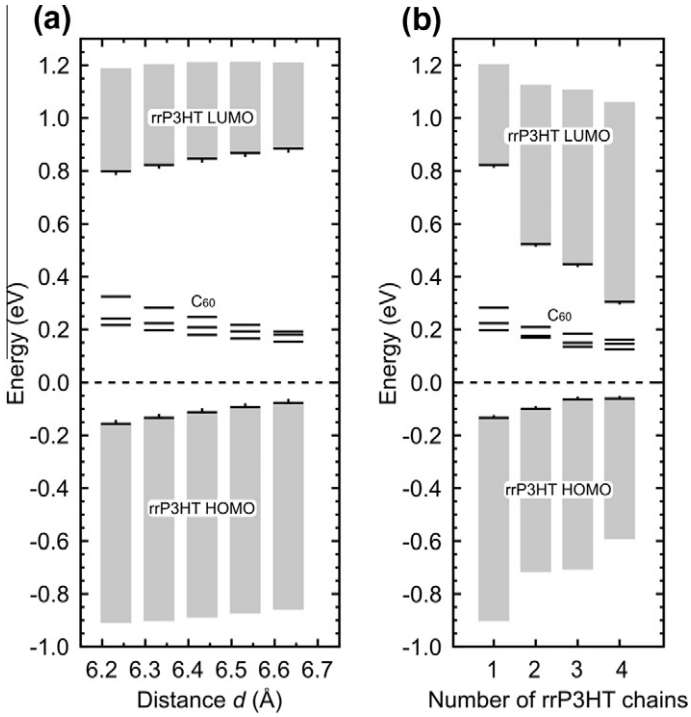

Fig. 5. Diagrams of the rrP3HT HOMO and LUMO and of the three C_{60} energy levels taken at Γ for a BHJ in configuration I as a function of (a) the distance d and (b) the number of rrP3HT chains in the crystal domain.

From Fig. 5a, artificially increasing the pressure on the unit cell in the π-stacked direction to reduce the dimension d would not modulate the optical gap and therefore it cannot rectify the mismatch between the solar spectrum and the rrP3HT absorption spectrum [57]. Nonetheless, a reduction of the interface distance d would still noticeably increase the efficiency of the organic photovoltaic cell through an increase of V_{oc} since the efficiency is more sensitive to a variation of V_{oc} than to a variation of the donor band gap [54].

The influence of rrP3HT crystal domain size as shown in Fig. 2 on the electronic properties of the BHJ is reported in Fig. 5b. The bottom of the LUMO band of rrP3HT is displaced toward higher BE by approximately 0.54 eV when the number of rrP3HT chains goes from 1 to 4, which also results in a major increase of its bandwidth and a large decrease of the rrP3HT band gap. The trend observed for the rrP3HT band gap with respect to the number of chains in the polymer π-stack will converge rapidly to the band gap value of the rrP3HT crystal. Considering π-stacked molecular systems, the band gap usually converges within 10 stacked molecules [58,59]. The calculated decrease of rrP3HT band gap (~ 0.6 eV) upon the formation of a π-crystal domain is consistent with the significant redshift observed experimentally (~ 0.5 eV) with the presence of H-aggregation [25]. Since we have considered periodic rrP3HT into the π-conjugated backbone direction which also contributes to maximize the π—π interactions between chains, the agreement with experimental results obtained on H-aggregates in solution is quite satisfying. Furthermore, the lowering of the rrP3HT LUMO band pushes the three C_{60} states toward higher BE which, combined with the shift of the top HOMO band toward lower BE, closes the $HOMO^{rrP3HT}$—$LUMO^{C60}$ separation. In contrast to the influence of d, an increasing size of rrP3HT crystal domains induces a significant decrease of rrP3HT band gap, and would also significantly decrease the value of V_{oc}. The variation of the rrP3HT band gap and $HOMO^{rrP3HT}$—$LUMO^{C60}$ separation have the same trend which suggests that the optical gap and V_{oc} cannot be optimized simultaneously. These theoretical results clearly reproduce and explain the V_{oc} decrease and the increase of spectral overlap with solar emission observed upon the formation of rrP3HT crystallite following the annealing of the BHJ [12,60].

It is also possible to notice in Fig. 5b an increase of the $LUMO^{rrP3HT}$ bandwidth with increasing rrP3HT crystal domain size, while an overall decrease of the $HOMO^{rrP3HT}$ bandwidth is observed simultaneously. Increasing the rrP3HT crystal domain size increases the number of $HOMO^{rrP3HT}$ like and $LUMO^{rrP3HT}$ like states between nearly fixed C_{60} states. Furthermore, due to the respective symmetry of the $HOMO^{rrP3HT}$ and $LUMO^{rrP3HT}$, the former is not allowed to cross the lower lying C_{60} states which forces a reduction of the $HOMO^{rrP3HT}$ bandwidth, while the latter is allowed to cross the higher lying C_{60} states which helps to increase the $LUMO^{rrP3HT}$ bandwidth.

4. Conclusions

We have investigated the structural and electronic properties of bulk heterojunctions formed by the inclusion of C_{60} in a rrP3HT π-crystal network. Among the different rrP3HT/C_{60} configurations considered, we found a cohesive

energy of around 1.9 eV per unit cell which is not significantly influenced by the relative position and orientation of the C_{60} molecule along the polymer chain. An increase in the size of crystal domain of rrP3HT induces the appearance of π-electron delocalization in both π-stacked and conjugated backbone directions. We have theoretically altered the levels alignment through a modulation of the interface distance between the nearest rrP3HT chain and the C_{60} molecule, and we corroborated the strong influence of the number of rrP3HT chains in the crystal domain mixed with C_{60} on the rrP3HT band gap and V_{oc}. These results suggest a potential optimization of photovoltaic devices through the use of an engineered mixture of C_{60} and nanostructured rrP3HT crystal domains.

Further calculations involving the presence of excited states (excitons) within the BHJ system are necessary to support this ground state band alignment, and to understand the influence of structural organization on the photophysical properties of excitons in such bulk heterojunction.

Hybrid inorganic–organic solar cells
Drift diffusion
Two-dimensional model

ABSTRACT

Carrier transport in hybrid inorganic–organic solar cells has been studied by means of a two-dimensional drift-diffusion-based model including the generation and motion of excitons. The devices consist of a polymer serving as donor material and a semiconducting small-band gap inorganic component as acceptor material. For the first time it is taken into account that, in strong contrast to purely organic or inorganic cells, charge carriers can be generated at the heterojunction (due to dissociation of the donor excitons) *and* in the bulk of the acceptor material (due to band to band generation in the inorganic material). The efficiencies of devices were investigated dependent on (i) the donor–acceptor interface geometry, (ii) the transport level offsets at the heterojunction, and (iii) the energy barriers formed at the contacts. For each case, a detailed analysis of the behavior is given. We demonstrate that, depending on the particular scenario, each of these three factors can be responsible for profoundly reduced efficiencies and pronounced s-shaped sections in the *I–V* curves. Moreover, we show that each of the investigated factors may give rise to equally serious efficiency losses. However, it is not possible to identify a dominant effect. Depending on the particular combination, the efficiency can vary by two orders of magnitudes. In order to avoid such losses, our theoretical assessment reveals that suitable material combinations are required to form (i) ohmic contacts, (ii) preclude formation of isolated islands or nanoparticles during growth, and (iii) possess a hole-blocking offset in the transport levels at the heterojunction.

1. Introduction

Inorganic–organic hybrid solar cells (hsc) represent one of the currently persued routes to produce low-cost solar cells. The introduction of an inorganic component rather than an organic material promises a good control over the morphology to arrive at an interdigited heterointerface, e.g., by incorporating nanowires of ZnO or TiO_2 [1,2] as acceptor materials. To combine these advantages with the desire to efficiently harvest sun light, the absorption spectra of the organic and inorganic phase are required to cover the solar spectrum in a preferably complementary fashion. One promising route to achieve this is to employ an organic material that covers the high-irradiance portion of the solar spectrum, i.e., visible light between 1.7 and 3.0 eV, and an inorganic component that absorbs in the long-wavelength tail well below 1.7 eV. Suitable inorganic semiconductors are, e.g., CdSe , CdTe, and $CuInS_2$ [3,4]. In hsc containing these materials, the organic and inorganic phase contribute differently to charge carrier generation. Upon light absorption, excitons are formed in the organic phase and need to diffuse to the heterojunction interface within their lifetime in order to dissociate into free

doi:10.1016/j.orgel.2010.08.015

charges. In the inorganic semiconductor, carriers are generated directly via band-to-band absorption throughout the bulk. Therefore, the question arises to which extent these two strongly differing generation mechanisms influence the efficiency of such cells. In particular, the impact on efficiency-related factors such as morphology, contact materials, and transport level alignment requires detailed investigation.

Hybrid inorganic–organic heterojunctions can be prepared in several distinct types of morphologies: Besides bilayer structures, (i) nanoporous inorganic templates infiltrated with polymers and (ii) blends of organic polymers co-deposited with inorganic (isotropic) nanoparticles or nanorods have been prepared. A comprehensive overview can be found, e.g., in Refs. [1b,2a]. Morphologies in which the photoactive materials are segregated perpendicular to the electrodes are particularly sought after, since this vertical alignment reduces shortenings and recombination [1e,2a]; such structures were achieved by co-deposition [4(b–f)] or a template approach [1a,4(g,h)]. Compared to hybrid bilayer structures, blend devices usually exhibit relatively low open-circuit voltages and fill factors, cf., e.g., Ref. [1a]. Devices made of blends containing nanorods of high aspect ratios systematically outperform nanoparticle blends in terms of short circuit currents, open circuit voltages, and higher efficiencies [1a,4(e,f)]. The performance of excitonic solar cells consisting either of hybrid blends/template structures containing wide bandgap inorganic semiconductors such as ZnO or TiO_2 [1a] or pure organic blends (containing C_{60}-derivatives or small molecules) [4j] is strongly dependent on the morphology. Previous studies related this effect to (i) an effective generation efficiency [5–7], (ii) the apparent length of the interface available for exciton cleavage [1a,8–13], (iii) the connectivity of transport paths [15], and (iv) a change in the effective mobility [16]. Moreover, the occurrence of an s-shaped *I–V* curve [1(a,b),9,14,17–19] has been linked to the selectivity of the contact materials [9,18], and the alignment of transport levels [19].

The optimization of the morphologies in purely excitonic solar cell targets structure sizes being comparable to typical exciton diffusion lengths of ca. 15 nm [1b]. The use of low-band gap inorganic materials can presumably obliterate the need for such small inorganic domain sizes, since generation due exciton migration is replaced by carrier generation in the bulk. Then, large inorganic domains offer the advantages of (i) providing efficient carrier generation due to bulk generation, (ii) a more efficient carrier abstraction at the contacts and, thus, less efficient recombination due to higher intrinsic mobilities, (iii) ensuring a better connectivity [4a], and, (iv) presumably leading to a higher average carrier mobility due to a significantly reduced number of interparticle hops [4a].

The main aim of this work is to theoretically investigate the impact of (i) cell morphology, (ii) transport level alignment, and (iii) choice of contacts on the carrier transport and, consequently, the efficiency of such hybrid inorganic–organic solar cells. Under consideration of the two charge generation mechanisms, the abovementioned effects were cast into a two-dimensional drift-diffusion model for both charge carrier and exciton transport. Based on this model, current–density voltage (*I–V*) curves of the entire device were simulated. The devices studied below consist of $CuInS_2$ as prototypical acceptor and P3EBT (poly[3-(ethyl-4-butanoate)thiophene-2,5-diyl]) as donor material (Fig. 1(d)). From a theoretical point of view, the combination of P3EBT with $CuInS_2$ is particularly intriguing due to a vanishing offset between the hole transport levels. Such a level alignment cannot be encountered in hsc based on wide-band gap semiconductors, such as ZnO and TiO_2. P3EBT can be of potential practical relevance due to an improved processability in comparison to the archetypical P3HT (poly(3-hexylthiophene)).

After introducing the details of the model, we will investigate the impact of the interface morphology on the carrier transport for selected heterojunction geometries. In a next step, the degeneracy in the hole transport levels is lifted to point out the impact of transport level alignment. In a last series of simulations, the dependence of the *I–V* curves and the power conversion efficiency on the nature of the imposed contacts is studied for the chosen representative morphologies. Based on these simulations we will derive criteria for material properties according to which major efficiency losses can be avoided.

2. The model

To get a deeper understanding of the device behavior due to variations (i) of the transport level offsets between the donor and acceptor material and (ii) their interface morphology, as well as the role of bulk vs. interface carrier generation, a two-dimensional drift-diffusion model for the device simulation is proposed. Such a two-dimensional model offers the possibility to regard actual morphologies such as isolated particles or ideal, i.e., interdigitated structures. Note that the feature size of the assumed interface geometries must be sufficiently large (ca. 15–20 nm) in order to define valid material parameters for the photoactive components as model input. Typical structure sizes in nanocomposite hybrid inorganic–organic solar cells are 5–20 nm for particle diameters, domain sizes, and nanorod diameters; nanorods of high aspect ratio are ca. 50–100 nm long [1b,2a]. Thus, it is possible to construct artifical interface geometries that represent limiting cases of real morphologies and feature structure sizes known from actual heterojunctions.

In contrast to drift-diffusion models, microscopic simulations are able to safely tackle morphologies with typical length scales below 15 nm. However, due to the extensive computational costs, most of the publications focus on interface generation and recombination processes [5,6,20,21]. Apart from the pioneering works of Marsh et al. [5] and Meng et al. [21a], subsequent carrier transport is not evaluated at the same level of complexity. Rather, it is either described by means of equivalent circuit models [21b] or by one-dimensional drift-diffusion models [16]. The former is not able to reflect a departure of the *I–V* curve from the ideal diode characteristic and the latter cannot take into account the actual morphology. Given that the hybrid inorganic–organic systems exhibit generation not only at the interface but also throughout the bulk,

The area corresponding to the donor (P3EBT) is indicated in green (/light gray), the one of the acceptor ($CuInS_2$) in blue (/dark gray). (d) Schematic structure of P3EBT. (For interpretation of references to color in this figure legend, the reader is referred to see the web version of this article.)

models as proposed in Refs. [5,21a] are neither computationally feasible nor are they suited to immediately interpret the results in terms of relevant macroscopic transport parameters.

Charge transport equations: In a drift-diffusion model, the motion of the charge carriers is caused by the electric field and carrier density gradients. The resulting current density is carried by electrons and holes in their respective transport levels. According to [22], the current density reads

$$\mathbf{J}(x,y) = \mathbf{J}_p(x,y) + \mathbf{J}_n(x,y) \tag{1}$$

with

$$\mathbf{J}_{n(p)}(x,y) = qn[/p](x,y)\mu_{n(p)}(x,y)\mathbf{E}_{n(p)}(x,y) \pm D_{n(p)}(x,y)q\nabla n[/p](x,y). \tag{2}$$

Here, $\mu_{n(p)}(x,y)$ denotes the electron (hole) mobility; k_B, the Boltzmann constant; T, the temperature; and q, the elementary charge ($q > 0$). Moreover, $n(x,y)$ and $p(x,y)$ are the density distributions and $\mathbf{E}_{n(p)}(x,y)$ the generalized electric fields (for definition see below) for electrons and holes, respectively. The electron (hole) diffusion constant is defined by the Einstein relation:

$$D_{n(p)} = \mu_{n(p)}(x,y)k_BT/q. \tag{3}$$

The current densities are coupled with the continuity equation for electrons and holes

$$\frac{\partial n[/p](x,y)}{\partial t} \mp \frac{1}{q}\nabla \mathbf{J}_{n(p)}(x,y) = G(x,y) - R(x,y) \tag{4}$$

where $G(x,y)$ and $R(x,y)$ are the charge carrier generation and recombination terms.

Generalized potentials: By defining a generalized potential $\widehat{\Psi}_{n(p)}$, the actual electrostatic potential Ψ and the "driving forces" excerted on the carrier at the heterojunction can be cast into one quantity [23,24]:

$$\widehat{\Psi}_{n(p)}(x,y) = \Psi(x,y) - \Theta_{n(p)}(x,y)/q. \tag{5}$$

Herein, the potential $\Psi(x,y)$, resulting from the Poisson equation

$$\nabla[\epsilon_0\epsilon_r(x,y)\nabla\Psi(x,y)] = q[n(x,y) - p(x,y)], \tag{6}$$

is caused by the charges in the active layer and the effective applied voltage V at the electrodes; ϵ_0 is the dielectric constant of vacuum and $\epsilon_r(x,y)$ the relative dielectric constant. V is the difference of the external applied voltage and the built-in voltage. At the non-conducting surfaces periodic boundary conditions were imposed. The additional terms $\Theta_{n(p)}(x,y)$ in Eq. (5) are the band parameters that are associated to the spatial energetic alignment of the transport levels [23,24]. In disordered materials, $\Theta_{n(p)}(x,y)$ is directly given by the relative spatial alignment of the transport levels [23]. For convinience, we set the band parameters to zero in the organic donor ($\Theta_{n(p)} = 0$) and to the transport level offsets in the inorganic acceptor ($\Theta_n = E_C - \text{LUMO}$; $\Theta_p = E_V - \text{HOMO}$). Thus, the generalized potential multiplied by the charge of the carrier yields the actual potential energy landscape in which the carrier traverses the device. Carrying out the spatial derivative of the generalized potential yields a generalized electric field that was formally introduced in Eq. (2):

$$\mathbf{E}_{n(p)}(x,y) = -\nabla \widehat{\Psi}_{n(p)}(x,y). \quad (7)$$

It consists of the true electric field across the device superimposed with an additional term occurring solely at the interface. For abrupt heterojunctions, this generalized electric field has no physical meaning due to the singularity at the interface. However, once cast in the final form, the transport equations (2) and (4) contain the generalized potential rather than its spatial derivative [24]. The associated terms account for the "driving force" acting on the carrier at the interface [23]; they penalize uphill and encourage downhill motion by means of an exponential factor containing the potential difference.

Recombination rates: The recombination term in Eq. (4) is assumed to be of Langevin type which reads

$$R(x,y) = \gamma n(x,y)p(x,y) \quad (8)$$

with $\gamma = q\mu/\epsilon_0\epsilon_r$ and $\mu = min[\mu_p, \mu_n]$ [25,26]. Note that this rate expression does not allow to explicitely discriminate between geminate pair and nongeminate pair recombination.

Generation rates and exciton motion: Assuming a Lambert–Beer type absorption profile across the device, an absorption rate $A(x,y)$ accounting for the number of photons absorbed per second and volume can be introduced as

$$A(x,y) = \int_0^{\frac{hc}{E_{gap}}} \Phi_0(\lambda)\frac{\lambda\alpha(\lambda)}{hc}e^{-\alpha(\lambda)x}d\lambda. \quad (9)$$

where $\alpha(\lambda)$ denotes the absorption coefficient related to the organic and inorganic species; c, the speed of light; h, the Planck constant; E_{gap}, the optical bandgap; and $\Phi_0(\lambda)$, the solar spectrum used (AM 1.5 with 1000 Wm^{-2}). In this formulation, Eq. (9) yields the photon number as a function of the material-dependent absorption and, in reasonable first approximation, the morphology of the device. As we intend to focus on investigating the role of the morphology for *carrier transport*, we will exclude additional morphology-related effects that may originate from strongly spatially varying absorption profiles [27] by introducing the following simplifications: (i) α enters Eq. (9) as a wavelength- and material-independent parameter and (ii) the optical band gap E_{gap} is treated as material-independent. This means that both materials are considered to be capable of absorbing the same number of photons per volume and time. Then, the actual number of photons absorbed anywhere in the device is only determined by Lambert–Beer's law, i.e., is solely dependent on the position of the considered volume element with respect to the transparent electrode. The coefficient α is set to the representative value of 2×10^7 m^{-1}. With the help of the simplifications made above, we are able to compare also materials whose optical absorption is not known quantitatively.

In the inorganic phase, light absorption leads directly to free charges. The generation rate $G(x,y)$ associated to this process is, thus, directly given by $G(x,y) = A(x,y)$ [28]. Within the organic phase, the absorbed photons give rise to an exciton density distribution $ex(x,y)$. Since excitons have no charge, exciton migration, described by a flux density $\Phi_{ex}(x,y)$, is determined only by diffusion:

$$\Phi_{ex}(x,y) = -k_B T \mu_{ex} \nabla ex(x,y) \quad (10)$$

with μ_{ex} being the exciton mobility. The continuity equation contains an exciton generation rate $G_{ex}(x,y) = A(x,y)$ and has the form [29]

$$\frac{\partial ex(x,y)}{\partial t} + \frac{1}{q}\nabla(\Phi_{ex}(x,y)) = G_{ex}(x,y) + \frac{1}{4}R(x,y) - R_{ex}(x,y) - G(x,y). \quad (11)$$

Herein, an exciton recombination rate R_{ex} is defined as

$$R_{ex}(x,y) = \frac{ex(x,y)}{\tau_{ex}} \quad (12)$$

where τ_{ex} is the exciton lifetime. Carrier recombination $R(x,y)$ (cf. Eq. (4)) can give rise to the formation of singlet excitons and, thus, increases the exciton density. Thus, the fraction of $R(x,y)$ yielding singlet states needs to be considered in Eq. (11) and is taken here as 1/4. Excitons dissociate into free charge carriers if they reach the organic–inorganic interface within their lifetime, i.e., the charge carrier generation rate $G(x,y)$ reads

$$G(x,y) = \begin{cases} 0, & x,y \text{ within organic material} \\ \frac{1}{\tau_{diss}} ex(x,y), & x,y \text{ at organic—inorganic interface.} \end{cases} \quad (13)$$

As a further simplification of Eqs. (10) and (12), the parameters μ_{ex} and τ_{ex} are set to fixed values. We chose the values to 3.86×10^{-6} m^2 V^{-1} s^{-1} and 1 ns [30], respectively, to arrive at a mean exciton diffusion length of 15 nm. The values of all constants used in our simulations to describe exciton formation and migration are summarized in Table 1.

The resulting coupled system of equations (Eqs. (2), (4)–(6), (10) and (11)) is solved self-consistently on a two-dimensional mesh with variable grid spacing by using the discretization of the current density equations according to Scharfetter and Gummel [31].

Important device parameters of solar cells are the fill factor (FF) and the power conversion efficiency (PCE) which are related to the open circuit voltage V_{oc}, the short circuit current density j_{sc}, the voltage V_{mpp}, and the current density j_{mpp} at the maximum power point by

$$FF = \frac{V_{mpp}j_{mpp}}{V_{oc}j_{sc}}$$

and

Table 1
Material parameters used in the device simulations

Donor: P3EBT HOMO/LUMO	−5.6 eV/−3.7 eV
Acceptor: $CuInS_2$ E_C/E_V	−5.6 eV/ −4.1 eV [32]
Relative dielectric constant: ϵ_r	3.0
Electron and hole mobility: $\mu_n = \mu_p$	10^{-8} $m^2/(V\,s)$
Exciton lifetime: τ_{ex}	1 nm [30]
Exciton mobility: μ_{ex}	3.86×10^{-6} $m^2/(V\,s)$
Absorption coefficient: α	2×10^7 m^{-1}
Optical bandgap: E_{gap}	1.5 eV
Hole concentration at the anode	10^{22} m^{-3}
Electron concentration at the cathode	10^{22} m^{-3}

$$PCE = \frac{V_{mpp} j_{mpp}}{P_{in}}$$

with P_{in} being the incident light power ($1000\,W/m^2$). All simulations were carried out for room temperature.

3. Results and discussion

At first, we define a model system that allows us to discriminate between the effects arising from (i) the cell morphology, (ii) the choice of contacts, and (iii) the transport level alignment. To prevent such effects to be obscured by a possible dependence on additional material parameters, we will use identical parameter values for the donor and acceptor phase whenever possible (see below).

In order to implement representative model morphologies, one needs to bear in mind that the shape of the interface between the organic donor and the inorganic acceptor material in nanocomposite solar cells depends strongly on the actual fabrication procedure, cf., e.g., [4(a–d)]. Such procedures aiming at obtaining a continuous phase of the acceptor material [1b,4(a–d)]. However, there are often acceptor nanoparticles that are fully surrounded by the organic material [4(a–d)]. Varying the processing conditions may give rise to many different degrees of conglomeration [4a,4b,4c,4d]. To capture the influence of such different interface morphologies, the following interface geometries were assumed in the simulation.

As a first limiting case, an interdigitated array of donor and acceptor, a "comb-like" structure, was considered (cf. Fig. 1(a)). Such a geometry ensures (i) continuous pathways for the charge carriers to travel from the interface to the contacts and (ii) promises the highest sensitivity of the short circuit current with respect to a varying digit width [33]. Nanoparticles entirely embedded into the donor polymer matrix are investigated as second limiting case (cf. Fig. 1(b)). Provided that the mobility of the phases can be assumed to be independent of the morphology, all other interface geometries can be considered as superpositions of interdigited phases and nanoparticles. A morphology as depicted in Fig. 1(c) is a mixture of a comblike and a single nanoparticle structure and may serve as a more realistic description of the donor–acceptor interface.

The material parameters assumed in the simulation are listed in Table 1. The position of the transport levels, i.e., the HOMO/LUMO levels of P3EBT, as determined from cyclovoltammetry, and E_C/E_V of $CuInS_2$ [32] are depicted in Fig. 2(a). The remaining transport-related parameters, the carrier mobilities and the dielectric constants, are not varied throughout the simulations. The impact of these quantities and variations thereof are beyond the scope of this paper. The mobility is set to be the same for electrons and holes and independent of the donor and acceptor. Eventhough the mobilities of the materials most likely differ from each other and change when tuning the interface structure in an actual device, our choice has, nevertheless, two advantages for the theoretical assessment: (i) We can independently study effects arising from the interface morphology and effects related to different mobilities in the donor and acceptor phase. Moreover, it guarantees that all considered morphologies are studied using the same set of mobility values. (ii) As will be shown in detail elsewhere [34], the ratio between the mobilities of the two materials has, as can be expected, a significant impact on the I–V characteristic. In the hybrid solar cells considered here, however, mobility effects can be shown to (i) occur largely independent from morphology-related effects and (ii) be less pronounced than the latter [34]. Also the dielectric constant is assumed to be identical in both materials. This simple choice constitutes a valid starting point for our investigations, since, as shown in detail elsewhere [34], the effect of differing dielectric constants on the I–V curve is independent of and less marked than the three factors studied below.

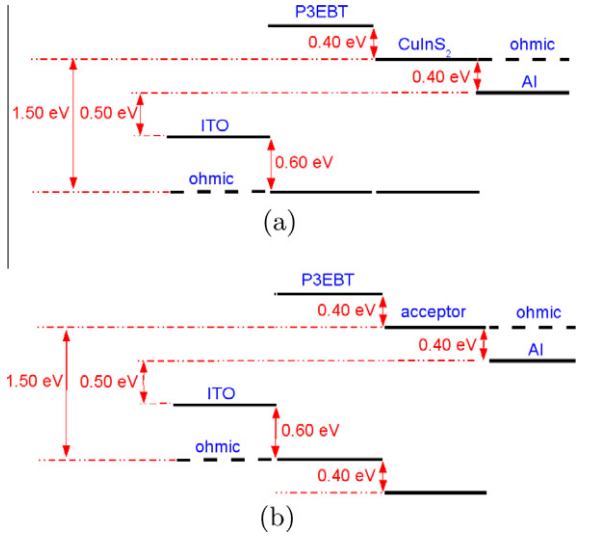

Fig. 2. Position of HOMO and LUMO levels in P3EBT and E_C, E_V for (a) $CuInS_2$ or (b) an idealized acceptor with equivalent transport level offsets with respect to P3EBT. Further shown is the alignment of the contact workfunctions corresponding to ohmic (dashed lines) contacts for holes towards P3EBT and for electrons towards the acceptor, or to an ITO anode and Al cathode (solid lines).

Two types of contacts were investigated. In a first case, ohmic contacts for holes towards P3EBT and electrons towards $CuInS_2$, respectively, were chosen (Fig. 2a). [35] In a second scenario, ITO as cathode and Al as anode were chosen as actual contacts. These contact materials give rise to substantial barriers for electrons and holes towards the contacts, cf. Fig. 2(a), i.e., form non-ohmic contacts. Throughout this work, we define the built-in voltage $V_{built\text{-}in}$ as the difference between the work functions of the contacts, i.e., the bias necessary to compensate the potential difference across the device imposed by the contacts [38]. In case of ohmic contacts, we obtain a built-in voltage of $V_{built\text{-}in} = 1.5$ V for the interdigitated structure (cf. Fig. 2(a)). For the nanoparticle structure, however, $V_{built\text{-}in}$ assumes the value of 1.9 V, since the cathode workfunction is aligned with the P3EBT donor LUMO level to ensure an ohmic contact. In case of the "real" structure, $V_{built\text{-}in} = 1.5$ V coincides with the value of the interdigitated structure.

Impact of interface geometry: In the following, we will turn our attention to the relationship between the three

aforementioned heterojunction morphologies and transport studied for a P3EBT/$CuInS_2$ device with ohmic contacts.

Interdigitated structures whose combwidth d is varied while keeping the area of the acceptor phase constant, give rise to I–V curves shown in Fig. 3(a). Table 2 lists the corresponding open circuit voltages V_{oc}, short circuit currents j_{sc}, fill factors (FF), and power conversion efficiencies (PCE). As can be seen from Fig. 3(a), the open circuit voltage V_{oc} remains constant at a value of 1.5 V independent of the combwidth d. This value coincides $V_{built\text{-}in} = 1.5$ V of this system, as expected for ohmic contacts [36]. The short circuit current density j_{sc} increases with reducing the finger width d, since an increased number of donor excitons are able to reach the interface. This behavior has already been observed experimentally when changing (i) the combwidth of nanoimprinted organic solar cells [13] and (ii) the surface roughness of the donor–acceptor interface in a layered solar cell [12,17]. Interestingly, as can be seen in Fig. 3(b), there is a pronounced dependence of j_{sc} on d. In the limit of small d, the d-dependent contribution to j_{sc} becomes nearly as large as the constant current contribution stemming from the acceptor phase due to bulk generation. A closer inspection of the evolution of $j_{sc}(d)$ reveals two distinct regimes: (i) As long as the width exceeds ca. 100 nm, essentially those excitons migrating perpendicular to the contacts (y-direction in Fig. 1(a)) reach the interface and contribute to the current. As a consequence, only small changes in $j_{sc}(d)$ are observed. (ii) However, once the structure size drops below 100 nm, $j_{sc}(d)$ is quickly rising with decreasing d. For such d, there is a non-neglible fraction of excitons migrating parallel to the contacts (x-direction in Fig. 1(a)) that is able to reach heterojunction facets that are oriented perpendicular to the contacts. This result is in full agreement with previous theoretical studies on excitonic solar cells [9,14,29]. When further decreasing d, $j_{sc}(d)$ begins to saturate as soon as d reaches the mean exciton diffusion length of 15 nm, as seen also in [9]. However, the maximum value of $j_{sc}(d)$ is reached at d considerably smaller than 15 nm. Then, however, the actual values j_{sc} have to be considered with care, as a macroscopic description is not necessarily valid at such small structure sizes.

To gain insight into the role of the two different carrier generation mechanisms for the formation of I–V curves, we consult a representative spatial distribution of electron and hole concentration within the power quadrant. The steady state quantities associated to the maximum power point are illustrated in Fig. 4; the generalized potential for electrons (upper potential) and holes (lower potential), and charge carrier distributions of the interdigited structure are shown in the left column. Note here that the generalized potential incorporates the electrostatic potential superimposed with the transport level offsets. At V_{mpp}, the potential across the interdigitated device (Fig. 4(a)) drops approximately linearly from the anode to the

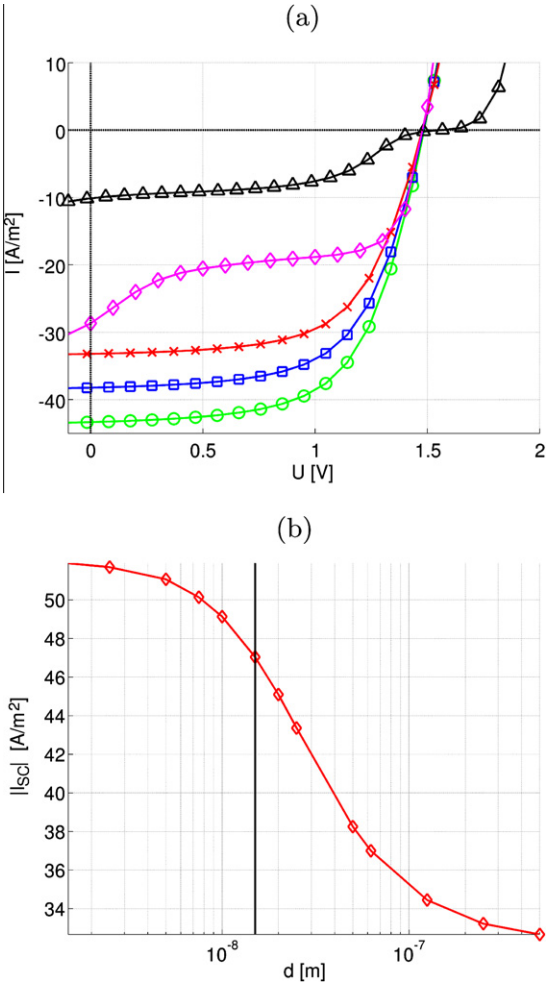

Fig. 3. (a) I–V curves for the P3EBT/$CuInS_2$ interdigitated interface with finger width $d = 250$ nm (crosses, ×), 50 nm (squares, □), and 25 nm (circles, ○), nanoparticles (triangles, △), and real structure (diamonds, ◇) in a device with ohmic contacts. (b) Dependence of the short circuit current density j_{sc} on finger width d for the interdigitated device with ohmic contacts. The exciton mean free path length of 15 nm is indicated by a vertical line.

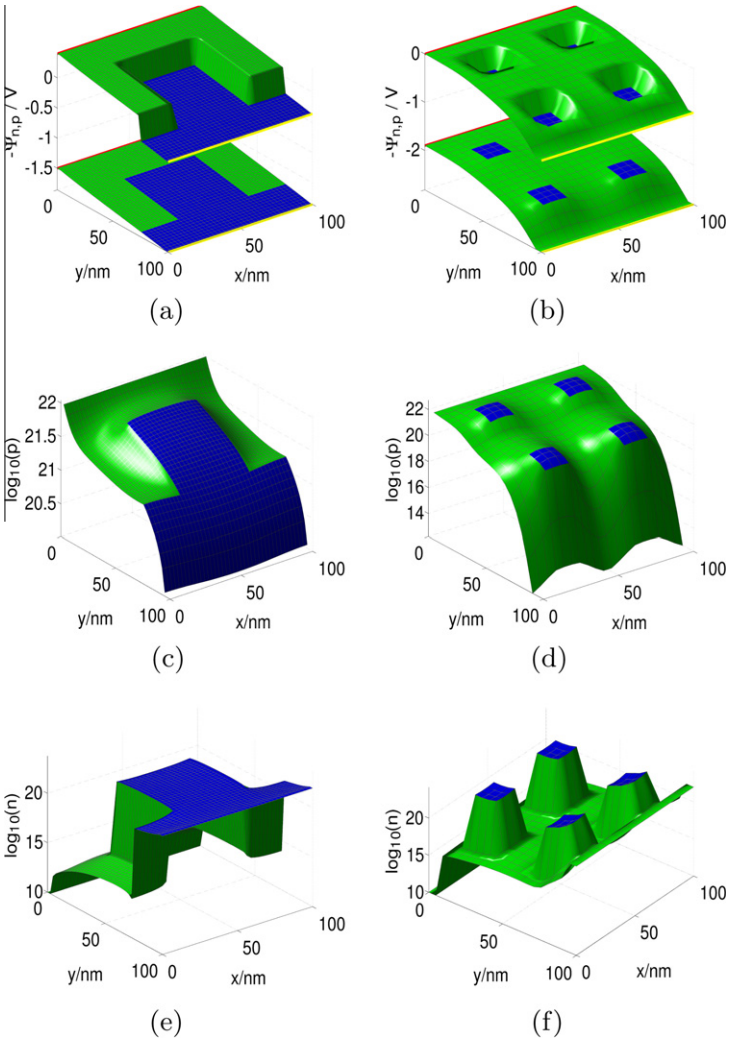

Fig. 4. Steady state distribution of the potential (a,b), hole (c,d), and electron concentration (e,f) related to the comblike structure (left column) and isolated nanoparticle structure (right column). The area corresponding to the donor (P3EBT) is indicated in green (/light gray), the one of the acceptor ($CuInS_2$) in blue (/dark gray). (For interpretation of references to color in this figure legend, the reader is referred to see the web version of this article.)

cathode. It resembles, as usually anticipated for this type of cells, the potential evolution predicted by the MIM model [37]. The resulting electric field, that is uniform in strength and position, ensures that electrons and holes being generated across the acceptor region can be spatially separated prior direct recombination. Driven by the field, the carriers accumulate at the contacts, i.e., the hole [electron] concentration (Fig. 4(c,e)) is highest at the anode [cathode].

However, a closer inspection of the two carrier distributions shown in Figs. 4(c,e) reveals profound differences: (i) The hole concentration drops continuously from anode to cathode, while there is a pronounced step in the electron distribution and (ii) the carrier concentrations at the heterojunction interface are enhanced with respect to the surrounding bulk. The first observation is a direct consequence of the level arrangement of the particular donor and acceptor materials investigated here. As a result of the vanishing barrier between donor and acceptor hole transport levels, holes lack a driving force enabling them to leave the acceptor region. Without being able to escape the acceptor, the holes are subject to significant recombination, since also electrons are confined to the acceptor region due to the barrier formed by the LUMO offset. The local enhancement of the carrier density at the interfaces is due to the *donor* excitons (formed throughout the organic bulk) that dissociate at the heterojunction. As we assume bulk carrier generation throughout the inorganic acceptor rather than exciton transport with subsequent interface cleavage, the local gradient in hole concentration is much more pronounced in the donor phase (Fig. 4(c)). Moreover, the effect is less pronounced among the electrons (Fig. 4(e)).

When turning to isolated nanoparticles, a profoundly different *I–V* characteristic is observed (cf. Fig. 3(a)). To provide a quantitative comparison to the interdigited case, the interface length of the nanoparticles is chosen to coincide with the corresponding length of 50 nm wide fingers. I.e., in both cases the same area for exciton dissociation

(i.e., interface carrier generation) is available. While V_{oc} is approximately the same, j_{sc} is reduced by a factor of almost four. Moreover, a pronounced plateau appears in the power quadrant that gives rise to an s-shaped curve. As a result of this shape, the fill factor of the cell is reduced (cf. Table 2). In combination with the low j_{sc}, PCE is reduced by a factor of five with respect to the cell with comb-like interface. The strong reduction of the photocurrent compared to the comb geometry results from the combination of two factors: (i) As the LUMO level is lower in the acceptor than in the P3EBT donor, electrons are accumulated in the, at least in part, inorganic nanoparticles (cf. Fig. 4(b,f)). Thus, the number of carriers reaching the cathode is reduced. (ii) In addition to a lacking support for hole migration into the donor (cf. HOMO and E_V level in Fig. 2(a)), generated holes prefer to stay close to the acceptor due to the space charge caused by the high electron density in the acceptor material, as can be seen well when comparing the carrier distributions in Fig. 4(d,f). As a result, recombination processes are strongly reducing the hole concentration within the inorganic phase. Thus, the reduction in PCE is to a large extent, as will be shown below, a consequence of the particular combination of semiconductors considered here.

The *I–V* curve which corresponds to an "actual" structure (Fig. 3(a)) is located between the characteristics of the single nanoparticle structure and the comblike structures, but exhibits the same V_{oc}. It possesses a pronounced plateau the onset of which is located at voltages lower than in the nanoparticle curve. In Fig. 5, the generalized potential and the current density distribution in *y*-direction corresponding to the maximum power point, i.e., an external voltage of 1.3 V, are depicted. The distribution of potential and carrier concentrations are reminiscent to those seen in the individual cases. Since the net dark current is zero at this bias, the current close to cathode is a pure electron photocurrent and at the anode a pure hole photocurrent. The pronounced negative maxima in the current density shown in Fig. 5(b) indicate that the main part of the electron current to the cathode is transported in the

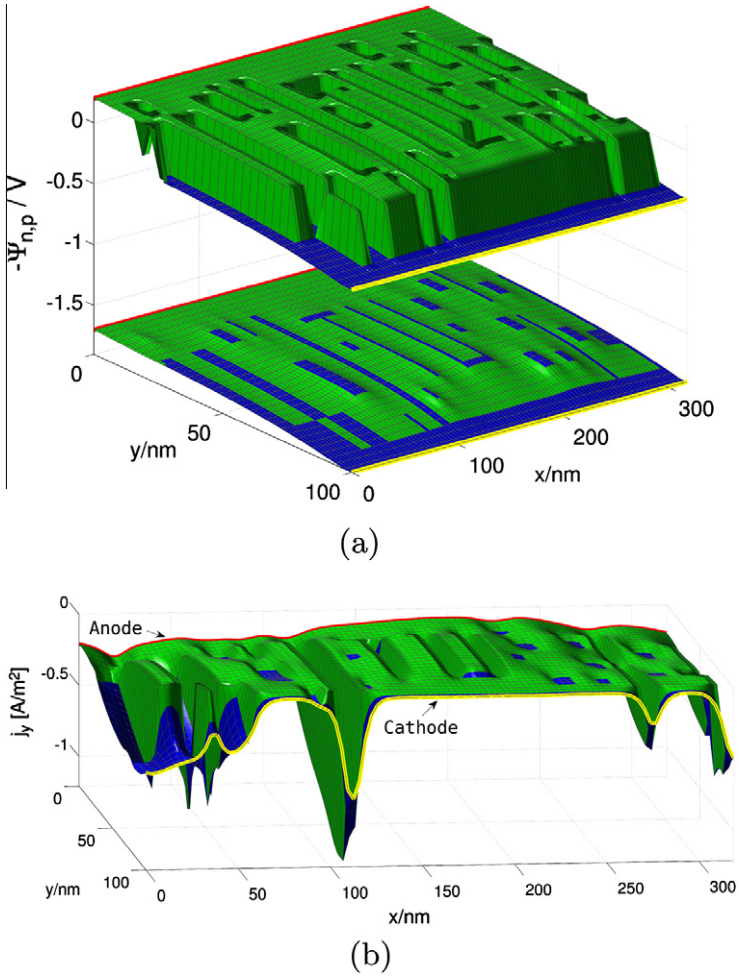

Fig. 5. Generalized potential $\tilde{\Psi}_{n(p)}$ for electrons (holes) (a) and current density distribution in *y*-direction (b) of the intermediate structure at the maximum power point ($V_{mpp} = 1.3$ V) of an illuminated cell. The area corresponding to the donor (P3EBT) is indicated in green (/light gray), the one of the acceptor ($CuInS_2$) in blue (/dark gray). The vertical position of the yellow line in the lower panel indicates the electron current density at the cathode and the vertical position of the the red line the hole current density at the anode. (For interpretation of references to color in this figure legend, the reader is referred to see the web version of this article.)

through-going acceptor paths. This adduces further evidence that comblike structures lead to best efficiencies. Moreover, it can be seen in regions close to the contacts depicted in Fig. 5(b) that the current is confined to the acceptor region, while the hole current appears to be spatially more uniform in the vicinity of the anode. This lack of confinement is related to the vanishing offset in the hole transport levels in donor and acceptor (Fig. 5(a)).

Impact of the level offset: To discriminate between the effect of morphology and the disadvantageous lack of an HOMO level offset, we replace $CuInS_2$ by a fictitious acceptor material whose HOMO and LUMO are equidistantly set off by 0.4 eV with respect to the P3EBT levels (Fig. 2(b)). All other parameters including $V_{\text{built-in}}$ were kept the same. The corresponding *I–V* characteristics for the three model geometries assuming ohmic contacts are shown in Fig. 6(b,filled symbols). Compared to the curves obtained in the original P3EBT/$CuInS_2$ device Fig. 6(a), the following differences arise: Independent from the interface structure, j_{sc}, V_{oc}, and PCE are increased (cf. also Table 2) for the idealized acceptor. However, the shape and, thus, FF are less ideal. While, e.g., the comb-like structure gives rise to an FF of 61.3% in P3EBT/$CuInS_2$, FF drops to 58.6% when changing the acceptor. At the same time, the enhanced values of j_{sc} and V_{oc} compensate for the loss in FF and effectively increase PCE from 3.25% to 4.31%.

The origin of the decrease in FF and increase in V_{oc} is presumably discussed best for the case of the interdigitated interface. The apparent departure of the *I–V* curve from an ideal diode-like shape (Fig. 6(b)) turns out to be related to the bias-dependence of hole transport. Fig. 6(c) schematically depicts the general transport scenario valid for biases within the power quadrant. As discussed already in Fig. 4(a,e), the contribution from electrons to the overall current is not affected by the actual bias. For voltages not exceeding V_{oc}, the corresponding electric field is not able to lift the electrons across the barrier at the interface. Therefore, all generated electrons diffuse towards the cathode (Fig. 6(c)). Holes that are generated throughout the acceptor and via exciton dissociation at the interface, give rise to a gradient in the concentration p that induces a desired diffusion current through the donor towards the cathode (cf. Fig. 6(c)). However, due to the external bias there is a non-vanishing electric field that drives holes, in particular those generated close to the anode, towards the wrong contact. The higher *V*, the higher the loss in hole current due to such drift currents. With the introduction of an offset between the hole transport levels, holes regard the transfer from the interface into the donor region as energetically favorable (cf. Fig. 6(c)). I.e., there is an effective diffusion process that (i) diminishes p within the acceptor and, thus, (ii) counteracts the disadvantegeous drift current. As a result, the photocurrent "decays" slowlier with *V* than in a device without level offset. Thus, V_{oc} is increased beyond $V_{\text{built-in}}$ and FF is reduced. Note that this effect is significantly less pronounced in purely exciton-based solar cells, since the predominant amount of holes contributing to the detrimental drift current, i.e., those generated in bulk, does not exist.

The most profound dependence of j on the type of acceptor is observed for the nanoparticle geometry. Aided

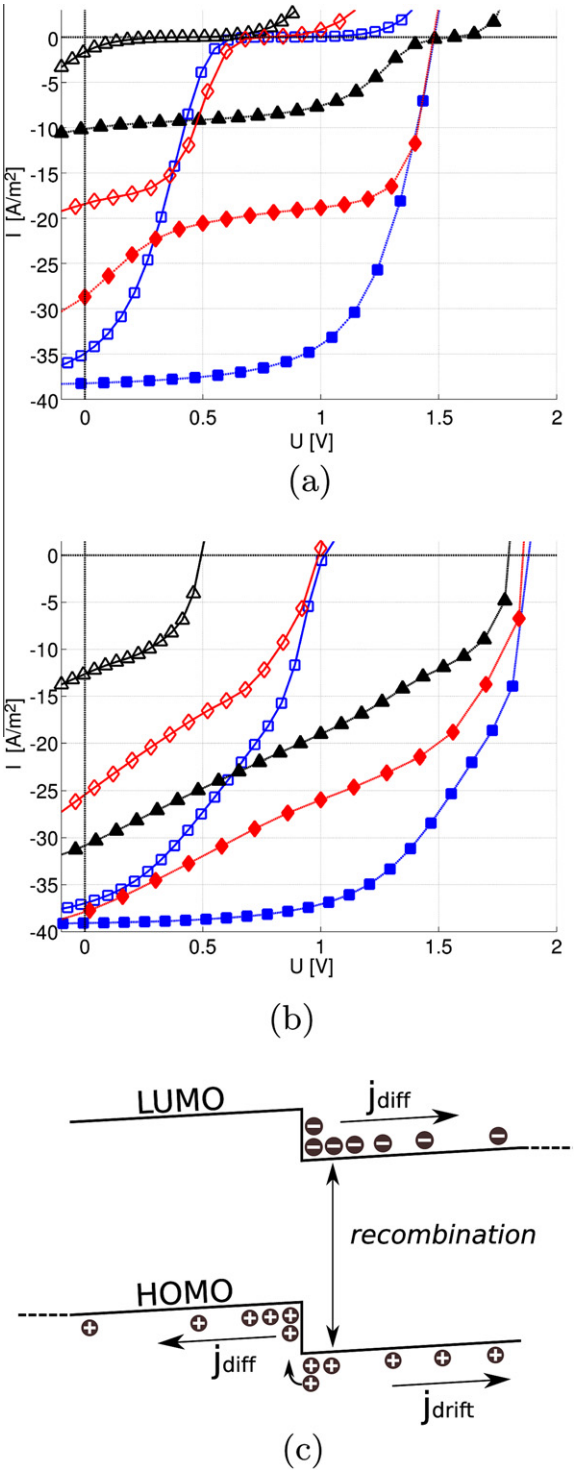

Fig. 6. *I–V* curves for the interfaces of (a) P3EBT/$CuInS_2$ and (b) P3EBT/idealized acceptor in a device with Al and ITO contacts (open symbols) and ohmic contacts (filled symbols). Shown are the curves for the interdigitated interface (squares) with a finger width $d = 50$ nm, nanoparticles (triangles), and real structure (diamonds). (c) Sketch of the current contributions for a P3EBT/idealized acceptor device operating in the power quadrant.

by a non-vanishing hole level offset, holes generated in the acceptor better escape into the donor and, thus, from the region of trapped electrons. Thus, recombination losses are strongly reduced.

Impact of contacts: To study the impact of actual contacts, aluminum with a workfunction of $\theta = -4.50$ eV (intrinsic electron concentration of 10^{29} m^{-3}) for the cathode and indium tin oxide (ITO) with a workfunction of $\theta = -5.0$ eV (intrinsic hole concentration of 10^{27} m^{-3}) have been considered. The position of the contact workfunctions with respect to the transport levels of P3EBT and $CuInS_2$ is depicted in Fig. 2(a). As the difference in the contact workfunctions is exclusively dictating the built-in voltage, we arrive at $V_{\text{built-in}} = 0.5$ V. The *I–V* curves considering Al/ITO contacts and interface geometries as introduced above are shown in Fig. 6(a) for P3EBT/$CuInS_2$ and in Fig. 6(b) for a P3EBT/idealized acceptor combination. In Table 2 the corresponding figures of merit can be compared between devices with ohmic and real contacts.

In comparison to the curves representing the ohmic case (indicated by closed symbols in Fig. 6), the *I–V* curves possess a lower V_{oc} (cf. also Table 2). This can be seen best for devices containing an idealized acceptor and through-going paths (Fig. 6(b), squares and diamonds): Actual contacts (open symbols) appear to shift the curves obtained for ohmic contacts (closed symbols) towards lower voltages by an amount of ca. 0.9 V. This value corresponds to $V_{\text{built-in}}^{ohmic} - V_{\text{built-in}}^{non-ohmic} = 1.0$ V corrected by small differences in diffusion contributions. As a result, PCE is reduced by at least a factor of 3, e.g., from 4.3 to 1.5 for the interdigitated interface. Note, that V_{oc} exceeds $V_{\text{built-in}}$ by ca. 0.4 V due to the aforementioned effective diffusion induced by

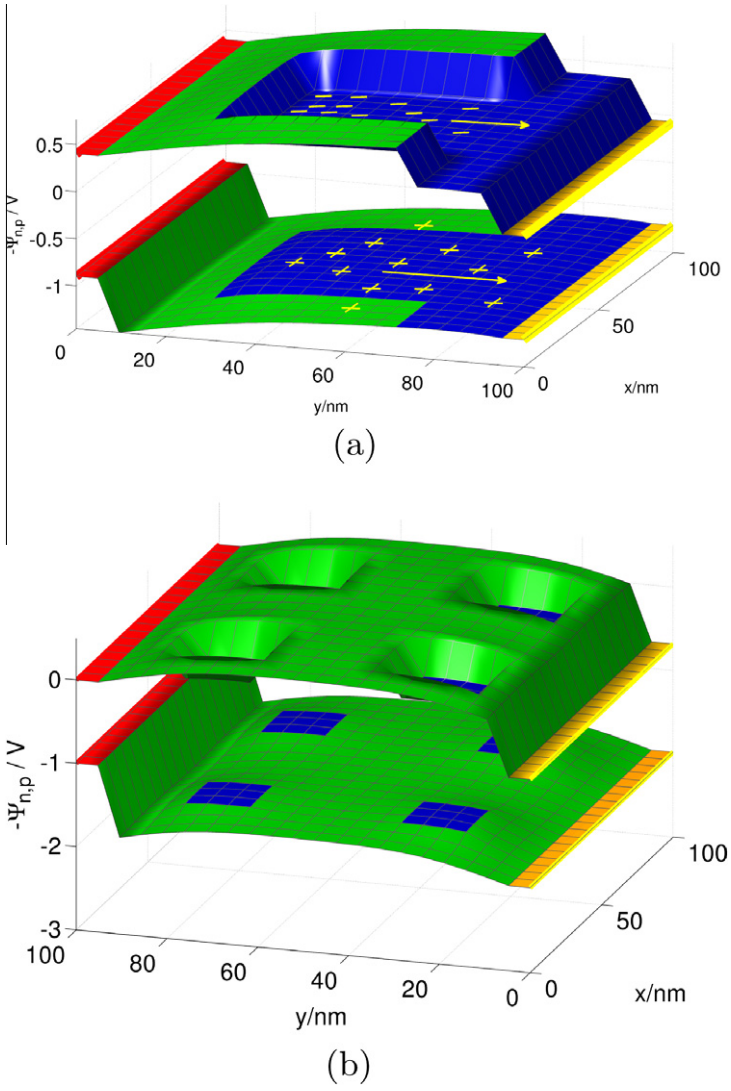

Fig. 7. Generalized potential $\widehat{\Psi}_{n(p)}$ for electrons (holes) of a device with (a) a comb-like interface at $V_{\text{ext}} = 0.83$ V bias and (b) a nanoparticle interface and Al/ITO contacts at $V_{\text{ext}} = 0.32$ V bias. The area corresponding to the donor (P3EBT) is indicated in green (/light gray), the one of the acceptor ($CuInS_2$) in blue (/dark gray). Electrons [/holes] in the E_C [/E_V] level are schematically indicated by "−" [/"+"]. (For interpretation of references to color in this figure legend, the reader is referred to see the web version of this article.)

the hole transport level offset. When turning to P3EBT/$CuInS_2$ devices, however, real contacts additionally induce strong changes in the shape with respect to their ohmic counterparts, as can be deduced from Fig. 6(a) and the FF values in Table 2. Correspondingly, both j_{sc} and PCE values are affected. Even for the most ideal heterojunction geometry, PCE drops by more than a factor of 4 from 3.25 to 0.75. For devices with through-going paths (Fig. 6(a), squares and diamonds), this change in shape is due to a photocurrent that (i) drops more rapidly with increasing V and (ii) collapses into a pronounced plateau that is approximately centered at V_{oc}. Already at biases beyond 0.6 V, the net *photocurrent* vanishes. Electron and hole photo currents *cancel* each other exactly. This can be readily understood from the corresponding generalized potential distribution, shown for a representative external bias $V_{ext} = 0.83$ V near V_{oc} in Fig. 7(a): The electron current is essentially caused by diffusion, as discussed previously (cf. Fig. 6(c)). All holes are driven by the drift force towards the cathode as their motion is not hampered by a band offset, and are, thus, moving into the same direction as the electrons (Fig. 7(a)). This condition, of course, promotes a further reduction of the carrier concentrations due to efficient recombination. A similar mechanism was revealed by Uhrich et al. [19] when changing the level offset between hole transporting moities in a layered organic solar cell. In the vicinity of V_{oc}, the I–V curves are already dominated by the dark characteristic. The onset of the dark electron current eventually occurs at a voltage of about 0.9 V, i.e., an appreciable amount of electrons can cross the non-illuminated device at biases exceeding the sum of $V_{built\text{-}in} = 0.5$ V and the barrier posed by the LUMO/LUMO band offset of 0.4 V. Note that the corresponding hole dark current is very small, since (i) the hole concentration at the ITO contact is small and (ii) a large injection barrier from ITO into P3EBT is present. The degree to which the s-shape evolves can be further influenced by the height of the injection barrier present at the contacts. For a given built-in voltage, an increase of the injection barrier height associated to thermoionic injection was shown to induce a sigmoidal shape in the I–V curve while not affecting V_{oc} [9].

The most significant influence of the contacts is seen for the nanoparticle devices (Fig. 6, upper triangles). The open circuit voltage is with $V_{oc} \approx V_{built\text{-}in} = 0.5$ V independent from the acceptor material. A vanishing photocurrent at voltages beyond $V_{built\text{-}in}$ is an indication for a loss in selectivity of the contacts. Indeed, when inspecting the generalized potential at a bias of 0.32 V near $V_{built\text{-}in}$ shown in Fig. 7(b), we recognize a strong deviation from a linear voltage drop from anode to cathode. Rather, the potential is almost flat and bends slightly downward from the device's center towards the contacts due to electron accumulation in the nanoparticle regions and close to the cathode. Therefore, electrons and holes experience an average similar driving forces towards each of the contacts; the *net* photo current vanishes.

For the P3EBT/$CuInS_2$ device, i.e., in the device lacking a hole transport level offset, j_{sc} vanishes almost to zero. Here, acceptor-generated holes do not leave the nanoparticles sufficiently fast and, thus, are subject to efficient recombination with electrons trapped in the acceptor. As a result, its I–V curve is characterized by a very small j_{sc} value of 2 A m^{-2}, and a broad plateau centered around V_{oc}, i.e., the fill factor is lowered from 0.23 to 0.10 (cf. Table 2). In comparison to the device with ideal contacts, the resulting PCE drops by an order of magnitude from 0.69 to 0.01.

4. Conclusion

The carrier transport in hybrid cells has been studied in the light of interplay between (i) energy barriers formed at the contacts, (ii) barriers at the donor–acceptor interface, and (iii) representative shapes of the heterojunction. Particular attention has been paid to the fact that carrier generation can occur at the heterojunction (due to dissociation of the donor excitons) *and* in the bulk of the acceptor material (due to band to band generation in the inorganic material).

Each of the three factors consitutes a major loss factor that profoundly determines the power conversion efficiency of hybrid organic–inorganic solar cells. As expected, the choice of the interface geometry has a crucial influence on the device efficiency even if perfect contacts are considered. In accord with previous investigations [5,33,42], interdigitated structures are found to yield the highest efficiencies. In such highly ordered systems, j_{sc} is limited by the digit width and, thus, by the exciton diffusion length [8,10]. This is true independent from the nature of the contacts.

The presence of isolated islands in the device, be them formed by the donor and/or acceptor material, reduces the overall efficiency. The extent of this reduction strongly depends on the actual ratio between through-going pathways and isolated particles. The location of the maximum power point is determined by an interplay of two essential effects: The more through-going paths exist, (i) the more short circuit current can be obtained and (ii) the larger the area at which advantageous contact barriers can be offered, i.e., the more the plateau (s-shape) formation in the I–V curve can be suppressed.

As a second factor, it turns out that a vanishingly small or a negative hole transport level offset leads to an accumulation of holes in the nominally electron transporting acceptor zone. The resulting reduction of the photocurrent due to (i) direct hole and electron photocurrent compensation and (ii) recombination represents a major contribution to the overall efficiency loss. A straightforward way to avoid losses due to non-ideally shaped I–V curves is, therefore, to select the semiconducting materials so that the hole transport level offset at the heterojunction promotes hole diffusion into the donor. Note, that this criteria for chosing transport levels has to be distinguished from other, already well employed rules: As a first requirement it is commonly accepted that a significant offset in the LUMO levels ensures efficient exciton dissociation [36]. Secondly, it is advantageous to block the charge carriers prior entering the opposing contact (see, e.g., in [41]); however, there are no restrictions in which part of the solar cell this blocking needs to occur.

Despite the determining influence of the level offsets, the efficiency of the device is strongly influenced by the choice of contacts. As soon as non-ohmic contacts to the

semiconductors are formed, the open circuit voltage is dictated by the contact workfunctions; V_{oc} differs from $V_{built\text{-}in}$ only by a small possible amount corresponding to the smallest transport level offset arising from diffusion. For our choice of materials, V_{oc} is halved when introducing Al/ITO contacts. Moreover and less expectedly, barriers at the semiconductor metal interfaces give rise to a substantial deviation from the ideal diode-shaped *I–V* curve and, thus, reduce the fill factor. As shown by Yip et al. [40] for ZnO-based bilayer hybrid solar cells, the systematic tuning of just the cathode workfunction via SAMs revealed fill factors varying by a factor of two.

From the considerations above it is possible to conclude that the three investigated factors give rise to equally serious efficiency losses. As each of these factors directly relates to the properties and processing of the chosen materials, we can derive the following guidelines to select suitable material combinations: (i) The formation of ohmic contacts ensures contact-independent open circuit voltages *and* high fill factors. (ii) A successful suppression of the formation of donor or acceptor islands is boosting the FF. And, (iii), holes need to be driven from the acceptor into the donor at the heterojunction by means of an effective diffusion induced by a transport level offset.

[26] *We use this convenient rate expression also for the pristine inorganic bulk. For the particular mobilities that will be used below (cf. Table 1), this expression is applicable and differs by the smallest possible factor of two [6] from the standard Langevin expression [39]. The actual recombination rate in bulk heterojunction cannot be expressed in a simple form using the mobilities [6]; for the ratio of mobilities employed in our work, however, the actual rate is limited from below by rate expression according to Koster et al. [25] and from above by the Langevin rate [6]. Careful testing revealed that the type of recombination rate had no detectable impact on the I–V curves. This result is supported by Maturova et al. [14], who showed that the standard Langevin rate and a Koster-type rate equivalently describe the bimolecular recombination in two-dimensional simulation.*

[27] *The consideration of the actual distribution of the electromagnatic field is beyond the scope of this paper.*

[28] *To be consistent with the numerical treatment of exciton dissociation, our implementation mimicks the direct charge generation by assuming that an incoming photon generates an exciton first which dissociates immediately into free charges. This somewhat underestimates the number of carriers generated in the inorganic phase; the corresponding relative error in $\Delta G/G$ does not exceed* 10^{-3}.

ABSTRACT

Single layer white organic light emitting diodes (WOLED) are obtained with a polymeric blend, whose constituents are three polyfluorene (PF) based materials emitting in the three fundamental colours thanks to the insertion of a single monomeric unit with different chemical nature at the core of the PF chain. The peculiar choice of three fully compatible polymers allows us to obtain stable and homogeneous active layers for highly performing WOLEDs. The high quality white electroluminescence with chromaticity coordinates (0.32; 0.33), correlated colour temperature of 5893 K and colour rendering index of 90, makes these compounds good candidates for low-cost solid-state lighting technologies.

1. Introduction

White organic light emitting diodes (WOLEDs) have gained increasing interest both in the scientific and in the industrial communities thanks to their great potential in lighting applications and as back-lights in liquid-crystal displays [1]. Lighting uses a significant part of the world energy resources, now partially wasted by inefficient incandescent lamps. In the future WOLEDs can represent a valuable alternative to incandescent lamps thanks to both their higher efficiencies and their unique properties such as large-area emission and processability in transparent and flexible devices. White-light emission can be obtained either by mixing the three fundamental colours or with two complementary colours and devices have been reported with multiple and single layer architectures [2,3]. Among many different approaches, devices based on soluble and processable polymeric materials are of particular interest since they provide a simple technology which allows for low-cost large area and flexible devices. The drawbacks of these materials are the poorer device performances when compared to devices fabricated with small molecules by using vacuum-deposition technologies, the incompatibility among different chemical components of the blends (with unwanted time-evolution of phase separation) and the voltage dependence of the emitted colour caused by the different nature of the emitting states.

An alternative approach is the use of blends of macromolecules with the same chemical nature, able to combine the colours to obtain white light [4]. Even though the efficiency of devices fabricated with only fluorescent materials is lower with respect to those employing phosphorescent ones, the advantages in terms of device stability, robustness, white light quality and ease of fabrication make them of great interest in indoor lighting applications. Most of the polymeric materials used in WOLEDs contain polyfluorene (PF) based polymers as blue emitting material, combined with lower energy gap materials to which only

doi:10.1016/j.orgel.2010.09.009

a limited amount of energy is transferred through a controlled resonant energy transfer (RET) mechanism [5] by a proper supramolecular structure of the materials [6].

In this work, we report on the fabrication and characterization of a single layer WOLED obtained with a polymeric blend whose constituents are three PF based polymers emitting in the three fundamental colours. The different emission colours of two of the three polymers, i.e. green and red, are achieved by an unprecedented core-type design approach which reduces the chemical effort in the synthesis and improve the reproducibility of the material composition with respect to random synthesized copolymer. Here, a molecular dye of different structure and emission colour, is inserted as bridging core between two identical polymeric arms. The polymeric arms, as well as the pure blue-emitting compound, consist of a fluorene-based alternating copolymer (hereafter **1**) made by a triphenylamine (TPA) substituted fluorene unit alternated with an alkyl substituted fluorene one. Worthy to mention, we have already shown that the insertion of TPA moiety resulted in reduced interchain interactions, an enhanced hole injection, and increased morphological stability with respect to conventional PFs [7]. Central yellow–green and red emitting molecules based on benzothiadiazole moiety are used as molecular dye core.

We demonstrate that the peculiar choice of such core-type polymers emitters, possessing the same chemical nature and therefore fully compatible, allows us to obtain stable and homogeneous active layers (AL) for high quality WOLEDs.

2. Materials and methods

2.1. Synthesis and characterization of core-type copolymers

Polymer **1-borolane** was synthesized by reacting 9,9-dioctylfluorene-2,7-diboronic acid bis(1,3-propanediol) ester (356 mg 0.62 mmol) with 9,9-bis(4-diphenylaminophenyl)-2,7-dibromofluorene (500 mg 0.62 mmol) for 10 h at 90 °C before adding the capper phenylboronic acid pinacol ester (3:1 M ratio) and stirring for further 15 h at 90 °C. The solution diluted with 10 ml of toluene was filtered through Celite, concentrated and **1-borolane** was recovered by precipitation in methanol. After extraction with acetone using a Soxhlet apparatus and drying 190 mg (42% yield) was obtained. 75 mg of **1-borolane** was dissolved in toluene and (0.32 mg, 0.27 μmol) of $Pd(Ph_3P)_4$ from a previously prepared toluene solution together with 7.5 ml of [2 M] K_2CO_3 aqueous solution and a droop of Aliquat were added. A toluene solution of 4,7-dibromo-benzothiadiazole (2.8 mg, 6.8 μmol in 4.0 ml) or 4,7-bis(5-bromothiophen-2-yl)benzothiadiazole (3.1 mg, 6.8 μmol in 4 ml) to get **2** and **3** core-type polymers respectively was slowly dropped in 8 h maintaining the reaction at 90 °C under stirring. The mixture was further stirred for 15 h, then phenylbromide (373 mg, 2.38 mmol) was added as a quencher of unreacted **1-borolane** and the stirring and heating were prolonged during 24 h. The solution was filtered through a Celite column and the polymer was precipitated in methanol. Extraction with acetone was used to remove any residue of dyes obtaining 50 mg of **2** and 62 mg of **3**, respectively.

^{1}H NMR of **2** (toluene-d_6, 298 K) δ (ppm): 8.11 (s, fluorenyl), 7.8–7.6 (m, fluorenyl + BT), 7.42 (m, fluorenyl), 7.2–6.8 (m, N-Ph), 2.07 (br, αCH_2 alkyl chain), 1.05 (br, CH_2), 0.81 (m, CH_3).

^{1}H NMR of **3** (toluene –d_6, 298 K) δ (ppm): 8.11 (m, fluorenyl + Th), 7.8–7.6 (m, fluorenyl + BT), 7.42 (m, fluorenyl), 7.25–6.8 (m, N-Ph + Th), 1.99 (br, αCH_2 alkyl chain), 1.05 (br, CH_2), 0.81 (m, CH_3).

A GPC determination of the molecular weight (Mn) of compounds **1**, **2** and **3** and **1-borolane** gave 10075 (Mw/Mn 1.95), 6887 (2.00), 8574 (2.29) and 6016 (1.92), respectively. The Mn values were referred to standard of polystyrene.

2.2. Measurements

^{1}H spectra were recorded with a Bruker ARX400 MHz spectrometer.

Gel permeation chromatography (GPC) measurements were carried out on Waters SEC system consisting of a pump, a 410 differential refractometer, and a 490 UV spectrophotometer as detectors. The column was a Ultrastyragel Waters; THF as solvent and polystyrene as standard were used.

Electrochemical experiments were performed at room temperature under nitrogen in three electrode cells. The counter electrode was platinum; reference electrode was a silver/0.1 M silver perchlorate in acetonitrile (0.34 V vs SCE). The core-polymers were generally investigated in millimolar concentration in acetonitrile + 0.1 M Bu_4NClO_4. The voltammetric apparatus (AMEL, Italy) included a 551 potentiostat modulated by a 568 programmable function generator and coupled to a 731 digital integrator. The working electrode for cyclic voltammetry was a platinum minidisc electrode (0.003 cm^2).

Photoluminescence (PL) and electroluminescence (EL) were obtained with monochromator equipped with a CCD detector, by exciting with a monochromated Xenon lamp, or by applying a constant bias, respectively. Solid-state PL quantum yields (PL-QY) were obtained by using a home-made integrating sphere [8]. Device optimization and characterization were performed following the methods reported elsewhere [9,10]. PL and EL microscopy images were obtained using a Nikon Eclipse TE2000-U inverted confocal microscope.

2.3. Film and OLED fabrication

Macromolecules were dissolved in toluene 15 mg/ml. Indium tin oxide (ITO; 15 Ω per square) substrates were cleaned by sonication in distilled water, acetone, and isopropyl alcohol. After treatment with nitrogen plasma, a 50 nm thick film of poly-(3,4-ethylenedioxythiophene)-poly(styrenesulfonic acid) (PEDOT:PSS) (Clevios P VP AI 4083, H.C. Starck) used as a hole-injection layer at the anode interface was spin-coated onto the ITO substrate, and then dried under nitrogen atmosphere at 100 °C for 15 min. Poly(vinylcarbazole) (PVK; Aldrich, MW 10^6 Da) from chlorobenzene solution was subsequently deposited

on top of the dried PEDOT:PSS layer and treated at 150 °C for 30 min. A thin film of copolymers or blends were then spin-coated inside a nitrogen-filled drybox. The active layer thickness was around 80–100 nm. A thin layer of Calcium (30 nm) or Barium (5 nm) and subsequently 100 nm layers of Aluminium were deposited on the top by vacuum (10^{-7} mbar) thermoevaporation. All device preparation steps and performance measurements were performed inside a MBraun drybox system.

3. Results and discussion

The chemical structure of the materials utilized in the paper is reported in Fig. 1. In a previous work [11] we reported the preparation of polymer **1** functionalized with a borolane group (**1-borolane**). The newly synthesized core-type copolymers **2** and **3** were prepared by reacting via a Suzuki coupling a large excess of **1-borolane** with 4,7-dibromo-benzothiadiazole (Aldrich) as the green core dye and 4,7-bis(5-bromothiophen-2-yl)benzothiadiazole as the red emitter [12].

UV–visible absorption spectra are dominated by fluorene backbone 388 nm band and absorption of core dyes is visible as weak shoulder at 450 nm and weak broad band at 520 nm for **2** and **3**, respectively (Fig. 2a). PL emission spectra of **1**, **2**, **3**, **blend1** (**3**:**2**:**1**) (1.5:1.75:96.75) and **blend2** (**3**:**2**:**1**) (0.3:0.45:99,25) films are reported in Fig. 2b and the corresponding PL-QY are summarized in Table 1.

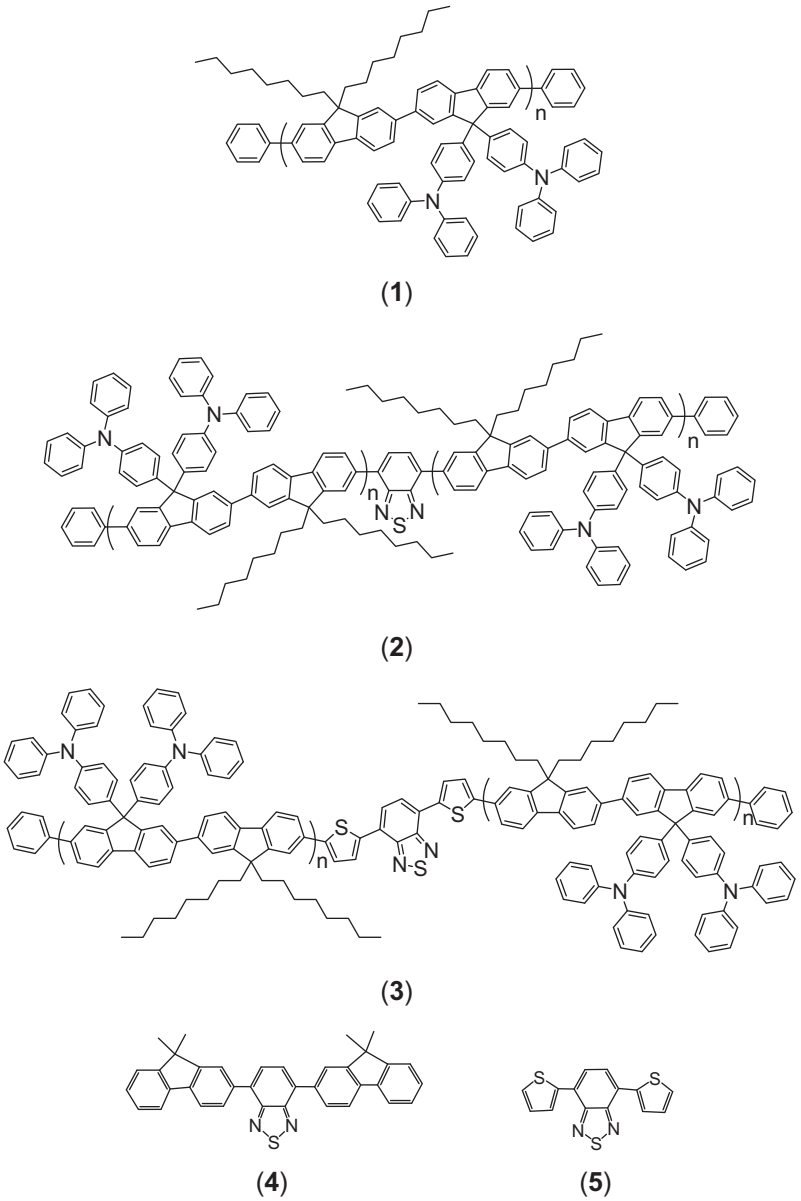

Fig. 1. Chemical structure of homopolymer (**1**) and core-type copolymers (**2**–**3**) and model compounds, oligomers (**4**–**5**).

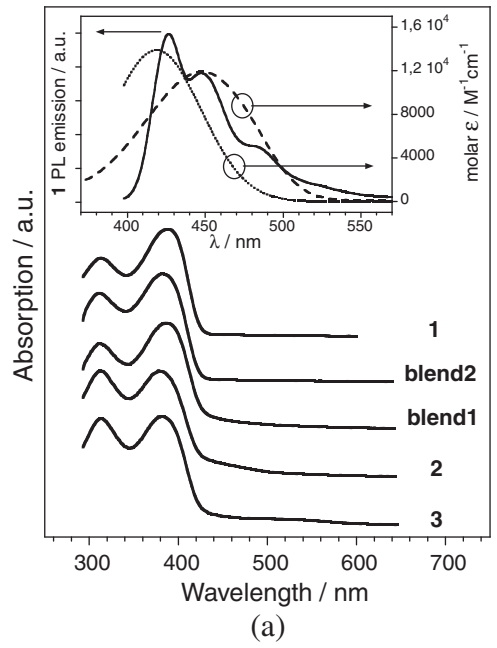

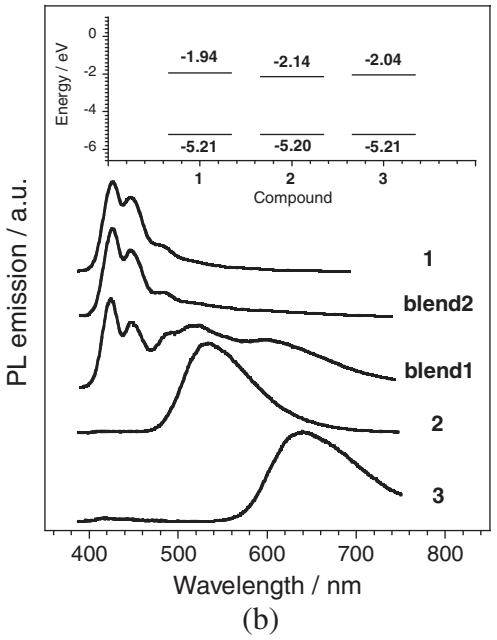

Fig. 2. (a) Normalized absorption spectra of **1**, **2**, **3**, **blend1** and **blend2** films. Spectra are vertically shifted for clarity. Inset: overlap between solid-state PL emission of **1** (solid line) and **4** (dotted line), **5** absorption in solution (dashed line); (b) PL spectra of **1**, **2**, **3**, **blend1** and **blend2** films. Spectra are vertically shifted for clarity. Inset: energy levels of the compounds.

The oligomers **4** 4,7-bis(9,9-dimethyl-9H-fluoren-2-yl)benzothiadiazole [13] and **5** 4,7-di(thiophen-2-yl) benzothiadiazole [14] are used as model compounds to theoretically investigate RET from the PF backbone towards the core dyes. Almost complete spectral overlap between the absorption of both the **4** and **5** dyes and the emission of **1** is obtained (see inset of Fig. 2a). This condition satisfies the request for an efficient RET from **1**, the excitation donor, to the core dyes, which behave as the acceptors.

The values of critical radius R_0, defined as the average distance between donor and acceptor when the RET rate is equal to the sum of all other relaxation rates of the donor are 3.1 and 3.2 nm for **2** and **3**, respectively.

The energy levels of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) have been derived from cyclovoltammetric measurements [15] for **1**, **2**, **3** compounds and are reported in the inset of Fig. 2b. For PVK we measured only the oxidation potential, derived the HOMO, while the LUMO value is obtained by using the optical energy gap of the polymer.

The effect of the substitution at the C9 position of fluorene moiety of functional groups for linear alkyl chains on supramolecular structure and optical properties of PF copolymers has been already reported [16]. The insertion of TPA groups increases stability with respect to radical oxidation, suppressing low-energy emission band related to keto-defect formation and leading to a stable blue emission. Moreover, as we have shown in our previous work, through hindering fluorene backbone aggregation, TPA contributes to tune RET process towards the acceptor [17], otherwise too efficient to observe the contemporary emission of all the chromophores.

To obtain white emission with high quality and efficiency, a series of devices with various compounds ratios were fabricated and evaluated. Devices were prepared with the standard architecture ITO/PEDOT:PSS/AL/Ca/Al for all compounds and blends, and the multilayer ITO/PEDOT:PSS/PVK/AL/Ba/Al ones for **1**, **blend1** and **blend2** only. By using a thin conductive polymeric interlayer between PEDOT:PSS and the emitting layer, the efficiency and lifetime can be improved [18]. In fact, PEDOT:PSS acidic nature may contribute to the active polymer degradation [19] and its poor electron blocking capability does not favour a good charge balancing [20]. After annealing treatment, the low solubility of the high molecular weight PVK interlayer allows to fabricate multilayer architecture by successive solution deposition. We think that a PVK interlayer, thanks to its HOMO and LUMO energy levels position, i.e. −5.44 and −1.84 eV, respectively, is able to block the radiative excitons from direct quenching by PEDOT:PSS and thus remove a nonradiative decay channel introduced by PEDOT:PSS itself. Moreover, due to both the electrons confinement into the emissive layer (produced by the energy barrier between PVK and active layer LUMO levels), and the rising of the energy barrier at the anode that could compensate the high hole mobility of the active layer based on **1**, **2**, **3** polymers, a better charge balance is feasible. Further investigations are in progress. [21] EL spectra (Fig. 3) were measured together with their current density–luminance–voltage (*J*–*L*–*V*) curves (see Fig. 4). All devices performances are summarized in Table 1.

Electro-optical characterization of **1** showed stable EL spectrum after several operating hours, under ambient conditions differently from the easily oxidable PF-based devices. Thus Polymer **1** provides a stable blue emitter and energy donor for both **2** and **3** copolymers. In **2** and **3** EL spectra, emission of the core dyes dominates, with peaks at 538 and 625 nm, respectively.

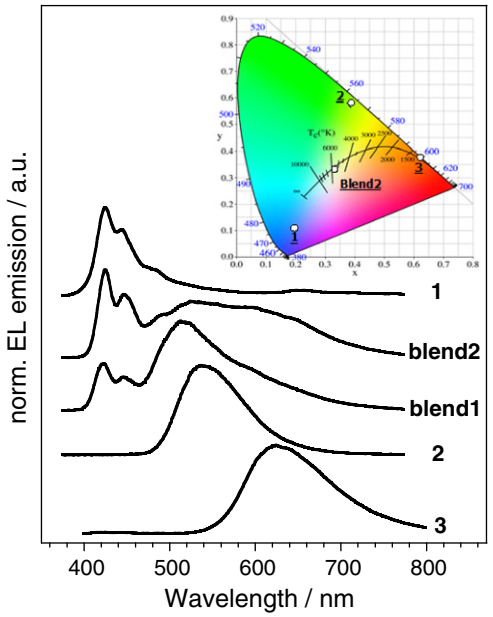

Fig. 3. EL spectra of ITO/PEDOT:PSS/AL/Ca/Al. Spectra are vertically shifted for clarity. Inset: CIE 1931 chromaticity space, also showing Planckian locus.

The high quality WOLED, with CIE (1931) chromaticity coordinates [22] (0.32; 0.33) at 7 V, a correlated colour temperature [23] of 5893 K (inset of Fig. 3) and an excellent colour rendering index [24] as high as 90, is obtained by blending **3**, **2** and **1** in the weight ratio (0.3:0.45:99.25) (**blend2**). The CIE coordinates remain in the region of white, with a slight shift to (0.34; 0.35) when the voltage is lowered to 6 V. The colour shift upon variation of the applied voltage is common in single emissive layer WOLEDs based on polymers or polymer–dye mixtures. It is usually attributed to the fact that the concentrations of acceptor chromophores (i.e. core molecular dyes with a lower energy gap with respect to the main polymer) are usually very low thus the possibility of charge trapping (see later) on such sites will decrease by increasing voltage as the low energy excited states are saturated [25]. Alternatively, the change in the emission spectra could be explained by a shift or broadening of the emission zone or a competition between electron trapping on low energy gap emitting sites and unperturbated charge transport through the organic layer [26]. By a proper balancing of relative concentration of **1**, **2** and **3** in a blend, EL spectra can be addressed in terms of the colour of the emission. Moreover, the same chemical nature, and therefore full compatibility of the components leads to a homogeneous and amorphous film with suppressed demixing tendency

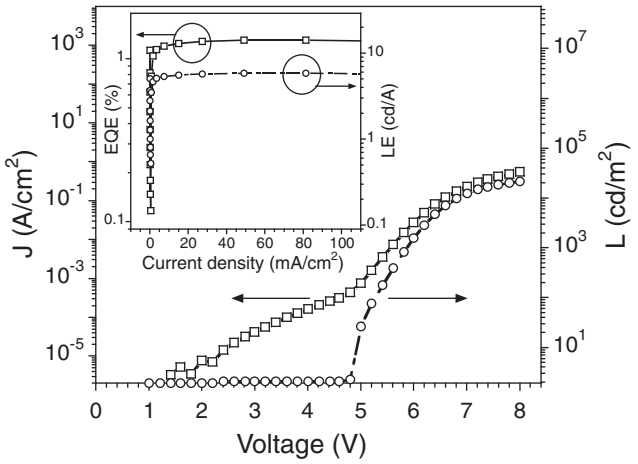

Fig. 4. *J–L–V* curves for ITO/PEDOT:PSS/PVK/**blend2**/Ba/Al device; Inset, EQE-J and LE-J curves.

as confirmed by AFM technique investigation of PFTPA-based film [11] and by PL spectra (see Fig. 5) of **blend2**, upon thermal treatment up to 150 °C for 1 h in room atmosphere. According to literature data [27], performances are further improved by optimizing device's architecture, reaching maximum EQE of 1.3% and luminance (L) of about 21250 cd/m^2 at 7 V. The corresponding maximum luminous efficiency (LE) of 5.8 cd/A (inset of Fig. 4) and power efficiency of 2.8 lm/W are remarkable for this type of blend [28]. In fact, the upper limit for device's EQE [29] based on **blend2** is expected to be around 5%. Further optimization steps are possible to reach this theoretical upper limit: we have observed on PFTPA-based polymers that, due to their amorphous character, the thermal treatments can be used to improve the efficiency of devices through the improvement of the cathode/polymer interfacial adhesion [27].

The coincidence of the current and light onsets [30] (4.8 V, Fig. 4) implies holes–electron balancing into the active layer. The observed pronounced difference in blend EL spectra as compared with corresponding PL, i.e. white PL emission from **blend1** but white EL from **blend2**, is due to a trapping of injected charge carriers on **2** and **3** compounds beside the RET mechanism discussed above. In fact, as could be deduced from energy band diagram of the compounds, the holes, once injected, can move freely in the whole bulk without energy barriers (same ionization potential for **1**, **2** and **3**) while electron would be trapped by **2** and **3** due to the lower electron affinity. Electron–hole pairs are then formed and its recombination mainly occurs on the core molecular dye. The similar energy transfer efficiency from the blue emitting polymer to the green and the red emitting copolymers, and the comparable electron-trapping aptness of the two low energy gap materials, makes the EL quite stable upon voltage variations.

Typical PL and EL micrographs of ITO/PEDOT:PSS/PVK/**blend2**/Ba/Al device are reported in Fig. 6. EL images are obtained in high luminance regime by applying a constant bias (15 V). Random areas with weaker emission are noticeable, corresponding to brighter spots in the PL micrograph. This difference in light intensity is related to preexisting defects associated with the device fabrication and not evidence of EL diode degradation. The typical dark spots previously observed in organic LEDs [31], i.e. none-missive areas due to degradation, are not visible here even after 2 h of operation in aerobic exposure.

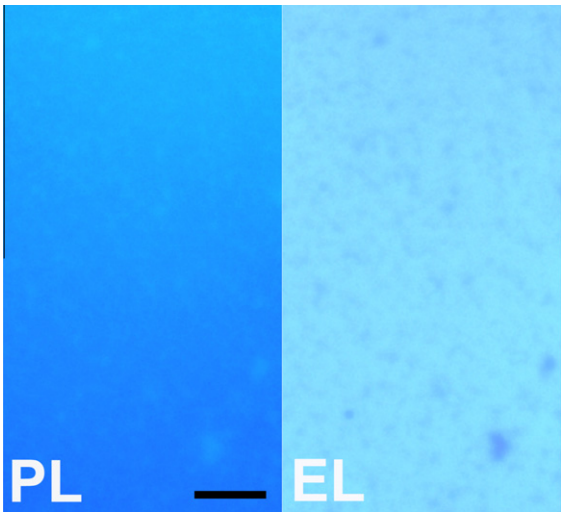

Fig. 6. PL and EL micrographs of ITO/PEDOT:PSS/PVK/**blend2**/Ba/Al device. Colours of micrographs doesn't match with real colours. The bar corresponds to 10 μm.

To support the fundamental antioxidant role of TPA groups, the comparison between PL spectra of **blend1** and **blend2** as fresh film and after 18 months aging in room atmosphere is shown in the inset of Fig. 5. Only a very weak low-energy emission band, commonly related to fluorenone formation, that usually heavily affects fluorene-based compounds emission, is observed for **blend2**, while **blend1** spectrum remains unchanged.

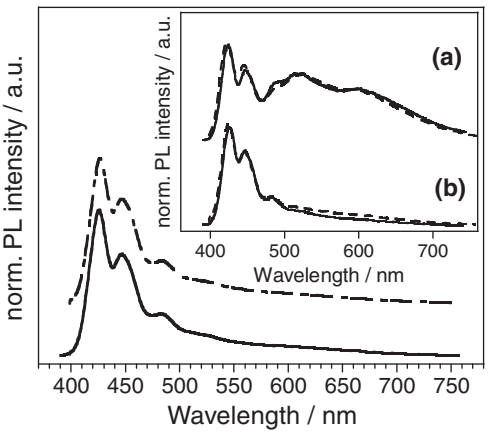

Fig. 5. Normalized PL spectra of pristine (solid line) and annealed **blend2** film (dashed line). Spectra are vertically shifted for clarity. In the inset, normalized PL spectra of fresh (solid line) and 18 months aged (dashed line) **blend1** (a) and **blend2** film (b).

4. Conclusions

In conclusion, high quality white emitting OLED in terms of CIE coordinates, EQE, CRI and stability is obtained from an all polymeric and solution processable single layer device. The excellent performance of the polymeric blend relies on both the high stability and the fully compatibility of the blue emitting PF copolymer and two green and red emitting PF based copolymers. The latter are obtained by an unprecedented core-type design approach which reduces the chemical effort in the synthesis and improve the reproducibility of the material composition with respect to random synthesized copolymers. The polymeric arms, as well as the pure blue-emitting compound, consist of an almost unoxidable fluorene-based alternating copolymer made by a triphenylamine substituted fluorene unit alternated with an alkyl substituted fluorene one. Well balanced energy transfer and electron trapping mechanisms control the colour emission in the highly homogeneous active layer blend.

ABSTRACT

We report a significant increase in the open circuit voltage (V_{oc}) and power conversion efficiency in both chloroaluminium phthalocyanine (ClAlPc)/fullerene (C_{60}) and boron subphthalocyanine chloride (SubPc)/C_{60} organic photovoltaic (OPV) cells with the insertion of a thin molybdenum oxide (MoO_x) hole-extracting layer. This improvement was not seen with copper phthalocyanine (CuPc)/C_{60}, and the addition of the MoO_x layer leads to reduced device performance for pentacene/C_{60} cells. Cells containing the MoO_x layer demonstrated significantly improved stability compared to the cells deposited on bare indium-tin oxide (ITO). External quantum efficiency (EQE) measurements taken before and after constant AM1.5G illumination for 60 min showed reduced current losses for all cells containing the MoO_x layer, especially in spectral regions where the donor layer contributes. We attribute this improvement to the increased stability at the MoO_x/donor interface.

1. Introduction

Organic photovoltaic (OPV) cells show great potential to be a low cost source of renewable energy. Interest in the field has grown substantially since Tang's initial discovery of the donor–acceptor small molecule planar heterojunction [1], with improvements in cell performance brought about by the use of new materials, the insertion of exciton blocking layers, and the nanostructuring of the interfaces [2,3]. Cells are now approaching the efficiencies and lifetimes required for niche commercial market applications [4], however it is widely accepted that significant further improvements in performance are still needed for commercialisation with higher power conversion efficiencies (η_p) requiring increases in open circuit voltage (V_{oc}), short circuit current density (J_{sc}) and fill factor (*FF*).

By utilising donor layers with different properties, the performance of small molecule OPV cells is constantly being improved. Wide band gap materials have enabled larger V_{oc} values, materials with high absorption coefficients give improved J_{sc}, and those with a large exciton diffusion length allow more efficient charge separation and photocurrent generation [5]. The non-planar molecule, chloroaluminium phthalocyanine (ClAlPc), has shown particular promise for small molecule OPVs due to its absorbance in the near infra-red [6], allowing greater coverage of the solar spectrum than the more commonly used planar copper phthalocyanine (CuPc) molecule [7]. Boron subphthalocyanine chloride (SubPc) has also shown recent promise as a donor material, as it produces a larger V_{oc} value due to a favourable energy level offset with the commonly employed C_{60} acceptor [8]. Heterojunctions based on oligoacenes, in particular pentacene, have also being extensively studied and benefit from the relatively long exciton diffusion length of >50 nm, allowing comparatively thicker layers to be used to increase light absorption [5,9].

Indium-tin oxide (ITO) is the most commonly used hole-extracting electrode for OPVs due to its good transparency and conductivity [10,11]. However, ITO has several disadvantages for use in organic electronics, in particular inhomogeneous electrical characteristics across

its surface, the diffusion of indium into organic layers, poor energy level alignment with many organic materials, and variation in its properties due to processing conditions [11]. Layers of poly(ethyleneoxythiophene):poly(styrenesulfonate) (PEDOT:PSS) have been spin-coated directly on top of ITO to provide better energy level alignment with the donor material due to the higher work function of PEDOT:PSS compared to bare ITO [12]. PEDOT:PSS has been shown to give significantly improved cell performance compared to ITO for both polymer and some small molecular based OPV systems [13]. However PEDOT:PSS still retains many undesirable characteristics, in particular significant device degradation and electrical inhomogenity [14]. Additionally the acidity of the PEDOT:PSS layer can lead to damage of the underlying ITO electrode, making the material unsuitable for future commercialisation [15,16].

The recognised problems with ITO and PEDOT:PSS has resulted in considerable recent research into the development of alternative hole-extracting materials for OPV cells, in particular metal oxides. Notably, Irwin et al. incorporated a 10 nm nickel oxide (NiO) film between ITO and a poly(3-hexylthiophene) (P3HT)/[6,6]-phenyl-C_{61} butyric acid methyl ester (PCBM) blend, improving the overall cell efficiency as well as providing increased device stability [14]. Tungsten oxide (WO_3) and vanadium oxide (V_2O_5) have also been used by several groups to improve the performance of polymer-based bulk heterojunction OPV cells [17,18]. Molybdenum oxide (MoO_x) has also been investigated as a potential hole-extracting layer for both polymer and small molecule based OPV cells [17,19,20]. It has the advantage of easily controlled deposition by thermal evaporation, with little variation in properties unless deposited at extremely fast rates [21]. However different groups have reported vastly different values of the optimal MoO_x layer thickness for OPV cells, varying between 3.5 and 50 nm, with the most commonly reported value being 5 nm [17,22]. The impact the MoO_x layer has on cell performance also varies widely in the literature. For example, Shrotriya et al. state that with a 5 nm layer of MoO_x, a P3HT/PCBM bulk heterojunction demonstrates a significantly improved V_{oc}, J_{sc} and *FF* when compared with the same cells fabricated on bare ITO [17]. By contrast, Kinoshita et al. showed that the V_{oc} of a tetraphenylporphyine/C_{60} cell increased greatly with an optimal MoO_x layer thickness of 50 nm, but J_{sc} remained comparable to the same cells fabricated on bare ITO [19]. Kim et al. found the insertion of MoO_x gave a significant increase in the *FF* in both a CuPc/C_{60} and a ClAlPc/C_{60} bulk heterojunction, due to a decrease in series resistance, R_s. They also reported an increased *FF* for a P3HT/PCBM bulk heterojunction compared to deposition on PEDOT:PSS/ITO [23].

Initial studies of thermally evaporated MoO_x layers indicated that the valence band and conduction band are at 5.3 and 2.3 eV, respectively [17,24,25]. More recently reported results show that these values are far greater, ranging between 9.37–9.70 eV and 6.18–6.70 eV, respectively [25–27]. The same reports suggest that MoO_x is a strongly *n*-type material, with the work function only 0.16–0.60 eV below the LUMO, and that there is a large positive vacuum level (V_l) shift for the MoO_x compared to that of the ITO substrate [25–27]. A negative V_l shift occurs from the MoO_x to the V_l of the organic material, due to formation of an interface dipole as a result of charge transfer. However, this still leads to a substantial barrier to hole-extraction through the MoO_x valence band for OPV devices. Kanai et al. reported evidence from ultra-violet photoemission spectroscopy (UPS) measurements of gap states within the MoO_x layer due to oxygen deficiencies, that facilitate hole-extraction from the organic layer [26]. Kröger et al. did not directly observe the gap states [25]. In the same study, WO_x was found to have a conduction band of 6.27 eV, a work function of 6.47 eV and a valence band of 9.66 eV, which are 0.53, 0.39 and 0.02 eV smaller than the corresponding MoO_x values.

In this paper we compare the performance of four different donor/C_{60} small molecule OPV cells using pentacene, CuPc, ClAlPc and SubPc, showing the different effects of inserting an optimised MoO_x interlayer on planar heterojunctions possessing different electronic energy levels (Fig. 1). Significant improvements in performance are seen for ClAlPc and SubPc, but not with CuPc or pentacene, the latter having a poorer performance after inclusion of the MoO_x layer. In all four systems the incorporation of MoO_x results in significantly improved cell stability. The changes in cell performance are attributed to the different electronic structure at the MoO_x/donor interface, whilst the improved overall stability is rationalised by the thin oxide layer providing a more stable electrode/donor interface.

2. Experimental methods

Devices were fabricated on commercially available ITO-coated glass substrates (Psiotec, 100 nm ITO thickness) after initial solvent cleaning. The ITO was then treated in ultraviolet/ozone to remove carbon residues. Organic layers were grown by vacuum deposition in a Kurt J. Lesker Spectros system with a base pressure of about 5×10^{-8} mbar. The organic materials used: pentacene (Aldrich – 99.9%), CuPc (Aldrich – 97%), ClAlPc (Acros Organics – 98%), SubPc (Aldrich – 85%), C_{60} (MER Corp – 99.5%) and bathocuproine (BCP, Aldrich), were all purified by thermal gradient sublimation before deposition. MoO_x and WO_x (Aldrich – 99.99%) were used as received. A deposition rate of 0.10 nm s^{-1} was used for pentacene, CuPc, ClAlPc, SubPc and BCP, with C_{60} grown at 0.05 nm s^{-1}. The aluminium cathodes were deposited *in situ* by evaporation through a shadow mask, to a thickness of 100 nm, to give an active

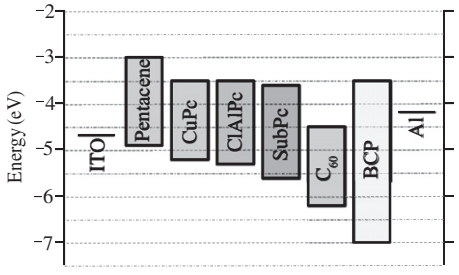

Fig. 1. Summary of the electronic energy levels for each material used in the OPV devices.

area of 0.16 cm^2. Data for direct comparison was obtained by simultaneous deposition of the same cells on both bare ITO and ITO/MoO_x.

Current–voltage (*J–V*) curves were measured using a Keithley 2400 sourcemeter under AM1.5G solar illumination at 100 mW cm^{-2} (1 sun) from a Newport Oriel solar simulator. External quantum efficiency (EQE) measurements were also carried out using this source, calibrated to a photodiode and signal measured using a Stanford research SR 830 lock-in amplifier. Atomic force microscopy (AFM) images were obtained using an Asylum Research MFP-3D (Santa Barbara, USA) in AC mode. A PANalytical X'Pert PRO diffractometer with Cu Kα radiation was used for X-ray diffraction (XRD). UV/vis absorption spectra were obtained using a Perkin-Elmer Lambda 25 spectrometer.

3. Results and discussion

Throughout this work the basic planar heterojunction cell architecture grown was ITO/*d* nm MoO_x/donor material/40 nm C_{60}/8 nm BCP/Al, with each donor layer thickness stated where appropriate. The optimum MoO_x layer thickness (*d*) was found to be 5 nm for cells fabricated with an optimised 20 nm ClAlPc donor layer. Deposition of $d < 5$ nm resulted in incomplete coverage of the ITO surface, with the donor layer in contact with both the ITO and MoO_x, and a range of V_{oc} values obtained in between that of the bare ITO cells and the optimised MoO_x/ITO system. Increasing *d* beyond 5 nm results in a reduction in both J_{sc} and *FF;* there is no additional gain in V_{oc} and so η_p decreases from 2.6% when $d = 5$ nm to 1.8% with $d = 50$ nm. The *J–V* curves shown in Fig. 2 show a clear increase in series resistance, R_s, with increased *d.* This detrimental increase in R_s is caused by the increased MoO_x layer thickness weakening the built-in electric field of the cells. Table 1 provides a summary of the data obtained for optimisation of *d* in the ClAlPc system.

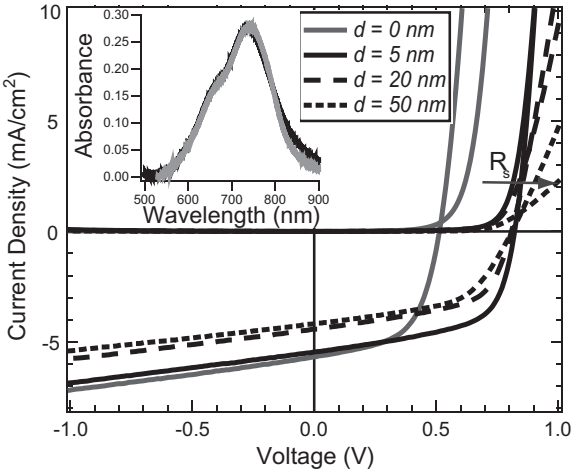

Fig. 2. *J–V* curves obtained under AM1.5G illumination for OPV devices with structures ITO/*d* nm MoO_x/20 nm ClAlPc/40 nm C_{60}/8 nm BCP/Al. The inset shows the corresponding UV–vis data for the ClAlPc/C_{60} heterojunction on bare ITO (grey line) and ITO/5 nm MoO_x (black line).

For both the 20 nm ClAlPc and 14 nm SubPc cells, a large increase in V_{oc} and η_p is seen with the insertion of $d = 5$ nm MoO_x compared to bare ITO. In the ClAlPc cell, V_{oc} increases from 0.51 V (ITO) to 0.82 V (ITO/5 nm MoO_x), resulting in a substantial increase in η_p from 1.6% to 2.6%. Insertion of the MoO_x layer gives a similar *FF* but marginally lower J_{sc} when compared to the same cell fabricated on bare ITO. It is worth noting that the work function of the ITO substrates were measured by Kelvin probe to be 4.7 eV, leading to a relatively low V_{oc} for the ClAlPc cells fabricated on bare ITO. As a comparison, ITO/5 nm WO_x/20 nm ClAlPc/40 nm C_{60}/8 nm BCP/Al cells were also fabricated generating the device results shown in Table 2. The WO_x cells produce V_{oc} and η_p values in between those of the same cells grown on bare ITO and on MoO_x, with 0.77 V and 2.3%, respectively. For the SubPc system there is a similar improvement in η_p, from 2.0% to 3.0% for ITO and ITO/5 nm MoO_x respectively, mainly due to the increase in V_{oc} from 0.82 to 1.05 V (Fig. 3). The use of MoO_x also leads to a slight improvement in J_{sc} and *FF*, and the cell data is summarised in Table 2.

For the 30 nm CuPc cell the introduction of the MoO_x layer causes a small drop in η_p from 1.1% for bare ITO to 1.0% with ITO/5 nm MoO_x, as shown in Fig. 4. The V_{oc} values are similar in both cases, but the *FF* and J_{sc} both decrease slightly with the introduction of the MoO_x layer. The performance of the 43 nm pentacene cell decreases significantly with the insertion of the MoO_x, with η_p reduced from 1.4% to 1.2% for $d = 5$ nm. This reduction in performance is mainly due to the lower values obtained for J_{sc} and *FF* for the cells fabricated with MoO_x. Fig. 5 shows that the insertion of a 5 nm MoO_x layer leads to increased R_s and a less ideal shunt resistance, R_{sh}.

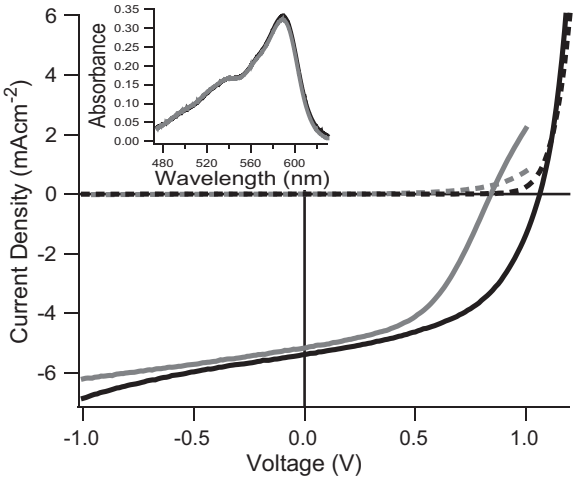

Fig. 3. *J–V* curves obtained under AM1.5G illumination for OPV devices with structures ITO/*d* nm MoO_x/14 nm SubPc/40 nm C_{60}/8 nm BCP/Al, for *d* = 0 nm (grey line) and *d* = 5 nm (black line). The inset shows the corresponding UV–vis data for the SubPc/C_{60} heterojunction on bare ITO (grey line) and ITO/5 nm MoO_x (black line).

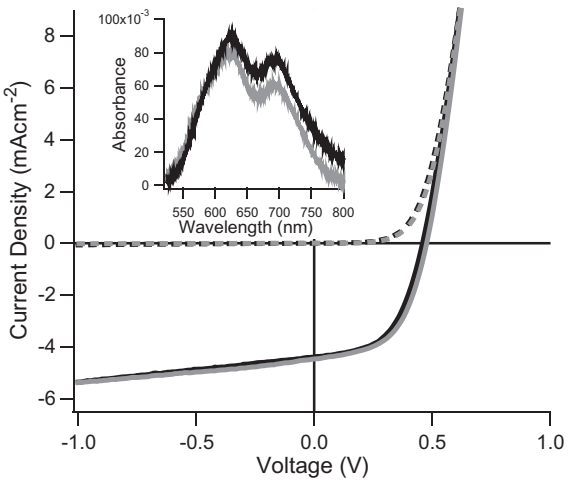

Fig. 4. *J–V* curves obtained under AM1.5G illumination for devices with structures ITO/*d* nm MoO_x/30 nm CuPc/40 nm C_{60}/8 nm BCP/Al, for *d* = 0 nm (grey line) and *d* = 5 nm (black line). The inset shows the corresponding UV–vis data for the CuPc/C_{60} heterojunction on bare ITO (grey line) and ITO/5 nm MoO_x (black line).

The factors influencing the changes in cell performance were explored for each of the four OPV heterojunction systems. To establish whether the changes in cell performance can be attributed to any modification of the structure and morphology of the donor layers as a consequence of deposition on the MoO_x layer, AFM, UV/vis absorption and XRD measurements were performed on each of the four donor layer films. The root mean square roughness (R_q) of the surfaces of bare ITO and ITO/5 nm MoO_x were extracted from topographic AFM images and are very similar, with R_q = 4.2 and 4.0 nm respectively. Similar topological features were seen in both cases, suggesting that a homogenous coverage of the ITO surface by a thin 5 nm MoO_x

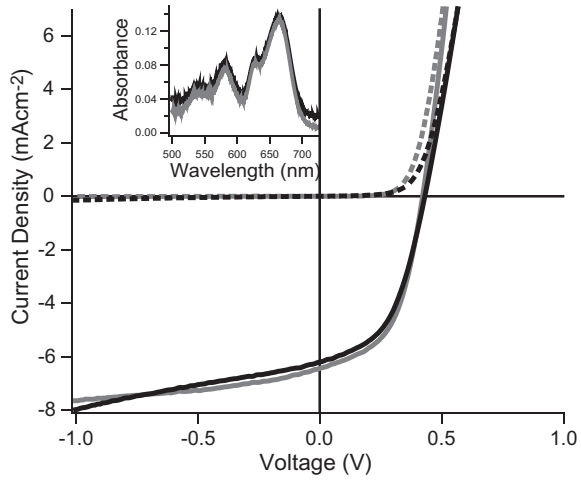

Fig. 5. *J–V* curves obtained under AM1.5G illumination for devices with structures ITO/*d* nm MoO_x/43 nm pentacene/40 nm C_{60}/8 nm BCP/Al, for *d* = 0 nm (grey line) and *d* = 5 nm (black line). layer does not lead to an electrode surface with its own distinct morphology. Each donor layer also gave a negligible change in R_q when deposited on 5 nm MoO_x. As an example, the AFM images in Fig. 6 compare the morphology of a thin SubPc layer grown on ITO and ITO/MoO_x. The similar R_q values of 2.3 and 2.4 nm suggest that surface morphology does not cause any significant changes in device behaviour when incorporating the MoO_x layer. The UV/vis absorption spectra of each donor material also showed negligible difference for thin films deposited on bare ITO and ITO/MoO_x; the main absorption peaks are shown in the insets of Figs. 2–5 for ClAlPc, SubPc, CuPc and pentacene, respectively. Fig. 7 shows XRD data obtained for 80 nm thick layers of CuPc (Fig. 7a) and ClAlPc (Fig. 7b) on both bare ITO and MoO_x. The XRD shows no shift in the main CuPc peak at $2\theta = 6.8^\circ$ after growth on MoO_x, indicating very little change in molecular stacking. Similarly, for ClAlPc layers the XRD results show the material to be essentially amorphous on both bare ITO and MoO_x (Fig. 7b). This rules out any effects such as templating, that have been recently demonstrated when using thin organic interlayers such as 3,4,9,10-perylenetetracarboxylic dianhydride (PTCDA) [28,29]. These results demonstrate clearly that the MoO_x layer has very little influence on the molecular stacking within the donor layer and the resulting thin film structure, morphology and absorption properties [17,19,20,23].

We propose that a possible reason for the increase in V_{oc} with the insertion of the thin MoO_x layer for the SubPc and ClAlPc cells is the difference in the electronic properties at the MoO_x/donor interface. These donor materials have

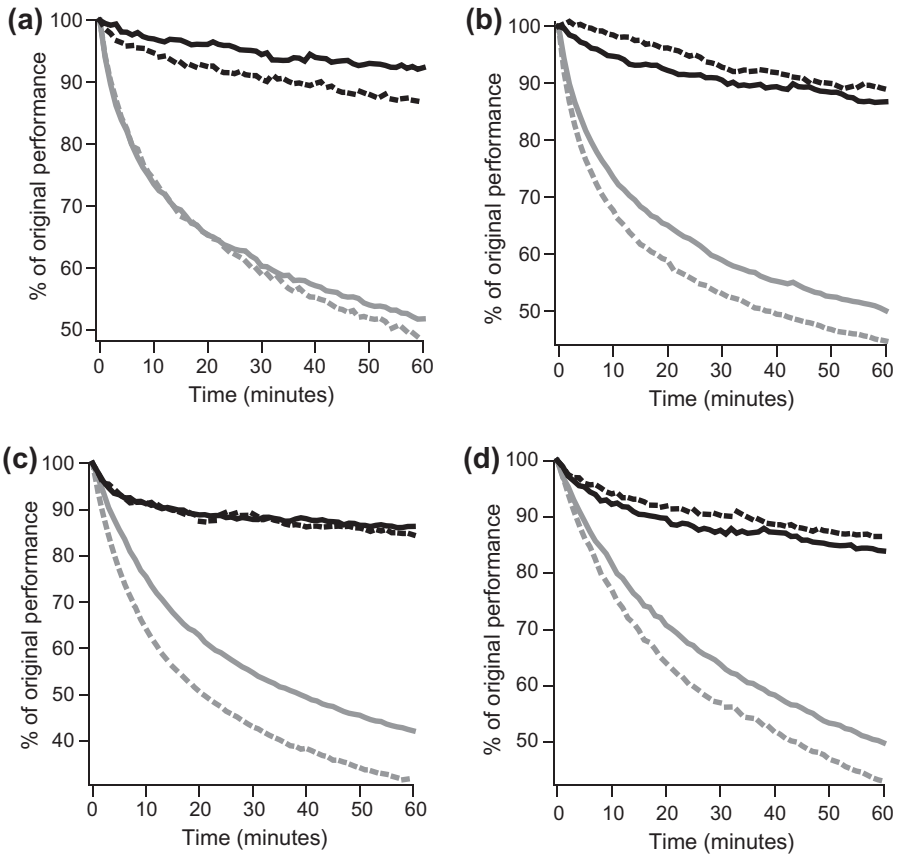

Fig. 9. Device degradation data for percentage decrease of η_p under constant illumination at 1 sun for 60 min for (a) ITO/d nm MoO_x/20 nm ClAlPc/40 nm C_{60}/8 nm BCP/Al, (b) ITO/d nm MoO_x/14 nm SubPc/40 nm C_{60}/8 nm BCP/Al, (c) ITO/d nm MoO_x/30 nm CuPc/40 nm C_{60}/8 nm BCP/Al, (d) ITO/d nm MoO_x/43 nm pentacene/40 nm C_{60}/8 nm BCP/Al. relatively high ionisation potentials and are therefore likely to exhibit significant band bending towards the gap states in the MoO_x layer, due to interface dipole effects from charge transfer [23,27], thus allowing more efficient hole-extraction from the more favourable electronic energy level alignment at the hole-extracting electrode. A very recent study by Kanai et al. on α-NPD/MoO_x/Au interfaces suggested that defects in the MoO_x layer allow charge collection from gap states [26]. We speculate that a similar favourable energy level alignment exists for the ClAlPc and SubPc OPV cells grown on MoO_x, as shown schematically in Fig. 8a. This alignment leads to a reduced loss in the built-in field of the cells and facilitates an increase in V_{oc}, as seen in the data in Table 2. The gap states within WO_x interlayers are likely to be positioned between the work function of bare ITO and the position of the gap states of MoO_x [25]. For ClAlPc and SubPc, the ability of the WO_x layers to extract holes efficiently should be better than bare ITO but not as favourable as MoO_x. This is shown in the resulting cell performance, with the V_{oc} values obtained being higher than for bare ITO, but not as large as the values obtained for the same cells fabricated on MoO_x.

For the CuPc OPV cell, the J_{sc} and *FF* are marginally decreased with the insertion of MoO_x, and for the pentacene cells, insertion of the MoO_x layer has a significant detrimental impact on cell performance. The smaller ionisation potential of these donor materials leads to a less favourable alignment with the MoO_x gap states and there is no benefit from any band bending effects, leading to less efficient hole-extraction compared to bare ITO (Fig. 8b). In this case there is an approximately 6% decrease in charge collection and a concomitant reduction in *FF*.

Although insertion of the MoO_x layer did not result in improved cell efficiencies for all of the four planar heterojunction systems studied, the overall stability of the cells was significantly improved in every case. Device variation for all cells grown on MoO_x was less (Table 2), the MoO_x layer providing an electrode surface with a more homogeneous work function and eliminating the 'hot' and 'dead' spots commonly present on bare ITO.

Each cell was tested under 60 min of continuous illumination at 100 mW cm^{-2} AM1.5G for both d = 0 and 5 nm of MoO_x. These measurements were performed under both N_2 and air atmospheres in order to test the degradation characteristics of each cell. Fig. 9 shows the change in η_p for each system, in terms of a percentage of the original performance of the cell. For ClAlPc on bare ITO, η_p dropped by 51% and 46% in air and N_2, respectively. This significant reduction in performance is due to the large decrease in V_{oc} and J_{sc}, which also produces a loss in *FF*. However, with the insertion of 5 nm MoO_x, η_p is reduced by only 13% and 8% under air and N_2 respectively. In this case there is little change in V_{oc} and *FF*, and a smaller loss in J_{sc} compared to the cell fabricated on bare ITO.

Fig. 9 shows comparable degradation performances for cells fabricated with the different donor layers. With d = 0 nm in an air atmosphere, η_p drops by 55%, 69% and 57% for SubPc, CuPc and pentacene cells, respectively. The degradation is only marginally less in an N_2 atmosphere. Inserting the 5 nm MoO_x layer greatly improves the stability of each cell with similar performances in both air and N_2 for each system. Of particular note is the stability of V_{oc} for the cells fabricated using the MoO_x interlayer, in addition to less degradation in J_{sc} and *FF*. Due to the severity of the degradation for the pentacene and CuPc cells on bare ITO, and the relative stability of the same cells after inserting MoO_x, it appears that it is still advantageous to fabricate these cells on the oxide interlayer for improved stability, despite the lower initial performance with these particular donor materials.

EQE measurements were performed before and after cell degradation under constant illumination and are shown in Fig. 10 for the SubPc system on both bare ITO and ITO/MoO_x. On MoO_x the overall degradation is less across the whole spectrum when compared to bare ITO, but the least degradation is between 550 and 650 nm, which is the region corresponding to the SubPc contribution. This indicates increased stability for the MoO_x/SubPc interface compared to ITO/SubPc. The large degradation for the bare ITO cells is likely to be due to diffusion of oxygen from the ITO into the active layer, a process that has been well documented in the literature [30–32]. Illumination is also known to accelerate the oxidation of the donor

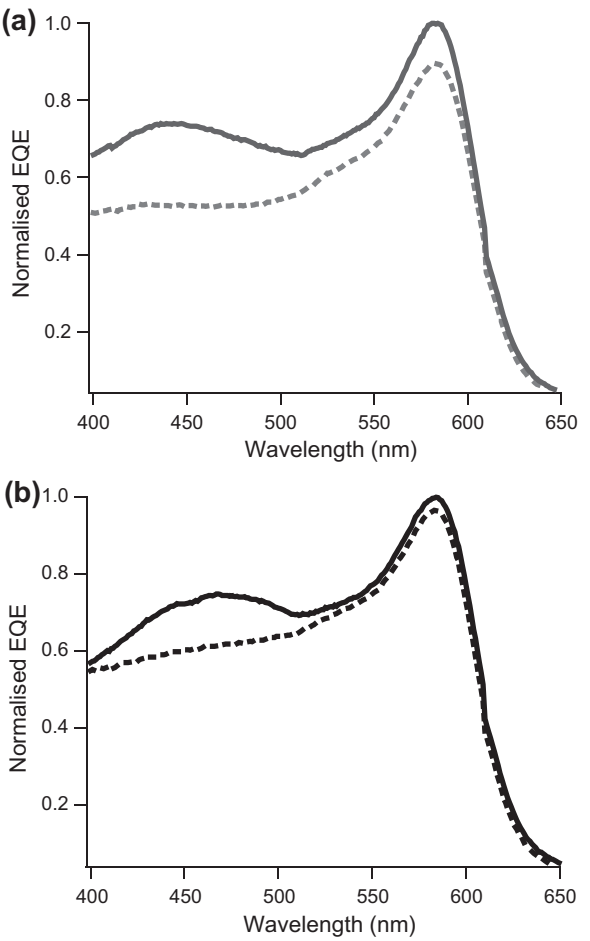

Fig. 10. EQE data taken before (solid lines) and after (dashed lines) degradation for 1 h under constant illumination for (a) ITO/14 nm SubPc/40 nm C_{60}/8 nm BCP/Al and (b) ITO/5 nm MoO_x/14 nm SubPc/40 nm C_{60}/8 nm BCP/Al.

layers [32]. These undesirable reactions cause disruption to the charge transport paths and morphology, reducing J_{sc}, and leading to charge build up. This charge build up opposes the built-in electric field of the cell and hence lowers the resulting V_{oc} for the ITO cells. However the MoO_x layer is able to act as a barrier and also has the advantage of being oxygen deficient and so is an ideal layer to minimise the chance of oxidation reactions being able to occur. Therefore the cells containing the MoO_x layer show increased stability, due to the interface between MoO_x and the donor materials.

4. Conclusions

We have demonstrated how the performance of OPV cells fabricated using planar molecular heterojunctions is influenced by the insertion of a 5 nm thin film of MoO_x for four different donor materials. Using ClAlPc and SubPc donor layers the η_p of the cells increases by ~60% and 50% respectively, predominantly due to increases in V_{oc} in both cases. The inclusion of MoO_x produces a marginally lower performance for CuPc based cells, and hinders the performance of cells with pentacene as a donor layer. We propose that the increase in V_{oc} for the ClAlPc and SubPc systems with the insertion of the MoO_x layer is likely to be due to band bending of the donor layers towards the more favourable energy alignment with the MoO_x gap states in comparison to the bare ITO, allowing more efficient extraction of holes at the interface. The performance decreases in the CuPc and pentacene systems are possibly due to detrimental energy alignment and band bending to the MoO_x layer for hole-extraction, leading to reduced hole-extraction efficiency.

Insertion of the MoO_x hole-extracting layer reduces the variability of the cells in each heterojunction system, a consequence of the more homogeneous work function across the surface. With cell degradation often overlooked in small molecule OPVs, degradation studies were carried out for each system on both bare ITO and MoO_x, in air and N_2 atmospheres. Incorporating MoO_x improves significantly improves the characteristics of the cells compared to bare ITO. Higher relative cell performance was obtained for all systems with the MoO_x layer inserted after 60 min of constant illumination at 1 sun, regardless of whether initial performance was preferable on bare ITO.

ABSTRACT

We developed a versatile platform to construct heterogeneous organic and metallic elements with micrometer features on a plastic substrate in a complementary transfer-assisted patterning (CTAP) scheme. The underlying concept relies on a high-resolution transfer-printing process of a sacrificial layer, producing complementary patterns of the elements, in combination with a lift-off technique for removing the sacrificial layer to leave only active patterns on a variety of substrates. No detrimental errors in sequentially defining patterns of both an organic material and a metal are involved during lifting-off the sacrificial layers in multilayer architecture. We demonstrated the generic principle of the CTAP in the fabrication of short-channel organic thin film transistors on glass substrates and organic inverters on plastic substrates for flexible electronics.

Recently, organic electronic materials have been attracted for the fabrication of a new class of electronic components needed for low-cost and flexible applications ranging from smart cards [1–3] and e-papers [4,5] to flexible information displays [6–9]. For such applications, the construction of basic components such as organic thin-film-transistors (OTFTs) and inverters satisfying proper levels of the driving current, the current on–off ratio, and the operational speed requires a simple and reliable patterning scheme of precisely defining active channels of an organic semiconductor and gate/source/drain electrodes in multilayered structures on a variety of substrates. In heterogeneous organic multilayers that necessarily form interfaces at a semiconductor–insulator, a semiconductor–electrode, and an insulator–electrode, it is critical to pattern each functional layer without causing the degradation of the material characteristics in the subsequent layer formation. Among the recently developed patterning techniques, an advanced photolithographic method, based on the use of an orthogonal solvent dissolving a new type of a photoresist [10,11], is promising for fabricating organic electronic devices. However, this photolithography still involves the patterning complexity and may experience the deterioration of underlying organic layers in multilayer architecture by the exposure of strong ultraviolet (UV) light. An interesting variant approach is based on the use of a screen-printed photoresist layer as a shadow mask [12], which is rather simple but limits feature resolutions. As another type, a dry-lift off method using metal patterns to peel-off residual layers of active organic materials has been demonstrated in organic patterns down to 4 μm [13] but it inevitably requires high pressure and temperature during patterning the metals.

In this work, we developed a complementary transfer-assisted patterning (CTAP) approach as a simple and generic platform to pattern heterogeneous organic/metal elements in high-resolution. The basic principle is the generation of high-resolution patterns of a sacrificial layer by transfer printing, complementary to active element patterns, and the lift-off of the sacrificial layer using a chemically inert solvent to leave only active patterns on a substrate. The unit process of the CTAP technique is described as follows: (i) high-resolution patterns of a sacrificial layer of a fluorous-polymer prepared on an elastomeric

doi:10.1016/j.orgel.2010.09.017

stamp are directly transfer-printed onto a substrate, (ii) an organic or a metallic layer is blanket-deposited over the entire surface of the substrate having transfer-printed patterns of the sacrificial layer, and (iii) the sacrificial layer is subsequently removed using an inert fluorous-solvent to leave only active regions that are complementary to the transfer-printed patterns of the sacrificial layer on the substrate. Fabrication of organic thin film transistors (OTFTs) using sequential CTAP processes of an organic semiconductor and metals is illustrated in Fig. 1. For preparing a sacrificial layer, a fluorous-polymer (Novec™ EGC-1700, 3M) dissolved in a fluorous-solvent (Novec™ HFE-7100, 3M) was first coated on the surface of an elastomeric stamp with predefined patterns. The fluorous-solvent is known to be chemically compatible to most of organic materials, and thus it involves essentially no disruption of heterogeneous multilayers during repetitive CTAP processes. Polydimethylsiloxane (PDMS) was chosen for fabricating a stamp to ensure low adhesion at the interface between the stamp and the fluorous-polymer layer because of a low surface energy. Note that, in contrast to a metal-based dry lift-off method [12] requiring high pressure or heat, intimate contact between the sacrificial layer and the substrate is spontaneously produced when the stamp is placed on the substrate. Thus any mechanical and/or physical damage on the underlying layer will be avoided during the transfer-printing. The formation of an organic semiconductor (OS) layer on a gate insulator (I) was shown in Fig. 1(a). In our study, poly(vinyl cinnamate) (PVCi) dissolved in cyclopentanone in 10 wt.% was spin coated at the rate of 3000 rpm for 30 s for a gate insulator [14]. Patterns of the sacrificial layer (SL) of about 600 nm thick, prepared on stamp 1 from a fluorous-polymer solution of 4% in concentration, were transfer-printed on the top of the PVCi film. The pentacene film for the OS layer was then blanket-deposited at the rate of 0.5 Å s^{-1} to be the thickness of 50 nm over the whole area. For lifting-off the OS on the SL to leave only active regions, the substrate was immersed in the fluorous-solvent for a few seconds. The complementary patterns, i.e., the regions covered with the sacrificial layer were then removed and only the active OS patterns were left on the substrate. We now describe a

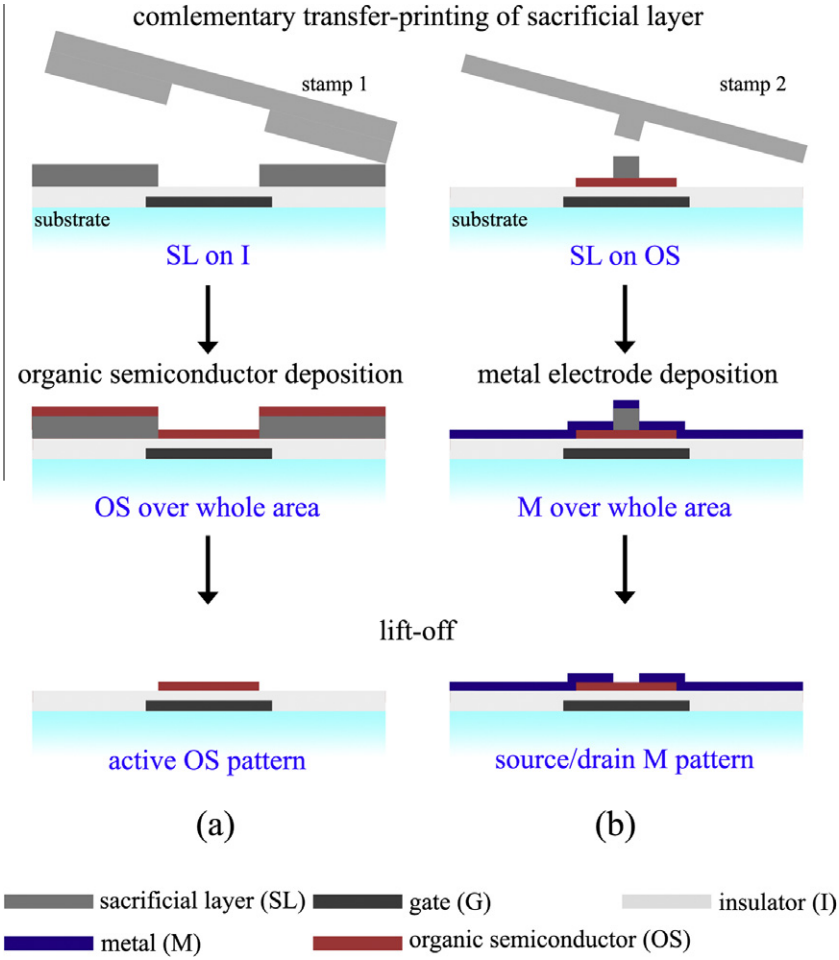

Fig. 1. Schematic illustration of each step of the CTAP for fabricating a top-contact OTFT with a short channel. Two serial processes of the CTAP are depicted for (a) active patterns of an organic semiconductor and (b) electrode patterns of a metal, respectively. Two elastomeric stamps of the PDMS, stamp 1 and stamp 2, are used for the two processes where different feature sizes may be adopted.

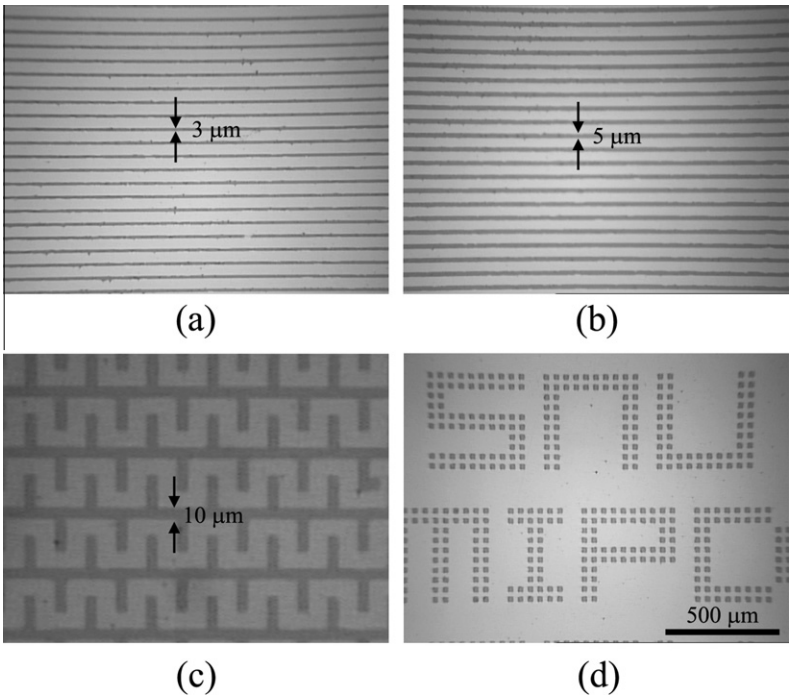

Fig. 2. Optical microscopic images of pentacene patterns showing (a) lines of 3 μm, (b) lines of 5 μm, (c) lines with branched segments (10 μm in resolution), and (d) different characters composed of squares of 25 μm in each side.

subsequent CTAP process of fabricating metal patterns on the OS layer to provide the source and drain electrodes. As shown in Fig. 1(b), the patterns of the sacrificial layer, complementary to the electrode patterns, were transfer-printed using stamp 2. A gold film of 80 nm thick was first deposited onto the entire substrate at the rate of 1 Å s^{-1}. The sacrificial layer was then lifted-off to leave only the electrode patterns on the top of the OS, yielding an OTFT in a top-contact configuration. Note that our CTAP is a powerful method of directly forming a very short channel length (down to a few micrometers) over the OS layer. A shadow mask, providing an easy and direct method, gives typically about 30 μm in resolution.

We first describe the pattern fidelity and the pattern resolution achieved in our CTAP approach. Basically, the feature resolutions of the heterogeneous patterns are governed by the complementary patterns of the sacrificial layer that were transfer-printed using a stamp. Three different types of patterns (lines, lines with branched segments, characters composed of isolated squares) with different resolutions ranging from 3 to 25 μm were shown in Fig. 2. As shown in Fig. 2(a) and (b), the resolution of 3 and 5 μm can be easily achieved and down to submicrometers depending on the pattern resolution of the stamp. A variety of patterns like lines with branched segments (10 μm in resolution) in Fig. 2(c) and different characters (25 μm in resolution) with high fidelity as shown in Fig. 2(d) were produced over the area of a few square centimeters using the CTAP technique.

Let us now examine both the morphology of the pentacene film on the PVCi gate insulator and the resultant

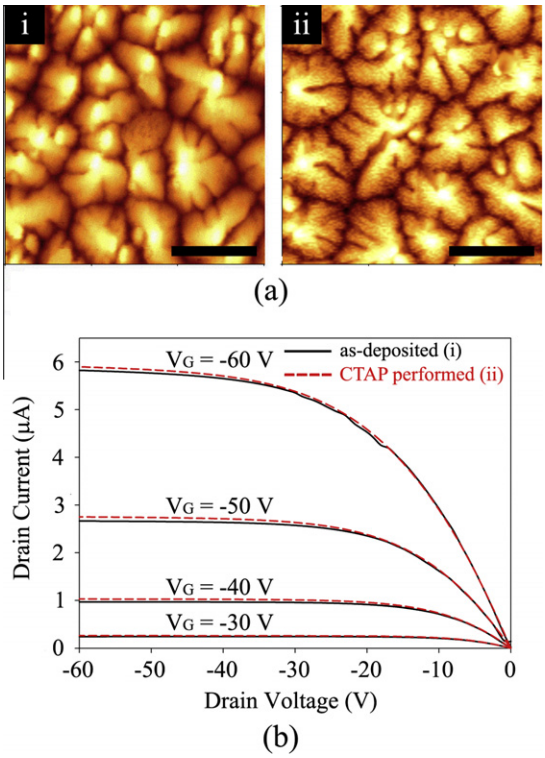

Fig. 3. (a) The AFM images of (i) an as-deposited pentacene layer and (ii) a pentacene layer experienced the transfer-printing and lifting-off processes of the sacrificial layer. electrical properties of the top-contact OTFT fabricated using the CTAP. In Fig. 3(a), the atomic force microscopic image (the surface morphologies) of an as-deposited pentacene film and that of a pentacene film experienced the transfer-printing and lift-off processes of the sacrificial layer were shown in (i) and (ii), respectively. Clearly, no considerable difference in the surface morphology was observed. Fig. 3(b) shows the output characteristic curves of two top-contact OTFTs made with the two types of the pentacene films described above. The drain current was measured as a function of the drain voltage for several different values of the gate voltage ranging from −30 to −60 V. It should be noted that the electrical properties of the two OTFTs are nearly identical. This indicates that the lift-off process in the CTAP approach essentially does not alter the morphological and electrical properties of the pentacene film.

More specifically, in pentacene-based OTFTs with different channel lengths (L) of 5, 10, 20, and 30 μm, we demonstrate the high-resolution patterning capability and the performance reliability of the CTAP approach. The channel width (W) was fixed as 1 mm. Fig. 4(a–d) shows the output curves of the four OTFTs whose channel length varies from 30 to 5 μm. Clearly, the saturation behavior of the drain current always appears irrespective of L. The transfer characteristic curves of the four OTFTs with different channel

lengths in linear and semi-logarithmic plots are shown in Fig. 4(e). From Fig. 4(e), it was found that the carrier mobility was about 0.10 $cm^2/V\,s$ and the current on–off ratio was on the order of 10^5 irrespective of the channel length. A slight off-current was observed only for the short channel case of $L = 5$ μm in Fig. 4(e). The turn-on voltage was estimated to be about 8 V. For fixed gate voltage ranging from −10 to −40 V, the drain current increases monotonically with decreasing L at a given drain voltage. For example, in the saturation regime, the drain current increases from 5.47 to 30.00 μA with decreasing L from 30 to 5 μm at the gate voltage of −40 V. Fig. 4(f) shows the drain current in the saturation regime at the gate voltage of −40 V as a function of $1/L$. As shown in Fig. 4(f), except for a very short channel case, a linear relationship between the drain current in the saturation regime and $1/L$ as expected from the following equation:

$$I_D = \frac{W}{2L} C_i \mu_{sat} (V_G - V_T)^2 \quad (1)$$

where I_D is the drain current, C_i is the capacitance per unit area of an insulator, μ_{sat} is the carrier mobility, and V_G and V_T are the gate voltage and the threshold voltage, respectively. A deviation from the linear relationship in the short channel case ($L = 5$ μm) may be attributed to the contact resistance which is believed to be critical in short channel devices [15]. Such contact resistance is one of the important issues to be explored from the device physics viewpoint which is beyond the scope of our work.

We now describe the applicability of the CTAP technique for the fabrication of flexible electronic devices on plastic substrates such as polyethersulphone (PES). An organic inverter, two OTFTs in series, was fabricated on the PES substrate by simultaneously forming all the source and drain electrodes on the OS patterns produced through the CTAP. The two OTFTs have the same dimensions of the channel length (10 μm) and the channel width (1 mm). A solvent dropping method was used for forming via holes required for the interconnection between two transistors. Fig. 5(a) shows a microscopic image of a single organic inverter with $L = 10$ μm together with a photographic image of inverter arrays fabricated on the PES substrate (3 cm × 4 cm in size) in bent environment. Neither delamination of organic and/or metal layers nor deterioration of the electric characteristics of the inverter was observed under a bent state with the curvature radius of a few centimeters. The voltage transfer characteristics (VTCs) of the organic inverter scanned for the input voltage from 0 to −60 V at $V_{DD} = -60$ V are shown in Fig. 5(b). The operation scheme of the organic inverter was depicted in the logic diagram of Fig. 5(b). In our inverter, the inversion voltage in the VTCs at $V_{DD} = -60$ V was found to be around −7 V at which the maximum gain of 9.5 was obtained. Note that our OTFT can be used as a load transistor in a zero drive load logic [16], requiring a turn-on state of the OTFT at the gate voltage of 0 V, since our OTFT has a positive turn-on voltage (8 V). The high and low states of the output voltage were well distinguished in the input voltage swing from 0 to −60 V. As shown in Fig. 5(b), the hysteresis measured during increasing and decreasing the input voltage between −60 and 0 V was negligibly small (<0.8 V).

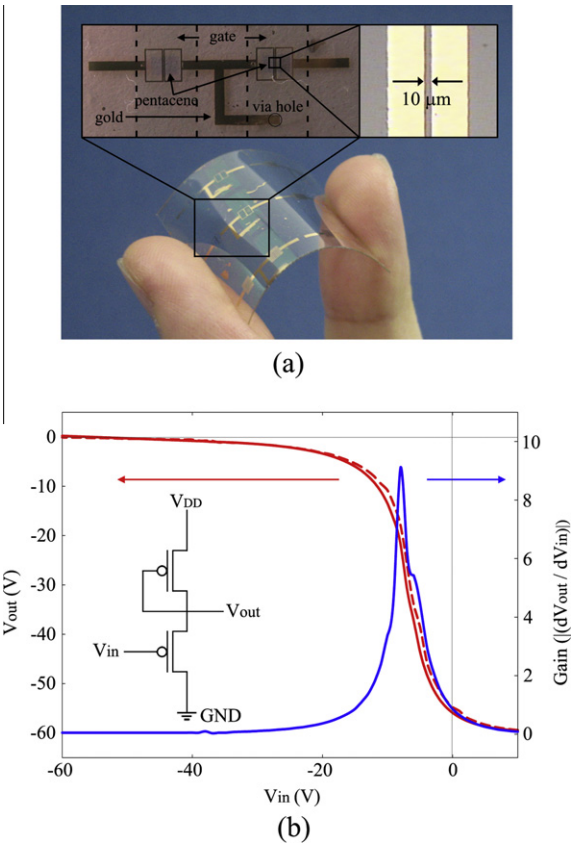

Fig. 5. (a) A microscopic image of a single organic inverter and a photographic image of inverter arrays (in the left inset) fabricated on a PES substrate. The channel of 10 μm in resolution was shown in the right inset. (b) The VTCs of an organic inverter as function of the input voltage. The red solid and dashed lines represent the VTC curves for the input voltage on increasing from −60 to 0 V and decreasing from 0 to −60 V, respectively. The blue line shows the gain of the organic inverter. The logic diagram represents the organic inverter in a zero drive load logic. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The optimization of the VTCs can be achieved through the variations of the channel length and width of an individual OTFT on the basis of the driving capability of each transistor (load or drive transistor) for specific applications. Moreover, it should be emphasized that on simply repeating the CTAP process, a variety of short channel inverters and circuits can be easily fabricated on a single plastic substrate and their electrical performances are well preserved under mechanically deformed environment such as in a bent state.

In summary, we developed a viable tool of patterning heterogeneous functional elements of organic and metallic materials in high resolution multilayer architecture for flexible electronics. The underlying mechanism comes from the lift-off of the sacrificial patterns complementary to active patterns on a variety of the substrates including a plastic film. We demonstrated that the simple repetition of the CTAP on successive layers in series enables to fabricate short channel OTFTs and organic inverters with high pattern fidelity and reliability. In principle, no detrimental

error was involved in defining high-resolution patterns down to submicrometers on the basis of the CTAP depending on the stamp resolution. The CTAP approach presented here is expected to be applicable for advanced flexible electronic systems including high-resolution organic light-emitting displays and highly integrated organic electronic circuits.

ABSTRACT

A general model to calculate short circuit current and spectral response of the bulk-heterojunction solar cell is discussed here. In order to get the short circuit current density at each wavelength the generation rate of electron and holes are calculated by the optical modelling based on transfer matrix approach. The drift–diffusion equation is then solved to get the current density at each wavelength using the calculated generation rate. Spectral response is found to be very similar to the experimental data of (3-hexylthiophene) (P3HT): [6,6]-phenyl C61-butyric acid methylester (PCBM) based bulk-heterojunction solar cell. The variation of short circuit current as a function of active layer thickness has been calculated using the model which matches with the experimental observations taken from literature. The sub-linear dependence of short circuit current on incident light intensity has also been explained by the model.

1. Introduction

Organic solar cells (OSC) have been gaining much attention recently because of its low cost and large area application [1]. Among various types of OSC, the bulk-heterojunction (BHJ) solar cells are becoming important as after absorbing light, photo-generated excitons break down to electron and holes directly due to the presence of the interpenetrating donor and acceptor material, thus the choice of the active layer thickness is not restricted by the small exciton diffusion length [2] typically of the order of 10 nm [3]. The ease of fabrication of BHJ solar cells by wet processing is also an important factor for its popularity as it makes the solar cell low cost. High efficiency 7.4% has recently [4] been reported for these devices. One of the typical shortcomings of BHJ devices is low spectral absorption range which can be observed from spectral response measurement. Recently it has been shown that inclusion of other material into the P3HT: PCBM active layer can enhance the spectral response range and hence the efficiency of the solar cells [5]. But a significant special overlap of different materials can make the charge collection and hence the BHJ solar cells inefficient. So to design efficient devices it is necessary to understand spectral response of such solar cells. Spectral responses of single layer organic devices [6] and bilayer organic solar cells [3] have been modelled recently. Elaborate device modelling for bulk-heterojunction solar cells of Koster et al. [7] and Lacic and Inganäs [8] discuss about the current voltage characteristics, charge generation inside the device etc. Dependence of the short circuit current on blend layer thickness has been discussed by Monestier et al. [9]. In this paper we shall discuss about the dependence of the short circuit current on the wavelength of incident light or spectral response of the bulk-heterojunction solar cells. We shall also show the effect of various loss mechanisms on short circuit current density (J_{sc}) of blend solar cells.

2. Theory

In this section we shall discuss about the mechanism and model of the external quantum efficiency (η_{EQE}) in the BHJ solar cells. After absorption of light excitons are generated in the active layer of the solar cells. Because of the presence of interpenetrating donor and acceptor layers in the blend, excitons dissociate efficiently at the donor–acceptor (D–A) interface and generates electron and holes. Then the electrons and holes diffuse through the active layer by the help of built-in potential present in the device and collected at the respective electrodes. The η_{EQE} of the BHJ solar cells can be described in terms of the product of several other efficiencies [2]:

$$\eta_{EQE} = \eta_A \times \eta_{ED} \times \eta_{CT} \times \eta_{CC} \tag{1}$$

where η_A, η_{ED}, η_{CT} and η_{CC} are the absorption efficiency of the active material, exciton diffusion efficiency (efficiency of excitons to reach the D–A interface), charge transfer efficiency of the D–A interface leading to holes in the donor and electron in the acceptor material and charge collection efficiency respectively. The generation of exciton (η_A) can be accurately modelled using optical modelling by the transfer matrix approach [3]. The presence of D–A interfaces makes both η_{ED} and η_{CT} very efficient [10,11], so we assumed η_{ED} and η_{CT} equal to one. But as a significant special overlap exists between the electron and holes in the active layer, trap generated and bimolecular recombination [2,9] become a dominant factor making η_{CC} less than one. To model the η_{CC} accurately the calculated generation rate is included in the drift–diffusion equation for electron and holes. The basic set of equations for the bulk-heterojunction solar cells are given below:

$$\frac{1}{e}\frac{dJ_n}{dx} = R - G \tag{2}$$

$$\frac{1}{e}\frac{dJ_p}{dx} = -(R - G) \tag{3}$$

where J_n and J_p are electron and hole current density, respectively and given by:

$$J_n = \mu_n eEn + \mu_n k_B T\frac{dn}{dx} \tag{4}$$

$$J_p = \mu_p eEp - \mu_p k_B T\frac{dp}{dx} \tag{5}$$

Here R and G are the recombination and generation rate of the electron and holes, n and p are the density of electron and holes inside the device, e is the electron charge, μ_n and μ_p are the electron and hole mobility of the active material, E is the electric field inside the device, k_B is the Boltzman constant and T is the temperature of the system taken in the absolute scale. The first and second part of the Eqs. (4) and (5) are the drift and diffusion part of the electron and hole current respectively. Both trap generated and bimolecular recombination are taken into consideration in the model. Generation rate of electron and holes are calculated using the optical modelling where optical constants and thicknesses of all the layers are taken into account. Current densities are calculated by solving the Eqs. (2)–(5) described above. The external quantum efficiency of the full device is then calculated by normalising the current by the incident photon flux using Eq. (6) below.

$$\eta_{EQE} = \frac{j/q}{\frac{1}{2}\varepsilon_0 c|\bar{E}_0|^2/(hc/\lambda)} \tag{6}$$

Short circuit current density of the solar cell has been calculated by integrating η_{EQE} with the solar spectrum using Eq. (7) below.

$$J_{sc} = q\int_{SolarSpectrum} S(\lambda)\eta_{EQE}(\lambda)d\lambda \tag{7}$$

where $S(\lambda)$ is the spectral shape of the solar spectrum. Trap generated recombination of electron and holes in the presence of impurities and inhomogeneity in D–A mixture can be described by $R_n \approx \frac{n}{\tau_n}$, $R_p \approx \frac{p}{\tau_p}$ for electrons and holes, respectively, where τ_n and τ_p are the electron and hole lifetime. Bimolecular recombination rate depends on both the electron and hole density and can be modelled as $R \approx rnp$, where r is the recombination rate constant. The boundary conditions are $n = 0$ and $J_n = 0$ at the ITO:PEDOT junction and $p = 0$ and $J_p = 0$ at the Ca:Al junction. As PEDOT and Ca:Al make ohmic contact with P3HT and PCBM, respectively, the electron and hole density at anode and cathode is assumed to be $n(\text{anode}) \approx N_c \exp\left(-\frac{E_{barrier}}{\kappa T/q}\right)$ and $p(\text{cathode}) \approx N_c \exp\left(-\frac{E_{barrier}}{\kappa T/q}\right)$, where N_c is the effective density of states typically $10^{26}/m^3$ for these materials and $E_{barrier}$ is the gap between HOMO of P3HT and the LUMO of PCBM. So the presence of electron and holes in the anode and cathode respectively would be extremely small. In the presence of large built-in electric field it is energetically favourable for the electrons and holes to go to cathode and anode, respectively which justifies the boundary conditions on current densities. Parameters like τ_n, τ_p and r are taken as free parameters to fit the model to the experimental data of the spectral response. Electric field inside the device is taken to be constant [9,12] and equal to V_{bi}/d where V_{bi} is the built in potential present in the device which is equal to 1.3 V [13]. Here the cathode work function becomes pinned close to the LUMO level of PCBM. The value of μ_n and μ_p are taken from the literature for similar condition (3-hexylthiophene) (P3HT): [6,6]-phenyl C61-butyric acid methylester (PCBM) system where $\mu_n = 3 \times 10^{-7}$ m^2 V^{-1} S^{-1} and $\mu_p = 2 \times 10^{-8}$ m^2 V^{-1} S^{-1} [14]. Similar values of mobility has been reported and used in literature [8,9,15]. Optical constants of the material used here are also taken from the literature [9,16–18].

3. Experimental details

We fitted our model on the spectral response of P3HT:PCBM based solar cells. In order to make the devices PEDOT:PSS is spin coated on cleaned and patterned indium tin oxide (ITO) substrates. After that 1:1 weight ratio P3HT:PCBM solution is spin coated on it and dried at 120 °C before depositing Ca:Al or cathode layer by shadow mask. Devices are exposed as less as possible in atmosphere before encapsulating it in glove box. So the final structure

of the solar cells becomes 140 nm indium tin oxide (ITO)/ 50 nm PEDOT:PSS/70 nm P3HT:PCBM/5 nm Ca/100 nm Al. These samples were then annealed in 110 °C for 1 h. Spectral responses of these solar cells are carefully measured in the system described elsewhere [6].

4. Results and discussion

Fig. 1(a) and (b) shows the simulated optical field distribution and the generation profile of excitons inside the device. The current density distribution inside the device at an electric field 3×10^5 V/m is shown in Fig. 2. In such built-in electric field both the drift and diffusion current has a considerable contribution in the total current. Our simulation result shows that at high field (5×10^6 V/m) diffusion current becomes around 3% of the total current. This satisfies the assumption of Ray et al. [19] of neglecting the diffusion current in the single layer TPD devices where the photogeneration was caused by the bulk generation of carriers. The comparison between experimentally achieved spectral response data and the fitted models is shown in Fig. 3. r, τ_n and τ_p are used as free parameter in this fitting. The model fits the experimental data quite well with the best fitted parameter $\tau_p = 0.2$ μs. At very low intensity of incident light used in SR measurement r does not play a critical role. Although this model fits the experimental data very well the slight discrepancy between the model and experimental data especially in the lower wavelength range can be attributed to the possibilities of inaccuracies in optical constant taken from literature for our devices. The effect of thickness on J_{sc} is also calculated by the process described above. Recently Monestier et al. [9] and Li et al. [20] have studied the effect of thickness on J_{sc}. Both the experimental data can be well described by our model as seen in Fig. 4. The thickness dependent J_{sc} data of Li et al. can be best described by $r = 1 \times 10^{-15}$ m^3/s and $\tau_p = 0.8$ μs where as the data of Monestier et al. can be described by $r = 1 \times 10^{-18}$ m^3/s and neglecting trap generated recombination. The experimental data in this case were found shifted by a constant amount from the modelled data. Here we have taken η_{ED} and η_{CT} is 100%, but for practical devices because of these efficiencies can be slightly lower than one depending upon the morphology.

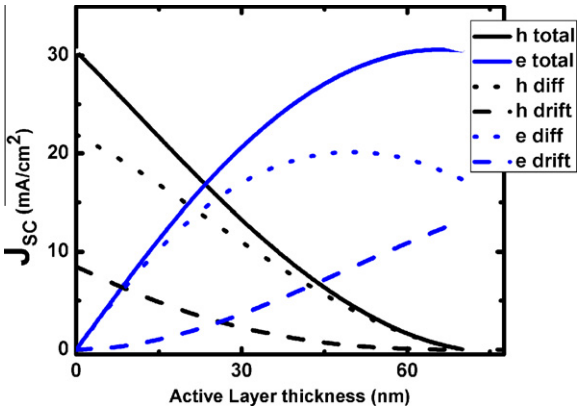

Fig. 2. Simulated current density distribution inside the device calculated using the model. The parameters used in the calculation are $E = 3 \times 10^5$ V/m, $\tau_p = 7$ μs and $r = 1 \times 10^{-16}$ m^3/s. The hole current is higher and the electron current is negligibly small at the anode. The electron current is higher and hole current is almost zero at the cathode.

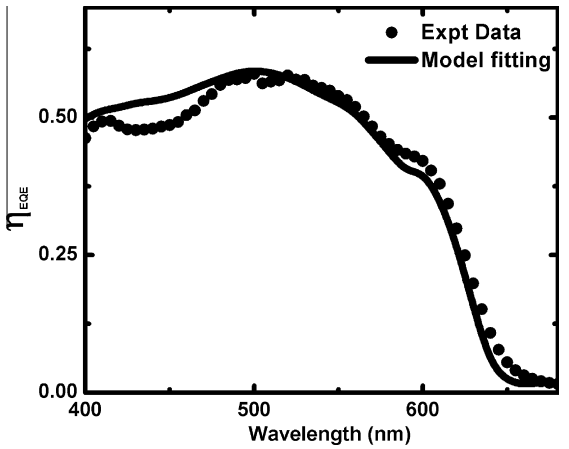

Fig. 3. Comparison between experimental data and fitted model is shown in the figure. The model fits the experimental data very well, but slight discrepancy is observed for lower wavelengths. The best fitted parameters are $\tau_n = 1$ μs, $\tau_p = 0.2$ μs.

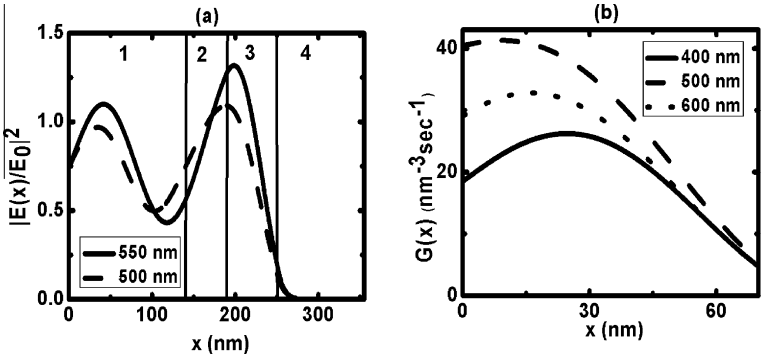

Fig. 1. The simulated electric field distribution inside the device is shown here. Layers 1–4 denoted in the (a) are 140 nm ITO, 50 nm PEDOT, 70 nm P3HT:PCBM and 105 nm Ca:Al, respectively and (b) is the generation profile of excitons inside the P3HT:PCBM layer. The generation rate is used in the drift–diffusion equation.

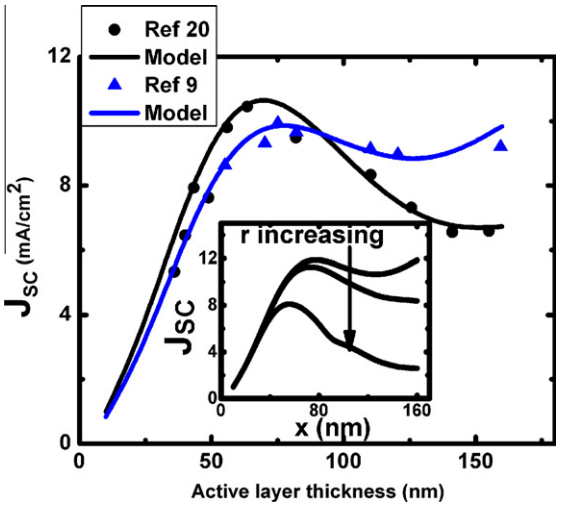

Fig. 4. Comparison between experimental data taken from the literature and fitted model is shown in the figure. The model fits the experimental data very well. The best fitted parameters are $\tau_p = 0.8\ \mu s$ and $r = 1\times 10^{-15}\ m^3/s$ for the data of Li et al. (Ref. [20]). The data of Monestier et al. (Ref. [9]) can be best fitted by $r = 1 \times 10^{-18}\ m^3/s$ and neglecting the trap generated recombination. Effect of bimolecular recombination coefficient on J_{sc} is shown in the inset. It can be seen as recombination increases J_{sc} decreases.

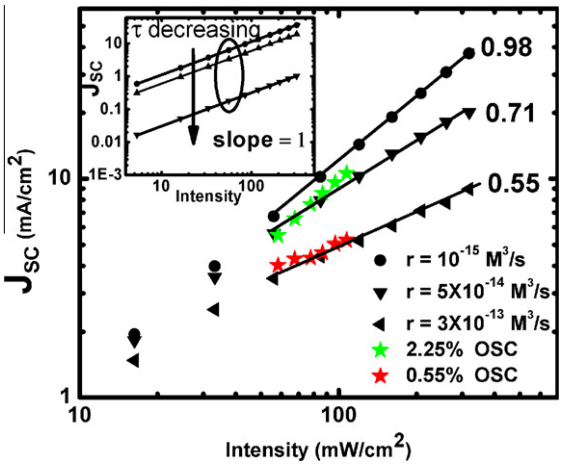

Fig. 5. Effect of intensity on J_{sc} is shown in the figure. At very low recombination J_{sc} follows linear behaviour with incident light intensities. For high recombination devices sub-linear dependence of J_{sc} on I_{LIGHT} is found. Experimental data of our low and high efficiency devices are also shown in the figure. In the inset the effect of I_{LIGHT} on J_{sc} in the case of trap generated recombination is shown. The power exponent in this case is found to be equal to one.

So J_{sc} can be lower than the calculated model. Finally we have calculated the effect of the incident light intensity on J_{sc}. We have found that for the devices with very low bimolecular recombination, J_{sc} increases with the incident light intensity I_{LIGHT} and follows a linear relation with I_{LIGHT} i.e. $J_{sc} \propto I_{LIGHT}^{1.0}$. But for the devices with high bimolecular recombination J_{sc} follows a sub-linear relation with I_{LIGHT} i.e. the power exponent is less than one. We have also seen in our low efficiency (0.55%) devices J_{sc} follows the sub-linear behaviour with the power exponent equal to 0.55 and from our modelling and calculation we can clearly see that the bimolecular recombination is limiting our device efficiency. But for our high efficiency (2.25%) devices we found fully linear behaviour due to almost no bimolecular recombination. We can compare this r to the Langevin bimolecular recombination coefficient $r_{LANGEVIN}$ where $r_{LANGEVIN} = \frac{q}{\varepsilon_r \varepsilon_0}(\mu_n + \mu_p)$.

We can assume $r = \xi \times r_{LANGEVIN}$ for our devices where ξ is the Langevin recombination prefactor. The prefactor value ξ varies order of magnitude starting from 10^{-4} to 1 [8,21] for various blend solar cells. The small value of ξ indicates the presence of extremely low bimolecular recombination. For P3HT: PCBM solar cells this low value of ξ can be attributed to extremely good morphology [8] of the blend and formation of fibrils in nanoscale and lamella-like chain packing [21]. In the intensity vs. J_{sc} curve we did not see any notable difference in α in the region $\xi \leqslant 1$. For instance the intensity vs. J_{sc} data of the 2.25% OSC can be fitted with $\xi \approx 1$ whereas the data of 0.55% solar cell can be fitted with $\xi = 148$. This high bimolecular recombination may cause due to the experimental condition. We think more controlled atmosphere experiment will lead to less recombination and small ξ value in the devices. For the case of monomolecular recombination, J_{sc} decreases as recombination increases but J_{sc} follows a linear behaviour with I_{LIGHT}. The effect of light intensity on J_{sc} is shown in Fig. 5. In the inset of Fig. 5 the effect of I_{LIGHT} on J_{sc} is shown for the case of trap generated recombination. In literature various authors [22,23] found the sub-linear relation of J_{sc} with incident light intensity, which they concluded is a signature of bimolecular recombination, also validates our model.

5. Conclusions

A general method to calculate the spectral response of a bulk-heterojunction solar cell has been described here. The generation rate of exciton and electron hole is calculated using optical interference method based on transfer matrix approach. First order and bimolecular recombination are taken into consideration in the model. Spectral response of the bulk-heterojunction solar cell has been found by solving the drift–diffusion equation. The simulated result matches with the spectral response of 1:1 P3HT:PCBM based bulk-heterojunction solar cell. We have also described the effect of thickness on short circuit current which matches with the experimental observations. We found that the best short circuit current density can be achieved from the devices of 60–75 nm. We have also described the effect of incident light intensity on short circuit current density which also matches with the experimental observations.

ABSTRACT

Organic thin film transistors with channel lengths below 20 μm have been fabricated on plastic substrates using a combination of rotogravure and ink-jet printing exclusively. Gravure is utilized to deposit thin, smooth, and narrow metal lines ideal for gate electrodes; a poly(4-vinylphenol) dielectric; and a poly(2,5-bis(3-tetradecylthiophene-2-yl)thieno[3,2-b]thiophene) (pBTTT) semiconductor using a heated roll. A novel fluid guiding technique is used to maintain closely spaced ink-jet printed source and drain (S/D) contacts. Together these printing processes yield aggressively scaled yet easily manufacturable TFTs with operating frequencies of 18 kHz.

1. Introduction

Printed electronics has received attention as a technology for the realization of low-cost circuits such as flexible displays, RFID tags, and sensors. While substantial work towards these goals has been performed using lithography and ink-jet printing, relatively little progress has been made in transferring these advances to higher speed processes such as gravure printing, flexography, etc. A few early demonstrations of OTFTs as well as simple circuits have been made [1–4] proving the feasibility of using rotogravure in combination with other printing techniques such as flexo and inkjet. However these devices suffered from large feature sizes, hampering their usability in any realistic applications.

We have developed a custom high-resolution rotogravure printer suitable for the development of printed electronics processes on a laboratory scale. Using this machine, an organometallic silver precursor ink and planarized polyethylene napthalate (PEN) films, we have previously demonstrated printed lines with feature sizes as small as 17.5 μm and a line edge roughness of <2 μm [5]. Scaling transistors with printed contacts, particularly gates, has been challenging to date because the processes used have provided relatively thick and rough films causing early breakdown and decreased yield [6]. In this work, by exploiting the small, well-controlled volume of our gravure wells and the use of an organometallic precursor ink, we demonstrate patterns of sufficient quality for use in fully-integrated devices with films as thin as 100 nm, allowing for the realization of high-performance, well-scaled devices.

In this paper we fabricate thin film transistors using these features, thus realizing the smallest rotogravure printed devices to date. In particular, we introduce a hybrid process using gravure for patterning high-resolution lines, thin dielectrics, and pBTTT semiconductor which until now, has been difficult to print; and using inkjet with a novel fluid guiding technique for precisely aligned upper electrodes to achieve an overall optimized process flow for

highly scaled printed devices offering high performance in a scalable, manufacturing-friendly process.

2. Experiment

Both a top gate and bottom gate transistor process was developed to explore the possibility of using gravure as a printing technique for TFTs. In the bottom gate process (Fig. 1 (left)), the gate and dielectric were printed using gravure followed by ink-jet printed source and drain contacts and gravure printed semiconductor. In the top gate process (Fig. 1 (right)) gravure was used to print the source and drain contacts, followed by the semiconductor and dielectric, and finally the gate was printed using ink-jet. A direct comparison of representative devices can be made in Figs. 5 and 6.

Details of the process to print and scale the feature sizes of the first gravure printed metal layer and dielectric are described elsewhere [5]. In brief, the metal lines were gravure printed using Inktec PR-010 silver precursor ink on planarized Q65FA PEN substrates by DuPont Teijin, which had been cleaned using an N_2 gun, and treated with UV ozone for 5 min. The line patterns where composed of 30 μm wide gravure cells with ~32 μm spacing such that the wells almost touched. For all gravure steps reported here prints were made at a speed of 1 m/s, which despite being slow compared with the speed used in the graphic arts (>10 m/s), is suitable for electronics. A doctor blade pressure of 12 PSI per inch, and a 3 mm nip contact where used. After printing, the lines were annealed in an oven at 150 °C for 15 min. Line widths were 20–21 μm with a thickness of 70 nm and a dome shaped profile giving a low roughness of 5.8 nm RMS and 20 nm peak to peak. Poly(4-vinylphenol) with 20% poly(melamine co-formaldehyde)methylated cross-linker was used as a dielectric by dissolving 1 g of the dielectric and cross-linker into 15 mL of propylene glycol monomethyl ether acetate and printing with electromechanically engraved gravure wells on a 40 l/cm pitch yielding an areal volume of 6.6 mL/m^2. After printing, the dielectric was cross-linked at 220 °C for 5 min.

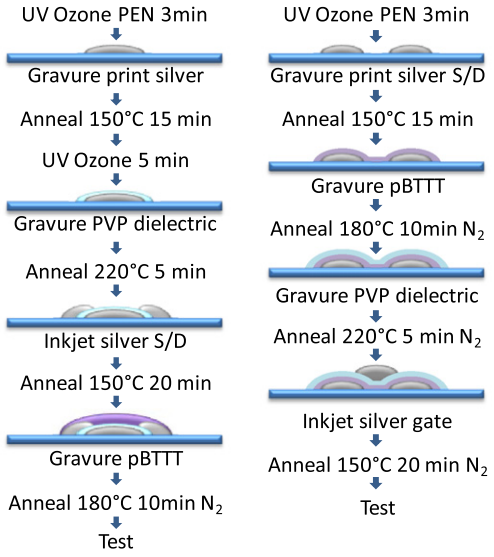

Fig. 1. Hybrid gravure/ink-jet process flow for bottom gate transistors (left) and top gate transistors (right).

2.1. Ink-jet printed contacts

A unique printing process was developed to allow the source and drain contact lines to be ink-jet printed close enough to each other to ensure overlap with the gate (<20 μm line spacing), yet avoid shorting the source and drain due to bulging, which is a common problem found when ink-jet printing two straight rows of drops (Cabot CCI-300 nanoparticle silver ink) in close proximity as seen in Fig. 2.

The growth mechanism for the bulges seen on the left side of the micrograph is also presented in Fig. 2. Drops merging at the beginning of an ink-jet printed line will try to adopt the least energetic shape possible: a larger, circular drop. As the line begins to get drawn out, ink deposited at the end of the line will flow towards the initial drop due to a pressure differential between the small deposited drop, the line, and the larger drop or bulge that was initially formed and is now growing. Eventually the pressure between the bulge and the line is equilibrated in part due to the increased size of the bulge, and in part due to the flow resistance of the long line, and the bulge ceases to grow [7,8].

The bulge is thus a natural result of steady state line formation that could be minimized using a few approaches including the use of larger drop spacing at the beginning of a line and higher print speeds [8]. Such a strategy is

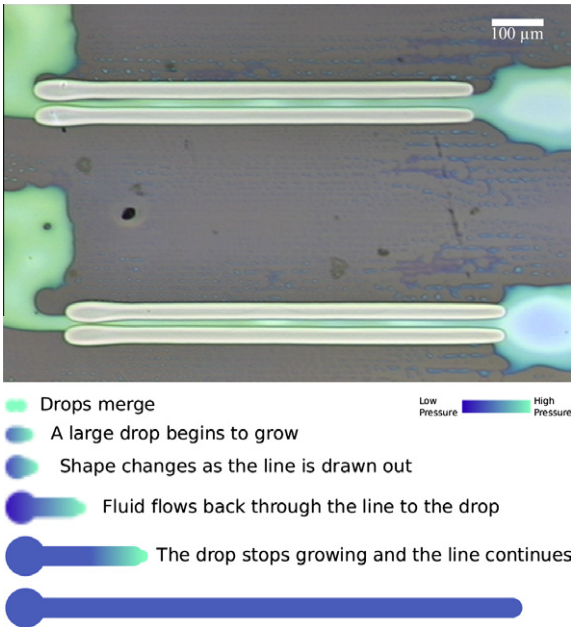

Fig. 2. Two printed thin film transistors (top) with channel lengths ~15 μm showing the risk of a source/drain short failure due to the bulge on the left side of the ink-jet printed lines. The bulge in these lines is due to the nature of line formation, as shown in the diagram (bottom).

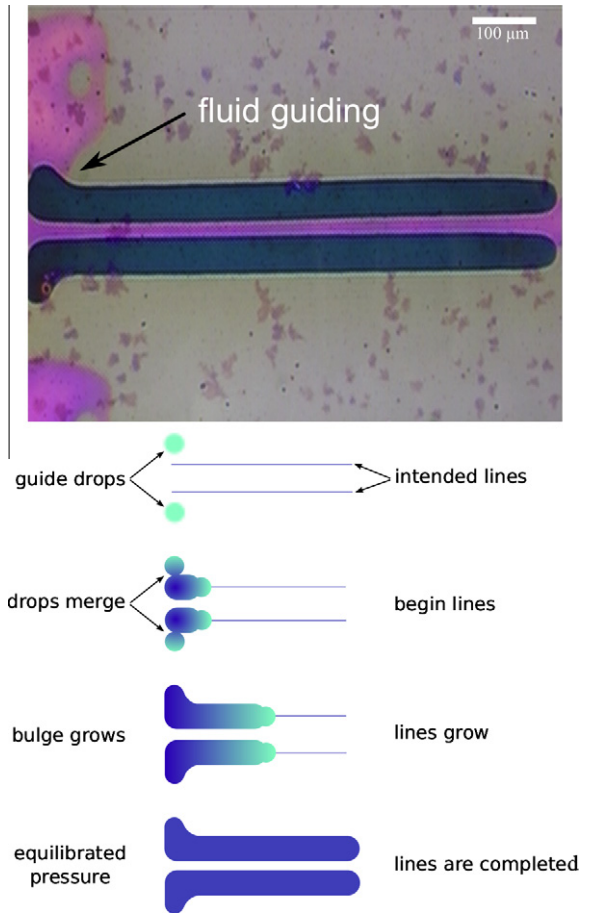

Fig. 3. Optical micrograph of a pBTTT TFT with ink-jet printed contacts employing fluid guiding to allow for a 15 μm channel length (top). Diagram of the fluid guiding process flow (bottom). Guide drops printed above and below contact lines, direct fluid flow away from the channel during the initial process of line formation.

not attractive for high-speed manufacturing, since rasterized constant-space printing is much more attractive from a throughput perspective. Instead, a novel fluid guiding approach was implemented where guiding drops are placed at the beginning of the source and drain lines, off-axis and away from the channel, such that the bulge that forms early in the print process contacts the guiding drops and is guided away from the channel (Fig. 3). Lines printed in this manner have a much reduced line edge waviness in the channel region allowing for much better control of the channel length and overlap to the gate, these features are now limited by the deposition accuracy of the drop which is ±5 μm. Transistor structures with channel lengths as small as 15 μm and leakage below 10^{-6} A/cm^2 at 1 MV/cm fields as tested before semiconductor deposition can be reliably made. These S/D contacts compare favorably with gravure printed ones where channel lengths below 20 μm are currently difficult to achieve.

2.2. Gravure printed semiconductor

pBTTT has been demonstrated to provide some of the highest field effect mobility and ambient stability obtained from a polymeric semiconductor [9]. However the polymer is difficult to dissolve into a solution and requires the use of hot solvents, which make it difficult to print this material with techniques such as ink-jet (due to the rapid evaporation of the heated solvents, causing clogging) or flexography (due to the swelling effects organic aromatic solvents can have on polymer masters). Gravure rolls and doctor blades are metallic and thus impervious to organic solvents regardless of their temperatures. Further they can be heated [10] to maintain pBTTT solubility and also to maintain consistent ink viscosity, thus making gravure a good candidate for depositing this material.

To test the thickness and uniformity of pBTTT films formed with gravure, an electromechanically engraved roll with eight different engravings as detailed in Table 1 was used. The gravure roll was heated prior to printing in an oven. Because of its high thermal mass, the roll could easily maintain its temperature through the print process which lasted approximately 5 min. Ink was delivered to the roll via a heated syringe just before the print. Substrates were treated with UV ozone for 4 min prior to printing to improve wetting of the pBTTT ink. After printing, the substrates were dried in an oven at 100 °C.

The optimal film thickness for pBTTT is known to be between 30 and 60 nm to provide high-quality film formation while minimization bulk leakage effects. Typical ink transfer volumes were found to be approximately half the cell volume; therefore, optimal ink dilutions could be estimated and inks with five different concentrations were prepared. Table 1 provides the expected film thicknesses printed from these solutions.

The prints were visually inspected to determine which patterns produced the most uniform films, and which concentration provided the most adequate thickness. Direct measurements of the film thickness where difficult to obtain because the flexibility of the PEN substrate prevents

Table 1
Gravure cell parameters–cell depth and areal volume for wells electromechanically engraved on a 40 l/cm pitch- and estimated film thicknesses provided from solutions of pBTTT as shown.

pBTTT concentration		% Vol.	Cell depth (μm)	45	50	55	60	65	70	75	80
(mg/mL)	(mg/mg)		Area volume (mL/m^2)	6.1	8	10	13.1	15.6	19.3	20.7	23.3

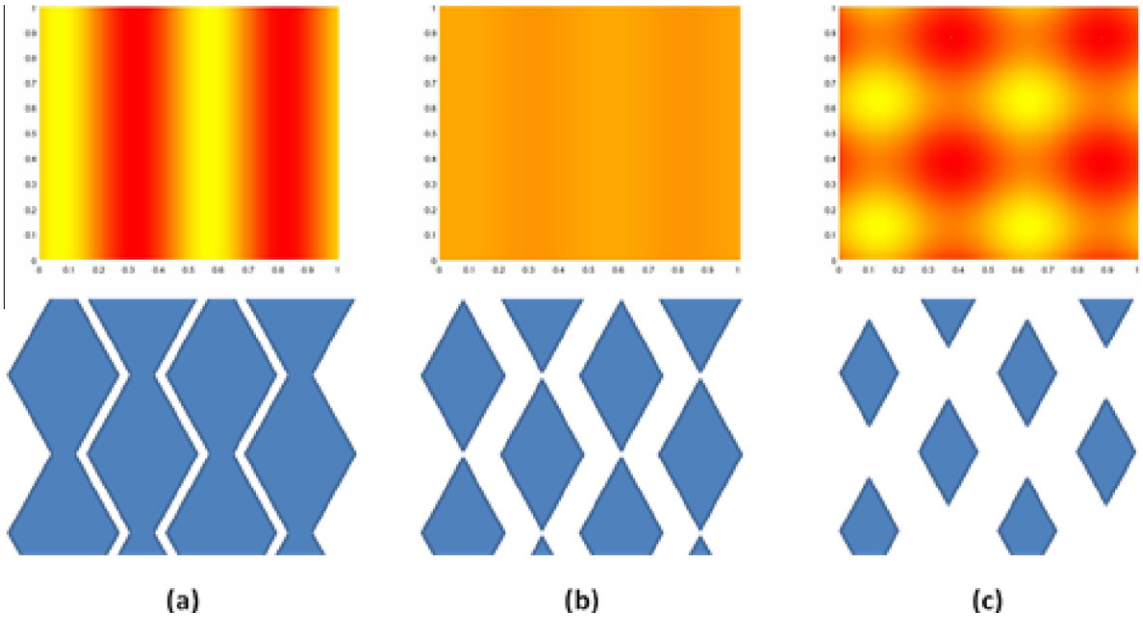

Fig. 4. Schematic of film thickness variation (top) and equivalent gravure cell volume (bottom) for gravure printed pBTTT films. Cells are spaced by 250 μm on the gravure. Large cells (a) merge in the vertical print direction causing band-like thickness variation. Small cells (c) are too far apart to allow ink to uniformly spread. An ideal cell spacing (b) allows for fluid flow to form uniform films.

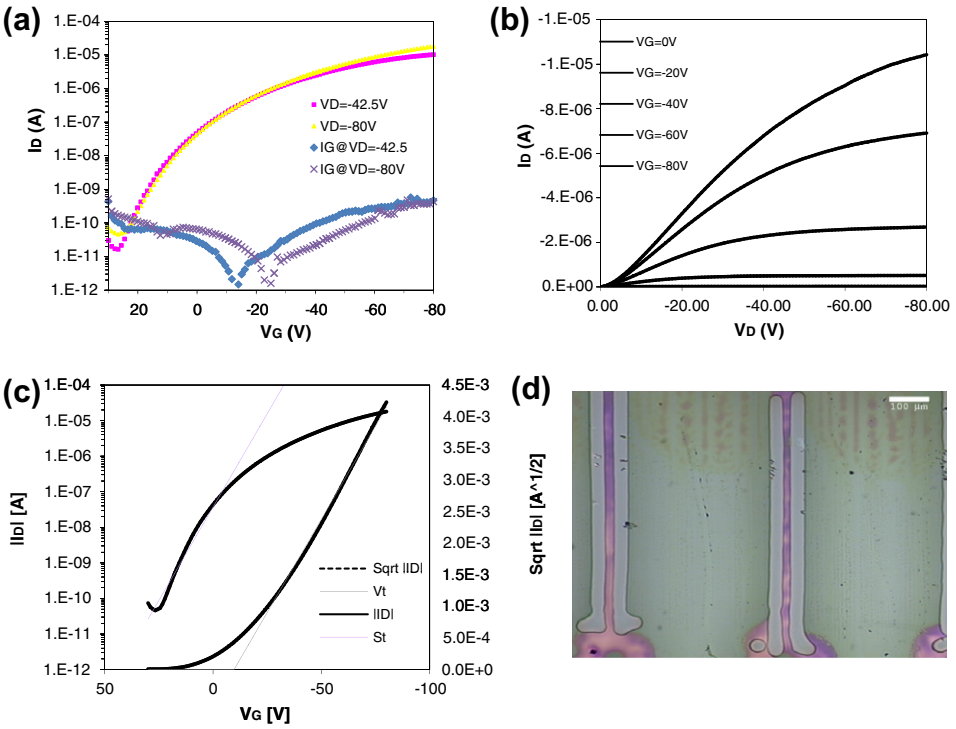

Fig. 5. (a) Transfer characteristics, (b) output characteristics, (c) transfer characteristic and $\sqrt{I_D}$ showing square law behavior with a −4 V V_T, and subthreshold slope of 9.5 V/dec. The transfer characteristic shows a low gate current throughout the operation range, and provides a μ_{SAT} = 1.5e−2 cm^2/Vs, on/off of 3.7e−5, μ_{LIN} = 2.6e−2 cm^2/Vs. d) Shows an optical micrograph of the device (center), W = 754 μm and L = 18 μm.

a flat reference to be obtained for step-height measurements and is too wavy for optical methods such as ellipsometry. The optimal pattern/concentration was thus determined by looking for the best uniformity and comparing the color of the printed film to a test sample which was spin coated with a 50 nm thick pBTTT film.

Variation of film thickness was observable when viewing the substrate at an oblique angle despite appearing uniform when viewed head on. The variation was too faint to be captured by camera or microscope. Instead, a schematic of these results is shown in Fig. 4. Patterns printed with a high print volume (21 or 23 mL/m^2) presented an oscillatory thickness perpendicular to the print direction but good uniformity in the print direction (Fig. 4(a)). Patterns printed with a low print volume (6 and 8 mL/m^2) had an incomplete film as wells were spaced too far apart for the deposited ink to spread and merge. Patterns with a slightly higher print volume (10 mL/m^2) were continuous films, but exhibited a similar color oscillation as for the dithered patterns (Fig. 4(c)), while a few print volumes (13 and 15.6 mL/m^2) yielded optically uniform films (Fig. 4(b)). Best results were found using a concentration of 3 mg/mL of pBTTT in dichlorobenzene and a 13.1 mL/m^2 pattern.

3. Results and discussion

3.1. DC results

DC characteristics where obtained in air using an Agilent 4156C semiconductor parameter analyzer. Mobilities where extracted using the square-law equations for linear and saturation mobility as appropriate and the peak transconductance extracted from the first derivative of the transfer characteristics in order to avoid including errors in extracting the threshold voltage.

As printed, the bottom gate devices exhibited reasonable saturation mobilities of 0.06 cm^2/Vs and a modest on/off ratio of 10^3. It was determined that the poor on/off ratios were due to leakage through the gate to the probe tip during testing, as the semiconductor had not been patterned over the gate contact. After eliminating the semiconductor around the gate contact, the off current decreased dramatically yielding devices with on/off ratios of 10^6. pBTTT is quite air-stable, and mobility stabilized at 0.01–0.02 cm^2/Vs after storing in air for 3 weeks. Transfer and output characteristics for a prototypical device are presented in Fig. 5. The onset voltage and threshold voltage for these devices have had a positive shift from their initial state, which could be an indication of the incorporation of moisture into the film [9]. These are among the highest performing gravure printed organic TFTs to date.

A top gate device structure was also investigated. In the process flow for this device, shown on the right of Fig. 1, gravure is utilized to define the source and drain. These contacts are printed first, using PR-010 and are printed in the same manner as the gate contacts for bottom gate devices. A key advantage to printing S/D contacts with gravure is that the spacing between the lines is determined on the roll, and can be accurately controlled during the print process because of the contact nature of the print technique. However a key disadvantage is that the non-image areas of a gravure roll remain coated with residual ink as ink removal by the doctor blade is never perfect [5]. This residual ink can cause chemical contamination of the semiconductor, and increase the roughness of the surface onto which the semiconductor is to be deposited decreasing its crystallinity and performance [11,12].

The electrical characteristics of these devices, shown in Fig. 6, exhibit very high off currents. The off-state leakage was determined not to be caused by gate leakage, but by S/D leakage. This could be caused by a poor semiconductor limited by the roughness of the surface onto which it was deposited, or by chemical doping and contamination from the residual ink in the channel. Further, test devices fabricated on silicon samples rule out that the performance of the material was compromised by subsequent processing of the dielectric and gate. Considering that the channel for these devices is formed on the top surface of the semiconductor which because of its roughness should cause increased carrier scattering, the saturation mobility, 0.015 cm^2/Vs, is comparable to that observed on bottom gate devices.

Removal of the scum deposited during gravure printing of the contacts is thus imperative to improving the performance of these devices, and will be necessary to realize top-gated devices by gravure printing.

3.2. AC performance

The DC characterization of printed pBTTT TFTs is essential to understanding the materials properties and electronic behavior of the devices. Performance parameters extracted from DC characterization are used to model how

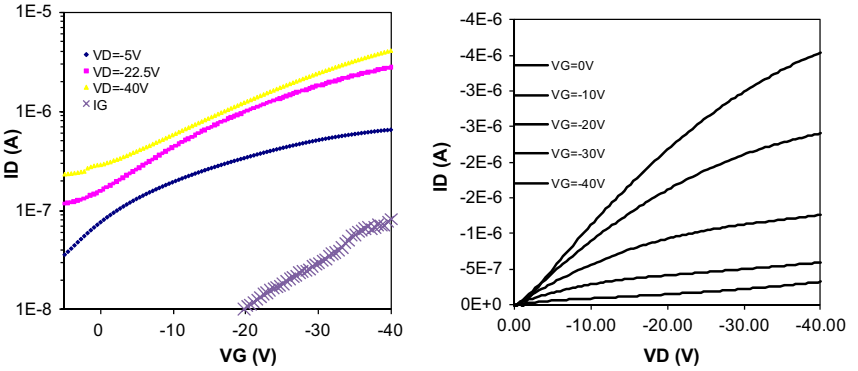

Fig. 6. Transfer and output characteristics for top gate, gravure printed TFTs. W = 854 μm, L = 21 μm, μ_{FE} = 6.8e−3, on/off = 17.5.

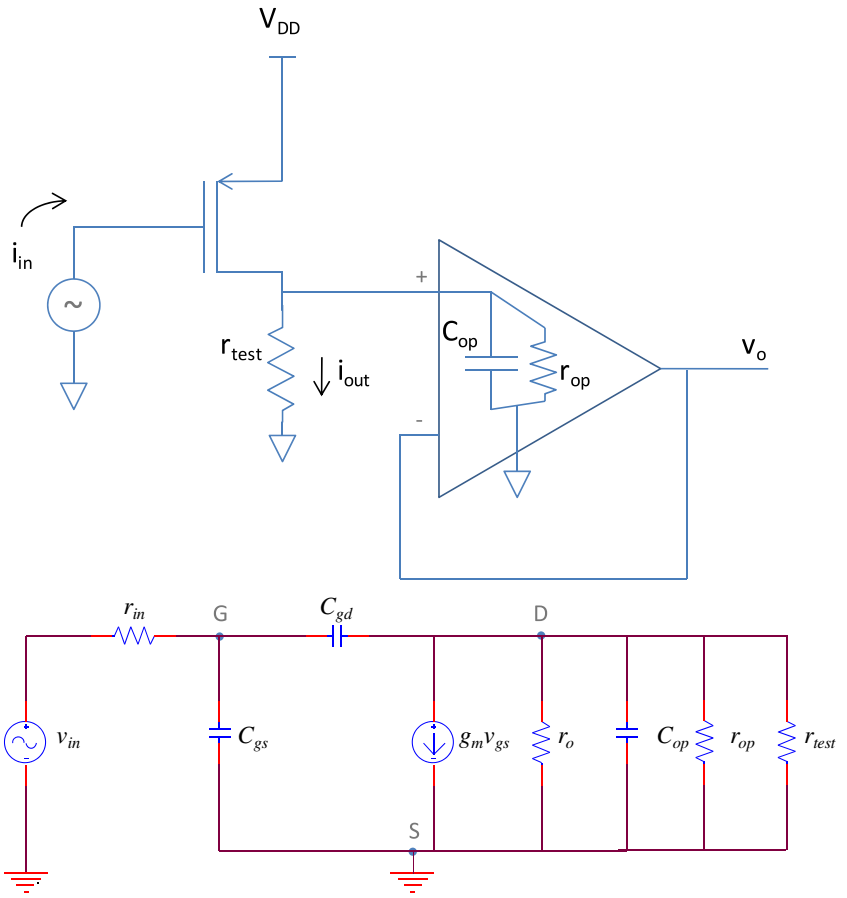

Fig. 7. Schematic of experimental setup (top) for f_T extraction and equivalent small signal circuit (bottom).

a device will operate in a real circuit. However, for actual applications, AC analysis and characterization is crucial, since DC characterization alone does not provide sufficient information about how a transistor will operate under these conditions. At high frequencies, capacitances dominate a transistors performance, shorting the signal from the gate to channel due to overlap capacitance, decreasing the gain of a transistor in an analog circuit; and ever increasing the drive current required to charge capacitive loads, limiting the rise and fall times of digital signals.

For organic thin film transistors, the operating speed of the device can also be limited by charge injection from the source/drain contacts into the channel [13–15]. In this case injection is limited by trapping and de-trapping rates at the metal/semiconductor interface, which can be difficult to measure directly.

A direct form of assessing the AC performance of a transistor is through the measurement of its *transition frequency*, f_T. The transition frequency is defined as the frequency at which an unloaded transistor exhibits unity current gain. This measurement is particularly useful for analog circuitry where f_T gives a clear bound on the maximum frequency an analog circuit can be expected to provide amplification. The relation of f_T to device parameters and its importance in understanding the scalability of such devices has been recently reviewed in this journal by Hoppe and coworkers [16].

In high performance transistors, the transition frequency is measured using high frequency test structures with load matched transmission lines connecting the contacts of the device and measurement results are fitted to a small signal model to obtain f_T [17,18]. For OTFTs, operating frequencies are much lower and microwave techniques can be avoided. Instead, a direct measurement of f_T can be made by the circuit in Fig. 7. The transistor is operated at its standard DC bias point (saturation), a small signal current is applied to the gate, and the corresponding output current is measured at the drain of the device.

In an ideal case, the ammeter at the drain behaves as a short in small signal and thus the output resistance of the transistor and any output capacitance are shorted. Ignoring r_{in}, which should be negligible for a good voltage source, $v_{in} = v_{gs}$ and the input current can then be expressed as

$$i_{in} = j\omega(C_{gs} + C_{gd})v_{gs} \tag{1}$$

the output current is

$$i_o = g_m v_{gs} \tag{2}$$

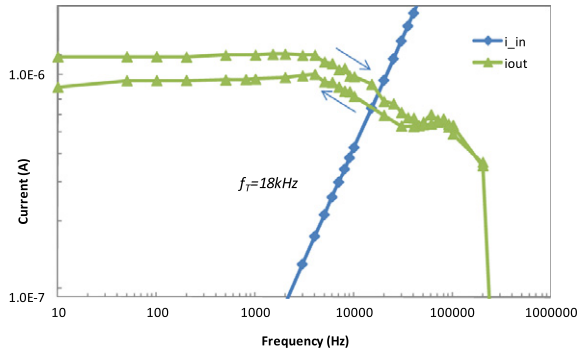

Fig. 8. Input and ouput current vs. frequency for an all printed pBTTT transistor. f_T is measured at the intersection of the two curves, indicating unity current gain. Data is for transistor presented in Fig. 5.

by substituting v_{gs} from Eq. (1), the current gain is given as

$$\frac{i_o}{i_{in}} = \frac{gm}{j\omega(C_{gs}+C_{gd})} \tag{3}$$

Which, when $\frac{i_o}{i_{in}} = 1$ gives f_T

$$f_T = \frac{g_m}{2\pi(C_{gs}+C_{gd})} \tag{4}$$

A low current small load ammeter was emulated by placing a test resistor in series with the drain such that $r_{test} << r_o$ and connecting a high impedance probe to accurately measure a voltage drop across the load such that the output current could be measured

$$i_o = \frac{v_o}{r_{test}}. \tag{5}$$

To further improve measurement accuracy, the impedance of the high impedance probe was taken into account and the circuit model in Fig. 7 was used to accurately extract i_o.

The input capacitance of the transistor was determined by using the measured dielectric capacitance per unit area, the size of the transistor, and the overlap area of the source and drain contacts (determined using optical microscopy) such that

$$C_{gs}+C_{gd} = C_{ins}W\left(\frac{2}{3}L + L_{S_{OL}}\right) + C_{ins}WL_{D_{OL}} \tag{6}$$

where C_{ins} is the dielectric capacitance per unit area in F/cm^2 W and L are the transistor width and length, respectively, and L_{SOL} and L_{DOL} are the overlap lengths for the source and drain contacts. The channel capacitance was assumed to be 2/3 of the channel length in saturation as is common practice. Assuming that the overlap lengths are the same for both source and drain, and expressing these lengths as a percentage ϕ of the channel length, the input capacitance can be written as

$$C_{gs}+C_{gd} = C_{ins}W\left(\frac{2}{3}L + 2\phi L\right) \tag{7}$$

With these equations and the measured output voltage, the small signal output current (i_{out}) and the input current (i_{in}) can be plotted to determine the f_T of the device. Biasing an all printed pBTTT TFT with V_{DS} = −60 V and V_{GS} = −56 V, and applying a 2 V peak-to-peak sinusoidal signal to the gate while sweeping its frequency measurements of i_{in} and i_o where made. The data in Fig. 8 show a transition frequency of 18 kHz which is an excellent result that compares quite favorably to other gravure printed transistors [1,2].

To better understand the source of this performance, Eq. (4) can be expanded to reflect the influence of device parameters by substituting $g_m = \mu C_{ins}\frac{W}{L}(V_{GS}-V_T)$ and Eq. (7) to yield

$$f_T = \frac{\mu(V_{GS}-V_T)}{2\pi\left(\frac{2}{3}L^2 + 2\phi L^2\right)} \tag{8}$$

which is similar to Eq. (11) from [16], where the contact resistance term has been ignored.

For the device presented here, a transition frequency of 27 kHz was calculated with Eq. (8), which is in good agreement with the measured value.

4. Conclusion and outlook

In this work, we have presented highly scaled gravure printed organic transistors offering excellent performance, including some of the highest switching speeds reported to date for fully-printed transistors. It is evident that though clear improvements to f_T can be obtained through improvements in field effect mobility, the operation of the device is extremely sensitive to its channel length, and substantial improvement can be achieving through proper device scaling. Herein lays the success of the presented devices where gravure printed features were scaled down to 20 μm providing devices with channel lengths of 18 μm. By comparison, the work from Huebler [1] and Jung [2], where channel lengths of 100 and 200 μm were printed, respectively, yielded devices with operation frequencies well below 1 kHz. With a 10× improvement in mobility that can be expected from the pBTTT semiconductor devices operating near 200 kHz could be fabricated using this process. Further, if the channel length can be reduced to 10 μm, a transition frequency of 900 kHz would be expected making these printed devices suitable for standards compliant RFID and high-resolution displays.

ABSTRACT

Two new conjugated small molecules (SMs), **M1** and **M2**, of low band gap with pyridine and pyran units, respectively, were synthesized by a convenient two-step reaction. They were soluble in common organic solvents and showed broad absorption ranging from 300 to 750 nm. Their long-wavelength absorption maximum was at 601–640 nm and the optical band gap was 1.60–1.67 eV. These SMs and [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) were used as donor and acceptor respectively to fabricate bulk heterojunction organic photovoltaic (OPV) devices through solution processing. The power conversion efficiencies (PCEs) for the OPV devices based on the as cast **M1**:PCBM and **M2**:PCBM are 1.42% and 1.80%, respectively. The higher PCE for the **M2**:PCBM based devices is attributed to the higher hole mobility, broader absorption spectra and lower band gap of **M2** as compared to **M1**. The PCEs have been improved up to 1.75% and 2.18% for the solvent treated **M1**:PCBM and **M2**:PCBM blends, respectively. Finally, they have been further enhanced to 2.03% and 2.77% for the thermally annealed solvent treated **M1**:PCBM and **M2**:PCBM blends, respectively. This improvement has been attributed to the increase in the crystallinity of the blend and balance charge transport of the devices based on the solvent treated and thermally annealed solvent treated blends.

1. Introduction

Intense research in the field of organic photovoltaics (OPVs) has led to a significant increase in their power conversion efficiencies (PCEs) over the past decade [1]. One of the most important advances in OPVs has been the introduction of the bulk heterojunction (BHJ) architecture [2], in which the photoactive thin film consists of an interpenetrating blend of electron donor and electron acceptor components. Extensive research efforts have focused on improving the polymeric electron donor component of the BHJ while retaining fullerene derivatives as the electron acceptor [3]. In BHJ devices using 6,6-phenyl-C61-butyric acid methyl ester (PC61BM) as the acceptor, a desirable processable polymer donor should exhibit not only a band gap between 1.2 and 1.9 eV with broad absorption to maximize sunlight absorption but also a highest occupied molecular orbital (HOMO) energy level between −5.2 and −5.8 eV and a lowest unoccupied molecular orbital (LUMO) energy level between −3.7 and −4.0 eV to ensure efficient charge separation while maximizing the

doi:10.1016/j.orgel.2010.10.002

open-circuit voltage (V_{oc}). In addition, good hole mobility is needed to allow adequate charge transport [1c]. On the other hand, the use of donor–acceptor structures has become an efficient strategy for obtaining low-band-gap polymers and modulating their electronic properties [4]. Recent developments concerning processes for the production of flexible large area polymer and generally organic solar cells have been reported [5].

Small-molecule (SM) donor materials can also form useable BHJ solar cells by solution processing, although it is more challenging to obtain high-quality films. The highest reported efficiencies for such devices have remained low relative to solution processed solar cells using polymeric donor materials. SM materials, however, offer advantages over polymeric materials in terms of ease of synthesis and purification, which greatly improve fabrication reproducibility, as well as possessing a greater tendency to self assemble into ordered domains, which leads to high charge carrier mobilities [6,7]. SMs do not suffer from batch to batch variations, broad molecular-weight distributions, end-group contamination, or difficult purification methods, which can be significant problems for polymeric materials. These considerations make SMs a promising class of donor material for BHJ solar cell applications [8]. PCE up to 2.3% and 3.0% have been reported [9] using an oligothiophene with dialkylated diketopyrrolopyrrole chromophere as donor and soluble fullerenes PCBM or [6,6]-phenyl C71 butyric acid methyl ester as an acceptor, respectively. The best performance of solution processed SM solar cells with a PCE of 4.4% has been reported by Nguyen et al. [9a]. Theoretical and experimental advances in OSCs have demonstrated that the donor–acceptor (D–A) type SMs have great potential as one class of promising materials in solution processed OPVs [10]. These encouraging results stimulate scientists to develop and investigate more solution processable organic donors for high performance OPVs.

Pyridine has been inserted into a bithiophene template to create a donor monomer. This monomer has been copolymerized with 2,1,3-benzothiadiazole and with thiophene and the resulting copolymers have been used for BHJ solar cells [11]. On the other hand, various polymers and SMs containing (4*H*-pyran-4-ylidine)propanedinitrile have been widely used for fabrication of BHJ solar cells [12–16].

Recently, we have synthesized a series of SMs of low band gap containing cyanovinylene 4-nitrophenyl segments which have been used as donors with PCBM as acceptor for BHJ solar cells [17–21]. In continuation of this research line, in the present article we report the synthesis, characterization and the BHJ solar cells performance of two new conjugated SMs, **M1** and **M2**, which contain pyridine and substituted-pyran as central unit, respectively. Besides, they contained terminal cyanovinylene 4-nitrophenyl units, which broadened and red-shifted their absorption spectrum, as well as a phenylenevinylene spacer. Pyridine is an electron-donating segment, while (4*H*-pyran-4-ylidine) propanedinitrile is a coplanar electron-withdrawing segment with high oxidative stability. These SMs were successfully synthesized by a two-step reaction sequence from inexpensive and widely used starting materials. The SMs, were used as electron donor materials along with PCBM as electron acceptor, to fabricate BHJ organic photovoltaic devices through solution processing. The PCEs for the OPV devices based on the as cast **M1**:PCBM and **M2**:PCBM are 1.42% and 1.80%, respectively. The higher PCE for the **M2**:PCBM based devices is attributed to the lower optical (1.60 vs. 1.67 eV) and electrochemical (1.70 vs. 1.75 eV) band gap, the higher hole mobility (7.8×10^{-6} vs. 4.5×10^{-6} cm^2/Vs) and broader absorption spectrum of **M2** as compared to **M1**. Since these SMs are differentiated only by their central unit, (4*H*-pyran-4-ylidine) propanedinitrile seems to be superior to pyridine from the viewpoint of PV performance. Moreover, the effect of solvent vapour treatment of blends and thermal annealing on the photovoltaic (PV) performance of the devices has been investigated. PCEs of 2.03% and 2.77% were achieved for OPVs based on thermally annealed solvent treated **M1**:PCBM and **M2**:PCBM blends, respectively.

2. Experimental

2.1. Reagents and solvents

(2,6-Dimethyl-4*H*-pyran-4-ylidine)propanedinitrile (**1b**) was synthesized from the condensation of 2,6-dimethyl-4-pyrone with malononitrile in acetic anhydride [22]. 4-Nitrobenzylcyanide was synthesized from the nitration of benzyl cyanide with concentrated nitric and sulfuric acid [23]. It was recrystallized from ethanol. Terephthaldehyde was recrystallized from water. *N*,*N*-dimethylformamide (DMF) and tetrahydrofuran (THF) were dried by distillation over CaH_2. All other reagents and solvents were commercially purchased and were used as supplied.

2.2. Preparation of compounds

2.2.1. 2,6-di(E)-4-formylstyrylpyridine (*2a*)

A flask was charged with a mixture of 2,6-dimethylpyridine (**1a**) (0.75 g, 6.99 mmol), terephthaldehyde (1.88 g, 13.98 mmol) and acetic anhydride (25 mL). It was stirred and refluxed for 12 h under N_2. The reaction product precipitated upon cooling at room temperature. It was filtered off, washed thoroughly four times with hot water and dried to afford **2a** (2.06 g, 87%).

FT-IR (KBr, cm^{-1}): 1696 (carbonyl); 3032, 1598, 1448 (aromatic).

^{1}H NMR ($CDCl_3$) ppm: 9.95 (s, 2H, formyl); 7.76 (m, 4H, phenylene ortho to formyl); 7.42 (m, 1H, pyridine H4); 7.32 (m, 4H, phenylene meta to formyl); 7.21 (m, 4H, vinylene); 6.93 (m, 2H, pyridine H3, H5).

Anal. Calcd. for $C_{23}H_{17}NO_2$: C, 81.40; H, 5.05; N, 4.13. Found: C, 80.63; H, 5.38; N, 4.52.

2.2.2. 2-(2,6-bis((E)-4-formylstyryl)-4H-pyran-4-ylidene)-malononitrile (*2b*)

Compound **2b** was prepared in 82% yield from the reaction of (2,6-dimethyl-4*H*-pyran-4-ylidine)propanedinitrile (**1b**) with terephthaldehyde in a mol ratio 1:2 in acetic anhydride according to the procedure described for **2a**.

FT-IR (KBr, cm^{-1}): 1700 (carbonyl); 2208 (cyano); 3056, 1578, 1508, 1430 (aromatic).

^1H NMR ($CDCl_3$) ppm: 9.98 (s, 2H formyl); 7.76 (m, 4H, phenylene ortho to formyl); 7.32 (m, 4H, phenylene meta to formyl); 7.21 (m, 4H, vinylene); 6.60 (s, 2H, pyran).

2.2.3. 2-(2,6-bis((1Z,1E)-4-((Z)-2-cyano-2-(4-nitrophenyl)-vinyl)styryl)pyridine (*M1*)

A flask was charged with a solution of **2a** (0.2315 g, 0.682 mmol) and 4-nitrobenzylcyanide (0.2212 g, 1.364 mmol) in DMF (15 mL). Sodium hydroxide (0.20 g, 5.00 mmol) dissolved in ethanol (8 mL) as added to this solution. The reaction mixture was stirred for 1 h at room temperature under N_2 and then was concentrated under reduced pressure. Water was added to the concentrate and **M1** precipitated as a dark green solid. It was recrystallized from DMF/water (0.2967 g, 69%).

FT-IR (KBr, cm^{-1}): 2156 (cyano); 1524, 1346 (nitro); 3028, 1584, 1504, 1446 (aromatic).

^1H NMR ($CDCl_3$) ppm: 8.19 (m, 4H, phenylene ortho to nitro); 7.83 (s, 2H, cyanovinylene); 7.52–7.30 (m, 4H, phenylene meta to nitro; 1H, pyridine H4; 8H, other phenylene); 7.21 (m, 4H, vinylene); 6.93 (m, 2H, pyridine H3, H5).

Anal. Calcd. for $C_{39}H_{25}N_5O_4$: C, 74.63; H, 4.01; N, 11.16. Found: C, 74.15; H, 4.28; N, 11.51.

2.2.4. 2-(2,6-bis((1Z,1E)-4-((Z)-2-cyano-2-(4-nitrophenyl)-vinyl)styryl)-4H-pyran-4-ylidene)malononitrile (*M2*)

Compound **M2** was prepared as a dark green solid in 75% yield from the reaction of **2b** with 4-nitrobenzylcyanide in DMF in the presence of sodium hydroxide.

FT-IR (KBr, cm^{-1}): 2193, 2170 (cyano); 1520, 1346 (nitro); 3032, 1590, 1508, 1458 (aromatic).

^1H NMR ($CDCl_3$) ppm: 8.19 (m, 4H, phenylene ortho to nitro); 7.83 (s, 2H, cyanovinylene); 7.52 (m, 4H, phenylene meta to nitro); 7.48–7.30 (m, 8H, other phenylene); 7.21 (m, 4H, vinylene); 6.60 (s, 2H, pyran).

Anal. Calcd. for $C_{42}H_{24}N_6O_5$: C, 72.83; H, 3.49; N, 12.13. Found: C, 72.35; H, 3.68; N, 11.75.

3. Characterization methods

IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrometer with KBr pellets. ^1H NMR (400 MHz) spectra were obtained using a Brucker spectrometer. Chemical shifts (δ values) are given in parts per million with tetramethylsilane as an internal standard. UV–vis spectra were recorded on a Beckman DU-640 spectrometer with spectrograde THF. Elemental analyses were carried out with a Carlo Erba model EA1108 analyzer.

The electrochemical properties of **M1** and **M2** were studied by cyclic voltammetry (CV) (CH Instruments). A glassy carbon coated with **M1** or **M2**, a Pt plate and an Ag/Ag^+ electrode were used as the working-, counter- and reference-electrode, respectively. The electrolyte solution was 0.1 M tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) in anhydrous accetonitrile. The potential scan rate was 100 mV s^{-1}. The films for the electrochemical measurements were coated from their THF solutions.

The crystallinity of the films was studied using the X-ray diffraction (XRD) technique (panalytical make USA) having CuKα, as radiation source of wavelength λ = 1.5405 A° with the films coated on the quartz substrates.

3.1. Device fabrication and characterization

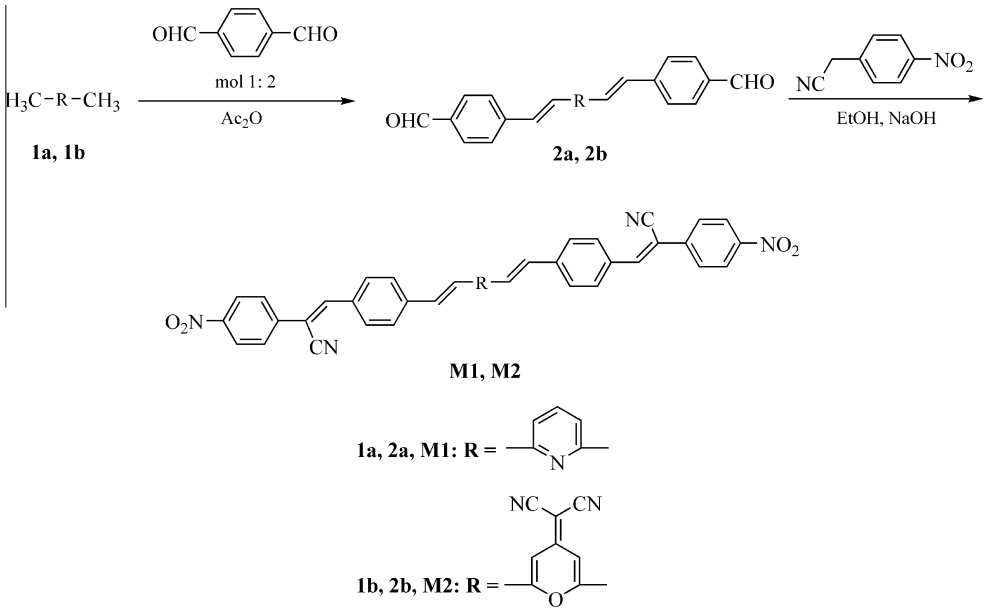
The BHJ devices were fabricated by the following ways. The indium doped tin oxide (ITO) coated glass serving as transparent anode was cleaned with detergent, acetone and isopropyl alcohol in an ultrasonic bath and then dried in oven. A 60 nm poly-[ethylenedioxy-thiophene]:(poly-(styrene sulphonic acid) (PEDOT:PSS) (BARTRON AG) as modified layer was then spin coated onto the pre-cleaned ITO glass substrate and dried at 80 °C for 15 min in vacuum oven. After cooling the substrate to room temperature, a solution of **M1** or **M2** (5 mg/mL) and PCBM (5 mg/mL) in THF was spin coated onto the top of PEDOT:PSS layer. For the solvent vapour treatment, the spin coated blend film was transferred into a jar filled with THF and remained there for 20 min. The thermal annealing of solvent vapour treated film was carried out at 100 °C for 2 min on the hot plate. Finally, an aluminum (Al), electrode (60 nm) was deposited on the top of the active BHJ layer through the thermal evaporation method. We have also fabricated the devices based on pure **M1** and **M2** having configuration ITO/PEDOT:PSS/**M1** or **M2**/Al to get information for the electrical and PV properties of these materials.

Current–voltage (*J–V*) characteristics of the PV devices were measured using a computer controlled Keithley 238 source meter in dark as well as under illumination intensity of 100 mW/cm^2. A xenon light source was used to give a simulated irradiance of 100 mW/cm^2 (equivalent to AM1.5 irradiation) at the surface of the device. The hole only and electron only devices having ITO/PEDOT:PSS/**M1** or **M2**: PCBM/Au and Al/**M1** or **M2**:PCBM/Al structures, respectively, were fabricated and *J–V* characteristics in dark at room temperature were recorded to estimate the hole and electron mobilities in the BHJ active layers.

4. Results and discussion

4.1. Synthesis and characterization

In this work we attempted to synthesize broadly absorbing SMs which are candidates for BHJ solar cells. Scheme 1 outlines the two-step reaction sequence of the target SMs. In particular, 2,6-dimethylpyridine (**1a**) and 2,6-dimethyl-4*H*-pyran-4-ylidine)propanedinitrile (**1b**) reacted with double molar amount of terephthaldehyde in acetic anhydride to afford dialdehydes **2a** and **2b**, respectively. In this reaction, the ratio of the reactants is crucial to limit the formation of poly(styrylpyridine). Moreover, the reaction product was thoroughly washed with hot water to dissolve possible unreactive terephthaldehyde. Dialdehydes **2a** and **2b** were condensed with 4-nitrobenzylcyanide in DMF in the presence of sodium hydroxide



Scheme 1. Synthesis of SMs **M1** and **M2**.

to give **M1** and **M2**, respectively as dark green solids in 69–75% yield. Even though these SMs lacked solubilising aliphatic chains, they were soluble in common organic solvents such as chloroform, dichloromethane and THF. Thin films of SMs could be obtained from their solutions by spin-casting.

The SMs were characterized by FT-IR and ^{1}H NMR spectroscopy. The IR spectra showed characteristic absorption bands around 2160 (cyano); 1520, 1346 (nitro) and 3030, 1590, 1500, 1450 cm^{-1} (aromatic). The ^{1}H NMR spectra displayed common signals at 8.19 (phenylene ortho to nitro); 7.83 (cyanovinylene) and 7.52 ppm (phenylene meta to nitro). It is worth mentioning that the unsubstituted vinylene protons resonated at lower shift (7.21 ppm) than the cyanovinylene protons (7.83 ppm) due to the electron-withdrawing cyano substituents of the latter.

4.2. Photophysical properties

The photophysical properties of SMs were investigated by UV–vis absorption spectroscopy in dilute (10^{-5} M) THF solution as well as in thin film (Fig. 1). All photophysical and electrochemical characteristics of SMs are summarized in Table 1. The absorption spectra were broad and extended from 300 nm up to approximately 750 nm which is a desirable feature for PV applications. The long-wavelength absorption maximum ($\lambda_{a,max}$) was at 601–640 nm which for **M1** could be attributed to an intramolecular charge transfer (ICT) between the electron-donating central pyridine and the electron-withdrawing terminal cyanovinylene 4-nitrophenyl. Upon going from solution to thin film, the $\lambda_{a,max}$ was red-shifted by ~35 nm owing to intermolecular interactions in solid state. The thin film absorption onset for **M1** and **M2** was located at 744 and

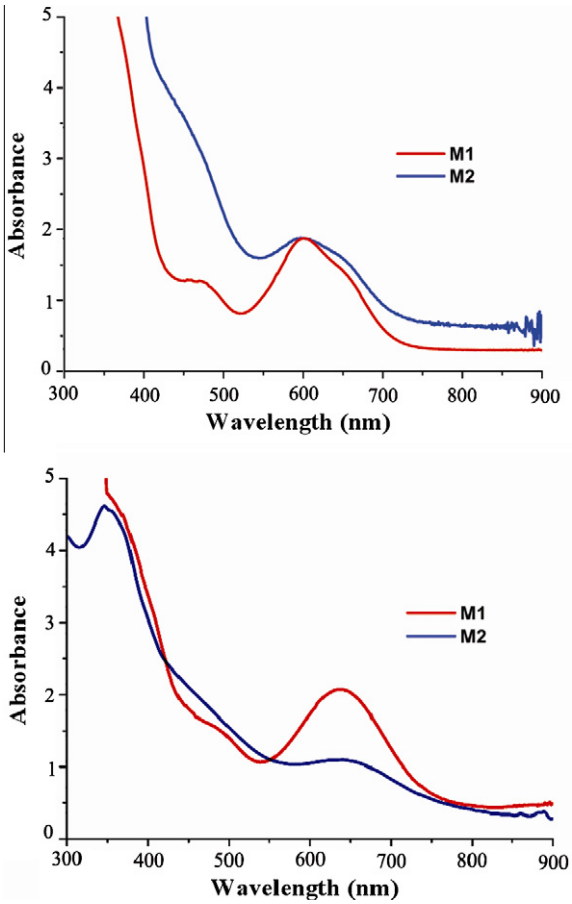


Fig. 1. UV–vis absorption spectra of SMs in THF solution (top) and thin film (bottom).

Table 1
Optical and electrochemical properties of SMs.

Molecule	M1	M2
$\lambda_{a,max}$[a] in solution (nm)	601	604
$\lambda_{a,max}$[a] in thin film (nm)	636	640
Thin film absorption onset (nm)	744	777
E_g^{opt} (eV)[b]	1.67	1.60
E_{onset}^{ox} (V)	0.65	0.45
E_{onset}^{red} (V)	−1.10	−1.25
HOMO (eV)	−5.35	−5.15
LUMO (eV)	−3.60	−3.45
E_g^{el} (eV)[c]	1.75	1.70

[a] $\lambda_{a,max}$: The absorption maxima from the UV–vis spectra in THF solution or in thin film.
[b] E_g^{opt}: optical band gap determined from the absorption onset in thin film.
[c] E_g^{el}: electrochemical band gap determined from cyclic voltammetry.

777 nm which corresponds to an optical band gap (E_g^{opt}) of 1.67 and 1.60 eV respectively. These values of E_g^{opt} are in line with those of other related SMs which have been synthesized in our laboratory [17–21]. Since both SMs showed comparable photophysical characteristics, the different chemical structure of the central unit did not influence considerably their photophysical properties.

4.3. Electrochemical properties

The electrochemical properties of **M1** and **M2** were studied by CV measurements as shown in Fig. 2. The onset reduction potential and oxidation potential have been measured with respect to a Ag/Ag^+ electrode. The values of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels were estimated from the following equations [24].

$$E_{HOMO}(eV) = -q(E_{onset}^{ox} + 4.7)$$
$$E_{LUMO}(eV) = -q(E_{onset}^{red} + 4.7)$$

where the unit of the potential is V vs. Ag/Ag+. The onset oxidation potential (E_{onset}^{ox}), onset reduction potential (E_{onset}^{red}), positions of HOMO and LUMO levels and electrochemical band gap of SMs are summarized in Table 1.

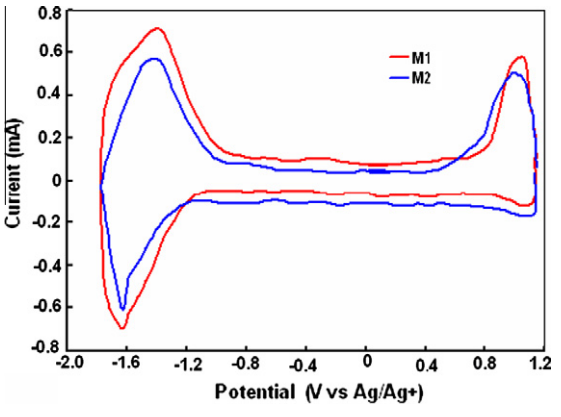

Fig. 2. Cyclic voltammogram of SMs **M1** and **M2** at scan rate of 50 mV/s.

The LUMO level of both M1 (−3.60 eV) and M2 (−3.45 eV) is higher than that of PCBM (−4.0 eV). The electrochemical band gap (E_g^{el}) of these materials is slightly higher than the corresponding E_g^{opt}, which is a common feature of most of the organic semiconductors due to the exciton binding energy [25]. It has been generally accepted that an energy difference of 0.35 eV between the LUMO levels of acceptor and donor materials (i.e. LUMO–LUMO offset) used in BHJ layer is necessary for efficient photoinduced electron transfer between donor to acceptor [26]. As it can be seen from Table 1, the difference between the LUMO levels of M1 or M2 and PCBM is greater than the binding energy of the excitons. Therefore, it is expected that excitons can be easily dissociated at the interface between M1 or M2 and PCBM in the organic solar cells based on blends with M1 or M2 as electron donor and PCBM as electron acceptor. Furthermore, the HOMO energy levels of M1 (−5.35 eV) and M2 (−5.15 eV) are well aligned with the HOMO level of PEDOT:PSS (−5.2 eV), indicating that holes can be easily transported from the HOMO level of M1 or M2 to PEDOT:PSS hole transport layer.

4.4. Electrical and photovoltaic properties of M1 and M2

We have measured the *J–V* characteristics of the devices based on pure SM sandwiched between the PEDOT:PSS and Al electrodes, in dark as well as under illumination and are shown in Fig. 3. The *J–V* characteristics (Fig. 3a) of both devices show a rectification effect, when positive potential is applied to PEDOT:PSS/ITO electrode with respect to the Al electrode. The HOMO level of the PEDOT:PSS (−5.2 eV) is very close to the HOMO level of **M1** (−5.35 eV) or **M2** (−5.15 eV) and forms a nearly Ohmic contact for hole injection from PEDOT:PSS into the HOMO of **M1** or **M2** in the respective devices. However, the LUMO level of both **M1** (−3.60 eV) or **M2** (−3.45 eV) is very far from the work function of Al (4.2 eV) and forms the Schottky barrier for the electron injection from the Al into the LUMO level of **M1** or **M2**. Therefore, the rectification effect observed in these devices is due to the formation of Schottky barrier at the Al-**M1** or Al-**M2** interfaces in the respective devices. From the *J–V* characteristics of the devices in dark, we concluded that both **M1** and **M2** behave as *p* type organic semiconductors.

The charge carrier mobilities of the organic materials used as photoactive layer is an important factor, which influences the PV performance of the organic solar cells. We have measured the hole mobilities of these molecules, using the *J–V* characteristics of the devices in dark with configuration ITO/PEDOT:PSS/**M1** or **M2**/Au, using the space charge limited current model [27]. The *J–V* characteristics of the devices, in dark at room temperature were plotted as $\ln [Jd^3/V_{app}–V_{bi})]$ vs. $[(V_{app}–V_{bi})/d]^{0.5}$, where V_{bi} is the built-in potential, and the hole mobilities of **M1** and **M2** estimated from the intercept on current axis of corresponding lines. The estimated values of hole mobility for **M1** and **M2** are 4.5×10^{-6} and 7.8×10^{-6} cm^2/Vs, respectively.

The PV parameters i.e. short circuit current (J_{sc}), open-circuit voltage (V_{oc}) and fill factor (FF) and power conversion efficiency (PCE) were extracted from the *J–V*

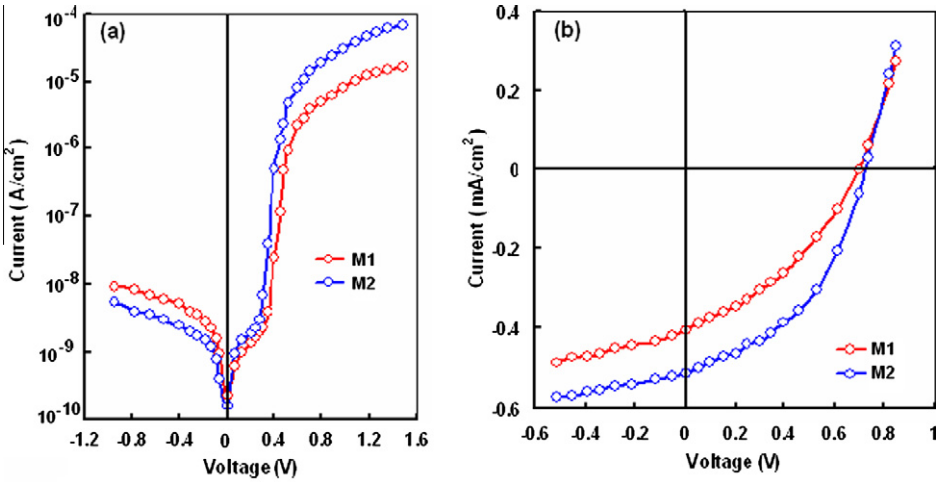

Fig. 3. Current–voltage characteristics of ITO/PEDOT:PSS/**M1** or **M2**/Al devices in (a) dark and (b) under illumination.

Table 2
Photovoltaic parameters of the ITO/PEDOT:PSS/**M1**or **M2**/Al devices.

Material	J_{sc} (mA/cm^2)	V_{oc} (V)	FF	PCE (%)
M1	0.40	0.70	0.32	0.09
M2	0.52	0.72	0.36	0.13

characteristics under illumination intensity of 100 mW/cm^2 (Fig. 3b) and are summarized in Table 2. It can be seen from this table that the values of J_{sc} and PCE are higher for the device based on **M2** in comparison to the device based on **M1** under the same experimental conditions. This can be attributed to the higher hole mobility of **M2** as compared to **M1**. The broader absorption band and lower E_g^{opt} of **M2** as compared to **M1** may contribute to the higher PCE of the device based on **M2** because more excitons are generated in this device. Moreover, the HOMO level of **M2** is very close to the HOMO level of PEDOT:PSS indicating better hole collection in the device of **M2**, which may also be a reason for higher PCE in this device. However, in the case of the device of **M1**, the holes may be trapped in the interface between **M1** and PEDOT:PSS, due to the difference between the HOMO levels of **M1** and PEDOT:PSS, which causes a slight band bending at the interface. The lower band gap, the higher hole mobility and the broader absorption band of **M2** as compared to **M1**, as well as the matching of the HOMO level of **M2** to the HOMO level of PEDOT:PSS are responsible for the higher photovoltaic effect of the **M2** device.

4.5. Electrical and photoelectrical properties of BHJ devices

The BHJ organic solar cells were fabricated with a structure of ITO/PEDOT:PSS/**M1** or **M2**:PCBM (1:1 w/w):Al, with **M1** and **M2** as electron donors and PCBM as electron acceptor. Fig. 4 shows the *J–V* characteristics of these devices in dark. It can be seen from this figure that the *J–V* characteristics in dark, clearly show a rectifying behaviour and exhibit three regions:

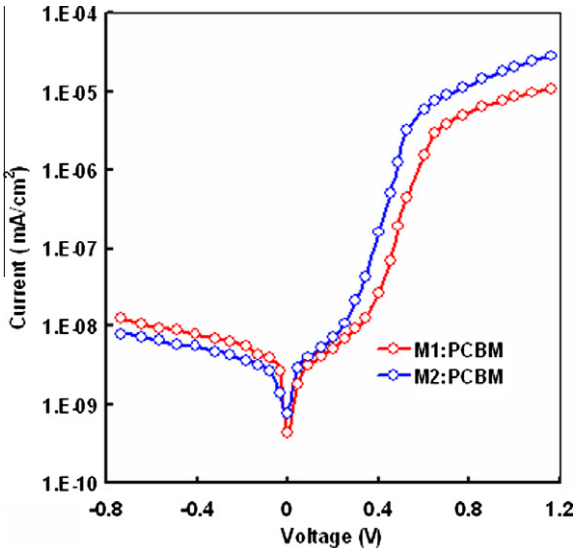

Fig. 4. Current–voltage (*J–V*) characteristics of ITO/PEDOT:PSS/**M1**or **M2**:PCBM/Al devices, using as cast blend, in dark.

(i) A linear region at reverse bias voltages and low forward bias voltages, where the current is controlled by the shunt resistance (R_s)
(ii) An exponential behaviour at intermediate forward bias voltages, where the current is controlled by diode, and
(iii) A second linear region at high forward bias voltages, where the current is controlled by the series resistance (R_{sh}).

Even though the physical and electrical properties of the organic semiconductors may be different, the principal loss mechanisms in the device are the same and consequently the *J–V* characteristics of the organic solar cells can be modelled using the one diode model [28]. The exponential region in the forward *J–V* characteristics is

attributed to the donor-acceptor (*D–A*) interface existing in the device. In the case of the device based on BHJ active layer, a well defined *D–A* interface is not formed as for the p–n junction and schottky barrier devices. In this case, the *D–A* interfaces are spread throughout the bulk of the active layer sandwiched between the two electrodes. The two materials used in the active layer, are arranged like the *D–A* interface, connect the electrode as pure phase or one material is completely enclosed by the other. The exponential behaviour of *J–V* characteristics depends on the properties of the two materials involved in the active layer. The slope of the *J–V* characteristics in exponential region depends upon the two parameters, i.e. ideality factor and reverse saturation current. The ideality factor gives an idea about the recombination process in the device, whereas the saturation current gives an idea about the number of charge carriers which are able to overcome the energetic barrier in the reverse bias. From the slope of *J–V* characteristics in exponential region, we have estimated the ideality factor of the devices, which is 1.50 and 1.23 for the devices based on **M1**:PCBM and **M2**:PCBM, indicating that the recombination of charge carriers is lower for the device fabricated from **M2**:PCBM as compared to the **M1**:PCBM, which may also be a reason for the higher photovoltaic response for the device based on **M2**:PCBM.

Photoluminescence (PL) measurements were performed to get information weather the photoinduced charge transfer or energy transfer is taking place in the blend after the absorption of light. Fig. 5 compares the PL spectra of **M1**, **M1**:PCBM and **M2**:PCBM in solid state. Both **M1** and **M2** show similar PL spectra with maximum emission at 820 nm. The intensity of both **M1**:PCBM and **M2**:PCBM is quenched by addition of PCBM, indicating that photoinduced charge transfer takes place effectively from SM to PCBM. The PL quenching in **M2**:PCBM is relatively higher than that for **M1**:PCBM, which supports the assumption that a more efficient charge transfer occurs in the former.

Fig. 6 shows the *J–V* characteristics of the devices based on the as cast, solvent vapour treated and thermally annealed solvent vapour treated blend under illumination intensity of 100 mW/cm^2 and the corresponding PV parameters are summarized in Table 3. It can seen from this Table that the J_{sc} (3.6 mA/cm^2) and PCE (1.42%) for the device based on the as cast **M2**:PCBM blend is higher than that for device based on the as cast **M1**:PCBM(J_{sc} = 4.57 mA/cm^2 and PCE = 1.81%) blend. The J_{sc} is directly related to the product of absorbed photons and external quantum efficiency (EQE). Since the absorption band of **M2**:PCBM blend is broader than that of **M1**:PCBM, more photons are absorbed by the former blend. Thus more excitons are generated in the **M2**:PCBM blend as compared to **M1**:PCBM due to the absorption of light. The EQE is determined by three processes: (i) migration/diffusion of photogenerated excitons towards the D/A interfaces, (ii) exciton dissociation into free charge carriers at the D/A interfaces, and (iii) collection of charge carriers by the electrodes i.e. holes by PEDOT:PSS/ITO and electrons by Al electrode. The process (i) depends on the nanoscale phase separation between the donor and acceptor materials used in the BHJ active layer. We have observed almost the same surface roughness for both **M1**:PCBM and **M2**:PCBM through the atomic force microscopic images, which indicates that the phase separation in both blends is almost the same. Therefore, we assume that the contribution in EQE or J_{sc} from the process (i) is the same. The process (ii) is related with difference between the LUMO energy levels of donor and acceptor, which is required for ultra fast photoinduced charge transfer in the device. This difference in **M2**:PCBM (0.55 eV) is higher that that in **M1**:PCBM (0.40 eV). This indicates that the exciton dissociation into free carriers and photoinduced charge transfer in the device of **M2**:PCBM blend is faster than that in the device of **M1**:PCBM blend. Process (iii) depends on the percolated path for electrons and holes in the photoactive layer, mobility of holes and also on the HOMO and LUMO energy level of the donor and acceptor materials, relative to the work function of anode and cathode. The HOMO level of **M2** (−5.15 eV) is closer to the HOMO level of PEDOT:PSS (−5.2 eV) and the mobility of holes in **M2**, results in more efficient hole collection. Therefore, we concluded that the higher PCE is due to the higher photocurrent generated in the device of **M2**:PCBM. This has been attributed to the broader absorption band, lower band gap and higher mobility of **M2**. Moreover, the PL quenching in the **M2**:PCBM blend is higher than that in **M1**:PCBM blend indicating faster photoinduced charge transfer in the device of **M2**:PCBM, which affords higher photocurrent in this device.

The V_{oc} (0.96 V) for the device of **M1**:PCBM blend is higher than that (0.88 V) for the device of **M2**:PCBM blend. Mixing of acceptor material with donor material completely modifies the nature of the photoactive layer. In the case of Ohmic contact, the work function of cathode (Al) and the HOMO level of anode (PEDOT:PSS) match the LUMO level of acceptor and HOMO level of donor, respectively. The maximum voltage in this case will be $(V_{oc})_{max} = E_{LUMO}$ (A)$-E_{HOMO}$ (D). The observed value of V_{oc} in the present devices is lower than that for the theoretical value. The HOMO level of **M1** (−5.35 eV) and **M2** (−5.15 eV) does not closely match the HOMO level of PEDOT:PSS (−5.2 eV), resulting in a nearly Ohmic contact for holes with some band bending. Moreover, the LUMO level of PCBM also does not closely match the work function of

[b] Solvent vapour treated film.
[c] Thermally annealed solvent treated film.

the Al electrode and a small band bending also occurs at the Al-PCBM interface. The V_{oc} can be expresses as $V_{oc} = [E_{LUMO}(D) - E_{HOMO}(A)] - \Delta V_b$, where ΔV_b is the voltage losses due to the band bending at the interfaces [29]. Therefore, the experimentally observed V_{oc} is smaller than the theoretical value. The difference between the LUMO–HOMO energy levels for **M1**:PCBM (1.35 eV) is higher than that for **M2**:PCBM (1.15 eV), which is attributed to the lower value of V_{oc} for the device of **M2**:PCBM as compared to that of **M1**:PCBM.

We have observed that the solvent and thermal annealing of blend film changes the thin film absorption spectra significantly. The absorption peak corresponding to the donor (**M1** or **M2**) is shifted after solvent and thermal annealing and in addition their intensities are higher than that in the as cast film. These absorption changes indicate increased crystallinity in both solvent and thermal annealed films.

Thin film XRD was used to determine the differences between the crystallinity of the as cast and annealed films. Fig. 7 gives the diffraction patterns of the as cast and annealed **M2** films. It can be seen that the pure **M2** films exhibit a peak around $2\theta = 7.5°$ corresponding to an interplanar distance of 13.2 A°. The annealing leads to higher peak intensity, indicating a higher degree of the crystallinity. Similar XRD patterns were also observed with **M1** films. When **M1** or **M2** blended with PCBM, this diffraction peak is not observed, suggesting the effectiveness of the PCBM acceptor in interfering the **M1** or **M2** molecular packing. However, when the blends are solvent and thermaly annealed, the diffraction peaks reappear. The diffraction peak for **M1**:PCBM and **M2**:PCBM is broad and centered at $2\theta = 8.4°$ and $2\theta = 7.64°$, respectively. The increase in the peak intensity in the XRD pattern after annealing leads to an increase in the crystallinity of the blend. These changes in film crystallinity after thermal annealing agree with the changes observed in the absorption data. A high degree of **M1** or **M2** crystallinity was also indicated by a red shift in the absorption band, clear vibronic shoulders appearance at long wavelengths owing to the enhanced interchain π–π^* stacking, and increased absorption intensity. The improved crystallinity in the annealed blend, facilitated through self organized chain stacking, can enhance not only the hole transport but also the light harvesting capabilities, improving the device photocurrent [27a].

The J–V characteristics of the devices based on the solvent treated and thermally annealed solvent treated blends are shown in Fig. 6 and the PV parameters are summarized in Table 3. It can be seen from Fig. 6 and Table 3, the device performance changes significantly after annealing (solvent vapour as well as thermal). These changes correlate well with the significant changes in the morphologies of the blended films. The devices fabricated with solvent vapour treated **M1**:PCBM and **M2**:PCBM showed PCE about 1.73% and 2.17%, respectively, which has been further enhanced up to 2.03% and 2.77% for the thermally annealed solvent treated **M1**:PCBM and **M2**:PCBM blends. The improvement of the PCE has been attributed mainly to the increase in the J_{sc} and FF. As we have discussed earlier, the absorption band is red shift

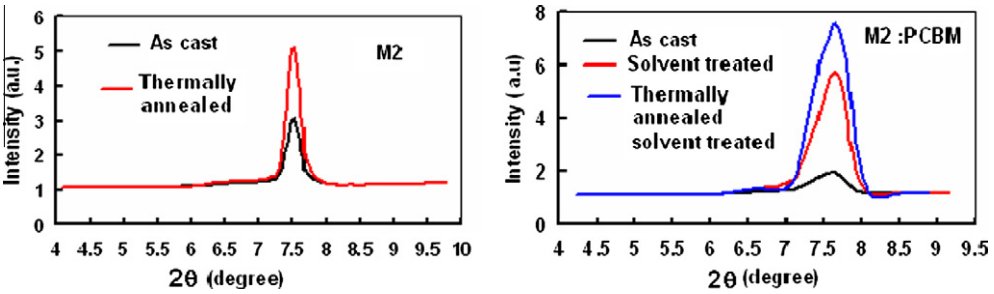

Fig. 7. XRD patterns of pure as cast and thermally annealed **M2**, and as cast, solvent vapour treated and thermally annealed solvent vapour treated **M2**:PCBM blends.

Table 4
Electron and hole mobilities of **M1**:PCBM and **M2**:PCBM blends with different conditions.

Blend	Electron mobility (μ_e) (cm^2/Vs)	Hole mobility (μ_h) (cm^2/Vs)	μ_e/μ_h
M1:PCBM[a]	4.5×10^{-5}	1.8×10^{-6}	25
M1:PCBM[b]	5.5×10^{-5}	3.5×10^{-6}	15.70
M1:PCBM[c]	6.2×10^{-5}	$8. \times 10^{-6}$	6.9
M2:PCBM[a]	5.2×10^{-5}	6.7×10^{-6}	7.76
M2:PCBM[b]	5.8×10^{-5}	1.3×10^{-5}	4.46
M2:PCBM[c]	6.1×10^{-5}	5.6×10^{-5}	1.08

[b] Solvent vapour treated film.
[c] Thermally annealed solvent treated film.

upon the solvent treatment and thermal annealing, which was interpreted as arising from the **M1** or **M2** crystallinity and the resulting hole mobility, which will be discussed later.

It can be seen from Table 3, a drop in V_{oc} occurred for all devices based on solvent treated and thermally annealed blend. It is widely accepted that the V_{oc} for the BHJ PV devices is determined by the energy difference between the HOMO level of donor and LUMO level of acceptor used in the BHJ active layer. The crystallization **of M1** or **M2** in the solvent treatment and subsequent thermal annealing reduced their optical band gaps, assuming that the HOMO level of **M1** or **M2** shifted upward due to the extension of the conjugation length as a result of interchain overlap, as we have observed in the absorption spectra of **M1** and **M2** films [30]. Therefore, the devices containing **M1** or **M2**:PCBM films with higher crystallinity resulting from solvent vapour treatment and thermal annealing, showed lower V_{oc} than the devices with films which have lower crystallinity.

To obtain efficient charge transport of the carriers, it is necessary to enhance the hole and electron mobilities to achieve a balanced mobility ratio [27a,31]. The SCLC method was employed to evaluate the hole and electron mobilities of devices prepared with the various thin active layers. SCLC *J–V* characteristics were obtained in dark from the hole only devices (ITO/PEDOT:PSS/**M1**or **M2**:PCBM/Au) and electron only devices (Al/M1 or M2:PCBM/Al) as a function of the applied bias voltage, which was corrected with the built in potential: $V = V_{appl} - V_{bi}$. The hole and electron mobilities were estimated by the dark *J–V* curves at low voltages, where the current is described by the Mott–Gurney square law i.e. $J = (9/8)\,\varepsilon\,\mu\,(V^2/L^3)$ [32], where the ε is the permittivity of the blend, μ is the charge carrier mobility, and L is the film thickness of the active layer. The values of the hole and electron mobilities are listed in Table 4. It can be seen from this table, that both electron and hole mobilities increase after solvent vapour treatment and thermal treatment. The increase in the hole mobility is higher than the electron mobility. The ratio between the electron and hole mobilities has been reduced for devices based on solvent vapour treated blend and thermally annealed blends, resulting in more balanced carrier transport. The well controlled morphology of the blend, obtained from the solvent vapour treatment and thermal annealing increased the carrier mobilities, particularly the hole mobility through the increase in the crystallinity of **M1** or **M2**, leading to balanced charge transport in the active layer and enhancement of the photocurrent.

5. Conclusions

Two new conjugated SMs, **M1** and **M2**, were successfully synthesized. They were soluble in common organic solvents, showed long-wavelength absorption maximum at 601–640 nm and optical band gap 1.60–1.67 eV. The band gap of these SMs is smaller than that of P3HT. The HOMO and LUMO levels estimated from cyclic voltammetry suggest that **M1** and **M2** can be used as electron donor materials and PCBM as electron acceptor for BHJ organic PV devices. The PCE of the devices based on **M1**:PCBM and **M2**:PCBM is 1.42% and 1.80%, respectively, which is attributed to the higher hole mobility, improved PL quenching and broader absorption spectra for **M2**:PCBM

blend. Moreover, the ratio of electron and hole motilities is lower for the **M2** device relative to **M1** thus supporting the higher value of PCE for the **M2**:PCBM based device. Solution processed organic PV devices with **M1** or **M2** and PCBM were fabricated with as cast, solvent vapour treated and thermally annealed solvent vapour treated blends. The PCEs for the devices fabricated with thermally annealed solvent vapour treated **M1**:PCBM and **M2**:PCBM blends were 2.05% and 2.77%, respectively, which are higher than those for the as cast blends. This improvement in the PCE has been attributed to the increase in crystallinity of the blend, induced by the thermal annealing and solvent vapour treatment and balanced charge transport in the device.

Capping layer

ABSTRACT

Highly efficient top-emitting white organic light-emitting diodes (TEWOLEDs) on silicon substrates based on complementary blue and yellow phosphors are demonstrated. The bottom copper anode with medium reflectance, which is compatible with standard complementary metal oxide semiconductor (CMOS) technology, and the semitransparent cathode with a top capping layer, are introduced to facilitate white light emission with improved contrast and reduced angular dependence. Both TEWOLEDs, with and without the capping layers, exhibit nearly lambertian-type emission. The spectrum of TEWOLED with a capping layer is similar to that of the bottom-emitting counterpart. Our TEWOLED reaches high efficiencies of 27.7 cd/A and 17.6 lm/W at a current density of 10 mA/cm^2, and low voltage of 4.4 V at 1000 cd/m^2.

1. Introduction

Organic light-emitting diodes (OLEDs) are considered as one of the most powerful candidates for the next generation mainstream flat panel displays and solid-state lighting sources [1–5]. In active matrix displays, top-emitting architectures are preferable due to their intrinsic large aperture ratio and the less risk of cross-talk in high resolution and large area displays. For full color and high resolution displays, white light combined with color filters is one of the best schemes for low-cost mass production due to the avoidance of precise and time-consuming shadow mask process for red-green-blue (RGB) pixilation [6,7]. It's pointed out that the technique which is capable of directly patterning the pixels in small dimensions (~10 μm pitch for RGB pixels) is not available so far [8]. Note that the pixel pitch of OLED microdisplays now is reduced to several micrometers to achieve high resolution. However, it's a great challenge to achieve uniform and angular independent white light emission in the top-emitting architectures due to intrinsic strong microcavity effects. Basically, a low reflective bottom anode and a highly transparent top cathode stack are beneficial for white light extraction from top-emitting architectures avoiding constructive interference inside the devices [3,9–17]. In order to achieve high resolution and high information-content Si-based microdisplays, which have vast potential application in military and consumer electronics market, TEWOLED is one of the prerequisites as well as CMOS process selection. As mentioned above, no technique is competent enough to directly pattern the full color OLED pixels in microdisplays. The solution now is based on white light and RGB color filters. For low cost mass production, a suitable active matrix driving circuit scheme introducing the standard CMOS metal interconnection (Al or Cu) is crucial, as it has to meet the requirement of fabricating OLEDs directly on the top metal layer of the chips. In addition, TEWOLEDs based on Cu foil with high flexibility are very promising for flexible full color active matrix displays.

In this letter, we demonstrate highly efficient TEWOLEDs based on Cu bottom anode, which is compatible with the standard foundry CMOS technology (for deep submicron and below), paving the way for integrating organic optoelectronic devices directly with the readily available Si wafer. It's reported that the production cost comes from the interconnect metallization process in integrated circuits is over 50% of the total budget [18]. A new choice of metal process, which is not compatible with the standard foundry technology, will cost even much more. Undoubtedly, this is a great obstacle for mass production. In previous reported TEWOLEDs, Ag [11,16], Ag/ITO [14], Al [17], Al/Ag [17], Al/Au [13], Al/ITO [19], Al/Ni [10], and Mo [15] are selected as anodes, respectively. However, only limited candidates are competent for commercialization. Here, a Cu anode is adopted for TEWOLED to meet the requirement of integrating OLEDs with foundry CMOS circuitry. Cu can then be used as contact material and as via connection in the CMOS process [18,20]. In contrast, an Al interconnect requires a W plug for via and subsequently creates an additional interface of Al and W. No such interface is existing between the via and interconnect for Cu as via and anode material for OLEDs. This does significantly simplify the fabricating process for OLED microdisplays aiming for low cost and small size with augmented reality that requires high resolution [4]. In addition, due to the excellent thermal conductivity, Cu-based devices usually exhibit superior heat dissipation [21], thus the issue of thermal management in highly dense integrated devices tends to be less severe. In order to further reduce the OLED microcavity effect, an additional capping layer, 4,4′,4″-tris(N-3-methylphenyl-N-phenyl-amino)triphenylamine (m-MTDATA), is deposited directly over the semitransparent cathode. It's proved here that the manipulation of white light emission profiles towards angular independence and broad spectral coverage is much easier in Cu-based TEWOLEDs than those based on highly reflective electrodes, such as Ag and Al.

2. Experimental

The white OLED is based on the blue emitter iridium(III) bis[(4,6-difluorophenyl)-pyridinato-N,$C^{2'}$] (FIrpic) and the yellow emitter bis(2-(2-fluorphenyl)-1,3-benzothiozolato-N,$C^{2'}$) ((F-BT)$_2$Ir(acac)) doped into a common host, N, N′-dicarbazolyl-3,5-benzene (mCP), respectively. Pristine m-MTDATA, N,N′-bis(naphthalene-1-yl)-N, N′-bis(phenyl)-benzidine (NPB), and 7-diphenyl-1,10-phenanthroline (BPhen) serve as hole injecting layer, hole transporting layer, and hole blocking/electron transporting layer, respectively. The Cu anode is thermally deposited onto Si substrate covered with insulating SiO_2, following with m-MTDATA:MoO_x p-doping layer to reduce the ohmic loss. The structures are listed below, Si/SiO_2/Cu (60 nm)/m-MTDATA:MoO_x (15wt.%, 10 nm)/m-MTDATA (18 nm)/NPB (5 nm)/mCP (15 nm)/mCP:FIrpic (10wt.%, 5 nm)/BPhen (2 nm)/mCP:(F-BT)$_2$Ir(acac) (4wt.%, 5 nm)/BPhen (40 nm)/LiF (1 nm)/Al (2 nm)/Ag (18 nm)/m-MTDATA (0 and 50 nm). For comparison, ITO/m-MTDATA:MoO_x(15wt.%, 10 nm)/m-MTDATA (18 nm)/NPB (5 nm)/mCP (15 nm)/mCP:FIrpic (10wt.%, 5 nm)/BPhen (2 nm)/mCP:(F-BT)$_2$Ir(acac) (4 wt.%, 5 nm)/BPhen (40 nm)/LiF (1 nm)/Al (100 nm), a bottom-emitting white OLED (BEWOLED) is also fabricated. In order to achieve high efficiency, the pristine 15 nm mCP is introduced to prevent the high energy triplet exciton of blue emitter from diffusing into the NPB layer, and 2 nm BPhen spacer is inserted between the blue and yellow emitters to balance white emission. The current–voltage–luminance characteristics were measured with a PR650 spectrascan spectrometer and a Keithley 2400 programmable voltage–current source. All the devices without encapsulation were measured in ambient atmosphere at room temperature.

It's reported that the out-coupling characteristics are significantly dependent on the interference effects in the cavity [22,23]. As depicted, the top light out-coupling stack design strongly influences the emission profiles [9–11,13–17,19,23,24]. In order to reveal the effects, we investigate the influences of the capping layer on the reflectance, transmittance and absorbance of the stack of BPhen/LiF/Al/Ag/m-MTDATA (x nm) with software SETFOS [25].

3. Results and discussion

For monochromatic emission, the out-coupling efficiency is not simply dependent on the transparency of the top electrode [23]. It's even more complicated in TEWOLEDs, because of the complex interplay of wide-angle and multiple-beam interference effects. As indicated in Fig. 1a and b, the stack with 50 nm capping layer exhibits a low reflectance and high transmittance in the blue region, but medium values in the yellow region. Additionally, the stack with above 50 nm capping layer has low absorbance over the visible region (Fig. 1c). However, the devices with a capping layer above 50 nm do not exhibit improved luminance (not shown here).

As shown in Fig. 2, TEWOLED with (Device A) and without (Device B) 50 nm capping layer exhibit similar luminance–voltage characteristics, while Device A has superior luminance due to the improved light out-coupling efficiency. In contrast, the luminance of BEWOLED (Device C) tends to grow more slowly as the voltage increased. One of the reasons may be attributed to the different series resistance of the electrodes. And also, the lower thermal conductivity of the ITO/glass substrate than that of Cu/SiO_2/Si substrate may play a role, as great joule heat generated on the poor thermal conductive substrate may accelerate the degradation at high luminance level. In view of practical use, the capping layer is not only beneficial for the improvement of luminance of TEWOLED, but also for the achievement of high contrast active matrix displays. Device A with the capping layer reaches a contrast ratio of 199, while that of Device B is only 66, under an ambient illumination of 140 lx [26,27]. A high contrast ratio is necessary to achieve high gray scale and reduce eyestrain in near-eye microdisplays with relative low perceptible luminance level. As for head-mount displays, the ambient illumination could be much lower. Taking 10 lx for example, the contrast ratio of Device A is up to 351 when the on-state brightness is set to 200 cd/m^2.

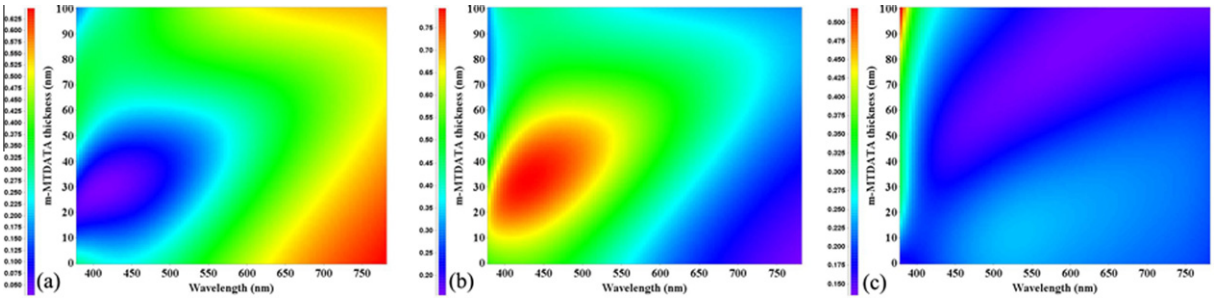

Fig. 1. (a–c) Calculated reflectance, transmittance and absorbance of the stack BPhen (40 nm)/LiF (1 nm)/Al (2 nm)/Ag (18 nm)/m-MTDATA (*x* nm) as a function of m-MTDATA capping layer thickness and the wavelength, respectively. The optical constants used in the calculation are obtained by variable-angle spectroscopic ellipsometry measurements. The dispersion of the complex refractive indices is also taken into account, as the emission profiles are dependent on the dispersion.

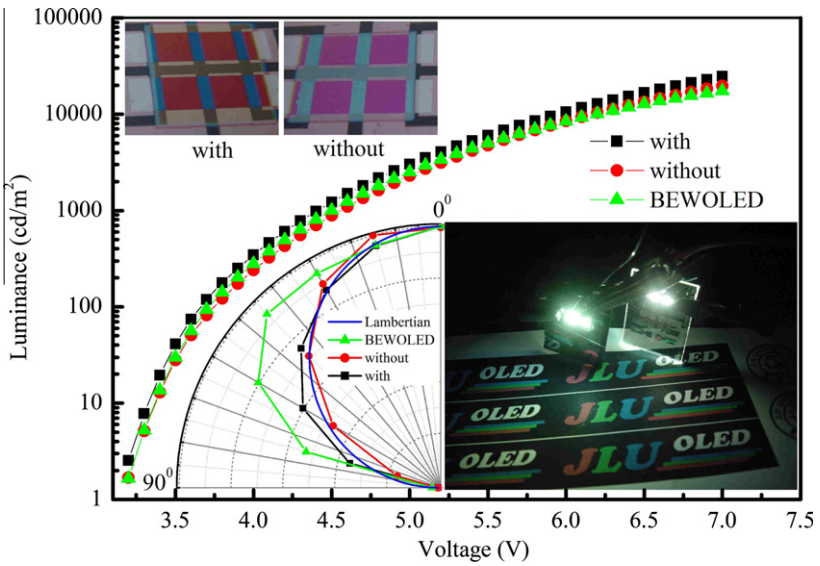

Fig. 2. Luminance–voltage characteristics of Device A, B and C, respectively. The lower left-hand inset indicates the measured angular distribution of the devices and the bluish solid line represents a Lambertian-type distribution. The upper left-hand inset shows the photos of TEWOLEDs with and without the capping layer, respectively. TEWOLED with the capping layer and BEWOLED radiate at a high brightness level are also presented in the lower right-hand inset.

The current efficiency–current density–power efficiency characteristics of the three devices are compared in Fig. 3. Apparently, TEWOLEDs exhibit lower efficiency at low luminance, while peak efficiency at low luminance is observed in BEWOLED, and subsequently the efficiency gradually decreases due to triplet–triplet annihilation as the current density increases [23]. At the current density of 10 mA/cm^2, the efficiencies are 27.7 cd/A (17.6 lm/W), 24.8 cd/A (15.4 lm/W) and 26.8 cd/A (16.5 lm/W) for Device A, B and C, respectively. As shown in the inset of Fig. 3, the spectra of TEWOLEDs are narrower in the red region due to interference effects and the poor transmittance of the cathode stack at long wavelengths, which have been indicated in Fig. 1. According to our calculation, the BEWOLED is not optimized with the structure used here. The optimized current efficiency is expected to be improved by 40%, simply adjusting the thicknesses of m-MTDATA:MoO_x and m-MTDATA layer to improve light out-coupling in BEWOLED. Hence the optimized BEWOLED would still have slightly superior efficiencies. A thick p-doping layer with negligible voltage drop is also expected to improve the yield of both TEWOLEDs and BEWOLEDs in mass production.

With the capping layer, the angular dependence of the spectrum in TEWOLED is reduced, while the spectrum of TEWOLED without the capping layer changes dramatically as the viewing angle changes, shown in Fig. 4a and b. BEWOLED exhibits almost no angular dependence of the spectrum (Fig. 4c). The Commission Internationale de L'Eclairage (CIE) coordinates measured in forward direction of Device A only change from (0.306, 0.430) to (0.330, 0.445) over the luminance range of 100–4000 cd/m^2, and the variation is only (±0.003, ±0.001) over 4000–20000 cd/m^2. Due to the dominant yellow emission as a result of constructive interference in Device B, the CIE coordinates are quite stable over 100–20000 cd/m^2, with negligible variation of (±0.009, ±0.004). Device C (BEWOLED) has a convoluted shape of the CIE coordinates over

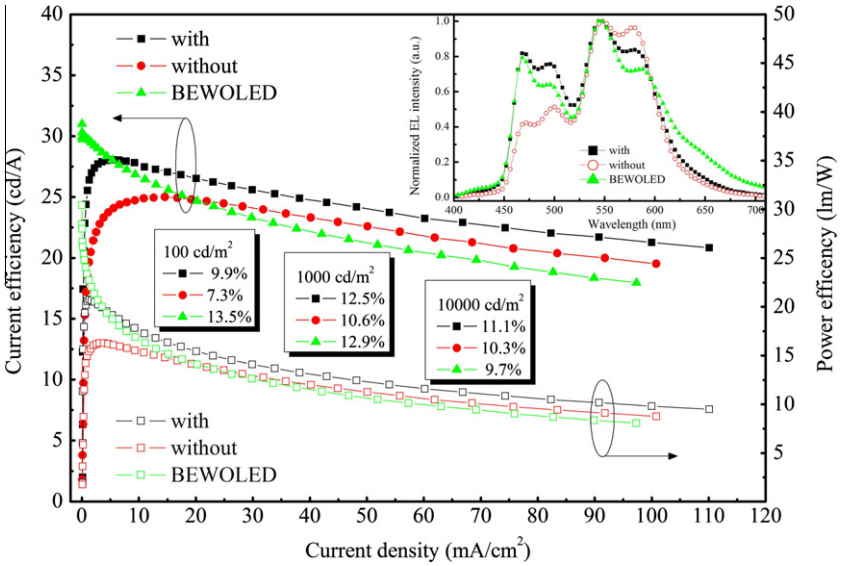

Fig. 3. Current efficiency–current density–power efficiency characteristics of Device A, B and C, respectively. The external quantum efficiencies at a luminance of 100, 1000, 10000 cd/m^2 are also shown in the boxes. Inset: the electroluminescent (EL) spectra of the devices at a current density of 40 mA/cm^2.

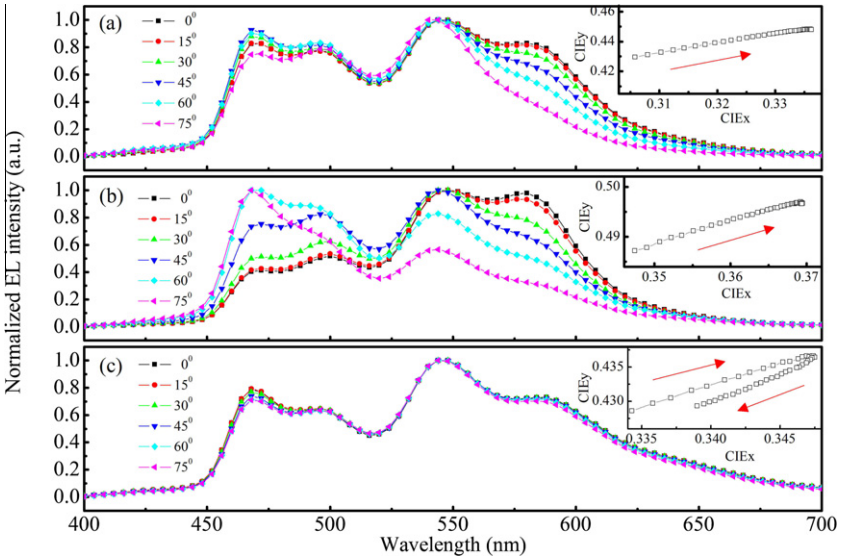

Fig. 4. Spectra of Device A, B and C at a current density of 40 mA/cm^2, respectively. CIE 1931 color coordinates measured in forward direction over a luminance range of 100–20,000 cd/m^2 are also plotted in the insets, respectively.

the luminance range, corresponding to a variation of (±0.006, ±0.004). The blue-shift of the color in Device C may be caused by the slightly increased residual NPB emission under high driving voltage. However, this emission is suppressed in TEWOLEDs with an optical cavity length of ~100 nm as the low light out-coupling efficiency in the deep-blue region, which is also indicated by the whole device simulation with software SETFOS. That's why the variation of the CIE coordinates with luminance of TEWOLEDs is different to that of BEWOLED.

4. Conclusions

In summary, we have demonstrated efficient TEWOLED based on Cu anode for potentially full color small and large area active matrix displays, or flexible OLED displays. In this embodiment, we have deliberately considered the technologic compatibility of integrating OLEDs with CMOS circuitry, aiming for commercially low-cost OLED microdisplays. In order to improve the contrast ratio (typical for microdisplays), and reduce the angular dependence

(typical for flexible displays), a low absorption loss capping layer is used to balance the degree of constructive and destructive interference for white light extraction.

Acknowledgements

We wish to acknowledge funding for this research from the National Key Basic Research and Development Program of China under grant No. 2010CB327701, and the National Natural Science Foundation of China (grant Nos. 60977024 and 60907013). The authors gratefully acknowledge Dr. Liying Zhang and Dr. Bin Li for providing $(F\text{-}BT)_2Ir(acac)$.

Aims and scope

Organic Electronics is a primary journal whose interdisciplinary focus is organic materials, devices and phenomena, with application to devices such as organic light emitting diodes, thin film transistors, photovoltaic cells, etc.

Papers suitable for publication in this journal cover such topics as photoconductive and electronic properties of organic materials, thin film growth and characterization, charge and exciton transport, organic electronic and optoelectronic devices, etc.

Organic Electronics provides the only forum for both applied and fundamental contributions spanning the many different disciplines addressing the wide range of electronic properties and applications of organic materials. A Letters section is included for rapid publication of short articles announcing significant and highly original results.

Publisher's Note

As of June 1st, after a decade as Editor of Organic Electronics, Stephen Forrest, one of the Founding Editors will retire from his role. In this time, the journal has grown from 4 issues per year to 12 issues and has a major influence in the community. I would like to thank Steve very much for his expertise and dedication in making this journal a success.

Although I am very sorry to see Steve go, I am delighted that Paul Heremans will join the board of Editors as of May 1st. Paul is currently a fellow of IMEC, a world-leading independent research centre in nanoelectronics and nanotechnology, and Professor at the Katholieke Universiteit Leuven, Belgium. Please join me in welcoming Paul to the journal!
